The energy of the broad band assigned to d-d transitions can provide a rough estimate of the equatorial ligand-field strength, since one of the electronic transitions comprised in the band envelope is $d_{xy} \leftarrow d_{x^2-y^2}$ and the energy associated with this transition is $10Dq$-$C$.[7,20] No comparison is possible between energies for d-d transitions for the Ni complexes with aliphatic imine bridges (complexes **5** and **6**) to those with aromatic imine bridges (complexes **1** to **4**), as they are not observed in the latter complexes. However, for those with aliphatic bridges (Ni and Cu complexes) it can be inferred that an increase in the number of bridging carbon atoms is associated with a small decrease in ligand field, as can be gathered from the lower energies of d-d

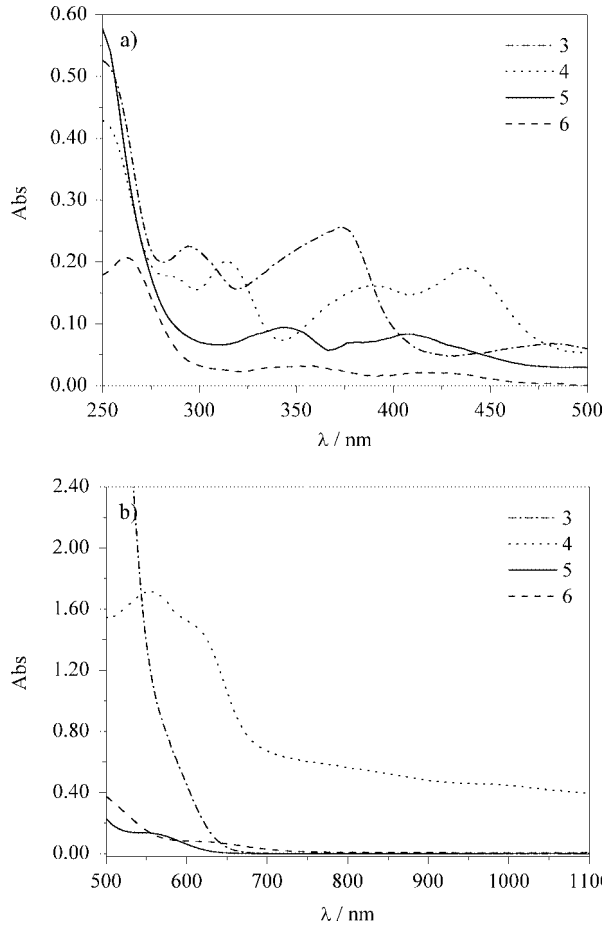

Figure 1. UV/Vis spectra of [Ni(3-MeOsalen)]-based complexes in solution recorded in the range: (a) $\lambda$ = 250–500 nm (complex concentration $1{\cdot}10^{-5}$ mol $dm^{-3}$) and (b) $\lambda$ = 500–1100 nm (complex concentration $1{\cdot}10^{-3}$ mol $dm^{-3}$).

transitions for the complexes with the 1,3-propanediamine bridge; this decrease must be due to an increase in the size of the ligand cavity. On the other hand, for Cu complexes the introduction of methyl groups in the ethylene bridge leads to a slight increase in ligand field strength due to the donor capacity of these groups. No trend in the values of $\lambda_{max}$ of the d-d band was detected when comparison is made between the nickel and the copper complexes with the same ligands.

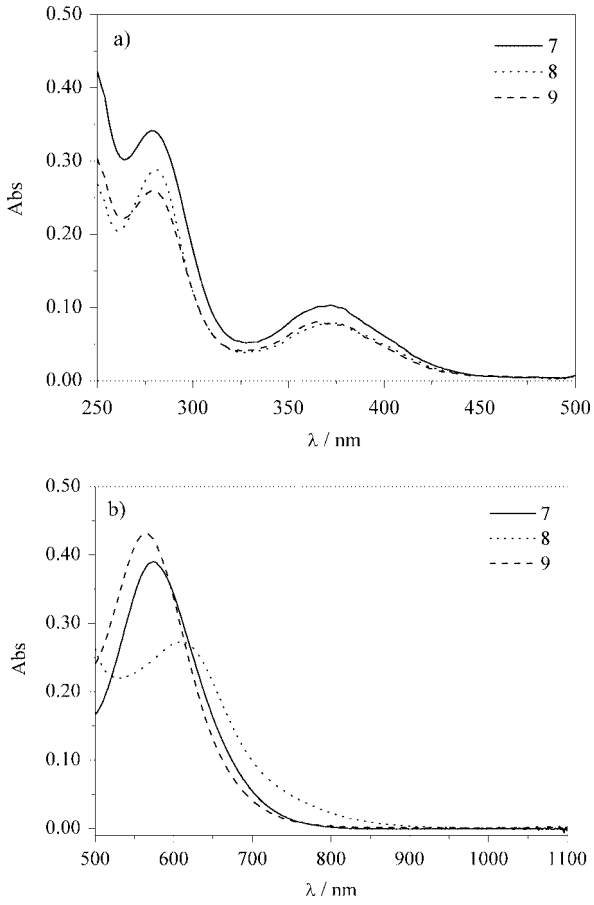

Figure 2. UV/Vis spectra of [Cu(3-MeOsalen)]-based complexes in solution recorded in the range: (a) $\lambda$ = 250–500 nm (complex concentration $1 \cdot 10^{-5}$ mol dm$^{-3}$) and (b) $\lambda$ = 500–1100 nm (complex concentration $1 \cdot 10^{-3}$ mol dm$^{-3}$).

Another key aspect to analyse in terms of the linear optical properties is the values of $\varepsilon$, for both types of electronic bands: d-d and charge-transfer bands. In this context it must be mentioned that the $\varepsilon$ values (d-d and CT bands) for the Cu complexes are always higher than those of the Ni homologues, and complexes with aromatic diimine bridges show higher values than those with aliphatic diimine bridges, with the complex **1** showing the most intense bands of the group of DA-salen studied in this work. These can be related to the degree of covalence in the M–L bonds, and thus copper complexes will have a high degree of covalence when compared with the homologous nickel complexes.

## Z-Scan Measurements

The Z-scan technique used to evaluate the NLO properties was developed by Sheik-Bahae et al.[21,22] and is based on the transformation of phase distortion during beam propagation. By using a single Gaussian laser beam, the transmittance of a nonlinear medium is measured as a function of the sample position (Z), measured with respect to the focal plane; further details on the Z-scan technique can be gathered from the literature.[21,22] This technique requires relatively simple experimental apparatus, when compared with other common techniques, such as nonlinear interferometry, degenerate four-wave mixing (DFWM) and third harmonic generation (THG) and provides the direct measurement of both nonlinear refractive index and absorption coefficient, along with their sign,[23] which allows the estimation of the third-order susceptibility coefficient $|\chi_3|$ in its real and imaginary components, respectively. Moreover, the measurement of third-order optical properties is not limited by restrictions in the system symmetry, which is an important advantage when compared with second-order techniques, which can only be used on noncentrosymmetric systems.

The experimental setup of the Z-scan technique was validated using carbon disulfide, which has been extensively studied in the literature.[2,21,22] Figure 3a shows the $CS_2$ Z-scan results and respective fitting curve obtained by the least-squares method: it shows the expected peak-valley curve with a pre-focal minimum followed by a post-focal maximum, which demonstrates a nonlinear refraction index with a positive sign. When compared with published works[21,22] the curve shape allows us to ignore nonlinear effects arising from nonelectronic processes, mostly thermal effects, since the refractive processes depend on the temperature and the use of high-energetic lasers could be a contribution to the rise in the local temperature of the sample region where the laser is focused. Under these conditions, if the complexes present nonlinear refractive indexes, they will be only due to electronic processes. The nonlinear refractive index of $CS_2$ was measured and is $1.09 \cdot 10^{-18}$ m$^2$ W$^{-2}$, which is very close to the reported value.[2]

All the complexes show a peak-valley curve with a pre-focal minimum followed by a post-focal maximum, which demonstrates a nonlinear refraction index with a positive sign. The almost symmetrical shape of the Z-scan plots of the complexes shows that nonlinear refraction effects dominate any nonlinear absorption. In Figure 3b a typical closed Z-scan result and the corresponding fitting curve are depicted for complex **3**.

The nonlinear refractive indexes of the complexes, $n_2^I$, were calculated using the $CS_2$ nonlinear refractive index by applying Equations (1) and (2), deduced from the theory inherent to the Z-scan technique[21] and considering the experimental conditions unchanged during all the measurements performed. The nonlinear absorption coefficients, $\alpha_2^I$, were calculated using Equation (3), based on the Beer–Lambert law, in which $\Delta T_{p,v}$ is the difference of normalized transmittance peak-valley due to nonlinear refraction,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

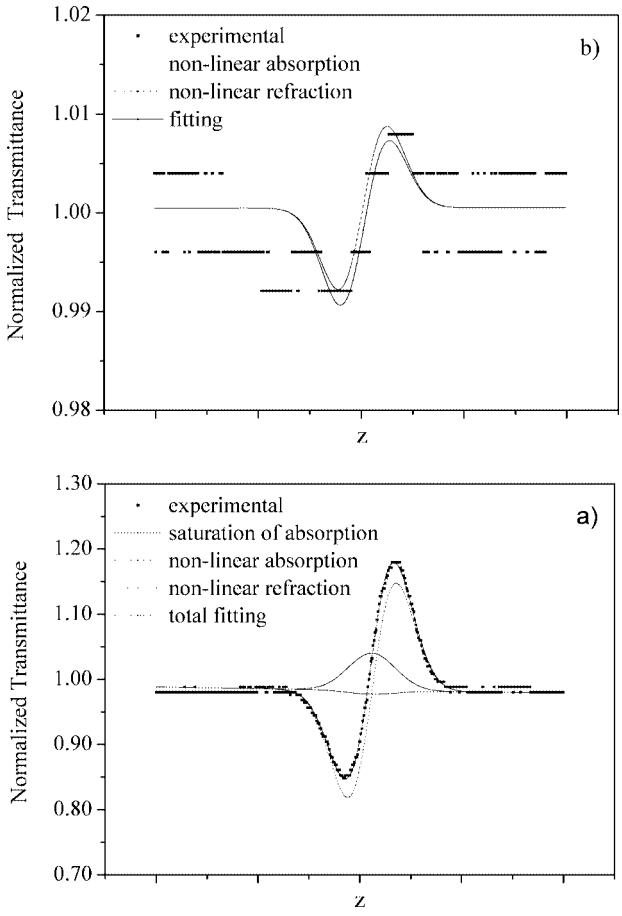

Figure 3. Closed Z-scan measurement at $\lambda_{inc}$ = 1064 nm; normalised transmission plotted as a function of sample position $z$ of: (a) $CS_2$ and (b) a solution of complex **3** in $CH_3CN$.

$\Delta T_{v(absorption)}$ is the difference of normalized transmittance occurring in the valley due to nonlinear absorption. Both $\Delta T$ values were obtained using the least-squares method, $L$ is the sample length and $a$ is the linear absorption coefficient.

$$n_2^I(sample) = \left(\frac{L_{eff\,(reference)}}{L_{eff\,(sample)}}\right) \times \left(\frac{\Delta T_{p,v(sample)}}{\Delta T_{p,v(reference)}}\right) \times n_2^I(reference) \quad (1)$$

$$L_{eff} = \left(\frac{1 - e^{-\alpha L}}{\alpha}\right) \quad (2)$$

$$\alpha_2^I = \left(\frac{\ln(1 - \Delta T_{v(absorption)} \cdot e^{\alpha L}}{I_0}\right) \quad (3)$$

The nonlinear refractive index and nonlinear absorption coefficients allow the estimation of the third-order susceptibility coefficient, $|\chi_3|$, in its real and imaginary components, respectively using Equations (4) and (5);[2] $n_0$ is the linear refractive index, $n_2^I$ is the nonlinear refractive index, $a_2^I$ is the nonlinear absorption coefficient, $c$ is the light velocity and $k$ the magnitude of the wave vector, $k = 2\pi/\lambda$, where $\lambda$ is the wavelength.

$$\chi_3^{(real)} = 2n_2^I \cdot {n_0}^2 \cdot {\varepsilon_0}^2 \cdot c \quad (4)$$

$$\chi_3^{(imaginary)} = \left(\frac{10^8 \cdot {n_0}^2 \cdot \alpha_2^I \cdot \varepsilon_0}{(2\pi \cdot k \cdot c)}\right) \quad (5)$$

In Table 2 are summarised the normalized values for nonlinear refractive indexes ($n_2^I$), nonlinear absorption coefficients ($a_2^I$) and the third-order susceptibility coefficient ($|\chi_3|$) and its real and imaginary components; data is normalised for a complex concentration of 1 mmol dm$^{-3}$.

The complexes show nonlinear refractive indexes ($n_2^I$) at $\lambda$ = 1064 nm in the range of 27.0–8.50·10$^{-21}$ m$^2$ W$^{-1}$and nonlinear absorption coefficients ($a_2^I$) within the range of 1.80–26.0·10$^{-17}$ m W$^{-1}$. The contribution of nonlinear refractive indexes and the nonlinear absorption coefficients to the overall magnitude of the third-order susceptibility

Table 2. Values of nonlinear refractive indexes ($n_2^I$), nonlinear absorption coefficients ($a_2^I$) and third-order susceptibility coefficients ($|\chi_3|$), real and imaginary components, for the [M(DA-salen)] complexes.[a]

| **2** | $CH_3CN$ | 9.53 | 4.07 | 9.09 | 5.85 | 9.11 |
| **5** | $CH_3CN$ | 8.52 | 3.90 | 8.13 | 5.61 | 8.14 |

[a] The complexes are displayed by decreasing values of $n_2^I$. All values are normalised for complex concentration of 1 mmol dm$^{-3}$. The values of $|\chi_3|$ have been calculated with the following expression: $|\chi_3| = \sqrt{\left|\chi_3^{real}\right|^2 + \left|\chi_3^{imaginary}\right|^2}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coefficient is presented in Figure 4. Analysis of the plot indicates that in general, the imaginary part of $|\chi_3|$, associated with $a_2{}^I$, contributes less than 10% to the overall $|\chi_3|$. Therefore, we can conclude that the NLO responses of [M(DA-salen)] complexes investigated in this work are mainly controlled by nonlinear refractive processes and this is an important result for our main objective of designing molecules with potential application for optical communications.

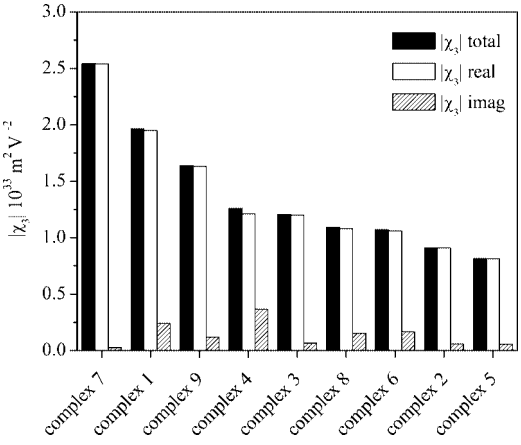

Figure 4. Different contributions for $|\chi_3|$ in [M(DA-salen)] complexes, M = Ni and Cu.

As mentioned previously, low values of $a_2{}^I$ are compatible with the absence of electronic transitions near $\lambda_{inc}$ and $\lambda_{inc}/2$. In fact, none of the complexes showed electronic transitions at $\lambda_{inc}$ = 1064 nm (see UV/Vis spectra). Nevertheless, complexes **1** and **4** show two intense electronic transitions in the vicinity of $\lambda_{inc}/2$ = 532 nm, the wavelength at which the double-photonic transitions occur, and thus are responsible for their highest nonlinear absorption coefficients.

The bis(salicylaldiminato)Ni$^{II}$ and -Cu$^{II}$ analogues[16] of the complexes described in this work show a similar trend for their third-order NLO properties measured at $\lambda$ = 532 nm: values of $n_2{}^I$ around $10^{-19}$ m$^2$ W$^{-1}$ and a small contribution of the nonlinear absorption to the overall $|\chi_3|$. This similarity can be attributed to the same geometry, ligand coordinating atoms and electronic structure of the metal centres in both types of complexes.

### Effect of the Substituents on the NLO Responses

For the group of Ni$^{II}$ complexes functionalised with methoxy groups in 3-position of the aldehyde moiety, complexes **3** to **6**, the highest NLO responses are shown by complexes with aromatic diimine bridges with electron acceptor properties, [Ni(3-MeOsaldiCN)] (**4**) and [Ni(3-MeOsalophen)] (**3**). The highest NLO response of these complexes is the result of the presence of intense low-energy charge-transfer bands that are associated with a high variation of the transition dipolar moment vector. These are induced by the high degree of aromaticity, and the proper combination between the π-donor properties of the methoxy group in the aldehyde moiety and the π-acceptor properties of the imine bridges; on the contrary the σ-donor groups ($CH_3$ and $CH_2$) in the aliphatic imine bridges of complexes **6** and **5** decrease the charge asymmetry and thus the NLO responses. Comparison between Ni$^{II}$ complexes with the same diimine bridge derived from 4,5-Me$_2$-1,2-phenylenediimine and different substituents in the aldehyde, complexes **1** and **2**, show that the former complex, which exhibits the largest number and most intense electronic bands is the one that presents the highest NLO response; in this case the proper combination between substituents to enhance the NLO response is the $CH_3$ σ-donor groups within the aromatic imine bridge and the pyrrol derivative in the 3-position of the aldehyde, that have electron-acceptor properties.

Within the Cu complexes, that are also functionalised with methoxy groups in the 3-position of the aldehyde, but have aliphatic imine bridges, the nonlinear refractive index of [Cu(3-MeOsalen)] (**7**) is considerably higher than those of [Cu(3-MeOsalpd)] (**8**) and [Cu(3-MeOsaltMe)] (**9**), following the same trend of the $\varepsilon$ values associated with the CT transitions. In this case, the NLO responses decrease with the increase in the number of $CH_3$ or $CH_2$ electron-donor groups in the aliphatic bridge, suggesting, as referred for Ni complexes, that methoxy groups still act as π-donor groups.

Between Ni$^{II}$ and Cu$^{II}$ complexes with the same DA-salen ligands, those of copper show higher $n_2{}^I$ values, indicating that, besides the presence of DA electron groups within the salen ligand, NLO responses can also be fine-tuned by the metal centre. The increase in the NLO responses on going from (DA-salen)Ni$^{II}$ to -Cu$^{II}$ complexes have also been observed in the studies performed by Di Bella and Lacroix on the second-order NLO properties of similar complexes[11,12] and in the study of the third-order NLO properties (at $\lambda$ = 532 nm) of the bis(salicylaldiminato)Ni$^{II}$ and -Cu$^{II}$ complexes.[16] Some insights into a possible explanation can be gathered from their UV/Vis spectra, although the number of complexes to be compared is small.

The UV/Vis spectra of homologous Ni$^{II}$ and Cu$^{II}$ complexes, **5**, **6**, **8** and **9**, in the range of $\lambda$ = 250–500 nm (Figure 5a) show no significant differences in the $\varepsilon$ values of the CT bands, suggesting that the differences within the NLO responses may depend on other factors. Nevertheless, analysis of the spectra in the range $\lambda$ = 500–1100 nm, Figure 5b, where d-d bands appear, show some interesting features: the d-d bands of the Cu$^{II}$ complexes are more intense than those of the Ni$^{II}$ analogues, and the intensity differences are higher for the complexes with the tetramethylethylene bridge; the NLO response follows exactly the same trend. The differences in third-order nonlinear responses for these complexes with salen ligands with aliphatic bridges suggests that the metal centre displays an important role in the variation of the molecular transition dipole moment and thus in the NLO response.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

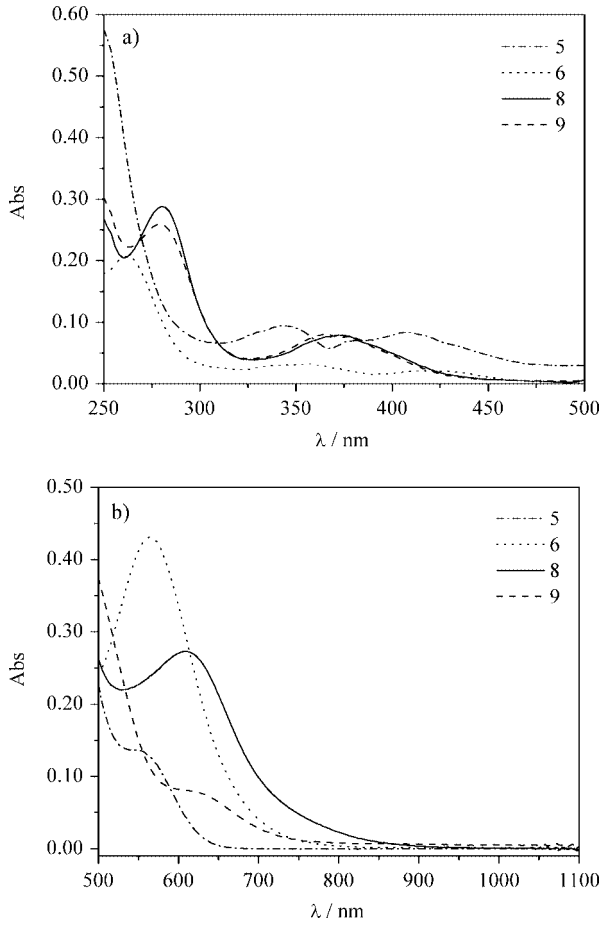

Figure 5. Comparison between UV/Vis spectra of $Ni^{II}$ and $Cu^{II}$ with the same DA-salen ligands in the range: (a) $\lambda$ = 250–500 nm (complex concentration $1 \cdot 10^{-5}$ mol dm$^{-3}$) and (b) $\lambda$ = 500–1100 nm (complex concentration $1 \cdot 10^{-3}$ mol dm$^{-3}$).

It is worthwhile to mention that [Cu(3-MeOsalen)] (**7**) is the complex with the highest $n_2^I$ of the compounds studied in this work, beyond those of nickel with high extensive π-delocalisation and efficient DA groups to create charge asymmetry. As the number of copper complexes used in this work is limited, no further conclusions can be made on the role of this cation in the NLO responses of Schiff-base ligands. Several Cu complexes with DA-salen ligands are now being prepared and their third-order NLO properties evaluated.

## Conclusions

The linear and third-order NLO properties of some nickel(II) and copper(II) complexes with salen ligands functionalised with donor/acceptor groups, [M(DA-salen)], were investigated by combining electronic spectroscopy and the Z-scan technique.

The [M(DA-salen)] complexes exhibit positive nonresonant nonlinear refractive indexes ($n_2^I$) in the range of 27.0–$8.50 \cdot 10^{-21}$ m$^2$ W$^{-1}$ and nonlinear absorption coefficients ($a_2^I$) within the range of 1.80–$26.0 \cdot 10^{-17}$ m$^2$ W$^{-1}$. The nonlinear absorption contribution is less than 10% of the overall magnitude of the third-order susceptibility, $|\chi_3|$, which is the result of the absence of electronic transitions near $\lambda_{inc}$ = 1064 nm or strong absorption near $\lambda_{in}/2$ = 532 nm, a consequence of the square-planar geometry of all the complexes coupled with a strong in-plane ligand field imposed by the DA-salen ligands.

The NLO responses follow the same trends observed for the number and ε values of the metal complexes electronic bands in the UV/Vis region, and therefore UV/Vis spectroscopy has been shown to be an important tool to complement the study of NLO properties for [M(DA-salen)] complexes.

The combination of electron-donor/acceptor groups in [M(DA-salen)] complexes strongly affects the nature and value of NLO response; nevertheless, more important than the strength of individual donor and/or acceptor groups is the combination of both D/A groups to achieve a high nonlinear response.

The results presented in this work also show that replacement of $Ni^{II}$ for $Cu^{II}$ in DA-salen with aliphatic bridges leads to a significant improvement in the NLO response; however, no further explanations could be anticipated, because of the low number of complexes that have been studied. In future, we intend to prepare more $Cu^{II}$ complexes with DA-salen and other metal complexes in order to better understand the role of the metal centre within the third-order NLO responses.

## Experimental Section

**Materials:** All the solvents were obtained from Merck; nickel(II) acetate 4-hydrate and copper(II) acetate 1-hydrate were obtained from Riedel–de Haën, and diaminomaleonitrile from Fluka. The reagents 2-hydroxy-3-methoxybenzaldehyd, 4,5-dichloro-1,2-phenylenediamine, 4,5-dimethyl-1,2-phenylenediamine, 1,2-phenylenediamine, 1,3-diamino-2-propanol, ethylenediamine, 1,3-diaminopropane and 2,3-dimethyl-2,3-dinitrobutane were obtained from Aldrich; all the chemicals were used as received. The compound 2,3-diamino-2,3-dimethylbutane was prepared by the method of Sayre,[24] and 4-(ethoxymethyl)morpholine was prepared as described elsewhere.[25] The DA-salen ligands were prepared by the standard method of refluxing an ethanolic solution containing stoichiometric amounts of the aldehyde and the diamines:[26] typically 10 mmol of the aldehyde was treated with 5 mmol of the diamines, leading to yields in the range of 70–90%. An exception was the preparation of the ligand 1,2-(4,5-dimethyl)phenylenbis(3-oxyethylpyrrole)salicylideneimine that was synthesised as described in the literature.[27] Similarly, the respective complexes were prepared by the usual method of refluxing an ethanolic solution of the DA-salen ligand and the metallic acetate in stoichiometric quantities[10,26] (typically 5 mmol of each reagent), leading to yields in the range of 50–80%. An exception was the complex [Ni(3-MeOsaldiCN)] (**4**), which was prepared by a procedure described in the literature.[12]

**Physical Measurements:** The solution UV/Vis spectra of the complexes were recorded with a Unicam UV-2 spectrometer in the ranges of $\lambda$ = 250–500 nm (complex concentration $1·10^{-5}$ mol dm$^{-3}$) and $\lambda$ = 500–1100 nm (complex concentration $1·10^{-3}$ mol dm$^{-3}$), using quartz cells with a 1-cm optical path. The Z-scan technique measurements were carried out using a 6-ns pulse Nd:YAG laser ($\lambda$ = 1064 nm) with a repetition rate of 10 Hz. The focal distance $f$ was 20 cm, the energy per pulse $E$ in the focus was 0.2 mJ, the beam radius at half-maximum in the focus $r_{1/2}$ was 1.5 mm and the aperture diameter $D$ was 2.2 mm (oscilloscope and photodiode). The spatial pulses were considered to be in the Gaussian transverse mode (TEM$_{00}$) and the sample is regarded as optically thin, because its length is small enough such that changes in the beam diameter within the sample due to either diffraction or nonlinear refraction can be neglected. The solutions were placed in a 1-cm quartz cuvette which was fixed in a controlled translation stage moving along the $z$-direction. All the Z-scan measurements were performed with the finite aperture placed in front of the photodiode: *closed* Z-scan mode. The possibility of analysing the contribution of different NLO processes to the overall NLO response (nonlinear absorption and nonlinear refraction) by using only the *closed* Z-scan mode, is described elsewhere.[22] This can be achieved because each process affects the transmittance through the aperture in a distinctive way: nonlinear absorption processes cause a symmetrical decrease of the transmittance with a minimum located in the focal point, linear processes are detected by a symmetrical rise in the transmittance around the focal point and nonlinear refractive processes are detected by the presence of a peak-valley profile, where the height and shape of the peaks are equal to the valley homologues, with an inflexion point placed at the focus. The fitting of experimental data was performed using a mathematical function composed of three different components that account for each phenomenon present within the sample: (i) a negative Gaussian associated with the nonlinear absorption coefficient, (ii) its first derivative which evaluates the nonlinear refractive index,[22] and (iii) a Gaussian component with positive sign to evaluate linear processes. The experimental data fitting was obtained using least-squares methods. None of the solvents used in the preparation of the complex solution showed nonlinear optical behaviour; the complex concentrations used were within the range of 4.5–6.0 mmol dm$^{-3}$.

# Organotin Compounds as Reagents for the Synthesis of Lanthanoid Complexes by Redox Transmetallation Reactions

Samar Beaini,[a] Glen B. Deacon,*[a] Matthias Hilder,[a] Peter C. Junk,[a] and David R. Turner[a]

**Keywords:** Redox transmetallation / Lanthanoid / Trimethyltin reagents / Pyrazolate / Aryl oxide / Ytterbium / Europium

Redox transmetallation reactions between trimethyltin compounds, $SnMe_3L$ [L = 3,5-diphenylpyrazolate ($Ph_2pz$), 2,6-di-*tert*-butyl-4-methylphenolate (OAr), or $C_6F_5$] and lanthanoid metals have yielded $[Ln(Ph_2pz)_2(DME)_2]$ (Ln = Eu, Yb), $[Ln(Ph_2pz)_3(DME)_2]$ (Ln = Y, La, Nd, Eu), $[Ln(Ph_2pz)_3(THF)_3]$ (Ln = Nd, Sm), $[Ln(Ph_2pz)_3(THF)_2]$ (Ln = Y, Yb), $[Sm(OAr)_3(THF)]$, $[Yb(OAr)_2(THF)_3]$, and $[Yb(C_6F_5)_2(THF)_4]$ complexes in yields generally competitive with those from other methods, and hexamethylditin. The crystal structures of $[Nd(Ph_2pz)_3(DME)_2]\cdot DME$, $[Eu(Ph_2pz)_3(DME)_2]\cdot 2DME$, and $[Sm(Ph_2pz)_3(THF)_3]\cdot 3THF$ were determined. All have nine-coordination of the lanthanoid atom and three $\eta^2$-$Ph_2pz$ ligands, the first two also having an $\eta^1$- and an $\eta^2$-DME ligand and the last having three THF ligands.

## Introduction

Redox transmetallation reactions between lanthanoid metals and mercury or thallium compounds [Equations (1) and (2); $n$ = 2, 3] have become an important route to rare earth organometallic compounds, organoamides, aryl oxides,[1] and thiolates.[2]

$$Ln + n/2\ HgL_2 \rightarrow Ln(L)_n + n/2\ Hg \quad (1)$$

$$Ln + n\ TlL \rightarrow Ln(L)_n + n\ Tl \quad (2)$$

On the other hand, there has been only one example of redox transmetallation between a tin reagent and a lanthanoid metal; viz formation of an ytterbium(II) organoamide from an $Sn^{II}$ precursor,[3] despite the widespread use of tin reagents in *non-redox* transmetallations.[4] Trialkyltin compounds can be envisaged as potential redox transmetallation reagents for the preparation of lanthanoid complexes [Equation (3)].

$$Ln + n\ SnR_3L \rightarrow Ln(L)_n + n/2\ Sn_2R_6 \quad (3)$$

Encouragement that such syntheses may be possible comes from the oxidation of bis(*tert*-butylcyclopentadienyl)-samarium(II) by trimethyltin fluoride to give the corresponding organosamarium(III) fluoride [Equation (4)].[5]

$$6\ [Sm(\eta^5\text{-}C_5H_4tBu)_2(THF)_2] + 6\ SnMe_3F \rightarrow 2\ [Sm(\eta^5\text{-}C_5H_4tBu)_2F]_3 + 3\ Sn_2Me_6 \quad (4)$$

However, the reduction of hexaphenylditin and triphenyltin halide by ytterbium giving $[Yb(SnPh_3)_2]$[6] sends a note of warning especially if excess Ln metal is used, despite the high $E_0$ value (–2.9 V) for reduction of $Ph_3SnSnPh_3$.[7]

Lead(II) compounds have also been used as oxidants,[8] and an attempted use in redox transmetallation unexpectedly gave a Pb/La dimetallic compound.[9] We now report proof of concept of reaction according to Equation (3) by syntheses of a range of lanthanoid pyrazolates and aryl oxides generally in good yield from appropriate trimethyltin reagents. In addition, in situ formation of $Yb(C_6F_5)_2$ from $SnMe_3(C_6F_5)$ has been demonstrated.

## Results and Discussion

The outcomes of the reactions of trimethyltin 3,5-diphenylpyrazolate [$SnMe_3(Ph_2pz)$],[10] trimethyltin 2,6-di-*tert*-butyl-4-methylphenolate [$SnMe_3(OAr)$] and trimethyl(pentafluorophenyl)tin with lanthanoid metals in 1,2-dimethoxyethane and tetrahydrofuran are summarised in Scheme 1. Reactions with $SnMe_3(Ph_2pz)$ gave both trivalent $[Ln(Ph_2pz)_3(DME)_2]$ (Ln = Y, La, Nd, Eu), $[Ln(Ph_2pz)_3(THF)_3]$ (Ln = Nd, Sm), $[Ln(Ph_2pz)_3(THF)_2]$ (Ln = Y, Yb) and divalent $[Ln(Ph_2pz)_2(DME)_2]$ (Ln = Eu, Yb) pyrazolate complexes [Equations (5) and (6); L = $Ph_2pz$; S = DME or THF].

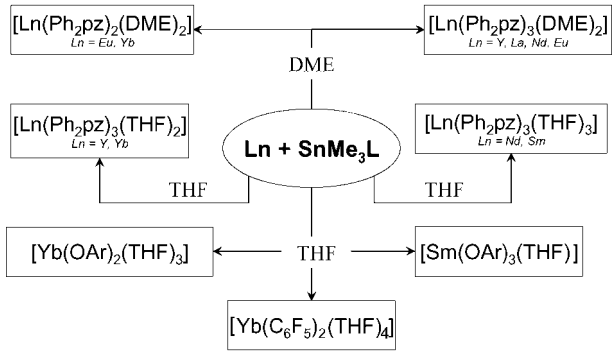
$$2\ Ln + 6\ SnMe_3L \xrightarrow{S} 2\ [LnL_3(S)_n] + 3\ Sn_2Me_6 \quad (5)$$

$$Ln + 2\ SnMe_3L \xrightarrow{S} [LnL_2(S)_n] + Sn_2Me_6 \quad (6)$$



Scheme 1. Redox transmetallation reactions between $SnMe_3L$ and Ln metals.

Similarly, $[Sm(OAr)_3(THF)]$ and $[Yb(OAr)_2(THF)_3]$ were obtained from analogous reactions of lanthanoid metals with $SnMe_3(OAr)$ in tetrahydrofuran [reactions according to Equations (5) and (6); Ln = Sm, Yb; L = OAr; S = THF]. Formation of hexamethylditin in all reactions was established by $^1H$ NMR spectroscopy[11] and in one case also by $^{119}Sn$ NMR spectroscopy.[12] Thus, the $^{119}Sn$ NMR spectrum of the filtrate after isolation of $[Yb(OAr)_2(THF)_3]\cdot THF$ showed the presence of a resonance attributable to $Sn_2Me_6$.[12] There was no resonance near $\delta$ = –95 ppm where the signal of the Yb–Sn-bonded species $[Yb\{Sn(CH_2tBu)_3\}_2(THF)_2]$ is observed,[13] suggesting significant amounts of $Yb(SnMe_3)_2$ are not formed despite the use of a large excess of Yb metal. Reactions were carried out with activation of the lanthanoid metal by Hg metal. Without activation, reactions occurred, but were slower. Initiation of reactions was faster in DME than in THF. Variation of the excess of europium metal in the reactions of $SnMe_3(Ph_2pz)$ in DME enabled either the $Eu^{II}$ or $Eu^{III}$ product to be obtained (Scheme 1) in good yield. On the other hand, the corresponding reaction of Yb metal has a solvent-dependent outcome, yielding a $Yb^{II}$ complex in DME but a $Yb^{III}$ complex in THF (Scheme 1), even though a greater excess of Yb metal was utilised for the latter. In THF, a deep orange-red colour suggestive of some $Yb^{II}$ was observed after sonication, but the solution turned yellow after removal from the excess of Yb due to oxidation by $SnMe_3(Ph_2pz)$ [Equation (7)].

$$2\ Yb(Ph_2pz)_2 + 2\ SnMe_3(Ph_2pz) \rightarrow 2\ Yb(Ph_2pz)_3 + Sn_2Me_6 \quad (7)$$

Reactions according to Equations (5) and (6) generally give yields comparable with those of alternative routes (Table 1). However, $[Nd(Ph_2pz)_3(DME)_2]$, $[Nd(Ph_2pz)_3(THF)_3]$, and $[Sm(Ph_2pz)_3(THF)_3]$ are obtained in higher yield by the present method, but $[Ln(Ph_2pz)_3(THF)_2]$ (Ln = Y, Yb) in lower yield. In addition, $[Ln(Ph_2pz)_3(DME)_2]$ (Ln = Y, Eu), and $[Sm(Ph_2pz)_3(THF)_3]$ are new complexes, while $[Nd(Ph_2pz)_3(DME)_2]\cdot DME$ is a new solvate. The last complex has previously been isolated as an unsolvated powder[14] and as a $C_6D_6$ solvate.[15] Of special interest is the formation of $[Yb(Ph_2pz)_3(THF)_2]$ by reaction according to Equation (5), as attempts to prepare this complex from Yb metal, $Hg(C_6F_5)_2$ and $Ph_2pzH$ led to gross decomposition,[16a] and the corresponding reaction using $HgPh_2$, and redox transmetallation between Yb metal and $Tl(Ph_2pz)$ both yielded $Yb^{II}$ complexes.[16b] Thus, previous access to $[Yb(Ph_2pz)_3(THF)_2]$ required a two-step synthesis[17] (Table 1). Attempted reaction of Yb metal with $SnMe_3(C_6F_5)$ in tetrahydrofuran at room temperature for 2 d failed, but, after 1 d of ultrasonication, incomplete formation of $Yb(C_6F_5)_2$ [Equation (6); Ln = Yb; L = $C_6F_5$] was detected. By contrast, redox transmetallation between Yb and $Hg(C_6F_5)_2$ in tetrahydrofuran requires only a few minutes induction and is complete in 4 h.[1c]

Table 1. Comparison of yields of $Ln(L)_n$ complexes of the current study with literature methods.

| $Ln(Ph_2pz)_n(S)_m$ | Ln + $SnMe_3L$ | Reported | Method |

[a] Ref.[14] [b] Ref.[16a] [c] Ref.[16b] [d] Ref.[18] [e] Ref.[19] [f] This work. [g] Ref.[17] [h] Ref.[20] [i] Ref.[21]

Known complexes (Table 1) were characterised by lanthanoid metal analyses, IR spectroscopy and $^1H$ NMR spectroscopy, which confirmed the DME or THF/$Ph_2pz$ or OAr ratio. However, 4-H(pz) and *o*-H(Ph) resonances of $[Nd(Ph_2pz)_3(THF)_3]\cdot THF$ were too broad for satisfactory integrations. Furthermore, single crystals of $[Nd(Ph_2pz)_3(THF)_3]\cdot THF$, $[Yb(Ph_2pz)_2(DME)_2]$ and $[Yb(OAr)_2(THF)_3]\cdot THF$ were grown, and their unit cells are in agreement with the reported data.[16,19,20] In the case of the known[16a] $[Eu(Ph_2pz)_2(DME)_2]$, fifteen of sixteen single crystals examined had unit cell data corresponding to that reported for *trans*-$[Eu(Ph_2pz)_2(DME)_2]$,[16a] the product of redox transmetallation between Eu metal and $Tl(Ph_2pz)$.[16a] However, the values for one crystal were close to those for *cis*-$[Yb(Ph_2pz)_2(DME)_2]$,[16b] and can be attributed to *cis*-$[Eu(Ph_2pz)_2(DME)_2]$. It previously seemed surprising that $[Eu(Ph_2pz)_2(DME)_2]$ crystallised with the $Ph_2pz$ ligands mutually *transoid* when the complex of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

adjacent Sm was isolated *cisoid*[16a] as was *cis*-[Yb($Ph_2pz$)$_2$($DME$)$_2$].[16b] Although only one crystal of *cis*-[Eu($Ph_2pz$)$_2$($DME$)$_2$] was identified from the reaction according to Equation (6), its existence is established.

The composition of the new complex Y($Ph_2pz$)$_3$($DME$)$_3$ was established by microanalysis, metal analysis, and the DME/$Ph_2pz$ ratio by $^1$H NMR spectroscopy. Single crystals could not be obtained, but as $Y^{3+}$ has a similar size to $Er^{3+}$, which gives a nine-coordinate [Er($Ph_2pz$)$_3$($\eta^2$-DME)($\eta^1$-DME)][14] complex, it is likely the yttrium complex is a nine-coordinate mono-DME solvate [Y($Ph_2pz$)$_3$($DME$)$_2$]·DME. Besides characterisation by IR and NMR spectroscopy, and lanthanoid metal analyses, the new complexes [Eu($Ph_2pz$)$_3$($DME$)$_2$]·2DME, [Sm($Ph_2pz$)$_3$($THF$)$_3$]·3THF and the new solvate [Nd($Ph_2pz$)$_3$($DME$)$_2$]·DME were characterised by single-crystal X-ray structure determinations (below). For the Nd complex, both 4-H(pz) and *o*-H(Ph) resonances were severely broadened. The DME of solvation was readily lost from crystals of the Eu complex and the %Eu value for the dried complex corresponded to the composition [Eu($Ph_2pz$)$_3$($DME$)$_2$], whilst the $^1$H NMR spectra from two separate preparations showed a DME/$Ph_2pz$ ratio of 4:3, as in single crystals, and 3:3. Similarly, the dried product from one preparation of the samarium complex showed a THF/$Ph_2pz$ ratio of 6:3 as in the single crystals, and the product from another a THF/$Ph_2pz$ ratio of 5:3. No other products showed a similar loss of lattice solvent of crystallisation.

The structures of [Eu($Ph_2pz$)$_3$($DME$)$_2$]·2DME (Figure 1) and the new solvate [Nd($Ph_2pz$)$_3$($DME$)$_2$]·DME have nine-coordinate lanthanoid atoms with three $\eta^2$-$Ph_2pz$ ligands, one chelating DME and one (less usual[22]) unidentate DME. Selected bond lengths and angles are given in Table 2. The complexes have similar connectivity to unsolvated [Er($Ph_2pz$)$_3$($DME$)$_2$][14] and [Nd($Ph_2pz$)$_3$($DME$)$_2$]·2$C_6D_6$,[15] but there are differences in the structural details. Notably, the uncoordinated end of the unidentate DME points away from the metal atom in the present complexes [Eu···O(2)$_{nonbonding}$ 5.47 Å, Nd···O(2)$_{nonbonding}$ 5.41 Å; Eu–O(1)···O(2) 162°, Nd–O(1)···O(2) 153°] more markedly than in the erbium complex (4.62 Å/122°) and the neodymium $C_6D_6$ solvate (4.92 Å/129°). Plausibly, packing effects associated with differing solvation in the crystals [2 DME (Eu), 1 DME (Nd) (this study); 0 DME (Er);[14] 2 $C_6D_6$ (Nd)[15]] affect the arrangements of the $\eta^1$-DME ligand. All $Ph_2pz$ and $\eta^2$-DME ligands are nearly symmetrically chelating with only a small divergence in Ln–N (0.01–0.05 Å) and Ln–O ($\eta^2$-DME) (0.01–0.03 Å) bond lengths (Table 2). Nevertheless, the differences between Nd–N bond lengths of each chelating pair in the DME solvate (0.018, 0.054, 0.012 Å) (Table 2) are slightly larger than in the $C_6D_6$ solvate (0.008, 0.026, 0.005 Å).[15] For [Eu($Ph_2pz$)$_3$($DME$)$_2$]·2DME (Table 2) and [Nd($Ph_2pz$)$_3$($DME$)$_2$]·2$C_6D_6$,[15] the Ln–O ($\eta^1$-DME) distance lies between the values for Ln–O ($\eta^2$-DME), whereas for [Nd($Ph_2pz$)$_3$($DME$)$_2$]·DME (Table 2) and the Er complex[14] Ln–O ($\eta^1$-DME) is the shortest Ln–O distance. Moreover, the pairings here do not conform to the $\eta^1$-DME conformational pairings. Whilst the <Ln–N(O)> distances decline in the sequence Nd, Eu, Er as expected from the lanthanoid contraction, <Eu-N>

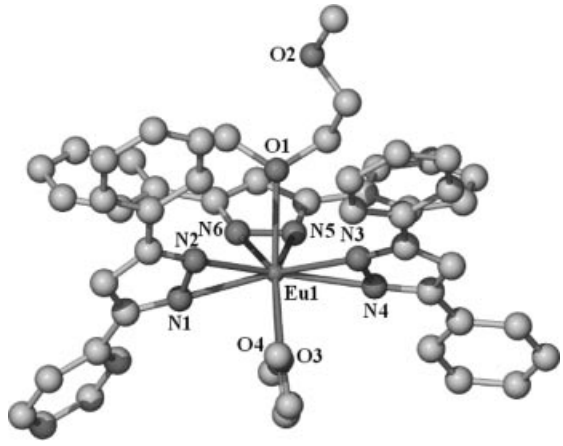

Figure 1. Molecular structure of [Eu($Ph_2pz$)$_3$($DME$)$_2$]·2DME. Selected bond lengths [Å] and angles [°] for this structure and the near isostructural Nd complex are given in Table 2. Only one disordered position of $\eta^2$-DME shown for clarity.

Table 2. Selected bond lengths [Å] and angles [°] for the new Ln($Ph_2pz$)$_n$ complexes.

| | [Nd($Ph_2pz$)$_3$($DME$)$_2$]·DME | [Eu($Ph_2pz$)$_3$($DME$)$_2$]·2DME | [Sm($Ph_2pz$)$_3$($THF$)$_3$]·3THF | | | |

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

exceeds <Er-N> by more (0.09 Å) than than expected (0.06 Å) from ionic radii,[23] whereas the corresponding <Ln–O> difference is less (0.03 Å) than expected.

$[Sm(Ph_2pz)_3(THF)_3]\cdot 3THF$ has nine-coordination for samarium with three $\eta^2$-$Ph_2pz$ and three THF ligands (Figure 2). It is isostructural with $[Nd(Ph_2pz)_3(THF)_3]\cdot THF$, which was isolated as a mono-THF solvate,[19] whereas the present complex has two closely related independent molecules and six THF solvent molecules in the asymmetric unit. The Sm–O bond lengths are very similar to the Nd–O bond lengths,[23] despite the expectation of a 0.03 Å difference based on ionic radii.[23] Molecule 2 has almost identical O–Ln–O angles to those of the Nd complex, but molecule 1 shows some deviation. More symmetrical $\eta^2$-$Ph_2pz$ bonding is observed in the present complex, and <Sm–N> is 0.02 Å shorter than <Nd–N>, near ionic radius expectations.[23]

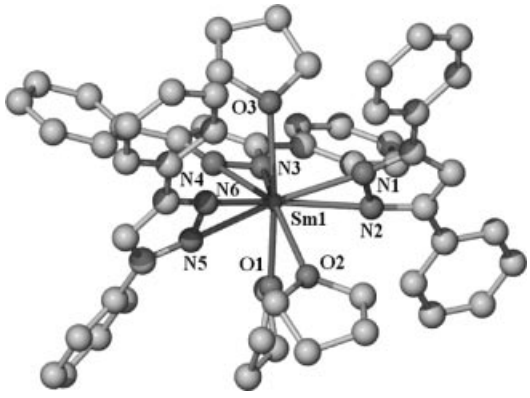

Figure 2. Molecular structure of $[Sm(Ph_2pz)_3(THF)_3]\cdot 3THF$. One of the two independent but closely related molecules is displayed.

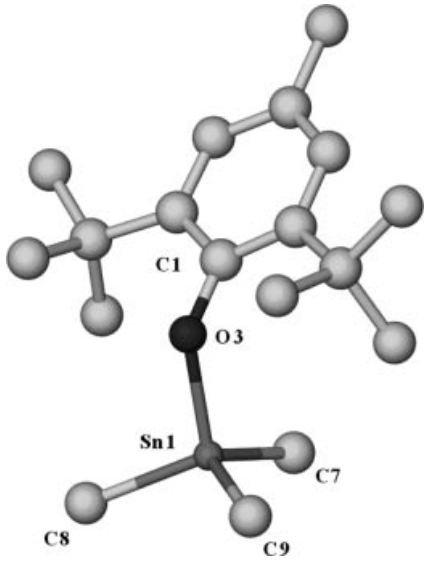

Figure 3. Molecular structure of $[SnMe_3(OAr)]$. Selected bond lengths [Å] and angles [°]: Sn(1)–O(3) 2.0082(15), O(3)–C(1) 1.363(3), Sn(1)–C(7) 2.127(2), Sn(1)–C(8) 2.139(3), Sn(1)–C(9) 2.127(3); C(1)–O(3)–Sn(1) 133.77(14), O(3)–Sn(1)–C(7) 105.56(9), O(3)–Sn(1)–C(8) 104.31(9), O(3)–Sn(1)–C(9) 106.44(9), C(7)–Sn(1)–C(8) 113.92(11), C(7)–Sn(1)–C(9) 117.10(11), C(8)–Sn(1)–C(9) 108.42(11).

An X-ray crystal structure was also obtained for the $[SnMe_3(OAr)]$ reagent (Figure 3). The compound is essentially isostructural with the known $[SiMe_3(OAr)]$.[24] The coordination environment around the tin atom is distorted tetrahedral. However, the C–O–Sn angle is significantly smaller than the C–O–Si angle within the silicon analogue,[24] presumably owing to reduced steric crowding by the *tert*-butyl groups due to the increased ionic radius of tin.

## Conclusions

This study shows that organotin(IV) compounds can be used in redox transmetallation reactions with lanthanoid elements to provide metal–organic lanthanoid complexes [Equations (5) and (6)]. Although their initial reactivity is somewhat lower than that of the analogous $Tl^I$ reagents or redox transmetallation with $HgR_2$ and LH, comparable or in some cases better yields have been obtained with the tin reagents (Table 1). Moreover, the different reactivity has enabled both $Eu^{II}$ and $Eu^{III}$ complexes to be isolated and a different Yb oxidation state outcome than with previous redox transmetallation methods. Besides variation of the alkyl groups, there is opportunity for considerable modulation of the tin reagents, e.g. (i) use of $SnMe_3Ar$ reagents with lanthanoid metals and protic reagents such as pyrazoles, phenols, and amines in redox transmetallation/ligand exchange, and (ii) exploration of $Sn^{VI} \rightarrow Sn^{II}$ reduction with the potentially more transfer efficient $SnMe_2L_2$ reagents. Evidence that Yb metal reacts with $SnMe_3(C_6F_5)$ to give $Yb(C_6F_5)_2$ in solution provides encouragement for the use of this compound in redox transmetallation/ligand exchange.

## Experimental Section

**General Remarks:** All reactions were carried out under dry nitrogen using standard Schlenk and dry-box equipment. THF was freshly distilled from sodium/benzophenone, while DME was distilled from sodium. Infrared spectra (4000–650 $cm^{-1}$) were recorded as Nujol mulls with a Perkin–Elmer 1600 FTIR spectrophotometer. $^1H$ NMR spectra were recorded with a Bruker DPX 300 MHz spectrometer using dry degassed deuteriobenzene or deuteriotetrahydrofuran solvents at 25 °C; resonances were referenced to residual hydrogen from the solvent. $^{119}Sn$ NMR spectra were obtained with a Bruker DRX 400 spectrometer and were referenced to tetramethyltin. $^{19}F$ NMR spectra were recorded with a Bruker DPX 300 spectrometer and were referenced to external $CFCl_3$. $^1H$ NMR spectra of all solutions following reactions of lanthanoid metals with $SnMe_3L$ reagents showed the presence of $Sn_2Me_6$ ($\delta$ = 0.20 ppm; $J_{^{117}Sn-CH_3}$ = 46.4 Hz, $J_{^{119}Sn-CH_3}$ = 48.4 Hz).[11] Metal analyses of the lanthanoid complexes were performed by EDTA titration with xylenol orange indicator following digestion in concentrated nitric and sulfuric acids and buffering with hexamine.[16a] Microanalysis samples were sealed in glass ampoules under purified $N_2$ and were determined by the Campbell Microanalytical service, University of Otago, New Zealand. 3,5-Diphenylpyrazole and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$SnMe_3(Ph_2pz)$ were prepared as reported.[25,10] A modification ($LiC_6F_5$ instead of $MgC_6F_5Br$) of the reported method[26] was used to obtain $SnMe_3(C_6F_5)$, which was distilled under reduced pressure and had IR and $^{19}F$ NMR spectra as reported.[26] Bis(pentafluorophenyl)mercury $Hg(C_6F_5)_2$ was prepared by a literature method.[27]

**(2,6-Di-*tert*-butyl-4-methylphenolato)trimethyltin(IV). Method (a):** *n*-Butyllithium (11.2 mL, 1.6 M in hexanes, 18.0 mmol) was added dropwise to pre-dried 2,6-di-*tert*-butyl-4-methylphenol (3.30 g, 15.0 mmol) in $Et_2O$ (50 mL), and the mixture was stirred for 1 h. Trimethyltin chloride (14.97 mL, 1.0 M in hexanes, 14.97 mmol) was then added dropwise. After stirring the reaction mixture overnight, the diethyl ether solution was filtered and the filtrate concentrated to crystallisation. Data of the crude product, which contained traces of lithium phenolate (NMR identification): IR: $\tilde{\nu}$ = 2726 w, 1603 w, 1418 vs, 1346 s, 1263 s, 1233 s, 1216 m, 1194 m, 1118 w, 1023 w, 918 w, 886 s, 861 m, 822 m, 772 m, 722 m $cm^{-1}$. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.34 (s, $^2J_{H,^{117}Sn}$ = 53 Hz, $^2J_{H,^{119}Sn}$ = 57 Hz, 9 H, $Me_3Sn$), 1.51 (s, 18 H, *t*Bu), 2.32 (s, 3 H, Me), 7.20 (s, 2 H, 3,5-H) ppm. Extraction with hexane and concentration of the solvent yielded pure $SnMe_3OAr$ as colourless crystals (1.99 g, 35%), identified by X-ray crystallography (below). $^{119}Sn\{^1H\}$ NMR (149 MHz, $C_6D_6$, 25 °C): $\delta$ = 131.5 ppm. **Method (b):** Excess of $SnMe_3Cl$ (1.80 g; 9.05 mmol) was added to a solution of lithium 2,6-di-*tert*-butyl-4-methylphenolate (LiOAr) (1.33 g; 5.90 mmol) in $Et_2O$ (50 mL), and the resulting solution was stirred at room temperature overnight. After filtration through a filter cannula, the $Et_2O$ was removed under vacuum yielding a very fine crystalline material, which was washed with 3×10 mL of hexane to remove $SnMe_3Cl$. M.p. 138–140 °C;1.35 g, 55%. The $^1H$ NMR spectrum ($C_6D_6$) as above, was void of LiOAr resonances. $C_{18}H_{32}OSn$ (383.16): calcd. C 56.42, H 8.41; found C 56.56, H 8.22.

**Redox Transmetallation Reactions**

**Preparation of Bis(3,5-diphenylpyrazolato)lanthanoid(II) and Tris(3,5-diphenylpyrazolato)lanthanoid(III) Complexes:** DME or THF (50 mL) was added to excess lanthanoid metal (powder or filings), $SnMe_3(Ph_2pz)$ and 1–2 drops of mercury. The resulting mixture was stirred or sonicated at room temperature usually for 5 d. A colour change was observed for most reactions within 4 h (Yb: 1 h). The filtrate was collected by a filter cannula, and the solvent volume reduced to 15 mL. Crystalline or powdered $Ln(Ph_2pz)_n$ ($n$ = 2,3) compounds were obtained by cooling of the concentrated solutions to –20 °C. In all cases, the $^1H$ NMR spectrum of the crude product was obtained to verify $Sn_2Me_6$ formation.[11] The product was then washed with hexane to remove $Sn_2Me_6$, and dried briefly under vacuum.

**$[Y(Ph_2pz)_3(DME)_2]\cdot DME$:** Y metal powder (0.59 g; 6.62 mmol) and $SnMe_3(Ph_2pz)$ (0.50 g; 1.32 mmol) in DME, stirred for 5 d, gave colourless crystals;0.36 g, 80%. IR: $\tilde{\nu}$ = 1603 m, 1512 w, 1420 w, 1260 m, 1225 w, 1192 w, 1154 w, 1130 w, 1107 m, 1072 m, 1057 s, 1026 m, 1000 w, 972 vs, 912 m, 872 s, 804 m, 794 m, 758 vs, 704 s, 696 vs, 688 s $cm^{-1}$. $^1H$ NMR ($C_6D_6$): $\delta$ = 2.98 (br. s, 18 H, $CH_3$-*DME*), 3.10 (br. s, 12 H, $CH_2$-*DME*), 7.04–7.07 (br. t, 6 H, *p*-H), 7.08 (s, 3 H, 4-H), 7.14 (br. s, 12 H, *m*-H), 7.90–7.93 (br. d, 12 H, *o*-H) ppm. $C_{57}H_{63}N_6O_6Y$ (1017.05): calcd. C 67.31, H 6.24, N 8.26, Y 8.74; found C 66.73, H 6.60, N 8.22, Y 8.91.

**$[La(Ph_2pz)_3(DME)_2]$:** La powder (1.03 g; 7.44 mmol) and $SnMe_3(Ph_2pz)$ (0.50 g; 1.31 mmol) in DME, stirred for 5 d, gave a white powder; 0.35 g, 82%. The IR spectrum is similar to that reported.[14] $^1H$ NMR ($C_6D_6$): $\delta$ = 3.02 (br. s, 12 H, $CH_3$-*DME*), 3.17 (br. s, 8 H, $CH_2$-*DME*), 7.01–7.12 (m, 21 H, *m*-H, *p*-H, 4-H), 7.86 (br. s, 12 H, *o*-H) ppm. $C_{53}H_{53}LaN_6O_4$ (976.93): calcd. La 14.22; found La 14.51.

**$[Nd(Ph_2pz)_3(DME)_2]\cdot DME$:** Nd metal powder (0.94 g; 6.55 mmol) and $SnMe_3(Ph_2pz)$ (0.52 g; 1.36 mmol) in DME, stirred for 5 d, gave lavender-blue crystals; 0.38 g, 79%. The IR spectrum is in agreement with that of $[Nd(Ph_2pz)_3(DME)_2]$.[15] $^1H$ NMR ($C_6D_6$): $\delta$ = –3.41 (br. s, 12 H, $CH_2$-*DME*), 0.29 (s, 18 H, $CH_3$-*DME*), 8.08-8.22 (m, 18 H, *m*-H, *p*-H), 12.4 (v. br. s, *o*-H), 17.8 (v. br. s, 4-H) ppm. $C_{57}H_{63}N_6NdO_6$ (1072.39): calcd. Nd 13.45; found Nd 13.71. X-ray crystallography established the composition $[Nd(Ph_2pz)_3(DME)_2]\cdot DME$.

**$[Eu(Ph_2pz)_2(DME)_2]$:** Eu metal filings (2.52 g, 16.6 mmol) and $SnMe_3(Ph_2pz)$ (0.60 g, 1.57 mmol) in DME, sonicated for 5 d, gave deep yellow crystals; 1.06 g, 88%. The IR spectrum is identical with that reported.[16a] $^1H$ NMR ($C_6D_6$): $\delta$ = 0.43 (br. s, 8 H, $CH_2$-*DME*), 0.92 (br. s, 12 H, $CH_3$-*DME*), 1.32–2.09 (br. m, 22 H, 4-H, *p*-, *m*-, *o*-H) ppm. $C_{38}H_{42}EuN_4O_4$ (770.73): calcd. Eu 19.73; found Eu 19.26. X-ray crystallographic examination of the yellow crystals gave *one* crystal: monoclinic, space group $P2_1/a$, $a$ = 7.8740, $b$ = 18.8715, $c$ = 23.9260 Å; $\beta$ = 91.042°, $V$ = 3554.67 $Å^3$; isomorphous with *cis*-$[Yb(Ph_2pz)_2(DME)_2]$[16b] [monoclinic, space group $P2_1/a$, $a$ = 7.882(4), $b$ = 18.959(3), $c$ = 24.080(14) Å; $\beta$ = 91.03(2)°, $V$ = 3598(3) $Å^3$] and *fifteen* crystals of *trans*-$[Eu(Ph_2pz)_2(DME)_2]$, monoclinic, space group $P2/c$, $a$ = 14.9771, $b$ = 12.5269, $c$ = 19.6728 Å; $\beta$ = 109.398°, $V$ = 3481.40 $Å^3$, in agreement with reported data[16a] [monoclinic, space group $P2/c$, $a$ = 19.746(3), $b$ = 12.635(2), $c$ = 15.396(2) Å; $\beta$ = 110.12(1)°, $V$ = 3607 $Å^3$].

**$[Eu(Ph_2pz)_3(DME)_2]\cdot 2DME$:** Eu metal chunks (0.73 g, 4.80 mmol) and $SnMe_3(Ph_2pz)$ (0.53 g, 1.38 mmol) in DME, stirred for 3 d, gave golden yellow crystals; 0.38 g, 70%. IR: $\tilde{\nu}$ = 1604 m, 1246 w, 1192 m, 1124 m, 1107 m, 1057 s, 1026 m, 971 s, 916 w, 865 m, 800 w, 758 vs, 724 w, 696 s, 684 s, 666 w $cm^{-1}$. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.23 (s, 3 H, 4-H), 2.09-3.68 (br. s, 40 H, $CH_3$ and $CH_2$-DME), 7.01-8.56 (m, 30 H, *o*-, *m*-, *p*-H) ppm. Metal analysis on dried crystals for $C_{53}H_{53}EuN_6O_4$ (loss of DME of solvation) (989.99): calcd. Eu 15.35; found Eu 15.36. Single crystals were obtained from another preparation that involved sonication of the DME mixture of Eu metal chunks and $SnMe_3(Ph_2pz)$ for 3 d (yield <5%). X-ray crystallographic examination revealed the composition $[Eu(Ph_2pz)_3(DME)_2]\cdot 2DME$. The $^1H$ NMR spectrum in $[D_8]THF$ showed loss of 1DME of solvation ($C_4D_8O$): $\delta$ = 3.47–3.59 (m, 30 H, $CH_3$-, $CH_2$-*DME*), 5.16 (s, 3 H, 4-H), 7.35 (br. t, 18 H, *m*- and *p*-H), 7.84 (d, 12 H, *o*-H) ppm.

**$[Yb(Ph_2pz)_2(DME)_2]$:** Yb metal filings (1.20 g, 6.96 mmol) and $SnMe_3(Ph_2pz)$ (0.66 g, 1.72 mmol) in DME, sonicated for 5 d, gave deep red crystals; 0.54 g, 80%. The IR spectrum is in agreement with that reported.[16b] $^1H$ NMR ($C_6D_6$): $\delta$ = 3.12 (br. s, 20 H, $CH_3$, $CH_2$-*DME*), 7.22 (br. s, 6 H, *p*-H, 4-H), 7.33 (br. s, 8 H, *m*-H), 8.10 (br. s, 8 H, *o*-H) ppm (reasonable agreement with data for a solution in $C_4D_8O$).[16b] $C_{38}H_{42}N_4O_4Yb$ (791.80): calcd. Yb 21.85; found Yb 20.32. A unit cell, monoclinic, space group $P2_1/a$, $a$ = 7.7214, $b$ = 18.7327, $c$ = 23.8207 Å; $\beta$ = 91.03°, $V$ = 3445.20 $Å^3$ is in agreement with that of *cis*-$[Yb(Ph_2pz)_2(DME)_2]$[16b] [monoclinic, space group $P2_1/a$, $a$ = 7.882(4), $b$ = 18.959(3), $c$ = 24.080(14) Å; $\beta$ = 91.03(2)°, $V$ = 3598(3) $Å^3$].

**$[Y(Ph_2pz)_3(THF)_2]$:** Y metal powder (1.01 g; 11.36 mmol) and $SnMe_3(Ph_2pz)$ (0.61 g; 1.60 mmol) in DME, sonicated for 5 d, gave a white powder; 0.26 g, 54%. The IR spectrum is identical with that reported.[18] $^1H$ NMR ($C_6D_6$): $\delta$ = 1.36 (s, 8 H, $CH_2$-*THF*), 3.43 (br. s, 8 H, $CH_2$-*THF*), 6.91 (br. s, 6 H, *p*-H), 7.02 (br. t, 12 H, *m*-H), 7.17 (br. s, 3 H, 4-H), 7.71 (br. s, 12 H, *o*-H) ppm. $C_{53}H_{49}N_6O_2Y$ (890.90): calcd. Y 9.98; found Y 9.28.

**$[Nd(Ph_2pz)_3(THF)_3]\cdot THF$:** Nd metal powder (0.95 g; 6.57 mmol) and $SnMe_3(Ph_2pz)$ (0.57 g; 1.49 mmol) in THF, stirred for 5 d, gave

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lavender-blue crystals; 0.51 g, 97%. The IR spectrum is identical with that reported.[19] $^1$H NMR ($C_6D_6$): $\delta$ = –5.59 (br. s, 16 H, $CH_2$-*THF*), –2.78 (br. s, 16 H, $CH_2$-*THF*), 7.90–8.01 (br. s, 18 H, *m*-H, *p*-H), 12.37–12.62 (v. br. s, *o*-H), 17.95–17.98 (v. br. s, 4-H) ppm. $C_{61}H_{65}N_6NdO_4$ (1090.45): calcd. Nd 13.22; found Nd 13.58. A unit cell on the lavender blue crystals, orthorhombic, space group $P2_12_12_1$, $a$ = 14.18(2), $b$ = 16.26(1), $c$ = 22.78(2) Å; $V$ = 5254(8) Å$^3$ is identical with that of $[Nd(Ph_2pz)_3(THF)_3]\cdot THF$[19] [orthorhombic, space group $P2_12_12_1$, $a$ = 14.009(9), $b$ = 16.280(8), $c$ = 22.640(16) Å; $V$ = 5163(5) Å$^3$].

**$[Sm(Ph_2pz)_3(THF)_3]\cdot 3THF$. Method (a). $SnMe_3(Ph_2pz)$ with Sm Metal in THF:** Sm metal powder (1.59 g; 10.6 mmol) and $SnMe_3(Ph_2pz)$ (0.52 g; 1.36 mmol) in THF, stirred for 5 d, then sonicated for 1 d, gave a brownish/yellow precipitate; 0.54 g, 96%. IR $\tilde{\nu}$ = 1602 m, 1562 w, 1424 w, 1298 w, 1225 w, 1154 w, 1071 m, 1050 (sh), 1026 m, 970 s, 915 m, 869 m, 803 w, 757 s, 697 m, 669 w cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 0.91 (m, 24 H, $CH_2$-*THF*), 2.66 (m, 24 H, $CH_2$-*THF*), 7.29 (t, 6 H, *p*-H), 7.60 (t, 12 H, *m*-H), 7.83 (s, 3 H, 4-H), 9.48 (d, 12 H, *o*-H) ppm. $C_{69}H_{81}N_6O_6Sm$ (1240.78): calcd. Sm 12.12; found Sm 11.98. In a similar reaction, sonicating the same amounts of Sm and $SnMe_3(Ph_2pz)$ for 6 d, the filtrate, after isolation of the bulk product as a powder, was allowed to stand for a few months and deposited single crystals of $[Sm(Ph_2pz)_3(THF)_3]\cdot 3THF$ (0.16 g, 30%). The IR spectrum and $^1$H NMR chemical shifts agree with those of the above preparation, but the solid had lost 1THF of solvation. An X-ray structure determination of the colourless crystals found two $[Sm(Ph_2pz)_3(THF)_3]\cdot 3THF$ molecules in the unit cell (see below). **Method (b):** Sm powder (0.22 g; 1.50 mmol), bis(pentafluorophenyl)mercury (0.80 g; 1.50 mmol) and 3,5-diphenylpyrazole (0.66 g; 3.00 mmol) were stirred in THF (30 mL) at room temperature for 5 d. After filtration through a diatomaceous earth pad, the pale yellow filtrate was concentrated to 2 mL. Petroleum spirit (20 mL) was added causing formation of a white precipitate, which was dried under vacuum for 3.5 h; 0.89 g, 0.72 mmol, 72%. The IR spectrum is as above. $C_{69}H_{81}N_6O_6Sm$ (1240.78): calcd. Sm 12.12; found Sm 12.30.

**$[Yb(Ph_2pz)_3(THF)_2]$:** Yb metal filings (1.36 g; 7.89 mmol) and $SnMe_3(Ph_2pz)$ (0.55 g; 1.44 mmol) in THF were sonicated for 5 d. The initial deep orange-red solution lightened to a yellow colour after filtration and concentration. A white powder was obtained after evaporation of THF; 0.24 g, 51%. The IR spectrum is similar to that reported.[17] $C_{53}H_{49}N_6O_2Yb$ (975.03): calcd. Yb 17.75; found Yb 18.34.

### Preparation of (2,6-Di-*tert*-butyl-4-methylphenolato)lanthanoid(II) and 2,6-Di-*tert*-butyl-4-(methylphenolato)lanthanoid(III) Complexes

**$[Sm(OAr)_3(THF)]\cdot THF$:** THF (50 mL) was added to a mixture of Sm metal powder (1.52 g; 10.1 mmol), $SnMe_3(OAr)$ (0.89 g; 2.33 mmol) and 2 drops of Hg metal, and the resulting solution was sonicated for 5 d. The deep-coloured solution was filtered through a filter cannula, and THF was removed under vacuum. The precipitate was washed with hexane to remove $Sn_2Me_6$, giving a yellow powder; 0.33 g, 45%. IR $\tilde{\nu}$ = 1602 w, 1550 w, 1420 m, 1272 s, 1217 w, 1196 w, 1040 s, 918 m, 888 m, 862 m, 818 s, 802 s. 789 s, 722 w, 668 w cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 1.24 (br. s, 8 H, $CH_2$-*THF*), 1.71 (s, 54 H, *t*Bu), 2.43 (s, 9 H, Me), 3.19 (br. s, 8 H, $CH_2$-*THF*), 7.42 (s, 6 H, 3,5-H) ppm. $C_{53}H_{85}O_5Sm$ (952.60): calcd. Sm 15.78; found Sm 16.08.

**$[Yb(OAr)_2(THF)_3]\cdot THF$:** THF (50 mL) was added to a mixture of $SnMe_3(OAr)$ (1.10 g, 2.87 mmol), Yb metal filings (1.70 g, 9.82 mmol) and 2 drops of Hg metal, and the resulting mixture was ultrasonicated for 5 d. After allowing the suspension to settle, the deep orange supernatant solution was filtered and concentrated to 25 mL, resulting in golden-yellow crystalline $[Yb(OAr)_2(THF)_3]\cdot THF$; 1.12 g, 87%. The IR spectrum corresponds to that reported.[21b] $C_{46}H_{78}O_6Yb$ (900.15): calcd. Yb 19.22; found Yb 19.92. The unit cell, monoclinic, space group $P2_1$, $a$ = 9.7489, $b$ = 15.2423, $c$ = 15.3858 Å; $\beta$ = 95.62°, $V$ = 2277.68 Å$^3$, is in agreement with that reported[21a] [monoclinic, space group $P2_1$, $a$ = 15.393(4), $b$ = 15.619(5), $c$ = 9.859(2) Å; $\beta$ = 95.62(2)°, $V$ = 2359 Å$^3$]. A $^{119}$Sn{$^1$H} NMR (149 MHz, $C_6D_6$, 25 °C) spectrum of the filtrate shows the presence of $Sn_2Me_6$: $\delta$ = –109.0 ppm (reported: $\delta$ = –108.7 ppm)[12] but no $SnMe_3(OAr)$ signal. The $^1$H NMR spectrum ($C_6D_6$) of the concentrated solution shows phenolate resonances: $\delta$ = 2.18 (s, 6 H, Me), 7.42 (s, 4 H, 3,5-H) ppm (*t*Bu methyl resonances hidden by the residual THF solvent resonances).

**$SnMe_3(C_6F_5)$ with Yb Metal in THF:** $SnMe_3(C_6F_5)$ (1 mL, 8.03 mmol) was added under $N_2$ to a stirred mixture of Yb filings (1.14 g, 6.60 mmol) and 2 drops of Hg metal in THF (50 mL). After 2 d, no colour change was observed. The reaction mixture was ultrasonicated for 1 d resulting in a deep-coloured solution. A $^{19}$F NMR spectrum (282 MHz, 25 °C) of the solution showed $[Yb(C_6F_5)_2(THF)_4]$[28] and $SnMe_3(C_6F_5)$[26] in a 2:1 ratio: $\delta$ = –108.3 (br. m, 8 F, *o*-F, $[Yb(C_6F_5)_2(THF)_4]$), –121.5 [m, 2 F, *o*-F, $SnMe_3(C_6F_5)$], –154.0 [m, 1 F, *p*-F, $SnMe_3(C_6F_5)$], –161.5 (m, 14 F, *m*-F, $SnMe_3(C_6F_5)$ and *m*-, *p*-F, $[Yb(C_6F_5)_2(THF)_4]$) ppm (in agreement with the respective reported data {$[Yb(C_6F_5)_2(THF)_4]$:[28] $\delta$ = –108.3 (*o*-F) and –161.4 (*m*-, *p*-F) ppm; $SnMe_3C_6F_5$:[26] $\delta$ = –122.2 (*o*-F), –153.9 (*p*-F), –161.4 (*m*-F) ppm}.

**X-ray Crystallography:** Crystalline samples of $SnMe_3(OAr)$, $[Nd(Ph_2pz)_3(DME)_2]\cdot DME$, $[Nd(Ph_2pz)_3(THF)_3]\cdot THF$, $[Eu(Ph_2pz)_2(DME)_2]$, $[Eu(Ph_2pz)_3(DME)_2]\cdot 2DME$, $[Yb(Ph_2pz)_2(DME)_2]$, $[Sm(Ph_2pz)_3(THF)_3]\cdot 3THF$, and $[Yb(OAr)_2(THF)_3]\cdot THF$ were mounted on glass fibres in viscous hydrocarbon oil. Crystal data were collected using an Enraf–Nonius Kappa CCD instrument (Sn, Sm, Eu, Yb) or Bruker ApexII diffractometer (Nd) both equipped with monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å. All data were collected at 123 K, maintained using an open flow of nitrogen from an Oxford Cryostreams cryostat. X-ray data were processed using the DENZO program (Nonius)[29] or SAINT package (Bruker).[30] Structural solution and refinement was carried out using SHELXL-97[31] and SHELXS-97[32] utilising the graphical interface X-Seed.[33] For $[Eu(Ph_2pz)_3(DME)_2]\cdot 2DME$ there was one disordered DME molecule in the lattice which was modelled over two sites. The $\eta^2$-DME contains two disordered positions of the $C_2$ backbone, also successfully modelled. For $[Sm(Ph_2pz)_3(THF)_3]\cdot 3THF$ there were three THF molecules in the lattice with varying degrees of disorder. These were refined isotropically and no hydrogen atoms were attached. For $[Nd(Ph_2pz)_3(DME)_2]\cdot DME$, one $Ph_2pz$ phenyl group was successfully modelled as being disordered over two positions. The corresponding phenyl group of the same $Ph_2pz$ ligand also showed signs of disorder but this could not be satisfactorily modelled. The $\mu_2$-DME showed signs of being disordered in an analogous manner to that in the Eu complex but could not be modelled adequately. Crystal data and refinement parameters for all complexes are compiled below. CCDC-288000 to -288002 and -607830 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystal Data for $SnMe_3(OAr)$:** $C_{18}H_{32}OSn$, $M$ = 383.16, 0.5 × 0.5 × 0.375 mm, monoclinic, space group $P2_1/c$ (No. 14), $a$ = 13.421(3), $b$ = 15.265(3), $c$ = 9.0962(18) Å, $\beta$ = 93.34(3)°, $V$ = 1860.5(6) Å$^3$, $Z$ = 4, $D_c$ = 1.368 g/cm$^3$, $F(000)$ = 792, $2\theta_{max}$ = 55.8°, 19949 reflections collected, 4416 unique ($R_{int}$ = 0.0434). Final *GooF*

# Study of the In Situ Postintercalative Polymerization of Metanilic Anions Intercalated in NiAl-Layered Double Hydroxides under a Nitrogen Atmosphere

Min Wei,[a] Xiaofei Tian,[a] Jing He,[a] Min Pu,[a] Guoying Rao,[a] Heli Yang,[a] Lan Yang,[a] Tao Liu,[b] David G. Evans,[a] and Xue Duan*[a]

**Keywords:** In situ polymerization / Polyaniline / Layered double hydroxides / Nitrogen atmosphere

A new route has been developed for preparing polyaniline (PANI) layered double hydroxide (LDH) nanocomposites through in situ chemical oxidative polymerization of metanilic anions ($m$-$NH_2C_6H_4SO_3^-$) intercalated in NiAl LDHs under a nitrogen atmosphere by using pre-intercalated nitrate as an oxidizing agent. The interlayer space of NiAl LDHs has been used as an original nanoreactor for the in situ polymerization of the intercalated monomer. The whole process involves the synthesis of the precursor LDH [$Ni_2Al(OH)_6(NO_3)\cdot nH_2O$], the intercalation of the monomer metanilic anions into the LDH and its in situ polymerization between the layers by thermal treatment under a nitrogen atmosphere. The interlayer polymerization reaction was monitored by thermogravimetric analysis (TG), differential thermal analysis (DTA), mass spectrometry (MS), UV/Vis absorption spectroscopy, in situ X-ray absorption near edge structure (XANES) spectroscopy, in situ high-temperature X-ray diffraction (HT-XRD) and in situ Fourier transform infrared (FTIR) spectroscopy. The UV/Vis spectra provide evidence for the polymerization of the intercalated metanilic anions, and an increase in the interlayer distance from 16.0 to 17.2 Å is observed by HT-XRD. It has been found by the in situ techniques that the pre-intercalated nitrate anions act as the oxidizing agent that induces the polymerization of the interlayer monomer under a nitrogen atmosphere upon heating at 300 °C. The orientation of the interlayer polymerization product has also been proposed.

## Introduction

In recent years, considerable interest has been devoted to nanocomposites prepared from the assembly of an organic polymer and an inorganic layered material. Polymer intercalation nanocomposites prepared by using layered materials are expected to consist of a high degree of polymeric ordering and to exhibit advanced physicochemical properties compared with the individual parts.[1–5]

Among the organic polymers, polyaniline (PANI) has been and continues to be extensively studied as an organic component in such systems. Polyaniline is a promising conjugated polymer because of its simple synthesis, high conductivity, and excellent environmental stability, although it is associated with rather poor properties with respect to processing. Consequently, there are many reports focusing on the preparation of novel nanocomposites consisting of PANI with various layered materials such as $V_2O_5$ xerogel,[6] $MoO_3$ bronze,[7] graphitic oxide,[8] α-$RuCl_3$,[9] montmorillonite,[10] and layered metal phosphates.[11]

As for the layered materials, LDHs have received considerable attention because of their special intercalation properties. LDHs, which are widely known as a class of anionic clays, can be represented by the general formula $[M_{1-x}^{II}M_x^{III}(OH)_2]^{x+}(A^{n-})_{x/n}\cdot mH_2O$, where $M^{II}$ and $M^{III}$ are divalent and trivalent metal cations, respectively. $A^{n-}$ is an exchangeable inorganic or organic anion and the $x$ value, i.e. the charge density, is equal to the molar ratio $M^{III}/(M^{III} + M^{II})$. LDHs have positively charged layers, and a wide variety of charge-balancing anionic species have been intercalated into the gallery region.[12] As a result, LDHs are now well established as excellent anion-exchange materials and their extensive intercalation chemistry has widespread applications in the area of organic/inorganic nanocomposites.[13]

PANI/LDH nanocomposites were first reported by Challier and Slade.[14] Prior to the incorporation, the LDH host structure was exchanged with terephthalate or hexacyanoferrate anions in order to expand the basal spacing. The pre-swollen LDH materials were then heated at reflux with pure aniline. Analysis of the XRD patterns of the products confirmed the presence of multiple phases. More recently, interlayer polymerization methods have concentrated on heat treatment after polymeric monomer intercalation into the LDH. This process is the so called "soft thermal treatment", which is a two-step soft chemistry route that in-

cludes the intercalation of aniline sulfonic acid between the sheets of the LDHs and its subsequent in situ polymerization at a temperature below 200 °C in air. This approach can avoid the ion-exchange reaction competing with the interlayer polymerization as well as the destruction of the layered structure by external oxidizing agents. As in the case of other lamellar nanocomposites, atmospheric oxygen was found to play a major role in the polymerization process.[15–17]

In the present study, we report a new route for preparing PANI/LDH nanocomposites by using pre-intercalated nitrates as the oxidizing agent. In situ chemical oxidative polymerization of metanilic anions ($m$-$NH_2C_6H_4SO_3^-$) intercalated in NiAl LDHs under a nitrogen atmosphere has been performed for the first time. The whole process involves the synthesis of the precursor LDH [$Ni_2Al(OH)_6(NO_3)\cdot nH_2O$], the intercalation of the monomer metanilic anions into the LDH and its in situ polymerization between the layers by thermal treatment under nitrogen. Advantages of this method are: (1) the restricted interlayer region of the LDH makes it easier to obtain nanosized oligomers with uniform size; (2) the pre-intercalated $NO_3^-$ acting as an oxidizing agent can prevent the influence of mass transfer and diffusion on the polymerization reaction of the interlayer monomer. A combination of techniques, including TG–DTA–MS, UV/Vis, in situ XANES, in situ HT-XRD, and in situ FTIR spectroscopy, was used for the characterization of intercalated metanilic anions and their in situ interlayer polymerization. UV/Vis spectroscopy provides evidence for the polymerization of the intercalated monomer, and an increase in the interlayer distance from 16.0 to 17.3 Å is observed by HT-XRD. It has been found by the in situ techniques that the pre-intercalated nitrate anions act as the oxidizing agent, which induces the polymerization of the interlayer monomer upon heating at 300 °C under nitrogen. The orientation of the interlayer polymerization product has also been proposed.

## Results and Discussion

### Structure of NiAl-Metanilic LDHs

The X-ray diffraction patterns of the precursor NiAl-$NO_3$ LDH and the metanilic anion intercalated LDH are shown in Figure 1. In each case, the reflections can be indexed to a hexagonal lattice with $R$-3$m$ rhombohedral symmetry, commonly used for the description of the LDH structures.[19] The main diffraction peaks for NiAl-$NO_3$ LDH appear at 9.9° (003), 19.9° (006), 29.5° (009), and 62.1° (110) (Figure 1a), while the corresponding peaks for NiAl-metanilic LDH are observed at 5.4°, 11.1°, 16.8°, and 61.7° (Figure 1b), respectively. Apparently, the XRD pattern for NiAl-metanilic LDH exhibits the characteristic reflections of LDH materials with a series of (00$l$) peaks, which are evidence for the layered character. The interlayer distance for the NiAl-$NO_3$ LDH is 8.9 Å which is larger than that reported by Prinetto et al. (8.3 Å, for the existence of a large amount of $CO_3^{2-}$).[20] After the intercalation of metanilic acid, the value of the interlayer distance increased to 16.3 Å, which is 7.4 Å larger than that of NiAl-$NO_3$ LDH. The expansion of the basal spacing was due to the intercalation of metanilic anions into the LDH lamellar. Thus, the interaction of NiAl-$NO_3$ LDH with an aqueous solution of metanilic acid at pH 7.0 led to the anion exchange of $NO_3^-$ for the metanilic anions with conservation of the layered structure. As for the (110) reflection, no obvious shift was observed after intercalation, indicating that no significant change occurred in the LDH layer.

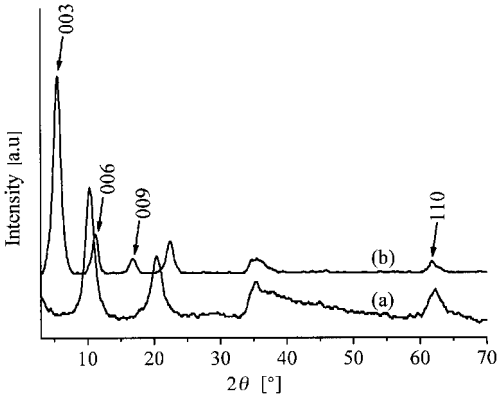

Figure 1. XRD patterns for (a) NiAl-$NO_3$ LDH and (b) NiAl-metanilic LDH.

The size of the gallery height of 11.5 Å, obtained by subtracting the thickness of the aluminium hydroxide layer (4.8 Å) from the interlayer distance (16.3 Å),[21] was much longer than a single perpendicular anion height (6.4 Å, calculated with Chemwin 6.0) but shorter than its double value. This may indicate that the guest anions are accommodated with an interpenetrating arrangement, leaving interstitial gaps between the monomers and the hydroxide sheets. Water molecules and nitrate anions occupy these interstitial spaces.

Compared with the NiAl-$NO_3$ LDH precursor (Figure 2a), three strong bands at 1599, 1484, and 1454 $cm^{-1}$ and two weak bands at 1257 and 1315 $cm^{-1}$ are observed in the FTIR spectrum of NiAl-metanilic LDH (Figure 2b), which can be attributed to the characteristic absorptions of metanilic anions.[22] The remarkable absorption band at 1384 $cm^{-1}$ resulting from the stretching vibration of $NO_3^-$ is also observed. It can be seen that not all of the $NO_3^-$ anions have been exchanged by metanilic anions, and similar results have also been reported by other researchers in studies of the intercalation of large anions into $NO_3$-LDH precursors.[23,24] Furthermore, elemental analysis data show that the chemical composition of the NiAl-metanilic LDH is $Ni_{0.66}Al_{0.34}(OH)_2(C_6H_4NH_2SO_3)_{0.23}(NO_3)_{0.11}\cdot 0.78H_2O$, which is consistent with the results of XRD and IR spectroscopy.

The structure of an LDH is based on brucite-like layers in which octahedrally coordinated metal ions share edges to form infinite sheets.[25] The area of each $[Ni_{1-x}Al_x(OH)_2]^{x+}$ octahedral unit is related to the unit cell parameter $a$ by the formula: $S = \sqrt{3}(a^2/2)$.[26] The value of $a$ can be

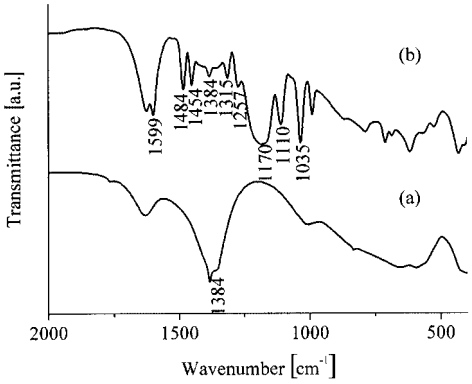

Figure 2. FT IR spectra for (a) NiAl-$NO_3$ LDH and (b) NiAl-metanilic LDH.

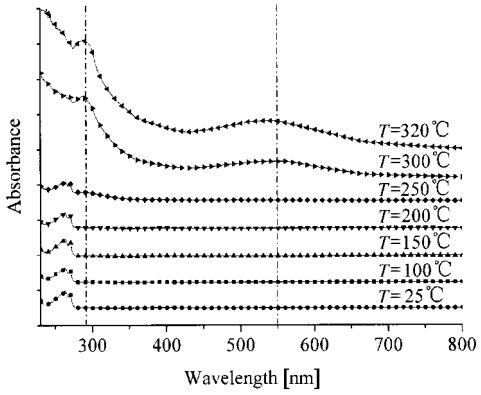

Figure 4. UV/Vis spectra of NiAl-metanilic LDH after heat treatment at different temperatures under nitrogen.

calculated from the XRD pattern in Figure 1b ($a = 2d_{110}$ = 2.99 Å). The area of each octahedral unit is therefore 7.74 Å$^2$, giving one positive charge per 23 Å$^2$ in the case of $x = 0.34$ (based on the chemical composition of NiAl-metanilic LDH given above). The maximum dimensions of the anion are calculated as 6–7 Å (calculated with Chemwin 6.0), and the corresponding cross-sectional area of the complex anions can thus be estimated to be in the range of 28–38 Å$^2$. Consequently, it is impossible for metanilic anions alone to balance the positive charge of the host layer, thereby accounting for the co-intercalation of $NO_3^-$.

On the basis of the discussion above, the structure of NiAl-metanilic LDHs can be represented as alternating NiAl-OH hydroxide layers and layers containing metanilic anions, $NO_3^-$, and water molecules. The schematic model of NiAl-metanilic LDHs is proposed in Figure 3.

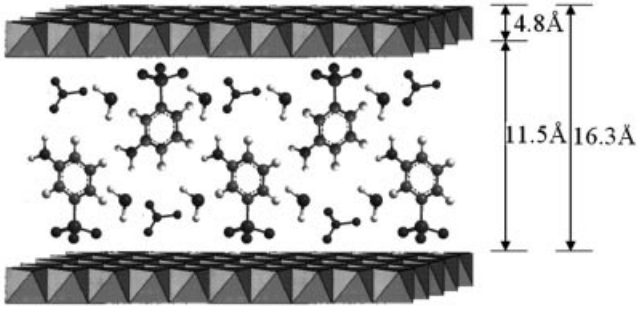

Figure 3. A schematic representation of the possible arrangement for NiAl-metanilic LDHs.

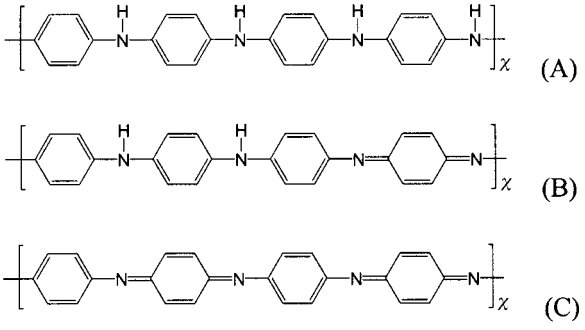
## UV/Vis Spectroscopy

Results obtained by UV/Vis spectroscopy give evidence for the polymerization of metanilic anions intercalated in NiAl LDHs by heat treatment under nitrogen. Figure 4 shows the optical absorption spectra, in the wavelength range 230–800 nm, of the synthesized NiAl-metanilic LDH and the resultant products after heat treatment at different temperatures.

It can be seen from Figure 4 that two absorption bands at 262 and 269 nm at room temperature are observed, which are associated with the phenyl group of the metanilic monomer. Along with the heat treatment, a strong absorption band (centered at 296 nm) corresponding to the $\pi_B$–$\pi_B$* transition appears when the temperature reaches 300 °C,[27] indicating that the polymerization of the intercalated monomer occurrs and the polymeric product possesses alternative benzenoid units (see structure A). The absorption band centered at 550 nm, attributable to charge transfer from the benzoid to the quinoid segments ($\pi_B$–$\pi_Q$*), becomes more obvious when the temperature increases to 320 °C (see structures B and C).[28] The $\pi_B$–$\pi_Q$* transition provides direct evidence that quinoid units are produced and the interlayer polyaniline sulfonic (PANIS) is present in its highly oxidized form. This result is consistent with reports on the study, by optical absorption spectroscopy, of the interconversion of polyaniline oxidation states.[27,29,30]



## In Situ XANES

Previous studies on PANI/CuCr LDH nanocomposites show that oxidative $Cu^{2+}$ has been used to induce the reaction of the oxidative polymerization of aniline in the interlayer galleries of pillared hosts.[14] In order to study whether $Ni^{2+}$ in the host layer participates in the interlayer polymerization in this system, in situ X-ray absorption near edge structure (XANES) measurements were carried out at the Ni *K*-edge. The features in the absorption edge are sensitive

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to the immediate Ni environment and local geometry. For the *K* edge, the existence of a pre-edge and its intensity are closely related to the degree of d–p orbital mixing, and loss of centrosymmetry can cause a large intensity of this peak. The dominant jump at the edge arises from the dipolar-allowed transition related to final electronic 4p states. Therefore, it is sensitive to the variation of the oxidation state of Ni.[31]

Figure 5 shows the normalized XANES spectra at the Ni *K*-edge of NiAl-metanilic LDH heated under nitrogen. The pre-edge peak (A) can be observed and this arises from the quadrupolar 1s→3d transition, which is directly related to the occupation of the 3d orbital and to the local symmetry. Peak C reflects the long-range ordering of the Ni–O or Ni–Ni shell.[32] During the heat treatment, a broadening of both peaks B and C was observed as a result of the thermal disorder. However, no significant shifts in the three peaks could be observed, implying that no dramatic redox process involving Ni occurred during the heat treatment. The results therefore demonstrate that $Ni^{2+}$ in the host layer does not serve as the oxidant for the interlayer oxidative polymerization and thus maintains the same valence in the temperature range 25–320 °C.

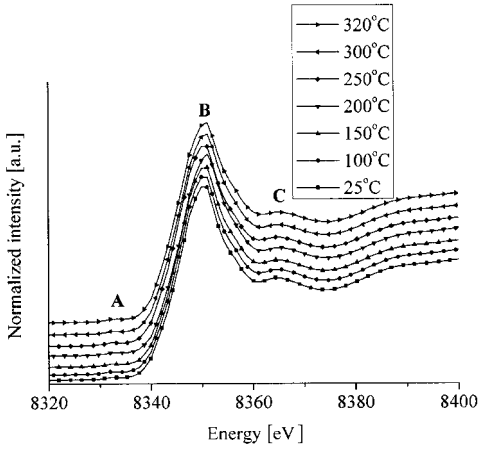


Figure 5. In situ XANES spectra at the Ni *K*-edge of NiAl-metanilic LDH heated from 25 to 320 °C under nitrogen.

## TG–DTA–MS Analyses

Simultaneous thermogravimetric (TG) and–differential thermal analyses (DTA) combined with analysis by mass spectrometry was found to be useful for following the in situ thermal behavior of the organic/inorganic nanocomposites over a wide temperature range.[33]

The TG, DTG, and DTA profiles for the pristine metanilic acid are shown in Figure 6. It can be seen that metanilic acid exhibits rather high thermal stability from room temperature to 400 °C under nitrogen. Two consecutive weight losses occur between 400 and 500 °C, with two corresponding strong endothermic peaks in the DTA curve attributable to the decomposition of metanilic anions.

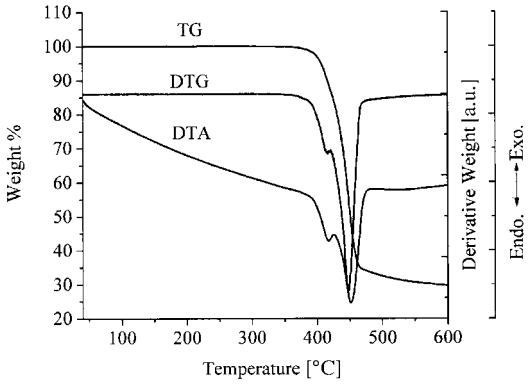

Figure 6. TG–DTA profiles of the pristine metanilic acid heated under nitrogen.

In the case of NiAl-metanilic LDH (Figure 7), the TG–DTA–MS determination shows that the thermal behavior under nitrogen can basically be described in four steps: the first step is observed between ambient temperature to about 100 °C. The TG curve displays a small weight loss with an endothermic peak in the DTA curve, and the corresponding MS determination (Figure 8 and Table 1) reveals one $H_2O^+$ ($m/z$ = 18) peak at ca. 100 °C. This process is associated with the volatilization of the adsorbed water in the composite.

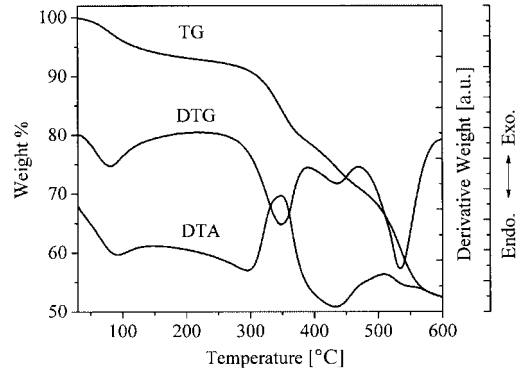

Figure 7. TG–DTA profiles of NiAl-metanilic LDH heated under nitrogen.

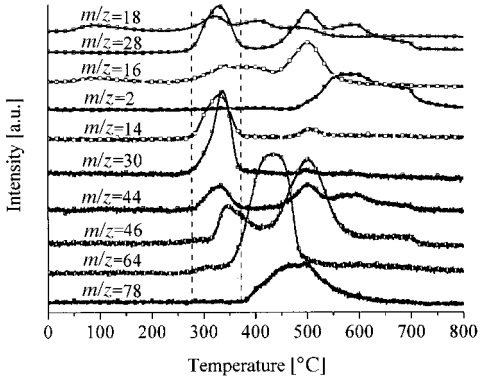

Figure 8. Mass analyses of NiAl-metanilic LDH heated under helium.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 1. Results for MS analyses of NiAl-metanilic LDH.

| Proposed positive ion | $H_2^+$ | $N^+$ | $O^+$ | $H_2O^+$ | $N_2^+$ | $NO^+$ | $N_2O^+$ | $NO_2^+$ | $SO_2^+$ | $C_6H_4^+$ |
|---|---|---|---|---|---|---|---|---|---|---|
| *m*/*z* | 2 | 14 | 16 | 18 | 28 | 30 | 44 | 46 | 64 | 76 |
| Intensity [A] | $10^{-11}$ | $10^{-11}$ | $10^{-11}$ | $10^{-10}$ | $10^{-10}$ | $10^{-11}$ | $10^{-11}$ | $10^{-12}$ | $10^{-12}$ | $10^{-13}$ |

The second step takes place in the temperature range 300–350 °C. The TG curve shows a big weight loss accompanied by a strong exothermic peak in the DTA curve. Several fragments assigned to $N_2^+$ (*m*/*z* = 28), $NO^+$ (*m*/*z* = 30), $N_2O^+$ (*m*/*z* = 44), $H_2O^+$ (*m*/*z* = 18), and $NO_2^+$ (*m*/*z* = 46) appear in the corresponding MS curves. For the nitrate-containing LDHs, the release of $NO_2$ and NO was generally attributable to the pyrolysis of nitrates, whereas the interlayer nitrate would be evolved as NO and $N_2O$ only during the TPR experiment under hydrogen.[34] In this work, the release of $N_2$, NO, and $N_2O$ at the same time provides evidence that the co-intercalated nitrate anions are involved in an interlayer redox reaction. The $NO_2^+$ peak lags behind the $N_2^+$, $NO^+$, $N_2O^+$, and $H_2O^+$ peaks, indicating that pyrolysis of the pre-intercalated nitrates occurs after reduction. The DTA curve in this step displays a strong exothermic peak at about 320 °C, which was not found in the DTA curve of the pristine metanilic acid. Roland-Swanson et al. have reported DTA traces with such an exothermic peak assigned to the polymerization of the 3-sulfopropyl methacrylate potassium salt (SPMA) intercalated in ZnAl LDHs by thermal treatment.[35] Because the reaction was complete without the use of any external chemical agent, the polymerization process was interpreted as an oxidative reaction induced by atmospheric oxygen. In the present study, this strong exothermic peak and the reduction of the co-intercalated nitrates correspond to the emergence of the new absorption bands attributable to the $\pi_B$–$\pi_B$* and $\pi_B$–$\pi_Q$* transitions in UV/Vis spectra, which demonstrates the polymerization of metanilic anions intercalated NiAl LDHs in the same temperature range. On the basis of the discussion above and of the comparison with other studies on the thermal behavior of the polymeric monomer/LDH nanocomposites, the strong exothermic process under an inert atmosphere in this work can be assigned to the chemical oxidative polymerization of the interlayer monomer with the co-intercalated nitrates acting as the oxidizing agent. This will be further discussed in the next sections.

The third weight loss (350–450 °C) is due to the pyrolysis of the hydroxide layers and the interlayer organic materials, which results in an enhanced signal of $H_2O^+$ (*m*/*z* = 18) and $SO_2^+$ (*m*/*z* = 64). The corresponding endothermic peak is observed at ca. 430 °C. The complete thermal decomposition of the nanocomposite occurs in the fourth step (450–600 °C).

### In Situ FTIR

Figure 9 shows the in situ FTIR spectra for NiAl-metanilic LDH heated to different scheduled temperatures under nitrogen. Table 2 summarizes the assignments of the IR absorption bands for metanilic-intercalated LDH and its thermal products.[36,37]

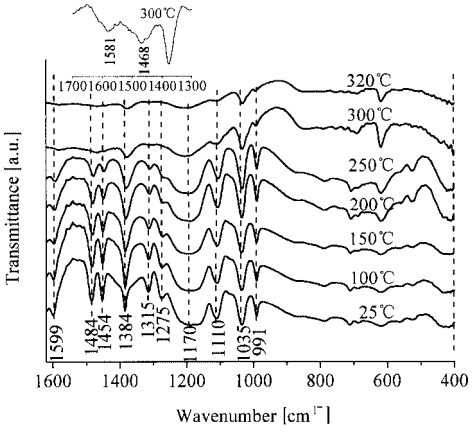

Figure 9. In situ FTIR spectra for the thermal polymerization of NiAl-metanilic LDH.

Table 2. Assignments for IR absorption bands for metanilic-intercalated LDH and its thermal products.[a]

| Frequency [$cm^{-1}$] | Assignment |
|---|---|
| 1599 | disorder-induced C–C ring stretching |
| 1581 | stretching of N=Q=N |
| 1484 | ring stretching of C=C |
| 1468 | stretching of N=B=N |
| 1453 | stretching of benzene ring |
| 1315 | N–H in or out of plane bending |
| 1275 | C–H bending or C–N stretching |
| 1170 | C–H bending in plane |
| 1110 | C–S bending in plane |
| 1035 | S=O bending |
| 991 | C–H bending out of plane |

[a] Abbreviations: B, benzenoid unit; Q, quinonoid unit.

It can be seen that very little change is observed for the three strong bands at 1599, 1484, and 1454 $cm^{-1}$ and the weak band at 1315 $cm^{-1}$, which are characteristic absorptions of metanilic anions from room temperature to 250 °C. When the temperature increases to 300 °C, the former four characteristic bands weaken remarkably because of the increase in the conjugated degree of the polymerization products upon thermal treatment. Moreover, the emergence of the bands at 1581 and 1468 $cm^{-1}$ in the spectrum of NiAl-metanilic LDH at 300 °C indicates that the polymerization product is in a high oxidation state.[38] The comparison of the IR spectrum of the original metanilic-intercalated LDH and those of its oxidation products after treatment at 300 °C reveals a sharp decrease in the intensity of the bands at 1170 ($\upsilon_{C-H}$ in plane), 1275, and 1315 $cm^{-1}$, which points to a substantial decrease in the number of amino groups ($-NH_2$). This further confirms the formation of an interlayer polyconjugated system. Moreover, the intensity of the band at 1384 $cm^{-1}$ attributable to cointercalated $NO_3^-$ decreases sharply as the temperature reaches 300 °C, thereby giving evidence that $NO_3^-$ is engaged in the interlayer redox reaction. This is in agreement with the results of UV/Vis spectroscopy and TG–MS.

### In Situ HT-XRD

In order to get further insight into the thermal polymerization process of the monomer intercalated NiAl LDH, in situ X-ray measurements were carried out. The temperatures at which the X-ray data were collected were defined on the basis of TG–DTA analysis. The in situ HT-XRD patterns of the intercalation product NiAl-metanilic LDH in the temperature range 25–320 °C under nitrogen are shown in Figure 10. The variation in the $d_{003}$ basal spacing of NiAl-metanilic LDH with temperature is displayed in Figure 11.

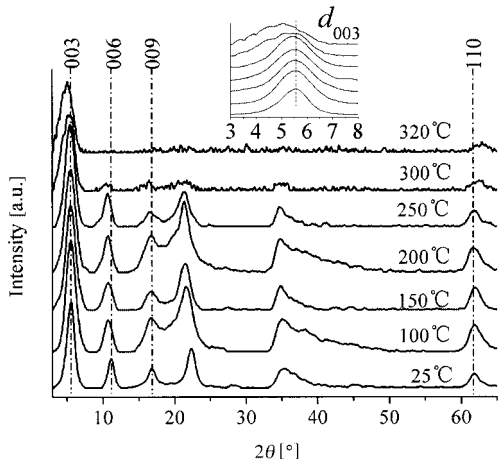

Figure 10. In situ HT-XRD patterns of NiAl-metanilic LDH in the temperature range 25–320 °C.

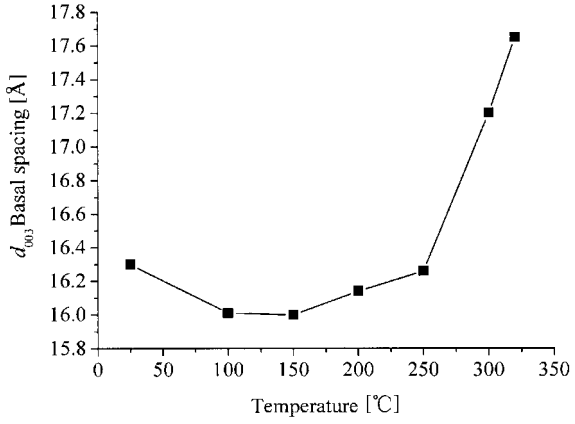

Figure 11. The relationship between the $d_{003}$ basal spacing and temperature.

Upon increasing the temperature, the (003), (006), and (009) reflections of NiAl-metanilic LDH move to a slightly higher $2\theta$ angle (as shown in Figure 10), and the (003) basal spacing decreases from 16.3 to 16.0 Å (Figure 11) when the material was heated from 25 °C to 150 °C. This contraction may result from the loss of absorbed water and parts of gallery water.[39] However, the value of $d_{003}$ slowly increases from 16.0 Å at 150 °C to 16.2 Å at 250 °C. This might be due to the reorientation of the interlayer monomer accompanied by the loss of the gallery water.

When the temperature reaches 300 °C, the (003) reflection of the nanocomposite becomes broader and moves to a remarkably lower $2\theta$ angle. The interlayer distance increases drastically from 16.2 Å at 250 °C to 17.2 Å at 300 °C, indicating that interlayer polymerization of the interlamellar species occurs. This phenomenon was also observed in the case of post-intercalative polymerization of aniline and its derivatives in layered metal phosphates after thermal treatment at 130 °C in air.[11] In addition, the color of the nanocomposite turns from bright green to dark brown after the heat treatment. The broadening of the (003) reflection and the decrease in intensity of other diffraction peaks of the nanocomposite at 300 °C indicate the decrease in ordered stacking sequences and in crystallinity during the polymerization process. Nevertheless, the diffraction maximum between the $2\theta$ values of 62 and 63° (the spectrum at 300 °C in Figure 10) can still be observed, indicating the conservation of the lamellar structure with no substantial structural collapse during the interlayer polymerization reaction.

The coupling between the monomers and the arrangement of their subsequent dimerization or polymerization have been discussed in term of the gap sizes, which can be calculated by using the peak fit program of XRD-6000 Version 4.1.[17] The geometry and atomic charges of the possible dimers have been optimized by using the MOPAC semi-empirical method, employing the PM3 Hamiltonian.[40]

Figure 12 shows the peak fit results of $d_{003}$ at 300 °C, at which the interlayer polymerization occurs. Three different $d_{003}$ values, i.e. 15.77, 17.48, and 20.07 Å were obtained in this case, and the corresponding gallery heights were calculated to be 10.97, 12.68, and 15.27 Å, respectively, by subtracting the inorganic layer thickness of 4.8 Å. The polymerization between monomers located on different layers (opposite inner side) may proceed iso- or syndiotactically, and the coupling between monomers may occur by a linkage (α,β), (β,β), or (N,N). The calculated lengths of the three possible dimers are 10.43, 11.63, and 12.42 Å (as shown in Scheme 1), respectively. It can be concluded that the coupling between monomers most likely occurs by the linkages (α,β) and (N,N) since the calculated lengths of the two possible dimers (10.43 and 12.42 Å) correspond well with the two gallery heights of 10.97 and 12.68 Å. As a result, the coupling between monomers on different layers hereinbefore should give rise to the quasi-monolayer arrangement by the linkage (α,β) (Figure 13a), whereas the gallery height of 15.27 Å may result from the bilayer arrangement when polymerization occurs between the two monomers on the same layer (Figure 13b).[17] The linkage of N and N charac-

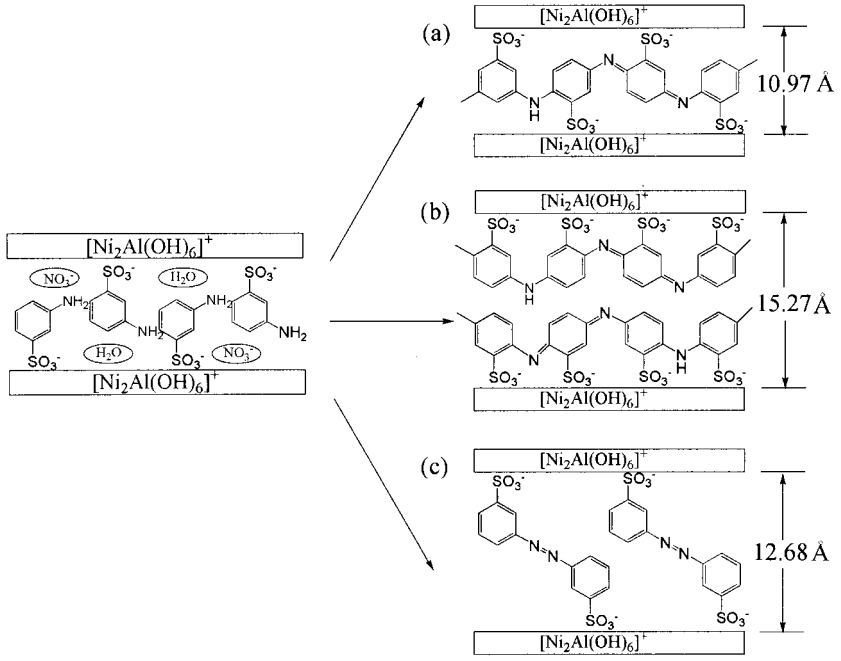

Figure 13. Schematic representations of the interlayer polymerization products.

teristics, which results from the "head-to-head" coupling (Figure 13c), was observed only in the spectra of products prepared under neutral or basic conditions. For instance, the formation of azobenzene derivatives in basic or in an acetonitrile/pyridine medium has also been reported by Wawzonek and MacIntyre.[41] On the basis of the discussion above, it can be concluded that the coupling between monomers most likely occurs by the (α,β) and (N,N) linkages, and the main coupling likely occurs by an (α,β) linkage. This is in agreement with the much earlier work of Mohilner et al., in which aniline oxidation products obtained in neutral or weakly acidic media have a predominantly "head-to-tail" arrangement.[42]

## TEM

The TEM micrographs of the prepared materials are illustrated in Figure 14. It can be seen that NiAl-metanilic LDH exhibits the characteristic LDH platelet, an ill-defined shape with a uniform size from 200 to 300 Å (Figure 14a). This morphological result is consistent with that from HT-XRD analysis. The polymerization product PANIS shows a similar platelike morphology (Figure 14b) with average particle size of 50–100 Å. Such a small size is possibly due to the restriction on the chain growth of PANIS afforded by the layers of LDH.

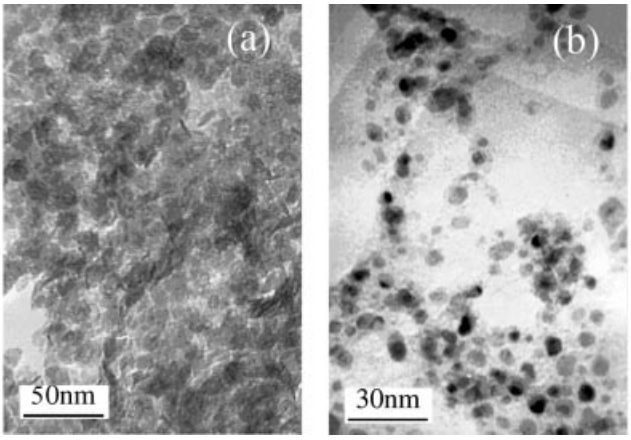

Figure 14. TEM images of (a) NiAl-metanilic LDH and (b) the polymerization product (PANIS).

## Conclusions

The in situ chemical oxidative polymerization of metanilic anions ($m$-$NH_2C_6H_4SO_3^-$) intercalated in NiAl LDH has been performed for the first time by the use of pre-intercalated nitrate as the oxidizing agent. From the characterization by XRD, IR spectroscopy, elemental analysis, and geometrical considerations, the schematic model of NiAl-metanilic LDH has been proposed in which the structure can be represented as alternating NiAl-OH hydroxide layers and layers containing metanilic anions, $NO_3^-$ ions, and water molecules.

Results obtained by UV/Vis spectroscopy give evidence for the polymerization of the metanilic anions intercalated NiAl LDH when the temperature reaches 300 °C. The particle sizes of 50–100 Å of the interlayer polymerization product determined by TEM microscopy indicates the low conjugation extent of the interlayer PANIS.

In situ XANES demonstrates that $Ni^{2+}$ in the host layer does not serve as the oxidant for interlayer oxidative polymerization. According to the results of TG–DTA–MS for the pristine metanilic acid and the NiAl-metanilic LDH under nitrogen, we propose that the pre-intercalated nitrate anions act as the oxidant, which induces the polymerization of the interlayer monomer under nitrogen upon heating at 300 °C.

In situ FTIR and in situ HT-XRD provide further insight into the thermal polymerization process. The basal spacing increases from 16.0 to 17.2 Å, and the characteristic vibrational absorptions of polyaniline emerge at 300 °C under nitrogen. It can be concluded, on the basis of the peak fit program and the MOPAC semi-empirical method, that the coupling between monomers most likely occurs by the (α,β) and (N,N) linkages. The possible schematic arrangement for the interlayer products has also been proposed.

## Experimental Section

**Reagents:** All chemicals used in this synthesis including $Ni(NO_3)_2{\cdot}6H_2O$, $Al(NO_3)_3{\cdot}9H_2O$, NaOH, and metanilic acid ($m$-$NH_2C_6H_4SO_3^-$) were of analytical grade and were purchased from Aldrich and used without any further purification. High purity nitrogen gas ($O_2 < 1$ ppm) and high purity helium gas ($O_2 < 1$ ppm) were purchased from the Beijing Chemical Plant Limited. All solutions were prepared with distilled and decarbonated water.

**Synthesis:** The precursor LDH $[Ni_2Al(OH)_6(NO_3)]{\cdot}nH_2O$ was prepared following a standard aqueous coprecipitation and thermal crystallization method.[18] A solution of NaOH (8.0 g, 0.20 mol) in water (100 mL) was added dropwise over 2 h to a solution (100 mL) containing $Ni(NO_3)_2{\cdot}6H_2O$ (19.4 g, 0.066 mol) and $Al(NO_3)_3{\cdot}9H_2O$ (12.5 g, 0.033 mol), with vigorous stirring under nitrogen. The pH value of the solution at the end of addition was 7.0. The resultant gelatinous precipitate was maintained at 100 °C for 72 h, centrifuged, and washed thoroughly with water before drying at 70 °C for 24 h under vacuum.

The metanilic intercalated NiAl-LDH was prepared following the ion-exchange method. A solution (100 mL) of metanilic acid (10.4 g, 6.0 mmol) with a pH value adjusted to 7.0 using NaOH (2.0 M) was added to a suspension of NiAl-$NO_3$ LDH (5.0 g, *ca.* 1.5 mmol) in water (100 mL). The mixture was held at 30 °C under nitrogen for 72 h. The product was washed extensively with water, centrifuged, and dried under vacuum for 24 h.

For the thermal treatment, the hybrid phase was placed in a tube furnace heated at 25, 100, 150, 200, 250, 300, or 320 °C for 0.5 h under nitrogen.

**Characterization Techniques:** Powder X-ray diffraction (XRD) measurements were performed on a Rigaku XRD-6000 diffractometer, using Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å) at 40 kV and 30 mA. Data were collected over the angular range of $2\theta$ from 3° to 70° at a scanning rate of 0.02° per second at room temperature. The UV/Vis spectra were collected in reflectance mode using a Shimadzu UV-2401 spectrophotometer in the 230–800 nm region (the samples were dissolved in 0.1 M hydrochloric acid). Fourier transform infrared (FTIR) spectra were recorded using a Vector 22 (Bruker) spectrophotometer in the range 4000 to 400 $cm^{-1}$ with 2 $cm^{-1}$ resolution. The standard KBr disk (1 mg of sample in 100 mg of KBr) was used. In situ XANES spectra were collected at the XAFS station (beam line 4W1B) of the Beijing Synchrotron Radiation Facility. The storage ring energy was 2.2 GeV and the current was 50–60 mA. The X-rays were monochromated by using a Si (111) single crystal. Samples were shaped into ingots with a thickness of about 1 mm. X-ray absorption spectra of the Ni $K$-edge were collected at ambient temperature up to 320 °C with a heating rate of 5 °C $min^{-1}$ under nitrogen in the transmission mode. The incident and transmission X-ray intensities were detected using ion chambers which were installed in front of and behind the sample, respectively. In situ HT-XRD measurements were performed on a Rigaku D/max 2500VB2+/PC diffractometer in the temperature range 25–320 °C under nitrogen by using Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å) at 40 kV and 30 mA. The samples as disoriented powders were scanned in steps of 0.02° in the $2\theta$ range 3°–70° by using a count time of 4 s per step. An α-$Al_2O_3$ substrate was used. In situ FTIR spectra were recorded with a Nicolet 60sxb spectrometer in the range 4000 to 400 $cm^{-1}$ with 2 $cm^{-1}$ resolution. The spectra were obtained every 10° with a heating rate of 5 °C $min^{-1}$ under nitrogen. The standard KBr disk method (1 mg of sample in 100 mg of KBr) was used. TG–DTA analyses were carried out under nitrogen (flux of 100 mL $min^{-1}$) with a Seiko 6300 simultaneous DTA–TGA apparatus from Seiko Instruments, at a heating rate of 5 °C $min^{-1}$, with $Al_2O_3$ as a reference. Simultaneous TG–MS analyses were performed with a Pyris Diamond TG–DTA instrument coupled to a ThermoStar™ QM220 mass spectrometer by a quartz capillary transfer line at 180 °C. The heating rate was 5 °C $min^{-1}$, with a helium flow of 100 mL $min^{-1}$. The scanning speed of mass was 1 a.m.u $s^{-1}$, with a filtering time 0.03 s. The TGA apparatus operated at atmospheric pressure, and the mass spectrometer at a working pressure of $3 \times 10^{-6}$ mPa and an electron energy of 70 eV. The proposed mass number, the ion current intensity, and the amplifying rate are listed in Table 1. Elemental analyses were performed with a Shimadzu ICPS-7500 instrument. C, H, and N content were determined by using an Elementarvario elemental analysis instrument. TEM images were obtained by using a JEOL JEM-1200 instrument operating at an acceleration voltage of 80 kV. The TEM samples were ultrasonically dispersed in water, and then a suspension was deposited onto a holey carbon film deposited on a Cu grid.

# Preparation of Hydroxylamine and *O*-Methylhydroxylamine Complexes of Manganese and Rhenium

**Gabriele Albertin,*[a] Stefano Antoniutti,[a] Jorge Bravo,[b] Jesús Castro,[b] Soledad García-Fontán,[b] Mª Carmen Marín,[b] and Marco Noè[a]**

**Keywords:** Hydroxylamine / *O*-Methylhydroxylamine / CO and P ligands / Manganese / Rhenium / Oxidation

Hydroxylamine and *O*-methylhydroxylamine complexes $[M(NH_2OH)(CO)_nP_{5-n}]BPh_4$ and $[M(NH_2OCH_3)(CO)_nP_{5-n}]BPh_4$ [M = Mn, Re; $n$ = 1, 2, 3; P = $P(OEt)_3$, $PPh(OEt)_2$, $PPh_2OEt$] were prepared by allowing hydrides $MH(CO)_nP_{5-n}$ to react first with triflic acid and then with an excess of hydroxylamine. Bidentate phosphane and phosphite can also be used to prepare both $NH_2OH$ and $NH_2OCH_3$ complexes of manganese and rhenium of the $[M(NH_2OR)(CO)_2(P–P)\{P(OEt)_3\}]BPh_4$ and $[M(NH_2OR)(CO)_3(P–P)]BPh_4$ [R = H, $CH_3$; P–P = $Ph_2POCH_2CH_2OPPh_2$, $Ph_2PO(CH_2)_3OPPh_2$, $Ph_2PN(CH_3)CH_2CH_2N(CH_3)PPh_2$] types with the use of $MH(CO)_2(P–P)\{P(OEt)_3\}$ and $MH(CO)_3(P–P)$ as precursors. The complexes were characterized spectroscopically and by the X-ray crystal-structure determination of $[Re(NH_2OCH_3)(CO)_2\{PPh(OEt)_2\}_3]BPh_4$ and $[Re(NH_2OCH_3)(CO)_3\{Ph_2PO(CH_2)_3OPPh_2\}]BPh_4$. Oxidation of the hydroxylamine complexes with $Pb(OAc)_4$ was studied at –40 °C and led to an unstable compound tentatively characterized as a nitroxyl [M]–N(H)=O derivative.

## Introduction

Despite the very large number of transition-metal complexes that contain monodentate nitrogenous ligands[1] such as ammonia, amines, imine, nitrile, nitrogen monoxide, hydrazine, etc., the coordination chemistry of hydroxylamine, $NH_2OH$, may be considered somewhat unexplored. A glance through the literature, in fact, shows that hydroxylamine complexes are very scarce,[2] and only recently have some examples of complexes of the $[MX(NH_2OH)(CO)_2(PPh_3)_2]CF_3SO_3$ (M = Ru, Os; X = Cl, Br) and $[Re(NH_2OH)(CO)_3(PPh_3)_2]CF_3SO_3$ types been reported.[3]

This feature is rather surprising in view of the fact that the hydrazine molecule, $NH_2NH_2$, which is isoelectronic to and somewhat similar to $NH_2OH$ forms a number of stable and isolable transition-metal complexes.[4,5] A reason for the scarce number of hydroxylamine derivatives may be a result of the presence of the OH group that is bonded to $NH_2$, which makes the $NH_2OH$ a poor ligand either as an *N*-bonded, or as an *O*-bonded group. However, the instability of the $NH_2OH$ molecule in the free state may also contribute to the fact that the synthesis of hydroxylamine derivatives is somewhat difficult.

We have interest in the chemistry of transition metal complexes with nitrogen-containing ligands and have reported the synthesis and the reactivity of hydrazine complexes of Mn, Re, Fe, Ru, and Os stabilized by phosphite ligands.[6] Recently, we have focused our attention on the $NH_2OH$ molecule and reported the preparation of both mono- and bis(hydroxylamine) complexes of ruthenium and osmium of the $[MH(NH_2OH)P_4]^+$ and $[M(NH_2OH)_2P_4]^{2+}$ types (M = Ru, Os; P = phosphites).[7]

These studies have now been extended to manganese and rhenium as a central metal to determine whether the synthesis of hydroxylamine complexes can be achieved for these metals and, if possible, to compare these complexes with related hydrazine derivatives.[6a,6g] The results of these studies, which allow the synthesis of the first hydroxylamine and methylhydroxylamine complexes of manganese and of new examples for rhenium, are reported here.

## Results and Discussion

The synthesis of hydroxylamine complexes of manganese(I) and rhenium(I) was achieved by the reaction of the $MH(CO)_nP_{5-n}$ hydride[6a,8] first with an equimolar amount of triflic acid (HOTf) and then with an excess of hydroxylamine, as shown in Scheme 1 and Scheme 2.

Protonation of the $MH(CO)_nP_{5-n}$ hydride with HOTf leads to the evolution of $H_2$ and the formation of the triflate complexes $M(\kappa^1\text{-OTf})(CO)_nP_{5-n}$.[6a,8] Substitution of the labile $\kappa^1$-OTf ligand with $NH_2OH$ afforded the final hydroxylamine complexes, which were isolated in good yields and characterized. Crucial for the success of the synthesis is to carry out the reaction at 0 °C for 5–8 hours and to use a large excess of free $NH_2OH$. Otherwise, either intractable

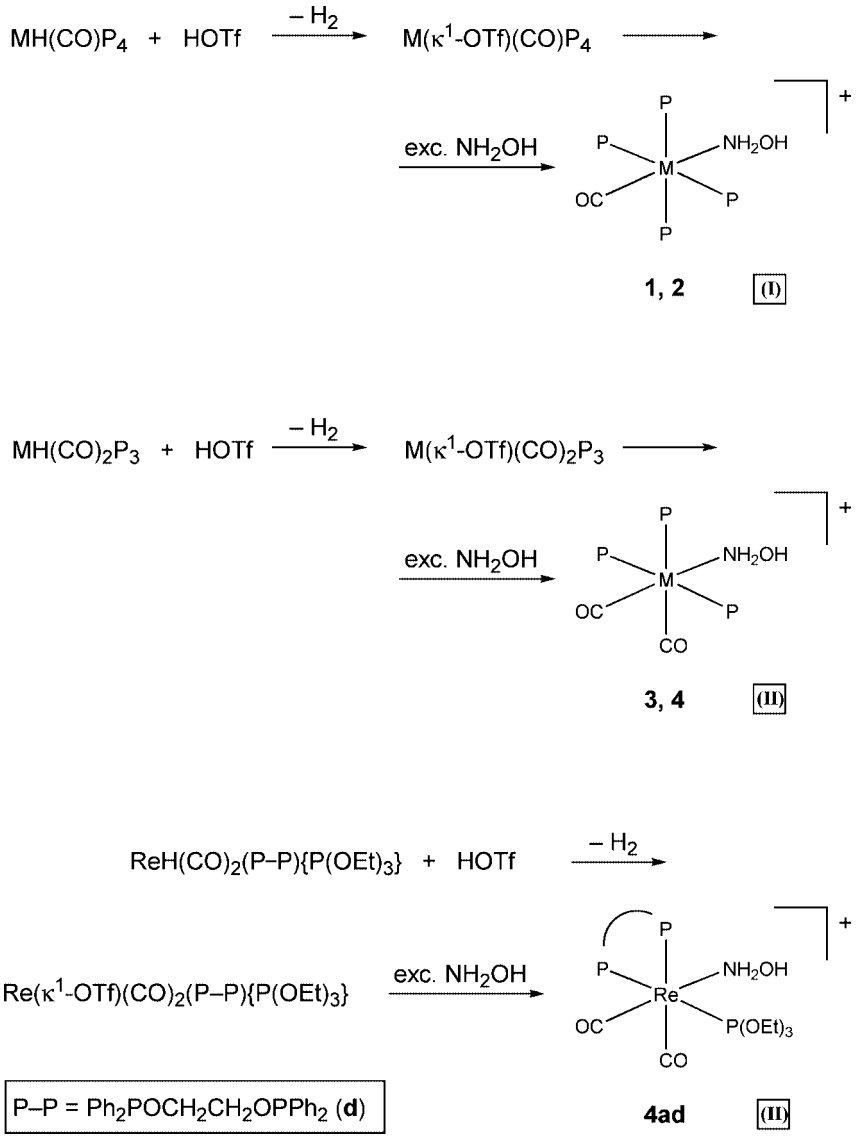

Scheme 1. M = Mn (**1**, **3**), Re (**2**, **4**); P = $P(OEt)_3$ (**a**), $PPh(OEt)_2$ (**b**); OTf = $CF_3SO_3$.

mixtures of products, or very low yields in the complexes are obtained. It should also be noted that only the mono- $[M(CO)P_4]$ and the dicarbonyl $[M(CO)_2P_3]$ fragments with $P(OEt)_3$ and $PPh(OEt)_2$ ligands allow the synthesis of hydroxylamine complexes. With tricarbonyl complexes $[M(CO)_3P_2]$, a different phosphane such as $PPh_2OEt$ or $Ph_2PN(Me)CH_2CH_2N(Me)PPh_2$ (P–P) must be used to yield hydroxylamine complexes $[Mn(NH_2OH)(CO)_3(PPh_2OEt)_2]BPh_4$ (**5c**) and $[Re(NH_2OH)(CO)_3(P–P)]BPh_4$ (**6e**) [Scheme 2].

It seems, therefore, that the electronic properties of the $[M(CO)_nP_{5-n}]$ (M = Mn, Re) fragment are important in determining the synthesis and the stabilization of the $NH_2OH$ complexes. In particular, it seems that an electron-poor metal center is not able to stabilize the coordination of $NH_2OH$. With good π-acceptor[9] phosphanes such as $P(OEt)_3$ and $PPh(OEt)_2$ only mono- and dicarbonyl compounds $[M(NH_2OH)(CO)P_4]^+$ and $[M(NH_2OH)(CO)_2P_3]^+$ were obtained, while stable tricarbonyl cations $[M(NH_2OH)(CO)_3P_2]^+$could only be prepared through the use of phosphanes that are less π-acidic than $PPh(OEt)_2$, such as $PPh_2OEt$ and P–P, which were used in complexes **5c** and **6e**. The presence of four strong π-acceptor carbonyl ligands in the $[M(CO)_4P]$ fragment makes the metal center so electron-poor that it does not allow for the preparation of hydroxylamine complexes with any phosphane used.

A comparison between the behavior of $NH_2OH$ and the somewhat related $NH_2NH_2$ ligands toward the $[M(CO)_nP_{5-n}]$ fragment reveals that when hydrazine was used the synthesis of mixed-ligand complexes of manganese and rhenium with carbonyl and phosphite compounds was easily achieved with every $[M(CO)_nP_{5-n}]$ fragment,[6a,6g] and stable complexes were even obtained with the tetracarbonyl $[M(NH_2NH_2)(CO)_4P]^+$ cation, but hydroxylamine was found to be a more problematic ligand. Only appropriate fragments, in fact, allow for the synthesis of the corresponding hydroxylamine derivatives, which highlights the fact that $NH_2OH$ is a molecule that is hard to coordinate.

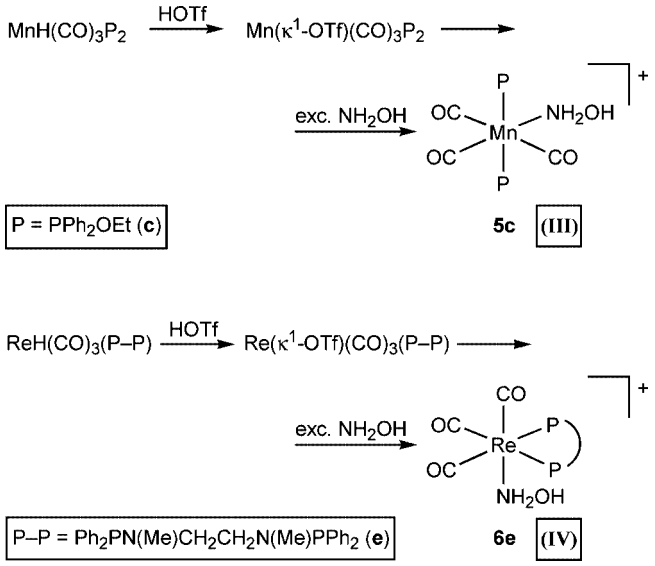


Scheme 2.

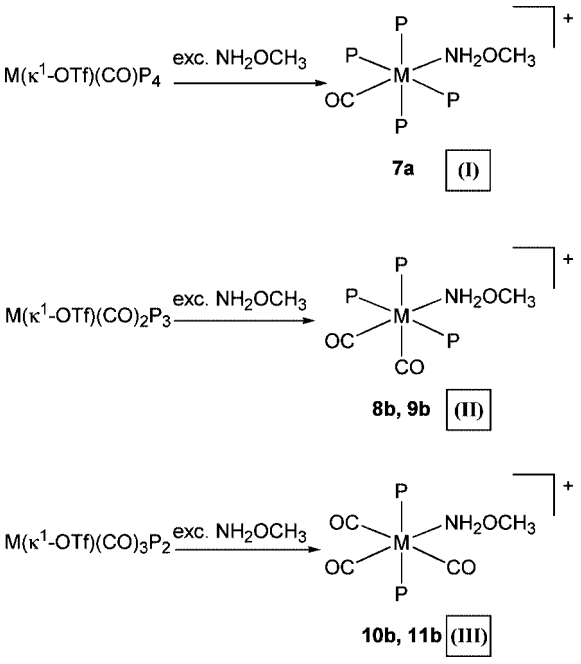
However, the use of the triflate complex $M(\kappa^1\text{-OTf})(CO)_nP_{5-n}$ ($n$ = 1, 2, 3) as a precursor allows for the synthesis of the first hydroxylamine complexes of manganese, in addition to new examples of rhenium derivatives. Only one example, in fact, of $NH_2OH$ complexes of rhenium[3b] is reported in the literature, while only quantum chemical calculations[10] are reported for hydroxylamine complexes of manganese.

The results obtained with hydroxylamine prompted us to extend our study to the use of both *N*- and *O*-substituted $NH_2OH$ as a ligand. We began to investigate the behavior of the *N*-methyl, $NH(CH_3)OH$, and hydroxylamine towards the triflate complex $M(\kappa^1\text{-OTf})(CO)_nP_{5-n}$, but in no case was an *N*-methylhydroxylamine complex obtained. The steric hindrance of the methyl group probably prevents the *N*-coordination of the $NH(CH_3)OH$ molecule.

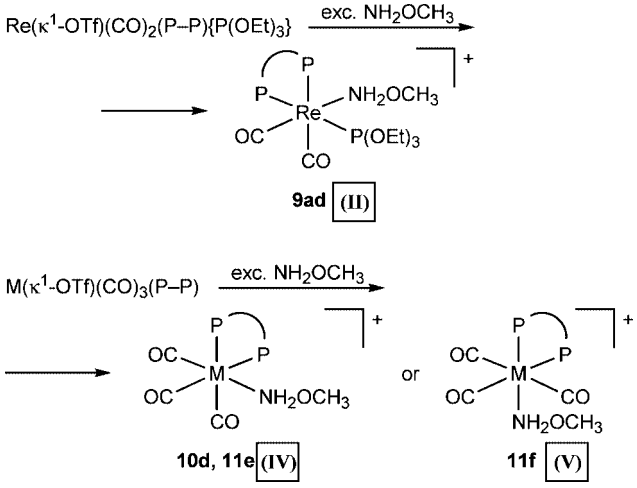
The *O*-methylhydroxylamine, on the other hand, quickly reacts with the triflate complexes $M(\kappa^1\text{-OTf})(CO)_nP_{5-n}$ containing monodentate phosphite ligands (P) to give the $NH_2OCH_3$ derivatives **7**–**11** which were isolated in good yield and characterized (Scheme 3).

The reaction also proceeds with triflate precursors $Re(\kappa^1\text{-OTf})(CO)_2(P–P)\{P(OEt)_3\}$ and $Re(\kappa^1\text{-OTf})(CO)_3(P–P)$, containing bidentate phosphane ligands, to yield the related $NH_2OCH_3$ complexes **9**–**11**, as shown in Scheme 4.

The syntheses of the $NH_2OCH_3$ complexes **7**–**11** can be carried out at room temperature and do not need particular attention to give the final complexes in good yields. Furthermore, in contrast to $NH_2OH$, the tricarbonyl fragment $M(CO)_3P_2$ afforded stable *O*-methylhydroxylamine complexes with all the phosphites used. These results may be attributed to the presence of the methoxy group in $NH_2OCH_3$, which makes *O*-methylhydroxylamine a better σ-donor than $NH_2OH$. As a result, more thermally stable



Scheme 3. M = Re (**7**, **9**, **11**), Mn (**8**, **10**); P = $P(OEt)_3$ (**a**), $PPh(OEt)_2$ (**b**).



Scheme 4. M = Mn (**10**), Re (**11**); P–P = $Ph_2POCH_2CH_2OPPh_2$ (**d**), $Ph_2PN(CH_3)CH_2CH_2N(CH_3)PPh_2$ (**e**), $Ph_2PO(CH_2)_3OPPh_2$ (**f**).

complexes were obtained with the $NH_2OCH_3$ ligand, and suitable crystals for X-ray crystal-structure determination were also obtained with the *O*-methylhydroxylamine complexes **9b** and **11f**.

Once crystallized, both the hydroxylamine complexes **1**–**6** and the *O*-methylhydroxylamine complexes **7**–**11** are stable as solids and in a solution of polar organic solvents, in which they behave like 1:1 electrolytes.[11] The complexes were characterized spectroscopically (Table 1 and Table 2) and by the X-ray crystal-structure determination of $[Re(NH_2OCH_3)(CO)_2\{PPh(OEt)_2\}_3]BPh_4$ (**9b**) and $[Re(NH_2OCH_3)(CO)_3\{Ph_2PO(CH_2)_3OPPh_2\}]BPh_4$ (**11f**), whose ORTEP drawings are shown in Figure 1 and Figure 2.

[a] In KBr pellets. [b] In $CD_2Cl_2$ at 20 °C, unless otherwise noted. [c] Phenyl proton resonances omitted. [d] Positive shift downfield from 85% $H_3PO_4$. [e] At –30 °C. [f] At –70 °C. [g] At 0 °C.

Compound **9b** does not show any interaction between the complex cation and the $BPh_4^-$ anion, but in the case of **11f** an interionic interaction, with parameters: distance H···Ct1 = 2.66(3) Å, distance N···Ct1 = 3.530(3) Å and angle NHCt1 = 167(3)° (where Ct1 is the centroid of one of the phenyl rings of the anion) indicates an NH-π hydrogen bond between the nitrogen of the *O*-methylhydroxylamine and a phenyl ring of the $BPh_4^-$ anion. Compound **11f** crystallized with a molecule of $CH_2Cl_2$ solvent to give a supramolecular arrangement of the crystal through a hydrogen-bonded network involving the cation [parameters, H···Ct2 = 2.98 Å, C···Ct2 = 3.805(4) Å, angle CHCt2 = 141.2°; H···O4′ = 2.74 Å, C···O4′ = 3.649(5) Å, angle CHO4′ = 152.4°. Symmetry operation 2–*x*, 2–*y*, 2–*z*; Ct2 stands for the centroid of the phenyl ring labeled as C31 to C36.]

In both cationic complexes the rhenium atom is coordinated in a slightly distorted octahedral fashion. In **9b** there are three meridional phosphonite ligands $PPh(OEt)_2$, two *cis* carbonyl ligands and an *N*-coordinated *O*-methylhydroxylamine. In **11f** there are three *mer* carbonyl ligands, two phosphorus atoms of the bidentated phosphinite ligand $PPh_2\{O(CH_2)_3O\}PPh_2$, and an *N*-coordinated *O*-methylhydroxylamine. The coordination polyhedra in **11f** is more irregular; the *cis* angles range from 86.26(9) to 95.47(3)°, and 95.47(3) is the largest value that corresponds to the chelate angle of the bidentate ligand. This fact was already observed in other compounds that bear this ligand[8d] and it is probably due to the steric requirement of the ligand.

For **11f**, the eight-membered ring adopts the disposition of a chair, in such a way that the phosphorus and the oxygen atoms are in a planar situation (rms deviation of 0.0229) with the rhenium atom slightly below the plane [0.463(2) Å], and the three carbon atoms form another almost parallel plane, [dihedral angle of 4.5(4)°] at 1.21(1) Å (average for the two nearest carbon atoms). This conformation was previously found for complexes with this ligand.[8d]

The Re–P bond lengths are in the range observed for complexes with phosphonite or phosphinite ligands.[8d,12] For **9b**, the Re–P distances for the mutually *trans* phosphonite ligands [2.381(3) Å (average)] are shorter than that of the phosphonite *trans* to a carbonyl ligand [2.413(3) Å] because of the stronger π-acceptor character of the CO group. The same behavior is observed in compound **11f** in which the Re–P1 distance is shorter [2.3647(8) Å] than Re–P2 [2.4608(8) Å].

The Re–C bond lengths in **9b** also show the different *trans* influence of the ligand: Re–C2 (*trans* to a P atom) is 0.063 Å longer than Re–C3 (*trans* to an N atom) because

of the stronger π-acceptor character of the phosphonite ligand.

In both cases, the geometrical parameters of the *O*-methylhydroxylamine ligand are in accordance with an $sp^3$ character for both the oxygen and the nitrogen atom,[13] and the conformation of the ligand is such that all the atoms belong to the same plane (Re–N1–O1–C1) (rms deviation of 0.0173 and 0.0405, respectively). The Re–N bonds are similar to those found in previously reported[3b] hydroxylaminerhenium(I) complexes.

