# Reflections and Resolutions

**Karen Hindson**
**Editor, EurJIC**

New Year is a time for reflection on the past and resolutions for the future. This year this editorial will cover the past year but also take a look to the future.

2005 was again a good year for the *European Journal of Inorganic Chemistry*. Although the number of submissions continue to rise (ca. 7% more by September), which kept all of us in the editorial office on our toes, we concentrated this year on reducing publication times. As a start in this ongoing effort, we have reduced the time from submission to online publication by 25−30%, depending on the type of article. The Short Communications, which are defined as brief reports on topics of high significance and urgency, have benefited the most and appear online about 100 days after submission, but on average only about a month faster than the other categories. By far the most time-consuming process is the peer review and revision. In this area a balance between speed and diligence will serve our science best. More on this topic later.

The number of downloads has also steadily increased over 2005. This statistic not only reflects the attention that a particular group has attracted to its work − this attention becomes concrete later when the articles are cited in the papers of other researchers. More reliably it shows the areas which are topical at present. Chart 1a lists the five Microreviews that were downloaded most often by mid November. In addition I would like to mention two from the issues that became available late in the year and which therefore have not had the opportunity to appear in the "Top 5" stakes (Chart 1b), but within one month of publication jumped into the top 50. Chart 2a and b (see page 6) give the Short Communications and Full Papers the same honours. Thus the hot topics range from supramolecular chemistry, molecular recognition and biomimetic ligands to catalysis, nanoscience and ionic ligands. Properties useful for applications, such as magnetism, porosity, electrochemistry and luminescence feature prominently. On these topics EurJIC will also be publishing Microreviews in the near future. In this issue you can read about triazine-based ligands in supramolecular chemistry. Coming are Microreviews on host−guest and intercalation chemistry of $C_{60}$, catalysis in ionic liquids, mesoporosity and model complexes for metalloenzymes.

Two projects, started as a result of the urging of readers, have been completed in 2005. Most often I have been asked at conferences about the online accessibility of predecessor journals to EurJIC. I am therefore pleased to announce that in January all issues from the inception of *Liebigs Annalen* and *Chemische Berichte* will become available electronically as part of the Chemistry Societies Backfile Collection: 27,100 articles from *Liebigs Annalen* (from 1832 to 1997) and 57,270 articles from *Chemische Berichte* (from 1868 to 1997) will be fully searchable. In addition the reference section has been tagged so that CrossRef allows jumping to the full-text of the citation, if the publisher is a member of CrossRef and the backfile is available (to find out more about CrossRef, see www.crossref.org). The other journals

Chart 1a. Most downloaded Microreviews published in 2005 (* indicates the correspondence author).

1. Stabilization of Organometallic Species Achieved by the Use of N-Heterocyclic Carbene (NHC) Ligands; **N. M. Scott, S. P. Nolan***, *Eur. J. Inorg. Chem.* **2005**, (10), 1815−1828.
2. Ordered Meso- and Macroporous Binary and Mixed Metal Oxides; **M. A. Carreon, V. Guliants***, *Eur. J. Inorg. Chem.* **2005**, (1), 27−43.
3. Molecular Recognition: Use of Metal-Containing Molecular Clefts for Supramolecular Self-Assembly and Host-Guest Formation; **J. D. Crowley, B. Bosnich***, *Eur. J. Inorg. Chem.* **2005**, (11), 2015−2025.
4. Luminescence from Lanthanide(3+) Ions in Solution; **A. Døssing***, *Eur. J. Inorg. Chem.* **2005**, (8), 1425−1434.
5. Ionic Liquids with Fluorine-Containing Cations; **H. Xue, J. M. Shreeve***, *Eur. J. Inorg. Chem.* **2005**, (13), 2573−2580.

Chart 1b. Microreviews from later issues that attracted a high number of downloads within one month.

1. Magnetic Nanoparticle Superstructures; **M. Giersig, M. Hilgendorff**, *Eur. J. Inorg. Chem.* **2005**, (18), 3571−3583.
2. Continuous Homogeneous Catalysis; **D. Vogt** et al., *Eur. J. Inorg. Chem.* **2005**, (20), 4011−4021.

Chart 2a. Most downloaded Short Communications (SC) and Full Papers (FP) published in 2005.

1. SC: $Co^{II}$ Complexes of Triazine-Based Tridentate Ligands with Positive and Attractive $Co^{II/III}$ Redox Couples; **G. S. Hanan** et al., *Eur. J. Inorg. Chem.* **2005**, (7), 1223−1226.
2. FP: A New Ligand for the Formation of Triangular Building Blocks in Supramolecular Chemistry; **I. M. Müller**, **D. Möller**, *Eur. J. Inorg. Chem.* **2005**, (2), 257−263.
3. FP: Solvothermal Synthesis of NiS 3D Nanostructures; **Y Qian** et al., *Eur. J. Inorg. Chem.* **2005**, (4), 653−656.
4. FP: *N*-Ferrocenyl-Substituted Planar-Chiral N-Heterocyclic Carbenes and Their $Pd^{II}$ Complexes; **A. Togni** et al., *Eur. J. Inorg. Chem.* **2005**, (2), 347−356.
5. FP: Carbon-Rich Ruthenium Complexes Containing Bis(allenylidene) and Mixed Alkynyl-Allenylidene Bridges; **S. Rigaut, D. Touchard, P. H. Dixneuf** et al., *Eur. J. Inorg. Chem.* **2005**, (3), 447−460.
6. SC: Preparation and Characterization of $Ag@TiO_2$ Core-Shell Nanoparticles in Water-in-Oil Emulsions; **F. Liu** et al., *Eur. J. Inorg. Chem.* **2005**, (9), 1643−1648.
7. FP: Three-Dimensional Lanthanoid-Containing Coordination Frameworks: Structure, Magnetic and Fluorescent Properties; **X.-Z. You, S. Gao** et al., *Eur . J. Inorg. Chem.* **2005**, (4), 766−772.
8. FP: Synthesis, Structure, and Photophysical and Electrochemical Properties of Cyclometallated Iridium(iii) Complexes with Phenylated Bipyridine Ligands; **K. Kam-Wing Lo, V. Guerchais** et al., *Eur. J. Inorg. Chem.* **2005**, (1), 110−117.
9. FP: A Structural and Magnetic Investigation of Ferromagnetically Coupled Copper(ii) Isophthalates; **P. Cheng** et al., *Eur. J. Inorg. Chem.* **2005**, (12), 2297−2305.
10. FP: Bis(1-methylimidazol-2-yl)propionates and Bis(1-methylbenzimidazol-2-yl)-propionates: A New Family of Biomimetic N,N,O Ligands − Synthesis, Structures and $Cu^{II}$ Coordination Complexes; **R. J. M. Klein, G. van Koten** et al., *Eur. J. Inorg. Chem.* **2005**, (4), 779−787.

Chart 2b. Short Communications (SC) and Full Papers (FP) from later issues that attracted a high number of downloads within one month.

1. SC: Self-Assembly of 1-D Coordination Polymers Using Organometallic Linkers and Exhibiting Argentophilic Interactions AgI···AgI; **H. Amouri** et al., *Eur. J. Inorg. Chem.* **2005**, (19), 3808−3810.
2. FP: Structures, Photoluminescence and Theoretical Studies of Two $Zn^{II}$ Complexes with Substituted 2-(2-Hydroxyphenyl)benzimidazoles; **S.-L. Zheng, X.-M. Chen** et al., *Eur. J. Inorg. Chem.* **2005**, (18), 3734−3741.
3. FP: Multiple Regulated Assembly, Crystal Structures and Magnetic Properties of Porous Coordination Polymers with Flexible Ligands; **L. P. Jin, S. Gao et al.,** *Eur. J. Inorg. Chem.* **2005**, (20), 4150−4159.
4. FP: Self-Assembly and Characterization of Grid-Type Copper(I), Silver(I), and Zinc(II) Complexes; **V. Patroniak, J. M. Lehn** et al., *Eur. J. Inorg. Chem.* **2005**, (20), 4168−4173.

included in the Chemistry Societies Backfile Collection are *Angewandte Chemie* and the first three volumes of *Chemistry − A European Journal.* In total the Chemistry Societies Backfile Collection comprises more than 872,000 pages (see http://www3.interscience.wiley.com/cgi-bin/collectionhome/CSCOL/HOME).

Thus retrospective literature researches can be performed from the convenience of your office desk. But forward-looking searches are useful, too. Often the quickest way to become aware of new research is to check the citations to an important paper in the field. Now with "Citation Tracking" in Wiley InterScience you can do just that with ease. From the Abstract or Reference link of any article you find a new link "Citation Tracking" (see Figure 1, page 7). A click provides a list of papers that cite the article. Not only articles in Wiley InterScience are found, but also articles from all CrossRef member publishers. And the lesson to be learned from these two projects? Continue to tell us what you would like to have from our journals − we take you seriously!

An important reaction to the reflection on the past year is gratitude to our Editorial and Advisory Board members, and our peer reviewers. Their expertise and sound advice is much appreciated. To all of them, and to our readers and authors, we wish every success in your research and good ideas from reading EurJIC.

Reminiscences on the less common events uncover areas where resolutions more substantial than the usual New Year's Resolution are required. This year brought a disheartening number of cases of plagiarism. Coincidence plays a large part in its discovery before publication. Two editors select the same referee, or a referee checks a citation or looks up a reference that appears pertinent. My sincerest thanks go to those referees whose conscientious review brought unacceptable behaviour to light. Such care takes time. In the interests of all involved in chemical research, peer review must not be rushed more than expedient. On the other hand, authors have the right to know the fate of their manusacript in a timely fashion. Informing an editor if the referee report will be delayed is also an ethical tenet.

Editors, societies and publishers cooperate closely to stamp out unethical practices. All steps directed at keeping the communication of our Science fair but efficient in these times of sharp competition must be welcomed. The American Chemical Society was pioneer and their Ethical Guidelines are prominent online as a link on all their journal pages. The initiative of the many European Chemical Societies to formulate unified Guidelines including measures to be taken against offenders is praiseworthy.

On confronting the problem of plagiarism in 2005 I was reminded of an experience of mine. After my degree in Chemistry I took an elective in the Humanities with several hundred fellow students at first semester level. I was expected to cite the same reference several times in one paragraph, although to me it was obvious from the context that the text was explaining one idea. The measures taken for failure to do so could not be overlooked by any student − zero credit for the assignment. The nature of the assignments in the Humanities lends itself far more readily than in the experimental sciences to education in this aspect essential to academia. Nevertheless, the difference is striking. Nowhere in my academic career in Chemistry did I receive as clear a message in the ethics of citation and the severity

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

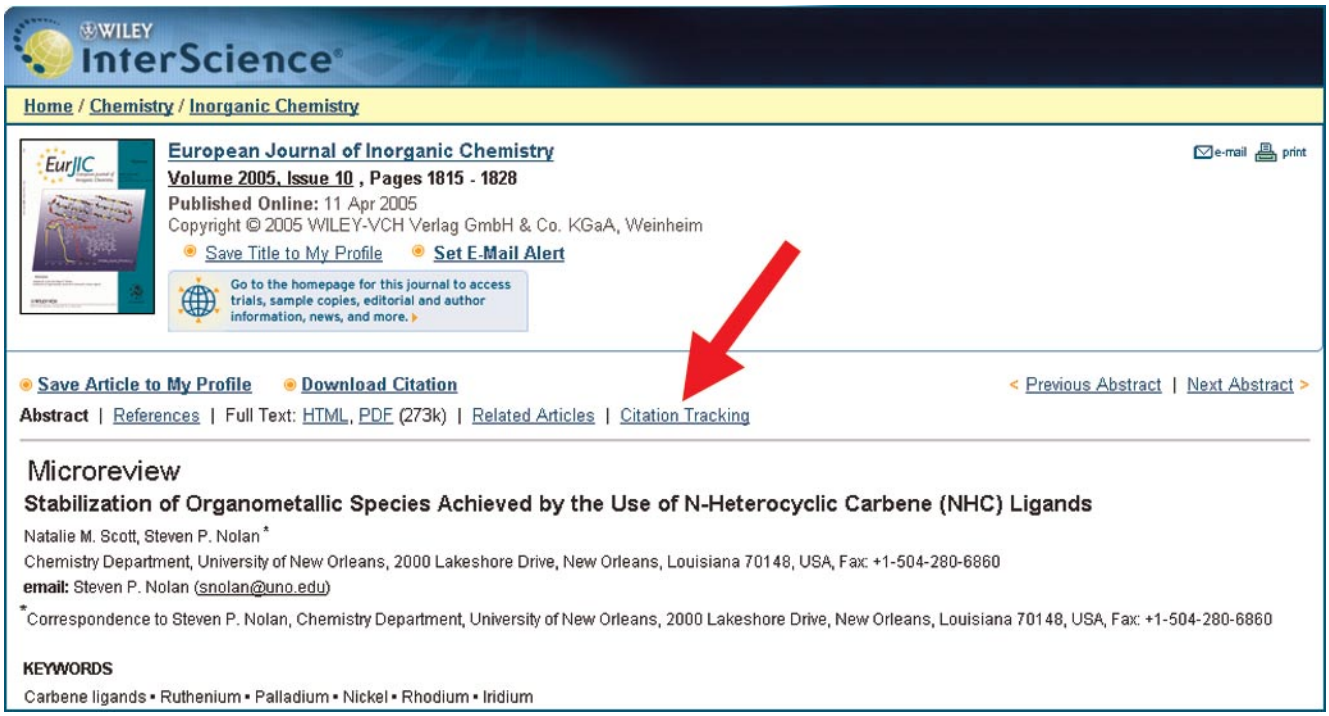

Figure 1. Abstract page of an article in Wiley InterScience showing the Citation Tracking link.

of the measures for omission. Only at a much later stage in my studies did I become conscious of the importance of references, more through my exposure to the chemical literature than through mentoring. Yet I am sure my professors are convinced that they instilled into their students the culture of citation.

At the latest when the research of a student is included in a manuscript for publication, that student must be formally educated in the ethics of publishing and the consequences of violation. All senior authors need to take this responsibility seriously, not only as an educational aim, but also as self-protection. No editor considers as excuse, or even extenuating circumstances, that the text was taken from the notes of a PhD student, although it is a fact that plagiarism has become more likely than in the days when "Copy and Paste" meant getting sticky with glue.

Changed circumstances always require an appraising reaction. This is as true in publishing as Newton's third law of motion. Let us make 2006 a turning point in awareness towards the ethics of our science.

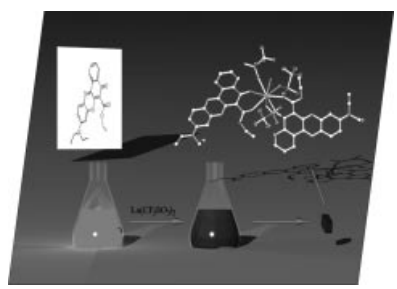
## COVER PICTURE

**The cover picture shows** that addition of lanthanum(III) triflate to the red solution of a fluorescent "Nile Red" derivative results in a bathochromic shift of the intense charge-transfer band due to the formation of a chelate lanthanum(III) complex, as shown by a structure determination of crystals isolated from the resulting blue solution. details are discussed in the Short Communication by A. Døssing et al. on p. 43 ff.



## MICROREVIEW

**Contents**

**29** **P. Gamez,* J. Reedijk***

1,3,5-Triazine-Based Synthons in Supramolecular Chemistry

**Keywords:** Supramolecular chemistry / Self-assembly / Crystal engineering / N ligands / Cyanuric chloride / 1,3,5-Triazine

## 1. General Information

The *European Journal of Inorganic Chemistry (EurJIC)* is published twice monthly.

**Manuscripts should be submitted online** using our online submission service at http://www.manuscriptXpress.org. You should prepare a **single file containing all tables, graphics, supporting information (where appropriate) etc.** Acceptable file formats are **Microsoft Word, Rich Text Format, Postscript and PDF**. Avoid the use of page breaks even between the title page and the introduction. If graphics are included at the end of the manuscript, try to fit as many as possible onto a single page. The file should have margins of 2 cm and be 1.5-line spaced.

Authors can follow the progress of their manuscript on their **personal homepage**, which is created automatically upon initial registration. This homepage is the same for the family of Wiley-VCH European journals and can be used to **store the latest version of a submitted paper** and to **upload the document file after acceptance**. Your referee reports for the family of Wiley-VCH European journals are also archived here.

**No paper copies of the manuscript are required when using this system.**

- The author must inform the editor of all manuscripts submitted, soon to be submitted, or in press at other journals that have a bearing on the manuscript being submitted.
- The correspondence author of a Microreview will receive a complimentary copy of the journal along with a PDF file of his/her paper restricted to 50 printouts; the correspondence author of other articles will receive a PDF file restricted to 25 printouts. Colour figures can be reproduced. Unless the editor deems colour to be essential for the understanding of a paper, authors will be requested to make a contribution towards the costs of colour reproduction. Details will be provided after acceptance of the manuscript.
- We encourage authors to submit pictures for the cover page. A template of our cover page, **eurjiccover.pdf**, can be reached by clicking the link "For Authors" on our journal homepage (http://www.eurjic.org), to help you visualize the final effect of your design.

**IMPORTANT:** Any manuscript already available on personal/group web pages will be considered by the editors as already published and will not be accepted.

On behalf of our authors who are also US National Institutes of Health (NIH) grantees, we will deposit in PubMed Central (PMC) and make public after 12 months the peer-reviewed version of the author's manuscript. By assuming this responsibility, we will ensure that our authors are in compliance with the NIH request, and make certain that the appropriate version of the manuscript is deposited. We await the release by PMC of the protocols regarding manuscript submission. We reserve the right to change or rescind this policy.

## 2. Types of Contributions

**EurJIC publishes articles on inorganic, organometallic, bioinorganic, physical inorganic and solid-state chemistry. All contributions undergo peer review. An author may appeal against the decision on his/her manuscript, in writing. Three types of contributions are accepted for publication:**

- **Full Papers** are articles with an Experimental Section that describe a significant contribution to the development of an area of research of importance. There are no restrictions placed on the length of a Full Paper.
- **Short Communications** are brief reports on results of high significance and urgency. Generally, they are no longer than 12−16 double-spaced pages or 3−4 typeset pages. An Experimental Section (as a separate paragraph or as part of the references) is desirable; if it is not included in the paper, the experimental data should be submitted as Supporting Information for refereeing purposes, and marked as such. A justification for urgent publication should accompany submission.
- **A Microreview** introduces the reader to a particular area of an author's research through a concise overview of a selected topic. As a rule, Microreviews are written on invitation, although unsolicited articles are also welcome. It is recommended, however, to contact the editor before submitting an unsolicited Microreview. The content should balance scope with depth; it should be a focused review of 25−30 double-spaced pages or 6−8 typeset pages. Reference to important work from others that is significant to the topic should be included. Microreviews will be refereed but will have no Experimental Section.

## 3. Manuscript Preparation

### 3.1 General

The whole of the manuscript should be 1.5-line spaced and in a large script (Times New Roman, 12 pt). We recommend that you prepare your text with **Microsoft Word (PC or Macintosh versions)** (see Section 3.2). Page numbers are essential: use the automatic pagination function incorporated in your word processing software. Leave a 2-cm margin around the perimeter of each page. Consult a current issue of the journal for an overview of the format. A manuscript should comprise: ◇ Title Page ◇ Keywords ◇ Abstract ◇ Main Text including Introduction, Results and Discussion etc. ◇ Experimental Section ◇ Acknowledgments (optional) ◇ Captions ◇ Tables ◇ References ◇ Schemes and Figures ◇ Graphical Abstract ◇ For Microreviews only: Biographical sketches and a portrait-quality photograph of all authors (when several authors from one institution are involved, group photographs are preferred).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### 3.2 Text

The text should be typed with carriage returns (hard returns) only at the end of a paragraph, title, heading and similar features. Avoid end-of-line word divisions.

**Abbreviations and acronyms** should be used sparingly and consistently. Where they first appear in the text, the complete term — apart from the most common ones such as NMR, IR, THF, *t*Bu etc. — should also be given.

**In the Experimental Section**, quantities of reactants, solvents etc. should be included in parentheses [e.g. A solution of triphenylphosphane (500 mg, 1.91 mmol) in dichloromethane (15 mL) was added to...].

**NMR spectroscopic data** should be quoted as in the following example: $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.3 (s, 18 H, $SiMe_3$), 0.9 (d, $^3J_{H,H}$ = 5.7 Hz, 2 H, 2-H) ppm. For each chemical shift, additional information should be given in the order: multiplicity, coupling constant, number of protons, assignment.

**The purity of all new compounds** should be verified by elemental analysis to an accuracy within ±0.4%. In special cases, for instance when the compound is unstable or not available in sufficient quantities for complete analysis, the exact relative molecular mass obtained from a high-resolution mass spectrum and a clean $^{13}$C NMR spectrum (as additional material for inspection by the referees) should be supplied.

**Symbols of physical quantities**, but not their units (e.g. *T* for temperature, *J*, $\lambda$), stereochemical information (*cis*, *trans*, *Z*, *R*), locants (*N*-methyl), symmetry and space groups ($P2_1/c$), and prefixes in formulas or compound names (*t*Bu, *tert*-butyl) **must be in italics**. Latin phrases, such as "in situ", should not.

**Stereochemical descriptors**, such as D- and L-, and molar (M) or normal (N) should be in **small capitals**. Use character formatting for italic and bold characters. Avoid any *special style sheets* to format these features. Write *capital letters* using the keyboard (shift + letter key), **not** the format "Capital letter" in Word.

**Use only characters from the Symbol and Normal Text character sets**, especially when inserting Greek letters and characters with umlauts, accents, tildes, etc.: α, ä, à, ã, Å.

There are three types of hyphens: normal dashes (-), en dashes (−), and em dashes (—). Use these as illustrated — spacing is important too — in the following examples:

| | |
|---|---|
| well-known reaction | C−H bond |
| six-membered ring | Tables 2−4 |
| 3-position of the ring | carbon−oxygen bond |
| signal-to-noise ratio | C−N stretch |
| Mo-$K_\alpha$ | Diels−Alder reaction |
| 1,2-dicyanobutane | structure−activity relationship |
| *p*-*tert*-butylphenol | 80−100 mg |
| (−)-tartaric acid | carried out at −10 °C |
| $[M^+ - CH_3]$ | $cm^{-1}$ |

Use the symbol × where appropriate, rather than the letter x:
... washed with water (2 × 150 mL) ...
Use the double quotation marks "..." rather than „...", "..." or «...».
**Graphics (including structural formulas, schemes, figures, equations and small graphical items that appear in captions) must be submitted camera-ready on separate pages after acceptance of the manuscript (see Section 3.5).**

**Lines** or **arcs**, for example to indicate ring compounds, cannot be used within the text. Another method for indicating such compounds must be devised. Please contact the Editorial Office if any help is needed.

If practical, authors should use a systematic name (IUPAC or Chemical Abstracts) for each title compound in the Experimental Section. Please try to avoid complicated, multi-line names if a simpler version (e.g. alcohol **4**, ketone **5**, compound **6**) could be used instead.

### 3.3 Tables

Use the Insert Table command from the Table menu or use the Insert Table button on the Standard toolbar for creating tables, and use tabs ONLY to move between cells.

### 3.4 References

We strongly recommend the use of the Endnotes feature of Word. If you prefer not to use this function, references should be indicated by numbers in square brackets as superscripts and, if applicable, after punctuation (example: text.[1]). Use the Format Font menu. Journal titles should be abbreviated according to the Chemical Abstracts Service Source Index (CASSI).

The Author is responsible for correct citations. The *European Journal of Inorganic Chemistry* is a member of Cross Ref. (http://www.crossref.org), a service which links reference citations to the online content that those references cite. This can only function if the citations are accurate. Please ensure that only one reference is cited under each reference number or that a composite reference is subdivided into parts a), b) etc. For example:

[1] A. Einstein, A. N. Other, *Eur. J. Inorg. Chem.* **2003**, 1−15.
[2] R. Schoenfeld, *The Chemist's English*, 3rd ed., VCH, Weinheim, **1990**, p. 111.

or

[1] a) A. Einstein, A. N. Other, *Eur. J. Inorg. Chem.* **2003**, 1−15; b) R. Schoenfeld, *The Chemist's English*, 3rd ed., VCH, Weinheim, **1990**, p. 111.

but not

[1] a) A. Einstein, A. N. Other, *Eur. J. Inorg. Chem.* **2003**, 1−15; R. Schoenfeld, *The Chemist's English*, 3rd ed., VCH, Weinheim, **1990**, p. 111.

### 3.5 Graphics

Graphics are schemes, figures, equations and small graphical items that appear in captions. Graphics differ fundamentally from the text portion of your manuscript in that they must be scanned or electronically processed. Schemes should be self-explanatory: reaction conditions should therefore be given above the arrows rather than in the caption.

In the revised version please submit **each graphic in its own file** within a graphic folder. For good reproduction, the following formats are preferred: *.cdr, *.cdx, *.tif, *.pdf, *.psd, *.ai, *.fh, *.qxd,*.pct, *.eps. The resolution should be a minimum of 300 dpi and 600 dpi for bitmap graphics.

Consult the following table for the appropriate size of lettering. Lettering smaller than 3.0 mm will reproduce poorly. Please use only one size of lettering per graphic and the same letter font for all graphics.

Table 1. Guide for preparing graphics

| Letter Size | Font | Maximum Graphic Width[a] 1-Column Format | 2-Column Format |
|---|---|---|---|
| | Times New Roman | | |
| 3.0 mm | 12 | 13 cm | 26 cm |
| **3.5 mm** | **14** | **15 cm**[b] | – |
| **4.0 mm** | **16** | **17 cm**[b] | – |
| 4.5 mm | 18 | 19 cm | – |

[a] Most graphics are in 1-column format. [b] We prefer lettering of 3.5 or 4.0 mm with maximum graphic widths of 15 or 17 cm, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The settings for one-column graphics constructed with Chem Draw are: Print Setup: Orientation Portrait. Caption and Label Settings: Font Times New Roman, Font Style Standard, Size 12.

**Note that the graphical abstract must be in one-column format and in black-and-white**.

These settings help ensure the correct letter-size-to-graphic-width ratio for best reproduction.
Use abbreviations such as $R^1$, $R^2$ (not $R_2$), R′, R″, Ph, Me, Et, *i*Pr, *t*Bu, Ph, Bn (benzyl), Bz (benzoyl), Hal, L, M (metal), X (heteroatom).

### 4. Crystallographic Data

Authors must deposit the data of X-ray structure analyses in a crystallographic database before submitting their manuscript, so that referees can access the information electronically. The two databases, the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have the same procedure for the deposition of data and both will be pleased to provide help. In general, you will receive a depository number from the database two working days after electronic deposition. Send your data to the appropriate address below and quote the standard text, including the depository number, in your manuscript.

- **For all compounds without C−H bonds:**

Fachinformationszentrum Karlsruhe (FIZ)
76344 Eggenstein-Leopoldshafen, Germany
Phone: +49-(0)7247/808-205
Fax: +49-(0)7247/808-666
E-mail: crysdata@fiz-karlsruhe.de
FTP: ftp.fiz-karlsruhe.de (under path /pub/csd)
WWW: http://www.fiz-karlsruhe.de (under "Products and Services")

Further details of the crystal-structure investigation(s) may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number(s) CSD-....

- **For all compounds with at least one C−H bond:**

Cambridge Crystallographic Data Centre (CCDC)
12 Union Road, Cambridge CB2 1EZ, UK
Phone: +44-(0)1223/336-408
Fax: +44-(0)1223/336-033
E-mail: deposit@ccdc.cam.ac.uk
WWW: http://www.ccdc.cam.ac.uk

CCDC-****** contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/datarequest/cif.

**NOTE:** Please use the free online **Checkcif** service provided by the International Union of Crystallography and submit the Checkcif report along with your manuscript: http://journals.iucr.org/services/cif/checkcif.html.
Finally, before you return your revised manuscript, please update your database entry if necessary.

### 5. Electronic Supporting Information

A manuscript may include Electronic Supporting Information which will be accessible only on the WWW. Authors must keep a copy to make available to readers who do not have access to the internet. As this material [text, tables, schemes, figures **but not crystallographic (CIF) data**, which must be submitted to either the FIZ or the CCDC] undergoes the peer review process, it must be included, clearly marked as "Supporting Information to be published electronically", when the paper is submitted. The following file formats are accepted: MS Winword or ASCII (*.doc, *.txt), MS Excel (*.xls), Encapsulated Postscript (*.eps), Portable Document Format (*.pdf), graphics embedded in MS Winword; if you wish to submit other formats, please consult the Editorial Office. When preparing such material, authors should keep in mind that — once accepted — it will be made available as provided by the author and not edited. Material accepted for electronic publication will be available mostly as PDF files (Adobe Acrobat Reader required) by following the Table of Contents link of EurJIC's WWW home page. A standard text will be added on the first page of the article in the printed version:

- Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

The supporting information file must start with the title of the paper, the authors and the CASSI abbreviation of the journal to which it was submitted (e.g. *Eur. J. Inorg. Chem.*).

### 6. Basic Keyword List

To increase the relevance of articles found by search engines of Wiley InterScience, we have compiled a keyword catalogue common to our chemistry journals that is printed here and is also available online (http://www.eurjic.org).

To assist you in finding keywords they are listed according to categories. You may choose keywords from any category. As with all such records, a few guidelines facilitate the catalogue's use, and these are briefly explained below:

1. As many as possible, but at least two, of the maximum of five keywords assigned to an article must come from this list.

2. Named reactions will be incorporated only in exceptional cases. Generally the reaction type is selected instead. For example, Diels−Alder reactions will be found under "Cycloadditions" and Claisen rearrangements under "Rearrangements".

3. Heteroanalogues of compounds are mainly classified under the C variants, for example, (hetero)cumulenes, (hetero)dienes. A few aza and phospha derivatives are exceptions.

4. Compounds with inorganic components that are central to the article are listed under the element, for instance, iron complexes under "Iron". Some group names like "Alkali metals" exist alongside the names of important members of the group like "Lithium". In such cases the group name is used for these members only when comparative studies are described. The members not appearing separately are also categorised under the group name.

5. A keyword in the form "N ligand" is only chosen if a considerable portion of the paper deals with the coordination of any ligand ligating through the atom concerned.

6. Spectroscopic methods are assigned as keywords only if the article is about the method itself, or if the spectroscopic technique has made an important contribution to the problem under investigation.

7. "Structure elucidation" is intended only if the crux of the paper is a structural elucidation or if a combination of several spectroscopic techniques were needed for conclusive solution of the structure.

8. An attempt has been made to avoid synonyms and to select more general concepts rather than specialized terms. Thus, the term "Double-decker complexes" is excluded in favour of "Sandwich complexes".

This list will be a "living" catalogue to be flexible enough to absorb the new developments in chemistry. We therefore welcome all suggestions from our authors that might improve its user-friendliness.

# 1,3,5-Triazine-Based Synthons in Supramolecular Chemistry

**Patrick Gamez*[a] and Jan Reedijk*[a]**

**Keywords:** Supramolecular chemistry / Self-assembly / Crystal engineering / N ligands / Cyanuric chloride / 1,3,5-Triazine

Interest in supramolecular chemistry has grown significantly during the past two decades. In this context, hydrogen bonding and/or coordinative interactions have been extensively used to generate self-assembled one-, two- or three-dimensional polymeric networks. Crystal structure prediction has progressed tremendously, and the challenge for the contemporary supramolecular chemist is now to produce custom-made functional (and multifunctional) materials involving intermolecular interactions. Since the early 1990s, 1,3,5-triazine derivatives have shown their potential as building blocks for the preparation of such materials. In this microreview, a selection of outstanding examples of supramolecular networks involving the 1,3,5-triazine unit are discussed, illustrating the possibility of forming remarkable architectures by means of coordination and/or hydrogen bonds and their applications in host–guest chemistry, catalysis, anion recognition, sensoring, electronics and magnetism.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## 1. Introduction

Supramolecular chemistry is one of the topical fields of contemporary chemistry and has first been defined in 1978 by Jean-Marie Lehn as the "chemistry of molecular assemblies and of the intermolecular bond".[1] Supramolecular chemistry is a vast interdisciplinary field of research and technology, where noncovalent bonding may be a common ground. A rapidly developing branch of supramolecular chemistry is crystal engineering, in which synthetic control is particularly required.[2,3] Nowadays, the main focus of crystal engineering is the design and synthesis of molecular building blocks whose intermolecular interactions[4] with other synthons would allow some degree of predictability regarding the form and/or function of the resulting materials.[5] For instance, the chemistry of hybrid nanostructured organic–inorganic solids involving metal–ligand coordination units is emerging as a primary research area,[6] since it offers the possibility of combining different properties at the molecular level and leading to new composite materials with unprecedented behaviour.[7,8] Furthermore, the combination of coordination chemistry with noncovalent contacts, such as hydrogen bonding[9,10] or π-interactions,[11,12] provides a powerful method for generating supramolecular networks from simple building blocks. These three types of bond are indeed important in conceiving unique frameworks, since they all involve directional interactions.[13] From the perspective of crystal engineering, the benefit of using transition-metal ions is that the shape of the coordination building unit can be controlled by choosing the coordination geometries of the metal ions properly. A more specific geometry can then be obtained by judiciously attaching suitable functional substituents to the ligands, which will act as intra- and/or intermolecular connectors. Thus inorganic–organic hybrid supramolecular assemblies with unusual network topologies should be accessible through noncovalent interactions,[14] i.e. H-bonding and π-interactions.

1,3,5-Triazine derivatives have proven their great potential in this rising area of material chemistry, both for their π-interaction abilities,[15] and for their aptitude to be involved in intricate H-bond networks.[16]

The present review deals with the background on supramolecular architectures involving the 1,3,5-triazine ring as the central building moiety. A number of triazine-containing molecules have been used in crystal engineering and have allowed outstanding new developments in the arena of tailored functional materials.[17]

## 2. Preparation of 1,3,5-Triazine-Based Organic Building Blocks

1,3,5-Triazine-containing compounds have found a number of applications in medicinal chemistry,[18] herbicides,[19] catalysis[20] or polymer chemistry.[21] Sophisticated *s*-triazine derivatives can be easily prepared from the cheap, readily available cyanuric chloride, i.e. 2,4,6-trichloro-1,3,5-triazine.[22] Cyanuric chloride is definitely an excellent synthon for the straightforward preparation of highly structured multitopic molecules.[23] Indeed, each chloride atom of 2,4,6-trichloro-1,3,5-triazine can be substituted by any nucleophile (Figure 1). The first substitution is exothermic and so the reaction mixture must be cooled down to 0 °C. The second chloride substitution can be performed at room temperature. Finally, the third position is functionalized under solvent reflux.

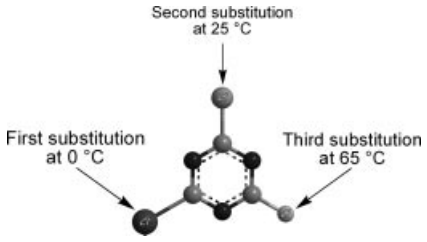

Figure 1. Differential reactivity of 2,4,6-trichloro-1,3,5-triazine.[23]

Therefore, by carefully controlling the temperature, 2,4,6-trisubstituted triazines can be synthesized by sequential, very selective addition of all kinds of nucleophiles, namely amines, alcohols, thiols or Grignard reagents (Figure 2). The yield of each substitution often exceeds 95% and the symmetric trisubstituted derivatives can even be obtained in a one pot synthesis. Various solvents can be used such as tetrahydrofuran, 1,2-dimethoxy ethane, acetonitrile, diethyl ether, and so on.

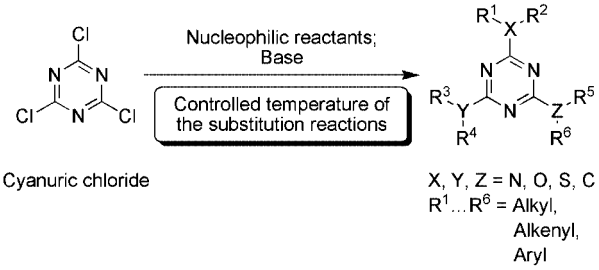

Figure 2. Preparation of polyfunctional triazine derivatives.

Numerous triazine derivatives have been prepared following this versatile synthetic pathway.[24–27]

## 3. Melamine Derivatives as Synthons for the Preparation of H-Bonded Self-Assemblies

Hydrogen bonds play a fundamental role in nature where they are particularly responsible for controlling the structure and function of many proteins, recognition of substrates by various enzymes and for the double-helix struc-

*Patrick Gamez (1967, Casablanca, Morocco) studied Chemistry at the University of Lyon in France where he obtained his first degree. In 1995, he received his D. Phil. in the field of enantioselective catalysis under the supervision of Professor M. Lemaire and was awarded the French Chemical Society Prize for his PhD research. After a period of postdoctoral research at the Max-Planck-Institut für Kohlenforschung in the group of Professor A. Fürstner and at the University of Strasbourg in the group of Dr C. Mioskowski, he joined the research group of Professor J. Reedijk. His current research interests are copper biomimetics and oxidation catalysis, and design of multidentate ligands for crystal engineering. He is (co)author of about 70 publications.*

*Jan Reedijk was born in 1943 in The Netherlands. He is currently Professor of Chemistry at the Leiden Institute of Chemistry, Leiden University, The Netherlands. After obtaining his PhD from Leiden University in 1968 (Thesis title: Methyl Cyanide as a Ligand) and a junior lectureship, he lectured in Delft University of Technology until November 1979, when he accepted his present position. During 1993 he was a visiting Professor at Cambridge University (UK), and during 2002 at the University of Louvain-la-Neuve (Belgium). His current research interests include coordination chemistry of transition-metal ions, bioinorganic chemistry (active-site structure and mechanism; models; metal–DNA interactions), applications of coordination chemistry in catalysis, medicine, ion-exchange and surface chemistry, extended (magnetic, electric) interactions in coordination compounds (dimers, clusters, chains), and molecular recognition and intermolecular interactions (catalysis, biomacromolecules). He has over 900 (co)-authored refereed research publications and patents and has supervised over 100 postdoctoral and graduate students (since 1973). Some of his major professional activities, honours and awards are: Director Leiden Institute of Chemistry (1993–2004); Member of the International Advisory Board of a number of International Conference Organisations, such as the EURASIA Conferences of Chemistry, Macromolecular Metal Complexes Conferences, EUROBIC and ICBIC. Other honours: elected as Executive Secretary of the International Coordination Chemistry Conferences (1989) and acted as President of the Royal Netherlands Chemical Society in 1990; Board member of the Chemistry Research Council (1998–2002); Elected Honorary member of the Royal Netherlands Chemical Society; Awardee of the Max Planck Research Award in Chemistry in 1992; Elected Member of the Finnish Academy of Sciences (1997); Elected Member of the Royal Netherlands Academy of Sciences (1996); Elected Member of the Academia Europaea (2004). He is and has been a member of the editorial boards of over 15 major chemistry journals, such as: Chem. Commun., Inorg. Chem., J. Chem. Soc., Dalton Trans., New J. Chem., Russian J. Coord. Chem., J. Inorg. Biochem. and the J. Biol. Inorg. Chem. He has served on several IUPAC committees on nomenclature of (bio)inorganic, biochemical, physical organic chemistry and terminology between 1978 and 1998. He is one of the founding editors of Eur. J. Inorg. Chem. (a merger from several European Chemical Society Journals).*

ture of DNA (Figure 3). Consequently, hydrogen bonding has become one of the most important noncovalent interactions in supramolecular chemistry.[28,29]

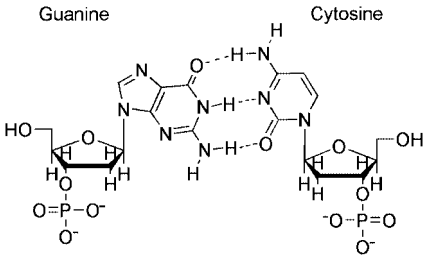

Figure 3. Watson–Crick base pairing in DNA.

Fifteen years ago, Whitesides and coworkers have shown that melamine derivatives could be used to generate outstanding aggregates.[30,31] The reaction of cyanuric acid (CA) with melamine (M) leads to the formation of an insoluble very stable (it can be heated to 450 °C without any alteration of the structure) H-bonded 2D network (Figure 4, CA·M),[30] which has been first reported in 1979 by Junichi and coworkers.[32]

In the earlier 1990s, Whitesides and coworkers have improved the preparation of this type of self-assemblies by using both substituted melamines and barbituric acids.[31] In that way, it is possible to control, by steric hindrance, the formation of the 2D frameworks. Reaction of 5,5-diethylbarbituric acid with 2-amino-4,6-(*N*-*p*-tolylamino)-1,3,5-triazine yields a linear tape (Figure 5a). If 2-amino-4,6-(*N*-*p*-methylbenzoatoamino)-1,3,5-triazine is combined with 5,5-diethylbarbituric acid, a crinkled tape is obtained (Figure 5b). Finally, with a bulkier group on the phenyl ring, i.e. *tert*-butyl, a rosette motif is achieved (Figure 5c).

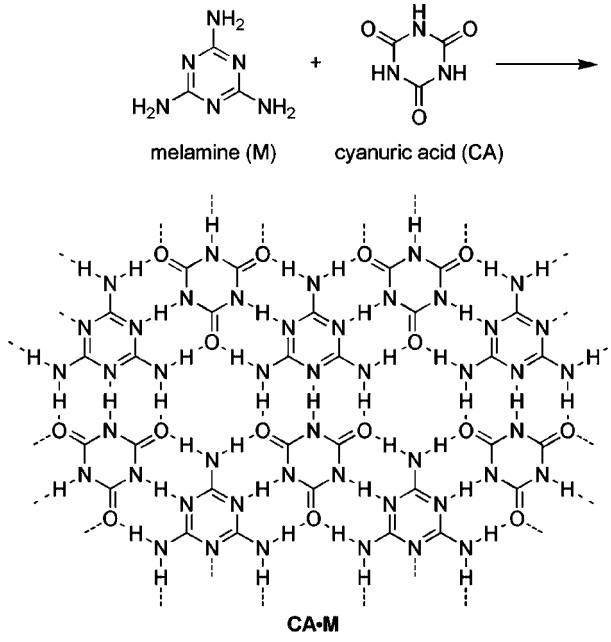

Figure 4. Self-assembly network by means of hydrogen bonds.[16,32]

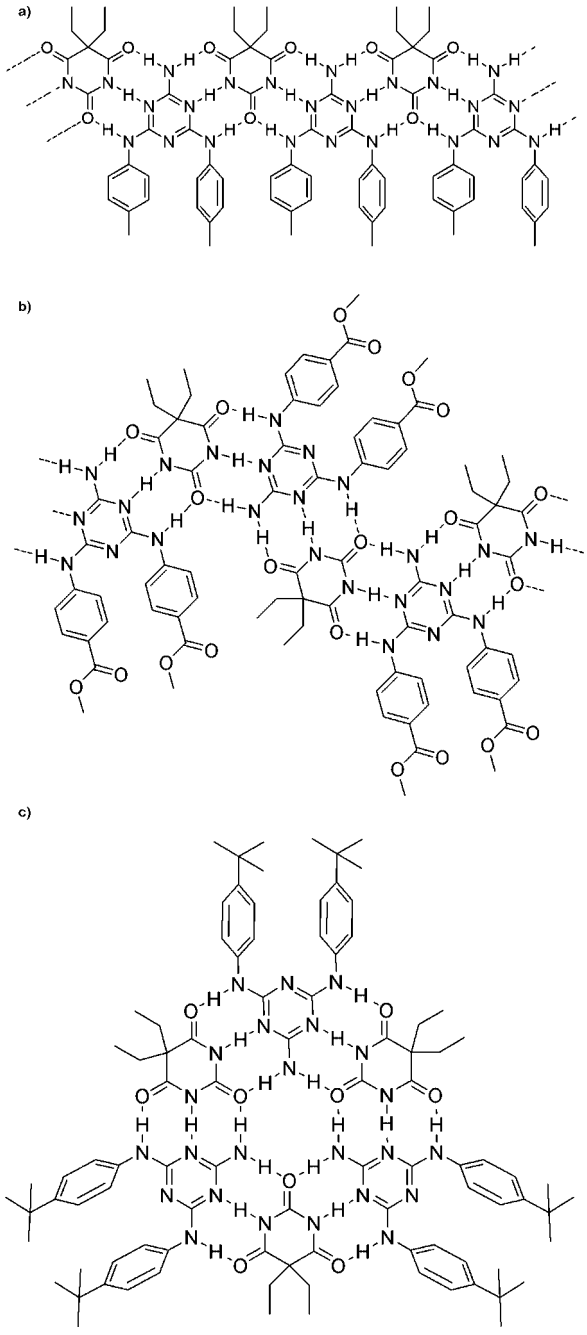

Figure 5. Structures of linear tape, crinkled tape, and rosette motifs.[16]

It has thus been evidenced that a competition takes place between nonbonded steric interactions (*para*-substituents) and a tendency for a high packing coefficient which is important in determining which type of structural motif is realized between the melamine derivative and 5,5-diethylbarbituric acid.[16] As a result, a small *para*-substituent like a methyl or a chloride group leads to a linear tape. If this substituent becomes larger than a trifluoromethyl unit, steric interactions between adjacent melamines prevent the linear structure and favour the crinkled motif where the hin

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

drance is minimized. When the size of the *para*-substituent is further increased, to a *tert*-butyl group for example, then the steric interactions are relieved in the rosette type assembly.[16]

More recently, Reinhoudt and coworkers have beautifully developed the above concept to design and prepare more intricate H-bonded networks.[33,34] Thus, molecular cage hosts can be generated by self-assembly of calixarene-based melamine derivatives and diethylbarbituric acid.[35] A non-covalent phenolic receptor has been successfully prepared by hydrogen-bonding directed association of a calixa[4]rene dimelamine compound with diethylbarbituric acid (Figure 6).[36]

For instance, the simple mixing of the building blocks **1** (1 equivalent) and DEB (2 equivalents) in an apolar solvent like chloroform or toluene produces the double rosette $\mathbf{2}_3\cdot(DEB)_6$ (Figure 7). The formation of this calixarene-bridged supramolecular structure can be followed by solution $^1H$ NMR spectroscopy.

$\mathbf{2}_3\cdot(DEB)_6$ holds six H-donor/acceptor side-arms which can act as phenol binding sites by means of H-bonds between a urea function [Figure 6, $R^1 = R^2 = CONH(CH_2)_2CH_3$] and the phenolic guest (Figure 7, G). The complexation of 4-nitrophenol by $\mathbf{2}_3\cdot(DEB)_6$ has been investigated by proton NMR spectroscopy at room temperature in $CDCl_3$. This comprehensive study clearly demonstrates that the double rosette is an *exo*-receptor able to accommodate six molecules of phenolic guest (one phenol unit per ureido group).

Last year, Meijer and coworkers reported another remarkable supramolecular rosette motif which has been evidenced by scanning tunnelling microscopy (STM).[37] For

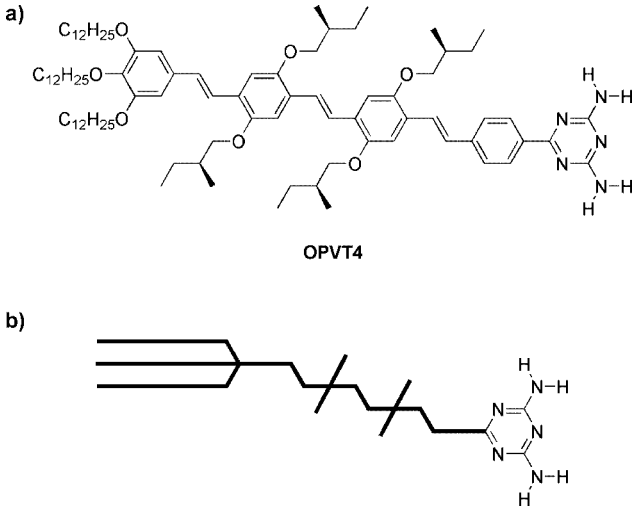

Figure 8. a) Melamine-based π-conjugated ligand OPVT4 and b) its schematic representation.[37]

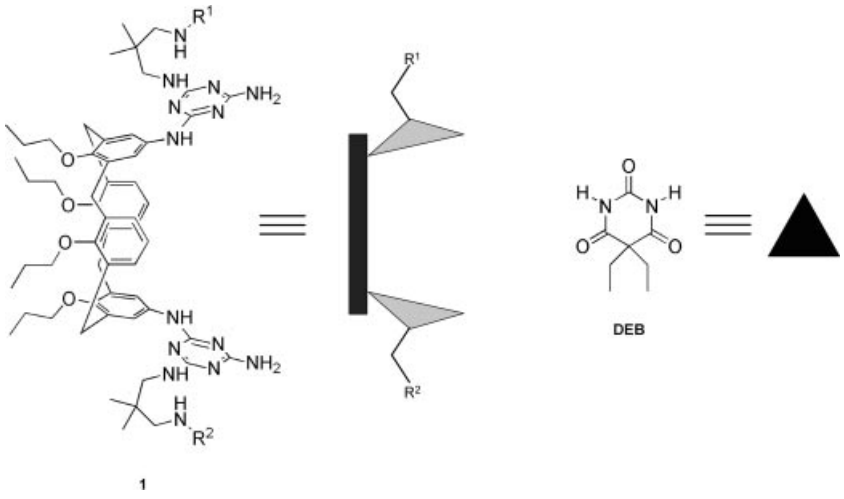

Figure 6. Building blocks for the formation of a double rosette assembly.[36]

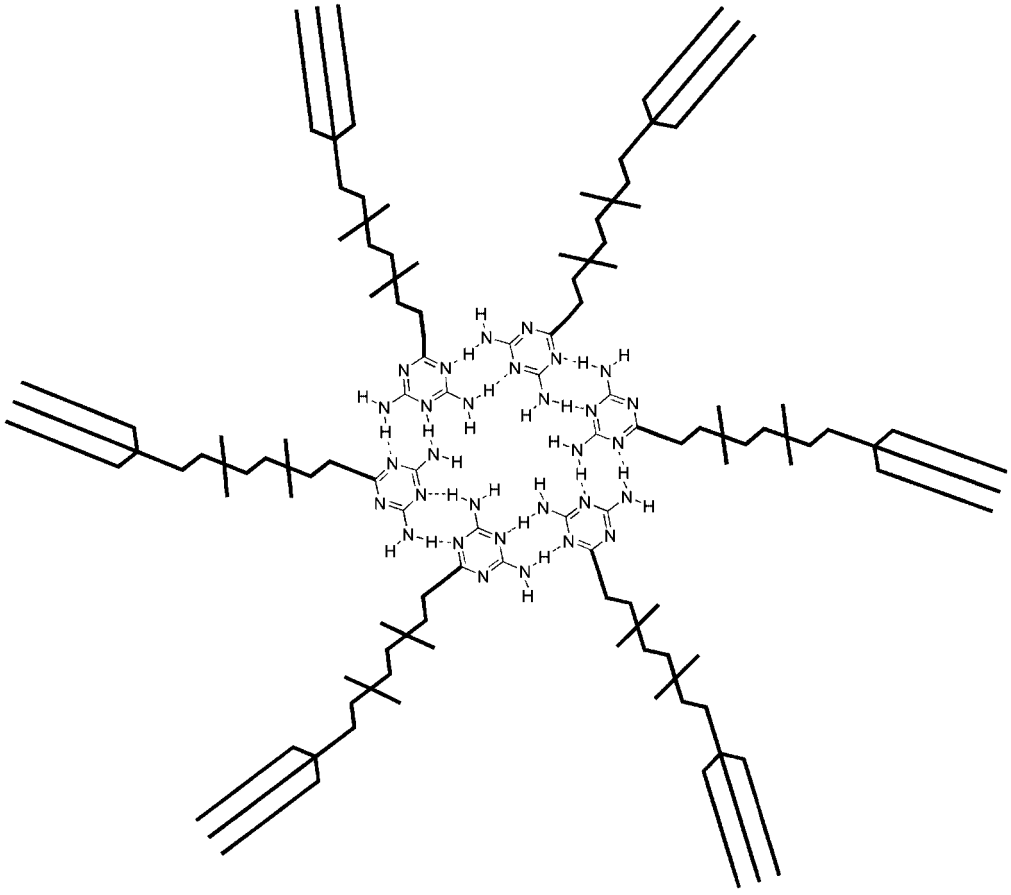

Figure 9. OPVT4 rosette.[37]

this purpose, the triazine-based ligand OPVT4 has been synthesized according to a reported procedure (Figure 8).[38] In solution in heptane, six OPVT4 molecules give a giant helical rosette with a width of about 10 nm (Figure 9).[37] This exceptional aggregation process has been followed by UV/Vis and circular dichroism (CD) in heptane and temperature-dependent measurements show that the rosette is dissociated at elevated temperature ($T$ = 305 K).

In addition, the hydrogen-bonded hexamer is chiral as proven by CD and by the counterclockwise rosette structure clearly visible in the STM images.[37] These rosettes can be stacked together to form fibres with lengths up to 10 μm as revealed by atomic force microscopy (AFM). The self-assembled tubular aggregates 6.4 nm in diameter are still soluble in heptane owing to the peripheral apolar alkyl chains (Figure 10).

The cavity generated by the formation of the hexameric rosette is about 1 nm wide and contains amine groups which would therefore find application as an ideal channel for transportation. Furthermore, the tubular stacks exhibit a well-defined and ordered π-conjugated outside shell with probable electronic properties.

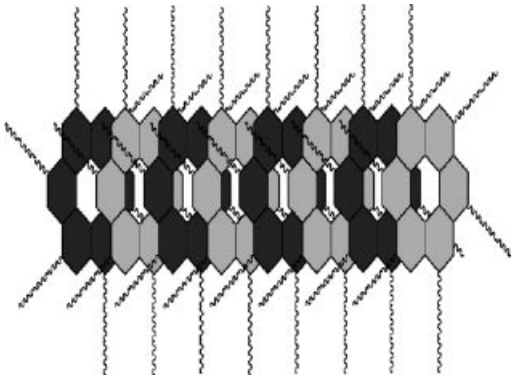

Figure 10. Rosette stacks leading to a tubular fibre.[37]

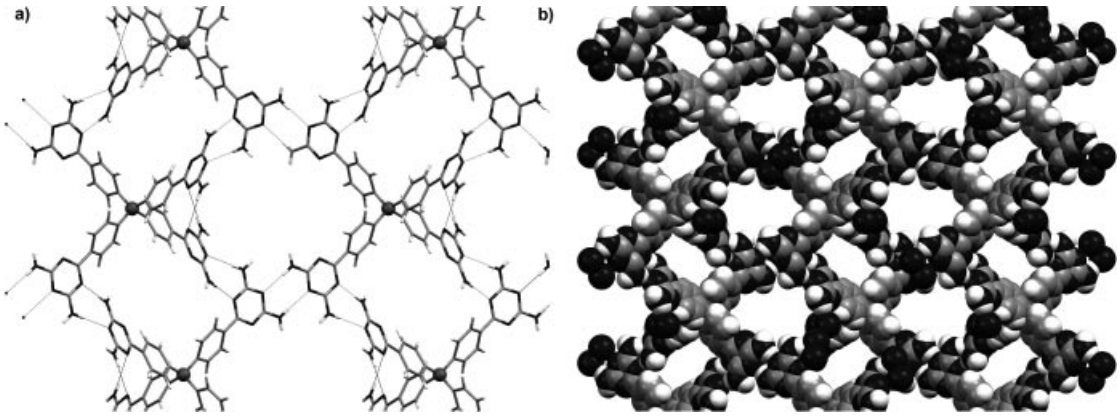

Figure 12. a) Anionic H-bonded network **2**. b) Interconnected channels.[39]

Very recently, Wuest and coworkers designed and synthesized a 3D triazine-based synthon, i.e. the tetraphenylborate Na·**2** (Figure 11).[39] The tetraphenylphosphanium salt of **2** is obtained quantitatively from the sodium salt by cation exchange. Single crystals of tecton $PPh_4$·**2** have been grown from a DMSO/toluene solution of the compound, whose solid-state structure reveals an aesthetic three-dimensional network, connected by multiple hydrogen bonds as expected (Figure 12). This anionic supramolecular architecture is extremely porous (Figure 12b), since 74% of the volume of the crystals is available for cations and guest molecules (DMSO in the present study). Materials with such great porosity are very important in the field of gas storage,[40] especially for fuel-cell applications.[41,42]

In addition, the cation can be exchanged within the crystalline solid compound. Thus, the same anionic framework is achieved when using phenazinium cation **3** (Figure 13) instead of tetraphenylphosphonium. These crystals of tecton **2** with phenazinium **3** as the counterion have been exposed to a solution of an excess of $PPh_4Br$ in DMSO for 24 h at room temperature. The resulting material remains transparent and crystalline, and diffracts with unit cell parameters analogous to those of $PPh_4$·**2**. This is an important result as a larger cation, **3**, has been replaced by a smaller one, namely tetraphenylphosphanium. Indeed, such exchange releases space within the porous material, which is available for additional neutral guest molecules. This finding gives rise to a novel approach of crystal engineering where new ionic host–guest materials can be produced by substitution of the initial cations to increase their porosity and/or physical properties without modification of their molecular arrangement.

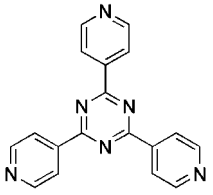
## 4. 1,3,5-Triazine Derivatives as Ligands for the Preparation of Coordination Self-Assemblies

Coordination compounds from 1,3,5-triazine-based ligands are increasingly reported in the literature.[43–48] This is undoubtedly due to the ease of preparing intricate polydentate star-shaped ligands using simple and high-yielding reactions.[23] Especially one ligand, namely 2,4,6-tri(4-pyridyl)-1,3,5-triazine (Figure 14, tpt), has been extensively used in the field of crystal engineering during the past ten years.[47,49] However, novel and attractive supramolecular architectures continue to be obtained with this simple tridirectional N-donor ligand.[50] Robson's group[49] published the first crystallographically characterized coordination polymer based on tpt 24 years after it was primarily reported by Yasumoto and coworkers.[51]



**tpt**

Figure 14. 2,4,6-tri(4-pyridyl)-1,3,5-triazine ligand (tpt).[49,51]

In 1996, Robson and coworkers described a unique system of two interpenetrating coordination networks based on tpt and copper(I) building blocks (Figure 15a).[52] The infinite (3,4)-connected network is built from repeated structural motifs with six copper centres at the corners of a regular octahedron (Figure 15b), each copper ion being shared by two adjacent motifs. This arrangement results in an infinite cubic collection of 18-Å-wide octahedral cavities filled with solvent molecules.

Almost at the same time, Fujita and coworkers reported a similar octahedral cage assembled from tpt and palladium(II) nodes.[53] The reaction of six equivalents of the $Pd^{II}$ complex **4** with four equivalents of tpt leads, in water, to the exclusive and quantitative formation of the supramolec-

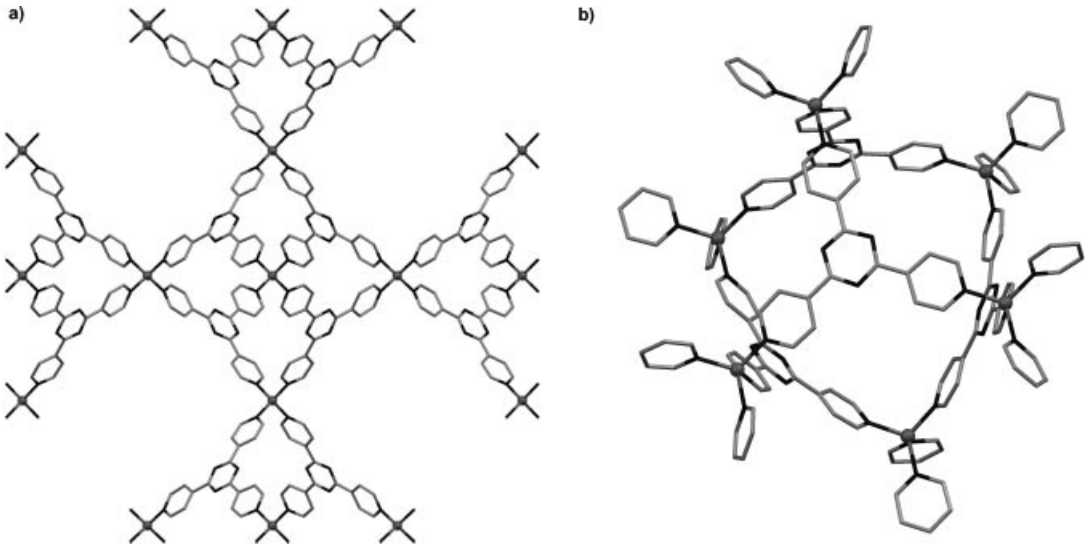

Figure 15. a) Cubic (3,4)-connected net. b) Octahedral host chamber.[52]

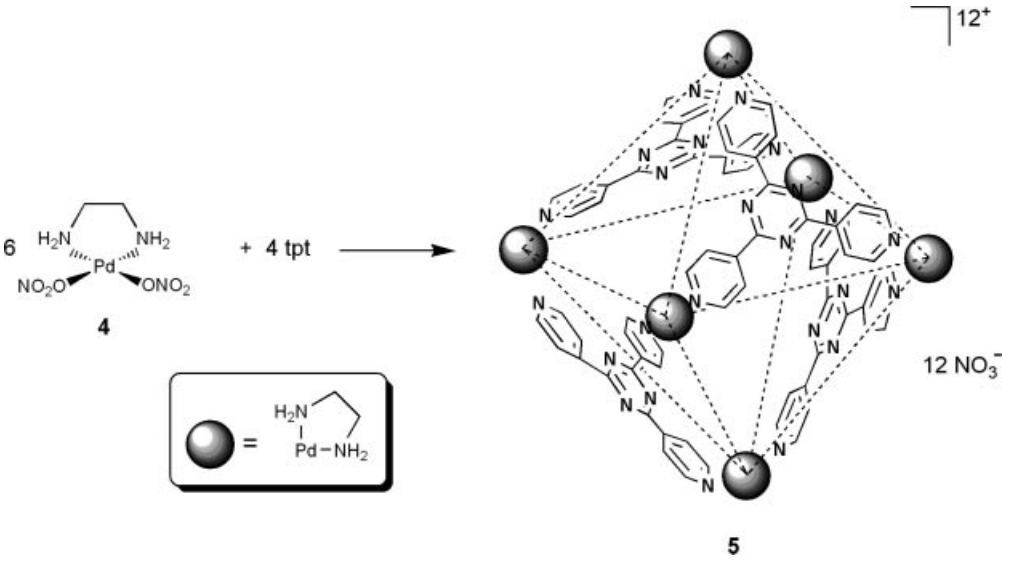

Figure 16. Self-assembly of a nanometer-scale octahedral cage.[53]

ular cage **5** (Figure 16).[53] The assembly of complex **5** has been followed by $^1$H NMR spectroscopy, which clearly demonstrated that the $M_6L_4$ compound is the thermodynamic product since its formation is not affected by the presence of an excess of **4**.

It has been shown that this coordination cage can bind efficiently various organic guest molecules[54,55] including radicals[56] as well as a water cluster[17] in its cavity. For example, *o*-carborane, an icosahedral carbon–boron cage molecule with a diameter of 8 Å, can be encapsulated in **5**.[57] This spherical, neutral molecule is apolar and insoluble in water. However, when a hexane solution of *o*-carborane is stirred with a $D_2O$ solution of **5**, four equivalents of *o*-carborane are transferred into the $D_2O$ phase to form **5**·(*o*-carborane)$_4$, as evidenced by $^1$H NMR spectroscopy. This host–guest complex has never been crystallized, but the analogous compound having 2,2′-bipyridine as *cis*-protecting ligand in place of ethylene diamine is easily crystallized in water (Figure 17).[54]

Fujita and coworkers then tried to use these cavities to perform catalytic reactions.[58] The palladium-catalyzed Wacker oxidation of styrene has been carried out in water with **5**, which can accommodate three molecules of styrene (**6**) in its cavity.[58] If the reaction is achieved at 80 °C with **4** or with **5**, only 4% of acetophenone (**7**) is detected. If the oxidation is performed in the presence of both **4** and **5**, then the yield in acetophenone is significantly increased to 86% (Figure 18a). Similarly, the ability of **5** to promote the isomerization of allylbenzene (**8**) has been examined. Once again, while the reaction does not occur in the absence of either **4** or **5**, 50% of β-methylstyrene (**9**) is obtained when a 2:1 mixture of **4** and **5** is used (Figure 18b).[59] Complex **5** acts as a phase-transfer reagent which brings the substrate, i.e. the organic molecule **6** or **8**, into the aqueous

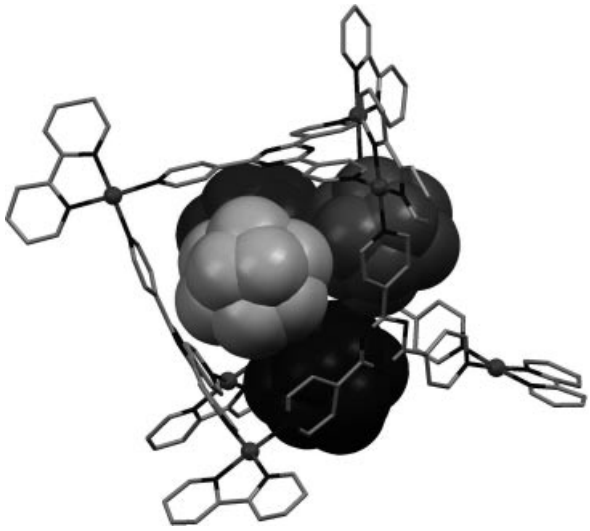

Figure 17. Encapsulation of four *o*-carborane in an $M_6L_4$ cage.[57]

phase where the palladium-mediated chemical transformation takes place. These outstanding results represent good examples of solvent-free organic reactions.

More recently, we have undertaken research investigations on coordination networks involving *s*-triazine-based N-donor ligands. For this purpose, a series of polydentate ligands have been prepared[23,60,61] according to the synthetic pathway depicted in Figure 2, and some of them are reported in Figure 19.

The simple dpyatriz ligand arises from the substitution of the three chlorides of cyanuric chloride by 2,2′-dipyridylamine and has been reported by some of us[23] and by Wang and coworkers.[62,63] Reaction of $Cu^{II}$ nitrate with dpyatriz in acetonitrile at room temperature produces a 1D ladder coordination polymer, whose crystal structure is depicted in Figure 20.[61] The polymeric compound is built up from pentanuclear copper units which are bridged by bidentate nitrate anions (Figure 20b). This uncommon molecular network[3] possesses large rectangular guest cavities with dimensions of approximately 10 × 5.5 Å, which are filled with seven acetonitrile molecules.[61] Thus, the uncoordinated solvent molecules cover 25% (652 Å$^3$) of the unit cell volume.

Thermogravimetric analysis (TGA) of the polymeric material shows 11.1% loss in weight, which exactly matches seven acetonitrile molecules. A second TGA experiment on the acetonitrile-free crystalline material left in air shows a decrease of 18.8% in weight. This decrease is attributed to the loss of water molecules rapidly taken up by the initial

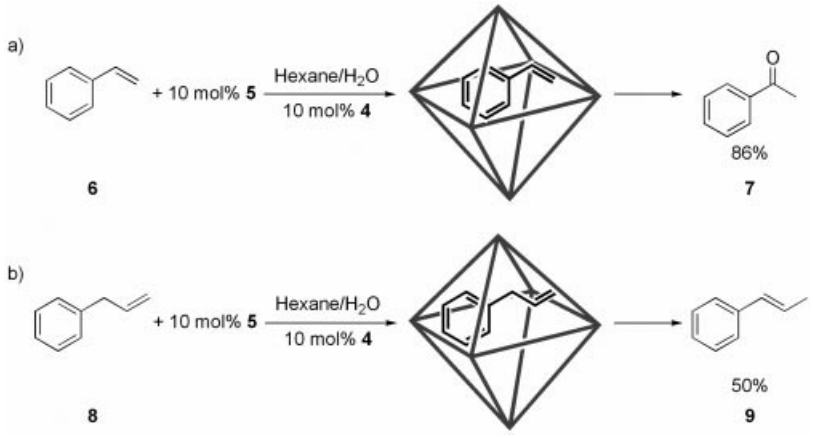

Figure 18. a) Wacker oxidation in the $M_6L_4$ cage.[59] b) isomerisation of an alkene in the $M_6L_4$ cage.[58]

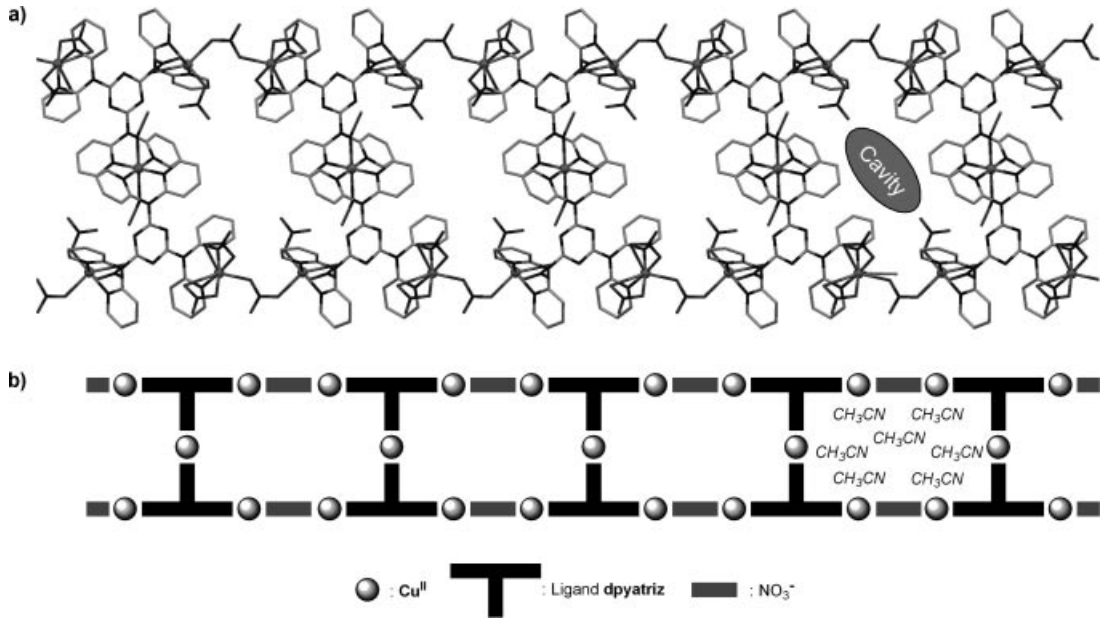

Figure 20. a) 1D ladder coordination polymer obtained from the ligand dpyatriz and $Cu(NO_3)_2$; and b) its schematic representation.[61]

material after removal of the acetonitrile molecules. This result demonstrates the possibility of using this 1D ladder coordination polymer in host–guest molecular recognition.

Another attractive coordination compound has been obtained by our group from the extended ligand opytrizediam (Figure 19). Indeed, the reaction of copper(II) chloride with this ligand in methanol leads to the formation of a 1D zigzag coordination polymer (Figure 21).[64] The polymeric compound is composed of trinuclear copper units that are connected by means of chloride bridges in a zigzag fashion, since the ligands are *up* and *down* alternated (Figure 21b). Despite its unusual arrangement,[3] this material exhibits interesting physical properties. First, a large amount of solvent molecules is present in the crystal lattice (29% of the unit cell volume, 1016 $Å^3$). The removal of these molecules may create space for the sorption of gases such as dinitrogen and dihydrogen. This is a vital feature in the field of fuel cell chemistry.[41,42,65] Second, the coordination polymer possesses ferromagnetic properties [$J$ = 6.4(1) $cm^{-1}$] inherent to the doubly chloro-bridged dicopper moieties linking the complexes to generate the infinite chain.

Recently, a very important finding in the field of anion recognition has been achieved by using the dendritic ligand azadendtriz (Figure 19).[66] Indeed, anions are ubiquitous in biochemical structures.[67,68] Contrary to that of cations, the binding of anions has received little attention. However, during the past two decades, an increasing number of anion receptors have been developed,[69,70] most likely because of their potential applications in medicine, biology, catalysis, or for the elimination of anionic polluting wastes.[71]

A number of recent publications have reported theoretical investigations on the binding of halides with the electron-deficient *s*-triazine ring.[72] All calculations clearly indicate energetically favourable noncovalent interactions between the halide and the electron-poor aromatic ring.[73,74] Consequently, *s*-triazine-based compounds are perfect candidates for the development of anion host chemistry. This

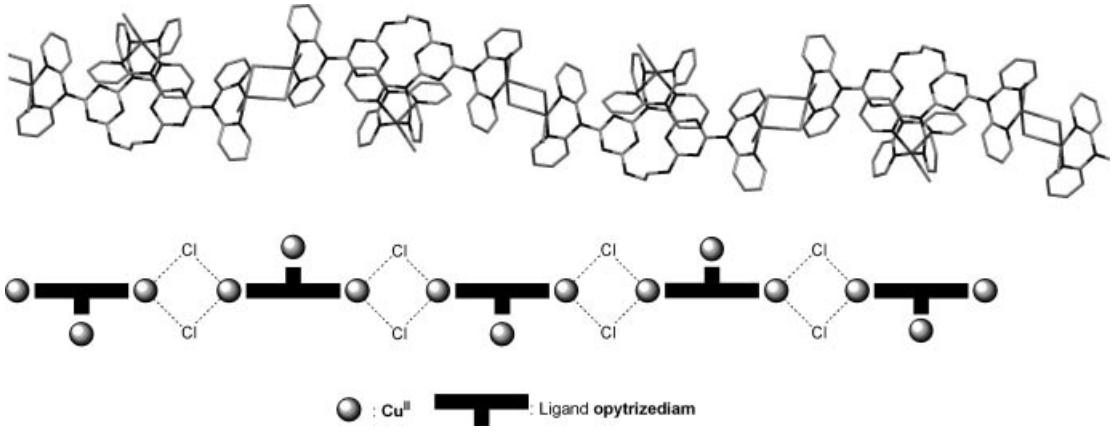

Figure 21. a) 1D zigzag coordination polymer obtained from the ligand opytrizediam and $CuCl_2$; and b) its schematic representation.[64]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

property was recently evidenced by the first crystallographic proof of such interactions.[75]

Reaction of copper(II) chloride with the ligand azadendtriz (Figure 19) in dichloromethane/water yields the tetracopper complex depicted in Figure 22a, where the triazinyl groups are stacked two by two in a parallel mode. This is often observed in triazine rings and is known as the Piedfort effect.[76] As a result, the copper ions are coordinated by two 2,2′-dipyridylamino units from two different *s*-triazine rings, generating two aromatic baskets, each formed by four pyridines (Figure 22b). These open cavities act as anion receptors for two chlorides through anion-π interactions. In addition, the chloride ions are close to the neighbouring triazine rings (Figure 22a), suggesting electrostatic interactions between the guest and the electron-deficient triazine moieties. Thus, the combination of both electronic effects produces the first non-hydrogen-bonding artificial anionic receptor.

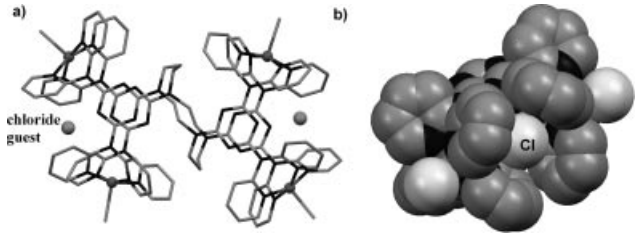

Figure 22. a) [$CuCl_2$–azadentriz] complex showing anion-binding properties; b) guest chloride anion embraced between four pyridine rings.[66]

Finally, the influence of the temperature and the pressure on the nature of the coordination framework obtained has been clearly demonstrated by using the ligand dpyatriz (Figure 19).[77] The reaction of zinc(II) nitrate with dpyatriz in acetonitrile at room temperature gives a tetranuclear zinc complex accommodating two triazine-based ligands (Figure 23).[78]

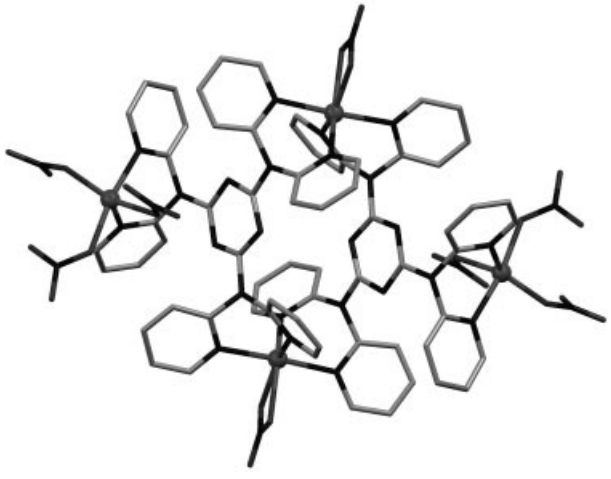

Figure 23. Tetrazinc complex obtained from the ligand dpyatriz and $Zn(^{no}3)2$ at room temperature.[78]

However, if the same reaction is performed in a sealed tube at 105 °C under autogenous pressure, a 1D polymeric chain is obtained (Figure 24).[77] The significantly different crystal packing observed at different crystallisation conditions illustrate the difficulty of anticipating a crystal structure. Crystal engineering involves various interactions between the synthons (ligand, metal ion, anion, solvent). In addition, the temperature and the pressure applied during the experiment are obviously important and hence should be considered for a better prediction of the crystal structure.

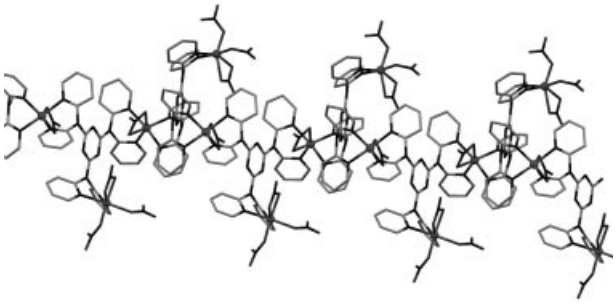

Figure 24. Coordination polymer obtained from the ligand dpyatriz and $Zn(NO_3)_2$ at 105 °C under autogenous pressure.[77]

A closely related 1D coordination polymer is achieved with copper(II) nitrate [in place of $Zn(NO_3)_2$] using the same crystallisation process, while a 1D ladder network is obtained at room temperature and normal pressure (Figure 20 and Figure 24).[61,77]

## 5. 1,3,5-Triazine Derivatives Combining Both H-Bonding and Coordination Interactions

There are only a few examples reported in the literature where the H-bonding ability of melamine derivatives has been used in combination with coordination bonds. Lehn and coworkers have described, in 1995, an ion-labelling system to detect by mass spectroscopy the formation of H-bonded networks by the binding of a metal ion, namely potassium(I).[79] The triazine **10** (Figure 25a) has been syn-

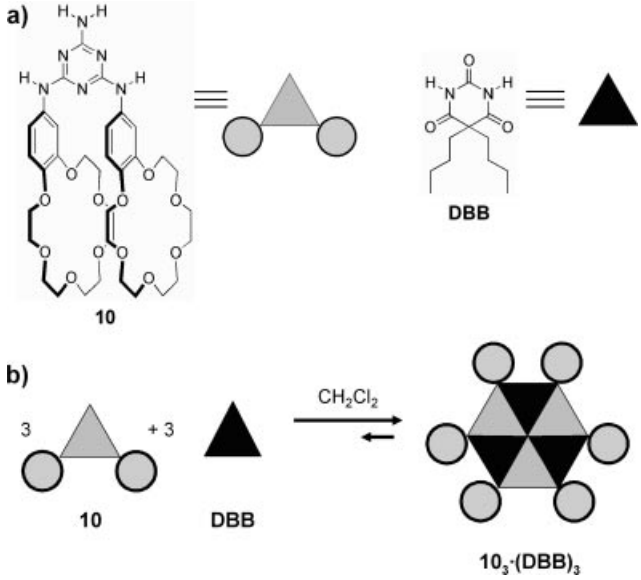

Figure 25. a) Benzocrown-containing triazine-based ligand **10**. b) Formation of the rosette assembly.[79]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thesized in 76% yield by reaction of two equivalents of 4′-aminobenzo[18]crown-6 with one equivalent of 6-amino-2,4-dichloro-1,3,5-triazine. The H-bonded self-assembly of **10** with 5,5-dibutylbarbituric acid (DBB) can lead to the formation of various architectures, namely linear tape, crinkled tape or rosette (Figure 5 and Figure 25b).

Equimolar $10^{-2}$ M solutions of **10** and DBB in dichloromethane are combined and treated with $KPF_6$. The resulting mixture is then analysed by electrospray mass spectrometry (ESMS), which shows ion compositions characteristic for the free ligand **10** and for the self-assemblies $\mathbf{10}_2{\cdot}(DBB)_3$, $\mathbf{10}_3{\cdot}(DBB)_2$ and $\mathbf{10}_3{\cdot}(DBB)_3$. The addition of methanol (which is known to disrupt H-networks) to this reaction mixture causes the disappearance of all peaks due to $\mathbf{10}_x{\cdot}(DBB)_y$ complexes, supporting their presence in the initial solution, since no additional assembly is observed in the gas phase (after addition of methanol). These ESMS studies clearly demonstrate the possibility of using this technique with weakly associated self-assemblies which are destroyed by protonation. The ingenious stratagem consists then of introducing a charge through cation binding to a well-designed synthon such as **10**. In that way, a component like **10** in the presence of a salt forms a neutral supramolecular coordination species that cannot be otherwise characterised by ESMS.[79]

In 1998, Reinhoudt and coworkers developed a similar labelling method for the characterisation of double rosette assemblies, comparable to $\mathbf{2}_3{\cdot}(DEB)_6$ (Figure 7), by MALDI-TOF mass spectrometry.[80] For this purpose, the ligand **11** has been prepared (Figure 26).

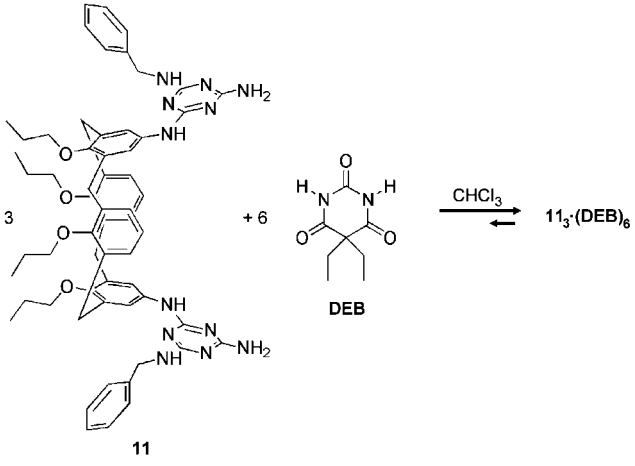

Figure 26. Components used to prepare the double rosette assembly.[80,81]

The $\mathbf{11}_3{\cdot}(DEB)_6$ adduct obtained by mixing **11** and DEB is then stirred with 1.5 equivalents of $Ag(CF_3COO)$ in chloroform for 24 h. Afterwards, the solution is analysed by MALDI-TOF mass spectrometry which shows an intense signal at $m/z$ = 4278.3 (calculated value: 4276.1), ascribed to the silver(I) complex of $\mathbf{11}_3{\cdot}(DEB)_6$ (Figure 27).[80] Moreover, these MS data are in perfect accordance with the $^1H$ NMR spectra of the hydrogen-bonded supramolecules in solution.

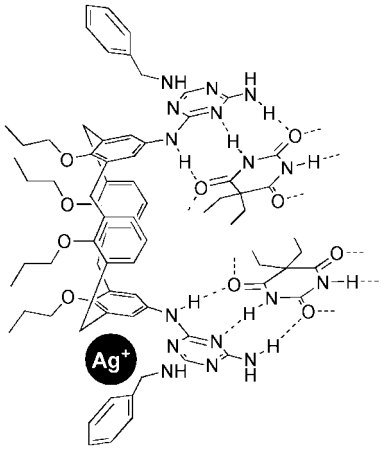

Figure 27. Proposed structure for the silver(I) complex of $\mathbf{11}_3{\cdot}(DEB)_6$. Only a small part of the double rosette is shown for clarity.[80]

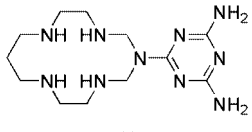
This silver(I) labelling technique has been extended to a variety of hydrogen-bonded assemblies and can be considered as a powerful tool to characterise noncovalent assemblies or host–guest complexes.[81]

In 1998, Bernhardt and coworkers[82] have reported the synthesis of a remarkable ditopic triazine-based ligand, namely [6-(4′,6′-diamino-1′,3′,5′-triazinyl)-1,4,6,8,11-pentaazacyclotetradecane] (**12**, Figure 28).



**12**

Figure 28. [6-(4′,6′-Diamino-1′,3′,5′-triazinyl)-1,4,6,8,11-pentaazacyclotetradecane] (**12**).[82,83]

As expected, this ligand can both bind a metal ion and be involved in the formation of a hydrogen network.[82,83] More recently, Bernhardt and coworkers have used this ligand to obtain a redox-active receptor for neutral guests.[84] The H-bonding abilities of the complex $[Cu(\mathbf{12})]^{2+}$ are obviously due to the presence of a melamine unit that can act as a donor–acceptor–donor entity (Figure 4). This intrinsic property has been used by Bernhardt and coworkers who have prepared a $[Cu(\mathbf{12})]^{2+}$/barbiturate adduct whose crystal structure is depicted in Figure 29.

H-bonded assemblies with barbitone and thymine (Figure 30) have also been obtained and crystallographically characterised. Solution electrochemical studies have been carried out in order to check the possibility of using $[Cu(\mathbf{12})]^{2+}$ as a redox-active receptor. The electrochemical detection is based on a shift of the redox potential of the host $[Cu(\mathbf{12})]^{2+}$ complex upon binding of the neutral guest molecule, i.e. barbitone, thymine, biuret or cytosine (Figure 30). These investigations have shown that the addition of complementary guests such as barbitone or biuret, which have an acceptor–donor–acceptor H-bonding pattern, leads to a significant shift in the $Cu^{II}/Cu^{I}$ redox potential. On the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

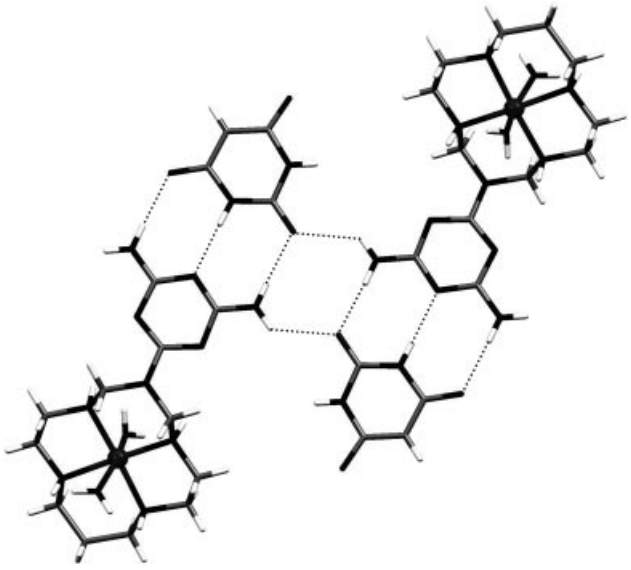


Figure 29. [Cu(**12**)]$^{+2}$/barbiturate H-bonded network.[84]

contrary, no significant shift has been observed with cytosine, which has a donor–acceptor–acceptor H-bonding pattern, mismatched with the donor–acceptor–donor pattern of [Cu(**12**)]$^{2+}$. The communication between the H-bonded element and the coordination unit of the triazine-based molecule has thus been clearly established and a host–guest selectivity has been evidenced. This type of material may be used as a sensor to detect specific polar organic compounds in solution.

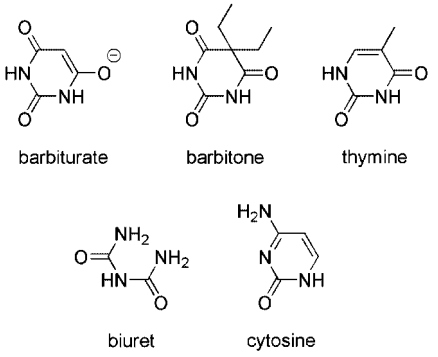

Figure 30. Guest molecules used with the complex [Cu(**12**)]$^{+2}$.[84]

## 6. Concluding Remarks

The vast development of supramolecular chemistry over the past twenty years has led to a huge diversity of chemical assemblies, obtained both by design[5] and serendipitous formation.[85] Tremendous progress has been made in the field of crystal structure prediction, using well-designed ligands and the reticular synthesis approach.[5] 1,3,5-Triazine-based synthons have proven their huge potential in this area, and the present microreview reports on some of the most remarkable examples published so far. The ability of melamine derivatives to generate H-bond networks has been elegantly applied by several research groups to produce host–guest or porous materials. The straightforward synthetic routes to generate sophisticated star-shaped polydentate N-ligands have allowed the preparation of molecular cages with applications in catalysis or separation, coordination polymers with magnetic properties or host–guest cavities, and anion hosting materials. Finally, the judicious combinations of H-bonding and coordinative interactions through the use of well-designed 1,3,5-triazine building blocks have generated functional materials with applications in mass spectrometry labelling and in sensoring. As summarized above, triazine-based supramolecules are highly promising synthons for the design and synthesis of exciting new polyfunctional compounds. The controlled preparation of hybrid inorganic–organic materials has remarkably improved since the late 1990s, and the important challenge of the contemporary supramolecular chemist is now to control the functionalization of such solids.[5] This includes the capacity to design intricate ligands which will act both as structural and functional buildings blocks to prepare custom-made materials possessing one or more specific properties, which can certainly be envisaged starting from the inexpensive, readily available 2,4,6-trichloro-1,3,5-triazine.

## Acknowledgments

Financial support from COST Action D21/003/2001 and the Dutch National Research School Combination Catalysis (HRSMC and NIOK) are thankfully acknowledged. The authors specially thank the coworkers who have been involved in the preparation and characterisation of triazine-based coordination supramolecules and whose names appear in the references list.

# Crystal Structure and Optical Properties of a Lanthanum(III) Complex of the Solvatochromic Dye "Nile Red"

**Anders Døssing,*[a] Magnus Magnussen,[a] and Anne Mette Frey[a]**

**Keywords:** Lanthanum / Heterocycles / N,O ligands / Chelates

A carbethoxy derivative of the push-pull chromophore benzo[*a*]phenoxazin-5-one (Nile Red) forms chelate complexes of the trivalent lanthanide ions that are stable in coordinating solvents with a bathochromic shift of the intense charge-transfer band in the Nile Red chromophore as a result. The complex formation results in quenching of the fluorescence from the free Nile Red ligand. Single crystals of a lanthanum(III) complex have been grown and the X-ray crystal structure showed that two Nile Red ligands are coordinated to the metal centre.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The benzo[*a*]phenoxazine compound Nile Red (nr) is a widely used fluorescent laser dye (Figure 1). The intense absorption band ($\varepsilon_{max} \approx 35000\ cm^{-1}\,M^{-1}$), located in the VIS range,[1] displays some charge transfer character in which electron density is moved from the diethylamino group to the carbonyl group, and nr is, accordingly, often referred to as a so-called push-pull chromophore. The positions of the absorption and emission bands are highly sensitive to the nature of the solvent (polarity and hydrogen-bond acidity), and the absorption maximum ranges from 484 nm in pentane to 629 nm in trifluoroacetic acid.[2] This solvatochromic effect has its origin in the fact that the molecule in the first excited singlet state is geometrically distorted with a significantly higher dipole moment than in the ground state. Exhibiting such twisted intramolecular charge transfer (TICT) properties nr has thus been used extensively as a polarity probe in chemical and biophysical environments.[3] Moreover, Verhoeven found recently that nr was able to sensitize a metal-centred NIR emission from the complexes [Ln(fod)$_3$(nr)] (Ln = Er or Yb, fod = 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dione) in benzene solution.[4] However, complex formation between the Lewis acids [Ln(fod)$_3$] and nr, that occurs through the carbonyl oxygen atom in nr, is weak and does not take place in more coordinating solvents such as acetonitrile (MeCN). In an attempt to overcome this obstacle we have, during our investigations in this field,[5] used a derivative of nr, namely nr-C(O)OEt shown in Figure 1. The attached carbethoxy group makes the formation of a chelate metal complex [Ln$^{III}${nr-C(O)OEt}] possible, resulting in enhanced stability of the metal complexes of nr-C(O)OEt. We present here results that show that nr-C(O)OEt forms complexes with lanthanide(III) (Ln$^{III}$) ions in coordinating solvents. Single crystals of a lanthanum(III) complex of nr-C(O)OEt have been grown, and the crystal structure of this complex has been determined. Despite the fact that nr has been widely used as a polarity probe and that the electronic structure of nr has been subject to numerous theoretical studies,[6] this contribution describes the first example of a crystal structure determination of a compound that includes an nr chromophore.

## Results and Discussion

The synthesis of nr-C(O)OEt has been described by Meng,[7] who prepared a whole series of nr derivatives. From an MeCN solution of nr-C(O)OEt and La(OSO$_2$CF$_3$)$_3$, single crystals of [La{nr-C(O)OEt}$_2$(OSO$_2$CF$_3$)$_3$(OH$_2$)$_2$]·H$_2$O (**1**) were grown. Figure 2 shows the molecular structure of **1**. The lanthanum(III) centre in **1** is coordinated by two molecules of nr-C(O)OEt (each bidentately coordinated as shown in Figure 1), two water molecules, and three triflate anions that are monodentately bound through the oxygen atoms. The coordination geometry is best described as tricapped trigonal prismatic. The La–O bond lengths are normal for these types of ligators. Of special note is the bonding geometry around the aliphatic, tertiary N1 and N3 atom. Firstly, the geometry is close to trigonal planar, and the C–N–C angles range from 115° to 122°, and the C–C8–N1–C and C–C31–N3–C dihedral angles range from 2° to 6° and from –170° to –178°, respectively. Secondly, the N1–C8 and N3–C31 bond lengths of 1.353(3) and 1.330(3) Å, respectively, are significantly shorter than expected for a N(sp$^3$)–C(sp$^2$) bond (1.467(2) Å in 4-aminobenzonitrile hydrochloride).[8] This can be rationalized if we take the ionic

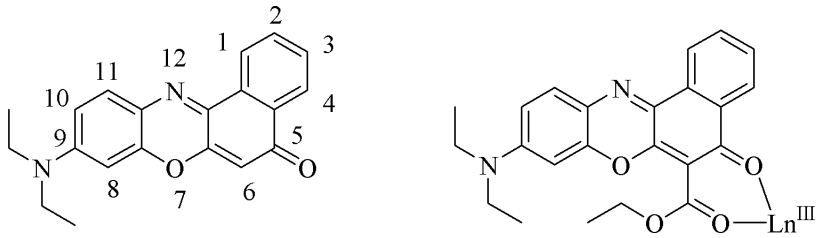

Figure 1. Structure of the ligands nr and nr-C(O)OEt; the latter ligand is chelated to a lanthanide(III) ion ($Ln^{III}$).

resonance structure shown in Figure 3 into account. Here, the lone pairs of electrons on N1 and N3 reside in a pure p orbital which is conjugated with the aromatic ring; this results in an increased order of the N1–C8 and N3–C31 bond and delocalization of a negative charge on the β-keto ester group, as shown in Figure 3. Similar behaviour was seen in other acceptor-substituted aromatic amines such as 4-(dimethylamino)benzonitrile[9] and 4-nitroso-*N*,*N*-diethylaniline[10] in which the analogous C–N bond length was 1.366(2) and 1.358(4) Å, respectively. Han et al. calculated, by density functional methods, the bond lengths of nr in the ground state and the first excited singlet state both in the gas phase and in $H_2O$ solution.[6b] It is worth noting that the bond lengths of the nr-C(O)OEt ligand in **1** agree (within 0.01 Å) with the calculated bond lengths of nr in the ground state in $H_2O$ solution. With regard to other metal complexes of nr, it should be noted in this context that Ghedini isolated the cyclometalated, square-planar complexes of the type [Pd(nr)(acac)] (acac = acetylacetonate or derivatives thereof) in which the nr ligand supposedly bidentately coordinates through the N12 and deprotonated C1 atoms (the atom numbering is taken from Figure 1).[11] No crystal structures were, however, reported.

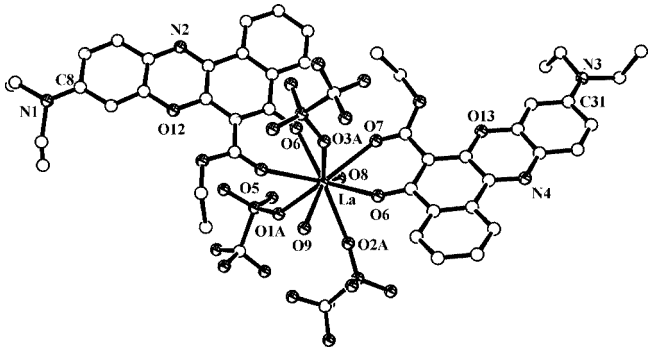

Figure 2. Molecular structure of the complex [La{nr-C(O)-OEt}$_2$($OSO_2CF_3$)$_3$($OH_2$)$_2$] with the hydrogen atoms omitted for clarity. The thermal ellipsoids are shown at the 50% probability. Ranges of bond lengths: La–O(triflate) 2.5623(16)–2.5985(16) Å, La–O(water) 2.5331(15)–2.5903(16) Å, La–O{nr-C(O)OEt} 2.4482(15)–2.5507(15) Å.

For the recording of the $^1$H NMR spectra excess $La(CF_3SO_3)_3$ was added to an acetonitrile solution of nr-C(O)OEt in order to ensure that all nr-C(O)OEt was complexed. In the $^1$H NMR spectrum of such a solution there

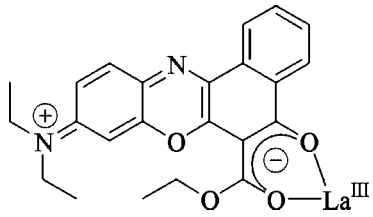

Figure 3. A resonance form of a lanthanum(III) chelate complex of nr-C(O)OEt.

are no peaks originating from free nr-C(O)OEt, and only one type of complexed nr-C(O)OEt is seen. The chemical shift values ($\delta$) for complexed and free nr-C(O)OEt are shown in Table 1. It should be noted that the chemical shifts move downfield on complexation owing to the electron-withdrawing inductive effect of the metal ion, with the exception of those for 2-H, 3-H, and 4-H. The excess $La(CF_3SO_3)_3$ in the solution favours a 1:1 stoichiometry for La/nr-C(O)OEt, but it is worth noting that the crystals that separate out from the solution after long-term storage have a stoichiometry of 1:2.

Table 1. Chemical shift ($\delta$/ppm) assignment of the $^1$H NMR spectra of nr-C(O)OEt and [$La^{III}${nr-C(O)OEt}] in $CD_3CN$ at 298 K.

| Nuclei | nr-C(O)OEt | La{nr-C(O)OEt} |
|---|---|---|
| $N(CH_2CH_3)_2$ | 1.21 | 1.40 |
| $OCH_2CH_3$ | 1.41 | 1.52 |
| $N(CH_2CH_3)_2$ | 3.48 | 3.73 |
| $OCH_2CH_3$ | 4.45 | 4.65 |
| 1-H | 8.19 | 8.38[a] |
| 2-H | 7.68 | 7.62 |
| 3-H | 7.78 | 7.62 |
| 4-H | 8.57 | 8.28[a] |
| 8-H | 6.55 | 6.59 |
| 10-H | 6.83 | 7.38 |
| 11-H | 7.61 | 7.81 |

Stužka et al.[12] studied the IR spectra of various substituted benzo[*a*]phenoxazine compounds, and on the basis of that work, we assign the bands at 1640 and 1733 $cm^{-1}$ in the IR spectrum of nr-C(O)OEt as carbonyl vibrations in the keto and ester groups, respectively. An IR spectrum of a solid with the formula [La{nr-C(O)OEt}$_3$]($CF_3SO_3$)$_3$·3$H_2O$ (**2**) shows that metal complexation to the ester carbonyl oxygen atom results, in accordance with the reso-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nance form in Figure 3, in a significant decrease in the ester carbonyl stretching frequency; this band appears as a shoulder (at $\tilde{\nu}$ = 1694 cm$^{-1}$) on the other (keto) carbonyl vibrational band at 1658 cm$^{-1}$.

The optical spectra of nr-C(O)OEt and its lanthanum(III) complex in solution can be seen in Figure 4. The pink colour of a MeCN solution of nr-C(O)OEt ($\lambda_{abs}^{max}$ = 553 nm) changes to blue ($\lambda_{abs}^{max}$ = 622 nm) upon addition of $La(CF_3SO_3)_3$. This bathochromic shift of the charge-transfer band is a result of the interaction between the electron-rich carbonyl group and the electron-withdrawing lanthanum(III) ion that lowers the diethylamino to carbonyl oxygen charge-transfer energy. A similar behaviour with other $Ln^{III}$ ions and in other solvents is observed. With regard to the luminescence properties, solutions of nr-C(O)OEt display strong fluorescence with the emission maximum in MeCN located at $\lambda_{em}^{max}$ = 627 nm ($\lambda_{ex}^{max}$ = 553 nm). Addition of $La(CF_3SO_3)_3$ reduces the fluorescence intensity to about 10% of the original, and the emission maximum shifts to $\lambda_{em}^{max}$ = 654 nm. Earlier studies of nr[13] have shown that the fluorescence lifetime and quantum yield is reduced significantly with increasing hydrogen-bond donating power of the medium, because hydrogen bonding that involves the electrons around the carbonyl oxygen atom will promote the nonradiative deactivation pathway by vibrational excitation of the resulting O–H group. However, coordination of a lanthanum(III) ion to the carbonyl oxygen atom cannot lead to deactivation through that mechanism. Instead, intersystem crossing to a triplet state promoted by the heavy metal ion could be a possible pathway for fluorescence quenching.

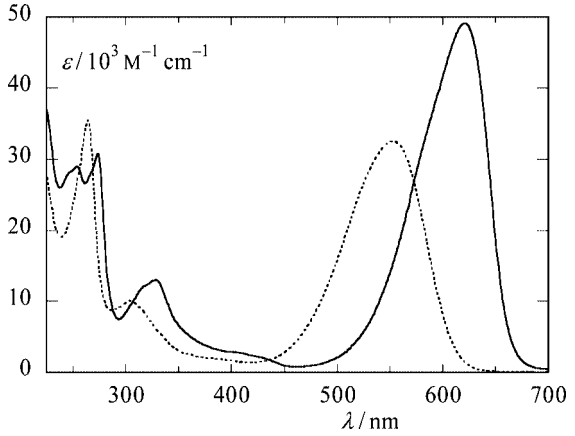

Figure 4. Optical absorption spectra of a $1.00 \times 10^{-5}$ M MeCN solution of nr-C(O)OEt before (–) and after addition of a ten-fold excess of $La(CF_3SO_3)_3$ (---).

In summary, we have shown that the present derivatisation of nr ensures that complex formation with lanthanide(III) ions *does* take place in solution. An nr chromophore might thus serve as a VIS absorbing sensitizer for the NIR emitters $Nd^{III}$, $Er^{III}$, and $Yb^{III}$. Such systems might find use as luminescent tags in biological systems and have accordingly attracted interest in recent years.[14] Our investigations in this field are ongoing, and the results will be published in due time.

## Experimental Section

**Physical Methods and Materials:** The starting material 6-carbethoxy-9-diethylamino-5*H*-benzo[*a*]phenoxazin-5-one [nr-C(O)OEt] was prepared as described in the literature.[7] Infrared spectra were obtained with a FT-IR 1760X spectrometer. $^1$H NMR studies were carried out with a Bruker 250 MHz instrument at room temperature with the $\delta$ values referenced to residual $^1$H impurities in the solvent. Optical absorption spectra were recorded with a Cary 5E UV/Vis-NIR spectrophotometer. Fluorescence spectra were recorded on a Spex Fluorolog FL3-22. Elemental analyses (C, H, N) were performed at the Department of Chemistry, University of Copenhagen.

**Single Crystals of Diaquabis(6-carbethoxy-9-diethylamino-5*H*-benzo[*a*]phenoxazin-5-one)tris(triflato-*O*)lanthanum(III) Monohydrate, [La{nr-C(O)OEt}$_2$(OSO$_2$CF$_3$)$_3$(OH$_2$)$_2$]·H$_2$O (1):** A mixture of $La(CF_3SO_3)_3$ (50 mg, 0.085 mmol), nr-C(O)OEt (10 mg, 0.026 mmol), and $CD_3CN$ (2 mL) was stirred, and undissolved $La(CF_3SO_3)_3$ was removed by centrifugation. The resulting blue solution was used for $^1$H NMR spectroscopy. After several months at 298 K, green plate crystals of **1** separated out from this solution. The crystals were isolated by decantation and dried under a flow of nitrogen.

**Tris(6-carbethoxy-9-diethylamino-5*H*-benzo[*a*]phenoxazin-5-one)lanthanum(III) Triflate Trihydrate, [La{nr-C(O)OEt}$_3$](CF$_3$SO$_3$)$_3$·3H$_2$O (2):** $La(CF_3SO_3)_3$ (200 mg, 0.34 mmol) was dissolved in dry acetonitrile (50 mL) with stirring. Then nr-C(O)OEt (50 mg, 0.13 mmol) was added, and the solution immediately turned dark blue. Slow evaporation of the solvent at room temperature over two weeks resulted in precipitation of a green microcrystalline material. The remaining mother liquor was decanted away, and the solid was washed thoroughly with water to remove excess $La(CF_3SO_3)_3$ and finally air-dried. Yield 40 mg (17%). $C_{72}H_{72}F_9LaN_6O_{24}S_3$ (1811.48): calcd. C 47.74, H 4.01, N 4.62; found C 47.81, H 3.69, N 4.63.

**X-ray Crystallography:** X-ray crystallographic study of **1**: $C_{49}H_{50}F_9LaN_4O_{20}S_3$, $M$ = 1421.02, triclinic, $P\bar{1}$, $a$ = 8.9240(9), $b$ = 13.0080(12), $c$ = 24.217(3) Å, $\alpha$ = 95.333(11), $\beta$ = 93.696(9), $\gamma$ = 90.493(9)°, $V$ = 2793.2(5) Å$^3$, $Z$ = 2, $\mu$(Mo-$K_\alpha$) = 0.987 mm$^{-1}$, 83979 reflections measured with a Nonius KappaCCD area-detector system at 122(1) K in the $\theta$ range 1.57–27.99°, 13422 unique reflections [$R$(int) = 0.0588] were used in the data analysis. The structure was solved using SHELXS-97 and refined using SHELXL-97.[15] During the refinement of **1** disorder was observed that involved one of the ethyl groups in one of the nr ligands. The disorder was resolved by refining the ethyl group in two conformations. The refinement converged at $R_1$ = 0.0293 for 12035 observed reflections with $I > 2\sigma(I)$, $wR_2$ = 0.0671 for all unique reflections, $S$ = 1.150, and an occupancy of 66% for the *cis* conformation of the disordered ethyl group. The anisotropic displacement parameters for all non-hydrogen atoms were refined. All hydrogen atoms were located in the difference Fourier map and included in the refinement riding on their parent atoms. The hydrogens on carbon were refined at idealised positions. Fourier peaks after the refinement were equal to 0.794 and –0.770 e/Å$^3$. CCDC-276918 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

Mr. F. Hansen is thanked for assistance with the crystal structure determination.

# Ruthenium Metallodendrimers Based on Nitrile-Functionalized Poly(alkylidene imine)s

**Cátia Ornelas,[a] Viatcheslav Vertlib,[a] João Rodrigues,*[a] and Kari Rissanen*[b]**

**Keywords:** Ruthenium / Dendrimers / N ligands / Sandwich complexes

The preparation of the first- and second-generation of nitrile-functionalized poly(alkylidene imine) dendrimers with the organometallic ruthenium complex [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] peripherally attached is described. The reaction of *N*,*N*′-bis-(cyanomethyl)piperazine (**1**), *N*,*N*′-bis[*N*′′,*N*′′′-bis(cyanoethyl)aminoethyl]piperazine (**2**), or *N*,*N*,*N*′,*N*′-tetrakis(cyanoethyl)ethylenediamine (**3**) with [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] (**4**) in the presence of $TlPF_6$ gives the new air-stable ruthenium metallodendrimers **5**, **6**, and **7**, respectively. These stable metallodendrimers are easily prepared and represent a novel quantitative method to solidify and chromatographically purify the otherwise semi-liquid nitrile-functionalized poly(alkylidene imine) dendrimers. The compounds were fully characterized by IR and $^1$H, $^{13}$C, and $^{31}$P NMR spectroscopy, and mass spectrometry. These dendrimers represent the first example of the utilization of nitrile-functionalized poly(alkylidene imine)s as cores in the preparation of metallodendrimers.

## Introduction

Coordination-chemistry-based dendrimers can be easily prepared by straightforward synthetic methods by an appropriate choice of metals and ligands.[1] One of the most promising aspects of metallodendrimers[1–4] is their applicability as renewable metallodendritic catalysts,[5–7] as well as nanoscale molecular materials[8] with unusual physical or optical properties to be used as nonlinear optics (NLO) materials.[9–12]

Even though poly(propylene imine) derivatives are well known building blocks for the preparation of dendrimers,[13] the direct use of nitrile-functionalized poly(alkylidene imine) as a core for the preparation of metallodendrimers has not been reported prior to this work. In a previous work[14] we succeeded in the preparation of hexa- and nonaruthenium star-shaped complexes by using [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] as the organometallic ruthenium reagent. The same reasoning was followed in this work and we explored the use of nitrile-functionalized poly(alkylidene imine)s (generation 0 and 1) for the coordination to the organometallic fragment [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$]. The aim was the development of novel methods for the preparation of new nanoscopic molecular materials (metallodendrimer-based) with particular physical (NLO) and/or chemical properties (catalytic activity).

## Results and Discussion

The core nitrile-functionalized poly(alkylidene imine)s *N*,*N*′-bis(cyanomethyl)piperazine (**1**), *N*,*N*′-bis[*N*′′,*N*′′′-bis-(cyanoethyl)aminoethyl]piperazine (**2**), and *N*,*N*,*N*′,*N*′-tetrakis(cyanoethyl)ethylenediamine (**3**) were obtained in good yields by reaction of piperazine with chloroacetonitrile (**1**). The precursor amine for **2** was obtained by reduction of nitrile **1** with $LiAlH_4$. The piperazine and ethylenediamine were then treated with acrylonitrile under classic Michael reaction conditions.[15] The exact synthetic details of the preparation of **1**–**3** will be reported elsewhere.

These organic cores were quantitatively coordinated to the ruthenium reagent [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] (**4**) by substitution of chloride and coordination to the nitrile nitrogen, using a slight excess of $TlPF_6$ in methanol, resulting in the bis- and tetrakisruthenium-bonded dendrimers (Schemes 1 and 2).

These organometallic dendrimers were isolated in good yields as air-stable, yellow powders and were characterized by UV/Vis, IR, and $^1$H, $^{13}$C, and $^{31}$P NMR spectroscopy, and mass spectrometry.

The IR spectra of **5**, **6**, and **7** show, besides the characteristic band of the $PF_6^-$ counterion at 840 and 521 cm$^{-1}$, the nitrile band shifted to higher energies by 5, 14, and 21 cm$^{-1}$, respectively, when compared with the free nitrile, thus indicating similar coordination of all termini of the cores to the ruthenium fragment. These results are in accordance with the $^1$H NMR spectra, which show only one signal for C$H_2$CN shifted downfield and good relation/integrations between the protons of the ruthenium fragment and the protons of the cores. The $^{13}$C NMR spectra also show the expected signals, except for the nitrile carbon, which could

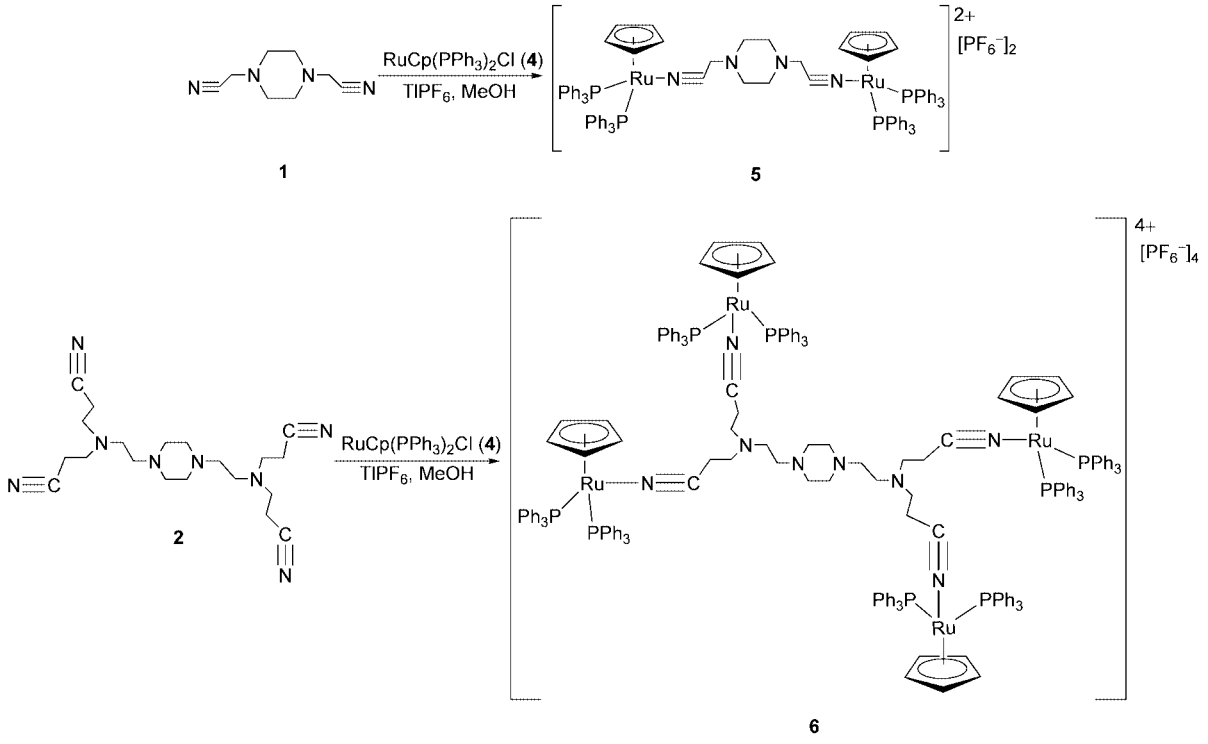
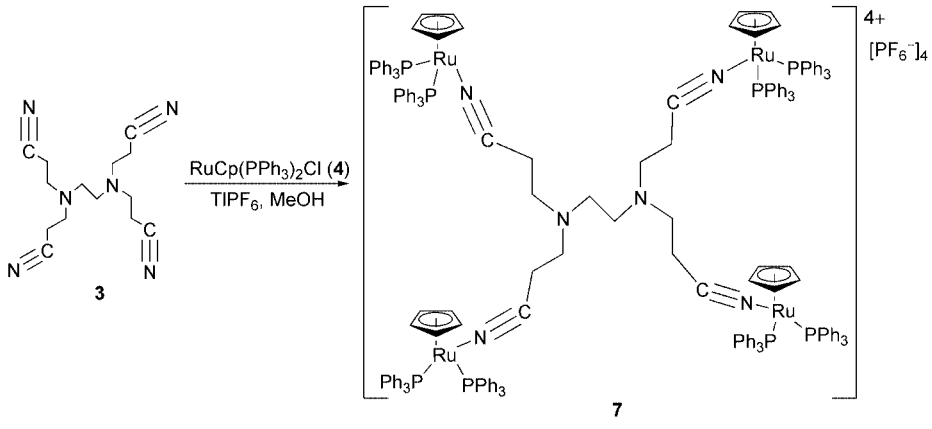


Scheme 1. First- and second-generation ruthenium metallodendrimers with piperazine cores.



Scheme 2. A ruthenium metallodendrimer with an imine core.

not be detected due to slow relaxation. The appearance of only one Cp-ring signal at around $\delta$ = 4.5 ppm in the $^1$H NMR spectrum and only one phosphorus signal in the $^{31}$P NMR spectrum ($\delta \approx 42$ ppm) for all products is due to the equivalence of the ruthenium fragments coordinated to the cores and confirms the bis and the tetra coordination.

Clean mass spectra were obtained for all products, showing the characteristic [M$^+$] peaks at $m/z$ = 1691 (**5**), 3583 (**6**, Figure 1), and 3471 (**7**) and some peaks of typical fragmentations of the molecule in this technique (TOF-MS; see Experimental Section).

All the UV/Vis electronic spectra of the ruthenium dendrimers, recorded in ca. $10^{-5}$ M solutions of $CH_2Cl_2$, show a shoulder at around 351 nm with $\varepsilon$ values in the range 0.7–$1 \times 10^4$ M$^{-1}$ cm$^{-1}$. This behavior is probably due to a metal-to-ligand charge-transfer (MLCT) transition, since a similar transition is absent both in [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] and in the uncoordinated cores.

Although there is not sufficient literature data for 1:4 complex salts,[16] the conductivity measurements, together with the spectroscopic data, indicate that the assumption of 1:2 and 1:4 complex salts is correct.

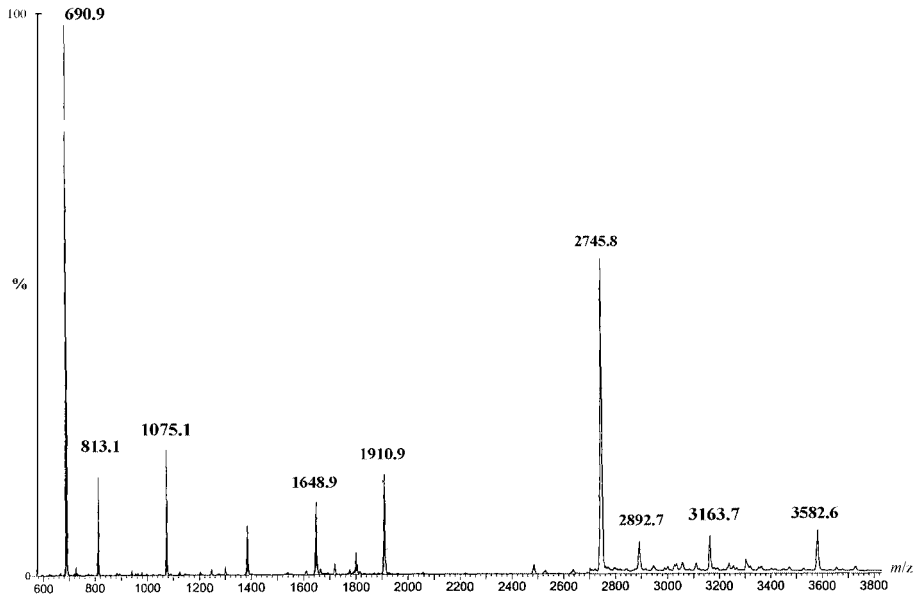

Figure 1. Mass spectrum of compound **6** showing the [$M^+$] peak at $m/z$ = 3583.

Several attempts to obtain crystals of these metallodendrimers for the elucidation of their structures in the solid state failed, producing only microcrystals unsuitable for X-ray diffraction.

## Conclusions

We have reported the preparation and characterization of the first- and second-generation poly(alkylidene imine) ruthenium dendrimers using nitrile-functionalized poly(alkylidene imine)s as cores and the organometallic fragment [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$] at the periphery. The easy preparation of these stable metallodendrimers represents a novel quantitative method to solidify and chromatographically purify the otherwise amorphous or semi-liquid nitrile-functionalized poly(alkylidene imine) dendrimers. The chromatographic purification of dendritic compounds is still rare and our method could be of help for purification of other dendritic nitriles. Our efforts are currently focused on the synthesis of higher generations of metallodendrimers and on the use of different metallic fragments to obtain dendrimers with different properties and applications.

## Experimental Section

**General:** All experiments were carried out under vacuum or nitrogen atmosphere by use of standard Schlenk techniques. With the exception of absolute methanol, which was used without further purification and degassed before use, all the solvents used were dried according to the usual published methods[17] and distilled prior to use. The compound [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] (**4**) was prepared and characterized as described in the literature.[18,19]

**Physical Measurements:** The UV/Vis spectra were recorded with a GBC-Cintra 40, UV/Vis spectrometer using 1-cm optical-path quartz cells with freshly prepared solutions of approximately $10^{-5}$ M concentration in $CH_2Cl_2$. The mass spectra (TOF-MS) were recorded on a Micromass LCT. FT-IR spectra were recorded with a Nicolet Avatar 360 FTIR spectrometer, calibrated with polystyrene, as KBr pellets; only significant bands are cited in the text. $^1$H, $^{13}$C{$^1$H}, and $^{31}$P{$^1$H} NMR spectra were recorded on a Bruker AM500 spectrometer at 500.13, 125.77, and 202.44 MHz, respectively, at 293.15 K (probe temperature). The $^1$H chemical shifts ($\delta$), reported in parts per million (ppm) downfield, are referenced to residual chloroform ($\delta$ = 7.24 ppm). The $^{13}$C{$^1$H} chemical shifts were reported in ppm relative to the carbon resonance of the deuterated NMR solvent ($CDCl_3$: $\delta$ = 77.00 ppm). The $^{31}$P{$^1$H} NMR spectra are reported in ppm downfield from external 85% $H_3PO_4$ ($\delta$ = 0.00 ppm). The elemental analysis of the complexes did not give satisfactory results after several tries and is not reported. The probable reasons for these irreproducible results are the evaporation of the possible lattice solvent molecules (MeOH, $CH_2Cl_2$, $CHCl_3$, or diethyl ether) and/or the adsorption/desorption of moisture. Conductivity measurements were made at 273.15 K on freshly made $10^{-3}$ M solutions of the complexes in nitromethane using a CRISON-microCM 2200. The cell constant was determined by measuring the resistance of an aqueous solution of KCl (0.0100 M, $\sigma$ = 0.001413 $\Omega^{-1}$ cm$^{-1}$ at 273.15 K). Molar conductivities ($\Lambda_M$) are given in units of $\Omega^{-1}$ cm$^2$ mol$^{-1}$. The accepted ranges for 1:2- and 1:4-type electrolytes under these conditions are 100–160 and 290–330 $\Omega^{-1}$ cm$^2$ mol$^{-1}$, respectively.[16]

**Synthesis of 5:** [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] (**4**; 0.4509 g, 0.620 mmol) and the dinitrile **1** (0.051 g, 0.310 mmol) were introduced with MeOH (30 mL), under nitrogen, into a flame-dried Schlenk flask. $TlPF_6$ (0.250 g, 0.713 mmol) was added and, after stirring the mixture for 13 h, the solvent was removed under vacuum. The product was extracted with $CH_2Cl_2$ and, after filtration, the solvent was removed under vacuum. The green product was dissolved in 10 mL

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of $CH_2Cl_2$ and precipitated with *n*-hexane, the solution was filtered, and the yellow precipitate was washed twice with 10 mL of *n*-hexane. The yellow powder was dried under vacuum. Yield: 0.2853 g (51%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 7.40–7.07 (m, $PPh_3$), 4.48 (s, 10 H, $C_5H_5$), 3.77 (s, 8 H, $CNCH_2$), 2.08 (s, 4 H, $NCH_2CH_2N$) ppm. $^{13}$C NMR (126 MHz, $CDCl_3$): $\delta$ = 135.7–133.3 ($PPh_3$), 83.8 ($C_5H_5$), 51.0 ($CNCH_2$), 48.1 ($NCH_2CH_2N$) ppm. $^{31}$P NMR (202 MHz, $CDCl_3$): $\delta$ = 42.2 (*s*, *P*$Ph_3$), –143 (m, *P*$F_6$) ppm. FT IR (KBr): $\tilde{\nu}$ = 2236 ($\nu_{CN}$), 839 and 522 $cm^{-1}$($\nu_{PF_6}$). TOF MS (ES$^+$): *m*/*z* (%) = 691 (100) [RuCp($PPh_3$)$_2$]$^+$, 855 (60) [RuCp($PPh_3$)$_2$(**1**)]$^+$, 1691 (10) **[M]$^+$**. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ [nm] ($\varepsilon$ [$M^{-1}cm^{-1}$]) = 351 ($0.8\times10^4$). $\Lambda_M$ = 157 $\Omega^{-1}cm^2mol^{-1}$.

**Synthesis of 6:** [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] (**4**; 0.3667 g, 0.505 mmol) and the ligand *N*,*N*′-bis[*N*′′,*N*′′′-bis(cyanoethyl)aminoethyl]piperazine (**2**; 0.047 g, 0.120 mmol) were introduced with MeOH (45 mL), under nitrogen, into a flame-dried Schlenk flask. $TlPF_6$ (0.2024 g, 0.579 mmol) was added and, after refluxing for 5 h, the mixture was stirred at room temperature for 16 h. The solvent was removed under vacuum and the product was extracted with $CH_2Cl_2$. After filtration the solvent was removed and the solid was washed twice with diethyl ether. The product was dissolved in 10 mL of $CH_2Cl_2$ and precipitated with diethyl ether. The yellow powder was dried under vacuum. Yield: 0.1933 g (45%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 7.35–7.05 (m, $PPh_3$), 4.47 (s, 20 H, $C_5H_5$), 2.55 (s, 4 H, $NCH_2CH_2N$), 2.43 (s, 8 H, $NCCH_2CH_2$) 2.35 (s, 16 H, $NCH_2$) ppm. $^{13}$C NMR ($CDCl_3$, 126 MHz): $\delta$ = 135.7–127.1 ($PPh_3$), 83.5 ($C_5H_5$), 55.4 ($NCH_2CH_2N$ piperazine center), 53.1 (inner $NCH_2CH_2$), 52.3 (inner $NCH_2CH_2$), 43.5 (outer $NCH_2CH_2$), 17.9 ($CH_2CN$) ppm. $^{31}$P NMR (202 MHz, $CDCl_3$): $\delta$ = 42.4 (s, *P*$Ph_3$), –143 (m, *P*$F_6$) ppm. FT IR (KBr): $\tilde{\nu}$ = 2259 ($\nu_{CN}$), 840 and 521 $cm^{-1}$($\nu_{PF_6}$). TOF MS (ES$^+$): *m*/*z* (%) = 691 (100) [RuCp($PPh_3$)$_2$]$^+$, 813 (20) [RuCp$PPh_3$(**2**)]$^+$, 1075 (25) [RuCp($PPh_3$)$_2$(**2**)]$^+$, 1649 (15) [Cp($PPh_3$)$_2$CpRu(**2**)RuCp$PPh_3$][$PF_6$], 1911 (20) [{RuCp($PPh_3$)$_2$}$_2$(**2**)][$PF_6$], 2746 (60) [{RuCp($PPh_3$)$_2$}$_3$(**2**)][$PF_6$]$_2$, 3583 (10) [M]$^+$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ [nm] ($\varepsilon$ [$M^{-1}cm^{-1}$]) = 350 ($1.1\times10^4$). $\Lambda_M$ = 279 $\Omega^{-1}cm^2mol^{-1}$.

**Synthesis of 7:** [Ru($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Cl] (**4**; 0.2505 g, 0.345 mmol) and the ligand *N*,*N*,*N*′,*N*′-tetrakis(cyanoethyl)ethylenediamine (**3**; 0.0245 g, 0.177 mmol) were introduced with MeOH (35 mL), under nitrogen, into a flame-dried Schlenk flask. $TlPF_6$ (0.1482 g, 0.424 mmol) was added and, after refluxing for 12 h, the mixture was stirred at room temperature for 12 h. The solvent was removed under vacuum and the product was extracted with $CH_2Cl_2$. After filtration the solvent was removed and the solid was washed twice with diethyl ether. The product was dissolved in 10 mL of $CH_2Cl_2$ and precipitated with diethyl ether. The yellow powder was dried under vacuum. Yield: 0.1804 g (60%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 7.31–7.06 (m, $PPh_3$), 4.47 (s, 20 H, $C_5H_5$), 2.57 (s, 8 H, $NCCH_2CH_2N$), 2.47 (s, 8 H, $NCCH_2$), 2.31 [s, 4 H, $N(CH_2)_2N$] ppm. $^{13}$C NMR (126 MHz, $CDCl_3$): $\delta$ = 136.1–128.6 ($PPh_3$), 83.8 ($C_5H_5$), 52.4 [$N(CH_2)_2N$], 49.0 ($NCH_2CH_2CN$), 18.9 ($CH_2CN$) ppm. $^{31}$P NMR(202 MHz, $CDCl_3$): $\delta$ = 42.5 (s, *P*$Ph_3$), –143 (m, *P*$F_6$) ppm. # Amino-phosphanes in $Rh^{I}$-Catalyzed Hydroformylation: Hemilabile Behavior of P,N Ligands under High CO Pressure and Catalytic Properties

**Jacques Andrieu,*[a] Jean-Michel Camus,[a] Philippe Richard,[a] Rinaldo Poli,[a,b] Luca Gonsalvi,[c] Francesco Vizza,[c] and Maurizio Peruzzini*[c]**

**Keywords:** Rhodium / Amino-phosphane ligands / Hemilability / Hydroformylation catalysis

The catalytic properties of rhodium complexes containing the α-, β-, or γ-amino-phosphane ligands $Ph_2PCH_2NEt_2$ (**α-P,N-1**), $Ph_2PCH(Ar)NHPh$ [**α-P,N-2**; Ar = $\eta^6$(*o*-$C_6H_4Cl$)$Cr(CO)_3$], $Ph_2PCH_2NPh_2$ (**α-P,N-3**), $Ph_2PCH_2CH(Ph)NHPh$ (**β-P,N**), $Ph_2PCH_2$(*o*-$C_6H_4$–$NMe_2$) (**γ-P,N-1**), $Ph_2PCH$(*o*-$C_6H_4$–$CH_2NHPh$) (**γ-P,N-2**), and the α,β-diamino-phosphane ligand $Et_2NCH_2P(Ph)CH_2CH(Ph)NHPh$ (**α,β-N,P,N**), in styrene hydroformylation have been examined. The results show that the activity increases when the number of backbone carbon atoms linking P and N decreases from 3 to 1. IR and $^{31}P$ HPNMR studies in solution show that all P,N ligands adopt exclusively a $\kappa^1$-*P* coordination mode in rhodium chloride carbonyl complexes under high CO pressure. In the solid state a $\kappa^1$-*P*-α-amino-phosphane coordination has been ascertained by X-ray methods in *trans*-[RhCl(CO)(**γ-P,N-1**)$_2$]. In contrast, an equilibrium between the $\kappa^2$-*P,N* and $\kappa^1$-*P*-coordination modes has been observed as a function of the CO pressure for the complex containing the **β-P,N** ligand. The basicity of the dangling amino group also plays an important role on the catalytic activity and a mechanism involving the nitrogen function in the catalytic cycle is proposed.

## Introduction

Bifunctional P,N ligands are being intensively investigated because they present advantages compared to common trialkyl phosphanes in the catalytic applications of their corresponding Pd, Ni, Ru, and Ir complexes.[1–8] These ligands can be either $\kappa^1$-*P* or $\kappa^2$-*P,N* coordinated and each coordination mode can modify the catalytic properties. For example, the chelating coordination mode enhances the nucleophilic character of the metal center and subsequently promotes hydrogen oxidative addition.[7,9,10] A comparative study between α- and β-amino-phosphanes in rhodium-catalyzed hydroformylation has led to the proposal that a bidentate coordination mode accelerates aldehyde reductive elimination from $RhH_2$(acyl)(P,N).[11] The authors conclude that uncoordinated amino functions do not act as bases. In contrast, the dangling amine function in a $Pd^{II}$-coordinated $\kappa^1$-*P*-pyridinylphosphane acts as a "proton messenger" in catalytic alkyne methoxycarbonylation.[1] In another study of rhodium-catalyzed hydroformylation, it was shown that the P,N,P type, $Ph_2PCH_2N(Ar)CH_2PPh_2$, ligand is much more active than its analogous $Ph_2P(CH_2)_3$-$PPh_2$. However, a rationalization for the latter observation was not proposed.[12]

One of the key questions related to the use of bifunctional ligands, particularly those associating soft and hard donor atoms, is whether there is reversible association/dissociation of one labile function during the catalytic cycle (*hemilability* concept). In our laboratory, we have developed different pathways to chiral α- or β-P,N and mixed α,β- and β,γ-N,P,N ligands and their coordination properties have been explored in palladium(II) and rhodium(I) complexes.[13–16] Particularly, we have reported that β-P,N ligands adopt a chelating mode whereas α-P,N ligands are only P-coordinated in $Cu^{I}$ or in $Rh^{I}$ complexes.[17,18] Separate work has shown that β-P,N ligands in $Rh^{I}$ complexes can adopt a monodentate $\kappa^1$-P-[19] or a $\kappa^2$-*P,N*-coordination mode.[15,20] Nevertheless, no direct evidence for a hemilabile character has been reported so far for β-P,N ligands in $Rh^{I}$ complexes. This behavior was only suggested for a few cationic complexes of type $[Rh(COD)(\beta\text{-P,N})]^+$ in order to rationalize a rapid fluxional process.[21] Nor is it known whether the coordinated N donor in these $Rh^{I}$ complexes and in related complexes with γ-amino-phosphanes is displaced by CO under catalytic conditions. A hemilabile behavior for related chiral P,N ligands could explain the low enantioselectivities observed in asymmetric Rh-catalyzed hydroformylation.[22,23] On the other hand, an optically pure $Ru^{II}$ β-amino-phosphane complex led to higher *ee* for

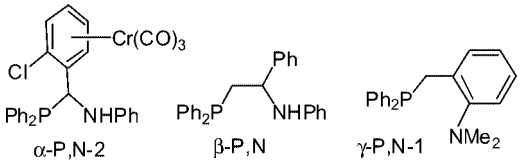
the asymmetric reduction of ketones, whereas a related Ru-γ-amino-phosphane complex led to the same product in racemic form.[6]

We now wish to provide new information on the effect of a dangling vs. a coordinated nitrogen function of chiral P,N ligands in rhodium hydroformylation catalysis, thus helping to clarify a few previously obscure points.[11,12] Consequently, we have (i) investigated the mono- or bidentate coordination mode of P,N ligands in rhodium complexes under CO pressure by $^{31}P$ HPNMR and IR spectroscopy, (ii) examined the catalytic properties of various $Rh^{I}$–P,N complexes in styrene hydroformylation in order to establish a relation with the coordination modes, and (iii) evaluated the effect of the N basicity in P,N ligands on the formation and properties of the catalytic species.

## Results

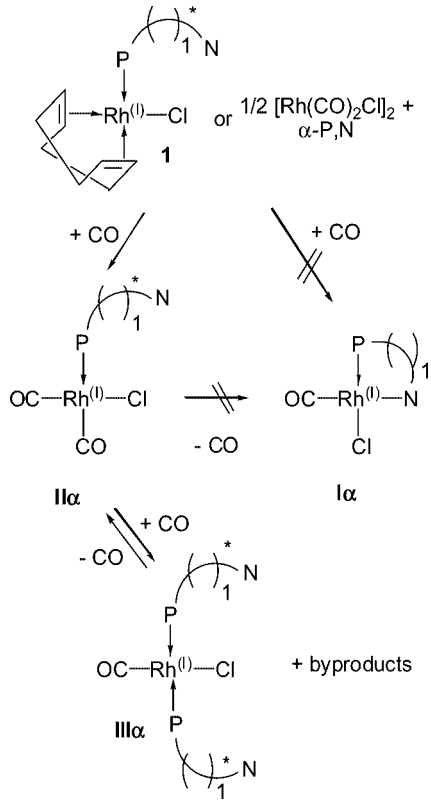
### Coordination, IR, and $^{31}P\{^{1}H\}$ HPNMR Studies of Amino-Phosphanes in $Rh^{I}$ Complexes

We first examined whether the nitrogen donor in different P,N ligands (see Scheme 1) is coordinated under catalytic conditions. This investigation completes our recent studies on the $Rh^{I}$ coordination chemistry of P,N ligands.[15,18] Indeed, we have already reported that complex RhCl(COD)(**α-P,N-2**) (complex **1**) adopts a $\kappa^1$-*P* coordination mode both in the solid state and in solution and that an analogous monodentate coordination mode is also adopted in the dicarbonyl complex $RhCl(CO)_2$(**α-P,N-2**) (**IIα**, see Scheme 2).[18] The latter was obtained by ligand exchange from RhCl(COD)(**α-P,N-2**) (COD = 1,5-cyclooctadiene) under high CO pressure. Lowering the CO pressure did not result in the formation of a $\kappa^2$-*P,N* mononuclear product (**Iα**), but rather induces a ligand redistribution to yield $RhCl(CO)$(**α-P,N-2**)$_2$ (**IIIα**) where both α-P,N ligands are once again $\kappa^1$-*P* coordinated.



Scheme 1.

The behavior of $Rh^{I}$ complexes containing the **β-P,N** and **γ-P,N-1** ligands was first studied by IR in $CH_2Cl_2$ solution under CO (see Figure 1). Irrespective of the amino-phosphane, the IR spectrum shows two absorption bands at 2092 and at 2010 $cm^{-1}$, corresponding to the type-**II** dicarbonyl rhodium complex (named **IIγ** and **IIβ**, with the **γ-P,N-1** and **β-P,N** ligands, respectively) where the amino-phosphane is $\kappa^1$-*P* coordinated. However, the IR spectrum of **IIβ** shows an additional absorption band at 1986 $cm^{-1}$ corresponding to **Iβ**, as will be discussed in detail below.



Scheme 2.

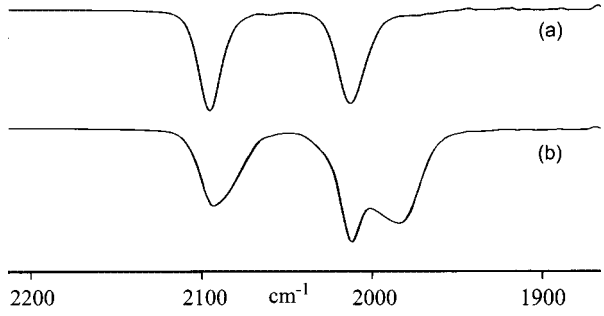


Figure 1. IR spectra of $[Rh(CO)_2Cl]_2$ + P,N ligand mixtures in 1:2 ratio prepared in $CH_2Cl_2$ under CO at room temperature, (a) with the **γ-P,N-1** ligand and (b) with the **β-P,N** ligand.

We then carried out $^{31}P\{^{1}H\}$ high pressure (HP) NMR studies for both dicarbonyl rhodium complexes **IIγ** and **IIβ** in order to confirm the IR results and to obtain additional information on their stability. When a solution of [RhCl(COD)(**γ-P,N-1**)] (complex **2**) was pressurized with CO, its doublet resonance at $\delta$ = 29.5 ppm [$^{1}J_{(Rh,P)}$ = 150 Hz] was replaced by a new one at $\delta$ = 26.9 ppm [$^{1}J_{(Rh,P)}$ = 126 Hz] (see Figure 2). The presence of a single complex is consistent with the IR data. After depressurization, complex **IIγ** evolved to complex **IIIγ**, [doublet at $\delta$ = 30.5 ppm with $^{1}J_{(Rh,P)}$ = 126 Hz] which became the only detectable product after flushing the solution for a few minutes with a dinitrogen stream (see Figure 2). The assignment of this

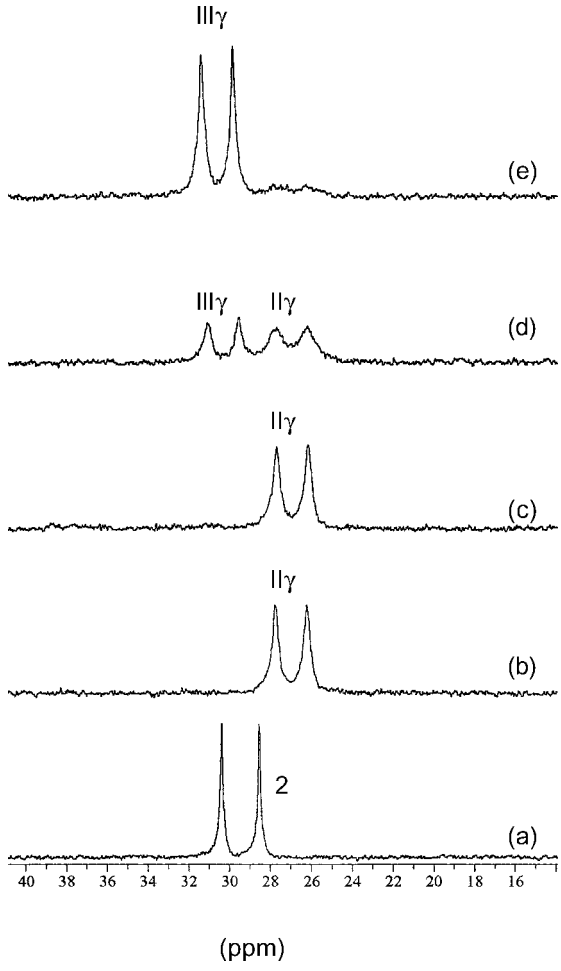

Figure 2. $^{31}P\{^{1}H\}$ HPNMR spectra under CO pressure for complex **2** in $CDCl_3$ solution. (a) Under $N_2$, (b) under CO, (c) under 20 bar of CO, (d) after depressurization, (e) solution after flushing 5 min with $N_2$.

signal to the monocarbonyl-bis-amino-phosphane rhodium complex **IIIγ** was confirmed by an X-ray structure analysis. Crystals of complex **IIIγ** (see Figure 3) were obtained upon attempting to crystallize complex **IIγ**, and their redissolution in $CDCl_3$ led to a $^{31}P$ NMR spectrum identical to spectrum (e) in Figure 2. Therefore, the final product of the NMR experiment in Figure 2 is unambiguously identified as a monocarbonyl-bis-amino-phosphane rhodium complex.

The evolution of **IIγ** to **IIIγ** must be accompanied by the formation of undefined organometallic CO-free by-products, as described previously for the analogous evolution of the **α-P,N-2** rhodium complex.[18] The $\nu_{CO}$ value at 1974 $cm^{-1}$ for **IIIγ** is close to that found for $[RhCl(CO)(PPh_3)_2]$ (1965 $cm^{-1}$),[24] thus suggesting similar electronic properties for the **γ-P,N-1** ligand and triphenylphosphane. Table 1 shows quite typical geometrical features and metric parameters for a complex of type $RhCl(CO)L_2$ (i.e.: L = trialkyl-, dialkyl-*N*-pyrrolidinyl-, or α-amino-phosphanes), namely a nearly ideal square-planar geometry around the rhodium atom with mutually *trans* phosphorus atoms.[18,24]

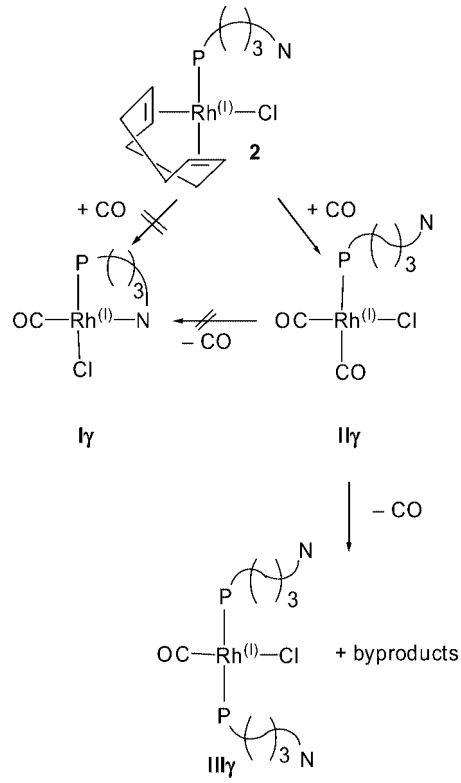
Worth noting in the structure is that the γ-P,N ligand does not chelate the rhodium center, contrary to what has been reported for a variety of Cu, Ru, Pd, and Rh complexes with the related ligands $Ph_2PCH_2[o\text{-}C_6H_4\text{–}N(Me)\text{-}CH_2CH_2OH]$, $Ph_2P(o\text{-}C_6H_4\text{–}CH_2NHtBu)$, $Ph_2P(o\text{-}C_6H_4\text{–}CH_2NMe_2)$, and $PhP[o\text{-}C_6H_4\text{–}CH(Me)NMe_2]_2$, respectively.[25–28] All the above results show that the α- and γ-P,N ligands adopt the same coordination mode in rhodium chloride complexes and undergo an identical ligand redistribution process (see Scheme 3).

A different situation was observed in the case of rhodium complexes containing the **β-P,N** ligand. Indeed, as mentioned above, the infrared spectrum recorded under CO shows an absorption band at 1986 $cm^{-1}$ (see Figure 1), in addition to the two carbonyl bands at 2092 and 2011 $cm^{-1}$ attributed to **IIβ**. This band corresponds to complex **Iβ**, as proven by its independent preparation and characterization (see Exp. Sect.). The simultaneous presence of **Iβ** and **IIβ** suggests the existence of an equilibrium between the two complexes under CO. This equilibrium could be followed by running two dedicated $^{31}P\{^1H\}$ NMR experiments.

The first experiment was carried out under CO on a $CDCl_3$ solution containing $[RhCl(CO)_2]_2$ and the **β-P,N** ligand. The $^{31}P\{^1H\}$ NMR spectrum showed two doublets at $\delta$ = 56 ppm [$^1J_{(Rh,P)}$ = 168 Hz] and at $\delta$ = 21 ppm [$^1J_{(Rh,P)}$ = 122 Hz] in ca. 1:2.5 ratio. The signal at $\delta$ = 56 ppm corresponds to complex **Iβ**, as verified by comparison with an authentic sample. Following the evidence provided by the IR spectrum (vide supra), the second resonance is assigned to the dicarbonyl complex **IIβ**. The second experiment was carried out under a higher CO pressure (20 bar) on a $CDCl_3$ solution containing complex [RhCl(COD)(**β-P,N**)], **3**, readily formed in situ from $[RhCl(COD)]_2$ and **β-P,N**. In this case, we observed only the doublet related to complex



Scheme 3.

**IIβ** and no signal at $\delta$ = 56 ppm [see spectra (a) and (b), Figure 4].

After keeping the NMR solution pressurized with CO for 14 h, it was surprising to observe a new broad doublet at $\delta$ = 19 ppm [with $^1J_{(Rh,P)}$ = 168 Hz], named **II′β**, [see spectrum (c), Figure 4]. Tentatively, we attribute this broad

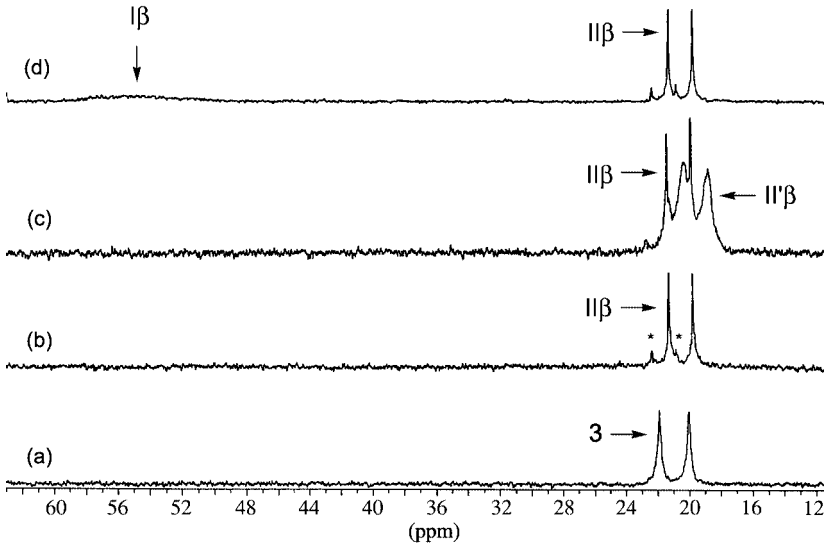


Figure 4. $^{31}P\{^1H\}$ HPNMR spectra under CO pressure of complex **3** in $CDCl_3$ solution. (a) Under $N_2$, (b) under 20 bar of CO, after 3 min, (c) under 20 bar of CO, after 14 h, (d) after depressurization. The asterisk denotes a small amount of a unidentified rhodium compound.

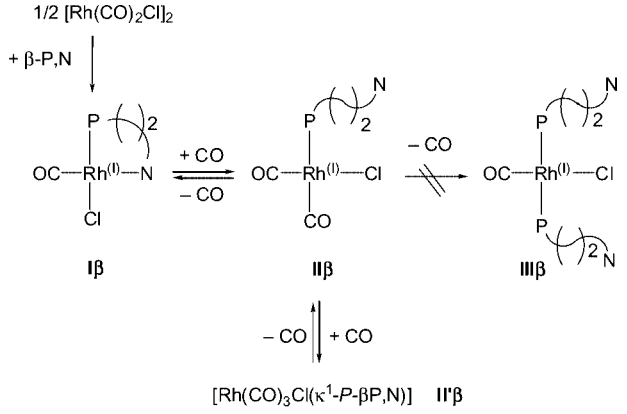
resonance to a pentacoordinate $Rh^I$ complex resulting from a further rhodium carbonylation of **IIβ** at this high CO pressure, although we have no further spectroscopic evidence to support this assignment at the moment. Depressurization of the NMR tube and purging the solution from dissolved CO with a dinitrogen stream removed the signal due to **II′β** and restored the equilibrium between complexes **Iβ** and **IIβ** [see spectrum (d), Figure 4]. The above IR and NMR observations are summarized in Scheme 4.

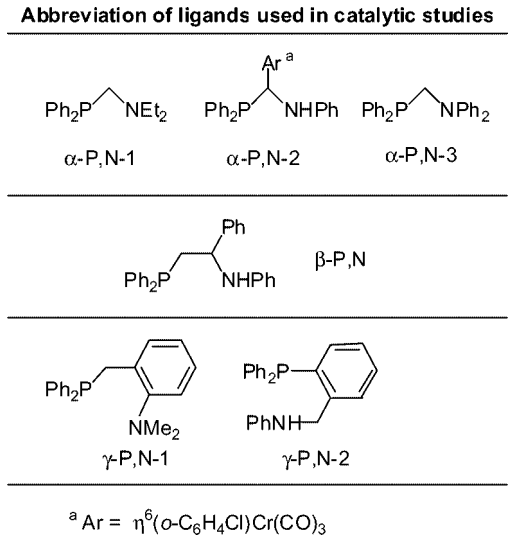


Scheme 4.

Both experiments confirm the occurrence of an equilibrium between **Iβ** and **IIβ** depending on the CO pressure as well as the hemilabile character of the **β-P,N** ligand in $Rh^I$ complexes. The combined IR and HPNMR experiments unambiguously prove the preference for keeping the amino group uncoordinated, under high CO pressure, in both β- and γ-P,N $Rh^I$ complexes, as previously shown for the related α-P,N $Rh^I$ complexes, resulting in a selective $\kappa^1$-P coordination mode. We now wish to examine the effects of the dangling amine group on the catalytic properties of the Rh-P,N hydroformylation.

## Catalytic Styrene Hydroformylation with Rh-Amino-Phosphane Complexes

The catalytic properties of different systems obtained from either $[RhCl(COD)]_2$ or $[Rh(acac)(CO)_2]$ and a variety of amino-phosphane ligands (see Scheme 5) in styrene hydroformylation tests are shown in Table 2.



Scheme 5.

All catalytic runs were monitored by periodical withdrawal of aliquots from the autoclave. The conversion was found to be essentially linear with time, without any induction period. Thus, each reported TOF is obtained from a plot obtained by using several data points and is affected by a small error (ca. ±5%, see experimental section for details). All investigated catalysts afforded complete chemoselectivities (no product other than aldehydes are observed) and essentially the same regioselectivity, namely ca. 9:1 in favor of the branched product, which is standard for styrene hydroformylation with rhodium catalysts.[29]

A blank experiment carried out with $[RhCl(COD)]_2$ and $PPh_3$ (run 1) showed no activity whatsoever under our mild catalytic conditions. As previously reported,[30] the transformation of the chloride precursor to the catalytically active hydride complex requires an external base to trap the HCl equivalent which forms as a by-product during the initial $H_2$ activation step. The addition of one equivalent of $Ph_2NH$ or $NEt_3$ as an external base to the previous $PPh_3$-based catalyst led to a weak catalytic activity (run 2). When an amino group, on the other hand, is incorporated into the tertiary phosphane ligand (runs 3 to 7), a similar or

Table 2. Activity of $Rh^I$-P,N complexes in styrene hydroformylation catalysis.

| Run[a] | Catalytic precursor | Ligand (1 equivalent) | TOF[b] [$h^{-1}$] | b/l ratio[c] |
|---|---|---|---|---|
| 1 | $[RhCl(COD)]_2$ | $PPh_3$ | <1 | – |

higher (quite substantial in some cases) increase of catalytic activity resulted. Although the formation of a very active phosphane-free carbonyl species could be envisaged during the ligand scrambling process for the γ-amino-phosphane complexes **IIγ** (see Scheme 3), the lower activities observed with the complexes (runs 3a,b) indicate that either this scrambling process does not take place under the catalytic conditions (high CO pressure) or that the species formed by such a process does not possess a very high catalytic activity. The conversion rate became progressively greater as the number of carbon atoms in the ligand backbone bridging the P and N donor ends decreased from 3 to 1. A jump in activity was particularly evident on going from the γ- (3 carbon atoms) to the α-P,N ligand (1 carbon atom), with essentially identical Brønsted basicities for the dangling amino groups (runs 3a, 4, and 6). The effects of the amine basicity on the catalyst activity were then investigated.

### Nitrogen Basicity

A comparison between runs 5 and 7 shows that when the uncoordinated $NPh_2$ moiety in the α-P,N ligand is replaced by the more basic $NEt_2$ unit, the activity (TOF) increases dramatically from 15 to 230 $h^{-1}$. A similar, albeit more moderate, effect is also observed for a similar change in γ-P,N ligands in which the amino group is farther from the metallic center (see run 3a and 3b). These observations highlight the fact that the presence of an uncoordinated basic function in proximity to the metal center has a beneficial effect on the overall catalytic activity. A similar activity/basicity relationship for an uncoordinated amine function was pointed out by Reetz et al.,[12] who reported that the activity of rhodium cationic complexes in styrene or octene hydroformylation increased significantly when the dppp ligand [dppp = $Ph_2P(CH_2)_3PPh_2$] was replaced by an amino-diphosphane ligand [$Ph_2PCH_2N(Ph)CH_2PPh_2$], in which the nitrogen atom remains uncoordinated. It is to be noted that this conclusion is exactly opposite to that of Abu-Gnim and Amer, although both the ligands and conditions employed by them are apparently quite similar to ours.[11] It is possible that such a divergence comes from Amer's conclusion, which is based on the TON values. Such data are obviously less significant than the related TOF and, in addition, have been calculated from only one catalytic experiment per ligand used, with different reaction times as a function of the ligand.[11] Our straightforward interpretation of the activity results presented in Table 3 is based on the fact that all P,N ligands display an uncoordinated amine function under catalytic conditions, as demonstrated above. Additionally, the presence of the free internal base is not devoid of consequence for the catalytic efficiency because the whole system becomes more efficient as the P–N distance decreases, respectively going from γ-, β- to α-P,N ligands, and as its basicity increases.

### Rhodium Acetylacetonate Catalyst

Under the assumption that the HCl molecule originating from the chloride catalyst precursor and $H_2$ is scavenged by the dangling amine function, the latter would be converted into an ammonium function. Thus, the active catalyst would turn over in the ammonium form, rather than in the free amine form. In order to check the effect of this protonation process on the catalytic activity, experiments have also been carried out using [Rh(acac)$(CO)_2$] as the catalytic precursor. This allows the uncoordinated amine to remain in the neutral form during the catalytic cycle, since the active hydride species forms with elimination of acetylacetone rather than HCl. These experiments were only carried out with the α-P,N ligands, and the results are collected in Table 3. Generally, [Rh(acac)$(CO)_2$] is known to be a better catalytic precursor than [RhCl(COD)]$_2$ and, indeed, a comparison between runs 1 (Table 2) and 8 (Table 3) shows that this is true also in our case.

The activity in the presence of $PPh_3$ (see run 8, Table 3) remains nevertheless lower than in the presence of the α-P,N ligands (see runs 9, 10, and 11, Table 3), highlighting the beneficial effect of the free amine on the catalysis rate-determining step. We then ran an additional catalytic experiment which consisted of the addition of one equivalent of $NEt_3$ into the **α-P,N-3** rhodium chloride catalytic system. This led to better conversions (TOF = 220 $h^{-1}$, run 12) than the $NEt_3$-free system (TOF = 15 $h^{-1}$, run 5), and rather close to those obtained with the Rh-acetylacetonate catalytic precursor (TOF = 285 $h^{-1}$, run 10).

## Discussion

The new results reported in this contribution show that all P,N ligands are $\kappa^1$-P coordinated to $Rh^I$ under hydroformylation conditions, no matter the distance between the N and P atoms, and that the catalytic activity is enhanced by the proximity of the amine function and by its basicity. The role of the free amine group can be proposed at two different levels. First, we recall that no induction time is ob-

Table 3. Activity of α-P,N-based $Rh^I$ complexes in styrene hydroformylation catalysis.

| Run[a] | Catalytic precursor | Ligand (1 equivalent) | TOF[b] [$h^{-1}$] | b/l ratio |
|---|---|---|---|---|
| 8 | Rh(acac)$(CO)_2$ | $PPh_3$ | 130 ± 7 | 93:7 |
| 9 | Rh(acac)$(CO)_2$ | $Ph_2PCH(Ar)NHPh$[b] | 170 ± 9 | 88:12 |
| 10 | Rh(acac)$(CO)_2$ | $Ph_2PCH_2NPh_2$ | 285 ± 13 | 90:10 |
| 11 | Rh(acac)$(CO)_2$ | $Ph_2PCH_2NEt_2$ | 325 ± 16 | 92:8 |
| 12 | [RhCl(COD)]$_2$ | $Ph_2PCH_2NPh_2$ + $NEt_3$[c] | 220 ± 11 | 90:10 |

[a] Conditions described in Table 2. [b] Ar = $\eta^6$(*o*-$C_6H_4Cl$)$Cr(CO)_3$. [c] 1 Equivalent relative to the rhodium complex.

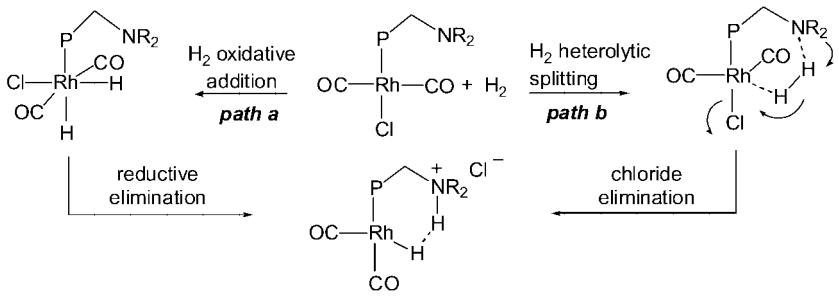


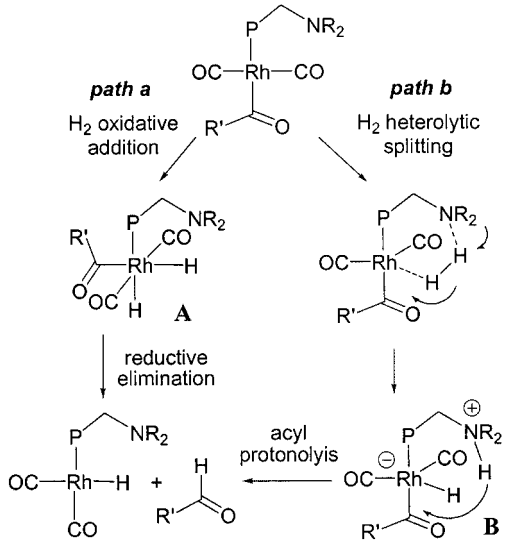
Scheme 6.

served for the generation of the catalytically active species. In order to generate the active Rh–H species, rhodium(I) chloride precursors typically show induction periods in the catalytic process because of the need to eliminate HCl after the dihydrogen oxidative addition to rhodium. The addition of an external amine favors this process and reduces or even eliminates the induction time.[30] In our own hands, $[RhCl(COD)]_2$ still affords a very active catalyst in the absence of any added phosphane ligand under the same conditions given in Table 3, but only after quite a long induction period (>3 h). It seems therefore reasonable to us that the dangling nitrogen function plays an important role in assisting the rapid formation of the Rh–H active species. We see two possible ways by which this "assistance" effect can operate. A first possibility involves, after the initial $H_2$ oxidative addition, the N-assisted promotion of HCl elimination from the intermediate $Rh^{III}$ dihydride (see Scheme 6, path a). On the other hand, an alternative mechanistic pathway could involve heterolytic cleavage of $H_2$ (see Scheme 6, path b). Indeed, many authors have proposed a base-assisted $H_2$ heterolytic splitting in relation to other catalytic processes (i.e. involving Ru,[31–34] Ir,[35] Pd,[36] and Rh[37]) over the last few years. Heterolytic splitting of $H_2$ is also shown by computational methods to be kinetically and thermodynamically more favorable than the classical dihydrogen oxidative addition for the interaction with the rhodium complex $Rh(PH_3)_2(HCO_2)$ in the presence of $NH_3$.[38] Consequently, a similar $H_2$ heterolytic activation process seems a reasonable possibility also for the rhodium hydroformylation catalytic systems here described, in particular with the basic $Ph_2PCH_2NEt_2$ ligand (see Scheme 6). In either case, the HCl produced during the activation step is likely to be trapped by the nearby amine function. However, this activation step cannot be enhancing the activity, because the chloride precursor is not the resting state of the catalytic cycle.

The second level where the external base is likely to have an effect concerns the rate-determining step of the catalytic cycle (*rds*), namely the hydrogenolysis of the rhodium acyl intermediate. Detailed kinetic and mechanistic studies carried out by van Leeuwen et al. have shown that the rate-determining step in rhodium catalyzed hydroformylation may be either the olefin insertion into the Rh–H bond or the Rh-acyl hydrogenolysis, depending on the ligand nature and on the conditions.[29,39] In the cases at hand, we have collected preliminary evidence, via H/D isotopic exchange experiments, that the hydrogenolysis is rate determining. Details of these studies are provided in a separate paper[40] In addition, no evidence for the accumulation of a hydride intermediate (as required if the olefin insertion step were rate determining) was obtained by HPNMR (vide infra).

We must now attempt to rationalize two different observations: (*i*) a proximal *free* amine function has a beneficial effect (i.e. see the experiments carried out with the acetylacetonate catalyst or with the chloride in the presence of an external base, cf. runs 12 and 2b); (*ii*) the beneficial effect is observed even when the dangling amine function is likely turned into an ammonium derivative (i.e. see all the experiments carried out with the chloride catalyst, without the use of an external base, runs 3–7).

Concerning the first point, we assume that the action of the uncoordinated amine function on the *rds* is similar to that proposed above for the activation of the chloride precursor, see Scheme 7. The greater activity could in principle be interpreted on the basis of two possible mechanistic routes. The first one (path a, Scheme 7) involves $H_2$ oxidative addition followed by aldehyde reductive elimination. On the basis of this mechanism, we would argue that the free amine ligand somehow helps either one or both of these elementary steps. However, the lack of interaction between the rhodium-acyl species and the dangling nitrogen moiety does not allow an obvious rationalization of the observed

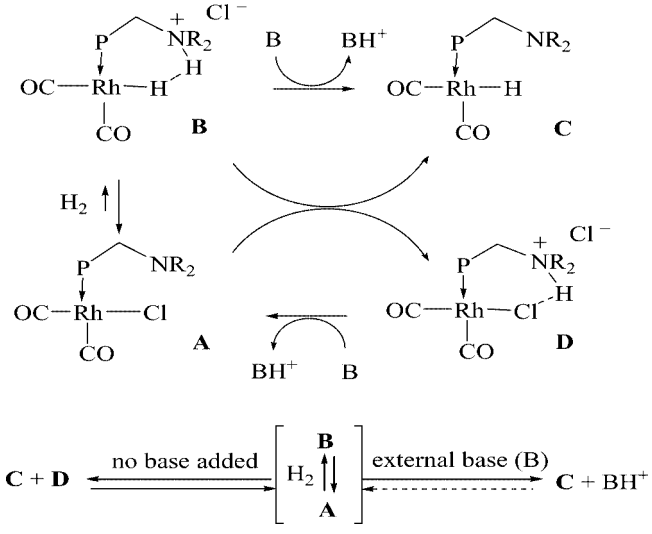


Scheme 7.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

effect. The second pathway (path b, Scheme 7) involves a base-assisted heterolytic $H_2$ splitting, leading to a zwitterionic rhodium monohydride intermediate. The latter would be stabilized by a P,N-ligand bearing a uncoordinated ammonium end. According to this mechanism, increasing the amine basicity could lower the activation barrier leading to the zwitterionic intermediate, thereby accelerating the *rds*. The aldehyde would then be formed by protonolysis of the rhodium-acyl bond by the dangling ammonium group, rather than by a reductive elimination process.

Clearly, the accelerating effect just discussed cannot be provided when the amine function is protonated. However, it is possible to envisage a proton exchange process, whereby the ammonium hydride derivative **B** formed during the catalyst activation step may equilibrate with the amine–chloride precursor **A** to yield an inactive ammonium chloride species **D** and an active amine–hydride complex **C**, identical to that obtained from the acetylacetonate precursor (see Scheme 8). Consequently, the different accelerating effect that is observed for the chloride systems in the absence of external base (runs 3–7) may be attributed to the presence of the equilibrium species **D**, which would again operate through the same mechanism of Scheme 7, the extent of the effect being a function of the equilibrium amount of that species. Acyl complexes are known to give hydrogenolysis even without the assistance of an internal amine function. However, the presence of an internal base increases the activity of the rhodium catalyst, to a growing extent as its basicity increases (see runs 8 through 11) and could then promote the hydrogenolysis step through a mechanism encompassing the $H_2$ heterolytic splitting.



Scheme 8.

In order to obtain further mechanistic information, we have carried out a $^1H$ HPNMR study of the $[RhCl(COD)]_2$-$Ph_2PCH_2NPh_2$ mixture in $CDCl_3$ under syngas (20 atm), approaching the experimental conditions of the catalytic runs. No Rh–H species could be observed under these conditions. This observation suggests that the **A**/**B** equilibrium proposed in Scheme 8 is only weakly shifted to the Rh–H hydride species **B**. The most active species **C** would then form only in minor proportion, leading to a low catalytic activity. According to Scheme 8, the amount of **C** could be increased only upon addition of a strong external base. On the other hand, the catalytic formation of aldehyde was immediately observed after the styrene introduction into the HPNMR tube, although the hydride resonance remained undetected. The latter result is consistent with the proposition that the olefin insertion step is not the *rds* for this system.

## Conclusions

The IR and $^{31}P$ HPNMR studies reported in this contribution have shown that the coordination properties of a variety of amino-phosphane ligands in $Rh^I$ complexes depend on the length of the P,N backbone. The γ-P,N ligands behave as κ¹-*P*-α-amino-phosphanes, whereas the β-P,N amino-phosphane leads to a solution equilibrium between κ²-*P,N* and κ¹-*P*-coordination modes, depending on the CO pressure. Under hydroformylation conditions, however, all the investigated Rh-amino-phosphane precatalysts exist as monodentate $[RhCl(CO)_2(\kappa^1\text{-}P\text{-}P,N)]$ complexes with a noncoordinated nitrogen function. The reported catalytic runs demonstrate that the dangling amino group favors the formation of the Rh–H active species when using $[RhCl(COD)]_2$ as the catalytic precursor and that both the basicity of the nitrogen end and its distance from the metal center have a crucial effect on the turnover frequency. The hydride formation could occur either by $H_2$ heterolytic splitting (assisted by the nearby amino group) or by a classical oxidative addition (with the amino group assisting the subsequent HCl reductive-elimination). Theoretical calculations are currently in progress in order to elucidate the preferred mechanistic pathway. We also suggest that the dangling amino group could take an additional mechanistic function as promoter of the hydrogenolysis step through a second heterolytic $H_2$ splitting. Isotopic H/D exchange studies under catalytic conditions using chiral P,N ligands, which are reported in a separate contribution,[40] provide additional mechanistic details in hydroformylation catalysis via rhodium amino-phosphane systems.

## Experimental Section

All manipulations were carried out under purified argon using standard Schlenk techniques. All solvents were dried and deoxygenated prior to use by standard methods. Standard pressure NMR measurements [$^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$] were carried out with a Bruker DRX300 spectrometer in $CDCl_3$ at room temperature. The peak positions are reported with positive shifts in ppm downfield of TMS as calculated from the residual solvent peaks [$^1H$ and $^{13}C\{^1H\}$] or downfield of external 85% $H_3PO_4$ ($^{31}P$). The high-pressure NMR (HPNMR) spectra were recorded by using a standard 10-mm probe tuned to $^{31}P$ and $^1H$ nuclei on a BRUKER AC 200 spectrometer operating at 81 MHz. The HPNMR experiments were performed in a 10-mm sapphire tube (Saphikon Inc., NH) charged with a solution of precatalyst (10 mg of P,N ligand, plus

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.5 equiv. of Rh precursor) in $CDCl_3$ (2 mL) under nitrogen, after which the first spectrum (reference) was recorded at room temp. The tube was then pressurized with CO 20 atm at room temp. The variable temperature experiment was started on a Bruker AC 200 spectrometer, recording a sequence of spectra up to 80 °C. After a chosen time, the probe was cooled to room temperature and another spectrum was recorded. The last spectrum was taken after venting the tube and flushing with nitrogen. The coordinated 1,5-COD (1,5-cyclooctadiene) C and H nuclei are labeled from 1 to 8, $C^1$ and $C^2$ being *trans* to P.

**CAUTION:** *All manipulations involving high pressure are potentially hazardous. Safety precautions must be taken at all stages of NMR studies involving high pressure tubes.*

All IR spectra were recorded in $CH_2Cl_2$ solution with a Bruker IFS 66 V spectrophotometer with KBr optics and the absorption vibration bands are given in $cm^{-1}$. Elemental analyses were carried out by the analytical service of the L.S.E.O. with a Fisons Instruments EA1108 analyzer. The commercial compounds $PPh_3$, $Ph_2NH$, $[RhCl(COD)]_2$, $[Rh(acac)(CO)_2]$, and $[Rh(CO)_2Cl]_2$ were used as received. The ligands $Ph_2PCH_2NEt_2$, $Ph_2PCH_2NPh_2$, $Ph_2PCH(Ar)NHPh$ {Ar = *o*-$C_6H_4Cl$ or *o*-$C_6H_4Cl[Cr(CO)_3]$}, $Ph_2PCH_2CH(Ph)NHPh$, $Ph_2PCH_2$(*o*-$C_6H_4$–$NMe_2$) (γ-P,N-1), and $Ph_2P$(*o*-$C_6H_4$–$CH_2NHPh$) (γ-P,N-2) were prepared according to literature.[13,14,17,41–44] The synthesis of complex [RhCl(COD)(α-P,N)] **1** with α-P,N=$Ph_2PCH$(*o*-$C_6H_4Cl[Cr(CO)_3]$)NHPh has previously been described.[18]

### Synthesis of [RhCl(COD)(P,N)] Complexes

The syntheses of the [RhCl(COD)(P,N)] complexes were generally carried out as follows. A mixture of $[RhCl(COD)]_2$ and P,N ligand were dissolved in $CH_2Cl_2$ (5 mL). The yellow solution obtained was stirred for 1 h. Addition of pentane afforded yellow or orange microcrystals which were isolated and dried in vacuo.

**[RhCl(COD)(γ-P,N-1)] (2):** $[RhCl(COD)]_2$ (84.4 mg, 0.171 mmol), **γ-P,N-1** (109 mg, 0.341 mmol) gave 144 mg of **2**, yield 75%. $^1H$ NMR: $\delta$ = 8.81–7.12 (m, 14 H, arom.), 5.61 (s, 2 H, $C_8H_{12}$, olefinic protons, *trans* to P), 4.21 [d, $^2J_{(P,H)}$ = 11.6 Hz, 2 H, $PCH_2$], 2.93 (s, 2 H, $C_8H_{12}$, olefinic protons, *cis* to P), 2.48 (s, 3 H, $NCH_3$), 2.49–1.86 (m, 8 H, $C_8H_{12}$, aliph. H) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 30.1 [d, $^1J_{(Rh,P)}$ = 150 Hz] ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 154.1–120.2 (m, 18 C, arom.), 104.3 (m, 2 C, $C^{1,2}$), 70.9 (s, 1 C, $C^5$), 70.7 (s, 1 C, $C^6$), 45.3 (s, 2 C, $NCH_3$), 33.3 (s, 2 C, $C^{3,8}$), 29.3 (s, 2 C, $C^{4,7}$), 28.5 [d, $^2J_{(P,C)}$ = 21 Hz, 1 C, $PCH_2$] ppm. $C_{29}H_{34}ClNPRh$ (565.92): calcd. C 61.55, H 6.05, N 2.48; found C 61.09, H 5.66, N 3.09.

**[RhCl(COD)(β-P,N)] (3):** $[RhCl(COD)]_2$ (85 mg, 0.172 mmol) and **β-P,N** (131 mg, 0.344 mmol) gave 152 mg of **3**, yield 80%. $^1H$ NMR: $\delta$ = 8.09–6.72 (m, 20 H, arom.), 7.02 [d, $^3J_{(P,H)}$ = 7 Hz, 1 H, NH, exchange with $D_2O$], 4.78 (m, 1 H, $NCH^c$), 3.36 [dt, $^2J_{(P,H^a)}$ = $^3J_{(H^a,H^b)}$ = 14, $^3J_{(H^a,H^c)}$ = 4 Hz, 1 H, $PCH^a$], 2.64 [t, $^2J_{(P,H^b)}$ = $^3J_{(H^b,H^a)}$ = 14 Hz, 1 H, $PCH^b$], 2.38–1.75 (m, 6 instead of 8 H, $C_8H_{12}$, aliph. H) ppm. The olefinic protons were not observed at room temp. due to an olefin rotation dynamic process. $^{31}P\{^1H\}$ NMR: $\delta$ = 21.7 [d, $^1J_{(Rh,P)}$ = 150 Hz] ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 147.1–114.9 (m, 24 C, arom.), 105.0 (s, very br., 2 C, $C^{1,2}$ of COD), 71.0 (s, very br., 2 C, $C^{5,6}$ of COD), 57.1 (s, 1 C, NCH), 37.7 [d, $J_{(P,C)}$ = 22 Hz, 1 C, PCH], 31.3 (br. s, 4 C, $C^{3,4,7,8}$ of COD) ppm. IR: $\tilde{\nu}$ = 3324 (m, $\nu_{NH}$) $cm^{-1}$. $C_{34}H_{36}ClNPRh{\cdot}0.5CH_2Cl_2$ (670.45): calcd. C 61.75, H 5.52, N 2.09; found C 62.15, H 5.77, N 2.23.

**[RhCl(CO)(β-P,N)] (Iβ):** $[RhCl(CO)_2]_2$ (36.1 mg, 0.093 mmol) and **β-P,N** (71 mg, 0.186 mmol) gave 76 mg of **Iβ**, 57% yield. $^1H$ NMR: $\delta$ = 8.22–6.83 (m, 20 H, arom.), 6.84 [d, $^3J_{(P,H)}$ = 10.8 Hz, 1 H, NH, exchange with $D_2O$], 3.91 (m, 1 H, $NCH^c$), 3.58 [dt, $^2J_{(P,H^a)}$ = $^3J_{(H^a,H^b)}$ = 14, $^3J_{(H^a,H^c)}$ = 4 Hz, 1 H, $PCH^a$], 2.86 [dt, $^2J_{(P,H^b)}$ = $^3J_{(H^b,H^a)}$ = 14, $^3J_{(H^b,H^c)}$ = 2 Hz, 1 H, $PCH^b$] ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 56.4 [d, $^1J_{(Rh,P)}$ = 168 Hz] ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 188.5 [dd, $^1J_{(Rh,C)}$ = 74, $^2J_{(P,C)}$ = 18 Hz according to CO *cis* to P,[45] 1 C, C=O], 145.7–125.5 (m, 24 C, arom.), 8.51 [d, $^2J_{(P,C)}$ = 8.6 Hz, 1 C, NCH], 38.8 [d, $J_{(P,C)}$ = 26 Hz, 1 C, PCH] ppm. IR: $\tilde{\nu}$ = 1986 $cm^{-1}$ (vs, $\nu_{CO}$) and $\nu_{NH}$ not observed. $C_{27}H_{24}ClNOPRh{\cdot}0.5CH_2Cl_2$ (590.28): calcd. C 55.90, H 4.24, N 2.37; found C 55.64, H 4.38, N 2.54.

***trans*-[RhCl(CO)(γ-P,N-1)$_2$] (IIIγ):** $[RhCl(CO)_2]_2$ (39 mg, 0.098 mmol) and **γ-P,N-1** (125 mg, 0.392 mmol) gave 113 mg of **IIIγ**, yield 71%. $^1H$ NMR: $\delta$ = 8.39–6.93 (m, 28 H, arom.), 4.40 (t not resolved, 4 H, $PCH_2$), 2.30 (s, 6 H, $NCH_3$). $^{31}P\{^1H\}$ NMR: $\delta$ = 31.20 [d, $^1J_{(Rh,P)}$ = 126 Hz] ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 188.0 [dt, $^1J_{(Rh,C)}$ = 76, $^2J_{(P,C)}$ = 14 Hz according to CO *cis* to both P,[45] 1 C, C=O], 154.2–120.1 (m, 36 C, arom.), 45.2 (s, 4 C, $NCH_3$). 26.8 [t, $J_{(P,C)}$ = 27 Hz, 2 C, $PCH_2$] ppm. IR: $\tilde{\nu}$ = 1974 (vs, $\nu_{CO}$) $cm^{-1}$. $C_{43}H_{44}ClN_2OP_2Rh$ (805.13): calcd. C 64.15, H 5.51, N 3.48; found C 64.46, H 5.55, N 3.34.

**Formation of the Unstable *cis*-[RhCl(CO)$_2$(γ-P,N-1)] (Iiγ). Method A:** A mixture of $[RhCl(CO)_2]_2$ (19.5 mg, 0.050 mmol) and **γ-P,N-1** (32 mg, 0.098 mmol) was dissolved in $CDCl_3$ (0.7 mL). After 10 min, the mixture was analyzed by $^1H$ and $^{31}P\{^1H\}$ spectroscopy showing **IIγ** as the major complex. $^1H$ NMR: $\delta$ = 7.75–7.03 (m, 14 H, arom.), 4.27 [d, $^2J_{(P,H)}$ = 12 Hz, 2 H, $PCH_2$], 2.34 (s, 6 H, $NCH_3$) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 31.1 [14%, d, $^1J_{(Rh,P)}$ = 125 Hz] ppm for **IIIγ** and 27.4 [86%, d, $^1J_{(Rh,P)}$ = 126 Hz] ppm for **IIγ**. After ca. 0.75 h and 12 h, the $^{31}P\{^1H\}$ NMR gave 1:4.5 and 1:2 ratios respectively for the **IIIγ/IIγ** mixture complexes. The above procedure was repeated in $CH_2Cl_2$ instead of chloroform. The atmosphere was then purged with CO and monitored by infrared. After 2 min, the pure dicarbonyl was formed. No $^{13}C$ NMR spectrum was recorded due to the increase of the ratio **IIIγ/IIγ** with time. The above procedure was repeated in $CH_2Cl_2$ and a slow diffusion of pentane to the yellow solution afforded poor quality yellow crystals which were identified as the complex **IIIγ**.

**Method B:** CO was introduced into a solution of [RhCl(COD)(**γ-P,N-1**)], **1a** (35 mg, 0.061 mmol) in $CH_2Cl_2$ (4 mL). Under CO and after 2 min, the IR spectrum showed only the pure dicarbonyl complex **IIγ** at 2092 and 2010 $cm^{-1}$ (both vs, $\nu_{CO}$), and this had not changed after two days under CO.

**Formation of the Unstable *cis*-[RhCl(CO)$_2$(β-P,N)] (Iiβ). Method A:** CO was introduced into a solution of [RhCl(COD)(β-P,N)] **1b** (42 mg, 0.071 mmol) in $CH_2Cl_2$ (4 mL). An IR spectrum was recorded after 2 min and showed a mixture of monocarbonyl complex **Iβ** at 1986 $cm^{-1}$ and dicarbonyl complex [RhCl(CO)$_2$(κ-*P*-P,N)] **IIβ** at 2011 and 2092 $cm^{-1}$. The ratio between the two complexes did not change after two days under CO.

**Method B:** A mixture of $[RhCl(CO)_2]_2$ (25.6 mg, 0.066 mmol) and β-P,N (54 mg, 0.131 mmol) was dissolved in $CDCl_3$ (1 mL). After 10 min, CO was introduced into the solution and the mixture was analyzed by $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy. The NMR spectra show a mixture of **IIβ** and **Iβ** in 1:2.5 ratio. $^1H$ NMR of **IIβ**: $\delta$ = 8.12–5.63 (m, 28 H, arom.), 5.78 [d, $^3J_{(P,H)}$ = 6 Hz, 2 H, NH, exchange with $D_2O$], 4.14 (m, 2 H, NCH), 3.58 (m, 2 H, $PCH^a$), 2.45 (m, 2 H, $PCH^b$) ppm. $^{31}P\{^1H\}$ NMR of **IIβ**: $\delta$ = 21.11 [d, $^1J_{(Rh,P)}$ = 122 Hz] ppm. No $^{13}C\{^1H\}$ NMR spectrum was recorded due to the low solubility of **IIβ** in $CDCl_3$ and $(CD_3)_2CO$.

**Crystal Structure Determination of Complex IIIγ:** Intensity data were collected with a Nonius Kappa CCD at 230 K. The structure was solved by the heavy atom method and refined by full-matrix

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

least-squares methods[46] with the aid of the WINGX program.[47] Non-hydrogen atoms were anisotropically refined. Hydrogen atoms were included in calculated positions and refined with a riding model. Crystallographic data for compound **IIIγ** are reported in Table 4.

Table 4. Crystal data and structure refinement for **IIIγ**.

**Catalytic Runs:** The hydroformylation reactions were carried out in a 300-mL stainless-steel Parr autoclave equipped with a magnetic drive, an internal glass vessel, and an immersion tube connected to a valve for solution withdrawals under pressure. The temperature was controlled by a rigid heating mantle and a single loop cooling coil. The autoclave was purged three times under vacuum/argon before introducing the catalytic solution. The 1:1 $CO/H_2$ mixture was prepared by mixing the pure gases in a 500-mL stainless-steel cylinder before introduction into the autoclave at the desired pressure (see Table 1 and Table 2). The zero time for kinetic runs was considered as the time at which the desired pressure was reached inside the autoclave. In order to maintain temperature and pressure conditions as constant as possible during each kinetic run, only a few mL of catalytic solution mixture were carefully withdrawn each time from the autoclave. The $CHCl_3$ or THF solvent was then rotary evaporated at room temperature and the yellow-orange residue was analyzed by $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy. The experimental error on the TOF determination was carried out from the TOF values obtained from three successive runs using three times the same solution for two different catalytic systems (run, 5 and 10). The experimental error for other catalytic runs has been estimated on the basis of the determination as above.

## Acknowledgments

This work was supported by COST D29 (WG009/03) and by the EC through the contracts HPRN-CT-2002–00176 (HYDROCHEM) and MRTN-CT-2003–503864 (AQUACHEM) and the contribution is kindly acknowledged. We are also grateful to the Ministère de la Recherche, the Centre National de la Recherche Scientifique (CNRS) and the Conseil Régional de Bourgogne for support of this work. J.-M. C. thanks the Ministère de la Recherche for a Ph. D. fellowship. HPNMR measurements have been possible through the NMR service of "FIRENZE HYDROLAB": a project sponsored by a generous grant by Ente Cassa di Risparmio di Firenze.

# Amino-phosphanes in $Rh^{I}$-Catalyzed Hydroformylation: New Mechanistic Insights Using $D_2O$ as Deuterium-Labeling Agent

**Jacques Andrieu,*[a] Jean-Michel Camus,[a] Cédric Balan,[a] and Rinaldo Poli*[b]**

**Keywords:** Rhodium / Amino-phosphane ligands / H/D isotopic exchange / Hydroformylation catalysis / Enantioselectivity

In previous work, we have demonstrated that the dangling amino group in amino-phosphane ligands increases the rate of Rh-catalyzed styrene hydroformylation as a function of the amino group basicity and of the distance between the P and N functions. We now report additional stereochemical and mechanistic insights resulting from new catalytic experiments performed with Rh-α-P,N catalytic systems in the presence of $D_2O$. In addition to the expected $D_0$ product, the formation of the β-$D_1$ aldehyde, $PhCH(CH_2D)CHO$ was observed in all cases by $^1H$ and $^{13}C$ NMR spectroscopy, indicating that H/D exchange occurs for the rhodium-hydride complex. Minor amounts of a β-$D_2$ product, $PhCH(CHD_2)CHO$, were also formed under certain conditions, demonstrating the reversibility of the olefin coordination step. The composition of the aldehyde mixture is slightly affected by the nature of the catalytic precursor or the P,N ligand used. In the specific case of the α-P,N ligand [α-P,N = ($S_{Ar}$,$S_C$)-$Ph_2PCH$-{*o*-$C_6H_4Cl(Cr(CO)_3)$}NHPh], in combination with the $[RhCl(COD)]_2$ precatalyst, products $PhCD(CH_3)CHO$ (α-$D_1$) and $PhCD(CH_2D)CHO$ (α,β-$D_2$) were also produced. This result suggests a reversible deprotonation assisted by an intramolecular H-bonding interaction between the dangling ammonium function and the carbonyl moiety. This isotopic exchange process decreases the asymmetric induction from 14 to 7 % *ee* when using the enantiopure version of this ligand. Aldehydes bearing a D atom on the formyl group, e.g. $PhCH(CH_3)CDO$, were never observed. The latter observation excludes protonolysis of the rhodium-acyl intermediate as the aldehyde forming step. In addition, it also excludes a bimolecular reaction involving the rhodium-acyl and rhodium-hydride intermediates.

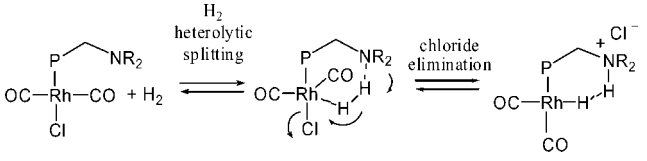
## Introduction

Metal complexes containing P,N bifunctional phosphanes have attracted considerable attention in the field of homogeneous catalysis, in particular with transition metals like Ni,[1] Pd,[2,3] Pt,[4] Ru,[5,6] Rh,[3,7] and Ir.[8–10] These ligands can be either $\kappa^1$:*P* or $\kappa^2$:*P*,*N* coordinated and each coordination mode can modify the catalytic properties. For example, when a pyridinylphosphane is only P-coordinated in a $Pd^{II}$ complex, the dangling amine function acts then as a "proton messenger" in alkyne methoxycarbonylation catalysis,[2] whereas a selective P,N chelation of a chiral phosphanediamine induces an effective chiral field in the rhodium complex leading to a higher selectivity in asymmetric hydrogenation of acrylic acid.[7]

In our laboratory, we have developed different access ways to chiral α-[11] or β-P,N[12,13] and mixed α,β- and β,γ-P,P,N[14] ligands and their coordination properties have been explored in copper(I),[15] palladium(II),[13,16] and rhodium(I) complexes[14,17,18] Recently, we have examined the coordination properties of various P,N ligands in rhodium-catalyzed hydroformylation and demonstrated the hemilabile character of β or γ-P,N ligands under CO pressure. Therefore, under these conditions, these ligands behave like their related α-P,N monophosphane ligands, for which the chelating mode is not observed under any operating conditions.[18] The presence of a dangling nitrogen group close to the rhodium metal center could promote the activation of dihydrogen by heterolytic cleavage (see Scheme 1). In this interaction, the Rh center acts as a Lewis acid, accepting $H^-$, whereas the nearby amine function acts as a Lewis base, capturing the proton.



Scheme 1.

Nevertheless, even in the presence of chiral α-,[17] β-P,N[12] or other P,N ligands,[19,20] the enantioselectivity of branched aldehydes formed in styrene hydroformylation were very low (<14%). We decided to further investigate the mechanistic details of the enantioselective process by additional experiments based on H/D isotopic exchanges

using $D_2O$ as a deuterium source. Indeed, deuterioformylations performed in the presence of $D_2$ instead of $H_2$ have been most effective for elucidating mechanistic details in catalytic processes, for instance the degree of reversibility for the olefins insertion reactions into the Rh–H bond,[21–23] or the different behavior of primary, secondary, and tertiary Rh–alkyl intermediates under hydroformylation conditions.[24] In addition, the use of deuterated reagents like $D_2$, EtOD, or (*S*)-$CH_3$–CH(Ph)OD have also provided mechanistic information, respectively, in iridium-catalyzed alkane dehydrogenation,[25] in palladium-catalyzed styrene hydroalkoxycarbonylation,[26] or in metal-catalyzed hydrogen transfer from alcohols to ketones.[27] Our choice of heavy water, $D_2O$, as the source of the deuterium label was suggested by the proposed implication of ammonium functionalities, with potentially exchangeable protons, near the catalytic center, as shown in Scheme 1. Furthermore, its use would allow us not only to follow the D-incorporation into organic compounds during the catalysis, but also to obtain useful information on the stability and/or reactivity of our Rh-P,N catalysts in aqueous media.[28–30] We could then evaluate their potential for extension to biphasic conditions.[31]

## Results and Discussion

The catalytic runs were carried out using $[RhCl(COD)]_2$ or $[Rh(acac)(CO)_2]$ as precatalyst, with an equimolar amount of the α-P,N ligands $Ph_2PCH_2NR_2$ (R = Me, Ph) or $Ph_2PCH(Ar)NHPh$ [Ar = $\eta^6$(*o*-$C_6H_4Cl$)$Cr(CO)_3$], in the presence of 1000 equivalents of $D_2O$ and styrene. Control experiments were also carried out with $PPh_3$ and in the absence of phosphane ligand. In a previous contribution, we have reported the catalytic activity and linear/branched selectivity of the above systems in dry $CHCl_3$.[18] The hydroformylation experiments in the presence of $D_2O$, reported in this paper, were carried out under similar conditions with the exception of the solvent, which was changed from $CHCl_3$ to THF in order to insure homogeneous conditions in the presence of water. In Figure 1, we compare the activity of the same Rh-P,N precatalyst under the two different solvent conditions.

Neither the branched/linear regioselectivity (91/9),[18] nor the turnover frequency at the beginning of the catalytic process are affected by this solvent change. However, the catalyst starts to lose activity after ca. 5 h. Conversions of 65 and 100% were obtained respectively after one and two days, whereas a complete conversion was achieved in $CHCl_3$ after only one day (see Figure 1). Therefore, the loss of activity seems related to catalyst decay due to the presence of the large excess of water. Since a complete conversion was achieved after two days, we decided to analyze the crude aldehyde mixture by NMR spectroscopy after this period for all catalytic runs. The nature and relative proportions of the branched aldehydes are summarized in Table 1. The small relative amounts of linear aldehyde did not permit the analysis of the deuterium incorporation and these data are therefore excluded from Table 1.

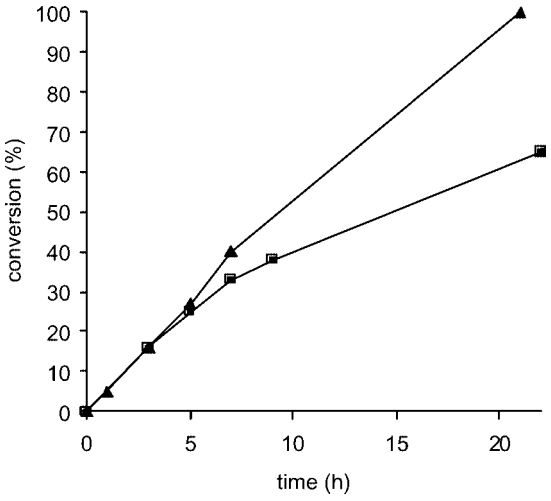

Figure 1. Conversion for the catalyzed styrene hydroformylation as a function of time: ■, in THF/$D_2O$, ▲, in $CHCl_3$. Both experiments were performed using the catalytic conditions described for run 5, Table 1.

The incorporation of the deuterium atoms either in the terminal methyl group or in the internal methyne group of the branched aldehydes was determined unambiguously by careful analysis of the primary and secondary isotope shifts and of the $J_{(CD)}$ patterns for the α- and β-C resonances in the $^{13}C\{^1H\}$ NMR spectrum (see Table 2). The relative amounts of the various products were quantified by integration of the $^{13}C\{^1H\}$ resonances affected by the secondary isotope shift, since the Overhauser effect does not depend on the substitution pattern at the adjacent C atom.[32–34] Thus, for instance, the relative proportion of compounds $PhCH(CH_3)CHO$ and $PhCH(CH_2D)CHO$ were obtained by integration of the two proton-decoupled methyne signals, whereas the relative proportions of compounds $PhCH(CH_3)CHO$ and $PhCD(CH_3)CHO$ were obtained by integration of the two proton-decoupled methyl signals.

Figure 2 shows the $^{13}C$ NMR spectra for three representative product mixtures. The mixture obtained from run 7 (Figure 2, a), as well as most other runs (see Table 1) shows only the β-$D_1$ compound in addition to the regular $D_0$ product, whereas run 5 produces a more complex mixture of deuterated aldehydes (Figure 2, c). The spectrum in Figure 2 (b) corresponds to a control mixture of $D_0$ and α-$D_1$ products, which was obtained by direct isotopic exchange between the $D_0$ aldehyde and $[PhND_3]^+[BF_4]^-$. It is to be remarked that in none of the runs was any deuterium atom found on the aldehyde function, i.e. $PhCH(CH_3)CDO$.

The ubiquitous formation of the β-$D_1$ derivative is a clear indication that $D^+$ finds its way into the hydride position during the catalytic cycle. Since the decayed catalyst (Figure 1) yields no (or a much lower amount of) new aldehyde, and since the aldehyde does not incorporate D under these conditions in the absence of the catalyst (vide infra), we can conclude that the isotopic distribution measured at the end of the experiment is not affected by the catalyst decomposition process. As this β-$D_1$ incorporation phe-

[a] Conditions: $[RhCl(COD)]_2$ ($2.62\times10^{-2}$ mmol) or $[Rh(acac)(CO)_2]$ ($5.23\times10^{-2}$ mmol), styrene/Rh and $D_2O$/Rh = 1000, plus ligand, THF (35 mL), 55 °C, *p*(syngas) = 600 psi, two days. [b] Ar = $\eta^6$(*o*-$C_6H_4Cl$)$Cr(CO)_3$. [c] P,N/$NEt_3$ ratio = 1.

Table 2. Selected $^{13}$C-NMR spectroscopic data and $J_{(CD)}$ coupling constants of deuterated compounds.

| Compounds | $C_\alpha$ δ [ppm] ($J_{(CD)}$ in Hz) | $C_\beta$ |
|---|---|---|
| $D_0$ | 51.82 | 13.43 |
| β-$D_1$ | 51.77 | 13.18 (19) |
| β-$D_2$ | 51.72 | very weak signal |
| α-$D_1$ | 51.41 (20) | 13.34 |
| α,β-$D_2$ | 51.36 (20) | 13.08 (19) |

nomenon occurs also when the phosphane ligand carries no amine function (runs 2 and 3) and even in the absence of any phosphane (run 1), a direct acid dissociation of the hydride intermediate in the protic medium or a reversible protonation to generate a dihydrogen complex or a classical dihydride intermediate (Scheme 2) appear as the most logical mechanisms for this H/D exchange.

The observation that all experiments where a phosphane ligand is present (runs 2–9) provided a greater $D_0$/β-$D_1$ ratio (≈3) than run 1 appears to be in better agreement with the hypothesis of acid dissociation. Note that the $D_0$/β-$D_1$ ratio is not greatly affected by the phosphane nature. For other processes, on the other hand, the amount of D incorporation by exchange with $D_2O$ was shown to greatly depend on the nature of the phosphane ligand and substrate.[30,35]

The formation of the β-$D_2$ product is observed only in the absence of phosphane ligand (run 1) and for run 4, using the $Ph_2PCH_2NPh_2$ ligand. The presence of this product must be the consequence of reversibility for the styrene insertion step. It is to be remarked that H elimination from the β-$D_1$-1-phenylethyl insertion product should be favored over D elimination by a kinetic isotope effect, since the C–H/D vibrational modes are stronger than those of the C···H/D and Rh···H/D interactions in the transition state.[36] The reversibility of the styrene coordination step is further confirmed by the recovery of free β-$D_1$-styrene, i.e. PhCH=CHD, when a catalytic experiment carried out under the same condition of run 1 was quenched and the organic phase analyzed after 30% conversion. The absence of α-$D_1$-styrene, i.e. $PhCD=CH_2$, indicates that the 1,2 insertion leading to the $\eta^1$-2-phenylethyl rhodium complex (precursor of the linear aldehyde) is irreversible. This is consistent with other previously reported results.[22,37,38] Reversible 2,1 styrene insertion has previously been evidenced for hydroformylation experiments carried out under $D_2$ with $Rh_4(CO)_{12}$ as the catalyst (without phosphane ligands) or with $[Rh(acac)(CO)_2]$ in the presence of the mono-, diphosphane, or (*R*,*S*)-binaphos ligand.[21,23,37,38] With the latter Rh–binaphos catalytic system, the amount of α-plus β-$D_1$-styrene was observed to increase significantly from 2 to 30% when the syngas pressure was increased from 1 to 100 atm. Our results indicate that the styrene insertion becomes less reversible in the presence of phosphane ligands, with the exception of run 4. The latter leads to quite comparable results to those of run 1 and to those of the process conducted with tetranuclear rhodium precatalysts in the absence of phosphane ligands.[38] In other previous work based on the use of mono or di-phosphane ligands, the amount of deuterium label found in styrene was reported to be very minor and to vary only slightly (from 0.1 to a few %) as a function of the phosphane nature.[21] The unusually high proportion of β-$d^2$ in run 4 could be due to a ligand dissociation, but we have no further evidence to confirm or refute this assumption at this time.

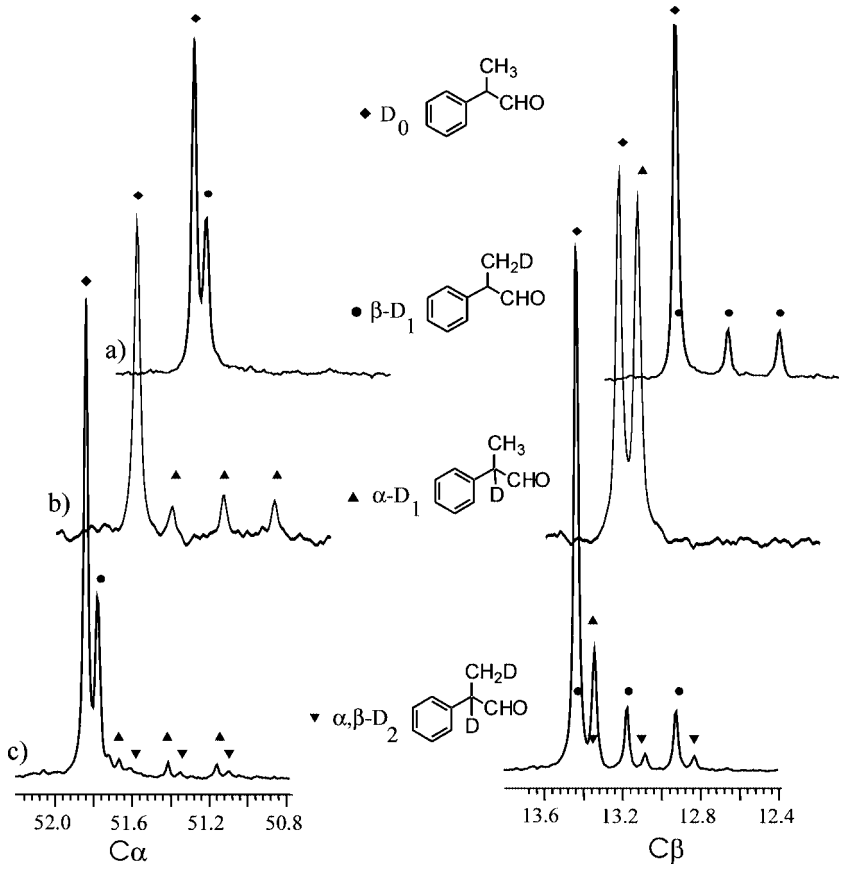

Figure 2. $^{13}C\{^1H\}$ NMR spectra of partially deuterated aldehyde mixtures. Only the peaks of the branched aldehydes are shown for clarity. $C_\alpha$ and $C_\beta$ correspond respectively to the methyne and methyl carbon atoms. (a) From run 7, after complete conversion. (b) From the reaction between $D_0$ aldehyde and 0.3 equivalent of $[PhND_3^+](BF_4^-)$, after 24 h, under catalytic conditions described in Table 1 without rhodium catalyst. (c) From run 5, after complete conversion.

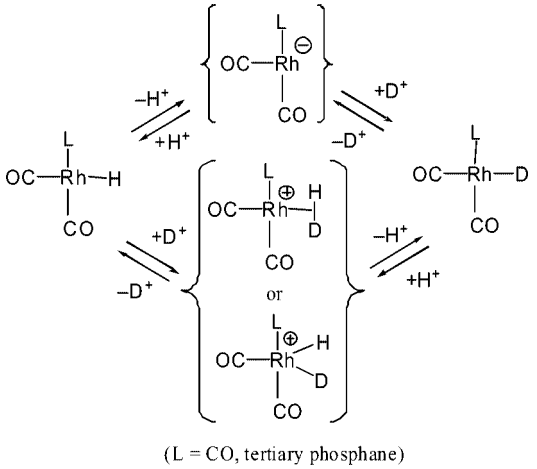
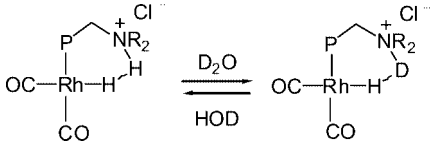


Scheme 2.

The absence of any observable deuterium incorporation into the formyl group has very important implications. As discussed above, an HCl equivalent is generated during the catalyst activation process when using the $[RhCl(COD)]_2$ precursor. This by-product will presumably be trapped by the internal amine function (see Scheme 1), since amines are more basic than water ($pK_a \approx 4.8$ for $PhNH_2Me^+$ and 10.7 for $NHEt_3^+$). The ammonium protons of the resulting Rh–ammonium species are likely to be exchanged by $D^+$ in the presence of $D_2O$, see Scheme 3.



Scheme 3.

Therefore, the outcome of the catalytic runs in the presence of $D_2O$ excludes Rh–acyl protonolysis by the ammonium function as the aldehyde forming step (see Scheme 4). In other words, the amino-phosphane ligand does not act as a "proton messenger", unlike the pyridinylphosphane ligand in the palladium catalyzed alkyne methoxy-carbonylation process.[2] Furthermore, this result also excludes the possibility of a binuclear aldehyde elimination process between a rhodium acyl and a rhodium hydride species,[39,40] for this system. These observations are summarized in Scheme 4.

The hydrogen atom that becomes part of the formyl group must derive from the $H_2$ molecule involved in the hydrogenolysis step. As discussed in our recent contribution,[18] hydrogenolysis could occur either by $H_2$ oxidative addition followed by aldehyde reductive elimination

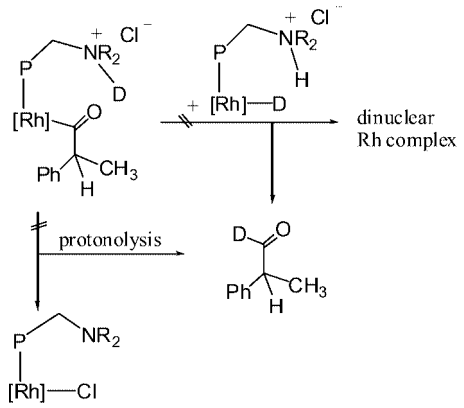
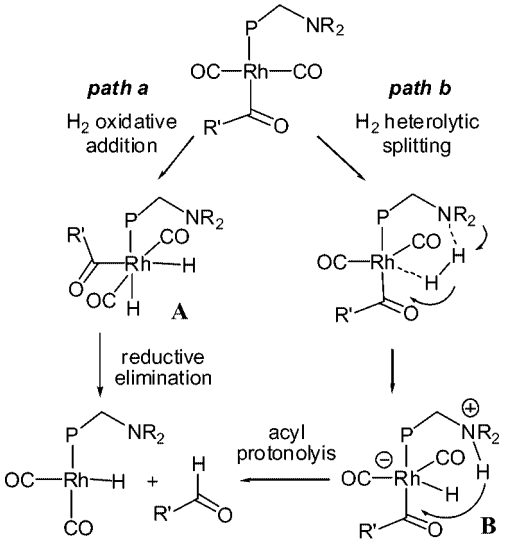


Scheme 4.

with a $Rh^{III}$ dihydride intermediate (**A**), or by $H_2$ heterolytic splitting via a zwitterionic ammonium-hydride complex (**B**), see Scheme 5. In either case, the aldehyde release from the intermediate must be faster than the H/D exchange at the site that ultimately delivers the H atom to the formyl unit.



Scheme 5.

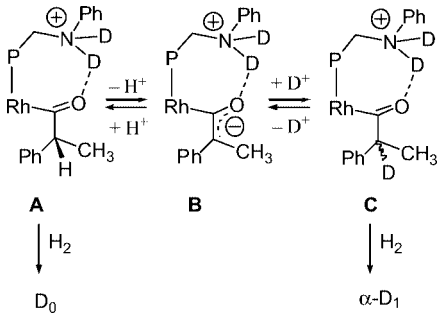
The most unexpected result of our investigation, however, is the observation of the α-$D_1$ and α,β-$D_2$ products for the [RhCl(COD)]$_2$/$Ph_2PCH(Ar)NHPh$ catalytic system (Table 1, runs 5 and 6). A possible pathway for the D incorporation from $D_2O$ at the α-position could in principle involve a β-elimination reaction from the Rh–acyl complex leading to a ketene-hydride intermediate. After Rh–H/Rh–D isotopic exchange with $D_2O$ and subsequent ketene insertion, the Rh–acyl complex with the deuterium atom at the α-position could be obtained. However, this mechanism is unlikely for three different reasons. The first one is that the high reactivity of ketene towards water[41] should lead to the related acid, which is not detected in NMR spectra. The second reason is that such a mechanism should lead to aldehydes without any *ee*.

Additional catalytic runs were performed with complexes RhCl(COD)(*S*,*S*-α-P,N) and Rh(acac)(CO)(*S*,*S* -α-P,N) prepared in situ from the chiral ligand [*S*,*S*-α-P,N = ($S_{Ar}$,$S_C$)-$Ph_2PCH\{o\text{-}C_6H_4Cl(Cr(CO)_3)\}NHPh$][17] and the rhodium precatalysts [RhCl(COD)]$_2$ and Rh(acac)$(CO)_2$, respectively. These tests, run either with RhCl(COD)(*S*,*S*-α-P,N) in $CHCl_3$ or with Rh(acac)(CO)(*S*,*S*-α-P,N) in $C_6H_6$, gave (*S*)-2-phenylpropanal with 7 and 14% *ee*, respectively. In order to verify that the low *ee* are not merely the consequence of racemization under our catalytic conditions, (*R*)-2-phenylpropanal was heated at 55 °C in $CHCl_3$ for one day. No significant change of the *ee* was observed. Thirdly, it is not possible to easily rationalize why the H/D exchange at the α position via the ketene intermediate would only be promoted by the [RhCl(COD)]$_2$/$Ph_2PCH(Ar)NHPh$ combination. Note that changing the P,N ligand to a more basic one (run 8), or changing the precursor to the acetylacetonate complex (run 7) suppresses this phenomenon.

The catalyst modifications alluded to above have an effect on the state of protonation of the dangling nitrogen atom, thus suggesting a direct role of this function in the H/D exchange at the α position. Therefore, a possible pathway for the formation of the α-$D_1$ and α,β-$D_2$ products in runs 5 and 6 could be based on the equilibrium between the Rh–acyl intermediate and its related enolate form (**A** and **B** in Scheme 6), with assistance from the ammonium function via hydrogen bonding. This assistance requires the presence of a proton-bearing ammonium functionality with sufficient acidity, thereby explaining the absence of this phenomenon when using the acetylacetonate precatalyst (the dangling amine is not protonated) or a more basic P,N ligand (insufficient acidity for the resulting ammonium function). The decreased amount of α-$D_1$ aldehyde from 15 to 4% when an addition external base is added to this catalytic system (from run 5 to run 6) is also consistent with this mechanistic proposal. A control experiment carried out under the same temperature and pressure conditions of run 5, in the presence of a catalytic amount of [$PhND_3$][$BF_4$] (0.1% vs. the aldehyde), but without the rhodium complex and the phosphane, shows no observable α-D incorporation. However, ca. 50% conversion to the α-$D_1$ aldehyde occurred when a higher amount of deuterated ammonium salt (20% vs. the aldehyde) was used under similar conditions (see Figure 2,b). Thus, H/D exchange at the α position can indeed occur in the presence of a sufficiently strong acid. Note that $PhND_3^+$ is a stronger acid than the dangling $Ph_2PCH(Ar)NPhH_2^+$ function and yet it is a less effective H/D exchange catalyst that the protonated, rhodium-coordinated amino-phosphane. This suggests cooperativity between the ammonium function and the metal center.

At this point, the enolate anion **B** can be protonated by either $H^+$ or $D^+$, originating from water or from the $-ND_2Ph^+$ fragment, leading to **A** or **C**. Further hydrogenolysis liberates the $D_0$ and α-$D_1$ aldehydes, respectively. On the basis of the basic properties of the dangling amine function, one would expect that the [RhCl(COD)]$_2$/$Ph_2PCH_2NPh_2$ (run 4) should also lead to H/D exchange

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 6.

at the α position, whereas no α-$D_1$ product is observed in this case. This result is probably associated with the insufficient basicity of the N atom (e.g. the p$K_a$ of $Ph_2NH_2^+$ is 0.8 vs. 4.85 for $PhNH_2Me^+$). Thus, the liberated HCl would be trapped by the aqueous solvent in this case, rather than by the dangling amine group.

It is to be noted that Rh-enolate intermediates have also been proposed in catalytic aldolization reactions or in one-pot catalytic tandem/aldol condensation, but in both cases the enolate moiety adopts a $\eta^1$-O coordination mode rather than a $\eta^1$-C one.[42,43] The H/D exchange process on the Rh–acyl, according to the proposed Scheme 6, must necessarily be associated to an intramolecular racemization before the aldehyde liberation by hydrogenolysis. In this respect, there is a correlation between the production of α-$D_1$ aldehyde for run 5 (and its absence for run 7) in Table 1 and the reduced enantioselectivity observed with the RhCl(COD)(*S*,*S*-α-P,N) precatalyst vs. the Rh(acac)-(CO)(*S*,*S*-α-P,N) precatalyst in chloroform (discussed above).

## Conclusions

The isotopic composition of aldehyde, obtained by styrene hydroformylation using Rh-α-P,N catalytic systems in the presence of $D_2O$, allows us to obtain new stereochemical and mechanistic information for this catalytic reaction. Specifically, the absence of $PhCH(CDO)CH_3$ in all cases shows that the rhodium-acyl intermediate does not release the aldehyde product by a protonolysis process, nor by bimetallic reductive elimination. The presence of $PhCD(CHO)CH_3$ in only one catalytic experiment shows, for the first time, that a Rh–acyl racemization may be catalyzed in the presence of certain ligands. An intramolecular H-interaction between the ammonium and Rh-enolate moieties is proposed to be responsible for this process, leading to M–acyl racemization before the reductive elimination step. This is a new phenomenon to be considered for the design of new ligands for use in the efficient and highly enantioselective branched hydroformylation process. It should also be considered for the extension of existing rhodium catalyzed asymmetric hydroformylation processes to ionic liquid media such as imidazolium or ammonium salts.

## Experimental Section

**General Procedures:** All manipulations were carried out under purified argon and in the dark using standard Schlenk techniques. All solvents were dried and deoxygenated by standard methods and distilled under dinitrogen prior to use. $^1H$ and $^{13}C\{^1H\}$ NMR measurements were carried out with a Bruker AC300 spectrometer. The peak positions are reported with positive shifts in ppm downfield of TMS as calculated from the residual solvent peaks. The commercial compounds $PPh_3$, $Ph_2NH$, $[RhCl(COD)]_2$, $[Rh(acac)(CO)_2]$, and $[Rh(CO)_2Cl]_2$ were used as received without further purification. The ligands $Ph_2PCH_2NEt_2$, $Ph_2PCH_2NPh_2$, $Ph_2PCH(Ar)NHPh$ [Ar = *o*-$C_6H_4Cl\{Cr(CO)_3\}$], were prepared according to the literature.[11,15,44,45] The preparation of the optically pure version of the latter ligand, (*S*,*S*)-**1**, has been previously reported[11] The synthesis of complex [RhCl(COD)(α-P,N)] **1** with α-P,N=$Ph_2PCH$(*o*-$C_6H_4Cl[Cr(CO)_3]$)NHPh has previously been described.[17] The (*R*)-2-phenylpropanal was prepared by an oxidation reaction using the Dess–Martin reagent[46] from commercially available (*R*)-2-phenyl-1-propanol (Aldrich) according to a previously described procedure[47] (*ee* = 93% by use of the NMR chiral shift reagent $[Eu(hfc)_3]$, according to the literature[48]).

**Catalytic Runs:** The hydroformylation reactions were carried out in a 300-mL stainless-steel Parr autoclave equipped with a magnetic drive, an internal glass vessel, and an immersion tube connected to a valve for solution withdrawals under pressure. The temperature was controlled by a rigid heating mantle and a single loop cooling coil. The autoclave was purged three times under vacuum/argon before introducing the catalytic solution (see Table 1). The 1:1 CO/$H_2$ mixture was prepared by mixing the pure gases in a 500-ml stainless steel cylinder before introduction into the autoclave at the desired pressure (see Table 1). The zero time for kinetic runs was considered as the time at which the desired pressure was reached inside the autoclave. In order to maintain temperature and pressure conditions as constant as possible during each kinetic run, only a few mL of catalytic solution mixture were carefully withdrawn each time from the autoclave. The THF solvent was then rotary evaporated at room temperature and the yellow-orange residue was analyzed by proton and carbon NMR spectroscopy. For the product obtained in the presence of the optically active catalyst, the *ee* as well as the absolute configuration of the enantiomer were determined by use of the NMR chiral shift reagent $[Eu(hfc)_3]$, according to the literature.[48]

# On the Usefulness of Bond Orders and Overlap Populations to Chalcogen–Nitrogen Systems

**Julianna Oláh,[a,b] Frank Blockhuys,[a] Tamás Veszprémi,[b] and Christian Van Alsenoy*[a]**

**Keywords:** Bond order / Overlap population / Hirshfeld partitioning / Chalcogen–nitrogen systems / Bonding

Bond orders calculated using the Mayer, Wiberg or NAO methodologies are incompatible with the observed bond lengths in chalcogen–nitrogen systems. To study this discrepancy four types of bond orders and three types of (scaled) overlap populations have been used to determine the bonding in these systems. A new overlap population based on the Hirshfeld partitioning of the electron density is compared to the Mayer, Wiberg, NAO and Fuzzy bond order schemes and the Mulliken and Fuzzy overlap population schemes. The correlation between the investigated bond orders and overlap populations is excellent for common organic molecules, but the (scaled) Hirshfeld and Fuzzy overlap population schemes produce the best results for a series of chalcogen-nitrogen systems.

## Introduction

There has been an increasing interest in low-molecular-weight derivatives of $(SN)_x$ polymer since the latter's metallic properties[1] and low-temperature superconductivity[2] were discovered in the 1970′s. In our earlier work we have dealt with various compounds containing an $(SN)_2$ fragment such as 1,3λ⁴δ²,2,4-benzodithiadiazine (**1**),[3] its fluorinated derivatives[4] and Roesky's ketone (**4**).[5] 3λ⁴δ²,1,2,4-Benzothiaselenadiazine (**2**) and 1,3λ⁴δ²,2,4-benzodiselenadiazine (**3**), the mono- and diselena analogues of **1**, are also of considerable interest and are presently targets for synthesis.[6] Figure 1 presents structural formulas of these compounds. According to single-crystal X-ray diffraction (XRD) studies,[7] the structure of **1** is planar in the solid state, whereas both gas-phase electron diffraction (GED) and quantum chemical calculations indicate a bent structure in the gas phase.[3] Compound **1** possesses a cyclic 12π-electron system, and the deviation from the planar structure was attributed to a pseudo-Jahn–Teller distortion to minimize the antiaromaticity.[3,8] Furthermore, the energy barrier to planarity is low (1.17 kJ·mol$^{-1}$ at the HF/6-31G* level) and in the crystal phase the molecule can be flattened without great effort.

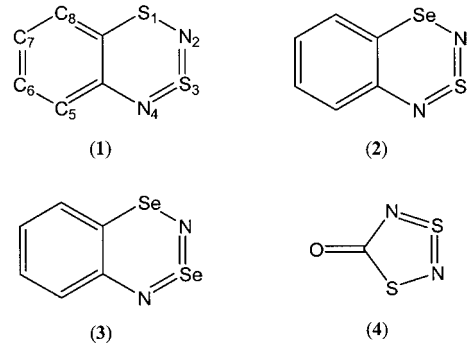

Figure 1. Structural formulas and atomic numbering of the chalcogen–nitrogen compounds under consideration. For compound **4** the formal Lewis structure is given.