The presence of the $NH_2OH$ or $NH_2OCH_3$ ligand in the complexes can be determined by IR and NMR spectroscopy (Table 1). The IR spectra of the hydroxylamine derivatives show one medium-intensity band at $\tilde{\nu}$ = 3381–3434 $cm^{-1}$ for the $\nu$OH stretch, and two bands at $\tilde{\nu}$ = 3212–3348 $cm^{-1}$ attributed to the $\nu$NH stretch of the $NH_2OH$ ligand. In the spectra of the related $NH_2OCH_3$ complexes only two medium-intensity bands at $\tilde{\nu}$ = 3215–3271 $cm^{-1}$ for the $\nu$NH stretch were observed.

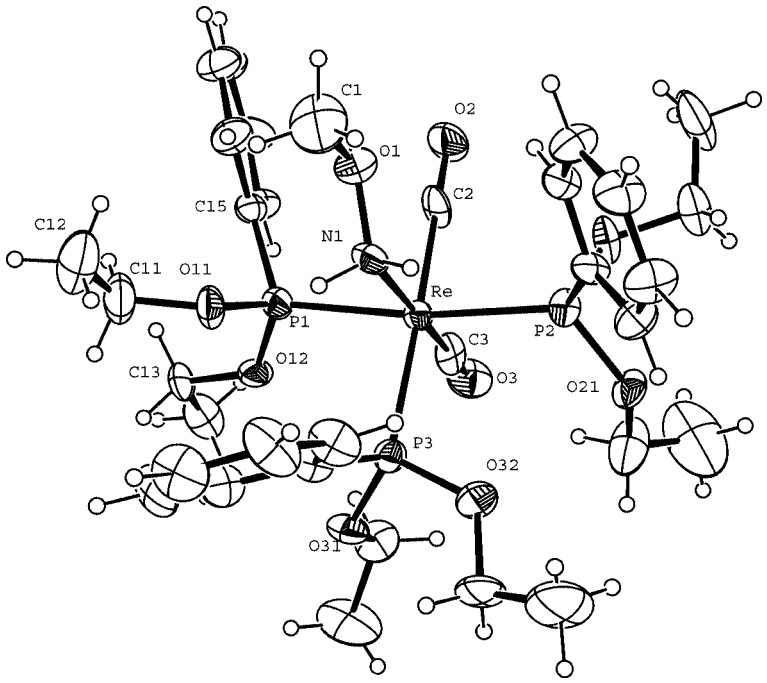

Figure 1. The cation of $[Re(NH_2OCH_3)(CO)_2\{PPh(OEt)_2\}_3]BPh_4$ (**9b**) drawn at 30% probability level.

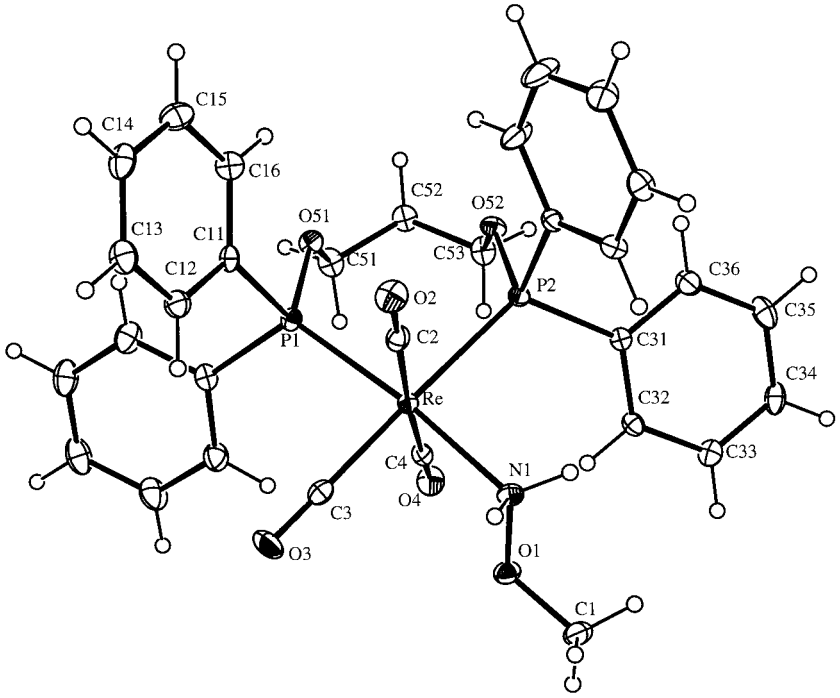

Figure 2. The cation of $[Re(NH_2OCH_3)(CO)_3\{Ph_2PO(CH_2)_3OPPh_2\}]BPh_4$ (**11f**) drawn at 30% probability level.

The NMR spectra of the $NH_2OH$ complexes **1**–**5**, which contain monodentate phosphite ligands, indicate that they are fluxional. The slightly broad signal that appears at room temperature in the proton spectra, in fact, resolves into two signals for the ligands at 243 K. At this temperature the spectra show, besides the signals for the phosphite and the $BPh_4$ anion, a triplet at $\delta$ = 4.41–6.39 ppm ($J_{H,H}$ = 2.3 Hz) attributed to the OH protons of the $NH_2OH$ ligand and one slightly broad multiplet at $\delta$ = 3.54–6.17 ppm for the $NH_2$ protons of $NH_2OH$ group. Decoupling experiments and COSY spectra were used to confirm these assignments and to determine the value of $J_{H,P}$ for the $NH_2$ protons. Values between $J_{H,P}$ = 2 and 3 Hz were determined for the $NH_2OH$ complexes **1**–**5**, which strongly supports the presence of an *N*-bonded $NH_2OH$ ligand.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The proton spectra of complexes **4ad** and **6e**, which contain the bidentate phosphane ligand show, apart from no fluxionality, the characteristic signals for the $NH_2$ and the OH protons , in agreement, also in this case, with the presence of the hydroxylamine ligand.

The $^1H$ NMR spectra of the $NH_2OCH_3$ derivatives show a singlet at $\delta$ = 2.39–3.49 ppm attributed to the methoxy group, $OCH_3$, and a multiplet at $\delta$ = 4.32–6.19 ppm for the $NH_2$ protons of the *O*-methylhydroxylamine ligand. Decoupling experiments indicate that the multiplet for the $NH_2$ protons is a result of the coupling of the phosphorus nuclei of the phosphane to the $NH_2OCH_3$ ligand with $J_{H,P}$ = 4–6 Hz, which is in agreement with the *N*-bonded coordination of the $NH_2OCH_3$ ligand.

The $^{31}P\{^1H\}$ NMR spectra of the monocarbonyl complexes $[M(NH_2OH)(CO)P_4]^+$ and $[M(NH_2OCH_3)(CO)P_4]^+$ (**1**, **2**, **7**) appear as a slightly broad signal at room temperature, which resolves into a sharp singlet at 243 K, in agreement with the magnetic equivalence of the four phosphite ligands. On the basis of these data, a geometry of type **I** (Scheme 1 and Scheme 3), with the carbonyl and the hydroxylamine ligands in a mutually *trans* position, can reasonably be proposed.

The IR spectra of the dicarbonyl complexes $[M(NH_2OR)(CO)_2P_3]^+$ (**3**, **4**, **8**, **9**) (R = H, $CH_3$) show two strong *v*CO bands which indicate a mutually *cis* position of the two carbonyl ligands. These two CO groups, however, are not magnetically equivalent, because they show two well-separated multiplets at 221.8 and 193.2 ppm in the $^{13}C$ NMR spectra (Table 2). At room temperature, the $^{31}P\{^1H\}$ NMR spectra of the dicarbonyl complexes that contain the monodentate phosphite ligands (**3b**, **4a**, **4b**, **8b**, **9b**) show a rather broad multiplet which resolves into an $AB_2$ pattern at temperatures between 0 and –70 °C. This indicates that there are two phosphites that are magnetically equivalent but different from the third phosphite. On the basis of these data, a *mer-cis* geometry of type **II** (Scheme 1 and Scheme 3) similar to that observed in the solid state for **9b** can reasonably be proposed for these dicarbonyl-hydroxylamine derivatives.

In the temperature range between +20 and –80 °C, the $^{31}P\{^1H\}$ NMR spectra of the dicarbonyl complexes **4ad** and **9ad** appear as an ABC multiplet, which can be easily simulated with the parameters reported in Table 1. These parameters indicate that, while two of the $J_{P,P}$ values are comparable($J_{P,P}$ = 27–34 Hz) the third is considerably higher than the others ($J_{P,P}$ = 245–248 Hz), which suggests that two of the three phosphanes are in a mutually *trans* position. Taking into account that the IR spectra suggest the presence of two CO groups in a mutually *cis* position, we can then reasonably propose a *mer-cis* geometry of type **II** (Scheme 1 and Scheme 4) for the complexes containing a bidentate phosphane ligand.

At room temperature, the $^{31}P$ NMR spectra of the tricarbonyl cations $[M(NH_2OH)(CO)_3P_2]^+$ (**5c**) and $[M(NH_2OCH_3)(CO)_3P_2]^+$ (**10b**, **11b**) appear as a rather broad signal which resolves into a sharp singlet as the temperature is lowered, which indicates the magnetic equivalence of the two phosphane ligands. The IR spectra show, in the *v*CO region, three bands; one band of medium intensity and two strong bands, which suggests a *mer* arrangement of the three carbonyl ligands. On the basis of these data, a *mer-trans* geometry **III** may be proposed for the tricarbonyl complexes **5c**, **10b**, **11b**.

The IR spectra of the tricarbonyl complexes **6e**, **10d** and **11e**, containing bidentate phosphane ligands, show three strong absorptions in the *v*CO region, which indicates a *fac* arrangement of the three carbonyl ligands. In the temperature range between +20 and –80 °C the $^{31}P\{^1H\}$ NMR spectra appear as a sharp singlet, in agreement with the magnetic equivalence of the two phosphite ligands. On the basis of these data, a *fac* geometry (**IV**) can reasonably be proposed for these hydroxylamine complexes. Finally, a *mer-cis* geometry of type **V** (Scheme 4), like that found in the solid state, can be proposed for the tricarbonyl complex $[Re(NH_2OCH_3)(CO)_3\{Ph_2PO(CH_2)_3OPPh_2\}]BPh_4$ (**11f**), whose IR spectrum shows one medium-intensity band and two strong bands in the *v*CO region. The $^{31}P$ NMR spectrum has an AB multiplet.

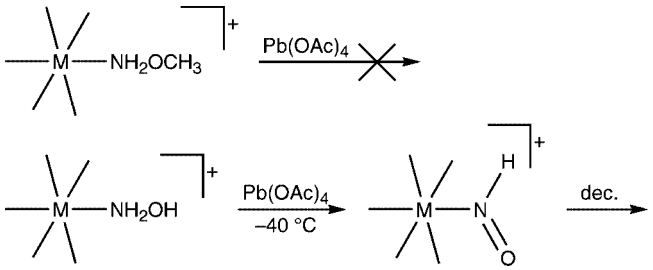
The *mer-cis* geometry observed for compound **11f** is unusual as compared with those of related complexes **10d**, **11e** that contain bidentate phosphane ligands and may be attributed to the steric requirement of the $Ph_2PO(CH_2)_3OPPh_2$ ligand, because the π-acceptor properties of the P–P phosphites are very similar in complexes **10d** and **11f**.

The fluxional behavior observed in some of our hydroxylamine complexes may be due to an intermolecular process that involves dissociation of $NH_2OR$ or phosphite ligands. NMR experiments in the presence of free phosphite or hydroxylamine, however, seem to exclude such a process. Therefore, it is plausible to assume that the fluxional process simply results in the inter-exchange of the position of both the P- and the $NH_2OR$ ligands at room temperature, and the progressive decrease of this change as the temperature is lowered leads to a static $A_2B$ or ABC system at –70 °C.

Reactivity studies of the hydroxylamine complexes were undertaken, and the preliminary results indicate that they are relatively robust complexes. Substitution of the $NH_2OH$ or $NH_2OCH_3$ ligand by carbonyl or phosphane is very slow at room temperature, while reflux conditions cause the decomposition of the complexes.

Oxidation reactions with $Pb(OAc)_4$ were also tested, and the results show (Scheme 5) that, while the *O*-methylhydroxylamine complexes **7**–**11** do not react with $Pb(OAc)_4$ under any conditions, hydroxylamines **1**–**6** quickly react with $Pb(OAc)_4$ at –40 °C to give a pale-yellow solution. Unfortunately, the solid separated from this solution is not a pure species, but its $^1H$ NMR spectrum shows, in the case of the oxidation of complex $[Re(NH_2OH)(CO)_2\{PPh(OEt)_2\}_3]BPh_4$ (**4b**), a slightly broad signal at $\delta$ = 19.7 ppm. This resonance may be attributed[2b,3b] to the NH proton of the N(H)=O group of the $[Re\{N(H)=O\}(CO)_2\{PPh(OEt)_2\}_3]^+$ cation, formed by selective oxidation of the $NH_2OH$ ligand, as shown in Scheme 5.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 5. M = Mn, Re.

Unfortunately, the nitroxyl $[Re\{N(H)=O\}(CO)_2P_3]^+$ derivatives are unstable even at –40 °C and were separated only as traces. The IR spectrum of the separated solid did not show a signal for the nitrosyl [Re]–NO complex, which would result from the deprotonation of [Re]-N(H)=O . This observation suggests that the deprotonation does not take place. Our results, therefore, prove that the $M(CO)_nP_{5-n}$ fragment is able to stabilize the coordination of the hydroxylamine group, but not that of the nitroxyl ligand.

## Conclusions

In this report we have highlighted that the synthesis of the unprecedented hydroxylamine and the *O*-methylhydroxylamine complexes of manganese can be achieved through the use of mixed-ligand $Mn(OTf)(CO)_nP_{5-n}$ complexes with mono- or bidentate phosphites and carbonyls as precursors. New $NH_2OH$ and $NH_2OCH_3$ derivatives of rhenium were also prepared which allowed for the first structural parameters of an *O*-methylhydroxylamine complex to be obtained. Oxidation of the hydroxylamine complexes with $Pb(OAc)_4$ at –40 °C was also studied and led to the unstable [M]–N(H)O nitroxyl derivative.

## Experimental Section

**General:** All synthetic work was carried out under an inert atmosphere by using standard Schlenk techniques or a ffacuum Atmosphere dry-box. Once isolated, the complexes were found to be relatively stable in air, but were stored under an inert atmosphere at –25 °C. All solvents were dried with appropriate drying agents, degassed on a vacuum line and distilled into vacuum-tight storage flasks. The phosphite $P(OEt)_3$ (Aldrich) was purified by distillation under nitrogen, while $PPh(OEt)_2$ and $PPh_2OEt$ were prepared by the method of Rabinowitz and Pellon.[14] The bidentate phosphanes $Ph_2PO(CH_2)_nOPPh_2$ ($n$ = 2, 3) and $Ph_2PN(CH_3)CH_2CH_2N(CH_3)PPh_2$ were prepared by the reported methods.[8c,8d,15] $Re_2(CO)_{10}$ was purchased from Pressure Chemical Co. (U.S.A.) while $Mn_2(CO)_{10}$ was purchased from Aldrich, and both compounds were used as received. Hydroxylamine ($NH_2OH$), *N*-methylhydroxylamine [$NH(CH_3)OH$], and *O*-methylhydroxylamine ($NH_2OCH_3$) were prepared by a slight modification of a reported method,[16] which involved the treatment of hydroxylamine hydrochloride with sodium ethylate in ethanol. The free $NH_2OH$ was isolated as a white solid, while $NH(CH_3)OH$ and $NH_2OCH_3$ were prepared in solution just prior to use. Other reagents were purchased from commercial sources in the highest available purity and used as received. Infrared spectra were recorded with a Nicolet Magna 750 FT-IR or Perkin–Elmer Spectrum One spectrophotometer. NMR spectra ($^1H$, $^{13}C$, $^{31}P$) were obtained with Bruker AC200, AVANCE 300, and ARX 400 spectrometers at temperatures varying between –90 and +30 °C, unless otherwise noted. $^1H$- and $^{13}C$ spectra are referred to internal tetramethylsilane, while $^{31}P\{^1H\}$ chemical shifts are reported with respect to 85% $H_3PO_4$, with downfield shifts considered positive. The COSY, HMQC, and HMBC NMR experiments were performed with their standard programs. The SwaN-MR and g-NMR software packages[17] were used to treat the NMR spectroscopic data and for the simulation. The conductivity of $10^{-3}$ mol·dm$^{-3}$ solutions of the complexes in $CH_3NO_2$ at 25 °C was measured with a Radiometer CDM 83 instrument.

**Preparation of the Complexes:** The hydride complexes $MH(CO)_nP_{5-n}$ [M = Mn, Re; P = $P(OEt)_3$, $PPh(OEt)_2$, $PPh_2OEt$; $n$ = 1, 2, 3, 4] were prepared by following the previously reported method.[6e,8a,8b] The related complexes $MH(CO)_2(P–P)\{P(OEt)_3\}$ and $MH(CO)_3(P–P)$ [P–P = $Ph_2POCH_2CH_2OPPh_2$, $Ph_2PO(CH_2)_3OPPh_2$, $Ph_2PN(CH_3)CH_2CH_2N(CH_3)PPh_2$] were also obtained by a known method.[8c,8d]

**$[Mn(NH_2OH)(CO)_nP_{5-n}]BPh_4$ (1b, 3b, 5c) [P = $PPh(OEt)_2$ (b), $PPh_2OEt$ (c); $n$ = 1 (1); $n$ = 2 (3); $n$ = 3 (5)]:** An equimolar amount of $CF_3SO_3H$ (0.2 mmol, 18 μL) was added to a solution of the appropriate hydride $MnH(CO)_nP_{5-n}$ (0.2 mmol) in $CH_2Cl_2$ (10 mL) cooled to –196 °C. The reaction mixture was brought to room temperature, stirred for 1 h, and then cooled again to –196 °C. An excess of hydroxylamine (1 mmol, 0.91 mL of a 1.1 M solution in ethanol) was added, and the resulting solution was brought to 0 °C and stirred for 8 h. The solvent was removed under reduced pressure. The oil that was obtained was treated with ethanol (1.5 mL) containing an excess amount of $NaBPh_4$ (0.4 mmol, 137 mg). A yellow solid slowly separated out from the resulting solution, which was allowed to stand at –25 °C overnight to complete the precipitation. The solid was filtered and crystallized at 0 °C from $CH_2Cl_2$ and ethanol. Yield: 115 mg for **1b** (47%), 131 mg for **3b** (62%), and 103 mg for **5c** (54%).

ment, a sample of the appropriate complex, $[M(NH_2OH)(CO)_nP_{5-n}]BPh_4$ or $[M(NH_2OCH_3)(CO)_nP_{5-n}]BPh_4$ (0.10 mmol), was placed in a three-necked, 25-mL, round-bottomed flask fitted with a solid-addition sidearm containing an equimolar amount of $Pb(OAc)_4$ (44 mg, 0.10 mmol). The system was evacuated, $CH_2Cl_2$ (10 mL) was added, the solution cooled to –40 °C, and the $Pb(OAc)_4$ was added portionwise over 10–20 min to the cold solution with stirring. The reaction mixture was then warmed to 0 °C, stirred for 10 min, and the solvent was removed under reduced pressure. The oil obtained was treated at 0 °C with ethanol (2 mL) containing $NaBPh_4$ (42 mg, 0.12 mmol), but no solid compound was separated from the resulting solution.

**X-ray Crystal-Structure Determination of $[Re(NH_2OCH_3)(CO)_2\{PPh(OEt)_2\}_3]BPh_4$ (9b) and $[Re(NH_2OCH_3)(CO)_3\{Ph_2PO(CH_2)_3OPPh_2\}]BPh_4$ (11f):** Suitable crystals for X-ray analysis were obtained by slow cooling of a saturated solution of the complexes in ethanol and $CH_2Cl_2$. The data was collected with a SIEMENS Smart CCD area-detector diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation, at room temperature in the case of **9b** and at –100 °C in the case of **11f**. Absorption corrections were carried out with SADABS with the use of semi-empirical methods from equivalents.[18] The structures were solved by direct methods in the case of **9b** and by Patterson methods in the case of **11f**. Both were refined by a full-matrix least-squares analysis based on $F^2$.[19] Non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in idealized positions and refined with isotropic displacement parameters, except those bonded to the nitrogen atom in **11f**, which were located on the density map and refined isotropically. Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from the International Tables for X-ray Crystallography (Tables 3, 4 and 5).[20]

# Amine-Intercalated Layered $Sn^{II}$ Phosphates with Open-Framework Structures

**Padmini Ramaswamy[a] and Srinivasan Natarajan*[a]**

**Keywords:** Template synthesis / X-ray diffraction / Layered compounds / Hydrogen bonds / Tin / Phosphorus

Three new $Sn^{II}$ phosphate materials, $[NH_3(CH_2)_3NH_2(CH_2)_2NH_2(CH_2)_3NH_3]\cdot 2[Sn_2P_2O_8]$ (**I**), $[(N_2C_5H_{14})_2][Sn_4P_4O_{16}]\cdot 3H_2O$ (**II**) and $[(N_2C_5H_{14})][Sn_2P_2O_8]\cdot H_2O$ (**III**), have been synthesised by means of hydrothermal methods using *N*,*N*′-bis(3-aminopropyl)ethylenediamine (BAPEN; for **I**) and homopiperazine (H-PIP; for **II** and **III**), respectively, as the structure-directing organic amines. The solids **I**–**III** have layered architectures. The structures of all three compounds consist of strictly alternating vertex-sharing trigonal-pyramidal $SnO_3$ and tetrahedral $PO_4$ moieties forming infinite layers possessing apertures bound by 4- and 8-T atoms (T = Sn, P). The distorted 4- and 8-membered apertures within the layers suggest the subtle influence of the lone-pair of electrons of $Sn^{II}$ on the structure. The interlamellar space is occupied by the protonated organic amine molecules which interact with the framework through N–H···O hydrogen bonding. The compounds **I**–**III** bear some structural relationship to the layered zinc phosphite phases.

## Introduction

The wide structural diversity along with the potential applications in the areas of catalysis, sorption and separation processes are the reasons for the continued interest in the area of open-framework materials.[1] The continuing research has clearly established that new materials with novel structures can be made in the presence of structure-directing organic amines.[2] It is now firmly established that tin(II) phosphates exhibiting open-framework structures can be prepared employing hydrothermal methods.[3–13] The chemistry of divalent tin and its related compounds, especially the phosphates[3–13] and the phosphonates,[14–16] continues to yield unexpected results with the lone-pair associated with $Sn^{II}$ playing a significant role. In the family of tin phosphates, the isolation of solids having zero-,[3] one-,[4,5] two-[6–8] and three-dimensionally[9–13] extended networks clearly indicates that the system is versatile like the other family of open-framework phosphates. It is noteworthy that one of the basic structural building blocks, present in most of the phosphate based open-framework solids, is a four-membered ring made of $[M_2P_2O_4]$ units. The analogue with M = Sn has also been isolated and characterised.[3] The main structural features present in all the tin phosphate and phosphonate materials are the presence of either three- and/or four-coordinated $Sn^{II}$ atoms that are vertex-linked to $PO_4$ tetrahedra forming channels and cavities. In general, it is observed that the Sn/P ratio in many of the tin phosphates is >1. In this paper, we report the hydrothermal synthesis and structures of three simple open-framework tin(II) phosphates, $[NH_3(CH_2)_3NH_2(CH_2)_2NH_2(CH_2)_3NH_3]\cdot 2[Sn_2P_2O_8]$ (**I**), $[(N_2C_5H_{14})_2][Sn_4P_4O_{16}]\cdot 3H_2O$ (**II**) and $[(N_2C_5H_{14})][Sn_2P_2O_8]\cdot H_2O$ (**III**), having an Sn/P ratio of 1.0. The compounds were prepared in the presence of *N*,*N*′-bis(3-aminopropyl)ethylenediamine (BAPEN; for **I**) and homopiperazine (H-PIP; for **II** and **III** ), respectively, as the structure-directing agent.

## Results and Discussion

Three new $Sn^{II}$ phosphates, $[\{NH_3(CH_2)_3NH_2(CH_2)_2NH_2(CH_2)_3NH_3\}_2]\cdot 2[Sn_2P_2O_8]$ (**I**), $[(N_2C_5H_{14})_2][Sn_4P_4O_{16}]\cdot 3H_2O$ (**II**) and $[(N_2C_5H_{14})][Sn_2P_2O_8]\cdot H_2O$ (**III**), were synthesised using hydrothermal methods. As a result of the synthesis being kinetically controlled solvent-mediated reactions, there is no relationship between the starting synthesis mixture composition and the stoichiometry of the final solid product. The compounds **I**–**III** have similar structures consisting of layers that are intercalated by the structure-directing organic amine molecules. The structures are based on a network of strictly alternating $SnO_3$ and $PO_4$ units. These units form infinite layers with the incorporation of the organic amine in the fully protonated form.

The asymmetric unit of **I** contains 18 independent non-hydrogen atoms, of which two Sn and P atoms are crystallographically independent. The structure of **I** is constructed from a network of $SnO_3$ and $PO_4$ units forming infinite layers which are anionic. The connectivity between these moieties creates 4- and 8-membered rings along the *b*-axis. The polyhedral connectivity between the $SnO_3$ and $PO_4$ units forming the two-dimensional layer is shown in Fig-

ure 1. As can be noted, each four-membered ring within the layer is connected to four eight-membered rings and each eight-membered ring is attached to four four-membered rings. The organic amine molecules (BAPEN) balance the charges of the anionic layers and are located in the spaces between the layers. The individual layers are held together by the fully protonated BAPEN molecules through hydrogen bonding interactions (Figures 2a and b).

The asymmetric unit of **II** contains 42 independent non-hydrogen atoms, of which 24 atoms belong to the framework and the remaining atoms to the lattice water and amine guest molecules. There are four Sn and P atoms that

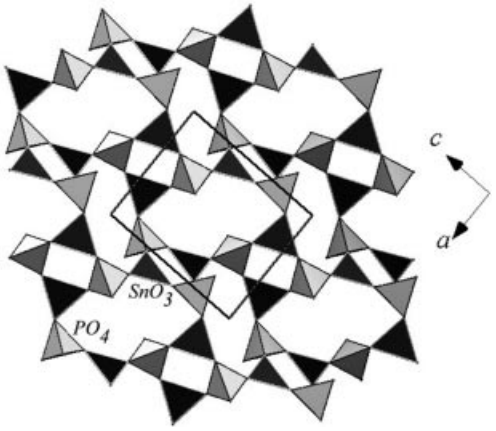

Figure 1. Polyhedral view of a single layer in $[NH_3(CH_2)_3NH_2(CH_2)_2NH_2(CH_2)_3NH_3]\cdot 2[Sn_2P_2O_8]$ (**I**) in the *ac* plane.

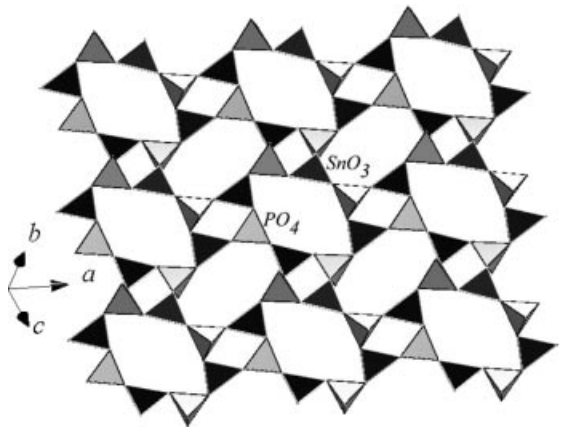

Figure 3. Polyhedral view of a single layer in $[(N_2C_5H_{14})_2][Sn_4P_4O_{16}]\cdot 3H_2O$ (**II**).

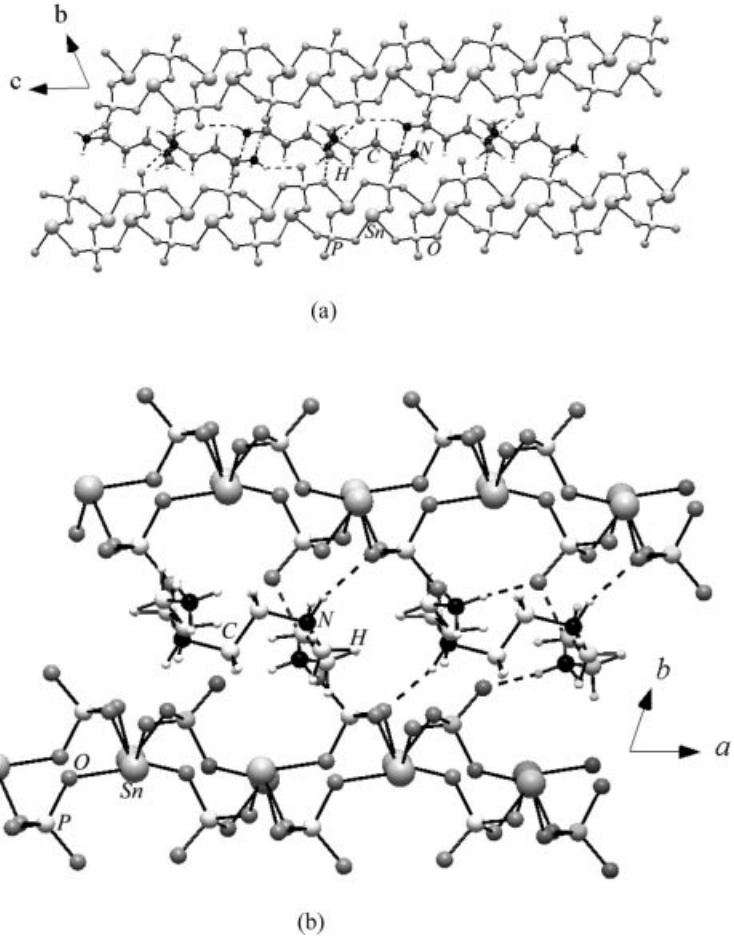

Figure 2. (a) Arrangement of the layers in **I** in the *bc* plane. (b) Arrangement of the layers in **I** in the *ab* plane. The dotted lines in both the cases represent possible hydrogen-bonding interactions.

are crystallographically independent. Similar to **I**, the structure of **II** is constructed by a network of $SnO_3$ and $PO_4$ units forming infinite layers that are anionic. The connectivity between these moieties creates 4- and 8-membered rings in the *ab* plane (Figure 3). In **II**, there appear to be two types of 4- and 8-membered apertures, the arrangement of which gives a three-dimensional character to the layers. The differences in the sizes and shapes of the apertures may be attributed to the relative positioning of the lone-pair of electrons on $Sn^{II}$. The charge-compensating protonated organic amine cations (H-PIP) are located in the inter-lamellar regions and are involved in hydrogen bonding through N–H···O, C–H···O and O–H···O interactions (Figure 4).

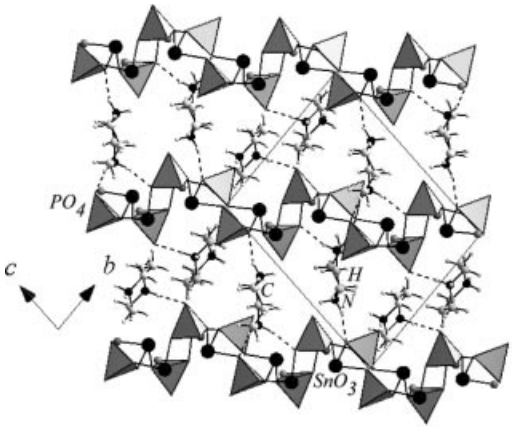

Figure 4. Arrangement of the layers in **II** in the *bc* plane. Dotted lines represent possible hydrogen-bonding interactions. The lattice water molecules are not shown.

The asymmetric unit of **III** contains 20 independent non-hydrogen atoms, of which two Sn and P atoms are crystallographically independent. The connectivity between the $SnO_3$ and $PO_4$ units creates 4- and 8-membered rings within the layer in the *bc* plane. The polyhedral connectivity of a single layer is shown in Figure 5. As can be noted, each 4-membered ring within the layer is connected to four 8-membered rings and each 8-membered ring is attached to four 4-membered rings. The 8-membered rings are considerably more distorted compared with those in the structures of **I** and **II**. The organic amine molecules (H-PIP) balance the charges of the anionic layers and are located in the spaces between the layers. The individual layers are held together by the protonated H-PIP molecules through hydrogen-bonding interactions (Figure 6).

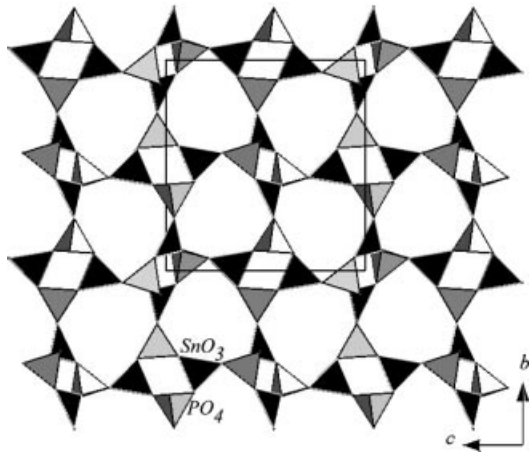

Figure 5. Polyhedral view of a single layer in $[(N_2C_5H_{14})][Sn_2P_2O_8]\cdot H_2O$ (**III**) in the *bc* plane.

Compounds **I**–**III** therefore represent examples of open-framework solids possessing alternating anionic and cationic layers. It may be noted that one of the basic building units present in many of the tin phosphates and other related materials, namely $M_2P_2O_4$ units (M = Sn in the present case),[3] can be observed in all the structures.

The Sn–O bond lengths are in the range from 2.0635(18) to 2.1234(17) Å and the O–Sn–O bond angles are between 82.76(6) and 93.42(14)° which is typical of three-coordinate $Sn^{II}$ centres[3–13] (Tables 1, 2 and 3). The Sn atoms are linked to P by means of the oxygen links. The P atoms are

Symmetry transformations used to generate equivalent atoms: [a] $-x + ½, y + ½, -z + ½$. [b] $x + ½, -y + ½, z + ½$. [c] $-x, -y + 1, -z$. [d] $-x + ½, y - ½, -z + ½$. [e] $x - ½, -y + ½, z - ½$.

The proton-decoupled $^{31}P$ pulsed MAS NMR spectra of **I** and **III**, shown in Figures 7a and b, clearly indicate the presence of two phosphorus sites with chemical shifts of $\delta_{iso}$ = 2.58 and 0.116 ppm for **I** and $\delta_{iso}$ = –3.475 and –4.507 ppm for **III**. The differences in the chemical shifts may be attributed to the involvement of the phosphate tetrahedra in hydrogen-bonding interactions. The observation of two distinct chemical shift peaks in the MAS NMR spectra indicates the presence of two crystallographically independent P sites which is in agreement with the single-crystal X-ray crystallographic data. Similar chemical shift values have been observed in other phosphate compounds.[18]

The lone pair of electrons on $Sn^{II}$ appears to play an important role in the present structures. The stereoactive lone-pair of electrons manifests itself in the lattice by creating open spaces between the two layers in the tin phosphates. It is likely that the differences in the arrangement of the 4- and 8-membered apertures within the layers, observed in the present compounds, are also subtly influenced by the presence of the lone-pair electrons. The lone-pair of

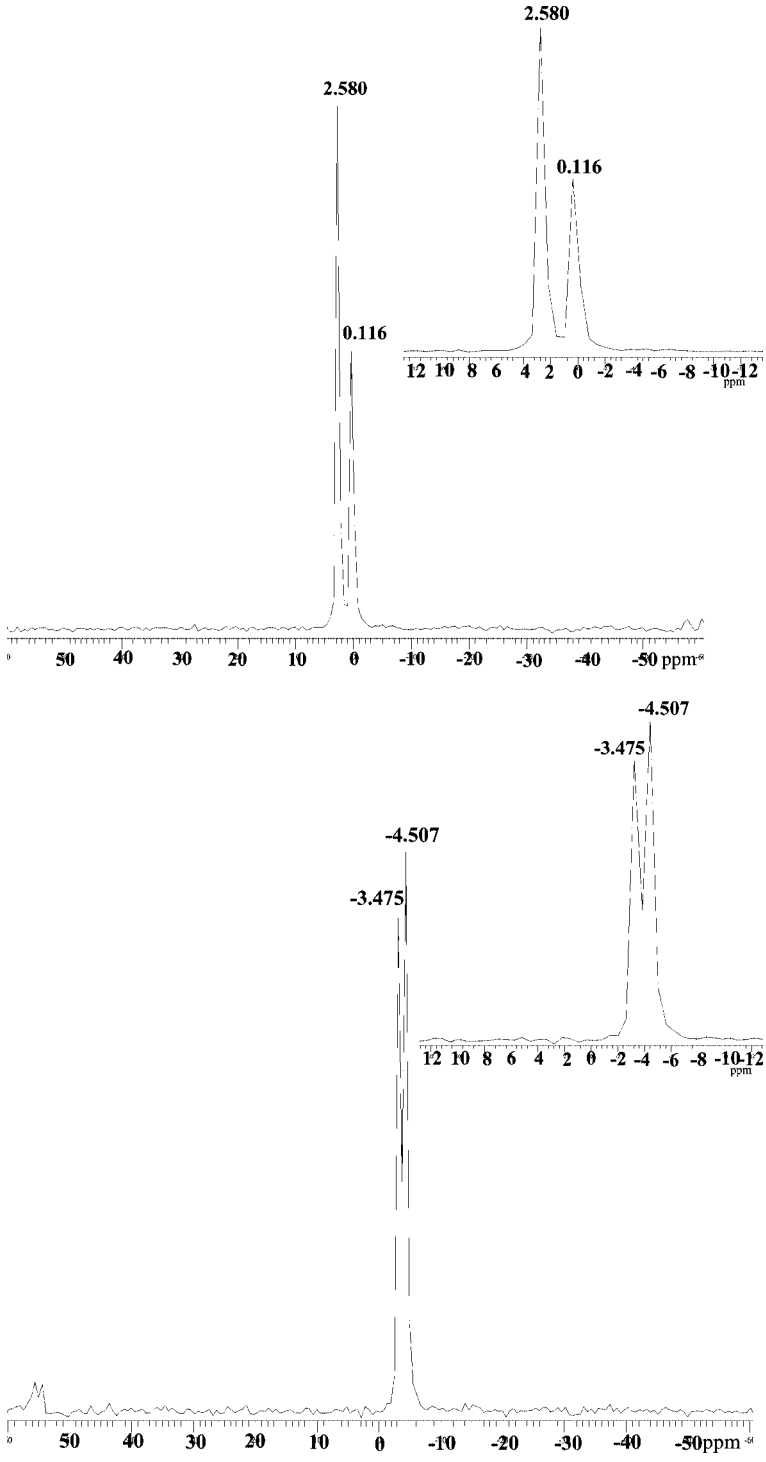

Figure 7. $^{31}$P-CPMAS NMR spectra for (a) $[NH_3(CH_2)_3NH_2(CH_2)_2NH_2(CH_2)_3NH_3]\cdot 2[Sn_2P_2O_8]$ (**I**) and (b) $[(N_2C_5H_{14})][Sn_2P_2O_8]\cdot H_2O$ (**III**).

electrons on $Sn^{II}$ generally points in a direction perpendicular to the plane of the layers. This is also expected since the amine molecules are cationic and located between the layers which would facilitate favourable interactions with the lone-pair of electrons. Similar lone-pair electron positions have been observed in many other layered $Sn^{II}$ phosphate materials.[6–8]

Multipoint hydrogen-bonding interactions help maintain structural stability and possibly help in the formation of many of the open-framework materials that have low-dimensional character.[3–8,19–24] In the present structures **I**–**III**, the hydrogen atoms of the amine molecule interact strongly with the framework oxygen atoms, especially with the double-bonded ones. Thus, a large number of N–H···O

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and C–H···O hydrogen-bonding interactions has been observed in **I**–**III**. In addition, the lattice water molecules also participate in hydrogen-bonding O–H···O interactions. Selected hydrogen-bonding interactions, observed in **I**–**III**, are listed in Table 4. The present compounds **I**–**III** thus provide good examples of multipoint hydrogen bonding and illustrate the importance of them in the structural stability of two-dimensional solids.

Table 4. Selected hydrogen-bonding interactions in $[NH_3(CH_2)_3NH_2(CH_2)_2NH_2(CH_2)_3NH_3]\cdot 2[Sn_2P_2O_8]$ (**I**), $[(N_2C_5H_{14})_2][Sn_4P_4O_{16}]\cdot 3H_2O$ (**II**) and $[(N_2C_5H_{14})][Sn_2P_2O_8]\cdot H_2O$ (**III**).

Symmetry transformations used to generate equivalent atoms: **I**: [a] $-x, 1-y, 1-z$. [b] $1-x, 1-y, -z$. [c] $x, y, 1+z$. [d] $-x, 1-y, -z$. **II**: [a] $1-x, 1-y, 1-z$. [b] $-x, 1-y, 1-z$. [c] $1-x, -y, 1-z$. [d] $1+x, y, -1+z$. [e] $x, y, -1+z$. **III**: [a] $½+x, ½-y, -½+z$. [b] $½+x, ½-y, ½+z$. [c] $-x, ½+y, ½-z$.

Structurally, the present compounds possess many features that are similar to other previously known open-framework solids, especially in $Sn^{II}$ phosphates with two-dimensional structures.[6–8] The layered arrangements in **II** and **III**, however, appear to be unique. Additionally, the $Sn^{II}$ phosphates can be compared with the structures of the recently discovered layered zinc phosphite networks.[23,24] While the $Sn^{II}$ phosphate structures are built up from $SnO_3$ trigonal pyramids and $PO_4$ tetrahedra, the $ZnO_4$ tetrahedra and $PO_3$ pseudo-tetrahedral units are vertex-linked in the zinc phosphite structures. Thus, the net available vertices for bonding in both the cases are similar. In the zinc phosphites, the fourth vertex of the pseudo-tetrahedra is occupied by a P–H bond and in the $Sn^{II}$ phosphates the fourth vertex is occupied by the lone-pair of electrons of the $Sn^{II}$ ions. Illustrative examples of some of the previously reported zinc phosphite structures in which the layers have 4- and 8-membered apertures along with the layer arrangement of **I** and **II** are shown in Figure 8. In the zinc phosphites, $[C_2N_2H_{10}][Zn_2(HPO_3)_3]$[23] and $[(C_4N_2H_{12})(C_5NH_4)]_4[Zn_6(HPO_3)_8]$,[24] (Figures 8a and b), the 8-membered rings are connected edge-wise and are separated by edge-sharing 4-membered rings. In the zinc phosphite $[C_3NH_{10}]_2[Zn_3(HPO_3)_4]$,[24] the connectivity within the layers is identical to that found in **I** (Figures 8c and d) which clearly establishes the net available vertices for bonding in both the structures. The structural features observed in the structures of **II** and **III** (Figures 8e and f) appear to be unique and, to the best of our knowledge, there are no corresponding zinc phosphite structures known in the literature. It may be noted that the 8-membered rings in **III** are distorted compared with those in **I** and **II**, indicating the subtle control exhibited, on the structure of **III**, by the lone-pair of electrons on $Sn^{II}$. In general, the layered phosphate/phosphite structures are held together by strong hydrogen-bonding interactions involving the P=O groups and the organic amine template molecules. The presence of trigonal-pyramidal $SnO_3$ and tetrahedral $PO_4$ units linking to form the layers and the interactions with the organic amine molecule renders the unique architectures seen in these materials.

## Conclusions

The synthesis of three new layered tin(ii) phosphate materials, $[NH_3(CH_2)_3NH_2(CH_2)_2NH_2(CH_2)_3NH_3]\cdot 2[Sn_2P_2O_8]$ (**I**), $[(N_2C_5H_{14})_2][Sn_4P_4O_{16}]\cdot 3H_2O$ (**II**) and $[(N_2C_5H_{14})][Sn_2P_2O_8]\cdot H_2O$ (**III**), consisting of alternating inorganic and organic layers has been accomplished. These materials, together with the previously reported $Sn^{II}$ phosphate and phosphonate solids, illustrate the profound structural influences of relatively minor modifications in the reaction conditions and/or changes in the starting source of tin. The present solids represent another example illustrating the importance of multipoint hydrogen bonding in the synthesis and stability of lower dimensional open-framework materials. The structures appear to a have close similarity to the phosphite-based ones. The stereoactive lone-pair of electrons on $Sn^{II}$ appears to subtly control the formation of the structure by manifesting itself in the open spaces. Our continuing research on the $Sn^{II}$ phosphates indicates that other related structures are formed under hydrothermal conditions in the presence of other structure-directing agents. While the isolation of a two-dimensional solid with strictly alternating $SnO_3$ and $PO_4$ moieties provides information about the stereochemical consequences of the $Sn^{II}$ lone-pair of electrons, further evaluation is required to exploit the structure-directing influences of this unit in the presence of other organic amines in the synthesis of open-framework materials.

## Experimental Section

**NMR Spectroscopy:** Solid-state NMR experiments were carried out with a Bruker DSX 300 spectrometer operating at 7 T with a resonance frequency of 121 MHz for $^{31}P$. A Bruker 5 mm double resonance probe was used for the experiments. The $^{31}P$ MAS spectra were recorded using standard cross-polarisation (CP) procedures and high proton decoupling employing a magic angle spinning (MAS) frequency of 7 kHz. In a typical experiment, radio-frequency fields of 120 kHz were used. The chemical shifts are reported relative to 85% $H_3PO_4$ as an external standard.

**Synthesis:** Compounds **I**–**III** were synthesised by hydrothermal methods starting from a tin phosphate gel and employing *N*,*N*′-bis(3-aminopropyl)ethylenediamine (BAPEN; for **I**) and homopiperazine (H-PIP; for **II** and **III**) as the structure-directing agents, respectively. For the synthesis of compound **I**, $Sn^{II}$ oxalate was used as the source of tin, whereas $SnCl_2{\cdot}2H_2O$ was employed for **II** and **III**. In a typical synthesis for **I**, tin(II) oxalate (0.211 g) was dispersed in distilled water (1 mL). To this were added 85% aq. $H_3PO_4$ (0.07 mL) and BAPEN (0.19 mL) and the mixture was stirred at room temperature until homogeneous (ca. 30 min.). The final reaction mixture with the composition $1.0SnC_2O_4/1.0H_3PO_4/1.0BAPEN/55H_2O$ was heated in a 23 mL PTFE-lined stainless steel autoclave at 180 °C for 72 h. The initial pH of the mixture was 9.0 and there was no appreciable change in pH after the reaction. The resultant product contained large quantities of block-shaped colourless crystals along with a small quantity of white powder. The yield of the product was ca. 70% based on the metal source. For **II**, a reaction mixture with the composition $1.0SnCl_2{\cdot}2H_2O/1.0H_3PO_4/3.0(H\text{-}PIP)/55H_2O$ was heated in a 23 mL PTFE-lined stainless steel autoclave at 150 °C for 48 h. The initial pH of the mixture was 7.0 and there was no change in pH during the reaction. The product contained predominantly unidentified powder with a few isolated plate-like single crystals. The white powder product was found to be poorly crystalline and did not correspond to the structure of **II**. In spite of our repeated attempts, we were not able to prepare **II** in pure form and hence other than the single-crystal structure, we have not been able to characterise the compound completely. For **III**, a reaction mixture with the composition $1.0SnCl_2{\cdot}2H_2O/1.0H_3PO_4/3.0(H\text{-}PIP)/110H_2O$ was heated at 150 °C for 24 h resulting in large quantities of block-like single crystals (yield 60%). In all the preparations, the products were washed with deionised water and dried under ambient conditions.

**Single-Crystal Structure Determinations:** A suitable colourless single crystal of each compound was carefully selected under a polarising microscope and glued to a thin glass fibre. The single-crystal diffraction data were collected with a Bruker AXS Smart Apex CCD diffractometer at room temperature (293 K). The X-ray generator was operated at 50 kV and 35 mA using Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation. Data were collected with $\omega$-scans of width 0.3°. A total of 606 frames were collected in three different settings of $\varphi$ (0, 90 and 180°), keeping the sample-to-detector distance fixed at 6 cm and the detector position fixed at –25°. Pertinent experimental details of the structure determinations are listed in Table 5. The data were reduced using SAINTPLUS[25] and an empirical absorption correction was applied using the SADABS program.[26] The crystal structures were solved and refined by direct methods using SHELXL-97 present in the WinGX suite of programs.[27] The hydrogen atoms were placed in geometrically idealised positions and refined using the riding model. The last cycles in the refinements included all the atomic positions, anisotropic thermal parameters for all the non-hydrogen atoms and isotropic thermal parameters for all the hydrogen atoms. Full-matrix least-squares structure refinement against $|F|^2$ was carried out using the WinGX suite of programs.[27] CCDC-299664, -299665 and -602825 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Initial Characterisations:** The initial characterisations of **I** and **III** were carried out using elemental analysis, powder X-ray diffraction (XRD), thermogravimetric analysis (TGA) and infrared spectroscopy (IR). Elemental analyses of the crystals were carried out using atomic absorption spectroscopy (ThermoFinnigan FLASH EA 1112 CHNS analyser). TGA measurements were performed in an atmosphere of flowing oxygen (flow rate 50 mL min$^{-1}$) in the temperature range 30–800 °C (heating rate 5 °C min$^{-1}$). Infrared spectra were recorded in the range 400–4000 cm$^{-1}$ using KBr pellets (Perkin-Elmer SPECTRUM 1000 instrument). The powder X-ray diffraction patterns were recorded on crushed single crystals in the $2\theta$ range 5–50° using Cu-$K_\alpha$ radiation (Philips X'pert Pro). The C,

H and N analyses of **I** and **III** are as follows: **I**: calcd. C 9.29, H 2.52, N 5.42; found C 9.92, H 2.64, N 5.49; **III**: calcd. C 10.97, H 2.92, N 5.12; found C 11.36, H 3.14, N 5.18. The powder X-ray diffraction patterns (XRD) for **I** and **III** indicated that the patterns were new and being entirely consistent with those simulated from the single-crystal structures.[28] The XRD pattern of the powder sample, obtained along with **I**, also indicated that it belongs to the structure of **I**. The IR spectra of **I** and **III** show similar features and the following bands were observed: **I**: $\tilde{\nu}$ = 3000 [$\nu_s$(N–H)], 2824 [$\nu_s$(C–H)], 1602 [δ(N–H)], 1465 [δ(C–H)], 1406 [$\nu_s$(C–N)], 1334 [$\nu_s$(C–C)], 1153 [$\nu_{as}(PO_4)$], 755 [$\nu_s(PO_4)$], 625 [δas($PO_4$)], 583 [δs($PO_4$)] $cm^{-1}$; **III**: $\tilde{\nu}$ = 3554 [$\nu_s$(O–H)], 3099 [$\nu_s$(N–H)], 2804 [$\nu_s$(C–H)], 1619 [δ(O–H)], 1505 [δ(N–H)], 1431 [δ(C–H)], 1377 [$\nu_s$(C–N)], 1238 [$\nu_s$(C–C)], 1109 [$\nu_{as}(PO_4)$], 843 [$\nu_s(PO_4)$], 638 [δas($PO_4$)], 587 [δs($PO_4$)] $cm^{-1}$. The TGA studies on **I** were carried out in flowing air (50 mL $min^{-1}$) in the temperature range 25–800 °C (heating rate 10 °C $min^{-1}$). The results indicate one sharp weight loss in the at around 325 °C with a tail up to 475 °C followed by a small increase in the weight. The observed weight loss of ca. 15% in the range 325–500 °C corresponds to the loss of the amine molecule (calcd. 17.2%). The weight gain of 3% after 500 °C is probably the result of the oxidation of $Sn^{II}$ to $Sn^{IV}$ in the oxygen atmosphere (calcd. 3.74%). The TGA studies of **III** showed an initial weight loss followed by a prominent one. The initial continuous weight loss of 4.14% in the temperature range 30–200 °C corresponds to the loss of the lattice water and some adsorbed water (calcd. 3.30%). The second and more prominent weight loss of 15.5% in the range 300–700 °C corresponds to the loss of the amine molecule (calcd. 18.6%). Similar to **I**, beyond 700 °C there was a small weight gain of 2.75% which may be due to the oxidation of $Sn^{II}$ to $Sn^{IV}$ in the oxygen atmosphere. In both cases, the powder X-ray diffraction pattern of the decomposed samples indicated a poorly crystalline $Sn^{IV}P_2O_7$ phase (JCPDS: 29-1352). It seems likely that an amorphous phase with a ratio Sn/P > 1:1 is also present.

**Supporting Information** (for details see the footnote on the first page of this article): Asymmetric units for all the compounds (**I**–**III**), experimental and simulated powder XRD patterns, IR spectra and TGA curves for compounds **I** and **III**.

# (Cyclen– and cyclam–pyridine)copper Complexes: The Role of the Pyridine Moiety in $Cu^{II}$ and $Cu^{I}$ Stabilisation

Sanae El Ghachtouli,[a] Cyril Cadiou,[a] Isabelle Déchamps-Olivier,[a] Françoise Chuburu,*[a] Michel Aplincourt,[a] and Thierry Roisnel[b]

**Keywords:** Copper / Cyclen and cyclam ligands / X-ray diffraction / UV/Vis and EPR spectroscopy / Electrochemistry / Configurational isomerisation

The protonation constants of cyclen– and cyclam–pyridine [1-(pyridin-2-ylmethyl)-1,4,7,10-tetraazacyclododecane ($\mathbf{L^1}$) and 1-(pyridin-2-ylmethyl)-1,4,8,11-tetraazacyclotetradecane ($\mathbf{L^2}$), respectively] and the stability constants ($\log\beta_{110}$) of the corresponding copper complexes ($[Cu\mathbf{L^1}]^{2+}$ and $[Cu\mathbf{L^2}]^{2+}$) were determined by potentiometric titrations. The complexes were subsequently isolated and characterised by X-ray diffraction, UV/Vis spectroscopy and electrochemical studies. The $[Cu\mathbf{L^2}]^{2+}$ complex adopts two distinct and stable geometries (*trans* I and III), which mainly differ by the macrocycle configuration. The *trans* III configurational isomer can be converted into the *trans* I one by electron transfer.

## Introduction

The coordination chemistry of tetraazamacrocyclic receptors like cyclen and cyclam is always of interest, as new fields like diagnostic imaging or therapeutic agent development have recourse to such ligands. Gadolinium complexes of polyamino carboxylate ligands are frequently used as contrast agents for magnetic resonance imaging (MRI) to improve the images.[1] Therapeutic metalloradiopharmaceuticals designed to localise tumour sites and deliver a cytotoxic radiation dose have become widespread.[2] These molecules are made up of a bifunctional chelator, which coordinates the metal ion and is covalently attached to a targeting molecule. The design of the chelator depends on the metal ion and, for instance, the complexation of copper radionucleides is provided by *N*-functionalised cyclams.[3] High thermodynamic and kinetic complex stabilities constitute crucial parameters for their in vivo applications. For this purpose, tetraazamacrocyclic receptors are very well suited, as the donor atoms, the ligand denticity and, above all, the ligand preorganisation ensure such stabilities. Finally, stereochemistry is often important when targeting complexes to specific receptors and, as far as tetraazamacrocyclic ligands are concerned, the orientation of the N–H bonds is important for receptor recognition.[4] It was recently shown that modifications of the macrocyclic substitution pattern can act directly on the stereochemistry and the properties of the metal complexes.[5–7] In particular, in metal complexes of *N*,*N*′,*N*′′,*N*′′′-tetrasubstituted tetraazamacrocycles, topological reorganisations can be induced by electron transfer. For these reasons, the preparation and characterisation of coordination compounds with tetraazamacrocyclic ligands bearing pendant substituents are still of interest. *N*-functionalisation may enhance the metal complexation and the coordination ability of the pendant arms may affect the stereochemistry of the metal complexes.

In this study, we focused on the copper coordination of cyclen– and cyclam–pyridine ($\mathbf{L^1}$ and $\mathbf{L^2}$, respectively; Scheme 1) in aqueous solution. The stability constants of the 1:1 copper complexes were determined. The complexes' stereochemistry was studied in solution (UV/Vis and EPR measurements) and supported by X-ray data. Finally, electrochemical experiments were carried out to give an insight into the behaviour of the copper complexes in solution.

## Results and Discussion

The ligands **L¹** and **L²** were prepared according to the bis(aminal) methodology.[8] The protonation constants of the ligands and the overall formation constants of the copper complexes (see Experimental Section) were determined by means of potentiometric titrations at 20 °C in a 1 mol·L$^{-1}$ $KNO_3$ medium.

### Acid/Base Behaviour of L¹ and L²

The titration of the **L¹** and **L²** solutions gave rise to neutralisation curves with a single inflexion point at pH ≈ 7 for both ligands. A nonlinear least-squares refinement of six independent data sets with PROTAF software[9] allowed the determination of the $\log K_{01h}$ values, which are summarised in Table 1 with those of cyclen, cyclam and a monopyridyl relevant derivative, **L³** (Scheme 1), for comparison. For both ligands, one should expect five protonation constants, four for the nitrogen atoms of the macrocycle and one for the pyridinic nitrogen atom ($N_{pyr}$).

For **L¹**, the first two constants, $\log K_{011}$ (10.6) and $\log K_{012}$ (9.77), are close to those determined for the parent cyclen.[10] It means that the beginning of the protonation pattern of **L¹** is similar to the cyclen one and that the first two added protons are bound inside the macrocyclic cavity. The same proposal can be formulated for the cyclam analogue **L²**, as the first two protonation constants ($\log K_{011}$ = 11.31 and $\log K_{012}$ = 10.47) are similar to the ones determined for the parent cyclam.[11]

For **L¹**, only the third protonation constant ($\log K_{013}$ = 3.42) can be reached, while the last two are too weak to be determined with sufficient accuracy, unlike **L²**, for which three additional protonation constants ($\log K_{013}$ = 2.88, $\log K_{014}$ = 2.32 and $\log K_{015}$ = 1.73) are calculated. For each ligand, the purpose is to identify as much as possible when the $N_{pyr}$-protonation occurs. In fact, for the ligands incorporating a pyridine moiety, the $N_{pyr}$-protonation occurs in a wide pH range: for example the $N_{pyr}$ protonation constant is $\log K_{012}$ = 2.46[12a] for the 2-pyridinylmethanamine, and $\log K_{013}$ = 3.91 for the relevant ligand cyclen–pyridine **L³** (Table 1[12b]). Consequently, for the studied ligands, the identification of the third (**L¹**) or third and fourth (**L²**) protonation sites remains ambiguous, as these protonation steps occur at pH < 3.5, and in this pH range at least two sites are in competition, the first one being the $N_{pyr}$ atom, the second one being a nitrogen atom from the macrocyclic cavity. This is particularly true for the cyclam ligand **L²**. In order to gain an insight into the protonation pattern of **L¹** and **L²**, UV absorption and $^1$H NMR evolutions taking place upon protonation were investigated. For **L¹** and **L²**, the acidification of the medium induces in the UV absorption spectra (Figure 1) the characteristic hyperchromic shift of the pyridine chromophore,[13] which begins to appear at pH = 3.7 for **L¹**, at pH = 2.9 for **L²** and increases with decreasing pH to a maximum for **L¹** at pH = 1.5 and for **L²** at pH = 1.6. The protonation patterns of **L¹** and **L²** ligands were then examined by recording $^1$H NMR spectra at different pH values. The proton assignment was firstly elucidated with the help of two-dimensional $^1$H-$^1$H COSY, $^1$H-$^{13}$C HMQC and $^1$H-$^{13}$C HMBC correlation charts. For **L¹** (Figure 2, see also SI-1 in the Supporting Information), the chemical shifts of the aromatic protons ($H_{ar}$) are sensitive reporters of the protonation state of the ligand amino

functions. In the pH range 4–12, no significant evolution of the $^1H_{ar}$ chemical shifts is observed (see also molecular modelling of **L¹**), which means that the first two protons bind the macrocycle (**L¹**H⁺ and **L¹**$H_2^{2+}$ species). In the pH range 2–4, a marked downfield shift is observed for the signals of the aromatic protons. This observation, in agreement with the UV data, strongly suggests that the third protonation step in **L¹** occurs on the $N_{pyr}$ atom.[14] For **L²** (Figure 3, see also SI-2,3 in the Supporting Information), the best reporters of the protonation steps are the $H_{ar}$ and the protons in the β-position with respect to the macrocyclic nitrogen atoms. In the pH range 9–12, a downfield shift is observed for the signals of the aliphatic protons, confirming that the first two protons added (species **L²**H⁺ and **L²**$H_2^{2+}$) bind to the macrocyclic cavity. In the pH range 1.5–3, a concomitant downfield shift of the signals of $H_{ar}$ and β-H is observed. In this region, the distribution diagram of the protonated **L²** species indicates that the existence domains of **L²**$H_3^{3+}$, **L²**$H_4^{4+}$ and **L²**$H_5^{5+}$overlap. It is worth noting that the coexistence of these three species induces a deep modification of the β-H signals with the coalescence of the β-H signals at pH ≈ 2 (see SI-3 of the Supporting Information). All these arguments mean that, for **L²**, the third and fourth protonation steps cannot be unambiguously attributed to the $N_{pyr}$ atom and to a macrocyclic nitrogen atom, respectively.

It is worth noting too that, for **L¹**, the difference between $\log K_{012}$ and $\log K_{013}$ is important. The third protonation constant attributed to the $N_{pyr}$ atom in **L¹** ($\log K_{013}$ = 3.42) is about two orders of magnitude smaller than that for the $N_{pyr}$-protonation in pyridine ($pK_a$ = 5.25[15]). This difference reflects the free-energy cost of protonating the third amino group in **L¹**, that is, the protonation of the $N_{pyr}$ atom is more difficult when the pyridine group is appended in proximity to the macrocyclic ring. At least two reasons can be invoked to explain this behaviour.[16] The first one takes into account the stabilisation of the diprotonated structure by intramolecular hydrogen bonding with the pyridine nitrogen atom (the protonation of this atom then induces hydrogen bond break-up). The second one corresponds to a conformational reorganisation upon protonation. To check these assumptions, molecular modelling of **L¹** and its protonated forms was undertaken.

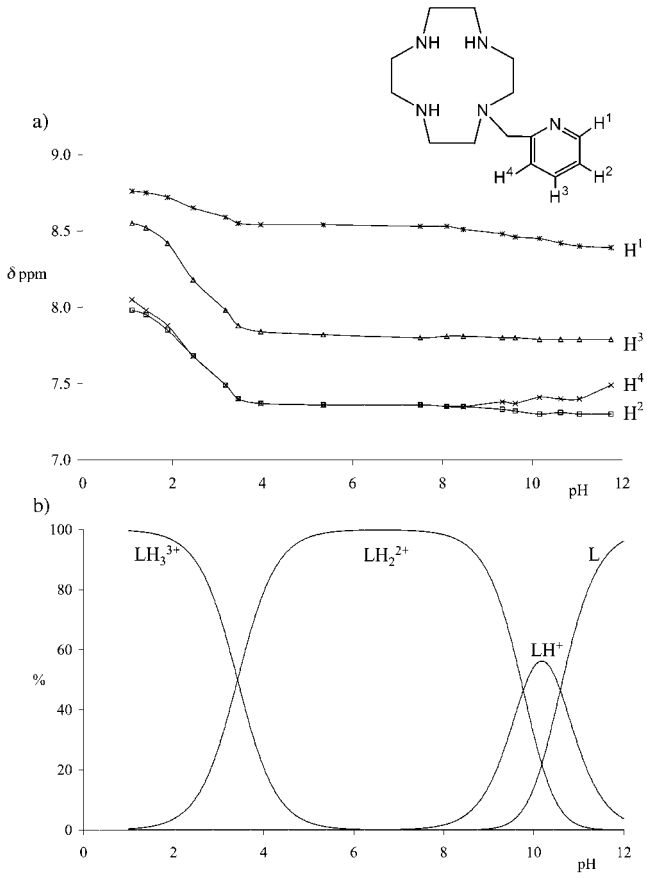

Figure 2. (a) pH dependence of the $^1H$ aromatic NMR signals of **L¹**. (b) Distribution diagram of the **L¹** protonated forms ([**L¹**] = $1.5\times10^{-3}$ mol·L$^{-1}$, $I$ = 1 mol·L$^{-1}$).

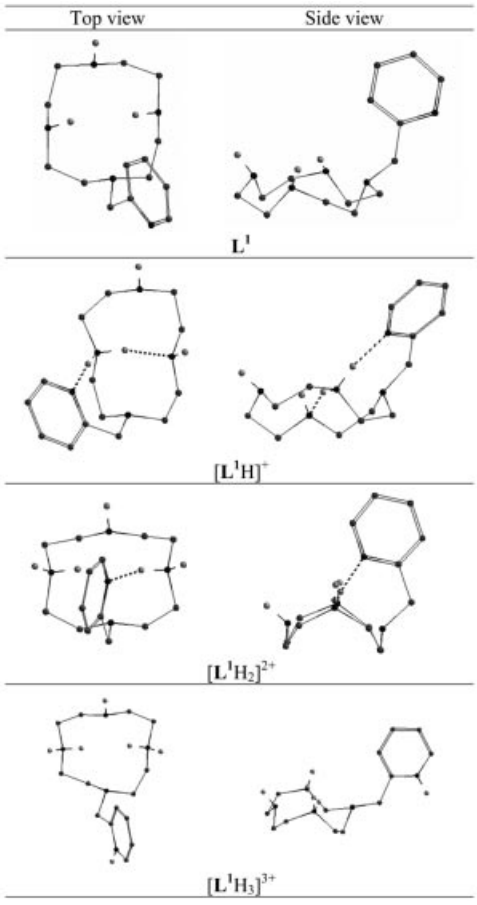
### Molecular Modelling of $L^1$ and Its Protonated Forms

Low-energy conformers generated by a conformational search performed at the semiempirical level (AM1 calculations) were optimised using the Gaussian package[17a] under DFT/B3LYP/6-31G* formalism. The results concerning the **L¹** ligand are gathered in Table 2.

Table 2. DFT-optimised molecular structures of **L¹**, $[\mathbf{L^1}H]^{1+}$, $[\mathbf{L^1}H_2]^{2+}$and $[\mathbf{L^1}H_3]^{3+}$. For the sake of clarity, only the pertinent hydrogen atoms are represented. The dashed lines correspond to hydrogen bonds.



The lowest-energy structure computed for the neutral ligand **L¹** shows an outward orientation of the pyridine moiety relative to the macrocyclic cavity. The macrocycle has two of the three hydrogen atoms of the secondary amine functions directed towards the centre of the cavity. For the stepwise addition of protons, all the protonation sites were considered and the most stable situations are reported in Table 2. As the first proton is added, the pyridine moiety moves towards the inside of the macrocyclic cavity. The optimised geometry shows that the added proton is stabilised by a hydrogen bond with the $N_{pyr}$ atom, the overall structure being stabilised by two intramolecular hydrogen bonds. These characteristics are reinforced when the addition of the second proton is considered. The diprotonated structure is symmetrical, the symmetry plane including the pyridine ring. The pyridine moiety is then in an apical position towards the macrocyclic cavity, the $N_{pyr}$ atom stabilising the added proton by hydrogen bonds. Finally, the addition of the third proton occurs on the $N_{pyr}$ atom and the pyridine moiety is moved outward the macrocyclic cavity. The $N_{pyr}$ atom can no longer stabilise the first two added protons, as the hydrogen bonds are broken up. Moreover, the comparison of the calculated macrocyclic shapes for the **L¹** ligand and its protonated forms shows conformational modifications. The reorganisation of the macrocyclic cavity as a function of an increased number of protons is a way to accommodate positive charges in proximity. The modification is particularly important between $[\mathbf{L^1}H_2]^{2+}$ and $[\mathbf{L^1}H_3]^{3+}$ structures, as it corresponds to the shift of the pyridine ring away from the cyclen cavity. All these considerations indicate that the protonation of the $[\mathbf{L^1}H_2]^{2+}$ species is difficult, which is in good agreement with the small $\log K_{013}$ value determined for **L¹**.

### Copper Complexation of $L^1$ and $L^2$

#### *Thermodynamic Stability of the Complexes $[CuL^1]^{2+}$ and $[CuL^2]^{2+}$*

The pH titration of the ligands **L¹** and **L²** in the presence of 1 equiv. of copper(II) showed the formation of $[Cu\mathbf{L^1}]^{2+}$ and $[Cu\mathbf{L^2}]^{2+}$ complexes. From the analysis of the titration data, the complexation constants $\log\beta_{110}$ of $[Cu\mathbf{L^1}]^{2+}$ (21.0 ± 0.2) and $[Cu\mathbf{L^2}]^{2+}$ (23.0 ± 0.2) were determined (Table 1). The comparison of these values with those determined for (cyclen)- and (cyclam)copper complexes shows that the *N*-functionalisation of the cavity provokes a decrease of the complexes' stability (Table 1). This decrease is, however, less pronounced than for the benzyl complexes $[Cu\mathbf{L^4}]^{2+}$ and $[Cu\mathbf{L^5}]^{2+}$ (Table 1). This suggests that in solution the pyridine moiety is weakly involved in copper coordination.

#### *Molecular Structures of the Complexes*

To provide a proof of the stoichiometry and the structure of the complexes, a crystallographic study of the copper(II) complexes of **L¹** and **L²** was carried out.

For the $[Cu\mathbf{L^1}]^{2+}$ complex, X-ray quality blue single crystals were grown from diffusion of diethyl ether into an acetonitrile solution of the complex. Selected geometrical parameters are given in Table 3. The X-ray structure of $[Cu\mathbf{L^1}]^{2+}$ showed that the metal ion is pentacoordinate (Figure 4), the coordination sphere of the copper centre consisting of the four macrocyclic nitrogen atoms and the pyridinic $N_{pyr}$ atom. The Cu–N(secondary) bond lengths [2.013(4)–2.022(4) Å] are in the range expected for a copper ion coordinated in a cyclen cavity;[18] the Cu–N(tertiary) bond length of 2.058(3) Å, longer than the average of the Cu–N(secondary) ones (2.018 Å), is a consequence of the macrocyclic *N*-alkylation.[19] The $N_{pyr}$ atom is coordinated to the copper ion and the Cu–$N_{pyr}$ bond length is rather short [2.164(4) Å] by comparison with the same situation in the corresponding bis(macrocyclic) compound (2.266 Å).[18] This leads, in the solid state, to an efficient five-membered

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chelate ring, as the $N_{pyr}$–Cu–N4 angle of 80.65(14)°, where the N4 atom bears the pyridine arm, is noticeably smaller than the other three $N_{pyr}$–Cu–N angles [99.00(17)–126.74(16)°].

Table 3. Selected bond lengths [Å] and angles [°] in $[CuL^1]^{2+}$.

| | | | |
|---|---|---|---|
| Cu–N1 | 2.013(4) | N1–Cu–N2 | 86.31(16) |
| Cu–N2 | 2.020(4) | N1–Cu–N3 | 146.94(18) |
| Cu–N3 | 2.022(4) | N1–Cu–N4 | 85.44(14) |
| Cu–N4 | 2.058(3) | N1–Cu–N5 | 111.24(16) |
| Cu–N5 | 2.164(4) | N2–Cu–N3 | 86.10(16) |
| | | N2–Cu–N4 | 152.46(17) |

| | | N3–Cu–N4 | 86.62(15) |
| | | N3–Cu–N5 | 99.00(17) |
| | | N4–Cu–N5 | 80.65(14) |

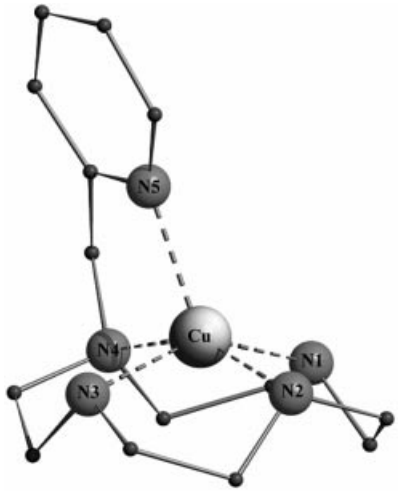

Figure 4. SCHAKAL diagram of $[CuL^1]^{2+}$.

For the $[CuL^2]^{2+}$ complex, as far as metal cation coordination by a cyclam derivative is concerned, one may expect the formation of stereoisomers for the complexes, according to the relative orientation of the NH group towards the macrocyclic cavity. The most frequently encountered configurational isomers are *trans* I (*R*,*S*,*R*,*S*) (++++) and *trans* III (*R*,*R*,*S*,*S*) (+–+–), where + indicates that the NH group is above the plane of the macrocycle and – indicates that it is below the plane.[20] Recently, it was demonstrated that, according to the redox state of the copper centre, different coordination modes around the metal ion are reached and can be responsible for the formation of the *trans* I and the *trans* III isomers.[6] Thus, depending on the experimental conditions, *trans* I and *trans* III isomers of $[CuL^2]^{2+}$ were isolated and characterised in the solid state. A $[CuL^2]^{2+}$ complex was easily obtained as a blue solid when the synthesis was performed with copper perchlorate in $CH_3OH$. The X-ray structure of the corresponding complex (Figure 5, Table 4a) showed that it adopts the *trans* I arrangement. The copper ion is pentacoordinate in a distorted square-pyramidal environment. The $N_{pyr}$ atom is therefore coordinated to the metal centre [2.220(2) Å]. The bond angles around the copper ion are different from those expected in an ideal square-pyramidal structure [e.g. N1CuN2, N4CuN1, N2CuN4, N3CuN1 of 86.20(5), 95.83(5), 170.96(5), 164.19(5)°, respectively]. The four macrocyclic nitrogen atoms define a plane and the copper ion is out of this plane by 0.218 Å.

When the complexation was performed with $L^2$ and $Cu(CH_3CN)_4PF_6$ as $Cu^I$ salt in $CH_3OH$ under aerobic conditions,[6] a violet solid resulting from the oxidation of $Cu^I$ by dioxygen was formed. The X-ray structure of the complex (Figure 6, Table 4b) highlighted the fact that it adopts a *trans* III configuration. The copper environment is still pentacoordinate, the $N_{pyr}$–Cu bond being a little longer [2.250(2) Å] than the corresponding one in the *trans* I complex. The main geometrical parameters are more or less the same as those observed for the *trans* I isomer, the copper ion being out of the macrocyclic plane by 0.224 Å.

| $[CuL^1]^{2+}$ | 595 (218) | 601 (247) | 600 |
| $[CuL^2]^{2+}$ *trans* I | 602 (129) | 588 (144) | 580 |
| $[CuL^2]^{2+}$ *trans* III | 541 (228) | 550 (125) | 551 |

In the $[CuL^2]^{2+}$ *trans* I/III complexes, with regard to the copper band, the spectrum of the *trans* I complex exhibits a $\lambda_{max}$ = 602 nm in $H_2O$ (588 nm in $CH_3CN$) and a $\lambda_{max}$ = 580 nm in the solid state. The concordance of solid-state and solution UV/Vis spectra means that on going from the solid state to solution, the copper environment is maintained. The $\lambda_{max}$ values are consistent with a pentacoordinate copper centre,[19b,21] where the pyridyl group coordination has to be considered, according to the X-ray data for the $[CuL^2]^{2+}$ *trans* I complex ($CuN_5$ chromophore). For the *trans* III complex, a $\lambda_{max}$ = 541 nm in $H_2O$ (550 nm in $CH_3CN$) and a $\lambda_{max}$ = 551 nm in the solid state were determined. The $\lambda_{max}$ values suggest then that the pyridyl group in the *trans* III complex is still coordinated to the metal centre ($CuN_5$ chromophore). When a 5 M perchloric acid solution was added to aqueous solutions of $[CuL^2]^{2+}$ *trans* I/III complexes, a blue shift was observed for the absorption maxima (from 602 to 531 nm for $[CuL^2]^{2+}$ *trans* I and from 541 to 511 nm for $[CuL^2]^{2+}$ *trans* III). The positions of the resulting bands (531 and 511 nm) are typical of a $CuN_4$ chromophore where the metal ion is held in an *N*-monofunctionalised cyclam cavity.[22] Then the acid addition triggered the pyridine decoordination.

In the $[CuL^1]^{2+}$ complex, the spectrum exhibits a broad band at $\lambda_{max}$ = 595 nm in $H_2O$ (601 nm in $CH_3CN$) and at $\lambda_{max}$ = 600 nm in the solid state. The positions of these bands are typical of a square-pyramidal complex[18] where the copper centre is pentacoordinate. The concordance of solid-state and solution UV/Vis spectra seems to indicate that the copper coordination is again the same in the solid state and in solution. On the basis of the X-ray structure, it means that the pyridine moiety participates in the metal coordination ($CuN_5$ chromophore). To test this proposal, a 5 M perchloric acid solution was added to an aqueous solution of the $[CuL^1]^{2+}$ complex. Under these conditions, no blue shift of the absorption maximum was observed. In fact, this is not surprising if we consider that under acidic conditions the pyridine moiety can be decoordinated and replaced by a water molecule, as it is well known that in the cyclen cavity the copper ion is always pentacoordinate.[18] The acidification of the $[CuL^1]^{2+}$ solution can lead to chromophore modification from $CuN_5$ to $CuN_4O$.

Electron paramagnetic resonance corroborates the coordination geometry proposed for the copper ion in $CuL^1]^{2+}$ and $[CuL^2]^{2+}$ *trans* I/III complexes. The EPR spectra of the three complexes were recorded in a DMF solution at 150 K to ensure good glasses, and the corresponding simulated anisotropic parameters are listed in Table 6. The X-band EPR spectra of $[CuL^1]^{2+}$ and $[CuL^2]^{2+}$ *trans* I/III frozen solutions exhibit a strong absorption at about 3200 G, imputable to the allowed transitions $\Delta M_S = 1$. The shapes of the spectra consisted of four equidistant absorptions in the parallel region as expected for the coupling of the unpaired copper electron to the copper nucleus ($I$ = 3/2) (SI-4 in the Supporting Information). These spectra with $g_\parallel > g_\perp$ and $G > 4$ are typical of axially symmetric $d^9$ copper(II) complexes in a ground-state doublet with the unpaired electron in the $d_{x^2-y^2}$ orbital.[21] Moreover, for $[CuL^2]^{2+}$ complexes, the $g_\parallel$ values are slightly larger than that for [Cu(cyclam)]$^{2+}$ (2.186),[23] which is again consistent with the *N*-alkylation of the macrocyclic cavity.[22] The hyperfine coupling constant $A_\parallel$ is also a good indicator of distortion from square-planar to square-pyramidal coordination in copper(II) complexes, with smaller values implying distortion.

Table 6. EPR parameters of $[CuL^{1,2}]^{2+}$ complexes in frozen solution (DMF) at 150 K.

| | $g_\parallel$ | $g_\perp$ | [a] | $A_\parallel$ [$10^{-4}$ cm$^{-1}$] | $A_\perp$ [$10^{-4}$ cm$^{-1}$] |
|---|---|---|---|---|---|
| $[CuL^1]^{2+}$ | 2.192 | 2.045 | 4.26 | 175.0 | 15.6 |
| $[CuL^2]^{2+}$ *trans* I | 2.190 | 2.045 | 4.22 | 177.5 | 25.5 |
| $[CuL^2]^{2+}$ *trans* III | 2.197 | 2.045 | 4.37 | 188.7 | 22.5 |
| [Cu(cyclen)]$^{2+}$[b] | 2.198 | 2.057 | | 184 | |
| [Cu(cyclam)]$^{2+}$[b] | 2.186 | 2.049 | | 205 | |

[a] $G = (g_\parallel - 2)/(g_\perp - 2)$. [b] Ref.[23]

The $A_{\parallel}$ values for $[Cu\mathbf{L^1}]^{2+}$and $[Cu\mathbf{L^2}]^{2+}$ *trans* I/III are smaller than the corresponding $A_{\parallel}$ values for $[Cu(cyclen)]^{2+}$ and $[Cu(cyclam)]^{2+}$ (Table 6), which is consistent with $[Cu\mathbf{L^1}]^{2+}$and $[Cu\mathbf{L^2}]^{2+}$ *trans* I/III X-ray structures and pentacoordinate copper centres.

### Redox Properties of the $[CuL^{1,2}]^{2+}$ Complex

The electrochemical behaviour of $[Cu\mathbf{L^1}]^{2+}$ in acetonitrile was determined. The reduction was quasireversible and occurred at $E_{1/2}^{red}$ = –0.89 V versus $Fc^+$/Fc ($\Delta E_p$ = 80 mV); the oxidation was irreversible with a peak potential at $E_p^{ox}$ = 1.55 V versus $Fc^+$/Fc. No change in the CV waves was observed when full scans were performed except a drop in the current intensities when the system was investigated at high potentials, because of the irreversible oxidation.

Electrochemical studies of acetonitrile solutions of $[Cu\mathbf{L^2}]^{2+}$ *trans* I/III were only performed on the $Cu^{II}/Cu^{I}$ reduction system as oxidation to $Cu^{III}$ is irreversible and produces highly oxidative species giving very high anodic currents.[24] For the *trans* I complex, a single quasireversible reduction system was observed at $E_{1/2}^{red}$ = –1.145 V versus $Fc^+$/Fc ($\Delta E_p$ = 130 mV) and the voltammogram was fully reproducible from the first scan to several scans in reduction. This means that the electrogenerated $[Cu\mathbf{L^2}]^{+}$ *trans* I complex is stable, as it does not evolve within the voltammetry timescale.[7] For the *trans* III complex, the reduction yielded the short-lived $[Cu\mathbf{L^2}]^{+}$ *trans* III complex, for which an irreversible wave was located at $E_p^{red}$ = –1.05 V versus $Fc^+$/Fc. The comparison of the reduction potential of $[Cu\mathbf{L^2}]^{2+}$ *trans* I and $[Cu\mathbf{L^2}]^{2+}$ *trans* III shows that the *trans* I complex is more difficult to reduce than the *trans* III one. This has to be correlated with the Cu–$N_{pyr}$ distances obtained from crystallographic measurements. For the *trans* I complex, the Cu–$N_{pyr}$ distance is 2.220 Å, while for the *trans* III one this distance is 2.250 Å; for the *trans* I isomer, the ligand field is therefore stronger. Consequently, the *trans* I isomer's antibonding $e_g$* orbitals are destabilised compared to the *trans* III ones, making, for the *trans* I isomer, the removal of an electron easier and its withdrawal more difficult.[22]

The electrogenerated $[Cu\mathbf{L^2}]^{+}$ *trans* III complex is a transient species. Effectively, it readily isomerises as the reversible *trans* I system at $E_{1/2}^{red}$ = –1.15 V versus $Fc^+$/Fc ($\Delta E_p$ = 140 mV) is immediately observed after the irreversible *trans* III one. On cycling, the consecutive voltammograms exhibit only the *trans* I system. This behaviour has been observed until now only on tetrasubstituted (cyclam)copper complexes,[6,7] and indicates that the topological rearrangement process of the electrogenerated $[Cu\mathbf{L^2}]^{+}$ *trans* III complex to a $[Cu\mathbf{L^2}]^{+}$ *trans* I complex is rapid. One can also conclude that the pyridine moiety greatly enhances the $[Cu\mathbf{L^2}]^{+}$ stabilities, particularly for the *trans* I complex, as it does not evolve towards other species within the voltammetry timescale.[7] Finally, as the *trans* III → *trans* I conversion has not been observed by other techniques, electrochemical experiments illustrate the relevance of electron transfer in mediating topological reorganisation of the functionalised cyclam cavity.

## Conclusion

In cyclen– and cyclam–pyridine ligands and their copper complexes, the pyridine moiety behaves as a "non-innocent" fragment and its influence can be felt at several levels.

In the ligands, it participates through intramolecular hydrogen bonds in the stabilisation of two added protons in the macrocyclic cavity. In the copper complexes, the pyridine nitrogen atom participates as a fifth coordination site for the metal ion, both in the solid state and in solution. Regarding the complexes' structures, the pyridine moiety does not significantly affect the flexibility of the macrocyclic shape, as two configurational (cyclam–pyridine)copper complexes (*trans* I and *trans* III) can be synthesised. Finally, the pyridine moiety facilitates the stabilisation of copper(I) complexes and, as a result, helps the mediated electron transfer topological reorganisation of the *trans* III complex into the *trans* I one.

## Experimental Section

**Syntheses:** The metal salts were purchased from Aldrich. All the other reagents were of the highest grade commercially available and used without further purification.

**Ligand Synthesis:** The ligands $\mathbf{L^1}$ and $\mathbf{L^2}$ were synthesised according to a published procedure.[8]

#### Preparation of the Copper Complexes

**$[Cu\mathbf{L^1}](ClO_4)_2$:** Copper perchlorate hexahydrate (130 mg, 0.35 mmol) in methanol (5 mL) was added dropwise to a solution of $\mathbf{L^1}$ (100 mg, 0.32 mmol) in methanol (15 mL). The blue solution was refluxed for 2 h and then concentrated by solvent evaporation. The blue solid complex was precipitated upon addition of diethyl ether, and collected by filtration under vacuum. This solid was further dissolved in acetonitrile and the diffusion of a diethyl ether solution produced blue monocrystals of $[Cu\mathbf{L^1}](ClO_4)_2$, suitable for X-ray analysis. $C_{14}H_{25}Cl_2CuN_5O_8{\cdot}H_2O$ (543.84): calcd. C 30.92, H 5.00, N 12.88; found C 31.06, H 4.72, N 12.70. ESI-MS; *m*/*z* (%): calcd. for $[Cu\mathbf{L^1}(ClO_4)]^+$ 425, found 425 (100); calcd. for $[Cu\mathbf{L^1}H_{-1}]^+$ 325, found 325 (75).

**$[Cu\mathbf{L^2}](ClO_4)_2$ *trans* I:** A similar procedure to that described for $[Cu\mathbf{L^1}](ClO_4)_2$ was used. Blue single crystals suitable for X-ray diffraction analysis were obtained by diffusion of diethyl ether in the acetonitrile solution of $[Cu\mathbf{L^2}](ClO_4)_2$. $C_{16}H_{29}Cl_2CuN_5O_8$ (553.88): calcd. C 34.70, H 5.28, N 12.64; found C 34.65, H 5.01, N 12.48. ESI-MS; *m*/*z* (%): calcd. for $[Cu\mathbf{L^2}(ClO_4)]^+$ 453, found 453 (100); calcd. for $[Cu\mathbf{L^2}H_{-1}]^+$ 353, found 353 (60).

***CAUTION:*** Perchlorate-containing complexes are potentially explosive and appropriate precautions should be in place for their preparation, handling and storage.

**$[Cu\mathbf{L^2}](PF_6)_2$ *trans* III:** $Cu(CH_3CN)_4PF_6$ (62 mg, 0.17 mmol, white powder) in methanol (5 mL) was added dropwise to $\mathbf{L^2}$ (50 mg, 0.17 mmol) in methanol (10 mL). The solution, which immediately turned blue, was stirred at room temperature in aerobic conditions for 1 d and then concentrated by solvent evaporation. The violet solid complex was precipitated upon addition of diethyl ether, and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

collected by filtration. This solid was further dissolved in methanol and the diffusion of a diethyl ether solution produced violet single crystals of $[Cu\mathbf{L^2}](PF_6)_2$, suitable for an X-ray analysis. $C_{16}H_{29}CuF_{12}N_5P_2{\cdot}CH_3OH$ (676.95): calcd. C 30.16, H 4.91, N 10.35; found C 30.29, H 4.73, N 10.45. ESI-MS; *m*/*z* (%): calcd. for $[Cu\mathbf{L^2}(PF_6)]^+$ 499, found 499 (70); calcd. for $[Cu\mathbf{L^2}H_{-1}]^+$ 353, found 353 (100).

**Potentiometric Measurements:** Potentiometric titrations were carried out with an automatic titrator composed of a microprocessor burette Metrohm Dosimat 665 and a Metrohm pH-Meter 713 connected to a computer. The titration procedure was fully automated.[25] All measurements were performed within a thermoregulated cell at 20.0 ± 0.1 °C under an argon stream to avoid the dissolution of carbon dioxide. The ionic strength was adjusted to 1 with potassium nitrate. The combined "U"-type Metrohm glass electrode used had a very low alkaline error. Solutions of ligand ($1\times10^{-3}$ to $2\times10^{-3}$ mol·L$^{-1}$) and ligand/copper nitrate mixture (ligand/metal ratio in the range 1.2–2) were titrated with a 0.1 mol·L$^{-1}$ KOH solution. For the complex titrations, an equilibration period of 1 month at 40 °C at acidic pH was observed until pH stabilisation. The potentiometric data were processed by using the PROTAF program[9] to obtain the best-fit chemical model and refined overall constants $\beta_{mlh}$.

$$m\,M + l\,L + h\,H^+ \rightleftharpoons M_mL_lH_h \qquad \beta_{mlh} = \frac{[M_mL_lH_h]}{[M]^m[L]^l[H^+]^h}$$

The stepwise protonation constants ($K_{0lh}$) related to the equilibrium of Equation (1) are defined by Equation (2) and were deduced from the refined ($\beta_{0lh}$) values by Equation (3).

$$LH_{h-1}^{(h-1)+} + H^+ \overset{K_{0lh}}{\rightleftharpoons} LH_h^{h+} \quad (1)$$

$$K_{0lh} = \frac{[LH_h^{h+}]}{[LH_{h-1}^{(h-1)+}][H^+]} \quad (2)$$

$$\beta_{0lh} = \prod_{i=1}^{h} K_{0li} \quad (3)$$

**Spectroscopic Measurements:** $^1$H and $^{13}$C NMR spectra were recorded with a Bruker DRX 500 spectrometer. $^1$H-$^1$H and $^1$H-$^{13}$C 2D correlation experiments were performed to assign the signals. In $^1$H NMR titrations, the pD was adjusted by additions of small amounts of a 4% diluted NaOD solution or a 3.5% diluted DCl solution to $D_2O$ solutions containing ligand $\mathbf{L^1}$ or $\mathbf{L^2}$ ($1.5\times10^{-3}$ mol·L$^{-1}$). The pH was calculated from the measured pD values using Equation (4).[26]

$$pH = pD - 0.40 \quad (4)$$

For both ligands, NMR measurements were performed after an equilibration time of 1 d. Mass spectra in acetonitrile were recorded with a Micromass Q-TOF instrument by electrospray positive ionisation. Electronic spectra in aqueous or acetonitrile solutions were all measured in the 200–900 nm range with a Perkin–Elmer Lambda 6 spectrophotometer. Solid-state spectra were obtained by depositing the complexes on a "Schleicher and Schüll" paper. EPR spectra were recorded with a Bruker ESP 300e spectrometer equipped with a Bruker E035M gaussmeter and an HP 5350B microwave frequency counter. Samples were prepared at a concentration of 5 mmol·L$^{-1}$ in DMF frozen solutions (150 K, Bruker ER4111VT variable-temperature unit). The simulation of the high-field EPR spectra was performed using XSophe software version

1.1.4 for Mandriva 2006 x86-64 developed by the centre for Magnetic Resonance and the Department of Mathematics of the University of Queensland, Brisbane, Australia, for Bruker Biospin GmbH.[27] The software uses an angular dependence of *g* linewidth model and a Hooke and Jeeves optimisation method with the copper element in a natural abundance (for $[Cu\mathbf{L^1}]^{2+}$: linewidth in the parallel region $23.7\times10^{-4}$ cm$^{-1}$, in the perpendicular region $19.8\times10^{-4}$ cm$^{-1}$; for $[Cu\mathbf{L^2}]^{2+}$ *trans* I: linewidth in the parallel region $35.0\times10^{-4}$ cm$^{-1}$, in the perpendicular region $27.0\times10^{-4}$ cm$^{-1}$; for $[Cu\mathbf{L^2}]^{2+}$ *trans* III: linewidth in the parallel region $32.5\times10^{-4}$ cm$^{-1}$, in the perpendicular region $17.5\times10^{-4}$ cm$^{-1}$).

**Electrochemical Measurements:** Voltammetric data were recorded with an "Autolab with PGSTAT12" potentiostat (ECO Chemie) associated to a conventional three-electrode electrochemical cell, the working electrode being a glassy carbon disk. A platinum plate was used as a counter electrode and a silver electrode separated from the complex solution was used as a pseudoreference. In acetonitrile, the potential of the pseudoreference was measured versus the ferricinium/ferrocene couple. Complex concentrations were always close to $10^{-3}$ mol·L$^{-1}$ and tetrabutylammonium hexafluorophosphate $10^{-1}$ mol·L$^{-1}$ was used as the supporting electrolyte.

**Computational Details:** The input geometries were obtained by a conformational search performed on each structure, $\mathbf{L^1}$, $[\mathbf{L^1}H^+]$, $[\mathbf{L^1}H^{2+}]$, $[\mathbf{L^1}H^{3+}]$, at the semiempirical level (AM1 calculations, Spartan software[17b]) to determine the lowest conformer for each. The low-energy conformers generated were then minimised using the Gaussian 98 program package.[17a] Both geometry and energy calculations were performed at the DFT/B3LYP/6-31G* level. Each molecular structure was fully optimised and characterised as a minimum by frequency calculations.

**Crystal Structure Determination:** The crystal diffraction data were collected with a Kappa CCD diffractometer (Centre de Diffractométrie X, Univ. Rennes, France) using monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 120 K. Data collection was performed with the COLLECT program.[28] Frames integration and data reduction procedures were realised using the DENZO and SCALEPACK program of the KappaCCD software package, respectively,[29] for the $Cu\mathbf{L^1}$ and $Cu\mathbf{L^2}$ *trans* I/III compounds and with EVAL[30] and SADABS[31] programs. The structures were solved using the direct-methods program SIR97,[32] which revealed all non-hydrogen atoms. SHELXL97[33] was used to refine the structure. Finally, hydrogen atoms were placed geometrically and held in riding mode in the least-squares refinement procedure. Final difference maps revealed no significant maxima. Further details are given in Table 7. CCDC-602318 ($[Cu\mathbf{L^1}]^{2+}$), -602319 ($[Cu\mathbf{L^2}]^{2+}$ *trans* I) and -602320 ($[Cu\mathbf{L^2}]^{2+}$ *trans* III) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Stack plots of $^1$H NMR spectra (aromatic region), EPR spectra, and Z-matrix of DFT-minimised (B3LYP/6-31G*) lowest-energy conformers.

## Acknowledgments

We thank Dr. J. M. Nuzillard and H. Ballia (Université de Reims Champagne Ardenne, France) for their help in the 2D NMR measurements. D. Harakat is thanked for ESI-MS measurements. Prof. G. R. Hanson (University of Queensland, Australia) is gratefully acknowledged for his valuable assistance during the implementation of XSophe.

# Crystal Structure and Properties of $MgCo_4Ge_6$

**Christine Gieck,[a] Martin Schreyer,[a] Thomas F. Fässler,*[a] Fabian Raif,[b] and Peter Claus[b]**

**Keywords:** Intermetallic phases / Germanium / Heterogeneous catalysis / ELF (Electron Localization Function) / Density functional theory

$MgCo_4Ge_6$ is a novel compound in the ternary system Mg-Co-Ge. Single crystals for a structure analysis were obtained from mixtures of the elements at high temperatures in sealed tantalum ampoules. The tetragonal structure [$I\bar{4}_2m$; $a$ = 6.1725(9) and $c$ = 8.660(2) Å; $YRu_4Sn_6$ structure type] was determined by X-ray single crystal analysis and refined to $R_1$ = 0.027 for all data. The electronic structure is discussed by means of density of states and band-structure analyses on the basis of density functional theory. Chemical bond analysis is performed using the electron localization function (ELF). The catalytic properties of the polar intermetallic alloy with respect to the selective hydrogenation of α,β-unsaturated aldehydes are discussed and compared with those of the recently investigated $MgCo_6Ge_6$.

## Introduction

The synthesis of polar intermetallic alloys with a well-defined stoichiometry is attempted in order to obtain substitutes for the expensive platinum group metal catalysts currently used for the selective hydrogenation of α,β-unsaturated aldehydes. While both the electronic and structural properties of intermetallic compounds, as well as the catalytic properties of some alloys on ceramic supports, have been studied extensively, no systematic investigations on the catalytic properties of well-defined alloys have been reported yet. A comparison of the ternary tetrelides of cobalt and ruthenium shows that isotypic compounds are obtained in many cases.[1–4] Besides this isotypic relationship, which can be taken as evidence for the similarity of the chemical properties of the two metals involved, we have also found that specific element combinations in alloys lead to an unexpected catalytic activity. In this context, we have recently reported the catalytic properties of $Mg_2Sn$[5] and $MgCo_6Ge_6$,[6] both of which show a remarkable activity and a high selectivity for the hydrogenation of *cis*/*trans* citral to geraniol and nerol. Since alloys of such compositions have not yet been considered as catalytically active materials, we extended our systematic study to other compounds in the ternary phase diagram Mg-Co-Ge and report here on the novel representative $MgCo_4Ge_6$.

## Results and Discussion

### Crystal Structure

$MgCo_4Ge_6$ crystallizes in the $YRu_4Sn_6$ structure type and can be derived from the $Au_3Cu$ structure.[7,8] The relationship between the structure of $MgCo_4Ge_6$ and that of $Au_3Cu$ is emphasized in Figure 1. The $Au_3Cu$ structure derives from a cubic close packing of Au atoms by replacing every fourth Au by a Cu atom in each close packed layer, whilst maintaining the Au triangles. The cubic packing of those trigonal layers labeled as A, B, and C is shown in Figure 1 (a). Replacement of every second Mg atom in the hypothetical, corresponding $MgGe_3$ structure by a $C_{2v}$ distorted tetrahedral $Co_4$ unit in an ordered manner (Figure 1, b) leads to the title compound ($Mg_2Ge_6$ → $MgCo_4Ge_6$). In the $Au_3Cu$ structure, Cu is cube-octahedrally coordinated by 12 Au atoms, and in $MgCo_4Ge_6$ Mg is similarly coordinated by 12 Ge atoms, although in a strongly distorted cube-octahedral manner. Two opposite squares of the six present in a cube-octahedron are rhomboidally distorted, with the orientation of the two short diagonals perpendicular to each other. The lengths of the short diagonals are in the range of the other Ge–Ge contacts within the cube-octahedron. The rhomboidal distorted squares of the $Ge_{12}$ cube-octahedra are strongly bent, thereby retaining the convex nature of the polyhedron. The remaining four squares of the cube-octahedron are capped by Co atoms. The resulting 16-vertex polyhedron $Mg@Ge_{12}Co_4$ is shown in Figure 2 (a). These polyhedra form a tetragonal body-centered packing and are interconnected by common vertices and external Co–Co bonds (Figure 2, b).

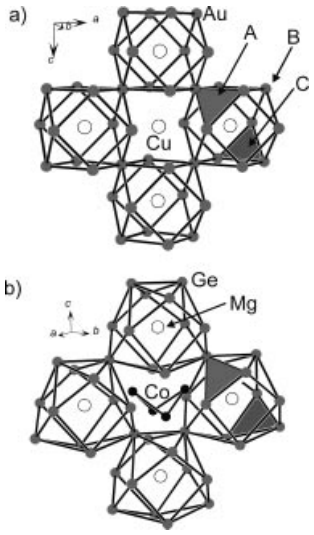

Figure 1. The relation between the $MgCo_4Ge_6$ and the $Au_3Cu$ structure. a) The $Au_3Cu$ structure; labels indicate atoms and the cubic stacking sequence of the layers A, B, and C; the $Au_3$ triangles of each layer are highlighted in grey. b) Related packing of $MgGe_{12}$ polyhedra in $MgCo_4Ge_6$, with inserted $Co_4$ units in black.

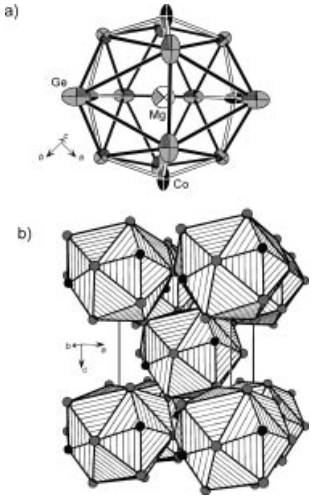

Figure 2. a) The $Ge_{12}Co_4$ coordination polyhedron around the Mg atom. All thermal ellipsoids are shown at 90% probability. b) Tetragonal body-centered packing of $Ge_{12}Co_4$ polyhedra (Co in black, Ge in grey).

An alternative description arises from the Ge sub-lattice, where the connection of the Ge atoms leads to layers of vertex-sharing $Ge_8$ units in the *ab* plane, with a close analogy between these units and the arrangement in the molecular compound $P_4S_4$ (Figure 3, a). The Ge substructure forms two-dimensional slabs in the *ab* plane that are stacked in the *c* direction, with each subsequent layer shifted by (1/2, 1/2, 1/2) to form the body-centered packing (Figure 3, b). The $P_4S_4$-like $Ge_8$ cages are "filled" with distorted tetrahedral $Co_4$ units (Figures 3, a and c), and the cavities formed by four vertex-sharing Ge atoms and four bridging Ge atoms host the Mg atoms. The coordination sphere of the Mg atoms is completed by two Ge–Ge contacts of − with respect to the Ge sub-lattice − three-connected Ge atoms of the previous and next Ge layers along the *c* direction (Figure 3, c). The Ge–Ge distances [2.906(1) and 2.987(1) Å] of the Ge sub-structure are longer than in typical covalently connected Ge atoms in Zintl phases, which are about 2.6 Å. Another interesting feature is the $Co_4$ unit that is present in the $P_4S_4$-type $Ge_8$ cages. These show two longer and four shorter Co–Co distances of 3.102(1) and 2.581(2) Å, respectively. The shorter distances

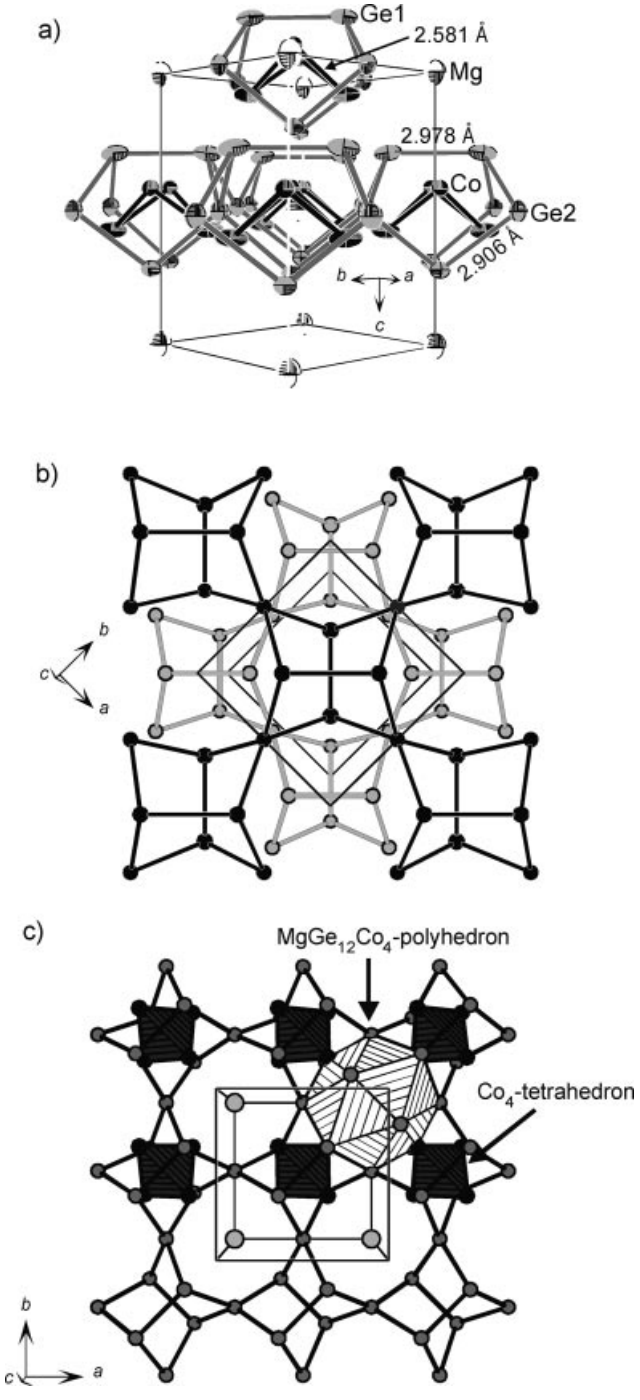

Figure 3. a) Crystal structure of $MgCo_4Ge_6$ as a combination of the Ge substructure centered by $Co_4$ units. All thermal ellipsoids are shown at 90% probability. b) [001] stacking of the germanium layers. c) Combination of the two views of a) and b).

are close to that observed in α-Co (2.506 Å).[9] Some binary cobalt germanides have even shorter Co–Co contacts, with the shortest being 2.377 Å in $Co_5Ge_7$.[10] Figure 3 (c) shows the combined picture of the packed polyhedra and the homoatomic Ge substructure: four 16-vertex polyhedra are interconnected in the *ab* plane by four fourfold-connected atoms of one $P_4S_4$-type $Ge_8$ entity. Further external interconnections between the polyhedra occur via the shorter Co–Co contacts of the $C_{2v}$ distorted $Co_4$ tetrahedra.

### Catalytic Properties

GC analysis revealed that citral undergoes no conversion in hydrogenation experiments under the reaction conditions described in the Experimental Section (reaction time: 150 min). Therefore, the experiments were repeated with a larger amount of $MgCo_4Ge_6$ (up to 500 mg) under $H_2$ pressure (7.5 MPa) for a longer reaction time (360 min) in a batch reactor (300 mL, Parr), but again, no conversion was observed. The absence of any catalytic activity is in contrast to the behavior of the intermetallic compound $MgCo_6Ge_6$, for which a citral conversion of 17% was observed at 453 K.[6]

### Quantum Chemical Calculations

The TB-LMTO band-structure calculations (Figure 4, a) reveal individual bands with a large dispersion crossing the Fermi level. The Fermi level is located at a local minimum of the density of states (DOS). Thus, $MgCo_4Ge_6$ is clearly a metal with delocalized states at the Fermi level. An analysis of the partial contributions to the DOS shows that the states at the Fermi level have predominantly Co orbital character (Figure 4, b). Ge orbital contributions are located well below the Fermi level, whereas there are virtually no Mg orbital contributions at all. This is consistent with the fact that Mg is the most electropositive element in the compound. The COHP curve in Figure 4 (c) indicates that bonding Ge–Co interactions are optimized up to $E_F$. Antibonding interactions occur only above $E_F$. The corresponding COHP curves of Ge–Ge contacts show that these interactions are much weaker. There is a noticeable flat COHP

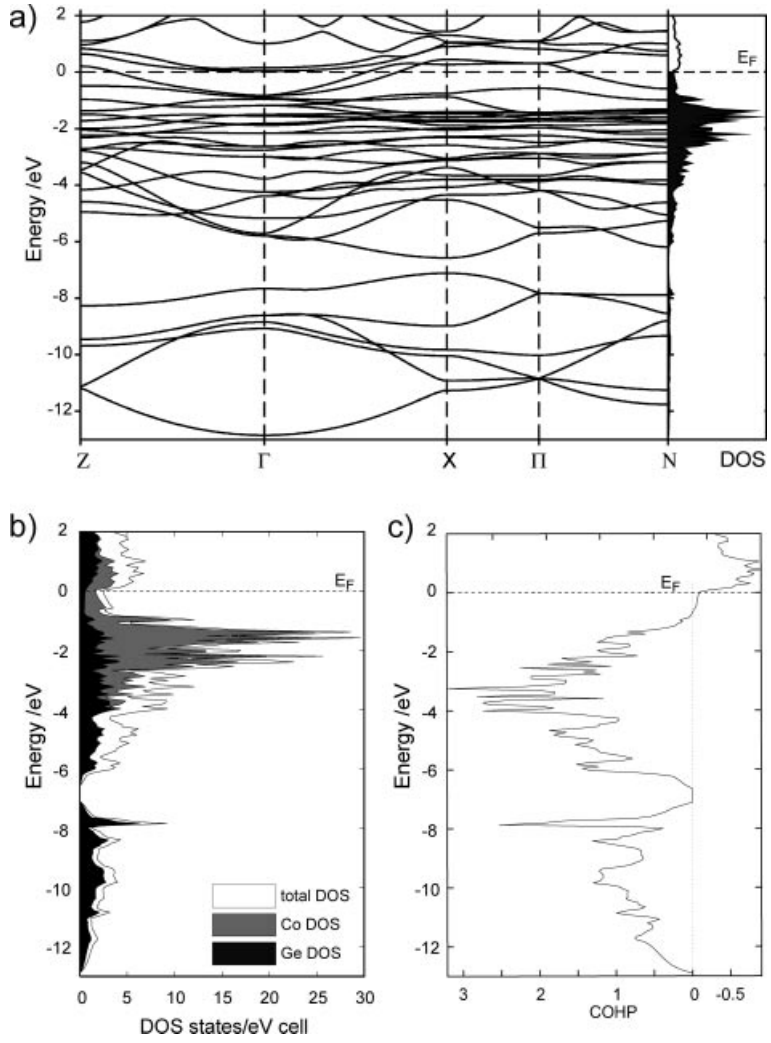

Figure 4. a) Band structure and DOS of $MgCo_4Ge_6$. b) Partial contributions of Co and Ge to the density of states.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

region in Figure 4 (c) as well as in the Ge–Ge COHP diagram (not shown) right below $E_F$. Since there are considerable Ge and Co contributions in the DOS plot of Figure 4 (b) those states must belong to nonbonding states. In order to detect nonbonding domains, chemical bonding was further analyzed by means of the electron localization function (ELF).

Figure 5 shows several two-dimensional cross-sections of the function parallel to the *ab* plane. The color of each pixel corresponds to a certain value of ELF, as illustrated by the color bar at the bottom of Figure 5 (d). Contour lines illustrate ELF isobars and are superimposed onto the pictures. The left-hand column of Figure 5 represents the ELF calcu-

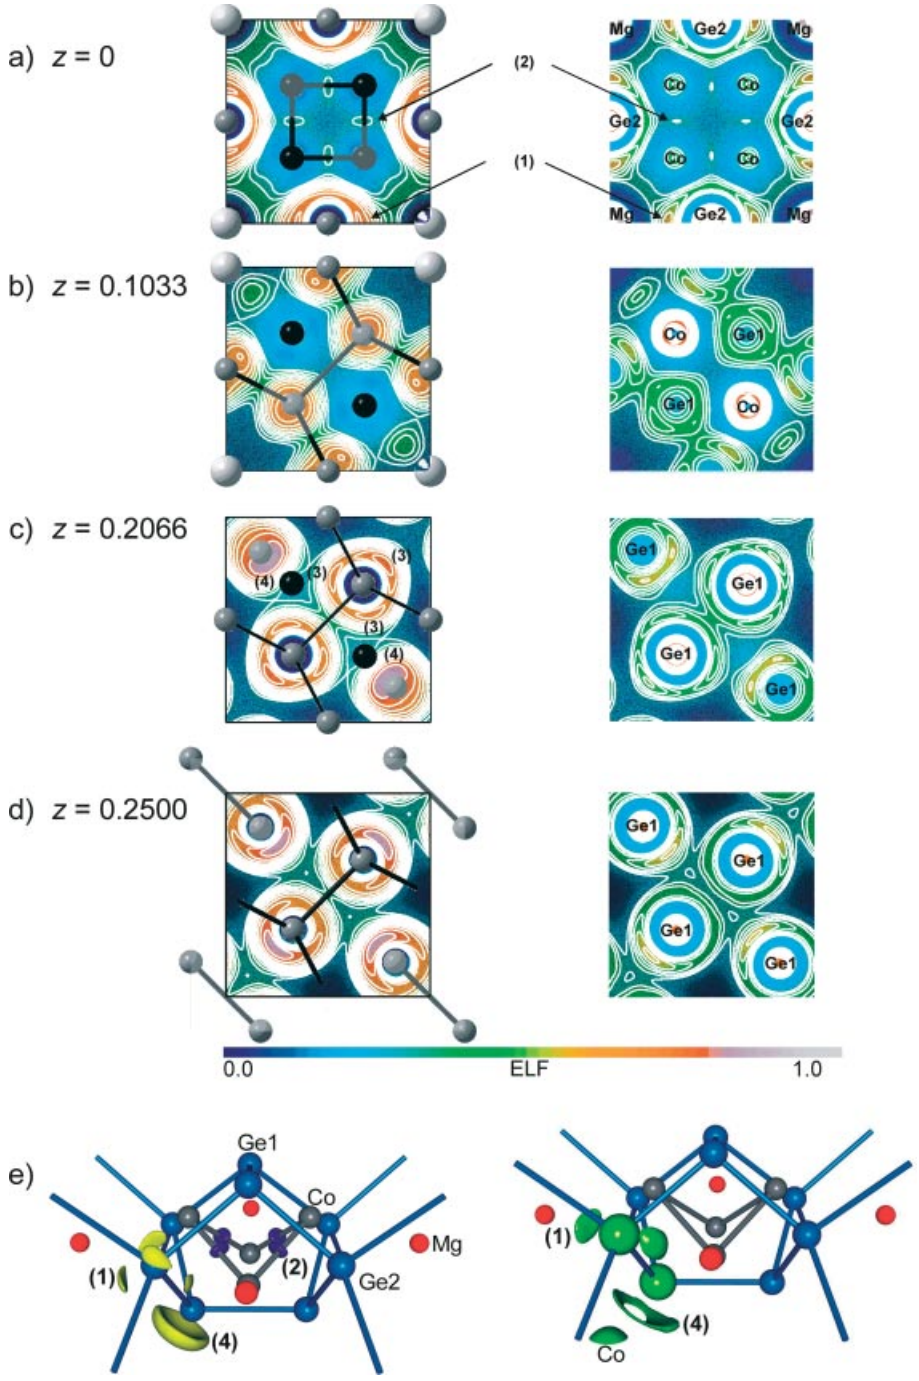

Figure 5. Two-dimensional cross-sections of the ELF in the *ab* plane at different values along the *c* direction. Isobars for $0.3 \leq \text{ELF} \leq 0.8$, with a step width of 0.05, are superimposed on the colored maps. Valence ELF is presented to the left, with all-electron ELF to the right. Structural motifs are superimposed on the valence ELF pictures. e) Left-hand side: 3D Isosurfaces of the ELF around selected atoms. Yellow: valence ELF (ELF = 0.759) at the two germanium sites. Violet: valence ELF (ELF = 0.3) between the cobalt atoms; right-hand side: as in Figure 5 (e), but all-electron ELF (ELF = 0.545 in green) around the germanium sites.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lated from a valence-electron treatment, while the right-hand column illustrates the ELF calculated from the electron density of all electrons, including core electrons. The atoms in the plane and their next neighbors are overlaid. At $z = 0$ the *ab* plane cuts though the Mg and Ge2 atoms and the four centers of the shorter Co–Co bonds of the $C_{2v}$ distorted tetrahedron (Figure 5, a). In both valence and all-electron ELF, maximum values of ELF are observed close to the Ge2 atoms pointing towards the neighboring Mg atoms. The regions (1) can be interpreted as lone-pair-type localization domains since the Ge2 and Mg atoms are ultimately separated by minimum values of ELF. Another small maximum (2) of the function with ELF = 0.3 is observed at the center of the Co–Co bonds, thus indicating a certain degree of covalency for these bonds. The second slice at $z = 0.1033$ (Figure 5, b) cuts through the center of the bonds between the three-connected Ge1 and four-connected Ge2 atoms. No maximum is observed here, and these contacts do not show any covalent contribution. The third cut (Figure 5, c), at $z = 0.2066$, cuts through the Ge1 positions. Three maxima are observed in a staggered position around each Ge1 atom with respect to the three Ge1–Ge2 contacts. Additionally, ELF maxima (4) that can be attributed to the Ge1 atoms of the adjacent layer become visible. In the valence-ELF picture these maxima point directly towards the Co atoms of adjacent layers, while, due to the repulsion between the core and the valence electrons, they appear to be separated into two smaller maxima in the case of the all-electron ELF. Finally, the cut at $z = 0.25$ (Figure 5, d) is located in the middle between two $P_4S_4$-type layers of $Ge_8$ cages, where no Ge–Ge bonds can be detected.

The situation in the vicinity of the $Ge_8$ cages is also outlined in Figure 5 (e), which shows the 3D isosurfaces of the valence ELF to the left and the all-electron ELF to the right. The yellow isosurfaces correspond to an ELF value of 0.76 of the valence ELF. There are five basins and these which must be interpreted as being of a lone-pair type since their ELF maxima are not located on an atom–atom connection vector. The larger one (4) is attached to the Ge1 atom and points away from the three Ge1–Ge2 contacts. Consistent with the 2D images (Figure 5, c) it points towards a Co atom of the adjacent Ge–Co layer. The four smaller, bean-shaped maxima are found around the four-bonded Ge2 atom; the positions of the four local maxima are due to the tetrahedrally oriented Ge2–Ge1 contacts. The valence-ELF isosurface with ELF = 0.3 is superimposed in violet color. The maxima are located at the centers of the shorter Co–Co contacts and confirm a certain degree of covalency, as already deduced from the 2D plots. The right-hand side of Figure 5 (e) shows the all-electron ELF isosurfaces of ELF = 0.545 around the two different germanium sites. The picture differs from that of the valence-ELF: the lone-pair attached to the Ge1 site is significantly flattened as compared to the one in the valence-ELF, and is turned into a crest due to the repulsion of the adjacent cobalt atom by the core electrons. The bean-shaped basins around the Ge2 atoms are contracted to two basins, which are oriented directly towards the adjacent Mg sites.

## Conclusions

Our search for other catalytically active alloys in the ternary phase system Mg–Co–Ge has led to the discovery of the novel compound $MgCo_4Ge_6$, which crystallizes in the $YRu_4Sn_6$ structure type first described by Venturini et al. The structure can be regarded as a coloring of the cubic-close packing observed in the $Au_3Cu$ structure. A closer investigation of the interatomic distances reveals peculiar and unprecedented homoatomic substructures for each of the Ge and Co atoms (Table 1). With respect to the dimensionality of the Ge sub-lattice, the structure is similar to $MgCo_6Ge_6$, which contains a graphite-type Ge sub-lattice with Ge–Ge contacts of about 2.9 Å. Quantum chemical investigations on the DFT level as well as the ELF interpretation of both compounds show that the Ge–Ge contacts of the Ge sub-lattices do not indicate any covalent bond contributions. However, in $MgCo_6Ge_6$ additional $Ge_2$ dimers with considerably localized bond character in the range of a Ge–Ge single bond were observed. In $MgCo_4Ge_6$ a combination of chemical bond types is found, with the main bonding contributions originating from Co–Ge interactions. ELF analysis reveals lone-pairs at the three-connected Ge atoms of the Ge subnet. These lone-pairs are oriented toward the Co atoms and thus a dative bonding between Ge and Co atoms can be formulated. Further small covalent contributions are found between the transition metal atoms.

Table 1. Interatomic distances [Å] for $MgCo_4Ge_6$.

| | | | |
|---|---|---|---|
| Ge(1)–Ge(2) | 2.906(1) (2×) | Mg(1)–Co(1) | 2.894(2) (4×) |
| Ge(1)–Ge(1) | 2.978(1) | Co(1)–Ge(1) | 2.285(2) |
| Co(1)–Co(1) | 2.581(2) (2×) | Co(1)–Ge(2) | 2.371(1) (2×) |
| Co(1)–Co(1) | 3.102(1) | Co(1)–Ge(1) | 2.419(2) (2×) |
| Mg(1)–Ge(1) | 2.945(1) (4×) | Co(1)–Ge(1) | 2.469(2) |
| Mg(1)–Ge(2) | 3.086(1) (4×) | | |

Despite some similarities with respect to chemical bonding properties, such as two-dimensional Ge networks and composition, all attempts to catalyze citral hydrogenation with $MgCo_4Ge_6$ failed, which is in contrast to the catalytic behavior of the intermetallic compound $MgCo_6Ge_6$.[6] This difference indicates that catalytic properties might also depend on the structure type and thus on the electronic properties and not only on the nature of the metals involved.

## Experimental Section

**Synthesis:** $MgCo_4Ge_6$ was synthesized by heating a stoichiometric mixture of the elements in a tantalum crucible to 750 °C for two days, followed by slow cooling of the reaction product to room temperature. The product consisted of xenomorphous crystals with a metallic luster, which were embedded in a microcrystalline silver-metallic matrix. The purity of the sample was established crystallographically, using a STOE STADI P powder diffractometer with a Cu-$K_\alpha$ source. The powder diffractogram, which could be indexed[11] with the help of the theoretical powder pattern calculated for $MgCo_4Ge_6$, showed only slight impurities of elementary Ge.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Crystal Structure Determination:** The crystal structure was determined from single-crystal X-ray diffraction data. A single crystal was selected from the reaction mixture and placed into an oil-filled glass capillary. The measurement was performed on a Nonius DIP 2020 diffractometer equipped with a monochromatic Mo-$K_\alpha$ source ($\lambda$ = 0.71073 Å). Data were collected by a scan of 2° in $\varphi$ in 180 frames. The exposure time was 300 seconds per frame. The collection of the intensity data was carried out with the HKL2000 program.[12] Cell parameters were initially calculated from reflections taken from five frames of reflections. The final lattice parameters were calculated from all reflections observed in the actual data collection. The data from the data collection were processed with the Scalepack[12] program and corrected for absorption using the PLATON[13] program suite. A summary of the experimental and crystallographic data is given in Table 2.

Table 2. Crystallographic data for $MgCo_4Ge_6$.

| Co | 8i | 8223(2) | 8223(2) | 4215(2) | 17(1) |
| Ge1 | 8i | 8294(1) | 8294(1) | 7066(1) | 18(1) |
| Ge2 | 4c | 0 | 5000 | 0 | 13(1) |

Further details of the crystal structure investigation may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (Fax: +49-7247-808-666; E-mail: crysdata@fiz-karlsruhe.de) on quoting the depository number CSD-416401.

**Hydrogenation Reaction:** The hydrogenation of citral (3,7-dimethyl-2,6-octadienal), which has three unsaturated bonds including conjugated C=C and C=O groups as well as an isolated C=C bond, was chosen as a test reaction. Hydrogenation was carried out in a high-pressure batch reactor system described earlier.[15] The reactor was filled with a solution of 1 mL of citral in 9 mL of hexane. After the addition of 100 mg of $MgCo_4Ge_6$ (particle size < 63 mm), the reaction mixture was stirred at 850 rpm, the reactor was flushed four times with argon (2 MPa), and heated up to 453 K within 45 min (0.8 MPa argon pressure was left in the reactor). The reaction was started by setting the hydrogen pressure to 7 or 9 MPa, respectively. Analysis of the reaction mixture by GC (HP 5890, flame ionization detector, DB-WAX capillary column) showed no conversion products.

**Quantum Chemical Calculations:** The electronic structure was investigated by means of the ab initio full-potential linear muffin-tin orbital (LMTO) method in the atomic sphere approximation (ASA), using the tight-binding (TB) program (TB-LMTO-ASA).[16] The calculations were based on the local-density approximation (LDA), and the Hedin–Lundquist parameterization was employed for exchange and correlation potentials.[17] The radii of the muffin-tin spheres and empty spheres were determined according to Jepsen and Andersen.[18] For the calculations, s, p, and "down-folded" d-partial waves for Ge, s, p, and "down-folded" d-partial waves for Mg, and s, p, and d-partial waves for Co were used. COHP (crystal orbital Hamilton populations) plots[24] show DOS curves, which were weighted by the contributions of each crystal orbital to some measure of the strength of a given bond. The contribution of the covalent part of a particular interaction to the total bonding energy of the crystal can be obtained from COHP analyses. All COHP curves presented here are in the following format: positive and negative values are bonding and antibonding, respectively.

For further insight into the chemical bonding in intermetallic compounds a topographical analysis of the electron density distribution using the Electron Localization Function (ELF), which was originally introduced for the deduction of the shell structure of atoms from the electron density, was performed.[19] ELF values were scaled between 0 and 1, with high ELF values and local ELF maxima corresponding to areas and centers of localized electrons, and low ELF values defining the spatial area around these maxima. The resulting partition of space into areas of high electron localization can be interpreted in terms of bonding and nonbonding electron pairs and reveals their three-dimensional shape. Thus, spatial domains of localized electrons become visible.[20–23] These calculations were carried out both with valence electrons only and with all electrons.

# Synthesis and NLO Properties of 4-(4*H*-Chalcogenopyran-4-ylidene and 4*H*-chalcogenochromen-4-ylidene)-1-(phenylthio)but-2-enylidene Complexes – Electronic Influence of the Carbene Fragment

**Nadège Faux,[a] Françoise Robin-Le Guen,[b] Pascal Le Poul,[b] Bertrand Caro,*[b] Keitaro Nakatani,[c] Eléna Ishow,[c] and Stéphane Golhen[d]**

**Keywords:** Chalcogeno- and benzochalcogenopyran / Fischer-type thiocarbene complexes / NLO properties / X-ray structure of thiocarbene

The synthesis of 4-(4*H*-chalcogenopyran-4-ylidene and 4*H*-chalcogenochromen-4-ylidene)-1-(phenylthio)but-2-enylidene complexes is described and their non-linear optical (NLO) properties have been investigated (as $\mu\beta$ by EFISH). NMR studies and X-ray crystallographic analyses show that the (phenylthio)carbene fragment has a better electron-withdrawing capability than the methoxy analogues and, likewise, the corresponding thiocarbenes have a more significant pyrylium character. The $\mu\beta$ values of these complexes were obtained from EFISH experiments. The microscopic NLO response is sensitive to the nature of the intracyclic chalcogen atom, the nature of the metal centre and the benzo-annulation of the heterocycle.

## Introduction

Due to the strong electron-withdrawing effect of the (carbene)pentacarbonylmetal fragment, alkenyl Fischer carbene complexes have been exploited extensively for synthetic purposes. The utility of these unsaturated organometallic reagents in the Dötz reaction[1] in 1,2-, 1,4- and 1,6-addition reactions[2] or in the synthesis of heterocyclic compounds by means of various cycloaddition processes[3] is well documented. In the field of organometallic complex utilisation for NLO applications,[4] this electronic ability has made the pentacarbonyl(methoxy- or aminocarbene)metal fragments attractive candidates as acceptors in push-pull structures.[5] Association by means of a π-spacer to classic organic or organometallic donors such as *para*-(dimethylamino)benzyl[6] or ferrocenyl[7] groups has proved the efficiency of this method. High values of the first molecular hyperpolarisability $\beta$ have been determined by Hyper Raleigh Scattering (HRS). The influences of the metal (W or Cr),[5] the unsaturated chain length[6,7] and the solvent[7] on the $\beta$ values have been investigated. The results have been analysed in the context of the two-level model developed by Oudar and Chemla[8] which is based on the predominance of a single electronic transition despite the presence of more than one electronic transition in the visible region.[7]

In fact, the role of the organometallic carbene fragment is not well understood. For aminocarbene complexes, polarisation of the π-cloud by the electronic inductive effect of the $M(CO)_5$ moiety is responsible for the important NLO response.[6] The influence of an MLCT transition is minimised due to the lack of conjugation between the unsaturated chain and the carbene fragment.[9] On the other hand, noticeable $\beta$ values were also obtained for highly π-conjugated unsaturated methoxycarbene complexes.[5] It is worth noting that despite significant electronic differences between these two classes of carbenes, a systematic comparison between them has never been carried out. In addition, surprisingly, there are no reports on the NLO properties of unsaturated (alkylthio)- or (phenylthio)carbene complexes.

In fact, unlike their alkoxy or amino counterparts, (alkenyl)(thio)carbene complexes are rare compounds.[10] Their properties and reactivity require further elucidation.[11] Only some unsaturated (alkylthio)- and (phenylthio)carbenes have been reported by Aumann et al. using a condensation reaction between non-enolizable aldehydes (benzaldehyde, cinnamaldehyde) and the carbanion of $CH_3(SR)$-

C=M(CO)$_5$ (M = Cr, W).[10] The low p$K_a$ values which characterise these complexes[12] [p$K_a$ = 8.37 for $CH_3$-($SCH_3$)C=W(CO)$_5$ compared with 12.36 for $CH_3$($OCH_3$)-C =W(CO)$_5$] enabled deprotonation by $NEt_3$. On the other hand, we have previously shown that 4*H*-pyran-4-ylidene fragments act as efficient electron-donors in push-pull methoxy Fischer-type carbene complexes.

The pyrylium character of these molecules was evaluated by using NMR spectroscopy, X-ray crystallographic measurements, DFT calculations and from their reactivity towards nucleophilic reagents.[2b,13] More recently, we have reported the NLO properties (as $\mu\beta$ by EFISH) of (4*H*-chalcogenopyran-4-ylidene and 4*H*-chalcogenochromen-4-ylidene)-1-methoxyalkenylidene complexes.[14] The $\mu\beta$ product is sensitive to the length of the unsaturated spacer, the nature of the chalcogen atom and to benzo-annulation of the heterocycle. Herein, we wish to report the formation and, for the first time, the first hyperpolarisability measurements of (phenylthio)carbene complexes. In addition, from NMR spectroscopic studies and X-ray structure analyses, we have shown that the carbonyl[(phenylthio)carbene]metal fragment acts as a powerful electron-withdrawing group. Comparison with analogous methoxycarbenes has been carried out.

## Results and Discussion

### Synthesis

To obtain the expected donor-acceptor structures, we first chose to repeat Aumann's procedure[10] using the appropriate heterocyclic aldehydes **1a**–**1e**[15] and the carbanion produced from $CH_3$(PhS)C=W(CO)$_5$ by treatment with $NEt_3$, but this was unsuccessful. Addition of chlorotrimethylsilane (TMSCl) to the reaction mixture induced an instant colour change from red-orange to blue. After hydrolysis and purification by silica-gel chromatography, the intense dark blue condensation products **2a**–**2e** could be isolated. The moderate to low yields reported (Scheme 1) are the consequence of a decomplexation reaction which arises during the workup leading to the corresponding thioester.[16] The lack of reactivity without the assistance of TMSCl could be due to the high zwitterionic character of the heterocyclic aldehydes which prevents the carbanion addition on the carbon atom of the carbonyl function (Scheme 1).

We suggest that addition of the chlorosilane reagent produces alkenylpyrylium salts and favours the conjugated addition of the carbanion as the first step in this reaction. Such a zwitterionic form is insignificant in benzaldehyde and cinnamaldehyde and the condensation reaction does not require the use of TMSCl.[10,17]

The new heterocyclic carbene complexes **2a**–**2e** were characterised by $^1$H and $^{13}$C NMR spectroscopy, UV/Vis spectroscopy, FTIR spectroscopy, elemental analysis and high resolution mass spectrometry (for **2a**). All the data are consistent with the proposed structures. In particular, the $^3J_{H,H}$ coupling constant values (ca. 13 Hz) are in agreement with an (*E*) configuration for the C2–C3 double bond of the unsaturated chain (Scheme 1).

### NMR Studies – Evaluation of the Pyrylium Character of the Heterocyclic Complexes 2 in Solution

To obtain information about the pyrylium character of complexes **2** in solution, three NMR spectroscopic criteria were taken into account: (i) the chemical shift values of the 2-H and 3-H signals, (ii) the differences in $^3J_{H,H}$ values ($\Delta J$) across adjacent C=C and C–C bonds of the unsaturated chain and (iii) the $^{13}$C NMR chemical shift of the carbene carbon signal. First, with regards to the $^1$H NMR spectra of all compounds **2**, the chemical shift values of 2-H and 3-H display an oscillatory behaviour [$\delta$(3-H) > $\delta$(2-H) > $\delta$(4-H)] (Scheme 1). In particular the respective 3-H, 2-H signal position, which leads to positive $\Delta$ values [$\delta$(3-H) – $\delta$(2-H)]

(Table 1), suggests a highly conjugated push-pull structure for which the zwitterionic resonance form **B** is of importance in the valence bond description of the heterocyclic molecules (Scheme 1). As shown in Table 1, a similar trend has been observed for the methoxycarbene **3**,[14,18] analogously to **2** (Figure 1).

Figure 1. Molecular structure of methoxycarbene complexes **3**.

As noted previously,[13a] this result differs from that found for other push-pull methoxy- and aminocarbene containing ferrocenyl,[7] *para*-(dimethylamino)phenyl[19] or 3,4-(methylenedioxy)phenyl groups[6] for which 2-H is more deshielded than 3-H (Table 2, Figure 2). For aminocarbenes, the predominance in solution of a conformation in which the (carbene)carbonylmetal fragment is perpendicular to the unsaturated part of the molecule would be responsible for this feature.[6,9] Owing to the low π-overlap, the inductive effect of the (carbene)carbonylmetal fragment controls the $^1$H NMR chemical shift values of the unsaturated chain and $\delta$(2-H) > $\delta$(3-H).

Table 2. $^1$H NMR spectroscopic data for push-pull alkenylidene complexes (Figure 2).

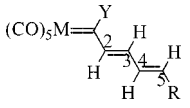

Figure 2. Structure of alkenyl Fischer-type carbene complexes.

It can be noted that the $\Delta$ values [$\delta$(3-H) – $\delta$(2-H)] of the (phenylthio)carbenes **2** are larger than those of methoxycarbenes **3**, indicating that the contribution of the pyrylium resonance structure in **3** is of lesser importance than in **2**. However, the $^1$H NMR chemical shift differences should reflect other factors such as the anisotropic effect of the phenyl group linked to the sulfur atom. Therefore, a comparison between the electronic influence of the methoxy- and the (phenylthio)carbene group requires other criteria.

Previously, it has been emphasised that the variation of $^3J_{H,H}$ values along a conjugated polyene chain provides a good estimate of the C–C bond lengths (or bond orders).[20] In push-pull molecules containing a similar donor (acceptor), the so-called bond length alternation (BLA) depends on the strength of the acceptor (donor). As a consequence, the difference $\Delta J$ between the coupling constant $^3J_{H,H}$ of concomitant C–C bonds ranges from 6.5 Hz for unconjugated molecules to 0 Hz for molecules in which all the C–C bond lengths are equal (cyanine limit). As shown in Table 1, calculated $\Delta J$ values for carbenes **2** and **3** are slightly negative or positive, in accordance with a reduced bond length alternation and, therefore, indicating a large degree of intramolecular charge transfer. Two features are noteworthy:

(1) The phenylthio complexes display lower $\Delta J$ values than those of their methoxy counterparts, in agreement with the better electron-withdrawing ability of the thiocarbene group as found above from the $\Delta$ [$\delta$(3-H) – $\delta$(2-H)] criterion. The negative values found for **2a** and **2b** strongly suggest that these molecules approach or even surpass the cyanine limit (predominance of resonance structure **B**) (Scheme 1). As proposed by Ali and Bernasconi from p$K_a$ values and kinetic constant determinations for both classes of complexes, the electronic difference can be mainly attributed to the smaller π-donor effect of the SR group compared with that of the methoxy group.[12] As a consequence, in complexes of type **2**, the conjugation between the ends of the molecule through the unsaturated chain is increased. However, concerning the π-effect strength of the SR group in Fischer-type carbene complexes, it should be noted that opposite conclusions were drawn from X-ray crystallographic data[21] and dynamic NMR studies (Figure 3).[22] In this context, the $^{13}$C NMR chemical shift values of the carbene carbon atom are of interest. In Fischer-type carbenes, the large upfield shift of the carbene carbon signal, when the heteroatom substituent is changed from an alkoxy to an amino group, has been attributed to the greater ability of the nitrogen atom to participate in dative π-bonding with the carbene carbon atom.[23] As shown in Table 3, such a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

difference exists in (4*H*-pyran-4-ylidene)alkenylidene complexes (comparison between the carbene carbon chemical shifts of complexes **4** and **3a**). Accordingly, the intramolecular charge transfer in donor-acceptor unsaturated amino complexes[13] is limited due to the predominance of a resonance form involving the lone pair of the nitrogen atom of the amino group and the p-orbital of the carbene carbon atom. The chemical shift difference $\Delta$ [$\delta$(3-H) – $\delta$(2-H)] and the $\Delta J$ value found for the unsaturated aminocarbene complex **4** also support this electronic description. Since the PhS group in complex **2** seems to possess a lesser π-electron-donating capability compared with that of a methoxy group, the upfield shift observed for the carbene carbon signal of **2a** (Table 3) seems, at first glance, to be surprising. This finding, which is in sharp contrast to the usually observed chemical shift [$\delta(C_{carb,thio}) > \delta(C_{carb,methoxy})$],[24] should again reflect the donor-acceptor intramolecular charge transfer enhancement for the thiocarbene complexes. It is actually well established that along a series, the $^{13}C$ NMR carbene carbon chemical shift is sensitive to the electronic influence of the ligand.[13b]

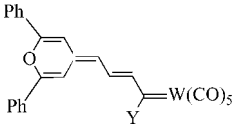

Figure 3. Structure of (4*H*-pyran-4-ylidene)alkenylidene complexes.

Table 3. NMR spectroscopic data for selected push-pull (4*H*-pyran-4-ylidene)alkenylidene complexes (Figure 3).

| | Y | $\Delta$ [$\delta$(3-H) – $\delta$(2-H)] [ppm] | $\Delta J$ [Hz] | $^{\delta 13}C$ [ppm] |
|---|---|---|---|---|
| **3a** | OMe | 0.94 | 0.4 | 289 |
| **4**[13a] | $N(CH_2)_4$ | –0.03 | 3.8 | 244 |
| **2a** | SPh | 1.44 | –0.6 | 261 |

(2) For the same organometallic phenylthio or methoxy fragment, $\Delta J$ values appear to increase from the pyran to the benzopyran series (methoxy and thiocarbene) (Table 1). This trend, which does, however, have an exception (see NMR values of **3e**), suggests a decrease in the electron-donor strength upon benzo-annulation (Table 1). Accordingly, the pyrylium characters of molecules **2a**, **2b**, **3a** and **3b** are greater than those of **2c**, **2d**, **3c** and **3d**, respectively. This view is corroborated by the low-field chemical shift values of the carbene carbon signals observed (even for **3e**) for the fused ring compounds. It should be noted that the chemical shift difference $\delta(C_{carb,benzopyran}) - \delta(C_{carb,pyran})$ is more pronounced for the (phenylthio)carbene indicating the great sensitivity of these complexes to π-electronic effects.

Very recently, effects of successive benzo-fusions for pyridinium acceptors in push-pull zwitterionic chromophores have been reported.[25] In such cases, and in agreement with the present results, it has been found that the annulation favours the neutral form thanks to the aromatic character of the fused benzene ring.

Finally, it is worth noting that the $\Delta J$ values reported here and those found for analogous derivatives of **3** increasing length[14,15] are much smaller than those calculated from previous studies for unsaturated methoxy complexes containing ferrocenyl[7] or *para*-(dimethylamino)phenyl donor groups[19] ($\Delta J_{av.} > 3.5$ Hz) (Table 2, Figure 2). This once again confirms the great electron-donor capability of the proaromatic pyran and benzopyran heterocycles and the powerful electron-withdrawing ability of the carbonyl-[(phenylthio)carbene]metal group.

## X-ray Analysis of 2a

Blue single crystals of **2a** suitable for the X-ray analysis were obtained by slow concentration of a diethyl ether/petroleum ether solution. The molecular view with the atom labelling is shown in Figure 4. As indicated by the ORTEP drawing, the determination of the (*E*) stereochemistry based on the *J* coupling constant values is correct. The molecule exhibits a nearly planar conformation. However, the phenyl ring linked to the sulfur atom is in a *syn* conformation and is twisted by 88.8(5)° with respect to the plane of the conjugated chain. In addition, C(3) and C(4) lie slightly away from the ideal plane. The –CH=CH–C(SPh)=W(CO)$_5$ fragment is in an *syn* conformation.

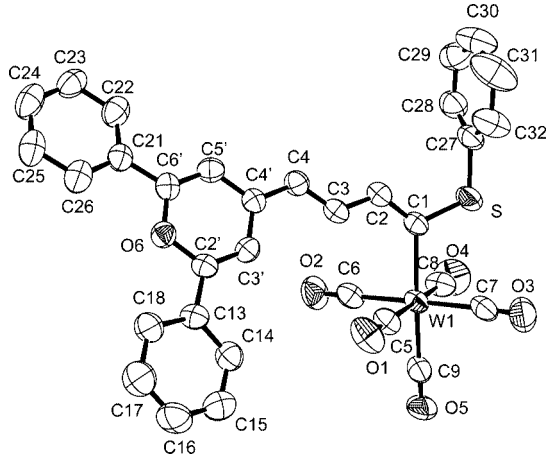

Figure 4. ORTEP drawing of **2a** showing the atom numbering. Hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å]: W(1)–C(1) 2.251(7), S–C(1) 1.719(7), C(1)–C(2) 1.398(10), C(2)–C(3) 1.377(9), C(3)–C(4) 1.373(9), C(4)–C(4′) 1.389(9), O(6)–C(6′) 1.359(8), O(6)–C(2′) 1.370(8), C(2′)–C(3′) 1.336(10), C(3′)–C(4′) 1.429(10), C(6′)–C(5′) 1.350(10), C(5′)–C(4′) 1.435(9).

Assuming that the solid-state molecular structure reflects the conformation of **2a** in solution, this situation should have an influence on the NLO properties (see below). In accordance with the NMR investigations, the nearly equal C(2)–C(3), C(3)–C(4) bond lengths together with the large C(1)–W bond length [2.251(7) Å] are indicative of significant delocalisation between the heterocyclic oxygen atom and the metal centre through the unsaturated backbone (large pyrylium character). On the pyran side, the intracyclic C–C and C–O bond length values appear to be close to those found for other (4*H*-pyran-4-ylidene)alkenylidene complexes for which DFT calculations and X-ray analyses

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

have indicated a pyrylium character.[13] It is noticeable that the 2,6-diphenylpyrylium salts bearing a 4-(dimethylamino)benzyl group donor display similar intraheterocyclic C–O and C–C bond lengths due to pronounced 4*H*-pyran-4-ylidene character.[26] Again, in accordance with the significant contribution from the pyrylium form, the exocyclic C=C bond length (1.389 Å) has single-bond character. This value is greater than that determined for lesser conjugated bis(4*H*-pyrans) (1.375 Å)[27] and is close to those reported by us for other methoxy(4*H*-pyran-4-ylidene)alkenylidene complexes.[2b,13b] Moreover, it is worth remarking that in chromenylideneacetaldehyde hydrazone containing $[(\eta^6\text{-arene})CpFe]^+$ as an electron-accepting group, the exocyclic C=C bond is 1.354 Å long indicating a weak benzopyrylium form.[28] Finally, the C–SPh distance (1.719 Å), which lies within the normal range (C–S, C=S),[20] provides evidence for back-bonding donation from the heteroatom lone pair and the carbene carbon atom (resonance structure **C**) (Scheme 1). It is noticeable that a lower value was reported from the pentacarbonyl[methyl(phenylthio)carbene]chromium complex X-ray analysis.[20b]

### Linear and Non-Linear Optical Properties

The UV/Vis electronic spectra of molecules **2** were recorded in four solvents of varying polarity (Table 4). For **2a**, **2b**, **2c** and **2′c**, a rapid decomplexation reaction occurs in DMSO ($\varepsilon_{25\,°C}$ = 48.9) leading to the corresponding thioester.[10] In such cases $CH_3CN$ ($\varepsilon_{25\,°C}$ = 37.5) was used. The UV/Vis spectra of the (phenylthio)carbenes **2** consist of two intense absorption bands in the visible region (Table 4). By comparison with the spectra of analogous methoxycarbene complexes, for which DFT computations have been performed,[13b] the lower and the higher energy bands can be assigned to the metal-to-ligand charge transfer transition (MLCT), corresponding to the HOMO–LUMO transition, and the intraligand charge transfer transition (ILCT or $\pi\rightarrow\pi^*$), respectively. In these complexes, the HOMO and the LUMO electronic density is mainly located on the metal centre and on the ligand, respectively.[13] However, despite the great similarity of the spectra, it can be noted that compared with their methoxy counterparts **3**, the corresponding electronic transitions of **2** are red-shifted, possibly as a consequence of a lowering of the π*-level (LUMO). On the other hand, under the intracyclic O→S atom substitution, a bathochromic shift can be observed for the two bands. Such a trend, also found for the methoxycarbenes,[14] should be a consequence of a decrease in the HOMO–LUMO and π→LUMO gaps. MNDO calculations have shown that such HOMO–LUMO gap lowering upon O→S substitution exists in push-pull chalcogenopyrylium salts.[29] Substitution of the Cr atom for W (**2c**, **2′c** comparison) leads to a clear bathochromic shift.

As expected, the MLCT band appears to be more sensitive to the metal change. The presence of a *t*Bu electron-donating group in **2d** (which, unlike a phenyl substituent, is not capable of conjugative interaction with the chalcogenobenzopyran ring) increases the energy of both transitions. Finally, influence of the benzo-annulation on the maximum absorptions seems more complex and depends on the nature of the chalcogen atom (Table 4) and on the solvent polarity. Thus, for **2a** and **2b**, the two characteristic CT bands exhibit a hypsochromic shift when the solvent polarity is increased, as expected from the zwitterionic character of the ground state (see above). It is worth remarking that for the less zwitterionic methoxy complexes **3a** and **3b** (Figure 1), analogous to **2a** and **2b**, a bathochromic shift occurs for the MLCT transition.[14] For the chalcogenobenzopyran complexes **2c**, **2d** and **2e**, a weak solvent influence can be observed for both electronic transitions, and an inversion of the solvatochromism cannot be totally excluded. The behaviour of the carbenechromium complex **2′c** differs from that of **2c** since the solvent change has a small influence on the $\pi\rightarrow\pi^*$ transition and the MLCT transition is only sensitive to the less polar solvents utilised ($CCl_4$, $CH_2Cl_2$ and $CH_3COCH_3$) (observation of a hypsochromic shift). In conclusion, the presence of two intense electronic transitions in the visible region should make the interpretation of the NLO results more difficult and precludes relevant analysis based on the two-level model.[8]

Second-order nonlinear properties were studied in $CHCl_3$ solution ($\varepsilon_{25\,°C}$ = 4.7) at 1907 nm by the electric-field-induced second-harmonic generation technique (EFISH) which provides information about the scalar product $\mu\beta$ ($2\omega$) of the vector component of the first hyperpolarisability tensor $\beta$ and the dipole moment vector. This product

Table 4. UV/Vis absorption properties of compounds **2** in various solvents.

| | Solvent | $\lambda_{max}$ [nm] ($\varepsilon\times10^{-4}$) | | | | | |
|---|---|---|---|---|---|---|---|

Table 5. $\mu\beta$ values for **2**–**3**.

| | **2a** | **2b** | **2c** | **2d** | **2e** | **2′c** | **3a**[14] | **3b**[14] | **3c**[14] | **3d**[15c] | **3e**[14] |
|---|---|---|---|---|---|---|---|---|---|---|---|
| $\mu\beta$ [$10^{-48}$ esu][a] | 173 | 518 | 420 | 374 | 421 | 140 | 505 | 665 | 219 | 310 | 402 |

[a] $\mu\beta(2\omega)$ at 1907 nm in $CHCl_3$. Molecular concentrations used for the measurements were in the range $10^{-3}$ to $10^{-2}$ M; 3-methyl-4-nitroaniline (MNA) for which $\mu\beta(CHCl_3) = 71.06 \times 10^{-48}$ esu was used as an external reference. $\mu\beta \pm 20\%$.

is derived according to Equation (1) and, considering $\gamma_0(-2\omega,\omega,\omega,0)$, the third-order term is negligible for the push-pull compounds under study. This approximation is usually used for push-pull organic and organometallic molecules.

$$\gamma_{EFISH} = \mu\beta/5kT + \gamma_0(-2\omega,\omega,\omega,0) \quad (1)$$

All complexes were thus tested away from resonance. It should be noted that the sign and values of $\mu\beta$ depend on the "direction" of the transition implied in the NLO phenomena and on the direction of the ground-state dipole moment. When $\beta$ and $\mu$ are parallel (antiparallel), positive (negative) maxima $\mu\beta$ values are reached.

DFT calculations performed on analogous methoxycarbenes have shown that the ground-state dipole moment is governed by the pyrylium character of these molecules (Figure 5).[13b] However, a slight variation in the dipole moment orientation can occur according to the degree of *syn* or *anti* conformation of the complexes (see X-ray analysis of **2a**).[30]

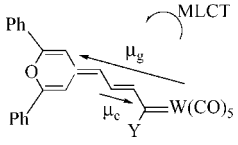

Figure 5. Orientations of the ground-state and excited-state (MLCT) dipole moment vectors.

As for the methoxycarbenes[14] **3**, all the $\mu\beta$ values of complexes **2** (Table 5) are large and positive, indicative of the implied transition(s) of the first excited states which are more polarized than the ground states and a vectorial $\beta$ with almost the same direction as the ground-state dipole moment. This is not in accordance with the negative solvatochromism or the low solvent polarity influence observed for the MLCT and π-π* transitions in **2a**–**2e** and **2′c**. Moreover, the MLCT charge transfer direction implies an excited dipole moment vector $\mu_e$ opposite to the ground-state dipole moment $\mu_g$ vector.[8] Therefore, this transition may only play a minor role in the first hyperpolarisability, since positive $\mu\beta$ values are found. On the other hand, the π→π* charge transfer implies a corresponding $\mu_e$ almost parallel to $\mu_g$. A positive or a negative $\mu\beta$ value could be expected with respect to the contribution of the two limit forms **A** and **B** (Scheme 1). Despite the complexity of this situation, important information can be deduced from the $\mu\beta$ values shown in Table 5.

First, substitution of W by Cr (**2c**, **2′c** comparison) lowers the first hyperpolarisability response. This shift, as previously[5] proposed, should be the consequence of a more polarisable metal electron shell for the W atom. However, a part of the $\mu\beta$ decrease should reflect the variation of the dipole moment (see NMR: $\Delta J$ values). From a comparison of **2a** and **2b** it seems once again (see **3a**, **3b**, **3c** and **3e** $\mu\beta$ values, Table 5)[14] that the presence of an intracyclic pyran sulfur atom favours the hyperpolarisability response. This effect could be relevant to the greater polarisability of the electrons of the sulfur compared with the electrons of the oxygen. However, it can be noted that this heteroatomic influence is not operative in the chalcogenobenzopyran structure, since similar responses are found for **2c** and **2e**. It seems that the presence of a fused benzene ring produces subtle electronic differences which make the analysis more difficult. On the other hand, annulation produces an increase in $\mu\beta$ for O-heterocycles and a decrease for S-heterocycles. This last result is in line with the behaviour of analogous methoxycarbenes (see **3a**, **3c** and **3b**, **3e** $\mu\beta$ values, Table 5).[14] It should be the consequence of the lower π-electron mobility in **2e** owing to the aromatic character of the appending benzene ring. The low $\mu\beta$ value observed for the pyran complex **2a**, which is responsible for the inverse $\mu\beta$ evolution for the two series, merits comments. As stated from NMR spectroscopic data, the pyrylium character of **2a** is important and is close to the thiopyrylium character of **2b** (see $\Delta J$ value, Table 1). Consequently, the greater aromaticity of the pyran ring in **2a**[29,31] should in part explain the lower NLO response. Finally, for the (phenylthio)carbenes, substitution of a phenyl group by a tertiary butyl group slightly reduced the $\mu\beta$ value (**2c**, **2d** comparison). The opposite trend (slight increase) may be observed for the methoxycarbenes (**3c**, **3d** comparison). In conclusion, from $\mu\beta$ and $\Delta J$ value comparison, it seems that the BLA factor has a minor influence on the NLO behaviour of these complexes.

## Conclusion

In the 4-(4*H*-chalcogenopyran-4-ylidene and 4*H*-chalcogenochromen-4-ylidene)-1-(phenylthio)but-2-enylidene complexes **2**, the carbonyl[(phenylthio)carbene]metal fragment acts as an exceptional electron-accepting group. Consequently, the pyrylium character is important and some of the complexes under investigation surpass the cyanine limit in [$D_8$]THF. From comparisons of NMR spectroscopic data, it seems that the carbonyl[(phenylthio)carbene]metal group in complexes **2** is a better electron-withdrawing group than a carbonyl(methoxycarbene)metal group. A single-crystal X-ray diffraction analysis of compound **2a** has shown an electronic structure which enables conjugation between the intracyclic oxygen atom and the metal centre which is in accordance with the pronounced pyrylium character of the heterocycle. The first hyperpolarisability of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thiocarbenes have been measured by the EFISH technique. The $\mu\beta$ values are close to those found for methoxycarbenes of similar lengths[14] and are sensitive to the intracyclic heteroatom, the benzo-annulation and the metal. However, the presence of two absorption bands in the visible region precludes analysis based only on a simple model. Theoretical calculations should be necessary to obtain more information on the electronic transitions and excited states implied by the NLO properties.

## Experimental Section

**General Remarks:** All preparations involving organometallic (4*H*-pyran-4-ylidene)alkenylidene compounds were carried out under dry nitrogen. Solvents were dried and distilled before use according to standard procedures.[32] $^1$H and $^{13}$C NMR spectra were recorded in [D$_8$]THF using a Bruker 500 MHz spectrometer. Infrared spectra were recorded with a Perkin–Elmer FTIR-1000 spectrometer using KBr plates. Microanalyses were performed using a Microanalyseur Flash EA 1112 instrument and mass spectra were obtained using a high-resolution MS/MS Zab spec Tof micromass system at the Centre Régional de Mesures Physiques de l'Ouest Université de Rennes 1. Optical absorption spectra were measured with a Perkin–Elmer Lambda 25 spectrophotometer.

**X-ray Structure Determination:** Blue single crystals of **2a** suitable for X-ray analysis were obtained by slow concentration of a diethyl ether/petroleum ether solution and were mounted on a Nonius four-circle diffractometer equipped with a CCD camera and a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) at the Centre de Diffractométrie (CDFIX), Université de Rennes 1, France. Data collection was performed at 293(2) K. $C_{32}H_{20}O_6SW$, $M$ = 716.39, monoclinic, $P2_1/c$, $a$ = 9.0690(2), $b$ = 14.7950(2), $c$ = 21.4990(5) Å, $\beta$ = 100.432(1)°, $V$ = 2836.9(1) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 1.677 g cm$^{-3}$. 12109 structure factors were collected before merging to yield 6506 unique intensities ($R_{int}$ = 0.0482). The structure was solved with SHELXS-97.[33] The refinement of 361 parameters against $F^2$ of 6506 unique intensities [4246 observed intensities $I > 2\sigma(I)$] was performed with SHELXL-97[34] with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were added to the structure model in calculated positions. Final residuals: $R$ = 0.0548, $wR$ = 0.1247. CCDC-297214 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthetic Methodology: General Procedure for the Synthesis of Complexes 2a–2e:** A solution of the aldehydes[15] **1a**–**1e** ($1.1\times10^{-3}$ mol) with 1 equiv. of $CH_3(SPh)C{=}W(CO)_5$[10,35] ($1.1\times10^{-3}$mol), 3 equiv. of $(CH_3)_3SiCl$ (TMSCl) and 3 equiv. of $(C_2H_5)_3N$ in THF (20 mL) was stirred at room temperature. The reaction, monitored by TLC, showed that the starting carbene complex quickly disappeared. Degassed water was poured onto the blue reaction mixture and the product was extracted with diethyl ether. The extract was dried with magnesium sulfate and the solvent was removed under reduced pressure. The residue was purified by chromatography on silica gel plates (elution with petroleum ether/dichloromethane, 70:30). The condensation products **2a**–**2e** were isolated after evaporation of the solvent and recrystallised from diethyl ether/petroleum ether solutions.

**Synthesis of Analogous Complex 2′c:** The above procedure was applied, but using the (phenylthio)carbene complex $CH_3(SPh)C{=}Cr(CO)_5$.

**NLO Measurements:** NLO measurements were carried out using the Electric Field Induced Second Harmonic (EFISH) technique.[36] The data were recorded using a nanosecond Nd:YAG pulsed (10 Hz) laser operating at 1064 nm, equipped with a hydrogen cell (1 m long, 40 bar) for Raman shifting. The 1907 nm beam was selected and used as the fundamental for EFISH. The compounds were dissolved in chloroform at various concentrations (typically in the range of $1 \times 10^{-3}$ to $9 \times 10^{-3}$ mol L$^{-1}$) and a specific cell mounted on a translation stage was used. The centrosymmetry of the solution was broken by dipolar orientation of the chromophores with a high voltage pulse (5 kV) synchronized with the laser pulse. The SHG signal was selected through a suitable interference filter, detected by a photomultiplier, and recorded by an oscilloscope. Translation of the cell allowed us to obtain the typical Maker fringes. The NLO response was analysed according to an already published procedure. 2-Methyl-4-nitroaniline was used as a reference ($\mu\beta = 71 \times 10^{-48}$ esu at 1907 nm) to determine the $\mu\beta$ value of our compounds.

**Supporting Information** (see footnote on the first page of this article): Table S1 lists the UV/Vis absorption properties of complexes **3** in various solvents.

[16] Hydrolysis performed with cold water decreases the thioester formation.
[17] Addition of chlorosilane reagents to heterocyclic aldehydes in $CH_2Cl_2$ solution gives a yellow precipitate of pyrylium salts: B. Caro, unpublished results. Another mechanism proposed by one referee is that the alkenylylidene complexes are produced in a two-step reaction. The first step is the reversible addition of a carbanion to the carbonyl group. This reaction occurs in any case (for benzaldehyde and heterocyclic aldehyde) but in the absence of TMSCl does not undergo the elimination to complexes **2a**–**2e** due to the electron-donating effect of the 4*H*-pyran-4-ylidene group.
[18] Carbene complex **3d** (Figure 1) is obtained from aldehyde **1d** (Scheme 1) and $CH_3(OCH_3)C{=}W(CO)_5$ by treatment with $NEt_3$ in the presence of TMSCl; see ref.[15c]

# Synthesis of a BEDT-TTF Bipyridine Organic Donor and the First $Fe^{II}$ Coordination Complex with a Redox-Active Ligand

**Katel Hervé,[a] Shi-Xia Liu,[b] Olivier Cador,[a] Stéphane Golhen,[a] Yann Le Gal,[a] Azzedine Bousseksou,[c] Helen Stoeckli-Evans,[d] Silvio Decurtins,[b] and Lahcène Ouahab*[a]**

**Keywords:** Iron / N ligands / BEDT-TTF / Synthesis design / Redox chemistry

The synthesis of the new ligand, BEDT-TTF-bipy [4,5-ethylenedithio-4′,5′-(4′-methyl-2,2′-dipyrid-4-ylethylenedithio)-tetrathiafulvalene] is reported. The first $Fe^{II}$ coordination complex, namely $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]\cdot CHCl_3$, with this redox-active ligand is obtained. Magnetic measurements and Mössbauer spectroscopy revealed the coexistence of high-spin and low-spin $Fe^{II}$ species with a ratio of 40:60 in this compound.

## Introduction

Charge transfer (CT) complexes based on organic donors such as TTF (tetrathiafulvalene) and its derivatives have been intensively studied.[1] Considerable efforts are currently devoted to the synthesis and investigations of new molecule-based materials involving interplay and synergy between multiple physical properties, such as electrical conductivity or superconductivity and magnetic effects, optical and magnetic properties or spin crossover.[2] Construction of such materials appears to be a challenging target for synthetic chemists who are faced with the difficult control of the self-assembly of molecular building blocks. This is indeed a crucial step to obtain a supramolecular compound that has the desired structure, stability and physical properties. Some significant achievements have been obtained in different directions: (i) light-induced magnetization[3] observed in a Prussian blue derivative, namely $K_{0.2}Co_{1.4}[Fe(CN)_6]\cdot 6.9H_2O$,[3c,3d] which exhibits a reversible photo-induced magnetization as a result of oxidation state changes for the metal ions from [$Co^{III}$, $S = 0$ and $Fe^{II}$, $S = 0$] to [$Co^{II}$, $S = 3/2$ and $Fe^{III}$, $S = 1/2$]; (ii) synergy between spin-crossover and magnetic interactions:[4] $[Fe(mnt)_2(rad)]$ [mnt = maleonitriledithiolate; rad = 2-(*para*-*N*-methylpyridinio)-4,4,5,5-tetramethylimidazolin-1-oxyl] exhibits a spin crossover between $S_{Fe} = 5/2$ at high temperature and $S_{Fe} = 1/2$ at low temperature and also an antiferromagnetic (AF) interaction at low temperature between the radical unit and $Fe^{III}$; (iii) electrical conductivity and magnetic interactions:[5–7] conducting materials incorporating localized spins are currently a subject of intense investigations and many compounds of this kind were obtained and characterized, such as $(BEDT\text{-}TTF)_3[MnCr(C_2O_4)_3]$ [BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene (or ET)],[6a] $(BETS)_2FeCl_4$ [BETS = bis(ethylenedithio)tetraselenafulvalene],[6b] $(C1\text{-}TET\text{-}TTF)_2FeX_4$ [X = Cl, Br; C1-TET-TTF = 4,5-bis-(methylthio)-4′,5′-ethylenedithiotetrathiafulvalene].[2a]

Only two examples of hybrids with a combination of a spin cross-over property and electrical conductivity have been reported so far, namely $Fe(abpt)_2(TCNQ)_2$[8] and $[Fe(sal_2\text{-}trien)][Ni(dmit)_2]$.[9] However, in both cases no conductivity was observed. In order to enhance interactions between the two subsystems, a strategy consisting of the covalent linkage of paramagnetic transition-metal ions to redox-active ligands has been addressed.[7] However, to the best of our knowledge, there is no example of such a system with TTF derivatives as ligands. As a first attempt in this direction, we report here a detailed study on the synthesis and characterizations of the new ligand BEDT-TTF-bipy as well as its $Fe^{II}$ complex, namely $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]\cdot CHCl_3$.

## Results and Discussion

### Synthesis

The synthesis of ligand **6** was performed as shown in Scheme 1 by a phosphate-mediated cross-coupling method between chalcogenones **4** and **5**. The former was prepared by transchalcogenation of the corresponding thione **3**, the synthesis of which was based on the thermal depolymerization of oligomer **1** on heating, followed by Diels–Alder re-

## Single-Crystal Structure of Compound 4

An ORTEP plot of molecule **4** with the atomic numbering scheme is shown in Figure 1.

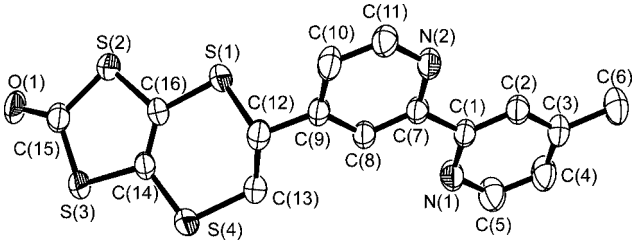

Figure 1. ORTEP (50% probability ellipsoids) structure of compound **4**. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å]: S1–C16 1.754(2), S2–C16 1.745(2), S2–C15 1.765(3), S3–C14 1.748(2), S3–C15 1.765(3), S4–C14 1.747(3), S1–C12 1.839(3), S4–C13 1.808(3), O1–C15 1.207(3).

Molecule **4** contains an essentially planar moiety, comprising atoms C(14), C(15), C(16), O(1) and all four sulfur atoms; this plane forms an angle of 126.5° with the mean plane calculated from the C(7)–C(8)–C(9)–C(10)–C(11)–N(2) atoms belonging to the pyridyl ring. All atoms of the bipyridyl moiety lie almost perfectly within one plane with atoms N1 and N2 situated in *anti* orientation. As expected, S(1)–C(12) and S(4)–C(13) are typical single bonds, while the other C–S bonds are considerably shorter than that of a single C–S bond, indicating some delocalized π-bonding through the interaction of the sulfur d-orbitals with the C=C and C=O π-bonds. These C–S bond-length differences have been found in other analogous compounds.[10]

## Single Crystal Structure of Compound 6

Although the quality of the crystal of compound **6** was poor, it was possible to determine its crystal structure. An ORTEP plot of the molecule with the atomic numbering scheme is shown in Figure 2. Compared to compound **4**, the nitrogen atoms of the bipyridyl moiety also lie in an *anti* position, but an angle of 11.8(11)° is observed between the two pyridyl rings. The mean plane calculated from the pyridyl ring [C(11)–C(12)–C(13)–C(14)–C(15)–N(1)] directly bonded to the BEDT-TTF moiety, forms an angle of 75.2(5)° (see Figure 3) with the almost planar TTF skeleton [S(3)–S(4)–C(5)–C(6)–S(5)–S(6)]. As usual, a boat conformation is observed for the ET molecule. One can notice that the S(7)–C(9) and S(8)–C(10) bonds are significantly shorter than the corresponding ones [S(1)–C(12) and S(4)–C(13)] observed in compound **4** (see Figures 1 and 2).

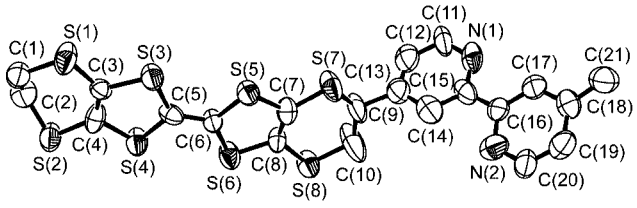

Figure 2. ORTEP structure of **6** with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å]: S6–C8 1.723(16), S6–C6 1.734(15), S3–C5 1.720(17), S3–C3 1.787(16), S8–C8 1.731(17), S8–C10 1.78(2), S4–C5 1.753(16), S4–C4 1.76(2), S5–C6 1.731(16), S5–C7 1.762(19), C5–C6 1.42(2), C8–C7 1.38(3), C4–C3 1.32(3), S7–C9 1.72(3), S7–C7 1.729(18).

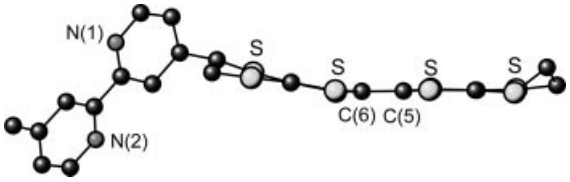

Figure 3. View of compound **6** showing the angle of 75.2(5)° between the TTF skeleton and the $N(1)C_5$ pyridyl ring.

## TGA of Compound 7

The detection of the temperature dependence of weight loss of $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]\cdot CHCl_3$ was carried

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

out on a powdered sample between 25 and 150 °C, where the compound starts to decompose. In total, a weight loss of 8.1% is observed within the range 25–65 °C. The gas analysis by means of mass spectrometry coupled to TGA revealed the presence of chloroform only. The calculated weight loss for one molecule of $CHCl_3$ is equal to 8.5%.

### Electrochemical Measurements of Compound 7

The solution redox properties of the new donor ligand **6** and of the target compound **7** were investigated by cyclic voltammetry (CV), in dichloromethane. Table 1 gives these results and those obtained for BEDT-TTF (ET) under the same conditions. In each case, two typical reversible single-electron redox couples are observed, corresponding to respective formations of the monocation followed by the dication. No difference is observed between ET and donor **6** redox potentials, showing that the methylbipyridyl group has no effect on the redox potentials. The first potential of compound **7** remains unaffected while the second potential decreases.

Table 1. Cyclic voltammetric data[a].

| Compound | $E_1^{1/2}$ [V] | $E_2^{1/2}$ [V] | $E(Fe^{2+}/Fe^{3+})$ [mV] | $\Delta E = E_2^{1/2} - E_1^{1/2}$ [mV] |
|---|---|---|---|---|
| ET | 0.52 | 0.94 | | 420 |
| **6** | 0.55 | 0.95 | | 400 |
| **7** | 0.55 | 0.86 | 1100 | 310 |

[a] All oxidation potentials were determined under $N_2$ in $CH_2Cl_2$ vs. ESC at room temperature. Measurements have been performed at a scan rate of 100 mV·s$^{-1}$ using 0.1 M $(Bu_4N)PF_6$ as the electrolyte and Pt as the working electrode.

### UV/Vis Spectra of Compound 7

The room-temperature UV/Vis absorption spectra of BEDT-TTF-bipy and $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]$ in DMF solution are shown in Figure 4. The spectra mainly reveal that upon complexation, an intense broad band appears at around 19000 cm$^{-1}$. This band is characteristic of the Fe–bipyridine metal-to-ligand charge transfer (MLCT).[11,12] The presence of this MLCT band reflects the formation of the complex $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]$. The intense absorption band observed at energies > 25000 cm$^{-1}$ corresponds to the tail of the intra-ligand charge transfer π-π*.[13,14]

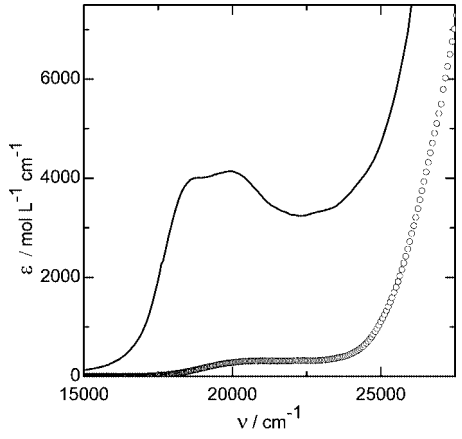

Figure 4. Absorption spectra of **6** (circles) and $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]$ (—) in dimethylformamide solution.

### Magnetic Susceptibility of Compound 7

The thermal dependence of the $\chi_M T$ product of $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]\cdot CHCl_3$ is represented in Figure 5. At room temperature, $\chi_M T$ is equal to 1.65 cm$^3$·K·mol$^{-1}$ and the value remains almost constant down to 60 K where it starts to decrease. The room-temperature value is, on the one hand, much lower than the expected value for a high-spin (HS) $Fe^{II}$ species ($\chi_M T \approx$ 3.7 cm$^3$·K·mol$^{-1}$)[15] and, on the other hand, much higher than the expected value for a purely low-spin (LS) $Fe^{II}$ species ($\chi_M T \approx$ 0.1 cm$^3$·K·mol$^{-1}$).[16] We may therefore conclude that both HS and LS $Fe^{II}$ species are mixed together, the ratio being close to 40:60. It may also be the result of the presence of *cis*/*trans* configurations in the complex, but this could not be answered conclusively. The lowering of $\chi_M T$ at low temperatures can be due to the zero-field splitting of $Fe^{II}$[17] and intermolecular antiferromagnetic interactions between the metal centres.

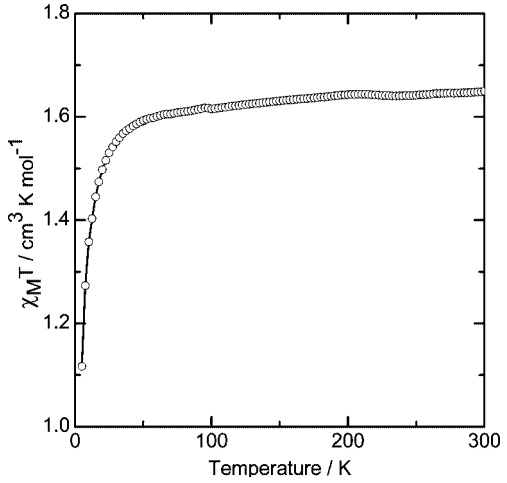

Figure 5. Thermal variation of $\chi_M T$ for a powdered sample of $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]\cdot CHCl_3$.

### Mössbauer Spectroscopy of Compound 7

The Mössbauer spectrum of $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]\cdot CHCl_3$ at 80 K is shown in Figure 6. The spectrum shows unambiguously the presence of two spin states for $Fe^{II}$: a high-spin state, characterized by a doublet with quadrupole splitting $\Delta E_Q$ = 2.70(1) and an isomer shift $IS$ = 1.000(6) mm·s$^{-1}$ and a low-spin state, characterized by a second quadrupolar doublet with quadrupole splitting $\Delta E_Q$ = 0.369(2) and an isomer shift $IS$ = 0.367(1) mm·s$^{-1}$. These Mössbauer parameters are in good agreement with those

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

observed in the literature for high-spin and low-spin $Fe^{II}$ compounds.[18] On the basis of equal Debye–Waller factors ($f$) for HS and LS $Fe^{II}$, the ratios $A_{HS}/A_{TOT}$ and $A_{LS}/A_{TOT}$ result in 0.25(1) and 0.75(1), respectively. However, this parameter for the resonating nuclei can differ distinctly for HS and LS $Fe^{II}$,[19] whereby the determined LS area ($A_{LS}$) overestimates the LS molar fraction if $f_{HS} = f_{LS}$ is assumed. Consequently, an HS $Fe^{II}$ fraction in the order of 0.3–0.4 can be estimated in fairly good agreement between the magnetic and the Mössbauer measurements.

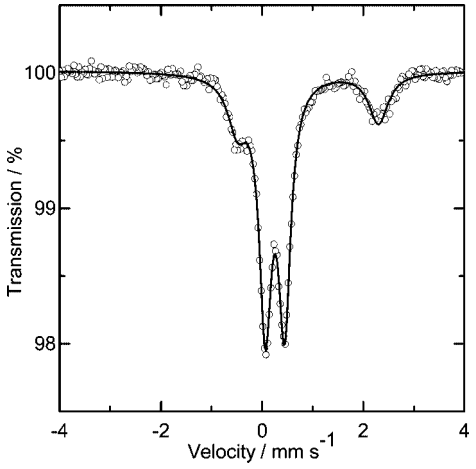

Figure 6. Mössbauer spectrum of $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]\cdot CHCl_3$ at 80 K. The spectrum is characterized by two quadruple doublet characteristics of high-spin and low-spin states of $Fe^{II}$, respectively.

## Conclusions

We reported in this contribution a detailed synthesis and structure of a new ligand, namely BEDT-TTF-bipy as well as the first $Fe^{II}$ coordination complex, namely $[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]\cdot CHCl_3$ with this redox-active ligand. Although it was not possible to obtain single crystals of this complex, the use of different techniques (TGA, elemental analysis, cyclic voltammetry, magnetic measurements, UV and Mössbauer spectroscopy) allowed us to fully characterize this material. Magnetic measurements and Mössbauer spectroscopy showed a mixture of high-spin and low-spin $Fe^{II}$ species with a ratio of 40:60 in this complex. Moreover, one of the reasons for the lack of crystallization might be the existence of several possible isomers for this compound. In order to limit the number of isomers, work is underway to prepare the corresponding ligand with a terminal C=C double bond [C(9)–C(10) in Figure 2].

## Experimental Section

**General:** X-ray data for compound **4** were collected at 253 K with a Stoe Image Plate Diffraction System,[20] while for compound **6** data were collected at room temperature with an Enraf–Nonius four-circle diffractometer equipped with a CCD camera (CDFIX centre of Université de Rennes 1). Both sets of data were collected using an Mo-$K_\alpha$ graphite-monochromated radiation source ($\lambda$ = 0.71073 Å). The room-temperature UV/Vis absorption spectra were obtained with a BIO-TEK Instruments UVIKON-XL spectrophotometer. The magnetic susceptibility $\chi_M$ was recorded with a Quantum Design MPMS SQUID magnetometer operating in the 2–300 K temperature range at a field of 1 T. The experimental data have been corrected from the diamagnetism of the sample holder and the intrinsic diamagnetism of the materials evaluated with Pascal's tables. Mössbauer measurements were obtained on a constant-acceleration spectrometer with a 50 mCi source of $^{57}Co$ (Rh matrix). The isomer shift values (*IS*) are given with respect to metallic iron at room temperature. The absorber was a sample of microcrystalline powder enclosed in a 2 cm diameter cylindrical plastic sample holder, the size of which was determined to optimize the absorption. The 80 K spectrum was obtained by using an MD306 Oxford cryostat, the thermal scanning being monitored by an Oxford ITC4 servocontrol device (±0.1 K). Fitting parameters for all spectra were obtained by using a least-squares computer program. The standard deviations of statistical origin of the Mössbauer parameters are given in parentheses. Cyclic voltammetry measurements were conducted with an EDAC EA161 Potentiostat. Thermogravimetric analysis was performed with a SETARAM LABSYS DTA-TG/DSC apparatus coupled to a Pfeiffer Omnistar mass spectrometer.

**Synthesis:** All reagents were of analytical grade and used as received. All reactions were carried out under argon, using freshly distilled and degassed solvents. The $[C_3S_5]_x$ oligomer **1**[21] and 4-methyl-4′-vinyl-2,2′-bipyridine (**2**)[22] were prepared according to literature procedures.

**4,5-[(4′-Methyl-2,2′-dipyrid-4-yl)ethylenedithio]-1,3-dithiole-2-thione (3):** A mixture of oligomer **1** (1 g) and compound **2** (1 g, 5.1 mmol) in dioxane (20 mL) was heated to 75 °C and stirred for 1.5 h. The resulting mixture was filtered hot and the precipitate was further washed with dichloromethane (3 × 25 mL) to completely extract the product. The filtrate and combined washings were treated with activated charcoal. After filtration, the solvent was evaporated under vacuum to give a yellow oil that was purified by chromatography on silica gel with dichloromethane/ethyl acetate (1:1) to afford a yellow powder (1.44 g, 72%). $C_{16}H_{12}N_2S_5\cdot 0.3C_4H_8O_2$ (419.05): calcd. C 49.30, H 3.46, N 6.69; found C 49.50, H 3.16, N 6.64.

**4,5-(4′-Methyl-2,2′-dipyrid-4-ylethylenedithio)-1,3-dithiol-2-one (4):** To a solution of **3** (0.4 g, 1 mmol) in chloroform (55 mL) and acetic acid (7 mL), was added $Hg(OAc)_2$ (0.935 g, 2.9 mmol). The mixture was stirred at room temperature for 45 min. During this period, the suspension changed colour from yellow to white. The resulting white precipitate was filtered off using Celite and washed thoroughly with $CHCl_3$. The filtrate and combined washings were neutralized with a saturated $Na_2CO_3$ aqueous solution and then extracted with water (3 × 40 mL). After drying with $Na_2SO_4$, the combined organic phases were concentrated under vacuum. The resulting oily product was solidified upon the addition of diethyl ether to give **4** as a pale yellow powder (0.28 g, 73%). $C_{16}H_{12}N_2OS_4\cdot 0.2C_4H_{10}O$ (391.36): calcd. C 51.56, H 3.60, N 7.16; found C 50.70, H 3.57, N 6.90.

**4,5-Ethylenedithio-4′,5′-(4′-methyl-2,2′-dipyrid-4-ylethylenedithio)-tetrathiafulvalene (6):** A suspension of 4,5-ethylenedithio-1,3-dithiole-2-thione (**5**)[23] (0.26 g, 1.16 mmol) and compound **4** (0.3 g, 0.54 mmol) in triethyl phosphite (5 mL) under nitrogen was heated to 120 °C and stirred for 2 h. After cooling to room temperature, a red precipitate had formed, which was filtered off and washed with diethyl ether to afford analytically pure **6** as a red powder

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(0.19 g, 44%). $C_{21}H_{16}N_2S_8{\cdot}0.5H_2O$ (561.89): calcd. C 44.89, H 2.85, N 4.99; found C 44.88, H 2.90, N 4.57.

**$[Fe(NCS)_2(BEDT\text{-}TTF\text{-}bipy)_2]{\cdot}CHCl_3$ (7):** A mixture of $FeSO_4{\cdot}7H_2O$ (25.2 mg, 0.09 mmol), KNCS (17.6 mg, 0.18 mmol) and a pinch of ascorbic acid in 3 mL of freshly distilled methanol was stirred at room temperature for 30 min. After filtration, the resulting colourless solution of $Fe(NCS)_2$ was added dropwise to a solution of compound **6** (100 mg, 0.18 mmol) in distilled chloroform (22 mL). A red-brown precipitate formed immediately, which was filtered off and washed with MeOH and $CHCl_3$ to give the desired $Fe^{II}$ complex as a dark-purple powder (87 mg, 75%). $C_{44}H_{32}FeN_6S_{18}{\cdot}CHCl_3$ (1397.17): calcd. C 38.68, H 2.38; N 6.01, S 41.31; Fe 4.00; found C 38.97, H 2.45, N 6.46, S 39.95, Fe 4.42.

**X-ray Crystallography. 4:** A pale-yellow, rod-like crystal of compound **4** ($0.42\times0.15\times0.11$ mm) was obtained by slow concentration of a solution of compound **4** in a mixture of $CH_2Cl_2$ and ethyl acetate. The intensity data were collected at 253 K. This compound crystallized in the $P\bar{1}$ triclinic space group with the following parameters: $a$ = 5.6428(7) Å, $b$ = 10.1851(13) Å, $c$ = 15.158(2) Å, $\alpha$ = 105.847(15)°, $\beta$ = 94.448(16)°, $\gamma$ = 103.526(15)°, $V$ = 805.5(2) Å$^3$, $Z$ = 2, $\mu$ = 0.594 mm$^{-1}$, 2911 unique for 5724 collected reflections, $R_1$ = 0.0392, $wR_2$ = 0.1039. **6:** Compound **6** was dissolved in a mixture of $CH_2Cl_2$ and ethyl acetate and heated in an ultrasonic bath. The resulting solution was filtered and a few drops of methanol were added to the solution. After slow concentration, a few crystals of **6** of very low quality were obtained. The intensity data were collected at room temperature. This compound crystallized in the monoclinic space group $P2_1/c$ with the following parameters: $a$ = 6.8420(4) Å, $b$ = 17.6760(11) Å, $c$ = 19.2560(14) Å, $\beta$ = 96.146(2)°, $V$ = 2315.4(3) Å$^3$, $Z$ = 4, $\mu$ = 0.785 mm$^{-1}$, 4026 unique for 13627 collected reflections, $R_1$ = 0.1949, $wR_2$ = 0.4551. All structures were solved by direct methods using the program SHELXS-97.[24] The refinement and all further calculations were carried out using SHELXL-97.[25] H-atom positions were calculated as a riding model. Non-H atoms were refined anisotropically, using weighted full-matrix least squares on $F^2$. CCDC-287337 and -600718 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Crystal Structure and Magnetic Behaviour of the New Gadolinium Carboxylates $Gd_2(ClF_2CCOO)_6(hypy)_2$, $Gd_2(F_3CCOO)_6(hypy)_2$, $Gd_2(F_2HCCOO)_6(hypy)_2$ and $Gd_2(Cl_2HCCOO)_6(H_2O)_2(hypy)_2$

**Daniela John[a] and Werner Urland*[a]**

**Keywords:** Gadolinium / Carboxylates / O ligands / X-ray diffraction / Crystal structures / Magnetic properties

Four complexes with the formulae $Gd_2(ClF_2CCOO)_6(hypy)_2$ (**1**), $Gd_2(F_3CCOO)_6(hypy)_2$ (**2**), $Gd_2(F_2HCCOO)_6(hypy)_2$ (**3**) and $Gd_2(Cl_2HCCOO)_6(H_2O)_2(hypy)_2$ (**4**) have been synthesised and characterised by single-crystal X-ray diffraction methods at room temperature. The title compounds have been obtained by reaction of the corresponding gadolinium carboxylates with 4-hydroxypyridine in a solution of ethanol and water. They crystallise in the triclinic space group $P\bar{1}$ ($Z$ = 2) [**1**: $a$ = 999.8(4) pm, $b$ = 1061.8(5) pm, $c$ = 1283.6(6) pm, $\alpha$ = 91.23(5)°, $\beta$ = 111.29(5)° and $\gamma$ = 105.27(5)°; **2**: $a$ = 972.4(4) pm, $b$ = 1053.5(5) pm, $c$ = 1252.4(6) pm, $\alpha$ = 94.23(5)°, $\beta$ = 110.21(5)° and $\gamma$ = 104.84(5)°; **3**: $a$ = 883.3(4) pm, $b$ = 1051.3(4) pm, $c$ = 1284.9(6) pm, $\alpha$ = 100.46(5)°, $\beta$ = 109.87(5)° and $\gamma$ = 97.43(5)°; **4**: $a$ = 913.7(4) pm, $b$ = 1079.0(5) pm, $c$ = 1137.5(5) pm, $\alpha$ = 93.41(5)°, $\beta$ = 109.36(5)° and $\gamma$ = 99.53(5)°]. The crystal structures consist of dinuclear $Gd^{3+}$–$Gd^{3+}$ units. The corresponding residuals (all data) for the refined structures are 4.82 % (**1**), 5.93 % (**2**), 5.68 % (**3**) and 4.04 % (**4**). The magnetic behaviour of the compounds was investigated over the temperature range 1.76–300 K. The magnetic data were interpreted by considering exchange interactions within the dimeric units [$J_{ex}$ = –0.019 $cm^{-1}$ (**1**), $J_{ex}$ = –0.034 $cm^{-1}$ (**2**), $J_{ex}$ = –0.064 $cm^{-1}$ (**3**), $J_{ex}$ = –0.011 $cm^{-1}$ (**4**)].

## Introduction

In connection with the investigations of the structural chemistry of polynuclear complexes of lanthanides that are of importance for the study of magnetic interactions,[1–16] we paid attention to the carboxylates $Gd_2(X_kH_mCCOO)_6(H_2O)_n(hypy)_2$ [X = Cl, F; $k$ = 2, 3; $m$ = 0, 1; $n$ = 0, 2; hypy: tautomerised 4-hydroxypyridine = 4-(1*H*)-pyridone]. There are no simple rules to predict the occurrence of ferro- or antiferromagnetic coupling, unlike those of Goodenough and Kanamori for compounds of d elements.[17] In order to eliminate this nescience we determined the magnetic behaviour of the title compounds. The magnetic data were interpreted by considering magnetic exchange coupling in the dinuclear $Gd^{3+}$–$Gd^{3+}$ units.[17,18]

## Results and Discussion

### Crystal Structures

The crystal data and details of the refinements for **1**, **2**, **3** and **4** are summarised in Table 1, selected bond lengths can be found in Table 2.

E-Mail: urland@acc.uni-hannover.de

The title compounds crystallise in the triclinic space group $P\bar{1}$ (Z = 2) with **1**: $a$ = 999.8(4) pm, $b$ = 1061.8(5) pm, $c$ = 1283.6(6) pm, $\alpha$ = 91.23(5)°, $\beta$ = 111.29(5)° and $\gamma$ = 105.27(5)°; **2**: $a$ = 972.4(4) pm, $b$ = 1053.5(5) pm, $c$ = 1252.4(6) pm, $\alpha$ = 94.23(5)°, $\beta$ = 110.21(5)° and $\gamma$ = 104.84(5)°; **3**: $a$ = 883.3(4) pm, $b$ = 1051.3(4) pm, $c$ = 1284.9(6) pm, $\alpha$ = 100.46(5)°, $\beta$ = 109.87(5)° and $\gamma$ = 97.43(5)°; **4**: $a$ = 913.7(4) pm, $b$ = 1079.0(5) pm, $c$ = 1137.5(5) pm, $\alpha$ = 93.41(5)°, $\beta$ = 109.36(5)° and $\gamma$ = 99.53(5)°.

#### *$Gd_2(ClF_2CCOO)_6(hypy)_2$ (1)*

The crystal structure is shown in Figure 1. The $Gd^{3+}$ ions are connected ($Gd^{3+}$–$Gd^{3+}$ distance is 386.6 pm) through two carboxylate groups ($\mu_2$-carboxylato-$\kappa^1O$:$\kappa^1O'$) and two 4-(1*H*)-pyridone molecules ($\mu_2$-pyridone-1:2$\kappa^2O$) to form dimers (Figure 2). In addition each $Gd^{3+}$ ion is chelated by two chlorodifluoroacetate ions and one pyridone molecule (Figure 2). The central ion is ninefold coordinated by oxygen atoms originating from the carboxylate groups ($Gd^{3+}$–O distances are 240.2–268.3 pm) and three pyridone molecules ($Gd^{3+}$–O distances are 226.4–246.6 pm).

The 4-(1*H*)-pyridone molecules form the extended structure through π–π stacking interactions (Figure 3).[19,20] The shortest orthogonal distance between two aromatic fragments is 325.4 pm.

### *$Gd_2(F_3CCOO)_6(hypy)_2$ (2) and $Gd_2(F_2HCCOO)_6(hypy)_2$ (3)*

The crystal structures of **2** (Figure 4) and **3** (Figure 5) comprise dimers [shown in Figure 6 (**2**) and Figure 7 (**3**); $Gd^{3+}$–$Gd^{3+}$ distance is 387.7 pm for **2** and 388.0 pm for **3**]. The structural characteristics are as described for **1**. The $Gd^{3+}$–carboxylate O distances for **2** are 240.3–267.2 pm and 241.1–268.0 pm for **3**. The $Gd^{3+}$–pyridone O distances for **2** are 224.8–247.3 pm and 228.1–249.6 pm for **3**.

The extended structures are also formed by the 4-(1*H*)-pyridone molecules through π–π stacking interactions as in **1**.[19,20] The shortest orthogonal distances between the two aromatic fragments are 331.1 (**2**) and 325.6 pm (**3**).

### *$Gd_2(Cl_2HCCOO)_6(H_2O)_2(hypy)_2$ (4)*

The crystal structure of **4** is shown in Figure 8. The structure comprises discrete dimers ($Gd^{3+}$–$Gd^{3+}$ distance is 405.1 pm) with two kinds of bridging carboxylate groups ($\mu_2$-carboxylato-$\kappa^1O$:$\kappa^1O'$ and $\mu_2$-$O'$;$\kappa^2O,O'$) along with a chelating dichloroacetate ion, a water and a 4-(1*H*)-pyridone molecule (Figure 9). The $Gd^{3+}$ ion is eightfold coordinated by oxygen atoms originating from five carboxylate

groups, one water and one pyridone molecule ($Gd^{3+}$–O distances are 224.6–263.8 pm).

Former results have shown that the $\mu_2$-*O*′;$\kappa^2$*O*,*O*′ mode is responsible for a ferromagnetic interaction, whereas the $\mu_2$-carboxylato-$\kappa^1$*O*:$\kappa^1$*O*′ bridging mode leads to an antiferromagnetic interaction.[21,10–16] The obtained crystal structures of the compounds **1-3** are of interest for magnetic investigations in order to study the influence of the bridging pyridone oxygen atom and of the $\mu_2$-carboxylato-$\kappa^1$*O*:$\kappa^1$*O*′ bridging mode of the carboxylate group. Compound **4** is interesting for magnetic investigations in order to study the influence of the coexistence of the $\mu_2$-*O*′;$\kappa^2$*O*,*O*′- and the $\mu_2$-carboxylato-$\kappa^1$*O*:$\kappa^1$*O*′ bridging modes.

### Magnetic Behaviour

The presentation of the magnetic data follows the recommendation of Hatscher et al.[22] Figures 10, 11, 12 and 13

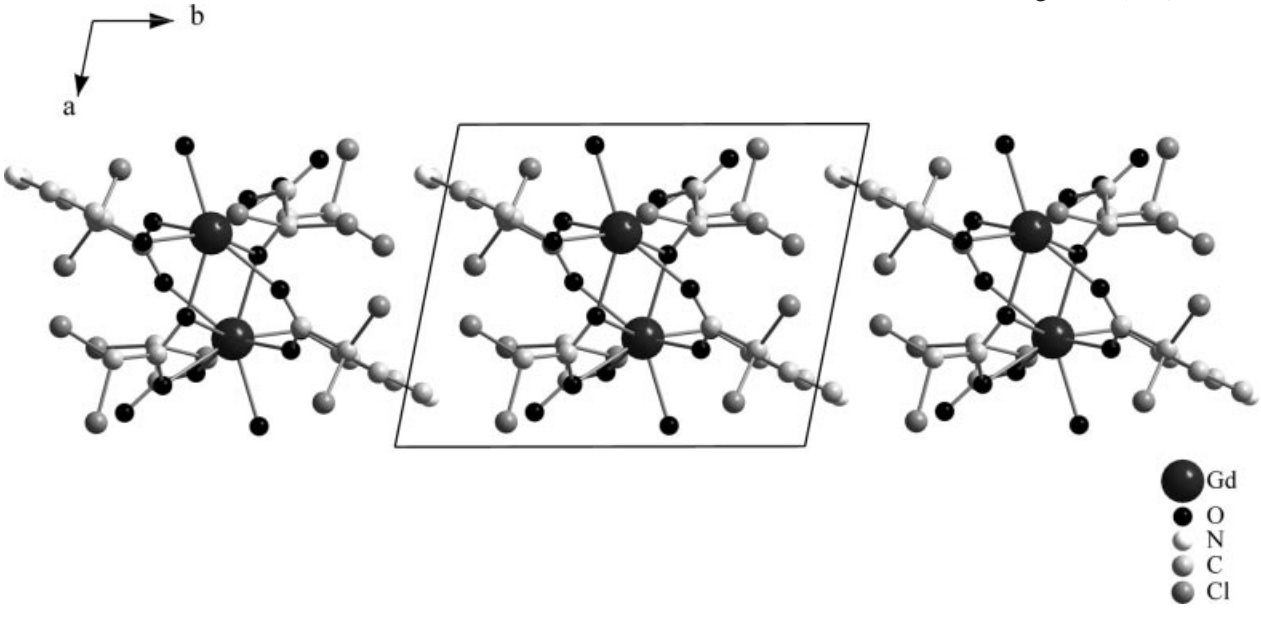

Figure 8. Crystal structure of $Gd_2(Cl_2HCCOO)_6(H_2O)_2(hypy)_2$ (**4**). The triclinic unit cell is given; H atoms are not displayed.

display the measured effective Bohr magneton numbers ($\mu_{eff}$) of **1**–**4** in the temperature range 1.76–300 K ($H^{(ir)}$ = 500 and 1000 Oe). The curve progression shows antiferromagnetic behaviour in each case. The measured magnetic susceptibility ($\chi_m^{(ir)}$) is interpreted by Equation (1) given below, where the intramolecular interaction within the dimeric unit is described by the Heisenberg model with a spin Hamiltonian $\hat{H}_{ex} = -2J_{ex}\hat{\boldsymbol{S}}_{Gd1}\cdot\hat{\boldsymbol{S}}_{Gd2}$ ($S_{Gd1} = S_{Gd2} = 7/2$):[18]

$$\chi_m^{(ir)} = \frac{N_A\mu_B^2 g^2}{k_B T}\cdot\frac{e^{2x}+5e^{6x}+14e^{12x}+30e^{20x}+55e^{30x}+91e^{42x}+140e^{56x}}{1+3e^{2x}+5e^{6x}+7e^{12x}+9e^{20x}+11e^{30x}+13e^{42x}+15e^{56x}}$$

$$\text{with} \quad x = J_{ex}/k_B T \tag{1}$$

where $N_A$ is the Avogadro constant, $\mu_B$ the Bohr magneton, $g$ the Landé factor, $k_B$ the Boltzmann constant, $T$ the absolute temperature and $J_{ex}$ the magnetic excoohange parameter.

The fitting procedure leads to $J_{ex}$ = –0.019 cm$^{-1}$ (**1**), $J_{ex}$ = –0.034 cm$^{-1}$ (**2**), $J_{ex}$ = –0.064 cm$^{-1}$ (**3**) and $J_{ex}$ = –0.011 cm$^{-1}$ (**4**), with $g$ = 2.00. The agreement between the measured and calculated $\mu_{eff}$ values [$\mu_{eff} = 2.8279\text{-}(T\chi_m^{(ir)})^{1/2}$] are shown in Figures 10–13.

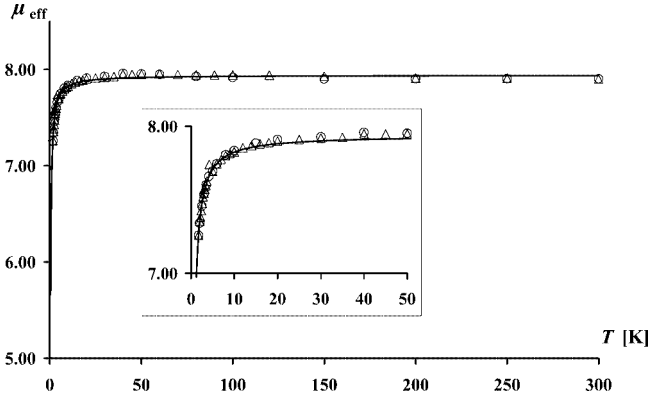

Figure 10. Comparison of measured (Δ, $H^{(ir)}$ = 0.5 kOe; ○, $H^{(ir)}$ = 1.0 kOe) and calculated (−) effective Bohr magneton numbers for $Gd_2(ClF_2CCOO)_6(hypy)_2$ (**1**).

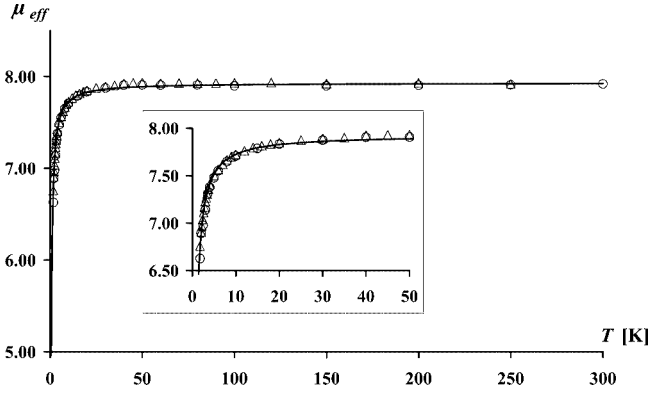

Figure 11. Comparison of measured (Δ, $H^{(ir)}$ = 0.5 kOe; ○, $H^{(ir)}$ = 1.0 kOe) and calculated (−) effective Bohr magneton numbers for $Gd_2(F_3CCOO)_6(hypy)_2$ (**2**).

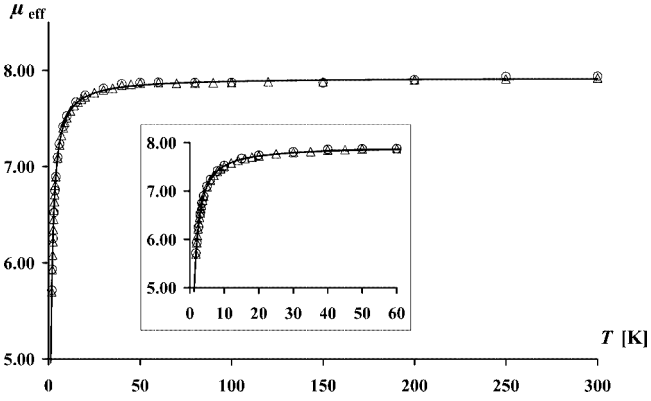

Figure 12. Comparison of measured (Δ, $H^{(ir)}$ = 0.5 kOe; ○, $H^{(ir)}$ = 1.0 kOe) and calculated (−) effective Bohr magneton numbers for $Gd_2(F_2HCCOO)_6(hypy)_2$ (**3**).

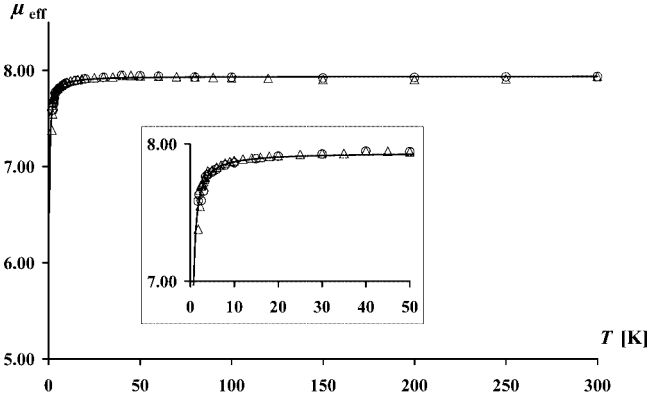

Figure 13. Comparison of measured (Δ, $H^{(ir)}$ = 0.5 kOe; ○, $H^{(ir)}$ = 1.0 kOe) and calculated (−) effective Bohr magneton numbers for $Gd_2(Cl_2HCCOO)_6(H_2O)_2(hypy)_2$ (**4**).

The values of $J_{ex}$ for the title compounds are comparable with those of other carboxylates containing $Gd^{3+}$. The coexistence of the $\mu_2$-pyridone-1:2$\kappa^2O$- or $\mu_2$-$O'$;$\kappa^2O,O'$ bridging mode and the $\mu_2$-carboxylato-$\kappa^1O$:$\kappa^1O'$ bridging mode in **1**–**4** leads to a negative exchange parameter (Table 3). Thus, only in the case where the carboxylate group exclusively bridges the $Gd^{3+}$ ions in a $\mu_2$-$O'$;$\kappa^2O,O'$ bridging mode is a ferromagnetic interaction observed.

## Experimental Section

Transparent, colourless, air stable single crystals of **1**–**4** have been obtained by reaction of the corresponding gadolinium carboxylate with 4-hydroxypyridine (Fluka, ≥95.0%) [molar ratio 2:1 for **1**, **2** and **4**; 1:2 for **3**] in a solution of ethanol (Sigma–Aldrich, 99.8%) and water (1:1). The starting compounds $Gd(ClF_2CCOO)_3(H_2O)_3$, $Gd(CF_3COO)_3(H_2O)_3$, $Gd(HF_2CCOO)_3(H_2O)_2{\cdot}H_2O$ and $Gd_3(H_2ClCCOO)_9(H_2O)_5$ were prepared as given in the literature.[11,16,21,23]

Well-grown single crystals were mounted on a STOE imaging plate diffractometer. The data collection was carried out at room temperature. The structures were solved by Patterson methods and

were refined with anisotropic displacement parameters based on $F^2$ by using the SHELXS-97[24] and SHELXL-97[25] programs. Each data analysis indicated the $P\bar{1}$ space group. The final refinement yielded $R_1$ (all data) = 4.82% (**1**), $R_1$ (all data) = 5.93% (**2**), $R_1$ (all data) = 5.68% (**3**) and $R_1$ (all data) = 4.04% (**4**). Hydrogen atoms were always included by using a riding model. The crystal data and details of the refinements are summarised in Table 1. Selected bond lengths can be found in Table 2.

Elemental analysis (Vario EL, Elementar Analysesysteme GmbH, Hanau, Germany) for **1** $C_{16}H_{10}Cl_3F_6GdN_2O_8$ (735.86): calcd. C 26.12, H 1.37, N 3.81; found C 26.03, H 1.41, N 3.78. For **2** $C_{16}H_{10}F_9GdN_2O_8$ (686.50): calcd. C 27.99, H 1.47, N 4.08; found C 28.01, H 1.49, N 4.00. For **3** $C_{16}H_{13}F_6GdN_2O_8$ (632.53): calcd. C 30.38, H 2.07, N 4.43; found C 30.36, H 2.10, N 4.41. For **4** $C_{11}H_{10}Cl_6GdNO_8$ (654.17): calcd. C 20.20, H 1.54, N 2.14; found C 20.26, H 1.59, N 2.14.

Pulverised single crystals of the title compounds were measured with a SQUID magnetometer (MPMS5, Quantum Design) over the temperature range 1.76–300 K at magnetic fields ($H^{(ir)}$) of 500 and 1000 Oe. No field dependence of the magnetic data was observed. The sample was weighed into the lid of a gelatine capsule. To avoid orientation effects during the measurement, another gelatine capsule was pressed on the sample to fix it. Subsequently, the container was sewn in a plastic straw. The raw magnetic data were corrected for diamagnetism of the sample carrier and the sample by using the increments of Haberditzl.[26]

# A Ferromagnetically Coupled, Bent, Trinuclear Copper(II) Complex: Synthesis, Structure, Hydrogen-Bonding Network, Magnetic Properties and DNA Interaction Study

**Sumana Sarkar,[a] Amrita Mondal,[a] Deepak Chopra,[b] Joan Ribas,[c] and Kajal Krishna Rajak*[a]**

**Keywords:** Copper / Reduced Schiff base / Magnetic properties / Hydrogen bonds / DNA recognition

A bent trinuclear copper(II) complex (**1**) incorporating μ-phenoxo, μ-*syn*-*syn* carboxylato, and $\mu_3$-chloro bridges and an *O*,*N*,*N*-coordinated reduced Schiff-base ligand is reported. The complex shows an intramolecular ferromagnetic interaction in the solid state. The EPR spectra also support the magnetic behaviour of the complex. In the compound, each copper centre has a square-pyramidal geometry. The separation between the adjacent copper ions is about 3.05 Å and that between the terminal copper ions is about 5.0 Å. The complex forms a supramolecular architecture through N–H···Cl hydrogen bonding between the amine group of the reduced Schiff-base ligand and the counter chloride anions. Absorption and fluorescence spectral studies and viscosity measurements have been performed to determine the type of interaction with calf-thymus DNA. The nuclease activity of the complex with plasmid DNA is also studied.

## Introduction

The chemistry of multinuclear copper complexes has aroused considerable interest in recent years as copper has been found in the active sites of a large number of metalloproteins[1,2] as well as because of their interesting magnetic properties.[3] Among the multicentred copper proteins, the active sites of particulate methane monooxygenase (pMMO),[4] laccase[5] and ascorbate oxidase[6] contain trinuclear copper(II) sub-units. It has been documented that trinuclear copper(II) centres exhibit the $S = 3/2$ ground state in the fully oxidised form of pMMO.[7] It is also reported that the oxidised form of the active site of ascorbate oxidase consists of an angled trinuclear copper(II) moiety with a Cu···Cu separation in the range 3.66–3.90 Å, with appropriate $C_2$ symmetry.[6] Although a few ferromagnetically coupled trinuclear copper(II) complexes have been reported,[8,9] to the best of our knowledge studies on mixed-bridged bent trinuclear copper(II) complexes are rare.[10] Thus, there is an increasing demand for mixed-bridged angular trinuclear copper(II) systems in order to better understand the underlying chemistry as well as the magnetic properties of biomolecules. Furthermore, the studies of such systems may be helpful in order to develop the fundamental knowledge about the exchange interactions between the paramagnetic centres of such systems and in the design of molecular-based ferromagnetic materials. These considerations have generated a lot of interest in the synthesis and characterisation of ferromagnetically coupled mixed-bridge bent trinuclear copper(II) complexes using conformationally labile reduced Schiff-base ligands.

The study of the interaction of polynuclear copper(II) complexes with DNA and their nuclease activity is also of abiding interest in the field of bioinorganic chemistry of copper.[11] This is because such polynuclear complexes might interact with DNA by different pathways and exhibit DNA cleavage activity.[8a,12] Thus, developments in the field of DNA interaction and cleavage studies with small molecules have prompted us to explore the binding of trinuclear copper(II) complexes with DNA and their nuclease activity.

Besides the importance of understanding the chemistry, magnetic properties and DNA interaction studies with biologically related polynuclear copper(II) complexes, the design of polynuclear coordination clusters by self-assembly of small building blocks has also received a great deal of attention in the context of crystal engineering, molecular recognition and supramolecular chemistry.[13–15] One particularly interesting method in the construction of self-assembled clusters involves using a ligand that can be involved in coordination and hydrogen-bonding interactions simultaneously, such that the transition metal cationic centres are linked through anions by hydrogen bonding to form a self-assembled cluster. Reduced Schiff-base ligands

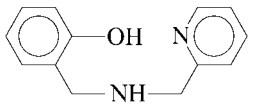
have great potential in the organisation of the primary molecule in the solid state by intermolecular hydrogen bonding.[16] This has also motivated us to undertake the task of designing a supramolecular cluster in the solid state by self-assembly with bifunctional reduced Schiff-base ligands.

Here we describe the synthesis of a mixed-bridge (μ-phenoxo, μ-carboxylato, and $\mu_3$-chloro) trinuclear copper(II) complex incorporating an *O*,*N*,*N*-coordinated reduced Schiff-base ligand. The X-ray structure of the complex has been determined, which allows the secondary interactions in the solid state to be investigated thoroughly. Variable temperature magnetic susceptibility measurements confirm the ferromagnetic behaviour, and the EPR spectra also support the magnetic behaviour. The solution properties are studied, and the interaction with DNA and nuclease activity of the complex is scrutinized.

## Results and Discussion

The reduced Schiff base ligand (**HL**) used in this work was prepared by $NaBH_4$ reduction of the corresponding Schiff base in methanol.[17]



**HL**

The stoichiometric reaction of copper(II) chloride dihydrate with **HL** and benzoic acid in the presence of piperazine in methanol afforded a dark coloured complex of formula $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ in good yield. This complex displays carboxylate stretches near 1560 and 1420 $cm^{-1}$, respectively. The splitting between the two peaks is 140 $cm^{-1}$, which indicates that the carboxylate group bridges the two copper ions in a *syn-syn* fashion.[18] The band at around 1200 $cm^{-1}$ is assigned to the $\nu(C–O_{phenolate})$ vibration. The hydrogen-bonded NH vibration occurs as a broad band near 3400 $cm^{-1}$.

The electronic spectra were recorded in Tris-HCl/NaCl buffer solution; the data are summarised in the Exp. Sect. The complex exhibits a single d-d absorption band near 650 nm which is characteristic of square-pyramidal copper(II) complexes.[19] The allowed intense band observed near 420 nm is believed to be due to an LMCT transition between bridging phenoxide and copper(II) ions.[19]

### Molecular Structure

The crystal structure of $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (**1**) was determined. The asymmetric unit consists of one half of a centrosymmetric molecule; Figure 1 shows the cationic part of the molecular structure and the bond parameters are listed in Table 1.

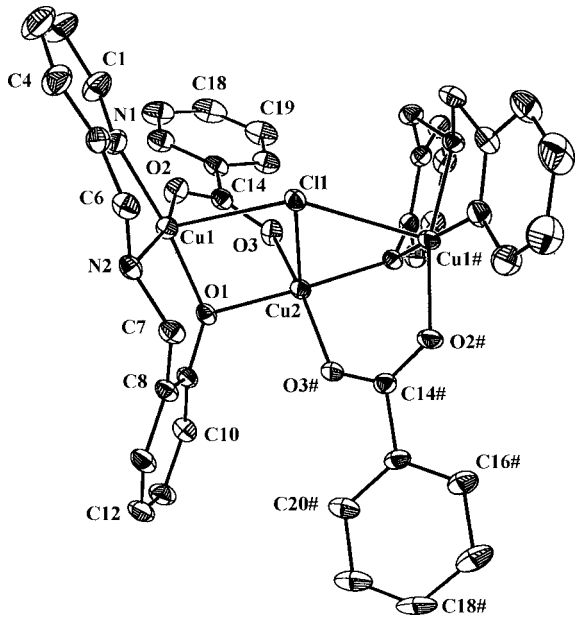


Figure 1. Perspective view and atom-labelling scheme for the cationic part of $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (**1**). All non-hydrogen atoms are represented by 30% thermal probability ellipsoids.

*syn-syn* benzoato group to give a bent trinuclear entity. The three copper atoms in the trinuclear moiety form an isosceles triangle with an adjacent Cu···Cu distance of 3.055(8) Å and a terminal Cu···Cu distance of 5.104(8) Å. The Cu(1)–Cu(2)–Cu(1)# and Cu–$O_{phenoxo}$–Cu angles are 113.31(3)° and 102.40(14)°, respectively. The geometry of each copper ion is distorted square-pyramidal in which the basal plane of the terminal copper atoms consists of two nitrogen (pyridine and amine) and two oxygen (phenoxo and benzoato) atoms while that of the central copper atom contains four oxygen atoms. The equatorial planes are essentially planar (mean deviation = 0.0649 and 0.2128 Å) and the dihedral angle between the terminal and central basal planes is 65.7°. The apical site of each copper ion is occupied by the $\mu_3$-chloro group. The Cu–($\mu_3$-Cl) bond lengths span the range 2.654(2) to 2.732(2) Å and are significantly larger than the terminal Cu–Cl bond. Cu(1) is displaced by 0.1550 Å whereas Cu(2) is shifted by 0.1381 Å towards the apical chloride group. The Cu–N and Cu–O bond lengths are normal.

## Hydrogen Bonding

The primary structure of the compound is remarkably different from its solid-state structure due to the involvement of secondary interactions in the lattice. In the extended solid-state structure a self-assembled cluster compound is formed by simultaneous coordinative and hydrogen-bonding interactions. The amine hydrogen atom of both the reduced Schiff-base ligands in the trinuclear entity engage in hydrogen bonding. The chloride ion is symmetrically hydrogen bonded with the amine hydrogen atom [Cl···N = 3.163(6) Å] of one of the reduced Schiff-base ligands of three different molecules. The basic unit of the cluster is shown in Figure 2. The remaining three amine hydrogen atoms of the three different molecules of the small building blocks are anchored within an extended hydrogen-bonding network. This interaction leads to the formation of macrocyclic cavities with six molecules of average diameter 25.0 Å; the hydrogen-bonded macrocyclic cavity is shown in Figure 3. The hexameric synthons are again assembled in the crystal lattice through similar types of intermolecular contacts to form a honeycomb-like supramolecular array. This honeycomb network is shown in Figure 4.

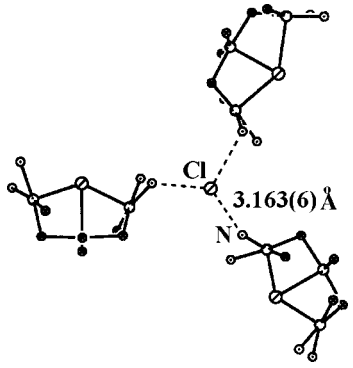

Figure 2. Basic unit of secondary interactions of $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (**1**); carbon and hydrogen atoms have been excluded for clarity.

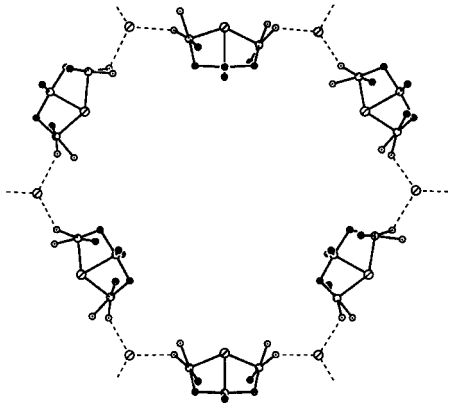

Figure 3. Hexameric macrocycle of **1**; carbon and hydrogen atoms have been excluded for clarity.

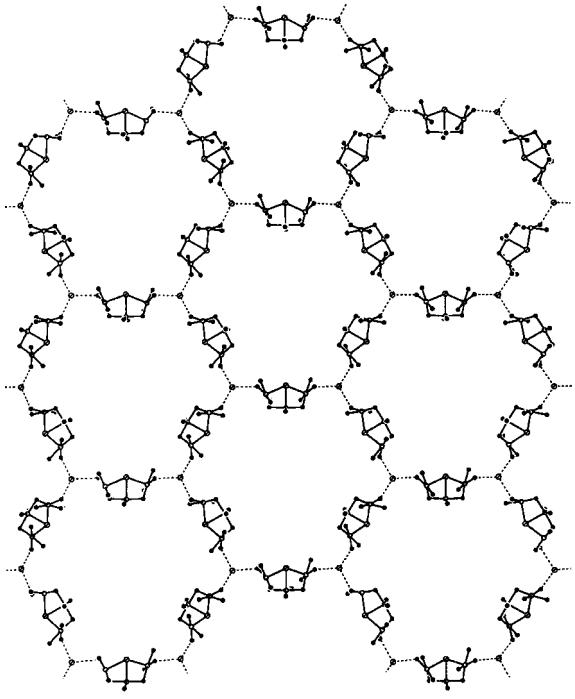

Figure 4. Supramolecular network in the lattice of **1**; carbon and hydrogen atoms have been excluded for clarity.

## Magnetic Studies

The variable-temperature magnetic susceptibility, $\chi_M$, per trinuclear copper(II) unit was measured in the temperature range 2–300 K. A $\chi_M T$ value of 1.32 $cm^3 mol^{-1} K$ is observed for **1** at 300 K, which is as expected for three magnetically quasi-isolated spin doublets ($g > 2.00$). Upon decreasing the temperature the $\chi_M T$ value increased to 1.87 $cm^3 mol^{-1} K$ at 7 K. Such magnetic behaviour is characteristic of a predominant ferromagnetic exchange coupling in a trinuclear copper(II) system. The plot of $\chi_M T$ vs.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$T$ is given in Figure 5. After passing through the maximum, the $\chi_M T$ value decreases quickly to 1.60 $cm^3 mol^{-1} K$ at 2 K. The magnetic orbitals of the terminal copper ions in **1** have predominantly $d_{x^2-y^2}$ character. A significant exchange interaction between two terminal copper atoms through the bridging chloride ligand may be excluded in the isolated trinuclear moiety because the delocalisation of an unpaired electron towards the apical chloride ion is likely to be less effective due to the large Cu–($\mu_3$-Cl) bond length.[20] The decrease of $\chi_M T$ at low temperature is probably either due to a zero-field splitting effect ($D$ parameter) for the $S = 3/2$ ground state or inter-cluster antiferromagnetic interactions ($J'$). Both $D$ and $J'$ exhibit the same behaviour in the low-temperature regime. However, in the case of copper(II), the possible $D$ parameters of the $S = 3/2$ ground state must be very small due only to the dipolar interactions. Therefore, for simplification, the $D$ parameter was not taken into consideration when fitting the experimental data. The fit of the susceptibility data was carried out using the molecular field approximation, with the $J'$ parameter, according to the method given by Kahn,[3] with the Hamiltonian

$$H = -J(S_1S_2 + S_2S_3) + g\beta H\mathbf{S}_z - zJ'\langle\mathbf{S}_z\rangle\mathbf{S}_z$$

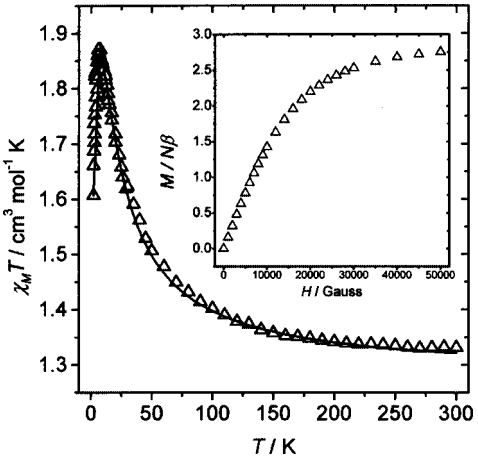

Figure 5. Plot of $\chi_M T$ vs. $T$ for $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (**1**) (open points are the experimental data and the solid line represents the best fit obtained). Plot of the reduced magnetisation, $M/N\beta$, vs. $H$ for **1** at 2 K (see inset).

With this molecular field approach (neglecting $D$ parameter), the best-fit parameters for complex **1** are: $J = 20.8 \pm 0.2$ $cm^{-1}$, $J' = -0.4 \pm 0.2$ $cm^{-1}$, $g = 2.13 \pm 0.01$ and $R = 1.2 \times 10^{-4}$ [$R = \Sigma(\chi_M^{calc} - \chi_M^{obs})^2/\Sigma(\chi_M^{obs})^2$].

The nature of the reduced molar magnetisation is shown in the inset of Figure 5. The $M/N\beta$ value at 5 T is close to $3N\beta$ and this value indicates the tendency to have three unpaired electrons ($S = 3/2$) at 2 K.

The ferromagnetic interaction in the present complex can be explained by considering the dihedral angle between the equatorial planes of the terminal and central copper(II) centres.[21] It is known that spin coupling between the paramagnetic centres becomes ferromagnetic when the dihedral angle decreases from 180°. In complex **1** the dihedral angle of 65.7° deviates significantly from the value of 180°. These results also support the ferromagnetic interactions.

## EPR Spectra

Variable-temperature EPR spectra of the complex were recorded to find out more about the behaviour of the unpaired electron within the trinuclear cluster in the solid state. The X-band EPR spectra of polycrystalline powdered complex at different temperatures are shown in Figure 6.

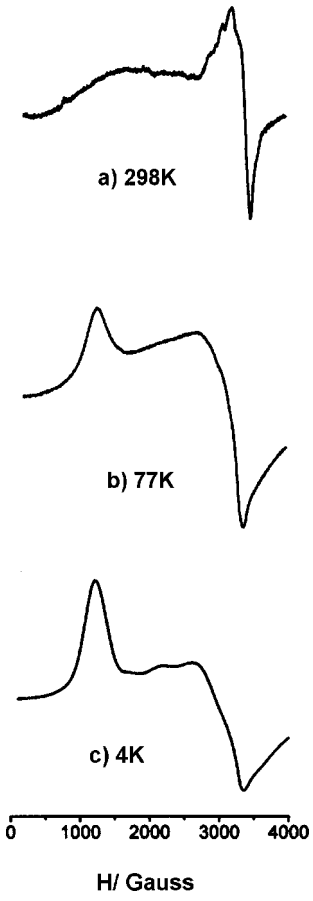

Figure 6. Solid powder X-band EPR spectra of $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (**1**).

The EPR spectrum at 4 K is dominated by a transition at 1215 G (Figure 6, c), which unambiguously identifies the $S = 3/2$ ground spin-state. At this temperature the signals within the ±1/2 and ±3/2 Kramer's doublets are observed. It is clear from the variable-temperature studies (Figure 6) that the intensity of the $M_S = \pm 1/2$ EPR spectra increases with decreasing temperature. At 4 K the effective $g_\perp$ value is found at 5.2; this value may arise due to the transition within $M_S = \pm 1/2$ of the Kramer doublet of quadruplets state ($S = 3/2$). The corresponding $g_\parallel$ value is observed at 2.15. It is interesting to note that the strong signal at low field gradually broadens and almost disappears with increasing temperature (Figure 6). However, the signal corresponding to $g \approx 2.0$ remains almost unchanged. These

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectral features have been attributed to the increasing population of the two $S = 1/2$ excited states with a rise in temperature. As a consequence, there is compensation of the $S = 3/2$ ground state and the room-temperature spectrum is more reminiscent of the $S = 1/2$ term. All the spectral observations are in good agreement with the magnetic moment of the complex.

### Interaction Between DNA and the Complex

Electronic absorption spectroscopic techniques are often employed to investigate the binding of DNA with complexes. To achieve this, the absorption spectra of the complex in the absence and presence of calf-thymus DNA at different concentrations were measured. The UV/Vis spectral change with increasing DNA concentration for **1** is shown in Figure 7. A considerable hypochromicity without appreciable change in wavelength of the d-d and charge-transfer transitions can be attributed to an interaction[22] between the surface of the DNA molecule and the trinuclear complex. The binding constant between DNA and the complex was determined from the UV/Vis spectroscopic data using the following equation[23]

$$[DNA]/(\varepsilon_a - \varepsilon_f) = [DNA]/(\varepsilon_b - \varepsilon_f) + 1/K_b(\varepsilon_a - \varepsilon_f)$$

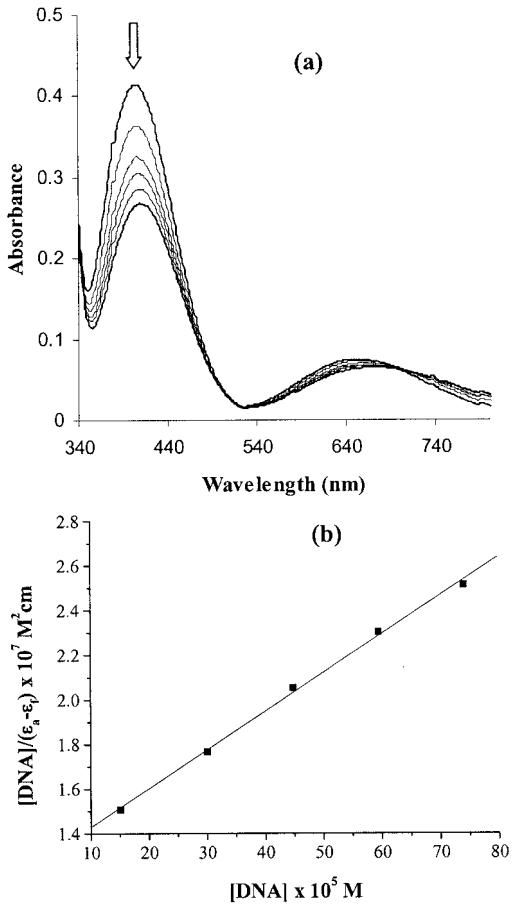

Figure 7. (a) Absorption spectra of $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (**1**) in 50 mM Tris-HCl and 18 mM NaCl buffer (pH 7.2) in the presence of increasing amounts of DNA ([DNA] = 0–75 μM). (b) Plot of $[DNA]/(\varepsilon_a - \varepsilon_f)$ vs.[DNA].

where $\varepsilon_a$, $\varepsilon_f$ and $\varepsilon_b$ correspond to $A_{obs.}/[Cu]$, the extinction coefficient of the free copper complex and the extinction coefficient of the copper complex in the fully bound form, respectively. The binding constant obtained is $1.38 \times 10^5$ M$^{-1}$.

Fluorescence spectra of the ethidium bromide–DNA intercalative adduct were recorded in the presence of the complex. No considerable quenching of fluorescence intensity was observed in the presence of **1**, which suggests that there is no significant intercalation between DNA and the metal complex.

Viscosity measurement is an important tool to ascertain the interaction mode[24] of DNA with complexes. It has been established that a significant enhancement in viscosity of a DNA solution is observed in the case of classical intercalative binding of complexes.[25] However, groove-face, electrostatic or surface binding of the compounds results in less or no change of viscosity of the DNA solution.[26] The $\eta/\eta_0$ values are given in Table 2. The results show that there is a slight decrease in relative viscosity of calf-thymus DNA solution in the presence of this trinuclear complex and this is probably due to interaction of the complex with the DNA surface.

Table 2. Data for DNA viscosity in the presence of complex **1**.

| [complex]/[DNA][a] | $\eta/\eta_0$ |
|---|---|
| 0.0 | 1.00 |
| 0.13 | 0.992 |
| 0.17 | 1.002 |
| 0.22 | 0.990 |
| 0.26 | 0.971 |
| 0.31 | 0.952 |
| 0.35 | 0.950 |

[a] [DNA] = 200 μM.

In summary, the UV/Vis spectral, fluorescence and viscosity measurements reveal that the trinuclear complex interacts with the DNA surface and is inhibited from intercalation with the DNA molecule. This interaction mode is different from that of previously reported trinuclear copper species.[8a]

### Cleavage of pUC18 DNA by $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (1)

The cleavage of supercoiled pUC18 DNA by the complex was studied by gel electrophoresis in Tris-HCl/NaCl buffer. Figure 8 shows the gel electrophoresis separation of plasmid DNA induced by our mixed-bridge, bent, trinuclear copper(II) complex. From this figure it can be seen (lane 5) that the complex itself converts plasmid supercoiled pUC18 DNA into a mixture of supercoiled (Form I) and nicked (Form II). The activity increases remarkably in the presence of $H_2O_2$ (lane 6). However, there is no significant increase (lane 7) in the conversion on addition of 2-mercaptoethanol to the complex and $H_2O_2$. Incubation with $H_2O_2$, 2-mercaptoethanol or both $H_2O_2$ and 2-mercaptoethanol without the complex does not cause strand scission of supercoiled DNA. These experimental results demonstrate that complex **1** exhibits DNA cleavage activity that is enhanced by the addition of hydrogen peroxide. We assume that there is a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

possibility of formation of copper-oxo species during the DNA cleavage reaction in the absence or presence of $H_2O_2$.[27] This copper species is probably responsible for the cleavage of DNA by the trinuclear complex alone (lane 5). Besides the copper-oxygen species, the generation of hydroxy radicals in the presence of $H_2O_2$ enhances the DNA cleavage activity (lane 6).[27]

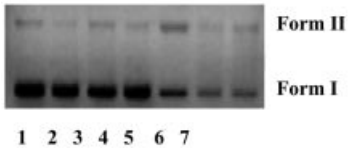

Figure 8. Electrophoretic separation of pUC18 DNA by $[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (**1**). DNA alone (lane 1), DNA + 2-mercaptoethanol (lane 2), DNA + $H_2O_2$ (lane 3), DNA + $H_2O_2$ + 2-mercaptoethanol (lane 4), DNA + **1** (lane 5), DNA + **1** + 100 μM $H_2O_2$ (lane 6), DNA + **1** + $H_2O_2$ + 2-mercaptoethanol (lane 7).

## Conclusions

A conformationally labile reduced Schiff-base ligand having coordinating and hydrogen-bonding sites has been successfully utilized to synthesise a phenoxo, carboxylato, chloro-bridged bent trinuclear copper(II) complex in good yields. The separations between the copper ions in the complex fall in the range 3.05–5.10 Å, which is in agreement with the trinuclear active sites of the oxidized form of ascorbate oxidase.[6] The ferromagnetic behaviour of the complex also resembles the oxidized form of particulate methane monooxygenase.[7] The variable-temperature EPR spectral measurements support the magnetic behaviour. Spectral and viscosity measurements reveal the surface binding of **1** to calf thymus DNA. Cleavage of pUC18 by **1** indicates that the complex exhibits nuclease activity. Interesting supramolecular structures are obtained in the solid state through the combination of hydrogen bonding between the chloride ion and the NH group of the reduced Schiff-base ligand. The results presented herein may be helpful in understanding the chemistry and magnetic properties of biomolecules containing trinuclear sub-units in their active sites. In addition, the studies also provide valuable insights into the synthesis of supramolecules by self-assembly of reduced Schiff-base ligands. Further research aimed at the synthesis of polynuclear mixed-bridged copper complexes containing different reduced Schiff-base ligands, investigation of their DNA interaction and clarification of the cleavage mechanism, along with their solid- and solution-state behaviour is currently in progress.

## Experimental Section

**Materials:** All the starting chemicals were analytically pure and were used without further purification. The ligand was prepared by reduction of the corresponding Schiff base derived from salicylaldehyde and 2-(aminomethyl)pyridine with $NaBH_4$.[17] Calf thymus (CT) DNA and supercoiled pUC18 DNA were obtained from Sigma. The concentration of calf thymus DNA (200 μM) was estimated spectrophotometrically from the extinction coefficient of DNA (6600 $M^{-1}cm^{-1}$) at 260 nm.[28] Agarose (molecular biology grade), 2-mercaptoethanol, and ethidium bromide were purchased from Sigma.

**Physical Measurements:** UV/Vis spectra were recorded with a Perkin–Elmer LAMBDA25 spectrophotometer and IR spectra were measured with a Perkin–Elmer L-0100 spectrometer. Electrochemical measurements were performed (acetonitrile solution) with a CH620A electrochemical analyzer using a platinum electrode. Tetraethylammonium perchlorate (TEAP)[29] was used as supporting electrolyte and the potentials are referenced to the standard calomel electrode (SCE) without junction correction. EPR spectra were recorded with a Bruker 300E automatic spectrometer, varying the temperature between 4–300 K. Magnetic measurements were carried out on polycrystalline samples with a Quantum Design MPMS XL SQUID susceptometer operating at a magnetic field of 0.1 T between 2 and 300 K. The diamagnetic corrections were evaluated from Pascal's constants. Elemental analyses (C, H, N) were performed with a Perkin–Elmer 2400 Series II elemental analyzer.
Viscosity measurements were performed with an Ubbelohde viscometer at 27 ± 0.1 °C. The concentration of DNA was 200 μM. The flow times were determined with a digital stop clock and each measured point is the average of four readings. Viscosity values are presented as $\eta/\eta_0$ vs. [complex]/[DNA], where $\eta$ is the viscosity of DNA in the presence of complex and $\eta_0$ is the viscosity of DNA solution alone.
The gel electrophoresis experiments were performed by incubation at 37 °C for 1 h as follows: pUC18 DNA (200 ng), complex (40 μM), $H_2O_2$ (100 μM), and 2-mercaptoethanol (100 μM) in 50 mM Tris-HCl/18 mM NaCl buffer (pH 7.2). The sample was electrophoresed for 2 h at 40 V on 1% agarose gel using Tris-boric acid-EDTA buffer (pH 8.3). After electrophoresis, the gel was stained using 1 μg mL ethidium bromide and photographed under UV light.

**$[Cu_3L_2(C_6H_5COO)_2Cl]Cl$ (1):** A methanolic solution (5 mL) of benzoic acid (70 mg, 0.6 mmol) containing piperazine (45 mg) was added to a solution of $CuCl_2{\cdot}2H_2O$ (90 mg, 0.6 mmol) in methanol (15 mL). A methanolic solution of **HL** (107 mg, 0.5 mmol) was added to the resulting solution. Slow evaporation of the dark-green solution yielded a dark-green crystalline product. Yield: 70% (340 mg). $C_{40}H_{34}Cl_2Cu_3N_4O_6$ (927.5): calcd. C 51.75, H 3.67, N 6.04; found C 51.4, H 3.4, N 5.9 ppm. IR (KBr): ν(C–$O_{phenolate}$) 1240; ν($COO^-$) 1420, 1560; ν(NH) 3400 $cm^{-1}$. UV/Vis [Tris-HCl/NaCl buffer]: $\lambda_{max}$ (ε) = 650 nm (1480 $M^{-1}cm^{-1}$), 420 (8260). $E_{pa}$ ($Cu_3^{II}/Cu_2^{II}Cu^{III}$ couple): 1.1 V (irr); $E_{pc}$ ($Cu_3^{II}/Cu_2^{II}Cu^{I}$ couple): –0.5 V (irr).

**Crystallographic Studies:** Suitable crystals of complex **1** were grown by slow evaporation of a methanolic solution. The X-ray intensity data were measured at 293 K with a Bruker AXS SMART APEX CCD diffractometer (Mo-$K_\alpha$, $\lambda$ = 0.71073 Å). The detector was placed at a distance of 6.03 cm from the crystal. A total of 606 frames were collected with a scan width of 0.3° in different settings of $\varphi$. The data were reduced with SAINTPLUS[30] and an empirical absorption correction was applied using the SADABS package.[30] Metal atoms were located by direct methods and the rest of the non-hydrogen atoms emerged from successive Fourier synthesis. The structure was refined by full-matrix least-square procedures on $F^2$. All non-hydrogen atoms were refined anisotropically. The amine hydrogen atoms were located directly in the difference Fourier maps and the remaining hydrogen atoms were included in calculated positions. Calculations were performed with the SHELXTL V5.03[31] program package. Relevant crystal data are given in Table 3.

# Carbon Dioxide Fixation by Organolanthanides and Thermal Degradation into Amorphous and Higher Condensed Ln/O/C/N Solids

**Ulrich Baisch,[a] Sandro Pagano,[a] Martin Zeuner,[a] and Wolfgang Schnick*[a]**

**Keywords:** Carbon dioxide fixation / Lanthanides / Organometallic precursors / IR spectroscopy

Ammine[tris(cyclopentadienyl)]-, amido[bis(cyclopentadienyl)]lanthanides, and tris[bis(trimethylsilylamido)]cerium have been studied with respect to $CO_2$ absorption under various reaction conditions. Subsequent thermal treatment of these complexes under gaseous and supercritical $CO_2$ yielded new higher condensed lanthanide Ln/O/C/N solids. IR spectroscopic studies of the $CO_2$-activated species reveal the formation of various oxonitridocarbonates, in particular carbamates ($O_2CNH_2^-$), imidocarbonates ($O_2CNH^{2-}$), isocyanates ($OCN^-$), and carbonates ($CO_3^{2-}$), which function as multidentate linkers between the lanthanide ions. Thereby, inorganic polymers are formed, which represent single-source precursors for application in various deposition methods and can therefore be utilized as pre-organized reagents in solid-state chemistry. In this context, we report on the structural characterization of one of the molecular precursors [$Cp_3YbNH_3$] [reticular pseudomerohedral twin, $P2_1/c$, $a$ = 826.8(2), $b$ = 1103.8(2), $c$ = 1482.0(3) pm, $\beta$ = 101.60(3)°, $Z$ = 4, $V$ = 1309.0(5)·$10^6$ pm$^3$]. Crystals of [$Cp_3YbNH_3$] appear red, orange, yellow, and dark green depending on the orientation under plane-polarized light (pleochroism).

## Introduction

Carbon dioxide ($CO_2$) is an interesting reagent for various synthetic approaches in the chemistry of catalysis and represents a reagent of growing interest in other fields of chemistry.[1–6] Novel methods to sufficiently activate $CO_2$ for an application in organic and inorganic solvent reactions have been reported emphasizing the potential of this compound in various processes.[7–12] We have discovered a novel approach for this "green" reagent as a pre-organized C/O donor in solid-state reactions for the synthesis of novel mixed N-containing lanthanide derivatives of carbonato compounds, which can be described as oxonitridocarbonates (i.e. $O_2CNH_2^-$, $O_2CNH^{2-}$, $O_3C_3N_3H^{2-}$, $OCN^-$). These groups can be envisaged to function as bidentate or multidentate linkers between the Ln ions (Ln = lanthanide = La–Lu) resulting in crosslinked inorganic polymers.

The present study revealed that several kinds of oxonitridocarbonates were formed by the reaction of $CO_2$ with N-containing inorganic complexes and it was therefore intended to investigate these $CO_2$ absorbants for the use as single-source precursors and potential Ln/O/C/N-dopants for applications in solid-state reactions. (Nitrido)lanthanide materials are of particular interest in materials chemistry of optically active or semiconducting compounds. Research previously carried out in our laboratory revealed that the introduction of oxygen into Ln nitridosilicates results in interesting luminescent properties.[13–17] The $CO_2$ reactivity studies of these precursor compounds reported herein enlarge the potential of amorphous O/C/N-containing solids as future reagents for materials science.

In this context we have focused on the study of the solid-state reactivity of activated ammine- and amidolanthanide compounds towards carbon dioxide under various reaction conditions. In particular we report the use of tris[bis(trimethylsilyl)amido]cerium (Ce-BTMSA) as well as ammine-[tris(cyclopentadienyl)]lanthanides (Ln-$NH_3$, cyclopentadienyl = Cp) and amido[bis(cyclopentadienyl)]lanthanides (Ln-$NH_2$) as reactive complexes for the absorption and insertion of $CO_2$ in the solid state.

[Ce{N(SiMe$_3$)$_2$}$_3$] (Ce-BTMSA) has been used as a dopant in materials chemistry yielding SrS:Ce.[18] Because of the sterically demanding nature of the BTMSA moiety, the central atom exhibits free coordination sites above and below the cerium atom, and – caused by the electron deficiency at the Ce center – these complexes can be considered to be highly reactive with respect to a variety of O-containing reagents and in particular against $CO_2$.

Lanthanide metallocenes have been shown to be interesting molecular reagents in materials chemistry.[19] Recently, the synthesis of aggregated nanocrystalline lanthanide nitride materials was reported to be successful using [$Cp_3LnNH_3$] and [{$Cp_2LnNH_2$}$_2$] as precursors.[20] These amido- and ammine(cyclopentadienyl)lanthanide com-

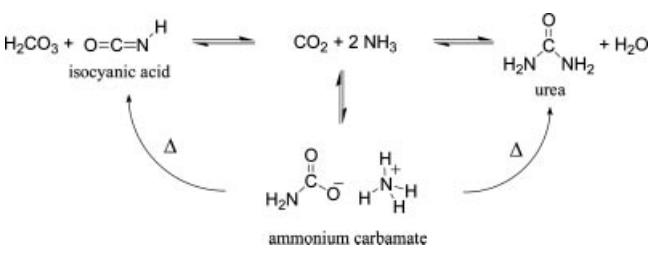
plexes are volatile under vacuum ($10^{-3}$ mbar) and at temperatures as low as 150–250 °C, which makes them potentially relevant for chemical vapor deposition (CVD) processes.[21,22]

These complexes have been described in the literature;[23–27] however, neither further applications nor crystal structure determinations have been reported for $[Cp_3YbNH_3]$. In the course of our work the crystal structure of $[Cp_3YbNH_3]$ (Yb-$NH_3$) has been determined successfully. Pleochroic behavior was observed viewing the crystals under plane-polarized light. Yb-$NH_3$ can therefore be considered as an interesting material for optical applications.

For further degradation processes, the Cp rings can be removed easily by thermal treatment or using inorganic bases like $LiNH_2$ or $CaH_2$.[20] The mild-temperature conditions, under which supercritical carbon dioxide is used, are of special interest for these precursor compounds.[2,5,10] In this manner, Yb-$NH_3$ can be carboxylated before thermal degradation of the Cp ligands occurs. Thus, this $CO_2$-activated compound represents a molecular single-source precursor.

The absorption of $CO_2$ and the resulting amorphous products have been studied by IR spectroscopy, elemental analysis, and temperature-dependent in-situ mass spectrometry (MS) studies. The higher condensed O/C/N materials obtained are rather difficult to characterize. Solid-state NMR studies can be considered to be rather inappropriate, because of the anisotropic environment around the metal ions resulting in very large quadrupole moments. Furthermore, most $Ln^{III}$ complexes exhibit unpaired electrons (paramagnetism).

As an important reference substance for IR spectroscopy, ammonium carbamate was used and re-characterized[28] more accurately by IR spectroscopy and X-ray structure analysis. This compound was synthesized by the reaction of liquid ammonia with gaseous $CO_2$. Whereas the reaction of these gases under normal conditions (pressure, temperature) always yields ammonium carbamate, amido and ammine metal complexes react with carbon dioxide in a different way.[7,29–35] Scheme 1 shows possible species formed by the nonstoichiometric reaction of $CO_2$ with $NH_3$. Apparently, some of these products are not stable in the protonated form, but are known as anionic ligands in inorganic chemistry.



Scheme 1. Protonated species formed by the reaction of $CO_2$ and $NH_3$.

## Results and Discussion

### Characterization and Reactivity of $[Cp_3YbNH_3]$ and $[\{Cp_2YbNH_2\}_2]$

The molecular structure of $[Cp_3YbNH_3]$ (Yb-$NH_3$) has been determined by X-ray diffraction analysis and is illustrated in Figure 1. The $Yb^{III}$ ion shows a coordination number CN = 10 taking into account only the binding electron pairs of the Cp and $NH_3$ ligands. The centroids (Ctr) of the Cp rings and the coordinated $NH_3$ ligand form a distorted tetrahedral environment around the Yb center. Selected bond lengths and angles are given in Table 1.

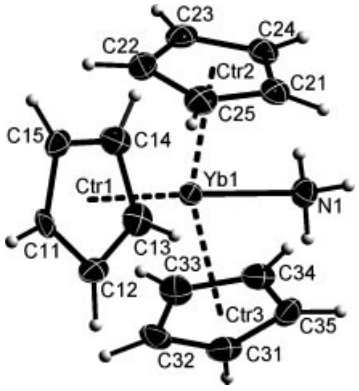


Figure 1. Molecular structure of $[Cp_3YbNH_3]$ at 130 K (50% probability ellipsoids). The hydrogen atoms were calculated and refined using a riding model with fixed isotropic thermal parameters.

Table 1. Selected bond lengths [pm] and angles [°] for $[Cp_3YbNH_3]$.

| $[Cp_3YbNH_3]$ | |
|---|---|
| Yb–N | 242.0(4) |
| Yb–Ctr(1) | 241.1(3) |
| Yb–Ctr(2) | 242.2(3) |
| Yb–Ctr(3) | 240.0(3) |
| N–Yb–Ctr(1) | 97.23(2) |
| N–Yb–Ctr(2) | 98.65(2) |
| N–Yb–Ctr(3) | 98.55(2) |
| Ctr(1)–Yb–Ctr(2) | 117.98(2) |
| Ctr(1)–Yb–Ctr(3) | 118.04(2) |
| Ctr(2)–Yb–Ctr(3) | 118.06(2) |

The three Cp ligands are $\eta^5$-coordinated to the central ion and the Yb–Ctr bond lengths lay within the expected ranges from 240.0(3) to 242.2(3) pm. The Yb–N bond is only slightly shorter [242.0(4) pm] compared with other reported structures of $[Cp_3LnNH_3]$ (Ln = Gd, Dy, Ho, Er).[20] Additional intermolecular interaction was observed for one Cp ring (Ctr1) to a neighboring ammonia ligand of another complex molecule. Intermolecular distances Yb–Ctr1 of 319.6(4) and 263.5(4) pm for C(15)–H(1N) were observed. The formation of a weak N–H–C interaction is probable as one proton of the coordinated ammonia is slightly acidic (Figure 2).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

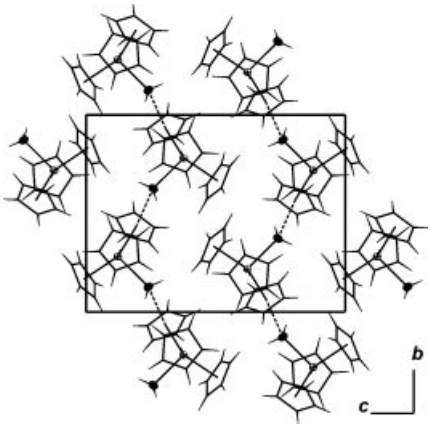

Figure 2. Projection of the unit cell of [$Cp_3YbNH_3$], view along axis *a*. Intermolecular interactions are depicted with dotted lines.

Crystals of Yb–$NH_3$ appear in different colors depending on the orientation of plane-polarized light under which they are viewed (pleochroism). In the literature, Cp-containing ytterbium complexes have been discussed controversially towards their colors. Often, explanations for this discrepancy were given taking into account also the presence of $Yb^{II}$. In the case of Yb-$NH_3$ all colors given elsewhere have been described correctly.[24,26,27] Along the crystal faces the crystallites appear red, orange, yellow, and dark green. Figure 3 displays two crystals at different orientations towards the light source. The emerald green powder of Yb-$NH_3$ sealed in an ampule is shown as well.

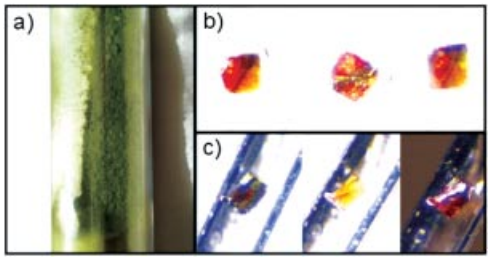

Figure 3. a) Yb–$NH_3$ sealed in an ampule under argon. b, c) Two crystals of Yb-$NH_3$ viewed under plane-polarized light and in three different orientations towards the light source.

Thermal treatment of Yb-$NH_3$ under argon (250 °C) causes deprotonation of the coordinated $NH_3$ ligand and abstraction of one cyclopentadiene molecule ($C_5H_6$) forming the more stable and sublimable dinuclear complex [{$Cp_2YbNH_2$}$_2$] (Yb-$NH_2$). The crystal structure of this complex has been determined recently.[20] The Yb–Ctr and Yb–N distances of 234.3(6)–234.6(7) pm and 229(1) and 233(1) pm, respectively, were observed to be significantly shorter than in the ammonia-coordinated derivative.

Yb-$NH_3$ has been characterized by IR spectroscopy (Figure 4). The coordinated ammonia can be identified by the strong N–H stretching vibrations at 3365, 3330, and 3250 $cm^{-1}$ and by the intense asymmetric and symmetrical N–H deformation and reticular vibrations at 1600, 1225, and 500 $cm^{-1}$. The vibrations differ only slightly within a range of ±7 $cm^{-1}$ from the corresponding ammine complexes of Sm, Gd, Dy, Ho, and Er.[20] The seven typical stretching [2 $\nu_{(CH)}$, 2 $\nu_{(CC)}$] and deformation vibrations [1 $\delta_{(CH)}$ parallel, 2 $\delta_{(CH)}$ perpendicular] of the cyclopentadienyl rings at 3090, 3070, 1440, 1360, 1010, 790, and 775 $cm^{-1}$ were also observed.[36]

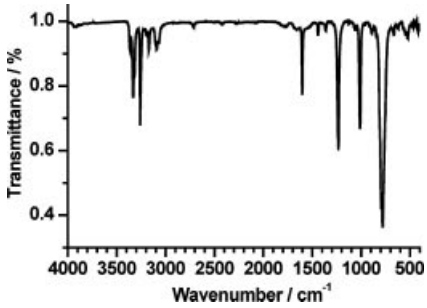

Figure 4. IR spectrum of Yb-$NH_3$.

In contrast to Ln-$NH_3$, the amido complexes (Ln-$NH_2$) are stable up to 360 °C until melting and decomposition to LnN occurs. Thus, the ammonia complex can be considered as a reactive reagent for low-temperature carboxylation reactions whereas the Ln-$NH_2$ compounds are interesting for solid-state reactions up to 350 °C under normal pressure. Both species (Ln = Ho, Yb) were used for decomposition reactions utilizing gaseous and supercritical carbon dioxide.

### Characterization of Ammonium Carbamate $[NH_4]^+[O_2CNH_2]^-$

The solid-state structure of thin colorless plate-like crystals was re-determined by X-ray diffraction analysis. The crystal parameters reported in older literature data were confirmed and the bond lengths and angles of the ammonium ion and the amido moiety were determined more accurately.[28] Ammonium carbamate crystallizes in the orthorhombic space group *Pbca*, with $a$ = 653.5(2), $b$ = 675.4(2), $c$ = 1711.9(4) pm, $V$ = 755.73(3)·$10^6$ $pm^3$.

The compound is stable in closed vessels or under $CO_2$. The IR spectrum was used as an important reference for further investigations, as it shows vibrations of an oxonitridocarbonate without any metal interaction (Figure 5).

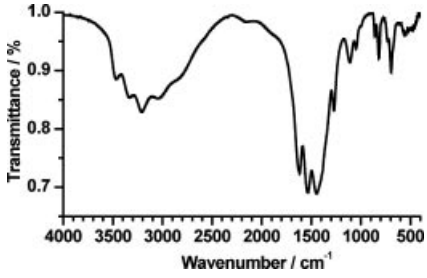

Figure 5. IR spectrum of ammonium carbamate.

Broad N–H and O–H stretching vibrations between 3500 and 2500 $cm^{-1}$ indicate the presence of N···H···O-bridging ligands of the carbonyl and the ammonium moiety. Three intense signals are attributed to the O=C and N=C valences of the carbamate ligand at 1615, 1535, and 1445 $cm^{-1}$.[29,32]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Additionally, the deformation vibrations of N–H and O–C–N can be located at 1272, 1112, 859, and 695 $cm^{-1}$.[29,32]

### Heterogeneous Solid-Gas Reactivity of $[Ce\{N(SiMe_3)_2\}_3]$ Towards $CO_2$

The structure of Ce-BTMSA has been determined elsewhere[18] and revealed a mononuclear species with the $Ce^{III}$ ion in the center of the three BTMSA ligands (CN = 3). It has been shown that the central atom displays a disorder in the *z* direction, occupying two sites positioned above and below the plane formed by the ligand nitrogen atoms. The compound has been described to be isostructural with other Ln derivatives.

Crystalline Ce-BTMSA was heated under argon to 150 °C and then brought into reaction with a slow stream of pure gaseous $CO_2$. The beige solid (Ce-1a) was analyzed by IR spectroscopy and showed 40.3% loss of weight. Subsequent thermal treatment of the reaction product under $NH_3$ to 650 °C resulted in the formation of a brown amorphous solid (Ce-1b). Further loss of weight was observed and IR spectroscopic measurements and elemental analysis were carried out. The product showed a composition of Ce/O/C/N = 4:14:7:4. Figure 6 represents the vibrational spectra of the reagent Ce-BTMSA and also includes the carboxylation product after thermal treatment at 150 °C and 650 °C.

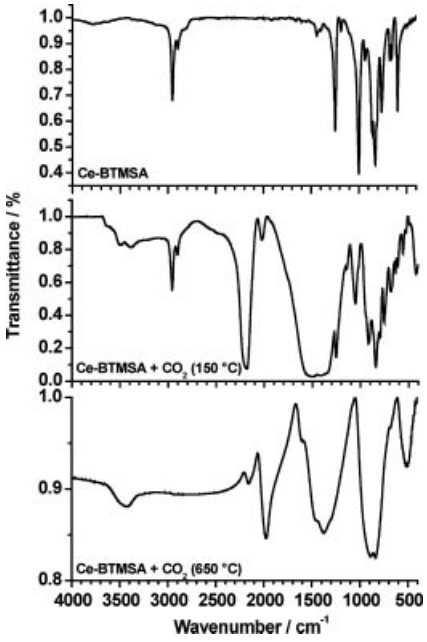

Figure 6. IR spectra of Ce-BTMSA (top) and the carboxylation products after annealing at 150 °C under $CO_2$ (center) and 650 °C (bottom).

Ce-1a heated to 150 °C still shows sharp signals at 2960, 1250, 1055, and 840 $cm^{-1}$, indicating the presence of stretching and deformation vibrations of Si–C and Si–N moieties.[37] A broad and intense absorption between 1700 and 1300 $cm^{-1}$ is characteristic of both carbonate and carbamate groups.[29,38] Additionally, an intensive large and a weak vibration are located between 2150 and 2250 and at 2015 $cm^{-1}$. They can be assigned to several kinds of molecular fragments: Strong absorptions can be observed in the region 2250–1950 $cm^{-1}$ if isocyanates are present.[38,39] Signals of weak and strong intensities have been reported upon occurrence of agostic Si–H or $CO_2$ adducts.[37,40] The formation of OCN groups can be regarded as improbable due to the low reaction temperature and the specific energy necessary for the conversion of a carbamic ligand into carbonate and isocyanate moieties according to Scheme 1.

The ammonolysis reaction of Ce-1a at 650 °C yielded a product (Ce-1b) with a largely different IR spectrum (Figure 6). Less-resolved vibrations typical of amorphous, more condensed solid-state compounds are present, thus proving further decomposition into an O/C/N-containing material. Considering the thermal conditions and peak profiles, this spectrum closely corresponds to typical isocyanato vibrations reported in the literature.[39] N–C–O stretching and deformation modes can be attributed to the signals at 2160 and 1975 as well as 887 and 837 $cm^{-1}$, respectively. Absorptions at 1595, 1455, and 1375 are situated in the characteristic region for both carbamato and carbonato ligands.[29,38]

A formula for the amorphous compound (Ce-1b) with composition $Ce_4O_{14}C_7N_4$ (according to elemental analysis) can be formulated as $[Ce_4(OCN)_3(O_3C)(O_2CN)]$. Further decomposition of the compounds at higher temperatures resulted in the formation of $Ce_2O_3$. The overall thermal treatment of Ce-BTMSA under $CO_2$ can by summarized as Equations (1) and (2).

$$4\ Ce\{N(SiMe_3)_2\}_3 + 7\ CO_2 \xrightarrow{150\ °C} "Ce_4\{N(SiMe_3)_2\}_{12}(CO_2)_7" + 4\ NH_3 \quad (1)$$

$$"Ce_4\{N(SiMe_3)_2\}_{12}(CO_2)_7" \xrightarrow{650\ °C} Ce_4O_{14}C_7N_4 + 12\ HN(SiMe_3)_2 \quad (2)$$

### Heterogeneous Solid-Gas Reactivity of $[\{Cp_2HoNH_2\}_2]$ Towards $CO_2$

Crystalline Ho-$NH_2$ was heated under purified gaseous $CO_2$, $H_2$, and $N_2$ ($CO_2/H_2/N_2$ = 1:1:1). The pink crystallites of Ho-$NH_2$ did not show reaction with the gases below a temperature of 200 °C. During the reaction, the compound decolorized forming a beige solid (Ho-1a). Subsequent heating to a temperature of 350 °C was carried out to achieve a complete thermal degradation of the Cp ligands. A brownish reaction product (Ho-1b) was isolated and analyzed by X-ray diffraction, elemental analysis, and IR spectroscopy. The solid was observed to be amorphous and showed a composition of Ho/O/C/N/H = 2:8:12:1:11. The vibrational spectra of the starting material Ho-$NH_2$ and the carboxylation product after thermal treatment at 200 °C and 350 °C are depicted in Figure 7.

Compared with Ho-$NH_2$ the N–H valence vibrations at 3504 $cm^{-1}$ are broadened in the spectrum of Ho-1a. Similar signals were observed in the IR spectrum of ammonium carbamate (vide supra) and indicate the formation of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

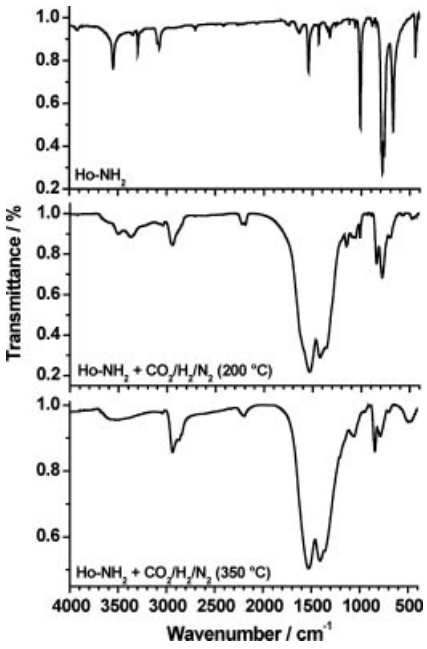

Figure 7. IR spectra of Ho-$NH_2$ (top) and the carboxylation products after annealing under $CO_2/H_2/N_2$ at 200 °C (center) and 350 °C (bottom).

N···H···N-bridged molecular units in the solid. Absorptions around 2950 and 2850 $cm^{-1}$ indicate the occurrence of $C_5H_6$ formed by degradation of the Cp ligands under $H_2$.[26]

Intense broad vibrations at 1620, 1598, and 1530 $cm^{-1}$ are characteristic of CO and CN moieties in carbamato derivatives.[38] Together with additional strong signals between 1480 and 1290 $cm^{-1}$ these absorptions confirm the formation of carbamates or carbonates.[29,32,38] Especially the shoulders at 1620, 1598, and 1290 $cm^{-1}$ are in accordance with vibrations observed for other lanthanide carbamates and ammonium carbamate. The C–O deformations can be attributed to the 950–750 $cm^{-1}$ region.

Only weak intensities were observed between 2250 and 2100 $cm^{-1}$. The presence of isocyanato moieties can therefore be excluded, but signals of similar shape and intensity in this region were described for several adduct complexes of $CO_2$ and $H_2$. The temperature conditions (200 °C) could still justify the occurrence of these species. As a matter of fact, the spectrum of Ho-1b clearly shows that the stretching vibrations for the $CO_2$ and $NCO_2$ fragments in the region 2250–1550 $cm^{-1}$ are diminished and thus a further thermal degradation apparently occurred.

For Ho-1a a possible formula can be formulated as $[Ho_2(CO_3)_2(O_2CNH)]_n$. A further thermal treatment of this compound at higher temperatures resulted in the formation of holmium carbonate, confirmed by X-ray powder diffraction. Therefore, the thermal treatment of Ho-$NH_2$ with $CO_2/H_2/N_2$ at temperatures between 200 and 350 °C can be written as Equation (3).

$$(Cp_2HoNH_2)_2 + 4\ CO_2 + 2\ H_2 \xrightarrow{200\ °C} Ho_2(CO_3)_2(O_2CNH) + 4\ C_5H_6 + NH_3 \quad (3)$$

In order to detect volatile species being potentially evolved during the degradation process of Ho-1a, mass spectra were acquired while heating an evacuated sample in a furnace up to 300 °C. Until 160 °C, a peak of relatively low intensity with $m/z$ = 18 dominates the spectra, which can be attributed to water adsorbed on the sample and adhering to the inside wall of the spectrometer and glass tube. A peak at $m/z$ = 44 shows increasing intensity between 80 and 180 °C; at 200 °C it dominates the spectra. Ammonia ($m/z$ = 17) simultaneously appears in the diagram between 140 and 260 °C, the associated intensity, however, being orders of magnitude smaller as compared to that of $CO_2$. The degradation of cyclopentadiene ($C_5H_6$, $m/z$ = 66) was detected beyond 200 °C. At temperatures above 220 °C the relative intensity of $CO_2$ ($m/z$ = 44) decreases, while the $m/z$ = 66 peak was observed to be the dominating species in the defragmentation pattern until the final temperature of 300 °C was reached. The MS measurement of Ho-1a proved the insertion of $CO_2$ into the N–H bond and showed that $C_5H_6$ was built during the degradation process. N–H moieties must have been present in the carboxylation product, otherwise a formation of $NH_3$ would not be observable.

### Heterogeneous Solid-Gas Reaction of $[Cp_3YbNH_3]$ in Supercritical $CO_2$

Yb-$NH_3$ shows high reactivity against supercritical $CO_2$ at 40–50 °C and at a pressure of 250–280 bar. The emerald green amido complex adsorbed $CO_2$ forming an orange-yellow solid (Yb-1). During the carboxylation process, Yb-$NH_3$ was transformed into Yb-$NH_2$. Under normal pressure conditions this reaction was observed to require temperatures between 200 and 290 °C. Yb-$NH_2$ formed in the first reaction stage as well as the reaction product Yb-1 and both were analyzed by IR spectroscopy. The spectra are depicted in Figure 8.

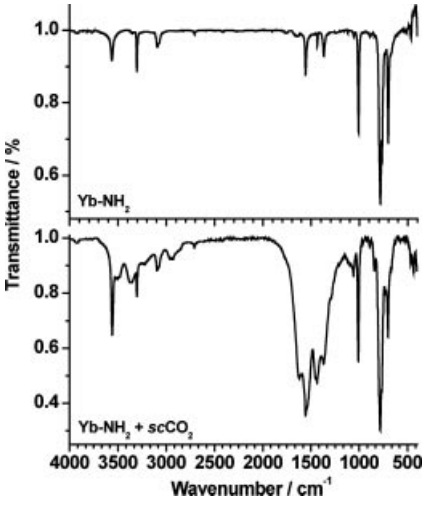

Figure 8. IR spectra of Yb-$NH_2$ (top) and the carboxylation product (bottom) after the reaction in supercritical $CO_2$ ($T$ = 50 °C, $p$ = 250–280 bar).

The $\mu_2$-bridged amido ligands of the dinuclear complex Yb-$NH_2$ can be identified by the intense N–H stretching

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vibrations around 3350 and 3290 $cm^{-1}$, and the asymmetric and symmetric N–H deformation modes around 1540, 670, and 440 $cm^{-1}$.[20] An intense vibration mode at 3500 $cm^{-1}$, probably due to a combination of two lower signals, is typical of these amido compounds.[20]

The characteristic stretching and deformation vibrations of Yb-$NH_2$ are observed in both spectra. Therefore, a degradation of the Cp ring did not occur, probably due to the mild thermal conditions under which the experiment was carried out. Additionally, broad N–H stretching vibrations can be identified in the 3500–3000 $cm^{-1}$ region and can be interpreted as N–H-bridging moieties (vide infra). Signals at 2950 $cm^{-1}$ indicate the occurrence of $C_5H_6$ formed by the decomposition process of Yb-$NH_3$ to Yb-$NH_2$. The most characteristic vibrations in the spectra of Yb-1 are the intense absorptions at 1640, 1540, 1450, and 1379 $cm^{-1}$. They fit well in the expected ranges of CO and CN stretching vibrations of carbamato complexes.[29] The deformation modes for these kinds of carbamato ligands can be observed at 841 and 670 $cm^{-1}$. Therefore, the formation of an isolated or higher condensed carbamato complex with the formula [{CpYb}$_2$O$_2$CNH] is very probable.

The synthesized oxonitridocarbonates were observed to be amorphous and not soluble in any common polar and nonpolar solvent. Attempts to crystallize these products by thermal treatment resulted in the decomposition of these precursors to the corresponding oxides or oxide cyanamides.

## Conclusions

Ce-BTMSA, Ln-$NH_3$, and Ln-$NH_2$ have been shown to be considerable molecular precursor compounds for thermal degradation reactions resulting in novel highly condensed lanthanide O/C/N materials. The carbonato, imidocarbonato, and carbamato species were synthesized using different kinds of heterogeneous solid-gas reactions.

The Ce-BTMSA precursor absorbs $CO_2$, leading to the formation of a mixed carbamato(carbonato)isocyanato compound. The IR spectra of the products differ significantly from the results reported for carboxylation reactions in solution or in sealed ampules.[35,41] The cerium precursor Ce-BTMSA is activated with $CO_2$ in the first step. According to the results of the elemental analysis two molecules of $CO_2$ are absorbed by one molecule of Ce-BTMSA. Subsequently, the $CO_2$ inserts into the Ce–N bond yielding a carbamato species. According to Scheme 1 further ammonolysis of the compound at higher temperatures results in the formation of an carbonato(isocyanato)cerium compound. The flowing gas stream provides for a better degradation of the $Me_3Si$ groups.

Lanthanide metallocenes were observed to be quite stable against thermal treatment under an inert gas, but they represent a highly reactive molecular precursor species under $CO_2$ at temperatures above 200 °C. The use of both a reducing ($H_2$) and oxidizing agent ($CO_2$) with $N_2$ as the carrier gas gave satisfying results forming a polymeric (imidocarbonato)holmium complex. The Cp ligands can be split off easily by the presence of $H_2$ with $CO_2$ occupying the free coordination sites of the lanthanide ion. The activation or doping of the surface of various materials with lanthanide carbonates or carbamates could therefore be achieved in this way.

The carboxylation reaction of Yb-$NH_3$ in supercritical carbon dioxide showed, that the temperature necessary for the $CO_2$ insertion into the Yb–N bond can be lowered significantly. The complex molecule reacted with $CO_2$ without simultaneous degradation of the Cp ligands. Thus, a molecular single-source precursor with the tentative formula [{CpYb}$_2$O$_2$CNH] has been synthesized. It represents an adequate compound for the deposition of predefined Ln/O/C/N material on various surfaces in materials chemistry.[19]

Furthermore, the observed pleochroism of [$Cp_3YbNH_3$] is a promising optical property for further applications of this compound as a future dopant in solid-state sciences. Thus, small amounts of this compound introduced during the synthesis of materials could change significantly the optical properties of the final products. The high volatility of [$Cp_3YbNH_3$] facilitates significantly the doping process using CVD techniques at very convenient conditions (180 °C, $10^{-3}$ mbar).

## Experimental Section

**General Procedures:** All manipulations described below were performed with rigorous exclusion of oxygen and moisture in flame-dried Schlenk-type glassware or tubes of silica glass, interfaced to a vacuum ($10^{-3}$ mbar) line. Argon was purified by passage through columns of silica gel, molecular sieve, KOH, $P_4O_{10}$, titanium sponge (650 °C), hydrogen and nitrogen by passage through columns of silica gel, molecular sieve, KOH, $P_4O_{10}$, BTS,[42] and $Cr^{II}$ oxide catalyst.[43] Carbon dioxide was purified by passage through columns of $P_4O_{10}$ and BTS catalyst.[42] Anhydrous lanthanide(III) chlorides were purchased from Alfa Aesar (99.99%, ultra dry) and were used without any further purification. The complexes [$Cp_3YbNH_3$] (Ln-$NH_3$) and [{$Cp_2LnNH_2$}$_2$] (Ln-$NH_2$, with Ln = Ho, Yb) as well as [Ce{N(SiMe$_3$)$_2$}$_3$] were prepared according to known procedures[20,25,44] and sublimed twice before use ($10^{-3}$ mbar, 120–250 °C). For thermal degradation experiments a Reetz collapsible tube furnace (LK-1100-45-250) handled by an Omron (RE.LB.1.P16) temperature controller was used. For $CO_2$ experiments under supercritical conditions a Parr high-pressure vessel (Type 4740) with a Parr gage block (Type 4316) was used. FT-IR spectra were recorded with a Bruker IFS 66v/S spectrometer with DTGS detector. The samples were thoroughly mixed with dried KBr and the preparation procedures were performed in a glovebox under dried argon. The spectra were collected in a range from 400 to 4000 $cm^{-1}$ with a resolution of 2 $cm^{-1}$. During the measurement, the sample chamber was evacuated. Elemental analysis was performed by Mikroanalytisches Labor Pascher, Remagen, Germany. Each element of the sample was analyzed twice. Temperature-dependent mass spectra were recorded using DEI+ (70 eV) with the sample contained in an evacuated ($10^{-4}$ mbar) Schlenk tube (length 330 mm, diameter 10 mm) connected with the gas inlet system of the spectrometer by glass tubes of about 200 mm total length, thus providing dynamic vacuum conditions. The Schlenk tube was placed horizontally in a Carbolite furnace

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

equipped with a Eurotherm temperature controller (Type 2132). The sample was heated up to 573 K in steps of 5 K min$^{-1}$ and mass spectra of the volatile decomposition products were acquired successively at intervals of 20 K.

**X-ray Crystallography:** Reflection data were collected with a STOE IPDS diffractometer. The Stoe IPDS software package was used for the determination of the unit-cell parameters, the data collection, and to transform the raw data into the reflection data file. Subsequent calculations after the determination of the unit-cell parameters and data reduction to the *hkl* format were carried out using the SHELXS[45] and SHELXL[46] program. The analytical scattering factors for neutral atoms were used throughout the analysis. Hydrogen atoms were either treated isotropically, if found in the Fourier maps, or were otherwise included manually using a riding model. Absorption correction was carried out using the Stoe IPDS program package. All non-hydrogen atoms were refined anisotropically. X-ray diffraction experiments on powder samples at room temperature were conducted with a STOE Stadi P diffractometer with Ge(111)-monochromated Cu-$K_{\alpha1}$ radiation ($\lambda$ = 154.06 pm). **[$Cp_3YbNH_3$]:** The structure of Yb-$NH_3$ was solved by direct methods and refined on $F^2$ by full-matrix least-squares techniques. Intrinsic reticular pseudo-merohedral twinning was observed for each of the isolated crystals.[47] The compound crystallizes as emerald-green or ruby (depending on the viewing direction and lighting) brick-shaped crystals. An appropriate extracted crystal was used and two data sets for each twin domain were extracted from the diffraction data. Yb-$NH_3$ showed pseudo-orthorhombic symmetry, but X-ray powder diffraction experiments (XRD) confirmed a monoclinic cell setting. The diffraction symmetry was 2/*m* and the systematic absences were consistent with the centrosymmetric monoclinic space group $P2_1/c$. The reflections were isolated unifying all of the overlapping reflections of the two domains to one reflection set of the most appropriate individual. Subsequent determination of the twin law and refinement of the data resulted in a satisfying crystal structure refinement, taking into account the problems encountered during the isolation and weighting of the overlapping reflections in the reciprocal space. Tables 1 and 2 show the crystallographic data as well as bond lengths and angles, and Figure 1 the molecular structure of Yb–$NH_3$. CCDC-603950 (for [$Cp_3YbNH_3$]) and -603951 (for $[NH_4]^+$-$[O_2CNH_2]^-$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis. Ce-1:** Ce-BTMSA was ground in a mortar, placed in an alumina boat and transferred into a silica tube situated in a tube furnace. First, the solid was heated under flowing argon to 150 °C and than predried $CO_2$ was added to the gas stream. Melting of the yellow Ce-BTMSA was observed immediately after the first contact with $CO_2$ and the yellow fluid solidified within 30 min yielding a beige product (Ce-1a). The solid was cooled slowly to room temperature and a small part of the solid was used for IR spectroscopic analysis. The residue was re-introduced into the silica tube and heated to 650 °C under flowing predried ammonia. Ammonia was dried by passage over KOH pellets, $Cr^{II}$ catalyst and condensed over Na and K before use. A dark-brown solid (Ce-1b) was isolated after the sample was cooled to room temperature (4 h) and analyzed by elemental analysis, IR spectroscopy, and X-ray powder diffraction. Ce-1b (0.0615 g) was isolated after the reaction process using an argon-filled glovebox. **Ho-1:** Ho-$NH_2$ was ground in a mortar, placed in an alumina boat and transferred into a silica tube situated in a tube furnace. The solid was heated under a flowing gas stream of a mixture of $CO_2/H_2/N_2$ = 1:1:1 and heated slowly to 200 °C. The temperature was maintained for 4 h. Cooling of the sample to room temperature yielded a beige solid (Ho-1a). A small part of the solid was used for IR spectroscopic analysis and the residue was re-introduced into the silica tube and heated to 350 °C (4 h) under the same conditions as described above. A dark-brown solid (Ho-1b) was isolated after the sample was cooled to room temperature (2 h) and analyzed by elemental analysis, IR spectroscopy, and X-ray powder diffraction. **Yb-1:** Yb-$NH_3$ was introduced into a high-pressure vessel and connected with a gas vacuum line. Purified carbon dioxide was desublimated by cooling the vessel to –80 °C until sufficient solid $CO_2$ was present. The reaction vessel was closed and warmed slowly to 50 °C. A pressure of 250–280 bar was observed during the reaction. After 1 d, the pressure was reduced carefully by opening the valve of the unit and the vessel was opened in an argon-filled glovebox. A yellow-orange powder (Yb-1) was isolated and analyzed by X-ray diffraction methods, IR spectroscopy, and elemental analysis.

# A Poly(bicyclic dimer) and a Cyclic Tetramer: Ligand Isomerism of $S_2O_2$ Macrocycles During the Assembly of Supramolecular Silver(I) Complexes

So Young Lee,[a] Joobeom Seo,[a] Il Yoon,[a] Chung-Sik Kim,[b] Kyu Seong Choi,[b] Jae Sang Kim,[a] and Shim Sung Lee*[a]

**Keywords:** Macrocycles / Silver / Self-assembly / Supramolecular chemistry / Polymers

Two isomeric $S_2O_2$ macrocycles ($\mathbf{L^1}$ and $\mathbf{L^2}$) with a 14-membered cavity have been synthesised as a model system with different binding modes. Self-assembly reactions of $\mathbf{L^1}$ and $\mathbf{L^2}$ with silver perchlorate afford the respective ligand-directed cyclic oligomer complexes with different shapes: a poly(bicyclic dimer) (**1**) and a discrete cyclic tetramer (**2**). The formation of these supramolecular complexes is discussed in terms of conformational discrimination of two isomeric macrocycles due to ring rigidity and interdonor distances.

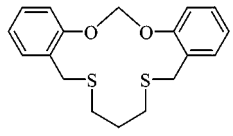
## Introduction

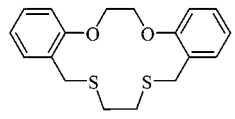
The programmed self-assembly of discrete supramolecular complexes and coordination networks has attracted intense interest not only for their potential applications as new functional materials but also their fascinating structural topologies.[1] A cyclic oligomer complex, which is one of the entities in the former category, has been reported to be capable of selective recognition and separation of guest species, including small molecules and anions.[2] As a methodology of emerging significance in supramolecular chemistry, there is an interest in understanding the factors that influence the way in which metal complexes self-assemble into cyclic oligomers. Rigid rod-like didentate ligands such as 4,4′-bipyridyl derivatives, together with corner-piece complexes based on late transition metal ions, are known to form a range of metallacycles.[3]

Besides its formation of numerous cyclic oligomer complexes with multidentate N-donor ligands, the soft silver(I) ion has a high affinity for sulfur ligands, such as linear thioethers, and such compounds can be used as building blocks to construct discrete metallomacrocyclic frameworks as well as network species. For their supramolecular assembly, the choice of length of the spacer unit in the ligand, anions and solvent are crucial to the structure of the final product.

Recently, we proposed the *exo* coordination properties of S/O or S/O/N donor macrocycles, which afford diverse types of supramolecular complexes, including cyclic oligomer silver(I) complexes, upon varying donor atoms, counteranions and solvents.[4] This approach is attractive because the *exo* coordination of sulfur donors[5] to the metal ion offers the possibility of linking the ligand building blocks in diverse modes. We are interested in extending this to a ligand-directed approach, such as ligand isomerism,[6] in order to construct new supramolecular structures, including cyclic oligomer complexes based on dithiaoxa macrocycles. By using two positional isomers with different interdonor distances ($\mathbf{L^1}$ and $\mathbf{L^2}$), we succeeded in generating two different cyclic oligomer complexes (**1** and **2**).



$\mathbf{L^1}$



$\mathbf{L^2}$

## Results and Discussion

### Synthesis and Characterisation of Ligands

Synthesis of the ligands began with salicylaldehyde (Scheme 1). Dichlorides ($m$ = 0 and 1) were prepared using a known procedure,[7] and $\mathbf{L^1}$ and $\mathbf{L^2}$ were obtained by macrocyclisation coupling reactions between these dichlorides and dithiols in the presence of $Cs_2CO_3$ under high-dilution condition in reasonable yield (28 and 41%, respectively). The $^1H$ and $^{13}C$ NMR spectra together with elemental analyses and mass spectra are clearly in agreement with the proposed structures.

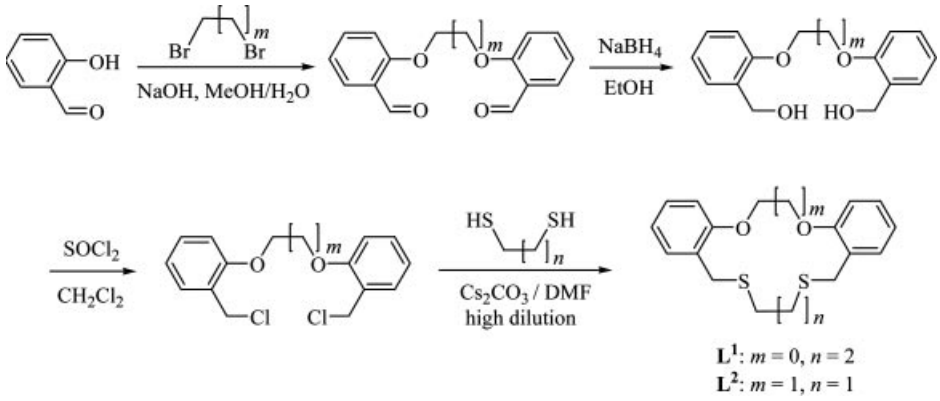

Scheme 1. Synthesis of ligands.

The structures of these macrocycles were also characterised in the solid state by single-crystal X-ray crystallography. Colourless crystals of **L¹** and **L²** suitable for X-ray analysis were obtained by slow concentration of their respective solutions in methanol (**L¹**) or dichloromethane (**L²**). Crystals of **L¹** and **L²** (Figure 1) have the acentric space groups *Pc* and $P2_12_12_1$, respectively. The conformations of the ring cavities in the two molecules differ only in their inter-donor distances. In both cases, the macrocyclic rings are relatively flattened and the two oxygen atoms are oriented endodentate, whilst the two sulfur atoms are arranged exodentate with respect to the ring cavity.[5] As expected, the observed S···S distance in **L¹** (5.627 Å) is significantly longer than that of **L²** (4.387 Å).

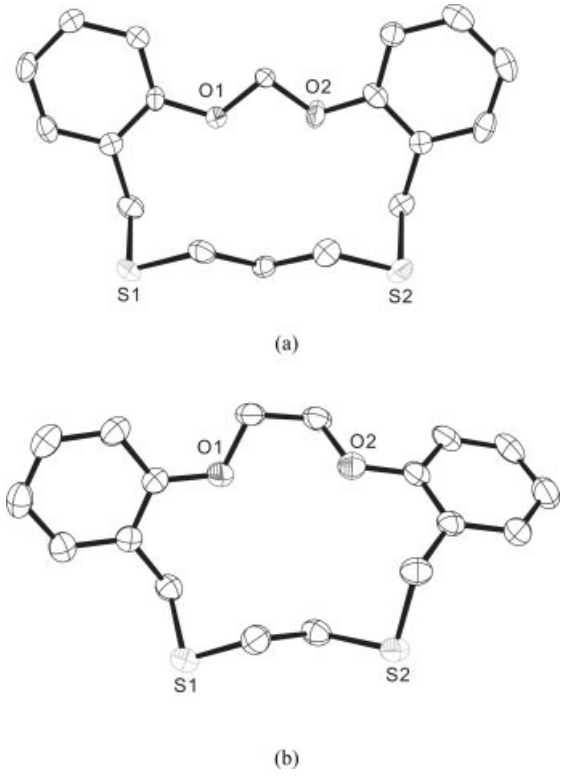

Figure 1. Molecular structures of **L¹** (a) and **L²** (b). Thermal ellipsoids are drawn at the 30% probability level. Selected interatomic distances [Å]: **L¹**: S1···S2 5.627(2); **L²**: S1···S2 4.387(1).