Despite the different conformations in the two phases the measured (by XRD and GED) and calculated geometrical parameters of **1** reflect similar bonding. In the heteroatomic part there are two virtually equally short N=S bonds (bond length about 1.55 Å) and one longer N–S bond (bond length about 1.70 Å). On the basis of a comparison between the average bond lengths for the N=S and N–S bonds, the two short bonds could be identified as being double bonds while the longer one fell within the range for a single bond. Indeed, according to the analysis of the Cambridge Structural Database by Allen et al.,[9] an average N–S single bond lies between 1.64 and 1.70 Å, while a N=S double bond is approximately 1.54 Å long [we note that the N=S bond length is only tabulated for conjugated N=S=N systems].

In many cases, conclusions on the structures of compounds are based on bond order considerations, and therefore, it is essential to obtain reliable values for it. According to the IUPAC Compendium of Chemical Terminology, a

bond order is a "theoretical index of the degree of bonding between two atoms relative to that of a single bond, i.e. the bond provided by one localized electron pair".[10] However, there exists no unique formula to calculate the bond order. Every bond order is partly arbitrary since it is based on a population analysis scheme which is arbitrary itself: different schemes for the partitioning of the electron density give rise to different definitions of bond orders.

Regardless of the differences between the various bond order methodologies, it is important that each one of them produces consistent results, and this is often the case for common organic molecules. This requirement is, however, not fulfilled in the case of compound **1** for which the Mayer,[11–13] Wiberg[14] and NAO (atom-atom-overlap-weighted Natural Atomic Orbital bond order)[15,16] methodologies predict a bond order value for the NS double bond which is much smaller than expected on the basis of the bond length. The same controversy is observed in the case of compounds **2**, **3** and **4**.

Since the early definition of Wiberg[14] there has been a long debate on the appropriate quantum chemical definition of bond orders (see ref.[17] and refs. 1–18 therein). Recently, Mayer and Salvador[18] have proposed bond orders based on 'fuzzy' atoms which are characterized by soft overlapping boundaries and defined using the Becke partitioning scheme. Clark and Davidson proposed a method for controlling the region of overlap between atoms and thoroughly examined the effect of the shape and sharpness of the interatomic boundaries on the obtained fuzzy atomic populations.[19] Mayer's fuzzy atom bond order, together with several other methods, was used by Clark et al.[20] in their investigation of the bonding properties of a number of actinide complexes. It was found that the fuzzy atom method[18] performed well for these compounds, even though the Natural Population Analysis (NPA) method exhibited the best performance of all the orbital-based partitioning schemes for these molecules.

Pauling was the first to suggest that bond orders can be related to bond lengths, and since then several relationships have been proposed.[21–24] These curves have found widespread applications. Among others, Lendvay[25] has reconfirmed the exponential relationship between the bond length and bond order using Equation (1),

$$n = \exp[-(r - r_0)/b] \tag{1}$$

where $n$ is the bond order, $r_0$ the equilibrium bond length of a single bond, $r$ the real bond length in the compound considered, and $b$ is a constant.

It is the purpose of this paper to address the discrepancies between observed bond lengths and the corresponding bond orders calculated using different methodologies, in particular for NS and NSe bonds in chalcogen-nitrogen compounds. For this purpose we have calculated and compared the Mulliken, Fuzzy and Hirshfeld overlap populations with the Mayer, Wiberg, NAO and Fuzzy bond orders. We have also investigated the relationship between these bond orders, overlap populations and the corresponding bond lengths. It has been known for decades that Mulliken overlap populations correlate reasonably well with Mayer bond orders,[26] even though Mayer insists that overlap populations and bond orders reflect different aspects of bonding, i.e. charge accumulation and exchange interactions, respectively. In the recent past the Hirshfeld partitioning scheme[27,28] has received considerable interest in relation to the calculation and interpretation of a variety of molecular quantities such as charges and dipoles,[28–33] enthalpies of formation,[34–36] global QMSI (quantum molecular similarity index) values[37] and Fukui functions (see ref.[38] and refs. therein).

## Theory and Computational Details

In the Hirshfeld Scheme[27,28] the number of electrons attributed to an atom A in a molecule, $N_A$, is defined as in Equation (2),

$$N_A = \int d\boldsymbol{r} \frac{\rho_A(\boldsymbol{r})}{\sum_X \rho_X(\boldsymbol{r})} \rho_M(\boldsymbol{r}) \tag{2}$$

in which $\rho_M(\boldsymbol{r})$ is the molecular density at position $\boldsymbol{r}$, $\rho_A(\boldsymbol{r})$ is the atomic density and $\sum_X \rho_X(\boldsymbol{r})$ constitutes the pro-molecular density. In a way similar to the definition of the atomic charge,[28–33] the Hirshfeld overlap population (HOP), $B_{AB}$, can be defined by Equation (3),

$$B_{AB} = \int d\boldsymbol{r} \frac{\rho_A(\boldsymbol{r})\rho_B(\boldsymbol{r})}{\left(\sum_X \rho_x(\boldsymbol{r})\right)^2} \rho_M(\boldsymbol{r}) \tag{3}$$

which is the special case of the fuzzy atom overlap population defined earlier[18] in which the weight factors have been replaced by those specified by Hirshfeld. Full geometry optimisations of the structures of all the molecules studied in this work were performed using the Gaussian 03 program package[39] applying Density Functional Theory (DFT) with the hybrid B3LYP functional[40] and the cc-pVTZ basis set; the basis set was used as it is implemented in the program. The Wiberg and NAO bond orders and the NPA charges were calculated using the NBO 3.0 program[41] as it is implemented in the Gaussian 03 program package. Mayer and Fuzzy bond orders and Mulliken and Fuzzy charges were calculated using the program Fuzzy.[42] The Hirshfeld overlap populations and stockholder charges were calculated using the BRABO program package.[43]

## Results and Discussion

### Comparison of Overlap Populations and Bond Orders for Homodiatomic and Simple Organic Molecules

In order to evaluate our new Hirshfeld overlap populations (HOP) as they are defined by Equation (3), the values

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were compared to the corresponding Mulliken and Fuzzy overlap populations and to the Mayer, Wiberg, NAO and Fuzzy bond orders for a set of simple organic and inorganic molecules. The results have been compiled in Table 1. The values of the overlap populations are considerably smaller than those of the bond orders. In order to make comparison of the data easier, we have scaled the overlap populations in such a way that they are in line with the formal bond orders of 1, 1.5, 2, and 3 for the CC bonds in ethane, benzene, ethene, and ethyne, respectively. Therefore, these four compounds and their bond order values were used to construct a linear function between the calculated and formal bond orders and this has been presented graphically in Figure 2; the relevant data of the trendlines have been given in Table 2. Although this scaling is arbitrary it does have the advantage that it produces numbers comparable to the bond orders expected by chemical intuition. For reasons of comparison similar linear regression curves were calculated for the bond order schemes as well. Figure 2 and Table 2 indicate that the slopes of the regression lines for the Wiberg, Mayer and Fuzzy bond orders are close to 1, precluding any form of scaling. The values of the NAO bond orders and of the three overlap populations are lower in absolute value, but correlate very well linearly with the formal bond orders as can be seen from the $R^2$ values given in Table 2. On the basis of the equations of the regression lines obtained for the three overlap populations and the NAO bond orders, scaled equivalents of these were calculated, and these are also given in Table 1 as sHOP (scaled Hirshfeld overlap population), sMOP (scaled Mulliken overlap population), sFOP (scaled Fuzzy overlap population) and sNAO (scaled NAO bond order).

The bond orders and overlap populations of the different bonds in a series of substituted ethynes (RC≡CH), ethenes ($RHC=CH_2$) and ethanes ($RH_2C–CH_3$) were calculated and the changes of the bond order or overlap population as a function of the substituents (R = H, $CH_3$, F, Cl and CHO) were examined. All schemes used reflect the expected trends. For the homodiatomic molecules, basic chemical knowledge suggests that there is a single bond in $H_2$, $F_2$ and $Cl_2$, a double bond in $O_2$ and a triple bond in $N_2$; the respective bond orders are then 1, 2 and 3. The scaled Hirshfeld overlap population of 1.91 for $O_2$ is remarkable, as is the value of 1.87 obtained with the Mayer scheme; the other methods show much lower or higher values, despite the commonly accepted bond order value of 2. In contrast, the values of sHOP for both $H_2$ and $F_2$ are quite low. It is important to note that there is a significant difference between the Wiberg and Mayer bond orders on the one hand, and the Hirshfeld and Fuzzy overlap populations and the NAO bond order on the other. In each case, the Wiberg/Mayer values are very close to the formal bond order of 1 but are independent of the strength of the bond, while the Hirshfeld/NAO/Fuzzy values seem to provide additional information on the bond strength (i.e. they give larger numbers for stronger single bonds and smaller values for weaker single bonds). The Wiberg bond order of the F–F bond is 1.01 and virtually equal to that of the H–H bond, while both sNAO and sHOP suggest a weaker bond in $F_2$ which is in accordance with the small dissociation energy of the F–F bond.[44] Table 1 also contains a number of negative values which are clearly due to the scaling procedure. Even though these values have lost their quantitative meaning they are still useful on a qualitative level.

In order to compare the values of the scaled Hirshfeld overlap population with those of the other investigated quantities, the latter were plotted against the scaled Hirshfeld overlap populations in Figure 3; all carbon–carbon bonds compiled in Table 1 have been included. As can be seen from Figure 3 the Hirshfeld overlap population correlates quite well with all the other bond order and overlap population schemes except with the Mulliken overlap population. The correlation with NAO is the best.

As mentioned in the introduction, since Pauling's original suggestion several authors have confirmed the bond orders' exponential decrease with the bond length. In Figure 4 the values of the bond orders and overlap population calculated using the different methods were plotted against the

Table 1. Calculated bond lengths ($r_e$ in Å), the corresponding Hirshfeld (HOP), Fuzzy (FOP) and Mulliken (MOP) overlap populations together with their scaled equivalents (sHOP, sFOP and sMOP), and the NAO (NAO), scaled NAO (sNAO), Wiberg (WBO), Mayer (MBO) and Fuzzy (FBO) bond orders for a number of organic and diatomic compounds. See text for details. * These compounds were used for scaling.

| | Mulliken (Δ) | $y = 4.005\ x - 0.410$ | 0.989 |

bond length for the carbon–carbon bonds presented in Table 1. The function in Equation (4),

$$n = A \cdot \exp[-r/b] \quad (4)$$

was then fitted to the data. Compared to Equation (1) a parameter $A$ was introduced which results from two considerations. First, instead of plotting $(r - r_0)$ against $n$, only $r$ was, which resulted in a right-shift of the curve by $r_0$. This does not effect the goodness of the exponential fit, the correlation coefficients or the decay parameter $b$. Secondly, the non-scaled bond orders and overlap populations were used in these fits in order to avoid confusion because of the scaling, taking into account that the latter values are much lower than the formal bond orders, which are present in Equation (1). Table 3 contains the parameters $A$ and $b$ used in the different fits. Our results are in accordance with the earlier findings: with the exception of the Mulliken overlap population all investigated quantities decrease exponentially with the bond length, with $R^2$ values above 0.97 (except for the fuzzy overlap population). The $R^2$ values are largest for the NAO bond order and the Hirshfeld overlap population. For the Wiberg and Mayer bond orders, the

value of the *b* parameter is about 0.29 Å, which is close to Pauling's "universal" value of 0.26 Å.

### Chalcogen–Nitrogen Compounds

For common organic compounds, all methodologies except the Mulliken overlap population give virtually equally good results. Consequently, it is logical to investigate their performance for more exotic systems, in particular compounds **1**–**4**, which are of special interest to our research.[3–6] First, a number of simple compounds which contain formal single, double and triple NS and NSe bonds were studied. The results are given in Table 4. On the basis of these the values, the bond orders and overlap populations calculated for compounds **1**–**4** can be interpreted in the second part of this discussion.

It is important to note that while the values of the scaled Hirshfeld overlap population (sHOP) and the Wiberg and Mayer bond orders correspond to a single NX (X = O,S,Se) bond in $NH_2OH$, $NH_2SH$ and $NH_2SeH$ and a double NX bond in HN=O and HN=S, the values of the scaled NAO bond order and the Mulliken overlap population are lower, and those of both the scaled Fuzzy overlap population and the Fuzzy bond order are larger. In every case the sulfur–nitrogen bonds have a larger bond order/overlap population than the corresponding selenium–nitrogen bonds (except in the case of the scaled Mulliken overlap population) which can be explained by the fact that heavier elements do not prefer to form double or triple bonds. Furthermore, the weakening of the double bond in the N=O > N=S > N=Se series is confirmed by all except the Mayer and Mulliken schemes.

While the NS bond length is considerably shorter in HN=S=NH and HN=Se=NH than in HN=S and HN=Se, respectively (in both cases by about 0.03 Å), the Wiberg, Mayer and Fuzzy bond orders are smaller in the diimino species. The Hirshfeld and NAO methods, on the contrary, show approximately the same bond order for the di- and monoimino species. As there seems to be a contradiction between the conclusions based on bond orders and bond lengths, we calculated the ellipticity and the electron density in the bond critical points of the N=X (X = S,Se) bonds of these four molecules with the Atoms In Molecules (AIM) theory.[45,46] Table 5 collects the results. The relatively large ellipticity values for all four compounds indicates the presence of NS and NSe double bonds in the compounds, but the values obtained for HN=X=NH are particularly large. The increase of the electron density in the bond critical point upon going from the monoimino to the diimino species

indicates a strengthening of the N=S and N=Se bonds as well. A possible explanation for the decrease of the values of the Wiberg, Mayer and Fuzzy bond orders and the Mulliken and Fuzzy overlap populations is that these methods are much more sensitive to the valence state of the atom than the other methods; after all, HN=X contains a divalent and HN=X=NH a tetravalent chalcogen atom. As a further possibility, we checked whether there is any bonding between the two nitrogen atoms in these molecules. The Mayer bond order value of about 0.24 shows weak bonding between these atoms, but none of the other methods supports this. The overlap-population-based methodologies can not be used for non-bonded atoms as the overlap populations in theses cases are always very low if not zero.

Table 5. Ellipticity ($\varepsilon$) and electron density in the bond critical point ($\rho_{BCP}$) of the N=S and N=Se bonds in HN=S, HN=S=NH, HN=Se and HN=Se=NH.

| | $\varepsilon$ | $\rho_{BCP}$ |
|---|---|---|
| HN=S | 0.083 | 0.250 |
| HN=S=NH | 0.392 | 0.275 |
| HN=Se | 0.125 | 0.206 |
| HN=Se=NH | 0.244 | 0.220 |

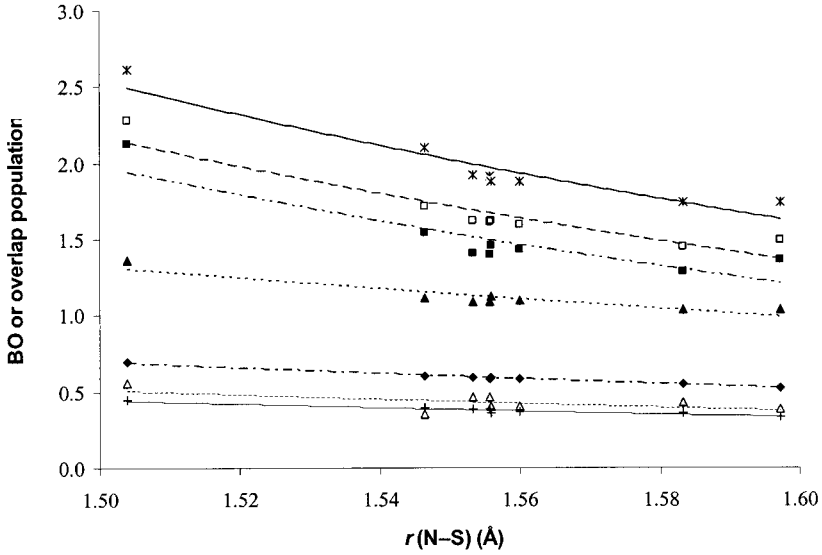

Figure 5. Exponential fit of the Wiberg (■), the Fuzzy (*), the Mayer (□) and the NAO (▲) bond orders and the unscaled Hirshfeld (♦), Fuzzy (+) and Mulliken (Δ) overlap populations vs. the *r*(N–S) of Table 4. See Table 3 for the values of the fitting parameters and the correlation coefficients.

In the second part of this discussion we will consider the bonding in compounds **1**–**4** with the above conclusion in mind. The calculated geometrical parameters and conformation of **1** are in accordance with earlier results.[3] An isolated molecule of **1** has a bent geometry and two short and one long NS bonds (see Table 4). Compounds **2** and **3** have the same conformation as **1** in the gas phase, and the bond lengths indicate similar bonding patterns in all three molecules. The scaled Hirshfeld and Fuzzy overlap populations and the Fuzzy bond orders in Table 4 are much larger than the other values for the N=S double bonds and they are in accordance with the conclusions based on the bond lengths. Only the Hirshfeld, Fuzzy bond order and NAO schemes suggest that the N=S bonds in **1** are of similar strength as those in HN=S=NH. In contrast, the Wiberg and Mayer bond orders are even smaller for the ring compounds than for HN=S=NH. As the NAO values are too small, only the scaled Hirshfeld overlap populations and Fuzzy bond orders are consistent with the conclusion based on the bond lengths. As was shown above, the AIM theory showed that for these compounds a shorter bond length indicates a stronger bond, and we can conclude that **1** contains two double and one single NS bonds. It is clear from Table 4 that the same conclusions can be drawn for compounds **2** and **3**. For the latter the bond order values have decreased in agreement with the observations made on the model compounds.

Comparison of the bond orders and bond lengths calculated for Roesky's ketone (**4**) further supports π-electron delocalisation and the aromaticity of Roesky's ketone. It was shown earlier that Roesky's ketone (**4**) is aromatic which is indicated by both the NICS value and the equalisation of the bond lengths within the ring.[5] When going from **1** to Roesky's ketone (**4**) the N=S double bond lengths increase from about 1.55 Å to about 1.58 and 1.59 Å, while the N–S single bond shortens from about 1.70 Å to about 1.64 Å. In accordance with this, the scaled Hirshfeld overlap populations of the double bonds in **4** are only 1.69 and 1.77, compared to 1.93 and 1.96 in **1**; the bond order of the single NS bond is 1.52 in **4**, while only 1.32 in **1**. The same trends can be seen in the Fuzzy, the Wiberg, the NAO and the Mayer bond orders, although the differences are far less pronounced.

Although it is known that for inorganic systems the relationship between bond order and bond length is much weaker than in organic molecules, we investigated whether Pauling's curve is applicable to our chalcogen-nitrogen systems. The calculated NS bond lengths were plotted against the values obtained from the different methodologies in Figure 5 for the tetravalent sulfur atoms; Table 3 contains the data relevant to the plots. The divalent sulfur atoms were not included in the fit, as the valence state of the atom may seriously influence this type of relationship. From Figure 5 and Table 3 it is clear that for these systems the exponential relationship between bond length and bond order/overlap population holds, but that the best correlation was found in the case of the Hirshfeld and Fuzzy overlap populations. The correlation in the case of bond orders is definitely inferior.

## Conclusions

Several types of overlap populations and bond orders were compared for a large set of common organic and diatomic molecules and applied to the description of chalcogen-nitrogen systems. It has been shown that the different overlap populations (with the exception of Mulliken) and bond orders correlate very well with bond lengths. In addition, the values obtained from the different methodologies correlate well amongst themselves. The particular use-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fulness of these schemes was demonstrated by examining the bonding in a set of chalcogen-nitrogen compounds which exhibit unusual bonding between heteroatoms. Only the (scaled) Hirshfeld and Fuzzy overlap population schemes produce results that are compatible with the observed bond lengths.

# Synthesis of New Half-Sandwich Ruthenium(II) Complexes Bearing Alkenyl- and Alkynylphosphane Ligands

**Josefina Díez,[a] M. Pilar Gamasa,*[a] José Gimeno,[a] Elena Lastra,*[a] and Amparo Villar[a]**

**Keywords:** Indenyl complexes / Phosphane ligands / Ruthenium / Sandwich complexes

Carbonyl substitution of the complex [RuI($\eta^5$-$C_9H_7$)$(CO)_2$] with the activated phosphanes $Ph_2PR$ (R = $CH_2CH{=}CH_2$, $CH_2CH_2CH{=}CH_2$, and C≡CPh) affords the complexes [RuI($\eta^5$-$C_9H_7$)(CO)($Ph_2PR$-κ*P*)] [R = $CH_2CH{=}CH_2$ (**1a**), $CH_2CH_2CH{=}CH_2$ (**1b**), C≡CPh (**1c**)]. The reaction of the complex [RuCl($\eta^5$-$C_9H_7$)$(PPh_3)_2$] with the corresponding phosphanes, in refluxing THF, gives the complexes [RuCl($\eta^5$-$C_9H_7$)($PPh_3$)($Ph_2PR$-κ*P*)] [R = $CH_2CH_2CH{=}CH_2$ (**2b**), C≡CPh (**2c**)] by substitution of $PPh_3$. The cationic derivatives [Ru($\eta^5$-$C_9H_7$)(L)($Ph_2PR$-κ$^3$*P,C,C*)][X] [L = CO, X = $SbF_6$, R = $CH_2CH{=}CH_2$ (**3a**), $CH_2CH_2CH{=}CH_2$ (**3b**); L = $PPh_3$, X = $PF_6$, R = $CH_2CH_2CH{=}CH_2$ (**4b**)] have been prepared by treatment of the complexes **1a**,**b** and **2b** with a halide abstractor such as $AgSbF_6$ or $NaPF_6$, respectively. Deprotonation reactions of the complexes **3b** and **4b** with cesium carbonate have been carried out, giving rise to the neutral complexes [Ru($\eta^5$-$C_9H_7$)(L)($Ph_2PCH_2CH{=}CHCH_2$-κ$^2$*P,C*)] [L = CO (**5a**), $PPh_3$ (**5b**)]. The reaction of complex **3a** with MeCN generates the complex [Ru($\eta^5$-$C_9H_7$)(MeCN)(CO)($Ph_2PCH_2CH{=}CH_2$-κ*P*)][$SbF_6$] (**6**). The vinylidene [Ru($\eta^5$-$C_9H_7$)($PPh_3$)($Ph_2PC{\equiv}CPh$-κ*P*)-{C=C(Ph)H}][$PF_6$] (**7**) and allenylidene [Ru($\eta^5$-$C_9H_7$)($PPh_3$)($Ph_2PC{\equiv}CPh$-κ*P*)(C=C=$CPh_2$)][$PF_6$] (**8**) derivatives have been synthesized by reaction of complex **2c** with phenylacetylene or 1,1-diphenylprop-2-yn-1-ol, respectively. The structures of the derivatives **1c**, **3a**, and **4b** have been determined by single-crystal X-ray diffraction analysis.

## Introduction

Functionalized phosphanes bearing a multiple carbon–carbon bond display a versatile behavior as ligands in coordination chemistry and have been reasonably well explored to date. Thus, alkenylphosphanes,[1] $R_2P(CH_2)_nCH{=}CH_2$ (*n* = 0–2), and alkynylphosphanes,[2] $R_2PC{\equiv}CR'$, have been used in coordination chemistry with a wide range of transition metals. Moreover, a number of ruthenium(II) complexes bearing different alkenylphosphanes, such as dicyclohexylvinylphosphane (DCVP),[3] vinyldiphenylphosphane (DPVP),[4] and allyldiphenylphosphane (ADPP)[5] have also been described and their ligand hemilabile properties have been repeatedly shown. However, the coordination properties and the hemilabile character of homoallylphosphanes have been much less exploited in the area of ruthenium chemistry. Recently, Kirchner and co-workers have studied the reactions of olefins and acetylenes with the complex [Ru($\eta^5$-$C_5H_5$)(MeCN)($Ph_2PCH_2CH_2CH{=}CH_2$-κ$^3$*P,C,C*)][$PF_6$], which give rise to interesting coupling products.[6] On the other hand, examples of complexes of ruthenium(II) with alkynylphosphanes[7] are also scarce, even though alkynylphosphanes have been extensively used in the synthesis of polynuclear complexes[2f,8] and have been reported to participate in interesting rearrangement processes, some of them involving phosphorus–carbon bond cleavage[9] or carbon–carbon bond formation.[10]

We have previously reported the synthesis and characterization of the ruthenium(II) complexes [Ru($\eta^5$-$C_9H_7$)($PPh_3$)($Ph_2PCH_2C$(R)=$CH_2$-κ$^3$*P,C,C*)][$PF_6$] (R = H, Me), which feature a κ$^3$*P,C,C* coordination mode of the allyldiphenylphosphane as well as a diastereofacial coordination of the olefin at the ruthenium center.[11] Moreover, these complexes have been demonstrated to be useful for further transformations, particularly as substrates in stereoselective nucleophilic addition[11] and intramolecular cycloaddition reactions,[12,13] which lead to interesting ruthenaphosphacyclopentane and ruthenaphosphabicycloheptene complexes, respectively. The progress of the latter reaction confirms the hemilabile character of the allyldiphenylphosphane ligand, a fact that has been corroborated by kinetic studies.[14] Continuing with these studies, we report here the synthesis of new half-sandwich indenyl complexes of ruthenium(II) containing alkenyl and alkynylphosphanes as well as some preliminary results on their reactivity.

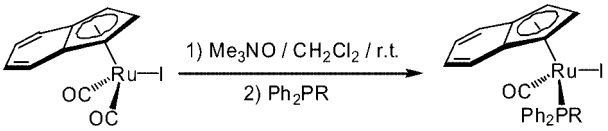
## Results and Discussion

### Complexes with Alkenyl and Alkynylphosphanes ($Ph_2PR$) Acting as κ*P* Monodentate Ligands

#### *Synthesis of [RuI(η⁵-C₉H₇)(CO)(Ph₂PR-κP)] [R = CH₂CH=CH₂ (1a), CH₂CH₂CH=CH₂ (1b), C≡CPh (1c)]*

The addition of the corresponding phosphane to a dichloromethane solution of the complex [RuI(η⁵-$C_9H_7$)(CO)($NMe_3$)] (prepared in situ by reaction of the complex [RuI(η⁵-$C_9H_7$)$(CO)_2$] with freshly sublimed trimethylamine oxide) generates the complexes [RuI(η⁵-$C_9H_7$)($Ph_2PR$-κ*P*)($PPh_3$)] [R = $CH_2CH=CH_2$ (**1a**), $CH_2CH_2CH=CH_2$ (**1b**), C≡CPh (**1c**)], which were isolated as air-stable red solids (78–97% yield) (Scheme 1).



R = $CH_2CH=CH_2$ (**1a**)
$CH_2CH_2CH=CH_2$ (**1b**)
C≡CPh (**1c**)

Scheme 1.

Complexes **1a**–**c** are soluble in $CH_2Cl_2$, THF, and diethyl ether and slightly soluble in hexane. Analytical and spectroscopic data (IR and $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy) support the proposed formulation (see Experimental Section for details). In particular, the IR spectra show the strong characteristic ν(CO) absorption at 1940 (**1a** and **1c**) and 1930 $cm^{-1}$ (**1b**) as well as the ν(C≡C) absorption at 2176 $cm^{-1}$ (**1c**), a singlet resonance is observed at $\delta$ = 45.0 (**1a**), 44.0 (**1b**) and 22.5 ppm (**1c**) for the phosphanes in the $^{31}P\{^1H\}$ NMR spectra, and a low-field doublet signal is observed in the $^{13}C\{^1H\}$ NMR spectra due to the carbonyl group at $\delta$ = 203.0 (**1a**), 203.5 (**1b**) and 202.4 ppm (**1c**) [$^2J_{C,P} \approx$ 20.7–21.3 Hz]. The $^{13}C\{^1H\}$ NMR spectrum of **1c** also shows two doublet signals for the alkynyl carbon nuclei at $\delta$ = 84.1 ($J_{C,P}$ = 93.6 Hz) and 108.9 ppm ($^2J_{C,P}$ = 14.4 Hz).

Slow diffusion of hexane into a solution of **1c** in diethyl ether allowed the isolation of crystals suitable for X-ray diffraction studies. An ORTEP-type representation of the molecule is shown in Figure 1. Selected bonding data are collected in the caption.

The molecule exhibits a pseudooctahedral three-legged piano-stool geometry. The η⁵-indenyl ligand displays the usual allylene coordination mode with the benzo ring oriented *trans* to the carbonyl group, as shown by the dihedral angle (1.14°) between the planes C*–C**–Ru and C*–Ru–C(10).[15]

The Ru–C(10) [1.840(4) Å] and C(10)–O(1) [1.132(5) Å] bond lengths are comparable to those found in other indenyl carbonyl ruthenium(II) complexes such as [RuI(η⁵-$C_9H_7$)(CO)($PCy_3$)] [1.817(13) and 1.142(15) Å][16] and [Ru(η⁵-1,2,3-$Me_3C_9H_4$)(CO)($PPh_3$)(C=C=$CPh_2$)][$BF_4$] [1.83(1) and 1.15(1) Å].[17]

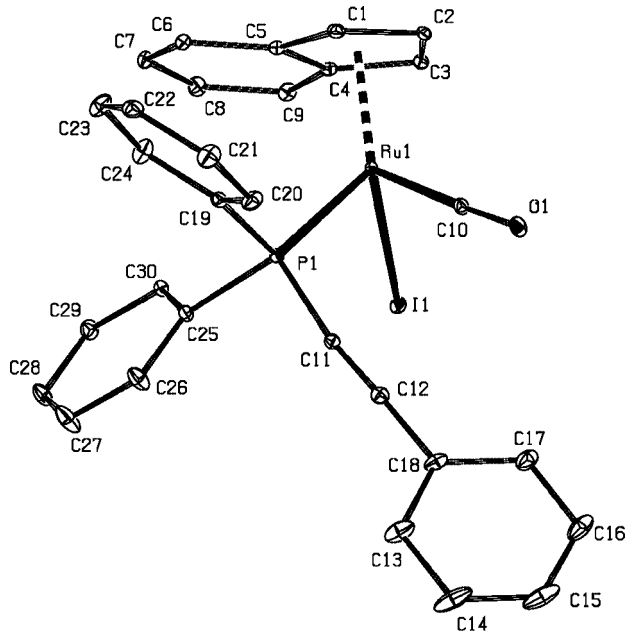


Figure 1. Molecular structure and atom-labelling scheme for complex **1c**. Non-hydrogen atoms are represented by their 10% probability ellipsoids. Hydrogen atoms and phenyl rings have been omitted for clarity. Selected bond lengths [Å]: Ru(1)–I(1) = 2.7224(4), Ru(1)–P(1) = 2.3087(9), Ru(1)–C(10) = 1.840(4), Ru(1)–C* = 1.9170, C(10)–O(1) = 1.132(5), P(1)–C(11) = 1.755(4), C(11)–C(12) = 1.210(6). Selected bond angles [°]: P(1)–Ru(1)–I(1) = 90.17(3), P(1)–Ru(1)–C(10) = 87.53(12), I(1)–Ru(1)–C(10) = 92.42(13), C*–Ru(1)–I(1) = 121.81, C*–Ru(1)–P(1) = 129.53, C*–Ru(1)–C(10) = 124.44, P(1)–C(11)–C(12) = 172.0(4), C(11)–C(12)–C(18) = 176.9(4). C* represents the centroid of atoms C(1), C(2), C(3), C(4), and C(5).

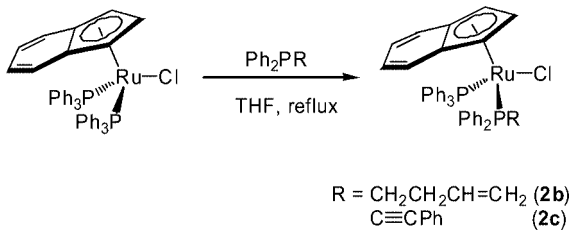
The alkynyl carbon–carbon bond length C(11)–C(12) [1.210(6) Å] is in the typical range for a carbon–carbon triple bond (1.205 Å in the free acetylene) and slightly longer than in other alkynylphosphaneruthenium complexes[7a] such as [$RuCl_2$(η⁶-*p*-cymene)($Ph_2PC\equiv CC_6H_4$-4-$CH_3$-κ*P*)] [1.198(3) Å] or [RuCl(η⁶-*p*-cymene)($Ph_2PC\equiv CtBu$-κ*P*)][OTf] [1.196(6) Å]. The alkynyl fragment of the phosphane displays a nearly linear geometry [C(11)–C(12)–C(18) = 176.9(4)°].

Both enantiomers are present in equal numbers in the crystal, as the crystal belongs to the centric space group $P\bar{1}$. The (*R*) enantiomer is shown in Figure 1.

#### *Synthesis of [RuCl(η⁵-C₉H₇)(Ph₂PR-κP)(PPh₃)] [R = CH₂CH₂CH=CH₂ (2b), C≡CPh (2c)]*

The reaction of the complex [RuCl(η⁵-$C_9H_7$)$(PPh_3)_2$] with the corresponding phosphane in refluxing THF results in the formation of the complexes [RuCl(η⁵-$C_9H_7$)($Ph_2PR$-κ*P*)($PPh_3$)] [R = $CH_2CH_2CH=CH_2$ (**2b**), C≡CPh (**2c**)], which were isolated as air-stable, red solids in 60% yield (Scheme 2). Complexes **2b**,**c** are soluble in dichloromethane and diethyl ether and insoluble in hexane, and were characterized by analytical and spectroscopic techniques (See Experimental Section for details).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

The most remarkable features of those complexes are (a) the ν(C≡C) absorption at 2168 $cm^{-1}$ in the IR spectrum for complex **2c**, (b) the expected doublets in the $^{31}P\{^1H\}$ NMR spectra at $\delta$ = 49.0 and 45.6 ppm ($^2J_{P,P}$ = 42.9 Hz) for **2b** and $\delta$ = 48.1 and 29.1 ppm ($^2J_{P,P}$ = 45.0 Hz) for **2c**, and (c) the $^{13}C\{^1H\}$NMR spectrum of **2c** shows two doublets at $\delta$ = 109.1 ($^2J_{C,P}$ = 11.5 Hz) and 87.2 ppm ($^2J_{C,P}$ = 80.7 Hz) for the acetylene carbons. One olefinic carbon appears at $\delta$ = 113.8 ppm in the $^{13}C\{^1H\}$NMR spectrum of **2b**, while the other one is overlapped by aromatic carbons.

### Complexes with Alkenylphosphanes $Ph_2P(CH_2)_nCH=CH_2$ ($n$ = 1, 2) Acting as $\kappa^3P,C,C$ Chelate Ligands: Synthesis of the Complexes $[Ru(\eta^5\text{-}C_9H_7)(L)(Ph_2PR\text{-}\kappa^3P,C,C)][X]$ [L = CO, X = $SbF_6$, R = $CH_2CH=CH_2$ (3a), $CH_2CH_2CH=CH_2$ (3b); L = $PPh_3$, X = $PF_6$, R = $CH_2CH_2CH=CH_2$ (4b)]

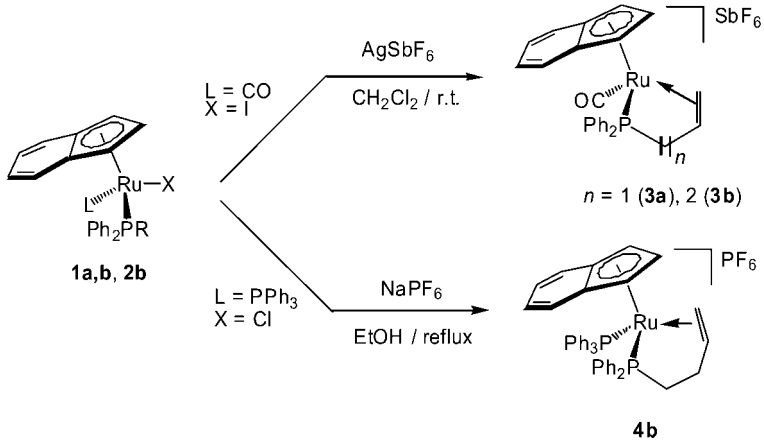
Due to the interest of the reactions carried out with the complex $[Ru(\eta^5\text{-}C_9H_7)(PPh_3)(Ph_2PCH_2CH=CH_2\text{-}\kappa^3P,C,C)][PF_6]$,[11–13] our interest focused on the synthesis of novel complexes with allyl- and homoallylphosphanes coordinated in a $\kappa^3P,C,C$ mode, which can be formed from complexes **1a**,**b** and **2b** by halide abstraction and subsequent olefin coordination to the metal. Thus, the treatment of complexes **1a**,**b** with $AgSbF_6$ in dichloromethane leads almost quantitatively to the complexes $[Ru(\eta^5\text{-}C_9H_7)(CO)(Ph_2PR\text{-}\kappa^3P,C,C)][SbF_6]$ [R = $CH_2CH=CH_2$ (**3a**), $CH_2CH_2CH=CH_2$ (**3b**)]. Similarly, the reaction of the complex **2b** with $NaPF_6$ in refluxing ethanol affords the complex $[Ru(\eta^5\text{-}C_9H_7)(PPh_3)(Ph_2PCH_2CH_2CH=CH_2\text{-}\kappa^3P,C,C)][PF_6]$ (**4b**) in 67% yield (Scheme 3).

Complexes **3a**,**b** and **4b** were isolated as air-stable, yellow solids that are soluble in dichloromethane and insoluble in diethyl ether and hexane. They were characterized analytically and spectroscopically (IR and $^1H$, $^{31}P\{^1H\}$, and $^{13}C\{^1H\}$ NMR spectroscopy; see Experimental Section for details).

The $^{31}P\{^1H\}$ NMR spectra show a singlet resonance for the complexes **3a** ($\delta$ = –56.4 ppm) and **3b** ($\delta$ = 74.6 ppm), while two doublet signals at $\delta$ = 69.3 [$Ph_2P(CH_2)_2CH=CH_2$] and 47.3 ppm ($PPh_3$; $^2J_{P,P}$ = 29.5 Hz) are found for complex **4b**. The phosphorus resonance of the allyldiphenylphosphane is clearly shifted upfield in the complex **3a** ($\delta$ = 74.6 ppm) in comparison with its precursor **1a** ($\delta$ = 45.0 ppm) wherein the allylphosphane acts as a monodentate ligand. However, the phosphorus resonances of the homoallyldiphenylphosphane in complexes **3b** and **4b** are shifted downfield with respect to those of the corresponding monodentate phosphanes in the complexes **1b** ($\delta$ = 44.0 ppm) and **2b** ($\delta$ = 45.6 ppm). The formation of five- (**3a**) and six-membered (**3b**, **4a**) ruthenaphosphacycles may account for the observed shift differences.[18]

Although the two olefin faces are diastereotopic when the alkenylphosphane ligands are bound in a didentate manner, the coordination to the metal is found to be completely selective, affording a sole diastereoisomer, as revealed by the analysis of the $^{31}P\{^1H\}$ NMR spectra of complexes **3a**,**b** and **4b**. Such a selectivity has also been reported previously for the complexes $[Ru(\eta^5\text{-}C_9H_7)(PPh_3)(Ph_2PCH_2CH=CH_2\text{-}\kappa^3P,C,C)][PF_6]$[11] and $[Ru(\eta^5\text{-}C_5H_5)(PPh_3)(Ph_2PCH_2CH=CH_2\text{-}\kappa^3P,C,C)][PF_6]$.[13] In addition, the $^{31}P\{^1H\}$ NMR spectra remain unchanged over a wide temperature range, thus ruling out a dynamic process between the two diastereoisomers on the NMR time scale. Contrary to these results, the analogous derivative $[Ru(\eta^5\text{-}C_5Me_5)(Ph_2PCH_2CH=CH_2\text{-}\kappa P)(Ph_2PCH_2CH=CH_2\text{-}\kappa^3P,C,C)][PF_6]$ was found to be fluxional, giving rise to a rapid equilibrium between the two diastereomeric conformations present in solution.[5c]

The relatively large difference of the $^1H$ NMR chemical shifts for the $CH_2$ geminal protons of the olefin in complexes **3a**,**b** and **4** points to a parallel orientation of the



Scheme 3.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

olefin with respect to the indenyl ring. Similar data have been reported in other cyclopentadienyl and indenyl π-olefin complexes.[19]

In order to compare the structure of the derivatives **3a** and **4b** with that of the complex $[Ru(\eta^5\text{-}C_9H_7)(PPh_3)(Ph_2PCH_2CH{=}CH_2\text{-}\kappa^3P,C,C)][PF_6]$,[11] and to find out which of the two olefin faces in the $Ph_2P(CH_2)_n\text{-}CH{=}CH_2\text{-}\kappa P$ ligand is most favored for coordination, an X-ray diffraction study was carried out. Single crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of diethyl ether into a solution of complexes **3a** and **4b** in dichloromethane. The crystals belong to the centrosymmetric space groups $P\bar{1}$ (**3a**) and $P2_1/c$ (**4b**), thereby indicating the presence of a racemic mixture.

In both cases, the asymmetric unit consists of two molecules. For complex **4b**, the two molecules are conformers with identical stereochemistry, the relative configuration at the ruthenium center being $R_{Ru}$ and the olefin being coordinated through the *re* face ($R_{Ru}$*re*). However, in the case of complex **3a** the two molecules in the asymmetric unit are a pair of diastereoisomers with relative configuration ($R_{Ru}$*si*) and ($S_{Ru}$*re*) (Figure 2). For both **3a** and **4b** the more relevant structural parameters are similar in both molecules,[20] and thus only the data corresponding to one molecule will be discussed.

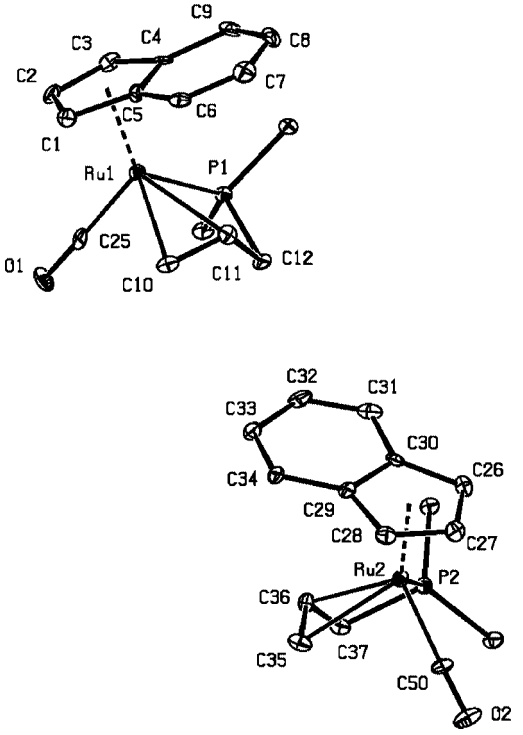


Figure 2. The two diastereoisomers found in the asymmetric unit for the cation of complex **3a** with configurations $R_{Ru}$*si* and $S_{Ru}$*re*. Non-hydrogen atoms are represented by their 20% probability ellipsoids. Hydrogen atoms and phenyl rings have been omitted for clarity.

ORTEP-type representations of the cations of one of the molecules for complexes **3a** and **4b** are shown in Figures 3 and 4, respectively. Selected bonding data are collected in Table 1.

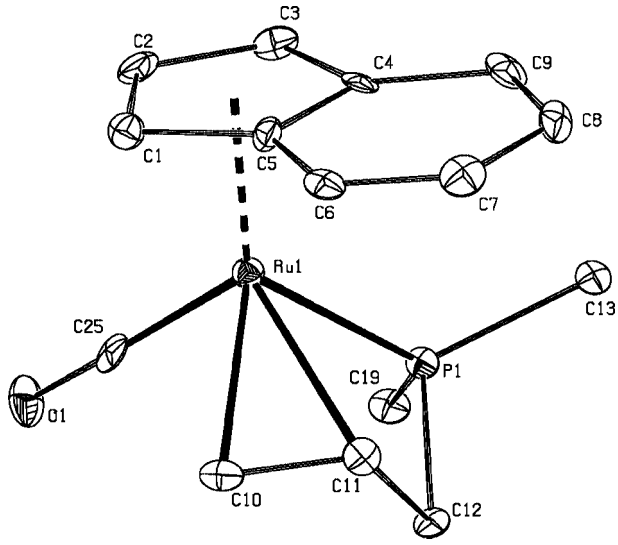

Figure 3. Molecular structure and atom-labelling scheme for the cation of complex **3a**. Non-hydrogen atoms are represented by their 10% probability ellipsoids. Hydrogen atoms and phenyl rings have been omitted for clarity.

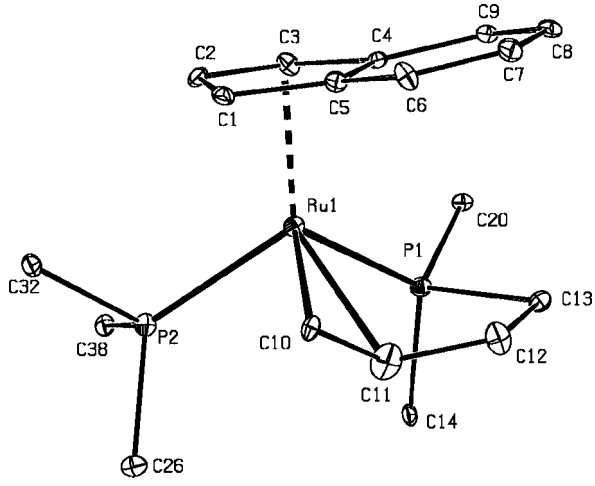

Figure 4. Molecular structure and atom-labelling scheme for the cation of complex **4b**. Non-hydrogen atoms are represented by their 10% probability ellipsoids. Hydrogen atoms and phenyl rings have been omitted for clarity.

Both structures exhibit a three-legged piano-stool geometry with the $\eta^5$-indenyl ligand displaying the usual allylene coordination mode. The Ru(1)–C(10) and Ru(1)–C(11) bond lengths reflect the coordination of the olefin to the metal center[20] [2.276(11) and 2.230(11) (**3a**) and 2.228(7) and 2.245(9) (**4b**)]. The C(10)–C(11) bond length is 1.389(17) Å in **3a** and 1.363(11) Å in **4b**, similar to that found in the complex $[Ru(\eta^5\text{-}C_9H_7)(PPh_3)(Ph_2PCH_2CH{=}CH_2\text{-}\kappa^3P,C,C)][PF_6]$.[11] It is also interesting to note that the benzo ring of the indenyl ligand is oriented almost *trans* to the CO group for complex **3a** and *trans* to the $PPh_3$ ligand for complex **4b**, as is shown by the dihedral angle between the planes C**–C*–Ru(1) and C*–Ru(1)–C(25) of 12.45° (**3a**) and C**–C*–Ru(1) and C*–Ru(1)–P(2)

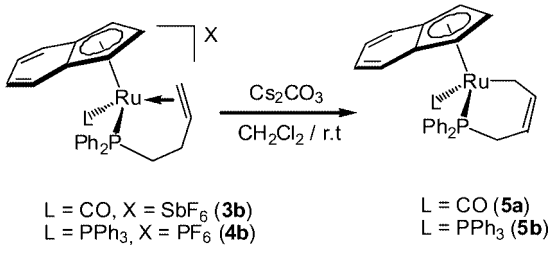
11.94° (**4b**).[15] The Ru(1)–C(25) [1.860(14) Å] and C(25)–O(1) [1.148(15) Å] bond lengths for complex **3a** are similar to those found in complex **1c**.

## Reactivity of the Complexes [Ru(η$^5$-$C_9H_7$)(L)($Ph_2PR$-κ$^3$*P,C,C*)][X]

### *Deprotonation Reactions: Synthesis of [Ru(η$^5$-$C_9H_7$)(L)($Ph_2PCH_2CH$=$CHCH_2$-κ$^2$*P,C*)] [L = CO (5a), $PPh_3$ (5b)]*

The complexes [RuCl(η$^5$-$C_9H_7$)(L)($Ph_2PCH_2CH_2CH$=$CH_2$-κ$^3$*P,C,C*)][X] [X = $SbF_6$, L = CO (**3b**); X = $PF_6$, L = $PPh_3$ (**4b**)] undergo deprotonation reactions in the presence of base. Thus, the treatment of **3b** and **4b** with KO*t*Bu or $Cs_2CO_3$ in $CH_2Cl_2$ gives the neutral allylruthenium complexes [Ru(η$^5$-$C_9H_7$)(L)($Ph_2PCH_2CH$=$CHCH_2$-κ$^2$*P,C*)] [L = CO (**5a**), $PPh_3$ (**5b**)], which were isolated as yellow solids in 80–86% yield (Scheme 4).

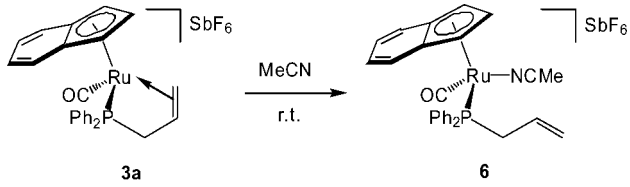


Scheme 4.

Their analytical and spectroscopic data support the proposed formulations (see Experimental Section for details).[21] The most significant spectroscopic features are (a) the IR spectrum of **5a** shows the ν(CO) absorption at 1920 cm$^{-1}$, (b) the $^{31}P\{^1H\}$ spectra of **5a** and **5b** show the resonance of the chelate-ring phosphorus atom at $\delta$ = 101.3 (singlet) and 91.8 ppm (doublet, $^2J_{P,P}$ = 33.7 Hz), respectively, and (c) the $^{13}C\{^1H\}$ NMR spectra show a high-field signal for the Ru–$CH_2$ carbon ($\delta$ = –4.1 ppm for **5a**; $\delta$ = –0.7 ppm for **5b**) and two signals for the olefinic carbons of **5a** ($\delta$ = 116.4 and 146.0 ppm; $^2J_{C,P}$ = 14.4 Hz) and **5b** ($\delta$ = 115.3 and 147.0 ppm; $^2J_{C,P}$ = 13.6 Hz). Moreover, the analogous complexes [Ru(η$^5$-$C_9H_7$)(L)($Ph_2PCH_2CH$=$CH_2$-κ$^3$*P,C,C*)][X] [L = CO, X = $SbF_6$ (**3a**); L = $PPh_3$, X = $PF_6$[11]] do not suffer deprotonation and are recovered unaltered after treatment with KO*t*Bu or $Cs_2CO_3$ under similar reaction conditions.

### *π-Olefin Exchange Reactions: Synthesis of the Complex [Ru(η$^5$-$C_9H_7$)(CO)(MeCN)($Ph_2PCH_2CH$=$CH_2$-κ*P*)]-[$SbF_6$] (6)*

The complex **3a** reacts with acetonitrile to generate the complex [Ru(η$^5$-$C_9H_7$)(CO)(MeCN)($Ph_2PCH_2CH$=$CH_2$-κ*P*)][$SbF_6$] (**6**), which was isolated as a yellow solid in 91% yield (Scheme 5).



Scheme 5.

Complex **6** was characterized analytically and spectroscopically (see Experimental Section for details). In particular, its IR spectrum shows a strong ν(CO) absorption at 1977 cm$^{-1}$, a broad singlet resonance is observed at $\delta$ = 2.2 ppm for the methyl group of the acetonitrile ligand in the $^1H$ NMR spectrum, a singlet signal appears in the $^{31}P\{^1H\}$ NMR spectrum at $\delta$ = 46.9 ppm, which is in the typical range for monodentate coordination of the phosphane and in agreement with the value found for complex **1a** ($\delta$ = 45.0 ppm), and the $^{13}C\{^1H\}$ NMR spectrum shows a singlet signal at $\delta$ = 3.7 ppm for the methyl group of the acetonitrile and a low-field doublet signal at $\delta$ = 200.2 ppm ($^2J_{C,P}$ = 18.9 Hz) for the CO ligand.

This result agrees with that reported recently for the derivative [Ru(η$^5$-$C_9H_7$)($PPh_3$)($Ph_2PCH_2CH$=$CH_2$-κ$^3$*P,C,C*)]-[$PF_6$], which reacts with acetonitrile to generate a $Ph_2CH_2CH$=$CH_2$-κ*P* complex, thus emphasizing the hemilabile character of the allylphosphane.[11,14] However, all attempts to open the $Ph_2PCH_2CH_2CH$=$CH_2$-κ$^3$*P,C,C* chelate ring of derivatives **3b** and **4b** by treatment with acetonitrile were unsuccessful, probably due to the higher stability of the six-membered ring.

### *Reaction of [RuCl(η$^5$-$C_9H_7$)($PPh_3$)($Ph_2PC$≡$CPh$-κ*P*)] (2c) with Alkynes: Synthesis of Vinylidene [Ru(η$^5$-$C_9H_7$)-($PPh_3$)($Ph_2PC$≡$CPh$-κ*P*){C=C(Ph)H}][$PF_6$] (7) and Allenylidene [Ru(η$^5$-$C_9H_7$)($PPh_3$)($Ph_2PC$≡$CPh$-κ*P*)-(C=C=$CPh_2$)][$PF_6$] (8) Derivatives*

Complex **2c** reacts with terminal alkynes to give cumulenylidene complexes. Thus, the reaction of **2c** with PhC≡CH or $Ph_2C$(OH)C≡CH in the presence of $NaPF_6$ in refluxing ethanol leads to the expected vinylidene [Ru(η$^5$-

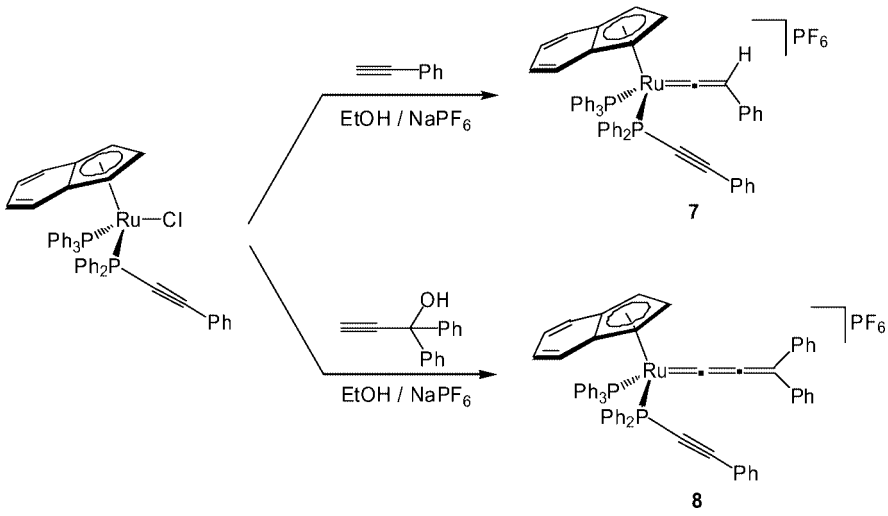

Scheme 6.

$C_9H_7$)($PPh_3$)($Ph_2PC{\equiv}CPh$-κ*P*){C=C(Ph)H}] (**7**; 82% yield) and allenylidene complexes [Ru(η$^5$-$C_9H_7$)($PPh_3$)($Ph_2P$-C≡CPh-κ*P*)(C=C=$CPh_2$)] (**8**; 76% yield) as orange and purple solids, respectively (Scheme 6).

Complexes **7** and **8** are soluble in $CH_2Cl_2$ and THF and insoluble in diethyl ether and hexane. Both complexes were characterized analytically and spectroscopically (see Experimental Section for details). In particular, some data should be noted: (a) the IR spectra show the ν(C≡C) absorption at 2171 (**7**) and 2169 cm$^{-1}$ (**8**) and the ν(C=C=C) absorption at 1931 cm$^{-1}$; (b) the $^{31}P\{^1H\}$ NMR spectra show two doublets at $\delta$ = 20.6 and 41.7 ppm ($^2J_{P,P}$ = 27.2 Hz) for complex **7** and $\delta$ = 26.0 and 48.3 ppm ($^2J_{P,P}$ = 28.7 Hz) for complex **8**; (c) the $^{13}C\{^1H\}$ NMR spectra show two signals for the alkynyl carbons at $\delta$ = 112.9 and 81.6 (**7**) and 111.3 and 81.7 ppm (**8**). A low-field pseudotriplet signal ($^2J_{C,P}$ = 18.5–16.4 Hz) is observed for the $C_\alpha$ nuclei of the cumulenic group at $\delta$ = 355.4 (**7**) and 293.2 ppm (**8**).

## Conclusions

In summary, the present work describes the synthesis of a series of chiral-at-ruthenium indenyl complexes containing alkynyl- and alkenylphosphane ligands. In the case of alkenylphosphane complexes both κ*P* and κ$^3$*P*,*C*,*C* coordination modes have been shown to occur. In complexes with κ$^3$*P*,*C*,*C*-alkenylphosphane coordination, an effective chiral recognition of a prochiral allyl group has been achieved, the olefin being coordinated to the metal in a diastereoselective way.[22]

The X-ray structure analysis of representative derivatives showing the κ$^3$*P*,*C*,*C* coordination mode has been performed and their structure compared with that of the previously described allylphosphane complexes [Ru(η$^5$-$C_9H_7$)($PPh_3$){$Ph_2PCH_2CR{=}CH_2$-κ$^3$*P*,*C*,*C*}][$PF_6$] (R = H, Me).[11] Moreover, these complexes can be used as model systems to study the diastereoselective coordination found for the alkenylphosphane ligand in $Ph_2P(CH_2)_nCH{=}CH_2$-κ$^3$*P*,*C*,*C* complexes.

The reactivity of the alkenylphosphane ligand is highly dependent on the size of the chelate ring. Thus, the complex **3a**, which contains the allylphosphane ligand $Ph_2PCH_2CHCH_2$-κ$^3$*P*,*C*,*C*, undergo ring opening upon reaction with two-electron ligands, thus emphasizing the hemilabile character of the ligand, while complexes **3b** and **4b**, with the six-membered chelate ring $Ph_2PCH_2CH_2CHCH_2$-κ$^3$*P*,*C*,*C*, undergo no transformation in acetonitrile.

The alkynylphosphane complex **1c** is able to activate terminal alkynes, leading to the formation of vinylidene [Ru(η$^5$-$C_9H_7$)($PPh_3$)($Ph_2PC{\equiv}CPh$-κ*P*){C=C(Ph)H}][$PF_6$] (**7**) and allenylidene [Ru(η$^5$-$C_9H_7$)($PPh_3$)($Ph_2PC{\equiv}CPh$-κ*P*)(C=C=$CPh_2$)][$PF_6$] (**8**) derivatives.

## Experimental Section

**General:** All manipulations were performed under an atmosphere of dry nitrogen using vacuum-line and standard Schlenk techniques. All reagents were obtained from commercial suppliers and used without further purification. Solvents were dried by standard methods and distilled under nitrogen before use. The compounds [RuCl(η$^5$-$C_9H_7$)($PPh_3$)$_2$],[23] [RuI(η$^5$-$C_9H_7$)(CO)$_2$],[24] $Ph_2PCH_2$-$CH{=}CH_2$,[25] $Ph_2PCH_2CH_2CH{=}CH_2$,[26] and $Ph_2PC{\equiv}CPh$[27] were prepared by previously reported methods. Infrared spectra were recorded with a Perkin–Elmer 1720-XFT or a Perkin–Elmer 599 IR spectrometer. The C, H, and N analyses were carried out with a Perkin–Elmer 240-B microanalyzer. NMR spectra were recorded with Bruker AC 300 and 300 DPX instruments at 300 ($^1$H), 121.5 ($^{31}$P), or 75.4 MHz ($^{13}$C) or a Bruker AC 400 instrument at 400.1 ($^1$H), 161.9 ($^{31}$P), or 100.6 MHz ($^{13}$C) with $SiMe_4$ or 85% $H_3PO_4$ as standards. DEPT experiments were carried out for all the complexes. The following atom labels have been used for the $^1$H and $^{13}C\{^1H\}$ NMR spectroscopic data.

**Synthesis of [RuI($\eta^5$-$C_9H_7$)(CO)($Ph_2PR$-κ*P*)] [R = $CH_2CH{=}CH_2$ (1a), $CH_2CH_2CH{=}CH_2$ (1b), C≡CPh (1c)]:** Previously sublimed $Me_3NO$ (188 mg, 2.50 mmol) was added to a solution of [RuI($\eta^5$-$C_9H_7$)$(CO)_2$] (500 mg, 1.25 mmol) in $CH_2Cl_2$ (5 mL), and the mixture was stirred for 10 min at room temperature. After this time, the initial orange solution turned nearly black, and the complex [Ru($\eta^5$-$C_9H_7$)$(NMe_3)$(CO)] had formed (checked by IR spectroscopy in solution). The corresponding phosphane ligand was then added (1.5 mmol) and the reaction mixture stirred for 15–30 min. The resulting solution was evaporated to dryness and the residue extracted with toluene (2 × 20 mL) and vacuum-dried. The solid residue was then recrystallized from $CH_2Cl_2$/hexane and complexes **1a**–**c** were obtained as red solids.

**1a:** Time: 15 min. Yield: 596 mg (80%). IR (KBr): ν(CO) = 1940 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$, 18 °C): $\delta$ = 3.33 (m, 1 H, P–$CH_2$), 3.51 (m, 1 H, P–$CH_2$), 3.58 (s, 1 H, 1-H or 3-H), 4.92 (m, 2 H, =$CH_2$), 5.28 (m, 1 H, 2-H), 5.58 (m, 2 H, =CH, 1-H or 3-H), 7.29 (m, 14 H, 4,5,6,7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CDCl_3$, 18 °C): $\delta$ = 38.1 (d, $J_{C,P}$ = 30.3 Hz, P–$CH_2$), 70.4 (s, C-1 or C-3), 71.3 (d, $^2J_{C,P}$ = 7.1 Hz, C-1 or C-3), 89.4 (s, C-2), 110.5, 111.9 (s, C-3a, C-7a), 119.3 (d, $^2J_{C,P}$ = 11.1 Hz, =$CH_2$), 123.0–137.4 (=CH, C-4,5,6,7, Ar), 203.0 (d, $^2J_{C,P}$ = 21.2 Hz, CO) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 18 °C): $\delta$ = 45.0 ppm (s). $C_{25}H_{22}IOPRu$ (597.39): calcd. C 50.26, H 3.71; found C 51.38, H 3.95.

**1b:** Time: 30 min. Yield: 596 mg (78%). IR (KBr): ν(CO) = 1930 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$, 18 °C): $\delta$ = 1.85 (m, 1 H, $CH_2$), 2.07 (m, 1 H, $CH_2$), 2.52 (m, 1 H, P–$CH_2$), 2.74 (m, 1 H, P–$CH_2$), 4.57 (s, 1 H, 1-H, 2-H or 3-H), 4.91 (m, 2 H, =$CH_2$), 5.28 (s, 1 H, 1-H, 2-H or 3-H), 5.60 (s, 1 H, 1-H, 2-H or 3-H), 5.69 (m, 1 H, =CH), 6.69 (d, $J_{H,H}$ = 8.26 Hz, 1 H, 4-H, 5-H, 6-H, or 7-H), 6.86 (t, $J_{H,H}$ = 7.4 Hz, 1 H, 4-H, 5-H, 6-H, or 7-H), 7.14–7.63 (m, 12 H, 4-H, 5-H, 6-H, or 7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CDCl_3$, 18 °C): $\delta$ = 28.4 (s, $CH_2$), 32.1 (d, $J_{C,P}$ = 30.5 Hz, P–$CH_2$), 70.6 (s, C-1 or C-3), 72.0 (d, $^2J_{C,P}$ = 7.4 Hz, C-1 or C-3), 89.7 (s, C-2), 111.0, 112.3 (s, C-3a, C-7a), 114.8 (s, =$CH_2$), 123.2–137.5 (=CH, C-4,5,6,7, Ar), 203.5 (d, $^2J_{C,P}$ = 21.3 Hz, CO) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 18 °C): $\delta$ = 44.0 ppm (s). $C_{26}H_{24}IOPRu$ (611.42): calcd. C 51.08, H 3.96; found C 52.47, H 4.44.

**1c:** Time 30 min. Yield: 797 mg (97%). IR (KBr): ν(C≡C) = 2176, ν(CO) = 1940 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$, 18 °C): $\delta$ = 4.82 (br. s, 1 H, 1-H or 3-H), 5.57 (pseudo t, $J_{H,H}$ = 2.6 Hz, 1 H, 2-H), 5.79 (br. s, 1 H, 1-H or 3-H), 6.95–7.73 (m, 19 H, 4,5,6,7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CDCl_3$, 18 °C): $\delta$ = 71.0 (s, C-1 or C-3), 73.7 (d, $^2J_{C,P}$ = 9.9 Hz, C-1 or C-3), 84.1 (d, $J_{C,P}$ = 93.6 Hz, P–*C*≡C), 90.0 (s, C-2), 108.9 (d, $^2J_{C,P}$ = 14.4 Hz, P–C≡*C*), 111.0, 111.7 (s, C-3a, C-7a), 121.2–134.1 (C-4,5,6,7, Ar), 202.4 (d, $^2J_{C,P}$ = 20.7 Hz, CO) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 18 °C): $\delta$ = 22.5 ppm (s). $C_{30}H_{22}IOPRu$ (657.44): calcd. C 54.81, H 3.37; found C 53.26, H 2.90.

**Synthesis of [RuCl($\eta^5$-$C_9H_7$)($PPh_3$)($Ph_2PCH_2CH_2CH{=}CH_2$-κ*P*)] (2b):** A solution of [RuCl($\eta^5$-$C_9H_7$)$(PPh_3)_2$] (500 mg, 0.64 mmol) and homoallyldiphenylphosphane (168 mg, 0.70 mmol) in THF (40 mL) was refluxed for 20 min. It was then concentrated to about 10 mL and CuI (183 mg, 0.96 mmol) was added. After 30 min at room temperature, the solution was evaporated to dryness and the residue extracted with diethyl ether (2 × 20 mL), vacuum-dried, and recrystallized from diethyl ether/hexane (1:10) to obtain complex **2b** as a red solid. Yield: 290 mg (60%). $^1H$ NMR (300 MHz, $CDCl_3$, 18 °C): $\delta$ = 0.81 (m, 1 H, $CH_2$), 0.97 (m, 1 H, $CH_2$), 1.50 (m, 1 H, $CH_2$), 2.56 (m, 1 H, $CH_2$), 4.67 (m, 4 H, 1-H, 3-H, =$CH_2$), 4.84 (t, $J_{H,H}$ = 2.0 Hz, 2-H), 5.33 (m, 1 H, =CH), 6.30 (d, $J_{H,H}$ = 8.2 Hz, 1 H, 4-H, 5-H, 6-H, or 7-H), 6.81–8.00 (m, 28 H, 4-H, 5-H, 6-H, or 7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CDCl_3$, 18 °C): $\delta$ = 20.3 (d, $J_{C,P}$ = 22.9 Hz, P–$CH_2$), 28.7 (d, $^2J_{C,P}$ = 8.3 Hz, $CH_2$), 61.6 (s, C-1 or C-3), 69.4 (d, $^2J_{C,P}$ = 11.4 Hz, C-1 or C-3), 90.6 (s, C-2), 109.8, 111.3 (s, C-3a, C-7a), 113.8 (s, =$CH_2$), 123.3–138.2 (=CH, C-4,5,6,7, Ar) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 18 °C): $\delta$ = 45.6 (d, $^2J_{P,P}$ = 42.9 Hz), 49.0 (d, $^2J_{P,P}$ = 42.9 Hz) ppm. $C_{43}H_{39}ClP_2Ru$ (754.24): calcd. C 68.47, H 5.21; found C 67.05, H 4.30.

**Synthesis of [RuCl($\eta^5$-$C_9H_7$)($PPh_3$)($Ph_2PC{\equiv}CPh$-κ*P*)] (2c):** A solution of [RuCl($\eta^5$-$C_9H_7$)$(PPh_3)_2$] (500 mg, 0.64 mmol) and phenylalkynyldiphenylphosphane (161 mg, 0.77 mmol) in THF (55 mL) was refluxed for 10 min. The solution was then evaporated to dryness and the solid residue extracted with diethyl ether (2 × 20 mL). The solution was concentrated under vacuum and the product precipitated as a red solid upon addition of hexane; it was vacuum-dried. Yield: 307 mg (60%). IR (KBr): ν(C≡C) = 2168 $cm^{-1}$. $^1H$ NMR (300 MHz, $C_6D_6$, 18 °C): $\delta$ = 3.80, 4.29, 4.87 (s, 4 H, 1,2,3-H and 4-H, 5-H, 6-H, or 7-H), 6.84–7.87 (m, 33 H, 4-H, 5-H, 6-H, or 7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $C_6D_6$, 18 °C): $\delta$ = 66.6 (s, C-1 or C-3), 69.5 (d, $^2J_{C,P}$ = 9.5 Hz, C-1 or C-3), 87.2 (d, $J_{P,C}$ = 80.7 Hz, P–*C*≡C), 91.8 (s, C-2), 109.1, (d, $J_{C,P}$ = 11.5 Hz, P–C≡*C*), 110.5 (s, C-3a or C-7a), 111.8 (d, $^2J_{C,P}$ = 3.8 Hz, C-3a or C-7a), 122.5–134.7 (C-4,5,6,7, Ar) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $C_6D_6$, 18 °C): $\delta$ = 29.1 (d, $^2J_{P,P}$ = 45.0 Hz), 48.1 (d, $^2J_{P,P}$ = 45.0 Hz) ppm. $C_{47}H_{37}ClP_2Ru{\cdot}CH_2Cl_2$ (800.27): calcd. C 65.13, H 4.44; found C 66.41, H 4.04.

**Synthesis of [Ru($\eta^5$-$C_9H_7$)(CO)($Ph_2PR$-κ$^3$*P*,*C*,*C*)][$SbF_6$] [R = $CH_2CH{=}CH_2$ (3a), $CH_2CH_2CH{=}CH_2$ (3b)]:** A solution of the complex [RuCl($\eta^5$-$C_9H_7$)($Ph_2PR$-κ$^1$*P*)(CO)] [R = $CH_2CH{=}CH_2$ (**1a**), $CH_2CH_2CH{=}CH_2$ (**1b**)] (0.82 mmol) and $AgSbF_6$ (337 mg, 0.98 mmol) in $CH_2Cl_2$ (80 mL) was stirred for 1 h at room temperature in the absence of light. A change of color from red to yellow was observed. After this time, the suspension was exposed to light for 1 h, then filtered through kieselguhr and the solvents evaporated to dryness. The solid residue was recrystallized from $CH_2Cl_2$/hexane (1:10), washed with hexane (2 × 20 mL), and vacuum-dried.

**3a:** Yield: 562 mg (97%). IR (KBr): ν(CO) = 2012, ν($SbF_6$) = 658 $cm^{-1}$. Conductivity (acetone): 123 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (400.1 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 2.36 (m, 1 H, =$CH_2$), 2.82 (m, 1 H, P–$CH_2$), 3.47 (m, 1 H, =$CH_2$), 3.92 (m, 1 H, =CH), 4.43 (m, 1 H, P–$CH_2$), 5.47 (pseudo t, $J_{H,H}$ = 2.5 Hz, 1 H, 2-H), 5.85, 6.05 (s, 1 H each, 1-H, 3-H), 6.78 (d, $J_{H,H}$ = 8.6 Hz, 1 H, 4-H, 5-H, 6-H, or 7-H), 7.16–7.71 (m, 13 H, 4-H, 5-H, 6-H, or 7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (100.6 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 34.0 (d, $J_{C,P}$ = 38.2 Hz, P–$CH_2$), 55.1 (d, $J_{C,P}$ = 20.1 Hz, =CH), 57.0 (d, $J_{C,P}$ = 6.0 Hz, =$CH_2$), 73.8, 76.3 (s, C-1, C-3), 93.9 (s, C-2), 106.9, 108.9 (s, C-3a, C-7a), 122.6–134.7 (C-4,5,6,7, Ar), 202.0 (d, $^2J_{C,P}$ = 16.1 Hz, CO) ppm. $^{31}P\{^1H\}$ NMR (161.9 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = –56.4 ppm (s). $C_{25}H_{22}F_6OPRuSb$ (706.24): calcd. $CD_2Cl_2$, 18 °C): $\delta$ = 74.6 ppm (s). $C_{26}H_{24}F_6OPRuSb{\cdot}CH_2Cl_2$ (720.26): calcd. C 40.28, H 3.25; found C 40.18, H 2.78.

**Synthesis of [Ru(η⁵-C₉H₇)(PPh₃)(Ph₂PCH₂CH₂CH=CH₂-κ³*P*,*C*,*C*)][PF₆] (4b):** A solution of the complex [RuCl(η⁵-$C_9H_7$)($PPh_3$)($Ph_2PCH_2CH_2CH=CH_2$-κ*P*)] (500 mg, 0.66 mmol) and $NaPF_6$ (222 mg, 1.32 mmol) in EtOH (30 mL) was refluxed for 5 min. After this time, the solution was evaporated to dryness and the residue extracted with $CH_2Cl_2$ (2×20 mL). The solvent was then concentrated to about 2 mL and diethyl ether (20 mL) was added. The yellow solid obtained was washed with diethyl ether (2×10 mL) and vacuum-dried. Yield: 382 mg (67%). IR (KBr): ν($PF_6$) = 838 $cm^{-1}$. Conductivity (acetone): 97 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (300.1 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 1.78 (d, $J_{H,H}$ = 8.8 Hz, 1 H, =$CH_2$), 2.24 (m, 2 H, $CH_2$), 2.54 (m, 2 H, $CH_2$), 3.57 (m, 1 H, =$CH_2$), 5.10 (s, 1 H, 1-H, 2-H or 3-H), 5.30 (m, 1 H, =CH), 5.37 (s, 1 H, 1-H, 2-H or 3-H), 5.51 (s, 1 H, 1-H, 2-H or 3-H), 6.79–7.69 (m, 29 H, 4,5,6,7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 24.4 (d, $^2J_{C,P}$ = 6.7 Hz, P–$CH_2$), 40.0 (d, $J_{C,P}$ = 33.5 Hz, $CH_2$), 79.3 (s, C-1 or C-3), 82.1 (d, $^2J_{C,P}$ = 12.0 Hz, C-1 or C-3), 87.6 (s, C-2), 97.5, 103.6 (s, C-3a, C-7a), 107.4 (d, $J_{C,P}$ = 3.4 Hz, =$CH_2$), 122.5–133.6 (=CH, C-4,5,6,7, Ar) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 47.3 (d, $^2J_{P,P}$ = 29.5 Hz), 69.3 (d, $^2J_{P,P}$ = 29.5 Hz) ppm. MS (FAB+): *m*/*z* = 719 [$M^+$].

**Synthesis of [Ru(η⁵-C₉H₇)(L)(Ph₂PCH₂CH=CHCH₂-κ²*P*,*C*)] [L = CO (5a), PPh₃ (5b)]:** A solution of [Ru(η⁵-$C_9H_7$)(L)-($Ph_2PCH_2CH_2CH=CH_2$-κ³*P*,*C*,*C*)][X] [X = $SbF_6$, L = CO (**3b**); X = $PF_6$, L = $PPh_3$ (**4b**)] (0.14 mmol) and $Cs_2CO_3$ (228 mg, 0.7 mmol) in $CH_2Cl_2$ (20 mL) was stirred for 1 h at room temperature. After this time the solution was filtered through kieselguhr and the solvents evaporated to dryness. The solid residue was extracted with 20 mL of diethyl ether and precipitated with hexane. The yellow solid obtained was washed with hexane (2×10 mL) and vacuum-dried.

**5a:** Yield: 46 mg (86%). IR (KBr): ν(CO) = 1920 $cm^{-1}$. $^1H$ NMR (400.1 MHz, $C_6D_6$, 18 °C): $\delta$ = 2.19 (m, 1 H, Ru–$CH_2$) 2.35 (m, 1 H, Ru–$CH_2$), 2.69 (m, 2 H, P–$CH_2$), 4.82 (s, 1 H, 1-H or 3-H), 5.04 (s, 1 H, 2-H), 5.34 (s, 1 H, 1-H or 3-H), 5.51 (m, 1 H, =CH), 6.46 (d, $J_{H,H}$ = 8.1 Hz, 1 H, 4-H, 5-H, 6-H, or 7-H), 6.78 (m, 1 H, =CH), 6.97–7.27 (m, 13 H, 4-H, 5-H, 6-H, or 7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (100.6 MHz, $C_6D_6$, 18 °C): $\delta$ = –4.1 (d, $J_{C,P}$ = 8.8 Hz, Ru–$CH_2$), 26.8 (d, $J_{C,P}$ = 22.4 Hz, $CH_2$), 72.0 (d, $^2J_{C,P}$ = 7.2 Hz, C-1 or C-3), 74.3 (s, C-1 or C-3), 98.3 (s, C-2), 108.1 (s, C-3a, C-7a), 116.4 (s, =CH), 122.5–141.6 (C-4,5,6,7, Ar), 146.0 (d, $J_{C,P}$ = 14.4 Hz, =CH), 205.4 (d, $^2J_{C,P}$ = 16.8 Hz, CO) ppm. $^{31}P\{^1H\}$(162.0 MHz, $C_6D_6$, 18 °C): $\delta$ = 101.3 ppm (s). MS (FAB+): *m*/*z* = 485 [$M^+$ + 1].

**5b:** Yield: 80 mg (80%). $^1H$ NMR (400.1 MHz, $CD_2Cl_2$, –50 °C): $\delta$ = 0.79 (m, 1 H, Ru–$CH_2$), 1.62 (m, 1 H, P–$CH_2$), 2.43 (m, 1 H, Ru–$CH_2$), 3.30 (m, 1 H, P–$CH_2$), 3.99 (s, 1 H, 1-H or 3-H), 4.19 (s, 1 H, 1-H or 3-H), 5.15 (s, 1 H, 2-H), 5.51 (m, 1 H, =CH), 6.67 (m, 1 H, =CH), 6.92–7.66 (m, 29 H, 4,5,6,7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (100.6 MHz, $CD_2Cl_2$, –50 °C): $\delta$ = –0.7 (br. s, Ru–$CH_2$), 25.8 (d, $J_{C,P}$ = 20.4 Hz, P–$CH_2$), 71.1 (s, C-1 or C-3), 74.0 (d, $^2J_{C,P}$ = 5.4 Hz, C-1 or C-3), 93.5 (pseudo t, $^2J_{C,P}$ = 4.7 Hz, C-2), 103.8, 109.7 (s, C-3a, C-7a), 115.3 (s, =CH), 121.0–144.9 (C-4,5,6,7, Ar), 147.0 (d, $J_{C,P}$ = 13.6 Hz, =CH) ppm. $^{31}P\{^1H\}$ NMR (162.0 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 56.2 (d, $^2J_{P,P}$ = 33.7 Hz), 91.8 (d, $^2J_{P,P}$ = 33.7 Hz) ppm. MS (FAB+): *m*/*z* = 719 [$M^+$ + 1].

**Synthesis of [Ru(η⁵-C₉H₇)(MeCN)(CO)(Ph₂PCH₂CH=CH₂-κ*P*)]-[SbF₆] (6):** A solution of [Ru(η⁵-$C_9H_7$)(CO)($PPh_2CH_2CH=CH_2$-κ³*P*,*C*,*C*)][$SbF_6$] (500 mg, 0.7 mmol) in MeCN (100 mL) was stirred at room temperature for 2.5 h. The solution was then evaporated to dryness and the residue extracted with $CH_2Cl_2$ (2×20 mL). The solvent was then concentrated to about 2 mL and hexane (20 mL) was added. The yellow solid obtained was washed with hexane (2×10 mL) and vacuum-dried. Yield: 530 mg (91%). IR (KBr): ν(CO) = 1977, ν($SbF_6$) = 658 $cm^{-1}$. Conductivity (acetone): 123 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$, 18 °C): $\delta$ = 2.23 (br. s, 3 H, $CH_3$), 3.35 (m, 2 H, P–$CH_2$), 5.15 and 5.28 (2×m, 5 H, =$CH_2$ and 1,2,3-H), 5.48 (m, 1 H, =CH), 7.22–7.68 (m, 14 H, 4,5,6,7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CDCl_3$, 18 °C): $\delta$ = 3.7 (s, $CH_3$), 36.6 (d, $J_{C,P}$ = 30.2 Hz, P–$CH_2$), 65.8, 67.1 (s, C-1, C-3), 93.3 (s, C-2), 109.3, 112.9 (s, C-3a, C-7a), 121.4 (d, $J_{C,P}$ = 12.1 Hz, =$CH_2$), 123.5–132.3 (C-4,5,6,7, Ar), 200.2 (d, $^2J_{C,P}$ = 18.9 Hz, CO) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 18 °C): $\delta$ = 46.9 ppm (s). $C_{27}H_{25}F_6OPNRuSb$ (747.29): calcd. C 43.40, H 3.37, N 1.87; found C 42.48, H 3.67, N 1.90.

**Synthesis of [Ru(η⁵-C₉H₇)(PPh₃)(Ph₂PC≡CPh-κ*P*){=C=C(Ph)H}]-[PF₆] (7):** A solution of [RuCl(η⁵-$C_9H_7$)($PPh_3$)($Ph_2PC{\equiv}CPh$-κ*P*)] (50 mg, 0.07 mmol), $NaPF_6$ (23 mg, 0.14 mmol), and phenylacetylene (36 mg, 0.35 mmol) in EtOH (8 mL) was refluxed for 15 min. After this time the solution was evaporated to dryness and the residue was extracted with $CH_2Cl_2$ (2×10 mL). The solvent was then concentrated to about 2 mL and hexane (20 mL) was added. The orange solid obtained was washed with hexane (2×10 mL) and vacuum-dried. Yield: 58 mg (82%). IR (KBr): ν(C≡C) = 2171, ν($PF_6$) = 838 $cm^{-1}$. Conductivity (acetone): 96 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (300 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 5.30, 5.54, 5.74 (s, 1 H each, 1,2,3-H), 5.94 (d, $J_{H,H}$ = 8.3 Hz, 1 H, 4-H, 5-H, 6-H, or 7-H), 6.21 (s, 1 H, =CH), 6.37 (d, $J_{H,H}$ = 8.3 Hz, 1 H, 4-H, 5-H, 6-H, or 7-H), 6.78–7.58 (m, 37 H, 4-H, 5-H, 6-H, or 7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $(CD_3)_2CO$, 18 °C): $\delta$ = 81.6 (d, $J_{C,P}$ = 95.0 Hz, P–*C*≡C), 82.5 (s, C-1 and C-3), 100.6 (s, C-2), 112.9 (d, $^2J_{C,P}$ = 12.3 Hz, P–C≡*C*), 115.1 (s, C-3a or C-7a), 117.2 (s, $C_\beta$), 120.9 (d, $J_{C,P}$ = 2.6 Hz, C-3a or C-7a), 123.9–135.2 (Ar), 355.4 (pseudo t, $^2J_{C,P}$ = 16.4, $C_\alpha$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 20.6 (d, $^2J_{P,P}$ = 27.2 Hz), 41.7 (d, $^2J_{P,P}$ = 27.2 Hz) ppm.

**Synthesis of [Ru(η⁵-C₉H₇)(PPh₃)(Ph₂PC≡CPh-κ*P*)(=C=C=CPh₂)]-[PF₆] (8):** A solution of [RuCl(η⁵-$C_9H_7$)($PPh_3$)($Ph_2PC{\equiv}$CPh-κ*P*)] (50 mg, 0.07 mmol), $NaPF_6$ (23 mg, 0.14 mmol), and 1,1-diphenylprop-2-yn-1-ol (72 mg, 0.35 mmol) in EtOH (8 mL) was refluxed for 20 min. After this time the solution was evaporated to dryness and the residue was extracted with $CH_2Cl_2$ (2×10 mL). The solution was concentrated under vacuum and the product precipitated and washed with hexane (2×10 mL). The violet solid obtained was vacuum-dried. Yield: 59 mg (76%). IR (KBr): ν(C≡C) = 2169, ν(C=C=C) = 1931, ν($PF_6$) = 837 $cm^{-1}$. Conductivity (acetone): 133 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$, 18 °C): $\delta$ = 5.24, 5.66, 5.72 (s, 3 H, 1,2,3-H), 6.22 (d, $J_{H,H}$ = 8.0 Hz, 1 H, 4-H, 5-H, 6-H, or 7-H), 6.88–7.84 (m, 43 H, 4-H, 5-H, 6-H, or 7-H, Ar) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CD_2Cl_2$, 18 °C): $\delta$ = 80.8 (d, $J_{C,P}$ = 5.8 Hz, C-1 or C-3), 81.7 (dd, $J_{C,P}$ = 92.5, $^3J_{C,P}$ = 3.5 Hz, P–*C*≡C), 82.6 (d, $J_{C,P}$ = 7.0 Hz, C-1 or C-3), 98.4 (s, C-2), 111.3 (d, $^2J_{C,P}$ = 10.4 Hz, P–C≡*C*), 113.5 (s, C-3a or C-7a), 119.5 (d, $^2J_{C,P}$ = 2.3 Hz, C-3a or C-7a), 122.6–142.8 (Ar), 158.5 (s, $C_\gamma$), 204.9 (s, $C_\beta$), 293.2 (pseudo t, $^2J_{C,P}$ = 18.5 Hz, $C_\alpha$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 18 °C): $\delta$ = 26.0 (d, $^2J_{P,P}$ = 28.7 Hz), 48.3 (d, $^2J_{P,P}$ = 28.7 Hz) ppm.

**X-ray Crystal Structure Determination of Complexes 1c, 3a, and 4b:** Crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of hexane (**1c**) or pentane (**3a** and **4b**) into a saturated solution of the complexes in dichloromethane. The most relevant crystal and refinement data are collected in Table 2. Diffraction data for **1c** were recorded with a Bruker Smart 6k CCD area-

[a] $R_1 = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}$½.

detector three-circle diffractometer (Cu-$K_\alpha$ radiation, λ = 1.5418 Å). The data were collected using 0.3°-wide $\omega$ scans with a crystal-to-detector distance of 40 mm. The diffraction frames were integrated using the SAINT package[28] and corrected for absorption with SADABS.[29] For **3a** diffraction data were recorded with a Nonius Kappa CCD single crystal diffractometer using Cu-$K_\alpha$ radiation (λ = 1.5418 Å) − the crystal-to-detector distance was fixed at 29 mm − and using the oscillation method, with 2° oscillation and 40 s exposure time per frame. The data collection strategy was calculated with the program Collect.[30] Data reduction and cell refinement were performed using the programs HKL Denzo and Scalepack[31] and absorption correction was applied by means of SORTAV.[32] Data for **4b** were collected on a Bruker Smart CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation (λ = 0.71073 Å). The data were collected using 0.3°-wide $\omega$ scans with a crystal-to-detector distance of 40 mm. The diffraction frames were integrated using the SAINT package[28] and corrected for absorption with SADABS.[29]

The software package WINGX was used for space group determination, structure solution, and refinement.[33] The structures were solved by Patterson interpretation and phase expansion using DIRDIF.[34] Isotropic least-squares refinement on $F^2$ using SHELXL97 was performed.[35] For all the complexes, during the final stages all non-hydrogen atoms were refined with anisotropic displacement parameters and the H atoms were geometrically located and their coordinates were refined riding on their parent atoms. The maximum residual electron density is located near to heavy atoms (Ru, I) for **1c** and near to the disordered $PF_6^-$ ions for **3a**.

The function minimized was $[\Sigma w(F_o^2 - F_c^2)/\Sigma w(F_o^2)]^{1/2}$ where $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ ($a$ = 0.0512 and $b$ = 0 for **1c**, $a$ = 0.0899 and $b$ = 0 for **3a**, $a$ = 0.0228 and $b$ = 0 for **4b**) with $\sigma(F_o^2)$ from counting statistics and $P = [\mathrm{Max}(F_o^2,0) + 2F_c^2]/3$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[36] Geometrical calculations were made with PARST.[37] The crystallographic plots were made with PLATON.[38] CCDC-276224 (**1c**), -276225 (**3a**), and -276226 (**4b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The Bromination of Bulky Trialkylphosphane Selenides $R_2R'PSe$ (R, R′ = *i*Pr or *t*Bu) Studied by Physical and Computational Methods

Cristian G. Hrib,[a] Frank Ruthe,[a] Emma Seppälä,[a] Michael Bätcher,[a] Christian Druckenbrodt,[a] Cathleen Wismach,[a] Peter G. Jones,[a] Wolf-W. du Mont,*[a] Vito Lippolis,[b] Francesco A. Devillanova,[b] and Michael Bühl[c]

**Keywords:** Phosphane selenide dibromides / Heteronuclear NMR / Raman spectroscopy / X-ray structures / Bromine exchange / Ab initio calculations

Bulky trialkylphosphane selenides *t*$Bu_3$PSe (**1a**), *i*$Pr_3$PSe (**1b**), *t*$Bu_2$(*i*Pr)PSe (**1c**) and *t*Bu(*i*$Pr)_2$PSe (**1d**) react with one equiv. of bromine providing "T-shaped" products $R_2R'P–SeBr_2$ (**2a–d**), which contain three-coordinate selenium atoms (10-Se-3). The solid compounds **2b** (bimorphic), **2c** and **2d** exhibit different extents of distortions of the $PSeBr_2$ moieties and different patterns of intermolecular soft–soft interactions. In mixtures containing **1** and **2**, exemplified by the "NMR-titration" of **1c** with molecular bromine, averaged $^{31}P$ NMR singlets and their $^{77}Se$ satellites indicate rapid intermolecular bromine exchange reactions (kinetic lability of the Se–Br bonds). Calculations modelling such bromine transfer support nucleophilic attack of $R_3PSe$ (Se → Br) on an electrophilic Br atom of $R_3PSeBr_2$. Among the phosphane selenides **1a–d**, *t*Bu(*i*$Pr)_2$PSe (**1d**) gives the largest $^{77}Se$ NMR upfield shift and *t*$Bu_2$(*i*Pr)PSe (**1c**) the lowest, that is, $^{77}Se$ NMR shifts do not correlate with increasing numbers of *tert*-butyl groups. GIAO-HF/962+(d) calculations on the $^{77}Se$ NMR shifts of compounds **1** allow correlation of surprising relative deshielding of **1c**, compared with **1b** and **1d**, with its particular population of rotamers (excluding a rotamer with *anti* arrangement of the SePCH moiety in **1c**). Bromine addition to compounds **1** leads to line broadening and extreme deshielding in the $^{77}Se$ NMR spectroscopy. Reaction of **2b** with bromine leads – inter alia – to P–Se cleavage with *P*-bromination. The structures of **1b**, **2b–d** and *t*$Bu_2$(*i*Pr)$PBr_2$ (**3c**) were determined by X-ray crystallography. In compounds **2b–d**, intramolecular C–H···Br interactions determine the conformation to a large extent.

## Introduction

Phosphane chalcogenides $R_2R'P=Y$ (Y = S, Se) are known to act as donors towards dihalogen molecules.[1–4] From phosphane selenides, which are stronger donors than the sulfides, a considerable number of 1:1 adducts $R_2R'PSeX_2$ have been isolated.[5–8] *Molecular* structures have recently been determined for $R_2R'PSeI_2$ (type **A**, [10-I-2], R, R′ = $C_6H_5$, $NMe_2$, $NEt_2$,[6] and R = *t*Bu, R′ = I)[7] and for $R_3PSeBr_2$ (type **B**, [10-Se-3] R, R′ = $NMe_2$, $C_6H_{11}$).[8] Ionic structures of solid 1:1 adducts of phosphane selenides with iodine involve $(R_3PSe)_2I^+$ cations with $I_3^-$ (type **C**, [10-I-2]),[5,9,10] whereas $R_3PSeI^+$ cations (type **D**) are formed as polyiodide salts (Scheme 1).[3,9,11]

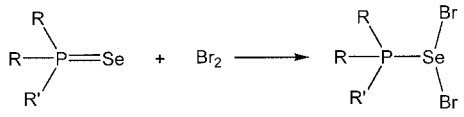
Averaged $^1$H-, $^{13}$C- and $^{31}$P-solution NMR singlet signals (including their $^{77}$Se satellite doublets) and spectra, however, suggest that equilibrium mixtures of several species are present in solutions of such 1:1 adducts.[5,7,9] Until now, no reports on $^{77}$Se NMR spectra of phosphane selenide halogen adducts have appeared in the literature. It was observed that addition of a few percent of iodine to a phosphane selenide solution leads to extreme broadening of the $^{77}$Se NMR doublet signal and after further addition of iodine, the $^{77}$Se NMR signal is no longer resolvable. In the context of the present discussion on theoretical descriptions of the addition of halogens and interhalogens to P=Se or C=Se bonds, it would be desirable to study hypervalent selenium products and their dynamics in solution by $^{77}$Se NMR spectroscopy. The present study was undertaken to follow for the first time the course of stepwise bromination of three related bulky trialkylphosphane selenides in solution by $^{31}$P and $^{77}$Se NMR spectroscopy and to elucidate the role of steric effects that might determine the nature of the products. In the case of phosphane selenide–iodine reactions, slight variations of the substituents attached to phosphorus determined – in an surprising way – the nature of the 1:1 adducts (*molecular* vs. *ionic*)[5,8,9] and the particular supramolecular structures of polyiodide salts from $[R_2R'PSeI]^+$ cations.[9,11]

## Reactions

### Formation of "1:1 Adducts"

Adding $Br_2$ in titration-like fashion to solutions of phosphane selenides $R_2R'P{=}Se$ (**1a**: R, R′ = *t*Bu; **1b**: R, R′ = *i*Pr; **1c**: R = *t*Bu, R′ = *i*Pr; **1d**: R = *i*Pr, R′ = *t*Bu) in dichloromethane leads to only one averaged $^{31}$P NMR signal, with a pair of $^{77}$Se satellites, in all $^{31}$P NMR spectra of such solutions. The magnitude of $^1J(^{77}Se,^{31}P)$ decreases with increasing amounts of $Br_2$; in $CD_2Cl_2$ the magnitudes of $^1J(^{77}Se,^{31}P)$ are smaller than in comparable $C_6D_6$ solutions. $^{77}$Se NMR resonances of bromination products cannot be resolved as easily as those of the parent phosphane selenides. Adding less than 5% $Br_2$ to the solution of any of the trialkylphosphane selenides **1** leads to severe broadening of the $^{77}$Se NMR doublet signal, which is shifted slightly to a lower field compared with pure **1**. With larger amounts of $Br_2$ the $^{77}$Se NMR signal becomes too broad to be resolved. $CD_2Cl_2$ solutions of pure $iPr_3PSeBr_2$ (**2b**) and $tBu(iPr)_2PSeBr_2$ (**2d**), however, allow resolution of $^{77}$Se NMR doublet signals, and $tBu_2iPrPSeBr_2$ (**2c**) gives a single broad $^{77}$Se resonance (all about 900–1000 ppm downfield from the parent phosphane selenides) (Table 1). These observations suggest kinetic lability of $R_3PSe/Br_2$ systems, involving exchange reactions that are *fast* at the $^1$H, $^{13}$C and $^{31}$P NMR timescales (and *medium* at the $^{77}$Se NMR timescale). Crystallisation of products from **1** with $Br_2$ provides solids $R_2R'PSeBr_2$ (**2a**–**d**). In each of these compounds, bromine has been oxidatively added to selenium, which becomes "hypervalent" (structure type **B**, 10-Se-3) (vide infra).



**1a**: R, R' = *t*Bu; **1b**: R, R' = *i*Pr; **1c**: R = *t*Bu, R' = *i*Pr; **1d**: R = *i*Pr, R' = *t*Bu **2a–d**

### Reactions with Excess Bromine

Addition of another equivalent of molecular bromine to the dibromides **2b** and **2c** led to their complete consumption in favour of unselective formation of new species. $^{31}$P NMR spectra of such a reaction mixture recorded immediately after addition of $Br_2$ to solutions of **2b** allowed the detection of a singlet ($\delta^{31}P$ = 72.7 ppm) with satellites exhibiting a coupling constant $^1J(^{77}Se,^{31}P)$ of ±499 Hz (5% smaller than that of **2b**). Isolating crystals from such a solution led, however, to a second polymorph of compound **2b**, and to crystals that apparently contain $iPr_3PBr^+$ cations, accompanied by severely disordered cationic P–Se species, and by bromoselenato(IV) anions ($SeBr_6^{2-}$ and $Se_2Br_9^-$). The $CH_2Cl_2$ solution from these crystals gives a $^{31}$P NMR signal ($\delta$ = 71 ppm) with $^1J(^{77}Se,^{31}P)$ = ±506 Hz, accompanied by the singlet signal of $iPr_3PBr^+$ ($\delta$ = 113.9, no $^{77}$Se satellites).[12,13] As reference compounds for the bromination products, $iPr_3PBr_2$ (**3b**)[12,13] and $tBu_2(iPr)PBr_2$ (**3c**) were prepared and characterised. Solid **3c** consists of ion pairs with weak Br···Br interactions. An attempt to generate the $iPr_3PSeBr^+$ cation from **2b** by bromide abstraction with $HgBr_2$ in $CH_2Cl_2$ solution led after two days to a mixture of products ($\delta^{31}$P 75 [very broad, $W_{1/2}$ about 85 Hz], $\delta^{31}$P = 80.0 [satellite doublet $J$ = ±430 Hz], 94.2 and 113.8). From this solution a single crystal of $[iPr_3PSe_3PiPr_3]^{2+}$ $[Hg_2Br_6]^{2-}$ (**4**) was obtained.[13b]

Table 1. Addition of bromine to **1b** and to **1c** followed by NMR (*J* values are in italics).

| Solution ($CD_2Cl_2$) | $\delta^{31}$P [ppm] $^1J(^{77}Se,^{31}P)$ [Hz] | | $\delta^{77}$Se [ppm] $^1J(^{77}Se,^{31}P)$ [Hz] | |
|---|---|---|---|---|

## $^{31}P$ and $^{77}Se$ NMR Spectra

Trialkylphosphane selenides ($R_3P$=Se) exhibit increasing $^{31}P$ downfield shifts with increasing α-branching of the alkyl groups to a lesser extent than do their parent trialkylphosphanes ($R_3P$) (Table 2).[15b] As expected, the $^{31}P$ signal of the mixed-substituted compounds $t$Bu$_2$($i$Pr)PSe (**1c**) [$\delta^{31}P$ = 79.2 and $t$Bu($i$Pr)$_2$PSe (**1d**) ($\delta$ = 85.8 ppm)] appears downfield from **1b** ($\delta$ = 72.2 ppm) but upfield from **1a** ($\delta$ = 94.7 ppm). Compared with their parent phosphanes $R_2R'P$, the $^{31}P$ resonances of phosphane selenides **1a**–**d** appear 30–50 ppm downfield, but the bromine addition products $R_2R'PSeBr_2$ (**2a**–**d**) appear slightly upfield from their respective selenides **1**. *Stepwise* addition of bromine to **1a**–**d** does not lead to new $^{31}P$ NMR signals of reaction products; the singlet signals are only shifted slightly upfield towards those of pure **2a**–**d**.

More indicative of the reaction course of phosphane selenides with electrophiles are coupling constants $^1J(^{77}Se,^{31}P)$, which are determined from satellite doublets in the $^{31}P$ NMR spectra. The magnitudes of $^{77}Se,^{31}P$ coupling constants of **1a**–**c** are comparable to those of $Me_3P$=Se or $Et_3P$=Se.[14,15b] These couplings are solvent-dependent, being about 2–3% smaller in polar solvents (e.g. acetonitrile, dichloromethane) than in benzene.[16,17]

With increasing amounts of added bromine, the $^1J$ values decrease continuously from about 700 ± 15 Hz (in the starting materials) to about 525 Hz in the 1:1 products with bromine.

In the $^{77}Se$ NMR spectra (Table 3), a straightforward correlation (like that of $\delta^{31}P$) between chemical shifts of $R_3P$=Se and increasing α-branching of the alkyl groups in **1a**–**d** does not exist. From comparison of $Me_3P$=Se ($\delta^{77}Se$ = –235[14]) via $Et_3P$=Se ($\delta^{77}Se$ = –428[15b]) to $i$Pr$_3$P=Se (**1b**, $\delta^{77}Se$ = –484[15b]), upfield shifts may be correlated with increasing α-branching. However, exchanging two $i$Pr groups of **1b** for two $t$Bu groups (in **1c**) does not lead to a further monotonic increase of $\delta^{77}Se$ (see Table 1). A comparable unexpected $^{125}Te$ NMR deshielding of $t$Bu$_3$P=Te,[15a] compared with $i$Pr$_3$P=Te, has already been recognised,[15b,16] but a conclusive explanation has not yet been given; as in the above $R_3P$=Se series, the $^{125}Te$ resonance of $t$Bu($i$Pr)$_2$P=Te appears further upfield than that of $i$Pr$_3$P=Te, whereas the $^{125}Te$ signals of the following members of the series ($t$Bu$_2$-$i$PrP=Te and $t$Bu$_3$P=Te) appear at significantly lower fields.[18]

### Calculations of $^{77}Se$ NMR Shifts

For a deeper understanding of the unexpected variation of magnitudes of $\delta^{77}Se$ and of $\delta^{125}Te$ in these sterically crowded phosphane chalcogenides, we carried out GIAO-HF/962+(d) ab initio calculations on various conformers of the known symmetric phosphane selenides **1a** and **1b** and of the new mixed-substituted compounds **1c** and **1d**.[19–22]

Qualitatively, the experimentally observed range of $^{77}Se$ NMR shieldings (**1c** < **1a** << **1b** < **1d**) reflects fairly well the calculated shift values of their energetically most favourable rotamers (**1cA** < **1a** << **1bA** < **1dA**) (Scheme 2). The range is similar (**1c**, **a** << **1b**, **d**) when the $^{77}Se$ NMR shifts are averaged according to a Boltzmann

Table 2. $^{31}P$ NMR shifts [ppm] and coupling constants $^1J$ ($^{77}Se,^{31}P$) [Hz] ($J$ values are in italics) of phosphane selenides $R_2R'PSe$ (R, R′ = $i$Pr or $t$Bu) **1a**–**d** and of phosphane selenide dibromides **2a**–**d**.

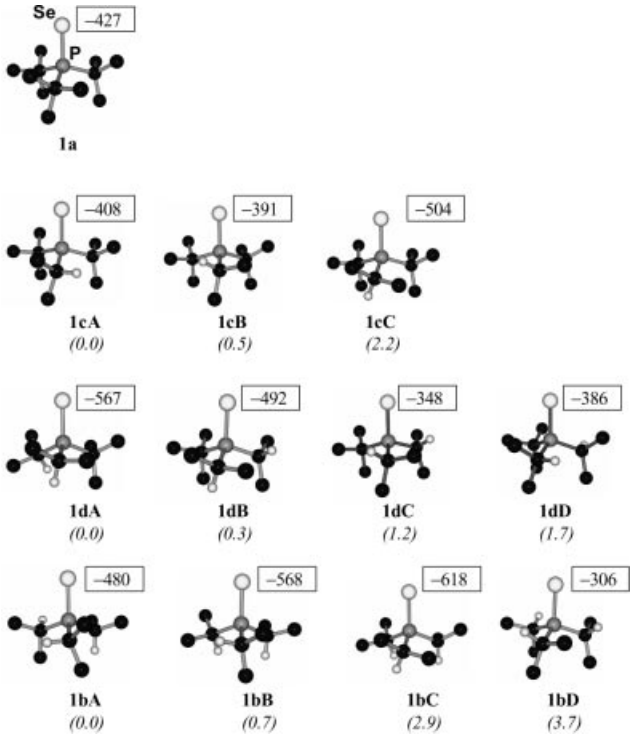
distribution of the respective rotamers at 298 K (**1c**: –403, **1a**: –427, **1b**: –519, **1d**: –500). Compound **1c**, showing the "abnormally deshielded" $^{77}$Se signal (compared with naive expectations from linear interpolation between **1a** and **1b**) is apparently the only compound among the isopropyl derivatives in which no rotamer with *anti* arrangement of the SePCH moiety (which would be **1cC**) contributes to the rotamer-population averaged $^{77}$Se NMR shift. Our theoretically determined energies and shifts may still involve significant inaccuracies because of the approximate nature of the methods used.[21,22] Nevertheless, the good qualitative accord between the current computational and experimental results is encouraging. In addition, the MP2/962(d) relative stabilities of rotamers of **1c** correlate fairly well with those calculated previously by an empirical force field (MM2) on the parent phosphane $t$Bu$_2i$PrP.[22] It was confirmed by NMR studies on $t$Bu$_2i$PrP and its Rh$^{I}$ and Ir$^{I}$ complexes that the preferred "GA conformation" (*gauche*/*anti* $CH_3$ groups, corresponding to **1cA/1cB**)[23] of $t$Bu$_2i$PrP is essentially retained in its metal complexes.[24,25] Another interesting result from the calculated $^{77}$Se NMR shifts is the observation that the shieldings relative to **1a** increase with increasing number of *anti* hydrogen atoms (*anti* arrangement of the SePCH moieties [**1cC** < **1dB** < **1bC**]) and decrease with increasing number of *gauche* hydrogen atoms (**1cA** > **1dC** > **1bD**) in the isopropylphosphorus groups. Direct evidence on these questions can be expected from structure determinations (vide infra) combined with forthcoming solid state $^{77}$Se NMR studies.



Scheme 2. Optimised rotamer structures of **1a**–**1d** (in italics: MP2-based relative energies [kcal/mol]; in boxes: GIAO-HF computed $^{77}$Se chemical shifts).

## Structure Determinations

### Phosphane Selenide Structures

The molecular structure of $t$Bu$_3$PSe (**1a**) has been determined recently,[26] but the structures of $i$Pr$_3$PSe (**1b**) and of the mixed substituted compounds **1c** and **1d** were not yet known. Differently from **1a**, which displays crystallographic $C_3$ symmetry implying twisted *tert*-butyl groups,[26] both crystallographically independent molecules of solid **1b** exhibit $C_s$ symmetry (Figure 1). Se,P and the C–H bond of one of the isopropyl groups lie within the mirror plane, and the H–C–P–Se moiety is in a *trans* arrangement. This structure is related to that of the telluride $i$Pr$_3$PTe.[15b] The fact that only one of the C–H bonds of the three isopropyl groups is in a *transoid* arrangement with respect to the PSe bond, and the two other groups display *gauche* type conformations, is in agreement with the calculated *lowest-energy* gas phase structures (**1bA** and **1bB**), but the symmetric orientation of the two twisted isopropyl groups with respect to the mirror plane is not in agreement with calculation. The increase of "1,3 dimethyl strain", also shown by the short contacts H(2A)···H(2A′) 224, H(3C)···H(3C′) 215, H(7A)···H(7A′) 220, H(8C)···H(8C′) 217 pm between the two symmetry-equivalent isopropyl groups in solid **1b**, is reflected by the expanded angle C(1)P(1)C(1′) 112° and C(6)P(1)C(6′) 113° compared with C(1)P(1)C(4) 105° and C(6)P(2)C(9) 105°. The P–C and C–C distances, however, are apparently not affected by this distortion. The related cell constants of **1b** and $i$Pr$_3$PTe (7.630, 11.856, 13.750 Å, $\beta$ = 100.29°) would suggest some similarity of packing. Figure 2 (a and b) shows the packing projected down the shortest axis in each case. Within the horizontal rows of molecules, the heights are however different; for **1b**, consecutive molecules lie at about 0, ¼, ½, ¼, 0… and for $i$Pr$_3$PTe at 0, ½, 0, ½… (in both cases for the upper row within the cell). One short methine C–H···Se interaction is observed for **1b**, namely H9···Se1 294 pm (within the asymmetric unit).

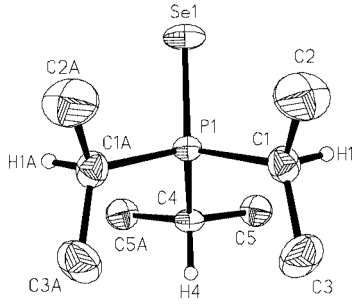


Figure 1. Structure of **1b**, molecule 1 (molecule 2 is very similar), selected bond lengths [pm] and angles [°]: P(1)–Se(1) 212.44(9), C(1)#1–P(1)–C(1) 112.20(15), C(1)#1–P(1)–C(4) 105.56(9), C(1)–P(1)–C(4) 105.56(9). Carbon atoms numbered 6–10 (see text) refer to molecule 2.

Single crystals of suitable quality for structure determinations have not yet been obtained from the mixed-substituted phosphane selenides **1c** and **1d**. A crystalline sample of $t$Bu($i$Pr)$_2$PSe (**1d**) was investigated, but poor crystal qual-

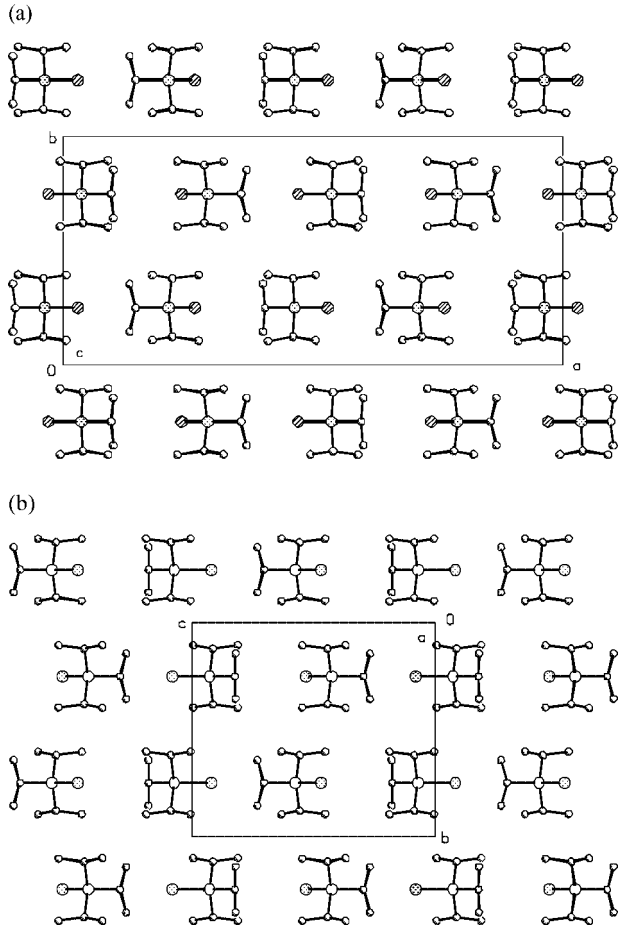

Figure 2. (a) Packing diagram in projection of $i$Pr$_3$PSe (**1b**). (b) Packing diagram in projection of $i$Pr$_3$PTe.

ity precluded a satisfactory refinement. The data indicate qualitatively that one of the isopropyl groups adopts a conformation with a *transoid* H–C–P–Se arrangement (as in calcd. structures **1dA**, **1dB**).

The crystalline bromophosphonium salt $t$Bu$_2$($i$Pr)-PBr$^+$Br$^-$ (**3c**) contains a cation that is isoelectronic with **1c**.

Within the asymmetric unit are two independent cation–anion pairs $t\mathrm{Bu}_2(i\mathrm{Pr})\mathrm{PBr}^+$ $\mathrm{Br}^-$ (Figure 3). Both pairs display approximately linear P–Br···Br moieties (175.5 ± 1°) with weak ($n \rightarrow \sigma^*$) Br···Br interactions (336.8 and 342.3 pm). Br(1)···Br(2) is roughly parallel to the *c* and Br(3)···Br(4) to the *a* axis. Within both $t\mathrm{Bu}_2(i\mathrm{Pr})\mathrm{PBr}^+$ cations, the H–C–P–Br moiety involving the C–H bond of the isopropyl group is in a *gauche* conformation, as predicted for selenide **1c** (calcd. structures **1cA**, **1cB**) and for the parent phosphane and its Rh and Ir complexes.[24,25] The ion pairs $t\mathrm{Bu}_2(i\mathrm{Pr})\mathrm{PBr}^+$ $\mathrm{Br}^-$ exhibit *inter*molecular C–H···Br contacts involving the bromide ions. Considering only contacts H···Br < 300 pm, Br(2) exhibits three and Br(4) four contacts, of which the shortest by far involve the methine protons [C(1)–H(1)···Br(2) 277 pm; C(12)–H(12)···Br(4) 273 pm]. Packing diagrams of the individual formula units (Figure 4, a and b) show that they occupy different regions of the cell at $y \approx 0$ and $y \approx ½$ respectively.

### Phosphane Selenide Dibromides

The discussion in the sequence **2b**, **2d**, **2c** follows the increasing steric strain with an increasing number of *tert*-butyl groups in the molecules.

From $i\mathrm{Pr}_3\mathrm{PSeBr}_2$ (**2b**), two different crystalline phases were isolated. The intended preparation of **2b** led by recrystallisation of the crude product from dichloromethane/pentane (vapour diffusion method) to monoclinic crystals ($P2_1/n$, $Z = 4$; **2b**#1). Bromination of **1b** with an excess of bromine led to a mixture of products from which two types of single crystals were collected by crystallisation from dichloromethane: about 50% of a complex material that is apparently $[(i\mathrm{Pr}_3\mathrm{PSeH}^+)_2(i\mathrm{Pr}_3\mathrm{PSeBr}^+)(\mathrm{SeBr}_6^{2-})(\mathrm{Se}_2\mathrm{Br}_9)^-]$ (partially disordered),[13b] and a few single crystals of **2b**#2 (monoclinic, $P2_1/n$, $Z = 8$).

All molecules in both phases of **2b** contain $i\mathrm{Pr}_3\mathrm{P}$ coordinated to the central selenium atoms of approximately linear BrSeBr groups ("10-Se-3" according to the J. C. Martin count).[10] The T structures around Se are distorted by unequal Se–Br bond lengths and by PSeBr angles that are larger than 90° (in the opposite sense to the distortion of the "classic" $\mathrm{ClF}_3$ structure). The latter distortion, as in previously known $\mathrm{R}_3\mathrm{PSeBr}_2$ structures, is attributed to steric repulsion between the $\mathrm{PR}_3$ substituent and the bromine atoms.

In the monomeric molecule **2b**#1 (Figure 5, a and b) the BrSeBr group differs from linearity by nearly 13° (angles PSeBr 95.5 and 96.8°) and from Se–Br equidistance by about 12 pm (252.52 and 264.35 pm). The PSe bond length is extended from 212.2 pm (**1b**) to 226.8 pm, which is very similar to that of known $\mathrm{R}_3\mathrm{PSeBr}_2$ structures.[8] The conformation of the $i\mathrm{Pr}_3\mathrm{PSe}$ group differs from that of solid *free* **1b** by lacking the formal mirror plane, but the mirror symmetry is maintained to a good approximation (r.m.s. deviation of molecular halves: 0.08 Å). One of the isopropyl groups adopts a conformation with a *transoid* H–C(1)–P–Se arrangement (as in the calculated structure **1bA**); the other two are twisted, leading to *gauche* type H–C–P–Se conformations. The orientation of the P–C(1) bond is orthogonal to the BrSeBr vector; the approximate mirror symmetry is also shown by the torsion angles [Br(1)SePC(7) –28.46(7)° and Br(2)SePC(4) 29.90(8)°]. As in solid **1b**, CPC angles involving the C atom of the *transoid* HCPSe moiety are significantly smaller (107.8, 108.7°) than that of the two other isopropyl groups [C(4)PC(7) 114.7°]. An explanation for this phenomena is the C–H···Br intramolecular interactions (see below; Figure 6, a). Three short H···Br (296–305 pm) and one short H···Se (3.02 Å) from H(1) link the molecules to form layers parallel to the *ac* plane.

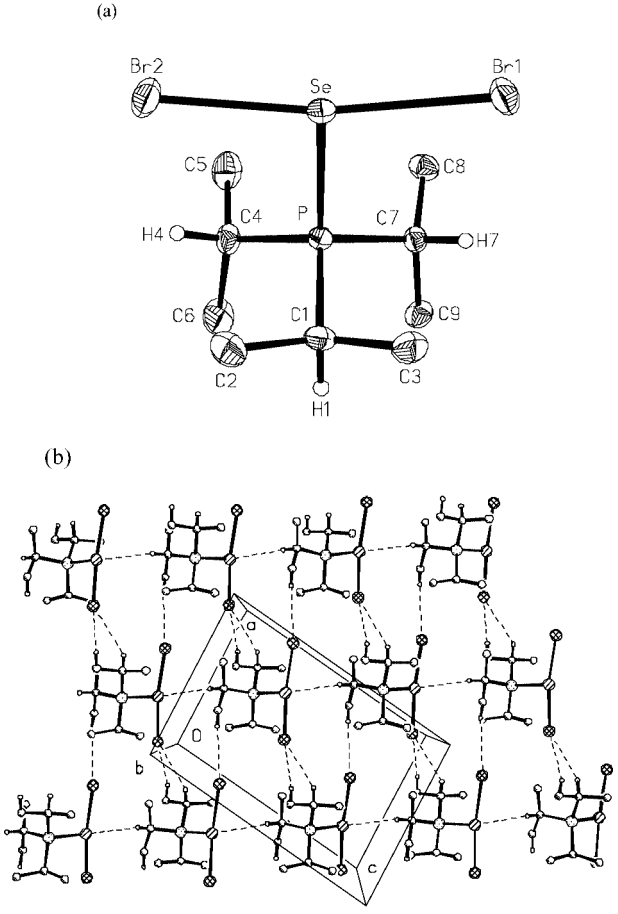

Figure 5. (a) Structure of **2b**#1, $Z = 4$, selected bond lengths [pm] and angles [°]: P–Se 226.81(5), Se–Br(1) 264.35(3), Se–Br(2) 252.52(3), P–Se–Br(1) 96.734(16), P–Se–Br(2) 95.485(16), Br(1)–Se–Br(2) 167.209(11), C(1)–P–C(7) 107.77(10), C(1)–P–C(4) 108.66(10), C(7)–P–C(4) 114.73(10). (b) Intermolecular interactions (CH···Se and CH···Br) in the packing diagram of **2b**#1.

Molecule **2b**#2 (Figure 7, a and b) involves two crystallographically independent molecules that are similar to each other (r.m.s. deviation 0.14 Å) and again display approximate mirror symmetry. The $\mathrm{SeBr}_2$ moieties are more regular than in **2b**#1, with Se···Br 257.56, 260.18 and 254.23, 260.55 pm. In contrast to **2b**#1, which has no significant short contacts of the type Se···Br and Br···Br, there are two such contacts in **2b**#2; Se(1)···Br(3) 346.23(8) within the

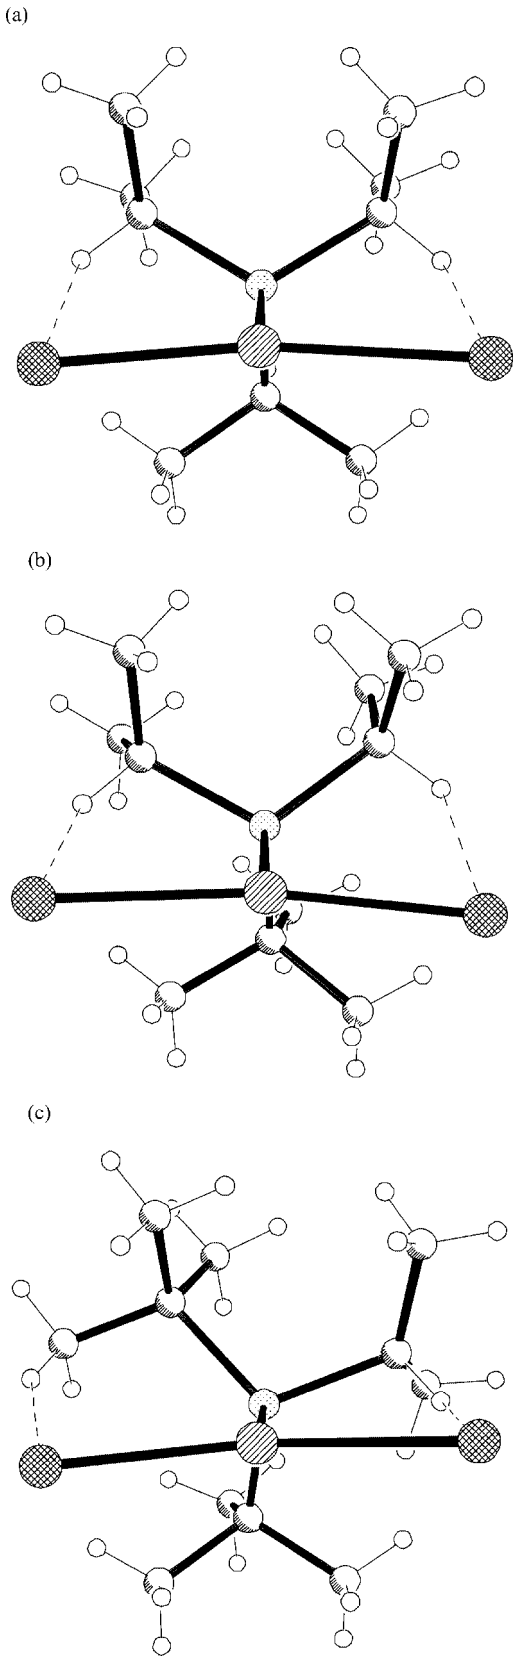

Figure 6. (a) Structure of $i$Pr$_3$PSeBr$_2$, **2b**#1, $Z$ = 4; H···Br intramolecular interactions: H(4)···Br(2) 272, H(7)···Br(1) 280 pm. (b) Structure of $t$Bu($i$Pr)$_2$PSeBr$_2$ (**2d**); H···Br intramolecular interactions: H(5)···Br(1) 299, H(8)···Br(2) 267 pm. (c) Structure of $t$Bu$_2$($i$Pr)PSeBr$_2$ (**2c**); H···Br intramolecular interactions: H(1)···Br(1) 262, H(9C)···Br(2) 271 pm.

asymmetric unit and Br(4)···Br(4′) 361.22(15) pm. The packing also involves the contact H(1)···Se(2) 303 pm and eight H···Br contacts under 315 pm. The net effect is to form layers parallel to 101.

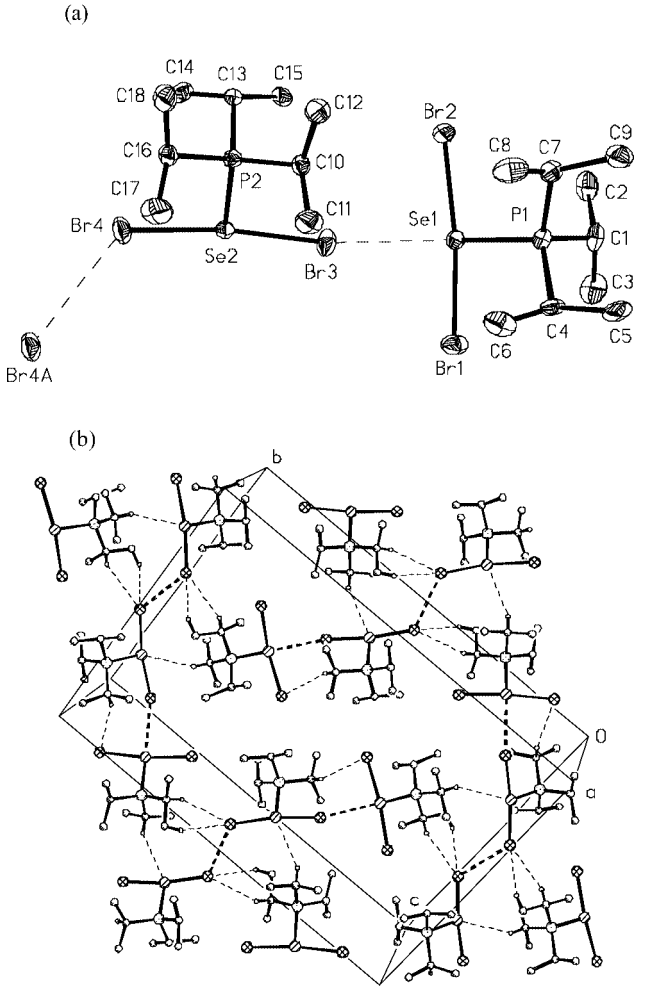

Figure 7. (a) Structure of **2b**#2, $Z$ = 8, selected bond lengths [pm] and angles [°]: P(1)–Se(1) 227.34(14), Se(1)–Br(1) 257.56(9), Se(1)–Br(2) 260.18(9), P(1)–Se(1)–Br(1) 94.36(4), P(1)–Se(1)–Br(2) 95.49(4), Br(1)–Se(1)–Br(2) 169.18(3), P(2)–Se(2) 227.15(14), Se(2)–Br(3) 260.55(9), Se(2)–Br(4) 254.23(9), P(2)–Se(2)–Br(3) 96.59(5), P(2)–Se(2)–Br(4) 95.10(5), Br(3)–Se(2)–Br(4) 168.19(3), C(4)–P(1)–C(1) 108.6(3), C(4)–P(1)–C(7) 113.2(2), C(1)–P(1)–C(7) 107.1(3), C(13)–P(2)–C(10) 109.1(3), C(13)–P(2)–C(16) 107.5(3), C(10)–P(2)–C(16) 114.8(2). (b) Intermolecular contacts involving the two types of molecules of **2b**#2.

Formal exchange of one isopropyl group by one *tert*-butyl group in **2b** affords **2d**. Compound **2d** crystallises as centrosymmetric Se–Br···Se-bridged dimers. Two T-shaped PSeBr$_2$ groups associate so that the bridging Br atom of one molecule exhibits contacts to the Se atom (382 pm) and to the bridging Br atom (388 pm) of the neighbouring molecule (Figure 8, a and b). The shorter Se–Br bond is involved in these intermolecular interactions (253.64, cf. 264.95 pm). Compound **2d** deviates significantly from mirror symmetry

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[e.g. torsion angles C(5)–P–Se–Br(1) –36.9, C(8)–P–Se–Br(2) 24.3°]. The conformation of the $t$Bu($i$Pr)$_2$PSe group within **2d** differs from that calculated for **2d** in the gas phase. The additional methyl group in **2d** formally replaces the H atom that was part of the *trans*-H–C–P–Se moiety of **2b**; that is, both remaining isopropyl group methine protons are part of *synclinal* H–C–P–Se conformations [H(5)C(5)PSe, $\Theta$ = 73.3°; H(8)C(8)PSe, $\Theta$ = –49°] (Figure 6, b). Compared with **2b**, the additional methyl group at C(1) [*transoid* C(4)–C(1)–P–Se] enhances the 1,3-dimethyl strain towards C(6) and C(9) of the isopropyl groups leading to approximately equal CPC bond angles (110.6, 111.24, 112.9°), compared with 105/112° in **1b** and 108/115 in **2b**#1. In case of **1d**, such a conformation is expected to be about 1.2 kcal above ground state (**1dC** in Scheme 2). Compounds **2d** and **2b**#1 are not isostructural, despite the similarity of cell constants; **2d** displays four H···Br contacts <315 pm but no H···Se contacts.

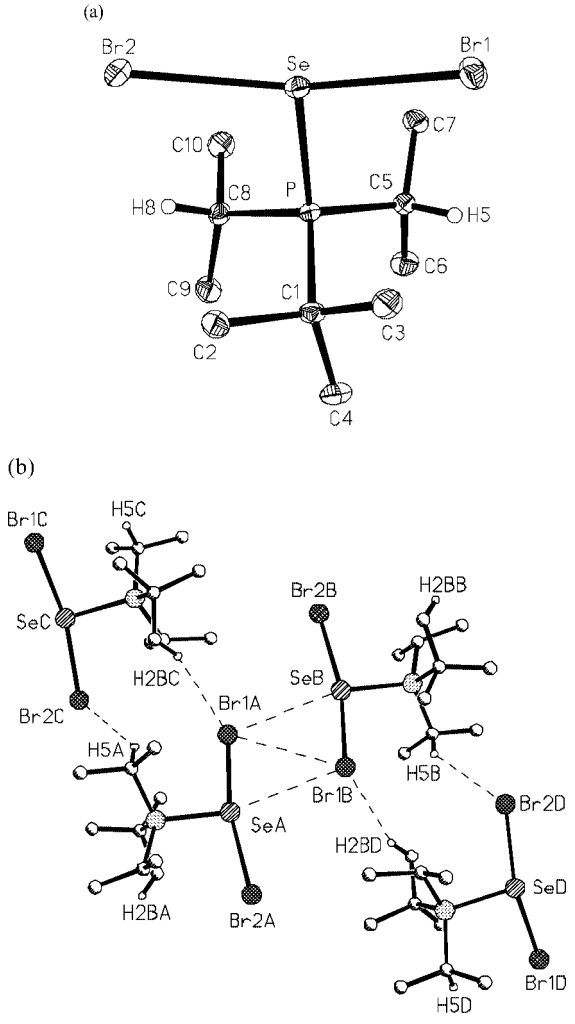

Figure 8. (a) Structure of **2d**, selected bond lengths [pm] and angles [°]: P–Se 228.67(4), Se–Br(1) 253.64(3), Se–Br(2) 264.95(3), P–Se–Br(1) 95.032(12), P–Se–Br(2) 97.462(12), Br(1)–Se–Br(2) 167.104(9), C(8)–P–C(5) 112.93(7), C(8)–P–C(1) 110.60(7), C(5)–P–C(1) 111.24(7). (b) Intermolecular interactions in the packing diagram of **2d**, selected contact distances [pm]: H(5)–Br(2) 305.3, H(2)–Br(1) 298.2, Se–Br(1) 381.68(3), Br(1)–Br(1) 388.02(4).

The structure of $t$Bu$_2$($i$Pr)PSeBr$_2$ is imprecisely determined for reasons given in the experimental section; the heavy atoms correspond closely to crystallographic mirror (pseudo)symmetry, but the light atoms do not (Figure 9, a). The reason is clearly the intramolecular hydrogen bond H(1)···Br(1) of 262 pm, cf. H(9C)···Br(2) 271 pm, from a methyl hydrogen of a butyl group (Figure 6, c). This leads to torsion angles [°] H(1)–C(1)–P–Se 42, C(1)–P–Se–Br(1) –15.8, cf. C(8)–P–Se–Br(2) 49.2; the bromine Br(1) is thus approximately synperiplanar with the isopropyl carbon C(1). The *tert*-butyl carbon C(6) is antiperiplanar to the selenium, with C(6)–C(4)–P–Se 168.2°.

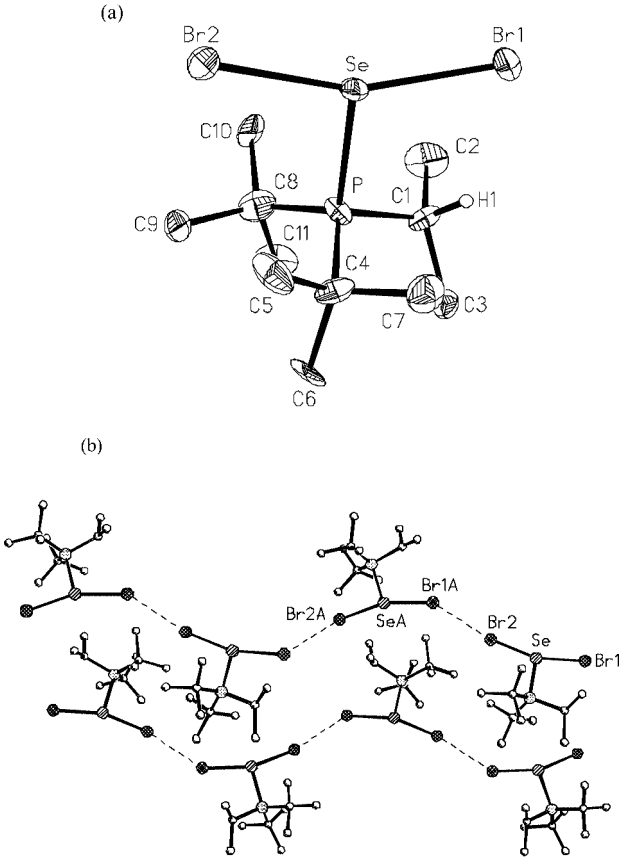

Figure 9. (a) Structure of **2c**, selected bond lengths [pm] and angles [°]: P–Se 230.39(19), Se–Br(1) 262.93(11), Se–Br(2) 255.49(11), P–Se–Br(1) 101.57(6), P–Se–Br(2) 99.22(6), Br(1)–Se–Br(2) 159.16(4), C(4)–P–C(1) 110.6(5), C(4)–P–C(8) 115.2(5), C(1)–P–C(8) 109.0(5). (b) Intermolecular interactions in the packing diagram of **2c**, array of molecules with Br···Br contacts, selected contact distances [pm]: Br(1)–Br(2) 358.90(11).

In view of inaccuracies associated with the pseudosymmetry, it would be unwise to regard light atom bond lengths and angles as reliable in detail. Among the heavy-atom dimensions, Se–Br(1) is appreciably longer than Se–Br(2) [262.93(11), 255.49(11) pm], but the angles BrSeP are almost equal [Br(2)–Se–P 99.22(6)°, Br(1)–Se–P 101.57(6)°], if rather wide.

The PSe bond is longer (230.39 pm) and the deviation of the BrSeBr group from linearity (BrSeBr 159.16°) larger

than in any other $R_3PSeBr_2$ structure. Intermolecular Br···Br contacts (358.90 pm) between T-shaped moieties of **2c** lead, as in solid $c$-Hex$_3$PSeBr$_2$,[8] to wave-like chains (Figure 9, b) that are packed into layers in the crystal. Additionally, the contact H(7b)···Se 302 pm and four H···Br contacts <315 pm lead to a complex three-dimensional packing.

The observation of the intramolecular C–H···Br interaction in **2c** prompted us to re-assess the other structures; in most cases, the isopropyl C–H groups, the most effective donors available, form a short intramolecular contact to the bromine. Compounds with two such donors thus tend to display exact or approximate mirror symmetry (Figure 6, a and b, Table 4). Hydrogen bonds of the type C–H···halogen have previously been adduced by us as conformation-determining factors.[27]

In summary, steric strain from *tert*-butyl groups correlates with increasing deviation from linearity of the Br–Se–Br groups and with increasing P–Se distances (Table 5). We do not observe, however, a straightforward correlation of intermolecular Se···Br and Br···Br interactions, steric effects and nonequidistance of Se–Br bonds in our series of related trialkylphosphane selenide dibromides. Intramolecular hydrogen bonds of the type C–H···Br determine, to a large extent, the local molecular symmetry.

## Bromine Exchange Reactions

The NMR phenomena in solutions containing selenides **1** together with the dibromides **2** can be explained by bromine exchange reactions (rapid on the $^{31}$P NMR timescale, however in coalescence on the $^{77}$Se timescale) that involve Se–Br bond breaking, but do not involve P–Se bond breaking, because $^1J(^{77}Se,^{31}P)$ can be observed at all times from the $^{31}$P NMR satellites.

Bromine exchange between selenium atoms has been observed in bromine adducts of bis(arylselanyl)benzenes,[28] but the kinetic lability (bromine exchange) of phosphane chalcogenide dibromides has apparently not yet been recognised in the literature. We suppose that the mode of halogen exchange will be related to that in phosphane–dihalogen equilibrium systems ($R_3PX_2/R_3P$; X = Br, I).[29] The latter involve nucleophilic attack at halogen atoms in α position ($R_3PX^+ \leftarrow PR_3$), whereas for the phosphane selenides the same should occur in β position ($R_3PSeX^+ \leftarrow SePR_3$) from the onium centres. As shown previously, $[R_3PSeISePR_3]^+$ cations can be stable species in such equilibria.[9] Cations $[R_3PSeBrSePR_3]^+$, however, have not yet been observed as ground state species.

Support for these interpretations is provided by computations for the model compound $Me_3PSe$ and its brominated derivatives. Both types of "1:1 adducts" with $Br_2$ are minima on the potential energy surface, namely the weak donor–acceptor complex **5A** and T-shaped **5B**, the oxidative addition product (Scheme 3). The latter is computed to be more stable than the former by 13.6 kcal/mol and is characterised by a $^{77}$Se resonance ($\delta_{calc}$ = 454) downfield from that of free $Me_3PSe$. The large stabilisation of **5B** over **5A** is consistent with the exclusive occurrence of type **B** adducts with $Br_2$ (see above). Heterolytical cleavage of **5A** or **5B** into $Me_3PSeBr^+$ (**6**) and $Br^-$ is highly unfavourable in the gas phase (109.3 and 123.2 kcal/mol, respectively), but may well be facilitated by polar solvents. The halogen transfer discussed above can proceed via complex **7A**. On the HF/641(d) potential energy surface (PES), **7A**, with its asymmetrical Se–Br···Se arrangement (distances 2.37 and 3.17 Å), is a shallow minimum, about 2 kcal/mol below the $C_{2h}$ symmetric transition state **7B** with equal Se···Br distances (2.65 Å). Inclusion of electron correlation effects by the MP2 single-point energies stabilises **7B**, to 8.7 kcal/mol below the apparent minimum **7A**. It is thus very likely that the symmetrical form is the actual minimum on the true PES (a notion which is supported by an MP2/962+(d) optimisation of **7A**, which afforded symmetrical **7B**); in any event, the proposed halogen transfer reaction by the sequence **7A** ⇌ **7B** ⇌ **7A′** (Scheme 3) is indicated to be a facile process.

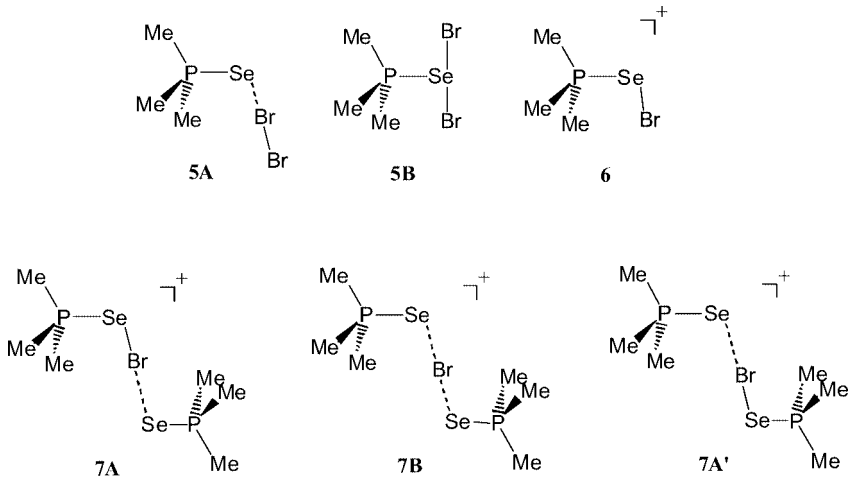

Scheme 3. Bromine transfer between $Me_3PSe$ molecules.

## Vibrational Spectra

It is well known that "T-shaped" adducts featuring a linear and symmetric Br–E–Br group (E = S, Se) show in their Raman spectra only one strong peak at around 160 $cm^{-1}$, because of the symmetric stretching vibration of the Br–E–Br system. A second lower peak at around 190 $cm^{-1}$, because of the antisymmetric vibration, appears when the Br–E–Br system is asymmetric.[30,31] This vibrational behaviour strictly resembles that observed for $[Br–X–Br]^-$ (X = I, Br) anions,[30,31] which are characterised by a very strong Raman peak at around 160 $cm^{-1}$ accompanied by a weaker one at 190 $cm^{-1}$ when these anions are slightly asymmetric. The FT-Raman spectra of **2b** and **2c** confirm the vibrational analogy between the aforementioned trihalides and the hypervalent Se adducts with $Br_2$. In fact, they are dominated by very strong peaks, at 169 and 163 $cm^{-1}$ for **2b** and **2c**, respectively, accompanied by weaker peaks at about 190 $cm^{-1}$, agreeing with the slight asymmetry of the Br–Se–Br groups observed for the two compounds by X-ray analysis. The Raman spectrum of **2d** also shows a peak at 163.9 $cm^{-1}$ accompanied by a weaker one at 190 $cm^{-1}$ with the difference that compared to **2b** and **2c** the intensity of the peak at 163.9 is much lower. In the FTIR spectra of **2b** and **2c** two broad bands at about the same frequencies of those observed in the Raman spectra are present with an increased intensity for the band because of the antisymmetric stretching of the Br–Se–Br group. For **2d**, the quality of the FTIR spectra does not provide any additional information.

The Raman spectrum of the ionic pair **3c** show a very weak peak at 180 $cm^{-1}$, which cannot be attributable to a Br–Br stretching vibration, the Br···Br distance being very long. Therefore, we think that this peak might be originated by vibration modes involving the P–Br bond and the remaining organic framework of the cation in the ionic pair.

## Discussion

GIAO-HF/962+(d) calculations on the $^{77}Se$ NMR shifts of related trialkylphosphane selenides **2a**–**d** allow an explanation of the differences between their $^{77}Se$ NMR shifts on the basis of particular conformations of their Se–P–C–H groups. The surprising $^{125}Te$ deshielding of $tBu_3PTe$ relative to $iPr_3PTe$[15] can be explained in a similar way.

All known phosphane selenide dibromides contain three-coordinate selenium in distorted T-shaped environments. Similar to related bromine adducts from precursors with C=Se bonds,[30] solid phosphane selenide dibromides tend to exhibit intermolecular Se···Br and/or Br···Br "*soft–soft interactions*". Small variations in the alkyl groups at phosphorus lead to large differences in the pattern of intermolecular contacts. In solution, phosphane selenide dibromides **2a**–**d** are kinetically labile with respect to reversible bromine transfer to their parent phosphane selenides (averaged $^1H$, $^{13}C$ and $^{31}P$ NMR signals, coalescing $^{77}Se$ signals in $R_3PSeBr_2/R_3PSe$ mixtures). Calculations show that nucleophilic attack of $R_3PSe$ at the Br atom of a $R_3PSeBr^+$ cation ($Br^+$ transfer) is a low-energy pathway for bromine exchange. $^{77}Se$ NMR signals of pure compounds $R_3PSeBr_2$ appear about 900–1000 ppm downfield from $R_3PSe$, and their $^1J(^{77}Se,^{31}P)$ coupling constants are 30% smaller than those of $R_3PSe$. Addition of electrophiles to dissolved compounds $R_3PSeBr_2$ led to a further decrease of $^1J(^{77}Se,^{31}P)$ to less than 500 Hz, but isolation of salts with $R_3PSeBr^+$ cations was not achieved.

## Experimental Section

**NMR Spectra:** NMR spectra were recorded using Bruker spectrometers AC 200, Avance 200, Avance 400 and AMX 300, with 85% $H_3PO_4$, $(CH_3)_2Se$ and $SiMe_4$ as external or internal standards. For the measurements of **1a**–**d** compounds we used 10% solution of $(CH_3)_2Se$ in $C_6D_6$ and $CD_2Cl_2$ as standards.

**FT-Raman Spectra:** FT-Raman spectra in the range 500–50 $cm^{-1}$ were recorded with a resolution of 2 $cm^{-1}$ on a Bruker RFS100 FT-Raman spectrometer, fitted with an In-Ga-As detector (room temperature) operating with a Nd-YAG laser (excitation wavelength 1064 nm; 100 mW), with a 180° scattering geometry. Infrared spectra were recorded with a Bruker IFS55 spectrometer at room temperature, purging the sample cell with a flow of dried air.

Polythene pellets with a mylar beam-splitter and polythene windows (500–50 $cm^{-1}$, resolution 2 $cm^{-1}$) were used.

**2a:** Bromine (330 mg, 2.1 mmol) was added slowly through a dropping funnel to a solution of $t$Bu$_3$PSe (**1b**) (590 mg, 2.1 mmol) in dichloromethane (10 mL) in a Schlenk tube. The red-orange solution was stirred for a further 2 h at room temperature, whereafter the crude product **2a** was isolated by vacuum evaporation of the solvent and purified by washing with pentane, drying by vacuum evaporation. Yield: approx. 89%; m.p. 92 °C; elemental analysis: $C_{12}H_{27}Br_2PSe$ (281.28): calcd. C 32.68, H 6.17; found C 30.62, H 5.94. MS (FAB, *o*-nitrobenzylamine matrix): *m*/*z*, pos. (%) = 57 [100, ($t$Bu)$^+$], 361 [78, ($t$Bu$_3$PSeBr)$^+$], 226 [17, ($t$Bu$_2$PSe)$^+$], 282 [33, ($t$Bu$_3$PSe)$^+$], 305 [31, ($t$Bu$_2$PSeBr)$^+$], 169 [28, ($t$BuPSe)$^+$], 89 [25, ($t$BuP)$^+$]; *m*/*z*, neg. (%) = 294 [100, {(NBA – NH$_2$) + SeBr}$^-$], 375 [85, {(NBA – NH$_2$) + SeBr$_2$}$^-$], 234 [36, (NBA + Br)$^-$], 79 [34, (Br)$^-$]; EI-MS: *m*/*z* (%) = 57 [100, ($t$Bu)$^+$], 170 [43, ($t$BuPSe)$^+$], 282 [17, ($t$Bu$_3$PSe)$^+$], 226 [17, ($t$Bu$_2$PSe)$^+$], 160 [10, (Br$_2$)$^+$], 111 [3, (PSe)$^+$]. $^{31}$P NMR (CH$_2$Cl$_2$/C$_6$D$_6$): $\delta$ = 83.0 (s, $^1J_{P,Se}$ = 514 Hz) ppm.

**2b:** Bromine (330 mg, 2.1 mmol) was added slowly through a dropping funnel to a solution of $i$Pr$_3$PSe (**1b**) (500 mg, 2.1 mmol) in dichloromethane (10 mL) in a Schlenk tube. The red-orange solution was stirred for a further 60 min at room temperature, whereafter the crude product **2b** was isolated by vacuum evaporation of the solvent and purified by washing with pentane, drying by vacuum evaporation and recrystallised by gas diffusion from dichloromethane/pentane. Yield: approx. 78%; m.p. 72 °C; elemental analysis: $C_9H_{21}Br_2PSe$ (239.20): calcd. C 27.09, H 5.30; found C 27.04, H 5.32. MS (FAB, *o*-nitrobenzylamine matrix): *m*/*z*, pos. (%) = 177 [100, ($i$Pr$_3$POH)$^+$], 319 [47, ($i$Pr$_3$PSeBr)$^+$], 353 [32, ($i$Pr$_3$PO)$_2$H$^+$], 240 [8, ($i$Pr$_3$PBr)$^+$]; *m*/*z*, neg. 7.0, $^3J_{H,P}$ = 15.4 Hz, CH(C$H_3$)$_2$] ppm. $^{13}$C NMR ($C_6D_6$): $\delta$ = 35.3 [d, $^1J_{C,P}$ = 34.3 Hz, *C*(CH$_3$)$_3$], 28.2 [d, $^2J_{C,P}$ = 0.9 Hz, C(*C*H$_3$)$_3$], 26.6 [d, $^1J_{C,P}$ = 36.3 Hz, *C*H(CH$_3$)$_2$], 19.5 [d, $^2J_{C,P}$ = 1.9 Hz, CH(*C*H$_3$)$_2$], $\delta$ = 18.8 [d, $^2J_{C,P}$ = 2.1 Hz, CH(*C*H$_3$)$_2$] ppm. $^{31}$P NMR ($C_6D_6$): $\delta$ = 79.9 (s, $^1J_{P,Se}$ = 712.7 Hz) ppm. $^{77}$Se NMR ($C_6D_6$): $\delta$ = –499.2 (d, $^1J_{Se,P}$ = 711.5 Hz) ppm.

**1d²**: $^1$H NMR ($CD_2Cl_2$): $\delta$ = 2.3 [m, $^3J_{H,H}$ = 7.0, $^2J_{H,P}$ = 9.1 Hz, C*H*(CH$_3$)$_2$], 1.22 [d,d, $^4J_{H,H}$ = 0.4, $^3J_{H,P}$ = 14.6 Hz, C(C$H_3$)$_3$], 1.21 [dd, $^3J_{H,H}$ = 6.9, $^3J_{H,P}$ = 15.9 Hz, CH(C$H_3$)$_2$], 1.19 [dd, $^3J_{H,H}$ = 7.0, $^3J_{H,P}$ = 15.5 Hz, CH(C$H_3$)$_2$] ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 35.5 [d, $^1J_{C,P}$ = 34.1 Hz, *C*(CH$_3$)$_3$], 28.2 [s, C(*C*H$_3$)$_3$], 26.7 [d, $^1J_{C,P}$ = 36.3 Hz, *C*H(CH$_3$)$_2$], 19.4 [d, $^2J_{C,P}$ = 2.0 Hz, CH(*C*H$_3$)$_2$], 18.4 [d, $^2J_{C,P}$ = 2.2 Hz, CH(*C*H$_3$)$_2$] ppm. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 79.5 (s, $^1J_{P,Se}$ = 695.8 Hz) ppm. $^{77}$Se NMR ($CD_2Cl_2$): $\delta$ = –493.2 (d, $^1J_{Se,P}$ = 694.8 Hz) ppm.

**Computational Details:** The same methods and basis sets as in two former computational studies on $^{77}$Se chemical shifts were employed.[19] Specifically, geometries were fully optimised at the restricted Hartree–Fock (HF) level employing the 641(d) basis set, that is, Binning and Curtiss' contracted [6s4p1d] basis on Se and Br,[19a] a contracted [2s] double-zeta Huzinaga basis on H (DZ),[20b] and standard 6-31G* basis on P and C.[20c,20d] All minima were characterised as such by computation of the harmonic vibrational frequencies. Single-point energy calculations for these geometries were performed at the electron-correlated second-order Møller–Plesset (MP2) level using the larger 962(d) basis, that is, a decontracted version of the 641(d) basis on Se and Br,[20a] DZ basis on H, Dunning's polarised ($\alpha_d$ = 0.75) [5s3p] basis on C,[20e] and McLean and Chandler's polarised ($\alpha_d$ = 0.465) [6s5p] basis on P.[20f] Relative energies are reported at the MP2/962(d)//HF/641(d) level (in the "level of energy evaluation // level of geometry optimisation" notation), corrected for the HF/641(d) zero-point energies (scaled by 0.9).

Magnetic shieldings were computed at the HF level with the Gauge-Including-Atomic-Orbitals (GIAO) method, as implemented[21] in the Gaussian 98 program,[22] employing the HF/641(d) geometries and 962+(d) basis, that is, the same as 962(d), but augmented with a set of diffuse s and p functions on Se ($\alpha_s$ = $\alpha_p$ = 0.022),[20a] which were shown to be beneficial in many cases.[19a] $\delta^{77}$Se chemical shifts are reported relative to $Me_2Se$, the experimental standard, for which an absolute shielding constant of 1905 ppm is obtained at the same level.

**X-ray Structure Determinations:** Numerical details are presented in Table 6. *Data collection and reduction*: Crystals were mounted in inert oil on glass fibres and transferred to the cold gas stream of the diffractometer (**1b**: Stoe STADI-4; **2b**#2, **2c**: Siemens P4; **2b**#1, **2d**, **3c**: Bruker SMART 1000 CCD). Measurements were performed with monochromated Mo-$K_\alpha$ radiation. Absorption corrections for the area detector were performed with the program SADABS, and for the serial diffractometers on the basis of $\psi$-scans. The crystal of **2c** decomposed appreciably even at low temperature and data were scaled accordingly. *Structure solution and refinement*: The structures were refined anisotropically against $F^2$ (program SHELXL-97, G.M. Sheldrick, University of Göttingen). H atoms were included with a riding model or as rigid methyl groups. *Special features of refinement*: Compound **2c** was refined as an enantiomeric twin, with Flack parameter 0.46(3); it is severely pseudosymmetric, with P, Se and Br atoms lying in a pseudomirror plane corresponding to the higher symmetry space group *Pnma*, but the alkyl groups clearly rotated out of the mirror-symmetric positions. Methyl hydrogens were placed in ideally staggered positions. Despite the use of distance restraints, the light atom bond lengths and angles were distorted and of limited reliability. CCDC-282196 (for **1b**), -282197 (for **2b**#1), -282198 (for **2b**#2), -282199 (for **2c**), -282200 (for **2d**) and -282201 (for **3c**) contain the supplementary crystallographic data for this paper. These data can

# Ferrocenylethynyltin Compounds – Characterization and Reactivity towards Triethylborane

**Bernd Wrackmeyer,*[a] Barbara H. Kenner-Hofmann,[a] Wolfgang Milius,[a] Peter Thoma,[a] Oleg L. Tok,[a] and Max Herberhold*[a]**

*Dedicated to Professor Henri Brunner on the occasion of his 70th birthday*

**Keywords:** Alkynes / Boranes / Ferrocenes / NMR spectroscopy / Tin

Ferrocenylethynyl(trimethyl)tin (**1**), bis(ferrocenylethynyl)dimethyltin (**2**), tetrakis(ferrocenylethynyl)tin (**3**), and chloro(ferrocenylethynyl)dimethyltin (**4**) have been prepared and characterized in solution by $^{1}H$, $^{13}C$, and $^{119}Sn$ NMR spectroscopy. Solid-state MAS $^{13}C$ and $^{119}Sn$ NMR spectra were measured for **2** and **3**, and the molecular structure of one of the modifications of **2** was determined by X-ray analysis. The reactivity of **1**–**4** towards triethylborane has been explored. 1,1-Organoboration takes place in all cases, and the reactions are stereoselective for **1** and **4** to give the alkenes **5** and **6**, respectively, in which the stannyl and the boryl groups are in *cis*-positions at the C=C bond. In the case of **2**, the final products are the 1-stannacyclopenta-2,4-diene **7a** and the 1-stanna-4-boracyclohexa-2,5-diene **8a**, whereas the reaction of **2** with triisopropylborane leads selectively to the six-membered ring **8b**. Zwitterionic intermediates **9a**,**b**, in which the tin atom is coordinated side-on to the C≡C bond of an alkynylborate, have been detected by NMR spectroscopy. Compound **3** reacts with triethylborane to give a mixture of three spirotin compounds **10**–**12** as the final products, where the tin atom connects five- and six-membered rings.

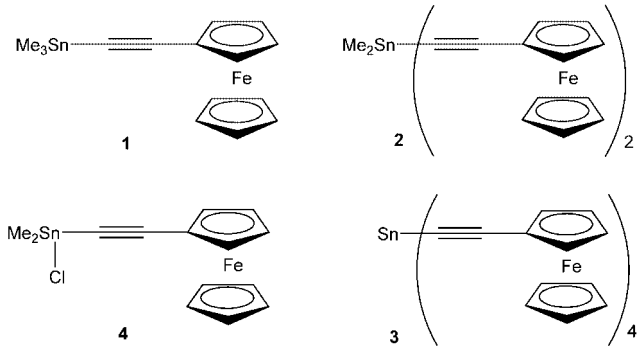
## Introduction

The synthetic potential of the C≡C bond in alkynes can be further enhanced by organometallic substituents.[1] This is well known for stannyl groups,[2] and the polar Sn–C≡ bonds in alkyn-1-yltin compounds are useful for various transformations. The reactivity of such alkyn-1-yltin compounds can be modified by the nature of other substituents at the tin atom and also by the second substituent at the C≡C bond, which may be hydrogen, an alkyl or aryl group, or another organometallic substituent. In the present work, we describe the synthesis and characterization of the ferrocenylethynyltin compounds **1**–**4** (Scheme 1) and report their reactivity towards triethylborane ($BEt_3$) and, in the case of **2**, triisopropylborane ($BiPr_3$).



Scheme 1. The ferrocenylethynyltin compounds studied.

## Results and Discussion

### Synthesis and NMR Spectroscopic Characterization of the Ferrocenylethynyltin Compounds

The most convenient synthesis of **1**–**3** starts from ethynylferrocene,[3] which is first converted into the alkynyllithium reagent and then treated with tin halides. (Scheme 2). Alternatively, the reaction of ethynylferrocene with the respective tin amides[4] [e.g. $Me_3SnNEt_2$, $Me_2Sn(NEt_2)_2$ and $Sn(NEt_2)_4$] can be used to obtain **1**–**3**. The reaction of **2** with one equivalent of dimethyltin dichloride at 110 °C in the presence of a small amount of toluene leads to **4**. A slight excess (10%) of $Me_2SnCl_2$ helps to convert **2** into **4** quantitatively. Compounds **1**–**4** are orange-red solids that are well soluble (**1**, **2**, **4**) or rather insoluble (**3**) in hydrocarbons. Single crystals of complex **2** suitable for X-ray structural analysis were isolated after recrystallization from hexane. The

[a] In $CD_2Cl_2$ at 296 K; coupling constants $J_{^{119}Sn,^{13}C} \pm 0.5$ Hz are given in brackets; isotope-induced chemical shifts $^n\Delta^{12/13}C(^{119}Sn) \pm 0.5$ ppb in braces with a negative sign for the shift of the more heavy isotopomer to lower frequency. [b] In $CDCl_3$ at 296 K. [c] Solid-state MAS $^{119}Sn$ NMR: $\delta_{^{119}Sn}$ = –144.0 (minor) and –150.5 ppm (major).

identity of the compounds **1**–**4** in solution follows from a consistent set of NMR parameters (Table 1). Even in the case of the sparingly soluble complex **3**, the $^{13}C$ NMR spectra could be recorded for determination of the $J_{^{117/119}Sn,^{13}C}$ coupling constants (Figure 1). The large magnitude of the $^nJ_{^{119}Sn,^{13}C}$ coupling constants is typical of tetraalkyn-1-yltin derivatives.[5,6] In the cases of **1** and **2**, the $^{119}Sn$ NMR spectra were recorded in order to measure isotope-induced chemical shifts $^n\Delta^{12/13}C(^{119}Sn)$ (Figure 2). Both the $^nJ_{^{119}Sn,^{13}C}$ coupling constants and isotope-induced chemical shifts $^n\Delta^{12/13}C(^{119}Sn)$ are observed in the expected ranges of the data previously determined for other alkyn-1-yltin compounds.[5–7] This indicates that the ferrocenyl group does not exert a special influence on the bonding situation in the Sn–C≡C–Fc fragment.

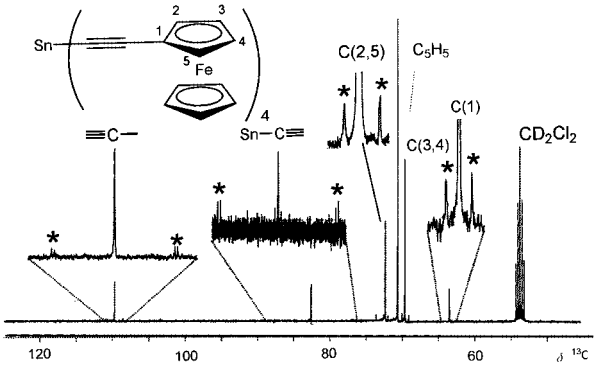

Figure 1. $^{13}C\{^1H\}$ NMR spectrum (100.5 MHz) of tetrakis(ferrocenylethynyl)tin (**3**; saturated solution in $CD_2Cl_2$) showing the $^{117/119}Sn$ satellites (marked by asterisks) for spin-spin coupling across one, two, three, and four bonds.

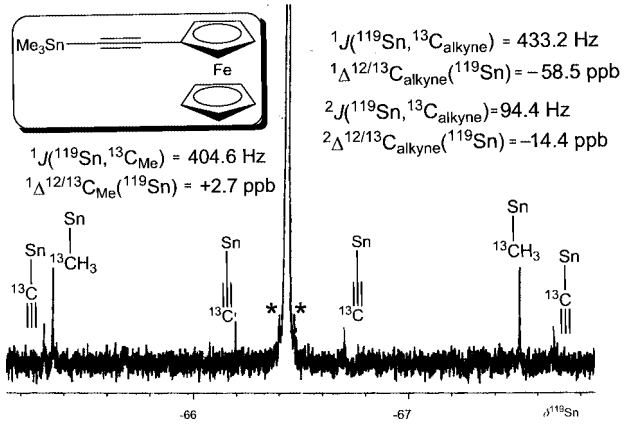

Figure 2. $^{119}Sn\{^1H\}$ NMR spectrum (refocused INEPT[25]; 186.5 MHz) of ferrocenylethynyl(trimethyl)tin (**1**; 5% in $CDCl_3$ at 296 K; acquisition time 5 s, repetition delay 2.5 s; 64 transients). The $^{13}C$ satellites are marked, and coupling constants and isotope-induced chemical shifts $\Delta^{12/13}C(^{119}Sn)$ are given. The $^{13}C$ satellites indicated by asterisks correspond to $^3J_{^{119}Sn,^{13}C_{Fc}}$ = 12.8 Hz.

### Structural Studies of Bis(Ferrocenylethynyl)Dimethyltin (2) and Tetrakis(Ferrocenylethynyl)tin (3)

The molecular structure of **2** in the solid state, determined by X-ray analysis, is shown in Figure 3. All bond

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lengths and angles are close to the expected values, when compared with other alkynes[1a] or ferrocenyl derivatives.[8,9] The cyclopentadienyl rings are almost exactly parallel to each other, and deviate by 6.3° from the eclipsed positions. The C2–C3 bond forms an angle of 2.7° (pointing away from the iron atom) with the $C_5H_4$ plane. There are no appreciable intermolecular interactions ($d_{Fe\cdots Fe}$ = 956.6 pm). The literature does not contain structural data on comparable di(alkyn-1-yl)dimethyltin compounds.

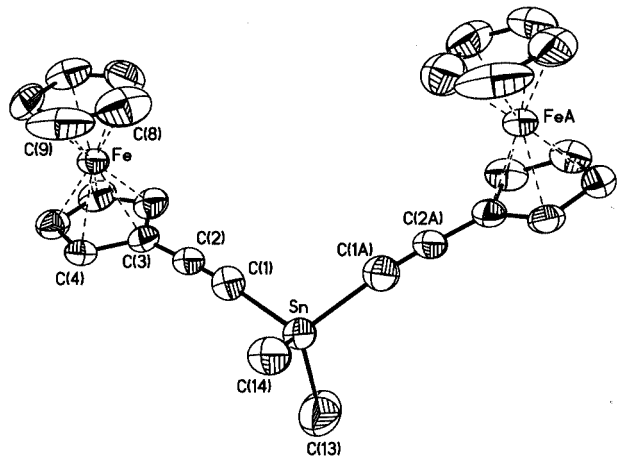

Figure 3. ORTEP representation (50% probability; hydrogen atoms have been omitted) of the molecular structure of bis(ferrocenylethynyl)dimethyltin (**2**). Selected bond lengths [pm] and angles [°]: Sn–C1 211.3(8), Sn–C13 211.3(12), Sn–C14 210.0 (12), C1–C2 119.0(9), C2–C3 141.3(9), C3–C4 143.0(8)m, C3–C7 142.2(9), C4–C5 146.1(8), C5–C6 149.2(9), Fe–centroid($C_5H_4$) 165.6, Fe–centroid($C_5H_5$) 164.4; C1–Sn–C1A 107.0(4), C1–Sn–C13 108.5(3), C1–Sn–C14 109.2(3), C13–SnC14 114.3(5), Sn–C1–C2 174.0(6), C1–C2–C3 177.1(7), centroid–Fe–centroid 178.7.

The symmetry in the solid-state structure of **2** is remarkable, and would be somewhat surprising if this structure is the sole modification of **2**. Therefore, solid-state MAS $^{13}C\{^1H\}$ and $^{119}Sn\{^1H\}$ NMR spectra were recorded (Figure 4). These measurements clearly show that the bulk material of crystalline **2** contains a second modification. There are two sites for tin with rather similar isotropic $^{119}Sn$ chemical shifts, close to the value for solutions of **2**. The solid-state MAS $^{13}C$ NMR spectrum reveals one set of alkynyl $^{13}C$ resonances, corresponding to the symmetric molecular structure found by X-ray analysis, and there are two additional sets of alkynyl $^{13}C$ resonances which can be expected for a less symmetric arrangement of the ferrocenylethynyl units in the second crystalline modification.

In the case of **3**, we have not been able to obtain single crystals so far. Only one tin site was detected in the solid-state MAS $^{119}Sn$ NMR of the microcrystalline powder of **3**, and this site shows an expectedly small chemical shift anisotropy.[10] Similarly, only one set of alkynyl $^{13}C$ resonances is observed in the solid-state MAS $^{13}C$ NMR spectrum. If there are several modifications of **3** present, it can be assumed that their structures are very similar.

## Reactivity of the Ferrocenylethynyltin Compounds Towards Triethylborane

The reactivity of Sn–C≡ bonds in alkyn-1-yltin compounds towards triorganoboranes is well documented.[11,12] The results of the reactions of **1** and **4** with triethylborane ($BEt_3$) are fully consistent with previous observations for 1,1-organoboration reactions, all of which proceed by cleavage of the Sn–C≡ bond via a borate-like zwitterionic intermediate.[12] The 1,1-ethylboration is regio- and stereospecific, and affords the alkenyltin compounds **5** and **6** in essentially quantitative yield (Scheme 3). The proposed structures follow from the NMR spectroscopic data (Table 2), and the *cis*-positions of the stannyl and boryl groups are confirmed by selective $^1H/^1H$ NOE experiments.[13]

The reaction of **2** with $BEt_3$ leads to a mixture of the stannacyclopenta-2,4-diene **7a** and the 1-stanna-4-boracyclohexa-2,5-diene **8a** in a ratio close to 1:2. This ratio was reproduced in several experiments in different solvents (toluene or $CH_2Cl_2$). The structural assignment follows conclusively from the NMR spectroscopic data (Table 3 and

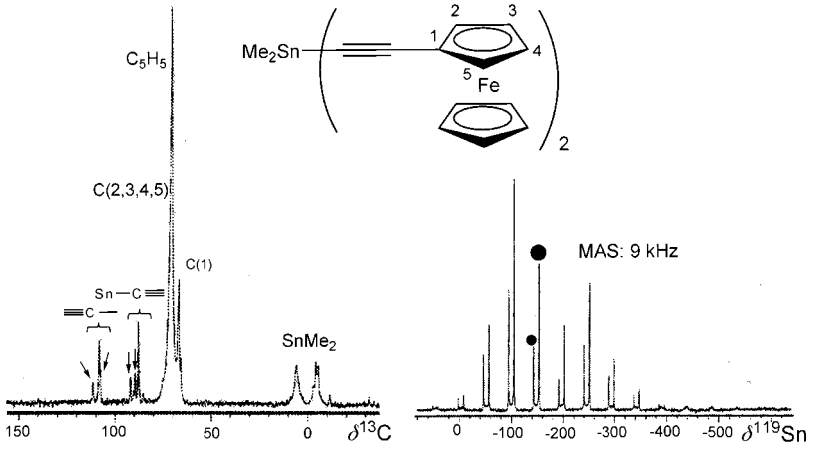

Figure 4. Solid-state VACP[27] MAS $^{13}C\{^1H\}$ (100.5 MHz) and $^{119}Sn\{^1H\}$ (149.1 MHz) NMR spectra of **2**, showing the presence of two modifications in the crystalline state. The signals for the isotropic $\delta_{^{119}Sn}$ values are marked by filled circles. The alkynyl $^{13}C$ NMR signals for the modification that is not represented by the crystal structure (Figure 3) are marked by arrows.

Table 4), and in particular from the $^{119}$Sn and $^{13}$C NMR spectra (Figure 5).

The formation of a mixture is reminiscent of the results of the 1,1-ethylboration of bis(phenylethynyl)dimethyltin.[14] Monitoring of the reaction of **2** with $BEt_3$ by NMR spectroscopy shows that there is a fairly stable intermediate **9a** which must be regarded as the immediate precursor of the heterocycles. Zwitterionic complexes similar to **9a** have been observed before,[12] and they have been fully characterized by NMR spectroscopic data in solution,[15] in the

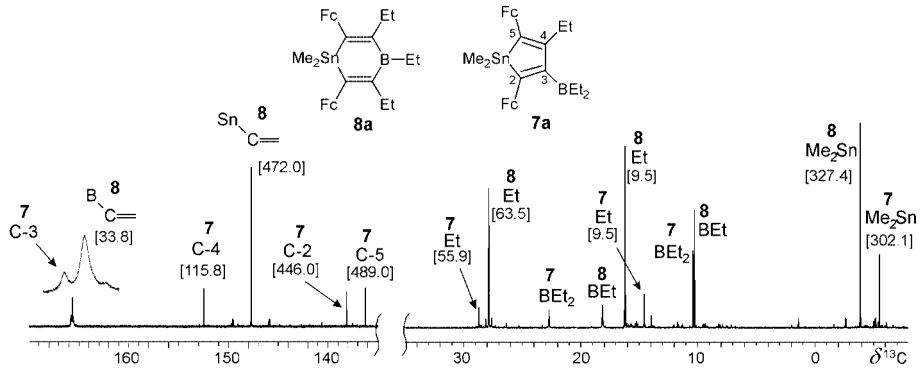

Figure 5. $^{13}C\{^1H\}$ NMR spectrum (100.5 MHz) of the mixture of products **7a** and **8a** showing the assigned $^{13}C$ NMR signals in the ranges expected for the olefinic and the aliphatic carbon atoms. $^{117/119}Sn$ satellites are indicated and $J_{^{119}Sn,^{13}C}$ coupling constants are given in brackets.

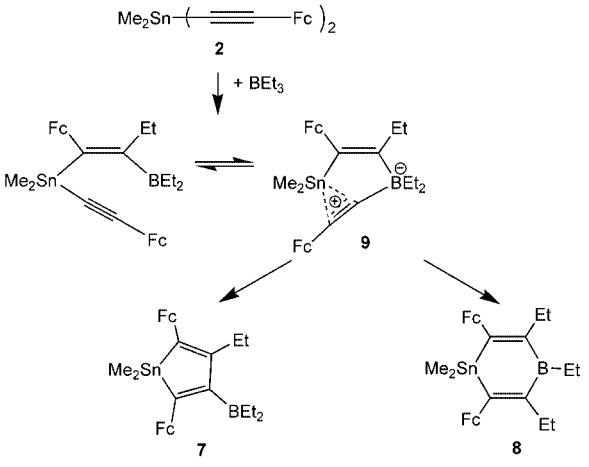
solid state,[16] and also by X-ray analysis.[15,17,18] In such related derivatives, with alkyl instead of the ferrocenyl groups, the $^{119}Sn$ resonances[15] ($\delta_{^{119}Sn}$ = +160 to +215 ppm) are found at slightly higher frequencies than for **9a** ($\delta_{^{119}Sn}$ = +147 ppm at 23 °C and +159 ppm at –20 °C). It is known, that the ferrocenyl group can stabilize a vinyl-cationic structure,[19] which may be considered for **9a** as an extreme case of unsymmetrical bridging. It should also be noted that triorganostannyl groups in the β-position to the carbocationic center exert a stabilizing effect.[20] The NMR spectroscopic evidence indicates that the ferrocenyl group stabilizes the bridged structure in **9a** much better than a phenyl group. In previous work, where the ferrocenyl was replaced with phenyl groups, the equilibrium shown for the intermediate **9a** in Scheme 4 was found, even at –10 °C, to be much more on the side of the nonbridged species[15] (cf. $\delta_{^{119}Sn}$ = +11.6 ppm and $\delta_{^{11}B}$ = +33.3 ppm at –10 °C[15] with $\delta_{^{119}Sn}$ = +147 ppm and $\delta_{^{11}B}$ = +0.2 ppm for **9a** at 23 °C).



Scheme 4. 1,1-Organoboration of the bis(ferrocenylethynyl)dimethyltin (**2**).

When the reaction of **2** with triisopropylborane (B*i*Pr$_3$) was studied under similar conditions, the formation of the intermediate **9b** took place more slowly than that of **9a**. The rearrangement of **9b** was also slow (several days at room temperature); however, in contrast to the behavior of **9a**, the six-membered ring **8b** was formed selectively. The $^{119}Sn$ and $^{11}B$ NMR spectroscopic data for **9b** at room temperature ($\delta_{^{119}Sn}$ +66 ppm and $\delta_{^{11}B}$ +34 ppm) indicate that the equilibrium is shifted towards the nonbridged species.

The reaction of **3** with BEt$_3$ proceeds slowly to give a mixture of three final products, the spirotin compounds **10**–**12** (in a ratio of 45:50:5). When the progress of the reaction was monitored by $^{119}Sn$ NMR spectroscopy (see Figure 6), the $^{119}Sn$ NMR signals for various intermediates were observed. In analogy to previous work,[17,21] these were assigned to the zwitterionic intermediates **13**–**15**, which have to be considered as precursors of the final products (Scheme 5). The structural assignment of the final products is based on the $\delta_{^{119}Sn}$ values together with the observation of relevant $^{13}C$ NMR signals in the olefinic region. The latter correspond closely to those for compounds **7a** and **8a** (see Figure 5). The $^{119}Sn$ resonances differ significantly, depending on whether the tin atom is part of a five- or six-membered ring. $^{119}Sn$ nuclei as part of five-membered rings are typically deshielded.[22]

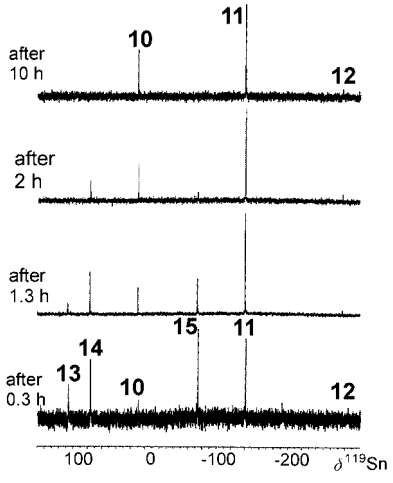


Figure 6. $^{119}Sn\{^1H$-inverse-gated$\}$ NMR spectra (149.1 MHz) of the $CD_2Cl_2$ solution from the reaction of tetrakis(ferrocenylethynyl)tin (**3**) with an excess of BEt$_3$. $^{119}Sn$ NMR signals of the zwitterionic intermediates **13**–**15** are observed in the beginning, and after 10 h at room temperature only $^{119}Sn$ NMR signals of the spirotin compounds **10**, **11** and **12** (ratio 45:50:5) are left.

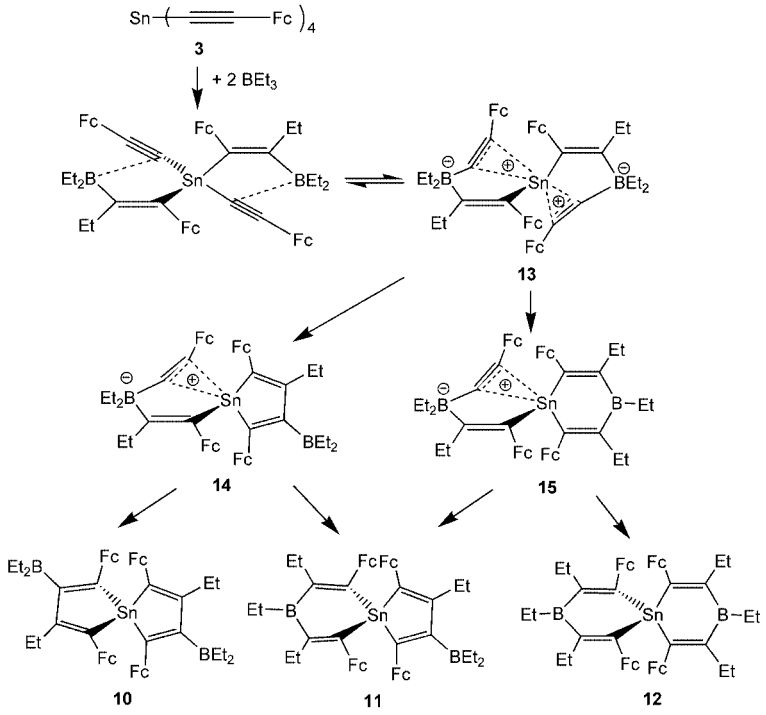

Scheme 5. 1,1-Ethylboration of tetrakis(ferrocenylethynyl)tin (**3**).

## Conclusions

All structural and spectroscopic data indicate that the ferrocenyl group does not exert any special effects on the C≡C bond in ferrocenylethynyltin compounds. This is also supported by the results of the 1,1-organoboration reactions. Novel organometallic-substituted alkenes with stannyl and boryl groups in *cis*-positions are accessible by 1,1-ethylboration of the mono(ferrocenylethynyl)tin compounds **1** and **4**. Fairly stable zwitterionic intermediates were detected in the course of 1,1-organoboration reactions of bis(ferrocenylethynyl)dimethyltin (**2**) and tetrakis(ferrocenylethylnyl)tin (**4**). These reactions give access to 1-stannacyclopenta-2,4-diene or 1-stanna-4-boracyclohexa-2,5-diene derivatives and the corresponding spirotin compounds. The product distribution is apparently dependent on the nature of the trialkylborane.

## Experimental Section

**General Procedures:** All reactions were carried out using the usual techniques to exclude oxygen and moisture. The starting materials ethynylferrocene,[3] tin amides,[23] and triisopropylborane[24] were prepared following literature procedures. BuLi, tin chlorides, and triethylborane were used as commercial products without further purification. Melting points were measured (Büchi 510 melting point apparatus) in sealed capillaries under argon and are uncorrected. Mass spectra (EI ionization, 70 eV) were obtained using a Finnigan MAT 8500 spectrometer with direct inlet. IR spectra: Perkin–Elmer, Spectrum 2000 FTIR instrument. NMR spectra: Bruker ARX 250, Bruker DRX 500 (both for $^{1}H$, $^{11}B$, $^{13}C$ and $^{119}Sn$ NMR spectra of solutions), and Varian Inova 400 (for solutions and for solid-state MAS $^{13}C$ and $^{119}Sn$ NMR spectra). $^{119}Sn$ NMR spectra of solutions were measured by using the refocused INEPT pulse sequence[25] for methyltin compounds, and by $^{1}H$ inverse-gated decoupling for all other cases. The chemical shifts are given relative to $SiMe_4$ [$\delta_{^1H}(C_6D_5H)$ = 7.15 ppm; $\delta_{^1H}(CHCl_3)$/$CDCl_3$ = 7.23 ppm; $\delta_{^1H}(CHDCl_2/CD_2Cl_2)$ = 5.33 ppm; $\delta_{^{13}C}(C_6D_6)$ = 128.0 ppm; $\delta_{^{13}C}(CDCl_3)$ = 77.0 ppm; $\delta_{^{13}C}(CD_2Cl_2)$ = 53.8 ppm], $SnMe_4$ [$\delta_{^{119}Sn}$ = 0 ppm for $\Xi(^{119}Sn)$ = 37.290665 MHz], or $BF_3{\cdot}OEt_2$ [$\delta_{^{11}B}$ = 0 ppm for $\Xi(^{11}B)$ = 32.083971 MHz]. For solid-state MAS NMR spectra, the $\delta_{^{13}C}$ and $\delta_{^{119}Sn}$ NMR spectroscopic data are given relative to external adamantane and $Sn(chex)_4$, respectively, and recalculated to the $SiMe_4$ and $SnMe_4$ scales.

**Ferrocenylethynyltrimethyltin (1):** [26] $^{1}H$ NMR (250 MHz, $CD_2Cl_2$): $\delta$ [$J_{^{119}Sn,^1H}$] = 0.31 [60.0] (s, 9 H, $SnMe_3$), 3.39, 4.13 [2m, 2×2 H, H(3,4,2,5)], 4.11 (s, 5 H, Cp) ppm. MS: *m/z* (%) = 374 (100) [$M^+$], 344 (82) [$M^+$ – 2Me], 329 (19) [$M^+$ – 3Me].

**Bis(ferrocenylethynyl)dimethyltin (2):** A THF (5 mL) solution of $Me_2SnCl_2$ (0.98 g, 4.46 mmol) was added, at 0 °C, to a solution of the Li salt of Fc-C≡C–H [prepared from 1.87 g of Fc-C≡C–H (8.92 mmol and an equimolar amount of BuLi (1.6 M in hexane)] in THF (15 mL). The mixture was kept stirring overnight, THF was removed under reduced pressure, and the residue was taken up in hexane (15 mL). After filtration, the product **2** was crystallized at –30 °C to give 1.21 g (48%) of orange crystals (m.p. 140–144 °C). $^{1}H$ NMR (400 MHz, $C_6D_6$, 296 K): $\delta$ [$J_{^{119}Sn,^1H}$] = 0.30 [68.6] (s, 6 H, $Me_2Sn$), 3.84 (m, 4 H, $C_5H_4$), 4.05 (s, 10 H, $C_5H_5$), 4.41 (m, 4 H, $C_5H_4$) ppm. IR (toluene): $\tilde{\nu}$ = 2140, 2114 $cm^{-1}$ (C≡C). MS: *m/z* (%) = 598 (80) [$M^+$], 418 (100) [$M^+$ – $SnMe_2$].

**Tetrakis(ferrocenylethynyl)tin (3):** A hexane (5 mL) solution of $SnCl_4$ (0.205 g, 1.74 mmol) was added, at 0 °C, to a solution of the Li salt of Fc-C≡C–H (prepared as above; 1.46 g, 6.94 mmol) in THF (15 mL). After stirring for 12 h at room temperature, insoluble materials were filtered off, and the solid was washed with toluene and dried to give the product **3** as an orange-yellow powder (0.877 g, 52%; m.p. 210–214 °C). $^{1}H$ NMR (400 MHz, $CD_2Cl_2$,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

296 K): $\delta$ = 4.26 (m, 8 H, $C_5H_4$), 4.27 (s, 20 H, $C_5H_5$), 4.56 (m, 8 H, $C_5H_4$) ppm. IR (toluene): $\tilde{\nu}$ = 2147 $cm^{-1}$ (C≡C).

**Chloro(ferrocenylethynyl)dimethyltin (4):** A mixture of the stannane **2** (213 mg, 0.376 mmol) and $Me_2SnCl_2$ (90.1 mg, 0.414 mmol) in toluene (1 mL) was heated at for 1 h. After removal of the solvent and the excess of $Me_2SnCl_2$ in vacuo, the tin chloride **4** was left as a brownish-red solid that could be used without additional purification. The purity of **4** (according to NMR spectroscopic data) was ≥ 95%. $^1$H NMR (400 MHz, $C_6D_6$, 296 K): $\delta$ [$J_{^{119}Sn,^1H}$] = 0.55 [69.1] (s, 6 H, $Me_2Sn$); 4.20 (m, 2 H, $C_5H_4$); 4.22 (s, 5 H, $C_5H_5$); 4.45 (m, 2 H, $C_5H_4$) ppm.

**Organoboration the of Stannanes 1–4 with Triethylborane (General Procedure):** A twofold excess of $BEt_3$ (four equivalents were used in the case of **3**) was added, at –78 °C, to a solution of the respective alkyn-1-yltin compound **1**–**4** (0.2–0.4 mmol) in $CH_2Cl_2$ and the reactions were monitored by $^{119}$Sn NMR spectroscopy. For multinuclear NMR characterization of the zwitterionic intermediates **9a** and **9b** the same reactions were carried out with 0.1 mmol of **2** in $CD_2Cl_2$. The reaction of **2** with B*i*Pr$_3$ was also done on a small scale (0.05 mmol) in $CD_2Cl_2$ for NMR studies.

**5:** Orange-red oil. $^1$H NMR (500.1 MHz. $CDCl_3$, 296 K): $\delta$ [$J_{^{119}Sn,^1H}$] = 0.05 [53.0] (s, 9 H, $Me_3Sn$), 2.19, 0.85 (q and t, 2 H and 3 H, =C-Et), 1.30, 1.11 (m and t, 10 H, $BEt_2$), 3.85–4.00 (m, 4 H. $C_5H_4$), 3.83 (s, 5 H, $C_5H_5$) ppm.

**6:** Orange-red, waxy solid.: $^1$H NMR (400 MHz, 296 K, $CD_2Cl_2$): $\delta$ [$J_{^{119}Sn,^1H}$] = 0.59 [55.0] (s, 6 H, $Me_2Sn$); 2.21 [8.5], 0.86 (q and t, 2 H nd 3 H, =C-Et), 1.36, 1.16 (m and t, 4 H and 6 H, $BEt_2$), 3.87 (s, 5 H, $C_5H_5$), 3.9–4.0 (m, 4 H, $C_5H_4$) ppm.

**7a:** Obtained as a mixture with **8a**. $^1$H NMR (400 MHz, 296 K, $CD_2Cl_2$): $\delta$ [$J_{^{119}Sn,^1H}$] = 0.73 [52.6] (s, 6 H, $Me_2Sn$), 0.9 1.1 (m, 9 H, Et, $BEt_2$), 1.5 (q, $^3J_{^{119}Sn,^1H}$ = 7.6 Hz, 4 H, $BEt_2$), 2.2 (q, $^3J_{^{119}Sn,^1H}$ = 7.6 Hz, 2 H, Et), 4.18 (s, 10 H, $C_5H_5$), 4.1–4.3 (m, 8 H, $C_5H_4$) ppm.

**8a:** Obtained as a mixture with **7a**. $^1$H NMR ($CD_2Cl_2$, 296 K): $\delta$ [$J_{^{119}Sn,^1H}$] = 0.53 [52.6] (s, 6 H, $Me_2Sn$), 0.9–1.1 (m, 9 H, Et, BEt), 1.5 (q, 2 H, BEt), 2.2 (q, 4 H, Et), 4.18 (s, 10 H, $C_5H_5$), 4.1–4.3 (m, 8 H, $C_5H_4$) ppm.

**10:** Obtained as a mixture with **11** and **12**. $^{13}$C{$^1$H} NMR (125.8 MHz, $CD_2Cl_2$, 296 K): $\delta$ [$J_{^{119}Sn,^{13}C}$] = 22.9 (br), 9.9 ($BEt_2$). 28.3 [67.3], 16.2 [9.6] (Et), 68.9–69.9 (overlapping signals for $C_5H_4$ and $C_5H_5$), 87.6 [71.4] [$C_5H_4$-(1)], 89.9 [72.8] [$C_5H_4$-(1)], 134.2 [454.7] (C-1), 165.3 [43.6] (br) (C-2), 152.3 [117.8] (C-3), 139.0 [473.8] (C-4) ppm. $^{119}$Sn{$^1$H inverse-gated} NMR (149.1 MHz, $CD_2Cl_2$, 296 K): $\delta$ = 10.3 ppm.

**11:** Obtained as a mixture with **10** and **12**. $^{13}$C{$^1$H} NMR (125.8 MHz, $CD_2Cl_2$, 296 K): $\delta$ [$J_{^{119}Sn,^{13}C}$] = 22.3 (br), 9.9 ($BEt_2$); 18.4 (br), 8.3 (BEt); 28.5 [57.6], 13.6 [10.1] (3-Et), 28.4 [56.4], 14.4 [9.5] (7-Et), 68.9–69.9 (overlapping signals for $C_5H_4$ and $C_5H_5$), 87.5 [79.7], 88.2 [71.0] [1,4-$C_5H_4$-(1)], 89.7 [76.1] [6-$C_5H_4$-(1)], 137.1 [409.0] (C-1), 164.5 [44.4] (br) (C-2), 153.7 [117.6] (C-3), 141.1 [428.8] (C-4), 150.0 [441.5] (C-6), 167.3 [36.6] (br) (C-7) ppm. $^{119}$Sn{$^1$H inverse-gated} NMR (149.1 MHz, $CD_2Cl_2$, 296 K): $\delta$ = –139.6 ppm.

**12:** A small amount as a mixture with **10** and **11**. $^{13}$C NMR (125.8 MHz, $CD_2Cl_2$, 296 K): $\delta$ = 18.6 (br), 8.2 (BEt), 28.5, 14.3 (2-Et), 68.9–69.9 (overlapping signals for $C_5H_4$ and $C_5H_5$), 87.9 [1-$C_5H_4$-(1)], 152.4 (C-1), 166.1 (br) (C-2) ppm. $^{119}$Sn{$^1$H} NMR (149.1 MHz, $CD_2Cl_2$, 296 K): $\delta$ = –275.7 ppm.

**X-ray Crystallography:** An orange-colored crystal of compound **2** of dimensions 0.18 × 0.16 × 0.12 $mm^3$ was sealed in a glass capillary under argon and measured on a Siemens P4 four-circle diffractometer at 293(2) K with Mo-$K_\alpha$ radiation (graphite monochromator). The structure was solved by direct methods and refined by a full-matrix least-squares procedure. A numerical absorption was carried out. The positions of the hydrogen atoms were calculated and refined isotropically by applying the riding model. All non-hydrogen atoms were refined anisotropically revealing $wR^2$ = 0.124 and $R1$ = 0.056 as final $R$ values. The final difference map had no peaks of chemical significance (min./max. residual electron density –0.76/0.62 e $10^{-6}$ $pm^{-3}$).
CCDC-275737 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis of Monodisperse CdS Nanospheres in an Inverse Microemulsion System Formed with a Dendritic Polyether Copolymer

**Fang Wang,[a] Guiying Xu,*[a] Zhiqing Zhang,[a] and Xia Xin[a]**

**Keywords:** Monodisperse nanospheres / Semiconductors / Dendrimers / X-ray diffraction / Microemulsion

Nanosized CdS spheres with diameters of about 25, 40, and 50 nm have been synthesized in three inverse microemulsions formed with a dendritic amphiphilic copolymer ($H_2O$/SD31/*n*-butanol/*n*-heptane) through the reaction of cadmium chloride ($CdCl_2$) with the $S^{2-}$ ions that were slowly released from thioacetamide (TAA). X-ray powder diffraction (XRD), transmission electron microscopy (TEM), and UV/Vis absorption and photoluminescence (PL) spectroscopy were used to characterize the CdS nanospheres obtained. TEM and XRD studies showed that monodisperse CdS nanospheres with the zinc blende structure were produced, and the size of the CdS spheres increased with increasing water-core size because of the increasing [water]/[dendrimer] mass ratio ($\omega$). The blue-shift of the maxima in the UV/Vis absorption and PL spectra indicated that the CdS spheres consisted of primary CdS nanocrystals showing a quantum confinement effect. The viscosities of the three microemulsions were also determined by rheological measurements. The viscosity of the inverse microemulsion system decreased as $\omega$ increased. The water core of the inverse microemulsion provided a soft template for the precipitation of CdS spheres.

## Introduction

Nanocrystals have attracted broad attention from researchers in various disciplines.[1] They exhibit size-dependent characteristics and often display novel electronic, magnetic, optical, chemical, and mechanical properties that cannot be obtained in their bulk counterparts. Among the various nanocrystals, semiconductor nanocrystals, represented by Group II–IV nanocrystals with either zinc blende or wurtzite structures, have been the most studied because of their nonlinear optical and luminescence properties, quantum size effect, and other important physical and chemical features.[2,3] Altering the size of the particles changes the degree of the confinement of the electrons and affects the electronic structure of the solid, especially the bandgap edges, which can be tuned by varying the particle size. Chalcogenides such as CdS,[4–14] ZnS,[15–21] HgS,[22–24] PdS,[25–29] and MnS,[30,31] have been intensively investigated. Among these inorganic nanoparticles, CdS nanoparticles have received great attention. CdS, as an important Group II–IV semiconductor compound with a wide bandgap (energy = 2.53 eV), has attracted much research interest due to its excellent properties of luminescence and photochemistry.

To date, various methods have been developed to synthesize nanoparticles of CdS semiconductors. Recently, solvothermal or hydrothermal methods,[32] evaporation processes,[33] mesoporous silica and monoliths,[34] and sol–gel methods[35] have been utilized to prepare CdS. Other methods involve arrested precipitation from simple inorganic ions using polyphosphate and low-molecular-weight thiols as stabilizers.[36–38] Surfactants,[39] block copolymers,[40] and dendrimers[41] have also been used as specific stabilizers and soft templates for the synthesis of CdS nanoparticles in solution. However, water-in-oil microemulsions with nanometer-sized water cores are well-suited for nanoparticles. As the method that uses such microemulsions works in mild and normal environments, it is advantageous and considered to have good viability. No special conditions of pressure, irradiation, etc. are required.[42] Many kinds of CdS nanoparticles have been synthesized by this method.[43] The nanowater core acts as a nanoreactor, and the size of the prepared nanoparticles can be controlled.[44]

In previous studies, microemulsions were generally composed of low-molecular-weight surfactants. However, amphiphilic macromolecules, in particular amphiphilic dendrimers, can also be used to prepare microemulsions. Dendrimers are defined as macromolecules containing highly branched and dimensional structures with a large number of reactive terminal groups.[45] Water-soluble amphiphilic dendrimers have attracted considerable attention due to their unique properties and as new polymeric materials for applications in many areas such as the preparation of micelles, liquid crystals, microemulsions, and molecular encapsulation.[46,47] The synthesis of an amphiphilic dendritic polyether copolymer and its demulsification on crude oil were studied in our previous work.[48]

In this article, we prepared water-in-oil microemulsions with an amphiphilic dendritic polyether copolymer SD31 as a microreactor to synthesize CdS nanoparticles and tested the feasibility of this method. As a result, nanosized monodisperse CdS spheres with diameters of 25–50 nm were obtained. The dimension of the CdS nanospheres encapsulated in microemulsion droplets could be controlled by varying the water-core size, i.e., varying the [water]/[dendrimer] mass ratio ($\omega$). The effects of the variation of $\omega$ on the synthesis were carefully examined and found to shed light on the mechanism of formation.

## Results and Discussion

Typical TEM images of CdS spheres with different sizes obtained in three different microemulsions are presented in Figure 1, which shows that the shape of all the products is spherical. However, the size is varied. The diameter of the spheres synthesized in microemulsion A is around 25 nm (Figure 1a and b), while the sphere diameters of other two samples synthesized in microemulsions B and C are about 40 and 50 nm, respectively (Figure 1c and d, e and f). It could be concluded that the size of the products increased as the [water]/[dendrimer] mass ratio ($\omega$) increased. The size of w/o microemulsion droplets is highly dependent on the concentration of each constituent in the microemulsion. However, it is recognized that the water-core size is dominantly characterized by the [water]/[surfactant] ratio, rather than the actual concentration. The radius of the water core is found to follow an approximately linear relationship with the [water]/[surfactant] ratio,[49] because the size of the water core of the microemulsion increases as $\omega$ increases. The larger water core acts as a nanoreactor that induces larger particle growth.[50] These properties and their reasons are discussed in detail below.

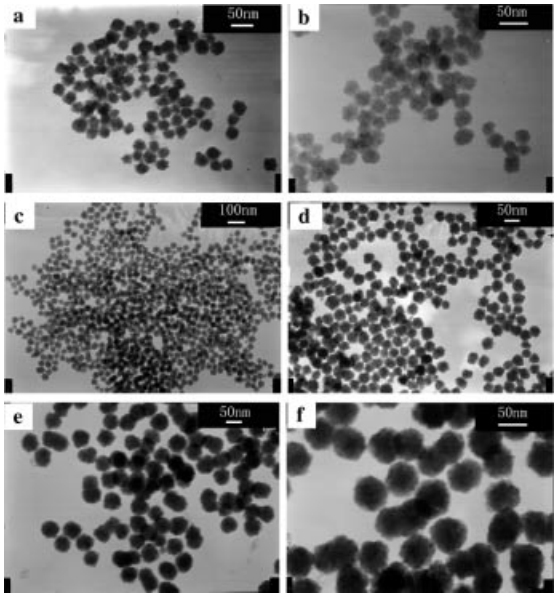

Figure 1. TEM images of CdS spheres obtained in three microemulsions with different [water]/[dendrimer] mass ratios ($\omega$): (a and b) products from microemulsion A ($\omega$ = 0.19); (c and d) products from microemulsion B ($\omega$ = 0.21); (e and f) products from microemulsion C ($\omega$ = 0.24).

The wide-angle XRD patterns for the CdS nanospheres prepared in the three microemulsions are shown in Figure 2. Diffraction peaks assigned to the (111), (200), (220), and (311) planes of bulk cubic CdS are observed for samples produced from microemulsions B and C. For the smallest sample produced from microemulsion A, the diffraction peaks are not obvious except for that of the (111) plane, which indicates incomplete crystallization of CdS and lattice defects. The diffraction peaks are fairly broad. We estimated roughly the average crystallite sizes of the primary particles by line-width analysis of the (111) diffraction peaks. Applying the Scherrer formula yielded particle sizes of 1.2, 1.6, and 2.7 nm for syntheses carried out in microemulsions A, B, and C, respectively.

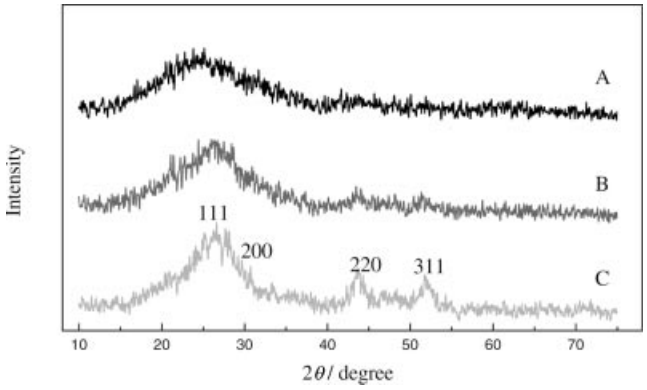

Figure 2. XRD patterns of CdS spheres obtained in the three microemulsion systems.

Figure 3 shows the intensities and wavelengths of the UV/Vis absorption peaks of the CdS spheres at various times during the process of formation. After addition of TAA, the mixture was kept at constant temperature (50 °C), and UV/Vis spectra were recorded at various time intervals. In the beginning, the solution was colorless, and there was no obvious peak in the absorption spectrum. After 30 min, the solution became slightly yellow, and an absorption peak appeared in the spectrum along with a considerable increase in absorbance. In Figure 3a, curves A′, B′, and C′ show that the absorption intensity increased with time, indicating a gradual formation of CdS particles accompanying the release of $S^{2-}$ ions from TAA. However, the position of the absorption peak was different in the three systems (Figure 3a, curves A, B, and C). The absorption peak of CdS synthesized in microemulsion A was at about 420 nm and the peak was obvious and sharp. With increasing time, the wavelength of the absorption peak remained essentially unchanged, even though the absorption intensity increased continuously, suggesting the formation of more and more CdS particles and the possible presence of large aggregates of the primary CdS particles, but the size of the primary CdS particles remained unchanged. The absorption of CdS obtained in microemulsion B displayed a shoulder peak close to 410 nm, and the absorption band of CdS obtained

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in microemulsion C was at wavelengths no longer than about 390 nm in the beginning. Curves B and C (Figure 3a) show that the absorption peaks continuously shifted towards higher wavelengths upon further heating of the solutions. This red-shifting phenomenon indicates that the primary CdS particles grew gradually and then aggregated to form larger particles due to the quantum confinement effect. From the changes in the UV/Vis spectra of the three microemulsions, it can be deduced that the mechanism of formation of the CdS spheres was different in each system. In microemulsion A, once the CdS particles nucleated, the particles ceased growing, but more CdS particles formed or aggregated. In microemulsions B and C, although the CdS particles initially nucleated were smaller than those in microemulsion A, the primary particles grew gradually and also aggregated to form larger particles.

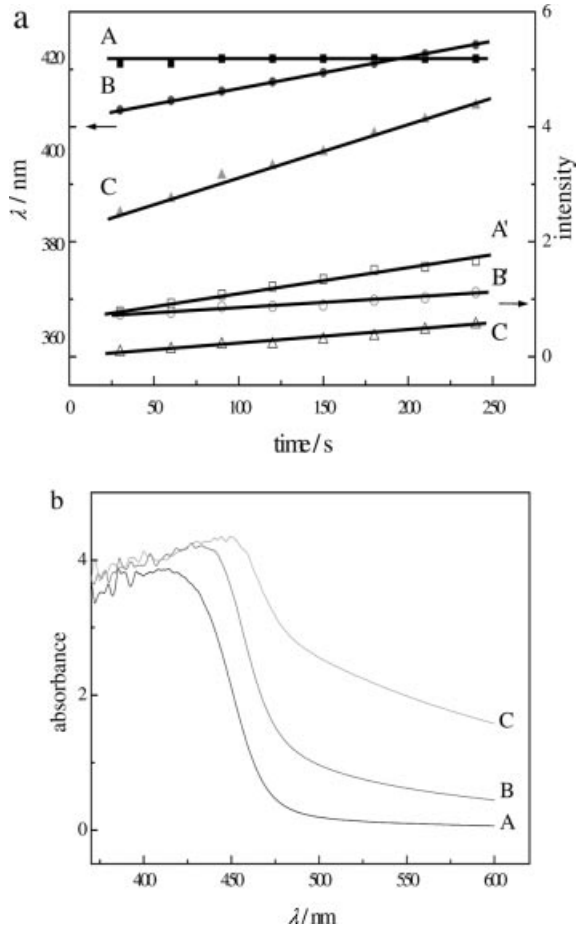

Figure 3. (a) Graphs of the wavelengths and intensities of the UV/Vis absorption peaks of the CdS products formed in the three microemulsions at earlier stages: curves A, B, and C show wavelength vs. time; curves A′, B′, and C′ show intensity vs. time. (b) UV/Vis absorption spectra of the final CdS products in the three microemulsions after eight hours. A and A′ represent microemulsion A ($\omega$ = 0.19); B and B′ represent microemulsion B ($\omega$ = 0.21); C and C′ represent microemulsion C ($\omega$ = 0.24).

Figure 3b shows the UV/Vis absorption spectra of the CdS products in the three microemulsions after eight hours. As shown in Figure 3b, the absorption spectra of the final products have peaks at 420 (microemulsion A), 440 (microemulsion B), and 450 nm (microemulsion C), which are all considerably blue-shifted relative to the absorption onset of bulk CdS (ca. 515 nm) because of the quantum confinement effect. It was interesting that CdS particles in microemulsions B and C were larger than those in microemulsion A in the end, so that the wavelength of the absorption maximum increased from A to C. The absorption peaks of B and C are obviously red-shifted relative to their initial positions, indicating the growth of the primary particles. The spectra of B and C also show a long absorption tail due to scattering by the particles in the dispersion. The absorption intensity increased with increasing particle size because of light scattering in the presence of bigger particles. From the experimental correlation between the onset of absorption and the particle diameter for CdS, the particle size of CdS nanocrystals was estimated to be about 2–3 nm and to increase from A to C.[36] These values follow the same trend as the results of XRD, which exhibit a quantum confinement effect.

The PL spectra of the CdS spheres are shown in Figure 4. The broad emission beginning around 430 nm is significantly blue-shifted from the emission of bulk CdS (ca. 520 nm). The broad PL peak observed is commonly attributed to the recombination of charged carriers trapped in the surface states and is related to the size of the CdS nanoparticles; that is, the PL bands of smaller nanoparticles appear at shorter wavelengths. Therefore, the PL emission of the CdS spheres indicates that they actually consist of primary CdS nanocrystals showing a quantum confinement effect.

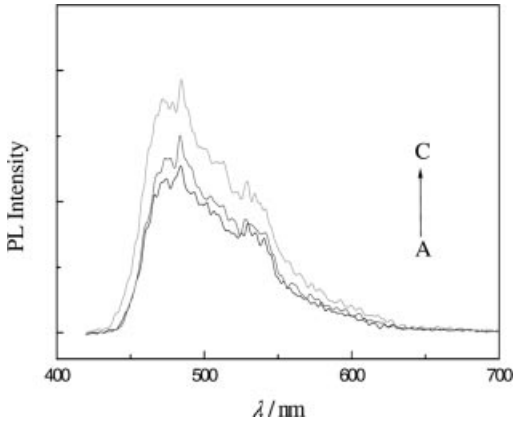

Figure 4. Photoluminescence spectra of CdS spheres obtained in three microemulsions after 8 h ($\lambda_{ex}$ = 400 nm).

Figure 5, which shows the stress at different shear rates, depicts the key results from steady-shear rheological measurements. During the experiments of shear rates, the three microemulsion systems were all Newtonian fluids. The relatively high viscosity was due to amphiphilic dendrimer content. It can be seen that shear stress increased as shear rate increased. In addition, the viscosity of the three microemulsions decreased with increased [water]/[dendrimer] mass ratio ($\omega$). This property of the microemulsion can be used to explain the different size of the products. High viscosity led to low ion flow and ion exchange, which affected the growth

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of CdS particles in the water core and further reduced the possibility of large aggregates of the primary CdS particles. The larger particles were obtained for microemulsion C with lower viscosity. This result is consistent with the observations of the TEM images and the UV/Vis absorption spectra.

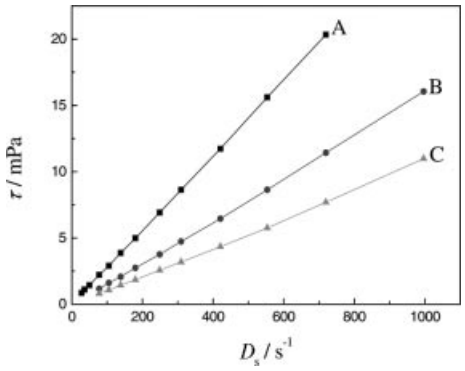

Figure 5. Shear stress vs. shear rate curves for the three microemulsion systems without CdS particles. (A) microemulsion A ($\omega$ = 0.19), (B) microemulsion B ($\omega$ = 0.21), (C) microemulsion C ($\omega$ = 0.24).

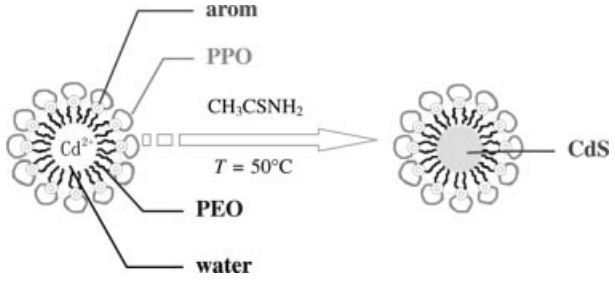
On the basis of the above observations and the monodisperse nanosphere structure we were able to propose a possible mechanism, as shown in Scheme 1. In the inverse microemulsion $H_2O$/SD31/*n*-butanol/*n*-heptane, the hydrophilic PEO of the amphiphilic dendritic polyether copolymer SD31 formed the water core, and the hydrophobic PPO and arom parts were oriented outwards. The cadmium ions that were initially dissolved in the water core reacted with the $S^{2-}$ ions that were slowly released from thioacetamide (TAA). Monodisperse CdS nanospheres were obtained because the reaction was restricted to the nanowater core.



Scheme 1. Proposed mechanism for the formation of monodisperse CdS nanospheres; PEO = poly(ethylene oxide), PPO = poly(propylene oxide), arom = bisphenol A.[48]

## Conclusions

Nanosized CdS spheres were facilely synthesized in water-in-oil microemulsions prepared by amphiphilic dendrimers through the slow release of $S^{2-}$ ions from thioacetamide under heating. It was shown that the nanometer-sized water cores are well-suited for nanoparticle synthesis. Particle growth occurs within the water core of the microemulsion, and the precursors of the semiconductor particles are water-soluble. The sizes of the CdS spheres obtained in three different systems are diverse, but all spheres are composed of cubic CdS crystals of the zinc blende structure. It was revealed that the diameter of the CdS spheres increased as the [water]/[dendrimer] mass ratio ($\omega$) increased, i.e., as the water-core size increased. The viscosity of the three microemulsions decreased with increased $\omega$, which affected the flow and exchange of the ions. High viscosity led to low ion flow and induced small particles to form, preventing the particles from aggregating. It is expected that this convenient synthetic route to CdS spheres may be readily extended to the fabrication of other metal chalcogenide semiconductor nanoparticles.

## Experimental Section

**Materials:** Unless otherwise noted, all chemicals were reagent grade and were used as received without purification. Amphiphilic dendritic polyether copolymer SD31 (MW = 10600 g mol$^{-1}$) was synthesized as per ref.[48] and the molecular structure is shown schematically in Figure 6. Thrice distilled water was used in all experiments.

**Determination of the Phase Diagram:** The quasiternary phase diagram was constructed at room temperature (25 ± 1 °C). SD31 and the cosurfactant, *n*-butanol, were combined in the mass ratio1:2. Then *n*-heptane was combined with the above mixture in the mass ratios 9:1, 8:2, 7:3, 6:4, 5:5, 4:6, 3:7, 2:8, and 1:9 and shaken vigorously. Water was gradually added dropwise to the above 10 samples under shaking, and then the samples were left to settle for two days. The formation of water-in-oil microemulsions was determined through visual observation, which revealed the phase transformation or phase separation of the ternary system. The quasiternary phase diagrams of the systems are given in Figure 7.

**Synthesis of CdS Nanoparticles:** In the water-in-oil microemulsion region, three systems (see Figure 7 A, B, and C) with the same amount of water (6% wt.) but different [water]/[dendrimer] mass ratios ($\omega$) were selected as nanometer-sized reaction cores to synthesize CdS. In a typical experiment, microemulsion A, containing $CdCl_2$ solution (1.44 mL, 0.1 M), dendrimer SD31 (7.5 g), and *n*-butanol (15 g), was prepared. Thioacetamide (TAA) solution (1.44 mL, 0.1 M in ethanol) was added to microemulsion A whilst stirring until a homogeneous mixture formed. Then the final microemulsion was sealed and placed under constant temperature (50 °C) for 8 h, where the slow release of $S^{2-}$ ions from TAA led to the formation of CdS particles. The resulting solution was centrifuged at 12000 rmp, washed with ethanol under sonication, and separated by repeated centrifugation. The final product was dried to yield a powder at 50 °C. Microemulsion B was composed of $CdCl_2$ (1.60 mL, 0.1 M), dendrimer SD31 (7.5 g), *n*-butanol (15 g), and *n*-heptane (2.5 g), while microemulsion C was composed of $CdCl_2$ (1.68 mL, 0.1 M), dendrimer SD31 (7 g), *n*-butanol (14 g), and *n*-heptane (5.3 g).

**Characterization:** Transmission electron microscopy (TEM, JEM100-CXII) was used to directly observe the morphology and size of products. Powder X-ray diffraction (XRD) patterns were recorded with a Rigaku D/Max 2200-PC diffractometer with Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å) and a graphite monochromator at ambient temperature. UV/Vis absorption spectra were obtained with

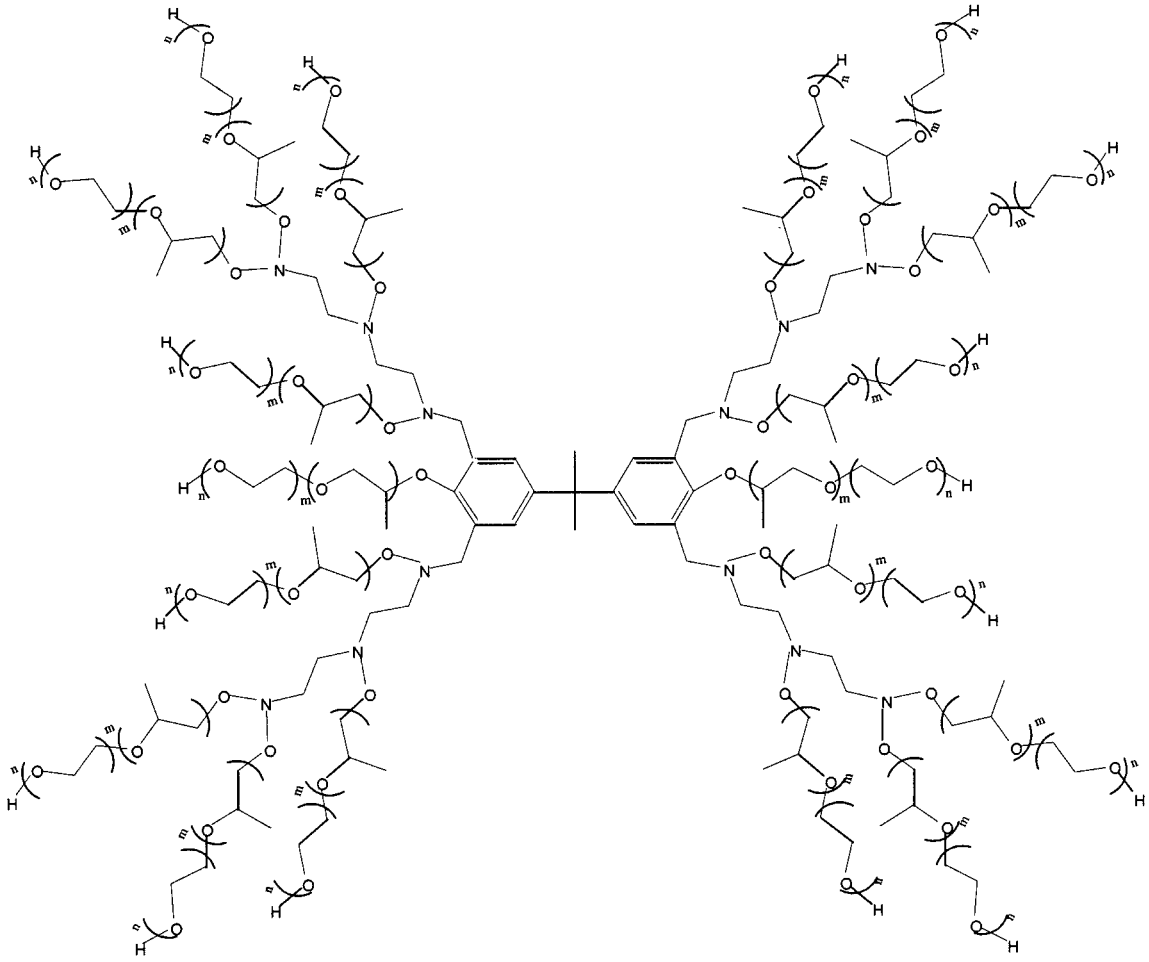

Figure 6. The molecular structure of the amphiphilic dendrimer SD31.

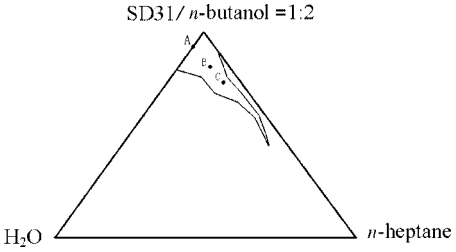

Figure 7. Ternary phase diagram of the $H_2O$/SD31/*n*-butanol/*n*-heptane system. Inset shows the water-in-oil (w/o) inverse microemulsion region. A ($\omega$ = 0.19), B ($\omega$ = 0.21), and C ($\omega$ = 0.24) were the three microemulsions used in nanoparticle synthesis.

a Hitachi U-4100 dual-beam grating spectrophotometer with a 10-mm quartz cell. PL spectra were obtained with a Perkin-Elmer LS-55 fluorescence spectrophotometer. The excitation wavelength $\lambda_{ex}$ was 400 nm, and the bandwidths of excitation and emission were both 10 nm. Fluorescence measurements were obtained on suspensions in quartz cuvettes. Shear stress versus shear rate rheological data was measured with an NXS-11A rotary viscometer.

# Copper Complexes with (2,7-Di-*tert*-butylfluoren-9-ylidene)methanedithiolate: Oxidatively Promoted Dithioate Condensation[‡]

**José Vicente,[a] Pablo González-Herrero,*[a] Yolanda García-Sánchez,[a] Peter G. Jones,[b] and Delia Bautista[c]**

**Keywords:** Copper / Dithiolates / Phosphane ligands / S ligands

The reaction of $[Cu(NCMe)_4]PF_6$ with piperidinium 2,7-di-*tert*-butyl-9*H*-fluorene-9-carbodithioate (pipH)[$S_2C$(*t*Bu-Hfy)] (**1**; *t*Bu-Hfy = 2,7-di-*tert*-butylfluoren-9-yl), affords $[Cu_n\{S_2C(t\text{Bu-Hfy})\}_n]$ (**2**), which reacts with various P ligands to give $[Cu\{S_2C(t\text{Bu-Hfy})\}L_2]$ [L = $PPh_3$ (**3a**), $PCy_3$ (**3b**), P*i*$Pr_3$ (**3d**); $L_2$ = 1,1′-bis(diphenylphosphanyl)ferrocene (dppf, **3c**), bis(diphenylphosphanyl)methane (dppm, **3e**)]. Compounds **3a**–**c** react with atmospheric oxygen and moisture in the presence of $NEt_3$ to give the dinuclear complexes $[Cu_2\{[SC=(t\text{Bu-fy})]_2S\}L_2]$ [*t*Bu-fy = 2,7-di-*tert*-butylfluoren-9-ylidene; L = $PPh_3$ (**4a**), $PCy_3$ (**4b**); $L_2$ = dppf (**4c**)], which contain a new dithiolato ligand formally resulting from the condensation of two dithioato ligands with loss of a sulfide ion and two protons. Neutral $Cu^I$ dithiolate complexes of the type $[Cu_4\{S_2C=(t\text{Bu-fy})\}_2L_4]$ [$S_2C$=(*t*Bu-fy) = [2,7-di-*tert*-butylfluoren-9-ylidene)methanedithiolate; L = $PPh_3$ (**5a**), $P(C_6H_4OMe\text{-}p)_3$ (**5b**), P*i*$Pr_3$ (**5d**) or $L_2$ = dppf (**5c**)] were obtained by treating **1** with $[Cu(NCMe)_4]PF_6$, the corresponding phosphane, and piperidine in a 1:2:2:1 molar ratio. The reaction of **1** with $Cu(ClO_4)_2{\cdot}6H_2O$ and $(Pr_4N)OH$ in a 2:1:2 molar ratio gives the $Cu^{II}$ complex $(Pr_4N)_2[Cu\{S_2C=(t\text{Bu-fy})\}_2]$ [$(Pr_4N)_2$**6**], which readily oxidizes to the $Cu^{III}$ complex $Pr_4N[Cu\{S_2C=(t\text{Bu-fy})\}_2]$ ($Pr_4N$**7**) in the presence of atmospheric oxygen and moisture. The salt PPN**7** [$PPN^+$ = $(Ph_3P)_2N^+$] was obtained from **1**, $CuCl_2{\cdot}2H_2O$, PPNCl, and piperidine in a 2:1:1:2 molar ratio under aerobic conditions. The crystal structures of **3a**, **3c**·$CH_2Cl_2$, **4a**·$4Me_2CO$, and **4c**·$CH_2Cl_2$ have been determined by X-ray diffraction studies.