## Complex Syntheses and Structural Description

Two crystalline supramolecular complexes were obtained from the assembly reactions of the ligands with silver perchlorate. A colourless precipitate was obtained from **L¹** and $AgClO_4$ in methanol/water, and colourless single crystals of **1** suitable for X-ray analysis were obtained by vapour diffusion of diethyl ether into a nitromethane solution of this complex. Similarly, a colourless precipitate was obtained from **L²** and $AgClO_4$ in dichloromethane/methanol, and colourless single crystals of **2** suitable for X-ray analysis were obtained by vapour diffusion of diethyl ether into its DMF solution (Scheme 2).

The X-ray analysis revealed that **1** is a poly(bicyclic dimer) $[\{Ag_2(\mathbf{L^1})_2(ClO_4)_2\}CH_3NO_2]_n$ (Figure 2a). The bicyclic dimer unit of **1** contains two bridging Ag atoms, two macrocycles, two perchlorate ions and one noncoordinating nitromethane molecule (not shown). Each five-coordinate Ag atom[8] that lies outside the cavity bridges two S donors from two different macrocycles in a bent fashion [S1–Ag1–S1C 161.95(6)°] such that the two metal centres point towards each other. However, the separation of the two Ag atoms [Ag1···Ag1A 4.8611(12) Å] is far from the range of an argentophilic interaction.[9] Interestingly, two diagonally opposite $ClO_4^-$ anions weakly bridge two Ag atoms in a bidentate manner to form a three-dimensional bicycle. It is known that in most reported $AgClO_4$ complexes with dithioether ligands, the $ClO_4^-$ anions usually take the role of a monodentate ligand or intercalating anion. However, the $ClO_4^-$ anions in **1** coordinate to two Ag atoms in the rare $\eta^2$-double-bridge mode through two O atoms to form an eight-membered ring.[8] Several cases of bicyclic dimeric $AgClO_4$ complexes with acyclic dithioethers[8] were ex-

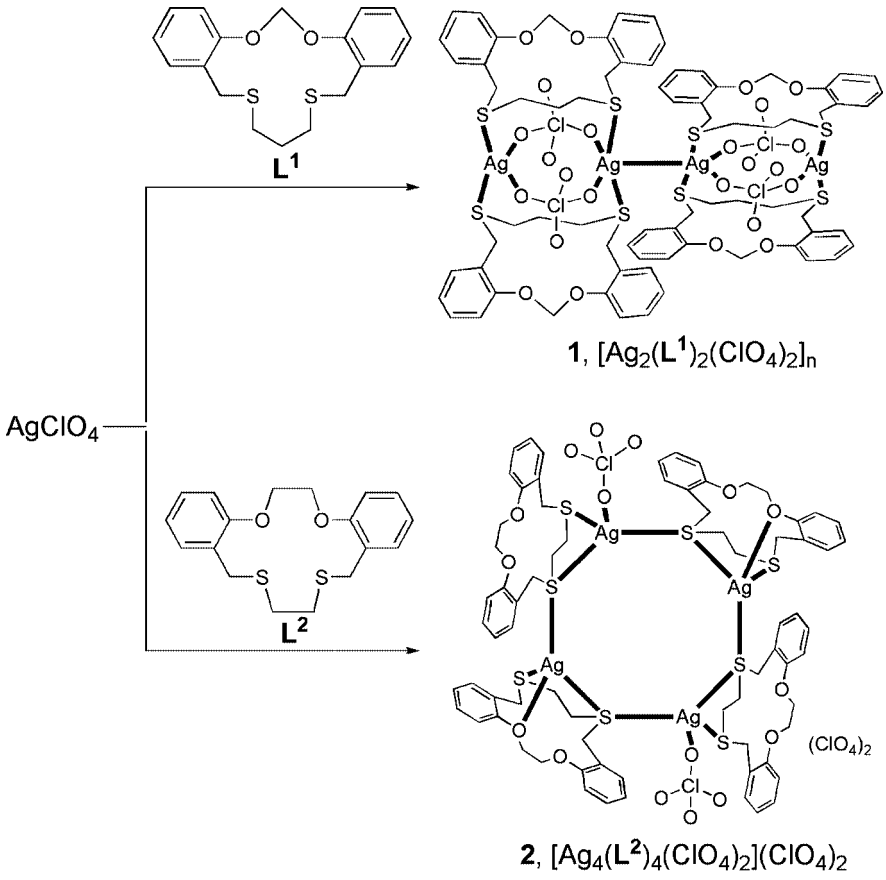

Scheme 2. Complexes prepared.

tracted from the Cambridge Crystallographic Database (CCDC).[10] As we understand, however, this is the first example of a bicyclic dimeric $AgClO_4$ complex based on a cyclic analogue. The bicyclic dimer unit is further held together by Ag–Ag contacts[9] [3.129(1) Å] to form a polymeric chain of the bicyclic dimer unit. Some $d^{10}$ metal ions show a tendency to form metal–metal bonds, and Ag–Ag contacts in the range 2.80–3.30 Å have been reviewed.[9] The two repeating adjacent bicyclic dimer units of **1** are perpendicular to each other and show a propeller-like side view (Figure 2b). In this case, no significant change of the S···S distance (5.622 Å for **1**) is observed compared with that for $\mathbf{L^1}$ (5.627 Å).

In the packing structure (Figure 2c), each 1D network is arranged side by side with an adjacent one such that they form an offset face-to-face-type π-π stacking interaction[11] through the aromatic rings. The dihedral angle between the two aromatic rings is 13.0(3)°, thereby indicating a slightly tilted orientation. The intercentroid distance between two aromatic rings is 4.153 Å, which falls at the mean of the literature range (3.7–4.6 Å) for such an interaction.[11]

The reaction of $\mathbf{L^2}$ with $AgClO_4$ in dichloromethane/methanol afforded a colourless precipitate. Vapour diffusion of diethyl ether into a DMF solution of this precipitate gave a crystalline product **2**. An X-ray analysis revealed that **2** is a cyclic tetramer $[Ag_4(\mathbf{L^2})_4(ClO_4)_2](ClO_4)_2{\cdot}2MeOH$ with inversion symmetry (Figure 3a). Tetranuclear $Ag^I$ complexes $[Ag_4\mathbf{L}_4]^{4+}$ of trithiamacrocycles (**L**) with similar cyclic tetrameric structure have been reported by Loeb et al.[12] Ag1, which lies outside the cavity, is bonded to one O and two S atoms of one macrocycle as well as to one S atom of the adjacent macrocycle to form a distorted tetragonal environment, whereas tetrahedrally coordinated Ag2 is surrounded by two S atoms of one macrocycle and one S atom of an adjacent macrocycle. The fourth site is occupied by an O atom of $ClO_4^-$ in a monodentate manner. Consequently, the repeating Ag1–S–Ag2–S bonding leads to an octagonal scaffold with an $Ag_4S_4$ core. The two coordinating $ClO_4^-$ ions are attached to the exterior and two other $ClO_4^-$ ions are included in the octagonal cavity. The resulting 3D structure of **2** is "doughnut"-like and has a diameter of approximately 13.8 Å and a thickness of 7.4 Å. The S···S distances in **2** (3.432 and 3.635 Å) are shorter than that in $\mathbf{L^2}$ (4.387 Å) due to conversion of the torsion angle between the two S atoms from *anti* to *gauche* upon complexation.

The FAB mass spectra of **1** and **2** contain peaks at *m*/*z* = 439 and 979, which correspond to $[Ag_2(\mathbf{L^1})_2]^{2+}$ and $[Ag_4(\mathbf{L^2})_4(ClO_4)_2]^{2+}$, respectively, according to their isotope patterns (Figure 4).

## Conclusion

The preparation and structural characterisation of two types of cyclic oligomer silver(I) complexes derived from isomeric $S_2O_2$ macrocycles have been presented. The tendency to adopt these respective arrangements shows the possibility that the metal coordination mode can be controlled by tuning the inter-donor distances in the backbone of each bound ligand.

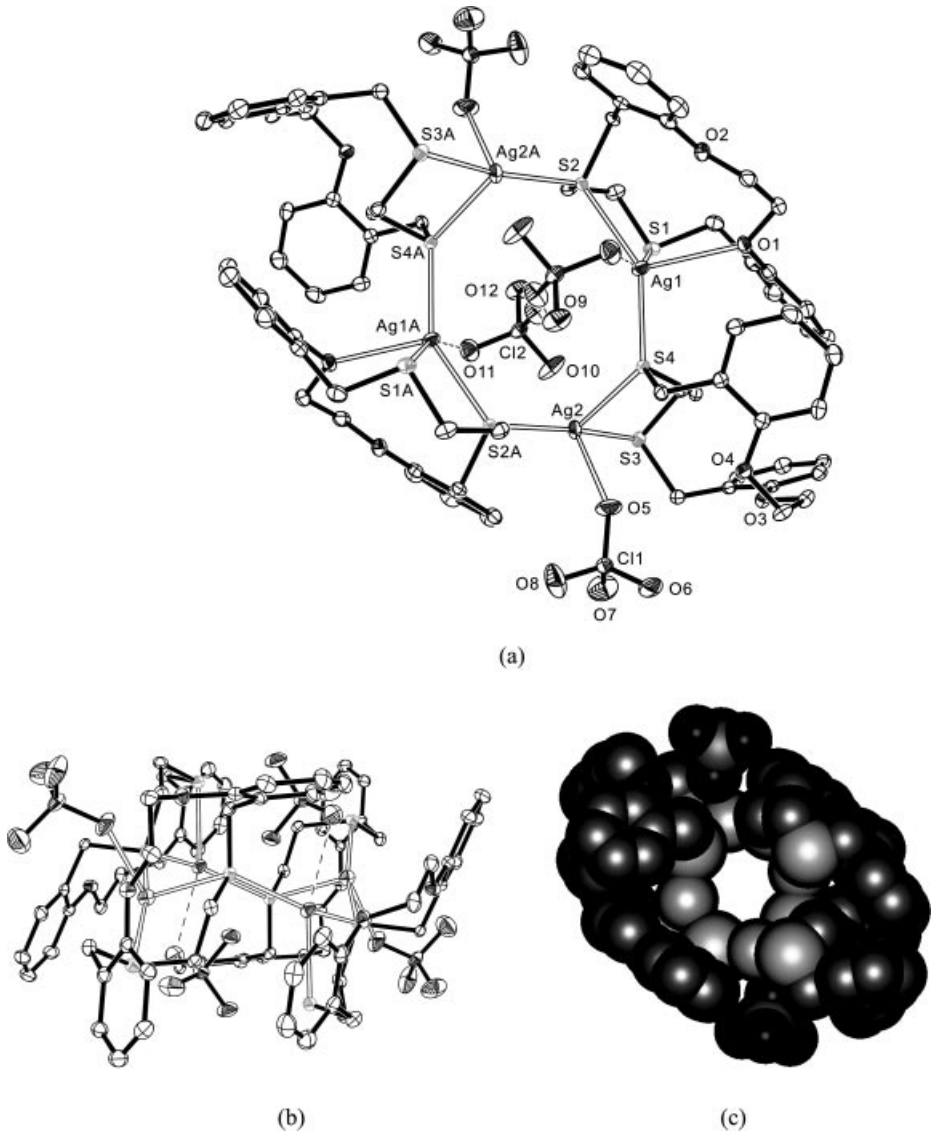

Figure 3. Cyclic tetramer structure of **2**: (a) top view, (b) side view and (c) space-filling view (noncoordinating anions are omitted). Hydrogen atoms and noncoordinating methanol molecules have been omitted for clarity. Thermal ellipsoids are drawn at the 30% probability level. Selected bond lengths [Å] and angles [°]: Ag1–S1 2.6102(14), Ag1–S2 2.6322(14), Ag1–S4 2.5245(12), Ag2–S3 2.4855(13), Ag2–S4 2.6990(13); S1–Ag1–S2 81.79(4), S4–Ag1–S2 145.60(4), S4–Ag1–S1 113.43(4), S3–Ag2–S4 88.92(4), Ag1–S4–Ag2 120.60(5); S1···S2 3.4320(18), S3···S4 3.6346(17), Ag1···Ag2 4.5381(7), Ag1···Ag1A 5.6148(9). Symmetry operation: A: $-x + 1, -y + 1, -z + 1$.

## Experimental Section

**General Remarks:** Chemical reagents and solvents were purchased commercially and used as received without further purification. Infrared spectra were measured with a Mattson Genesis Series FTIR spectrophotometer, and the NMR spectra were recorded with a Bruker 300 MHz spectrometer. Mass spectra were obtained with a JEOL JMS-700 spectrometer at the Central Laboratory of Gyeongsang National University.

**Synthesis and Characterisation of $L^1$:** Cesium carbonate (11.22 g, 34.46 mmol) was dissolved in DMF (1000 mL) in a 3-L, round-bottomed flask. 1,3-Propanedithiol (2.12 g, 22.5 mmol) and the dichloride (6.7 g, 22.5 mmol) were dissolved in DMF (30 mL) and this solution was taken up in a 50-mL glass syringe. Under nitrogen, the contents of the syringe were added dropwise (0.6 mL $h^{-1}$) to the DMF solution of $Cs_2CO_3$ at 45–50 °C over 50 h. The reaction mixture was rapidly stirred for a further 10 h, cooled to room temperature and filtered. The filtrate was concentrated and the residue was partitioned between water and dichloromethane. The aqueous phase was separated and extracted with two further portions of dichloromethane. The combined organic phases were dried with anhydrous sodium sulfate and then concentrated to dryness. Flash column chromatography on silica gel with 20% ethyl acetate/*n*-hexane as the eluent led to the isolation of $\mathbf{L^1}$ as a colourless crystalline product in 28% yield. M.p. 78–80 °C. $C_{18}H_{20}O_2S_2$ (332.48): calcd. C 65.02, H 6.06; found C 64.79, H 6.12. IR (KBr): $\tilde{\nu}$ = 2924, 2290, 1590, 1491, 1415 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.60–7.04 (m, 8 H, Ar), 5.83 (s, 2 H, $OCH_2$), 3.69 (s, 4 H, $ArCH_2$), 2.34 (t, $J$ = 7.57 Hz, 4 H, $SCH_2CH_2$), 1.63 (t, $J$ = 2.24 Hz, 2 H, $SCH_2CH_2$) ppm. $^{13}C$ NMR (125 MHz, $CDCl_3$): $\delta$ =

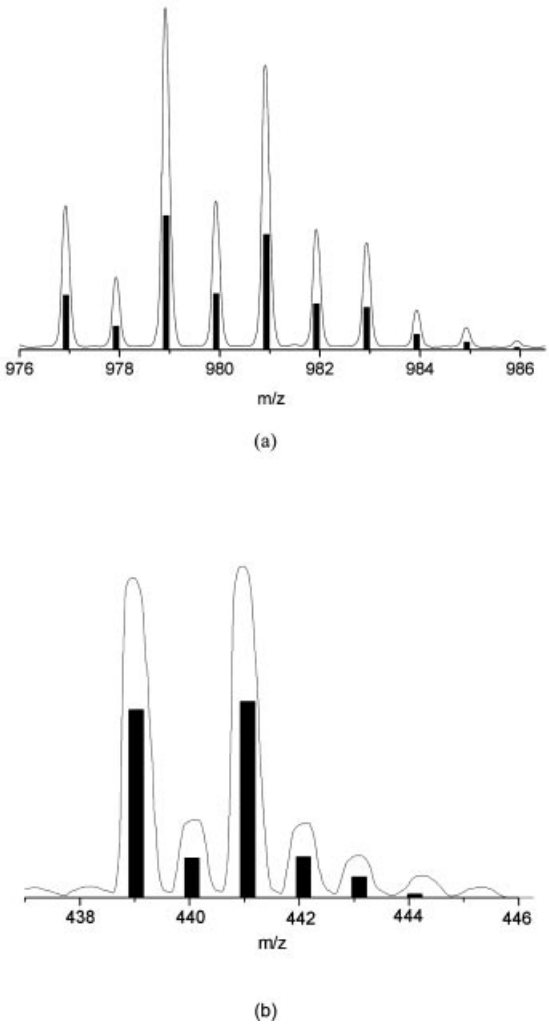

Figure 4. Observed isotopic distribution for $\mathbf{1}^{2+}$ (a) and $\mathbf{2}^{2+}$ (b) in the FAB mass spectra of **1** and **2**. The bars represent the predicted mass spectral distribution for this ion.

154.73, 130.95, 128.21, 123.09, 114.58, 92.19, 31.10, 29.82, 28.81 ppm. FAB-MS: $m/z$ = 332 [$M^+$].

**Synthesis and Characterisation of $L^2$:** The synthetic procedure was almost the same as for $\mathbf{L^1}$ except for the use of a different dichloride ($m$ = 1) and 1,2-ethanedithiol as the thiol (Scheme 2). Flash column chromatography ($SiO_2$; *n*-hexane/ethyl acetate, 1:1) afforded the product as a white solid in 41% yield. M.p. 128–130 °C. $C_{18}H_{20}O_2S_2$ (332.48): calcd. C 65.02, H 6.06, S 19.29; found C 64.88, H 6.25, S 19.47. IR (KBr): $\tilde{\nu}$ = 2921, 2358, 1592, 1490, 1452, 1288 $cm^{-1}$. $^1H$ NMR (500 MHz, $CDCl_3$): $\delta$ = 6.87–7.38 (m, 8 H, Ar), 4.34 (s, 4 H, $OCH_2$), 3.78 (s, 4 H, $ArCH_2$), 2.73 (s, 4 H, $SCH_2CH_2S$) ppm. $^{13}C$ NMR (125 MHz, $CDCl_3$): $\delta$ = 155.95, 131.02, 128.59, 128.06, 121.52, 111.07, 66.65, 31.61, 28.17 ppm. FAB-MS: $m/z$ = 332 [$M^+$].

**$[Ag_2(L^1)_2(ClO_4)_2]\cdot 2H_2O$ (1):** A colourless precipitate was obtained by mixing of equimolar amounts of $\mathbf{L^1}$ and $AgClO_4$ in methanol/water. The product was filtered off and washed with methanol and dried under vacuum. Yield: 78%. M.p. 180–181 °C. $C_{36}H_{44}Ag_2Cl_2O_{14}S_4$ (1115.63): calcd. C 38.76, H 3.98, S 11.50; found C 38.75, H 3.96, S 11.49. IR (KBr): $\tilde{\nu}$ = 2928, 1595, 1492, 1454, 1418, 1294, 1226, 1097 ($ClO_4^-$), 1001, 756, 621 $cm^{-1}$. FAB-MS: $m/z$ = 439 $[Ag_2(\mathbf{L^1})_2]^{2+}$.

**$[Ag_4(L^2)_4(ClO_4)_2](ClO_4)_2\cdot 1.5MeOH$ (2):** Reaction of $\mathbf{L^2}$ with $AgClO_4$ in dichloromethane/methanol afforded a colourless precipitate. Vapour diffusion of diethyl ether into a DMF solution gave rise to a crystalline product. The product for microanalysis was dried under vacuum. Yield: 90%. M.p. 159–160 °C. $C_{73.5}H_{86}Ag_4Cl_4O_{25.5}S_8$ (2207.26): calcd. C 40.44, H 4.28; found C 40.00, H 3.93. IR (KBr): $\tilde{\nu}$ = 2932, 1593, 1493, 1452, 1246, 1097 ($ClO_4^-$), 930, 758, 621 $cm^{-1}$. FAB-MS: $m/z$ = 979 $[Ag_4(\mathbf{L^2})_4]^{2+}$.

***CAUTION!*** *Perchlorate salts of metal complexes are potentially explosive and should be handled with great care.*

**X-ray Crystallography:** All data were collected with a Bruker Smart diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation source and a CCD detector; 45 frames of two-dimensional diffraction images were collected and processed to obtain the cell parameters and orientation matrix. The first 50 frames were retaken after complete data collection. The crystal showed no significant decay. The frame data were processed with

# A $Zn^{II}$-Based Chiral Crystalline Nanotube

Hong-Tao Zhang,*[a] Yi-Zhi Li,[a] Tian-Wei Wang,[a] Emmanuel N. Nfor,[a] Hua-Qin Wang,[b] and Xiao-Zeng You*[a]

**Keywords:** Coordination polymer/ Chirality / Nanotubes / Triple helix / Nonlinear optics / Fluorescence

A novel metal-organic chiral nanotube, $\{[Zn(C_{14}H_{10}N_2O_4)\cdot(H_2O)_4]_2\cdot H_2O\}_n$ (**1**), with the walls consisting of homochiral triple-stranded right-handed (*P*) helices has been constructed by the reaction of acyclic ligands and zinc ions. All guest water molecules are arranged in a helical fashion inside the hydrophilic channel of the nanotube. This coordination polymer shows blue-emitting fluorescence and displays a second harmonic generation (SHG) response in the solid state.

## Introduction

Nanotubular supramolecular architectures are currently of intense interest in chemistry, biology, and materials science, owing to their potential applications in mimicking ion channels, water channels, and as small molecule transport systems.[1,2] The construction of synthetic nanotubes is achieved through the self-assembly of suitable cyclic building blocks such as cyclic peptides[3] and cyclic oligoureas.[4] Another motif in the formation of nanotubes is achieved by the self-assembly of acyclic oligopeptides which, like cyclic peptides, are building blocks that can also result in chiral tubular structures.[5] However, most of the previously reported nanotubes are made up of synthetic organic molecules and to date, the construction of metal-containing nanotubular structures has received scant attention.[6] In forming channel structures, the coordination polymer approach has the advantage of preparative convenience, functionalization, and thermal stability.[7] The metal-organic nanotubes could be generated through the self-assembly of metal ions with organic ligands and such metal-organic nanotubes might display opto-electronic or magnetic properties induced by the coordination moiety. Furthermore, the employment of chiral organic molecules can induce a noncentrosymmetric structure in the resulting nanotubes which may be useful in the field of nonlinear optics (NLO) applications.[8] In view of the above, we present herein the construction of a novel metal-organic chiral nanotube, ZnL (**1**) [L = (2*S*,2′*S*)-2,2′-(benzene-1,4-dicarboxamido)dipropionate], with the walls consisting of homochiral triple-stranded right-handed (*P*) helices and its optical properties.

## Results and Discussion

### Crystal Structure

Compound **1** was obtained by the reaction of zinc acetate with the chiral ligand $H_2L$. The crystal structure of **1** reveals that, there is one zinc ion, one ligand dianion, and two coordination water molecules as well as half of one guest water molecule in the asymmetric unit. Crystallographic data of **1** is summarized in Table 1. As shown in Figure 1, the coordination motif of the zinc ion has a trigonal-bipyramidal geometry. Two coordinated water O atoms (O1 and O2) occupy an axial position of the Zn trigonal

bipyramid, while three carboxylato O atoms (O3, O5A, and O6B) bond to the equatorial positions. At one end of the ligand, the side methyl group C14 is almost coplanar with the amide group O8/C11/N2 with a torsion angle of 176.8(6)° for C11–N2–C12–C14, while the carboxyl group O5/C13/O6 is almost perpendicular to the amide plane. At the other end of the ligand, the methyl group C3 is vertical on the amide plane O7/C4/N1 with a torsion angle of 81.1(7)° for C4–N1–C2–C3. The carboxyl group O4/C1/O3 lies slightly out of the plane of the amide group O7/C4/N1 with a torsion angle of –6.2(8)° for N1–C2–C1–O3 (selected bond lengths, angles, and torsion angles are listed in Table 2). Thus, the two sides of the phenyl ring are not equivalent with each other, owing to the different coordination modes of the two carboxylate groups (O3/C1/O4 as a monodentate ligand and O5/C13/O6 as a carboxyl bridge) and their conformations. Consequently, two ligands connect a pair of zinc ions in a head-to-tail fashion through the O3 and O6 atoms, thus forming a right-handed twofold single-

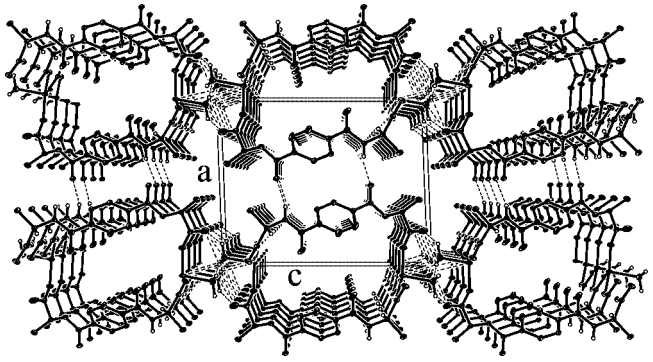

Figure 5. The nanotube arrays in complex **1**. The guest water molecules and H atoms except for the amide H atoms are omitted for clarity.

stranded helix propagating along the *b*-axis. The O5 atoms at "the head" and at "the tail" link two zinc ions from different single-stranded helices, respectively, thus constructing a homochiral triple-stranded (*P*) helix as depicted in Figure 2. In the previously reported triple helical coordination polymers, the interwoven helices just form rod-like structures owing to the small screw diameter.[9] However, in complex **1**, the triple-stranded helix around the screw axis generates an open-ended tube with an average internal diameter of 5 Å including the van der Waals contact (approximately 3 Å excluding the van der Waals contact), which is attributed to the expansion of the screw diameter by the phenyl ring. The interior of the channel is hydrophilic owing to the presence of the guest water molecules as shown in Figure 3. All guest water molecules are arranged in a helical fashion inside the polymeric structure (Figure 4). In the lattice, as depicted in Figure 5, all nanotubes are packed together to produce three-dimensional arrays by means of the inter-tubular hydrogen-bonding interactions between amide groups, coordination water molecules and guest water molecules as well as carboxylate groups (for details see Table 3).

## Thermal and Optical Properties

The TGA performed under flowing $N_2$ shows a gradual weight loss of 1.95% in the temperature range of 30–64 °C corresponding to the guest water molecule's liberation from the channels (calcd. 2.16%). The weight loss of 8.29% in the range 64–135 °C is attributed to the removal of coordination water molecules (calcd. 8.64%) and the decomposition of compound **1** starts at 386 °C. A crystal of compound **1** was stable at room temperature; however, it cracked when it had been left to stand at 45 °C for 14 d in order to release guest water molecules. Compound **1** is insoluble in water and common organic solvents such as methanol, ethanol, acetone, acetonitrile, DMF, and DMSO.

As shown in Figure 6, compound **1** exhibits a blue-fluorescent emission around 439 nm upon excitation at 338 nm in the solid state at room temperature. This has a blue shift and an enhancement of intensity in comparison with the emission of the ligand (a very weak emission is observed for the free ligand around 450 nm upon excitation at 348 nm in the solid state). This indicates that the emission is neither MLCT (metal-to-ligand charge transfer) nor LMCT (ligand-to-metal charge transfer) in nature and can thus be tentatively assigned to intraligand fluorescent emission.[10] The significant enhancement of fluorescent intensity is probably ascribed to the coordination of ligand to the Zn ion, increasing the ligand conformational rigidity, thereby reducing the nonradiative decay of the intraligand $^1(\pi\text{-}\pi^*)$ excited state.[11]

Given that **1** crystallizes in a noncentrosymmetric space group, its powder second harmonic generation (SHG) measurement was performed according to the method previously reported by Kurtz.[12] When a beam at $\lambda = 1064$ nm fundamental wavelength from a Q-switched Nd:YAG laser falls onto compound **1**, a green light can be seen with the naked eye. The preliminary experimental result shows that the powder SHG intensity of **1** is about 0.6 times that of urea. This intensity is comparable to the previously reported helical coordination polymers.[13]

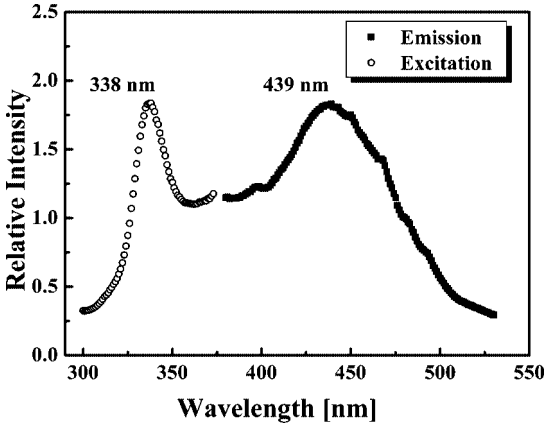

Figure 6. Fluorescent spectra of **1** in the solid state at room temperature.

## Conclusions

In conclusion, the reported nanotubular coordination polymer **1** has hydrophilic channels surrounded by homochiral triple helices, emits an enhanced blue fluorescence, and exhibits a second harmonic generation response. The transparency of the complex and its insolubility in common solvents, such as water, methanol, and ethanol among others, makes it an attractive candidate for blue-emitting fluorescent materials and in nonlinear optics (NLO) applications. Therefore, it can be developed towards a new motif in the formation of chiral nanotubes with opto-electronic properties.

## Experimental Section

**General:** Elemental analyses were carried out with a Perkin–Elmer 240C elemental analyzer. IR spectra were recorded with a Bruker VECTOR22 FT-IR spectrometer using the KBr pellet technique. Thermogravimetric analyses (TGA) were performed with a TA-SDT 2960 thermal analyzer at a heating rate of 10 °C min$^{-1}$ from room temperature to 600 °C under flowing nitrogen. The solid-state excitation-emission spectrum was acquired with an AMINCO Bowman Series AB2 Luminescence Spectrometer at room temperature. Approximate estimations of second-order NLO intensity were obtained by a comparison of the results from a powdered sample, in the form of a pellet (Kurtz powder test),[12] with those obtained for urea. A pulsed Q-switched Nd:YAG laser at a wavelength of 1064 nm was used to generate an SHG signal from samples. The backward-scattered SHG light was collected using a spherical concave mirror and passed through a filter that transmits only 532 nm radiation.

**$\{[Zn(C_{14}H_{10}N_2O_4)\cdot(H_2O)_4]_2\cdot H_2O\}_n$ (1):** The diacid, (2*S*,2′*S*)-2,2′-(benzene-1,4-dicarboxamido)dipropionic acid ($H_2L$), was synthesized by treating 1,4-benzenedicarbonyl dichloride with L-alanine ethyl ester according to a published procedure.[14] The ligand $H_2L$ (31.0 mg, 0.1 mmol) and zinc acetate dihydrate (22.0 mg, 0.1 mmol) were dissolved in water (10 mL). The resulting solution was left to stand for several weeks at room temperature. Colorless block crystals that formed were collected by filtration (16.0 mg, yield 40%). $C_{28}H_{38}N_4O_{17}Zn_2$ (833.36): calcd. C 40.35, H 4.60, N 6.72; found C 40.30, H 4.68, N 6.69. IR (KBr): $\tilde{\nu}$ = 3392 (m), 3268 (m), 2994 (w), 1654 (s), 1619 (s), 1578 (s), 1550 (s), 1490 (s), 1396 (m), 1320 (m), 1176 (w), 1055 (w), 870 (w), 746 (w), 594 (w) cm$^{-1}$.

**Crystallography:** A single crystal with dimensions 0.6 × 0.4 × 0.3 mm was used for structural determination with an Enraf–Nonius CAD-4 diffractometer with graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) using a $\omega$-2$\theta$ scan mode at 298 K. Intensity data were collected in the $\theta$ range of 1.39–25.97°, data reduction was made with the MolEN package.[15] Absorption corrections from $\psi$ scans were applied. The structure was solved by direct methods using SHELXS-97[16] and refined by least-squares treatment on $F^2$ by full-matrix least squares using SHELXL-97 with anisotropic displacement parameters for all non-hydrogen atoms.[17] The guest water molecule O1W was refined as occupancy disorder. CCDC-279580 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# METALLOENZYMES AND CHEMICAL BIOMIMETICS

**Luigi Casella[a]**

Bioinorganic enzymology, the chemistry of metalloenzymes and closely related areas dealing with metalloprotein functions, is a broad interdisciplinary research field, representing an intellectually attractive and experimentally demanding frontier in modern chemical and biological sciences. Inorganic chemists should play a major role in this area because metal ions and their properties/reactivity are a primary feature characterizing these biological systems. Metalloproteins are basically highly elaborated metal complexes where the ligand is a structured polypeptide chain. They contain one or more metal ions in the active site and are optimally designed to accomplish evolutionary directed functions. The ultimate goal of biological inorganic chemistry research is to gain an understanding of these functions in terms of structure and reactivity. Inorganic chemists, in particular, recognize that the structural and electronic properties of biological metal centres are often modulated from those of small molecules containing the same metal ion. Understanding these differences is essential for understanding function, and for this reason the contribution of synthetic and biomimetic chemistry is extremely important for the progress of this field.

**Major role for Inorganic Chemisty**

The significance of the metal-centred chemistry performed by metalloenzymes is not limited to the biological environment. It has a strong impact on the medical sciences (e.g. generation of oxygen radicals, production and reactions of nitric oxide), pharmacological sciences (e.g. enzyme inhibition, protein receptors, metal toxicity), and environmental sciences (e.g. nitrogen and sulphur cycles, soil and water detoxification). But the capacity of metalloenzymes to carry out energetically difficult processes efficiently under mild conditions should also be attractive to chemical industry, with the aim of developing environmentally friendly processes.

As with other interdisciplinary research fields, it is clear that bringing together scientists with different expertise is essential for the progress in the area. The key importance of metallobiochemistry has been recognized at the European level with the launch of several COST Actions, and ultimately D21 (2000−2006) had the objective of coordinating the research efforts by a large number of European groups on topics of timely and relevant interest, and promoting more intensive exchange between individual groups. More than 100 laboratories were involved in this programme, which developed along the following priority areas: (a) structural, mechanistic and spectroscopic studies of metalloenzymes; (b) synthetic studies of mononuclear and polynuclear metal complexes with biomimetic ligands as active site models and biomimetic catalysts; (c) structural and spectro-

**Interdisciplinary exchange promoted**

scopic studies on electron transfer proteins; (d) characterisation and biological role of metal-protein interactions; (e) small molecules activation at biological and biomimetic metal centres. A large body of high quality scientific progress has been made during the years through this COST Action. Much of this would have probably been made also in the absence of this programme, but it is true that facilitating the collaborations increased the scientific impact that would have been obtained if individual groups carried out their research independently. Given the dimension of COST D21, a huge number of papers have been published in the literature within this programme. A "flavour" of the broad scope of D21 "Metalloenzymes and chemical biomimetics" is given by the fully peer-reviewed microreviews and research papers appearing in the present and following issues of the European Journal of Inorganic Chemistry. These papers span several research topics which characterized D21, and in particular focus on insulin mimetic vanadium complexes (Gätjens et al., Kiss et al.), DNA cleavage by artificial nucleases (Borras et al.), metal-protein interactions (Kiss et al.), enzyme inactivation by radical species (Golding et al.), protein-protein interactions (Moura et al.), enzymatic production of toxic small inorganic molecules (Obinger et al.), inhibition of zinc enzymes (Santos et al.), distribution of vanadate in human blood (Gorzsas et al.), biomimetic chemistry of dinuclear zinc complexes (Meyer et al.), vanadium complexes (Pessoa et al., Geraldes et al.) and manganese clusters (McKenzie et al.), and engineering of electron transfer proteins (Canters et al.). We hope that this collection will stimulate more inorganic chemists to be involved into the field of metallobiochemistry, perhaps initiating interdisciplinary collaborations.

## COVER PICTURE

**The cover picture shows** a symbolic representation of the fate of vanadate in human blood. Since the transition metal vanadium is named after Vanadis, the Nordic goddess of beauty, she is represented by the famous Venus de Milo sculpted in metal. Her cloth is decorated with the functional groups of the ligands that can form a complex ("dress") with the metal while travelling in the blood vessels, the latter being symbolised by the caverns in the background. The water in the caves represents the aqueous solutions in which speciation studies have been carried out in the group of Professor Lage Pettersson. Further references to these studies are found as cave paintings on the walls: a distribution diagram and a set of $^{51}V$ NMR spectra. The studies have been carried out in the framework of the COST D21/009 working group. The geographical locations of the research groups within this working group are shown by illuminated dots on the map of Europe in the background. The goal of the studies was to better understand the ability of vanadium to lower blood glucose levels (represented by the sugar cubes washed ashore on the left) and thus its potential as an orally applicable drug against diabetes. A Microreview, covering the results of the above mentioned speciation studies dealing with the fate of vanadate in human blood, is represented by A. Gorzsás, I. Andersson, and L. Pettersson on p. 3559ff. The digital artwork for this cover was created by András Gorzsás.

# On the Fate of Vanadate in Human Blood

**András Gorzsás,*[a][‡] Ingegärd Andersson,[a] and Lage Pettersson[a]**

**Keywords:** Vanadium / Bioinorganic chemistry / Equilibria in aqueous solution / Diabetes

As a summary of recent activities at our research group, a model describing the distribution of pentavalent vanadium (referred to as vanadate throughout the present work) in human blood has been constructed based on our speciation studies performed in the physiological medium of 0.150 M Na(Cl) with various blood constituents. In addition, other data (most notably with the high mass serum constituents albumin and transferrin) have also been used to give as broad a view as possible. Two antidiabetic drug candidate ligands, picolinate and maltol, have also been included in order to investigate the stability of their vanadium complexes in the presence of blood constituents, i.e. to account for ligand-exchange possibilities. The model predicts transferrin to be the major carrier of vanadium in the bloodstream. It is capable of almost completely replacing the vanadium-bound picolinate even if the latter is in large excess. Maltol, on the other hand, can retain most of the vanadium when it is supplied in about a 5 mM concentration. The model still has certain limitations but it serves as a useful base for investigating structure, stability, relationship effects and provides insight into the fate of vanadate in human blood.

## Introduction

Arguably the biggest contribution to the renewed interest in the bioinorganic chemistry of vanadium originates from the discovery of the insulin-enhancing properties of this transition metal and its compounds. *Diabetes mellitus*, with its explosively increasing incidence worldwide[1] and many global and societal implications,[2] is one of the most threatening and costly "epidemics" of our times. Currently insulin is used as the core treatment in both type I and type II diabetes. Although it is extremely important, there is need for substitutes, especially when dealing with type II diabetes. In addition, being destroyed in the stomach, insulin cannot be administered orally in mammals and the constant use of subcutaneous injections is inconvenient. Thus, the ideal substitute would be orally applicable and effective, particularly in the case of type II diabetes. It also should meet other criteria regarding its absorption, stability in body fluids, a desired high specificity and low toxicity.[3]

Vanadium compounds have long been shown to exert insulin-like effects both in vitro,[4–8] and in vivo,[3,9,10,11–20] the first example being documented as early as 1899.[21] In all these tests, vanadium has been demonstrated to perform insulin-like actions in virtually all respects.[9,22,23] The amount of vanadium needed to induce the required metabolic effects has been found to be in the range of micromolar to millimolar concentrations,[4,6,7,8,24] depending not only on the nature of the compound but also on the time course of the management (generally lower doses are needed when long-term treatment is applied). It is worth noting that usually a longer time has been required during in vivo experiments to observe the desired insulin-like effects as compared to in vitro tests. On the other hand, the effects have mostly been long lasting, even after stopping the administration of the compounds. These indicate a possible accumulation of the active component(s) in the body,[9] as has been shown in the case of bones.[25,19,20] It is also important to point out that plasma insulin levels have not been increased during the treatments. Thus, the glucose-lowering effects are not due to a vanadium-induced increase in insulin secretion,[14,26] but rather they are realised by mechanisms that are (at least partly) different from that of insulin.[3,27] However, these mechanisms are not yet completely elucidated. In addition, different vanadium compounds operate along (partially) different pathways, further complicating the picture.[9,28,29]

**MICROREVIEWS:** This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Unfortunately, mostly owing to the low adsorption and specificity of vanadium, problems with toxicity and side effects arise. On the other hand, these problems can in theory be overcome by applying the proper ligands. In fact a great advantage of vanadium compounds is that virtually all of their important features, such as stability, oral availability, as well as absorption, toxicity, etc. can be fine-tuned by means of different ligands. While investigating the effects of different vanadium complexes, it has also been suggested that it is always the uncomplexed vanadium that is the active component, irrespective of the introduced species.[30] In other words, the only role of the ligand could be to deliver vanadium as efficiently as possible, including translocation across the cell membrane. In opposition to this hypothesis, different mechanisms of action have been suggested for different vanadium complexes, depending on the nature of the compound.[9,28] Whatever the case may be, ligands may still play an important role in facilitating the uptake and/or transport of vanadium, thereby reducing toxicity and side effects and possibly increasing effectiveness.

It should also be noted that the incidence of diabetes is increasing among pets, for similar reasons as in the case of humans, namely sedentary lifestyle and obesity.[31] Food supplies often contain nutrients in much higher amounts than the natural diet of the animal would do or require. For instance, there is a large amount of carbohydrates in certain commercial cat foods, despite the well-known fact that cats are strict carnivores, and hence their diet naturally is based mostly on protein and fat with very little carbohydrates.[32] This causes serious malnutrition as the high carbohydrate diet leads to decreased insulin sensitivity in cats.[33] However, applying regular injections in animal treatment is even more troublesome than in the case of humans. Thus, oral medication is also desired in veterinary practices, and vanadium compounds may represent one type of solution.

Finally, it has to be pointed out that, although research in this field involves vanadium in its +4 and +5 oxidation states (as well as +3, to a much lesser extent), in the present article we focus solely on the +5 oxidation state. Thus, from here on, vanadium in the text refers to vanadium(V), unless otherwise specified.

## Speciation Studies and Modelling

Numerous drugs are known to be bound to plasma proteins when entering the bloodstream. The extent and nature of this interaction has a profound effect on the distribution of the drug into other compartments and on its therapeutic as well as toxic effects.[34–36]

Complete speciation studies are of great value in the fundamental research of this field. By the pH-independent formation constants obtained from such studies modelling of physiological conditions can be done, which is of fundamental interest in revealing vanadium interactions in humans as well as in drug design and production. Once vanadium speciation is established with all the major components in blood, including mixed ligand species, modelling can be used to determine the fate of any particular vanadium complex under physiological conditions, provided that

*András Gorzsás was born in Hajdúböszörmény, Hungary. He graduated in chemistry and English special translator majors at Lajos Kossuth University (now Debrecen University), Debrecen, Hungary, in 1999. He received his PhD in inorganic chemistry from Umeå University in 2005. He is currently a postdoctoral fellow at Umeå Plant Science Centre, working on the chemical analysis of wood cell walls by FT-IR microspectroscopy.*

*Ingegärd Andersson was born in Röbäck, close to Umeå, Sweden. She became an engineer in chemistry in 1965 in Skellefteå, Sweden. She has been working at the Department of Chemistry, Inorganic Chemistry, Umeå University since then.*

*Lage Pettersson was born in Holmsund, close to Umeå, Sweden. He received his MSc degree at the University of Uppsala (Sweden) in 1965. He joined Umeå University in 1966 and received his PhD in chemistry there in 1974. He became professor in inorganic chemistry at Umeå University in 1995. His group has specialised in equilibrium and structure studies of vanadium bioinorganic systems and polyoxometallate systems with molybdenum and vanadium.*

the speciation with the given ligand in the complex is also known. This paper represents such an attempt. Although some of the constituents of human blood had to be excluded (see below), our ongoing series of investigations,[37–39] have provided us with enough data to form a base for model calculations that are of interest to researchers in this field.

Albumin is found in approximately 630 μM concentration (Table 1) in human blood, and it (together with $\alpha_1$-acid glycoprotein) is one of the most common nonspecific binding proteins. Transferrin is another binding protein that is important in the case of metal transportation[40,41] (especially with iron, hence the name). It is present in human blood in about a 37 μM concentration (Table 1), and has two binding sites per protein to accommodate metal ions.[42] In normal serum, only about 30% of the total binding sites are occupied by iron.[43] This means that there are still sites available for other metal ions, without needing to replace the tightly bound iron. It has to be noted that there is a bidentate carbonate in the active site, usually referred to as the synergistic anion,[44,45] without which practically no iron–transferrin binding occurs.

Since both albumin and transferrin play important roles in the distribution and transportation of different compounds, they cannot be ignored when evaluating the interactions of any introduced vanadium-containing drugs in human blood. Indeed, it has been demonstrated that vanadium binds to both of these proteins,[46–54] although the binding is approximately 1000-times stronger to transferrin than to albumin.[55] Interestingly, vanadium has been found to be bound to transferrin even in the absence of $HCO_3^-$.[56]

Beside these two proteins, other constituents should also be included in a model that attempts to elucidate the fate of vanadium in human blood. Table 1 lists five additional low mass bioligands: glycine, lactate, phosphate, citrate and histidine, with their respective concentrations in human blood. Some constituents, such as carbonate, sulfate, cysteine, etc. have been excluded owing to the lack of (reliable) formation constants for their vanadate complexes. Of these excluded ligands, only hydrogen carbonate should be of considerable importance, because of its high concentration in blood (almost 25 mM).

In addition to the physiological concentrations of the selected blood constituents, Table 1 also lists the complexes they form with vanadate. These species have been included in the model calculation. Unfortunately, some of the formation constants given in Table 1 have not been determined in the physiological medium, which introduces an error in the model calculations. Moreover, in the case of transferrin, another simplification has been made. As explained earlier, transferrin is capable of binding two metals per protein, which could lead to the formation of a $V_2$Trf-type complex with vanadium. On the other hand, iron is present and competes with vanadium for the binding sites under physiological conditions. What is more, the binding of iron is favoured over other metal ions by transferrin. Since no iron is included in the model calculation, this kind of competitive binding has to be included in another way. It has been achieved by performing the calculation with VTrf-type complexes only. The other binding site can then be occupied by iron, as is most probably the case. Thus, the complex VTrf can in fact be considered as FeVTrf. Although this is a rather arbitrary simplification, it should give satisfactorily accurate results, since the amount of vacant binding sites of transferrin is estimated to be around 40 μM in human serum in the presence of iron.[42]

Table 1. Vanadate complexes with selected constituents in human blood. The concentrations of the ligands in healthy human subjects are given according to ref.[57] Maltol and picolinate are included to represent drug candidate ligands. The simplified notations for the complexes represent only their nuclearities and charges. Whenever charge is not indicated, it has not been determined in the study. Asterisks denote complexes with the same composition but different structures. The higher number of asterisks, the less dominating the species is. Formation constants for the complexes are shown at 25 °C, and the ionic media in which they have been determined are also noted.

| Ligand (Abbreviation) | Concentration in human blood | Complex notation | log$\beta$ | Medium |
|---|---|---|---|---|
| Glycine (Gly) | 2.3 mM | VGly | 1.8[a,i] | 1.0 M KCl, HEPES buffer |

In all cases, only those mononuclear complexes that may be relevant at the pH of human blood have been listed. Higher nuclearity species have been omitted completely, as they are extremely unlikely to be present at very low total concentrations of vanadium. For the present modelling $[V]_{tot}$ = 1 μM has been chosen, since vanadate species have shown insulin-like effects at this concentration, but no toxicity.[8] For a more complete list of vanadate species formed with a given ligand at various pH values and total concentrations, consult the references.

In order to represent an introduced vanadium-containing drug, either vanadate–picolinate or vanadate–maltol complexes (Table 1) have also been included in the model. This has been done to investigate whether the carrier ligand gets replaced by any of the blood constituents. Picolinate and maltol have been chosen since they form very stable mononuclear complexes with vanadium.[59,60] Extensive clinical research and in vitro tests have been carried out on complexes of vanadium and either of these ligands (or derivatives).[15,61,62,63–66] In addition, both ligands bind to vanadium over a wide pH range, covering conditions from acidic (stomach) to nearly neutral and slightly alkaline (blood, small intestines). This is of importance when taking a designed drug orally.

The calculations presented here have been performed using WINSGW,[67] a programme package based on the SOLGASWATER algorithm.[68] For the species formed in the $H^+$–$H_2VO_4^-$ binary system, formation constants have been taken from ref.[69] In cases of the different ternary $H^+$–$H_2VO_4^-$ ligand systems, only the complexes listed in Table 1 have been taken into consideration with the formation constants given there. For the model, $[V]_{tot}$ = 1 μM and pH = 7.4 have been used, with $[Ligand]_{tot}$ set to values given in Table 1 for each of the ligands. Thus, the matrix consisted of inorganic vanadates together with all the vanadate–ligand complexes given in Table 1.

Figure 1 shows the results of one of the model calculations. As can be seen, when there is no carrier ligand introduced with vanadium and the high mass serum constituents (HMS), albumin and transferrin, are excluded from the model, most of the metal is present as inorganic monovanadate, $H_2VO_4^-$ and $HVO_4^{2-}$ (Figure 1, a). Approximately 12% of vanadium is bound to glycine, and about 1–2% to other constituents (mostly phosphate). When the proteins are also included, however, more than 98% of the total vanadium is bound to transferrin (Figure 1, b). To illustrate the strength of picolinate itself as a carrier ligand in the absence of HMS, the distribution is also shown for that case (Figure 1, c). The diagram shows that a substantial fraction of vanadium (about 90%) is bound to picolinate when neither of the proteins is present. However, when HMS are included the transferrin binds almost all of the vanadium (approximately 90%), despite the high concentration of picolinate (20 mM, Figure 1, d). This is in accordance with the results obtained with canine blood,[47] where it has been shown that almost 80% of vanadium is bound to transferrin, regardless of what kind of inorganic vanadium species has been injected originally. It is also in accordance with the fact that introduced vanadium seems to be targeted towards iron-rich cells,[70] i.e. the transport route of vanadium follows that of iron.

Interesting results are found when doing the same kind of modelling with maltol, instead of picolinate (Figure 2). Using the same concentration for maltol as for picolinate in the previous calculation (20 mM), it is obvious how much stronger this ligand binds to vanadate at physiological pH (Figure 2, a). Even in the presence of HMS, almost 97% of the total vanadium is bound as $VMa_2^-$ (Figure 2, b). When lowering the total concentration of maltol to 5 mM, more vanadium is bound to transferrin, but still not more than approximately 34% (Figure 2, c). This means that although transferrin binds vanadium very strongly, a considerable fraction of the metal can still be bound to its original carrier if an appropriate ligand is applied. Certainly the ligand needs to be in excess, but it does not have to be at extreme concentrations to be able to effectively compete with the HMS. In contrast, recent findings with vanadium(IV)–bismaltolato complexes suggest that transferrin is capable of

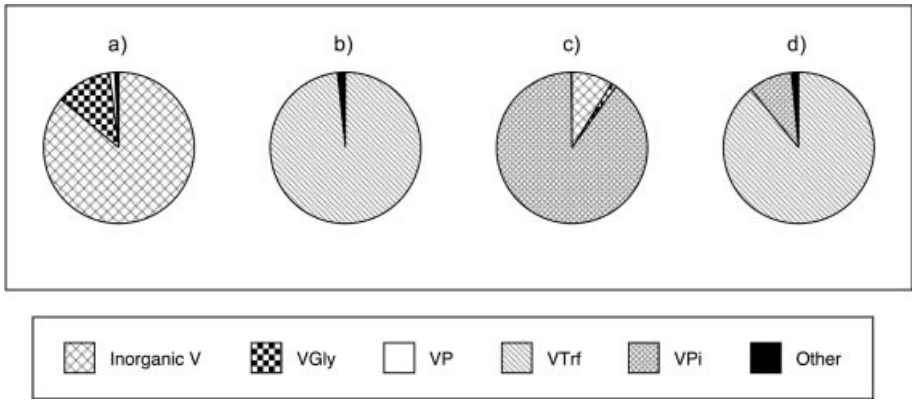

Figure 1. Distribution of vanadate in the presence of different blood constituents at pH = 7.4. $[V]_{tot}$ = 1 μM in all cases, concentrations of the constituents are according to Table 1. HMS is short for the high mass serum constituents, albumin and transferrin. Gly stands for glycine, P for phosphate, Trf for transferrin and Pi for picolinate in the legend. From left to right: (a) No HMS, no Pi (b) No Pi, HMS included (c) No HMS, $[Pi]_{tot}$ = 20 mM (d) $[Pi]_{tot}$ = 20 mM, HMS included.

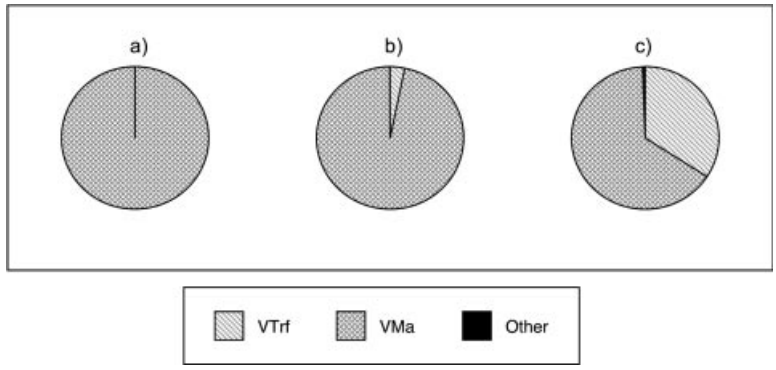

Figure 2. Distribution of vanadate in the presence of blood constituents at pH = 7.4. $[V]_{tot}$ = 1 μM in all cases, concentrations of blood constituents are according to Table 1. HMS is short for high mass serum constituents (albumin and transferrin). Trf stands for transferrin and Ma for maltol in the legend. From left to right: (a) No HMS, $[Ma]_{tot}$ = 20 mM (b) HMS included, $[Ma]_{tot}$ = 20 mM (c) HMS included, $[Ma]_{tot}$ = 5 mM.

replacing the maltol ligand(s) of the introduced complex at certain concentration ratios.[71] However, it is worth noting that vanadium(IV) has a higher affinity to transferrin than does vanadium(V).[56] In other words, vanadium(V) complexes generally have a better chance to avoid ligand replacement by transferrin than the corresponding ones with vanadium(IV). This is especially interesting when comparing the vanadium–bismaltolato complexes in each oxidation state. Vanadium(IV)–maltol (or derivative) complexes have been extensively studied,[61–65] and have shown promising insulin-enhancing properties. However, the corresponding vanadium(V) species seems to be considerably less active in this regard.[72] Why that is so is hard to explain by our speciation model alone, especially when taking into account the ease by which vanadium(V) and (IV) could interconvert under physiological conditions. Our model indicates that vanadium(V) forms very strong complexes with maltol (Figure 2), but says nothing about the kinetic lability of the formed species. A too inert species may effectively remove vanadium from the system by binding it too tightly and thereby prohibiting its interactions with other compounds. Additionally, it could be a charge effect. The bismaltolato complex of vanadium(IV) is neutral, whereas the corresponding vanadium(V) species is –1 charged. This certainly affects the way the complex can enter the cells and might be at least one of the reasons why they show different insulin-enhancing activities.

It has to be mentioned that limitations do apply to the models presented above. First of all, the formation constants used are from different media and a considerable simplification has been made when considering only VTrf but not $V_2$Trf in the model. In addition, mixed ligand vanadate complexes so far have only been determined with lactate and citrate[39] out of all the bioligands shown in Table 1. Although these are extremely weak complexes, others (with phosphate, for instance) might not necessarily be. In addition, recent data on the interactions of the vanadium(IV)–bismaltolato complex with HMS indicated that albumin may take part in the formation of such mixed-ligand complexes (in that case a vanadium(IV)–maltol–albumin species).[71] While no such species have yet been reported with vanadium(V) complexes, their existence cannot be ruled out. Nevertheless, these are not likely to cause major changes in the overall picture, and the model should be valid for all the major features and trends.

## Concluding Remarks

Speciation studies are very useful for the bioinorganic and medicinal chemistry of vanadium compounds in many respects. First of all, they provide insight to the complex formation patterns and preferences of vanadate in the presence of various biologically important or potential drug candidate ligands. This is extremely valuable, since it helps in tailoring the properties of the complex and also casts light on the fate of vanadium in the presence of e.g. blood constituents. In addition, by means of the formation constants obtained from such studies, parameters can be optimised for crystallisation studies or in general to obtain a maximum yield in the synthesis of a given complex. Moreover, physiological conditions can also be modelled (with certain restrictions) to predict what happens to any introduced vanadium compound when it enters e.g. the stomach, bloodstream, etc. Naturally, care must be taken to use the proper ionic medium for the studies (e.g. 0.150 M Na(Cl), to represent the ionic strength of human blood). A series of speciation studies with pentavalent vanadium has been carried out with different blood constituents in this context.[37–39] As incomplete as this series is, it forms a solid base for model calculations aiming to elucidate the fate of vanadate (compounds) in human blood. Although certain limitations apply to the model presented in this paper, the major features should be valid nonetheless, providing a useful overview and practical guidelines.

## Acknowledgments

This work has been supported by the Swedish Research Council and the European Union (COST project D21/009-01). The authors would like to thank the members of the various working groups within the COST framework, especially Prof. Dieter Rehder.

# Pressure-Induced Metal–Semiconductor–Metal Transitions in an MMX-Chain Complex, $Pt_2(C_2H_5CS_2)_4I$

**Atsushi Kobayashi,[a] Aya Tokunaga,[b] Ryuichi Ikeda,[b] Hajime Sagayama,[c] Yusuke Wakabayashi,[c] Hiroshi Sawa,[c] Masato Hedo,[d] Yoshiya Uwatoko,[d] and Hiroshi Kitagawa*[a]**

**Keywords:** Mixed-valent compounds / Conducting materials / MMX chain / Metal–insulator transition / High pressure

The electrical conductivity and X-ray diffraction measurements were performed for a highlyconductive halogen-bridged binuclear-metal mixed-valence complex (the so-called MMX chain), $Pt_2(C_2H_5CS_2)_4I$, under high pressure up to 2.5 GPa. The complex exhibited pressure-induced metal–semiconductor–metal transitions at 0.5 and 2.1 GPa. The X-ray diffuse scatterings were observed at $k = n+0.5$ ($n$: integer) under ambient pressure, which are derived from the charge-density wave (CDW: ···$Pt^{2+}$–$Pt^{2+}$···I–$Pt^{3+}$–$Pt^{3+}$–I···) fluctuation in the MMX chain. Above 0.5 GPa, where the pressure-induced metal–semiconductor transition occurred, these scatterings disappeared. The electronic phases under high pressure ($P$) were found to be attributable to the metallic averaged-valence state (AV: –$Pt^{2.5+}$–$Pt^{2.5+}$–I–$Pt^{2.5+}$–$Pt^{2.5+}$–I–) with CDW fluctuation of $P < 0.5$ GPa, semiconducting charge-polarization state (CP: ···$Pt^{2+}$–$Pt^{3+}$–I···$Pt^{2+}$–$Pt^{3+}$–I···) of $0.5 < P < 2.1$ GPa, and metallic AV state of $P > 2.1$ GPa. The electronic state of $Pt_2(C_2H_5CS_2)_4I$ is very sensitive to pressure, which implies that the phase competition among the CP, CDW, and AV phases is present in the MMX chain.

## Introduction

One-dimensional (1D) halogen-bridged mixed-valence binuclear-metal complexes (MMX chain) have drawn much attention because of their various electronic structures that originate from the internal degree of freedom of charge distribution in metal-dimer units as follows:[1–2]

(1) Averaged-valence (AV) phase
–$M^{2.5+}$–$M^{2.5+}$–X–$M^{2.5+}$–$M^{2.5+}$–X–

(2) Charge-polarization (CP) phase
···$M^{2+}$–$M^{3+}$–X···$M^{2+}$–$M^{3+}$–X···

(3) Charge-density wave (CDW) phase
···$M^{2+}$–$M^{2+}$···X–$M^{3+}$–$M^{3+}$–X···

(4) Alternate-charge-polarization (ACP) phase
···$M^{2+}$–$M^{3+}$–X–$M^{3+}$–$M^{2+}$···X···

$Pt_2(C_2H_5CS_2)_4I$, which is an MMX chain complex as shown in Figure 1, exhibits a high electrical conduction and a metal–insulator (M–I) transition at 205 K.[3] This M–I transition temperature ($T_{MI}$) is relatively lower than typical 1D $d$-electron conductors in comparison with transition-metal complexes such as $K_2Pt(CN)_4Br_{0.3}\cdot nH_2O$ (commonly called KCP(Br); $T_{MI}$ = 250 K at 0 GPa).[4] It was revealed that the electronic state changes variously with decreasing temperature; the AV phase occurs with CDW fluctuation

above 205 K, the CP phase between 160–205 K, and the ACP phase below 160 K.[3,5] This phase competition is derived from the fact that the several interactions, such as the electron transfer integral ($t$), electron correlation (on-site ($U$) and inter-site ($V$) Coulombic repulsive energies), and electron-lattice interaction ($S$) are antagonistic to each other in this complex.[1d,1e,6]

The application of a high pressure to low-dimensional complexes gives rise to a drastic change in their physical properties because of an increase in the electron transfer integral $t$ and a suppression of electron-lattice interaction $S$.[7] For example, $(CH_3)_4N[Ni(dmit)_2]_2$ shows a pressure-induced transition at 0.32 GPa from the normal metallic state to the superconducting state below 3 K.[8] Since the title complex exhibits various electronic states, the application of pressure may create a novel electronic phase. Therefore, we have investigated the electronic state of the MMX-chain complex under high pressure by electrical resistivity and X-ray diffuse scattering measurements.

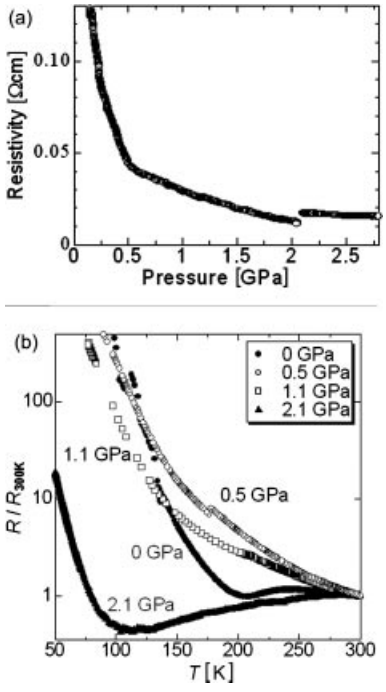

Figure 2. (a) Pressure dependence of the electrical resistivity at 298 K up to 2.5 GPa. (b) Temperature dependence of the electrical resistivity under several pressures (0, 0.5, 1.1 and 2.1 GPa).

## Results and Discussion

Figure 2(a) shows the pressure dependence of the electrical resistivity along the $b$-axis (parallel to the 1D chain) at 298 K. As the pressure is increased, the resistivity decreases rapidly up to 0.5 GPa and gradually between 0.5 and 2.1 GPa. The pressure coefficients of the resistivity below and above 0.5 GPa are –1.8 and –0.16 $GPa^{-1}$, respectively. Above 2.1 GPa, the resistivity is almost constant. The change in the pressure coefficients at 0.5 and 2.1 GPa implies that some phase transitions occur at these pressure points. A small resistance jump observed at 2.1 GPa is due to the resistance hysteresis derived from a cycle of cooling and heating processes in the electrical conductivity measurements.

The temperature dependences of the electrical resistivity at 0, 0.5, 1.1, and 2.1 GPa along the $b$-axis are shown in Figure 2(b). The resistivity is normalized at 300 K. At ambient pressure, $Pt_2(C_2H_5CS_2)_4I$ exhibited metallic conduction ($\approx$ 5 $Scm^{-1}$ at 300 K) and underwent a metal–insulator transition at 205 K, which is consistent with our previous work.[3] As a little pressure was applied, a pressure-induced metal–semiconductor transition occurred at 0.5 GPa; the metallic conduction disappeared and a behavior consistent with a semiconductor was observed in the whole temperature range. This pressure-induced metal–semiconductor transition is in agreement with the discontinuity of the pressure coefficient observed at 0.5 GPa [Figure 2(a)]. The activation energy decreased with applied pressures from 72 meV at 0.5 GPa to 54 meV at 1.1 GPa, which is considered to be due to an increase in the bandwidth $W$ ($\approx 4t$ for 1D electronic system). At 2.1 GPa, metallic behavior was again observed, and an M–I transition occurred at 114 K. This pressure-induced semiconductor–metal transition is also in agreement with the discontinuity of the pressure coefficient observed at 2.1 GPa. Compared with the $T_{MI}$ = 210 K of KCP(Br) under 3.2 GPa,[4d] the transition temperature 114 K is a significantly lower value, which means that the metallic state of $Pt_2(C_2H_5CS_2)_4I$ is very stable as a 1D electronic system.

To clarify the electronic state under high pressure, an X-ray diffraction measurement was performed on a single-crystal with a diamond-anvil cell at room temperature.[8] Figure 3(a) shows the X-ray diffraction photograph taken at 0.1 GPa. Diffuse scatterings were clearly observed at $k = n + 0.5$ ($n$: integer), which corresponds to the CDW fluctuation that exists at ambient pressure as mentioned above. The intensities of the pixels located on the solid-line arrow from A to B in Figure 3(a) are shown in Figure 3(b). These scatterings observed at $k = n + 0.5$ disappeared gradually with increasing pressure, and were hardly observed above 0.5 GPa. The disappearance of these diffuse scatterings indicates that the CDW fluctuation is lost above 0.5 GPa where the pressure coefficient changed, as shown in Figure 2. Since no remarkable change in X-ray diffraction photographs was observed in the pressure region between 0.5 and 2.5 GPa, the superstructures with twofold periodic ordering such as CDW or ACP are absent in the high-pressure range.

In general, the application of high pressure to the complex suppresses the electron-lattice interaction $S$ and increases the electron transfer integral $t$ because of the increase in the elastic energy and the decrease in the interatomic distance. This in turn results in an increase in the conductivity, and the behavior of the complex tends to change from an insulator to a semiconductor or a metallic species.[7] Actually, with pressure the conductivity of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

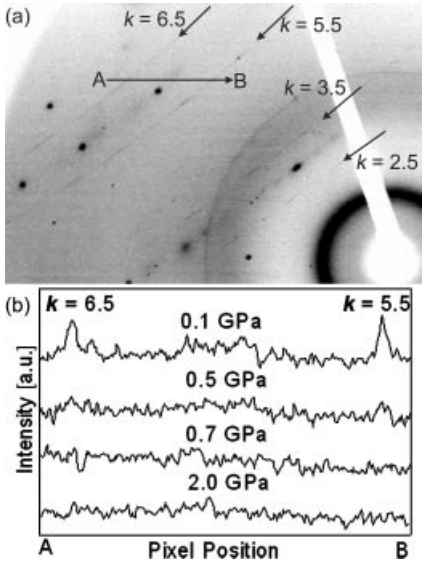

Figure 3. (a) X-ray diffraction photograph under 0.1 GPa at room temperature. (b) Intensity on the solid-line arrow from A to B in Figure 3(a) under several pressures (0.1, 0.5, 0.7 and 2.0 GPa).

$Pt_2(C_2H_5CS_2)_4I$ increased drastically and the CDW fluctuation of ···$Pt^{2+}$–$Pt^{2+}$···I–$Pt^{3+}$–$Pt^{3+}$–I··· was suppressed, which would disturb the itinerancy of the conduction of the electrons. The pressure-induced metal–semiconductor transition was nevertheless observed at 0.5 GPa. Recent theoretical calculations performed by Yamamoto et al. pointed out that the inter-site Coulombic repulsive energy $V$ increases as the interatomic distance is decreased with pressure, and in the case of $V > t$, the CP phase of ···$Pt^{2+}$–$Pt^{3+}$–I···$Pt^{2+}$–$Pt^{3+}$–I··· could be stabilized.[6a,6b] The CP phase can be regarded as a charge-ordered (or charge-localized) state, that is, a Mott insulating state.[9] With the consideration of the absence of any twofold structures, the semiconducting state of the complex in the region of 0.5–2.1 GPa is attributable to the CP phase. Above 2.1 GPa, the metallic phase appeared again in the temperature range of 114–300 K, which would be derived from the AV state of –$Pt^{2.5+}$–$Pt^{2.5+}$–I–$Pt^{2.5+}$–$Pt^{2.5+}$–I– under the delicate competitive condition of $t > V$. No twofold structures were observed, which is not in conflict with the AV state.

In summary, the electrical conductivity and X-ray diffraction measurements under high pressure have been performed for a highly conductive MMX-chain complex, $Pt_2(C_2H_5CS_2)_4I$. Pressure-induced metal–semiconductor–metal transitions were observed at 0.5 and 2.1 GPa, which is considered to be derived from the phase transitions of the metallic AV state with CDW fluctuation to the semiconducting CP state, and from the CP state to the metallic AV state, respectively. The electronic state of $Pt_2(C_2H_5CS_2)_4I$ is very sensitive to pressure, which implies that the phase competition among the CP, CDW, and AV phases is present in the MMX chain. To determine the origin of these metal–semiconductor–metal transitions, theoretical calculations, Raman and IR spectroscopic studies under high pressure, are in progress.

## Experimental Section

**Synthesis:** Single-crystals of $Pt_2(C_2H_5CS_2)_4I$ were prepared according to the literature (see ref.[3a]).

**Electrical Conductivity:** The dc electrical resistivity of $Pt_2(C_2H_5CS_2)_4I$ along the *b*-axis (parallel to the 1D chain) was measured for several single-crystals with the four-probe-method with the use of a clump-cell and a cubic-anvil press system at the ISSP, the University of Tokyo.

**X-ray Diffraction:** X-ray diffraction measurements under high pressure were performed with a diamond-anvil cell at the BL-1B beamline in KEK-PF ($\lambda$ = 0.688 Å). Pressure was calibrated by the ruby luminescence technique.

# Pressure Effect Investigations on the Spin Crossover Systems {Fe[$H_2B(pz)_2]_2$(bipy)} and {Fe[$H_2B(pz)_2]_2$(phen)}

**Ana Galet,[b] Ana Belén Gaspar,[a] Gloria Agusti,[a] M. Carmen Muñoz,[b] Georgii Levchenko,[c] and José Antonio Real*[a]**

**Keywords:** Spin transition / Bistability / Cooperative effects / Pressure / Phase Transitions

Pressure effect studies on the spin crossover behaviour of the mononuclear compounds {Fe[$H_2B(pz)_2]_2$(bipy)}(**1**) and {Fe[$H_2B(pz)_2]_2$(phen)}(**2**) have been performed in the range of $10^5$ Pa–1.02 GPa at variable temperatures (100–310 K). Continuous spin transitions and displacement of its characteristic temperature has been observed for **1** with increasing pressure. Meanwhile the response of **2** under applied pressures is quite unexpected, and can only be understood in terms of a crystallographic phase transition or change in the bulk modulus of the compound.

## Introduction

The ability of spin crossover (SCO) materials to change their magnetic, structural, dielectric and optical properties, induced by a variation of temperature and/or pressure or light, has led to an increase in the interest of their potential use in technological applications. Because of their switching properties, SCO materials are potentially useful for rewritable optical, thermal or pressure memories at a nanometric scale.[1–6]

While thermally induced spin crossover behaviour in $Fe^{II}$ complexes is increasingly common, pressure induce high and low spin (HS and LS) $Fe^{II}$ complexes are scarcely reported in the literature. Systematic and detailed studies related to the concerted action of both temperature and pressure variation on SCO compounds have only recently become possible with the development of special hydrostatic pressure cells in connection with magnetic susceptibility, optical and Mössbauer measurements, EXAFS and vibrational spectroscopy.[7–8] Here we present pressure effect investigations on the magnetic behaviour of {Fe[$H_2B(pz)_2]_2$(bipy)}(**1**) and {Fe[$H_2B(pz)_2]_2$(phen)} (**2**) complexes carried out in the range of $10^5$ Pa–1.2 GPa.

Both **1** and **2** undergo thermal- and light-induced SCO.[9] The thermal spin transition of **2** is more cooperative than that of **1**, as shown by the more abrupt spin transition that takes place with hysteresis (with characteristic temperatures of $T_c\downarrow$ = 165 K and $T_c\uparrow$ = 169 K). Structural data has been previously reported for both the HS and LS states.[10] As illustrated in Figure 1, the structures of **1** and **2** are composed of mononuclear neutral species where the positive charge of the iron(II) ion is neutralized by the coordination of two bidentate dihydrobis(pyrazolyl)borate $[H_2B(pz)_2]^-$ anions; bipy or phen neutral ligands are then used to fill the iron(II) coordination sphere. The molecular structures for both compounds are very similar with Fe–N bond lengths in the 2.212–2.158 Å and 2.007–1.996 Å range for the HS and LS states, respectively. Contrary to **1**, the spin transition of **2** is accompanied by a crystallographic phase transition [*C*2/*c* (HS) and $P\bar{1}$(LS)].[10]

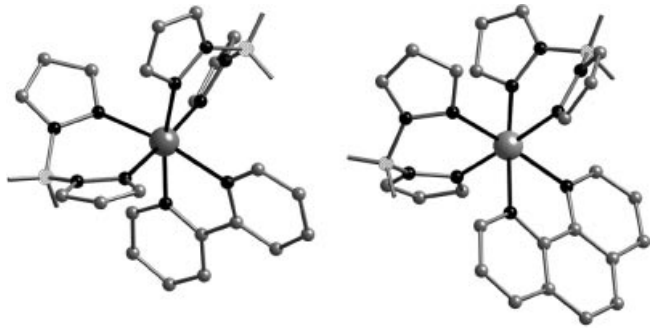

Figure 1. Molecular structure of **1** (left) and **2** (right).

## Results and Discussion

Figure 2 gathers a collection of $\chi_M T$ versus $T$ curves ($\chi_M$ is the molar magnetic susceptibility, and $T$ the temperature) at different hydrostatic pressures for complex **1**. The measurements have been performed at the rate of 1 K·min$^{-1}$ on single-microcrystals. At 300 K and $10^5$ Pa, a $\chi_M T$ value of 3.52 cm$^3$·K·mol$^{-1}$ indicates a S = 2 spin state configuration

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for the iron(II) ions. $\chi_M T$ remains constant down to 220 K, where it progressively diminishes as a consequence of the spin transition to the S = 0 spin state and attains a value of 0.06 $cm^3 \cdot K \cdot mol^{-1}$ at 100 K. The transition is complete and relatively abrupt. The temperature at which the number of molecules in the HS and LS states is equal, $T_{1/2}$, is 160 K. Application of pressures as high as 0.26 GPa have a strong effect on the $T_{1/2}$ value and shifts it upwards to 210 K. At this pressure, the $\chi_M T$ value at 300 K is slightly lower than that observed at atmospheric pressure which indicates that a small amount of molecules are in the LS state (300 K: 3.42 $cm^3 \cdot K \cdot mol^{-1}$, 97% HS molecules). An increase in the pressure up to 0.4 and 0.5 Gpa results in a displacement of $T_{1/2}$ to 233 K and 255 K, respectively. At room temperature, the $\chi_M T$ value at these two last pressures also decreases to 3.23 $cm^3 \cdot K \cdot mol^{-1}$ and 3.12 $cm^3 \cdot K \cdot mol^{-1}$, respectively.

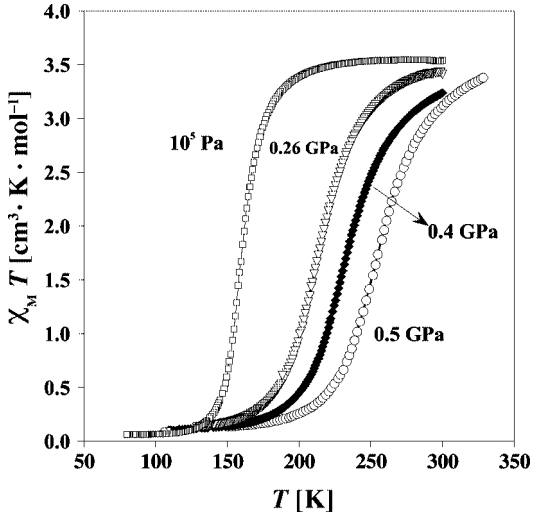

Figure 2. Thermal dependence of $\chi_M T$ at different pressures for **1**.

It is worth mentioning the remarkable continuous character of the spin transition as pressure is increased. The spin crossover takes place in temperature intervals of 150 K, whereas at $10^5$ Pa the spin crossover occurs within 70 K. Also, the linear pressure dependence of $T_{1/2}$ for **1** should be noted. The slope of the line in the $T_{1/2}$ versus $P$ plot, $dT_{1/2}/dP$ = 187.5 $K \cdot GPa^{-1}$ (Figure 4), is in the range of values observed for several mononuclear compounds such as $[Fe(abpt)_2(NCS)_2]$ polymorph B,[11] $[Fe(phen)_2(NCS)_2]$ polymorph II,[12] $[Fe(dpa)_2(NCS)_2]$[13] and $[Fe(pic)_3]Cl_2 \cdot EtOH$[14] (Table 1).

Table 1. $dT_{1/2}/dP$ in $K \cdot GPa^{-1}$.

| | |
|---|---|
| $[Fe(abpt)_2(NCS)_2]$ | 176 |
| $[Fe(phen)_2(NCS)_2]$ polymorph II | 220 |
| $[Fe(dpa)_2(NCS)_2]$ | 187.5 |
| $[Fe(pic)_3]Cl_2 \cdot EtOH$ | 150 |

Figure 3 shows the thermal dependence of **2** for $\chi_M T$ at different pressures. As for **1**, the measurements have been performed on single-microcrystals in the cooling and warming modes at a rate of 1 $K \cdot min^{-1}$. At 300 K and atmospheric pressure, the $\chi_M T$ value is 3.60 $cm^3 \cdot K \cdot mol^{-1}$, which indicates a HS configuration of the iron(II) ions. This value remains virtually constant up to the point of the spin transition, which takes place abruptly at $T_c\downarrow$ = 165 K and $T_c\uparrow$ = 169 K. The application of a hydrostatic pressure of 0.19 GPa dramatically influences the spin crossover behaviour of **2** particularly in the width of the hysteresis loop. Indeed, $\Delta T_c$ is equal to 20 K. Meanwhile, at atmospheric pressure $\Delta T_c$ is only 4 K. At 0.19 GPa, the critical temperature for the cooling mode is $T_c\downarrow$ = 169 K and for the warming mode it is $T_c\uparrow$ = 189 K. Another remarkable fact is the decrease in the abruptness of the spin transition in the cooling mode. This is in contrast to the transition in the warming mode, which remains steep. A further increase in the pressure up to 0.33 GPa results in a considerable shift of the spin transition to higher temperatures, $T_c\downarrow$ = 238 K and $T_c\uparrow$ = 240 K, with the hysteresis width being very narrow. A complete transformation to a second order phase transition occurs at 0.55 GPa, where $T_{1/2}$ is approximately 270 K. At 1.02 GPa, almost all of the molecules are in the LS state at room temperature. Reversibility of these measurements was checked after a complete relaxation of the pressure because the magnetic behaviour of **2** at $10^5$ Pa was perfectly reproducible. Moreover, the magnetic behaviour of **2** in the range of $10^5$ Pa–1.02 GPa was investigated in two independent experiments, and the exact same results were obtained.

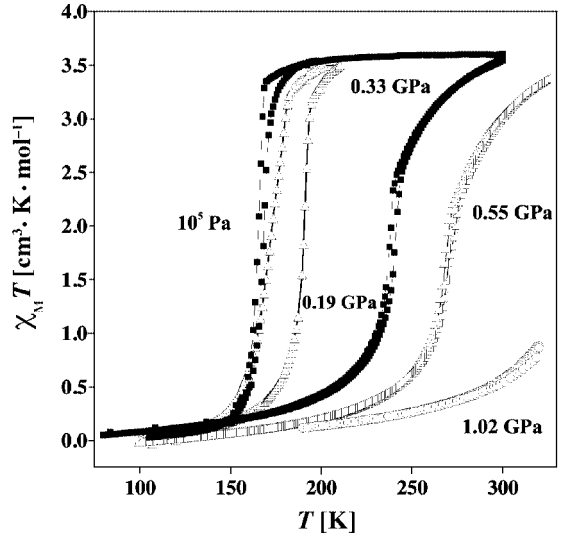

Figure 3. Thermal dependence of $\chi_M T$ at different pressures for **2**.

Figure 4 displays the pressure dependence of the average $T_c^{av}$ values calculated as $T_c^{av} = (T_c^{down} + T_c^{up})/2$ for **2**. As it can be seen, there is a strong nonlinearity in the case of compound **2** that contrasts the almost linear dependence observed for **1**. This is an unexpected result in view of the fact that the mean field theory of phase transitions in SCO compounds predicts a decrease in the hysteresis width and in the slope of the transition curve with an increase in the pressure. The hysteresis vanishes at a critical pressure, and at even higher pressures the transition transforms into a second order continuous phase transition.[7,8,15] However, there are several SCO systems in which the effect of pres-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sure on the SCO behaviour cannot be adequately described by this theory. Occurrence of structural phase transitions and/or a change in the bulk modulus of the materials under the applied pressure has been proposed for the observed anomalous behaviour (e.g. increase in the hysteresis width, nonlinear behaviour of $T_c(P)$ versus $P$).[5,7,8,16]

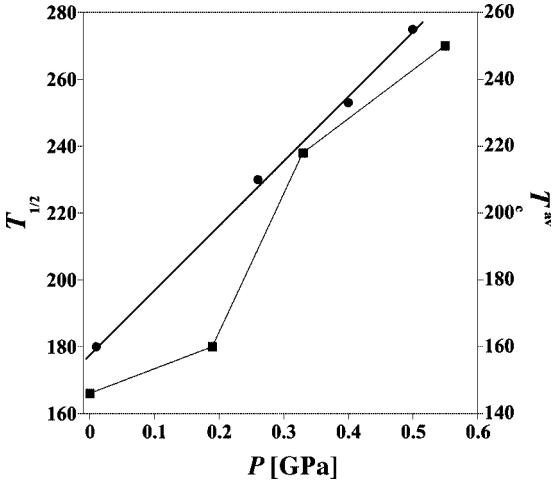

Figure 4. $T_{1/2}$ versus $P$ plots for **1** (filled circles) and $T_{av}$ versus $P$ plot for **2** (filled squares). The straight line corresponds to the linear fit for **1**.

As mentioned above, the crystallographic phase transition that involves the space group change $C2/c$ (HS) ↔ $P\bar{1}$(LS) takes place concomitantly with the thermally induced HS ↔ LS spin transition in **2**. The response of **2** under the applied pressures increases the hysteresis width at 0.19 GPa, and the nonlinear behaviour of $T_{1/2}$ versus $P$ could be due to the occurrence of a crystallographic phase transition under these applied pressures. The unexpected pressure effects will be understood from the crystal structure determination under applied pressure and, of course, at variable temperature.

## Experimental Section

**Synthesis of 1 and 2:** Single-crystals of both compounds were obtained as discussed previously in the literature.[9]

**Magnetic Susceptibility Measurements Under Hydrostatic Pressure:** The variable-temperature magnetic susceptibility measurements were performed on small single-crystals with a Quantum Design MPMS2 SQUID susceptometer equipped with a 5.5 T magnet and operated at 1 T and 1.8–375 K. The hydrostatic pressure cell was made of hardened beryllium bronze with silicon oil as the pressure-transmitting medium, and was operated in the pressures range $10^5$ Pa–1.2 GPa (accuracy $\approx \pm 0.025$ GPa). Cylindrically shaped powder sample holders with dimensions of 1 mm in diameter and 5–7 mm in length were used. The pressure dependence of the superconducting transition temperature of the built-in pressure sensor, which is made of high purity tin, was used to measure the pressure.[17] Experimental data were corrected for diamagnetism with Pascal's constants.

# Characterization and Insulin-Mimetic Potential of Oxidovanadium(IV) Complexes Derived from Monoesters and -carboxylates of 2,5-Dipicolinic Acid

**Jessica Gätjens,*[a][‡] Beate Meier[b] Yusuke Adachi,[c] Hiromu Sakurai,[c] and Dieter Rehder[a]**

**Keywords:** Vanadium / N,O Ligands / Picolinates / Insulin mimesis

The monomethyl ester 2MeOdipicH (**1**) of 2,5-dipicolinic acid, characterized as its magnesium salt $[Mg(H_2O)_6](2MeOdipic)_2$, was converted, via the diesters 2MeO-5ROdipic and the copper complexes $[Cu(5ROdipic)_2]$, to the ligands 5ROdipicH (R = *i*Pr **2a**, (*S*)-2-Bu **2b**). The proligands 2MeO-5ROdipic (with R = diisopropyl-D-galactose **2c**, *myo*-inositol-orthoformate **2d**) and 2MeO-5R′NHdipic (where R′ represents the ethyl-protected L-amino acid residues Gly **3a**, Ala **3b**, Val **3c** and Phe **3d**) were obtained from 2-MeO-5Cldipic and the amino acid ethyl esters. Reaction of **2** and **3** with $VOSO_4$ afforded the complexes $[VO(H_2O)(5ROdipic)_2]$ (**4a–d**) and $[VO(H_2O)(5R'NHdipic)_2]$, **5a–d**, respectively. $[Mg(H_2O)_6](2MeOdipic)_2{\cdot}4H_2O$, **2b**, **3a** and **4a**$\cdot 0.5H_2O$ were characterized by single-crystal X-ray diffraction analysis. Selected type **4** and **5** complexes were submitted to in vitro tests (fibroblasts, SV 3T3 mice fibroblasts) for their uptake kinetics and insulin-mimetic behavior. The compounds were comparable to insulin in their ability to stimulate cellular glucose uptake and metabolism. In vitro tests with rat adipocytes showed that the complexes also mimic the ability of insulin to inhibit lipolysis.

## Introduction

During the last two decades, in vitro and in vivo studies have demonstrated the potential of many vanadium compounds as insulin-mimetic (or insulin-enhancing) agents.[1–3] Among those which have been shown to be effective are bis(maltolato)oxidovanadium complexes,[4a] which successfully passed clinical tests phase I,[4b] $[VO(pic)_2]$ which normalizes serum glucose and fatty acid levels in rats with streptozotozin-induced diabetes type 1,[5] and $[VO_2(H_2O)(2,6\text{-dipic})]^-$, which had beneficial effects in cats suffering from diabetes type 2.[6] Picolinato complexes of vanadium appear to be generally effective,[7] the extent, however, to which they actually mimic the involvement of insulin in the glucose and lipid metabolisms is subject to variations in the coordination periphery. We have recently shown that the methyl ester derivative $[VO(H_2O)(5MeOdipic)_2]$, where 5MeOdipic is the monomethyl ester of 2,5-dipicolinate, is clearly more effective than the corresponding ethyl ester both in the ability to trigger cellular glucose uptake (and metabolism) and to inhibit lipolysis.[8] These differences in impact correlate with the net amount of vanadium taken up by the cells, possibly indicative for a balanced hydro/lipophilicity being a key factor in efficacy.

An apparent advantage of vanadium complexes in the treatment of *diabetes mellitus* type 1 (lacking insulin production) and type 2 (tolerance/resistance against insulin) is their application per os, and the possibility to design the compounds so as to provide minimal toxicity and optimal efficiency along with stability against redox- and hydrolytic break-down. The compound has to survive the acidic conditions pertinent to the stomach (pH typically around 2), as well as the slightly alkaline conditions in the small intestines (pH 7–8) and the blood stream (pH 7.35). It has to resist to a certain extent competing ligands such as the plasma constituents citrate, phosphate and transferrin in order to preserve the information implanted by the specific properties of the ligands used in the synthesis of the potential drug. The complex should be easily absorbed in the gastrointestinal tract, transported by the blood stream at least partly intact, and traffic across the cell membrane. Oxidovanadium complexes carrying monoesters of 2,5-dipicolinic acid as ligands have been shown to fulfil several of these conditions.[8] Picolinates are natural metabolites; toxicity by degradation of the complexes thus will be minimized. In order to improve the trans-membrane transport, a fine-tuning of the hydro/lipophilicity by choosing the "correct" sub-

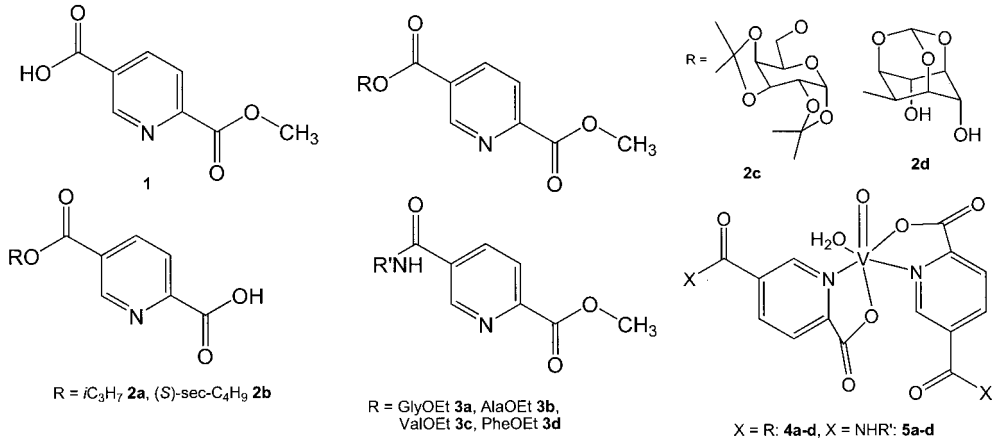

Scheme 1.

stituents in the ligand periphery is one option. A second option is to attach groups to the periphery for which membrane receptors exist and which can thus be recognized by the cell. Following these concepts, we have extended earlier investigations on picolinates to galactose and inositol derivatives on the one hand, and carboxamides derived from amino acids on the other hand. Scheme 1 gives an overview of the types of compounds discussed in the present work. Along with the vanadium complexes and their in vitro insulin-mimetic properties, structural features of ligands and ligand precursors will be described.

## Results and Discussion

### Synthesis, Characterization and Structure Determination

The syntheses of the ligands **2a**–**b** followed the route depicted in Scheme 2. 6-(Methoxycarbonyl)pyridine-3-carboxylic acid (**1**) was converted into the corresponding acyl chloride by reaction with thionyl chloride. Addition of a solution of the acid chloride in toluene to a solution of the alcohol ROH (R = *i*Pr, (*S*)-*s*Bu, in 1.4 fold excess) in pyridine yielded the mixed diesters 2MeO-5ROdipic, which were converted via the copper complexes [Cu(5ROdipic)$_2$] into the acids 5ROdipicH, **2a**–**b**. For the structure of the anion of **1**, **1**H$_{-1}$, see below.

Single crystals of **2b** were grown from aqueous acetone solution. **2b** crystallizes in the monoclinic space group $P2_1$. Bond lengths and angles are in the expected range (Table 1). The molecular structure and a picture showing the hydrogen-bonding network are displayed in Figure 1. The molecules are linked through OH···N hydrogen bonds, comparable to the features exhibited by other members of this family of dipicolinic acid derivatives.[8]

The proligands **2c**–**d** were synthesized in analogy to the ligands **2a**–**b**, with the modification that equimolar amounts of acyl chloride and alcohol were reacted. The deprotection step via the copper complexes was omitted. The cleavage of the methyl ester group occurred in situ under the conditions chosen for the synthesis of the vanadium complexes and concomitantly with the coordination of the carboxylate function to vanadium.

For the syntheses of the amino acid derivatives **3a**–**d**, cf. Scheme 2, a solution of the acyl chloride in dichloromethane was treated with a solution containing the amino acid ethyl ester hydrochloride and triethylamine in $CH_2Cl_2$,

which led to the formation of the desired products in good yields. The compounds were characterized by the standard spectroscopic and spectrometric methods. In the case of the glycine ethyl ester derivative **3a**, colorless single crystals were grown from dichloromethane/hexane at room temperature. **3a** crystallizes in the monoclinic space group $P2_1/c$. The molecular structure is shown in Figure 2. Bond lengths and angles are in the expected range (Table 1).

The magnesium salt of **1**, $[Mg(H_2O)_6](\mathbf{1}H_{-1})_2 \cdot 4H_2O$, was isolated in low yields as a by-product of the synthesis of the amino acid derivatives and characterized by IR and $^1H$ NMR spectroscopy. The magnesium apparently stemmed from $MgSO_4$ employed as a drying agent for the solvents. Single crystals grew from a methanolic solution by slow evaporation of the solvent. The compound crystallizes in the monoclinic space group $P2_1/c$ with two independent molecules in the asymmetric unit. The magnesium cation is octahedrally coordinated by six water ligands. The molecular structure is depicted in Figure 3, bonding parameters are contained in Table 2. There are hydrogen bonds between the waters of crystallization O8 and O9 (2.74 Å), O8 and the pyridine-N (2.83 Å), and O9 and water coordinated to $Mg^{2+}$ (2.79 Å).

Following a procedure described previously,[8] the vanadium(IV) complexes **4a**–**b** were isolated from the reaction of vanadyl sulfate and the acids **2a**–**b** as green microcrystalline powders. Green single crystals of compound $\mathbf{4a} \cdot 0.5H_2O$ were obtained from a hot aqueous solution on slow cooling.

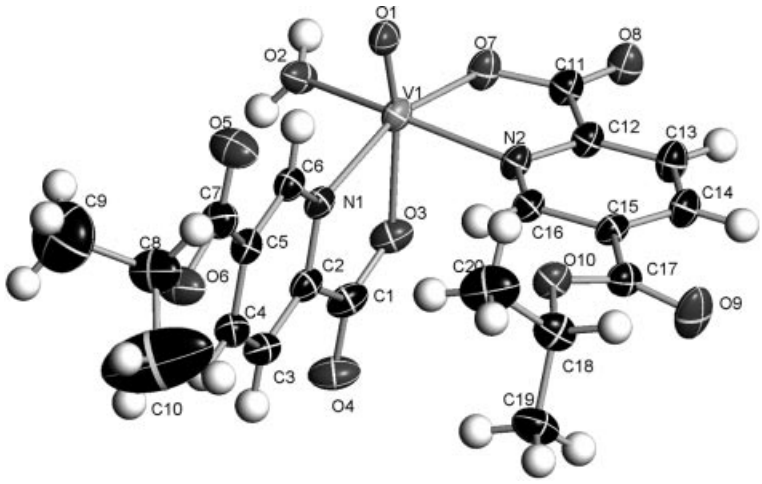

Figure 4. XSHELL plot of **4a** (50% probability level). Only one of the two independent molecules, containing one of the *i*Pr substituents in a disordered state, is shown. Water of crystallization omitted. Selected bonding parameters: V1–O1 1.5989(14), V1–O2 2.0175(14), V1–O3 1.1290(15), V1–O7 1.9890(15), V1–N1 2.1503(17), V1–N2 2.1072(16) Å; O1–V1–O3 164.55(7), O2–V1–N2 164.62(7), O7–V1–N1 161.62(6)°.

crystallization, disordered over two positions, in the asymmetric unit. Two ligands coordinate in the expected bidentate manner to form, together with an aqua ligand (O2) in the equatorial plane and an oxo ligand (O1) in the apical position, a distorted octahedron, Figure 4. The oxygen O3 of one of the carboxylato groups occupies the axial position *trans* to the oxo ligand, leading to the rather long V1–O3 distance 2.1290(15) Å due to the *trans* influence of the doubly bonded oxygen. The isopropyl group of one of the ligands is disordered over two positions (1:1) in one of the two independent molecules. The bonding parameters for the coordinated ligand anion are the same within the error limits as in the free ligand **2a** (Table 1). The water of crystallization is in hydrogen-bonding contact with the carboxylate oxygens O4 (2.79 Å) and O3 (2.83 Å).

For the synthesis of the vanadium(IV) complexes **4c**–**d** and **5a**–**d**, an aqueous solution of vanadylsulfate was mixed with a solution of the proligand and sodium acetate in THF/water and heated to reflux for 6 h. Under these conditions, the deprotection of the 2-position of the ligand precursor and the subsequent formation of the desired vanadium complex took place. The resulting dark green solution was evaporated to dryness. Recrystallization from THF yielded complexes **4c**–**d** and **5a**–**d** as green solids. All analyses confirmed the coordination of two ligand molecules to the metal center plus a solvent molecule, commonly water; cf. Scheme 1 and **4a** in Figure 4.

### Insulin-Mimetic Tests

The biological tests with regard to glucose uptake and metabolism were carried out with a modified (see below) MTT reduction assay using Simian virus transformed mice fibroblasts as described earlier.[16] In this assay, yellow soluble MTT is reduced to insoluble formazan blue by reduction equivalents generated by the metabolism of glucose by the mitochondrial respiratory chain. The amount of formazan blue is determined photometrically and correlates with the ability of either insulin or the vanadium compound to stimulate cellular glucose uptake and metabolism by the cells. The cells were grown to sub-confluency, and incubated in insulin-free medium for 24 h in order to minimize effects other than those imparted by the vanadium compound. This procedure was followed by 3 h incubation with the medium supplemented with the vanadium compound. This modified MTT test has previously been verified using D-[C6–$^3$H]glucose.[16] In order to determine the time dependent effect, a sample was taken every 15–30 minutes. Compounds included in this study are **4c**, **5a**, **5c**, **5d**, $VOSO_4$, and [VO(5MeOdipic)$_2$], the insulin-mimetic activity of which has been established earlier, and which proved most effective among the alkyl derivatives [VO(5ROdipic)$_2$].[8] The amino acid derivative with alanine, **5b**, displayed a behavior similar to the glycine derivative **5a**.

Figure 5 shows the absorbance for different concentrations of the vanadium compounds relative to a control group (without vanadium or insulin), and cells incubated with insulin instead of the vanadium compound. The data after 60 minutes incubation time are shown. During this time, about 90% of the overall effect is observed (see below). Except for the glycine derivative **5a**, all compounds exhibit insulin-mimetic properties in the concentration range (1 μM $\leq c \leq$ 200 μM) tested. The most promising results are those for the phenylalanine derivative **5d**, showing comparable stimulation of glucose uptake and metabolism as insulin. Particularly noteworthy is the fact that even at rather low concentrations ($c <$ 10 μM) the vanadium complexes are still active (Figure 5).

The time-dependent effect of compounds **4c** and **5a**, [VO(5MeOdipic)$_2$] and [VO(pic)$_2$] is shown in Figure 6. At an intermediate vanadium concentration of $c$ = 40 μM the maximum level of activity is reached after an incubation time of approximately 90 minutes. Similar results have been found for other concentrations and other complexes. The

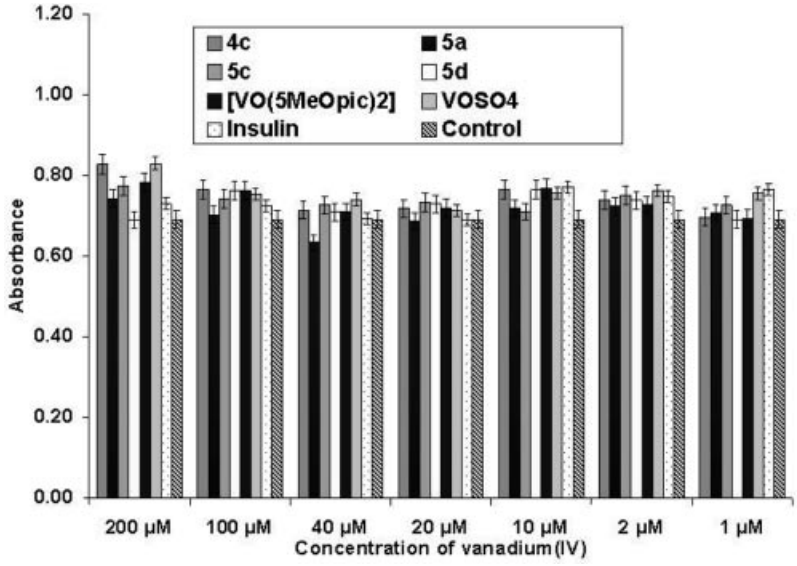

Figure 5. Glucose uptake stimulated by the vanadium picolinates **4c**, **5a**, **5c** and **5d** after 60 min. The absorbance, shown relative to a control group, reflects the efficacy of the compounds. The diagram also shows the data for $[VO(5MeOdipic)_2]$, $VOSO_4$, and a group of cells where insulin was added instead of vanadium.

time dependence in activity for the compounds apparently is not as significant as one might expect when considering the differences in the ligand spheres. Further, Figure 6 clearly shows that the galactose derivative **4c** exhibits, at this specific concentration, an insulin-mimetic activity comparable to the well established efficiency of $[VO(pic)_2]$[5] and $[VO(5MeOdipic)_2]$.[8] The time dependent insulin-mimetic effect of **4c** at different concentrations reveals that the maximum level of activity at high concentrations ($c$ = 400 µM and 200 µM) is already reached after an incubation time of approx. 45 minutes, cf. Figure 7. In this respect, **4c** is unique, since all of the other compounds considered in this study displayed the highest activity after 60 to 90 minutes, even at high concentrations (not shown). Furthermore, the effect promoted by **4c** at $c$ = 400 µM and 200 µM is significantly higher than the activity of insulin itself.

Testing of compounds **4c** and **5a**–**c** with respect to their ability to inhibit lipolysis in rat adipocytes required the presence of 1 mM ascorbic acid as a reducing agent. In the absence of ascorbic acid, aerial oxidation ($^{51}V$ NMR evidence) in the Krebs–Ringer buffer to species of low activity occurred. Figure 8 shows the effects on the release of free fatty acids (FFA) by $[V^{IV}O(pic)_2]$, the four vanadium(IV) complexes **4c** and **5a**–**c**, and the two dioxidovanadium(V) complexes $K[VO_2(pic)_2]$ and $K[VO_2(2,5dipic)_2]$. All of the compounds show an inhibitory effect with respect to the control C (epinephrine [= adrenalin], which works as an effective antagonist to insulin), an effect which increases as concentration is increased from 0.1 to 1 mM. The results obtained with insulin (B in Figure 8) are not quite reached. There is no sizeable difference in efficiency between the neutral oxidovanadium(IV) and the anionic dioxidovanadi-

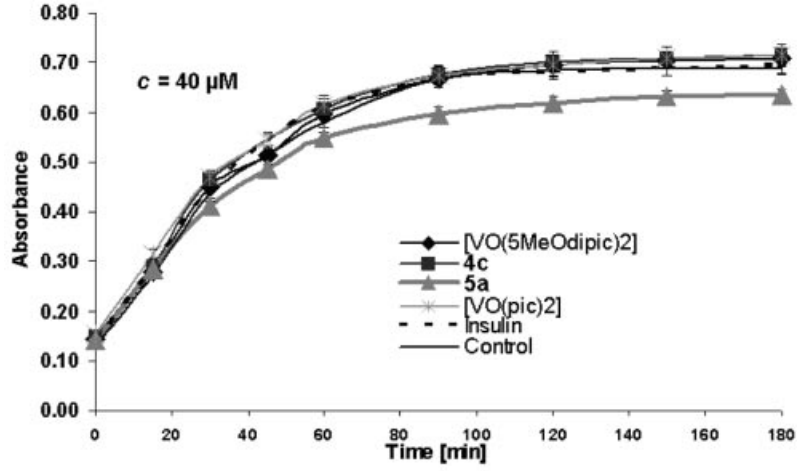

Figure 6. Glucose uptake stimulated by **4c** and **5a** ($c$ = 40 µM) presented as a function of time. This diagram also includes the results for $[VO(pic)_2]$, $[VO(5MeOdipic)_2]$ and insulin. Data are not corrected for background.

um(V) compounds, nor between the different picolinate derivatives. The ligands themselves did not show any appreciable activity (data not shown).

## Conclusions

In extension of earlier work,[8] we have introduced here a new concept for the design of potentially insulin-mimetic vanadium(IV) compounds. The framework represented by pyridine-2,5-dicarboxylic acid was extended by introducing, into the 5-position, organic molecules into the ligand sphere for which membrane receptors exist and/or which modify the hydro/lipophilicity of the dipicolinatovanadium complexes. Here, we have employed amino acids, galactose and inositol residues, along with alkyl derivatives for comparison. Selected compounds were subjected to in vitro studies of their ability to stimulate glucose uptake and oxidative degradation by modified fibroblasts on the one hand, and to inhibit lipolysis by adipocytes on the other hand. Except for the glycine and L-alanine derivatives, all compounds were effective insulin-mimetics in the glucose uptake experiments in the concentration range 200 to 1 µM. The galactose containing complex initiated an earlier saturation of glucose uptake in the time-dependent studies than other compounds, which can be interpreted in terms of a faster uptake of the galactosyl complex by the cells. All of the complexes also showed insulin-mimetic activity in the inhibition of li-

polysis, in particular at relatively high concentrations of 1 mM.

## Experimental Section

**General and Chemicals:** All preparations of vanadium complexes in the oxidation state +IV were carried out under nitrogen atmosphere, using Schlenk techniques. For further handling of the complexes, Schlenk techniques were dispensable. Chemicals were obtained from Merck, Aldrich and Fluka and used without further purification unless stated otherwise. Solvents were dried and purified by standard procedures. Tetrahydrofuran (THF) was dried and deoxygenated by refluxing for at least three hours over $LiAlH_4$ and distilled in an $N_2$ stream. Triethylamine was distilled (88–90 °C) and stored over molecular sieves (4 Å). Dichloromethane was refluxed for 24 h over calcium hydride. Toluene was refluxed for 24 h over sodium and then distilled in an $N_2$ stream. Pyridine ($H_2O \leq 0.005\%$) was stored over molecular sieve. Deionized water was degassed before use. Products were dried at room temperature under vacuum and stored under $N_2$. The following compounds were prepared according to published procedures: 6-(methoxycarbonyl)-pyridine-3-carboxylic acid (**1**),[9] methyl 5-(chlorocarbonyl)pyridine-2-carboxylate,[10] *myo*-inositol-orthoformate,[11,12] 1,2:3,4-di-*O*-isopropylidene-*α*-D-galactose,[13] [VO(pic)$_2$],[14]K[$VO_2$(pic)$_2$],[14] K[$VO_2$(2,5dipic)].[15]

**Analyses and Methods:** Elemental analyses were carried out in the Analytical Laboratory of the Chemistry Department, University of Hamburg. Infrared spectra were recorded as KBr pellets on a Perkin–Elmer 1720 FT–IR spectrometer. NMR spectra were obtained either on a Varian Gemini 200 BB or a Bruker Avance 400 spectrometer at room temperature in 5 mm tubes. Chemical shifts $\delta$ are reported in ppm (parts per million) relative to TMS for $^1H$ and $^{13}C$ NMR spectra. Coupling constants ($J$) are quoted in Hertz. Mass spectrometry was carried out at the Institute of Organic Chemistry, University of Hamburg, with the usual spectrometer settings on a Varian MAT 311A (70 eV, EI) or a VG Analytical 70–250 S (FAB). EPR spectra of **4a**–**d** and **5a**–**d** were scanned at ca. 9.6 GHz (X-band) on a Bruker ESP-300 E spectrometer at room temperature and 100 K. Parameter adaptations by simulation were achieved by using the Bruker software SimFonia. X-ray structure analyses were carried out at 153(2) K using Mo-$K_\alpha$ irradiation ($\lambda$ = 0.71073 Å, graphite monochromator) on a Smart Apex CCD diffractometer. Hydrogen atoms were usually found, and otherwise calculated into idealized positions and included in the last cycles of refinement. Absorption corrections were carried out by SADABS. Structure solution and refinement were carried out using the SHELXTL-Plus software package (G. M. Sheldrick, Version 5.1, Bruker AXS, 1998). For crystal data and structure refinement see Table 2.

CCDC-22102, -285853, -225187, and -257605 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Insulin-Mimetic Tests:** Tests for the glucose uptake activity were based on the MTT (MTT = 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide) reduction assay.[16] The cells were cultured in glucose-rich DMEM medium (Dulbecco's modification of Eagle's medium) supplemented with 10% fetal calf serum at 37 °C/5% $CO_2$ to subconfluency. Afterwards, the cells were passed to an insulin-free, DMEM high glucose medium for 24 h. For the MTT tests, DMEM (without phenol red) supplemented with MTT (Sigma; 0.5 g/L) and solutions of the vanadium complexes in different concentrations were added to the cells and incubated for up to 3 h at 37 °C in a 5% $CO_2$ atmosphere. The cells were separated from the medium and the reaction was stopped by addition of 0.1 M HCl in 2-propanol. The insoluble dye was extracted by HCl/2-propanol, and the amount of formazan blue formed by reduction of MTT was measured at 570 nm in a multi-well reader (SLT 340 ATC). All measurements were carried out in triplicate; standard deviations for the absorbances typically amount to 4 ± 2%.

Tests for the inhibition of free fatty acid (FFA) release were performed on epidymal fat pads, excised from male Wistar rats (7 weeks) anesthetized with diethyl ether. The pads were cut into appropriately sized pieces and were incubated with collagenase in KRB buffer (Krebs–Ringer hydrogen carbonate buffer; 120 mM NaCl, 1.27 mM $CaCl_2$, 1.2 mM $MgSO_4$, 4.75 mM KCl, 1.2 mM $KH_2PO_4$, and 24 mM $NaHCO_3$; pH 7.4) containing 2% BSA at 37 °C with gentle shaking at 100 cycle/min for 1 h. At the end of the incubation period, the prepared cells were filtered through sterilized cotton gauze and washed three times with the KRB buffer. The cells were incubated at 37 °C for 30 min with the vanadium complexes, dissolved in DMSO, at various concentrations (0.1–1.0 mM), including 1 mM ascorbic acid to prevent their oxidations in KRB buffer containing 2% DMSO. A 10 μM solution of epinephrine was then added to the reaction mixtures, and the resulting solutions were incubated at 37 °C for 3 h. The mixtures were centrifuged at 3000 rpm for 10 min at 4 °C. On the outer solution of the cells, the FFA level was determined with a FFA kit (NEFA C test; Wako, Osaka, Japan).

All animal experiments in the present study were approved by the Experimental Animal Research Committee of Kyoto Pharmaceutical University (KPU), and were performed according to the Guideline for Animal Experimentation of the KPU.

**Synthesis and Characterization**

For the NMR assignments, the numbering of the ring-H and -C atoms follows the usual one. C1 and C7 refer to the carboxylic carbons in the ring positions 2 and 5, respectively.

**[$Mg(H_2O)_6$](1H$_{-1}$)$_2$:** This compound was obtained in low yields as a by-product during the syntheses of the amino acid derivatives **3a**–**d** (see below). Single crystals were grown by slow evaporation of a methanolic solution. IR (KBr) $\tilde{\nu}$ = 3114, 3075 (ar. C–H); 2955, 2924, 2851 (C–H); 1730 (sh), 1708 (C=O); 1636, 1605, 1561 (C=C), (C=N); 1479, 1439, 1391, 1324 (C–H); 1287, 1258 (C=C), (C=N); 1158, 1122, 1072, 1030, 1005 (C–O–C); 818 (ar. C–H), ν(C–$CO_2$); 746 (ar. C–H) cm$^{-1}$. $^1H$ NMR (400 MHz, $CD_3OD$/TMS): $\delta$ = 9.19 (m, 1 H, H-2), 8.47–8.45 (m, 1 H, H-4), 8.18–8.16 (m, 1 H, H-5), 3.98 (s, 3 H, H-1) ppm.

**General Procedure for the Syntheses of the Ligands 2a–b:** To a solution of methyl 5-(chlorocarbonyl)pyridine-2-carboxylate (1.5 g, 7.56 mmol) in toluene (5 mL) was added dropwise and with cooling a 1.4 fold excess of the alcohol in pyridine (15 mL). After the addition of a catalytic amount of 4-(dimethylamino)pyridine, the resulting dark solution was stirred overnight at room temperature. The solvent was evaporated and the residue dissolved in water. The aqueous solution was extracted with dichloromethane (5 × 30 mL). The organic layer was dried with $Na_2SO_4$ and the solvent evaporated. Purification was carried out using column chromatography on silica gel, elutant ethyl acetate/*n*-hexane, 1:1, to give a light yellow solid (yield 59–65%) which was treated with an equimolar amount of $Cu(NO_3)_2 \cdot 3H_2O$, followed by treatment with hydrogen sulfide as has been described earlier[8] to produce the ligands as white solids in yields of 50–85%.

**5-(Isopropyloxycarbonyl)-2-pyridinecarboxylic Acid (2a):** Yield 44% (0.69 g). $C_{10}H_{11}NO_4$ (209.20): calcd. C 57.41, H 5.30, N 6.70; found

**Preparation of the Galactose/Inositol Derivatives 2c, 2d:** To a solution of methyl 5-(chlorocarbonyl)pyridine-2-carboxylate (600 mg, 3.0 mmol) in toluene (10 mL) in an ice bath was added a solution of the corresponding alcohol (3.0 mmol) in pyridine (15 mL). After addition of a catalytic amount of 4-(dimethylamino)pyridine, the resulting solution was stirred for 12 h at room temperature. The solvent was evaporated and the residue extracted with toluene (10 mL), followed by dichloromethane (10 mL). The galactose derivative was dissolved in 1-butanol and the organic phase washed with water and a diluted solution of $Na_2CO_3$. The organic layer was dried with $MgSO_4$ and the solvent was evaporated to yield a yellow oil. The inositol derivative was dissolved in water and the aqueous phase was extracted with ethyl acetate. The organic layer was dried with $MgSO_4$ and the solvent was evaporated to yield a light yellow solid.

**2MeO-5GalOdipic (2c):** Yield 89% (0.98 g). $C_{20}H_{25}NO_9{\cdot}2H_2O{\cdot}0.5(C_4H_{10}O)$ (496.51): calcd. C 53.22, H 6.90, N 2.82; found C 53.56, H 6.52, N 2.66. **General Procedure for Compounds (2MeO-5R′NHdipic) 3a–d:** To a solution of the L-amino acid ethyl ester hydrochloride (5.0 mmol) in dichloromethane (10 mL) was added triethylamine (1.52 mL, 1.11 g, 11.0 mmol). The resulting mixture was stirred for 5 minutes (sometimes formation of a white precipitate was observed). Then a solution of methyl 5-(chlorocarbonyl)pyridine-2-carboxylate (1.0 g, 5.0 mmol) in dichloromethane (10 mL) was added drop wise with cooling (5–10 °C). The resulting yellow solution was stirred for 12 h at room temperature. The solvent was removed by evaporation and the residue was dissolved in ethylacetate. The solution was filtered, and the precipitate washed with a small amount of ethylacetate. The filtrate was concentrated. Purification was carried out using column chromatography on silica gel; elutant ethyl acetate/*n*-hexane, 1:1. The products were isolated as slightly yellow oils, which solidified upon cooling. Yields were 36 to 66%. Single crystals of compound **3a** were obtained by slow diffusion of *n*-hexane into a saturated solution of the compound in dichloromethane.

**2MeO-5GlyNHdipic (3a):** Yield 36% (0.50 g). $C_{12}H_{14}N_2O_5$ (266.25): calcd. C 54.13, H 5.30, N 10.52; found C 54.15, H 5.57, N 9.71. IR (KBr): $\tilde{\nu}$ = 3355 (N–H); 3063 (ar. **Preparation of the Vanadium(IV) Compounds 4a–d and 5a–d. 4a–b:** A solution of the ligand (1.0 mmol) and sodium acetate·$3H_2O$ (136 mg, 1.0 mmol) in water (10 mL) and THF (1 mL) was mixed with a solution of $VOSO_4$·$5H_2O$ (127 mg, 0.5 mmol) in water (2 mL) at 50 °C to yield light green solids. **4c–d**, **5a–d:** To a solution of the proligand (1.0 mmol) and sodium acetate·$3H_2O$ (136 mg, 1.0 mmol) in water (3 mL) and THF (6 mL) was added a solution of vanadyl sulfate·$5H_2O$ (127 mg, 0.5 mmol) in water (3 mL). The resulting green slurry was kept at reflux for ca. 6 h to yield a clear green solution. The solvent was evaporated, the residue was dissolved in THF and filtered. Evaporation to dryness yielded green solids.

# Crystal Structure of the $V^V$ Dimer $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$ and Its Equilibrium with the $V^V$ Trimer $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$ in Methanol/Water Solutions

**Fernando Avecilla,*[a] Carlos F. G. C. Geraldes,[b] Anjos L. Macedo,[c] and M. Margarida C. A. Castro*[b]**

**Keywords:** Vanadium / Pyridinone complexes / NMR spectroscopy / X-ray crystallography

The behaviour of the cyclic trimeric $V^V$ complex $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$, $V_3L_3$, (L = Hdmpp = 3-hydroxy-1,2-dimethyl-4-pyridinone) was studied in methanol and methanol/water solutions by using $^{51}V$ and 1D- and 2D $^1H$ NMR spectroscopy. Red crystals, isolated from a highly concentrated methanol solution of the trimeric complex, were analysed by X-ray crystallography. The solid-state structure of the compound showed the presence of a new dinuclear $V^V$ cluster and allowed for its formulation as a $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$ complex, $V_2Y_2L_2$ (Y = $OCH_3$). This complex crystallises in the monoclinic system: $P2_1/c$, $a$ = 8.4573(11) Å, $b$ = 15.034(2) Å and $c$ = 15.849(2) Å, $\beta$ = 105.300(2)°, $V$ = 1943,7(4) Å$^3$, $Z$ = 2, and $R_1(wR_2)$ = 0.0492(0.1706). The trimer $V_3L_3$ complex dissolved in a dry methanol solution fully decomposes, as shown by the $^{51}V$ NMR signals at –388, –450 and –551 ppm, which are assigned to a monomer complex $[VO(OMe)(dmpp)_2]$ ($VYL_2$), the dimer $V_2Y_2L_2$ and the monomethyl ester of monovanadate, $V_1Y$ ($V_1$ = monovanadate; Y = $OCH_3$), respectively. In methanol/water solutions, a new $^{51}V$ NMR signal appears at $\delta$ = –492 ppm, which is assigned to the $[VO_2(dmpp)(H_2O)_2]$ (VL) complex. When the percentage of water in the mixture increases, the relative intensities of the $V_2Y_2L_2$ and $V_1Y$ signals decrease sharply, and a broad signal at –488 ppm appears, corresponding to the original $V^V$ trimer complex, which is the only species present in 94 % water. A temperature-dependent $^1H$ NMR study of a $CD_3OD$ solution of $V_3L_3$ confirmed the presence, at room temperature, of the dinuclear $V_2L_2$ complex and the $VL_2$ species. At temperatures below 0 °C down to –50 °C, the appearance of new signals reflects the presence of isomers for the $V_2Y_2L_2$ and $VYL_2$ species with different stabilities and symmetries. 2D $^1H$ homonuclear NMR exchange experiments (EXSY) allowed us to establish the isomeric equilibria that take place in solution, and indicates intramolecular exchange between the two ligands of the major isomer of $VYL_2$ and intermolecular exchange between the major and minor isomers of species of different nuclearity, $V_2Y_2L_2$ and $VYL_2$. However, no evidence was found for intermolecular exchange between the major isomers and between the minor isomers of species of different nuclearity or between isomers of species of the same nuclearity.

## Introduction

Vanadium is an essential biological trace element of the utmost importance.[1,2] It is present in some biological systems in high concentrations, where it seems to have a relevant role, such as in the *Amanita muscaria* mushroom as the amavadin complex[3] and in some ascideas in the form of tunichromes.[4] Vanadium is the cofactor of some enzymes, like the vanadium-dependent haloperoxidases in algae and lichens[5] and the vanadium-nitrogenases in some bacteria.[6] It also interferes with the activity of certain enzymes, in particular those involved in phosphorylations,[7] where it acts as a phosphate analogue, and it is responsible for many physiological and metabolic effects observed in different organisms, where it is essential at low concentrations although toxic at concentrations higher than 1 mM.[8] Vanadium in biological systems mainly occurs as the anionic vanadate ($V^V$), which is isostructural to phosphate, or the cationic vanadyl ($V^{IV}$), depending on the redox properties of the medium.[8] The insulin-mimetic properties of inorganic vanadate and vanadyl,[9] as well as of some $V^{IV}$ and $V^V$ complexes,[10] have stimulated the search for a vanadium complex that can be used as an effective oral substitute for insulin. The well-recognised biological importance of vanadium has attracted much interest for its coordination and redox chemistry both in the $V^{IV}$ and $V^V$ oxidation states and both in the solid state and in solution. The interest extends to the modeling of the interaction of vanadium

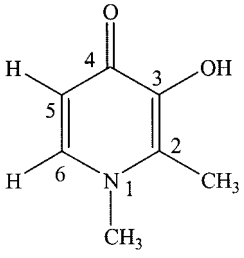
with living systems, with particular focus on the structural and functional biological activity of this element.

The aqueous chemistry of vanadium(V) is very complex. Hydrolysis, redox and oligomerization reactions can occur in solution, resulting in different species, depending on the pH, ionic strength and total vanadium concentration in the medium,[11] which together determine the coordination properties of vanadium(V). The structure and reactivity of vanadate in other solvents, in particular alcohols, have been largely studied.[12] Vanadium complexes with different geometries and coordination modes containing O and/or N and/or S as donor atoms in their structures[6b,11,13] have been useful model compounds to understand the coordination chemistry of vanadium in living systems. In particular, the solid-state structures of $V^{IV}$ and $V^V$ compounds with ligands from the class of pyrones and pyridinones (with one ketonic and one enolic group as donor atoms) have been determined by X-ray crystallography[14a,15] and EXAFS.[16] The speciation of these vanadium compounds in solution has been extensively studied by using potentiometry, UV/Vis, $^{51}V$ and $^1H$ NMR and EPR spectroscopy.[14a,16–18] Compound bis(maltolato)oxidovanadium(IV) [BMOV, $VO(ma)_2$, ma = maltolate] was the first example to be used as an insulin-mimetic complex,[14,19] and phase 1 clinical trials in humans have been completed on bis(ethylmaltolato)oxidovanadium(IV) (BEOV).[20] Several other oxovanadium(IV) complexes have also been reported to exhibit insulin-mimetic properties in vivo.[21] The compound bis(3-hydroxy-1,2-dimethyl-4-pyridinone)oxidovanadium(IV), $VO(dmpp)_2$ (see Scheme 1 for the structure of the ligand Hdmpp), as well as the ternary systems formed with low molecular mass components of blood serum have also been studied in aqueous solution under anaerobic and aerobic conditions.[17,18] At physiological pH, $VO(dmpp)_2$ showed low toxicity in erythrocyte suspensions[22] and promising in vitro insulin-like properties in fibroblast cell lines[23a] and in rat adipocytes.[23b]



Scheme 1.

The interaction of vanadate with the ligand Hdmpp in aqueous solution has been extensively studied by us.[18] A new trinuclear oxovanadium(V) complex was isolated from aqueous solution at a pH of 4–5 and was characterised in the solid state by X-ray crystallography as $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$ that contains a cyclic $V^V$ cluster and in aqueous solution by mass spectrometry and $^{51}V$ and $^1H$ NMR spectroscopy.[24] In this work, we report on the behaviour of this trinuclear $V^V$ compound in methanol and methanol/water solutions investigated by $^{51}V$ NMR spectroscopy and 1D and 2D $^1H$ NMR spectroscopy. The red crystals that formed from a highly concentrated $CD_3OD$ solution of the $V^V$ trimer were structurally analysed, and the X-ray crystallographic data obtained indicated the formation of a new dinuclear $V^V$ compound $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$.

## Results and Discussion

### X-ray Structure

The X-ray structure obtained for the crystalline $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$ complex ($V_2Y_2L_2$) is shown in Figure 1 with the atomic numbering scheme, and the corresponding bond lengths and angles are listed in Table 1. It consists of a dinuclear oxovanadium(V) complex with two anionic dmpp ligands, one oxygen atom bridge and two methoxy groups, each coordinated to one vanadium atom. The oxygen atom bridge links the two vanadium atoms, each one of which is also coordinated to one oxo group. Both V1 and V2 atoms adopt a distorted six-coordinate octahedral geometry (Figure 2). The V1 coordination sphere is composed of an enolate oxygen atom [V1–O6 = 2.040(3) Å], a ketonic oxygen atom [V1–O7 = 1.989(3) Å], a deprotonated alkoxide oxygen atom of a methoxy group [V1–O1M = 1.787(4) Å], a terminal oxo atom [V1–O1 = 1.594(3) Å] and a second oxo atom [V1–O4 = 1.824(3) Å] that forms a strong bridge to V2 [V2–O4 = 1.804(3) Å]. The remainder of the V2 coordination sphere is completed by an enolate oxygen [V2–O3 = 2.060(3) Å], a ketonic oxygen atom [V2–O5 = 1.972(3) Å], an alkoxide oxygen atom of the other methoxy ligand [V2–O2M = 1.783(3) Å] and a terminal oxo atom [V2–O2 = 1.594(3) Å]. A second, weaker

bridge between V1 and V2 is formed by an enolate oxygen (O3) of the ligand coordinated to V2 (see Table 1) and an enolate oxygen (O6) of the ligand coordinated to V1. The V2–O3 and V1–O6 distances are 2.060(3) Å and 2.040(3) Å, respectively, as compared with the V1–O3 and V2–O6 bond lengths of 2.464(3) Å and 2.589(3) Å, respectively. The vanadium atom V1 is located at 0.33697 Å from the axial plane defined by O4, O6, O7 and O1M, and the vanadium atom V2 is 0.4010 Å from the basal plane defined by O3, O4, O5 and O2M (Figure 2). Both vanadium atoms have a strong V=O bond, as the values of the V1–O1 and V2–O2 distances are compatible with those found in other similar structures.[25] All bond lengths are in the range of the values reported in the literature for other known polynuclear vanadium(V) complexes.[14a,15,26]

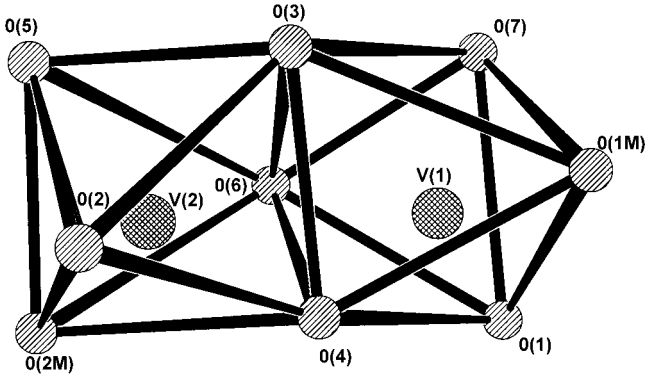

Figure 2. Coordination polyhedra in the crystal structure of the vanadium cluster in the dimeric species $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$.

The oxido and methoxido ligands of the $V_2Y_2L_2$ dimer, which exert a strong *trans* influence, are *cis* to one another. The preference of these ligands for a *cis* configuration in such complexes has been demonstrated in VO(OMe)(L) compounds {where L represents the tetradentate Schiff bases *N*,*N*′-2,2-dimethyltrimethylenebis[salicylidenaminato(2–)] (salnptn) and *N*,*N*′-ethylenebis[salicylideneaminato(2–)] (salen)}.[27] In these complexes, a *cis*-VO(OMe) arrangement was allowed by forcing the normally planar tetradentate Schiff base ligands into three equatorial and one axial coordination positions. The oxido and methoxido ligands are also *cis* to one another in the *cis*-VO(OMe)-$(ma)_2$ complex, which results from aerobic oxidation of the bis(maltolato)oxidovanadium(IV) complex $[VO(ma)_2$, BOMV] in methanol.[14a,15a]

The $V_2Y_2L_2$ dimer complex has an enolic dmpp oxygen atom (O3 in V1) that is *trans* and four dmpp oxygen atoms (enolic O6 and ketonic O7 in V1, and enolic O3 and ketonic O5 in V2) that are *cis* relative to the strong V=O bond in each vanadium atom.[14a,15a] The dmpp oxygen atoms belonging to the enolic groups are deprotonated (O3 and O6). The *trans* position is destabilised with respect to the other positions, as shown by the length of the V1–O3 and V2–O6 bonds in the $V_2Y_2L_2$ species, in a manner similar to that in other dimeric and monomeric compounds.[28] The dmpp ligand has a strong preference for meridional coordination, except when a methoxy group or a water molecule competes with it for the *cis* position relative to the oxo group.

The dinuclear complex contains the $V_2O_3$ framework,[15b] which exhibits one bridging oxygen atom (O4) and the formal enolic oxygen atoms (O3 and O6) of the two dmpp groups. From the X-ray results one could not unambiguously distinguish between a keto-O5 and an enolate-O3 structure for this bifunctional binding group, as the C–O bond lengths to the formal keto and enolate oxygen atoms in the C–O–V–O–C chain are almost the same {e.g. C8–O3 [1.338(5) Å], C14–O5 [1.317(6) Å] for the V2 cycle}. It is possible that the π electron cloud is delocalised over all the atoms that form each C–O–V–O–C cycle, giving an intermediate character to all the formal ketonic and enolic oxygen atoms of each dmpp molecule.[24] As expected, the doubly bridging (O3 and O6) dmpp atoms have V–O bond [2.464(3) and 2.060(3) Å for (O3), 2.040(3) Å and 2.589(3) Å for (O6)] that are longer than the V–O bond for the bridging oxygen atom (O4) [1.824(3) and 1.804(3) Å]. The V2–O6 distance [2.589(3) Å] is even longer than the V1–O3 distance. The average value of the V–O–V bond lengths is 1.81(2), which is similar to that obtained for other polynuclear vanadium compounds.[29] In the $V_2O_3$ framework, the bond angle V1–O4–V2 [110.35(16)°] is very different from the bond angles V1–O3–V2 [81.81(11)°] and V1–O6–V2 [79.12(11)°]. This is in agreement with the results published for the trimeric species $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$.[24]

Figure 3 shows an upper view of the complex along the pseudo-$C_2$ axis, which passes along the oxygen atom O4.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

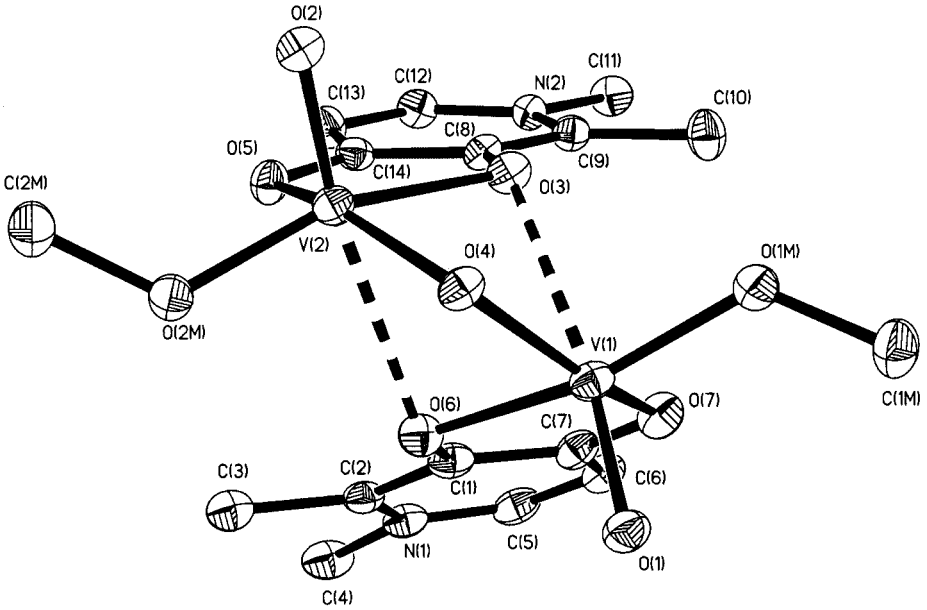

Figure 3. Upper view of the complex $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$. Hydrogen atoms have been omitted for simplicity. The ORTEP plot is at the 30% probability level.

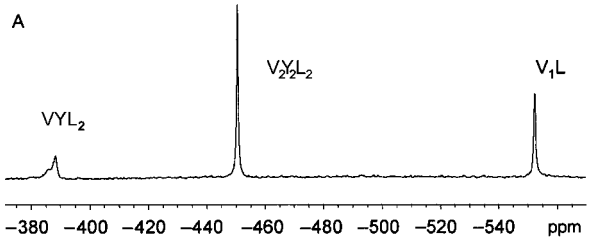
This view clearly illustrates the pseudo-$C_2$ symmetry of the complex. Each of the two methoxy groups is coordinated to each of the two vanadium atoms. The angle between the planes of the two dmpp ligands is 34.6°. In this view, it is easy to foresee that a dynamic equilibrium between different isomers can occur in solution.

## Solution Studies

### *$^{51}V$ NMR Spectroscopic Studies*

The behaviour of the cyclic $V^V$ trimer compound $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$, $(V_3L_3)$[24] was studied as a function of solvent composition by $^{51}V$ NMR spectroscopy. Dissolution of black crystals of $V_3L_3$ in dry methanol gives a $^{51}V$ NMR spectrum that shows four signals with different intensities at –386 (shoulder), –388, –450 and –551 ppm (Figure 4A), which indicates the presence of four different vanadium(V) species in solution. The signal at –551 ppm corresponds to the monomethyl ester of vanadate $V_1Y$ ($V_1$ = monovanadate; Y = $OCH_3$),[12c] which was previously detected as one of the products resulting from the aerobic oxidation in methanol solution of $VO(ma)_2$ to $[VO(OCH_3)(ma)_2]$ and was described as $[VO(OCH_3)]^{2+}$.[15a] The signal at –450 ppm, with the highest intensity, was assigned to the dimer $V^V$ complex $V_2Y_2L_2$. This assignment is corroborated by the observation of $^{51}V$ high frequency shifts of the signals for the dimer with respect to those of the monomer in other systems, such as the oxovanadium alkoxides $VO(OR)_3$ or vanadate complexes of hydroxy acids such as glycerate or lactate.[30]

In a highly concentrated methanol solution, this compound precipitates as red crystals, which were analysed by X-ray crystallography. The crystal structure is presented in this work. The signal at –388 ppm was assigned to *cis*-$[VO(OCH_3)(dmpp)_2]$ ($VYL_2$) containing one methoxy



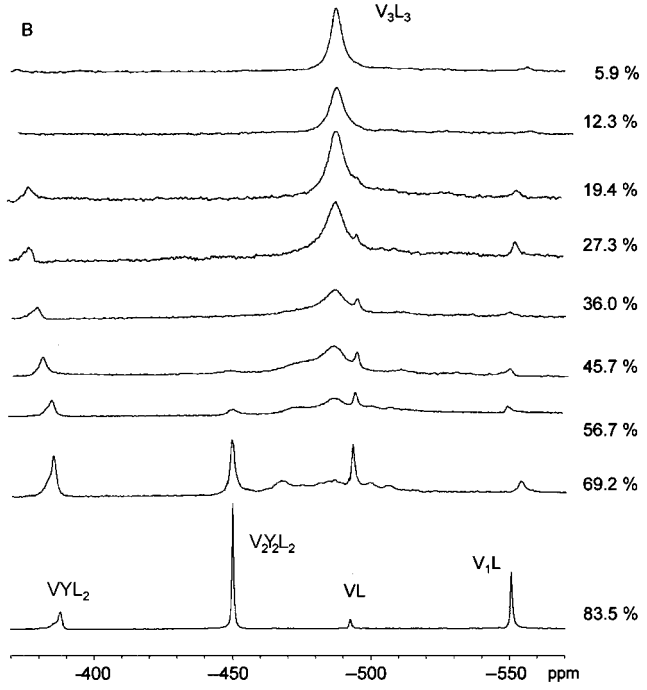


Figure 4. $^{51}V$ NMR spectra of solutions of the crystalline $V^V$ compound $[V_3O_6(dmpp)_3(H_2O)]\cdot(H_2O)_2$ obtained at 131.404 MHz and at 22.0 ± 0.5 °C in (A) dry $CH_3OH$; (B) $CH_3OH/H_2O$ mixtures, at pH ≈ 4 and different $CH_3OH/H_2O$ mol ratios. The $CH_3OH$ mol% is shown in the figure.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

group, analogous to the bis(maltolato) complex $[VO(OCH_3)(ma)_2]$,[14a,15a] and its shoulder at –386 ppm to the corresponding *trans* isomer.

The $^{51}V$ NMR spectra of the trimer $V_3L_3$ dissolved in methanol/water solutions with different percentages of the two solvents dramatically change with the solvent composition, as shown in Figure 4B. In a solution where the mol fraction of $CH_3OH$ is 83.5%, a new signal appears at $\delta$ = –492 ppm, in addition to those already present. This signal, which is absent in pure methanol and only appears when water is present in solution, was assigned to the $[VO_2(dmpp)(H_2O)_2]$ (VL) complex with no methoxy group in its structure, which, at pH ≈ 4 appears at –492 ppm, as previously reported.[18] The relative intensities of the $V_2Y_2L_2$ and $V_1Y$ signals decrease sharply when the percentage of water in the solution increases. The first signal completely disappears at 36.0% $CH_3OH$ and the second one at 12.3% $CH_3OH$. The signals for the VL and $VYL_2$ species disappear at 12.3% $CH_3OH$. Furthermore, the $VYL_2$ signals gradually shift with increasing water content, up to a value of –376 ppm, reflecting the formation of the $[VO(OH)(dmpp)_2]$ complex, which dominates in water solution at pH ≈ 4.[18] In addition, at 69.2% $CH_3OH$, a broad signal appears at –488 ppm. Its intensity increases with the percentage of water, and when water is present at 94.1%, it is the only signal observed in the $^{51}V$ NMR spectrum (Figure 4B). This signal corresponds to the original $V^V$ trimer complex $V_3L_3$, whose $^{51}V$ NMR signal in aqueous solution at pH ≈ 4 has already been reported.[24] This was confirmed by slowly evaporating the methanol from a water/methanol solution of the $V^V$ trimer at room temperature, which leads to an aqueous solution that gives a $^{51}V$ NMR spectrum consisting of the same single, broad signal at –488 ppm. After some time, black crystals were isolated from the solution, and characterisation of their structure by X-ray crystallography confirmed that these are indeed crystals of the $V^V$ trimer $V_3L_3$ compound, whose structure had been previously reported.[24]

### *$^1$H NMR Spectroscopic Studies*

$^1$H NMR spectra of solutions of the $V^V$ trimer, $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$, in dry [D$_4$]MeOH ($CD_3OD$, no water present) were obtained at different temperatures. Figure 5A shows the signals for the $H^5$ and $H^6$ aromatic dmpp protons (6.0–8.0 ppm) from 25 °C down to –40 °C, while Figure 5B shows the signals corresponding to the $H^5$ (6.0–7.0 ppm) and C(2)–$CH_3$ (1.5–3.0 ppm) dmpp protons at –50 °C.[14,19] At 25 °C (Figure 5A) two doublets are observed at $\delta$ = 7.69 ppm and 7.55 ppm, corresponding to the $H^6$ protons of the $V_2Y_2L_2$ and $VYL_2$ species, respectively, and a doublet at $\delta$ = 6.55 ppm and a broad signal at $\delta$ = 6.28 ppm, assigned to the $H^5$ protons of the $V_2Y_2L_2$ and $VYL_2$ species, respectively. These assignments were made taking into account the $^{51}V$ NMR spectra previously discussed, which show the absence of the VYL and VL species when no water is present.

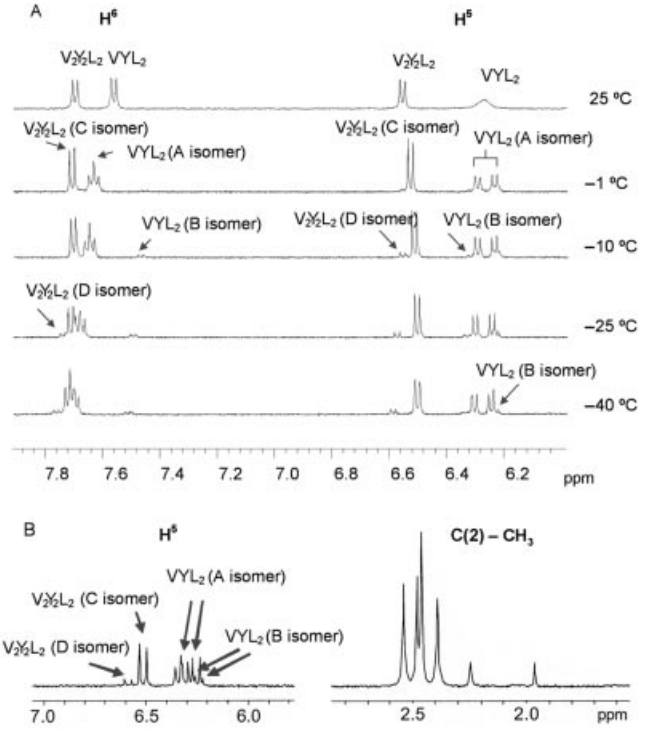

Figure 5. (**A**) 400 MHz $^1$H NMR spectra of solutions of the crystalline $V^V$ compound $[V_3O_6(dmpp)_3(H_2O)]\cdot(H_2O)_2$ in $CD_3OD$, at different temperatures, showing only the signals corresponding to the $H^5$ and $H^6$ protons of the ligand dmpp; (**B**) 200 MHz $^1$H NMR spectrum of a solution of the crystalline $V^V$ compound $[V_3O_6(dmpp)_3(H_2O)]\cdot(H_2O)_2$ in $CD_3OD$, at –50 °C, showing only the signals corresponding to the $H^5$ (6–7 ppm) and C(2)–$CH_3$ (1.5–3 ppm) protons of the ligand dmpp. The assignments in the spectra of Figure 5A are made according to the structures of the isomers presented in Figure 6.

The $^1$H NMR spectra at lower temperatures become more complex, revealing the presence of isomers of these complexes in solution. At –1 °C, the 6.28 ppm (25 °C) broad signal splits into two doublets at $\delta$ = 6.32 ppm and 6.25 ppm, while the 7.55 ppm (25 °C) signal originates from the triplet centred at $\delta$ = 7.63 ppm formed by two partially overlapping doublets (Figure 5A, b), which correspond to the nonequivalent $H^5$ and $H^6$ protons of the two ligands of the $VYL_2$ compound.[14a,14c,19] These features reflect the slowing down of the intramolecular dynamic processes, which, at higher temperature, average the two different environments of the $H^5$ and $H^6$ protons of the two ligands in the dominant *cis* isomer of $VYL_2$ compound (isomer A, Figure 6A), making them nonequivalent. At –10 °C, the new low-intensity doublets appearing at $\delta$ = 6.32 ppm and $\delta$ = 7.45 ppm (Figure 5A) are indicative of the presence of isomeric forms, and correspond to the $H^5$ and $H^6$ protons of the less stable *trans* isomer of the $VYL_2$ species (isomer B, Figure 6B), respectively. The doublet at $\delta$ = 6.56 ppm with a weak intensity corresponds to the $H^5$ proton of an isomer of the $V_2Y_2L_2$ dimer with the methoxy groups in a *cis* position (Figure 6D); this isomer is less stable than the major isomer with *trans* methoxy groups (Figure 6C), which is similar to the structure obtained in the crystal form. This

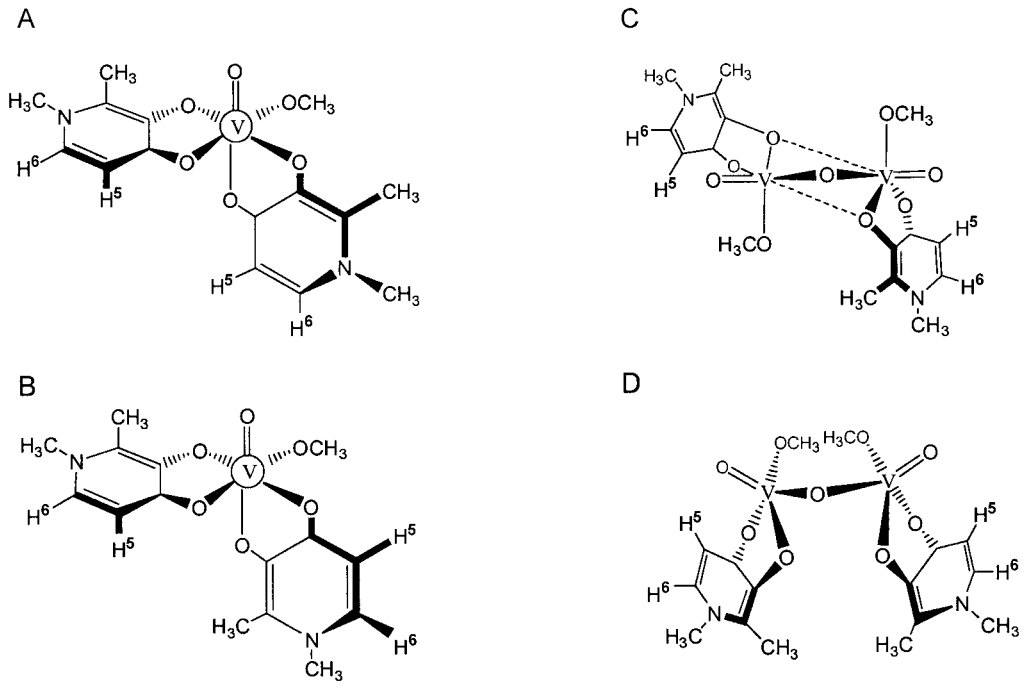

Figure 6. Schematic representation of the chemical structures of the possible isomers of: (A) the more stable and (B) the less stable isomers of the $VYL_2$ species [$VO(dmpp)_2(OMe)$]; and (C) the more stable and (D) the less stable isomers of the $V_2Y_2L_2$ species [$V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2$], in methanol solution.

doublet is shifted to 6.57 ppm at –25 °C and to 6.58 ppm at –40 °C (Figure 5A). At –10 °C the $H^6$ signal of this isomer is not observed, as it overlaps with the large $H^6$ signal of the major $V_2Y_2L$ isomer. However, at –25 °C it can be seen at $\delta$ = 7.75 ppm and it shifts to 7.76 ppm at –40 °C. At lower temperatures the signals of the $H^6$ proton of the two isomers of $VYL_2$ are shifted to higher frequencies– the signal of the major isomer (isomer A) becomes superimposed with the $H^6$ proton signals of the $V_2Y_2L_2$ compound.

A schematic representation of the proposed chemical structures of the two isomers for each of these two species, which is in agreement with the NMR spectroscopic data, is presented in Figure 6. From the $^1H$ NMR spectroscopic data, it is expected that the two $H^6$ protons of the dmpp ligands in the $V_2Y_2L_2$ compound are equivalent in each isomer; the same can be said for the two $H^5$ protons (Figure 6C and D). These protons in the $VYL_2$ species are nonequivalent in both isomers (Figure 6A and B), although they are indistinguishable at 25 °C (Figure 5A) because of the presence of intramolecular averaging processes that are fast on the NMR time-scale. The structures A and C of Figure 6 are assumed to represent the more stable isomers of $VYL_2$ and $V_2Y_2L_2$, respectively. This assumption is based on the present X-ray crystal structure data for $V_2L_2$ and on the literature data for $VYL_2$ (L = ma).[14,15] However, a more precise knowledge of the relative stability of the structures in solution would require a study involving theoretical energy calculations.

Figure 5B presents an $^1H$ NMR spectrum obtained at –50 °C that shows the spectral regions 5.8–7.0 ppm, corresponding to the $H^5$ protons, and 1.5–3.0 ppm, corresponding to the protons of the $CH_3$ group attached to the C(2) atom of the dmpp molecule. The different doublets corresponding to the $H^5$ protons in the different species in solution are better resolved and corroborate the presence of two isomers for the $V_2Y_2L_2$ complex (one doublet at $\delta$ = 6.51 ppm for the more stable isomer C and one doublet at $\delta$ = 6.59 ppm for the less stable isomer D) and two isomers of the $VYL_2$ compound (two doublets at $\delta$ = 6.24 ppm and 6.35 ppm for the less stable isomer B and two doublets at $\delta$ = 6.25 ppm and 6.31 ppm for the more stable isomer A). With respect to the protons of the C(2)–$CH_3$ group, six singlets are observed: two signals are assigned to the $CH_3$ protons of the two isomers of the $V_2Y_2L_2$ complex, each one corresponding to the six protons of the two equivalent $CH_3$ groups of each isomer, and the other four signals correspond to the four $CH_3$ groups (two nonequivalent $CH_3$ groups in each isomer of the $VYL_2$ complex).

### *2D NMR Spectroscopic Experiments*

Two-dimensional (2D) $^1H$ NMR experiments, COSY (*J* correlated spectroscopy) and EXSY [exchange correlated spectroscopy, obtained using a phase-sensitive nuclear Overhauser spectroscopy (NOESY) pulse sequence], were carried out to further investigate the existence of different isomeric forms in solution, complementing the data obtained through one-dimensional (1D) $^1H$ NMR spectra at low temperature (–1 °C to –50 °C).

Figure 7 shows the low field region (6.0–8.0 ppm) of the 2D-COSY (Figure 7A) and 2D-EXSY (Figure 7B) spectra at –10 °C. This temperature value and the region in which the $H^5$ and $H^6$ signals of the dmpp ligand appear proved to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

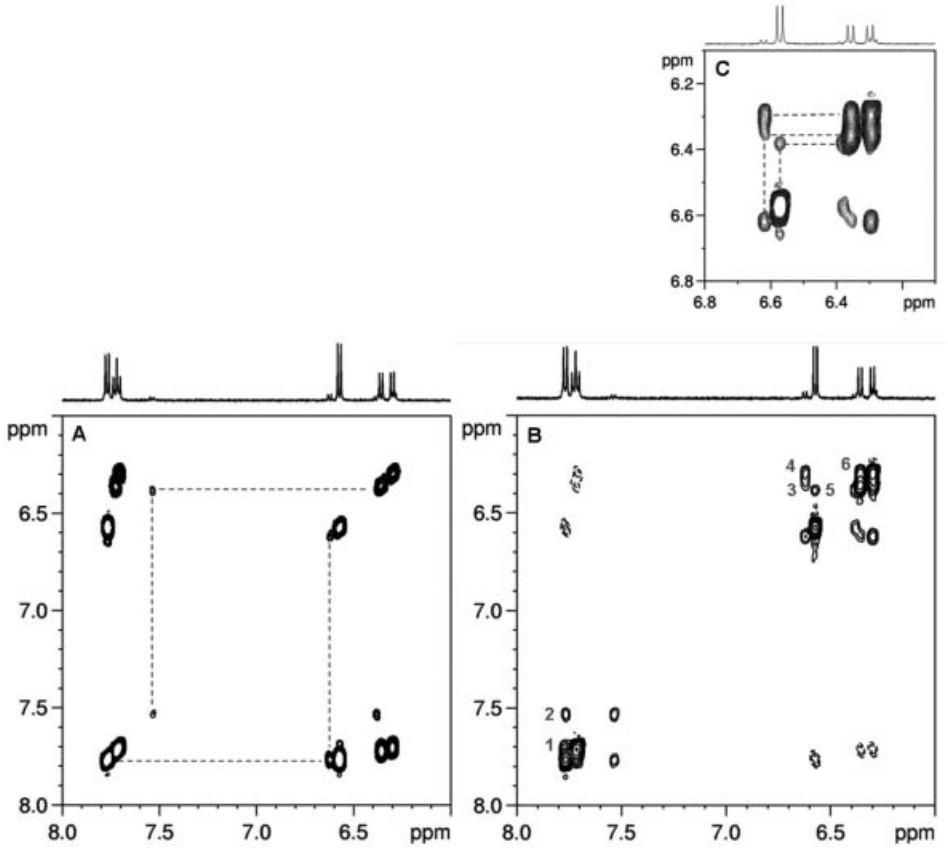

Figure 7. 400 MHz 2D $^1$H homonuclear NMR spectra (spectral region 6–8 ppm) of solutions containing the $V^V$ compound $[V_3O_6(dmpp)_3(H_2O)]\cdot(H_2O)_2$, in $CD_3OD$, at –10 °C: (A) COSY spectrum; and (B) EXSY spectrum (mixing time 800 ms) with (C) an expansion of the $H^5$ proton region. The contours of positive and negative peaks are defined by continuous and dashed lines, respectively.

give the most relevant information. In the COSY spectrum, cross-peaks correlating the protons $H^5$ and $H^6$ of each species in solution are expected. One cross-peak for each of the isomers C and D of $V_2Y_2L_2$, two cross-peaks for the two ligands of the major isomer of $VYL_2$ (isomer A) and only one of the two expected for its minor isomer (isomer B) can be observed. These observations confirm the assignments described above for the 1D $^1$H NMR spectra.

The phase sensitive 2D-EXSY spectrum in the pure double absorption mode contains two types of cross-peaks. For small molecules, like those studied here, the cross-peaks resulting from nuclear Overhauser effects (nOes) that are based on the intramolecular dipolar interactions of protons $H^5$ and $H^6$ of the same ligand, which are close in space, have negative intensities and appear at the same positions as the COSY cross-peaks. Only three nOe cross-peaks are observed, two for the major isomer (A) of $VL_2$ and one for the major isomer (C) of $V_2Y_2L_2$, as those for the minor isomers could not be detected. The diagonal peaks and the exchange cross-peaks resulting from the exchange processes that occur between different species and/or between the isomeric forms of a given species have positive intensities. The exchange cross-peaks observed for mixing times $\tau_m > 1/R$, where $R = k_{ex}/\Delta\upsilon_o$ is the ratio of the exchange rate constant and the chemical shift difference between the exchanging peaks of the same proton in the two species, give useful information about the dynamic equilibria in solution.[31] Their intensities are related to the corresponding exchange rate constants of the exchange equilibrium. A qualitative analysis of the exchange patterns of Figure 7B shows six cross-peaks, two in the $H^5$ region and four in the $H^6$ region. In the $H^5$ region, there are two stronger correlations – one between the two ligands of the major isomer of $VYL_2$ (A) and one between the minor isomer of $V_2Y_2L_2$ (D) and one of the two $H^5$ protons of the major isomer of $VYL_2$ (A). Two weaker correlations in the $H^5$ region are observed between the minor isomer of $V_2Y_2L_2$ (D) and the other $H^5$ protons of the major isomer of $VL_2$ (A), and between the major isomer of $V_2Y_2L_2$ (C) and the minor isomer of $VYL_2$ (B). In the $H^6$ region, two weak cross-peaks are observed – one involving correlation of the major or minor isomers of $V_2Y_2L_2$ (C or D) with the major isomer of $VYL_2$ (A) and the other with its minor isomer (B). This uncertainty results from the overlap of the $H^6$ resonances of isomers C and D of $V_2Y_2L_2$. However, taking into account the exchange pattern observed for the $H^5$ protons, the A↔D and B↔C correlations between the $H^6$ protons are more plausible. There is no evidence of cross-peaks correlating the $H^5$ or $H^6$ protons of the two isomers of the same species.

In conclusion, the $^{51}$V NMR spectroscopic data show that two different oligomeric species containing $V^V$ and dmpp can be isolated in water and methanol. Their X-ray

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

crystal structures show that the water species is a cyclic $V_3L_3$ trimer, $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$, while the methanol species is a $V_2Y_2L_2$ dimer, $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$. Dissolution of black crystals of the $V_3L_3$ trimer in methanol leads to its complete dissociation into a $V_2Y_2L_2$ dimer, a $VYL_2$ monomer and monovanadate, each of which has one methoxy group coordinated to the $V^V$ atoms. Red crystals of the dimer were isolated from the methanol solution. Increasing the amount of water in mixtures with methanol leads successively to the appearance of VL, the disappearance of $V_2Y_2L_2$ and the monomer species, while the trimer dominates at high water content.

On the basis of the results from the 2D-EXSY NMR experiments, the following intermolecular exchange equilibria between the different species were detected in a $CD_3OD$ solution of the trimer $V^V$ complex:

$V_2Y_2L_2$ (C isomer) ⇆ $VYL_2$ (B isomer)

$V_2Y_2L_2$ (D isomer) ⇆ $VYL_2$ (A isomer)

These equilibria involve exchange between the major isomer and the minor isomer of species of different nuclearity. Intramolecular exchange was also detected between the two ligands of $VYL_2$ (isomer A), but no evidence was found for intermolecular exchange between the major and minor isomers of species of different nuclearity or between isomers of species of the same nuclearity.

## Experimental Section

**Reagents:** Sodium metavanadate, $NaVO_3$, and methanol were purchased from Sigma, and the ligand 1,2-dimethyl-3-hydroxy-4-pyridinone (Hdmpp) from ACROS Organics and used without further purification. KOH, HCl and $CH_3OH$ were obtained from Merck, while KOD, DCl, $D_2O$ (99.9 atom% D) and $CD_3OD$ (99.9 atom% D) from Cambridge Isotope Laboratories. All the experiments were carried out under aerobic conditions.

**Synthesis:** The synthesis of the trimer $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$ was carried out following the procedure described in the literature.[24] Red crystals of $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$ were isolated from methanolic solution of the trimer; however, under atmospheric conditions these crystals turn black after replacement of methanol by water.

**Solutions:** Solutions of the trimer $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$ used for the $^{51}V$ NMR spectroscopic experiments contained $CH_3OH$ or $CH_3OH/H_2O$ mixtures, and were prepared by dissolving the appropriate amount of the solid compound in the solvent (or solvents) in order to have the desired concentrations. The $CH_3OH/H_2O$ mol ratios were checked by integration of the $^1H$ NMR signals of the solvents. 1D $^1H$ NMR spectra as well as 2D $^1H$ COSY and EXSY NMR spectra were acquired in $CD_3OD$ solutions. pH values were measured by using a Crison MicropH 2002 pH meter with an Ingold 405-M5 combined electrode.

### Methods

**NMR Spectroscopy:** $^{51}V$ NMR spectra at 22.0 ± 0.5 °C were recorded with a Varian Unity-500 Spectrometer operating at 131.404 MHz, using a 5 mm broad band probe. $^{51}V$ NMR chemical shifts were externally referenced to a $VOCl_3$ solution at 0 ppm. The $^{51}V$ NMR acquisition parameters were: 33 kHz spectral width, 25 μs pulse width, 0.5 s acquisition time and 10 Hz line broadening. $^1H$ NMR spectra were obtained by using a pre-saturation pulse sequence to eliminate the residual water signal. The low-temperature 1D and the 2D $^1H$ NMR spectra were obtained with a Bruker ARX400 NMR Spectrometer operating at 400.13 MHz, using a 5 mm inverse probe and a controlled-temperature unit. Magnitude COSY and phase sensitive NOESY (800 ms mixing time) were acquired with a spectral width of 4000 Hz in both F1 and F2, with 1024×256 data points. Spectra were processed with unshifted sine bell (COSY) and sine$^2$ (NOESY) functions. The $^1H$ NMR spectrum at –50 °C was obtained with a Bruker AC 200 F Spectrometer operating at 200.13 MHz, using a 5-mm probe and a controlled-temperature unit.

**ES Mass Spectrum:** Electron spray (ES) mass spectra were recorded with an MSD spectrometer with a fragmentation of 50 V in a mixture of 98% methanol/2% formic acid: $m/z$ = 457 $[V_2O_3(C_7H_8O_2N)_2(OCH_3)]^+$, 343 $[VO(C_7H_8O_2N)_2]^+$, 236 $[VO(C_7H_8O_2N)(OCH_3)]^+$.

**X-ray Crystallography:** The crystalline trimer $[V_3O_3(\mu\text{-}O)_3(dmpp)_3(H_2O)](H_2O)_2$ was dissolved in methanol until saturation was reached. After a few hours, slow evaporation of this solution gave dark red crystals of X-ray quality. A suitable crystal of $[V_2O_2(\mu\text{-}O)(dmpp)_2(OCH_3)_2]$ was coated with Fomblin oil, placed at the end of a silica fibre and mounted on a goniometer head of a Bruker SMART CCD diffractometer in a stream of cold nitrogen gas. These crystals are unstable and turn black when left in contact with atmospheric conditions.

Selected crystallographic data are shown in Table 2. Three-dimensional X-ray data were collected at low temperature (173 K) in the range $1.90 < 2\theta < 28.32°$ with a Siemens SMART 1000 CCD diffractometer by the $\Omega$-scan method. Complex scattering factors were taken from the programme package SHELXTL.[32] The structure was solved by direct methods and refined by using full-matrix least-squares methods on $F^2$. The data were processed and corrected for Lorentz and polarisation effects and for absorption (semi-empirical method). The non-hydrogen atoms were refined with anisotropic thermal parameters in all cases. The hydrogen atoms were refined to carbon, which were placed in idealised positions and refined by using a riding mode. A final difference Fourier map showed no residual density outside –1.064 to +0.845 e Å$^{-3}$. Selected bond lengths and bond angles appear in Table 1.

# Vanadium (IV and V) Complexes of Reduced Schiff Bases Derived from the Reaction of Aromatic *o*-Hydroxyaldehydes and Diamines Containing Carboxyl Groups

**João Costa Pessoa,*[a] Susana Marcão,[a] Isabel Correia,[a] Gisela Gonçalves,[a] Agnes Dörnyei,[b] Tamás Kiss,*[b] Tamás Jakusch,[b,c] Isabel Tomaz,[a,d] M. Margarida C. A. Castro,[d] Carlos F. G. C. Geraldes,[d] and Fernando Avecilla[e]**

**Keywords:** Salen-like ligands / N,O ligands / Vanadium / Coordination modes / Equilibrium and structural studies

The reduced Schiff bases of salicylaldehyde [and *o*-vanillin (*o*-van)] with D,L- and L-diaminopropionic acid (DPA), designated by salDPA, and L-2,4-diaminopentanoic acid [ornithine (Orn)], designated by salOrn, as well as the $V^{IV}O^{2+}$ and $V^{V}O_2^{+}$ complexes of salDPA were prepared. The compounds were characterised in the solid state and in solution. The structure of $H_4$salDPA$^+$Cl$^-$ was determined by X-ray diffraction. Complexation of $V^{IV}O^{2+}$ and $V^{V}O_2^{+}$ with salDPA and salOrn (only the $V^{IV}O$ system) in aqueous solution was studied by potentiometry, UV/Visible spectroscopy and circular dichroism, as well as by EPR spectroscopy for the $V^{IV}O$–salDPA system and by $^1$H- and $^{51}$V NMR spectroscopy for the $V^{V}O_2$–salDPA system. Stoichiometries and complex formation constants were determined by potentiometry at 25 °C and $I$ = 0.2 M KCl. Practically only 1:1 complexes were formed in both systems with composition (VO)$LH_2$ and (VO)L in the $V^{IV}O$–salDPA system, and with composition ($VO_2$)LH and ($VO_2$)L in the $V^{V}O_2$–salDPA system. Spectroscopic data provided information about the most probable binding modes of each stoichiometry.

## Introduction

The presence of vanadium in biological systems, its insulin-enhancing action[1–4] and anticancer activity[5–7] has driven a considerable amount of research. Particular interest has been given to the study of the potential benefits of vanadium compounds as oral insulin substitutes for the treatment of diabetes.[8–12] Coordinated ligands should be able to improve the absorption and possibly the transport of vanadium to the cells, reducing the dose necessary for producing an equivalent effect. Several vanadium complexes of the dianionic tetradentate Schiff base salen (*N*,*N*′-disalicylideneethylenediamine)-type ligands have been proposed for use as insulin-enhancing agents, and for treatment of obesity and hypertension.[13–15] Durai and Saminathan[13] reported the ability of $V^{IV}O$(salen) to reverse the hyperglycemic condition of alloxan-induced diabetic rats to near normal, thereby exerting insulin-like action. However, rats tended to become hypoglycemic, and withdrawal of treatment brought about an immediate return of the hyperglycemia. Oxidovanadium(IV) complexes of hydroxysalen derivatives have also been reported to possess nuclease activity in the presence of an activating agent (mercaptopropionic acid or Oxone).[16]

Salen-type ligands present versatile steric, electronic and lipophilic properties. They may be easily prepared by the condensation of two compounds: (i) an aromatic *o*-hydroxyaldehyde and (ii) a diamine, the hydrophilic–lipophilic balance being easily fine-tuned by choosing the appropriate amine precursors and ring substituents of the aldehyde. However, Schiff base (SB) ligands have the disadvantage that they hydrolyse in solution. This instability can be overcome by the reduction of the SB to give an amine, i.e. ligands often designated as salan compounds. This presents interesting possibilities, as the reduced SB will be more flexible and not restrained to remain planar when coordinated to a metal centre. Moreover, some of the $V^{IV}O^{2+}$ and $V^{V}O_2^{+}$ complexes with salan ligands have been shown to be several orders of magnitude more stable than the corresponding salen compounds.[15,17]

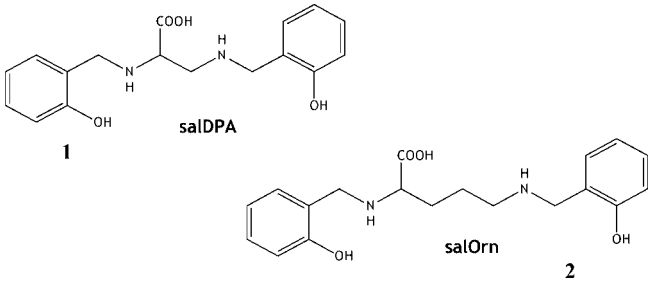
We report the preparation of salan compounds derived from the condensation of salicylaldehyde [in one case also of *o*-vanillin (*o*-van)] with D,L- and L-diaminopropionic acid (DPA), L-2,4-diaminopentanoic acid (L-ornithine) and L-2,5-diamino-hexanoic acid (L-lysine), which are designated by salDPA (**1**), salOrn (**2**) and salLys (**3**), respectively, and the preparation of $V^{IV}O$– and $V^{V}O_2$–salDPA complexes. The compounds were characterised in the solid state and in solution. The molecular formulas of two of the salan compounds prepared (salDPA and salOrn) are depicted in Scheme 1.



Scheme 1. Molecular formulae of two of the ligands prepared. Those of salLys (**3**) and vanDPA (**4**) are represented in the Supporting Information. The totally protonated compound **1** corresponds to $H_5salDPA^{2+}$. We obtained two different solid compounds: $H_3salDPA$ (**1**) and $H_4salDPA^+Cl^-$ (**1A**). When designating these and the other salan compounds obtained in this work without specific attention to their protonation state, we will omit the protonation state, e.g. we will normally designate **1** as salDPA.

Most of the biologically important reactions of vanadium occur in water-based environments such as blood plasma or other biological fluids and intracellular media. Therefore, the knowledge of the distribution and chemical speciation of the vanadium compounds in aqueous solution is of utmost importance. Most of the salen-type ligands and their vanadium complexes prepared so far are not water-soluble. The vanadium compounds prepared using salDPA are moderately soluble in water; therefore, they may be useful for therapeutic use. The salOrn ligand (**2**) was obtained in a low yield and only a few studies were made using this compound. However, as salLys (**3**) is not soluble in water or in ethanol/water at least up to 10% ethanol, this compound was characterised in the solid state but was not further studied.

Studies of moderately water-soluble Schiff bases and their hydrolytically more stable salan derivatives were previously reported,[15,17] namely several $V^{IV}O$– and $V^{V}O_2$–pyran complexes [pyran = *N*,*N*′-ethylenebis(piridoxylaminato)] were prepared and their properties studied. The ligands were found to form basically similar complexes coordinating through the O and N atoms ($2\times O_{phenolate}$, $2\times N_{amine/imine}$). EPR spectroscopic ($V^{IV}O$–pyran system) and $^1H$- and $^{51}V$ NMR spectroscopic ($V^{V}O_2$–pyran system) studies indicated the presence of various isomeric species in solution. The additional carboxylate group of salDPA may alter the structure and stability of the complexes. In fact salDPA forms very stable complexes with $Cu^{II}$ and $Fe^{III}$,[18] and in this work we also find that it is an effective ligand for $V^{IV}O^{2+}$ and $V^{V}O_2^+$. Moreover, the pendant carboxylate group may help with the coupling of the salan moiety to other molecules that may target the compound to specific biological sites, thereby anticipating the possibility of minimising its toxicity and increasing its efficacy.

## Results and Discussion

### Synthesis and Characterisation

The reduced SBs **1**–**2** depicted in Scheme 1 were prepared by the condensation of two equivalents of the appropriate aldehyde derivative with one equivalent of the diamine derivative. Treatment of these condensation products with sodium borohydride resulted in the reduction of the two imine bonds, yielding the reduced SBs (salan compounds) depicted in Scheme 1. The compounds gave good elemental analysis and were characterised by $^1H$ NMR spectroscopy. A reduced SB derived from the reaction of *o*-vanillin and DPA [vanDPA (**4**)] was also obtained and characterised in the solid state.

Crystals of $H_4salDPA^+Cl^-$ (**1A**) suitable for X-ray diffraction studies were obtained and more details are given in the Supporting Information. The amine nitrogen atoms are both protonated and the carboxylate group is not protonated. An ORTEP diagram with the molecular structure is depicted in Figure 1.

The bond lengths found for **1A** are within the expected range, and are similar to those of two related Schiff base compounds,[19] except for the C=N distance. In these com-

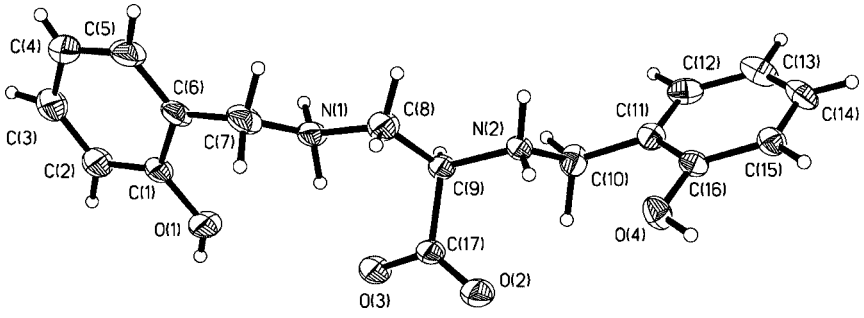


Figure 1. ORTEP diagram of $H_4salDPA^+\cdot Cl^-$ (**1A**) with the thermal ellipsoids of the non-hydrogen atoms drawn at the 30% probability level.

pounds this distance is 1.248(6) and 1.277(4) Å, and in **1A** it corresponds to two single C–N bonds [1.491(7) and 1.524(6) Å, for N(1)–C(7) and N(2)–C(10), respectively].

Some selected IR data for the ligands and vanadium complexes are shown in the Supporting Information (Table S1)[20–23]. The $\nu_{as}$(COO) bands appear at 1620–1650 $cm^{-1}$, while the $\nu_s$(COO) bands are assigned to the bands observed at 1415–1480 $cm^{-1}$. The characteristic $\nu$(V=O) band appears as a strong band at 960 $cm^{-1}$ in the IR spectrum of $V^{IV}O$(salDPA). For Na[$V^{V}O_2$(salDPA)] the strong $\nu$(V=O) bands appear at 880 and 906 $cm^{-1}$.

## Solution Studies

### *salDPA and salOrn*

The totally protonated form of compound **1** (Scheme 1) corresponds to $H_5$salDPA$^{2+}$. The protonation constants and respective p$K_a$ values derived from the potentiometric titrations are listed in Table 1. These values agree well with those obtained by Jancsó et al.,[18] for a different medium. The p$K_a$ of the carboxyl group is too low to be determined by potentiometric measurements, this is because of the strong electron-withdrawing effect of the neighbouring amino groups and/or H-bond formation involving these groups. In the Supporting Information (Section 2), we include Figure S1 where the $^1$H NMR chemical shifts of salDPA are represented as a function of pD. The chemical shift of the proton attached to C(9) (proton b) shows important changes at pD < 2, but the protons attached to C(8) (protons c) also show some much less important changes in this pH range. The $H_4L^+$ form is dominant in the pH range 2–5 and its deprotonation (p$K_{a2}$ = 5.91) is well separated from the following consecutive deprotonation steps. Since practically no change in the UV spectra occurs during this step, this can be assigned to the deprotonation of an amino group.[18] In Figure S1 it is clear that only the chemical shifts of the protons attached to C atoms close to the $N_{amine}$ atoms show significant changes at pD ≈ 6, in particular the proton attached to C(9) shows important changes. This indicates that p$K_{a2}$ is mainly associated with the deprotonation of atom N(2). Further deprotonation processes are followed by a continuous increase of the absorption bands at 238 and 292 nm, attributed to intramolecular transitions of the phenolate rings. In Figure S1, for pD > 8 there is a progressive change in the chemical shifts of all protons (except for proton b) as pD is increased. Therefore, the three consecutive deprotonations of $H_3$salDPA involve overlapping deprotonation processes related to the second amino group and the two phenol OH groups. However, the behaviour of the chemical shifts of the H atoms of C(7) (proton d) and C(8) (proton c) suggests that the second –$NH_2^+$– group is slightly more acidic than the two phenol protons whose deprotonation occurs at higher pD values, as shown particularly by the changes in the chemical shifts of the aromatic H atoms of C(4) and C(13) (protons $f_1$) and of C(2) and C(15) (protons $f_2$) (see Figure S1).

The protonation constants and p$K_a$ values of salOrn, determined by potentiometry, are also included in Table 2. The p$K_a$ values of salOrn (**2**) are higher than those of salDPA by a factor of 0.3–1.8 units. Since one of the amino groups is two carbon atoms further from the carboxyl group, when compared with salDPA, the p$K_a$(COOH) is higher for salOrn and could be determined by potentiometric measurements. The difference |p$K_{a2}^{salOrn}$ – p$K_{a2}^{salDPA}$| (equal to 1.8) suggests that the –$NH_2^+$– group associated with this deprotonation is the one that is closer to the $COO^-$ group.

Table 1. Formation constants (log$\beta_{pqr}$ for species $M_pL_qH_r$)[a] for the proton, $V^{IV}O^{2+}$ and $V^{V}O_2^+$ complexes of salDPA and salOrn,[b] and some derived data ($I$ = 0.2 M KCl and 25 °C).

[a] Three times the standard deviation is reported in parentheses. [b] A figure with a species distribution diagram for the complexes formed in the $V^{IV}O$–salOrn system is included in Section 4 of the Supporting Information. [c] M = (VO) for $V^{IV}O$ complexes and M = ($VO_2$) for $V^{V}O_2$ complexes. [d] One of the "good" equilibrium models obtained with PSEQUAD from the potentiometric data included stoichiometry (VO)$LH_{-1}$ with log$\beta$ = 12.92 (other constants have similar log$\beta$ values). However, for this different model, (VO)$LH_{-1}$ starts forming at pH = 9 and this is not compatible with the Vis spectroscopy and CD results. [e] A $V^{V}$–salDPA complex forms at pH < ca. 5.5, but precipitation of a grey solid and the possible occurrence of redox reactions precluded the reliable determination of its stoichiometry and log$\beta$.

### *$V^{IV}O$ Complexes*

The complex formation constants calculated from the potentiometric titrations carried out at different vanadium/salDPA ratios are also included in Table 1.[24] Slow equilibration of the solutions only occurred at pH > 10.5 (some potentiometric measurements) or at pH > 11 (some spectroscopic measurements). With $V^{IV}O^{2+}$ the concentration distribution diagram (Figure 2) includes the stoichiometries (oxidation state and charges omitted): VO, $(VO)LH_2$, $(VO)_2L$ (minor species) and (VO)L. For pH > ca. 12 the CD spectra recorded indicate the formation of a distinct $V^{IV}O$–salDPA complex [stoichiometry probably $(VO)LH_{-1}$]; however, a reliable log$\beta$ for this species could not be obtained (see below).

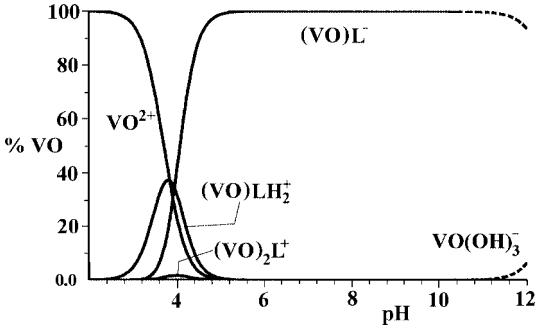

Figure 2. Species distribution diagram for the complexes formed in the $V^{IV}O$–salDPA system for solutions for which $C_{VO}$ = 1.0 mM and L/M = 1 (25 °C and $I$ = 0.2 M KCl).

It is clear from the speciation diagram that the salDPA ligand forms very stable complexes with $V^{IV}O^{2+}$, its hydrolysis products are not formed in measurable concentration at least in the pH range 2–11 and $(VO)L^-$ corresponds to ca. 100% of total V in the pH range 5–11 (at the experimental conditions specified). In $(VO)LH_2^+$ the tridentate coordination of the ligand seems to be the most probable, then by the cooperative deprotonation of the other half of the molecule a significant rearrangement of the coordinating donors occurs, which results in the formation of a joint chelate-ring system (for the possible binding modes see later).

Potentiometric pH measurements were also carried out to determine the equilibrium model and formation constants for the $V^{IV}O$–salOrn system. The best model includes the stoichiometries $(VO)LH_2$, (VO)LH and (VO)L; the corresponding log$\beta$ values are included in Table 2, and a calculated species distribution diagram is shown in the Supporting Information (Section 3, Figure S2). Compound salOrn also forms stable complexes with $V^{IV}O^{2+}$, but the hydrolysis products of oxidovanadium(IV), namely $[(VO)_2(OH)_5^-]_n$ and $VO(OH)_3^-$,[25] have a much higher relative importance in the pH range for the formation of species VOL in the $V^{IV}O$–salOrn system than for the $V^{IV}O$–salDPA system. This results from the lower stability of this VOL species, as one ring of the joint chelate system formed with salOrn is larger than that formed with salDPA (the carbon chain between the two NH groups is two carbon atoms longer in Orn than in DPA).

Figure 3 includes some of the CD spectra recorded in solutions containing $V^{IV}O^{2+}$ and sal-L-DPA. Globally the CD spectra agree well with the speciation diagram included in Figure 2. Up to pH 2.60, as the only V-containing species present in solution is $VO(H_2O)_5^{2+}$, the CD signal in the wavelength range 400–1000 nm (where vanadium-related bands are expected to show up) is almost zero. As $(VO)LH_2^+$ forms, spectra with the band pattern (–,+,–) are recorded up to pH ca. 3.4 with $\lambda_{max} < 400$ nm ($\Delta\varepsilon_m < 0$), ca. 565 nm ($\Delta\varepsilon_m > 0$) and ca. 790 nm ($\Delta\varepsilon_m < 0$). For pH > 3.5 and up to 5.0, the band pattern gradually changes (see Figure 3), but in the pH range 5–10.5 the CD spectra remain the same, with two main bands at 585 nm ($\Delta\varepsilon_m$ = –0.23 mol$^{-1}$ dm$^3$ cm$^{-1}$) and 945 nm ($\Delta\varepsilon_m$ = +1.46 mol$^{-1}$ dm$^3$ cm$^{-1}$), and only show small changes in the pH range 10.5–11.5.

The PSEQUAD computer programme[24] and the CD spectra obtained at different pH values were used to calculate the log$\beta$ and/or the spectrum of each individual species formed in the $V^{IV}O$–salDPA system. The calculated log$\beta$ values agree reasonably well with those obtained from the potentiometry (within ±0.1 log unit), and reasonable CD spectra could be calculated for $VOLH_2$ and VOL (see Figure 3d). This confirms that the speciation model proposed and the stability constants calculated from the potentiometric measurements are correct and reliable.

Figure 4 includes some of the visible absorption (Vis) spectra recorded with solutions containing $V^{IV}O^{2+}$ and salDPA. Globally the Vis spectra also agree well with the speciation diagram included in Figure 2. At pH < 2.60 the Vis spectra are quite similar to the spectrum of $VO(H_2O)_5^{2+}$ (see Figure 4a). For pH > 2.6 bands II ($d_{xy} \rightarrow$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

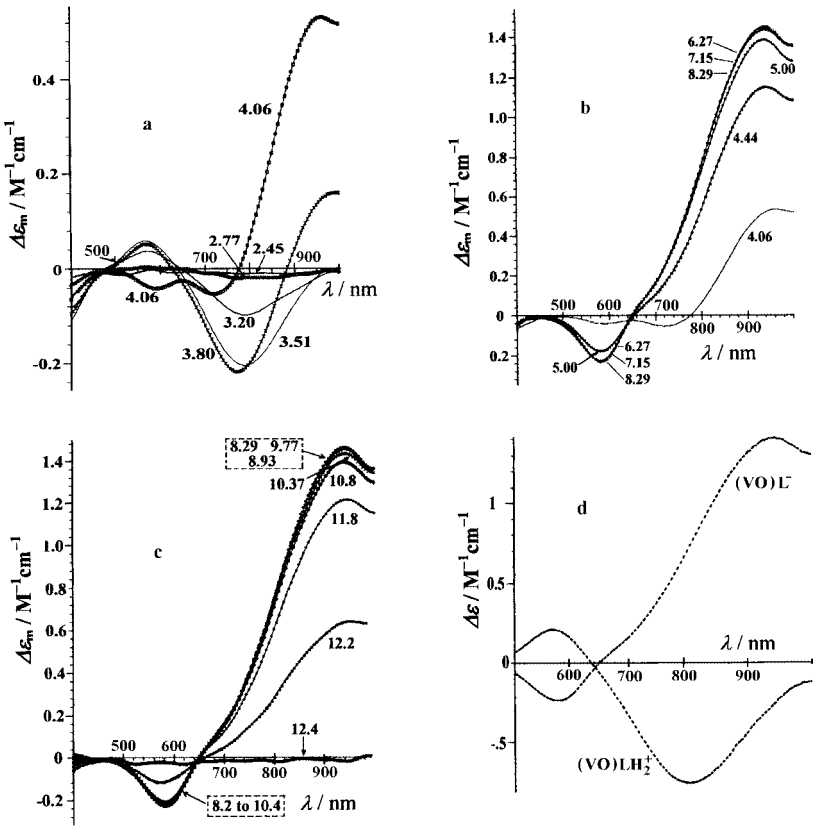

Figure 3. In a, b and c some CD spectra recorded for the $V^{IV}O$–salDPA system at a 1:1 metal ion/ligand ratio at several pH values (indicated) and $C_{VO}$ = 1 mM are represented. The $\Delta\varepsilon_m$ values recorded at pH = 1.96, 2.18, 2.45, 12.4 are close to zero. Spectra in d are the individual CD spectra calculated for stoichiometries $(VO)LH_2$ and (VO)L by the PSEQUAD programme[24] from the experimental CD spectra and the equilibrium constants included in Table 2.

$d_{x^2-y^2}$) and I ($d_{xy} \rightarrow d_{xz}$, $d_{yz}$) separate gradually, indicating an increase in the field strength. In the pH range 5.5–11.0 the Vis spectra do not change much (Figure 4b) showing two bands at ca. 575 nm ($\varepsilon_m \approx 65$ $mol^{-1}\,dm^{-3}\,cm^{-1}$) and ca. 910 nm ($\varepsilon_m \approx 43$ $mol^{-1}\,dm^{-3}\,cm^{-1}$), which indicate the presence of a single predominating species, VOL.

There is an important increase in the absorbance at ca. 400 nm between pH ca. 2.6 and 3.0, a less important one between 3.0 and 4.0, and then not much change up to pH 12 (Supporting Information, Section 5, Figure S3). This means that the equatorial coordination of the $O^-_{Phen}$ donors is already important at relatively low pH, and its contribution to the $\varepsilon_m$ values at 380–400 nm does not increase at pH > 4.0. At pH > 5 the absorbance at ca. 400 nm is sensitive to small percentages of hydrolysis or oxidation of the metal ion, but for this system the $\varepsilon_m$ values do not change much in this pH range.

EPR spectra were measured in "frozen" solutions (77 K) to check the speciation model and to elucidate the binding modes of the species. Some of the EPR spectra obtained for the $V^{IV}O$–salDPA system, in the region corresponding to $M_I$ = 5/2 and 7/2, are depicted in Figure 5. Table 2 shows the spin Hamiltonian parameters obtained by simulation of the experimental spectra. For the $V^{IV}O$–systems Chasteen[26] developed an additivity rule to estimate the hyperfine coupling constant $A_z^{est}$ [Equation (1)], on the basis of the contributions $A_{z,i}$ of each of the four equatorial donor groups. The estimated accuracy of $A_z^{est}$ is $\pm 3 \times 10^{-4}$ $cm^{-1}$.

$$A_z^{cst} = \sum_{i=1}^{4} A_{z,i} \quad (1)$$

Most of the $A_{z,i}$ relevant for this work were presented by Chasteen.[26] The contribution of the carboxylate ($COO^-$) donor in Equation (1) was estimated by Chasteen as $42.7 \times 10^{-4}$ $cm^{-1}$, on the basis of the $A_z$ of the VO-(oxalato)$_2^{2-}$ complex, assuming that the four $COO^-$ groups coordinate equatorially. However, the solution structure presumably involves the set $(3 \times COO^-, H_2O)_{eq}$,[27] so this contribution should be $42.1 \times 10^{-4}$ $cm^{-1}$, the value used in the present work. This data can be used to establish the most probable binding mode of the complexes formed, but care must be taken as the contributions of the donor groups to the hyperfine coupling may depend e.g. on their orientation,[28] or the charge of the ligand.[29] The influence of the axial donor groups (if any) is not taken into account.

Table 2[30] summarises the EPR parameters obtained, mostly from the simulation of the spectra by using the computer programme of Rockenbauer and Korecz.[30] Globally the EPR spectra (Figure 5) agree well with the speciation diagram depicted in Figure 2. Namely, for pH < 3 the only species detected is the aqua complex $[VO(H_2O)_5^{2+} \equiv VO \equiv$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

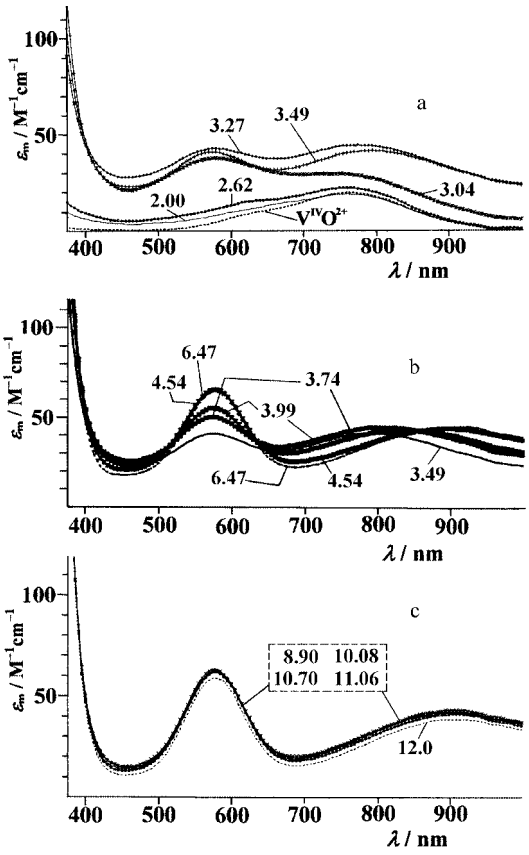

Figure 4. Some of the Vis absorption spectra recorded with aqueous solutions containing $V^{IV}O^{2+}$ and salDPA at a 1:1 metal ion/ligand ratio at several pH values (indicated) and $C_{VO}$ ca. 3 mM.

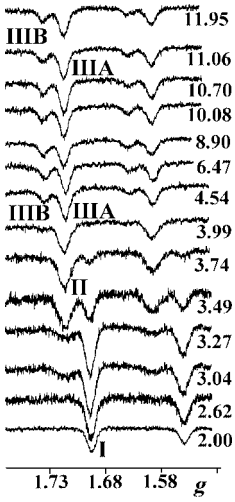

Figure 5. High field region of the EPR spectra (77 K) of frozen solutions containing $V^{IV}O^{2+}$ and salDPA at several pH values, with L/M = 1 and $C_{VO}$ ca. 3 mM. Four main components are detected: **I**-$[VO(H_2O)_5]^{2+}$, **II**-$(VO)LH_2^+$, **IIIA**-$(VO)L^-$ and **IIIB**-$(VO)L^-$.

**I**]. At pH = 3.04, besides a signal for VO, a signal corresponding to $(VO)LH_2^+$ (**II**) can already be detected. At pH 3.49 the signals corresponding to VO and $(VO)LH_2^+$ show similar intensities, but it should be noted that one of the signals corresponding to $(VO)L^-$ (**IIIA**) also starts appearing in this field range. In the pH range ca. 4.5–12 only two EPR components, designated by **IIIA** and **IIIB** and corresponding to $A_z$ values of 167.9 and $161.4\times10^{-4}$ cm$^{-1}$, respectively, are detected. Their relative intensity is always the same so they must correspond to isomeric structures of the same stoichiometry, $(VO)L^-$. Up to pH 12 apparently no other species forms, and this is consistent with the Vis and CD spectra obtained. If any small amount of $VO(OH)_3^-$ is present at high pH, as its $A_z$ is ca. $162\times10^{-4}$ cm$^{-1}$, it would not be distinguished from the lines of $(VO)L^-$ (**IIIB**).

It has been previously emphasised[25] that, as the V atom in most oxidovanadium(IV) complexes is a stereogenic centre, most complexes in solution correspond to two enantiomers. If the ligand contains stereogenic centres and/or if one of the coordinating atoms becomes a stereogenic centre, several isomers corresponding to the same binding mode necessarily form. This is the case of the $V^{IV}O$–salDPA system where C(9) is a stereogenic centre. Moreover, for the same stoichiometry more than one type of binding mode may form. Some may yield distinct EPR signals, others not.

Species $(VO)LH_2^+$ may correspond to binding modes [($COO^-$, $N_{amine}$, $2\times H_2O)_{eq}$($N_{amine}$ or $O_{Phen}$)$_{ax}$] **BMa**, [($O_{Phen}$, $N_{amine}$, $2\times H_2O)_{eq}$($H_2O$ or $COO^-$)$_{ax}$] **BMb**, or [($O_{Phen}$, $COO^-$, $2\times H_2O)_{eq}$ ($N_{amine}$)$_{ax}$] **BMc** (see Scheme 2). These binding modes correspond to $A_z^{est}$ values of 173.5, 170.2 or $172.3\times10^{-4}$ cm$^{-1}$, respectively. The Vis spectra (Figure 4) indicate a significant equatorial coordination of $O_{Phen}$ starting at pH < 3; this rules out **BMa1** and **BMa2**. As the calculated CD spectrum for $VOLH_2$ is quite strong (Figure 3d), this suggests that the $COO^-$ group is coordinated equatorially, since this group should induce a strong CD effect and is near the stereogenic centre. Therefore, the predominant binding mode is probably **BMc**, where a set of (5+6)-membered chelate rings forms, the part of the salDPA molecule involved in the coordination being the one closer to the stereogenic centre.

Species $(VO)L^-$ involves at least two types of isomers, corresponding to species **IIIA** ($A_z = 167.9\times10^{-4}$ cm$^{-1}$) and **IIIB** ($A_z = 161.4\times10^{-4}$ cm$^{-1}$) detected in the EPR spectra (e.g. Figure 5). Species with binding mode [($2\times O_{Phen}$, $2\times N_{amine})_{eq}$($H_2O$ or $COO^-$)$_{ax}$] correspond to $A_z^{est}$ = $157.9\times10^{-4}$ cm$^{-1}$, quite different from the experimental $A_z$; therefore, this binding mode does not form significantly. Species **IIIB** may correspond to binding modes such as [($O_{Phen}$, $COO^-$, $2\times N_{amine})_{eq}$($O_{Phen}$)$_{ax}$] (**BMe**) corresponding to $A_z^{est}$ = $161.2\times10^{-4}$ cm$^{-1}$, or [($2\times O_{Phen}$, $COO^-$, $N_{amine})_{eq}$($N_{amine}$)$_{ax}$] (**BMf**) corresponding to $A_z^{est}$ = $160.0\times10^{-4}$ cm$^{-1}$ (see Scheme 2). On the other hand, given the donor groups available, species **IIIA** corresponds to quite a high $A_z$ value. The highest reasonable $A_z^{est}$ is obtained for the binding mode [($2\times O_{Phen}$, $COO^-$, $H_2O)_{eq}$-($N_{amine}$)$_{ax}$] (**BMd**), which corresponds to $A_z^{est}$ = $165.5\times10^{-4}$ cm$^{-1}$, compatible with the experimental value ($167.9\times10^{-4}$ cm$^{-1}$). However, this binding mode assumes that the amino group N(2)H is deprotonated and noncoordinated, which is hardly probable, even if, not considering the carboxylate, this group has a lower macroscopic p$K_a$

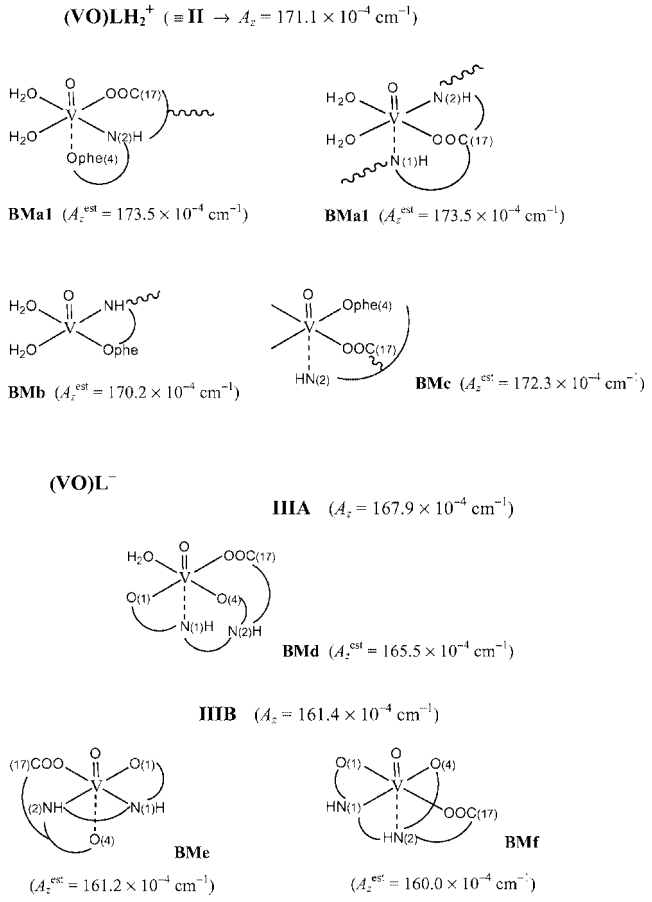

Scheme 2. Schematic representation of the plausible structures for the main stoichiometries that form in the $V^{IV}O$–salDPA system; the corresponding $A_z^{est}$ values are also included. In some of these representations the numbering of atoms of salDPA used in Figure 1 is also included to specify more clearly to which atoms they correspond. For the EPR component **IIIA**, other plausible binding modes cannot be ruled out (see text).

($pK_{a2}$ = 5.91) value. Possible binding modes that involve coordination of all groups with high $pK_a$ values are: e.g. [($O_{Phen}$, $H_2O$, $2\times N_{amine})_{eq}(O_{Phen})_{ax}$] ($A_z^{est}$ = $164.6\times10^{-4}$ cm$^{-1}$) and [($2\times O_{Phen}$, $H_2O$, $N_{amine})_{eq}(N_{amine})_{ax}$] ($A_z^{est}$ = $163.8\times10^{-4}$ cm$^{-1}$), these also correspond to relatively high $A_z$ values and cannot be completely ruled out. Scheme 2 summarises the set of the most plausible binding modes for $VOLH_2$ and VOL.

The CD spectrum of the isolated Na[$V^{IV}O$(sal-L-DPA)] complex (see Figure S4) resembles the CD spectrum corresponding to $(VO)L^-$ (Figure 3d). The spectrum in Figure 3d is the calculated spectrum for stoichiometry $(VO)L^-$; therefore, it is a weighted average of the CD spectra of all isomeric complexes present, i.e. all complex species corresponding to the EPR components **IIIA** and **IIIB**.

### *$V^VO_2$ Complexes*

The complex formation constants derived from the potentiometric titrations carried out at different salDPA/vanadium(V) ratios are also included in Table 2. For the $V^V$–salDPA system, the distribution diagram (Figure 6) includes the stoichiometries (oxidation state and charges omitted) M, $MLH_2$, MLH and ML ($M=V^VO_2$). Hereafter, $MLH_2$, MLH and ML will be designated by $(VO_2)LH_2$, $(VO_2)LH^-$ and $(VO_2)L^{2-}$, respectively. The system was also studied by $^{51}$V- and $^1$H NMR and CD spectroscopy. Some of the $^{51}$V NMR spectra recorded are included in Figure 7 and the CD spectra are included in Figure 8. Under the experimental conditions used to obtain these spectra, as the pH was decreased the colour changed from yellow to yellow-grey and then to grey (pH ≈ 4). For pH < 5 the pH was not stable and a solid precipitated. At pH ≈ 4 there was no important concentration of $V^V$ in solution as was indicated by the low intensity of the $^{51}$V NMR spectra. In the potentiometric titrations similar observations were made but in the experiments at lower vanadium concentrations (0.5–1 mM) no precipitation of any solid compound was detected upon decreasing the pH. However, as the pH readings were not stable, only titration points for pH > 5

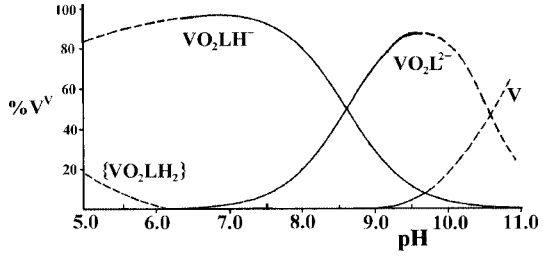

Figure 6. Approximate species distribution diagram for the complexes formed in the $V^V$–salDPA system for solutions for which $C_V$ ca. 3.0 mM and L/M = 1 (t = 25 °C, $I$ = 0.2 M KCl). The potentiometric data suggest that the $V^V$–salDPA species that forms for pH < 6 corresponds to a $(VO_2)LH_2$ stoichiometry. The full lines were calculated from the log$\beta$ values included in Table 1. The dashed lines are an estimate of the relative importance of the $V^V$–species present in solution, partly on the basis of the relative areas of the $^{51}$V NMR peaks.

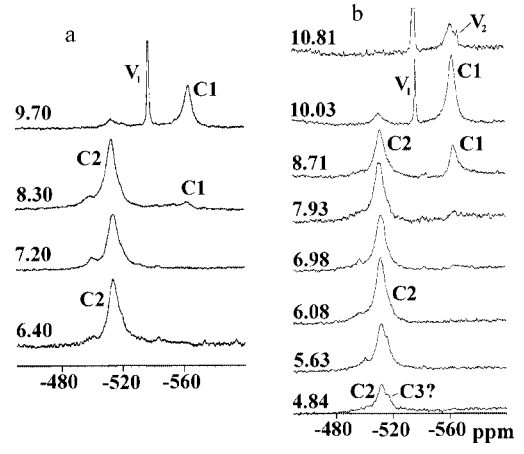

Figure 7. $^{51}$V NMR spectra, obtained at 131.404 MHz and at 25.0 ± 0.5 °C, of solutions containing sodium vanadate and salDPA. Spectra corresponding to two different sets of experiments are shown, (a) $C_V$ ca. 3.0 mM and L/M = 1.27 ($D_2O$ solution), the pD values are indicated in each spectrum; (b) $C_V$ ca. 4.0 mM and L/M = 1.2 ($H_2O$ solution), the pH values are indicated in each spectrum.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

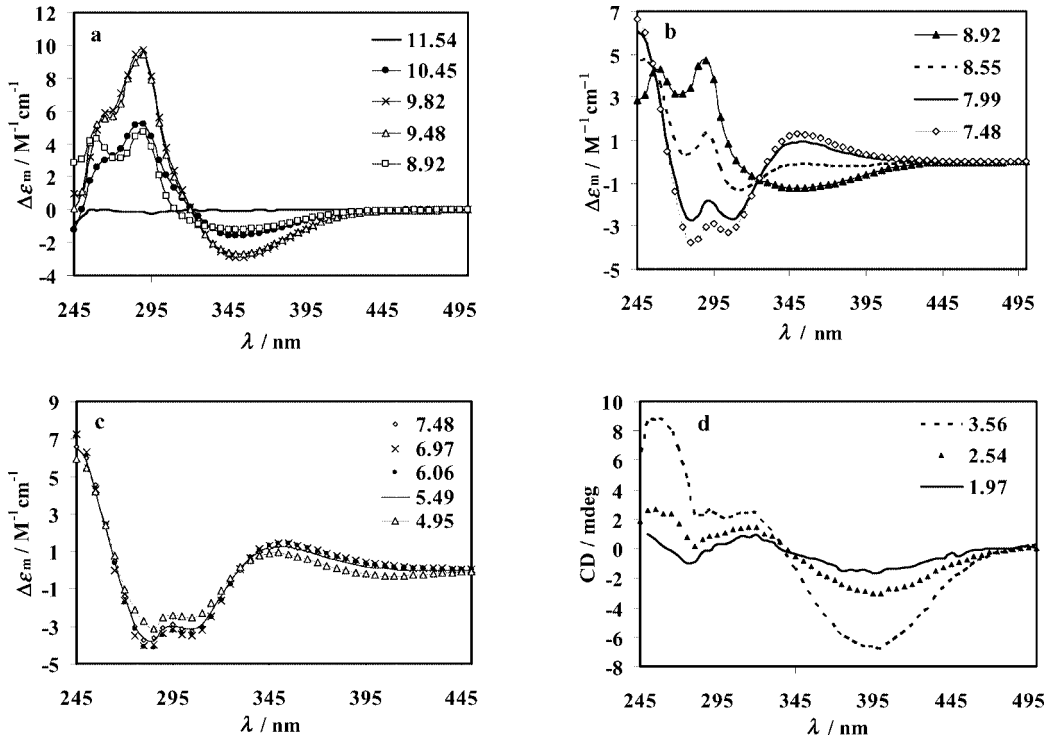

Figure 8. Some CD spectra recorded for the $V^{V}O_2$–salDPA system at a 1.2:1 ligand/metal ion ratio at several pH values (indicated) and $C_V$ = ca. 3 mM. The measurements started at pH ca. 11.5 and were made by making successive additions of an HCl solution. For pH < 5 a grey precipitate started to form, and the amount of this precipitate increased for pH < 4. The CD spectra for pH < 4 were recorded from clear samples after filtration of the mixture. The CD spectra of species $(VO_2)LH^-$ and $(VO_2)LH^{2-}$ calculated with the PSEQUAD programme[24] by using the log$\beta$ values included in Table 1 are shown in Section 8 of the Supporting Information.

were used in the calculations with the PSEQUAD programme.

In Figure 7 the $^{51}V$ NMR peak at –563 ppm (**C1**), detected between ca. pH 11 and 7.6, corresponds to the $(VO_2)L^{2-}$ species. In this complex the ligand is probably tetradentate and is coordinated by the two phenolate and two amine donors (see **BMg** in Scheme 3), as was observed in the $V^V$–pyran system where $^{51}V$ NMR peaks also appeared at ca. –565 ppm.[15] However, as this complex corresponds to a relatively intense CD signal (see below), structures involving the coordination of the $COO^-$ group instead of one $O_{phen}$ or one $NH_{amine}$ cannot be ruled out.

The broad peak around –512 ppm (**C2**), has a peak/shoulder at –500 ± 2 ppm, and shoulder(s) may also be seen at ≈–516 ± 2 ppm. Apparently, the relative intensity of the peaks at ca. –512 and ca. –500 ppm does not change with pH, so they correspond to isomeric forms of the same stoichiometry, $(VO_2)LH^-$. Scheme 3 includes several plausible structures for these species.

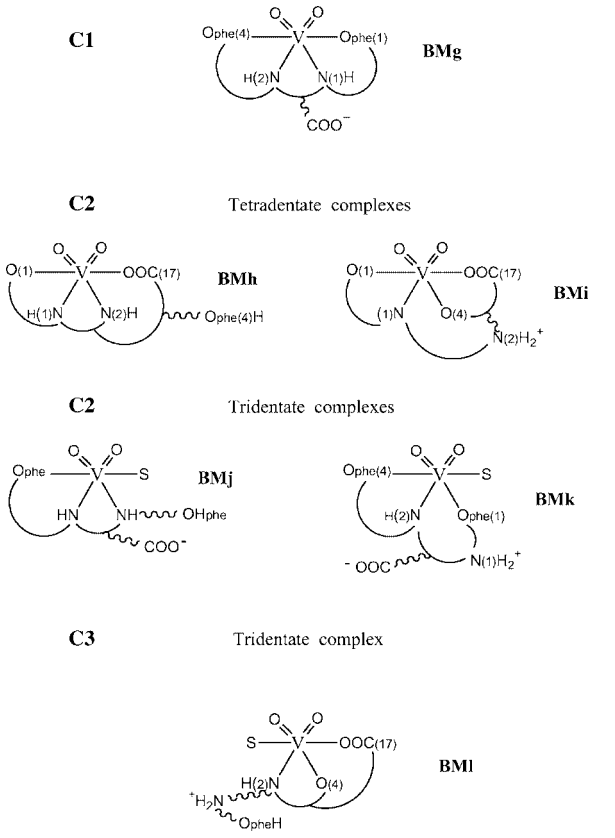
As mentioned above, for pH < 5 a precipitate forms, most of the $V^V$ is removed from the solution, and the $^{51}V$ NMR signals are very weak. Upon addition of an HCl solution, this grey precipitate dissolves, forming a blue solution; therefore, the solid contains a $V^{IV}$ species. However, as neither the grey solid nor its mother solution show an EPR signal, most of it is probably vanadyl hydroxide (see also Section 6 in the Supporting Information).

In solutions initially containing 3 mM $V^V$ and salDPA, a weak signal at ca. –515 ppm (**C3**) could be detected between ca. pH 5.6 and 4.0 (together with the peak **C2** and at least four other peaks which presumably correspond to oligomeric vanadates, not shown in Figure 7). The dashed line in the pH range 5–6 in Figure 6 was estimated on the basis of these observations. It is reasonable to assume that this $^{51}V$ NMR peak corresponds to complex $(VO_2)LH_2$, as suggested by the potentiometric calculations.

CD spectra were recorded for aqueous solutions containing sal-L-DPA at several pH values, but the $\Delta\varepsilon_m$ values were approximately zero in the range 240–700 nm. Several CD spectra recorded for the $V^V$–salDPA system are included in Figure 8. The sal-L-DPA ligand itself has no significant CD spectrum for $\lambda$ > 240 nm and no absorption for $\lambda$ > 320 nm; therefore, the CD bands observed must mainly be metal-related induced CD signals. We expect that the efficiency of the sal-L-DPA donor groups in inducing dissymmetry in the metal-related bands follows the order $COO^-$ > N(2) > N(1) >> $O_{Phen}$,[31] i.e. strong CD signals are expected only when N(2) and particularly $COO^-$ are coordinated to the metal centre.

At pH ca. 11.5 the $\Delta\varepsilon_m$ values are approximately zero, so there are no $V^V$–sal-L-DPA complexes in solution. At pH 10.5 the pattern of the CD spectrum is the same as that observed at pH 9.8 or 9.5, but $|\Delta\varepsilon_m|^{pH10.4} \approx 1/2|\Delta\varepsilon_m|^{pH9.8\text{ or }9.4}$ (see Figure 8a). These CD spectra correspond to the species $(VO_2)L^{2-}$. Between pH 11.4 and 9.5, all CD spectra cross at ca. 325 nm, $\Delta\varepsilon_m$ = 0, indicating the presence of only one optically active species in equilibrium with the $V^V$ hydrolysis products. For pH < 9.4 the pattern

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Schematic representation of the plausible structures for the main stoichiometries that form in the $V^{V}O_2$–salDPA system. In some of these representations the numbering of atoms of salDPA used in Figure 1 is also included to specify more clearly to which atoms they correspond. Note that, for each of the schematic binding modes represented, (i) more than one isomer may form, (ii) other plausible binding modes can be envisaged.

of the CD spectra gradually change, and between pH 8.9 and 7.0 they show an isodichroic point, indicating the presence of two types of optically active species, $VO_2L^{2-}$ and $VO_2LH^{-}$ (Figure 8b). Between pH 7.5 and 5.0, the spectra remain approximately the same and correspond to $(VO_2)LH^{-}$ (Figure 8c).

For lower pH values, precipitation of a dark-grey solid occurs. CD spectra could be obtained after filtering the mixture. Figure 8d includes some of the spectra recorded, but $\Delta\varepsilon_m$ values could not be obtained as the $V^{V}$ concentration in these solutions is not known. The pattern of these CD spectra differs from that corresponding to $(VO_2)LH^{-}$ (Figure 8c), so this optically active complex corresponds to a distinct stoichiometry, $(VO_2)LH_2$, as suggested by the potentiometric data.

Species **C3**, detected by $^{51}V$ NMR and CD spectroscopy, probably corresponds to the binding mode **BMl** indicated in Scheme 3. This is the only reasonable way to obtain an optically active $V^{V}$–salDPA complex with a $(VO_2)LH_2$ stoichiometry, i.e. the (5+6)-chelate rings containing atoms O(2 or 3)–C(17)–C(9)–N(2)–C(10)–C(11)–C(16)–O(4) (see Figure 1), which are involved in the chelate rings.

Species **C2** corresponds to the CD spectra shown in Figure 8c (and in Figure S6) and to more than one isomer, as indicated by the $^{51}V$ NMR spectrum, where at least two distinct broad peaks are detected: an intense one at $-512 \pm 2$ ppm and a weaker one at $-500 \pm 2$ ppm; the difference in chemical shift between **C1** and **C2** indicates quite different binding modes. The broadness of the peaks may suggest a nonsymmetrical binding mode, **BMh** and **Bmi**, corresponding to a plausible hypothesis. For the tridentate structures such as **BMk** and particularly **BMj**, we would expect a weak CD signal (see above), but this is not the case here. However, tridentate structures cannot be ruled out, as this appears to be the most reasonable explanation for the large difference in chemical shift between **C1** and **C2**.

## Conclusions

The reduced Schiff bases of salicylaldehyde with diaminopropionic acid (salDPA) and ornithine (salOrn), as well as the $V^{IV}O^{2+}$ and $V^{V}O_2^{+}$ complexes of salDPA were prepared and characterised in the solid state and in solution. The structure of one of the protonated forms of salDPA, $H_4$salDPA$^{+}Cl^{-}$, was determined by X-ray diffraction. Complexation of $V^{IV}O^{2+}$ and $V^{V}O_2^{+}$ with salDPA in aqueous solution was studied by potentiometry, UV/Visible spectroscopy and circular dichroism, as well as by EPR spectroscopy for the $V^{IV}O$–salDPA system and by $^{1}H$- and $^{51}V$ NMR spectroscopy for the $V^{V}O_2$–salDPA system. The $V^{IV}O$–salOrn system was studied by potentiometry.

These reduced Schiff base ligands are less susceptible to hydrolysis than their corresponding Schiff base compounds, which we did not isolate in pure form. They also form much more stable complexes than the corresponding Schiff bases. As expected for a salen-type ligand derived from an ethylenediamine rather than a butylenediamine moiety, the $V^{IV}O$ complexes formed with salDPA are much more stable than those formed with salOrn. In fact, in aqueous solutions containing 1:1 ligand/metal stoichiometry, no $V^{IV}O$ hydrolytic products were detected in the pH range 4 to 11 in the salDPA system, while for the salOrn system significant concentrations of $[(VO)_2(OH)_5^{-}]_n$[25] formed in the pH ranges 5–7.5 and 10.5–12.

Practically only 1:1 complexes are formed. The main species formed have the composition $(VO)LH_2^{+}$ and $(VO)L^{-}$ in the $V^{IV}O$–salDPA system, $(VO)LH_2^{+}$, (VO)LH and $(VO)L^{-}$ in the $V^{IV}O$–salOrn system and $(VO_2)LH^{-}$ and $(VO_2)L^{2-}$ in the $V^{V}O_2$–salDPA system. Spectroscopic data provided information about the most probable binding mode of each stoichiometry of the vanadium–salDPA systems. In most cases, the $COO^{-}$ groups are involved in the coordination to $V^{IV}O^{2+}$ or $V^{V}O_2^{+}$, so the binding modes of the ligand may differ from those typically found in vanadium–salen systems.

Globally salDPA is a very effective ligand for $V^{IV}O^{2+}$ and $V^{V}O_2^{+}$, namely in the pH range 6–9. The pendant carboxylate group may help the coupling of the salan moiety to other molecules that may target the compound to specific

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

biological sites. Therefore, we anticipate the possibility of using salDPA systems as carriers of vanadium or other metal ions for this purpose.

## Experimental Section

### Synthesis of Solid Compounds

**salDPA (1):** Triethylamine (3 g, 29.8 mmol) was added to a suspension of L- or D,L-2,3-diaminopropionic acid (DPA) (2 g, 14.2 mmol) in methanol (50 mL) in order to neutralise the mixture. Small portions of a solution of salicylaldehyde in MeOH (3.6 g, 29.1 mmol) were slowly added to this mixture. The mixture became yellow, and this colour became stronger and stronger until the dissolution of DPA was completed. The solution was cooled in ice, and sodium borohydride (2.4 g, 63.9 mmol) was slowly added. A white solid soon precipitated; it was filtered and suspended in MeOH for 3 h. The solid was then filtered, washed with water and MeOH and dried under vacuum. Yield 62%. The number of molecules of water of crystallization found in the several syntheses performed varied from 0 to 1 and the values reported are only examples of some of those found. Yield: 2.8 g, 60%. For $H_3$sal-D,L-DPA, $C_{17}H_{20.6}N_2O_{4.3}$ [$C_{17}H_{20}N_2O_4{\cdot}0.3H_2O$] (321.7): calcd. C 63.46, H 6.45, N 8.71; found C 63.6, H 6.7, N 8.6. $^1$H NMR (300 MHz, $D_2O$, ≈25 °C): 4.30 (s, 5 H, Ar–CH2–N and –CH–*N*–), 3.55 (d, 2 H, NH–$CH_2$), 6.92 (s, 4 H, $CH_{aromatic}$), 7.28 (d, 4 H, $CH_{aromatic}$) ppm. A second method was also used; in the final stage the white solid was suspended in MeOH, and the pH was lowered with a methanol solution of HCl (pH < 1.5). The solid dissolved, and ca. 30 min later another white solid precipitated. This was filtered and washed with water and MeOH. (Yield: 37%). From the mother solution, kept at room temperature for one week, white crystals (small needles) suitable for single-crystal X-ray diffraction were obtained. Yield: 0.132 g, 37%. For $H_4$sal-D,L-DPA·Cl (**1A**), $C_{17}H_{21}N_2O_4Cl$ (358.2): calcd. C 57.87, H 6.00, N 7.94; found C 58.0, H 6.3, N 7.9. For $H_4$sal-L-DPA·Cl, $C_{17}H_{21.6}N_2O_{4.3}Cl$ [$C_{17}H_{21}N_2O_4Cl{\cdot}0.3H_2O$] (358.2): calcd. C 56.99, H 6.08, N 7.82; found C 57.1, H 6.3, N 7.7.

**sal-L-Orn (2):** An ethanol solution (5 mL) of salicylaldehyde (0.230 mL; 2.2 mmol) was added to an aqueous solution (20 mL) of L-ornithine (0.169 g, 1 mmol). The yellow solution was stirred for ca. 1 h and then cooled to ca. 0 °C. As a solution of sodium borohydride (0.095 g, 2.5 mmol) in ethanol (2 mL) containing a few drops of a NaOH (4 M) solution was slowly added, the yellow colour gradually disappeared. After ca. 2 h, the pH was set to ca. 5.2 with HCl (3 M). The solution was kept in a refrigerator at ca. 4 °C for one week. A small amount of a white precipitate formed, which was filtered, washed with cold water, ethanol and ether and dried in vacuo. Yield: 0.051 g, 13%. For $H_3$sal-L-Orn, $C_{19}H_{28.4}N_2O_{6.7}$ [$C_{19}H_{24}N_2O_4{\cdot}2.7H_2O$] (393.0): calcd. C 58.06, H 7.54, N 7.13; found C 58.0, H 7.5, N 7.1.

**sal-L-Lys (3):** The procedure was identical to the one used for sal-L-Orn, but the white solid sal-L-Lys precipitated overnight. Yield: 28%. The number of molecules of water of crystallization found in the several solids obtained varied from 2 to 3, and the value included here corresponds to one of the batches. Yield: 0.114 g, 28%. For $H_3$sal-L-Lys, $C_{20}H_{31.4}N_2O_{6.7}$ [$C_{20}H_{26}N_2O_4{\cdot}2.7H_2O$] (407.0): calcd. C 59.01, H 7.77, N 6.88; found C 59.0, H 7.8, N 6.8. The compound is not soluble in water or in ethanol/water (at least up to 10% ethanol).

**van-D,L-DPA (4):** A methanol solution (5 mL) of *o*-vanillin (0.339 g, 2.2 mmol) was added to a suspension of D,L-2,3-diaminopropionic acid (DPA) (0.142 g, 1 mmol) in methanol (10 mL). Triethylamine was added in order to obtain a pH value of ca. 7.0. The yellow solution was stirred for 3 h at room temperature and then cooled to ca. 0 °C. Sodium borohydride was then slowly added (0.113 g, 3.0 mM), and the solution became colourless. A small amount of a white solid precipitated, which was washed with cooled water (ca. 4 °C), methanol and ether and then dried in vacuo. Yield: 0.092 g, ca. 22%. For $H_3$van-D,L-DPA, $C_{19}H_{28.8}N_2O_{8.4}$ [$C_{19}H_{24}N_2O_6{\cdot}2.4H_2O$] (419.6): calcd. C 54.38, H 6.92, N 6.65; found C 54.4, H 6.4, N 6.6.

**Na[$V^{IV}O$(salDPA)]:** salDPA was (0.322 g, 1 mmol) dissolved in 20 mL of ethanol/water (1:3), and a few drops of NaOH (4 M) were added to promote total dissolution. An aqueous solution (2 mL) of sodium acetate (0.675 g, 5 mmol) was then added, followed by the addition of an aqueous solution (2 mL) of $VOSO_4{\cdot}5H_2O$ (0.26 g, 1 mmol). The solution became pink, and a pink solid precipitated, which was filtered, washed with cold water (≈4 °C), ethanol and ether, and dried under vacuum. Yield: 0.0987 g, 23%. For Na[$V^{IV}O$(sal-D,L-DPA)], $C_{17}H_{16}N_2NaO_5V$ [$C_{17}H_{16}N_2O_5VNa{\cdot}1.5H_2O$] (429.2): calcd. C 47.57, H 4.46, N 6.53, Na 5.36; found C 47.8, H 4.7, N 6.5, Na 6.3. All procedures were performed under $N_2$ and both Na[$V^{IV}O$(sal-D,L-DPA)] and Na[$V^{IV}O$(sal-L-DPA)] were prepared.

**Na[$V^{V}O_2$(salDPA)]:** sal-D,L-DPA (0.322 g, 1 mmol) was dissolved in 25 mL of water, and a few drops of NaOH (4 M) were added to promote total dissolution. An aqueous solution (5 mL) of ammonium vanadate was prepared, also containing a few drops of NaOH (4 M). Under vigorous stirring, the vanadate solution was slowly added to the salDPA solution. A solution of HCl (3 M) was then slowly added until pH ca. 8 was obtained. While adding the acid, a dark solid first appeared, but it disappeared upon stirring. The initial yellow colour became greenish. After 2 h of stirring, a greyish solid formed, it was filtered, and the filtrate was kept. After ca. 20 h a lemon-green solid was formed, which was filtered and washed with cold water (≈4 °C), ethanol and ether, and dried under vacuum. Yield: 0.188 g, 40%. For Na[$VO_2$(sal-D,L-DPA)], $C_{17}H_{20}N_2NaO_7V$ [$C_{17}H_{16}N_2O_5VNa{\cdot}2H_2O$] (470.2): calcd. C 44.95, H 4.44, N 6.17, Na 5.05; found C 44.9, H 4.4, N 6.0, Na 4.6.

### Potentiometric Measurements

All measurements were made in aqueous solution. The purity of the ligands was checked potentiometrically and the exact concentration of solutions was determined by the Gran method.[32] The stock solution of $V^{IV}O$ was prepared and standardised as reported earlier.[33,34] The $H_3O^+$ concentration in the stock solutions were determined by potentiometry. The $V^V$ stock solution was prepared by dissolving $KVO_3$ (Sigma–Aldrich) in an accurately measured volume of a KOH solution of known molarity (0.1977 M), and its $OH^-$ concentration was calculated by taking into account the total volume of the $V^V$ stock solution prepared.

All solutions were manipulated in an inert atmosphere (high purity $N_2$ or purified argon). The ionic strength was adjusted to 0.20 M KCl and the temperature was 25.0 ± 0.1 °C. The pH was measured with an Orion 710A precision digital pH meter equipped with an Orion Ross 8103BN type combined glass electrode, calibrated for hydrogen ion concentration as described earlier.[33] The ionic product of water was $pK_w$ = 13.76.

The protonation constants of salDPA were determined from five titration curves of 4- to 8-mL samples with initial concentrations in the range 0.002 to 0.01 M. Those of sal-L-Orn were determined from five titration curves of 2- to 4-mL samples with a similar concentration range.

Stability constants of the $V^{IV}O$–salDPA system were determined by potentiometric titrations of six 10.0-mL samples. The metal con-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

centrations were in the range 0.0005–0.003 M, and the L/M ratio was from 0.7 to 4. Titrations were normally performed from pH 2.0 up to 11, unless very extensive hydrolysis, precipitation (only for L/M = 0.7, at pH = 4.0) or very slow equilibration was detected, with KOH solution of known concentration (ca. 0.2 M) under a purified argon atmosphere. For the $V^{IV}O$–sal-L-Orn system, the metal concentrations were in the range 0.001–0.004 M, and the L/M ratios varied from 1 to 4. Titrations were normally performed from pH 2.0 up to 11 in a 5-mL thermostatted cell, by using the same criteria as for the $V^{IV}O$–salDPA system.

The stability constants of the $V^{V}O_2$–salDPA system were also determined by potentiometric titrations of six 10.0 mL samples from pH 12 to ca. 4 (or down to pH ca. 5 for the more concentrated samples, as some precipitation was detected at pH < 5) with an HCl solution of known concentration (ca. 0.2 M). The reversibility of the $V^{V}$ complexation was checked for three L/M ratios by titrating samples starting from pH ca. 5. The reproducibility of titration points included in the evaluation was within 0.005 pH units in the pH range 5–11.

The concentration stability constants $\beta_{pqr} = [M_pL_qH_r]/[M]^p[L]^q[H]^r$ were calculated by using the PSEQUAD computer programme.[24] The formation of the following $V^{IV}O$ hydroxido complexes was taken into account: $[V^{IV}O(OH)]^+$, $[(V^{IV}O)_2(OH)_2]^{2+}$, $[(V^{IV}O)_2(OH)_5]^-$ and $[V^{IV}O(OH)_3]^-$.[25,35,36] As is discussed in ref.[25], the $\log\beta$ of $[(V^{IV}O)_2(OH)_5]^-$ and $[V^{IV}O(OH)_3]^-$ are not known accurately. Therefore, the calculations for pH > 4 may not be entirely reliable, particularly for systems and experimental conditions where these $V^{IV}O$-hydroxido complexes have significant concentrations. For the $V^{IV}O$–salDPA this is not the case, but for the salOrn system some inaccuracies may result from this. For the $V^{V}$ systems, the stability constants were similarly defined, where M refers to $VO_2^+$. The speciation of vanadate into monomeric, dimeric, tetrameric, pentameric and decameric species[37] was taken into account.

### Spectroscopic Measurements

**General:** IR spectra were recorded either with a BioRad FTS 3000 MX FTIR or with a Jasco FTIR 430 spectrometer. Visible spectra were recorded either with a Hitachi U-2000 or a Perkin–Elmer Lambda 9 UV/Vis/NIR spectrophotometer. The CD spectra were recorded with a JASCO 720 spectropolarimeter, either with a red-sensitive photomultiplier (EXEL-308) suitable for the 400–1000 nm range or with the photomultiplier suitable for the 200–700 nm range. The EPR spectra were recorded at 77 K (with glass made by freezing solutions in liquid nitrogen) with a Bruker ESP 300E X-band spectrometer. The $^1$H- and $^{51}$V NMR spectra were obtained with a Varian Unity-500 NMR spectrometer operating at 499.824 and 131.404 MHz, respectively, by using a 5-mm-broadband probe and a controlled-temperature unit set at 25 ± 1 °C. Most of the $^1$H NMR spectra were obtained with a Varian Unity 300 spectrometer also at ca. 25 °C.

**UV/Vis and CD Spectroscopy:** All measurements were made in water. The temperature was kept at 25.0 ± 0.3 °C with circulating water. Unless otherwise stated, by visible (Vis) or circular dichroism (CD) spectra we mean a representation of $\varepsilon_m$ or $\Delta\varepsilon_m$ values vs. $\lambda$ [$\varepsilon_m$: absorption/($bC_M$) and $\Delta\varepsilon_m$: differential absorption/($bC_M$), where $b$: optical path and $C_M$: total $V^{IV}$ or $V^{V}$ concentration]. The spectral range covered was normally 350–900 (Vis) and either 240–600 or 400–1000 nm (CD). All measurements and operations of the spectropolarimeter were computer-controlled. Normally the spectra were recorded by changing the pH with approximately fixed total vanadium and ligand concentrations. The CD spectra of polycrystalline samples were obtained as described in ref.[38]

**EPR Spectroscopy:** In the absence of ethylene glycol, a relatively broad background was present in most of the frozen solution EPR spectra; therefore, most spectra were run with aqueous solutions containing 5% of ethylene glycol. The $V^{IV}O$ EPR spectra were simulated by using a programme by Rockenbauer and Korecz.[30] The EPR spectra help to elucidate which groups coordinate in solution.[26] For the $V^{IV}O$ systems, we used the additivity rule to estimate the hyperfine coupling constant $A_z^{est}$ (see above).

**$^1$H- and $^{51}$V NMR Spectroscopy:** All samples were prepared at room temperature immediately before the acquisition of the NMR spectra. Ligand solutions for the $^1$H NMR pH titrations were prepared in $D_2O$ (99.995%D) by weighing the appropriate amount of the ligand in order to have the desired concentration. The pD values of these solutions were adjusted with DCl and $CO_2$-free NaOD solutions, and measured by using either a Crison MicropH 2002 pH-meter with an Ingold 405-M5 combined electrode, or a Thermo Orion 420A+ pH meter with a Mettler Toledo U402-M3-S7/200 combined microelectrode (all calibrated at 20 ± 1 °C with standard aqueous buffers at pH 4.0 and 7.0). The final values of pD were determined from pD = pH* + 0.40, where pH* corresponds to the reading of the pH meter.[39] To obtain $^{51}$V NMR spectra, the solutions containing the $V^{V}$–salDPA complexes were normally prepared by adding the appropriate amounts of the ligand salDPA to aqueous sodium vanadate solutions of known concentrations and at pH ca. 11–12 in order to have the desired L/M ratios (L/M = 1–1.2). The initial $V^{V}$ concentration in the samples was 3 to 5 mM. The measurements normally started at pH ca. 12 and were continued down to pH 4 (in one set of experiments down to pD 1.8) by addition of an HCl solution. In these experiments, a dark grey precipitate formed at pH < 4–5 (depending on the concentrations), but as the solid settled at the bottom of the NMR tubes, NMR spectra could be obtained from the clear solution. For the acquisition of $^1$H NMR spectra from which data shown in Figure S1 was obtained, a ca. 5-mM solution of salDPA was prepared at pD ca. 13 in $D_2O$, by addition of $CO_2$-free NaOD. The measurements were performed down to pH 1 by addition of DCl (or NaOD, whenever necessary). For pH < 5 the salDPA started to precipitate, but as it agglomerated at the bottom of the NMR tubes, the spectra could be obtained from the clear solution in the upper part. The $^1$H- and $^{51}$V NMR chemical shifts were referenced to DSS (sodium [2,2,3,3-$D_4$]-3-trimethylsilylpropionate) at 0 ppm and to a $VOCl_3$ external solution at 0 ppm, respectively. $^{51}$V NMR acquisition parameters were: 33 kHz spectral width, 30 μs pulse width, 1 s acquisition time and 10 Hz line broadening. The signal intensities of the NMR resonances were obtained by using the line-fitting routine supplied with the NUTS™ PC-based NMR spectral analysis programme.[40]

**X-ray Crystal Structure Determination of 1:** Three-dimensional room temperature X-ray data were collected with a Bruker Smart 1000 CCD instrument by the $\varphi$-$\omega$ scan method. Reflections were measured from a hemisphere of data collected from frames each covering 0.3° in $\omega$. Of the 10878 reflections measured, all were corrected for Lorentz and polarization effects and for absorption by multiscan methods based on symmetry-equivalent and repeated reflections, and 1765 independent reflections exceeded the significance level ($|F|/\sigma|F|$) > 4.0. Complex scattering factors were taken from the programme package SHELXTL,[41] implemented on a Pentium computer. The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$. Hydrogen atoms were left to refine freely with isotropic thermal parameters, except for hydrogen atoms of N(1), O(4), C(8) and C(9), which were localised in the Fourier map and then fixed to the corresponding atoms. Refinement was performed with the allowance for thermal anisot-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ropy of all non-hydrogen atoms. Complex scattering factors were taken from the programme package SHELXTL. Further details of the crystal structure determination and X-ray data are given in the Supporting Information (Section 10). CCDC 602814 (for **1A**) contains the supplementary crystallographic data for the structure reported in this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article):

1. Infrared spectra of the compounds.

2. $^{1}H$ NMR chemical shifts of salDPA as a function of pD.

3. Speciation in the $V^{IV}O$–salOrn system.

4. CD spectra of $V^{IV}O$–salDPA solutions at pH > 11.

5. Representation of $\varepsilon_m$ values vs. pH for $V^{IV}O$–salDPA solutions.

6. Circular dichroism spectra of solid polycrystalline samples.

7. Structures of ligands synthesized in this work for which complex formation in solution was not studied.

8. Circular dichroism spectra of $(VO_2)LH^-$ and $(VO_2)L^{2-}$.

9. Comparison of the $V^V$–salDPA species concentration estimated from the $^{51}V$ NMR spectra and the distribution diagram.

10. Crystal and structural data for $H_4salDPA^+ \cdot Cl^-$ (**1A**).

## Acknowledgments

This work was carried out in the frame of a COST D21 project. The authors are grateful to the National Research Fund (OTKA NI61786 and OTKA T49417), to the Hungarian Academy of Sciences, the Fundo Europeu para o Desenvolvimento Regional, Fundação para a Ciência e Tecnologia, the POCI Programme (project POCI/56949/QUI/2004 and POCI/55985/QUI/2004), the Hungarian-Portuguese Intergovernmental S & T Cooperation Programme for 2004–2005, University of A Coruña and the Spanish-Portuguese Bilateral Programme (Acção Integrada E-56/05). We also thank Tamás Gajda for supplying some of the sal-D,L-DPA ligand used in the preliminary experiments.

# Binding Constant of $V^{IV}O$ to Transferrin

**Tamás Kiss,*[a,b] Tamás Jakusch,[b] Saâd Bouhsina,[c] Hiromu Sakurai,[d] and Éva Anna Enyedy[a]**

**Keywords:** $V^{IV}O$–Transferrin complexes / EPR spectroscopy / UV spectroscopy / Stability constants

The interactions of bis-$V^{IV}O$-1,2-dimethyl-3-hydroxy-4(1*H*)-pyridinone (DHP) with apotransferrin (apoTF) were followed by means of electron paramagnetic resonance spectroscopy (EPR) at room temperature and at liquid nitrogen temperature. Partial ligand displacement between DHP and apoTF was observed, and the reaction was used to determine the binding constant of $V^{IV}O$ to apoTF. A value of $\log K = 14.3 \pm 0.6$ was obtained for the binding of the first $V^{IV}O$ to apoTF. In order to confirm the validity of the binding constant, UV spectroscopy was used to monitor the displacement reaction between $V^{IV}O$–apoTF and nitrilotriacetic acid (NTA). The difference between the binding constants obtained by the two different methods (ca. one log unit) was explained in terms of the possible ternary complex formation between $V^{IV}O$–apoTF and the displacing ligand. The binding constants obtained exhibit a reasonably good agreement with the linear free energy relationship (LFER) estimation.

## Introduction

There is considerable interest in the binding strength of metal ions to human serum transferrin (TF) because of its natural, therapeutic, diagnostic and toxicological importance.[1] The serum transport protein TF has two very similar metal binding sites (C-lobe and N-lobe), and their affinities for metal ions differ only slightly. Each lobe contains a distorted octahedral site consisting of two Tyr-$O^-$ anions, one His-N group, one Asp-$COO^-$ anion and one usually bidentate hydrogen carbonate anion (the synergistic anion).[2,3] Normally, the two stepwise binding constants ($\log K$ values) differ by approximately one unit, which is beyond the purely statistical factor of four (0.6 log unit), because of a slight difference in the intrinsic binding affinities of the two lobes. The mode of binding of metal ions at the two sites depends upon the nature of the metal ion, the synergistic anion and the pH, but binding is generally a little more preferred at the C-terminal site than at the N-terminal site.[2]

A number of experimental techniques have been used to determine the stability constants of metal–TF complexes. Difference UV spectroscopy, based on the production of new absorption bands at ca. 240 nm and ca. 295 nm[2] on the complexation of metal ions to the phenolic groups of the Tyr residues, has been applied most frequently.[4–9] Other methods include equilibrium dialysis, EPR[5] and multinuclear NMR spectroscopy,[10] the latter two also being used to distinguish the modes of metal ion binding between the two sites.[11–14]

Interest in the biochemistry of vanadium has increased enormously in the past twenty years partly because of its insulin-mimetic or more precisely insulin-enhancing properties.[15] It has been proposed that the transport of vanadium in higher organisms is mediated by TF,[16] and it was recently proved that most of the vanadium in the serum is bound to TF.[17,18] The complexation of vanadium to TF in oxidation states of +3,[19–22] +4[13,14,20–27] or +5[21–24,28–30] has been extensively studied by various research groups. The results uniformly indicate that two vanadium ions are bound to the metal-ion-free apoTF, at the usual specific $Fe^{III}$ binding sites. Using X-band and Q-band EPR spectroscopic methods, Chasteen et al.[13,14] distinguished three $V^{IV}O$ binding environments at a physiological pH (ca. 7.4), all having similar O-donor-rich environments, but with slightly different conformations. One possibly has the normally preferred square-pyramidal or square-bipyramidal $V^{IV}O$ geometry, in which the $V^{IV}O$ oxygen atom occupies an apical position (A environment), while for the other two ($B_1$ and $B_2$) [although in-plane anisotropy (rhombic spectra) is not observed] the noncoincidence of the magnetic axes suggests significant distortion around the $V^{IV}O$ ar-

rangement. The relative intensities of the A and B resonances are strongly pH dependent. The two interconvertible A and B conformational states are believed to belong to the C-terminal and N-terminal binding sites of the protein, respectively.[31]

The binding of $V^{IV}O$ to TF is strong, and thus only stoichiometric formation of the complexes can be observed.[13,14,21] We are not aware of any attempt to characterise the complexation of $V^{IV}O$ with TF in a quantitative way; only the competition between $V^{IV}O$ and $Fe^{II}$ binding to ferritin[26] and the equilibrium distribution of $V^{IV}O$ between albumin and TF have been studied.[24] Sun et al.[2] suggested that the LFER between the binding constants ($\log K_1$) of metal ions to the first lobe of TF and the stability constants, $\log K_{OH^-}$ for the binding of hydroxide, can be used for the prediction of unknown stability constants of metal-ion–TF complexes. Other possible correlations between the metal ion binding to TF and small N,O-donor ligands such as nitrilotriacetic acid (NTA), oxalate, acetate, glycine, malonate and lactate were also examined but none of them were as good as that with $OH^-$. This suggests that the two Tyr moieties at the metal-binding site of TF play predominant roles in determining the strength of the metal binding.[2] We used the above approach in our previous work in order to describe the speciation of various insulin-mimetic $V^{IV}O$ complexes in blood serum,[32] and obtained a value of $\log K_1(TF) = 13.2 \pm 1.6$ for $V^{IV}O$ binding to TF. During the study EPR spectroscopy revealed a partial displacement of apoTF by one of the low-molecular-mass carrier ligands, 1,2-dimethyl-3-hydroxy-4(1*H*)-pyridinone (DHP). It was decided to make use of this reaction to assess the binding of $V^{IV}O$ to apoTF.

Accordingly, in this paper we report, to the best of our knowledge, the first binding constants of $V^{IV}O$ to human serum TF obtained by means of EPR and UV spectral monitoring of the ligand displacement reactions between the $V^{IV}O$ complexes formed with apoTF and DHP or NTA.

## Results and Discussion

The EPR spectra of the $V^{IV}O$–apoTF system at a metal-ion-to-ligand ratio of 1:1 at pH 7.5 at room temperature and at 77 K (LNT: liquid nitrogen temperature) are depicted in Figure 1. In agreement with the earlier result,[33] the room temperature spectrum of [$V^{IV}O$(apoTF)] (Figure 1, II) is axial because of the slow tumbling motion of the protein. However, on the parallel part only two types of vanadium species are clearly observable (A and B), while the not completely perfect simulation of the spectrum might indicate the presence of a third species ($B_2$). The measured ratio of environments A and B is almost identical, but the difference between the two –7/2 peaks is only 1.5 mT (instead of 2.5 mT as reported earlier in ref.[33]).

The –3/2 peak of the perpendicular part of the LNT X-band spectra clearly shows three species in contrast with Chasteen's earlier findings, where only the Q-band spectra could differentiate between the $B_1$ and $B_2$ environments. In

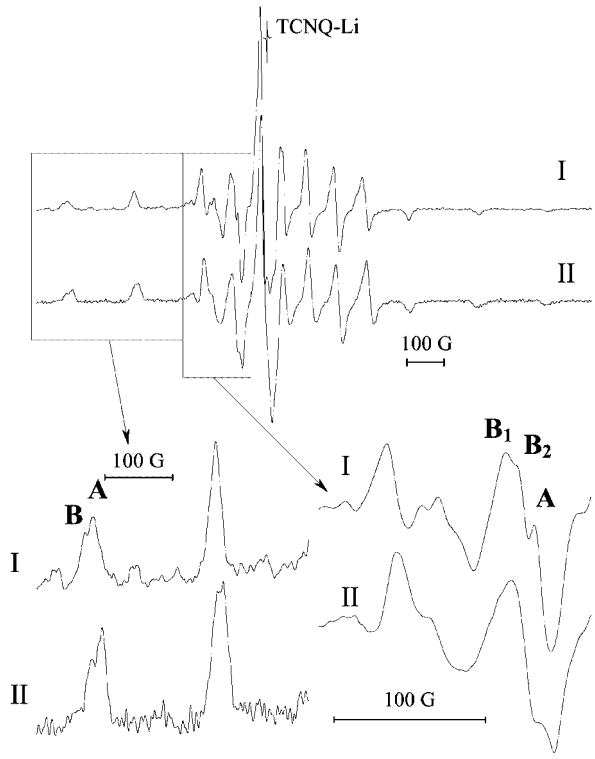

Figure 1. EPR spectra of $V^{IV}O$–apoTF, 1:1 at pH 7.5 (I) at liquid nitrogen temperature and (II) at room temperature.

the parallel part of the spectra, the peaks strongly overlap and accordingly $g_{\|}$ and $A_{\|}$ parameters were not determined.

The mechanism of the insulin-enhancing effect of $V^{IV}O$ compounds is still unknown, and the speciation of the $V^{IV}O$ insulin-mimetic compounds in the blood is therefore interesting.[34–37] The estimated [$V^{IV}O$(apoTF)] stability constants obtained from the LFER prediction clearly demonstrated that in most cases of the insulin-mimetic $V^{IV}O$ complexes (with maltol, picolinic acid, 6-Me-picolinic acid, 2-OH-pyridine *N*-oxide and 2-SH-pyridine *N*-oxide)[32,36] apoTF completely displaces the carrier ligands in equimolar concentration. Orvig et al. recently reached a similar conclusion with regard to the interactions of [$V^{IV}O(maltol)_2$] with the serum proteins albumin and apoTF:[38] TF is capable of binding two equivalents of the complex to produce a [$(V^{IV}O)_2$(TF)] species in which the metal ions occupy both $Fe^{III}$ binding sites with the concomitant release of the free maltol. The bis complex of DHP seems to be an exception – only partial displacement of the DHP occurred because it forms exceptionally stable complexes with $V^{IV}O$.[37] Although [$V^{IV}O(DHP)_2$] is present exclusively at pH 7.5 (see speciation in Figure 2), the EPR spectrum obtained at this pH (Figure 3a: LNT, 3b: room temperature) indicates the presence of two isomers. The formation of *cis* and *trans* isomers (see Scheme 1) among the bis-$V^{IV}O$ complexes of chelating O-donor ligands is well documented in the literature.[34–37] There is no general rule regarding the preferential formation of one or other of the isomers, but it has been found, for instance, that the charge of the coordinating ligands and the size of the chelate ring can affect this.[39] The

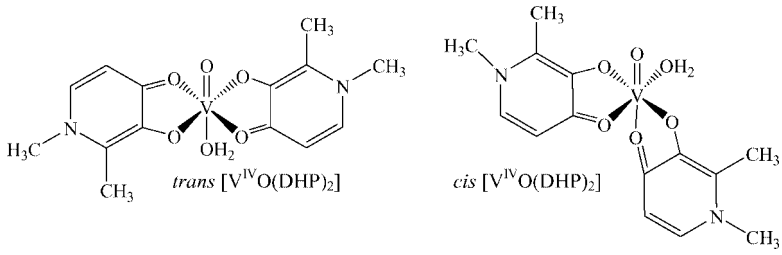

Scheme 1. Binding modes of the *cis* and *trans* isomers of $[V^{IV}O(DHP)_2]$.

EPR parameters of the bis complexes of $V^{IV}O$ and DHP, together with the ratios of the two isomers, are given in Table 1. The data reveal that *trans* isomer formation is favoured with DHP, when a water molecule is *trans* to the oxo group of $V^{IV}O$.

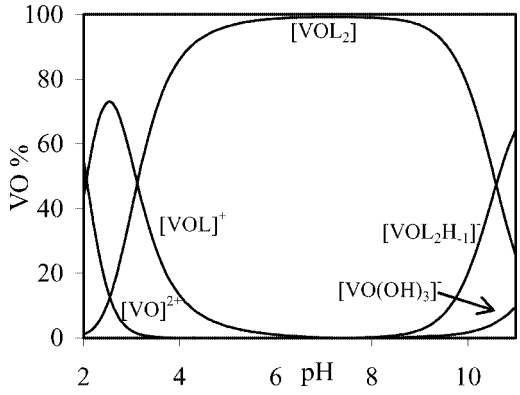

Figure 2. Speciation curves for complexes formed in the $V^{IV}O$–DHP system at a 1:2 metal-ion-to-ligand ratio, $[V^{IV}O]$ = 0.001 M. Calculated with stability constants, $\log\beta(HL)$ = 9.76, $\log\beta(H_2L)$ = 13.46, $\log\beta([V^{IV}OL]^+)$ = 12.18, $\log\beta([V^{IV}OL_2])$ = 22.83, $\log\beta([V^{IV}OL_2H_{-1}]^-)$ = 12.24, $\log\beta([V^{IV}OL_3H_2]^+)$ = 38.5, $\log\beta([V^{IV}O_2L_2H_{-2}]^{2-})$ = 16.43, taken from ref.[40]

After the detailed equilibrium and EPR spectral description of the binary systems, measurements were made on the ternary system $V^{IV}O$–apoTF–DHP at different metal-ion-to-ligand ratios at both room temperature and 77 K. For easier comparison, the room temperature spectra of the $V^{IV}O$–apoTF (1:1), $V^{IV}O$–DHP (1:2) and $V^{IV}O$–apoTF–DHP (1:1:2) systems are depicted together in Figure 4. It is clearly seen that the ternary spectrum is a composite of the isotropic spectrum of the $[V^{IV}O(DHP)_2]$ and the axial one of the $[(V^{IV}O)(apoTF)]$. This observation indicates partial displacement of the carrier ligand by apoTF or vice versa, i.e. $[V^{IV}O(DHP)_2]$ + apoTF ⇌ $[(V^{IV}O)(apoTF)]$ + 2 DHP. (As a first approximation, ternary complex formation with the protein and the carrier ligand was neglected in order to make further calculations possible.) The +7/2 and +5/2 parts of the LNT spectra of these three systems are depicted together in Figure 5.

As a first step in the quantitative evaluation of the spectral changes, the extent of ligand displacement was determined by calculating the ratio of the concentrations of $V^{IV}O$ bound to the two ligands through double integration

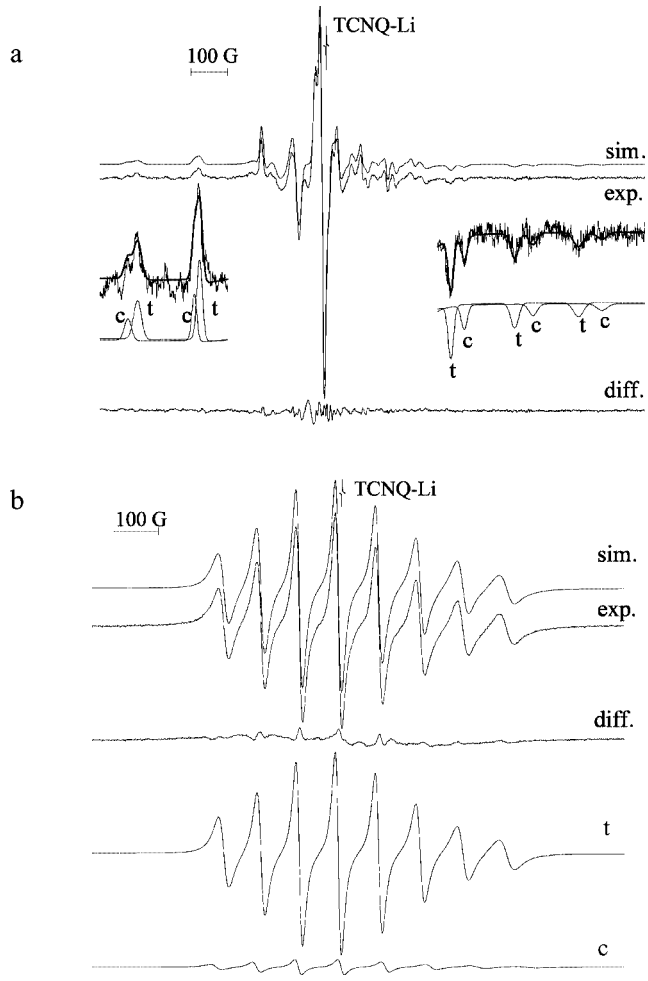

Figure 3. EPR spectra (sim. = simulated, exp. = experimental) of $V^{IV}O$–DHP, 1:2 at pH 7.5 (a) at liquid nitrogen temperature and (b) at room temperature, *t* = *trans* isomer, *c* = *cis* isomer.

of the enlarged sections of the simulated EPR spectra shown in Figure 5. From these data, the concentrations ($[V^{IV}O(apoTF)]$, [DHP], $[V^{IV}O(DHP)_2]$ and [apoTF]) and the displacement constant $K = [[V^{IV}O(apoTF)]]\cdot[[DHP]]^2/[[V^{IV}O(DHP)_2]]\cdot[[apoTF]]$ can be calculated. We used this displacement constant ($\log K = -3.6 \pm 0.3$) to obtain the binding constant for the $V^{IV}O$–apoTF interaction. The conditional stability constant for the competitive complex $[V^{IV}O(DHP)_2]$ at pH 7.5 was first calculated by taking into account the protonation equilibria of the ligand DHP, Equation (1):

[a] In the case of the axial geometry: $g_x = g_y = g_\perp$; $A_x = A_y = A_\perp$; $g_z = g_\parallel$ and $A_z = A_\parallel$. A is given in $10^4$ $cm^{-1}$. [b] This work. [c] Isotropic spectra $g_x = g_y = g_z = g_0$ and $A_x = A_y = A_z = A_0$. [d] The parameters are not resolved.

$$\log \beta^c([V^{IV}O(DHP)_2]) = \log \{\beta([V^{IV}O(DHP)_2])/(1 + \beta_1^{II}(DHP)\ 10^{-pH} + \beta_2^{II}(DHP)\ 10^{-2pH})^2\} \quad (1)$$
$$= \log (10^{22.83}/(1 + 10^{9.76}10^{-7.5} + 10^{13.46}10^{-15.0})^2 = 18.31$$

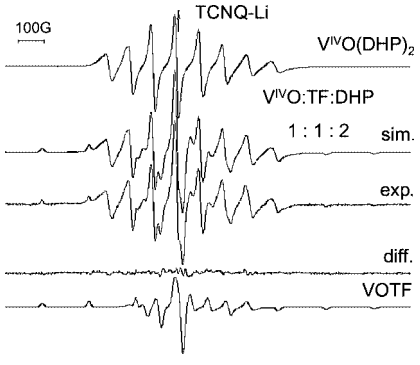

Figure 4. Room-temperature EPR spectra of (a) the binary $V^{IV}O$–DHP 1:2 (simulation), (b) the ternary $V^{IV}O$–apoTF–DHP 1:1:2 and (c) the $V^{IV}O$–apoTF 1:1 systems (simulation) at pH 7.5. Simulations were performed with EPR parameters given in Table 1.

A value of $\log\beta^c([V^{IV}O(DHP)_2]) = 18.31 \pm 0.06$ was obtained. (Stability constants for the formation of the proton and $V^{IV}O$ complexes were taken from ref.[40]) The conditional binding constant could now be calculated as $\log K_1^c([V^{IV}O(apoTF)]) = \log\beta^c([V^{IV}O(DHP)_2]) + \log K_{displacement} = 18.31 - 3.6 = 14.7$. The ratios ($[V^{IV}O(apoTF)]/[V^{IV}O(DHP)_2]$) and the $\log K_1^c([V^{IV}O(apoTF)])$ values determined for all spectra are listed in Table 2. From EPR spectroscopic studies, where formation of both the ternary complex and $[(V^{IV}O)_2(apoTF)]$ was neglected, $K_1^c([V^{IV}O(apoTF)]) = 14.7 \pm 0.3$ was determined. The binding constant $\log K_2^c$, characteristic of the binding of the second $V^{IV}O$ to apoTF, can be estimated by using the observed difference between the stepwise binding constants for transition metal ions (ca. one log unit),[2] as $\log K_2^c([V^{IV}O(apoTF)]) = 13.7 \pm 0.5$.

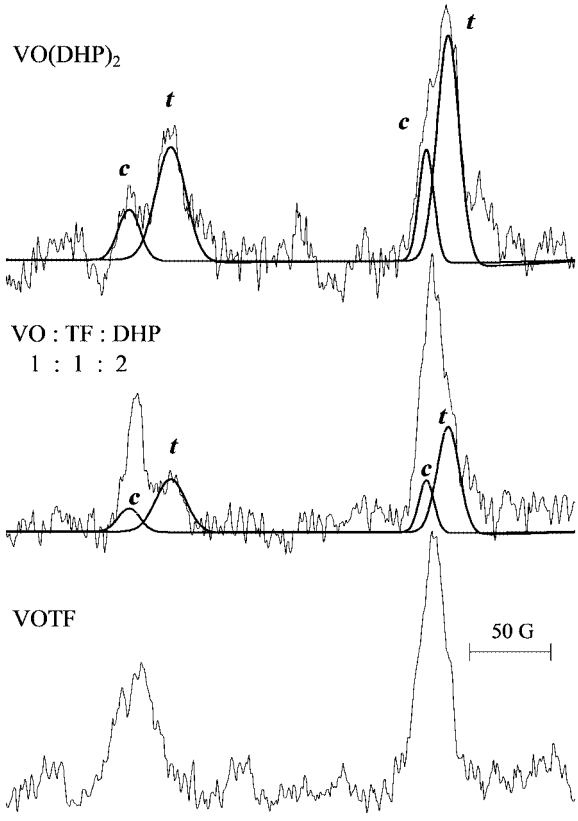

Figure 5. Lowfield region (parallel +7/2, +5/2 peaks) LNT EPR spectra of (a) the binary $V^{IV}O$–DHP 1:2, (b) the ternary $V^{IV}O$–apoTF–DHP 1:1:2 and (c) the $V^{IV}O$–apoTF 1:1 systems at pH 7.5.

In order to confirm the conditional [$V^{IV}O$(apoTF)] binding constants obtained, UV spectrophotometry was also used in the hope that this would furnish more accurate binding constants. In this case, we had to apply a rather low apoTF concentration (8 μM) so as to be able to measure the UV absorbance, and we used a different second ligand, NTA, to displace apoTF from the vanadium coordination sphere. The shape and the intensity of the individual difference spectra (see Figure 6) are in good agreement with that reported by Bertini et al. earlier.[20]

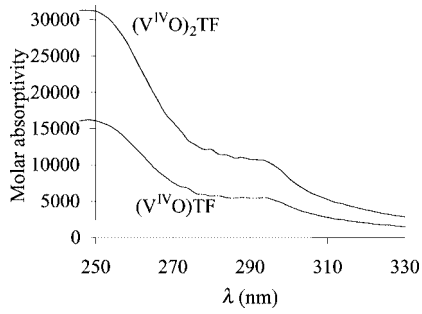

Figure 6. Individual difference spectra of [$V^{IV}O$(apoTF)] and [$(V^{IV}O)_2$(apoTF)] calculated from UV spectroscopic measurements.

The determined $\log K_1^c$ and $\log K_2^c$ values are listed in Table 2. Unfortunately, there is a 0.7 unit difference in the $\log K_1^c$ values determined with DHP and NTA, and both are outside the uncertainty range of the same constants determined by EPR spectroscopy.

Table 2. Stepwise stability constants {$V^{IV}O^{2+}$ + apoTF ⇌ [$V^{IV}O$(apoTF)] ($\log K_1^c$) and $VO^{2+}$ + [$V^{IV}O$(apoTF)] ⇌ [$(V^{IV}O)_2$(apoTF)]} ($\log K_2^c$) determined by different methods {pH 7.5, [$HCO_3^-$] = 0.025 M, $T$ = 25 °C}.

The difference between the binding constants determined from the EPR and UV spectra may be explained in part by the slightly different experimental conditions: different total concentrations of apoTF, ca. 1 mM for EPR and ca. 0.01 mM for UV spectroscopic measurements; different solvents, 10% (v/v) DMSO for the LNT EPR spectroscopy and water for the other measurements; and different temperatures, ca. –5 °C for the LNT measurements and 25 °C for the others.

The rather low value obtained for $\log K_2^c$ by UV spectroscopy is more worrying. However, this value is probably very uncertain because of the very low concentration of the ligand used in the UV spectroscopic measurements, and thus the rather high error from any disturbing circumstances affecting the concentration of the interacting species, or from the light absorption of the sample, such as slight oxidation of the metal ion. Accordingly, $\log K_2^c$ determined by means of UV spectroscopic measurements can be considered only a tentative value. The constants $K_1^c$ and $K_2^c$ are conditional constants for pH 7.5 and 25 mM hydrogen carbonate concentration.

The differences between the binding constants $\log K_1^c$ obtained by the three experimental methods (room-temperature EPR spectroscopy, LNT EPR and UV spectroscopy) are about 0.5–1.5 orders of magnitude higher than that obtained from the LFER prediction ($13.2 \pm 1.6$) (see Figure 6 in ref.[32]), although they are within the uncertainty range of the latter.

As mentioned above, the absence of ternary complex formation between [$V^{IV}O$(apoTF)] and the competitor ligand had to be assumed as a precondition for the calculation of the binding constant. This has not been proven,[38] and NMRD measurements[41] have suggested that displaced DHP ligand(s) do not move far away from the metal ions, which to some extent continues to feel their presence. More detailed studies are currently being carried out in our laboratories in order to explore the possibility of ternary complex formation between $V^{IV}O$–apoTF and low molecular mass carrier ligands. This process may be the reason for the differing LFER estimated value.

Although the measurements reported here were carried out with metal-ion-free apoTF, the binding constants determined can be applied with a good approximation to the interaction of $V^{IV}O$ with TF, as only ca. 30% of the metal-binding sites of the protein are saturated with $Fe^{III}$ under normal conditions, and thus there are enough free sites to bind other, mostly hard metal ions (e.g. $Al^{III}$ or $V^{IV}O$) and to transport them in the blood stream.

## Materials and Methods

### Chemicals

DHP, NTA and human apotransferrin (apoTF) were obtained from Sigma Co. The purities of the small organic ligands were checked, and the exact concentrations of their solutions were determined by the Gran method.[42] The concentrations of protein solutions were estimated from their UV absorption ($\varepsilon_{280}$(TF) = 92.300 $m^{-1} cm^{-1}$[24]). The $V^{IV}O$ stock solution was prepared as described in ref.[43] and standardised for metal ion concentration by a permanganate titration.

### EPR Spectroscopic Measurements

As a consequence of the ready oxidation of $V^{IV}O$ to $V^{V}$ under neutral or basic conditions, extreme care was taken to exclude oxygen during the preparation of the samples and during the measurements. It has been reported that $V^{IV}O$ ions bound to human serum TF are very unstable towards aerobic oxidation,[24] and the half-life for the oxidation is estimated to be between 5 and 13 min. Aqueous solutions (0.5 mL) of samples containing DHP and apoTF in ratios of 0.001 M:0.0005 M, 0.0015 M:0.0005 M and 0.001 M:0.0008 M were prepared in 0.1 M HEPES buffer and 0.025 M sodium hydrogen carbonate adjusted to pH 7.5. The solutions were carefully purged with argon and then sealed under an argon atmosphere. A $V^{IV}O$ stock solution (5 μL) was then added to each sample through a rubber septum with a Hamilton syringe. Samples for the EPR spectroscopic measurements were taken out by syringe and were immediately transferred into the EPR tube (LNT) or into the capillary (room temperature). X-band EPR spectra (9.59 or 9.40 GHz) were recorded in aqueous solution at LNT (77 K) and at room temperature with a Bruker EMX or JEOL JES-RE-1X spectrometer. The samples for low-temperature measurements contained 10% (v/v) of DMSO to ensure good glass formation (dilution of the samples was taken into account). The EPR spectra were evaluated and simulated with the EPR computer programme of Rockenbauer and Korecz.[44]

### UV Spectroscopic Measurements

At physiological pH, vanadium(IV) undergoes extensive hydrolysis. Hence, the stability constants of apoTF were determined by a displacement reaction with NTA and with DHP. Both ligands form appropriately stable complexes with $V^{IV}O$, and the stability constants are available at 25 °C and $I$ = 0.2 M (KCl).[40,45] However, while NTA does not exhibit significant UV absorption at pH 7.5, which simplifies the determination, at pH 7.5 the complex $[V^{IV}OL]^-$ of NTA is partly hydrolysed and a ternary complex, $[V^{IV}OL(OH)]^{2-}$, is formed, which makes the system somewhat more complicated. On the other hand, DHP forms a single $[V^{IV}OL_2]$ complex at pH 7.5, but both the complex and the ligand exhibit significant UV absorption, which imposes a limit to the use of a high excess of the ligand.

In contrast with the difference UV spectroscopic method (frequently applied by Harris and coworkers to determine the stability constants of TF complexes with different metal ions[4–9]), we simply measured the absorbance and fitted the data (wavelength range 250–330 nm) and individual spectra by using the computer programme PSEQUAD.[46]

The apoTF concentration was 8 μM, the molar ratio between apoTF and NTA was 1:0, 0:1, 1:1, 1:5, 1:25 or 1:120 and that between apoTF and DHP was 0:1, 1:1, 1:2.5 or 1:5 at 25 °C in 0.025 M $HCO_3^-$, and $I$ = 0.2 M (KCl) in 0.1 M HEPES buffer adjusted to pH 7.5. The starting volume was 2.0 mL and at each titration point 25 μL of 0.16 mM $V^{IV}OCl_2$ was added until an apoTF to $V^{IV}O$ ratio of 1:4 was reached. (When the calculation suggested hydrolysis of $V^{IV}O$ at a titration point, the data of the spectrum were omitted from the calculation.) An HP 8452 diode array spectrophotometer was used with a silica cell with a pathlength of 1.00 cm. During measurements, the cell was closed, and during the addition of $V^{IV}O$, argon was bubbled through the sample to exclude air.

# Interactions of Insulin-Mimetic Vanadium Complexes with the Cell Constituents ATP and Glutathione

Ágnes Dörnyei,[a] Susana Marcão,[b] João Costa Pessoa,*[b] Tamás Jakusch,[c] and Tamás Kiss*[a,c]

**Keywords:** Insulin mimetics / Vanadium oxido complexes / Coordination modes

In order to assess the molecular form of vanadium insulin-mimetic complexes in cells, the interactions of $V^{IV}O$–maltolate and $V^{IV}O$–dipicolinate systems with adenosine 5′-triphosphate (ATP) and glutathione (GSH) in aqueous solution were studied by employing pH potentiometry, and EPR, CD and UV/Vis spectroscopy. The stoichiometries and stability constants of the complexes formed were determined at 25 °C with an ionic strength of $I = 0.2\ mol\,dm^{-3}$ (KCl). The most probable binding mode of the complexes formed in solution was determined by means of various spectral methods. The results suggest that from among the important cell constituents, GSH mostly takes part in the reduction of $V^{V}$ to $V^{IV}$ and helps keep $V^{IV}$ in this oxidation state. ATP, which is a strong $V^{IV}O$ binder, chelates the metal ion, forming binary and/or ternary complexes. The results of this work strongly suggest that ATP binds relevant $V^{IV}O$ species under cellular conditions and thus might somehow be involved in the insulin-mimetic action of $V^{IV}O$ compounds.

## Introduction

Since the insulin-mimetic effects of vanadium compounds were first reported, a large number of vanadium complexes in the oxidation states III to V and as peroxo complexes have been prepared, tested biologically and found to be efficient,[1–3] but only one of them, bis(maltolato)oxidovanadium(IV) ($VO(malt)_2$), has participated in clinical studies; it passed the phase I test in Canada.[2,4] In vitro, vanadium compounds may enter cells by several pathways, including passive diffusion, whereas when given orally vanadium(III,IV,V) complexes undergo parallel ligand exchange and redox reactions with the endogenous or exogenous bioligands of the human body;[1,5,6] this is mostly independent of the original form, and depends primarily on the nature of the interacting bioligand.

For this reason, the interactions of various insulin-mimetic $V^{IV}O$ compounds have been studied with the high molecular mass (h.m.m.) serum components, albumin and transferrin, and also with some of the low molecular mass (l.m.m.) components, such as lactate, oxalate, phosphate and citrate, which may be potential transporters of $V^{IV}O$ in the blood.[7–13] Detailed speciation studies led to the suggestions concerning the actual chemical forms of the vanadium compounds formed from the original carrier complex during their transport in the blood. We found that little of the vanadium remains bound to the original carrier: l.m.m. serum components (citrate) and h.m.m serum components (transferrin) displace most of the carrier molecules.[6,11–13] Accordingly, vanadium can enter cells in the oxidation state IV through the iron path, and in part in the oxidation state V through the phosphate path.

In the intracellular medium, reducing agents can interact in a redox manner with vanadium(V,IV) complexes. The most frequently discussed candidate for reduction is glutathione (GSH).[14,15] The extent to which vanadium is reduced in the redox equilibrium largely depends on the stabilisation of vanadium(IV,V) by complexation. A high intracellular excess of GSH (the usual concentration level is millimolar), i.e. about three orders of magnitude more than the biologically relevant concentration of vanadium (the usual concentration level is micromolar) increases the possibility of vanadium being present in lower oxidation states. Excess GSH and also GSSG (oxidized glutathione) readily coordinate to $V^{IV}O$.[16,17] The vanadium complexes thus formed may undergo ligand exchange with a variety of l.m.m. and h.m.m. biogenic ligands available in cells. Among the l.m.m. binders, adenosine 5′-triphosphate (ATP) may be of importance[18] as it efficiently binds $V^{IV}O$ and is present in millimolar concentrations in cells.

Sakurai and Tsuji considered the most relevant oxidation state of vanadium in the cell to be IV because of the reducing agents present in the cell (e.g. GSH or cysteine).[19] We

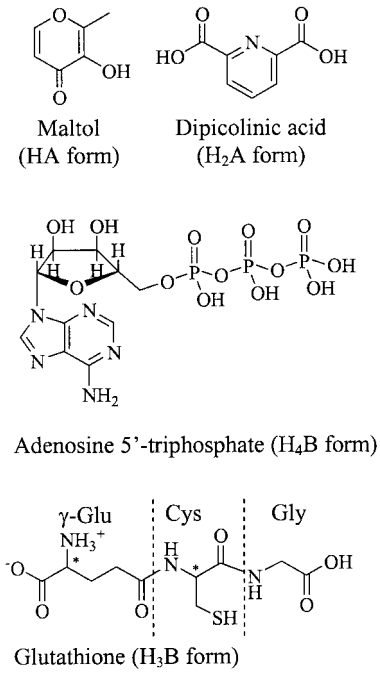
accepted this and studied vanadium only in the $V^{IV}O$ form, even though reoxidation of $V^{IV}O$ to $V^{V}$ is an obvious assumption, which can have different importance at different compartments of the cell. Accordingly, the aim of the present work was to attain a better understanding of the behaviour of $V^{IV}O$ insulin-mimetic complexes as they enter cells and interact with l.m.m. cell constituents. Of the $V^{IV}O$ complexes, we chose the $V^{IV}O$–dipicolinate and $V^{IV}O$–maltolate systems, and as cell constituents we selected GSH and ATP (see Scheme 1). The equilibria in the systems were studied by a combination of pH potentiometry and spectroscopic methods [electron paramagnetic resonance (EPR), electronic absorption (UV/Vis) and circular dichroism (CD)].



Scheme 1.

The complex-forming properties of $V^{IV}O$ with dipicolinate (dipic),[12] maltolate (malt),[7,8,20] ATP[18] and GSH[17] have been studied, and stability constants measured under similar experimental conditions have been reported previously.

Maltolate forms mono and bis complexes with the $V^{IV}O$ ion by the formation of five-membered ($O^-$, = O) chelates. The neutral bis complex $[VO(malt)_2(H_2O)]$ is the predominant species in the pH range 5–7. It occurs in two geometrical isomeric forms depending on the position of the solvent molecule; the water molecule can be either *cis* or *trans* to the oxido group of $V^{IV}O$. In aqueous solution at room temperature and neutral pH, the EPR spectra clearly indicate that the *cis* form predominates.[7,8,20] In a recent paper based on detailed EPR and ENDOR spectroscopic studies, Mustafi and Makinen concluded that in aqueous solution at room temperature maltolate coordinates to $V^{IV}O$ only in the *cis* form.[21]

Dipicolinate forms mono and bis complexes with the $V^{IV}O$ ion.[12] In the neutral mono complex, $[VO(dipic)(H_2O)_2]$, the ligand coordinates in a tridentate manner; the coordinating donor groups are two carboxylates, besides the two water molecules, and the pyridyl-N atom is in an axial position (*trans* to the oxido group). Bis complex formation in the $V^{IV}O$–dipic system is not as favoured as it is with maltolate. In $[VO(dipic)_2]^{2-}$, the first ligand coordinates in a tridentate manner, and the second ligand in a bidentate manner, having an uncoordinated carboxylate group. At the biologically relevant neutral pH values, dipicolinate is not a very efficient $V^{IV}O$ binder; mixed hydroxo and oligonuclear binary hydroxo species of $V^{IV}O$ are present in the solution, besides the neutral mono complex and the double negatively charged bis complex.[12]

## Results and Discussion

### $V^{IV}O$ Ternary Systems with ATP

ATP was found to coordinate to $V^{IV}O$ through the terminal phosphate donor(s) in the weakly acidic and neutral pH range to yield $[VOBH_x]^{x-2}$ ($x$ = 2, 1, 0) and $[VOB_2]^{6-}$.[18] In the basic pH range, at low excess, ATP is not a very efficient $V^{IV}O$ binder because oligonuclear hydroxo species $\{[(VO)_2(OH)_5]^-\}_n$ are present in the solution besides the $V^{IV}O$–ATP complexes. At pH 7–8 the pH readings drift and pH equilibrium is reached within 10 min; in the pH range 8.8–10.4, pH stabilization was not reached within this time even at a 10-fold excess of ATP. Thus, the formation constants of the species formed in this pH region are only estimates. In contrast with our earlier report,[18] the formation of dinuclear species had to be assumed either to fit the pH-metric data or to explain the slight decrease in intensity of the EPR spectra. In the earlier work, formation of the binary hydroxo-bridged hydrolysed $V^{IV}O$ species $[(VO)_2(OH)_5]^-$ was not considered, though it is undoubtedly formed[22,23] and may be responsible for the decrease in the intensity of the signal rather than the dihydroxo-bridged $V^{IV}O$–ATP species: $[(VO)_2B_2H_x]^{x-4}$ ($x$ = –2, –3, –4).

In the cells, ATP is present in high excess relative to $V^{IV}O$ and also relative to the carrier ligands. As the proton competition for the alcoholate donors decreases the ribose moiety becomes a more efficient binding site. In the slightly basic pH range, the complex $[VOB_2H_{-2}]^{8-}$ forms involving a mixed binding mode with one ATP coordinating through the phosphate chain and the other through the ribose moiety. In the species $[VOB_2H_{-4}]^{10-}$, both ATP molecules coordinate to the $V^{IV}O$ species through the ribose residue.[18] The CD spectra furnish information on the species in which the ribose moiety is coordinated to the $V^{IV}O$; these species are mostly formed above the physiological pH. In the highly basic pH range an extra deprotonation is detected by pH potentiometry and also by CD spectroscopy (see ESI-1), corresponding to the formation of $[VOB_2H_{-5}]^{11-}$. In this species the extra proton is probably lost from a coordinated water molecule.

### $V^{IV}O$–dipic–ATP System

Our speciation calculations indicated that, in the ternary system with dipicolinic acid, ATP, as a stronger $V^{IV}O$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

binder, will displace one of the dipicolinates from the coordination sphere of $V^{IV}O$. As a result, ternary complexes will exist, besides the binary ATP complexes, at physiological pH. The potentiometric data could be fitted by assuming the formation of the species $[VOAB]^{4-}$, $[VOABH_{-1}]^{5-}$ and $[VOABH_{-2}]^{6-}$ (see Table 1). The distribution diagram for the $V^{IV}O$–dipic–ATP system (Figure 1) reveals that the formation of the ternary complex $[VOAB]^{4-}$ is favoured in the weakly acidic pH range. Besides the carboxylate groups of dipic, the phosphate groups of ATP are expected to be coordinated in this complex while in $[VOABH_{-2}]^{6-}$, formed in the neutral pH range, the deprotonated ribose alcoholate groups are in equatorial positions.

Table 1. Stability constants of mixed ligand $V^{IV}O$ complexes of dipicolinate and maltolate (ligands A) with ATP (ligand B).

| Ligand A | VOAB | $VOABH_{-1}$ | $VOABH_{-2}$ |
|---|---|---|---|
| Dipicolinate | 11.0(1) | 4.3(2) | –2.5(1) |
| Maltolate | 13.5(2) | – | –2.8(9) |

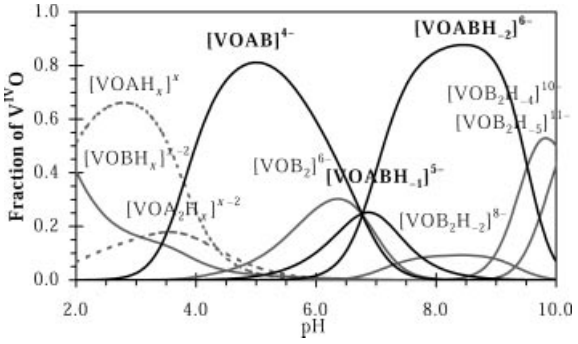


Figure 1. Concentration distribution diagram of the $V^{IV}O$–dipic(A)–ATP(B) system at 1:2:10 metal ion-to-ligand ratio, $C_{VO} \approx 0.004$ mol dm$^{-3}$.

The X-band EPR spectra of frozen solutions of the $V^{IV}O$–dipic binary system and the ternary system with ATP at pH < 8 could be simulated as axial spectra. At pH > 8, the species with the $(O^-,O^-)(O^-,O^-)$ donor set has a rhombic EPR spectrum. The high-field region corresponding to $A_\parallel$ or $A_z$ and $M_I$ = 5/2 and 7/2 yields more information on the type and number of species formed. As may be seen in Figure 2, the EPR spectra for the $V^{IV}O$–dipic–ATP system resemble those recorded for the $V^{IV}O$–ATP system; no new signals could be detected. Ternary complex formation is accompanied only by phosphate/carboxylate substitution in the equatorial plane, and does not result in any significant change in the EPR parameters. The EPR parameters of the binary complexes VOA of dipic and $[VOB_2]^{6-}$ of ATP with carboxylate or phosphate groups in the equatorial plane of $V^{IV}O$ are also expected to be the same within the uncertainties of the parameters (see Table 2). However, as dipic retards the hydrolysis of the $V^{IV}O$ complexes present in the basic pH range, an improved signal-to-noise ratio may be observed in the ternary system as compared with the binary $V^{IV}O$–ATP system; dipic helps to keep $V^{IV}O$ in solution. A similar observation may be made concerning the CD spectra; they are more intense for the ternary system.

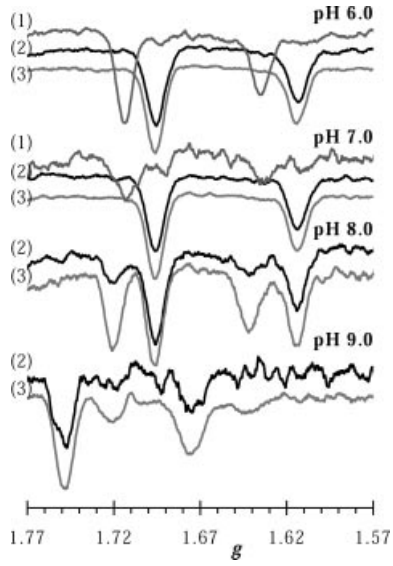

Figure 2. High field range of the first-derivative EPR spectra at 77 K of frozen solutions containing: (1) $V^{IV}O$ – dipic 1:2, (2) $2V^{IV}O$ – ATP 1:10, (3) $V^{IV}O$ – dipic – ATP 1:2:10 metal ion-to-ligand ratio, $C_{VO} \approx 0.004$ mol dm$^{-3}$. The pH values are indicated.

Table 2. EPR parameters ($g_\parallel$, $A_\parallel$)[a] for the binary and ternary complexes of $V^{IV}O$ formed with dipicolinate, maltolate and ATP.

| Species | $g_\parallel$ | $A_\parallel$ ($\times 10^4$ cm$^{-1}$) | Chelating set |
|---|---|---|---|
| $[VO(H_2O)_5]^{2+}$ | 1.933 | 182.6 | $4\times H_2O$ |
| Dipicolinate | | | |
| VOA | 1.931 | 178.4 | $(COO^-,COO^-)\ 2\times H_2O$ |
| $[VOA_2]^{2-}$ | 1.939 | 167.8 | $(COO^-,COO^-)(COO^-,$pyridyl–N$)$ |
| Maltolate | | | |
| $[VOA]^+$ | 1.937 | 175.1 | $(O^-,=O)\ 2\times H_2O$ |
| $VOA_2$ | 1.938 | 171.4 | $(O^-,=O)\ (O^-,=O_{ax})\ H_2O$ |
| $[VOA_2H_{-1}]^-$ | 1.942 | 166.8 | $(O^-,=O)\ (O^-,=O_{ax})\ OH^-$ |
| ATP | | | |
| $[VOBH_x]^{x-2}$ | 1.930 | 181.8 | $(PO_3^{2-}–O–PO_2^-–O–PO_2^-–)\ 2\times H_2O$ |
| $[VOB_2]^{6-}$ | 1.933 | 178.4 | $2\times(PO_3^{2-}–O–PO_2^-–O–PO_2^-–)$ |
| $[VOB_2H_{-2}]^{8-}$ | 1.946 | 166.8 | $(PO_3^{2-}–O–PO_2^-–O–PO_2^-–)\ (O^-,O^-)$ |
| $[VOB_2H_{-4}]^{10-}$ | 1.958 | 151.8 | $(O^-,O^-)\ (O^-,O^-)$ |
| Dipicolinate + ATP | | | |
| $[VOAB]^{4-}$ | 1.933 | 178.1 | $(COO^-,COO^-)\ (PO_3^{2-}–O–PO_2^-–O–PO_2^-–)$ |
| $[VOABH_{-1}]^{5-}$ | – | – | [b] |
| $[VOABH_{-2}]^{6-}$ | 1.946 | 167.0 | $(COO^-,COO^-)\ (O^-,O^-)$ |
| Maltolate + ATP | | | |
| $[VOAB]^{3-}$ | 1.941 | 169.1 ? | $(O^-,=O)\ (PO_3^{2-}–O–PO_2^-–O–PO_2^-–)$ |
| $[VOABH_{-2}]^{5-}$ | 1.943 | 166.4 ? | $(O^-,=O)\ (O^-,O^-)$ |

[a] The relative uncertainty in the calculation of the parameters is estimated to be ca. 0.005 for $g_\parallel$ and ca. 1.0 for $A_\parallel$. In the case of rhombic distortion $g_\parallel$ and $A_\parallel$ are in fact $g_z$ and $A_z$, respectively. [b] A log$\beta$ value for this stoichiometry was obtained from the pH-potentiometric data and calculations. However, its EPR signals are possibly under the complex pattern of other signals recorded and we did not find a distinct signal for this complex. Therefore we do not propose any binding mode.

In accordance with the pH-potentiometric speciation results, electronic absorption spectroscopy unambiguously revealed a new species ($[VOAB]^{4-}$) in the pH range 2.5–5.5,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with an extra band in the CT region, caused by the coordination of dipic (not shown). The difference between the CD spectra of the $V^{IV}O$–ATP and $V^{IV}O$–dipic–ATP systems (ESI-2) indicates the formation of a new type of ternary complex above the physiological pH range, where the ribose moiety becomes a more efficient binding site ($[VOABH_{-2}]^{6-}$).

### $V^{IV}O$–Maltolate–ATP System

Under physiological conditions (pH ≈ 7), maltolate is a stronger $V^{IV}O$ binder than dipic. For this reason, participation of maltolate in in vivo binding (even in binary complexes) can be expected to be more significant than was found in the case of dipic. The potentiometric data were fitted with a speciation model[24] with the assumption of two mixed-ligand complexes, $[VOAB]^{3-}$ and $[VOABH_{-2}]^{5-}$ (see Table 1). The concentration distribution diagram for $V^{IV}O$–maltolate–ATP depicted in Figure 3 displays the species formed under the conditions of the spectroscopic measurements. The pH-metric measurements demonstrate that ternary complex formation is not as dominant as with dipic, where binary bis complexes of maltolate are present in significant amounts.

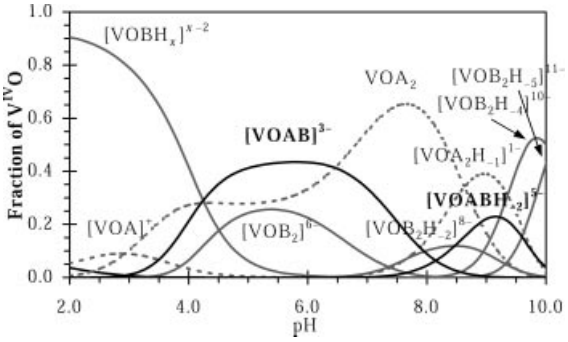

Figure 3. Concentration distribution diagram of the $V^{IV}O$ – maltol(A) – ATP(B) system at 1:2:10 metal ion-to-ligand ratio, $C_{VO} \approx 0.004$ mol dm$^{-3}$.

The EPR spectra of the systems $V^{IV}O$–maltolate, $V^{IV}O$–ATP and $V^{IV}O$–maltolate–ATP are presented in Figure 4, and the EPR parameters of the mixed-ligand species are listed in Table 2. Because of the difference in the type of donor groups involved in the coordination ternary complex formation is clearly indicated. Below pH 7, water and a carbonyl group are substituted by one or two phosphates, resulting in a detectable change ($A_{\parallel}$ from $171.4 \times 10^{-4}$ cm$^{-1}$ for $VOA_2$ to $169.1 \times 10^{-4}$ cm$^{-1}$ for $[VOAB]^{3-}$) in the EPR parameters.