## Introduction

The importance of copper complexes and clusters with thiolato ligands is associated with their use as models for the understanding of the structure, bonding, and function of the active sites of copper–sulfur enzymes and proteins,[1–6] which perform crucial functions such as electron-transfer and dioxygen transport to redox systems and copper transport and delivery.[7–11] Among the variety of sulfur ligands employed for the synthesis of copper complexes, 1,1-ethylenedithiolates ($XYC=CS_2^{2-}$) and related dithio ligands have received special attention because of their ability to form high-nuclearity clusters, some of which have found industrial applications as antioxidant additives for lubricant oils.[12–20] Previously described 1,1-ethylenedithiolates that have been used for the preparation of copper complexes are limited to those with X = Y = CN (*i*-mnt), $CO_2R$ [R = Me (dmd), Et (ded), *t*Bu (*t*Bu-ded)] and X = CN and Y = $P(O)(OEt)_2$ (cpdt). The anionic $Cu^I$ clusters $[Cu_8(i\text{-mnt})_6]^{4-}$,[12,13,19] $[Cu_8(ded)_6]^{4-}$,[14] and $[Cu_8(t\text{Bu-ded})_6]^{4-}$[15,16] stand out as the best-studied 1,1-ethylenedithiolato complexes of copper, and theoretical calculations have been carried out in order to understand the bonding in the $Cu_8S_{12}$ core.[21,22] The tetranuclear cluster $[Cu_4(i\text{-mnt})_4]^{4-}$ has been obtained from the reaction of the sulfur-rich dithiolato cluster $[Cu_6\{S_3C=C(CN)_2\}_6]^{6-}$ with triphenylphosphane.[19] Clusters of higher nuclearities have been obtained by protonation of $[Cu_8(ded)_6]^{4-}$ and $[Cu_8(t\text{Bu-ded})_6]^{4-}$.[15,16] A series of clusters of $Cu^I$ with the cpdt ligand and bis(diphenylphosphanyl)methane (dppm) has also been prepared from the reaction between $[Cu_2(dppm)_2(NCMe)_2](PF_6)_2$ and $K_2$cpdt.[23] The $Cu^{II}$ complexes are represented by the mononuclear species $[Cu(i\text{-mnt})_2]^{2-}$,[12,24] $[Cu(ded)_2]^{2-}$,[25,26] and [Cu(*i*-mnt)(N–N)] (N–N = 1,2-ethanediamines).[27] The $Cu^{III}$ complex $[Cu(ded)_2]^-$ has also been prepared by the oxidation of $[Cu(ded)_2]^{2-}$ with $H_2O_2$, $I_2$, or $Cu^{2+}$ ions.[25,26]

Part of our recent research in this field has been devoted to the coordination chemistry of the (fluoren-9-ylidene)me-

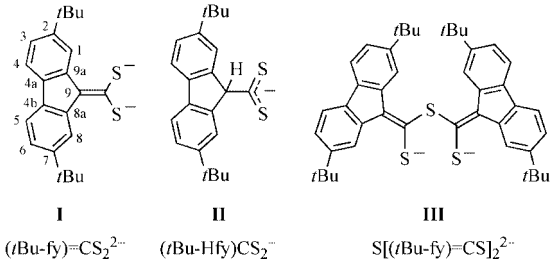
thanedithiolato ligand and its 2,7-disubstituted derivatives. These ligands have revealed remarkable differences with respect to the previously used 1,1-ethylenedithiolates; these differences are largely attributable to the absence of strongly electron-withdrawing substituents and affect the photophysical properties and redox behavior of their metal complexes.[28,29] Given the multiple coordination possibilities and stoichiometries observed for copper/dithiolate systems, we thought it of interest to carry out an initial exploration of the chemistry of copper complexes with (2,7-di-*tert*-butylfluoren-9-ylidene)methanedithiolate [(*t*Bu-fy)=$CS_2^{2-}$ (**I**) Scheme 1], and to study the effects of the strongly electron-donating character of this ligand on their structures and reactivity. In this paper, we describe the preparation of a series of $Cu^{I}$ complexes with 2,7-di-*tert*-butyl-9*H*-fluorene-9-carbodithioate [(*t*Bu-Hfy)$CS_2^-$ (**II**), the protonated precursor of **I**] obtained from the piperidinium salt (pipH)[(*t*Bu-Hfy)$CS_2$] (**1**), which, upon deprotonation in the presence of an oxidizing agent, afford dinuclear complexes with the new ligand S[(*t*Bu-fy)=$CS]_2^{2-}$ (**III**), formally resulting from the condensation of two dithiolates with loss of a sulfide ion and two protons. The direct syntheses of $Cu^{I}$, $Cu^{II}$, and $Cu^{III}$ complexes containing the (*t*Bu-fy)=$CS_2^{2-}$ ligand from **1** and suitable copper precursors are reported.



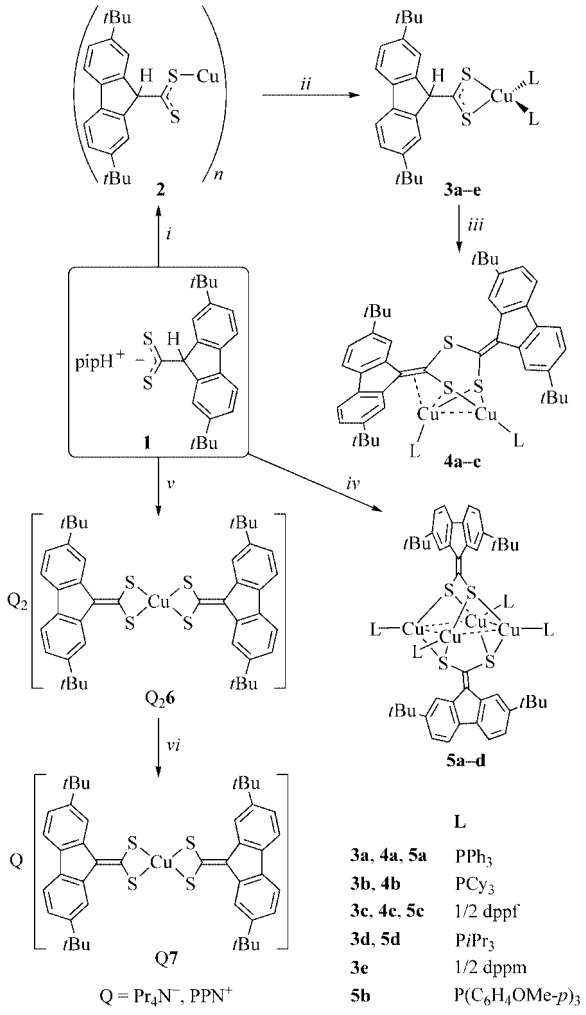
Scheme 1.

## Results and Discussion

### Copper(I) Complexes with the (*t*Bu-Hfy)$CS_2^-$ Ligand

The previously described metal complexes with the (fluoren-9-yliden)methanedithiolato ligand and its 2,7-disubstituted analogs were obtained by treating appropriate metal precursors with the corresponding piperidinium fluorene-9-carbodithioate in the presence of a base. The deprotonation of the dithiolato ligand to form the corresponding dithiolate takes place after its coordination to the metal center, which increases the acidity of the H9 atom on the fluoren-9-yl moiety. In some cases, dithioato complexes have been obtained when the reactions are carried out in the absence of a base.[28] The synthesis of $Cu^{I}$ complexes with (*t*Bu-Hfy)-$CS_2^-$ was undertaken in order to use them as precursors for the preparation of complexes with the dithiolato ligand (*t*Bu-fy)$CS_2^{2-}$.

The reaction of the piperidinium dithioate **1** with $[Cu(NCMe)_4]PF_6$ in a 1:1 molar ratio in MeCN gave the dark brown complex $[Cu_n\{S_2C(tBu\text{-}Hfy)\}_n]$ (**2**; Scheme 2), which precipitated in almost quantitative yield. Complex **2** is scarcely soluble in most organic solvents and all attempts to grow crystals suitable for X ray diffraction studies were unsuccessful. Its $^1H$ NMR spectrum displays only one set of signals for the dithioato ligand, suggesting a highly symmetrical oligomeric structure. A tetrameric structure has been found for the related copper(I) dithioate $[Cu_4(S_2CC_6H_4Me\text{-}p)_4]$[30] (Figure 1, a). Compound **2** was



Scheme 2. (i) $[Cu(NCMe)_4]PF_6$; (ii) 2L; (iii) $NEt_3$, $O_2$ (air) or 1/2 1,4-benzoquinone; (iv) 2 $[Cu(NCMe)_4]PF_6$, 2L, pip; (v) 1/2 $Cu(ClO_4)_2{\cdot}6H_2O$, $(Pr_4N)OH$ or 1/2 $CuCl_2$, PPNCl, pip; (vi) $O_2$ (air).

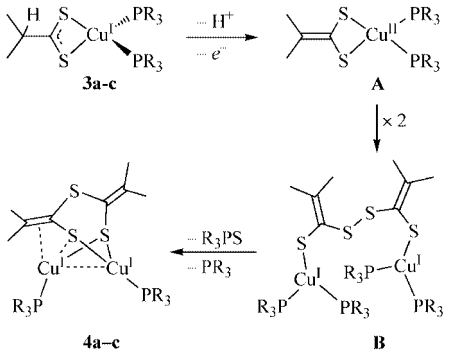
employed as starting material for the preparation of the series of complexes [Cu{$S_2C$(*t*Bu-Hfy)}$L_2$] with L = $PPh_3$ (**3a**), $PCy_3$ (**3b**), P*i*$Pr_3$ (**3d**), or $L_2$ = dppf (**3c**), dppm (**3e**). The products were obtained as salmon-pink or orange solids from the reactions of **2** with the corresponding phosphane (1:2) or diphosphane (1:1) and isolated in moderate to high yields.

### Deprotonation and Oxidation of Dithioato Complexes. Dithiolate Condensation

The deprotonation of the dithioato ligand (*t*Bu-Hfy)$CS_2^-$ in complexes **2** and **3a**–**e** was attempted by using $NEt_3$ as the base. The expected results of these reactions included the formation of anionic clusters. In the case of **3a**–**e**, anionic complexes of the type [Cu{$S_2C$=(*t*Bu-fy)}$(PR_3)_2$]$^-$ were expected as the primary products, since an analogous mononuclear complex with the *i*-mnt ligand has been described.[31] However, complexes **2** and **3a**–**e** were recovered unchanged after treatment with $NEt_3$ in MeCN or THF under an inert atmosphere. A different, unexpected result was obtained when the reactions were carried out in the presence of atmospheric oxygen and moisture. Thus, under these conditions, treatment of **3a** with $NEt_3$ in a 1:1 molar ratio in MeCN led to the gradual formation of a green solution from which a yellowish orange solid precipitated after 4 h. The X-ray structure analysis of a single crystal of this product revealed the formation of the dinuclear complex [$Cu_2${[SC=(*t*Bu-fy)]$_2$S}$(PPh_3)_2$] (**4a**), which contains only one $PPh_3$ per Cu and a new dithiolato ligand that formally results from the condensation of two (*t*Bu-Hfy)$CS_2^-$ ligands with loss of a sulfide ion and two protons (Scheme 2). The yield of **4a** was 67% after recrystallization. The oily residue obtained by evaporation of the supernatant contained $Ph_3P$=S, $Ph_3P$=O, and free $PPh_3$ as the major components, as determined by $^1$H and $^{31}$P NMR spectroscopy. Additionally, a very small amount of the dithiolato complex [$Cu_4${$S_2C$=(*t*Bu-fy)}$_2(PPh_3)_4$] (**5a**; see below) was produced. The formation of **4a** also took place when stirring **3a** in MeCN under aerobic conditions in the absence of $NEt_3$, but the reaction was much slower. It is therefore clear that an oxidant is required for this reaction to take place and that the deprotonation does not require an added base. Finally, the reaction of **3a** with the oxidant base 1,4-benzoquinone in a 2:1 molar ratio was carried out under a nitrogen atmosphere in MeCN at room temperature. Under these conditions, the gradual formation of a yellowish orange precipitate of **4a** was observed within seven hours. The product was isolated in 73% yield after recrystallization and the compounds $Ph_3P$=S, 1,4-hydroquinone, and free $PPh_3$ were identified by $^1$H and $^{31}$P NMR spectroscopy as the major components present in the supernatant.

The analogous complexes [$Cu_2${[SC=(*t*Bu-fy)]$_2$S}$L_2$] with L = $PCy_3$ (**4b**) or $L_2$ = dppf (**4c**) were similarly obtained by stirring suspensions of **3b** or **3c**, respectively, in MeCN in the presence of $NEt_3$ and atmospheric oxygen. The yield of **4b** (75%) was appreciably higher than of **4c** (51%) because of the formation of considerable amounts of the dithiolato complex [$Cu_4${$S_2C$=(*t*Bu-fy)}$_2$(dppf)$_2$] (**5c**; see below). Under the same conditions, compound **2** or the dppm derivative **3e** did not give products of definite composition, while in the case of the P*i*$Pr_3$ derivative **3d** a mixture that contained the corresponding dithiolato complex **5d** as the main component was obtained.

A possible reaction path leading to the formation of **4a**–**c** is outlined in Scheme 3. It is very likely that in the initial steps the deprotonation and oxidation of the dithioato complexes **3a**–**c** to give a $Cu^{II}$ intermediate (**A**) take place, which would account for the green color of the initial reaction mixtures. This species can be considered an oxidized analog of the reported $Cu^{I}$ complex [Cu(*i*-mnt)$(PR_3)_2$]$^-$.[31] It is well known that the combination of $Cu^{II}$ with thiolates usually results in reduction to $Cu^{I}$ and formation of disulfides.[10,32,33] Such a process would cause intermediate **A** to dimerize and form a disulfide-bridged dinuclear species such as **B**, which would subsequently undergo sulfur abstraction by one of the phosphanes to give the final monosulfide-bridged dithiolate. Tetraalkylthiuram disulfides $R_2NC(S)SSC(S)NR_2$ have been reported to undergo a similar reaction when treated with $Cu^{I}$ halides in the presence of $PPh_3$, which leads to the formation of complexes containing the corresponding monosulfide $R_2NC(S)SC(S)NR_2$.[34] The formation of the condensed ligand in **4a**–**c** is also related to the well-established reactions of organic disulfides with phosphanes, which afford thioethers and phosphane sulfide, although they usually require more vigorous reaction conditions, such as refluxing in high boiling point solvents.[35–37]



Scheme 3. Proposed reaction path for the formation of **4a**–**c** from **3a**–**c**. *t*Bu-fy groups have been omitted for clarity.

In contrast, similar sulfide-bridged dithiolato ligands have not been produced from previously described dithioato complexes of the type [Cu($S_2$CR)$(PR'_3)_2$] containing a hydrogen atom in the β position, such as those with R = Me,[38] or CH=C(OH)$C_6H_4$Me-*p*.[39] Both the presence of the relatively acidic H9 hydrogen atom in (*t*Bu-Hfy)$CS_2^-$ and the electron-donating ability of (*t*Bu-fy)=$CS_2^{2-}$ appear to be crucial for the initial deprotonation/oxidation steps leading to **4a**–**c**.

### Copper(I) Complexes with the (*t*Bu-fy)=$CS_2^{2-}$ Ligand and Phosphanes

The neutral $Cu^I$ complexes $[Cu_4\{S_2C=(tBu\text{-}fy)\}_2L_4]$ [L = $PPh_3$ (**5a**), $P(C_6H_4OMe\text{-}p)_3$ (**5b**) and $PiPr_3$ (**5d**) or $L_2$ = dppf (**5c**)] were obtained by treating **1** with $[Cu(NCMe)_4]PF_6$, the corresponding phosphane, and piperidine in a 1:2:2:1 molar ratio in MeCN (Scheme 2). The products precipitate in this solvent as bright yellow (**5a**,**b**,**d**) or yellowish orange (**5c**) microcrystalline solids and can be isolated in moderate to high yields. Compounds **5a**–**d** display a moderate stability in solution, which depends on the phosphane; thus, the $PiPr_3$ complex **5d** is the least stable and decomposes in $CDCl_3$ within 2 h, while the $CDCl_3$ solutions of the $P(C_6H_4OMe\text{-}p)_3$ complex **5b** are stable for more than 24 h. The preparation of analogous complexes with $PCy_3$ or dppm did not succeed under similar conditions, probably because of their lower stabilities.

The structures of **5a**–**d** could not be determined by X-ray diffraction studies because the crystals were not of sufficient quality or presented severe twinning problems. However, their composition and the copper/dithiolate/phosphane ratio were unambiguously determined by means of elemental analyses and $^1H$ NMR spectroscopy (see Experimental Section for details). The $^1H$, $^{13}C$, and $^{31}P$ NMR spectroscopic data are consistent with highly symmetrical structures containing equivalent dithiolato ligands and phosphanes. Given the preference of $Cu^I$ for a trigonal planar or tetrahedral coordination geometry and its tendency to form high nuclearity thiolato complexes with extensive cuprophilic interactions, a dinuclear formulation for **5a**–**d** is unlikely. Evidence for a tetranuclear formulation was obtained from their positive-ion FAB mass spectra. The tetranuclear $[M^+]$ ions are observed with very low relative abundances for **5b** ($m/z$ = 2368) and **5c** ($m/z$ = 2068). Heavier ions are not observed, except for the $[M + Cu]^+$ ions. All four complexes undergo very extensive fragmentations in FAB, which result in the loss of phosphane ligands and $CuL^+$ units and/or the cleavage of C–S bonds to form sulfide complexes, most of which are tetranuclear. Significantly abundant fragments that support the tetranuclear formulation are $[Cu_4\{S_2C=(tBu\text{-}fy)\}_2L_3]^+$ for **5b**, $[Cu_4S\{S_2C=(tBu\text{-}fy)\}L]^+$ and $[Cu_4S\{S_2C=(tBu\text{-}fy)\}_2L]^+$ for **5a**,**b**, $[Cu_4\{S_2C=(tBu\text{-}fy)\}_2L]^+$ and $[Cu_4\{S_2C=(tBu\text{-}fy)\}_2]^+$ for **5a**,**d**, and $[Cu_4S\{S_2C=(tBu\text{-}fy)\}(dppf)_2]^+$ for **5c** (see Supporting Information). Tetranuclear structures have been found for the related complexes $[M_4(cpdt)_2(dppm)_4]$ (M = Cu[23] and Ag[40]), $[Ag_4(i\text{-}mnt)_2(dppm)_4]$,[41] and $[Cu_4(CS_3)_2(dppm)_4]$,[42] which have their metal atoms in a nearly planar arrangement and the dithiolato ligands acting as bridging tetradentate ligands above and below the $M_4$ core (Figure 1, b). The structures of **5a**–**d** probably have similar $Cu_4S_4$ cores but with four phosphane groups instead of eight (Scheme 2), which would be consistent with their NMR spectroscopic data.

Complexes **5a**–**d** are luminescent at room temperature in the solid state and also in solution at 77 K. Their excitation and emission properties are currently under investigation and a complete study will be reported elsewhere.

### Copper(II) and Copper(III) Complexes with the (*t*Bu-fy)=$CS_2^{2-}$ Ligand

The poorly soluble $Cu^{II}$ complex $(Pr_4N)_2[Cu\{S_2C=(tBu\text{-}fy)\}_2]$ [$(Pr_4N)_2$**6**] precipitated as a brown solid upon treatment of the dithioate **1** with $Cu(ClO_4)_2{\cdot}6H_2O$ and $(Pr_4N)OH$ in a 2:1:2 molar ratio in MeCN under an inert atmosphere, (Scheme 2). Although [$(Pr_4N)_2$**6**] is air stable in the solid state, it is slowly oxidized by atmospheric oxygen to the $Cu^{III}$ complex $[Cu\{S_2C=(tBu\text{-}fy)\}_2]^-$ (**7**) when suspended in MeCN or $CH_2Cl_2$. Thus, the green salt $Pr_4N$**7** was obtained almost quantitatively by bubbling air through an MeCN suspension of $(Pr_4N)_2$**6**. Alternatively, $Pr_4N$**7** was obtained in high yield when the reaction of **1** with $Cu(ClO_4)_2{\cdot}6H_2O$ and $(Pr_4N)OH$ was carried out under atmospheric conditions. The salt PPN**7** was similarly obtained from **1**, $CuCl_2{\cdot}2H_2O$, PPNCl, and piperidine in a 2:1:1:2 molar ratio. The only previously reported $Cu^{III}$ complex with a 1,1-ethylenedithiolato ligand is $[Cu(ded)_2]^-$, which was prepared from the oxidation of $[Cu(ded)_2]^{2-}$ with $H_2O_2$, $I_2$, or $Cu^{2+}$ ions.[25,26] In comparison, the formation of the $Cu^{III}$ complex **7** takes place under milder conditions and represents an uncommon example of aerobic oxidation of a $Cu^{II}$ complex. We have previously observed that the (fluoren-9-ylidene)methanedithiolato ligand and its 2,7-disubstituted derivatives facilitate the oxidation of $Au^I$ to $Au^{III}$ [28] and $Pt^{II}$ to $Pt^{IV}$,[29] which can be attributed to their stronger electron-donating character as compared with other, more commonly studied 1,1-ethylenedithiolato ligands.

### Crystal Structures of the Complexes

The crystal structures of **3a** (Figure 2), **3c**·$CH_2Cl_2$ (Figure 3), **4a**·$4Me_2CO$ (Figure 4), and **4c**·$CH_2Cl_2$ (Figure 5) were solved by X-ray diffraction studies. Selected bond lengths and angles are listed in Tables 1, 2, and 3. The molecular structures of **3a** and **3c** show the copper atom in a distorted tetrahedral environment. The main distortion originates from the constraints imposed by the four-membered chelate ring, which lead to S–Cu–S angles of 74.48(2)° (**3a**) and 74.38(3)° (**3c**). The steric hindrance of the $PPh_3$ ligands leads to a relatively wide P(1)–Cu–P(2) angle of 129.25(3)° in **3a**. The chelating dppf ligand in **3c** adopts a staggered conformation leading to a bite angle of 112.76(4)°, which is closer to the ideal value for a tetrahedral geometry. Similar coordination environments around the Cu atom and Cu–S bond lengths have been found in the analogous dithioato complexes $[Cu(S_2CR)(PPh_3)_2]$ [R = Me,[38] Ph,[43] *p*-To,[30] $C_5Me_5$[44] $CO_2Me$[45] and $CH{=}C(OH)C_6H_4Me\text{-}p$].[39]

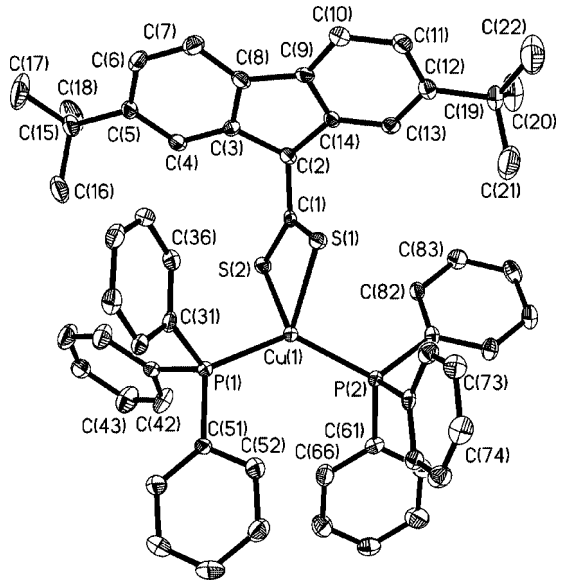

Figure 2. Thermal ellipsoid plot (50% probability) of complex **3a**. H atoms have been omitted for clarity.

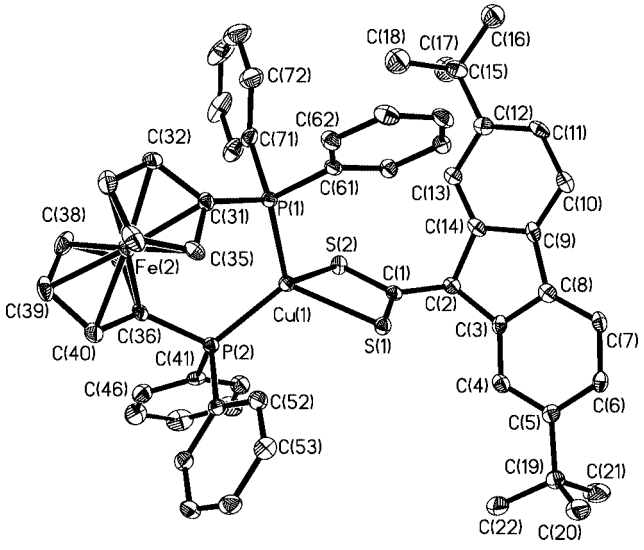

Figure 3. Thermal ellipsoid plot (50% probability) of complex **3c**. H atoms have been omitted for clarity.

Complexes **4a** and **4c** exhibit essentially the same structural arrangement for the $Cu_2\{[SC=(t\text{Bu-fy})]_2S\}$ unit as the condensed dithiolato ligand coordinates to the two copper atoms in different ways. The atom Cu(1) is bonded to the two terminal sulfur atoms S(1) and S(2) and one $PPh_3$ ligand (or one of the $PPh_2$ units of dppf), resulting in a slightly distorted trigonal planar geometry, whereas the atom Cu(2) is attached to the other $PPh_3$ ligand or the second $PPh_2$ unit, and to the dithiolato ligand through the C(29)=C(30) double bond and the terminal S(1) atom, which thus bridges the two copper atoms. The coordination around Cu(2) is also trigonal planar if we consider the atoms S(1), P(1), and the C(29)=C(30) bond centroid. The Cu(1)–S(2) and Cu(2)–S(1) bond lengths are very similar [range 2.2156(10)–2.2659(9) Å] and slightly shorter than the

C(29)=C(30) bond centroid of 2.056 (**4a**) or 2.072 Å (**4c**) is close to the upper limit of the range found for the majority of alkene complexes of copper(I) in the Cambridge Structural Database (1.840–2.110 Å).[46] The bond length of the uncoordinated C(9)=C(10) double bond [1.360(4) (**4a**) or 1.369(5) Å (**4c**)] is similar to the corresponding distances found for 1,1-ethylenedithiolato ligands,[28] which are usually close to the higher limit of the range found for C(sp$^2$)=C(sp$^2$) double bonds (1.294–1.392 Å),[47] whereas the C(29)–C(30) distance of 1.401(4) (**4a**) or 1.396(5) Å (**4c**) is slightly longer, as expected for a coordinated C=C bond. The Cu(1)–Cu(2) distance of 2.6999(5) (**4a**) or 2.7568(6) Å (**4c**) is slightly shorter than the sum of the van der Waals radii for Cu (2.80 Å[48]) and typical of the cuprophilic interactions found in numerous di- or polynuclear copper(I) complexes with bridging thiolato ligands.[49–53] The planes S(1)–C(10)–S(3) and S(3)–C(30)–S(2) form an angle of 75° (**4a**) or 77° (**4c**). The fluoren-9-ylidene fragments are nearly planar, with their respective mean planes being perpendicular to each other [89° (**4a**) or 90° (**4c**)] and slightly rotated with respect to the corresponding S–C–S planes. The dppf ligand in **4c** adopts an eclipsed conformation, with the P(1)–C(81) and P(2)–C(86) bonds rotated by 79° with respect to each other. This results in a large distance between both phosphorus atoms (5.275 Å) and allows the flexible dppf ligand to bridge the copper atoms in such a way that the $PPh_2$ groups occupy the same positions as the two independent $PPh_3$ ligands in **4a** (P···P = 5.438 Å).

## NMR Spectra

The $^1$H and $^{13}$C{$^1$H} NMR spectra of complexes **2** and **3a**–**e** show one set of signals for the protons and carbon atoms of the dithioato ligand, which are slightly modified with respect to those of the free dithioate **1**,[54] with the 9-H resonance in the range $\delta$ = 5.35–5.68 ppm and the *C*S$_2$ resonance in the range $\delta$ = 251.5–259.3 ppm. On the basis of these data, complex **2** most probably has a highly symmetrical oligomeric structure (see above).

The crystal structures of **4a** and **4c** show that the condensed ligand contains two *t*Bu-fy groups in different environments. Because the rotation around the C9=CS$_2$ double bonds is expected to be hindered at room temperature, the two halves of each of these groups are not equivalent. Therefore, if their solid-state structures were retained in solution, the $^1$H and $^{13}$C{$^1$H} NMR spectra of **4a**–**c** should display the resonances corresponding to four different *t*Bu groups, four sets of signals for the aromatic H and C atoms, and two signals for both the C9 and CS$_2$ atoms. Additionally, two different resonances should be expected in the $^{31}$P NMR spectra. However, the $^1$H, $^{13}$C{$^1$H}, and $^{31}$P{$^1$H} NMR spectra of **4a**–**c** reveal that the *t*Bu-fy groups are equivalent in solution, as are the two $PPh_3$ or $PCy_3$ ligands in **4a**,**b** or the $PPh_2$ groups of the dppf ligand in **4c**. Thus, the $^1$H NMR spectra show only two singlets for the *t*Bu groups and two sets of resonances for the aromatic protons; the two signals corresponding to the 1-H and 8-H atoms are considerably downfield-shifted, as is the case for coordinated (fluoren-9-ylidene)methanedithiolato ligands,[28] and also the most affected by the lack of symmetry of the *t*Bu-fy groups, appearing at very different chemical shifts (ranges $\delta$ = 9.61–9.71 and 8.55–8.69 ppm, respectively). The $^{13}$C{$^1$H} NMR spectra show two sets of resonances for the carbon atoms of the ligand except for the C-9 and CS$_2$ atoms, each of which gives rise to only one resonance; the CS$_2$ resonance appears as a slightly broad signal for **4a**,**b**, but in the case of **4c** resolves as a triplet because of coupling with two equivalent phosphorus atoms. The $^{31}$P NMR spectra show a relatively broad singlet. The dppf ligand in **4c** gives rise to six multiplets in the room temperature $^1$H NMR spectrum corresponding to the two inequivalent Ph rings of each $PPh_2$ group, and four broad resonances corresponding to the protons of the two equivalent Cp rings. This means that the diphosphane is essentially rigid in solution and does not undergo the fluxional process observed in **5c** (see below) and other metal complexes with bridging dppf,[55–60] which involves a conformation change leading to the equivalence of the phenyl groups and the two $H_\alpha$ and $H_\beta$ atoms of the Cp rings on the NMR timescale. The absence of any dynamic process affecting the dppf ligand was further confirmed by a variable-temperature NMR study of **4c**, which revealed no changes in the $^1$H and $^{31}$P resonances arising from this diphosphane between –65 and +50 °C in $CDCl_3$.

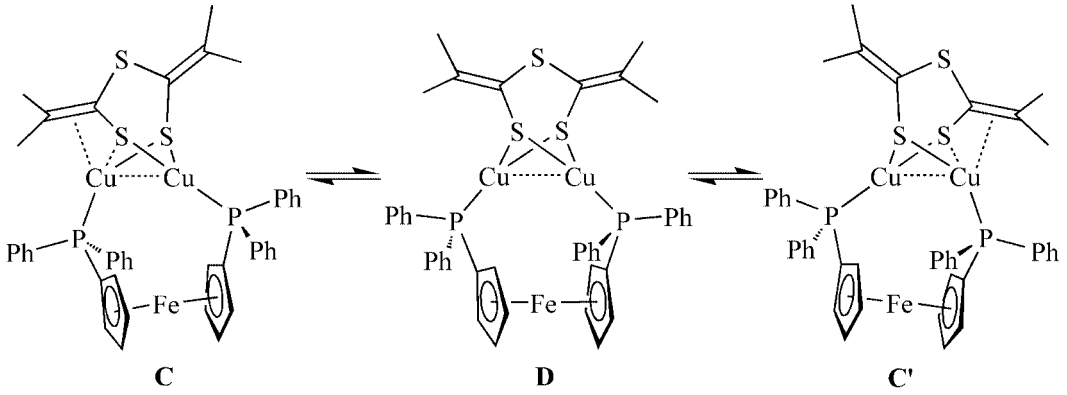

Scheme 4. *t*Bu-fy groups have been omitted for clarity.

In view of these observations, the two possible explanations for the NMR spectroscopic data of **4a**–**c** are: (*i*) the existence of a dynamic process mainly affecting the $Cu_2\{[SC=(t\text{Bu-fy})]_2S\}$ unit that causes the copper atoms to interchange their coordination environments, or (*ii*) a different, symmetrical structure of the complexes in solution. The possible dynamic process is represented in Scheme 4 for **4c**. The transition from the solid state form **C** (or its equivalent **C**′) to the intermediate, $C_2$-symmetrical form **D** requires only minor rearrangements of the molecules involving the rupture of the relatively weak coordination of C(29)=C(30) to Cu(2) and the strengthening of the Cu(2)–S(2) interaction to form a symmetrical bridge, while retaining the conformation of the dppf ligand. However, the $^1H$ and $^{31}P$ NMR spectra of **4a**–**c** show that the signals arising from the condensed ligand and the phosphorus atoms do not split, even at –90 °C in $CD_2Cl_2$, which could be due to a very low activation energy and/or to negligible differences in the chemical shifts of the H nuclei of the inequivalent *t*Bu-fy groups (or the P nuclei of the phosphanes) in form **C**. The possibility that the actual structure in solution is form **D** would also be consistent with the experimental observations; in this case, the arrangement found in the solid-state structures would most probably be a consequence of packing forces in the crystals.

The $^1H$ and $^{13}C\{^1H\}$ NMR spectra of complexes **5a**–**d** display very similar sets of resonances for the protons and carbon atoms of the $(t\text{Bu-fy})=CS_2^{2-}$ ligand, which indicate that all of them have similar structures with equivalent and symmetrical dithiolates. The resonances of the 1-H and 8-H atoms are typically downfield-shifted (range $\delta$ = 9.37–9.54 ppm). The resonances of the Ph and Cp protons of the dppf ligand in **5c** are observed as broad signals at room temperature, suggesting fluxional behavior. At –40 °C, the Cp resonances resolve into four signals, while the Ph rings give rise to five broad signals, indicating that the two Cp rings and $PPh_2$ groups of each dppf are equivalent, while the two Ph rings of each $PPh_2$ group are not. The fluxional behavior of a bridging dppf ligand has been observed previously and thoroughly described for other di- or polynuclear complexes.[55–60] The opposite twisting of the two halves of the ferrocene fragment around the Cp centroid–centroid axis, together with the concerted twist around the P–$C_{ipso(Cp)}$ and P–Cu bonds, causes the two $H_\alpha$ and $H_\beta$ atoms and the Ph rings on each $PPh_2$ group to exchange their positions. The resonances of the protons of the dithiolato ligands in **5c** remain practically unchanged between –40 and 25 °C.

The $^1H$ NMR spectrum of the $Cu^{II}$ complex $(Pr_4N)_2$**6** in $CDCl_3$ shows broad signals for the $Pr_4N^+$ cation, while the resonances corresponding to the ligand protons are not observed, which can be attributed to its paramagnetic nature. The $^1H$ and $^{13}C$ NMR spectroscopic data of the Q**7** salts (Q = $Pr_4N^+$, $PPN^+$) are fully consistent with a square-planar structure. The chemical shifts of the H and C resonances of the dithiolato ligand are very similar to those observed for the analogous $Au^{III}$ complex.[28]

## IR Spectra

The solid-state infrared spectrum of the dithioato complex **2** displays one band at 975 $cm^{-1}$ assignable to one of the two $\nu(CS_2)$ modes,[43] while for the phosphane complexes **3a**–**e** the corresponding absorption appears around 1010 $cm^{-1}$. The dinuclear complexes **4a**–**c** give rise to one band associated with the $C=CS_2$ double bonds at around 1500 $cm^{-1}$. The expected $\nu(C=CS_2)$ band[61] arising from the $(t\text{Bu-fy})=CS_2^{2-}$ ligand in complexes **5a**–**d** occurs in the range 1482–1490 $cm^{-1}$, while for the $Cu^{II}$ complex $(Pr_4N)_2$**6** it is observed at 1480 $cm^{-1}$ and for the $Cu^{III}$ salts Q**7** at 1548 ($Pr_4N^+$) or 1552 $cm^{-1}$ ($PPN^+$). We have previously shown that the variations in the energies of the $\nu(C=CS_2)$ bands can be attributed to the oxidation state of the metal center and the nature of the ligands attached to it, which affect the strength of the $\pi$ component of the $C=CS_2$ bond.[28] Usually, a higher oxidation state and/or the presence of weaker donor ligands increase the energy of the $\nu(C=CS_2)$ band, which is consistent with the high energy observed for the $Cu^{III}$ complex. The spectra of the salts Q**7** also show one intense band at 416 ($Pr_4N^+$) or 420 $cm^{-1}$ ($PPN^+$) assignable to the $\nu$(Cu–S) mode.

### Electronic Absorption Spectra

The UV/Visible absorption spectra of compounds **2**–**7** were measured in the range 200–700 nm in $CH_2Cl_2$ at 298 K. All of them display the bands arising from the aromatic part of the dithioato or dithiolato ligands at around 230, 260–270 and 300 nm.[28] The bands above 300 nm are listed in Table 4. The low intensity band centered at about 360 nm for dithioato complexes **3a**–**d** is probably the result of the modification of the band observed for the free dithioate **1b** at 346 nm, which arises from n–π* transitions within the $CS_2^-$ group. In the case of **3e** ($L_2$ = dppm) this band appears at 391 nm. The spectrum of compound **2** shows two very broad bands at 393 and 438 nm, which are probably also related to these transitions.

Table 4. Electronic absorption data for compounds **2**–**7** in $CH_2Cl_2$ solution (ca. $5\times10^{-5}$ M) at 298 K ($\lambda > 300$ nm).

| Compound | $\lambda$ [nm] ($\varepsilon$ [$M^{-1}cm^{-1}$]) |
|---|---|
| **2** | 393, 438[a] |
| **3a** | 353 (5200) |
| **3b** | 360 (6000) |
| **3c** | 356 (6800) |
| **3d** | 357 (6100) |
| **3e** | 391 (4100) |
| **4a** | 369 (20900), 409 (24600), 467 (sh, 9000) |
| **4b** | 372 (sh, 20700), 407 (22700), 500 (sh, 7800) |
| **4c** | 367 (19800), 403 (29100), 452 (sh, 9300) |
| **5a** | 415 (sh, 36300), 435 (42200) |
| **5b** | 418 (sh, 36900), 440 (48000) |
| **5c** | 411 (sh, 31700), 442 (37400) |
| **5d** | 423 (sh, 63800), 442 (76800) |
| $(Pr_4N)_2$**6** | 399 (36800), 430 (62500) |
| $Pr_4N$**7** | 376 (16200), 397 (43600), 451 (64100) |
| PPN**7** | 377 (29900), 397 (51300), 451 (67100) |

[a] Accurate concentration and $\varepsilon$ values could not be measured for this compound because of its very low solubility.

The absorptions of complex **4a** above 300 nm occur as broad, medium-intensity bands at 369 and 409 nm, with a shoulder at 467 nm. The analogous complexes **4b** and **4c** show a very similar pattern. The probable origins of these bands are intraligand transitions associated with the $C{=}CS_2$ units and ligand-to-metal charge-transfer transitions (LMCT), which are usually observed in this region for $Cu^I$ complexes with sulfur donor ligands.[62]

The spectra of the dithiolato complexes **5a**–**d** display a very intense absorption band at around 440 nm, with a shoulder on the higher energy slope between 411 and 420 nm. Very similar absorptions have been observed for neutral $Au^I$–phosphane complexes containing the (fluoren-9-yliden)methanedithiolato ligand or its substituted derivatives (415 nm), which are assignable to LMCT transitions.[28]

The absorption spectra of the $Cu^{III}$ salts Q**7** are almost identical and show two medium intensity bands at 377 and 397 nm and a very intense band at 450 nm. The two higher energy bands appear with very little differences from those in the spectra of other square-planar $Au^{III}$ and $Pt^{II}$ complexes containing the ($t$Bu-fy)$=CS_2^{2-}$ ligand and can be assigned to intraligand transitions associated with the $C{=}CS_2$ unit. The lowest-energy band can be assigned to a metal-to-ligand charge-transfer (MLCT) transition by analogy with other isoelectronic bis(dithiolato) complexes.[24] The $Au^{III}$ and $Pt^{II}$ complexes with the same dithiolato ligand show this band at 410[28] or 490 nm,[29] respectively. The absorption spectrum of the $Cu^{II}$ complex $(Pr_4N)_2$**6** is similar to those of the Q**7** salts, except for the lowest-energy band, which is observed at 430 nm.

## Conclusions

The series of complexes [Cu{$S_2C$($t$Bu-Hfy)}$L_2$] [L = $PPh_3$ (**3a**), $PCy_3$ (**3b**), P$i$Pr$_3$ (**3d**); $L_2$ = dppf (**3c**), dppm (**3e**)] were prepared by the reaction of the oligomeric compound [$Cu_n${$S_2C$($t$Bu-Hfy)}$_n$] (**2**) with different P ligands. Compounds **3a**–**c** react with atmospheric oxygen in the presence of $NEt_3$ to give the dinuclear complexes [$Cu_2${[SC=($t$Bu-fy)]$_2$-S}$L_2$] [L = $PPh_3$ (**4a**), $PCy_3$ (**4b**); $L_2$ = dppf (**4c**)], containing a novel, sulfide-bridged dithiolato ligand, formally resulting from the condensation of two dithioato ligands with loss of a sulfide ion and two protons. The proposed reaction path for the formation of **4a**–**c** involves the initial deprotonation and oxidation of **3a**–**c**, the formation of a disulfide-bridged dinuclear species and the subsequent sulfur abstraction by one of the phosphane ligands. The first family of Cu complexes with the (2,7-di-*tert*-butylfluoren-9-ylidene)-methanedithiolato ligand has been prepared, including a series of $Cu^I$ complexes of the type [$Cu_4${$S_2C$=($t$Bu-fy)}$_2L_4$] [L = $PPh_3$ (**5a**), P($C_6H_4$OMe-$p$)$_3$ (**5b**), P$i$Pr$_3$ (**5d**) or $L_2$ = dppf (**5c**)] and salts of the $Cu^{II}$ complex [Cu{$S_2C$=($t$Bu-fy)}$_2$]$^{2-}$ (**6**) and the $Cu^{III}$ complex [Cu{$S_2C$=($t$Bu-fy)}$_2$]$^-$ (**7**).

## Experimental Section

**General Considerations, Materials, and Instrumentation:** All reactions were carried out at room temperature under an atmosphere of nitrogen using Schlenk techniques, except in the cases indicated. Solvents were dried by standard methods and distilled under nitrogen before use. The compounds [Cu(NCMe)$_4$]$PF_6$ [63] and (pipH)[($t$Bu-Hfy)$CS_2$][54] (**1**) were prepared following published procedures. All other reagents were obtained from commercial sources and used without further purification. NMR spectra were recorded on Bruker Avance 200, 300, or 400 spectrometers at 298 K, unless otherwise indicated. Chemical shifts are referenced to internal TMS ($^1$H and $^{13}$C{H}) or external 85% $H_3PO_4$ ($^{31}$P{H}). The assignments of the $^1$H and $^{13}$C{H} NMR spectra were made with the help of HMBC and HSQC experiments. Scheme 1 shows the atom numbering of the dithiolato ligand. Melting points were determined on a Reichert apparatus and are uncorrected. Elemental analyses were carried out with a Carlo Erba 1106 microanalyzer. Infrared spectra were recorded in the range 4000–200 $cm^{-1}$ on a Perkin–Elmer 16F PC FT-IR spectrophotometer as Nujol mulls between polyethylene sheets or KBr pellets. UV/Visible absorption spectra were recorded on an Unicam UV500 spectrophotometer. FAB mass spectra were recorded on a VG Autospec 500 mass spectrometer using 3-nitrobenzyl alcohol as matrix.

**[$Cu_n${$S_2C$($t$Bu-Hfy)}$_n$] (2):** Dithioate **1** (473 mg, 0.99 mmol) was added to a solution of [Cu(NCMe)$_4$]$PF_6$ (359 mg, 0.96 mmol) in MeCN (20 mL). An immediate reaction was observed, with forma-

**[Cu{$S_2$C(*t*Bu-Hfy)}(P*i*Pr$_3$)$_2$] (3d):** P*i*$Pr_3$ (167 μL, 0.88 mmol) was added to a suspension of **2** (182 mg, 0.44 mmol) in MeOH (8 mL) and the mixture was stirred for 2 h. A salmon-pink precipitate formed, which was filtered off, washed with methanol (2×2 mL), and vacuum-dried to give **3d**. Yield: 269 mg (84%), m.p. 110 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1012 $cm^{-1}$ ($CS_2$). $^1H$ NMR (400.9 MHz, $CDCl_3$): $\delta$ = 7.72 (s, 2 H, 1-H, 8-H), 7.58 (d, $^3J_{H,H}$ = 7.9 Hz, 2 H, 4-H, 5-H), 7.36 (d, $^3J_{H,H}$ = 7.9 Hz, 2 H, 3-H, 6-H), 5.46 (s, 1 H, 9-H), 2.13 (m, 6 H, C*H*$Me_2$), 1.35 (s, 18 H, *t*Bu), 1.22 (m, 36 H, CH*Me*$_2$) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CDCl_3$): $\delta$ = 252.8 ($CS_2$), 149.1 (C-2, C-7), 145.9 (C-8a, C-9a), 138.4 (C-4a, C-4b), 124.4 (C-3, C-6), 122.1 (C-1, C-8), 118.7 (C-4, C-5), 72.4 (C-9), 34.9 (*C*$Me_3$), 31.6 (C*Me*$_3$), 23.6 (*C*H$Me_2$), 20.1 (CH*Me*$_2$) ppm. $^{31}P\{^1H\}$ NMR (162.3 MHz, $CDCl_3$): $\delta$ = 21.93 ppm. $C_{40}H_{67}CuP_2S_2$ (737.60): calcd. C 65.14, H 9.16, S 8.69; found: C 65.01, H 9.23, S 8.56.

**[Cu{$S_2$C(*t*Bu-Hfy)}(dppm)] (3e):** This orange compound was prepared as described for **3c**, from **2** (262 mg, 0.63 mmol) and bis(diphenylphosphanyl)methane (251 mg, 0.65 mmol). Yield: 415 mg (82%), m.p. 151 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1010 $cm^{-1}$ ($CS_2$). $^1H$ NMR (400.9 MHz, $CDCl_3$): $\delta$ = 7.70 (br., 2 H, 1-H, 8-H), 7.59 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, 4-H, 5-H), 7.35 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, 3-H, 6-H), 7.20 (br. m, 8 H, *o*-H, Ph), 7.13 (br. m, 4 H, *p*-H, Ph), 6.96 (br. m, 8 H, *m*-H, Ph), 5.61 (s, 1 H, 9-H), 3.00 (s, 2 H, $CH_2$), 1.23 (s, 18 H, *t*Bu) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CDCl_3$): $\delta$ = 256.1 ($CS_2$), 149.3 (C-2, C-7), 145.8 (C-8a, C-9a), 141.8 (C-4a, C-4b), 138.4 (C-1, Ph), 135.0 (C-2, C-6 Ph), 129.1 (C-4, Ph), 128.1 (C-3, C-5, Ph), 124.2 (C-3, C-6), 122.4 (C-1, C-8), 118.7 (C-4, C-5), 71.4 (C-9), 34.8 (*C*$Me_3$), 31.6 (C*Me*$_3$) ($CH_2$ of dppm not observed) ppm. $^{31}P\{^1H\}$ NMR (162.3 MHz, $CDCl_3$): $\delta$ = –12.42 ppm. $C_{47}H_{47}CuP_2S_2$ (801.52): calcd. C 70.43, H 5.91, S 8.00; found C 70.18, H 6.21, S 7.76.

**[$Cu_2${[SC=(*t*Bu-fy)]$_2$S}($PPh_3$)$_2$] (4a). Method A:** $NEt_3$ (22 μL, 0.17 mmol) was added to a suspension of **3a** (160 mg, 0.17 mmol) in MeCN (10 mL) and the mixture was stirred under atmospheric conditions for 4 h. The poorly soluble starting material slowly reacted to give a green solution, from which a yellowish orange solid gradually precipitated. The suspension was cooled to –15 °C and the solid collected by filtration and washed with cold MeCN (3×4 mL). Recrystallization from $CH_2Cl_2$/MeCN gave orange crystals of **4a**, which turned red upon drying under vacuum. Yield: 76 mg (67%).

**Method B:** A solid mixture of **3a** (203 mg, 0.22 mmol) and 1,4-benzoquinone (12 mg, 0.11 mmol) was suspended in MeCN (10 mL) and stirred for 7 h under an atmosphere of nitrogen. The reaction took place gradually to give a yellowish orange precipitate, which was isolated and purified as described for method A to give red crystals of **4a**. Yield: 104 mg (73%), m.p. 145 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1506 $cm^{-1}$ (C=$CS_2$). $^1H$ NMR (400.9 MHz, $CDCl_3$): $\delta$ = 9.64, 8.66 (both d, $^4J_{H,H}$ = 1.4 Hz, 2 H each, 1-H, 8-H), 7.48, 7.40 (both d, $^3J_{H,H}$ = 8.0 Hz, 2 H each, 4-H, 5-H), 7.24–7.16 (m, 10 H, 3-H, 6-H + C-4, Ph), 7.06 (m, 12 H, C-2, C-6, Ph), 6.94 (m, 12 H, C-3, C-5, Ph), 1.25, 1.14 (both s, 18 H each, *t*Bu) ppm. $^{13}C\{^1H\}$ NMR (75.45 MHz, $CDCl_3$): $\delta$ = 148.9, 148.8 (C-2, C-7), 140.1, 139.1 (C-8a, C-9a), 138.8 (br., $CS_2$), 136.4, 136.2 (C-4a, C-4b), 133.5 (d, $^2J_{C,P}$ = 15.0 Hz, C-2, C-6, Ph), 132.0 (C-9), 130.9 (d, $^1J_{C,P}$ = 38.4 Hz, C-1, Ph), 129.8 (C-4, Ph), 128.4 (d, $^3J_{C,P}$ = 10.0 Hz, C-3, C-5, Ph), 123.8, 123.7, 123.0, 122.9 (C-1, C-8, C-3, C-6), 118.1, 117.9 (C-4, C-5), 34.9, 34.8 (*C*$Me_3$), 31.6, 31.4 (C*Me*$_3$) ppm.

$^{31}P\{^1H\}$ NMR (162.3 MHz, $CDCl_3$): $\delta$ = 7.38 ppm. $C_{80}H_{78}Cu_2P_2S_3$ (1324.7): calcd. C 72.53, H 5.94, S 7.26; found C 72.56, H 5.88, S 7.03.

**$[Cu_2\{[SC=(tBu\text{-}fy)]_2S\}(PCy_3)_2]$ (4b):** $NEt_3$ (30 μL, 0.24 mmol) was added to a suspension of **3b** (215 mg, 0.22 mmol) in MeCN (8 mL) and the mixture was stirred under atmospheric conditions for 4 h. A red precipitate gradually formed, which was filtered off and washed with MeCN (3×4 mL). The crude product was recrystallized from $CH_2Cl_2$/MeCN and vacuum-dried to give **4b** as a red microcrystalline solid. Yield: 113 mg (75%), m.p. 134 °C (dec.). IR (KBr): $\tilde{\nu}$ = 1498, 1486 $cm^{-1}$ (C=$CS_2$). $^1H$ NMR (400.9 MHz, $CDCl_3$): $\delta$ = 9.61, 8.55 (both d, $^4J_{H,H}$ = 1.5 Hz, 2 H each, 1-H, 8-H), 7.61, 7.57 (both d, $^3J_{H,H}$ = 8.0 Hz, 2 H each, 4-H, 5-H), 7.33, 7.20 (both dd, $^3J_{H,H}$ = 8.0 Hz, $^4J_{H,H}$ = 1.5 Hz, 2 H each, 3-H, 6-H), 1.67 (br. m, 6 H, CH, Cy), 1.60 (br. m, 24 H, $CH_2$, Cy), 1.42, 1.19 (both s, 18 H each, *t*Bu), 1.16–0.99 (br. m, 36 H, $CH_2$, Cy) ppm. $^{13}C\{^1H\}$ NMR (75.45 MHz, $CDCl_3$): $\delta$ = 148.9, 148.7 (C-2, C-7), 140.9 (C-8a, C-9a), 140.6 (br., $CS_2$), 139.5 (C-8a, C-9a), 136.5, 135.8 (C-4a, C-4b), 131.7 (C-9), 123.8, 123.5, 122.9, 122.5 (C-1, C-8, C-3, C-6), 117.9, 117.8 (C-4, C-5), 35.1, 34.9 (*C*$Me_3$), 32.1 (d, $^1J_{C,P}$ = 16.8 Hz, C-1, Cy), 31.8, 31.6 (C*Me*$_3$), 30.1 (vdd, *N* = 44.1 Hz, C-2, C-6, Cy), 27.4 (d, $^3J_{C,P}$ = 11.0 Hz, C-3, C-5, Cy), 25.9 (C-4, Cy) ppm. $^{31}P\{^1H\}$ NMR (162.3 MHz, $CDCl_3$): $\delta$ = 21.9 ppm. $C_{80}H_{114}Cu_2P_2S_3$ (1361.0): calcd. C 70.60, H 8.44, S 7.07; found C 70.37, H 8.63, S 7.84.

**$[Cu_2\{[SC=(tBu\text{-}fy)]_2S\}(dppf)]$ (4c):** $NEt_3$ (21 μL, 0.17 mmol) was added to a suspension of **3c** (160 mg, 0.16 mmol) in MeCN (8 mL) and the mixture was stirred for 24 h. The reaction took place gradually to give a brown suspension. The solvent was removed under vacuum and the residue was stirred in $CH_2Cl_2$ (10 mL) for 7 h. The dark-brown solution was filtered through Celite and concentrated to about 4 mL. Addition of acetone (12 mL) led to the slow precipitation of an orange solid, which was filtered off, washed with acetone (3×2 mL), and vacuum-dried to give **4c**. Yield: 57 mg (51%), m.p. 200 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1504 $cm^{-1}$ (C=$CS_2$). $^1H$ NMR (400.9 MHz, $CDCl_3$): $\delta$ = 9.71, 8.69 (both d, $^4J_{H,H}$ = 1.5 Hz, 2 H each, 1-H, 8-H), 7.77 (m, 4 H, *o*-H, Ph), 7.46–7.37 (m, 8 H, 4-H, 5-H + *m*-H, *p*-H, Ph), 7.27 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, 4-H, 5-H), 7.23 (dd, $^4J_{H,H}$ = 1.7, $^3J_{H,H}$ = 8.0 Hz, 2 H, 3-H, 6-H), 7.14–7.09 (m, 4 H, 3-H, 6-H + *p*-H, Ph), 6.83 (m, 4 H, *m*-H, Ph), 6.52 (m, 4 H, *o*-H, Ph), 5.34 (br., 2 H, Cp), 4.22 (br., 2 H, Cp), 3.94 (br., 2 H, Cp), 3.47 (br., 2 H, Cp), 1.25, 1.24 (both s, 18 H each, *t*Bu) ppm. $^{13}C\{^1H\}$ NMR (100.8 MHz, $CDCl_3$): $\delta$ = 149.0, 148.6 (C-2, C-7), 140.2 (t, $^3J_{C,P}$ = 4.1 Hz, $CS_2$), 140.0, 139.1 (C-8a, C-9a), 136.3 (C-4a, C-4b), 134.4 (d, $^2J_{C,P}$ = 15.5 Hz, C-2, C-6, Ph), 132.4 (d, $^1J_{C,P}$ = 38.5, C-1, Ph), 131.0 (d, $^2J_{C,P}$ = 14.5 Hz, C-2, Ph), 130.65 (C-4, Ph), 130.63 (C-9), 128.9 (C-4, Ph), 128.4 (d, $^3J_{C,P}$ = 10.4 Hz, C-3, C-5, Ph), 128.2 (d, $^3J_{C,P}$ = 9.7 Hz, C-3, C-5, Ph), 123.7, 123.6, 123.2, 123.0 (C-1, C-8, C-3, C-6), 118.3, 117.9 (C-4, C-5), 80.2 (br. d, $J_{C,P}$ = 27.8 Hz, CH, Cp), 72.9 (d, $J_{C,P}$ = 3.4 Hz, CH, Cp), 72.7 (d, $^1J_{C,P}$ = 44.1 Hz, C-1, Cp), 71.9 (d, $J_{C,P}$ = 9.9 Hz, CH, Cp), 71.4 (br., CH, Cp), 34.94, 34.89 (*C*$Me_3$), 31.62, 31.60 (C*Me*$_3$) ppm. $^{31}P\{^1H\}$ NMR (162.3 MHz, $CDCl_3$): $\delta$ = –1.39 ppm. $C_{78}H_{76}Cu_2FeP_2S_3$ (1354.5): calcd. C 69.16, H 5.66, S 7.10; found C 69.28, H 5.77, S 6.91.

**$[Cu_4\{S_2C=(tBu\text{-}fy)\}_2(PPh_3)_4]$ (5a):** A solid mixture of $[Cu(NCMe)_4]PF_6$ (239 mg, 0.64 mmol), $PPh_3$ (177 mg, 0.67 mmol), and **1** (163 mg, 0.34 mmol) was suspended in MeCN (15 mL) and treated with piperidine (36 μL, 0.36 mmol). The resulting orange suspension was stirred for 1 h, whereupon a yellow precipitate formed, which was filtered off, washed with MeCN (3×5 mL), and vacuum dried to give **5a** as a bright-yellow microcrystalline solid. Yield: 228 mg (71%), m.p. 123 °C (dec.). IR (KBr): $\tilde{\nu}$ = 1482 $cm^{-1}$ (C=$CS_2$). $^1H$ NMR (400.9 MHz, $CDCl_3$): $\delta$ = 9.37 (d, $^4J_{H,H}$ = 1.4 Hz, 4 H, 1-H, 8-H), 7.60 (d, $^3J_{H,H}$ = 7.9 Hz, 4 H, 4-H, 5-H), 7.25–7.18 (m, 28 H, 3-H, 6-H + *o*-H, Ph), 6.97 (t, $^3J_{H,H}$ = 7.3 Hz, 12 H, *p*-H, Ph), 6.72 (t, $^3J_{H,H}$ = 7.0 Hz, 24 H, *m*-H, Ph), 1.03 (s, 36 H, *t*Bu) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CDCl_3$): $\delta$ = 157.9 (br., $CS_2$), 147.7 (C-2, C-7), 140.9 (C-8a, C-9a), 135.7 (C-4a, C-4b), 133.8 (d, $^2J_{C,P}$ = 14.6 Hz, C-2, C-6, Ph), 133.3 (C-9), 132.6 (d, $^1J_{C,P}$ = 30.7 Hz, C-1, $PPh_3$), 129.3 (C-4 $PPh_3$), 128.2 (d, $^3J_{C,P}$ = 9.1 Hz, C-3, C-5, $PPh_3$), 124.8 (C-1, C-8), 121.3 (C-3, C-6), 116.9 (C-4, C-5), 34.8 (*C*$Me_3$), 31.8 (C*Me*$_3$) ppm. $^{31}P\{^1H\}$ NMR (162.3 MHz, $CDCl_3$): $\delta$ = –4.04 ppm. $C_{116}H_{108}Cu_4P_4S_4$ (2008.5): calcd. [a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ for reflections with $I > 2\sigma(I)$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{0.5}$ for all reflections; $w^{-1} = \sigma^2(F_2) + (aP)^2 + bP$, where $P = (2F_c^2 + F_o^2)/3$ and $a$ and $b$ are constants set by the program.

**$(Pr_4N)_2$[Cu{$S_2C$=(*t*Bu-fy)}$_2$] [$(Pr_4N)_2$6]:** A previously degassed 1.0 M solution of ($Pr_4N$)OH in water (0.60 mL, 0.60 mmol) and a solution of $Cu(ClO_4)_2$·$6H_2O$ (85 mg, 0.23 mmol) in MeCN (5 mL) were added successively to a solution of **1** (234 mg, 0.49 mmol) in MeCN (10 mL). Reaction was observed to give a dark-brown suspension, which was stirred for 5 min. The supernatant was decanted and the precipitate was washed with MeCN (3 × 5 mL) and vacuum-dried to give $(Pr_4N)_2$**6** as a brown powder. Yield: 208 mg (79%), m.p. 237 °C (dec.). IR (KBr): $\tilde{\nu}$ = 1480 cm$^{-1}$ (C=$CS_2$). $C_{68}H_{104}CuN_2S_4$ (1141.4): calcd. C 71.56, H 9.18, N 2.45, S 11.24; found C 71.36, H 9.23, N 2.50, S 11.45.

**$Pr_4N$[Cu{$S_2C$=(*t*Bu-fy)}$_2$] ($Pr_4N$7):** A solution of **1** (607 mg, 1.27 mmol) in MeCN (15 mL) was treated successively with a 1.0 M solution of ($Pr_4N$)OH in water (1.4 mL, 1.4 mmol) and Cu($ClO_4)_2$·$6H_2O$ (228.7 mg, 0.617 mmol). The resulting brown suspension was stirred for 2.5 h under atmospheric conditions, whereupon a green precipitate formed, which was filtered off, washed with MeCN (3 × 3 mL), and vacuum-dried to give $Pr_4N$**7**. Yield: 544 mg (92%), m.p. 233 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1548 cm$^{-1}$ (C=$CS_2$), 416 (Cu–S). $^1$H NMR [400.9 MHz, $(CD_3)_2CO$]: $\delta$ = 8.46 (d, $^4J_{H,H}$ = 1.3 Hz, 4 H, 1-H, 8-H), 7.68 (d, $^3J_{H,H}$ = 8.0 Hz, 4 H, 4-H, 5-H), 7.29 (dd, $^3J_{H,H}$ = 8.0, $^4J_{H,H}$ = 1.7 Hz, 4 H, 3-H, 6-H), 3.31 (m, 8 H, $NCH_2$), 1.78 (m, 8 H, $CH_2$), 1.39 (s, 36 H, *t*Bu), 0.95 (t, $^3J_{H,H}$ = 7.2 Hz, 12 H, Me, $Pr_4N^+$) ppm. $^{13}$C{$^1$H} NMR [75.5 MHz, $(CD_3)_2CO$]: $\delta$ = 154.1 ($CS_2$), 149.6 (C-2, C-7), 140.2 (C-8a, C-9a), 135.7 (C-4a, C-4b), 128.2 (C-9), 122.8 (C-3, C-6), 120.7 (C-1, C-8), 119.2 (C-4, C-5), 35.4 ($CMe_3$), 32.1 ($CMe_3$) ppm. $C_{56}H_{76}CuNS_4$ (955.03): calcd. C 70.43, H 8.02, N 1.47, S 13.43; found C 70.66, H 8.29, N 1.50, S 13.79.

**PPN[Cu{$S_2C$=(*t*Bu-fy)}$_2$] (PPN7):** Piperidine (46 μL, 0.46 mmol) and $CuCl_2$·$2H_2O$ (34 mg, 0.20 mmol) were added successively to a solution of **1** (212 mg, 0.45 mmol) and PPNCl (130 mg, 0.23 mmol) in MeCN (15 mL). The resulting red solution was stirred for 1 h under atmospheric conditions, after which time a green solid precipitated. The product was filtered off, washed with ethanol (3 × 2 mL) and diethyl ether (2 mL), and vacuum-dried to give PPN**7**. Yield: 184 mg (63%), m.p. 238 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1552 cm$^{-1}$ (C=$CS_2$), 420 (Cu–S). $^1$H NMR [400.9 MHz, $(CD_3)_2$-CO]: $\delta$ = 8.46 (d, $^4J_{H,H}$ = 1.4 Hz, 4 H, 1-H, 8-H), 7.72–7.65 (m, 22 H, 4-H, 5-H + $PPN^+$), 7.56–7.51 (m, 12 H, $PPN^+$), 7.28 (dd, $^4J_{H,H}$ = 1.7, $^3J_{H,H}$ = 8.0 Hz, 4 H, 3-H, 6-H), 1.38 (s, 36 H, *t*Bu) ppm. $^{13}$C{$^1$H} NMR [75.5 MHz, $(CD_3)_2CO$]: $\delta$ = 154.3 ($CS_2$), 149.6 (C-2, C-7), 140.3 (C-8a, C-9a), 135.7 (C-4a, C-4b), 128.2 (C-9), 122.7 (C-3, C-6), 120.7 (C-1, C-8), 119.1 (C-4, C-5), 35.4 ($CMe_3$), 32.1 ($CMe_3$) ppm. $C_{80}H_{78}CuNS_4$ (1245.3): calcd. C 73.50, H 6.01, N 1.07, S 9.81; found: C 73.50, H 5.80, N 1.10, S 9.52.

**X-ray Structure Determinations:** Crystals of **3a**, **3c**·$CH_2Cl_2$, **4a**·4$Me_2CO$, and **4c**·$CH_2Cl_2$ suitable for X-ray diffraction studies were obtained from chloroform/pentane (**3a**), $CH_2Cl_2$/hexane (**3e**), acetone/hexane (**4a**), or $CH_2Cl_2$/pentane (**4c**). Numerical details are presented in Table 5. The structures of **3a** and **3c** were measured on a Bruker Smart APEX diffractometer, and those of **4a** and **4c** on a Bruker SMART 1000 CCD diffractometer. Data were collected using monochromated Mo-$K\alpha$ radiation in $\omega$-scan mode. The structures were solved by direct methods and refined anisotropically on $F^2$ using the program SHELXL-97 (G. M. Sheldrick, University of Göttingen, Germany). Restraints to local aromatic ring symmetry or light-atom displacement factor components were applied in some cases. The methyl groups were refined using rigid groups, and the other hydrogen atoms were refined using a riding model. *Special features of refinement*: For compound **3a**, the Flack parameter is 0.047(10). For compounds **3c**, **4a**, and **4c** the Me groups of one *t*Bu group are disordered over two positions. The solvent in the crystals of **4a** was so badly resolved that no sensible refinement model could be developed. For this reason the program SQUEEZE (A. L. Spek, University of Utrecht, Netherlands) was used to remove the effects of the solvent mathematically. The solvent content of four acetone molecules is only an approximate estimate. The dichloromethane molecule in **4c** is disordered over two positions.

CCDC-277675 (**3a**) -277674 (**3c**·$CH_2Cl_2$), -277676 (**4a**·4$Me_2CO$), and -277673 (**4c**·$CH_2Cl_2$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Positive ion FAB mass spectra of **5a**–**d**.

# $\eta^2$-Iminoacyl and $\eta^2$-Acyl Monocyclopentadienyl Tantalum Complexes Bearing Oxo and Oxo-Borane Ligands

**Javier Sánchez-Nieves,[a] Pascual Royo,*[a] and Marta E. G. Mosquera[a][‡]**

*Dedicated to J. Antonio Abad, an excellent scientist and friend*

**Keywords:** Tantalum / Oxo ligands / Insertion reactions / Isocyanide / Carbon monoxide

Alkyl-chloro ligand exchange by the reaction of [TaCp'$R_2${O·B($C_6F_5$)$_3$}] (R = $CH_2Ph$, Me) with $Ph_3CCl$ gave the monoalkyl compounds [TaCp'RCl{O·B($C_6F_5$)$_3$}] (R = $CH_2Ph$, Me). Insertion of CNAr (Ar = 2,6-$Me_2C_6H_3$) and CO into a Ta–C bond of the mono- and dialkyl complexes gave the iminoacyl compounds [TaCp'X{$\eta^2$-C(R)=NAr}{O·B($C_6F_5$)$_3$}] (X = R = $CH_2Ph$, Me; X = Cl, R = $CH_2Ph$) and the acyl compounds [TaCp'X{$\eta^2$-C(R)=O}{O·B($C_6F_5$)$_3$}] (X = R = $CH_2Ph$, Me; X = Cl, R = $CH_2Ph$), respectively. The related chloro compound [TaCp'Cl{$\eta^2$-C(Me)=NAr}{O·B($C_6F_5$)$_3$}] was isolated from the reaction of the oxo derivative [TaCp'Cl{$\eta^2$-C(Me)=NAr}(O)] with the Lewis acid B($C_6F_5$)$_3$. Addition of CNAr or pyridine to [TaCp'($CH_2Ph$){$\eta^2$-C($CH_2Ph$)=NAr}{O·B($C_6F_5$)$_3$}] afforded the borane-free complex [TaCp'($CH_2Ph$){$\eta^2$-C($CH_2Ph$)=NAr}(O)] and the acid-base adduct L·B($C_6F_5$)$_3$ (L = py, CNAr). The molecular structures of [TaCp'Cl{$\eta^2$-C(Me)=NAr}{O·B($C_6F_5$)$_3$}] and [TaCp'($CH_2Ph$){$\eta^2$-C($CH_2Ph$)=O}{O·B($C_6F_5$)$_3$}] were obtained from X-ray diffraction studies.

## Introduction

The formation of C–C bonds through insertion of isocyanides (CNR) and carbon monoxide (CO) into M–C bonds is well-documented, and this reaction initially affords iminoacyl and acyl complexes, respectively.[1] For a given metal atom, the stability and further evolution of these compounds are determined by the nature of the ancillary ligands. Many reaction pathways may follow to give a broad variety of products:[1] (a) migratory insertion of a second alkyl or aryl group to give $\eta^2$-imine or $\eta^2$-ketene complexes;[2–5] (b) intra- or intermolecular coupling of iminoacyl or acyl units affording diaza- or dioxobutene complexes;[6,7] (c) transfer of the NR or O moieties to the metal centre;[8–11] (d) insertion of a second CNR[12–16] or CO[17] molecule into the new M–C bond formed after the first insertion process and (e) hydrogen migration.[18,19]

We reported the results of our studies on the insertion reactions of CNR into the Ta–C(methyl) bond of monocyclopentadienyl complexes of the type [TaCp*$Cl_xMe_{4-x}$][8–10] for which processes (a) and (c) were observed. Similar reactions with imido compounds of the type [TaCp*MeX(N*t*Bu)] (X = Cl, Me, OR, NH*t*Bu) gave the imine-$\eta^2$-iminoacyl derivatives [TaCp*(N*t*Bu)X{$\eta^2$-C[C(Me)=NR]=NR}].[20] With regard to the CO insertion reactions, double migration of the alkyl group [process (a)] was observed for [TaCp*$Cl_2Me_2$],[10] whereas the coupling of the acyl groups [process (b)] occurred for [TaCp*$Me_2$(NR)] (R = 2,6-$Me_2C_6H_3$) to give the dinuclear compound [TaCp*(NR)Me]$_2${μ-$\eta^2$-OC(Me)=C(Me)O},[10] and ligand exchange [process (c)] for complexes [TaCp*ClMe(NR)] (R = 2,6-$Me_2C_6H_3$,[10] *t*Bu)[11] led to the oxo compounds [TaCp*Cl(O){$\eta^2$-C(Me)=NR}]. Furthermore, the $\eta^2$-(methyl)acyl complexes remained elusive and were only detected as intermediates by NMR spectroscopy, whereas the related $\eta^2$-iminoacyl complexes are stable.

It was observed that for monocyclopentadienyl imido tantalum derivatives addition of a second CNR molecule into the iminoacyl compounds [TaCp*(NR)X{$\eta^2$-C(Me)=NR}] (R = 2,6-$Me_2C_6H_3$, *t*Bu; X = Cl, Me) resulted in differing behaviours depending on the R group of the imido ligand. No reaction was found for R = 2,6-$Me_2C_6H_3$,[10] whereas a second insertion occurred for R = *t*Bu.[20] Conversely, the imido complexes [TaCp*MeX(NR)] (R = 2,6-$Me_2C_6H_3$, *t*Bu; X = Cl, Me) reacted with CO to give the dinuclear compound [TaCp*(NR)Me]$_2${μ-$\eta^2$-OC(Me)=C(Me)O} for X = Me[10] and one of the few mononuclear derivatives [TaCp*Cl(O){$\eta^2$-C(Me)=NR}] containing a terminal tantalum-oxo double bond for X = Cl.[10,11]

The versatility and potential applications of all these results determined by the R and X substituents of the imido

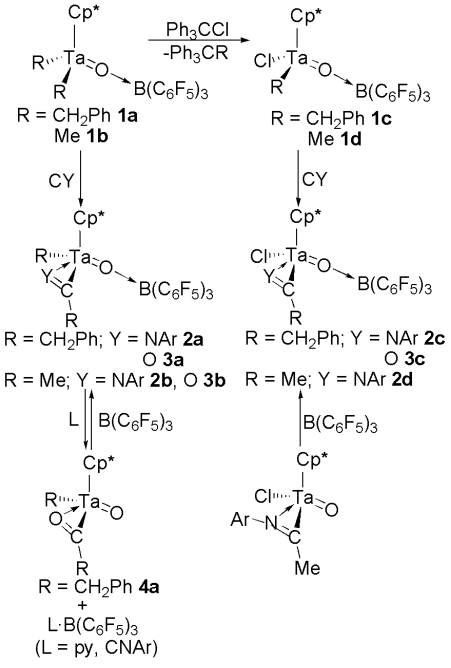
complexes [TaCp*MeX(NR)] led us to extend our studies to similar insertion reactions of CNR and CO into the Ta–alkyl bonds of the related oxo-borane compounds [TaCp*$X_2${O·B($C_6F_5$)$_3$}] that have recently been isolated.[21]

## Results and Discussion

The monoalkyl oxo-borane compounds [TaCp*RCl{O·B($C_6F_5$)$_3$}] (R = $CH_2Ph$ **1c**, Me **1d**) were synthesised by an alkyl-chloro metathesis reaction of [TaCp*$R_2${O·B($C_6F_5$)$_3$}] (R = $CH_2Ph$ **1a**, Me **1b**) with one equiv. of $Ph_3CCl$ as chlorinating agent (Scheme 1). The reaction for **1c** proceeded smoothly at room temperature to give a pale yellow solid in good yield, whereas complex **1d** could not be isolated in the solid state. The formation of **1d** was demonstrated on a small scale by $^1$H NMR spectroscopy with a $C_6D_6$ solution of **1b** that was treated with $Ph_3CCl$ and heated to 40 °C. All attempts made to obtain the monomethyl complex through alkylation of [TaCp*$Cl_2${O·B($C_6F_5$)$_3$}] and redistribution reactions between [TaCp*$Cl_2${O·B($C_6F_5$)$_3$}] and [TaCp*$Me_2${O·B($C_6F_5$)$_3$}] failed. The $^{11}$B and $^{19}$F NMR spectra of complexes **1c** and **1d** are consistent with the presence of a tetracoordinate boron atom,[21–31] and the $^1$H NMR spectra with the monosubstitution of only one of the alkyl ligands.



Scheme 1.

The alkyl complexes [TaCp*$R_2${O·B($C_6F_5$)$_3$}] (R = $CH_2Ph$ **1a**, Me **1b**) and [TaCp*($CH_2Ph$)Cl{O·B($C_6F_5$)$_3$}] (**1c**) immediately reacted at room temperature with one equiv. of the isocyanide CNAr (Ar = 2,6-$Me_2C_6H_3$) to give the corresponding $\eta^2$-iminoacyl compounds [TaCp*X{$\eta^2$-C(R)=NAr}{O·B($C_6F_5$)$_3$}] (X = R = $CH_2Ph$ **2a**, Me **2b**; X = Cl, R = $CH_2Ph$ **2c**) in high yields by insertion of the isocyanide ligand into a Ta–C bond (Scheme 1). These pale yellow complexes are air and thermally stable in solution. The $^{13}$C NMR resonance at ca. $\delta$ = 240 ppm is the most apparent spectroscopic feature and confirms the presence of the $\eta^2$-iminoacyl ligand in complexes **2**.

We previously reported[10] on the isolation of the related oxo complex [TaCp*Cl{$\eta^2$-C(Me)=NAr}(O)] from the reaction of the monomethyl compound [TaCp*ClMe(NAr)] with CO through a process that involved insertion of CO into the Ta–Me bond and further rearrangement of the $\eta^2$-acyl intermediate with intramolecular oxo-imido exchange. Since the starting oxo-borane chloro-methyl complex could not be isolated, thus preventing access to the oxo-borane compound [TaCp*Cl{$\eta^2$-C(Me)=NAr}{O·B($C_6F_5$)$_3$}] (**2d**) by insertion of CNAr into the Ta–C bond of the corresponding alkyl-chloro compound, we tried to obtain this compound by an alternative route. With this aim, we investigated the reaction of the oxo iminoacyl compound [TaCp*Cl{$\eta^2$-C(Me)=NAr}(O)] with B($C_6F_5$)$_3$, which afforded **2d** in high yield. The formation of **2d** was confirmed by $^{13}$C and $^{19}$F NMR spectroscopy. The $^{13}$C NMR spectrum shows the resonance corresponding to the $C_{sp^2}$ atom of the $\eta^2$-iminoacyl ligand ($\delta$ = 240.1 ppm) to be slightly low-field shifted with respect to that of the starting compound [TaCp*Cl{$\eta^2$-C(Me)=NAr}(O)] ($\delta$ = 236.8 ppm). An analogous behaviour was observed in the $^1$H NMR spectrum for the methyl-iminoacyl group, which was shifted from $\delta$ = 2.65 ppm in [TaCp*Cl{$\eta^2$-C(Me)=NAr}(O)] to $\delta$ = 2.94 ppm in **2d**.

The molecular structure of compound [TaCp*Cl{$\eta^2$-C(Me)=NAr}{O·B($C_6F_5$)$_3$}] (Ar = 2,6-$Me_2C_6H_3$) (**2d**) was obtained by X-ray diffraction studies. Figure 1 depicts an ORTEP drawing of **2d** with selected bond lengths and angles. Compound **2d** exhibits the typical geometry known for group 5 half-sandwich iminoacyl compounds with a tetrahedral coordination environment around the tantalum atom. Considering the centroid of the Cp* ring and the midpoint of the C(10)–N bond as coordination sites, the other two positions are occupied by the chloro and oxo ligands. The N atom of the $\eta^2$-iminoacyl group is located in a *trans* position with respect to the oxo ligand, as in analogous half-sandwich imido complexes and in [TaCp*Cl{$\eta^2$-C(Me)=NAr}(O)]. Furthermore, the oxygen atom is attached to the boron atom of the B($C_6F_5$)$_3$ group.

All the values of the bond lengths and angles of compound **2d** are very close to the corresponding bond lengths and angles found for the parent compound [TaCp*Cl{$\eta^2$-C(Me)=NAr}(O)][10] except for the Ta–O bond, which is longer in [TaCp*Cl{$\eta^2$-C(Me)=NAr}(O)] [1.731(7) Å] than in **2d** [1.809(5) Å] as a consequence of the coordination of the oxygen atom to the B($C_6F_5$)$_3$ ligand.[21,23–28,30,31] The linear Ta–O–B angle [174.4(6)°] and the B–O bond length [1.52(1) Å] are typical of oxo-borane compounds.[21–31] The Ta–O bond in **2d** is longer than that in the oxo-borane compound [TaCp*$Cl_2${O·B($C_6F_5$)$_3$}][21] [1.784(2) Å]. This bond length is similar to the lower end of the range of Ta–O bond lengths for compounds with Ta–O–Ta bridges (1.82–2.10 Å)[32–35] and with terminal Ta–OH bonds (1.85–1.97 Å).[36–38] However, the single bond Ta–O distances are ca. 2.18 Å,

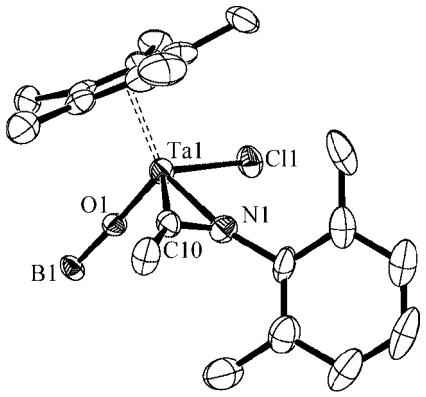

Figure 1. ORTEP diagram of the X-ray structure of compound **2d**. Thermal ellipsoids are drawn at the 50% level, and hydrogen atoms and $C_6F_5$ groups have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ta–O 1.809(5), Ta–N 2.127(7), Ta–C(10) 2.120(9), Ta–Cl 2.392(2), B–O 1.525(11), N–C(10) 1.26(1), N–Ta–C(10) 34.5(3), C(10)–N–Ta 72.4(5), N–C(10)–Ta 73.1(5), B–O–Ta 174.4(6).

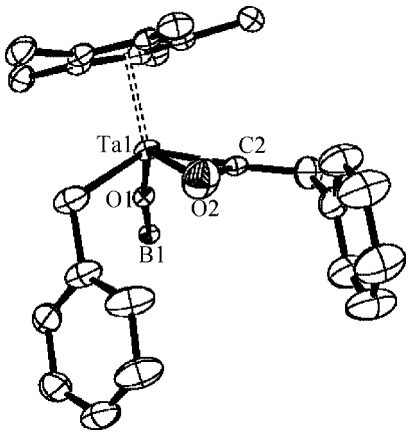

Figure 2. ORTEP diagram of the X-ray structure of compound **3a**. Thermal ellipsoids are drawn at the 50% level, and hydrogen atoms and $C_6F_5$ groups have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ta–O(1) 1.816(2), Ta–O(2) 2.110(3), Ta–C(1) 2.229(4), Ta–C(2) 2.011(3), B–O(1) 1.512(4), O(2)–C(2) 1.209(4), O(2)–Ta–C(2) 34.02(12), C(2)–O(2)–Ta 68.5(2), O(2)–C(2)–Ta 77.5(2), B–O(1)–Ta 173.02(19).

and thus a bond order of two should be considered for the Ta–O bond in **2d**.

The reaction of the dialkyl [TaCp*$R_2${O·B($C_6F_5$)$_3$}] (R = $CH_2$Ph **1a**, Me **1b**) and the monobenzyl [TaCp*($CH_2$Ph)Cl{O·B($C_6F_5$)$_3$}] (**1c**) complexes with CO in toluene gave the η²-acyl compounds [TaCp*X{η²-C(R)=O}{O·B($C_6F_5$)$_3$}] (X = R = $CH_2$Ph **3a**, Me **3b**; X = Cl, R = $CH_2$Ph **3c**) after ca. 24 h at room temperature in moderate yields (Scheme 1). These pale yellow compounds were air and thermally stable below 120 °C for several hours. The $^{13}$C NMR spectra showed a resonance at ca. $\delta$ = 305 ppm corresponding to the $C_{sp^2}$ atom of the η²-acyl fragment. The slowness of the insertion reactions of CO is in contrast with the rapid transformations observed for complexes **1** with isocyanide and the behaviour observed[10,11] for the reactions of the imido compounds [TaCp*MeX(NR)] (R = 2,6-$Me_2C_6H_3$, *t*Bu; X = Cl, Me) with CO. This difference may be attributed to the lower oxophilicity of the tantalum atom in compounds **1** that is caused by the presence of the oxo ligand.

The X-ray structure of compound **3a** is shown in Figure 2. The environment around the Ta atom is analogous to that described for compound **2d** (see above) with the oxygen atom of the acyl group located *trans* to the oxo-borane ligand, as expected. The Ta–O(1) bond length of 1.816(2) Å is similar to that observed for compound **2d**, and the O(1)–B bond length [1.512(4) Å] and Ta–O(1)–B angle [173.0(2)°] have values that are normally seen for these types of compounds.[21–31]

The whole set of angles and bond lengths of the [Ta-(η²-acyl)] group is in line with compounds of this type[1] and is similar to those found in the other two tantalum-acyl complexes for which X-ray structures are known, [TaCp*Me{η²-C($CH_2CMe_2$Ph)=O}{N(2,6-$Me_2C_6H_3$)}][39] and [TaCp*$Cl_3${η²-C($CH_2CMe_3$)=O}].[40] However, in the particular case of the isostructural imido derivative [TaCp*Me{η²-C($CH_2CMe_2$Ph)=O}{N(2,6-$Me_2C_6H_3$)}], the Ta–O bond [2.21(1) Å] is slightly longer than the corresponding bond in compound **3a** [2.110(3) Å], because of the different *trans* effect and higher donor capacity of the imido ligand.

The insertion of a second CNAr or CO molecule into these new acyl and iminoacyl oxo-borane complexes was not observed, in contrast with the behaviour observed for the analogous *tert*-butyl imido complexes.[20] Rather, all complexes **2**–**3** released the acid-base adduct L·B($C_6F_5$)$_3$ (L = py, CNAr) in the presence of donor ligands such as isocyanide or pyridine.[41] Only in the case of compound **2a** were we able to isolate the borane-free 18-electron compound [TaCp*($CH_2$Ph){η²-C($CH_2$Ph)=NAr}(O)] (**4a**), with a terminal oxo-tantalum bond. The remaining oxo-borane complexes decomposed under similar conditions. The $^{13}$C NMR spectrum of the new oxo iminoacyl compound **4a** showed the η²-iminoacyl $C_{sp^2}$ resonance at $\delta$ = 240.3 ppm. A comparison of this $^{13}$C resonance and that assigned to the $CH_2$–iminoacyl group in the $^1$H NMR spectrum with the corresponding resonances in the parent compound **2a**, showed a behaviour that is opposite to that observed for **2d** and [TaCp*Cl{η²-C(Me)=NAr}(O)].

## Conclusions

The dialkyl oxo-borane compounds [TaCp*$R_2${O·B($C_6F_5$)$_3$}] can be transformed into the monoalkyl derivatives [TaCp*RX{O·B($C_6F_5$)$_3$}] by alkyl-chloro exchange with $Ph_3CCl$. All of these complexes reacted with one molecule of isocyanide or carbon monoxide to give the η²-iminoacyl or η²-acyl compounds, respectively. No further insertion processes have been observed. This behaviour is analogous to that observed for the imido compounds [TaCp*MeX(NR)] (R = 2,6-$Me_2C_6H_3$; X = Cl, Me), although in the oxo-borane compounds the insertion of CO gave stable η²-acyl derivatives because of the presence of a Ta–O multiple bond, which prevents further rearrangement.

## Experimental Section

All manipulations were carried out under argon, and solvents were distilled from appropriate drying agents. NMR spectra were recorded at 300.13 ($^1$H NMR), 188.31 ($^{19}$F NMR), 75.47 ($^{13}$C NMR) and 128.38 Hz ($^{11}$B NMR) at room temperature with a Varian Unity 300 ($^1$H, $^{13}$C, $^{19}$F) or Bruker Advance 400 ($^{11}$B NMR) instrument. Chemical shifts ($\delta$, $CDCl_3$) are given in ppm, relative to internal TMS ($^1$H and $^{13}$C NMR), and external $CFCl_3$ ($^{19}$F NMR) and $BF_3{\cdot}OEt_2$ ($^{11}$B NMR). Elemental analyses were performed with a Perkin–Elmer 240C instrument. Compounds [TaCp*Me$_4$],[42] [TaCp*(CH$_2$Ph)$_2${O·B(C$_6$F$_5$)$_3$}],[21] [TaCp*Me$_2${O·B(C$_6$F$_5$)$_3$}],[21] [TaCp*Cl{$\eta^2$-C(Me)=NAr}(O)][10] and B(C$_6$F$_5$)$_3$[43] were prepared by literature methods, and H$_2$O·B(C$_6$F$_5$)$_3$[44] was prepared from H$_2$O and B(C$_6$F$_5$)$_3$ in toluene at room temperature and used in situ without further purification.

**[TaCp*Cl(CH$_2$Ph){O·B(C$_6$F$_5$)$_3$}] (1c):** A suspension of $Ph_3CCl$ (0.14 g, 0.50 mmol) and [TaCp*(CH$_2$Ph)$_2${O·B(C$_6$F$_5$)$_3$}] (**1a**) (0.50 g, 0.49 mmol) in toluene (5 mL) was stirred overnight at room temperature, with a colour change from yellow to brown. Later, all volatile components were removed under vacuum until the volume was ca. 1 mL, leaving a dark oil that was washed with hexane (2 × 10 mL) to yield **1c** as a brownish solid (0.36 g, 76%). $C_{35}H_{22}BClF_{15}OTa$ (970.75): calcd. C 43.31, H 2.28; found C 42.99, H 2.25. $^1$H NMR: $\delta$ = 2.14 (s, 15 H, C$_5$*Me*$_5$), 2.52 (d, $^2J_{H,H}$ = 14.0 Hz, 1 H, C*H*$_2$Ph), 2.80 (d, $^2J_{H,H}$ = 14.0 Hz, 1 H, C*H*$_2$Ph), 6.74 (m, 2 H, C$_6$*H*$_5$), 7.02 (m, 3 H, C$_6$*H*$_5$) ppm. $^{11}$B NMR: $\delta$ = 0.10 [O·B(C$_6$F$_5$)$_3$] ppm; $^{13}$C NMR{$^1$H}: $\delta$ = 11.5 (C$_5$*Me*$_5$), 82.3 (*C*H$_2$Ph), 125.7 (*C*$_5$Me$_5$), 127.1 (*C*$_6$H$_5$), 128.2 (*C*$_6$H$_5$),128.3 (*C*$_6$H$_5$), 131.4 (*C*$_6$H$_5$), 135.0 (*C*$_6$F$_5$), 138.3 (*C*$_6$F$_5$), 145.9 (*C*$_6$F$_5$), 149.1 (*C*$_6$F$_5$) ppm; $^{19}$F NMR: $\delta$ = –132.9 (*o*-C$_6$F$_5$), –157.7 (*p*-C$_6$F$_5$), –163.3 (*m*-C$_6$F$_5$) ppm.

**[TaCp*ClMe{O·B(C$_6$F$_5$)$_3$}] (1d):** A solution of $Ph_3CCl$ (0.080 g, 0.028 mmol) and [TaCp*Me$_2${O·B(C$_6$F$_5$)$_3$}] (**1d**) (0.025 g, 0.028 mmol) in $C_6D_6$ was heated at 45 °C for 18 h. Total transformation of **1b** to **1d** was then observed. $^1$H NMR ($C_6D_6$): $\delta$ = 1.26 (s, 3 H, Ta–*Me*), 2.13 (s, 15 H, C$_5$*Me*$_5$) ppm. $^{11}$B NMR ($C_6D_6$): $\delta$ = 0.05 [O·B(C$_6$F$_5$)$_3$] ppm. $^{19}$F NMR ($C_6D_6$): $\delta$ = –133.0 (*o*-C$_6$F$_5$), –157.2 (*p*-C$_6$F$_5$), –163.3 (*m*-C$_6$F$_5$) ppm.

**[TaCp*Cl{η²-C(CH₂Ph)=O}{O·B(C₆F₅)₃}] (3c):** The procedure used for **3a**, but starting from [TaCp*Cl(CH₂Ph){O·B(C₆F₅)₃}] (**1c**) (0.50 g, 0.52 mmol) and CO, gave **3c** as a yellowish solid (0.40 g, 78%). $C_{36}H_{22}BClF_{15}O_2Ta$ (998.76): calcd. C 43.29, H 2.22; found C 43.17, H 2.24. $^1$H NMR: $\delta$ = 2.05 (s, 15 H, $C_5Me_5$), 4.41 (d, $^2J_{H,H}$ = 19.0 Hz, 1 H, C–C$H_2$Ph), 4.91 (d, $^2J_{H,H}$ = 19.0 Hz, 1 H, C–C$H_2$Ph), 7.05–7.40 (m, 5 H, $C_6H_5$) ppm. $^{13}$C NMR{$^1$H}: $\delta$ = 10.5 ($C_5Me_5$), 49.2 (C–$C$H$_2$Ph), 123.7 ($C_5$Me$_5$), 127.8–130.0 ($C_6$H$_5$), 135.8, 138.3, 139.2, 141.7, 146.8 and 150.1 ($C_6F_5$), 310.5 (Ta–$C$=O) ppm. $^{19}$F NMR: $\delta$ = –132.5 ($o$-$C_6F_5$), –156.9 ($p$-$C_6F_5$), –162.9 ($m$-$C_6F_5$) ppm. IR (KBr): $\tilde{\nu}$ = 1658 (C=O) cm$^{-1}$.

**[TaCp*(CH₂Ph){η²-C(CH₂Ph)=NAr}(O)] (Ar = 2,6- Me₂C₆H₃) (4a):** A solution of [TaCp*(CH$_2$Ph){η$^2$-C(CH$_2$Ph)=NAr}-{O·B(C$_6$F$_5$)$_3$}] (**2a**) (0.25 g, 0.22 mmol) in toluene (5 mL) was treated with pyridine (0.026 g, 0.33 mmol), and the mixture was stirred for 2 h at room temperature. All volatile components were removed under vacuum until ca. 1 mL remained, and hexane (10 mL) was added to precipitate a white solid that was washed with a hexane/toluene mixture (2 × 10 mL, 9:1) to give **4a** (0.10 g, 72%). $C_{33}H_{38}NOTa$ (645.62): calcd. C 61.39, H 5.93, N 2.17; found C 61.00, H 5.83, N 2.21. $^1$H NMR: $\delta$ = 1.25 (s, 3 H, $Me_2C_6H_3$), 1.72 (d, $^2J_{H,H}$ = 11.9 Hz, 1 H, Ta–C$H_2$Ph), 1.80 (s, 3 H, $Me_2C_6H_3$), 1.99 (s, 15 H, $C_5Me_5$), 2.77 (d, $^2J_{H,H}$ = 11.9 Hz, 1 H, Ta–C$H_2$Ph), 3.75 (d, $^2J_{H,H}$ = 17.6 Hz, 1 H, C–C$H_2$Ph), 4.25 (d, $^2J_{H,H}$ = 17.6 Hz, 1 H, C–C$H_2$Ph), 6.50–7.26 (m, 13 H, $C_6H_3$ and $C_6H_5$) ppm. $^{13}$C NMR{$^1$H}: $\delta$ = 10.9 ($C_5Me_5$), 17.2 ($Me_2C_6H_3$), 18.4 ($Me_2C_6H_3$), 39.3 (C–$C$H$_2$Ph), 48.8 (Ta–$C$H$_2$Ph), 121.1 ($C_5$Me$_5$), 126.1–149.8 ($C_6$H$_5$ and Me$_2C_6$H$_3$), 240.3 (Ta–$C$=N) ppm. IR (KBr): $\tilde{\nu}$ = 1631 (C=N) cm$^{-1}$.

**Crystal Structure Determination for 2d and 3a:** Selected crystals were covered with perfluoropolyether oil and mounted on a Nonius KAPPA-CCD single crystal diffractometer. The crystal structure was solved by direct methods and refined using full-matrix least-squares on $F^2$ (SHELXL-97). All non-hydrogen atoms were anisotropically refined. Hydrogen atoms were geometrically placed and left riding on their parent atoms. Two molecules of toluene crystallised with every molecule of **2d**; both solvent molecules were found in the difference Fourier map but one of them was very disordered and it was not possible to get a chemically sensible model for it, so the Squeeze procedure[45] was used to remove its contribution to the structural factors. In **3a** some restraints on the solvent molecule were applied. Crystal data for both compounds are given in Table 1. CCDC-272817 (for **2d**) and CCDC-272818 (for **3a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# An Original Supramolecular Helicate from a Bipyridine–Bipyrazine Ligand Strand and $Ni^{II}$ by Self-Assembly

**Julien Mathieu,[a] Bernard Fraisse,[b] Daniel Lacour,[d] Noureddine Ghermani,[c] François Montaigne,[d] and Alain Marsura*[a]**

*Dedicated to the memory of Professor Claude Selve*

**Keywords:** Magnetic properties / N ligands / Nickel / Self assembly / Supramolecular chemistry

A new discrete supramolecular pseudo-helicate has been obtained from a saturated heterotopic methylbipyrazyl–methylbipyridyl ligand strand and $NiCl_2$. The X-ray structure of the dinuclear complex shows the 2-oxapropylene bridge oxygen atoms are engaged in coordination to the octahedral metal centre and a selective ligand inter-strand orientation is promoted in the complex. The crystal packing shows a perfect regular linear arrangement of the asymmetric units giving a packing of interacting molecules having well-defined rectangular and polygonal open channels. Although a paramagnetic behaviour is observed above 10 K, below this temperature a significant deviation of this behaviour suggests the presence of an $Ni^{II}$–$Ni^{II}$ magnetic coupling.

## Introduction

Over the last ten years of intensive research, numerous supramolecular architectures obtained by self-assembly processes have been reported in the literature, and several reviews[1–6] give an overview of these compounds and their properties. Looking at exploratory investigations, one can see that the didentate heterocyclic 2,2′-bipyridine ligand has played a central role in the spontaneous formation of the main, from simple to sophisticated, supramolecular inorganic architectures.[7,8] A variety of discrete and highly organised species have been obtained by means of ligands designed to afford a well-defined architecture of a single type with given metal ions.[7,8] Famous examples in the literature involve oligobipyridine strands, which lead to double-stranded, triple-stranded or circular helical complexes depending on the metal ion coordination geometry and the nature of the spacer between the bipyridine nuclei.[9–12] Recently, we have studied the self-assembly of sequential 2-oxapropylene-bridged bipyridine–bidiazine ligand strands with tetracoordinate metal ions into selectively oriented H-H (head-to-head) or H-T (head-to-tail) double-stranded helicates.[13,14]

## Results and Discussion

As far as we know no supramolecular inorganic architectures obtained by spontaneous self-assembly of sequential 2-oxapropylene-bridged bipyridine–bidiazine ligand strands with an $Ni^{II}$ cation have been reported in the literature. The formation of the metal complexes was monitored by UV/Vis spectrophotometric titration of a solution of the heterotopic bipyridine–bipyrazine ligand **1**[13,14] at room temp. with $NiCl_2$ (Figure 1) in dry acetonitrile.

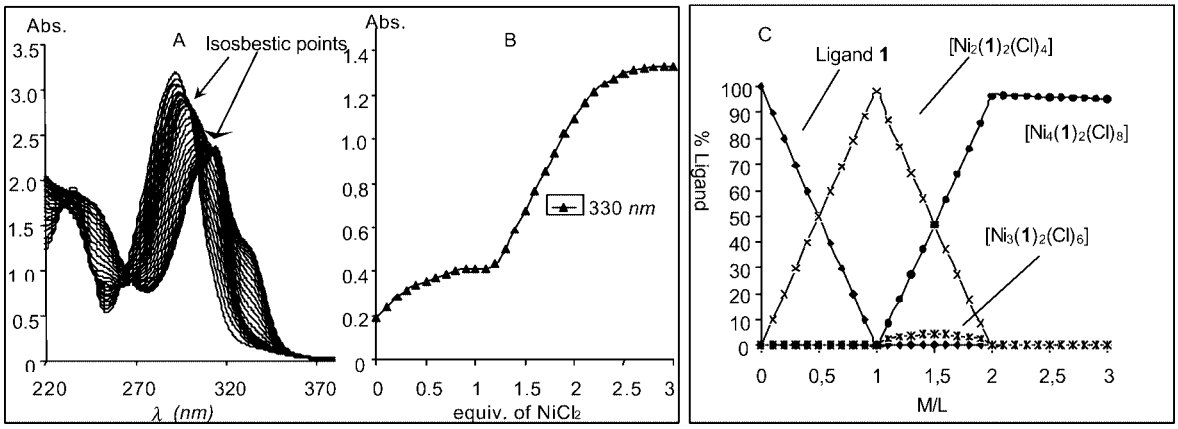

Figure 1. Spectrophotometric titration of the ligand **1** ($10^{-4}$ M) with $NiCl_2$ ($6\times10^{-3}$ M) in MeCN: (A) UV/Vis absorption spectra; (B) plot of absorbance vs. added salt at 330 nm; (C) calculated ligand speciation curves in $CH_3CN$ for ligand **1** and [$Ni^{II}$/ligand **1**] in the range 0.1–3.0.

The titration spectra of ligand **1** display two successive isosbestic points between 220 and 400 nm over the complete titration range. On the addition of $NiCl_2$, a red shift of the absorption spectrum occurs, and a strong absorption and a marked shoulder appear distinctly and successively at $\lambda_{max}$ = 315 ($\varepsilon$ = 21500) and 333 nm ($\varepsilon$ = 12600), thereby indicating the effective coordination of the $Ni^{II}$ ions. The titration plot [Figure 1(B)] shows the formation of a first species with a composition of approximately one Ni ion for 1 equiv. of **1**, in agreement with the X-ray structure of the isolated nickel complex **2**. This is followed by the appearance of a second species upon addition of a second equivalent of $Ni^{II}$ to reach a composition of about two Ni atoms for every equivalent of **1**. UV titration and analysis of the data indicate that the second species could be the complex $[Ni_4(\mathbf{1})_2Cl_8]$, which corresponds to coordination of the remaining nitrogen sites (Figure 2). The binding constants $\log(\beta_{ml})$ for the species $M_mL_l$ were calculated with the SPECFIT program:[15] $[Ni_2(\mathbf{1})_2Cl_4]$ $\log(\beta_{22}) = 34.5\pm0.5$; $[Ni_3(\mathbf{1})_2Cl_6]$ $\log(\beta_{32}) = 41.6\pm1.4$; $[Ni_4(\mathbf{1})_2Cl_8]$ $\log(\beta_{42}) = 51.0\pm2.3$. The distribution curves computed from the formation constants show that the $[Ni_2(\mathbf{1})_2Cl_4]$ and $[Ni_4(\mathbf{1})_2Cl_8]$ complexes are formed quantitatively for M/L = 1 and 2, respectively. According to the speciation [Figure 1(C)], the formation of $[Ni_3(\mathbf{1})_2Cl_6]$ can be neglected.

Figure 2. Proposed structure of the complex $[Ni_4(\mathbf{1})_2Cl_8]$.

ES-MS studies of the MeCN or $CH_2Cl_2$ solutions revealed the presence of ions that could be assigned to $[\{Ni_2(\mathbf{1})_2Cl_2\}]^{2+}$, $[\{Ni_2(\mathbf{1})_2Cl_3\}]^{+}$ and $[\{Ni_3(\mathbf{1})_2Cl_5\}]^{+}$ (all charges were confirmed by partial mass isotopomer distributions and corresponding simulated profiles). This shows unambiguously that the discrete complex **2** contains two ligands and two $Ni^{II}$ ions.

The Ni complex **2** crystallises in the centrosymmetric $P\bar{1}$ space group. The asymmetric unit contains one nickel ion, one bipyridine (bpy) and one bipyrazine (bpz) ligand. The two parts of the dinuclear Ni helicate are related by a centre of inversion, as shown in the ORTEP[16] diagram (Figure 3). In this double-stranded complex, each Ni ion is in a pseudo-octahedral coordination that involves two chlorine anions, two nitrogen atoms of the bipyridine ligand, one nitrogen atom of the bipyrazine molecule and the bridging oxygen atom, which means that the bpz N4, N5 and N6 nitrogen atoms are not connected to any metal centre. The metal–ligand bonds are Ni–N1 = 2.010(6), Ni–N2 = 2.113(5), Ni–N3 = 2.242(7), Ni–O1 = 2.290(5), Ni–Cl2 = 2.327(2) and Ni–Cl1 = 2.369(2) Å.

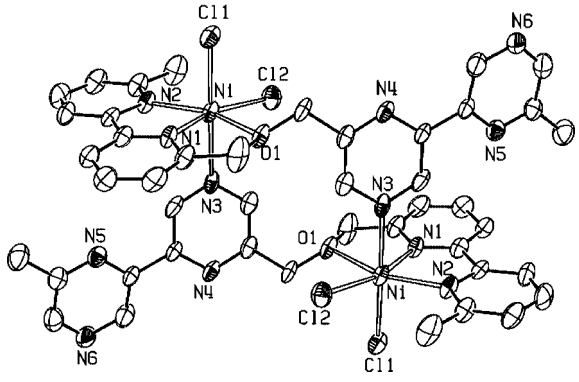

Figure 3. ORTEP drawing of the $Ni^{II}$ complex (H atoms have been omitted for clarity). Thermal ellipsoids are at the 50% probability level.

The distorted octahedra of Ni are characterised by internal angles varying from 74.9(2)° (N1–Ni–O1) to 94.7(1)° (Cl1–Ni–Cl2). In comparison, Ni–N bonds with bpy ligands are found in the range from 2.060 to 2.078 Å in the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bis[3,6-(dipyrid-2-ylmethyl)pyridazine]nickel dinuclear helicate,[17] where the metal ion is also octahedrally coordinated. In our Ni complex, the bpy ligand is rigorously planar whereas the bpz one has an N5–C–C–N4 torsion angle of –162.4(7)° (see Figure 3). The metal–metal distance in our Ni complex is 6.96 Å and is much longer than those found in our previous Ag and Cu helicate structures.[13,14] Figure 4 depicts the crystal packing of the (bpy–bpz)Ni complex. The regular linear arrangement of the helicates along the *b* axis gives rise to open rectangular and polygonal channels in the structure. The closest ligand distances found are between two bpy moieties (5.96 Å).

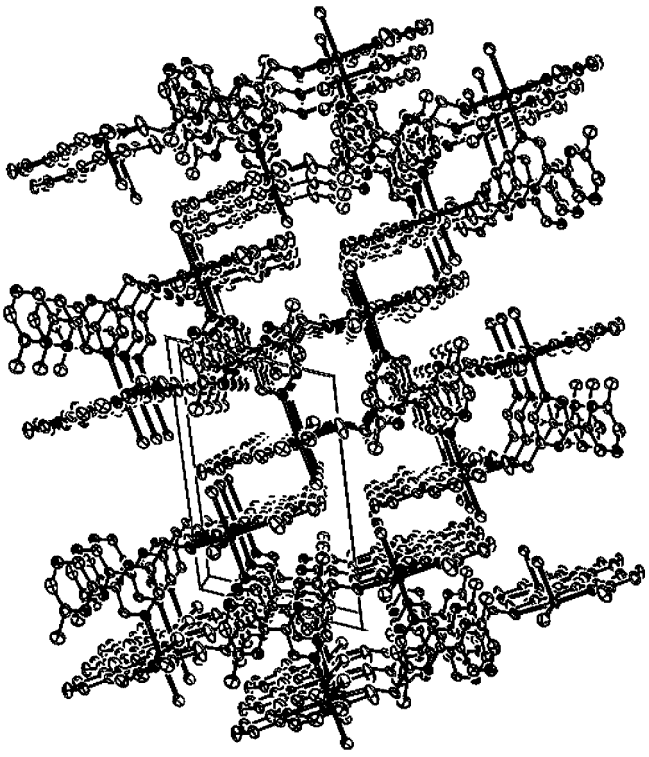

Figure 4. Crystal packing viewed along the *b* axis (Ni bonds are in bold).

### Monocrystal Magnetic Properties

Both the magnetic moment and the AC and DC magnetic susceptibility ($\chi$) of single crystals of the nickel complex **2** were investigated from 2 K to room temperature. Above 100 K the sample magnetic moment is lower than the diamagnetic signal originating from the sample holder and so is close to zero ($< 2\times10^{-7}$ A m$^2$). A plot of the $\chi T$ product vs. $T$ is shown in Figure 5(A) for temperatures between 2 K and 100 K. Figure 5(B) presents the measured magnetic moment vs. the field/temperature ratio for different applied fields and temperatures. The $\chi T$ product is constant from 100 K to about 10 K and the magnetic moment vs. the field/temperature ratio curves are superimposed. This suggests a simple paramagnetic behaviour in this temperature range. Below 10 K, $\chi T$ varies strongly with the temperature, indicating that the sample is not in a paramagnetic regime anymore. This is confirmed by the data set presented in Figure 5(B). Indeed, the magnetic moment vs. the field/temperature curves are not superimposed anymore below 10 K. The continuous line presented in Figure 5(B) is the Brillouin function calculated for two isolated $S = 1$ nuclei with a Landé factor of $g = 2.57$. Below 10 K, the measured magnetic moment is always smaller than expected, suggesting an antiferromagnetic interaction.

Recently, weak magnetic exchange between two $Ni^{II}$ metal centres operating in some diazine complexes over six bonds and over large Ni–Ni internuclear distances up to 6.6 Å has been reported.[18] It is interesting to note that such a weak coupling is maintained at higher internuclear distances in our case, with values of 6.9 Å for the intra-helicate Ni–Ni distance and up to 9.4 Å for the inter-helicate distance.

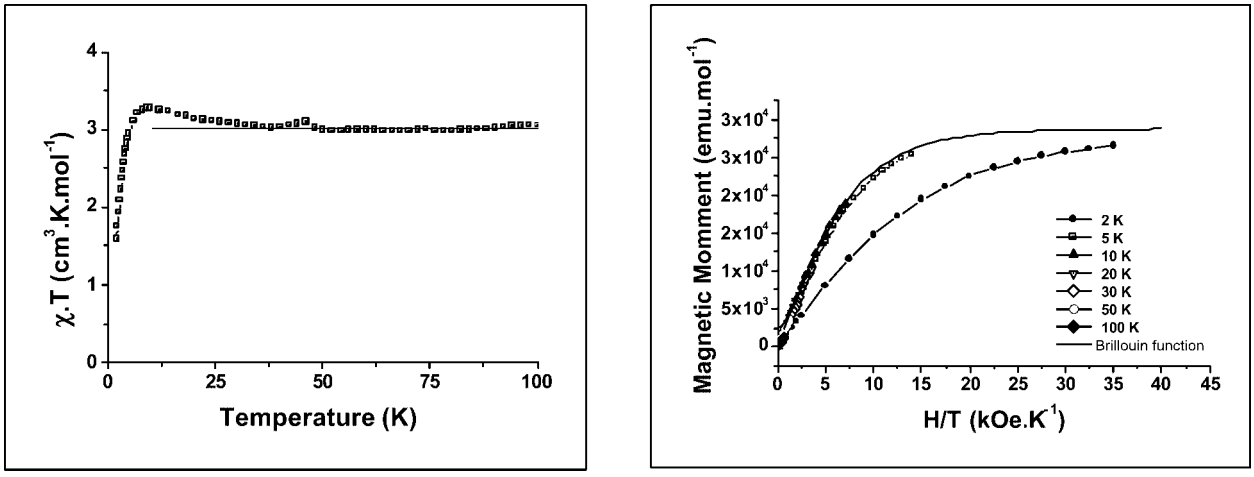

Figure 5. (A, left) DC magnetic susceptibility temperature product vs. temperature. The straight line corresponds to the behaviour expected in a paramagnetic regime. (B, right) Magnetic moment vs. applied field/temperature ratio for different temperatures. The lines between dots are guides for the eyes. The continuous line corresponds to a Brillouin function calculated for two isolated $S = 1$ nuclei (see text).

## Conclusions

In contrast to previously reported double-stranded helicates, afforded by the self-assembly of tetracoordinate cations and homotopic or heterotopic bis(didentate) ligands, the nickel cation gives a new discrete assembly involving oxygen atoms of the 2-oxapropylene bridges and two chlorine atoms in a hexacoordinate mode with the metal ion, and so satisfies the "maximum occupation of sites" principle. Moreover, as observed previously with the same heterotopic sequence,[13,14] one can notice a selective interstrand orientation which promotes exclusively $Ni^{II}$ coordination between a bipyrazine and a bipyridine unit in the system. From a magnetic point of view, both observation of a simple paramagnetic behaviour and the deviation from this behaviour below 10 K suggest the presence of a weak, antiferromagnetic $Ni^{II}$–$Ni^{II}$ interaction. In light of these first results, and in order to build a new library of supramolecular systems, complexation studies with other ligands and potentially hexacoordinated metal centres along with deeper investigations of their physical properties are now underway.

## Experimental Section

**General Remarks:** The synthesis of heterotopic ligand **1** has been described by us previously.[13] UV/Vis spectra were recorded with a UVmC$^2$ Safas spectrometer. Mass spectra (ES) were recorded with a Micromass Platform spectrometer. Elemental analyses were obtained with a Perkin–Elmer 240C CHN-O-S analyser.

**$[Ni_2(1)_2Cl_4]$ (2):** $NiCl_2{\cdot}6H_2O$ (31 mg, 0.13 mmol) was added to the ligand **1** (50 mg, 0.13 mmol) in anhydrous $CH_3CN$ (10 mL) under argon. The green solution was stirred at room temp. and, after evaporation of the solvent, the solid residue was crystallised by slow diffusion of diethyl ether into an acetonitrile/chloroform solution. After 2 d, suitable green crystals were obtained. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$) = 298 nm (28300), 315 (23500), 333 (shoulder) (12600). ESI MS: $m/z$ = 1122.2 [{$Ni_3$(**1**)$_2Cl_5$}]$^+$, 992.6 [{$Ni_2$(**1**)$_2$-$Cl_3$}]$^+$, 478.6 [{$Ni_2$(**1**)$_2Cl_2$}]$^{2+}$. $C_{44}H_{40}Cl_4N_{12}Ni_2O_2$ (1029.4): calcd. C 51.29, H 3.88, N 16.32; found C 50.85, H 3.95, N 15.97.

**Magnetic Measurements:** Both the magnetic moment and the DC magnetic susceptibility ($\chi$) of single crystals of the $Ni^{2+}$ pseudohelicate were investigated from 2 K up to room temperature. The sample mass was 2.4 mg. The magnetic moment evolution with temperature (denoted $T$ as mentioned above) was monitored by SQUID magnetometry in a magnetic field of 0.1 T. The small magnetic contribution originating from the substrate holder was subtracted from the analysed data.

**X-ray Crystallographic Study:** The crystal structure of $C_{44}H_{40}Cl_4N_{12}Ni_2O_2$ [$\rho_{calcd.}$ = 1.61 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 1.19 mm$^{-1}$] was determined from a single-crystal X-ray diffraction experiment performed with an Enraf–Nonius CAD-4F diffractometer (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) at room temperature. A large crystal (green, 0.60 × 0.50 × 0.30 mm) was chosen for the experiments. The compound crystallised in the triclinic space group $P\bar{1}$, $Z$ = 1. The unit-cell parameters were obtained by least-squares fit to setting angles of 25 reflections in the range $8° < 2\theta < 30°$. Cell parameters: $a$ = 8.647(2), $b$ = 10.063(8), $c$ = 13.658(4) Å, $\alpha$ = 106.78(4)°, $\beta$ = 106.76(2)°, $\gamma$ = 96.98(4)°, $V$ = 1062(1) Å$^3$. The $\omega$-$2\theta$ scan mode was used to record the diffraction intensities. Three standard reflections were monitored every 2 h in order to control the intensity decay, which did not occur significantly. 6409 reflections were collected up to $2\theta_{max}$ = 59.96°. Lorentz-polarisation corrections and data reduction were performed using the WINGX package[19] for CAD4 collected intensities. The structures were solved by direct methods using the SIR92 program[20] and refined by the full-matrix least squares based on $F^2$ using SHELX97.[21] Thermal displacements of non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at their idealised positions. During the last cycles of refinement, the best results were obtained with empirical absorption corrections using the XABS2 program in the WINGX package.[19] The final statistical factors were $R1$(all data) = 0.214, $wR2$ = 0.308 for 6166 data and 289 parameters, $R1[F^2 > 2\sigma(I)]$ = 0.0906 for 3009 data with $F^2 > 2\sigma(I)$ and the final residual densities in the unit cell were +1.47 and –1.66 e Å$^{-3}$. CCDC-234807 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We would like to thank the French MESR and the CNRS for support, J. M. Ziegler and D. Bouchu for recording the mass spectra, and Mrs. N. Marshall for correcting the manuscript.

**Keywords:** Arsaalkenes / Heteroallyl ligands / Molybdenum / Phosphavinylidene complexes / Tungsten

The reaction of the phosphavinylidene complexes [Cp(CO)$_2$-M=P=C(SiMe$_3$)$_2$] [Cp = C$_5$H$_5$, M = Mo (**2**), W (**3**)] with the ferrioarsaalkene [Cp*(CO)$_2$Fe–As=C(NMe$_2$)$_2$] (**1a**) (Cp* = C$_5$Me$_5$) afforded the novel η$^3$-2-phospha-1-arsaallyl complexes [η$^3$-{[Fe]–As–P–C(SiMe$_3$)$_2$}M(CO)$_2$Cp] {M = Mo, [Fe] = [Cp*(CO)$_2$Fe] (**4a**);W (**5a**)}. Similarly, treatment of equimolar amounts of **3** with arsaalkene *t*Bu–C(O)–As=C(NMe$_2$)$_2$ (**1b**) gave rise to the formation of [η$^3$-{*t*BuC(O)–As–P–C(SiMe$_3$)$_2$}-W(CO)$_2$Cp] (**5b**) by an arsinidene transfer process. In contrast to this, the more reactive arsaalkene 4-Et–C$_6$H$_4$C(O)–As=C(NMe$_2$)$_2$ (**1c**) and complex **3** underwent reaction to give the cyclic phosphenium complex [Cp(CO)$_2$W=P–O–C$^a$(4-Et–C$_6$H$_4$)=As–C$^b$(SiMe$_3$)$_2$(*P*–*C$^b$*)] (**6**). The novel compounds **4a**, **5a**, **5b**, and **6** were characterized by elemental analyses and by means of spectroscopy (IR, $^1$H, $^{13}$C, $^{31}$P NMR). Moreover, the molecular structures of **4a**, **5b**, and **6** were elucidated by X-ray diffraction analyses.

## Introduction

The search for novel ligand systems remains an important target for both academic and industrial reasons. Prominent examples are N-heterocyclic carbenes, which, as ancillary ligands in transition-metal complexes, have significantly improved the efficiency of a number of catalyzed processes.[1] Other remarkable examples concern phosphaalkenes, phospholyl compounds, and phosphinines, which have recently emerged from the status of laboratory curiosities to become valuable ligands in complex catalysis.[2] Compared to a plethora of synthetically useful η$^3$-allyl complexes[3,4] only a few coordination compounds with η$^3$-1-phosphaallyl ligands such as **I**[5] or η$^3$-1,3-diphosphaallyl ligands such as **II**[6] and **III**[7] have been described. In the dinuclear complexes of type **IV** the 1,3-diphosphaallyl unit is incorporated in a 2,4-phospha-1-metallabutadiene ligand (Scheme 1).[8]

Complex **III** exhibits catalytic activity in ethylene polymerization.[7] Whereas 1,2-diphosphaallyllithium compounds[9] and η$^1$-complexes of the isomeric 1,2-diphosphaallyl ligand **V** have been known for some years,[10] a paper concerning η$^3$-complex **VI** was only recently published.[11]

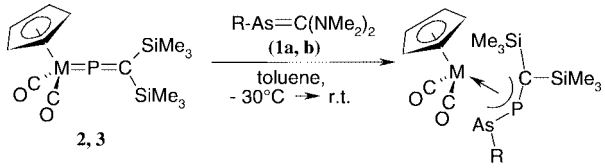
In this paper we report on the reactivity of inversely polarized arsaalkenes R–As=C(NMe$_2$)$_2$ [**1**: **a**: R = Cp*(CO)$_2$-Fe, **b**: *t*BuC(O), **c**: 4-Et–C$_6$H$_4$C(O)] with phosphavinylidene complexes [Cp(CO)$_2$M=P=C(SiMe$_3$)$_2$] (**2**: M = Mo; **3**: M = W),[12] whereby the first complexes with $\eta^3$-2-phospha-1-arsaallyl ligands are formed. Part of this work has previously been published in a short communication.[13]

## Results and Discussion

Treatment of complexes [Cp(CO)$_2$M=P=C(SiMe$_3$)$_2$] (**2**: M = Mo; **3**: M = W) with an equimolar amount of ferrioarsaalkene [Cp*(CO)$_2$Fe–As=C(NMe$_2$)$_2$] (**1a**)[14] in toluene solution over a temperature range of –30 °C to ambient temperature afforded the deep red crystalline $\eta^3$-2-phospha-1-arsaallyl complexes **4a** (35% yield) and **5a** (52% yield). Purification of the products was effected by column chromatography on Florisil with a mixture of hexane/diethyl ether (2:1, v/v) (**4a**) or pentane/diethyl ether (5:1, v/v) (**5a**) as eluents. The air- and moisture-sensitive complexes are well soluble in saturated hydrocarbons, ethereal and aromatic solvents. Analogously, reaction of compound **1b** with an equimolar amount of **3** gives rise to the formation of heteroallyl complex **5b** as an orange solid in 63% yield (Scheme 2). Tetrakis(dimethylamino)ethene is formed as a by-product. After removal of toluene from the reaction mixture, a few drops of the alkene were distilled off and identified by comparison of the $^1$H and $^{13}$C NMR spectra with those of an authentic sample.



| | R | M |

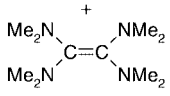

Scheme 2. Formation of the 2-phospha-1-arsaallyl complexes **4a**, **5a**, **5b**.

A singlet at $\delta$ = 4.1 ppm in the $^{31}$P{$^1$H} NMR spectrum of **4a**, a doublet in the $^{13}$C{$^1$H} NMR spectrum at $\delta$ = 49.9 ppm ($J_{P,C}$ = 105 Hz), and singlets in the $^1$H NMR spectrum for two different trimethylsilyl groups ($\delta$ = 0.26, 0.61 ppm), the pentamethylcyclopentadienyl ($\delta$ = 1.46 ppm) and the cyclopentadienyl ligands ($\delta$ = 5.10 ppm) as well as the absence of resonances due to the C(NMe$_2$)$_2$ fragment indicate the combination of the phosphavinylidene unit of **2** and the arsanediyl group of **1a** to a novel ligand system in complex **4a**. Accordingly, the tungsten analogue **5a** and the (pivaloylphosphaarsaallyl)tungsten complex **5b** display singlets at $\delta$ = –18.7 and –8.9 ppm in the $^{31}$P{$^1$H} NMR spectrum. This high-field position is typical for $^{31}$P{$^1$H} resonances of $\eta^3$-phosphaallyl complexes of tungsten as evident from [$\eta^3$-(2,4,6-*t*Bu$_3$C$_6$H$_2$PCHCH$_2$)W(CO)$_2$Cp] ($\delta$ = –48.9 and –28.0 ppm for both isomers).[15] In the $\eta^3$-1,2-diphosphaallyl complex **VI** the resonances for the central P atom were observed at $\delta$ = –6.8 ppm (M = Mo, R = *t*Bu) and $\delta$ = –61.6 ppm (M = W, R = *t*Bu).[11] In the $^{13}$C{$^1$H} NMR spectra of **4a**, **5a**, and **5b** the carbon atoms of the 2-phospha-1-arsaallyl ligands appear as doublets at $\delta$ = 49.9 ppm ($J_{P,C}$ = 105.0 Hz), 35.7 ($J_{P,C}$ = 101.2 Hz), and 31.8 ($J_{P,C}$ = 98.5 Hz) ppm. The $^{13}$C NMR resonances of the carbonyl ligands were observed at $\delta$ = 234.0 (s), 236.0 (s) (Mo–CO); 216.7 (s), 218.65 (d, $J_{P,C}$ = 11.5 Hz) (Fe–CO) for **4a**, at $\delta$ = 222.7 (s), 224.6 (s) (W–CO); 217.1 (s), 219.0 (s) (Fe–CO) for **5a**, and at $\delta$ = 222.8 (s), 223.9 (s) for **5b**. A $^{13}$C NMR doublet at δ = 233.5 ($J_{P,C}$ = 4.1 Hz) ppm in the spectrum of **5b** was attributed to the acylic carbonyl group. These resonances are shifted to a lower field relative to those of precursors **2** ($\delta$ = 230.4 ppm)[12b] and **3** ($\delta$ = 218.9 ppm)[12b] indicating the improved donor capacity of the $\eta^3$-2-phospha-1-arsaallyl ligands over the phosphavinylidene system. Similar observations were made with the $\eta^3$-1,2-diphosphaallyl complexes of type **VI** [e.g., M = Mo, R = *t*Bu; $\delta^{13}$CO = 234.3 (s), 235.5 (s) ppm]. This is also mirrored by the carbonyl stretching frequencies in the IR spectra of **4a**, **5a**, and **5b**, which are observed as intense bands at $\tilde{\nu}$= 1929, 1850 cm$^{-1}$ (**4a**), at $\tilde{\nu}$= 1923, 1843 cm$^{-1}$ (**5a**), and at $\tilde{\nu}$= 1941, 1874 cm$^{-1}$ (**5b**). The differences between the ν(CO) absorptions of **5a** and **5b** are due to the electron-donating iron substituent in **5a** and the electron-withdrawing pivaloyl group in **5b**. The corresponding bands in the precursors **2** and **3** appear at $\tilde{\nu}$= 1944, 1882 cm$^{-1}$ (KBr) and 1952, 1880 cm$^{-1}$ (*n*-hexane).[12b] In the IR spectrum of 1,2-diphosphaallyl complexes **VI** ν(CO) bands were registered at $\tilde{\nu}$= 1943, 1877 cm$^{-1}$ (M = Mo; R = *t*Bu) and at $\tilde{\nu}$= 1938, 1851 cm$^{-1}$ (M = W; R = *t*Bu).[11]

Single crystals of **4a** and **5a** suitable for an X-ray diffraction analysis were grown from a 1:9 mixture of diethyl ether/*n*-pentane at –30 °C. Compound **5a** is isostructural to **4a**, and only the latter will be discussed in detail.

The analysis (see Figure 1) displays a molecule with a distorted piano-stool geometry [As(1)–Mo(1)–C(20) = 63.87(7)°, C(20)–Mo(1)–C(21) = 80.83(11)°, C(21)–Mo(1)–C(13) = 69.07(9)°], with two nearly linear carbonyl ligands [Mo(1)–C(20)–O(3) = 170.9(2)°, Mo(1)–C(21)–O(4) = 175.7(2)°]. The most interesting part of the molecule is the unprecedented 2-phospha-1-arsaallyl ligand which is unsymmetrically linked to the metal atom in an $\eta^3$-fashion through bonds Mo(1)–As(1) [2.7644(3) Å], Mo(1)–P(1) [2.4940(6) Å], and Mo(1)–C(13) [2.420(2) Å]. The latter bond length significantly exceeds the Mo(1)–C distances of the [CpMo] part of the molecule [2.316(2)–2.371(2) Å]. In the (1,2-diphosphaallyl)molybdenum complex **VI** the corresponding Mo–C bond length was determined to be 2.437(1) Å.[11] The distances between the Mo atom and the terminal carbon atom in **4a** as well as in **VI** clearly exceed the corresponding Mo–C bond lengths in 1-phosphaallyl complex **VII** [2.357(3) Å].[5c]

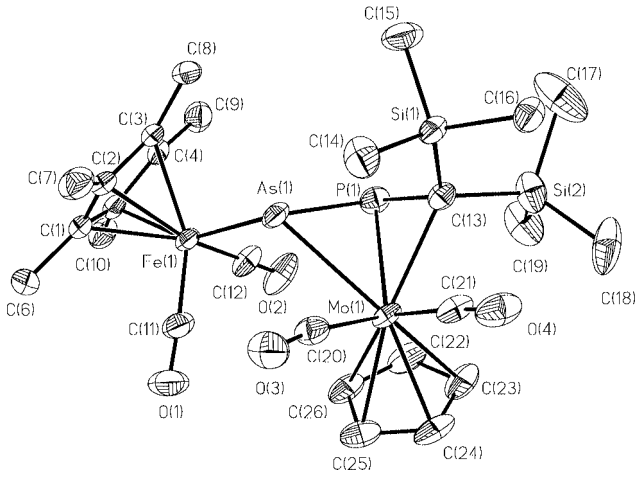

Figure 1. Molecular structure of **4a** in the crystal. Selected bond lengths [Å] and angles [°]: Mo(1)–C(20) 1.953(2), Mo(1)–C(21) 1.959(2), Mo(1)–C(13) 2.420(2), Mo(1)–P(1) 2.4940(6), Mo(1)–As(1) 2.7644(3), P(1)–As(1) 2.2507(7), P(1)–C(13) 1.791(2), As(1)–Fe(1) 2.4098(4), C(13)–Si(1) 1.898(2), C(13)–Si(2) 1.895(2), C(20)–Mo(1)–C(21) 80.83(11), C(21)–Mo(1)–C(13) 69.07(9), C(20)–Mo(1)–As(1) 63.83(7), As(1)–P(1)–C(13) 99.15(7), P(1)–As(1)–Fe(1) 106.59(2), P(1)–C(13)–Si(1) 120.88(12), P(1)–C(13)–Si(2) 108.67(11).

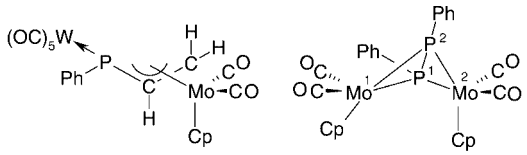
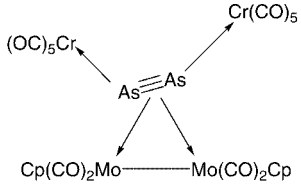


**VII** **VIII**

The metal–phosphorus distances in both complexes **4a** [2.4940(6) Å] and **VI** (M = Mo) [2.4960(3) Å] are identical, and intermediate between the Mo–P bond lengths Mo(1,2)–P(1) [2.466, 2.470 Å] and Mo(1,2)–P(2) [2.542, 2.546 Å] in **VIII**.[16] The Mo(1)–As(1) bond in **4a** is lengthened when compared with the Mo–As contacts in tetrahedrane **IX** [2.531(3), 2.645(3) Å].[17]



**IX**

Due to the π-interaction with a metal atom, the As–P distance within the 2-phospha-1-arsaallyl ligand in **4a** [2.2507(7) Å] is longer than the unsupported As=P double bonds in the structurally characterized compounds {$(Me_3Si)_2CH$}As=P(2,4,6-$tBu_3C_6H_2$) [2.124 Å][18] or [Cp*-$(CO)_2$FeAs{$Cr(CO)_5$}=P(2,4,6-$tBu_3C_6H_2$)] [2.155(1) Å].[19]

The bond length P(1)–C(13) in **4a** [1.791(2) Å]–as is also found in **VI** (M = Mo) [1.7875(12) Å]–is elongated with respect to a localized and unsupported P=C double bond (1.65–1.72 Å),[20] but is clearly shorter than a P–C single bond (av. 1.85 Å).[21] In **VII** the corresponding bond length was determined to be 1.755(3) Å.[5c] The atoms Fe(1) and Si(2) in **4a** are directed towards the phosphorus atom enclosing angles Fe(1)–As(1)–P(1) [106.59(2)°], As(1)–P(1)–C(13) [99.15(7)°], and P(1)–C(13)–Si(2) [108.67(11)°]. Substituent $Si(1)(CH_3)_3$ at C(13) is located above the plane defined by the atoms As(1), P(1), and C(13) with an angle P(1)–C(13)–Si(1) of 120.88(12)°.

From the view-point of the Wade–Mingos rules molecule **4a** as well as the related compounds **5a** and **5b** possess four skeleton atoms and 14 skeleton electrons and thus have to be regarded as *arachno* clusters.[22] Orange single crystals of the ($\eta^3$-2-phospha-1-arsaallyl)tungsten complex **5b** were grown from diethyl ether/*n*-pentane (1:5) at –30 °C (see Figure 2). The analysis shows a molecule, the core of which is similar to that of **4a** with the pivaloyl substituent and the group $Si(1)Me_3$ directed towards the central atom P(1) of the $\eta^3$-heteroallyl ligand. The bonds As(1)–P(1) [2.269(1) Å] and P(1)–C(8) [1.806(2) Å] within the 2-phospha-1-arsaallyl ligand of **5b** are slightly longer than in **4a**. The bond As(1)–C(15) to the carbonyl carbon atom of the pivaloyl substituent [2.063(2) Å] is markedly elongated when compared with the As–C(O) contact in the precursor arsaalkene [1.938(4) Å].[23] The sum of single bond radii of As and C is 1.98 Å.[24] The formal As=C double bond of precursor **1b** was elongated to 1.924(5) Å[23] [in Cp*$(CO)_2$Fe–As=C$(NMe_2)_2$: As–C = 1.876(8) Å].[14] The bond length C(15)–O(3) is that of a localized carbonyl group.[24] The atoms C(15) and Si(1) are located in the plane defined by the atoms C(8), P(1), and As(1). These atoms are attached to the tungsten center by bonds W(1)–As(1) [2.759(1) Å], W(1)–P(1) [2.498(1) Å], and W(1)–C(8) [2.439(2) Å]. They are all well comparable to those in **5a**: W(1)–As(1) [2.7854(2) Å], W(1)–P(1) [2.4955(5) Å], and W(1)–C(8)

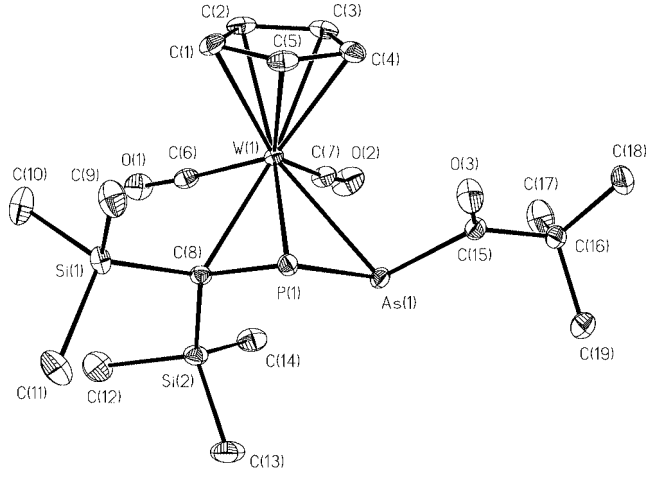


Figure 2. Molecular structure of **5b** in the crystal. Selected bond lengths [Å] and angles [°]: W(1)–C(6) 1.968(2), W(1)–C(7) 1.977(2), W(1)–C(8) 2.439(2), W(1)–P(1) 2.498(1), W(1)–As(1) 2.759(1), P(1)–C(8) 1.806(2), P(1)–As(1) 2.269(1), As(1)–C(15) 2.063(2), C(8)–Si(1) 1.912(2), C(8)–Si(2) 1.922(2), O(3)–C(15) 1.214(2), C(15)–C(16) 1.541(2), C(6)–W(1)–C(7) 80.30(8), C(6)–W(1)–C(8) 67.13(7), C(7)–W(1)–As(1) 67.62(6), C(8)–P(1)–As(1) 97.66(6), P(1)–As(1)–C(15) 93.86(5), As(1)–C(15)–O(3) 122.37(13), O(3)–C(15)–C(16) 122.47(16), As(1)–C(15)–C(16) 115.07(12), P(1)–C(8)–Si(1) 107.49(9), P(1)–C(8)–Si(2) 122.05(10), Si(1)–C(8)–Si(2) 114.60(9).

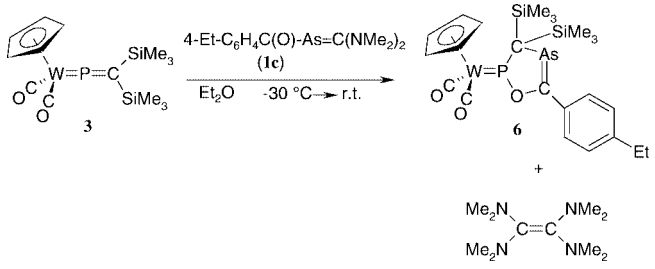
[2.411(2) Å]. The W–As π-bonds in [η¹:η²-PhAs=AsPhW(CO)$_5$]$_2$ [2.728(4) and 2.769(4) Å] are similar to the W–As bond length in **5b**. The W–P π-bond length in η³-{2,4,6-*t*Bu$_3$C$_6$H$_2$–P(O)CHCH$_2$}W(CO)$_2$Cp [2.488(1) Å] is also in good agreement with the respective atom distance in **5b**.[25] The W(1)–C(8) bond in **5b** [2.439(2) Å], however, is markedly lengthened in comparison to those in η³-{2,4,6-*t*Bu$_3$C$_6$H$_2$P(O)CHCH$_2$}W(CO)$_2$Cp [2.344(5), 2.335(4) Å].[25]

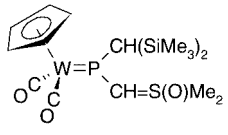
To the best of our knowledge compounds **4a**, **5a**, and **5b** are the first η³-2-phospha-1-arsaallyl complexes. One η¹-2-phospha-1-arsaallyl complex (η⁵-C$_5$Me$_5$)(CO)$_2$FeAs(SiMe$_3$)–P=C(SiMe$_3$)$_2$ was recently described.[26] 2-Phospha-1-arsapropenes are rare compounds. To the best of our knowledge there are two accounts in the literature of such species. Thermolabile Ph$_2$As–P=C(Ph)SiMe$_3$[27] decomposes within 1 d to Ph$_4$As$_2$ and a diphosphabicyclobutane, whereas *t*Bu$_2$As–P=C(SiMe$_3$)$_2$ is stable at ambient temperature.[28]

Reaction of phosphavinylidene complex **3** with the more reactive arsaalkene 4-Et–C$_6$H$_4$C(O)As=C(NMe$_2$)$_2$ (**1c**) in diethyl ether took a completely different course. Here the cyclic phosphenium complex **6** was isolated as red crystals in 41% yield. (Scheme 3).



Scheme 3. Formation of the phosphenium complex **6**.

The $^{31}$P{$^{1}$H} NMR spectrum of **6** displays a singlet at $\delta$ = 313.2 ppm with $^{183}$W satellites ($J_{P,W}$ = 728 Hz), which indicates the presence of a W=P double bond. The data are comparable with the $^{31}$P NMR spectra of complexes **Xa**, **b** ($\delta$ = 306.4 ppm; 244.8 ppm, $J_{P,W}$ = 604 Hz)[29] and **IV** (M = Mo: $\delta$ = 304 ppm; M = W: $\delta$ = 246.8 ppm, $J_{P,W}$ = 638 Hz).[8]



**Xa**: M = Mo
**Xb**: M = W

Both silyl groups are chemically and magnetically equivalent giving rise to a singlet at $\delta$ = 0.47 ppm in the $^{1}$H NMR spectrum and a singlet at $\delta$ = 1.9 ppm in the $^{13}$C{$^{1}$H} NMR spectrum of the compound. A doublet of low intensity at $\delta$ = 60.1 ppm ($J_{P,C}$ = 50.3 Hz) is due to a quaternary carbon atom adjacent to the P atom. The two chemically and magnetically equivalent carbonyl ligands give rise to a singlet at $\delta$ = 226.9 ppm with $^{183}$W satellites ($J_{W,C}$ = 183 Hz). A singlet at $\delta$ = 222.8 ppm is assigned to the $^{13}$C nucleus of an As=C double bond. This value falls in the range of $\delta$ = 200.6 ppm in MesAs=CHNMe$_2$ to $\delta$ = 241.5 ppm in Me$_3$Si-As=C(OSiMe$_3$)*t*Bu.[30] The IR spectrum in the region of the CO stretching modes is characterized by two intense bands at $\tilde{\nu}$ = 1938, 1859 cm$^{-1}$. No bands are found for the $\tilde{\nu}$(CO) mode of an acylarsane (e.g., $\tilde{\nu}$ = 1660 cm$^{-1}$ in **5b**). Yellow single crystals of compound **6** (Figure 3) were obtained from a diethyl ether solution at –30 °C. The analysis displays a molecule with a distorted piano-stool geometry [P(1)–W(1)–C(1) 95.1(1)°, P(1)–W(1)–C(2) 96.2(1)°, C(1)–W(1)–C(2) 84.6(1)°] with two nearly linear carbonyl ligands [W(1)–C(1)–O(1) 177.8(3)°, W(1)–C(2)–O(2) 175.1(2)°].

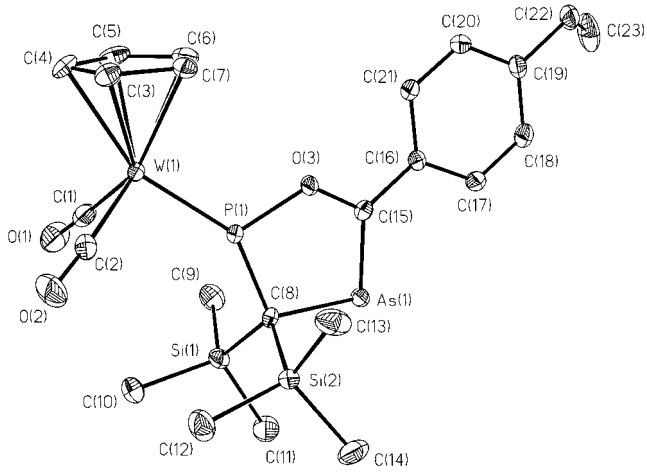


Figure 3. Molecular structure of **6** in the crystal. Selected bond lengths [Å] and angles [°]: W(1)–C(1) 1.976(3), W(1)–C(2) 1.960(3), W(1)–P(1) 2.232(1), P(1)–O(3) 1.698(2), O(1)–C(1) 1.159(3), O(2)–C(2) 1.164(3), O(3)–C(15) 1.372(3), C(15)–C(16) 1.472(3), As(1)–C(15) 1.832(2), As(1)–C(8) 2.023(2), C(8)–Si(1) 1.932(3), C(8)–Si(2) 1.941(3), C(1)–W(1)–C(2) 84.6(1), C(1)–W(1)–P(1) 95.1(1), C(2)–W(1)–P(1) 146.0(1), W(1)–P(1)–O(3) 114.2(1), W(1)–P(1)–C(8) 146.0(1), O(3)–P(1)–C(8) 99.8(1), P(1)–C(8)–As(1) 106.7(1), C(8)–As(1)–C(15) 92.1(1), As(1)–C(15)–O(3) 118.5(2), P(1)–O(3)–C(15) 118.7(1), O(3)–C(15)–C(16) 114.5(2), As(1)–C(15)–C(16) 127.0(2).

The third leg is represented by a 1,2,4-oxaphospharsolenium ligand which is linked to the metal atom through a W=P double bond of 2.232(1) Å. The bond length lies between those in [Cp(CO)$_2$W=PO$^a$–CMe$_2$–CMe$_2$–O$^b$(*P*–*O*$^b$)] [2.181 Å][31] and Cp(CO)$_2$W=P(*t*Bu)$_2$ [2.284(4) Å].[32] This ring ligand without precedent features an As–C(15) double bond of 1.832(2) Å, which is well comparable to the As–C separation in the metalloarsaalkene [Cp(CO)$_2$Fe–As=C(OSiMe$_3$)*t*Bu] [1.821(2) Å].[33] The bond length C(15)–O(3) [1.372(3) Å] is similar to the one in the metalloarsaalkene [1.356(3) Å], both being shorter with respect to an sp$^2$ C–O single bond (ca. 1.41 Å).[34] The contacts P(1)–O(3) [1.698(2) Å] and P(1)–C(8) [1.814(2) Å] are markedly shorter than the sum of the covalent radii (1.76 and 1.87 Å) but still reflect bond orders of unity. The five-membered ring is slightly puckered (sum of endocyclic angles 535°). The plane defined by the atoms P(1), O(3), and C(8) bisects the angle C(1)–W(1)–C(2), enclosing angles of 43° with vector W(1)–C(1) and 41° with vector W(1)–C(2).

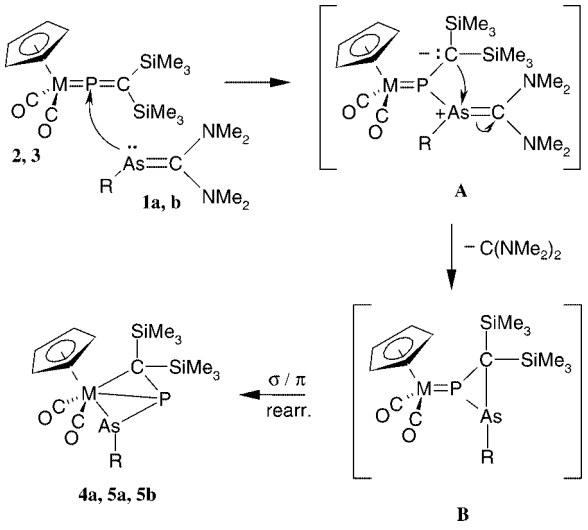
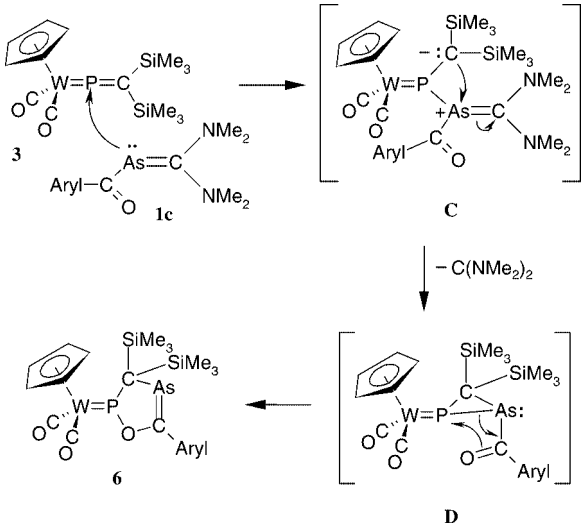
### Mechanisms

It is conceivable that the formation of complexes **4a**, **5a**, and **5b** is initiated by the nucleophilic attack of the arsaalkene through its As atom on the phosphorus center of precursors **2** and **3** to give adduct **A**. Extrusion of $C(NMe_2)_2$ would lead to intermediate **B**. A σ/π-type rearrangement of **B** affords the final products (see Scheme 4).



Scheme 4. Proposed mechanism for the formation of **4a**, **5a**, and **5b**.

The formation of the functionalized phosphenium complex **6** may be initiated by the nucleophilic attack of arsaalkene **1c** through its electron-abundant arsenic atom at the phosphorus center of **3** affording zwitterion **C**, which collapses to phospharsirenium complex **D**. Incorporation of the carbonyl group into the As–P bond of the strained ring leads to the observed product **6** (Scheme 5).



Scheme 5. Proposed mechanism for the formation of **6**.

## Conclusions

Transition-metal-induced cleavages of inversely polarized arsaalkenes to give cyclotriarsanes[35] or an $\eta^2$-diarsene complex[36] were observed. Here the smooth generation of $\eta^3$-2-phospha-1-arsaallyl complexes **4a**, **5a**, **5b**, and complex **6** featuring the 1,2,4-oxaphospharsolenium ligand underlines the ability of arsaalkenes to act as convenient sources for arsanediyl (arsinidene) units under mild conditions.

## Experimental Section

**General:** All manipulations were performed under dry, oxygen-free nitrogen using standard Schlenk techniques. Solvents were rigorously dried with an appropriate drying agent and freshly distilled under $N_2$ before use. The following compounds were prepared according to literature procedures: $[Cp(CO)_2M{=}P{=}C(SiMe_3)_2]$ [M = Mo (**2**), W (**3**)],[12] $[Cp^*(CO)_2Fe{-}As{=}C(NMe_2)_2]$ (**1a**),[14] $Me_3Si{-}As{=}C(NMe_2)_2$.[14] IR: Bruker FT-IR VECTOR 22. $^1$H-, $^{13}$C-, and $^{31}$P NMR ($C_6D_6$, room temp.): Bruker AM Avance DRX 500 ($^1$H: 500.13 Hz; $^{13}$C: 125.75 MHz; $^{31}$P: 202.46 MHz); references: $SiMe_4$ ($^1$H, $^{13}$C), 85% $H_3PO_4$ ($^{31}$P). Florisil (Merck), pivaloyl chloride, and 4-ethylbenzoyl chloride were purchased commercially.

***t*BuC(O)As=C(NMe$_2$)$_2$ (1b):** A solution of pivaloyl chloride (0.18 g, 1.50 mmol) in *n*-pentane (10 mL) was added dropwise to a chilled solution (–30 °C) of $Me_3SiAs{=}C(NMe_2)_2$ (0.37 g, 1.50 mmol) in *n*-pentane (30 mL). A yellow precipitate separated. Stirring was continued for 30 min, and the solvent was decanted. The precipitate was washed twice with cold *n*-pentane (30 mL, –30 °C) and dried in vacuo to afford 0.27 g (69%) of **1b** as a pale yellow solid. IR (Nujol): $\tilde{\nu}$= 1584, 1530 cm$^{-1}$. $^1$H NMR: $\delta$ = 1.40 (s, 9 H, *t*Bu), 2.65 (s, 12 H, $NCH_3$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 27.9 [s, $C(CH_3)_3$], 43.5 (s, $NCH_3$), 49.8 [s, $C(CH_3)_3$], 210.7 (s, $CN_2$), 240.1(s, CO) ppm. Because of the pronounced thermolability of the compound it was not possible to obtain reliable elemental analyses.

**[Cp(CO)$_2$Mo{η$^3$-[Cp*(CO)$_2$Fe]AsPC(SiMe$_3$)$_2$}] (4a):** A solution of **1a** (0.76 g, 1.81 mmol) in toluene (20 mL) was added dropwise to a well-stirred chilled solution (–30 °C) of **2** (0.72 g, 1.81 mmol) in toluene (25 mL). It was slowly warmed to ambient temperature and stirring was continued for 12 h. The reaction mixture was freed from solvent and volatile components. The black residue was dissolved with diethyl ether (10 mL), then Florisil was added (5 g) and the slurry was concentrated to dryness. The coated Florisil was transferred to the top of a column ($d$ = 1.5 cm, $l$ = 6 cm) charged with Florisil (20 g). A dark red zone was eluted with a 2:1 mixture of diethyl ether/*n*-pentane. Removal of solvents from the eluate afforded 0.46 g (35%) of dark red crystalline **4a**. IR (KBr): $\tilde{\nu}$= 1850, 1929, 1977 cm$^{-1}$ (C≡O). $^1$H NMR: $\delta$ = 0.26 (s, 9 H, $SiMe_3$), 0.61 (s, 9 H, $SiMe_3$), 1.46 (s, 15 H, $C_5Me_5$), 5.10 (s, 5 H, Cp) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 4.27 (s, $SiCH_3$), 4.35 (s, $SiCH_3$), 9.4 [s, $C_5(CH_3)_5$], 49.9 (d, $J_{P,C}$ = 105 Hz, $PCSi_2$), 91.2 (s, Cp), 95.6 [s, $C_5(CH_3)_5$], 216.7 (s, FeCO), 218.65 (d, $J_{P,C}$ = 11.5 Hz, FeCO), 234.3 (s, MoCO), 236.8 (s, MoCO) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 4.1 (s) ppm. $C_{26}H_{38}AsFeMoO_4PSi_2$ (728.44): calcd. C 42.87, H 5.26; found C 43.17, H 5.29.

**[Cp(CO)$_2$W{η$^3$-[Cp*(CO)$_2$Fe]AsPC(SiMe$_3$)$_2$}] (5a):** Analogously, the combination of **1a** (0.76 g, 1.81 mmol) in toluene (20 mL) with **3** (0.89 g, 1.81 mmol) in toluene (25 mL) at –30 °C and identical workup [Florisil, diethyl ether/*n*-pentane (5:1)] afforded 0.77 g (52%) of dark red crystalline **5a**. IR (KBr): $\tilde{\nu}$= 1843, 1923, 1975 cm$^{-1}$ (C≡O). $^1$H NMR ($C_6D_6$): $\delta$ = 0.25 (s, 9 H, $SiMe_3$), 0.66

(s, 9 H, $SiMe_3$), 1.47 (s, 15 H, $C_5Me_5$), 5.13 (s, 5 H, Cp) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 4.4 (d, $J_{P,C}$ = 9.2 Hz, $SiCH_3$), 9.5 [s, $C_5(CH_3)_5$], 10.1 (s, $SiCH_3$), 35.7 (d, $J_{P,C}$ = 101.2 Hz, $PCSi_2$), 89.6 (s, Cp), 95.6 [s, $C_5(CH_3)_5$], 217.1 (s, FeCO), 219.0 (s, FeCO), 222.7 (s, WCO), 224.6 (s, WCO) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = –18.7 (s) ppm. $C_{26}H_{38}AsFeO_4PSi_2W$ (816.35): calcd. C 38.26, H 4.49; found C 38.68, H 4.90.

**[Cp(CO)$_2$W{η$^3$-{*t*BuC(O)}AsPC(SiMe$_3$)$_2$}] (5b):** A chilled solution (–30 °C) of arsaalkene **1b** (1.81 mmol) in diethyl ether (20 mL) was added dropwise to a well-stirred cold solution (–30 °C) of complex **3** (0.89 g, 1.81 mmol) in diethyl ether (25 mL). Stirring at –30 °C was continued for 4 h before the reaction mixture was slowly warmed to room temp. After 12 h of stirring, solvent and volatile components were removed in vacuo. The black residue was dissolved in diethyl ether (10 mL). Florisil (5 g) was added and the slurry was concentrated to dryness. As described earlier, the crude material was chromatographed on a Florisil column ($d$ = 1.5 cm, $l$ = 6 cm) charged with Florisil (20 g). An orange-red zone was eluted with a diethyl ether/pentane mixture (5:1). Removal of solvents from the eluate afforded 0.75 g (63%) of orange crystalline **5b**. IR (KBr): $\tilde{\nu}$= 1941, 1874 (C≡O), 1660 (C=O) cm$^{-1}$. $^1H$ NMR: $\delta$ = 0.16 (d, $J_{P,H}$ = 1.6 Hz, 9 H, $SiMe_3$), 0.45 (s, 9 H, $SiMe_3$), 1.05 (s, 9 H, *t*Bu), 4.96 (s, 5 H, Cp) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 4.0 (d, $J_{P,C}$ = 9.7 Hz, $SiCH_3$), 8.5 (s, $SiCH_3$), 26.2 [s, $C(CH_3)_3$], 31.8 [d, $J_{P,C}$ = 98.5 Hz, $C(SiMe_3)_2$], 50.1 [s, $C(CH_3)_3$], 90.1 (s, Cp), 222.8 (s, WCO), 223.9 (s, WCO), 233.53 (d, $J_{P,C}$ = 4.1 Hz, AsCO) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = –8.9 (s) ppm. $C_{19}H_{32}AsO_3PSi_2W$ (654.38): calcd. C 34.87, H 4.93; found C 34.82, H 4.92.

**[Cp(CO)$_2$W=POC$^a$(4-Et–C$_6$H$_4$)=AsC$^b$(SiMe$_3$)$_2$(*P*–*C*$^b$)] (6):** A solution of 4-ethylbenzoyl chloride (0.61 g, 3.62 mmol) in diethyl ether (10 mL) was added dropwise to a chilled solution (–30 °C) of $Me_3Si$-iAs=$C(NMe_2)_2$ (0.89 g, 3.62 mmol). Stirring was continued for 30 min to give **1c**. A solution of complex **3** (0.89 g, 1.81 mmol) in diethyl ether (20 mL) was slowly added with vigorous stirring. It was slowly warmed to room temp. and stirring was continued for 12 h. It was concentrated to dryness and the black residue was dissolved in diethyl ether (10 mL). Florisil (5 g) was added and the slurry was freed from solvent. The coated Florisil was transferred onto the top of a column ($d$ = 1.5 cm, $l$ = 6 cm) charged with Florisil (20 g). A red zone was eluted with pentane. Removal of solvents in vacuo afforded 0.52 g (41%) of deep red crystalline **6**. IR (KBr): $\tilde{\nu}$= 1859, 1938 (C≡O) cm$^{-1}$. $^1H$ NMR: $\delta$ = 0.47 (s, 18 H, $SiMe_3$), 1.01 (t, $J_{H,H}$ = 7.5 Hz, 3 H, $CH_3CH_2$), 2.30 (q, $J_{H,H}$ = 7.5 Hz, 2 H, $CH_3CH_2$), 5.15 (s, 5 H, Cp), 6.87 (d, $J_{H,H}$ = 8.2 Hz, 2 H, Ph), 7.77 (d, $J_{H,H}$ = 8.2 Hz, 2 H, Ph) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 1.9 (s, $SiMe_3$), 15.4 (s, $CH_3CH_2$), 29.2 (s, $CH_3CH_2$), 60.1 [d, $J_{P,C}$ = 60.3 Hz, $C(SiMe_3)_2$], 89.6 (s, Cp), 124.4 (s, Ph), 128.3 (s, Ph), 128.7 (s, Ph), 147.4 (s, Ph), 222.8 (s, As=C), 226.9 (s, $J_{W,C}$ = 183 Hz, C≡O) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 313.2 ($J_{P,W}$ = 728 Hz) ppm. $C_{23}H_{32}AsO_3PSi_2W$ (702.42): calcd. C 39.33, H 4.59; found C 39.47, H 4.69.

**X-ray Crystallography:** Crystallographic data were collected with a Nonius Kappa CCD diffractometer with Mo-$K_\alpha$ (graphite monochromator, $\lambda$ = 0.71073 Å) at 100 K. Crystallographic programs used for the structure solution and refinement were SHELXS-97,[37] SIR-97,[38] and SHELXL-97.[37] The structures were solved by direct methods and were refined by using full-matrix least squares on $F^2$ of all unique reflections with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were included at calculated positions with $U$(H) = 1.2 $U_{eq}$ for $CH_2$ groups, $U$(H) = 1.5 $U_{eq}$ for $CH_3$ groups. Crystal data for the compounds are listed in Table 1. CCDC-250373 (**4a**), -279437 (**5b**), and -279438 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Self-Assembly and Characterization of Homo- and Heterodinuclear Complexes of Zinc(II) and Lanthanide(III) Ions with a Tridentate Schiff-Base Ligand

**Violetta Patroniak,*[a,b] Artur R. Stefankiewicz,[a,b] Jean-Marie Lehn,[b] Maciej Kubicki,[a] and Marcin Hoffmann[a]**

**Keywords:** Dinuclear complexes / Lanthanides / Tridentate Schiff-base ligand / Self-assembly / Zinc

Tridentate Schiff-base ligand H**L** (L = $C_{12}H_9N_2O$) reacts with lanthanide(III) nitrates to give complexes of formulae $[M_2\mathbf{L}_3(NO_3)_3]$, where M = $Y^{3+}$ (**1**), $La^{3+}$ (**2**), $Nd^{3+}$ (**3**), $Sm^{3+}$ (**4**), $Eu^{3+}$ (**5**), $Gd^{3+}$ (**6**), $Tb^{3+}$ (**7**), $Dy^{3+}$ (**8**), $Ho^{3+}$ (**9**), $Lu^{3+}$ (**10**), and $[MM^1\mathbf{L}_3(NO_3)_x]$, where M = $Eu^{3+}$, and $M^1$ = $Dy^{3+}$ (**11**), $Zn^{2+}$ (**12**); x = 3 for **11** and 2 for **12**. The structures of the complexes have been assigned on the basis of the spectroscopic data (solution analysis) and microanalyses. In the case of complexes **3**, **5**, **8** and **12** the structures have been confirmed by X-ray crystallography. The structural analysis of the dinuclear complexes showed the presence of two metal atoms [M(1) and M(2)] and three ligands, **L**. Each lanthanide atom is coordinated to by 9 donor atoms with typical Ln–N and Ln–O distances. Zinc(II) is coordinated to by two oxygen atoms and four nitrogen atoms from two ligands. The metal ions are bridged by the phenoxo oxygen atoms of the ligands. We have obtained a heterodinuclear complex by a rapid one-step reaction. Quantum mechanical calculations indicated that the formation of heterodinuclear complex **12** is slightly favored energetically over the homodinuclear complex **5**.

## Introduction

Schiff-base ligands with N,O-donor sets may be employed in the metal ion directed assembly of coordination architectures.[1,2] These ligands are fascinating and versatile complexing agents because their metal complexes are known to serve as luminescent probes in the visible and near-IR spectral domains,[3,4] as precursors for doped materials where the metal centers must be at fixed distances from each other, as catalysts for specific DNA[5] and RNA[6] cleavage reactions, and as analytical sensors for the in vivo mapping of $Ca^{2+}$ concentration.[7,8] The complexes of paramagnetic ions have been tested as contrast enhancement agents, especially the complexes of gadolinium(III).[9–15] Dinuclear lanthanide complexes are continuing to attract considerable research interest due to their potential biological,[16–18] medical,[19] chemical and technological importance.[20] A dinuclear terbium(III) complex containing phthalocyanines is very good example of the effect of f-f interactions on dynamic magnetism.[21,22]

There is increasing interest in heterometallic 3d-4f complexes because of their magnetic[23,24] and luminescent properties.[25–29] Thermodynamic assembly processes lead to the strongly luminescent triple-helical heterodinuclear complexes of lanthanides (Ln = La to Lu) and zinc.[30,31] Dinuclear d-f complexes with Schiff-base ligands have been reported.[32–34] A novel synthetic approach for a $(3d)_2(4f)$ heterotrinuclear complex by transmetallation has been described.[35] We have obtained the heterodinuclear complex by a rapid one-pot reaction.

In view of the successful synthesis of the $Zn^{II}$, $Cd^{II}$,[36] and $Mn^{II}$ [37] complexes with H**L** (Figure 1), we attempted to prepare an analogous series of lanthanide complexes. Previously obtained complexes with zinc and cadmium had the M/L stoichiometry of 1:2. However, all of the syntheses that we attempted using lanthanides resulted in compounds with a M/L stoichiometry of 2:3 in the solid state, which was confirmed by X-ray analyses of complexes **3**, **5**, **8**, and **12**. The ESI-MS spectra of all the complexes included the $[M\mathbf{L}_2]^{n+}$ and $[\mathbf{L}]^+$ signals, which means that in solution significant dissociation of the $M_2\mathbf{L}_3$ complexes to mononulcear species and ligand molecules occurs. We also performed quantum mechanical calculations to gain an insight into the factors that affect the stability of heterodinuclear and homodinuclear complexes.

Herein we report that our investigations into the lanthanide coordination chemistry of the ligand **HL** have successfully demonstrated that this ligand is able to form novel dinuclear complexes. We describe and compare the structures of the complexes formed.

## Results and Discussion

### Synthesis and Characterization of the Complexes

Schiff-base ligands with N,O-donor type sets have been employed infrequently in the metal ion directed assembly of coordination architectures.[38] Ligand **HL** leads to the generation of $[M_2L_3(NO_3)_3]$, where M = $Y^{3+}$ (**1**), $La^{3+}$ (**2**), $Nd^{3+}$ (**3**), $Sm^{3+}$ (**4**), $Eu^{3+}$ (**5**), $Gd^{3+}$ (**6**), $Tb^{3+}$ (**7**), $Dy^{3+}$ (**8**), $Ho^{3+}$ (**9**), $Lu^{3+}$ (**10**), and $[MM^1L_3(NO_3)_x]$, where M = $Eu^{3+}$, $M^1$ = $Dy^{3+}$ (**11**), $Zn^{2+}$ (**12**); $x$ = 3 for **11** and 2 for **12**. The structures of the complexes have been assigned on the basis of the spectroscopic data (solution analysis), microanalyses, and in the case of complexes **3**, **5**, **8** and **12**, confirmed by X-ray crystallography.

ESI-MS is a highly sensitive and accurate analytical tool widely used for the characterization of large charged biomolecules, such as proteins and DNA. The technique has also been found to be particularly suited for the identification of large metallosupramolecular architectures present in solution, in which multiply charged ions are generated by the sequential loss of counterions resulting in characteristic isotopic patterns in the spectrum.[39] The ESI-MS investigations were performed with the complexes dissolved in acetonitrile at an approx concentration of $10^{-4}$ M. For the samarium(III) complex (**4**) the ESI mass spectrum showed a mixture of the following complexes: 1171 (5%) $[Sm_2L_3(NO_3)_3(H_2O)_5 + H]^+$, 1153 (5%) $[Sm_2L_3(NO_3)_3(H_2O)_4 + H]^+$, 546 (100%) $[SmL_2]^+$, 450 (30%) $[SmL(NO_3)(H_2O)_2]^+$, 413 (5%) $[SmL(NO_3)]^+$, 341 (5%) $[Sm_2L(NO_3)_3]^{2+}$, 253 (5%) $[Sm_2L_2(NO_3)]^{3+}$, 199 (20%) $[L]^+$. This result confirmed the previously observed behavior of lanthanide complexes in solution.[40]

### Crystallographic Characterization of Complexes 3, 5, 8, and 12

Crystals of complexes **3**, **5**, **8**, and **12** were obtained by diffusion of diethyl ether into a solution of the complex in acetonitrile. Compounds **3** (Figure 2), **5**, and **8** are isostructural. In all three complexes both lanthanide ions are nine-coordinate, albeit unsymmetrically; one of the ions is coordinated by two ligand molecules and one nitrate ion, while the other lanthanide ion binds to one ligand and two nitrate ions. The ligand molecules are tridentate, and they coordinate to the metal ions by the pyridine nitrogen atom N1, the N8 atom and by the hydroxy oxygen atom. The latter bridges the two metal ions. The bond lengths and angles are quite typical. There are also molecules of solvent (acetonitrile) in the crystal structures. In the mixed complex **12** (Figure 3), the $Eu^{III}$ ion is nine-coordinate, while the $Zn^{II}$ ion is six-coordinate and has distorted octahedral geometry.

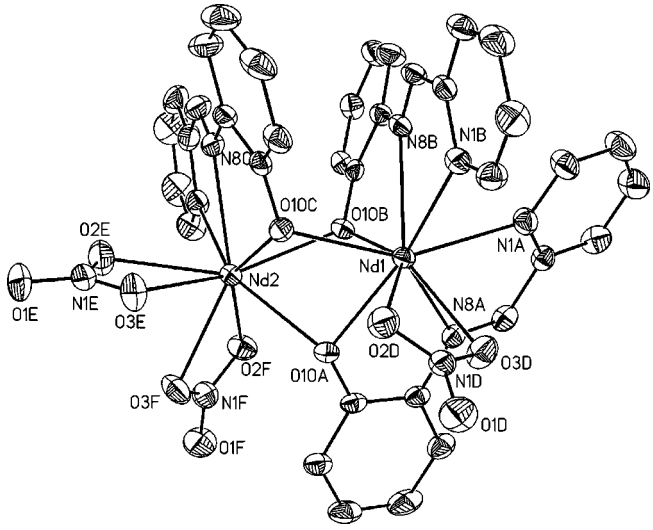

Figure 2. Anisotropic-ellipsoid representation of molecule **3** together with numbering scheme. The ellipsoids are drawn at the 50% probability level; hydrogen atoms are represented by spheres of arbitrary radii.

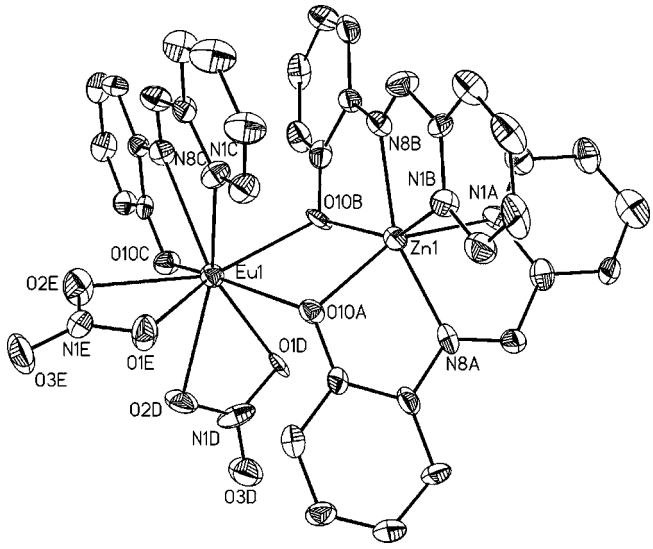

Figure 3. Anisotropic-ellipsoid representation of molecule **12** together with numbering scheme. The ellipsoids are drawn at the 50% probability level; hydrogen atoms are represented by spheres of arbitrary radii.

### Stability of Heterodinuclear and Homodinuclear Complexes

In order to assess the energy difference between heterodinuclear complex **12** and homodinuclear complex **5**, the energetics of the *fictitious* reaction of complex **12** with $Zn(NO_3)_2$, leading to the complex **5** with $Eu(NO_3)_3$, was calculated. Table 1 presents absolute energies for these species calculated with a SDD basis set. The energy difference between the species on both sides of the fictitious reaction is

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

small, about 1.8 kcal/mol, and favours the reaction leading to the heterodinuclear complex. This seems to indicate that the formation of the heterodinuclear Eu/Zn complex **12** is slightly preferred over the formation of the homodinuclear complex **5**, due to larger energy gain and thus larger thermodynamic stability of the complex **12**. This is further supported by an experimental observation − the heterodinuclear complex **12** is formed in a rapid one-step reaction.

Table 1. Absolute energies (in Hartrees) for the species involved in the fictitious reaction connecting complexes **5** and **12**.

| Molecule | Energy |
|---|---|
| $[Eu_2L_3(NO_3)_3]$ | –1779.179268 |
| $Zn(NO_3)_2$ | –342.946213 |
| $[EuZnL_3(NO_3)_2]$ | –1238.050066 |
| $Eu(NO_3)_3$ | –884.078243 |

## Conclusions

We were able to synthesize homo- and heterodinuclear zinc(II) and lanthanide(III) complexes comprising a tridentate Schiff-base ligand. The complexes were characterized in solution by ESI-MS spectroscopy. The molecular structures of complexes **3**, **5**, **8**, and **12** were investigated by X-ray crystallography, which confirmed that the coordination number is 9 for the lanthanide(III) ions, and 6 for the zinc(II) ions. Quantum mechanical calculations indicated that energetic factors slightly favour the formation of heterodinuclear as opposed to homodinuclear complexes, at least for Eu and Zn. The present results provide a facile and rapid synthetic protocol for the preparation of heterodinuclear complexes by a one-pot reaction.

In conclusion, the investigated complexes may be of use in several fields of lanthanide coordination chemistry, in nanotechnology, and as functional components of molecular electronic devices. Hydroxo-bridged Zn complexes are attractive because of their potential relevance as models for sugar-metabolizing enzymes.[41]

## Experimental Section

**General:** $CH_3CN$ was freshly distilled under argon over $CaH_2$. Ligand H**L** was prepared according to a published method.[37,42] The metal salts were used as supplied by Aldrich without further purification. Mass spectra were recorded by a Waters Micromass ZQ spectrometer in positive-ion mode. The samples were dissolved in acetonitrile ($10^{-4}$ mol dm$^{-3}$). Sample solutions were introduced into the mass spectrometer source with a syringe pump at flow rate of 40 μL min$^{-1}$ with a capillary voltage of +3 kV, and a desolvation temperature of 300 °C. The source temperature was 120 °C. The cone voltage ($V_c$) was set to 30 V to allow transmission of ions without fragmentation occuring. Scanning was performed from *m*/*z* = 200 to 1000 for 6 s, and 10 scans were summed to obtain the final spectrum. Microanalyses were obtained using a Perkin–Elmer 2400 CHN microanalyzer. IR spectra were obtained with a Perkin–Elmer 580 spectrophotometer, and are reported in cm$^{-1}$.

**Y Complex (1):** A mixture of $Y(NO_3)_3{\cdot}6H_2O$ (40 mg, 0.1 mmol) and ligand H**L** (40.0 mg, 0.2 mmol) in MeCN (15 mL) was stirred at room temperature for 24 h. The red solution was evaporated under reduced pressure to give complex **1** as an orange solid in quantitative yield. ESI-MS: *m*/*z* = 893 (5%) $[Y_2L_3(NO_3)_2]^+$, 483 (100%) $[YL_2]^+$, 366 (25%) $[YL(NO_3)(H_2O)]^+$, 348 (45%) $[YL(NO_3)]^+$, 288 (75%) $[Y_2L(NO_3)_3(H_2O)]^{2+}$, 199 (5%) $[L]^+$. IR (KBr [cm$^{-1}$]): ṽ = 3609 (OH), 3210 (OH), 3066 (CH arom), 3029 (CH imin), 1733 ($NO_3^-$), 1652 (CN), 1596 (py), 1587 (py), 1489 (py), 1470 (py), 1384 ($NO_3^-$), 1299 (py), 1272 (py), 1153 (py), 1032 (py), 870 (OH), 809 ($NO_3^-$), 750 (py), 592 (py), 536 (py). $Y_2(L)_3(NO_3)_3{\cdot}H_2O$ (973.48): calcd. C 44.25, H 3.00, N 12.95; found C 44.13, H 2.98, N 12.87.

**La Complex (2):** A mixture of $La(NO_3)_3{\cdot}6H_2O$ (44 mg, 0.1 mmol) and ligand H**L** (40.0 mg, 0.2 mmol) in MeCN (15 mL) was stirred at room temperature for 24 h. The orange solution was evaporated under reduced pressure to give complex **2** as a yellow solid in quantitative yield. ESI-MS: *m*/*z* = 533 (100%) $[LaL_2]^+$, 466 (20%) $[La_2L_3(NO_3)]^{2+}$, 398 (20%) $[LaL(NO_3)]^+$, 290 (10%) $[La_2L_3]^{3+}$, 199 (5%) $[L]^+$. IR (KBr [cm$^{-1}$]): ṽ = 3421 (OH), 3066 (CH arom), 3021 (CH imin), 1638 (CN), 1586 (py), 1567 (py), 1552 (py), 1486 (py), 1470 (py), 1451 (py), 1384 ($NO_3^-$), 1300 (py), 1265 (py), 1180 (py), 1148 (py), 868 (OH), 801 ($NO_3^-$), 748 (py), 587 (py), 526 (py). $La_2(L)_3(NO_3)_3{\cdot}H_2O$ (1073.48): calcd. C 40.28, H 2.72, N 11.74; found C 40.27, H 2.63, N 11.57.

**Nd Complex (3):** A mixture of $Nd(NO_3)_3{\cdot}6H_2O$ (45 mg, 0.1 mmol) and ligand H**L** (40.0 mg, 0.2 mmol) in MeCN (15 mL) was stirred at room temperature for 24 h. The orange solution was evaporated under reduced pressure to give complex **3** as a yellow solid in quantitative yield. ESI-MS: *m*/*z* = 1138 (5%) $[Nd_2L_3(NO_3)_3{\cdot}4H_2O]^+$, 1004 (10%) $[Nd_2L_3(NO_3)_2]^+$, 540 (50%) $[NdL_2]^+$, 471 (20%) $[Nd_2L_3(NO_3)]^{2+}$, 199 (35%) $[L]^+$, 155 (100%) $[Nd_2L(NO_3)(H_2O)]^{4+}$. **Crystal Structure Determination of Complexes 3, 5, 8 and 12:** Data were collected by the ω-scan technique in the $\theta$ range of 2–30° on a KUMA KM4CCD four-circle[43] diffractometer equipped with a CCD detector, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Accurate cell parameters were determined by the least-squares fit of 10137 (for **3**), 13161 (for **5**), 8403 (for **8**) and 2785 (for **12**) reflections of highest intensity chosen from the complete dataset. Data were corrected for Lorentz-polarization effects[44] and for absorption.[45] The structure was solved by direct methods with SHELXS-97[46] and refined with SHELXL-97.[47] Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed at calculated positions and refined with a 'riding model' with their isotropic thermal parameters set to 1.2 times the $U_{eq}$ of the appropriate carrier atom. Relevant crystal data and refinement details are listed in Table 2. Selected geometrical parameters for complexes **3**, **5**, **8** and **12** are listed in Table 3.

Table 3. Selected geometrical parameters.

CCDC-274721 (for **8**), -274722 (for **5**), -274723 (for **3**), and -274724 (for **12**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Quantum Mechanical Calculations:** The set of Cartesian coordinates determined by X-ray diffraction for the atoms in complexes **5** and **12** served as a starting point for geometry optimization utilizing the density functional theory (DFT). The B3LYP method[48,49] was utilized, and a composite basis set in which Eu, and Zn were treated with a SDD basis set in which Stuttgart-Dresden pseudopotentials[50,51] substituted for the innermost electrons to account for relativistic effects was applied. Ligands atoms from the first coordination sphere were treated with a 6-31G basis set,[52] while the remaining atoms were treated with a STO-3G basis set.[53] Single point energies were calculated with a SDD basis set[50,51] for all atoms. All calculations were preformed with Gaussian 03.[54]

# Dinuclear Lanthanide Schiff-Base Complexes Forming a Rectangular Columnar Mesophase

**Koen Binnemans,*[a] Katleen Lodewyckx,[a] Thomas Cardinaels,[a] Tatjana N. Parac-Vogt,[a] Cyril Bourgogne,[b] Daniel Guillon,[b] and Bertrand Donnio*[b]**

**Keywords:** Columnar mesophases / Lanthanides / Liquid crystals / Metallomesogens / Rare earths

The Schiff base $\mathbf{L}H_3$ obtained by condensation of 3-formyl-4-hydroxyphenyl-3,4,5-tris(tetradecyloxy)benzoate with 1,3-diamino-2-propanol reacts with lanthanide(III) acetate salts to form dinuclear complexes of the type $Ln_2L_2$ with the trivalent ions from the first half of the lanthanide series (Ln = Nd, Sm, Gd). These stable and neutral metallomesogens exhibit a rectangular columnar mesophase over a broad temperature range.

## Introduction

*N*,*N*′-Bis(salicylidene)ethylenediamine (*salen*) and similar Schiff-base ligands derived from diamines other than ethylenediamine have often been used as building blocks for metal-containing liquid crystals.[1] This work was focused mainly on copper(II), nickel(II) or oxovanadium(IV) (vanadyl) complexes that exhibit smectic mesophases,[2,3] essentially smectic A and smectic C phases, but also the more ordered smectic E phase.[2e] Similar mesomorphic properties were also observed in calamitic cobalt(II) complexes,[2g] and the enhancement of the molecular anisotropy of such $Ni^{II}$, $Cu^{II}$ and $VO^{IV}$ *salen* complexes by the use of alkylphenylazo groups results in new mesomorphic systems showing a high temperature SmC phase, and in some cases, the nematic phase.[4] Binnemans et al. reported the first mesomorphic lanthanide complexes of *salen*-type Schiff base, but owing to the elevated transition temperatures, unequivocal identification of the mesophase formed was not possible.[5] Swager and co-workers studied vanadyl complexes derived from such Schiff bases, possessing a hexacatenar structure, that exhibit a rich columnar mesomorphism,[6] whereas Binnemans et al. synthesized mixed f-d metallomesogens, derived form the related hexacatenar ligand, that contain both a transition metal ion and a lanthanide(III) ion.[7] These compounds showed a hexagonal columnar phase over a broad temperature range. Depending on the radius of the lanthanide(III) ion, either dinuclear f-d[7] or trinuclear f-d-f complexes were formed.[7,8] Note that all these complexes can be considered as adducts of a mesogenic Cu(salen) or Ni(salen) complex of a trivalent lanthanide ion. Because the Cu(salen) and Ni(salen) complexes are electrically neutral, three nitrate groups are necessary to compensate for the positive charge of the lanthanide ion in the resulting mixed f-d complexes. Additionally, if such a doubly negatively charged ligand is to be used to prepare purely lanthanide complexes, a further small inorganic anion (e.g. X = Cl, $NO_3$) has to be present to obtain electric neutrality in the corresponding LnXL complexes, otherwise neutral complexes with a different stoichiometry such as $Ln_2L_3$ type may be formed instead. By modifying the *salen*-type Schiff-base ligand, it should be possible to obtain an organic species that contains three deprotonable OH groups and which can be used as triply negatively charged anionic ligand to form neutral complexes with the trivalent lanthanide cations. Such a ligand can be obtained by condensing the aldehyde that is used to prepare the *salen*-type Schiff base, with 1,3-diamino-2-propanol instead of 1,2-diaminoethane.

In this paper, we show that the chemical modification of the *salen*-type Schiff base by using 1,3-diamino-2-propanol instead of 1,3-diaminopropane in the reaction with the appropriate 3-formyl-4-hydroxyphenyl-3,4,5-tris(tetradecyloxy)benzoate appears to be a judicious approach to prepare neutral dinuclear complexes of the type $Ln_2\mathbf{L}_2$ with trivalent lanthanide ions. Moreover, these complexes are mesomorphic and exhibit a rectangular columnar mesophase over a large temperature range, as shown by small-angle X-ray diffraction. With the help of molecular mechanics, a model for the organization of these compounds in the columns is proposed.

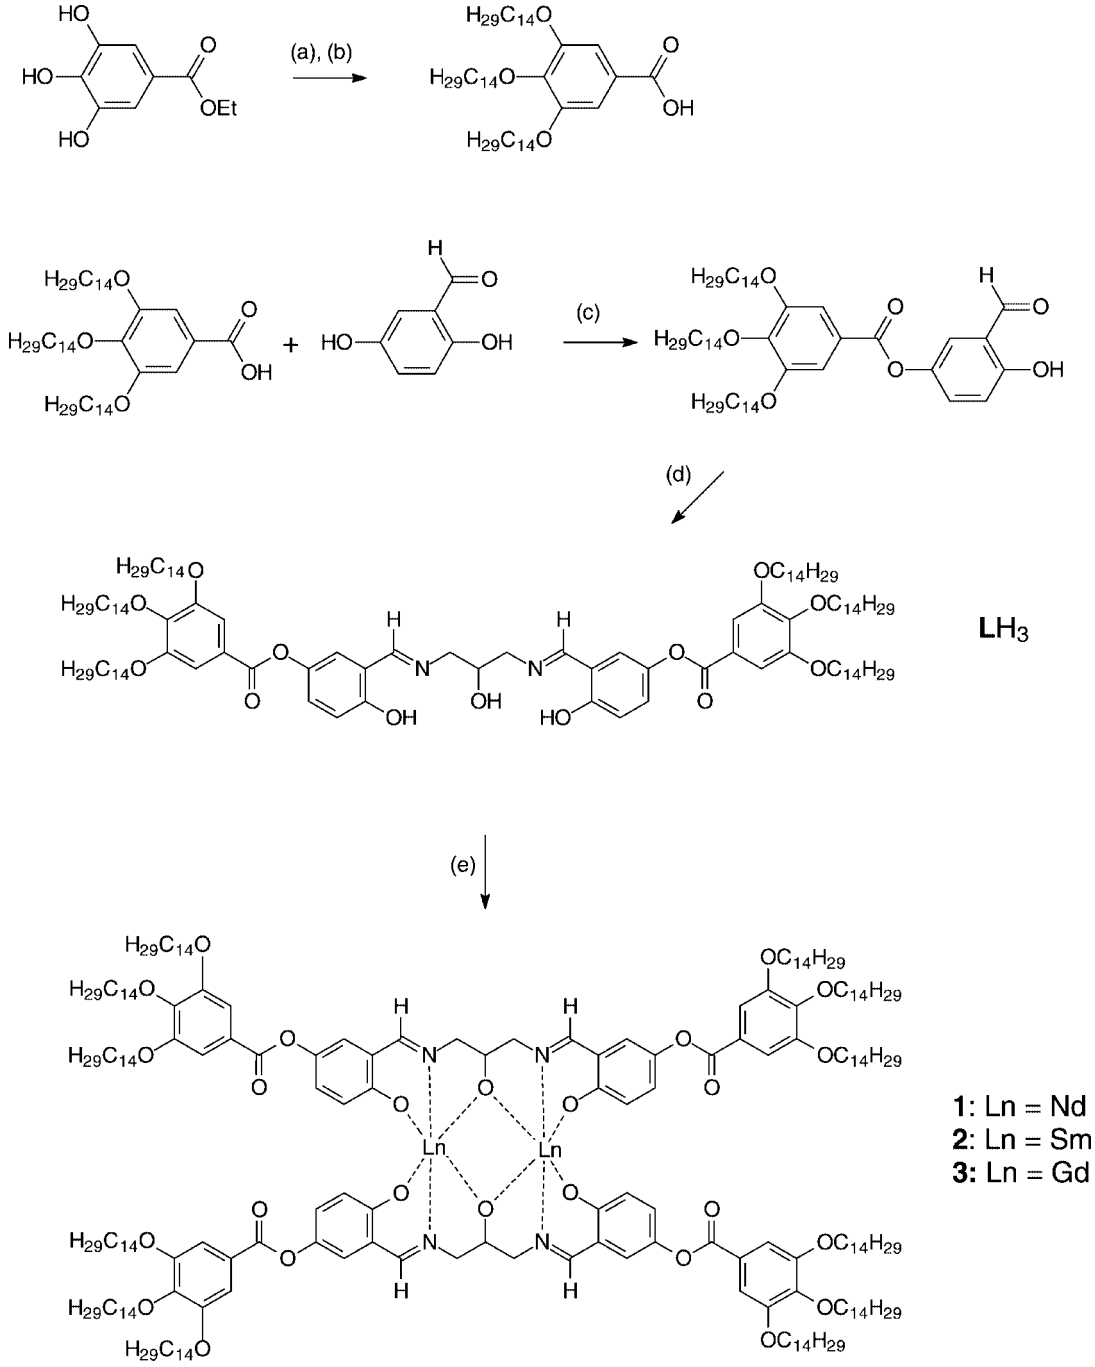
## Results and Discussion

The Schiff-base ligand $\mathbf{L}H_3$ was obtained by condensation of the aldehyde 3-formyl-4-hydroxyphenyl-3,4,5-tris(tetradecyloxy)benzoate (1 equiv.) and 1,3-diamino-2-propanol (0.5 equiv.) in toluene, with azeotropic removal of the water. The three dinuclear lanthanide(III) complexes (Ln = Nd, Sm, Gd) were synthesized by reaction between the lanthanide acetate salt $Ln(CH_3COO)_3{\cdot}xH_2O$ (1.1 equiv.) and the Schiff base (0.5 equiv.) in chloroform at refluxing temperature. The synthesis of ligand and complexes **1**–**3** is outlined in Scheme 1.

A schematic representation of the dinuclear lanthanide(III) complexes is given in Scheme 1 (compounds **1**, **2**, **3**). Because each ligand carries a triple negative charge, the positive charge of the two trivalent lanthanide ions is counterbalanced and the dinuclear complexes are neutral; therefore no counterions are necessary. This is in contrast with



Scheme 1. Synthesis of the Schiff-base ligand and the corresponding dinuclear Ln–Ln complexes **1**–**3**. Reagents and conditions: (a) RBr (3 equiv.), $K_2CO_3$ (6 equiv.), DMF, KI (catalytic amount), reflux overnight; (b) NaOH, ethanol, reflux for 4 hours; acidification by dilute HCl solution; (c) DCC, DMAP, dichloromethane, 24 hours at room temp.; (d) 1,3-diamino-2-propanol (0.5 equiv.), glacial acetic acid (catalyst), toluene, Dean–Stark trap, 3 hours at reflux; (e) $Ln(CH_3COO)_3{\cdot}xH_2O$ (1.1 equiv.), chloroform, reflux overnight.

the f-d complexes with *salen*-type ligands,[7,8] the lanthanide complexes with salicylaldimine Schiff bases which have counterions such as nitrate groups.[1f,9,10] or lipophilic bis(benzimidazole)pyridine-based ligands.[11] The reasons why a dinuclear complex is formed instead of a mononuclear species are due to the tendency of the lanthanide(III) ions to achieve a high coordination number and to the nature of the ligand itself, auspicious to such a coordination mode (fused chelating parts). Typically, the coordination number of the trivalent lanthanide ions in coordination compounds is eight or nine. Also six-coordinate lanthanide(III) complexes are known, for example the tris(β-diketonato)lanthanide(III) complexes. When the ligand does not offer a sufficient number of donor atoms to the lanthanide(III) ion to achieve a high coordination number, some of the donor atoms can coordinate in a bridging mode. Alternatively, adducts can be formed with Lewis bases, such as water molecules. Unfortunately, we were unable to obtain single crystals, so that the structure of the complex is still unknown. It was also not possible to grow single crystals of similar complexes with shorter alkyl chains and due to the presence of paramagnetic ions, $^1$H NMR spectra of the complexes were not resolved. It is however unlikely to consider the structure of the dinuclear lanthanide(III) complex as totally flattened and planar (as drawn in Scheme 1) by simply considering the coordination chemistry of *d* and *f* elements and entropic phenomena. The geometric preferences of lanthanides to adopt coordination numbers higher than six support that such extended planarity is absent, and that the ligands are wrapped around the metallic centers. Thus, a more energetically favorable structure for these dinuclear species would imply the ligand to be bent or V-shaped (due to the flexible spacer), and that they are either entwined around the two metal ions as in helicates[12–14] (Figure 1a, $D_2$ symmetry) or coordinated to the two cations in such a way that a sandwich complex with a mesocate structure is formed (part b in Figure 1, $C_{2h}$ symmetry).[13] Whatever the exact structure is, it has been shown recently for some $M_2L_3$ complexes, that both species exist in equilibrium in solution, and the helicate to mesocate isomerization only requires inversion at one metal center,[15] and that this low-energy cost equilibrium may be generalized to other systems. The driving forces for the formation of helicates and/or mesocates result from the minimization of energy of the ultimate self-assembly. Such a formation depends on the metal-imposed (number and coordination geometry) and ligand-imposed constraints (type, nature of the spacer and distance between bridging units), as well as to some degree of pre-organization of the ligand. In the case of lanthanides, helicates mainly possess a three-stranded helicate $Ln_2L_3$ structure (in such case, the two lanthanide ions are wrapped by three ligands), while mesocate complexes of the type $M_2L_2$ – schematically shown in Figure 1, b – are common for both d and f elements.[13] For instance, Gelasco and Pecoraro described the crystal structure of a closely related dimeric manganese(III) complex of the Schiff base 1,3-bis(5-nitrosalicylidenimino)-2-propanol:[16] this dimeric manganese complex has a $\mu^2$-alkoxy core with a symmetric environment for the manganese(III) ions. The authors showed that the ligands adopt a hairpin conformation and that two of them wrap the two metallic ions in an antiparallel mode to form the neutral mesocate $Mn_2L_2$ complex as schematically drawn in Figure 1, b. This particular dimeric structure could be representative of the chelating mode of this type of ligand with two metallic nuclei and generalized to other dinuclear species. We have thus extrapolated this mode of chelation to the presently studied dinuclear lanthanide(III) complexes, the close proximity of the two sets of donor atoms of the bidentate bridging ligand, and the presence of the central hydroxy coordinating group slightly disfavoring the formation of the helicate structure at the expense to the mesocate one; this assumption is comforted by some molecular calculations, too (vide infra).

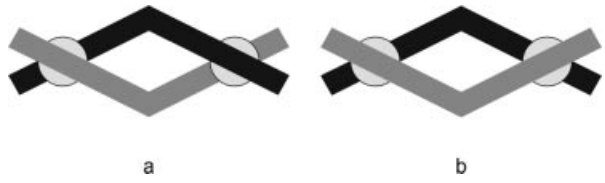

Figure 1. Schematic representation of the two possible structures given by the $Ln_2L_2$ complexes. The two bischelate bent-like ligands, may entwine the two metallic species to form a double-stranded helicate (**a**, $D_2$ symmetry) or sandwich the metal ions to form a non-helical *meso* structure or mesocate instead (**b**, $C_{2h}$ symmetry).

In this model, the two lanthanide(III) ions are in a six-coordinate environment, with the coordination polyhedron being a (distorted) octahedron. The two coordinating octahedral cages of the two lanthanide ions share a common edge, and the alkoxide group bridges the two lanthanide(III) centers (Figure 2). For a further investigation of the conformation of this dinuclear complex and to support the mesocate structure, molecular simulations were performed on both mesocate and helicate conformers (Gaussian 03, rb3lyp/3-21g**). For compatibility with the calculation bases, the lanthanide(III) cations were replaced in these models by yttrium(III), chosen because of its great proximity to the lanthanide series (located just above the lanthanum in the periodic table of elements) and for the similarity of the ionic radius between $Y^{III}$ and $Ln^{III}$. The minimization yielded two stable structures with an energetic gap of 44.9 kJ·mol$^{-1}$ in favor of the mesocate conformation. For both conformers in these theoretical structures (taken as isolated molecule in the gas phase), the angle formed by the phenyl groups of the ligands is quite wide in comparison with the manganese complex just mentioned,[16] but a search in the Cambridge Crystallographic Database shows that the very flexible *salen*-type ligand can be very distorted by packing constraints in condensed phase. It is then reasonable to propose that the present dinuclear lanthanide(III) complexes adopt preferentially a mesocate form, with the ligands in the hairpin conformation. Furthermore, with this assumption, the pinched ligand structure could be even more stabilized by intramolecular π-stacking of the benzoate rings (vide infra).

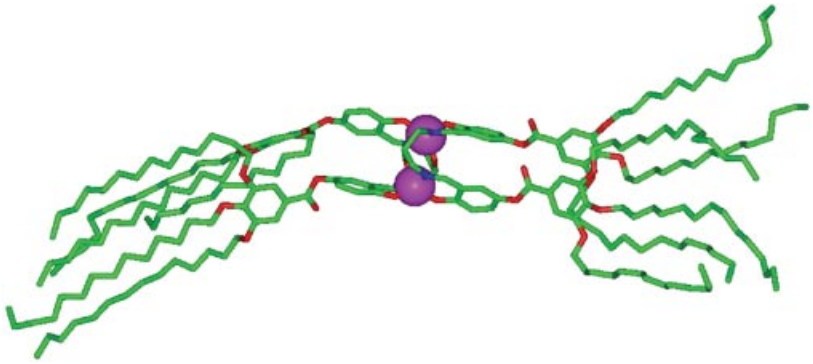

Figure 2. Minimized structure of the dinuclear diligand species (see text; purple: lanthanide cation; blue: nitrogen atom; red: oxygen atom, green: carbon atom. Hydrogen atoms have been omitted for clarity.).

The Schiff-base ligand $\mathbf{L}H_3$ is itself mesomorphic, not totally unexpected, because of its polycatenar-like molecular structure, a priori compatible with mesophase formation.[17] Observation by polarizing optical microscopy (POM) indicated a monotropic liquid-crystalline phase behavior. On heating the sample, an isotropic liquid is obtained at 82 °C, which was confirmed by an intense endothermic peak transition (82 kJ·mol$^{-1}$) in the first heating run of the DSC curve. Heating was continued above 100 °C without detecting additional thermal events, and the sample was then cooled down. At 62 °C, a phase transformation is detected by the growth of birefringent dendritic features from the isotropic liquid, remembering one of the typical texture of the hexagonal columnar phase (Figure 3). A peak of –2.50 kJ·mol$^{-1}$ in the DSC curve corresponds to this monotropic phase transition. The phase remained stable down to room temperature. On second heating, the compound cleared straight into the isotropic liquid at 62 °C, that is 20 °C lower than during the first heating. Subsequent cooling and heating repeated the behavior of the second cycle so crystallization from a solvent must result in a crystalline form that needs to rearrange on heating before it clears into the isotropic liquid. The X-ray diffractogram of the mesophase registered on cooling the sample from the isotropic liquid does not contradict the mesophase assignment made by POM, nor gives conclusive information about the mesophase symmetry, and so the mesophase remains assigned from its optical texture alone. The pattern recorded at 50 °C on cooling showed only one single, but sharp and intense small-angle diffraction peak at ca. 38 Å, which was indexed as the [10] reflection of a 2D hexagonal lattice. The liquid-like order of the aliphatic chains was confirmed by the presence of the broad scattering at ca. 4.5 Å. To conclude, the optical texture shows enough evidence that a hexagonal columnar phase was formed (Figure 3), and the thermal properties of the ligand can be summarized as follows: Cr 82 ($Col_h$ 62) I.

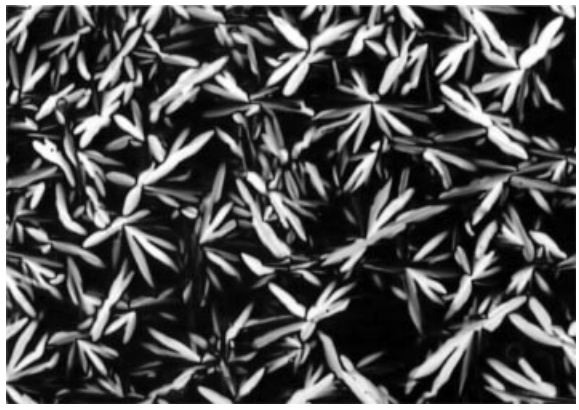

Figure 3. Optical texture of hexagonal columnar phase formed by the Schiff-base ligand $\mathbf{L}H_3$ at 58 °C.

The lanthanide(III) complexes **1**–**3** are also mesomorphic, and exhibit a mesophase over a temperature range of more than 100 °C. The clearing temperatures of the complexes could not be determined due to extensive decomposition well above 200 °C. The transition temperatures are summarized in Table 1. At room temperature, the complexes are in a semi-crystalline or *condis* (conformationally disordered) phase as revealed by XRD: only broad and diffuse scatterings were observed in the angular range of study ($0 < 2\theta < 35°$). The halo in the wide angle part at 4.5 Å corresponds to the liquid-like order of the molten chains, whereas those in the small angle part, obtained within the ratio 1:2:3 (at ca. 30.5, 15.3, and 10.2 Å) indicate some short-range layering correlations of the system. This lamellar structure is formed again on subsequent cooling/heating runs, proving the high reversibility of the phase transformation and the good thermodynamic stability of this phase. Above 100 °C, and for the three dinuclear complexes, a change in the optical texture concomitant to a phase transformation was detected. However, the optical textures observed by microscopy were not sufficiently characteristic to permit the unambiguous identification of the mesophase. With regards to the molecular structure of the complexes, which resembles to that of related dinuclear complexes constructed from hexacatenar ligands, the mesophase is likely columnar.[18] The definitive mesophase identification was achieved by temperature-dependent X-ray diffraction. The XRD pattern of the neodymium(III) complex **1** at 200 °C, chosen as representative example for the three complexes, is shown in Figure 4 and the relevant data are summarized in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2. The X-ray pattern recorded at 200 °C was chosen instead of those recorded at lower temperatures as it provided the most suitable information. Indeed, the reflections appear to sharpen and to become more intense as the temperature was raised, a result of the temperature-induced micro-segregation. The pattern reveals two diffuse scattering halos (**5** and **6**) observed in the mid and wide-angle region. The halo at 4.5 Å (**6**), corresponds to the liquid-like order of the aliphatic chains and to the loose lateral interactions between rigid parts of the complex, whereas the other diffuse halo (**5**), corresponding to an average distance of ca 10 Å, very likely conveys to the existence of dimeric species (vide infra). In the small angle region, four large reflections were observed and indexed into a rectangular 2D lattice with the pairs of Miller's indices [*hk*] = [11], [20], [22] and [40] (Table 2). This pattern is typical for a centered rectangular lattice with a *c2mm* plane group. Since two indexations of the reflections are possible (only harmonics of the fundamental reflections were measured), we have chosen the most likely one (Table 2). The first option consists of chosing [11] = 26.0 Å and [20] = 38.25 Å, but this yields to a highly anisometric rectangular lattice, the parameters of which ($a$ = 76.5 Å and $b$ = 27.45 Å) are highly incompatible with the molecular dimensions (length, width and thickness) of the dinuclear complexes. In contrast, the other option ([11] = 38.25 Å and [20] = 26.0 Å), leads to lattice parameters that are more relevant here ($a$ = 52.0 Å and $b$ = 56.45 Å) and in agreement with the size of the complexes.

Table 1. Transition temperatures of the dinuclear lanthanide complexes.

| Compound | Ln | Transition temperatures[a] [°C] |
|---|---|---|
| **1** | Nd | X · 116 · $Col_r$-*c2mm* · 257 (dec.) |
| **2** | Sm | X · 108 · $Col_r$-*c2mm* · 227 (dec.) |
| **3** | Gd | X · 106 · $Col_r$-*c2mm* · 236 (dec.) |

[a] X: semi-crystalline lamellar solid or *condis* (conformationally disordered) phase; $Col_r$-*c2mm*: rectangular columnar phase with the centered *c2mm* symmetry; dec.: decomposition.

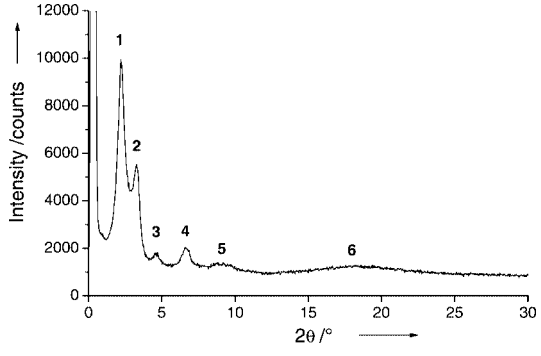

Figure 4. X-ray diffractogram of neodymium(III) complex **1** at 200 °C.

The similarity of the lattice parameters $a$ and $b$ in this case expresses that the rectangular lattice is in fact nearly square-like, that is that the cross-section of the columnar hard core (i.e. constituted of the rigid molecular parts) is not so elliptic, but rather more circular instead. In order to understand the molecular packing of the complexes in the columns and to propose a model, we first compared the molecular dimensions and volume with the columnar cross-section and rectangular cell volume of the $Col_r$ phase, and followed the methodology explained elsewhere[19] to evaluate the number of molecules per a given length of column, $h$. Of course, $h$ can be chosen arbitrarily, but in the following calculation a value of 10 Å has been assumed, corresponding to the broad signal **5** seen in the X-ray pattern (vide supra), which suggests that there is a periodicity at this distance and the breadth of the signal that there is a correlation which persists over several molecules. The minimization of the complex also showed a thickness of about 10 Å, concordant with this assumption. Thus, from the molecular volumes $V_{mol}$ of the $Ln_2L_2$ complexes (for Ln = Nd, $V_{mol}$ = 7340 Å$^3$ at 200 °C), it was found that two complexes molecular equivalents occupy the rectangular cell, 10 Å thick. Similar data were obtained for the corresponding dinuclear gadolinium and samarium complexes (see Table 2).

Table 2. XRD data of the neodymium(III) complex **1** at 200 °C.[a]

| Reflection no.[b] | $d_{exp}$[c] | [*hk*] | *I*[d] | $d_{theo}$[c] | Cell parameters[c,e] |
|---|---|---|---|---|---|
| 1 | $38.2_5$ | [11] | vs | $38.2_5$ | $Col_r$ – *c2mm* |
| 2 | 26.0 | [20] | vs | 26.0 | $a$ = 52.0 Å |
| 3 | 19.1 | [22] | m | 19.1 | $b = 56.4_5$ Å |
| 4 | $13.1_5$ | [40] | m | 13.0 | $S$ = 2.935 Å$^2$ |
| 5 | 10.0 | – | broad | – | $V_{cell}$ = 14.675 Å$^3$ |
| 6 | 4.5 | | broad | – | $N_{col}$ = 2 |

[a] For complexes **2** and **3**, similar data were obtained: Sm complex **2**: $a$ = 52.2 Å, $b$ = 56.3 Å, $V_{mol}$ = 7360 Å$^3$, $N_{col}$ = 2; Gd complex **3**: $a$ = 52.4 Å, $b$ = 56.1 Å, $V_{mol}$ = 7380 Å$^3$, $N_{col}$ = 2. [b] The numbering of X-ray reflections corresponds to the one in Figure 4. [c] $d_{exp}$ and $d_{theo}$ are the experimentally measured and theoretical diffraction spacings. Distances are given in Å. $a$, $b$ are the parameters of the $Col_r$ phase, $S$ is the lattice area and $V_{cell}$ the volume of the rectangular cellule 10 Å thick. [d] Intensity of the reflection. vs: very strong, m: medium. [e] $a$, $b$ are deduced from the measured spacings $d_{11}$ and $d_{20}$: $a = 2d_{20}$; $b = A$, with $A = \sqrt{\frac{2}{\frac{1}{d_{11}^2} + \frac{1}{d_{1\bar{1}}^2} - \frac{1}{2d_{20}^2}}}$; $d_{theor}$ is deduced from the following mathematical expression and the lattice parameters $a$ and $b$: $\frac{1}{d_{hk}} = \sqrt{\frac{h^2}{a^2} + \frac{k^2}{b^2}}$. $S = a \times b$, and $V_{cell}$ = ½×$S$×10. $N_{col}$ is the aggregation number or the number of molecular equivalents per stratum of column 10 Å thick, $N_{col} = V_{cell}/V_{mol}$.

On the basis of the molecular minimization shown above (Figure 2), it is possible to consider the formation of a dimeric species which takes an overall "bow-tie" conformation, with a thickness of approximately 10 Å, and be stabilized by lateral intermolecular interactions between the phenyl rings of the ligand strands as shown in the Figure 5. This interaction, which depends on the molecular structure, is short range and is limited in the plane to a dimeric species only because of the important number of irradiating aliphatic chains ('bow-tie'-like dimer, Figure 5), which results in the strong curvature of the hard-flexible interface and disfavors molecular associations higher than in pairs. The formation of columnar stacking is mainly driven by the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

micro-segregation between the hard and flexible parts (Figure 6). The hard part of the dimer forms the rigid spine of the column, and the voids between these "hard" columns is filled by the homogeneous matrix of aliphatic chains. The stability of the edifice is mainly ensured by weak van der Waals interactions and by inter-dimeric interactions along the columnar axis (Figure 6). These columns then self-organize into the 2D rectangular lattice (Figure 7). A molecular dynamics model has been built from two dimers disposed respectively on the edge and at the center of a rectangular cell based on the parameters determined by XRD. Due to the incompatibility of the lanthanide ions with common forcefields used for organic compounds, and according to our previous discussion about the shape of these salen-type dimetallic complexes, the geometry of the central part of the complex was tethered to a template structure obtained from the crystallographic data of the dinuclear manganese complex mentioned above.[15] Nevertheless, each molecule was allowed to move freely from each other within the cell during the simulation. This model led to a consistent result, with a density of the packing very close to unity, similar to that of the mesophase.

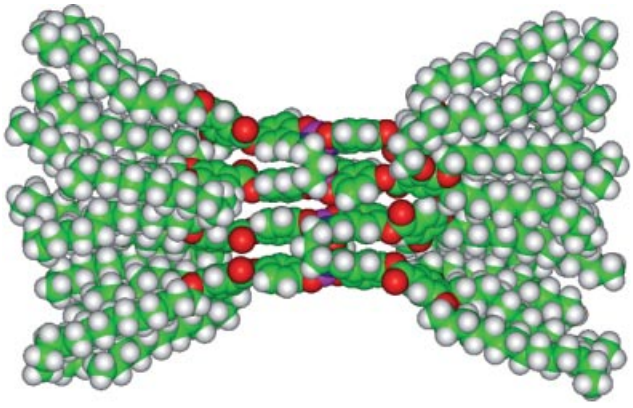

Figure 5. The 'bow-tie'-like dimeric species viewed along the columnar axis (i.e. cross-section of column).

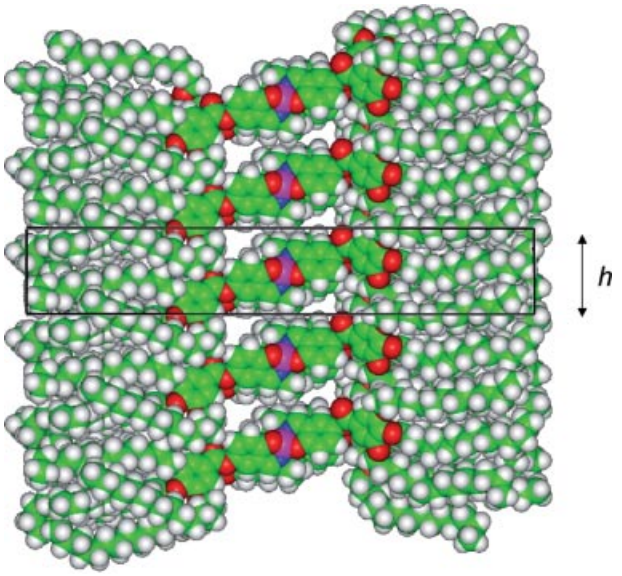

Figure 6. View of the stacking along the columnar axis, with the stacking periodicity, *h*, also representing the molecular thickness.

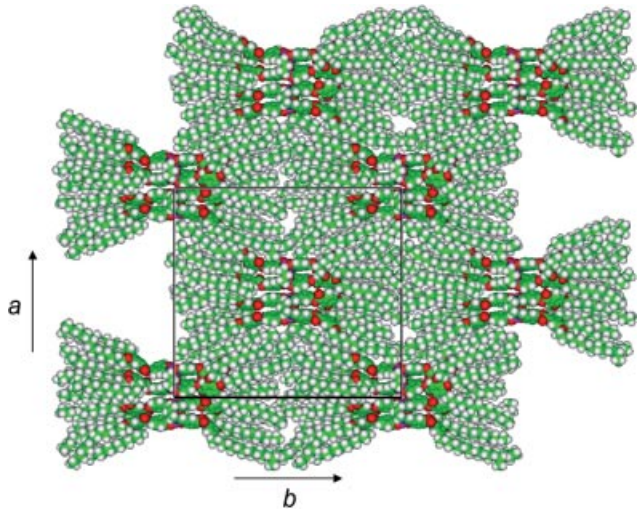

Figure 7. Arrangement of the 'bow-tie'-like dimers within the 2D rectangular lattice.

## Conclusions

In this paper, we report the first examples of neutral, liquid-crystalline dinuclear f-f complexes, i.e. complexes that contain two lanthanide ions. The ligand was designed in such a way that the resulting complexes are electrically neutral, so that no additional inorganic or organic counterions are needed to counterbalance the electric charges of the complex. Due to the synthetic methodology specifically elaborated here, only homodinuclear f-f complexes were prepared. The complexes exhibit a rectangular columnar mesophase, and a model, based on X-ray diffraction data and molecular modelling, is proposed for the molecular self-organization.

## Experimental Section

**Techniques:** The nuclear magnetic resonance (NMR) spectra were recorded on a Bruker Avance 300 spectrometer (operating at 300 MHz) and on a Bruker AMX-400 (operating at 400 MHz), using $CDCl_3$ as solvent and tetramethylsilane (TMS) as internal standard. The NMR shifts were assigned with the help of $^{13}C$ DEPT spectroscopy, two dimensional correlation spectroscopy (COSY) and proton-carbon heteronuclear multiple-quantum coherence (HMQC) spectroscopy. FTIR spectra were recorded on a Bruker IFS-66 spectrometer, using the KBr pellet method. Elemental analyses were obtained on a CE-Instrument EA-1110 elemental analyzer. MALDI-TOF mass spectra were measured on a VG Tofspec SE (Micromass, UK) equipped with a $N_2$-laser (337 nm). Optical textures of the mesophases were observed with an Olympus BX60 polarizing microscope equipped with a LINKAM THMS600 hot stage and a LINKAM TMS93 programmable temperature-controller. DSC traces were recorded with a Mettler- Toledo DSC821e module. The XRD patterns were obtained with two different exper-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

imental set-ups, and in all cases, the powdered sample was filled in Lindemann capillaries of 1 mm diameter. A linear monochromatic Cu-$K\alpha_1$ beam ($\lambda$ = 1.5405 Å) obtained with a sealed-tube generator (900 W) and a bent quartz monochromator were used (both generator and monochromator were manufactured by Inel). One set of diffraction patterns was registered with a curved counter Inel CPS 120, for which the sample temperature is controlled within ±0.05 °C; periodicities up to 60 Å can be measured. The other set of diffraction patterns was registered on Image Plate. The cell parameters are calculated from the position of the reflections at the smallest Bragg angle, which are in all cases the most intense. Periodicities up to 90 Å can be measured, and the sample temperature is controlled within ±0.3 °C. The molecular modeling calculations were performed on a SGI Origin 2800 20 CPU computer and on an SGI Octane² calculators using Insight II and Discover 3 software from Accelrys (www.accelrys.com) with the cvff forcefield. For all models, prior to the dynamics, the systems were minimized to a gradient of 0.05 kcal mol$^{-1}$. The simulation then consisted of a 200 ps isotherm at 473 K in the NVT-PBC ensemble and with a 1 fs time step.

**Synthesis of the Schiff-Base Ligand $LH_3$:** The aldehyde 3-formyl-4-hydroxyphenyl-3,4,5-tris(tetradecyloxy)benzoate was synthesized as described elsewhere.[7] To a solution of 3-formyl-4-hydroxyphenyl-3,4,5-tris(tetradecyloxy)benzoate (1.33 g, 0.002 mol) in 200 mL of toluene was added 1,3-diamino-2-propanol (90 mg, 0.001 mol) and 5 drops of glacial acetic acid (as the catalyst). The mixture was heated for 3 hours at reflux and water formed by the reaction was removed azeotropically (Dean–Stark trap). After allowing the solution to cool down to room temperature, the solvent was removed at reduced pressure. The crude product was purified by crystallization from absolute ethanol. Yield: 80% (1.11 g). $^1$H NMR ($CDCl_3$): $\delta$ = 0.89 (m, 18 H, $CH_3$), 1.20–1.40 (m, 120 H, $CH_2$), 1.49 (m, 12 H, C*H*$_2$–$CH_2$–$CH_2$–O), 1.70–1.90 (m, 12 H, C*H*$_2$–$CH_2$–O), 3.70–3.95 (m, 4 H, N–C*H*$_2$), 4.05 (m, 12 H, $CH_2$–O), 4.30 (m, 1 H, CH), 7.01 (d, 2 H, $H_{arom}$), 7.14 (s, 2 H, $H_{arom}$), 7.16 (d, 2 H, $H_{arom}$), 7.39 (s, 4 $H_{arom}$), 8.40 (s, 2 H, C*H*=N), 13.0 (br., OH) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 14.1 ($CH_3$), 22.7 ($CH_2$), 26.1 ($CH_2$), 29.3–30.3 ($CH_2$), 31.9 ($CH_2$), 63.3 ($CH_2$–N), 69.3 ($CH_2$–O), 70.5 (CH), 73.6 ($CH_2$–O), 108.7 ($C_{arom}$), 117.9 ($C_{arom}$), 118.5 ($C_{arom}$), 123.7 ($C_{arom}$), 123.9 ($C_{arom}$), 126.2 ($C_{arom}$), 158.8 (C=O), 166.7 (C=N) ppm. IR (KBr): $\tilde{\nu}$ = 1641 (C=N), 1201 (C–O) cm$^{-1}$. $C_{115}H_{194}N_2O_{13}$ (1812.78): calcd. C 76.19, H 10.79, N 1.55; found C 76.18, H 10.99, N 1.42.

**Synthesis of the Lanthanide(III) Complexes:** The dinuclear lanthanide complexes (Ln = Nd, Sm, Gd) of the Schiff-base ligand **L**$H_3$ were synthesized by reaction between the lanthanide acetate salt $Ln(CH_3COO)_3{\cdot}xH_2O$ (1.1 equiv.) and the Schiff base (1 equiv.) in chloroform at refluxing temperature overnight. The acetate ions act as the base to deprotonate the ligand. The complexes were purified by crystallization from a water/ethyl acetate mixture, and were obtained in moderate yields: 74% for the Nd complex **1**, 62% for the Sm complex **2** and 49% for the Gd complex **3**. MALDI-TOF measurements show a molecular peak that corresponds to the dinuclear species with the stoichiometry [$Ln_2$**L**$_2$] for the neodymium(III) and samarium(III) complexes.

**Nd Complex 1:** $C_{230}H_{382}N_4Nd_2O_{26}$ (3907.99): calcd. C 70.69, H 9.85, N 1.43; found C 70.79, H 9.84, N 1.44. MALDI-TOF: $M_w$(isotopic) = 3907.68 *m/e*; $M_w$(found) = 3909.30 *m/e*. IR (KBr): $\tilde{\nu}$ = 1633 (C=N) cm$^{-1}$.

**Sm Complex 2:** $C_{230}H_{382}N_4O_{26}Sm_2$ (3920.23): C 70.47, H 9.82, N 1.43; found C 69.97, H 9.69, N 1.41. MALDI-TOF: $M_w$(isotopic) = 3920.71 *m/e*; $M_w$(found) = 3921.65 *m/e*. IR (KBr): $\tilde{\nu}$ = 1633 (C=N) cm$^{-1}$.

**Gd Complex 3:** $C_{230}H_{382}Gd_2N_4O_{26}$ (3934.01): C 70.22, H 9.79, N 1.42; found C 69.67, H 9.96, N 1.34. IR (KBr): $\tilde{\nu}$ = 1633 (C=N) cm$^{-1}$.

# Silver and Rhodium Complexes of Stable, Monomeric Imidazolidin-2-ylidenes: Synthesis, Reactivity and Decomposition Pathway

**Martin Paas,[b] Birgit Wibbeling,[c] Roland Fröhlich,[c] and F. Ekkehardt Hahn*[a]**

**Keywords:** Carbenes / Carbene ligands / Nitrogen heterocycles / Silver / Sulfur

Silver(I) complexes of the freely stable carbenes 1,3-bis(2,4,6-trimethylphenyl)imidazolidin-2-ylidene (**3**) and 1,3-bis(2,6-diisopropylphenyl)imidazolidin-2-ylidene (**4**) were prepared from the imidazolinium chlorides **1** and **2**, respectively, and silver oxide. These two air-stable and light-sensitive carbene complexes [AgCl(**3**)] (**5**) and [AgCl(**4**)] (**6**) were characterized by NMR spectroscopy, and the molecular structure of **6** was confirmed by X-ray diffraction. The imidazolidin-2-thiones **7** and **8** were obtained by reaction of the silver carbene complexes **5** and **6**, respectively, with elemental sulfur at ambient temperature. Spectroscopic evidence for the formation of the rhodium(I) complex [(cod)Rh(Cl)(**10**)] (**11**) with the sterically demanding 1,3-di-*tert*-butyl-imidazolidin-2-ylidene ligand **10** obtained in situ from 1,3-di-*tert*-butyl-imidazolinium tetrafluoroborate **9** is presented. Because of the steric demand of the carbene ligand **10**, complex **11** decomposed rapidly in solutions of chlorinated or polar solvents.

## Introduction

Metal complexes of N-heterocyclic carbenes have emerged as an important class of compounds with widespread applications in homogeneous catalysis.[1,2] For example, such complexes represent efficient catalysts for palladium-catalyzed carbon–carbon coupling reactions,[3,4] ruthenium-catalyzed olefin metathesis reactions,[5–7] or iridium-catalyzed transfer hydrogenation reactions.[8] In general, metal complexes of "saturated" (nonaromatic) imidazolidin-2-ylidenes[9] reveal higher catalytic activity than the analogous complexes of "unsaturated" (aromatic) imidazolin-2-ylidenes[10] or benzannulated benzimidazol-2-ylidenes.[11] This is regarded as a consequence of the stronger basicity and nucleophilicity of the nonaromatically stabilized carbene ligands. However, in contrast to unsaturated N-heterocyclic carbenes, imidazolidin-2-ylidenes can occur as carbene dimers (enetetramines) if the steric demand of their *N*-substituents is small (e.g. *N*-methyl,[12] *N*-ethyl,[12] and *N*-phenyl[13]) and the kinetic barrier for dimerization is low. Imidazolidin-2-ylidenes with bulky *N*-substituents [e.g. *N*-*tert*-butyl,[12] *N*-(2,4,6-trimethylphenyl),[14] and *N*-(2,6-diisopropylphenyl)[14]] showed no tendency to dimerize and could be isolated and characterized as monomeric compounds. Recently, a simple procedure for the formation of unsymmetrical *N*,*N*′-substituted imidazolidin-2-ylidenes was described, and it was demonstrated that only one sterically demanding *N*-substituent is sufficient to prevent the dimerization of the carbene.[15]

Initially, transition metal complexes with imidazolidin-2-ylidene ligands were synthesized by cleavage of the enetetramines under forceful conditions.[16,17] The direct formation of such carbene-metal complexes by utilization of monomeric saturated carbenes is less attractive since the free ligands are extremely sensitive towards oxygen and moisture. However, preparation of the free carbenes by in situ deprotonation of imidazolinium salts with strong bases and subsequent reaction with suitable transition-metal precursors produced an improvement. In contrast to this, transmetalation has emerged as an interesting alternative for the synthesis of numerous transition-metal carbene complexes.[18] Silver(I)-carbene complexes have turned out to be the transmetalation agent of choice and were first employed by Wang and Lin in order to prepare rhodium and palladium complexes of benzimidazol-2-ylidene ligands.[19] The analogous silver complexes of imidazolidin-2-ylidene ligands were prepared by Pytkowicz et al. from silver(I) oxide and imidazolinium salts.[20]

In this contribution we report on the preparation and characterization of silver complexes **5** and **6** (Scheme 1), along with the sterically demanding imidazolidin-2-ylidene ligands **3** and **4**. We demonstrate that complexes **5** and **6** do not react in the transmetalation reaction with $PdI_2$ and [(*p*-cymene)RuCl(μ-Cl)]$_2$, most likely because of the steric demand of the carbene ligands, which shows the limitations of the transmetalation reaction. Furthermore, the rhodium

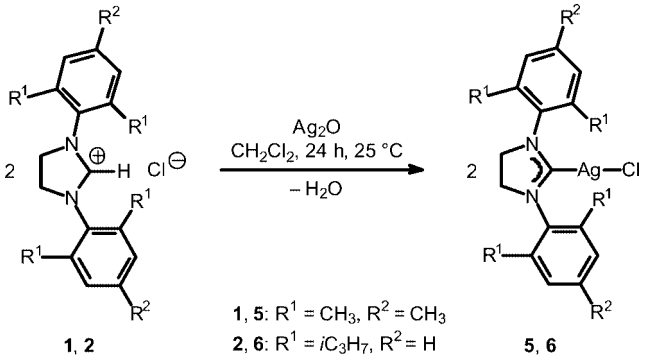
complex **11** with the *N*-*tert*-butyl-substituted carbene **10** is described (Scheme 3). These three complexes contain ligands that are also stable as monomeric imidazolidin-2-ylidenes when they are not coordinated to a metal center. In addition, the reaction of the complexes **5** and **6** with elemental sulfur to give imdazolidin-2-thiones is described (Scheme 2).