A new signal from the formation of the complex $[VOABH_{-2}]^{5-}$ with a sugar-like binding mode of the ATP is not clearly seen as it is formed only from ca. 20% of the total V according to the speciation calculations. This species could be characterised by pH potentiometry only with a large uncertainty since the species distribution for the $V^{IV}O$–ATP (see above) and $V^{IV}O$–maltolate binary systems at pH > 9 is also uncertain as a result of the slight aerobic

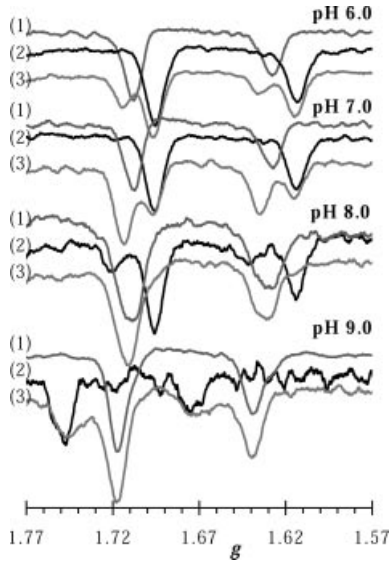

Figure 4. High field range of the first-derivative EPR spectra at 77 K of frozen solutions containing: (1) $V^{IV}O$–maltol 1:2, (2) $V^{IV}O$–ATP 1:10, (3) $V^{IV}O$–maltol–ATP 1:2:10 metal ion-to-ligand ratios; $C_{VO} \approx 0.004$ mol dm$^{-3}$. The pH values are indicated.

redox reaction of $V^{IV}O$–maltolate that may take place,[20] and/or the slow hydroxo complex formation processes.[13] However, in the CD spectra (ESI-3), a new type of signal can be observed at pH 8–9, unambiguously indicating coordination of the ribose residue corresponding to the formation of $[VOABH_{-2}]^{5-}$. At pH ≥ 9, the CD spectra for the binary and ternary systems become very similar, in agreement with the speciation results: both carrier molecules are displaced by the ribose-coordinated nucleotide ligands, resulting in the formation of the binary ATP complex $[VOB_2H_{-4(-5)}]^{7-(8-)}$.

### $V^{IV}O$ Ternary Systems with GSH

GSH is a cysteine-containing tripeptide (γ-Glu-Cys-Gly) with eight potential donor atoms. As mentioned above, it is possible that GSH plays an important role in relation to the biochemistry of vanadium. It is present in high excess in cells, but GSH is a much weaker $V^{IV}O$ binder than ATP. For $V^{IV}O$ concentrations above ca. 1 mM and more than a 10-fold excess of the ligand, the bis amino acid type binding mode ($[VOB_2H_2]^{2-}$) with the donor set $2\times(COO^-, NH_2)_{eq}$ is relevant in the pH range 5.0–6.5.[15,17,25,26] Participation of the thiolate donor may occur above pH ca. 7, forming the complex $[VOBH_{-1}]^{2-}$. This $[VOBH_{-1}]^{2-}$ stoichiometry corresponds to two different EPR components, and coordination of the deprotonated $N_{amide}$ group can be assumed in the minor isomer.[17] At a 10-fold excess of GSH, ternary complex formation could be detected only with rather high uncertainty in the pH-potentiometric titrations (see Table 3), and this excess of GSH was not enough to prevent the hydrolysis of the metal ion at pH > 6.5 for the dipic system and at pH > 8.0 for the maltolate system. Higher GSH concentrations could not be used in the pH potent-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

iometry because of the high buffer capacity of the ligand, and thus there was even higher uncertainty in the pH-potentiometric calculations. Most of the measured pH effect resulted from deprotonation of the excess ligand, and only a very small amount of it related to the metal-induced proton displacement reaction. Hence, complex formation between $V^{IV}O$ and GSH could be monitored by pH potentiometry only with great uncertainty. Accordingly, mostly spectroscopic measurements (EPR, UV/Vis and CD) were used to detect the formation of ternary complexes.

Table 3. Stability constants of mixed ligand $V^{IV}O$ complexes of dipicolinate and maltolate (ligands A) with GSH (ligand B).

| Ligand A | $VOABH_2$ | $VOA_2BH_2$ | $VOA_2BH$ |
|---|---|---|---|
| Dipicolinate | 25.9(8) | – | – |
| Maltolate | 28.6(3) | 35.5(8) | 27.7(5) |

### $V^{IV}O$–dipic–GSH System

A concentration distribution diagram for the $V^{IV}O$–dipic–GSH system with the metal ion-to-ligand ratio and $V^{IV}O$ concentration used in the spectroscopic measurements is depicted in Figure 5 (the formation constants of the binary complexes used in the speciation calculation were taken from ref.[12] and ref.[17]).

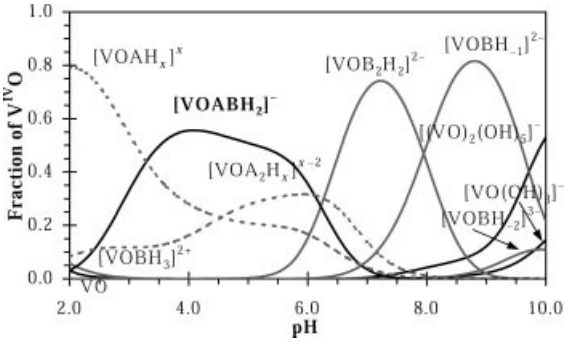

Figure 5. Concentration distribution diagram of the $V^{IV}O$–dipic(A)–GSH(B) system at a 1:2:50 metal ion-to-ligand ratio, $C_{VO} \approx 0.004$ mol dm$^{-3}$.

The speciation calculations suggested that $V^{IV}O$ starts to coordinate to dipic at pH < 2. At a 10-fold or higher excess of GSH, besides the binary species, a ternary complex $[VOABH_2]^-$ could be detected in which GSH most probably coordinates in a monodentate way through the C-terminal $COO^-$ or with the possibility of chelation together with the peptide carbonyl-O. Neither CD nor EPR spectroscopy can distinguish between these two different binding modes. This complex can be determined potentiometrically only with high uncertainty because the coordinating carboxylate donor is in the deprotonated form over most of the pH range of formation (p$K$(COOH) ca. 3.5),[17] and thus its coordination does not result in a direct pH change. At pH > 6, binary complexes of GSH are formed. Subsequently, because of the significantly weaker $V^{IV}O$-binding ability of GSH, even a 10-fold excess of GSH was not sufficient to prevent hydrolysis of the metal ion and formation of the oligonuclear hydroxo species $\{[(VO)_2(OH)_5]^-\}_n$.

By EPR spectroscopy (Figure 6, Table 4) a new species could be detected in the pH range 3–6; this is probably the ternary species $[VOABH_2]^-$. However, at pH ca. 7, the EPR spectrum of the $V^{IV}O$–dipic–GSH system coincides fully with that of $V^{IV}O$–GSH, indicating that GSH completely displaces the carrier ligands from the coordination sphere of the metal ion. Although GSH is a weaker vanadium binder than dipic, it is present at a 50–100-fold excess relative to dipic.

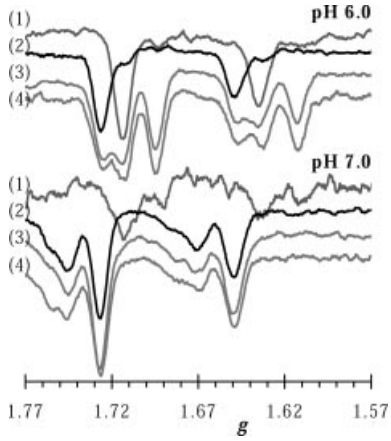

Figure 6. High-field range of the first-derivative EPR spectra at 77 K of frozen solutions containing: (1) $V^{IV}O$–dipic 1:2, (2) $V^{IV}O$–GSH 1:50, (3) $V^{IV}O$–dipic–GSH 1:2:50 and (4) 1:2:100 metal ion-to-ligand ratios, $C_{VO} \approx 0.004$ mol dm$^{-3}$. The pH values are indicated.

Table 4. EPR parameters ($g_\parallel$, $A_\parallel$)[a] for the binary and ternary complexes of $V^{IV}O$ formed with dipicolinate, maltolate and GSH.

| Species | $g_\parallel$ | $A_\parallel$ ($\times 10^4$ cm$^{-1}$) | Chelating set |
|---|---|---|---|
| GSH | | | |
| $[VOBH_2]^+$ | 1.937 | 174.2 | |
| VOBH | 1.941 | 170.0 | |
| $[VOB_2H_2]^{2-}$ | 1.948 | 163.8 | 2×($COO^-$, $NH_2$) |
| $[VOBH_{-1}]^{2-}$ (I) | 1.956 | 154.5 | ($COO^-$/amide-O, $NH_2$, $S^-$) $OH^-$ |
| $[VOBH_{-1}]^{2-}$ (II) | 1.959 | 147.0 | |
| Dipicolinate + GSH | | | |
| $[VOABH_2]^-$ | 1.930 | 177.2 | ($COO^-$,$COO^-$) ($COO^-$, amide-O/$H_2O$) |
| Maltolate + GSH | | | |
| $VOABH_2$ | 1.936 | 174.2 | ($O^-$, =O) ($COO^-$, amide-O/$H_2O$) |
| $[VOA_2BH_2]^-$ | 1.941 | 169.0 | ($O^-$, =O) ($O^-$, $=O_{ax}$) $COO^-$ |
| $[VOA_2BH]^{2-}$ | 1.949 | 159.1 | ($O^-$, =O) ($O^-$, $=O_{ax}$) $S^-$ |

[a] The relative uncertainty in the calculation of the parameters is estimated to be ca. 0.005 for $g_\parallel$ and ca. 1.0 for $A_\parallel$. In the case of rhombic distortion $g_\parallel$ and $A_\parallel$ are in fact $g_z$ and $A_z$, respectively.

### $V^{IV}O$–Maltolate–GSH System

A concentration distribution diagram of the $V^{IV}O$–maltolate–GSH system under the experimental conditions of the spectral measurements is depicted in Figure 7. In accord-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ance with the species distribution, new EPR signals could be detected that can be assigned to the ternary species (see Table 4).

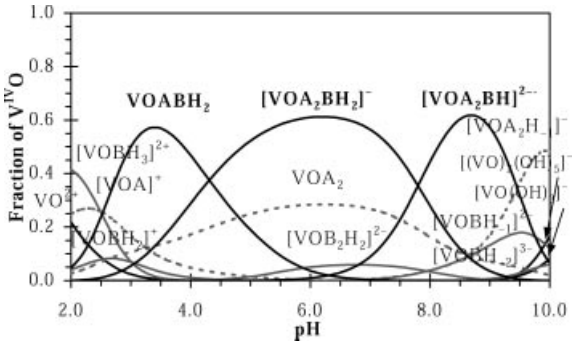

Figure 7. Concentration distribution diagram of the $V^{IV}O$–maltolate(A)–GSH(B) system at a 1:2:50 metal ion-to-ligand ratio, $C_{VO} \approx 0.004$ mol dm$^{-3}$.

In the pH range 2.5–4.0, besides the signals from the species $[VOBH_x]^{x-1}$ ($x$ = 2, 3), a new complex ($g_{\|}$ = 1.941 and $A_{\|} = 169.5 \times 10^{-4}$ cm$^{-1}$) was detected that was not seen in the EPR spectra of the binary systems. In the pH range 6–7, this signal was slightly shifted ($g_{\|}$ = 1.941 and $A_{\|} = 168.6 \times 10^{-4}$ cm$^{-1}$), but remained in the uncertainty range of the EPR parameters. Above pH 7, another new signal appeared at $g_{\|}$ = 1.949 and $A_{\|} = 159.1 \times 10^{-4}$ cm$^{-1}$. Some of the EPR spectra recorded by varying the B ligand concentration at pH 7.0 are shown in Figure 8.

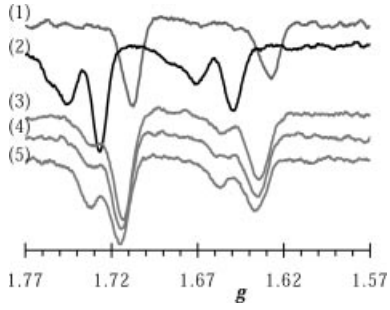

Figure 8. High field range of the first-derivative EPR spectra at 77 K of frozen solutions containing: (1) $V^{IV}O$–maltolate 1:2, (2) $V^{IV}O$–GSH 1:50, (3) $V^{IV}O$–maltolate–GSH 1:2:25,(4) 1:2:50 and (5) 1:2:100 metal ion-to-ligand ratios, $C_{VO} \approx 0.004$ mol dm$^{-3}$ at pH 7.0.

The EPR spectra clearly indicate ternary complex formation in the $V^{IV}O$–maltolate–GSH system at a 25-fold excess of GSH. Considering the EPR parameters (Table 4) and the low CD signals recorded (not shown), we conclude that GSH most probably coordinates at the Gly end through ($COO^-$, O-amide/$H_2O$) donors, while participation of the thiolate donor occurs only at pH > 7. The most likely binding modes of the complexes formed in the $V^{IV}O$–maltolate–GSH system are shown in Table 4. In the complex $VOABH_2$ formed in the slightly acidic pH range, GSH coordinates bidentately or monodentately in the equatorial plane, while in $[VOA_2BH_2]^-$ formed in the neutral pH range, GSH coordinates in a monodentate manner through the C-terminal $COO^-$ function to the fourth equatorial position of $V^{IV}O$. In the case of $VOA_2$, the *cis* complex, with one empty equatorial coordination site, is the predominant or the exclusive isomeric form. In the species $[VOA_2BH]^{2-}$, when Equation (1) is applied to the equatorial donor set, (2 × ($O^-$, =O), $S^-$) may be assumed. The estimated value $A_{\|}^{est}$ = $157.6 \times 10^{-4}$ cm$^{-1}$ agrees fairly well with the experimental value $A_{\|} = 159.1 \times 10^{-4}$ cm$^{-1}$. This suggests equatorial thiolate coordination.

### $V^{IV}O$–Carrier Ligand–ATP–GSH Systems

When ATP and GSH are simultaneously considered as potential $V^{IV}O$ binders, GSH is not expected to be able to compete with ATP for binding to $V^{IV}O$ since ATP is a much stronger ligand. The competition reaction was studied by EPR spectroscopy (see Figure 9) in the absence and in the presence of the insulin-mimetic complexes. In the case of dipic, no spectral changes could be detected between the spectra measured in the presence or absence of GSH, in agreement with what was found in the $V^{IV}O$–dipic–ATP system. Therefore, EPR spectroscopy does not give any information on the changes that might have occurred in the coordination sphere because of the high similarity of the partial contributions of the coordinating donors to the $A_{\|}$ value (see above).

For the $V^{IV}O$–ATP–GSH ternary system, when ATP was in a 10-fold excess relative to $V^{IV}O$, only the EPR signals of the $V^{IV}O$–ATP complexes were detected. New signals appeared only at a 2.5-fold excess (EPR parameters: $A_{\|}$ = $172.1 \times 10^{-4}$ cm$^{-1}$ and $165.7 \times 10^{-4}$ cm$^{-1}$). Comparison of the EPR spectra of solutions containing $V^{IV}O$, maltolate, ATP and GSH at pH ca. 7 (see Figure 9) revealed significant changes only when ATP was not present in at least a 10-

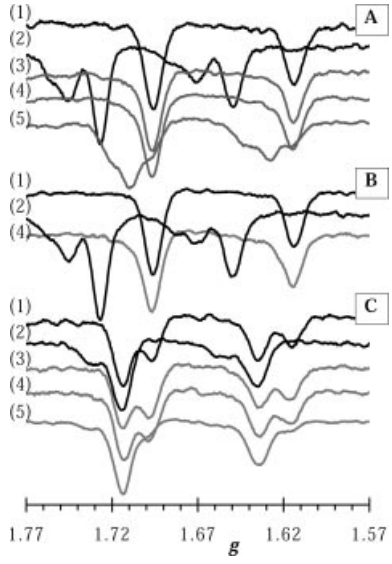

Figure 9. High field range of the first-derivative EPR spectra at 77 K of frozen solutions: (A) without carrier ligand, (B) with 8 mM dipicolinate, (C) with 8 mM maltolate, (1) $V^{IV}O$–ATP 1:10, (2) $V^{IV}O$–GSH 1:50, (3) $V^{IV}O$–ATP–GSH 1:10:25,(4) 1:10:50 and (5) 1:2.5:50 metal ion-to-ligand ratios; $C_{VO} \approx 0.004$ mol dm$^{-3}$ at pH 7.0.

fold excess (see above). Below such an excess of ATP, the changes in the ratio of the predominating signals seem to indicate the participation of GSH in complex formation.

## Conclusions

With respect to the two important cell constituents GSH and ATP, our results indicate that if the carrier ligands can somehow find a way to enter the cell strong $V^{IV}O$-binder cell constituents will partly displace the carrier ligands and ternary complexes with relevant biomolecules of the cell will be formed. Some of the ternary species are highly anionic, which are partly neutralised and probably undergo ion paring with cations, $K^+$ and $Mg^{2+}$, of the cell.

From among the important cell constituents, GSH will possibly take part in the reduction of $V^V$ to $V^{IV}$ and will help keep $V^{IV}$ in this oxidation state. As a strong $V^{IV}O$ binder, ATP will chelate the metal ion, forming binary and/or ternary complexes. The results of this work strongly suggest that ATP binds relevant $V^{IV}O$ species under cell conditions, and thus might somehow be involved in the insulin-mimetic action of $V^{IV}O$ compounds. However, the time courses of these parallel redox and complexation reactions require further investigations.

## Experimental Section

**Materials:** The ligands investigated were Sigma products of the highest analytical purity. They were used without further purification, but their purities were checked and the exact concentrations of their solutions was determined by the Gran method.[27] The $V^{IV}O$ stock solution, prepared as described earlier,[28] was standardized for metal ion concentration by permanganate titration and for hydrogen ion concentration by potentiometry, using the appropriate Gran function. The ionic strength was adjusted to 0.20 mol dm$^{-3}$ KCl. The temperature was 25.0 ± 0.1 °C for potentiometric measurements, and 25.0 ± 0.3 °C for CD and Vis spectra.

**Potentiometric Measurements:** For potentiometric titrations, an automatic titration set, including a Dosimat 665 autoburette, an Orion 710A precision digital pH meter and an IBM-compatible personal computer was used. A Metrohm 6.0234.100 semimicro combined glass electrode was calibrated for hydrogen ion concentration according to the method of Irving et al.[29] The ionic product of water was taken as $pK_w = 13.76 \pm 0.01$.

When we refer to the stoichiometries of complexes present in solution, the notation $M_pA_qB_rH_s$ is used, where M = $V^{IV}O^{2+}$, $H_2A$ or HA refers to the fully protonated form of dipicolinate acid or maltolate, respectively, and $H_5B^+$ denotes totally protonated ATP. However two of the four protons of the triphosphate chain dissociate in very acidic media (pH < 1). $H_4B^+$ refers to totally protonated GSH. The concentration stability constants, $\beta_{pqrs} = [M_pA_qB_rH_s]/([M]^p[A]^q[B]^r[H]^s)$, were calculated by using the computer programme PSEQUAD.[30] The equilibria corresponding to the formation of hydroxo complexes of $V^{IV}O$ were taken into account in the calculation of the stability constants of the complexes. The following stability constants ($\log\beta$) were assumed for these complexes: $[VO(OH)]^+$ ($\log\beta_{100-1} = -5.94$); $[(VO)_2(OH)_2]^{2+}$ ($\log\beta_{200-2} = -6.95$), calculated from the data published by Henry et al.,[31] using the Davies equation to take into account the different ionic strengths; $[VO(OH)_3]^-$ ($\log\beta_{100-3} = -18.00$);[22] and $[(VO)_2(OH)_5]^-$ ($\log\beta_{200-5} = -22.50$),[22,23] were taken from the literature.

**Spectroscopic Measurements:** The CD spectra were recorded with a JASCO 720 spectropolarimeter with a red-sensitive photomultiplier (EXWL-308). Visible spectra were recorded with a Perkin–Elmer Lambda 9 spectrophotometer. The spectral range covered was normally 400–900 nm (Vis) and 400–1000 nm (CD). By Vis and CD spectra, we mean representations of $\varepsilon_m$ or $\Delta\varepsilon_m$ values vs. $\lambda$ [$\varepsilon_m$ = absorption/($bC_{VO}$) and $\Delta\varepsilon_m$ = differential absorption/($bC_{VO}$), where $b$ = optical path and $C_{VO}$ = total $V^{IV}O$ concentration].

The EPR spectra were recorded at 77 K with a Bruker ESR-ER 200D X-band spectrometer. The spin-Hamiltonian parameters were obtained by simulation of the spectra with the aid of the modified computer programme of Rockenbauer and Korecz.[32] The EPR spectra of the $V^{IV}O$ systems help to elucidate the binding mode of the complexes formed in solution; Chasteen developed an additivity rule to estimate the hyperfine coupling constant $A_z^{est}$ [Equation (1)], based on the contributions $A_{z,i}$ of each of the four equatorial donor groups.[33] The estimated accuracy of $A_z^{est}$ is ca. $3 \times 10^{-4}$ cm$^{-1}$.

$$A_z^{est} = \sum_{i=1}^{4} A_{z,i} \quad (1)$$

Most of the $A_{z,i}$ data relevant for this work were presented by Chasteen.[33] For the carboxylate ($COO^-$) donor, Chasteen estimated its contribution in Equation (1) to be $42.7 \times 10^{-4}$ cm$^{-1}$, based on the $A_z$ of the VO(oxalato)$_2^{2-}$ complex, assuming that the four $COO^-$ groups coordinate equatorially. However, the solution structure presumably involves the set ($3 \times COO^-$, $H_2O)_{eq}$,[34] so this contribution should be $42.1 \times 10^{-4}$ cm$^{-1}$, the value used in the present work. The contribution of each O donor of maltolate in Equation (1) was taken to be $41–42 \times 10^{-4}$ cm$^{-1}$. This value was calculated from the $A_z$ parameters of *cis* and *trans* complexes of VO(malt)$_2$, determined by assuming the [($O^-$, =O)($O^-$, $=O_{ax}$) $H_2O$] and [($O^-$, =O)($O^-$, =O)] sets, respectively.[8] These data can be used to establish the most probable binding mode of the complexes formed, but care must be taken as the contributions of the donor groups to the hyperfine coupling may depend, for instance on their orientation,[35] or the charge of the ligand.[36] The influence of the axial donor groups (if any) is not taken into account. In the absence of ethylene glycol, a relatively broad background was present in most of the frozen solution EPR spectra, and therefore most spectra were obtained from aqueous solutions containing 5% of ethylene glycol.

# Mechanism-Based Inactivation of Coenzyme $B_{12}$-Dependent 2-Methyleneglutarate Mutase by (*Z*)-Glutaconate and Buta-1,3-diene-2,3-dicarboxylate

**Wolfgang Buckel,*[a] Antonio J. Pierik,[a] Sandra Plett,[a] Ashraf Alhapel,[a] Diana Suarez,[b] Shang-min Tu,[b] and Bernard T. Golding*[b]**

**Keywords:** 2-Methyleneglutarate / Mutase / Coenzyme $B_{12}$ / Inhibition / Buta-1,3-diene-2,3-dicarboxylic acid / Glutaconic acid

In the presence of *holo* 2-methyleneglutarate mutase, buta-1,3-diene-2,3-dicarboxylate and (*Z*)-glutaconate [(*Z*)-pent-2-ene-1,5-dicarboxylate], but not (*E*)-glutaconate, each induced homolysis of the Co–C bond of coenzyme $B_{12}$ to afford cob(II)alamin and the 5′-deoxyadenosyl radical. The latter probably added to the double bond in (*Z*)-glutaconate and one of the double bonds in buta-1,3-diene-2,3-dicarboxylate to afford a corresponding "radical adduct". The formation of new radicals and cob(II)alamin was diagnosed by UV/Visible and EPR spectroscopy. (*Z*)-Glutaconate rapidly inactivated the mutase with formation of aquocobalamin, which was possibly derived by electron transfer from cob(II)alamin to the radical adduct. In contrast, buta-1,3-diene-2,3-dicarboxylate was a much slower inactivator. In this case, the spectroscopic data revealed a relatively stable complex of the radical adduct with cob(II)alamin in the active site of the enzyme.

## Introduction

Coenzyme $B_{12}$-dependent enzymes comprise eliminases and mutases, both of which catalyse molecular rearrangements, whereby a functional group undergoes a 1,2-shift enabling conversion of substrate to product. In the eliminases, the migrating group is amino or hydroxy, whereas in the mutases it is either amino or a carbon-based group. The mechanisms of these reactions have been extensively discussed and reviewed.[1–3] For the mutases, experimental and theoretical data have recently led to the proposal that in the mutases cob(II)alamin assists the group migration by stabilising intermediate methylene radicals.[3]

2-Methyleneglutarate mutase from the strict anaerobic bacterium *Eubacterium barkeri*, formerly called *Clostridium barkeri*, catalyses the reversible carbon-skeleton rearrangement of 2-methyleneglutarate (**1a**) to (*R*)-3-methylitaconate (**2a**, 2-methylene-3-methylsuccinate) in the pathway of nicotinate fermentation.[4] Binding of the substrate **1a** to the enzyme induces homolytic cleavage of the Co–C σ bond in the prosthetic group coenzyme $B_{12}$ to afford cob(II)alamin and the 5′-deoxyadenosyl radical. This highly reactive methylene radical abstracts the 4-*Re*-hydrogen atom from 2-methyleneglutarate to yield the substrate-derived 2-methylene-4-ylglutarate radical (**1b**) and 5′-deoxyadenosine. Cob(II)alamin coupled to an organic radical, possibly 2-methylene-4-ylglutarate (**1b**), can be observed by EPR spectroscopy.[5] It has been proposed that the substrate radical either fragments into acrylate and the 2-acrylate radical ($CH_2{=}C^{\cdot}HCO_2^-$), which recombine to the product-related (*R*)-3-methylene-itaconate radical (**2b**), or the latter radical is derived via an intermediate 1,2-dicarboxycyclopropylmethyl radical (**3**) (see Scheme 1).[5] Recently, Newcomb and Miranda have proposed a variant ("polar/heterolytic") of fragmentation–recombination in which the intermediates are the 2-carbanion of acrylate ($CH_2{=}C^-CO_2^-$) and the carboxyl radical of acrylate ($CH_2{=}CHCO_2^{\cdot}$).[6] The reaction cycle is completed by a H-atom transfer from 5′-deoxyadenosine to the 3-methylene-itaconate radical (**2b**) yielding the product **2a**. Finally, the coenzyme is regenerated by combining cob(II)alamin and the 5′-deoxyadenosyl radical, thereby reforming the Co–C σ-bond. In this paper we report the use of stable analogues of the proposed intermediate radicals with π bonds at those carbon atoms that during catalysis are converted into the $sp^2$ centres of radicals. In principle, these compounds could either competitively inhibit the enzyme or the 5′-deoxyadenosyl radical might add at a double bond to form an adduct radical and cob(II)alamin, thus leading to inactive enzyme. We synthesised (*Z*)-glutaconic acid [**4a**, (*Z*)-pent-2-ene-1,5-dicarboxylic acid] as a potential analogue of the 2-methylene-4-ylglutar-

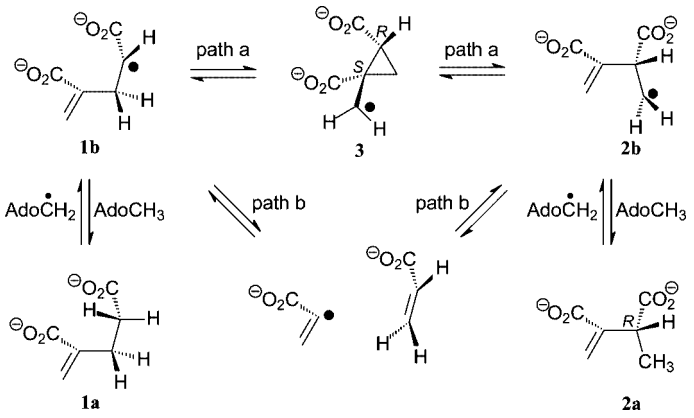
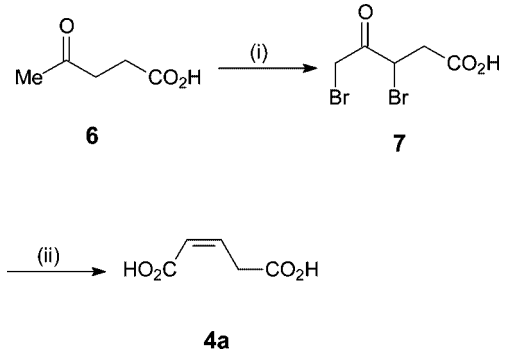


Scheme 1. Proposed reaction pathways for 2-methyleneglutarate mutase. (Path a) Addition-elimination mechanism with the participation of an intermediate 1-methylene-1,2-cyclopropanedicarboxylate radical **3**, for which the (1*S*,2*R*)-isomer is shown {$AdoCH_2$ = 5′-deoxyadenosyl; $AdoCH_3$ = 5′-deoxyadenosine}. (Path b) Fragmentation–recombination mechanism for 2-methyleneglutarate mutase involving an acrylate molecule and a 2-acrylate radical.

ate radical (**1b**), as well as buta-1,3-diene-2,3-dicarboxylic acid (**5**) as an analogue of the (*R*)-3-methyleneitaconate radical (**2b**). The commercially available (*E*)-glutaconic acid (**4b**) was also studied. Interestingly, compounds **4a** and **5** were inactivators of 2-methyleneglutarate mutase, whereas **4b** had no effect on the enzyme.

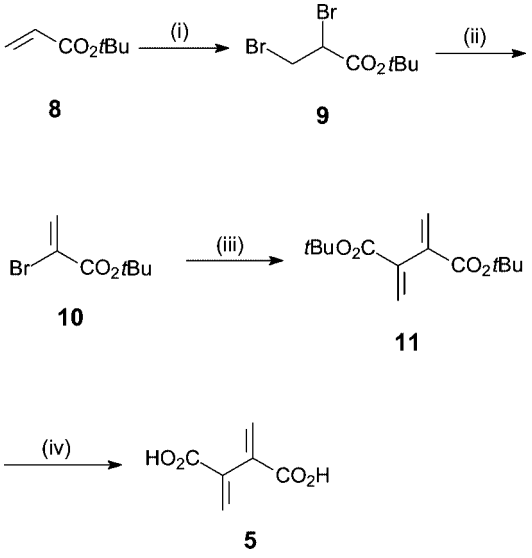
## Synthesis of Inhibitors

The synthesis of (*Z*)-glutaconic acid (**4a**, Scheme 2) was based on the procedure described in ref.[7] (Scheme 2). Thus, laevulinic acid (**6**) was cleanly dibrominated to 3,5-dibromolaevulinic acid (**7**), which underwent a Favorski rearrangement on treatment with potassium hydrogen carbonate to give exclusively (*Z*)-glutaconic acid with no trace of the (*E*)-isomer **4b** according to $^1$H NMR analysis.



Scheme 2. Synthesis of (*Z*)-glutaconic acid (**4a**) [reagents: (i) $Br_2$, aq. 48% HBr; (ii) aq. $KHCO_3$].

The synthesis of buta-1,3-diene-2,3-dicarboxylic acid (**5**, Scheme 3) was performed via the corresponding di-*tert*-butyl ester, the preparation of which was closely modelled on that of dimethyl buta-1,3-diene-2,3-dicarboxylate.[8] Thus, *tert*-butyl acrylate (**8**) was treated with bromine to give *tert*-butyl 2,3-dibromopropionate (**9**), which was dehydrobrominated to *tert*-butyl 2-bromoacrylate (**10**) using triethylamine as base. The *tert*-butyl 2-bromoacrylate was subjected to nickel(0)-induced coupling to afford di-*tert*-butyl buta-1,3-diene-2,3-dicarboxylate (**11**), which was deprotected with trifluoroacetic acid to give buta-1,3-diene-2,3-dicarboxylic acid (**5**).



Scheme 3. Synthesis of buta-1,3-diene-2,3-dicarboxylic acid (**5**) [reagents and conditions: (i) $Br_2$, DCM, <10 °C; (ii) $Et_3N$, diethyl ether, 0 °C to room temperature; (iii) $(cycloocta\text{-}1,5\text{-}diene)_2Ni$, $Ph_3P$, diethyl ether, 25 °C, 4.5 h; (iv) TFA, room temperature].

## Enzyme Inhibition Studies

The activity of 2-methyleneglutarate mutase was determined in a coupled assay using 3-methylitaconate Δ-isomerase as an auxiliary enzyme.[5] The formation of 2,3-dimethylmaleate was followed spectrophotometrically at $\lambda$ = 256 nm. At first all three compounds were checked for their ability to inhibit or inactivate the isomerase. Whereas the glutaconates (**4a**, **4b**) did not affect the enzyme at all, 1 mM buta-1,3-diene-2,3-dicarboxylate (**5**) caused complete inactivation within 3 min under the conditions of the assay. Possibly a cysteine residue at the active site of the isomerase

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

added to one of the conjugated double bonds of this substrate analogue. This interesting result was not pursued further for the time being.

Because both glutaconates did not inhibit the isomerase, their action on the mutase could be studied directly in the coupled assay. It was found that 0.2 mM (*Z*)-glutaconate (**4a**) already inactivated the mutase by 60% within 1 min; after 5 min the inactivation was complete. Furthermore, whereas 1 mM (*Z*) isomer **4a** completely inactivated the mutase within 1 min, 1 mM (*E*) isomer **4b** exhibited no effect during this time. Only with 4 mM **4b** was there a slight deviation from the control observed after the first minute. $^1$H NMR spectroscopy revealed that the commercial **4b** used in this study contained ca. 2% **4a**. This was deduced from the integrated signal at $\delta$ = 6.55 ppm (β-H of **4a**) as compared to 7.03 ppm (**4b**). Hence the observed inactivation is completely specific for the (*Z*) isomer **4a**. In order to show that inactivation of 2-methyleneglutarate mutase only occurred with the *holo*-enzyme, coenzyme $B_{12}$-free *apo*-2-methyleneglutarate mutase was incubated for 10 min with **4a**, which was then removed by gel filtration through Sephadex G25. Following the addition of coenzyme $B_{12}$ to the recovered *apo*-enzyme, the reconstituted *holo*-enzyme was found to be fully active towards 2-methyleneglutarate.

The effect of **5** on the enzyme was assessed with 15 μM *apo*-2-methyleneglutarate mutase (subunit $m$ = 67 kDa), 100 μM coenzyme $B_{12}$, 2 mM dithiothreitol and 1 mM **5** in 100 mM potassium phosphate (pH 7.4) which were incubated for 30 min at 25 °C. Afterwards, the inhibitor was removed by gel filtration and the activity of the recovered enzyme was measured in the coupled assay. The results showed that incubation of the *holo*-enzyme with **5** decreased the activity of the enzyme by 45 ± 2% as compared to that of a control without **5**. We also studied the mutase under steady-state conditions and found that in the presence of excess of coenzyme $B_{12}$ and 10 mM 2-methyleneglutarate the *apo*-mutase lost 80% of its activity after 20 min (50% after 10 min) or about 6 million turnovers; within the next 20 min the decrease was much slower, leading to 15% residual activity. In the absence of either coenzyme $B_{12}$ or substrate the enzyme remained stable during this time.

UV/Visible spectroscopy of the reconstituted (*holo*) 2-methyleneglutarate mutase, from which the excess of coenzyme $B_{12}$ had been removed by gel filtration, exhibited a broad peak at 535 nm and a shoulder at around 570 nm (Figure 1). Upon addition of 25 mM 2-methyleneglutarate the absorbance of both features decreased, and the peak shifted by about 5 nm to 530 nm. A new peak arose at 470 nm indicating the formation of cob(II)alamin. These spectral changes were already observed after 1 min; incubation for a further 5 min revealed only a slight increase in the intensities of the new peaks. Addition of 10 mM **5** to *holo*-mutase resulted in the same changes but with a twofold increase in intensity. An almost identical spectrum was obtained after 30 min incubation of the apoenzyme with 1 mM **5** and an excess of coenzyme $B_{12}$, followed by removal of the unbound small molecules through gel filtration. Different spectral changes were observed by addition of 10 mM **4a** to the *holo*-enzyme. The peak at 535 nm shifted to 521 nm and a new peak arose at 495 nm. The same concentration of the (*E*) isomer **4b** modified the spectrum in a similar manner but to a lesser extent, and is ascribed to 2% **4a** as an impurity. The new peaks revealed the formation of aquocobalamin, the oxidation product of cob(II)alamin.

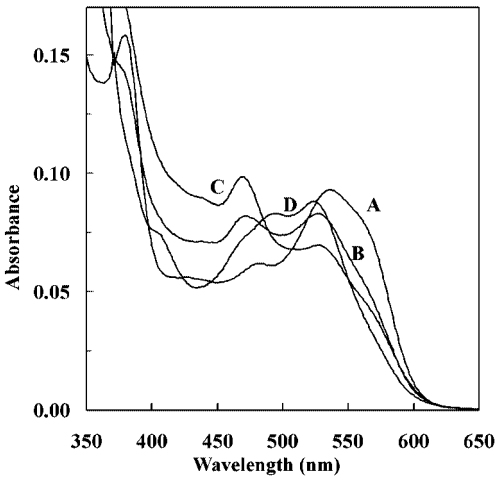


Figure 1. Visible spectra of 20 μM reconstituted *holo*-2-methyleneglutarate mutase (A) in the presence of 25 mM 2-methyleneglutarate (B) or 10 mM buta-1,3-diene-2,3-dicarboxylate (**5**, C) or 10 mM (*Z*)-glutaconate (**4a**, D). The addition of the dicarboxylate caused 10% dilution. The spectra were run 6 min after the additions.

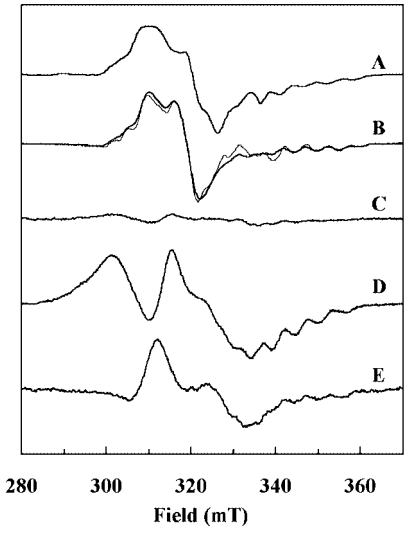

Figure 2. EPR spectra of 270 μM 2-methyleneglutarate mutase incubated in the presence of 1.6 mM coenzyme $B_{12}$ and 40 mM of 2-methyleneglutarate (A) or acrylate (B) or [2,3,3-$^2H_3$]acrylate (B, sharper trace) or (*E*)-glutaconate (**4b**, C) or (*Z*)-glutaconate (**4a**, D) or buta-1,3-diene-2,3-dicarboxylate (**5**, E). EPR conditions: temperature, 40 K for A, 77 K for B–E; microwave power 2 mW (A), 1.3 mW (B), 10 mW for C–E; microwave frequency 9463 ± 1 MHz (A) or 9435 ± 2 MHz (B–E); modulation amplitude 0.5 mT (A), 1.25 mT (B–E). Spectra were normalised to identical amplitudes, except for (*E*)-glutaconate. Thus, the spectra of the glutaconates can be directly compared.

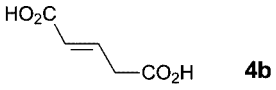
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

EPR spectra were obtained by mixing 270 μM *apo*-methyleneglutarate mutase (final concentration; 18 mg protein $mL^{-1}$) in 50 mM Tris/HCl (pH 7.5) and 75 mM NaCl with 1.6 mM coenzyme $B_{12}$, and 40 mM substrate or inactivator, followed by freezing in liquid pentane/$N_2$ within 30 s. The results are shown in Figure 2. The spectra revealed that 2-methyleneglutarate, as well as the inactivators **4a** and **5**, led to the formation of stable enzyme-bound organic radicals, which interact with cob(II)alamin.[5] In the case of **4a** the concentration dependence of the EPR signal was studied. Saturation was observed with an apparent $K_i$ of $0.9 \pm 0.1$ mM. The determination of the nature of the radicals (see below) has to await the syntheses of $^2H$- and $^{13}C$-labelled inactivators. Interestingly, acrylate also induced the formation of radicals even though it was recently shown not to act as an inhibitor.[5] This result was confirmed with perdeuterated acrylate, which sharpened the signal.

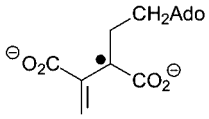
## Discussion

In this paper we describe two mechanism-based inactivators of 2-methyleneglutarate mutase. Buta-1,3-diene-2,3-dicarboxylate (**5**) can be regarded as a close analogue of the product (*R*)-3-methylitaconate (**2a**): just the methyl group is converted to a second methylene group. Unfortunately we were not able to perform steady-state kinetics with **5**, because it reacted rapidly and irreversibly with the auxiliary enzyme, the isomerase. However, incubation of **5** with the mutase resulted in partial inactivation, formation of oxygen-insensitive cob(II)alamin and induction of an organic radical interacting with cob(II)alamin. Interestingly the same features were observed with the substrate 2-methyleneglutarate (**1a**) itself; only the EPR spectrum was somewhat different. Hence **5** behaved superficially like 2-methyleneglutarate. However, whereas the 5′-deoxyadenosyl radical abstracts a hydrogen atom from C-4 of 2-methyleneglutarate, with **5** the 5′-deoxyadenosyl radical most likely added at one of its methylene groups leading to an allyl radical **12**. A similar proposal has been made for the inactivation of glutamate mutase induced by 2-methyleneglutarate.[9] The partial inactivation of 2-methyleneglutarate mutase by **5** suggests that the proposed radical addition may be reversible. The substrate analogue **5** may fit sufficiently well into the enzyme active site that the adduct produced by the interaction of **5** with the 5′-deoxyadenosyl radical protects cob(II)alamin from interaction with oxygen.

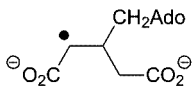
The inactivator **4a** is not so closely related to the substrate 2-methyleneglutarate because it lacks the *exo*-methylene group. However, it apparently fits well into the active site, possibly because the distance between the two carboxylates is similar to that in the enzyme-bound conformation of (*R*)-3-methylitaconate. This could be the explanation for the inability of the (*E*) isomer **4b** to inactivate the enzyme. The (*Z*) isomer reacts rapidly with the mutase as shown by activity measurements and EPR spectroscopy. Already 60 s after mixing under anoxic conditions an organic radical interacting with cob(II)alamin was detected. In the visible spectra, however, which were taken after 1 and 6 min (Figure 1), only aquocob(III)alamin rather than cob(II)alamin could be seen. This could be due to an electron transfer from cob(II)alamin to the initially derived adduct radical from **4a** and the 5′-deoxyadenosyl radical.



**4b**



**12**



**13**

(AdoCH$_2$ = 5'-deoxyadenosyl)

The adduct radical is possibly **13**, arising from addition of the 5′-deoxyadenosyl radical to C-3 of **4a**. Similar electron transfers have been observed from cob(II)alamin to substrate-derived radicals in β-lysine 5,6-aminomutase[10] and in variants of methylmalonyl-CoA mutase.[11]

## Experimental Section

**Enzymology:** The preparation and assay of 2-methyleneglutarate mutase and 3-methylitaconate Δ-isomerase, as well as the method of recording the EPR spectra, have been described previously.[5] In the standard assay, 2-methyleneglutarate mutase activity (0.05–0.1 unit) was measured with 10 mM 2-methyleneglutarate as substrate in 100 mM potassium phosphate (pH 7.4, 25 °C) using 3-methylitaconate isomerase (10–30 units/mL) as auxiliary enzyme. The 2,3-dimethylmaleate formed was measured by its UV absorbance ($\varepsilon_{256}$ = 0.66 $mM^{-1} cm^{-1}$). For the inactivation studies (*E*)- and (*Z*)-glutaconate and buta-1,3-diene-2,3-dicarboxylate were dissolved in aqueous KOH to give 0.1 M solutions (pH ca. 7). In order to remove small molecules from the enzymes, PD-10-desalting columns containing Sephadex® G-25 Medium from GE Healthcare (Amersham Biosciences) were used. Concentrations (mM or μM) given in this paper are the final concentration for a particular component in the reaction mixture.

**3,5-Dibromolaevulinic Acid (7):** Bromine (13.7 g, 86 mmol) was added dropwise to a mixture of laevulinic acid (5.0 g, 43 mmol) and 48% aqueous HBr (4.3 mL, 38 mmol) at 0 °C over 30 min. The mixture was stirred at 0 °C for 4 h. The excess of bromine was removed using a nitrogen flow. The resulting solution was stirred overnight at 0 °C to give a solid, which was taken up in ethyl acetate (40 mL) and washed with saturated aqueous sodium metabisulfite (3 × 25 mL). After drying ($MgSO_4$), the solvent was removed to afford crude product as a pale yellow solid. Recrystallisation from ethyl acetate/petroleum ether afforded the title compound as a white solid (7.83 g, 66% yield). M.p. 110–112 °C (lit.[7] m.p. 111–113). $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 2.97 (dd, $J$ = 5.6 and 17.6 Hz, 1 H, C*H*$HCO_2H$), 3.29 (dd, $J$ = 8.1 and 17.4 Hz, 1 H, CH*H*$CO_2H$), 4.07 (d, $J$ = 13.2 Hz, 1 H, C*H*HBr), 4.28 (d, $J$ = 12.9 Hz, 1 H, CH*H*Br), 4.94 (br. t, $J$ = 6.0 Hz, 1 H, CHBr) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 30.9 (C-2), 38.4 (C-5), 41.1 (C-3), 174.5 (C-1), 194.4 (C-4) ppm. $C_5H_6O_3Br_2$: calcd. C 21.93, H 2.21, found C 22.02, H 2.27. IR (KBr disc): $\tilde{\nu}$ = 3000 (m), 1724 (s), 1700 (s), 611 (m) $cm^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**(*Z*)-Glutaconic Acid (4a):** $KHCO_3$ (17.0 g, 169 mmol) in water (210 mL) was added to 3,5-dibromolaevulinic acid (5.5 g, 21 mmol). The mixture was vigorously stirred for 19 h. When constant titration values against methyl orange were obtained, the reaction was quenched by acidification (aq. HCl) and extracted with diethyl ether (10 × 30 mL). After drying the combined organic extracts ($Na_2SO_4$) the solvent was removed. The resulting yellow solid was recrystallised from acetonitrile (decolourisation by charcoal) to give the title compound as a white solid (0.21 g, 8% yield). M.p. 130–132 °C (lit.[7] m.p. 136–136.5, lit.[12] 136–136.5). $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 3.71 (dd, $J$ = 3.0 and 7.0 Hz, 2 H, $CH_2CO_2H$), 5.93 (dt, $J$ = 2.0 and 11.5 Hz, 1 H, CH), 6.52 (dt, $J$ = 7.0 and 11.6 Hz, 1 H, CH) ppm. $^{13}$C NMR [$\delta_C$ (75 MHz, $CD_3OD$)]: $\delta$ = 35.2 (C-4), 123.5 (C-3), 142.2 (C-2), 169.5 (C-1), 174.7 (C-5) ppm. $C_5H_6O_4$: calcd. C 46.16, H 4.65; found C 45.99, H 4.62. IR (KBr disc): $\tilde{\nu}$ = 3066 (m), 1686 (s), 1649 (s) cm$^{-1}$.

***tert*-Butyl 2,3-Dibromopropionate (9):** Bromine (2.9 ᴍ ) in DCM (10 mL) was added dropwise to *tert*-butyl acrylate (2.0 g, 15.6 mmol) in DCM (20 mL), cooled below 10 °C over 20 min. The mixture was stirred at ca. 5 °C for 2 h at which stage an orange colour persisted. The solvent was removed to afford the title compound as a colourless oil (4.41 g, 90% yield). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.43 [s, 9 H, $C(CH_3)_3$], 3.57 (dd, $J$ = 4.4 and 9.8 Hz 1 H, CH*H*Br), 3.81 (dd, $J$ = 9.8 and 11.3 Hz, 1 H, C*H*HBr), 4.27 (dd, $J$ = 4.4 and 11.3 Hz, 1 H, $CHBr_2$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 28.1 [$C(CH_3)_3$], 41.0 (C-3), 43.3 (C-2), 83.9 [$C(CH_3)_3$], 166.8 (C-1) ppm.

***tert*-Butyl 2-Bromoacrylate (10):** Triethylamine (0.77 g, 0.80 mL, 7.7 mmol) in diethyl ether (5 mL) was added dropwise to *tert*-butyl 2,3-dibromopropionate (3.0 g, 7.0 mmol) in dry diethyl ether (15 mL), cooled to 0 °C . The mixture was stirred overnight at room temperature and then filtered. The filtrate was washed with water (3 × 10 mL), dried ($Na_2SO_4$) and the solvent was removed. The title compound was obtained as a pale yellow oil for which no further purification was needed (1.72 g, 80% yield). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.45 [s, 9 H, $C(CH_3)_3$], 6.13 (d, $J$ = 1.5 Hz, 1 H, CH*H*), 6.77 (d, $J$ = 1.5 Hz, 1 H, C*H*H) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 28.3 [$C(CH_3)_3$], 83.4 [$C(CH_3)_3$], 123.8 (C-3), 129.2 (C-2), 161.1 (C-1) ppm.

**Di-*tert*-butyl Buta-1,3-diene-2,3-dicarboxylate (11):** Bis(1,5-cyclooctadiene)nickel(0) (1.5 g, 5.3 mmol) and triphenylphosphane (2.8 g, 10.6 mmol) were suspended in dry diethyl ether (20 mL) at 25 °C under nitrogen in a flame-dried Schlenk tube. Neat *tert*-butyl 2-bromoacrylate (1.87 g, 8.9 mmol) was added rapidly via syringe and the reaction mixture was stirred at 25 °C for 4.5 h. The mixture was diluted with diethyl ether (20 mL), washed with water (2 × 25 mL), dried ($MgSO_4$) and the solvent was removed. The crude product was purified by medium pressure chromatography (silica, elution with 5% ethyl acetate in petrol). The product containing fractions ($R_f$ = 0.36 on silica, same solvent system) were collected and the solvent was removed to afford the title compound as a colourless oil (0.48 g, 47% yield). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.42 [s, 18 H, $C(CH_3)_3$], 5.60 (d, $J$ = 1.7 Hz, 2 H, CH*H*), 6.06 (d, $J$ = 1.7 Hz, 2 H, C*H*H) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 28.4 [$C(CH_3)_3$], 81.3 [$C(CH_3)_3$], 116.6 ($CH_2$), 126.0 (C-2, C-3), 165.3 (C-1) ppm.

**Buta-1,3-diene-2,3-dicarboxylic Acid (5):** Trifluoroacetic acid (TFA) (1.0 mL) was added to di-*tert*-butyl buta-1,3-diene-2,3-dicarboxylate (0.16 g, 0.63 mmol) in DCM (2 mL). The resulting solution was stirred at room temperature for 20 min. The solvent was removed and the title compound was obtained as a white solid (0.08 g, 90% yield). Recrystallisation from acetonitrile gave an analytically pure sample. M.p. 184–186 °C (lit.[13] m.p. 186–188, lit.[8] 192–192.5). $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 5.85 (d, $J$ = 1.5 Hz, 2 H, C*H*H), 6.22 (d, $J$ = 1.5 Hz, 2 H, CH*H*) ppm. $^{13}$C NMR (75 MHz, $CD_3OD$): $\delta$ = 128.1 ($CH_2$), 140.1 (C-2, C-3), 167.1 (C-1) ppm. IR (KBr disc): $\tilde{\nu}$ = 3066 (m), 1675 (s), 1614 (s) cm$^{-1}$.

# $La_{17}Si_9Al_4N_{32-x}O_x$ ($x \leq 1$): A Nitridoaluminosilicate with Isolated Si/Al-N/O Clusters

**Guillaume Pilet,*[a,b] Jekabs Grins,[a] Mattias Edén,[c] and Saeid Esmaeilzadeh[a]**

**Keywords:** Aluminosilicates / Anions / Lanthanides

A nitrogen-rich aluminosilicate with nominal composition $La_{17}Si_9Al_4N_{33}$ has been synthesised at 1500–1650 °C under a $N_2$ atmosphere by reaction of La metal, AlN and $Si_3N_4$. Its crystal structure was solved and refined in space group $F\bar{4}3m$, with $a$ = 15.4279(6) Å and $Z$ = 4, to $R_f$ = 1.9 %. The structure contains two novel types of discrete tetrahedral aluminosilicate clusters, with respective nominal compositions $Al_4Si_4N_{17}$ and $Si_5N_{16}$, with La atoms in between. Bulk samples were also investigated by powder X-ray and electron diffraction. The $^{29}Si$ and $^{27}Al$ solid-state NMR results indicate that the phase contains minor amounts of oxygen and has a narrow compositional range with probable end limits $La_{17}Si_9Al_4N_{33}$ and $La_{16.67}Si_9Al_4N_{32}O$.

## Introduction

Nitridosilicates and sialons are well known to exhibit useful physical properties, such as high strength, good wear resistance, high decomposition temperature, good oxidation resistance, excellent thermal-shock properties and resistance to corrosive environments. They have traditionally been investigated with an aim towards applications such as cutting tools, burners, welding nozzles, heat exchangers and engine applications. Phase-formation conditions and phase-compatibility relationships have therefore been systematically studied in many M-Si-Al-O-N sialon systems [e.g. M = Ca, Y and rare-earth (RE) elements].[1] During the last decades, however, more efforts have also been directed towards the synthesis of novel compounds with more complex crystal structures.[2] In particular, the use of electropositive metals as starting materials has proven to be a successful synthesis route.[3] The new compounds found have crystal structures that exhibit features that are distinctly different from those found for oxosilicates.[4–6] For example, whereas the O atoms in oxosilicates are connected to either one or two Si atoms,[7] the N atoms in nitridosilicates and sialons may also be shared by three, and even four, Si tetrahedra.[8,9] The network connectivity for nitridosilicates is therefore, as a rule, higher than for oxosilicates.

We report here on the structure determination and bulk synthesis of a new nitridoaluminosilicate with nominal composition $La_{17}Si_9Al_4N_{33}$. Two features make it noteworthy. First, its crystal structure does not contain any continuous linkage of tetrahedra, but instead two types of isolated Si-(Al)-N/(O) clusters. The same type of clusters is found in the similar structure of $Pr_{63}Si_{40}Al_{12}O_{20}N_{115}$,[10] the first known example of a nitridosilicate structure with all Al and Si atoms in isolated clusters. However, $Pr_{63}Si_{40}Al_{12}O_{20}N_{115}$ crystallises with a cubic *primitive* unit cell, in space group $P\bar{4}3m$ with $Z$ = 1 and $a$ = 15.185(2) Å, and the clusters are different with respect to their composition and connectivity, as described further below. Counterparts to the cluster types are also found in oxosilicate structures, although obviously they contain O instead of N atoms. Secondly, $La_{17}Si_9Al_4N_{33}$ is, according to its formal composition, a rare example of a pure nitridoaluminosilicate. The few other members include the wurtzite-type phases $MAlSiN_3$ (M = Be, Mg, Mn, Ca),[11,12] filled α-$Si_3N_4$-type compounds,[13] $Ca_5Si_2Al_2N_8$[12] and $Ca_4SiAl_3N_7$.[12]

However, although it is clear that the phase is very rich in nitrogen, it cannot be ruled out that it may contain minor amounts of oxygen, considering, for example, that the starting materials were not free of oxygen. In order to obtain local structural insight, $^{27}Al$ and $^{29}Si$ NMR spectra were therefore recorded. The NMR results indicate that there is a minor substitution of N by O and that the phase is likely a solid solution with end limits $La_{17}Si_9Al_4N_{33}$ and $La_{16.67}Si_9Al_4N_{32}O$. In what follows, the nominal composition will first be assumed, the NMR results presented, and conclusions about compositional variations then addressed in the Discussion.

## Results

### Crystal Structure Determination and Refinement

The single-crystal data for $La_{17}Si_9Al_4N_{33}$ could be indexed with a cubic F-centred unit cell with $a$ = 15.410(1) Å. The F-centring, and the absence of further reflection conditions, was confirmed by electron diffraction (ED). The [011] zone axis pattern in Figure 1a shows the absence of 00l reflections with $l \neq 2n$ and $hk0$ reflections with $h + k \neq 2n$. Tilting of the sample (see Figure 1b) showed that an equivalent set of reflections appear in the first-order Laue zone (FOLZ), thus implying the extinction symbol F---.[14] The structure was solved in the space group $F23$ by direct methods, using the SIR97 program[15] in combination with Fourier difference syntheses. It was refined against $F$ using the CRYSTALS program[16] and reflections with $I/\sigma(I) > 3$. An inspection of refined atomic positions showed that the space group symmetry could be increased to $F\bar{4}3m$ (no. 216), and the final refinements made using this space group yielded a weighted $R_f$ value of 1.9% for 294 unique reflections. Thermal displacement parameters were refined anisotropically for Si and La atoms, and isotropically for N atoms. Refinement data are given in the Experimental Section, with structural parameters in Table 1 and selected bond lengths in Table 2.

### Structure Description

The unit cell contains four nominal formula units of $La_{17}Si_9Al_4N_{33}$. Possible deviations from this formula are addressed in the Discussion. There are four tetrahedral T (T = Si/Al) sites in the structure. One site has a considerably larger average T–N distance than the other ones and is concluded to be occupied by Al atoms. The other three T sites are accordingly occupied by only Si atoms. The structure contains two types of isolated tetrahedral clusters. One type has a composition of $Al_4Si_4N_{17}^{-23}$ and is illustrated in Figure 2 (a). In each $Al_4Si_4N_{17}$ unit, a central N atom, on the

4*c* site at (1/4,1/4,1/4), is common to four $AlN_4$ tetrahedra. Each of four $SiN_4$ tetrahedra then shares three of its N corner atoms with separate $AlN_4$ tetrahedra, and has one free apex N atom pointing outwards from the unit. A crystal-chemical formula[17] for the crystal is $[Al_4^{1;6}Si(2)_4^{1;3}N(4)^{[1]}N(2)_{12}^{[2]}N(5)^{[4]}]^{23-}$. A similar cluster is found in the structure of $Pr_{63}Si_{40}Al_{12}O_{20}N_{115}$.[10] This has the composition $Al_4Si_4N_{13}O_4^{-19}$ and differs by having O atoms on the Si tetrahedra apex atom sites. An identical atomic arrangement is also found for the $Be_4Si_4O_{17}$ cluster in the structure of $Na_{10}Be_4Si_4O_{17}$.[18]

The other type of cluster, illustrated in Figure 2 (b), has a composition of $Si_5N_{16}^{-28}$ and a crystal-chemical formula of $[Si(1)^{[1;4]}Si(3)_3^{[1;1]}N(1)_{12}^{[1]}N(3)^{[2]}]^{28-}$. It has at its centre, on the 4*a* site at (0,0,0), a $SiN_4$ tetrahedron that is connected by corner-sharing to four surrounding $SiN_4$ tetrahedra. Similar clusters, with composition $Si_5O_{16}$, are found in the structure of zunyite $[Al_{13}Si_5O_{20}(OH)_{18}Cl]$.[19] The structure of $Pr_{63}Si_{40}Al_{12}O_{20}N_{115}$ also contains $Si_5N_{16}$ zunyite-type clusters, but four such clusters are further interlinked by four additional $SiON_3$ tetrahedra to form a much larger cluster with composition $Si_{24}N_{64}O_4^{-104}$. The arrangement of two types of clusters in the unit cell of $La_{17}Si_9Al_4N_{33}$ is illustrated in Figure 3. There are four different La atom positions in the structure; the coordination of N atoms around them is illustrated in Figure 4. La1 is coordinated by six N atoms at 2.53–2.60 Å that form a distorted square bipyramid, La2 by a distorted cube of eight N atoms at 2.64–2.84 Å, La3 by a distorted octahedron of six N atoms at 2.56–2.63 Å, and La4 by 12 N atoms that form a cube-octahedron.

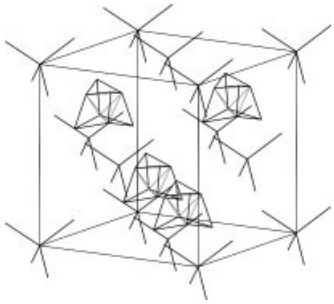

Figure 3. An illustration of the arrangement of the two types of clusters in the unit cell of $La_{17}Si_9Al_4N_{33}$. The drawn lines connect tetrahedral atom positions.

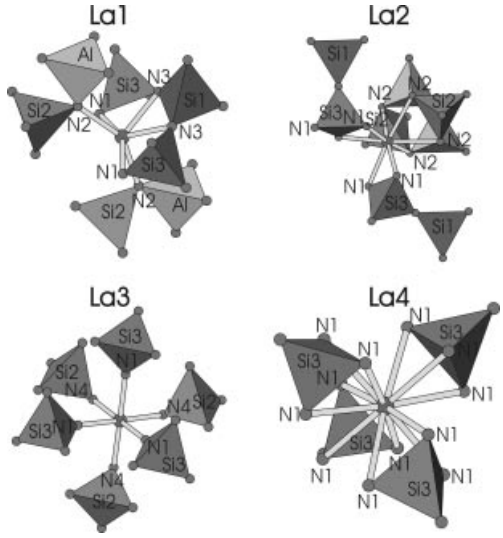

Figure 4. The coordination of N atoms around the four crystallographically different La atoms in the structure of $La_{17}Si_9Al_4N_{33}$.

## Bulk Synthesis

Initial syntheses showed that the $La_{17}Si_9Al_4N_{33}$ phase could be obtained together with LaN in the presence of a large excess (double amount) of La metal. The crystallinity was good, but the sample decomposed over a period of about one week, simultaneously with hydrolysis of the LaN, when left in contact with air. When stoichiometric amounts of the starting materials were used, and also when adding a smaller excess (10%) of La, yellow to yellow-green coloured samples were obtained after applying two consecutive heat treatments at 1500 and 1600 °C. These samples contained two minority phases in addition to $La_{17}Si_9Al_4N_{33}$. The reflections of one could be indexed using a small monoclinic unit cell with $a$ = 5.2582(9), $b$ = 5.5717(9), $c$ = 3.9909(6) Å, and $\beta$ = 92.35(1)°, thus indicating that its structure may be perovskite related. The reflections of the second could be indexed with an *I*-centred tetragonal unit cell with $a$ = 6.821(2) and $c$ = 11.133(6) Å. The cell strongly suggests that the phase is related to $La_3AlO_3N_2$, which crystallises in *I*4/*mcm* with $a$ = 6.855(2) and $c$ = 11.199(5) Å.[20] A third heat treatment did not decrease the amounts of these secondary phases. However, their amounts could be drastically reduced by mixing the obtained samples with 3 wt.-% fine-grained carbon and then further heat-treating them at 1500 °C, i.e. by a carbothermal reduction and nitridation of the secondary phases. The powder pattern of the stoichiometric, yellow sample then only contained two weak reflections, with relative intensities below 1.5%, for the impurity phases. A good agreement was found between the observed reflection intensities and the intensities calculated from the single crystal data. The obtained unit-cell parameter was $a$ = 15.4279(6) Å and the indexed powder pattern is given in Table 3. Unfortunately, we were not able to obtain samples with this level of purity in larger amounts, for example to perform neutron powder diffraction or physical property measurements.

To find an alternative synthetic route, a 4-g stoichiometric mixture of LaN, $Si_3N_4$ and AlN was hot-pressed at 1600 °C and 50 MPa for 4 h. The powder pattern of the prepared sample contained, however, only broad reflections from unreacted starting materials, cuspidine-type $La_4Si_2O_7N_2$ and unidentified phases. In order to investigate whether Al and O can be simultaneously incorporated into $La_{17}Si_9Al_4N_{33}$ according to the common sialon substitution mechanism ($Si^{4+} + N^{3-} \leftrightarrow Al^{3+} + O^2$) three 1.5-g samples of $La_{17}Si_{9-x}Al_{4+x}N_{33-x}O_x$, with $x$ = 2, 4, and 6, were prepared with $SiO_2$ as oxygen source. The powder patterns of

the samples with $x$ = 2 and 4 showed no change in the unit-cell parameter for $La_{17}Si_9Al_4N_{33}$ and the presence of several additional phases, among them AlN and the two secondary phases described above. The sample with $x$ = 6 contained no $La_{17}Si_9Al_4N_{33}$ at all. These results show that the $La_{17}Si_9Al_4N_{33}$ phase does not accept any significant simultaneous incorporation of Al and O. A comparison of the obtained unit-cell parameters for all preparations of $La_{17}Si_9Al_4N_{33}$ showed, however, very small but significant variations. The largest unit-cell parameter was observed for the sample prepared with a large excess of La [$a$ = 15.4402(9) Å], and the smallest one for the stoichiometric sample that was further heat-treated with added carbon at 1500 °C [$a$ = 15.4279(6) Å]. The difference is very small [0.012(1) Å], but indicates nevertheless that $La_{17}Si_9Al_4N_{33}$ shows smaller compositional variations. It may be noted that the two samples have nominally the same Al/Si ratio. Finally, attempts were made to prepare isostructural phases with the rare-earths Pr, Sm, Gd and Y at 1500–1650 °C. These were not successful, but in the case of Y yielded a very distinct powder pattern from YN and a hexagonal phase with $a$ = 9.8027(4) and $c$ = 10.6235(6) Å. The unit-cell parameters indicate that the phase is isostructural with $Y_{6+x/3}Si_{11}N_{20+x}O_{1-x}$,[21] a structure type that can also incorporate Al according to the more general formula $RE_{6+x/3}Si_{11-y}Al_yN_{20+x+y}O_{1-x+y}$, e.g. $Nd_7Si_8Al_3N_{20}$.[22]

## Solid-State NMR Spectroscopy

### *$^{27}$Al NMR*

Figure 5 shows $^{27}$Al MAS and 3QMAS[24] NMR spectra recorded for a freshly prepared sample of $La_{17}Si_9Al_4N_{33}$. The MAS spectrum displays two signals at around $\delta$ = 112 and 90 ppm, which were assigned to $AlN_4$ and $AlN_3O$ tetrahedra, respectively, on the basis of typical chemical shifts for such units.[25,26]

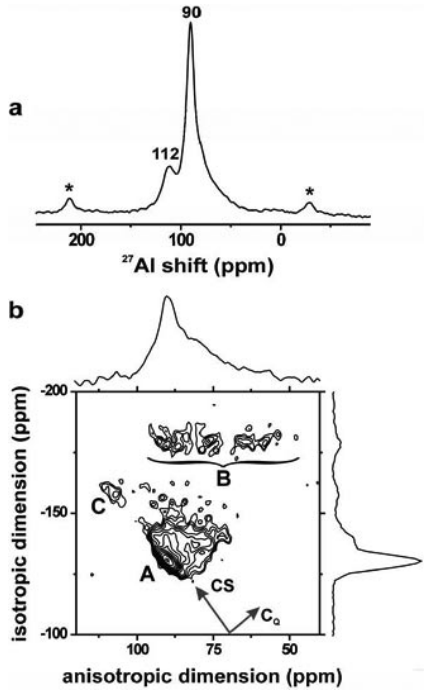

Figure 5. (a) Zoom around the centre-band region of an $^{27}$Al MAS spectrum recorded for $La_{17}Si_9Al_4N_{33}$ at a MAS frequency of 12.5 kHz. It results from the summation of 192 signal transients, each obtained using a relaxation delay of 200 s and short excitation pulse of flip angle ca. 12°. The nutation frequency was 94 kHz, measured relative to $Al^{3+}$(aq). 200 Hz full width at half maximum height (FWHM) Lorentzian broadening was applied prior to Fourier transformation. Chemical shift values are displayed on the top of the peak maxima and asterisks indicate spinning sidebands. (b) 3QMAS spectrum recorded by the shifted-echo technique[23] at 13.3 kHz MAS, using 96 transients per $t_1$-value and relaxation delays of 30.5 s. Arrows indicate the direction of peak displacement due to changes in isotropic chemical shifts and quadrupolar coupling constants.

However, the higher spectral resolution in the 3QMAS spectrum reveals a significantly more complex signal pattern than hinted from the 1D MAS spectrum. The signal region labelled A corresponds to the peak at $\delta$ = 90 ppm in the MAS spectrum. From the 3QMAS data, we estimated the isotropic chemical shift as $\delta_{iso}$ = 92 ppm. As the asymmetry parameter of the electric-field tensor could not be determined for any of the sites discussed below, we have henceforth assumed that $\eta$ = 0, for site A, which results in a corresponding quadrupolar coupling constant $C_Q = e^2qQ/h$ = 1.7 MHz. The same chemical shift value was obtained by using the frequency positions of central and satellite transition peaks, as described previously.[26] Signal A extends along both spectral dimensions due to spreads in isotropic chemical shifts as well as quadrupolar coupling constants. In the MAS spectrum in part a of Figure 5, these dispersions are manifested as the signal "tail" extending towards lower shifts (ppm values). However, the broad peak labelled B (Figure 5, b) also contributes to this spectral re-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gion. Signal B is associated with an aluminium site experiencing a significant quadrupolar coupling constant (estimated as $CQ$ = 7.4 MHz), but unlike the other sites, it is not associated with dispersions in quadrupolar couplings or chemical shifts. Based on its isotropic chemical shift ($\delta_{iso}$ = 108 ppm), this peak is assigned to an $AlN_4$ environment.[25,26]

The 3QMAS spectral intensities are not quantitative[24] due to the widely differing quadrupolar coupling constant of site B compared to A and C. This is evident, for example, from the fact that the anisotropic MAS projection of Figure 5 (b) differs from the 1D MAS spectrum in Figure 5 (a), as is the incomplete excitation of the peak around $\delta$ = 112 ppm (corresponding to signal C in Figure 5, b).

The MAS spectrum was deconvoluted into three components (not shown), from which the relative integrated intensities for A–C were estimated. This (highly uncertain) calculation showed that 55, 34 and 11% of the total signal portion derives from A, B and C, respectively. It now remains to reconcile the information from the $^{27}$Al NMR spectrum, which shows signals from (at least) three distinct Al environments (for the proposed structure of $La_{17}Si_9Al_4N_{33}$ only a *single* tetrahedral $AlN_4$ site is expected). Several scenarios of O↔N and Si↔Al substitution were considered. It turned out to be most plausible that (i) the weak signal C derives from a minor impurity phase that is not detected by XRD (incidentally, its NMR parameters are almost identical to those of AlN) and (ii) the remaining two sites may be accounted for by noting that if oxygen substitutes for nitrogen at the 4*c* position, four $AlN_4$ units are converted into four $AlN_3O$ units for every N→O replacement. After renormalising the integrals of A and B, this implies that the structure contains 62% $AlN_3O$ and 38% $AlN_4$ units, which translates roughly into 62% oxygen substitution at the 4*c* positions and the net formula $La_{17}Si_9Al_4N_{32.4}O_{0.6}$.

### *$^{29}$Si NMR*

The corresponding $^{29}$Si MAS spectrum is shown in Figure 6. It has a poor signal-to-noise ratio due to the very slow $^{29}$Si T1 relaxation coupled to relatively broad NMR signals, and displays two main groups of peaks, one extending between $\delta$ = –51 and –56 ppm and another centred at $\delta$ = –70 ppm. Both signals are attributed to $SiN_4$ tetrahedra. However, whereas the chemical shift of the former peak is representative for such units, a shift of around $\delta$ = –70 ppm is more typical of $SiN_2O_2$ groups.[27–29] Therefore, $^{29}$Si NMR spectroscopy alone cannot exclude additional oxygen substitution leading to "mixed" $SiN_nO_{4-n}$ environments. Nevertheless, we note that a relatively broad span of $^{29}$Si NMR chemical shifts has already been found from a still fairly small collection of nitridosilicates, ranging from $\delta$ = –36 ppm in $Y_3Si_6N_{11}$ to $\delta$ = –65 ppm in $LaSi_3N_5$.[27–29] Thus the very strong shielding of the $^{29}$Si nuclei of the $SiN_4$ tetrahedra may originate from a unique combination of structural factors (bond lengths and angles) in the present compound. From the single-crystal XRD analysis, we expect three distinct $^{29}$Si signals with relative intensities 1:4:4. It is possible to reconcile the spectrum of Figure 6 with the proposed structure of $La_{17}Si_9Al_4N_{33}$ by noting that if the $^{29}$Si signals from the two Si 16*e* sites overlap, a spectrum with two peaks of relative intensity 1:8 would result. This is not unlikely when considering that overlap between signals from *distinct* $SiN_nO_{4-n}$ environments has previously been reported in the $^{29}$Si NMR spectra of oxynitridosilicates.[27,28,30] In fact, the width (FWHM ≈ 10 ppm) of the peak centred at $\delta$ = 70 ppm (Figure 6) is exceptional for a crystalline nitridosilicate. As neither of the two peaks from $La_{17}Si_9Al_4N_{33}$ fitted well to a single Lorentzian, Gaussian or mixed lineshape, this indeed suggests that they either arise from several partially overlapping signals or that the peaks are broadened by residual MAS non-averaged dipolar couplings between $^{29}$Si and the quadrupolar spins in its surroundings ($^{14}$N, $^{27}$Al and $^{139}$La).[27,31] The ratio between the integrated peaks in Figure 6 was estimated to be 1:(8.5 ± 2). The deviation from the ratio 1:8 may be due to different degrees of saturation of the three $^{29}$Si sites caused by differing $T_1$ relaxation times or possibly from interfering signals of minor impurity phases.

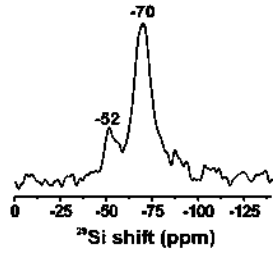

Figure 6. $^{29}$Si MAS spectrum recorded at 9.4 T employing MAS at 6.5 kHz. It is the result of 68 co-added signal transients using 30° excitation pulses and 50 min relaxation delays. 150 Hz FWHM Lorentzian broadening was applied in the data processing.

## Discussion

EDS microanalysis was performed on both the obtained crystals and the powder bulk samples and yielded 57(2)% La, 30(1)% Si, 13.3(9)% Al and 56(3)% La, 30(2)% Si, 13(1)% Al, which correspond to the formulae $La_{17.0(6)}Si_{9.0(4)}Al_{4.0(3)}$ and $La_{16.8(7)}Si_{9.1(5)}Al_{3.9(3)}$, respectively. The analytical results are thus in very good agreement with the structural cation composition $La_{17}Si_9Al_4$, obtained by placing Al atoms on the 16*e* sites with $x$ = 0.1800(3) and Si atoms on the remaining tetrahedral sites. Therefore, if all cation and anion positions are fully occupied, one can conclude by charge balancing that all anions are $N^{3-}$ and that the compound formula is $La_{17}Si_9Al_4N_{33}$.

Considering the diffraction data alone, it cannot be ruled out, however, that the phase contains smaller amounts of oxygen. First, the starting materials $Si_3N_4$ and AlN contain some oxygen, corresponding to an estimated O/N ratio in the final, fully nitrided mixture of about 0.5:33, which may partly explain why pure bulk samples were not obtained using stoichiometric metal compositions. Secondly, oxygen might also have been taken up by the sample during the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

heat treatment, as we have observed for other syntheses, even though it was performed in a graphite furnace under a $N_2$ gas flow. Furthermore, as described above, the amounts of the formed secondary phases could be significantly reduced by further carbothermal reduction and nitridation of the samples.

$^{27}$Al NMR spectroscopy has provided direct evidence of O substitution at the N5 4*c* position by showing the presence of both $AlN_3O$ and $AlN_4$ tetrahedral units, whereas the $^{29}$Si NMR spectroscopic data could not rule out additional oxygen substitution. The smaller total anion charge resulting from O substitution is probably compensated by vacancies on some of the La sites, leading to a formula $La_{17-x/3}Si_9Al_4N_{33-x}O_x$ ($x \leq 1$). However, no reliable conclusions concerning La vacancies could be drawn from structure refinements. We see no way of incorporating more substantial amounts of oxygen without larger changes in the cation composition, which would contradict the results of the EDS analysis, the single crystal diffraction data, and the observed near constancy of the unit-cell parameter for bulk samples. We therefore conclude that the compound has a formula very close to $La_{17}Si_9Al_4N_{33}$ but that it contains variable minor amounts of oxygen, with probable end-limit compositions being $La_{17}Si_9Al_4N_{33}$ and $La_{16.67}Si_9Al_4N_{32}O$.

The unit-cell parameters and atomic coordinates of $La_{17}Si_9Al_4N_{33}$ suggest that its structure could be a $4\times4\times4$ superstructure of the perovskite type, similar to $Ce_{16}Si_{15}O_6N_{32}$ for example,[6,9] which is notable as its structure contains silicon octahedrally coordinated by nitrogen. Following Liebau,[6] the latter formula may accordingly be rewritten as $Ce_{16}(Si^{[6]}Si_{14}^{[4]}\square)(O_6N_{32}\square_{10})$. The relationship to the cubic perovskite $ABX_3$ structure rests on the fact that the atoms corresponding to A and B do not deviate significantly from the highly symmetrical positions in the ideal perovskite structure, even when the coordination number for B atoms is reduced from six to four. The anion X positions may, however, deviate extensively from their ideal positions and are expected to contain vacancies due to the decreased coordination number of the B atoms.

For $La_{17}Si_9Al_4N_{33}$ the relationship with perovskite is not so close. While many of the La atoms are found in positions corresponding to perovskite A atoms, this set of positions is in addition occupied by Si1 atoms (at the centres of the $Si_5N_{16}$ zunyite-type clusters), N1 atoms (at the centres of the $Al_4Si_4N_{17}$ clusters), and also contains vacancies [at the 4b sites (1/2,1/2,1/2)]. Further, the Al atom positions are significantly displaced from the positions corresponding to perovskite B atoms and the $Al_4Si_4N_{17}$ clusters cannot readily be described as part of a perovskite structure. It should also be noted that the $Al_4Si_4N_{17}$ clusters cannot be described as being a part of an anion close packing.

According to the formula $La_{17}Si_9Al_4N_{33}$, the compound is one of the rare examples of a pure nitridoaluminosilicate. More noteworthy, however, is that $La_{17}Si_9Al_4N_{33}$ is a nitrido(alumino)silicate with a structure where all the tetrahedral atoms are part of isolated complex anions or clusters that contain only, or predominantly, N atoms. Nitridosilicate crystal chemistry differs from that of oxosilicates mainly due to the common occurrence of $N^{(3)}$, and to a much less extent of $N^{(4)}$, atoms.[9] For oxonitridosilicates and sialons, the crystal chemistry is more similar to that of oxosilicates, especially for low N/O ratios. As the T/X ratio increases [T = (Si/Al) and X = (N/O)] the structures exhibit a condensation of the tetrahedra in the sequence of isolated $TX_4$ tetrahedra → isolated $T_2X_7$ groups → rings or chains of tetrahedra → layers of tetrahedra → frameworks of tetrahedra.[11] Structures containing more complex isolated clusters built up from $TX_4$ tetrahedra are virtually non-existent for all of these types of silicates. The compound $La_{17}Si_9Al_4N_{33}$ has a T/X ratio of 1:2.54, from which one might anticipate a structure containing rings, chains or sheets of tetrahedra. Instead, the structure contains isolated tetrahedral clusters and 48.5% $N^{(1)}$, 48.5% $N^{(2)}$ and 3.0% $N^{(4)}$ atoms. Despite its high nitrogen and silicon content, there are no $N^{(3)}$ atoms, which are the common structural characteristic for nitridosilicates.

## Experimental Section

Powder samples of $La_{17}Si_9Al_4N_{33}$ were prepared at 1500–1650 °C in a graphite furnace under nitrogen, from La metal (Chempure, 99.9%), $Si_3N_4$ (UBE, SN-E10) and AlN (H. C. Starck, Berlin, grade A) as starting materials. During the synthesis the La metal reacts with $N_2$ to form reactive LaNd. The powders were mixed, in amounts of ca. 1 g, and ground in a dry-box under argon to prevent oxidation of the La metal, and then placed in Nb tubes that were sealed with parafilm during the transfer to the furnace. In a typical run, the sample was heated to the synthesis temperature over 2 h, kept there for 12 h, then cooled to 1200 °C over 4 h, whereupon the furnace was switched off. Yellow to orange single crystals were found in preparations at 1650 °C.

The heat-treated powder samples were characterised by their X-ray powder patterns, which were recorded with a Guinier–Hägg camera, using Cu-$K_{\alpha1}$ radiation and Si as internal standard. The data were evaluated using a film scanner system[32] and, for the majority of patterns, the Rietveld program FullProf.[33] Energy-dispersive X-ray (EDX) microanalyses of the metal composition were made using a JEOL 820 scanning electron microscope equipped with a LINK AN10000 EDX system. Electron diffraction (ED) studies were carried out with a JEOL 200FX transmission electron microscope (TEM), operating at 200 kV, in order to confirm the crystal system and space group. Single-crystal X-ray diffraction (XRD) data for $La_{17}Si_9Al_4N_{33}$ were collected with a STOE image-plate detector system (IPDS), using a Siemens rotating anode and Mo-$K_\alpha$ radiation, up to $2\theta = 52°$ and *d*-values ≥ 0.81 Å (Table 4). The STOE IPDS software package[34] was used for indexing and integration.

Further details of the crystal-structure investigations may be obtained from the Fachinformationzentrum, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-416358.

Magic-angle spinning (MAS) NMR experiments were carried out on a finely ground powder of $La_{17}Si_9Al_4N_{33}$ using a Varian/Chemagnetics Infinity-400 spectrometer at a magnetic field of 9.4 T, with the Larmor frequencies 79.50 and –104.28 MHz for $^{29}$Si and $^{27}$Al, respectively. 6-mm and 4-mm probeheads were employed for $^{29}$Si and $^{27}$Al acquisitions, respectively. Chemical shifts are reported in

# The Template Effect of Palladium(II): Synthesis, Characterization, and Crystal Structures of 2,4-Substituted 1,3,5-Triazapentadienatopalladium(II) Complexes

Jian-Ping Guo,[a] Wai-Kwok Wong,*[a] and Wai-Yeung Wong[a]

**Keywords:** Amidinate ligands / Hydrogen bonds / Palladium / N ligands

The reaction of $LiN(SiMe_3)_2$ with two equivalents of 2-, 3-, or 4-cyanopyridine followed by the addition of half an equivalent of $[PdCl_2(PhCN)_2]$ gives neutral 1,3,5-triazapentadienato complexes of the general formula $[Pd\{HNC(Py)NC(Py)NH\}_2]$ (Py = 2-pyridyl **1**, 3-pyridyl **2**, 4-pyridyl **3**). When the above reaction was carried out with benzonitrile and then 3- or 4-cyanopyridine was added followed by half an equivalent of $[PdCl_2(PhCN)_2]$ neutral unsymmetrical 1,3,5-triazapentadienato complexes of the general formula $[Pd\{HNC(Ph)NC(Py)NH\}_2]$ (Py = 3-pyridyl **4**, 4-pyridyl **5**) were obtained. When $LiN(SiMe_3)_2$ was treated with one equivalent of benzonitrile in THF, followed by the addition of a quarter of an equivalent of anhydrous palladium chloride and workup in air, the trinuclear complex tetrakis(benzamidinato)bis(2,4-diphenyl-1,3,5-triazapentadienato)tripalladium(II) (**6**) was obtained as yellow crystals in 19% yield. All complexes were fully characterized by elemental analysis, $^1H$ NMR spectroscopy, and mass spectrometry. The solid-state structures of compounds **2**, **3**, and **6** were determined by X-ray crystallography. Structural analyses revealed that the 2,4-bis(pyridyl)-1,3,5-triazapentadienyl ligands in **2** and **3** behave as didentate ligands to form six-membered rings with the metal ion. For **6**, the 2,4-diphenyl-1,3,5-triazapentadienyl ligands also behave as didentate ligands to form six-membered rings with the metal ion, whereas the amidinato ligands behave as bridging didentate ligands.

## Introduction

Didentate, monoanionic, nitrogen-based L–X$^-$ ligands and their complexes are one of the subjects of intense study in the field of amidinates.[1] Among this class of compounds, the coordination chemistry and potential application in catalysis of β-diketiminato ligands and their metal complexes have received significantly increasing attention recently. A series of β-diketiminate complexes have been synthesized by the nucleophilic addition reaction of α-hydrogen-free nitriles to substituted methyllithiums, and the catalytic properties of some of these complexes have been investigated.[2,3] Similar diimine ligands, namely *N*-phosphanyl-β-diimine ligands,[4] sterically demanding aromatic diimine ligands,[5] and their complexes have also been developed. Many metal β-diiminate complexes, such as magnesium,[6] aluminum,[7] nickel and palladium,[8] zirconium,[9] rhodium,[10] gallium,[11] and scandium[12] etc. have been reported. Moreover, these diimine and similar complexes have been found to be effective catalysts for the polymerization of ethylene.[8,13]

However, there are very few reports on the isoelectronic 1,3,5-triazapentadienato ligands and their complexes. Transition metal complexes with chelating 1,3,5-triazapentadienato ligands have been isolated by (i) evaporating a methanol solution of nickel chloride hexahydrate and acetamidine,[14] (ii) treating lithium benzamidinate with $[PtCl_2(PhCN)_2]$,[15] (iii) treating acetonitrile with the dinuclear nickel complex $[Ni_2(\mu\text{-}OH)_2(tpa)_2](ClO_4)_2$ [tpa = tris(2-pyridylmethyl)-amine],[16] (iv) treating triazine with copper acetate,[17] and (v) a coupling reaction between amidine and ligated nitriles.[18] Bis(perfluoroalkyl)triazapentadiene and its transition metal complexes have also been synthesized.[19,20]

We have synthesized the complex bis[2,4-bis(*n*-pyridyl)-1,3,5-triazapentadienato]nickel(II) (*n* = 3 or 4) in about 30% yield by the reaction of anhydrous nickel(II) chloride with the addition product of cyanopyridine with $LiN(SiMe_3)_2$.[21] We have since extended our study to $[PdCl_2(PhCN)_2]$ and the results are described here. Depending on the nature of the aryl group, $[PdCl_2(PhCN)_2]$ reacts with the addition product of lithium *N*,*N*′-bis(trimethylsilyl)arylamidinate, $[(Me_3Si)N(Li)C(Ar)N(SiMe_3)]$ (Ar = phenyl, 2-pyridyl, 3-pyridyl, 4-pyridyl) and an aryl nitrile to give the neutral mononuclear triazapentadienyl complexes bis(2-Ar-4-Ar′-1,3,5-triazapentadienato)palladium(II) (Ar = Ar′ = 2-pyridyl **1**; Ar = Ar′ = 3-pyridyl **2**; Ar = Ar′ = 4-pyridyl **3**; Ar = Ph, Ar′ = 3-pyridyl **4**; Ar = Ph, Ar′ = 4-pyridyl **5**) and trinuclear triazapentadienyl complex tetrakis(benzamidinato)bis(2,4-diphenyl-1,3,5-triazapentadienato)tripalladium(II) (**6**; Scheme 1). This is in contrast to the reaction of $[MCl_2(PhCN)_2]$ (M = Pd or Pt) with lithium *N*,*N*′-diphenylbenzamidinate [PhN(Li)C(Ph)NPh],

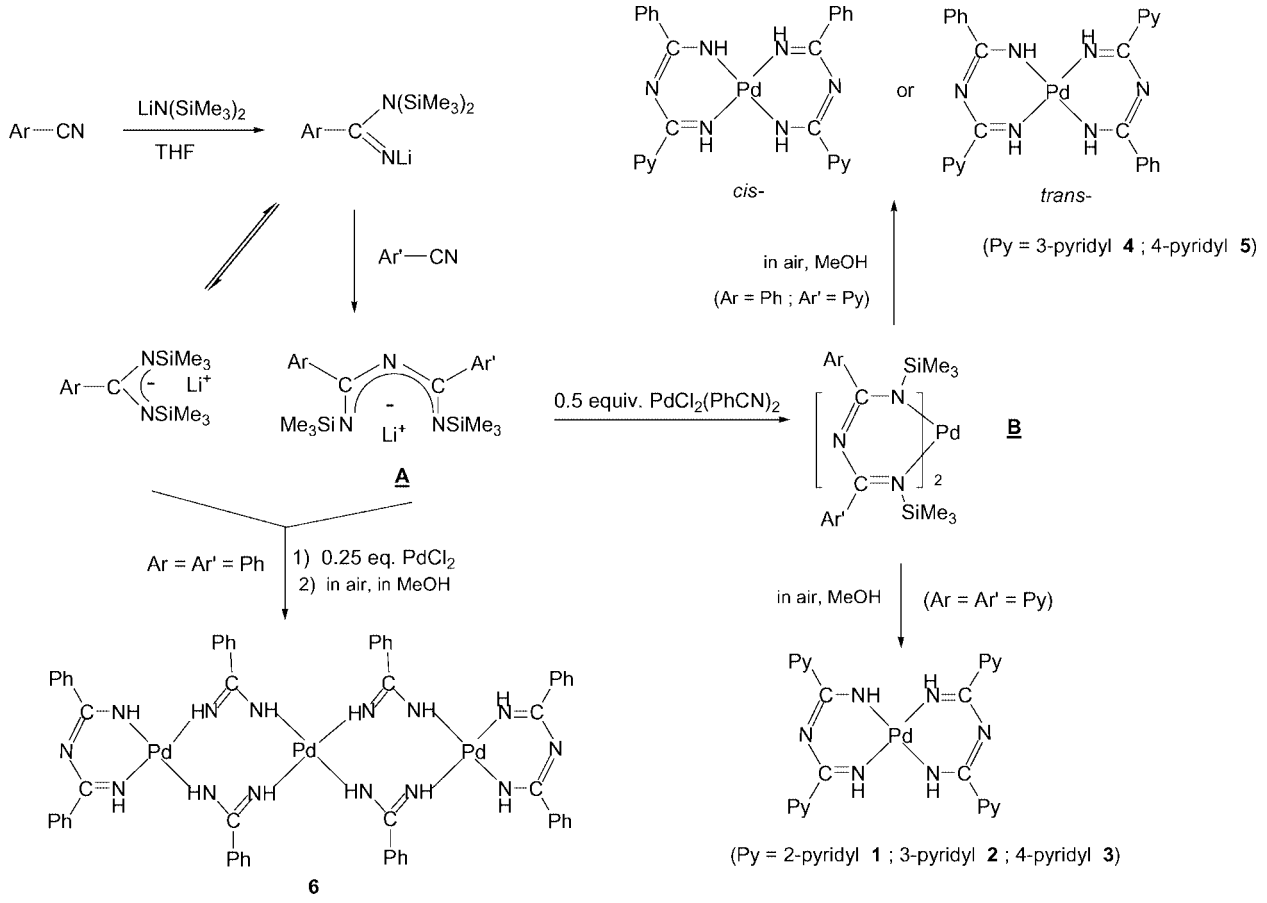

Scheme 1.

which gives the bis(amidinato) complexes [M{PhNC(Ph)NPh}$_2$].[22] The fact that the palladium complexes are isolated with higher yields than the related nickel complexes and the formation of compound **6** suggest that palladium plays a more evident template role in the synthesis of 1,3,5-triazapentadienato metal complexes. In other words, palladium may be specially suited to stabilizing the six-membered ring formed by palladium and the 1,3,5-triazapentadienato ligand.

## Result and Discussion

### Synthesis and Structural Characterization

Yellow crystals of the neutral, symmetrical 2,4-disubstituted 1,3,5-triazapentadienato complexes [Pd{HNC(Py)NC(Py)NH}$_2$] (Py = 2-pyridyl **1**; 3-pyridyl **2**; 4-pyridyl **3**), were obtained in good yields (71, 70, and 71%, respectively) when LiN(SiMe$_3$)$_2$ was treated with two equivalents of 2-, 3-, or 4-cyanopyridine in THF, followed by the addition of half an equivalent of [PdCl$_2$(PhCN)$_2$] and workup in air. Elemental analyses and electrospray ionization high resolution mass spectroscopic (ESI-HRMS) data confirmed the formulation of the compounds. The ESI mass spectra (positive mode) of **1**–**3** exhibit the $[M+1]^+$ peak at *m*/*z* 555.0947, 555.0944, and 555.1032, respectively, which deviate less than 10 ppm from the theoretical value of 555.0985 for the elemental composition $C_{24}H_{21}N_{10}Pd$. The observed isotopic distribution patterns of these peaks also match the expected theoretical signals.

Compounds **1**–**3** should have a similar structure. The solid-state structures of **2** and **3** were ascertained by X-ray crystallography. Perspective drawings of **2** and **3** are shown in Figures 1 and 2, respectively; selected bond lengths and angles are given in Table 1.

The structural analyses of **2** and **3** revealed that their structures are similar to the corresponding nickel(II) complexes [Ni{HNC(Py)NC(Py)NH}$_2$][21] and the analogous Pt complex [Pt{HNC(Ph)NC(Ph)NH}$_2$].[15] Both **2** and **3** are centrosymmetric with the palladium(II) ion adopting a square-planar geometry. The palladium(II) ion in **2** is located at the center of the plane defined by the four nitrogen atoms of the two didentate 1,3,5-triazapentadieno ligands [HNC(3-Py)NC(3-Py)NH]$^-$, with Pd–N distances of 1.980(3) [Pd(1)–N(1)] and 1.974(3) Å [Pd(1)–N(2)], and an N(1)–Pd(1)–N(2) angle of 87.12(12)°. Each didentate 1,3,5-triazapentadienato ligand forms a six-membered metallacycle with the metal ion. This six-membered ring is nearly planar with a mean deviation of 0.0278 Å from the plane. Within the 1,3,5-triazapentadieno ligand, the N(1)–C(1) [1.299(5) Å], C(1)–N(3) [1.353(5) Å], N(3)–C(7) [1.344(4) Å], and C(7)–N(2) [1.307(4) Å] distances are very

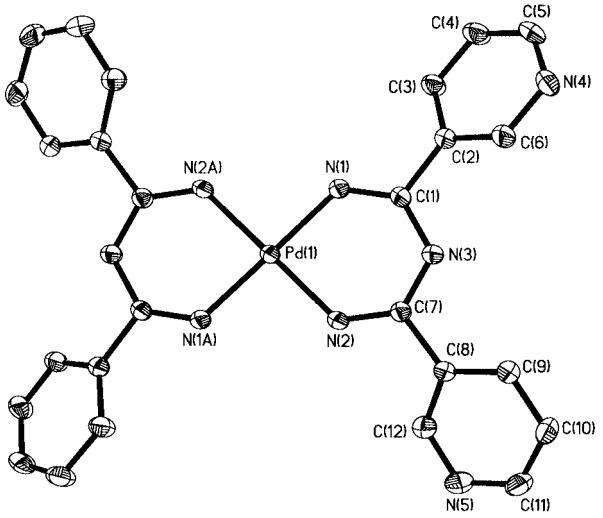

Figure 1. ORTEP drawing (30% probability level) of the molecular structure of **2**. Hydrogen atoms have been omitted for clarity.

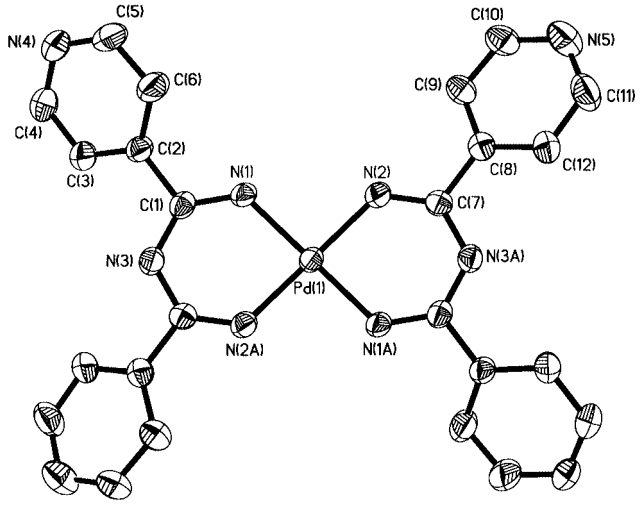

Figure 2. ORTEP drawing (30% probability level) of the molecular structure of **3**. Hydrogen atoms have been omitted for clarity.

similar, thereby indicating complete delocalization within the N–C–N–C–N framework. The plane of the six-membered ring forms dihedral angles of 37.8° and 30.7° with the N(4)- and N(5)-pyridyl planes, respectively, thus indicating that the N(4)-pyridyl and N(5)-pyridyl rings are not coplanar with the metal-containing six-membered ring.

Figure 2 shows the palladium(II) ion of **3** positioned at the center of the N(1)N(2)N(1A)N(2A) plane, with Pd–N distances of 1.980(4) [Pd(1)–N(1)] and 1.971(4) Å [Pd(1)–N(2)], and an N(1)–Pd(1)–N(2) angle of 92.38(16)°. Each didentate 1,3,5-triazapentadienato ligand forms a six-membered metallacycle with the metal ion. This six-membered ring is almost planar, with a mean deviation of 0.0086 Å from the plane. Within the 1,3,5-triazapentadienato ligand, the similarity between the N(1)–C(1) [1.316(6) Å], C(1)–N(3) [1.339(6) Å], N(3)–C(7A) [1.339(6) Å], and C(7A)–N(2A) [1.304(3) Å] distances shows complete delocalization within the N–C–N–C–N framework. The planes of the N(4)-pyridyl and N(5A)-pyridyl rings are not coplanar with the metal six-membered ring; they form a dihedral angle of 27.1° and 26.8° with the plane of the six-membered metallacycle, respectively.

When $LiN(SiMe_3)_2$ was treated with one equivalent of benzonitrile, then one equivalent of 3- or 4-cyanopyridine in THF, followed by the addition of half an equivalent of $[PdCl_2(PhCN)_2]$ and workup in air, the unsymmetrical complexes $[Pd\{HNC(Ph)NC(Py)NH\}_2]$ (Py = 3-pyridyl **4**; 4-pyridyl **5**) were obtained as yellow crystals in 31 and 27% yields, respectively. The formulation of the compounds was confirmed by elemental analyses and ESI-HRMS data. The ESI mass spectra (positive mode) of both compounds in methanol exhibit the corresponding $[M+1]^+$ peak at *m*/*z* 553.1106 for **4** and 553.1049 for **5**, both of which deviate by less than 10 ppm from the theoretical value of 553.1080 for the elemental composition $C_{26}H_{23}N_8Pd$. The observed isotopic distribution patterns of the $[M+1]^+$ peak also match the expected theoretical signals. It is clear that the lithium benzamidinate undergoes a nucleophilic addition reaction with 3-cyanopyridine or 4-cyanopyridine

and $[PdCl_2(PhCN)_2]$ to form the respective palladium(II) complex. Attempts to grow crystals of **4** and **5** suitable for an X-ray diffraction study were unsuccessful. However, the structures of **4** and **5** are expected to be similar to those of **2** and **3**. Compounds **4** and **5** could adopt either a *cis* or a *trans* configuration (Scheme 1). Unfortunately, the existing spectroscopic data cannot distinguish between these two configurations.

When $LiN(SiMe_3)_2$ was treated with an excess amount of benzonitrile followed by addition of a quarter of an equivalent of $PdCl_2$, the neutral trinuclear palladium complex $[Pd_3\{[HNC(Ph)NC(Ph)NH]_2[\mu_2\text{-}HNC(Ph)NH]_4\}]$ (**6**) was isolated in low yield (19%). This contrasts with the reaction with anhydrous $NiCl_2$, which gave the ionic salt $[Ni\{H_2NC(Ph)NH\}_4]Cl_2$.[21] The solid-state structure of **6** was ascertained by X-ray crystallography; a perspective drawing is shown in Figure 3. Selected bond lengths and angles are also given in Table 1. This structural analysis revealed that **6** is centrosymmetric, with Pd(1) at the inversion center. There are two kinds of coordinated anions − benzamidinato and 2,4-diphenyl-1,3,5-triazapentadienato − and three palladium atoms in the molecule of **6**. All three palladium(II) ions adopt a square-planar geometry. The distance between two neighboring palladium atoms is 2.933 Å, which is too long for any significant interaction between the two metal centers. The N(2)–Pd(2)–N(1) and N(5)–Pd(2)–N(7) angles are 88.3(4)° and 86.8(4)°, respectively, and the N(4)–Pd(1)–N(6) angle is 88.5(4)°. The lengths of the bonds between palladium and the coordinated nitrogen atoms of the 2,4-bis(phenyl)-1,3,5-triazapentadienato ligand are 1.998(9) [Pd(2)–N(1)] and 1.931(8) Å [Pd(2)–N(2)], respectively. The Pd–N bond lengths between the palladium atoms and the coordinated nitrogen atoms of benzamidinato are 2.022(9) [Pd(2)–N(5)], 2.044(8) [Pd(2)–N(7)], 1.986(10) [Pd(1)–N(4)], and 2.067(9) Å [Pd(1)–N(6)], which are similar to the Pd–N distance [2.038(3) Å] in $[Pd\{PhNC(Ph)NPh\}_2]$.[22] The didentate 1,3,5-triazapentadienato ligand forms a six-membered metallacycle with the metal ion. This six-membered ring is nearly planar, with a mean deviation of 0.0224 Å from the plane. Within the 1,3,5-triazapentadieno ligand, the N(1)–C(1) [1.360(13)], C(1)–N(3) [1.238(15)], N(3)–C(8) [1.306(15)], and C(8)–N(2) [1.391(12) Å] distances are similar, thus indicating delocalization within the N–C–N–C–N framework. The plane of the six-membered ring forms dihedral angles of 35.1° and 2.5° with the C(2)–C(7) and C(9)–C(14) phenyl planes, respectively, presumably due to solid-state packing effects. This indicates that the C(9)–C(14) phenyl plane is coplanar with the metal six-membered ring.

There are two benzamidinato anions in half a molecule of **6**. Each of them forms a five-membered ring with two palladium ions. The five-membered rings Pd(1)N(4)C(15)N(5)Pd(2) and Pd(1)N(6)C(22)N(7)Pd(2) are nearly planar with a mean deviation of 0.0615 and 0.0399 Å from the plane, respectively. The N(4)–C(15) [1.332(15) Å] and C(15)–N(5) [1.305(15) Å] bond lengths are indicative of delocalization within the N–C–N framework, which is also the case for the N(6)–C(22) [1.239(14) Å] and C(22)–N(7) [1.336(15) Å] bonds. The Pd(1)N(4)C(15)N(5)Pd(2) and Pd(1)N(6)C(22)N(7)Pd(2) planes form a dihedral angle of 36.3° and 53.0° with the C(16)–C(21) and C(23)–C(28) phenyl planes, respectively. The dihedral angle between the two five-membered planes is 87.9°.

### Template Effect of Palladium(II) for the Formation of 1,3,5-Triazapentadienato Complexes

The above discussion can be summarized as follows:
(1) Under the same reaction conditions, the yields of compounds **2** (70%) and **3** (71%) are much higher than those

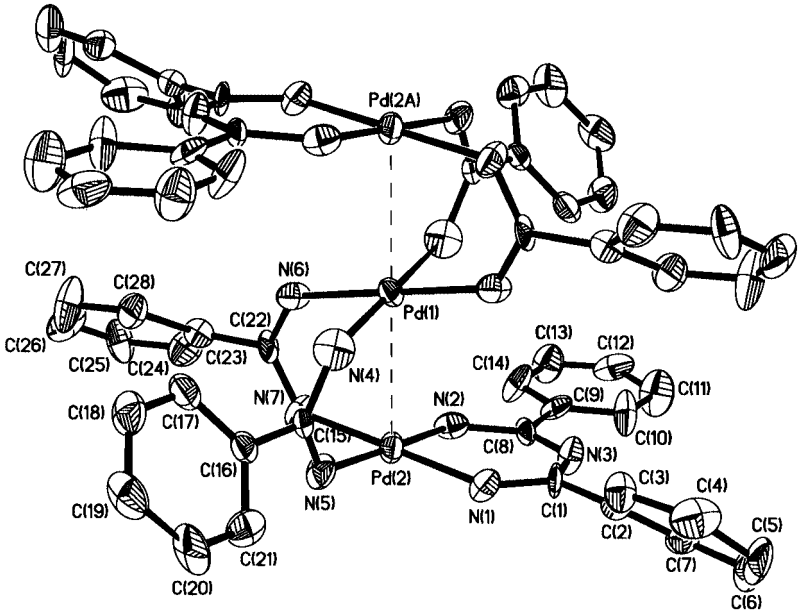

Figure 3. ORTEP drawing (30% probability level) of the molecular structure of **6**. Hydrogen atoms have been omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for the corresponding nickel complexes (28 and 30%, respectively).[21]

(2) If $[PdCl_2(PhCN)_2]$ is replaced by $ZnCl_2$, under the same reaction conditions as for the preparation of compound **3**, the product is 4-pyridylamidinatozinc chloride instead of bis[2,4-bis(pyridyl)-1,3,5-triazapentadienato]zinc.[23]

(3) The ligand 2,4-bis(pyridyl)-1,3,5-triazapentadiene $[HN=C(4\text{-}Py)N=C(4\text{-}Py)\text{-}NH_2]$ is not stable in air as it could not be isolated from the hydrolysis products obtained from the hydrolysis of the intermediate derived from reaction of lithium 4-pyridylamidinate with 4-cyanopyridine. If the hydrolysis product was analyzed very quickly after the hydrolysis, the $[M+1]^+$ peak (226.1198) could be found in the ESI spectra. Moreover, MS-MS analysis of the $[M+1]^+$ peak showed that $[HN=C(4\text{-}Py)N=C(4\text{-}Py)NH_2]$ is cleaved into 4-cyanopyridine and 4-pyridylamidine.

(4) Rapid mass spectral analysis of the hydrolysis products derived from reaction of lithium benzamidinate with benzonitrile did not locate the $[M+1]^+$ peak of the ligand 2,4-diphenyl-1,3,5-triazapentadiene $[HN=C(Ph)\text{–}N=C(Ph)\text{-}NH_2]$. This indicates that the ligand cannot exist in air.

(5) Under the same reaction conditions as for compound **6**, but with nickel chloride instead of palladium chloride, the product was tetrakis(benzamidine)nickel chloride rather than the analogous nickel complex.[21]

From the observations mentioned above it is clear that the nickel or palladium center plays a key role in the formation of 1,3,5-triazapentadienato complexes. The lithium arylamidinate attacks another aryl nitrile followed by a 1,3-silyl shift to produce the 1,3,5-triazapentadienatolithium intermediate **A** (see Scheme 1). When palladium chloride is added to the reaction system, the 1,3,5-triazapentadienato metal intermediate complexes **B** are produced, and these are hydrolyzed during work up in air to give the stable bis(2,4-aryl-1,3,5-triazapentadienato)-coordinated metal complexes. It is clear that the square-planar geometry of nickel and palladium ions leads to a template effect in the synthesis. Moreover, the high yield of palladium complexes and the formation of compound **6** indicate that palladium is a very effective template for the formation of bis(2,4-aryl-1,3,5-triazapentadienato)palladium complexes.

## Conclusions

We have developed a simple and effective method for the synthesis of symmetric and unsymmetrical 1,3,5-triazapentadienyl-based transition metal complexes. The 1,3,5-triazapentadienyl ligands, which are generated in situ by the interaction of amidinate with aryl nitrile, react with palladium and nickel ions to form a six-membered planar metallacycle. Structural analyses have revealed that the N–C–N–C–N framework within the 1,3,5-triazapentadienyl ligand is completely delocalized.

## Experimental Section

**General Procedures:** All reactions were carried out under nitrogen in flame-dried Schlenk-type glassware on a dual manifold Schlenk line unless otherwise stated. Solvents were pre-dried prior to use. All chemicals used were of reagent grade and obtained from Aldrich or Fisher Scientific Chemical Company. NMR spectra were measured in $[D_6]$DMSO either on a Varian INOVA 400 MHz FT-NMR or a Bruker DRX-300 spectrometer. Fast atom bombardment (FAB) mass spectra were recorded with a Finnigan MAT SSQ710 mass spectrometer, and electrospray ionization high resolution mass spectra (ESI-HRMS) with a quadrupole time-of-flight (Q-TOF) mass spectrometer equipped with a turbo ionspray source (PE SCIEX API QSTAR Pulsar i, Applied Biosystem). IR spectra (KBr pellets) were recorded with a Perkin–Elmer Paragon 1000PC or Nicolet Nagan-IR 550 Series II FTIR spectrometer. Elemental analyses were performed with a Vario EL-III instrument.

**Preparation of Bis[2,4-bis(2-pyridyl)-1,3,5-triazapentadienato]palladium(II) (1):** 2-Cyanopyridine (0.416 g, 4.0 mmol) and $LiN(SiMe_3)_2$ (0.334 g, 2.0 mmol) were placed in THF (20 mL) at 0 °C. The resultant red solution was warmed to room temperature and stirred for an additional 2 h before cooling down to –78 °C. Anhydrous $[PdCl_2(PhCN)_2]$ (0.383 g, 1.0 mmol) was then added to the reaction mixture which was stirred at –78 °C for an hour before warming up to room temperature and allowed to react overnight. Solvent was then removed in vacuo. The reaction system was exposed to air, methanol (20 mL) was added to the residue and the solution was filtered. Slow evaporation of the methanol solution gave yellow crystals of **1**. Yield: 0.392 g (0.708 mmol, 71%); m.p. > 300 °C. MS (FAB, +ve): *m/z* 554.4 $[M]^+$. ESI-HRMS (in methanol, +ve) calcd. for $C_{24}H_{21}N_{10}Pd$: 555.0985; found 555.0947 $[M+H]^+$. $^1$H NMR ($[D_6]$DMSO): NH protons: $\delta$ = 9.31 (s, 4 H); 2-pyridyl protons: $\delta$ = 8.79 (dd, $J$ = 5.6 and 1.6 Hz, 4 H), 8.65 (d, $J$ = 7.6 Hz, 4 H), 8.04 (td, $J$ = 7.6 and 1.6 Hz, 4 H), 7.62 ppm (ddd, $J$ = 7.6, 5.6 and 1.6 Hz, 4 H). IR (KBr): $\tilde{\nu}$ = 3448 m, 3286 s, 3057 w, 1576 s, 1550 vs, 1483 m, 1431 vs, 1265 w, 1241 w, 1057 m, 1997 m, 813 mm, 751 s, 708 s cm$^{-1}$. See also Table 2. $C_{24}H_{20}N_{10}Pd\cdot 2H_2O$ (590.94): calcd. C 48.78, H 4.09, N 23.70; found C 48.65, H 4.14, N 23.50.

**Preparation of Bis[2-phenyl-4-(3-pyridyl)-1,3,5-triazapentadienato]-palladium(II) (4):** Compound **4** was prepared under similar reaction conditions to **1**. Benzonitrile (0.26 mL, 2.5 mmol) and $LiN(SiMe_3)_2$ (0.418 g, 2.5 mmol) were placed in THF (20 mL) at 0 °C. The resultant yellow solution was warmed to room temperature and stirred for an additional 2 h. 3-Cyanopyridine (0.26 g, 2.5 mmol) was then added at room temperature and allowed to react overnight. Anhydrous $[PdCl_2(PhCN)_2]$ (0.479 g, 1.25 mmol) was then added to the reaction mixture at –78 °C which was stirred at this temperature for an hour before warming up to room temperature and allowed to react overnight. Solvent was then removed under vacuum. The reaction mixture was exposed to air, saturated with methanol (20 mL), and filtered. Slow evaporation of the methanol filtrate gave yellow crystals of **4**. Yield: 0.189 g (0.34 mmol, 27%); m.p. > 300 °C. ESI-HRMS (in methanol, +ve) calcd. for $C_{26}H_{23}N_8Pd$: 553.1080; found 553.1106 $[M+H]^+$. $^1H$ NMR ([D$_6$]-DMSO): $\delta$ = 9.26 (d, $J$ = 2.4 Hz, 2×1 H, NH) 8.76 (s, 2×1 H, NH), 8.69 (m, 2×2 H), 8.43 (m, 2×1 H), 8.08 (m, 2×2 H), 7.52 (m, 2×4 H). IR (KBr): $\tilde{\nu}$ = 3299 bm, 3062 w, 1593 m, 1544 vs, 1473 s, 1421 s, 1285 s, 1029 m, 822 w, 720 s $cm^{-1}$. See also Table 2. $C_{26}H_{22}N_8Pd{\cdot}0.5H_2O$ (561.94): calcd. C 55.58, H 4.13, N 19.93; found C 55.53, H 4.11, N 19.51.

**Preparation of Bis[2-phenyl-4-(4-pyridyl)-1,3,5-triazapentadienato]-palladium(II) (5):** Compound **5** was prepared under the same reaction conditions as compound **4** from benzonitrile (0.41 mL, 4.0 mmol), $LiN(SiMe_3)_2$ (0.67 g, 4.0 mmol), 4-cyanopyridine (0.41 g, 4.0 mmol), and anhydrous $[PdCl_2(PhCN)_2]$ (0.77 g, 2.0 mmol). Slow evaporation of the methanol filtrate gave yellow crystals of **5**. Yield: 0.34 g (0.62 mmol, 31%); m.p. > 300 °C. ESI-HRMS (in methanol, +ve) calcd. for $C_{26}H_{23}N_8Pd$: 553.1080; found 553.1049 $[M+H]^+$. $^1H$ NMR ([D$_6$]DMSO): NH protons: $\delta$ = 8.85 (s, 2×1 H), 8.79 (s, 2×1 H, NH); 4-pyridyl protons: $\delta$ = 8.74 (m, 2×2 H), 8.08 (m, 2×2 H), 8.01 (m, 2×2 H), 7.52 (m, 2×3 H) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 121.7, 127.6, 128.3, 130.2, 138.4, 145.7, 150.1, 158.5, 160.7 ppm. IR (KBr): $\tilde{\nu}$ = 3430 bw, 3317 bm, 3231 bm, 3042 bw, 1602 w, 1585 m, 1565 m, 1535 vs, 1453 s, 1403 vs, 1295 s, 1064 m, 844 w, 825 w, 712 s, 530 w $cm^{-1}$. **Preparation of Tetrakis(benzamidinato)bis(2,4-diphenyl-1,3,5-triazapentadienato)tripalladium(II) (6):** Benzonitrile (0.412 mL, 4 mmol) and $LiN(SiMe_3)_2$ (0.67 g, 4 mmol) were placed in THF (20 mL) at 0 °C. The resultant red solution was warmed to room temperature and stirred for an additional 2 h before cooling down to –78 °C. Anhydrous $PdCl_2$ (0.177 g, 1 mmol) was then added to the reaction mixture, which was stirred at –78 °C for an hour before warming up to room temperature and allowed to react overnight. Solvent was then removed under vacuum. The mixture was exposed to air, dichloromethane (20 mL) was added to the residue, and the solution was filtered. The solvent of the filtrate was removed in vacuo to give a dark-red oily product. The product was dissolved in THF (10 mL) and the solvent was allowed to evaporate slowly in air to afford yellow crystals of **6**. Yield: 0.12 g (0.097 mmol, 19%), m.p > 300 °C. $^1H$ NMR ([D$_6$]DMSO): NH protons, $\delta$ = 8.22 (s, 2×1 H), 8.03 (m, 2×2 H), 7.75 (m, 2×2 H), 6.83 (s, 2×1 H); phenyl protons: 7.66–7.45 ppm (m, 2×20 H). IR (KBr): $\tilde{\nu}$ = 3404 m, 3375 s, 3357 m, 3057 w, 3021 w, 1648 w, 1559 vs, 1540 vs, 1472 s, 1445 s, 1273 m, 1218 w, 1028 w, 783 w, 697 vs, 651 m $cm^{-1}$. See also Table 2. $C_{56}H_{52}N_{14}Pd_3{\cdot}0.5H_2O$ (1247.2): calcd. C 53.88, H 4.28, N 15.72; found C 53.85, H 4.14, N 15.33.

**X-ray Crystallography:** Crystals of **2**·2$CH_3OH$, **3**·2$CH_3OH$, and **6** suitable for X-ray diffraction were grown by slow evaporation of the respective methanol solution of these compounds in air. The intensity data were collected with a Bruker AXS SMART 1000 CCD area-detector diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 293 K. The collected frames were processed with the proprietary software SAINT[25] and an absorption correction was applied (SADABS[26]) to the collected reflections. The structures of these molecules were solved by direct methods and expanded by standard difference Fourier syntheses using the software SHELXTL.[27] Structure refinements were made on $F^2$ using the full-matrix least-squares technique. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were placed in their idealized positions and allowed to ride on the respective carbon atoms. Pertinent crystallographic data and other experimental details are summarized in Table 3.

# Diatom-Templated Synthesis of Ordered Meso/Macroporous Hierarchical Materials

Xiaohui Cai,[a,b] Guangshan Zhu,*[b] Weiwei Zhang,[b] Huanyu Zhao,[b] Ce Wang,*[a] Shilun Qiu,[b] and Yen Wei*[c]

**Keywords:** Hierarchical materials / Nanomaterials / Porosity / Sol–gel processes / Template synthesis

Ordered meso/macroporous hierarchical silica materials have been prepared using block copolymer P123 ($EO_{20}$-$PO_{70}EO_{20}$) and an inverse carbon replica of diatom as templates. The silica wall of the diatom was replaced by ordered mesoporous silica, while the micron-sized diatom architecture was replicated by using an inverse carbon replication technique. The mesoporous silica was found to have macroporous structures of both columnar and discoid diatom templates. The presence of hierarchical meso/macroporous systems was confirmed by the results from scanning and transmission electron microscopy, powder X-ray diffraction, and nitrogen adsorption–desorption studies. The materials with columnar and discoid morphologies have BET surface areas of about 400 $m^2 g^{-1}$.

## Introduction

In recent years hierarchical porous materials with two or more levels of porosities have attracted much attention owing to their potential applications in catalysis, separation, and ion-exchange.[1–7] Such materials improve the diffusion of the guest molecules through the inorganic network of pores and channels, because larger pores allow for better molecular accessibility while the smaller pores provide high surface areas and large pore volumes.[8] Zhao et al. reported that sponge-like silica membranes with 3D mesoporous/macroporous structures were obtained by a multiphase process of acid-catalyzed silica sol–gel chemistry.[9] Wood cells were used to prepare micro/macroporous materials by a zeolite-seeded growth method.[10] Many nonsiliceous hierarchical porous materials, for example carbon or metal oxide monoliths, were replicated from porous silica monoliths by Smått et al.[11] During the preparation of hierarchical porous materials, the simplicity of the synthesis and abundance of raw materials are important considerations. For example, a micro/macroporous composite material was prepared readily with the use of abundant diatomaceous earth.[12]

Diatoms are microscopic aquatic, single-celled algae.[13] Diatomaceous earth, the residue of decayed diatoms, largely consists of amorphous silica with a macroporous architecture.[14] Diatomaceous earth is extremely abundant and available at low cost.[15] It is commonly used in sound and heat insulation, abrasives, filters, absorbents, and explosives.[16] The introduction of mesoporosity or microporosity to macroporous diatom architecture may extend or improve their use in many applications. Diatom zeolitization is a method of obtaining micro/macroporous hierarchical materials.[12,17] A meso/macroporous material with a BET surface area of 284 $m^2 g^{-1}$ has been prepared using hexadecyltrimethylammonium bromide (CTAB) ($C_{16}$TMABr) as the template in a previous investigation.[8] The technique of introducing ordered mesoporosity into the macrostructure of diatoms is based on "pseudomorphic synthesis", which has been utilized by Di Renzo and co-workers to prepare discrete micrometer-sized spherical particles of MCM-48, MCM-41, and large-pore micelle-templated silica (MTS).[18–20] However, when it was used to rearrange the silica wall of diatoms, both ordered and disordered mesostructures co-existed.[8]

Carbon is often used as the hard template to prepare zeolite or mesoporous materials because of its easy removal. Zeolite hollow fibers have been prepared by employing carbon fibers as the hard template.[21–23] Carbon nanofibers and carbon black aggregates were also capable of acting as a template for preparing mesoporous materials.[24,25] ZSM-5 zeolite/porous carbon composite has been prepared from carbonized rice husk.[26] Carbon aerogel was employed as the template to produce zeolite of mesoporous channels.[27,28] Zeolite single crystals of mesoporous channels were synthesized by using carbon particles as the tem-

plate.[29] Activated carbon is another template for making nanoporous silica.[30]

Since ordered mesoporous carbons were prepared by Ryoo et al.,[31] many ordered mesoporous silica materials and zeolites have been prepared using mesoporous carbon as the hard template.[32–36] However, to the best of our knowledge, there has been no report in the literature on the use of carbon replicas of biomaterials as templates. Here, we present the first synthesis of ordered meso/macroporous hierarchical materials using carbon replicas of biomaterials as hard templates for macroporosity and a block copolymer as the templating surfactant for mesoporosity. The nonionic block copolymer and the inverse carbon replica of diatom are used as direct templates under acidic conditions. Although the diatom is an indirect template, it is vital for keeping the microscopic morphology of the hierarchical materials. In this process the silica wall of the diatom is replaced by ordered mesoporous silica completely and the near perfect macroporous diatom architecture is well replicated.

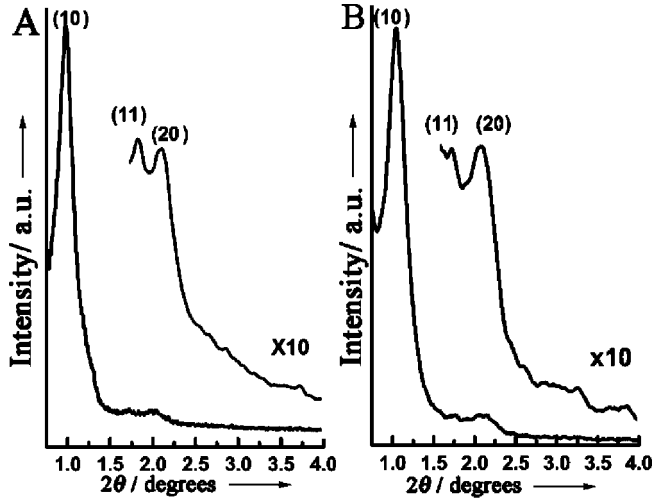

Figure 1. Powder XRD patterns of hierarchical porous materials templated by the diatoms with (A) columnar and (B) discoid morphologies.

## Results and Discussion

The preparation of ordered meso/macroporous hierarchical materials with carbon replicas of diatoms as templates is achieved as follows: sucrose was first introduced in the macropores of the diatom; after carbonizing the sucrose and etching the diatom, the carbon replica of the diatom was prepared; using the carbon replica of the diatom as the hard template, a solid product with both carbon and silica was obtained through the solvent evaporation technique.[39] After removing the carbon replica and the organic template, the ordered meso/macroporous hierarchical materials were finally prepared.

Figure 1 shows small-angle X-ray diffraction (XRD) patterns for the hierarchical porous materials that were prepared using columnar and discoid diatoms as templates. Three resolved peaks appearing at low angles in Figure 1 A and Figure 1 B can be indexed as 10, 11, and 20 reflections associated with two-dimensional hexagonal pore ordering in the *p6mm* space group.[37] The morphologies of the initial diatoms were revealed by scanning electron microscopy (SEM). Figure 2 shows the diatoms with columnar and discoid morphologies. The columnar diatoms have a diameter of about 7 μm and a length of about 15 μm (Figure 2 A). A high-magnification image (Figure 2 B) shows that the diameter of subpores is about 0.6 μm. The top of the hollow columnar diatom presents a hole with a diameter of about 5 μm, as shown in Figure 2 C. Low-magnification images display the discoid diatoms with a diameter of about 30 μm (Figure 2 D). From high-magnification observations of the surface, the subpore sizes range from approximately 350 to 550 nm (Figure 2 E). The thickness of the discoid diatom is about 5 μm, as identifiable from the side view in Figure 2 F. There is a cavum in each type of diatom. Part of the diatom wall is represented in Scheme 1 a.

The extent of carbonization depends on the amount of sucrose adsorbed on the inner surface of the diatom. After the diatom was dissolved in HF solution, a carbon frame-

work as an inverse replica of the diatom was obtained, as shown in Figure 3. Figure 3 A–C show the inverse carbon replicas of columnar diatoms, while Figure 3 D shows the carbon replica of the discoid diatom. At a high weight ratio of sucrose/diatom, it is a carbon rod that inversely replicates the subpores of diatoms (Figure 3 A–C), which is illustrated in Scheme 1 b1. When the sucrose is in large excess, the carbon layers are formed not only on the internal surface but also on the external surface of the diatoms (Figure 3 C), which is represented in Scheme 1 b3. When the weight ratio of sucrose/diatom is low, insufficient sucrose is absorbed on the surface of the subpores, which is transformed not to carbon rods but carbon tubes (Figure 3D), as illustrated in Scheme 1 b2.

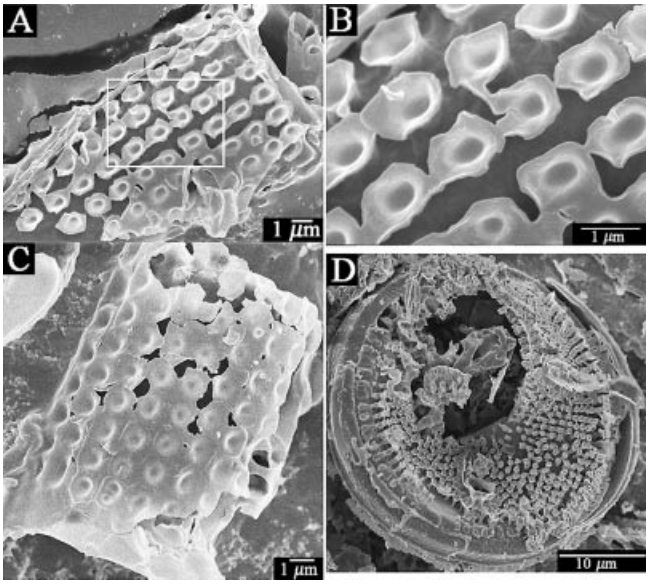

Figure 3. SEM images of inverse carbon replicas of diatoms with (A, B, C) columnar and (D) discoid morphologies.

After the inverse carbon replicas were immersed in the silica reaction mixture, they were coated with mesoporous silica upon evaporation of ethanol. When the carbon and the surfactant were removed by calcination, the diatom-replicated silica framework possessing an ordered mesostructure was obtained as depicted in Scheme 1 c and evidenced by SEM images (Figure 4) for the resultant mesoporous silicas with columnar (Figure 4 A and B) and discoid (Figure 4 C and D) morphologies. It is apparent that both the macroporous structure and the morphology of the initial diatom can be replicated by this method. As observed from the TEM images in Figure 5, the wall of the above final

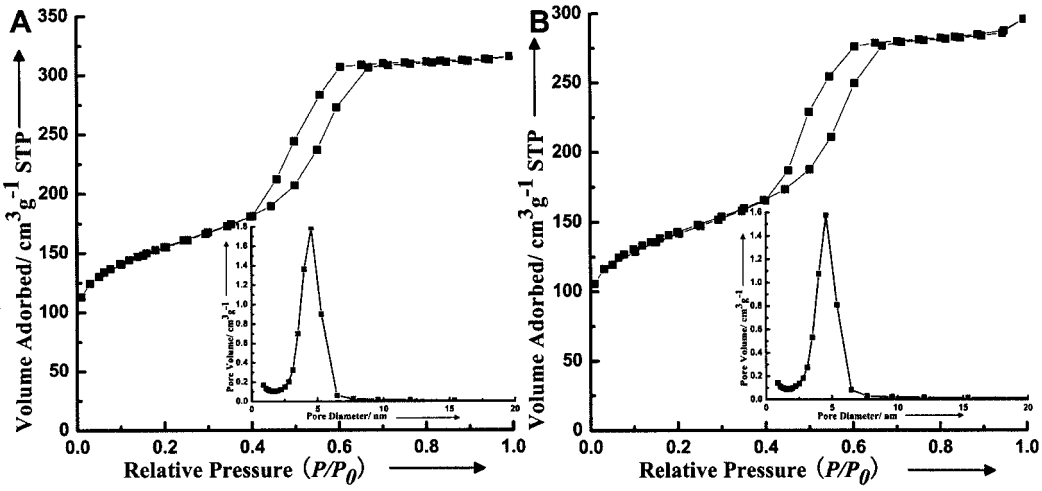

Figure 6. $N_2$ adsorption–desorption isotherms and pore-size distribution (inset) of hierarchical porous materials templated by diatoms with (A) columnar and (B) discoid morphologies.

hierarchical porous silica possesses ordered mesopores, which is in agreement with results of powder X-ray diffraction (Figure 1).

Nitrogen adsorption–desorption isotherm measurements were performed on both columnar (Figure 6 A) and discoid (Figure 6 B) hierarchical porous silica materials. In both cases, type IV isotherms with large hystereses were obtained, which are characteristic of mesoporous materials. The BET surface areas of the columnar and discoid hierarchical porous materials are 405 and 381 $cm^2 g^{-1}$ and the pore volumes are 0.41 and 0.37 $cm^3 g^{-1}$, respectively. It is noted that the BET surface area of about 400 $m^2 g^{-1}$ as obtained here because of the presence of mesoporosity is much higher than that of previously reported materials templated by diatoms.[8] The average pore diameter of both hierarchical materials is about 4.5 nm, as calculated from the BJH method of mesopore size analysis on the adsorption branch of the $N_2$ isotherms.

## Conclusions

We have demonstrated the synthesis of ordered hierarchical porous silica using block copolymer P123 and a carbon replica of a diatom as dual templates. The P123 functions as a soft template for the formation of mesoporosity and the inverse carbon replica as a direct hard template for macroporous structures. The macrostructure of the diatom is inversely replicated by the carbon replica. The weight ratio of sucrose/diatom was found to be important for the preparation of carbon replicas. High sucrose/diatom ratios lead to the formation of carbon layers on both internal and external surfaces of diatoms and of carbon rods in the subpores of diatoms; while low ratios resulted in the formation of a carbon layers only on the internal surface and of carbon tubes in pores. SEM results show that hierarchical materials with macropores 350–550 nm in diameter exhibit columnar and discoid morphologies. Nitrogen sorption studies indicate that the materials have high BET surface areas of about 400 $m^2 g^{-1}$. Powder XRD and TEM results indicate that the mesopore in the hierarchical structure has a two-dimensional hexagonal pore ordering. These ordered hierarchical porous materials have the advantages of both mesoporosity and macroporosity, which may find a broad range of potential applications in catalysis, adsorption, and separation.

## Experimental Section

Two types of diatomaceous earth (consisting of columnar and discoid diatoms) were purchased from Aldrich (Celatom FW80) and Tianjin Chemical Graduate School, respectively, and were purified further by sedimentation and ultrasonication. A sedimentary method in deionized water was used to remove the mixed scrappy mineral and ultrasonication in ethanol solution was performed to separate the clay from the diatom. The inverse carbon replication technique that was used in this work was adopted from the literature.[38] Thus, the purified diatom was impregnated with an aqueous solution of sucrose in the presence of sulfuric acid, and then the resulting mixture was dried and carbonized at 373 K and subsequently at 433 K. Diatom silica was removed by HF. The detailed procedure is as follows: purified diatom (1 g) was added to a solution obtained by dissolving sucrose (0.6 g) and $H_2SO_4$ (0.14 g) in $H_2O$ (5 g). The mixture was placed in a drying oven at 373 K for 6 h, and subsequently the oven temperature was increased to 433 K for another 6 h. After dissolving the diatom in an aqueous solution of HF for 12 h, the inverse carbon replica was obtained. A silica reaction mixture was prepared as follows:[39] P123 (0.3 g) was dissolved in ethanol (4.5 g), followed by addition of an aqueous HCl solution (0.03 g, 2 M), deionized water (0.24 g), and tetraethyl orthosilicate (TEOS) (0.7 g), whilst stirring. The mixture was stirred at room temperature for 2 h. Inverse carbon replica (0.23 g) was added to the above reaction mixture under agitation and the whole mixture was transferred to an uncovered vessel until the air bubbles in the solution disappeared. The volatiles were evaporated under a flow of air after almost 12 h. The black solid was isolated after the weight of the mixture had lost about 60% by evaporation of ethanol and was dried at 373 K; it was then calcined at 823 K for 5 h to remove the inverse carbon replica and surfactant. The final product was a white powder. We also employed other silica sources,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

including water glass, silica sol, and fumed silica, and so forth, but so far no good results have been obtained under the same experimental conditions. When triblock copolymer F127 ($EO_{106}$-$PO_{70}EO_{106}$) was used instead of P123, meso/macroporous hierarchical materials could also be prepared and the mesoporous structure had a cubic *Im*3*m* space-group symmetry with a pore size of 5–6 nm. X-ray diffraction (XRD) measurements were conducted with a Siemens D5005 diffractometer using Cu-$K_\alpha$ radiation ($\lambda$ = 1.54 Å). Transmission electron micrograph was obtained with a JEM-3010 using a copper grid-type sample holder. Scanning electron microscopy was performed with a JSM-6700F. Nitrogen adsorption–desorption isotherms were measured at the temperature of liquid nitrogen using a Micromeritics ASAP 2010 system. The samples were degassed at 573 K for 10 h before the measurements.

# Solvothermal Synthesis and Crystal Structure of Uranyl Complexes with 1,1-Cyclobutanedicarboxylic and (1*R*,3*S*)-(+)-Camphoric Acids – Novel Chiral Uranyl-Organic Frameworks

**Pierre Thuéry*[a]**

**Keywords:** Uranium / Carboxylate ligands / Metal-organic frameworks / Solvothermal synthesis / Structure elucidation

Reaction of the 1,1-cyclobutanedicarboxylic ($H_2L^1$) or (1*R*,3*S*)-(+)-camphoric ($H_2L^2$) acids with uranyl nitrate under solvothermal conditions gives novel uranyl-organic assemblages. The complex $[Hpy]_2[UO_2L^1(NO_3)]_2$ (**1**), obtained in pyridine, is a dimeric, dinuclear species in which the closeness of the two carboxylate groups prevents the formation of a more extended architecture. The chiral complexes $[UO_2L^2(py)_2]\cdot py$ (**2**) and $[UO_2L^2MeOH]\cdot MeOH$ (**3**), obtained with the enantiopure, divergent camphorate ligand in either pyridine (**2**) or methanol/water (**3**), are comprised of zigzag chains defining channels and a microporous assemblage or of undulated sheets based on tessellated 8- and 32-membered rings, respectively. Apart from a zinc(II) complex previously described, compounds **2** and **3** are the only examples of metal complexes with camphoric acid crystallographically characterized.

## Introduction

Several research groups have recently illustrated the potential of hydrothermal methods for the synthesis of uranyl-organic polymers, with a particular emphasis on obtaining microporous or luminescent materials.[1] Most of the compounds thus investigated include organic polycarboxylic acids as ligands and exploit the huge variety of this class of molecules. Even polyacid complexes recalcitrant to other crystallization procedures can be obtained in this way, as evidenced lately by the cases of uranyl citrate and tricarballylate.[2] Among organic polyacids, particularly interesting are those which, through a proper choice of geometry and rigidity, can assemble uranyl ions to form metallacycles, as is the case for tetrahydrofuran-2*r*,3*t*,4*t*,5*c*-tetracarboxylic acid.[3] The latter reacts with uranyl ions in organic solvents at room temperature to give tri- or tetranuclear cyclic species. Other candidates that seemed promising in this context are 1,1-cyclobutanedicarboxylic ($H_2L^1$) and (1*R*,3*S*)-(+)-camphoric ($H_2L^2$) acids, but these two ligands, when treated with uranyl nitrate in the presence of bases such as triethylamine or alkali metal hydroxides, did not give crystals, neither in organic solvents at room temperature nor under hydrothermal conditions. Suitable crystals could only be obtained, albeit in very low yields, under solvothermal conditions, using pyridine or methanol/water as the solvent and the crystal structures of the three species thus characterized are reported herein. A search of the Cambridge Structural Database (CSD, Version 5.27)[4] indicates that, apart from a polymeric terbium(III) complex,[5] all the metal complexes of 1,1-cyclobutanedicarboxylic acid which have been crystallographically characterized include 3d ions [platinum(II) and palladium(II) in particular]. In the case of (1*R*,3*S*)-(+)-camphoric acid, only one zinc(II) complex has been reported.[6] The present complexes are thus the first with an actinide ion for both ligands and with an f element for the second. Much work has recently been devoted to the synthesis of chiral nanoporous materials, with potential applications in enantioselective separation or heterogeneous asymmetric catalysis.[7] A particularly simple way to obtain such assemblages is the use of enantiopure chiral ligands, such as L- or D-tartaric acid,[7e,7g,7h] as metal bridges. The present results show that (1*R*,3*S*)-(+)-camphoric acid deserves to be considered as a useful building block in this context.

## Results and Discussion

In the presence of pyridine, the diacid $H_2L^1$ gives the centrosymmetric, dinuclear complex $[Hpy]_2[UO_2L^1(NO_3)]_2$ (**1**), represented in Figure 1. The $L^1$ dianions chelate each of the metal ions, one of them through one oxygen atom of each acid group (O3, O5) and the other by a single acid group (O5, O6). The oxygen atoms O5 and O5′ are thus bridging the two metal centres in a $\mu_2$ fashion. The four U–$O_{carboxy}$ bond lengths are quite different (Table 1), likely as a result of the constraints arising from the rigid geometry of the ligand, the shortest being U–O3 and the longest U–O6′; the average U–(O5,O5′) bond [2.45(3) Å] is longer

than U–O3 due to the bridging nature of these oxygen atoms. All these values are in the range of U–$O_{carboxy}$ distances for uranyl complexes reported in the CSD, 2.24–2.64 Å [mean value 2.42(7)]. The coordination sphere of the metal atom is completed by a bidentate nitrate ion, with an average U–O bond length of 2.509(3) Å, close to the mean value for bidentate nitrate ions in the CSD, 2.52(3) Å. The uranium atom is thus in a hexagonal-bipyramidal environment, quite usual when small-bite bidentate ligands are used, and is located at 0.0820(8) Å from the mean plane defined by the six equatorial donor atoms (r.m.s. deviation 0.039 Å). The coordination polyhedra of the two metal atoms share a common edge (O5–O5′), with a U···U′ distance of 4.2896(3) Å. A similar coordination mode is observed with other diacids, such as adipic acid, in which case the uranyl dimers are further linked in a three-dimensional network.[1c] The double negative charge of the complex is balanced by the positive charges of two pyridinium ions, which are involved in hydrogen bonds with the uncoordinated carboxylic oxygen atoms O4 and O4′ [N2···O4 2.677(4) Å, N2–H2···O4 170°]. It appears that, in contrast with tetrahydrofuran-2*r*,3*t*,4*t*,5*c*-tetracarboxylic acid, in which the acid groups are in the β- or γ-position relative to one another, their α-position in $L^1$ and the ensuing easy chelation of the metal ion through one oxygen atom from each result in these acid groups being nearly coplanar [dihedral angle between the two COO planes 34.3(4)°]. This ligand thus appears badly adapted to the synthesis of cyclic uranyl complexes.

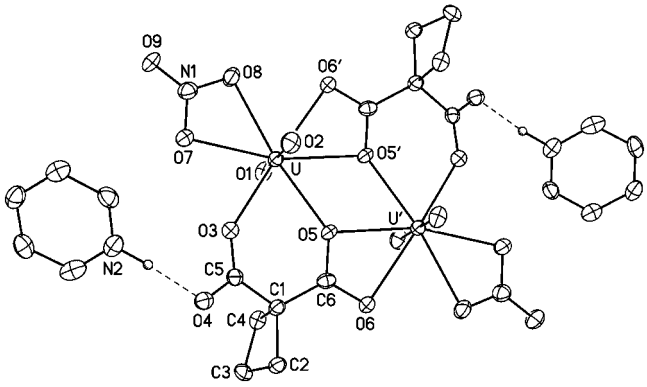

Figure 1. View of the complex $[Hpy]_2[UO_2L^1(NO_3)]_2$ (**1**). Hydrogen atoms not involved in hydrogen bonds have been omitted for clarity. Hydrogen bonds are shown as dashed lines. Displacement ellipsoids are drawn at the 50% probability level. Symmetry code: ′: 1 – *x*, 1 – *y*, 2 – *z*.

When treated with uranyl nitrate under conditions similar to those leading to complex **1**, $H_2L^2$ gives the complex $[UO_2L^2(py)_2]\cdot py$ (**2**). The two acid groups being in γ-positions with respect to one another and separated by the bulky methyl substituents, metal ion chelation through one atom from each group is no longer possible. Each acid group chelates a metal ion instead, giving rise to a one-dimensional polymer in which the motifs are related to one another by a binary screw axis (Figure 2a). The uranium atom is in a hexagonal-bipyramidal environment, being

bound, in addition to the two oxo atoms, to four carboxylic oxygen atoms [mean U–$O_{carboxy}$ bond length 2.45(2) Å] and two pyridine molecules in *trans* positions [mean U–N bond length 2.561(8) Å]. The metal atom is located at 0.010(3) Å from the mean equatorial plane (r.m.s. deviation 0.083 Å) and the dihedral angle between the equatorial planes of two successive metal atoms along the chain is 72.80(11)°. The geometry of the rigid ligand is not modified by metal ion coordination since the dihedral angle between the two COO planes is 63.2(8)° in **2**, whereas values in the range 61.9–63.4° are observed in the uncomplexed camphoric acid.[8,9] Such a value of the angle between uranyl equatorial planes and the overall coordination geometry could in principle lead to a cyclic species, but five units would be necessary for ring closure, giving a large complex probably less stable than the chiral, undulated chain which is formed instead. The packing of these chains gives rise to chiral channels directed along the *a*-axis in the crystal structure, in which the solvent pyridine molecules are located (Figure 2b) and which could in principle be interesting for the recognition of chiral guests. The absence of any significant π-stacking or CH···π interactions between host and guest suggests that the included pyridine molecules, held primarily by van der Waals interactions, have at most little contribution in the framework formation. This assemblage presents some similitude with several hydrogen-bonded organic-organic polymers including $H_2L^2$ and polyamines recently re-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ported.[9] With polyamines such as 1,2-bis(4-pyridyl)ethane or DABCO (1,4-diazabicyclo[2.2.2]octane), zigzag chains with curved parts defined by camphoric acid are observed, whereas 4,4′-bipyridine gives a spiral arrangement and other polyamines give more intricate sheets or frameworks. The coordination bonds with uranyl ions being much more directional than hydrogen bonds, the chains in **2** appear more regular (the polyamine complexes are highly disordered) and the separation between camphoric acid units is reduced. Moreover, no channels are formed in the case of the organic-organic chains analogous to those in complex **2**. This analogy between linear spacers such as 4,4′-bipyridine, which is much used, in association with 3d transition metal ions, to generate squares, boxes or cubes,[10] and the stereochemically constrained uranyl ion has been pointed out previously and several examples have been given of the use of uranyl ions as edge- or face-defining units.[3,11]

The presence of coordinated pyridine in complex **2** can be thought of as preventing the formation of a more extended assemblage. For this reason, the reaction between camphoric acid and uranyl nitrate under solvothermal conditions was repeated in a methanol/water solution and in the presence of NaOH as a base. The chiral complex thus obtained, $[UO_2L^2MeOH]\cdot MeOH$ (**3**), differs markedly from **2**. Each camphorate dianion bridges three uranium atoms, two of them in a monodentate ($\mu_2$-carboxylato-*O*,*O*′) and the other in a bidentate, chelating fashion (Figure 3a). Each metal atom is bound in its turn to three $L^2$ molecules [average $U–O_{carboxy}$ bond length 2.32(2) Å for the $\mu_2$-carboxylato-*O*,*O*′ groups and 2.46(5) Å for the chelating groups] and its environment is completed by a methanol molecule [average U–O bond length 2.379(14) Å, in agreement with the mean value from the CSD, 2.39(11) Å]. The metal atom environment is thus pentagonal-bipyramidal, as

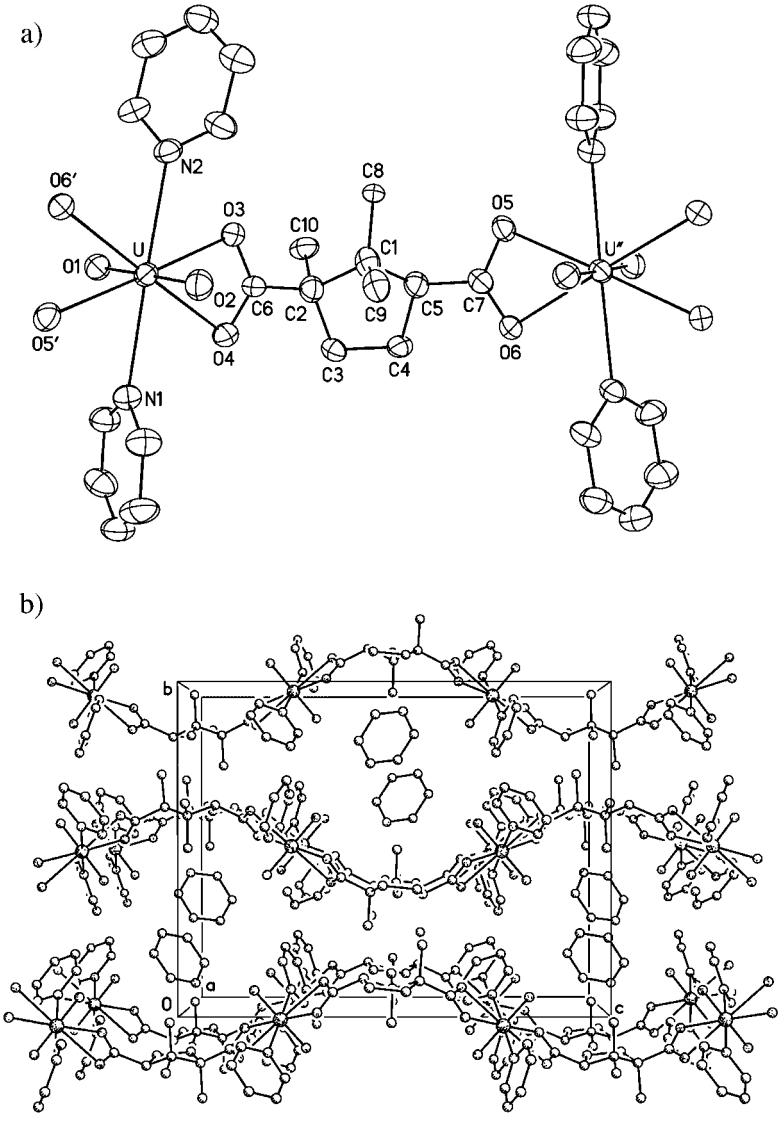

Figure 2. (a) View of the complex $[UO_2L^2(py)_2]\cdot py$ (**2**). Hydrogen atoms and solvent molecules have been omitted for clarity. Displacement ellipsoids are drawn at the 30% probability level. Symmetry codes: ′: 1.5 – *x*, –*y*, 0.5 + *z*; ″: 1.5 – *x*, –*y*, *z* – 0.5. (b) View of the packing along the *a*-axis. A single chain is shown at the top.

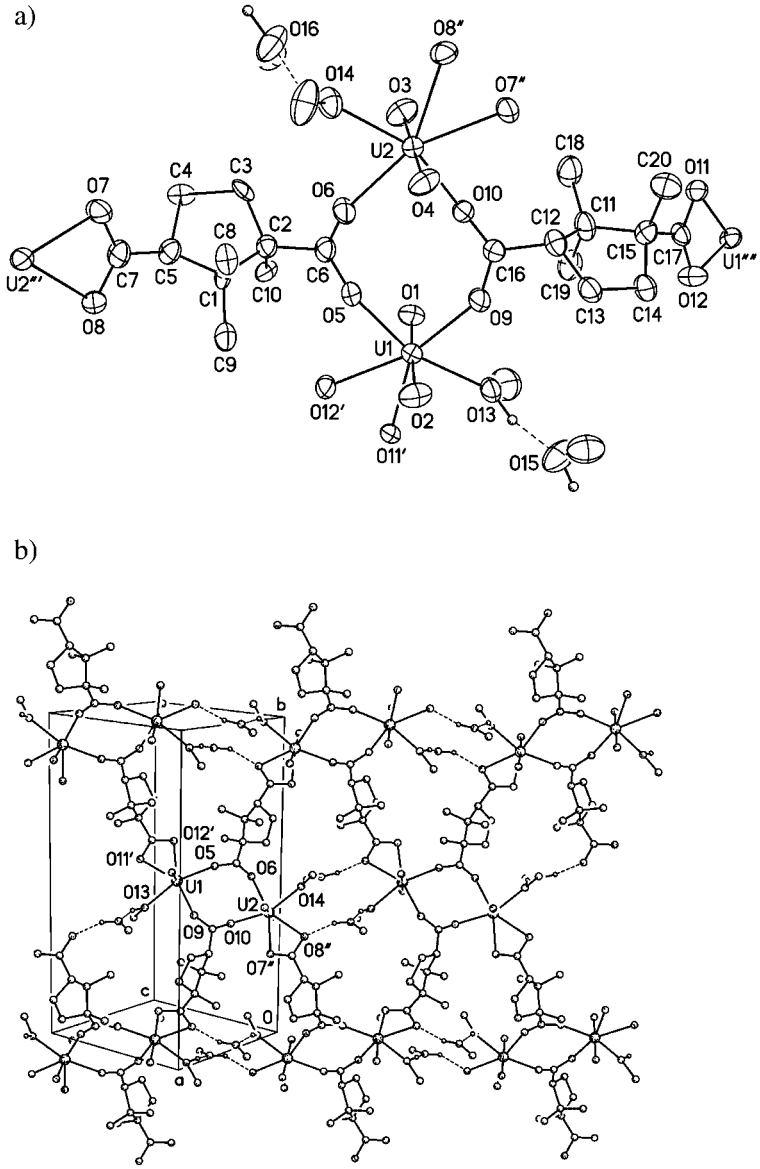

Figure 3. (a) View of the complex $[UO_2L^2MeOH]\cdot MeOH$ (**3**). Hydrogen atoms not involved in hydrogen bonds have been omitted for clarity. Hydrogen bonds are shown as dashed lines. Displacement ellipsoids are drawn at the 50% probability level. Symmetry codes: ′: 1 – *x*, 0.5 + *y*, 1 – *z*; ″: –*x*, *y* – 0.5, –*z*; ‴: –*x*, 0.5 + *y*, –*z*; ⁗: 1 – *x*, *y* – 0.5, 1 – *z*. (b) View of the two-dimensional assemblage in **3**.

expected since only one ligand is chelating. The metal centres are displaced by 0.004(4) and 0.003(4) Å from the associated equatorial mean planes (r.m.s. deviations 0.09 and 0.04 Å). The two uranium atoms linked by the $\mu_2$-carboxylato-*O*,*O*′ groups are separated by 5.5737(5) Å and they are part of a nearly planar eight-membered ring subunit [the dihedral angle between the two average uranyl equatorial planes is 7.2(4)°]. The four $L^2$ molecules which diverge from each subunit further assemble these subunits to form undulated sheets in which the curved parts correspond to the $L^2$ linkers [dihedral angle between the two COO planes: 66.2(12) and 63.3(10)° in the two independent molecules]. Larger, 32-membered elongated rings are formed in the process, which unite four $L^2$ ligands and four uranyl ions and are doubly bridged in their centre by the hydrogen-bonded and coordinated methanol molecules (Figure 3b). However, no channel is formed through the packing of these sheets, which does not involve inter-sheet hydrogen bonding. By contrast with the case of compound **2** in which it behaves as a simple spacer, $L^2$ appears in **3** to be able to act as a ring assembler, although not as a molecular metallacycle linker.

## Conclusions

The two acids investigated in this work present some characteristics, such as multiple coordination sites and rigidity, which make them attractive ligands for the synthesis of uranyl complexes, in the wake of the results previously obtained with other polyacids. However, the proximity of the two carboxylic groups in the α-diacid $H_2L^1$ favours ura-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nyl chelation through one oxygen atom from each group, leading, with further chelation of a second metal atom by one of the carboxylate groups, to the formation of a dimeric, dinuclear species. Conversely, the separation of the two carboxylic acid functions in the γ-diacid $H_2L^2$ prevents similar chelation, but, due to the insufficient curvature of the ligand, either chiral zigzag chains or undulated sheets are formed instead of a molecular metallacycle, which should likely be pentanuclear. Camphoric acid appears nevertheless to be a versatile ligand for metal complexation, leading to very different, one- or two-dimensional assemblages upon varying reaction conditions, and it should therefore benefit from a reappraisal in metal coordination chemistry, particularly for its potential in the synthesis of built-in chiral frameworks. The present results also illustrate the potential of solvothermal synthesis, which can permit the obtention of species unattainable through the more widely used hydrothermal method and also the synthesis of different species from the same building blocks with different organic solvents.

## Experimental Section

**Starting Materials:** 1,1-Cyclobutanedicarboxylic acid and (1*R*,3*S*)-(+)-camphoric acid were purchased from Aldrich and used without further purification.

**$[Hpy]_2[UO_2L^1(NO_3)]_2$ (1):** 1,1-Cyclobutanedicarboxylic acid (57 mg, 0.40 mmol), $UO_2(NO_3)_2{\cdot}6H_2O$ (100 mg, 0.20 mmol) and pyridine (3 mL) were placed in a 15-mL tightly closed vessel and heated at 145 °C under autogenous pressure. A few light-yellow single crystals of complex **1** were obtained in about two weeks.

**$[UO_2L^2(py)_2]{\cdot}py$ (2):** (1*R*,3*S*)-(+)-Camphoric acid (61 mg, 0.30 mmol), $UO_2(NO_3)_2{\cdot}6H_2O$ (151 mg, 0.30 mmol) and pyridine (4 mL) were placed in a 20-mL tightly closed vessel and heated at 125 °C under autogenous pressure. Light-yellow single crystals of complex **2** were obtained within 2 d.

**$[UO_2L^2MeOH]{\cdot}MeOH$ (3):** (1*R*,3*S*)-(+)-Camphoric acid (61 mg, 0.30 mmol), $UO_2(NO_3)_2{\cdot}6H_2O$ (151 mg, 0.30 mmol), NaOH (12 mg, 0.30 mmol), demineralized water (1.5 mL) and methanol (3 mL) were placed in a 20-mL tightly closed vessel and heated at 140 °C under autogenous pressure. Light-yellow single crystals of complex **3** were obtained within 3 d.

**X-ray Crystallography:** The data were collected at 100(2) K with a Nonius Kappa-CCD area detector diffractometer[12] using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The crystals were introduced in glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit-cell parameters were determined from ten frames, then refined on all data. The data ($\varphi$- and $\omega$-scans) were processed with HKL2000.[13] The structures were solved by Patterson map interpretation (**1** and **2**) or by direct methods (**3**) with SHELXS-97 and subsequent Fourier difference synthesis and refined by full-matrix least squares on $F^2$ with SHELXL-97.[14] Absorption effects were corrected empirically with SCALEPACK.[13] All non-hydrogen atoms were refined with anisotropic displacement parameters. The solvent pyridine molecule in **2** was refined as an idealized hexagon with restraints on displacement parameters. The hydrogen atoms bound to the nitrogen atom of the pyridinium ion in compound **1** and to the oxygen atoms of the methanol molecules in **3** were found on Fourier difference maps and all the others were introduced at calculated positions; all were treated as riding atoms with an isotropic displacement parameter equal to 1.2 (OH, NH, CH, $CH_2$) or 1.5 ($CH_3$) times that of the parent atom. The absolute configuration in compounds **2** and **3** indicated by the value of the Flack parameter[15] is in agreement with that of the uncomplexed ligand $H_2L^2$. Crystal data and struc-

# Bis[bis(oxazolinato)] Complexes of Yttrium and Lanthanum: Molecular Structure and Use in Polymerization of DL-Lactide and DL-β-Butyrolactone

**Ali Alaaeddine,[a] Abderramane Amgoune,[a] Christophe M. Thomas,[a] Samuel Dagorne,[b] Stéphane Bellemin-Laponnaz,[b] and Jean-François Carpentier*[a]**

**Keywords:** Homogeneous catalysis / Lanthanides / N ligands / Polymerization

Bis[bis(oxazolinato)]lanthanide complexes of general type $[Box]_2Ln[N(SiHMe_2)_2]$ (Ln = Y, La; Box = deprotonated chiral and nonchiral 2,2′-methylene[bis(oxazoline)] ligands) have been prepared by amine elimination protocols. The complexes have been characterized by $^1H$ and $^{13}C$ NMR spectroscopy and elemental analysis. The solid-state structure of the first bis[bis(oxazolinato)]-lanthanide complex, i.e. $\{2,2'$-(α-methylmethylene)bis(4,4-dimethyl-2-oxazolinato)$\}_2$-$Y[N(SiHMe_2)_2]$ (**1**), is reported. Complex **1** features a five-coordinate yttrium center in a distorted trigonal bipyramidal geometry, where the Box ligands adopts a conformation to minimize nonbonded interactions. The prepared complexes are among the most active initiators known in the ring-opening polymerization of DL-lactide and DL-β-butyrolactone, with TOF up to 31200 $h^{-1}$ at room temperature, and are highly productive (TON up to 2400). The produced poly(lactide)s and poly(hydroxybutyrate)s have narrow polydispersities ($M_w/M_n$ = 1.08–1.44) and controlled number-average molecular masses ($M_n$ up to 182000 g $mol^{-1}$). However, whether chiral or nonchiral Box ligands are used, the polymers show an atactic microstructure.

## Introduction

Ring-opening polymerization (ROP) of lactides (LA) and related lactone monomers has become a quite topical research field in recent years.[1] A reason for this interest is that the resulting biodegradable/biocompatible polymers, in addition to their high-tech applications,[1a,1b] could replace conventional polyolefinic materials.[2] An interesting challenge in this chemistry is to control the stereoselective ROP of *racemic* monomers, to produce in turn either syndiotactic, heterotactic, or isotactic stereoblock polymers, which each have their own peculiar physico-chemical properties.[1] Group 3 metal complexes are among the best catalysts/initiators for such ROP reactions.[1b,1c] For instance, we have recently reported that discrete group 3 complexes having a tetradentate [amino-ether-bis(phenolate)] ligand are highly active single-site initiators in the synthesis of heterotactic and syndiotactic poly(lactide) (PLA) from *rac*-lactide and *meso*-lactide, respectively.[3] The same complexes are also very active and stereoselective initiators for the controlled polymerization of *rac*-β-butyrolactone (BBL), generating highly syndiotactic poly(3-hydroxybutyrate) (PHB).[4]

Bis(oxazoline) (Box) are some of the most effective transition-metal ligands for a variety of asymmetric catalytic transformations.[5] Although the synthesis of mono- and bis[bis(oxazolinato)] organogroup 3 metal complexes has been known since 1999,[6] their use in catalysis has been so far limited to asymmetric hydroamination.[7] In this study we synthesized chiral and nonchiral bis[bis(oxazolinato)]-lanthanide complexes for the ROP of *rac*-lactide and *rac*-BBL. Their activity and degree of control have been investigated. The first X-ray-characterized bis[bis(oxazolinato)]-lanthanide catalyst precursor is also presented.

## Results and Discussion

### Synthesis of Complexes

Bis[bis(oxazolinato)]-lanthanide complexes **1**–**6** of the type $[Box]_2Ln[N(SiHMe_2)_2]$ (Ln = Y, La; Box = deprotonated ligand) were prepared following the general σ-bond metathesis procedure reported by Anwander et al.[6,7] The reaction between 2 equiv. of a neutral Box ligand and a homoleptic precursor $Ln[N(SiHMe_2)_2]_3(THF)_2$ in benzene or toluene resulted in the protonolysis of two of the bulky (dimethylsilyl)amido ligands by the relatively acidic methine (**1**–**3**) or methylene (**4**–**6**) protons (Scheme 1). Yttrium and lanthanum were chosen for this study because they are representative of small and large lanthanides, respectively, and allow straightforward NMR studies thanks to their diamagnetism. The reaction is readily monitored by $^1H$ NMR spectroscopy. For all the ligand/metal systems investigated, the resulting reaction mixture remains a clear, homogeneous

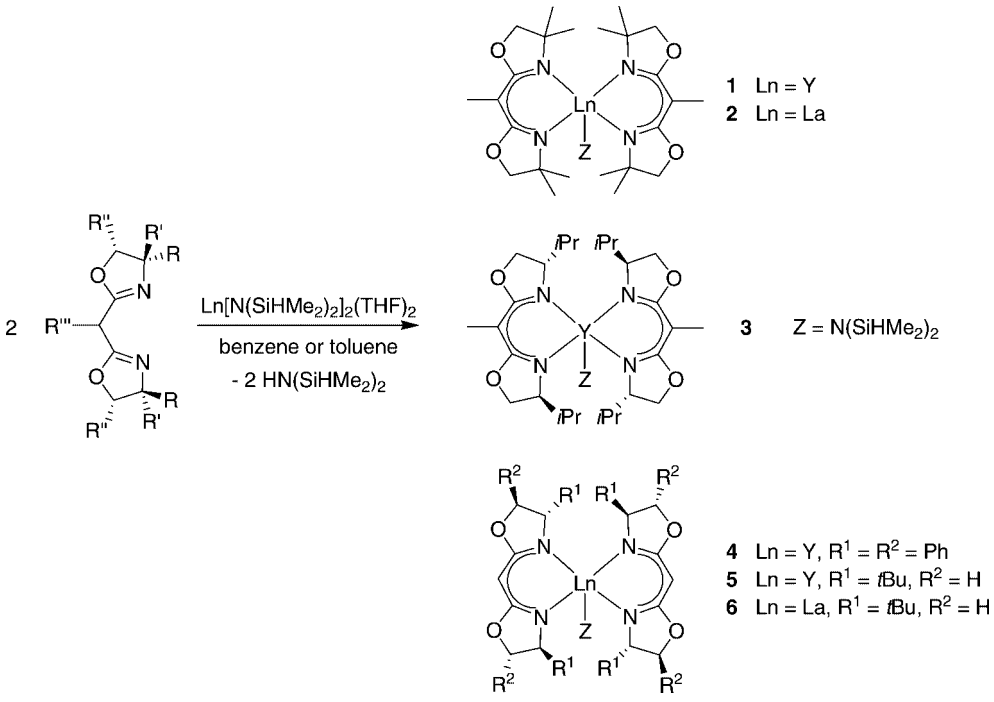

Scheme 1.

solution, and complete conversion of reagents is observed within 2 h at 20 °C. The resulting crude NMR shows clean release of 2 equiv. of $HN(SiHMe_2)_2$, with resonances for one major or exclusive (>95–99%) product $[Box]_2$-$Ln[N(SiHMe_2)_2]$. This good reactivity and selectivity allowed us to generate effectively in situ some of the complexes, and thus investigate the performances of a broad range of polymerization precursors (only a few of these are described in this report).

In addition to previously reported compounds **5** and **6**,[6] the identity of new complexes **1**–**4** was fully established by means of 1D and 2D $^1H/^{13}C$ NMR experiments and elemental analyses. Key NMR spectroscopic data include a single set of $^1H$ and $^{13}C$ resonances for two Box ligands equivalent on the NMR timescale at 20 °C. Also, two distinct $^{13}C$ resonances for inequivalent $SiH\mathit{Me}_2$ groups are observed in **1** ($\delta$ = 3.58, 3.29), **3** ($\delta$ = 3.71, 3.57) and **4** ($\delta$ = 3.51, 2.84); this is further confirmed by $^1H$ NMR spectroscopy in **3** ($\delta$ = 0.35, 0.32) and **4** ($\delta$ = 0.35, 0.18), but does not appear in the lower field $^1H$ NMR spectra (200–300 MHz) of **1**. The 300 MHz $^1H$ and 125 MHz $^{13}C$ NMR spectra of **2** show a single resonance for the $SiH\mathit{Me}_2$ groups, though incidental overlapping cannot be discarded.[6] Comparable to the case of **5** and **6**,[6] coordination of the chiral ligands in **3** and **4** renders the $SiHMe_2$ groups diastereotopic and inequivalent; however, this explanation cannot stand for the achiral complex **1**. On the other hand, the chemical shifts of the SiH protons (**1**, $\delta$ = 5.26; **2**, $\delta$ = 5.34; **3**, $\delta$ = 5.01; **4**, $\delta$ = 4.82 ppm) argue against any significant Si–H–Y β-agostic interaction.[8]

### Molecular Structure of {1,1-Bis[4,4-dimethyl-1,3-oxazolin-2-yl]}$_2$Y[N(SiHMe$_2$)$_2$] (1)

To gain a better insight into the above-mentioned structural features, an X-ray diffraction study was conducted on **1**. This is the first molecular structure reported for a bis-[bis(oxazolinato)]-lanthanide compound[9] and it can be compared to the only two examples of mono[bis(oxazolinato)]-lanthanide complexes that have been characterized so far in the solid state.[6,7] Suitable crystals of **1** were grown at room temperature from a saturated benzene solution. The unit cell contains two independent molecules (**A** and **B**), which feature overall the same structural arrangement and coordination geometry, but noticeable differences in bond lengths and angles; nonetheless, structural trends remain comparable within both molecules and mostly data of molecule **A** will be discussed below. An ORTEP view of molecule **A** is presented in Figure 1 and a partial list of bond lengths and angles for both molecules **A** and **B** is given in Table 1; complete details of the crystallographic analysis are given in Table 3.

Compound **1** is monomeric in the solid state, with a five-coordinate yttrium center ligated by the four nitrogen atoms of the two Box ligands, and one $N(SiHMe_2)_2$ group. The geometry at the yttrium center is distorted trigonal bipyramidal, with the apical sites being occupied by two Box nitrogen atoms [N(101) and N(121) in molecule **A**]. An approximate [noncrystallographic] $C_2$ symmetry axis exists through the $Y^{3+}$ and $N(SiHMe_2)_2$ centers. The Box ligands are oriented away from the $N(SiHMe_2)_2$ group in a horse

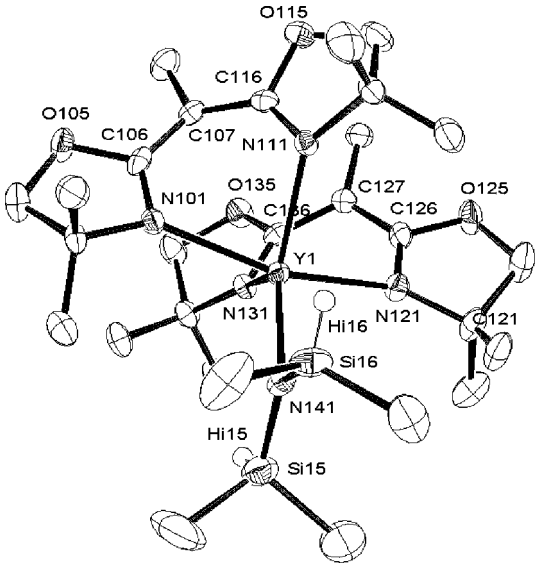

Figure 1. Molecular structure of $[Me_2Box]_2Y[N(SiHMe_2)_2]$ (**1**) (only molecule **A** is displayed). All hydrogen atoms, except those on Si atoms (Hi15 and Hi16), are omitted for reasons of clarity. Ellipsoids are drawn at the 50% probability level.

saddle fashion, thus minimizing steric hindrance. Comparable to that found in mono(Box)-lanthanide,[6,7] -copper,[10a] -rhodium,[10b] -aluminum,[11a] and -gallium[11b] complexes, significant delocalization of the ligand negative charge is suggested by the elongated N(101)–C(106) and N(111)–C(116) distances [1.321(3) and 1.322(3) Å, respectively] and the shortened C(106)–C(107) and C(116)–C(107) distances [1.401(4) and 1.406(4) Å, respectively]. The bis(oxazolinato) ligands in molecule **A** are somewhat dissymmetrically coordinated as apparent from the ca. 0.05–0.06 Å difference between the Y(1)–N(101)/Y(1)–N(111), and Y(1)–N(131)/Y(1)–N(131) distances, but the dissymmetry is less pronounced in molecule **B** (0.01–0.03 Å). Those Y–N(Box) distances in **1** [2.325(2)–2.389(2) Å] are longer than those in the four-coordinate mono[bis(oxazolinato)]-yttrium complex $[t\text{BuBox}]Y[N(SiHMe_2)_2]_2$ reported by Anwander et al. [2.288(5) Å],[6] reflecting the hindrance induced by the second Box ligand. Steric crowding in **1** is also reflected by the twisting angle between the two oxazoline ring planes relative to one another [mean plane N(101)/mean plane N(111), 32.7°; N(121)/N(131), 31.9°; N(201)/N(211), 32.4°; N(221)/N(231), 32.7°], values which are sig-

nificantly larger than those observed in mono[bis(oxazolinato)]-lanthanide complexes [12.4°, 15.7°].[6,7] On the other hand, the Y(1)–N(141) [2.253(2) Å] and Y(2)–N(241) [2.241(2) Å] silylamide bonds compare well to those in the four-coordinate [*t*BuBox]Y[N(SiHMe$_2$)$_2$]$_2$ [2.222(6) Å] and in the five-coordinate precursor amide complex [2.229(4)–2.276(4) Å].[12] The normal angles at the silylamide nitrogen atom and the long Y···H contact distances (>3.03 Å) argue against any significant β(Si–H)-Y agostic interaction, which is consistent with the NMR spectroscopic data (vide supra).

### Ring-Opening Polymerization of *rac*-Lactide and *rac*-β-Butyrolactone

The prepared bis[bis(oxazolinato)]-lanthanide complexes are very active in the ROP of *rac*-lactide and *rac*-β-butyrolactone under mild conditions (Scheme 2, Table 2); polymerization experiments conducted with mono[bis(oxazolinato)]-yttrium complexes, e.g. [*t*BuBox]Y[N(SiHMe$_2$)$_2$]$_2$, gave poorly reproducible results. Complexes **1**–**4** allow complete conversion of 100 equiv. of lactide within 5–10 min at room temperature in either toluene or THF solutions at [*rac*-LA] = 0.5–1.0 mol/L. The yttrium complex **5** that bears bulky *tert*-butyl-substituted BOX ligands is inactive in toluene (entry 4), which possibly reflects the large steric crowding at the metal center. However, this complex shows good activity in THF (entry 5), stressing the crucial importance of solvent in these ROPs.[3,4,13] Disappointingly, the use of chiral Box ligands in the initiators does not lead to stereocontrol of the polymerization: all PLA and PHB polymers, including also those produced with the achiral initiators **1** and **2**, show atactic (or slightly isotactic-enriched) microstructures, as determined by NMR analysis.[4,14] Contrary to our previous observations with [amino-ether-bis-

(phenolate)]-lanthanide systems,[3,4] decreasing the temperature down to –20 °C and changing the solvent (toluene, THF) resulted in no enhancement in stereoselectivity. Polymerization of L-lactide by **1** (entry 11) or **3** resulted in pure isotactic PLA; the decoupled $^1$H NMR spectrum of the polymer showed one sharp resonance for the methine region. This observation supports the lack of base-promoted epimerization of L-lactide or PLA and argues against an anionic polymerization mechanism being operative.[15]

Because of the absence of stereocontrol with [Box]$_2$-Ln[N(SiHMe$_2$)$_2$] catalysts, further experiments aimed at investigating the degree of control of polymerization were carried out with the nonchiral systems **1** and **2** (entries 8–18). All the PLAs and PHBs obtained with amido complexes showed monomodal GPC traces with relatively narrow polydispersity values ($M_w/M_n$ = 1.14–1.44). In most cases, the experimental (uncorrected) number-average molecular mass ($M_n$) values are close to the theoretical ones (calculated on the assumption that each silylamide group initiates the polymerization). As shown by the monotonous relationship between the monomer-to-metal ratio and $M_n$ values (Figure 2), which is linear at least up to LA-to-Y = 1000, a good control of *rac*-LA polymerization is achieved with **1**. Even a catalyst loading of 0.05% yielded almost quantitatively PLA with $M_n$ as high as 182000 g mol$^{-1}$ (entry 16). The productivity of this system is remarkable, enabling high conversion for an unprecedented high *rac*-LA-to-Y ratio of 4000 within 5 min (TOF = 31200 h$^{-1}$) (entry 17). Very narrow polydispersities of 1.07–1.08 were obtained by pre-reacting the amido complex **1** with 2-propanol, to generate in situ the corresponding isopropoxide bis[bis(oxazolinato)] species (entries 13, 15). It is well known that isopropoxide is usually a better initiating group than amido [-N(SiMe$_3$)$_2$, -N(SiHMe$_2$)$_2$] for the ROP of *rac*-lactide at room temperature.[3b,16]

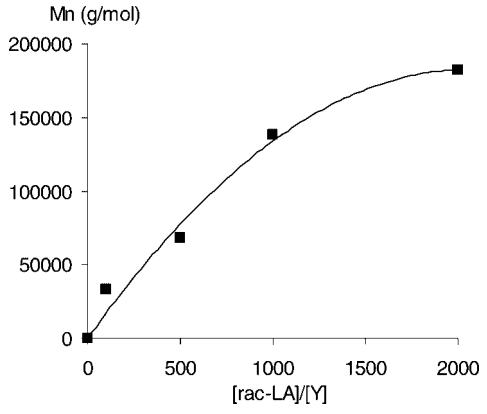

Figure 2. Variation of number-average molecular masses ($M_n$) with monomer-to-yttrium ratio in the polymerization of *rac*-lactide with complex **1** (see Table 2 for conditions).

The ROP of 200 equiv. of *rac*-BBL proceeded also in a controlled manner (entries 18–20). Surprisingly, the apparent rate is faster with **5** (TOF > 6000 h$^{-1}$) than **1** (TOF = 3600 h$^{-1}$). Even when the polymerization is conducted in toluene, **5** enables fast conversion of *rac*-BBL, i.e. the opposite trend to that observed for *rac*-lactide polymerization (entry 4). Reasons for this contradictory trend remain unclear to date, but concur with the peculiar behaviors of LA and BBL monomers in ROPs.

## Conclusions

Amido-bis[bis(oxazolinato)] complexes of yttrium and lanthanum, readily prepared from a tris(amido) lanthanide precursor and a Box ligand, are very active single-site initiators for the ROP polymerization of *rac*-lactide and *rac*-β-butyrolactone. Their performances in terms of kinetics and productivity compare favorably with the best systems so far disclosed. The polymerizations proceed in a controlled fashion, leading to PLAs and PHBs with relatively narrow polydispersities and number-average molecular masses in good agreement with calculated values. However, such complexes based on well-known chiral Box ligands appear unable to control the microstructure of the polymer: only atactic PLAs and PHBs are produced, which can be achieved as well with a cheaper nonchiral bis[bis(oxazolinato)]-lanthanide complex.

## Experimental Section

**General Considerations:** Synthesis of lanthanide complexes and polymerization experiments were carried out under purified argon using standard Schlenk techniques or in a high-performance (<1 ppm $O_2$, <2 ppm $H_2O$) glove box. Solvents (toluene, THF) and deuterated solvents ([D$_6$]benzene, [D$_8$]toluene, [D$_8$]THF/99.5% D, Eurisotop) were freshly distilled from Na/K alloy under nitrogen and degassed thoroughly by freeze-thaw-vacuum cycles prior to use. Bis(oxazoline) ligands were prepared following reported procedures[11a] or purchased from Aldrich and used as received. Lanthanide precursors Y[N(SiHMe$_2$)$_2$]$_3$(THF)$_2$ and La[N(SiHMe$_2$)$_2$]$_3$-(THF)$_2$,[17] and complexes **5** and **6**,[6] were prepared following literature procedures. Racemic lactide and *S*-lactide (Aldrich) were recrystallized twice from dry toluene and then sublimed under vacuum at 50 °C. Racemic β-butyrolactone (Aldrich) was freshly distilled from $CaH_2$ alloy under nitrogen and degassed thoroughly by freeze-thaw-vacuum cycles prior to use.

**Instruments and Measurements:** NMR spectra were recorded with Bruker AC-200, AC-300, and AC-500 spectrometers in Teflon valve NMR tubes. $^1$H and $^{13}$C chemical shifts are reported in ppm vs. SiMe$_4$ and were determined by reference to the residual solvent peaks. Assignment of signals was made from multinuclear 1D [$^1$H, $^{13}$C{$^1$H}] and 2D (COSY, HMQC, HMBC) NMR experiments. Coupling constants are given in Hertz. Size exclusion chromatography (SEC) of PLAs and PHBs was performed in THF at 20 °C using a Waters SIS HPLC pump, a Waters 410 refractometer, a DAD-UV detector, and Waters styragel columns (HR2, HR3, HR4, HR5E) or PL-GEL Mixte B and 100A columns. The number average molecular masses ($M_n$) and polydispersity index ($M_w/M_n$) of the resultant polymers were calculated with reference to a polystyrene calibration. The microstructure of PLAs was measured by homodecoupling $^1$H NMR spectroscopy at 20 °C in $CDCl_3$ with a Bruker AC-500 spectrometer. The microstructure of PHBs was measured by analyzing the carbonyl region of $^{13}$C{$^1$H} NMR spectra at 40 °C in $CDCl_3$ with a Bruker AC-500 spectrometer operating at 125 MHz.

**{2,2′-(α-Methylmethylene)bis(4,4-dimethyl-2-oxazolinato)}$_2$Y[N(SiHMe$_2$)$_2$] (1):** A solution of 2,2′-(α-methylmethylene)bis[4,4-dimethyl-2-oxazoline] (100 mg, 0.446 mmol) in toluene (5 mL) was added slowly under an inert atmosphere to a solution of Y[N(SiHMe$_2$)$_2$]$_3$(THF)$_2$ (140 mg, 0.223 mmol) in toluene (5 mL) at room temperature. The mixture was warmed at 70 °C and then stirred for 12 h. Volatiles were removed in vacuo and the resulting white solid was washed with cold hexane (1.0 mL), and dried under vacuum to give **1** (95 mg, 62%). $^1$H NMR (200 MHz, $C_6D_6$): $\delta$ = 5.26 (m, 2 H, Si*H*Me$_2$), 3.58 (d, $J$ = 7.7, 4 H, C*H*$_2$O), 3.45 (d, $J$ = 7.7, 4 H, C*H*$_2$O), 2.23 (s, 6 H, C*H*$_3$CCN), 1.43 (s, 12 H, C*H*$_3$), 1.04 (s, 12 H, C*H*$_3$), 0.45 (d, $J$ = 2.8 Hz, 12 H, Si*H*Me$_2$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $C_6D_6$): $\delta$ = 171.40 (N*C*O), 77.28 (*C*H$_2$O), 67.94 (Me*C*CN), 66.20 (*C*Me$_2$), 28.20 (C*Me*$_2$), 26.31 (C*Me*$_2$), 11.23 (*Me*CCN), 3.58 (SiH*Me*Me), 3.29 (SiHMe*Me*) ppm. $C_{28}H_{52}N_5O_4Si_2Y$ (667.82): calcd. C 50.36, H 7.85, N 10.49; found C 49.86, H 7.98, N 10.25.

**{2,2′-(α-Methylmethylene)bis(4,4-dimethyl-2-oxazolinato)}$_2$La[N(SiHMe$_2$)$_2$] (2):** Using the same procedure as used for synthesizing **1** (vide supra), compound **2** was obtained from La[N(SiHMe$_2$)$_2$]$_3$(THF)$_2$ (26.0 mg, 0.038 mmol) as a white solid (15 mg, 54%). $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 5.34 [m, 2 H, Si*H*(CH$_3$)$_2$], 3.64 (m, 8 H, C*H*$_2$O), 2.35 (s, 6 H, C*H*$_3$CCN), 1.46 (s, 12 H, C*H*$_3$), 1.33 (s, 12 H, C*H*$_3$), 0.56 (d, $J$ = 2.8, 12 H, Si*H*Me$_2$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $C_6D_6$): $\delta$ = 169.90 (N*C*O), 77.39 (*C*H$_2$O), 64.57 (Me*C*CN), 62.21 (*C*Me$_2$), 29.99 (C*Me*Me), 27.62 (CMe*Me*), 11.62 (*Me*CCN), 2.81 (SiH*Me*$_2$) ppm. $C_{28}H_{52}LaN_5O_4Si_2$ (717.82): calcd. C 46.85, H 7.30, N 9.76; found C 46.12, H 7.68, N 9.65.

**{2,2′-(α-Methylmethylene)bis[(4*S*)-4-isopropyl-2-oxazolinato]}$_2$Y[N(SiHMe$_2$)$_2$] (3):** Using the same procedure as used for synthesizing **1** (vide supra), compound **3** was obtained from 2,2′-(α-methylmethylene)bis[(4*S*)-4-isopropyl-2-oxazoline] (100 mg, 0.400 mmol) and Y[N(SiHMe$_2$)$_2$]$_3$(THF)$_2$ (165 mg, 0.200 mmol) in benzene (10 mL) at 20 °C, and recovered as a white solid (73 mg, 66%). $^1$H NMR (500 MHz, $C_6D_6$): $\delta$ = 5.01 (m, 2 H, Si*H*Me$_2$), 3.92 (d, $J$ = 10.2, 4 H, C*H*$_2$O), 3.86 (d, $J$ = 10.2, 4 H, C*H*$_2$O), 3.65 (m, 2 H, NC*H*), 2.27 (s, 6 H, C*H*$_3$CCN + sept, 4 H, C*H*i Pr), 0.81 (d, $J$ = 6.7, 12 H, C*H*$_3$ *i*Pr), 0.72 (d, $J$ = 7.0, 12 H, C*H*$_3$ *i*Pr), 0.36 (d, $J$ = 1.9, 6 H, SiH*Me*$_2$), 0.32 (d, $J$ = 1.9, 6 H, SiH*Me*$_2$) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $C_6D_6$): $\delta$ = 173.25 (N*C*O), 68.77 (*C*HN), 66.16 (*C*H$_2$O), 64.90 (Me*C*CN), 32.80 (*C*H *i*Pr), 19.80 (*C*H$_3$ *i*Pr), 15.06 (*C*H$_3$ *i*Pr), 12.26 (*Me*CCN), 3.71 (SiH*Me*Me), 3.57 (SiHMe*Me*) ppm. $C_{20}H_{32}N_5O_4Si_2Y$ (551.58): calcd. C 43.55, H 5.85, N 12.70; found C 43.26, H 5.93, N 12.67.

**NMR Scale Generation of {2,2′-Methylenebis[(4*S*,5*S*)-4,5-diphenyl-2-oxazolinato]}$_2$-Y[N(SiHMe$_2$)$_2$] (4):** Using the same procedure as used for synthesizing **3** (vide supra), compound **4** was generated at the NMR scale from Y[N(SiHMe$_2$)$_2$]$_3$(THF)$_2$ (14.0 mg, 0.022 mmol) and 2 equiv. of 2,2′-methylenebis[(4*S*,5*S*)-4,5-diphenyl-2-oxazoline] (20.0 mg, 0.044 mmol). NMR spectroscopy revealed complete conversion of the reagents to **4** with release of 2 equiv. of HN(SiHMe$_2$)$_2$ ($^1$H NMR: $\delta$ = 4.71, 0.11 ppm. $^{13}$C NMR: $\delta$ = 0.23 ppm). $^1$H NMR (200 MHz, $C_6D_6$): $\delta$ = 6.89 (m, 40 H, *Ph*), 5.94 [d, $J$ = 7.7, 4 H, C*H*Ph(O)], 5.56 [d, $J$ = 7.6, 4 H, C*H*PhN], 5.32 (s, 2 H, C*H*CCN), 5.06 (m, 2 H, Si*H*Me$_2$), 0.35 (d, $J$ = 2.8, 6 H, SiH*Me*$_2$), 0.18 (d, $J$ = 1.9, 6 H, SiH*Me*$_2$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $C_6D_6$): $\delta$ = 174.47 (N*C*O), 139.37 ($C_q$ Ph), 135.83 ($C_q$ Ph), 127.89 (*Ph*), 127.36 (*Ph*), 126.65 (*Ph*), 85.48 (*C*HPh), 71.77 (*C*HPh), 58.56 (*C*HCN), 3.51 (SiH*Me*Me), 2.84 (SiHMe*Me*) ppm.

**Crystal Structure Determination of 1:** A suitable single crystal of **1** was mounted onto a glass fiber using the "oil-drop" method. Diffraction data were collected at 100 K with an APEX 2 AXS-Bruker diffractometer with graphite monochromatized Mo-$K_\alpha$ radiation. The crystal structure was solved by means of direct methods, the remaining atoms were located from difference Fourier synthesis, followed by full-matrix least-squares refinement based on $F^2$ (program SIR-97).[18] Many hydrogen atoms could be found from the Fourier difference. Carbon-bound hydrogen atoms were placed at calculated positions and forced to ride on the attached carbon atom. The hydrogen atom contributions were calculated but not refined. All non-hydrogen atoms were refined with anisotropic displacement parameters. The unit cell of **1** was found to contain two independent molecules. The main crystallographic data are summarized in Table 3.

Table 3. Crystal data and structure refinement for **1**.

CCDC-603139 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**General Procedure for Lactide Polymerization:** In the glovebox, a Schlenk flask was charged with a solution of the initiator (typically 0.019 mmol, ca. 10 mg) in toluene (0.2 mL) or THF (0.2 mL). To this solution was added rapidly a solution of the monomer (*rac*-LA, S-LA, BBL) in the appropriate ratio in toluene or THF (3.0 mL). The mixture was immediately stirred with a magnetic stir bar at room temperature. Aliquots were periodically removed with a pipette for monitoring by $^1$H NMR spectroscopy. After the desired time, the reaction was quenched with acidic methanol (0.5 mL of a 1.2 M HCl solution), and the polymer was precipitated with excess methanol (100 mL). The polymer was then dried under vacuum to constant weight.

**General Procedure for *rac*-β-Butyrolactone Polymerization:** In the glovebox, a Schlenk flask was charged with a solution of the initiator (typically 0.014 mmol, ca. 10 mg) in toluene (1.0 mL) or THF (1.0 mL). *rac*-β-Butyrolactone (typically 2.64 mmol, 216 μL) was then syringed in dropwise under vigorous stirring at room temperature. After a small sample of the crude material was removed with a pipette for characterization by $^1$H NMR, the reaction was

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

quenched with acidic methanol (0.5 mL of a 1.2-M HCl solution in MeOH), and the polymer was precipitated with excess methanol (ca. 100 mL). The polymer was then dried under vacuum to constant weight.

## Acknowledgments

This research was in part supported by the Region Bretagne (COPOBIO program to AA) and the CNRS (ATIPE program to JFC). We gratefully thank Dr. Thierry Roisnel (X-ray diffraction center, University of Rennes 1) for the determination of the molecular structure of **1**.

**Keywords:** Functional coordination polymers / Polycarboxylate ligands / 4,4′-Bipyridine / Luminescence

Two coordination polymers of mixed ligands, 2,2′-(1,3-phenylenedioxy)bis(acetate) (pdoa) and 4,4′-bipyridine (bipy), namely $[Zn(pdoa)(bipy)]_n$ (**1**) and $\{[Mn(pdoa)(bipy)](bipy)\}_n$ (**2**), have been hydrothermally synthesized and characterized by single-crystal X-ray diffraction and IR spectra. Complex **1** crystallizes in the triclinic space group $P\bar{1}$ with $a$ = 6.8826(18) Å, $b$ = 11.202(3) Å, $c$ = 12.295(3) Å, $\alpha$ = 86.854(4)°, $\beta$ = 85.759(5)°, $\gamma$ = 72.629(4)° and is a novel folded-paper-shaped coordination compound with polymeric sheets formed by the five-coordinate $Zn^{II}$ centers and bridging pdoa and bipy. Complex **2** crystallizes in the monoclinic space group $P2_1/c$ with $a$ = 11.507(2) Å, $b$ = 23.254(5) Å, $c$ = 9.8710(19) Å, $\beta$ = 96.418(4)° and exhibits a robust three-dimensional framework with nanosized rectangular channels (11.627 × 11.507 Å). They both display blue fluorescent emission and could be considered as new luminescent materials. In addition, the magnetic properties of complex **2** were investigated and the magnetic susceptibility data were rationally fitted with $g$ = 2.072(5), $J$ = –1.11(4) $cm^{-1}$, and $zJ'$ = –0.161(7) $cm^{-1}$, showing it is an unprecedented luminescent open-framework antiferromagnet.

## Introduction

In recent years, metal-organic coordination polymers based on multicarboxylate ligands have been of great interest because of their fascinating molecular topologies and crystal-packing motifs along with their outstanding properties in spectroscopy, magnetism, and catalysis, and potential applications as functional materials.[1] Much work has been focused on rigid ligands and flexible ligands such as benzenedicarboxylates[2] and aliphatic carboxylates,[3] respectively. However, there are few examples of ligands containing both aromatic and aliphatic features.[4] Moreover, the combination of both dicarboxylate and 4,4′-bipyridine ligands helps to assemble higher-dimensional supramolecular networks.[5] Meanwhile, chemists have been pursuing multifunctional materials for molecule devices. But, to the best of our knowledge, porous coordination networks usually exhibit a single functionality, such as luminescence or magnetic ordering.[6–9]

We are interested in the utilization of polycarboxylate ligands with characteristics of both flexibility and rigidity, such as 2,2′-(1,4-phenylenedioxy)bis(acetate) and 2,2′-(1,3-phenylenedioxy)bis(acetate), which were initially investigated as herbicides and remained almost unexplored in the field of crystal engineering and supramolecular chemistry to construct coordination polymers.[10] The $–OCH_2–$ group makes these ligands more flexible in comparison with the corresponding benzenedicarboxylate, whilst the existence of the benzene ring provides a rigid element. Herein, we report hydrothermal syntheses, crystal structures, and solid-state photoluminescent and magnetic properties of two novel coordination polymers with mixed ligands, 2,2′-(1,3-phenylenedioxy)bis(acetate) (pdoa) and 4,4′-bipyridine (bipy), $[Zn(pdoa)(bipy)]_n$ (**1**) and $\{[Mn(pdoa)(bipy)](bipy)\}_n$ (**2**), in which complex **1** is an interesting 2D folded-paper-shaped structure, whereas complex **2** is an intriguing 3D framework structure with rectangular nanosized channels. Both, **1** and **2** display blue fluorescent emission, and complex **2** exhibits the characteristics of a weak antiferromagnetic coupling between metal ions in the system mediated by both types of the bridging ligands. Interestingly, to the best of our knowledge, complex **2** is the first example of an open-framework coordination polymer with conjugation of blue fluorescent emission and antiferromagnetic long-range ordering.

## Results and Discussion

### Description of the Crystal Structures

The asymmetric unit of compound **1** contains one $Zn^{2+}$ ion, one 2,2′-(1,3-phenylenedioxy)bis(acetate) ligand, and two half bipy molecules (Figure 1a). The zinc ion is five-coordinate in a distorted square-pyramidal environment of asymmetry with three oxygen atoms of two different carboxylate groups, one bipy nitrogen atom in the basal plane (O1, O2, O5, N2), and one nitrogen atom of another bipy ligand at the apex position (N1). Two carboxylate groups in the same pdoa molecule have different coordination modes, in which one acts as a chelating bidentate and the other serves as a monodentate ligand. The unequal coordination of two oxygen atoms (O1 and O5) from the chelating bidentate carboxylate moiety of pdoa results from the asymmetrical five-coordination environment. From the crystallographic data and selected bond lengths and angles for the title complexes (Tables 1 and 2), the lengths of Zn1–O1 [2.244(2) Å] and Zn1–O5 [2.131(2) Å] are similar to those, relative to the chelating bidentate carboxylate ligand, found in $[Zn_3(Hcit)_2(H_2O)_2]_n$ [2.318(2)–2.071(2) Å][11a] and $[Zn_4(OH)_2(fa)_3(bipy)_2]$ [2.367(4)–2.089(4) Å][11b] (Hcit and fa denote citric acid anion and fumarate, respectively). However, the separation of Zn1 from O2 of the monodentate $COO^-$ group [Zn1–O2 1.9369(18) Å] is significantly shorter than those relative to the chelating bidentate carboxylate ligand, but consistent with those referring to the monodentate carboxylate ligand in $[Zn_3(\mu_3\text{-}OH)(\mu_2\text{-}OH)(bipy)_{0.5}(oba)_2]\cdot 0.5H_2O$ [1.939(4) Å, oda = 4,4′-oxybis-(benzoate)][11c] and $[Zn_3(Hcit)_2(H_2O)_2]_n$ [2.028(2) Å],[11a] implying the existence of a certain tension in the four-membered ring formed between the chelating bidentate $COO^-$ group and the zinc ion. The Zn–N distances [Zn1–N1 2.048(2) Å and Zn1–N2 2.090(2) Å] are slightly shorter than those in structurally related polymers $[Zn(tp)(4,4'\text{-bipy})]_n$ [2.154(2) and 2.186 Å] (tp denotes terephthalate).[12] The $Zn^{2+}$ ions are linked by pdoa ligands forming infinite straight-linear chains along the *b*-axis. Furthermore, such linear chains are bridged at the point of $Zn^{2+}$ ions by bipy ligands to form two-dimensional sheets (Figure 2a), which have an interesting folded-paper-like topology as illustrated in Figure 2b. The two pyridine rings of the bipy molecule are almost coplanar (dihedral angle about 0.93°) and there is an inversion center at the midpoint of the C1–C1′ bond of each bipy ligand. The adjacent Zn···Zn distance due to the pdoa ligand in the same chain is 11.202(3) Å and the Zn···Zn distance between adjacent chains due to bipy is 11.170 (2) Å. Furthermore, the resulting 2D wave-like sheets superpose on each other with crest to crest, forming a 3D supramolecular lattice of noninterpenetration by weak C–H···O H bonds [C17#1–H17#1···O20 or C17–H17···O20#1, with a C···O distance of 3.468 Å and a C–H···O angle of 148.86°; symmetry code: #1: $1 - x$, $1 - y$, $1 - z$] and the offset face-to-face π–π stacking interactions between the pyridine ring of bipy and the phenyl ring of pdoa (represented as *α* and *β* in Figure 3, respectively, with a separation of 3.397 Å from *α* to *β*, and with an angle of 164.1° between them). These weak H bonds and π–π interactions are important in the construction of supramolecules, as is well documented in the literature.[13] Another interesting feature of the structure is that the pdoa ligands jut out and stand on the crests of folded-paper-like sheets, filling the voids among the layers (Figure 3).

As shown in Figure 1b, the asymmetric unit of complex **2** contains one $Mn^{2+}$ ion, one pdoa ligand, one coordinated, and one free bipy molecule. The Mn atom is in an octahedral environment with two bipy nitrogen donors (N1, N2#3) occupying the axial positions and four oxygen atoms (O2, O3#2, O5#4, O6#1) from four different pdoa ligands in the equatorial plane (symmetry codes: #1: $-1 + x$, $y$, $-1 + z$; #2: $x$, $1.5 - y$, $-0.5 + z$; #3: $1 - x$, $0.5 + y$, $0.5 - z$; #4: $-1 + x$, $1.5 - y$, $-0.5 + z$). The two pyridine rings of each coordinated or guest bipy molecule are not coplanar, and twisted around each other with dihedral angles 6.63(2)° and 6.75(2)° for coordinated and guest bipy, respectively, in contrast to those in complex **1** in which they are virtually coplanar. The axial Mn–N distances [Mn–N1 2.386(3);

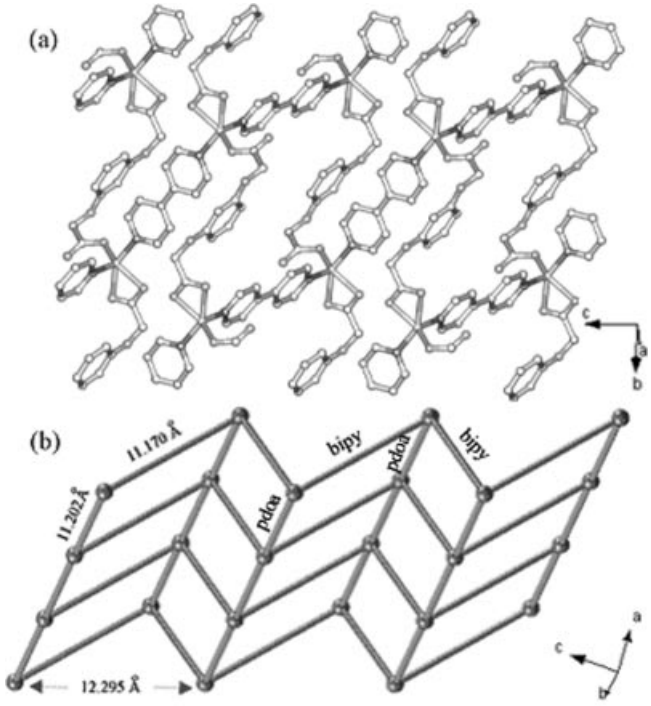

Figure 2. (a) Schematic illustration of the 2D network with all the H atoms omitted for clarity; (b) folded-paper-like topologic diagram of $[Zn(pdoa)(bipy)]_n$ (gray spheres denote zinc atoms).

Mn–N2#3 2.164(2)] and the Mn–O distances [Mn–O2 2.2044(19) Å; Mn–O3#2 2.1422(17) Å; Mn–O5#4 2.2379(18) Å; Mn–O6#1 2.108(2) Å] are comparable to those of analogous complexes,[14] indicating the manganese asymmetric coordination environment in terms of diversities of bond strength. All the carboxylate groups act as bis(unidentate) ligands and each pdoa ligand links four different manganese ions to form an equatorial $[Mn(pdoa)]_n$ sheet (Figure 4a), in which all the phenyl rings are parallel to each other and vertical to the crystallographic *ac* plane. The Mn···Mn separation due to pdoa is 11.507(3) Å, significantly larger than that of $[Mn(5\text{-methylpyrazole})_2(tp)]_n$ (9.655–9.659 Å) based on a tp ligand.[14b] It can be easily seen, from the view of the $[Mn(pdoa)]_n$ layer along the *c*-axis (Figure 4b), that all the manganese ions are not in one plane, instead alternatively situated above and below the plane between them. Interestingly, as shown in Figure 4a, this sheet contains distinctive duplex helixes of –Mn–O–C–O–Mn– with $Mn(O–C–O–)_2Mn$ eight-membered rings; the Mn···Mn distance relative to the bridging carboxylate group is 4.999(2) Å, similar to that of $[Mn(5\text{-methylpyrazole})_2(tp)]_n$ (4.917 Å),[14b] and shorter than that of $[Mn(bipy)(H_2O)(C_4H_4O_4)]\cdot 0.5bipy$ [5.264(1) Å, $C_4H_4O_4$ = succinate dianion].[14c] The analogous duplex helix was found in $Tb(bdc)NO_3\cdot 2DMF$ (bdc = 1,4-benzenedicarboxylate).[15]

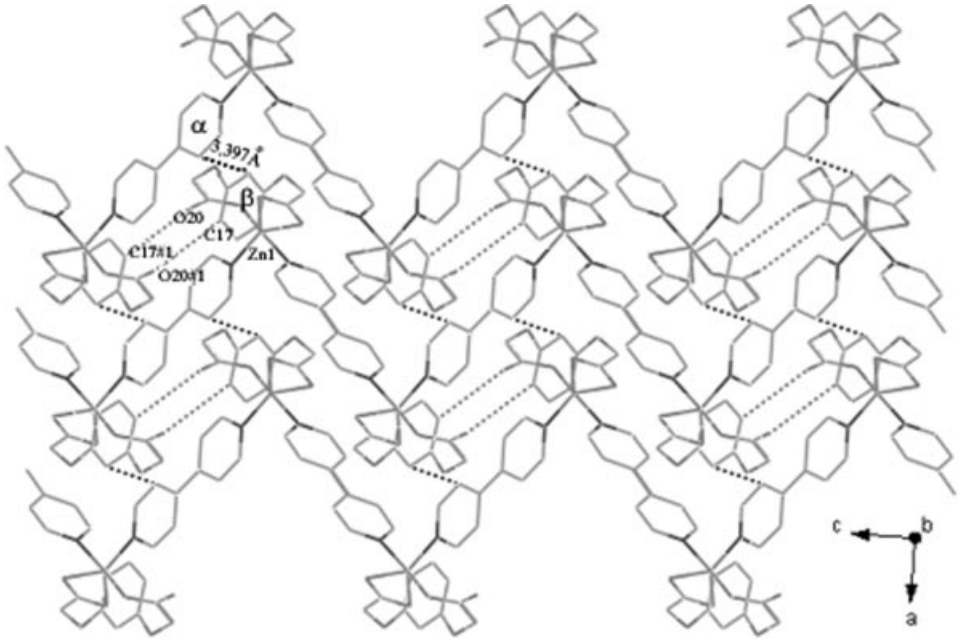

Figure 3. Perspective view along the *b*-axis of complex **1** showing the weak C–H···O H bonds (gray dotted lines) and the offset face-to-face π–π stacking interactions (dark gray dotted lines) between the puckered layers. All the H atoms have been omitted for clarity (symmetry code: #1: 1 – *x*, 1 – *y*, 1 – *z*).

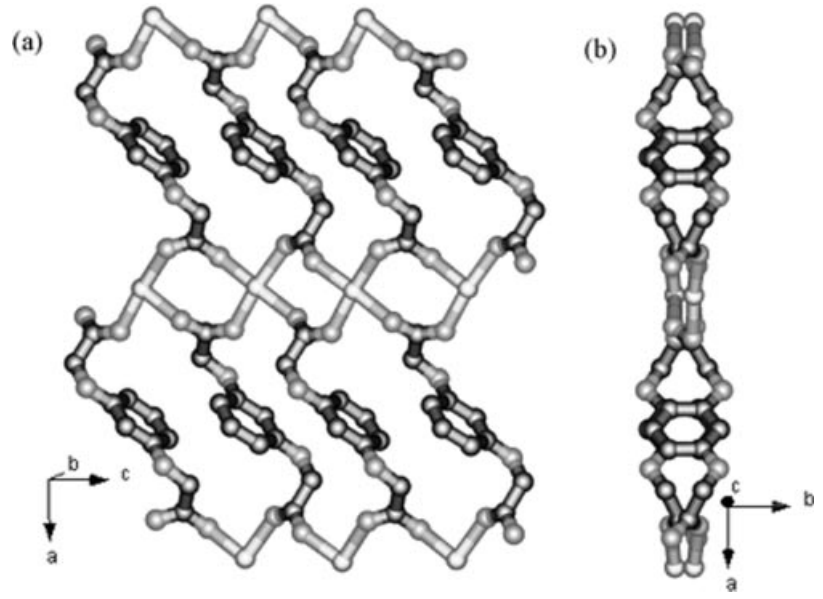

Figure 4. (a) Representation of the $[Mn(pdoa)]_n$ plane in complex **2**. (b) View of the $[Mn(pdoa)]_n$ plane in complex **2** along the *c*-axis. All hydrogen atoms have been omitted for clarity.

It is noteworthy that such a uniform $Mn^{II}$ carboxylate 2D sheet with only one coordination mode of the carboxylate moiety acting as bis(unidentate) bridging ligand to connect four metal ions in complex **2** is unprecedented.

Furthermore, the $[Mn(pdoa)]_n$ sheets are pillared by the rigid μ-4,4′-bipyridine ligands to form a 3D open framework exhibiting one-dimensional rectangular tunnels along the *c*-axis with dimensions of 11.627 × 11.507 Å (Figure 5a), which is considerably larger than that of reported manganese analogues.[14a,14c] To the best of our knowledge, this manganese inorganic-organic hybrid polymer with a noninterpenetration three-dimensional framework exhibits the largest channel among similar $Mn^{II}$ pillar-layered structures documented to date.[14]

The free bipy ligands as guest molecules and templates, like the examples,[16] reside at the 1D channel (Figure 5b). Unfortunately, removing the guest bipy molecules will give rise to collapse of the framework and decomposition of the whole complex, which was confirmed by thermal gravimetric analyses. Moreover, there exist weak H bonds between the guest and coordinated bipy molecules, as represented in Figure 5b, C4#5–H4#5···N3 and C4#7–H4#7···N3#6

(symmetry codes: #5: 1 – *x*, 1 – *y*, 1 – *z*; #6: 2 – *x*, 1 – *y*, 1 – *z*; #7: 1 + *x*, *y*, *z*); the C···N distance and the angle of C–H···N are 3.30 Å and 146.05°, respectively.

### IR Spectrum

As well documented in the literature,[17] IR spectra are very helpful in diagnosing characteristic coordination modes of carboxylate groups and determining the whole structure of previously unknown carboxylate complexes. The crystal structures provide us with an opportunity to investigate the IR spectral characters of pdoa complexes with three coordination modes [unidentate, chelating bidentate, and bridging bis(monodentate)]; representative data of IR spectra for pdoa, **1**, and **2** are tabulated in Table 3. Although the IR spectra of both complexes are complicated because of the overlap of the absorption of pdoa and bipy, several strong bands can be assigned in comparison with those of pdoa, bipy and other related complexes. The absence of the $\nu$(COOH) band at 1762 $cm^{-1}$ and the $\nu$(C–OH) band at 1267 $cm^{-1}$ of $H_2$pdoa in **1** and **2** suggests that all the carboxylate groups are completely deprotonated. The bands at 3086 and 3048 $cm^{-1}$ for **1** and **2** can be assigned to the C–H stretching vibration of the pdoa ligand in contrast to that of $H_2$pdoa (3083 $cm^{-1}$).[18] For complex **1**, the values of $\nu_{asym}$(OCO) and $\nu_{sym}$(OCO) corresponding to the unidentate mode are 1622 $cm^{-1}$ and 1380 $cm^{-1}$ respectively, which are similar to those of some carboxylate complexes with only unidentate coordination of the carboxylate group, such as [Zn(Pht)(py)$_2$] ($\nu_{asym}$: 1618 $cm^{-1}$; $\nu_{sym}$: 1390 $cm^{-1}$), [Zn(Pht)(mepy)$_2$] ($\nu_{asym}$: 1622 $cm^{-1}$; $\nu_{sym}$: 1372 $cm^{-1}$; here Pht, py, and mepy denote *o*-phthalic dianion, pyridine, and 3-methylpyridine, respectively),[19a] $ZnCl_2$(Hpipe-2)$_2$ ($\nu_{asym}$: 1635 $cm^{-1}$; $\nu_{sym}$: 1397 $cm^{-1}$), $ZnCl_2$(Hpipe-3)$_2$·3$H_2O$ ($\nu_{asym}$: 1626 $cm^{-1}$, $\nu_{sym}$ = 1387 $cm^{-1}$; Hpipe-2 = DL-piperidine-2-carboxylic acid, Hpipe-3 = DL-piperidine-3-carboxylic acid).[19b] However, the values of $\nu_{asym}$(OCO) and $\nu_{sym}$(OCO) relative to those of the chelating bidentate carboxylate group are 1608 $cm^{-1}$ and 1537 $cm^{-1}$, respectively, similar to those of [Zn(ip)(bipy)$_2$][Zn(ip)(bipy)]·0.25$H_2O$ ($\nu_{asym}$: 1615 $cm^{-1}$; $\nu_{sym}$: 1555 $cm^{-1}$; ip = iosphthalate).[19c] Because the $COO^-$ group has only one coordination mode in complex **2**, the very strong absorptions at 1596 and 1407 $cm^{-1}$ are assigned to $\nu_{asym}$(OCO) and $\nu_{sym}$(OCO), which are both highly blue-shifted in comparison with an analogous compound, [Mn(5-methylpyrazole)$_2$(tp)]$_n$ ($\nu_{asym}$: 1558 $cm^{-1}$; $\nu_{sym}$: 1374 $cm^{-1}$).[14b] Conclusively, the order of the separation between the asymmetric and symmetric stretching vibrations resulting from complexes **1** and **2** is Δ(unidentate, 242 $cm^{-1}$) > Δ(bridging bidentate, 189 $cm^{-1}$) > Δ(chelating bidentate, 71 $cm^{-1}$), supposing that the effects of variation of metal ions are relatively little to the value of Δ($\nu_{asym}$ – $\nu_{sym}$), which are well in accordance with the documented results of Deacon and Phillips.[17] In addition, the IR characteristics of bipy in complexes **1** and **2** are different. For complex **1**, the two pyridyl rings of bipy acting as a bidentate ligand are almost coplanar. Meanwhile, the bipy molecule has a center of symmetry, as indicated in the X-ray structure, and the in-plane C–H bending vibration (about 1215 $cm^{-1}$) loses its IR activity. However, for **2**, the two pyridyl rings of each free and coordinated bipy molecule are not coplanar; the IR properties of bipy in **2** are thus similar

Table 3. The data of IR spectra for $H_2$pdoa and complexes **1** and **2**.

| | |
|---|---|
| $H_2$pdoa | 3083 (w), 1762 (vs), 1710 (vs), 1596 (vs), 1494 (vs), 1433 (vs), 1340 (m), 1267 (s), 1248 (s), 1192 (vs), 1156 (s), 1087 (vs), 960 (m), 847 (s), 769 (s) |
| **1** | 3086 (w), 1638 (vs), 1608 (vs), 1537 (s), 1418 (s), 1380 (s), 1292 (s), 1220 (m), 1157 (vs), 1068 (s), 848 (m), 810 (vs), 764 (s), 725 (s), 638 (s) |
| **2** | 3048 (w), 1596 (vs), 1486 (w), 1407 (vs), 1322 (w), 1283 (s), 1181 (s), 1156 (vs), 1067 (s), 832 (m), 807 (vs), 717 (s), 626 (s), 605 (m) |

to those of pyridine. The strong absorption band at 1181 $cm^{-1}$ can be rationally attributed to the in-plane C–H bending vibration of bipy according to the literature.[20]

### Luminescent Properties

The excitation and emission spectra for $H_2$pdoa, $[Zn(pdoa)(bipy)]_n$, and $\{[Mn(pdoa)(bipy)](bipy)\}_n$ are shown in Figure 6. The excitation bands at 350 nm for $H_2$pdoa could be assigned to π→π* transitions of the O–$C_6H_4$–O group. Accordingly, the emissions spectra ($\lambda_{ex}$ = 350 nm) centered approximately at 394 nm can be assigned to the transition emission from the $T_1\pi,\pi^*$ and $T_1n,\pi^*$ to the ground state of the –$OC_6H_4O$– group.[21] For complex **1**, the band at 358 nm in the excitation spectra, similar to that of $H_2$pdoa, is associated with the π→π* transition of the O–$C_6H_4$–O unit. The band at 473 nm with a shoulder band at 530 nm in the emission spectrum is obviously different to that of $H_2$pdoa, and accordingly may be assigned to ligand-to-metal charge transfer (LMCT).[11b,11c,22] The excitation and emission spectra of **2** are very similar to those of **1** both in shape and position and are not characteristic of $Mn^{2+}$, with $3d^5$ electron configuration and octahedral coordination sphere according to the literature,[23] thus the excitation band at 356 nm can be assigned to the π→π* transition of the O–$C_6H_4$–O group, and the emission at 472 nm with the shoulder band at 535 nm to LMCT. Conclusively, both **1** and **2** may be used as blue-light-emitting functional materials. Complex **2**, with a combination of luminescent and magnetic properties (see below), may especially be a promising candidate for luminescent molecular magnetic materials.

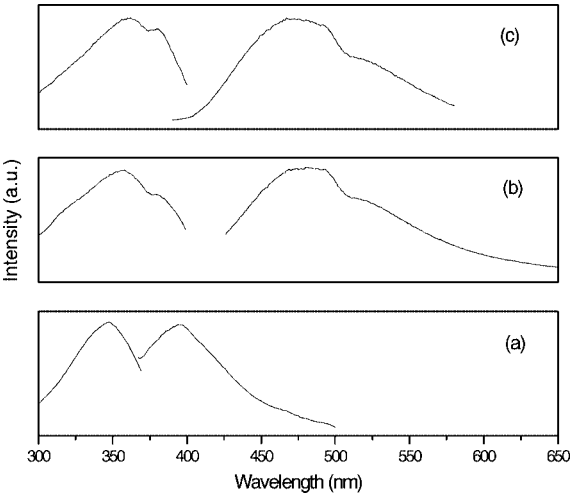

Figure 6. Solid-state excitation-emission spectra of $H_2$pdoa (a), complex **1** (b), and complex **2** at room temperature (c).

### Magnetic Properties

The temperature dependence of the magnetic susceptibility of complex **2** is depicted in Figure 7 in the form of the product $\chi_M T$ versus $T$ in the range of 300–1.8 K. The magnetic susceptibility is corrected for diamagnetism by using Pascal's constants. At room temperature, the product is 4.41 emu K $mol^{-1}$, which is the same as the spin-only value for $Mn^{2+}$ ($s$ = 5/2 and $g$ = 2.008 determined by EPR). As the temperature is lowered, the product $\chi_M T$ decreases steadily in the whole temperature range to 0.4 emu K $mol^{-1}$ at 1.8 K, indicating the antiferromagnetic interaction between $Mn^{II}$ ions through both bridging ligands bipy and carboxylate. Equally, a maximum was observed in the plot of $\chi_M$ versus $T$ (Figure 7), which is the nature of antiferromagnetic coupling between $Mn^{II}$ ions. The magnetic susceptibility data were fitted assuming that the carboxylate bridges between $Mn^{II}$ ions form a uniform chain with exchange constant $J$ and then bipy and pdoa connect the chains to form the 3D structure of this complex with an exchange constant $zJ'$. Thus, the expression in the literature can be written as Equations (1) and (2) for the magnetic fittings,[24] where $u = \coth[JS(S+1)/kT] - kT/JS(S+1)$.

$$\chi_{chain} = \frac{Ng^2\beta^2}{3kT}\frac{1+u}{1-u}S(S+1) \quad (1)$$

$$\chi_M = \frac{\chi_{chain}}{1-\chi_{chain}(2zJ'/Ng^2\beta^2)} \quad (2)$$

The best parameters obtained by a standard least-squares fitting were $g$ = 2.072(5), $J$ = –1.11(4) $cm^{-1}$, and $zJ'$ = –0.161(7) $cm^{-1}$ with $R = 4.3\times10^{-6}$ [$R = \sum|(\chi_M)_{exp} - (\chi_M)_{calc}|^2/\sum(\chi_M)^2_{exp}$]. Thus, the bipy and pdoa ligands mediate the very weak antiferromagnetic interaction between the $Mn^{II}$ ions in this system.

For a 3D antiferromagnetic complex, an observed maximum in the plot of $\chi_M$ versus $T$ implies the presence of a possible long-range anriferromagnetic ordering. It is confirmed by the specific heat ($C_p$) determination with a physical property measurement system (PPMS) at $10^{-4}$ Torr and zero field. The total specific heat ($C_p$) of complex **2** at low temperatures in the range of 1.8–8.5 K was determined ex-

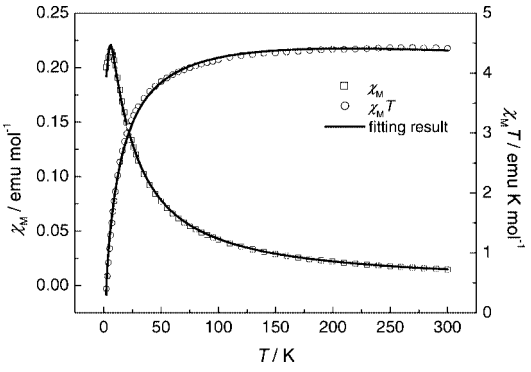

Figure 7. Temperature dependence of magnetic properties of complex **2** in the form of $\chi_M T$ (○) vs. $T$ and $\chi_M$ (□) vs. $T$; the solid line is the fitting of experimental data.

perimentally and the result is shown in Figure 8. It is accepted that the lattice-specific heats generally vary smoothly with the temperature and are not influenced greatly by the details of the structure. Therefore, we can gain insight into the magnetic properties from the variance of the total specific heat with the change of temperature. As seen in Figure 8, a peak is observed at 1.9 K and the lambda shape is similar to those of some one-dimensional antiferromagnetic compounds, such as $CsMnCl_3 \cdot 2H_2O$, $MnF_2$, and $(CH_3)_4NMnCl_3$.[25] The plot of $C_p$ versus $T$ further confirms the antiferromagnetic interaction between the $Mn^{II}$ ions in complex **2**; there is long-range ordering below 1.9 K (Neel temperature). Similar behavior was found in $[Mn_2(pm)]$, where pm represents 1,2,4,5-benzenetetracarboxylate.[26] To the best of our knowledge, complex **2** represents the first example of an open-framework coordination polymer with conjugation of blue fluorescent emission and antiferromagnetic long-range ordering, a promising candidate for multifunctional materials, such as luminescent molecular magnetic materials.

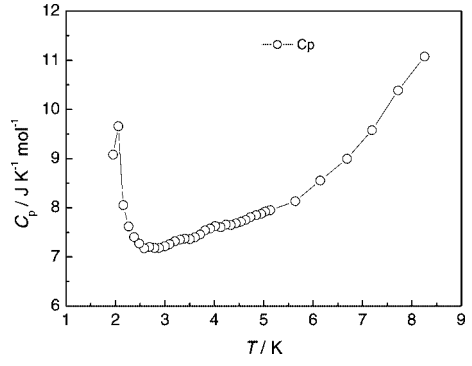

Figure 8. Total specific heat, $C_p$, plotted against temperature, $T$, for complex **2** between 1.8 and 8.5 K.

## Conclusions

Two coordination polymers containing 2,2′-(1,3-phenylenedioxy)bis(acetate) (pdoa) and 4,4′-bipyridine (bipy) with formulae $[Zn(pdoa)(bipy)]_n$ (**1**) and $\{[Mn(pdoa)(bipy)](bipy)\}_n$ (**2**) have been synthesized and characterized by single-crystal X-ray diffraction analyses and IR spectra and their luminescent properties and the magnetic behaviors have been investigated. The reactions of $ZnCl_2$ and $Mn(OOCCH_3)_2$ with pdoa and bipy under the same conditions result in strikingly different structures. Complex **1** has an interesting 3D noninterpenetration supramolecular structure, whereas complex **2** forms under the same reaction conditions an intriguing 3D open-framework structure with rectangular nanosized channels. The order of the separation between the asymmetric and symmetric stretching vibration is Δ(unidentate) > Δ(bridging bidentate) > Δ(chelating bidentate) according to the IR data. Both **1** and **2** display blue fluorescent emission, indicating that they are potentially luminescent materials. The magnetic studies in the range 300–1.8 K indicate that complex **2** displays the characteristics of a weak antiferromagnetic coupling between metal ions in the system mediated by both types of bridging ligands between the $Mn^{II}$ ions. Complex **2** is the first example of an open-framework coordination polymer with conjugation of blue fluorescent emission and antiferromagnetic long-range ordering, a promising candidate for multifunctional materials, such as luminescent molecular magnetic materials.

## Experimental Section

**Materials and Methods:** 2,2′-(1,3-Phenylenedioxy)bis(acetatic acid) was prepared according to a literature method;[10c] other reagents were commercially available and used without further purification.

**Synthesis of $[Zn(pdoa)(bipy)]_n$ (1):** A mixture of $ZnCl_2$ (0.07 g, 0.5 mmol), 4,4′-bipyridine (0.078 g, 0.5 mmol), 2,2′-(1,3-phenylenedioxy)bis(acetic acid) (0.113 g, 0.5 mmol), methanol (10 mL), and $H_2O$ (10 mL) was placed in a 25-mL Teflon-lined autoclave and heated to 120 °C for 72 h. Then the solution was cooled to room temperature and prismatic yellow crystals were obtained, which were filtered and washed with water and air-dried. Yield (based on $ZnCl_2$): 0.0141 g (20.1%). $C_{20}H_{16}N_2O_6Zn$ (445.74): C 53.89, H 3.62, N 6.28; found C 53.71, H 3.34, N 6.08.

**Synthesis of $\{[Mn(pdoa)(bipy)](bipy)\}_n$ (2):** Synthesized as brown block-shaped crystals in an identical manner to that of **1** with manganese(II) acetate tetrahydrate (0.122 g, 0.5 mmol) in place of $ZnCl_2$. Yield [based on $Mn(CH_3COO)_2 \cdot 4H_2O$]: 0.020 g (16.4%). $C_{30}H_{24}MnN_4O_6$ (591.47): C 60.92, H 4.09, N 9.47; found C 60.71, H 3.82, N 9.23.

**Physical Measurements:** Elemental analyses were carried out with a PE-2400CHN analyzer. The IR spectra were recorded with a Bruker VECTOR22 FTIR spectrometer in KBr pellets. Fluorescence measurements were performed with an AMINCO-Bowman Series $AB_2$ Luminescence Spectrometer. EPR spectra were measured with a Bruker EMX 10/12 EPR spectrometer. Magnetic susceptibility data on a crushed polycrystalline sample of **2** were collected over a temperature range of 300–1.8 K using a Quantum Design MPMS-XL superconducting quantum interference device (SQUID) magnetometer and diamagnetic corrections were made using Pascal's constants. The specific heat measurements were performed using a Quantum Design PPMS Heat Capacity System in the temperature range 300–1.8 K.

**X-ray Data Collection and Structure Determination:** Suitable single crystals of complexes **1** and **2** were mounted on a Pyrex fiber with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

epoxy and affixed to a brass pin for the X-ray experiment. The intensity data were collected at room temperature with a Bruker Smart Apex CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The data were collected over a hemisphere of the reciprocal space by a combination of three sets of exposures; each set had a different $\varphi$ angle (0°, 88°, and 180°) for the crystal and each exposure of 30 s covered 0.3° in $\omega$. The crystal–detector distance was 4 cm and the detector swing angle was –35°. Coverage of the unique set was over 99% complete. The 30 initial frames were recollected at the end of data collection to monitor crystal decay by analyzing the duplicate reflections, but no significant decays were observed. The raw data collected were reduced and corrected for Lorentz and polarization effects using the SAINT program and for absorption using the SADABS program.[27] The structures were solved by direct methods using SHELXS 97[28a] and all the non-hydrogen atoms were refined anisotropically by full-matrix least squares based on $F^2$ values.[28b] The largest residual density peak was close to the metal atom. Hydrogen atoms were added geometrically and were not refined. CCDC-294484 (for **1**) and -294485 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Silica Supported Submicron $SiO_2@Y_2SiO_5:Eu^{3+}$ and $SiO_2@Y_2SiO_5:Ce^{3+}/Tb^{3+}$ Spherical Particles with a Core–Shell Structure: Sol–Gel Synthesis and Characterization

**Cuikun Lin,[a] Huan Wang,[b] Deyan Kong,[a] Min Yu,[b] Xiaoming Liu,[a] Zhenling Wang,[a] and Jun Lin*[a]**

**Keywords:** Sol–gel processes / Luminescence / Core–shell structures / Silicates / Materials science

$X_1$-$Y_2SiO_5:Eu^{3+}$ and $X_1$-$Y_2SiO_5:Ce^{3+}$ and/or $Tb^{3+}$ phosphor layers have been coated on nonaggregated, monodisperse, submicron spherical $SiO_2$ particles by a sol–gel process, followed by surface reaction at high temperature (1000 °C), to give core/shell structured $SiO_2@Y_2SiO_5:Eu^{3+}$ and $SiO_2@Y_2SiO_5:Ce^{3+}/Tb^{3+}$ particles. X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM), TEM, photoluminescence (PL), low voltage cathodoluminescence (CL), and time-resolved PL spectra and lifetimes are used to characterize these materials. The XRD results indicate that $X_1$-$Y_2SiO_5$ layers have been successfully coated on the surface of $SiO_2$ particles, as further verified by the FESEM and TEM images. The PL and CL studies suggest that $SiO_2@Y_2SiO_5:Eu^{3+}$, $SiO_2@Y_2SiO_5:Tb^{3+}$ (or $Ce^{3+}/Tb^{3+}$), and $SiO_2@Y_2SiO_5:Ce^{3+}$ core/shell particles exhibit red ($Eu^{3+}$, 613 nm: $^5D_0$–$^7F_2$), green ($Tb^{3+}$, 542 nm: $^5D_4$–$^7F_5$), or blue ($Ce^{3+}$, 450 nm: 5d-4f) luminescence, respectively. PL excitation, emission, and time-resolved spectra demonstrate that there is an energy transfer from $Ce^{3+}$ to $Tb^{3+}$ in the $SiO_2@Y_2SiO_5:Ce^{3+},Tb^{3+}$ core/shell particles.

## Introduction

The synthesis of nanostructured inorganic materials with hierarchical morphologies has attracted considerable attention in the fields of catalysis, separation technology, microelectronic devices, and biomaterials engineering.[1] In particular, the term core/shell nowadays comprises a huge area of particles that are in the broadest sense defined by a core of matter that is surrounded by a shell of different matter.[2] Core/shell materials can be used to protect drugs or other materials from dissolving or hydrolysis and to strength polymeric materials,[3] and a gold core has been found to act as an antenna that absorbs light that is then transferred to a bound rare-earth oxide shell, thereby enhancing the oxide luminescence.[4] There are numerous methods for preparing core/shell structured materials, including vapor deposition, plasma-assisted techniques, chemical reduction, self-assembly, and co-precipitation.[5] In most cases, however, the degree of surface coverage is low and the coating is not uniform.[6] The sol–gel process is an effective method for preparing such materials since the reactants can be homogeneously mixed at molecular level in solution.

The current demand for high-resolution, high brightness, and high efficiency in phosphors for cathode-ray tubes, field-emissive displays, and plasma display panels has promoted the development of new phosphors, particularly those with a nonagglomerated, monodisperse, spherical (<2 μm) morphology as they offer higher packing density, lower scattering of light, brighter luminescent performance, higher definition, and more improved screen packing.[7] Nowadays, many synthetic routes have been developed to control the size, morphology, and distribution of phosphor particles, such as spray pyrolysis[8] and flux precipitation,[9] but it is still difficult to obtain highly monodisperse and spherical phosphor particles by these methods.

It is well known that monodisperse and spherical silica particles in the nano- to submicron range can be prepared by the hydrolysis and condensation of tetraethoxysilane (TEOS) catalyzed by ammonia.[10] If the silica spheres are coated with phosphors layers, a kind of core/shell phosphor material with spherical morphology will be obtained and the size of the phosphor particles can be controlled by the silica cores. Furthermore, because silica is cheaper than most of the phosphor materials, which often employ expensive rare-earth elements as activators and/or host components, core/shell phosphor materials should be cheaper than the pure phosphor materials. $Y_2SiO_5$ is an important material that shows many interesting properties, and rare-earth (RE) oxyorthosilicates [$(RE)_2SiO_5$] doped with $Eu^{3+}$,

$Ce^{3+}$, and $Tb^{3+}$ are well-known luminescent materials.[11–13] It is well known that $Y_2SiO_5$ is a good laser host[14] and $Y_2SiO_5$:Tb is one of the best green-emitting cathodoluminescent phosphors.[15] $Y_2SiO_5$:Eu has also been found to be a promising candidate for coherent time-domain optical memory (CTDOM) applications.[16] Therefore, rare-earth-doped yttrium orthosilicates have been attracting the attention of many research groups.

In this paper, we employ monodisperse $SiO_2$ spheres as supporting cores to prepare $SiO_2@Y_2SiO_5:Eu^{3+}$ and $SiO_2@Y_2SiO_5:Ce^{3+}/Tb^{3+}$ core/shell-structured phosphor particles by a sol–gel process, and thoroughly characterize the structure, morphology, and luminescent properties of these samples.

## Results and Discussion

The procedures for preparation of monodisperse core/shell-structured $SiO_2@Y_2SiO_5:Eu^{3+}$ and $SiO_2@Y_2SiO_5:Ce^{3+}/Tb^{3+}$ submicron spherical particles together with their luminescence photos are given in Figure S1 (see Supporting Information). The synthesis of the monodisperse $SiO_2$ core particles was carried out by the well-known Stöber method, i.e., hydrolysis of TEOS in an ethanol solution containing water and ammonia.[10] This process yielded a colloidal solution of silica particles with a narrow size distribution in the submicron range, with the particle size of silica dependent on the relative concentration of the reactants. A sol–gel technique was used for the deposition of the $Y_2SiO_5:Eu^{3+}$ and $Y_2SiO_5:Ce^{3+}/Tb^{3+}$ shells on the $SiO_2$ cores to produce core/shell-structured $SiO_2@Y_2SiO_5:Eu^{3+}$ and $SiO_2@Y_2SiO_5:Ce^{3+}/Tb^{3+}$ particles.

### Formation and Morphology of Core–Shell Particles

The formation and morphology of the core/shell particles were performed representatively for $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ by X-ray diffraction (XRD), field emission scanning electron microscopy (FESEM), and TEM. The results for the other compounds were similar to those of $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ and will not be discussed further.

The oxyorthosilicates $(RE)_2SiO_5$ of the larger rare-earth ions (RE = La–Tb) possess a monoclinic $X_1$-type structure with the space group $P2_1/C$ (no. 14),[17] whereas the smaller ones (RE = Dy–Lu, Sc) have an $X_2$-type structure with the space group $B2/b$ (no. 15).[18] $Y_2SiO_5$ crystallizes in the $X_1$ structure when annealed at a temperature below 1190 °C and in the $X_2$ structure above this temperature.[19] Figure S2 (Supporting Information) shows the structure of $X_1$-$Y_2SiO_5$. This structure contains isolated $SiO_4$ tetrahedra and nonsilicon-bonded oxygen. There are two types of Y positions. Y1 is coordinated by nine oxygen atoms, eight of which are bonded to silicon, and Y2 is coordinated by seven atoms, four of which are bonded to silicon.[20]

Figure 1 shows the XRD profiles for the pure $Y_{1.9}Tb_{0.1}SiO_5$ powder (a) and $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ (b), both annealed at 1000 °C, as well as the JCPDS 21-1456 card for $X_1$-$Y_2SiO_5$ (c) as the reference. For the $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ sample (Figure 1, b), besides the broad band at $2\theta = 22°$ due to amorphous $SiO_2$,[7] all the diffraction peaks can be indexed according to the standard data of $X_1$-$Y_2SiO_5$ (JCPDS 21-1456). This agrees well with the pure $Y_{1.9}Tb_{0.1}SiO_5$ powder sample annealed at 1000 °C, which also crystallizes with the $X_1$-$Y_2SiO_5$ phase structure. No second phase was detected. In general, the nanocrystallite size can be estimated from the Scherrer formula: $D_{hkl} = K\lambda/(\beta\cos\theta)$, where $\lambda$ is the X-ray wavelength (0.15405 nm), $\beta$ is the full-width at half-maximum, $\theta$ is the diffraction angle, $K$ is a constant (0.89), and $D_{hkl}$ is the size along the ($hkl$) direction.[21] Here, we use diffraction data at 29.60°, 31.02°, 32.58°, and 33.64° to calculate the crystallite size, which give an estimated average crystallite size of 22 nm for $Y_{1.9}Tb_{0.1}SiO_5$ on the $SiO_2$ sphere and 29 nm for pure $Y_{1.9}Tb_{0.1}SiO_5$. The unit cell parameters and crystallite size of $Y_2SiO_5$ powder and $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ core/shell particles, as well as the internuclear distances and angles of the $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ core/shell particles, were calculated using Jade 5.0 and CASTEP,[22] respectively. The results are listed in Table 1 and Table S1, respectively.

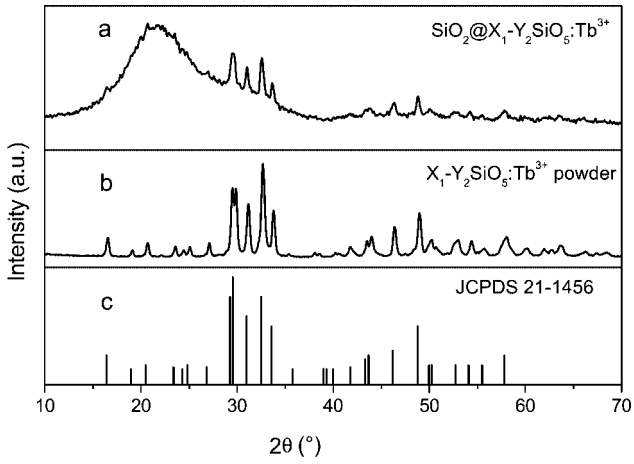

Figure 1. XRD patterns of $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ (a) and $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ (b) particles annealed at 1000 °C as well as the standard data for JCPDS No. 21-1456 (c) as a reference.

Table 1. Calculated unit-cell parameters and crystalline size of $Y_2SiO_5$ powder and $SiO_2@Y_2SiO_5$:Tb core/shell particles.

| Sample | *a* [nm] | *b* [nm] | *c* [nm] | *β* [°] | Crystal size [nm] |
|---|---|---|---|---|---|
| $Y_2SiO_5$ powder | 0.905 | 0.690 | 0.664 | 106.41 | 29 |
| $SiO_2@Y_2SiO_5$:Tb core/shell particles | 0.899 | 0.694 | 0.662 | 106.48 | 22 |

Figure 2 shows the SEM micrographs of the as-formed $SiO_2$ particles (a) and $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ (coated four times) core/shell particles (b). From the SEM micrograph in Figure 2 (see part a), we can see that the as-formed $SiO_2$ sample consists of spherical particles with an average size of 385 nm and that these particles are nonaggregated and have a narrow size distribution. After functionalizing the silica particles by coating four times with $Y_{1.9}Tb_{0.1}SiO_5$, the

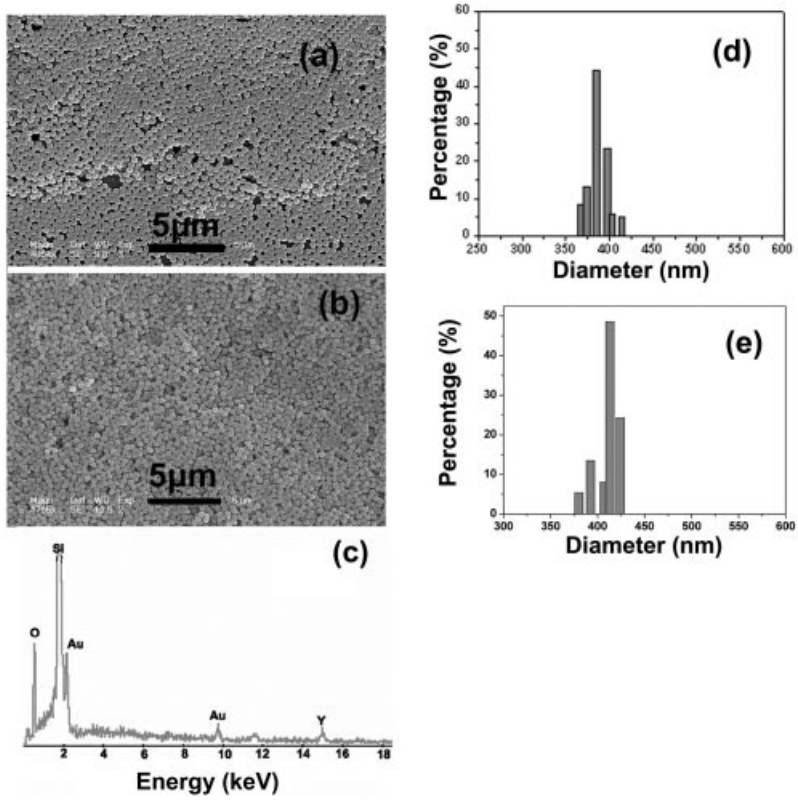

Figure 2. FESEM micrographs of amorphous $SiO_2$ (a) and core/shell-structured $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ particles (b) as well as the histograms for their size distribution (d for a, e for b) and EDX analysis of the core/shell-structured $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ particles (c).

resultant $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ particles are still spherical and uniform and keep the morphological properties of the silica particles, as shown in Figure 2 (b). The mean size of these particles is about 413 nm, which is a little larger than pure silica. The core/shell spheres were examined by energy-dispersive X-ray (EDX) analysis, which confirmed the presence of Y, Si, and O on the surface (Figure 2, c). Tb was not detected due to its low concentration, although it can be detected in the luminescence spectra (see below).

In order to investigate the inner structure of $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$, TEM was performed. Figure 3 shows the $SiO_2$ particles coated by four layers of $Y_{1.9}Tb_{0.1}SiO_5$ shells; the core/shell structure of the sample can be seen clearly due to the different electron penetrability of the core and shell. The core can be seen as a black sphere with an average size of 350 nm and the shells have a gray color and an average thickness of 50 nm. Electron diffraction measurements were performed at the interface region of the core and shell of a particle, as shown in the inset of Figure 3 (b). The electron-diffraction rings demonstrate the existence of a crystalline phase at the surface of the core/shell particles.

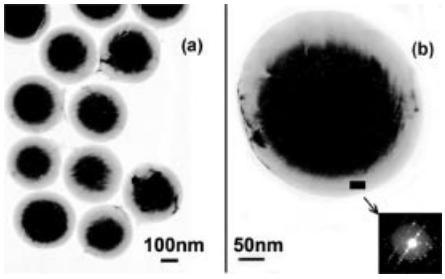

Figure 3. TEM micrographs of $SiO_2@$ $Y_{1.9}Tb_{0.1}SiO_5$ (a, b). The inset in (b) is the electron-diffraction pattern of the selected region.

## Photoluminescence Properties

The as-prepared core/shell particles of $SiO_2@Y_2SiO_5:Eu^{3+}$, $SiO_2@Y_2SiO_5:Tb^{3+}$ (or $Ce^{3+}/Tb^{3+}$), and $SiO_2@Y_2SiO_5:Ce^{3+}$ can be dispersed in solvents such as ethanol and water to form a relatively stable colloidal solution. Under UV excitation, these colloidal solutions show bright red ($SiO_2@Y_2SiO_5:Eu^{3+}$), blue ($SiO_2@Y_2SiO_5:Ce^{3+}$), and green ($SiO_2@Y_2SiO_5:Tb^{3+}$ and $SiO_2@Y_2SiO_5:Ce^{3+},Tb^{3+}$) luminescence, as shown in Figure S1.

### *$SiO_2@Y_2SiO_5:Eu^{3+}$*

$SiO_2@Y_2SiO_5:Eu^{3+}$ core/shell particles exhibit a strong red emission under UV irradiation. Figure 4 (a) shows the excitation and emission spectra of $SiO_2@Y_{1.8}Eu_{0.2}SiO_5$ core/shell particles. The excitation spectrum (Figure 4, part a, left) consists of a broad, intense band, with a maximum at 253 nm, and some weak lines. The former is due to the charge-transfer band (CTB) of $Eu^{3+}$–$O^{2-}$, and the latter are

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

due to f-f transitions within the $Eu^{3+}$ $4f^6$ electron configuration (320: $^7F_0 \rightarrow {}^5H_6$; 364: $^7F_0 \rightarrow {}^5D_4$; 384: $^7F_0 \rightarrow {}^5G_2$; 397: $^7F_0 \rightarrow {}^5L_6$, 468: $^7F_0 \rightarrow {}^5D_2$).[23] Upon excitation into the CTB at 253 nm, the emission spectrum was found to be composed of $^5D_0 \rightarrow {}^7F_J$ ($J$ = 0, 1, 2, 3, 4) emission lines of $Eu^{3+}$, with the hypersensitive red emission $^5D_0 \rightarrow {}^7F_2$ (612 nm) transition being the most prominent group (Figure 6, part a, right). When the $Eu^{3+}$ is located at a low-symmetry local site (without an inversion center), the hypersensitive $^5D_0 \rightarrow {}^7F_2$ transition is often dominant in its emission spectrum.[24] This is actually the case for $X_1$-$Y_2SiO_5$, which adopts a monoclinic structure with a space group of $P2_1/c$ where the two $Y^{3+}$ sites have a $C_1$ point symmetry (without an inversion center).[12,24] The doped $Eu^{3+}$ ions occupy the $Y^{3+}$ sites in the $SiO_2@X_1$-$Y_2SiO_5$ core/shell particles, which results in the hypersensitive red emission $^5D_0 \rightarrow {}^7F_2$ transition of $Eu^{3+}$ being the most prominent group in its emission spectrum.

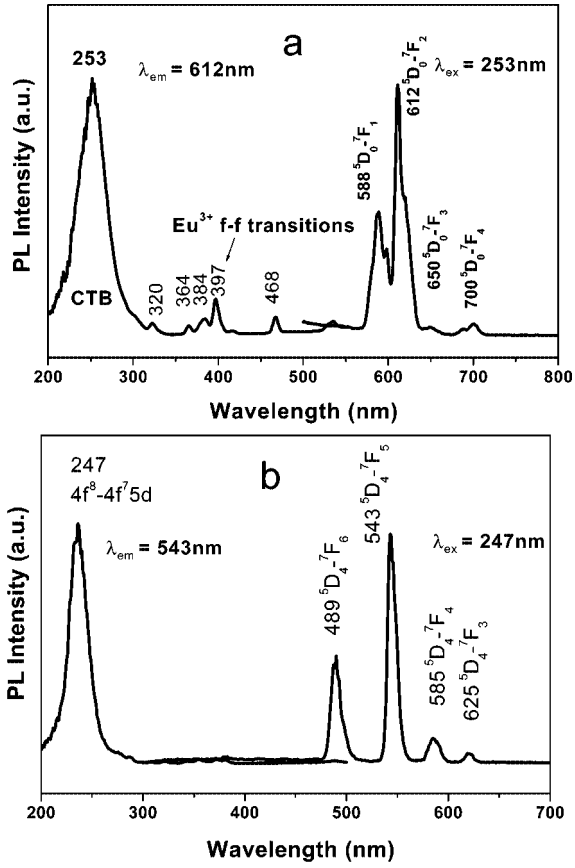

Figure 4. Excitation (left) and emission (right) spectra for $SiO_2@Y_{1.8}Eu_{0.2}SiO_5$ core/shell particles (a) and excitation (left) and emission (right) spectra for $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ core/shell particles (b).

The decay curve for the $^5D_0 \rightarrow {}^7F_2$ transition of $Eu^{3+}$ in $SiO_2@Y_{1.8}Eu_{0.2}SiO_5$ core/shell particles is shown in Figure S3; it can be well fitted to a single-exponential function as $I = A\exp(-\tau/\tau_0)$[25] (the fitting parameters are shown in the figure). A lifetime, $\tau$, of 2.31 ms is obtained for the $^5D_0 \rightarrow {}^7F_2$ emission of $Eu^{3+}$.

Because of the invariability of the $Eu^{3+}$ $^5D_0 \rightarrow {}^7F_1$ transition intensity, it can be taken as a reference for the calculation of luminescent quantum yield.[26,27] On obtaining the intensity parameters of the $Eu^{3+}$ emission spectra, the total radiative rate of $^5D_0$ can be expressed by Equation (1),[27,28]

$$k_r = k_{r(0-1)} \frac{\sum_{J=0}^{4} S_{(0-J)}}{S_{(0-1)}} \quad (1)$$

where $S_{(0\rightarrow J)}$ and $S_{(0\rightarrow 1)}$ are the integral intensities of the $^5D_0 \rightarrow {}^7F_J$ and $^5D_0 \rightarrow {}^7F_1$ transitions, respectively, and $k_{r(0\rightarrow 1)}$ is the radiative rate of the $^5D_0 \rightarrow {}^7F_1$ transition. Since $[k_{r(0\rightarrow 1)}]_{vac}$ is 14.65 $s^{-1}$,[29] when an average index of refraction, $n$, equal to 1.506 is considered, the value of $k_{0-1}$ is equal to $n^3[k_{r(0\rightarrow 1)}]_{vac}$, about 50 $s^{-1}$.[26,29–32]

The total radiative rate of $^5D_0$ was determined to be 0.137 $ms^{-1}$ from Equation (1). All the $^5D_0$ decay curves determined for the samples could be fitted well to a single-exponential function, which reflects the existence of the $Eu^{3+}$ local site symmetry.[33,34] The fitted lifetime is 2.31 ms. From these data, the total decay rate of $^5D_0$ ($K_{tot}$), which can be given as Equation (2), is 0.433 $ms^{-1}$. Finally, the absolute emission quantum yield ($\eta$) determined from Equation (3) is around 32%. This quantum value seems rather low considering that the materials have been annealed at 1000 °C, which generally leads to high quantum yields for this rare-earth ion. This may be due to the concentration quenching effect. It should be noted that Equation (3) describes the quantum efficiency of the $Eu^{3+}$ $^5D_0$ level and not the absolute emission quantum yield of the $SiO_2@Y_2SiO_5$:$Eu^{3+}$ core/shell particles, and that the absolute emission quantum yield is a more general quantity that involves the ratio between light absorption and light emission. Therefore, the absolute emission quantum yield and the quantum efficiency of the $^5D_0$ level are equal if all the energy absorbed is transferred to the $^5D_0$ level.

$$k_{tot} = \frac{1}{\tau} = k_r + k_{nr} \quad (2)$$

$$\eta = \frac{k_r}{k_r + k_{nr}} \quad (3)$$

### *$SiO_2@Y_2SiO_5$:$Tb^{3+}$*

$SiO_2@Y_2SiO_5$:$Tb^{3+}$ core/shell particles exhibit a strong green emission under UV irradiation. Figure 4 (b) shows the excitation and emission spectra of $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ core/shell particles. The excitation spectrum (Figure 4, part b, left) contains an intense, broad band with a maximum at 247 nm due to the spin-allowed $4f^8 \rightarrow 4f^75d$ transition ($\Delta S$ = 0) of $Tb^{3+}$.[34] The excitation lines in the longer wavelength regions within the $Tb^{3+}$ $4f^8$ electron configuration cannot be seen at this magnification due to their weak intensity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Excitation into the spin-allowed $4f^8 \rightarrow 4f^7 5d$ band at 247 nm yields the characteristic emission lines of $Tb^{3+}$ $^5D_4 \rightarrow {}^7F_J$ ($J$ = 3, 4, 5, 6) transitions, with the $^5D_4 \rightarrow {}^7F_5$ (543 nm) green emission as the most prominent group (Figure 4, part b, right).

The decay curve for $^5D_4 \rightarrow {}^7F_5$ of $Tb^{3+}$ in $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ core/shell particles is shown in Figure S4, which can also be well fitted to a single-exponential function like the situation for $Eu^{3+}$ in $SiO_2@Y_{1.8}Eu_{0.2}SiO_5$; the fitting parameters are shown in the figure. A lifetime value of 3.29 ms is obtained for the $^5D_4 \rightarrow {}^7F_5$ emission of $Tb^{3+}$.

The PL intensity of $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ core/shell particles can be tuned by the number of coatings. Figure 5 shows the PL intensity of the sample as a function of the coating number. Obviously, the PL intensity increases with an increase of coating number, which can be attributed to an increase of the thickness of the $Y_{1.9}Tb_{0.1}SiO_5$ shells on the $SiO_2$ spheres. The PL intensity of the four-layer $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ core/shell particles reaches about 62% of that of the pure $Y_{1.9}Tb_{0.1}SiO_5$ sample, as indicated in Figure 5.

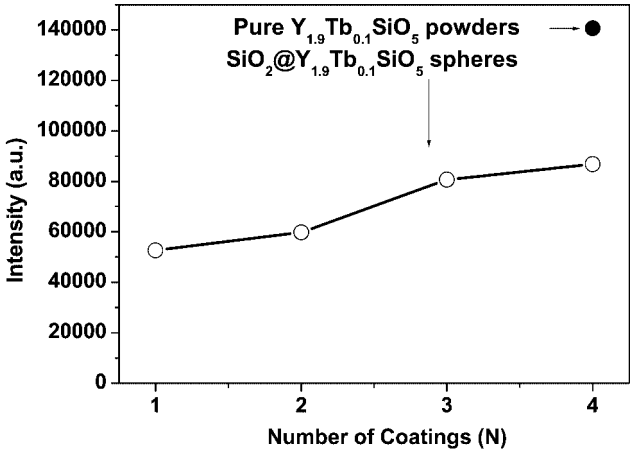

Figure 5. The photoluminescence intensity of $Tb^{3+}$ as a function of the number of coatings (N) of $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ core/shell particles. The photoluminescence intensity of pure $Y_{1.9}Tb_{0.1}SiO_5$ is also given for comparison.

### *$SiO_2@Y_2SiO_5:Ce^{3+}$ and $SiO_2@Y_2SiO_5:Ce^{3+},Tb^{3+}$*

The $SiO_2@Y_2SiO_5:Ce^{3+}$ core/shell particles show a blue emission under longer wavelength UV excitation. The excitation (a) and emission (b) spectra of $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$ core/shell particles are shown in Figure 6. The excitation spectrum mainly consists of a strong band with a maximum at 370 nm and a weak band at 282 nm, corresponding to the transitions from the ground state $^2F_{5/2}$ to the excited 5d states of $Ce^{3+}$. The emission of $Ce^{3+}$ includes a broad band with a maximum at 443 nm, which is assigned to the parity-allowed transitions of the lowest component of the 5d state to the ground state of $Ce^{3+}$.[35]

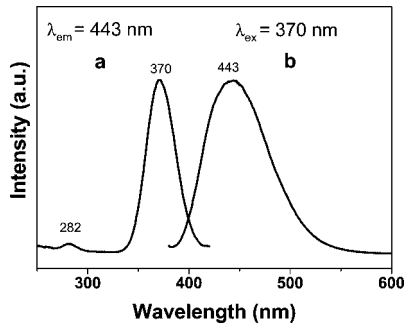

Figure 6. Excitation (a) and emission (b) spectra for $SiO_2$ @ $Y_{1.94}Ce_{0.06}SiO_5$ core/shell particles.

$SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ core/shell particles show a blue-green emission under UV excitation. The excitation spectrum monitored with the 543 nm emission ($^5D_4 \rightarrow {}^7F_5$) of $Tb^{3+}$ contains an intense band at 247 nm, a weak band at 282 nm, and a strong band with a maximum at 370 nm. By comparison with the excitation spectra for $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$ (Figure 4, b) and $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$ (Figure 5), we can easily ascribe the former band at 247 nm to the $4f^8 \rightarrow 4f^7 5d$ transitions of $Tb^{3+}$, and the latter bands at 282 and 370 nm to 4f–5d transitions of $Ce^{3+}$ in Figure 7 (a). The presence of the excitation bands of $Ce^{3+}$ in the excitation spectrum monitored with $Tb^{3+}$ emission indicates that an energy transfer has occurred from $Ce^{3+}$ to $Tb^{3+}$ in the $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ sample. Excitation into the $Ce^{3+}$ excitation band at 370 nm yields both the emission of $Ce^{3+}$ (380–470 nm, which is identical to the emission spectrum of $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$ core/shell particles, dotted line) and that of $Tb^{3+}$ ($^5D_4 \rightarrow {}^7F_J$ at 488, 543, 586, 625 nm), as shown in Figure 7 (b), and is further indicative of the energy transfer from $Ce^{3+}$ to $Tb^{3+}$ in $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$.

The kinetic decay curves for the emission of $Ce^{3+}$ in $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$ and in $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ were also measured (see Supporting Information, Figure S4, parts a and b, respectively). Both of the decay curves for $Ce^{3+}$ can be well-fitted to a single-exponential function, and the lifetimes ($\tau$) for $Ce^{3+}$ were determined to be 39.8 ns in the former and 20.1 ns in the latter. The shortening of the lifetime in $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$ with respect to $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ is due to the occurrence of the energy transfer from $Ce^{3+}$ to $Tb^{3+}$ in the latter sample. The $Ce^{3+} \rightarrow Tb^{3+}$ energy transfer is not complete due to the presence of the strong $Ce^{3+}$ emission. The energy-transfer efficiency from a donor ($Ce^{3+}$) to an acceptor ($Tb^{3+}$) can be calculated according to the formula $\eta_{ET} = 1 - I_d/I_{d0}$ (= $1 - \tau/\tau_0$), where $I_d$ ($\tau$) and $I_{d0}$ ($\tau_0$) are the corresponding luminescence intensities (lifetimes) of the donor ($Ce^{3+}$) in the presence and absence of the acceptor ($Tb^{3+}$) for the same donor concentration, respectively.[36] The energy-transfer efficiency from $Ce^{3+}$ to $Tb^{3+}$ is 48%, as calculated from the lifetimes of $Ce^{3+}$.

In order to study the energy-transfer process from $Ce^{3+}$ to $Tb^{3+}$ in $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ in more detail, the time-resolved emission spectra were measured by excitation

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

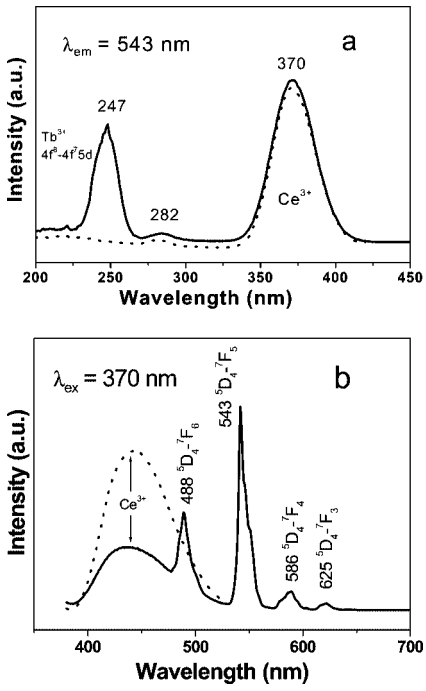

Figure 7. Excitation (a) and emission (b) spectra for $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ core/shell particles.

into the $Ce^{3+}$ band with a 370-nm laser. The emission spectra collected at different delay times $t$ are shown in Figure 8. When $t$ = 0.25 μs, only the broad emission of $Ce^{3+}$ is observed; no $Tb^{3+}$ emission is present because the excitation energy of $Ce^{3+}$ has not been transferred to $Tb^{3+}$ within this short time. When $t$ = 1.25 μs, the emission of $Ce^{3+}$ starts to decreases and is accompanied by a $Tb^{3+}$ emission due to the energy transfer from $Ce^{3+}$. The emission of $Ce^{3+}$ decreases gradually with further increase of the delay time, while that of $Tb^{3+}$ begins to increase (a large part of the $Tb^{3+}$ emission is from the $^5D_3$ level) due to transfer of more excitation energy from $Ce^{3+}$ to $Tb^{3+}$. When $t$ = 7.75 μs, the emission of $Ce^{3+}$ disappears, and the emission spectrum contains exclusively that of $Tb^{3+}$. The emission from the $^5D_3$ level of $Tb^{3+}$ then begins to decrease until it is quenched completely at $t$ = 100 μs. This quenching of the $^5D_3$ emission of $Tb^{3+}$ is due to cross-relaxation between two adjacent $Tb^{3+}$ ions, i.e. $Tb^{3+}$ ($^5D_3$) + $Tb^{3+}$ ($^7F_6$) → $Tb^{3+}$ ($^5D_4$) + $Tb^{3+}$ ($^7F_0$), which occurs at a longer delay time.[36]

The mechanism of nonradiative energy transfer from $Ce^{3+}$ (5d-level) to $Tb^{3+}$ (mainly the $^5D_3$ level) is an inductive resonant process. Since the concentration of $Ce^{3+}$ ions is not great, a dipole–dipole interaction between $Ce^{3+}$ and $Tb^{3+}$ in the excited state is the most likely one.[37,38] The absolute constant of the energy-transfer rate can be defined by the formula $K_t = 1/\tau - 1/\tau_0$, where $\tau$ and $\tau_0$ are the decay times of luminescence for the donor ions with and without the acceptor, respectively.[38,39] So, for $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$, the energy-transfer rate from $Ce^{3+}$ to $Tb^{3+}$ is 25 $\mu s^{-1}$ (at room temperature). This is much faster than the radiative rate of $Tb^{3+}$.[40] As a result, the excited state of $Tb^{3+}$ ($^5D_4$) can be populated many times by energy transfer from $Ce^{3+}$ before the depopulation occurs, which result in the increase of emission intensity during this period. Thus, the emission characteristics of $Ce^{3+}$ and $Tb^{3+}$ in Figure 8 can be understood.

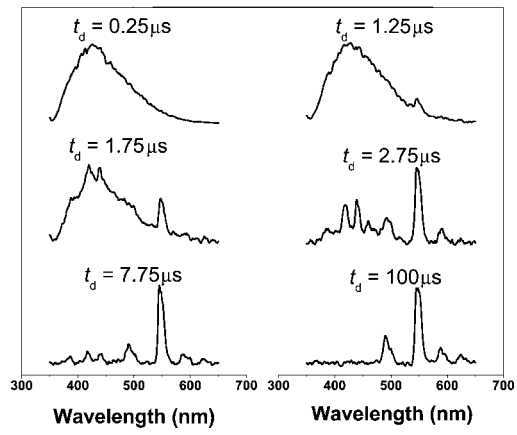

Figure 8. Time-resolved PL spectra of $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ core/shell particles ($\lambda_{ex}$ = 370 nm).

A summary of the emission and energy-transfer processes in $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ is shown schematically in Figure 9.[41] An electron on $Ce^{3+}$ ion is excited from the ground state (4f) to the excited state (5d) by UV light. In the excited state, this electron either relaxes to the lowest 5d crystal-field-splitting state then returns to the ground state to produce the blue emission, or transfers its excitation energy to the higher excited energy levels of $Tb^{3+}$ ($4f^8$), which relax to the $^5D_4$ level, where the green emission ($^5D_4 \rightarrow {}^7F_J$) takes place.[41] Competition between the above two processes results in the occurrence of emission from $Ce^{3+}$ and $Tb^{3+}$ simultaneously in $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ (Figure 9, b)

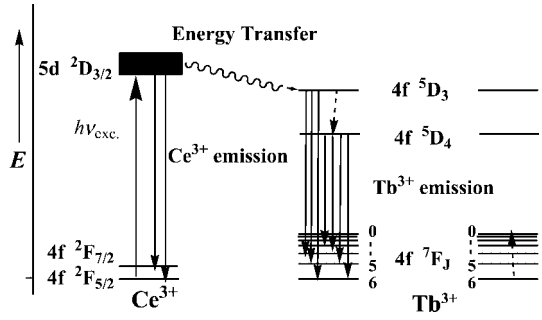

Figure 9. Scheme of energy transfer from $Ce^{3+}$ to $Tb^{3+}$.

## Cathodoluminescence Properties

Similar to the emission under UV excitation, the $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$, $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$, and $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ core/shell particles also exhibit strong red-green, blue, and blue-green luminescence, respectively, upon excitation with an electron beam (3 kv). Typical

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

emission spectra are shown in Figure 10 (a–c), respectively. These emission spectra basically agree with the corresponding PL emission spectra (Figure 4 and Figure 7). The CL emission for $SiO_2$ particles coated with four layers of $Y_{1.94}Ce_{0.06}SiO_5$, $Y_{1.9}Tb_{0.1}SiO_5$, $Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ were investigated as a function of accelerating voltage, as shown in Figure S6 (a–c, respectively). When the filament is fixed at 14 mA, the CL intensities of $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$, $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$, and $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ core/shell particles increase upon raising the acceleration voltage from 1 to 5 kV. For cathodoluminescence, the $Ce^{3+}$ and $Tb^{3+}$ ions are excited by the plasmons produced by the incident electrons. The electron penetration depth can be estimated by Equation (4)[42,43]

$$L\,[\text{Å}] = 250\left(\frac{A}{\rho}\right)\left(\frac{E}{Z^{\frac{1}{2}}}\right)^{n} \quad (4)$$

where $n = 1.2/(1 - 0.29\cdot\log_{10} Z)$, and A is the atomic weight, $\rho$ is the density, $Z$ is the atomic number, and $E$ is the accelerating voltage (V).[44] For $SiO_2@X_1$-$Y_2SiO_5:Tb^{3+}$ and $SiO_2@X_1$-$Y_2SiO_5:Ce^{3+}$, the electron penetration depth at 5 kV is 16.5 nm. This value is within the $X_1$-$Y_2SiO_5:Tb^{3+}$, $X_1$-$Y_2SiO_5:Ce^{3+}$, and $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ shell for the $SiO_2@X_1$-$Y_2SiO_5:Tb^{3+}$, $SiO_2@X_1$-$Y_2SiO_5:Ce^{3+}$, and $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ core/shell particles, respectively. With the increase of accelerating voltage, more plasmons will be produced by the incident electrons, which results in more $Ce^{3+}$ and $Tb^{3+}$ions being excited and thus a higher CL intensity. The increase in electron energy is attributed to deeper penetration of the electron into the shell, which is governed by Equation (4).

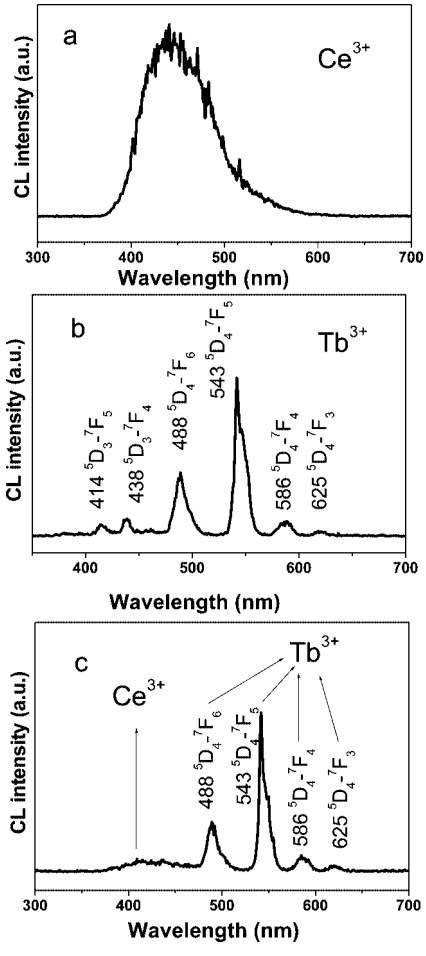

Figure 10. CL spectra of $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$ (a), $SiO_2@Y_{1.9}Tb_{0.10}SiO_5$ (b), and $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.10}SiO_5$ (c) core/shell particles (voltage: 3 kV).

The deeper penetration of electrons into the shell results in an increase in the electron–solid interaction volume in which excitation of $Ce^{3+}$ and $Tb^{3+}$ions, which is responsible for light emission, takes place. Therefore, an increase in interaction volume, which effectively determines the generation of light inside the shell, with an increase in electron energy brings about an increase in the CL brightness of $SiO_2@Y_2SiO_5:Tb^{3+}$ and $SiO_2@Y_2SiO_5:Ce^{3+}$ core/shell particles.[45]

## Conclusions

A simple and effective sol–gel process has been developed to coat $X_1$-$Y_2SiO_5$: $RE^{3+}$ (RE = $Eu^{3+}$, $Ce^{3+}$, and/or $Tb^{3+}$) phosphor layers on monodisperse spherical $SiO_2$ particles. The obtained $SiO_2@Y_2SiO_5:Eu^{3+}$, $SiO_2@Y_2SiO_5:Tb^{3+}$, $SiO_2@$-$Y_2SiO_5:Ce^{3+}$, and $SiO_2@Y_2SiO_5:Ce^{3+},Tb^{3+}$ core/shell-structured phosphors maintain the spherical morphology, submicrometer size, and narrow size-distribution of the originals. Under the excitation of UV light and electron beams, these core/shell phosphors show red, green, blue, and green luminescence, respectively. An energy transfer from $Ce^{3+}$ to $Tb^{3+}$ exists in $SiO_2@Y_2SiO_5:Ce^{3+},Tb^{3+}$ core/shell phosphors, and this has been studied by time-resolved spectroscopic methods. This process can be extended to prepare other phosphor materials with a homogeneous spherical morphology.

## Experimental Section

The core/shell samples with general compositions $SiO_2@Y_{1.8}Eu_{0.2}$-$SiO_5$, $SiO_2@Y_{1.9}Tb_{0.1}SiO_5$, $SiO_2@Y_{1.94}Ce_{0.06}SiO_5$, and $SiO_2@Y_{1.84}Ce_{0.06}Tb_{0.1}SiO_5$ were prepared by a sol–gel process. The main starting materials were $Y_2O_3$ (99.99%), $Eu_2O_3$ (99.99%), $Ce_2(CO_3)_3$ (99.99%), and $Tb_4O_7$ (99.99%), all of which were purchased from Shanghai Yuelong Nonferrous Metals Limited, tetraethyl orthosilicate $Si(OC_2H_5)_4$ (TEOS, 99 wt.-%, analytical reagent, Beijing Beihua Chemicals Co., Ltd.), polyethylene glycol (PEG, molecular weight 10000, analytical reagent), and ammonium hydroxide (25 wt.-%, analytical reagent, Beijing Beihua Chemicals Co., Ltd.).

First, monodisperse silica spheres were prepared by the well-known Stöber method.[10] In a typical experiment, 7.8 mL of TEOS, 18 mL of deionized $H_2O$, and 98 mL of $NH_4OH$ were added to 75 mL of absolute ethanol and stirred at room temperature for 3 h to give a white silica colloidal suspension. The silica particles were centrifugally separated from the suspension and washed with ethanol three times. Then, coating of the $SiO_2$ particles with $Y_2SiO_5$-based phos-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phor layers was performed by a sol–gel process. According to the compositions in the above formulae, stoichiometric amounts of $Y_2O_3$, $Eu_2O_3$, $Tb_4O_7$, and $Ce_2(CO_3)_3$ were dissolved in dilute $HNO_3$ with vigorous stirring. Then, a certain amount of TEOS and water/ethanol (v/v = 1:7) was added to the solution and PEG was added with a concentration of 0.1 g/mL. The solution was stirred for 3 h to form a sol, and then silica particles were added with stirring. After stirring for 3 h, the silica particles were separated by centrifugation. The samples were immediately dried at 100 °C for 1 h. The dried samples were annealed to 1000 °C at a heating rate of 2 °C $min^{-1}$ and held there for 2 h in air (for samples containing Eu) or in a reducing atmosphere (CO for samples containing Ce and/or Tb). The above process was repeated several times to increase the thickness of the phosphor shells. For comparison, the coating sol was evaporated in a similar way to produce the pure $Y_2SiO_5$-based powder phosphors. The whole process is shown schematically in Figure 1.

X-ray diffraction (XRD) studies of the powder samples were performed with a Rigaku-Dmax-IIB spectrometer with using Cu-$K_\alpha$ radiation ($\lambda$ = 0.15405 nm). The morphology of the samples was inspected with a field emission scanning electron microscope (FE-SEM, XL30, Philips) and a transmission electron microscope (JEOL-2010, 200 kV). The excitation and emission spectra were recorded with a Hitachi F-4500 spectrofluorimeter equipped with a 150-W xenon lamp and 1–6-kv electron gun (self-made) as the excitation source. Luminescence decay curves were obtained with a Lecroy Wave Runner 6100 Digital Oscilloscope (1 GHz) using a 250-nm laser (pulse width: 4 ns, gate: 50 ns) as the excitation source (Continuum Sunlite OPO). All the measurements were performed at room temperature.

# Synthesis and Electroluminescence Properties of *fac*-Tris(2-phenylpyridine)-iridium Derivatives Containing Hole-Trapping Moieties

**Katsuhiko Ono,*[a] Michitoshi Joho,[a] Katsuhiro Saito,[a] Masaaki Tomura,[b] Yosuke Matsushita,[c] Shigeki Naka,[c] Hiroyuki Okada,[c] and Hiroyoshi Onnagawa[c]**

**Keywords:** Amines / Charge-carrier injection / Doping / Iridium / Luminescence

In order to investigate an effective method for carrier injection into the phosphor of organic electroluminescent (EL) devices, we synthesized *fac*-tris(2-phenylpyridine)iridium [Ir(ppy)$_3$] derivatives containing hole-trapping moieties, such as diphenylamine, carbazole, and phenoxazine. Their photoluminescent maxima were observed around the maximum of Ir(ppy)$_3$. These values were slightly shifted depending on the hole-trapping moieties: redshifted due to diphenylamine and blueshifted due to carbazole and phenoxazine. Further, these moieties affected the oxidation potentials of Ir complexes in cyclic voltammetry. EL devices using an Ir complex with diphenylamine exhibited high EL performance because 1,1-bis[4-(di-*p*-tolylamino)phenyl]cyclohexane (TAPC) was employed as a hole-transporting layer. The maximum external quantum efficiency ($\eta_{ext}$) was recorded as 12.2 %. This value is comparable to that observed in a device using Ir(ppy)$_3$. These results indicate that the diphenylamino substituent is favorable to serve as a hole-trapping moiety of Ir(ppy)$_3$.

## Introduction

Currently, organic electroluminescent (EL) devices are an active area of research because of their potential applications in flat-panel displays.[1] The research to synthesize phosphorescent materials with heavy metals such as platinum and iridium has attracted considerable attention[2,3] because an internal quantum efficiency of 100% can be achieved by the energy transfer from both the singlet and triplet states to the phosphor triplet state at the emitting layer.[4,5] *fac*-Tris(2-phenylpyridine)iridium [Ir(ppy)$_3$] is a well-known green emitter.[3,6] A phosphorescent EL device using Ir(ppy)$_3$ demonstrated a high performance with a maximum external quantum efficiency of 19.2%.[3e] This value was comparable to the theoretical limit of around 20% obtained from simple classical optics.[7] However, further investigation of phosphorescent materials is still required for the research and development of phosphorescent EL devices. Also, synthetic studies on various materials such as Ir,[8,9] Pt,[10] and other metal[11] complexes have been conducted. These substances are used as dopants at the emitting layer. For example, the addition of an amount of ca. 6 wt.-% of Ir(ppy)$_3$ to the host material afforded the highest external quantum efficiency.[3a,3b] Therefore, the combination of phosphorescent and host materials is crucial for effective injection of holes and electrons into the

phosphor. 4,4′-Bis(carbazol-9-yl)-1,1′-biphenyl (CBP), which is an aromatic amine, is generally employed as the host material.[2b] Thus, we synthesized $Ir(ppy)_3$ derivatives as new types of phosphorescent materials, which are composed of aromatic amines such as diphenylamine, carbazole, phenoxazine, and phenothiazine[12] (see Scheme 1); these amine units act as effective hole-trapping moieties.[13] As a compound related to **1a**, its acetylacetonate (acac) complex $[Ir(ppy\text{-}NPh_2)_2(acac)]$ has been recently synthesized.[14] It was reported that the phosphorescent EL performance of this complex was better than that of $Ir(ppy)_2(acac)$. In this paper, we report the synthesis and properties of Ir complexes **1** and their applications in the study of phosphorescent EL devices.

## Results and Discussion

### Preparation and Properties of Ir Complexes Containing Hole-Trapping Moieties

The synthesis of the Ir complexes **1** is illustrated in Scheme 2. 2-(4-Bromophenyl)pyridine (**3**) was synthesized with a yield of 43% by the reaction of 2-fluoropyridine (**2**) with 4-bromophenyllithium;[15] this was utilized as the key compound in the following amination reaction. The ligands **4a**–**d** were prepared with yields of 82–91% by the Pd-catalyzed cross-coupling reaction of **3** with aromatic amines such as diphenylamine, carbazole, phenoxazine, and phenothiazine.[16] This reaction required a selective use of an additive base. Sodium *tert*-butoxide was selected for the reaction of diphenylamine, and potassium carbonate was employed for those of rigid amines, namely, carbazole, phenoxazine, and phenothiazine. The ligands **4a**–**c** produced the cyclometalated $Ir^{III}$ μ-chloro-bridged dimers **5a**–**c** with yields of 80–88% by treatment with $IrCl_3{\cdot}nH_2O$ in 2-ethoxyethanol and water at 120 °C.[6a] However, the Ir dimer **5d** was not obtained. The Ir complexes **1a**–**c** were prepared with yields of 48–78% by stirring **4** and **5** in glycerol with $K_2CO_3$ at 240 °C.[17] These Ir complexes were obtained in the form of orange solids for **1a** and yellow solids for **1b** and **1c**. Their melting points were above 300 °C. Structural determination was performed by using $^1H$ NMR, MALDI-TOF mass spectrometry, and elemental analysis. The stereochemistry of these complexes was determined to be that of facial isomers because the NMR chemical shifts observed in the three ligands were equivalent. In order to investigate the molecular structures of the Ir complexes, an X-ray crystallographic analysis of **1a** was performed. Two crystallographically independent molecules existed in this crystal. The structure of one of these molecules is shown in Figure 1. Three sets of linear C–Ir–N bonds are observed, indi-

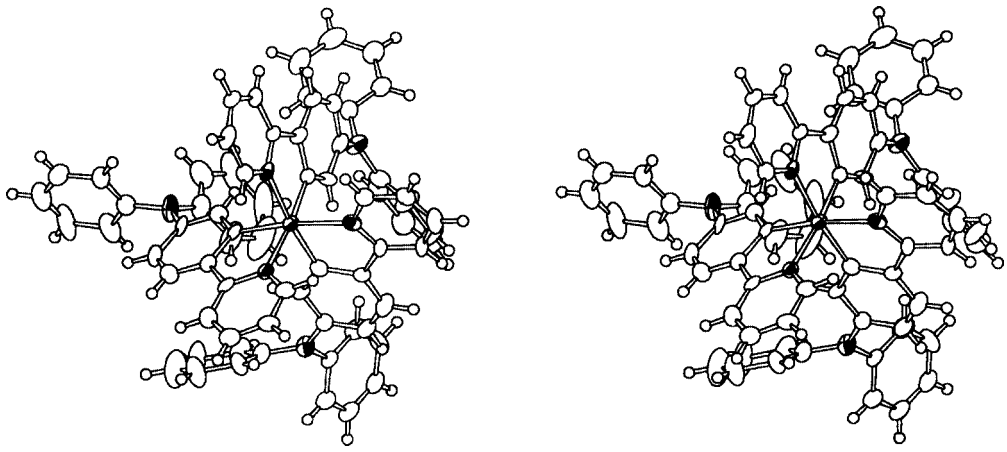

Figure 1. Molecular structure of Ir complex **1a** (stereo view). Ir and N atoms are depicted as shaded octants.

cating that complex **1a** is a facial isomer. Three diphenylamine moieties, resembling antennas, exist on the side of the $Ir(ppy)_3$ core.

The ligands **4** exhibited photoluminescence (PL) maxima between 400 and 540 nm in dichloromethane. The emission and absorption maxima are listed in Table 1. The Stokes shifts (Δ) for **4c**–**d** are greater than those for **4a**–**b**, indicating that the insertion of chalcogens such as O and S atoms into the carbazole moieties results in large Stokes shifts. The PL spectra of Ir complexes **1** are shown in Figure 2, and their emission and absorption maxima are listed in Table 2. The absorption maxima of the Ir complexes are redshifted as compared to those of the ligands. These maxima can be attributed to the metal–ligand charge-transfer (MLCT) excitation. The PL maxima of **1** are almost similar to that of $Ir(ppy)_3$, indicating the $Ir(ppy)_3$ cores as the source of the emission. The emission maxima marginally shifted depending on the molecular structure of the hole-trapping moiety. The maximum of **1a**, possessing a flexible amine, is redshifted from that of $Ir(ppy)_3$, and the maxima of **1b** and **1c**, possessing rigid amines, are blueshifted. The redshift is attributed to the resonance effect of the diphenylamino substituent, which reduced the energy gap between HOMO and LUMO. On the other hand, the π-conjugation on the rigid frameworks of carbazole and phenoxazine prevents the electron donation to the phenylpyridine (ppy) chelates. Furthermore, the emission maxima of the Ir complexes **1a** and **1b** are redshifted by ca. 100 nm from those of the ligands **4a** and **4b**, and the maximum of **1c** is similar to that of **4c** because of the large Stokes shift in the ligand. In addition, the emission maximum of **1a** is comparable to that of $Ir(ppy\text{-}NPh_2)_2(acac)$ ($\lambda_{em}$ = 530 nm).[14] The PL quantum yields of **1a**–**c** were measured in dichloromethane using $Ir(ppy)_3$ as the standard ($\Phi_{PL}$ = 0.40),[6b] and these values are listed in Table 2. The quantum yield of **1b** is greater than those of **1a** and **1c**.

In order to investigate the redox properties of the Ir complexes **1**, cyclic voltammetry (CV) was performed in dimethylformamide (DMF) with 0.1 M $nBu_4NClO_4$ as the supporting electrolyte. The voltammograms of **1** indicated reversible redox waves. The half-wave oxidation potentials of **1a**–**c** were recorded as +0.19, +0.48, and +0.23 V vs. $Fc/Fc^+$, respectively.[18] The values of **1a** and **1c** were lower than that of $Ir(ppy)_3$ (+0.32 V), indicating higher electron-donating abilities of **1a** and **1c**. On the other hand, the electron-donating ability of **1b** was lower than that of $Ir(ppy)_3$ owing to the introduction of a carbazole moiety. These results were attributed to the redox behavior of the ligands **4a**–**c**. The half-wave oxidation potentials of **4a** and **4c** (quasi-reversible and reversible waves) were measured to be +0.54 and

+0.30 V, respectively. The peak oxidation potential of **4b** (irreversible wave) was observed as +0.91 V. In addition, the half-wave reduction potentials of ligands **4a**–**c** were observed as –2.78, –2.69, and –2.64 V, respectively. Thus, the hole-trapping moieties affected the oxidation states of Ir complexes **1**.

### EL Properties of Ir Complex 1a Compared to Those of Ir(ppy)$_3$

An organic EL device using Ir complex **1a** as the emitter was fabricated, and its performance was investigated. The structure of ITO/TPD (50 nm)/Ir complex/CBP (20 nm)/BCP (30 nm)/LiF (1 nm)/Al (70 nm) was examined. *N*,*N*′-Diphenyl-*N*,*N*′-bis(3-methylphenyl)-1,1′-biphenyl-4,4′-diamine (TPD), Ir complex (5 wt.-%), and CBP were employed as the hole-transporting layer, emitter, and carrier combination host, respectively. 2,9-Dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) was used as an electron-transporting and hole-blocking layer. Figure 3(a) demonstrates the luminance/current density (*L*/*J*) characteristics of the EL devices using **1a** and Ir(ppy)$_3$ as the emitters. The EL from **1a** was over 40000 cd m$^{-2}$ at 14.4 V, although the emission from **1a** was weak as compared to that from Ir(ppy)$_3$ at the same current density. This result indicated that Ir complex **1a** as well as Ir(ppy)$_3$ were good emitters. The turn-on voltage was 4.8 V; this value was greater than that observed in the device with Ir(ppy)$_3$ (3.0 V). The external quantum efficiency ($\eta_{ext}$) of the device with **1a** also was lower than that of the device with Ir(ppy)$_3$ [Figure 3(b)]. Figure 3(c) shows the EL spectra. The spectrum from **1a** is similar to its PL spectrum shown in Figure 2. The EL maximum from **1a** was observed at 528 nm, which was slightly redshifted as compared to that from Ir(ppy)$_3$ (514 nm). In addition, a weak EL emission from TPD was observed in the wavelength region between 390 and 470 nm. This result indicated that an energy transfer occurred from the MLCT singlet state of **1a** to the singlet state of TPD by the Förster mechanism.

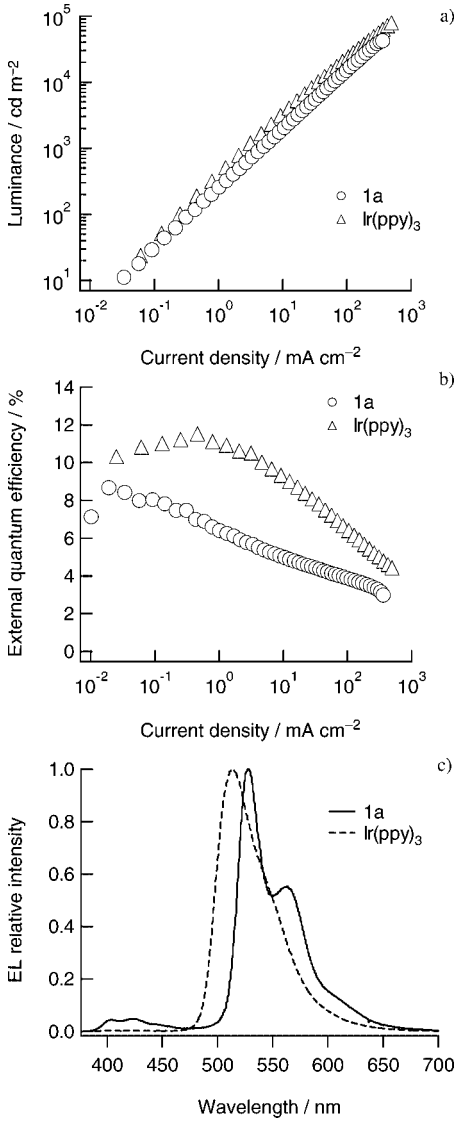

Figure 3. EL characteristics of ITO/TPD (50 nm)/Ir complex (5 wt.-%)/CBP (20 nm)/BCP (30 nm)/LiF (1 nm)/Al (70 nm). Ir complex = **1a** (circles), Ir(ppy)$_3$ (triangles). (a) Luminance (*L*)/current density (*J*) plots. (b) External quantum efficiency ($\eta_{ext}$)/current density (*J*) plots. (c) EL spectra.