## Results and Discussion

The preparation of the silver complexes **5** and **6** was carried out in an analogous procedure to that described by Wang and Lin for the preparation of silver complexes with benzimidazolin-2-ylidene ligands.[19] The reaction of the imidazolinium salts **1** and **2** with 0.5 equiv. silver oxide in dichloromethane afforded the monocarbene complexes after a reaction time of 24 h (Scheme 1).



Scheme 1. Preparation of the silver carbene complexes **5** and **6**.

During the reaction, the dark suspension of silver oxide and the imidazolidinium salt became a clear and colorless solution as the silver oxide was consumed. The reaction did not require an exclusion of oxygen or moisture. This represents a substantial advantage compared with the complex synthesis using air-sensitive free carbenes and silver(I) precursors. However, complexes **5** and **6** decompose under the influence of light, as expected for silver complexes, giving the free carbenes **3** and **4** and silver chloride. Nevertheless, both novel silver carbene complexes could be fully characterized by NMR and mass spectroscopy.

Single crystals of **6**·4$CH_2Cl_2$ suitable for an X-ray diffraction analysis were obtained by layering *n*-pentane over a saturated dichloromethane solution of complex **6**. The molecular structure of the silver carbene complex **6** is depicted in Figure 1.[21] The X-ray diffraction data led, even after application of an absorption correction,[22–25] only to a poor structure model which, however, confirmed the overall composition and geometry of **6**. The quality of the X-ray data does not allow a detailed discussion of molecular parameters of **6**. Complex **6** resides on a crystallographic twofold axis that bisects the C4–C4* bond. The Ag–C2 bond in complex **6** [2.059(9) Å] is slightly shorter than the analogous bond in the silver(I) bromide complex with an *N*,*N*′-benzyl-substituted imidazolidin-2-ylidene ligand [2.09(2) Å].[20] However, the Ag–C2 bond length in **6** has a value that is similar to that found for the complex [AgCl(NHC)] (NHC = imidazolin-2-ylidene) [2.056(7) Å].[26]

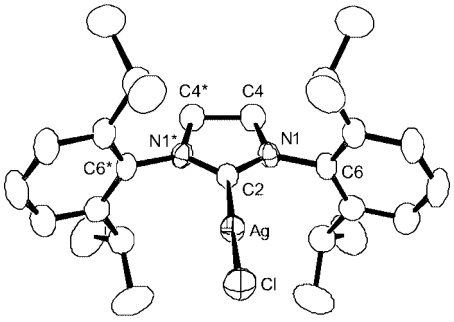


Figure 1. Molecular structure of one molecule of **6** in crystals of **6**·4$CH_2Cl_2$. Hydrogen atoms and solvent molecules have been omitted for clarity. Selected bond lengths [Å] and bond angles [°]: Ag–Cl 2.306(2), Ag–C2 2.059(9), N1–C2 1.324(7), N1–C4 1.457(8), C4–C4* 1.538(14); C2–Ag–Cl 173.5(2), C2–N1–C4 114.2(6), C2–N1–C6 123.1(5), Ag–C2–N1 125.9(4), N1–C2–N1* 107.8(8).

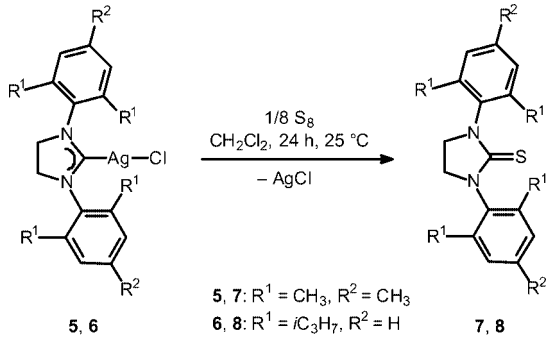
The transmetalation reactions with selected complexes of ruthenium and palladium {$PdI_2$, [(*p*-cymene)RuCl(μ-Cl)]$_2$} that use **5** and **6** as transmetalation agents were unsuccessful, most likely owing to the steric demand of the carbene ligands. We also studied the reactions of the complexes **5** and **6** with elemental sulfur. The imidazolidin-2-thiones **7** and **8** were obtained by simple addition of sulfur to a solution of the silver carbene complexes **5** and **6**, respectively, in dichloromethane at ambient temperature (Scheme 2).



Scheme 2. Preparation of the thiones **7** and **8**.

The formation of a carbene intermediate during the reaction of complexes **5** and **6** with sulfur is very likely. This transformation represents the reverse reaction of the sequence thione reduction[27] and reaction of the free carbene with a transition metal to give transition-metal carbene complexes. The $^{13}C$ NMR spectrum of **8** reveals the characteristic resonance signal for the carbon atom of the thiocarbonyl group at $\delta$ = 184.1 ppm. Furthermore, the spectrum shows the resonance signal for the methylene carbon atom of the *N*-heterocyclic ring at $\delta$ = 50.2 ppm. The cyclic thioureas **7** and **8** were characterized by X-ray diffraction to confirm the assigned structures. Crystals of **7** and **8** were obtained by diffusion of *n*-hexane into saturated dichloromethane solutions of the thiones. Figure 2 (**7**) and Figure 3 (**8**) depict the molecular structures of the thiones.[21–25]

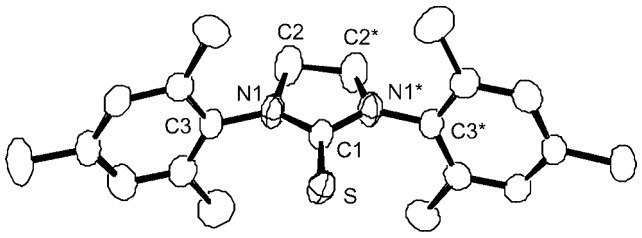

Figure 2. Molecular structure of one molecule of **7** in the crystal. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and bond angles [°]: S–C1 1.666(2), N1–C1 1.355(2), N1–C2 1.460(2), N1–C3 1.428(2), C2–C2* 1.513(4); C1–N1–C2 112.3(1), C1–N1–C3 125.3(1), C2–N1–C3 121.96(12), S–C1–N1 126.12(9), N1–C1–N1* 107.8(2).

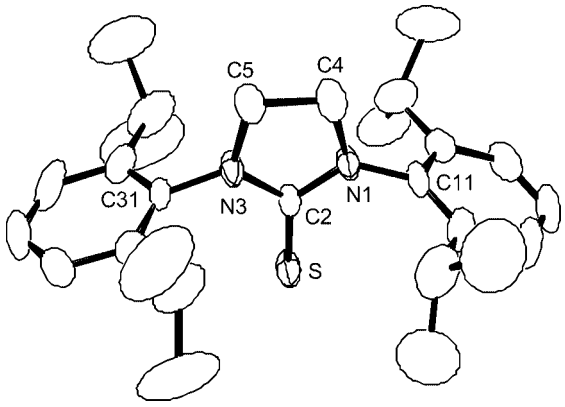

Figure 3. Molecular structure of one molecule of **8** in the crystal. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and bond angles [°]: S–C2 1.6611(15), N1–C2 1.347(2), N1–C4 1.453(2), N1–C11 1.440(2), N3–C2 1.353(2), N3–C5 1.457(2), N3–C31 1.425(2), C4–C5 1.495(3); C2–N1–C4 112.61(13), C2–N1–C11 124.75(13), C4–N1–C11 122.63(13), C2–N3–C5 112.45(13), C2–N3–C31 126.25(13), C5–N3–C31 121.15(12), S–C2–N1 126.54(11), S–C2–N3 125.77(11), N1–C2–N3 107.69(13).

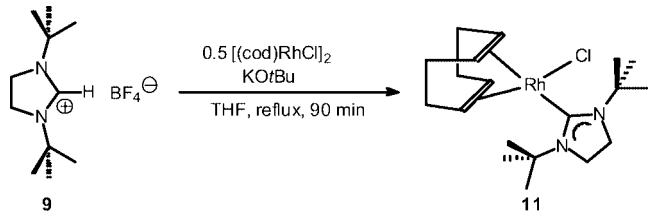
The carbon–sulfur bond lengths in both thioureas are similar to those reported for symmetrically *N*,*N*′-substituted[28] or unsymmetrically substituted spirocyclic imidazolidin-2-thiones.[15b] The N–C–N angles in thiones **7** and **8** are similar to those observed in the carbene complexes.[15]

Imidazolidin-2-thiones can act as ligands by using the sulfur atom for coordination. The molecular structure of the complex *cis*-[$PdCl_2$(**7**)$_2$] has been determined. The structure analysis reveals that coordination of the thiourea to a transition metal leaves the C–S bond length as well as the N–C–N angles of the ligand unchanged within experimental error.[29]

Complexes with *N*-*tert*-butyl-substituted imidazolidin-2-ylidenes are rare because of the steric demand of the *N*-substituents of the carbene ligand that hampers coordination and facilitates ligand dissociation from the metal center.[30] However, we found that the rhodium carbene complex **11** can be synthesized from the imidazolidinium tetrafluoroborate **9**, potassium *tert*-butoxide, and the dinuclear complex [(cod)Rh(Cl)]$_2$ by heating to reflux in THF (Scheme 3).



Scheme 3. Synthesis of the carbene complex **11**.

The rhodium atom in **11** is coordinated by carbene ligand **10**, which is stable in the free state and was previously isolated as such by Denk et al.[12] The *N*,*N*′-*tert*-butyl-substituted imidazolinium salt **9** is easily obtained from *N*,*N*′-di-*tert*-butylethylenediamine, triethylorthoformate, and ammonium tetrafluoroborate.[31] The $^{13}$C NMR spectrum of **11** exhibits a resonance signal for the carbene carbon atom at $\delta$ = 212.1 ppm with a $^{103}$Rh-$^{13}$C coupling constant of $^1J_{Rh,C}$ = 45 Hz. This constitutes clear evidence for complex formation. Both spectroscopic parameters are in good agreement with the analogous parameters for rhodium cod [(1*Z*,5*Z*)-1,5-cyclooctadiene] complexes with unsymmetrically *N*,*N*′-substituted carbene ligands.[15a] In comparison with rhodium complexes with benzannulated[32] and "unsaturated" (imidazolin-2-ylidene)[33] carbene ligands, the carbene carbon resonance in the $^{13}$C NMR spectrum of **11** is shifted to a lower field, whereas compared to acyclic carbene ligands,[34] a small upfield shift is observed for the carbene carbon resonance in **11**. This corroborates the expectation that the σ-donor capability of carbenes with a saturated five-membered ring is higher than that for unsaturated carbenes of the imidazolin-2-ylidene type.

Complex **11** exhibits only two resonance signals for the olefinic carbon atoms of the cod ring ($\delta$ = 68.7 ppm, $^1J_{Rh,C}$ = 15 Hz, and $\delta$ = 93.0 ppm, $^1J_{Rh,C}$ = 8 Hz). In contrast to this, the $^{13}$C NMR spectra of the rhodium complexes with unsymmetrically *N*,*N*′-substituted imidazolidin-2-ylidene ligands exhibit four signals for the olefinic carbon atoms of the cod ring, each with a $^1J$ coupling to the $^{103}$Rh nucleus.[15a] This is attributed to the loss of symmetry in the rhodium(I) complexes with unsymmetrically *N*,*N*′-substituted carbene ligands.

Rhodium complex **11** is air stable when stored as a solid, but it decomposes in solutions of dichloromethane. This lability can be rationalized by the weak bond between the rhodium atom and the carbene carbon atom, which is presumably caused by the steric demand of the *N*-*tert*-butyl substitutents of the carbene ligand. Similar observations have been made with nickel complexes of ligand **10**.[30]

## Conclusions

We have prepared the silver(I) complexes **5** and **6** along with the two monomeric imidazolidin-2-ylidenes **3** and **4**[14] starting from the imidazolinium salts **1** and **2**, respectively. The reaction of the silver complexes **5** and **6** with elemental sulfur gave the imidazolidin-2-thiones **7** and **8**, respectively. These thioureas were characterized by X-ray diffraction

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

analysis. It was shown that the rhodium(I) complex with the *N*,*N*′-*tert*-butyl-substituted imidazolidin-2-ylidene ligand **10** can be synthesized in spite of the steric bulk of this carbene ligand.

## Experimental Section

**General:** Reactions with air- and moisture-sensitive compounds or reagents were carried out in dry argon by using Schlenk and vacuum techniques. Solvents were dried by standard methods and freshly distilled prior to use. NMR spectra were recorded with a Bruker AC 200 (200 MHz) spectrometer and are reported relative to TMS as an internal standard. Mass spectra (EI) were measured with a Varian MAT 212 or a Bruker Reflex IV (MALDI) instrument. Elemental analyses (C, H, N) were obtained by using a Vario EL III elemental analyzer at the Westfälische Wilhelms-Universität Münster. The following compounds were prepared according to published procedures: 1,3-bis(2,4,6-trimethylphenyl)imidazolinium chloride (**1**),[14] 1,3-bis(2,6-diisopropylphenyl)imidazolinium chloride (**2**),[14] 1,3-di-*tert*-butyl-imidazolinium-tetrafluoroborate (**9**),[31] and {[(cod)Rh(Cl)]$_2$}.[35] All other compounds were used as purchased without further purification.

**[AgCl(3)] (5):** Silver(I) oxide (0.348 g, 1.5 mmol) was added to a solution of the imidazolinium salt **1** (1.029 g, 3.0 mmol) in dichloromethane (50 mL). The mixture was stirred at room temperature until the solid was completely consumed (24 h). The resulting solution was filtered through Celite and concentrated under vacuum. After recrystallization from dichloromethane/*n*-hexane, the silver carbene complex was obtained as a colorless solid (1.28 g, 95%). $C_{21}H_{26}N_2AgCl$ (449.8): calcd. C 56.08, H 5.83, N 6.23; found C 55.77, H 5.95, N 6.38. $^1$H NMR (200.1 MHz, $CD_3CN$): $\delta$ = 2.31 (s, 12 H, *o*-Ar–$CH_3$), 2.37 (s, 6 H, *p*-Ar–$CH_3$), 4.05 (s, 4 H, NC$H_2$C$H_2$N), 6.90, 7.08 (2×s, 4 H, Ar–H) ppm. $^{13}$C NMR (50.3 MHz, $CD_3CN$): $\delta$ = 18.1 (*o*-Ar–*C*$H_3$), 21.1 (*p*-Ar–*C*$H_3$), 51.8 ($NCH_2$), 130.1, 135.6, 137.0, 139.2 (Ar–C) ppm. The resonance for the carbene carbon atom was not observed. MS (MALDI): *m*/*z* = 719 [Ag(**3**)$_2$]$^+$.

**[AgCl(4)] (6):** Silver(I) oxide (0.348 g, 1.5 mmol) was added to a solution of **2** (1.281 g, 3.0 mmol) in dichloromethane (50 mL). The mixture was stirred at room temperature until the solid was completely consumed (24 h). It was then filtered through Celite and concentrated under vacuum. After recrystallization from dichloromethane/*n*-hexane, the silver carbene complex was obtained as a colorless solid (1.47 g, 92%). $C_{27}H_{38}N_2AgCl$ (533.9): calcd. C 60.74, H 7.17, N 5.25; found C 60.51, H 7.29, N 5.43. $^1$H NMR (200.1 MHz, $CD_3CN$): $\delta$ = 1.19, 1.27 [2×d, $^3J$(H,H) = 6.6, 7.6 Hz, 24 H, CH(C$H_3$)$_2$], 3.17 [sept, 4 H, C*H*($CH_3$)$_2$], 4.11 (s, 4 H, NC$H_2$C$H_2$N), 7.31–7.46 (m, 6 H, Ar–H) ppm. $^{13}$C NMR (50.3 MHz, $CD_3CN$): $\delta$ = 23.9, 25.5 [CH(*C*$H_3$)$_2$], 29.2 [*C*H($CH_3$)$_2$], 54.7 ($NCH_2$), 125.4, 130.7, 134.4, 148.1 (Ar–C) ppm. The resonance for the carbene carbon atom was not observed.

**1,3-Bis(2,4,6-trimethylphenyl)imidazolidin-2-thione (7):** A mixture of the silver complex **5** (0.450 g, 1 mmol) and sulfur (0.032 g, 1 mmol) was suspended in dichloromethane (50 mL) and stirred for 24 h at room temperature. After removal of silver chloride by filtration, the solvent was evaporated in vacuo. The crude product was purified chromatographically [silica gel, *n*-hexane/diethyl ether (5:1, v:v)] to give a yellow solid (0.269 g, 80%). $C_{21}H_{26}N_2S$ (338.5): calcd. C 74.51, H 7.74, N 8.28; found C 75.32, H 7.48, N 8.29. $^1$H NMR (200.1 MHz, $CDCl_3$): $\delta$ = 2.25 (s, 18 H, *p*-Ar–$CH_3$, *o*-Ar–$CH_3$), 4.00 (s, 4 H, NC$H_2$C$H_2$N), 6.99 (s, 4 H, Ar–H) ppm. $^{13}$C NMR (50.3 MHz, $CDCl_3$): $\delta$ = 17.5 (*o*-Ar–*C*$H_3$), 21.0 (*p*-Ar–*C*$H_3$), 47.5 ($NCH_2$), 129.3, 134.4, 136.3, 138.0 (Ar–C), 180.8 (C=S). MS (EI, 70 eV): *m*/*z* (%) = 338 (48) [M]$^+$.

**1,3-Bis(2,6-diisopropylphenyl)imidazolidin-2-thione (8):** A mixture of the silver complex **6** (0.534 g, 1 mmol) and sulfur (0.032 g, 1 mmol) was suspended in dichloromethane (50 mL) and stirred for 24 h at room temperature. After removal of silver chloride by filtration, the solvent was evaporated in vacuo. The crude product was purified chromatographically [silica gel, *n*-hexane/diethyl ether (5:1, v:v)] to give a yellow solid (0.262 g, 62%). $C_{27}H_{38}N_2S$ (422.7): calcd. C 76.73, H 9.06, N 6.63; found C 76.99, H 8.68, N 6.65. $^1$H NMR (200.1 MHz, $CDCl_3$): $\delta$ = 1.33, 1.37 [2×d, $^3J_{H,H}$ = 4.4, 5.2 Hz, 24 H, CH(C$H_3$)$_2$], 3.10 [sept, 4 H, C*H*($CH_3$)$_2$], 4.05 (s, 4 H, NC$H_2$C$H_2$N), 7.24–7.41 (m, 6 H, Ar–H) ppm. $^{13}$C NMR (50.3 MHz, $CDCl_3$): $\delta$ = 24.3 [CH(*C*$H_3$)$_2$], 28.9 [*C*H($CH_3$)$_2$], 50.2 ($NCH_2$), 124.2, 129.1, 134.7, 147.3 (Ar–C), 184.1 (C=S) ppm. MS (EI, 70 eV): *m*/*z* (%) = 422 (85) [M]$^+$, 407 (6) [M – $CH_3$]$^+$.

**[(cod)Rh(Cl)(10)] (11):** A solution of {[(cod)Rh(Cl)]$_2$} (0.098 g, 0.20 mmol) in THF (20 mL) was added to a suspension of the imidazolinium tetrafluoroborate **9** (0.108 g, 0.40 mmol) and potassium *tert*-butoxide (0.045 g, 0.40 mmol) in THF (20 mL). The resulting mixture was heated under reflux for 90 min. After cooling and evaporation of the solvent, the residue was suspended in toluene (10 mL) and filtered. The solvent of the filtrate was removed under vacuum, and the crude product was purified chromatographically [silica gel, hexane/ethyl acetate (5:1, v:v)] to give a yellow solid (0.067 g, 78%). $C_{19}H_{34}N_2RhCl$ (428.9): calcd. C 53.21, H 7.99, N 6.53; found C 53.56, H 7.78, N 6.59. $^1$H NMR (200.1 MHz, $CDCl_3$): $\delta$ = 1.64–1.93 [m, 8 H, cod($CH_2$)], 1.84 (s, 18 H, $CH_3$), 3.61 (s, 4 H, NC$H_2$C$H_2$N), 3.43–3.61 [m, 2 H, cod(CH)], 4.85 [m, 2 H, cod(CH)] ppm. $^{13}$C NMR (50.3 MHz, $CDCl_3$): $\delta$ = 28.2 [cod($CH_2$)], 30.8 ($CH_3$), 31.8 [cod($CH_2$)], 45.6 (N*C*$H_2$*C*$H_2$N), 57.4 [*C*($CH_3$)$_3$], 68.7 [d, $^1J_{Rh,C}$ = 15 Hz, cod(CH)], 93.0 [d, $^1J_{Rh,C}$ = 8 Hz, cod(CH)], 212.1 (d, $^1J_{Rh,C}$ = 45 Hz, NCN) ppm.

# Synthesis and Characterization of Two Novel, Mono-Lacunary Dawson Polyoxometalate-Based, Water-Soluble Organometallic Ruthenium(II) Complexes: Molecular Structure of $[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]^{8-}$

**Yoshitaka Sakai,[a] Akira Shinohara,[a] Kunihiko Hayashi,[a] and Kenji Nomiya*[a]**

**Keywords:** Arene ligands / Polyoxometalates / Ruthenium / X-ray diffraction

The synthesis and structural characterization of a novel class of mono-lacunary Dawson polyoxometalate-(POM-)based, water-soluble organometallic complexes, which are expected to be effective homogeneous oxidation catalyst precursors in water, is described. The organometallic complexes $K_8[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 12H_2O$ (**1**) and $K_8[\{(p\text{-cymene})Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 16H_2O$ (**2**) were successfully prepared by direct reactions of the mono-lacunary Dawson POM $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]\cdot 19H_2O$ with the organometallic precursors $[(C_6H_6)RuCl_2]_2$ and $[(p\text{-cymene})RuCl_2]_2$, respectively, in aqueous media and characterized by complete elemental analysis, thermogravimetric and differential thermal analyses (TG/DTA), and FT-IR and solution ($^1H$, $^{13}C$, $^{31}P$, and $^{183}W$) NMR spectroscopy. The molecular structure of $[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]^{8-}$ (**1a**), in which the binding of the cationic organometallic group $\{(C_6H_6)Ru(H_2O)\}^{2+}$ occurs through two oxygen atoms of the four available oxygen atoms in the mono-lacunary site of the POM, resulting in overall $C_1$ symmetry, was successfully determined by single-crystal X-ray analysis. Interestingly, the hydrophilicity of the organometallic precursors is greatly enhanced by binding to a mono-lacunary Dawson POM with higher hydrophilicity.

## Introduction

Polyoxometalates (POMs) are molecular metal oxide clusters that are of current interest as soluble metal oxides and for their application in catalysis, medicine, and materials science.[1] It has been stressed that it is important to discover more reliable and efficient procedures of synthesis before exploration of any possible new reactivity patterns.[2] The incorporation of transition metal ions into mono-lacunary Keggin and Dawson POMs has been found to give inorganic analogs of metalloporphyrin complexes[1a] and, in fact, metalloporphyrin-like catalysts that promote olefin epoxidation and aliphatic and aromatic hydroxylations have been realized.[3] The 4d or 5d transition metal ion substituted Keggin and Dawson POMs have been pointed out from the viewpoints of anticipated catalysis, in which the lacunary POM species work as π-acceptor ligands.[2]

In a separate area, water-soluble organometallic complexes that work as oxidation catalysts in water at ambient temperature are interesting from the viewpoint of green chemistry based on homogeneous catalysis by organometallic complexes.[4]

Recently, we have prepared the mono-$Ru^{III}$-substituted Dawson POM $K_7[\alpha_2\text{-}P_2W_{17}O_{61}Ru^{III}(H_2O)]\cdot 19H_2O$ as a black crystalline solid from the reaction of the mono-lacunary Dawson POM $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]\cdot 19H_2O$ with *cis*-$[RuCl_2(DMSO)_4]$ as the ruthenium source.[5] The purity of the POM obtained here was less than 95%, which has been attributed to a serious issue involving the starting ruthenium source, i.e. some of the coordinating DMSO molecules are difficult to remove because of their strong bonding to the $Ru^{II}$ atom. Ruthenium complexes without coordinated DMSO molecules are also desirable because these DMSO molecules act as a catalyst poison during the homogeneous catalysis by the ruthenium center. POM-supported ruthenium(II) complexes such as $[Ru(DMSO)_3(H_2O)\text{-}XW_{11}O_{39}]^{6-}$ (X = Ge, Si)[6a] and $[HW_9O_{33}Ru_2(DMSO)_6]^{7-}$,[6b] prepared from *cis*-$[RuCl_2(DMSO)_4]$, have been reported and also contain some DMSO molecules coordinated to the $Ru^{II}$ atoms. For preparation of POMs that do not contain any coordinated DMSO molecules, we therefore sought other ruthenium(II) precursors without DMSO molecules, and selected the organometallic ruthenium(II) complexes $[(C_6H_6)RuCl_2]_2$ and $[(p\text{-cymene})RuCl_2]_2$.

In this work, we have obtained the novel, POM-based, diamagnetic ruthenium(II) complexes $K_8[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 12H_2O$ (**1**) and $K_8[\{(p\text{-cymene})Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 16H_2O$ (**2**) by the direct reaction of $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ with the organometallic ruthenium(II) complexes in aqueous media, and unexpectedly found that the products **1** and **2** are water-soluble. The molecular structure

of the polyoxo anion $[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]^{8-}$ (**1a**) was successfully determined by single-crystal X-ray analysis. The cationic organometallic group $\{(C_6H_6)\text{-}Ru(H_2O)\}^{2+}$ was found to be attached to two oxygen atoms of the four available oxygen atoms in the mono-lacunary site of the POM, resulting in overall $C_1$ symmetry.

Organometallic complexes supported on mono-lacunary Keggin and Dawson POMs have until now only been reported without X-ray structure analysis, such as $[(CpTi)\text{-}PW_{11}O_{39}]^{4-}$ (Cp = $C_5H_5$),[8a,8b] $[\{(C_6H_5)Sn\}PW_{11}O_{39}]^{4-}$,[8b] $[\{(RSi)_2O\}SiW_{11}O_{39}]^{4-}$ {R = $C_2H_5$, $C_6H_5$, $NC(CH_2)_3$, $C_3H_5$},[8b] $[(C_6H_5Sn)P_2W_{17}O_{61}]^{7-}$,[8b] metal–metal bonded derivatives[8c] such as $[\{CpFe(CO)_2Sn\}SiMo_{11}O_{39}]^{5-}$, $[\{[(OC)_3CoGe]_2OSiW_{11}O_{39}\}^{5-}]_n$, and $[\{(C_7H_8)_2RhSn\}\text{-}PW_{11}O_{39}]^{4-}$, and water-soluble organometallic complexes supported on tri-lacunary Keggin POM $[(CpTi)_3\text{-}XW_9O_{37}]^{7-}$ (X = Si, Ge).[8e]

As for X-ray structure analysis, POM-supported $(\eta^6\text{-arene})Ru^{2+}$ complexes have been recently reported by Proust and co-workers,[7] including $(\eta^6\text{-arene})Ru^{2+}$ complexes (arene = benzene, toluene, *p*-cymene, hexamethylbenzene) supported on mono-lacunary Keggin POMs such as $[\{[Ru(\eta^6\text{-arene})]PW_{11}O_{39}\}_2(WO_2)]^{8-}$ and $[\{Ru(\eta^6\text{-arene})(H_2O)\}\text{-}PW_{11}O_{39}]^{5-}$.[7e]

On the other hand, several saturated POMs, for example the triniobium(v)- and trivanadium(v)-substituted Keggin and Dawson POMs $[XW_9M_3O_{40}]^{n-}$ (M = Nb, V; X = Si, P) and $[P_2W_{15}M_3O_{62}]^{9-}$, have been used as molecular oxide supports for various cationic organometallic groups such as $CpTi^{3+}$, $Cp^*Rh^{2+}$, $(C_6H_6)Ru^{2+}$, $(cod)Pt^{2+}$, $(cod)Ir^+$, $(cod)\text{-}Rh^+$, $Re(CO)_3^+$, $Ir(CO)_2^+$, $Rh(CO)_2^+$, etc.[9–12] However, only a few successful X-ray structure analyses have been reported, such as $(Bu_4N)_6Na[(Cp^*Rh)(\alpha\text{-}1,2,3\text{-}P_2W_{15}Nb_3O_{62})]\cdot 10CH_3CN\cdot 10Me_2CO$[9a] and $[\{[Ag(2,2'\text{-}bpy)]_2[Ag_2(2,2'\text{-}bpy)_3]_2\}\alpha\text{-}PW_9V_3O_{40}]$.[10e]

Herein we report full details of the synthesis and unequivocal characterization of **1** and **2**, with complete elemental analysis, thermogravimetric and differential thermal analyses (TG/DTA), and FT-IR and solution ($^1H$, $^{13}C$, $^{31}P$, and $^{183}W$) NMR spectroscopy, and the molecular structure of **1a**.

## Results and Discussion

### Synthesis and Compositional Characterization

The two novel 1:1-type complexes of the cationic organometallic groups with the POM (**1** and **2**) were formed by direct reaction of the organometallic precursors $[(L)\text{-}RuCl_2]_2$ (L = $C_6H_6$, *p*-cymene) with the mono-lacunary POM $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]$, in aqueous solution, at room temperature, under air. They were isolated as analytically pure, orange and yellow-brown powders in 24.5% (0.49 g scale) and 33.2% (0.67 g scale) yields, respectively.

The formation of **1** and **2** is represented in Equation (1).

$$1/2\ [(L)RuCl_2]_2 + K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}] + H_2O \rightarrow K_8[\{(L)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})] + 2\ KCl \quad (1)$$

Although the organometallic precursors $[(L)RuCl_2]_2$ are insoluble in water, complexes **1** and **2** containing the organometallic fragments are water-soluble.

The molecular formulae and the 1:1-type compositions of **1** and **2** were established by complete elemental analyses (all elements, including oxygen, 100.06 and 99.7% total observed, respectively), which were carried out for the samples dried at room temperature at $10^{-3}$–$10^{-4}$ Torr overnight. The weight losses observed during drying before analysis were 3.79% for **1**, which corresponds to 10–11 adsorbed and/or hydrated water molecules, and 4.2% for **2**, which corresponds to 11–12 water molecules. In the TG/DTA measurements under atmospheric conditions, the weight loss of 3.90% observed below 124 °C in **1** corresponds to 12 water molecules and that of 6.24% observed below 189 °C in **2** corresponds to 17 water molecules, in accordance with the findings of elemental analyses plus the weight losses found before analysis (see Exp. Sect.). In these complexes, the Cl analysis (calcd. 0; found <0.1% for **1** and <0.05% for **2**) indicated no contamination by Cl atoms, thus suggesting that the reaction of Equation (1) progresses completely; complexes **1** and **2** were isolated with high purity. The diamagnetic nature of **1** and **2** was supported by solution ($^1H$, $^{13}C$, $^{31}P$, and $^{183}W$) NMR spectra; all signals were found in the region usually observed in the diamagnetic POMs.

The solid-state FT-IR measurements of $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]$, **1**, and **2** (Figures 1a, 1b, and 1c, respectively) show the spectral patterns characteristic of the Dawson POM framework.[13] The FT-IR spectra of **1** and **2** in the polyoxometalate region are very similar to that of $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]$, especially with regards to the multiple P–O bands (1086, 1054, and 1017 $cm^{-1}$ for **1**; 1086, 1055, and

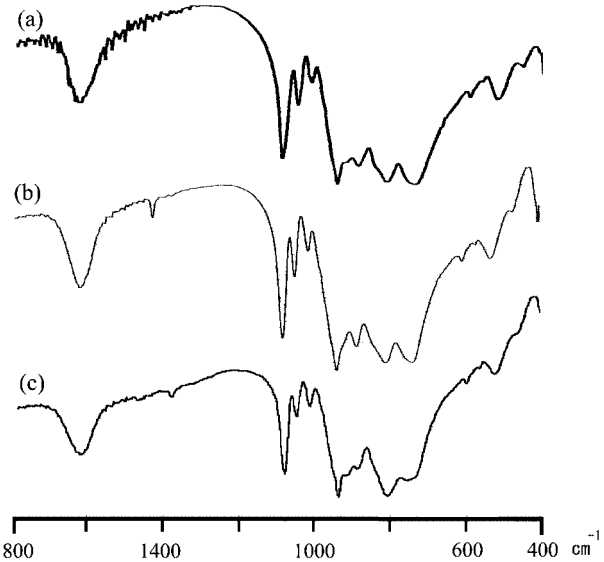

Figure 1. FT-IR spectra in the polyoxo anion regions, measured as KBr disks, of (a) $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]\cdot 19H_2O$, (b) $K_8[\{(C_6H_6)\text{-}Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 12H_2O$ (**1**), and (c) $K_8[\{(p\text{-cymene})\text{-}Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 16H_2O$ (**2**).

1016 $cm^{-1}$ for **2**; 1085, 1052, and 1016 $cm^{-1}$ for $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$), the bands assignable to $M–O_{terminal}$ oxygen atoms (940 $cm^{-1}$ for **1**, 941 $cm^{-1}$ for **2**, and 939 $cm^{-1}$ for $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$) and in the bands assignable to edge-sharing M–O–M oxygen atoms (810 and 741 $cm^{-1}$ for **1**; 809 and 742 $cm^{-1}$ for **2**; 810 and 737 $cm^{-1}$ for $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$). No change was seen in the bands assignable to corner-sharing M–O–M oxygen atoms (885 $cm^{-1}$ for **1**, **2**, and $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$). Compared with the spectrum of $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$, the FT-IR spectra of **1** and **2** show weaker bands due to the presence of the coordinating aromatic rings at 1434 $cm^{-1}$ for **1** and 1473 and 1389 $cm^{-1}$ for **2**. The aromatic–Ru vibrational data of the precursors are observed at 1433 $cm^{-1}$ for $[(C_6H_6)RuCl_2]_2$ and at 1496, 1471, 1458, 1448, 1408, 1389, and 1362 $cm^{-1}$ for [(*p*-cymene)$RuCl_2]_2$.

### Solution NMR Spectra

The $^{31}P$ NMR spectra in $D_2O$ show clean, two-line spectra with resonances at $\delta$ = –8.36 and –14.02 ppm for **1** (Figure 2b) and at $\delta$ = –8.28 and –14.08 ppm for **2** (Figure 2c), which are different from those of $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$ at $\delta$ = –7.00 and –14.17 ppm (Figure 2a). The upfield resonance is known to be due to the phosphorus P(1) atom closer to the $W_3O_6$ cap (Figure 6b), whereas the downfield resonance is assigned to the phosphorus P(2) atom closest to the opposite site. The two-line, impressively clean $^{31}P$ NMR spectra strongly suggest the presence of a single species in solution, thereby precluding the presence of even minor, phosphorus-containing impurities in **1**, **2**, and $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$. Further, the observed $^{31}P$ chemical shifts are in the usual region for diamagnetic species of various Dawson POMs,[5,9,12b,12c] supporting the suggestion that **1** and **2** are diamagnetic $Ru^{II}$ complexes.

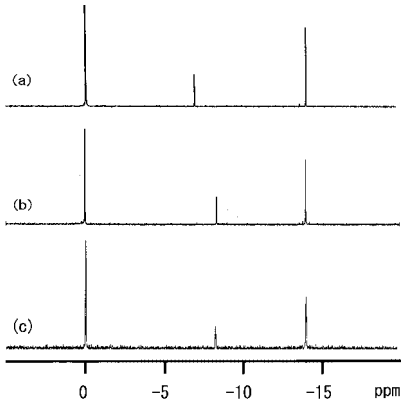

Figure 2. $^{31}P$ NMR spectra (in $D_2O$) of (a) $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$·$19H_2O$, (b) $K_8[\{(C_6H_6)Ru(H_2O)\}(\alpha_2$-$P_2W_{17}O_{61})]$·$12H_2O$ (**1**), and (c) $K_8[\{$(*p*-cymene)$Ru(H_2O)\}(\alpha_2$-$P_2W_{17}O_{61})]$·$16H_2O$ (**2**). In each case a very high level of purity is indicated (i.e., with respect to any other P-containing polyoxo anions or other materials).

The $^{183}W$ NMR spectrum of $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$ in $D_2O$ (Figure 3a) shows nine primary resonances at $\delta$ = –117.1, –140.4, –151.7, –181.0, –183.1, –218.1, –220.5, –224.0, and –242.6 with integration intensities of 2:2:2:2:1:2:2:2:2, consistent with the overall $C_s$ symmetry of the mono-lacunary Dawson structure. The $^{183}W$ NMR measurements of **1** in $D_2O$ were unsuccessful because of an insufficient concentration of the aqueous solution (see Exp. Sect.). On the other hand, the $^{183}W$ NMR spectrum of **2a**, which was derived by cation exchange of the potassium salt **2** with an excess of $NaClO_4$ (see Exp. Sect.), in $D_2O$ consists of virtually 17 lines at $\delta$ = –117.6, –125.1, –138.6, –139.0, –163.8, –177.1, –177.3, –186.5, –207.6, –217.3 (1 + 1), –218.2, –219.5, –220.6, –221.9, –239.6, and –241.6. The relative intensity of all signals, except the signals at $\delta$ = –217.3 ppm, is one (Figure 3b), thus suggesting its overall $C_1$ symmetry. These resonances are substantially different from those of $[\alpha_2$-$P_2W_{17}O_{61}]^{10–}$.

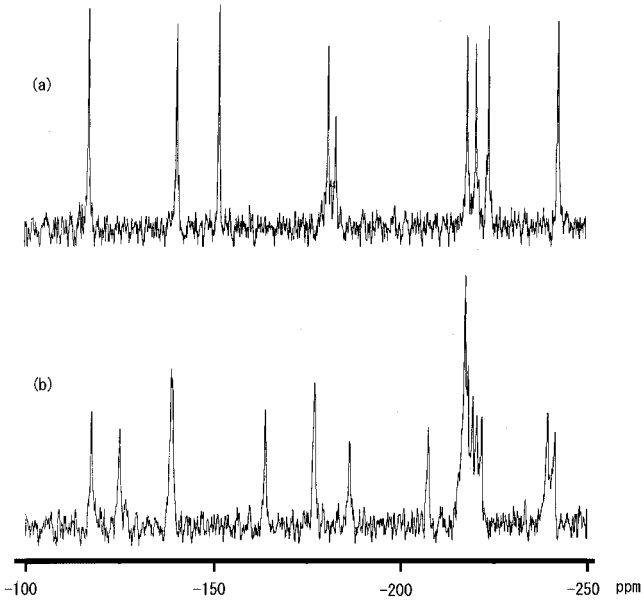

Figure 3. $^{183}W$ NMR spectra (in $D_2O$) of (a) $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]$·$19H_2O$ and (b) $[\{$(*p*-cymene)$Ru(H_2O)\}(\alpha_2$-$P_2W_{17}O_{61})]^{8–}$ (**2a**), which was prepared by cation exchange of **2** using an excess amount of $NaClO_4$.

The $^1H$ (Figure 4a) and $^{13}C$ NMR (Figure 5a) spectra of **1** in $D_2O$ show single peaks at $\delta$ = 6.18 and 82.98 ppm, respectively, due to the benzene ring coordinated to the Ru atom. On the other hand, the $^{13}C$ NMR spectrum of **2** in $D_2O$ (Figure 5b) shows 10 lines due to the *p*-cymene ring coordinated to the Ru atom, thus suggesting that all carbon atoms of the coordinated *p*-cymene are inequivalent, i.e. $C_1$ symmetry. Correspondingly, the $^1H$ NMR spectrum of **2** in $D_2O$ (Figure 4b) shows that the ring protons (H2, H3, H5, H6) are inequivalent; they were actually observed as apparent three-line signals with a 1:2:1 intensity ratio. The $^1H$ and $^{13}C$ NMR spectra show the local symmetry around the coordinated benzene and the coordinated *p*-cymene, whereas the $^{31}P$ and $^{183}W$ NMR spectra show the overall symmetry of **1a** and **2a**. In the coordinated *p*-cymene ligand, all the carbon atoms are inequivalent (local symmetry

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$C_1$) as its rotational movement is probably restricted, whereas in the coordinated benzene all the carbon atoms seem equivalent because of its free rotation on the NMR timescale. Similar observations have recently been made by the Proust group.[7e] On the other hand, the overall symmetry of **1a** is $C_1$, as revealed by single-crystal X-ray structure analysis, and that of **2a** should also be $C_1$, as suggested by the 17-line $^{183}W$ NMR spectrum.

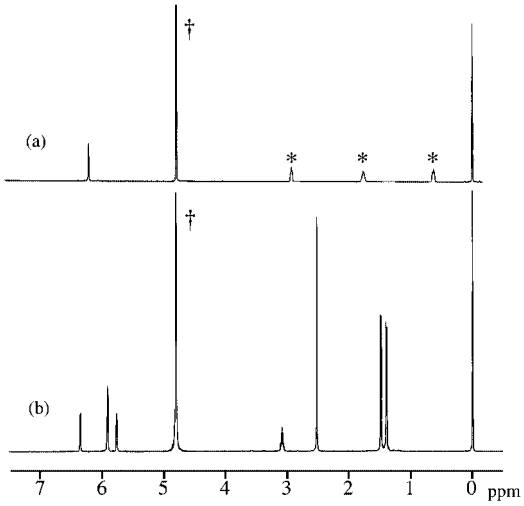

Figure 4. $^1H$ NMR spectra (in $D_2O$) of (a) $K_8[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 12H_2O$ (**1**), with an internal reference of DSS, and (b) $K_8[\{(p\text{-cymene})Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 16H_2O$ (**2**) with an internal reference of TSP. The proton signals denoted by an asterisk in (a) are from the methylene groups of the DSS, and in both (a) and (b) the proton signals denoted by a dagger are from $H_2O$.

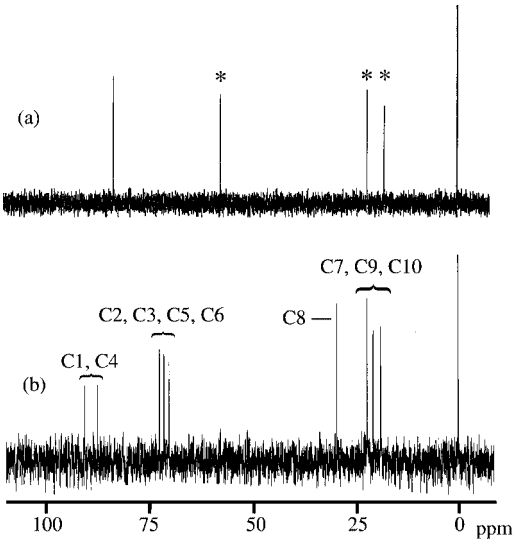

Figure 5. $^{13}C$ NMR spectra (in $D_2O$) of (a) $K_8[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 12H_2O$ (**1**), with an internal reference of DSS, and (b) $K_8[\{(p\text{-cymene})Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 16H_2O$ (**2**), with an internal reference of TSP. The carbon signals denoted by an asterisk in (a) are from the methylene groups of the DSS.

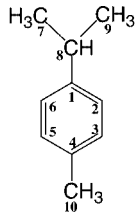

*p*-cymene ligand and its numbering

### Molecular Structure of 1a

The crystal of **1** contains discrete cluster anions, potassium cations, and lattice water molecules, all at general positions in the triclinic space group ($P\bar{1}$), except for three water oxygen atoms at special positions with a site occupancy factor fixed at 0.5. The solid-state packing of the polyoxo anion **1a** is shown in Figure 6a. The observed electron densities of the Ru and W atoms are quite different, and the data unequivocally distinguished and defined the Ru and W atoms. The 17 tungsten atoms, the one ruthenium atom, and the two P atoms were clearly identified. Thus, the main features of the molecular structure of the POM were clarified. However, the resolution obtained for the structure of the salt was limited by the poor quality of the available crystals and by the considerable disorder of the countercations and the solvent of crystallization. These features are all too common in POM crystallography.[14]

The molecular structure of **1a** is composed of the monolacunary Dawson POM unit $\alpha_2\text{-}P_2W_{17}O_{61}$ and the $\{(C_6H_6)Ru\}^{2+}$ unit, to which one oxygen atom is bonded in the form of a water molecule [Ru1A–O62A = 2.067(17) Å]. The benzene ring is disordered [C–C distances: 1.35(4)–1.47(4) Å; Ru–C distances: 2.12(3)–2.20(3) Å]. The $[(C_6H_6)Ru(H_2O)]^{2+}$ group is coordinated to only two [Ru1A–O56A (cap W) = 2.090(17) Å; Ru1A–O52A (belt W) = 2.056(18) Å] of the four available oxygen atoms (O47A, O52A, O55A, O56A) in the lacunary site of the POM support, resulting in the chiral configuration of **1a** based on $C_1$ symmetry. Thus, the polyoxo anion is found as a set of enantiomeric pairs in the unit cell (Figure 6a). As a matter of fact, there are four polyoxo anion units, denoted as units A, A′, B, and B′, in the unit cell ($Z$ = 4). The relative configurations of the benzene ring and the water molecule coordinated to the ruthenium(II) center are somewhat different between units A and B, although their polyoxo anion moieties have the same structure. Thus, the units A/A′ and B/B′ are actually the different set of enantiomeric pairs, respectively, and therefore the unit cell contains two types of the racemic mixture.

The molecular structure of unit A is depicted in Figure 6b, and that of unit B is deposited in the Supporting Information as Figure S1. Figure 6c shows a polyhedral representation of the polyoxo anion **1a**.

A few examples where only two of the four available oxygen atoms in the mono-lacunary site in the Keggin POM are utilized for coordination to the organometallic center are known. These include $[\{C_6H_5P(O)\}_2PW_{11}O_{39}]^{3-}$,[15]

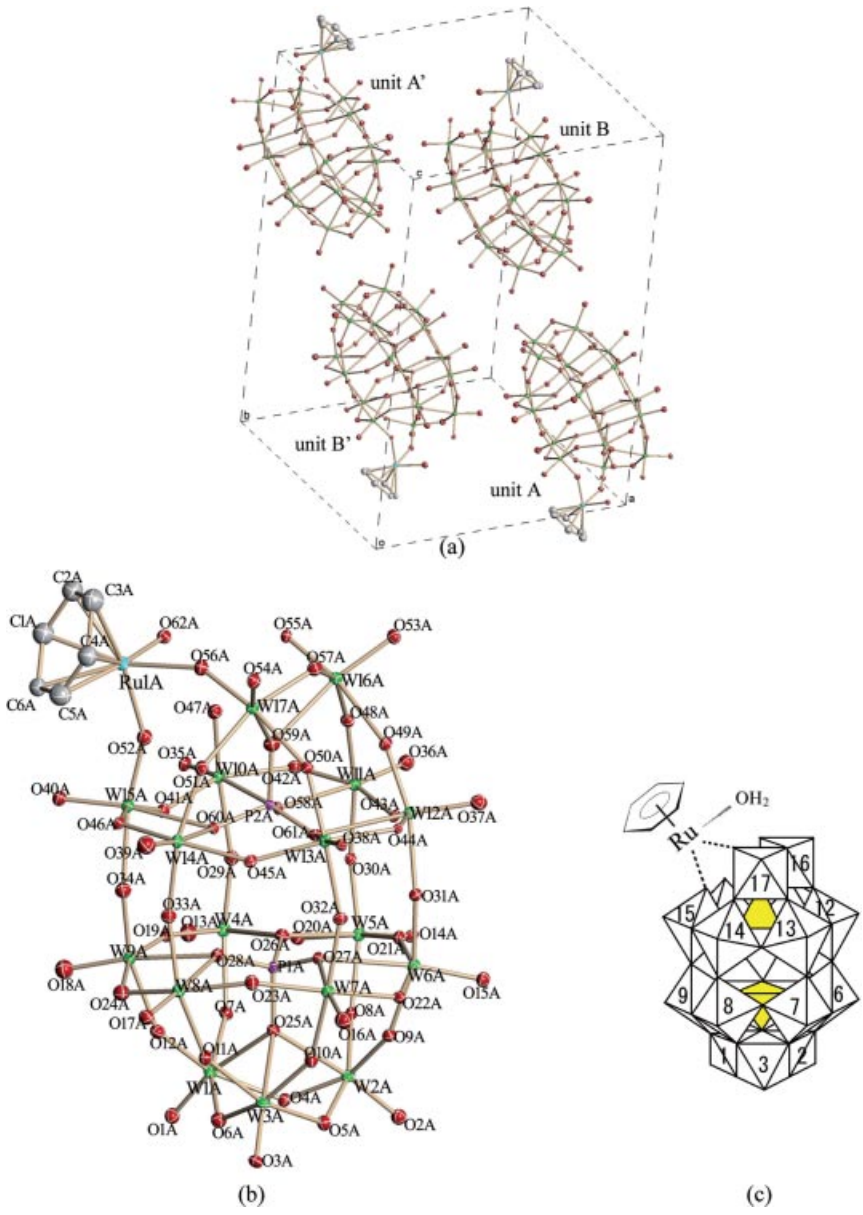

Figure 6. (a) Solid-state packing of the polyoxo anion $[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]^{8-}$ (**1a**) (Z = 4). (b) Molecular structure of unit A in **1a** with 50% probability ellipsoids. (c) Polyhedral representation of the polyoxo anion **1a**. In (a), the units (A, A′) and (B, B′) are the different sets of enantiomeric pairs, and the relative configurations of the benzene ring and the water molecule coordinated to the ruthenium(II) center are somewhat different between the units (A and B), although their polyoxo anion moieties take the same structure. Thus, the unit cell contains two types of the racemic mixture. The molecular structure of unit A is depicted in (b); that of unit B is deposited in Supporting Information as Figure S1. In (c), the internal yellow tetrahedra represent the $PO_4^{3-}$ core, while the white octahedra represent the $WO_6$ fragment with a tungsten atom in the center of the octahedra and oxygen atoms at each corner. The cationic $[(C_6H_6)Ru(H_2O)]^{2+}$ group binds to two terminal oxygen atoms in the lacunary site. The two phosphorus atoms, P(2) and P(1), are defined as "close to Ru (north)" and "far from Ru (south)", respectively.

$[Ru(DMSO)_3(H_2O)XW_{11}O_{39}]^{6-}$ (X = Ge, Si),[6a] and $[\{Ru(\eta^6\text{-arene})(H_2O)\}PW_{11}O_{39}]^{5-}$.[7e]

Selected bond lengths and angles around the ruthenium(II) atom in **1a** are given in Table 1 and Table S1, with average bond lengths and angles for the Dawson POM unit in Table S2.

In the lacunary site, the W–O distances should be noted: W15A–O52A (bonding to Ru atom) = 1.775(18) Å; W15A–O40A (terminal) = 1.739(17) Å; W17A–O56A (bonding to Ru atom) = 1.772(17) Å; W17A–O54A (terminal) = 1.738(17) Å; W10A–O47A (terminal) = 1.767(17) Å; W10A–O35A (terminal) = 1.714(16) Å; W16A–O55A (terminal) = 1.728(16) Å; W16A–O53A (terminal) = 1.743(17) Å. These bond lengths indicate the double-bond character of the W–O (terminal) bonds. It is likely that the coordination of the Ru atom to the two oxygen atoms (O52A, O56A) in the lacunary site influences the W–O distances less than the distances W10A–O47A and W16A–O55A. On the other hand, the W–O distances in the $W_3$ cap and the two $W_6$ belts, i.e. the W–Ot (Ot: terminal oxy-

gen atom), W–Oe (Oe: edge-sharing oxygen atom), W–Oc (W belt) (Oc: corner-sharing oxygen atom), and W–Oa (Oa: oxygen atom coordinated to P atom) distances, are in the normal range.[1b] The Dawson unit contains two central P atoms in an almost regular tetrahedral environment of $PO_4$: the $PO_4$ unit closest to the lacunary site [P–O distances: 1.534(19)–1.571(17) Å; O–P–O angles: 107.7(9)–111.3(9)°] and the $PO_4$ unit closest to the $W_3$ cap [P–O distances: 1.516(17)–1.568(17) Å; O–P–O angles: 106.3(9)–112.6(9) °].

The bond valence sums (BVS),[16] calculated using the observed bond lengths for **1a**, are in the range of 5.97–6.33 for the 17 W atoms and 4.84–5.00 for the two P atoms, which reasonably correspond to the formal valences of $W^{6+}$ and $P^{5+}$. Furthermore, the BVS values (2.17–1.50) of all oxygen atoms, except the O(62A) atom (0.45), which is bonded to the $Ru^{II}$ atom, show that they are not protonated. The BVS value of the O(62A) atom (0.45) suggests that this oxygen atom is part of a water molecule. These results are in good agreement with those of the related compounds, $[Ru(DMSO)_3(H_2O)XW_{11}O_{39}]^{6-}$ (X = Ge, Si)[6a] and $[\{Ru(p\text{-cymene})(H_2O)\}PW_{11}O_{39}]^{5-}$.[7e]

The molecular structure of **1a** is consistent with the results of the solution NMR spectra, and suggests that the solid-state structure of **1a** is maintained in aqueous solution.

### Bonding of the Organometallic Groups to the Mono-Lacunary POM

The $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ POM support, the formula of which can also be rewritten as $[(PO_4^{3-})_2(W_{17}O_{53}^{4-})]$, suggests that it possesses enough basicity of the surface oxygen atoms, i.e. an extra four-minus negative charge in comparison with the saturated Dawson POM $[P_2W_{18}O_{62}]^{6-}$ $[(PO_4^{3-})_2(W_{18}O_{54}^{0})]$, and, therefore, the cationic organometallic groups can be covalently bonded to this POM. The present work shows that the higher hydrophilicity of the mono-lacunary POM is kept even after attachment of the cationic organometallic groups.

These features can be compared with the formation of the previously reported cationic organometallic complexes supported on the trivanadium(V)- and triniobium(V)-substituted Dawson POMs $[P_2W_{15}M_3O_{62}]^{9-}$ (M = $V^V$ and $Nb^V$; $[P_2W_{15}M_3O_{62}]^{9-} = [(PO_4^{3-})_2(W_{15}M_3O_{54}^{3-})]$), which have an extra three-minus negative charge in comparison with the parent POM $[P_2W_{18}O_{62}]^{6-}$.[9,10] It should be noted that the all-sodium salts of organometallic complexes supported on Dawson and Keggin POMs, namely $Na_7[(Cp^*Rh)(\alpha\text{-}1,2,3\text{-}P_2W_{15}Nb_3O_{62})]\cdot 7DMSO\cdot 5H_2O$[9c] and $Na_5[(Cp^*Rh)(\beta\text{-}1,2,3\text{-}SiW_9Nb_3O_{40})]\cdot 3DMSO\cdot 2H_2O$,[11d] have been prepared by crystallization from aqueous media. However, these compounds are relatively unstable in water.

The present complexes **1** and **2** can also be compared with our previous $[\alpha_2\text{-}P_2W_{17}O_{61}]$-based 1:2-type $Ru^{II}$ complex $K_{18}[Ru^{II}(DMSO)_2(\alpha_2\text{-}P_2W_{17}O_{61})_2]$, which was obtained from the reaction of *cis*-$[RuCl_2(DMSO)_4]$ with $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]$ in ice-cooled, aqueous HCl solution.[5] Oxidation of the 1:2-type compound with $Br_2$ gave the 1:1-type $Ru^{III}$ compound $K_7[P_2W_{17}Ru^{III}(H_2O)O_{61}]$, without DMSO molecules. There are several factors in the formation of the 1:2- and 1:1-type complexes: (1) the ionic radius of the $Ru^{II}$ atom is much larger than that of the $Ru^{III}$ atom (0.82 Å for the six-coordinate, low-spin geometry[17]), and (2) the binding of several DMSO molecules to the $Ru^{II}$ atom is so strong that removal of all DMSO molecules is not easy.

## Conclusions

The cationic organometallic groups $\{(C_6H_6)Ru(H_2O)\}^{2+}$ and $\{(p\text{-cymene})Ru(H_2O)\}^{2+}$ have been covalently bound to the lacunary site of the mono-lacunary Dawson POM $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$. These complexes are water-soluble and stable in water. The molecular structure of $[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]^{8-}$ (**1a**) was successfully determined. These POM complexes can be compared with the previously reported organometallic complexes supported on the multicenter active sites in the triniobium(V)- and trivanadium(V)-substituted Dawson POMs $[\alpha\text{-}1,2,3\text{-}P_2W_{15}M_3O_{62}]^{9-}$ (M = Nb, V).[9–12] The formation of complexes $K_8[\{(C_6H_6)Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 12H_2O$ (**1**) and $K_8[\{(p\text{-cymene})Ru(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]\cdot 16H_2O$ (**2**) brings up several interesting points: (1) the hydrophilicity of the organometallic precursors is greatly enhanced by binding to the mono-lacunary

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Dawson POM with higher hydrophilicity, (2) the mono-lacunary POM has enough basicity of the surface oxygen atoms for the cationic species, suggesting the possible formation of other water-soluble organometallic complexes, (3) the mono-lacunary POM works as a bidentate O-donor ligand to the ruthenium centers, resulting in the formation of a chiral configuration (overall $C_1$ symmetry), and (4) the catalytic oxidation behaviors of the ruthenium(II) centers can be anticipated in water at ambient temperature. Thus, POMs **1** and **2** will be of interest as water-soluble, organometallic ruthenium(II) complexes, oxidation catalysis by which is anticipated in water.[3n] Studies in this direction are in progress and the data will be reported in due course.

## Experimental Section

**Materials:** The following were obtained as reagent grade and used as received: KCl, 85% aq. $H_3PO_4$, $Na_2WO_4{\cdot}2H_2O$, $KHCO_3$, $CH_3CN$, MeOH, EtOH, $Et_2O$ (all from Wako); $D_2O$ (Isotec); [(*p*-cymene)$Ru^{II}Cl_2]_2$ and $[(C_6H_6)RuCl_2]_2$ (both from Aldrich). The mono-lacunary POM $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]{\cdot}19H_2O$ was prepared according to the literature and characterized accordingly.[3b,18]

**Instrumentation/Analytical Procedures:** Complete elemental analyses were carried out by Mikroanalytisches Labor Pascher (Remagen, Germany). The samples were dried at room temperature at $10^{-3}$–$10^{-4}$ Torr overnight before analysis. The C,H,N analyses were performed with a Perkin–Elmer PE2400 series II CHNS/O Analyzer (Kanagawa University). Infrared spectra were recorded with a Jasco 300 FT-IR spectrometer in KBr disks at room temperature. TG/DTA data were acquired with a Rigaku TG8101D and TAS 300 data-processing system. TG/DTA measurements were run under air with a temperature ramp of 4 °C/min between 30 and 500 °C. $^1H$ (399.65 MHz), $^{13}C\{^1H\}$ (100.40 MHz), and $^{31}P\{^1H\}$ (161.70 MHz) NMR spectra in solution were recorded in 5-mm outer-diameter tubes with a Jeol JNM-EX 400 FT NMR spectrometer using a Jeol EX-400 NMR spectroscopic data processing system. $^{31}P\{^1H\}$ (202.47 MHz) NMR spectra in solution were also recorded in 5-mm outer-diameter tubes with a Jeol ECP 500 FT NMR spectrometer using a Jeol ECP-500 NMR spectroscopic data processing system. $^1H$ and $^{13}C\{^1H\}$ NMR spectra of the complexes were measured in $D_2O$ solution with reference to internal DSS or TSP {sodium [2,2,3,3-$D_4$]-3-(trimethylsilyl)propionate}. Chemical shifts are reported as positive for resonances downfield of DSS or TSP ($\delta$ = 0 ppm). $^{31}P\{^1H\}$ NMR spectra were measured in $D_2O$ solution with reference to an external standard of 25% $H_3PO_4$ in $H_2O$ in a sealed capillary. Chemical shifts are reported as negative for resonances upfield of $H_3PO_4$ ($\delta$ = 0 ppm). $^{183}W$ NMR (16.50 MHz) spectra were recorded in 10-mm outer-diameter tubes with a Jeol JNM-EX 400 FT NMR spectrometer equipped with a Jeol NM-40T10L low-frequency tunable probe and a Jeol EX-400 NMR spectroscopic data-processing system. These spectra, measured in $D_2O$, were referenced to an external standard of a saturated $Na_2WO_4/D_2O$ solution. Chemical shifts are reported as negative for resonances upfield of $Na_2WO_4$ ($\delta$ = 0 ppm).

**Preparation of $K_8[\{(C_6H_6)Ru^{II}(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]{\cdot}12H_2O$ (1):** $[(C_6H_6)RuCl_2]_2$ (0.10 g, 0.20 mmol) was added to a stirred solution of $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]{\cdot}19H_2O$ (2.00 g, 0.41 mmol) in 50 mL of water. The brown suspension was stirred at room temperature for 1 h and then the brown powder was filtered off through a folded filter paper (Whatman No. 2). The clear brown filtrate was concentrated to a volume of about 15 mL in a rotary evaporator at 35 °C, and then placed in a refrigerator at 5 °C overnight. The brown powder formed was collected on a membrane filter (JG, 0.2 μm) and washed with $CH_3CN$ (2 × 5 mL) and then $Et_2O$ (3 × 50 mL). At this stage the yield was 1.0–1.5 g. All the brown powder was suspended in 15 mL of water at 60 °C. The suspension was cooled to room temperature and then placed in a refrigerator at 5 °C for 1 h. The yellow-brown powder that deposited was filtered off through a membrane filter (JG, 0.2 μm) and the clear brown filtrate was concentrated to about 7 mL in a rotary evaporator at 30 °C. After standing at room temperature for 30 min, the solution was passed through a folded filter paper (Whatman No. 2). The filtrate was slowly concentrated at room temperature in the dark. The orange plate-like crystals formed were collected on a membrane filter (JG, 0.2 μm), washed with $CH_3CN$ (2 × 5 mL) and $Et_2O$ (3 × 50 mL), and dried in vacuo for 2 h. The orange powder, obtained in 24.5% (0.49 g scale) yield, was soluble in water and DMSO, but insoluble in $CH_3CN$, MeOH, EtOH, and $Et_2O$. $K_8[\{(C_6H_6)Ru(H_2O)\}\text{-}P_2W_{17}O_{61}]{\cdot}2H_2O$ = $C_6H_{12}O_{64}K_8P_2W_{17}Ru$ (4709.4): calcd. C 1.53, H 0.26, Cl 0.00, K 6.64, O 21.74, P 1.32, Ru 2.15, W 66.37; found (repeat trials for C,H analysis) C 1.49 (1.47), H 0.33 (0.41), Cl < 0.1, K 6.26, O 22.1, P 1.25, Ru 2.23, W 66.4; total 100.06%. A weight loss of 3.79% was observed during the course of drying at room temperature at $10^{-3}$–$10^{-4}$ Torr overnight before analysis, suggesting the presence of 10–11 weakly solvated or adsorbed water molecules. TG/DTA data under atmospheric conditions: weight losses of 3.90% below 124 °C and 3.12% between 124 and 500 °C were observed with endothermic peaks at 30, 101, 147, and 185 °C and an exothermic peak at 481 °C; calcd. 3.71% for $x$ = 12 in $K_8[\{(C_6H_6)Ru(H_2O)\}P_2W_{17}O_{61}]{\cdot}xH_2O$. FT-IR (KBr disk, polyoxometalate region): $\tilde{\nu}$ = 1434 w, 1086 s, 1054 m, 1017 m, 940 vs, 885 s, 810 s, 741 s, 601 w, 528 w $cm^{-1}$. $^{31}P$ NMR ($D_2O$, 22.9 °C): $\delta$ = –8.36 (1 P), –14.02 (1 P) ppm. $^1H$ NMR ($D_2O$, 23.7 °C): $\delta$ = 6.18 (s, 6 H, $C_6H_6$) ppm. $^{13}C$ NMR ($D_2O$, 24.5 °C): $\delta$ = 82.98 ppm. Preparation of an aqueous solution of **1a** for $^{183}W$ NMR measurements was attempted by methods (1)–(3) described below, but a sufficient concentration of the pure form of **1a** was not attained. (1) A saturated $D_2O$ solution of **1** was prepared at 70 °C and the $^{183}W$ NMR spectrum was measured at this temperature over about 12 h. Clean signals of **1a** were not observed because of partial decomposition. Decomposition of **1** after 12 h at this temperature was also confirmed by a $^{31}P$ NMR measurement at room temperature. (2) The sodium salt of **1a** was generated in situ by reaction of the potassium salt of **1a** in aqueous solution with an excess amount of $NaClO_4$. After filtering the $KClO_4$ produced, the $^{31}P$ NMR spectrum of the filtrate was measured, which showed the two signals of **1a** as well as those due to the mono-lacunary POM $[P_2W_{17}O_{61}]^{10-}$. Partial dissociation of the supported organometallic group takes place during the metathesis reaction. On the other hand, complex **2a** was stable during the metathesis and a clean, two-line $^{31}P$ NMR spectrum of the in situ generated sodium salt of **2a** was observed. (3) The sodium salt of $[P_2W_{17}O_{61}]^{10-}$ was generated by a metathesis reaction of the potassium salt, $K_{10}[P_2W_{17}O_{61}]{\cdot}19H_2O$, with an excess amount of $NaClO_4$. Thus, an excess amount of $[(C_6H_6)\text{-}RuCl_2]_2$ was added to a stirred solution of the in situ generated sodium salt in water. The brown suspension was stirred at room temperature. for 1 h After filtration, the $^{31}P$ NMR spectrum of the filtrate was measured, which showed four signals due to **1a** and unreacted $[P_2W_{17}O_{61}]^{10-}$.

**Preparation of $K_8[\{(p\text{-cymene})Ru^{II}(H_2O)\}(\alpha_2\text{-}P_2W_{17}O_{61})]{\cdot}16H_2O$ (2):** [(*p*-cymene)$RuCl_2]_2$ (0.125 g, 0.20 mmol) was added to a stirred solution of $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]{\cdot}19H_2O$ (2.00 g, 0.41 mmol) in 50 mL of water and the brown suspension was stirred at room temperature for 1 h. The greenish powder was then filtered off through a folded

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

filter paper (Whatman No. 2). The clear brown filtrate was concentrated to a volume of about 10 mL in a rotary evaporator at 30 °C and then placed in a refrigerator at 5 °C overnight. The yellow-brown powder formed was collected on a membrane filter (JG, 0.2 μm) and washed with $CH_3CN$ (3 × 30 mL) and then $Et_2O$ (3 × 50 mL). All the yellow-brown powder was suspended in 10 mL of ice-cooled water. The suspension was stirred for 30 min and then placed in a refrigerator at 5 °C for 30 min. The gray powder that deposited was filtered off through a membrane filter (JG, 0.2 μm) and the clear brown filtrate was added dropwise to 500 mL of ice-cooled MeOH. After stirring for 30 min, the yellow-brown powder was collected on a membrane filter (JG, 0.2 μm), washed with MeOH (3 × 50 mL) and then $Et_2O$ (3 × 50 mL), and dried in vacuo for 2 h. The yellow-brown powder, obtained in 32.7% (0.67 g scale) yield, was hygroscopic, soluble in water, but insoluble in MeOH, $CH_3CN$, and $Et_2O$. $K_8[\{(p\text{-cymene})Ru(H_2O)\}P_2W_{17}O_{61}]$ = $C_{10}H_{16}O_{62}K_8P_2W_{17}Ru$ (4729.5): calcd. C 2.54, H 0.34, Cl 0.00, K 6.61, O 21.0, P 1.31, Ru 2.14, W 66.1; found C 2.64, H 0.32, Cl < 0.05, K 6.49, O 20.6, P 1.29, Ru 2.07, W 66.3; total 99.7%. A weight loss of 4.2% was observed during the course of drying at room temperature at $10^{-3}$–$10^{-4}$ Torr overnight before analysis, suggesting the presence of 11–12 weakly solvated or adsorbed water molecules. TG/DTA data under atmospheric conditions: a weight loss of 6.24% below 189 °C with exothermic peaks at 206 and 265 °C; calcd. 6.11% for $x$ = 16 in $K_8[\{(p\text{-cymene})Ru(H_2O)\}P_2W_{17}O_{61}]\cdot xH_2O$. FT-IR (KBr disk, polyoxometalate region): $\tilde{\nu}$ = 1086 s, 1055 m, 1016 m, 941 vs, 885 s, 809 vs, 742 s, 670 w, 661 w, 601 w, 527 m, 420 w $cm^{-1}$. $^{31}P$ NMR ($D_2O$, 21.9 °C): $\delta$ = –8.28 (1 P), –14.08 (1 P) ppm. $^1H$ NMR ($D_2O$, 23.3 °C): $\delta$ = 1.40 (d, $J$ = 6.87 Hz, 3 H), 1.48 (d, $J$ = 6.87 Hz, 3 H) (H7 and H9), 2.51 (H10), 3.07 [m (7), $J$ = 6.87 Hz 3 H] (H8), 5.73 (d, $J$ = 5.96 Hz, 1 H), 5.88 (d, $J$ = 6.42 Hz, 2 H), 6.32 (d, $J$ = 5.96, 1 H) (relative intensity ratio 1:2:1, H2, H3, H5 and H6) ppm. $^{13}C$ NMR ($D_2O$, 25.8 °C): $\delta$ = 21.5, 23.5, 25.2 (C7, C9, C10), 33.6 (C8), 80.2, 81.5, 81.6, 82.9 (C2, C3, C5, C6), 99.9, 103.5 (C1, C4) ppm. $^{183}W$ NMR of **2a** as the sodium salt ($D_2O$, 22.6 °C): $\delta$ = –117.6, –125.1, –138.6, –139.0, –163.8, –177.1, –177.3, –186.5, –207.6, –217.3 (1 + 1), –218.2, –219.5, –220.6, –221.9, –239.6, –241.6 ppm; the relative intensity of all signals, except the signals at $\delta$ = –217.3 ppm, is one. The sodium salt of **2a** was prepared in 70.6% yield (0.56 g scale) by a cation-exchange reaction of the potassium salt **2** in aqueous solution with an excess amount of $NaClO_4$, followed by concentration of the filtrate in a rotary evaporator after filtering off the produced $KClO_4$ and then re-precipitation with ice-cooled ethanol. The characterization data of the sodium salt (IR and $^1H$ and $^{31}P$ NMR spectra) are in good agreement with those of **2**. On the other hand, for $^{183}W$ NMR measurements, a cation-exchange reaction of **2** performed using an excess amount of $LiClO_4$ was unsuccessful because of partial dissociation of the supported organometallic group.

**X-ray Crystallography of 1:** An orange plate crystal (0.18 × 0.06 × 0.02 mm) was surrounded by liquid paraffin (Paratone-N) to prevent its degradation. Data collection was performed with a Bruker SMART APEX CCD diffractometer at 90 K in the range 1.86° < 2$\theta$ < 56.42°. The intensity data were automatically corrected for Lorentz and polarization effects during integration. The structure was solved by direct methods (SHELXS-97)[19a] followed by subsequent difference Fourier calculation and refined by a full-matrix, least-squares procedure (SHELXL-97).[19b] Absorption correction was performed with SADABS (empirical absorption correction).[19c] Crystal data for $C_6H_{30}K_8O_{74}P_2RuW_{17}$: $M$ = 4887.56, triclinic, space group $P\bar{1}$, $a$ = 18.972(3), $b$ = 19.175(4), $c$ = 24.569(6) Å, $\alpha$ = 67.522(3)°, $\beta$ = 76.297(5)°, $\gamma$ = 88.825(3)°, $V$ = 7999(3) Å$^3$, $Z$ = 4, $D_c$ = 4.058 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 25.080 mm$^{-1}$. $R1$ = 0.1093, $wR2$ = 0.1779 (for all data). $R_{int}$ = 0.0595, $R1$ = 0.0773, $wR2$ = 0.1651, GOF = 1.160 [85964 total reflections, 39013 unique reflections where $I > 2\sigma(I)$]. The maximum and minimum residual densities (7.075 and –4.137 e Å$^{-3}$) were located at 0.61 Å from K8 and 0.61 Å from K10, respectively. Three water oxygen atoms (O1S, O2S and O3S) were in special position and their site occupancy factors were fixed at 0.5. The site occupancy factors of five water oxygen atoms (O24S, O25S, O26S, O27S, and O28S) and eight potassium atoms (K11, K12, K13, K14, K15, K16, K17, and K18) were also fixed at 0.5. CCDC-270035 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Molecular structure (Figure S1) of unit B of **1a** shown in Figure 6a in the text, and its bond lengths and angles around the ruthenium(II) atom (Table S1) and average bond lengths and angles for **1a** (Table S2).

# The Ligation Properties of some Reduced Schiff Base Selena/Telluraaza Macrocycles: Versatile Structural Trends

**Snigdha Panda,[a] Sanjio S. Zade,[a] Harakesh B. Singh,*[a] and Ray J. Butcher[b]**

**Keywords:** Chalcogenaaza macrocycles / Selenium tellurium ligands / Nickel / Palladium / Platinum

The chalcogenaaza macrocycles **4**, **5** and **6** show versatility in ligation properties towards various transition metal ions. The structure of the reduced 22-membered selenaaza macrocycle **4** ($C_{32}H_{36}N_4Se_2$) has been determined. The $Ni^{II}$ complex **7** exhibits coordination by the N4Se2 donor sites. The $Pd^{II}$ complexes **8**, **9**, **10**, and **14** have been structurally characterized. The molecular structures of these complexes reveal interesting versatile ligating behaviors of the ligands. The Pd complexes **8**, **9**, and **14** display coordination by hard nitrogen donor atoms only, whereas the complex **10** showed coordination by N2Te2 donor centers. The $Pt^{II}$ complex **11** shows the formation of a cationic metallamacrocycle with C–Pt–Se linkage. The crystal structures suggest that the coordination of metal atoms to donors is determined by the geometrical arrangement around the metal and by the conformation of the macrocycle rather than by the HSAB (hard/soft acid/base) principle.

## Introduction

The mixed donor macrocycles have attracted considerable interest due to their high selective nature for complexation of ions. Amongst the chalcogenaaza macrocycles, oxaaza and thiaaza have been well studied[1] relative to their heavier counterparts. Incorporation of the larger Se and Te would lead to a change in the size of the cage cavity and hence allow for some interesting coordination behavior. There are only a few reports on homodonor selenium- and tellurium-containing macrocycles and their ligating behavior towards the metal ions.[2,3] Only recently, some mixed donor macrocycles incorporating selenium and tellurium have been reported.[4–7]

As part of our research on the design and synthesis of heavier chalcogenaaza macrocycles, we recently reported the synthesis and complexation studies of the selenaaza and telluraaza Schiff base macrocycles **1**–**3**.[5–7] However, these Schiff base macrocycles are prone to transmetallation and hydrolysis on treatment with metal salts, which leads to cleavage of the macrocycle. The selenaaza Schiff base macrocycle **1** forms the hydrolyzed product with the $Pd^{II}$ cation,[7] whereas the telluraaza Schiff base macrocycle **2** forms transmetallated products with $Pt^{II}$ and $Hg^{II}$ cations.[5] The hydrolysis of the selenaaza macrocycle **1** may be due to excessive strain on the ring, which is forced by the metal to adopt a planar geometry. The facile cleavage of the C–Te bond in **2** is due to strong N→Te intramolecular interactions, which activate the *trans* C–Te bond. This strong intramolecular interaction is mainly due to the presence of the $sp^2$ nitrogen atom. To synthesize stable complexes of chalcogenaaza macrocycles, we are now interested in the ligation behavior of the reduced forms of the Schiff base macrocycles **4**–**6**. The reduced forms of the macrocycles are more flexible. Also these macrocycles have only $sp^3$ hybridized atoms and can accommodate a larger range of shapes and sizes than the Schiff base macrocycles that have $sp^2$ hybridized donor atoms. In the reduced forms, the macrocycles have weaker E···N (E = Se, Te) interactions as evidenced from the multinuclear NMR spectra and single-crystal X-ray structures (vide infra). We reported, in a preliminary communication, the ligation properties of **4** and **5** with $Pd^{II}$ and $Pt^{II}$.[8] It was found that the macrocycle **4** forms a 23-membered metallamacrocycle on ligation with $Pt^{II}$, in which a C–Se bond is oxidatively added to the $Pt^{II}$ center to form a hexacoordinate $Pt^{IV}$ complex (**11**). Complexes **8** and **10** show contrasting ligation behavior of the macrocycles **4** and **5** with $Pd^{II}$. In **8**, the coordination sites are hard nitrogen donors only, whereas in **10** the coordination sites are occupied by N2Te2. In this paper, we now report a systematic study of the ligation properties of the reduced selena/telluraaza macrocycles with transition metal ions. The ligation properties of the reduced selenaaza macrocycle **4** with a series of transition metal cations ($Ni^{II}$, $Pd^{II}$, $Pt^{II}$ $Cu^{II}$, and $Hg^{II}$), the ligation properties of the telluraaza macrocycle **5** with $Pd^{II}$, and the ligation properties of the 28-membered selenaaza macrocycle **6** with $Pd^{II}$ have been investigated.

## Result and Discussion

The ligands **4**–**6** were prepared by following known procedures.[5–7] The molecular structure of the ligand **4** (Figure 1, Table 1) is centrosymmetric, and only half of the molecule represents the asymmetric unit. The structure confirms the complete reduction of the Schiff base macrocycle. Of two possible nitrogen atoms available for interaction, only one interacts weakly with the Se atom. The Se···N(1A) distance (3.01 Å) is shorter than the sum of the van der Waals radii of Se (1.99 Å) and N (1.53 Å). The transannular Se···Se distance (4.75 Å) is longer than the Se···Se distance (3.808 Å) in the parent Schiff base **1**.[7] The geometry around Se is V-shaped. The C(1B)–Se–C(1A) bond angle is 98.04°, which is smaller than that in the parent Schiff base (100.2°). The macrocycle framework is puckered so as to suit the bonding pattern of the individual atoms.

Table 1. Significant bond lengths [Å] and angles [°] for **4**.

| N(1B)–C(8B)–C(8A)# | 1110.6(2) | | |

Equimolar amounts of **4** and $Ni(OCOCH_3)_2$ in MeOH were heated to reflux for 30 min, and subsequent addition of $NH_4PF_6$ yielded a purple complex **7**, which was crystallized by slow diffusion of diethyl ether into the acetonitrile solution of the complex at room temperature (Scheme 1). The complex was soluble in MeCN, $MeNO_2$, acetone, DMSO, and DMF, and stable in air. The elemental analysis data of the complex suggest the formation of the 1:1 product. The molecular ion peak was not observed in the FAB mass spectrum of the complex, however, there are peaks centered at $m/z$ = 838 for M – $PF_6$ and at $m/z$ = 693 for M – $2PF_6$. The IR spectrum shows peaks at 840 and 557 $cm^{-1}$ corresponding to $\nu$(P–F) and $\nu$(F–P–F), respectively. The solution phase electronic spectrum (>200 nm) of the complex consists of three bands centered at 304 ($\varepsilon$ = 2400 $dm^3 mol^{-1} cm^{-1}$), 699 (15 $dm^3 mol^{-1} cm^{-1}$), and 895 nm (29 $dm^3 mol^{-1} cm^{-1}$). The solid-state absorption spectrum of the complex exhibits the same type of bands centered at 316, 564, and 894 nm. This indicates that the complex is stable in solution and in the solid state and has the same structure in both states. The $\mu_{eff}$ (B.M.) is 3.39, which is larger than the value usually observed. Larger values are

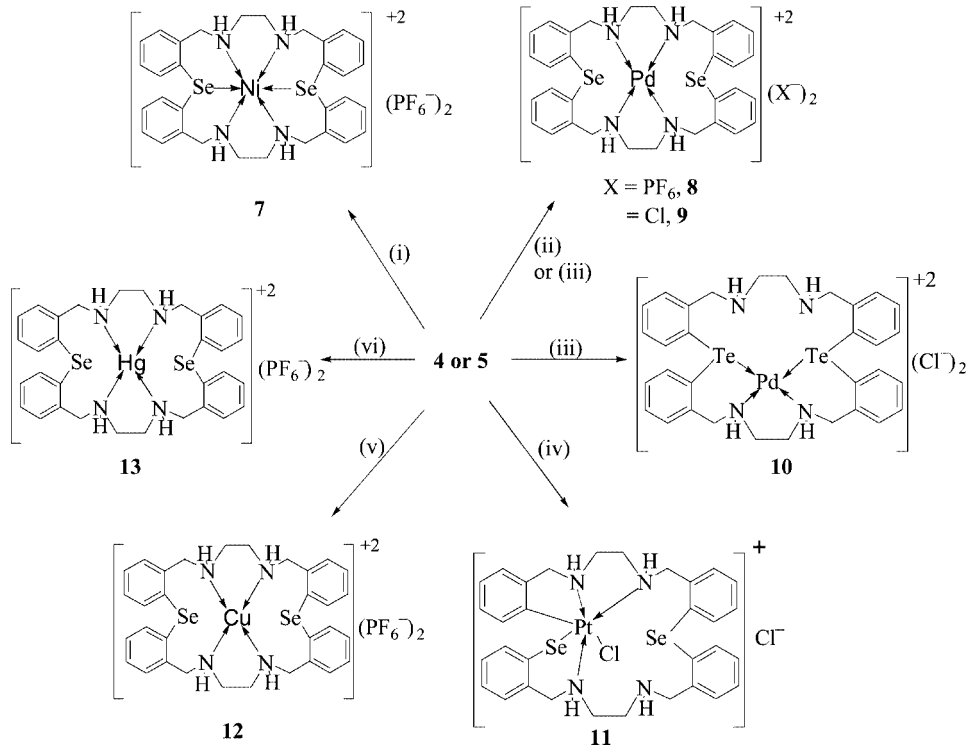

Scheme 1. Reagents: MeOH (reflux), (i) $Ni(OCOCH_3)_2$, $NH_4PF_6$; (ii) $Pd(C_6H_5CN)_2Cl_2$, $NH_4PF_6$; (iii) $PdCl_2$, (iv) $PtCl_2$; (v) $Cu(CH_3CN)_4ClO_4$, $NH_4PF_6$; (vi) $Hg(OCOCH_3)_2$, $NH_4PF_6$.

generally observed as a result of orbital contributions derived from the mixing of low-lying excited states into the ground state or because the ground state is orbitally degenerate. As expected for octahedral $Ni^{II}$ complexes, complex **7** is EPR silent.[9,10] The cyclic voltammogram of the $Ni^{II}$ complex **7** shows a quasi-reversible oxidation peak at –0.211 V and a reduction peak at –0.092 V. There is a substantial shift to a more negative potential on changing from imine to amine nitrogen donors,[7] as expected, given that this change results in a reduction of π-acceptor ability.[11]

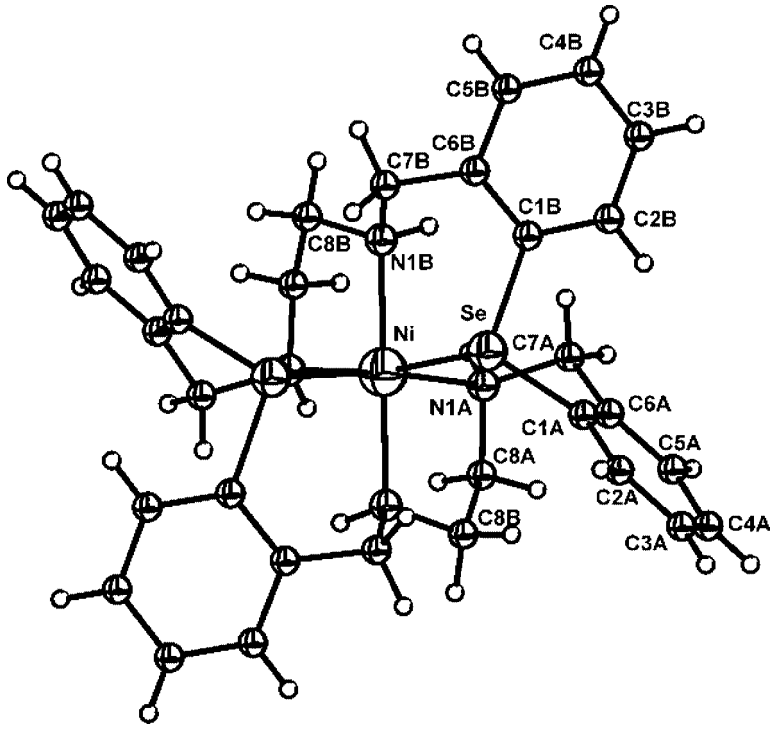

Figure 2. ORTEP diagram for **7**.

There are very few reports on the molecular structures of Ni complexes of selenium-containing macrocycles. This is the third example of the molecular structure of a nickel complex with a selenium-containing macrocycle.[7] The molecular structure (Figure 2, Table 2) is centrosymmetric and is similar to that of the $Ni^{II}$ complex of the parent ligand. The structure shows that the $Ni^{II}$ ion occupies the macrocyclic cavity and is bonded to all four nitrogen and two selenium donors of the macrocycle thus adopting an octahedral geometry. The bond lengths are: Ni–N(1B) 2.104(2) Å, Ni–N(2B) 2.104(2), Ni–N(1A) 2.115(2), Ni–N(2A) 2.115(2), Ni–Se 2.6189(4) Å. The Ni–Se bond length is comparable to Ni–Se distances in *trans*-[$NiCl_2$(Me-$SeCH_2CH_2SeMe_2$)][12] and is also comparable to that observed for the parent Schiff base Ni complex.[7] The C–Se–C bond angle is 101.73(10)°, which is larger than that of the parent Schiff base Ni complex [97.1(7)°]. The two Se atoms are *cis* to each other in the distorted octahedral geometry as they are in the parent Schiff base Ni complex.

The corresponding palladium complexes **8** and **9** were obtained by the reaction of $Pd(C_6H_5CN)_2Cl_2$ and $PdCl_2$, respectively, with 1 mol of ligand **4** in refluxing methanol, followed by the addition of excess $NH_4PF_6$ in the case of **8** (Scheme 1). The complexes are soluble only in DMSO. The elemental analysis data suggest the formation of a 1:1 complex. The crystals were grown from DMSO/ether. The peaks at 843 and 558 $cm^{-1}$ in the IR spectrum confirms the presence of a $PF_6^-$ ion. The molecular ion peak of complex **8** is not observed in its FAB mass spectrum; peaks at *m*/*z* = 886 and 735 correspond to M – $PF_6$ and M – 2 $PF_6$, respectively. The ESI-MS spectrum of **9** exhibits a peak at *m*/*z* = 840, which corresponds to M + $2H_2O$, and a peak at *m*/*z* = 741, which corresponds to M – 2Cl. The $^1$H- and $^{13}$C NMR spectra for both **8** and **9** are too complicated for complete analysis. The $^{77}$Se NMR spectra of **8** and **9** display peaks at 869 and 787 ppm, respectively. As the $^{77}$Se NMR spectra of both complexes exhibit single signals, which were shifted downfield relative to that of the free ligand ($\delta$ = 329 ppm), it is possible that metal coordination to selenium occurs in solution. Variable-temperature $^1$H NMR spectroscopy was carried out on **8** at higher temperatures (20 °C–120 °C) in DMSO solution (Figure 3). As the temperature was increased, line broadening resulted in the coalescence of the peaks. Upon cooling to room temperature, the original spectrum was restored. The coalescence phenomena of the spectra may occur as a result of the fluxional behavior of the complex in solution. The only fluxional process that achieves this result is one in which the metal effectively hops between the six donor sites of the macrocycle, as illustrated in Scheme 2. This hopping of the $Pd^{II}$ center between the N4Se2 coordination sites is similar to that reported by McAuley et al.,[13] where, in a square-planar palladium complex, the $Pd^{II}$ center hops between any four of the six donor sites. However, an N3Se coordination is ruled out, since the $^{77}$Se NMR spectrum shows a single peak. The $^1$H NMR spectra at ambient and high temperatures do not exhibit any resonances that could be assigned to the free ligand in solution, which suggests that the interconversion does not proceed though a dissociative mechanism.

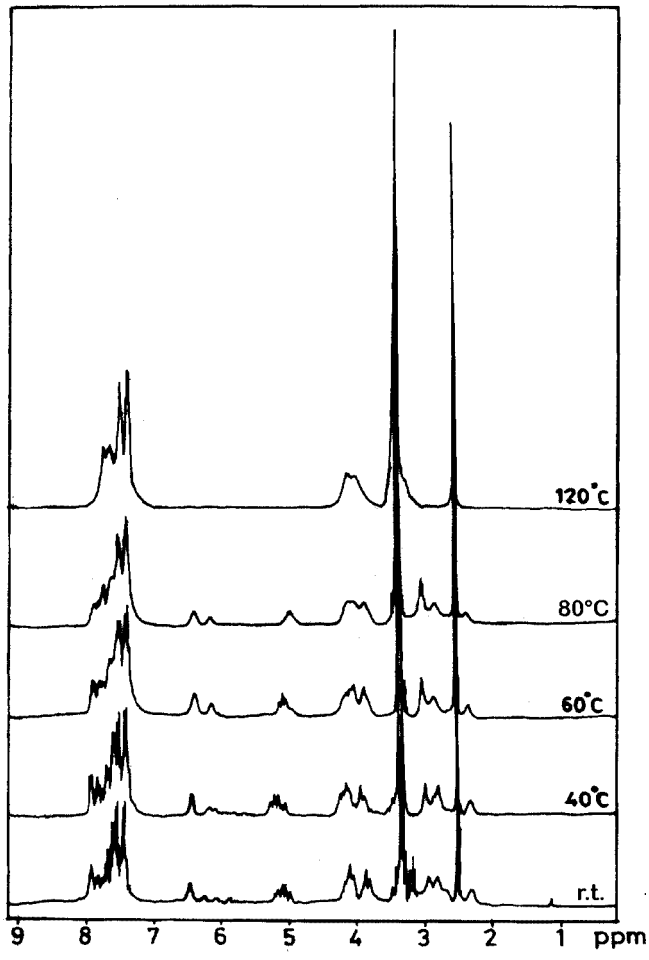

Figure 3. Variable-temperature $^1$H NMR ([$D_6$]DMSO, 300 MHz) spectra of **8**.

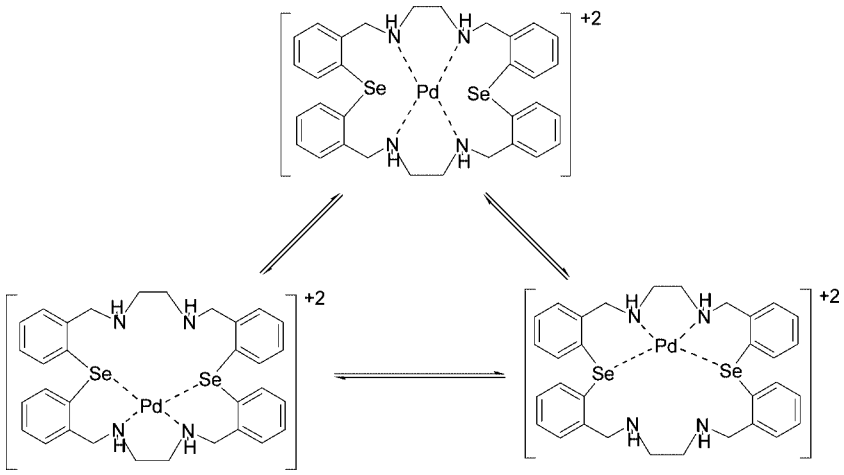
Since complexes **8** and **9** are isostructural (Figure 4, Figure 5, Table 3, Table 4), the crystal structure of only **8** will be discussed, and major differences between the structures will be highlighted. Both structures are centrosymmetric like the parent macrocycle **4**, and only half of the molecule represents the asymmetric unit. The cation adopts a square-planar geometry and is coordinated to the four nitrogen atoms. The N–Pd–N bond angles are ca. 180° and ca. 90°. The Pd–N bond lengths are in good agreement with the sum of the single-bond covalent radii of Pd (1.31 Å) and N (0.75 Å).[14] However, these bond lengths are slightly longer than that observed for the hydrolyzed parent Schiff base [2.019(6) Å],[7] which has $sp^2$ hybridized N donor atoms. In the solid-state molecular structures, the palladium atom

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Fluxional process for **8** in solution.

does not coordinate to the Se atom. This is in contrast to the solid-state structures of $Pd^{II}$ complexes of the mixed donor Se/Te macrocycles that contain O or P, in which $Pd^{II}$ coordinates to the soft Se/Te donor centers.[4] This anomalous behavior may be due to the formation of stable five-membered chelate rings rather than to the formation of six-membered chelate rings that would result in coordination to the Se donors. In this case, the absence of any interaction between the Se and $Pd^{II}$ atoms probably results from the conformational requirement of the ligand around the central $Pd^{II}$ atom for coordination with donor atoms, as well as the chelate ring effect. Complex **9** crystallizes with two waters of crystallization; however, there is no hydrogen bonding between the water molecules and the chloride counterions. The transannular Se···Se bond length of **8** is 9.310 Å and that of **9** is 9.670 Å.

Equimolar amounts of **5** and $PdCl_2$ in MeOH were heated to reflux for 15 min to yield a clear solution of the complex **10**; brown crystals were obtained by slow diffusion of diethyl ether into the reaction mixture at room temperature (Scheme 1). Complex **10** is not very soluble in $CH_3CN$ and $CH_3NO_2$ but highly soluble in DMSO. The elemental analysis data confirm the formation of a 1:1 complex. The molecular ion peak of complex **10** is not observed in its ESI

mass spectrum; the highest peak at $m/z$ = 838 corresponds to the M – 2Cl fragment. The $^{125}$Te NMR spectrum of complex **10** in [$D_6$]DMSO shows a peak at $\delta$ = 710 ppm, which disappeared after half an hour due to decomposition of the complex. A complex pattern of signals that were difficult to assign was observed in the $^1$H and $^{13}$C NMR spectra.

An ORTEP diagram of compound **10** is shown in Figure 6, and selected bond lengths and angles are given in Table 5. The molecule crystallizes with seven waters of crystallization. The $Pd^{II}$ cation adopts a square-planar geometry and is coordinated to the two nitrogen and two tellurium atoms. The tellurium atoms are slightly disordered. The Pd–N(1A) [2.114(6) Å] and Pd–N(2A) [2.118(8) Å] are slightly longer than the sum of the single bond covalent radii of Pd (1.31 Å) and N (0.75 Å).[14] However, these bond lengths are well within the sum of van der Waals radii. The Te–Pd bond lengths [Te(1A)–Pd 2.5770(16) Å, Te(2A)–Pd 2.5675(12) Å, Pd–Te(1B) 2.480(7) Å, and Te(2B)–Pd 2.431(4) Å] are significantly shorter than the sum of covalent radii (2.68 Å) and are comparable to those in the parent Schiff base macrocycle Pd complex.[5] The N–Pd–N, Te–Pd–Te, and N–Pd–Te bond angles are close to 90° and 180°. The coordination to Te in **10** may be due to the greater σ-donor property of the Te than Se, which leads to a stronger soft–soft interaction and stabilization of the six-membered chelate ring. The packing diagram (Figure 7) shows that the water molecules are sandwiched between the complexes and that there is extensive hydrogen bonding between the N–H hydrogen atom, chloride counterion, and the water molecules.

Equimolar amounts of **4** and $PtCl_2$ in MeOH were heated to reflux for 15 min to yield a clear solution of the complex **11**; brick-red crystals were obtained by slow diffusion of diethyl ether into the reaction mixture at room temperature (Scheme 1). The complex formed was not very soluble in most of the organic solvents and only partially soluble in MeOH. The elemental analysis data suggest the formation of a 1:1 complex. The molecular ion peak of complex **11** is absent in its ESI mass spectrum; the highest peak observed at $m/z$ = 863 corresponds to M – (Cl + 2 $H_2O$). The $^1$H and $^{13}$C NMR spectra of complex **11** are too complicated for complete analysis. As complex **11** is only partially soluble in MeOH, no satisfactory $^{77}$Se NMR spectrum could be recorded even after overnight data acquisition.

The X-ray crystal structure of **11** (Figure 8, Table 6) clearly suggests the formation of a novel 23-membered metallamacrocyclic complex. The geometry around $Pt^{IV}$ is octahedral.[8] The Pt–N bond *trans* to Pt–Se is longer (ca. 0.15 Å) than the other two Pt–N bonds because of the strong *trans* influence of –SePh.[15] The Pt–C bond length [2.010(4) Å] is shorter than those of the reported $Pt^{IV}$ selenolate compounds,[15–17] whereas the Pt–Cl bond length [2.4291(12) Å] is longer than those in related compounds.[16] This lengthening of the Pt–Cl bond and the shortening of the C–Pt bond may be ascribed to the stronger *trans* influence of phenyl ring than of Cl. The behavior of the macrocycle to form the cationic $Pt^{IV}$ complex by oxidative addition of the C–Se bond to the $Pt^{II}$ center is in contrast to those of the reported stable $Pt^{II}$ and $Pt^{IV}$ complexes with homodonor and mixed donor cyclic selenoether ligands.[4,18] The facile oxidative addition in this case may be facilitated by the more polar nature of C–Se bond that results from the N→Se intramolecular interaction present in the parent macrocycle (vide supra). Though the oxidative addition of halogens and alkyl halides to the $Pt^{II}$ center are

common,[19] this is the second example of oxidative addition of C–Se bond to $Pt^{II}$.

Complex **12** was obtained by the reaction of $Cu(CH_3CN)_4ClO_4$ with 1 mol of ligand **4** in refluxing methanol, followed by the addition of excess $NH_4PF_6$. The complex is soluble in DMSO, MeCN, and $MeNO_2$. The crystals obtained from DMSO lose luster after removal of the solvent.

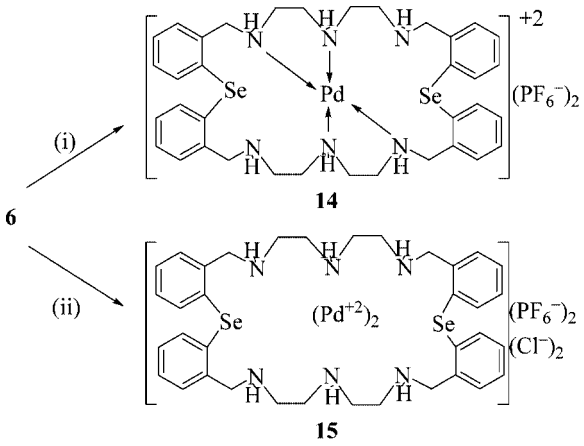
The elemental analysis data confirm the formation of a 1:1 complex. Complex **12** was found to be a 1:2 electrolyte in acetonitrile ($\Lambda_{M,}$ 393 $\Omega^{-1}\,cm^2\,mol^{-1}$). The infrared spectrum of the complex exhibits two NH stretching vibrations at 3301 and 3235 $cm^{-1}$ as sharp singlets and a bending vibration at 1629 $cm^{-1}$ as a broad singlet, while the IR spectrum of the ligand shows the stretching vibrations at 2794–3323 $cm^{-1}$ (sharp multiplets) and the bending vibration at 1687 $cm^{-1}$(sharp singlet). This implies that N–H of the ligand is involved in coordination to the metal center. The peaks at 843 and 557 $cm^{-1}$ confirm the presence of $PF_6$ in the complex. The solution-phase electronic spectrum (>200 nm) of the complex consists of two intense bands centered at 298 ($\varepsilon$ = 2485 $dm^3\,mol^{-1}\,cm^{-1}$) and 583 nm (148 $dm^3\,mol^{-1}\,cm^{-1}$), which can be assigned to the intraligand π–π* transitions. The reflectance spectrum of the solid sample exhibits the same type of bands centered at 315 and 584 nm. This indicates that the complex is stable in solution. The observed magnetic susceptibility value for the complex is 1.79 BM. This value is close to that for the square-planar copper complexes (1.84 BM).[20] The electron spin resonance spectrum further confirms the square-planar geometry of the complex. The spectrum of the powdered form is not well resolved; however, at the temperature for liquid nitrogen, an anisotropic ESR spectrum is obtained. The spectrum exhibits a line shape that is typical for a mononuclear $Cu^{II}$ complex with a $d_{x^2-y^2}$ ground state. The $g_\perp$ value for the complex is 2.052. The value for $A_\parallel$ was calculated from the difference between the peak positions i.e. 180G. The $g_z$ value is 2.24. This $g_z$ value is greater than that of $g_\perp$. The anisotropic value for $g_x$ and $g_y$ has not been resolved and no $A_\perp$ hyperfine constant was observed. The quotient $(g_z \times 10^4)/A_\parallel$ is an indication of the stereochemistry of the chelates in solution.[21] It has been suggested that this quotient may be an empirical index of tetrahedral distortion from tetragonal geometry, i.e. values that are lower than 140 are observed for square-planar structures and those that are higher than 150 for tetrahedral complexes. A value of 124 for **12** indicates a square-planar geometry. The $Cu^{II}$ complexes of tetraaza macrocyclic ligands generally exhibit irreversible redox processes. The $Cu^{II}$ complex **12** is reduced directly to $Cu^0$ by a single two-electron process at –0.524 V. Such behavior may stem from the higher flexibility of the ligand, which does not allow the $Cu^I$ complex to be kinetically stable and enables the reduction of the $Cu^{II}$ center directly to $Cu^0$.[22]

The reaction of $HgCl_2$ with ligand **4** gave an insoluble white product, which was not soluble in any of the common solvents. However, when the reaction was performed with $Hg(OCOCH_3)_2$, a white product **13** was obtained, which is soluble in MeCN and $MeNO_2$, and decomposes in DMSO. The elemental analysis data suggest the formation of a 1:1 complex. The IR spectrum shows a broad multiplet in the region of NH stretching (2911–3671 $cm^{-1}$). The peaks at 841 and 558 $cm^{-1}$ correspond to $\nu$(P–F) and $\nu$(F–P–F), respectively. The molecular ion peak of complex **13** is not

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

observed in the ESI mass spectrum, as is the case for the other complexes; the peak observed at $m/z$ = 981 is assigned to M – $PF_6$, and the peak at $m/z$ = 834 corresponds to M – 2 $PF_6$. This indicates the formation of the complex with two $PF_6$ counterions, and the peak at $m/z$ = 635 shows that the macrocycle remains intact. The broadening of the $^1$H NMR signal in the aliphatic region indicates the presence of molecular motion, which is somewhat slow on the NMR time scale. The existence of isomeric species in solution is also a possibility. The $^{13}$C NMR shows the expected number of peaks. The $^{77}$Se NMR spectrum exhibits a single signal at $\delta$ = 315 ppm, which indicates that there is no interaction between Se and $Hg^{II}$. The $Hg^{II}$ complex **13** shows two irreversible reduction peaks at 0.505 and 0.032 V, which implies the sequential reduction of $Hg^{II}$ to $Hg^{I}$ and then to $Hg^0$.

Reaction of ligand **6** with 1 and 2 equiv. Pd(COD)$Cl_2$, followed by the addition of $NH_4PF_6$ afforded the complexes **14** and **15** in a 1:1 and 1:2 (ligand/metal) ratio, respectively (Scheme 3).



Scheme 3. Reagents: MeOH (reflux), (i) **6**:Pd(COD)$Cl_2$ (1:1), $NH_4PF_6$; (ii) **6**:Pd(COD)$Cl_2$ (1:2), $NH_4PF_6$.

Complex **14** is light yellow, whereas complex **15** is yellow. The complexes are not very soluble in all solvents even on prolonged heating. Due to the partial solubility of the complexes, complete characterization of the complexes was difficult. The elemental analysis data for **14** and **15** suggest the formation of 1:1 and 1:2 (ligand/metal) complexes respectively. The IR spectra exhibit peaks in the range 840–849 and at 556 $cm^{-1}$, which correspond to $\nu$(P–F) and $\nu$(F–P–F), respectively. In the ESI mass spectrum of complex **14**, the molecular ion peak is observed at $m/z$ = 1116.88, and the peaks for [M – $PF_6$], [M – 2 $PF_6$], and [M – (Pd + 2 $PF_6$)] are observed at $m/z$ = 971.9, 826.9, and 719, respectively. However, for complex **15**, no molecular ion peak is observed; peaks at $m/z$ = 1148.96, 1112.95, 1075.95, and 928.98 are observed for [M – $PF_6$], [M – ($PF_6$ + Cl)], [M – ($PF_6$ + 2 Cl)], and [M – 2 ($PF_6$ + Cl)]. Due to the poor solubility of complexes, it was challenging to record the $^{77}$Se NMR spectrum of the complexes. The $^{77}$Se NMR spectrum of complex **14** was recorded in 50% $CD_3CN/CD_3OD$ solution and shows one peak at $\delta$ = 303 ppm after long data accumulation. However, the $^{77}$Se NMR spectrum of compound **15** could not be recorded. The $Pd^{II}$ complexes did not show well-defined redox processes that could be interpreted.

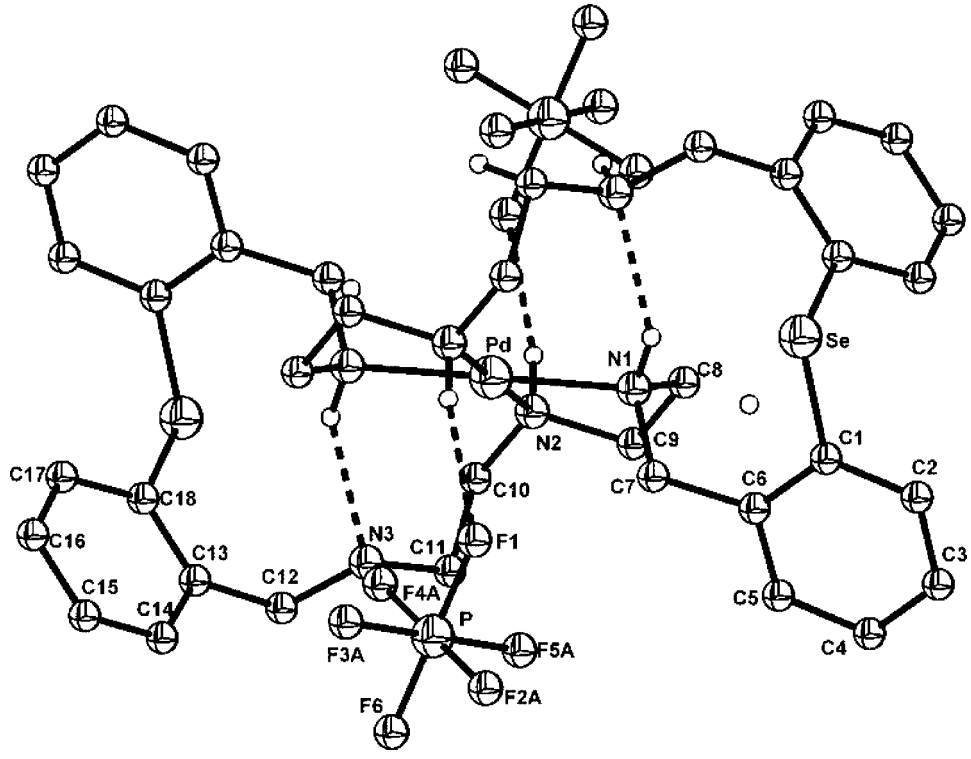


Figure 9. ORTEP diagram of **14**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The ORTEP view of compound **14** is shown in the Figure 9, and selected bond lengths and angles are given in the Table 7. The molecule is centrosymmetric: only half of the molecule represents the asymmetric unit, and there is one molecule per unit cell. The cation adopts a square-planar geometry and coordinates to four nitrogen atoms out of the possible N6Se2 coordination sites. The N(1)–Pd–N(1)# and N(2)–Pd–N(2)# bond angles are 180°. The N(1)–Pd–N(2) bond angle is 84.05(13)°, and these atoms are part of a five-membered ring containing two nitrogen donor atoms. The N(1)–Pd–N(2)#1 bond angle is 95.95(13)°, and these atoms are part of a 13-membered ring containing an Se atom. The Pd–N(1) and Pd–N(2) bond lengths are 2.067(3) and 2.081(3) Å, respectively, and are marginally longer than the sum of the covalent radii of Pd (1.31 Å) and N (0.75 Å); however, they are much shorter than the sum of the van der Waals radii. The phenyl rings and the two selenium atoms bend away from the square plane that contains the Pd cation. The transannular distance between the two Se atoms is 10.422 Å.

The synthesis of the $Pt^{II}$ analogues of **14** and **15** has been attempted. Though elemental analysis, and IR and ESI mass spectrometry show the formation of the desired complexes, no satisfactory NMR spectra could be obtained because of the highly insoluble nature of the complexes. Attempts to get suitable crystals were also unsuccessful.

## Conclusions

In conclusion, macrocycle **4** shows versatile coordination behavior towards the metal cations $Ni^{II}$, $Pd^{II}$, $Pt^{II}$, $Cu^{II}$, and $Hg^{II}$. In general, molecular structures of the complexes show that the coordination behavior of the metal ions towards the donors is determined by the geometrical arrangement of the ligands around the metal atom, by the stability of the chelate ring formed by metal coordination, and to a lesser extent, by the HSAB principle.

## Experimental Section

**General:** All reactions were carried out under nitrogen or argon using standard vacuum line techniques. Solvents were purified and dried by standard procedures[23] and were freshly distilled prior to use. Melting points were recorded in capillary tubes and are uncorrected. The $^1H$ (299.4), $^{13}C$ (75.42), and $^{77}Se$ (57.22) NMR spectra were recorded in [$D_6$]DMSO or $CD_3CN$ on a Varian VXR 300S spectrometer. Chemical shifts cited were referenced to TMS ($^1H$, $^{13}C$) as internal and $Me_2Se$ ($^{77}Se$) as external standards. The elemental analysis was performed on a Carlo–Erba model 1106 and Eager 300 EA1112 elemental analyzers. The IR spectra were recorded as KBr pellets with a Thermo Nicolet Avatar 320 FTIR spectrometer. The UV/Vis spectra in solution were recorded with 3-cm path length quartz cells on a UV-260 Shimadzu spectrophotometer, and reflectance spectra were recorded with a UV-160A spectrophotometer. The electronic spectra of all the complexes were recorded at room temperature in acetonitrile. The spectra were recorded in the range 200–1100 nm. The FAB mass spectra were recorded on a JEOL SX 102/DA-6000 mass spectrometer/data system using Argon/Xenon (6 KV, 10 mA) as the FAB gas. The ESI mass spectra were recorded at room temperature with a Q-Tof micro (YA-105) micromass spectrometer. The magnetic susceptibility of the complexes **7** and **12** was studied at room temperature. Complex $Hg[Co(SCN)_4]$ was used as the standard. The EPR spectra were recorded at room temperature and at the temperature for liquid nitrogen. TCNQ was taken as the standard. $Cu(CH_3CN)_4ClO_4$, $Pd(C_6H_5CN)_2Cl_2$, and $Pd(COD)Cl_2$ were prepared by literature procedures.[24] All the complexes were vacuum dried after preparation. The solution electrical conductivity was measured using a Elico CM-180 Conductivity meter with KCl solution in water as standard. Cyclic voltammetric (CV) experiments were performed on a CH instruments electrochemical analyzer with a three-electrode device. The experiments were performed with a glassy carbon working electrode, a platinum counter electrode, and a standard Ag/AgCl reference electrode. Tetrabutylammonium perchlorate (Aldrich) was used as the supporting electrolyte. All solutions were purged with nitrogen before the CV data were recorded. Measurements were recorded with 0.1 M $NBu_4ClO_4$ in acetonitrile with a sample concentration 0.05 mM. Ferrocene was taken as the standard.

**Syntheses**

Ligands **4**, **5**, and **6** were prepared following known procedures.[6,7]

**[$NiC_{32}H_{36}N_4Se_2P_2F_{12}$] (7):** $Ni(OCOCH_3)_2$ (0.026 g, 0.15 mmol) was added to ligand **4** (0.1 g, 0.15 mmol) in methanol (20 $cm^3$). The reaction mixture was then heated to reflux for 30 min. The resulting reaction mixture was filtered, and to the filtrate excess $NH_4PF_6$ was added to give the complex as a purple powder. Crystallization from an acetonitrile solution by diffusion of diethyl ether afforded purple crystals of the complex. Yield: 0.078 g, 52%. M.p. 269 °C (d.). Magnetic susceptibility: 3.39$\mu_B$. IR (KBr): $\tilde{\nu}_{max}$ = 3286 (m), 2923 (s), 1641 (b), 1461 (m), 1308 (w), 1083 (m), 951 (w), 840 (s), 760 (s), 557 (s) $cm^{-1}$. $\lambda_{max}$ (MeCN; $\varepsilon$/$dm^3 mol^{-1} cm^{-1}$): 304 (2400), 699 (15) and 895 (29) nm. FAB MS: *m*/*z* = 839 [M – $PF_6$], 693 [M – 2 $PF_6$]. $C_{32}H_{36}N_4Se_2NiP_2F_{12}$ (983.2): calcd. C 39.09, H 3.69, N 5.69; found C 38.41, H 3.60, N 7.05.

**[$PdC_{32}H_{36}N_4Se_2P_2F_{12}$] (8):**[8] Complex **8** was prepared in a manner similar to that of **7**, but with the metal precursor $Pd(C_6H_5CN)_2Cl_2$. Cream-coloured crystals were obtained from a DMSO/ether solution. Yield: 0.087 g, 56%. M.p. 247–249 °C (d.). IR (KBr): $\tilde{\nu}_{max}$ = 3426 (b), 3220 (m), 2924 (w), 1631 (w), 1449 (m), 1020 (w), 843 (s), 764 (s), 558 (s) $cm^{-1}$. $^{77}Se$ NMR ([$D_6$]DMSO): $\delta$ = 869 ppm. FAB MS: *m*/*z* = 886 [M – $PF_6$], 738 [M – 2 $PF_6$]. $C_{32}H_{36}N_4Se_2PdP_2F_{12}$: calcd. C 37.28, H 3.52, N 5.43; found C 36.88, H 3.68, N, 5.02.

**[$C_{32}H_{40}Cl_2N_4O_2PdSe_2$] (9):** $PdCl_2$ (0.027 g, 0.15 mmol) was added to **4** (0.1 g, 0.15 mmol) in MeOH (20 $cm^3$), and heated to reflux for 30 min. The reaction mixture was filtered. The solvent volume was reduced to 2 $cm^3$ in vacuo, followed by diffusion of diethyl ether to afford yellowish crystals of the complex. Yield: 0.075 g, 61%. M.p. 225 °C (d.). IR (KBr): $\tilde{\nu}_{max}$ = 3426 (s), 3226 (s), 3052 (m), 2849 (s), 1632 (s), 1464 (s), 1440 (s), 1340 (w), 1199 (w), 1025 (s), 755 (s), 633 (w), 452 (w) $cm^{-1}$. $^{77}Se$ ([$D_6$]DMSO): $\delta$ = 787 ppm. ESI-MS: *m*/*z* = 840 [M + 2 $H_2O$], 741 [M – 2 Cl]. $C_{32}H_{40}Cl_2N_4O_2PdSe_2$ (847.9): calcd. C 45.34, H 4.76, N 6.61; found C 45.58, H 5.05, N 6.27.

**[$PdC_{32}H_{36}N_4Te_2Cl_2$] (10):**[8] This complex was prepared in a manner similar to that described for **9** and was isolated as brownish red crystals from a methanol/ether solution. Yield: 0.2 g, 78%. M.p. 196 °C (d.). IR (KBr): $\tilde{\nu}_{max}$ = 3417 (s, br), 3320 (s), 3049 (m), 2881 (s), 2850 (s), 1621 (m), 1439 (s), 1205 (m), 1120 (m), 837 (s), 752 (s) $cm^{-1}$. ESI-MS: *m*/*z* = 838 [M – 2 Cl]. $C_{32}H_{36}N_4Te_2PdCl_2H_2O$: calcd. C 41.45, H 4.13, N 6.04; found C 40.88, H 4.22, N 5.77.

**[$PtC_{32}H_{40}N_4O_2Se_2Cl_2$] (11):**[8] This complex was prepared in a manner similar to that described for **9** and was isolated as red crystals by the slow diffusion of diethyl ether. Yield: 0.074 g, 52%. M.p. 252 °C (d.). IR (KBr) $\tilde{\nu}_{max}$ = 3429 (br), 2923 (s), 2848 (s), 1635 (s), 1439 (s), 1327 (s), 1105 (w), 1026 (s), 751 (s) $cm^{-1}$. ESI-MS: 863.2 [M – Cl], 827.21 [M – 2 Cl]. $C_{32}H_{40}N_4O_2Se_2PtCl_2$: calcd. C 41.05, H 4.30, N 5.98; found C 41.93, H 3.46, N 6.41.

**[$CuC_{32}H_{36}N_4Se_2P_2F_{12}$] (12):** This complex was prepared by following the method used for preparing complex **7** but with $Cu(CH_3CN)_4ClO_4$. Yield: 0.050 g, 33%. M.p. 212–214 °C (d.). Magnetic susceptibility: 1.79$\mu_B$. IR (KBr): $\tilde{\nu}_{max}$ = 3434 (m), 3301 (s), 2941 (w), 1629 (w), 1465 (s), 1347 (w), 1302 (w), 1199 (w), 1106 (m), 1042 (m), 927 (s), 843 (s), 622 (s), 760 (s), 577 (s) $cm^{-1}$. $\lambda_{max}$ (MeCN; $\varepsilon$/$dm^3\,mol^{-1}\,cm^{-1}$): 298 (2485), 583 (148). Molar conductivity (acetonitrile, 298 K): $\Lambda_M$ = 393 $\Omega^{-1}\,cm^2\,mol^{-1}$. FAB MS: *m*/*z* = 697 [M – 2 $PF_6$], 637 [M – (2 $PF_6$ + Cu)]. $C_{32}H_{36}N_4Se_2CuP_2F_{12}$ (988.1): calcd. C 38.90, H 3.67, N 5.67; found C 39.38, H 3.87, N 6.27.

**[$HgC_{32}H_{36}N_4Se_2P_2F_{12}$] (13):** This complex was prepared in a manner similar to that described for **7** but with the metal precursor $Hg(OCOCH_3)_2$. Yield: 0.066 g, 38%. M.p. 180 °C (d.). IR (KBr): $\tilde{\nu}_{max}$ = 3671 (w), 3271 (w), 2928 (w), 1587 (w), 1461 (s), 1439 (s), 1204 (w), 1018 (w), 841 (s), 760 (s), 558 (s) $cm^{-1}$. $^{13}C$ NMR ($CD_3CN$): $\delta$ = 47.1 ($CH_2NH$), 54.3 ($CH_2Ar$), 129.6, 131.3, 131.6, 135.2, 136.9 (Aromatic C) ppm. $^{77}Se$ NMR ($CD_3CN$): $\delta$ = 315 ppm. ESI-MS: *m*/*z* = 981 [M – $PF_6$], 835 [M – 2 $PF_6$]. $C_{32}H_{36}N_4Se_2HgP_2F_{12}$ (1125.1): calcd. C 34.16, H 3.22, N 4.98; found C 33.93, H 3.31, N 4.86.

**[$PdC_{36}H_{46}N_6Se_2P_2F_{12}$] (14):** Pd(COD)$Cl_2$ (0.057 g, 0.2 mmol) was added to **6** (0.15 g, 0.2 mmol) in MeOH (20 $cm^3$) and was heated to reflux for 30 min. The reaction mixture was filtered, and to the filtrate excess $NH_4PF_6$ was added. The solvent volume was reduced to 2 $cm^3$ in vacuo, followed diffusion of diethyl ether to afford colorless crystals. Yield: 0.15 g, 32%. M.p. 220 °C (d.). IR (KBr): $\tilde{\nu}_{max}$ = 3343 (br), 3236 (s), 2927 (br), 840 (s), 557 (s) $cm^{-1}$. $^{77}Se$ NMR

C 33.41, H 3.58, N 6.49; found C 32.72, H 3.44, N 6.52.

**X-ray Crystallography:** The diffraction measurements for the ligand as well as for the complexes were performed at room temperature on a Bruker P4 diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) (Table 7 and Table 8) The data were corrected for Lorentz, polarization, and absorption effects The structures were determined by routine heavy-atom with SHELXS 97[25] and Fourier methods, and were refined by full-matrix least-squares by means of the SHELEXL 97[26] program with anisotropic non-hydrogen atoms and a fixed isotropic thermal parameter of 0.07 $Å^2$ for hydrogen. The hydrogen atoms were partially located from difference electron-density maps and the rest were fixed at predetermined positions. Scattering factors were obtained from common sources.[27] Some details of the data collection and refinement are given in Table 8 and Table 9. CCDC-221526 (**11**), -221527 (**8**), -241757 (**4**), -241758 (**7**), -241759 (**9**), -241760 (**10**), and -241761 (**14**) contain the supplementary data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac/uk/data_request/cif.

## Acknowledgments

We are grateful to the Department of Science and Technology (DST), New Delhi for funding this work. Additional help from the Regional Sophisticated Instrumentation center (RSIC), Indian Institute of Technology (IIT), Bombay, for 300 MHz NMR spectroscopy, RSIC, CDRI Lucknow, for the mass recording facility, and Tata Institute of Fundamental Research (TIFR), Bombay, for 500 MHz NMR spectroscopy is gratefully acknowledged.

# New, Multi-Dimensional Cu(tn)-$[M(CN)_6]^{n-}$ Cyano-Bridged, Bimetallic Coordination Materials (M = $Fe^{II}$, $Co^{III}$, $Cr^{III}$ and tn = 1,3-Diaminopropane)

**Smail Triki,*[a] Jean Sala-Pala,[a] Franck Thétiot,[a] Carlos J. Gómez-García,[b] and Jean-Claude Daran[c]**

**Keywords:** Bridging ligands / Cyanides / Heterometallic complexes / Magnetic properties

Reaction of the $[Fe^{III}(CN)_6]^{3-}$ anion with $[Cu^{II}(tn)(H_2O)_n]^{2+}$ (tn = 1,3-diaminopropane) affords the compounds $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]\cdot KCl\cdot 5H_2O$ (**1**), $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]\cdot 4H_2O$ (**2**), and $[\{Cu^{II}(tnH)_2(H_2O)_2\}\{Fe^{II}(CN)_6\}]\cdot 2H_2O$ (**3**). Each iron center in **1** and **2** is linked to six copper(II) ions by six cyanide bridges, while each copper ion is linked to three equivalent iron(II) ions. Despite these resemblances, the two compounds present large structural differences caused by two different orientations of the Cu–NC–Fe bridges: compound **1** has a 2D structure which can be described as successions of "$Cu_4Fe_3$" defective cubane units, while compound **2** displays a 3D arrangement. Compound **3**, in which only two *trans*-CN groups are bridging, displays a 1D structure. The tn ligand is chelating in **1**, as is usually observed in several parent compounds, but is unexpectedly a bridging ligand in **2** and a terminal protonated $tnH^+$ ligand in **3**. Thus, the dimension of the three compounds seems to depend on the tn coordination modes. For the three iron compounds **1**–**3**, the synthetic processes involve the spontaneous reduction of the paramagnetic $[Fe^{III}(CN)_6]^{3-}$ anion into the diamagnetic $[Fe^{II}(CN)_6]^{4-}$ anion. In order to avoid such diamagnetic building blocks, the paramagnetic $[Cr(CN)_6]^{3-}$ anion was used instead of the iron(III) analog, leading to $[\{Cu^{II}(tn)\}_3\{Cr^{III}(CN)_6\}_2]\cdot 3H_2O$ (**4**), which is the first 2D ferromagnet containing "-Cu–NC–Cr-" linkages. A similar study was performed using the diamagnetic $[Co(CN)_6]^{3-}$ anion, leading to $[\{Cu^{II}(tn)\}_3\{Co^{III}(CN)_6\}_2]\cdot 3H_2O$ (**5**), which is the Co analog of **4**. The magnetic properties of compounds **1**–**3** and **5** show the presence of isolated $Cu^{II}$ ions with weak ferromagnetic (**1**) or antiferromagnetic (**2**, **3**, and **5**) interactions. Compound **4** presents a long-range ferromagnetic ordering below $T_c$ = 9.5 K.

## Introduction

Bimetallic cyano-bridged assemblies based on polycyanometalates have attracted a great deal of attention because of their remarkable magnetic, photomagnetic, electric-field-induced conductance, catalytic, and porous properties.[1–6] Prussian blue analogs, derived from hexacyanometalate anions and hexa-solvated metal complexes, exhibit novel magnetic and electronic properties, and some of them present magnetic ordering at a critical temperature ($T_c$) as high as 376 K.[1] However, the difficulty of obtaining crystals suitable for X-ray structure determination precludes a thorough magneto-structural correlation of these 3D systems of high symmetry.[7] In order to tailor their dimensionality and connectivity, and to tune their properties, a different synthetic strategy involving two different families of cyano-bridged coordination assemblies was envisaged. The first family associates $[M(CN)_6]^{n-}$ building-block anions (M = divalent or trivalent first-row transition metal ion) and cationic assembling units of the general formula $[M'L_x(H_2O)_m]^{n+}$ (M′ = divalent first row transition metal ion; L = polyamine, macrocyclic ligand, Schiff base, ...) having selected free coordination sites, instead of simple hexa-solvated complexes;[8–11] the second one involves anionic complexes of general formula $[ML'(CN)_y]^{m-}$ as building blocks instead of the potentially hexadentate $[M(CN)_6]^{n-}$ anions.[12,13] In both families, a large number of such low-symmetry cyano-bridged assemblies display rich and fascinating structural architectures ranging from discrete polynuclear complexes[11,13] to extended 3D networks,[8–10,12] and in some cases exhibit interesting properties such as high $T_c$ magnets, high-spin molecules, or single-molecule magnets. For the first family built on $[M'L_x(H_2O)_m]^{2+}$ and $[M(CN)_6]^{n-}$ units, most of the materials are extended bimetallic compounds having a three- or four-coordinate $[M'L_x]^{2+}$ assembling block which constrains the number of adjacent hexacyanometalate building blocks to two and/or a limited dimensionality of two.[8–10] In contrast, examples in which the assembling block acts as a $\mu_4$-bridging "complex ligand" are very rare. In order to explore such extended bimetallic assemblies with higher connectivities and/or

higher dimensionalities, we decided to focus on the use of two-coordinate assembling units containing the $Cu^{II}$ ion, whose versatility as regards to coordination number and geometry is well known. Reactions of the $[Fe^{III}(CN)_6]^{3-}$ anion with the $[Cu^{II}(tn)(H_2O)_n]^{2+}$ ion (tn = 1,3-diaminopropane) afford the compounds $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]\cdot KCl\cdot 5H_2O$ (**1**), $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]\cdot 4H_2O$ (**2**) and $[\{Cu^{II}(tnH)_2(H_2O)_2\}\{Fe^{II}(CN)_6\}]\cdot 2H_2O$ (**3**). Compounds **1**–**3** display 2D, 3D, and 1D structures, respectively, generated by Cu–NC–Fe bridges. For all three compounds the synthetic processes involve the spontaneous reductions of the paramagnetic $[Fe^{III}(CN)_6]^{3-}$ anion into the diamagnetic $[Fe^{II}(CN)_6]^{4-}$ anion, as previously observed for some parent complexes.[14] Therefore, despite the original structural features of these three compounds, their magnetic properties only show weak exchange couplings between $Cu^{II}$ ions through the diamagnetic $[Fe^{II}(CN)_6]^{4-}$ anion. In order to avoid this reduction, the paramagnetic $[Cr(CN)_6]^{3-}$ anion was used instead of the iron(III) analog, leading to the new compound $[\{Cu(tn)\}_3\{Cr(CN)_6\}_2]\cdot 3H_2O$ (**4**), which is the first 2D ferromagnet involving "-Cu–NC–Cr-" linkages. In order to compare with a diamagnetic $[M(CN)_6]^{3-}$ building block, similar attempts were made using the $[Co(CN)_6]^{3-}$ anion; this leads to **5**, the $Co^{III}$ analog of **4**. Herein we report the syntheses, a detailed structural discussion, and the magnetic properties of these five cyano-bridged bimetallic materials. Note that compounds **1** and **4** have recently been briefly communicated by us.[9c,10d]

## Results and Discussion

### Syntheses and Characterization

The reaction of $CuCl_2$ with $K_3[Fe^{III}(CN)_6]$ and KOH in aqueous solution in the presence of 1,3-diaminopropane (tn) affords $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]\cdot KCl\cdot 5H_2O$ (**1**) as brown crystals. A similar reaction with $(Et_4N)_3[Fe^{III}(CN)_6]$ and $Et_4NOH$ instead of $K_3[Fe^{III}(CN)_6]$ and KOH results in the formation of $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]\cdot 4H_2O$ (**2**) as prismatic black crystals. Further concentration of the filtrate afforded $[\{Cu^{II}(tnH)_2(H_2O)_2\}\{Fe^{II}(CN)_6\}]\cdot 2H_2O$ (**3**) as hexagonal, dark-green crystals after several weeks under aerobic conditions. It is likely that the synthetic procedure leading to the slow formation of **3** corresponds to a decrease of the pH by slow aerobic carbonation of the basic solution after several weeks; this allows formation of the $tnH^+$ unit since the $pK_a$ of the $tnH^+$/tn couple is around 10.5 (the pH of the solution is about 10.0).[15] Finally, the reaction of $CuCl_2$ and tn with $Cr^{III}$ or $Co^{III}$ hexacyanometalate anions in basic aqueous solution afforded compounds $[\{Cu^{II}(tn)\}_3\{Cr^{III}(CN)_6\}_2]\cdot 3H_2O$ (**4**) and $[\{Cu^{II}(tn)\}_3\{Co^{III}(CN)_6\}_2]\cdot 3H_2O$ (**5**). The crucial role of the base (KOH, $Et_4NOH$) in these experimental processes must be pointed out: the presence of this base curiously avoids the immediate precipitation of insoluble species and provides the stable two-coordinate aqueous $[Cu(tn)]^{2+}$ unit, which can then react with the hexacyanometalate anions. It is also worthy to note that all the above reactions with $[Fe^{III}(CN)_6]^{3-}$ involve, as shown by the crystal structures and magnetic measurements, its reduction into the diamagnetic $[Fe^{II}(CN)_6]^{4-}$ anion. The reason for this reduction is not clear for the moment. However, on the basis of our observations during this work and careful examination of the literature, we suggest a mechanism that successively involves (i) partial decomplexation of $CN^-$ ligands from the $[Fe^{III}(CN)_6]^{3-}$ complex which, although kinetically inert, is more reactive with regard to ligand substitution than its $Fe^{II}$ analog,[16] (ii) reduction of the aqueous $Cu^{II}$ moiety into the corresponding $Cu^{I}$ unit by the $CN^-$ ions with formation of cyanogen or cyanate,[17] and (iii) reduction of $[Fe^{III}(CN)_6]^{3-}$ into $[Fe^{II}(CN)_6]^{4-}$ by the $Cu^{I}$ species with formation of the $Cu^{II}$ species.[18] Such a $[Fe^{III}(CN)_6]^{3-}$ to $[Fe^{II}(CN)_6]^{4-}$ reduction has been observed previously for some parent $M^{II}$–L–$[Fe^{III}(CN)_6]^{3-}$ ($M = Cu^{II}$, $Ni^{II}$, $Mn^{II}$) systems.[14]

The infrared spectra of **1**–**5** exhibit the bands expected for compounds built from $[Cu(tn)]^{2+}$ and $[M(CN)_6]^{n-}$ units, the presence of the latter being clearly indicated by strong absorption bands assignable to $\nu_{CN}$ stretching vibrations in the 2000–2200 $cm^{-1}$ range. Previous studies have shown that the positions of these absorption bands in $[Fe(CN)_6]^{n-}$-containing derivatives can be used as a diagnostic tool for identifying the oxidation state of the metal ion and detecting the presence of cyanide bridges.[19] Terminal CN ligands are typically characterized by absorption bands at around 2120 $cm^{-1}$ when bonded to $Fe^{III}$ and around 2040 $cm^{-1}$ when bonded to $Fe^{II}$, the shift to lower wavenumbers upon reduction resulting from greater π back-bonding from the $Fe^{II}$ ion to the CN π* antibonding orbital.[20] Coordination of the CN ligand to a second metal ion through its nitrogen atom results in an increase of these values to around 2150–2180 $cm^{-1}$ for $[Fe(CN)_6]^{3-}$ and 2050–2110 $cm^{-1}$ for $[Fe(CN)_6]^{4-}$.[19–21] The $\nu_{CN}$ stretching vibrations are found at 2091 and 2079 $cm^{-1}$ for **1** and 2085 and 2056 $cm^{-1}$ for **2**; although unambiguous assignments are difficult, it is likely that these compounds are built from $[Fe^{II}(CN)_6]^{4-}$ units that have their six CN ligands acting as bridging units with Cu ions. For compound **3**, three absorption bands are found at 2095, 2060, and 2032 $cm^{-1}$; this is in good agreement with the presence of $[Fe^{II}(CN)_6]^{4-}$ units having at last one terminal CN ligand, as indicated by the lower wavenumber band. Similarly, compound **4** exhibits a strong absorption band at 2175 $cm^{-1}$ and two weaker ones at 2149 and 2128 $cm^{-1}$ for the bridging and terminal cyanide groups, respectively. For compound **5**, which contains the $[Co(CN)_6]^{3-}$ unit, the strongest $\nu_{CN}$ absorption is observed at 2175 $cm^{-1}$; the increase of this value with respect to the Fe compound is normal since the CN bond is strengthened as the Co–CN bond involves σ-donation from an antibonding orbital.[22] Finally, the 1,3-diaminopropane ligand is easily characterized by the presence in the IR spectrum of bands due to $\nu_{NH}$ stretching vibrations of the $NH_2$ groups in the 3350–3150 $cm^{-1}$ region and to $\nu_{CH}$ stretching vibrations of the $CH_2$ groups in the 2980–2800 $cm^{-1}$ region.[23a] For compound **3**, the supplementary weak bands observed in the 2700–2500 $cm^{-1}$ region could be tentatively

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

assigned to $\nu_{NH}$ stretching vibrations of the uncoordinated $NH_3^+$ group.

### Crystal Structures

Pertinent bond lengths and angles for compounds **1**–**5** are given in the tables below. Crystallographic data and structure-refinement parameters are given in the Experimental Section.

The crystal structure of compound **1** has been recently communicated;[9c] thus, we limit ourselves to discussing some structural features that are relevant for structural discussion of compound **2** since both present some interesting similarities despite their large structural differences. The asymmetric unit of **1** consists of one $[Fe^{II}(CN)_6]^{4-}$ anion, two $[Cu^{II}(tn)]^{2+}$ cations, one $K^+$, one $Cl^-$, and five $H_2O$ molecules, all in general positions. Figure 1 shows an ORTEP drawing of this asymmetric unit with the atom-labeling scheme and the metal-ion environments; pertinent bond lengths and bond angles are given in Table 1. The two nonequivalent copper(II) ions (Cu1 and Cu2) exhibit a $CuN_5$ geometry (Figure 1), which arises in both cases from two nitrogen atoms of the chelating tn ligand (N7 and N8 for Cu1 and N9 and N10 for Cu2) and from three nitrogen atoms of the cyano groups [N3, N4(f), and N5(d) for Cu1 and N1(a), N2, and N6(c) for Cu2]. The Cu2 ion is located in an approximately square-pyramidal geometry, as indicated by the low value of the trigonality index, $\tau$,[24] of 0.18 [$\tau = (\beta - \alpha)/60$, where $\alpha$ and $\beta$ are the two greatest basal plane angles ($\beta \geq \alpha$) when the polyhedron is viewed as a square pyramid; for a perfectly square-pyramidal geometry $\tau$ is equal to zero, and it becomes unity for a perfectly trigonal bipyramidal geometry. For Cu2, $\alpha$ = N6(c)–Cu2–N10 = 162.3(2)° and $\beta$ = N2–Cu2–N9 = 173.3(2)°]. This slightly distorted square-pyramidal geometry is in good agreement with the structural data, which indicate that the four equatorial bond lengths are equivalent [Cu2–N2 = 2.005(4), Cu2–N6(c) = 2.008(4), Cu2–N9 = 2.011(4), Cu2–N10 = 2.004(4) Å], while the Cu2–N1(a) apical bond length [2.230(5) Å] is significantly longer. For the Cu1 ion, the corresponding $\tau$ value of 0.55 [$\alpha$ = N4(f)–Cu1–N8 = 141.4(2)°, $\beta$ = N3–Cu1–N7 = 174.2(2)°] indicates that the coordination geometry of the Cu1 ion is intermediate between the two ideal geometries. This coordination geometry can be described as trigonal bipyramidal distorted square-based pyramidal in which one of the equatorial bond lengths is significantly longer [Cu1–N5(d) = 2.122(4) Å] than the other two [Cu–N4(f) = 2.027(6) and Cu1–N8 = 2.039(5) Å] and the apical bond lengths [Cu1–N3 = 2.002(4) and Cu–N7 = 2.009(4) Å].

Each iron ion, which has an almost regular octahedral geometry, is linked to six copper(II) ions by six cyanide bridges, while each copper ion is linked to three equivalent iron(II) ions. The Fe–C–N units are essentially linear while the C–N–Cu angles deviate significantly from linearity (see Table 1). This leads to an infinite $[\{Cu(tn)\}_2\{Fe(CN)_6\}]$ lamellar structure, which can also be described as a 2D layered structure generated by the defective cubane units

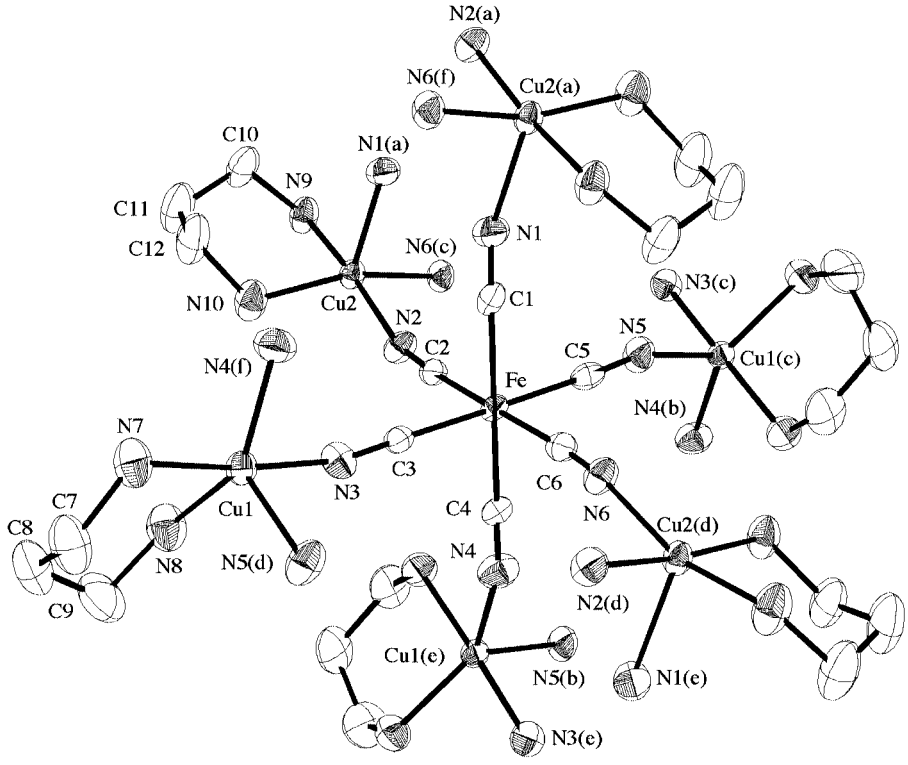

Figure 1. ORTEP view showing the atomic labeling scheme and the metal ion (M = Fe, Cu1 and Cu2) environments in compound **1** (40% probability ellipsoids). Codes of equivalent positions: (a) $-x, -y, 1 - z$; (b) $-x, -y, 2 - z$; (c) $-x, -1/2 + y, 3/2 - z$; (d) $-x, 1/2 + y, 3/2 - z$; (e) $x, 1/2 - y, 1/2 + z$; (f) $x, 1/2 - y, -1/2 + z$.

Table 1. Pertinent bond lengths [Å] and bond angles [°] in compound **1**.

| Fe–C–N–Cu | Fe–C | C–N | N–Cu | Fe–C–N | C–N–Cu | Fe···Cu |
|---|---|---|---|---|---|---|
| Fe–C1–N1–Cu2(a) | 1.929(6) | 1.138(8) | 2.230(5) | 175.4(4) | 156.0(4) | 5.194(1) |
| Fe–C2–N2–Cu2 | 1.918(5) | 1.145(6) | 2.005(4) | 175.3(5) | 161.2(5) | 4.980(1) |
| Fe–C3–N3–Cu1 | 1.899(4) | 1.159(6) | 2.002(4) | 178.3(4) | 162.0(5) | 4.997(1) |
| Fe–C4–N4–Cu1(e) | 1.895(6) | 1.147(8) | 2.027(6) | 178.5(4) | 160.1(4) | 4.991(1) |
| Fe–C5–N5–Cu1(c) | 1.931(4) | 1.137(6) | 2.122(4) | 176.7(5) | 159.0(5) | 5.114(1) |
| Fe–C6–N6–Cu2(d) | 1.919(5) | 1.138(6) | 2.008(4) | 175.8(5) | 163.0(5) | 4.998(1) |

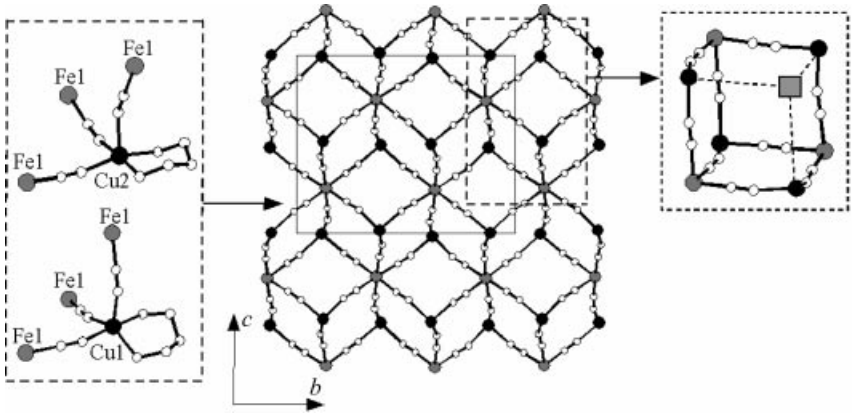

Figure 2. View of the structure of compound **1** showing the 2D arrangement generated by the square-pyramidal units of $Cu^{II}$ and a view of the "$Cu_4Fe_3$" cubane unit. The chelating tn ligands have been omitted, in the 2D arrangement, for the sake of clarity.

"$Cu_4Fe_3$", as shown in Figure 2. The distance between two neutral eclipsed parallel sheets is the *a* parameter [15.1478(3) Å], which gives rise to a large interlayer space where the chloride anions, the potassium ions, and the water molecules are accommodated. The shortest Cu···Cu distance is 6.845(1) Å.

Compound **2** crystallizes in the monoclinic system (space group $P2_1/n$); the asymmetric unit consists of one $[Fe^{II}(CN)_6]^{4-}$ anion, located at the special position (0,0,0), one $[Cu^{II}(tn)]^{2+}$ ion, and two $H_2O$ molecules, all in general positions. The copper(II) ion (Cu1) exhibits a $CuN_5$ geometry (Figure 3) arising from two nitrogen atoms of two equivalent tn ligands (N1, N5) and from three nitrogen atoms of the cyano groups (N11, N12, and N13). As for the Cu1 ion of compound **1**, the corresponding $\tau$[24] value of 0.57 [$\alpha$ = N12–Cu1–N13 = 142.9(2)°, $\beta$ = N1–Cu1–N5 = 177.0(2)°] indicates that the coordination geometry of the Cu1 ion is a trigonal bipyramidal distorted square-based pyramid with almost equivalent Cu–N bond lengths except for one of the equatorial ones [Cu–N11 = 2.228(4) Å], which is significantly longer than the other four [equatorial: Cu1–N12 = 2.001(4) and Cu1–N13 = 1.987(3) Å; apical: Cu1–N1 = 2.035(3) and Cu–N5 = 2.001(3) Å]. Examination of the N–Cu–N angles in the pseudo base plane [101.8(2), 115.3(2), 142.9(2)°] also indicates that the Cu environment deviates strongly from the ideal trigonal-bipyramidal geometry.

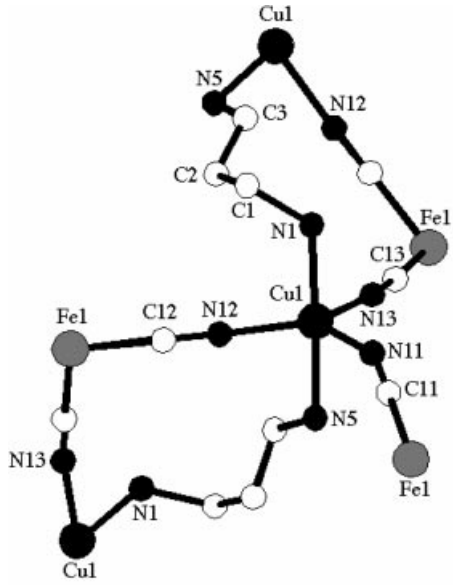

Figure 3. View of the copper ion environment in compound **2**.

As in compound **1**, the iron ion, which has an almost regular octahedral geometry, is linked to six copper(II) ions by six cyanide bridges, while the copper ion is linked to three equivalent iron(II) ions (Figure 4). This leads to a 3D

arrangement in which the Fe–C–N units are essentially linear, while one of the Cu–N–C units deviates significantly from linearity (Table 2). Careful examination of this 3D arrangement shows two interesting structural features. The first one concerns the projections along the [001] and [010] directions; as shown in Figure 4, they seem to give the same lamellar structure as observed for the 2D structure of **1**. The second one concerns the unexpected coordination mode of the tn ligand; usually chelate, this unit acts in compound **2** as a bridging ligand.

To clearly describe this sophisticated structure, these two structural characteristics are detailed below. The extended structures of compounds **1** and **2** present important structural similarities: (i) they have the same chemical formula $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]_n$, (ii) in both structures each $Cu^{II}$ ion is linked to three $Fe^{II}$ ions while each $Fe^{II}$ ion is linked to six $Cu^{II}$ ions, and (iii) the projections of **2** along the [001] and [010] directions (parts a, b in Figure 4) seem similar to that of compound **1** along the [100] direction (Figure 2). Despite these common features, large structural differences are observed and the question now is why compound **1** displays a 2D layered structure while the structure of compound **2**, generated only by the cyanide bridges, is 3D. To clarify these differences, the best way seems to be to describe the structural arrangement of **2** on the basis of that of **1**. To simplify such complicated arrangements, the tn ligands are initially omitted. Thus, the extended arrangements of both compounds can be viewed as two different successions of the elemental units depicted in Figure 5 (trigonal pyramid for **1** and trigonal plane for **2**).

For compound **1**, the 2D structure of the "$Cu_4Fe_3$" defective cubane units depicted in Figure 2 can be easily viewed as a succession of the trigonal-pyramidal units depicted in Figure 5, while for compound **2** the trigonal planes do not allow such a structural arrangement. Thus, the projections of **2** along the [001] and the [010] directions (see a, b in Figure 4) are misleading since they are not appropriate to explain clearly the large differences between the two

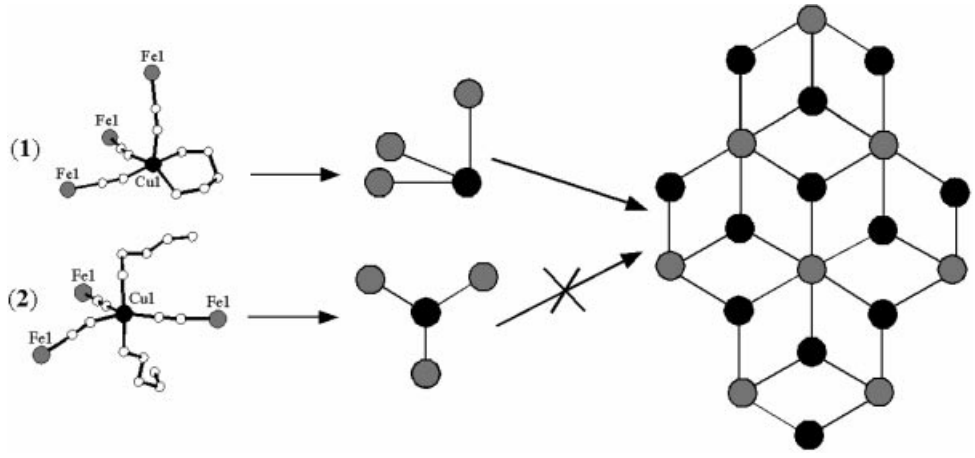

Figure 5. Schematic view showing that the 2D arrangement described as a succession of defective cubane units in compound **1** is not possible in the case of compound **2**.

structural arrangements. A correct description of this 3D arrangement is obtained after rotation of the unreal defective cubane unit around the *a* axis, as shown for this structure in Figure 6 (b); such a rotation shows the real geometry of this unit (Figure 6, c).

The bimetallic cyano-bridged units of **2** differ markedly from the defective cubane units observed in compound **1**, as shown by the schematic view of these units in both compounds (Figure 7).

Slight rotation around the Fe(A)–Fe(A) axis shows a nearly similar view for the structural unit and generates the 2D structure of **1**; the Cu(A) atoms are linked to the Fe(B) atoms by the CN bridges of the same unit leading, as described above, to the 2D structure parallel to the $[Cu(B)]_4$ plane. For compound **2**, a similar slight rotation around the Fe(A)–Fe(A) axis shows that the structural unit is not discrete since the Cu(A) atoms are not linked to Fe(B) atoms as observed for **1**, but linked to the Fe(A) atoms in a third direction that is orthogonal to the $[Cu(B)]_4$ plane. Finally, it is worthy to note that the unusual coordination mode of the tn ligand in compound **2** leads to a helical chain running along the [010] direction with a Cu···Cu distance of 6.719(1) Å (Figure 8). These bridges have no consequences for the structural dimension since compound **2** was described above as having a 3D structure only on the basis of the cyanide bridges.

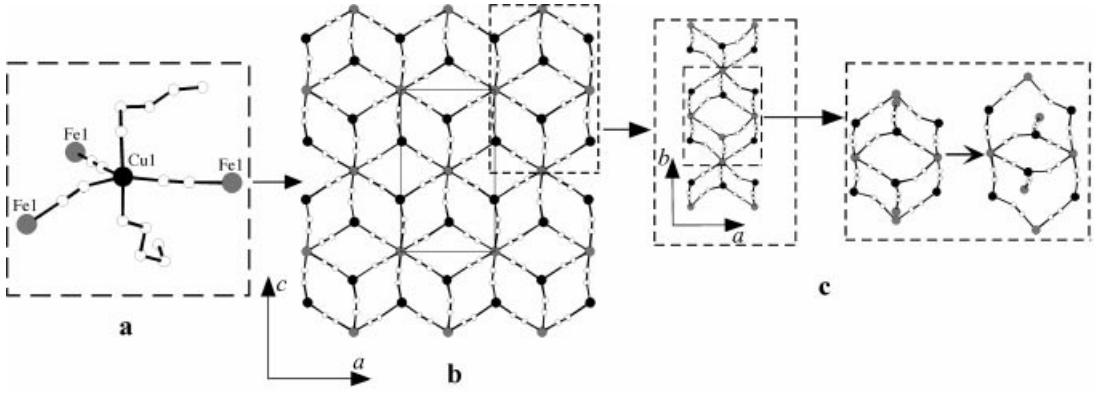

Figure 6. Careful examination of the 3D structure of compound **2**: a) scheme for the copper environment; b) projection of the structure on the *ac* plane; c) the clear structure of fragment unit after rotation around the *a* axis. In (b) and (c), the tn ligands have been omitted for the sake of clarity.

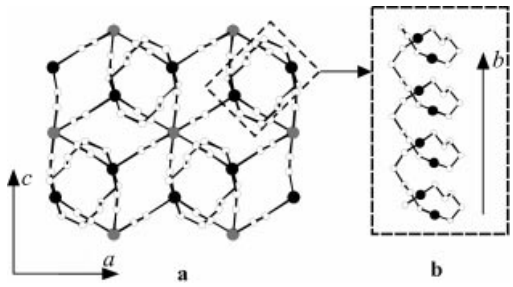

Figure 8. The bridging tn ligand in the 3D structure of compound **2**: a) projection on the *ac* plane; b) the helical chain running along the [010] direction.

Compound **3** crystallizes in the monoclinic system (space group $P2_1/n$); the asymmetric unit consists of one $[Cu(tnH)_2(H_2O)_2]^{4+}$ and one $[Fe(CN)_6]^{4-}$ unit, both localized at special positions[ (1/2,0,0) and (0,0,0) respectively], and a water molecule in a general position. Figure 9 shows this asymmetric unit with the atom labeling scheme and the coordination mode of the $[tnH]^+$ ligand. The $Cu^{II}$ ion presents a strongly elongated centrosymmetric $CuN_4O_2$ environment with four almost equivalent CuN bonds involving two N atoms of CN groups [Cu–N3 and Cu–N3$^{(b)}$: 1.961(4) Å], two N atoms of tn [Cu–N4 and Cu–N4$^{(d)}$: 2.044(4) Å], and two elongated CuO bonds [Cu–O2$^{(e)}$ and Cu–O2$^{(f)}$: 2.633(4) Å] (Figure 10). The $Fe^{II}$ ion presents an almost perfect octahedral $FeC_6$ coordination [Fe–C bond lengths from 1.914(5) to 1.921(4) Å]. The structure can be described as being formed by linear chains with alternating $[Cu(tnH)_2(H_2O)_2]^{4+}$ and $[Fe(CN)_6]^{4-}$ units linked by a CN bridge (Figure 9). Within a chain, each $[Fe(CN)_6]^{4-}$ is bonded to two Cu ions by two CN groups in a *trans* configuration while each $[Cu(tnH)_2(H_2O)_2]^{4+}$ acts as a $\mu_2$ ligand and not $\mu_3$ as described above for compounds **1**–**2**; the shortest Cu···Fe and Cu···Cu intrachain distances correspond to the *a*/2 and *a* parameter [*a* = 10.0586(4) Å], respectively. It is worthy to note that the tn unit in **3** is protonated; the $tnH^+$ ligand presents a monodentate coordination mode, with the protonated amine group being uncoordinated (Figure 9).

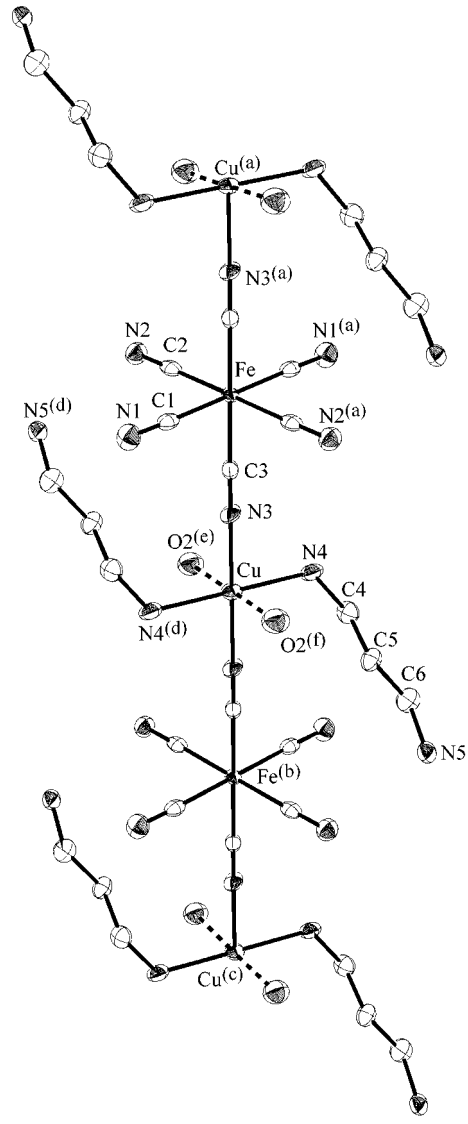

Figure 9. 1D structure of compound **3** showing the atomic labeling scheme and the terminal protonated $[tnH]^+$ ligand (30% probability ellipsoids). Codes of equivalent positions: (a) –*x*, –*y*, –*z*; (b) –1 + *x*, *y*, *z*; (c) 2 – *x*, –*y*, –*z*; (d) –1 – *x*, –*y*, –*z*; (e) –1/2 + *x*, –1/2 – *y*, –1 + *z*; (f) –1/2 – *x*, 1/2 + *y*, 1/2 – *z*.

Compounds **4** and **5** are isostructural and crystallize in the orthorhombic system (space group *Pbcn*). The asymmetric unit contains one $[M(CN)_6]^{3-}$ anion, located at a general position, and two $[Cu(tn)]^{2+}$ (Cu1 and Cu2) ions at special positions (1/2,*y*,1/4). Figure 10 shows an ORTEP drawing of this asymmetric unit with the atom-labeling scheme and the coordination polyhedra of the metal ions; pertinent bond lengths and bond angles of **4** and **5** are given in Table 3. In both structures, the Cu1 atom exhibits a distorted $CuN_5$ coordination environment (Figure 10) arising from two nitrogen atoms of a chelating tn ligand (N7, N8) and three nitrogen atoms from CN groups [N1, N2(a), and N3$^{(f)}$]. The value of the trigonality index $\tau$[24] is 0.22 for **4** [$\alpha$ = N3$^{(f)}$–Cu1–N7 = 159.2(3)°, $\beta$ = N1–Cu1–N8 = 172.4(3)°] and 0.20 for **5** [$\alpha$ = N3$^{(f)}$–Cu1–N7 = 159.1(2)°, $\beta$ = N1–Cu1–N8 = 171.0(2)°]. In agreement with these low values, the coordination geometry of the Cu1 environment can be described in both cases as distorted square-pyramidal, with an apical bond length 0.15–0.18 Å longer than the four equatorial ones. The coordination polyhedron of the Cu2 atom differs strongly from that of Cu1 and can be described as a $CuN_4N_2$ elongated octahedron generated by a $CuN_4$ equatorial plane arising from two nitrogen atoms of the chelating tn ligand [N9 and N9(a)] and two equivalent nitrogen atoms of CN groups [N4 and N4(a)], and two axial positions defined by two equivalent nitrogen atoms [N5(b) and N5(c)] of CN groups, the two axial Cu–N5 bond lengths being approximately 0.6 Å longer than the other four in both cases, as shown in Figure 10 and Table 3.

Each $M^{III}$ ion, although bound to six carbon atoms arising from one terminal and five bridging CN ligands, presents an almost regular octahedral coordination geometry, the Cr–C bond lengths being, as usually observed, 0.15–0.18 Å longer than the Co–C ones. In both cases, the ex-

tended structure can be more clearly described by taking the twelve-membered tetrametallacycle M–CN–Cu–NC–M–CN–Cu–NC as the elemental unit. The molecular arrangement can be seen as a zig-zag "chain" of such "MCuMCu" cycles sharing alternatively one side (Cu1M) and one vertex (Cu1), as shown in Figure 11 (a). The adjacent "chains" are connected to each other through the CN bridges (M–C5–N5–Cu2) to lead to the neutral 2D structure depicted in part b of Figure 11.

As shown in Figure 12, the chelating tn ligands are oriented out of the plane of the bimetallic layers; this imposes a large separation between adjacent layers (adjacent layer distance: *a*/2; shortest Cu–M interlayer distance: ca. 7.0 Å), which is responsible for the presence of the nonbridging C(6)N(6) nitrile group. Careful examination of the 3D structure of $[Mn(en)]_3\{Cr(CN)_6]_2 \cdot 4H_2O$ (**6**), reported by Okawa et al.,[25] shows remarkable structural similarities with the 2D structures of **4** and **5**. Despite important differ-

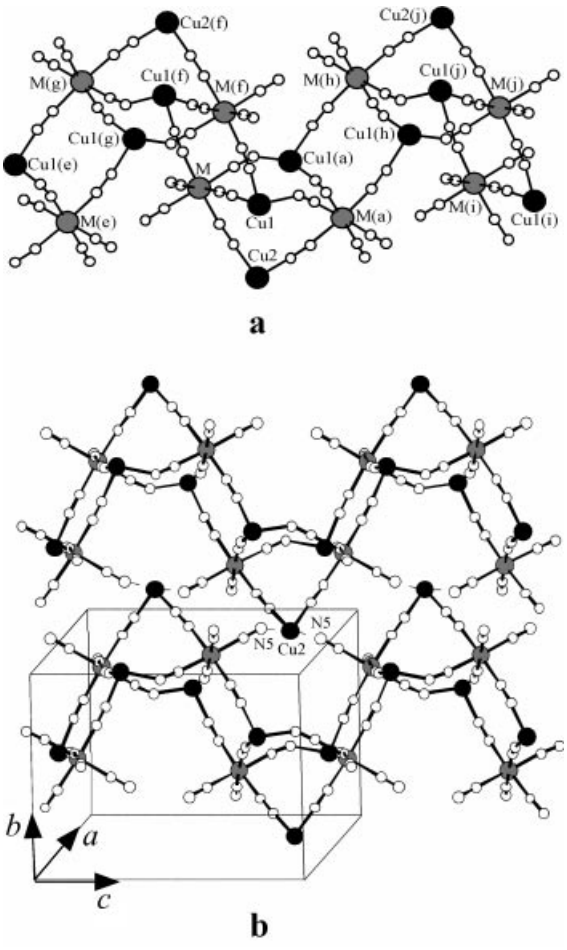

Figure 11. Structure of compounds **4** and **5**: a) schematic view of a zigzag chain unit; b) 2D arrangement. The tn chelating ligands have been omitted for clarity. Codes of equivalent positions: (a) 1 – *x*, *y*, 1/2 – *z*; (e) 1 – *x*, *y*, –1/2 – *z*; (f) 1 – *x*, –*y*, –*z*; (g) *x*, –*y*, –1/2 + *z*; (h) *x*, –*y*, 1/2 + *z*; (i) *x*, *y*, 1 + *z*; (j) 1 – *x*, –*y*, 1 – *z*.

ences related essentially to their dimensionalities, the 3D structure of **6** can be easily described from the 2D structure of **4** and **5** by taking into account that the cyano group, which is terminal in the latter [C(6)N(6)], adopts a bridging coordination mode in **6** (see Figures 10 and 12). This supplementary cyano bridge may be explained by the presence of the en ligand in **6**, which has a lower steric hindrance than the tn ligand.

### Magnetic Properties

The magnetic properties for compounds **1**–**3** and **5** are displayed in Figure 13 as the thermal variation of the $\chi_m T$ product ($\chi_m$ being the molar magnetic susceptibility per formula unit). Compounds **2**, **3**, and **5** show similar behaviors, with a constant $\chi_m T$ value from room temperature down to low temperatures (20–30 K); below this temperature, they show smooth decreases of the $\chi_m T$ product due to weak antiferromagnetic interactions between $Cu^{II}$ ions through the diamagnetic hexacyanometalate building block anions in the $d^6$ low-spin configuration {$[Fe^{II}(CN)_6]^{4-}$ for compounds **2** and **3** and $[Co^{III}(CN)_6]^{3-}$ for compound **5**}. Compound **1** displays the same behavior in the high-temperature range but shows an increase in the $\chi_m T$ value at low temperatures, which is characteristic of weak, but significant, ferromagnetic interactions between $Cu^{II}$ ions through the diamagnetic building block anion.

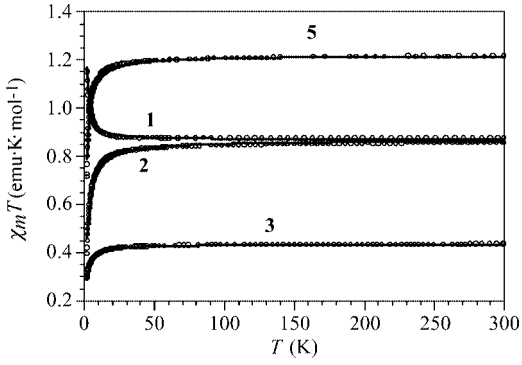

Figure 13. Thermal variation of $\chi_m T$ for compounds **1**, **2**, **3**, and **5**. Solid lines are the best fits to the Curie–Weiss law (see text).

These behaviors indicate that the four compounds behave essentially as paramagnets with weak $Cu^{II}$–$Cu^{II}$ magnetic

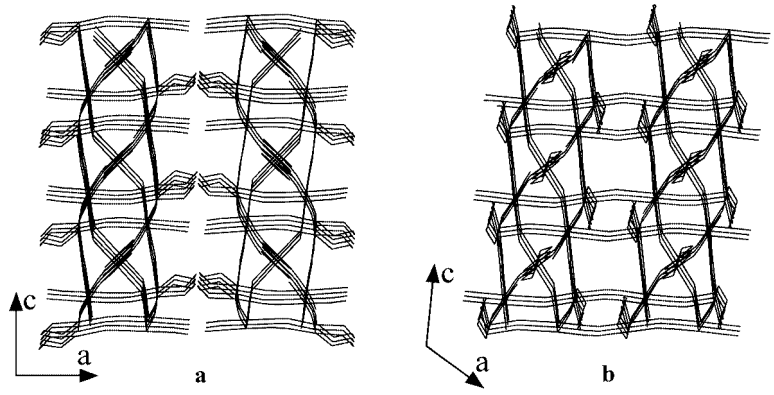

Figure 12. a) Schematic view of two adjacent layers in compounds **4** and **5** showing the nonbridging CN groups and the chelating tn ligands; b) view of the 3D arrangement of compound **6** (obtained from crystal data given in the cif file of ref.[25]); the nonbridging CN group observed in **4** and **5** is bridging here.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

interactions, as expected from the structural data that show that the $Cu^{II}$ ions are quite well isolated due to the diamagnetic building blocks that preclude the existence of significant exchange interactions between the $Cu^{II}$ ions. Thus, for each of these four compounds, the magnetic data can be very well reproduced with a simple Curie–Weiss law: $\chi_m = C/(T - \theta)$. In all cases, this expression gives a very satisfactory agreement with the experimental data in the whole temperature range (solid lines in Figure 13) with the sets of parameters displayed in Table 4; these results corroborate the presence of weak ferromagnetic interactions in **1** and weak antiferromagnetic interactions in **2**, **3**, and **5**.

Table 4. Magnetic parameters for compounds **1**–**3** and **5**.

| | $Cu^{II}_nM$ | $C$ [emu K mol$^{-1}$] | $g$ | $\Theta$ [K] |
|---|---|---|---|---|
| **1** | $Cu^{II}_2Fe^{II}$ | 0.869(1) | 2.152 | +0.515(3) |
| **2** | $Cu^{II}_2Fe^{II}$ | 0.866(1) | 2.149 | –1.76(2) |
| **3** | $Cu^{II}Fe^{II}$ | 0.435(1) | 2.153 | –0.97(2) |
| **5** | $Cu^{II}_3Co^{III}$ | 1.218(3) | 2.081 | –0.98(2) |

A confirmation of the spin ground-state and the weak magnetic interactions in compounds **1**, **2**, **3**, and **5** comes from the isothermal magnetization of these compounds at 2 K. In all cases, the magnetization can be well reproduced with a Brillouin function for one (**3**), two (**1** and **2**), or three (**5**) independent $S = 1/2$ ions with reduced (**2**, **3**, and **5**) or increased (**1**) $g$ values accounting for the weak interactions observed at low temperatures. The magnetic behavior of **1** is similar to that observed in the previously reported compound $[Cu^{II}(en)(H_2O)\}_2\{Fe^{II}(CN)_6]\cdot 4H_2O$, which contains Cu–NC–$Fe^{II}$–CN–Cu bridges.[23b] In this compound, the nature of the ferromagnetic coupling was explained as having two possible origins: (i) intrachain interactions through the diamagnetic -NC–$Fe^{II}$–CN- bridges, or (ii) interchain interactions through double end-on cyanide bridges. As shown above, the crystal structure of **1** involves infinite 2D sheets that are eclipsed and about 15.0 Å apart. This large distance means that the adjacent sheets are well isolated and precludes consideration of any inter-sheet interaction. Thus, the weak magnetic coupling in **1** can be attributed to the interaction between $Cu^{II}$ ions through the diamagnetic -NC–$Fe^{II}$–CN- bridges. Note that such an assignment needs more experimental support but examples involving extended and discrete cyano-bridged compounds with similar diamagnetic -NC–M–CN- bridges (M = $Fe^{II}$ in $[Fe(CN)_6]^{4-}$, M = $Fe^{III}$ in $[Fe(CN)_5(NO)]^{2-}$, and M = $Co^{III}$ in $[Co(CN)_6]^{3-}$) between $Cu^{II}$ ions are very rare.[13e,23,26,27] However, such diamagnetic bridges lead to the same situation in some $Ni^{II}$–$Fe^{II}$ and $Mn^{II}$–$Fe^{II}$ bimetallic compounds;[14a,14b,26d,28] taking into consideration the electronic configuration of $Ni^{II}(t_{2g}^6e_g^2)$ or $Mn^{II}$ $(t_{2g}^3e_g^2)$ and $Fe^{II}$ $(t_{2g}^6e_g^0)$, a σ-superexchange pathway between $Ni^{II}$ (or $Mn^{II}$) ions through the empty $d_\sigma$ orbital of the $Fe^{II}$ ion was proposed to explain the ferromagnetic exchange coupling. Thus, it seems likely that a similar ferromagnetic behavior occurs in compound **1** even if the $Cu^{II}$ ion presents a nonoctahedral environment. Consequently, such ferromagnetic behavior should also occur in compounds **2** and **3** instead of the weak antiferromagnetic or the paramagnetic behavior actually observed. For compound **5**, which also involves diamagnetic bridges between $Cu^{II}$, the weak antiferromagnetic behavior observed is similar to those of a few examples recently reported.[27] Finally, on the basis of this study and on some reported examples involving diamagnetic -NC–M–CN- bridges between $Cu^{II}$ ions, we can conclude, as expected from the structural data (Cu···Cu ≥ 6.7 Å), that weak magnetic interactions occur through such diamagnetic bridges. In contrast, a clear exchange mechanism concerning the nature of the magnetic coupling needs more examples of M–$Cu^{II}$ cyano-bridged bimetallic compounds.

As expected, substitution of the diamagnetic $[Co(CN)_6]^{3-}$ anion by the paramagnetic $S = 3/2$ $[Cr(CN)_6]^{3-}$ anion results in a drastic modification of the magnetic properties, as will be shown below. The thermal variation of the molar magnetic susceptibility ($\chi_m$) of compound **4** shows an abrupt increase below about 15 K (maximum slope at about 11 K) followed by an almost saturation at low temperatures (Figure 14). This behavior suggests the presence of a long-range ordering in this compound below about 10 K. The thermal variation of the $\chi_m T$ product (per "$Cu_3Cr_2$" formula unit) shows a room-temperature value of about 5.0 emu K mol$^{-1}$, which is close to the expected value (4.875 emu K mol$^{-1}$) for three noninteracting $Cu^{II}$ ($S = 1/2$) and two $Cr^{III}$ ($S = 3/2$) ions with $g = 2$ (inset in Figure 14). On cooling the sample, the $\chi_m T$ product shows a continuous increase, which is indicative of a ferromagnetic coupling between the $Cr^{III}$ and $Cu^{II}$ ions in **4**. In fact, the magnetic susceptibility of **4** follows a Curie–Weiss law above about 100 K with $C = 4.97(1)$ emu K mol$^{-1}$ and $\theta = +46.0(2)$ K; note that the positive sign of $\theta$ confirms the presence of dominant ferromagnetic interactions between neighboring $Cr^{III}$ and $Cu^{II}$ ions. On cooling the sample further, the $\chi_m T$ product shows a maximum of about 58 emu K mol$^{-1}$ at about. 11 K; below this temperature the $\chi_m T$ product decreases sharply, due to saturation effects of the $\chi_m$ at low temperatures, to reach a value of around 15 emu K mol$^{-1}$ at 2 K (inset in Figure 14).

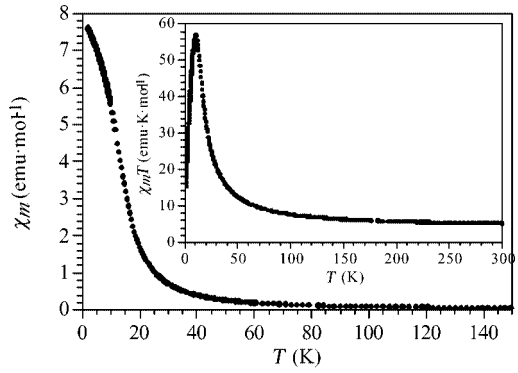

Figure 14. Thermal variations of $\chi_m$ and $\chi_m T$ (inset) for compound **4**.

To confirm the ferromagnetic nature of the long-range order transition and to determine the exact transition temperature, we performed magnetic susceptibility measure-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ments in an alternating field (AC susceptibility, Figure 15). These measurements show: (i) a frequency-independent peak at about 9.0 K and an additional frequency-dependent shoulder at lower temperatures in the in-phase susceptibility ($\chi'_m$) ,and (ii) a non-zero frequency-independent out-of-phase susceptibility ($\chi''_m$) below about 9.5 K that presents a frequency-dependent broad maximum at lower temperatures (3.6–4.7 K). From these data, we can conclude that compound **4** presents a ferromagnetic long-range ordering and that the ordering temperature is about 9.5 K. Furthermore, the presence of the frequency-dependent shoulders (in $\chi'_m$) and broad maxima (in $\chi''_m$) suggests that the movement of the domain walls in the ferromagnetically ordered phase is strongly hindered below about 5 K. A possible explanation is that the magnetic transition at 9.5 K corresponds to a ferromagnetic ordering within the layer (which is frequency independent, as observed in the $\chi'_m$ peak at about 9.0 K), and that at lower temperatures (below ca. 5 K) the dipolar coupling induces a 3D ferromagnetic ordering in which the domain walls are anchored.

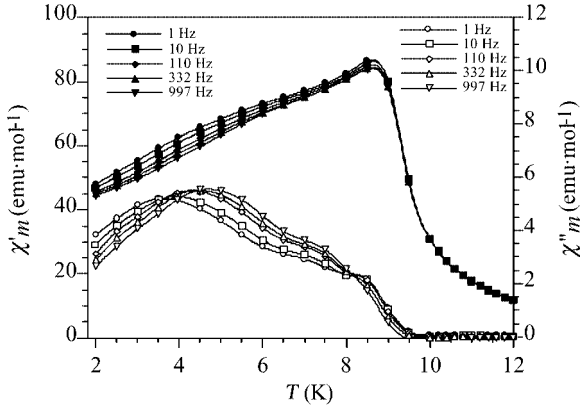

Figure 15. Thermal variation of the in-phase ($\chi'_m$, filled symbols, left scale) and out-of-phase ($\chi''_m$, empty symbols, right scale) signals of compound **4** at 1, 10, 110, 332, and 997 Hz (circles, squares, rhombs, up-triangles and down-triangles, respectively).

In this case, the frequency dependence of $\chi'_m$ can be related to the activation energy required to unlock these domain walls. This activation energy ($E_a$) can be deduced from the frequency dependence of the maximum of $\chi''_m$, which follows an Arrhenius la w, as $E_a$ = 112(2) K. An additional proof comes from the fact that the application of increasing DC fields in the AC measurements reduces the shoulder in $\chi'_m$ and the broad maximum in $\chi''_m$; both features disappear when the DC field is above about 100 mT (Figure 16). Furthermore, the temperature of these two features decreases as the DC field increases (Figure 16), indicating, as expected, that the magnetic field helps the unlocking of the domain walls. A very similar behavior has recently been observed in $[Ni(trans\text{-}C_6H_{14}N_2)_2]_3\{Fe(CN)_6]_2\cdot 2H_2O$, a similar layered cyanide-bridged bimetallic ferromagnet ($T_c$ = 14.0 K, $E_a$ = 111.6 K) with the same stoichiometric $M^{II}_3$-$M^{III}_2$ ratio[8g] and in the two pure enantiomeric derivatives of the same compound obtained with *trans*-(1*S*,2*S*)-$C_6H_{14}N_2$ and *trans*-(1*R*,2*R*)-$C_6H_{14}N_2$ ($T_c$ = 13.8 K, $E_a$ = 156 K).[8h] Note that the ordering temperature of **4** ($T_c$ = 9.5 K) is lower than that reported for the 3D compound $[Cu(EtOH)_2][Cu(en)]_2\{Cr(CN)_6]_2$ ($T_c$ = 57 K),[10e] which was previously the only known example of a cyano-bridged $Cu_3Cr_2$ ferromagnet. The difference in the ordering temperature can be related to the lower dimensionality and/or to the lower Cr–Cu exchange interactions of **4** as a result

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the different Cu–CN–Cr angles observed in both compounds.

An additional proof of the ferromagnetic nature of the long-range ordering comes from the isothermal magnetization of **4** at 2 and 5 K, which shows (i) a rapid saturation of the magnetization for magnetic fields above about 0.5 T (Figure 17), (ii) a saturation value of around 9.2 $\mu_B$, which is the expected value for the parallel alignment of three $S = 1/2$ plus two $S = 3/2$ spins with a $g$ value close to 2, and (iii) a hysteresis with small and similar coercive fields of 1.0 mT at 2 and 5 K, indicating that **4** is a soft ferromagnet.

## Conclusions

This study involves the design of some new bimetallic materials that contain a hexacyanometalate $[M(CN)_6]^{n-}$ ion and a two-coordinate $[CuL]^{2+}$ unit (L = $H_2NCH_2CH_2CH_2NH_2$). With $[Fe(CN)_6]^{3-}$, spontaneous Fe reduction was observed to afford the $[Fe(CN)_6]^{4-}$ ion. This diamagnetic building block leads to three new Cu–Fe combinations corresponding to different diamine coordination modes: chelating, bridging, and terminal, with protonation of one of the $NH_2$ groups. These three bimetallic compounds, for which magnetic properties only show weak exchange couplings between $Cu^{II}$ ions through diamagnetic hexacyanometalate bridges, have original 1D or 2D structures whose dimensionalities seems to be related to the coordination mode of the diamine unit. In order to obtain interesting magnetic behavior with paramagnetic building blocks, similar studies were performed using the $S = 3/2$ $[Cr(CN)_6]^{3-}$ building block; this leads to the first 2D ferromagnet involving Cr–CN–Cu linkages. Despite important differences related essentially to their dimensionality, this compound, $[Cu(H_2NCH_2CH_2CH_2NH_2)\}_3\{Cr(CN)_6]_2 \cdot 3H_2O$, and the recently reported $[Mn(H_2NCH_2CH_2NH_2)][Cr(CN)_6]\cdot 4H_2O$ show some remarkable structural similarities. These results, associated with some others already reported in the literature, show the ability of the $[M(CN)_6]^{n-}/[CuL]^{2+}$ system to afford a wide variety of bimetallic combinations depending not only on the nature of M and L but also on other parameters such as the pH and the nature of the counteranions. Extension of this study to other amine ligands and to other experimental conditions is in progress in order to obtain a more unified view of the structural data/magnetic behavior relationship in these bimetallic combinations.

## Experimental Section

**General:** All reagents were purchased from commercial sources and used as received. $(Et_4N)_3[Fe^{III}(CN)_6]$ and $(Et_4N)_3[Co^{III}(CN)_6]$ were prepared from the corresponding potassium hexacyanometalate in two steps via the corresponding silver salt with a procedure adapted from that reported by Le Magueres,[29] using acetonitrile as solvent instead of water. Elemental analyses were obtained from the Service Central d'Analyses (Vernaison) and Service de Micro-analyses de ICSN-CNRS (Gif-sur-Yvette). Infrared spectra were recorded in the range 4000–200 $cm^{-1}$ as KBr pellets on a FT-IR Nexus Nicolet spectrometer. Variable temperature susceptibility measurements were carried out in the temperature range 2–300 K with applied magnetic fields of 0.1 T on polycrystalline samples for all the compounds with a Quantum Design MPMS-XL-5 SQUID magnetometer. The susceptibility data were corrected for the sample holders previously measured using the same conditions and for the diamagnetic contributions of the salt, as deduced by using Pascal's constant tables. For **4**, the AC susceptibility measurements were performed in the temperature range 2–20 K with an alternating field of 0.395 mT at different frequencies in the 1–1000 Hz range with the SQUID susceptometer and with an alternating field of 1.7 mT at different frequencies in the 1–10 kHz range applying different DC magnetic fields (between 0 and 100 mT) with a Quantum Design Physical Properties Measurement System, PPMS-9.

**Synthesis of $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]\cdot KCl\cdot 5H_2O$ (1) (tn = 1,3-diaminopropane):** This compound was prepared as brown crystals by a procedure similar to that given below for **2**, from $K_3[Fe^{III}(CN)_6]$ (0.66 g, 2.0 mmol) and KOH (0.67 g, 12.0 mmol) instead of $(Et_4N)_3[Fe^{III}(CN)_6]$ and $Et_4NOH$. This procedure and the analytical and IR data of **1** have been previously communicated.[9c] Yield: 0.52 g (40%).

**Synthesis of $[\{Cu^{II}(tn)\}_2\{Fe^{II}(CN)_6\}]\cdot 4H_2O$ (2) and $[\{Cu^{II}(tnH)_2(H_2O)_2\}\{Fe^{II}(CN)_6\}]\cdot 2H_2O$ (3):** 1,3-Diaminopropane (1.0 mL, 12.0 mmol) was added under aerobic conditions to a concentrated aqueous solution (5 mL) of $CuCl_2\cdot 2H_2O$ (2.05 g, 12.0 mmol) with continuous stirring, leading to the immediate precipitation of a green powder. An aqueous solution of $Et_4NOH$ (0.52 g, 3.5 mmol) was then added with stirring and the resulting dark-blue solution was warmed (ca. 60 °C for about 5 min) and then filtered in order to remove the small amount of precipitate that remained. An aqueous solution (20 mL) of $(Et_4N)_3[Fe^{III}(CN)_6]$ (3.62 g, 6.0 mmol) was then added with continuous stirring. Slow concentration of the resulting solution at room temp. afforded prismatic black crystals of **2**, which were filtered and air-dried. Further evaporation afforded hexagonal dark green crystals of **3** after several weeks under aerobic conditions; these were filtered and air-dried.

**2:** Yield: 0.84 g (25%). $C_{12}H_{28}Cu_2FeN_{10}O_4$ (559.38): calcd. C 25.77, H 5.05, Cu 22.72, Fe 9.98, N 25.04; found C 25.68, H 5.02, Cu 22.61, Fe 9.85, N 25.13. IR: $\tilde{\nu}$ = 3588 m $cm^{-1}$, 3517 br, 3388 br, 3300 m, 3285 m, 3251 m, 3169 m, 2950 w, 2936 w, 2884 w, 2085 s, 2056 s, 1608 m, 1471 m, 1228 w, 1190 w, 1136 w, 1104 w, 1068 w, 1047 w, 1030 w, 667 br, 583 m, 462 br, 398 br.

**3:** Yield: 0.90 g (30%). $C_{12}H_{30}CuFeN_{10}O_4$ (497.82): calcd. C 28.95, H 6.07, Cu 12.76, Fe 11.22, N 28.14; found C 28.83, H 6.18, Cu 12.90, Fe 10.99, N 28.07. IR: $\tilde{\nu}$ = 3519 m $cm^{-1}$, 3384 br, 3277 s, 3235 s, 3166 m, 3014 br, 2979 m, 2888 m, 2819 m, 2705 w, 2613 w, 2526 w, 2492 w, 2095 s, 2060 s, 2032 s, 1685 w, 1660 w, 1618 w, 1604 m, 1497 m, 1477 w, 1411 w, 1335 w, 1242 w, 1214 m, 1144 w, 1102 w, 1062 w, 1038 w, 1004 w, 950 w, 754 m, 659 w, 584 m, 493 br, 419 w.

**Synthesis of $[\{Cu^{II}(tn)\}_3\{Cr^{III}(CN)_6\}_2]\cdot 3H_2O$ (4):** This compound was prepared as blue crystals by a procedure similar to that given below for **5**, from $(Et_4N)_3[Cr^{III}(CN)_6]$ (3.59 g, 6.0 mmol) instead of $(Et_4N)_3[Co^{III}(CN)_6]$. This procedure and analytical data have been previously communicated.[10d] Yield: 1.06 g (40%). IR: $\tilde{\nu}$ = 3627 m $cm^{-1}$, 3482 br, 3359 m, 3323 m, 3243 m, 3159 m, 2952 w, 2892 w, 2175 s, 2149 w, 2128 w, 1595 m, 1462 w, 1445 w, 1407 w, 1278 w, 1250 w, 1161 s, 1143 m, 1106 w, 1075 w, 1033 w, 1013 m, 914 m, 885 w, 677 w, 614 w, 493 s, 466 s, 378 m, 354 m.

**Synthesis of $[\{Cu^{II}(tn)\}_3\{Co^{III}(CN)_6\}_2]\cdot 3H_2O$ (5):** Under aerobic conditions, 1,3-diaminopropane (1.0 mL, 12.0 mmol) was slowly

[a] The asymmetric unit contains 0.5 of the chemical formula. [b] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [c] $R_w(F_o) = \{\Sigma[w(F_o - F_c)^2]/\Sigma[w(F_o)^2]\}^{1/2}$, $R_w(F_o^2) = wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. [d] GooF = $S = \{\Sigma[w(F_o^2 - F_c^2)^2]/(N_{obsd.} - N_{var})\}^{1/2}$.

added with stirring to a concentrated aqueous solution of $CuCl_2{\cdot}2H_2O$ (2.05 g, 12.0 mmol). A concentrated aqueous solution of NaOH (0.48 g, 12.0 mmol) was then added leading to a clear solution, which was boiled for five minutes and then filtered. An aqueous solution of $(Et_4N)_3[Co^{III}(CN)_6]$ (3.63 g, 6.0 mmol) was then added to the resulting blue filtrate. Slow concentration of this solution at room temp. afforded **5** as blue crystals, which were filtered and air dried. Yield: 1.48 g (55%). $C_{21}H_{36}Co_2Cu_3N_{18}O_3$ (897.13): calcd. C 28.11, H 4.04, Co 13.14, Cu 21.25, N 28.10; found C 27.98, H 4.22, Co 12.97, Cu 21.32, N 28.01. IR: $\tilde{\nu}$ = 3618 w cm$^{-1}$, 3466 br, 3366 m, 3321 m, 3232 m, 3154 m, 2953 w, 2892 w, 2175 s, 2135 m, 2125 w, 1586 m, 1458 w, 1447 w, 1407 w, 1278 w, 1259 w, 1162 s, 1143 w, 1109 w, 1077 w, 1036 w, 1013 m, 913 m, 885 w, 681 w, 668 w, 493 s, 463 s, 447 m, 433 m, 418 br.

**X-ray Crystallography:** Data for **2** were collected on an Xcalibur 1 diffractometer (Oxford Diffraction) at 180 K whereas the data for all other compounds were collected at 288 K on an Xcalibur 2 Diffractometer (Oxford Diffraction). The structures were solved by direct methods and successive Fourier difference syntheses, and were refined on $F^2$ by weighted anisotropic full-matrix least-squares methods.[30] The crystal used for compound **2** presented a pseudo-merohedral twinning with a monoclinic cell having a $\beta$ angle of nearly 90°, which emulates an orthorhombic cell with possible space group $Pmn2_1$. The structure was solved and refined using the $P2_1/n$ monoclinic space and the following twinning law: 1 0 0 0 –1 0 0 0 –1. The two components were in the ratio 0.53/0.46, which explains the pseudo-orthorhombic symmetry.

The hydrogen atoms of **1**, **2**, **4**, and **5** were calculated [$d$(C–H) = 0.95 Å], except for the hydrogen atoms of the water molecules of **1**, **4**, and **5**; the thermal parameters were taken as $U_{iso} = 1.3\,U_{equ}$(C) and therefore included as isotropic fixed contributors to $F_c$. For compound **3**, all hydrogen atoms were located in the difference Fourier map and were refined isotropically. Scattering factors and corrections for anomalous dispersion were taken from the International Tables for X-ray Crystallography.[31] The thermal ellipsoid drawings were made with the ORTEP program.[32] All calculations were performed on an Alphastation 255 4/233 computer. Pertinent crystallographic data and structural refinement parameters are listed in Table 5. CCDC-175834, -274145, -275481, -175842, and -275482 (for **1**–**5**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Copper(I) Complexes with a $Cu_4S_6$- and $CuS_4$-Type Core Obtained from the Reaction of Copper(0) with $HN(SPPh_2)_2 \cdot I_2$

**M. Carla Aragoni,[a] Massimiliano Arca,[a] M. Bonaria Carrea,[a] Francesco Demartin,[b] Francesco A. Devillanova,[a] Alessandra Garau,[a] Michael B. Hursthouse,[c] Susanne L. Huth,[c] Francesco Isaia,*[a] Vito Lippolis,[a] Helen R. Ogilvie,[c] and Gaetano Verani[a]**

**Keywords:** Cluster compounds / Copper / Coordination chemistry / Phosphanes / S ligands

The copper(I) compounds $[Cu^I_4(L)_3]I_3$ (**1**) and $[Cu^I(HL)_2]I_3 \cdot CH_3CN$ (**2**) [HL = $HN(SPPh_2)_2$] have been obtained from the reaction of the adduct $HL \cdot I_2$ with copper(0) powder in diethyl ether solution. Compound **1** contains a tetrahedron of Cu atoms with three anionic L ligands coordinated to the coppers through the sulfur atoms to build a $Cu_4S_6$ core. The mean Cu–Cu and Cu–S bond lengths related to the $Cu_4S_6$ core in copper-loaded transcription factors CuAce1 and CuMac1, and in the model compound $[Cu_4(SPh)_6]^{2-}$, have been compared with those of the $[Cu_4(L)_3]^+$ cation, and the geometric volumes of the $Cu_4$ cores have been evaluated. The results suggest that the cation $[Cu_4(L)_3]^+$ is a possible structural model compound for the metal site in Ace1 and Mac1 transcription factors. In compound **2**, two neutral HL ligands bind a $Cu^I$ ion in an *S*,*S*′-isobidentate chelating fashion to form a slightly distorted tetrahedral $CuS_4$ core. The $^{31}P$ NMR spectroscopic data of compound **1** are consistent with the maintenance of its structure in solution. Moreover, phosphorus variable-temperature measurements indicate a change from a two-spin coupled AB system at 0 °C to an $A_2$ spin system at 40 °C. The reaction of $[Cu_4(L)_3]^+$ with HI, monitored by $^{31}P$ NMR spectroscopy, leads to the protonation of the complexed ligands at the $Cu_4$ core and formation of the cation $[Cu_4(HL)_3]^{4+}$. The protonation reaction is reversible: increasing the amount of organic base 1,8-bis(dimethylamino)naphthalene (DMAN) regenerates the starting cation $[Cu_4(L)_3]^+$.

## Introduction

The tetraphenyldithioimidodiphosphanic acid ligand HL, and its deprotonated derivative L, have been extensively used in coordination chemistry[1] since they feature a flexible SPNPS skeleton along with a large S···S bite that enables the formation of an unstressed six-membered, MSPNPS chelate ring with a great variety of metal ions.[1] A literature survey reveals that there have been some studies on the reaction of L with $Cu^{II}$ salts, and these have led to the synthesis of complexes $[Cu^{I,II}_3L_4]$, $[Cu^I_3L_3]$, $[Cu^I_4L_3][Cu^ICl_2] \cdot CCl_4$[2a] and, more recently, $[Cu^I_4L_3][BF_4]$.[2b] Furthermore, the ability of L to form a tetrahedral $CuS_4$ core with the $Cu^{II}$ ion has been used by Bereman et al.[3] to propose the complex $[Cu(L)_2]$ as a potential model for type-I $Cu^{II}$ sites in metalloenzymes; unfortunately, the complex was not stable for more than a few days at room temperature, either in the solid state or in solution, due to autoreduction to $Cu^I$. Recently, Woollins et al. have described three other complexes of general stoichiometry $[Cu^I_3D_3]$ (D = $[N(SPiPr_2)_2]^-$, $[N(SPiPr_2)(SPPh_2)_2]^-$ and $[N\{SP(EtO)_2\}\{SP(OPh_2)\}_2]^-$) obtained from the reaction of either $Cu^{II}$ or $Cu^I$ ions with the corresponding anionic ligand D.[4] The X-ray crystal structures of these complexes revealed that the molecules contain a six-membered $Cu^I_3S_3$ ring in their core, with each copper atom being tricoordinate in an approximately trigonal geometry resulting from the coordination of one terminal and two bridging S-donors.

The $Cu^I_xS_y$ cores[5] may be of interest as structural model compounds for the active-sites in copper(I)-containing enzymes and proteins, which are far less known or studied than the copper(II) analogues. For example, the $Cu^I_4S_6$ core is currently generating great interest since two copper-regulated transcription factors central to yeast copper homeostasis, Ace1 and Mac1, in *Saccharomyces cerevisiae*, have revealed the presence of a remarkably similar polycopper cluster in these two proteins.[6]

In this paper, we have delved into the synthesis of new copper complexes of HL and/or L using the well-tested route based on the iodine adduct of HL, $HL \cdot I_2$, as oxidising/complexing agent towards metal(0) powders. In fact,

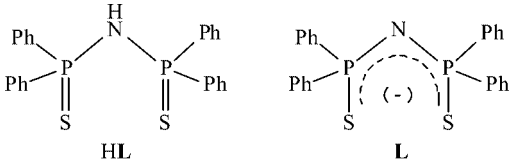
this kind of reaction has proved to be an interesting and promising synthetic route, as it has often led to the preparation of complexes with unusual stoichiometries and geometrical features.[7] The reaction between the $HL{\cdot}I_2$ adduct and copper(0) powder has been investigated, and the X-ray crystal structures of complexes $[Cu_4(L)_3]I_3$ (**1**) and $[Cu(HL)_2]I_3{\cdot}CH_3CN$ (**2**) are reported. The $Cu^I_4S_6$ core in complex **1** has been studied by solid-state $^{31}P$ NMR spectroscopy and solution variable-temperature NMR spectroscopy as well. The results, along with the structural data, suggest that $[Cu_4(L)_3]^+$ is a possible structural model compound for the metal site in Ace1 and Mac1 transcription factors. The reactivity of complex **1** to form the cationic complex $[Cu^I_4(HL)_3]^{4+}$ has also been evaluated as a dependence on the acid/base behaviour of the metal-complexed ligands L and HL (Scheme 1).



Scheme 1.

## Results and Discussion

### Syntheses and Crystal Structures of $[Cu^I_4(L)_3]I_3$ (1) and $[Cu^I(HL)_2]I_3{\cdot}MeCN$ (2)

The reaction between the adduct $HL{\cdot}I_2$ and Cu powder (1:1 molar ratio) was carried out in diethyl ether at room temperature for two days. During this time the dark-red colour of the mixture turned to pale-orange with separation of an orange powder. $^{31}P$ NMR spectroscopic analysis of the solution after two days indicated that the reaction was quantitative since no signal related to HL was detectable. The $^{31}P$ MAS NMR spectrum of the solid remaining after removal of the solvent revealed resonances at $\delta$ = 52.4, 32.9, 31.4, 30.4, 28.9 and 26.6 ppm, which are indicative of the presence of metal-complexed ligands both in their protonated, HL, and deprotonated, L, forms. Resonances in two specific ranges of the spectrum, namely $\delta$ = 60–50 and 40–20 ppm, can be considered highly diagnostic in identifying the species HL and L, respectively.[8] Treatment of the crude precipitate with $CHCl_3$ caused a partial dissolution of the solid; after slow evaporation of the solvent, orange crystals of stoichiometry $[Cu^I_4(L)_3]I_3$ (**1**) were isolated. The remaining crude precipitate was then dissolved in MeCN to produce orange crystals of $[Cu^I(HL)_2]I_3{\cdot}MeCN$ (**2**) on slow evaporation of the solvent. From the $^{31}P$ MAS NMR resonances of compounds **1** and **2** it was possible to confirm that both copper complexes are present in the orange powder separated from the ethereal reaction solution. The separation of the two complexes is, therefore, attributable to their markedly different solubility in the solvents employed. The structure of the cation of **1** has been reported before as its $CuCl_2$ and $BF_4$ salts; however, it was re-determined, and is briefly reported here, to provide a solid basis for the interpretation of the $^{31}P$ NMR measurements.

Compound **1** consists of discrete $[Cu^I_4(L)_3]^+$ cations and $I_3^-$ anions separated by normal van der Waals contacts. The molecular structure of the cation $[Cu^I_4(L)_3]^+$ is shown in Figure 1, while selected bond parameters are reported in Table 1. The cation consists of a tetrahedron of copper(I) atoms surrounded by three didentate L ligands coordinated to the copper atoms through the sulfur atoms. The arrangement of the ligands around the metal core resembles that found in $[Cu^I_4(L)_3]^+[CuCl_2]^-{\cdot}CCl_4$ (**3**),[2a] i.e. it conforms to a pseudo-trigonal idealised symmetry, with the threefold symmetry axis passing through the unique Cu(4) and the mid-point of the three remaining copper atoms (Figure 1). One sulfur atom of each ligand binds the Cu(4) atom and one of the three remaining copper atoms [Cu(1), Cu(2) and Cu(3)], while the second sulfur atom binds a couple of copper atoms of the basal plane. Thus, each copper of the basal plane is coordinated by two S atoms of the same ligand and by the sulfur atom of a different ligand. The distances of the unique Cu(4) atom to the remaining copper atoms are, on average, slightly shorter than those found between the other couples of copper atoms (2.787 vs. 2.812 Å). These values compare well with those found in the analogous complex **3** (mean values of 2.777 vs. 2.806 Å), although significant variations in the single copper–copper distances are observed in the two compounds due to local packing effects associated with different counteranions and with the presence of a solvent molecule. In **3**, the Cu–S bond lengths involving the unique Cu(4) atoms are not significantly different from each other and range from 2.257 to 2.278 Å. This range is wider in **1** (2.256–2.291 Å), with the larger Cu–S bonds being those with Cu(4). Very small changes are observed in the P–S and P–N bonds of the two compounds,

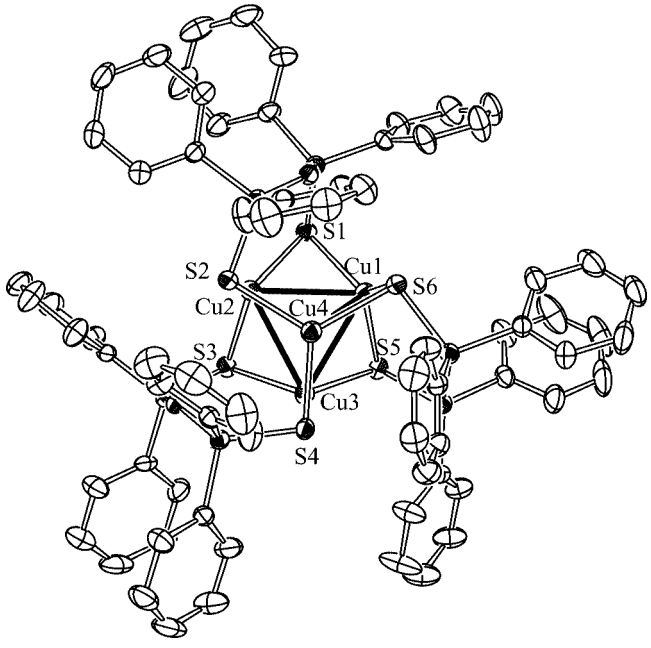


Figure 1. ORTEP drawing of the $[Cu_4(L)_3]^+$ complex cation of **1**. Thermal ellipsoids are drawn at 30% probability.

while a significant increase in the P–N–P angle occurs on passing from **1** to **3** (133.5° and 138.0°, respectively). The triiodide anion is slightly asymmetric and almost linear [174.60(2)°], and no I···I contacts between different anions are observed.

The molecular structure of $[Cu^{I}(HL)_2]I_3$·MeCN (**2**) is shown in Figure 2 and selected bond lengths and angles are collected in Table 2. In the complex cation $[Cu^{I}(HL)_2]^+$ the copper is coordinated by two neutral HL ligands in an *S*,*S*′-isobidentate chelating fashion, resulting in the formation of two six-membered $CuS_2P_2N$ rings; the charge is balanced by a slightly asymmetric $I_3^-$ ion. One solvent molecule (MeCN) per formula unit is also present in the structure, giving rise to weak hydrogen bonding with an imido group [N(2)–H(N2)···N(3) = 2.925 Å; N(2)–H···N(3) = 166.63°]. The $[Cu^{I}(HL)_2]^+$ cation contains a slightly distorted tetrahedral $CuS_4$ core, with S–Cu–S angles ranging from 101.10(8)° to 117.92(8)°. The four Cu–S interatomic distances are slightly different and range from 2.338(2) [Cu(1)–S(3)] to 2.376 Å [Cu(1)–S(2)]. The CuSPNPS metallacycles display a pseudo-boat conformation with a P and an S atom of the ring acting as the stern and bow of the boat,

respectively. As a result of metal complexation, some degree of π-electron delocalisation over the [Cu(SP)$_2$N] ring can be recognised from the slight increase in P–S bond lengths: from 1.937(1)–1.950(1) Å in the free ligand[9] to 1.959(3)–1.963(3) Å in **2**. Conversely, the P–N bond lengths remain substantially similar to those found in free HL [HL:[9] 1.672(2)–1.683(2) Å; **2**: 1.666(7)–1.689(6) Å].

### Solution and Solid-State $^{31}$P NMR Spectroscopy

The solid-state $^{31}$P NMR spectrum of complex **1** shows resonances at $\delta$ = 32.9 ($\Delta\nu$½ = 168 Hz), 31.4 ($\Delta\nu$½ = 134 Hz), 30.4 ($\Delta\nu$½ = 159 Hz), 28.9 ($\Delta\nu$½ = 183 Hz) and 26.6 ppm ($\Delta\nu$½ = 213 Hz), indicative of different crystallographically independent phosphorus atoms in the complex. Conversely, complex **2** shows the presence of a single resonance at $\delta$ = 52.4 ppm with a spectral line-width of 410 Hz, suggesting that the phosphorus atoms in the asymmetric unit have a closely similar environment. The variable-temperature $^{31}$P NMR spectra of **1** in $CHCl_3$ are shown in Figure 3. The spectrum recorded at 25 °C shows two distinct signals ($\delta$ = 28.5 and 28.1 ppm) with an intensity ratio of 1:1, also consistent with the maintenance of the solid structure in solution. (For $[Cu^I_4L_3][BF_4]$ in $CD_3CN$, a single broad peak at $\delta$ = 27.05 ppm has been reported, although no temperature is given).[2b] As the temperature of the solution is lowered from 25 °C to 0 °C, the $^{31}$P NMR spectra reveal two interesting spin-coupled doublets (AB system) with a $^2J_{P,P}$ coupling constant of 11.0 Hz; the spectrum at –40 °C shows that this coupling constant is temperature-invariant. The appearance of two spin-coupled doublets confirms that both phosphorus resonances are from the same complex molecule rather than from different isomers present in solution, and that the most likely explanation for this observation is the stabilisation of a conformer of the $CuS_2P_2N$ rings. As the temperature of the solution is increased to 37.5 °C, the two well-separated resonances at $\delta$ = 28.5 and 28.1 ppm coalesce ($k_{coal}$ = 126 s$^{-1}$),[10] and at 40 °C, the highest temperature reached, the phosphorus atoms become equivalent and the spectrum degenerates to an $A_2$ system. At this point, a fast exchange process on the NMR timescale makes the four copper atoms equivalent. The dynamic process that averages the phosphorus NMR resonances seems to be non-dissociative, since the reaction of **1** with HL, or with the mixed sulfur/oxygen ligand HN(SPPh$_2$)(OPPh$_2$), in the 25–40 °C ($CHCl_3$) range results in no ligand exchange. Moreover, the conductivity measured in $CHCl_3$ does not show changes in the range 25–40 °C.

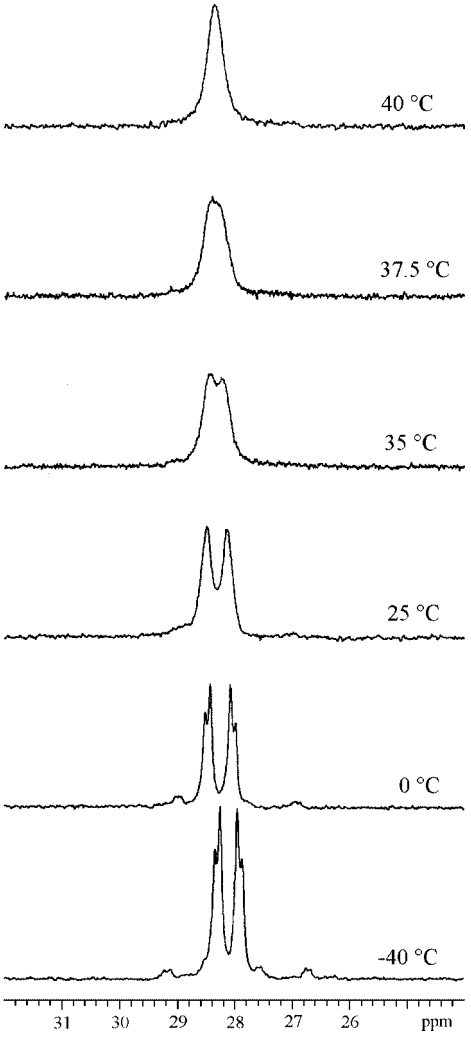

Figure 3. Variable-temperature $^{31}$P NMR spectra of complex **1** ($1.0\times10^{-2}$ M, $CDCl_3$).

### Reactivity of the $[Cu_4(L)_3]^+$ Cluster

Several studies have demonstrated that Cu activation of Ace1 and Mac1 involves formation of a tetracopper cluster within the Cu-regulatory domain. EXAFS data for CuAce1 and CuMac1[6b] suggests the presence of a distorted tetranuclear copper cluster; the $Cu^I$ ions are trigonally coordinated with Cu–S distances of about 2.25 Å and a Cu–Cu distance of 2.7 and 2.9 Å when two different Cu···Cu interactions were considered (Table 3). In this context, the $Cu_4S_6$ core in the cation $[Cu_4(L)_3]^+$ might represent a useful model compound for the metal centres in CuAce1 and CuMac1, since the mean Cu–S and Cu–Cu bond lengths (Table 3) compare well with those reported for these clusters. Moreover, unlike the copper thiolate model compound[11] $[Cu_4(SPh)_6]^{2-}$, in which the $Cu^I$ ions are chemically equivalent, the cation $[Cu_4(L)_3]^+$ contains two chemically different sets of $Cu^I$ ions [Cu(1)/Cu(2)/Cu(3) and Cu(4), respectively] that might structurally better represent the distorted tetracopper cluster within the Cu-regulatory domain. Although the two ionic complexes $[Cu_4(L)_3]^+$ and $[Cu_4(SPh)_6]^{2-}$ feature the same $Cu_4S_6$ core type, a significant difference in the "volume" of the $Cu_4$ cages is calculated from the mean Cu···Cu bond lengths (Table 3). Interestingly, the $Cu_4$ volume in the CuAce1 and CuMac1 transcriptions factors proves to be intermediate between those found in the ionic model compounds. The possibility of the $Cu_4$ cluster expanding or contracting as a result of the nature of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ligands forming the $Cu_4S_6$ cores and of the charge transferred by the ligands upon it seems to be a peculiar characteristic of this species.

Table 3. Mean Cu–Cu and Cu–S bond lengths in selected copper complexes with a $Cu_4S_6$ core, and $Cu_4$ cluster volume.

| Sample | Interaction | $N$[a] | Interatomic distances [Å] | $Cu_4$ volume[b] [Å$^3$] |
|---|---|---|---|---|

[f] Interatomic distance calculated as the mean of the Cu(1)–Cu(4), Cu(2)–Cu(4) and Cu(3)–Cu(4) bond lengths. [g] Value calculated as the mean of all Cu–S bond lengths. [h] Data from ref.[11] [i] Value calculated as the mean value of all Cu–Cu bond lengths. [j] Value calculated as the mean value of all Cu–S bond lengths.

Dance et al.[5,6c] have reported on the stability of $Cu^I$ tetracopper $Cu_4S_6$ clusters with small thiolate ligands and have shown that the clusters are held together by bridging thiolates and that the Cu···Cu bonding is a minor energetic factor in the stability of the clusters. In this regard, since both ligands L and HL can act as chelating agents towards a copper(I) ion, although a substantial difference in nucleophilicity is to be taken into account,[12] we thought of verifying the ability of the $Cu_4$ core to remain stable even if coordinated by a set of neutral HL ligands.

The treatment of **1** with the acid HI (55 wt.-% in water) in a mixture of MeCN and $CDCl_3$ (1:10 v:v) at 25 °C until a 1:2.8 molar ratio was reached resulted in a considerable change in the $^{31}P$ NMR spectrum of the complex (Figure 4a–d): the two distinct signals of **1** at $\delta$ = 28.5 and 28.1 ppm are lower in intensity, while a new signal at low-field ($\delta$ = 52.9 ppm) increases with the amount of HI. The latter value is strongly indicative of the formation of a new complex with all the ligands in their *N*-protonated form; interestingly, no other resonances due to copper complexes bearing L and HL ligands at the same time were detected for any molar ratio of the reagents used. Values for the $\delta$(*P*S) in the 60–50 ppm range have, in fact, been observed previously in the neutral complexes $[Pd(HL)I_2]$[13] [$\delta$(*P*S) = 56.5 ppm (MeCN/$CHCl_3$, 1:1 v:v) and $[Hg(HL)I_2]$[14] [$\delta$(*P*S) = 57.8 ppm, $CH_2Cl_2$]. To rule out that ligand protonation has caused the dismantling of the $Cu_4$ core, we also verified that the protonation reaction is reversible. The reaction of the acidic mixture with a strong base like 1,8-bis(dimethylamino)naphthalene (DMAN) causes the deprotonation of the coordinated ligands and the regeneration of the cation $[Cu_4(L)_3]^+$, as shown by the $^{31}P$ NMR peaks at $\delta$ = 28.5 and 28.1 ppm. (Figure 4, e and f). The overall reactions involving the protonation/deprotonation of the ligands in the cationic complexes $[Cu_4(L)_3]^+$ and $[Cu_4(HL)_3]^{4+}$ are summarised in Scheme 2.

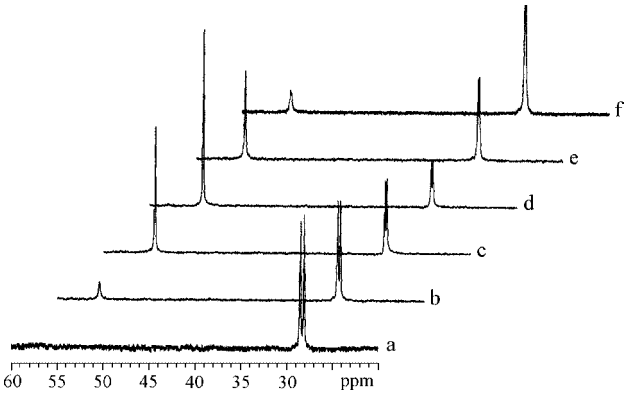

Figure 4. $^{31}P$ NMR spectra of (a) **1** ($3.4\times10^{-3}$ M); (b), (c), and (d) solution of **1** after the addition of HI to realise **1**/HI molar ratios of 1:1, 1:2 and 1:2.8, respectively; (e) the solution of (d) after addition of DMAN (**1**/HI/DMAN = 1:2.8:0.65); (f) the solution from (e) after addition of more DMAN (**1**/HI/DMAN, 1:2.8:1.3), all in MeCN/$CDCl_3$ (1:10 v:v) at 25 °C.

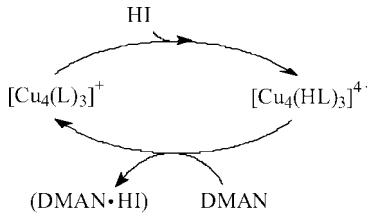

Scheme 2.

Although we were not able to isolate any solid compound from the reaction of **1** with HI, the reported results point to the ability of the $Cu_4$ cluster to be stabilised by neutral and anionic ligands.

## Conclusions

The reaction of the adduct $HL{\cdot}I_2$ with copper(0) powder under mild conditions affords complexes $[Cu^I_4(L)_3]I_3$ (**1**) and $[Cu^I(HL)_2]I_3{\cdot}CH_3CN$ (**2**). The latter compound represents a rare example of a structurally characterised complex of HL. To the best of our knowledge, only two other complexes are known in the literature, namely $[Hg(HL)I_2]$[14] and $[Ag(HL)_2BF_4]$[2b]. The copper(I) ion is coordinated by two neutral HL ligands in an *S*,*S*′-isobidentate chelating fashion to give a $CuS_4$ core. Compound **1** features a distorted tetrahedral $Cu_4$ cluster encapsulated by three bidentate anionic L ligands where only three of the four copper atoms of the $Cu_4S_6$ core are chemically equivalent. $^{31}P$ NMR variable-temperature measurements have confirmed that the solid structure is retained in solution and highlight a fast exchange process that makes all coppers equivalent ($T_{coal}$ = 37.5 °C). Interestingly, the $Cu_4S_6$ core in the cation $[Cu^I_4(L)_3]^+$ might be considered as a new structural model

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compound for the distorted tetranuclear copper(I) cluster within the Cu-regulatory domain in proteins Ace1 and Mac1. Moreover, it constitutes a valid alternative to the higher symmetric $Cu_4S_6$ core found in the anionic copper thiolate compound $[Cu_4(SPh)_6]^{2-}$. A comparison of the "volume" of the $Cu_4$ cluster in **1** and in the anion $[Cu_4(SPh)_6]^{2-}$ reveals a significant difference that can be related to the different set and charge of the ligands complexing the $Cu_4$ unit. The stability of the $Cu_4S_6$ core in the species $[Cu_4(HL)_3]^{4+}$, obtained from the reaction of **1** with HI, was also established by $^{31}P$ NMR measurements. The expansion/contraction of the $Cu_4$ cluster may be important as regards the activation of Ace1 and Mac1 transcription factors. The electronic charge-modulation by cysteinyl residues at the metal sites in the proteins might reasonably act as a regulating device in building up, modifying or dismantling the $Cu_4$ cluster structural unit.[6b,15]

## Experimental Section

**Materials and Instrumentation:** Reagents were used as purchased from Aldrich. Diethyl ether was distilled from over $LiAlH_4$ shortly before use. Hydroiodic acid: ACS reagent, 55 wt.-% in water. $^{31}P\{^1H\}$ NMR spectra were recorded with a Varian Unity Inova 400 spectrometer operating at 161.9 MHz. The $^{31}P$ chemical shifts are referenced to an external standard of $H_3PO_4$ 85% peak ($\delta$ = 0.0 ppm). Variable-temperature $^{31}P$ NMR spectroscopic data for compound **1** were collected for a $1.0\times10^{-2}$ M solution in $CHCl_3$. $^{31}P$ MAS NMR spectra were calibrated indirectly through the $H_3PO_4$ 85% peak ($\delta$ = 0.0 ppm). IR spectra were measured as KBr (4000–400 $cm^{-1}$) or polyethylene pellets (400–50 $cm^{-1}$) on a Bruker IFS 55 FT-IR spectrometer. FT-Raman spectra were measured as solid samples on a Bruker IFS 100 spectrometer. Conductometric measurements on compound **1** ($1.0\times10^{-3}$ M in $CHCl_3$) were carried out at 20, 30 and 40 °C.

**Synthesis:** Compound HL was prepared according to ref.[16] The adduct $HL{\cdot}I_2$ was prepared in situ in freshly distilled $Et_2O$ from equimolar amounts of HL and $I_2$.

**$[Cu_4(L)_3]I_3$ (1):** A mixture of HL (0.100 g, 0.222 mmol) and $I_2$ (0.0565 g, 0.223 mmol) in $Et_2O$ (100 mL) was stirred at room temperature until complete dissolution of the reagents. Copper powder (submicron; 0.0141 g, 0.226 mmol) was then added while stirring and the mixture was allowed to react at room temperature for about 2 days. The resulting air-stable orange solid (149 mg) was isolated by suction filtration, then treated with 10 mL of $CHCl_3$ for 1 h. The mixture was filtered, and the resulting solution evaporated to dryness to give 0.100 g of **1** ($5.05\times10^{-2}$ mmol; yield 89%, based on metal). $C_{72}H_{60}Cu_4I_3N_3P_6S_6$ (1980.3): calcd. C 43.67, H 3.05, N 2.12, S 9.71; found C 44.0, H 3.1, N 2.0, S 9.6. FT-IR (KBr): $\tilde{\nu}$ = 3435 $cm^{-1}$ br. m, 3118 br. m, 3054 m, 1587 w, 1572 w, 1479 s, 1436 w, 1288 ms, 1106 vs, 1026 w, 998 w, 900 s, 788 s, 735 vs, 721 ms, 687 s, 636 m, 613 ms, 551 vs, 528 ms, 495 m, 413 w. FT-Raman (500–50 $cm^{-1}$): $\tilde{\nu}$ = 114 $cm^{-1}$. $^{31}P$ NMR ($CHCl_3$, 25 °C): $\delta$ = 28.5 and 28.1 ppm.

**$[Cu(HL)_2]I_3{\cdot}MeCN$ (2):** A mixture of HL (0.100 g, 0.222 mmol) and $I_2$ (0.0565 g, 0.223 mmol) in $Et_2O$ (100 mL) was stirred at room temperature until complete dissolution of the reagents. Copper powder (submicron; 0.0141 g, 0.226 mmol) was then added while stirring and the mixture was allowed to react at room temperature for about 2 days. The resulting air-stable orange solid was isolated by suction filtration, then treated with 10 mL of $CHCl_3$ for 1 h. The mixture was filtered, the separated solid compound washed with $CHCl_3$ and then dissolved in $CH_3CN$ (5 mL); slow evaporation of the solution afforded orange crystals of **2** (0.030 g, $2.08\times10^{-2}$ mmol; yield 10%, based on metal). $C_{50}H_{45}CuI_3N_3P_4S_4$ (1348.3): calcd. C 43.38, H 3.28, N 3.04, S 9.26; found C 43.5, H 3.2, N 3.1, S 9.0. FT-IR (KBr): $\tilde{\nu}$ = 3435 $cm^{-1}$ br. vs, 3052 w, 1477 m, 1435 vs, 1385 m, 1205 vs, 1177 s, 1106 vs, 1026 w, 998 w, 913 w, 874 w, 743 m, 721 m, 693 vs, 550 vs, 531 m, 493 m, 414 w. FT-Raman (500–50 $cm^{-1}$): $\tilde{\nu}$ = 135 $cm^{-1}$ (2.8), 112 (10), 79br (1.6) (relative intensities in parentheses, highest value: 10). $^{31}P$ NMR (MeCN): $\delta$ = 52.9 ppm.

**X-ray Crystallography:** Crystal data and details of the refinement for compounds **1** and **2** are reported in Table 4. Diffraction data were collected on a Bruker SMART CCD diffractometer at room temperature for compound **1** and at 120(2) K on a Bruker–Nonius area-detector diffractometer for compound **2**, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Cell parameters and orientation matrix were obtained from least-squares refinement of reflections measured in the range $2.23 < \theta < 22.41°$ for **1** and $2.91 < \theta < 27.48°$ for **2**. An absorption correction was applied using the SADABS routine[17] for **1** and the SORTAV algorithm[18] for **2**. The structures were solved by direct methods and refined on $F^2$ by using the SHELX[19] program implemented in the WinGX suite.[20] Anisotropic displacement parameters were assigned to all non-hydrogen atoms. Hydrogen atoms were included in the structure using the riding model.

# Preparation of Semiconductor/Polymer Coaxial Nanocables by a Facile Solution Process

**Shenglin Xiong,[b] Linfeng Fei,[a] Zhenghua Wang,[b] Hong Yang Zhou,[b] Weizhi Wang,[b] and Yitai Qian*[a,b]**

**Keywords:** Hydrothermal synthesis / Nanostructures / Photoluminescence / Semiconductors / Tellurium

We report on the preparation of ultralong semiconductor tellurium/cross-linked PVA coaxial nanocables with a core 20–30 nm in diameter and a surrounding sheath about 5–20 nm in thickness by a simple hydrothermal process. The length of these nanocables can be up to 500–800 μm. In the present synthesis PVA was used as the reducing agent to react with $Na_2TeO_3$, and it also serves as the capping reagent and the source of the sheaths. The synergistic effects of the interaction of cross-linked PVA with the tellurium nanowires could play an important role in the formation of the morphology of the resulting products.

## Introduction

Nanomaterials with a core/sheath structure as another new type of one-dimensional nanostructures have, in recent years, been attracting more and more interest since these heterostructured nanostructures are constructed of cores and shells of different chemical compositions, which could further improve their functions by the preparation of the core and sheath from different materials.[1–5] In particular, coaxial nanocables with a wire/sheath structure are a kind of potentially useful 1D nanostructure. Recently, some methods have been developed to synthesize nanocables having coaxial structures. For example, $Si/SiO_2$ nanocables and three-layered nanocables consisting of silicon carbide (SiC) cores, amorphous silica intermediate layers, and sheaths of boron nitride and carbon (BNC) have been prepared by a laser ablation method,[6] and a $\beta$-$SiC/SiO_2$ nanocable has been obtained by a carbothermal reduction method.[7] In addition, several solution-based methods have also been developed to generate polymer/polymer, semiconductor/polymer, and metal/polymer nanocables at relatively low temperatures. For instance, polypyrrole/poly(methyl methacrylate) coaxial nanocables have been synthesized by sequential polymerization of monomers within the channels of mesoporous silica, followed by dissolution of the template.[8] CdSe/poly(vinyl acetate) hybrid nanocables have been obtained by growing the semiconductor nanowires inside polymer tubules.[9] Gold nanorods have recently been coated with polystyrene or silica to form cable-like structures,[10] and layer-by-layer deposition of oppositely charged species on nickel nanorods has been adopted to prepare nickel/composite nanocable structures.[11] $Ag/SiO_2$ nanocables can be formed by using a sol–gel method to coat Ag nanowires with amorphous silica,[12] and silver/carbon nanocables can be synthesized by a hydrothermal carbonization co-reduction (HCCR) technique.[13] Very recently, a one-step synthesis of silver/cross-linked PVA nanocables by in situ reduction of $Ag^+$ and $Ag^+$-catalyzed cross-linking of PVA chains under hydrothermal conditions inspired us to evaluate whether such a simple route can be applied to semiconductor/polymer nanocables.[14] Our experimental results are in good agreement with our expectations.

Based on the above idea and strategy, we successfully synthesized ultralong and uniform semiconductor tellurium/polymer nanocables with a 25–35 nm core and 30–40 nm diameter sheath and lengths of 500–800 μm by a facile hydrothermal reduction process using PVA and $Na_2TeO_3$ as starting material at relatively low temperature via a solid solution-solid transformation and the synergistic soft–hard template mechanism. Surprisingly, we found that the aspect ratio of the nanocables with semiconductor tellurium as core and polymer as shell is between 10 and 20000, which may stem mainly from their geometry-dependent properties, and may suggest their use as attractive basic building blocks that can be applied in a variety of applications.[15] In addition, an interesting feature of some nanocables is their tendency to entangle with each other to form raft-like cable bundles in a parallel fashion. The mechanism of formation of these tellurium nanostructures is discussed. To the best of our knowledge, the synthesis of flexible tellurium/poly-

mer nanocables has not yet been reported. Meanwhile, this synthetic method may be applied to the fabrication of other semiconductor/polymer nanostructures.

## Results and Discussions

The panoramic morphology of tellurium was observed by field-emission scanning electron microscopy (FESEM), in which the solid samples were mounted on a copper mesh without any dispersion treatment. Parts a and b in Figure 1 show that the final product is composed of nanowires in high yields (close to 100%), with lengths up to 500–800 μm and a uniform morphology. Higher magnification FSEM images (Figure 1, b) indicate that the average diameter of an individual nanowire is about 25–35 nm. TEM images (Figure 1, c–e) reveal that all wires are actually a composite comprised of a smooth core about 25–35 nm in diameter and a surrounding sheath about 5–10 nm in thickness, from which the contrast between surrounding polymer and inner core can be easily observed. One can see that the sheath has a relatively uniform thickness over the entire surface of each nanowire, including both ends, as shown in Figure 1 (c–e). FESEM and TEM both demonstrate that some bundles of cables are formed, and each bundle is composed of several nanocables packed in a parallel fashion (Figure 1, b–d). More-detailed TEM observations revealed that the nanocables structures have a closed end, as shown in Figure 1, e. It is clear that the uniformity in lateral dimension, the level of perfection, and the richness in quantity are obviously due to a good growth environment for the tellurium nanostructures in the current system (see part a in Figure 1).

The as-obtained samples were also examined by XRD (Figure 2). All the reflection peaks in a $2\theta$ range from 20° to 70° can be readily identified with the hexagonal phase of tellurium, with calculated lattice parameters $a$ = 4.457 and $c$ = 5.927 Å, which shows good consistency with the reported data (JCPDS 36-1452).

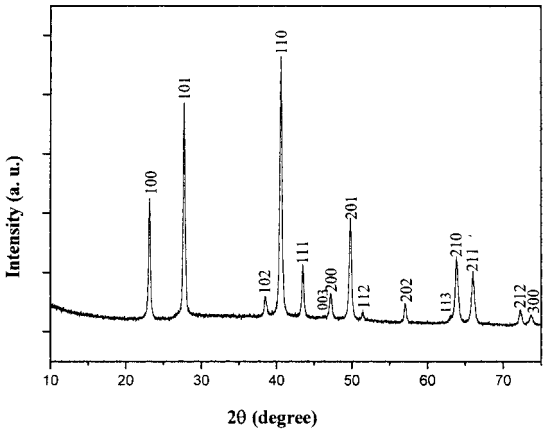

Figure 2. XRD patterns of the nanocables obtained at 180 °C for 24 h.

Further evidence for the surface composition of the samples was obtained from the X-ray photoelectron spectra of the products. The results are shown in Figure 3. The spectra of the nanocables show two strong peaks at 284.60 and 532.10 eV corresponding to the C 1s and O 1s binding energies of the obtained sample, respectively. However, the binding energy at 573.6 and 583.8 eV for $Te^0$ $3d_{5/2}$ and $3d_{3/2}$, respectively, are quite weak and almost cannot be detected. These XPS results confirm that the tellurium nanowires are confined within shells of the cross-linked PVA. The IR spectrum for the as-obtained nanocables is shown in Figure 4. Several absorption peaks located at about 3449, 2923, and 1461 $cm^{-1}$ in Figure 4 correspond to the O–H stretching vibration [ν(O–H)], the C–H stretching vibration [ν(C–H)], and the C–H bending vibration [δ(C–H)], respectively, as in the IR spectrum of pure PVA, while the wide absorption peak at about 1097 $cm^{-1}$ can be assigned to the $\nu_{as}$(C–O–

C) absorption of cross-linked PVA. These results confirm that coating of the tellurium nanowires with cross-linked PVA has been achieved using the current hydrothermal method.

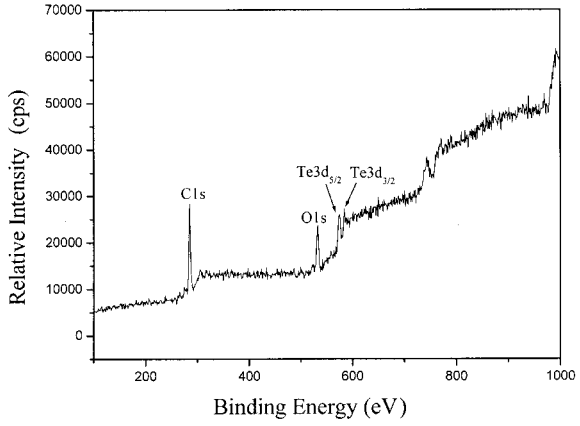

Figure 3. XPS spectrum of the nanocables obtained at 180 °C for 24 h.

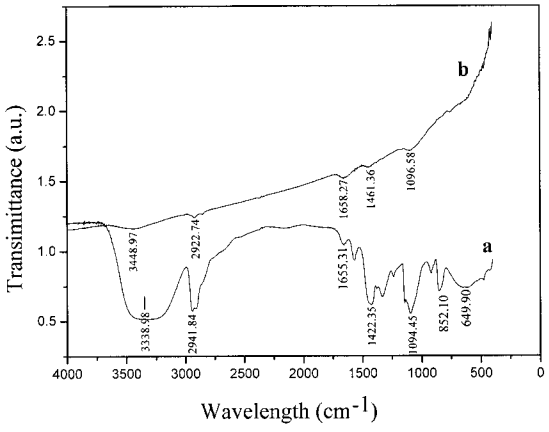

Figure 4. FTIR spectra: (a) pure PVA; (b) the nanocables obtained after reaction at 180 °C for 24 h.

The structure and morphology of the as-obtained nanocables were further observed by high-resolution TEM (HRTEM) and selected-area electron diffraction (SAED), in which the sample was treated by ultrasonic dispersion in ethanol for 15 min and then put onto a copper mesh. Figure 5 (a) shows a typical TEM image of the nanostructures, which confirms that they are composed of a very uniform diameter of the crystalline core surrounded by an amorphous coating. The average diameter of the core of this nanowire is about 25 nm, and the total diameter including the amorphous sheath is about 35 nm. The HRTEM image in Figure 5 (c) recorded from the core tellurium nanowires reveals that the core nanowire shown in the image is about 0.20 nm, which agrees with the (003) lattice planes of t-Te. Figure 5 (b) shows the corresponding ED pattern of the core tellurium nanowires, which was obtained by focusing the electron beam along the [1$\bar{1}$0] zone axis of an individual cable. Moreover, the SAED patterns taken from various regions of the core nanowire are essentially the same. The HRTEM image and ED pattern both demonstrate that the core tellurium nanowire is single-crystalline, with the growth direction along [001]. The perfect diffraction pattern and lattice fringes indicate that the core nanowire is well-crystallized.

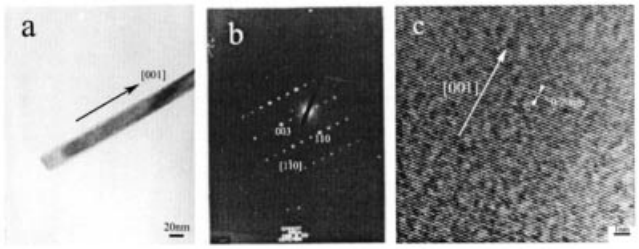

Figure 5. The electron diffraction pattern and HRTEM image of a typical nanocable. HRTEM image (c) taken from the edge of the core tellurium nanowire (a) with growth direction [001], fringe spacing d = 0.2 nm, showing that the core tellurium nanowire is structurally uniform, dislocation free, and single-crystalline. The corresponding ED pattern (b) was obtained from the same tellurium nanostructure, indicating the growth direction and the single-crystalline nature of the core tellurium nanowire.

Further advancement of this approach to nanocables' synthesis requires a clear understanding of the nucleation and growth mechanism. We therefore investigated the evolution of Te nanostructures (taken at the early stages) by TEM. Figure 6 shows the scenarios for the formation of Te nanostructures prepared by the hydrothermal treatment at different times. These images clearly show the evolution of tellurium nanostructures from nanoparticles to nanowires (cables) over time at 180 °C. After heating for 3.5 h, a gray precipitate was formed. The TEM results demonstrated that a large number of irregular nanoparticles with sizes of 10–20 nm and their larger aggregates had formed (Figure 6, a). The SAED patterns (insets of Figure 6, a) clearly reveal that the initial product of the reduction reaction was a mixture of amorphous Te (a-Te) colloids and t-Te nanocrystals. In addition, the colorless solution changed to a yellow-brown color, which implies that PVA has been oxidized by $Na_2TeO_3$ into cross-linked PVA, which is insoluble in water. After 5 h, the products were composed of a mixture of spherical nanoparticles and a small fraction of nanowires. Figure 6 (b) is a typical TEM image of the sample taken from the solution at this stage. It is clear that these nanowires have diameters of about 30 nm and lengths of several hundreds of nanometers. The ED pattern (insets of Figure 6, b) shows that these nanowires are single crystalline t-Te and that the spherical nanoparticles are composed of a mixture of a-Te and t-Te nanoparticles (marked by arrow). After heating for 8 h, nanowires with diameters of about 30 nm and lengths of up to several micrometers can be distinctly observed (Figure 6, c). In addition, at this stage the products also contain a small quantity of nanparticles (less than 10%). Further extending the heating time led to the formation of ultralong nanowires. Figure 6 (d) is a typical TEM image of a sample prepared after heating for 24 h, indicating that the obtained products are dominated by the ultralong wire-like nanostructures. These nanowires are uni-

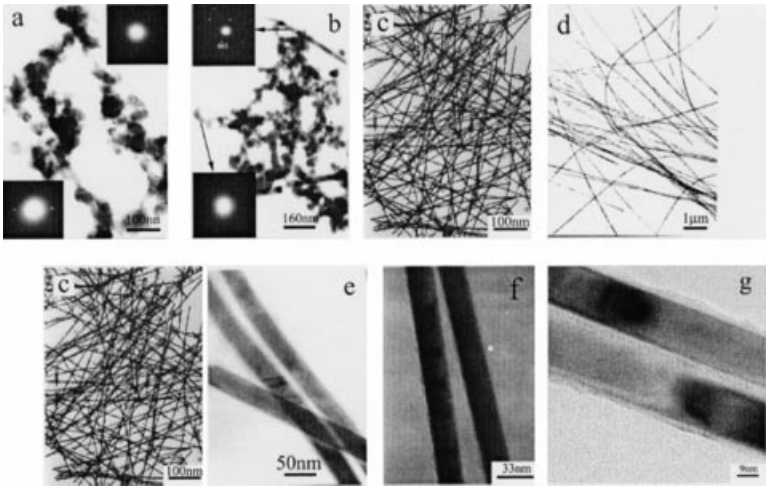

Figure 6. TEM images of Te nanostructures generated by the hydrothermal process after different times: (a) 3.5 h [the insets in Figure 6, part a, show the ED patterns, which indicate that both t-Te (bottom left) and a-Te nanoparticles (upper right) coexist in the initial products]. (b and e) 5 h, a few short nanowires can be observed. (c and f) 8 h and (d and g) 24 h. The insets in Figure 6, part b, are the ED patterns, which reveal that both t-Te nanowires/nanoparticles (upper left) and a-Te nanoparticles (bottom left) coexist in this product (as indicated by arrows).

form in diameter (25–35 nm) and their lengths extend to hundreds of micrometers. From Figure 6 (b–d) one can see that the growth of these nanowires along the longitudinal direction is quite quick, while the growth of their lateral dimensions is very slow and the diameter of nanowires almost does not change during the whole reaction. In addition, one can see that all these nanowires are actually a composite comprised of a core–sheath structure (see Figure 6, e–g), which suggests that the growth of wires and the formation of core–sheath structures occurs simultaneously. Furthermore, the lengths of these nanocables are mainly determined by the original tellurium nanowires and can be as long as several hundreds of micrometers.

As we all know, PVA chains crosslink after treatment at high temperature (250 °C); however, in the absence of $Na_2TeO_3$, we found that hydrothermal treatment of a PVA solution cannot make it cross-linked at 180 °C or even 200 °C, while the cross-linking reaction occurs at 160–180 °C in the presence of $Na_2TeO_3$. These results clearly demonstrate that the current hydrothermal process is an efficient method for promoting the cross-linking reaction. In this hydrothermal process, PVA can be oxidized by $Na_2TeO_3$ at 160–180 °C into cross-linked PVA, which is insoluble in water. As a result, the presence of $Na_2TeO_3$ is essential for the formation of cross-linked PVA and the formation of cables. In addition, when PVA was not added to the reaction system, we found that the reaction could not be initiated at all. In fact, PVA could serve as both reducing reagent and capping reagent in the present synthesis. $Na_2TeO_3$ can be reduced by PVA at 180 °C into tellurium nanoparticles and further grow into nanowires with the assistance of PVA; in turn, the tellurium nanowires serve as a hard template on which the core–sheath structures will form. It is reasonable to assume that, under the present hydrothermal conditions, the formation of the hybrid nanostructures is by synergistic growth, as both the growth of wires and the formation of core–sheath structures occur at the same time and are tightly linked to each other. The good agreement between the experimental data and our expectations suggests that it should be possible to rationally choose appropriate reaction

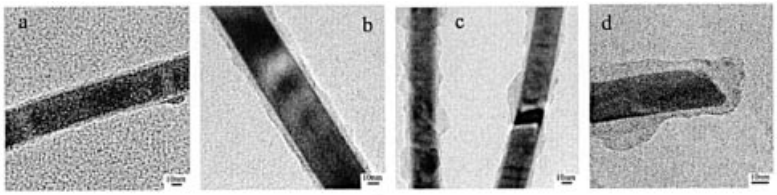

Figure 7. TEM images of tellurium/PVA coaxial nanocables obtained after the coating reaction had processed for (a) 8, (b) 24, (c) 36, and (d) 48 h, clearly showing that the thickness of the sheath increases from 2 to 10–20 nm.

systems for the synthesis of nanocables. In addition, it is worth pointing out that the pH value remains almost the same (10.40 for the starting initial solution to 9.42 for the residual solution) during reaction, thus suggesting that the solution after reaction is still more basic. According to the above results, the reaction that occurs under the current hydrothermal conditions can be formulated as shown in Scheme 1.

The final morphology of the tellurium nanostructures synthesized by the hydrothermal process is highly reliant on the amount of PVA added to the reaction solution. A number of experiments were performed with a procedure similar to that mentioned in the Experimental Section, and we found that the amount of PVA was crucial for the formation of nanocables, with the amount of PVA (5 mL) being suitable for the formation of cables. When the amount of PVA was relatively high (10 mL), no cables and only short tellurium nanorods were obtained as the final products (data not shown). The absence of nanowires (or cables) in the final product could be attributed to the high concentration of PVA, which might lead to the formation of a thick coating over the surface of the nanoparticles. Therefore, the selectivity of the interaction between PVA and various crystallographic planes is weakened, and anisotropic growth can essentially not be induced.

The thickness of the sheath can also be controlled by changing the reaction time. Figure 7 (a–d) show a set of TEM images of the cables that were obtained after different periods of time, and reveal that the thickness of the sheath can be increased by up to 10–20 nm by increasing the reaction time to 48 h. In addition, the amount of PVA and concentration of $Na_2TeO_3$ also play a key role in the formation of tellurium nanostructures. The reaction of $Na_2TeO_3$ (2 mmol) with less PVA (1 mL), with the other conditions remaining the same, gives only tellurium nanoparticles; no nanocables were observed. Moreover, if less $Na_2TeO_3$ (0.5 mmol) was used, with the other conditions remaining unchanged, no cables were obtained.

On the basis of the above results, we propose that the formation of tellurium nanocables follows the PVA-assisted solid solution-solid (SSS) transformation and the synergistic soft–hard template (SSHT) mechanism. It is clear that PVA is responsible for both the formation of tellurium nanoparticles and the subsequent oriented growth of tellurium nanowires. Firstly, the a-Te and t-Te nanoparticles a produced by the reduction of $TeO_3^{2-}$ by PVA at 180 °C. The colloids of a-Te would dissolve into the solution due to their higher free energies than those of t-Te nanocrystals. This dissolved Te (at the expense of a-Te) colloid subsequentlyforms crystalline nanowires on the seeds of t-Te due to the assistant of PVA and the anisotropic nature along the [001] direction.[16] In turn, the tellurium wires serve as a template on which cross-linked PVA forms. In addition, the newly formed cross-linked PVA will act as an effective bridge to connect nearby single cables to form raft-like cable bundles in a parallel fashion. It is worth mentioning that the growth of nanowires and the formation of core–sheath structures occur at the same time (see Figure 6, e–g).

## Conclusions

In conclusion, we have demonstrated a facile hydrothermal synthesis of ultralong nanocables with tellurium as cores and cross-linked PVA as sheaths in high yield. In the present system, the synergistic actions of both the stabilization of PVA and the binding interaction of cross-linked PVA with the tellurium nanowires could play a key role in the formation of the morphology of the resulting products. The current elegant nanocables with a high aspect ratio may have potential technological applications in nanoscience and nanotechnology. Meanwhile, we believe that the present convenient method could be extended to prepare other semiconductor/polymer or metal/polymer coaxial cables by an appropriate choice of reaction system and experimental conditions. Further work in this area is in progress.

## Experimental Section

**Synthesis:** In a typical experimental procedure, analytically pure $Na_2TeO_3$ (2 mmol) and 5 mL of PVA (5 wt.-%) solution were put into 40 mL of distilled water at room temperature to form a clear solution, which was then stirred strongly for about 0.5 h and transferred into a 50-mL Teflon-lined stainless-steel autoclave. The autoclave was sealed and maintained at 180 °C for 24 or 48 h and then air-cooled to room temperature naturally. A large quantity of black-gray, wire-like flocculent material was found floating on the top of the solution. This material was collected and washed with distilled water and anhydrous alcohol several times to remove ions and possible remnants in the final product. It was then dried in a vacuum oven at 60 °C for 4 h.

**Characterization:** The X-ray powder diffraction (XRD) analysis was performed with a Japanese Rigaku D/max-γA rotating anode X-ray diffractometer equipped with monochromatic, high-intensity Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178). The X-ray photoelectron spectra (XPS) were collected on an ESCALab MKII X-ray photoelectron

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectrometer, using nonmonochromatized Mg-$K_\alpha$ X-rays as the excitation source. Field emission scanning electron microscope (FESEM) images were taken on a JEOL JSM-6300F SEM. Transmission electron microscopy and electron diffraction (ED) patterns were taken with a Hitachi Model H-800 instrument using an accelerating voltage of 200 kV with a tungsten filament. TEM and high-resolution TEM (HRTEM) were obtained on a JEOL-2010 transmission electron microscope at an acceleration voltage of 200 kV. Infrared (IR) analysis of the precursor was conducted on a Magna IR-750FT Spectrometer ranging from 400 to 4000 $cm^{-1}$ at room temperature with the samples mulled in KBr wafer.

# Theoretical Study of the Effects of Phosphane Substituents on the Bonding Properties of Acetylene with $Ni(PR_3)_2$ (R = H, $CH_3$, F, $CF_3$, $C_6H_5$)

**Manuel Piacenza,[a] Julia Rakow,[a] Isabella Hyla-Kryspin,*[a] and Stefan Grimme*[a]**

**Keywords:** Alkyne ligands / Density functional calculations / Nickel / Phosphane ligands

The bond-formation processes between the $d^{10}$ metal fragments $Ni(PR_3)_2$ (R = H, $CH_3$, F, $CF_3$, Ph) and acetylene have been studied by density functional theory with the BP86 functional and large TZV(2df,2pd) basis sets. The Ni–acetylene bonds have been analyzed in terms of distortion and intrinsic interaction energies within the Dewar–Chatt–Duncanson model of bonding. The intrinsic interaction energies have been corrected for basis set superposition error (BSSE). Linear relationships have been found between the intrinsic interaction energies and the distances of the Ni–C and C≡C bonds as well as with the acetylene–nickel π-backbonding. No linear relationship with respect to the total interaction energies was found. Despite using large basis sets, BSSE still contaminates the interaction energies by 5–10 %. For the $PR_3$ ligands, the BSSE-corrected intrinsic interaction energies of acetylene bonding increase in the order $P(CF_3)_3 < PF_3 < PPh_3 < PH_3 < P(CH_3)_3$ from 58.9 to 77.9 kcal mol$^{-1}$, while the total interaction energies range from 32.9 to 42.4 kcal mol$^{-1}$ in the order $PPh_3 < P(CF_3)_3 < P(CH_3)_3 < PH_3 < PF_3$. These results reveal that the total influence of $PH_3$ and $PPh_3$ on the thermodynamics of the acetylene bonding is different and therefore in this sense $PH_3$ is not a good model of $PPh_3$ in theoretical calculations.

## Introduction

Alkynes and tertiary phosphanes coordinated to transition metals (TM) have been the subject of extensive experimental and theoretical studies.[1,2] This can be attributed to the specific reactivities of these species, which in the field of organometallic synthesis and catalysis give rise to a wide variety of products.[3,4] Because of the early work of Reppe et al.,[5] it is well known that nickel complexes promote the reactivity of the acetylene triple bond in several catalytic processes such as carbonylation, cyclooligomerization, and cooligomerization. Common to these processes is the presence of acetylene complexes with low-valent $Ni(PR_3)_2$ fragments, where R is mostly a bulky alkyl or aryl group.[3i,6]

In general, the reactivities of coordinated ligands are discussed in terms of steric and electronic effects, although the distinction between them is not always straightforward because both effects are interconnected. The steric properties of $PR_3$ ligands are usually measured by the cone angle, $\theta$, introduced by Tolman.[7] The steric effects for acetylene are less important, but in the case of alkynes with bulky substituents they may also influence the bonding.[8] The electronic effects of alkynes and phosphanes are inherently connected with the Dewar–Chatt–Duncanson (DCD) model,[9] i.e., with the ability of ligands to act as electron density donors and acceptors. Thus, the electronic contribution to a TM–P bond stems from two factors: a σ-donation from the phosphorus lone-pair orbital to empty metal orbitals, and a π-back-donation from occupied metal orbitals to the virtual σ* P–R MOs of the $PR_3$ ligands.[10] It is clear that electron-withdrawing substituents change the basicity of the $PR_3$ ligands and consequently their ability for σ-donation. The classification of donor/acceptor properties of $PR_3$ ligands has long been of interest in both experimental[7,10b,10c,11] and theoretical studies.[2f,2h,12] Due to the presence of a double π-system in alkyne ligands, two donor and two acceptor interactions are possible. As a result, alkynes exhibit a remarkable flexibility of coordination modes, and are able to act as two- or four-electron donors and to occupy up to four coordination sites.[13,14]

In the present work we are interested in the structural, electronic, and energetic properties of the bond-formation processes shown in Scheme 1.

The chosen phosphane substituents offer a broad variety of steric and electronic effects. While theoretical investigations of the effects of phosphane substituents on direct $TM–PR_3$ bonds are more common,[2f,h,12] investigations of the inductive effects on bonding of other ligands are scarce.[2l] To the best of our knowledge, a systematic study of the inductive effect of phosphane substituents on acetylene bonding in complexes **c**, including electron withdrawing and sterically demanding substituents, has not been reported so far. Furthermore, our chosen substituents should provide insight into the question of whether the $PH_3$

ligand, which is frequently used in theoretical studies as a model for bulky organophosphanes,[2,4a,15] is a good substitute for the $PPh_3$ ligand, which is more common in experimental studies.

## Results and Discussion

Before we discuss our results in more detail, we present a simplified picture (Figure 1) of the well known DCD model for the donor–acceptor interactions between the valence π-MOs of acetylene (**a**) and the metal fragments $Ni(PR_3)_2$ (**b**).

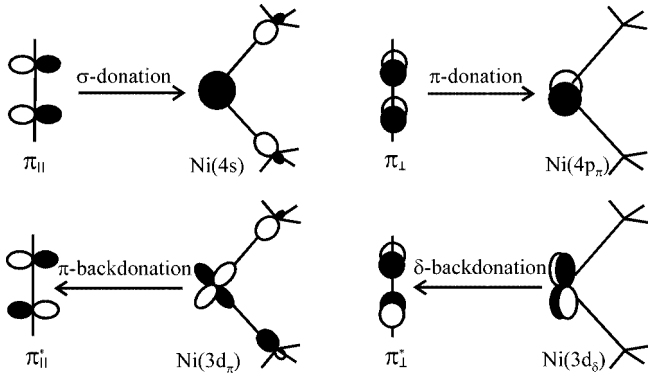

Figure 1. Simplified representation of the DCD model for synergic donor–acceptor interactions between valence MOs of acetylene and $Ni(PR_3)_2$.

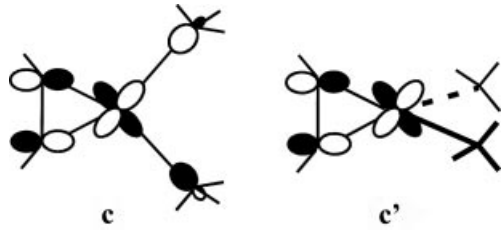
Since the nickel 3d levels are fully occupied in complexes **b**, the donation of electron density from acetylene in-plane ($\pi_\parallel$) and out-of-plane ($\pi_\perp$) MOs can take place to the empty nickel levels with predominant 4s and 4p character (Figure 1 top). In these L → TM donation interactions the occupied nickel 3d levels can participate due to second-order mixing only, i.e., due to three-orbital two-electron interactions.[16] In complexes **c** two occupied Ni 3d levels may be involved in backbonding interactions with the empty $\pi_\parallel$* and $\pi_\perp$* MOs of acetylene (Figure 1 bottom). From previous investigations it is well known that the contributions from the out-of-plane L → TM π-donation and M →L δ-back-donation are by far less important than those from the in-plane σ-donation and π-back-donation interactions.[2]

Contrary to homoleptic acetylene–nickel compounds,[13d–13f] complexes **c** prefer a planar molecular structure over a twisted one (Scheme 2).[6,8] In structure **c** the acetylene, nickel, and phosphorus atoms are placed in the same plane while in the twisted structure **c′** the acetylene is rotated by 90° around the $C_2$ axis. Previous calculations on the model complex **1c** have shown that backbonding interactions from the nickel $3d_\pi$ orbital to the acetylene in-plane $\pi_\parallel$* MO account for the stability and preferred molecular geometry of this class of compounds.[2a–2e,2i,2k] In the planar geometry **c** the acetylene–nickel in-plane π-backbonding interaction is enforced by electron density donation from a phosphorus lone-pair out-of-phase combination, which in the twisted geometry **c′** is not possible (Scheme 2).



**c** **c'**

Scheme 2.

In order to find out the preferred arrangements of the phosphane ligands in the planar molecular structure of the acetylene complexes **1c**–**5c** and their molecular fragments **1b**–**5b** we first investigated the rotation of the $PR_3$ ligands around the Ni–P bond. For **1b**–**4b** and **1c**–**4c** we considered one $C_s$-symmetric and two $C_{2v}$-symmetric rotamers (Scheme 3). Complexes **5b** and **5c** were optimized in $C_s$ and $C_1$ symmetry. For the sake of clarity the lowest energy structures of **5b** and **5c** are shown in Figure 2; the relative energies of the optimized conformers are presented in Table 1 and selected optimized parameters of the lowest energy structures are collected in Table 2. The energetics for the bond formation between acetylene (**a**) and $Ni(PR_3)_2$ (**b**) are summarized in Table 3 and the results of NBO population analyses in Tables 4 and 5.

From Table 1 it is evident that the different rotamers of **1b**–**4b** and **1c**–**4c** are energetically almost equivalent and the lowest energy structures adopt $C_{2v}$ symmetry. For **1b**–**4b**, **1c**, and **3c** the energy differences are below 0.3 kcal mol$^{-1}$ and for **2c** and **4c** they are only slightly larger [0.7 kcal mol$^{-1}$ (**2c**), 0.9 kcal mol$^{-1}$ (**4c**)]. Due to the steric requirements of the $PPh_3$ ligands, **5b** and **5c** prefer nonsymmetric over $C_s$-symmetric structures, which are less stable by 9.5 and 2.2 kcal mol$^{-1}$, respectively (Table 1).

From Table 1 it is also evident that the lowest energy rotamers of the complexes **2c**–**5c** and the metal fragments **2b**–**5b** are characterized by the same conformation of the phosphane ligands. Although the preferred conformation of the phosphane ligands in the metal fragment **1b-2** differs from that in the complex **1c-1**, the energy difference between **1b-1** and **1b-2** (0.1 kcal mol$^{-1}$) is not relevant for our discussion.

The experimental molecular structures of **1c**–**4c** are not known and only that of **5c** has been determined by X-ray

crystallography.[6] Although the optimized bond lengths of **5c-4** are slightly longer than the experimental values (Table 2) the differences are not large (0.03–0.04 Å), and the most important geometrical features are well reproduced by the calculations. Taking into account that the theoretical data refer to the gas phase and are not subject to crystal-packing forces, such small deviations are understandable and are not considered relevant. Furthermore, it is well known that the BP86 functional usually slightly overestimates the bond lengths. The optimized bond lengths and angles of **1c-1** and **2c-1** are in good agreement with results obtained at different levels of theory in previous calculations.[2e,2i,2l]

The Ni–P bonds of **3c-2** (2.094 Å) and **4c-1** (2.130 Å) are shorter than those of **1c-1** (2.145 Å), **2c-1** (2.161 Å), and **5c-4** (2.185/2.189 Å). An opposite effect is observed for the nickel–acetylene bonds, where for complexes with electron-withdrawing substituents in the phosphane ligands the Ni–C bonds are longer [1.914 (**3c-2**) and 1.931 Å (**4c-1**)] than in the other investigated compounds (1.897–1.903 Å). The shortening of the Ni–P bonds as well as the lengthening of the Ni–C bonds of **3c-2** and **4c-1** vs. **1c-1**, **2c-1**, and **5c-4** can be well understood in the framework of the DCD model. The calculated occupancy of the σ*(P–R) NBOs of **3c-2** (0.653) and **4c-1** (0.682) is significantly higher than in the remaining compounds (0.244–0.380; Table 4). Thus, with respect to **1c-1**, **2c-1**, and **5c-4**, the Ni–σ*(P–R) back-bonding interactions of **3c-2** and **4c-1** are stronger. It is clear that an enhancement of Ni–σ*(P–R) backbonding shortens the Ni–P bonds and diminishes the competitive Ni–acetylene backbonding, which, in turn, leads to longer Ni–C bonds. Indeed, the occupancy of acetylene π* NBOs of **3c-2** and **4c-1** is significantly lower than that of **1c-1**, **2c-1**, and **5c-4** (Table 4).

Our results are consistent with the experimental observation that π-acceptor phosphanes normally exhibit shorter TM–P bonds.[17] Furthermore, Table 2 shows that substitution of $PH_3$ by $P(CH_3)_3$ and $PPh_3$ results in an elongation of the Ni–P bonds. It is interesting to note that similar properties have been observed in theoretical studies of $[Fe(CO)_4PR_3]$ compounds.[2f]

The coordination of acetylene (**a**) with $Ni(PR_3)_2$ (**b**) results in molecular deformations, which are obviously endothermic processes (Scheme 4, Table 3). Independent of the phosphane ligands, the deformation of acetylene ($\Delta E_1$) requires more energy than that of the metal fragments $Ni(PR_3)_2$ ($\Delta E_2$) (Table 3).

In complexes **c** acetylene is no longer linear and adopts a *cis* bent structure **d** with a significantly elongated C≡C bond (Table 2). The reasons for the deviation from linearity of coordinated alkynes are similar to those for the pyramidalization of complexed alkenes and have been discussed in detail in the literature.[14a,14b,18] Since, according to NBO population analyses, the electron-density distributions in acetylene with a deformed geometry **d** are the same as for the equilibrium geometry **a**, one can ask whether the deformation energy, $\Delta E_1$, as well as the geometrical changes of the HC≡C bond angle, $\Delta\alpha$, and the C≡C bond length, $\Delta R_{C\equiv C}$, are influenced by the chemical nature of the phosphane ligands. In Figure 3 we present the deformation energies, $\Delta E_1$, as a function of $\Delta\alpha$ and $\Delta R_{C\equiv C}$. From this figure it is evident that almost perfect linear correlations are found.

The $\Delta E_1$ values increase in the order: $P(CF_3)_3 \geq PF_3 >> PPh_3 \geq PH_3 >> P(CH_3)_3$. Thus, phosphanes with electron-withdrawing substituents cause the smallest deformation of the acetylene ligand. Furthermore, the above ordering of the phosphane ligands essentially agrees with the predicted decrease of π-backbonding and an increase of σ-bonding contributions to the Fe–$PR_3$ bonds.[2f] It should also be noted that the inductive effects from the $PH_3$ and $PPh_3$ ligands on acetylene deformation are very similar, as re-

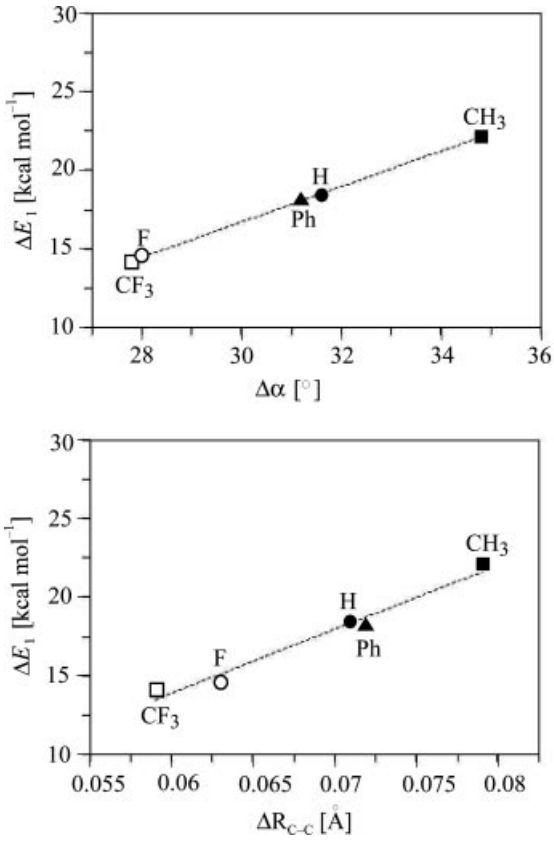

Figure 3. Deformation energy of acetylene ($\Delta E_1$) as a function of the changes in the HC≡C bond angle $\Delta\alpha$ (top) and the C≡C bond length $\Delta R_{C\equiv C}$ (bottom) for the transformation from the equilibrium geometry **a** to the geometries **d** of the $[C_2H_2Ni(PR_3)_2]$ complexes **c** (R = H, $CH_3$, F, $CF_3$, and Ph).

flected by the very close $\Delta E_1$, $\Delta\alpha$, and $\Delta R_{C\equiv C}$ values (Figure 3).

The optimized structures of the metal fragments **1b**–**4b** are bent, where the P–Ni–P bond angles, $\beta$, range from 131° to 167°, while **5b** prefers a linear arrangement of the P–Ni–P unit (Table 2, Figure 2). Our bent structures of **1b**–**4b** agree well with those obtained in an all-electron B3LYP study,[19] but are in disagreement with previous BP86/TZV and B3LYP/LANL2DZ calculations, where linear arrangements were found for the equilibrium geometries of **1b** and **2b**.[2e,2l] Nevertheless, the deformation energies, $\Delta E_2$, of **1b-2** (+13.1 kcal mol$^{-1}$) and **2b-1** (+16.8 kcal mol$^{-1}$) are very close to those reported for the linear structures (12.7 and 16.4 kcal mol$^{-1}$, respectively).[2l] This suggests that the energies of **1b-2** and **2b-1** with a linear P–Ni–P unit should be close to those of the global-minimum bent structures with $\beta$ angles of 148.4° and 167.2°, respectively (Table 2).

In Figure 4 we show the correlation between the deformation energies, $\Delta E_2$, and the $\Delta\beta$ values for the transformation of the $Ni(PR_3)_2$ equilibrium structures **b** into geometries **e**, i.e., to those that they adopt in the corresponding complexes **c** (Scheme 4). Although the $Ni(PPh_3)_2$ fragment bends more strongly upon coordination with acetylene than the $Ni[P(CH_3)_3]_2$ one, the deformation energies, $\Delta E_2$, are the same for both molecular units. This can be attributed to the fact that the distortion from the equilibrium structures **b** to geometries **e** leads not only to geometrical changes but also to different electron-density distributions. For the same reasons, no correlation was found between the $\Delta E_2$ values and the changes in the Ni–P bond lengths. Similar to the $\Delta E_1$ values of acetylene, the lowest $\Delta E_2$ values are obtained for metal fragments with electron-withdrawing substituents (F and $CF_3$).

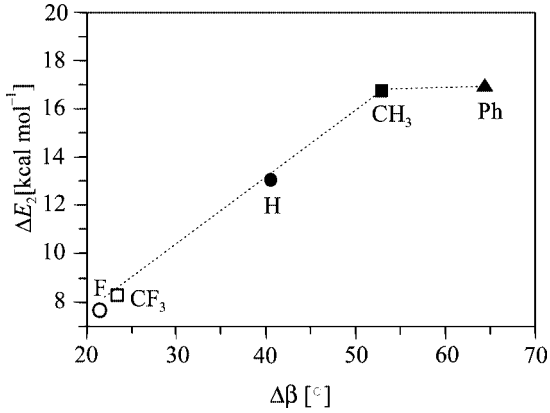

Figure 4. Deformation energy, $\Delta E_2$, as a function of the change in the P–Ni–P bond angle, $\Delta\beta$, for the transformation of the $Ni(PR_3)_2$ (R = H, $CH_3$, F, $CF_3$, Ph) metal fragments from the equilibrium geometries **b** to complex geometries **e**.

Despite using large and flexible basis sets in our studies, the intrinsic interaction energies, $\Delta E_3$, suffer from significant BSSE (Table 3). The BSSE contamination differs from one complex to the other. Thus, in the case of **3c-2** and **5c-4**, for example, the counterpoise corrections increase the difference of the bond-formation energies [$\Delta\Delta E_3 = \Delta E_3$(**3c-2**) – $\Delta E_3$(**5c-4**)] from 0.8 to 3.3 kcal mol$^{-1}$, while an opposite effect is observed for **5c-4** and **1c-1**. The $\Delta\Delta E_3$ values of **5c-4** and **1c-1** diminish from 7.6 to 3.2 kcal mol$^{-1}$ due to counterpoise corrections. Since relative energies are important for our discussion, in the following we will only consider the counterpoise corrected interaction energies. (Note that in theoretical investigations on TM compounds BSSE corrections are rather rarely taken into account, and when low-quality basis sets are used this may lead to wrong conclusions.) As an example, we recalculated the bond-formation process of **2c-1** by using the SV(d) basis set (Table 3). Although the use of the SV(d) basis set does not significantly change the distortion energies $\Delta E_1$ and $\Delta E_2$, the intrinsic interaction energy $\Delta E_3$ (–126.3 kcal mol$^{-1}$) is largely overestimated as compared with the TZV(2df,2pd) value (–84.0 kcal mol$^{-1}$) and the BSSE contamination increases from 7.2% [TZV(2df,2pd)] to 13.9% [SV(d)] (Table 3).

In accord with the DCD model from Scheme 1, the bond-formation processes between acetylene (**d**) and the metal fragments $Ni(PR_3)_2$ (**e**) are accompanied by donor–acceptor interactions between both molecular fragments (Table 5).

The data from Table 5 confirm the very weak nature of the acetylene–nickel out-of-plane π-donation and δ-back-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

donation interactions. The change in occupancy of acetylene $\pi_\perp$ and $\pi_\perp$* NBOs is much smaller than that of the $\pi_\parallel$ and $\pi_\parallel$* NBOs. In complexes **1c**–**5c**, the decrease of the occupancy of the acetylene $\pi_\parallel$ NBO is of the same magnitude and, consequently, the acetylene–nickel σ-donation interaction cannot be responsible for the different bond strengths. However, sufficiently large differences in NBOs' occupancies are discernible for acetylene–nickel π-backbonding interactions (Table 5). The increase of the occupancy of the acetylene $\pi_\parallel$* NBO as well as the decrease of the occupancy of the relevant Ni 3d$_\pi$ level shows a linear correlation with the intrinsic interaction energies, $\Delta E_3^{CP}$ (Figure 5). It should also be noted that analogous correlations of the entire interaction energies, $\Delta E^{CP}$, are not found.

The changes of bond lengths during bond-formation or bond-breaking processes are often correlated with the bond strengths, i.e., with the corresponding $\Delta E$ or, more rigorously, $\Delta E^{CP}$ values. From the bottom of Figure 6, it is evident that such correlations do not exist either for the newly formed Ni–C bonds or for the elongation of the acetylene triple bond. However, a linear relationship is found with the intrinsic interaction energies $\Delta E_3^{CP}$ (Figure 6, top) for which the ordering of the $PR_3$ ligands [$P(CF_3)_3 < PF_3 < PPh_3 < PH_3 < P(CH_3)_3$] is the same as found for acetylene deformation energies $\Delta E_1$ (Figure 3) or acetylene–nickel in-plane π-backbonding (Figure 5).

In agreement with the opinion of other authors,[2l] these findings point to the conclusion that the intrinsic interaction energies provide a better insight into the chemical nature of the ligand–metal bonds than the usually used $\Delta E$ ($\Delta E^{CP}$) or $D_e$ values. We are aware that the DCD model represents a simplified picture of the acetylene bonding as well as that the intrinsic interaction energies may be further decomposed into contributions from Pauli repulsion and electrostatic and orbital interaction terms. Nonetheless, the correlations from Figures 5 and 6 support the DCD bonding model for the nickel compounds investigated here.

The thermodynamics of bond-formation or bond-breaking processes depend upon the total interaction energies ($\Delta E^{CP}$ or $D_e$). In the case of the $PH_3$ and $PPh_3$ ligands the $\Delta E^{CP}$ values for acetylene bonding differ by 6.7 kcal mol$^{-1}$ and therefore $PH_3$ cannot be considered as a good model for $PPh_3$. It is evident from Table 3 that this difference stems from the deformation energies, $\Delta E_2$, of the $Ni(PH_3)_2$ and $Ni(PPh_3)_2$ fragments and the corresponding intrinsic interaction energies, $\Delta E_3^{CP}$. Upon going from **5c-4** to **1c-1** the deformation energy, $\Delta E_2$, decreases by 3.8 kcal mol$^{-1}$, the intrinsic interaction energy $\Delta E_3^{CP}$ increases by 3.2 kcal mol$^{-1}$, and the deformation energy of acetylene, $\Delta E_1$, changes by only –0.3 kcal mol$^{-1}$ (Table 3). On the other hand, similar $\Delta E^{CP}$ values to those of **1c-1** and **2c-1** do not necessarily indicate a very similar chemical nature of the acetylene bonding. **1c-1** and **2c-1** have almost the same $\Delta E^{CP}$ values (–39.6 and –39.0 kcal mol$^{-1}$, respectively), but their $\Delta E_3^{CP}$ values differ by 6.8 kcal mol$^{-1}$ (Table 3). Finally, it should be noticed that the influence of phosphanes on the bonding properties of other ligands is not necessarily the same as in cases involving cleavage or formation of TM–P bonds. Thus, for example, the $\Delta E^{CP}$ values calculated for the cleavage of the Fe–$PH_3$ and Fe–$P(CH_3)_3$ bonds differ by about 10 kcal mol$^{-1}$, but with respect to $PPh_3$ the Fe–$PH_3$ bond is only 0.5 kcal mol$^{-1}$ stronger.[2f] Since the computational advantage of using H instead of Ph is clear, one can ask whether the change of the cone angle of $PH_3$ may lead to a better model for $PPh_3$. Unfortunately, such changes affect the electronic structure and all energy components. Test calculations on **1c-1** with various cone angles of the $PH_3$ ligands have shown that it is not possible to predict whether and which contributions add up or cancel out without computational knowledge about the $PPh_3$ compound. Therefore, computational model systems should rather be avoided. In our case, calculations on the $PH_3$ com-

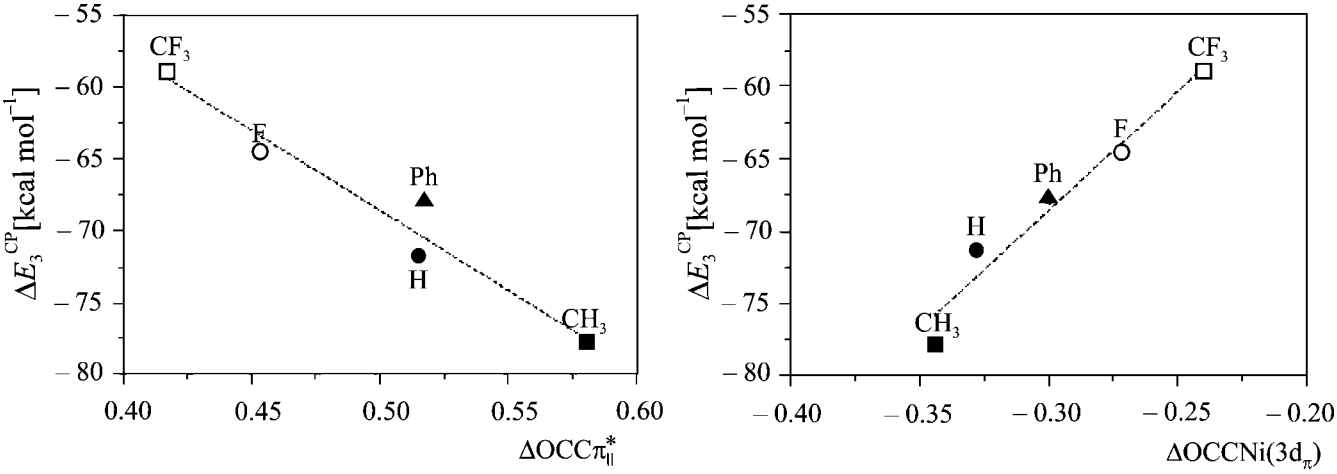

Figure 5. Correlation between intrinsic interaction energies, $\Delta E_3^{CP}$, and changes of the occupancy of acetylene $\pi_\parallel$* NBO and the Ni 3d$_\pi$ level in complexes **1c**–**5c** relative to $C_2H_2$ (**d**) and the metal fragments $Ni(PR_3)_2$ (**e**) (R = H, $CH_3$, F, $CF_3$, Ph).

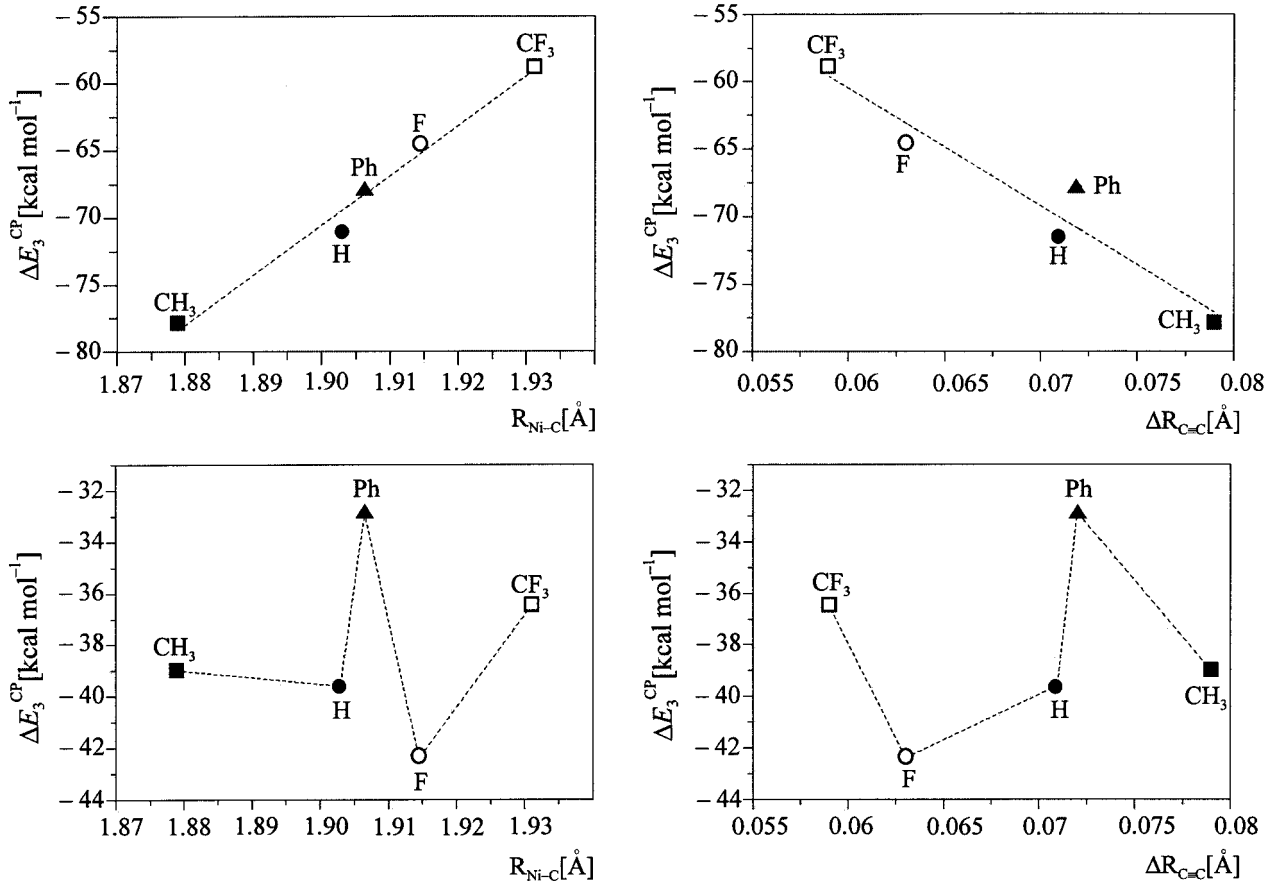

Figure 6. Correlation of the Ni–C bond lengths and the elongation of the C≡C bonds with the interaction energies $\Delta E_3^{CP}$ (top) and $\Delta E^{CP}$ (bottom) for the complexes $(C_2H_2)Ni(PR_3)_2$ (**c**) (R = H, $CH_3$, F, $CF_3$, Ph).

pound **1c-1** with the cone angles of $PPh_3$ from **5c-4** did not improve the model character of the $PH_3$ substitute.

### Concluding Remarks

In this study we have investigated the structures and energetics for the bond-formation processes between acetylene and the metal fragments $Ni(PR_3)_2$. We were interested in the question of how the substituents R (H, $CH_3$, F, $CF_3$ and Ph) in the phosphane ligands influence the nickel–acetylene bonding as well as whether the $PPh_3$ ligand may be modeled in computational studies by smaller, i.e., computationally less demanding, phosphanes. The bond-formation processes were analyzed in terms of distortion energies of acetylene ($\Delta E_1$) and $Ni(PR_3)_2$ ($\Delta E_2$), intrinsic interaction energies ($\Delta E_3$), and the DCD model. We have shown that despite using large TZV(2df,2pd) basis sets, BSSE still contaminates the $\Delta E_3$ values by 5–10% and therefore should be considered in accurate studies, especially in cases where double-ς basis sets with only a single polarization function are used. The effects of phosphane substituents on nickel–acetylene bonding cannot be correlated with total interaction energies ($\Delta E^{CP}$ or $D_e$), although linear correlations were found between the intrinsic interaction energies $\Delta E_3^{CP}$ and (i) the acetylene–nickel in-plane π-backbonding interactions, (ii) the distances of the newly formed Ni–C bonds, and (iii) the elongation of the acetylene triple bond. In these correlations the $\Delta E_3^{CP}$ values change in the order $P(CF_3)_3 < PF_3 < PPh_3 < PH_3 < P(CH_3)_3$. The total interaction energies increase in the order $PPh_3 < P(CF_3)_3 < P(CH_3)_3 < PH_3 < PF_3$. The effects of the phosphane ligands $PPh_3$ and $PH_3$ on the thermodynamics of acetylene bonding are different and therefore $PH_3$ cannot be regarded as a good substitute of $PPh_3$. The differences stem in an almost equal footing from the deformation energies of the metal fragments ($\Delta E_2$) and the intrinsic interaction energies ($\Delta E_3^{CP}$).

## Experimental Section

**Calculational Details:** The geometry optimizations of the complexes $C_2H_2Ni(PR_3)_2$ (**c**) and their molecular fragments $C_2H_2$ (**a**) and $Ni(PR_3)_2$ (**b**) were carried out with the TURBOMOLE 5.6 suite of programs.[20] As a quantum chemical method we have used density functional theory (DFT)[21] with the gradient-corrected BP86 functional[22] and the RI approximation which takes advantage of density fitting for the calculations of the Coulomb integrals.[23] All atoms were described with an all-electron valence triple-ς basis set augmented with polarization functions: (17s11p6d1f)/[6s4p3d1f] for Ni, (14s9p2d1f)/[5s5p2d1f] for P, (11s6p2df)/[5s3p2df] for C and F, and (6s2pd)/[3s2pd] for H, which we denote as TZV(2df,2pd). These basis sets, together with the corresponding auxiliary basis

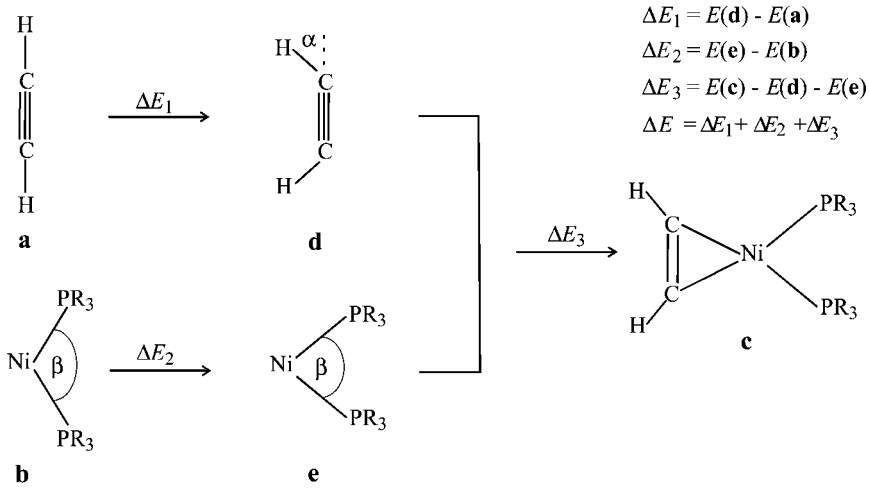

Scheme 4.

sets for the RI approximation, were taken from the TURBOMOLE basis set library.[24] Note that the TZV(2df,2pd) basis sets used here are of significantly higher quality than those employed in many previous theoretical studies on TM compounds of similar size.

The nature of ligand–metal bonds is usually discussed in terms of bond dissociation energies, $D_e$. It is obvious that the bond-formation energy of acetylene (**a**) with fragments $Ni(PR_3)_2$ (**b**) to give the complexes **c**, $\Delta E$, is equal to the negative of the dissociation energy $D_e$, see Equation (1).

$$-D_e = \Delta E = E(\mathbf{c}) - [E(\mathbf{a}) + E(\mathbf{b})] \quad (1)$$

$E(\mathbf{c})$, $E(\mathbf{a})$, and $E(\mathbf{b})$ are the total energies of the corresponding equilibrium structures. In order to obtain deeper insight into acetylene–nickel bonding, the bond-formation energy, $\Delta E$, was partitioned into deformation (also called preparation) energies ($\Delta E_1$ and $\Delta E_2$) and the intrinsic interaction energy ($\Delta E_3$), as shown in Scheme 4.

$\Delta E_1$ and $\Delta E_2$ are the energies that are necessary to transform acetylene (**a**) and $Ni(PR_3)_2$ (**b**) from their equilibrium geometries into the geometries that they adopt in the complexes **c**. $\Delta E_3$ represents the intrinsic interaction energy between the two "prepared" fragments **d** and **e** in the complex **c**. This partitioning scheme allows us to correct the intrinsic interaction energy ($\Delta E_3$) and, consequently, the bond-formation energy, $\Delta E$, for basis set superposition error (BSSE). The BSSE was calculated according to the counterpoise method[25] and the corrected energies are denoted as $\Delta E_3^{CP}$ and $\Delta E^{CP}$. The bond-formation processes were calculated for the closed-shell singlet states of the complexes **c** and their molecular fragments **a**,**d** and **b**,**e**. The electron-density distributions in complexes **c** and the molecular fragments **a**,**d** and **b**,**e** were investigated with the help of natural bond orbital (NBO) procedures.[26] Calculations of the harmonic frequencies for the equilibrium structures were carried out with the SNF program.[27]

# Monophosphanylcalix[6]arene Ligands: Synthesis Characterization, Complexation, and Their Use in Catalysis

Yasushi Obora,[a] Yun Kui Liu,[a] Sho Kubouchi,[a] Makoto Tokunaga,[a] and Yasushi Tsuji*[a]

**Keywords:** Calixarenes / Heterogeneous catalysis / Phosphanes / Platinum / Rhodium

Novel phosphanylcalix[6]arenes having mono-*O*-diphenylphosphanylmethyl (**3**) and mono-*O*-(4-diphenylphosphanylphenyl)methyl substituents (**5**) have been synthesized. The structures of these monophosphanylcalix[6]arenes were determined by NMR spectroscopy, mass spectrometry, and X-ray crystal structure analysis. The X-ray structure reveals that **3** adopts a flattened 1,2,3-alternate conformation in the crystalline state, while the NMR spectra show that **3** and **5** have a cone conformation in solution. Structure optimization and energy calculations for **3** and **5** at the B3LYP/LANL2DZ-CONFLEX5/MMFF94s level of theory show that the cone conformation is slightly more stable than the 1,2,3-alternate conformation by 0.36 kcal mol$^{-1}$ for **3** and 0.96 kcal mol$^{-1}$ for **5**. Complexation of **3** with $[PtCl_2(COD)]$ and $[Rh(COD)_2]BF_4$ gives *cis*-coordinated $[PtCl_2(\mathbf{3})_2]$ and $[Rh(COD)(\mathbf{3})_2]BF_4$, respectively. The X-ray analysis of $[PtCl_2(\mathbf{3})_2]$ shows that **3** adopts a cone conformation upon complexation. Combination of **3** and **5** with $[Rh(COD)_2]BF_4$ provides an active catalyst for the hydroformylation of a variety of terminal alkenes.

## Introduction

Calixarenes are macrocyclic compounds having well-defined cavities, and a number of synthetic procedures for their selective functionalization have been developed.[1] In particular, phosphanylcalixarenes,[2] namely phosphanes bearing calixarene moieties, have received considerable attention. Phosphane ligands in general play an important role in transition-metal-catalyzed reactions, and a wide variety of phosphanes have been prepared to realize high catalytic activity and selectivity.[3,4] The phosphanylcalixarenes are attractive ligands since they integrate the strong coordination ability of phosphanes and the unique cavity of the calixarenes to create a spatially confined environment upon complexation with transitional metals.[2]

As far as the size of the cavity is concerned, major attention has been paid to phosphanylcalix[4]arenes[5] due to their rigid conformations. As for the phosphanylcalix[4]arenes, we have reported $Pt^{II}$ and $Pd^{II}$ complexes of a bis(diphenylphosphanyl)calix[4]arene,[6a] solid-state and solution structures of a tetrakis(diphenylphosphanyl)calix[4]arene,[6b] and an $Ru^{II}$ complex of a tetrakis(diphenylphosphanylmethyl)calix[4]arene.[6c] Calix[6]arenes having larger cavities generally display more flexible and variable conformations[7] than calix[4]arenes. Therefore, the chemistry of phosphanylcalix[6]arenes[8] is essentially unexplored owing to their intricacy. We recently synthesized 1,3,5-triphosphanylcalix[6]arene, which functions as a tripodal phosphane ligand to afford novel, capsule-shaped $Ir^{I}$ and $Rh^{I}$ complexes.[9]

In the present study, we describe the synthesis and characterization of novel phosphanylcalix[6]arenes having mono-*O*-diphenylphosphanylmethyl (**3**) and mono-*O*-(4-diphenylphosphanylphenyl)methyl substituents (**5**) as the first examples of a calix[6]arene moiety bearing monodentate phosphane ligands.[10] The monodentate phosphanes are an important class of ligands in transition-metal-catalyzed reactions.[3,11] Furthermore, we have synthesized $Pt^{II}$ and $Rh^{I}$ complexes of **3**, and found that the $Rh^{I}$ complexes of **3** and **5** are active catalysts in the hydroformylation of terminal alkenes.

## Results and Discussion

The monophosphanylcalix[6]arene ligands **3** and **5** were prepared as shown in Scheme 1. According to the reported synthetic procedure for phosphanylcalix[4]arenes[5n,12] and triphosphanylcalix[6]arenes,[9] **3** was prepared as follows. Reaction of **1**[13] with $Ph_2P(O)CH_2OTs$[14] with NaH as a base, in toluene at 90 °C for 2 d, gave the phosphane oxide **2** in 95% yield. Reduction of **2** was carried out with $PhSiH_3$

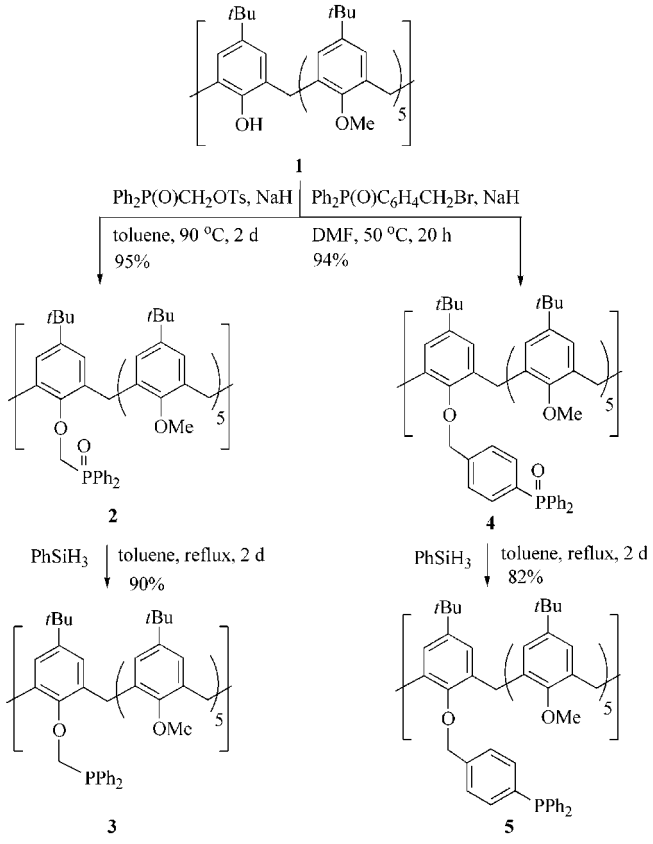
in toluene under reflux to afford **3** in 90% yield. With regard to the synthesis of **5**, the corresponding phosphane oxide (**4**) was prepared from **1**, $Ph_2P(O)C_6H_4CH_2Br$,[15] and NaH in DMF at 50 °C for 20 h by modifying the reported procedure for mono-*O*-benzylation of calix[6]arenes.[16] The desired phosphane (**5**) was obtained in 82% yield after reduction of **4** with $PhSiH_3$.



Scheme 1.

These phosphane compounds (**3** and **5**) were characterized by means of NMR spectroscopy, mass spectrometry, elemental analysis, and X-ray crystal structure analysis. The $^{31}P\{^1H\}$ NMR spectra (in $CDCl_3$) of **3** and **5** at 25 °C display single resonances at $\delta$ = –16.5 and –5.6 ppm assignable to alkyldiaryl- and triarylphosphanes, respectively. The ESI or FD mass spectra of **3** and **5** show peaks at *m*/*z* = 1264 $[M + Na]^+$ (for **3**) and 1318 $[M^+]$ (for **5**). The X-ray structure of **3** is shown in Figure 1. The crystallographic data are listed in the Experimental Section and selected atom distances and bond angles of **3** in Table 1. The X-ray structure shows that **3** adopts a 1,2,3-alternate conformation in which three pairs of diametrically opposite phenyl rings (**A** vs. **D**, **B** vs. **E**, and **C** vs. **F**) orient *anti* to each other.[17] Four of these aromatic rings (**A**, **C**, **D**, and **F**) almost stand up in pinched positions whereas the other two aromatic rings (**B** and **E**) splay outwards in flattened positions. Thus, the dihedral angles between the aromatic rings (**A**–**F**) and the calixarene reference plane (the average plane defined by the six bridging methylene carbon atoms; the maximum deviation is 0.2162 Å) are 84.3(1)°, 137.2(1)°, 66.9(1)°, 73.4(1)°, 136.2(1)°, and 68.7(1)°, respectively. This structure can also be designated as a (u,uo,u,d,do,d) conformation, as suggested by Gutsche.[18] Similar 1,2,3-alternate conformations in the crystalline state have also been reported for several hexasubstituted calix[6]arene derivatives.[19]

To elucidate the structures of **3** and **5** in solution, $^1H$ and $^{13}C\{^1H\}$ NMR spectra of **3** and **5** were measured in $CDCl_3$ at 25 °C. All the $^1H$ and $^{13}C$ resonances were completely assigned by means of HMBC[20] 2D NMR spectroscopy. In solution, both compounds **3** and **5** show quite similar NMR spectra in terms of the conformation of calix[6]arene moieties. The $^1H$ NMR spectrum of **3** exhibits axial bridging methylene proton resonances as three doublets at $\delta$ = 4.03, 4.19, and 4.35 ppm in a 1:1:1 ratio, and the corresponding equatorial proton resonances as three doublets at $\delta$ = 3.85, 3.70, and 3.48 ppm in a 1:1:1 ratio, with geminal couplings ($J$ = 14–15 Hz). Similarly, the $^1H$ NMR spectrum of **5** displays signals of three axial bridging methylene protons at $\delta$ = 4.04, 4.16, and 4.43 ppm and of three equatorial protons at $\delta$ = 3.81, 3.68, and 3.51 ppm as doublets. With regard to the bridging methylene resonances in the $^1H$ NMR spectra, the difference of the chemical shift ($\Delta\delta$) between the axial and the equatorial pairs is dependent on the orientation of the two adjacent aromatic rings.[21] The $\Delta\delta$ values (0.87, 0.49, and 0.18 ppm for **3** and 0.92, 0.48, and 0.23 ppm for **5**) are quite similar to the values reported for mono-*O*-benzyl-substituted calix[6]arene (0.94, 0.50, and 0.21 ppm), which was assigned a cone conformation in solution.[22] Furthermore, the *tert*-butyl protons appear as four singlet peaks in a 1:1:2:2 ratio ($\delta$ = 0.92, 1.27, 1.06, and 1.30 ppm for **3** and $\delta$ = 0.97, 1.23, 1.02, and 1.24 ppm for **5**), and the methoxy

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

protons as three singlet peaks in a 1:2:2 ratio ($\delta$ = 2.81, 2.50, and 3.26 ppm for **3** and $\delta$ = 2.76, 2.49, and 3.22 ppm for **5**) in the $^1$H NMR spectra. It is well known that a signal arising from the bridging methylene carbon atoms (Ar-$CH_2$-Ar) appears at $\delta \approx 31$ ppm in the $^{13}C\{^1H\}$ NMR spectrum when two adjacent aryl rings are in the *syn* orientation, and close to $\delta$ = 37 ppm for the *anti* orientation.[22,23] Here, the bridging methylene carbon resonances appear at $\delta$ = 30.38, 30.48, and 30.64 ppm for **3** and $\delta$ = 30.42, 30.76, and 30.80 ppm for **5** in 1:1:1 ratios, with no methylene resonances at $\delta$ = 36–38 ppm. The ROESY spectrum of **3** at 25 °C shows that all the equatorial protons have ROE correlations with one of the aromatic protons of the calixarene moiety; no ROE correlation was observed between the axial protons and the aromatic protons (see Figure S2 in the Supporting Information). Variable-temperature $^{13}C\{^1H\}$NMR spectra of **3** in the range from –50 to 25 °C showed that the bridging methylene carbon signals ($\delta$ = 29–31 ppm) remained virtually unchanged, whereas the $^1$H NMR spectra showed that two pairs of bridging methylene doublets ($\delta$ = 4.19/3.70 and 4.03/3.85 ppm) became slightly broadened, while the remaining pair ($\delta$ = 4.35/3.48 ppm) remained as a sharp peak on lowering the temperature to –50 °C. All these NMR spectroscopic data clearly indicate that **3** and **5** adopt a cone conformation[22–24] in solution.[25]

The CPMAS solid-state $^{13}C\{^1H\}$ NMR spectra of **3** (Figure 2) and **5** (as a powder, not a single crystal) show comparable chemical shifts to the solution spectra, although the resonances in the solid state are considerably broader ($\Delta\nu_{1/2}$ = 50–180 Hz). The diagnostic bridging methylene carbon resonances appear at $\delta \approx 30.5$ ppm ($\Delta\nu_{1/2}$ = 172 Hz) for **3** and $\delta \approx 31.1$ ppm (for **5**), rather than at $\delta$ = 36–38 ppm, thus indicating that **3** and **5** have the same cone structure in the solid state as in solution.

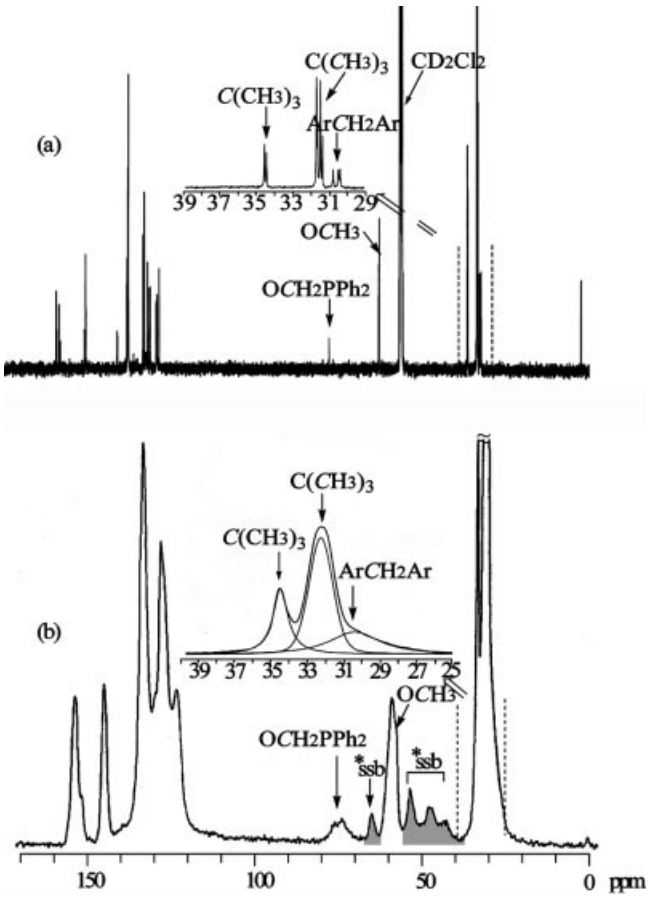

Figure 2. $^{13}C\{^1H\}$ NMR spectra of **3** at 25 °C: (a) measured in $CD_2Cl_2$; (b) measured in the solid state (CPMAS). *ssb: spinning side-band.

The structural differences between the solution (cone), powder (cone), and the single crystal (1,2,3-alternate) suggest that the energy difference between these conformations is very small. Thus, an MO calculation was carried out for the 1,2,3-alternate (Figure 3a for **3**; Figure 3d for **5**) and the cone conformations (Figure 3b for **3**; Figure 3e for **5**) as well as a common 1,3,5-alternate[18] conformation (Figure 3c for **3**; Figure 3f for **5**). In each conformation, conformational analysis of **3** and **5** was carried out by CONFLEX5[26]/MMFF94s[27] to find the lowest-energy structure. The structures were then further optimized by DFT calculations at the B3LYP[28]/LANL2DZ[29] level. The optimized structures are shown in Figure 3a–f, which reproduce the characteristic structural features: (u,uo,u,d,do,d) for the 1,2,3-alternate (Figure 3a and d), (u,u,u,u,u,u) for the cone (Figure 3b and e), and (u,di,u,d,ui,d)[18] for the 1,3,5-alternate conformation (Figure 3c and f). The energy calculations on these optimized structures at the same level (B3LYP/LANL2DZ) revealed that the energy difference between the 1,2,3-alternate and the cone conformations is very small: the latter is slightly more stable than the former but only by 0.36 (for **3**) and 0.96 kcal mol$^{-1}$ (for **5**). However, the 1,3,5-alternate conformation is considerably less stable (11.93 kcal mol$^{-1}$ for **3** and 12.67 kcal mol$^{-1}$ for **5**) than the cone conformation. This result can explain why no 1,3,5-alternate conformations were observed for **3** and **5** and that facile conformational interconversion between the 1,2,3-alternate and the cone takes place to afford the 1,2,3-alternate conformation in the crystal structure, possibly by a preferential crystallization of this conformation.[30]

The $^{13}$C NMR chemical shifts of **3** were calculated by the GIAO (Gauge-Independent Atomic Orbital)[31] method at the HF/6-31G(d) level of theory for the optimized cone (Figure 3b) and the 1,2,3-alternate (Figure 3a) structures. As shown in Table 2 and Figure 4, the calculated chemical shifts of the cone structure are in good correlation with the values observed in $CD_2Cl_2$ ($r^2$ = 0.996), thereby indicating that the calculation is reliable, although the calculated values are smaller than the observed ones by 1.5–5 ppm. It is noteworthy that among the six bridging methylene carbon atoms of the 1,2,3-altenate structure, the calculated chemical shifts of the four carbon atoms ($\delta$ = 28.04, 28.44, 28.45, and 28.46 ppm) of the *syn* orientation are definitely smaller than those of the two carbon atoms of the *anti* orientation ($\delta$ = 32.40 and 32.42 ppm). Such explicit differences would warrant the aforementioned diagnostic bridging methylene carbon resonances of the *syn* and *anti* orientations.

### Preparation of Platinum(II) and Rhodium(I) Complexes of 3

$Pt^{II}$ and $Rh^{I}$ complexes of **3** were prepared. Compound **3** (2 equiv.) was treated with [$PtCl_2$(COD)] (COD = 1,5-cyclooctadiene) to afford [$PtCl_2$(**3**)$_2$] in 78% yield [Equation (1)]. Characterization of [$PtCl_2$(**3**)$_2$] was performed by NMR spectroscopy, mass spectrometry, elemental analysis, and X-ray crystal structure analysis. The ESI mass spectrum of [$PtCl_2$(**3**)$_2$] exhibits an intense signal for $[M + Na]^+$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

($m/z$ = 2770). The structure of $[PtCl_2(\mathbf{3})_2]$ was unequivocally confirmed by X-ray diffraction. Figure 5 shows the molecular structure of $[PtCl_2(\mathbf{3})_2]$. The crystal data and selected bond lengths and angles are summarized in the Experimental Section and Table 3, respectively. In contrast to the structure of **3** (Figure 1), the two calix[6]arene moieties in $[PtCl_2(\mathbf{3})_2]$ adopt a cone conformation. The platinum atom is *cis*-coordinated by two phosphane groups and the P1–Pt–P2 bond angle is 97.6(5)°, which is comparable to the value of 98.1(3)° found in *cis*-$[PtCl_2(PMePh_2)_2]$.[32] The Cl(1)–Pt(1)–P(1) and Cl(2)–Pt(1)–P(2) angles are 170.82 (5)° and 172.15 (6)°, respectively. Thus, the geometry of the platinum center is approximately square-planar with a slightly tetrahedral distortion. The Pt–P bond lengths [2.255(1) and 2.247(2) Å] and the Pt–Cl bond lengths [2.359(2) and 2.349(1) Å] are similar to those in *cis*-$[PtCl_2(PMePh_2)_2]$[32] and other phosphanylcalixarene-based $Pt^{II}$ complexes.[33]

$$[PtCl_2(COD)] + \mathbf{3} \xrightarrow[\text{r.t., 2 h}]{CH_2Cl_2} [PtCl_2(\mathbf{3})_2] \quad (1)$$

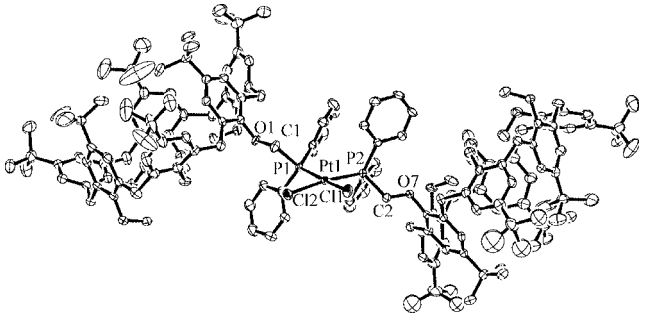

Figure 5. ORTEP drawing of $[PtCl_2(\mathbf{3})_2]$ with thermal ellipsoids at 50% probability levels. Hydrogen atoms have been omitted for clarity.

Table 3. Selected bond lengths [Å] and angles [°] for $[PtCl_2(\mathbf{3})_2]$.

| | | | |
|---|---|---|---|
| Pt(1)–P(1) | 2.255(1) | Pt(1)–P(2) | 2.247(2) |
| Pt(1)–Cl(1) | 2.350(2) | Pt(1)–Cl(2) | 2.359(2) |
| P(1)–C(1) | 1.847(7) | P(2)–C(2) | 1.857(7) |
| O(1)–C(1) | 1.430(8) | O(7)–C(2) | 1.424(7) |
| P(1)–Pt(1)–P(2) | 97.57(5) | Cl(1)–Pt(1)–Cl(2) | 87.28(6) |
| Cl(1)–Pt(1)–P(1) | 170.82(6) | Cl(2)–Pt(1)–P(2) | 172.15(6) |
| O(1)–C(1)–P(1) | 108.9(3) | O(7)–C(2)–P(2) | 109.0(4) |

In solution, the $^1H$ NMR spectrum of $[PtCl_2(\mathbf{3})_2]$ shows the bridging methylene protons as five distinct doublets with geminal couplings of 15 Hz; the other doublet is overlapped by the methoxy proton resonances. The *tert*-butyl protons appear as four singlets in a 1:1:2:2 ratio and the methoxy protons exhibit three distinct resonances with a 1:2:2 ratio. The $^{13}C$ NMR resonances of the bridging methylene carbon atoms appear at $\delta$ = 29.84, 30.33, and 30.54 ppm in a ratio of 1:1:1. All these NMR spectroscopic data indicate that the calixarene moieties of $[PtCl_2(\mathbf{3})_2]$ remain in the cone conformation in solution, as is also the case in the crystalline state (Figure 5). The $^{31}P\{^1H\}$ NMR spectrum displays a singlet peak at $\delta$ = 6.0 ppm with a $^1J_{Pt,P}$ coupling constant of 3611 Hz, which indicates the *cis* coordination of the phosphane ligand.[5a,34] When the *cis* complex was heated at 60 °C for 24 h, no *cis*/*trans* isomerization[35] was observed.

Treatment of **3** with $[Rh(COD)_2]BF_4$ in $CH_2Cl_2$ afforded $[Rh(COD)(\mathbf{3})_2]BF_4$ in 68% yield [Equation (2)]. The ESI mass spectrum of this complex shows an intense peak at $m/z$ = 2694 ($[M - BF_4^-]^+$). In the $^1H$ and $^{13}C\{^1H\}$ NMR spectra of $[Rh(COD)(\mathbf{3})_2]BF_4$ (see Experimental Section), the resonances for the bridging methylene protons and carbon atoms and the *tert*-butyl and methoxy protons indicate that the calix[6]arene moieties also maintain the cone conformation in the complex. The $^{31}P$ NMR spectrum of the complex shows a resonance at $\delta$ = 20.8 ppm ($^1J_{Rh,P}$ = 141 Hz), which is consistent with a *cis*-planar structure as was reported for $[Rh(COD)(DPPB)]BF_4$ [DPPB = 1,4-bis(diphenylphosphanyl)butane; $\delta$ =23.5 ppm ($^1J_{Rh-P}$ = 144 Hz)].[36]

$$[Rh(COD)_2]BF_4 + \mathbf{3} \xrightarrow[\text{r.t., 3 h}]{CH_2Cl_2} [Rh(COD)(\mathbf{3})_2]BF_4 \quad (2)$$

## Hydroformylation Experiments

It is known that (phosphanylcalix[4]arene)rhodium complexes have been found to be active catalysts for the hydroformylation of olefins.[5c,5g,5k,5n,5o] Phosphanylcalix[6]arenes have a larger cavity than phosphanylcalix[4]arenes; therefore, in order to examine the catalytic performance (catalytic activity and regioselectivity) of the novel monophosphanylcalix[6]arene ligands **3** and **5**, $Rh^I$-catalyzed hydroformylations of four different terminal olefins were examined [Equation (3) and Table 4]. The hydroformylation reactions were carried out with a 1:1 mixture of $CO/H_2$ (10 atm) in the presence of $[Rh(COD)_2]BF_4$ combined with **3** or **5** (olefin/Rh/P ratio = 2000:1:4) in benzene at 70 °C. When 1-hexene was employed as substrate, 1-heptanal (linear) and 2-methylhexanal (branched) were formed in 79% (with **3**) and 85% (with **5**) total yields (Entries 1 and 2). The present catalysts also show high activity in hydroformylation of styrene to afford the branched aldehyde as the major product (Entries 3 and 4). These regioselectivities (linear/branched ratios) are similar to those reported with phosphanylcalix[4]-arene ligands[5c,5g,5k,5o,5n] and conventional phosphanes.[37] In the hydroformylation of vinyl acetate and vinyl benzoate, the rhodium catalyst with **3** shows a better catalytic activity than that with **5** and affords branched aldehydes exclusively (Entries 5–8). Thus, the rhodium catalyst system combined with **3** or **5** displays a high catalytic activity for the hydroformylation of various terminal alkenes.

(3)

Table 4. $Rh^{I}$-catalyzed hydroformylations of terminal olefins.[a]

| Entry | Olefin | Ligand | Aldehydes [%] | Linear/branched[b] |
|---|---|---|---|---|
| 1 | 1-hexene | **3** | 79 | 66:34 |
| 2 | | **5** | 85 | 71:29 |
| 3 | styrene | **3** | 81 | 8:92 |
| 4 | | **5** | 91 | 10:90 |
| 5 | vinyl acetate | **3** | 67 | –[c] |
| 6 | | **5** | 24 | –[c] |
| 7 | vinyl benzoate | **3** | 96 | –[c] |
| 8 | | **5** | 57 | –[c] |

[a] Olefin (1.0 mmol), $[Rh(COD)_2]BF_4$ (0.005 mmol), ligand (**3** or **5**) (0.02 mmol) in benzene (2 mL) at 70 °C under 10 atm $CO/H_2$ (1:1). [b] Determined by GC. [c] No linear adduct was detected.

In conclusion, novel monophosphanylcalix[6]arene ligands having mono-*O*-diphenylphosphanylmethyl (**3**) and mono-*O*-(4-diphenylphosphanylphenyl)methyl (**5**) moieties have been prepared, and complexation of **3** with $Pt^{II}$ and $Rh^{I}$ complexes has been carried out. Conformational analysis of the ligands and complexes suggests that the cone is the most stable conformer in both solution and the solid state. However, in the crystalline state, due to a small energy difference between the cone and 1,2,3-alternate conformations, facile interconversion between these conformations takes place to afford the 1,2,3-alternate conformation by preferential crystallization of this conformer.

## Experimental Section

**General:** All reactions were performed under argon using standard Schlenk techniques. Solvents were dried and purified before use by usual methods.[38] $[Rh(COD)_2]BF_4$,[39] $[PtCl_2(COD)]$,[40] and 5,11,17,23,29,35-hexa-*tert*-butyl-38,39,40,41,42-pentamethoxycalix-[6]aren-37-ol (**1**)[15] were prepared according to literature procedures. Medium-pressure column chromatography (Yamazen YFLC-540) was performed on silica gel (Wakogel C-400HG; particle size 20–40 μm) with a UV detector (Yamazen UV-10V). Preparative-scale GPC was carried out with a Japan Analytical Industry LC-9104 instrument equipped with Jaigel-1H-40 and Jaigel-2H-40. $^1H$ (400 MHz), $^{13}C\{^1H\}$ (100 MHz), and $^{31}P\{^1H\}$ NMR (162 MHz) spectra were recorded with a Bruker ARX 400 instrument. The $^1H$ NMR spectroscopic data are referenced relative to residual protonated solvent ($\delta$ = 5.32 and 7.26 ppm in $CD_2Cl_2$ and $CDCl_3$, respectively). $^{13}C$ NMR chemical shifts are reported relative to either $CD_2Cl_2$ ($\delta$ = 53.1 ppm) or $CDCl_3$ ($\delta$ = 77.0 ppm). The $^{31}P$ NMR spectroscopic data are given relative to external 85% $H_3PO_4$. HMBC[20] 2D NMR spectra were recorded with a JEOL α-500 or a JEOL ECX-400 instrument. CPMAS solid-state $^{13}C\{^1H\}$ NMR (100 MHz) spectra were recorded with a JEOL CMXP400 or a JEOL ECX-400 instrument with magic-angle spinning at 8 kHz (for **3**) or 5 kHz (for **5**); the $^{13}C$ NMR spectroscopic data are referenced relative to hexamethylbenzene ($\delta$ = 17.4 ppm). FD and ESI mass spectra were recorded with a JEOL JMS-SX102A instrument at the GC-MS & NMR Laboratory of the Faculty of Agriculture at Hokkaido University. Elemental analysis was performed at the Center for Instrumental Analysis of Hokkaido University. Molecular-orbital calculations were performed with the Gaussian 03 program[41] on a HIT HPC-IA642/SS 1.3/3D-4G.

**5,11,17,23,29,35-Hexa-*tert*-butyl-37-(diphenylphosphanylmethoxy)-38,39,40,41,42-pentamethoxycalix[6]arene (2):** $Ph_2P(O)CH_2OTs$[14] (0.44 g, 1.1 mmol) was added to a suspension of **1**[13] (1.04 g, 1.0 mmol) and NaH (24 mg, 10 mmol) in 24 mL of toluene. The reaction mixture was heated to 90 °C and stirred at this temperature for 2 d. After cooling, the unreacted NaH was neutralized carefully by adding aq. 3% HCl. The crude product was extracted with chloroform and dried with $MgSO_4$. Analytically pure product was obtained by medium-pressure column chromatography with ethyl acetate as an eluent, followed by recrystallization from dichloromethane/ethanol (1:5). Yield: 1.20 g (95%). M.p. 172–174 °C. ESI-MS: $m/z$ = 1256 $[M]^+$. $^1H$ NMR ($CDCl_3$): $\delta$ = 0.83 (s, 9 H), 0.98 (s, 18 H), 1.26 (s, 9 H), 1.29 (s, 18 H), 2.23 (s, 6 H, OC$H_3$), 2.70 (s, 3 H, OC$H_3$), 3.32 (d, $^2J_{H,H}$ = 15 Hz, 2 H, ArC$H_2$Ar), 3.37 (s, 6 H, OC$H_3$), 3.62 (d, $^2J_{H,H}$ = 14 Hz, 2 H, ArC$H_2$Ar), 3.76 (d, $^2J_{H,H}$ = 14 Hz, 2 H, ArC$H_2$Ar), 4.12 (d, $^2J_{H,H}$ = 14 Hz, 2 H, ArC$H_2$Ar), 4.16 (d, $^2J_{H,H}$ = 15 Hz, 2 H, ArC$H_2$Ar), 4.25 (d, $^2J_{H,H}$ = 14 Hz, 2 H, ArC$H_2$Ar), 4.74 [d, $^2J_{P,H}$ = 7 Hz, 2 H, OC$H_2$P(O)$Ph_2$], 6.68 (s, 2 H), 6.77 (s, 2 H), 6.86 (s, 2 H), 7.13 (s, 2 H), 7.15 (s, 4 H), 7.45–7.58 (m, 6 H), 8.03–8.10 (m, 4 H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 29.90, 30.14, 30.19, 31.05, 31.25, 31.48, 31.52, 33.97, 34.00, 34.13, 59.73, 59.86, 60.00, 71.20 [d, $^1J_{P,C}$ = 96 Hz, O*C*H$_2$P(O)$Ph_2$], 124.23, 124.47, 124.87, 126.78, 127.15, 127.43, 128.70 (d, $^2J_{P,C}$ = 11 Hz), 130.84 (d, $^1J_{P,C}$ = 110 Hz), 131.70 (d, $^2J_{P,C}$ = 9 Hz), 132.30, 132.86, 133.20, 133.24, 133.52, 133.58, 145.60, 145.64, 146.56, 151.95 (d, $^3J_{P,C}$ = 13 Hz), 153.34, 154.14, 154.32 ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 27.9 ppm. $C_{84}H_{105}O_7P{\cdot}H_2O$ (1275.7): calcd. C 79.08, H 8.45; found C 79.44, H 8.40.

**5,11,17,23,29,35-Hexa-*tert*-butyl-37-(diphenylphosphanylmethoxy)-38,39,40,41,42-pentamethoxycalix[6]arene (3):** $PhSiH_3$ (2.78 g, 25.8 mmol) was added to a solution of **2** (1.08 g, 0.86 mmol) in 20 mL of toluene. The reaction mixture was refluxed for 2 d and then cooled down. After evaporation of the volatiles, an analytically pure product was obtained by recrystallization from dichloromethane/ethanol (1:5). Yield: 0.96 g (90%). M.p. 117–119 °C. ESI-MS: $m/z$ = 1264 $[M + Na]^+$. $^1H$ NMR ($CDCl_3$): $\delta$ = 0.92 (s, 9 H), 1.06 (s, 18 H), 1.27 (s, 9 H), 1.30 (s, 18 H), 2.50 (s, 6 H, OC$H_3$), 2.81 (s, 3 H, OC$H_3$), 3.26 (s, 6 H, OC$H_3$), 3.48 (d, $^2J_{H,H}$ = 15 Hz, 2 H, ArC$H_2$Ar), 3.70 (d, $^2J_{H,H}$ = 14 Hz, 2 H, ArC$H_2$Ar), 3.85 (d, $^2J_{H,H}$ = 15 Hz, 2 H, ArC$H_2$Ar), 4.03 (d, $^2J_{H,H}$ = 15 Hz, 2 H, ArC$H_2$Ar), 4.19 (d, $^2J_{H,H}$ = 14 Hz, 2 H, ArC$H_2$Ar), 4.35 (d, $^2J_{H,H}$ = 15 Hz, 2 H, ArC$H_2$Ar), 4.74 (d, $^2J_{P,H}$ = 4 Hz, 2 H, OC$H_2$P$Ph_2$), 6.78 (s, 2 H), 6.87 (s, 2 H), 6.93 (s, 2 H), 7.11 (s, 2 H), 7.15 (s, 2 H), 7.24 (s, 2 H), 7.34–7.38 (m, 6 H), 7.60–7.63 (m, 4 H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 30.38, 30.48, 30.64, 31.15, 31.30, 31.49, 31.53, 33.99, 34.04, 34.15, 59.88, 59.92, 60.00, 74.74 (d, $^1J_{P,C}$ = 9 Hz, O*C*H$_2$P$Ph_2$), 124.20, 124.82, 125.11, 126.62, 126.78, 127.42, 128.50 (d, $^2J_{P,C}$ = 6.3 Hz), 128.83, 133.18, 133.30, 133.42, 133.45, 133.62, 136.37 (d, $^1J_{P,C}$ = 11 Hz), 145.57, 145.90, 153.25 (d, $^3J_{P,C}$ = 5 Hz), 153.56, 154.20, 154.38 ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 30.38, 30.48, 30.64, 31.15, 31.30, 31.49, 31.53, 33.99, 34.04, 34.15, 59.88, 59.92, 60.00, 74.74 (d, $^1J_{P,C}$ = 9 Hz, O*C*H$_2$P$Ph_2$), 124.20, 124.82, 125.11, 126.62, 126.78, 127.42, 128.50 (d, $^2J_{P,C}$ = 6.3 Hz), 128.83, 133.18, 133.30, 133.42, 133.45, 133.62, 136.37 (d, $^1J_{P,C}$ = 11.4 Hz), 145.57, 145.90, 153.25 (d, $^3J_{P,C}$ = 5 Hz), 153.56, 154.20, 154.38 ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 30.44, 30.53, 30.81, 31.38, 31.48, 31.63, 31.68, 34.34, 34.43, 60.20, 60.24, 60.37, 75.02 (d, $^1J_{P,C}$ = 9 Hz, O*C*H$_2$P$Ph_2$), 124.60, 125.09, 125.41, 127.19,

**$[PtCl_2(3)_2]$:** A solution of ligand **3** (200 mg, 0.16 mmol) in $CH_2Cl_2$ (10 mL) was added to a solution of $[PtCl_2(COD)]$ (29.9 mg, 0.08 mmol) in 6 mL of $CH_2Cl_2$ over a period of 15 min. The solution was stirred at room temperature for 2 h. The resulting solution was then concentrated to about 0.5 mL under vacuum and the product was precipitated with ethanol (3 mL). The solid obtained was filtered and washed with ethanol to afford a pure product. Yield: 172 mg (78%). ESI-MS: *m*/*z* = 2770 $[M + Na]^+$. $^1H$ NMR ($CDCl_3$): $\delta$ = 0.76 (s, 18 H), 0.88 (s, 36 H), 1.31 (s, 18 H), 1.32 (s, 36 H), 2.03 (s, 12 H, $OCH_3$), 2.43 (s, 6 H, $OCH_3$), 3.05 (d, $^2J_{H,H}$ = 15 Hz, 4 H, $ArCH_2Ar$), 3.47–3.57 (m, 16 H, $OCH_3$ overlapped with $ArCH_2Ar$), 3.66 (d, $^2J_{H,H}$ = 15 Hz, 4 H, $ArCH_2Ar$), 3.72 (d, $^2J_{H,H}$ = 15 Hz, 4 H, $ArCH_2Ar$), 4.23 (d, $^2J_{H,H}$ = 15 Hz, 4 H, $ArCH_2Ar$), 4.30 (d, $^2J_{H,H}$ = 15 Hz, 4 H, $ArCH_2Ar$), 5.07 (br. s, 4 H, $OCH_2PPh_2$), 6.51 (br. s, 4 H), 6.69 (br. s, 4 H), 6.74 (br. s, 4 H), 7.06 (br. s, 4 H), 7.10–7.23 (m, 16 H), 7.27–7.37 (m, 4 H), 7.78–7.90 (m, 8 H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 29.84, 30.33, 30.54, 31.40, 31.60, 31.98, 34.33, 34.38, 34.57, 59.82, 60.34, 77.27, 77.59, 124.24, 124.63, 125.40, 126.53, 127.49, 127.66, 128.22, 128.76, 131.90, 133.14, 133.44, 133.55, 133.93, 134.05, 135.06, 135.15, 136.37 145.87, 146.01, 146.91, 153.47, 154.70 ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 6.0 ($^1J_{Pt,P}$ = 3611 Hz) ppm. $C_{168}H_{210}Cl_2O_{12}P_2Pt{\cdot}CH_2Cl_2$ (2834.3): calcd. C 71.62, H 7.54; found C 71.45, H 7.57.

**$[Rh(COD)(3)_2]BF_4$:** A solution of ligand **3** (100 mg, 0.08 mmol) in $CH_2Cl_2$ (12 mL) was added to a solution of $[Rh(COD)_2]BF_4$ (17.2 mg, 0.04 mmol) in 6 mL of THF over a period of 15 min. The solution was stirred at room temperature for 3 h. Removal of the solvent gave a crude product as yellow solid, which was purified by reprecipitation from $CH_2Cl_2$ solution with hexane. Yield: 72.4 mg (68%). ESI-MS: *m*/*z* = 2694 $[M - BF_4^-]^+$. $^1H$ NMR ($CDCl_3$): $\delta$ = 0.76 (s, 18 H), 0.91 (s, 36 H), 1.30 (s, 18 H), 1.34 (s, 36 H), 2.09 (s, 12 H, $OCH_3$), 2.24–2.41 (m, 8 H), 2.46 (s, 6 H, $OCH_3$), 2.58 (br., 4 H), 2.66 (d, *J* = 15 Hz, 4 H, $ArCH_2Ar$), 3.51 (s, 12 H, $OCH_3$), 3.61 (d, *J* = 14 Hz, 4 H, $ArCH_2Ar$), 3.66 (d, $^2J_{H,H}$ = 15 Hz, 4 H, $ArCH_2Ar$), 4.23 (d, $^2J_{H,H}$ = 15 Hz, 4 H, $ArCH_2Ar$), 4.30 (d, $^2J_{H,H}$ = 15 Hz, 4 H, $ArCH_2Ar$), 4.54 (br., 4 H, $OCH_2PPh_2$), 5.10 (br., 4 H), 6.46 (br., 4 H), 6.72 (br., 4 H), 6.78 (br., 4 H), 6.99 (br., 4 H), 7.16 (br., 4 H), 7.19 (br., 4 H), 7.34–7.47 (m, 12 H), 7.86–7.98 (m, 8 H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 30.04, 30.27, 30.45, 31.16, 31.42, 31.62, 31.96, 32.00, 34.32, 34.40, 34.61, 60.01, 60.39, 77.62, 99.10, 124.40, 124.84, 127.60, 127.92, 128.56, 129.60, 132.02, 132.78, 132.92, 133.53, 133.88, 133.97, 134.93, 146.09, 146.78, 152.45, 153.47, 154.60 ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 20.8 (d, $^1J_{Rh,P}$ = 141 Hz) ppm. $C_{176}H_{222}BF_4O_{12}P_2Rh{\cdot}CH_2Cl_2$ (2866.2): calcd. C 74.17, H 7.88; found C 74.27, H 7.91.

**Hydroformylation:** In a typical experiment, $[Rh(COD)_2]BF_4$ (2 mg, 0.005 mmol) and **3** (25 mg, 0.02 mmol) were introduced into a 50-mL stainless-steel autoclave (Toyo koatsu) under argon. Benzene (2 mL), decane (71 mg, 0.5 mmol, as an internal standard), and 1-hexene (84 mg, 1 mmol) were then added and the resulting solution was stirred under argon for 1 h. The autoclave was then pressurized to 10 atm with $H_2$/CO (1:1) and the reaction mixture was stirred at 70 °C for 16 h. The products were analyzed by GC and GC-MS and the structures were confirmed by spectral comparison with authentic aldehydes. The GC yields were determined by the internal standard method.

**X-ray Crystallography:** Details of the crystal data and a summary of intensity data collection parameters for **3** and $[PtCl_2(3)_2]$ are given in Table 5. Single crystals of **3** and $[PtCl_2(3)_2]$ were grown by slow diffusion of ethanol into a toluene solution of **3** and diffusion of methanol into a toluene solution of $[PtCl_2(3)_2]$. Data were collected with a Rigaku Saturn CCD diffractometer area detector with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.7107 Å) to a maximum $2\theta$ value of 55.0°. The structures were solved by direct methods using the program SIR2002[42] and expanded using Fou-

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $I > 2.3\sigma(I)$. [c] $I > 2.0\sigma(I)$. [d] $wR_2$ $[I > 2.3\sigma(I)] = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2}$, $w = [0.0010F_o^2 + 3.0000\sigma(F_o^2) + 0.5000]^{-1}$. [e] $wR_2$ (all data) $= [\Sigma\{w(F_o^2 - F_c^2)^2\}/\Sigma w(F_o^2)^2]^{1/2}$, $w = [\sigma^2(F_o^2) + (0.0713P)^2 + 43.3300P]^{-1}$ where $P = [\mathrm{Max}(F_o^2,0) + 2F_c^2]/3$.

rier techniques.[43] For **3**, non-hydrogen atoms except some of the solvent molecules were refined anisotropically. Hydrogen atoms were included in fixed positions. The final cycle of full-matrix least-squares refinement on $F$ was based on 8953 observed reflections [$I > 2.3\sigma(I)$] and 881 variable parameters. A Sheldrick weighting scheme was used. For $[PtCl_2(\mathbf{3})_2]$, non-hydrogen atoms except some *tert*-butyl carbon atoms and solvent molecules were refined anisotropically. Some *tert*-butyl carbon atoms were disordered over multiple positions, which were refined isotropically at fixed positions with appropriate occupation factors without hydrogen atoms. Hydrogen atoms were refined using the riding model. The final cycle of full-matrix least-squares refinement on $F^2$ was based on 41459 observed reflections (using all data) and 1785 variable parameters. Neutral-atom scattering factors were taken from Cromer and Waber.[44] Anomalous dispersion effects were included in $F_c$.[45] All calculations were performed with the CrystalStructure[46] crystallographic software package except for the refinement of $[PtCl_2(\mathbf{3})_2]$, which was performed with SHELXH-97.[47] CCDC-278415 (**3**) and -278416 $[PtCl_2(\mathbf{3})_2]$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis, Structure and Reactivity of Homo- and Heterobimetallic Complexes of the General Formula [Cp*Ru(μ-Cl)$_3$ML] [LM = (arene)Ru, Cp*Rh, Cp*Ir]

**Laurent Quebatte,[a] Rosario Scopelliti,[a][‡] and Kay Severin*[a]**

**Keywords:** Heterometallic complexes / Iridium / Rhodium / Ruthenium

The homo- and heterobimetallic complexes [Cp*Ru(μ-Cl)$_3$-ML] [LM = ($C_6H_6$)Ru, (cymene)Ru, (1,3,5-$C_6H_3i$Pr$_3$)Ru, Cp*Rh, Cp*Ir] were prepared by reaction of [Cp*Ru(μ-OMe)]$_2$ with $Me_3SiCl$ and subsequent addition of [LMCl$_2$]$_2$. The complexes [Cp*Ru(μ-Cl)$_3$Ru(cymene)] and [Cp*Ru(μ-Cl)$_3$-IrCp*] were characterized by single-crystal X-ray analyses. In crossover experiments with [Cp*Rh(μ-Cl)$_3$RuCl(PPh$_3$)$_2$] and [Cp*Ru(μ-Cl)$_3$Ru(1,3,5-$C_6H_3i$Pr$_3$)] in $CD_2Cl_2$, a dynamic equilibrium with the complexes [Cp*Rh(μ-Cl)$_3$RuCp*] and [(1,3,5-$C_6H_3i$Pr$_3$)Ru(μ-Cl)$_3$RuCl(PPh$_3$)$_2$] was rapidly established, demonstrating the kinetic lability of the triple chloro bridge. Upon reaction of [Cp*Rh(μ-Cl)$_3$RuCp*] with benzene, the ionic complex [Cp*Ru($C_6H_6$)][Cp*RhCl$_3$] was formed, which was characterized by X-ray crystallography.

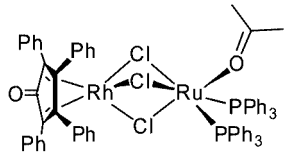
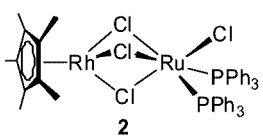
## Introduction

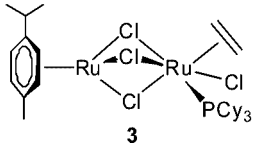
Bimetallic complexes, in which two different metal fragments are connected by either two or three halogeno bridges, have been employed as catalyst precursors for ring-opening and ring-closing metathesis reactions,[1] for the Oppenauer-type oxidation of alcohols,[2] and for atom-transfer radical reactions.[3] The heterobimetallic Rh$^{I}$–Ru$^{II}$ complex **1**, for example, can be used as an efficient catalyst for the oxidation of secondary alcohols under mild conditions,[2a] whereas the Rh$^{III}$–Ru$^{II}$ complex **2**[3c] and the Ru$^{II}$–Ru$^{II}$ complex **3**[3a] are among the most active catalysts available for the atom-transfer radical addition of $CCl_4$ and $CHCl_3$ to olefins.



**1**



**2**



**3**

The synthesis of mixed, halogeno-bridged complexes can be accomplished by several synthetic routes.[4] Mixed complexes with two halogeno bridges are most conveniently obtained in metathesis reactions starting from the corresponding homodimeric compounds. Reactions of this kind were first described by the groups of Stone[5] and Masters[6] in the 1970s. More recent investigations have shown that this method is quite general.[7,8] Mixed complexes with three halogeno-bridges can likewise be obtained in metathesis reactions[9,10] but alternative pathways such as ligand-transfer[11] or substitution[3a,3b,12] reactions have also been explored.[4] The various methods allow the synthesis of a structurally diverse set of homo- and heterobimetallic complexes in relatively short time. This is of interest for the generation of catalyst libraries in combinatorial catalysis.[3c] In the following, we introduce a new procedure that allows the synthesis of complexes of the general formula [Cp*Ru(μ-Cl)$_3$ML] [LM = (arene)Ru, Cp*Rh, Cp*Ir] in excellent yields.

## Results and Discussion

For the synthesis of mixed complexes containing the Cp*RuCl fragment, the tetrameric complex [Cp*RuCl]$_4$ (**4**) seemed to be well suited as it is known that the chloro bridges of **4** can be easily cleaved.[13–16] The reaction of **4** with two equivalents of the dimeric half-sandwich complex [(π-ligand)MCl$_2$]$_2$ was thus expected to give the mixed complex [Cp*Ru(μ-Cl)$_3$M(π-ligand)] in an entropically favored reaction. Complex **4** can be obtained by reduction of [Cp*RuCl$_2$]$_2$ with $LiHBEt_3$[14] or with Zn.[15] Alternatively, it can be obtained by reaction of the methoxy-bridged complex [Cp*Ru(μ-OMe)]$_2$ (**5**) with $Me_3SiCl$.[16] We chose the latter method for our reactions.

For the synthesis of the homo- and heterobimetallic complexes **6**–**10**, the tetramer **4** was generated in situ by addition of $Me_3SiCl$ to complex **5** in $CH_2Cl_2$. Subsequent ad-

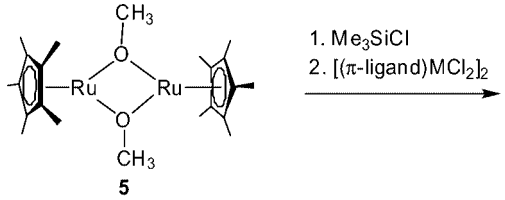
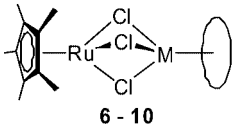
dition of $[(\pi\text{-ligand})MCl_2]_2$ gave the mixed products **6**–**10** (Scheme 1). Complex **4** displays a high solubility in a variety of nonpolar organic solvents and even in hydrocarbons such as pentane. It was thus possible to use a slight excess of **5** (1.2×) with respect to the dimer $[(\pi\text{-ligand})MCl_2]_2$ because additional **4** could easily be removed by washing with pentane. The homobimetallic product **10**, on the other hand, is itself soluble in pentane. We therefore used a slight excess of $[(1,3,5\text{-}C_6H_3iPr_3)RuCl_2]_2$ (1.2×) and purified the product **10** by extraction with pentane.





| | (π-ligand)M |
|---|---|
| **6** | $(C_6H_6)Ru$ |
| **7** | (cymene)Ru |
| **8** | Cp*Rh |
| **9** | Cp*Ir |
| **10** | $(C_6H_3iPr_3)Ru$ |

Scheme 1. Synthesis of the complexes **6**–**10**.

The new complexes **6**–**10** were characterized by $^1H$ and $^{13}C$ NMR spectroscopy and by elemental analysis. In addition, complexes **7** and **9** were analyzed by single-crystal X-ray analysis (Figures 1 and 2, respectively). The crystallographic analyses confirmed that the two metal fragments are connected by three chloro bridges. The planes defined by the π-ligands and the plane defined by the three bridging chloro ligands are nearly parallel to each other. For complex **7**, the distances of the chloro atoms to the Ru atom attached to the cymene π-ligand (Ru–Cl = 2.42–2.45 Å) are shorter than those to the Ru atom attached to the Cp* ligand (Ru–Cl = 2.50–2.56 Å). A likely explanation for this difference is the increased Lewis acidity of the (cymene)-$Ru^{2+}$ fragment compared to the $Cp^*Ru^+$ fragment. The two Ru atoms in **7** are 3.344(8) Å apart from each other. This is longer than what is found for the cationic dimer [(cymene)-$Ru(\mu\text{-}Cl)_3Ru$(cymene)]$^+$ [Ru···Ru = 3.283(3) Å].[17]

In the highly symmetrical dimer **9**, a $Cp^*Ru^+$ fragment is connected by three chloro bridges to a $Cp^*Ir^{2+}$ fragment. As was observed for **7**, the M–Cl bond lengths are shorter for the more Lewis-acidic metal fragment: the Ir–Cl distances range from 2.41 to 2.45 Å, whereas the Ru–Cl distances range from 2.50 to 2.52 Å. Complex **9** is isoelectronic with the mixed-valence $Ru^{II}$–$Ru^{III}$ complex [$Cp^*Ru(\mu\text{-}Cl)_3$-RuCp*] described by Koelle et al.,[16a,19] although due to the lack of structural data for the latter a direct comparison was not possible.

The prevalence of polynuclear ruthenium complexes with the $Ru(\mu\text{-}Cl)_3M$ structural motif suggests that the connection by three chloro bridges is thermodynamically very stable. In fact, it has been shown that some catalysts can be deactivated by the formation of face-bridged dimers.[20] In order to investigate the kinetic stability of the bimetallic complexes described above, crossover experiments were performed. Thus, a solution of complex **2** was mixed with a solution of complex **10** (both in $CD_2Cl_2$) and a $^1H$ NMR spectrum was recorded immediately after mixing. Apart from signals of the complexes **2** and **10**, the signals of two other complexes were observed (Figure 3). These were identified as the mixed complexes **8** and **11** by comparison with the $^1H$ NMR spectra of authentic samples (Scheme 2). The time-invariant integrals of the respective signals showed a nearly equimolar distribution of the four species. This suggests that a dynamic equilibrium between the four complexes is rapidly established after the mixing process.

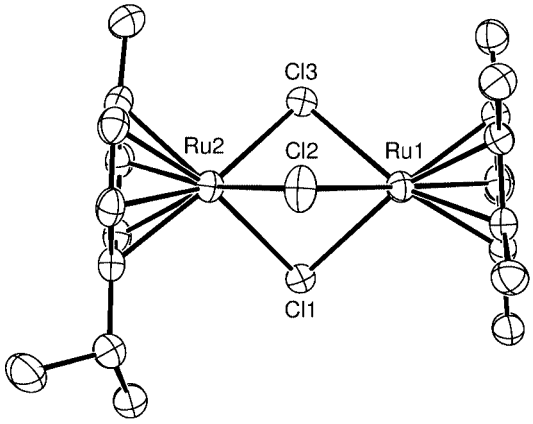


Figure 1. ORTEP[18] drawing of the molecular structure of **7** in the crystal. The hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–Cl1 2.5591(13), Ru1–Cl2 2.5024(14), Ru1–Cl3 2.5075(14), Ru2–Cl1 2.4521(13), Ru2–Cl2 2.4222(13), Ru2–Cl3 2.4205(13); Ru1–Cl1–Ru2 83.70(4), Ru1–Cl2–Ru2 85.53(4), Ru1–Cl3–Ru2 85.45(4), Cl1–Ru1–Cl2 76.70(4), Cl1–Ru2–Cl2 80.23(5).

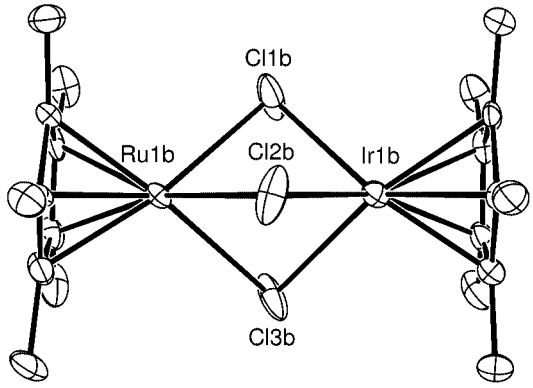

Figure 2. ORTEP[18] drawing of the molecular structure of **9** in the crystal. Only one of the two crystallographically independent molecules is shown. The hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1b–Cl1b 2.516(3), Ru1b–Cl2b 2.509(3), Ru1b–Cl3b 2.523(3), Ir1b–Cl1b 2.413(3), Ir1b–Cl2b 2.410(3), Ir1b–Cl3b 2.428(3); Ru1b–Cl1b–Ir1b 85.32(8), Ru1b–Cl2b–Ir1b 85.54(8), Ru1b–Cl3b–Ir1b 84.86(8), Cl1b–Ru1b–Cl2b 77.90(10), Cl1b–Ir1b–Cl2b 81.85(11).

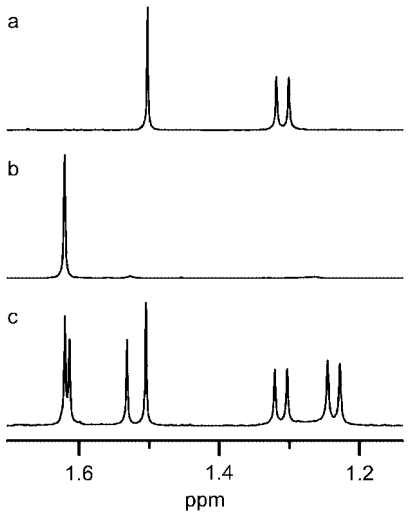

Figure 3. Part of the $^1$H NMR spectrum of a) complex **10**, b) complex **2**, and c) an equimolar mixture of complex **2** and **10**, for which the additional signals of the complexes **8** and **11** are visible.

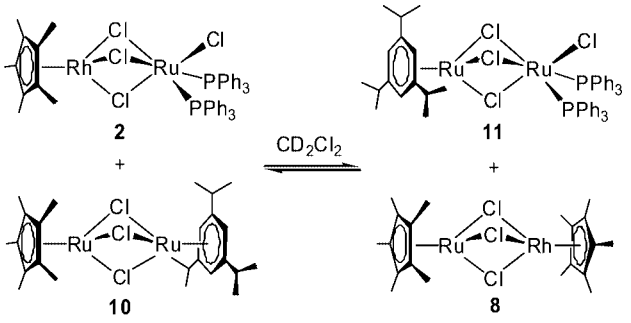
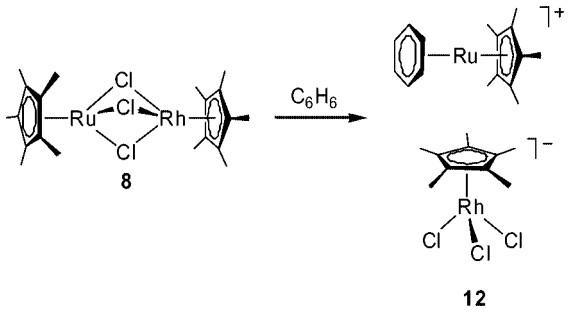


Scheme 2. In solution ($CD_2Cl_2$), complexes **2** and **10** are in a dynamic equilibrium with complexes **8** and **11**.

The results described above are in agreement with a report by Stephenson et al. in which they show that upon mixing of $[(C_6H_6)Ru(\mu\text{-}Cl)_3Ru(C_6H_6)]^+$ and $[(C_6H_6)Os(\mu\text{-}Cl)_3Os(C_6H_6)]^+$, the heterobimetallic complex $[(C_6H_6)Ru(\mu\text{-}Cl)_3Os(C_6H_6)]^+$ is obtained in equilibrium with the two homobimetallic starting materials.[21] We have previously shown that the triply bridged complex [(dcypb)$(N_2)$Ru(μ-Cl)$_3$RuCl(dcypb)] reacts rapidly with doubly bridged complexes of the general formula $[LMCl_2]_2$ [L = (cymene)Ru, Cp*Rh, Cp*Ir] to give the mixed complexes [(dcypb)ClRu(μ-Cl)$_3$ML].[9b] Taken together, these results point to the fact that $[L_nRu(\mu\text{-}Cl)_3ML'_n]$ complexes are generally very labile, despite their apparent thermodynamic stability.

Complexes **6**–**10** are soluble in a variety of organic solvents such as acetone, THF, $CH_2Cl_2$, and $Et_2O$. The very lipophilic **10** can even be dissolved in pentane. Aromatic solvents, on the other hand, are not suited because of the very high tendency of the $Cp^*Ru^+$ fragment to form sandwich complexes of the general formula [Cp*Ru(arene)]-X.[14–16,22] When complex **8** was dissolved in benzene, crystals of the ionic complex $[Cp^*Ru(C_6H_6)][Cp^*RhCl_3]$ (**12**) formed after a few hours (Scheme 3). Larger amounts of **12** could be obtained by slow diffusion of hexane into a solution of **8** in benzene.



Scheme 3. The ionic complex **12** is obtained by reaction of complex **8** with benzene.

The structure of complex **12** was analyzed by single-crystal X-ray analysis (Figure 4). The bond lengths found for the cation $[Cp^*Ru(C_6H_6)]^+$ ($Ru\text{–}C_{benzene}$ = 2.21–2.22 Å; $Ru\text{–}C_{Cp^*}$ = 2.18–2.19 Å) are very similar to those reported for related $[Cp^*Ru(arene)]^+$ complexes.[22a,22d,23] The corresponding anion $[Cp^*RhCl_3]^-$ displays a typical "pianostool" geometry, with Rh–Cl bond lengths of 2.4114(14) and 2.420(2) Å, respectively. The formation of this anion is rather unusual[24] given the thermodynamic stability of the $[Cp^*Rh(\mu\text{-}Cl)_3RhCp^*]^+$ cation,[11,25] and underlines the fact that the generation of $[Cp^*Ru(C_6H_6)]^+$ is the driving force for the reaction.

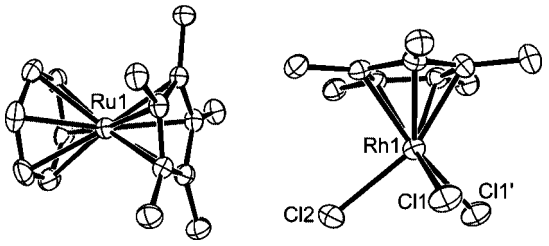


Figure 4. ORTEP[18] drawing of the molecular structure of **12** in the crystal. The hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Rh1–Cl1 2.4114(14), Rh1–Cl2 2.420(2); Cl1–Rh1–Cl2 90.97(5), Cl1–Rh1–Cl1′ 91.15(7). ′: $x$, $1/2 - y$, $z$.

## Conclusions

Bimetallic complexes, in which two different metal fragments are connected by either two or three halogeno bridges, have recently emerged as a promising new class of catalysts.[1–3] New synthetic routes to generate such complexes are thus highly warranted. In this report, we have described the homo- and heterobimetallic complexes $[Cp^*Ru(\mu\text{-}Cl)_3ML]$ [LM = $(C_6H_6)$Ru, (cymene)Ru, (1,3,5-$C_6H_3iPr_3$)Ru, Cp*Rh, Cp*Ir]. They can be prepared in excellent yield by reaction of $[Cp^*Ru(\mu\text{-}OMe)]_2$ with $Me_3SiCl$ and subsequent addition of $[LMCl_2]_2$. Crossover experiments have demonstrated that these complexes undergo fast scrambling reactions with other triply bridged complexes. The dimers are thus kinetically very labile, a fact which is of importance for possible catalytic applications. In a reaction with benzene, the chloro bridge of the complex $[Cp^*Ru(\mu\text{-}Cl)_3RhCp^*]$ is cleaved in a completely asymmet-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ric fashion to give the cation $[Cp^*Ru(C_6H_6)]^+$ and the anion $[Cp^*RhCl_3]^-$. This type of reactivity is unusual for $[L_nRu(\mu\text{-}Cl)_3ML'_n]$ complexes but can be explained by the high intrinsic affinity of the $Cp^*Ru^+$ fragment for aromatic compounds.

## Experimental Section

**General:** All reactions were performed under an atmosphere of dry dinitrogen. The solvents and $Me_3SiCl$ were distilled from appropriate drying agents and stored under dinitrogen. The complexes $[Cp^*Ru(OMe)]_2$,[26] $[(cymene)RuCl_2]_2$,[27] $[(C_6H_6)RuCl_2]_2$,[28] $[Cp^*RhCl_2]_2$,[29] $[Cp^*IrCl_2]_2$,[29] $[(1,3,5\text{-}C_6H_3iPr_3)RuCl_2]_2$,[30] and $[Cp^*Rh(\mu\text{-}Cl)_3RuCl(PPh_3)_2]$ (**2**)[2b] were prepared according to literature procedures. An authentic sample of complex **11** was synthesized by mixing equimolar amounts of $[(PPh_3)_2ClRu(\mu\text{-}Cl)_3Ru(acetone)(PPh_3)_2]$ and $[(1,3,5\text{-}C_6H_3iPr_3)RuCl_2]_2$ in $CH_2Cl_2$.[9b] The $^1H$ and $^{13}C$ NMR spectra were recorded on a Bruker Advance DPX 400 spectrometer with the residual protonated solvent as internal standards. All spectra were recorded at room temperature.

**General Method for the Synthesis of Complexes 6–9:** $Me_3SiCl$ (71 μL, 561 μmol) was added to a solution of $[Cp^*Ru(OMe)]_2$ (100 mg, 187 μmol) in $CH_2Cl_2$ (10 mL). After addition of the respective dimer $[(\pi\text{-ligand})MCl_2]_2$ (156 μmol), the solution was stirred for 20 min. The solvent was then removed in vacuo and the resulting powder was suspended in pentane (10 mL) in order to dissolve the excess of complex $[CpRuCl]_4$. The product was isolated by filtration, washed with additional pentane (3 × 2 mL) and dried under vacuum (yield: 88–96%).

**Complex 6:** Red powder. $^1H$ NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.50 (Cp*), 5.60 (benzene) ppm. $^{13}C$ NMR (101 MHz, $CD_2Cl_2$): $\delta$ = 10.4 ($CH_3$, Cp*), 70.9 (C, Cp*), 80.5 (benzene) ppm. $C_{16}H_{21}Cl_3Ru_2 \cdot 1/6\,C_5H_{12}$ (533.9): calcd. C 37.87, H 4.34; found C 37.96, H 4.51.

**Complex 7:** Red powder. Crystals suitable for X-ray analysis were obtained by slow diffusion of pentane into a solution of **7** in dichloromethane. $^1H$ NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.29 [d, $^3J$ = 7.1 Hz, 6 H, $CH(CH_3)_2$], 1.51 (s, 15 H, $CH_3$, Cp*), 2.18 (s, 3 H, $CH_3$, cymene), 2.82 [sept, $^3J$ = 7.1 Hz, 1 H, $CH(CH_3)_2$], 5.21 (d, $^3J$ = 6.0 Hz, 4 H, CH), 5.43 (d, $^3J$ = 6.0 Hz, 4 H, CH) ppm. $^{13}C$ NMR (101 MHz, $CD_2Cl_2$): $\delta$ = 10.4 ($CH_3$, Cp*), 19.0, 22.4 ($CH_3$, cymene), 31.6 [$CH(CH_3)_2$], 70.6 (C, Cp*), 77.8, 78.9 (CH, cymene), 95.3, 100.3 (C, cymene) ppm. $C_{20}H_{29}Cl_3Ru_2$ (577.9): calcd. C 41.56, H 5.06; found C 41.56, H 5.23.

**Complex 8:** Red powder. $^1H$ NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.52 (Cp*Ru), 1.61 (Cp*Rh) ppm. $^{13}C$ NMR (101 MHz, $CD_2Cl_2$): $\delta$ = 9.5, 10.5 ($CH_3$, Cp*), 70.0 (C, Cp*Ru), 93.6 (d, $^1J_{C,Rh}$ = 10.1 Hz, C, Cp*Rh) ppm. $C_{20}H_{30}Cl_3RhRu$ (580.0): calcd. C 41.36, H 5.21; found C 41.51, H 5.26.

**Complex 9:** Orange powder. Crystals suitable for X-ray analysis were obtained by slow diffusion of pentane into a solution of **9** in a mixture of dichloromethane and hexane (1:9). $^1H$ NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.57 (Cp*), 1.58 (Cp*) ppm. $^{13}C$ NMR (101 MHz, $CD_2Cl_2$): $\delta$ = 9.5, 10.5 ($CH_3$), 70.3, 85.2 (C) ppm. $C_{20}H_{30}Cl_3IrRu$ (670.1): calcd. C 35.85, H 4.51; found C 35.99, H 4.57.

**Synthesis of Complex 10:** $Me_3SiCl$ (30 μL, 240 μmol) was added to a solution of $[Cp^*Ru(OMe)]_2$ (43 mg, 80 μmol) in $CH_2Cl_2$ (5 mL). After addition of $[(C_6H_3iPr_3)RuCl_2]_2$ (72 mg, 96 μmol), the solution was stirred for 20 min. The solvent was then removed in vacuo and the product was extracted with pentane (2 × 5 mL). The product was isolated by evaporation of the pentane and drying under vacuum. Yield: 94 mg (92%). $^1H$ MNR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.31 [d, $^3J$ = 7.1 Hz, 18 H, $CH(CH_3)_2$], 1.50 (s, 15 H, $CH_3$, Cp*), 2.90 [sept, $^3J$ = 7.1 Hz, 3 H, $CH(CH_3)_2$], 5.09 (s, 3 H, CH) ppm. $^{13}C$ NMR (101 MHz, $CD_2Cl_2$): $\delta$ = 10.5 ($CH_3$, Cp*), 22.5 [$CH(CH_3)_2$],

Table 1. Crystallographic data for complexes **7**, **9**, and **12**.

32.0 [*C*H($CH_3$)$_2$], 70.3 (CH), 70.4 (C, Cp*), 106 (C, $C_6H_3iPr_3$) ppm. $C_{25}H_{39}Cl_3Ru_2$ (648.1): calcd. C 46.33, H 6.07; found C 46.30, H 6.13.

**Exchange Reactions:** Complex **10** (5.5 mg, 8.6 μmol) was dissolved in $CD_2Cl_2$ (500 μL) and a $^1$H NMR spectrum of the solution was recorded (400 MHz). A sample of complex **2** (8.7 mg, 8.6 μmol) was analyzed in the same fashion. The two solutions were subsequently mixed and immediately analyzed by $^1$H NMR spectroscopy (400 MHz).

**Synthesis of Complex 12:** Complex **8** (15.0 mg, 25.8 μmol) was dissolved in benzene (2 mL). The resulting mixture was allowed to react for 2 h, after which small crystals of complex **12** could already be observed. Slow addition of hexane (5 mL) by diffusion over 12 h resulted in the formation of crystalline **12**, which was isolated by filtration. Isolated yield: 12.5 mg (73%). The reaction was quantitative, as evidenced by $^1$H NMR analysis of the remaining solution. $^1$H NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.57, 2.07 (Cp*), 6.05 (benzene) ppm. $^{13}$C NMR (101 MHz, $CD_2Cl_2$): $\delta$ = 9.4, 11.3 ($CH_3$, Cp*), 87.7 (benzene), 94.4 (d, $^1J_{C-Rh}$ = 14 Hz, C, Cp*Rh), 97.1 (C, Cp*Ru) ppm. $C_{26}H_{36}Cl_3RhRu$ (658.9): calcd. C 47.39, H 5.51; found C 47.55, H 5.12.

**X-ray Crystallography:** Details of the crystals and their structure refinement are listed in Table 1; relevant geometrical parameters are given in the respective figure captions. Data collection was performed at 140(2) K on a four-circle goniometer having kappa geometry and equipped with an Oxford Diffraction KM4 Sapphire CCD (**9**) or a mar345 imaging plate detector (**7** and **12**). Data reduction was carried out with CrysAlis RED, release 1.7.0.[31] An absorption correction was applied to all data sets. Structure solution and refinement were performed with the SHELXTL software package, release 5.1.[32] The structures were refined using the full-matrix least-squares on $F^2$ with all non-H atoms anisotropically defined. H atoms were placed in calculated positions using the "riding model".

CCDC-279177 to -279179 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Mu-34: a New Porous Layered Fluorogallophosphate Material Obtained by in Situ Generation of Ethylamine

**Louwanda Lakiss,[a] Angélique Simon-Masseron,[a] Florence Porcher,[b] and Joël Patarin*[a]**

**Keywords:** Fluorogallophosphate / Ethylformamide / Solvothermal synthesis / Ethylamine / Porous layered solids / Microporous materials

A new two-dimensional microporous fluorogallophosphate with porous layers, named Mu-34, has been synthesized by in situ generation of ethylamine as the structure-directing agent, the latter arising from the decomposition of ethylformamide. The fluorogallophosphate Mu-34, $Ga_6P_8O_{32}FC_{14}N_7H_{56}$ ($Z$ = 2), crystallizes in the triclinic space group $P\bar{1}$ with the following unit cell parameters: $a$ = 11.0832(6), $b$ = 11.393(6), $c$ = 21.335(1) Å, $\alpha$ = 100.62(4), $\beta$ = 99.66(5), $\gamma$ = 108.34(5)°. The structure was solved from single crystal XRD data. This new fluorogallophosphate displays porous layers with apertures delimited by 12-membered rings intercalated by protonated ethylamine molecules. Mu-34 was also characterized by powder XRD, SEM, elemental and thermal analyses, and $^{13}C$, $^{19}F$, and $^{31}P$ MAS solid state NMR spectroscopy.

## Introduction

Since the discovery of the microporous aluminophosphates by Wilson et al.,[1] research in the field of microporous materials has attracted considerable interest, owing to their potential uses as molecular sieves, heterogeneous catalysts, or ion exchangers.[2] The family of crystalline microporous phosphates is not limited to aluminophosphates; it also includes in particular zincophosphates and gallophosphates. These latter compounds allow a wide variety of structures to be formed, because gallium atoms can adopt 4-, 5-, and 6- coordinations. A main advance in the synthesis of these solids was achieved when fluoride anions were introduced in the starting mixture.[3] Thus, numerous fluorogallophosphates were obtained[4,5] such as cloverite, which was until now the molecular sieve with the largest 3D pore channel system.[6] In most cases $F^-$ was found to be present in the inorganic framework as terminal Ga-F groups, bridging gallium atoms or trapped into small building units such as the so-called double four rings (D4R units). In the latter case it seems that fluorine, besides its mineralizing role, plays a templating role stabilizing these units.[5–8] To date, a large number of metallophosphates with 0D, 1D, 2D, or 3D frameworks have been reported.[3–13] Some of these solids were obtained through a newly developed synthesis route that consists of the in situ formation of the structure-directing agent (SDA).[9–13] In this synthesis route, alkylformamides are introduced as the main solvents in the starting mixture and during the synthesis they partly decompose into the corresponding amine which acts as a template and is occluded in the final material. With this method, it was possible to produce the two-layered aluminophosphates, Mu-4,[9] Mu-7[10] and, more recently, the three new gallophosphates MIL30,[11] Mu-30,[12] and Ea-TREN-GaPO.[13]

In this paper, we report the synthesis, structure determination, and characterization of a new porous 2D fluorogallophosphate named Mu-34 (Mu standing for Mulhouse), which was prepared in a quasi nonaqueous medium using ethylformamide (EFD) as the main solvent. As for the other solids described above, in this case too, the in situ formation of ethylamine seems to play a key role in the formation of this solid.

## Results and Discussion

### Synthesis and Crystal Morphology

The synthesis results are summarized in Table 1. The fluorogallophosphate Mu-34 crystallizes after 4 days at 200 °C (Table 1, sample A). With a similar starting molar composition but with a longer heating period (50 days) the gallophosphate ULM-3 was obtained as a pure phase (sample B). Such a result reveals the instability of Mu-34 in this reaction medium. Under these experimental conditions, it appears that the pH has to be high enough otherwise, whatever the gallium source (GaOOH or $Ga_2O_3$), the gallophos-

[a] $H_2O$ arising from the orthophosphoric acid (85% $H_3PO_4$) and hydrofluoric acid (40% HF). [b] The two phases crystallize with the same proportion. [c] Unknown phase. * The gallium source was $Ga_2O_3$.

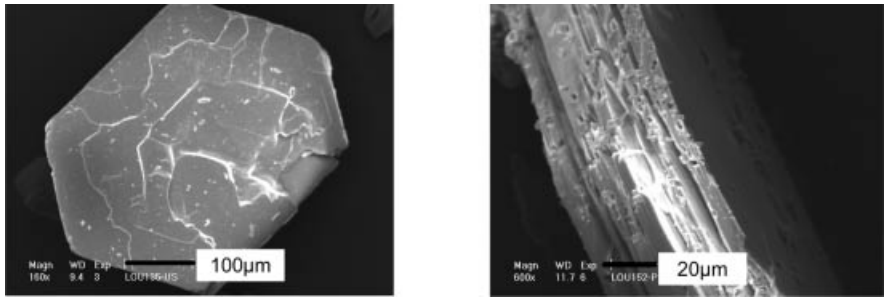

Figure 1. Scanning electron micrographs of the fluorogallophosphate Mu-34.

phates Ea-TREN-GaPO[13] and $GaPO_4$–C4[14] co-crystallize. This is clearly reflected by the experiments C and D performed in the absence of tripropylamine as a pH modifier. The presence of fluorine is also crucial. In its absence no crystalline phase is obtained. However, too large an amount leads to the formation of the gallophosphate ULM-4[15] (see sample E).

As can be seen in Figure 1, the crystals of Mu-34 display a pseudo-hexagonal shape. A close-up view shows that the crystals are in fact stacks of plate-like crystallites. This is indicative of a lamellar material.

## XRD Analysis

The experimental powder diffraction pattern of the fluorogallophosphate Mu-34 is reported in part a of Figure 2 (a). From the single crystal XRD analysis, it has been indexed in a triclinic symmetry with the following unit cell parameters: $a$ = 11.0832(6), $b$ = 11.393(6), $c$ = 21.335(1) Å, $\alpha$ = 100.62(4), $\beta$ = 99.66(5), $\gamma$ = 108.34(5)°. For comparison, the simulated XRD pattern of Mu-34 is reported in Figure 2 (b).

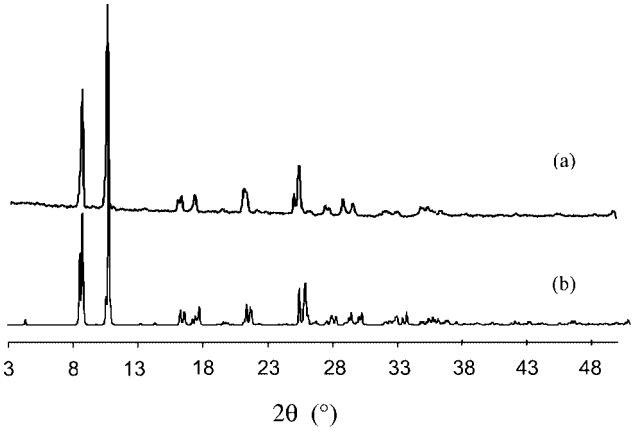

Figure 2. XRD patterns of the fluorogallophosphate Mu-34: (a) experimental pattern; (b) simulated pattern (radiation Cu-$K_\alpha$1).

## Chemical and Thermal Analyses

According to the elemental analyses, the as-synthesized Mu-34 sample has the following composition (wt.-%): Ga 27.46; P 15.56; F 1.57; N 6.19; C 10.74. Such results are in agreement with the composition obtained from the structure determination (wt.-%) Ga 27.20; P 16.11; F 1.26; N 6.37; C 10.93. The experimental C/N molar ratio equal to 2 is different from the value expected for ethylformamide (3C:1N), suggesting that the solvent partly decomposed into carbon monoxide and ethylamine (EA) during synthesis. This was later confirmed by $^{13}C$ NMR spectroscopy (see below). As previously shown for other phosphate-based materials synthesized in the presence of alkylformamide,[9–13] the in situ release of the corresponding protonated amine during the synthesis appears to be a key step in the crystallization of this lamellar gallophosphate. Indeed, experiments using ethylamine directly in the starting mixture led to the crystallization of the fluorogallophosphate ULM-3 with a nonidentified impurity.

The Ga/P molar ratio smaller than one (0.78 from chemical analyses, 0.75 from the structure determination) would indicate the presence of an interrupted framework, and more precisely the presence of terminal P=O and/or P–OH groups.

The thermal behavior of the fluorogallophosphate Mu-34 was investigated by TG/DTA thermal analyses. The TG and DTA curves of the as-synthesized fluorogallophosphate

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Mu-34 are reported in Figure 3. The total weight loss occurs mainly in one step. However, a small weight loss close to 0.8 wt.-% appears before 200 °C. It might correspond to the loss of water molecules or fluorine (probably under the form of HF) since a weak and broad endothermic peak is observed on the DTA curve. The main weight loss (20.2 wt.-%), between 200 and 800 °C, is associated with at least three endothermic components on the DTA curve. This probably corresponds to desorption and decomposition of the organic template, to the removal of fluorine, and to the collapse of the gallophosphate framework. The exothermic signal, which is expected from the oxidation of the EA, is probably masked by the overwhelming endothermic collapse of the structure. The latter is confirmed by the XRD analysis of the residue left after heating to 800 °C, which shows that the starting material is transformed via an amorphization-recrystallization process into a cristobalite-type gallophosphate. This recrystallization might occur in two steps as reflected by the presence of two exothermic peaks on the DTA curve at 600 °C and 750 °C. Such a thermal behavior is often observed for microporous gallophosphates.[16] All of these analyses are in good agreement with the unit cell formula found by structure analysis: $[Ga_{12}(PO_4)_{16}F_2(C_2H_8N)_{14}]$.

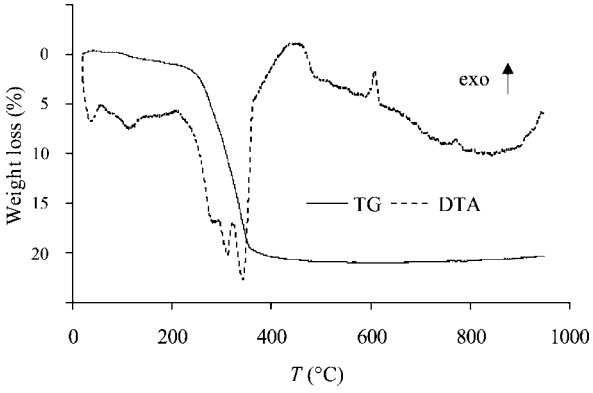

Figure 3. Thermal analysis (TG and DTA) under air of the fluorogallophosphate Mu-34.

## Structure Description

The fluorogallophosphate Mu-34 displays a 2D structure composed of porous macroanionic layers, parallel to the {–111} faces of the crystal and containing 12-membered ring apertures (12MR) arranged in a pseudo-hexagonal way (Figure 4). The asymmetric unit (not reported) contains six crystallographically distinct Ga-sites, three in fourfold coordination with oxygen atoms (Ga1, Ga5, and Ga6) and three in fivefold coordination with four oxygen atoms and one fluorine (Ga2, Ga3, and Ga4). The $GaO_4$ tetrahedra exhibit a regular geometry, with an average Ga–O bond length of 1.81(±1) Å. The $GaO_4F$ trigonal bipyramids have more disperse Ga–O bond lengths [<Ga–O> = 1.84(±3) Å] with three shorter bonds in the basal plane and a larger apical one, opposite to the Ga–F bond. Eight crystallographically distinct P-sites are also present: each phosphorus atom shares three of its oxygen atoms (labeled O1–O24) with gallium neighbors whereas the fourth oxygen atom (O25–O32) points towards the layer (Figure 5). The P–O distances involving these nonbonding oxygen atoms, 1.50(±1) Å, are typical of P=O bonds. They are significantly shorter than those involving bridging oxygen atoms [<P–O> = 1.54(±1) Å], except for O12 and O15 whose interaction with phosphorus is increased [P3–O12 = 1.503(6) Å, P4–O15 = 1.516(8) Å] as their bonding with gallium is weakened by

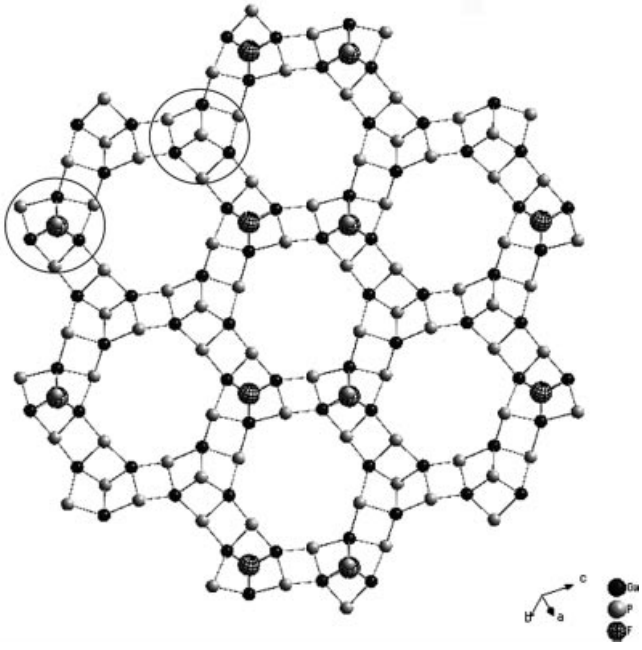

Figure 4. Projection of the structure of the fluorogallophosphate Mu-34 along the [–111] direction, showing the inorganic layers with the 12 MR openings. (For clarity, the oxygen atoms are omitted).

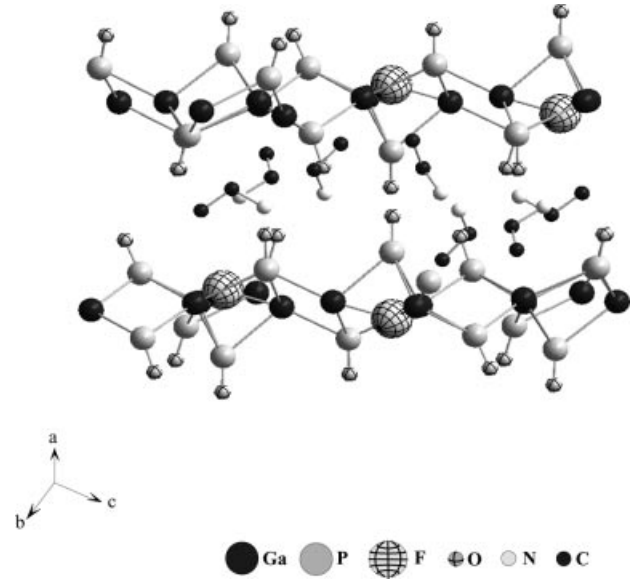

Figure 5. Projection of the structure of the fluorogallophosphate Mu-34, showing the localization of the protonated amine. (For clarity, the framework oxygen atoms are omitted except the terminal ones).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the presence of the supplementary fluoride ion. The crystal structure shows that all the terminal oxygen atoms act as hydrogen-bond acceptors for the seven crystallographically distinct protonated ethylamine molecules located in the interlayer space (Figure 5 and Figure 6). The positive charges of the organic molecules (see section $^{13}C$ NMR) compensate exactly the global negative charge of the layers if one considers formal $P^{+5}$, $Ga^{+3}$, $O^{2-}$, $F^{-}$ ions. As expected, in protonated ethylamine molecules, the displacement parameters are smaller for the nitrogen atoms which are precisely in interaction with O=P groups. The water molecules, which might be observed by thermal analysis, were not detected by XRD, which is not surprising considering their predictable high mobility and low site occupancy factors.

The 12-membered ring porous anionic layers can be described as resulting from the connection of two types of building units, encircled in Figure 4, via four-membered rings ($Ga_2P_2O_4$). The first type of these building units (Figure 7, left) has already been observed in other 12 MR porous layered aluminophosphates.[17–19] It is a phosphate-capped six-membered ring ($Ga_3P_3O_6$) containing three tetracoordinate gallium atoms and four tetracoordinate phosphorus ones. The second building unit is original (Figure 7, right) and consists of a phosphate and fluorine (F1) capped six-membered ring. The six-membered ring is composed of three gallium and three phosphorus atoms located on crystallographic sites Ga2, Ga3, Ga4 and P6, P7, P8, respectively. These three gallium atoms are also connected to fluorine F1 and phosphorus P1 and adopt a distorted trigonal bipyramidal geometry, the angle between apical O–Ga–F angles ranging from 177.0(3) to 178.8(3)°. Fluorine is three-coordinate to gallium atoms with one short bond [*d*(Ga3–F) = 2.080(5) Å] and two long bonds [*d*(Ga4–F) = 2.274(5) Å and *d*(Ga2–F) = 2.402(6) Å]. Such bond lengths are larger than those previously found in other fluorogallophosphates[16] [typically $1.94 < d(\text{Ga–F}) < 2.04$ Å] but the presence of the third interaction could explain the difference between these values and those reported for ideal bonds.

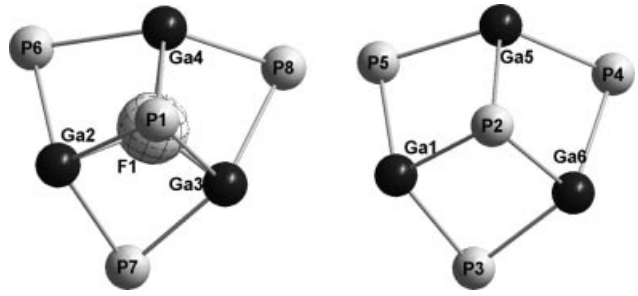

Figure 7. The two basic building units of the fluorogallophosphate Mu-34. (For clarity, the framework oxygen atoms are omitted).

### $^{13}C$ CP MAS NMR Spectroscopy

The $^{13}C$ CP MAS NMR spectrum of the fluorogallophosphate Mu-34 reported in Figure 8 shows two main

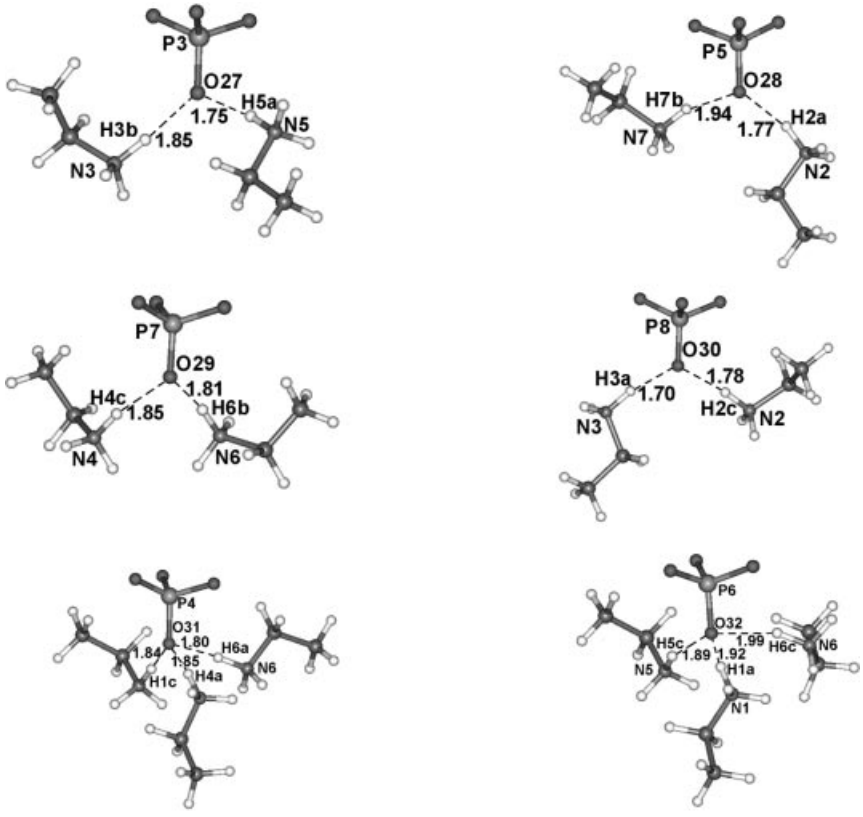

Figure 6. Hydrogen bonding scheme (dotted lines) for each phosphorus site.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

peaks situated at $\delta$ = 15.0 and 36.4 ppm. They are assigned to the $CH_3$ and $CH_2$ groups of the ethylamine molecule, respectively.[20] No carbonyl group is observed on this spectrum (line expected at $\delta \approx 160$ ppm),[9] which means that EFD is decomposed into ethylamine (EA) and carbon monoxide under our experimental conditions. The $^{13}C$ isotropic chemical shifts for protonated and nonprotonated EA in the liquid state are at $\delta$ = 13 and 18 ppm, respectively for the methyl group, and at $\delta$ = 37 and 36 ppm, respectively for the $CH_2$ group. Thus, as suggested in the previous section, the EA occluded in Mu-34 appears to be protonated.

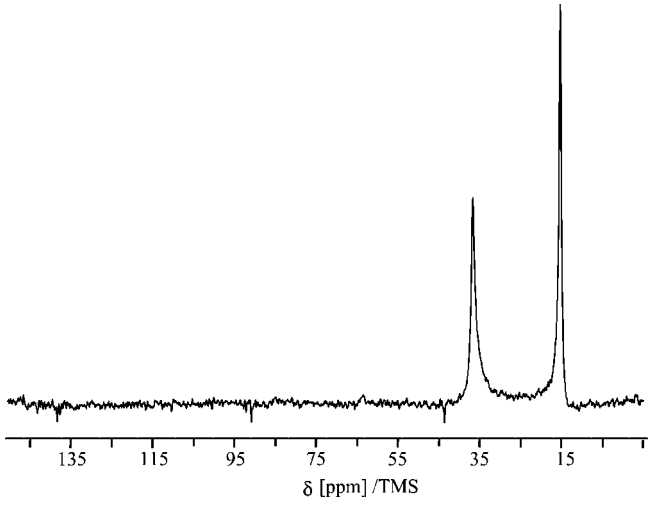

Figure 8. $^{13}C$ CP MAS NMR spectrum of the fluorogallophosphate Mu-34.

### $^{19}F$ MAS NMR Spectroscopy

The $^{19}F$ MAS NMR spectrum of the as-synthesized product, reported in Figure 9, exhibits one signal located at $\delta$ = –82 ppm. As observed for the gallophosphate Mu-28[16] and in good agreement with the crystal structure analysis, such a chemical shift value could be assigned to the three-coordinate fluorine atoms.

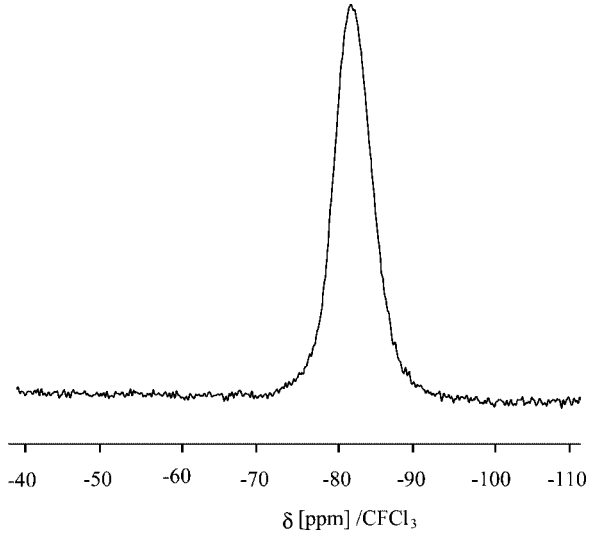

Figure 9. $^{19}F$ MAS NMR spectrum of the fluorogallophosphate Mu-34.

### $^{31}P$ MAS NMR Spectroscopy

The $^{31}P$ MAS NMR spectrum of the fluorogallophosphate Mu-34, shown in Figure 10, displays six signals at $\delta$ = 2, –2.3, –4.4, –6.6, –7.7, and –9.9 ppm. After decomposition, the relative areas are close to 1:1:1:2:1:2 respectively, indicating, in agreement with the structure determination, the existence of eight crystallographically distinct phosphorus sites. $^1H$-$^{31}P$ CP MAS NMR experiments have also been performed (spectrum not reported) and whatever the contact time (0.1, 0.05 ms) no significant difference was observed between the MAS and CP MAS spectra which means that all the atoms have the same proton environment. According to the structure and despite the low field chemical shift values observed no terminal P–OH group is present. Such a result is quite expected since all P atoms are hydrogen bonded via their P=O group (see Figure 6). A tentative assignment of the NMR peaks might be proposed on the basis of the empirical relationship between the $^{31}P$ isotropic chemical shift and the bond valence sum of the oxygen atoms connected to the phosphorus atom.[21] From the equation developed by Brown[22] and using the P–O and Ga–O bond lengths, the total oxygen bond valences [$\Sigma$s(O)] including the contribution of the hydrogen bonds[23] for the phosphorus atoms P1, P2, P3, P4, P5, P6, P7, and P8 are equal to 8.04, 8.23, 8.27, 8.48, 8.35, 8.64, 8.29, and 8.27, respectively. Consequently, the assignment of the eight NMR peaks might be made as follows. The most highfield signal is attributed to the phosphorus atom, which has the highest oxygen bond valence. Therefore, the peak at $\delta$ = –9.9 ppm, which has a relative area close to 2, could be assigned to P6 and P4 respectively [$\Sigma$s(O) = 8.48 for P4 and

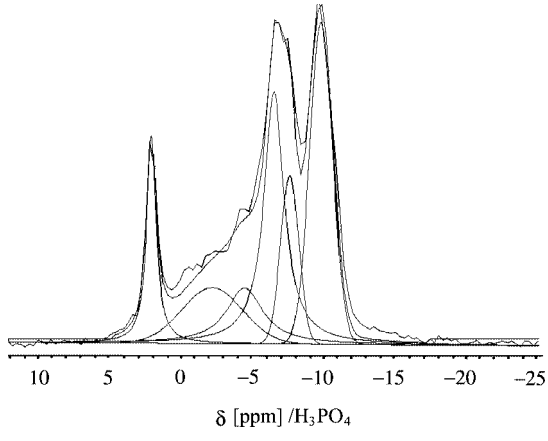

Figure 10. $^{31}P$ MAS NMR spectrum of the fluorogallophosphate Mu-34 and its decomposition.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

8.64 for P6], the signal at $\delta$ = –7.7 ppm to P5 [Σs(O) = 8.35], and the signal at $\delta$ = 2 ppm to P1 [Σs(O) = 8.04]. Due to similar Σs(O) (8.23, 8.27, and 8.29), the other remaining signals are more difficult to assign.

## Conclusions

In this paper the synthesis and characterization of a novel fluorogallophosphate Mu-34, with a rather unusual structure, has been reported. It was prepared in a quasi nonaqueous medium using ethylformamide as the main solvent. As in several similar syntheses, the solvent decomposed during the synthesis, and the corresponding amine was found to be occluded in the final structure. The in situ release of the protonated amine during the synthesis appears to be a key step in the crystallization of this lamellar gallophosphate. Indeed, experiments using ethylamine in the starting mixture directly did not lead to the crystallization of this material.

The fluorogallophosphate Mu-34 displays porous layers built up from 4-, 6-, and 12-membered rings and resulting from the connection of two types of building units: a phosphate-capped six-membered ring and a phosphate and fluorine capped six-membered ring. It is noteworthy that in this latter unit, the fluorine atom is three-coordinate to gallium atoms. In order to compensate the negative charges of the anionic layers protonated ethylamine molecules are intercalated between. These molecules interact strongly with the inorganic layers via hydrogen bonds.

## Experimental Section

**Synthesis:** The fluorogallophosphate Mu-34 was prepared in a quasi nonaqueous fluoride medium at 200 °C from a mixture containing the ethylformamide as a precursor of the SDA (ethylamine). The molar composition of the starting mixture was 2 GaOOH : 2 $H_3PO_4$ : 1 HF : 10 ethylformamide (EFD) : 4.7$H_2O$. The amount of water arises from the phosphorus and fluoride sources. The pH value of the reaction mixture was adjusted to 4.5 with tripropylamine (TPA, Fluka 98 wt.-%), the latter presenting no structure-directing effect in the fluorine-containing gallophosphate system.[24] The amorphous gallium oxyhydroxide GaOOH was prepared by heating a gallium nitrate aqueous solution at 250 °C for 24 h. The other reactants were orthophosphoric acid (Labosi $H_3PO_4$ 85 wt.-%), hydrofluoric acid (Prolabo HF 40 wt.-%), and EFD (Fluka 99 wt.-%). The starting mixture was prepared by adding the amorphous gallium source (1.13 g) to the ethylformamide (3.65 g) under magnetic stirring. Then orthophosphoric acid (1.15 g) and hydrofluoric acid (0.25 g) were introduced. In order to increase the pH value, tripropylamine was added (0.72 g) and the mixture was stirred until it was homogeneous. Then, it was transferred to a 20 mL PTFE-lined stainless-steel autoclave and heated at 200 °C for 4 days. The product was filtered, washed with distilled water and dried at 60 °C overnight.

**Characterization:** The as-synthesized product was characterized by powder X-ray diffraction (XRD) with a STOE STADI-P diffractometer equipped with a curved germanium (111) primary monochromator and a linear position-sensitive detector using Cu-$K_\alpha$1 radiation ($\lambda$ = 1.5406 Å). The morphology and average size of the crystals were determined by scanning electron microscopy (SEM) with a Philips XL30 microscope. Elemental analyses were carried out with the Induced Coupled Plasma technique using Atomic Energy Spectroscopy (ICP AES) for Ga and P, and by coulometric and catharometric methods for C and N quantifications, respectively. Thermogravimetric (TGA) and differential thermal (DTA) analyses were performed under air with a Setaram Labsys thermoanalyser with a heating rate of 5 °C min$^{-1}$ up to 1000 °C. The $^{13}$C CP MAS NMR spectrum was recorded with a Bruker MSL 300 spectrometer and the $^{19}$F MAS, $^{31}$P MAS, and $^{31}$P CP MAS spectra with a Bruker DSX 400 spectrometer. The recording conditions are reported in Table 2. For the structure determination, a crystal plate was cut out of a larger aggregate and selected after optical examination under crossed polars. The single-crystal X-ray diffraction experiment was carried out at room temperature with an Oxford diffraction Xcalibur diffractometer equipped with a CCD detector. A full redundant Ewald sphere was collected with Mo-$K_\alpha$ radiation up to the maximum resolution $\sin\theta/\lambda_{max.}$ = 0.78 Å$^{-1}$. Bragg intensities were integrated with CrysAlis software,[25] and averaged in Laue group $P\bar{1}$ with the SORTAV program[26] after an absorption correction ($\mu$ = 3.633 mm$^{-1}$) based on the crystal shape. Data collection details are summarized in Table 3. The crystal structure was solved by direct methods using SHELXS[27] and refined with JANA2000.[28] The positions of all non-H atoms were found straightforwardly on successive Fourier maps. Hydrogen atoms were introduced in the structural model assuming ideal conformations for all protonated ethylamine molecules. Atomic displacement parameters of H atoms were restrained to 1.5 times the value of that of the heavy atom they were attached to. All bond lengths and bond angles of protonated ethylamine molecules were also restrained to the expected values observed in $CH_3$ (methyl), $CH_2$ (methylene), and $NH_3$ (amine) groups.[29] The refinement converged to $R$ = 0.0575 ($R = \Sigma||F_o| - |kF_c||/\Sigma|F_o|$) and $Rw$ = 0.0591 [$R_w = \{\Sigma w(|F_o| - |kF_c|)^2/\Sigma w(|F_o|^2)\}^{1/2}$] for 6644 reflections [$I > 3\sigma(I)$]. The supplementary crystallographic data are available online via http://www.fiz-karlsruhe.de (the reference file number is CSD-415650).

# Formation of Triple-Stranded Dinuclear Helicates with Dicatecholimine Ligands: The Influence of Steric Hindrance at the Spacer

**Ingo Janser,[a] Markus Albrecht,*[a] Katharina Hunger,[a,b] Simon Burk,[a] and Kari Rissanen[b]**

**Keywords:** Dinuclear complexes / Helicates / Meso-helicates / Self-assembly / Titanium / Bulky ligands

A series of new imine-bridged dicatechol ligands **3a**–**f**-$H_4$ with sterically demanding groups at the spacers are used for the formation of titanium(IV) complexes $M_4[(\mathbf{3})_3Ti_2]$. All three ligands **3a**–**c**-$H_4$ form triple-stranded dinuclear helicates. When the bulky ligands **3a**-$H_4$ or **3c**-$H_4$ are used with potassium as the countercation, oligomeric or polymeric side products are also observed. The imine-bridged ligand **3e**-$H_4$ quantitatively forms helicates $M_4[(\mathbf{3e})_3Ti_2]$ and not a $M_4L_6$ tetrahedron as observed with Raymond's analogous amide-bridged dicatechol ligand **3i**-$H_4$. NMR spectroscopic investigations at variable temperature show that ligand **3f**-$H_4$, which possesses a spiro fluorenyl group at the central unit of the spacer, forms the *meso*-helicate $M_4[(\mathbf{3f})_3Ti_2]$.

## Introduction

In the last two decades double- and triple-stranded helicates have been investigated very intensely as model compounds in metallosupramolecular chemistry.[1] In order to perform a systematic study on the influences of different geometric factors on the helicate formation we needed an easy way of preparing a variety of different ligands with different geometric constraints and demands. Several groups[2,3] have shown that bis(iminopyridine) ligands can be obtained by simple imine condensation from readily available starting materials. These ligands form double- or triple-stranded helicates with a series of different metal ions. Recently, we[4,5] and others[6] introduced imine condensation to obtain dicatechol ligands for the formation of helicates.[7–11]

Herein we use this concept to obtain several new ligands with different steric demands at the spacer, which can then be used for the self-assembly of triple-stranded dinuclear helicates and *meso*-helicates.

## Results and Discussion

### Synthesis and Characterisation of the Dicatechol Ligands 3a–f-$H_4$

The dicatechol ligands **3a**–**f**-$H_4$ were prepared in two different ways (Scheme 1): (i) The diamines **1a**–**1d** and 2 equiv. 2,3-dihydroxybenzaldehyde (**2**) were dissolved in toluene and heated to reflux in a Dean–Stark apparatus overnight in the presence of catalytic amounts of *p*-TosOH. Water was removed by continuous distillation of the water/toluene azeotrope. After cooling to room temperature, the precipitated product was isolated by filtration, washed with toluene, and the derivatives were obtained in 86% (**3a**-$H_4$, yellow solid), 81% (**3b**-$H_4$, red solid), 91% (**3c**-$H_4$, red solid) and 72% (**3d**-$H_4$, orange solid) yield. (ii) The diamines **1e** and **1f** and 2 equiv. 2,3-dihydroxybenzaldehyde (**2**) were dissolved in methanol. After 12 h at room temperature, the precipitated diimines were isolated by filtration in 99% (**3e**-$H_4$, red solid) or 93% (**3f**-$H_4$, red solid) yield, respectively.

The compounds were characterised by MS, elemental analysis and $^1$H NMR spectroscopy, and selected examples were also characterised by $^{13}$C NMR spectroscopy. The resonance of the imine proton is a characteristic signal in the $^1$H NMR spectra ([$D_6$]DMSO), which appears for the ligands **3a**–**f**-$H_4$ in the region of $\delta$ = 8.45–9.03 ppm. In two of the cases we were able to observe the signals for the two OH protons of the catechol moieties. For **3e**, two signals at $\delta$ = 13.17 and 9.37 ppm are detected. For **3f**, the two resonances of the OH protons can be found at $\delta$ = 13.21 and 9.23 ppm. The signal that appears downfield is assigned to the 2-hydroxy group, which forms an unsymmetric intramolecular hydrogen bond to the imine with a transfer of a proton to the nitrogen atom. At low temperatures form **A** is favoured, while form **B** is observed at higher temperatures (Scheme 2). The resonance of the 2-hydroxy group appears downfield because of shielding.[5]

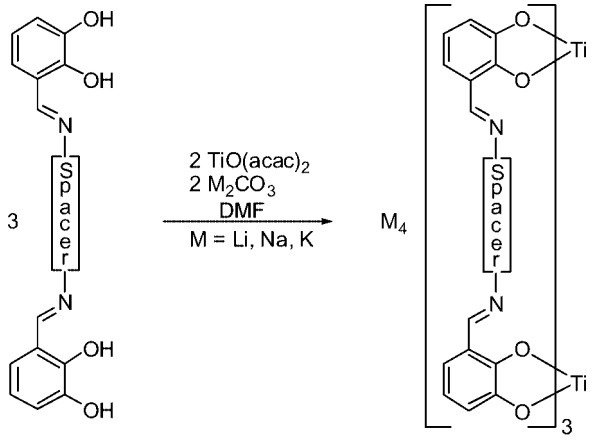
### Formation of Dinuclear Triple-Stranded Helicates $M_4[(3a–f)_3Ti_2]$ (M = Li, Na, K)

For the preparation of the titanium(IV) complexes $M_4[(3a–f)_3Ti_2]$, the ligands **3a**–**f**-$H_4$ (3 equiv.), $[TiO(acac)_2]$ (2 equiv.) and the corresponding alkali metal carbonate $M_2CO_3$ (2 equiv., M = Li, Na, K) were mixed in DMF (Scheme 3). Within a few minutes the solution turned orange-red and was stirred overnight at room temperature. Volatile components were removed in vacuo to obtain the complex salts $M_4[(3a–f)_3Ti_2]$ as red solids.



Scheme 3. Synthesis of the triple-stranded dinuclear helicates $M_4[(3a–f)_3Ti_2]$.

### *Formation and Characterisation of $M_4[(3a)_3Ti_2]$ (M = Li, Na, K)*

Ligands **3a**–**c** were introduced to study the influence of sterically demanding ligands on the self-assembly of helicates. The dinuclear complex salts $M_4[(3a)_3Ti_2]$ (M = Li, Na, K) of the phenyl-type ligand **3a** were characterised by elemental analysis, FAB MS and $^1H$ NMR spectroscopy. Positive FAB MS (3-NBA) reveals characteristic peaks at $m/z$ = 1305 $\{H_2Li[(3a)_3Ti_2]^+\}$, 1343 $\{HNa_2[(3a)_3Ti_2]^+\}$, or 1337 $\{H_2K[(3a)_3Ti_2]^+\}$. Upon complex formation, the imine proton, which appears in the $^1H$ NMR spectrum of **3a**-$H_4$ in $[D_6]$DMSO at $\delta$ = 8.45 ppm, is shifted upfield to $\delta$ = 8.10–8.16 ppm. The signals of the methyl groups of the spacer appear as a singlet at $\delta$ = 1.91 (Li), 1.91 (Na), and 1.89 ppm (K), and the catechol resonances [detected at $\delta$ = 7.03, 6.36 and 6.17 ppm (M = Li); 7.03, 6.37 and 6.19 ppm (M = Na); 6.93, 6.37 and 6.19 ppm (M =K)] appear as a doublet, triplet and doublet, respectively. No significant differences are observed for the NMR shifts of different salts of $[(3a)_3Ti_2]^{4-}$.

In earlier studies we investigated the complexation of ligand **3g**-$H_4$ with titanium(IV) ions (Figure 1). Ligand **3g**-$H_4$ possesses a phenyl spacer that is similar to that of ligand **3a**-$H_4$ but with protons instead of the four methyl groups. It could be shown that this ligand leads in a quantitative self-assembly process to the triple-stranded dinuclear helicate $M_4[(3g)_3Ti_2]$.[5]

Ligand **3a**-$H_4$ with four methyl groups at the phenyl spacer also leads to the triple-stranded dinuclear helicates $M_4[(3a)_3Ti_2]$ (M = Li, Na, K). However, in the case of the potassium salt $K_4[(3a)_3Ti_2]$, additional broad signals appear in the $^1H$ NMR sprectra ($[D_6]$DMSO) at $\delta$ = 8.28, 8.18, 7.20, 7.08, 6.17 ppm, which indicate the presence of polymeric or oligomeric species besides the triple-stranded dinuclear helicate as the main product. As can be seen from the X-ray analysis of $K_4[(3g)_3Ti_2]$ (Figure 1),[5] the complex possesses the structure of a triple-stranded dinuclear helicate. The long imine–aryl–imine spacers lead to a large sepa-

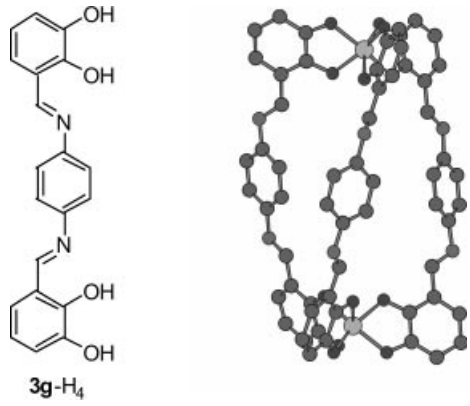

Figure 1. Ligand **3g**-$H_4$ and part of the X-ray structure of $K_4[(\mathbf{3g})_3Ti_2]$.[5]

ration of the titanium centres, and a big internal cavity is formed. As we know from other catechol-derived helicates, alkaline metal countercations are encapsulated in the interior and bind to the internal oxygen atoms of the catecholate ligands.[12,13] The coordination sphere at the cations is saturated by binding solvent molecules. It seems that the alkali cations act as a template in stabilising the formation of a triple-stranded dinuclear helicate. In the case of ligand **3a**-$H_4$, the potassium cation is not able to stabilise this formation quantitatively. The reason for this is the steric influence of the methyl groups that are probably directed into the interior of the complex, and this influence therefore suppresses the binding of big potassium cations. The lithium or sodium cations are smaller and because of this they fit into the cavity and stabilise the triple-stranded dinuclear complex more effectively.

### *Formation and Characterisation of $M_4[(3b–c)_3Ti_2]$ (M = Li, Na, K)*

In ligands **3b** and **3c** with elongated aromatic spacers, methyl groups are introduced at the *ortho* position of the imine spacers. In the presence of lithium, sodium or potassium cations, the two ligands **3b**-$H_4$ and **3c**-$H_4$ form triple-stranded helicates $M_4[(\mathbf{3b/c})_3Ti_2]$. The dinuclear complexes were characterised by elemental analysis, FAB MS and $^1H$ NMR spectroscopy. In the $^1H$ NMR spectrum of **3b**-$H_4$, the resonance for the imine proton appears at $\delta$ = 8.95 ppm and in the complexes at $\delta$ = 8.61 (Li), 8.65 (Na), and 8.60 ppm (K). The upfield shift of the resonance indicates that the conformation at the imine unit changes upon metal complexation (vide supra). The signals of the spacer can be detected for $Li_4[(\mathbf{3b})_3Ti_2]$ at $\delta$ = 7.43 (s, 6 H), 7.34 (d, $J$ = 7.5 Hz, 6 H), 7.00 (d, $J$ = 7.5 Hz, 6 H) and 2.30 ppm (s, 18 H) , for $Na_4[(\mathbf{3b})_3Ti_2]$ at $\delta$ = 7.44 (s, 6 H), 7.32 (d, $J$ = 8.0 Hz, 6 H), 7.05 (d, $J$ = 8.0 Hz, 6 H) and 2.30 ppm (s, 18 H) and for $K_4[(\mathbf{3b})_3Ti_2]$ at $\delta$ = 7.43 (s, 6 H), 7.33 (d, $J$ = 8.0 Hz, 6 H), 7.03 (d, $J$ = 8.0 Hz, 6 H) and 2.30 ppm (s, 18 H).

For the $Ti^{IV}$ complexes of ligand **3c**-$H_4$, similar MS and NMR spectroscopic results can be obtained (see Experimental Section). However, in the case of the potassium salt $K_4[(\mathbf{3c})_3Ti_2]$, additional signals appear in the $^1H$ NMR spectra ([$D_6$]DMSO) at $\delta$ = 8.57, 7.26 (br), 7.10 (br), 6.45 (br), 6.15 ppm (br), which indicate that some polymeric or oligomeric species are formed besides the triple-stranded dinuclear helicate as the main product.

In earlier studies we already investigated the coordination chemistry of the sterically less demanding ligand **3h**-$H_4$ (Figure 2) with titanium(IV) ions. Ligand **3h**-$H_4$ possesses a biphenyl spacer that is similar to ligand **3c**-$H_4$ but without the methyl substituents.[14] As we have shown, ligand **3h**-$H_4$ leads quantitatively to the formation of a triple-stranded dinuclear helicate $M_4[(\mathbf{3h})_3Ti_2]$. The X-ray structure of the complex $Na_4[(\mathbf{3h})_3Ti_2]$ shows (Figure 2) that the linear rigid ligands form a triple-stranded helicate with two similar-configured titanium(IV) complex units. Three ligands **3h**-$H_4$ wrap around the metals and adopt a conformation with the imine hydrogen atoms that point into the interior, directed towards the catecholate oxygen atoms, and therefore form a big cavity. In the solid state, two sodium cations are bound in the interior of the helicate, each binding to the internal catecholate oxygen atoms and to three DMF molecules.[14] Following this, it is reasonable to suggest that ligand **3b**-$H_4$ with its two additional methyl groups is able to form triple-stranded dinuclear complexes with lithium, sodium or potassium cations. The situation changes somewhat by using ligand **3c**-$H_4$. In the case of potassium as the countercation, the four additional methyl groups of the spacer are too big to fit into the cavity. In this case, potassium is not able to form the triple-stranded dinuclear helicate quantitatively, and therefore some oligomers and polymers are formed as side products, as is the case with ligand **3a**-$H_4$.

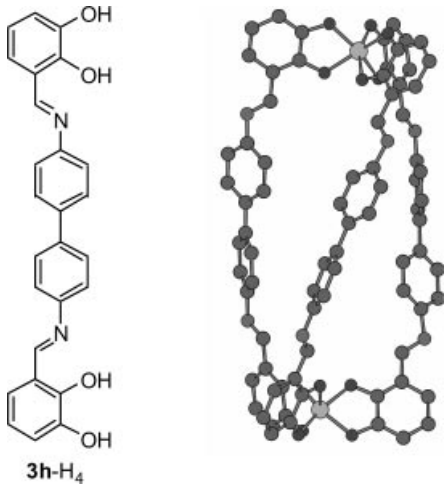

Figure 2. Ligand **3h**-$H_4$ and part of the X-ray structure $Na_4[(\mathbf{3h})_3Ti_2]$.[14]

These three examples demonstrate the influence of the spacer on the formation of the complexes. Ligand **3a**-$H_4$, with four methyl groups at the phenyl spacer, exclusively forms triple-stranded dinuclear helicates with lithium and sodium only. When potassium is the countercation both oligomeric and polymeric species can be observed. The size dependence is also observed in the yields of the three complexes $M_4[(\mathbf{3a})_3Ti_2]$. Upon coordination, the oligomeric or

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

polymeric species precipitate and the triple-stranded dinuclear helicates can be isolated by filtration in 66% (M = Li), 60% (M = Na), 37% (M =K) yield. Ligand **3b**-$H_4$, with an elongated spacer and two methyl groups in the *ortho* position of the imine spacers, forms a triple-stranded helicate in good yields (≥75%) with all three countercations. Ligand **3c**-$H_4$, with four methyl groups in the *ortho* position of the imine-spacers, leads to the formation of side products upon complexation with titanium(IV)ions and potassium as the countercations, which indicates that the cavity is too small for the four methyl groups and the big potassium cations.

### *Coordination Studies with Ligand 3d-$H_4$*

Ligand **3d** possesses two $CF_3$ groups that can act as a stereochemical probe for $^{19}F$ NMR spectroscopy. Unfortunately, we were not able to obtain triple-stranded dinuclear helicate-type compounds with ligand **3d**-$H_4$. Upon complex formation, residual water in the solvent hydrolyses the imine bond. $^1H$ NMR spectra in [$D_6$]DMSO show only resonances of the products from the cleavage reaction.

### *Formation of $M_4[(3e)_3Ti_2]$ (M = Li, Na)*

The imine-bridged dicatechol ligand **3e**-$H_4$ with a sterically demanding naphthyl spacer was introduced to study the differences from the amide-bridged dicatechol ligand **3i**-$H_4$ (Figure 3). With ligand **3i**-$H_4$, Raymond and coworkers obtained a molecular $M_4L_6$ tetrahedron, $[Ga_4\mathbf{3i}_6]^{12-}$, and no helicate was observed.[15]

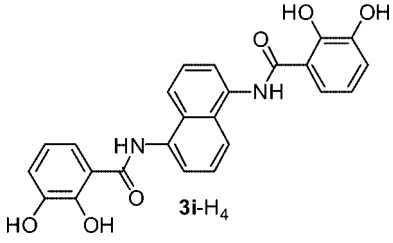

Figure 3. Ligand **3i**-$H_4$.[15]

In contrast, we obtained the triple-stranded dinuclear complexes $M_4[(\mathbf{3e})_3Ti_2]$ (M = Li, Na) in quantitative yield. Elemental analyses show the correct composition for the compounds, and characteristic peaks are observed in the positive FAB mass spectra for the dinuclear triple-stranded helicate. $^1H$ NMR spectroscopy in [$D_6$]DMSO reveals the resonances for the imine proton at $\delta$ = 8.26 (M = Li) and 8.34 ppm (M = Na), for the spacer at $\delta$ = 7.60, 7.18, and 7.02 (M = Li) and 7.65, 7.25, and 7.11 ppm (M = Na), and for the catecholate units at $\delta$ = 6.68, 6.36, and 6.12 (M = Li) and 6.78, 6.44, and 6.21 ppm (M = Na). No significant differences are observed when comparing the spectra of the complex salts $M_4[(\mathbf{3e})_3Ti_2]$ with those of different cations $M^+$. This shows that the formation of Raymond's tetrahedron in comparison to our helicate depends on the orientation of the amide versus the imine C–N group. In the case of the amide ligand **3i**, overcrowding of the spacers prevents the formation of the helicate. To explain this, we have to consider the different orientations of the imine- or amide-bridged dicatechol ligands **3e**-$H_4$ and **3i**-$H_4$ (Figure 4). We have reported earlier that the imine moiety possesses a preferred conformation **B**. In this conformation the C=N double bond is directed towards the outside of the cavity of the complex.[14] This conformation is preferred because there are electrostatic attractions between the internal catecholate oxygen atoms and the imine proton. Additional repulsion takes place between the oxygen and the imine-nitrogen lone pairs. The situation in Raymond's amide-bridged dicatechol ligand **3i**-$H_4$ is "reversed". Here an inward orientation of the amide nitrogen atom occurs (**D**), which forms an intramolecular hydrogen bond. Therefore, upon complexation of ligand **3e** with titanium(IV), a much bigger cavity is formed. In the case of the ligand **3i**-$H_4$, hydrogen bonding forces the sterically demanding naphthyl spacers into an orientation facing towards the interior of the complex. This prevents the formation of the helicate because the spacers would be forced "into each other". To prevent this, a molecular $M_4L_6$ tetrahedron is formed.[16]

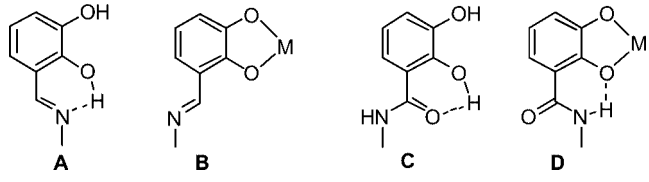

Figure 4. Possible orientations of the imine moiety in the free ligand (**A**) or in the catecholato metal complex (**B**) and of the amino moiety in the free ligand (**C**) or in the catecholato metal complex (**D**).

### *Formation of $M_4[(3f)_3Ti_2]$ (M = Li, Na, K)*

Ligand **3f**-$H_4$ possesses a big group at the central unit of the spacer and is therefore not as flexible as the related compound **3j**-$H_4$ (Figure 5). We investigated this ligand **3f**-$H_4$ in order to determine whether it is able to form *meso*-helicates with titanium(IV) and the corresponding alkali metal counterions as ligand **3j**-$H_4$ does.[14] Reaction of titanium(IV) ions with ligand **3f**-$H_4$ in the presence of an alkali metal carbonate in DMF leads to the assembly of dinuclear complex salts $M_4[(\mathbf{3f})_3Ti_2]$ in quantitative yield. The complexes $M_4[(\mathbf{3f})_3Ti_2]$ (M = Li, Na, K) were characterised by elemental analysis, ESI-MS, IR and NMR spectroscopy. In the ESI mass spectra, characteristic peaks can be detected at *m/z* = 1869 $\{Li_3[(\mathbf{3f})_3Ti_2]^-\}$, 1918 $\{Na_3[(\mathbf{3f})_3Ti_2]^-\}$, 1928 $\{HK_2[(\mathbf{3f})_3Ti_2]^-\}$. The lithium salt $Li_4[(\mathbf{3f})_3Ti_2]$ in [$D_6$]DMSO shows peaks in the $^1H$ NMR spectrum at $\delta$ = 8.53 (s, 6 H, imine), 7.89 (br., 6 H, spacer-fluorenyl), 7.48 (d, *J* = 7.3 Hz, 6 H, spacer-fluorenyl), 7.42–7.32 (m, 12 H, spacer-fluorenyl), 7.14 (d, *J* = 8.0 Hz, 12 H, spacer-phenyl), 7.04 (d, *J* = 8.0 Hz, 12 H, spacer-phenyl), 6.93 (d, *J* = 7.7 Hz, 6 H, cat), 6.30 (t, *J* = 7.7 Hz, 6 H, cat), 6.06 ppm (d, *J* = 7.7 Hz, 6 H, cat). Complex $Na_4[(\mathbf{3f})_3Ti_2]$ as well as $K_4[(\mathbf{3f})_3Ti_2]$ show similar spectra. For all three complexes, the signals for the spacer appear at room temperature as half a set of signals.

Recently, we described the formation of a triple-stranded dinuclear *meso*-helicate $M_4[(\mathbf{3j})_3Ti_2]$ with ligand **3j**-$H_4$, tita-

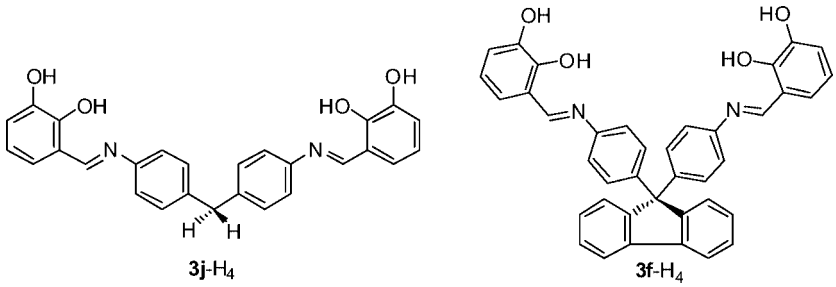

Figure 5. Ligands **3j**-$H_4$ and **3f**-$H_4$.

nium(IV) ions and the corresponding countercations ($Li^+$, $Na^+$, $K^+$).[14] The relative stereochemistry of the complex units of $M_4[(\mathbf{3j})_3Ti_2]$ was shown by X-ray diffraction as well as by NMR spectroscopy at variable temperature.

### *Temperature-Dependent NMR Spectroscopic Investigations of $Na_4[(3f)_3Ti_2]$*

For dinuclear helicate-type complexes with an odd number of $CH_2$ units in the spacer, NMR spectroscopy is a powerful tool for distinguishing between the helicate and the *meso*-helicate form.[17–22]

Figure 6 shows schematic representations of the situation that is found for dinuclear complexes with a $C_1$ unit incorporated into the spacer of either a helicate or a *meso*-helicate. In the case of the helicate, one set of signals is expected, whereas two diastereotopic groups are present in the *meso*-helicate. Therefore, we can expect two sets of signals for the substituents at the $C_1$ unit of the *meso*-helicate $[(\mathbf{3f})_3Ti_2]^{4-}$.[17–19,22]

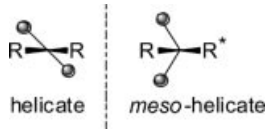

Figure 6. Schematic representation of the orientation of ligands with a $C_1$ spacer in the helicate and *meso*-helicate. Diasterotopic substituents are indicated.

As shown in Figure 5, spiro compound **3f**-$H_4$ (like **3j**-$H_4$) possesses a "C"-shaped conformation, and the *meso*-helicate should therefore be formed upon complexation with titanium(IV) ions. Thus, a full set of signals is expected for the protons of the fluorenyl group. The $^1H$ NMR spectrum of $Na_4[(\mathbf{3f})_3Ti_2]$ in [$D_4$]methanol at room temperature shows only half a set of signals (two doublets and two triplets) for the protons of the diastereotopic fluorenyl phenyl rings. Upon cooling of the NMR sample, the signals broaden and start to split. At 273 K, a full set of signals is observed, which reveals that the *meso*-helicate $Na_4[(\mathbf{3f})_3Ti_2]$ is present in solution (Figure 7).

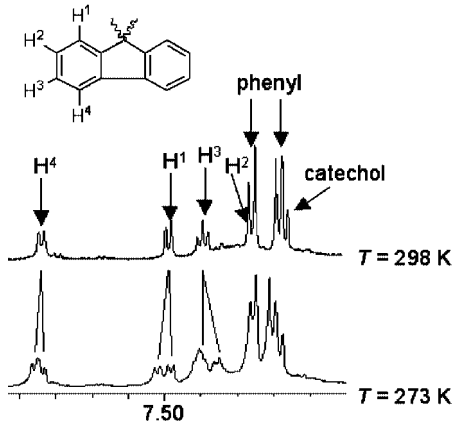

Figure 7. Temperature-dependent NMR spectrum of $Na_4[(\mathbf{3f})_3Ti_2]$ in [$D_4$]methanol at room temperature (298 K) and at 273 K. The signal of the $H^2$ proton is covered by a signal of the phenyl ring. (Two additional catechol protons are observed at $\delta$ = 6.44 and 6.51 ppm.)

## Conclusions

In this paper we demonstrated the influence of steric hindrance at the spacer of triple-stranded helicates for the self-assembly process. Therefore, a series of imine-bridged dicatechol ligands **3a**–**f**-$H_4$ with sterically demanding groups at the spacer were synthesised. The complexation of the ligands with titanium(IV)ions and the corresponding alkaline metal carbonate $M_2CO_3$ (M = Li, Na, K) has shown that the groups influence the formation of the complexes. In general, triple-stranded dinuclear complexes were formed. However, in some cases oligomeric and polymeric species could be observed as side products. In the case of a ligand with a high steric demand, it is possible that the groups of the spacer do not fit into the cavity and suppress the binding of the countercation. In this case, the cation cannot act as a template to stabilise the formation of a triple-stranded complex, and therefore oligomers or polymers are formed. The ligands **3a**-$H_4$ and **3c**-$H_4$ are bulky, and triple-stranded dinuclear helicates $K_4[(\mathbf{3a})_3Ti_2]$ or $K_4[(\mathbf{3c})_3Ti_2]$ are not obtained in quantitative yields.

Ligand **3e**-$H_4$ quantitatively formed a triple-stranded dinuclear helicate $[(\mathbf{3e})_3Ti_2]^{4-}$. The corresponding amide-bridged dicatechol ligand **3i**-$H_4$ leads to a molecular $M_4L_6$

tetrahedron, $K_5[Et_4N]_7[Ga_4\mathbf{3i}_6]\cdot 8H_2O$, and no helicate is observed. Here, hydrogen bonding of the amide group forces the sterically demanding naphthyl spacers to be oriented towards the interior of the complex. This prevents the formation of the helicate because the spacers would be forced "into each other". With ligand **3e**, the spacers are oriented "outwards", and the dinuclear complex can be formed.

Ligand **3f**-$H_4$ with a sterically demanding group at the central unit of the spacer quantitatively formed a *meso*-helicate. To prove this result, we used temperature-dependent NMR spectroscopy as a tool for distinguishing between the helicate and the *meso*-helicate form. This shows that the big fluorenyl group does not influence the formation of the complexes because the group is not directed into the cavity of the complex but is rather oriented outwards.

## Experimental Section

**General Remarks:** NMR spectra were recorded with a Bruker DRX 500, WM 400 or a Varian Inova 400 spectrometer. FT-IR spectra were recorded by diffuse reflection (KBr) with a Bruker IFS spectrometer. Mass spectra (EI 70 eV, FAB with 3-NBA as matrix) were recorded with a Finnigan MAT 90, 95 or 212 mass spectrometer. Elemental analyses were obtained with a Heraeus CHN-O-Rapid analyser.

**General Procedure for the Preparation of the Ligands 3a–f-$H_4$**

**Method A:** The corresponding diamine **1a**–**d** (1 mmol, 1 equiv.) and 2,3-dihydroxybenzaldehyde (**2**, 2 mmol, 2 equiv.) were heated in toluene in the presence of catalytic amounts of *p*-TosOH. Water was removed by azeotropic distillation. After cooling to room temperature, the precipitated product was isolated by filtration, washed with toluene and dried in vacuo.

**Method B:** The corresponding diamine **1e**–**f** (1 mmol, 1 equiv.) and 2,3-dihydroxybenzaldehyde (**2**, 2 mmol, 2 equiv.) were dissolved in methanol. After a few minutes, the product started to precipitate, and was then isolated by filtration after standing overnight, washed with ice-cold methanol and dried in vacuo.

**Ligand 3a-$H_4$ (Method A):** Yield: 86% of a yellow solid. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.45 (s, 2 H), 7.07 (d, $J$ = 8.0 Hz, 2 H), 6.97 (d, $J$ = 8.0 Hz, 2 H), 6.79 (t, $J$ = 8.0 Hz, 2 H), 2.09 (s, 12 H) ppm. MS (EI, 70 eV): $m/z$ = 404 (100) $[M]^+$. $C_{24}H_{24}N_2O_4\cdot 1/2H_2O$ (413.47): calcd. C 69.72, H 6.09, N 6.78; found C 69.92, H 5.74, N 6.87.

**Ligand 3b-$H_4$ (Method A):** Yield: 91% of a red solid. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.95 (s, 2 H), 7.70 (s, 2 H), 7.60 (d, $J$ = 8.5 Hz, 2 H), 7.48 (d, $J$ = 8.5 Hz, 2 H), 7.13 (d, $J$ = 7.5 Hz, 2 H), 6.94 (d, $J$ = 7.5 Hz, 2 H), 6.77 (t, $J$ = 7.5 Hz, 2 H), 2.44 (s, 6 H) ppm. MS (EI, 70 eV): $m/z$ = 452 (100) $[M]^+$. $C_{28}H_{24}N_2O_4\cdot 1/3H_2O$ (458.52): calcd. C 73.35, H 5.42, N 6.11; found C 73.31, H 5.17, N 6.11.

**Ligand 3c-$H_4$ (Method A):** Yield: 72% of an orange solid. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.62 (s, 2 H), 7.48 (s, 4 H), 7.09 (d, $J$ = 8.0 Hz, 2 H), 6.97 (d, $J$ = 8.0 Hz, 2 H), 6.80 (t, $J$ = 8.0 Hz, 2 H), 2.24 (s, 12 H) ppm. MS (EI, 70 eV): $m/z$ = 480 (100) $[M]^+$. $C_{30}H_{28}N_2O_4\cdot$ 1/4toluene (503.60): calcd. C 75.72, H 6.00, N 5.56; found C 75.68, H 5.99, N 5.15.

**Ligand 3d-$H_4$ (Method A):** Yield: 81% of a red solid. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.95 (s, 2 H), 7.53–7.44 (m, 8 H), 7.12 (d, $J$ = 8.0 Hz, 2 H), 6.96 (d, $J$ = 8.0 Hz, 2 H), 6.80 (t, $J$ = 8.0 Hz, 2 H) ppm. MS (EI, 70 eV): $m/z$ = 574 (100) $[M]^+$. $C_{29}H_{20}F_6N_2O_4\cdot$ 1/4$H_2O$ (578.98): calcd. C 60.16, H 3.57, N 4.84; found C 60.19, H 3.63, N 4.54.

**Ligand 3e-$H_4$ (Method B):** Yield: quantitative of a red solid. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 13.17 (s, 2 H), 9.37 (s, 2 H), 9.03 (s, 2 H), 8.15 (d, $J$ = 7.9 Hz, 2 H), 7.71 (t, $J$ = 7.9 Hz, 2 H), 7.55 (d, $J$ = 7.9 Hz, 2 H), 7.23 (dd, $J$ = 7.4, 1.4 Hz, 2 H), 7.03 (dd, $J$ = 7.4, 1.4 Hz, 2 H), 6.86 (t, $J$ = 7.4 Hz, 2 H) ppm. MS (EI, 70 eV): $m/z$ = 398 (100) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 1616, 1460, 1407, 1360, 1273, 1209, 1071, 1026, 981, 928, 781, 734, 522 cm$^{-1}$. $C_{24}H_{18}N_2O_4$ (398.42): calcd. C 72.35, H 4.55, N 7.03; found C 71.65, H 4.46, N 6.73.

**Ligand 3f-$H_4$ (Method B):** Yield: 93% of a red solid. $^1$H NMR ([D$_6$]-DMSO): $\delta$ = 13.21 (br., 2 H), 9.23 (br., 2 H), 8.88 (s, 2 H), 7.98 (d, $J$ = 7.2 Hz, 2 H), 7.52 (d, $J$ = 7.4 Hz, 2 H), 7.47–7.39 (m, 4 H), 7.34 (d, $J$ = 8.7 Hz, 4 H), 7.24 (d, $J$ = 8.7 Hz, 4 H), 7.08 (dd, $J$ = 7.8, 1.4 Hz, 2 H), 6.97 (dd, $J$ = 7.8, 1.4 Hz, 2 H), 6.79 (t, $J$ = 7.8 Hz, 2 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 164.3 (CH), 150.8 (C), 149.8 (C), 147.0 (C), 146.1 (C), 144.6 (C), 140.0 (C), 129.2 (CH), 128.5 (CH), 128.4 (CH), 126.5 (CH), 123.3 (CH), 121.9 (CH), 121.2 (CH), 119.8 (C), 119.5 (CH), 119.3 (CH), 64.9 (C) ppm. MS (EI, 70 eV): $m/z$ = 588 (100) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 3410, 1621, 1583, 1501, 1464, 1366, 1271, 1211, 1016, 873, 827, 735 cm$^{-1}$. $C_{39}H_{28}N_2O_4$ (588.66): calcd. C 79.57, H 4.79, N 4.76; found C 79.14, H 4.80, N 4.42.

**General Procedure for the Preparation of the Complexes $M_4[(\mathbf{3a}–\mathbf{f})_3Ti_2]$**

Ligand **3a**–**f**-$H_4$ (3 equiv.), $TiO(acac)_2$ (2 equiv.) and $M_2CO_3$ (2 equiv., M = Li, Na, K) were dissolved in DMF, and the orange mixture was stirred overnight. Volatiles were removed in vacuo to obtain the dinuclear complexes $M_4[(\mathbf{3a}–\mathbf{f})_3Ti_2]$ as red solids.

**Complex $Li_4[(\mathbf{3a})_3Ti_2]$:** Yield: 66% of a red solid. $^1$H NMR ([D$_6$]-DMSO): $\delta$ = 8.16 (s, 6 H), 7.03 (d, $J$ = 7.0 Hz, 6 H), 6.36 (t, $J$ = 7.0 Hz, 6 H), 6.17 (d, $J$ = 7.0 Hz, 6 H), 1.91 (s, 36 H) ppm. MS (pos. FAB, 3-NBA): $m/z$ = 1305 $\{H_2Li[(\mathbf{3a})_3Ti_2]^+\}$, 1299 $\{H_3[(\mathbf{3a})_3Ti_2]^+\}$, 649 $\{H_2[(\mathbf{3a})_3Ti_2]^{2+}\}$. $C_{72}H_{60}Li_4N_6O_{12}Ti_2\cdot$ 6($C_3H_7NO$)·10$H_2O$ (1943.59): calcd. C 55.62, H 6.33, N 8.65; found C 55.64, H 5.63, N 8.86.

**Complex $Na_4[(\mathbf{3a})_3Ti_2]$:** Yield: 60% of a red solid. $^1$H NMR ([D$_6$]-DMSO): $\delta$ = 8.16 (s, 6 H), 7.03 (d, $J$ = 7.0 Hz, 6 H), 6.37 (t, $J$ = 7.0 Hz, 6 H), 6.19 (d, $J$ = 7.0 Hz, 6 H), 1.91 (s, 36 H) ppm. MS (pos. FAB, 3-NBA): $m/z$ = 1343 $\{HNa_2[(\mathbf{3a})_3Ti_2]^+\}$, 1299 $\{H_3[(\mathbf{3a})_3Ti_2]^+\}$, 649 $\{H_2[(\mathbf{3a})_3Ti_2]^{2+}\}$. $C_{72}H_{60}Na_4N_6O_{12}Ti_2\cdot$ 6($C_3H_7NO$)·7$H_2O$ (1953.74): calcd. C 55.33, H 5.98, N 8.60; found C 55.15, H 5.38, N 8.86.

**Complex $K_4[(\mathbf{3a})_3Ti_2]$:** Yield: 37% of a red solid. $^1$H NMR ([D$_6$]-DMSO): $\delta$ = 8.10 (s, 6 H), 6.93 (d, $J$ = 7.0 Hz, 6 H), 6.37 (t, $J$ = 7.0 Hz, 6 H), 6.19 (d, $J$ = 7.0 Hz, 6 H), 1.89 (s, 36 H) ppm. MS (pos. FAB, 3-NBA): $m/z$ = 1337 $\{H_2K[(\mathbf{3a})_3Ti_2]^+\}$, 1299 $\{H_3[(\mathbf{3a})_3Ti_2]^+\}$, 649 $\{H_2[(\mathbf{3a})_3Ti_2]^{2+}\}$. $C_{72}H_{60}K_4N_6O_{12}Ti_2\cdot$ 6($C_3H_7NO$)·7$H_2O$ (2018.17): C 53.56, H 5.79, N 8.33; found C 53.61, H 5.30, N 8.69.

**Complex $Li_4[(\mathbf{3b})_3Ti_2]$:** Yield: quantitative of a red solid. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.61 (s, 6 H), 7.43 (s, 6 H), 7.34 (d, $J$ = 7.5 Hz, 6 H), 7.08 (d, $J$ = 7.0 Hz, 6 H), 7.00 (d, $J$ = 7.5 Hz, 6 H), 6.38 (t, $J$ = 7.0 Hz, 6 H), 6.16 (d, $J$ = 7.0 Hz, 6 H), 2.30 (s, 18 H) ppm. MS (pos. FAB, 3-NBA): $m/z$ = 1443 $\{H_3[(\mathbf{3b})_3Ti_2]^+\}$, 721 $\{H_2[(\mathbf{3b})_3Ti_2]^{2+}\}$. $C_{84}H_{60}Li_4N_6O_{12}Ti_2\cdot 4(C_3H_7NO)\cdot 10H_2O$ (1941.53): calcd. ## COVER PICTURE

**The cover picture shows** that Raman spectroscopy can reveal drastically different N–N stretching frequencies in dinuclear, dinitrogen-bridged titanium complexes. In the article by F. Tuczek et al. on p. 291 ff., the recently synthesized complex [{($\eta^5$-$C_5Me_5$)Ti[$\eta^6$-$C_5H_4C$(*p*-tolyl)$_2$]}$_2$($\mu$-$\eta^1$:$\eta^1$-$N_2$)] (**1**; R. Beckhaus et al., *Eur. J. Inorg. Chem.* **2005**, 1003) is compared to the dinuclear (dinitrogen)titanium complex [{$(Me_3Si)_2$NTiCl(TMEDA)}$_2$($\mu$-$\eta^1$:$\eta^1$-$N_2$) (**3**; R. Duchateau et al., *J. Am. Chem. Soc.* **1991**, *113*, 8986). With respect to **3** [$\nu$(NN) = 1284 cm$^{-1}$], **1** exhibits an unusually high N–N stretching frequency [$\nu$(NN) = 1749 cm$^{-1}$]. These spectroscopic differences reflect different degrees of dinitrogen activation, which are explained by the fact that only one of the $N_2$ $\pi$*-orbitals is occupied in **1**, whereas both $\pi$*-orbitals are occupied in **3**.

# Bioinorganic Chemistry of Group 12 Complexes Supported by Tetradentate Tripodal Ligands Having Internal Hydrogen-Bond Donors

**Lisa M. Berreau*[a]**

**Keywords:** Zinc / Hydrogen bonding / Hydrolysis / Cadmium / Group 12

Inspired by the proposed role of secondary hydrogen-bonding interactions in modulating the chemistry of mononuclear zinc centers in metalloenzymes, zinc complexes supported by tetradentate tripodal ligands having one or more internal hydrogen-bond donors have been prepared, characterized, and investigated for biologically relevant reactivity. Complexes of this class have been examined in terms of water activation and $CO_2$ reactivity, alcohol/alkoxide coordination, and amide methanolysis and phosphate ester hydrolysis reactivity. The results of these studies indicate that the presence of internal hydrogen-bond donors will lower the p$K_a$ of a zinc-bound water molecule, stabilize zinc alkoxide species with respect to hydrolysis, and enhance the phosphate ester cleavage reactivity of mononuclear zinc complexes. In addition, use of tripodal ligands having a single internal hydrogen-bond donor has enabled the isolation of a novel cadmium hydroxide complex and examination of its $CO_2$ chemistry, as well as the identification of a novel amide cleavage reaction which proceeds by initial formation of a deprotonated amide intermediate.

## Introduction

Secondary hydrogen-bonding interactions are suggested to play important roles in modulating the chemistry of mononuclear zinc centers in metalloenzymes.[1,2] For example, as outlined below for specific enzymes, these interactions have been proposed to: (1) influence the p$K_a$ of a zinc-bound water molecule, (2) orient a substrate or nucleophile for catalysis, (3) stabilize a transition state or reactive species, or (4) activate a substrate for a reaction (e.g. hydrolysis). Over the past few years, several laboratories have worked toward understanding the influence of hydrogen bonding on the chemistry of zinc centers by examining the chemistry of synthetic zinc complexes supported by novel tripodal tetradentate chelate ligands containing internal hydrogen-bond donors. In an approach akin to metal ion substitution studies of zinc enzymes, in some cases analog complexes of the heavier group 12 metals have also been prepared, characterized, and examined for biologically relevant reactivity. Overall, these studies have provided important new fundamental chemical insight with which to evaluate the proposed role of secondary hydrogen bonding in the catalytic cycles of zinc enzymes.

Carbonic anhydrases (CAs) catalyze the reversible hydration of carbon dioxide to form hydrogen carbonate. These enzymes are classified in four distinct classes, designated α-, β-, γ- and δ-CAs.[3] In the first three classes, a mononuclear zinc center mediates the hydrolysis of $CO_2$ by a two-step mechanism.[4] In the first step, a zinc-bound hy-

droxide serves as a nucleophile for attack on $CO_2$. The second step involves regeneration of the active site Zn–OH moiety through water activation. In the active site of a typical mammalian α-type carbonic anhydrase (e.g. carbonic anhydrase II), the resting state tetrahedral zinc center, ligated by three histidine ligands and one hydroxide/water ligand [$(N_{His})_3Zn–OH$], acts as a hydrogen-bond donor to an active-site threonine residue (Thr-199, Figure 1). This interaction is suggested to be important toward determining the p$K_a$ of the $Zn–OH_2$ moiety and orienting the hydroxide lone pair for attack on $CO_2$.[5,6] Hydrogen bonding involving Thr-199 is also suggested to be important for stabilization of the transition state and product-bound forms of the enzyme. Notably, an X-ray structure of carbonic anhydrase II shows that the zinc-bound hydroxide oxygen atom also accepts hydrogen bonds from the surrounding water molecules (Figure 1).[7]

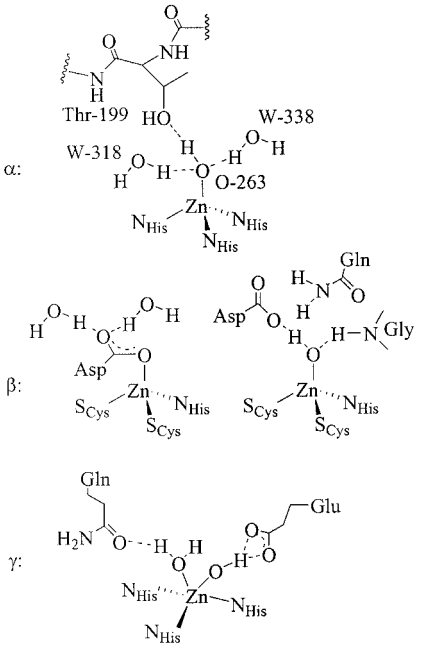

Figure 1. Active-site primary and secondary coordination environments of α-, β-, and γ-type carbonic anhydrases.

The β-type CAs contain a mononuclear zinc center ligated by two conserved cysteine residues, one conserved histidine residue, and an aspartate or water ligand (Figure 1).[8–12] On the basis of the X-ray structure of the *P. sativum* β-CA, secondary hydrogen-bonding interactions involving active site aspartate, glutamine, and glycine residues are suggested to be involved in catalysis.[9] In the γ-CA "Cam" from the archaeon *Methanosarcina thermophila*, a trigonal-bipyramidal zinc center is ligated by three histidine residues and two water/hydroxo ligands (Figure 1).[13,14] Hydrogen-bonding interactions are present between the water/hydroxo ligands and two active-site residues (Gln-75 and Glu-62). The glutamate residue has also been implicated in proton transfer and in stabilization of a hydrogen carbonate bound form of the enzyme. Finally, a δ-type carbonic anhydrase, TWCA1, from the marine diatom *Thalassiosira weissflogii*, has been identified as having an $(N_{His})_3Zn–OH_2/OH$ motif akin to α-type CAs.[15] Notably, under conditions wherein the level of TWCA1 is low in *T. weissflogii*, a putative naturally occurring, cadmium-containing carbonic anhydrase (CDCA1) has been identified.[16] The sequence of CDCA1 is significantly different from those of all other classes of CAs.[17] X-ray absorption spectroscopic studies suggest that the cadmium center in CDCA1 is tetrahedral and is ligated by two or more cysteine thiolates and a water molecule.[17]

Liver alcohol dehydrogenase (LADH) catalyzes the oxidation of alcohols to aldehydes and ketones using $NAD^+$ as a cofactor.[18] The resting state form of the enzyme contains a tetrahedral $(N_{His})(S_{Cys})_2Zn–OH_2$ center, with a nearby serine residue (Ser-48) positioned to form a hydrogen-bonding interaction with the zinc-bound water molecule (Figure 2).[18] In a proposed catalytic cycle for LADH, the active-site water molecule is replaced by the alcohol substrate.[19] An X-ray crystallographic study of $C_6F_5CH_2OH$ bound to the active-site zinc center of LADH suggests the presence of a hydrogen-bonding interaction between the hydroxy proton of the zinc-bound alcohol and the oxygen atom of Ser-48.[20] Following deprotonation of the zinc-bound alcohol, Ser-48 is proposed to form a strong hydrogen-bonding interaction with the alkoxide oxygen atom.[21,22] This interaction is then proposed to weaken upon hydride transfer and formation of a zinc-bound aldehyde or ketone product.[22] Notably, X-ray crystallographic studies of formamide-[23–25] and sulfoxide-inhibited[26,27] forms of LADH also indicate the presence of hydrogen bonding between the zinc-bound oxygen atom of the inhibitor and Ser-48.

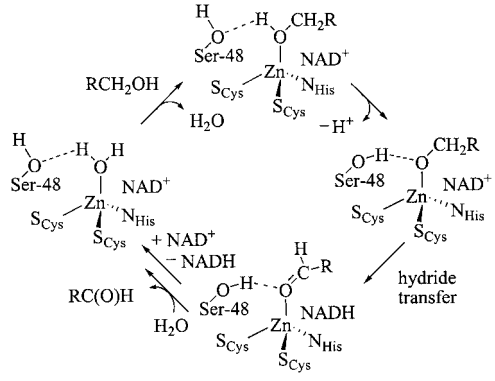

Figure 2. Hydrogen-bonding interactions proposed in the catalytic cycle of liver alcohol dehydrogenase.

Zinc enzymes that catalyze the hydrolysis of amide bonds in many cases have active-site residues within hydrogen-bonding distance of the metal-bound water and/or the substrate carbonyl group.[28,29] For example, in the active site of carboxypeptidase A, hydrogen-bonding interactions involving several residues (Glu-270, Arg-71, Arg-127, Asn-144, Arg-145, and Tyr-248) have been identified (Figure 3).[30,31]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

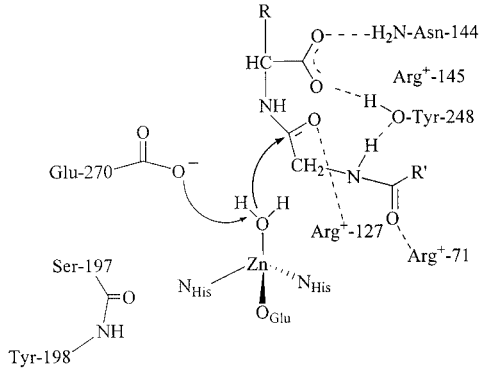

Figure 3. Proposed secondary interactions in the active site of carboxypeptidase A in the presence of substrate.

Similary, within the active site of several metalloenzymes that catalyze the hydrolysis of phosphate ester linkages, are positively charged amino acid side chains that are proposed to stabilize the transition state by hydrogen bonding and/or provide a proton for the leaving group. For example, in the catalytic cycle of alkaline phosphatase, phosphate monoester hydrolysis involves substrate interactions with arginine guanidinium and histidine imidazolium groups.[32]

In this Microreview, I summarize recent advances in the use of tripodal tetradentate ligand systems having internal hydrogen-bond donors in studies directed at evaluating the influence of secondary interactions on chemical reactions of relevance to carbonic anhydrase, liver alcohol dehydrogenase, and amide and phosphate ester hydrolyzing enzymes. In an ideal scenario, such studies would be performed using a tetrahedral enforcing ligand having internal hydrogen-bond donors, as this type of ligand would provide the most accurate mimic of both the primary and secondary coordination environment of the biological metal centers described above. However, despite recent attempts to incorporate secondary hydrogen-bond donors into tetrahedral enforcing ligands,[33] little coordination chemistry of such systems has been reported.

## Water Activation: (Aqua)- and (Hydroxo)zinc Complexes

A key step in the catalytic cycle of several zinc enzymes, including carbonic anhydrases, is the activation of a water molecule to produce a reactive Zn–OH moiety. To gauge the influence of secondary hydrogen bonding on the acidity of a metal-bound water molecule, Mareque-Rivas and co-workers have examined the acidity of a $Zn–OH_2$ moiety supported by a variety of tripodal $N_4$-donor ligands having internal hydrogen-bond donors.[34,35] For ligands having a primary amine hydrogen-bond donor [bpapa, bapapa, tapa; Figure 4 (left)], the acidity of the $Zn–OH_2$ moiety increases by ca. 0.7–0.9 $pK_a$ units per hydrogen-bond donor present in the chelate ligand. This can be rationalized by the fact that the formation of hydrogen-bonding interactions with the zinc-bound water molecule withdraws electron density from the water molecule, thus lowering the $pK_a$ value. Notably, a parallel study involving neopentylamine-appended ligands [bpnpa, bnpapa, tnpa; Figure 4 (right)] yielded a different result. Specifically, the ligand system having the largest number of internal hydrogen-bond donors (tnpa) was found to produce an (aqua)zinc complex that was intermediate in acidity between complexes supported by ligands having one (bpnpa) or two (bnpapa) internal hydrogen-bond donors. This difference may be due to steric effects involving the bulkier neopentylamine hydrogen-bond donors. In this regard, X-ray structures of zinc hydroxide complexes of both the bnpapa and tnpa ligands have been reported (Figure 5).[35,36] In $[(bnpapa)Zn–OH]ClO_4$, the zinc-bound hydroxide oxygen atom accepts two hydrogen bonds from the neopentylamine donors. These secondary interactions are characterized by a heteroatom N···O distance of ca. 2.73 Å. In $[(tnpa)Zn–OH]ClO_4$, the hydroxide oxygen atom also accepts two hydrogen bonds from the supporting chelate ligand. However, in this complex the average heteroatom distance is longer [$N···O_{avg}$ 2.82 Å; $N···O_{avg}$ 2.88 Å (two independent X-ray structures reported)].[35,36] Notably, this change in the secondary hydrogen-bonding interactions does not produce a significant difference in the Zn–O(H) bond length {$[(bnpapa)Zn–OH]ClO_4$, 1.941(3) Å; $[(tpna)Zn–OH]ClO_4$ [1.9315(8) Å, 1.957(2) Å]}.

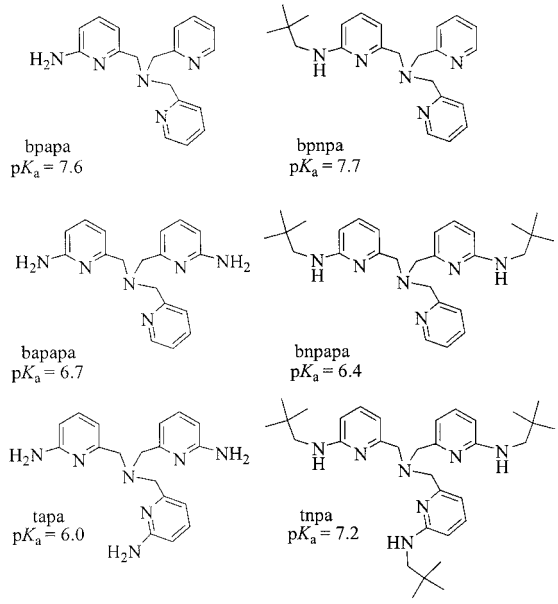

Figure 4. Tetradentate, tripodal chelate ligands having internal hydrogen-bond donors. The $pK_a$ values for the $[(ligand)Zn–OH_2]^{2+}$ complexes are given.

Chin and co-workers have determined the acidity of a zinc-bound water molecule in complexes supported by tetradentate tripodal $N_3O$-type ligands having internal hydrogen-bond donors.[37] A $Zn^{II}$ complex of the L2 ligand (Figure 6), which has two internal primary amine hydrogen-bond donors, has more acidic $pK_a$ values than a $Zn^{II}$ complex of the L1 ligand. These values, determined by potentiometric titration, are for ionization of the pendant alcohol of the chelate ligand and a zinc-bound water molecule, albeit the individual values have not been definitively as-

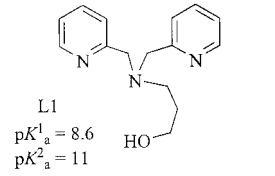
signed. As with the ligand systems described above, the enhanced acidity for the zinc-bound water molecule is attributed to secondary hydrogen-bonding interactions involving the ligand amine groups. To date, no X-ray structural characterization data has been reported for (aqua)- or (hydroxo)-zinc derivatives of the L1 or L2 ligands.



L1
$pK^1_a = 8.6$
$pK^2_a = 11$

## Metal Hydroxide/$CO_2$ Chemistry

As noted above, studies of both α- and γ-carbonic anhydrases suggest that $HCO_3^-$ binding to the zinc ion is stabilized by hydrogen-bonding interactions.[14,38] Interestingly, several isolated mononuclear metal hydrogen carbonate complexes also demonstrate both hydrogen-bond-donor and -acceptor interactions involving the metal-bound hydrogen carbonate ligand.[39–43] To date, a mononuclear zinc hydrogen carbonate complex of relevance to carbonic anhydrase has not been structurally characterized. However, Masuda and co-workers recently reported that a zinc hydroxide complex of the tnpa chelate ligand {[(tnpa)Zn–OH]$ClO_4$, Figure 5} undergoes reaction in the presence of $CO_2$ to produce a putative zinc hydrogen carbonate complex, which has been characterized by $^1$H and $^{13}$C NMR and electrospray mass spectrometry.[36] In the proton NMR spectrum in [$D_6$]DMSO, evidence for the formation of the hydrogen carbonate complex is derived from a shift of the neopentylamine proton resonance from δ = 9.21 ppm in the hydroxide complex to δ = 7.71 ppm in the hydrogen carbonate complex. In the $^{13}$C NMR spectrum in $CD_3OD$, a new resonance at $\delta$ = 160.8 ppm has been assigned as the sp$^2$ carbon atom of the coordinated hydrogen carbonate ligand. The strongest evidence for the formation of [(tnpa)-Zn($HCO_3$)]$ClO_4$ comes from electrospray mass spectrometry where a new isotope cluster is found at $m/z$ = 670.3. This value corresponds to the cationic formula [(tnpa)-Zn($HCO_3$)]$^+$. The reaction to produce [(tnpa)Zn($HCO_3$)]-$ClO_4$ is reversible, as purging with argon results in the regeneration of the spectroscopic signals associated with [(tnpa)Zn–OH]$ClO_4$. Recently, the same laboratory reported that [(bnpapa)Zn–OH]$ClO_4$[35,44] (Figure 5) undergoes reaction with $CO_2$ to produce a zinc hydrogen carbonate species, [(bnpapa)Zn($HCO_3$)]$ClO_4$.[45] Though not relevant to carbonic anhydrases, we note that in the presence of $H_2O_2$, this hydrogen carbonate complex undergoes further reaction with a zinc hydroperoxide intermediate, [(bnpapa)Zn–OOH]$ClO_4$, to produce a novel dinuclear zinc peroxocarbonate complex, [(bnpapaZn)$_2$($O_3$CO)]($ClO_4$)$_2$.[45] X-ray crystallographic studies of this peroxocarbonate complex indicate stabilization of peroxocarbonate dianion coordination by hydrogen-bonding interactions involving the bnpapa supporting chelate ligand.

In reactions with relevance to β-type CAs and the novel cadium-containing carbonic anhydrase that was recently reported,[16,17] we have examined the $CO_2$ reactivity of dinuclear zinc and cadmium hydroxide complexes, [(benpaZn)$_2$-(μ-OH)$_2$]($ClO_4$)$_2$[46] and [(bmnpaCd)$_2$(μ-OH)$_2$]($ClO_4$)$_2$, supported by tripodal $N_2S_2$ chelate ligands containing a single internal hydrogen-bond donor (Scheme 1).[47,48] For the zinc complex, the reaction with $CO_2$ leads to the formation of a bridging carbonate complex, [(benpaZn)$_2$(μ-$CO_3$)]-($ClO_4$)$_2$, having bidentate carbonate coordination to both zinc centers. The reaction of [(bmnpaCd)$_2$(μ-OH)$_2$]($ClO_4$)$_2$ with $CO_2$ leads to the formation of [(bmnpaCd)$_2$(μ-$CO_3$)]-($ClO_4$)$_2$, a dinuclear complex wherein the carbonate ligand is coordinated in a bidentate fashion to one Cd$^{II}$ center and in an anisobidentate mode to the other Cd$^{II}$ ion. Notably, while addition of water to the zinc carbonate complex results in the release of $CO_2$ and the regeneration of [(benpaZn)$_2$(μ-OH)$_2$]($ClO_4$)$_2$, the cadmium carbonate complex exhibits no reaction in the presence of water. This difference in reactivity may be due to several factors, including the weak nature of thioether ligation to Zn$^{II}$.[49,50] In [(benpaZn)$_2$(μ-$CO_3$)]($ClO_4$)$_2$, long Zn–S interactions [2.561(1) Å and 2.594(1) Å] suggest the possibility that a coordinated thioether may dissociate or could possibly be displaced in favor of a water ligand. Water coordination could facilitate the hydrolysis of the bridging carbonate moiety and the release of $CO_2$. Subtle differences in hydrogen-bonding interactions involving the bridging carbonate ligands in [(benpaZn)$_2$(μ-$CO_3$)]($ClO_4$)$_2$ and [(bmnpaCd)$_2$(μ-$CO_3$)]($ClO_4$)$_2$ may also contribute to the observed differences in $CO_2$ release reactivity.

## Nitrogen/Sulfur-Ligated Zinc–Alcohol, –Aryloxide, and –Alkoxide Complexes

Comparative structural studies of mononuclear zinc–alcohol, –formamide, and –sulfoxide complexes, supported by the $N_2S_2$-donor chelate ligands bmapa {[(6-amino-2-pyridyl)methyl]bis[2-(methylthio)ethyl]amine} and bmpa {bis-[2-(methylthio)ethyl][(2-pyridyl)methyl]amine} (Figure 7), revealed, in some cases, differences as a consequence of the presence of a hydrogen-bond-donor amine group in the former ligand.[51,52] For example, while mononuclear bmapa- and bmpa-ligated zinc–methanol complexes showed no difference in the Zn–O(alcohol) distance, a subtle elongation (ca. 0.025 Å) was identified for the Zn–O(formamide) distances in [(bmapa)Zn(DMF)]$(ClO_4)_2$ and [(bmapa)-Zn(NMF)]$(ClO_4)_2$ relative to their bmpa-ligated analogs. This bond lengthening may be due to the removal of electron density from the formamide carbonyl unit through the intramolecular hydrogen-bonding interaction, which would make the formamide a weaker donor to the cationic zinc center. However, alternative rationales for the Zn–O bond elongation in the bmapa-ligated zinc–formamide derivatives must also be considered. For example, the presence of the secondary amine group may impart additional steric hindrance that is responsible for the slight Zn–O(formamide) bond elongation. In addition, the amine substituent on the pyridyl ring of the bmapa ligand makes this heterocycle a slightly better base (pyridine: $pK_a$ = 5.14; 2-aminopyridine: $pK_a$ = 6.71) and thus a better donor to the zinc center.[53,54] This could result in a slightly decreased Lewis acidity for the zinc center in the bmapa-ligated derivatives. Overall, the degree to which each of these factors influences the neutral oxygen-donor binding properties of the $N_2S_2$-ligated zinc center remains to be fully elucidated.

As noted above, a mononuclear nitrogen/sulfur-ligated zinc–alkoxide derivative is proposed as the active species for hydride transfer in the catalytic cycle of liver alcohol dehydrogenase.[19] To examine the influence of hydrogen bonding on the formation and reactivity of nitrogen/sulfur-ligated zinc–aryloxide and –alkoxide complexes, two new tetradentate tripodal ligand systems containing one or more internal hydrogen-bond donors were employed

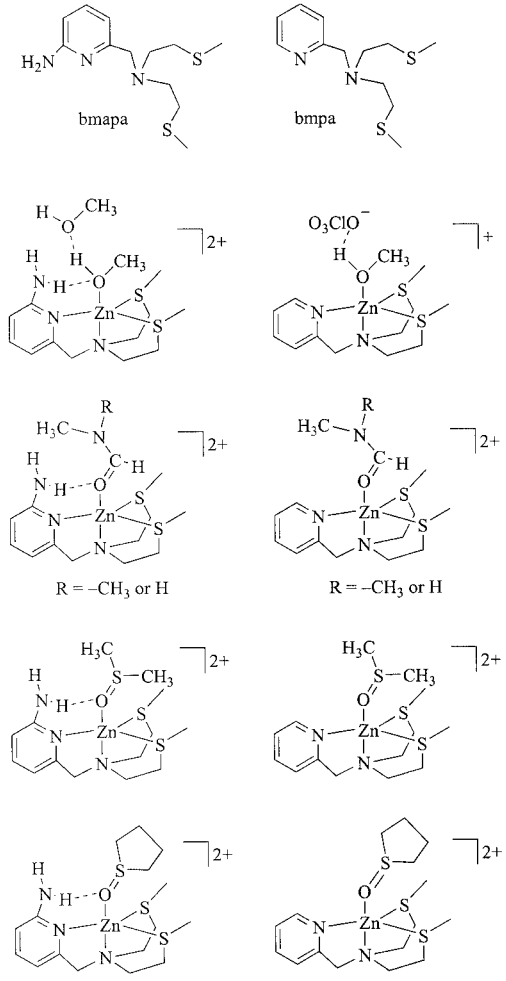

Figure 7. Zinc–alcohol, –formamide, and –sulfoxide complexes of the bmapa and bmpa ligands. All complexes have perchlorate counteranions.

(Figure 8).[46,55] Using the bmnpa and benpa ligands, a series of mononuclear $N_2S_2$-ligated zinc–aryloxide complexes were prepared and characterized.[46] In each complex, a hydrogen-bonding interaction is present between the zinc-bound aryloxide oxygen atom and the secondary amine moiety of the supporting chelate ligand. $^1$H NMR

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

studies of this family of complexes indicated that this hydrogen-bonding interaction is perturbed upon change in the basicity of the aryloxide ligand. Specifically, whereas in the *p*-methoxyphenolate complex [(benpa)Zn(*p*-$OC_6H_4OCH_3$)]$ClO_4$ the secondary amine N–H resonance is found at $\delta$ = 9.97 ppm ($CD_3CN$, ambient temperature), in the *p*-nitrophenolate complex [(benpa)Zn(*p*-$OC_6H_5NO_2$)]$ClO_4$ the same resonance is found at $\delta$ = 8.93 ppm. The downfield position of the N–H resonance in the *p*-methoxyphenolate derivative relative to the *p*-nitrophenolate analog indicates that a stronger hydrogen-bonding interaction is present in [(benpa)Zn(*p*-$OC_6H_4OCH_3$)]$ClO_4$. This is consistent with the relative basicity of the two anions (*p*-methoxyphenol: p$K_a$ = 10.2; *p*-nitrophenol: p$K_a$ = 7.14).

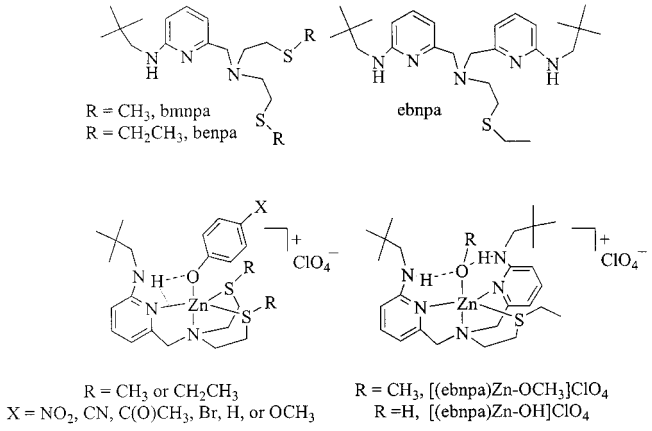

Figure 8. Top: Tripodal tetradentate nitrogen/sulfur ligands containing internal hydrogen-bond donors. Bottom: Mononuclear zinc–aryloxide and –methoxide/hydroxide complexes.

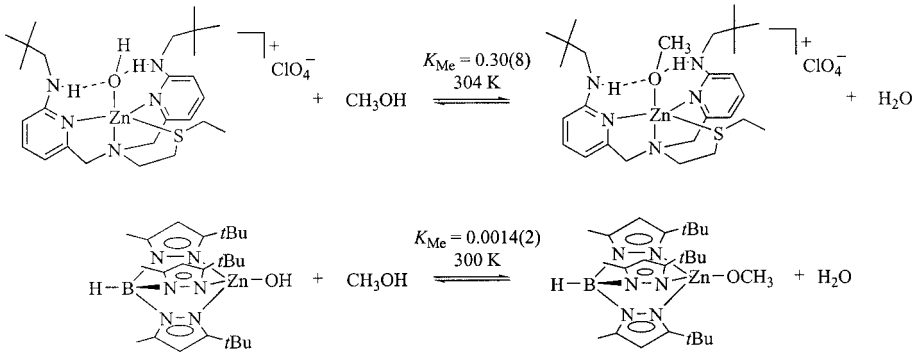
Particularly interesting results were obtained using the tripodal $N_3S$-donor ebnpa {[2-(ethylthio)ethyl]bis[(6-neopentylamino-2-pyridyl)methyl]amine} ligand (Figure 8).[55] The mononuclear zinc–methoxide and –hydroxide complexes, [(ebnpa)Zn–$OCH_3$]$ClO_4$ and [(ebnpa)Zn–OH]$ClO_4$, were isolated and characterized. Notably, determination of the equilibrium constant for the methanolysis of the hydroxide derivative revealed a value [$K_{Me}$ (304 K) = 0.30(8)] that is orders of magnitude greater than that of an equilibrium involving Zn–OH and Zn–$OCH_3$ derivatives of the hydrophobic $Tp^{tBu,Me}$ ligand [$Tp^{tBu,Me}$ = tris(3-*t*Bu-5-Me-pyrazolyl)hydroborate, Scheme 2] [$K_{Me}$ (300 K) = $1.4(2)\cdot10^{-3}$].[56,57] Examination of the temperature dependence of the equilibrium constants for the ebnpa- and $Tp^{tBu,Me}$-ligated systems yielded $\Delta H_{Me}$ = –0.9 kcal/mol and 1.2(1) kcal/mol, respectively. The negative $\Delta H_{Me}$ value for the ebnpa-ligated system indicates that spontaneous alkoxide formation will occur from a zinc hydroxide precursor at low temperature. In contrast, the positive $\Delta H_{Me}$ value for the $Tp^{tBu,Me}$-ligated system indicates that alkoxide formation from a zinc hydroxide species is thermodynamically unfavorable at all temperatures. Overall, this work has implications for the catalytic cycle of LADH as it suggests that active-site ligand effects, including hydrogen-bonding interactions involving Ser-48, likely influence the hydrolytic stability of the proposed zinc–alkoxide moiety in the catalytic cycle.

## Amide Cleavage

Secondary hydrogen-bonding interactions are proposed to play important roles in the amide hydrolysis reactions mediated by carboxypeptidase A and other metalloamidases. For example, hydrogen bonding may be involved in the activation of the amide carbonyl moiety, and/or in transition-state stabilization. To probe the influence of hydrogen bonding on amide cleavage reactivity, Mareque-Rivas and co-workers have examined the amide cleavage properties of tripodal $N_4$-ligated systems having one internal amide substrate and from zero to two internal hydrogen-bonding interactions involving the zinc-bound amide carbonyl oxygen atom (Figure 9).[58–60] X-ray crystallographic studies of [(ppbpa)Zn]$(ClO_4)_2$, [(amppa)Zn]$(ClO_4)_2$ (amppa = [(6-amino-2-pyridyl)methyl]{[6-(pivaloylamido)-2-pyridyl]-methyl}[(2-pyridyl)methyl]amine) and [(bampa)Zn]$(ClO_4)_2$ (bampa = bis[(6-amino-2-pyridyl)methyl]{[6-(pivaloylamido)-2-pyridyl]methyl}amine) revealed that each complex contains a distorted trigonal-bipyramidal zinc center with the tertiary amine and the amide oxygen donors of the chelate ligand in the axial positions.[59,61] Comparison of the zinc–ligand distances in this series of complexes indicated that as the number of internal hydrogen-bonding interactions involving the coordinated amide oxygen atom increased, the Zn–O(amide) bond elongated by ca. 0.02 Å and the Zn–N(*tert*-amine) shortened by ca. 0.02–0.03 Å



Scheme 2. Zinc–hydroxide/methoxide equilibria.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(Figure 9). Notably, the magnitude of this elongation of the Zn–O bond in this series of complexes per hydrogen-bond donor is identical to that found upon comparison of the Zn–O bond lengths in the $N_2S_2$-ligated zinc–formamide complexes {[(bmapa)Zn(DMF)]$(ClO_4)_2$, [(bmapa)Zn(NMF)]-$(ClO_4)_2$, Figure 7} vs. structurally similar compounds lacking the internal hydrogen-bond donor {[(bmpa)Zn(DMF)]-$(ClO_4)_2$, [(bmpa)Zn(NMF)]$(ClO_4)_2$, Figure 7}.[52] The hydrogen-bonding interactions for the complexes shown in Figure 7 and Figure 9 may all be classified as moderate hydrogen bonds.[62]

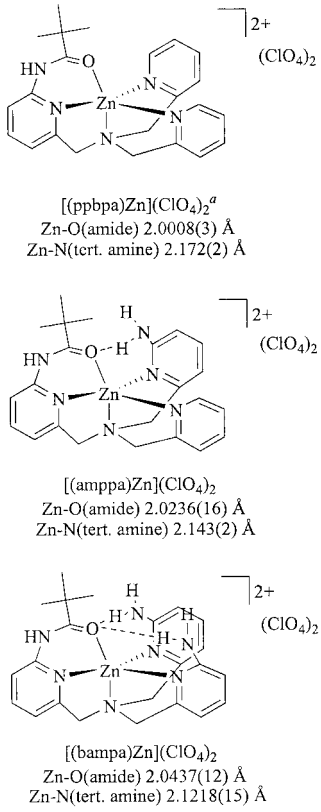


Figure 9. Amide-appended complexes containing zero to two internal hydrogen-bond donors.[63]

Treatment of the amide-appended zinc complexes shown in Figure 9 with 1 equiv. of $Me_4NOH{\cdot}5H_2O$ in methanol at 50(1) °C results in amide alcoholysis to produce 1 equiv. each of methyl trimethylacetate and $Me_4NClO_4$, and one or more zinc complexes of a modified chelate ligand having a new primary amine appendage derived from the cleavage of the amide moiety. For example, the reaction of [(ppbpa)-Zn]$(ClO_4)_2$ under the conditions cited above produces a mixture of zinc–hydroxide and –methoxide complexes of the ambpa {[(6-amino-2-pyridyl)methyl]bis[(2-pyridyl)-methyl]amine}. Mareque-Rivas and co-workers have shown that the half-life for the amide methanolysis reaction in the series of complexes shown in Figure 9 increases dramatically with the addition of each internal hydrogen-bond donor. Specifically, the half-life for the amide bond in [(ppbpa)Zn]$(ClO_4)_2$ is ca. 0.4 h, whereas for [(amppa)-Zn]$(ClO_4)_2$ and [(bampa)Zn]$(ClO_4)_2$, the half-life is ca. 9 h and ca. 320 h, respectively.[59] To interpret these results, as well as other amide cleavage studies involving similar complexes reported in the literature, we thought it essential to further investigate the reaction mechanism of amide cleavage operative in these systems. In this regard, we recently completed kinetic and mechanistic studies of the amide methanolysis reaction of [(ppbpa)Zn]$(ClO_4)_2$.[61] As depicted in Scheme 3, these studies revealed that the treatment of [(ppbpa)Zn]$(ClO_4)_2$ with 1 equiv. of $Me_4NOH{\cdot}5H_2O$ in methanol/acetonitrile solution at ambient temperature results in the stoichiometric formation of a deprotonated amide intermediate complex, [(ppbpa$^-$)Zn]$ClO_4$, which was isolated and characterized ($^1$H and $^{13}$C NMR, FTIR, and elemental analysis). Heating of analytically pure [(ppbpa$^-$)-Zn]$ClO_4$ in methanol/acetonitrile solution at 65(1) °C results in amide methanolysis. Kinetic studies of this reaction revealed a first-order dependence on both [(ppbpa$^-$)Zn]-$ClO_4$ and methanol in the rate-determining step. Analysis of the rate of decay of a $^1$H NMR signal of [(ppbpa$^-$)Zn]-$ClO_4$ as a function of time yielded activation parameters that are consistent with an intramolecular amide-cleavage process [$\Delta H^{\ddagger}$ = 15.0(3) kcal/mol, $\Delta S^{\ddagger}$ = –33(1) eu].[63] On the basis of this data and other experiments, a reaction mechanism was proposed in which the deprotonated amide species [(ppbpa$^-$)Zn]$ClO_4$ is an intermediate produced prior to the rate-limiting step.[61] The reaction of this intermediate with methanol is proposed to produce a Lewis activated type structure from which amide cleavage is initiated. The rate-determining step in this reaction pathway should be either the attack of the zinc-bound alkoxide nucleophile at the amide carbonyl carbon atom or the breakdown of the resulting tetrahedral intermediate. On the basis of these kinetic and mechanistic studies, we suggest that the slowing of the rate of amide methanolysis for the series of complexes shown in Figure 9 results from steric hindrance imparted by the hydrogen-bond donor amine groups, which limits the approach of the nucleophile to the amide carbonyl carbon atom, or from stabilization of the tetrahedral intermediate by hydrogen-bonding interactions. Further experiments directed at differentiating between these possibilities are underway.

Notably, a $Zn^{II}$ complex of the $N_2S_2$ donor ligand bmppa (Scheme 4) also undergoes amide methanolysis in the presence of $Me_4NOH{\cdot}5H_2O$ in methanol-containing solutions.[64] In addition, we have discovered that $Cd^{II}$ and $Hg^{II}$ analogs, [(bmppa)Cd$(ClO_4)$]$ClO_4$ and [(beppa)-Hg$(ClO_4)$]$ClO_4$, also undergo amide methanolysis under similar conditions.[64,65] The X-ray structures of these heavier group 12 analogs provide evidence that simultaneous amide oxygen and anion coordination can occur. Specifically, in the solid-state structures of [(bmppa)Cd$(ClO_4)$]-$ClO_4$ and [(beppa)Hg$(ClO_4)$]$ClO_4$ (Figure 10) a weak perchlorate interaction yields a six-coordinate cation having a distorted trigonal-prismatic geometry. Interestingly, the metal-bound oxygen atom of the coordinated perchlorate anion is positioned adjacent to the amide carbonyl oxygen atom in an arrangement that may be relevant to the proposed active form of the metal complexes for amide meth-

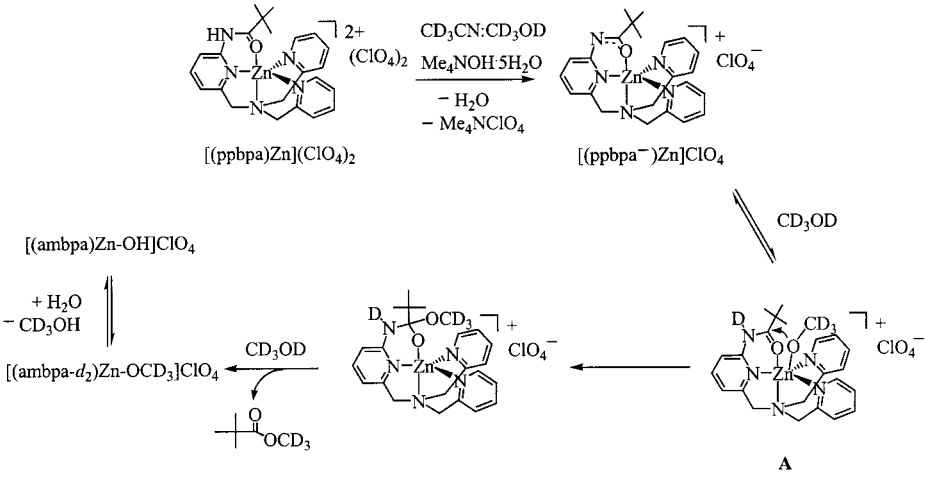
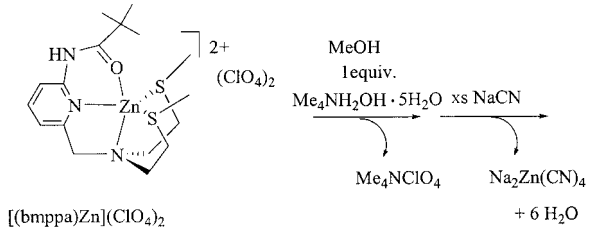
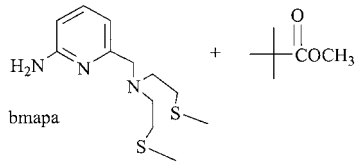


Scheme 3. Proposed mechanistic pathway of the amide methanolysis for $[(ppbpa)Zn](ClO_4)_2$.

anolysis (Scheme 3, "A"). Preliminary mechanistic studies indicate that the amide-cleavage reactions of $[(bmppa)Cd(ClO_4)]ClO_4$ and $[(beppa)Hg(ClO_4)]ClO_4$ also proceed by the formation of an intermediate deprotonated amide complex.





Scheme 4. Amide methanolysis reaction of $[(bmppa)Zn](ClO_4)_2$.

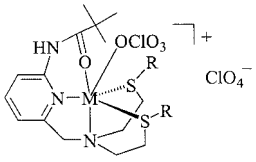


Figure 10. Drawing of the cationic portions of $[(bmppa)M(ClO_4)]ClO_4$ ($M = Cd^{II}$ or $Hg^{II}$).

The studies outlined above indicate that group 12 complexes supported by tripodal ligands having a single internal amide appendage exhibit novel amide-cleavage reactivity in basic methanol solution. This is interesting in that amide-appended tetradentate tripodal ligands have been used to stabilize a variety of 3d-metal complexes of relevance to biological systems, including metal hydroxide complexes, without any reported amide-cleavage side reactions. For example, Borovik has used amide-appended tripodal, trianionic ligands to stabilize a variety of terminal M–X (M = Fe, Mn; X = O, OH, S, Se, NHR, NR) complexes.[66,67] Masuda has also demonstrated that amide-appended tetradentate tripodal $N_4$-donor ligands can be used to stabilize a variety of novel copper– and/or iron–hydroxo, –hydroperoxo, and –alkylperoxo species.[68–73] These latter complexes are particularly interesting in that each contains the {[6-(pivaloylamido)-2-pyridyl]methyl}amine structural component within the supporting chelate ligand. Further studies are clearly needed to determine how changes in the nature of the metal ion influence the amide-cleavage reactivity.

## Phosphate Ester Coordination and Hydrolysis

There is considerable current interest in the development of synthetic compounds that catalyze the selective and/or catalytic hydrolysis of phosphate esters.[74–90] In this contribution, discussion in this area is limited to recent studies of phosphate ester coordination and hydrolysis mediated by zinc complexes of tetradentate tripodal ligands having internal hydrogen-bond donors.

Mareque-Rivas and co-workers recently compared the phosphate monoester binding properties of $[(bapapa)Zn(OH_n)]^{2+}$ ($n$ = 1 or 2; $pK_a$ = 6.7) and $[(tpa)Zn(OH_2)]^{2+}$ (Figure 11).[91] In aqueous solution at pH = 7, the former compound exhibits a higher affinity for $PhOPO_3^{2-}$ coordination ($\log K = 3.6 \pm 0.1$) than the tpa-ligated analog complex ($\log K = 4.4 \pm 0.1$). Although an X-ray structure of a phosphate monoester adduct was not reported for either system, X-ray crystallographic characterization of a zinc nitrate complex of the bapapa ligand, $[(bapapa)Zn(NO_3)]NO_3$, showed that the zinc-bound oxygen atom of the anion can participate in two moderate hydrogen-bonding interactions [O(1)···$N(amine)_{avg}$ 2.93 Å] with the supporting chelate ligand. Presumably, the bound phosphate ester monoanion can coordinate in a similar fashion.

[(tapa)Zn(H$_2$O)](X)$_2$

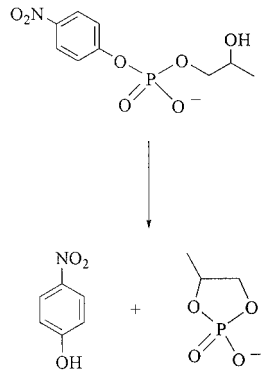

Figure 12. Top: Drawing of [(tapa)Zn(H$_2$O)](X)$_2$. Bottom: Intramolecular transesterification reaction of 2-hydroxypropyl 4-nitrophenyl phosphate.

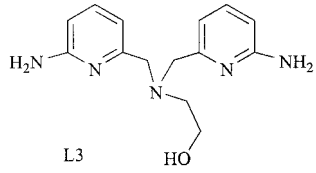
A dinuclear zinc–phosphate diester complex, [{(bpapa)Zn}$_2$(μ-DMP)$_2$](PF$_6$)$_2$ (DBP = dibenzyl phosphate) having one internal hydrogen-bond donor per chelate ligand has been characterized by X-ray crystallography.[92] At each zinc center in [{(bpapa)Zn}$_2$(μ-DMP)$_2$](PF$_6$)$_2$, a bound phosphate diester oxygen atom accepts one hydrogen-bonding interaction from the amine group of the supporting chelate ligand. In solution [CD$_3$CN/D$_2$O (pD = 7.4)], using $^{31}$P NMR spectroscopy as a detection method, it was found that the affinity of the [(bpapa)Zn(OH/H$_2$O)]$^{2+}$ cation for DBP$^-$ was higher than that of [(tpa)Zn(H$_2$O)]$^{2+}$, which is similar to the reactivity found for the phosphate monoester binding studies described above.

In further investigations of the impact of secondary hydrogen-bonding interactions on the phosphate ester reactivity of zinc complexes, Mareque-Rivas and Williams recently reported a comparative study of the transesterification of 2-hydroxypropyl 4-nitrophenyl phosphate catalyzed by [(tapa)Zn(H$_2$O)]$^{2+}$ (Figure 12) and [(tpa)Zn(H$_2$O)]$^{2+}$ (Figure 11).[93] Notably, the rate of cyclization of the substrate is accelerated 3·10$^6$-fold by [(tapa)Zn(H$_2$O)]$^{2+}$ and 4·10$^3$-fold by [(tpa)Zn(H$_2$O)]$^{2+}$. The significant rate enhancement found for [(tapa)Zn(H$_2$O)]$^{2+}$ was attributed to enhanced stabilization of the dianionic intermediate that is formed in the rate-limiting step of the transesterification reaction, presumably by hydrogen-bonding interactions.

Studies of phosphate ester transesterification and hydrolysis have also been reported using tripodal N$_3$O-donor ligands having a variable number of internal hydrogen-bond donors.[37] Treatment of Zn$^{II}$ complexes of the L1–L3 ligands (Figure 6 and Figure 13) with bis(*p*-nitrophenyl) phosphate (BNP) results in the production of either phosphate ester transesterification or hydrolysis products, depending on the identity of the supporting chelate ligand. For L1 and L2 (Figure 6), *p*-nitrophenol and the *O*-phosphorylated chelate ligand are generated, indicating a transesterification reaction pathway involving the alkoxide moiety of the chelate ligand. For L3 (Figure 13), only phosphate ester hydrolysis products are produced.



L3

Figure 13. L3 ligand.

Comparison of the reactivity of the zinc complex of L2 (second-order rate constant: 9.7·10$^{-2}$ M$^{-1}$ s$^{-1}$) vs. the spontaneous hydrolysis of BNP at pH = 7.0 and 25 °C reveals an acceleration of approximately six orders of magnitude. This rate acceleration was attributed to the involvement of an alkoxide (vs. hydroxide) nucleophile and the presence of secondary hydrogen-bonding interactions. The presence of the hydrogen-bond donors may provide additional Lewis acid activation for the zinc-bound substrate, or as suggested above, may stabilize a dianionic intermediate in the transesterification reaction. Further evidence for the impact of secondary hydrogen bonding is derived from the comparison of the second-order rate constants for BNP transesterification mediated by the zinc complex of L1 (4.2·10$^{-4}$ M$^{-1}$s$^{-1}$) vs. that of L2, which reveals a 230-fold reactivity increase. For the phosphate ester hydrolysis reaction catalyzed by the zinc complex of L3, which includes two internal hydrogen-bond donor groups, the rate acceleration is ca. 10$^5$ over that of the uncatalyzed reaction.

## Conclusions

Through studies of synthetic zinc complexes supported by tetradentate tripodal ligands containing one or more internal hydrogen-bond donors, chemical precedent has been elucidated which can be used to interpret the proposed roles for secondary hydrogen bonding in modulating the chemistry of mononuclear zinc centers in biological systems. For example, by using synthetic complexes, it has been determined that the presence of hydrogen-bond donors to a zinc-bound water molecule reduces the p$K_a$ of the bound water by 0.7–0.9 p$K_a$ units per secondary interaction. This result has relevance to carbonic anhydrases (CAs), where the formation of a zinc hydroxide moiety is required for $CO_2$-hydration reactivity. Hydrogen-bonding interactions are also likely important toward influencing the hydroxide and hydrogen carbonate anion coordination within the active site of CAs. In regard to the latter, spectroscopic evidence has been recently reported for the formation of a novel mononuclear zinc hydrogen carbonate complex supported by a tripodal ligand having three internal hydrogen-bond donors. Use of an $N_2S_2$-donor chelate ligand having one internal hydrogen-bond donor has enabled the isolation of a novel Cd–OH complex. This complex is reactive toward $CO_2$, thus providing the first chemical precedent relevant to the reactivity of a recently reported naturally occurring cadmium-containing carbonic anhydrase. The catalytic cycle of liver alcohol dehydrogenase is proposed to involve hydrogen-bonding interactions between a zinc-coordinated neutral oxygen donor or an alkoxide ligand and a nearby serine residue. Comparative structural studies of tripodal $N_2S_2$-ligated zinc–alcohol, –formamide, and –sulfoxide complexes revealed only minor perturbations in Zn–O bonding as a consequence of the presence of an internal hydrogen-bond donor. However, studies of the methanolysis reactivity of an $N_3S$-ligated zinc–hydroxide complex revealed that the presence of internal hydrogen-bond donors enhances the stability of a zinc–methoxide species with respect to hydrolysis. This result indicates that hydrogen bonding involving Ser-48 in LADH may play an important role in stabilizing the proposed zinc–alkoxide species.

Amide methanolysis reactivity has been identified for group 12 complexes of tetradentate tripodal $N_4$- and $N_2S_2$-donor ligands having one internal amide appendage. Kinetic and mechanistic studies of the amide methanolysis reaction of one $N_4$-ligated system indicate a novel reaction pathway involving initial formation of a deprotonated amide intermediate. Incorporation of hydrogen-bond donors into this $N_4$-donor ligand, such that they interact with the zinc-bound amide oxygen atom, significantly slows the rate of amide methanolysis. This may be the result of steric hindrance and/or hydrogen-bond stabilization of a tetrahedral intermediate. Importantly, these systems now provide a unique opportunity to systematically examine an amide-cleavage process as a function of both supporting ligand and metal ion present in the complex. Such studies are expected to provide additional insight into how secondary interactions, including hydrogen bonding, influence amide-cleavage reactions.

The presence of hydrogen-bond donors in a tetradentate tripodal $N_4$-ligated zinc complex enhances the affinity of the zinc center for coordination of a phosphate ester monoanion. In terms of phosphate ester hydrolysis reactivity, zinc complexes having internal hydrogen-bond donors have been found to exhibit significant rate enhancement over analogs lacking such secondary interactions. These combined results provide chemical precedent to support the notion that hydrogen bonding interactions play an important role in modulating biological phosphate ester cleavage reactions.

# CO Cleavage Promoted by Acetylide Addition to Vinyliminium Diiron Complexes

**Luigi Busetto,[a] Fabio Marchetti,[a] Stefano Zacchini,[a] and Valerio Zanotti*[a]**

**Keywords:** CO cleavage / Bridging ligands / Vinyliminium / Diiron complexes

The vinyliminium complex [$Fe_2$\{μ-$\eta^1$:$\eta^3$-C(Me)=C(Me)-C=N(Me)(Xyl)\}(μ-CO)(CO)$(Cp)_2$][$SO_3CF_3$] (**1**; Xyl = 2,6-$Me_2C_6H_3$) reacts with LiC≡CR [R = $C_6H_4$Me = Tol, Ph, H, *n*Bu, $SiMe_3$, C(Me)=$CH_2$] affording the amido-functionalized allylidene complexes [$Fe_2$\{μ-$\kappa^1$(O):$\eta^1$(C):$\eta^3$(C)-C(C≡CR)-C(Me)C(Me)C(O)N(Me)(Xyl)\}(μ-CO)$(Cp)_2$] [R = $C_6H_4$Me = Tol, **2**; R = Ph, **3**; R = H, **4**; R = *n*Bu, **5**; R = $SiMe_3$, **6**; R = C(Me)=$CH_2$, **7**] in good yields. Labelling experiments with $^{13}$CO-enriched **1** indicate that formation of **2**–**7** occurs through cleavage of the carbon–oxygen bond of a coordinated CO ligand. The molecular structure of **2** has been determined by an X-ray diffraction study.

## Introduction

Recently, we described the successful preparation of bridging vinyliminium diiron complexes[1] and demonstrated the electrophilic character of the bridging ligand. Regio- and stereoselective additions of hydride ($NaBH_4$) to the μ-vinyliminium have been described in detail.[2] With the aim of extending our investigations to the addition of carbon nucleophiles, we have examined the reaction with lithium acetylides. Here, we report on the rearrangement occurring at the bridging ligand as a consequence of acetylide attack. This involves a terminally coordinated carbonyl, which undergoes CO cleavage and incorporation in the bridging ligand.

## Result and Discussion

Complex *cis*-[$Fe_2$\{μ-$\eta^1$:$\eta^3$-C(Me)=C(Me)C=N(Me)(Xyl)\}-(μ-CO)(CO)$(Cp)_2$][$SO_3CF_3$] (**1**) rapidly reacts with an excess of lithium acetylide (LiC≡CR), affording the air-stable compounds *cis*-[$Fe_2$\{μ-$\kappa^1$(O):$\eta^1$(C):$\eta^3$(C)-C(C≡CR)C(Me)-C(Me)C(O)N(Me)(Xyl)\}(μ-CO)$(Cp)_2$] (**2**–**7**), in about 60–70% yield (Scheme 1).

The molecular structure of **2** has been determined by X-ray diffraction: two different views of the molecule are shown in Figure 1, whereas relevant bond lengths and bond angles are reported in Table 1; the structure of the bridging ligand is also shown in Scheme 2.

The molecule is composed by a $Fe_2$(μ-CO)$(Cp)_2$ core with a bridging amido-functionalized allylidene μ-$\kappa^1$-(O):$\eta^1$(C):$\eta^3$(C)-{C(C≡CR)C(Me)C(Me)C(O)N(Me)(Xyl)} ligand, which is σ-coordinated to Fe(1) [Fe(1)–C(12) 1.923(4) Å] and $\eta^3$-coordinated to Fe(2) [Fe(2)–C(12) 2.004(4) Å; Fe(2)–C(21) 2.030(4) Å; Fe(2)–C(23)–2.157(4) Å], in an allyl-like fashion (see structure **A** in Scheme 2). The Fe(2)–C(23) interaction is significantly longer than that of Fe(2)–C(12) and Fe(2)–C(21), suggesting that an alternative description of the bridging ligand is possible (Scheme 2, **B**). The $C_\beta$–$C_\gamma$–$C_\delta$ sequence [C(23)–C(21)–C(12)] can be considered as a vinyl-substituted μ-alkylidene, which corresponds to a coordination mode commonly found in diiron[2] and diruthenium[3] complexes. However, because the C(12)–C(21) interaction [1.417(5) Å] is shorter than in C(21)–C(23) [1.455(6) Å] a description of the ligand as $\eta^1$:$\eta^2$-vinyl connected to an alkynyl and an amido-functionality also appears possible (structure **C**). The coordination of the amido group to Fe(1) is presumably crucial in determining the observed geometry of the bridging ligand. The oxygen atom O(2) coordinates to Fe(1) forming a five-membered oxadimetallacycle with a Fe–O

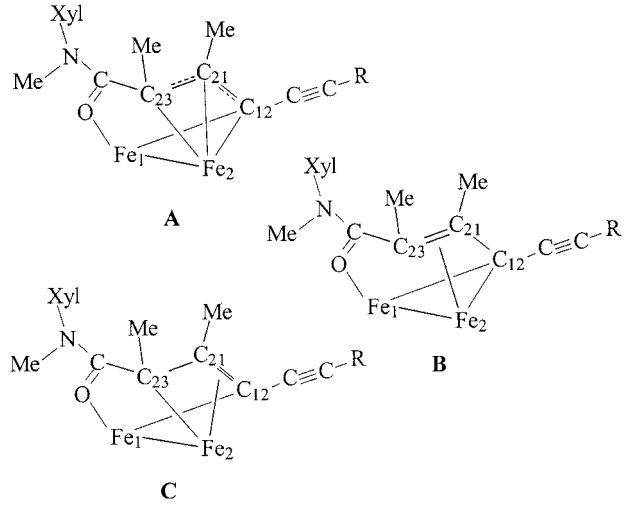

Scheme 2.

bond length [Fe(1)–O(2) 1.941(3) Å] slightly shorter than in $[Fe_2(CO)_5(\mu\text{-}PPh_2)(\mu\text{-}\eta^1(O):\eta^1(C):\eta^2(C)\text{-}\{O{=}C(N\textit{t}BuH)\text{-}CH_2\}C{=}CH_2)]$ [2.017(5) Å][4] and $[Fe_2(CO)_4(\mu\text{-}PPh_2)(\mu\text{-}dppm)\{C(CO_2\text{–}Me){=}CHC(OMe){=}O\}]$ [2.024(3) Å],[5] which contain a diiron five-membered oxametallacycle.

The spectroscopic data of **2** are in agreement with its structure: the IR spectrum (in $CH_2Cl_2$ solution) exhibits one band for the bridging carbonyl group, at 1753 $cm^{-1}$, whereas weaker absorptions at 2169 $cm^{-1}$ and 1511 $cm^{-1}$ are attributable to the C≡C and to the amide C–O interactions, respectively. NMR assignments, based on gs-HSQC, gs-HMBC and NOE experiments evidence a single $^1H$ NMR resonance for each of the six different Me groups present in **2** (at $\delta$ = 2.75, 2.42, 2.40, 2.30, 1.55 and 0.47 ppm, assigned to $C_\gamma\textit{Me}$, N*Me*, $C_6H_4\textit{Me}$, $\textit{Me}_2C_6H_3$, $C_\beta\textit{Me}$, respectively). In particular, assignments of the $C_\gamma\textit{Me}$ and $C_\beta\textit{Me}$ resonances are based on observed NOE effects between $C_6H_3\textit{Me}_2$ (Xyl) and $C_\beta\textit{Me}$. $^{13}C$ NMR resonances at $\delta$ = 179.7 and 155.5 ppm, are assigned to $C_\alpha$ and $C_\delta$, respectively. The attribution of these two signals is crucial in the later described experiment and deserves some comments: the gs-HMBC spectrum evidences correlation between the $^1H$ NMR resonance at $\delta$ = 2.42 ppm (N*Me*) and the $^{13}C$ resonance at $\delta$ = 179.7 ppm, while the $^{13}C$ NMR signal falling at $\delta$ = 155.5 ppm presents only one correlation, i.e. with the $^1H$ NMR resonance at $\delta$ = 2.75 ppm ($C_\gamma\textit{Me}$). It is worth noting that the *C*O resonance, in other analogous iron-coordinated amido functionalities, is reported at ca. 182 ppm.[4] Moreover, the $C_\gamma$ and $C_\beta$ carbon atoms give raise to signals at $\delta$ = 96.6 and 52.3 ppm, whereas the *sp* carbon atoms of the acetylenic group typically fall at $\delta$ = 104.5 and 101.6 ppm.

The reaction sequence leading to **2**–**7** is far from being obvious. One possibility is that the reaction proceeds

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

through initial attack of the acetylide to the terminal carbonyl group of **1**, originating an acyl intermediate, which further rearrange involving the μ-vinyliminium ligand. Support for this hypothesis comes from the observation that acetylides selectively attack the terminal CO in the related complexes $[Fe_2(\mu\text{-}CNMe_2)(\mu\text{-}CO)(CO)_2(Cp)_2][SO_3CF_3]$.[6] Moreover, nucleophilic attack to CO is often followed by coupling with the bridging ligands. For instance, LiC≡CPh addition to the CO in the thiocarbyne complex $[Fe_2(\mu\text{-}CSMe)(\mu\text{-}CO)(CO)_2(Cp)_2][SO_3CF_3]$ is followed by the migration of the acyl ligand, leading to the formation of the μ-carbene complexes $[Fe_2\{\mu\text{-}C(SMe)C(O)CCPh\}(\mu\text{-}CO)(CO)(Cp)_2]$.[7] Similarly, the allenyl $[Fe_2\{\mu\text{-}PPh_2\}(\mu\text{-}\eta^1{:}\eta^2\text{-}(H)C{=}C{=}CH_2)(CO)_6]$ undergoes amine addition to the terminal CO, with consequent migration of the resulting amide to the allenyl moiety.[4] The unexpected formation of **2**–**7** does not simply concern the coupling between acyl- and vinyliminium ligands: if we assume that the $C_\delta$–C≡C–R moiety in the bridging ligand of **2**–**7** originates from an acyl intermediate [C(O)C≡C–R], this implies the cleavage of the C=O.

Alternatively, the $C_\alpha$=O moiety in the bridging ligand of **2**–**7** could be originated from a migration of the terminal CO group, and acetylide addition at the $C_\alpha$ of the vinyliminium ligand. This, in turn, would require a considerable rearrangement of the iminium moiety, with 1,2 shifts of the Me and $NR_2$ groups, in order to explain the formation of **2**–**7**.

With the aim of obtaining more evidence for the reaction mechanism, we have prepared a $^{13}CO$-enriched sample of **1**, which has been reacted with Li–C≡C–Tol (see Exp. Section). The reaction yielded compound **2**, as expected, and the corresponding $^{13}C$ NMR spectrum exhibited two clearly enhanced signals at $\delta$ = 291.6 (μ-CO) and 155.8 ppm ($C_\delta$), and doublets at $\delta$ = 96.1 ($^1J_{CC}$, 50.7 Hz, $C_\gamma$), 52.4 ($^2J_{CC}$, 11.9 Hz, $C_\beta$), and 20.9 ppm ($^2J_{CC}$, 4.5 Hz, $C_\gamma Me$). Moreover, the IR spectra showed an isotopic effect for the bridging CO group and not for the $C_\alpha$=O of the bridging ligand. The above mentioned experiment indicates that the $C_\delta$ in **2** is originated from a carbonyl ligand, and implies that CO cleavage must occur at some stage of the reaction, as suggested in the former hypothesis. Interestingly, in the conversion of **1** to **2**, the three-carbon-atom chain of the bridging ligand grows by several units as a consequence of the inclusion of both the alkynyl (C≡C–Tol) group and the $C_\delta$ carbon atom, the latter originating from a CO.

Finally, it is to be remarked that reactions of organometallic complexes involving CO cleavage are of great interest, because this is considered an early and fundamental step in the heterogeneous conversion of carbon monoxide to hydrocarbons (Fischer–Tropsch process).[8] Examples, so far reported, mainly concerns: carbonyl clusters, which generally provide metal carbides,[9] polynuclear early transition-metal complexes, that take advantage of the oxophilic character of these metals for promoting CO dissociation,[10] and dinuclear tungsten complexes, with multiple metal–metal bonds.[11] Our results further support the conviction[8b] that dinuclear complexes are effective organometallic models for studying CO cleavage and C–C bond formation.

## Experimental Section

**General Remarks:** All reactions were routinely carried out under nitrogen, using standard Schlenk techniques. Solvents were distilled immediately before use under nitrogen from appropriate drying agents. Infrared spectra were recorded at 298 K with a Perkin–Elmer Spectrum 2000 FT-IR spectrophotometer and elemental analyses were performed with a ThermoQuest Flash 1112 Series EA Instrument. All NMR measurements were performed at 298 K with a Mercury Plus 400 instrument. The chemical shifts for $^1H$ and $^{13}C$ were referenced to internal TMS. The spectra were fully assigned by $^1H$,$^{13}C$ correlation measured by means of gs-HSQC and gs-HMBC experiments.[12] NOE measurements were recorded using the DPFGSE-NOE sequence.[13] All the reagents, included $^{13}CO$, were commercial products (Aldrich) of the highest purity available and used as received. Compound **1** was prepared by published methods.[1a]

**Synthesis of $[Fe_2\{\mu\text{-}\kappa^1(O){:}\eta^1(C){:}\eta^3(C)\text{-}C(C{\equiv}CR)C(Me)C(Me)C(O)N(Me)(Xyl)\}(\mu\text{-}CO)(Cp)_2]$ [R = $C_6H_4Me$ = Tol, 2; R = Ph, 3; R = H, 4; R = *n*Bu, 5; R = $SiMe_3$, 6; R = $C(Me){=}CH_2$, 7]. General Procedure:** A solution of *cis*-$[Fe_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C(Me){=}C(Me)\text{-}C{=}N(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$ (**1**) (0.150 mmol), in THF (10 mL) was treated with LiC≡CR (0.350 mmol), freshly prepared from *n*BuLi and HC≡CR. The mixture was stirred for 30 min, and then it was filtered through a Celite pad. The solvent was removed under reduced pressure; hence the residue was dissolved in diethyl ether and filtered through alumina. The final product was obtained as a red powder upon removal of the solvent. Crystals of **2** suitable for X ray analysis were obtained from a hexane solution at –20 °C.

**2:** $C_{35}H_{35}Fe_2NO_2$ (613.35): calcd. C 68.54, H 5.75, N 2.28; found: C 68.46, H 5.64, N 2.33. **7:** $C_{31}H_{33}Fe_2NO_2$ (563.29): calcd. C 66.10, H 5.91, N 2.49; found C 65.99, H 5.94, N 2.50. Yield: 55 mg, 65%. $^1$H NMR ($CDCl_3$): $\delta$ = 7.23–6.80 (m, 3 H, Me$_2$C$_6$*H*$_3$), 5.47, 5.31 (m, 2 H, CH$_2$), 4.50, 4.05 (s, 10 H, Cp), 2.68 (s, 3 H, C$_\gamma$Me), 2.41 (s, 3 H, NMe), 2.28, 1.53 (s, 6 H, *Me*$_2$C$_6$H$_3$), 2.23 (s, 3 H, C≡CC*Me*), 0.45 (s, 3 H, C$_\beta$Me) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 327.8 (μ-C), 253.9 (μ-CO), 208.1 (t-CO), 133.5–129.5 (Me$_2$*C*$_6$H$_3$), 91.4, 89.9 (Cp), 56.3 (NMe), 19.3, 18.2 (*Me*$_2$C$_6$H$_3$) ppm. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2160 w (C≡C), 1757 vs. (μ-CO), 1514 w (C$_\alpha$O) cm$^{-1}$.

**Synthesis of $^{13}$CO-Labelled 2:** The aminocarbyne complex [Fe$_2${μ-CN(Me)(Xyl)}(μ-CO)(CO)(Cl)(Cp)$_2$] (450 mg, 0.938 mmol), prepared by published method,[14] was dissolved in $CH_2Cl_2$ (10 mL). $^{13}$CO was bubbled through the solution, then $AgSO_3CF_3$ (289 mg, 1.12 mmol) was added. The mixture was stirred for 20 minutes, then it was filtered through an alumina column. Elution with methanol gave [Fe$_2${μ-CN(Me)(Xyl)}(μ-CO)($^{13}$CO)$_2$(Cp)$_2$][$SO_3CF_3$]. $^{13}$CO enrichment occurred exclusively at the terminally coordinated CO.

Conversion of $^{13}$CO labelled [Fe$_2${μ-CN(Me)(Xyl)}(μ-CO)($^{13}$CO)$_2$-(Cp)$_2$][$SO_3CF_3$] into $^{13}$C-labelled **2** was performed in further five steps, according to known procedures,[1,14] including the reaction described in this paper. The sequence included: [Fe$_2${μ-CN(Me)(Xyl)}(μ-$^{13}$CO)($^{13}$CO)(NCMe)(Cp)$_2$][$SO_3CF_3$], [Fe$_2${μ-CN(Me)(Xyl)}(μ-$^{13}$CO)($^{13}$CO)(Cl)(Cp)$_2$], $^{13}$CO-enriched **1** and $^{13}$C-labelled **2**. At each step the products were isolated and characterized to reveal the enhanced signals.

**$^{13}$C-Labelled 2:** $^1$H NMR ($CDCl_3$): $\delta$ = 7.61–6.81 (m, 7 H, Me$_2$C$_6$*H*$_3$ and C$_6$*H*$_4$Me), 4.56, 4.08 (s, 10 H, Cp), 2.76 (d, $^3J_{CH}$ = 3.66 Hz, 3 H, C$_\gamma$Me), 2.42 (s, 3 H, NMe), 2.40 (s, 3 H, C$_6$H$_4$*Me*), 2.30, 1.56 (s, 6 H, *Me*$_2$C$_6$H$_3$), 0.48 (s, 3 H, C$_\beta$Me) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 291.6 (μ-CO), 179.7 (C$_\alpha$), 155.8 (C$_\delta$), 143.1 (*ipso*-Me$_2$*C*$_6$H$_3$), 136.8–123.5 (Me$_2$*C*$_6$H$_3$ and *C*$_6$H$_4$Me), 104.5, 101.6 (C≡C), 96.1 (d, $^1J_{CC}$ = 50.7 Hz, C$_\gamma$), 85.4, 82.9 (Cp), 52.4 (d, $^2J_{CC}$ = 11.9 Hz, C$_\beta$), 39.7 (NMe), 22.2 (C$_\beta$*Me*), 21.4 (C$_6$H$_4$*Me*), 20.9 (d, $^2J_{CC}$ = 4.5 Hz, C$_\gamma$*Me*), 18.5, 17.3 (*Me*$_2$C$_6$H$_3$) ppm. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2169 w (C≡C), 1750 vs. (μ-CO), 1717 s (μ-$^{13}$CO), 1511 w (C$_\alpha$O) cm$^{-1}$.

**X-ray Crystallographic Study:** Crystal data and collection details for **2** are reported in Table 2. The diffraction experiments were carried out with a Bruker SMART 2000 diffractometer equipped with a CCD detector using Mo-$K_\alpha$ radiation. Data were corrected for Lorentz polarization and absorption effects (empirical absorption correction SADABS).[15] Structures were solved by direct methods and refined by full-matrix least-squares based on all data using $F^2$.[16] Hydrogen atoms were fixed at calculated positions and refined by a riding model. All non-hydrogen atoms were refined with anisotropic displacement parameters.

# Spectroscopic Comparison of Dinuclear $Ti^{+}$ and $Ti^{2+}$ μ-η¹:η¹ Dinitrogen Complexes with Cp*/Pentafulvene and Amine/Amide Ligation: Moderate versus Strong Activation of $N_2$

**Felix Studt,[a] Nicolai Lehnert,[a] Beatrix E. Wiesler,[a][‡] Axel Scherer,[b] Rüdiger Beckhaus,*[b] and Felix Tuczek*[a]**

**Keywords:** Metallocenes / Nitrogen fixation / Titanium / Raman spectroscopy / Density functional calculations

The two dinuclear, end-on dinitrogen-bridged titanium complexes with cp*/pentafulvene ligation, [{($\eta^5$-$C_5Me_5$)Ti($\eta^6$-$C_5H_4CR_2$)}$_2$(μ-$\eta^1$:$\eta^1$-$N_2$)], R = *p*-tolyl (**1**) and >$CR_2$ = adamantylidene (**2**), are compared to an analogous titanium dinitrogen complex with a mixed amine/amide/chloride ligand set, [{($Me_3Si)_2$NTiCl(TMEDA)}$_2$(μ-$\eta^1$:$\eta^1$-$N_2$)] (**3**; TMEDA = tetramethylethylenediamine). The N–N stretching vibrations of complexes **1** and **2** are observed at 1749 and 1755 $cm^{-1}$, respectively, indicative of a moderate activation of the dinitrogen ligand. In contrast, the N–N stretch of **3** is located at 1284 $cm^{-1}$, reflecting a much more highly activated $N_2$ ligand. These findings are in qualitative agreement with N–N bond lengths that have been observed experimentally. DFT calculations reveal that the major difference in the electronic structures of **1**, **2**, and **3** is the fact that only one of the $N_2$ π* orbitals is (doubly) occupied in the case of **1** and **2**, whereas both π* orbitals are (doubly) occupied in the case of **3**. The reason for this finding is that in **1** and **2** two of the three electrons of each $Ti^{+}$ are involved in back-bonding interactions with the terminal fulvene ligands, whereas no such interactions exist between the $Ti^{2+}$ centers of **3** and its terminal set of donor ligands.

## Introduction

The bonding and activation of $N_2$ by early transition-metal complexes is of continued interest.[1–4] In titanium systems dinitrogen is usually coordinated in an end-on bridging geometry.[5] The activation of the $N_2$ ligand can generally be determined by considering N–N bond lengths obtained from X-ray diffraction data and N–N stretching frequencies obtained from vibrational spectroscopy. These data allow titanium dinitrogen compounds to be divided into moderately and strongly activated species.[6] Moderately activated dinitrogen complexes are generally found for titanocene-based systems with N–N bond lengths in the range of 1.15–1.20 Å.[7–12] Strong activation, on the other hand, is observed for titanium complexes with ligand sets that are different from cyclopentadienyl, exhibiting N–N bond lengths of 1.25–1.30 Å.[13–15] A collection of N–N bond lengths of different dinitrogen complexes is given in Table 1. The two complexes with cp*/pentafulvene ligation, [{($\eta^5$-$C_5Me_5$)Ti($\eta^6$-$C_5H_4CR_2$)}$_2$(μ-$\eta^1$:$\eta^1$-$N_2$)], R = *p*-tolyl (**1**) and >$CR_2$ = adamantylidene (**2**), both have N–N bond lengths of 1.160 Å and thus can be considered to be moderately activated.[7] On the other hand, the complex [{($Me_3Si)_2$-NTiCl(TMEDA)}$_2$(μ-$\eta^1$:$\eta^1$-$N_2$)] (**3**; TMEDA = tetramethylethylenediamine) that exhibits a mixed amine/amide/chloride set of coligands has an N–N bond length of 1.29 Å and therefore activates $N_2$ to a higher degree (cf. Scheme 1).[13] This would indicate that the activation of $N_2$ is higher in compound **3**, formally a $Ti^{2+}$–$Ti^{2+}$ species, than in compounds **1** and **2**, formally $Ti^{+}$–$Ti^{+}$ complexes. At first sight this observation appears to be contradictory.

Table 1. Comparison of N–N bond lengths of different dinitrogen complexes.

| Compound | N–N bond lengths [Å] | Ref. |

troscopy. The vibrational analysis was assisted by DFT calculations performed on structures **I** and **III**, which are models of complexes **1/2** and **3**, respectively. The UV/Vis spectra of **1/2** and **3** were interpreted on the basis of MO schemes of models **I** and **III**. The electronic-structural features leading to the observed differences in $N_2$ activation were identified through this combined spectroscopic-theoretical approach. The general implications of this result are discussed below.

## Results and Analysis

### Vibrational Spectra and Analysis

Solid-state resonance Raman spectra of complexes **1**–**3**, recorded with an excitation wavelength of 514.5 nm, are shown in Figure 1. The most intense peak in the Raman spectrum of **1** is located at 1749 $cm^{-1}$. This feature is assigned to the N–N stretching mode of the Ti–$N_2$–Ti unit on the basis of its high intensity and energetic position. The first and second overtones of this mode are found at 3475 and 5173 $cm^{-1}$, respectively. In the Raman spectrum of **2** the N–N stretching mode is identified at 1755 $cm^{-1}$ by the same arguments. The overtones are located at 3490 and 5185 $cm^{-1}$. The most prominent feature in the Raman spectrum of **3** is observed at 1284 $cm^{-1}$. Again, this peak is assigned to the N–N stretching frequency of the Ti–$N_2$–Ti unit because of its high intensity and energetic position.

DFT calculations were performed for structures **I** and **III**. In structure **I** the ligands of **1** and **2** are replaced by

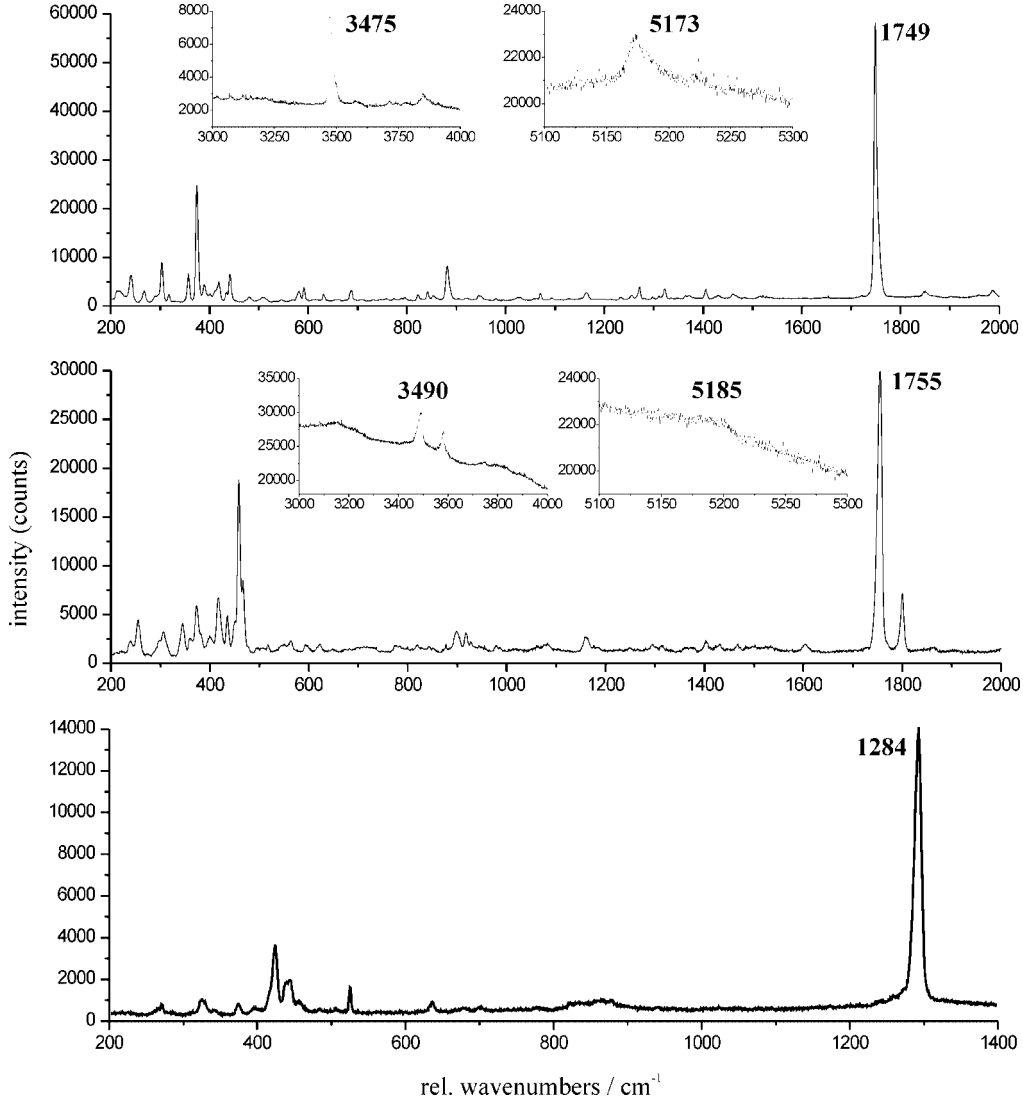

Figure 1. Top: Raman spectrum of **1**. Middle: Raman spectrum of **2**. Bottom: Raman spectrum of **3**. All Raman spectra were recorded with an excitation wavelength of 514.5 nm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

unsubstituted cyclopentadienyl and fulvene groups, thus providing a model system for both complexes **1** and **2**. Note, however, that in model **I** the dihedral angle between the Ct*–Ti vectors of the two halves of the dimers is approximately zero (Ct* is the center of the cp* ligand). This reproduces the structure of complex **1** but not that of complex **2**, which exhibits a twisted configuration (dihedral angles between the Ct*–Ti vectors are 19.1° and 20.0°, respectively, for the two independent molecules in the asymmetric unit). Model **III** has been simplified with respect to complex **3** by approximating the TMEDA and $(Me_3Si)_2N$ ligands through coordinated $NH_3$ and $NH_2$ groups, respectively. Structural parameters resulting from the DFT geometry optimizations are compared with the experimental values in Table 2; a comparison between the experimentally determined frequencies (see above) and the values derived from DFT (B3LYP) is given in Table 3. The calculated frequencies qualitatively reproduce the experimentally observed trend. The N–N stretching frequency of **I** is calculated at 1806 $cm^{-1}$, in good agreement with the experimentally determined value of 1749 $cm^{-1}$. The N–N stretching mode of the model complex **III** is theoretically predicted to be at a much lower energy (1371 $cm^{-1}$), in fair agreement with the corresponding peak in the Raman spectrum of **3** (1284 $cm^{-1}$). In this case the larger deviation from the experimental data probably results from the greater simplification of the terminal ligands employed in the calculation.

Table 2. Comparison of structural parameters of **1**, **2**, and **I**.

| Complex | N–N | Ti–N | Ti–Ct* | Ti–$Ct^{Fv}$ | Ti–N–N | $\theta$ |
|---|---|---|---|---|---|---|
| **1** | 1.160 | 1.999 | 2.056 | 1.965 | 170.0 | 28.3 |
| **2** | 1.160 | 2.008 | 2.064 | 1.986 | 169.8 | 31.6 |
| **I** | 1.204 | 1.916 | 2.087 | 2.043 | 176.9 | 35.7 |

Table 3. Comparison of the observed and calculated frequencies of complexes **1**–**3** with model systems **I** and **III**.

| Mode | Experimental | | | B3LYP | |
|---|---|---|---|---|---|
| | **1** | **2** | **3** | **I** | **III** |

| 2 $\nu_{NN}$ | 3475 | 3490 | – | – | – |
| 3 $\nu_{NN}$ | 5173 | 5185 | – | – | – |

### Electronic Structure

An understanding of the electronic structure of complexes **1/2** and complex **3** is achieved on the basis of the MO schemes of the corresponding models **I** and **III**, respectively (Figure 2). Model **I** is oriented such that the *x* axis is directed along the N–N vector and the *y* axis along the fulvene/cyclopentadienyl ligands. Figure 2 (left) shows contour plots of important molecular orbitals of **I**. The HOMO of **I** represents a bonding combination between the $\pi_z$* orbital of dinitrogen and the metal $d_{xz}$ orbitals, forming a metal–dinitrogen π bond; this orbital has nearly equal contributions from the nitrogen p orbitals and the d functions of titanium. The LUMO of **I** is the bonding combination of the $N_2$ $\pi_y$* orbital and the metal $d_{xy}$ functions. The corresponding orbital has 19% metal and 40% nitrogen character. The LUMO+1 of **I** is an antibonding combination of the metal $d_{xz}$ orbitals with the dinitrogen $\pi_z$ orbital having 6% nitrogen character. As only one π* orbital of the dinitrogen ligand is occupied, the $N_2$ ligand has been formally reduced by the $Ti^{+}$ centers of **I** to an $N_2^{2-}$ oxidation state. The remaining electrons of the two titanium atoms are located in the two sets of $d_{z^2}$ orbitals (in-phase and out-of-phase combinations) both of which interact in a bonding fashion with fulvene π* orbitals to form two $d_{z^2}$_Fv orbitals. Both MOs have 61% fulvene character, indicative of a significant back-bonding from the metals to the fulvene ligands.

Model **III** is also oriented such that the *x* axis is along the N–N vector; the *y* axis lies in the plane of the paper, between the amino and amido ligands on the one side and the amido and chloro ligands on the other side of the dinuclear complex. The π* orbitals of the dinitrogen ligand ($\pi^*_z$ and $\pi^*_y$) form the two dinitrogen–metal π bonding combinations $\pi^*_z$_$d_{xz}$ and $\pi^*_y$_$d_{xy}$, respectively, which have nearly equal charge contributions from dinitrogen and metal d functions (Figure 2, right). Both of these orbitals are now occupied, corresponding to the HOMO–1 and the HOMO of **III**, respectively. Model **III** therefore has two metal–dinitrogen π bonds, and the dinitrogen ligand of **3** is formally reduced by its two $Ti^{2+}$ centers to a (–4) charge state. In Figure 2 the orbitals of **I** and **III** are arranged in a way that clarifies the relationship between the electronic structures of **1/2** and **3**. Evidently, the dinitrogen parts of the frontier orbitals are very similar; the major difference between the two systems lies in the fact that both π* orbitals of dinitrogen are occupied for **3**, whereas for **1** and **2** one dinitrogen π* orbital (the HOMO) is occupied and the other (the LUMO) is empty.

Table 4 summarizes the atomic charges obtained for models **I** and **III** by natural population analysis (NPA). As already inferred from the preceding orbital analysis, a significant amount of electronic charge is transferred from the titanium centers of both **I** and **III** to the bridging dinitrogen ligand. However, the negative charge on this ligand is much larger for **III** (–0.80) than for **I** (–0.24), in qualitative agreement with the fact that both π* orbitals of $N_2$ are occupied in **III** whereas only one π* orbital is occupied in **I**. As the $\pi^*$_$d_\pi$ orbitals of **I** and **III** have roughly equal contributions from the metal d orbitals and the dinitrogen π* functions, the formal charges of –2 and –4 are approximately halved, leading to approximate descriptions of the $N_2$ ligand as $N_2^{1-}$ in **1/2** and $N_2^{2-}$ in **3**. The actual charges determined by NPA (–0.24 for **I** and –0.80 for **III**; vide supra) reflect a further charge donation from lower-energy π and σ bonding orbitals of $N_2$ back into the unoccupied metal d orbitals. The titanium atoms, in turn, are calculated to have charges of +0.34 for model **I** and +1.00 for model **III**, in qualitative agreement with the different formal oxidation states obtained after interaction with $N_2$ ($Ti^{2+}$ for **I** and

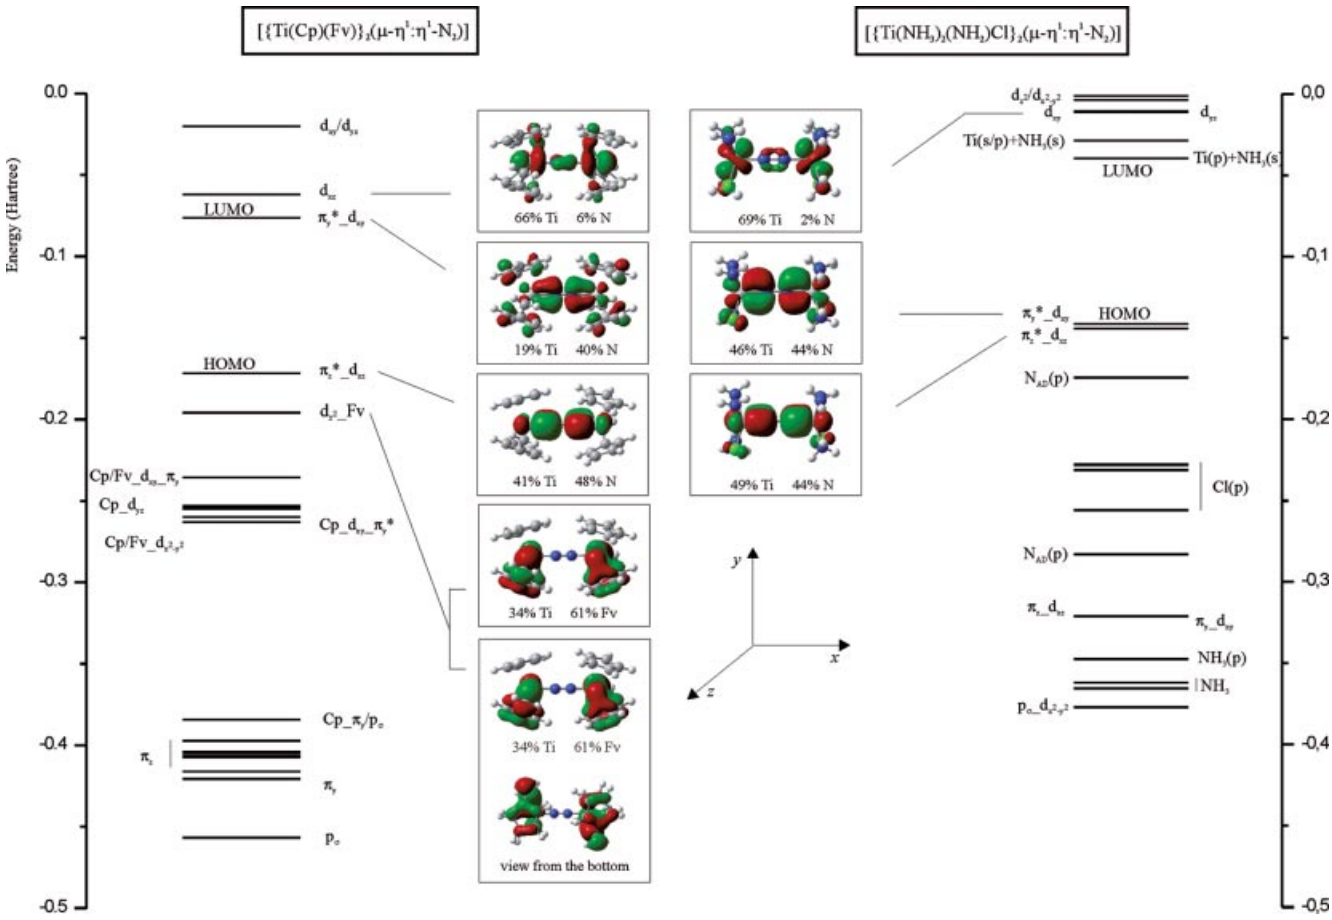

Figure 2. MO diagram of models **I** and **III** together with contour plots of important molecular orbitals of **I** and **III**.

$Ti^{4+}$ for **III**). The actual charges on the metal atoms are further influenced by donor/acceptor interactions with the terminal ligands. It can be inferred from Table 4 that the cp* ligands of **I** donate 0.93 charge units to the metal centers (resulting charge –0.07), whereas the (formally neutral) fulvene ligands act as charge acceptors (resulting charge –0.16).

Table 4. NPA charges of model systems **I** and **III**.

### UV/Vis Spectroscopy

The UV/Vis spectra of **1** and **2** are very similar. The absorption spectrum of **2** (Figure 3, left) exhibits two bands at 970 ($\varepsilon$ = 900 $M^{-1}cm^{-1}$) and 650 nm ($\varepsilon$ = 6700 $M^{-1}cm^{-1}$). As there is no band at lower energies, the 970-nm band is assigned to the lowest energy transition of **2**, which corresponds to the HOMO–LUMO transition of model **I**. This transition is intrinsically of low intensity, as it involves two $\pi^*_d_\pi$ orbitals that are perpendicular to each other. The intense band at 650 nm in the UV/Vis spectrum of **2** is assigned to the symmetry- and orbital-allowed $\pi\rightarrow\pi^*$ transition from the $\pi_z^*_d_{xz}$ orbital (HOMO) to the $d_{xz}_\pi_z$ orbital (LUMO+1) of **I**. The UV/Vis spectrum of complex **3** exhibits two weak absorptions at 465 ($\varepsilon$ = 500 $M^{-1}cm^{-1}$) and 630 nm ($\varepsilon$ = 100 $M^{-1}cm^{-1}$), which are assigned to orbital-forbidden ($\pi\rightarrow\sigma$) transitions from the $\pi_y^*_d_{xy}$ and $\pi_z^*_d_{xz}$ orbitals (HOMO and HOMO–1) to unoccupied orbitals at the Ti centers. The absorption edge at 380 nm probably results from symmetry- and orbital-allowed $\pi\rightarrow\pi^*$ transitions from the central dinitrogen ligand to the Ti d functions which are therefore at a higher energy than the $\pi\rightarrow\pi^*$ transitions of **1** and **2**.

## Discussion

In the preceding section resonance Raman spectra of the moderately activated dinitrogen complexes **1** and **2** were measured and compared with the Raman spectrum of the strongly activated complex **3**. In order to theoretically determine N–N stretching frequencies and evaluate the electronic structure, DFT calculations were performed on structurally simplified models. The UV/Vis spectra of **1/2** and **3** have been interpreted on the basis of the corresponding MO schemes. The N–N stretching frequencies of complexes **1** and **2** were assigned to peaks at 1749 and 1755 $cm^{-1}$, respectively, which is supported by a DFT frequency calculation predicting the position of this mode at 1806 $cm^{-1}$. The N–N stretching mode of the strongly activated dinitrogen complex **3**, on the other hand, was identified with a peak at 1284 $cm^{-1}$ in the Raman spectrum, which is supported by a DFT prediction of 1371 $cm^{-1}$ for this mode. The difference in N–N stretching frequency between complexes **1/2** and **3** is thus large (ca. 500 $cm^{-1}$), which is in agreement with the markedly different N–N bond lengths of these compounds (1.16 Å for **1/2** and 1.29 Å for **3**). The reduction of the N–N stretching frequency of free $N_2$ at 2231 $cm^{-1}$[16] to the value observed for complexes **1** and **2** (ca. 1750 $cm^{-1}$) implies a slight elongation of the N–N bond in these compounds. The N–N stretching frequency of 1284 $cm^{-1}$ found for **3**, on the other hand, corresponds to a significant decrease of the N–N bond order which is comparable to that of a related end-on dinitrogen-bridged zirconium complex for which an N–N stretching frequency of 1211 $cm^{-1}$ and an N–N bond length of 1.30 Å have been determined.[17]

The electronic structure of strongly activated end-on $N_2$ bridged complexes was described earlier in terms of interactions of dinitrogen π and π* orbitals with metal $d_\pi$ functions. It was shown that the metal centers primarily interact with the empty π* orbitals of the $N_2$ to form two metal–dinitrogen π bonding MOs, leading to a significant charge transfer from the metals to this ligand.[18–20] This would agree with the electronic structure of **3** where both π* orbitals of the dinitrogen ligand are occupied (HOMO and HOMO–1), explaining the high degree of activation found for this complex. The electronic structures of the moderately activated complexes **1** and **2** differ from this scheme since only one π* orbital of the dinitrogen ligand is doubly occupied. The two remaining electrons of each titanium center are involved in strong back-bonding interactions with the fulvene ligands and are nonbonding with respect to the bridging dinitrogen ligand. The second π* orbital of the dinitrogen ligand thus remains unoccupied, forming the LUMO of complexes **1** and **2**.

Further information on the electronic structures of **1**–**3** can be inferred from electronic absorption spectroscopy. Inspection of the UV/Vis spectra of **2** leads to the assignment of the 970-nm band to the lowest energy transition of **I**, the HOMO–LUMO transition. On the basis of overlap considerations the intensity of this absorption band should be weak, which is in agreement with the experimental data. The 650-nm transition, on the other hand, is assigned to an electric-dipole-allowed transition from the HOMO to the LUMO+1. In complex **3** the electric-dipole-allowed transitions involving the dinitrogen ligand are located at higher energies. The MO schemes of **I** and **III** further explain the experimental findings that **1**, **2** and **3** are diamagnetic. In model **I**, which exhibits a dihedral angle of about 0° between the Ct*–Ti vectors, the two electrons in the Ti $d_{xz}$ orbitals are strongly coupled via the dinitrogen $\pi^*_z$ orbital. This is an accurate picture for complex **1** but has to be slightly modified for complex **2**, which exhibits a twisted configuration (dihedral angle between the neighboring Ct*–Ti bonds = 19.1° and 20.0° for the two independent molecules in the asymmetric unit). This reduces the interaction between the two unpaired electrons in the $d_{xz}$ orbitals via the dinitrogen $\pi^*_z$ orbital, leading in the extreme case, i.e. for a dihedral angle of 90°, to a ferromagnetic coupling ($S$ = 1 ground state).[21] Nevertheless, compound **2** is found to be diamagnetic, i.e. the same as compound **1**, demonstrating that the coupling is predominantly antiferromagnetic (ground state $S$ = 0).

To conclude, the activation of the dinitrogen ligand in **3** is found to be much larger than in **1** and **2**, in contrast to what is expected on the basis of formal oxidation states ($Ti^{+}$–$Ti^{+}$ for **1** and **2** vs. $Ti^{2+}$–$Ti^{2+}$ for **3**). It is shown in this paper that this discrepancy can be attributed to the donor/acceptor properties of the set of coligands: whereas **3** has a set of purely electron-donating ligands, strong back-bonding interactions exist between the titanium d orbitals and the fulvene π* orbitals in **1** and **2** which take up four metal d-electrons, preventing them from interacting with the bridging $N_2$ ligand. This exemplifies once again that the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

actual degree of dinitrogen activation in transition-metal complexes depends equally on the set of ancillary ligands and the nature and oxidation state of the metal centers.[22]

## Experimental Section

**Synthesis of 1, 2, and 3:** Compounds **1**,[7] **2**,[7] and **3**[13] were synthesized by literature methods.

**Resonance Raman Spectroscopy:** Resonance Raman spectra of **1** and **2** were measured with a Dilor XY Raman spectrograph with triple monochromator and CCD detector. An Ar/Kr mixed-gas laser with a maximum power of 5 W was used for excitation. The spectra were recorded with an excitation wavelength of 514.5 nm. The spectra were measured on KBr pellets cooled to 10 K with a helium cryostat. The spectral bandpass was set to 2 $cm^{-1}$.

Resonance Raman spectra of **3** were measured on a setup involving the following components: Spectra Physics 2020 5 W $Ar^+$-laser; SPEX 1404 0.85 double monochromator equipped with a CCD camera (PI Instruments, 1024 × 256 pixels EEV chip) and a Peltier cooled RCA 31034 detector connected to a Stanford Research SR 400 photon counter allowing spectra to be recorded in spectrograph or scanning modes; liquid helium cryostat (Cryovac) for measurements from 4.2 to 300 K. The spectra were recorded at 20 K with an excitation wavelength of 514.5 nm and with the spectral bandpass set to 4.5 $cm^{-1}$.

**UV/Vis Spectroscopy:** Optical absorption spectra of **2** were obtained from the neat compound pressed between two sapphire plates. The spectra were recorded at 10 K on a Varian Cary 5 UV/Vis/NIR spectrometer. Extinction coefficients were determined by comparison with UV/Vis spectra of **2** in solution. Optical absorption spectra of **3** were obtained from a toluene solution of **3** in an ESR tube. The spectra were recorded with a Bruins Omega10 Spectrophotometer.

**Density Functional Theory Calculations:** Spin-restricted DFT calculations using Becke′s three-parameter hybrid functional with the correlation functional of Lee, Yang, and Parr (B3LYP)[23–25] were performed for the singlet ground state of model complexes **I** and **III**. Model **I** was optimized in $C_1$ symmetry. For DFT frequency calculations, model **III** was also optimized in $C_1$ symmetry, whereas the structure of model **III** used for the single point calculation was derived from the X-ray structure. The LanL2DZ basis set, which applies Dunning/Huzinaga full double-zeta (D95) basis functions[26] on first-row atoms and Los Alamos effective core potentials plus DZ functions on all other atoms, [27,28] was used for the calculations. Convergence was reached when the relative change in the density matrix between subsequent iterations was less than $1 \times 10^{-5}$ for single points and $1 \times 10^{-8}$ for optimizations. Charges were analyzed by using the natural bond orbital (NBO) formalism.[29–32] All of the computational procedures were used as implemented in the G98 package.[33] Wave functions were plotted with the visualization program Gaussview 2.1.

Am. Chem. Soc.* **1974**, *96*, 5087.
[22] On the basis of the strong back-bonding interaction of the fulvene ligands, it would appear justified to assign a 2– charge to the fulvene ligands. In that case the titanium centers would have a 3+ charge and be able to transfer one electron each to the dinitrogen ligand, making it an $N_2^{2-}$ unit. However, it is customary to treat the fulvene ligands as neutral.

# Glycerol as Ligand: The Synthesis, Crystal Structure, and Properties of Compounds $[Ln_2(H_2L)_2(H_3L)_4][Re_6Q_8(CN)_6]$, Ln = La, Nd, Gd, Q = S, Se

**Nikolai G. Naumov,*[a] Maria S. Tarasenko,[a] Alexander V. Virovets,[a] Youngmee Kim,[b] Sung-Jin Kim,*[b] and Vladimir E. Fedorov[a]**

**Keywords:** Lanthanide(III) complexes / Glycerol / Rhenium(III) octahedral cluster / Cyanide complexes / Crystal structure

The interaction of aqueous solutions of octahedral cluster anions $[Re_6Q_8(CN)_6]^{4-}$ with rare earth cations in the presence of glycerol resulted in the formation of a new family of compounds $[Ln_2(H_2L)_2(H_3L)_4][Re_6Q_8(CN)_6]$ (where Ln = La, Nd, and Gd; Q = S, Se; $H_3L$ = glycerol; $H_2L^-$ = glycerolate anion). All compounds are isostructural and crystallize in the $P\bar{1}$ space group. Crystal structures are built from octahedral cluster anions $[Re_6Q_8(CN)_6]^{4-}$ and centrosymmetrical dimers $[Ln_2(H_2L)_2(H_3L)_4]^{4+}$ that have three different binding modes of glycerol.

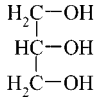
## Introduction

The chemistry of octahedral cyanocluster complexes of the type $[Re_6Q_8(CN)_6]^{4-}$ (where Q = S, Se, Te) has been extensively studied over the past decade. The reactions of these anions with transition metal cations lead to the formation of cluster polymers that have Re–CN–M bridges.[1–5] The use of 3d metal complexes with chelating N-donor ligands resulted in formation of low dimensional structures [en,[6,7] trien,[8] 1,2*S*,3*S*,4-butanetetramine (threotab),[9] *N*,*N*′-bis(salicylidene)ethylenediamine (salen)[2]]. Up to now, all the compounds formed by $[Re_6Q_8(CN)_6]^{4-}$ anions and rare earth cations have 3D polymeric structures.[10–12] Attempts to use N-donor ligands were unsuccessful because of their basicity in aqueous solutions and precipitation of rare earth hydroxides.

In search of appropriate chelating ligands that are able to bind the rare earth cations, we have examined polyatomic alcohols. They are good candidates for such complexation because of their high affinity to coordinate rare earth cations, their variable steric requirements and their ability to bridge more then one metal center. The possibility of partial or full deprotonation allows the adjustment of the charge balance of the complexes. In the present work we examined glycerol, a simple, potentially tridentate ligand that may demonstrate variable chelating/bridging modes.



Here we report the synthesis, crystal structure and properties of a series of new compounds of composition $[Ln_2(H_2L)_2(H_3L)_4][Re_6Q_8(CN)_6]$ (Ln = La, Nd, Gd; Q = S, Se; $H_3L$ = glycerol; $H_2L^-$ = glycerolate anion), which contain $[Ln_2(H_2L)_2(H_3L)_4]^{4+}$ dimers. These dimeric structures contain three different modes of chelating glycerol molecules: bidentate, tridentate, and bridging/chelating.

## Results and Discussion

X-ray single crystal analysis shows that compounds **1**–**6** are isostructural. Their structures contain $[Re_6Q_8(CN)_6]^{4-}$ (Q = S, Se) anions and binuclear $[Ln_2(\mu\text{-}H_2L)_2(H_3L)_4]^{4+}$ cations. Both anion and cation lie in the centers of symmetry of the unit cell with the space group $P\bar{1}$.

The $[Re_6Q_8(CN)_6]^{4-}$ (Q = S, Se) anions have the typical $M_6Q_8L_6$ structure (Figure 1). The rhenium octahedron is surrounded by eight chalcogen atoms to form the cube $Q_8$. Additionally, each rhenium atom is coordinated by a terminal CN group. Bond lengths and angles are given in Table 1.

The new centrosymmetric binuclear cation $[Ln_2(H_2L)_2(H_3L)_4]^{4+}$ is shown in Figure 2, Figure 3 and Figure 4. Binding modes of $H_2L^-$ and $H_3L$ are schematically presented in Scheme 1. Two lanthanide atoms are connected by two deprotonated glycerol molecules (C9, C10, C12, O7, O8, O9) (Scheme 1a).

In structures **1**, **3**, **4**, and **6**, all ligands are ordered, while in **2** and **5** one of the carbon atoms of a bridging glycerolate ligand is disordered over two positions with equal weights. Each of the Ln atoms are additionally coordinated by two glycerol molecules as tridentate (C1, C2, C3, O1, O2, O3) and bidentate (C4, C5, C6, O4, O5, O6) ligands (Scheme 1b and c). The Ln–O bond lengths (for OH groups) lie within

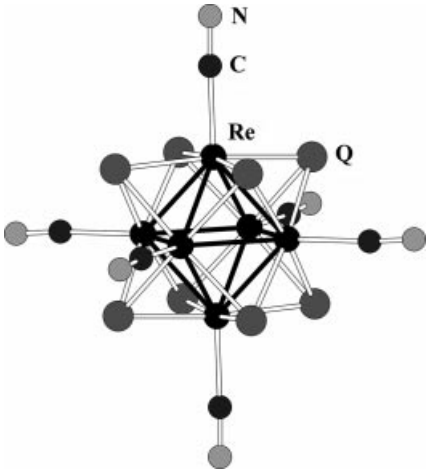

Figure 1. Structure of $[Re_6Q_8(CN)_6]^{4-}$ anions.

Figure 2. Structure of $[La_2(\mu\text{-}H_2L)_2(H_3L)_4]^{4+}$ cation. Hydrogen atoms are omitted for clarity.

2.540–2.706, 2.485–2.664, and 2.440–2.631 Å for Ln = La, Nd, and Gd, respectively. The Ln–(μ-O) bonds are distinctly shorter. The mean distances are equal to 2.397, 2.346, and 2.312 Å for Ln = La, Nd, and Gd, respectively (see Table 2). The coordination number of the $Ln^{III}$ ion in the complexes is nine, and the coordination polyhedron of lanthanide(III) may be described as a distorted tricapped trigonal prism.

In the crystal packing, there is an extensive system of hydrogen bonds between the nitrogen atoms of the CN groups and the OH groups of glycerol and glycerolate ligands (Figure 5). The shortest contacts lie within the range 2.70–3.00 Å.

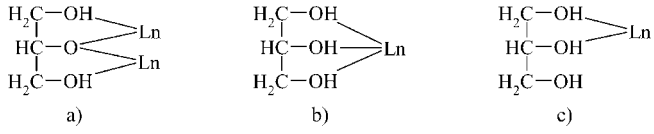

Scheme 1. Coordination modes of the glycerol molecule to lanthanide(III) cations in compounds **1**–**6**.

According to the Cambridge Structural Database (CSD V.5.25), there are no known examples of lanthanide(III) complexes bearing glycerol or glycerolate anions. Scheme 2 presents the coordination modes of glycerol and glycerolate anions ($H_2L^-$, $HL^{2-}$, and $L^{3-}$) in structurally characterized complexes of transition metals.

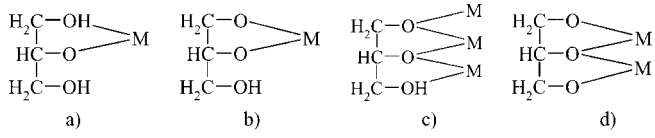

Scheme 2. Coordination modes of the glycerolate anions ($H_2L^-$, $HL^{2-}$, and $L^{3-}$) to transition metals in structurally characterized complexes; a) chelating coordination of $H_2L^-$;[13] b) chelating coordination of $HL^{2-}$;[14–17] c) chelating/bridging coordination of $HL^{2-}$;[18,19] d) chelating/bridging coordination of $L^{3-}$.[17,20]

There is only one crystal structure in which glycerol exists in the form of $[H_2L]^-$. Coordination of this ligand to a vanadium atom by one oxo- and one hydroxo group was found in oxo(propane-1,3-diol-2-olato)(salicylaldehyde hydroxyphenylmethylenehydrazonato-*N*,O,O′)vanadium(v)[13] (Scheme 2a). As in the cases of **1**–**6**, deprotonation of glycerol also occurred during crystallization in the presence of excess glycerol. The chelating coordination of $HL^{2-}$ (Scheme 2b) has been reported for several molecular complexes of platinum,[14,15] vanadium,[16] and copper.[17] The glycerolate anions $HL^{2-}$ and $L^{3-}$ often served as both chelating and bridging ligands (Scheme 2c and d). These coordination modes were encountered in numerous complexes of transition metals, e.g. Co*H*L,[18] Zn*H*L,[19] $Li_3[Cu_3L_3]\cdot 19H_2O$,[20] $Na_3[Cu_3L_3]\cdot 7H_2O$, and $Na_{10}[Cu_3L_3]_3(NO_3)\cdot 30H_2O$.[17]

## Mass Spectra

In the ESI (positive mode) mass spectra of complex **1** in glycerol/water solution several peaks appear that clearly support the proposed structure. Specifically, an intense signal at $m/z$ = 207.2 (75%) is assigned to $[La_2(\mu\text{-}H_2L)_2(H_3L)_4]^{4+}$. In addition, several mass peaks consistent with the association of this cation with glycerol molecules $\{[La_2(\mu\text{-}H_2L)_2(H_3L)_4]^{4+}\cdot(H_3L)_n\}$, $n$ = 2, 4, 6, 8 [$m/z$ = 253.3 (96%), 299.1 (100%), 345.1 (47%), 391.3 (10%)] are observed. The spectrum also contains minor peaks belonging to unidentified species. These data unequivocally confirm the presence of the $[La_2(\mu\text{-}H_2L)_2(H_3L)_4]^{4+}$ cations in solution that were observed in the solid state.

## IR Spectra

The different coordination modes of glycerol molecules and the presence of the deprotonated $H_2L^-$ species lead to changes in the vibrational frequencies of the ligand in complexes **1**-**6** relative to those of pure glycerol. In complexes **1**–**6** $\nu_{CO}$ vibrations are shifted to lower frequencies relative to those of the free ligand. For example, in complex **1** the $\nu_{CO}$ vibrations are shifted to 1095 and 1029 $cm^{-1}$, while in pure glycerol these vibrations are located at 1109 and 1034 $cm^{-1}$. The $\delta_{COH}$ vibrations centered at 1331 $cm^{-1}$ in glycerol are shifted to higher frequencies and are split into several well-defined peaks. Although the vibrational frequencies of the glycerol ligand change upon coordination in compounds **1**–**6**, these frequencies are almost insensitive to nature of lanthanide(III) ions.

The $\nu_{CN}$ vibrations of $[Re_6Q_8(CN)_6]^{4-}$ are split into three peaks and are shifted to higher frequencies relative to those of $K_4[Re_6S_8(CN)_6]$ (2117 $cm^{-1}$)[21] and $K_4[Re_6Se_8(CN)_6]\cdot 3.5H_2O$ (2107 $cm^{-1}$).[22] The $\nu_{OH}$ vibrations in **1**–**6** gave broad bands in the range 3500–3250 $cm^{-1}$ with no resolved lines in the spectra.

## Magnetic Data

Magnetic measurements carried out in the range 5–300 K show that La compounds **1** and **4** are diamagnetic, while Nd and Gd compounds **2**, **3**, **5**, and **6** are paramagnetic.

Neodymium-containing compounds **2** and **5** demonstrate complex temperature dependence of the magnetic susceptibility and effective magnetic moments. The effective magnetic moments for these complexes at 300 K are 4.61 and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

3.91 B.M. per $Nd^{3+}$ cation (6.53 and 5.61 B.M. per $[Nd_2(H_2L)_2(H_3L)_4]^{4+}$ dimer), and 4.40 and 3.48 at 5 K – the moments gradually increase with an increase in temperature. The room-temperature values per ion appreciably exceed the usual value of 3.62 B.M. known for $Nd^{III}$.[23] Moreover, as illustrated in Figure 6a, even at 300 K the magnetic moment does not reach a plateau but continues to grow. Further studies are needed to interpret this behavior.

The effective magnetic moments for **3** and **6** at 300 K are 8.05 and 7.71 B.M. per $Gd^{III}$ cation (11.38 and 10.9 B.M. per $[Gd_2(H_2L)_2(H_3L)_4]^{4+}$ dimer), which are close to the usual value of 7.9 B.M. for isolated $Gd^{III}$ ions.[23] The behavior of the susceptibility upon a decrease in temperature of these complexes for gadolinium-containing compounds **3** and **6** is very similar. Magnetic susceptibility for these complexes can be satisfactorily described with Curie–Weiss law $\chi_M = C/(T - \theta)$. Fitting of the experimental data gave equations $\chi_M = 18.0/(T + 1.20)$ and $\chi_M = 14.83/(T + 1.10)$ for **3** and **6**, respectively. Such dependence is typical for $Gd^{III}$ ions having a half-filled shell, $4f^7$. The values of $\theta$ are comparable to those found in other O-bridged $Gd^{III}$ dimers.[24,25] The temperature-dependent magnetic data for **6** are shown in Figure 6b.

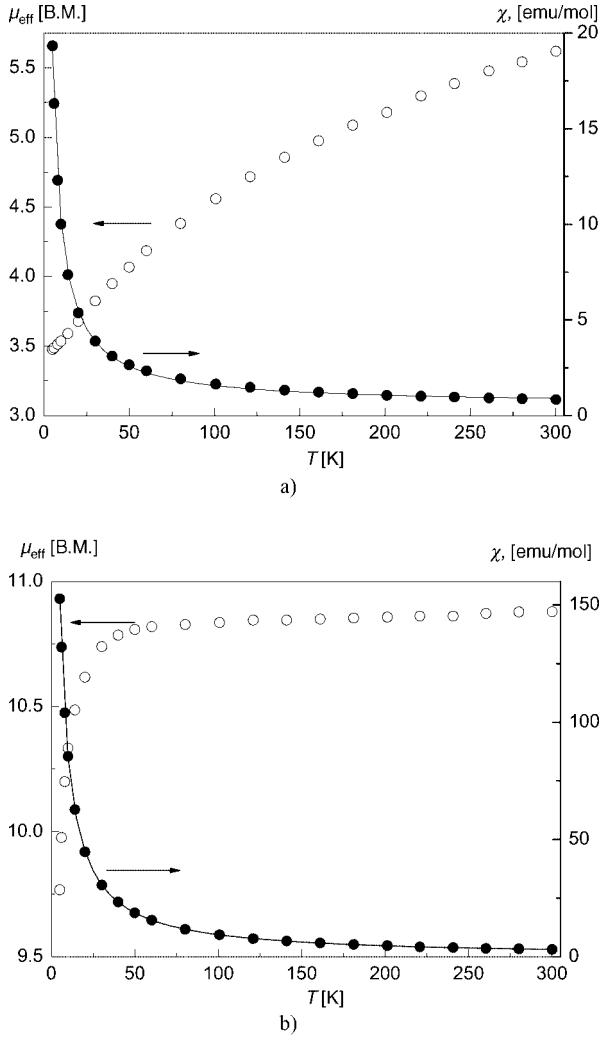

Figure 6. Magnetic susceptibility (solid circles) and effective magnetic moments (open circles) for **5** (a) and **6** (b).

Using equation

$$\theta = \frac{2S(S+1)}{3k_B}\sum_i^n z_i J_{ex,i}$$

for the case of two magnetic centers, we may estimate the exchange interactions in these dimers.[26] The values of $J$ are –0.079 and –0.073 $cm^{-1}$ for **3** and **6**, respectively, which correspond to very weak antiferromagnetic interactions between the two gadolinium cations in the $[Gd_2(H_2L)_2(H_3L)_4]^{4+}$ dimers.

## Conclusions

Glycerol molecules effectively coordinate with rare earth cations resulting in the formation of a new dimeric moiety $[Ln_2(\mu\text{-}H_2L)_2(H_3L)_4]^{4+}$. The observation of three different binding modes of glycerol in these structures demonstrates that this ligand is very attractive and potentially may form numerous complexes with rare earth cations.

## Experimental Section

### The Materials and Methods

**General:** Elemental analyses for C, H, N, and S (Carlo Erba 1106) were performed in the Laboratory of Microanalysis of the Institute of Organic Chemistry, Novosibirsk. IR spectra were recorded on KBr disks with a Scimitar FTS 2000c spectrometer in the range 4000–375 $cm^{-1}$. Magnetic susceptibility measurements for powder samples were carried out in the temperature range from 5 to 300 K in an applied magnetic field of 100 G using a Quantum Design MPMS-5 SQUID magnetometer. The starting cluster compounds $K_4[Re_6S_8(CN)_6]$[21] and $K_4[Re_6Se_8(CN)_6]\cdot 3.5H_2O$[22] were synthesized as described previously. Other reagents were used as purchased.

**Synthesis of $[La_2(H_2L)_2(H_3L)_4][Re_6S_8(CN)_6]$ (1):** To a solution of $LaCl_3\cdot 7H_2O$ (150 mg, 0.404 mmol) in $H_2O$ (20 mL) were added KOH (0.3 mL of a 0.1 M solution) and glycerol (3 mL), and the mixture was boiled for 15 min. The obtained clear solution was mixed with a solution of $K_4[Re_6S_8(CN)_6]$ (80 mg, 0.0474 mmol) in $H_2O$ (10 mL) and boiled (evaporated under heating) until the precipitation of yellow-orange compound **1**. The crystals were filtered, washed with ethanol (4 × 10 mL), and dried in air. Yield: 75.5 mg (67.5%). $C_{24}H_{46}La_2N_6O_{18}Re_6S_8$: calcd. C 12.22, H 1.97, N 3.56; found C 12.42, H 2.00, N 3.66%. IR: $\nu_{CN}$ = 2118, 2129, 2141 $cm^{-1}$; $\nu_{CO}$ = 1095, 1029 $cm^{-1}$; $\delta_{COH}$ = 1361, 1348, 1334 $cm^{-1}$.

**Synthesis of $[Nd_2(H_2L)_2(H_3L)_4][Re_6S_8(CN)_6]$ (2):** Compound **2** was prepared using the same procedure, though $NdCl_3\cdot 6H_2O$ (150 mg, 0.418 mmol) was used instead of $LaCl_3\cdot 7H_2O$. Yield: 63.0 mg (56.1%). $C_{24}H_{46}Nd_2N_6O_{18}Re_6S_8$: calcd. C 12.17, H 1.96, N 3.55; found C 12.22, H 2.06, N 3.45%. IR: $\nu_{CN}$ = 2118, 2129, 2141 $cm^{-1}$; $\nu_{CO}$ = 1095, 1028 $cm^{-1}$; $\delta_{COH}$ = 1359, 1346, 1332 $cm^{-1}$.

**Synthesis of $[Gd_2(H_2L)_2(H_3L)_4][Re_6S_8(CN)_6]$ (3):** Compound **3** was prepared using the same procedure as for **1**, though $GdCl_3\cdot 6H_2O$ (150 mg, 0.404 mmol) was used instead of $LaCl_3\cdot 7H_2O$. Yield: 66.1 mg (58.2%). $C_{24}H_{46}Gd_2N_6O_{18}Re_6S_8$: calcd. C 12.04, H 1.94,

Yield: 92.0 mg (70.5%). For $C_{24}H_{46}Gd_2N_6O_{18}Re_6Se_8$: calcd. C 10.41, H 1.67, N 3.03; found C 10.10, H 1.80, N 2.90%. IR: $\nu_{CN}$ = 2104, 2120, 2129 cm$^{-1}$; $\nu_{CO}$ = 1095, 1028 cm$^{-1}$; $\delta_{COH}$ = 1357 cm$^{-1}$.

**X-ray Structural Studies:** Diffraction measurements were carried out by standard technique on a Bruker SMART AXS diffractometer equipped with a CCD area detector (**1**) and a Buker-Nonius X8Apex CCD (**2**–**6**) using graphite-monochromated Mo-$K_\alpha$ radiation. Details of diffraction experiments, structure solution and refinement parameters are given in Table 3. Absorption corrections were applied using the SADABS program.[27,28] The crystal structures were solved independently by direct methods and then refined using the SHELX package.[29] Hydrogen atoms of CH and $CH_2$ groups were refined geometrically. Hydrogen atoms of OH groups were located from last different electron density maps and fixed. Our attempts to refine them were unsuccessful. Final refinement was done by full-matrix least-squares method. All non-hydrogen atoms were refined anisotropically. CCDC-269462 to -269467 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# *N*-Methylation Effects on the Coordination Chemistry of Cyclic Triamines with Divalent Transition Metals and Their $Co^{II}$ Dioxygen Carriers

**Silvia Del Piero,[a] Andrea Melchior,*[a] Pierluigi Polese,[a] Roberto Portanova,[a] and Marilena Tolazzi*[a]**

**Keywords:** Cadmium / Cobalt / Density functional calculations / N ligands / Thermodynamics

The thermodynamics of complex formation of $Co^{II}$ and $Cd^{II}$ ions with the triaza macrocyclic ligand 1,4,7-triazacyclononane (tacn) and its *N*-methylated derivative 1,4,7-trimethyl-1,4,7-triazacyclononane ($Me_3$tacn) has been studied in dimethyl sulfoxide (DMSO) at 298.1 K and in an ionic medium (0.1 M $Et_4NClO_4$) by means of potentiometric, UV/Vis, calorimetric and FT-IR techniques. The results are discussed by taking into account electronic and steric effects as well as solvation of the species concerned. Computational methods based on density functional theory (DFT) have been used to obtain structural information about the ligands and their complexes in order to provide further, independent insights into the effect of *N*-methylation on the coordination affinity of the ligands towards the metal ions. The computational suggestions are of great help to correlate steric effects and thermodynamic results. The kinetics of dioxygen uptake for the formation of the $Co(tacn)_2O_2$ superoxo adduct has also been studied by means of UV/Vis measurements.

## Introduction

In the last few years a wide variety of polyamines have been investigated in water[1–11] and in non-aqueous solvents[12–16] with the aim of studying how basicities and steric effects affect the selectivity pattern in metal coordination and for making direct comparison with the corresponding macrocyclic ligands.

As examples of these ligands' great interest and application, their potential use as sequestering agents for metals of environmental importance,[10] both toxic and essentials, and their employment as models for small molecules carriers,[16–21] such as in $Cu^{I}$ or $Co^{II}$ complexes, should be remembered.

In this context, previous studies of our group[16] on the complexation of divalent transition metal ions such as $Cd^{II}$ and $Co^{II}$ with differently *N*-alkylated linear di-, tri- and tetraamines in aprotic media have shown that: (i) the stabilities of the species formed decrease strongly with the increase of *N*-alkylation, with the enthalpy term being more responsible for that;[16a,16c] (ii) nitrogen functionalisation also strongly influences the stoichiometry and the nature of the metal complexes formed and, very interestingly, also the selectivity of these ligands (a higher affinity for $Co^{II}$ than for $Cd^{II}$ is displayed by primary and secondary polyamines, whereas the opposite is true when tertiary ones are involved);[16d] (iii) as far as cobalt(II) complexes are concerned, different *N*-alkylation of polyamines also has important effects on the behaviour of these complexes as better or worse dioxygen carriers:[16c,16e] in fact, electron transfer between the metal centre and the dioxygen depends on the electron density available at the central metal ion which, in turn, is greatly affected by the ligands;[17,20,21] (iv) steric effects due to *N*-alkylation inhibit the solvent exchange when dioxygen binding is considered, thus slowing down the oxygenation rate in the formation of the final adducts.

As an extension of this work we present here a study in the aprotic solvent dimethyl sulfoxide (DMSO) on the complex formation of $Co^{II}$ and $Cd^{II}$ ions with the simplest polyaza macrocyclic ligand 1,4,7-triazacyclononane (tacn) and its *N*-methylated derivative 1,4,7-trimethyl-1,4,7-triazacyclononane ($Me_3$tacn), whose bulky methyls cause the ligand to change both its electronic and steric properties.

Despite its small cavity size, tacn is known to show an effective, strong macrocyclic effect which is manifested in its increased thermodynamic stability with respect to chelated acyclic triamines, for example in water. In addition, a

stronger ligand field has been observed with respect to linear analogous.[22,23] These cyclic ligands also show interesting properties as potential oxidation catalysts[24,25] due to their ability in stabilizing reaction intermediates,[24] and they influence the electron-transfer rates, which are accompanied by a change in spin-state, such as in the $Co^{II}$/$Co^{III}$ couple.[26]

Finally, tacn is ideally suited to coordinate[22,23,27] the metal-ion coordination sphere facially, thus functioning as a blocking group for three coordination sites.[22,28] Moreover, in the presence of suitable pendant arms the derivatised ligands are also very interesting as they can open-up a variety of fields of investigation, such as those of inorganic crystal engineering,[29] biological tracers,[30] MRI contrast agents[31] and the selective extraction and sequestering of metal ions.[1,23,32–34]

The aim of this work is mainly related to gaining information on the behaviour of simple triaza macrocycles that do not yet bear pendant arms and, in particular, on: (i) the macrocyclic effect in complex formation in solvating media other than water; (ii) the influence of *N*-methylation; (iii) the specific match of metal-ion size and the coordination requirements of the cyclic ligands; (iv) the effects of these preorganised ligands and of their *N*-methylation on the dioxygen affinity of their $Co^{II}$ complexes.

The effect of *N*-methylation on the coordination affinity of the ligands towards $Co^{II}$ and $Cd^{II}$, characterised by different types of electron configuration ($d^7$ and $d^{10}$), is also investigated here by computational methods using density functional theory (DFT). DFT provides an excellent framework to obtain structural information and a number of chemical reactivity indices about ligands and their complexes and is able to give results of quality comparable to those obtainable by correlated ab initio calculations. DFT has previously been used to study the influence of *N*-methylation on the structural[35] and electrochemical properties of transition-metal complexes with cyclic polyaza ligands[8] and to describe the properties of polyamines, such as their basicity, both in the gas phase[36] and in solvent models.[37] The kinetics of dioxygen uptake is also studied by means of UV/Vis measurements as far as the $Co(tacn)_2$ species is concerned as this is the only complex capable of binding $O_2$.

## Results

The structures of the ligands were optimised by DFT calculations (see Supporting Information) and were compared with X-ray data available in the literature only for $Me_3$tacn (although in its protonated forms).[38] Some of the calculated and experimental parameters of this ligand are summarised in Table 1, and show that a good match exists between optimised and available X-ray data for $Me_3$tacn. This correlation is of interest as it can be taken as a proof of the reliability of these computational results and thus gives confidence in the initial calculated structure of tacn.

Table 1. Experimental[38] and calculated values for selected structural parameters of the ligand $Me_3$tacn.

| | Distances [Å] | | | Angles [°] | |
|---|---|---|---|---|---|
| | Exp. | Calcd. | | Exp. | Calcd. |
| N–C | 1.356–1.458 | 1.457 | C–N–C | 112.4–115.1 | 113.4 |
| $N–C_{(methyl)}$ | 1.450 | 1.451 | $C–N–C_{(methyl)}$ | 110.5–115.2 | 116.4 |
| C–C | 1.403–1.488 | 1.542 | | | |

The optimised structures of the $ML^{2+}$ complexes in the gas phase, together with calculated M–N distances, are reported in Figure 1: as far as the $M(tacn)^{2+}$ structures are concerned (Figure 1a and b), the M–N distances are shorter than the X-ray ones (Cd–N = 2.351–2.382 Å;[39] Co–N = 2.127–2.157 Å[40]), and this is true especially in the case of the $Co^{II}$ complexes. This may be due to the simplified models chosen, to the limited basis sets and also because repulsive interactions present in the experimental structures are absent in the model complexes. As a matter of fact, when optimised structures of $M(tacn)_2^{2+}$ are considered (Figure 1c and d) the M–N distances are longer and very close to the experimental data.

The calculated binding energies ($E_{bind} = E_{ML^{2+}} - E_{M^{2+}} - E_L$) for the complex formation in vacuo are reported in Table 2, and the energies of the ligands in their "free" form and at the coordinates in the optimised complexes are given in Table 3.

The overall stability constants obtained after the analysis of the potentiometric (for $Cd^{2+}$) and UV/Vis data (for $Co^{2+}$) are listed in Table 4 for metal(II)–tacn and –$Me_3$tacn systems. In the same table the whole of the thermodynamic functions, with the corresponding error limits, are also reported together with the available data in water.[41] Previously published data[16a,16b] hare given for the same metal(II)–*N*,*N*′′-dimethyldiethylenetriamine (dmdien) and –*N*,*N*,*N*′,*N*′′,*N*′′-pentamethyldiethylenetriamine (pmdien) systems, which were chosen as examples of comparable secondary and tertiary linear triamines.

The spectral changes observed during reactions between $Co^{II}$ and the ligands in the presence of $Cd^{II}$ as a competitive ion,[42] under anaerobic conditions, in terms of molar absorptions of the *j* species vs. wavelengths, are similar to the previous ones[16a] and are therefore not reported. The absorption maximum for $Co(ClO_4)_2$ in DMSO occurs at 535 nm ($\varepsilon$ = 11.9 $M^{-1}cm^{-1}$) and is shifted to lower wavelengths after ligand addition, in line with an increase in the ligand field strength when $CoL_j$ species are formed.

$\Delta h_v$, the total molar enthalpy change, is plotted as a function of $R_c$ (= $C_L/C_M$, total ligand/total metal concentration) for the $Cd^{II}$– and $Co^{II}$–ligand systems in Figure 2.

The shape of the curves confirms the formation of consecutive, stable $ML_j$ complexes when L = tacn (*j* = 1,2), whereas the absence of heat evolved after $R_c$ = 1 clearly indicates that no other species are formed beyond ML when L = $Me_3$tacn. The fit between experimental and calculated (full lines) data is good.

This species then evolves and decreases in concentration very slowly, as can be seen from curve 3 in Figure 3a.

The best fit of the analysed experimental data reported in Figure 3b is consistent with the reaction mechanism (charges omitted) proposed in Equation (1).

Degradation reactions appear to be negligible in the time range investigated, as can also be seen from the above-described analysis of the curves (Figure 3a).

The kinetics of the process obey a second-order rate law and the values of the obtained kinetic constants, calculated by the computer treatment of the absorbance values at 336 nm, are given in Table 5 together with the equilibrium constant for the overall reaction relative to the formation of species A. This is calculated by combining the rate constants of the direct and reverse reactions at 298.1 K, which is the standard state for $O_2$ in 1 M solution.

## Discussion

### DFT Calculations

The distances reported in Figure 1 show that the introduction of a methyl group on the tacn secondary nitrogens results in an elongation of the calculated M–N bond lengths (Figure 1e and f), which is more evident in the $Co^{II}$–L complexes (approx. 0.02 Å) than in the $Cd^{II}$–L complexes (approx. 0.005 Å). A similar elongation has been observed in the solid state for dinuclear $Co^{II}$ complexes of formula $[Co_2(Me_3tacn)_2X_3]$[43] for which X-ray data are available. This finding is in agreement with previous observations which show that the metal–N bond lengths increase with *N*-methylation as a consequence of steric effects in the gas phase,[44] and also of solvation effects in solution, thus leading to a stabilisation of the lower oxidation state in the $ML_j^{n+1}/ML_j^n$ redox couples.[10]

As far as the binding energies in Table 2 are concerned, it should be underlined that they are important only as far as their relative trends are conscerned: the high values found ($E_{bind}$ ≈ –970 to –1200 kJ mol$^{-1}$) cannot be compared to experimental values as environmental effects are not taken into account in the calculations, which means that additional energy terms, such as breaking of M–dmso bonds, are not considered.

Some interesting points can be outlined: i) $Co^{2+}$ binds much more strongly than $Cd^{2+}$ to the two polyamines, ii) the binding energies are higher for $Me_3$tacn than tacn for both metal ions, and iii) the difference between $Me_3$tacn and tacn is much higher when $Co^{II}$ is concerned [$\Delta E_{bindCo^{II}}$ = $E_{bind(Co–Me_3tacn)}$ – $E_{bind(Co–tacn)}$ = –51.3 kJ mol$^{-1}$; $\Delta E_{bindCd^{II}}$ = –16.5 kJ mol$^{-1}$].

Point i) may be reasonably explained by taking into account that $Co^{II}$, given its higher charge density, is a stronger Brønsted acid than $Cd^{II}$.

The higher affinity of the methylated amine for the two ions [point ii)] reflects the gas-phase basicity order of amines, which has been shown to be higher for tertiary amino groups than for secondary ones both experimentally[45] and theoretically.[35,36a,37] The effect of methyl groups on gas-phase basicity has been explained not only by the inductive effect of the $CH_3$ groups but also considering that, in the interaction of the amines with the $H^+$ ion, methyl groups are responsible for a better redistribution of the positive charge,[46] thus stabilizing the resulting cation. Even though in this case dipositive metal ions and not protons are involved, the same factors should be considered to be governing the energy trends found here.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As far as point iii) is concerned, the enhancement of stabilisation is probably due to a synergistic action that is effective when the stronger Brønsted acid $Co^{II}$ reacts with the stronger base $Me_3$tacn.

Steric effects due to *N*-methylation are investigated here with a particular attention to the fact that they are also reflected in the reorganisation of the ligands when they bind the metal ion, which influences their stability. Therefore, the energies of the ligands have been calculated in their "free" form and at the coordinates in the optimised complexes (Table 3): their difference $\Delta E_{strain} = E_{free} - E_{bound}$ can be considered a measure of this reorganisation. Although these differences are relatively low ($\Delta E_{strain} \approx 20$–$40\ kJ\,mol^{-1}$), they are nevertheless very important as these values are intrinsic in the ligands and therefore act in the gas phase as well as in solution.

The data for ML complexes in Table 3 mean that both ligands have to spend more energy to reorganize around $Co^{II}$ than $Cd^{II}$ ($\Delta\Delta E_{strain(L)} = \Delta E_{strain(Cd-L)} - \Delta E_{strain(Co-L)} = 9.3$ and $9.5\ kJ\,mol^{-1}$ for L = $Me_3$tacn and tacn, respectively); this is reasonable due to the larger ionic radius of $Cd^{II}$, which allows longer bond lengths and therefore lower strain, both of which imply lower steric repulsions and minor energy costs for the reorientation of the dipoles represented by N–H/$CH_3$ bonds.

To sum up, the DFT results for the gas phase forecast a higher affinity of both polyamines for $Co^{II}$ than for $Cd^{II}$, the higher difference found for $Me_3$tacn than for tacn being rationalised in terms of their gas-phase basicities. In addition, the importance of steric strain in the reorganisation of the ligands around the metals is pointed out.

## Thermodynamics

### *General Remarks*

The complex formation is accompanied by negative enthalpy values, typical of reactions between metal ions and neutral ligands in aprotic solvents.[12] The negative entropy terms found here are in line with the fact that the release of solvent molecules from the coordination sphere of the metal ions does not compensate the decrease in internal entropy of the ligand and the loss of translational entropy by the reagents upon complexation.

Thermodynamic data are available in water[41] for tacn systems, and these are also reported in Table 1. Although the enthalpy data are referred to a slightly different experimental ionic medium (0.2 M), this value nevertheless reflects different, significant effects of the two solvent media on complex formation: in water the stability with tacn is mainly due to a less favourable enthalpy term ($\Delta H°_1 = -31.8\ kJ\,mol^{-1}$), whereas the entropy term is positive. This trend has already been observed for other primary and secondary polyamines and generally results in a lower complex stabilisation in water than in DMSO.[16]

In polar solvents, where ion-pairing of counterions with metal cations and their complexes is negligible, the equilibrium constant for the complexation reaction varies with the solvation energies of the reactants (cations and ligands) and products (complexes). In many cases, the free-energy changes for ligand and complex solvation cancel each other out and the free-energy term for cation solvation is largely dominant.[12] The free-energy changes for metal-ion transfer from water to DMSO available for $Cd^{II}$ ($\Delta G°_{tr(water\rightarrow dmso)} = -60.4\ kJ\,mol^{-1}$),[47] and reasonably hypothesized to be negative for $Co^{II}$,[16a] show that these metal ions are more strongly solvated in DMSO than in water. This is in agreement with the different electron-donating abilities of the two solvent molecules, as measured by the empirical Gutmann's donor number (DN = 29.8 for DMSO and 18 for $H_2O$).[48]

In the hypothesis that the solvation energies of $Cd^{II}$ and $Co^{II}$ are the dominating solvation terms in our complexation reactions, we should expect a greater complex stability in water than in DMSO. As this does not occur, this suggests that amine solvation, rather than metal-ion solvation, plays a major role in determining the stability of tacn complexes in the two solvents. Indeed, it is known that primary and secondary amines are more solvated in water than in DMSO[15,49] and, consequently, are stronger bases in DMSO than in water. Tacn is more solvated in water, therefore complexation is a more expensive desolvation process, in terms of enthalpic contribution, but produces a greater gain in translational entropy. Accordingly, the enthalpic contribution available for the $Cd^{II}$–tacn system in water is largely less favourable than in DMSO, while the entropic one shows an opposite trend.

### *Complex Formation with Cyclic Triamines in DMSO*

Cyclisation of linear polyamines affects the stabilities and selectivities of their metal complexes: in particular, an extra stability is observed when complex formation with cyclic rather than linear polyamines is concerned. Although enthalpic and entropic arguments have been presented to account for this effect, it does not appear that one factor is unequivocally more important than the other.[3]

The results reported here show that an increase of the complex stability with both $Cd^{II}$ and $Co^{II}$ ions is effective when tacn (but also its methylated analogues) is considered with respect to the linear dmdien. This is true even if the comparison is extended to the more σ-donating primary linear triamine diethylenetriamine (dien).[16a]

This effect can be better understood by a separate analysis of the $\Delta H°$ and $\Delta S°$ contributions, which, in turn, are associated with metal, ligand and/or complex structural features.

It should be remembered that when macrocyclic rings such as 9-ane$X_3$ (X = N,O,S) are concerned, the metal ions do not enter the cavity of these small macrocycles, so that these do not represent examples of classical size-match selectivity. Rather, the metal ions are responding to the geometrical requirements for coordination out of the plane of the three donor atoms,[50] that is, the mode of coordination imposed by these ligands is stereorestrictive as they sterically constrained to facial coordination, whereas linear triamines may coordinate either facially or meridionally.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*1:1 Complexes*

Some important considerations can be made: (i) for the $Cd^{II}$ system with tacn, especially in the first complexation step, the extra stability with respect to the linear dmdien arises mainly from the entropy term as $\Delta H°_{\beta 1}$ is almost the same [the entropy term is far less unfavourable also when $Cd(Me_3tacn)^{2+}$ formation is considered vs. $Cd(pmdien)^{2+}$]; (ii) the opposite occurs when $Co^{II}$ complexation by the cyclic vs. the linear triamines is analysed. It must be underlined that both $Cd^{II}$ and $Co^{II}$ are octahedrally coordinated by six DMSO molecules in solution and that this coordination mode is retained in their 1:1 complexes, as indicated by UV/Vis measurements. In addition, from FT-IR spectra recorded for solutions where $R_c$ − the tacn-to-metal ratio − is varied up to 2, it can be seen that only the bands due to the bonded amine (at 3233 $cm^{-1}$) are present and no bands for free secondary (at 3345 $cm^{-1}$) amino groups could be detected, thus showing that the *N*-donor groups are all bonded to the central metal ion both in ML and $ML_2$ species.

The restricted conformational freedom of the cyclic tacn (but also $Me_3tacn$) before coordination, and hence the lower entropy loss on coordination, with respect to the linear one is one of the factors affecting this trend but certainly not the only one, as this should also influence the $Co^{II}$ system. The constraining nature of the rigid ligand, which forces a distorted octahedral structure in its facial coordination, is probably also responsible for this behaviour: in fact, with the larger $Cd^{II}$ ion (octahedral Shannon radius = 0.95 Å)[51] the steric strains of the three coordinated nitrogen atoms should be better minimised with respect to the small $Co^{II}$ ion (octahedral Shannon radius, high spin = 0.74 Å) and this may explain the great difference in entropy terms. These conclusions are also supported by the computational results in the gas phase, which show lower $\Delta\Delta E_{strain}$ values for Cd complexes than Co ones (Table 3). As a matter of fact, a special disorder has also been shown to be present in a $Cd(tacn)_2^{2+}$ solid structure,[39] and has been explained by observing that the ligands have two alternative positions which are twisted by about 56° with respect to each other.

The enthalpy values are, on the contrary, much more favourable when the $Co^{II}$–tacn system is considered with respect to $Cd^{II}$ and this should reflect stronger coordination bonds when the more (Brønsted) acidic $Co^{II}$ centre interacts with the ligands. This agrees with observed data which propose that, for metal ions which have considerable tendency for covalent bond formation, the enthalpic contribution to chelate formation can be important if their electronegativities are appreciable.[3]

Some additional points are outlined when the metal(II)–$Me_3tacn$ systems are considered: (i) a huge drop occurs in the complex stability with respect to the tacn system, and (ii) a huge gain in stability is observed as far as the complexation of the same ions with the tertiary, linear pmdien ligand are considered.

Point (i) may be explained as being due to several main reasons, especially: the different basicity of the amino group, which decreases in the order $NH_2 > NHR > NR_2$, in DMSO,[52] opposite from what occurs in gas phase; the elongation of the M–N bonds, due to the steric hindrance of the ligands[10] and the decreased solvation of the complexes as a consequence both of their increased radii and of the minor extent of hydrogen bonding brought about by the *N*-alkylated amines.[10]

The great importance of steric effects in the stability of the metal complexes formed is again clearly evident from the computational results in Table 3: the relative strain energies, in other words the repulsive forces in the $M^{II}$ complexes, are higher for $Me_3tacn$ complexes than for tacn itself ($\Delta\Delta E_{strain(tacn\rightarrow Me3tacn)}$ = 10.6 and 10.4 kJ $mol^{-1}$ for Cd and Co respectively). This destabilisation must be overcome in complex formation and thus is one of the causes of the decrease in complex stability.

As far as point (ii) is concerned, it should be remembered that data relative to pmdien agree with a bidentate behaviour of the ligand due to steric repulsions between the methyl groups.[16a,16b] In the case of $Me_3tacn$, the thermodynamic data suggest that the three nitrogens are all involved in coordination: the preorganisation of the cyclic ligand "drives" the N atoms towards the metal centre and evidently prevails over the steric repulsions between the methyl groups.

It is interesting to note that in the formation of the 1:1 complexes, $\Delta\Delta H°_1$, which is the difference between $\Delta H°_{\beta 1}{}^{Cd^{II}}$ and $\Delta H°_1{}^{Co^{II}}$ is less markedly positive for $Cd^{II}$ in the case of $Me_3tacn$ (Table 4, $\Delta\Delta H°_1$ = 19.8 kJ $mol^{-1}$) than in the case of tacn ($\Delta\Delta H°_{\beta 1}$ = 26.4 kJ $mol^{-1}$). This should once more be due to the better ability of the large $Cd^{II}$ to minimise steric hindrances. In addition, the increasingly soft nature of the tertiary amino groups should cause a less marked preference for $Co^{II}$ than for $Cd^{II}$ with respect to the secondary ones.

*1:2 Complexes*

*N*-Methylation is also responsible for the inability of $Me_3tacn$ to form an $M(Me_3tacn)_2^{2+}$ species: in fact, strong intramolecular repulsive forces would be exerted by the two rings due to non-bonding Me–Me interactions. Only one example of an $ML_2$ structure exists in the literature for this methylated ligand, namely the $Ag(Me_3tacn)_2^{+}$ complex.[53] In this case the Ag–N bond lengths are much greater (approx. 2.6 Å) and therefore the methyl groups are distant enough to allow a stabilisation of the $ML_2$ compound.

The thermodynamic data for $M(tacn)_2^{2+}$ systems show that the formation of the second complex is accompanied by a great stability (log $K_2$ = 9.03 and 9.2 for Cd and Co, respectively), which once more overcomes that relative to $M(dmdien)_2^{2+}$ complex formation. The presence of a stronger ligand-field for cyclic vs. linear triamines is evident from a comparison between the experimental UV/Vis spectra for the $Co(dmdien)_2$ and $Co(tacn)_2$ complexes: the value of $\lambda_{max}$ in the former is shifted from 535 [$\lambda_{max}$ for $Co(ClO_4)_2$ in DMSO solution] to 490 nm, whereas in the latter it is centred at 471 nm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

If we examine the values of the stepwise enthalpy and entropy data for M–tacn systems more deeply we can observe that the trend with both metals is in agreement with desolvation effects being more extensive in the first complexation step, and more markedly for $Cd^{II}$ than for $Co^{II}$. This desolvation effect should also play a role in explaining the low unfavourable entropy value found in the first step for Cd.

### Kinetics in Aerobic Conditions

The $k_1$ value found here for reaction (1) is slightly lower, although of the same order of magnitude, as that found for the formation of the saturated superoxo species $[Co(dien)_2O_2]^{2+}$ ($k_1$ = 69 $M^{-1}s^{-1}$), higher than that found for the formation of $[Co(dmdien)_2O_2]^{2+}$ ($k_1$ = 0.035 $M^{-1}s^{-1}$)[16h] and much lower than those found for $[CoL_2O_2]^{2+}$ [L = ethylenediamine (en), *N*,*N*′-dimethylethylenediamine (dmen)].[16e] The trend in $k_1$ values is therefore in agreement with a dissociative mechanism,[54] where a higher activation energy is required for the Co–N bond cleavage due to $O_2$ coordination in $Co(tacn)_2^{2+}$ than for the Co–$O_{(dmso)}$ bond cleavage in unsaturated $CoL_2$ complexes, the Co–N interaction being stronger than the Co–$O_{(dmso)}$ one.

The presence of steric interactions due to the methyl groups in dmdien makes the $O_2$ coordination slower[55] and this is in agreement with the $k_1$ value found for the $Co(dmdien)_2$ system with respect to $Co(tacn)_2$.

The stability constant for $O_2$ uptake is similar to that found when the secondary dmdien ligand is used [$\log K_{O_2}^{Co(dmdien)_2}$ = 2.8] and lower than that found for dien [$\log K_{O_2}^{Co(dien)_2}$ = 4.6]. The value of $\log K_{O_2}$ has been related[17] to the sum of $\log K_a$ of the ligands in water, which is a measure of the simple σ-donor ability of a ligand and therefore of the consequent electron density on the metal centre. When tacn is considered, a strongly acidic behaviour is observed for the first dissociation step due to the close proximity of the $NH_2^+$ groups, which results from the cyclic nature of the amine. Therefore, $\Sigma\log K_a$ of tacn is not available for a direct comparison with dmdien ($\Sigma\log K_a$ = 22.59) or with dien ($\Sigma\log K_a$ = 23.22). In a previous work the huge difference in stability of the dioxygen complexes of dmdien and dien systems was explained mainly by taking into account the statistical presence of a primary amino group (in dien) *trans* to the coordinated $O_2$,[16h] and this argument can also be used to explain the lower $\log K_{O_2}$ value found for the $[Co(tacn)_2O_2]^{2+}$ system with respect to $[Co(dien)_2O_2]^{2+}$. As far as the tacn and dmdien systems are compared, both possess only secondary amino groups, thus similar $\log K_{O_2}$ values are expected, as is the case. In light of the fact that the repulsion between the methyl groups in the dmdien system should lower the thermodynamic stability of the $O_2$ adduct with respect to tacn, the opposite result found here can be explained by supposing that the opening of a Co–N bond in $[Co(tacn)_2O_2]^{2+}$ causes the over-stability gained thanks to effects of "preorganisation" to partially drop.

## Conclusions

Some interesting features emerge from the combination of thermodynamic and DFT investigations. The extra stability of tacn complexes with respect to tridentate dmdien is mainly due to entropic effects for Cd, whereas the enthalpy term plays a fundamental role when Co is concerned.

This is an example of the great influence of the metal's ionic radius in satisfying the out-of-plane, facial coordination requirements of the cyclic triamine: in fact, the larger $Cd^{II}$ can better minimize steric strain, as clearly emerges from the values of the calculated strain energies in the gas phase for the same systems. On the other hand, the smaller $Co^{II}$ is more acid and achieves stronger coordination bonds than $Cd^{II}$, as confirmed by calculated binding energies of their complexes and by quite lower metal–N bond lengths in the Co–ligand systems. The enthalpy and entropy terms are therefore the result of a subtle interplay of steric and electronic effects. The *N*-methylation of tacn does not prevent $Me_3$tacn from behaving as a terdentate ligand, as occurs when linear pmdien is considered, due to a "preorganisation" of the ligand, which prevails over Me–Me steric repulsions. On the other hand, *N*-methylation, which is responsible for a less basic character of $Me_3$tacn than tacn in DMSO, causes a less marked preference for $Co^{II}$ than for the softer, larger $Cd^{II}$ with respect to tacn.

Finally, *N*-methylation strongly influences the stoichiometry of the species formed, as the $M(Me_3tacn)_2^{2+}$ (M = Co, Cd) species do not exist. As a consequence, only in the $Co(tacn)_2^{2+\cdot}$ complex does the central metal ion achieve sufficient electron density to be able to take up dioxygen.

## Experimental Section

**Materials:** $[Co(DMSO)_6(ClO_4)_2]$ and $[Cd(DMSO)_6(ClO_4)_2]$ were prepared as described previously.[16a] Tetraethylammonium perchlorate (TEAP; >97%, Aldrich ) was recrystallised from methanol and then dried under vacuum at 110 °C. The ligands tacn and $Me_3$tacn (Aldrich) were used without further purification. Dimethyl sulfoxide (99%, Aldrich) was purified by distillation according to the described procedures[16a] and stored under nitrogen over 4-Å molecular sieves. Perchlorate stock solutions of $Cd^{II}$ and $Co^{II}$ ions were prepared by dissolving weighed amounts of the adducts in anhydrous degassed DMSO; their concentrations were checked by titration against EDTA.[56]

Solutions of the ligands were prepared by dissolving weighed amounts in DMSO and standardised by thermometric titration with standard $HClO_4$ solutions. All standard solutions were prepared and stored in an MB Braun 150 glovebox under a controlled atmosphere containing less than 1 ppm of water and less than 1 ppm of oxygen. The water content in the solutions, typically 10–20 ppm, was determined with a Metrohm 684 KF Coulometer.

**Potentiometric Measurements:** All measurements employed for the determination of the stability constants of the $Cd^{II}$ complexes with tacn and $Me_3$tacn were carried out in 0.1 M $NEt_4ClO_4$ by using a thermostatted cell maintained at 298.1 ± 0.1 K, and kept under inert atmosphere in an MB Braun 150 glovebox. The concentrations of $Cd^{II}$ were obtained from the emf data of a galvanic cell measured

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with an Amel 338 pHmeter equipped with a Weiss WCD1001 Cd ion selective electrode as working electrode and a Metrohm 6.0718.000 silver electrode as reference electrode. Aliquots of ligand solutions of known concentrations were added to solutions of cadmium(II) perchlorate only ($[Cd^{2+}]$ = 2.00–10.00 mM) of known concentration and the free-metal concentration was measured. Equilibrium was reached typically in 2–5 min. The Nernstian response of the Cd electrode was obtained in the range $10^{-7}$–$10^{-2}$ M.

The computer program Hyperquad[57] was used for the calculation of the stability constants.

**Calorimetric Measurements:** A Tronac model 87–558 precision calorimeter was checked by titration of tris(hydroxymethyl)aminomethane (tham) with a standard solution of HCl in water and used to measure the reaction heats. The experimental value of the heat of neutralisation of tham was found to be $\Delta H° = -47.58$ kJ mol$^{-1}$, in good agreement with the accepted value of $-47.53 \pm 0.13$ kJ mol$^{-1}$.[1b]

The calorimetric titrations were performed at $298.15 \pm 0.02$ K by adding known volumes of ligand solutions ([L] = 20–50 mM) to 20 mL of metal ($Cd^{II}$, $Co^{II}$) solutions ([M] = 2.00–5.00 mM). The measured heats were corrected for the dilution heat of the ligands.

The least-squares computer program Letagrop Kalle[58] was used for the calculation of the enthalpy changes.

**FT-IR Spectroscopy:** The FT-IR spectra were obtained using a Bio-Rad FTS 40 spectrometer (maximum resolution 4 cm$^{-1}$; 16 scans). Cells with barium fluoride windows (thickness of 25 μm) were used. The cells were filled and closed in a glovebox and quickly transferred to the spectrometer. Spectra were also collected for solutions containing the ligand alone.

**UV/Vis Spectrophotometric Measurements:** UV/Vis spectra were recorded with a Varian Cary 50 Spectrophotometer directly inside the glovebox when the anaerobic $CoL_j$ ($j$ = 1, 2, L = tacn; $j$ = 1, L = $Me_3$tacn) complex formation was studied. Optic fibre probes and a quartz cuvette with a path length of 1 cm (117.100 Bracco cell) were used. The data were recorded over the wavelength range 300–650 nm.

The formation constants of the $CoL_j$ complexes were obtained by performing different titrations with varying $Co^{II}$ and $Cd^{II}$ concentrations in order to obtain the best competition between the two metal ions for the same ligand and/or provide evidence of possible formation of mixed or polynuclear species, and treating the data with the Hyperquad program.[57]

The kinetics of oxygenation reactions of $Co(tacn)_2$ species were studied using an analogous apparatus by means of optic fibre probes (Hellma) of 1 cm length dipped directly into the reaction vessel. The appearance of the MLCT band(s) associated with the formation of the dioxygen adduct/s[16,17a,20,21] was followed.

The whole of the apparatus and the automatic procedure used to collect the kinetic runs, in the range 270–670 nm, were as described previously.[16e] The concentration of dissolved $O_2$ in solution was calculated assuming the validity of Henry's law[59] and a value of $2.1 \times 10^{-3}$ M for the equilibrium concentration of $O_2$ in DMSO + TEAP solution at 298 K with a partial pressure of 760 Torr of $O_2$ in the gas phase.[60] The data were analysed with the DYNAFIT program.[61]

**Computational Details:** The acyclic systems were not considered for calculations as they are flexible and give many possible coordination isomers, especially as far as the dmdien ligand is concerned. On the other hand, DFT calculations were performed on the cyclic triamines, which are more suitable to gain information about *N*-methylation effects, and on their $ML_j^{2+}$ complexes (M = Co, Cd). For this purpose, the program PC GAMESS version 6.5[62] was used with the B3LYP three-parameter hybrid density functional,[63] which has been shown to be reliable for the description of metal complexes. The split-valence basis set 6-31G+(d) was employed for the atoms of the ligands, while a 3-21G basis set was employed for the metal ions. For the $Co^{2+}$ complexes the unrestricted formalism was employed with three unpaired electrons ($S$ = 4).

All the geometries were optimised without symmetry constraints, except the $M(tacn)_2^{2+}$ complexes, which were optimised within the $C_i$ point group, until the maximum component of the gradient of the energy was below 0.0001 Hartree/Bohr and the rms gradient below 1/3 of the latter. After the optimisations, stationary points were characterised by the calculation of the vibrational frequencies in order to confirm they were local minima.

The binding energies ($E = E_{ML^{2+}} - E_{M^{2+}} - E_L$) were corrected for the basis set superposition error (BSSE) by the counterpoise correction.[64]

**Supporting Information** (see footnote on the first page of this article): Figure S1 shows the DFT-optimised structures of tacn and $Me_3$tacn with the numbering scheme and Table S1 contains the distances between all the ligands' numbered atoms.

**Keywords:** Chelates / Cobalt / Ligand design / N ligands / Stability constants

The new, tridentate, facially coordinating ligand 1,4-diazepan-6-amine (daza) has been prepared from ethane-1,2-diamine and 2,3-dibromo-1-propanol in a seven-step procedure with an overall yield of 22 %. The conformation of the free ligand has been elucidated by pH- and temperature-dependent $^1$H NMR spectroscopy and by a single-crystal X-ray structure analysis of $H_3dazaCl_3{\cdot}H_2O$. A twisted chair with a predominantly equatorial orientation of the primary amino group has been established for daza and its protonation products $H_xdaza^{x+}$ ($1 \leq x \leq 3$). The formation constants of $[M(daza)]^{2+}$ and $[M(daza)_2]^{2+}$ have been determined in aqueous solutions for M = $Ni^{II}$, $Cu^{II}$, $Zn^{II}$, $Cd^{II}$, and $Co^{II}$ by potentiometric and spectrophotometric measurements, and a remarkably high stability has been found for the bis complexes $ML_2$ in comparison to the mono complexes ML. This effect is discussed in terms of the particular steric requirements of the daza ligand. $[Cu(daza)Cl_2]$, $[Ni(daza)_2]Cl_2{\cdot}3.2H_2O$ and $[Zn(daza)_2]SO_4{\cdot}5H_2O$ have been characterized by single-crystal X-ray analyses. Aerial oxidation of $Co^{2+}$ in the presence of daza results in the formation of the inert $[Co(daza)_2]^{3+}$, which was isolated as a mixture of the *cis* and *trans* isomers. These two isomers were separated by chromatographic methods and identified by NMR spectroscopy and single-crystal X-ray structure analysis of *cis*-$[Co(daza)_2][ZnBr_4]Br{\cdot}H_2O$ and *trans*-$[Co(daza)_2]_3[ZnBr_4]_2Br_5{\cdot}4H_2O$. The redox potentials of $[Ni(daza)_2]^{3+/2+}$ (1.04 V vs. NHE) and $[Co(daza)_2]^{3+/2+}$ (–0.21 V vs. NHE) were determined by cyclic voltammetry. The values are slightly more positive than for corresponding complexes with related cyclic triamines. This effect is again discussed in terms of the particular steric requirements of these ligands.

## 1. Introduction

Triamines with a cyclic backbone and a restriction to facial coordination such as all-*cis*-1,3,5-cyclohexanetriamine (*cis*-tach),[1] 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (taci),[2–4] or 1,4,7-triazacyclononane (tacn)[5,6] have received considerable attention in coordination chemistry. In particular, these ligands have been used to model the active site of metalloenzymes and to stabilize catalytically active metal centers.[7,8] In contrast to their open-chain aliphatic analogs, the restricted and well-defined coordination modes of the cyclic representatives allow a straightforward design of a specific coordination sphere, and the amino groups can readily be substituted with moieties carrying additional donor groups to give tetra-, penta-, or hexadentate chelators.[9–11]

The two triamines *cis*-tach and tacn may be regarded as the corner points of an entire series of triamine ligands containing a specific number of endocyclic (secondary) and exocyclic (primary) amino groups (Scheme 1). In view of the rich and interesting coordination chemistry opened up by *cis*-tach and tacn, it is rather remarkable that the intermediate members of this series have not received more attention as metal binding agents in coordination chemistry.[12–16] This is particularly surprising because asymmetric substitution of such species would easily open-up convenient routes to chiral derivatives and consequently to promising building blocks for new, enantioselective catalysts.

In two previous contributions,[14,15] we described the coordination chemistry of the two triamines *cis*-3,4-diaminopyrrolidine (*cis*-dap) and *cis*-3,5-diaminopiperidine (*cis*-dapi) and suggested that the seven-membered ring derivative 1,4-diazepan-6-amine (daza) would be a further, interesting member of this series. The use of *cis*-dapi as a building block for the construction of coordination polymers has meanwhile been described.[13] Substituted derivatives of 1,4-diazepan-6-amine are known as serotonine and dopamine receptor antagonists.[17] Moreover, a preliminary communication, proposing a 6-methyl-*N*,*N*′,*N*″,*N*‴-tetraacetic acid derivative of this compound as a potential Gd chelator for MRI applications, appeared very recently.[16] However, the unsubstituted 1,4-diazepan-6-amine ligand appears to be unknown, and to the best of our knowledge its coordination chemistry has hitherto not been investigated. We report here an efficient synthetic pathway for this interesting triamine and discuss its coordination properties with a range

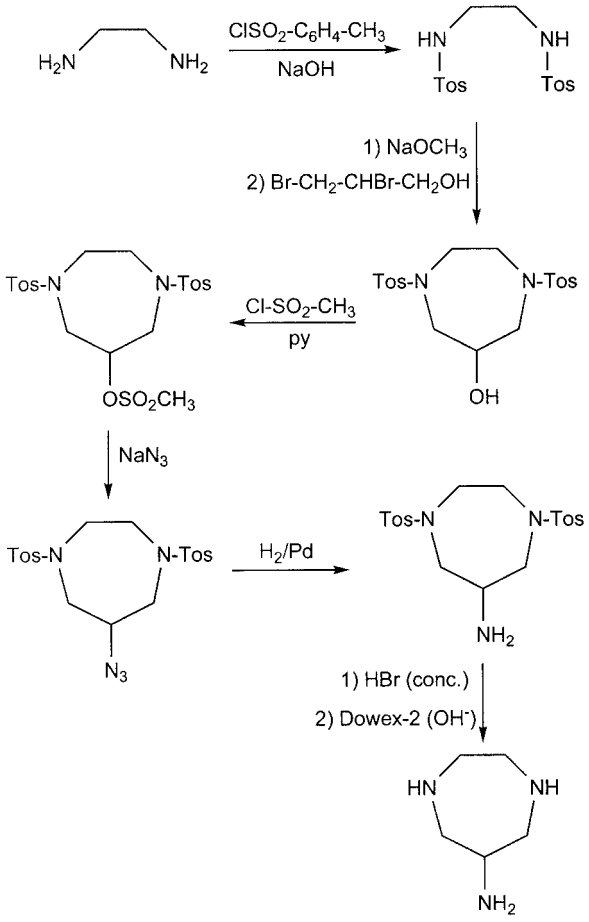
of divalent and trivalent metal cations. The coordinating properties of the new ligand will be compared with the other cyclic triamines shown in Scheme 1, and characteristic differences will be analyzed in terms of the specific steric requirements of these compounds.

## 2. Results and Discussion

### 2.1. Preparation and Characterization of the Ligand

In previous protocols, construction of the 1,4-diazepane ring was achieved by a nitro-Mannich-type reaction.[16] We used a different approach (Scheme 2), however, and obtained the seven-membered ring by the reaction of an activated diaminoethane derivative with 2,3-dibromo-1-propanol.[18] The resulting 1,4-ditosyl-1,4-diazepan-6-ol was then transformed into the corresponding azide by converting the alcoholic OH group into a suitable leaving group followed by substitution with $N_3^-$.[19] Solutions of the azide were directly transferred into an autoclave and were hydrogenated to give the amine. Due to its potentially explosive nature, the isolation of the pure azide was usually avoided and only a small quantity of this compound was separated for characterization. The two remaining tosyl groups were finally removed in concd. aqueous hydrobromic acid, and the pure triamine was obtained as the trihydrochloride from a cation-exchange resin.

As expected, $H_3daza^{3+}$ reacts as a triprotic acid. The corresponding p$K_a$ values were determined at 25 °C by pH-metric titrations in aqueous solution for an ionic strength of 0.1 and 1 M (Table 1). The values for 0.1 M KCl and 0.1 M $KNO_3$ are closely related and an individual, direct interaction between the polyammonium cation and $Cl^-$ or $NO_3^-$ appears therefore not to be significant. The cyclic $H_3daza^{3+}$ is more acidic than the triply protonated, open-chain 3-azapentane-1,5-diamine ($H_3den^{3+}$), as shown in Table 2.[20] In particular, the second p$K_a$ value of the cyclic triamine is



Scheme 2. Synthetic pathway for 1,4-diazepan-6-amine (daza).

considerably lower than that of the aliphatic triamine. This result is clearly a consequence of the steric constraints within the cyclic structure and can be understood in terms of simple electrostatic interactions between the positive charges located at the protonated amino groups.[15] It is also noteworthy that $H_3daza^{3+}$ is a stronger acid than $H_3(cis\text{-}dapi)^{3+}$ (Scheme 1), with a particularly pronounced effect for the first and the second deprotonation steps. The exocyclic amino groups of such ring systems preferentially adopt an equatorial orientation,[14,21] and in terms of electrostatic repulsion, it is therefore more difficult to protonate the endocyclic amino groups. These considerations are consistent with the observation that the triply protonated 1,4,7-triazacyclononane ($H_3tacn^{3+}$), where exocyclic amino groups are not present, is a strong acid that is not stable in $H_2O$.[22]

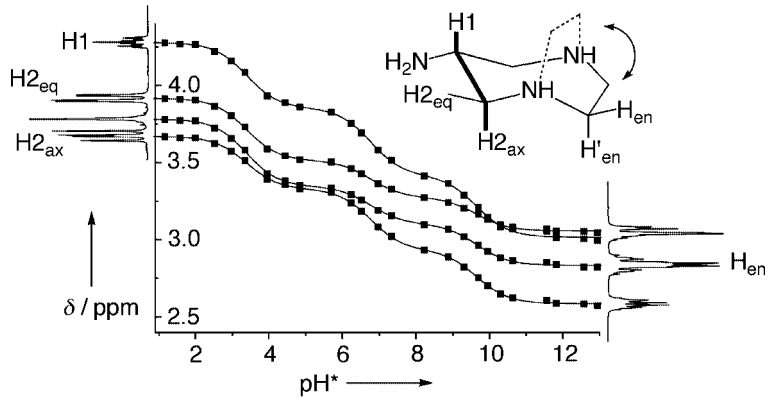

Figure 1. pH*-dependence[24] of the $^1$H NMR resonances of $H_xdaza^{x+}$ ($0 \le x \le 3$); squares correspond to experimental values; the lines were calculated (minimization of $[\delta_{obsd.} - \delta_{calcd.}]^2$). Inset: boat and chair conformations with averaged $C_s$ symmetry of $H_xdaza^{x+}$, compatible with the NMR spectroscopic data (see text); the H1–C–C–$H2_{ax}$ fragment responsible for the large vicinal coupling constant is highlighted in bold.

troscopy.[23] A series of spectra of daza as a function of pH* was recorded at 28 °C (Figure 1).[24] Assignments were established by $^1$H-$^1$H and $^1$H-$^{13}$C 2D correlation experiments, and the $\delta$ vs. pH* curves were evaluated using a least-squares procedure. The resulting apparent p$K_a$ values are 3.4, 6.8, and 9.7. Considering the different media ($D_2O$, no inert electrolyte vs. $H_2O$, 0.1 or 1 M KCl) these values agree well with the p$K_a$'s obtained from the potentiometric measurements (Table 1). It is well known that C–H protons near a basic site are deshielded in the course of protonation and this effect increases with a decreasing number of bonds between the basic site and the hydrogen atom under consideration.[25] It is possible to model this effect with a suitable set of deshielding constants and this information can then be used to identify the different tautomeric forms that are possible for the partially protonated species.[14,15] Based on such considerations, we showed that the first protonation step of daza is rather unspecific, with the proton of $Hdaza^+$ almost equally distributed over the three amino groups. For $H_2daza^{2+}$, however, the tautomer with a protonated primary amino group is strongly predominant ($\ge$ 90%).

The determination of coupling constants as a function of pH* proved helpful to follow conformational changes in the course of deprotonation.[26] At pH* < 3, H1 appears as a well-resolved, sharp triplet of triplets with two vicinal coupling constants ($J_a$ = 10.5 and $J_b$ = 3.1 Hz), indicative of an axial orientation of the hydrogen atom and thus an equatorial orientation of the primary amino group. Such a conformation of $H_3daza^{3+}$ was also observed in the crystal structure of daza·3HCl·$H_2O$ (Figure 2), where the diazepane ring adopts a twisted chair conformation (puckering parameters: $q_2$ = 0.522 Å, $q_3$ = 0.670 Å, $\theta_2$ = 41.4°, and $\theta_3$ = 193.5°).[27] The coupling constants also allowed an unambiguous identification of $H2_{eq}$ and $H2_{ax}$. As expected, the hydrogen atom with an equatorial orientation appears at higher frequency. The coupling constants change slightly with increasing pH* (pH* 4: $J_a$ = 8.4, $J_b$ = 3.7 Hz; pH* 6: $J_a$ = 7.4, $J_b$ = 4.1 Hz). As is well known, the cycloheptane ring is flexible and a variety of twisted chair and twisted boat conformations of similar energy could account for the solution structure. However, the coupling constants clearly indicate that the equatorial orientation of the primary amino group is maintained in the course of deprotonation. This assumption is also supported by the observation that an intercrossing of $H2_{eq}$ and $H2_{ax}$ in the pH* range investigated has not been noted.[14,21] Moreover, recording the spectra in MeOH/$H_2O$ (5:1) at low temperature showed only slight line broadening at 243 K, and individual signals for different conformers could not be observed.

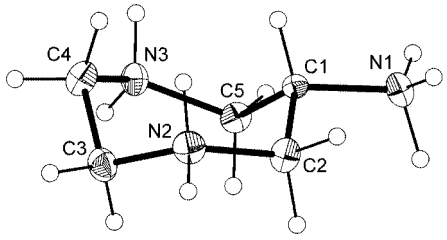

Figure 2. Molecular structure of $H_3daza^{3+}$ showing the twisted chair conformation of the seven-membered diazepane ring. The thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms are shown as spheres of arbitrary size. All bond angles and bond lengths fall in the expected ranges.

### 2.2. Preparation and Structural Characterization of Metal Complexes

Bis complexes of $Co^{III}$ were prepared conventionally by aerial oxidation of the $Co^{II}$ precursors in aqueous solution. As is well established for $Co^{III}$–hexaamine complexes, the resulting species proved highly inert towards ligand substitution, and they could thus be used as illustrative models for studying the properties of individual isomers. Separation of different components of the reaction mixture by means of chromatographic methods yielded two major orange products, an achiral, $C_{2h}$-symmetric *trans*-$[Co(daza)_2]^{3+}$ ($\mathbf{1}^{3+}$, 25%) and a chiral, $C_2$-symmetric *cis*-$[Co(daza)_2]^{3+}$ ($\mathbf{2}^{3+}$, 20%). The two isomers could unambiguously be identified by their NMR spectra, and this assignment was further confirmed by single-crystal X-ray structure analysis (Figure 3). The crystal structures of both complexes suffered from some disorder. In the structure of the *trans* isomer, three crystallographically independent complex molecules ($\mathbf{1a}^{3+}$, $\mathbf{1b}^{3+}$, $\mathbf{1c}^{3+}$) were located, with their metal centers Co1, Co2, and Co3 all placed on twofold rotational axes. As mentioned above, the complex cation itself is centrosymmetric. It is thus noteworthy that the three complex cations are *not* placed on a crystallographic center of inversion, even though the compound crystallizes in a centrosymmetric space group. In the complex of Co1, the ligand adopts a major and a minor orientation having occupancies of 80% and 20%, respectively. In the structure of the *cis* complex $\mathbf{2}^{3+}$, the three atoms N17, C2, and C13 are placed on a crystallographic mirror plane. All other atoms are doubled, and the entire molecule was thus found to be distributed equally over two symmetry-related positions with the above-mentioned three atoms in common.

$[Ni(daza)_2]^{2+}$ ($\mathbf{3}^{2+}$) and $[Zn(daza)_2]^{2+}$ ($\mathbf{4}^{2+}$) form immediately by the simple combination of aqueous solutions of the ligand and the hydrated metal salt. Both complexes are labile. The equilibrium between individual isomers is thus rapid and it was not possible to isolate the different isomeric species in the form of solid compounds. The two complexes $\mathbf{3}^{2+}$ and $\mathbf{4}^{2+}$ were crystallized as their chloride and sulfate salts, respectively. A single crystal structure analysis showed the *trans* form for both complexes, and two crystallographically independent complex cations ($\mathbf{4a}^{2+}$ and $\mathbf{4b}^{2+}$) were located in the structure of the Zn complex. All three complex cations $\mathbf{3}^{2+}$, $\mathbf{4a}^{2+}$, and $\mathbf{4b}^{2+}$ lie on crystallographic centers of inversion, and we attribute the exclusive observation of the *trans* form to better packing of the centrosymmetric isomer.

A comparison of bond lengths and bond angles within the coordination spheres of the bis complexes $\mathbf{1a}^{3+}$–$\mathbf{1c}^{3+}$, $\mathbf{2}^{3+}$, $\mathbf{3}^{2+}$, $\mathbf{4a}^{2+}$, and $\mathbf{4b}^{2+}$ indicates some characteristic deviation from an ideal octahedral geometry. Intraligand N–M–N angles are generally smaller than 90° and interligand N–M–N angles are larger than 90°. This effect increases with the increasing ionic radius of the metal center. Moreover, the M–N bonds of the primary (exocyclic) amino groups are somewhat shorter than the M–N bonds of the secondary (endocyclic) amino groups (Table 3). We regard this effect as a consequence of the steric constraints of the ligand framework rather than a result of the different donor capacity of the two types of nitrogen donors (the secondary nitrogen donor is usually considered to be a stronger nucleophile).

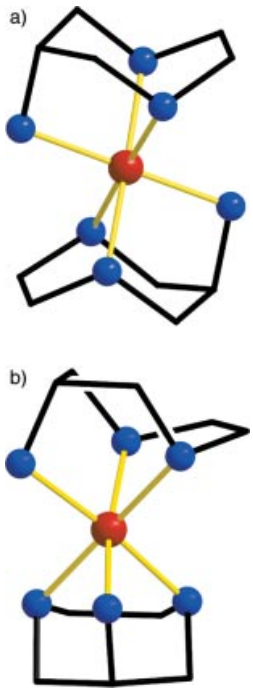

Figure 3. Molecular structure of a) the *trans*- and b) the *cis*-isomer of $[Co(daza)_2]^{3+}$ ($\mathbf{1}^{3+}$ and $\mathbf{2}^{3+}$). Color code: Co brown, N blue; the carbon skeleton is shown as a stick model (black); hydrogen atoms have been omitted for clarity. $[Ni(daza)_2]^{2+}$ ($\mathbf{3}^{2+}$) and $[Zn(daza)_2]^{2+}$ ($\mathbf{4}^{2+}$) adopt virtually the same *trans* structure as shown for the $Co^{III}$ complex $\mathbf{1}^{3+}$ (a).

The reaction of hydrated $CuCl_2$ with an excess of daza in aqueous solution resulted in the formation of a mononuclear, neutral 1:1 complex $[Cu(daza)Cl_2]$ (**5**). A crystal-structure analysis of this compound revealed a coordination number of five with a distorted square-pyramidal geometry ($\tau$ = 0.04).[28] Again, the intraligand N–Cu–N angles are significantly smaller than 90° and this effect mainly contributes to the deviation of the complex geometry from an ideal square pyramid. Complex **5** and the previously reported $[Cu(cis\text{-dapi})Cl_2]$ have closely related structures. In both complexes, the two chloro ligands and two of the nitrogen donors form the basal plane of the square pyramid. The third nitrogen donor is placed at the apex and has a considerably longer Cu–N bond (Table 3). In both structures, it is the endocyclic (secondary) nitrogen donor which forms this long bond to the apical position (Figure 4). With regard to the number of endocyclic and exocyclic nitrogen donors, the two triamine ligands *cis*-dapi (two exocyclic one endocyclic nitrogen atoms) and daza (one exocyclic, two endocyclic nitrogen atoms) are complements, and this is clearly reflected in the molecular structures of $[Cu(daza)Cl_2]$ and $[Cu(cis\text{-dapi})Cl_2]$. The free ligands *cis*-dapi and daza are both bisected by a mirror plane ($C_s$ symmetry);

however, this mirror plane is only retained in the *cis*-dapi complex, while the daza complex is devoid of any symmetry ($C_1$).

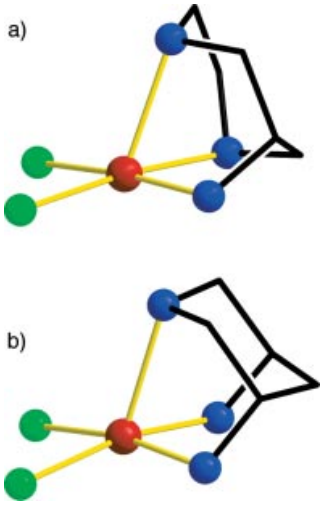

Figure 4. Molecular structure of a) $[Cu^{II}(daza)Cl_2]$ (**5**) and b) $[Cu^{II}(cis\text{-dapi})Cl_2]$ (from ref.[14]). Color code: Cu brown, N blue, Cl green; the carbon skeleton is shown by a stick model (black); hydrogen atoms have been omitted for clarity.

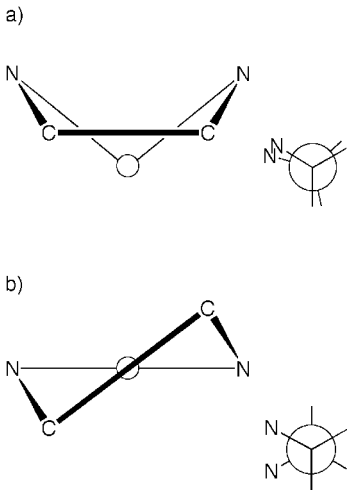
In all the complexes reported here the seven-membered diazepane ring adopts a regular chair conformation as indicated by the four puckering parameters $q_2$, $q_3$, $\theta_2$, and $\theta_3$ (Table 3).[27] This structural type is imposed by the tridentate coordination mode and implies an almost eclipsed orientation of the $N–CH_2–CH_2–N$ fragment (Table 3). It is noteworthy that the conformation of the corresponding five-membered chelate rings differs markedly from the well known λ/δ conformation observed in complexes with the open-chained ethane-1,2-diamine (Scheme 3), and also from the conformation that has been found for the noncoordinated ligand (Figure 2). It is thus obvious that a tridentate coordination mode of daza enforces some torsional strain within the metal complex.



Scheme 3. Conformation of five-membered chelate rings in a metal complex with daza (a) and the open-chained ethane-1,2-diamine (b).

### 2.3. Stability of the Metal Complexes

The formation constants of daza complexes with $Co^{II}$, $Ni^{II}$, $Cu^{II}$, $Zn^{II}$, and $Cd^{II}$ were measured in aqueous media by potentiometric methods (Figure 5). A summary of these results is presented in Table 4. The main species formed in solution are $[M(daza)]^{2+}$ and $[M(daza)_2]^{2+}$. For $Cu^{II}$, however, formation of the protonated $[Cu(Hdaza)]^{3+}$ and $[Cu(daza)(Hdaza)]^{3+}$ was also verified unambiguously. As shown by their $pK_a$ values of 3.82 and 4.67, the two protonated complexes behave as acids of moderate strength.

[b] 0.1 M KCl; the expression [M] and [ML] in the previous footnote should be interpreted as $\Sigma[MCl_i]$ and $\Sigma[MLCl_i]$, $i$ = 0, 1, respectively, see Section 2.3. [c] 0.1 M $KNO_3$.

It is well known that complexes with rigid ligands, having a cyclic backbone, often undergo ligand-exchange reactions that are slow relative to related ligands that do not have the same steric constraints. Moreover, comparatively slow substitution characteristics are well established for the $Ni^{II}$ center. Consequently, $Ni^{II}$–amine complexes such as $[Ni(cis\text{-tach})]^{2+}$ are inert,[29] and equilibration during a titration experiment is slow. In our previous investigations, a series of batch titrations were performed to investigate the $Ni^{II}$-*cis*-dapi, $Ni^{II}$-tmca, and $Ni^{II}$-taci system in aqueous solution.[14,21,30] In the $Ni^{II}$-daza system reported here, we therefore checked for complete equilibration by performing back titrations. To our surprise, the $Ni^{II}$-daza complexes proved to be labile, and an equilibration time of a few minutes after addition of an increment of titrant was sufficient even in the acidic range of the titration curve! It is well known that seven-membered rings readily undergo conformational changes, whereas six-membered chair structures, such as those observed in *cis*-dapi or taci, are rigid. The different flexibility of these ligand backbones obviously accounts for the variable lability of these tridentate systems.

In some of the titration experiments of the $Ni^{II}$ and $Cu^{II}$ complexes, the titration cell was equipped with an immersion probe, which was connected to a spectrophotometer with a diode array detector. This allowed the acquisition of additional spectrophotometric data, which were used to confirm the applied model and to evaluate the formation constants by an independent method (Figure 6). Moreover, the spectra of the individual species, which were calculated from the data, provided valuable information about the nature of the coordinated donor set. Due to the low intensity of the observed d–d transitions, the total metal concentration was increased to 10 mM and the inert electrolyte concentration was set at 1.0 M.

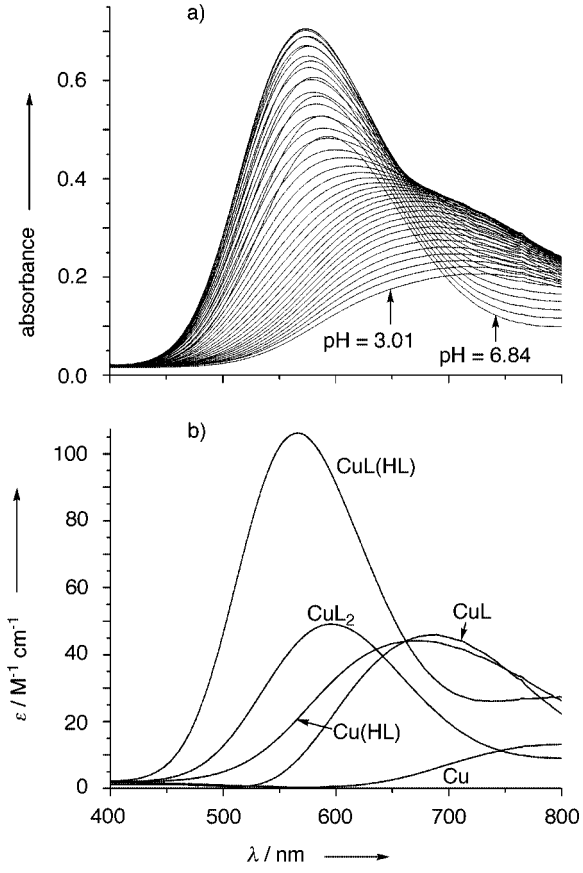

Figure 6. Determination of the formation constant $\log \beta_{xyz}$ of $[Cu_x(daza)_yH_z]^{2x+z}$ by spectrophotometric methods: a) the sample spectra of the spectrophotometric titration with total Cu/total daza = 1:2 in the range $3.0 < pH < 6.8$; b) calculated spectra of the individual $[Cu_x(L)_yH_z]^{2x+z}$ species (L = daza). The spectra of $Cu^{2+}$ was measured separately and was imported without refinement. The free ligand and its protonation products were considered as colorless.

As shown in Table 5, the agreement between the potentiometric and spectrophotometric measurements is generally good. $[Ni(daza)]^{2+}$ and $[Ni(daza)_2]^{2+}$ both exhibit the well-known three bands of a $d^8$ electron configuration, with maxima of the middle band [$^3A_{2g} \rightarrow {}^3T_{1g}(F)$ transition] at 590 and 513 nm, respectively. These values strongly sup-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

port an octahedral triamine-triaqua-$Ni^{II}$ and hexaamine-$Ni^{II}$ chromophore, respectively (Figure 7),[31] and confirm that the tridentate coordination mode of daza observed in the crystal structure of $[Ni(daza)_2]Cl_2 \cdot 3.2H_2O$ is retained in solution. The $Cu^{II}$ complexes all show a single, broad, unresolved band. For $[Cu(daza)(Hdaza)]^{3+}$, the maximum of this band is found at 566 nm. Such a value is characteristic of a $CuN_4$ chromophore with all four nitrogen donors occupying equatorial positions, and one or two additional, weakly bonded $H_2O$ molecules in apical positions.[32] $[Cu(daza)_2]^{2+}$ exhibits a maximum at 596 nm. The corresponding red shift of about 30 nm, which follows from deprotonation of $[Cu(daza)(Hdaza)]^{3+}$, is very characteristic of the coordination of one additional nitrogen donor in one of the apical positions ("pentaamine effect").[23,33] Coordination of a sixth nitrogen donor obviously does not take place, because the maximal absorption for a tetragonally elongated $CuN_6$ chromophore would appear at even higher wavelength (around 620–640 nm).[31] As a result, we have assigned a bis-didentate coordination mode to the protonated $[Cu(daza)(Hdaza)]^{3+}$ and a combination of a didentate and tridentate coordination mode to $[Cu(daza)_2]^{2+}$. The protonated mono complex $[Cu(Hdaza)]^{3+}$ also absorbs at somewhat shorter wavelength than the nonprotonated $[Cu(daza)]^{2+}$. For these two species, the difference in wavelength is, however, relatively minor. For $Hdaza^+$, only didentate coordination is reasonable, and the red shift observed upon deprotonation is again indicative of a tridentate coordination mode for daza. Such a coordination mode is the same as that which has been observed in the solid-state structure of $[Cu(daza)Cl_2]$ (Figure 4). However, a comparison of the stability constants of $[Cu(en)]^{2+}$ ($\log \beta = 10.5$) and $[Cu(daza)]^{2+}$ ($\log \beta = 11.1$) reveals only a minor increase in stability upon going from the didentate to the tridentate ligand systems ($\Delta \log \beta = 0.6$). Obviously, the third nitrogen donor of daza undergoes only weak binding to the $Cu^{II}$ center. This is in marked contrast to the $Ni^{II}$ system, where $[Ni(daza)]^{2+}$ is considerably more stable than $[Ni(en)]^{2+}$ ($\Delta \log \beta = 3.2$).[15]

Table 5. Comparison of formation constants[a] of $Ni^{II}$– and $Cu^{II}$–daza complexes derived either from potentiometric (pot) or spectrophotometric (spec) titrations (25 °C, 1 M $KNO_3$) together with spectrophotometric data. Estimated standard deviations (3σ) are given in parentheses.

| | $x,y,z$ | $\log \beta_{xyz}$ (pot/spec) | $\lambda_{max}$ [nm]/ε [$M^{-1}cm^{-1}$] |
|---|---|---|---|
| $[Cu(daza)]^{2+}$ | 1,1,0 | 11.19(3)/11.33(9) | 682/45 |
| $[Cu(Hdaza)]^{3+}$ | 1,1,1 | 15.43(1)/15.52(6) | 674/44 |
| $[Cu(daza)_2]^{2+}$ | 1,2,0 | 20.76(1)/20.91(6) | 596/49 |
| $[Cu(Hdaza)(daza)]^{3+}$ | 1,2,1 | 25.95(2)/26.06(6) | 566/108 |
| $[Ni(daza)]^{2+}$ | 1,1,0 | 10.72(1)/10.7(1) | 590/8 |
| $[Ni(daza)_2]^{2+}$ | 1,2,0 | 20.85(1)/20.9(1) | 513/11 |

[a] $\beta_{xyz} = [M_xL_yH_z] \times [M]^{-x} \times [L]^{-y} \times [H]^{-z}$.

As noted previously for *cis*-dapi,[14] the formation constants measured for the bis complex $[Cd(daza)_2]^{2+}$ are significantly different in 0.1 M KCl or 0.1 M $KNO_3$, whereas the formation constants of the mono complex are virtually the same in the two media. This result can be explained in terms of the formation of the chloro complexes $[CdCl]^+$ and $[Cd(daza)Cl]^+$. The formation constant of $[CdCl]^+$ is known to be $K^{Cl} = [CdCl^+] \times [Cd^{2+}]^{-1} \times [Cl^-]^{-1} = 33\ M^{-1}$.[20] Conditional constants of the type $\beta_i^{cond} = \{[CdL_i] + [CdL_iCl]\} \times \{[Cd]+[CdCl]\}^{-1} \times [L]^{-i}$ may be used to describe the equilibria in the chloride medium, and $\beta_1^{cond} = \beta_1$ is thus indicative of approximately the same affinity of $Cd^{2+}$ and $CdCl^+$ for the binding of one daza ligand. The difference between $\beta_2$ and $\beta_2^{cond}$ corresponds to the value of $K^{Cl} \times [Cl^-]$ within experimental error, and this result demonstrates that $[Cd(daza)_2]^{2+}$ does not interact directly with $Cl^-$ to a significant extent, which lends strong support for a coordination number of six within the hexaamine complex.

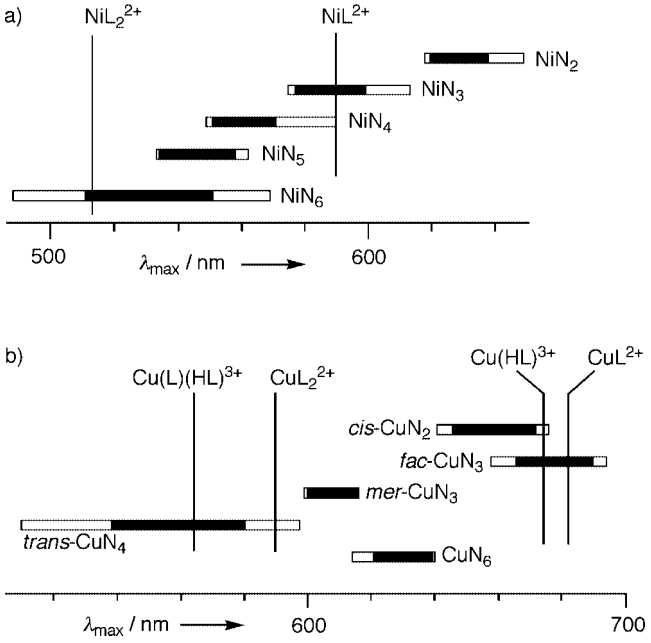

Figure 7. Correlation of the observed $\lambda_{max}$ values of the individual a) $Ni^{II}$– and b) $Cu^{II}$–daza complexes formed in aqueous solution with the $\lambda_{max}$ values of some chromophores reported in the literature.[31] Only complexes with a defined coordination environment containing a set of $sp^3$-nitrogen donors as indicated and $H_2O$ as additional ligands were considered. The data of the $Ni^{II}$ complexes refer to the $^3A_{2g}$–$^3T_{1g}(F)$ transition. Open boxes refer to the entire range reported, black boxes represent the averages ± one standard deviation.

A synopsis of the formation constants for some representative cyclic triamine ligands is given in Figure 8. The following general trends are noteworthy:

(i) With the exception of tacn, all the ligands shown have a remarkably low affinity for $Cu^{II}$ in comparison to $Ni^{II}$. For *cis*-tach, daza, and *cis*-dapi, $[Cu^{II}L]^{2+}$ is only of slightly higher stability than $[Ni^{II}L]^{2+}$ (Figure 8a). For 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (taci), and its *O*-methylated derivative *all-cis*-2,4,6-trimethoxycyclohexane-1,3,5-triamine (tmca), the Irving–Williams order is even inverted, and the Ni complex is more stable. This effect is markedly

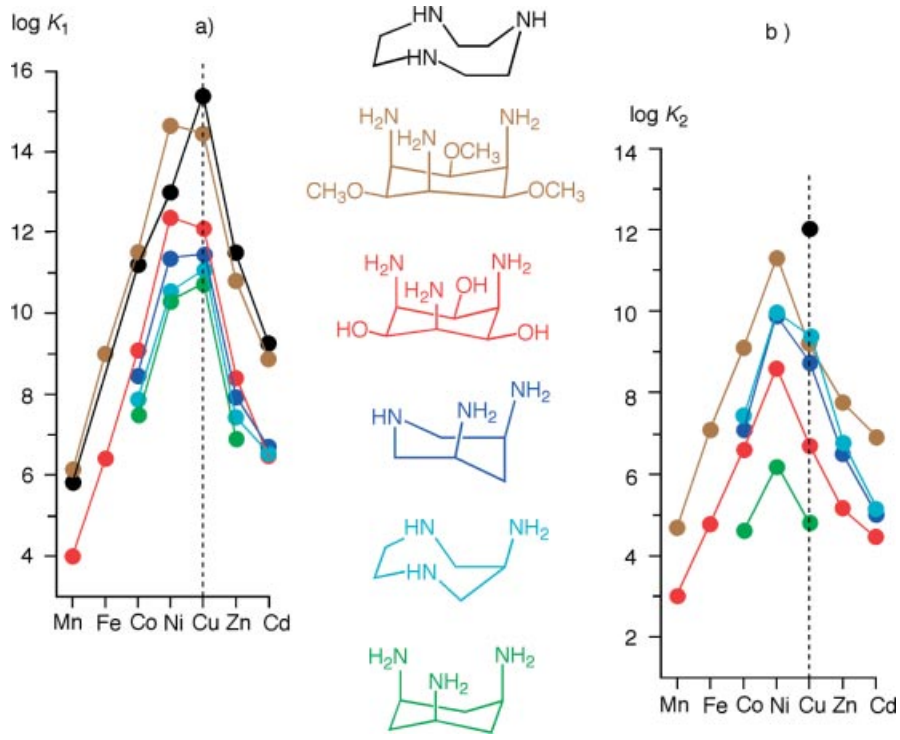

Figure 8. Survey of formation constants for complexes with divalent cations and various cyclic triamine ligands as indicated. Note that the values of the individual formation constants ($K_1 = [ML] \times [M]^{-1} \times [L]^{-1}$ and $K_2 = [ML_2] \times [ML]^{-1} \times [L]^{-1}$) rather than overall constants ($\beta_1$ and $\beta_2$) are shown. The constants of the daza complexes are from this work (Table 4), the formation constants of the other ligands are from refs.[3,14,20,21,36]

more pronounced for the addition of a second ligand moiety (Figure 8b), where a distinct maximum is now observed at $Ni^{II}$ for all the ligands. The preferred binding of $Ni^{II}$ is obviously due to the exclusive facial coordination mode of these ligands, which results in the above-mentioned weak binding of the third amine donor to the $Cu^{II}$ center.

(ii) In comparison to the other cyclic triamine ligands, the stability of the $[M(daza)]^{2+}$ species is generally low. As a matter of fact, only *cis*-tach forms 1:1 complexes of slightly lower stability. The relatively poor stability of the *cis*-tach complexes, and to a lesser extent of the *cis*-dapi complexes, is readily understood in terms of the high-energy conformation (primary amino groups all in axial positions), which is required for complex formation.[34] For taci and tmca, both chair conformations are destabilized by 1,3-diaxial repulsive interactions and metal binding does thus not require such an additional amount of energy. For daza, the primary amino group in the free ligand also has a preferred equatorial orientation (see Section 2.1), however, compared to *cis*-tach and *cis*-dapi, one would expect that much less energy is needed to bring it into an axial position. As already outlined in Section 2.2, it is the enforcement of the unfavorable chair conformation of the diazepane ring (local $C_s$ symmetry) with the eclipsed arrangement of the $N_{endo}$–$CH_2$–$CH_2$–$N_{endo}$ fragment that accounts for the low stability.

(iii) In contrast to the relatively low stability of the $[M(daza)]^{2+}$ complexes, the binding of a second ligand moiety (formation of $[ML_2]^{2+}$) is a highly favored process (Figure 8b). The ratio $\log K_1/K_2$ for the cyclohexane-based ligands *cis*-tach, taci, and tmca (excluding $Cu^{II}$) lies in the range of 2.0–4.1, whereas for daza it is 0.4–0.7. A similar behavior has previously been reported for *cis*-dapi ($\log K_1/K_2 \approx 1.4$),[14] although the ratio observed for daza is even smaller. A purely statistical approach would require that $K_1/K_2 = 16$ ($\log K_1/K_2 = 1.2$),[35] and thus it is evident that the two ligands in the $[M(daza)_2]^{2+}$ complexes show some cooperativity. As discussed previously,[14,36] the different behavior of the ligands with three exocyclic amino groups on the one hand and of *cis*-dapi and daza on the other can be explained by means of steric requirements, which result in different interligand interactions (Scheme 4). Moreover, some symbiotic behavior appears to further enlarge the binding of the second ligand.[37] The high cooperativity between the two ligand moieties in the $[M(daza)_2]^{2+}$ complexes results in some effects that are rather unusual in solution chemistry (Figure 9). For example, for ligands such as tmca, with "normal" behavior, $[ML]^{2+}$ is usually the only species that is present to a significant extent in solutions with equal concentrations of total ligand and total metal, and formation of $[ML_2]^{2+}$ is generally negligible. Furthermore, in solutions with a total metal/total ligand concentration of 1:2, the mono complex appears as the dominant species in the acidic range. In contrast, for daza, significant amounts of $[ML_2]^{2+}$ already form up to 30% in solutions with equal concentrations of total M and total L according to $2ML \rightarrow M + ML_2$, and in solutions with excess ligand $[ML]^{2+}$ appears only as a minor species within a narrow pH range.

## 2.4. Redox Properties

The redox properties of $[Co(daza)_2]^{3+/2+}$ and $[Ni(daza)_2]^{3+/2+}$ were investigated by means of cyclic voltammetry. For comparison, corresponding complexes with *cis*-dapi and taci were also studied. All the complexes investigated revealed quasi-reversible redox behavior (Figure 10), and the peak current was found to be linearly dependent on the square root of the scan rate, as expected for a diffusion-controlled process (Table 6). For the investigation of the $[Co(daza)_2]^{3+/2+}$ couple, crystalline samples of the distinct $Co^{III}$ complexes were used for the preparation of the test solutions. The *cis*- and the *trans*-isomers were investigated

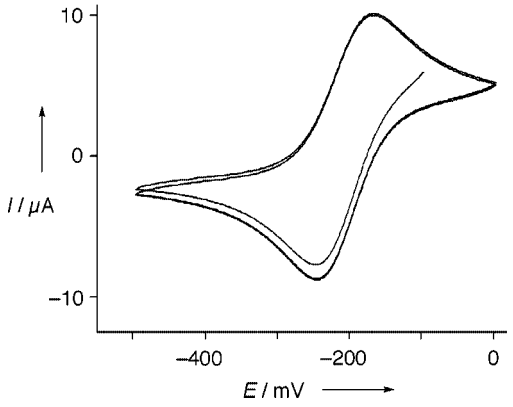

Figure 10. Cyclic voltammogram of $[Co(daza)_2]^{3+/2+}$ in aqueous solution (referenced against NHE, pH 10, 25 °C, $v$ = 50 mV s$^{-1}$).

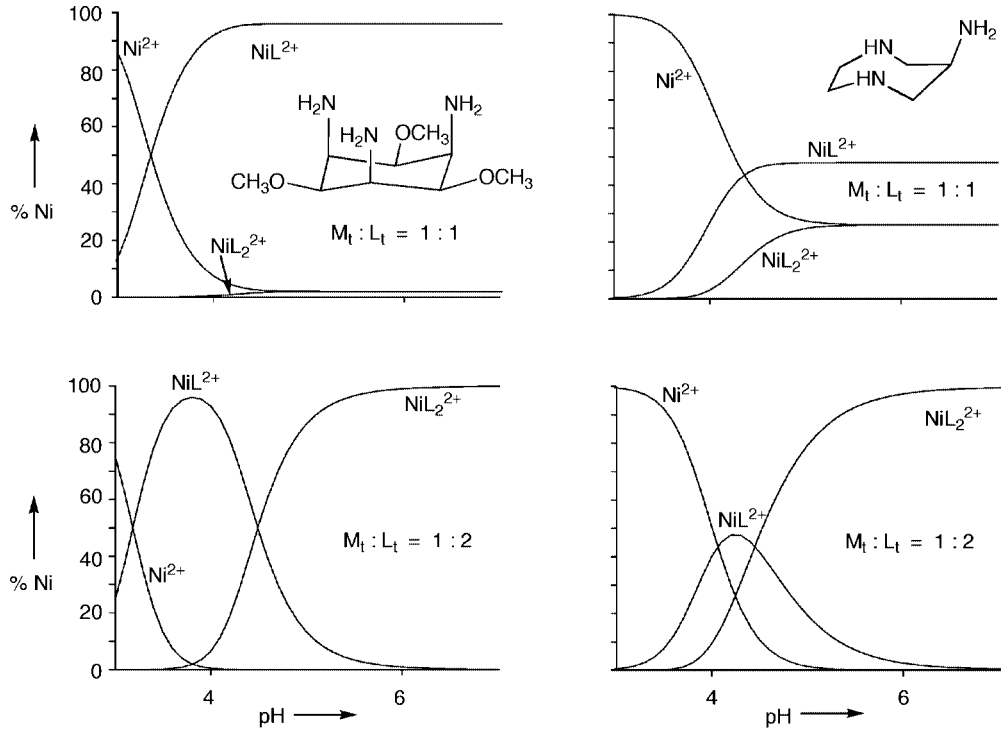

Figure 9. Illustration of the different solution properties for triamine complexes with a low (left side) and a high (right side) cooperativity between the two ligand moieties in a 1:2 complex. The species distribution was calculated for a total metal concentration of $10^{-3}$ M and a total ligand concentration of $10^{-3}$ M (top) and $2\times10^{-3}$ M (bottom). The formation constants used for the $Ni^{II}$–daza system are from this work (Table 4), the formation constants of 2,4,6-trimethoxy-1,3,5-cyclohexanetriamine are from ref.[21]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

separately; however, the cyclic voltammograms of the two isomers did not differ to a significant extent. A similar observation has previously been reported for the $[Co(cis\text{-dapi})_2]^{3+/2+}$ system.[14]

Table 6. Electrochemical data from cyclic voltammetry for the $[CoL_2]^{3+/2+}$ and $[NiL_2]^{3+/2+}$ couples in aqueous solution.

| $[ML_2]^{3+/2+}$ | $E_{1/2}$ [V][a] | $\Delta E_p$ [mV][b] | $R$[c] |
|---|---|---|---|
| $[Co(daza)_2]^{3+/2+}$ | –0.21 | 74, 95 | 0.9998 |
| $[Co(taci)_2]^{3+/2+}$ | –0.35 | 75, 114 | 0.9995 |
| $[Co(cis\text{-dapi})_2]^{3+/2+}$ | –0.38 | 69, 91 | 0.9999 |
| $[Ni(daza)_2]^{3+/2+}$ | 1.04 | 86, 132 | 0.9978 |
| $[Ni(taci)_2]^{3+/2+}$ | 0.95 | 76, 98 | 0.9999 |
| $[Ni(cis\text{-dapi})_2]^{3+/2+}$ | 0.92 | 72, 94 | 0.9999 |

[a] Reduction potentials relative to NHE. [b] Peak separation for a scan rate of 20 mV s$^{-1}$ and 1000 mV s$^{-1}$, respectively. [c] Correlation coefficients for the linearity of $I$ vs. $\sqrt{(v)}$ in the range 20 mV s$^{-1}$ $\leq$ $v$ $\leq$ 1000 mV s$^{-1}$ with a total of eight data points for each couple.

In general, the reduction potentials of corresponding *cis*-dapi and taci complexes are in close agreement, whereas the redox potentials of the daza complexes are all somewhat more positive (Table 6). Obviously, the taci- and *cis*-dapi- (= $L^a$) complexes with divalent cations are stronger reducing agents than corresponding daza (= $L^b$) complexes, and this means that in a taci- or *cis*-dapi complex the trivalent cation is stabilized according to

$$\Delta E_{1/2} = E_{1/2}(L^a) - E_{1/2}(L^b) = -RT/F \times \{\ln[\beta_2^{III}(L^a)/\beta_2^{II}(L^a)] - \ln[\beta_2^{III}(L^b)/\beta_2^{II}(L^b)]\} = -RT/F \times \Delta\ln(\beta_2^{III}/\beta_2^{II})$$

where $\beta_2^{III}$ and $\beta_2^{II}$ stand for the formation constants of the bis complexes with the trivalent and divalent cations, respectively. For *cis*-dapi and daza, one obtains $\Delta\log(\beta_2^{III}/\beta_2^{II}) = 2.9$ for $Co^{III/II}$ and 2.0 for $Ni^{III/II}$. It is interesting to note that Hancock has proposed some characteristic size selectivity for five- and six-membered chelate rings. The steric constraints of five-membered chelate rings are more suited for the binding of a large metal cation, whereas formation of six-membered chelate rings is more favorable for small cations.[38] Since the higher oxidation state generally implies a smaller ionic size, one would thus expect a less-negative redox potential for a ligand forming exclusively five-membered chelate rings, and that is indeed what we observe. The somewhat smaller $\Delta\log(\beta_2^{III}/\beta_2^{II})$ value of Ni (in comparison to Co) can be attributed to the well-known Jahn–Teller distortion caused by the low-spin $d^7$ electron configuration. This type of distortion would destabilize the $Ni^{III}$ complex with a cyclic triamine ligand in a similar way as described for $Cu^{II}$ (see Section 2.3),[23] and this effect is obviously more pronounced for the rigid taci or dapi than for daza.

## 3. Conclusions

In this paper, we have shown that 1,4-diazepan-6-amine (daza) readily forms 1:1 and 1:2 complexes with divalent transition metal cations in aqueous solution and exhibits mainly a tridentate facial coordination mode. The specific coordinating properties of daza are as follows:

a) In contrast to the $C_{3v}$-symmetric representatives such as tacn or *cis*-tach (Scheme 1), the $C_s$-symmetric ligand daza (similar to *cis*-dapi) is of lower symmetry and thus gives rise to a more complex stereochemistry. In particular, bis complexes exist in the form of *cis*- and *trans*-isomers. Due to the labile nature of most of the metal centers used, the different forms equilibrate rapidly and cannot be isolated. For the inert $Co^{III}$, we obtained approximately equal amounts of *cis*-$[Co(daza)_2]^{3+}$ and *trans*-$[Co(daza)_2]^{3+}$ which indicates that the energy of the two isomers does not differ significantly.

b) In comparison with other triamine ligands, the stability of the complexes is not exceptionally high. As an example, the open-chained 3-azapentane-1,5-diamine (den) forms a $NiL^{2+}$ complex with a formation constant, $\log \beta_1$, of 10.55,[20] which corresponds closely to the value (10.53) found for daza (Table 4). This result was somewhat unexpected because the donor set of the daza ligand has a much higher degree of pre-orientation. In comparison to other cyclic ligands (Scheme 1), the stability of daza complexes is relatively poor. We attribute the lower stability to the unfavorable, eclipsed conformation of the $N_{endo}$–$CH_2$–$CH_2$–$N_{endo}$ moiety, which is enforced in the course of coordination. In making comments about apparent stability, however, one should note that daza is a much weaker base than, for instance, the open-chained den, and although the formation constants of the two triamines are similar, daza is a much more effective chelator in neutral or slightly acidic media.[15]

c) The cooperativity between two daza moieties of a bis complex is even higher than for *cis*-dapi, and, as a consequence, a significant amount of the bis complex is formed already if the ligand and the metal are added in a 1:1 ratio. With regard to possible applications (catalysis, modeling of the active site of a metalloenzyme), as outlined in the introduction, this high cooperativity is disadvantageous − binding of a substrate requires at least one free coordination site and the formation of the bis complexes should thus be avoided.[39] This problem can, however, be solved by adding additional substituents to some of the nitrogen donors in such a way that the steric demands, and thus interligand repulsion, disfavor the binding of a second ligand entity. This topic will be the issue of a subsequent paper.[40]

d) Compared to the *cis*-tach and *cis*-dapi backbone, the daza backbone appears to be rather flexible and this results in fast ligand-substitution behavior. The kinetics of ligand formation, although not yet studied in detail, resemble that of an open-chained ligand system.

e) The daza ligand exclusively forms five-membered chelate rings and this favors complex formation with relatively large cations. As a consequence, the redox potential of $M^{III}(daza)_x/M^{II}(daza)_x$ couples is somewhat more positive (less negative) than corresponding couples with *cis*-dapi or taci complexes.

## Experimental Section

**General:** The commercially available chemicals used for the synthetic work were of reagent grade quality and were used as obtained. DMSO was from Fluka (puriss., p. a.). MeOH and EtOH were purified by distillation prior to use. Dowex 50 W-X2 (100–200 mesh, $H^+$ form) and Dowex 2-X8 (50–100 mesh, $Cl^-$ form) were from Fluka. The anion resin was converted into the $OH^-$ form by treatment with 0.3 M aqueous NaOH. For the potentiometric and spectrophotometric titrations, metal salts of highest available quality (>99.95%) were used. $H_2O$ was distilled twice (quartz apparatus). UV/Vis spectra of the $Co^{III}$ complexes were measured with an Uvikon 941 spectrophotometer ($H_2O$, 25 ± 3 °C). IR spectra were recorded with a Bruker Vector 22 FT IR spectrometer equipped with a Golden Gate ATR unit. Semi-quantitative determinations of $Co^{II}$ in solution were performed with Merckoquant 10002 test strips (Merck). C,H,N analyses were performed by H. Feuerhake (Universität des Saarlandes).

**NMR:** $^1H$ and $^{13}C\{^1H\}$ NMR spectra were measured in [$D_6$]-DMSO, $CD_3OD$, or $D_2O$ at 28 °C using a Bruker DRX Avance 400 MHz NMR spectrometer (resonance frequencies: 400.13 MHz for $^1H$ and 100.6 MHz for $^{13}C\{^1H\}$). Chemical shifts are given in ppm relative to [$D_4$]sodium (trimethylsilyl)propionate ($D_2O$) or tetramethylsilane ([$D_6$]DMSO and $CD_3OD$) as internal standards ($\delta$ = 0 ppm). A Hamilton SPINTRODE glass electrode, which was calibrated with aqueous ($H_2O$) buffer solutions, was used to measure pH* directly in the NMR tube.[24] The pH* of each sample was adjusted with appropriate solutions of DCl and NaOD in $D_2O$.

**Cyclic Voltammetry:** Cyclic voltammograms were recorded at ambient temperature (25 ± 2 °C) in a BAS C2 cell (0.5 M KCl), using a BAS 100B/W2 potentiostat, a gold (for the Co complexes) or glassy carbon (for the Ni complex) working electrode, a platinum counter electrode, and an Ag/AgCl reference electrode. Sample solutions of the Co complexes were made up using solid $[CoL_2]^{3+}$ salts. The total Co concentration was 0.004 M and the pH was adjusted to 10 (KOH). Ni samples were prepared in situ using a $Ni^{II}$ salt and the trihydrochloride of the ligands (total $Ni^{II}$ = 0.012 M, total L = 0.03 M, L = daza, taci, *cis*-dapi). 0.5 M KOH was then added to bring the pH to a value of 7.

**Potentiometric and Spectrophotometric Measurements:** The titration experiments were performed at 25.0 °C under $N_2$ or Ar (for the Co complexes) as described previously.[41] Simple potentiometric titrations were carried out with total M/total daza ratios of 1:1 and 1:2 in 0.1 M KCl or 0.1 M $KNO_3$ (Figure 5). Titration experiments, which were followed by potentiometric and spectrophotometric methods, were performed in 1 M KCl. A Metrohm 665 piston burette was used for addition of the titrant (KOH, HCl or $HNO_3$), and the pH was recorded using a Metrohm glass electrode with an incorporated Ag/AgCl reference, connected to a Metrohm 713 pH/mV meter. For spectrophotometric measurements, the titration cell was equipped with an immersion probe (HELLMA), which was connected to a spectrophotometer equipped with a diode array detector (J&M, TIDAS-UV/NIR/100-1). The titrations were performed with a total metal concentration of 0.01 M and a total daza concentration of 0.02 M. A PC was used to trigger recording of a spectrum just prior to the addition of each new aliquot of base.[41]

**Calculations of Equilibrium Constants:** Equilibrium constants were generally calculated as concentration quotients (pH = –log[$H^+$]) using the computer programs HYPERQUAD and SPECFIT.[42,43] The total concentrations of the reactants and the p$K_w$ (13.78 for $\mu$ = 0.1 M, 13.77 for $\mu$ = 1.0 M)[20] were not refined. The protonation constants of the diazepane ligand were evaluated separately and were kept fixed when refining formation constants of the metal-containing species. The UV/Vis spectra of the free $Ni^{2+}$ and $Cu^{2+}$ were recorded separately and were imported as fixed data sets for the evaluation of the formation constants of the metal complexes. The free ligand and its protonation products were treated as nonabsorbing species.

***N*$^1$,*N*$^2$-Ditosyl-1,2-ethanediamine:**[44] Toluene-4-sulfonyl chloride (95 g, 0.5 mol) was suspended in diethyl ether (200 mL). The suspension was cooled with an ice bath, and a mixture of NaOH (20 g, 0.5 mol) and ethane-1,2-diamine (15 g, 0.25 mol, dissolved in 200 mL of $H_2O$) was added dropwise. The resulting white suspension was stirred overnight at room temperature. The residue was filtered off and recrystallized from MeOH (white crystals, 86.2 g, 94%). $C_{16}H_{20}N_2O_4S_2$ (368.5): calcd. C 52.15, H 5.47, N 7.60; found C 52.66, H 5.41, N 7.46. $^1H$ NMR (DMSO): $\delta$ = 2.39 (s, 6 H), 2.72 (s, 4 H), 7.38 (d, *J* = 8.2 Hz, 4 H), 7.61 (d, *J* = 8.2 Hz, 4 H) ppm. $^{13}C$ NMR (DMSO): $\delta$ = 21.0, 42.2, 126.5, 129.7, 137.4, 142.8 ppm. IR: $\tilde{\nu}$ = 664, 709, 748, 818, 875, 1020, 1058, 1092, 1153, 1188, 1240, 1292, 1307, 1330, 1404, 1452, 1496, 1598, 3282 $cm^{-1}$.

**Disodium *N*$^1$,*N*$^2$-Ditosyl-1,2-ethanediamide:** Sodium metal (4.6 g, 0.2 mol) was allowed to react with water-free MeOH (150 mL), then *N*$^1$,*N*$^2$-ditosyl-1,2-ethanediamine (36.8 g, 0.1 mol) was added. The white suspension was refluxed for half an hour, the solvent evaporated completely and the remaining white residue dried in vacuo (40.0 g, 97%). $C_{16}H_{18}N_2Na_2O_4S_2$ (412.4): calcd. C 46.60, H 4.40, N 6.79; found C 46.76, H 4.77, N 6.70. $^1H$ NMR (DMSO): $\delta$ = 2.32 (s, 6 H), 2.58 (s, 4 H), 7.18 (d, *J* = 8.0 Hz, 4 H), 7.50 (d, *J* = 8.0 Hz, 4 H) ppm. $^{13}C$ NMR (DMSO): $\delta$ = 20.9, 46.3, 126.4, 128.6, 139.2, 142.6 ppm. IR: $\tilde{\nu}$ = 658, 708, 811, 844, 884, 982, 1072, 1117, 1153 $cm^{-1}$.

**1,4-Ditosyl-1,4-diazepan-6-ol:**[18] Powdered KOH (1.9 g, 0.034 mol) was dissolved in absolute EtOH (250 mL) and 2,3-dibromo-1-propanol (3.5 mL, 0.034 mol) was added dropwise to this solution. The resulting white suspension was refluxed and disodium *N*$^1$,*N*$^2$-ditosyl-1,2-ethanediamide (14 g, 0.034 mol) was added. The mixture was refluxed for an additional six hours and the remaining solid was removed from the boiling solution by filtration. The clear solution was then cooled to 4 °C, yielding 10.1 g (70%) of colorless crystals, which were filtered off and dried in vacuo. $C_{19}H_{24}N_2O_5S_2$ (424.5): calcd. C 53.75, H 5.70, N 6.60; found C 53.38, H 5.52, N 6.31. $^1H$ NMR (DMSO): $\delta$ = 2.39 (s, 6 H), 2.85 (dd, *J* = 13.9, 8.1 Hz, 2 H), 3.11 (m, 2 H), 3.48 (m, 4 H), 3.75 (sept, *J* = 4.2 Hz, 1 H), 5.28 (br., 1 H), 7.42 (d, *J* = 8.2 Hz, 4 H), 7.67 (d, *J* = 8.1 Hz, 4 H) ppm. $^{13}C$ NMR (DMSO): $\delta$ = 20.9, 49.0, 53.0, 68.4, 126.6, 129.8, 135.5, 143.3 ppm. IR: $\tilde{\nu}$ = 610, 653, 722, 805, 911, 972, 1036, 1086, 1151, 1266, 1330, 1400, 1442, 1493, 1598, 2922, 3502 $cm^{-1}$.

**1,4-Ditosyl-1,4-diazepan-6-mesylate:** 1,4-Ditosyl-1,4-diazepan-6-ol (10 g, 0.024 mol) was dissolved in anhydrous pyridine (50 mL) and cooled to 0 °C with an ice bath. Methanesulfonyl chloride (1.87 mL, 0.024 mol) was then added dropwise to this solution. A yellow solid precipitated, and the suspension was stirred for an additional 2 h at 0 °C. 3 M HCl (200 mL) was then added and the solid turned white. Stirring was continued for a further 2 h at 0 °C. The residue was then filtered off and washed with $H_2O$. The solid was extracted with boiling EtOH and dried in vacuo. Yield: 10.6 g (88%). $C_{20}H_{26}N_2O_7S_3$ (502.6): calcd. C 47.79, H 5.21, N 5.57; found C 47.77, H 5.19, N 5.63. $^1H$ NMR (DMSO): $\delta$ = 2.39 (s, 6 H), 3.23 (m, 2 H), 3.27 (s, 3 H), 3.37 (m, 2 H), 3.53 (d, *J* = 5.1 Hz, 4 H), 4.87 (quint, *J* = 5.1 Hz, 1 H), 7.42 (d, *J* = 8.2 Hz, 4 H), 7.69 (d, *J* = 8.2 Hz, 4 H) ppm. $^{13}C$ NMR: $\delta$ = 20.9, 37.8, 50.4, 51.2, 76.7, 126.7, 129.9, 135.3, 143.6 ppm. IR: $\tilde{\nu}$ = 570, 619, 652, 702,

715, 743, 807, 904, 916, 949, 974, 1001, 1074, 1090, 1148, 1161, 1282, 1310, 1331, 1347, 1442, 1496, 1598 $cm^{-1}$.

**6-Azido-1,4-ditosyl-1,4-diazepane:** *Caution: Organic azides are potentially explosive. These must be handled with care and should not be isolated in large amounts*![19] Solid 1,4-ditosyl-1,4-diazepan-6-mesylate (5 g, 0.01 mol) was added to a solution of $NaN_3$ (1.95 g, 0.03 mol) in absolute DMF (100 mL). The resulting white suspension was heated to 100–110 °C for 48 h. A white solid was removed by filtration, yielding a clear, yellow solution of the desired product. A small sample to be used for IR and NMR characterization was precipitated by the addition of $H_2O$ to a few milliliters of the DMF solution. The resulting white solid was separated by filtration and air-dried. $^1H$ NMR (DMSO): $\delta$ = 2.40 (s, 6 H), 3.19 (m, 2 H), 3.39 (m, 6 H), 3.89 (m, 1 H), 7.43 (d, $J$ = 8.3 Hz, 4 H), 7.69 (d, $J$ = 8.3 Hz, 4 H) ppm. $^{13}C$ NMR (DMSO): $\delta$ = 20.9, 50.1, 50.9, 58.6, 127.0, 130.1, 135.5, 143.7 ppm. IR: $\tilde{\nu}$ = 656, 696, 720, 813, 860, 909, 958, 1036, 1090, 1158, 1245, 1306, 1332, 1381, 1455, 1494, 1599, 2110 $cm^{-1}$. The crystal structure has been published in a previous communication.[45]

**1,4-Ditosyl-1,4-diazepan-6-amine:** The experiment reported in the previous section was repeated one more time and the resulting DMF solutions of the azide were combined to one single solution. This solution was then transferred into an autoclave and hydrogenated (5 atm $H_2$) using 10% Pd/C (500 mg) as catalyst. After 48 h the catalyst was removed by filtration and the resulting solution (300 mL) was diluted with 1 L of $H_2O$. The white solid that precipitated was filtered off and dried in vacuo. This product proved to be of sufficient purity to be used for the next step, however the elemental analysis was not satisfactory. The product could be isolated as analytically pure hydrobromide by dissolving the amine in EtOH (100 mL) and adding aqueous concd. HBr (10 mL). The resulting yellow solution was filtered through Celite and the solvents evaporated to dryness. A colorless solid was obtained which was dried in vacuo (7.1 g, 70%). $C_{19}H_{25}N_3S_2O_4{\cdot}HBr$ (504.5): calcd. C 45.24, H 5.19, N 8.33; found C 45.34, H 5.38, N 8.06. $^1H$ NMR (DMSO): $\delta$ = 3.40 (m, 3 H), 3.45 (m, 4 H), 3.63 (dd, $J$ = 14.4, $J$ = 4.1 Hz, 2 H), 7.47 (d, $J$ = 8.2 Hz, 4 H), 7.72 (d, $J$ = 8.2 Hz, 4 H) ppm. $^{13}C$ NMR (DMSO): $\delta$ = 20.9, 48.9, 49.4, 50.0, 126.6, 130.1, 134.9, 143.8 ppm. IR: $\tilde{\nu}$ = 571, 653, 721, 813, 905, 967, 1030, 1089, 1152, 1330, 1449, 1494, 1597 $cm^{-1}$. The crystal structure of the free amine has been published in a previous communication.[46]

**1,4-Diazepan-6-amine·3HBr:** 1,4-Ditosyl-1,4-diazepan-6-amine (5 g, 0.012 mol) was refluxed in concd. aqueous HBr (150 mL) for 3 h. The solution was cooled to room temperature and was then concentrated to a volume of 50 mL on a rotary evaporator. A white solid crystallized which was filtered off and washed with cold EtOH. Drying in vacuo yielded 3.2 g of the trihydrobromide salt (75%). $C_5H_{16}Br_3N_3$ (357.9): calcd. C 16.78, H 4.51, N 11.74; found C 16.87, H 4.58 N 11.74. $^1H$ NMR ($D_2O$, pH < 3): $\delta$ = 3.67 (dd, $J$ = 14.1, $J$ = 10.5 Hz, 2 H), 3.77 (m, 4 H), 3.89 (dd, $J$ = 14.1, $J$ = 3.1 Hz, 2 H), 4.26 (tt, $J$ = 10.5, $J$ = 3.1 Hz, 1 H) ppm. $^{13}C$ NMR ($D_2O$, pH < 3): $\delta$ = 45.9, 47.1, 49.3 ppm. IR: $\tilde{\nu}$ = 767, 844, 864, 882, 910, 991, 1020, 1050, 1127, 1180, 1265, 1298, 1326, 1392, 1429, 1447, 1465, 1524, 1548, 2781 $cm^{-1}$.

**1,4-Diazepan-6-amine·3HCl·1.5H$_2$O:** This compound was obtained from the trihydrobromide by ion-exchange chromatography on Dowex 50. $C_5H_{16}N_3Cl_3{\cdot}1.5H_2O$ (251.6): calcd. C 23.87, H 7.61, N 16.70; found C 23.45, H 7,88, N 17.09. The $^1H$ and $^{13}C$ NMR spectra were identical with those of the trihydrobromide. IR: $\tilde{\nu}$ = 773, 852, 868, 890, 1000, 1055, 1092, 1135, 1199, 1234, 1271, 1396, 1435, 1539, 2718 $cm^{-1}$. Single crystals of composition $H_3dazaCl_3{\cdot}H_2O$, suitable for X-ray analysis were grown by slow evaporation of an aqueous solution.

**[Co(daza)$_2$]Cl$_3$:** 1,4-Diazepan-6-amine·3HBr (2.5 g, 7.0 mmol) was dissolved in $H_2O$ (50 mL), and the pH of the solution was adjusted to 8.5 by adding NaOH (1 M). Solid $CoCl_2{\cdot}6H_2O$ (0.83 g, 3.5 mmol) was then added, resulting in a red-orange solution, which was stirred in an open beaker for 3 d. The solution was tested for $Co^{2+}$ (negative), and sorbed onto Dowex 50. The column was washed successively with $H_2O$ (500 mL), aqueous 0.5 M HCl (500 mL), and aqueous 1 M HCl (500 mL). The product was then eluted from the column with aqueous 3 M HCl (500 mL). The last fraction was evaporated to dryness, and the resulting orange solid was dissolved in a small amount of $H_2O$ and sorbed onto a column of SP-Sephadex C-25 (column length: 2 m). The column was eluted with trisodium citrate (0.2 M). Beside several minor bands, two major orange bands ($\mathbf{1}^{3+}$, $\mathbf{2}^{3+}$) were observed. The two major bands were collected separately, desalted on Dowex 50 (3 M HCl), and the solvents evaporated to dryness.

***trans*-[Co(daza)$_2$]Cl$_3$·4H$_2$O (1Cl$_3$·4H$_2$O):** Yield: 25%. $C_{10}H_{26}CoCl_3N_6{\cdot}4H_2O$ (467.7): calcd. C 25.68, H 7.33, N 17.97; found C 25.75, H 7.11, N 18.52. $^1H$ NMR ($D_2O$): $\delta$ = 2.69 (d, $J$ = 13.4 Hz, 4 H), 2.88 (d, $J$ = 8.3 Hz, 4 H), 3.42 (br. s, 2 H), 3.43 (m, 4 H), 3.62 (d, $J$ = 13.4 Hz, 4 H) ppm. $^{13}C$ NMR ($D_2O$): $\delta$ = 55.7, 56.9, 62.3 ppm. IR: $\tilde{\nu}$ = 626, 780, 884, 981, 1044, 1092, 1128, 1183, 1231, 1314, 1379, 1417, 1614, 2114, 3032 $cm^{-1}$. UV/Vis: $\lambda_{max}$ ($\varepsilon$) = 335 nm (75), 470 (79).

***cis*-[Co(daza)$_2$]Cl$_3$·1.5H$_2$O (2Cl$_3$·1.5H$_2$O):** Yield: 20%. $C_{10}H_{26}Cl_3CoN_6{\cdot}1.5H_2O$ (422.7): calcd. C 28.42, H 6.92, N 19.88; found C 28.21, H 6.85, N 19.91. $^1H$ NMR ($D_2O$): $\delta$ = 2.71 (d, $J$ = 13.5 Hz, 4 H), 3.04 (m, 4 H), 3.44 (m, 4 H), 3.49 (br. s, 2 H), 3.56 (d, $J$ = 13.5 Hz, 2 H), 3.78 (m, 2 H) ppm. $^{13}C$ NMR ($D_2O$): $\delta$ = 55.6, 56.3, 57.4, 61.9 (two C atoms) ppm. IR: $\tilde{\nu}$ = 886, 988, 1048, 1092, 1151, 1230, 1285, 1316, 1356, 1444, 1496, 1590, 1981, 2051, 2165, 2323, 2430, 2754, 2875, 3030 $cm^{-1}$. UV/Vis: $\lambda_{max}$ ($\varepsilon$) = 345 nm (140), 470 (157).

Single crystals: $\mathbf{1}Cl_3{\cdot}4H_2O$ (24 mg) and $\mathbf{2}Cl_3{\cdot}1.5H_2O$ (24 mg) were separately dissolved in $H_2O$. $ZnBr_2$ (59 mg, 0.26 mmol) was added to each of the solutions. The solutions were acidified with 3 M aqueous HBr to pH < 1. Slow evaporation yielded orange crystals of composition $[\mathbf{1}]_3(ZnBr_4)_2Br_5{\cdot}4\,H_2O$ and $[\mathbf{2}](ZnBr_4)Br{\cdot}H_2O$, suitable for X-ray analysis.

**[Cu(daza)Cl$_2$]:** 1,4-Diazepan-6-amine·3HCl·H$_2$O (100 mg, 0.41 mmol) was dissolved in 1 mL of $H_2O$. $CuCl_2{\cdot}2H_2O$ (35 mg, 0.21 mmol) was added to this solution, and the pH was adjusted to 7 with 0.5 M NaOH (2 mL). The solution was then diluted with EtOH and was allowed to stand at 4 °C for a few days, yielding a small number of blue crystals which were suitable for the single crystal analysis. IR: $\tilde{\nu}$ = 666, 768, 853, 872, 966, 1041, 1098, 1149, 1319, 1444, 1605, 2848, 2871, 3167, 3242, 3300, 3322 $cm^{-1}$.

**[Ni(daza)$_2$]Cl$_2$·3.2H$_2$O:** 1,4-Diazepan-6-amine·3HCl·H$_2$O (100 mg, 0.41 mmol) was dissolved in 1 mL of $H_2O$. Solid $NiCl_2{\cdot}6H_2O$ (50 mg, 0.21 mmol) was then added and the pH was adjusted to 8 with 0.1 M KOH (12 mL). The resulting purple solution was allowed to evaporate slowly over a period of several days at room temperature, yielding a small number of purple crystals suitable for the X-ray analysis. IR: $\tilde{\nu}$ = 628, 914, 965, 1043, 1064, 1099, 1143, 1614 br, 2875, 3166, 3227, 3313 $cm^{-1}$.

**[Zn(daza)$_2$]SO$_4$·5H$_2$O:** 1,4-Diazepan-6-amine·3HBr (200 mg, 0.56 mmol) was deprotonated on Dowex 2 ($OH^-$ form). The volume of the resulting solution was reduced to 10 mL. Solid $ZnSO_4{\cdot}7H_2O$ (81 mg, 0.28 mmol) was added, and the solution was

layered with acetone, yielding single crystals suitable for X-ray analysis.

**Single Crystal X-ray Diffraction Studies:**[47] Data sets were collected on the following diffractometers: STOE IPDS (daza·3HCl·$H_2O$ and [$Cu(daza)Cl_2$]), STOE STADI-4 ([$Ni(daza)_2$]$Cl_2$·3.2$H_2O$ and [$Zn(daza)_2$]$SO_4$·5$H_2O$), Nonius Kappa-CCD (*trans*-[$Co(daza)_2$]$_3$-($ZnBr_4$)$_2Br_5$·4$H_2O$, and *cis*-[$Co(daza)_2$]($ZnBr_4$)Br·$H_2O$). Graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) was used throughout. The data for the two Co complexes were collected at 100(2) K, daza·3HCl·$H_2O$ and [$Cu(daza)Cl_2$] were measured at 200(2) K, and the other data sets were collected at ambient temperature. An absorption correction was performed for *cis*-[Co-($daza)_2$]($ZnBr_4$)Br·$H_2O$ (face-indexed numerical), *trans*-[Co-($daza)_2$]$_3$($ZnBr_4$)$_2Br_5$·4$H_2O$ (faced-indexed numerical), and [$Zn(daza)_2$]$SO_4$·5$H_2O$ (empirical). Further details of data collection and structure solution are summarized in Table 7. The structures were solved by direct methods (SHELXS-97) and refined by full-matrix, least-squares calculations on $F^2$ using SHELXL-97.[48] Anisotropic displacement parameters were refined for all non-hydrogen atoms. The hydrogen atoms of daza·3HCl·$H_2O$, [$Zn(daza)_2$]-$SO_4$·5$H_2O$, and [$Ni(daza)_2$]$Cl_2$·3.2$H_2O$ were located and refined isotropically. The H-atom positions of the other complexes were calculated (riding model). The disorder problems of the Co complexes **1**a$^{3+}$ and **2**$^{3+}$ are described in detail in Section 2.2. In the structure of **2**$^{3+}$, a total of 21 restraints was used to adjust corresponding bond lengths and angles of the two ligands to the same value within suitable limits (SAME instruction of SHELXL-97). Puckering parameters were calculated using the computer program PLATON.[49]

## Acknowledgments

X-ray diffraction data of $H_3dazaCl_3$·$H_2O$ and of the Ni, Cu, and Zn complexes were recorded by Dr. Volker Huch (Saarbrücken). We thank Dr. Peter Osvath (Melbourne) for valuable advice. Financial support by the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

# Evidence for Hydrogen-Bond-Mediated Exchange Coupling in an Aqua-Bridged $Cu^{II}$ Dimer: Synthesis, Magnetic Study and Correlation with Density Functional Calculations

**Pritha Talukder,[a] Soma Sen,[a] Samiran Mitra,*[a] Lutz Dahlenberg,[b] Cédric Desplanches,[c] and Jean-Pascal Sutter*[c,d]**

**Keywords:** Bridging ligands / Copper / Density functional calculations / Exchange interactions / Hydrogen bonds

A rare example of a mono-aqua-bridged copper(II) dimer, namely $[Cu_2(\mu_2\text{-}H_2O)L_2(H_2O)_2](ClO_4)_2{\cdot}2H_2O$ (**1**), has been synthesised and its structure determined by single-crystal X-ray diffraction. Each $Cu^{II}$ centre is in a square-pyramidal surrounding formed by a Schiff base and a terminal $H_2O$ ligand; a second $H_2O$ ligand, which acts as a bridge, is common to two metal ions. Hydrogen bonds between the $H_2O$ ligand and the Schiff base of the adjacent centre complete the intra-dimer linkages. This compound exhibits an antiferromagnetic behaviour ($J = -13.2\ cm^{-1}$, $H = -J\boldsymbol{S}_1{\cdot}\boldsymbol{S}_2$), and density functional calculations clearly establish that the main exchange does not proceed through the bridging $H_2O$ but is mediated by the intra-dimer H-bonds.

## Introduction

$Cu^{II}$ centres coordinated by an O,N,N-tridentate Schiff base derived from 2-hydroxyacetophenone and 2-(dimethylamino)ethylamine can form a variety of chelates by filling out the coordination environment, resulting in a square-planar, square-pyramidal or distorted square-bipyramidal polyhedron. Depending on the proportions and physicochemical properties of the co-ligands, monomeric, dimeric, oligomeric or polymeric crystal structures are formed. Several copper(II) dimeric complexes containing a singly hydroxo-bridged system[1,2] reveal that the hydroxo group acts commonly in the $\mu_2$-O or $\mu_3$-O bridging modes. The aqua ligand almost invariably exhibits the terminal mode in copper(II) complexes, although complexes for which $H_2O$ acts as a bridge have been reported.[3–6]

There are only two $Cu^{II}$ complexes having a single aqua bridge in the CSD (July 2004). Interestingly, it has been shown that such a bridge can induce spin-exchange interactions between the linked $Cu^{II}$ centres.[3]

In our earlier articles, we have reported a mononuclear $Cu^{II}$ complex, its ferrocyanide-bridged pentanuclear complex[7] and a mononuclear $Co^{II}$ complex,[8] all containing the same Schiff base (LH), where the Schiff base acts as a tridentate chelating ligand. Here, the synthesis, structure, spectral properties and the magneto-structural correlation studies of the complex $[Cu_2(\mu_2\text{-}H_2O)L_2(H_2O)_2](ClO_4)_2{\cdot}2H_2O$ (**1**) are reported. An exchange interaction between the $Cu^{II}$ ions was found, and density functional calculations clearly establish that the main exchange does not proceed through the bridging $H_2O$ but is mediated by the intra-dimer H-bonds.

## Results and Discussion

The complex $[Cu_2(\mu_2\text{-}H_2O)L_2(H_2O)_2](ClO_4)_2{\cdot}2H_2O$ (**1**) was synthesised by mixing an aqueous solution of copper(II) perchlorate with a methanolic solution of the Schiff-base ligand LH, which was obtained by the condensation of 2-hydroxyacetophenone and 2-(dimethylamino)ethylamine.

### Crystal Structure of Complex 1

Complex **1** contains a cationic dimeric unit consisting of two $\{Cu(L)(H_2O)\}^+$ moieties bridged by one water molecule. The dinuclear cation is positioned on the twofold rotation axis of the unit cell (orthorhombic, *Fdd*2), which is shown in Figure 1. The two perchlorate counterions present in the lattice show threefold disorder. The unique $Cu^{II}$ atom adopts a (4+1) square-pyramidal geometry, formed by an O,N,N-tridentate Schiff base and an O atom of a water

molecule in the basal plane. The apical position is occupied by the oxygen atom (O3) of the bridging water molecule. The resulting dimer, which contains one bridging water molecule, is reinforced by intra-dimer H-bonds between the $H_2O$ ligand (O2) in an equatorial position and the phenolate O atom (O1) of the adjacent $Cu^{II}$ unit [O1···O2 = 2.627(9) Å; Figure 2 and Table 1]. A number of intermolecular hydrogen bonds are also formed between the dimeric cations, the solvate $H_2O$ molecules and the $ClO_4^-$ ions. The coordination polyhedra of the two central $Cu^{II}$ atoms in **1** are uniformly square-pyramidal. The equatorial Cu1–O2(water) bond length in the basal plane of the pyramid is decreased to 1.980(8) Å (see Table 2) and the apical Cu1–O3 bond length is increased to 2.496(7) Å, resembling a Jahn–Teller effect. The Cu–O(water) lengths are comparable to the average lengths (1.95 and 2.43 Å) of these bonds in related Cu complexes reported in the Cambridge Structural Database (version 5.25.3). The Cu1–N2(imine) bond is shorter [1.959(8) Å] than the Cu1–N1(amine) bond [2.018(9) Å].

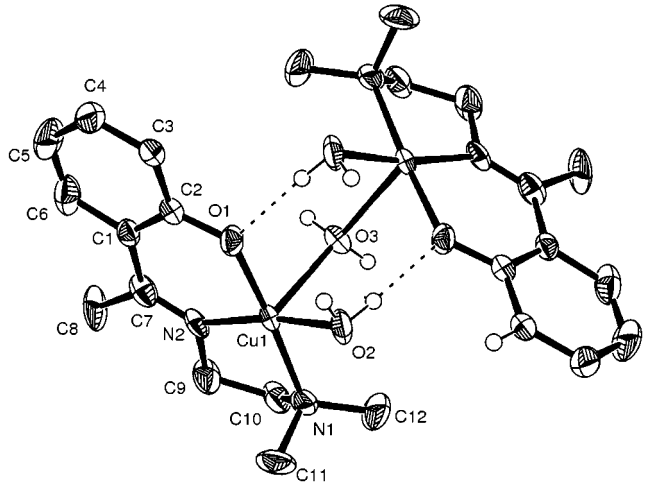

Figure 1. ORTEP view of the dinuclear cation of **1** positioned on the twofold axis of the unit cell.

The phenoxo oxygen atom (O1) is deprotonated, producing a negative charge on the Schiff-base moiety. The square base of each polyhedron is nearly planar, with the Cu atoms being shifted by 0.1171 Å from the mean plane containing the four basal atoms in the direction of the oxygen atom (O3) of the bridging water molecule. The least-squares deviations of the basal atoms from their mean plane are –0.0414, 0.0421, –0.0420 and 0.0414 Å for N1, N2, O1 and O2, respectively. The benzene ring and the six-membered metallochelate ring are puckered. The dihedral angle between the planes of the six-membered and five-membered metallochelate rings is 6.32°. The Cu–Cu distance in the dimer is 4.079 Å.

The perchlorate counterion shows threefold disorder. The disordered perchlorate counterion, the two lattice waters as well as the coordinated terminal and bridging water molecules are extensively hydrogen-bonded. The multiple hydrogen bonds are shown in Figure 2 and the interactions are listed in Table 1.

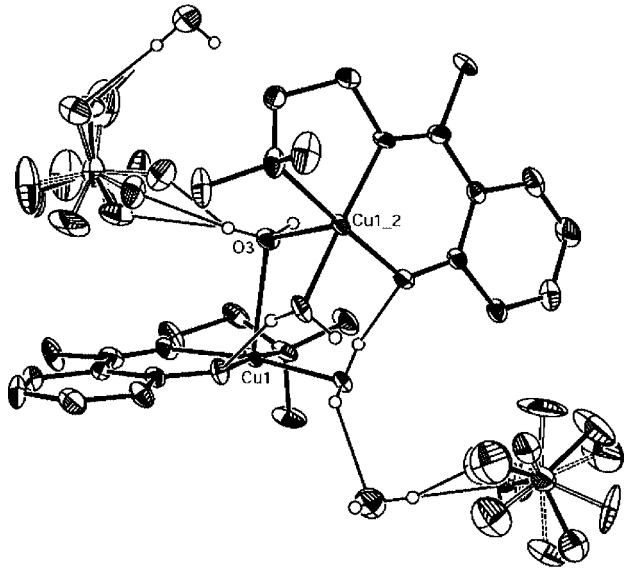

Figure 2. View of the hydrogen bonding (thin lines) in compound **1** ($ClO_4^-$ is threefold disordered).

### Spectroscopic Properties

The IR spectrum of complex **1** shows a sharp band at 1600 $cm^{-1}$ assigned to the δ(H–OH) mode. Again, a band at 410 $cm^{-1}$ may be assigned to the $\rho_W(H_2O)$ mode and the bands at 846 and 857 $cm^{-1}$ to the $\rho_r(H_2O)$ vibrations, thereby showing presence of both coordinated and uncoordinated lattice water in the complex.[9] This also confirms the presence of hydrogen bonding in the complex.[10] The strong $\nu_{C=N}$ band occurring at 1635 $cm^{-1}$, which is shifted considerably towards lower frequencies compared to that of the free Schiff base (1650 $cm^{-1}$), suggests coordination of the imino nitrogen atom. The phenolic stretching band is found at 1258 $cm^{-1}$. The band at 1160 $cm^{-1}$ for the $\nu_3(F_2)$ $ClO_4^-$ mode is broadened and split, thus indicating the involvement of this anion in hydrogen bonding, as established from the X-ray analysis.[11] Ligand coordination to the metal centre is substantiated by two bands appearing at 405 and 332 $cm^{-1}$ for $\nu_{M-N}$ and $\nu_{M-O}$, respectively.

The electronic spectroscopic data for **1** in acetonitrile solvent are in good agreement with its geometry. A charge-transfer transition (CT) in the range 400–360 nm may be assigned to a ligand-to-metal charge-transfer transition. Much weaker, less well-defined shoulders are found in the lower energy region and are associated with d–d transitions. The d–d bands generally fall below 700 nm and are more consistent with a square-pyramidal geometry for **1**, as in certain related $Cu^{II}$ complexes.[12]

### Magnetic Properties

The temperature dependence of the molar magnetic susceptibility, $\chi_M$, for compound **1** was measured on a polycrystalline sample in the temperature range 2–300 K. The plot of $\chi_M T$ vs. $T$ for the dinuclear $Cu^{II}$ compound is shown in Figure 3. At 300 K the value of $\chi_M T$ is 0.76 $cm^3 K mol^{-1}$, in good agreement with the value expected for two non-interacting $Cu^{II}$ ions. This value decreases very slightly as the temperature is lowered to 100 K, and below this temperature it decreases rapidly to reach 0.03 $cm^3 K mol^{-1}$ at 2 K, thereby revealing the occurrence of antiferromagnetic interactions between the $Cu^{II}$ centres. A classical Bleaney–Bowers law, using the phenomenological Hamiltonian $H = -J\boldsymbol{S}_1 \cdot \boldsymbol{S}_2$, is suitable to simulate the magnetic behaviour for compound **1**, the resulting expression for $\chi_M T$ is given below. The best fit of this expression to the experimental data yields the exchange parameter $J = -13.23 \pm 0.01$ $cm^{-1}$ with $g = 2.03$.

$$\chi_M T = \frac{2Ng^2\beta^2}{k[3 + \exp(-J/kT)]}$$

The structural data for compound **1** indicate that the bridging $H_2O$ ligand is connected in an apical position to both the linked Cu ions. As a consequence, there is no overlap with the magnetic orbitals of the metal centres and the exchange interaction through this bridging ligand is expected to be very weak.[13] The magnitude found for $J$ is thus surprisingly high and suggests the occurrence of alternative exchange pathways. In order to clarify the origin of this magnetic coupling, density functional calculations were carried out.

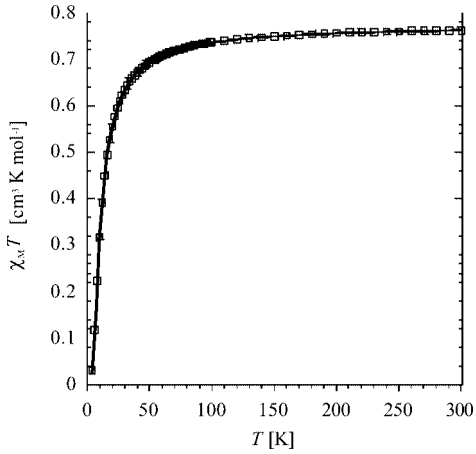

Figure 3. Experimental (□) and calculated (−) temperature dependence of $\chi_M T$ for compound **1**.

### Computational Methodology for the Density Functional Calculations

The calculated coupling constant, $J$, was deduced from two separate density functional computations carried out for the highest-spin state (triplet state for compound **1**) and for the broken-symmetry state. The hybrid B3LYP[14] functional was used, as implemented in Gaussian98.[15] The basis set used in all calculations was the triple-ζ basis-set proposed by Ahlrichs et al.[16] for transition metals and the double-ζ basis set proposed by the same authors for the other atoms.[17] The obtained $J$ values were deduced from the energy difference $E_{HS} - E_{BS} = -J$, where $E_{HS}$ and $E_{BS}$ are the energies of the high-spin and broken-symmetry states, respectively. We consider that the energy of the broken-symmetry state is a good approximation of the low-spin state energy, according to Ruiz et al.[18] The spin densities on the atoms were calculated according to the NBO method.[19]

#### *DFT Calculations for Compound 1*

Sets of calculations were carried out for the whole Cu dimer of compound **1** and for the same dimer but without the bridging $H_2O$ molecule. The isotropic interaction parameters that were obtained in both cases were very similar ($J = -8.1$ and $-7.9$ $cm^{-1}$, respectively), in rather good agreement with the experimental exchange parameter. The spin

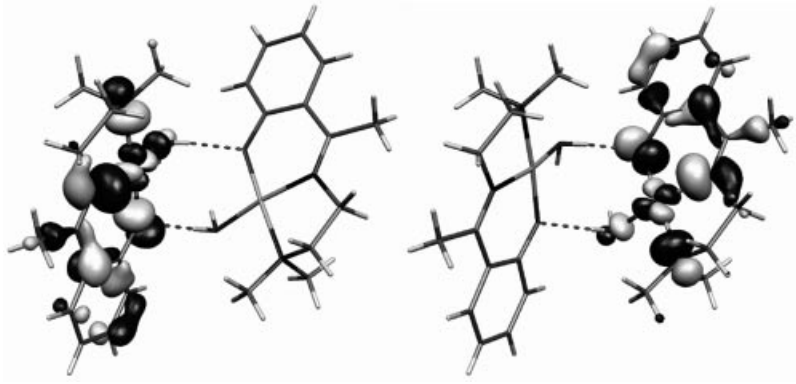

Figure 4. Localised magnetic orbitals issuing from the broken symmetry of the dehydrated compound.

density found on the two equivalent copper atoms is +0.577, whereas that located on the oxygen atoms is +0.116 for O1, +0.051 for O2 and –0.0007 for O3.

The negligible spin density on the bridging oxygen atom is in line with the very small difference in the calculated $J$ values for a dimer with and without a bridging $H_2O$ ligand. This result clearly confirms that the bridging water molecule is in no way responsible for the magnetic behaviour exhibited by the complex. In order to rationalise this behaviour, the localised magnetic orbitals issuing from the broken-symmetry state were scrutinised. These orbitals are represented in Figure 4 for the complex without the bridging $H_2O$ ligand (those of the $H_2O$-bridged system have exactly the same shapes). As expected from simple ligand-field models, the magnetic orbitals are directed towards the four short Cu–N/O distances. Indeed, in a square-pyramidal environment ($C_{4v}$ point group), the five d orbitals split into four sets: $d_{xz}$ and $d_{yz}$ (e); $d_{yx}$ ($b_2$); $d_{z^2}$ ($a_1$); and $d_{x^2-y^2}$ ($b_1$). As it is the only orbital involved in four bonds, the $d_{x^2-y^2}$ orbital has the highest energy and is singly occupied in a $d^9$ configuration. This explains the negligible influence of the bridging water molecule, which is in an apical position and therefore has no overlap with the magnetically active orbitals of the $Cu^{II}$ ions. Conversely, a significant amount of spin density is found on the oxygen atoms located in the equatorial positions (O1 and O2). The hydrogen bonds linking these atoms within a dimer (dashed lines in Figure 4) may thus provide an alternative pathway for the magnetic interaction between the two $Cu^{II}$ centres.[20] As a matter of fact, doubly H-bridged copper dimers can exhibit experimental coupling constants between limiting values of –4[21] and –94 $cm^{-1}$.[22] Different intermediate values have also been reported,[23] as well as density functional calculations on these dimers.[24] For compound **1**, the relatively weak exchange interaction is essentially due to the fact that the two basal planes of the copper geometry are not coplanar. This reduces the overlap of the magnetic orbitals, which causes decreased interactions between the two coppers centres.

This study clearly establishes that the main exchange interaction for compound **1** proceeds through the hydrogen bonds existing within the dimer, whereas the $H_2O$ ligand bridging the two Cu ions has a poor contribution.

## Conclusions

A rare example of a [(Schiff-base)$Cu^{II}$] dimer with a single $H_2O$ ligand bridging the two metal ions has been characterised. A striking feature of this compound is the absence of the $\mu_2$-coordination of the phenolato oxygen atoms often observed for such compounds. Instead, these atoms are involved in hydrogen bonds with the adjacent Cu unit, which reinforce the cohesion of the dimer. These hydrogen bonds are also the pathway for the antiferromagnetic interaction ($J$ = –13.2 $cm^{-1}$) between the Cu centres of the dimer. This is strongly supported by density functional calculations, which show that the contribution of the $H_2O$ bridge is negligible.

## Experimental Section

**Materials:** 2-Hydroxyacetophenone, 2-(dimethylamino)ethylamine and copper perchlorate were used as supplied by Aldrich. All other chemicals or solvents used were of reagent or analytical grade and used without further purification.

**Synthesis of the Ligand and Complex:** ***Caution!*** *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only a small amount of the material should be prepared and should be handled with caution*. The ligand LH was prepared by refluxing 2-hydroxyacetophenone (0.60 mL, 5 mmol) and 2-(dimethylamino)-ethylamine (0.545 ml, 5 mmol) in methanol (30 mL) for 0.5 h. The resulting mixture gave a yellow solution containing the tridentate ligand (LH). The ligand was used without further purification. The complex $[Cu_2(\mu_2\text{-}H_2O)L_2(H_2O)_2](ClO_4)_2{\cdot}2H_2O$ (**1**) was prepared by slowly adding 10 mL of a methanolic solution of LH (2 mmol) to 20 mL of an aqueous solution of copper(II) perchlorate (0.740 g, 2 mmol). The mixture was kept at room temperature. After a few days, green crystals of **1** had formed on slow evaporation of the solvent. Crystals suitable for X-ray diffraction were collected. Yield: 0.541 g (65%). $C_{24}H_{44}Cl_2Cu_2N_4O_{15}$ (826.61): calcd. C 34.9, H 5.4, N 6.8; found C 34.2, H 5.3, N 6.1.

**Physical Measurements:** Elemental analyses were carried out using a Perkin–Elmer 2400 II elemental analyser. The IR spectrum was recorded with a Perkin–Elmer Spectrum RX FTIR instrument in the range of 4000–350 $cm^{-1}$ as KBr pellets. The electronic spectrum was measured with a Perkin–Elmer Lambda-40 (UV/Vis) spectrophotometer in dichloromethane. Magnetic susceptibility measurements were carried out with a Quantum Design MPMS-5S SQUID

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

magnetometer under an applied magnetic field of 5000 Oe. Magnetic data were corrected for diamagnetic contributions estimated from Pascal tables and for the sample holder contribution.

**X-ray Data Collection and Structure Refinement:** Single crystals of the copper complex ($0.29 \times 0.22 \times 0.04$ mm) were grown from a methanol/water medium. Diffraction measurements were carried out at 153(2) K with an Enraf–Nonius CAD-4 MACH 3 diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å): orientation matrices and unit-cell parameters from the setting angles of 25 centred medium-angle reflections; collection of the diffraction intensities by ω scans. The structure was solved by direct methods and subsequently refined by full-matrix least-squares procedures on $F^2$ with allowance for anisotropic thermal motion of all non-hydrogen atoms by employing the WinGX package[25] and the relevant programs (SIR-97,[26] SHELXL-97,[27] ORTEP-3[28]) implemented therein. All hydrogen atoms were positioned geometrically and allowed to ride on their parent atoms with isotropic displacement parameters fixed at 1.2-times $U_{eq}$ of their parent atoms. $C_{24}H_{44}Cl_2Cu_2N_4O_{15}$ (826.61); orthorhombic, *Fdd*2, $a$ = 18.853(4), $b$ = 36.452(8), $c$ = 9.816(2) Å, $V$ = 6746(2) Å$^3$, $Z$ = 8, $d_{calcd.}$ = 1.628 Mg m$^{-3}$, $\mu$(Mo-$K_\alpha$) = 1.493 mm$^{-1}$; $F$(000) = 3424; $2.23° \leq \Theta \leq 25.56°$, 2482 reflections collected ($-2 \leq h \leq 22$, $-2 \leq k \leq 44$, $-2 \leq l \leq 11$; including Friedel pairs), 2075 independent reflections ($R_{int}$ = 0.0988); Completeness to $\theta$ = 25.56°: 100.0%; absorption correction: none; 267 parameters and 121 restraints ($ClO_4^-$ anion as geometrically idealised tetrahedron); final $R$ indices [$I > 2\sigma(I)$]: $R_1$ = 0.0629, $wR_2$ = 0.1738; $R$ indices (all data): $R_1$ = 0.0825, $wR_2$ = 0.1853; absolute structure parameter $x$ = –0.01(4);[29] largest difference peak/hole: 0.844/–1.478 e Å$^{-3}$. CCDC-279057 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# An Experimental and Theoretical (DFT) Investigation of the Coordination Mode of 2,4-Dithiouracil (2,4-dtucH$_2$) in Copper(I) Complexes with 1,2-Bis(diphenylphosphanyl)benzene (dppbz): The Crystal Structures of [Cu(μ-Br)(dppbz)]$_2$ and [CuBr(dppbz)(2,4-dtucH$_2$)]

**Paraskevas Aslanidis,*[a] Philip J. Cox,[b] Andreas Kaltzoglou,[a] and Athanasios C. Tsipis*[c]**

**Keywords:** Copper / Density functional calculations / Phosphane ligands / S ligands

Novel copper(I) mixed-ligand complexes containing 1,2-bis(diphenylphosphanyl)benzene (dppbz) and 2,4-dithiouracil (2,4-dtucH$_2$) ligands have been synthesised by addition of the thione ligand to the dinuclear [Cu(μ-X)(dppbz)]$_2$ intermediate in acetonitrile/methanol or acetone solution. The molecular structures of both the precursor [Cu(μ-Br)(dppbz)]$_2$ and the [CuBr(dppbz)(2,4-dtucH$_2$)] complexes were established by single-crystal X-ray diffraction. Interestingly, the structure of the thione-free dimer involves two diphosphane-chelated Cu$^I$ centres bridged by two bromide ligands, thus forming a non-planar Cu$_2$Br$_2$ core. The structure of [CuBr(dppbz)(2,4-dtucH$_2$)] corresponds to a four-coordinate Cu$^I$ centre in a tetrahedral coordination environment with the heterocyclic dithione ligand being coordinated to the metal centre in a unidentate fashion through its exocyclic sulfur donor atom. The structural, bonding and electronic properties of the model complexes [Cu(μ-X)(dppbz)]$_2$ and [CuX(dppbz)(2,4-dtucH$_2$)] (X = Cl, Br, or I) are adequately described by DFT/B3LYP computational techniques. All model dinuclear [Cu(μ-X)(dppbz)]$_2$ complexes exhibit π-type MOs delocalised over the entire four-membered Cu(μ-X)$_2$Cu ring, thereby accounting for the near equivalency of the Cu–X bonds. Moreover, the [Cu(μ-X)(dppbz)]$_2$ dimers possess a σ-type MO corresponding to weak Cu···Cu bonding interactions, which further stabilize the Cu(μ-X)$_2$Cu ring. According to our calculations, the interaction energies of the 2,4-dtucH$_2$ ligand with the Cu$^I$ centre are predicted to be about 13–16 kcal mol$^{-1}$. The coordination of the 2,4-dtucH$_2$ ligand is further stabilized by an X···H–N hydrogen bond that is perpendicular to the plane of the dppbz ligand.

## Introduction

The coordination chemistry of heterocyclic thiones has grown enormously in the recent past, mainly because of their relevance to biological systems.[1,2] The salient feature of these heterocyclic thioamides is their ability to bind to a metal centre in a variety of coordination modes. Along these lines a wealth of complexes exhibiting variable nuclearities and often unusual geometries have been synthesised and studied so far.[1–7] A large number of mixed-ligand complexes of the univalent coinage metals, particularly those of Cu$^I$, incorporating tertiary arylphosphanes as a second, bulky soft donor ligand have been thoroughly investigated in an attempt to understand the factors that may affect the stoichiometric and geometrical preferences of these compounds.[3] In this context, some examples of three-coordinate Cu$^I$ complexes, where the steric requirements of the phosphane ligands exert an influence on the coordination number, have also been reported.[4] Moreover, a number of halo- or thione-S-bridged dinuclear mixed-ligand complexes have been synthesised and structurally well characterised.[3,5] In contrast to the monodentate triarylphosphanes, didentate P-donor ligands, especially the oligomethylene-backboned symmetric diphosphanes formulated as Ph$_2$P(CH$_2$)$_n$PPh$_2$ ($n$ = 1, 2 or 4), favour the formation of dinuclear complexes.[6] On the other hand, the rigid *cis*-1,2-bis(diphenylphosphanyl)ethane (*cis*-dppen) and 1,3-bis(diphenylphosphanyl)propane (dppp) have been found to chelate at a single metal centre, yielding mononuclear pseudo-tetrahedral Cu$^I$ species.[7] Another didentate P-donor ligand capable of forming chelate five-membered symmetric rings is the sterically demanding 1,2-bis(diphenylphosphanyl)-benzene, hereafter abbreviated as dppbz. Although dppbz has already been used extensively as a chelating ligand for many metal centres,[8] no structurally characterised Cu$^I$ or Ag$^I$ derivatives of this rigid diphosphane, as far as we know, are currently known.

Among the heterocyclic thiones, the coordination properties of the thio derivatives of uracil, such as 2-thiouracil

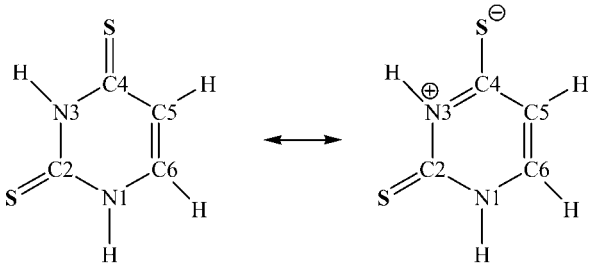
(2-tucH$_2$), 4-thiouracil (4-tucH$_2$) and 2,4-dithiouracil (2,4-dtucH$_2$) are of particular interest as these ligands have significant biological interest.[9] Very recently, the gas-phase reactivity of uracil, 2-tucH$_2$, 4-tucH$_2$, and 2,4-dtucH$_2$ towards $Cu^+$ and $Cu^{2+}$ cations has been thoroughly investigated using electronic structure calculation methods.[10] In this work we report on the synthesis, characterisation and electronic structure calculations of new copper(I) coordination compounds bearing dppbz and/or 2,4-dtucH$_2$ as ligands. In effect, what we want to address here is the coordination bonding mode of the versatile 2,4-dtucH$_2$ ligand (Scheme 1), which has two exocyclic sulfur donor atoms of different basicity that are capable of coordinating to $Cu^I$ metal centres.



Scheme 1. Resonance structures of 2,4-dtucH$_2$.

## Results and Discussion

### Synthesis

The new compounds were prepared following a synthetic pathway that has already produced a number of mixed-ligand copper(I) halide complexes. Thus, 1 mmol of CuCl or CuBr was first treated with an equimolar quantity of dppbz to yield an intermediate adduct formulated as [CuX(dppbz)] (X = Cl, Br). This intermediate was then allowed to react with one equivalent of 2,4-dtucH$_2$ in refluxing dry acetonitrile for 2 h to afford the corresponding pure mixed-ligand complexes [CuX(dppbz)(2,4-dtucH$_2$)] (X = Cl: **1**; Br: **2**) in good yields. During the reaction of 2,4-dtucH$_2$ with CuBr, a small quantity of greenish yellow crystals was separated at the initial stages of the evaporation of the diluted acetonitrile mother liquid; their analytical and spectroscopic data were identical to those of the [CuBr(dppbz)] intermediate. In this way we were able to characterise the intermediate by X-ray crystallography as the thione-free dimer [CuBr(dppbz)]$_2$ (**3**). It should be noted that **3** is inert in the reactions with a number of heterocyclic thiones [e.g. 5-methyl-1,3,4-thiadiazole-2-thione (mtdztH) or 4-methyl-5-trifluoromethyl-4*H*-1,2,4-triazoline-3(2*H*)-thione (mftztH)]. Treatment of CuI with equimolar quantities of dppbz readily yielded the intermediate 1:1 adduct [CuI(dppbz)]$_x$ (**4**) as a white microcrystalline solid, which, however could not be converted into the corresponding [CuI(dppbz)(2,4-dtucH$_2$)] (**5**). Compound **5** was obtained following a reverse synthetic procedure, i.e., by adding a twofold excess of the 2,4-dtucH$_2$ ligand to a $Cu^I$ solution, followed by addition of dppbz. The orange-red precipitate formed before adding dppbz probably corresponds to the polymeric species [CuI(2,4-dtucH$_2$)]$_x$ (**6**), which depolymerises upon addition of dppbz to give **5** as an orange solid. The analogous polymeric species [CuBr(2,4-dtucH$_2$)]$_x$ (**7**) was also isolated as an orange-red powder following the same synthetic procedure. To investigate the ability of 2,4-dtucH$_2$ for further coordination to CuX through both exocyclic thione-S donor atoms, a series of reactions using variable stoichiometries and reaction conditions were carried out, but in all cases $Cu^I$ complexes involving 2,4-dtucH$_2$ coordination in the mono-hapto or $\mu_2$-coordination mode via the S donor atom at the 4-position were isolated.

All new complexes are diamagnetic, air-stable, microcrystalline solids that are moderately soluble in acetonitrile and only marginally soluble in chloroform and acetone. Their solutions in acetone and chloroform are non-conducting. The stoichiometry and structure of the complexes were confirmed by elemental analysis and spectroscopic measurements. Moreover, the molecular structures of [CuBr(dppbz)(dtucH$_2$)] (**2**) and [CuBr(dppbz)]$_2$ (**3**) were determined by X-ray crystallographic analyses.

### Spectroscopy

The electronic absorption spectra of the new compounds in chloroform solution at room temperature show an intense, broad band with maxima in the region of 243–255 nm, which can be attributed, with reference to the absorption bands of the uncoordinated dppbz, to intraligand $\pi^*\leftarrow\pi$ transitions on the phenyl groups of the phosphane ligand. Moreover, the spectra of compounds **1**, **2** and **5**–**7** display an additional broad band in the region of 285–310 nm, where the free thiones normally absorb. This band experiences a small red-shift as a consequence of the coordination to $Cu^I$ and may be ascribed to a thione-originating intraligand transition. The IR spectra of compounds **1**–**3**, **6** and **7**, recorded in the range 4000–250 cm$^{-1}$, all show the expected strong phosphane bands, which remain practically unshifted upon coordination. Moreover, the spectra of compounds **1**, **2** and **4**–**7** contain all of the bands required by the presence of the heterocyclic thione ligand, with shifts due to coordination indicative of an exclusive S-coordination mode.

### X-ray Structural Investigations

The X-ray crystal structures of [CuBr(dppbz)(dtucH$_2$)] (**2**) and [Cu(μ-Br)(dppbz)]$_2$ (**3**) corroborate the spectroscopic results discussed above. Selected bond distances and angles of complexes **2** and **3** are listed in Tables 1 and 2, respectively.

Compound **2** crystallises in the monoclinic space group $P2_1/c$ with four formula units in the unit cell. Figure 1 depicts a perspective of the molecule showing the atom-labelling scheme.

The tetrahedral environment of the copper atom formed by the two P atoms of the chelating dppbz unit, one Br and one of the two exocyclic S donor atoms of the dithione ligand is considerably distorted, with the largest deviation from the ideal geometry being reflected by the P(1)–Cu(1)–P(2) and P(1)–Cu(1)–Br(1) angles of 86.61(2)° and 122.05(19)°, respectively, which are markedly different from the ideal tetrahedral value of 109.4°.

As expected, the carbon atoms of the phenylene backbone and the two adjacent phosphorus atoms are coplanar and the CuPCCP five-membered ring adopts an envelope conformation with the metal atom out of the plane containing the four diphos ligand donor atoms by 1.034(1) Å. The two phenyl rings on each phosphorus atom are nearly perpendicular to each other. However, the C(17)–C(22) and C(29)–C(34) phenyl rings have their planes in an almost parallel arrangement, with a π-stacking interaction of 3.827(1) Å between them. Likewise, the inclination of the pyrimidine ring to the C(11)–C(16) phenyl ring results in a π-stacking interaction of 4.116(1) Å. The two Cu–P distances [2.2393(6) and 2.2953(6) Å] are significantly different, but are within the limits of the range expected for tetrahedrally coordinated $Cu^I$.

The coordinated 2,4-dithiouracil ligand, which adopts its most stable dithione tautomeric form (**a**, Scheme 1) is coordinated to the $Cu^I$ metal centre in a monodentate coordination mode through the S atom in the 4-position. Considering that the corresponding carbon–sulfur bond of the uncoordinated 2,4-dtuc$H_2$ has been found to be significantly longer than that in the 2-position [1.684(6) vs. 1.645(6) Å],[11] the favourable coordination of that specific sulfur atom can be interpreted as the inevitable consequence of its strong polarisation towards the amidic [–$HN^+$=C($S^-$)–] configuration (**b**). However, coordination to $Cu^I$ does not affect these two bond lengths significantly.

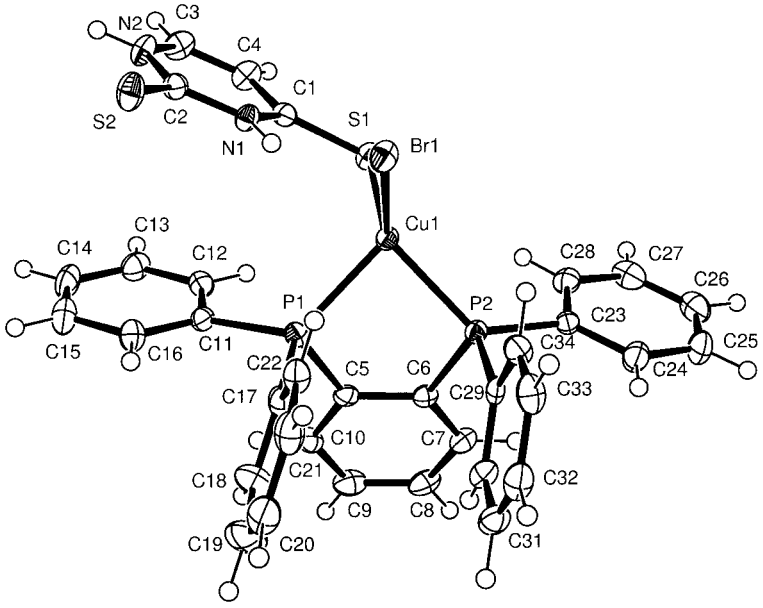

Figure 1. Structure of complex **2** together with the atom-labelling scheme (50% probability ellipsoids with hydrogen atoms omitted for clarity).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

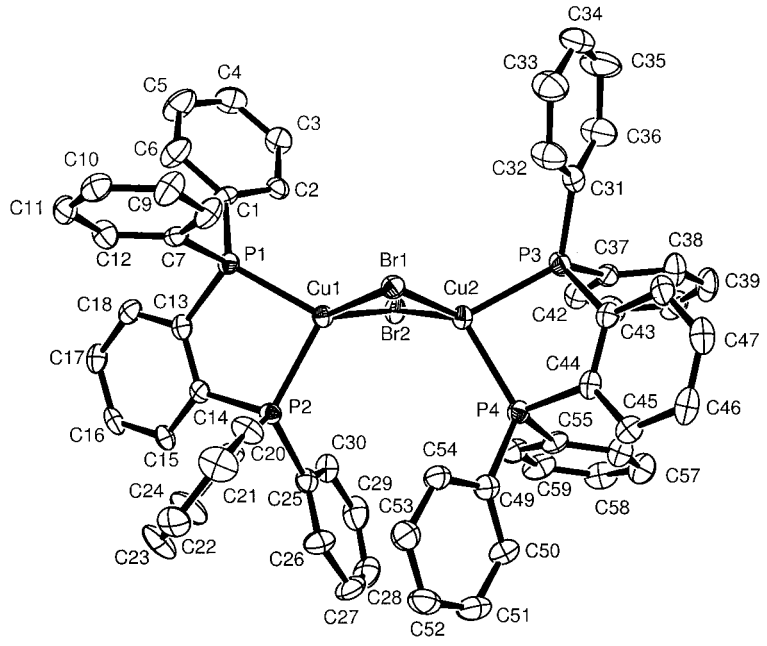

Figure 2. Structure of complex **3** together with the atom-labelling scheme (50% probability ellipsoids with hydrogen atoms omitted for clarity).

Likewise, the structural parameters within the heterocyclic backbone remain practically unaffected upon coordination.

Light-green single crystals of **3** were grown from the acetonitrile/methanol mother liquid of **2** during the earlier stages of the slow evaporation. Complex **3** crystallises in the monoclinic space group $P2_1$ with two formula units in the unit cell. The structure of **3**, together with the atom-labelling scheme, is shown in Figure 2.

The crystal structure features a dinuclear unit in which the two copper(I) centres are joined by two bromine bridges to form a four-membered $Cu_2Br_2$ core with a Cu···Cu separation distance of 2.8410(6) Å, which is suggestive of a weak metal–metal interaction, as further substantiated by the electronic structure calculations (vide infra). The strongly distorted tetrahedral coordination around each copper(I) central atom is completed by the two P donor atoms of the chelating dppbz unit.

The most salient, and quite unexpected, feature of the structure is the remarkable non-planarity within the $Cu_2Br_2$ central core. Unlike in other bromide-bridged dinuclear complexes that exhibit a strictly planar $Cu_2Br_2$ core, such as $[Cu(\mu_2\text{-Br})(tmtp)(tzdtH)]_2$ (tmtp = tri-*m*-tolylphosphane),[5] the two main planes in **3** through Br(1), Cu(1), Br(2) and Br(1), Cu(2), Br(2) form a dihedral angle of 150.10(2)°, with Br(2) being displaced from the mean plane defined by Cu(1), Br(1) and Cu(2) by 0.7201(8) Å. The same uncommon non-planarity adopted by the $Cu_2I_2$ moiety previously observed in $[Cu(\mu_2\text{-I})(dppet)]_2$ [dppet = *cis*-1,2-bis(diphenylphosphanyl)ethane] is noteworthy.[7b]

Each of the two CuPCCP five-membered chelate rings adopts the envelope conformation with the metal atoms out of the plane containing the four diphos ligand donor atoms by 0.665(3) and –0.951(2) Å for Cu(1) and Cu(2), respectively. Consequently, the bite angles of the two diphosphane units (Table 2) are clearly different, with the larger intraligand P–Cu–P angle belonging to the more distorted $C_2P_2Cu$ ring. The four individual Cu–P bonds lie in the narrow range of 2.2546(11)–2.2600(11) Å and match those observed in $[Cu(dppet)_2]PF_6$,[12] as well as in other copper(I)–diphosphane complexes having a tetrahedral coordination environment.[6,7] Moreover, there are four clearly different Cu–Br bond lengths within the $Cu_2Br_2$ backbone, lying in the range 2.4279(6)–2.5316(6) Å.

## Computational Studies Using DFT

In an attempt to understand some marked structural features of the complexes under investigation, we performed electronic structure calculations based on density functional theory for compounds **2** and **3**, as well as for some related model species. To obtain a computationally convenient size for the compounds, we used models resulting from substitution of the phenyl groups of the diphosphane ligands by H atoms. The use of such models does not alter the description of the "core" region of the compounds and is ultimately the most efficient and productive route to modelling the electronic structure and related properties of relatively big-sized copper(I) complexes. In particular, we sought an explanation for the exclusive coordination of 2,4-dithiouracil through the thione-S atom at C(4) and explored the origin of the unexpected bend of the $Cu_2Br_2$ central core in compound **3**.

### *Equilibrium Geometries, Electronic Structure and Bonding Mechanism in the Series of Model Mononuclear Complexes [CuX(dpbz)] [X = Cl, Br, or I; dpbz = 1,2-bis(diphosphanyl)benzene]*

Selected structural and electronic properties of the mononuclear complexes [CuX(dpbz)] (X = Cl, **M1**; Br, **M2**; I,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**M3**) computed at the B3LYP/DGDZVP level of theory are given in Table 3.

All [CuX(dpbz)] species are three-coordinate $Cu^{I}$ complexes that adopt a trigonal planar structure with the central copper(I) atom and the three donor atoms lying in a plane. As is to be expected, the Cu–X bond lengths increase upon going from the chloro to bromo to iodo derivative, which is compatible with the computed $\nu$(Cu–X) stretching vibrational frequencies at 354, 260 and 235 $cm^{-1}$, respectively. However, no other significant structural differences could be observed for the [CuX(dpbz)] (X = Cl, Br or I) complexes. Based on the HOMO–LUMO energy gap − the hardness values ($\eta$) are shown in Table 3 − one would expect the tendency for dimerisation to follow the order **M3** > **M2** > **M1**.

The most relevant molecular orbitals of the mononuclear complexes [CuX(dpbz)] related to the bonding mechanism are depicted schematically in Scheme 2. According to the natural bond orbital (NBO) population analysis, the $Cu^{I}$ centre acquires a positive natural atomic charge of about 0.61–0.7 |e|. Moreover, the natural electron configuration (*nec*) indicates that the electron density is mainly transferred to the 4s orbital of the copper(I) atom. The nature of the halide ligand does not affect the natural electron configuration of the central $Cu^{I}$ atom significantly. Interestingly, the computed bond overlap populations (*bop*) of the Cu–Br, Cu–Cl and Cu–I bonds are of almost equal size.

It can be seen that the Cu–X bond is a composite bond that acquires a partial double-bond character involving both σ and π components. The HOMO corresponds to a π*-antibonding Cu–X interaction that is strongly polarized towards the halide ligand X. Below the HOMO there is a set of σ- (HOMO–2) and π-bonding MOs (HOMO–3 and HOMO–6) that correspond to Cu–X interactions as well as describing the σ and π dative bonding of the halide ligands. Finally, the LUMO is delocalised over the benzene ring of the diphosphane ligand.

### *Equilibrium Geometries, Electronic Structure and Bonding Mechanism of the Dinuclear Compounds [Cu(μ-X)-(dpbz)]$_2$ (X = Cl, Br or I)*

Selected structural parameters and electronic properties of the dinuclear compounds [Cu(μ-Cl)(dpbz)]$_2$ (**M4**), [Cu(μ-Br)(dpbz)]$_2$ (**M5**) and [Cu(μ-I)(dpbz)]$_2$ (**M6**) computed at the B3LYP/DGDZVP level of theory are compiled in Table 4.

[a] Hardness $\eta = (\varepsilon_{LUMO} - \varepsilon_{HOMO})/2$. [b] Natural charges. [c] Mulliken bond-overlap population. [d] Natural electron configuration.

As is to be expected, the dicopper(I) compounds adopt a "diamond like" structure of $C_{2h}$ symmetry with the plane of the Cu(μ-X)$_2$Cu "rhombus" bisecting the P–Cu–P bond angles and being perpendicular to the plane of the diphosphane ligands. The four equivalent Cu–X bonds defining the Cu(μ-X)$_2$Cu "rhombus" are elongated by about 0.2 Å compared to the corresponding Cu–X bonds of the monomers. The calculated structural parameters are in line with those of the "real" complex **3** derived from the X-ray structural analysis. However, the non-planarity of the $Cu_2Br_2$ central core of complex **3** is not observed for the $Cu_2X_2$ core in the optimised structures of the model compounds **M4**, **M5**, and **M6**, thus indicating that steric and/or crystal-packing effects in the solid state should be responsible for the $Cu_2Br_2$ folding across the Br···Br line and the non-equivalent coordination spheres around the two Cu$^I$ metal centres.

To verify this hypothesis, the rigid and relaxed PES of the "real" complex **3** and the model compound **M5** were calculated at the B3LYP/DGDZVP level of theory. It was found that the bending of the $Cu_2Br_2$ core in the "real" complex **3** and the model compound **M5** demands only 0.6 and 0.4 kcal mol$^{-1}$, respectively, thus indicating a very flat potential energy surface for both complexes. Therefore, factors such as the 4.298-Å π-stacking interaction between two almost parallel phenyl groups of the dppbz ligand could enforce the bending of the $Cu_2Br_2$ core in the real complex **3**. It should be noted that in an analogous dinuclear Ag$^I$ complex containing bulky diphosphane or diarsane ligands the folding of the Ag(μ-Br)$_2$Ag core has been attributed to steric strain in the crystal.[13] The intermetallic Cu···Cu distance follows the order **M4** > **M5** > **M6**, in line with our previous results[7a] on analogous systems with general formula [Cu(μ-X)(PH$_3$)$_2$]$_2$ (X = Cl, Br or I), as well to the observations made by Soloveichic et al.[14] in the framework of EHMO theory for the complexes [L$_n$Cu(μ-X)CuL$_n$] ($n$ = 1 or 2, L = PR$_3$). Alvarez et al.[15] have also found from MP2 and B3LYP calculations that the Cu···Cu distance in a series of [CuXL]$_2$ (X = Cl, Br or I) complexes decreases upon increasing the size of the bridging halide ligand. The X–Cu–X bond angle in **M6** was found to be more obtuse relative to that found for **M5** or **M4**, while the opposite holds true for the Cu–X–Cu bond angle (Table 4).

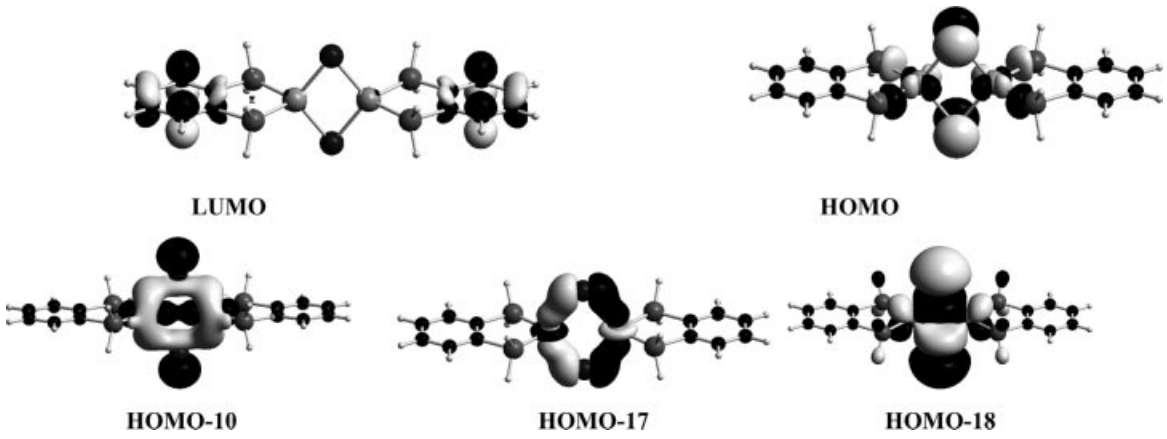
The computed $\nu_{sym}$(X–Cu–X) stretching vibrational frequencies at 140, 110 and 87 cm$^{-1}$ for the chloro, bromo and iodo derivatives, respectively, are compatible with the elongated Cu–X bonds in the dimers. The same also holds true for the computed $\nu_{sym}$(Cu–X–Cu) stretching vibrational frequencies at 202, 172 and 160 cm$^{-1}$ for **M4**, **M5** and **M6**, respectively.

All [Cu(μ-X)(dpbz)]$_2$ (X = Cl, Br, or I) molecules are predicted to be thermodynamically more stable than the corresponding monomers; the calculated heat of reaction $\Delta_R H$ for the dimerisation process was found to be 25–26 kcal mol$^{-1}$ at the B3LYP/DGDZVP level of theory. In addition, both **M4** and **M5** exhibit almost equal HOMO–LUMO energy gaps as well as hardness values, indicating comparable stability. On the other hand, **M6** exhibits the highest HOMO–LUMO energy gap and hardness value, and is expected to be the most stable amongst the [Cu(μ-X)(dpbz)]$_2$ (X = Cl, Br, or I) complexes.

No significant differences could be observed between the natural and net atomic charges on the Cu$^I$ bridging halide and phosphorus donor atoms of **M4**, **M5** and **M6** (Table 4). The Cu$^I$ metal centres acquire positive natural charges of about 0.6–0.8 |e|, while the halide bridging ligands acquire negative natural charges of around –0.7 |e|. According to the natural electron configurations, the electron density is mainly transferred from the valence p atomic orbitals of the bridging halide ligands to the 4s orbitals of the Cu$^I$ metal centres.

The most important MOs of the [Cu(μ-X)(dpbz)]$_2$ dimers are depicted in Scheme 3. The HOMO corresponding to π* antibonding Cu–X interactions is polarized towards the bridging halide ligands, while the LUMO is delocalised over the benzene rings of the diphosphane ligands. There

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. The most important molecular orbitals of the dinuclear complex $[Cu(\mu\text{-}Br)(dppbz)]_2$ (isodensity contours of 0.03 a.u.). The relevant MOs for $[Cu(\mu\text{-}Cl)(dppbz)]_2$ and $[Cu(\mu\text{-}I)(dppbz)]_2$ are analogous.

are σ-type MOs (HOMO–17 and HOMO–18) delocalised over the entire four-membered $Cu(\mu\text{-}X)_2Cu$ ring. The delocalisation of the σ-electron density over the $Cu(\mu\text{-}X)_2Cu$ rhombus having eight framework electrons[16] could probably account for the almost equivalent Cu–X bonds. Interestingly, all $[Cu(\mu\text{-}X)(dpbz)]_2$ dimers exhibit a σ-type MO (HOMO–10), which suggests the existence of weak intermetallic Cu···Cu interactions.

### *Equilibrium Geometries, Electronic Structure and Bonding Mechanism of Mononuclear [CuX(dpbz)(2,4-dtucH$_2$)] (X = Cl, Br or I) Complexes*

Selected structural parameters and electronic properties of the model compounds mononuclear [CuCl(dpbz)(2,4-dtucH$_2$)] (**M7**), [CuBr(dpbz)(2,4-dtucH$_2$)] (**M8**) and [CuI(dpbz)(2,4-dtucH$_2$)] (**M9**) computed at the B3LYP/DGDZVP level of theory are summarised in Table 5.

The complexes are four-coordinate with a tetrahedral coordination environment. The calculated structural parameters of **M8** are in excellent agreement with those obtained from the X-ray structural analysis of the "real" complex **2**. The most remarkable structural difference between **M8** and **2** is the orientation of the 2,4-dithiouracil ring − in **M7**, **M8** and **M9** the plane of the 2,4-dithiouracil ring is perpendicular to the plane of the diphosphane ligand and bisects the P–Cu–P bond angle. The 2,4-dithiouracil ligand in **M7**, **M8** and **M9** is further stabilized by a hydrogen bond between the halide ligand and an H atom of the 2,4-dithiouracil. The calculated X···H distances are predicted to be 2.113, 2.302 and 2.597 Å for **M7**, **M8** and **M9**, respectively. The H-bond formation is reflected in the computed X···H *bop* values, which were found to be 0.16, 0.14 and 0.12 for **M7**, **M8** and **M9**, respectively, as well as in the existence of a MO, with a σ component (Scheme 4, **b**), describing the

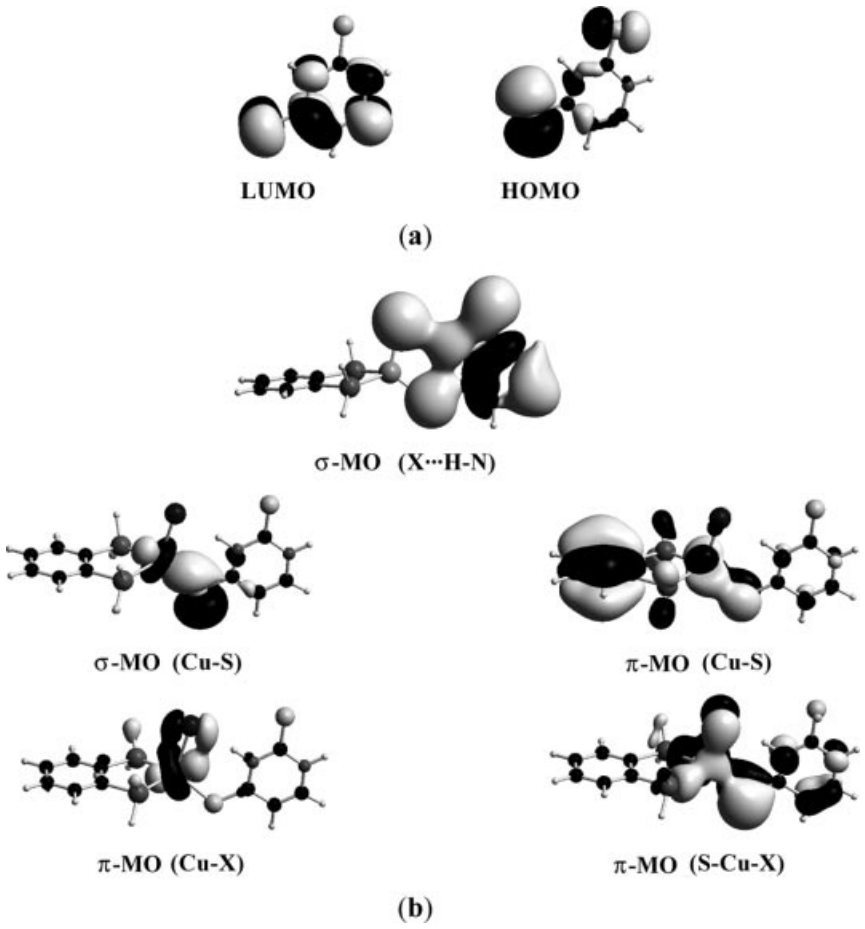

Scheme 4. The most important molecular orbitals of 2,4-dithiouracil (a) and the mononuclear compound [CuBr(dpbz)(2,4-dtucH$_2$)] (b) (isodensity contours of 0.03 a.u.). the relevant MOs for [CuCl(dpbz)(2,4-dtucH$_2$)] and [CuI(dpbz)(2,4-dtucH$_2$)] are analogous.

X···H interaction. The latter introduces an elongation to the N–H bond only about 0.03–0.02 Å in the 2,4-dithiouracil ligand with respect to that of the "free" ligand.

The computed unscaled *ν*(N–H) stretching vibrational frequencies appear at 3002, 3068 and 3160 cm$^{-1}$ for **M7**, **M8** and **M9**, respectively, while in the "free" 2,4-dithiouracil ligand it appears at 3564 cm$^{-1}$. The strong shift of the *ν*(N–H) stretching vibrational band towards lower frequencies upon coordination of the 2,4-dithiouracil ligand to the Cu$^{I}$ centre is indicative of the involvement of the H atom in H-bond formation with the halide ligand. In all [CuX(dpbz)(2,4-dtucH$_2$)] (X = Cl, Br, or I) complexes the X···H–N moiety is almost linear, the calculated X···H–N bond angle being equal to 175–177°. On the other hand, the S–Cu–X and Cu–S–C bond angles were found to be smaller, ranging from 114–120° and 110–114°, respectively. Coordination of 2,4-dithiouracil to the Cu$^{I}$ centre does not alter its structure significantly. However, in the [CuX(dpbz)(2,4-dtucH$_2$)] (X = Cl, Br, or I) complexes the coordination of the 2,4-dithiouracil through the S donor atom in the 4-position lengthens the C=S bond by about 0.03 Å. This could be attributed to electron-density transfer from the C=S group of the 2,4-dithiouracil ligand to the Cu$^{I}$ centre, leading to formation of the Cu–S coordination bond. The latter has a composite nature and exhibits both σ and π components, as can be seen from the corresponding MOs shown in Scheme 4b. The electron density is transferred from the HOMO of the 2,4-dithiouracil ligand, which is a non-bonding (lone pair) p-type MO localised mainly on the S donor atom at the 4-position and to a lesser extent on the S atom at the 2-position (Scheme 4a), to a vacant orbital of the Cu$^{I}$ metal centre, thus forming the σ(Cu←S) dative coordination bond. Obviously, the nature of the HOMO accounts well for the inability of the S atom at the 2-position to act as a second donor atom coordinated to another Cu$^{I}$ metal centre. In addition, there is π back-bonding through the interaction of an occupied orbital of the Cu$^{I}$ centre with the LUMO of the 2,4-dithiouracil ligand, which is a delocalised π*-type MO having a high contribution from the 3p orbitals of the S(4) acceptor atom (Scheme 4a). The Cu–S coordination bond is relatively weak, with a predicted bond-dissociation energy (BDE) of 16.2, 14.8 and 13.2 kcal mol$^{-1}$ for **M7**, **M8** and **M9**, respectively, at the B3LYP/DGDZVP level.

Upon coordination of the 2,4-dithiouracil ligand to the [CuX(dpbz)] (X = Cl, Br, or I) fragment the Cu–X bond is elongated by about 0.14–0.15 Å. This elongation is accompanied by a decrease of the *bop* values compared to those found for the [CuX(dpbz)] fragments. The coordination of the 2,4-dithiouracil to the Cu$^{I}$ centre of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[CuX(dpbz)] fragments does not affect the natural atomic charges significantly, while the same holds true for the natural electron configurations of the respective atoms.

## Conclusions

We have described the synthesis and structural characterisation of copper(I) coordination compounds bearing 1,2-bis(diphenylphosphanyl)benzene (dppbz) and/or 2,4-dithiouracil (2,4-dtucH$_2$) as ligands. The reaction of 1,2-bis(diphenylphosphanyl)benzene (dppbz) with copper(I) halides yields [CuX(dppbz)] adducts, which for X = Br corresponds to a dimer of the formula [Cu(μ-Br)(dppbz)]$_2$ containing a non-symmetrical, bent Cu$_2$Br$_2$ core structure. The Cu···Cu separation distance of 2.8410(6) Å is indicative of weak intermetallic interactions. The latter is further corroborated by DFT calculations on the model dinuclear compound [Cu(μ-Br)(dpbz)]$_2$, which exhibits a characteristic σ-type MO (HOMO-10) describing these weak intermetallic Cu···Cu interactions. However, the non-planarity of the central Cu$_2$Br$_2$ core is not observed for the Cu$_2$X$_2$ core in the optimised model structures, thus indicating that π-stacking interactions between the two almost parallel phenyl groups of the diphosphane ligand are probably responsible for the Cu$_2$Br$_2$ folding across the Br···Br axis. The presence of σ-type MOs delocalised over the entire four-membered Cu(μ-X)$_2$Cu ring containing eight framework electrons accounts for the equivalent Cu–X bonds of the rhombus. The dimerisation energy of the [Cu(μ-X)(dpbz)]$_2$ (X = Cl, Br, or I) dimers is predicted to be 25–26 kcal mol$^{-1}$ at the B3LYP/DGDZVP level. The [CuBr(dppbz)]$_2$ dimer and its chloride and iodide analogues prove to be good precursors for the preparation of other derivatives and are used, in the course of the present study, for the synthesis of heteroleptic complexes which contain, besides the chelating dppbz, a 2,4-dithiouracil ligand. In line with theoretical predictions, the 2,4-dithiouracil ligand, which adopts the dithione form as its stable conformation, acts as a monodentate ligand that is coordinated to the metal ion exclusively through its thione-S atom at the 4-position. The nature of the HOMO − a non-bonding, lone-pair, π-type MO localised mainly on the S donor atom at the 4-position − accounts well for the inability of the S atom at the 2-position to act as a second donor to another Cu$^{I}$ centre. Moreover, the 2,4-dithiouracil ligand in the [CuX(dpbz)(dtucH$_2$)] complexes is predicted to be loosely associated with the Cu$^{I}$ centre, the interaction energies being 13–16 kcal mol$^{-1}$ at the B3LYP/DGDZVP level.

## Experimental Section

**Materials and Instrumentation:** Commercially available copper(I) chloride, bromide and iodide, and 1,2-bis(diphenylphosphanyl)benzene were used as received, while pyrimidine-2,4-dithione (Aldrich) was recrystallised from hot ethanol prior to use. All the solvents were purified by standard methods and stored over molecular sieves. IR spectra in the region of 4000–200 cm$^{-1}$ were obtained in KBr discs with a Perkin–Elmer 1430 spectrophotometer, while a Perkin–Elmer–Hitachi 200 spectrophotometer was used to obtain the electronic absorption spectra. Melting points were measured in open tubes with a STUART scientific instrument and are uncorrected. Molar conductivities, magnetic susceptibility measurements and elemental analyses for carbon, nitrogen and hydrogen were performed as described elsewhere.[17]

**Computational Details:** The structural, electronic and energetic properties of all compounds were computed with Becke's three-parameter hybrid functional[18] combined with the Lee–Yang–Parr correlation functional,[19] abbreviated as B3LYP, using the DGDZVP basis set.[20] We used the all-electron, double-zeta valence DGDZVP basis set, which is comparable with the 6-31G(d) level,[21] because it has been found previously[22] that it provides a satisfactory description of the structural and energetic properties of analogous Cu$^{I}$ complexes (overall closer to the experiment) but it is less time consuming for computations with such big-sized transition metal complexes than the larger 6-31G(d,p) basis set. No constraints were imposed on the geometry in any of the calcualtions. Full geometry optimisation was performed for each structure using Schlegel's analytical gradient method[23] and the attainment of the energy minimum was verified by calculating the vibrational frequencies that result in an absence of imaginary eigenvalues. All calculations were performed using the Gaussian 03 suite of programs.[24]

**Crystal Structure Determination:** Single crystals suitable for crystal-structure analysis were obtained by slow evaporation of acetonitrile/methanol solutions of the complexes at room temperature. X-ray diffraction data were collected on an Enraf–Nonius Kappa CCD area-detector diffractometer. The programs DENZO[25] and COLLECT[26] were used for data collection and cell refinement, respectively. Details of crystal and structure refinement are shown in Table 6. The structures were solved using the program SIR97[27] and refined with SHELX-97.[28] Molecular plots were obtained with the program ORTEP-3.[29]
CCDC-243707 (for **2**) and -269670 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Complexes 1 and 2:** 1,2-Bis(diphenylphosphanyl)benzene (223.2 mg, 0.1 mmol) was added to a suspension of CuCl or CuBr (0.5 mmol) in 30 mL of dry acetonitrile and the mixture was stirred for 2 h at 50 °C, during which time a greenish precipitate was formed. A solution of pyrimidine-2,4-dithione (0.5 mmol) in a small amount (≈20 mL) of methanol was then added and the reaction mixture was stirred under reflux for two hours, whereupon the precipitate gradually disappeared. The resulting clear solution was filtered off and left to evaporate at ambient temperature. The microcrystalline solid, which was deposited upon standing for several days, was filtered off and dried in vacuo.

**[CuCl(dppbz)(2,4-dtucH$_2$)] (1):** Orange-red solid (125 mg, 70%), m.p. 261 °C. $C_{34}H_{28}ClCuN_2P_2S_2$ (689.70): calcd. C 59.21, H 4.09, N 4.06; found C 59.75, H 4.05, N 3.93. **Keywords:** Cluster compounds / Density functional calculations / Mass spectrometry / X-ray diffraction

The reaction of $PhSeSiMe_3$, CuCl, $InCl_3$, and $Ph_4AsCl$ in $CH_2Cl_2$ results in crystals of the structurally closely related, ionic clusters $(AsPh_4)_2[Cu_6In_4Cl_4(SePh)_{16}]$ and $(AsPh_4)[Cu_7In_4(SePh)_{20}]$, with product ratios dependent on the initial $PhSeSiMe_3$ concentration. Both molecules display a fused four-adamantoid structure related to the solid-state structure of $CuInSe_2$. Since the crystallographic analysis for $[Cu_7In_4(SePh)_{20}]^-$ remained ambiguous with respect to the assignment of one of the copper atoms, we performed a high-resolution mass spectrometric analysis as well as DFT computations to address this problem.

## Introduction

There has been considerable interest in the synthesis and properties of ternary transition metal chalcogenide and chalcogenolate cluster molecules. Examples for different classes of compounds include $[Cu_6In_3(SEt)_{16}](PPh_4)$,[1] $[M^I_6M^{III}_8Cl_4E_{13}(PPh_3)_6]$ ($M^I$ = Cu, Ag; $M^{III}$ = Ga, In; E = S, Se),[2] $[Cu_{11}In_{15}Se_{16}(SePh)_{24}(PPh_3)_4]$,[3] $[Ag_{26}In_{18}S_{36}Cl_6(dppm)_{10}(THF)_4][InCl_4(THF)]_2$,[4] $[Hg_{15}Cu_{20}S_{25}(P\text{-}nPr_3)_{18}]$,[5,6] $[Cu_4Nb_2Se_6(PMe_3)_8]$,[7] $[Ta_4Cu_{12}Cl_8S_{12}(PMe_3)_{12}]$[8] and $[(N,N,N',N'\text{-tmeda})_5Zn_5Cd_{11}Se_{13}(SePh)_6(THF)_2]$.[9] Interest in these compounds arises for several reasons: (a) investigation of the structural build-up of a certain composition of elements with respect to existing and nonexisting bulk phases, (b) development of precursor compounds for the production of thin films of ternary materials and (c) investigation of the properties of nano-sized species. With respect to (a), it was found that most of the cluster structures formed by elements of group 11–13–16 have, at this stage of growth, no resemblance to the bulk chalcopyrite structure of these materials. On the other hand, stable compounds such as $[Hg_{15}Cu_{20}S_{25}(PnPr_3)_{18}]$ could be formed for compositions of elements that have no stable counterpart in the bulk phase. Kanatzidis et al. studied the suitability of mixed copper indium chalcogenolates as precursor materials for the photovoltaic materials $CuInE_2$ (E = S, Se).[1,10] Corrigan et al. observed room-temperature fluorescence for the ternary 12–12′–16 cluster (12 = Zn; 12′ = Cd; 16 = Se), $[(N,N,N',N'\text{-tmeda})_5Zn_5Cd_{11}Se_{13}(SePh)_6(THF)_2]$,[9] while binary cadmium or zinc selenide clusters showed weak luminescence only at temperatures below 50 K. During recent studies, it was found that the investigation of these compounds containing complex mixtures of elements needs a combination of various investigative approaches to reach conclusions with confidence.[4]

We report herein the synthesis, structural characterization, and theoretical investigation of $[As(C_6H_5)_4]_2[Cu_6In_4(SeC_6H_5)_{16}Cl_4]$ and $[As(C_6H_5)_4][Cu_7In_4(SeC_6H_5)_{20}]$.

## Results and Discussion

### Synthesis and Structure Determination by X-ray Crystallography

Depending on the amount of $PhSeSiMe_3$ used, the reaction of CuCl, $InCl_3$ and $Ph_4AsCl$ in $CH_2Cl_2$ results in the formation of crystals of either $(AsPh_4)_2[Cu_6In_4Cl_4(SePh)_{16}]$ (**1**) or $(AsPh_4)[Cu_7In_4(SePh)_{20}]$ (**2**), as outlined in Scheme 1.

$$3\,CuCl + 2\,InCl_3 + Ph_4AsCl \xrightarrow[CH_2Cl_2]{+\,10\,PhSeSiMe_3} (AsPh_4)_2[Cu_6In_4Cl_4(SePh)_{16}]\ (\mathbf{1})$$

$$3\,CuCl + 2\,InCl_3 + Ph_4AsCl \xrightarrow[CH_2Cl_2]{+\,15\,PhSeSiMe_3} (AsPh_4)[Cu_7In_4(SePh)_{20}]\ (\mathbf{2})$$

Compound **1** crystallizes in the triclinic space group $P\bar{1}$ (Table 1). The tetrahedrally shaped core of the cluster anion in **1** (Figure 1) is composed of four fused distorted $\{InCu_3Se_6\}$ adamantoid cages. In this way, all six copper atoms (Cu1–Cu6) and four $\mu_3$-$SePh^-$ ligands (Se1–Se4) build a central adamantoid cage $[Cu_6(SePh)_4]^{2+}$, which is face-capped by four $[(\mu_2\text{-}SePh)_3InCl]^-$ (In1–In4, Cl1–Cl4) units through $\mu_2$-SePh ligands (Se5–Se16). All copper and indium atoms display a distorted tetrahedral coordination environment [bond angles: Se–Cu–Se 95.88(6)–124.33(7)°; Se–In–Se 100.35(4)–122.44(4)°; Cl–In–Se 102.44(8)–110.71(8)°]. The Cu-$\mu_2$-Se bonds {246.16(18) [Cu(2)–Se(6)] to 252.0(2) pm [Cu(1)–Se(8)]} are found to be slightly longer than the corresponding Cu-$\mu_3$-Se bonds ranging from 239.42(12) (Cu6–Se4) to 245.13(19) pm (Cu3–Se2). The In-$\mu_2$-SePh bond lengths range from 256.07 (In2–Se14) to 258.30(14) pm (In4–Se9), and the In–Cl bond lengths from 240.5 to 242.8 pm. The so-formed tetrahedral cluster cage is isostructural to known binary and ternary cluster molecules like $[Cd_{10}(SCH_2CH_2OH)_{16}]^{4+}$,[11] $[M_{10}E_4(SPh)_{16}]^{4-}$ (M = Zn, Cd; E = S, Se)[12,13] $[M_{10}E_4(E'Ph)_{12}(PR_3)_4]$ (M = Zn, Cd, Hg; E, E′ = S, Se, Te; R = organic group)[14–19] and $[In_{10}Se_{16}]^{6-}$.[20]

Compound **2** crystallizes in the tetragonal space group $I\bar{4}$ with a crystallographic $\bar{4}$ axis running through As(1) of the $Ph_4As^+$ cation and Cu(2)/Cu(2′) of the cluster anion. The molecular structure of the anion core, $[Cu_7In_4(SePh)_{20}]^-$, is, with the exception of two differences, very similar to the structure of **1** (Figure 2). First, the use of an excess of $PhSeSiMe_3$ leads to an exchange of the terminal chloro ligands with $SePh^-$ groups. The second, and more remarkable, difference concerns the stoichiometry and

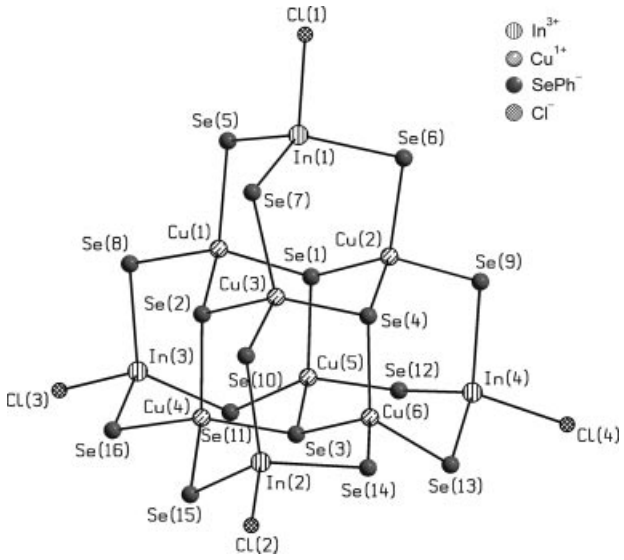

Figure 1. Molecular structure of the cluster anion $[Cu_6In_4Cl_4(SePh)_{16}]^{2-}$ in $(AsPh_4)_2[Cu_6In_4Cl_4(SePh)_{16}]$ (**1**). C and H atoms are omitted for clarity. Selected bond lengths [pm]: Cu(1)–Se(1) 243.81(17), Cu(1)–Se(2) 244.02(17), Cu(1)–Se(5) 248.25(18), Cu(1)–Se(8) 252.0(2), Cu(2)–Se(1) 242.26(18), Cu(2)–Se(4) 244.24(17), Cu(2)–Se(6) 246.16(18), Cu(2)–Se(9) 249.52(17), Cu(3)–Se(4) 2.4274(17), Cu(3)–Se(2) 245.13(19), Cu(3)–Se(10) 248.88(18), Cu(3)–Se(7) 251.0(2), Cu(4)–Se(3) 242.96(17), Cu(4)–Se(2) 244.83(18), Cu(4)–Se(16) 247.3(2), Cu(4)–Se(15) 247.86(18), Cu(5)–Se(1) 242.72(17), Cu(5)–Se(3) 243.48(17), Cu(5)–Se(11) 246.69(19), Cu(5)–Se(12) 249.57(18), Cu(6)–Se(4) 239.42(18), Cu(6)–Se(3) 241.50(19), Cu(6)–Se(13) 246.40(19), Cu(6)–Se(14) 247.37(19), In(1)–Cl(1) 240.5(3), In(1)–Se(7) 256.57(15), In(1)–Se(5) 257.27(16), In(1)–Se(6) 257.90(14), In(2)–Cl(2) 242.6(3), In(2)–Se(14) 256.07(15), In(2)–Se(15) 256.07(16), In(2)–Se(10) 257.02(16), In(3)–Cl(3) 242.8(3), In(3)–Se(16) 256.14(15), In(3)–Se(11) 256.33(14), In(3)–Se(8) 257.91(15), In(4)–Cl(4) 241.3(3), In(4)–Se(13) 256.16(15), In(4)–Se(12) 257.20(16), In(4)–Se(9) 258.30(14).

charge of the cluster anion. In the difference Fourier map, we found additional electron density on four symmetry-equivalent sites of the cluster, which were initially refined as one fourfold degenerated copper atom Cu(3). Compared to the cluster anion of **1**, this results in a reduction of the overall charge of the cluster anion from –2 to –1 if we assign the metal atoms as $In^{3+}$ and $Cu^+$. In agreement with this, we found only one tetraphenylarsonium countercation in the crystal structure. However, the observed density could also be the result of four real atoms of roughly a quarter of the atomic number and weight (e.g. oxygen). In order to maintain the overall charge of the cluster at –1, the electronic structure of the cluster must be significantly altered. Mass spectrometry and DFT computations were performed to address this problem (see further below). The additional copper atom [Cu(3)] is located in the middle of a six-membered ring [Se(4), In(1), Se(2), Cu(1′), Se(5′′) and Cu(1′′)] and has a nearly trigonal-planar coordination environment [Se–Cu–Se: 118.62(18) to 120.8(2)°]. The other copper atoms [Cu(1), Cu(2) and symmetry-equivalent positions] and indium atoms [In(1) and symmetry-equivalent positions] are all coordinated in distorted tetrahedral form by the selenium atoms of the SePh ligand [bond angles: Se–

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Cu–Se 98.92(6)–123.55(5)°; Se–In–Se 103.23(3)–110.72(3)°]. As a consequence of the incorporation of an additional copper atom, the selenium atoms of the SePh ligands display a different set of bridging modes in **2** compared to those in **1**. Se(1), Se(1′), Se(1′′) and Se(1′′′) are terminally bonded to In(1) and its symmetry-equivalent positions. Eight SePh ligands [Se(2), Se(2′), Se(2′′), Se(2′′′), Se(4), Se(4′), Se(4′′) and Se(4′′′)] are $\mu_3$-bridging between two copper and one indium atom, whereas Se(3), Se(3′), Se(3′′) and Se(3′′′) act as $\mu_2$ bridges between two copper atoms. Se(5), Se(5′), Se(5′′) and Se(5′′′) function as $\mu_4$ bridges between four copper atoms. The Cu–SePh bond lengths range from 241.99(12) (Cu1–Se5) to 263.8(5) pm (Cu3–Se2) and the In–SePh bond lengths vary from 253.46(10) (In1–Se1) to 260.32(10) pm (In1–Se2).

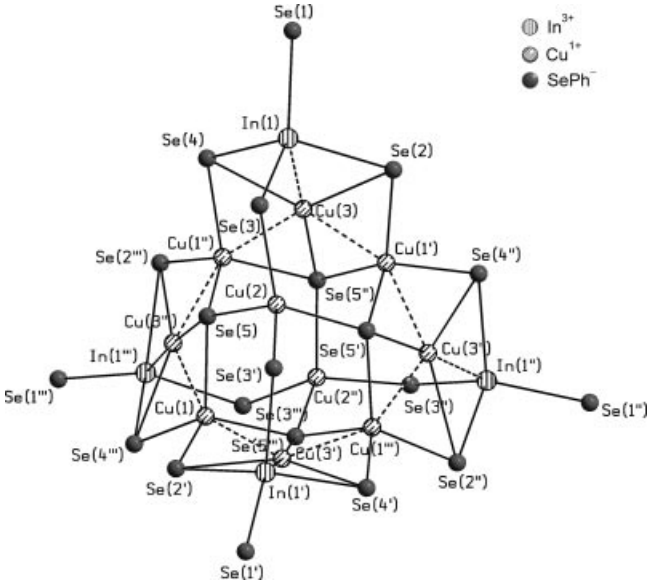

Figure 2. Molecular structure of the cluster anion $[Cu_7In_4(SePh)_{20}]^-$ in $(AsPh_4)[Cu_7In_4(SePh)_{20}]$ (**2**). C and H atoms are omitted for clarity. Selected bond length [pm] (solid lines): In(1)–Se(1) 253.46(10), In(1)–Se(3) 259.29(10), In(1)–Se(4) 260.25(9), In(1)–Se(2) 260.32(10), Cu(1)–Se(5) 241.99(12), Cu(1)–Se(5′′′) 243.92(12), Cu(1)–Se(2′) 246.77(14), Cu(1)–Se(4′′′) 250.26(14), Cu(2)–Se(5) 245.96(12), Cu(2)–Se(5′) 245.96(12), Cu(2)–Se(3′) 247.40(12), Cu(2)–Se(3) 247.40(12), Cu(3)–Se(5′′) 235.3(5), Cu(3)–Se(4) 251.5(5), Cu(3)–Se(2) 263.8(5), Se(2)–Cu(1′) 246.77(14), Se(4)–Cu(1′′) 250.26(14), Se(5)–Cu(3′′′) 235.3(5), Se(5)–Cu(1′′) 243.92(12). Weak contacts [pm] (dashed lines): Cu(1)–Cu(3′) 227.4(6), Cu(1)–Cu(3′′′) 228.4(5), In(1)–Cu(3) 261.0(5). Symmetry transformations for the generation of equivalent atoms: ′: $-x, -y-1, z$; ′′: $-y-0.5, x-0.5, -z+0.5$; ′′′: $y+0.5, -x-0.5, -z+0.5$.

Kanatzidis et al. reported the structure of a closely related singly charged cluster anion, $[Cu_6In_3(SEt)_{16}]^-$, in which one $[(\mu_2\text{-}SEt)_3InSEt]^-$ cap, which is needed to form the ideal four-fused adamantoid structure of $[Cu_6In_4(SEt)_{20}]^{2-}$, is missing.[1] Apparently, the hypothetical species of $[Cu_6In_4(ER)_{20}]^{2-}$ (E = S, Se) is unstable as the dianion.

The solid-state UV/Vis spectra of **1** and **2** (Figure 3, bottom part) are quite similar, with a first shoulder at 400 nm (3.1 eV) and a broad maximum at 310 nm (4.0 eV). In solution, one observes similar absorption features with the bands shifted to 370 nm (3.4 eV) and 265 nm (4.7 eV), respectively. As mass spectrometry indicates the existence of the intact cluster anions in solution, the shift between solid-state and solution spectra likely arises from inhomogeneities of the crystal-oil mull between the quartz plates, which has been observed for other samples.[21]

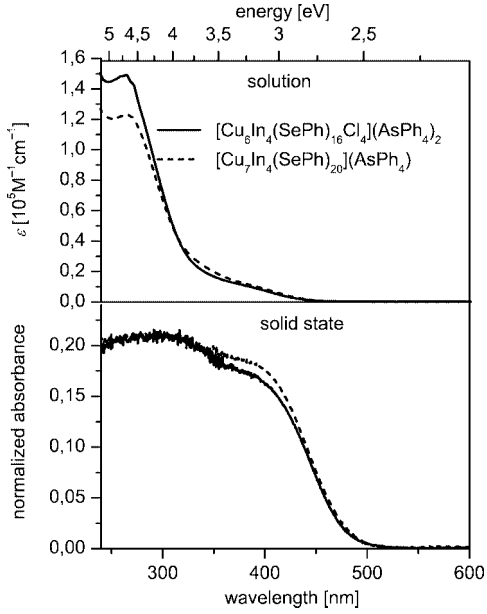

Figure 3. UV/Vis spectra of $(AsPh_4)_2[Cu_6In_4Cl_4(SePh)_{16}]$ (**1**) and $(AsPh_4)[Cu_7In_4(SePh)_{20}]$ (**2**) in solution ($CH_2Cl_2$) and in the solid state (mull in nujol between two quartz plates).

## Mass Spectrometry

The additional charge density found in the X-ray diffraction analysis of compound **2**, leading to the proposed seventh (and fourfold degenerate) copper atom Cu(3), rendered another experimental technique desirable which might give further proof of the stoichiometry and charge state. Electrospray mass spectrometry, which has been proven very powerful for this class of compounds,[22,23] was employed here in conjunction with collision-induced dissociation. The negative-ion mass spectrum of **2** (Figure 4) is governed by several strong ion signals which are all singly charged and can be clearly assigned as indicated in the graphic. The highest mass peak observed ($m/z \approx 4025$) is in complete agreement with the expected isotopomer distribution of the singly charged cluster anion $[Cu_7In_4(SePh)_{20}]^-$, as can be seen from the inset in Figure 4. We note in passing that the two small peaks marked with an asterisk and shifted by 120 amu to lower mass are due to known ligand-exchange reactions of an $SePh^-$ group with a $Cl^-$ ion in solution, as has been observed previously.[24,25] In order to answer the question whether the other strong ion signals next to the parent ion $[Cu_7In_4(SePh)_{20}]^-$ could be explained as fragments of the gas-phase ion $[Cu_7In_4$-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$(SePh)_{20}]^-$, we performed a collision-induced dissociation study on the $[Cu_7In_4(SePh)_{20}]^-$ cluster anion (Figure 5). Interestingly, the observed fragment ions differ significantly from the ion signals obtained by direct spraying of **2**. The fragmentation pattern indicates that the parent ion $[Cu_7In_4(SePh)_{20}]^-$ first looses sequentially two $In(SePh)_3$ units from the corner sites of the tetrahedral cluster cage (see Figure 2) with further dissociation of Cu(SePh) units. On the other hand, the four major ion peaks of Figure 4 can be formally added up pairwise {namely $[Cu_6In_3(SePh)_{19}]^-/[In(SePh)_4]^-$ and $[Cu_3In_3(SePh)_{13}]^-/[Cu_3In(SePh)_7]^-$} to give a $[Cu_6In_4$-

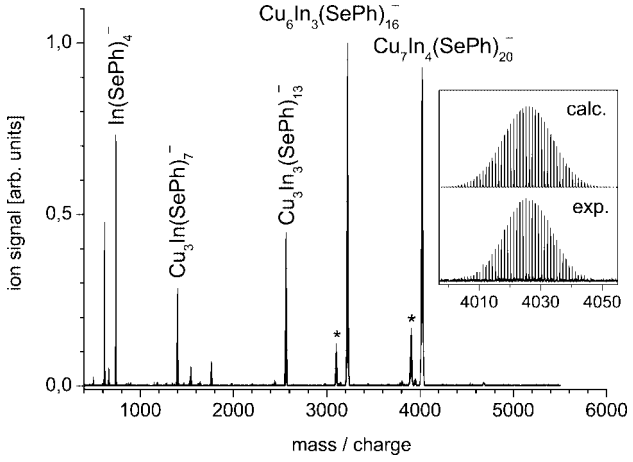

Figure 4. Negative-ion electrospray mass spectrum of **2**. The inset shows a high-resolution mass spectrum of the ion peak at $m/z \approx 4025$ displaying the isotopomer splitting in comparison to the calculated distribution expected for $[Cu_7In_4(SePh)_{20}]^-$.

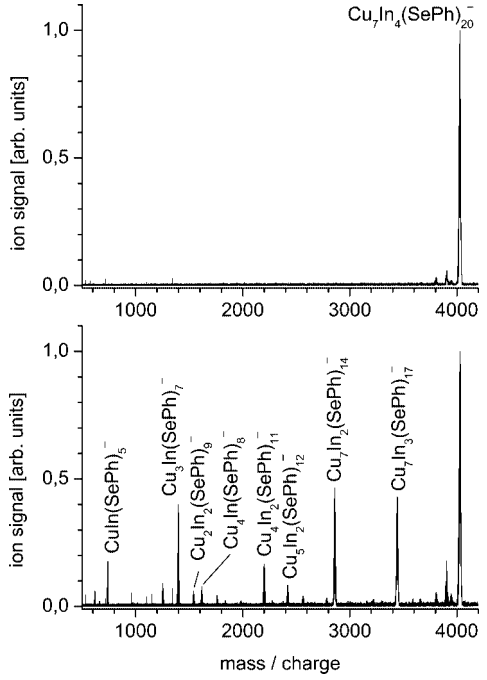

Figure 5. Mass spectrum of $[Cu_7In_4(SePh)_{20}]^-$ isolated in the ICR cell (top panel) and after collision-induced dissociation with argon (bottom panel). The fragmentation pattern can be fully described by sequential loss of $In(SePh)_3$ and Cu(SePh) units consistent with the structure shown in Figure 2.

$(SePh)_{20}]^{2-}$ entity which would rather point towards a solution-phase dissociation of **2**, i.e., loss of $Cu^+$.

However, the fragmentation pattern of **2** strongly supports the identity of the parent ion as $[Cu_7In_4(SePh)_{20}]^-$ ruling out other possibilities like the incorporation of oxygen.

## DFT Calculations

For the $Cu_7$ compound, the X-ray structure has some ambiguities in assignment. The crystallographically imposed $\bar{4}$ symmetry distributes the effective electron density of the seventh copper atom over four identical sites, but the observed density could conceivably be due to four full-occupancy oxygen atoms. There should be, however, significant structural differences between the postulated $Cu_7$ and $Cu_6O_4$ cluster cores due to the vastly different electronic structure needed to maintain the –1 overall cluster charge.

Density functional theory has been successfully applied to similar cluster compounds,[26] and should allow us to differentiate between these two putative assignments, as well as confirming that either are physically reasonable. The $Cu_6O_4$ case was quickly eliminated as it was highly unstable to geometry optimization and the electronic structure indicated a highly paramagnetic system, with essentially no HOMO–LUMO gap, contradicting the observed pale yellow color of the compound. The $Cu_7$ system was not, however, obviously the correct assignment. If addition of the seventh copper atom altered the rest of the cluster significantly from $S_4$ symmetry, the compound would be strongly disfavored from crystallizing in the observed space group.

Initial geometry optimization of the $[Cu_7In_4(SeR)_{20}]^-$ anion was simplified by replacing the phenyl rings of the selenium ligands with methyl groups.[27] Addition of a $Cu^+$ ion to one of the adamantoid faces caused strong deviations in the geometry, the seventh copper atom having burrowed into the cluster, resulting in a related structure with $C_2$ symmetry. Geometry optimization of the fully phenylselenolate-ligated cluster proceeded successfully, with the extra copper atom remaining in the center of an external adamantoid face, and no major (e.g. bond-breaking) changes when compared to the crystal structure.

To test the assumption that the observed crystal structure is indeed the superposition of four orientations of $[Cu_7In_4(SePh)_{20}]^-$, the DFT structure must be symmetrized under $S_4$ before comparison to experiment. The symmetrization procedure produced an averaged structure almost identical to that from the crystal, with an RMS distance of 13.7 pm between corresponding atoms in the superimposed structures, and well within the expected thermal motion. Calculated bonds in the cluster core tend to be consistently slightly longer than their respective distances in the crystal {calc – obs [pm]: In–Se: $4.30 \pm 1.59$; Cu–Se: $4.93 \pm 2.01$; Cu"7"–(Cu,Se): $5.15 \pm 4.35$}, as is expected when comparing gas-phase to solid-state structures. The final electronic structure (diamagnetic, HOMO–LUMO gap = 1.7 eV) is also in agreement with observations.

## Experimental Section

**General:** All experiments were carried out under dry nitrogen. $CH_2Cl_2$ and $CH_3CN$ were dried with $CaH_2$, followed by distillation under nitrogen. Anhydrous $InCl_3$ and $Ph_4AsCl$ hydrate were obtained from Aldrich. $Se(SiMe_3)_2$ was prepared as reported in the literature.[28] CuCl was subsequently washed with HCl, $CH_3OH$, and diethyl ether to remove traces of $CuCl_2$, and dried under vacuum. $Ph_4AsCl{\cdot}xH_2O$ was dissolved in $CH_3CN$, dried with molecular sieves, and obtained as a white solid after filtration and removal of the solvent.

**$(AsPh_4)_2[Cu_6In_4Cl_4(SePh)_{16}]$ (1):** CuCl (55 mg, 0.56 mmol), $InCl_3$ (82 mg, 0.37 mmol), and $Ph_4AsCl$ (78 mg, 0.19 mmol) were dissolved in $CH_2Cl_2$ (50 mL). After the solution was cooled to –20 °C, $PhSeSiMe_3$ (0.47 mL, 1.9 mmol) was added. The final mixture was warmed to room temperature whilst stirring to give a yellow solution. Careful evaporation of the solvent yielded **1** as yellow crystalline needles. Yield: 263 mg; 67%. $C_{144}H_{120}Cl_4Cu_6In_4Se_{16}As_2$ (4246.1): calcd. C 40.73, H 2.85; found C 40.93, H 2.92.

**$(AsPh_4)[Cu_7In_4(SePh)_{20}]$ (2):** CuCl (43 mg, 0.43 mmol), $InCl_3$ (63 mg, 0.29 mmol), and $Ph_4AsCl$ (60 mg, 0.14 mmol) were dissolved in $CH_2Cl_2$ (75 mL) and cooled to –20 °C. $PhSeSiMe_3$ (0.52 mL, 2.15 mmol) was added to give a clear, orange solution. After stirring at room temperature for 24 h, the volume was reduced to 15 mL and left to stand. A few days later, orange blocks of **2** started to crystallize. Yield: 117 mg; 43%. $C_{144}H_{120}Cu_7In_4Se_{20}As$ (4408.8): calcd. C 39.23, H 2.74; found C 38.23, H 2.73.

**Crystallography:** Crystals suitable for single-crystal X-ray diffraction were taken directly from the reaction solution of the compound and then selected in perfluoroalkylether oil. Single-crystal X-ray diffraction data of **1** and **2** were collected using graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) with a STOE IPDS II (Imaging Plate Diffraction System) equipped with a Schneider rotating anode. The structures were solved with the direct-methods program SHELXS[29] of the SHELXTL PC suite of programs, and were refined with the use of the full-matrix least-squares program SHELXL.[29] Molecular diagrams were prepared using SCHAKAL 97.[30] All Cu, In, Se, As, Cl, and C atoms of the cluster molecules were refined with anisotropic displacement parameters, while Cl and C atoms of the solvent molecules were refined isotropically. CCDC-281603 (**1**) and -281604 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. X-ray powder diffraction patterns (XRD) were measured with a STOE STADI P diffractometer (Cu-$K_{\alpha1}$ radiation, germanium monochromator, Debye–Scherrer geometry) in sealed glass capillaries. Simulated powder diffraction patterns for **1** and **2** were calculated on the basis of the atom coordinates obtained from single-crystal X-ray analysis by using the program package STOE WinXPOW.[31]

**Mass Spectrometry:** Mass spectrometry was performed with a 7T-Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer (Bruker Daltonics, Billerica, MA, USA), equipped with an electrospray ionization source (Analytica of Branford, Branford, CT, USA) which has been modified by us for improved ion sensitivity by means of home-built ion optics. Solutions of **1** and **2** in $CH_2Cl_2$ were prepared at a concentration of ca. 0.1 mmol/ L under nitrogen and sprayed at typical flow rates of 300µL/h. Collision-induced dissociation experiments were taken in an MS/MS mode, i.e., the parent ion of interest was first mass-selected in the ICR cell by standard ICR techniques (resonant ejection sweeps) and subjected to collisions with argon ($p = 5{\cdot}10^{-8}$ mbar) at elevated kinetic energies to induce fragmentation.

**Physical Measurements:** UV/Vis absorption spectra of cluster molecules in solution were measured with a Varian Cary 500 spectrophotometer in quartz cuvettes. Solid-state reflection spectra were measured as micron-sized crystalline powders between quartz plates with a Labsphere integrating sphere.

**Calculation Technical Details:** Density functional theory calculations were performed with the TURBOMOLE program package[32] employing the BP86 functional with the very efficient MARI-J approximation,[33] and TZVP basis set.[34] Starting geometries were adapted from the crystal structure, and then optimized with default convergence criteria. Due to electronic convergence problems, the $[Cu_6O_4In_4(SePh)_{20}]^-$ cluster was calculated spin-unrestricted with Fermi electronic occupation smearing. The metal–chalcogen core of the seven-copper cluster was symmetrized while ignoring the seventh copper atom. The pseudo-$S_4$ axis was determined by a simple linear combination of symmetry-related (in the ideal case) atom position vectors, and was then re-oriented to bring the axis in line with +$z$. The symmetry-equivalent coordinates were averaged, and the cluster was rotated about the $z$ axis to minimize differences with the X-ray data.

# Neodymium(II) and Dysprosium(II) Iodides in the Reactions with Metallocenes of d-Transition Metals

**Mikhail E. Burin,[a] Marina V. Smirnova,[a] Georgy K. Fukin,[a] Eugeny V. Baranov,[a] and Mikhail N. Bochkarev*[a]**

**Keywords:** Dysprosium / Neodymium diiodide / Metallocenes / Reduction

Heating $NdI_2$ (**1**) or $DyI_2$ (**2**) with vanadocene (**3**) in benzene at 85 °C led to the formation of bis(benzene)vanadium in 10 and 24 % yields, respectively. The lanthanide products were isolated in the form of $CpLnI_2(THF)_3$ after crystallization from THF. The interaction of **2** with **3** in isopropylbenzene at 90 °C yielded a mixture of $(arene)_2V$ complexes from which a small amount of bis(isopropylbenzene)vanadium was isolated. The same reaction did not occur in mesitylene. From the reaction of **2** with **3** in molten naphthalene at 100 °C, the heterobimetallic cluster $\{[CpDy(\mu\text{-}I)_2]_7Cp_2V(\mu\text{-}I)\}$(**4**) was isolated in low yield. The reaction of $Cp_2Cr$ with **1** or **2** in benzene at ambient temperature afforded the dimer $[CpCr(\mu\text{-}I)]_2$ (**5**) and a dysprosium complex, $Cp_2DyI$ (**6**) (in the reaction with **2**). When the reaction with **2** was carried out at 80 °C, along with compound **6**, the -ate complex $\{[Cp_2DyI_2]^-[Cp_2Cr]^+\}$(**7**) was crystallized from the reaction solution. Nickelocene was reduced by **2** in benzene at 80 °C to nickel metal. The dysprosium product was isolated as solvent-free complex **6**. Ferrocene and cobaltocene did not react with **1** and **2** in benzene. The molecular structures of compounds **4**, **5**, and **7** were characterized by X-ray diffraction analysis.

## Introduction

The diiodides $NdI_2$ (**1**), $DyI_2$ (**2**), and $TmI_2$, which recently became available for broad chemical investigations, have proven themselves as powerful reducing reagents in reactions with various organic substrates.[1] The reactivity of these salts towards organometallic compounds has been studied. Most of the examples are metathesis reactions of $TmI_2$ with alkali-metal derivatives to give the corresponding divalent thulium complexes, $R_2Tm(solv.)_n$, or the products of their oxidation by the solvent and disproportionation.[2] The reactions of $LnI_2$ with RM {R = 2,6-*t*$Bu_2C_6H_3O$,[3] $[(Me_3Si)_2]_2N$,[3] $C_5Me_5$,[2b] $(Me_3Si)C_5H_4$,[2b] $(Me_3Si)_2C_5H_3$;[2a,2b] M = Na, K} in THF or ether, conducted in nitrogen, yielded the corresponding nitrogen-containing complexes of the type $[(R_2Ln)_2(\mu_2\text{-}N_2)]$. The addition of $Ph_2Hg$, $Ph_3GeH$, $Ph_3GeGePh_3$, or $Ph_4Sn$ to a solution of **1** or **2** in THF caused the formation of the triiodide $LnI_3(THF)_3$ and a mixture of monoiodide complexes of the type LnIRR′ containing fragments of split solvent.[4,5] Reaction of **1** with $Me_3SiCl$ in THF proceeds vigorously to give $Me_3SiH$, $Me_3SiSiMe_3$, and $Me_3SiOBu$.[6] Pentafluorophenyl germanes $(C_6F_5)_3GeH$ and $(C_6F_5)_3GeBr$ react with **1** in THF to produce a hyperbranched polymer $[(C_6F_5)_2Ge(C_6F_4)]_n$.[5] The reactivity of **1** and **2** (as well as all other $LnI_2$) towards organometallic compounds of d-transition metals has never been studied. In an effort to fill this gap, we have investigated the reactions of **1** and **2** with metallocenes of vanadium, chromium, iron, cobalt, and nickel. The second aim of this work was to develop a new way to arene complexes of these metals; therefore, the reactions were carried out in aromatic solvents. Neodymium and dysprosium diiodides were selected because they are the most active reductants among all the $LnI_2$.

## Results and Discussion

The main preparative route to bis(arene) complexes of d-transition metals is still Fischer's method – the reflux of a mixture of the metal halide, $AlCl_3$, and aluminum powder in the appropriate aromatic solvent and subsequent hydrolysis of the formed intermediates.[7] We have found that bis(benzene)vanadium can be obtained by the reaction of **1** or **2** with vanadocene (**3**) in benzene at 80 °C.[8] When the mixture was heated for 10 h, the yield of $(C_6H_6)_2V$ was 10% for **1** and 24% for **2**. An increase in reaction time did not lead to greater yields of bis(benzene)vanadium. Changing the molar ratio **2**/**3** from 2 to 4 increased the yield of $(C_6H_6)_2V$ from 15% to 24%. Despite a great excess of $LnI_2$ most of the vanadocene could be isolated from the reaction mixture. This can be explained by the heterogeneous nature of the processes: the formed lanthanide product $CpLnI_2$, sparingly soluble in benzene, covers the surface of iodide **2** and prevents it from reacting further with **3**. The neodym-

 © 2006 Wiley-VCH Verlag GmbH & Co. KgaA, Weinheim InterScience 

ium derivative has especially low solubility; therefore, only a few crystals of it were isolated as the solvated $CpNdI_2(THF)_3$ after crystallization from THF.

$$2\,LnI_2 + Cp_2V \xrightarrow{\text{benzene}} (C_6H_6)_2V + 2\,CpLnI_2$$

Ln = Nd, Dy

An attempt to use $VCl_4$ instead of **3** in this synthesis failed: the reduction of vanadium with **2** proceeds rapidly but stops at the formation of the benzene-insoluble $VCl_3$.

The mechanism of $(C_6H_6)_2V$ formation from **3** and $LnI_2$ remains unclear, but taking into account the generation of lanthanide–naphthalene–vanadium(0) complexes $[CpLn(THF)(\mu\text{-}C_{10}H_8)VCp]_n$ (Ln = Sm, Eu, Yb)[9] or the triple-decker vanadium compound $CpV(\mu\text{-}C_{10}H_8)VCp$[9a] in the reactions of **3** with other strong reductants such as lanthanide(II) naphthalenides $(C_{10}H_8)Ln(THF)_x$ suggests that reduction of **3** by **1** and **2** also proceeds via intermediates of the type $CpV(\mu\text{-}C_6H_6)LnI_2$, probably generated on a surface of $LnI_2$. However, in the reaction of **2** with **3** in molten naphthalene, where the formation of naphthalene–vanadium derivatives seemed very plausible, we were unable to isolate any arene–vanadium product although almost all of the vanadocene was consumed. The reaction readily proceeds at 100 °C to give a black solution from which only heterobimetallic cluster **4** has been isolated by crystallization from benzene. The black insoluble pyrophoric precipitate, remaining after the removal of the reaction solution, contained (according to elemental analysis and IR spectroscopy) dysprosium, vanadium, cyclopentadienyl, and arene groups. This is consistent with above supposition. Note that naphthalene–ytterbium, –samarium, and –europium are also pyrophoric.

The molecule **4** (Figure 1) is a bimetallic polynuclear complex. The metal atoms [Dy(1–3), V(1) and Dy(4–7)] are positioned at the apexes of distorted tetrahedrons and are bonded to each other by the bridging iodine atoms that form a distorted octahedron around each dysprosium atom. The iodine atoms occupy equatorial positions and the one apical position inside the cluster. The apical positions outside of the cluster are occupied by Cp ligands. The Dy(1–3) atoms, $\mu_2$-I [I(12), I(13), and I(23)] atoms, and the $\mu_3$-I(123), and $\mu_3$-I(321) atoms are located at the apexes of a distorted hexagonal bipyramid. The deviation of the Dy(1–3) and I (12, 13, and 23) atoms from the plane are 0.079 Å. The Dy(1–3)–$\mu_2$-I distances in the Dy(1–3),V(1) metallofragment vary in the range 3.0568(4)–3.1269(4) Å and are shorter than the Dy(1–3)–$\mu_3$-I distances [3.1544(4)–3.2248(4) Å]. The Dy(4, 6, 7), I(47, 67, 456) (planar location) and I(467, 654) (apical location relative to the plane) atoms in the Dy(4–7) metallofragment are also located at the apexes of a distorted hexagonal bipyramid. However there is a significant difference between the Dy(4, 6, 7)–I(47, 67, 456,467, 654) and Dy(1–3)–I (12, 13, 23, 123, 321) fragments of the cluster. The Dy(5) atom in the Dy(4, 5, 6, 7) fragment is positioned under the I(456)···I(654) edge and it interacts with these iodine atoms, whereas the vanadium atom has no additional V–I interactions. As a result, the I(654) atom is a bridging four-coordinate atom. The Dy(5, 7)–$\mu_4$-I(654) distances [3.3609(4), 3.3381(4) Å] are significantly longer than the Dy(4–7)–$\mu_2$-I [3.0407(4)–3.1261(5) Å] and Dy(4–7)–$\mu_3$-I [3.1420(4)–3.1816(5) Å] distances. It should be noted that the Dy(4, 6)–$\mu_4$-I(654) bonds [3.2191(4) and 3.2406(4), respectively] are shorter than the Dy(5, 7)–$\mu_4$-I(654) bonds. The Dy–$Cp_{center}$ and V–$Cp_{center}$ distances vary in the range 2.309(6)–2.331(6) Å and 1.934(6)–1.939(6) Å, respectively, and are typical for similar fragments ($[Cp_2DyBr]_2$, 2.327–2.360 Å;[10] $Cp_2V$, 1.918 Å;[11] $Cp_2VCl$, 1.944, 1.946 Å[12]).

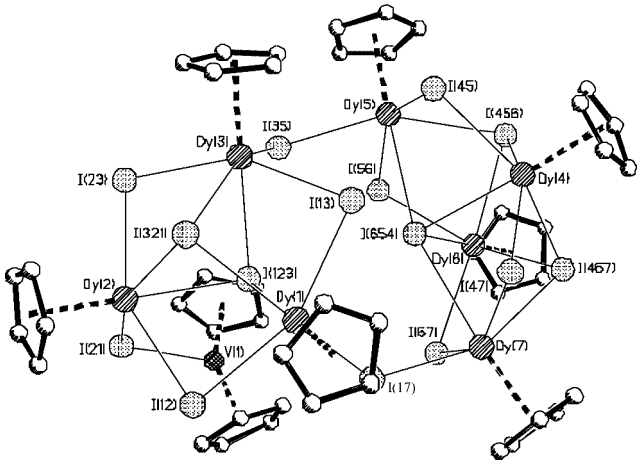

Figure 1. Molecular structure of $\{[CpDy(\mu\text{-}I)_2]_7Cp_2V(\mu\text{-}I)\}$ (**4**). Hydrogen atoms have been omitted for clarity. Relevant bond lengths [Å] and angles [°]: Dy(1)–I(12) 3.1077(4), Dy(1)–I(13) 3.0568(4), Dy(1)–I(17) 3.1451(4), Dy(1)–I(123) 3.1544(4), Dy(1)–I(321) 3.2248(4), Dy(1)–C(11–15) 2.592(5)–2.609(5), Dy(7)–I(17) 3.0583(4), V(1)–I(21) 2.8203(10), V(1)–I(1–10) 2.259(6)–2.297(6); I(13)–Dy(1)–I(12) 149.595(12), I(13)–Dy(1)–I(17) 95.692(12), I(12)–Dy(1)–I(17) 92.424(12), I(12)–Dy(1)–$Cp_{center}$ 103.5, $Cp_{center}$–V(1)–$Cp_{center}$ 142.3, I(21)–V–$Cp_{center}$ 108.6 (109.0).

No changes were observed when a mixture of **2** and **3** was heated in mesitylene at 90 °C. The same reaction in isopropylbenzene afforded a mixture of bis(arene)vanadium complexes [arene = $C_6H_6$, $C_6H_5C_3H_7$, $C_6H_4(C_3H_7)_2$] isolated as a dark brown oily liquid. A similar mixture of arene–vanadium products is formed in the reaction of $VCl_3$ with $AlCl_3$ and Al in $i\text{-}C_3H_7C_6H_5$.[13] From the reaction mixture, we were able to isolate a small amount of bis(isopropylbenzene)vanadium as yellow crystals.

Chromocene reacted with **1** in benzene at ambient temperature but did not give the expected bis(benzene)chromium. Instead, from the cherry solution, the dimer **5** was isolated as an air-sensitive, dark cherry-red crystalline solid soluble in benzene and hexane. Single crystals of **5** suitable for X-ray analysis were obtained by crystallization from hexane.

The centrosymmetric molecule **5** (Figure 2) consists of two CpCrI fragments bonded by iodine bridges. The four-membered Cr(1)I(1)Cr(1A)I(1A) cycle has a butterfly shape characteristic of similar fragments.[14] The dihedral angles between the Cr(1)I(1)I(1A) and Cr(1A)I(1)I(1A) fragments is 87.6°. The Cr(1)–I and Cr(1)–C(Cp) distances are 2.6678(5)–2.6592(5) Å and 2.242(2)–2.295(2) Å, respectively,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and are typical for the same type of complexes [2.671–2.707 Å for Cr–μ-I and 2.192–2.241 Å[15] for Cr–C(Cp)]. A short Cr···Cr contact [2.4921(7) Å] in the molecule indicates the existence of bonding between the two metal atoms. Similar Cr–Cr bonding has been found before in the complexes $[Cp^*Cr(\mu\text{-}Cl)]_2$ [2.642(2) Å], $[Cp^*Cr(\mu\text{-}Me)]_2$ [2.263(3) Å], and $[(Cp^*Cr)_2(\mu\text{-}Me)(\mu\text{-}Ph)]$ [2.289(4) Å].[14]

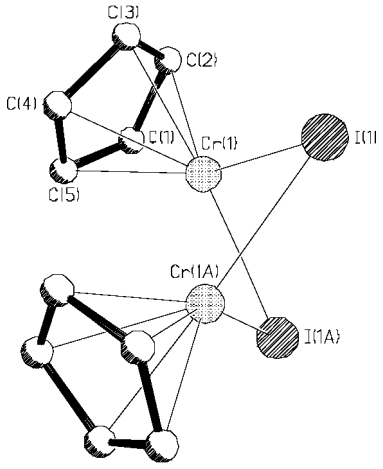

Figure 2. Molecular structure of $[CpCr(\mu\text{-}I)]_2$ (**5**). Hydrogen atoms have been omitted for clarity. Relevant bond lengths [Å] and angles [°]: Cr(1)–Cr(1A) 2.4921(7), Cr(1)–I(1) 2.6678(5), Cr(1A)–I(1) 2.6592(5), Cr(1)–C(Cp) 2.242(2)–2.295(2); Cr(1A)I(1)Cr(1) 55.787(2), I(1A)Cr(1)I(1) 94.905(2).

Increasing the reaction temperature to 80 °C did not lead to the formation of $(C_6H_6)_2Cr$. In this case, extensive transformations resulted in the formation of a green intractable mixture from which no definite products were isolated.

Similar to the neodymium salt, dysprosium iodide (**2**) reacted with $Cp_2Cr$ in benzene at room temperature to give dimer **5** and dysprosium(III) complex **6**. When the reaction was carried out at 80 °C the dimer **5** was not found in the mixture but product **6** was isolated in 34% yield. Its formation was confirmed by elemental analysis and IR spectroscopic data; however, the single crystal selected for X-ray diffraction analysis quite unexpectedly turned out to be the -ate complex $\{[Cp_2DyI_2]^-[Cp_2Cr]^+\}$(**7**), which can be considered as a combined product of $Cp_2DyI$ and $Cp_2CrI$.

According to X-ray data, molecule **7** contains the counterions $[Cp_2DyI_2]^-$ and $[Cp_2Cr]^+$ (Figure 3). The dysprosium and chromium atoms are located on the $C_2$ axis and the mirror plane, respectively. The bond angles $Cp_{cent}$–Dy(1)–$Cp_{cent}$ and I(1)–Dy(1)–I(1A) are 128.3 and 95.4°, respectively, and the distances Dy(1)–C(Cp) and Dy(1)–I vary in the ranges 2.615(4)–2.648(4) Å and 2.9818(5)–2.9926(5) Å, respectively. The Dy(1)–C(Cp) bond length in **7** is similar to the bond lengths in **4** [2.566(6)–2.637(6) Å] but the Dy–I bonds in **7** are somewhat shorter than the analogous bonds in **4**. The shortening of the Dy–I bonds in **7** probably reflects a different type of coordination of the iodine atoms in these two compounds. The iodine atoms in **7** are terminal, whereas all I atoms in **4** are bridging. The $[Cp_2Cr]^+$ cation has an ordinary geometry. To the best of our knowledge, the structure of only one complex containing the $[(Me_5C_5)_2LnI_2]^-$ anion (Ln = Yb) has been published previously.[16]

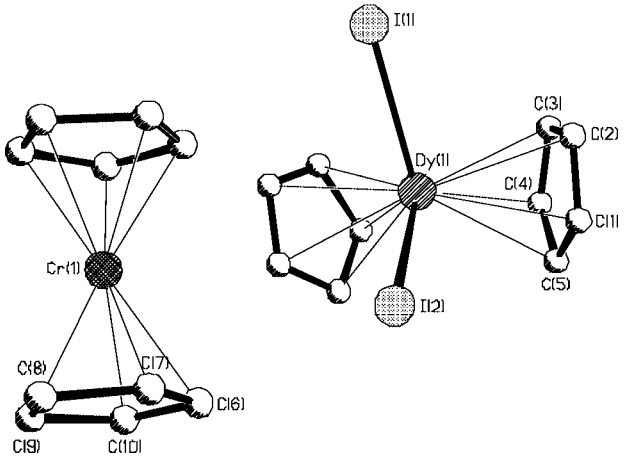

Figure 3. Molecular structure of $[Cp_2DyI_2]^-[Cp_2Cr]^+$ (**7**). Hydrogen atoms have been omitted for clarity. Relevant bond lengths [Å] and angles [°]: Dy(1)–I(1) 2.9926(5), Dy(1)–I(2) 2.9818(5), Dy(1)–C(Cp) 2.615(4)–2.648(4), Cr(1)–C(Cp) 2.188(4)–2.201(4); I(1)–Dy(1)–I(2) 95.41(1), $Cp_{center}$–Dy–$Cp_{center}$ 128.3, $Cp_{center}$–Cr–$Cp_{center}$ 179.0.

The only definite product isolated from the reaction of **2** with nickelocene in benzene at 80 °C was the dysprosium(III) complex **6**. Reduced nickel was deposited as a mirror on the walls of the reaction flask.

No transformations were observed when $Cp_2Fe$ and $Cp_2Co$ were heated with **1** or **2** in benzene at 80 °C for 10 h. Interestingly, addition of $Cp_2Fe$ to a THF solution of **2** caused immediate formation of $DyI_3$ and DyIRR' (R,R′ = fragments of THF). Ferrocene was isolated unchanged from the reaction mixture. As it was mentioned above, similar transformations have been observed before in the reactions of **1** and **2** with aromatic compounds or phenyl derivatives of mercury, germanium and tin in THF or DME.[4]

## Conclusions

The study revealed that the iodides **1** and **2** could react with metallocenes of vanadium, chromium, and nickel in nonsolvating aromatic solvents, but only in the reactions with vanadocene in benzene was the expected bis(arene) complex obtained in noticeable amounts indicative of the redox character of the transformations. In all other cases, the isolated products $CpLnI_2$, **4**, **5**, and **7** were arene-free. Formation of dimer **5** and cluster **4** reveals that most of these reactions are accompanied by Cp/I exchange. Ferrocene and cobaltocene turned out to be inert toward iodides **1** and **2** in benzene.

## Experimental Section

**General Remarks:** All procedures were performed under vacuum using standard Schlenk-tube techniques. Benzene, cumene, and mesitylene were dried by refluxing over sodium and treated with **1** for 30 min before use. Diiodides **1** and **2** were purchased from Synor

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(Nizhny Novgorod) and used without additional purification. Vanadocene and cobaltocene were prepared according to published procedures.[17,18] Ferrocene, nickelocene, and chromocene were purchased from Aldrich. The ESR spectra were recorded with a Bruker 200D-SRC instrument. The IR spectra of the samples, prepared as Nujol mulls, were recorded with a Specord M-75 spectrometer. Melting points were determined in sealed capillaries.

**Reaction of $DyI_2$ (2) with $Cp_2V$ (3) in Benzene:** A solution of **3** (0.2 g, 1.10 mmol) in benzene (10 mL) was added to a powder of **2** (1.89 g, 4.54 mmol), and the mixture was stirred at 80 °C for 10 h. The resultant dark brown solution was separated from the precipitate by decantation, the solvent was removed by evaporation in vacuo, and the residue was extracted with hexane (2×10 mL). The extract was placed into an apparatus for sublimation, hexane was evaporated in vacuo, and the solid residue was heated gradually up to 110 °C. The sublimed mixture of violet and dark brown crystals was sublimed again. At 50–60 °C (0.1 Torr) violet crystals of **3** (0.11 g, 54%) were collected and separated [ESR (77 K): $g_\perp$ = 4.0, $A_\perp$ ($^{51}$V) = 2.8 mTs, $g$ = 2.0]. Sublimation of the remaining substance at 100–110 °C (0.1 Torr) gave dark brown crystals of $(C_6H_6)_2V$. Yield 55 mg (24%); m.p. 275–277 °C; ESR (293 K): $A_i(^{51}V)$ = 6.35 mT, $g_i$ = 1.986. The solid residue after extraction with hexane was recrystallized from THF to give $CpDyI_2(THF)_3$ (75 mg, 5%). Decomposition temperature, IR spectrum and results of elemental analysis of the product were identical to those of the previously synthesized compound.[19]

**Reaction of $NdI_2$ (1) with $Cp_2V$ (3) in Benzene:** Compound **1** (3.46 g, 8.69 mmol) reacted with compound **3** (0.35 g, 1.93 mmol), under the conditions of the previous experiment, to give $(C_6H_6)_2V$ (42 mg, 10%). The sublimation of the solid products gave unreacted **3** (0.24 g, 69%). From the solid residue after hexane extraction, a few crystals of $CpNdI_2(THF)_3$ were isolated by recrystallization from THF. Characteristics of the product were identical to those of the complex obtained in the reaction of **1** with cyclopentadiene.[19]

**Reaction of $DyI_2$ (2) with $Cp_2V$ (3) in Isopropylbenzene:** A mixture of **2** (1.01 g, 2.43 mmol), **3** (0.2 g, 1.11 mmol), and isopropylbenzene (7 mL) was stirred at 90 °C for 20 h. The resultant red-brown solution was separated from the precipitate by decantation, and cumene was removed in vacuo. A waxy residue was extracted with hexane (10 mL), and the extract was transferred into a sublimation apparatus. After evaporation of hexane, the solid products were sublimed in vacuo by gradually increasing the temperature from 20 °C to 150 °C. Unreacted **3** (57 mg, 29%), which sublimed at 50–60 °C, was collected in the top part of the apparatus. At 100–120 °C, yellow needle crystals of $(i\mathrm{PrC_6H_5})_2V$ (4 mg, 1%) sublimed; ESR (300 K): $a_i(^{51}V)$ = 6.29 mT, $g_i$ = 1.988, $A_i$(H) = 5 G.

**Reaction of $DyI_2$ (2) with $Cp_2V$ (3) in Naphthalene:** A mixture of **2** (1.6 g, 3.84 mmol), **3** (0.26 g, 1.44 mmol), and naphthalene (2.5 g) was stirred at 110–120 °C in a sealed ampoule. After 20 h, the resultant black mixture was cooled to room temperature to give a black solid from which a mixture of naphthalene and unreacted **3** was separated by sublimation in vacuo at 50–60 °C. The black residue was extracted with benzene (3×30 mL), the greenish solution obtained was concentrated to 8 mL and cooled to 8–10 °C to give violet crystals of **4**. The product was separated by decantation and dried in vacuo at room temperature. A sample of **4** isolated under these conditions contained three molecules of benzene. Yield 0.28 g (5%); m.p. >240 °C (dec.). $C_{63}H_{63}Dy_7I_{15}V$ (3910.94): calcd. C 19.20, H 1.81; found C 19.33, H 1.61. IR (nujol, KBr): $\tilde{\nu}$ = 1010 (s), 796 (s), 673 (m) cm$^{-1}$. The black residue after separation of the benzene extract was dried in vacuo at room temperature to give a black pyrophoric powder (1.35 g). IR (nujol, KBr): $\tilde{\nu}$ = 1600 (w), 1011 (m), 842 (sh), 800 (s), 677 (w), 619 (w) cm$^{-1}$.

**Reaction of $NdI_2$ (1) with $Cp_2Cr$ in Benzene (at 20 °C):** A solution of $Cp_2Cr$ (0.34 g, 0.19 mmol) in benzene (10 mL) was added to a powder of **1** (1.53 g, 0.38 mmol), and the mixture was stirred for 10 h at ambient temperature. The resultant dark-cherry solution was separated from the precipitate, and the solvent was removed in vacuo. The waxy residue was extracted with hexane (2×10 mL). Slow evaporation of hexane from the extract afforded **5** (0.18 g, 39%) as dark cherry-red crystals with m.p. 84–87 °C (dec.). $C_{10}H_{10}Cr_2I_2$ (487.90): calcd. C 24.60, H 2.05, Cr 21.32; found C 25.01, H 2.50, Cr 21.05. IR (nujol, KBr): $\tilde{\nu}$ = 3088 (w), 1011 (s), 815 (s), 784 (s), 720 (m), 665 (m), 561 (m) cm$^{-1}$.

**Reaction of $DyI_2$ (2) with $Cp_2Cr$ in Benzene (at 20 °C):** Under the conditions of the previous experiment, compound **2** (1.12 g, 2.69 mmol) was treated with $Cp_2Cr$ (0.24 g, 1.32 mmol) in benzene (8 mL). The resultant dark-cherry solution was separated from the precipitate, the solvent was removed in vacuo, and the residue was extracted with pentane. Cooling the extract to 0 °C gave **5** (0.142 g, 44%). The residue after pentane extraction was recrystallized from toluene to give **6** (0.146 g, 26%) as light yellow crystals. $C_{10}H_{10}DyI$ (739.02): calcd. Dy 38.74; found Dy 38.72. IR (nujol, KBr): $\tilde{\nu}$ = 1008 (s), 890 (w), 781 (s), 727 (m), 661 (m) cm$^{-1}$.

**Reaction of $DyI_2$ (2) with $Cp_2Cr$ in Benzene (at 80 °C):** A mixture of **2** (0.537 g, 1.29 mmol) and $Cp_2Cr$ (0.14 g, 0.77 mmol) in benzene (8 mL) was stirred at 80 °C for 12 h. The initial orange-red color of the solution gradually turned pale green. The solution was decanted from the black precipitate, and the solvent was evaporated in vacuo to leave behind a greenish powder, which was extracted with toluene. Cooling of the toluene extract in a refrigerator yielded yellow crystals of **6** (92 mg, 34%). $C_{10}H_{10}DyI$ (739.02): calcd. C 26.61, H 2.38, Dy 38.74; found C26.35, H 2.56, Dy 38.56. The IR spectrum was identical to that of the compound from the previous experiment. Among the isolated yellow crystals of **6**, a few greenish-yellow crystals were found. X-ray diffraction investigation of one of them revealed the compound to be -ate complex **7**. The amount of isolated **7** was not enough for elemental and spectroscopic analyses.

**Reaction of $DyI_2$ (2) with $Cp_2Ni$ in Benzene:** A solution of $Cp_2Ni$ (0.12 g, 0.64 mmol) in benzene (15 mL) was added to a powder of **2** (0.56 g, 1.34 mmol), and the mixture was stirred at 70 °C for 12 h. Formation of a nickel mirror on the walls of the reactor was observed. The resultant wine-colored solution was separated from the precipitate, and the latter was washed with benzene (15 mL). The reaction solution and benzene wash were combined, and the solvent was evaporated in vacuo. The solid residue was recrystallized from benzene to give **6** (0.11 g, 42%).

**X-ray Diffraction Study:** The X-ray diffraction data were collected with a SMART APEX diffractometer (graphite-monochromated, Mo-$K_\alpha$-radiation, φ-ω-scan technique, $\lambda$ = 0.71073 Å). The intensity data were integrated by the SAINT program.[20] SADABS[21] was used to perform area-detector scaling and absorption corrections. The structures were solved by direct methods and refined on $F_2$ using all reflections with the SHELXTL package.[22] All non-hydrogen atoms were refined anisotropically. The H atoms in **5** and **7** [except H(2)] were found from Fourier synthesis and refined isotropically. The H atoms in **4** and the H(2) atom in **5** were placed in calculated positions and refined in the "riding-model". In the unit cell of **4** were found the solvated molecules of benzene. The details of crystallographic, collection, and refinement data for **4**, **5**, and **7** are shown in the Table 1. The selected geometric characteristics for **4**, **5**, and **7** are given in the captions to Figure 1, Figure 2,

# Tetra- and Decanuclear Iron(II) Complexes of Thiacalixarene Macrocycles: Synthesis, Structure, Mössbauer Spectroscopy and Magnetic Properties

Cédric Desroches,[a] Guillaume Pilet,[a] Petra Á. Szilágyi,[b] G. Molnár,[b] Serguei A. Borshch,[c] Azzedine Bousseksou,[b] Stéphane Parola,[a] and Dominique Luneau*[a,d]

**Keywords:** Calixarenes / Hydrothermal synthesis / Iron / Magnetic properties / Mössbauer spectroscopy

Two iron(II) complexes, namely $[Fe_4(L)_2]\cdot H_2O$ (**1**) and $[Fe_{10}(L)_4Cl_4]\cdot 2H_2O$ (**2**), have been synthesised under solvothermal conditions by treating *p-tert*-butylthiacalix[4]arene ($LH_4$) with $FeCl_2$ in methanol. Compound **1** crystallises in the orthorhombic system (space group *Immm*) with the unit-cell parameters $a$ = 17.8308(4), $b$ = 19.1372(3), $c$ = 28.8391(6) Å and $V$ = 9840.8(3) Å$^3$ ($Z$ = 2). Compound **2** crystallises in the triclinic system (space group $P\bar{1}$) with the unit-cell parameters $a$ = 13.8036(4), $b$ = 18.8373(4), $c$ = 20.1978(6) Å, $\alpha$ = 65.772(2)°, $\beta$ = 74.120(1)°, $\gamma$ = 71.922(1)° and $V$ = 4487.6(2) Å$^3$ (Z = 1). Compound **1** is a neutral tetranuclear complex and is best described as an iron(II) square sandwiched between two thiacalixarene macrocycles. Each iron centre is six-coordinate in a trigonal-prismatic geometry made up of four phenoxy oxygen atoms plus two sulfur atoms. Compound **2** is a neutral centrosymmetric decanuclear complex and may be viewed as a dimer of double chloro-bridged pentanuclear complexes. Mössbauer spectra of compounds **1** and **2** have been recorded at different temperatures between 80 and 298 K. Each sub-spectrum can be characterised by a quadrupolar doublet corresponding to different iron environments where all iron ions are in high-spin state ($S$ = 2). The hyperfine parameters (quadrupole splitting, isomer shift and line width) as well as the Mössbauer spectra area-ratios are in good agreement with the crystallographic data. The two compounds exhibit magnetic behaviours indicating that antiferromagnetic interactions occur between the iron(II) centres. The simulation of the magnetic susceptibility was done in the case of compound **1** with a single exchange coupling constant ($J$ = –4 cm$^{-1}$ and $g$ = 2.02) between the iron(II) ions [$H = -J(S_1S_2 + S_2S_3 + S_3S_4 + S_1S_4)$].

## Introduction

As part of our involvement in molecular magnetism[1,2] we are interested in molecular polymetallic species. One of our motivations lies in the so-called single-molecule magnets (SMMs),[3,4] which behave as single-domain magnetic particles. Their relevance as potential components of quantum computing[5] has triggered much of the recent progress in the field of molecular magnetism, as well as in those of the polynuclear complexes.[6] Many polynuclear complexes have been isolated but few exhibit SMM properties, or at temperatures that are too low for applications. Therefore, there is a real need for discovering new systems. Another motivation lies simply in the chemical point of view, where there is a general interest in finding rational routes for synthesising molecular polymetallic species in the frame of the emerging nanosciences. Up to now many clusters have been obtained serendipitously, but as more examples become available we may be expected to find some rules for predetermination.[7] The main difficulty in the formation of molecular polymetallic aggregates is to avoid the polycondensation of the metal ions, which is generally afforded by using multidentate and bulky organic capping ligands.[8]

With this in mind, we have investigated the coordination chemistry of thiacalixarene macrocycles, whose chemistry is well known by some of us.[9–12] Compared to the related calixarenes, the chemistry of thiacalixarenes is recent as the synthesis of thiacalixarenes and their sulfinyl and sulfonyl derivatives has been known only since the late 90's.[13–20] These early reports pointed out the high complexation ability of thiacalixarene macrocycles.[16,17,21,22] This was then proved by the isolation and structural characterisation of complexes of *p-tert*-butylthiacalix[4]arene with $Co^{II}$,[23,24] $Ni^{II}$,[23] $Cu^{II}$,[25] $Zn^{II}$,[24,26] $UO_2$,[27] $Nd^{III}$,[28] and also with the alkali metals.[29] These complexes are either mononu-

clear ($UO_2$ and $Zn^{II}$),[26,27] dinuclear ($Co^{II}$ and $Ni^{II}$),[23] trinuclear ($Co^{II}$ and $Zn^{II}$)[24] or tetranuclear ($Cu^{II}$ and $Nd^{III}$).[25,28] Higher nuclearities have even been found for complexes of *p-tert*-butylthiacalix[6]arene,[30,31] with examples of tetranuclear $Ni^{II}$,[30] pentanuclear $Co^{II}$,[30] decanuclear $Cu^{II}$[31] and also some pentanuclear heterometallic[30] $Ni^{II}_4M^{II}$ (M = Mn, Co, Cu) complexes. In a few cases the magnetic properties of these complexes were also reported.[24–26,31] Despite these attractive results, thiacalixarene complexes are still somewhat scarce, which may be attributed to complications when crystallising them following conventional methods.[24] In contrast, we found that, under solvothermal conditions, *p-tert*-butylthiacalix[4]arene and its sulfonyl and sulfinyl derivatives give polynuclear complexes with most d- and f-block transition-metal ions. We recently reported the synthesis, crystal structures and magnetic properties of two tetranuclear manganese(II) complexes that we synthesised under solvothermal conditions in methanol with *p-tert*-butylthiacalix[4]arene and *p-tert*-butylsulfinylthiacalix[4]arene.[32]

In this paper we describe the syntheses, crystal structures and Mössbauer and magnetic properties of a tetranuclear complex $[Fe^{II}_4(L)_2]$ (**1**) and a decanuclear complex $[Fe^{II}_{10}(L)_4Cl_4]$ (**2**), both of which were obtained with *p-tert*-butylthiacalix[4]arene (L).

## Results and Discussion

### Synthesis

Most previously reported thiacalixarene complexes were synthesised and crystallised under conventional conditions, that is in an open vessel and below the boiling point of the solvent.[24–31] Typical solvents are $CHCl_3$ or $CH_2Cl_2$, in which the thiacalixarenes are very soluble,[15] or DMF or DMSO, where they dissolve quickly upon adding a base such as triethylamine. The down side is that the resulting complexes are also generally very soluble in those solvents, which complicates the growth of single crystals. This is generally achieved with help of a second solvent in which the thiacalixarene complexes are not or sparingly soluble, such as $CH_3CN$, EtOH or MeOH. After trials we found that these conditions and solvents did not afford a strong control of the formation of the clusters and their crystallisation. Water or alcohol are generally better solvents as regards the solubility of the metal salts. Unfortunately, under normal conditions the thiacalixarene macrocycles are sparingly soluble in these solvents This caused us to try the solvothermal synthesis method, which is known to be particularly suited for the reaction and crystallisation of materials with poor solubility as it allows high temperatures with a large panel of solvents in a way that generally favour solubilisation.[33,34] The advantage of this method is that not only is it a way to synthesise new compounds but it is also a way to get them in a crystalline form, which is generally not an easy task under normal conditions. During the last decade this method, which has long been restricted to water (hydrothermal), has undergone a real renaissance with the increasing use of non-aqueous solvents and has also proved to be particularly efficient in coordination chemistry for the synthesis of polyoxometallates,[35,36] metal clusters[37–42] or extended compounds.[43–46]

Under standard conditions we were unable to isolate any iron(II) complexes of the thiacalixarene. In contrast, under solvothermal conditions in methanol, as described in the Experimental Section, we were able to synthesise the two iron(II) compounds (**1** and **2**) reported in this paper reproducibly, in good yields and in the form of single crystals. No base was required for the deprotonation of the phenol groups for either complex. In both cases the compounds were obtained by treating $FeCl_2$ with *p-tert*-butylthiacalix[4]arene ($LH_4$). The difference in the synthesis of compounds **1** and **2** lies in the use of a different thiacalixarene/Fe ratio: for ratios from 1:2 up to 1:3 only the tetranuclear complex **1** is obtained, while compound **2** is obtained only when the thiacalixarene/Fe ratio becomes greater than 1:4. Ascorbic acid was used to avoid possible oxidation of the iron(II) ions. This was particularly required for compound **2**, which is better kept under argon. Indeed, when the reaction is carried without ascorbic acid then the isolated crystals always show some dark zones due to some oxidation of the iron(II) ions. When ascorbic acid is used no oxidation occurs, as demonstrated by the Mössbauer spectra. In contrast, compound **1** is insensitive to oxygen and can be handled without any particular care.

### Description of the Crystal Structures

#### *$[Fe^{II}_4(L)_2]\cdot H_2O$ (1)*

The crystal structure of compound **1** comprises two crystallographically independent entities called hereafter M1 and M2 and exemplified for M1 in Figure 1. One water molecule crystallises per $[Fe_4(L)_2]$ entity. A selection of interatomic distances and angles is given in Table 1.

The asymmetric unit of the M1 entity is built from two independent iron(II) ions (Fe1 and Fe2), two *tert*-butylphenoxy groups and two sulfur atoms (S1 and S2). These latter play the role of linker between the *p-tert*-butylphenoxy groups (four in total) to form the thiacalixarene macrocycle. The asymmetric unit of the M2 entity is built from only one crystallographically independent iron(II) ion (Fe3), two independent *p-tert*-butylphenoxy groups and one sulfur atom (S3). As above, these sulfur atoms link the phenoxy groups to form the thiacalix[4]arene macrocycle. Thus, each of the M1 and M2 entities is built from an iron square sandwiched between two *p-tert*-butylthiacalix[4]arene macrocycles. All phenoxy oxygen atoms are doubly bridging. The complex molecules are neutral. A similar molecular structure $[M^{II}_4(L)_2]$ has been reported previously for a tetranuclear copper(II) complex[24] and by us with manganese(II).[32]

In both entities (M1 and M2) the eight phenoxy oxygen atoms lie at the corner of a compressed square-based parallelepiped. The edges of the parallelepiped are nearly orthogonal [89.5(1)° and 90.0° for M1 and M2, respectively]. The

| Fe1–O1 | 2.04(1) [×4] | Fe2–O1 | 2.04(1) [×4] |
| Fe3–O2 | 2.03(1) [×2] | Fe3–O3 | 2.04(1) [×2] |
| Fe1–S1 | 2.639(4) [×2] | Fe2–S2 | 2.623(4) [×2] |
| Fe3–S3 | 2.621(3) [×2] | | |
| Fe1–O1–Fe2 | 102.5(6) | Fe3–O2–Fe3 | 103.36(6) |
| Fe3–O3–Fe3 | 103.6(8) | | |

[a] Numbers in square brackets indicate the number of identical bonds due to symmetry.

parallelepiped is capped above and below by the two thiacalixarene macrocycles on the square bases (Figure 1). The iron(II) ions are located in the middle and above each of the four lateral faces of the parallelepiped (Figure 1). The deviations of the iron(II) ions from the $[O_4]$ mean plane made by the four phenoxy oxygen atoms are 0.7511 (Fe1), 0.7617 (Fe2) and 0.8032 Å (Fe3).

Each iron(II) ion exhibits the same six-coordinate $[O_4S_2]$ environment (Figure 2) made by four phenoxy oxygen atoms [Fe1–O1 = 2.04(1), Fe2–O1 = 2.04(1), Fe3–O2 = 2.03(1) and Fe3–O3 = 2.04(1) Å] and two sulfur atoms [Fe1–S1 = 2.639(4), Fe2–S2 = 2.623(4) and Fe3–S3 = 2.621(3) Å]. The Fe–O bond lengths are in agreement with previously reported $Fe^{II}$–O(phenoxy) distances.[47–54] The $Fe^{II}$–S bond lengths are longer than the few previously reported for thioether complexes of high-spin iron(II) (2.20–2.29 Å).[55] This should be due to the rigidity of the macrocycle, which does not allow the sulfur atoms to come closer to the iron(II) ions. Careful analysis of the interatomic distances and angles around the iron(II) ions reveals that the coordination polyhedrons are distorted trigonal-prismatic, as shown in Figure 2. The triangular faces of the trigonal prism are defined by two phenoxy oxygen atoms and one sulfur atom belonging to the same thiacalixarene macrocycle and are equilateral. The trigonal twist angles[56] are zero but the triangular faces are not parallel and make angles of 42.16°(Fe1), 42.35°(Fe2) and 41.44°(Fe3). The four coordination polyhedra are orthogonal to each other (Figure 2). The Fe–O–Fe angles are in the range 102.5(6)–103.6(8)° (Table 1).

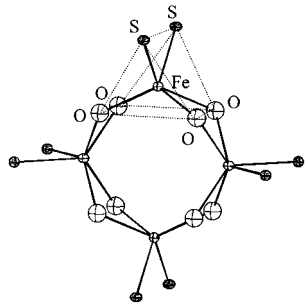

Figure 2. Representation of the iron(II) coordination polyhedra in $[Fe_4(L)_2]$ (**1**); dotted lines indicate the trigonal prism.

In the crystal the $[Fe_4(L)_2]$ entities are packed in infinite molecular chains running parallel to the *b* axis of the unit-cell in such a way that two successive molecules are rotated by 90° with respect to each.

### *$[Fe_{10}(L)_4Cl_4]\cdot 2H_2O$ (2)*

The crystal structure of compound **2** is made up of neutral, centrosymmetrical decanuclear iron(II) moieties which are dimers of two pentanuclear $[Fe^{II}_5\ (L)_2Cl_2]$ units linked by a bis-chloro bridge, as shown in Figure 3. A selection of interatomic distances and angles is given in Table 2.

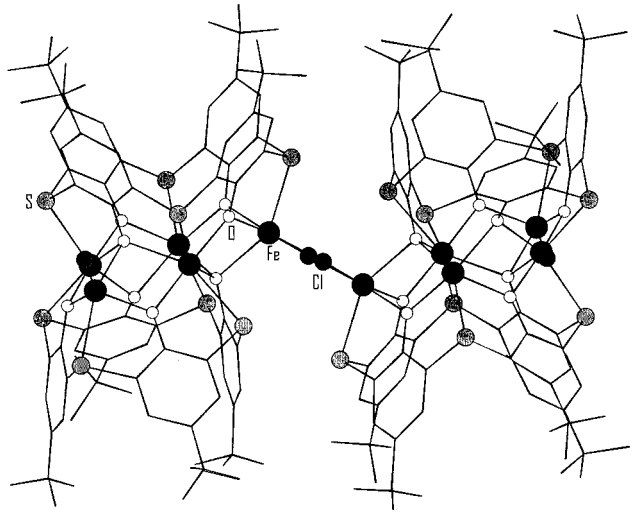

Figure 3. Molecular structure of the $[Fe_{10}(L)_4Cl_4]$ decanuclear iron(II) entities in compound **2**; Fe: black; Cl: dark grey; S: grey; O: white.

Each asymmetric $[Fe^{II}_5\ (L)_2Cl_2]$ unit comprises five iron(II) ions sandwiched between two thiacalixarene macrocycles. The coordination scheme is drastically different from that found for compound **1**, where the two thiacalixarene

[a] Symmetry transformations used to generate equivalent atoms: #1 $-x, -y, -z$.

macrocycles bring eight $\mu_2$-oxygen phenoxy atoms and eight sulfur atoms equally shared between the four iron(II) ions. This is sufficient to provide the charge and coordination number required by the four iron(II) centres with an identical environment. The situation is completely different for compound **2**. As in **1** there are two thiacalixarenes but they have to accommodate five iron(II) ions. The eight sulfur atoms and the eight phenoxy oxygens are not sufficient to fulfil both electro-neutrality and the iron(II) coordination. So in this case this is assumed by two extra chloride ions (Cl1 and Cl2) coordinated to Fe2 and Fe1, respectively, and by $\mu_3$-phenoxy oxygen atoms. What may seem messy at first glance, however, does show some symmetry (Figure 4). Let us consider only the asymmetric $[Fe^{II}_5(L)_2Cl_2]$ unit (Figure 4). Fe1 and Fe2 have practically the same environment of three phenoxy oxygen atoms, one sulfur atom and one chloro ligand. The difference between the two is that in the case of Fe1 the chloride ion is bridging a symmetric Fe1 ion such that Fe1 is six-coordinate with a distorted octahedral polyhedron. In the case of the Fe2 ion, however, the chloro ligand is not bridging and the Fe2 ion is only five-coordinate. It may seem surprising that Cl1 is bridging but Cl2 is not, therefore the structure was checked for possible links to neighbouring iron(II) centres; none was found. The five-coordinate geometry of Fe2 was determined by means of the geometric parameter $\tau = (\beta - \alpha)/60$, where $\beta$ and $\alpha$ are the two largest ligand–metal–ligand bond angles and $\beta > \alpha$.[57] In the case of Fe2 $\beta$ is 149.3(2)° (O5–Fe2–S4 angle) and $\alpha$ is 144.1(2)° (O3–Fe2–Cl1), which gives a $\tau$ parameter of 0.09, in agreement with a square-pyramidal geometry. The Fe4 and Fe5 ions are both six-coordinate to two sulfur atoms, three phenoxy $\mu_2$-oxygen atoms and one phenoxy $\mu_3$-oxygen atom. The Fe3 ion is also six-coordinate but is bound to two sulfur atoms, two $\mu_2$-oxo phenoxy atoms and two $\mu_3$-oxo phenoxy atoms (Figure 4). The six-coordinate geometry around Fe5 and Fe4 is a distorted octahedron. Fe3 is connected through the phenoxy oxygen atoms to the four other iron(II) ions (Fe1, Fe2, Fe4, Fe5). Fe3 and Fe1 and Fe3 and Fe2 are $\mu_2$-O and $\mu_3$-O bridged, respectively, while Fe3 and Fe4 and Fe3 and Fe5 are $\mu_3$-O bridged. Fe1 and Fe5 and Fe2 and Fe4 are $\mu_2$-O and $\mu_3$-O bridged, respectively, while Fe4 and Fe5 are doubly $\mu_2$-O bridged. Fe1 and Fe1# are doubly $\mu_2$-Cl bridged.

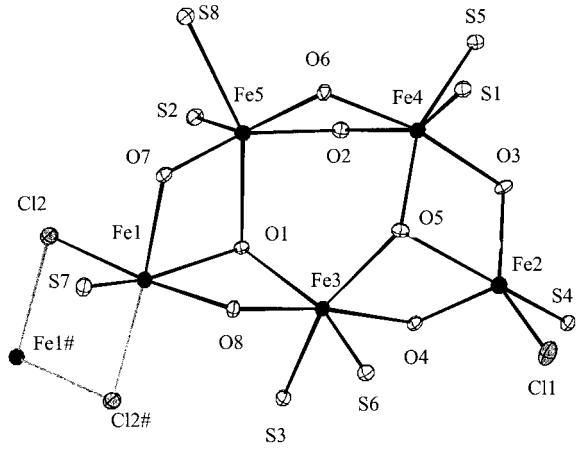

Figure 4. Representation of the coordination environment in compound **2**.

The mean value for the Fe–O($\mu_2$) bond length [2.11(10) Å] in **2** is slightly longer than that for **1** [2.04(1) Å] (Tables 1 and 2). The Fe–O($\mu_3$) bond length [2.202(7)–2.287(7) Å] and Fe–O–Fe bond angles [92.9(3)–115.7(3)°] are in the range of those previously reported.[51]

## Mössbauer Spectroscopy

### *$[Fe^{II}_4(L)_2]\cdot H_2O$ (1)*

Mössbauer spectra of compound **1** recorded at 80 and 293 K are shown in Figure 5. The Mössbauer parameters are given in Table 3. The spectra exhibit one quadrupolar doublet with characteristics of an iron(II) species in a high-spin state ($S = 2$). The four crystallographically slightly different iron centres (identical microenvironments: four oxygen and two sulfur donor atoms) are not distinguishable. The high value of the quadrupole splitting corresponding to a singlet orbital level (2.83 mm s$^{-1}$ at 80 K) can be well explained by the trigonal-prismatic geometry of these sites, which represents a very low symmetry compared to the highest, octahedral one. In addition, the relative independence of the quadrupole splitting with the temperature suggests that the ground state is well isolated.

### *[Fe$_{10}$(L)$_4$Cl$_4$]·2H$_2$O (2)*

Mössbauer spectra of compound **2**, shown in Figure 6, were recorded at 80, 150 and 298 K. The Mössbauer parameters are given in Table 4. The shape of these spectra could indicate some texture effect (asymmetrical spectra). In order to clarify this point, another measurement was carried out at 80 K after thoroughly grinding the sample. The resulting spectrum (not shown) revealed no difference compared to the previous one. The most evident fit of these spectra would be two doublets referring to the sites with five- and sixfold coordination. Possible reasons for this behaviour are as follows: 1) a large difference in their isomer shift, 2) a large difference in their quadrupole splitting, and 3) a quadrupole splitting distribution (if the isomer shifts are the same). However, none of these hypotheses describes the global spectra properly, therefore either the molar ratio of the different sites is not in good agreement with the crystallographic data or the hyperfine parameters cannot be correlated with the X-ray structure. Fitting by three Lorentzian functions was found to describe the spectra reasonably well. The preliminary assumptions for finding the best fits were the following:

the sub-spectrum corresponding to the iron centre with fivefold coordination shows the largest quadrupole splitting;[58]

the molar ratios of the different iron microenvironments Fe1, Fe2 and (Fe3, Fe4, Fe5), as given from the X-ray structure (Figure 4), are 20, 20 and 60%;

the sub-spectrum representing three different iron centres at the same time (Fe3, Fe4 and Fe5; Figure 4) has the largest line-width because of the slight differences between these sites.

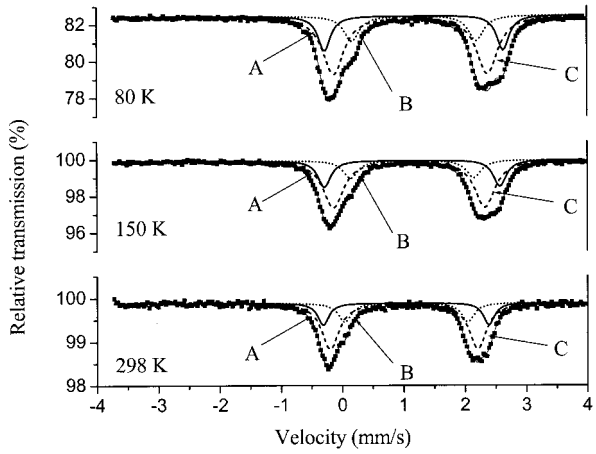

Figure 6. Mössbauer spectra of compound **2** at 80, 150 and 298 K. The sub-spectra A (solid lines), sub-spectra B (dotted lines) and sub-spectra C (dashed lines) hold for the fit of the data as explained in the text.

[a] Iron site(s) in compound **2** (see Figure 4). [b] $A/A_{tot}$: Mössbauer spectrum area ratio. [c] Isomer shift relative to natural iron at room temperature. [d] Quadrupole splitting. [e] Full line width at half maximum.

The temperature dependence of the isomer shift of every sub-spectrum representing different iron microenvironments must be linear, following the second-order Doppler shift.[59]

The best fit is displayed in Figure 6. Each doublet represents iron(II) species in a high-spin state ($S$ = 2). Sub-spectra A represent the Fe2 iron centre within a fivefold coordination (Figure 4) because it displays the largest quadrupole splitting, sub-spectra B represent the Fe1 iron centre (Figure 4) with the apparently low molar ratio (Table 4) and sub-spectra C represent the Fe3, Fe4 and Fe5 (Figure 4) iron centres, which have the same neighbouring atoms in the ligand sphere (four oxygen and two sulfur atoms). The Mössbauer parameters of these sub-spectra should be different because of the slight differences in the crystallographic environments, although these are not resolved in the spectra. However, this doublet has a higher line-width than the other doublets (see Table 4). The isomer shift of each doublet is relatively low despite the high electronegativity of the coordinating atoms. This is due to the bridging oxygen atoms, which are coordinated to three (O1, O5) or to two (O2, O3, O4, O6, O7 and O8) different iron centres

at the same time, and therefore the donated electron density decreases. The relative independence of the quadrupole splitting with the temperature suggests that the electronic excited states are not populated at 298 K.

### Magnetic Properties

The results are displayed in the form of the product of the magnetic susceptibility and the temperature ($\chi T$) in Figures 7 and 8. For both compounds, all features of the curves were reproducible with different samples and no loss of water occurred during the measurements (see Experimental Section).

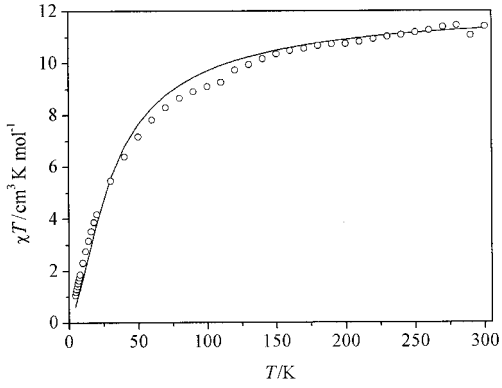

Figure 7. Temperature dependence of the product of the molar magnetic susceptibility ($\chi$) with temperature ($\chi T$) for compound **1** (circles). The solid line shows the best fit of the data.

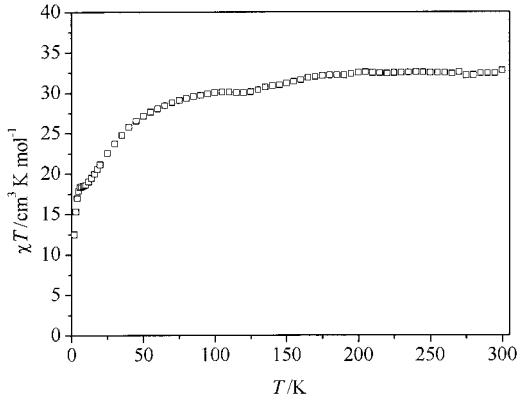

Figure 8. Temperature dependence of the product of the molar magnetic susceptibility ($\chi$) with temperature ($\chi T$) for compound **2** (squares).

### *[$Fe^{II}_4(L)_2$]·$H_2O$ (1)*

At 300 K the $\chi T$ product is 11.4 $cm^3 K mol^{-1}$ for **1** (Figure 7). This value is close to that expected for four uncoupled iron(II) ions (12.0 $cm^3 K mol^{-1}$). Upon cooling the $\chi T$ product decreases continuously down to zero while the magnetic susceptibility ($\chi$) shows a maximum at 5 K. Linearisation of the $1/\chi$ vs. $T$ curve in the range 100–300 K shows Curie–Weiss regimes with a Curie constant, $C$, of 12.9 $cm^3 mol^{-1}$, which is also close to the value expected for four uncoupled iron(II) ions (12.0 $cm^3 K mol^{-1}$). This behaviour indicates that antiferromagnetic interactions occur between the iron(II) ions. Intermolecular interactions can be ruled out because the tetranuclear cores are well separated from each other due to screening by the bulky thiacalixarene ligands. The shortest intermolecular Fe–Fe distances are longer than 16.95(3) Å.

As shown in the structural section, the four iron centres, independently of the entities M1 and M2, have identical environments, which is also in agreement with the Mössbauer study. Moreover, the Fe–O(phenoxy) bond length and the Fe–O–Fe bond angles, which are relevant to magnetic exchange couplings, do not show any striking differences. Accordingly, the magnetic data of compound **1** were analysed by considering one iron(II) square with the four exchange couplings on the edges as equal (i.e. $J = J_{12} = J_{13} = J_{34} = J_{14}$) and no diagonal interactions ($J_{13} = J_{24} = 0$), based on the Heisenberg Hamiltonian $H = -J(S_1S_2 + S_2S_3 + S_3S_4 + S_1S_4)$.

The energy levels of this Hamiltonian can be expressed as $E = -J[S(S + 1) - S_{13}(S_{13} + 1) - S_{24}(S_{24} + 1)]$, where $S$ is the total spin and $S_{13}$ and $S_{24}$ are the intermediate spins. The $S_{13}$ and $S_{24}$ values vary from 0 to 4, and for each pair of intermediate spins the total spin takes values from $|S_{13} - S_{24}|$ to $S_{13} + S_{24}$.

The best least-square fitting of the $\chi T$ vs. $T$ data with the van Vleck equation based on the above energy levels gives a poor fit, with $J = -4\ cm^{-1}$ and $g = 2.02$. However, the value of the exchange coupling is in the range of those previously reported for other $Fe^{II}$–O–$Fe^{II}$ systems.[47,48,60–62] The discrepancy between the fit with the experimental data at low temperatures is due to the fact that no zero-field splitting terms were taken into account. The apparent plateau between 100 and 120 K, which is not accounted for by the calculated curve, cannot yet be explained.

### *[$Fe_{10}(L)_4Cl_4$]·$2H_2O$ (2)*

The $\chi T$ product for this complex is 32.8 $cm^3 K mol^{-1}$. This value is slightly larger than that expected for ten uncoupled iron(II) ions (spin only 30.0 $cm^3 K mol^{-1}$) as is normally observed for high-spin iron(II) complexes. Upon cooling, $\chi T$ decreases slowly while the magnetic susceptibility ($\chi$) increases continuously without any maximum in the temperature range 300–2 K. At 9 K there is a small shoulder on the $\chi T$ curve (with a value of 18.4 $cm^3 K mol^{-1}$), then $\chi T$ decreases rapidly. Linearisation of the $1/\chi$ vs. $T$ curve in the range 100–300 K shows Curie–Weiss regimes with a Curie constant of 34 $cm^3 mol^{-1}$. This behaviour indicates that antiferromagnetic interactions also occur between the iron(II) ions in **2** that are weaker than in compound **1**. One explanation for the shoulder at 9 K is that the magnetic interaction (Fe1···Fe1#) through the bis-chloro bridge is weaker than those within the pentanuclear moieties through the phenoxy and oxo bridges. Therefore, the antiferromagnetic coupling of the $Fe^{II}$ ions within each pentanuclear moiety leads to a non-zero resultant spin, which explains the shoulder; the decrease at lower temperatures is due to the coupling through the bis-chloro bridge. We did not try to fit the magnetic data owing to the large number of mag-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

netic interactions between the iron(II) centres in **2**. Indeed, the fitting of such a system by matrix-diagonalizing techniques is very complicated due to the high nuclearity of the cluster and its low symmetry. The Monte Carlo technique has previously been used for the magnetic data analysis of a decanuclear iron(III) cluster,[63] but the corresponding Heisenberg Hamiltonian contained only three parameters. In our case we have at least five exchange parameters to take into account and a zero-field splitting parameter must probably also be added.

## Concluding Remarks

The two iron(II) complexes reported here, which were obtained by a solvothermal route, confirm the high coordination ability of the thiacalixarene macrocycles. They are among the very few iron(II) polynuclear complexes of high nuclearities. Indeed, there are less than ten $Fe^{II}_4$ clusters[51,64–68] and, to the best of our knowledge, compound **2** is the first iron(II) decanuclear complex. It should be noted that compound **1** is particularly stable as it appears to be insensitive to oxidation by air. Both compounds exhibit weak Fe···Fe intramolecular antiferromagnetic exchange couplings. We are now engaged in a program to synthesise clusters of higher nuclearities with mixed-valence or different metals.

## Experimental Section

All chemicals and solvents were used as received; all preparations and manipulations were performed under aerobic conditions. The *p-tert*-butylthiacalix[4]arene ligand was synthesised by the published procedures.[13,14]

**Synthesis of $[Fe^{II}_4(L)_2]\cdot H_2O$ (1):** Compound **1** was isolated in the form of pale-yellow, needle-shaped crystals from the reaction of *p-tert*-butylthiacalix[4]arene ($LH_4$; 0.15 g, 0.2 mmol) with $FeCl_2$ (0.050 g, 0.4 mmol), ascorbic acid (0.07 g, 0.4 mmol) and methanol (23 mL) in a 43-mL, Teflon-lined autoclave under autogenous pressure at 170 °C for 3 d. The crystals were isolated by filtration then washed with methanol and dried in vacuo. Compound **1** is stable in air and is insoluble in common organic solvents. Yield: 66%. $C_{80}H_{90}Fe_4O_9S_8$ (1675.5): calcd. C 57.34, H 5.41, Fe 13.33, S 15.32; found C 57.77, H 5.4, Fe 13.05, S 15.6.

**Synthesis of $[Fe_{10}(L)_4Cl_4]\cdot 2H_2O$ (2):** Compound **2** was obtained in the form of pale-yellow, irregular, parallelepiped-shaped crystals from the reaction of *p-tert*-butylthiacalix[4]arene ($LH_4$; 0.15 g, 0.2 mmol) with $FeCl_2$ (0.10 g, 0.8 mmol), ascorbic acid (0.07 g, 0.4 mmol) and methanol (23 mL) in a 43-mL, Teflon-lined autoclave under autogenous pressure at 170 °C for 3 d. The crystals were isolated by filtration then washed with methanol and dried in vacuo. Compound **2** is best kept under argon and was found to be soluble in most common organic solvents ($CHCl_3$, $CH_2Cl_2$, etc.). Yield: 52%. $C_{160}H_{180}Cl_4Fe_{10}O_{18}S_{16}$ (3604.4): C 53.31, H 5.03, Cl 3.93, Fe 15.50, S 14.23; found C 53.03, H 4.87, Cl 4.05, Fe 16.05, S 14.57.

### X-ray Crystallography

**Data Collection:** Experimental details for $[Fe_4(L)_2]\cdot H_2O$ (**1**) and $[Fe_{10}(L)_4Cl_4]\cdot 2H_2O$ (**2**) are given in Table 5. Data processing was performed with the KappaCCD analysis software[69] and the lattice constants were refined by a least-squares refinement using 6303 reflections ($1.0° < \theta < 27.9°$) and 12035 reflections ($1.0° < \theta < 27.5°$) for **1** and **2**, respectively.

**Structure Solution and Refinement:** $[Fe^{II}_4(L)_2]\cdot H_2O$ (**1**) crystallises in the orthorhombic system. According to the observed systematic extinctions, the structure was solved in the *Immm* space group (no. 71). $[Fe^{II}_{10}(L)_4Cl_4]\cdot 2H_2O$ (**2**) crystallises in the triclinic system and the structure was solved in the $P\bar{1}$ space group (no. 2). The unit-cell parameters, crystal system, space group and refinement details for both of them are summarised in Table 5. Both structures were

Table 5. Crystal data and structure-refinement parameters for compounds **1** and **2**.

solved by direct methods using SIR97[70] in combination with Fourier difference syntheses and then refined against $F$ using reflections with [$I > 3\sigma(I)$] with the CRYSTALS program.[71] Hydrogen atoms were not refined and were placed either theoretically or found in the Fourier difference maps. All the thermal atomic displacements for non-hydrogen atoms and non-oxygen atoms from water molecules were successfully refined anisotropically.
CCDC-278036 (for **1**) and -278037 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Magnetic Measurements:** The magnetic susceptibilities were measured on bulk polycrystalline samples placed in a Teflon-capped basket, in the range 2–300 K, with a Quantum Design MPMS SQUID magnetometer operating at a field strength of 0.5 T. The data were corrected for the sample holder, the diamagnetism of the previously measured thiacalixarene macrocycle and the diamagnetism of other constituent atoms using Pascal's constants. As the compounds described in the paper contain water of crystallisation, which may be lost during the measurements, every sample was weighed before and after measurement and did not show any lost of weight. For both compounds, the magnetic measurements were also performed on several samples from different preparations.

**Mössbauer Spectroscopy:** Mössbauer spectra were recorded using a constant acceleration type spectrometer equipped with a $^{57}$Co source (15 mCi). The spectra of compounds **1** and **2** were recorded at 80 and 293 K and at 80, 150 and 298 K, respectively. Mössbauer isomer shifts are given relative to natural iron at room temperature. Least-squares fitting of the Mössbauer spectra was carried out with the assumption of a Lorentzian line-shape using MossWinn 3.0.[72]

# Chelate [2-(Iminoethyl)pyridine *N*-oxide]metal Complexes – Synthesis and Structural Comparison with Their Chemically Related 2-(Iminoethyl)pyridine-Derived Systems

**Katrin Nienkemper,[a] Vasily V. Kotov,[a] Gerald Kehr,[a] Gerhard Erker,*[a] and Roland Fröhlich[a]**

**Keywords:** Chelates / Coordination chemistry / N,O ligands / Transition metals

The N,O-chelate ligands 2-(iminoethyl)pyridine *N*-oxide (**2a**) and 2-(iminoethyl)-6-isopropylpyridine *N*-oxide (**2b**) were prepared by conventional synthetic routes, the latter involving a variant of the Reissert–Henze reaction. Treatment of **2a** with $FeCl_2$ resulted in a deoxygenation reaction of the ligand and formation of the salt [bis{2-(iminoethyl)-pyridine}FeCl]$^+$[$FeCl_4$]$^-$ (**18a**). In contrast, the reaction of **2a** with $PdCl_2$ or $CoCl_2$ cleanly furnished the six-membered chelate [κ*N*,*O*-2(iminoethyl)pyridine *N*-oxide]$MCl_2$ complexes (**19a**, M = Pd) or (**20a**, M = Co), respectively, which were both characterised by X-ray diffraction. Treatment of **2b** with [$NiBr_2$(dme)], followed by crystallisation from THF, gave the complex [(κ*N*,*O*-**2b**)$NiBr_2$(THF)] (**21b**), which features a distorted trigonal-bipyramidal coordination geometry of the central metal atom. The reaction of **2a** with [$NiBr_2$(dme)] gave the structurally related complex [(κ*N*,*O*-**2a**)$NiBr_2$(κ*O*-**2a**)] (**21a**). The N,O-chelate Pd complex **19a** was shown to be an active catalyst for the Suzuki coupling reaction. The ligand systems **2a**,**b** and their related 2-(iminoethyl)-pyridines **3a**,**b** and a variety of metal complexes of ligands **3** were also prepared and characterised for comparison by X-ray diffraction.

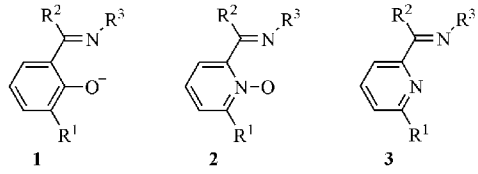
## Introduction

Chelating ligand systems are of considerable importance in metal-catalysed organic reactions[1] and in polymerisation catalysis.[2] Among the various chelating ligand types, many salicylaldimine-derived bi- and multidentate ligands have been found to be very useful. The monoanionic bidentate systems **1**, which feature various types of substituent patterns at the central framework, have been employed extensively in homogeneous Ziegler–Natta-type polymerisation catalysis[3–5] as well as in asymmetric organic reactions,[6] and they form the basis of the many salen-type ligands whose metal complexes have found extensive catalytic uses.[7]

The neutral pyridine *N*-oxide aldimines or ketimines **2** (see Scheme 1) are the neutral analogues of the ubiquitous anionic ligand systems **1**. A variety of such examples and their metal complexes have been described so far[8–12] but overall much less is known about these interesting bidentate ligand systems than their phenolic counterparts, especially with a bulky alkyl substituent ($R^1$) in the 6-position. We have therefore prepared several examples of metal complexes of this class of neutral bidentate ligand systems **2** and compared their structural features with those of the related [2-(iminoethyl)pyridine]metal complex systems **3**.



Scheme 1.

## Results and Discussion

### Preparation of the Chelating Ligand Systems

For this study two general lines of acetylpyridine ($R^2$ = $CH_3$) derived ligands were employed, namely the parent systems ($R^1$ = H) and the 6-isopropyl analogue ($R^1$ = *i*Pr). We also briefly investigated the corresponding *tert*-butyl system ($R^1$ = *t*Bu), but encountered some difficulties that will be described below. All the imine systems of this study were derived from 2,6-diisopropylaniline as the coupling component of the Schiff-base synthesis. 2-Acetylpyridine (**4**) was, thus, condensed with 2,6-diisopropylaniline to yield the Schiff-base product **3a** (see Scheme 2).[13] Oxidation of **4** with *m*-chloroperbenzoic acid in chloroform gave the cor-

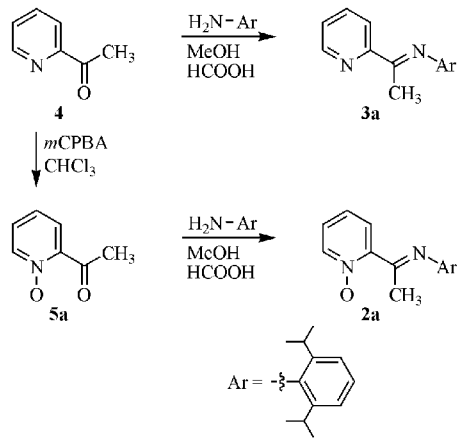
responding 2-acetylpyridine *N*-oxide (**5a**),[14] which was then treated with diisopropylaniline to yield **2a**.



Scheme 2.

The synthesis of the 6-isopropyl and 6-*tert*-butyl derivatives of **2** and **3** started from 2-ethylpyridine (**6**, see Scheme 3). Deprotonation of **6** with *n*-butyllithium at –30 °C followed by treatment with methyl iodide at –50 °C furnished 2-isopropylpyridine (**7b**, 67%).[15] Subsequent α-deprotonation of **7b** was achieved by treatment with the stronger base potassium diisopropylamide (generated in situ from isopropylamine, KO*t*Bu and *n*BuLi) at –50 °C. Quenching with MeI at –75 °C then gave **7c** in 68% yield.[15] The 2-cyano substituent was introduced by a modified Reissert–Henze reaction.[16] For that purpose, compounds **7b** and **7c** were first converted into their respective pyridine *N*-oxides **8b** and **8c** by treatment with *m*-chloroperbenzoic acid in chloroform at 0 °C.[17] The selective CN introduction was achieved by treatment of compounds **8** with $Me_3SiCN$ in the presence of dimethylcarbamoyl chloride in $CH_2Cl_2$ at ambient temperature. Distillation gave the products **9b** (61%) and **9c** (65%) in good yield. The products **9** were then converted into the corresponding 2-acetyl-6-alkyl-pyridines **10b** (25%) and **10c** (36%) by treatment with methyllithium in diethyl ether (–25 °C), followed by aqueous workup and distillation. Subsequent treatment of compounds **10** with 2,6-diisopropylaniline (MeOH, catalysed by formic acid) eventually gave the 6-alkyl-substituted 2-(iminoethyl)pyridine ligands **3b** (R = *i*Pr) and **3c** (R = *t*Bu), respectively.

2-Acetyl-6-isopropylpyridine (**10b**) was converted into the corresponding pyridine *N*-oxide product **11b**. First attempts to achieve the selective oxidation by treatment with *m*-chloroperbenzoic acid were unsuccessful, and stronger oxidation conditions, such as 30% $H_2O_2$ at 80 °C in acetic acid for 20 h, were required to achieve the conversion of **10b** into **11b** (61% isolated). The *tert*-butyl-substituted analogue **10c** even proved inert under these forcing oxidation conditions and could not be converted into the corresponding *N*-oxide under the applied reaction conditions. Eventually, condensation of **11b** with 2,6-diisopropylaniline gave the *N*-aryl-2-(iminoethyl)-6-isopropylpyridine *N*-oxide system **2b**, which was used as a sterically more hindered chelate ligand in this study.

The chelate ligands **3a**, **3b** and **3c** and the pyridine *N*-oxide systems **2a** and **2b** were characterised by X-ray diffraction. Details of **3c** are given in the Supporting Information. The structures of the chelate ligand pairs **3a/2a** and **3b/2b** are depicted for comparison in Figures 1 and 2, respectively.

In the crystal, the ligand system **3a** features a close to planar central (iminoethyl)pyridine framework with an *s-trans* arrangement of the pyridyl and the imino subunits [dihedral angle $\theta 1$ = –177.1(1)° (see Table 1)]. The C7–N9 bond length [1.280(2) Å] is in the typical C=N double bond range,[18] which is (*E*)-configured in **3a**, i.e. the bulky pyridyl and 2,6-diisopropylphenyl substituents are oriented *trans* to each other. The plane of the 2,6-diisopropylphenyl

[a] Bond lengths in Å and angles in °. [b] Two independent molecules.

ring is rotated close to normal from the central C=N plane [$\theta$3 = 104.0(2)/–81.9(2)°].

The conformational arrangement of the corresponding *N*-aryl[2-(iminoethyl)]pyridine *N*-oxide system **2a** is related. The attachment of the oxygen atom to the pyridyl nitrogen atom [N1–O = 1.301(1) Å] causes the adjacent imino moiety to rotate away from the central plane by about 140° ($\theta$2, see Table 1 and Figure 1). This conformational arrangement appears to be the best compromise between competing repulsive interactions between the bulky =*N*-aryl group attached at the ($sp^2$) carbonyl carbon atom C7 or its $CH_3$ group, respectively, with the newly introduced N–O functionality. Again, the 2,6-diisopropylphenyl plane is oriented close to normal [$\theta$3 = 93.1(2)/–92.5(2)°] to the C=N plane in **2a**.

In the ligand system **3b** the bulky isopropyl substituent is attached to the pyridyl 6-position. The framework conformation in **3b** is *s-trans* [$\theta$1 = –179.0(1)°; see Table 1]. The central trisubstituted imino C=N double bond [1.274(2) Å] remains (*E*)-configured and the 2,6-diisopropylphenyl plane is close to normal to the C=N plane [$\theta$3 = 98.0(2)/–88.5(2)°; see Table 1].

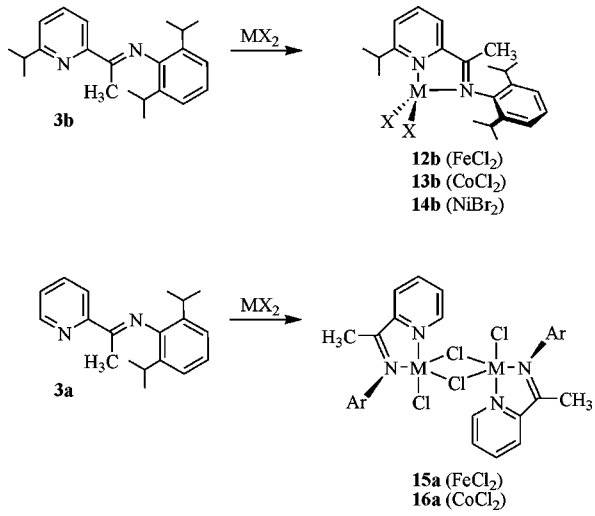
In the pyridine *N*-oxide derivative **2b** the C=N double bond is again substantially rotated away from planarity. Actually, the observed dihedral angle $\theta$2 in **2b** [averaged absolute value 135.6(3)°] is very close to that observed in **2a** (see above and Table 1). Thus, compound **2b** has almost the same optimal rotational angle around the C2–C7 vector, which probably leads to an optimal compensation of the N–O vs. C7–$CH_3$ and C7–N9(Ar) steric interactions. Again, the 2,6-diisopropylphenyl substituent plane is oriented close to normal to the C=N substituent plane [averaged $\theta$3 = –93.1(4)°; see Table 1].

The ligand systems **2** and **3** seem to adopt similar conformational structures in solution. A perpendicular arrangement between the C=N and 2,6-diisopropylphenyl planes would create an axially prochiral subunit in all these compounds. This would be monitored by the occurrence of pairwise diastereotopic methyl groups of the isopropyl substituents of the *N*-aryl substituent. For **3b**, the *i*$Pr_2C_6H_3$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

methyl resonances in the $^1$H NMR spectrum are, by chance, isochronous in $CDCl_3$ at ambient temperature, but they split upon cooling of the sample to –65 °C {$^1$H NMR: $\delta$ = 2.74 [sept, 2 H, C*H*$(CH_3)_{2ar}$], 1.12 and 1.10 [each d, 6 H, CH(C*H*$_3)_{2ar}$] ppm; $^{13}$C NMR: $\delta$ = 27.7 [*C*H$(CH_3)_{2ar}$], 23.1, 23.0 [CH(*C*H$_3)_2]_{ar}$ ppm}. The $^1$H NMR resonances of the remaining isopropyl group at C6 of the pyridyl ring occur at $\delta$ = 3.08 [sept, 1 H, C*H*$(CH_3)_{2py}$] and 1.32 [d, 6 H, CH(*C*H$_3)_{2py}$] ppm {$^{13}$C NMR: $\delta$ = 36.2 [*C*H$(CH_3)_{2py}$], 22.7 [CH(*C*H$_3)_{2py}$] ppm}.

The corresponding pyridine *N*-oxide derivative **2b** also shows a single CH(C*H*$_3)_{2py}$ $^1$H NMR resonance even at –60 °C in $CDCl_3$ [$\delta$ = 1.28 (d, 6 H) ppm; $^{13}$C: $\delta$ = 20.5 (25 °C) ppm]. In contrast, the CH$(CH_3)_{2ar}$ methyl groups of **2b** are diastereotopic at room temperature [$^1$H: $\delta$ = 1.23, 1.16 (each d, each 6 H) ppm; $^{13}$C: $\delta$ = 23.5, 22.9 ppm] which indicates that the rotation around the imino =N–C(aryl) vector is "frozen" on the NMR timescale under these conditions and that the *N*-aryl substituent plane is oriented substantially out of the N=C plane in solution, as was observed in this and the related systems in the crystal.



Scheme 4.

## Metal Complex Formation and Structural Characterisation

First, we treated the ligand system **3b** (R = *i*Pr) with $FeCl_2$, $CoCl_2$, and $NiBr_2$(dme). In clean reactions the corresponding 1:1 chelate complexes [(**3b**)$MX_2$] were obtained in high yields. Single crystals were obtained from all the three complexes **12b** [(**3b**)$FeCl_2$], **13b** [(**3b**)$CoCl_2$] and **14b** [(**3b**)$NiBr_2$], and their molecular structures in the solid state determined (see Table 2 and Scheme 4). Since the three compounds are structurally analogous, we will briefly describe only the nickel system **14b** (see Figure 3 for the structure). The structural data of **12b**, **13b** and **14b** are listed in Table 2. For additional information see the Supporting Information.

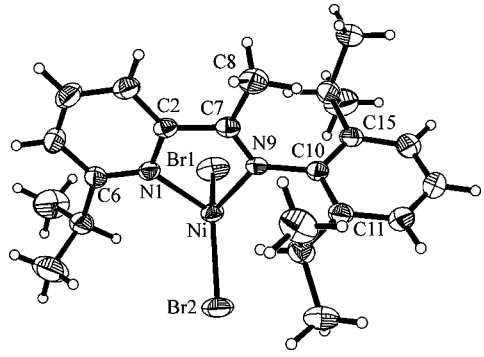


Figure 3. Molecular structure of the nickel chelate complex **14b**.

In complex **14b** the ligand system adopts a *cisoid* conformation [$\theta$(N1–C2–C7–N9) = 2.8(3)°] that allows both the nitrogen centres N1 and N9 to coordinate to the nickel atom. The C7–N9 bond length in the ligand system is not affected by the coordination and retains its value of

1.286(3) Å. The metal–nitrogen bond lengths amount to 1.994(2) Å (Ni–N1) and 1.995(2) Å (Ni–N9). In complex **14b** the nickel atom has a pseudo-tetrahedral coordination geometry with a small N1–Ni–N9 angle of 81.7(1)° inside the five-membered chelate ring and, consequently, a much larger complementary Br1–Ni–Br2 angle of 123.64(2) Å. Again, an (*E*)-trisubstituted C=N unit is found and the 2,6-diisopropylphenyl substituent at the imine nitrogen atom is rotated close to perpendicular to the plane of the central (iminoethyl)pyridine moiety (angle between the planes: 99.7°).

The less bulky parent ligand system **3a** also reacts readily with the metal dihalides $FeCl_2$ or $CoCl_2$. In both cases we were able to obtain single crystals and characterise the structures of the products (**15a** and **16a**, respectively) by X-ray diffraction. The coordination of the *cisoid* chelate ligand in **15a** and **16a** (see Scheme 4) is very similar to that in **12b** and **13b** (see Table 2). However, use of the less bulky ligand **3a** results in the formation of a chloro-bridged dimer.[19] In both **15a** and **16a** the coordination geometry of the central metal atom can best be described as distorted trigonal-bipyramidal with two equivalent half molecules in an overall $C_2$-symmetric framework. The pyridyl nitrogen atom (N1) and Cl1 mark the apical centres of the distorted trigonal bipyramid {**15a**: N1–Fe–Cl1 = 155.6(2)° [163.77(4)°]; the value in brackets is the corresponding value of the isostructural cobalt complex **16a**}. The angles between the three equatorial ligands amount to 126.0(2)° (N9–Fe–Cl1*) [122.86(4)°], 116.7(2)° (N9–Fe–Cl2) [114.03(4)°] and 115.5(1) (Cl1*–Fe–Cl2) [119.79(2)°], which amounts to a sum of the three bonding angles of 358.2° in the iron complex **15a** [356.68° in the cobalt complex **16a**]. Most angles between the apical and basal ligands are rather close to the expected value of 90° [Fe complex **15a**: between 84.1(2)° and 99.1(2)°; Co complex **16a**: between 83.18(4)° and 99.41(4)°] with the exception of the smaller chelate nitrogen angle [N1–Fe–N9 = 74.8(2)°; N1–Co–N9 = 76.64(5)°] and the correspondingly enlarged angle between the bridging halide ligands [Cl1–Fe–Cl2 = 105.3(1)°; Cl1–Co–Cl2 = 103.42(2)°]. The structure of the dimeric (chelate ligand) $FeCl_2$ complex **15a** is depicted in Figure 4 (for further details of the isostructural cobalt system **16a** see the Supporting Information).

The reaction of **3a** with [$NiBr_2$(dme)] in dichloromethane at room temperature takes a slightly different course. We isolated the 2:1 reaction product **17a** (see Scheme 5) of the composition $[(\mathbf{3a})_2NiBr]^+Br^-$ as a green-yellow solid.[20] The general trigonal-bipyramidal structural type of **17a** with the pyridyl nitrogen atoms was determined by X-ray diffraction but the quality of the X-ray crystal structure analysis of **17a** was too poor to allow for any detailed discussion.

Let us now turn to the reactions of the chelate pyridine *N*-oxide ligands with the metal halides. The reaction of **2a** with $FeCl_2$ did not give an (iminoethyl)pyridine *N*-oxide complex as one might have expected. Instead, it turned out that the *N*-oxide is reduced by part of the iron. Crystallisation of the crude reaction product furnished single crystals of the $Fe^{II}/Fe^{III}$ salt of the deoxygenated (iminoethyl)pyridine ligand $[(\mathbf{3a})_2FeCl]^+[FeCl_4]^-$ (**18a**; see Scheme 6 and Figure 5). The X-ray crystal structure analysis of **18a**, although of a rather poor quality, shows a distorted trigonal-bipyramidal coordination geometry around the $Fe^{II}$ centre in the cation (the $Fe^{III}$ centre in the $[FeCl_4]^-$ ion is tetrahedrally coordinated) with the pyridine nitrogen atoms oriented *trans* to each other at the apical positions [N1A–Fe1–N1B = 159.5(3)°] and a sum of the basal ligand angles [Cl1–Fe1–N9A = 117.2(2)°; Cl1–Fe–N9B = 117.8(2)°; N9A–Fe–N9B = 124.9(3)°] of 359.9°.

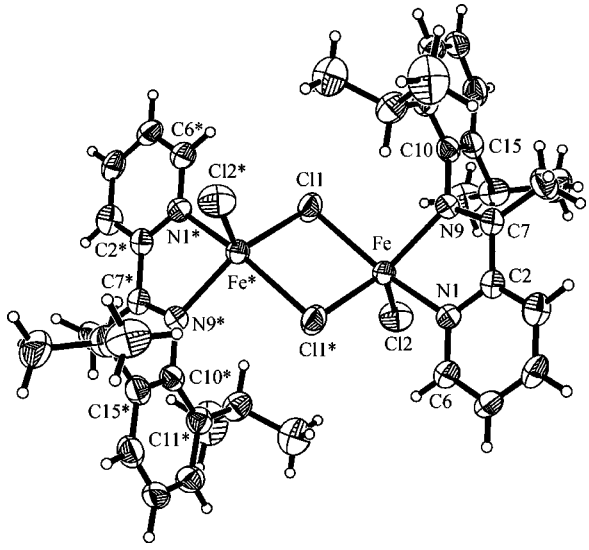

Figure 4. View of the molecular structure of the dimeric iron complex **15a**.

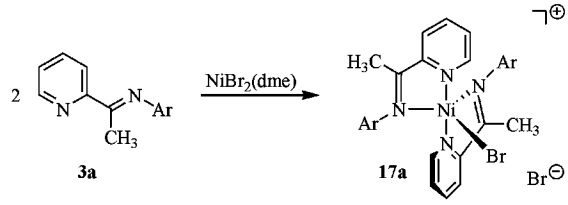
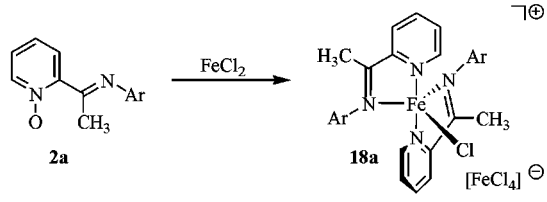


Scheme 5.



Scheme 6.

The reaction of the N,O-chelate ligand **2a** with $PdCl_2$ gave complex **19a** (see Scheme 7), which was isolated as a yellow solid in 75% yield. The X-ray crystal-structure analysis showed a six-membered chelate structure where both the pyridine *N*-oxide oxygen atom and the imino nitrogen atom are coordinated to the palladium atom [Pd–O1 = 2.029(1) Å; N9–Pd = 2.035(2) Å]. In complex **19a** both the N–O [1.343(2) Å] and the C7–N9 [1.284(2) Å] bond lengths are almost unchanged relative to the free ligand (see

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

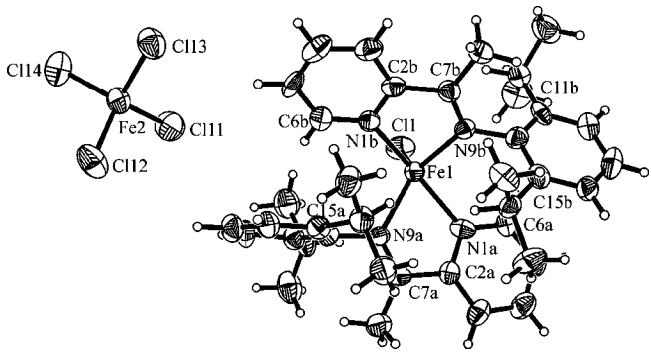


Figure 5. Molecular structure of the salt $[(\mathbf{3a})_2FeCl]^+[FeCl_4]^-$ (**18a**).

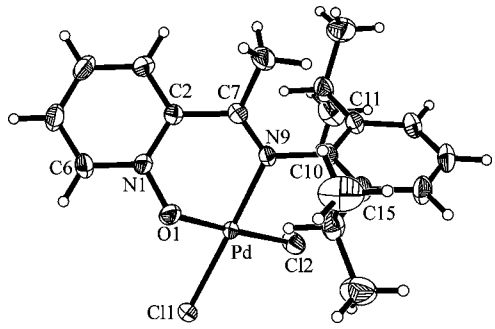

Figure 6. Molecular structure of palladium complex **19a**.

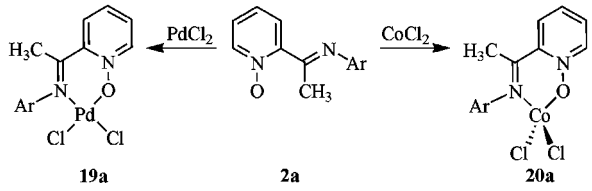
Table 3 and Table 1). The palladium atom in complex **19a** features a square-planar coordination geometry with Pd–Cl bond lengths of 2.2945(5) Å (Cl1) and 2.2678(5) Å (Cl2). The bond angles at Pd amount to 91.52(2)° (Cl1–Pd–Cl2), 90.46(4)° (Cl1–Pd–O1), 84.92(6)° (O1–Pd–N9) and 93.12(4)° (N9–Pd–Cl2) (sum of bonding angles at Pd: 360.02°). In contrast to the free ligand **2a**, the chelate core of complex **19a** is markedly rotated away from planarity, with central dihedral angles of 40.7(3)° (N9–C7–C2–N1) and –1.5(3)° (C7–C2–N1–O1). The six-membered core of complex **19a** features a twist-boat-like conformation (see Figure 6), and the 2,6-diisopropylphenyl substituent at the imine nitrogen centre N9 is rotated almost as far out of the adjacent imine C=N plane as in the free ligand **2a** [C7–N9–C10–C11 = –77.3(2)° in **19a** and –92.5(2)° in **2a**].



Scheme 7.

Complex **19a** is one of the few diamagnetic chelate systems obtained in this study, and could thus be characterised by NMR spectroscopy. Its most prominent feature is the observation of pair-wise diastereotopic methyl groups of the 2,6-diisopropylphenyl substituent at the C=N nitrogen atom [$^1$H NMR: $\delta$ = 1.59, 1.19 (each d, each 6 H) ppm; $^{13}$C: $\delta$ = 24.9, 23.8 ppm].

The [2-(*N*-aryliminoethyl)pyridine *N*-oxide]cobalt complex **20a** was obtained from the reaction of **2a** with $CoCl_2$ (see Scheme 7). The X-ray crystal structure analysis of **20a** features a pseudo-tetrahedral coordination geometry of the central transition metal atom. The intact chelate ligand is again N,O-coordinated, with the 2,6-diisopropylphenyl substituent oriented close to normal to the C=N plane (see Table 3 and Figure 7). The complex framework also features a twist-boat-type six-membered ring conformation with dihedral angles of –22.6(4)° (N1–C2–C7–N9) and 2.2(4)° (C7–C2–N1–O1).

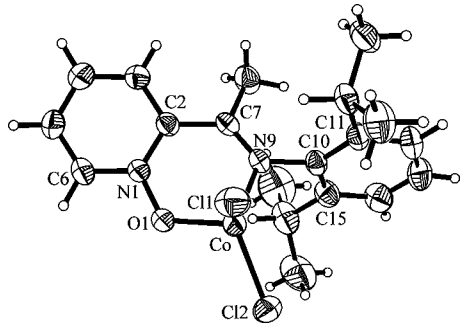


Figure 7. View of the molecular structure of the cobalt complex **20a**.

The reaction of the N,O-chelate ligand **2b** with $[NiBr_2(dme)]$ takes a different course. Again, a 1:1 addition product (**21b**, see Scheme 8) was obtained. Single crystals

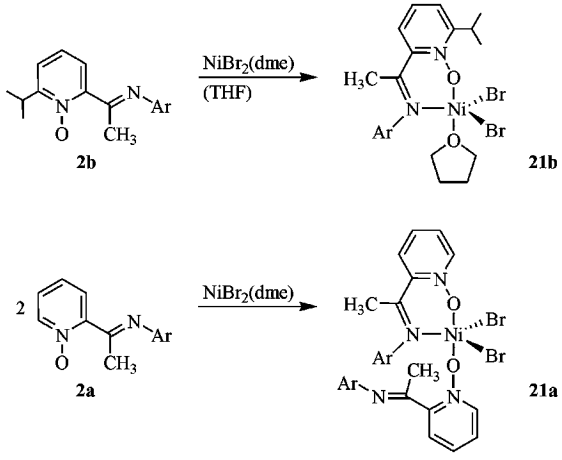
were obtained from THF solution. In **21b** (see Figure 8) the (iminoethyl)pyridine *N*-oxide ligand coordinates to the nickel atom through both the oxygen atom and the imino nitrogen atom to form a favoured six-membered chelate ring. The ring conformation is twisted, with the core atoms N1–C2–C7–N9 deviating from coplanarity by about –32° (see Table 3). The corresponding dihedral angles amount to 57.6(3)° (C2–N1–O1–Ni), 5.9(4)° (C2–C7–N9–Ni), 31.8(2)° (C7–N9–Ni–O1) and –62.2(2)° (N1–O1–Ni–N9). The N1–O1 bond length in complex **21b** is 1.336(3) Å, which is similar to that found in the free ligand **2b**. The nickel atom in complex **21b** features a distorted trigonal-bipyramidal coordination geometry, with the pyridine *N*-oxide oxygen atom O1 [Ni–O1 = 2.005(2) Å] and the oxygen atom of a coordinated THF ligand [Ni–O25 = 2.160(2) Å] being at the apical positions [O1–Ni–O25 = 174.1(1)]. The imino-nitrogen atom N9 [Ni–N9 = 2.041(3) Å] and the pair of bromide ions [Ni–Br1 = 2.4407(6) Å; Ni–Br2 = 2.4173(6) Å] are oriented in the central plane [N9–Ni–Br1 = 96.17(7)°; N9–Ni–Br2 = 126.67(8)°; Br1–Ni–Br2 = 136.84(3)°]. The 2,6-diisopropylphenyl substituent at N2 is rotated almost normal to the C=N imine plane [C7–N9–C10–C11 = –94.3(4)°] as is the bulky $CHMe_2$ group at the α-position of the pyridine *N*-oxide ring.



Scheme 8.

The reaction of the less bulky chelate pyridine *N*-oxide ligand **2a** with [$NiBr_2$(dme)] takes a similar course, except that a 2:1 adduct (**21a**, see Scheme 8 and Figure 9) was obtained after recrystallisation. The X-ray crystal-structure analysis of **21a** revealed the presence of a six-membered chelate ring that is very similar to the corresponding substructural unit in **21b** (see above and Table 3), but instead of the THF solvent the nickel atom in **21a** has picked up a second (iminoethyl)pyridine *N*-oxide ligand (**2a**) and is coordinated to it only through the N–O oxygen atom (κO) to complete its distorted trigonal-bipyramidal coordination sphere [Ni–O1a = 2.055(2) Å; N1a–O1a–Ni = 123.2(2)°]. The κO-coordinated ligand **2a** in **21a** features a conformation that is similar to that of the free ligand [N1a–C2a–C7a–N9a = –126.8(4)°].

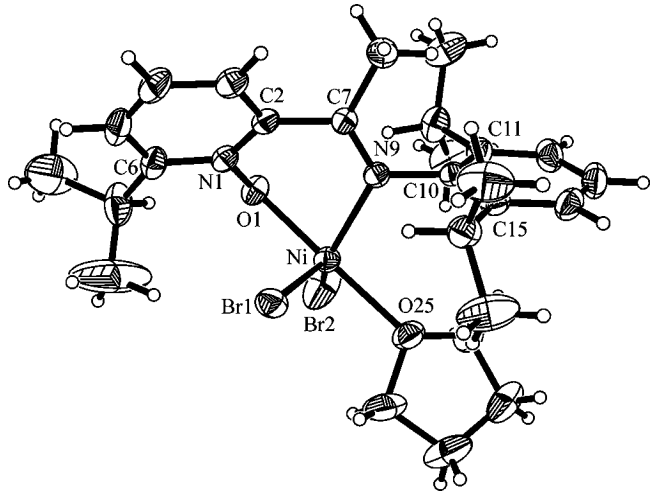


Figure 8. Molecular geometry of the nickel(II) complex **21b**.

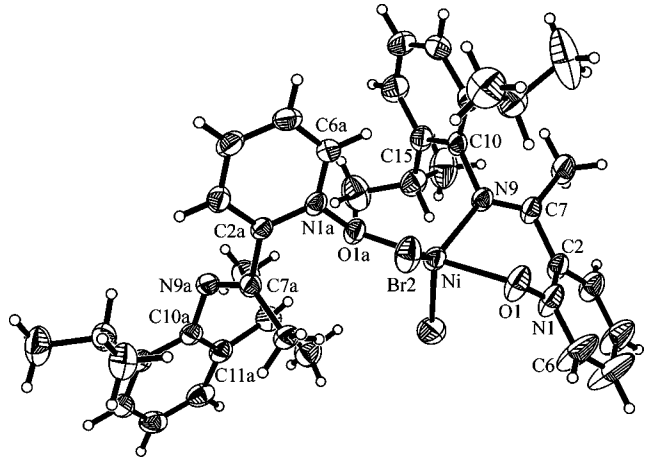

Figure 9. View of the molecular structure of complex **21a**.

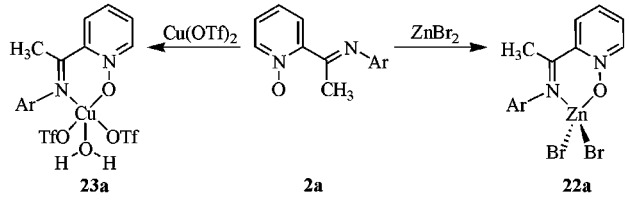
In addition to the metal complexes described above, we also prepared a zinc and a copper complex of the unsubstituted N,O-ligand **2a** (see Scheme 9).



Scheme 9.

The reaction of ligand **2a** with $ZnBr_2$ in acetonitrile at room temperature yielded a bright yellow solid (**22a**). The molecular structure is depicted in Figure 10 and shows a monomeric complex with a four-coordinate zinc atom. The geometry around the metal centre can be described as distorted tetrahedral with an N9–Zn–O1 angle of 84.3(1)° and a Br1–Zn–Br2 angle of 121.60(4)°. Again, the six-membered metallacycle features a twist-boat-type conformation [dihedral angles C2–N1–O1–M = –52.3(5)° and N1–C2–C7–N9 = 26.8(7)°; all values for molecule A].

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

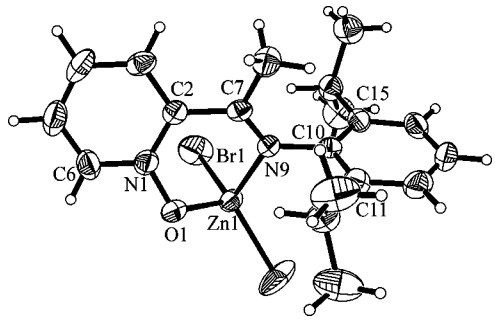


Figure 10. View of the molecular structure of complex **22a**.

Compound **23a** was obtained from the reaction of Cu(OTf)$_2$ with **2a** in dichloromethane (see Figure 11). In this case the metal centre is five-coordinate. The geometry can be regarded as distorted square-pyramidal, with the nitrogen atom of the imino bridge, the pyridine *N*-oxide oxygen atom, the oxygen atom of one triflate group and the oxygen atom of an additional water molecule as the four basal atoms [O2–Cu–N9 = 167.5(1)°; O1–Cu–O6 = 168.1(1)°]. The oxygen atom of the second triflate group occupies the axial coordination site.

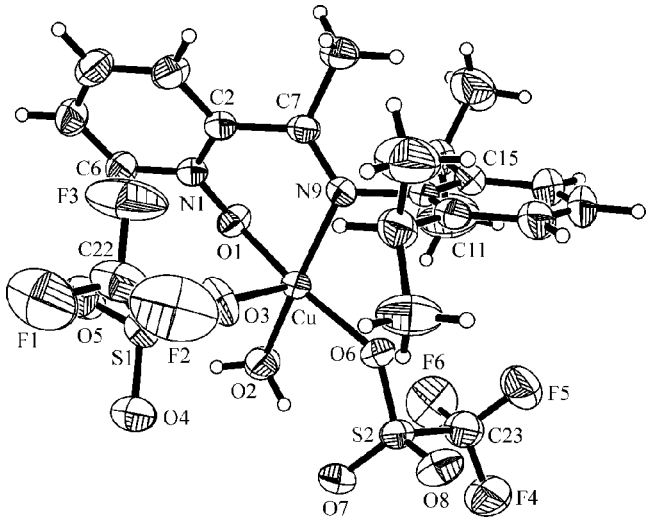

Figure 11. View of the molecular structure of complex **23a**.

We have only begun to investigate the chemistry of the (iminoethyl)pyridine *N*-oxide chelate metal complexes. In a first experiment, the (N,O-chelate)PdCl$_2$ system **19a** was employed as a catalyst in the Suzuki coupling reaction of bromobenzene with phenylboronic acid to yield biphenyl. With 3 mol-% of **19a** in the presence of the base $K_2CO_3$ (toluene, 80 °C, 8 h) a practically quantitative yield of the Ph-Ph coupling product was obtained, which is superior to the reaction catalysed by PdCl$_2$ alone in the absence of a supporting ligand, which gives only a 62% yield of biphenyl under these general reaction conditions. This makes it probably worthwhile to explore the catalytic potential of the [(iminoalkyl)pyridine *N*-oxide]metal complexes described in this article and related systems.

## Conclusion

We have shown that pyridine *N*-oxide systems can readily be obtained in a straightforward synthetic way. The systems **2a** and **2b** in many cases serve as rather stable chelate ligands, cleanly forming the respective κN,O-coordinated complexes with a variety of metal systems. Only in an exceptional case did we observe a redox reaction that resulted in loss of the pyridine *N*-oxide oxygen atom with concurrent formation of a corresponding (iminoethyl)pyridine chelate metal complex. The (iminoethyl)pyridine *N*-oxide complexes are structural analogues of the ubiquitous (salicylimino)metal complexes. However, the (iminoethyl)pyridine *N*-oxides are neutral ligands in contrast to their negatively charged salicylimino ligand analogues. Therefore, one might envision a variety of complementary use of these chelating ligand systems, both in coordination chemistry and catalysis.

## Experimental Section

**General:** All reactions involving air- or moisture-sensitive compounds were carried out under an inert gas using Schlenk-type glassware or in a glovebox. Solvents were dried and distilled prior to use. The following instruments were used for physical characterisation of the compounds: melting points: DSC 2010 TA-instruments; elemental analyses: Foss–Heraeus CHNO-Rapid; MS: Micromass Quattro LC-Z electrospray mass spectrometer; NMR: Bruker AC 200 P ($^1$H: 200 MHz; $^{13}$C: 50 MHz), ARX 300 ($^1$H: 300 MHz; $^{13}$C: 75 MHz), Varian UNITY plus NMR spectrometer ($^1$H: 600 MHz; $^{13}$C: 151 MHz). 2-Isopropylpyridine (**7b**),[15] 2-*tert*-butylpyridine (**7c**),[15] 2-acetylpyridine *N*-oxide (**5a**)[14] and (2,6-diisopropylphenyl)(1-pyridin-2-ylethylidene)amine (**3a**)[13] were synthesised according to methods published elsewhere. Compounds **8b** and **8c** were synthesised by a general procedure for the preparation of amine *N*-oxides.[17] Compounds **9b** and **9c** were synthesised according to a modified Reissert–Henze reaction.[16]

**X-ray Crystal Structure Determinations:** Data sets were collected with Enraf Nonius CAD4 and Nonius KappaCCD diffractometers, with Mo-$K_\alpha$ radiation, equipped with a rotating anode generator. Programs used: data collection EXPRESS (Nonius B.V., 1994) and COLLECT (Nonius B.V., 1998); data reduction MolEN (K. Fair, Enraf–Nonius B.V., 1990) and Denzo-SMN;[21] absorption correction for CCD data SORTAV[22] and Denzo;[23] structure solution SHELXS-97;[24] structure refinement SHELXL-97;[25] graphics XP (BrukerAXS, 2000). CCDC-277028 to -277044 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**2-Isopropylpyridine *N*-Oxide (8b):** A solution of **7b** (70.0 g, 578 mmol) in chloroform (700 mL) was cooled to 0 °C and *m*-chloroperbenzoic acid (143 g, 578 mmol), dissolved in chloroform (400 mL), was added dropwise. The resulting mixture was warmed to ambient temperature within 3 h, then passed through a column of alkaline alumina. Evaporation of the solvent yielded the product as a yellow oil (63.0 g, 79%). $^1$H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta$ = 8.19 (d, $^3J$ = 6.4 Hz, 1 H, 6-H), 7.18 (m, 2 H, 3-H/5-H), 7.12–7.01 (m, 1 H, 4-H), 3.74 [sept, $^3J$ = 6.8 Hz, 1 H, C*H*(CH$_3$)$_2$], 1.24 [d, $^3J$ = 6.9 Hz, 6 H, CH(C*H*$_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$, 25 °C): $\delta$ = 157.7 (C-2), 139.6 (C-6), 125.5 (C-5), 122.9 (C-4), 122.6 (C-3), 27.4 [*C*H(CH$_3$)$_2$], 20.1 [CH(*C*H$_3$)$_2$] ppm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**2-*tert*-Butylpyridine *N*-Oxide (8c):** In an analogous procedure, reaction of **7c** (33.0 g, 244 mmol) in chloroform (750 mL) with *m*-chloroperbenzoic acid (60.2 g, 244 mmol) yielded **8c** as a yellow oil (29.0 g, 79%). $^1$H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta$ = 8.15 (dd, $^3J$ = 6.1, $^4J$ = 1.8 Hz, 1 H, 6-H), 7.29 (dd, $^3J$ = 7.9, $^4J$ = 2.4 Hz, 1 H, 3-H), 7.15 (dt, $^3J$ = 7.9, $^4J$ = 1.8 Hz, 1 H, 4-H), 7.11–7.02 (m, 1 H, 5-H), 1.48 [s, 9 H, C(C$H_3$)$_3$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$, 25 °C): $\delta$ = 157.9 (C-2), 141.6 (C-6), 125.3 (C-5), 123.5 (C-4), 123.4 (C-3), 36.1 [*C*(CH$_3$)$_3$], 26.8 [C(*C*H$_3$)$_3$] ppm.

**6-Isopropylpyridine-2-carbonitrile (9b):** Dimethylcarbamoyl chloride (52.7 mL, 574 mmol) was added dropwise to a solution of **8b** (62.3 g, 454 mmol) and trimethylsilyl cyanide (71.8 mL, 574 mmol) in dichloromethane (400 mL). The resulting mixture was stirred at room temperature for 2 d and the progress of the reaction was monitored by TLC (pentane/chloroform/triethylamine, 20:5:1). Then, a 10% aqueous $K_2CO_3$ solution was added and stirring continued for 15 min. The organic phase was separated and the aqueous layer extracted with dichloromethane. The combined organic layers were dried ($MgSO_4$), the solvent was evaporated and the crude product distilled to give the **9b** as a bright-yellow oil (40.2 g, 61%). $^1$H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.71 (t, $^3J$ = 7.9 Hz, 1 H, 4-H), 7.47 (dd, $^3J$ = 7.9, $^4J$ = 1.0 Hz, 1 H, 3-H), 7.36 (dd, $^3J$ = 7.9, $^4J$ = 1.0 Hz, 1 H, 5-H), 3.06 [sept, $^3J$ = 7.0 Hz, 1 H, C*H*(CH$_3$)$_2$], 1.25 [d, $^3J$ = 7.0 Hz, 6 H, CH(C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$, 25 °C): $\delta$ = 169.3 (C-6), 137.1 (C-4), 133.0 (C-2), 125.8 (C-3), 124.3 (C-5), 117.5 (*C*N), 36.2 [*C*H(CH$_3$)$_2$], 22.1 [CH(*C*H$_3$)$_2$] ppm.

**6-*tert*-Butylpyridine-2-carbonitrile (9c):**[26] Analogously to the preparation of **9b**, reaction of **8c** (29.0 g, 192 mmol), trimethylsilyl cyanide (30.4 mL, 243 mmol) and dimethylcarbamoyl chloride (22.3 mL, 243 mmol) in dichloromethane (200 mL) yielded **9c** as a bright-yellow oil (20.0 g, 65%). $^1$H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.72 (t, $^3J$ = 7.9 Hz, 1 H, 4-H), 7.53 (dd, $^3J$ = 7.9, $^4J$ = 1.1 Hz, 1 H, 3-H), 7.46 (dd, $^3J$ = 7.9, $^4J$ = 1.1 Hz, 1 H, 5-H), 1.32 [s, 9 H, C(C$H_3$)$_3$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$, 25 °C): $\delta$ = 171.4 (C-6), 137.0 (C-4), 132.7 (C-2), 125.3 (C-3), 122.7 (C-5), 117.7 (*C*N), 37.9 [*C*(CH$_3$)$_3$], 29.8 [C(*C*H$_3$)$_2$] ppm.

**2-Acetyl-6-isopropylpyridine (10b):** A solution of **9b** (38.0 g, 260 mmol) in diethyl ether (400 mL) was cooled to –25 °C and methyllithium (179 mL, 286 mmol, 1.6 M solution in diethyl ether) was added dropwise. The reaction mixture was warmed to ambient temperature within 2 h and then quenched with a mixture of aqueous ammonium chloride solution and hydrochloric acid. The organic phase was separated and the aqueous phase extracted with diethyl ether. The ethereal solution was dried ($Na_2SO_4$) and the solvent evaporated. Distillation yielded the product as a colourless oil (10.6 g, 25%). $^1$H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.79 (dd, $^3J$ = 7.7, $^4J$ = 1.2 Hz, 1 H, 5-H), 7.67 (t, $^3J$ = 7.7 Hz, 1 H, 4-H), 7.28 (dd, $^3J$ = 7.7, $^4J$ = 1.2 Hz, 1 H, 3-H), 3.07 [sept, $^3J$ = 7.0 Hz, 1 H, C*H*(CH$_3$)$_2$], 2.68 (s, 3 H, COC$H_3$), 1.29 [d, $^3J$ = 7.0 Hz, 6 H, CH(C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$, 25 °C): $\delta$ = 200.8 (*C*O), 166.6 (C-6), 153.0 (C-2), 136.8 (C-4), 124.2 (C-3), 118.6 (C-5), 36.0 [*C*H(CH$_3$)$_2$], 25.5 (CO*C*H$_3$), 22.4 [CH(*C*H$_3$)$_2$] ppm. $C_{10}H_{13}NO$ (163.22): calcd. C 73.59, H 8.03, N 8.58, found C 73.30, H 8.21, N 8.94.

**2-Acetyl-6-*tert*-butylpyridine (10c):** Analogously to the preparation of **10b**, **10c** was prepared from the reaction of **9c** (18.4 g, 115 mmol) with methyllithium (79.4 mL, 127 mmol, 1.6 M solution in diethyl ether) in diethyl ether (180 mL). After aqueous workup and distillation, the product was obtained as a colourless oil (7.33 g, 36%). $^1$H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.79 (dd, $^3J$ = 7.7, $^4J$ = 1.3 Hz, 1 H, 3-H), 7.69 (t, $^3J$ = 7.7 Hz, 1 H, 4-H), 7.46 (dd, $^3J$ = 7.7, $^4J$ = 1.3 Hz, 1 H, 5-H), 2.69 (s, 3 H, COC$H_3$), 1.36 [s, 9 H, C(C$H_3$)$_3$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$, 25 °C): $\delta$ = 201.0 (*C*O), 168.7 (C-6), 152.4 (C-2), 136.8 (C-4), 122.4 (C-5), 118.1 (C-3), 37.6 [*C*(CH$_3$)$_3$], 30.5 [C(*C*H$_3$)$_3$], 25.6 (CO*C*H$_3$) ppm. $C_{11}H_{15}NO$ (177.24): calcd. C 74.54, H 8.53, N 7.90; found C 74.30, H 8.64, N 7.85.

**2-Acetyl-6-isopropylpyridine *N*-Oxide (11b):** Compound **10b** (6.00 g, 36.8 mmol), dissolved in glacial acetic acid (25 mL), was treated with hydrogen peroxide solution (5.6 mL, 30%). The mixture was allowed to react at 70–80 °C for 10 h. Additional hydrogen peroxide solution (4.6 mL, 30%) was then added and the mixture was heated for another 10 h. After cooling to room temperature, the solvent was evaporated and the crude residue was treated with sodium carbonate solution. The aqueous phase was extracted with dichloromethane, the combined organic layers dried ($Na_2SO_4$) and the solvent evaporated. The product was obtained as a yellow oil (3.99 g, 61%). $^1$H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.40 (dd, $^3J$ = 7.8, $^4J$ = 2.2 Hz, 1 H, 3-H), 7.30 (dd, $^3J$ = 7.8, $^4J$ = 2.2 Hz, 1 H, 5-H), 7.21 (t, $^3J$ = 7.8 Hz, 1 H, 4-H), 3.72 [sept, $^3J$ = 7.1 Hz, 1 H, C*H*(CH$_3$)$_2$], 2.71 (s, 3 H, COC$H_3$), 1.26 [d, $^3J$ = 7.1 Hz, 6 H, CH(C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$, 25 °C): $\delta$ = 196.1 (*C*O), 158.6 (C-6), 147.5 (C-2), 124.9 (C-4), 124.3 (C-5), 123.4 (C-3), 30.2 (CO*C*H$_3$), 27.2 [*C*H(CH$_3$)$_2$], 20.1 [CH(*C*H$_3$)$_2$] ppm. $C_{10}H_{13}NO_2$ (179.22): calcd. C 67.02, H 7.31, N 7.82; found C 66.63, H 7.49, N 8.11.

**General Procedure for the Preparation of the Ketimines 3a, 3b, 2a, 2b:** A mixture of the appropriate 2-acetylpyridine compound (12 mmol), 2,6-diisopropylaniline (16 mmol), a catalytic amount of formic acid and sodium sulfate in methanol was refluxed for several hours. The progress of the reaction was monitored by TLC. After cooling to room temperature, the precipitate was removed by filtration, the solvent was evaporated and the crude product purified by column chromatography on silica gel. In most cases crystals suitable for the X-ray crystal structure analysis were grown from pentane at room temperature by means of solvent evaporation.

**General Procedure for the Preparation of Metal Complexes:** The metal precursor (1 mmol) was suspended in the appropriate solvent (20 mL), stirred, and a solution of the ligand (1 mmol) in the same solvent (10 mL) was added. The resulting mixture was stirred for several hours. For workup, the mixture was filtered, the solvent evaporated, the crude product washed with pentane and dried in vacuo. In most cases crystals suitable for X-ray analyses were grown from a concentrated solution of the complex in a mixture of acetonitrile/dichloromethane/THF layered with pentane.

**Reaction of Ligand 3b with $FeCl_2$; Synthesis of Compound 12b:** A suspension of anhydrous $FeCl_2$ (393 mg, 3.1 mmol) in THF was heated to 70 °C and a solution of **3b** (1.00 g, 3.1 mmol) in THF was added. The resulting mixture was stirred for 2 h. After workup and drying, the product was obtained as brown powder (1.22 g, 87%). MS (ESI): *m*/*z* (%) = 535.3 (100) [$FeCl_2$(**3b**) + $BF_4$]$^-$. $C_{22}H_{30}Cl_2FeN_2$ (449.24): calcd. C 58.82, H 6.73, N 6.24; found C 57.01, H 6.67, N, 5.71.

**X-ray Crystal Structure Analysis of 14b:** Formula $C_{22}H_{30}Br_2N_2Ni$, $M$ = 541.01, yellow crystal 0.50 × 0.30 × 0.08 mm, $a$ = 8.685(1), $b$ = 19.351(1), $c$ = 27.866(1) Å, $V$ = 4683.3(6) Å$^3$, $\rho_{calcd.}$ = 1.535 g cm$^{-3}$, $\mu$ = 42.50 cm$^{-1}$, empirical absorption correction (0.225 ≤ $T$ ≤ 0.727), $Z$ = 8, orthorhombic, space group $Pbca$ (no. 61), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 10395 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.66 Å$^{-1}$, 5573 independent ($R_{int}$ = 0.036) and 4039 observed reflections [$I \geq 2\sigma(I)$], 251 refined parameters, $R$ = 0.038, $wR^2$ = 0.079, max. residual electron density 0.91 (–0.89) e Å$^{-3}$, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 3a with $FeCl_2$; Synthesis of Compound 15a:** Reaction of $FeCl_2$ (1.00 g, 7.89 mmol) in THF with **3a** (2.21 g, 7.89 mmol) at 80 °C yielded a black solid (1.99 g, 62%).

**X-ray Crystal Structure Analysis of 15a:** Formula $C_{19}H_{24}Cl_2FeN_2$, $M$ = 407.15, red crystal 0.30 × 0.25 × 0.15 mm, $a$ = 14.151(1), $b$ = 10.073(1), $c$ = 14.431(1) Å, $\beta$ = 109.97(1)°, $V$ = 1933.4(3) Å$^3$, $\rho_{calcd.}$ = 1.399 g cm$^{-3}$, $\mu$ = 10.59 cm$^{-1}$, empirical absorption correction (0.742 ≤ $T$ ≤ 0.857), $Z$ = 4, monoclinic, space group $P2_1/n$ (no. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 6709 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.62 Å$^{-1}$, 3913 independent ($R_{int}$ = 0.043) and 2907 observed reflections [$I \geq 2\sigma(I)$], 222 refined parameters, $R$ = 0.096, $wR^2$ = 0.291, max. residual electron density 1.97 (–0.62) e Å$^{-3}$, the remaining electron density is located around $x$,0,$z$, all attempts to refine these in a chemically meaningful way failed, analysis only done to confirm the geometry of the complex, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 3a with $CoCl_2$; Synthesis of Compound 16a:** In an analogous procedure, complex **16a** was obtained by treating $CoCl_2$ (1.0 g, 7.70 mmol) with compound **3a** (2.16 g, 7.70 mmol) in THF and collected as a green powder (2.10 g, 66%). MS (ESI): *m*/*z* (%) = 496.1 (100) $[CoCl_2(\mathbf{3a}) + BF_4]^-$. $C_{19}H_{24}Cl_2CoN_2$ (410.25): calcd. C 55.63, H 5.90, N 6.83; found C 56.96, H 6.90, N 5.10.

**X-ray Crystal Structure Analysis of 16a:** Formula $C_{19}H_{24}Cl_2CoN_2$, $M$ = 410.23, pink crystal 0.30 × 0.25 × 0.10 mm, $a$ = 14.132(1), $b$ = 10.132(1), $c$ = 14.308(1) Å, $\beta$ = 110.48(1)°, $V$ = 1919.2(3) Å$^3$, $\rho_{calcd.}$ = 1.420 g cm$^{-3}$, $\mu$ = 11.75 cm$^{-1}$, empirical absorption correction (0.719 ≤ $T$ ≤ 0.892), $Z$ = 4, monoclinic, space group $P2_1/n$ (no. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 21540 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.66 Å$^{-1}$, 4559 independent ($R_{int}$ = 0.044) and 3700 observed reflections [$I \geq 2\sigma(I)$], 222 refined parameters, $R$ = 0.031, $wR^2$ = 0.070, max. residual electron density 0.30 (–0.32) e Å$^{-3}$, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 3a with $[NiBr_2(dme)]$; Synthesis of Compound 17a:** A suspension of $[NiBr_2(dme)]$ (680 mg, 2.22 mmol) in dichloromethane was treated with a solution of **3a** (622 mg, 2.22 mmol) in dichloromethane. The resulting mixture was stirred at room temperature for 2 d, then another 300 mg of **3a** (1.07 mmol) was added, and stirring was continued for 2 d. After workup, compound **17a** was isolated as a green solid (1.46 g, 84%). MS (ESI): *m*/*z* (%) = 699.4 (100) $[NiBr(\mathbf{3a})_2]^+$. $C_{38}H_{48}Br_2N_4Ni$ (779.32): calcd. C 58.57, H 6.21, N 7.19; found C 57.46, H 6.48, N 6.82.

**Reaction of Ligand 2a with $FeCl_2$; Synthesis of Compound 18a:** The reaction of $FeCl_2$ (107 mg, 0.84 mmol) with **2a** (500 mg, 1.69 mmol) in THF at room temperature yielded a black powder (0.52 mmol, 62%). MS (ESI): *m*/*z* (%) = 651.4 (100) $[FeCl(\mathbf{3a})]^+$, 102.0 (45). $C_{38}H_{48}Cl_5Fe_2N_4$ (849.77): calcd. C 53.71, H 5.69, N 6.59; found C 53.02, H 5.78, N 6.58.

**X-ray Crystal Structure Analysis of 18a:** Formula $C_{38}H_{48}ClFeN_4{\cdot}FeCl_4$, $M$ = 849.76, red crystal 0.30 × 0.30 × 0.10 mm, $a$ = 8.835(1), $b$ = 15.414(1), $c$ = 15.138(1) Å, $\beta$ = 95.31(1)°, $V$ = 2052.7(3) Å$^3$, $\rho_{calc}$ = 1.375 g cm$^{-3}$, $\mu$ = 10.64 cm$^{-1}$, empirical absorption correction (0.741 ≤ $T$ ≤ 0.901), $Z$ = 2, monoclinic, space group $P2_1$ (no. 4), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 17177 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.59 Å$^{-1}$, 6886 independent ($R_{int}$ = 0.064) and 6040 observed reflections [$I \geq 2\sigma(I)$], 452 refined parameters, $R$ = 0.099, $wR^2$ = 0.267, Flack parameter 0.01(4), max. residual electron density 2.42 (–0.56) e Å$^{-3}$, very poor, partly amorphous crystal leads to an analysis of limited accuracy, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 2a with $PdCl_2$; Synthesis of Compound 19a:** A suspension of $PdCl_2$ (500 mg, 2.82 mmol) in acetonitrile was treated with a solution of **2a** (836 mg, 2.82 mmol) in acetonitrile. After workup, the product was obtained as an orange solid (1.0 g, 75%). $^1$H NMR (600 MHz, $CH_3CN$, 25 °C): $\delta$ = 8.68 (dd, $^3J$ = 6.5, $^4J$ = 1.3 Hz, 1 H, 6-$H_{py}$), 8.18 (dd, $^3J$ = 8.0, $^4J$ = 1.8 Hz, 1 H, 3-$H_{py}$), 8.08 (dt, $^3J$ = 8.0, $^4J$ = 1.3 Hz, 1 H, 4-$H_{py}$), 7.82 (ddd, $^3J$ = 8.0, $^3J$ = 6.5, $^4J$ = 1.8 Hz, 1 H, 5-$H_{py}$), 7.33 (m, 2 H, 3-/5-$H_{ar}$), 7.28 (m, 1 H, 4-$H_{ar}$), 3.32 [sept, $^3J$ = 6.8 Hz, 2 H, C$H$(CH$_3$)$_{2ar}$], 2.23 (s, 3 H, CNC$H_3$), 1.59 [d, $^3J$ = 6.8 Hz, 6 H, CH(C$H_3^A$CH$_3^B$)$_{ar}$], 1.19 [d, $^3J$ = 6.8 Hz, 6 H, CH(CH$_3^A$C$H_3^B$)$_{ar}$] ppm. MS (ESI): *m*/*z* (%) = 561.0 (100) $[PdCl_2(\mathbf{2a}) + BF_4]^-$. $C_{19}H_{24}Cl_2N_2OPd$ (473.73): calcd. C 48.17, H 5.11, N 5.91; found C 47.94, H 5.49, N 5.97.

**X-ray Crystal Structure Analysis of 19a:** Formula $C_{19}H_{24}Cl_2N_2OPd{\cdot}C_2H_3N$, $M$ = 514.76, red crystal 0.50 × 0.40 × 0.30 mm, $a$ = 9.307(1), $b$ = 17.942(1), $c$ = 13.611(1) Å, $\beta$ = 97.51(1)°, $V$ = 2253.4(3) Å$^3$, $\rho_{calcd.}$ = 1.517 g cm$^{-3}$, $\mu$ = 10.77 cm$^{-1}$, empirical absorption correction (0.615 ≤ $T$ ≤ 0.738), $Z$ = 4, monoclinic, space group $P2_1/n$ (no. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 14417 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.66 Å$^{-1}$, 5323 independent ($R_{int}$ = 0.034) and 5074 observed reflections [$I \geq 2\sigma(I)$], 259 refined parameters, $R$ = 0.026, $wR^2$ = 0.068, max. residual electron density 1.04 (–0.83) e Å$^{-3}$, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 2a with $CoCl_2$; Synthesis of Compound 20a:** Reaction of $CoCl_2$ (1.0 g, 77 mol) with **2a** (2.28 g, 77 mmol) in THF yielded a blue powder (3.12 g, 95%). $C_{19}H_{24}Cl_2CoN_2O$ (426,25): calcd. C 53.54, H 5.68, N 6.57; found C 54.79, H 6.65, N 5.95.

**X-ray Crystal Structure Analysis of 20a:** Formula $C_{19}H_{24}Cl_2CoN_2O{\cdot}C_5H_{12}$, $M$ = 498.38, green crystal 0.60 × 0.10 × 0.05 mm, $a$ = 32.646(1), $b$ = 10.395(1), $c$ = 13.788(1) Å, $\beta$ = 93.73(1)°, $V$ = 4669.1(6) Å$^3$, $\rho_{calcd.}$ = 1.418 g cm$^{-3}$, $\mu$ = 9.83 cm$^{-1}$, empirical absorption correction (0.590 ≤ $T$ ≤ 0.953), $Z$ = 8, monoclinic, space group $C2/c$ (no. 15), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 24564 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.67 Å$^{-1}$, 5836 independent ($R_{int}$ = 0.054) and 3644 observed reflections [$I \geq 2\sigma(I)$], 251 refined parameters, $R$ = 0.052, $wR^2$ = 0.166, max. residual electron density 0.48 (–0.41) e Å$^{-3}$, solvent molecule refined as pentane with geometrical restraints, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 2a with [$NiBr_2$(dme)]; Synthesis of Compound 21a:** A solution of the ligand **2a** (0.77 g, 26 mmol) in dichloromethane was added to a suspension of [$NiBr_2$(dme)] (1.0 g, 26 mmol) in dichloromethane. The resulting mixture was refluxed for 2 h. After workup, compound **21a** was obtained as a brown solid (1.17 g, 54%). MS (ESI): $m/z$ (%) = 731.3 (40) [NiBr(**2a**)$_2$]$^+$, 325.2 (80), 297.2 (100), 178.0 (70), 101.9 (70).

**X-ray Crystal Structure Analysis of 21a:** Formula $C_{38}H_{48}Br_2N_4NiO_2$, $M$ = 811.33, red crystal 0.35 × 0.30 × 0.20 mm, $a$ = 11.156(1), $b$ = 30.146(1), $c$ = 12.011(1) Å, $\beta$ = 109.81(1)°, $V$ = 3800.4(5) Å$^3$, $\rho_{calcd.}$ = 1.418 g cm$^{-3}$, $\mu$ = 26.50 cm$^{-1}$, empirical absorption correction (0.457 ≤ $T$ ≤ 0.619), $Z$ = 4, monoclinic, space group $P2_1/c$ (no. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 22711 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.62 Å$^{-1}$, 7688 independent ($R_{int}$ = 0.059) and 4718 observed reflections [$I \geq 2\sigma(I)$], 434 refined parameters, $R$ = 0.047, $wR^2$ = 0.103, max. residual electron density 0.63 (–0.52) e Å$^{-3}$, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 2b with [$NiBr_2$(dme)]; Synthesis of Compound 21b:** [$NiBr_2$(dme)] (453 mg, 1.48 mmol) was suspended in dichloromethane and **2b** (500 mg, 1.48 mmol) in dichloromethane was added. After workup compound **21b** was isolated as dark-brown solid (610 mg, 74%). MS (ESI) $m/z$ (%) = 477.3 (100) [NiBr(**2b**)]$^+$, 339.4 (61) [**2b** + H]$^+$. $C_{22}H_{30}Br_2N_2NiO$ (556.99): calcd. C 47.44, H 5.43, N 5.03; found C 48.02, H 5.40, N 4.83.

**X-ray Crystal Structure Analysis of 21b:** Formula $C_{26}H_{38}Br_2N_2NiO_2$, $M$ = 629.11, red crystal 0.75 × 0.15 × 0.10 mm, $a$ = 8.744(1), $b$ = 33.910(1), $c$ = 9.367(1) Å, $\beta$ = 95.39(1)°, $V$ = 2765.1(4) Å$^3$, $\rho_{calcd.}$ = 1.511 g cm$^{-3}$, $\mu$ = 36.16 cm$^{-1}$, empirical absorption correction (0.172 ≤ $T$ ≤ 0.714), $Z$ = 4, monoclinic, space group $P2_1/n$ (no. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 19041 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.68 Å$^{-1}$, 6690 independent ($R_{int}$ = 0.054) and 5100 observed reflections [$I \geq 2\sigma(I)$], 305 refined parameters, $R$ = 0.045, $wR^2$ = 0.115, max. residual electron density 1.20 (–1.30) e Å$^{-3}$, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 2a with $ZnBr_2$; Synthesis of Compound 22a:** Reaction of $ZnBr_2$ (0.76 g, 3.37 mmol) with ligand **2a** (1.0 g, 3.37 mmol) in acetonitrile yielded after workup a bright yellow powder (1.70 g, 97%).

**X-ray Crystal Structure Analysis of 22a:** Formula $C_{19}H_{24}Br_2N_2OZn{\cdot}0.5C_4H_8O$ $M$ = 557.64, colourless crystal 0.30 × 0.12 × 0.08 mm, $a$ = 15.943(1), $b$ = 10.254(1), $c$ = 28.396(1) Å, $\beta$ = 97.36(1)°, $V$ = 4603.9(6) Å$^3$, $\rho_{calcd.}$ = 1.609 g cm$^{-3}$, $\mu$ = 45.54 cm$^{-1}$, empirical absorption correction (0.342 ≤ $T$ ≤ 0.712), $Z$ = 8, monoclinic, space group $P2_1/c$ (no. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 29515 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.68 Å$^{-1}$, 11531 independent ($R_{int}$ = 0.075) and 5668 observed reflections [$I \geq 2\sigma(I)$], 506 refined parameters, $R$ = 0.062, $wR^2$ = 0.144, max. residual electron density 1.34 (–1.25) e Å$^{-3}$, hydrogen atoms calculated and refined as riding atoms.

**Reaction of Ligand 2a with $Cu(OTf)_2$; Synthesis of Compound 23a:** $Cu(OTf)_2$ (1.0 g, 2.76 mmol) was treated with ligand **2a** (0.82 g, 2.76 mmol) at room temperature in dichloromethane. After workup a green powder was isolated (1.38 g, 76%).

**X-ray Crystal Structure Analysis of 23a:** Formula $C_{19}H_{24}CuN_2O(H_2O)(CF_3SO_3)_2{\cdot}CH_2Cl_2$, $M$ = 761.02, green crystal 0.40 × 0.15 × 0.05 mm, $a$ = 8.881(1), $b$ = 19.970(1), $c$ = 18.480(1) Å, $\beta$ = 97.77(1)°, $V$ = 3247.4(4) Å$^3$, $\rho_{calcd.}$ = 1.557 g cm$^{-3}$, $\mu$ = 10.44 cm$^{-1}$, empirical absorption correction (0.680 ≤ $T$ ≤ 0.950), $Z$ = 4, monoclinic, space group $P2_1/n$ (no. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\varphi$ scans, 22468 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.68 Å$^{-1}$, 8157 independent ($R_{int}$ = 0.052) and 5356 observed reflections [$I \geq 2\sigma(I)$], 399 refined parameters, $R$ = 0.052, $wR^2$ = 0.132, max. residual electron density 0.71 (–0.51) e Å$^{-3}$, hydrogen atoms at water from difference Fourier calculations, other calculated and all refined as riding atoms.

**Supporting Information** (see footnote on the first page of this article): X-ray crystal structure analyses of **3c**, **12b**, **13b** and **16a**, and additional spectroscopic information for **2a**,**b**, **3b**,**c** and **19a**.

# Bis(stannyl)phosphanyl-Substituted Dichlorosilanes/Germanes − Potential Precursors for a Novel Strategy Toward P–Si/Ge Multiple Bonds?

**Marion Bender,[a] Edgar Niecke,*[a] Martin Nieger,[a] and Rudolf Pietschnig*[b]**

**Keywords:** Silicon / Tin / Phosphorus / Hyperconjugation

A general synthetic route to bis(stannyl)phosphanyl-substituted dichlorosilanes/germanes of the type R–$SiCl_2$–$P(SnMe_3)_2$ and R–$GeCl_2$–$P(SnMe_3)_2$ is reported. For R = Cp* (= 1,2,3,4,5-pentamethylcyclopentadienyl) crystal structures for the corresponding silane and germane could be obtained. These compounds are the first structurally characterized bis(stannyl)phosphanyl-substituted dichlorosilanes/germanes that due to their functionalities should be ideal precursors for the generation of unsaturated PSi and PGe units and possibly phosphasilynes and phosphagermynes.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

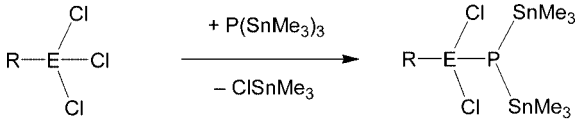
## Introduction

After the recent success of preparing stable disilynes,[1–3] the synthesis of triple-bonded systems of silicon and germanium towards other elements remains one of the major challenges in main group chemistry. While examples for transition-metal complexed silylynes and germylynes have been reported,[4–6] triple bonds of silicon and germanium towards other main group elements have not to date been stabilized, despite theoretical predictions.[7,8] In this respect, 1,2-chlorosilane elimination has proven to be unsuccessful, while the analogous chlorostannane elimination has not been exploited for this purpose to date. This prompted us to investigate whether chlorostannane elimination might be a better alternative for generating unsaturated PSi and PGe units.

In this contribution we report on the synthesis and structural characterization of Cp*–$SiCl_2$–$P(SnMe_3)_2$ and Cp*–$GeCl_2$–$P(SnMe_3)_2$ (Cp* = 1,2,3,4,5-pentamethylcyclopentadienyl). They are the first structurally characterized bis(stannyl)phosphanyl-substituted dichlorosilanes/germanes. Owing to their functionalities, they should be ideal precursors for the generation of unsaturated PSi and PGe units and possibly phosphasilynes and phosphagermynes.

## Results and Discussion

To synthesize Cp*–$SiCl_2$–$P(SnMe_3)_2$ (**3a**) and Cp*–$GeCl_2$–$P(SnMe_3)_2$ (**4**), we started from the corresponding trichlorosilane Cp*–$SiCl_3$ (**1**) and trichlorogermane Cp*–$GeCl_3$ (**2**), respectively. In order to introduce the bis(stannyl)phosphanyl group we reacted **1** and **2** with tris(trimethylstannyl)phosphane $P[Sn(CH_3)_3]_3$ neat in the absence of any solvent. At elevated temperature the reaction proceeds under chlorotrimethylstannane elimination, which is continuously sublimed out of the reaction mixture. This approach is necessary to avoid further exchange reactions of the stannaphosphanes.[9,10] In both cases the desired products (**3a**) and (**4**) are obtained in high yield. In addition the related bis(stannyl)phosphanyl dichlorosilanes R-$SiCl_2$–$P(SnMe_3)_2$ [R = Mes (**3b**) (Mes = 2,4,6-trimethylphenyl), Tip (**3c**) (Tip = 2,4,6-triisopropylphenyl)] have been prepared which underlines the generality of this method (Scheme 1).



**1,2** **3,4**

Scheme 1. Synthesis of bis(stannyl)phosphanyl dichlorosilanes/germanes **3a**–**c** [E = Si; R = Cp* (**3a**), Mes (**3b**), Tip (**3c**)], **4** (E = Ge; R = Cp*) from **1** (E = Si) and **2** (E = Ge).

Compounds **3a**–**c** and **4** show an NMR signal in the high field region of the $^{31}P$ NMR spectra (Table 1), which is typical for stannylated phosphanes.[11] Due to the presence of the isotopes $^{117/119}Sn$ in the molecules, the $^1J_{P,Sn}$ coupling constants can be determined directly from the satellite transitions in these spectra. These coupling constants provide valuable information about the P–Sn bond situation which is significantly affected by the electronic behavior of the other substituents at the phosphorous atom. In principle, changing to a more electron-withdrawing substituent (R) should decrease the s-character of the P–Sn σ-bond in compounds of this constitution and therefore the $^1J_{P,Sn}$ coupling

constants. Surprisingly at first sight, we observe just the opposite trend in our series of compounds (Table 1). In the same direction the $^{31}P$ NMR shift values were found to be shifted downfield. Similar observations have been made for other stannylphosphanes.[9–11] A notable feature is the relatively high $^{1}J_{P,Si}$ coupling constant observed in **3a**–**c**, which can be interpreted as an indication of strong electronic interaction within the silylphosphane unit. This is also supported by the short Si–P bond length found in the crystal structure of **3a**. Usually typical $^{1}J_{P,Si}$ values for silylphosphanes range between 16 and 53 Hz [exception $LiP(SiH_3)_2$, 256 Hz].[12] This strong electronic interaction within the silylphosphane unit can be understood assuming hyperconjugative interaction of occupied states at the phosphorus atom with vacant σ*-states derived from the Si–Cl bonds.[13,14] The decrease of $^{1}J_{P,Si}$ on going from **3a** to **3b**,**c** might be explained by the reduced phosphorus s-character of the P–Si bond due to an increase of the electron demand at the silicon atom. In line with these interpretations, the $^{31}P$ chemical shift of **4** appears at a lower field than that of **3a**, since germanium is more electronegative than silicon. Similarly, the formal $sp^2$ centers attached to silicon in **3b**,**c** should be more electron withdrawing than the formal $sp^3$ carbon atoms in **3a** resulting in a deshielding of the phosphorus center. Somewhat more subtle is the situation for the $^{1}J_{P,Sn}$ coupling constants for which an increase is observed with increasing electron demand at the E(IV) center. This trend is most likely a result of two counteracting tendencies. Again a higher electron demand on E(IV) should result in reduced phosphorus s-character of the P–Sn bond and therefore lower $^{1}J_{P,Sn}$ coupling constants. This however, is not observed, and therefore this effect is obviously not the dominant mechanism. The dominant effect leading to the observed increase of the $^{1}J_{P,Sn}$ coupling constants might, however, be attributed to the above-mentioned hyperconjugative interaction of occupied states at the phosphorus atom with vacant σ*-states derived from the Si–Cl bonds. Such occupied states could involve the σ-P–Sn bonds or alternatively the phosphorus lone pair. Increasing the electron demand on the E(IV) center should also increase this hyperconjugative interaction. Therefore, the simultaneous interaction of the phosphorus lone pair (predominant s-character) and the σ-P–Sn bonds with the σ*-states at the E(IV) atom might be responsible for an increase of the $^{1}J_{P,Sn}$ coupling that even overcompensates the decrease expected for more electron-withdrawing groups.

Table 1. Characteristic NMR spectroscopic data of **3a**–**c** and **4**.

| | $\delta(^{31}P)$ [ppm] | $^{1}J(P,^{117}Sn)$ [Hz] | $^{1}J(P,^{119}Sn)$ [Hz] | $^{1}J(P,Si)$ [Hz] |
|---|---|---|---|---|
| **3a** | –272.1 | 669.2 | 721.0 | 116.1 |
| **3b** | –242.5 | 681.2 | 713.4 | 99.0 |
| **3c** | –235.0 | 692.9 | 724.7 | 101.4 |
| **4** | –242.4 | 718.4 | 751.5 | – |

We were able to obtain single crystals of **3a** and **4** that were suitable for X-ray diffraction. The crystal structure analysis of **3a** confirms that one chlorine atom in **1** has been displaced by a bis(stannyl)phosphanyl group (Figure 1). The phosphorus atom shows a pyramidal coordination environment with an angular sum of 309.83(7)°. The silicon atom shows a slightly distorted tetrahedral environment with a Cl–Si–Cl angle of 100.6(1)° and a Cl(2)–Si–P angle of 114.31(9)°. The central Si–P bond is at 2.209(2) Å short compared to standard bond lengths (2.24–2.28 Å) and the sum of the covalence radii (2.28 Å).[15,16] Again this contraction can be understood assuming hyperconjugative interaction of occupied σ-states assigned to the P–Sn bond with vacant σ*-states derived from the Si–Cl bonds.[13,14] This interaction should be concomitant with an elongation of the Si–Cl bonds, which in fact is observed. The Si–Cl distances are at 2.078(2) and 2.080(2) Å longer than the standard bond length of 2.02 Å.[15] As a consequence of such hyperconjugative interaction also the Sn–P bond length should be affected. However, the values are at 2.505(1) and 2.510(1) Å for **3a** in the typical range for P–Sn single bonds.[23] The significant elongation of the Si–Cl bonds with no structural change of the P–Sn bonds might be an indication that the hyperconjugative interaction of the phosphorus lone pair with σ*-states derived from the Si–Cl bonds might in fact be more significant in this case. From a Newman projection along the Si–P bond, the eclipsed conformation becomes obvious (Figure 2). The lone pair of the phosphorus atom points towards the Cp* moiety. The almost perfect synperiplanar arrangement of the stannyl groups relative to the Cl atoms deviates only slightly, with dihedral angles Sn–P–Si–Cl of 0.2° and 7.4°. Within these planes the Sn···Cl distances are at 3.639 and 3.706 Å shorter than the sum of the van der Waals radii (Figure 3).[17]

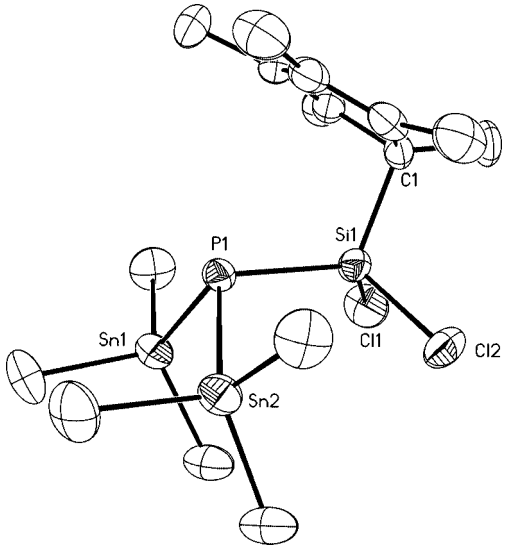

Figure 1. ORTEP plot of **3a** (thermal ellipsoids at 30% probability level).

A similar situation is found in the crystal structure of dichlorogermane **4** (Figure 4). The P–Ge distance is at 2.274(2) Å in the short range of single bond lengths observed for this element combination (2.30–2.36 Å).[18,19] Again, the substituents flanking this central bond show an eclipsed conformation concomitant with attractive Sn···Cl

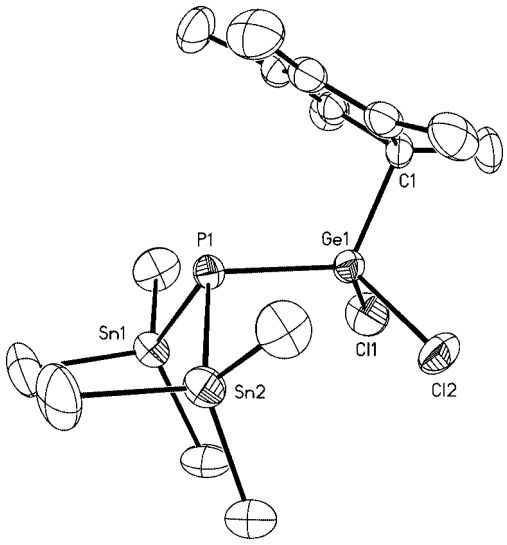

Figure 4. ORTEP plot of **4** (thermal ellipsoids at 30% probability level).

interaction. The Sn···Cl distances are at 3.701 and 3.784 Å close to those found in **3a**. The Ge–Cl distances show values of 2.189(2) and 2.192(2) Å. As in **3a**, the P–Sn distances in **4** show with values of 2.511(2) and 2.519(2) Å no peculiarities. The dihedral angles, by which the Sn–P–Ge–Cl planes differ from a perfect synperiplanar arrangement, are 1.1° and 6.2°.

In both structures the short Si–P or Ge–P bond lengths in addition to the attractive Sn···Cl interaction seem to underline the tendency of both molecules to eliminate chlorostannane. Interestingly in the mass spectra of **3a** and **4**, the molecular ions both lose one equivalent of chlorotrimethylstannane. The elimination of a second equivalent of chlorotrimethylstannane from the resulting phosphasilene and phosphagermene cations is not observed, however.

While solutions of these compounds in aprotic solvents are stable at room temperature, heating of **3a** or **4** as neat substances up to 200 °C leads to elimination of trimethylchlorostannane. During this process polymeric materials are formed which we have not been able to characterize yet. Preliminary results suggest that intermolecular condensation processes via chlorostannane elimination are favored over intramolecular elimination under these conditions.[20]

As outlined earlier, the structural and spectroscopic parameters of **3a**–**c** and **4** suggest significant hyperconjugative interaction in this type of molecules. To get further insight into the bonding situation we performed quantum chemical calculations on the germanium compound **4** which shows the largest hyperconjugative effect. As a result we find good agreement of the theoretical with the experimental structural data. Moreover, a population analysis provides evidence that bonding states at the phosphorus atom as well as the lone pair interact with σ*-states derived from the Ge–Cl bonds. The HOMO-1 of **4** is mainly located at the phosphorus atom but shows some mixing with the Ge–Cl bonds (Figure 5). Quite similar is the situation for the Cp*–centered HOMO-2 that also partially involves the phosphorus atom. In the HOMO-3 the antibonding Ge–Cl σ*-states mix with bonding Sn–P σ-states (Figure 6).

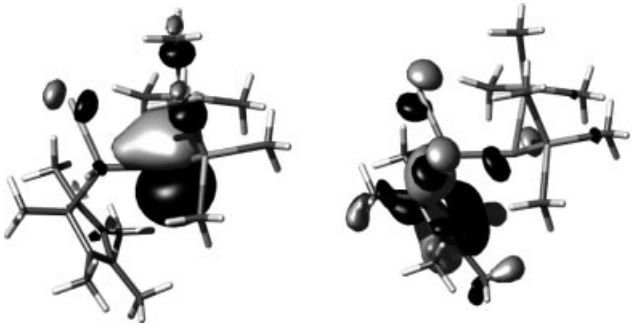

Figure 5. Surface plot of the HOMO-1 (left) and the HOMO-2 (right) in **4**.

In summary, we presented a general synthetic route to bis(stannyl)phosphanyl-substituted dichlorosilanes and germanes that should allow a novel approach towards the first

generation of hypothetical phosphasilylynes and phosphagermylynes. The molecular structures of two representative examples show substantial hyperconjugative interaction between the stannylphosphanyl and the chlorosilyl/germyl units, which are ideally preorganized for chlorostannane elimination.

## Experimental Section

All chemical experiments were performed under argon using standard Schlenk techniques or a glovebox. Solvents were dried with sodium/potassium alloy and stored under argon. $^{1}H$, $^{13}C$, $^{31}P$, $^{29}Si$, and $^{119}Sn$ NMR spectra were recorded with a Bruker AMX 300 at room temperature. Chemical shift values are given in ppm and were referenced to external standards. Mass spectra were measured on Kratos MS-50 and Masslab VG 12–250 spectrometers using the EI ionization technique. Compounds **1**, **2**, and $P(SnMe_3)_3$ were prepared according to published procedures.[21,22]

**Synthesis of 3a–c and 4:** Tris(trimethylstannyl)phosphane (1.05 g, 2 mmol) was placed in a sublimation apparatus together with an equimolar amount of the corresponding trichlorosilanes **1a**–**c** or trichlorogermane **2**. The mixture was heated to 150 °C until all the chlorotrimethylstannane sublimed off (approximately 1 h). The remaining residue was dissolved in pentane (10 mL) and stored at –20 °C. After 12 h, **3a**–**c** precipitated as colorless (**3a**) to slightly yellow (**3b**,**c**; **4**) crystalline solids in 95% (**3a**), 92% (**3b**), 94% (**3c**) and 95% (**4**) yield.

**3a:** M.p. 181 °C. $^{31}P$ NMR ($C_6D_6$): $\delta$ = –272.1 ($^{1}J_{P(119),Sn}$ = 721.0, $^{1}J_{P(117),Sn}$ = 669.2 Hz) ppm. $^{29}Si$ NMR ($C_6D_6$): $\delta$ = 33.1 (d, $^{1}J_{Si,P}$ = 116.1 Hz) ppm. $^{119}Sn$ NMR ($C_6D_6$): $\delta$ = 36.6 (d, $^{1}J_{Sn,P}$ = 721.0, $^{1}J_{Sn,C}$ = 320.4, $^{2}J_{Sn,Si}$ = 36.7, $^{2}J_{(119)Sn,(117)Sn}$ = 219.3 Hz) ppm. $^{1}H$ NMR ($C_6D_6$): $\delta$ = 1.90 (12 H), 1.85 (3 H), 0.44 (d, 18 H, $^{3}J_{H,P}$ = 2.39, $^{2}J_{H(119),Sn}$ = 54.9, $^{2}J_{H(117),Sn}$ = 52.7 Hz) ppm. $^{13}C$ NMR ($C_6D_6$): $\delta$ = 140.0, 134.5, 33.0 (d, $^{2}J_{C,P}$ = 12.0 Hz), 12.7, 12.2, –3.1 (d, $^{2}J_{C,P}$ = 7.6 Hz; $^{1}J_{C(119),Sn}$ = 320, $^{1}J_{C(117),Sn}$ = 305 Hz) ppm. MS (EI): *m*/*z* = 635.8953 ($\delta$ = 0.57 ppm dev.) $[M]^+$, 12%, 438 $[M – ClSn(CH_3)_3]^+$, 35%, 423 $[M – ClSn(CH_3)_3 – CH_3]^+$, 58%, 165 $[Sn(CH_3)_3]^+$, 100%. $C_{16}H_{33}Cl_2GePSn_2$ (637.34): calcd. C 30.15, H 5.22; found C 30.26, H 5.28.

**Crystallographic Details for 3a:** A colorless crystal of **3a** with dimensions 0.40 × 0.35 × 0.35 mm was sealed in a glass capillary. The measurements were performed with a Nicolet R3M diffractometer using graphite-monochromatized Mo-$K_a$ radiation at 273 K. A total of 4578 reflections were collected ($\Theta_{max}$ = 25.00°), from which 4383 were unique ($R_{int}$ = 0.0361), with 4380 having $I > 2\sigma(I)$. The structure was solved by direct methods and refined by full-matrix least-squares techniques against $F^2$ with SHELXTL-Plus[28]. The non-hydrogen atoms were refined with anisotropic displacement parameters without any constraints. For 210 parameters final *R* indices of *R* = 0.0573 and $wR_2$ = 0.1048 (*GOF* = 0.989) were obtained.

**Crystallographic Details for 4:** A yellow crystal of **4** with dimensions 0.55 × 0.55 × 0.25 mm was sealed in a glass capillary. The measurements were performed with a Nicolet R3M diffractometer using graphite-monochromatized Mo-$K_a$ radiation at 293 K. A total of 4549 reflections were collected ($\Theta_{max}$ = 25.00°), from which 4399 were unique ($R_{int}$ = 0.0780), with 4396 having $I > 2\sigma(I)$. The structure was solved by direct methods and refined by full-matrix least-squares techniques against $F^2$ with SHELX-97.[28] The non-hydrogen atoms were refined with anisotropic displacement parameters without any constraints. For 210 parameters final *R* indices of *R* = 0.0744 and $wR_2$ = 0.1174 (*GOF* = 0.946) were obtained (Table 2).

# From Molecular Double-Ladders to an Unprecedented Polycatenation: A Parallel Catenated 3D Network Containing Bicapped Keggin Polyoxometalate Clusters

**Zhenyu Shi,[a] Xiaojun Gu,[a] Jun Peng,*[a] Xia Yu,[a] and Enbo Wang[a]**

**Keywords:** Coordination polymers / Parallel catenation / Double ladders / Hydrothermal synthesis

A new three-dimensional coordination polymer, $\{Cu_3(4,4'\text{-bpy})_3(H_2O)[PMo_{12}O_{40}(VO)_2]\cdot 5H_2O\}_n$ (**1**) (4,4′-bpy = 4,4′-bipyridine), which represents the first example of 3D polycatenation generated by unprecedented parallel catenation of the 1D double ladders, has been hydrothermally synthesized.

## Introduction

Self-assembly of entangled network structures based upon the principle of crystal engineering has attracted much attention not only because of their promising potential applications in catalysis, ion exchange, photochemistry, and electromagnetism, but also because of their intriguing architectures and topologies.[1] Up to now, a number of entangled networks have been reported, however, the "true" engineering is still a great challenge because of the existence of numerous weak interactions in crystal packing. Recently, thanks to the work of Robson, Batten, Ciani and others,[1a,2] many entangled networks have been engineered under a strategy of "network approach". Success in producing such structures depends on understanding and controlling the topological and geometric relationships between molecular modules, along with the coordination characteristics of the metal ions. Of the many reported entangled network structures, those constructed from molecular ladder motifs are very attractive, while relatively rare.[1a] The main reason is probably attributed to the difficulty of obtaining T-shaped building blocks, which are essentially used to build up the ladder structures. So far two kinds of entanglement modes have been found in polycatenated ladders, namely, inclined catenation and parallel catenation (Scheme 1). Usually, inclined catenation of 1D ladders can generate 1D→2D and 1D→3D arrays,[3] while parallel catenation can produce 1D→1D, 1D→2D,[4] and 1D→3D arrays. To the best of our knowledge, no 3D polycatenation produced by parallel catenation of 1D ladders (1D→3D parallel) has been reported.

Scheme 1. Schematic representation of two kinds of entanglement modes of 1D molecular ladders: (top) inclined catenation, (bottom) parallel catenation.

Polyoxometalate (POM) clusters, known to have large sizes and interesting properties for medicine and nonlinear optics, are an outstanding class of linkers for the construction of interpenetrating networks.[1f] They have capabilities similar to those of organic ligands in linking metal centers, as evidenced in the recently reported literature.[5] Hence, directly utilizing POM clusters as linkers promises to be an appealing route to design new entangled network structures. Unfortunately, this strategy remains unexplored owing to the difficulties in choosing suitable POM clusters as a linker whose skeleton can be fully maintained during preparation. Our previous work has proved that bicapped Keggin POM clusters can function as rigid bidentate bridging ligands.[6] Thus, our synthetic strategy is to introduce two kinds of bidentate bridging ligands, i.e. Keggin clusters and 4,4′-bpy, as linkers into the metal centers with potential T-type coordination sites in order to construct new molecular ladders.

Herein, we report a new compound, $\{Cu_3(4,4'\text{-bpy})_3(H_2O)[PMo_{12}O_{40}(VO)_2]\cdot 5H_2O\}_n$ (**1**) (4,4′-bpy = 4,4′-bipyr-

idine), which is based on a new motif 1D double ladder. The polycatenation of 1D double ladders in **1** gives a 3D polycatenation (1D→3D parallel). In comparison with other catenated ladders, **1** has several unique features: (i) a bicapped Keggin cluster $\{PMo_{12}O_{40}(VO)_2\}$ is utilized as a linker, (ii) the new motif, 1D double ladder, is introduced into an entangled system for the first time, and (iii) the 3D architecture is generated by unusual 1D→3D parallel catenation.

## Results and Discussion

The successful isolation of compound **1** relies on the exploitation of hydrothermal techniques and the choice of organic reductant species. So far hydrothermal synthesis has become a powerful method for the preparation of organic-inorganic hybrid materials because of its advantages over other methods (e.g., diffusion and sol-gel techniques), such as the effective use of inorganic and organic reagents with low solubility. Although in most cases the reaction mechanisms under hydrothermal conditions remain elusive and the control and prediction of crystal structures are very difficult, the architecture of the final product depends directly on the interplay of starting materials, pH value, reaction temperature, and pressure. Our interest is to construct new molecular ladders by using 4,4′-bpy and presynthesized Keggin clusters as linkers. Experiments demonstrated that triethylamine was crucial for obtaining compound **1**. Under hydrothermal conditions, triethylamine with moderate ability to reduce can activate the Keggin cluster by reducing $Mo^{VI}$ to $Mo^{V}$ without metal-exchange or decomposition. On the other hand, $Cu^{II}$ ions can also be reduced by it to $Cu^{I}$ ions with potential T-type coordination sites.[6c]

Single crystal X-ray diffraction reveals that **1** is a polycatenated 3D molecular double ladder. As shown in Figure 1, the 1D double ladder is composed of three crystallographically unique $Cu^{I}$ atoms as nodes linked by bicapped Keggin clusters $\{PMo_{12}O_{40}(VO)_2\}$ and 4,4′-bpy molecules. Each $Cu^{I}$ atom displays T-shaped trigonal geometry. Atoms Cu1 and Cu2 are coordinated by two nitrogen atoms from two 4,4′-bpy ligands and one oxygen atom from one {VO} group belonging to a $[PMo^{VI}_8Mo^{V}_4O_{40}(V^{IV}O)_2]^{3-}$ polyanion, while the Cu3 atom is coordinated by two nitrogen atoms from two 4,4′-bpy ligands and one oxygen atom from a water molecule. All the Cu2 atoms are joined together by 4,4′-bpy to form a middle rail of the double ladder. The alternate Cu1 and Cu3 atoms are also linked together by 4,4′-bpy to form the edge rails. The polyanion $[PMo^{VI}_8Mo^{V}_4O_{40}(V^{IV}O)_2]^{3-}$ functions as a rung of the double ladder, linking the two adjacent atoms Cu1 and Cu2 together. The structure of the polyanion $[PMo^{VI}_8Mo^{V}_4O_{40}(V^{IV}O)_2]^{3-}$, similar to that of $[PMo^{V}_6Mo^{VI}_6O_{40}(V^{IV}O)_2]^{5-}$,[7] can best be described as a bicapped Keggin structure that is essentially built on an α-Keggin core $\{PMo_{12}O_{40}\}$ capped by two{VO} units. The central atom P in the polyanion is located at the inversion center, which results in a disordered $PO_4$ tetrahedron, that is, the central atom P is surrounded by a cube of eight oxygen atoms, and each oxygen site is half-occupied. The valence sum calculations,[8] ESR and XPS spectra show that all the vanadium atoms are in the +4 oxidation state, while the four molybdenum atoms are in the +5 oxidation state, which confirms the molecular formula of **1**.

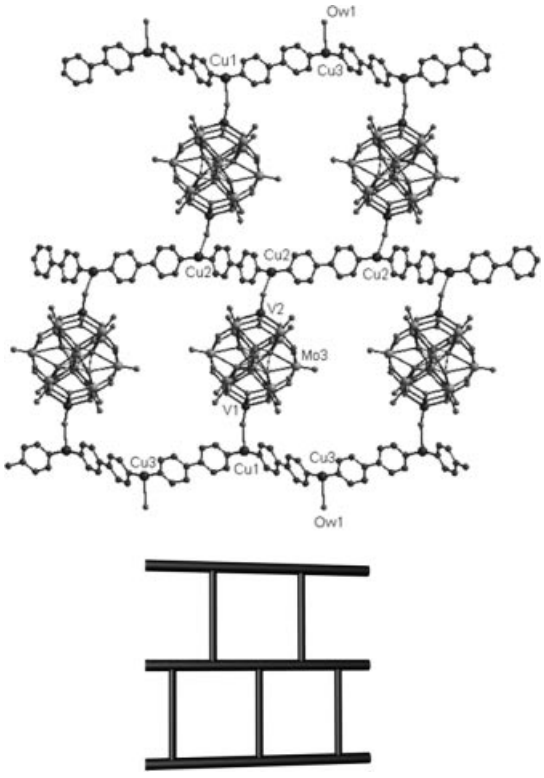

Figure 1. (top) View of part of the infinite 1D double ladder; (bottom) the schematic representation of the 1D double ladder.

In **1**, each rectangle (size ca. 17 × 14 Å) of the double ladder is penetrated by two other parallel double ladders that are staggered with each other (Figure 2). Although all the ladders run in the same direction (*b* axis), the staggered interpenetration by the parallel ladders increases the dimensionality of the whole polymeric system and thus leads to the 1D→3D expansion (Figure 3). To the best of our knowledge, among the few examples of polycatenated 3D molecular ladders (1D→3D), this is the first example of 3D structures generated by parallel catenation. Interpenetration in nature is a space-filling effect to produce a dense framework, but, surprisingly, the multiple catenation of the 1D double ladder does not occupy all the voids formed by one independent ladder. As shown in Figure S1 (Supporting Information), there are 1D channels running along the *c* axis direction that are filled by the guest water molecules. Hydrogen-bonding interactions between the ladders and clathrate water molecules generate a 3D complex supramolecular architecture (Figure S2).

Compared with recently reported Keggin-based compounds with 4,4′-bpy ligands, whose structures are very interesting but noninterpenetrated,[5] compound **1** is a polycatenated 3D molecular double ladder. The formation of such catenation may be ascribed to the bigger sizes of the rectangle grids.

Figure 2. Schematic illustration of entanglement modes of the double ladder in compound **1**.

Figure 3. Schematic view of the 3D structure of compound **1** generated by parallel catenation of 1D double ladders.

The IR spectrum exhibits the characteristic peaks of the α-Keggin structure at 1060, 945, 860, and 775 $cm^{-1}$ in **1**, which are attributed to $\nu$(P–$O_a$), $\nu$(M–$O_t$), $\nu$(M–$O_b$–M), and $\nu$(M–$O_c$–M) (M = V or Mo). The peaks at 1640, 1515, and 1462 $cm^{-1}$ are characteristic of the 4,4′-bpy molecules. In the UV spectrum of **1**, there is a strong absorption peak at 206 nm and a weaker absorption band at 236 nm, which are consistent with the characteristic absorption bands of the Keggin skeleton. The EPR spectrum of **1** exhibits the $V^{IV}$ signal at 293 K with $g$ = 1.9704 (Figure S3). The XPS spectra give a peak at 516.2 eV for **1**, which is attributed to $V^{IV}$, and two overlapped peaks at 232.4 and 231.0 eV attributed to $Mo^{VI}$ and $Mo^{V}$, respectively (Figure S4). All of these results further confirm the structure analysis.

Thermogravimetric analysis in $N_2$ indicates three steps of weight loss. The first two stages of weight loss of 3.98% occur in the temperature range 45–320 °C and correspond to the release of the guest water molecules. The third weight loss of 17.51% occurs from 360 to 570 °C, because of the release of the 4,4′-bpy ligands (Figure S5).

In order to study the redox property of **1**, a **1**-bulk-modified carbon paste electrode (**1**-CPE) was fabricated as the working electrode because of its insolubility in water and most organic solvents. The cyclic voltammetric behavior of **1**-CPE was measured in an aqueous solution of NaCl and HCl (0.2 M, pH = 2.3). In the potential range from +600 to –350 mV, there are three pairs of reversible redox peaks, and the average peak potentials, $E_{1/2}$ = (Ecp + Eap)/2, are +370, +50, and –150 mV (Figure S6). Each pair of redox peaks can be ascribed to a two-electron process involving molybdenum.[9]

In conclusion, using the Keggin cluster and 4,4′-bpy ligand as linkers, we have successfully isolated the first example of polycatenated 3D molecular double ladders generated from parallel catenation. This method may lead to a new family of interpenetrated networks that can be obtained by using suitable POM clusters as linkers.

## Experimental Section

**Materials:** All reagents and solvents for syntheses were purchased commercially and used as received.

**Physical Methods:** Elemental analyses (C, H, and N) were performed with a PerkinElmer 2400 CHN Elemental Analyzer. P, Mo, V, and Cu were determined with a Leaman inductively coupled plasma (ICP) spectrometer. IR spectra were obtained with an Alpha Centaurt FT/IR spectrometer with KBr pellets in the 400–4000 $cm^{-1}$ region. XPS analyses were performed with a VG ESCALAB MK II spectrometer with a Mg-$K_\alpha$ (1253.6 eV) achromatic X-ray source. The vacuum inside the analysis chamber was maintained at $6.2 \times 10^{-6}$ Pa during analysis. The ESR spectrum was recorded with a Japanese JES-FE3AX spectrometer at room temperature. UV/Vis spectra were recorded with a 756 CRT UV/Vis spectrophotometer made in Shanghai, China. The TG analyses were performed with a Perkin–Elmer TGA7 instrument in flowing $N_2$ at a heating rate of 10 °C $min^{-1}$. Cyclic voltammograms were obtained with a CHI 660 electrochemical workstation at room temperature. Platinum gauze was used as the counter electrode and an Ag/AgCl was used as the reference electrode. A chemically bulk-modified carbon paste electrode (CPE) was used as the working electrode.

**Synthesis of $\{Cu_3(4,4'\text{-bpy})_3(H_2O)[PMo_{12}O_{40}(VO)_2]\cdot 5H_2O\}_n$ (1):** The starting materials $Cu(NO_3)_2\cdot 4H_2O$ (0.1298 g, 0.5 mmol), $H_3[PMo_{12}O_{40}]\cdot xH_2O$ (0.4658 g, 0.25 mmol), $NH_4VO_3$ (0.0585 g, 0.5 mmol), 4,4′-bpy (0.0961 g, 0.5 mmol), triethylamine (0.14 mL), and $H_2O$ (9 mL) were mixed together. The resulting suspension was stirred for 1 h, sealed in a Teflon-lined reactor, and heated at 160 °C for 72 h. Then the autoclave was cooled at 5 °C $h^{-1}$ to room temperature. Black prism crystals of compound **1** were filtered, washed with water, and dried at room temperature. Yield: 0.395 g (58% based on molybdenum). $C_{30}H_{36}Cu_3Mo_{12}N_6O_{48}PV_2$ (2723.46): calcd. C 13.23, H 1.33, Cu 7.00, Mo 42.27, N 3.08, P 1.14, V 3.74; found C 13.31, H 1.22, Cu 7.09, Mo 42.13, N 3.01, P 1.03, V 3.81. IR (KBr): 1640 (w), 1515 (m), 1462 (w), 1060 (w), 945 (m), 860 (w), 775 (m) $cm^{-1}$.

**Preparation of 1-CPE:** Graphite powder (90 mg) and **1** (15 mg) were mixed and ground together by an agate mortar and pestle to achieve an even, dry mixture. Nujol (0.12 mL) was added to the mixture and stirred with a glass rod. The homogenized mixture was then packed into a 1.2 mm inner diameter glass tube, and the surface was wiped with paper. Electrical contact was established with a copper rod through the back of the electrode.

**X-ray Crystallography:** Crystal data for the compound were collected with a Rigaku R-AXIS RAPID IP diffractometer, with Mo-$K_\alpha$ monochromated radiation ($\lambda$ = 0.71073 Å) at 293 K. The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELXTL crystallographic software package.[10] The positions of the hydrogen atoms on carbon atoms were calculated theoretically. Crystal data: $C_{30}H_{36}Cu_3Mo_{12}N_6O_{48}PV_2$,

# Solid-State Luminescence and π-Stacking in Crystalline Uranyl Dipicolinates

**Jack M. Harrowfield,*[a] Noël Lugan,[b] Gholam H. Shahverdizadeh,[c] Ali A. Soudi,[c] and Pierre Thuéry[d]**

**Keywords:** Uranyl luminescence / Crystal structures / π-Stacking / Dipicolinates

Crystal structure determinations on the hydrated forms of the complexes $M_2UO_2(dipic)_2$, M = H, Rb, Cs, dipic = dipicolinate = pyridine-2,6-dicarboxylate, all of which show strong solid-state luminescence from the uranyl centre, have as a common feature extended π-stacking arrays of the dipicolinate ligands. Comparisons with related but non-luminescent complexes indicate that these stacking arrays may be associated with efficient energy transfer from the dipicolinate "antennae" to the uranyl unit.

## Introduction

Pyridine-2,6-dicarboxylic acid (dipicolinic acid, $dipicH_2$) is a widely employed and versatile complexing agent known to bind in its singly, doubly and even non-deprotonated and diester forms, often as mixed-ligand species.[1–5] Related ligands such as chelidamic acid (4-hydroxypyridine-2,6-dicarboxylic acid) and benzimidazole derivatives of dipicolinate also display interesting coordination properties.[6,7] Dipicolinic acid and its anions appear to bind well to all metals in the periodic table, though specific properties such as the strong luminescence of $Eu^{III}$ and $Tb^{III}$[8] and the biological activity of transition-metal complexes[3,9,10] have led to a strong focus in certain areas and to a relative neglect of actinide complexation. Nonetheless, in the specific case of the uranyl ion, a variety of species,[11–14] including the remarkable helical polymer, $[UO_2(dipic)(OH_2)]_n$,[15] has long been known and has recently been significantly expanded, principally through the characterisation of several binuclear complexes.[16] During a structural study, reported herein, of further members of the dipicolinate family, we noted that one property of these compounds that varies strikingly is their solid-state luminescence and hence we have attempted to rationalise this through an analysis of the different lattices.

## Results and Discussion

A particularly useful technique for the production of crystals of rather insoluble metal complexes has proven to be the "branched tube" method[17] of diffusion along a thermal gradient.[18] In the extension of this procedure used here to uranyl complexes of dipicolinic acid, the product obtained from a mixture of reagents with a 1:2 ratio of $U^{VI}$/acid was found to be a mixture of crystalline materials, one of which was a complex containing the metal and ligand in this ratio but the other a 1:1 species. Both can also be obtained by direct reaction of $[UO_2(OH_2)_5]^{2+}$ with the appropriate ligand species in these different ratios in aqueous solution; the 1:2 complex appears to be of very low solubility and crystallising readily, whereas the 1:1 complex appears to be more soluble and deposits rather slowly. Structure determinations (Table 1) on crystals selected from the mixed product showed the 1:1 species, which crystallises as clusters of very fine, pale yellow needles, to be the known helical polymer, $[UO_2(dipic)(OH_2)]_n$,[15] and the 1:2 species, which crystallises as obviously greenish-yellow plates, to be $[UO_2(dipicH)_2]\cdot 4H_2O$. The dipicolinate units function as tridentate ligands in both cases, the uranium coordination environment being close to pentagonal bipyramidal $UNO_6$ in the 1:1 complex and close to hexagonal bipyramidal $UN_2O_6$ in the 1:2 complex.

The lattice of $[UO_2(dipicH)_2]\cdot 4H_2O$ is similar to that of $[NH(C_2H_5)_3]_2[UO_2(dipic)_2]\cdot 2H_2O$[16] (both crystals being monoclinic, space group *C*2/*c*, though they are not isomorphous) as is emphasised by a view down *c* (Figure 1). Hydrogen bonding in the lattice of the latter compound has been analysed in detail and the protons of the triethylammonium groups appear to form near-symmetrical bridges between the coordinated oxygen atoms of opposite dipicolinate units within the one complex unit. The complex can thus be considered to have a "pseudo-macrocyclic" form

somewhat like that well-known in $M^{II}$ complexes of the dimethylglyoxime monoanion.[19] In $[UO_2(dipicH)_2]\cdot 4H_2O$, while a water molecule bridges the coordinated oxygen atoms to give a similar form (Figure 2), in addition the residual acid protons appear to be located on the outer (uncoordinated) carboxylate oxygen atoms, O(3), and to be involved in H-bonding chains involving two water molecules and the confronting O(3′) atoms, defining another mode of formation of a "pseudo-macrocycle". The potentially more rigid resulting structure is associated with a closer approach to planarity of the $U(dipicH)_2$ unit, although it is both slightly bowed [N–U–N 174.05(8)°] and twisted into a chiral configuration, as is the case for the $U(dipic)_2$ unit in $[NH(C_2H_5)_3]_2[UO_2(dipic)_2]\cdot 2H_2O$, but there the bowing is more marked [N–U–N 165.21(10)°]. The H-bonded water molecule pairs which bridge complex ion units intramolecularly are also within H-bonding distances of carboxylate oxygen atoms of other complex units, so linking the lattice in at least two dimensions.

Perhaps significantly, H-bonding is not the only form of extended interaction apparent in the lattice. Parallel to $c$, the complex units can be considered to form undulating columns [for example, within the ovoid entities apparent in the view down $c$ (Figure 1)] in which there is considerable overlap of parallel dipicolinate rings of adjacent complexes of alternating chirality. This stacking[20,21] extends down $b$, so that there are two types of ring projections (Figure 3), describable as intra- and inter-ovoid, contributing to the formally infinite array. While projection of one ring onto its parallel neighbour in a given stack does not involve eclipsing of all atoms, there are numerous C···C contacts of <3.5 Å, associated in the case of the more strongly overlapped intra-ovoid array with an inter-centroid distance of 3.63 Å and a centroid offset of 1.35 Å. It is especially in this regard that the lattice differs from the remarkably beautiful lattice of $[UO_2(dipic)(OH_2)]_n$.[15] In the present redetermination of this structure, the crystal chosen was one in which the helical polymer units (Figure 4) present were all right-handed, with the pitch of the helices [9.26(1) Å] being such that projecting dipicolinate units are very remote. These helices interlock to some extent in a way which involves no short contacts between constituent atoms of the dipicolinate rings (shortest inter-centroid distance 5.54 Å), though there are some involving C and O of the carboxylate units. Instead, there is a rather short contact [3.04(1) Å] of one uranyl-$O$ to ring atom C2 [as well as UO···N of 3.09(1) Å]. Such uranyl group interactions are seen in other systems[22] and indeed in $[UO_2(dipicH)_2]\cdot 4H_2O$, there are longer UO···C(aromatic) approaches of 3.17(1) Å, though essentially in the plane of the ring.

Such points of difference between $[UO_2(dipicH)_2]\cdot 4H_2O$ and $[UO_2(dipic)(OH_2)]_n$ may be the cause of their marked difference in solid-state luminescence. Thus, 354 nm (Hg lamp) irradiation of $[UO_2(dipicH)_2]\cdot 4H_2O$ produces bright green luminescence characteristic of a uranyl centre[23] (and the greenish colour of the crystals under solar illumination

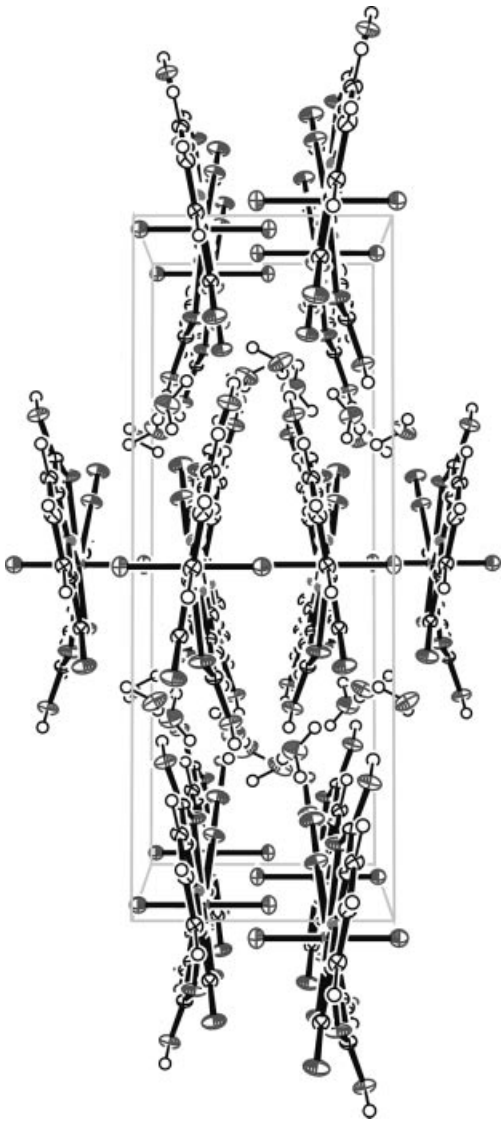

Figure 1. A view, down *c*, of the lattice of $[UO_2(dipicH)_2]\cdot 4H_2O$ which displays the columnar structures of ovoid cross-section present. Displacement ellipsoids are drawn at the 50% probability level. H atoms are shown with arbitrary radii of 0.1 Å.

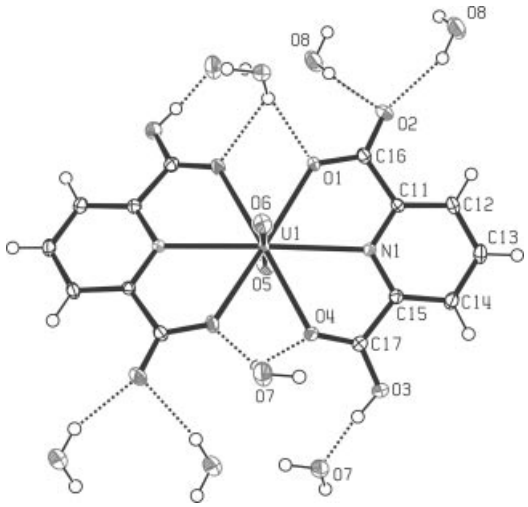

Figure 2. The hydrogen-bonding array present in the lattice of $[UO_2(dipicH)_2]\cdot 4H_2O$ (displacement ellipsoids at the 50% probability level).

may be explained as of the same origin), with the principal emission maxima at 487, 509, 532 and 558 nm (Figure 5) being a much closer match to those of hexagonal bipyramidal $U^{VI}$ as in $[UO_2(NO_3)_2(OH_2)_2]$[24] than to those of pentagonal bipyramidal $U^{VI}$ as in $[UO_2(OH_2)_5]^{2+}$[23]. $[UO_2(dipic)(OH_2)]_n$ is not luminescent by eye under the same conditions, though very weak luminescence, with maxima at 465, 490, 515 and 535 nm can be detected by use of a fluorimeter. Obviously, issues such as the presence of two dipicolinate ligands in the first and of a possibly electronically deactivating aqua ligand in the second (though even in the case of $[UO_2(OH_2)_5]^{2+}$, [23b] this does not seem to apply) must be considered, and then it is important to note that neither complex is strongly luminescent in aqueous solution. Further, deprotonation of $[UO_2(dipicH)_2]$ with $[NBu_4][OH]$ to produce a chloroform-soluble species, for which the electrospray mass spectrum (Supporting Information; for Supp. Inf. see also the footnote on the first page of this article) in this solvent shows a parent peak of the dianion, also results in loss of emission (thus excluding the possibility that the negligible luminescence in water is a consequence of deactivation by bound water after ligand hydrolysis), though evaporation of this solution produces a luminescent solid. Thus, even if dipicolinate units as "antennae" for energy absorption and transfer to the uranyl emissive state are only efficient when there are at least two per uranium atom, this efficiency must be associated with the solid-state structure. This is true also for $[NH(C_2H_5)_3]_2[UO_2(dipic)_2]\cdot 2H_2O$, which is luminescent as the solid,[25] again differing in this regard from several binuclear species having a single dipicolinate ligand per uranium.[16] In the lattices of these binuclear species, it is possible to discern parallel arrays of dipicolinate entities indicative of stacking interactions but, significantly, these all involve either relatively remote atom···atom contacts (>3.5 Å) or limited overlaps or pairwise interactions in one-dimensional arrays, unlike the extended two-dimensional arrays described above for $[UO_2(dipicH)_2]\cdot 4H_2O$ and which can also be discerned in $[NH(C_2H_5)_3]_2[UO_2(dipic)_2]\cdot 2H_2O$. [In the first complex, there are also O(carboxylate)···C(aromatic) contacts ca. 3.3 Å which produce a third dimension to the interactions between the aromatic entities.] In all the complexes presently discussed, there are UO···C(aromatic) contacts between 3.0 and 3.4 Å which vary in a way which seems unrelated to the luminescence properties of the solids. Thus, it would seem plausible that strong uranyl emission in these complexes is an indicator of extended stacking interactions with significant electronic consequences

An indication of the utility of the branched-tube method for crystal formation was provided in efforts to extend characterisation of the $M_2UO_2(dipic)_2$ family to the cases where M is an alkali metal cation. All (M = Li, Na, K, Rb, Cs) these compounds are of low water solubility and precipitate very rapidly as green, luminescent materials, of very similar

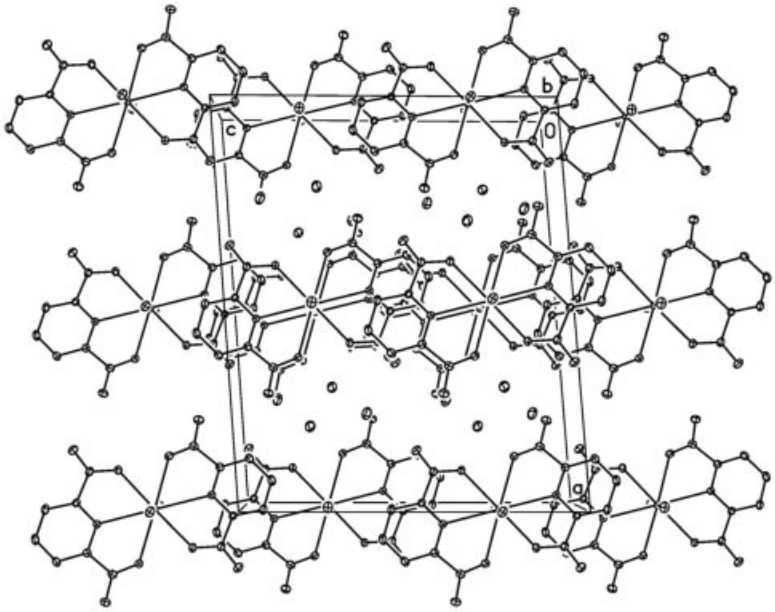

Figure 3. A view, perpendicular to the mean ring planes, showing the two types of dipicolinate stacks ("intra-" and "inter-ovoid") in the lattice of $[UO_2(dipicH)_2]\cdot 4H_2O$. The greater degree of ring overlap corresponds to the intra-ovoid stacks (displacement ellipsoids at the 50% probability level).

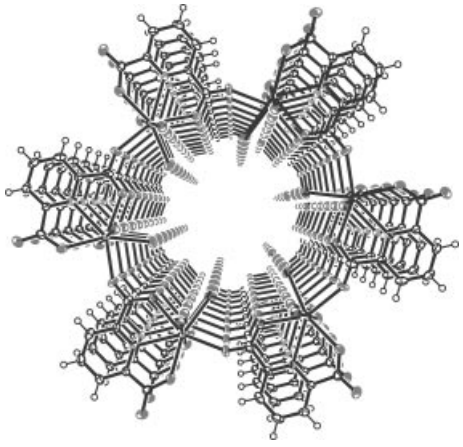

Figure 4. A view down the axis of one of the (right-handed) infinite helices present in the lattice of $[UO_2(dipic)(OH_2)]_n$ (displacement ellipsoids at the 50% probability level).

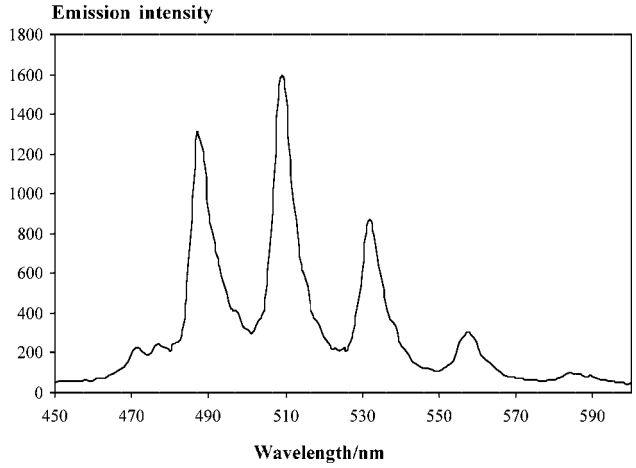

Figure 5. The room-temperature luminescence spectrum of powdered $[UO_2(dipicH)_2]\cdot 4H_2O$. Excitation wavelength 320 nm.

appearance to the M = H complex, when hot solutions are cooled. Despite numerous attempts at careful recrystallisation, the only members of this series obtained in a form suitable for X-ray structure determinations in this way were the Rb and Cs species (Table 1). While the Rb complex retains the same space group ($C2/c$) as the triethylammonium and proton compounds, the Cs complex crystallises in $P\bar{1}$, though this has only rather minor consequences in terms of the structure and self-interactions of the $U(dipic)_2$ entities. In both the Rb and Cs complexes, the $U(dipic)_2$ units are planar, with N–U–N 180° due to the location of the uranium atom on a symmetry centre. Perhaps as a reflection of this move to coplanarity, the U–N bond lengths (Table 2) are the longest of any in a uranyl dipicolinate. Their extension, however, is slight, and U–O bond lengths (Table 2) fall essentially within the range of those in other $U(dipic)_2$ species.

However, the Rb and Cs complexes do differ most obviously in the orientation of chains of the alkali metal atoms with respect to the array of $[UO_2(dipic)_2]^{2-}$ units. (Figure 6). Viewed down $c$, for example, both lattices can be regarded as containing sheets of uranium atoms lying parallel to [100], each U atom visible in the view down $c$ being the head of a column of such atoms lying parallel to $c$. Using the two shortest (and nearly equal) M···M separations [M = Rb, 4.0926(12) and 4.4260(12); M = Cs, 4.3109(9) and 4.9406(9) Å] to define association between M atoms, these can be considered to form zig-zag columns which, in the

[d] Symmetry codes: ′ for $1-x, -y, -z$; ′′ for $2-x, 1-y, 1-z$; # for $1+x, y, 1+z$; $ for $3-x, 1-y, 1-z$; * for $2-x, -y, 1-z$.

case of M = Rb, lie along *c* and so define sheets for which the mean plane is parallel to those of the U atoms, i.e. to [100], whereas in the case of M = Cs these zig-zag columns lie parallel to *b*, forming undulating sheets with their mean planes parallel to [001]. An explanation of the difference in these alkali metal arrays may be that only Rb is involved in coordinative interaction with uranyl-*O* [Rb–O 3.035(6) Å]. As seems to be commonly the case with heavy and apparently weakly coordinating metals,[6,21,27–31] it is difficult to define a precise cutoff distance for interactions considered to be bonding but the coordination numbers of both Rb and Cs here appear to be high, involving *O*-donors only, with rather irregular geometry about the metals. Interestingly, the extreme M···O separations approach those of M···U, which, if they are correctly considered as contacts of closed-shell species of similar charge, would be regarded as involving negligible interactions, thus indicating that the extreme M···O contacts must also be of little significance.

In relation to development of the argument presently that uranyl luminescence in solid dipicolinate complexes may be associated with extended interactions of the dipicolinate "antennae", it is important to note that both the Rb and Cs complexes share with other luminescent uranyl dipicolinate species an essentially infinite stacked array of dipicolinates involving numerous relatively short C···C approaches (ca. 3.4 Å), corresponding in both compounds to a shortest centroid···centroid distance of 3.76 Å and centroid offsets of 1.37 and 1.62 Å for the Rb and Cs complexes, respectively. In the Rb complex, this stacking is apparent in the view down *c*, this axis being close to perpendicular to the mean ring planes, whereas in the Cs complex, it is a view down *a*, which exposes a similar array.

## Conclusions

If indeed it is true that stacking within the lattices of uranyl dipicolinates can produce efficient population of uranyl excited states, then these generally rather insoluble materials may have applications as solid photocatalysts, as recently described for some mixed U/Ag compounds also characterised by extended ligand stacking within the crystals.[26] Even more recently,[32] some uranyl complexes of isomeric (2,4- and 3,4-)pyridine dicarboxylates, though of different stoichiometry to the present materials, have also been described as luminescent due to uranyl centre emission. Though stacking of the pyridine units is extended in these solids, the ring atom separations are relatively large (ca. 3.7 Å) and the compounds are described as yellow, indicating that their luminescence is weak and that their polyuranate cores may not be as effective as $[UO_2(dipic)_2]^{2-}$ in creating lattices which may be considered to contain "antenna" units of the ligands. The stoichiometry of bis(dipicolinato)dioxouranium(VI) derivatives is obviously open to straightforward variations which may result in useful control of their photoreactivity and we are presently investiga-

ting lanthanide(III) species in which it appears possible to switch between uranyl and lanthanide ion luminescence.

## Experimental Section

**Synthesis:** $[UO_2(dipicH)_2]\cdot 4H_2O$ and $[UO_2(dipic)(OH_2)]$ (mixed): $[UO_2(O_2CCH_3)_2(OH_2)]\cdot H_2O$ (212 mg) and dipicolinic acid (167 mg) were placed in one arm of an inverted Y-tube ("branched tube"[17]) and the apparatus then carefully filled with water. The arm containing the partially soluble reactants was heated at 45 °C, with the other arm kept at ambient temperature. After 1 week, the cooler arm contained greenish-yellow plates mixed with clusters of pale yellow needles. Samples of both crystals were withdrawn for structure determinations, these showing the plates to be the new complex $[UO_2(dipicH)_2]\cdot 4H_2O$.

**$[UO_2(dipicH)_2]\cdot 4H_2O$:** A solution obtained by mixing dipicolinic acid (34 mg) and $Na_2CO_3$ (11 mg) in water (2 mL) and heating to 90 °C was mixed with a solution of $[UO_2(dmso)_5](ClO_4)_2$[22] (86 mg) in water (2 mL, 90 °C). The clear, pale yellow solution was allowed to stand at ambient temperature as plate-like crystals slowly deposited in essentially quantitative yield. After air-drying only, analysis of the sample was consistent with a higher degree of hydration than that of the single crystal taken for the structure determination. $[UO_2(dipicH)_2]\cdot 7H_2O$: calcd. C 23.09, H 3.04, N 3.85; found: C 22.9, H 2.8, N 3.5.

**$M_2UO_2(dipic)_2\cdot nH_2O$ (M = Li, Na, K, Rb, Cs):** Clear solutions, obtained by mixing dipicolinic acid ($2\cdot 10^{-4}$ mol) and $M_2CO_3$ ($2\cdot 10^{-4}$ mol) in water (2 mL) and heating at 90 °C until $CO_2$ evolution was complete, were mixed separately with solutions of $[UO_2(dmso)_2(NO_3)_2]$ ($10^{-4}$ mol; 55 mg) in hot (90 °C) water (2 mL). Cooling of the mixtures led to rapid and essentially quantitative

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

precipitation of microcrystalline greenish-yellow solids. Partial precipitation resulting when the initial solutions were allowed to slowly evaporate at 90 °C provided larger but still generally rather small crystals. On collection and washing with acetone, the crystals appeared to undergo some efflorescence, and analyses of the Rb and Cs compounds indicated a lower degree of hydration than found from the structure solutions. $Li_2UO_2(dipic)_2{\cdot}2H_2O$: calcd. C 25.86 (26.0); H 1.55 (2.0); N 4.31 (4.3); found C 26.0, H 2.0, N 4.3. $Na_2UO_2(dipic)_2$: calcd. C 26.02, H 0.94, N 4.33; found C 25.9, H 1.8, N 4.3. $K_2UO_2(dipic)_2{\cdot}1.5H_2O$: calcd. C 23.84, H 1.28, N 3.97; found C 23.9, H 2.0, N 3.9. $Rb_2UO_2(dipic)_2$: calcd. C 21.80, H 0.85, N 3.63; found C 21.8, H 1.3, N 3.5. $Cs_2UO_2(dipic)_2{\cdot}H_2O$: calcd. C 19.02, H 0.91, N 3.17; found C 19.4, H 1.3, N 2.9.

**Luminescence Measurements:** To obtain luminescence spectra for solid samples, the powdered complexes were pressed between two quartz plates with a spacing of ca. 0.1 mm. The plates were mounted in the normal cell holder of an AMINCO-Bowman Series 2 fluorimeter with the faces at 45° to the incident beam.

**Crystallography:** Intensities for both $[UO_2(dipicH)_2]{\cdot}4H_2O$ and $[UO_2(dipic)(OH_2)]$ were collected at 180(2) K with an Oxford Diffraction Xcalibur diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Cell refinement and data processing were performed using Crysalis RED.[33] All subsequent calculations were carried out using the WinGX system.[34] The structures were solved by using the SIR92 program,[35] which revealed in each instance the position of most of the non-hydrogen atoms. All remaining non-hydrogen atoms were located by the usual combination of full-matrix least-squares refinement and difference electron density syntheses by using the SHELXL97 program.[36] Atomic scattering factors were taken from the usual tabulations. Anomalous dispersion terms for U atoms were included in $F_c$. Analytical[37] ($[UO_2(dipicH)_2]{\cdot}4H_2O$) or semi-empirical[38] ($[UO_2(dipic)(OH_2)]$) absorption corrections were applied.

The data for $[UO_2Rb_2(dipic)_2(H_2O)_3]$ and $[UO_2Cs_2(dipic)_2(H_2O)_4]$ were collected at 100(2) K with a Nonius Kappa-CCD area detector diffractometer[39] using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The data were processed with HKL2000.[40] The structures were solved by direct methods or Patterson map interpretation for the two compounds, respectively, with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on $F^2$ with SHELXL-97.[41] Absorption effects were corrected empirically with the program DELABS in PLATON.[42]

In all compounds, all non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms attached to the pyridine ring were introduced at idealised positions and were treated as "riding" atoms with C($sp^2$)–H = 0.93 Å and $U_{iso}$(H) = 1.2 times that of the parent atom. The hydrogen atoms of the water molecules (and hydroxy group when present) in the structures of $[UO_2(dipicH)_2]{\cdot}4H_2O$, $[UO_2Rb_2(dipic)_2(H_2O)_3]$ and $[UO_2Cs_2(dipic)_2(H_2O)_4]$ were located from Fourier-difference maps and their position was refined using a constrained model (O–H = 0.86 Å or left as found; $U_{iso}$ = 1.2 times that of the parent atom). The final Fourier-difference map for $[UO_2(dipic)(OH_2)]$ showed randomly distributed residual peaks all located in the vicinity of the U atom. No attempts were further made to locate the hydrogen atoms attached to the coordinated water molecule in this case. The molecular plots were drawn with ORTEP3[43] and SHELXTL.[41]

CCDC-279058 to -279061 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Hybrid Inorganic–Organic 1D and 2D Frameworks with $[As_6V_{15}O_{42}]^{6-}$ Polyoxoanions as Building Blocks

**Shou-Tian Zheng,[a] Yong-Mei Chen,[b] Jie Zhang,[a] Ji-Qing Xu,[c] and Guo-Yu Yang*[a,d]**

**Keywords:** Polyoxometalate / Vanadium / Arsenic

Three novel heteropolyoxovanadates, $[Ni(2,2'\text{-bpy})_3]_2[\{Ni(en)_2\}As_6V_{15}O_{42}(H_2O)]\cdot 9.5H_2O$ (**1**), $[Zn_2(dien)_3(H_2O)_2]_{1/2}\{[Zn_2(dien)_3]As_6V_{15}O_{42}(H_2O)\}\cdot 2H_2O$ (**2**), and $[Co(enMe)_2]_3[As_6V_{15}O_{42}(H_2O)]\cdot 2H_2O$ (**3**), were hydrothermally synthesized and characterized by single-crystal X-ray diffraction. Crystal data: **1**, monoclinic, $P2_1/n$, $a$ = 14.0324(9) Å, $b$ = 13.9900(8) Å, $c$ = 30.5785(19) Å, $\beta$ = 102.861(1)°, $Z$ = 2; **2**, monoclinic, $P2_1/c$, $a$ = 13.361(5) Å, $b$ = 23.979(8) Å, $c$ = 22.873(8) Å, $\beta$ = 102.459(4)°, $Z$ = 4; **3**, triclinic, $P\bar{1}$, $a$ = 13.2976(1) Å, $b$ = 15.0583(1) Å, $c$ = 20.1661(2) Å, $\alpha$ = 85.620(8)°, $\beta$ = 79.553(9)°, $\gamma$ = 65.087(9)°, $Z$ = 2. Compound **1** consists of 1D $[\{Ni(en)_2\}As_6V_{15}O_{42}(H_2O)]^{4-}$ chains and $[Ni(2,2'\text{-bpy})_3]^{2+}$ cations, in which the chain host has a molecular recognition ability for the chiral guest cations. Compound **2** is constructed from linking of the $[As_6V_{15}O_{42}]^{6-}$ polyoxoanions and novel dinuclear $[Zn_2(dien)_3]^{4+}$ cations into the first 1D helical As–V–O cluster chain. Compound **3** is the first 2D framework based on $[As_6V_{15}O_{42}]^{6-}$ polyoxoanions as building blocks.

## Introduction

Since the first polyoxometalates (POMs) were reported over 150 years ago, attention has been focused on their synthesis and various structural topologies, as well as their unexpected properties in such diverse fields as catalysis, materials science, and medicine.[1–3] To date, hundreds of POMs based on Mo–O clusters, V–O clusters, and W–O clusters and so on have been synthesized and described.[4,5] They provide a wide variety of robust structural motifs of different sizes and topologies ranging from closed cages and spherical shells to basket-, bowl-, barrel-, and belt-shaped structures. Those intriguing structures and potential applications attract more and more researchers and make the chemistry of POMs of continuous interest.[6] The preparation of extended structure solids with controllable and desirable properties and functions is of both fundamental and practical interest.[7] Now one of the challenging tasks in POM chemistry is to find some bridging units and then to link POM building units up into extended solid frameworks.[8,9] This approach is quite attractive and appears to hold the key to the development of rational approaches for tailor-made materials based on POMs with desirable features. During the past few years, a lot of research efforts have been focused on the application of secondary transition-metal complexes (TMCs) as bridging ligands linking POM clusters into 1-, 2-, and 3D networks under hydrothermal conditions.[10–13] Compounds $[\{Cu(enMe)_2\}_7\{V_{16}O_{38}(H_2O)\}_2]\cdot 4H_2O$[14] and $[Co(en)_2][Co(2,2'\text{-bpy})_2]_2[PMo_8V_8O_{44}]\cdot 4.5H_2O$[15] are recent examples. The former is made up of the hexadecavanadate clusters linked by the $[Cu(enMe)_2]^{2+}$ complex fragments into a rare 3D open framework, while the latter exhibited a novel 2D Mo–V–O polyoxometalate with two types of cobalt complex fragments as bridges. More recently, Khan et al. reported three novel 2D frameworks that consist of spherical $\{V_{18}O_{42}(X)\}$ shells linked by bridging $\{M(en)_2\}$ groups (X = $H_2O$, $Br^-$, $Cl^-$; M = Zn, Cd).[16]

An important subclass of the large POM family is As–V–O clusters with arsenic and vanadium in low oxidation states, which often act as cryptates encapsulating neutral molecules or anions. Since the first As–V–O cluster $K_6[As_6V_{15}O_{42}(H_2O)]\cdot 8H_2O$ was presented by Müller and Döring in 1988,[17] a number of As–V–O clusters have been synthesized,[18–27] such as $K_7[AsV_{14}O_{40}]\cdot 12H_2O$,[18] $Na_5[V_{12}As_8O_{40}(HCO_2)]\cdot 18H_2O$,[19] $[As_8V_{14}O_{42}(X)]^{6-}$ (X = $SO_3^{2-}$ or $SO_4^{2-}$),[20] $[N(Me)_4]_4[As_8V_{14}O_{42}(0.5H_2O)]$,[21] and $[NBu^n_4]_4[As_8V_6O_{26}]$.[23] However, most of them are discrete clusters; the linking of As–V–O clusters into extended

structures remains largely unexplored and a rewarding challenge. The aim of our work is to synthesize extended solids based on As–V–O clusters in the presence of TMCs. By this means, we recently successfully prepared a novel 2D sinusoidal layer structure constructed from $[As_8V_{14}O_{42}(SO_4)]^{6-}$ clusters and $[Ni(en)_2]^{2+}$ fragments.[28] As a part of continuing work in this system, here we describe the hydrothermal synthesis and structural characterization of the following three extended POMs based on $[As_6V_{15}O_{42}(H_2O)]^{6-}$ clusters as building blocks: $[Ni(2,2'\text{-bpy})_3]_2[\{Ni(en)_2\}As_6V_{15}O_{42}(H_2O)]\cdot 9.5H_2O$ (**1**), a 1D straight chain, $[Zn_2(dien)_3(H_2O)_2]_{1/2}\{[Zn_2(dien)_3]As_6V_{15}O_{42}(H_2O)\}\cdot 2H_2O$ (**2**), a 1D helical chain, and $[Co(enMe)_2]_3[As_6V_{15}O_{42}(H_2O)]\cdot 2H_2O$ (**3**), which is the first 2D $[As_6V_{15}O_{42}(H_2O)]^{6-}$ framework.

## Results and Discussion

Compounds **1**–**3** are made of the $[As_6V_{15}O_{42}(H_2O)]^{6-}$ ($As_6V_{15}$) clusters linked by corresponding TMCs into extended structures. The structure of the $As_6V_{15}$ anion, which has crystallographic $D_3$ symmetry, was first reported by Müller and Döring in $K_6[As_6V_{15}O_{42}(H_2O)]\cdot 8H_2O$.[17] It consists of fifteen $VO_5$ square pyramids and three handle-like $As_2O_5$ units. As shown inpart a of Figure 1, twelve $VO_5$ square pyramids form two triangles by sharing edges and sharing corners. In addition, another three $VO_5$ square pyramids and three $As_2O_5$ units are alternately joined together to form a ring (Figure 1, b). Then the two triangles are coordinated to each face the ring through sharing O

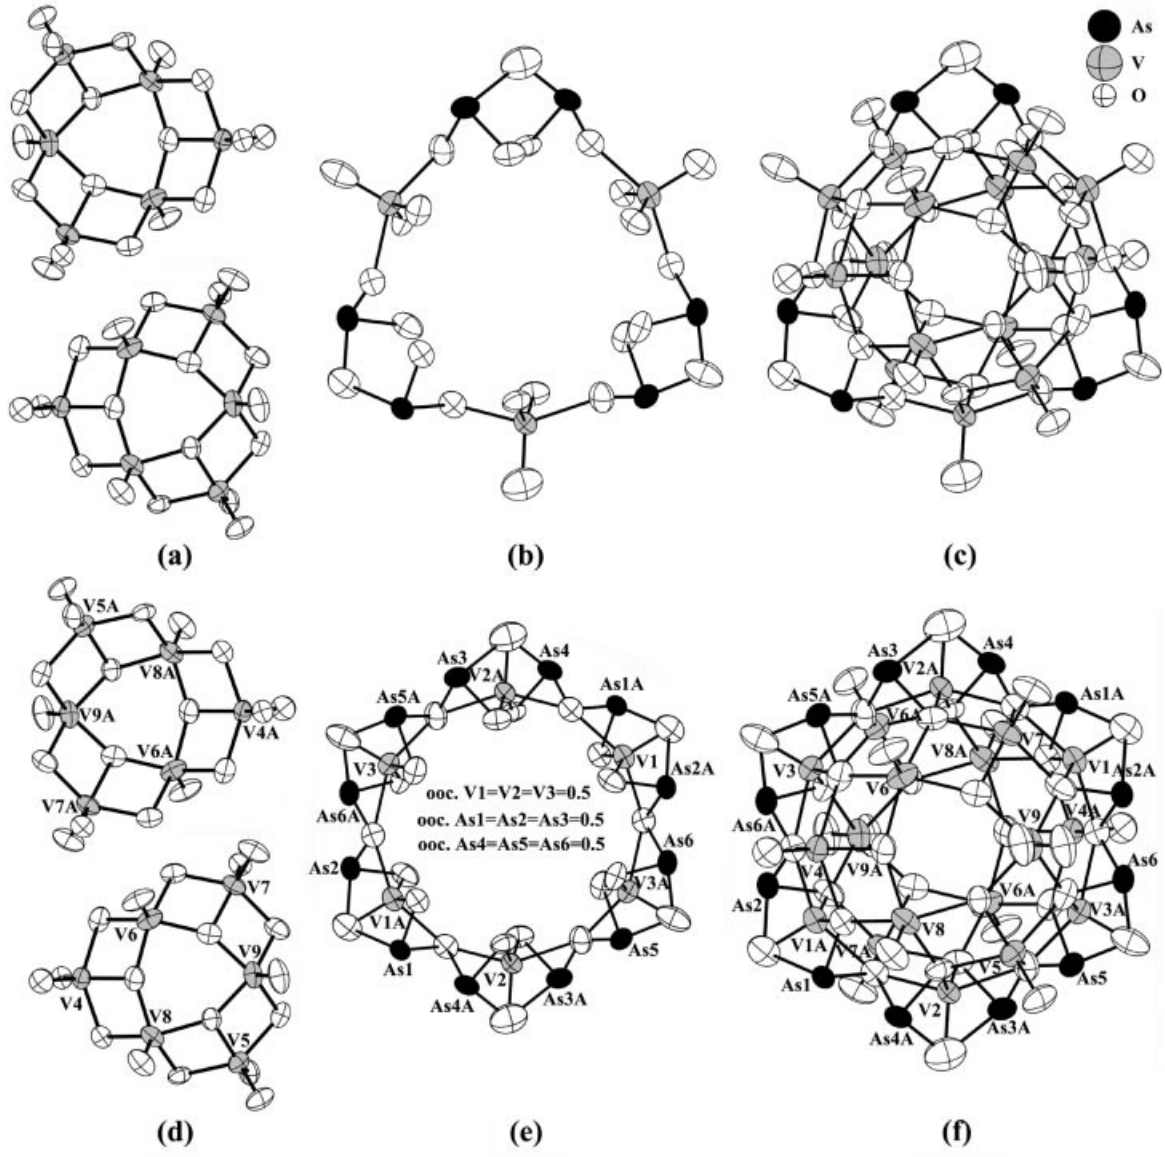

Figure 1. Structural contrast between normal $[As_6V_{15}O_{42}]^{6-}$ anion and disordered $[As_6V_{15}O_{42}]^{6-}$ anion in **1**. (a, b) Two $V_3$ triangles and one $As_6V_3$ ring in the normal $[As_6V_{15}O_{42}]^{6-}$ anion, respectively. (c) The normal $[As_6V_{15}O_{42}]^{6-}$ anion. (d, e) Two $V_3$ triangles and one disordered $As_6V_3$ ring in the disordered $[As_6V_{15}O_{42}]^{6-}$ anion in **1**. (f) The disordered $[As_6V_{15}O_{42}]^{6-}$ anion in **1**. atoms, and form a ball-like $As_6V_{15}$ anion (Figure 1, c). In the structure of the $As_6V_{15}$ cluster in **1**, twelve $VO_5$ square pyramids form two identical triangles as described above (Figure 1, d). However, an interesting phenomenon is that the ring in the $As_6V_{15}$ anion of **1** was found to be disordered. As shown in Figure 1 (e), three positions occupied by $As_2O_5$ units are disordered over six positions with free refined occupancy of 0.5 for each position. At the same time, three positions occupied by $VO_5$ square pyramids are also disordered over six positions (V1, V2, V3, V1A, V2A, and V3A atoms) with free refined occupancy of 0.5 for each position. Then, similarly, the two triangles are coordinated to each face of the disordered ring through sharing O atoms, and form a disordered $As_6V_{15}$ anion (Figure 1, f). The structure of the disordered $As_6V_{15}$ anion in **1** can also be described as a well-known $\{V_{18}O_{42}\}$ rhombicuboctahedron[29] embedded with an arsenic ring (Figure S1). The $As_6V_{15}$ anion in **2** and **3** is essentially identical to that of the isolated cluster in $K_6[As_6V_{15}O_{42}(H_2O)]\cdot 8H_2O$[17] and is not disordered. In **1**–**3**, all V=O, V–O, and As–O bond lengths fall in the ranges 1.520(5)–1.631(6), 1.817(10)–2.107(9), and 1.748(6)–1.887(5) Å, respectively. On the basis of bond valence sum ($\Sigma_s$) calculations,[30] the oxidation states of all V atoms are +4 ($\Sigma_s$ = 4.04–4.48, **1**; $\Sigma_s$ = 4.02–4.15, **2**; $\Sigma_s$ = 4.03–4.16, **3**) and the As atoms are +3 ($\Sigma_s$ = 2.73–2.99, **1**; $\Sigma_s$ = 3.05–3.20, **2**; $\Sigma_s$ = 3.04–3.18, **3**). The oxidation states of the V atoms and the As atoms are consistent with the formulas of **1**–**3**. The EPR spectra of **1** and **2** at room temperature show the *g* values are 1.9591 and 1.9493, corresponding to the signal of $V^{4+}$, respectively. For **3**, no EPR signal of $V^{4+}$ was observed in **3** at room temperature. But at liquid nitrogen temperature, the EPR spectrum of **3** shows the *g* value is 1.9631, corresponding to the signal of $V^{4+}$.

The extended structure of **1** consists of disordered $As_6V_{15}$ sphere-like clusters. Each one is linked to two other neighboring clusters by two $[Ni2(en)_2]^{2+}$ bridges, generating a 1D straight chain of $[-As_6V_{15}-\mu_2\text{-}Ni2(en)_2-As_6V_{15}-]_\infty$ arrays (Figure 2). The bridging Ni2 atom shows an octahedron with four nitrogen donors of two en ligands [Ni2–N: 2.040(2)–2.061(18) Å] and two *trans* terminal oxo oxygen atoms coming from two adjacent $VO_5$ groups [Ni2–O: 2.199(11) Å, O–Ni2–O: 180(8)°]. An interesting feature is that another kind of TMC $[Ni1(2,2'\text{-bpy})_3]^{2+}$ rather than $[Ni(en)_3]^{2+}$ occupies the interchain regions as charge compensation. As shown in Figure 3, the $\{[Ni(en)_2]As_6V_{15}O_{42}(H_2O)\}^{4-}$ chains are aligned to the *b* axis and parallel packed beside each other along the *a* axis, generating a cluster anion layer along the *ab* plane, while the $[Ni(2,2'\text{-bpy})_3]^{2+}$ cations are exactly deposited between cluster anion layers

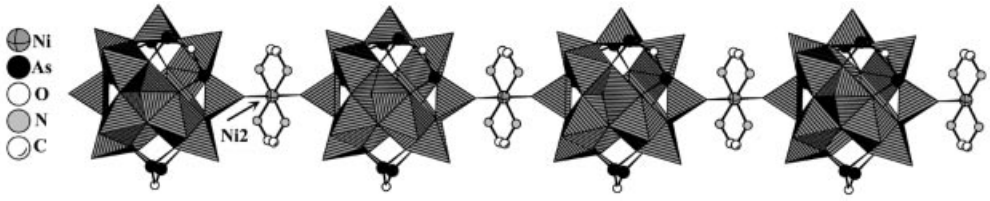

Figure 2. A view of the infinite straight chain in **1**. Half of the disordered atoms and H atoms were omitted for clarity.

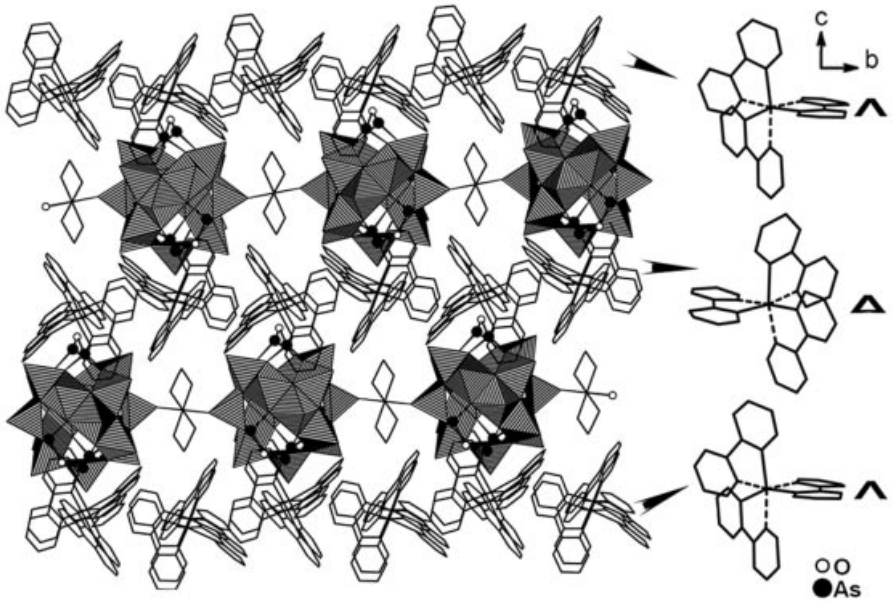

Figure 3. Packing diagrams of **1** along the *a* axis showing host chains have a molecular recognition ability for the guest metal complexes. All H atoms were omitted for clarity.

to form the cation layer along the *ab* plane. The $[Ni(2,2'\text{-bpy})_3]^{2+}$ cations in **1** present both Δ and Λ enantiomers. An unusual feature is that the Δ and Λ enantiomers of $[Ni(2,2'\text{-bpy})_3]^{2+}$ are separated orderly and deposited in alternate cluster anion layer regions, that is, the isolated $[Ni(2,2'\text{-bpy})_3]^{2+}$ cations are separated into Δ configuration layers and Λ configuration layers by cluster chain layers. The orderly separation of the enantiomers of $[Ni(2,2'\text{-bpy})_3]^{2+}$ indicates that the inorganic host has a molecular recognition ability for the guest TMCs.[31] Such a phenomenon is rarely reported in the POM system. The shortest inter-ring separation of 2,2′-bpy ligands along the *a* axis is 12.27 Å, hence, there is no notable π–π interaction in **1**.

POMs with helical or chiral structures are of particular interest.[32] For instance, a spiral-shaped chain has been described in $[H_2en]_2[\{Cu(en)(OH_2)\}Mo_5P_2O_{23}]\cdot 4H_2O$[33] and a double helical chain in $[(CH_3)_2NH_2]K_4[V_{10}O_{10}(H_2O)_2(OH)_4(PO_4)_7]\cdot 4H_2O$.[34] Single-crystal X-ray diffraction analysis revealed that compound **2** presents the first helical chain made of As–V–O clusters. As shown in Figure 4, the $As_6V_{15}$ clusters are connected to each other through novel $[(dien)Zn1(dien)Zn2(dien)]^{4+}$ dimeric cations by corner-sharing interactions of the type V=O–Zn1 to form an infinite 1D chain along the *b* axis, which arranged about a twofold screw axis and formed a left-hand helical array. Because compound **2** crystallizes in a centric space group $P2_1/c$, there are an equal number of right-handed (Figure S2) and left-handed helices (Figure 4) in the structure. As illustrated in Figure 5, it is interesting that the right-handed helical chains and the left-handed helical chains are aligned parallel to the *ab* plane to give right-handed helical chain layers and left-handed helical chain layers, respectively. Furthermore, these right-handed helical chain layers and left-handed helical chain layers are alternatively stacked along the *c* axis with another kind of novel dimeric cation, $[Zn_2(dien)_3(H_2O)_2]^{4+}$, occupying the interlayer regions (Figure 5, Figure 6). Hydrogen bonds play important roles in stabilizing the crystal structure of **2**. The isolated $[Zn_2(dien)_2(H_2O)_5]^{4+}$ cations link the chains through three pairs of hydrogen bonds [N10–O40a (a: $-x$, $y + 1/2$, $-z + 1/2$), 3.01(2) Å; N10–O37b (b: $-x$, $-y + 1$, $-z$), 3.25(3) Å; and N11–O41 3.02(2) Å, respectively] generating 2D networks along the *bc* plane, while $[Zn_2(dien)_3]^{4+}$ bridging cations interact with the chains along the *a* axis through strong hydrogen bonds [N···O: 2.835(10)–3.175(10) Å, listed in Table S1]. These hydrogen bonds force the structure of compound **2** to extend into a 3D supramolecular array.

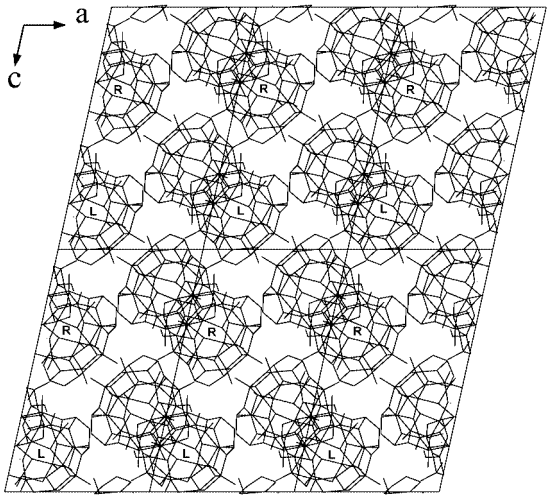

Figure 5. Packing diagram of **2** viewed along the *b* axis showing alternative right-hand and left-hand helical chain layers. All H atoms, water molecules, and isolated $[Zn_2(dien)_3(H_2O)_2]^{4+}$ cations are omitted for clarity.

The second unusual feature of **2** is that each Zn1(dien) bridging fragment hangs a $[Zn2(dien)]^{2+}$ complex linked through a tridentate dien ligand to form a novel dinuclear

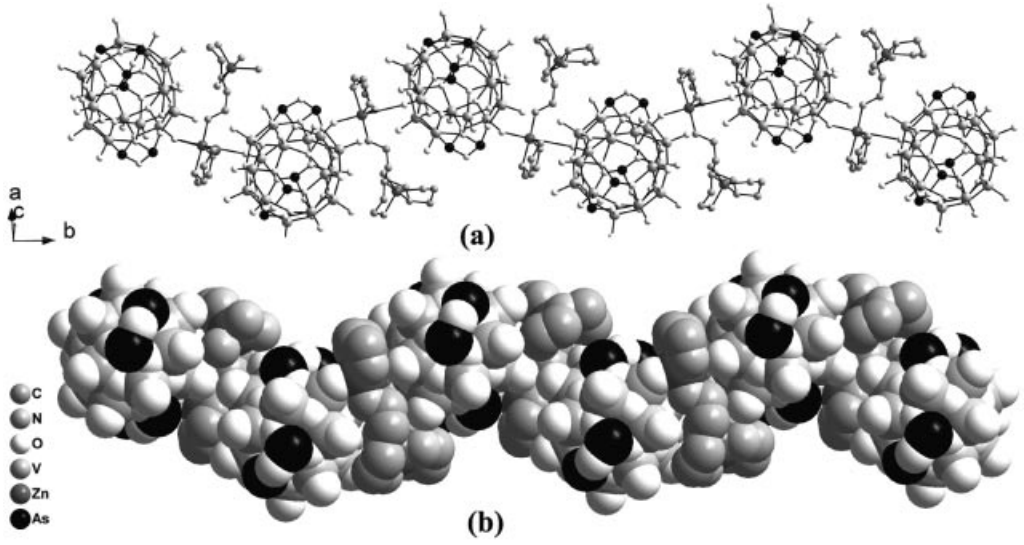

Figure 4. A ball-and-stick (a) and a space-filling (b) view of the left-hand helical chain of **2** showing the connectivity between the $[As_6V_{15}O_{42}(H_2O)]^{6-}$ clusters and $[Zn_2(dien)_3]^{4+}$ complexes and orientation of the chain. (Structure of right-hand helical chain of **2** can be seen in Figure S2.) All H atoms were omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

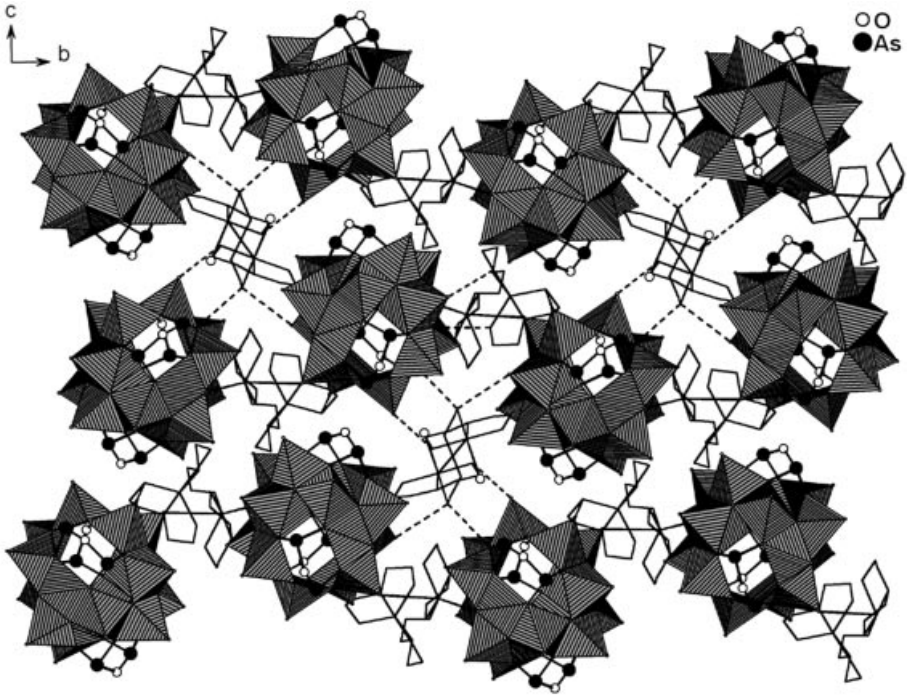

Figure 6. View of the 2D networks of **2** along the *a* axis showing the hydrogen bonds between helical chains and discrete $[Zn_2(dien)_3(H_2O)_2]^{4+}$ cations.

$[(dien)Zn1(dien)Zn2(dien)]^{4+}$ cation (Figure 7, b). Two N atoms of the bridging dien ligand coordinate to the Zn2 center, while the third N atom coordinates to the Zn1 center. Each Zn atom in dinuclear TMC is bound to two dien ligands in different coordination modes, respectively. Thus the Zn1 center is defined by four N donors from two dien ligands and two *trans* terminal oxo oxygen atoms from two adjacent arsenic–vanadium clusters to form a distorted octahedron [Zn1–N: 1.981(7)–2.155(9) Å; Zn1–O: 2.142(5) Å], whereas the five-coordinate Zn2 center is best described as a distorted trigonal bipyramidal configuration, with the atoms N5 and N8 occupying the axial positions [Zn2–N5: 2.265(8) Å; Zn2–N6: 2.049(6) Å; Zn2–N7: 2.081(7) Å; Zn2–N8: 2.187(7) Å; Zn2–N9: 2.017(9) Å]. Khan et al. has recently reported an unexpected binuclear $[Zn_2(en)_5]^{4+}$ cation (Figure 7, a) in compound $[Zn_2(en)_5][\{Zn(en)_2\}_2V_{18}O_{42}(H_2O)]\cdot 9H_2O$.[16] One striking difference between $[Zn_2(dien)_3]^{4+}$ and $[Zn_2(en)_5]^{4+}$ cations is that the former act as $\mu_2$-bridging units that link $As_6V_{15}$ clusters to form a 1D chain, while the latter just act as balance cations. Another distinct difference is that the $[Zn_2(en)_5]^{4+}$ cation is a centrosymmetric ion and the two zinc sites display the same coordination environments: distorted $ZnN_5$ trigonal bipyramidal configuration, while the $[Zn_2(dien)_3]^{4+}$ cation is a noncentral ion and two independent zinc sites display two kinds of different coordination environments: distorted $N_4Zn1O_2$ octahedron and distorted $Zn2N_5$ trigonal bipyramid. The average Zn–N distance (2.120 Å) in $[Zn_2(dien)_3]^{4+}$ is somewhat shorter than that of the $[Zn_2(en)_5]^{4+}$ cation (2.134 Å). The Zn1···Zn2 separation distance [6.492(7) Å] in the $[Zn_2(dien)_3]^{4+}$ cation is obviously shorter than that of the $[Zn_2(en)_5]^{4+}$ cation [7.592(2) Å].

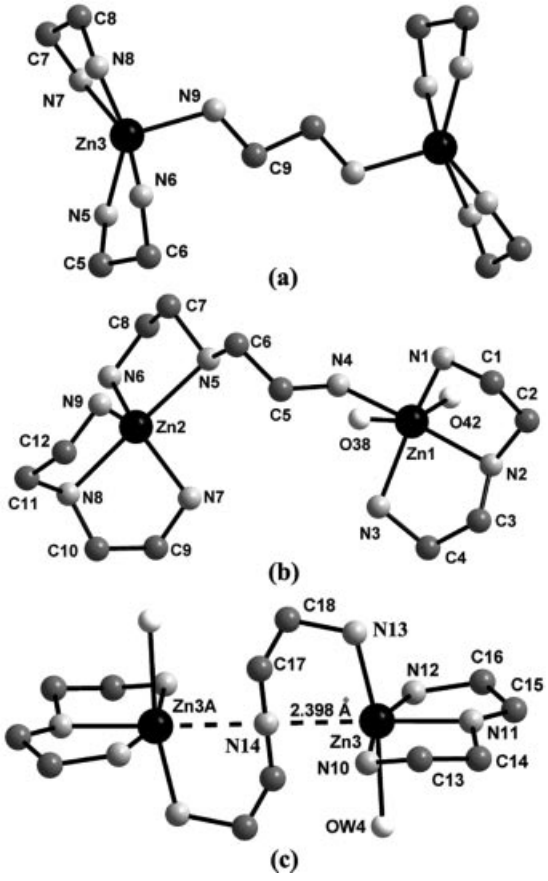

Figure 7. (a) Structure of binuclear TMC in ref.[16]. (b, c) Structures of binuclear TMCs in **2**, showing two unique coordination modes. All the H atoms are omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The third unusual feature of **2** is that the structure contains another kind of novel isolated binuclear $[Zn_2(dien)_3(H_2O)_2]^{4+}$ cation providing charge compensation (Figure 7, c). The structure of the $[Zn_2(dien)_3(H_2O)_2]^{4+}$ cation can be described as two $[Zn(dien)(H_2O)]^{2+}$ moieties linked across an inversion center by a bridging dien ligand. The two terminal N13 and N13A atoms of bridging dien exhibit strong attachment to the Zn3 and Zn3A atoms, respectively, with Zn–N distances of 2.036(18) Å, while the middle N14 atom occupies the central site of the binuclear cation and exhibits weak attachment to both Zn3 and Zn3A atoms with Zn–N distances of 2.398(3) Å, which are much longer than the usual Zn–N values (about 1.90–2.20 Å) observed in many reported studies.[16,35,36] Such a coordination mode between the Zn atoms and the bridging dien ligand is peculiar. The Zn3–O distance [2.430(2) Å] and the bond valence sum[30] value (0.17) identify the O atom coordinated to the Zn3 center as $H_2O$ (denoted as OW4 in this paper). The Zn3···Zn3A separation distance [4.796(10) Å] is even shorter than that of Zn1···Zn2 [6.493(7) Å].

The solid architectures of **1** and **2** provide examples of a different way of connecting $As_6V_{15}$ clusters and TMCs groups. This suggests that further condensation of $As_6V_{15}$ clusters into higher dimensional solids through the linkage of TMCs groups could be feasible. Suitable modification of the synthetic conditions results in the successful crystallization of solid **3**, which is the first 2D $As_6V_{15}$ framework. As shown in Figure 8, the $As_6V_{15}$ cluster acts as a hexadentate ligand coordinating to six $Co^{2+}$ ions through the terminal oxo oxygen atoms with Co–O distances ranging from 2.180(6) to 2.278(6) Å, such that each $As_6V_{15}$ cluster is connected with six others through *trans*-{$Co(enMe)_2O_2$} groups to generate a 2D framework (Figure 9). Each Co atom in **3** acts as a bridge and is located at a distorted octahedral center, being coordinated by two O atoms from the arsenic–vanadium polyoxoanion and four N atoms from two enMe ligands with Co–N bond lengths ranging from 2.049(8) to 2.110(9) Å. These layers are stacked along the [1$\bar{1}$0] direction in AAAA sequence with an interlamellar separation of approximately 9.0 Å (see Figure S3 in the Supporting Information), forming *pseudo*-1D channels along the *c* axis, which are occupied by lattice water molecules and organic ligands (Figure S4).

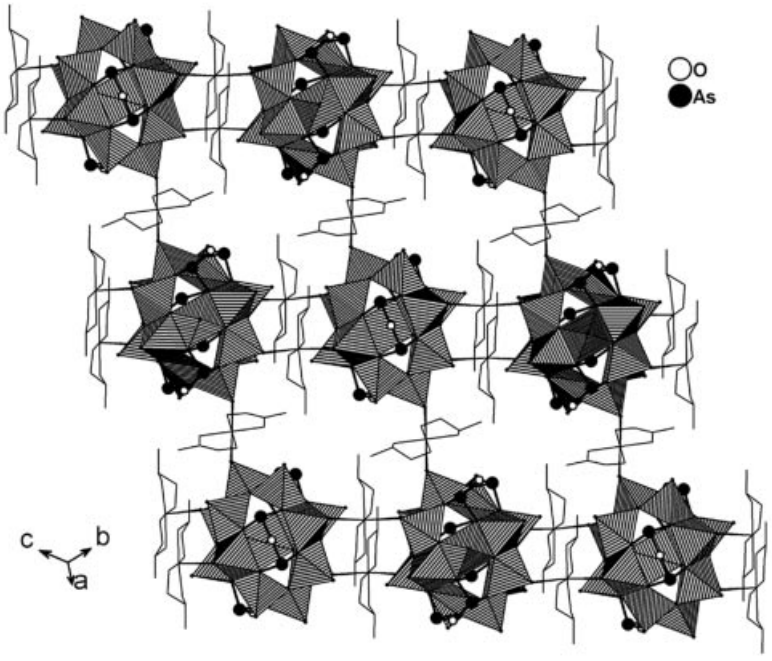

Figure 9. View of the 2D structure of **3** along the [111] direction. All the H atoms and water molecules are omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The infrared spectrum of **1** exhibited features characteristics of $\nu$(M–O–M) (M = V or As) in the 480–800 $cm^{-1}$ regions. The strong bands at 983 can be assigned to the stretching vibrations of V=O bonds. The region of interest in determining the mode of 2,2′-pyridine binding and the bending bands of the $NH_2$ and $CH_2$ are from 1161–1599 $cm^{-1}$. The infrared spectrum of **2** shows the bending bands of the $NH_2$ and $CH_2$ present at around 1583, 1458, and 1362 $cm^{-1}$. While the strong peak 980 $cm^{-1}$ is attributed to the vibrations of V=O bands, a series of bands in the 480–760 $cm^{-1}$ region is characteristic of $\nu$(M–O–M) (M = V or As) and $\nu$(As–O). The infrared spectrum of **3** exhibits a number of absorption bands in the 1100–1600 $cm^{-1}$ region. Many of these bands are attributed to the fundamental vibration modes of enMe. The strong and sharp bands at 973 $cm^{-1}$ are assigned to the vibrations of V=O bands. Furthermore a broad band between 833 and 500 $cm^{-1}$ with maximum at 701 $cm^{-1}$ is attributed to asymmetric and symmetric {M–O–M} (M = V or As) stretching. These positions of the bands and their assignments of **1**–**3** are consistent with literature reports.[16,24,37]

The thermogravimetric analyses were carried out in flowing $N_2$ with a heating rate of 10 °C·$min^{-1}$ in the temperature range 30–1000 °C for compounds **1**–**3** (Figure 10). Three distinct weight-loss stages are observed on the TGA curve of compound **1**. The first stage, which occurs from 46 to 109 °C, is attributed to the loss of 10.5 water molecules; the observed weight loss (4.84%) is in agreement with the calculated value (5.71%). The remaining two stages occur between 156 and 847 °C, and are due to the loss of two en molecules and six 2,2′-bpy molecules, and the sublimation of three $As_2O_3$ molecules; the observed weight loss (49.68%) is consistent with the calculated value (49.89%). Assuming that the residue corresponds to $VO_2$ and NiO, the observed total weight loss (54.52%) is also in agreement with the calculated value (55.59%). The TG curve of **2** shows two major mass losses in the regions 46–132 °C and 178–776 °C. The first step corresponds to the loss of four water molecules (exp. 2.01%, calcd. 2.75%). The second huge mass loss can be assigned to the loss of 4.5 dien molecules and the sublimation of three $As_2O_3$ molecules (exp. 41.19%, calcd. 40.41%). Assuming that the residue corresponds to $VO_2$ and ZnO, the observed total weight loss (43.20%) is in good agreement with the calculated value (43.16%). The TG curve of **3** indicates that the weight loss of **1** cannot be completely divided into distinct stages. The whole stage, which occurs from 58 to 786 °C, is attributed to the loss of $H_2O$ and enMe, and the sublimation of $As_2O_3$. Assuming that the residue corresponds to $VO_2$ and CoO, the observed weight loss (43.29%) is in good agreement with the calculated value (42.74%).

The variable temperature magnetic susceptibilities of **1** and **2** were measured between 2 and 300 K. Figure 11 shows the magnetic behaviors of **1** and **2** in the form of the product $\chi_M T$ versus temperature, where $\chi_M$ is the molar magnetic susceptibility. The $\chi_M T$ value of complex **1** at 300 K is 3.33 $cm^3$·$mol^{-1}$·K, much smaller than the expected value (8.40 $cm^3$·$mol^{-1}$·K) for the fifteen uncoupled $S$ = 1/2 spins of $V^{4+}$ atoms (5.40 $cm^3$·$mol^{-1}$·K, $g$ = 1.9591 for $V^{4+}$ from EPR result) and three uncoupled $S$ = 1 spins of the $Ni^{2+}$ atoms (3.0 $cm^3$·$mol^{-1}$·K, $g$ = 2.0). Upon cooling, the $\chi_M T$ value decreases nearly linearly to 2.48 $cm^3$·$mol^{-1}$·K at 50 K, and then decreases rapidly from 50 K and reaches a minimum value of 1.74 $cm^3$·$mol^{-1}$·K at 2 K. Such magnetic behavior is characteristic of the combination of zero-field splitting of $Ni^{2+}$ in distorted octahedral environments and strong antiferromagnetic couplings between adjacent paramagnetic centers. The short V···V distance (≤ 3.006 Å) and structural disorder of $V^{4+}$ ions are probably mainly responsible for the strong magnetic interaction at high temperature.[38–40] For **2**, $\chi_M T$ at room temperature is 1.83 $cm^3$·$mol^{-1}$·K, which is also much lower than the value expected for 15 uncoupled electrons (5.34 $cm^3$·$mol^{-1}$·K, $g$ = 1.9493 for $V^{4+}$ from EPR result). As the temperature decreases, the $\chi_M T$ value decreases rapidly until 150 K to stabilize approximately at 1.08 $cm^3$·$mol^{-1}$·K. Below 25 K another faster decrease of $\chi_M T$ is observed, with about 0.47 $cm^3$·$mol^{-1}$·K at 2.0 K. Because the $Zn^{2+}$ ion is nonmagnetic, the magnetic behavior of **2** can be attributed to the exchange interactions between $V^{4+}$ ions in $[As_6V_{15}O_{42}]^{6-}$

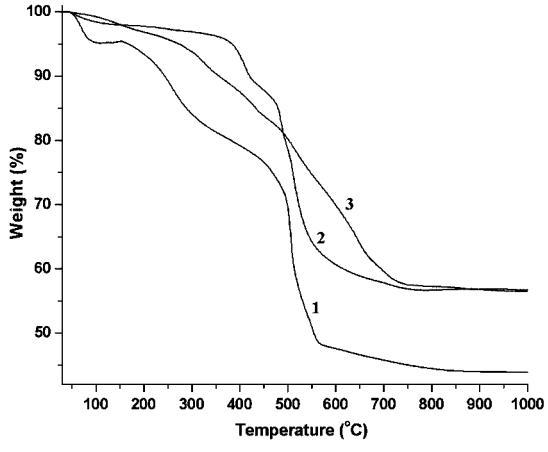

Figure 10. TGA curves of compounds **1**–**3**.

polyoxoanions. The short neighboring V···V distances of V1···V3 (2.846 Å), V2···V4 (2.834 Å), V5···V6 (2.839 Å), V10···V11 (2.868 Å), V12···V13 (2.885 Å), and V14···V15 (2.882 Å) pairs with double O bridges lie in the range expected for strong antiferromagnetic coupling,[29,38–40] thus resulting in a low $\chi_M T$ value at high temperature. The remaining three vanadium ions are largely uncorrelated at high temperature. When temperature is lowered further, a weak antiferromagnetic coupling occurs between these three vanadium centers through the $[As_2O_5]^{4-}$ bridge, which corresponds to the second decrease below 25 K. The value (1.08 $cm^3 \cdot mol^{-1} \cdot K$) of the plateau of $\chi_M T$ in the range 150–25 K is in agreement with the calculated value for three uncoupled $V^{4+}$ ions.

The temperature dependences of $\chi_M T$ for **1** and **2** demonstrate the existence of strong antiferromagnetic coupling interactions, which are a common feature for most polyoxovanadate clusters.[29,41] Unfortunately, it is too difficult to fit the experimental magnetic data of these extended high-nuclearity heteropolymetallic spin systems using a suitable theoretical model.[42]

## Conclusions

In this paper, we have described three extended As–V–O compounds synthesized by a hydrothermal method, all constructed from $[As_6V_{15}O_{42}(H_2O)]^{6-}$ cluster units. These results emphasize the potential of $[As_6V_{15}O_{42}(H_2O)]^{6-}$ clusters as building blocks for constructing new materials and demonstrate that the hydrothermal techniques are a vital tool for the realization of materials design. Moreover, the construction of these new materials may facilitate the formation of unexpected species[16] such as the novel $[Zn_2(dien)_3]^{4+}$ and $[Zn_2(dien)_3(H_2O)_2]^{4+}$ cations observed during the course of this work. Linking discrete POMs to build solid-state materials is of great interest not only from a structural point of view, but also because they are potentially interesting for applications in different areas. Further research will concentrate on the suitable modification of the synthetic conditions to obtain 3D As–V–O cluster architecture, which has never been reported to date to the best of our knowledge and is a challenging task.

## Experimental Section

**General Remarks:** All reagents were purchased commercially and used without further purification. The contents of V, Ni, Zn, Co, and As were determined with an Utlima2 spectrometer. Elemental analyses (C, H, and N) were performed on an Elementar Vario III analyzer. IR spectra were recorded with an ABB Bomem MB102 spectrometer in KBr pellet. Thermal analyses were performed in a dynamic nitrogen atmosphere with a heating rate of 10 °C·min$^{-1}$, using a METTLER TGA/ SDTA851$^e$ thermal analyzer. EPR spectra were carried out on powder samples at X-band frequency with a Bruker ER-420 spectrometer at room temperature. Variable temperature susceptibility measurements were carried out in the temperature range 2–300 K at a magnetic field of 1 T on polycrystalline samples with a SQUID MPMS-7 magnetometer manufactured by Quantum Design. Background corrections for the sample holder assembly and diamagnetic components of the compound were applied.

**Synthesis of $[Ni(2,2'\text{-bpy})_3]_2[\{Ni(en)_2\}As_6V_{15}O_{42}(H_2O)]\cdot 9.5H_2O$ (1):** A mixture of $V_2O_5$ (0.30 g, 1.65 mmol), $As_2O_3$ (0.10 g, 0.51 mmol), $Ni(CH_3COO)_2\cdot 4H_2O$ (0.05 g, 0.20 mmol), 2,2′-bpy (0.05 g, 0.32 mmol), en (0.30 mL), and $H_2O$ (12 mL, 0.67 mol) was heated to 160 °C for 3 days and then cooled to room temperature. The product was isolated as brown blocks (0.473 g, 65.1% yield based on V). $C_{64}H_{85}As_6N_{16}Ni_3O_{52.50}V_{15}$ (3308.23): calcd. C 23.21, H 2.59, As 13.59, N 6.77, Ni 5.32, V 23.10; found C 22.96, H 2.71, As 13.16, N 6.58, Ni 5.09, V 22.94. IR (KBr) for **1**: $\tilde{\nu}$ = 1632 (m), 1599 (s), 1491 (w), 1471 (m), 1442 (s), 1318 (m), 1161 (w), 1020 (m), 983 (s), 778 (s), 754 (s), 738 (s), 633 (m), 488 (w), 464 (m) $cm^{-1}$.

**Synthesis of $[Zn_2(dien)_3(H_2O)_2]_{1/2}[\{Zn_2(dien)_3\}As_6V_{15}O_{42}(H_2O)]\cdot 2H_2O$ (2):** A mixture of $V_2O_5$ (0.20 g, 1.10 mmol), $As_2O_3$ (0.24 g, 1.21 mmol), dien (0.40 mL), $Zn(CH_3COO)_2\cdot 2H_2O$ (0.54 g, 2.10 mmol), and $H_2O$ (15 mL, 0.83 mol) was sealed in a Teflon-lined steel autoclave and heated to 160 °C for 3 days and then cooled to room temperature. The product was isolated as brown blocks (0.220 g, 57.3% yield based on V). $C_{18}H_{66.5}As_6N_{13.5}O_{46}V_{15}Zn_3$ (2618.08): calcd. C 8.25, H 2.56, As 17.17, N 7.22, V 29.19, Zn 7.49; found C 7.64, H 2.63, As 16.75, N 6.77, V 30.16, Zn 7.06. IR (KBr) for **2**: $\tilde{\nu}$ = 1583 (s), 1458 (m), 1386 (w), 1362 (w), 1326 (w), 1285 (w), 1144 (m), 1092 (m), 980 (s), 738 (s), 633 (s), 541 (m), 484 (m), 460 (m) $cm^{-1}$.

**Synthesis of $[Co(enMe)_2]_3[As_6V_{15}O_{42}(H_2O)]\cdot 2H_2O$ (3):** A mixture of $V_2O_5$ (0.55 g, 3.02 mmol), $As_2O_3$ (0.20 g, 1.01 mmol), $H_2C_2O_4\cdot 2H_2O$ (0.382 g, 3.04 mmol), enMe (0.30 mL), $CoSO_4\cdot 4H_2O$ (0.34 g, 1.50 mmol), and $H_2O$ (10 mL, 0.55 mol) was sealed in a Teflon-lined steel autoclave and heated to 160 °C for 6 days and then cooled to room temperature. The product was isolated as brown blocks (0.282 g, 27.3% yield based on V). $C_{18}H_{72}As_6Co_3N_{12}O_{45}V_{15}$ (2567.29): calcd. C 8.44, H 2.83, As 17.51, Co 6.89, N 6.55, V 29.76; found C 8.25, H 2.96, As 16.92, Co 6.80, N 6.38, V 29.05. IR (KBr) for **3**: $\tilde{\nu}$ = 1633 (m), 1578 (s), 1448 (m), 1300 (w), 1267 (m), 1081 (m), 1020 (s), 973 (s), 701 (s), 510 (s), 446 (m) $cm^{-1}$.

**X-ray Crystallography:** Crystal structure determinations by X-ray diffraction were performed with a Siemens SMART CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation in the $\omega$ scanning mode at room temperature. The program SADABS was used for the absorption correction. The structures were solved by the direct methods and refined by full-matrix least-squares on $F^2$. All calculations were performed using the SHELX97 program package. For **1**, in the cluster structure, three positions occupied by $As_2O_5$ dimers and three positions occupied by $VO_5$ square pyramids were disordered. Each of the six disordered positions was occupied either by an $As_2O_5$ dimer or a $VO_5$ square pyramid. The ratios $[As_2O_5]/[VO_5]$ were refined to 0.5:0.5 for all six disordered positions. The respective occupancies of those disordered As and V atoms were fixed finally according to the value of free refined occupancies. Although the final residuals ($R_1$ = 0.1122, $wR_2$ = 0.1967) were relatively large, the molecular anion and transition-metal complexes were well behaved, and there were no unusual temperature factors or excursions of electron density in these regions of the structure. The space group was unambiguous. For **2**, the Zn1 atom was disordered over two positions (Zn1 with SOF = 0.60 and Zn1A with SOF = 0.40). In addition, difference Fourier maps showed two significant regions (7.95 and 2.70 e·Å$^{-3}$) of electron density close to the Zn3 atom. A disordering effect of the Zn3 atom over three adjacent positions with occupancy of 0.57, 0.38, and 0.05 was therefore modeled. In each structure, hydrogen

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

atoms of organic ligands were geometrically placed and refined using a riding model. These above-mentioned disordered atoms and several disordered C atoms (C31 and C32 in **1**, C6, C7, and C9 in **2**, and C12 in **3**) were refined isotropically; the other atoms were refined anisotropically. Experimental details for the structural determinations of **1**–**3** are presented in Table 1. Ranges of selected bond lengths of **1**–**3** are listed in Table 2.

# Manganese Azides Based on Co-Ligands with a Flexible Tail: Diverse Structural and Magnetic Properties

Shi-Qiang Bai,[a] En-Qing Gao,[a,b] Zheng He,[a] Chen-Jie Fang,[a] Yan-Feng Yue,[a] and Chun-Hua Yan*[a]

**Keywords:** Azides / Coordination polymers / Ligand design / Magnetic properties / Manganese

Three azido-bridged coordination polymers, namely $[Mn(L^1)(N_3)_2]_n$ (**1**), $[Mn(L^2)(N_3)_2]_n$ (**2**), and $[Mn(L^3)(N_3)_2]_n$ (**3**) [$L^1$ = *N*-(2-pyridylmethylene)methylamine, $L^2$ = *N*-(2-pyridylmethylene)ethylamine, and $L^3$ = *N*-(2-pyridylmethylene)octylamine], have been synthesized with Schiff-base co-ligands with flexible tails, and their structures and magnetic properties characterized. Complex **1** is composed of one-dimensional, uniform chains with double end-on (EO) azido bridges, complex **2** consists of (6,3) net layers in which double EO azido-bridged dimers are interlinked by single end-to-end (EE) azido bridges, and complex **3** contains chains of $Mn^{II}$ ions bridged by alternating double EO and double EE azido bridges. Magnetically, **1** is a metamagnet built of ferromagnetic chains, **2** exhibits weak ferromagnetism due to spin canting, and **3** shows alternate ferro- and antiferromagnetic intrachain interactions.

## Introduction

Magnetic coordination polymers have attracted intense interest due not only to fundamental research into magnetic interactions but also the need for new molecule-based materials. Their magnetic properties depend on the nature of the interacting metal ions, and can be tuned by the nature of the bridging ligand and by the whole structural arrangement.[1] In recent years, an increasing number of azidomanganese(II) coordination polymers with different co-ligands have been reported that present a remarkable diversity in bridging topology, polymeric dimensionality, and bulk magnetic properties.[2–6] The main factors causing such diversity are the extreme versatilities of the azido ligating mode in bridging metal ions and in transmitting magnetic interactions. The azido bridge transmits mainly ferromagnetic (FM) interactions for the end-on (EO) binding mode and antiferromagnetic (AFM) interactions for the end-to-end (EE) mode.

Despite the large number of manganese azide complexes, no general correlation has been found so far between the properties of the co-ligand and the coordination mode of the azido bridge. Recently, we have reported a series of azidomanganese(II) complexes with didentate Schiff bases derived from 2-pyridylaldehyde and aniline derivatives, which exhibit similar one-dimensional (1D) structures with alternating double EO and double EE azido bridges despite the different substituents on the aniline moiety.[3i] Along this line, we decided to extend this study to similar didentate Schiff bases derived from aliphatic amines to investigate the correlation between the polymeric structures and the co-ligands. Here, we report the structural and magnetic properties of three new azidomanganese(II) complexes with didentate Schiff-base co-ligands derived from methylamine, ethylamine, and octylamine (Scheme 1). As will be shown, although they have the same $[Mn(L^i)(N_3)_2]_n$ stoichiometry, the structures vary from a 1D uniform chain with double EO azido bridges {$[Mn(L^1)(N_3)_2]_n$, **1**}, through a two-dimensional (2D) layer with double EO, and single EE azido bridges {$[Mn(L^2)(N_3)_2]_n$, **2**}, to a 1D chain with alternating double EO and double EE azido bridges {$[Mn(L^3)(N_3)_2]_n$, **3**} with increasing steric demand of the co-ligands $L^1$, $L^2$, and $L^3$, respectively. Consequently, these complexes exhibit different magnetic properties.

## Results and Discussion

Complex **1** was prepared as crystals by slow interdiffusion between a methanol solution containing $Mn(ClO_4)_2 \cdot 6H_2O$ and $L^1$ and a methanol solution of $NaN_3$. Crystals of **2** and **3** were obtained by slow concentration of methanol solutions containing $Mn(ClO_4)_2 \cdot 6H_2O$, $NaN_3$, and the appropriate Schiff-base ligands.

### IR Spectra

The IR spectra of the three complexes display characteristic bands for the azido bridges and the C=N group. A sharp and strong band at 2067 $cm^{-1}$ in the spectrum of complex **1** is attributed to $\nu_{as}(N_3)$ in the EO mode. For complex **2**, a very strong band at 2067 $cm^{-1}$ with a small shoulder at the higher-frequency side indicates the presence of two different azido groups. Two sharp and strong bands at 2064 and 2095 $cm^{-1}$ indicate the presence of two different azido groups in complex **3**.[3a,7] The characteristic $\nu$(C=N) absorption of the Schiff-base ligands in these complexes appears at around 1595 $cm^{-1}$ as a medium-intensity band.

### X-ray Structures

Selected bond lengths and bond angles for the three complexes are summarized in Table 1. The three crystal structures exhibit different hydrogen-bonding patterns, and all the hydrogen-bonding parameters are given in Table 2.

Complex **1** contains neutral 1D chains constructed by double EO azido bridges linking $Mn^{II}$ ions along the *a* direction. The asymmetric unit consists of a binuclear unit involving two independent $Mn^{II}$ ions, each of which is octahedrally coordinated by six N atoms from a chelating $L^1$ and four azido ligands in the EO mode [Figure 1(a)]. The binuclear unit is further linked to its two neighbors through two pairs of double EO azido bridges, giving rise to a 1D chain with a Mn(2B)–Mn(2)–Mn(1)–Mn(1A) sequence with three different pairs of bridges between them [Figure 1(b)]. The Mn–N–Mn bridging angles in the centrosymmetric Mn(2B)···Mn(2) and Mn(1)···Mn(1A) pairs are 102.5(1)° and 103.96(9)°, respectively, and those for the noncentrosymmetric Mn(2)···Mn(1) pair are 100.85(9)° and 102.33(9)°. The three different Mn···Mn distances spanned by double EO azido bridges are in the range of 3.420 to 3.486 Å. All the azido ligands are essentially linear, with asymmetric N–N distances. In the lattice, a weak intrachain C–H···N hydrogen bond (Table 2) is formed between the pyridyl group (C8–H) of $L^1$ and the uncoordinated terminal nitrogen (N7) of the bridging EO azido ligands. Weak interchain C–H···N hydrogen bonds also exist between the azomethine and pyridyl C–H in $L^1$ and the uncoordinated terminal N atom of the bridging azido ligands [Figure 1(c)]. Neighboring pyridine rings from different chains are parallel to and overlap each other with an interplanar distance of 3.54 Å and a centroid–centroid distance of 4.00 Å; the displacement angle, as defined by Janiak, is about 27.7°.[8] These features indicate a weak π–π stacking interaction between neighboring chains. The nearest interchain Mn···Mn distance is 9.267 Å.

Complex **2** has a 2D layer structure constructed by binuclear units interconnected through single EE azido bridges. A perspective view of the binuclear unit of complex **2** is shown in Figure 2(a). Each $Mn^{II}$ ion is ligated by two N atoms from a chelating $L^2$ ligand and four azido N atoms, with Mn–N distances ranging from 2.172(3) to 2.299(4) Å. Two neighboring $Mn^{II}$ ions related by an inversion center are linked by double EO azido bridges, the Mn–N–Mn angle and the Mn···Mn distance being 103.5(1)° and 3.509 Å, respectively. Each binuclear unit is linked to four neighboring equivalent units through four single EE azido bridges to form a neutral 2D layer with a pseudo-honeycomb (6,3)

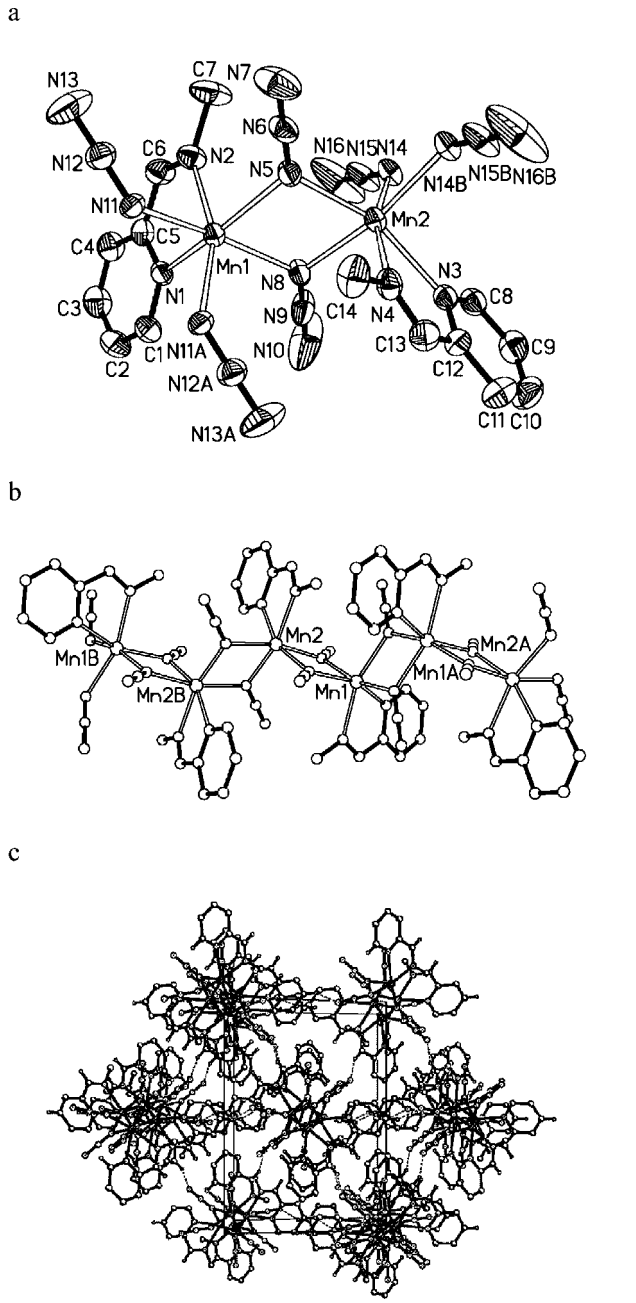

Figure 1. Thermal ellipsoid plot (30% probability), with atom-labeling scheme and H atoms omitted for clarity (a), chain plot (b), and packing of the chains along the *a* direction (c) in **1**.

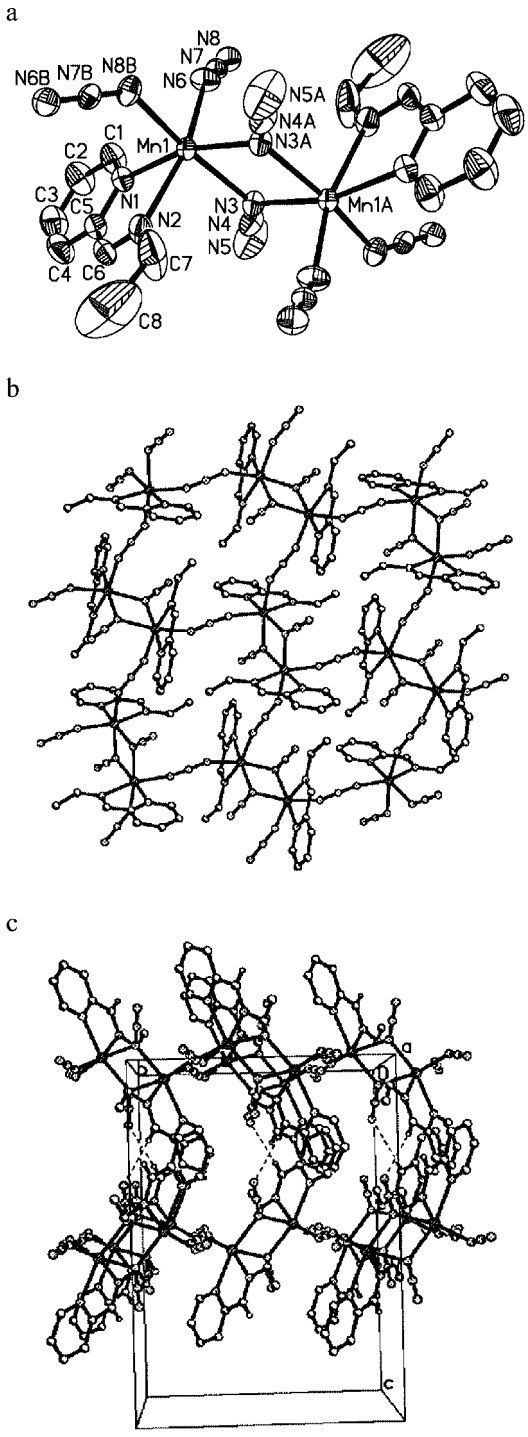

Figure 2. Thermal ellipsoid plot (30% probability), with atom-labeling scheme and H atoms omitted for clarity (a), 2D (6,3) net layer (b), and interactions of neighboring layers (c) in **2**.

topology [Figure 2(b)]. The neighboring $Mn_2N_2$ units are interrelated by a $2_1$ screw operation, with an acute dihedral angle (*a*) between their $Mn_2N_2$ planar rings (79.5°).

Just like the structures we reported previously,[4i] the structure can also be described as a layer consisting of EE azido-bridged Mn–$N_3$ helical chains interlinked by double EO azido bridges. The helical chain runs around a twofold screw axis along the *a* direction, and neighboring chains are related by inversion centers and hence have opposite chirality. Within the chain, the Mn–N–N angles are 146.0(3)° and 136.2(3)°, the N–Mn–N angle is 90.9(2)°, and the Mn–$N_3$–Mn torsion angle ($\tau$) is 7.1°. The Mn···Mn distance spanned by the EE azido bridge is 6.332 Å, and the helical pitch is 10.672 Å.

In the crystal packing, a weak intralayer C–H···N hydrogen bond (Table 2) is formed between the methylene C7–H

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of $L^2$ and the N7 atom of the bridging EE azido ligand. Weak interlayer C–H···N hydrogen bonds also exist between the azomethine C–H of $L^2$ and the uncoordinated terminal nitrogen of the bridging EO azido ligand from neighboring layers [Figure 2(c)]. The 2D layers are stacked down the *c* direction, with the minimum interlayer Mn···Mn distance being 9.257 Å, which is significantly shorter than the distances found in most 2D Mn–azido systems. This short interlayer separation in **2** may be a consequence of deep complementary interdigitation between the consecutive layers. As can be seen from Figure 2(c), the pyridine groups of the $L^2$ ligands on each side of a layer extend deeply into the "empty" space of neighboring layers.

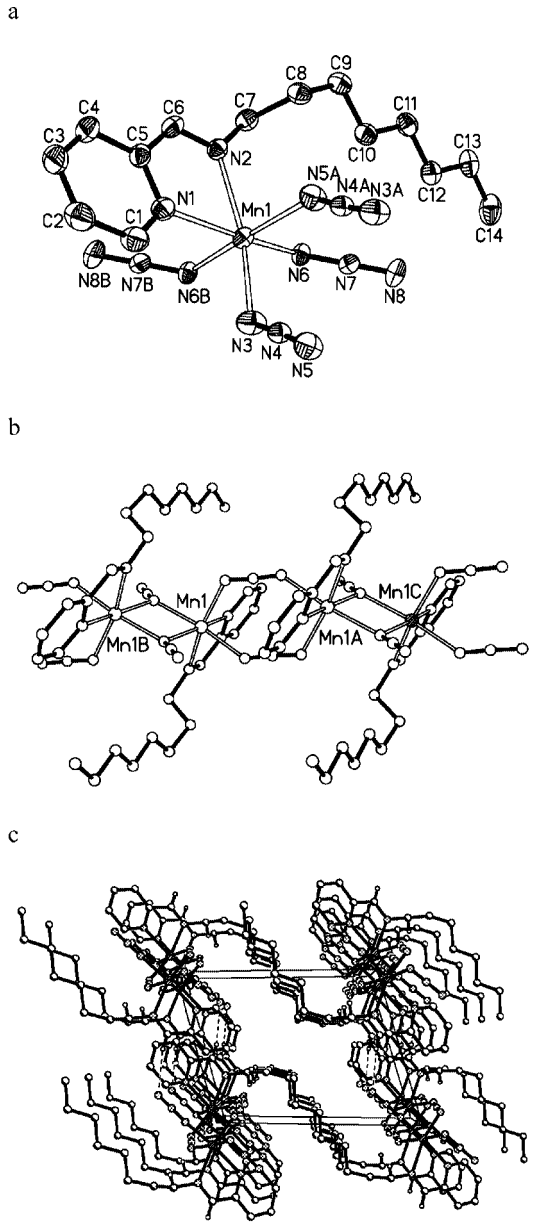

Figure 3. Thermal ellipsoid plot (30% probability), with atom-labeling scheme and H atoms omitted for clarity (a), chain plot (b) and packing of the chains along the *a* direction (c) in **3**.

In complex **3**, each $Mn^{II}$ center exhibits a distorted octahedral $MnN_6$ coordination sphere and is bonded by two EO and two EE azides with two N atoms from the chelate Schiff-base $L^3$ (Figure 3). Neighboring $Mn^{II}$ ions are linked alternately by double EO and double EE azido bridges to form an alternate chain running along the *a* direction. All the Mn–N distances are in the range of 2.190(1) to 2.287(1) Å. The small chelate angle [N1–Mn1–N2 = 72.66(5)°] indicates the severe distortion of the $Mn^{II}$ coordination geometry. The EO azido bridges possess asymmetric N–N distances, while the EE bridges are essentially symmetric. In the EO bridging moiety, the Mn1–N6–Mn1B angle and the Mn···Mn distance are 101.71(5)° and 3.440 Å, respectively. In the EE bridging moiety, the Mn–N–N angles are 126.1(1)° and 141.3(1)° and the Mn–$N_3$–Mn torsion angle is 15.9°. The dihedral angle between the (EE–$N_3$)$_2$ plane and the N5–Mn1–N3A plane is only 7.6°, thereby indicating a slight chair conformation for the Mn–(N$_3$)$_2$–Mn ring. The Mn···Mn distance separated by EE bridges is 5.466 Å.

In the crystal packing, a weak intrachain C–H···N hydrogen bond (Table 2) exists between the methylene C7–H of $L^3$ and the coordinated nitrogen (N3) of the bridging EE azido ligand. The azomethine C–H group of the $L^3$ also forms a weak interchain C–H···N hydrogen bond with the uncoordinated terminal N atom of the bridging EO azido ligands from neighboring chains along the *b* direction [Figure 3(c)]. The long tails of the $L^3$ ligands from neighboring chains interdigitate one another and separate the chains by 12.007 Å. Neighboring pyridine rings from different chains parallel and overlap each other with an interplanar distance of 3.52 Å and a centroid–centroid distance of 3.80 Å; the displacement angle is about 22.0°.[8] These features indicate weak π–π stacking interactions between neighboring chains. The minimum interchain Mn···Mn distance is 8.556 Å along the *b* direction.

## Magnetic Properties

### *Complex 1*

The magnetic susceptibility of **1** was measured at a field of 5 kOe in the temperature range 2–300 K [Figure 4(a)]. The temperature dependence of $\chi_M^{-1}$ above 21 K obeys the Curie–Weiss law with a positive Weiss constant ($\theta$ = 15.91 K), indicating an intrachain ferromagnetic interaction, as expected for the azido bridges in the double EO mode. The room-temperature $\chi_M T$ value is around 4.41 emu K mol$^{-1}$ per $Mn^{II}$ ion, which is close to the spin-only value (4.38 emu K mol$^{-1}$) for a high-spin $Mn^{II}$ ion. Upon cooling, $\chi_M T$ increases smoothly to a maximum at about 6 K, and then decreases rapidly. This may indicate an overall intrachain ferromagnetic interaction and an interchain antiferromagnetic interaction. The magnetic behavior of **1** was analyzed by fitting the experimental susceptibility to Fisher's calculation[9] for a classical or infinite spin chain, scaled to a real spin of 5/2.[10] The expression for

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

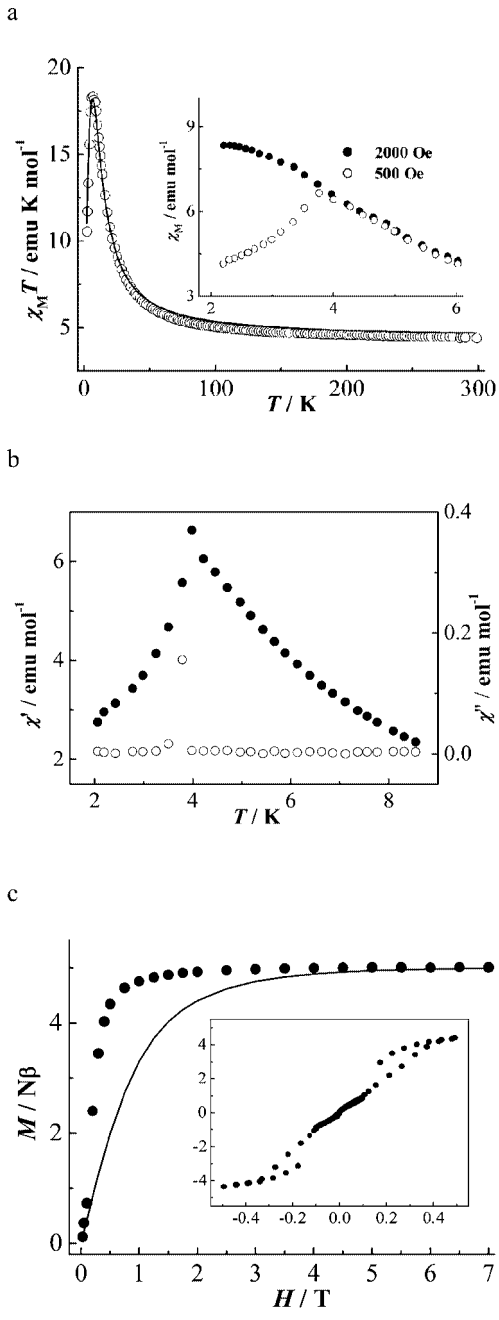

Figure 4. (a) $\chi_M T$ vs. $T$ plot of **1**. The solid line was plotted according to the fit parameters given in the text. Inset: fc magnetization curves at 500 and 2000 Oe. (b) Temperature-dependence of the ac magnetic susceptibility at zero applied dc field and an ac field of 2 Oe and 277 Hz. (c) Field dependence of the magnetization. The solid line was plotted according to the Brillouin function for an $S$ = 5/2 system with $g$ = 2. The inset is the hysteresis loop at 1.8 K.

the magnetic susceptibility is given by Equation (1), where $u = (T/T_o) - \coth(T_o/T)$ with $T_o = JS(S + 1)/k$.

$$\chi_{chain} = [Ng^2\beta^2S(S + 1)/(3kT)][(1 - u)/(1 + u)] \quad (1)$$

The $J$ parameter is based on the spin-Hamiltonian $H = -J\Sigma S_iS_{i+1}$. The interchain interaction ($zJ'$) was accounted for by the molecular-field approximation [Equation (2)].[14]

$$\chi_M = \chi_{chain}/[1 - (zJ'/Ng^2\beta^2)\chi_{chain}] \quad (2)$$

The best fit leads to $J$ = 2.54(2) cm$^{-1}$ and $zJ'$ = –0.41(5) cm$^{-1}$, with the $g$-value fixed at 2.0.

Although double EO azido bridges have been found in many metal azide complexes, chains with exclusive double EO azido bridges are still rare. One such compound, [Mn(2-bzpy)$(N_3)_2]_n$ (2-bzpy = 2-benzoylpyridine), which also exhibits ferromagnetic intrachain interactions, has been reported previously.[3d] Compared with EO azido-bridged complexes with similar structures, it has been suggested that the M–N–M bridging angle ($\theta$) is the main factor that controls the magnetic interaction between metal ions. The ferromagnetic intrachain interaction ($J$ = 2.54 cm$^{-1}$) for **1**, in which the bridging angles average to 102.4°, is stronger than that ($J$ = 0.8 cm$^{-1}$) for [Mn(2-bzpy)$(N_3)_2]_n$, in which the average bridging angle (100.5°) is smaller. This trend is consistent with the density functional calculations on model $Mn^{II}$ compounds performed by Ruiz et al.[12] This calculation predicts that a crossover between ferro- and antiferromagnetic interactions occurs at $\theta$ = 98°, and that the ferromagnetic interaction increases when the Mn–N–Mn bridging angle increases above 98°.[12]

To investigate further the magnetic behavior of **1**, field-cooled (fc) magnetization at different fields was measured and the plot is given in Figure 4(a, inset). At 500 Oe, the magnetization presents a maximum at around 3.7 K, suggesting the onset of 3D antiferromagnetic ordering among the ferromagnetic chains. However, the magnetization at 2 kOe shows no maximum and tends to saturate at lower temperature, thus indicating that the interchain antiferromagnetic interaction is overcome by the external field. These features are indicative of a metamagnet built of ferromagnetic chains. The temperature dependence of the ac magnetic susceptibility was also measured at zero dc field and confirmed the occurrence of the magnetic ordering, with $T_N$ = 3.9 K, at which both $\chi'$ (the in-phase component) and $\chi''$ (the out-of-phase component) reach maximum values [Figure 4(b)].

The metamagnetic behavior was confirmed by the field dependence of the magnetization, as shown in Figure 4(c). The sigmoid shape of the $M$ vs. $H$ curve at 1.8 K clearly indicates a field-induced transition from an antiferromagnetic to a ferromagnetic state, which is characteristic of a metamagnet. The critical field is about 2 kOe, estimated as the field at which a maximum $\partial M/\partial H$ value is reached. Upon increasing the field, the magnetization increases rapidly and saturates at 5.0 $N\beta$, and the saturation is much more rapid than that predicted by the Brillouin function. This definitely confirms the presence of ferromagnetic interactions. Hysteresis loop measurements revealed that **1** is a metamagnet with a typical crossover magnetic hysteresis [Figure 4(c, inset)].

In contrast to **1**, the previous compound [Mn(2-bzpy)$(N_3)_2]_n$ does not exhibit long-range magnetic ordering above 2 K. This may be due to its longer interchain Mn···Mn distance of 9.931 Å than that of **1** (9.267 Å), which weakens the interchain interactions.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### *Complex 2*

The magnetic susceptibility of **2** was measured in the range 2–300 K at 5 kOe and is shown as $\chi_M$ vs. $T$ and $\chi_M T$ vs. $T$ plots in Figure 5(a). The $\chi_M T$ value at 300 K is about 3.91 emu K mol$^{-1}$. Upon cooling, $\chi_M T$ decreases monotonically and vanishes when $T$ approaches zero, indicating an overall antiferromagnetic interaction. As the temperature is lowered, $\chi_M$ value increases first to a rounded maximum of 0.045 emu mol$^{-1}$ at about 36 K, then decreases to a minimum value of 0.044 emu mol$^{-1}$ at 21 K, and finally increases to 0.045 emu mol$^{-1}$ at 2 K. The behaviors above 20 K are typical of 1D and 2D $Mn^{II}$ complexes with dominant antiferromagnetic interactions, and the increase of $\chi_M$ below 20 K may be due to the presence of a spin-canted structure (see below).

To evaluate the magnetic interactions via the azido bridges in **2**, we used an approximate approach that has been used for similar compounds.[4e,4i] This approach treats the 2D layer as EE azido-bridged antiferromagnetic chains interacting ferromagnetically through the double EO azido bridges. Consequently, Equations (1) and (2) are applicable, where $J$ is the interaction through the EE azido bridge and z$J'$ is the interaction through the double EO azido bridges. The least-squares fit of the experimental data above 26 K to the above expressions led to $J$ = –4.85(4) cm$^{-1}$ and z$J'$ = 2.5(4) cm$^{-1}$ with $g$ = 2.0. These values are comparable to those for related compounds and confirm that the interactions mediated by the single EE and the double EO bridges are antiferro- and ferromagnetic, respectively. Selected structural and magnetic parameters for **2** and similar 2D $Mn^{II}$–azido complexes are collected in Table 3 for comparison. EHMO calculations have shown that the antiferromagnetic interactions through the single EE azido bridge should maximize as the Mn–N–N bond angle approaches 110° and the Mn–$N_3$–Mn torsion angle ($\tau$) approaches 0 or 180°.[4b] The data listed in Table 3 suggest that the influence of the torsion angle dominates in these systems: the strongest interaction is observed for compound **I**, in which the torsion angle is 180°, although the compound has the largest Mn–N–N angles. On the other hand, compound **III**, which has a torsion angle close to 90°, exhibits the lowest |$J$| value, although the Mn–N–N angles are the closest to 110°. Other compounds, including **2**, have in-between angles (the torsion angles are between 90 and 180 or 0°) and $J$ values. The interaction parameters of the double azido bridges for these complexes fall in the range 1.1–3.1 cm$^{-1}$, with the Mn–N–Mn angles in the narrow range of 100.8–103.5°. Apparently, the general trend whereby the ferromagnetic interaction increases with increasing bridging angle is not well followed: the largest $J$ value is obtained for the compound that has a relatively small angle (compound **II**, 101.9°), and the compound that has the largest angle exhibits a relatively small $J$ value (compound **2**, 2.5 cm$^{-1}$). This may be due to the

operation of other factors such as Mn–N bond lengths and coordination environments, which should influence the magnetic orbitals around the metal center.

It has been shown that, except for compound **I** in Table 3, all the previous layered compounds with double EO and single EE bridges exhibit spin-canting behavior, which is consistent with the structural observation that the coordination polyhedra (or the double EO bridged $Mn_2N_2$ moieties) linked by the single EE azido bridges are slanted with respect to each other.[4b,4d,4g,4i] The absence of spin-canting in **I** has been related to the crystallographic centrosymmetry of the single EE azido bridges.[4e,4i] According to the structural data, **2** should exhibit a spin-canted structure. To confirm this point, the field-cooled and zero-field-cooled (zfc) magnetizations were measured at an applied field of 200 Oe [Figure 5(b)]. It is evident that the complex exhibits weak spontaneous magnetization below 22 K, which is characteristic of weak ferromagnets due to the spin-canting. Field-dependent magnetizations at 2 K were also measured, and the magnetization at 50 kOe is 0.46 $N\beta$, far below the saturation value expected for an $S = 5/2$ system (5.0 $N\beta$ with $g = 2.0$). No hysteresis was detected.

### *Complex 3*

The magnetic susceptibility of **3** was measured in the temperature range 2–300 K at 20 kOe. The $\chi_M$ and $\chi_M T$ vs. $T$ plots are shown in Figure 6. The experimental $\chi_M T$ value at 300 K is 3.63 emu K mol$^{-1}$. Upon cooling, the $\chi_M T$ product decreases monotonically, indicating a dominant antiferromagnetic interaction. The $\chi_M$ value increases monotonically, and a rapid increase below 17 K may be caused by the presence of a small amount of paramagnetic impurities.

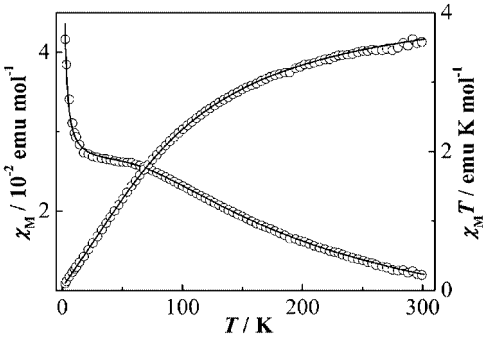

Figure 6. $\chi_M$ and $\chi_M T$ vs. $T$ plots of **3**. The solid line was plotted according to the fit parameters given in the text.

According to the structural data, complex **3** should possess alternating ferro- and antiferromagnetic interactions mediated by double EO and double EE azido bridges, respectively.[3a,3d,3i] To simulate the experimental magnetic behavior, we used a theoretical model proposed by Cortés et al. for alternating $S = 5/2$ chains.[3a] The nearest-neighbor exchange interactions are described by the spin-Hamiltonian given in Equation (3). The expression of the molar susceptibility is given by Equation (4).

$$H = -J_1\Sigma S_{2i}S_{2i+1} - J_2\Sigma S_{2i+1}S_{2i+2} \quad (3)$$

$$\chi_M = [Ng^2\beta^2S(S+1)/3kT]\{[(1+u_1+u_2+u_1u_2)/(1-u_1u_2)](1-\rho)+\rho\} \quad (4)$$

where $u_i = \coth[J_iS(S+1)/kT] - kT/[J_iS(S+1)]$ ($i = 1, 2$). In this expression we have included a $\rho$ parameter, which is related to the amount of paramagnetic impurities (presumably a monomeric $Mn^{II}$ complex), to account for the in-

Table 4. Structural and magnetic parameters for alternating double EE and double EO 1D $Mn^{II}$–azido complexes.

crease of $\chi_M$ below 17 K. The best fit of the experimental data led to $J_1$ = 1.6(2) cm$^{-1}$, $J_2$ = –13.9(1) cm$^{-1}$, and $\rho$ = 0.01 with $g$ fixed at 2.0. The $J_1$ and $J_2$ parameters verify the alternating ferro- and antiferromagnetic interactions, with the antiferromagnetic one dominating.

A chain structure with alternating double EO and double EE azido bridges is the most frequently encountered Mn–azido motif. In our previous work,[3i] this class of $Mn^{II}$ compounds follows the general trend that the ferromagnetic interaction through the double EO bridge increases with the Mn–N–Mn angle, and that the antiferromagnetic interaction through the double EE bridge decreases with the increase of the dihedral angle ($\delta$) between the $(N_3)_2$ plane and the N(EE azido)–Mn–N(EE azido) plane. Since then, several new compounds have been characterized structurally and magnetically. Relevant structural and magnetic data for the known compounds, along with **3**, are collected in Table 4 for comparison. As can be seen, the general trends, which have also been demonstrated by theoretical studies,[3a,12] are followed by most compounds, but it should be noted that there are some evident deviations. The most remarkable example is $[\{Mn(N_3)_2\}_2L']_n$, in which $Mn^{II}$ chains with alternating double EO and double EE azido bridges are linked into a 3D network by 4,5-diazafluoren-9-one azine (L′):[6e] the double EO bridge with a much smaller Mn–N–Mn angle (77°) than the AF–F crossover angle (98°) predicted by density functionl calculations mediates a ferromagnetic interaction, instead of antiferromagnetic interaction, and the double EE bridge with a very small $\delta$ angle (2.9°) mediates a relatively weak antiferromagnetic interaction. For **3** and $[Mn(TaiEt)(N_3)_2]_n$,[3k] the $J_{EO}$ values seem to be too small for their medium and large M–N–M angles, respectively. These deviations may be due to the influence of other structural parameters. Further pragmatic but laborious studies are therefore needed to get more accurate magneto-structural correlations.

## Conclusions

We have presented the syntheses, structures, and magnetic properties of three new azido-bridged $Mn^{II}$ coordination polymers with flexible tail co-ligands. With increasing steric demand of the co-ligands $L^1$, $L^2$, and $L^3$, the structures vary from a double EO azido-bridged uniform chain (**1**), through a double EO and single EE azido-bridged 2D layer (**2**), to a double EO and double EE azido-bridged alternate chain (**3**), respectively. Magnetically, **1** is a metamagnet built of ferromagnetic chains, **2** exhibits a weak ferromagnetism due to spin-canting, and **3** shows alternate ferro- and antiferromagnetic intrachain interactions. We are currently working with other flexible tail co-ligands by varying their substituents to get more information about the relationship between the final structures and the co-ligands and to study their magnetic behaviors towards the preparation of molecule-based magnetic materials.

## Experimental Section

**Materials and Physical Measurements:** All the starting chemicals were of A.R. grade and were used as received. The Schiff-base ligands $L^1$, $L^2$, and $L^3$ were prepared according to literature procedures.[13] Elemental analyses (C,H,N) were performed on an Elementar Vario EL analyzer. IR spectra were recorded with a Nicolet Magna-IR 750 spectrometer equipped with a Nic-Plan Microscope. Temperature- and field-dependent magnetic measurements were carried out on an Oxford MagLab 2000 magnetometer. Diamagnetic corrections were made with Pascal's constants.[14]

***Caution!*** *Azide and perchlorate complexes of metal ions are potentially explosive. Only a small amount of the materials should be prepared, and it should be handled with care.*

**$[Mn(L^1)(N_3)_2]_n$ (1):** A methanol solution (10 mL) containing $Mn(ClO_4)_2{\cdot}6H_2O$ (0.181 g, 0.5 mmol) and $L^1$ (0.061 g, 0.5 mmol), and a methanol solution (10 mL) of $NaN_3$ (0.065 g, 1.0 mmol) were added respectively to the two arms of an H-tube, then methanol was carefully added to both arms until the bridge of the tube was filled. Slow interdiffusion of the two solutions afforded yellow crystals of **1** after two weeks. Yield: 0.042 g (32%). $C_{14}H_{16}Mn_2N_{16}$ (518.31): calcd. C 32.45, H 3.11, N 43.24; found C 32.48, H 3.30, N 43.50. IR: $\tilde{\nu}$ = 2067 vs, 1595 m, 1441 m, 1334 m, 1305 m, 1283 m, 1014 m, 775 m cm$^{-1}$.

**$[Mn(L^2)(N_3)_2]_n$ (2):** A methanol solution (10 mL) of $Mn(ClO_4)_2{\cdot}6H_2O$ (0.181 g, 0.5 mmol) was added to a solution of $L^2$ (0.068 g, 0.5 mmol) in the same solvent. The mixture was stirred for 5 min, then a methanol (10 mL) solution of $NaN_3$ (0.065 g, 1 mmol) was added with continuous stirring. Slow evaporation of the resulting orange solution at room temperature yielded yellow crystals after two weeks. Yield: 0.080 g (59%). $C_8H_{10}MnN_8$ (273.18): calcd. C 35.18, H 3.69, N 41.02; found C 35.14, H 3.85, N 41.42. IR: $\tilde{\nu}$ = 2067 s, 1595 m, 1479 m, 1475 m, 1443 m, 1339 m, 1305 m, 1156 m, 1106 m, 1013 m, 779 m cm$^{-1}$.

**$[Mn(L^3)(N_3)_2]_n$ (3):** This complex was prepared in the same way as **2**, using $L^3$ instead of $L^2$. Yield: 0.043 g (24%). $C_{14}H_{22}MnN_8$ (357.34): calcd. C 47.06, H 6.21, N 31.36; found C 47.07, H 6.27, N 31.79. IR: $\tilde{\nu}$ = 2095 vs, 2064 vs, 1595 m, 1467 m, 1442 m, 1334 m, 1013 m, 775 m cm$^{-1}$.

**X-ray Crystallographic Study:** Diffraction intensity data for single crystals of **1**, **2**, and **3** were collected at room temperature on a Nonius Kappa CCD area detector equipped with graphite-mono-

chromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Empirical absorption corrections were applied using the Sortav program.[15] The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ with anisotropic thermal parameters for all non-hydrogen atoms.[11] Hydrogen atoms were placed geometrically and refined isotropically. Pertinent crystallographic data and structure refinement parameters are summarized in Table 5.

CCDC-279815 (for **1**), -279816 (for **2**), and -279817 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Electronic Structure of Binary Phosphoric and Arsenic Triazides

Zeng Xiaoqing,[a,b] Wang Weigang,[a,b] Liu Fengyi,[a] Ge Maofa,*[a] Sun Zheng,[a] and Wang Dianxun*[a]

**Keywords:** Phosphorus / Arsenic / Triazides / Photoelectron spectroscopy / Ionization potentials

Two highly explosive binary triazides of the group 15 elements $P(N_3)_3$ and $As(N_3)_3$ have been obtained in the gas phase through the heterogeneous reaction of $PCl_3$ and $AsCl_3$, respectively with $AgN_3$ at room temperature. The electronic structures of both triazides have been characterized by photoelectron spectroscopy, combined with quantum chemical calculations. This represents the first electronic study of covalent triazides. The first experimental vertical ionization potentials for $P(N_3)_3$ and $As(N_3)_3$ are 9.74 and 9.98 eV, with the contribution primarily from the lone pairs of the azido moiety and the arsenic atom, respectively. The results indicate the relative "isolation" of azido moieties in triazides and less stability of these highly explosive compounds in comparison to monoazides and diazides.

## Introduction

The first synthesis of a covalent azide $HN_3$ was reported by Curtius more than 100 years ago.[1] However, the chemistry of covalent azides received little attention until the early 1960s, presumably because of their explosive nature and shock sensitivity.[2] Especially the synthesis, isolation, and structural characterization of high-energy compounds are an experimental challenge for chemists.[3] Binary azides of group 15 elements belong to this class of compounds, and little is known about their synthesis, structure, and properties.[4] For nitrogen azides, most studies are focused on theoretical predictions, such as the structures and stabilities of the azidamines $N(N_3)_3$ and $HN(N_3)_2$, the $N(N_3)_2^-$ anion, and the $N(N_3)_4^+$ cation.[5] However, the successful synthesis of the novel $N_5^+$ cation[6] by Christe et al. has greatly encouraged more research on polynitrogen compounds.[7] The binary phosphorus azides $P(N_3)_3$, $P(N_3)_4^+$, $P(N_3)_5$, $P(N_3)_6^-$, and $N_5^+[P(N_3)_6]^-$ have been characterized by vibrational methods and $^{31}P$ NMR spectroscopy, but no structural information is available.[8,9] For arsenic azides, much research has been devoted to the preparation and characterization of these compounds:[10] the first preparation of $As(N_3)_3$ and $As(N_3)_4^+$ was reported by Klapötke et al. in 1995;[10a,10c] the crystal structure of $As(N_3)_3$ was determined by Christe et al. in 2004;[11] and the crystal structure of $As(N_3)_6^-$ was determined by Klapötke et al. in 2000.[10c]

The electronic and molecular structures of many azides (unstable molecules) have been studied with theoretical and spectroscopic methods.[12] Recently, photoelectron spectroscopy in combination with high-level quantum chemical calculations has been successfully performed for elucidating many interesting aspects of monoazides[13] and diazides.[14] The focus of these studies is the interaction taking place between the off-the-axis substituent group and the nearly linear $N_3$ moiety, as well as the interaction between the $N_3$ moieties. In 1994, Novak et al. studied the electronic structures of $(CF_3)_2AsN_3$ and $CF_3As(N_3)_2$.[15] However, reports on the electronic structure of triazide are rare because of their explosiveness. Herein, we report the experimental and calculated electronic structures of binary phosphorus and arsenic triazides.

## Results and Discussion

### Molecular Structures

Geometry optimizations were performed for $P(N_3)_3$ and $As(N_3)_3$ using the DFT method (B3LYP). All stationary points were verified as local minima by vibrational analysis. Three local minima were located for both triazides (see Figure 1 and Table 1). The relative energies for the stable conformers are listed in Table 2. Zero-point vibrational-energy corrections for these minima of $P(N_3)_3$ and $As(N_3)_3$ differ by less than 0.4 and 0.2 kcal mol$^{-1}$, respectively. The most stable structure at the B3LYP/6-311++G(3df) level is the conformer **b** with $C_s$ symmetry, in which two azido ligands adopt an approximate *gauche* orientation relative to the stereochemically active lone pair on the P/As atom, with the remaining azido ligand in an *anti* orientation. For $P(N_3)_3$,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the calculated P–N bond length, 1.73–1.74 Å, is slightly shorter than a typical P–N single bond with 1.76 Å,[16] while longer than a typical P=N double bond with 1.55 Å in iminophosphane (HP=NH).[17] Meanwhile, the azido moiety lies in an almost planar environment with the central P atom (see Table 1); this may provide an opportunity for interactions between the lone pair on the P atom with the three azido ligands to stabilize this conformer. The second most stable conformer of phosphorus triazide, **a**, with $C_3$ symmetry, is 1.46 kcal mol$^{-1}$ higher in energy than conformer **b** and has all three azido ligands in a *gauche* orientation. This energy gap may be the result of the interactions between the sterically active lone pair on the phosphorus atom and the three azido ligands. Finally, the least stable structure, **c** ($C_3$ symmetry), has all three azido ligands pointing away from the phosphorus lone-pair, and is 2.90 kcal mol$^{-1}$ higher in energy than conformer **b**. This structure was calculated to be a real local minimum at the B3LYP/6-311++G(d) level of theory,[18] however, the distances between N2 and N2′, and N3 and N3′ are 3.38 and 4.37 Å, respectively, which are much shorter than those in conformer **a** (4.41 and 6.21 Å, respectively). Also, the natural atomic population (NAO)[19] net charges calculated for this conformer are $Q_P$ = +1.11 e on phosphorus, $Q_{N1}$ = –0.68 e on the adjacent nitrogen atom, $Q_{N2}$ = +0.43 e on the second nitrogen atom, and $Q_{N3}$ = –0.12 e on the last nitrogen atom, indicating that the interactions between N1 and N1′, N2 and N2′, as well as N3 and N3′ might decrease the stability of this conformer.

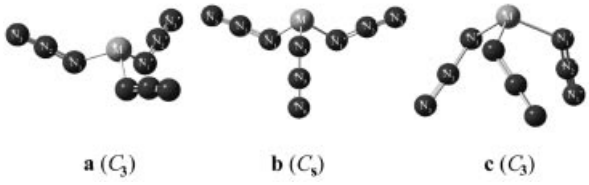

Figure 1. Local minima calculated for $M(N_3)_3$ (M = P, As) at the B3LYP/6-311++G(3df) level of theory. (The geometric parameters are given in Table 1.).

For $As(N_3)_3$, three similar stable conformers were located, with conformer **b** being the most stable structure. However, the most stable conformer previously reported by

using second-order perturbation theory (MP2), which had $C_1$ symmetry with two azido ligands adopting an *anti* orientation and the third azido ligand in a *gauche*-like orientation,[11] was calculated to be not a real local minimum at the B3LYP/6-311++G(3df) level of theory, and the relative energies for the two less stable conformers **a** and **c** here were calculated to be 2.06 and 0.94 kcal mol$^{-1}$ higher than conformer **b**, including the zero-point energy (ZPE) corrections.

### Photoelectron Spectroscopy

The He I photoelectron spectra of $P(N_3)_3$ and $As(N_3)_3$ are shown in Figure 2. Table 3 lists photoelectron spectroscopy (PES) experimental vertical ionization energies (IP in eV), theoretical vertical ionization energies ($E_v$ in eV), molecular orbital symmetries, and characters of outer valence shells for the most stable conformers by OVGF calculations for both triazides. The ionization potentials calculated for the other two stable conformers are also included. Because the three conformers with comparable energies are possible in some cases, first we should investigate whether the spectra can originate from a mixture of all three conformers or some of them dominate. However, in comparison to the calculated orbital energies, we limit our discussions to the analysis of the slightly more stable $C_s$-conformer **b** for $P(N_3)_3$ and $As(N_3)_3$.

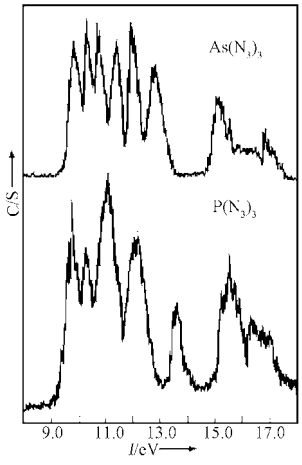

Figure 2. Full He I photoelectron spectra of $P(N_3)_3$ and $As(N_3)_3$.

#### *P(N$_3$)$_3$*

The photoelectron (PE) spectrum of $P(N_3)_3$ is much more complicated than that of $HN_3$,[20] owing to the participation of the phosphorus lone-pair. In the low ionization region (<15 eV) there are five bands with no obvious vibrational structure. From the calculated orbital characters shown in Table 3 and Figure 3, it can be easily concluded that all five bands originate from the removal of the lone pair on the phosphorus or the nitrogen atoms of the azido moieties. The first broad band centered at 9.74 eV matches well with the calculated value 9.81 eV, which is attributed to the ionization of lone pairs from the three azido moieties with almost equal contributions. Similar ionization processes also occur in other azides, such as $CH_3N_3$ (9.81 eV)[21] and $SO(N_3)_2$ (10.18 eV).[14] However, as we know, the removal of lone pair electrons or degenerate π orbital electrons leads to sharp peaks and lower ionization potentials in the PE spectrum of the molecule studied. This indicates that the peak caused by removing electrons from 25a′, with a calculated energy of 9.83 eV, overlaps with the peak caused by removing electrons from HOMO 14a′′. The calculated MO character of the second highest occupied orbital (SHOMO) 25a′ indicates that it has the dominant attribution from the P lone-pair (P3p) (Figure 3). The ionization of similar P lone-pairs actually happens in the low ionization region as well, such as $PH_3$ (10.59 eV)[22] and $(CH_3O)_3P$ (9.30 eV).[23] The second observed band with

Table 3. Experimental and calculated [ROVGF/6-311G(d)] ionization energies [eV].

vertical ionization energy of 10.37 eV agrees well with the calculated value 10.43 eV for orbital 24a′, as can be seen in Figure 3; it has the character of nitrogen lone-pairs on the three azido moieties. The third kind of linear combination is embodied in the third broad band (11.08 eV), which ranges from 10.50 to 11.70 eV. Based on the calculated results and experimental intensity of this band, it is assigned to the removal of electrons from 13a′′ and 12a′′ orbitals. The $\pi_{P-N4}$ formed by the interaction of P3p with the N4 lone-pair is also attributed. The fourth band with experimental vertical ionization energy of 12.17 eV, corresponding to the calculated 12.19 eV for 23a′, has the character $\pi_{N1-P-N1'}$, $\pi_{N5-N6}$ (Figure 3). The next band with a vertical ionization of 13.59 eV corresponds to MO 22a′, which has the dominant character of the P3p lone-pairs. A similar band also occurs in $PH_3$ (13.6 eV).[22] The band centered near 15.6 eV in the high ionization region (>15.0 eV) is considered to be the ionization of electrons from several deep-shell orbitals in $P(N_3)_3$.

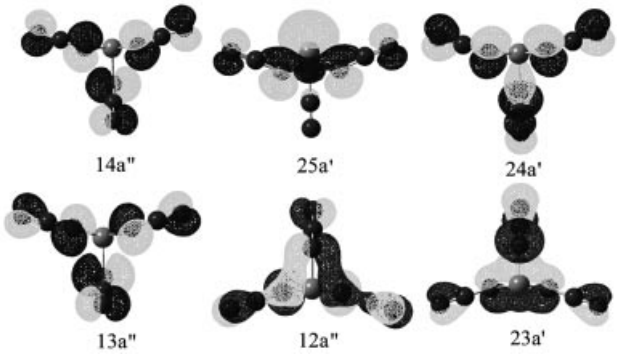

Figure 3. Characters of the six highest occupied molecular orbitals (HOMOs) of $C_s$: $P(N_3)_3$ (isovalue = 0.04).

### *As(N₃)₃*

The electronic structures of two arsenic azides $(CF_3)_2AsN_3$ and $CF_3As(N_3)_2$ have been reported previously.[15] The main interest in the analysis was the interactions taking place between the off-the-axis substituent and the linear (or nearly so) azido group. It was concluded that the larger bandwidth in their PE spectra may signify greater delocalization and bonding interaction between the azido moieties and the rest of the molecule. Compared with the PE spectra of the two above-mentioned azides, the bands in the PE spectrum of $As(N_3)_3$ are clearer and narrower in the low ionization region (<15.0 eV). The calculated MO characters (Figure 4) of this triazide reveal that the lone pair electrons on the azido moieties are more pronounced than in the monoazide and diazide, and imply weaker azido–azido interactions. These weaker interactions also lead to the lower stability of triazide.

In the low ionization region (<15.0 eV), six bands are clearly displayed. Because of the electronic similarity of phosphorus and arsenic, most outer valence shells for $As(N_3)_3$ are similar to that of $P(N_3)_3$. However, the HOMO in arsenic triazide is primarily the attribution of the 4p lone-pair from the As atom (As4p). The vertical ionization potential is 9.98 eV, which is slightly smaller than that of $(CF_3)_2AsN_3$ (10.40 eV) and $CF_3As(N_3)_2$ (10.23 eV),[15] and it corresponds to the calculated 9.73 eV for conformer **b**. Similar to the first band in the PE spectrum of $P(N_3)_3$, the ionization of electrons in the SHOMO 31a′ also happens in this region, with the contribution of the lone pair on nitrogen atoms of the three azido moieties being calculated as 9.87 eV. The second band at 10.22 eV originates not only from the lone pair of the nitrogen atoms on the azido ligands, but also the As4p lone-pair. The third band at 10.70 eV mainly comes from the ionization of the 16a′′ LPN3 (azido lone-pair) electron, and the fourth band at 11.43 eV should be from the 15a′′ $\pi_{As-N4}$, $\sigma_{As-N1}$, $\sigma_{As-N1'}$ (see Figure 4). In $P(N_3)_3$, the bands caused by removal of electrons from these two orbitals overlap. The main characters for the remaining two bands at 11.61 and 12.95 eV are similar to those of $P(N_3)_3$ (Figure 4). In the high ionization region (>15.0 eV), there also exist several broad bands, ranging from 15.00 to 17.50 eV, which might be the ionization of electrons from inner molecular orbitals.

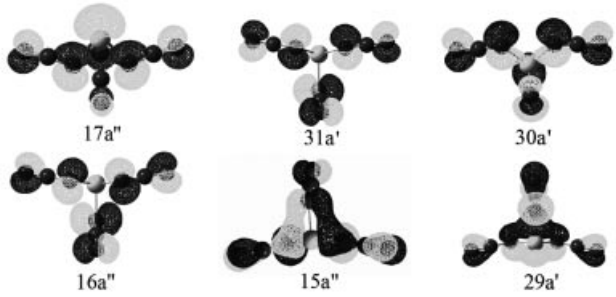

Figure 4. Characters of the six highest occupied molecular orbitals (HOMOs) of $C_s$: $As(N_3)_3$ (isovalue = 0.04).

## Conclusions

The electronic structures of two similar triazides, $P(N_3)_3$ and $As(N_3)_3$, were studied by means of PES and ab initio calculations. Three stable conformers for $P(N_3)_3$ and $As(N_3)_3$ were located at the B3LYP/6-311++G(3df) level of theory. It was found that the conformer **b** with $C_s$ symmetry is the most stable for both triazides. The first ionization potentials of these two stable conformers for $P(N_3)_3$ and $As(N_3)_3$ are 9.74 and 9.98 eV respectively, with the primary characters being the azido lone-pairs for $P(N_3)_3$ and the As4p lone-pairs for $As(N_3)_3$. The SHOMO for the two compounds mainly comes from the P3p lone-pair for $P(N_3)_3$, in comparison to the lone pairs of the azido group for $As(N_3)_3$. Another interesting aspect is that the PES bands for both triazides are almost all sharp without recognizable vibrational structure. And it is known that triazides are usually much less stable than the corresponding di- and mono- derivatives. The relative "isolation" of azido groups and less delocalization in triazides may account for this experimental fact.

## Experiment and Calculation

Recently, many azide-containing compounds have been successfully prepared and characterized,[13,14] and it was found that $AgN_3$ is an ideal precursor for the in situ preparation of highly explosive azides through the heterogeneous reactions with reactive halogen-containing molecules. $P(N_3)_3$ and $As(N_3)_3$ were prepared in a similar manner by the heterogeneous reactions of gaseous $PCl_3$ and $AsCl_3$ with $AgN_3$ at low pressure ($10^{-5}$ Torr). Both reactants were purchased from ACROS and distilled before the PES experiment, and their PE spectra were identical with those in the literature.[23,24] Solid $AgN_3$ was prepared as reported.[14] For efficient reaction, freshly prepared $AgN_3$ was loosely dispersed on the surface of quartz wool and filled the quartz inlet tube. After the vacuum reached $10^{-5}$ Torr, the vapor of the $PCl_3$ or $AsCl_3$ was passed through the solid $AgN_3$ at ambient temperature. The reactions [Equation (1) and Equation(2)] proceeded smoothly without the evolution of the possible decomposition product $N_2$. The He I PE spectra of $P(N_3)_3$ and $As(N_3)_3$ were recorded with a double-chamber machine[25] that was built specifically to detect transient species at a resolution of about 30 meV as indicated by the $Ar^+$ ($^2P_{3/2}$) photoelectron band. Experimental vertical ionization energies ($I_v$ in eV) were calibrated by simultaneous addition of a small amount of argon to the sample.

$$PCl_3\,(g) + 3AgN_3\,(s) \longrightarrow P(N_3)_3\,(g) + 3AgCl\,(s) \quad (1)$$

$$AsCl_3\,(g) + 3AgN_3\,(s) \longrightarrow As\,(N_3)_3\,(g) + 3AgCl\,(s) \quad (2)$$

Geometric optimizations of all possible conformers for phosphorus triazide were performed using density functional theory methods, and three stable conformers for each triazide were located. The calculations were carried out at the B3LYP level of theory with a 6-311++G(3df) basis set. The B3LYP is a hybrid functional method based on Becke's three-parameter nonlocal exchange functional,[26] with Lee et al.'s nonlocal correlation.[27] For the arsenic triazide, geometry optimization was carried out according to the reported stable conformers[11] at the same level of theory. To assign the PES bands of both triazides, OVGF calculations were performed for those three stable conformers of $P(N_3)_3$ and $As(N_3)_3$ using the 6-311G(d) basis set based on optimized structures. The vertical ionization energy ($E_v$) was calculated at the ab initio level according to Cederbaum's outer valence Green's function (OVGF) method,[28] which includes the effect of electron correlation and reorganization beyond the Hartree–Fock approximation. The self-energy part was expanded up to the third order, and contributions of higher orders were estimated by means of a renormalization procedure. All calculations were performed using the Gaussian 98 program.[29]

# Synthesis, Characterization, and Electrochemical Properties of Novel Transition Metal–Fullerene Complexes Containing Di- and Tetraphosphane Ligands

**Li-Cheng Song,*[a] Fu-Hai Su,[a] Qing-Mei Hu,[a] Emanuela Grigiotti,[b] and Piero Zanello[b]**

**Keywords:** Electrochemistry / Fullerenes / Palladium / Phosphane ligands / Platinum

This paper reports the synthesis, characterization, and some properties of transition metal–fullerene complexes containing *trans*-1,1′-bis(diphenylphosphanyl)ethylene (dppet, *trans*-$Ph_2PCH{=}CHPPh_2$) and *N*,*N*,*N*′,*N*′-tetra(diphenylphosphanylmethyl)ethylene diamine (dppeda, $[(Ph_2PCH_2)_2NCH_2]_2$), including $[(\eta^2\text{-}C_{60}M)(dppet)_2]$ (M = Pt **1**, Pd **2**), $[(\eta^2\text{-}C_{60}M)(dppet)]_2$ (M = Pt **3**, Pd **4**), $[(\eta^2\text{-}C_{60}Pd)(\eta^2\text{-}C_{60}Pt)(dppet)_2]$ (**5**), $[(\eta^2\text{-}C_{60}Pd)(\eta^2\text{-}C_{70}Pd)(dppet)_2]$ (**6**), $[(\eta^2\text{-}C_{70}Pd)(dppet)]_2$ (**7**), $[(\eta^2\text{-}C_{60}M)(dppeda)]$ (M = Pt **8**, Pd **9**), and $[(\eta^2\text{-}C_{60}M)_2(dppeda)]$ (M = Pt **10**, Pd **11**). Interestingly, while complexes **1**, **2**, **8**, and **9** are the first examples of metallacyclopropafullerene diphosphane ligands containing fullerene cores, complexes **3**–**7**, **10**, and **11** are the first group 10 metal-containing, dumbbell-shaped bisfullerenes. All the complexes **1**–**11** were characterized by elemental analysis, spectroscopy, and, particularly for **4** and **5**, by X-ray crystallography and cyclic voltammetry. Pathways for the formation of **1**–**11** are suggested.

## Introduction

Since the isolation and characterization of the first transition metal–fullerene complex $[(\eta^2\text{-}C_{60})Pt(PPh_3)_2]$,[1] a large number of such complexes with unique structures and novel properties have been prepared and structurally characterized.[2–6] Previously, we have reported several series of transition metal–fullerene complexes that contain various phosphane ligands, such as $Ph_2PCH_2CH_2PPh_2$ (dppe),[7] 1,2-$(Ph_2P)_2C_6H_4$ (dppb),[8] DIOP,[9] $Ph_2PCH_2(CH_2OCH_2)_n\text{-}CH_2PPh_2$,[10] $[(\eta^5\text{-}Ph_2PC_5H_4)_2Fe]$ (dppf),[11] and $[(\eta^5\text{-}Ph_2PC_5H_4)_2Ru]$ (dppr).[12] Now, as a continuation of this research program, we report other types of transition metal–fullerene complexes that contain either the diphosphane ligand *trans*-1,1′-bis(diphenylphosphanyl)ethylene (dppet) or the tetraphosphane ligand *N*,*N*,*N*′,*N*′-tetra(diphenylphosphanylmethyl)ethylene diamine (dppeda). It should be noted that although some of the dppet-containing complexes were preliminarily reported in our recent communication,[13] this paper systematically describes both the dppet- and dppeda-containing fullerene complexes and includes new results, such as the crystal structure of $[(\eta^2\text{-}C_{60}Pd)(\eta^2\text{-}C_{60}Pt)(dppet)_2]$, the electrochemical properties of $[(\eta^2\text{-}C_{60}Pd)(dppet)]_2$ and $[(\eta^2\text{-}C_{60}Pd)(\eta^2\text{-}C_{60}Pt)(dppet)_2]$, as well as the synthesis and characterization of the dppet-containing [70]fullerene complexes $[(\eta^2\text{-}C_{60}Pd)(\eta^2\text{-}C_{70}Pd)(dppet)_2]$ and $[(\eta^2\text{-}C_{70}Pd)(dppet)]_2$ along with the dppeda-containing [60]fullerene complexes $[(\eta^2\text{-}C_{60}M)(dppeda)]$ and $[(\eta^2\text{-}C_{60}M)_2(dppeda)]$ (M = Pt, Pd).

## Results and Discussion

### Synthesis and Characterization of Dppet-Containing Fullerene Complexes

A toluene solution of $C_{60}$ was treated with $[M(dba)_2]$ or $[Pt_2(dba)_3]$ (M = Pt, Pd; dba = dibenzylideneacetone) and dppet in a 1:1:2 molar ratio at room temperature to give the metallacyclopropa[60]fullerene complex $[(\eta^2\text{-}C_{60}Pt)(dppet)_2]$ (**1**) in 35–58% yield and complex $[(\eta^2\text{-}C_{60}Pd)(dppet)_2]$ (**2**) in 75% yield. The two different starting materials $[Pt(dba)_2]$ and $[Pt_2(dba)_3]$ can be used interchangeably, although $[Pt_2(dba)_3]$ is much more reactive than $[Pt(dba)_2]$, as judged by the rapidity of the development of the green color characteristic of product **1**, and when used in a slight excess this starting material gives the highest yield. Similarly, a toluene solution of $C_{60}$ was treated with $[Pt(dba)_2]$ and dppet in a 1:1:2 ratio or with $[Pd(dba)_2]$ and dppet in a 1:2:1 molar ratio at room temperature to give the homodinuclear bismetallacyclopropa[60]fullerene complexes $[(\eta^2\text{-}C_{60}M)(dppet)]_2$ (M = Pt **3**, Pd **4**) in 82% and 92% yields, respectively (Scheme 1).

We further found that treatment of a toluene solution of $C_{60}$ with $[Pd(dba)_2]$ and dppet in a 1:1:2 molar ratio at room temperature, followed by treatment with a mixture of $C_{60}$ and $[Pt_2(dba)_3]$ in a 2:1 molar ratio or $C_{70}$ and [Pd-

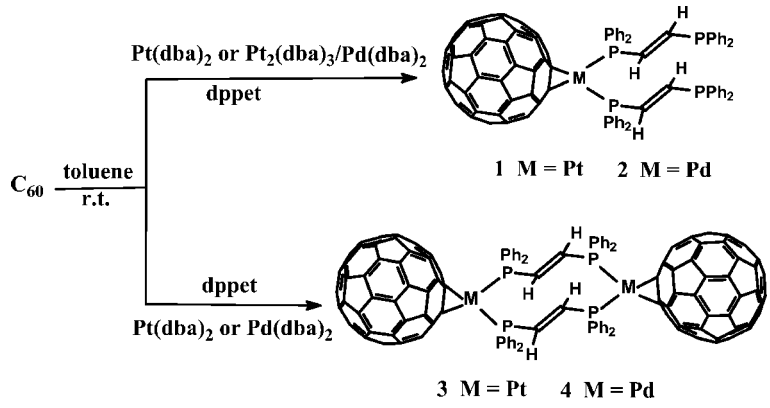
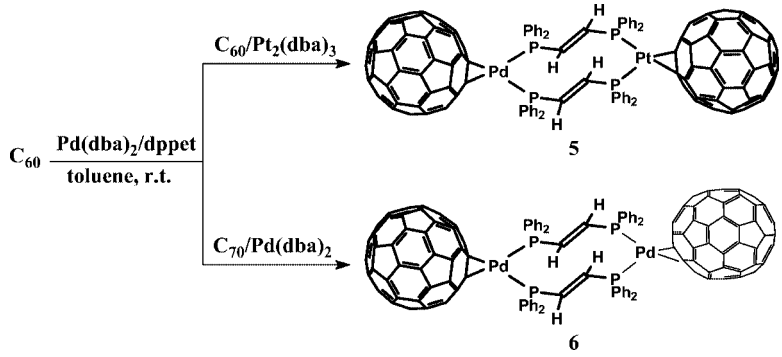


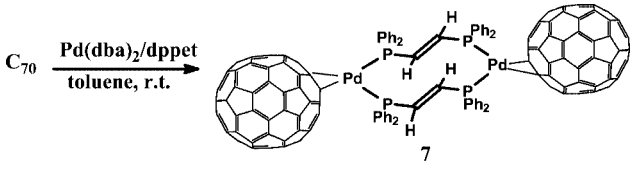
Scheme 1.



Scheme 2.

$(dba)_2$] in a 1:1 molar ratio, gave the heterodinuclear bismetallacyclopropa[60]fullerene complex [($\eta^2$-$C_{60}$Pd)($\eta^2$-$C_{60}$Pt)(dppet)$_2$] (**5**) and the homodinuclear bismetallacyclopropa[60]/[70]fullerene complex [($\eta^2$-$C_{60}$Pd)($\eta^2$-$C_{70}$Pd)(dppet)$_2$] (**6**) in 65% and 37% yields, respectively (Scheme 2).

Similarly, the homodinuclear bismetallacyclopropa[70]fullerene complex [($\eta^2$-$C_{70}$Pd)(dppet)]$_2$ (**7**) could be prepared by treatment of $C_{70}$ in toluene with [Pd(dba)$_2$] and dppet in a 1:1:2 molar ratio at room temperature in 44% yield (Scheme 3).



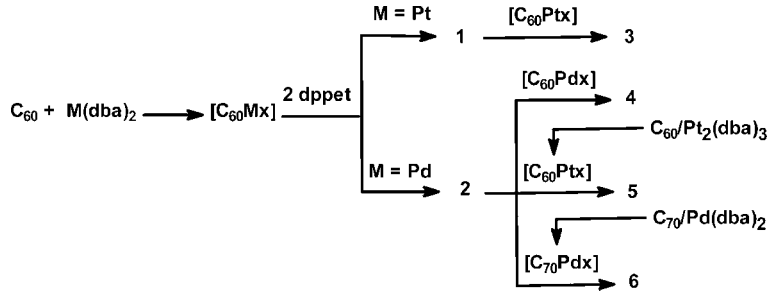
Scheme 3.

Interestingly, the above-mentioned dinuclear bisfullerene complexes **3**–**6** can be also prepared by another method in which the [60]fullerene-derived diphosphanes **1** and **2** were used as starting materials. Thus, treatment of **1** in toluene with $C_{60}$ and [Pt(dba)$_2$] in a 1:1:1 molar ratio at room temperature gave **3** in 59% yield, whereas treatment of **2** with $C_{60}$ and [Pd(dba)$_2$] under similar conditions gave **4** in 53% yield. In addition, while **2** reacts with $C_{60}$ and [Pt(dba)$_2$] in toluene at room temperature to produce the heterodinuclear bisfullerene **5** in 55% yield, the reaction of **2** with $C_{70}$ and [Pd(dba)$_2$] under similar conditions gives rise to the homodinuclear bisfullerene complex **6** in 38% yield.

It follows that the possible pathways for the formation of **1**–**7** might be as suggested in Scheme 4. That is: (i) **1** and **2** are produced by $\eta^1$-coordination of two molecules of dppet with the polymeric species [$C_{60}M_x$] (M = Pt, Pd; $x$ = 1) formed in situ from $C_{60}$ and [Pd(dba)$_2$], [Pt(dba)$_2$], or [$Pt_2$(dba)$_3$],[14,15] (ii) subsequent chelation of **1** as a bidentate ligand with [$C_{60}Pt_x$] gives **3**, (iii) subsequent chelation of **2** with [$C_{60}M_x$] affords **4** and **5**, and (iv) subsequent chelation of **2** with the polymeric species [$C_{70}Pd_x$] formed in situ from $C_{70}$ and [Pd(dba)$_2$][14,15] produces **6**. Apparently, **7** can be formed through similar elementary steps to those indicated in Scheme 4.

The dppet-containing fullerene complexes **1**–**7** were characterized by elemental analysis and spectroscopic methods. For example, the IR spectra of **1**–**5** display four absorption bands in the range 1434–513 cm$^{-1}$ for their $C_{60}$ cores,[16] whereas the IR spectrum of **6** exhibits nine absorption bands in the region 1433–456 cm$^{-1}$ for its $C_{60}$ and $C_{70}$ spheres,[16] and that of **7** shows nine absorption bands in the range 1432–457 cm$^{-1}$[16] for its $C_{70}$ cores. In addition, the $^{31}$P NMR spectra of **1** and **2** show one singlet and one triplet or two singlets at $\delta \approx -7$ and 20 ppm for their two identical uncoordinated P atoms and two identical coordinated P atoms, respectively, whereas the spectra of **3**–**7** display the corresponding signals for their four coordinated P atoms. That the chemical shifts of the coordinated P atoms

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4.

lie at much lower field relative to the corresponding free P atoms can be ascribed to transfer of electron density from the P atom to the metal center, which is consistent with other phosphane-coordinated fullerene complexes.[1,9,12] It is well-known that in single addition of a transition metal to fullerenes the $C_{60}$ ligand is bonded to the metal center in an $\eta^2$-fashion through its single C–C 6:6 bond, whereas the $C_{70}$ ligand is preferentially bonded to a metal center in an $\eta^2$-manner through one Ca–Cb 6:6 bond at the poles of the $C_{70}$ ligand.[3] Therefore, the structures of **1**–**7** are most likely as shown in Schemes 1, 2, and 3. The structures of **4** and **5** were unequivocally confirmed by X-ray crystal diffraction analysis.

### Crystal Structures of 4 and 5

The molecular structures of **4** and **5**, as determined by X-ray diffraction techniques, are presented in Figures 1 and 2, respectively; selected bond lengths and angles are given in Tables 1 and 2, respectively. The X-ray diffraction analysis

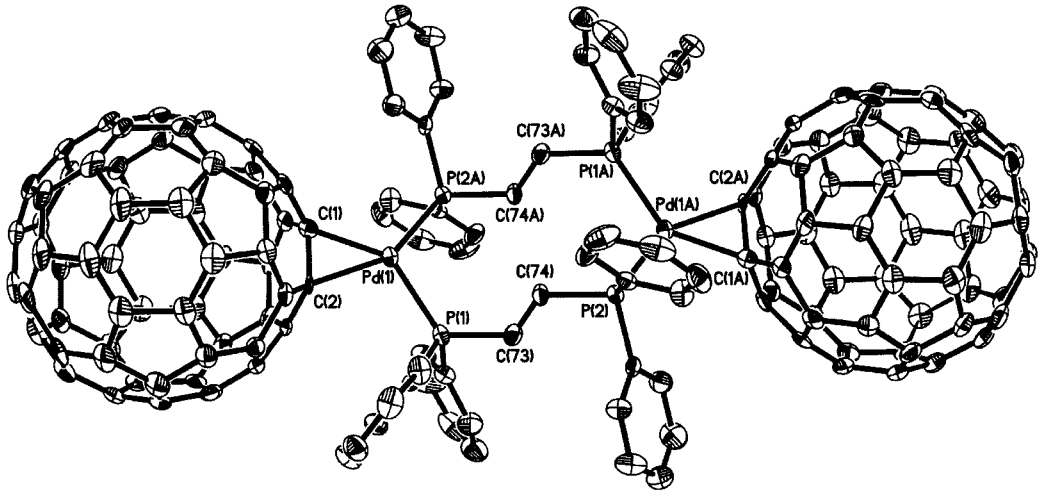


Figure 1. ORTEP drawing of **4** (30% thermal ellipsoids).

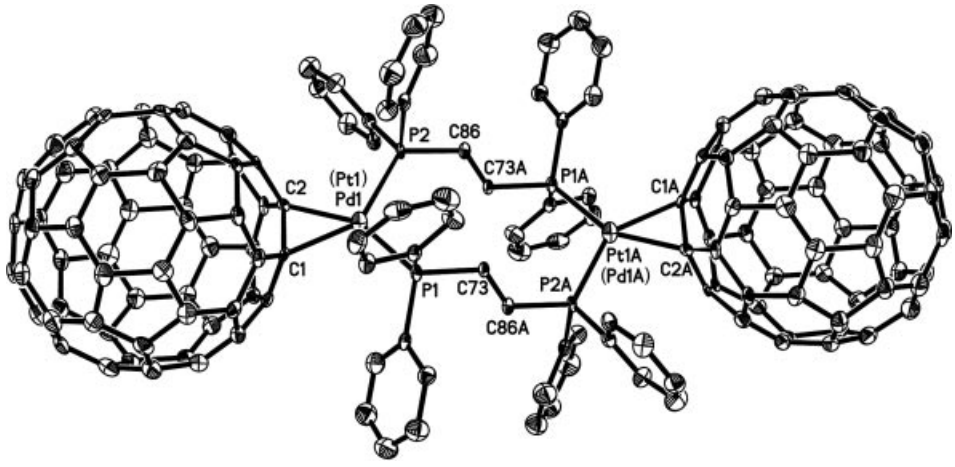

Figure 2. ORTEP drawing of **5** (30% thermal ellipsoids).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

revealed that **4** (Figure 1) and **5** (Figure 2) are isostructural; they both consist of two $C_{60}$ spheres that are ligated to two metal centers of a ten-membered metallacycle in which two *trans*-dppet ligands are coordinated to Pd/Pd or Pd/Pt metal centers, respectively. It is worth pointing out that the Pd/Pt atoms in the structure of **5** are 50% disordered and therefore the geometric parameters associated with Pd/Pt atoms cannot be distinguished. In addition, the solvent molecules $C_6H_5Cl$ and $C_6H_5Me$ present in the crystal of **5** are also disordered, which might be responsible for the relatively high *R* value for the structure of **5**. Interestingly, **4** and **5** are the first structurally characterized group 10 metal-containing homo- and heterodinuclear fullerene complexes. The fullerene center-to-center separations of 16.869 Å for **4** and 16.807 Å for **5** are close to that of 16.559 Å in the dinuclear $Ir_2$ complex. However, the nonbonded metal-to-metal distances (6.83 Å for **4** and 6.82 Å for **5**) are much shorter than the corresponding intermetallic distance of 8.104 Å in the $Ir_2$ complex.[17] The two C–C double bonds [C(73)–C(74) = C(73A)–C(74A) = 1.290(14) Å for **4** and C(73)–C(86A) = C(73A)–C(86) = 1.26(2) Å for **5**] are slightly shorter than the common C–C double bond (1.34 Å). Each of the zero-valent metal centers has a square-planar geometry. For example, all the five atoms Pd(1), C(1), C(2), P(1), and P(2A) in **4** and Pt(1A), C(1A), C(2A), P(1A), and P(2A) in **5** are nearly coplanar, with a mean deviation of 0.0528 and 0.0483 Å, respectively. The $\eta^2$-coordinated 6:6 bonds [C(1)–C(2) = 1.473(14) Å for **4** and C(1)–C(2) = 1.50 (2) Å for **5**] are obviously longer than the other 58 uncoordinated 6:6 bonds in each $C_{60}$ sphere due to the metal-to-$C_{60}$ π back-donation.[5]

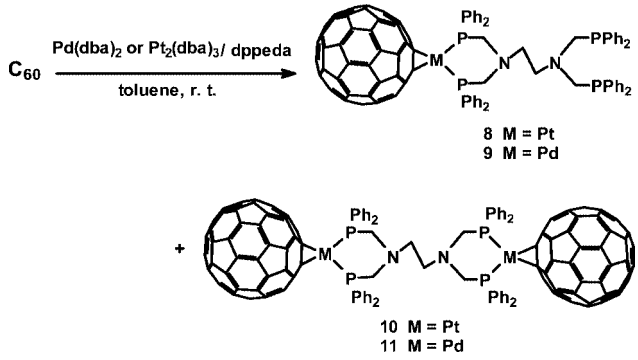
## Synthesis and Characterization of Dppeda-Containing Fullerene Complexes

More interestingly, the first examples of a tetraphosphane ligand-containing metallacyclopropafullerene complexes [($\eta^2$-$C_{60}$M)(dppeda)] (M = Pt **8**, Pd **9**) and bismetallacyclopropafullerene complexes [($\eta^2$-$C_{60}$M)$_2$(dppeda)] (M = Pt **10**, Pd **11**) were synthesized by treatment of a toluene solution of $C_{60}$ with [$Pt_2(dba)_3$] and the tetraphosphane ligand dppeda or with [$Pd(dba)_2$] and dppeda in 1:1:1 molar ratio at room temperature in ca. 26% and 45% yields, respectively (Scheme 5).



Scheme 5.

It is apparent that complexes **8**–**11** are produced through similar pathways to those mentioned above for the production of **1**–**7**. Complexes **8**–**11** are air-stable, green solids, which were characterized by elemental analysis and IR, $^1$H NMR, and $^{31}$P NMR spectroscopy. For example, the IR spectra of **8**–**11** show four absorption bands in the range 1434–526 cm$^{-1}$ characteristic of their $C_{60}$ spheres.[16] In addition, the $^{31}$P NMR spectra of **8** and **9** display one singlet and one triplet or two singlets at $\delta \approx -28$ and 6 ppm for their two identical uncoordinated P atoms and two identical coordinated P atoms, respectively, whereas the spectra of **10** and **11** exhibit one triplet and one singlet at $\delta \approx 6$ ppm for their four identical coordinated P atoms. In fact, the $^{31}$P NMR behavior of the tetraphosphane-containing complexes **8**–**11** is very similar to that of the diphosphane-containing complexes **1**–**7**, as well as that of the other phosphane-containing fullerene complexes.[1,9,12] Interestingly, while the $^1$H NMR spectrum of the free ligand dppeda shows one singlet at $\delta = 3.50$ ppm for its four $CH_2$ groups attached to P atoms and one singlet at $\delta = 2.88$ ppm for its two $CH_2$ groups attached to N atoms, the spectra of **8**–**11** display two broad singlets or multiplets at $\delta = 3.75$–3.35 ppm for their $CH_2$ groups attached to P atoms and one multiplet at $\delta = 2.45$–2.28 ppm for their $CH_2$ groups bound to N atoms.

## Electrochemical Study of 4 and 5

In order to ascertain if the presence of the p-π conjugated P–C=C–P structural units in the dppet ligands of the dinuclear bisfullerenes **3**–**7** could trigger inter-fullerene electronic communication, we examined the electrochemical behavior of the representative complexes **4** and **5**. Figure 3 shows the cyclic voltammetric profiles exhibited by complexes **4** and **5** in 1,2-dichlorobenzene solution.[18]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

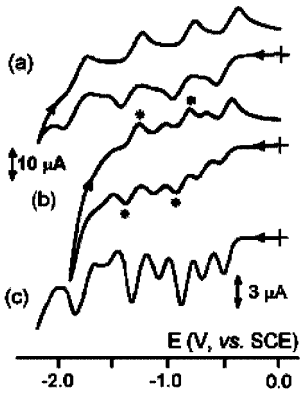


Figure 3. Cyclic voltammograms recorded at a platinum electrode in 1,2-$Cl_2C_6H_4$ solutions of (a) complex **4** ($1.1 \times 10^{-3}$ M) and (b) complex **5** ($1.1 \times 10^{-3}$ M). (c) Osteryoung square-wave voltammogram of **5** ($1.1 \times 10^{-3}$ M). $n$-$Bu_4NClO_4$ (0.2 M) supporting electrolyte. Scan rates: (a, b) 0.2 V $s^{-1}$; (c) 0.1 V $s^{-1}$.

As Figure 3a illustrates, the homodinuclear complex **4** exhibits four fullerene-centered reductions possessing features of chemical reversibility on the cyclic voltammetric timescale ($E°'$ = –0.48, –0.87, –1.34, and –1.85 V, vs. SCE). Controlled potential coulometry ($E_w$ = –0.65 V) proved that the first cathodic process involves two electrons per molecule, thus indicating that the stepwise addition of four electrons to each fullerene moiety proceeds simultaneously. As happens for most bisfullerene systems,[19] this suggests that no mutual electronic interaction exists between the two metallofullerene subunits. It should be noted that the mentioned processes take place at potential values essentially coincident with those of free fullerene. Cyclic voltammetry in chlorobenzene solution affords a quite similar profile ($E°'$ = –0.52, –0.93, and –1.46 V vs. SCE), but in such a solvent the difference with respect to free fullerene is better defined ($E°'$ = –0.49, –0.86, and –1.35 V, vs. SCE). Therefore, since the instantaneous complete decomposition of the original complex can be reasonably ruled out − the original green color of the solution ($\lambda_{max}$ = 602 and 656 nm) does not change with time − such an uncommon result can be likely accounted for by assuming that the cathodic shift induced by the $\eta^2$-coordinated C–C double bond of the [60]-fullerene, which is directly linked to the coordinating power of the metal ion, is just compensated by the anodic shift caused by the electron-withdrawing effects of the phosphane substituents.[19]

As Figure 3 (b) shows, a different reduction pattern is displayed by the heterodinuclear complex **5**. In fact, the sequential reductions appearing in correspondence of the preceding profile ($E°'$ = –0.49, –0.88, and –1.33 V, respectively) are followed by an interposed series of further cathodic steps ($E°'$ = –0.71, –1.08, and –1.6 V, respectively). Coulometric measurements showed that the first two processes involve one-electron additions (exhaustive electrolysis at $E_w$ = –0.75 V consumed 1.8 electrons per molecule). The fact that the height of the starred peak-systems is somewhat higher than that of the respective interposed peak-systems (as better seen from the square-wave voltammogram shown in Figure 3c) has to be attributed to slow release of free fullerene (two mols per mol of decomposed complex) following the concomitant addition of the first electron to each metallofullerene subunit, which is reflected in the high peak-height of the return peak associated with the first step. It seems that the appearance of separate sequential reductions in **5** has to be attributed to the higher coordination ability of Pt with respect to Pd towards fullerene, which renders the two metallofullerene subunits inequivalent, rather than the eventual presence of intramolecular electronic communication, as, in contrast, happens in [$Rh_6$-$(CO)_5$(dppm)(CNR)($\mu_3$-$\eta^2$,$\eta^2$,$\eta^2$-$C_{60}$)$_2$] (dppm = diphenylphosphanylmethane; R = $CH_2C_6H_5$).[20]

It follows that complexes **4** and **5** display no intramolecular electronic communication even though two p-π-conjugated P–C=C–P structural units are present in the sandwiched metallacycle. However, it can be expected that bismetallofullerenes having electronic communication could be obtained by variation of the spacer between the two metallofullerene subunits.

In summary, we have prepared the first diphosphane (dppet)- and tetraphosphane (dppeda)-containing transition metal–fullerene complexes **1**–**11** by simple and convenient synthetic methods in satisfactory yields. While complexes **1**, **2**, **8**, and **9** are diphosphane ligands with fullerene cores, complexes **3**–**7**, **10**, and **11** are bisfullerene complexes in which either a 10-membered metallacycle or two six-membered metallacycles are sandwiched between two fullerene spheres. Possible pathways for production of complexes **1**–**11** have been preliminarily proposed, and the crystal structures of **4** and **5** along with their electrochemical properties have been determined by X-ray diffraction and cyclic voltammetry. It is worth pointing out that in view of the widespread uses of phosphorus-donor ligands in transition metal chemistry,[21] the fullerene-containing diphosphane ligands **1**, **2**, **8**, and **9** can be expected to play an important role in the development of transition metal and fullerene chemistry.

## Experimental Section

**General:** All reactions were carried out under highly purified nitrogen using standard Schlenk or vacuum-line techniques. Toluene and hexane were distilled from Na/benzophenone ketyl. Other solvents were bubbled with nitrogen for at least 15 min before use. [$Pd(dba)_2$],[22] [$Pt(dba)_2$],[23] [$Pt_2(dba)_3$],[23] and [$(Ph_2PCH_2)_2NCH_2]_2$ (dppeda)[24] were prepared according to literature methods. $C_{60}$ (99.9%) and *trans*-$Ph_2PCH$=$CHPPh_2$ (dppet) were available commercially. $^1H$ and $^{31}P$ NMR spectra were recorded with a Bruker Avance 300 spectrometer, whereas IR spectra were taken on a Bio-Rad FTS 135 spectrophotometer. Elemental analysis was performed with an Elementar Vario EL analyzer. Melting points were determined on a Yanaco MP-500 apparatus.

**Preparation of [($\eta^2$-$C_{60}$Pt)(dppet)$_2$] (1):** A 100-mL, three-necked flask equipped with a magnetic stir-bar, a rubber septum, and a nitrogen inlet tube was charged with $C_{60}$ (0.072 g, 0.10 mmol), [$Pt(dba)_2$] (0.066 g, 0.10 mmol) or [$Pt_2(dba)_3$] (0.056 g, 0.10 mmol), and toluene (50 mL) to form a brown solution. *trans*-Dppet (0.078 g, 0.20 mmol) was added to this solution and then the mix-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ture was stirred at room temperature for 1.5 h. The resulting green mixture was filtered and the green filtrate was layered with 60 mL of hexane overnight to give a green precipitate. The precipitate was washed with hexane (2 × 5 mL) and diethyl ether (2 × 5 mL) sequentially, and then was dried in vacuo to afford 0.060 g (35%) of **1** from [Pt(dba)$_2$] or 0.098 g (58%) of **1** from [Pt$_2$(dba)$_3$] as a green solid. M.p. > 300 °C. $^1$H NMR (300 MHz, CS$_2$/CDCl$_3$): $\delta$ = 7.24–7.60 (m, 44 H, 8 C$_6$H$_5$ + 4 CH) ppm. $^{31}$P NMR (121.48 MHz, CS$_2$/CDCl$_3$, H$_3$PO$_4$): $\delta$ = –7.24 (s, 2 P, 2 PPh$_2$), 19.88 (t, $J_{Pt,P}$ = 3682 Hz, 2 P, 2 PPt) ppm. IR (KBr disk): $\tilde{\nu}$ = 1434 (s), 1184 (m), 577 (m), 524 (vs) (C$_{60}$), 1571 (m), 967 (m) (C=C) cm$^{-1}$. $C_{112}H_{44}P_4Pt$ (1708.6): calcd. C 78.73, H 2.60; found C 78.75, H 2.41.

**Preparation of [($\eta^2$-C$_{60}$Pd)(dppet)$_2$] (2):** The same procedure as that for the preparation of **1** was followed, but [Pd(dba)$_2$] (0.057 g, 0.10 mmol) was used instead of [Pt(dba)$_2$] or [Pt$_2$(dba)$_3$] to give 0.123 g (75%) of **2** as a green solid. M.p. > 300 °C. $^1$H NMR (300 MHz, CS$_2$/CDCl$_3$): $\delta$ = 7.09–7.63 (m, 44 H, 8 C$_6$H$_5$ + 4 CH) ppm. $^{31}$P NMR (121.48 MHz, CS$_2$/CDCl$_3$, H$_3$PO$_4$): $\delta$ = –7.48 (s, 2 P, 2 PPh$_2$), 20.21 (s, 2 P, 2 PPd) ppm. IR (KBr disk): $\tilde{\nu}$ = 1434 (s), 1183 (m), 578 (m), 513 (vs) (C$_{60}$), 1570 (m), 966 (m) (C=C) cm$^{-1}$. $C_{112}H_{44}P_4Pd$ (1619.9): calcd. C 83.04, H 2.74; found C 82.87, H 2.75.

**Preparation of [($\eta^2$-C$_{60}$Pt)(dppet)]$_2$ (3). Method (i):** The flask described above was charged with C$_{60}$ (0.072 g, 0.10 mmol), [Pt(dba)$_2$] (0.066 g, 0.10 mmol), *trans*-dppet (0.078 g, 0.20 mmol), and toluene (50 mL). The mixture was stirred at room temperature for 5 h to give a green precipitate. The precipitate was washed with toluene (2 × 10 mL), hexane (2 × 10 mL), and diethyl ether (2 × 10 mL), and finally dried in vacuo to afford 0.108 g (82%) of **3** as a dark-green solid. M.p. > 300 °C. $^1$H NMR (300 MHz, CS$_2$/CDCl$_3$): $\delta$ = 6.90–7.60 (m, 44 H, 8 C$_6$H$_5$ + 4 CH) ppm. $^{31}$P NMR (121.48 MHz, CS$_2$/CDCl$_3$, H$_3$PO$_4$): $\delta$ = 19.71 (t, $J_{Pt,P}$ = 3794 Hz, 4 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 1434 (s), 1183 (m), 577 (m), 524 (vs) (C$_{60}$), 1571 (m), 969 (m) (C=C) cm$^{-1}$. $C_{172}H_{44}P_4Pt_2$ (2624.3): calcd. C 78.72, H 1.69; found C 78.71, H 1.70.

**Method (ii):** A mixture of diphosphane **1** (0.086 g, 0.05 mmol), C$_{60}$ (0.036 g, 0.05 mmol), and [Pt(dba)$_2$] (0.034 g, 0.05 mmol) in toluene (20 mL) was stirred at room temperature for 5 h to give a precipitate. The same workup as that in method (i) gave 0.078 g (59%) of **3**.

**Preparation of [($\eta^2$-C$_{60}$Pd)(dppet)]$_2$ (4). Method (i):** The flask described above was charged with C$_{60}$ (0.072 g, 0.10 mmol), [Pd(dba)$_2$] (0.114 g, 0.20 mmol), *trans*-dppet (0.039 g, 0.10 mmol), and toluene (50 mL). The mixture was stirred at room temperature for 5 h. The resulting mixture was filtered to give a green precipitate, which was purified by the same method used above for **3** to afford 0.112 g (92%) of **4** as a dark-green solid. M.p. > 300 °C. $^1$H NMR (300 MHz, CS$_2$/CDCl$_3$): $\delta$ = 7.20–7.66 (m, 44 H, 8 C$_6$H$_5$ + 4 CH) ppm. $^{31}$P NMR (121.48 MHz, CS$_2$/CDCl$_3$, H$_3$PO$_4$): $\delta$ = 20.22 (s, 4 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 1432 (m), 1183 (m), 577 (m), 524 (vs) (C$_{60}$), 1571 (m), 964 (m) (C=C) cm$^{-1}$. $C_{172}H_{44}P_4Pd_2$ (2447.0): calcd. C 84.43, H 1.81; found C 84.16, H 2.00.

**Method (ii):** A mixture of diphosphane **2** (0.080 g, 0.05 mmol), C$_{60}$ (0.036 g, 0.05 mmol), and [Pd(dba)$_2$] (0.029 g, 0.05 mmol) in toluene (20 mL) was stirred at room temperature for 5 h to give a precipitate. The same workup as that in method (i) produced 0.064 g (53%) of **4**.

**Preparation of [($\eta^2$-C$_{60}$Pd)($\eta^2$-C$_{60}$Pt)(dppet)$_2$] (5). Method (i):** A mixture of C$_{60}$ (0.036 g, 0.05 mmol), [Pd(dba)$_2$] (0.029 g, 0.05 mmol), *trans*-dppet (0.039 g, 0.10 mmol), and toluene (25 mL) was stirred at room temperature for 1 h to give a green solution. C$_{60}$ (0.036 g, 0.05 mmol) and [Pt$_2$(dba)$_3$] (0.028 g, 0.025 mmol) were added to this solution. The new mixture was stirred at room temperature for 5 h to give a green precipitate. The precipitate was purified by the same method used for **3** to give 0.085 g (65%) of **5** as a green solid. M.p. > 300 °C. $^1$H NMR (300 MHz, CS$_2$/CDCl$_3$): $\delta$ = 7.08–7.60 (m, 44 H, 8 C$_6$H$_5$ + 4 CH) ppm. $^{31}$P NMR (121.48 MHz, CS$_2$/CDCl$_3$, H$_3$PO$_4$): $\delta$ = 19.79 (s, 2 P, 2 PPd), 20.12 (t, $J_{Pt,P}$ = 3848 Hz, 2 P, 2 PPt) ppm. IR (KBr disk): $\tilde{\nu}$ = 1434 (s), 1183 (m), 579 (m), 523 (vs) (C$_{60}$), 1571 (m), 967 (m) (C=C) cm$^{-1}$. $C_{172}H_{44}P_4PdPt$ (2535.6): calcd. C 81.47, H 1.75; found C 81.40, H 2.00.

**Method (ii):** A mixture of diphosphane **2** (0.080 g, 0.05 mmol), C$_{60}$ (0.036 g, 0.05 mmol), and [Pt(dba)$_2$] (0.034 g, 0.05 mmol) in toluene (20 mL) was stirred at room temperature for 5 h to give a precipitate. The same workup as that in method (i) afforded 0.070 g (55%) of **5**.

**Preparation of [($\eta^2$-C$_{60}$Pd)($\eta^2$-C$_{70}$Pd)(dppet)$_2$] (6). Method (i):** A mixture of C$_{60}$ (0.036 g, 0.05 mmol), [Pd(dba)$_2$] (0.029 g, 0.05 mmol), and *trans*-dppet (0.039 g, 0.10 mmol) in toluene (25 mL) was stirred at room temperature for 1 h to give a green solution. C$_{70}$ (0.042 g, 0.05 mmol) and [Pd(dba)$_2$] (0.029 g, 0.05 mmol) were then added to this solution. The new mixture was stirred at room temperature for 5 h to give a green precipitate. The precipitate was purified by the same method as that utilized for **3** to give 0.048 g (37%) of **6** as a brown solid. M.p. > 300 °C. $^1$H NMR (300 MHz, CS$_2$/CDCl$_3$): $\delta$ = 7.09–7.54 (m, 44 H, 8 C$_6$H$_5$ + 4 CH) ppm. $^{31}$P NMR (121.48 MHz, CS$_2$/CDCl$_3$, H$_3$PO$_4$): $\delta$ = 25.64–27.50 (m, 4 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 1433 (s), 1183 (m), 576 (m), 510 (vs) (C$_{60}$), 1130 (w), 1097 (m), 793 (m), 673 (m), 640 (w), 456 (s) (C$_{70}$), 1569 (w), 967 (m) (C=C) cm$^{-1}$. $C_{182}H_{44}P_4Pd_2$ (2567.09): calcd. C 85.15, H 1.72; found C 84.95, H 1.88.

**Method (ii):** A mixture of diphosphane **2** (0.080 g, 0.05 mmol), C$_{70}$ (0.042 g, 0.05 mmol), and [Pd(dba)$_2$] (0.029 g, 0.05 mmol) in toluene (20 mL) was stirred at room temperature for 5 h. The same workup as that in method (i) afforded 0.049 g (38%) of **6**.

**Preparation of [($\eta^2$-C$_{70}$Pd)(dppet)]$_2$ (7):** A mixture of C$_{70}$ (0.042 g, 0.05 mmol), [Pd(dba)$_2$] (0.029 g, 0.05 mmol), and *trans*-dppet (0.039 g, 0.10 mmol) in toluene (25 mL) was stirred at room temperature for 1.5 h. The resulting mixture was filtered to give a brown precipitate, which was purified by the method used for purification of **3** to afford 0.023 g (44%) of **7** as a dark-green solid. M.p. > 300 °C. $^1$H NMR (300 MHz, CS$_2$/CDCl$_3$): $\delta$ = 7.15–7.67 (m, 44 H, 8 C$_6$H$_5$ + 4 CH) ppm. $^{31}$P NMR (121.48 MHz, CS$_2$/CDCl$_3$, H$_3$PO$_4$): $\delta$ = 21.15, 22.77 (2s, 4 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 1432 (vs), 1129 (w), 1097 (m), 794 (m), 673 (s), 641 (w), 577 (m), 534 (s), 457 (s) (C$_{70}$), 1567 (m), 967 (m) (C=C) cm$^{-1}$. $C_{192}H_{44}P_4Pd_2$ (2687.2): calcd. C 85.82, H 1.65; found C 85.60, H 1.73.

**Preparation of [($\eta^2$-C$_{60}$Pt)(dppeda)] (8) and [($\eta^2$-C$_{60}$Pt)$_2$(dppeda)] (10):** A brown mixture of C$_{60}$ (0.036 g, 0.05 mmol) and [Pt$_2$(dba)$_3$] (0.028 g, 0.05 mmol) in toluene (25 mL) was stirred at room temperature for 15 min, and then dppeda (0.043 g, 0.05 mmol) was added to cause an immediate color change from brown to green. The green mixture was stirred at room temperature for 5 h and was then filtered to give a green filtrate and a green precipitate. Whereas the green filtrate was treated by a procedure similar to that used in the preparation of **1** to afford 0.025 g (28%) of **8**, the precipitate was purified by the method used for purification of **3** to afford 0.033 g (49%) of **10**.

**8:** Green solid. M.p. 300 °C (dec.). $^1$H NMR (300 MHz, CS$_2$/CDCl$_3$): $\delta$ = 2.37–2.45 (m, 4 H, NCH$_2$CH$_2$N), 3.35–3.47, 3.70–3.75 (2m, 8 H, 4 CH$_2$P), 7.27–7.74 (m, 40 H, 8 C$_6$H$_5$) ppm. $^{31}$P NMR

**X-ray Crystal Structure Determinations of 4 and 5:** Single-crystals of **4** and **5** suitable for X-ray diffraction analyses were obtained by slow diffusion of hexane into their $C_6H_5Cl/CS_2$ solutions at room temperature. A single crystal of **4** or **5** was glued to a glass fiber and mounted on a Bruker SMART 1000 automated diffractometer. Data were collected using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature in the $\omega$–$2\theta$ scanning mode. Absorption corrections were performed using the SADABS method. The structures were solved by direct methods using the SHELXS-97 program[25] and refined by full-matrix least-squares techniques (SHELXL-97)[26] on $F^2$. Hydrogen atoms were located by a geometric method. All calculations were performed on a Bruker Smart computer. Details of the crystals, data collections, and structure refinements are summarized in Table 3. The calculations were performed using the TEXSAN crystallographic software package.[27]

CCDC-232273 (for **4**) and -232274 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and the Effect of a Peripheral *N*-Arylcarbazole Moiety on the Acid-Base and DNA Binding Properties of a Novel $Ru^{II}$ Complex

**Yuan-Yuan Lü,[a] Li-Hua Gao,[a,b] Mei-Jiao Han,[a] and Ke-Zhi Wang*[a]**

**Keywords:** Ruthenium / N ligands / DNA / Sensors / Luminescence / UV/Vis spectroscopy

A novel $Ru^{II}$ complex of $[Ru(bpy)_2(cpipH)](ClO_4)_2$ (where bpy = 2,2′-bipyridine, cpipH = 2-[4-(9*H*-carbazol-9-yl)phenyl]-1*H*-imidazol[4,5-*f*][1,10]phenanthroline) was synthesized. The binding of the complex to calf thymus DNA was investigated with UV/Vis absorption and luminescence titrations, steady-state emission quenching by $[Fe(CN)_6]^{4-}$, DNA competitive binding with ethidium bromide, and thermal denaturation. The pH effects on the UV/Vis absorption and emission spectra of the complex were also studied, and the ground- and excited-state ionization constants were derived. The results indicated that the complex intercalatively bound to the DNA, with an intrinsic binding constant of $(8.2 \pm 0.8) \times 10^5\ M^{-1}$ in buffered 50 mM NaCl, is stronger than the parent complex, $[Ru(bpy)_2(pip)]^{2+}$ (pip = 2-phenylimidazo[4,5-*f*][1,10]phenanthroline), and its excited states are 0.7–0.8 p$K_a$ units more basic than those of the ground states.

## Introduction

Over the past two decades ruthenium(II) polypyridyl complexes have attracted much attention with regard to DNA interaction studies because of their potential applications as nonradioactive structural probes of nucleic acids, in DNA cleaving, and as chemotherapeutic agents.[1,2] The results have shown that the subtle changes in the molecular structures of $Ru^{II}$ complexes might bring about substantial effects on binding modes, sites, and affinities, and provide a chance to explore valuable information on conformation- or site-specific DNA probes. The various factors of ligand planarity, the charge carried on the complex, enantioselectivity, the formation of intramolecular hydrogen bonding, and the hydrophobicity of ancillary ligands, etc., have been effectively explored, but the new $Ru^{II}$ complexes are still needed to establish the DNA binding property-structure relationships.[1,2] On the other hand, the $Ru^{II}$ complexes that append protonatable/deprotonatable groups, e.g. hydroxy, carboxyl and amino groups may respond sensitively to the changes in environmental pH, providing a chance to make pH sensing or switching molecular devices,[3] and to greatly modulate their biological functionalities.[4] The ruthenium(II) complexes containing imidazole groups have been well studied with respect to their interaction with DNA[5–8] or reversible acid-base interconversion.[6a,9–12] However, studies of the $Ru^{II}$ complexes with both the DNA-binding and acid-base interconversion properties remain relatively scarce. We have been interested in the syntheses and studies of the acid-base and DNA binding properties of both mononuclear and dinuclear imidazole-containing $Ru^{II}$ complexes.[6,13]