### Scope and Limitations of Ir Complexes Containing Hole-Trapping Moieties

Because the EL emission from TPD was observed in the device with **1a**, 1,1-bis[4-(di-*p*-tolylamino)phenyl]cyclohexane (TAPC) was employed as a hole-transporting layer. The EL structure of ITO/TAPC (50 nm)/Ir complex/CBP (20 nm)/BCP (30 nm)/LiF (1 nm)/Al (70 nm) was examined. As an emitter, 5 wt.-% of **1a** was employed. Figure 4(a) shows the plots of the variation of the external quantum efficiency ($\eta_{ext}$) vs. the current density (*J*), indicating that the efficiency increased by replacing TPD (circles) with TAPC (triangles) as the hole-transporting layer (HTL). Thus, a maximum external quantum efficiency of 9.6% was observed at 7.4 V. The EL from **1a** was over 26000 cd m$^{-2}$ at 14.4 V. According to the EL spectrum shown in Figure 4(b), emission from the hole-transporting layer (TAPC) was not observed. This result implied that the energy transfer from **1a** to the hole-transporting layer was suppressed because the HOMO–LUMO energy gap of TAPC is larger than that of TPD (TAPC: 3.4 eV; TPD: 3.1 eV). Further, the phosphor triplet excitons were effectively confined by the TAPC layer, thereby leading to the high EL efficiency.[19]

An optimized amount of the Ir complex dopant was used at the emitting layer. The highest EL efficiency was observed when an amount of approximately 10 wt.-% of **1a** was doped. The molar ratio of the optimized amount was slightly higher as compared to that used for Ir(ppy)$_3$. The luminance (*L*) of **1a** was observed as 51900 cd m$^{-2}$ at 13.0 V. This resulted in the maximum external quantum efficiency ($\eta_{ext}$) of 12.2% [Figure 4(a)]. This value is comparable to those observed in devices using Ir(ppy)$_3$ [$\eta_{ext}$ = 11.5%, Figure 3(b)] and Ir(ppy-NPh$_2$)$_2$(acac) ($\eta_{ext}$ = 11.8%).[14] Table 3

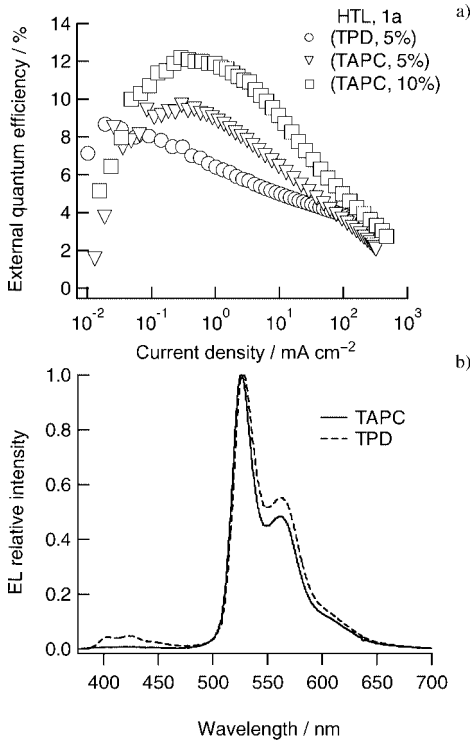

Figure 4. EL characteristics of ITO/HTL (50 nm)/**1a**/CBP (20 nm)/BCP (30 nm)/LiF (1 nm)/Al (70 nm). (a) External quantum efficiency ($\eta_{ext}$)/current density ($J$) plots. HTL/**1a** with TPD (5 wt.-%, circles), TAPC (5 wt.-%, triangles), TAPC (10 wt.-%, squares). (b) EL spectra.

summarizes the EL performances of devices with Ir complexes **1a**–**c**. The luminance increased in the following order: **1b**, **1c**, and **1a**. This may be attributed to their redox behavior as explained in the CV study. The EL efficiency of **1a** is higher than those of **1b** and **1c**. These results indicate that the diphenylamine moiety with a branched structure is acceptable as the hole-trapping moiety of Ir(ppy)$_3$.

## Conclusions

We prepared *fac*-tris(2-phenylpyridine)iridium [Ir(ppy)$_3$] derivatives containing hole-trapping moieties such as diphenylamine (**1a**), carbazole (**1b**), and phenoxazine (**1c**). Their PL maxima were observed around the maximum of Ir(ppy)$_3$. These values were marginally shifted depending on the hole-trapping moieties: redshifted for **1a** and blueshifted for **1b** and **1c**. The electron-donating ability of Ir(ppy)$_3$ was increased due to the diphenylamine and phenoxazine moieties, and the oxidation state became more unstable due to the carbazole unit. Organic EL devices using Ir complex **1a** as the emitter exhibited stronger luminance than devices that used **1b** and **1c**. Particularly, high EL efficiency was observed when TAPC was used as the hole-transporting layer. The maximum external quantum efficiency from the device was comparable to that observed in a device that used Ir(ppy)$_3$. Therefore, the introduction of a branched aromatic amine into phosphor is effective for the research and development of new phosphorescent materials.

## Experimental Section

**General:** Iridium trichloride *n*-hydrate ($IrCl_3 \cdot nH_2O$) was purchased from Soekawa Chemicals. Melting points were measured with a Yanaco micro melting point apparatus and are uncorrected. IR, UV/Vis, and PL spectra were obtained with JASCO FT/IR-5300, V-550, and FP-6300 spectrometers, respectively. Mass spectra were determined with a Hitachi M-2000S mass spectrometer (EI) operating at 70 eV by a direct inlet system and a Voyager-DE STR mass spectrometer (MALDI-TOF) using dithranol as a matrix. Elemental analyses were performed with a Perkin–Elmer 2400II analyzer. $^1$H and $^{13}$C NMR spectra were recorded with Varian GEMINI spectrometers (300 and 50 MHz) and a Bruker AVANCE 600 spectrometer (600 and 150 MHz) with tetramethylsilane as an internal standard.

**Preparation of 2-(4-Bromophenyl)pyridine (3):** *n*BuLi in hexane (1.60 M, 16.0 mL, 25.6 mmol) was added dropwise to a suspension of 1,4-dibromobenzene (5.90 g, 25.0 mmol) in dry diethyl ether (40 mL) at –78 °C under nitrogen. 2-Fluoropyridine (**2**) (1.72 mL, 20.0 mmol) was added after stirring for 30 min. The mixture was stirred at –78 °C for 1 h and at room temperature for 1 h. The reaction mixture was poured into water (50 mL), and diethyl ether (50 mL) was added. The organic layer was separated and the aqueous layer was extracted with diethyl ether (50 mL × 2). The combined organic solutions were extracted with a 5% HCl solution (200 mL × 3), and the aqueous layer was adjusted to an alkaline pH with KOH (63 g). The aqueous layer was extracted with diethyl ether (200 mL × 3). The organic solution was dried with $MgSO_4$ and concentrated. The residue was sublimed at 65–70 °C under $10^{-2}$ Torr to afford compound **3** (2.02 g, 43%) as colorless needles. M.p. 60–62 °C. IR (KBr): $\tilde{\nu}$ = 3052, 3007, 1586, 1462, 1433, 1391, 1154, 1100, 1071, 1005, 841, 774 cm$^{-1}$. $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 7.23–7.28 (m, 1 H), 7.60 (dt, $J$ = 8.8, 2.2 Hz, 2 H), 7.68–7.79 (m, 2 H), 7.88 (dt, $J$ = 8.8, 2.2 Hz, 2 H), 8.69 (ddd, $J$ = 4.8, 1.8, 1.1 Hz, 1 H) ppm. $^{13}$C NMR ($CDCl_3$, 50 MHz): $\delta$ = 120.3, 122.4, 123.4, 128.4, 131.8, 136.9, 138.2, 149.7, 156.2 ppm. MS (EI): $m/z$ (%) = 235 (100) [M$^+$], 233 (99) [M$^+$], 154 (84). $C_{11}H_8BrN$ (234.09): calcd. C 56.44, H 3.44, N 5.98; found C 56.47, H 3.55, N 5.89.

**Preparation of Ligands 4a–d:** A solution of $Pd(OAc)_2$ (28 mg, 0.12 mmol) and $t$Bu$_3$P (90 mg, 0.44 mmol) in toluene (4 mL) was

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

added to a suspension of compound **3** (0.94 g, 4.0 mmol), diphenylamine (0.68 g, 4.0 mmol), and *t*BuONa (0.47 g, 4.9 mmol) in toluene (4 mL) under nitrogen. The mixture was refluxed for 3 h. After cooling, the reaction mixture was poured into water (10 mL), and ethyl acetate (10 mL) was added. The organic layer was separated and the aqueous layer was extracted with ethyl acetate (10 mL × 2). The combined organic solutions were dried with $Na_2SO_4$ and concentrated. The residue was chromatographed on alumina gel (hexane/$CH_2Cl_2$, 2:1) to give ligand **4a** (1.17 g, 91%) as pale yellow needles. M.p. 177–177.5 °C (from ethanol). IR (KBr): $\tilde{\nu}$ = 3057, 1586, 1491, 1466, 1433, 1325, 1279, 787, 756, 698, 515 $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 7.05 (tt, $J$ = 7.3, 1.4 Hz, 2 H), 7.12–7.20 (m, 7 H), 7.24–7.31 (m, 4 H), 7.65–7.74 (m, 2 H), 7.87 (dt, $J$ = 8.8, 2.4 Hz, 2 H), 8.65 (ddd, $J$ = 4.9, 1.7, 1.0 Hz, 1 H) ppm. $^{13}C$ NMR ($CDCl_3$, 50 MHz): $\delta$ = 117.8, 119.8, 121.4, 123.2, 124.7, 127.7, 129.3, 133.1, 136.6, 147.5, 148.7, 149.6, 157.1 ppm. MS (EI): $m/z$ (%) = 322 (100) [$M^+$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (log$\varepsilon$) = 346 (4.42), 308 (4.23) nm. $C_{23}H_{18}N_2$ (322.40): calcd. C 85.68, H 5.63, N 8.69; found C 85.63, H 5.80, N 8.56. Similar reaction conditions were applied to the synthesis of ligands **4b**–**d**. These were carried out using $K_2CO_3$ (3 equiv.) as a base instead of *t*BuONa. The reaction mixtures were refluxed for 24 h. **4b:** Yield 87% (0.56 g). Pale yellow crystals (from ethanol). M.p. 179–180.5 °C. IR (KBr): $\tilde{\nu}$ = 1603, 1516, 1453, 1366, 1335, 1318, 1235, 779, 750, 725 $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 7.27–7.33 (m, 3 H), 7.40–7.51 (m, 4 H), 7.69 (dt, $J$ = 8.8, 2.2 Hz, 2 H), 7.81–7.83 (m, 2 H), 8.16 (d, $J$ = 7.8 Hz, 2 H), 8.23 (dt, $J$ = 8.8, 2.2 Hz, 2 H), 8.76 (dt, $J$ = 4.9, 1.1 Hz, 1 H) ppm. $^{13}C$ NMR ($CDCl_3$, 50 MHz): $\delta$ = 109.8, 120.1, 120.3, 120.5, 122.4, 123.5, 126.0, 127.2, 128.4, 136.9, 138.3, 138.4, 140.7, 149.8, 156.5 ppm. **Preparation of *fac*-Ir Complexes 1a–c:** A mixture of Ir dimer **5a** (130 mg, 0.075 mmol), ligand **4a** (49 mg, 0.15 mmol) and $K_2CO_3$ (106 mg, 0.77 mmol) in glycerol (5 mL) was stirred under nitrogen at 240 °C for 11 h. After cooling, water (5 mL) and dichloromethane (10 mL) were added. The organic layer was separated and the aqueous layer was extracted with dichloromethane (10 mL × 2). The combined organic solutions were dried with $Na_2SO_4$ and concentrated. The residue was chromatographed on silica gel ($CH_2Cl_2$) to afford *fac*-Ir complex **1a** (82 mg, 48%) as orange solid. M.p. > 300 °C (from $CH_2Cl_2$). $^1H$ NMR ($CDCl_3$, 600 MHz): $\delta$ = 6.24 (dd, $J$ = 8.4, 2.1 Hz, 3 H), 6.58 (d, $J$ = 2.1 Hz, 3 H), 6.78 (t, $J$ = 6.4 Hz, 3 H), 6.83 (d, $J$ = 7.7 Hz, 12 H), 6.87 (t, $J$ = 7.7 Hz, 6 H), 7.09 (t, $J$ = 7.7 Hz, 12 H), 7.27 (d, $J$ = 8.4 Hz, 3 H), 7.52–7.55 (m, 6 H), 7.68 (d, $J$ = 8.0 Hz, 3 H) ppm. $^{13}C$ NMR ($CDCl_3$, 150 MHz): $\delta$ = 114.6, 117.7, 120.5, 122.2, 124.5, 124.8, 128.6, 130.2, 135.4, 137.6, 147.2, 147.6, 148.2, 161.9, 166.2 ppm. MALDI-TOF MS: $m/z$ = 1156.42 [$M^+$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (log$\varepsilon$) = 398 (4.68), 367 (4.70), 320 (4.67), 261 (4.69), 227 (4.80) nm. $C_{69}H_{51}IrN_6$ (1156.4): calcd. C 71.67, H 4.45, N 7.27; found C 71.65, H 4.32, N 7.33. Similar reaction conditions, stirring at 240 °C for 48 h and 24 h, were applied to the synthesis of *fac*-Ir complexes **1b** and **1c**, respectively. **1b:** Yield 78% (0.27 g). Yellow solid. M.p. > 300 °C. $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 6.87 (br. m, 6 H), 6.96–7.03 (m, 18 H), 7.20 (d, $J$ = 2.2 Hz, 3 H), 7.71 (td, $J$ = 8.0, 1.5 Hz, 3 H), 7.76 (d, $J$ = 4.7 Hz, 3 H), 7.81 (d, $J$ = 8.2 Hz, 3 H), 7.94 (d, $J$ = 7.1 Hz, 6 H), 7.99 (d, $J$ = 8.0 Hz, 3 H) ppm. MALDI-TOF MS: $m/z$ = 1150.35 [$M^+$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (log$\varepsilon$) = 378 sh (4.40), 346 (4.70), 238 (5.18) nm. $C_{69}H_{45}IrN_6$ (1150.4): calcd. C 72.04, H 3.94, N 7.31; found C 72.20, H 4.03, N 7.26. **1c:** Yield 54% (0.20 g). Yellow solid. M.p. > 300 °C. $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 5.69 (dd, $J$ = 7.8, 1.4 Hz, 6 H), 6.01 (td, $J$ = 7.8, 1.4 Hz, 6 H), 6.39 (td, $J$ = 7.8, 1.4 Hz, 6 H), 6.52 (dd, $J$ = 7.8, 1.4 Hz, 6 H), 6.72 (d, $J$ = 2.0 Hz, 3 H), 6.76 (dd, $J$ = 8.1, 2.0 Hz, 3 H), 7.02 (t, $J$ = 5.9 Hz, 3 H), 7.69–7.73 (m, 6 H), 7.81 (d, $J$ = 8.1 Hz, 3 H), 7.92 (d, $J$ = 7.7 Hz, 3 H) ppm. MALDI-TOF MS: $m/z$ = 1198.34 [$M^+$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (log$\varepsilon$) = 375 sh (4.23), 330 (4.52), 283 (4.85), 241 (5.20) nm. $C_{69}H_{45}IrN_6O_3$ (1198.4): calcd. C 69.16, H 3.78, N 7.01; found C 69.14, H 3.90, N 6.89.

**X-ray Crystallographic Analysis for *fac*-Ir Complex 1a:** A single crystal was obtained as a greenish brown platelet by recrystallization of **1a** from a mixture of dichloromethane and ethyl acetate. Crystal data for **1a**: 0.15 × 0.13 × 0.03 mm, $C_{69}H_{51}IrN_6$, $M$ = 1156.42, monoclinic, space group $P2_1/n$, $a$ = 13.9742(9), $b$ = 17.1467(9), $c$ = 44.590(3) Å, $\beta$ = 98.158(3)°, $V$ = 10576(1) $Å^3$, $Z$ = 8, $D_c$ = 1.452 $g\,cm^{-3}$, $\mu$ = 25.82 $cm^{-1}$, $F(000)$ = 4672. A total of 21884 unique reflections for $2\theta_{max}$ = 55° was collected [$I > 2\sigma(I)$] with a Rigaku MSC MercuryCCD diffractometer (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71070 Å, graphite monochromator) at 173 K. A numerical absorption correction was applied. The structure was solved

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

using the direct method (SHELXS-97)[20] and refined by the full-matrix least-squares analysis (SHELXL-97)[21] giving values of $R_1$ = 0.088, $R_w$ = 0.165, $S$ = 1.26, $\rho_{max}/\rho_{min}$ = 3.44/–2.31 e·Å$^{-3}$. All calculations were performed using the teXsan programs.[22] CCDC-294487 contains the supplementary crystallographic data for this paper. The data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electrochemical Measurements:** CV was performed with a Toho Technical Research polarization unit PS-07 potentiostat/galvanostat. The CV studies of compounds **1** and **4** were carried out in DMF with 0.1 M $n$Bu$_4$NClO$_4$ using Pt and SCE electrodes. The values are expressed in potentials vs. Fc/Fc$^+$.

**Electroluminescence Measurements:** An ITO-coated glass substrate was patterned and cleaned by scrubbing, ultrasonication, and irradiation in a UV/ozone chamber. Organic layers were deposited on the ITO at an evaporating rate of 1 nm/s. The cathode of a LiF/Al bilayer was formed by sequential deposition. The rate and thickness of the films were monitored with a quartz oscillator. The sample area was 2×2 mm. Current and luminance on applied voltage were measured with an HP 4145A semiconductor parameter analyzer, which was connected with a Topcon BM-3 luminance meter. The electroluminescence spectra were measured with an Ocean Optics S2000 spectrometer. The external quantum efficiency ($\eta_{ext}$) was calculated from the luminance, the current density, and the emission spectrum of each device assuming that the observed emission was the Lambertian one.

## Acknowledgments

This work was supported by a Grant-in-Aid (nos. 17750037, 17550033) from the Ministry of Education, Culture, Sports, Science and Technology, Japan and a grant from Innovation Plaza Tokai ("Investigation of organic device integration using self-alignment technology"). K. O. wishes to thank the Yazaki Memorial Foundation for Science and Technology and Research Foundation for the Electrotechnology of Chubu for financial support. We would like to thank the Research Center for Molecular-Scale Nanoscience, Institute for Molecular Science, for the crystal analysis.

# Galactose Oxidase Models: Creation and Modification of Proton Transfer Coupled to Copper(II) Coordination Processes in Pro-Phenoxyl Ligands

**Fabien Michel,[a] Fabrice Thomas,*[a] Sylvain Hamman,[a] Christian Philouze,[a] Eric Saint-Aman,[b] and Jean-Louis Pierre[a]**

**Keywords:** Copper / Phenoxyl / Tripodal ligands / Proton transfer / Radicals

Two tripodal ligands containing two pyridyl and one 4-(benzimidazol-2-yl)-2-*tert*-butylphenol ($HL^H$) and one 2-*tert*-butyl-4-(*N*-methylbenzimidazol-2-yl)phenol ($HL^{Me}$) unit have been synthesized. They possess a $N_3O$ donor set that is known to stabilize phenoxyl radicals more efficiently than the corresponding $N_2O_2$ donor unit. Reaction of one molar equiv. of $Cu(ClO_4)_2{\cdot}6H_2O$ with $HL^H$ or $HL^{Me}$ affords the zwitterionic benzimidazolium phenolate complexes $[Cu^{II}(HL^H)]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ via a proton transfer reaction coupled to copper(II) coordination. Addition of $HClO_4$ to $[Cu^{II}(HL^H)]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ results in the formation of the benzimidazolium phenol complexes $[Cu^{II}(H_2L^H)]^{3+}$ and $[Cu^{II}(H_2L^{Me})]^{2+}$, while addition of $NEt_3$ affords the benzimidazol-phenolate complexes $[Cu^{II}(L^H)]^{2+}$ and $[Cu^{II}(L^{Me})]^{2+}$, respectively. The phenol's $pK_a$ is remarkably low due to the strong withdrawing effect of the benzimidazolium substituent. X-ray crystallographic analysis of the copper(II) complexes shows that deprotonation of the axial phenol forces the metal to move out of the square plane towards the oxygen atom, and one (or two) $Cu–N_{pyridine}$ equatorial bond length increases. The copper(II) phenoxyl species $[Cu^{II}(HL^H)]^{\cdot 3+}$ and $[Cu^{II}(HL^{Me})]^{\cdot 3+}$ were prepared electrochemically, or by addition of two molar equiv. of copper(II) to $HL^H$ or $HL^{Me}$. Under these conditions, radical formation has never been observed for tripodal ligands containing two pyridyl and one 2,4-di-*tert*-butylphenol group. This difference is explained in terms of the proton transfer mechanism and redox potentials.

## Introduction

Galactose Oxidase (GO) is a copper(II) enzyme that catalyses the oxidation of primary alcohols to the corresponding aldehydes, with concomitant reduction of dioxygen to hydrogen peroxide.[1–11] This two electron chemistry is promoted by a single copper atom, working in synergy with a tyrosyl radical from the protein. Galactose Oxidase possesses a $N_2O_2$ donor set: One oxygen atom, from the $Tyr_{272}^{\cdot}$ radical residue, is the organic redox center, while the other (from $Tyr_{495}$) controls the proton transfer process. The mechanism by which the radical is generated is of major interest. It has been shown recently that mixing apo-GO with copper (I or II) in the presence of $O_2$ affords the $Cu^{II}$ radical enzyme.[12–15] During the last few years, several model compounds for the GO active site have been developed.[16–48] Tripodal ligands have been widely used, and it has been shown that they are good structural models, which reproduce quite well the spectroscopic signatures of GO, and sometimes are able to model GO's reactivity towards alcohol oxidation.[17,25,27,28,35,38,41,45] It has also been shown that tripodal ligands possessing a $N_3O$ donor set stabilize more efficiently copper(II) coordinated phenoxyl radicals than the corresponding $N_2O_2$ set.

We have recently developed a biomimetic approach to radical cofactor formation. In this context, we have studied the solution chemistry of several tripodal ligands,[49] involving one pro-phenoxyl group (mimicking the amino acids of the GO active site), under various copper(II), base, and dioxygen reagent conditions.[50] We have shown that $Cu^{II}$ phenoxyl radical species could be obtained by adding two equiv. of copper(II) to ligands possessing a $N_3O$ coordination moiety, such as $HLt^{Bu}$ (Scheme 1), in the presence of one equiv. of triethylamine ($O_2$ is not involved in the reaction). In the absence of base, only a small amount of radical species is formed. In order to bypass this base requirement for radical formation, and thus to obtain more biologically relevant systems, we have synthesized the ligands $HL^H$ and $HL^{Me}$ (Scheme 1). Their structures are also tripodal, with two pyridyl and one phenol moiety joined together by a pivotal amino nitrogen atom. The 2-*tert*-butylphenol unit is substituted at its 4-position (with respect to the coordinating oxygen atom) by a benzimidazole ($HL^H$) or *N*-methylbenzimidazole ($HL^{Me}$) group in order to control the proton transfer processes, as do some non-coordinating histidine

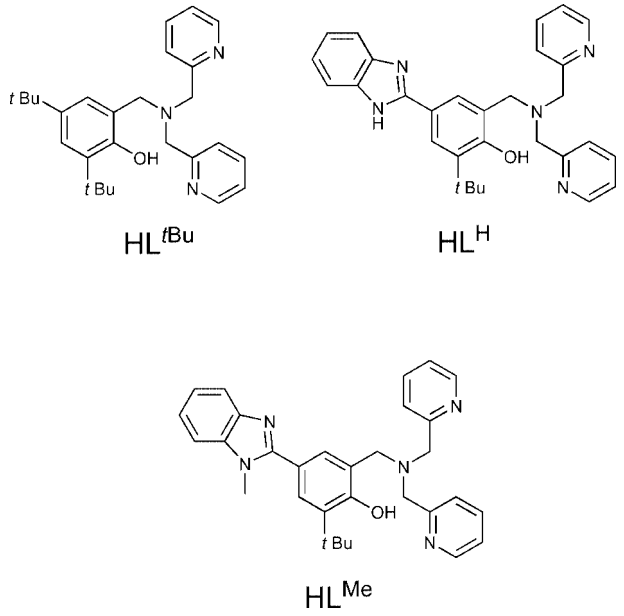
residues in enzymes. This substituent is also known to stabilize phenoxyl radicals.[51–52] Another aspect highlighting the originality of $HL^H$ and $HL^{Me}$ is their ability to manage the two proton/two electron shuttle process (like GO), unlike other copper(II) complexes containing $N_3O$ ligands. The phenoxyl oxygen atom and the copper(II) ion may control the two electron transfer, while the benzimidazolium/benzimidazole and phenol/phenoxyl acidobasic couples may be involved in the transfer of two protons. Their chemistry is therefore close to that of copper complexes of ligands possessing a $N_2O_2$ donor set, while their $N_3O$ donor set is expected to enhance the stability of the phenoxyl radicals.



Scheme 1. Formulae for the ligands.

The coordination and solution chemistry of the copper(II) complexes of $HL^H$ and $HL^{Me}$ are described in this paper, and compared to that of an already published system based on the ligand $HLt^{Bu}$ (Scheme 1).[50]

## Results and Discussion

### Synthesis of the Ligands

The ligands $HL^H$ and $HL^{Me}$ were obtained by using a Mannich reaction: In a one-pot synthesis, $HL^H$ is obtained by mixing bis(2-pyridylmethyl)amine and 4-(1*H*-benzoimidazol-2-yl)-2-*tert*-butylphenol in the presence of one equiv. of formaldehyde. Ligand $HL^{Me}$ is obtained by mixing bis(2-pyridylmethyl)amine and 2-*tert*-butyl-4-(1-methyl-1*H*-benzoimidazol-2-yl)phenol in the presence of one equiv. of formaldehyde.

The phenol benzimidazole (and not phenolate benzimidazolium) protonation state was confirmed by $^1H$ NMR ([$D_6$]DMSO) due to the hydroxy proton resonance ($\delta$ = 11.73 ppm and 11.76 ppm for $HL^H$ and $HL^{Me}$ respectively). Its structural attributes were confirmed by GHMBC and QHMQC sequences, showing $^3J$ correlations between the C2 carbon atom ($\delta$ = 136.9 ppm and 136.8 ppm for $HL^H$ and $HL^{Me}$ respectively), the *tert*-butyl protons ($\delta$ = 1.50 ppm and 1.49 ppm for $HL^H$ and $HL^{Me}$ respectively) and the hydroxy proton (see ESI).

### Structures of the Copper(II) Complexes

The copper(II) phenolate complexes $[Cu^{II}(HL^H)]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ were obtained by mixing stoichiometric amounts of the ligands and $Cu(ClO_4)_2{\cdot}6H_2O$ in acetonitrile. Dark blue single crystals were obtained on slow diffusion of di-*iso*-propyl ether into acetonitrile solutions of the complexes (Table 1). The ORTEP views of the phenolate complexes $[Cu^{II}(HL^H)]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ are depicted in

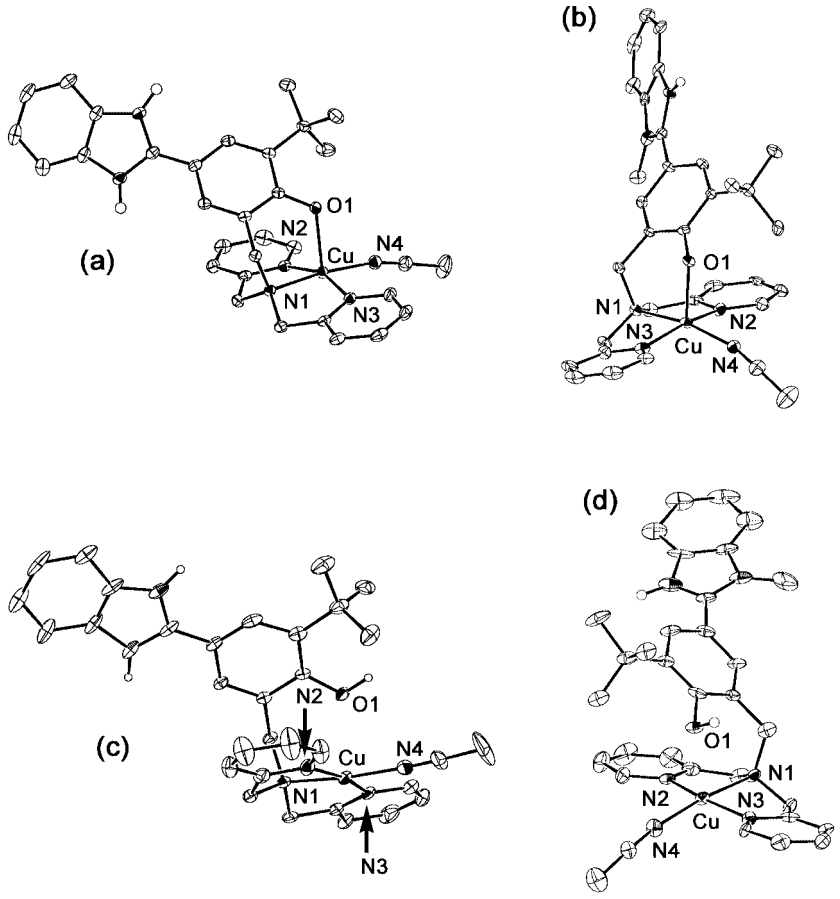

Figure 1. ORTEP view showing 35% displacement ellipsoids, and partial atomic labelling for (a) $[Cu^{II}(HL^{H})]^{2+}$, (b) $[Cu^{II}(HL^{Me})]^{3+}$, (c) $[Cu^{II}(H_2L^{H})]^{2+}$ and (d) $[Cu^{II}(H_2L^{Me})]^{3+}$. Hydrogen atoms, except the phenolic proton as well as the iminium protons, have been omitted for clarity. Weakly coordinating perchlorates are not shown (see text). Selected distances and angles are reported in Table 2.

Figure 1 (see parts a and b, respectively), and selected bond lengths and angles listed in Table 2. The geometry around the metal center is octahedral, with the copper(II) ion coordinated in a square plane by one tertiary nitrogen atom, N1, two pyridine nitrogen atoms, N2 and N3, and one acetonitrile nitrogen atom, N4. The phenolate oxygen atom, O1, occupies one axial position, and one perchlorate oxygen atom, O8, is very weakly coordinated at the opposite axial position.

In $[Cu^{II}(HL^{H})]^{2+}$ (Figure 1, a), the bond lengths are 2.021(1) Å (Cu–N1), 1.982(2) Å (Cu–N2), 1.978(1) Å (Cu–N3), 1.973(2) Å (Cu–N4), 2.156(1) Å (Cu–O1) and 2.813(2) Å (Cu–O8), while the angles N1–Cu–N2, N1–Cu–N3, N2–Cu–N4 and N3–Cu–N4 differ only slightly from 90° [83.8(1)°, 82.9(1)°, 96.2(1)° and 95.1(1)° respectively]. The mean deviation from the least square plane defined by atoms N1, N2, N3, N4, and Cu is 0.0801 Å, and the copper atom is displaced 0.205(2) Å above the basal plane towards the axial O1 oxygen atom.

In $[Cu^{II}(HL^{Me})]^{2+}$ (Figure 1, b), the Cu–N1, Cu–N2, Cu–N3, and Cu–N4 bond lengths are 2.039(5), 1.995(5), 1.999(5) and 1.981(3) Å respectively. The mean deviation from the least square plane defined by atoms N1, N2, N3, N4, and Cu is 0.036 Å. The copper atom is displaced 0.245(6) Å above the basal plane towards the axial oxygen atom, with a Cu–O1 bond length of 2.133(4) Å [the Cu–O8 distance is 2.875(5) Å].

In both $[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$, the benzimidazolium (or *N*-methylbenzimidazolium) rings of two separate molecules, of the same complex, are π-stacked head-to-tail, with distances between the phenyl and imidazolium centroids of 3.45 and 3.53 Å for $[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ respectively. In both $[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ the iminium hydrogen atom, H1, is hydrogen bonded to the O9 oxygen atom of a perchlorate molecule.

Adding one equiv. of $HClO_4$ to acetonitrile solutions of $[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ affords the copper(II) phenol complexes $[Cu^{II}(H_2L^{H})]^{3+}$ and $[Cu^{II}(H_2L^{Me})]^{3+}$ that were recrystallized by diffusion of diisopropyl ether into the solution (Table 1). In $[Cu^{II}(H_2L^{H})]^{3+}$ and $[Cu^{II}(H_2L^{Me})]^{3+}$ (Figure 1, c and d, respectively) the copper(II) atoms have similar octahedral geometry. The square plane is defined by one tertiary nitrogen atom, N1, two pyridine nitrogen atoms, N2 and N3, and one acetonitrile nitrogen atom, N4. The phenolic oxygen atom, O1, and one perchlorate oxygen atom (O7 for $[Cu^{II}(H_2L^{Me})]^{3+}$ and O20 for $[Cu^{II}(H_2L^{H})]^{3+}$) occupy the apical positions.

The Cu–N1, Cu–N2 and Cu–N4 bond lengths in $[Cu^{II}(H_2L^{H})]^{3+}$ (phenol copper) are similar to those ob-

served for $[Cu^{II}(HL^{H})]^{2+}$ (phenolate copper). This is not the case for the Cu–N3 bond length that is 1.964(5) Å for $[Cu^{II}(H_2L^{H})]^{3+}$, which is 0.015 Å shorter than in $[Cu^{II}(HL^{H})]^{2+}$ [1.978(1) Å]. One can also notice that the Cu–O1 bond length in $[Cu^{II}(H_2L^{H})]^{3+}$ is much longer than in $[Cu^{II}(HL^{H})]^{2+}$, it is 2.509(5) Å in $[Cu^{II}(H_2L^{H})]^{3+}$ but only 2.156(1) Å in $[Cu^{II}(HL^{H})]^{2+}$. The $Cu–O_{perchlorate}$ distance in $[Cu^{II}(H_2L^{H})]^{3+}$ [Cu–O20, 2.432(6) Å] is shorter than observed in $[Cu^{II}(HL^{Me})]^{2+}$ [Cu–O8, 2.813(2) Å].

Even more marked geometric variations, were observed for $[Cu^{II}(H_2L^{Me})]^{3+}$. The Cu–N1 and Cu–N4 bond lengths in $[Cu^{II}(H_2L^{Me})]^{3+}$ are similar to those observed in $[Cu^{II}(HL^{Me})]^{2+}$, while both the Cu–N2 and Cu–N3 bond lengths are 0.02 Å shorter (1.967(6) and 1.972(6) Å, respectively for $[Cu^{II}(H_2L^{Me})]^{3+}$, 1.995(5) and 1.999(5) Å, respectively for $[Cu^{II}(HL^{Me})]^{2+}$). The Cu–O1 bond length in $[Cu^{II}(H_2L^{Me})]^{3+}$ is significantly longer than in $[Cu^{II}(HL^{Me})]^{2+}$ (2.401(5) Å in $[Cu^{II}(H_2L^{Me})]^{3+}$, 2.133(4) Å in $[Cu^{II}(HL^{Me})]^{2+}$). The copper(II) atom is less displaced above the mean basal plane towards the axial oxygen atom in $[Cu^{II}(H_2L^{Me})]^{3+}$ [0.121(7) Å] than in $[Cu^{II}(HL^{Me})]^{2+}$ [0.245(6) Å]. The Cu–O7 distance in $[Cu^{II}(H_2L^{Me})]^{3+}$ [2.714(7) Å] is shorter than observed in $[Cu^{II}(HL^{Me})]^{2+}$. A weak π-stacking interaction (rings are slightly eclipsed) exists between the phenol unit and the imidazole ring of $[Cu^{II}(H_2L^{H})]^{3+}$, and between the *N*-methylbenzimidazolium rings of two $[Cu^{II}(H_2L^{Me})]^{3+}$ complexes, the rings are stacked head-to-tail, as in $[Cu^{II}(HL^{Me})]^{2+}$. Hydrogen bonds are present between the two iminium hydrogen atoms, H2 and H3, of $[Cu^{II}(H_2L^{H})]^{3+}$ and the perchlorate oxygen atoms, O4 and O14. One hydrogen bond is present between the iminium hydrogen atom, H2, of $[Cu^{II}(H_2L^{Me})]^{3+}$ and the perchlorate oxygen atom, O15, while another is present between the phenolic proton, H1, and the oxygen atom, O2, of one perchlorate molecule.

In these structures, another important point of note is the torsion angle between the phenol(ate) and the *para* substituent of the ring. It is significantly higher for the *N*-methylbenzimidazole (40° and 35° for $[Cu^{II}(H_2L^{Me})]^{3+}$ and $[Cu^{II}(HL^{Me})]^{2+}$, respectively) than for the benzimidazole (4° and 27° for $[Cu^{II}(H_2L^{H})]^{3+}$ and $[Cu^{II}(HL^{H})]^{2+}$, respectively), this may be explained, at least partially, by consideration of the steric hindrance of the methyl group. The consequence of this difference will be weaker electronic communication between the groups in the former case.

Complexes $[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ belong to the small class of structurally characterized mononuclear copper(II) complexes of tripodal ligands, in which the phenolate group occupies the unusual axial position. The complexes that belong to this class usually involve only one coordinating phenolate, and exhibit a relatively long Cu–O bond (higher than 2.17 Å).[24] In $[Cu^{II}(HL^{H})]^{2+}$, and espe-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cially in $[Cu^{II}(HL^{Me})]^{2+}$, the Cu–O1 distances are shorter [2.156(1) and 2.133(4) Å, respectively], making them the shortest bonds reported for axially coordinated phenolates.

We have previously reported the X-ray crystal structures of both the copper(II) phenol and the copper(II) phenolate complexes of $HL^{NO2}$, the structures of which are related to $HL^{H}$ (they bear a nitro instead of a benzimidazole substituent).[49] Unfortunately, the exogenous ligand was different in these structures, an acetonitrile molecule in the phenol form, and a chloride ion in the phenolate form. Thus, the influence of the protonation of the axial phenolate on the equatorial bonds could not be visualized. Here, we report X-ray structures in which the phenolate and phenol forms have been crystallized with the same exogenous ligand (acetonitrile molecule) coordinated to the metal center. To the best of our knowledge, this is the first example in which changes in the copper(II) ion geometry, induced by deprotonation of the axial phenol, could be visualized so clearly: the metal moves out of the basal plane towards the oxygen atom as a consequence of a stronger axial bond, and one (or both) Cu–$N_{pyridine}$ bond length(s) increase, reflecting the weakening of the equatorial bonds (Figure 2).

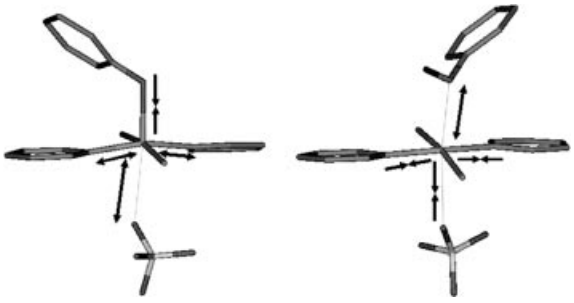

Figure 2. Influence of the phenol protonation state on the Cu–O and Cu–N bond lengths in $[Cu^{II}(HL^{Me})]^{2+}$ (left) and $[Cu^{II}(H_2L^{Me})]^{3+}$ (right).

## Spectroscopic Properties of the Copper(II) Complexes

The electronic spectra of acetonitrile solutions of $[Cu^{II}(H_2L^{H})]^{3+}$ and $[Cu^{II}(H_2L^{Me})]^{3+}$ show d-d transitions at around 600 nm (Table 3, Figure 3). This suggests that the phenol subunit remains protonated in solution, and that the copper(II) atom resides within an octahedral (with a very weakly coordinated perchlorate) or square pyramidal coordination sphere (without the perchlorate). The EPR spectra of frozen $CH_3CN$ solutions of $[Cu^{II}(H_2L^{H})]^{3+}$ and $[Cu^{II}(H_2L^{Me})]^{3+}$ are typical of axial mononuclear copper(II) complexes, and similar to that of $[Cu^{II}(HL^{tBu})]^{2+}$ (Table 4).[49] In all three complexes, the copper(II) atoms have roughly similar geometry, in agreement with the X-ray diffraction analysis. The influence of the phenol *para* substituent cannot be visualized in the EPR spectra, as a consequence of the very weak phenolic oxygen–copper(II) bond (see above). Complexes $[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ exhibit, in their electronic spectra, the phenolate-to-copper(II) CT transition centered at 524 and 508 nm, respectively (Figure 3, Table 3). The low energy tail in the 700–900 nm region originates from d-d transitions. On addition of one equiv. of $NEt_3$ to $CH_3CN$ solutions of

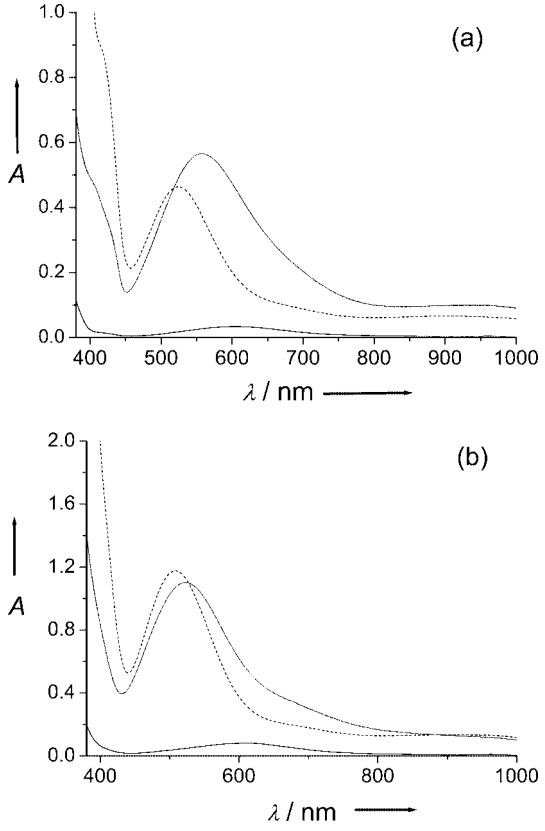

Figure 3. 298 K electronic spectra of $CH_3CN$ solutions of: (a) 0.1 mM $[Cu^{II}(H_2L^{H})]^{3+}$ (solid line), $[Cu^{II}(HL^{H})]^{2+}$ (dashed line) and $[Cu^{II}(L^{H})]^{+}$ (dotted line); (b) 0.2 mM $[Cu^{II}(H_2L^{Me})]^{3+}$ (solid line), $[Cu^{II}(HL^{Me})]^{2+}$ (dashed line) and $[Cu^{II}(L^{Me})]^{+}$ (dotted line).

Scheme 2. Protonation equilibria for $[Cu^{II}(HL^{Me})]^{2+}$ and $[Cu^{II}(HL^{H})]^{2+}$.

$[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ the phenolate-to-copper(II) CT transition is displaced towards lower energy regions (556 nm and 521 nm, respectively). Such a shift can be explained by the increased donor ability of the *p*-phenolate substituent, and the subsequent deprotonation of the *N*-methylbenzimidazolium and benzimidazolium groups by $NEt_3$, affording the phenolate benzimidazole complexes $[Cu^{II}(L^{H})]^{+}$ and $[Cu^{II}(L^{Me})]^{+}$. Both the phenolate benzimidazolium and phenolate benzimidazole forms exhibit, in their EPR spectra, a signal typical of mononuclear copper(II) complexes (Table 4). The phenolate oxygen atom does not bridge two copper atoms (as observed when the phenolate *ortho* substituent is not sufficiently sterically hindered). The protonation equilibria involving $[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ are summarized in Scheme 2.

### Protonation Constants of the Complexes

The protonation constants were determined from pH-metric titrations that were monitored by UV/Vis spectroscopy (Figure 4). After dissolution of single crystals of $[Cu^{II}(H_2L^{H})]^{3+}$ and $[Cu^{II}(H_2L^{Me})]^{3+}$ into a $CH_3CN/H_2O$ (1:1) mixture (the complexes are poorly soluble in pure $H_2O$), the $^{s}_{w}$pH was increased by addition of NaOH. The thermodynamic constants were obtained from refinement of the UV/Vis data by the commercial SPECFIT 32 software (Spectrum Software Associated). Their calculation was based on the spectral changes induced by addition of base. At $^{s}_{w}$pH = 2, the visible spectra of both complexes consist of $Cu^{II}$ d-d transitions at around 650 nm ($\varepsilon < 100\ M^{-1}\,cm^{-1}$), consistent with the phenol benzimidazolium complexes being the major species present at this $^{s}_{w}$pH. The shift of the $\lambda_{max}$ band that occurs when $CH_3CN$ is replaced by $CH_3CN/H_2O$ (1:1) suggests that the coordinating acetonitrile in $[Cu^{II}(H_2L^{H})]^{3+}$ and $[Cu^{II}(H_2L^{Me})]^{3+}$ is replaced by a water molecule from the solvent mixture. Increasing the $^{s}_{w}$pH to 5 results in the appearance of a phenolate-to-copper(II) CT in the 475–500 nm region, showing that the phenolate benzimidazolium complexes are formed. The first p$K_a$ values, 3.40 ± 0.01 and 3.55 ± 0.02 for the copper(II) complexes of $HL^{H}$ and $HL^{Me}$ respectively, are thus attributed to the deprotonation of the phenol group. Such values are remarkable, as they are much lower than those reported

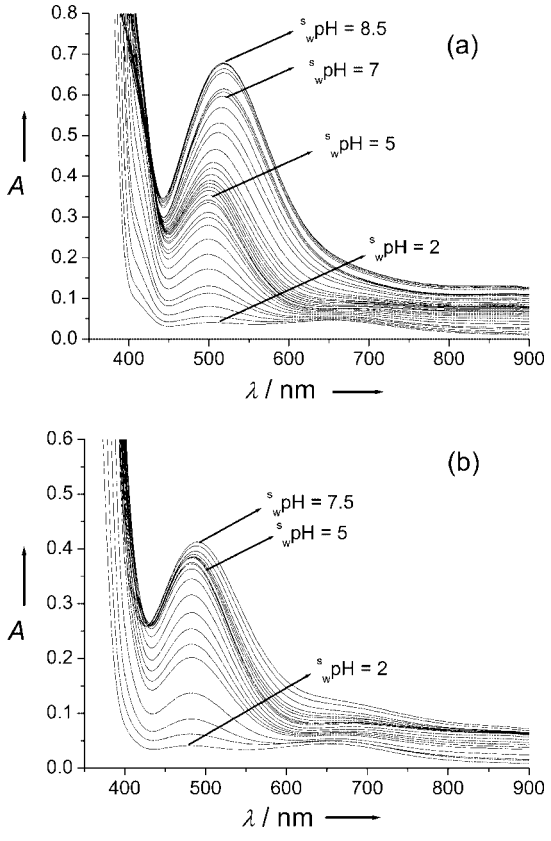

Figure 4. $^{s}_{w}$pH dependence of the electronic spectra of 0.1 mM $CH_3CN/H_2O$ (1:1) solutions of $[Cu^{II}(H_2L^{H})]^{3+}$ (a) and $[Cu^{II}(H_2L^{Me})]^{3+}$ (b). $^{s}_{w}$pH was increased by addition of NaOH, $T$ = 298 K, $l$ = 1.000 cm, $I$ = 0.1 M ($NaClO_4$).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for phenol copper(II) complexes of tripodal ligands (6.66–7.31),[50] and for GO itself (7.9).[53] This can be explained by the strong electron-withdrawing effect of the benzimidazolium (or *N*-methylbenzimidazolium) substituent that very efficiently stabilizes the phenolate form, and therefore lowers its p$K_a$. As a consequence, deprotonation of the phenol group occurs prior to deprotonation of the coordinated water molecule. This is in contrast with GO, for which deprotonation of the tyrosine occurs after deprotonation of the coordinated water molecule (in the absence of substrate). When the $^{s}_{w}$pH is raised to 7.5, a shift of the LMCT transition towards lower energy regions is observed, while the $\varepsilon$ value increases by a factor of 1.7 for the copper(II) complex of $HL^H$, and a factor of 1.1 for the $HL^{Me}$ complex. This structural evolution is close to that observed during addition of $NEt_3$ to neat acetonitrile solutions of $[Cu^{II}(HL^H)]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$. We therefore attribute these spectral changes to deprotonation of the benzimidazolium (or *N*-methylbenzimidazolium) group, rather than deprotonation of a coordinated water molecule. The corresponding deprotonation constants, 6.56 ± 0.02 for the copper(II) complex of $HL^H$ and 6.22 ± 0.06 for the $HL^{Me}$ complex are within the range of those reported for free benzimidazolium and *N*-methylbenzimidazolium (5.63 and 5.67 respectively).[54] Further increasing the $^{s}_{w}$pH results in the precipitation of the copper(II) complex of $HL^{Me}$. A shift of the $\lambda_{max}$ band is observed for the copper(II) complex of $HL^H$, which may be attributed to the deprotonation of a coordinated water molecule (p$K_a$ = 8.03 ± 0.10).

### Electrochemistry of the Copper(II) Complexes

The CV curves of $[Cu^{II}(H_2L^H)]^{3+}$ and $[Cu^{II}(H_2L^{Me})]^{3+}$ in $CH_3CN$ (0.1 M TBAP) at 298 K display an oxidation wave at $E_p^a$ = 1.01 and 0.95 V (referred to the $Fc/Fc^+$ system) respectively, attributed to the oxidation of the phenol moiety (Figure 5, c). It is irreversible, attesting to the primary oxidation products not being stable over the timescale of the measurement. Therefore, the redox processes will not be investigated further.

The CV curves of the phenolate complexes $[Cu^{II}(HL^H)]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ in $CH_3CN$ display quasi reversible electrochemical signals centered at $E_{1/2}$ = 0.50 V ($I_p^a/I_p^c$ 2.5) and $E_{1/2}$ = 0.59 V vs. $Fc^+/Fc$ ($I_p^a/I_p^c$ = 5), respectively (Figure 5, b). Coulometric titrations reveal that one electron redox processes are occurring in both cases, suggesting that these signals correspond to the oxidation of the phenolate to give a phenoxyl radical (vide infra). The lower $I_p^a/I_p^c$ ratio obtained for $[Cu^{II}(HL^H)]^{2+}$ suggests that its oxidation product is more stable than the oxidation product of $[Cu^{II}(HL^{Me})]^{2+}$. Resonance effects may contribute to this, as the planarity between the phenolate ring and its *para* substituent is greater for $[Cu^{II}(HL^H)]^{2+}$ than for $[Cu^{II}(HL^{Me})]^{2+}$ in the solid state. The $E_{1/2}$ values obtained for $[Cu^{II}(HL^H)]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ fall within the range for related copper(II) complexes in which the phenolate *para* substituent is either $NO_2$ or $CF_3$,[49,55] namely, an electron-withdrawing group.

Complexes $[Cu^{II}(L^H)]^+$ and $[Cu^{II}(L^{Me})]^+$ exhibit, in their CV curve, oxidation waves centered at $E_{1/2}$ = 0.23 V ($I_p^a/I_p^c$ = 1.6) and $E_{1/2}$ = 0.32 V vs. $Fc^+/Fc$ ($I_p^a/I_p^c$ = 3.9), respectively (Figure 5, a). As for $[Cu^{II}(HL^H)]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$, these signals correspond to the oxidation of the phenolate moieties to give phenoxyl radicals. The $I_p^c/I_p^a$ ratio, as well as the $E_{1/2}$ values, obtained for the *N*-methyl- or benzimidazolyl-phenolate complexes are lower than those found for the corresponding phenolate benzimidazolium (or *N*-methylbenzimidazolium) complexes. This reflects an increase in the stability of the oxidation products of the former complexes with respect to the latter. Deprotonation of the benzimidazolium (or *N*-methylbenzimidazolium) substituent makes the group less electron-withdrawing (inductive effect), and thus easier to be oxidized. These results nicely illustrate how an external perturbation (protonation) can influence the value of the phenoxyl/phenolate redox couple.

### One Electron Oxidized Copper(II) Complexes

Upon one electron electrochemical oxidation, the violet solutions of each copper(II) phenolate complexes turn blue.

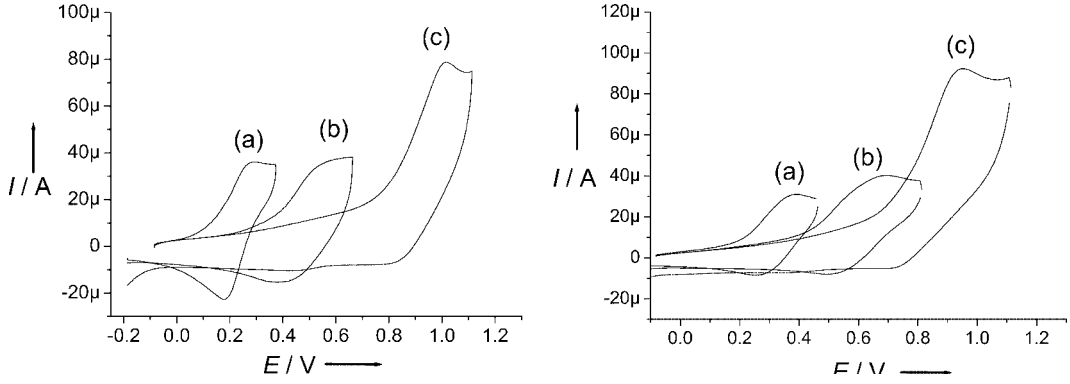

Figure 5. Cyclic voltammetry curves recorded on a vitrous carbon disc of 1 mM $CH_3CN$ (+0.1 M TBAP) solutions of, on the left: $[Cu^{II}(L^H)]^+$ (a), $[Cu^{II}(HL^H)]^{2+}$ (b), and $[Cu^{II}(H_2L^H)]^{3+}$ (c). On the right: $[Cu^{II}(L^{Me})]^+$ (a), $[Cu^{II}(HL^{Me})]^{2+}$ (b), and $[Cu^{II}(H_2L^{Me})]^{3+}$ (c). Scan rate 0.1 V $s^{-1}$, $T$ = 298 K, reference electrode $Fc^+/Fc$.

Two intense absorption bands at 400 and 435 nm and a lower intensity band at ca. 700 nm dominate the visible spectra, at 233 K, of the electrochemically generated $[Cu^{II}(L^{H})]^{\cdot 2+}$, $[Cu^{II}(HL^{H})]^{\cdot 3+}$ and $[Cu^{II}(HL^{Me})]^{\cdot 3+}$ complexes in $CH_3CN$ (Figure 6 and Figure 7).[56] Such bands, which have been previously reported for copper(II) phenoxyl complexes[57–59] and $[Cu^{II}(L^{tBu})]^{\cdot 2+}$,[49] are attributed to the π-π* transitions of the radical.[60–67]

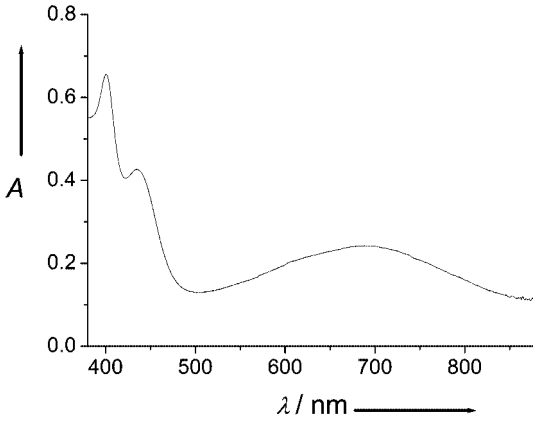

Figure 6. 233 K electronic spectra of a 0.1 mM $CH_3CN$ solution of $[Cu^{II}(L^{H})]^{\cdot 2+}$ ($l$ = 1.000 cm).

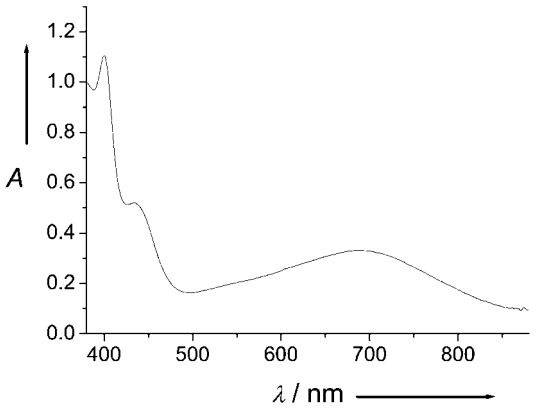

Figure 7. 233 K electronic spectra of a 0.1 mM $CH_3CN$ solution of $[Cu^{II}(HL^{H})]^{\cdot 3+}$ ($l$ = 1.000 cm).

The 4 K X-Band EPR spectra of the electrogenerated species $[Cu^{II}(L^{H})]^{\cdot 2+}$ and $[Cu^{II}(HL^{H})]^{\cdot 3+}$ in $CH_3CN$ show broad $\Delta M_S = \pm 1$ transitions at 250 and 390 mT. The associated $\Delta M_S = \pm 2$ signal is seen at 150 mT. This signal is split into four hyperfine lines separated by 8 mT (Figure 8), which are attributed to the interaction of the electronic spin with the nuclear spin of the copper(II) ($I$ = 3/2). This is clear evidence of ferromagnetic coupling between the spins of the radical and the copper(II). An additional mononuclear copper(II) signal, corresponding to degradation products, is also present in each EPR spectrum. $[Cu^{II}(L^{Me})]^{\cdot 2+}$ exhibits a weak transition at 160 mT, while $[Cu^{II}(HL^{Me})]^{\cdot 3+}$ was too unstable to be prepared in sufficient amounts to enable its EPR spectrum to be recorded.

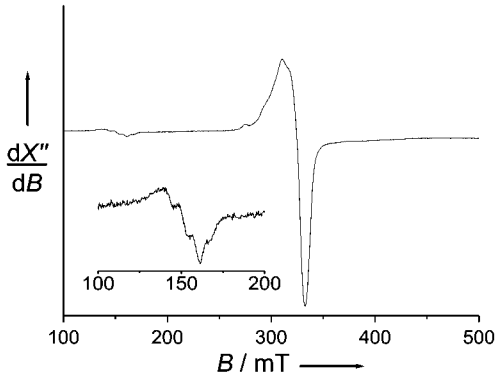

Figure 8. X-Band EPR spectra of a 1 mM $CH_3CN$ solution of $[Cu^{II}(L^{H})]^{\cdot 2+}$. Microwave frequency 4485 GHz, power 1 mW, mod. frequency 100 kHz, amp. 1.0 mT, $T$ = 4 K.

The temperature dependence of the UV/Vis spectrum of $[Cu^{II}(L^{Me})]^{\cdot 2+}$ precludes any investigation of its stability at 298 K, while $[Cu^{II}(HL^{Me})]^{\cdot 3+}$ was too unstable and degraded significantly even at 233 K. Complex $[Cu^{II}(L^{H})]^{\cdot 2+}$ has a decomposition rate constant $k_{decay}$ of 0.067 $min^{-1}$ ($t_{1/2}$ = 10.4 min at 298 K). This is 2.5 times weaker than that of $[Cu^{II}(L^{tBu})]^{\cdot 2+}$ ($k_{decay}$ = 0.155 $min^{-1}$), this is likely to be due to resonance stabilization in $[Cu^{II}(L^{H})]^{\cdot 2+}$. Moreover, $[Cu^{II}(L^{H})]^{+}$ exhibits an $E_{1/2}$ value (0.23 V vs. $Fc^{+}$/Fc) that is roughly similar to that of $[Cu^{II}(L^{F})]^{+}$ ($E_{1/2}$ = 0.20 V),[4] the structure of which differs from that of $[Cu^{II}(L^{H})]^{+}$ by the nature of phenolate *para* substituent, which is a fluorine atom. As the radical species $[Cu^{II}(L^{F})]^{\cdot 2+}$ decomposed during electrolysis at 233 K, $[Cu^{II}(L^{H})]^{\cdot 2+}$ it should be, in principle, too unstable to be characterized. This is not true, showing that charge delocalization over the benzimidazolium group contributes significantly to the chemical stability of the radical species $[Cu^{II}(L^{H})]^{\cdot 2+}$. This also shows that the usual correlation between the chemical stability of copper(II) phenoxyl radical species, and the potential values of the phenoxyl/phenolate redox couple, is not so evident when charge delocalization occurs. Complex $[Cu^{II}(HL^{H})]^{\cdot 3+}$ was much less stable than $[Cu^{II}(L^{H})]^{\cdot 2+}$ ($k_{decay}$ = 0.99 $min^{-1}$, $t_{1/2}$ = 0.7 min at 298 K), this is in agreement with the spectroscopic and electrochemical data. Protonation of benzimidazole, to produce a positively charged benzimidazolium group, makes it electron-withdrawing, which destabilizes the phenoxyl radical.

### Copper(II) Titration: Addition of 0 to 1 Molar Equivalent

The solution chemistry of each ligand has been studied in acetonitrile by increasing the ratio of copper(II) perchlorate to $HL^{H}$ and $HL^{Me}$. When one molar equiv. of copper(II) perchlorate is slowly added to an acetonitrile solution of $HL^{H}$, an absorption band appears gradually in the visible spectra at 526 nm (Figure 9), and EPR reveals the formation of a mononuclear copper(II) complex. These spectroscopic features well match those reported for the isolated copper(II) phenolate benzimidazolium species $[Cu^{II}(HL^{H})]^{2+}$. Likewise, the addition of one molar equiv.

of copper(II) to $HL^{Me}$ affords the copper(II) phenolate *N*-methylbenzimidazolium complex $[Cu^{II}(HL^{Me})]^{2+}$ (Figure 10). Thus, the coordination of the ligands to copper(II) induces a transfer of the phenolic proton to the benzimidazole (or *N*-methylbenzimidazole) substituent (Scheme 3, a). This behavior is in sharp contrast with that of $HL^{tBu}$ (Scheme 3, b), which after addition of one molar equiv. of copper(II) affords the copper(II) phenol complex $[Cu^{II}(HL^{tBu})]^{2+}$.[50] Moreover, formation of this phenol complex was more complicated than the simple reaction between the ligand $HL^{tBu}$ and copper(II). As 0 to 0.5 molar equiv. of copper(II) perchlorate was added, a progressive increase in the phenolate to copper(II) CT transition was observed, showing that once the copper is chelated to by some of the available ligand in solution, the tertiary amine of the remaining free ligand deprotonates the weakly coordinated phenol (i.e. the $pK_a$ of the coordinated phenol is lower than that of the tertiary ammonium, Scheme 3, b). When 0.5 to one molar equiv. of copper(II) is added to $HL^{tBu}$, the spectrum of the copper(II) phenolate complex $[Cu^{II}(L^{tBu})]^{+}$ vanishes and is replaced by that of the copper(II) phenol complex $[Cu^{II}(HL^{tBu})]^{2+}$. Complexation of copper(II) to the free protonated ligand $H_2L^{tBu+}$ induces deprotonation of its tertiary ammonium group; the proton is transferred to the coordinated phenolate of $[Cu^{II}(L^{tBu})]^{+}$, affording the copper(II) phenol complex $[Cu^{II}(HL^{tBu})]^{2+}$ (Scheme 3, b).

Thus proton transfer, coupled to copper(II) complexation, occurs in all cases ($HL^{tBu}$, $HL^{H}$ and $HL^{Me}$). Nevertheless, a major difference exists between $HL^{tBu}$ and $HL^{H}$ (and $HL^{Me}$) namely, the endogenous base: proton transfer is managed either by the tertiary amine of $HL^{tBu}$, or by the benzimidazole moiety in $HL^{H}$ or $HL^{Me}$. In all these tripodal ligands, the tertiary amine is involved in copper(II) coordination. When the proton is transferred from the tertiary amine (ammonium form), it does not chelate the metal thus, a mixture of the protonated ligand and the copper(II) phenolate complex is obtained when 0.5 molar equiv. of copper(II) is added to $HLt^{Bu}$. The benzimidazolium group does not interfere with the complexation processes. Thus, when the proton is transferred from the benzimidazole (or *N*-methylbenzimidazole) group of $HL^{H}$ and $HL^{Me}$, all of the ligand in solution chelates to the metal, and no free ligand remains, even when only 0.5 molar equiv. of copper(II) is added to the ligand. The existence, and location, of the proton acceptor in the ligand is therefore of crucial importance in dictating the mechanism by which copper(II) is chelated by tripodal ligands.

### Copper(II) Titration: Addition of 1 to 2 Molar Equivalents

The acetonitrile solutions of $HL^{H}$ and $HL^{Me}$ were titrated against copper(II), at 233 K, and up to two molar equiv. of copper(II) was added. When one to two molar equiv. of copper(II) was added, the phenolate to copper(II) CT transition at 524 nm (and 508 nm) of $[Cu^{II}(HL^{H})]^{2+}$ (and $[Cu^{II}(HL^{Me})]^{2+}$) progressively decreases in intensity and then vanishes, while new intense transitions appear at around 400, 450 and 700 nm. The UV/Vis spectrum of the final species exhibits intense absorption bands at 401, 435 and 700 nm [396, 440 (shoulder) and 700 nm for $HL^{Me}$]. These features are similar to those of the electrogenerated $[Cu^{II}(HL^{H})]^{\cdot 3+}$ complex (and $[Cu^{II}(HL^{Me})]^{\cdot 3+}$). The copper(II) phenolate complexes $[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$ are thus quantitatively oxidized by excess copper(II) to give the corresponding copper(II) phenoxyl complexes $[Cu^{II}(HL^{H})]^{\cdot 3+}$ and $[Cu^{II}(HL^{Me})]^{\cdot 3+}$, releasing free copper(I) according to Scheme 3 (a).[68]

When one molar equiv. of copper(II) was added to an acetonitrile solution of $HL^{tBu}$, the copper(II) phenol complex $[Cu^{II}(HL^{tBu})]^{2+}$ was obtained quantitatively. Continuing to add copper(II) results in the oxidation of a small amount of the $[Cu^{II}(HL^{tBu})]^{2+}$ complex (less than 8%) to give the radical species $[Cu^{II}(L^{tBu})]^{\cdot 2+}$, this is consistent with the oxidation potential of the phenol in $[Cu^{II}(HL^{tBu})]^{2+}$ being too high to allow it to be oxidized by copper(II) to produce the corresponding phenoxyl radical.[50]

After addition of one molar equiv. of copper(II) to $HL^{H}$ or $HL^{Me}$ deprotonation of the phenol occurs, induced by proton transfer to the benzimidazole or *N*-methylbenzimidazole substituent, which lowers its redox potential, making oxidation by exogenous copper(II) possible in the absence of exogenous base.[69] Deprotonation of the phenol group of $HL^{tBu}$ does not occur in the presence of one molar equiv. of copper(II), thus preventing its oxidation by excess copper(II).

On the other hand, if free copper(II) oxidizes the copper(II) phenolate complex, then one should expect the formation of a copper(II) phenoxyl complex at a copper(II)/ligand ratio lower than 1:1. This is not the case, showing that a comproportionation reaction consumes the radical once it is formed (as in the case of GO[70] and other $N_3O$ ligands[50]) according to Equation 1.

$$\text{copper(II) phenoxyl} + \text{copper(I)} \rightarrow 2\ \text{copper(II)}-\text{phenolate} \qquad (1)$$

## Conclusion

Herein we have reported a fine structural approach to the protonation/deprotonation sequence of the axial $Tyr_{495}$ in the GO active site. We have also provided evidence of a proton transfer reaction coupled to a copper(II) coordination process occurring in the ligands: in the presence of one molar equiv. of copper(II) the phenolic proton moves towards the *p*-benzimidazole (or *N*-methylbenzimidazole) substituent affording *p*-benzimidazolium phenolate complexes. In the presence of excess copper(II) (in absence of an exogenous base), a copper(II) phenoxyl radical is obtained, which was not observed for related ligands possessing a *p*-*tert*-butyl group. The existence and location of the proton acceptor (tertiary amine or benzimidazole) in the ligand is therefore of crucial importance in dictating the mechanism by which copper(II) is chelated, and influences the reactivity of the complex towards an exogenous oxidizer.

The control of the proton transfer and the metal coordination, are of prime importance in stabilizing phenoxyl radicals in proteins.[71–79] Recently, each phenomenon has been explored independently in biomimetic systems. This lead to the characterization of metal coordinated phenoxyl radicals,[16–50] or hydrogen bonded phenoxyl radicals generated by proton coupled to electron transfer.[80–83] Ligands $HL^H$ and $HL^{Me}$ are the first systems where both proton transfer and metal coordination occur simultaneously, contributing to the stabilization of the phenoxyl radical (by deprotonation, lowering of the redox potential by at least 0.35 V, metal coordination, and by resonance).

## Experimental Section

**General:** All chemicals were of reagent grade and used without purification. Microanalyses were performed by the Service Central d'Analyses du CNRS (Lyon, France).

Low-temperature visible spectra were recorded on a CARY 50 spectrophotometer equipped with a low temperature Hellma immersion probe (1.000 cm path length quartz cell). The temperature was controlled with a Lauda RK8 KS cryostat.

X-band EPR spectra were recorded on a BRUKER ESP 300E spectrometer equipped with a BRUKER nitrogen flow cryostat, and a BRUKER EMX spectrometer equipped with an ESR 900 helium flow cryostat (Oxford Instruments). Spectra were treated using the WINEPR software and simulated using the BRUKER SIMFONIA software.

Rate constants for the self-decomposition of the radical species were obtained spectrophotometrically. The absorbance decay at 450 nm (298 K) was fitted using the Biokine software (Bio Logic Co, Claix, France).

The cyclic and differential pulse voltammograms of each compound (1 mM) in $CH_3CN$, containing 0.1 M tetra-*n*-butylammonium perchlorate (TBAP) as the supporting electrolyte, were recorded on a CHI potentiostat at 298 K. The working electrode was a glassy carbon disc, and the secondary electrode was a Pt wire, and the reference electrode was 0.01 M $Ag/AgNO_3$. The potential of the regular ferrocenium/ferrocene ($Fc^+/Fc$) redox reaction, +0.087 V under our experimental conditions, was used as an internal reference. Electrolysis was performed at 233 K at a carbon felt electrode using a PAR 273 potentiostat.

**Crystal Structure Analysis:** For all structures, collected reflections were corrected for Lorentz and polarization effects, but not for absorption. The structures were solved by direct methods and refined using the TEXSAN software. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were generated at idealized positions, and were modeled as riding on the carrier atoms, and refined with isotropic thermal parameters.

CCDC-259962, -259841, -275709 and -275881 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**3-*tert*-Butyl-4-hydroxybenzaldehyde:** 2-*tert*-Butylphenol (20 g, 133 mmol) was dissolved in MeOH (80 mL), NaOH (80 g) was dissolved in water (80 mL) and added dropwise to the reaction mixture. Then $CHCl_3$ was added (during the course of 1 h) at 60 °C. The reaction mixture was stirred for 3 h, then cooled to 0 °C and hydrolyzed with 4 N HCl until the solution reached pH 5–6. The mixture was extracted with $CHCl_3$ and the combined organic layers were dried with $Na_2SO_4$ and then concentrated. Column chromatography on silica gel [ethyl acetate:pentane (1:20) was the eluent] yielded 3-*tert*-butyl-4-hydroxybenzaldehyde (24 g, 40%) as an orange solid. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 1.44 (s, 9 H), 6.85–6.89 [d, $^3J_{H,H}$ = 8.2 Hz, 1 H], 7.62–7.67 [dd, $^3J_{H,H}$ = 8.2 Hz, $^4J_{H,H}$ = 1.7 Hz, 1 H], 7.84–7.85 [d, $^4J_{H,H}$ = 1.7 Hz, 1 H], 9.84 ppm (s, 1 H). $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 29.7 (t, 3C), 35.1 (q), 117.5 (s), 129.9 (q), 130.6 (s), 137,6 (q), 161.2 (q), 192.3 ppm (s). M.p. 125 °C. $C_{11}H_{14}O_2$ (178.23): calcd. C 74.13, H 7.92; found C 73.45, H 7.85.

**2-*tert*-Butyl-4-(1-methyl-1*H*-benzoimidazol-2-yl)phenol:** To 3-*tert*-Butyl-4-hydroxybenzaldehyde (1.04 g, 5.8 mmol) in MeOH (20 mL) was added *N*-methyl-1,2-phenylenediamine (0.709 g, 5.8 mmol) at 0 °C. The mixture was stirred for 0.5 h at 0 °C, and then for 3 h at room temperature. Benzofuroxane (0.795 g, 5.8 mmol) was dissolved in $CH_3CN$ (5 mL), and added to the reaction mixture at room temperature. The mixture was stirred for 12 h at 60 °C, then cooled to 0 °C, and 10% NaOH (10 mL) was added. The reaction was poured into 200 mL of water, and concentrated HCl was added to neutralize the solution. The brown precipitate was filtered, washed with cold water and $CHCl_3$, and then dried under vacuum. Yield: 50%. $^1H$ NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 1.46 (s, 9 H), 3.89 (s, 3 H), 7.22–7.31 (m, 2 H), 7.54–7.60 (m, 2 H), 7.66–7.69 (m, 2 H), 10.00 ppm (s, 1 H). $^{13}C$ NMR (75 MHz, [D$_6$]DMSO): $\delta$ = 30.1 (t, 3C), 32.6 (t), 35.3 (q), 111.1 (s), 117.0 (s), 119.4 (s), 121.2 (q), 122.5 (s), 122.7 (s), 128.8 (s), 128.9 (s), 137.5 (q), 143.4 (q), 154.7 (q), 158.3 ppm (q). M.p. > 250 °C. MS (DCI, $NH_3$/isobutane) *m/z* (%): 280 (100) $[M+H]^+$. $C_{18}H_{20}N_2O$ (280.36): calcd. C 77.11, H 7.19, N 9.99; found C 75.40, H 7.21, N 9.76.

**$HL^{Me}$:** 2-*tert*-Butyl-4-(1-methyl-1*H*-benzoimidazol-2-yl)phenol (1.016 g, 3.6 mmol), bis(2-pyridylmethyl)amine (722 mg, 3.6 mmol) and formaldehyde (1.4 mL of a 37% aqueous solution) in EtOH/$H_2O$ (5:1, 100 mL) were refluxed together for 12 h. The reaction mixture was then extracted with ethyl acetate, dried with $Na_2SO_4$ and then concentrated. Column chromatography on silica gel [ethyl acetate/methanol (9:1) + 1% isopropylamine was the eluent] yielded $HL^{Me}$ (600 mg, 35%) as a pale orange solid. $^1H$ NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 1.49 (s, 9 H), 3.89 (s, 3 H), 3.91 (s, 4 H), 3.95 (s, 2 H), 7.21–7.34 (m, 4 H), 7.42–7.44 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H), 7.52–7.53 (d, $^4J_{H,H}$ = 2.0 Hz, 1 H), 7.56–7.60 (m, 1 H), 7.63–7.64 (d, $^4J_{H,H}$ = 2.0 Hz, 1 H), 7.65–7.68 (m, 1 H), 7.78–7.84 (m, $^3J_{H,H}$ = 4.7 Hz, $^4J_{H,H}$ = 1.7 Hz, 2 H), 8.59–8.60 (d, $^3J_{H,H}$ = 4.7 Hz, 2 H), 11.76 ppm (s, 1 H). $^{13}C$ NMR (75 MHz, [D$_6$]DMSO): $\delta$ = 32.6 (t), 35.4 (q), 57.2 (d), 59.2 (d), 111 (s), 119.4 (q), 120.5 (q), 122.5 (q), 122.7 (s), 123.4 (s, 2C), 124.0 (s, 2C), 128.1 (s), 129.8 (s), 136.8 (q), 137.5 (q), 137.7 (s, 2C), 149.7 (s, 2C), 154.6 (q), 158.4 ppm (q, 2C). MS (DCI, $NH_3$/isobutane) *m/z* (%): 492 (100) $[M+H]^+$. M.p. 150 °C. $C_{31}H_{33}N_5O$ (491.63): calcd. C 75.73, H 6.77, N 14.25; found C 75.65, H 7.01, N 14.19.

**$[Cu^{II}(HL^{Me})](ClO_4)_2$:** Ligand $HL^{Me}$ (132 mg, 0.269 mmol) was dissolved in $CH_3CN$ (10 mL) and $Cu(ClO_4)_2 \cdot 6H_2O$ (99 mg, 0.267 mmol) in $CH_3CN$ (2 mL) was then added dropwise. The solution was stirred for 15 min and then the volume was reduced to 2 mL. Single crystals of $[Cu^{II}(HL^{Me})](ClO_4)_2$ were obtained by slow diffusion of diisopropyl ether into the $CH_3CN$ solution (102 mg, yield: 68%). ESI MS (*m/z*): 553 $[M - H - (CH_3CN) - 2(ClO_4)]^+$. $C_{33}H_{36}Cl_2CuN_6O_9$ (795.13): calcd. C 49.85, H 4.56, N 10.57, Cu 7.99; found C 49.57, H 4.82, N 10.11, Cu 7.45.

**$[Cu^{II}(H_2L^{Me})](ClO_4)_3$:** Compound $[Cu^{II}(HL^{Me})](ClO_4)_2$ (23 mg, 0.029 mmol) was dissolved in $CH_3CN$ (1 mL), and $HClO_4$ (70%, 2.4 μL) was added. The solution was stirred for 5 min. Single crys-

tals of $[Cu^{II}(H_2L^{Me})](ClO_4)_3$ were obtained by slow diffusion of isopropyl ether into the $CH_3CN$ solution (18 mg, yield: 90%). ESI MS (*m*/*z*): 653 $[M - H - (CH_3CN) - 2(ClO_4)]^+$. $C_{33}H_{37}Cl_3CuN_6O_{13}$ (895.58): calcd. C 44.26, H 4.16, N 9.13, Cu 7.10; found C 44.18, H 4.13, N 9.13, Cu 6.88.

**4-(1*H*-Benzimidazol-2-yl)-2-*tert*-butylphenol:** To 3-*tert*-Butyl-4-hydroxybenzaldehyde (1.04 g, 5.8 mmol) in MeOH (20 mL) was added benzene-1,2-diamine (0.631 g, 5.8 mmol) at 0 °C. The mixture was stirred for 0.5 h at 0 °C, and then for 1 h at room temperature. Benzofuroxane (0.795 g, 5.8 mmol) was dissolved in $CH_3CN$ (5 mL), and added dropwise (over a 10 min period) to the reaction mixture. The mixture was stirred for 2 h at 60 °C, then cooled to 0 °C and then 10% NaOH (10 mL) was added. The reaction mixture was poured into 200 mL of water and concentrated HCl was added to neutralize the solution. The brown precipitate was filtered, washed with cold water and $CHCl_3$, and then dried under vacuum. Yield: 52%. $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 1.48 (s, 9 H), 6.95 (d, $J$ = 8.1 Hz, 1 H), 7.17 (dd, $^3J$ = 5.9 Hz, $^4J$ = 3.2 Hz, 2 H), 7.57 (dd, $^3J$ = 5.7 Hz, $^4J$ = 3.2 Hz, 2 H), 7.87 (dd, $^3J$ = 8.1 Hz, $^4J$ = 1.5 Hz, 1 H), 8.05 (d, $^4J$ = 1.5 Hz, 1 H), 9.94 (s, 1 H), 12.68 ppm (s, 1 H). $^{13}$C NMR (75 MHz, [D$_6$]DMSO): $\delta$ = 29.7 (t), 34.9 ($C_q$), 114.9 (CH), 116.8 (CH), 121.0 ($C_q$), 121.9 (CH), 125.6 (CH), 125.9 (CH), 136.2 ($C_q$), 139.7 ($C_q$), 152.6 ($C_q$), 158.2 ppm ($C_q$). M.p. > 250 °C. MS (DCI, $NH_3$/isobutane) *m*/*z* (%): 267 (100) $[M+H]^+$. $C_{17}H_{18}N_2O$ (266.34): calcd. C 76.66, H 6.81, N 10.52; found C 75.78, H 6.94, N 9.37.

**$HL^H$:** 2-*tert*-Butyl-4-(1*H*-benzoimidazol-2-yl)phenol (0.500 g, 1.88 mmol), bis(2-pyridylmethyl)amine (374 mg, 1.88 mmol) and formaldehyde (0.7 g of a 37% aqueous solution, 9.4 mmol) in EtOH/$H_2O$ (2:1, 100 mL) were refluxed together for 12 h. The reaction mixture was then extracted with ethyl acetate, washed with a saturated NaCl aqueous solution, dried with $Na_2SO_4$ and then concentrated. Column chromatography on silica gel [ethyl acetate/methanol (5:1)] yielded $HL^H$ (270 mg, 30%) as a beige solid. $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 1.50 (s, 9 H), 3.90 (s, 4 H), 3.94 (s, 2 H), 7.19 (dd, $^3J$ = 5.9 Hz, $^4J$ = 3.2 Hz, 2 H), 7.30 (d, $^3J$ = 6.5 Hz, 1 H), 7.32 (d, $^3J$ = 7.1 Hz, 1 H), 7.41 (d, $J$ = 7.8 Hz, 2 H), 7.50–7.62 (m, 2 H), 7.78 (td, $^3J$ = 7.6 Hz, $^4J$ = 1.6 Hz, 2 H), 7.87 (d, $^4J$ = 1.8 Hz, 1 H), 8.01 (d, $^4J$ = 1 Hz, 1 H, 8 Hz), 8.58 (d, $^3J$ = 4.0 Hz, 2 H), 11.73 (s, 1 H), 12.70 ppm (s, 1 H). $^{13}$C NMR (75 MHz, [D$_6$]DMSO): $\delta$ = 30.3 (*t*Bu), 35.6 ($C_q$), 57.6 ($CH_2$), 59.1 ($CH_2$Py), 121.0 ($C_q$), 122.4 (CH), 123.4 (CH), 123.9 (CH), 124.5 ($C_q$), 125.4 (CH), 127.6 (CH), 135.9 ($C_q$), 137.2 ($C_q$), 137.7 (CH), 144.9 ($C_q$), 149.7 (CH), 153.0 ($C_q$), 158.5 ($C_q$), 158.8 ppm ($C_q$). M.p. 200 °C. MS (DCI, $NH_3$/isobutane) *m*/*z* (%): 478 (100) $[M+H]^+$. $C_{30}H_{31}N_5O$ (477.60): calcd. C 75.44, H 6.54, N 14.66; found C 75.16, H 6.55, N 14.50.

**$[Cu^{II}(HL^H)](ClO_4)_2$:** $[Cu^{II}(HL^H)](ClO_4)_2$ was obtained in a similar way to $[Cu^{II}(HL^{Me})](ClO_4)_2$ by using $HL^H$ instead of $HL^{Me}$ (yield: 75%). ESI MS (*m*/*z*): 539 $[M - H - (CH_3CN) - 2(ClO_4)]^+$. $C_{32}H_{34}Cl_2CuN_6O_9{\cdot}H_2O{\cdot}CH_3CN$ (781.10): calcd. C 48.61, H 4.68, N 11.67, Cu 7.56; found C 47.92, H 4.51, N 11.68, Cu 7.50.

**$[Cu^{II}(H_2L^H)](ClO_4)_3$:** Complex $[Cu^{II}(H_2L^H)](ClO_4)_3$ was obtained in a similar way to $[Cu^{II}(H_2L^{Me})](ClO_4)_3$ by using $HL^H$ instead of $HL^{Me}$ (yield: 90%). ESI MS (*m*/*z*): 539 $[M - H - (CH_3CN) - 2(ClO_4)]^+$. $C_{32}H_{35}Cl_3CuN_6O_{13}$ (881.56): calcd. C 44.16, H 4.38, N 9.36, Cu 7.08; found C 44.51, H 4.35, N 9.70, Cu 6.75.

## Acknowledgments

The authors thank the Institute of Metals in Biology of Grenoble who provided facilities for performing the 4 K EPR studies, and Dr. Stephane Ménage for technical assistance with these experiments.

[55] UV/Vis data [$\lambda_{max}$ (nm) ($\varepsilon$ {$M^{-1}cm^{-1}$})] for $[Cu^{II}(L^{H})]^{\cdot 2+}$: 401 (6560), 435 (4270), 694 (2420); for $[Cu^{II}(HL^{H})]^{\cdot 3+}$: 400 (11044), 435 (5200), 689 (3310). Complex $[Cu^{II}(L^{Me})]^{\cdot 2+}$ was too unstable to allow accurate $\varepsilon$ values to be determined. The UV/Vis spectrum of $[Cu^{II}(L^{Me})]^{\cdot 2+}$ was found to be temperature-dependent (reversible process): the absorption bands at 395, 450 (shoulder) and 700 nm are only present at 298 K. Lowering the temperature to 233 K results in the disappearance of the lower energy absorption band, and changes in the 450 nm region. The same behavior is observed in the presence of excess pyridine (acting as an exogenous ligand, see ref.[4]). This is therefore not due to temperature dependent copper(II) coordination by the *p*-*N*-methylbenzimidazole moiety. Given the lack of additional information, more detailed discussion of this phenomenon would be premature.

[68] The thermodynamic feasibility of the reaction has been probed by recording the CV curve of $Cu(ClO_4)_2 \cdot 6H_2O$ in $CH_3CN$. The curve revealed a reduction peak at 0.32 V corresponding to the metal centered reduction wave of the hexaaquacopper(II). On the reverse scan, the oxidation peak is observed at a much higher value, 0.80 V, showing that a rearrangement in the metal coordination sphere occurs [this can be interpreted as the replacement of the water molecules by acetonitrile that stabilizes the copper(I) formal oxidation state]. The copper(II) ion is thus a strong oxidizer in acetonitrile, which can readily oxidize all of the copper(II) phenolate complexes ($[Cu^{II}(HL^{H})]^{2+}$ and $[Cu^{II}(HL^{Me})]^{2+}$) to the corresponding copper(II) phenoxyl radical complexes.
[69] When zero to one molar equiv. of copper(II) is added to acetonitrile solutions of $HL^{H}$, $HL^{Me}$ and $HL^{tBu}$, in the presence of $NEt_3$, the phenolate copper(II) complexes are obtained, whichever ligand is used (the exogenous base $NEt_3$ scavenges the phenolic proton). Addition of one to two molar equiv. of copper(II) results in the disappearance of the phenolate copper(II) complex (characterized by its phenolate to copper CT transition). The UV/Vis spectra, after the addition of two molar equiv. of copper(II), exhibit absorption bands at around 400, 435 and 700 nm for $HL^{H}$ and $HL^{Me}$, and 416 and 650 nm for $HL^{tBu}$. These features are similar to those of the electrogenerated $[Cu^{II}(L^{H})]^{\cdot 2+}$ and $[Cu^{II}(L^{tBu})]^{\cdot 2+}$ complexes, respectively. The copper(II) phenolate complexes are thus quantitatively oxidized by excess copper(II) to give the corresponding copper(II) phenoxyl complexes.

# Highly Ordered Functional Organosilicas by Template-Directed Hydrolysis-Polycondensation of Chiral Camphorsulfonamide Precursors

**Benoît Gadenne,[a] Peter Hesemann,[a] Vivek Polshettiwar,[a] and Joël J. E. Moreau*[a]**

**Keywords:** Mesoporous materials / Organic-inorganic hybrid composites / Sol–gel processes / Supported catalysts / Template synthesis

Trialkoxysilylated camphorsulfonamides have been used for the synthesis of functional organosilicas in a template-directed hydrolysis-polycondensation with tetraethylorthosilicate (TEOS). The sol–gel transformation leading to the formation of highly ordered materials indicates that trialkoxysilylated camphorsulfonamides allow the synthesis of functional organosilicas with high structural regularity. This behaviour arises from the affinity of the chiral precursors towards the lyotropic phase of the ionic surfactants in the aqueous hydrolysis-polycondensation mixture.

## Introduction

Since the discovery of the template-directed synthesis of nanostructured silica by Kresge et al. in 1992,[1] these materials have attracted considerable interest due to the unique properties related to their specific morphology, namely high specific surface, high pore volume and narrow pore-size distribution on a mesoscopic scale. These features make these materials the candidates of choice for numerous applications, for example in the fields of catalysis, separation and sensing.

The incorporation of functional organic groups into nanostructured silica can be achieved either in two steps by post-grafting of silylated precursor molecules onto the surface of nanostructured silica or in one step by a template-directed one-pot hydrolysis-polycondensation of a silica precursor with a functional organosilane.[2,3] The two methodologies lead to organosilicas with different morphological features: although materials obtained by the post-grafting method are structurally better defined and hydrothermally more stable than samples obtained by the direct one-step method, they often suffer from inhomogeneous distribution of the functional groups on the support surface. Contrary to this, the one-step condensation procedure affords materials with a homogeneous distribution of the functional organic groups over the whole surface.[4] However, in most cases only low functionalisation degrees can be achieved following the one-step method. Low-structured materials are obtained when high molar fractions of functional organosilane or bulky silylated precursors are used.[5,6] The upper limit of preservation of structural ordering is often reached with 20 mol-% of added organosilane.[6] For this reason, the elaboration of methods that allow the incorporation of bulky functional groups within a highly structured mesoporous organosilica material is highly desirable.

Our current interest in the preparation of ordered organosilicas led us to explore the synthesis of nanostructured silica hybrids containing ionic species.[7] As an example, we achieved the immobilisation of bis-alkylated imidazolium species on a silica support by a template-directed hydrolysis-polycondensation procedure. Supported ionic liquid phases have attracted large interest in the last few years[8] as these materials that consist of an ionic layer that covers the whole surface of a solid support are promising systems for applications in catalysis,[9–12] separation[13] and chromatography.[14] We were interested in exploring whether functional precursor molecules bearing ionic substructures would allow us to enhance the structural regularity of the obtained functional materials in template directed sol–gel processes. We report here a new nanostructured organosilica containing ionic and non-ionic (+)-camphorsulfonamide substructures as these moieties have been shown to be efficient auxiliaries in asymmetric catalysis.[15,16]

## Results and Discussion

We first focused on the synthesis of functional organosilanes bearing camphor substructures. The synthesis of the trialkoxysilylated camphorsulfonamide precursors **1** and **3** is shown in Scheme 1. The precursor **1** was obtained by the reaction of (+)-camphorsulfonyl chloride with 3-aminopropyltriethoxysilane (Scheme 1, top). Compound **3**, which bears an ionic imidazolium substructure, was synthesised by

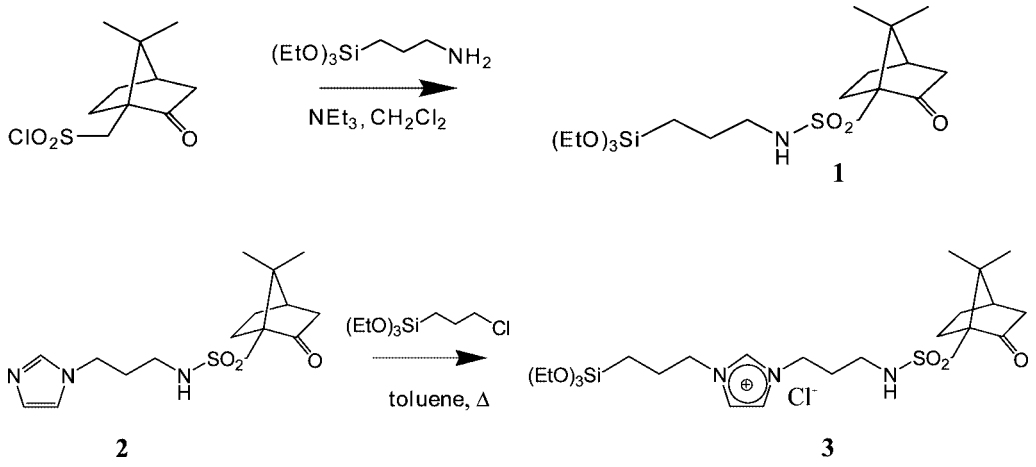
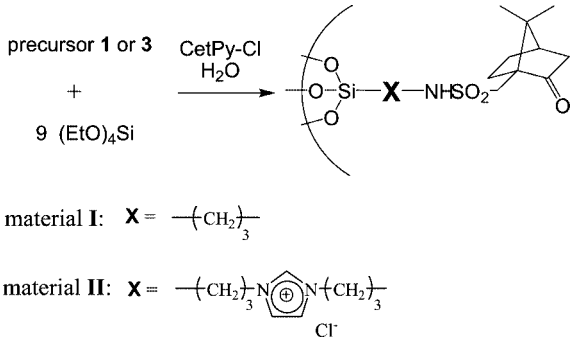


Scheme 1. Synthesis of the trialkoxysilylated camphorsulfonamides **1** (top) and **3** (bottom).

grafting 3-chloropropyltriethoxysilane to the camphorsulfonamide **2**[15] (Scheme 1, bottom). All reactions were quantitative, and the products could be used without further purification.

The synthesis of the organosilicas incorporating chiral camphorsulfonamide entities was then realised by a hydrolysis-polycondensation involving the chiral precursor **1** or **3** and tetraethoxysilane (TEOS; Scheme 2). All materials were prepared from alkaline mixtures containing TEOS, the trialkoxysilylated precursor **1** or **3**, water, ammonia and the surfactant hexadecylpyridinium chloride in the molar composition 0.9:0.1:114:8:0.12. We chose a pyridinium salt as template rather than an ammonium halide as the interaction between the imidazolium precursor **3** and pyridinium salts may be more favourable than that between imidazolium salts and surfactants based on ammonium substructures such as CTAB.[17] The resulting reaction mixture was heated to 80 °C for 48 h. The surfactant was then removed by washing in a Soxhlet apparatus and the materials were finally dried at 110 °C for 24 h.



Scheme 2. Immobilisation of camphorsulfonamide species on the surface of mesoporous nanostructured silica.

Elemental analysis of the materials **I** and **II** indicated nearly complete incorporation of the organic precursors **1** and **3** into the organosilica materials during the sol–gel procedure. The incorporation of the organic entities within the silica network was also qualitatively monitored by FT-IR and $^{29}Si/^{13}C$-CP MAS NMR spectroscopy. The $^{29}Si$ CP-MAS NMR spectrum of material **I** is shown as an example in Figure 1. As reported for other functionalised mesoporous silica materials,[6] the spectrum shows the $T^3$ peak at $\delta$ = –65.8 ppm arising from the $RSiO_3$ substructures and the $Q^3$ and $Q^4$ peaks ($\delta$ = 101.4 and 109.6 ppm) which can be ascribed to $SiO_4$ substructures with different condensation degrees.

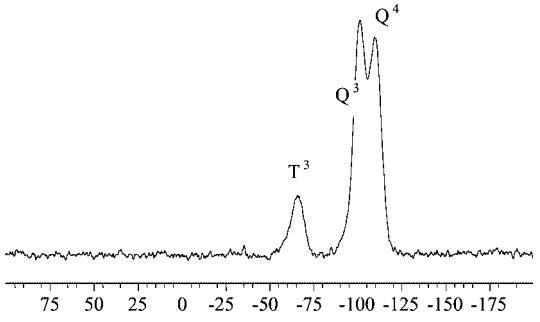


Figure 1. $^{29}Si$ CP MAS NMR spectrum of material **I**.

The morphological properties of materials **I** and **II** were investigated by XRD, TEM and nitrogen adsorption/desorption experiments. The XRD patterns of **I** and **II** are nearly identical and contain the (100), (110) and (200) peaks characteristic of hexagonal silica mesophases (Table 1). We have already obtained a material with a hexagonal architecture, although less regularly structured, using an ionic silylated dodecylimidazolium precursor.[7] The X-ray diffractograms of **I** and **II** are shown in Figure 2.

Table 1. XRD spacings of materials **I** and **II**.

| | *d* Spacings [nm] | | |
|---|---|---|---|
| | 100 | 110 | 200 |
| Material **I** | 4.00; | 2.31 | 2.00 |
| Material **II** | 4.00 | 2.30 | 1.99 |

The morphology of the materials was also studied by TEM. The TEM micrographs of **I** and **II** show a highly structured regular hexagonal array of two-dimensionally

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

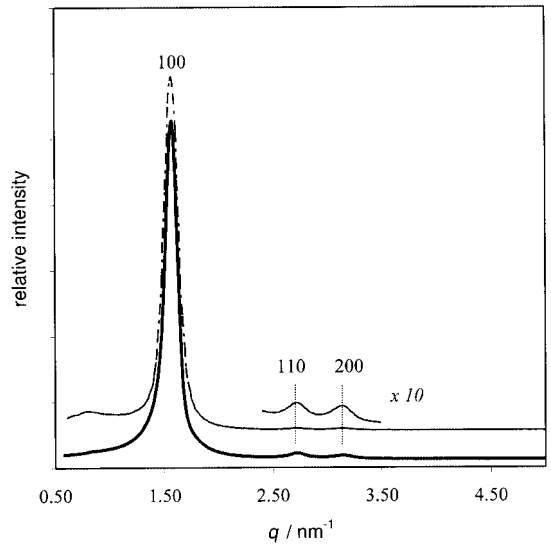

Figure 2. XRD patterns of the organosilica materials **I** (solid line) and **II** (dashed line).

aligned channels (Figure 3). In both cases, the distance between two pore centres was determined to be 4.0 nm, which corresponds to the (100) reflection in the XRD patterns.

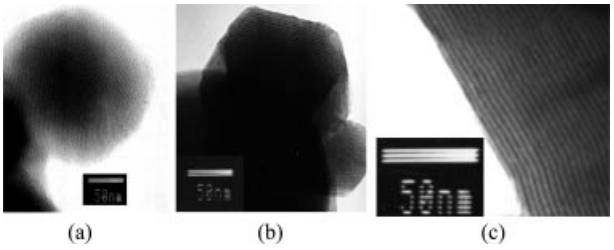

Figure 3. TEM micrographs of the functionalised organosilicas **I** (a) and **II** (b) along the (100) direction. (c) View along the (110) direction.

Thus, the TEM and XRD experiments give concordant results concerning the morphologies of materials **I** and **II**, which both appear as highly regularly structured solids with hexagonal symmetry. It has to be pointed out that the ionic substructure of precursor **3** does not have a significant effect on the structuration of the functionalised organosilica. The high structuration can rather be explained by the cosurfactant behaviour of the hydrolysed silylated precursors **1** and **3** in the basic aqueous media during the template-directed sol–gel procedure.

In a second experiment we studied the reduction of the carbonyl groups of the immobilised camphorsulfonamide entities in the porous material **II**. This reaction was performed with a suspension of sodium borohydride in methanol under reaction conditions identical to those reported for the reduction in homogeneous media.[15] This led to the formation of silica-supported borneol (material **III**). The reaction was monitored by FT-IR spectroscopy (disappearance of the absorption of the carbonyl group at $\tilde{\nu}$ = 1738 $cm^{-1}$). The ratio of the immobilized diastereoisomers could not be determined, but both borneol (*endo*) and isoborneol (*exo*) are probably formed. In solution, a 60:40 ratio has been reported (Scheme 3).[15]

Nitrogen adsorption/desorption experiments with materials **I**–**III** give information about the porosity and the pore volume of the samples. The isotherms of materials **I** and **II** reflect the formation of mesoporous silica hybrid materials with specific surface areas of 832 and 759 $m^2 g^{-1}$ and pore volumes of 0.52 and 0.49 $mL g^{-1}$, respectively. In both cases, the sorption curves show typical type-IV isotherms, thereby suggesting an ordered silica mesophase with pore diameters of 2.5 nm. The isotherm of material **II** shows a slight hysteresis loop due to capillary condensation of adsorbed nitrogen within the pores.[18] In contrast, material **III** shows a strongly reduced specific surface (82 $m^2 g^{-1}$), even after washing with acidic ethanol in a Soxhlet apparatus for three days. The reduced porosity of material **III** is probably due to the inclusion of borate ions within the pores during the reduction reaction. However, TEM and XRD experiments with material **III** confirm that the regular hexagonal structure of the silica framework is not affected. The sorption isotherms of materials **I**–**III** are presented in Figure 4.

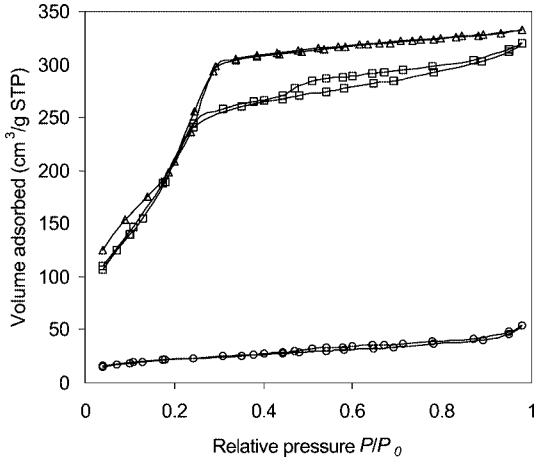

Figure 4. $N_2$ sorption curves of materials **I** (Δ), **II** (□) and **III** (○).

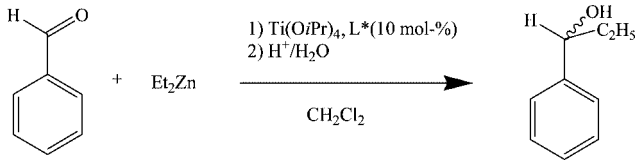
[a] General reaction conditions: benzaldehyde:ligand:Ti(O*i*Pr)$_4$:Et$_2$Zn = 1.0:0.1:1.1:1.2 (molar ratio), reaction time 18 h, reaction temperature 25 °C. [b] Determined by $^1$H NMR spectroscopy. [c] Determined by HPLC using a Daicel Chiralcel OD column.

### Heterogeneous Asymmetric Catalysis Using the Functional Organosilicas

The use of catalysts supported on mesoporous silica has been studied intensively.[19,20] Our interest in organic-inorganic hybrid materials as heterogeneous auxiliaries in asymmetric catalysis[21–23] led us to investigate materials **II** and **III**, which contain imidazolium substructures, as chiral auxiliaries in the asymmetric addition of diethylzinc to benzaldehyde. We also compared the catalytic properties of **II** and **III** with similar imidazolium salts bearing camphor or borneol substructures in homogeneous catalysis. The results of the utilisation of the various chiral auxiliaries in the addition of diethylzinc to benzaldehyde[24,25] (Scheme 4) are shown in Table 2.



Scheme 4. Addition of diethylzinc to benzaldehyde.

Materials **II** and **III** act as catalytic auxiliaries and lead to the formation of 1-phenylpropanol in quantitative yield (entries 1 and 3) after hydrolytic work-up with hydrochloric acid (1 N). Despite its low porosity, material **III** shows a higher enantioselectivity than material **II**. However, the selectivities of both materials are lower than those obtained with the related imidazolium salts in homogeneous solution, thus indicating a limited complexation of the catalytic Ti$^{IV}$ species by the immobilised chiral camphorsulfonamide entities (entries 2 and 4). The reduced enantioselectivities obtained with silica-immobilised camphorsulfonamide ligands are probably due to the reaction being catalysed by Ti$^{IV}$ species in a nonchiral environment, for example by Ti(*i*OPr)$_4$ in homogeneous solution or by Ti$^{IV}$ species grafted onto the silica surface via Si–O–Ti bonds. Furthermore, material **III** appears to be of low recyclability. The second utilisation still gave high conversion, but no enantioselectivity was observed. We conclude therefore that the acidic work-up after the first reaction cycle strongly modifies the surface of the material by condensing oxidic Ti and Zn species, thus inhibiting the accessibility of the immobilised chiral ligand.

## Conclusion

We have shown the formation of highly ordered mesoporous silica with a hexagonal architecture containing chiral camphorsulfonamide substructures located in the pores. Both ionic and non-ionic precursors lead to the formation of highly structured materials with hexagonal symmetry. The high structuration of the materials can be explained by the high affinity of the silylated camphorsulfonamides towards the organised micellar phase of the surfactants in aqueous medium: the trialkoxysilylated camphorsulfonamides behave as co-surfactants and fit in the micellar arrangement of the hexadecylpyridinium chloride.[26] The ionic imidazolium substructure of precursor **3** does not show a significant effect during the template-directed hydrolysis polycondensation: material **II** does not show a higher structural regularity than material **I**. The utilisation of these functional organosilicas as chiral auxiliaries in asymmetric catalysis indicated inferior catalytic properties of the materials compared to related task-specific imidazolium salts in terms of selectivity and recyclability. These results are probably due to incomplete complexation of the titanium-based complexes to the camphorsulfonamide sites; considerable amounts of titanium may be linked to the silica support by covalent Si–O–Ti bonds.

To the best of our knowledge, material **II** is the first example of a chiral ionic substructure grafted onto a nano-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structured silica support. We believe that these highly porous functionalised materials may find applications in molecular recognition, in particular as chiral stationary phases in liquid chromatography.

## Experimental Section

**General:** All reactions were performed under nitrogen or argon using Schlenk-tube techniques when necessary. Elemental analyses were performed by the "Service Central de Microanalyse du CNRS" at Vernaison, France. Mass spectra were measured with a Jeol JMS-DX300 mass spectrometer. FT-IR spectra were recorded from KBr pellets or films with a Perkin–Elmer 1000 FT-IR spectrometer. $^1$H, $^{13}$C and $^{29}$Si liquid NMR spectra were recorded with a Bruker AC-250 spectrometer. $CDCl_3$ and [$D_6$]DMSO were used as NMR solvents. Chemical shifts are reported as $\delta$ values in ppm relative to TMS. $^{13}$C and $^{29}$Si CP MAS solid-state NMR spectra were recorded with a Bruker FT AM 400 FT-NMR spectrometer. Specific surface areas were determined by nitrogen adsorption/desorption experiments using a Micromeritics Gemini 2375 apparatus. TEM was performed with a Jeol 1200EX II electron microscope. X-ray diffraction measurements and data treatment were performed at the Groupe de Dynamique de Phases Condensées at the University of Montpellier 2. The X-ray diffraction experiments were carried out on solid powders in glass capillaries (1 mm diameter) in a transmission configuration. A copper rotating anode X-ray source (4 kW) with a multilayer focusing "Osmic" monochromator giving high flux ($10^8$ photons per second) and a pinhole collimation was employed. An "image plate" 2D detector was used, and the data obtained were radially averaged to yield the diffracted intensity as a function of the wave vector $q$. The diffracted intensity was corrected for exposure time, transmission and the background scattering arising from an empty capillary. The enantiomeric excess of 1-phenylpropanol was determined by chiral HPLC using a Waters 515 HPLC pump with a Waters 2487 UV detector and a Daicel Chiralcel OD column using a hexane/2-propanol mixture as eluent. All reagents were obtained from commercial sources and used without purification. In experiments requiring dry solvents, THF, toluene and diethyl ether were distilled from sodium/benzophenone, DMF was distilled from $CaH_2$, dichloromethane was distilled from $P_2O_5$ and alcohols were distilled from Mg. *C*-(7,7-Dimethyl-2-oxobicyclo[2.2.1]heptan-1-yl)-*N*-(3-imidazol-1-ylpropyl)-methanesulfonamide (**2**) was synthesised as described before.[15]

**Synthesis of the Trialkoxysilylated Precursors**

**1-(7,7-Dimethyl-2-oxobicyclo[2.2.1]heptan-1-yl)-*N*-[3-(triethoxysilyl)-propyl]methanesulfonamide (1):** (+)-Camphor-10-sulfonyl chloride (1 g, 4 mmol), (3-aminopropyl)triethoxysilane (0.9 g, 4 mmol) and triethylamine (0.45 g, 4.5 mmol) were stirred in dichloromethane (10 mL) at room temperature for 6 h. After completion, dichloromethane was evaporated and the resulting residue was extracted with diethyl ether. After evaporation of the solvent, the product was obtained as a colourless oil. Yield: 1.66 g (95%). $^1$H NMR ($CDCl_3$): $\delta$ = 0.68 (m, 2 H), 0.92, 1.04 (2 s, 6 H, 2×$CH_3$), 1.23 (t, $J$ = 7.1 Hz, 9 H), 1.4–1.5 (m, 1 H), 1.72 (m, 2 H), 1.85–2.45 (m, 6 H), 2.91 (d, $J$ = 14.6 Hz, 1 H), 3.17 (m, 2 H), 3.41 (d, $J$ = 14.6 Hz, 1 H), 3.83 (q, $J$ = 7.1 Hz, 6 H), 5.42 (broad t, 1 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 7.9, 18.6, 19.9, 20.2, 24.0, 26.7, 27.4, 43.1, 43.2, 46.4, 48.9, 49.6, 58.8, 59.4, 216.9 ppm. FT-IR (film): $\tilde{\nu}$ = 3288 cm$^{-1}$, 2973, 2888, 1746, 1330, 1147, 1079. HRMS [FAB+]: calcd. for $C_{19}H_{38}NO_6SSi$ [M + H]$^+$ 436.2189; found 436.2193.

**1-[3-(2-Hydroxy-7,7-dimethylbicyclo[2.2.1]hept-1-ylmethylsulfonylamino)propyl]-3-(3-triethoxysilyl)propyl-1*H*-imidazol-1-ium Chloride (3):** Under argon, 1 g (2.94 mmol) of **2** was dissolved in toluene (20 mL) and 3-chloropropyltriethoxysilane (0.71 g, 2.94 mmol) was added whilst stirring. The reaction mixture was heated to 80 °C during 48 h. After cooling to room temperature, the biphasic mixture was washed with diethyl ether (3×30 mL). Finally, the ether-insoluble layer was dried under reduced pressure. The product was obtained as a highly viscous yellow liquid. Yield: 1.60 g (94%). $^1$H NMR ($CDCl_3$): $\delta$ = 0.54 (m, 2 H), 0.84, 0.97 (2 s, 6 H, 2×$CH_3$), 1.15 (t, 9 = H, $J$ = 7.2 Hz), 1.38 (m, CH), 1.8–2.1 (m, 6 H, 3×$CH_2$), 2.29 (m, 4 H, 2×$CH_2$), 2.85 (d, $J$ = 15 Hz, 1 H), 3.11 (m, 2 H, $CH_2$), 3.33 (d, $J$ = 15 Hz, 1 H), 3.72 (q, $J$ = 7.2 Hz, 6 H), 4.17 (t, $J$ = 6.6 Hz, 2 H, $NCH_2$), 4.40 (t, $J$ = 6.8 Hz, 2 H), 6.40 (t, $J$ = 6.4 Hz, 1 H, NH), 7.68 (s, 2 H), 9.65 (s, 1 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 7.6, 14.4, 18.7, 20.0, 20.3, 20.7, 24.5, 26.1, 27.4, 30.7, 34.5, 40.2, 43.2, 47.6, 48.3, 52.4, 59.0, 122.3, 123.4, 137.0, 216.5 ppm. HRMS [FAB+]: calcd. for $C_{25}H_{46}N_3O_6SSi$ [M]$^+$ 544.2877; found 544.2859 (cation).

**Synthesis of the Materials:** Whilst stirring, the trialkoxysilylated precursor **1** or **3** was added to a solution of cetylpyridinium chloride in aqueous ammonia. The resulting mixture was vigorously stirred for 20 min at 30 °C. After this time, TEOS was added to the reaction mixture dropwise. The molar composition of the hydrolysis-polycondensation mixture was as follows: TEOS/**1**(**3**)/water/ammonia/hexadecylpyridinium chloride = 0.9:0.1:114:8:0.12. The resulting mixtures were heated to 80 °C for 48 h. The surfactant was removed by repeated washing with acidic ethanol and the materials were finally dried at 110 °C for 24 h.

**Material I:** $^{29}$Si CP MAS NMR: $\delta$ = –65.8, –101.5, –109.6 ppm. $^{13}$C CP MAS NMR: $\delta$ = 7.9, 18.1, 21.7–25.1, 42.6, 47.9, 58.7, 217.1 ppm. BET surface area: 832 m$^2$g$^{-1}$. FT-IR (KBr pellet): $\tilde{\nu}$ = 2969 cm$^{-1}$, 1640, 1224, 1067. Elemental analysis: C 15.83, H 2.87, N 1.56, S 2.73, Si 31.88.

**Material II:** $^{29}$Si CP MAS NMR: $\delta$ = –66.3, –101.0, –110.0 ppm. $^{13}$C CP MAS NMR: $\delta$ = 7.9, 21.9, 25.0, 42.9, 49.7, 58.3, 124.2, 133.7, 216.5 ppm. BET surface area: 759 m$^2$g$^{-1}$. FT-IR (KBr pellet): $\tilde{\nu}$ = 3452 cm$^{-1}$, 2973, 1738, 1636, 1225, 1146, 1071. Elemental analysis: C 18.23, H 3.20, N 3.26, S 2.50, Si 27.27.

**Material III:** The organosilica **II** (1.00 g) was suspended in methanol (10 mL) and cooled to 0 °C. Sodium borohydride (50 mg) was then added and the resulting mixture was stirred at this temperature for 2 h. The suspension was then filtered. The resulting residue was extracted in a Soxhlet apparatus with acidified ethanol for 72 h and finally dried at 110 °C for 24 h. Yield: 960 mg. $^{29}$Si CP MAS NMR: $\delta$ = –66.1, –100.0, –109.1 ppm. $^{13}$C CP MAS NMR: $\delta$ = 8.0, 19.0, 29.6, 45.5, 48.6, 49.8, 124.0, 134.0. BET surface area: 82 m$^2$g$^{-1}$. FT-IR (KBr pellet): $\tilde{\nu}$ = 3458 cm$^{-1}$, 2961, 1645, 1225, 1065. Elemental analysis: C 17.84, H 3.31, N 3.20, S 2.66, Si 26.73.

**General Procedure for the Addition of Diethylzinc to Benzaldehyde:** The functional organosilica was placed in a Schlenk tube and dried under vacuum at 100 °C dfor 1 h. After cooling to room temperature, dichloromethane (10 mL) and Ti(*i*OPr)$_4$ (313 mg, 1.1 mmol) were added to the solid. The resulting suspension was stirred at room temperature for 1 h. After this time, diethylzinc (1.2 mL of a 1 M solution in hexanes) was added and the mixture was stirred for another 15 min. Finally, after the addition of benzaldehyde (100 μL, 1 mmol), the suspension was stirred for 18 h at room temperature. The reaction mixture was then filtered and the residue was washed with dichloromethane. 1 mL of ethanol was added to the filtrate, which was completely hydrolysed by the addition of 15 mL of hydrochloric acid (1 N). Extraction of the solution with dichloromethane, drying and evaporation afforded the reaction products, which were analysed in order to determine the conversion

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and the enantiomeric excess. The recovered organosilica was dried at 100 °C under reduced pressure.

# Lanthanide(III) Double-Decker Complexes with Octaphenoxy- or Octathiophenoxyphthalocyaninato Ligands – Revealing the Electron-Withdrawing Nature of the Phenoxy and Thiophenoxy Groups in the Double-Decker Complexes

**Guifen Lu,[a] Ming Bai,[a] Renjie Li,[a] Xianxi Zhang,[a] Changqin Ma,[a] Pui-Chi Lo,[b] Dennis K. P. Ng,[b] and Jianzhuang Jiang*[a]**

**Keywords:** Phthalocyanine / Rare earth / Double-decker / Phenoxy group / Thiophenoxy group

A series of heteroleptic and homoleptic bis(phthalocyaninato) lanthanide(III) complexes, namely M(Pc)[Pc(OPh)$_8$], M[Pc(OPh)$_8$]$_2$, Eu(Pc)[Pc(SPh)$_8$], and Eu[Pc(SPh)$_8$]$_2$ [M = Eu, Ho, Lu; Pc = unsubstituted phthalocyaninate; Pc(OPh)$_8$ = 2,3,9,10,16,17,23,24-octaphenoxyphthalocyaninate; Pc(SPh)$_8$ = 2,3,9,10,16,17,23,24-octathiophenoxyphthalocyaninate] (**1**–**8**) have been prepared. The molecular structure of Eu[Pc(OPh)$_8$]$_2$ (**4**) has been determined by single-crystal X-ray diffraction analysis. All of the new sandwich compounds have been characterized with various spectroscopic methods. Their electrochemical characteristics show that the introduction of phenoxy or thiophenoxy groups onto the peripheral positions of the phthalocyaninato ligand makes the double-decker harder to oxidize and easier to reduce than the analogous compounds without the (thio)phenoxy group. Theoretical calculations, with the semi-empirical PM3 method, indicate that the change in the energy level of the frontier orbitals of these ligands induced by the electron-withdrawing substituents is responsible for these unusual electrochemical properties.

## Introduction

It is well established that bis(phthalocyaninato) metal complexes can serve as molecular materials for electronic devices such as semiconductors, visual displays, and field-effect transistors because of their intriguing electrical and optical properties.[1–3] As the bulk characteristics of molecular materials are closely related to the properties of individual molecules, various modifications have been made on these sandwich compounds with the goal to improve their performance as advanced materials. To facilitate the solution processing fabrication and formation of various mesophases and supramolecular structures, long alkyl chains, oxyethylene chains, or crown-ether units are usually added onto the peripheral or non-peripheral positions of the macrocyclic ligands.[1–3] However, to the best of our knowledge, there has been no report on double-decker complexes that contain phthalocyanine ligands substituted with eight bulky phenoxy groups at either the peripheral or non-peripheral positions. In this paper, we describe the synthesis, structure, spectroscopic, and electrochemical properties of a new series of eight homoleptic and heteroleptic lanthanide(III) complexes with octa-β-phenoxy or thiophenoxy phthalocyaninato ligands. Schematic structures of these compounds are shown in Figure 1.

It is worth noting that the electronic nature of the phenoxy and thiophenoxy groups has been a point of debate. They are usually regarded as an electron-donating group because of their similarity to the alkoxy or thioalkoxy groups,[4] but they can also act as an electron-withdrawing group depending on the nature of the group connected to these substituents.[5] In the present case, electrochemical studies showed that the introduction of eight phenoxy or thiophenoxy groups on the peripheral positions of the phthalocyaninato ligands slightly hinders the oxidation and facilitates the reduction of the resulting double-decker complexes. Similar results have also been previously observed for the metal-free 2(3),9(10),16(17),23(24)-tetraphenoxyphthalocyanine and 2,3,9,10,16,17,23,24-octaphenoxyphthalocyanine.[6] The results also revealed the electron-withdrawing nature of these substituents in the double-decker complexes. This was in agreement with the calculations on the frontier molecular orbitals of the metal-free phthalocyaninato ligands $H_2Pc$, $H_2Pc(OPh)_8$, and $H_2Pc(SPh)_8$.

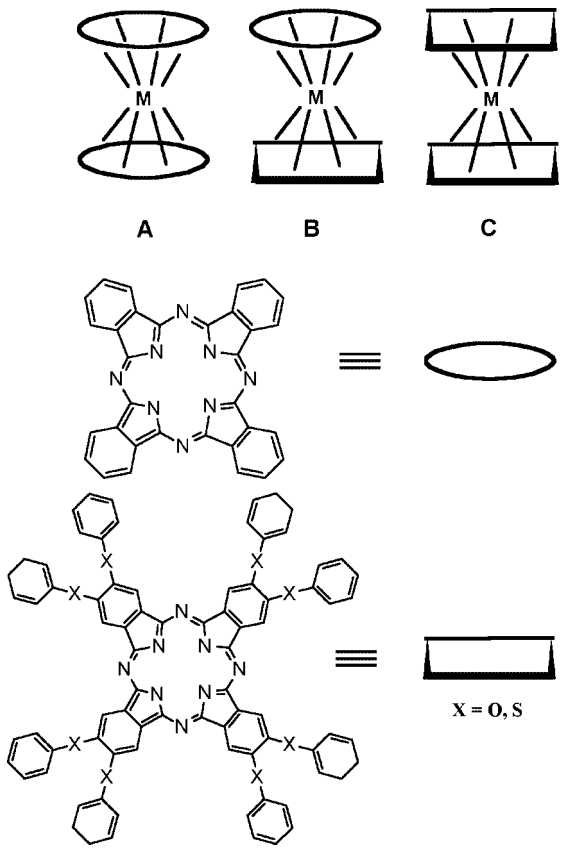

Figure 1. Schematic structures of bis(phthalocyaninato) lanthanide(III) complexes.

## Results and Discussion

### Synthesis

A substantial number of bis(phthalocyaninato)rare earth complexes have been synthesized and characterized.[1–3] A classical method for the preparation of homoleptic sandwich compounds involves the self-cyclic tetramerization of phthalonitriles in the presence of metal salts, whereas the heteroleptic analogues are usually prepared by the treatment of a rare earth acetate with two different lithium phthalocyaninates.[7–9] To facilitate the preparation and purification, in the present work, heteroleptic double-deckers M(Pc)[Pc(OPh)$_8$] (M = Eu, Ho, Lu) (**1**–**3**) and Eu(Pc)[Pc(SPh)$_8$] (**7**) were obtained by cyclic tetramerization of the corresponding disubstituted phthalonitriles with the half-sandwich compounds M(Pc)(acac) as the template in refluxing *n*-pentanol in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU).[10] It is worth mentioning that half-sandwich phthalocyaninato rare earth complexes M(Pc)(acac) were usually prepared by the reaction of M(acac)$_3$·*n*H$_2$O with Li$_2$Pc.[1b,1c] We found that M(Pc)(acac) could be easily synthesized and isolated by the treatment of M(acac)$_3$·*n*H$_2$O with phthalonitrile and DBU in *n*-pentanol at 100 °C for a short period of time (1.5 h). This method could also be applied to substituted phthalonitriles for the preparation of M[Pc(OPh)$_8$](acac) and Eu[Pc(SPh)$_8$](acac) complexes.

For the purpose of comparative studies, homoleptic analogues M[Pc(OPh)$_8$]$_2$ (M = Eu, Ho, Lu) (**4**–**6**) and Eu[Pc(SPh)$_8$]$_2$ (**8**) were also synthesized by the general cyclic tetramerization method.

### Spectroscopic Characterization

Satisfactory elemental analyses (Table 1) were obtained for both the heteroleptic and homoleptic double-decker complexes **1**–**8**, which had been repeatedly purified by column chromatography and recrystallization. These new sandwich compounds were also characterized with a range of spectroscopic methods. The MALDI-TOF mass spectra of **1**–**8** showed an intense cluster corresponding to the molecular ion (M$^+$); these data are also given in Table 1.

The electronic absorption data of this series of compounds were measured in CHCl$_3$ and are compiled in Table 2. Typical electronic absorption spectra of heteroleptic and homoleptic bis(phthalocyaninato)rare earth(III) complexes were observed for these newly prepared compounds, and the bands could therefore be assigned in a similar manner. Figure 2 displays the electronic absorption spectra of Eu(Pc)[Pc(OPh)$_8$] (**1**) and Eu[Pc(OPh)$_8$]$_2$ (**4**) as typical examples of the heteroleptic and homoleptic series, together with that of the unsubstituted Eu(Pc)$_2$. Compared with the unsubstituted analogues, almost all of the absorptions of M(Pc)[Pc(OPh)$_8$] (**1**–**3**) and Eu(Pc)[Pc(SPh)$_8$] (**7**) were redshifted when one Pc ring was replaced by the substituted ligand Pc(OPh)$_8$ or Pc(SPh)$_8$. Further redshifts were observed in the electronic absorption spectra of

M[Pc(OPh)$_8$]$_2$ (**4**–**6**) and Eu[Pc(SPh)$_8$]$_2$ (**8**) as a result of the replacement of the second Pc ring by Pc(OPh)$_8$ or Pc(SPh)$_8$ (Table 2). It is worth noting that in comparison with those of the alkoxy-substituted bis(phthalocyaninato)europium counterparts, namely Eu(Pc)[Pc(OC$_5$H$_{11}$)$_8$][10a] and Eu[Pc(OC$_5$H$_{11}$)$_8$]$_2$,[10d] a significant redshift takes place in the main absorption band in the near IR range of the thiophenoxy-substituted double-decker compounds **7** and **8**. In contrast, an insignificant shift was observed for the same band of phenoxy-substituted double-decker compounds **2** and **3**.

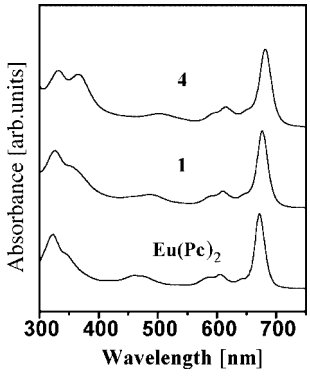

Figure 2. UV/Vis spectra of Eu(Pc)$_2$, Eu(Pc)[Pc(OPh)$_8$] (**1**), and Eu[Pc(OPh)$_8$]$_2$ (**4**) in $CHCl_3$.

IR spectroscopy is a very useful tool for the characterization of the phthalocyaninato ligand in sandwich tetrapyrrole complexes.[11] The IR spectra of **1**–**8** shows a medium-to-strong band in the range of 1317–1326 cm$^{-1}$, as observed for M(Pc)$_2$ (M = Eu, Ho, Lu), which is a diagnostic marker band for the phthalocyanine π-radical anions Pc$^{\bullet-}$, [Pc(OPh)$_8$]$^{\bullet-}$, and [Pc(SPh)$_8$]$^{\bullet-}$.

Upon the addition of hydrazine hydrate as a reducing agent,[12,13] well-resolved $^1$H NMR spectra were obtained for the reduced form of bis(phthalocyaninato)lanthanide(III) complexes **1**–**8**, in which both the macrocyclic ligands become diamagnetic dianions. Figure 3 shows the $^1$H NMR spectrum of the reduced form of **7**. For this heteroleptic compound, the non-peripheral and peripheral protons of the unsubstituted phthalocyaninato ligand resonate at $\delta$ = 11.08 and 9.09 ppm, respectively, as two relatively broad signals, whereas the non-peripheral protons of the substituted phthalocyanine ring resonate as a singlet at $\delta$ = 10.79 ppm. Three well-resolved signals at $\delta$ = 8.79–8.82 (doublet), 8.29–8.34 (triplet), and 8.07–8.12 (triplet) ppm in the ratio of 2:2:1 are shown for the thiophenoxy *ortho*, *meta*, and *para* protons, respectively. The observation of only one group of signals for the pairs of *ortho* and *meta* protons of the thiophenoxy group suggests that the thiophenoxy group is relatively free to rotate along the C$_{ipso}$–S bond in the double-decker complex under these conditions. Similar results were observed for phenoxy analogues **1**–**6**. This is in contrast to the restricted rotation of the aryl groups of *meso*-tetraarylporphyrinato ligands in double-decker complexes M(Por)(Ring) [Por = *meso*-tetrakis(4-chlorophenyl)porphyrinate (TClPP), *meso*-tetrakis(4-*tert*-butylphenyl)porphyrinate (TBPP); Ring = general phthalocyaninate (Pc′), general naphthalocyaninate (Nc′)].[12,14,15] This could be due to the lower steric hindrance of the additional *O*/*S* atom.

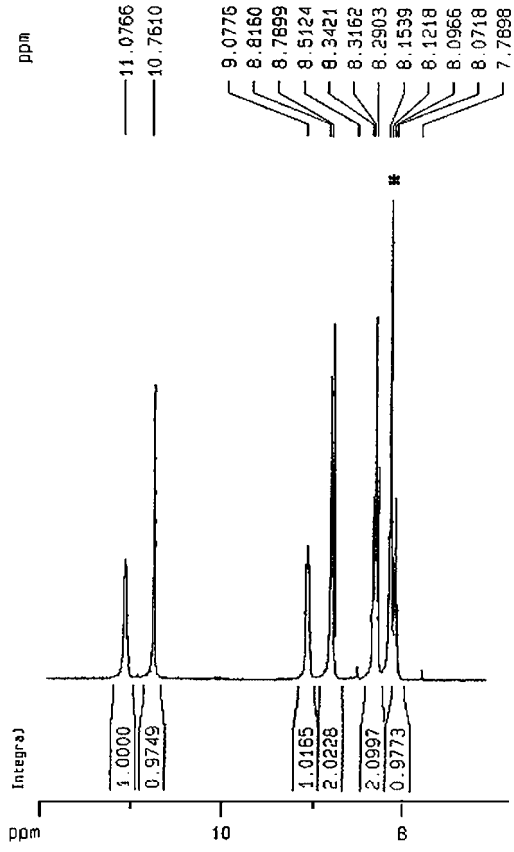

Figure 3. $^1$H NMR spectrum of the reduced form of Eu(Pc)[Pc(SPh)$_8$] (**7**) in $CDCl_3$/[D$_6$]DMSO (1:1) which contains ca. 1% hydrazine hydrate; * indicates residual $CHCl_3$.

### Structural Studies

Single crystals of Eu[Pc(OPh)$_8$]$_2$ (**4**) for X-ray diffraction analysis were obtained by the slow diffusion of MeOH into a THF solution of this compound. Unfortunately, the quality of the crystals was not high enough to obtain a suitable X-ray structure. Even when the data were collected at –150 °C, the $R_1$ value (0.1854) was still relatively high. This might be related to the disorder of the phenoxy groups. According to this set of data, the compound crystallizes in the orthorhombic system with eight double-decker molecules per unit cell. Figure S1 (Supporting Information) shows the molecular structure of **4** from two different perspectives. The europium center is octa-coordinated by the isoindole nitrogen atoms of the two octaphenoxyphthalocyaninato ligands with an average Eu–N bond length of 2.439 Å, and forms a square antiprism. The two $N_4$ mean planes are virtually parallel (dihedral angle = 0.4°) with a plane-to-plane separation of 2.851 Å with the europium atom lying in the center between the two ligands. In a similar structure to that of other bis(tetrapyrrole)rare earth double-decker complexes, such as Ce(Pc)(TPyP),[12] the two ligands are not planar and display a saucer shape. The extent of ligand deformation, as defined by the average dihedral angle $\varphi$ of the individual isoindole rings with respect to the corresponding $N_4$ mean plane, is 7.2°. The twist angle, which is defined as the rotation angle of one ring away from the eclipsed conformation of the two rings, is close to 45° for this complex; this shows that the two ligands are almost fully staggered. This staggered orientation probably acts to minimize the nonbonding interactions between the two substituted phthalocyanines.

### Electrochemical Properties

The electrochemical behavior of compounds **1**–**8** was examined by cyclic voltammetry (CV) and by differential pulse voltammetry (DPV), and the results are summarized in Table 3. For comparison, the data for the unsubstituted analogue Eu(Pc)$_2$ were also listed.[16] For all these complexes, one to two quasi reversible one-electron oxidation(s) and four to five quasi reversible one-electron reductions were revealed. The first oxidation and the first reduction processes involve the removal of an electron from and the addition of an electron to the singly occupied molecular orbital, respectively. Comparison of the first oxidation potentials and the first reduction potentials among the set M(Pc)$_2$, M(Pc)[Pc(OPh)$_8$], and M[Pc(OPh)$_8$]$_2$, and among the set Eu(Pc)$_2$, Eu(Pc)[Pc(SPh)$_8$], and Eu[Pc(SPh)$_8$]$_2$, reveals that the incorporation of the eight phenoxy or thiophenoxy groups on the phthalocyanine ring makes the compounds slightly harder to oxidize and easier to reduce than the analogous compounds without the (thio)phenoxy group. These results are in contrast to those found for alkoxy- or alkyl-substituted phthalocyanines, which clearly reveal the electron-withdrawing nature of these phenoxy and thiophenoxy substituents on the phthalocyaninato ligand.[16]

According to our calculations on the frontier molecular orbitals, with the semi-empirical PM3 method, the introduction of eight phenoxy or thiophenoxy groups on the peripheral positions of the phthalocyaninato ligand results in a decrease in the energy of the HOMO of the macrocycle ligand (Figure 4). As a result, these substituents at the peripheral positions of the phthalocyaninato ligand act mainly as electron-withdrawing groups and make this macrocyclic ligand harder to oxidize and easier to reduce.

On the basis of previous discussions, the interactions between the two rings of the monomer cause a splitting of their π-HOMO and π-LUMO, which results in a decrease in the energy of the HOMO and LUMO of the bis(phthalocyaninato)europium double-decker complexes.[16,17] This is supported by the experimental results. As shown in Table 3, the halfwave potentials for the first oxidation and reduction potentials (Oxd$_1$ and Red$_1$), which involve the HOMO of the double-decker complexes, are shifted in the more positive direction along with the increase in the number of Pc(OPh)$_8$ or Pc(SPh)$_8$ ligands from M(Pc)$_2$, M(Pc)[Pc(OPh)$_8$], to M[Pc(OPh)$_8$]$_2$ or from Eu(Pc)$_2$, Eu(Pc)[Pc(SPh)$_8$], to Eu[Pc(SPh)$_8$]$_2$, whereas the potentials for the second and third reductions, Red$_2$ and Red$_3$, which now involve the LUMO of these compounds, are also shifted in the positive direction in the same order.

The effect of the size of the rare earth metal is demonstrated, again, by the fact that the halfwave potentials for the first oxidation and for the first reduction of M(Pc)[Pc(OPh)$_8$] and M[Pc(OPh)$_8$]$_2$ are slightly shifted in the negative direction as the radius of the rare earth metal decreases in the order Eu, Ho, Lu (Table 3).[16]

## Conclusions

A series of lanthanide(III) double-decker complexes with the octaphenoxy- or octathiophenoxyphthalocyaninato ligand were synthesized and characterized. Their solution structures were investigated by $^1H$ NMR spectroscopy, which indicated that the phenoxy and thiophenoxy substituents are relatively free to rotate along the $C_{ipso}$–O or $C_{ipso}$–S bonds. Their electrochemical characteristics revealed that these substituents are electron-withdrawing when connected to the peripheral positions of the phthalocyanine ring. This conclusion was supported by the theoretical calculations on the energy levels of the frontier molecular orbitals of the corresponding phthalocyaninato ligands.

## Experimental Section

**General:** Hexanes and *n*-pentanol were distilled from anhydrous $CaCl_2$ and sodium, respectively. Phthalonitriles and the electrolyte $[Bu_4N][ClO_4]$ were recrystallized from toluene and acetone, respectively. Dichloromethane for voltammetric studies was freshly distilled from $CaH_2$ under a nitrogen atmosphere. Column chromatography was carried out on silica gel (Merck, Kieselgel 60, 70–230 mesh) with the indicated eluents. All other reagents and solvents were of reagent grade and used as received. The compounds $M(acac)_3{\cdot}nH_2O$,[18] 4,5-bis(phenoxy)phthalonitrile,[19] and 4,5-bis(thiophenoxy)phthalonitrile[19] were prepared according to the literature methods.

The UV/Vis and near-IR spectra were obtained with a Hitachi U-4100 spectrophotometer. IR spectra (KBr pellets) were recorded with a BIORAD FTS-165 spectrometer. MALDI-TOF mass spectra were recorded with a Bruker APEX47e ultra-high resolution Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer with α-cyano-4-hydroxycinnamic acid as the matrix. Elemental analyses were performed by the Institute of Chemistry, Chinese Academy of Sciences. $^1H$ NMR spectra were measured with a Bruker DPX 300 spectrometer in $CDCl_3$/[$D_6$]DMSO (1:1) in the presence of ca. 1% (by volume) hydrazine hydrate. Spectra were referenced internally with residual DMSO ($\delta$ = 2.49 ppm).

Electrochemical measurements were carried out with a BAS CV-50W voltammetric analyzer. The cell comprised inlets for a glassy carbon disk working electrode of 2.0 mm in diameter and a silver-wire counter electrode. The reference electrode was $Ag/Ag^+$, which was connected to the solution by a Luggin capillary whose tip was placed close to the working electrode. The electrode was corrected for junction potentials by being referenced internally to the ferrocenium/ferrocene ($Fe^+/Fe$) couple [$E_{1/2}$ ($Fe^+/Fe$) = 501 mV vs. SCE]. Typically, a 0.1 mol dm$^{-3}$ solution of $[Bu_4N][ClO_4]$ in $CH_2Cl_2$ containing 0.5 mmol dm$^{-3}$ of sample was purged with nitrogen for 10 min, the voltammograms were then recorded at ambient temperature. The scan rates were 20 and 10 mV s$^{-1}$ for CV and DPV, respectively.

The frontier molecular orbital energy calculations for unsubstituted and substituted phthalocyanines were carried out with the semi-empirical PM3 method.[20] The input structures of $H_2[Pc(OPh)_8]$ and $H_2[Pc(SPh)_8]$ were derived from the optimized geometry of metal free $H_2Pc$.[21] All calculations were carried out with the Gaussian98W program.[22]

**X-ray Crystallography:** Crystal data and details of data collection and structure refinement for **3** are given in Table S1 (Supporting Information). Data were collected with a Bruker SMART CCD diffractometer with an Mo-$K_\alpha$ sealed tube ($\lambda$ = 0.71073 Å) at –150 °C, with a $\omega$ scan mode and an increment of 0.3°. Preliminary unit cell parameters were obtained from 300 frames. Final unit cell parameters were derived by global refinements of reflections obtained from the integration of all the frame data. The collected frames were integrated with the preliminary cell-orientation matrix. The SMART software was used for collecting frames of data, indexing reflections and determination of lattice constants; SAINT-PLUS for integration of intensity of reflections and scaling;[23] SADABS for absorption correction;[24] and SHELXL for space group and structure determination, refinements, graphics and structure reporting.[25] All the H atoms in these compounds were obtained geometrically. These H atoms were included in the subsequent least-squares refinement as fixed contributors. The final refinement with anisotropic temperature factors for non-H atoms led to R = 0.1854 for compound **4**.

**General Procedure for the Preparation of Heteroleptic M(Pc)[Pc(OPh)$_8$] (1–3) and Eu(Pc)[Pc(SPh)$_8$] (7):** A mixture of $M(acac)_3{\cdot}nH_2O$ (93 mg, 0.20 mmol), phthalonitrile (102 mg, 0.80 mmol), and DBU (20 mg, 0.13 mmol) in *n*-pentanol (3 mL) was heated at 100 °C for 1.5 h under a slow stream of nitrogen to yield the half-sandwich compound M(Pc)(acac). The resulting blue solution was cooled to room temperature. The crude product was precipitated by the addition of hexanes into the solution and purified by chromatography with $CHCl_3$/MeOH (1:1) as the eluent (94 mg, 48%). The obtained product, M(Pc)(acac) (76 mg, 0.10 mmol), was mixed with DBU (20 mg, 0.13 mmol) and 4,5-bis(phenoxy)phthalonitrile (124 mg, 0.40 mmol) or 4,5-bis(thiophenoxy)phthalonitrile (137 mg, 0.40 mmol) in *n*-pentanol (3 mL), and the resulting mixture was heated at reflux for 8 h. The volatiles were removed under reduced pressure to afford a dark green residue which was chromatographed with $CHCl_3$/MeOH (9:1) as the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

eluent. A small amount of metal-free phthalocyanine $H_2Pc(OPh)_8$ or $H_2Pc(SPh)_8$ was collected first, and then the heteroleptic product M(Pc)[Pc(OPh)$_8$] or Eu(Pc)[Pc(SPh)$_8$] was developed. Repeated chromatography followed by recrystallization from $CHCl_3$ and MeOH afforded pure M(Pc)[Pc(OPh)$_8$] (**1**–**3**) or Eu(Pc)[Pc(SPh)$_8$] (**7**) as a darkish-blue powder with a yield of ca. 30%. It is noteworthy that these heteroleptic double-decker complexes could also be prepared from the reaction of M[Pc(OPh)$_8$](acac) or M[Pc(SPh)$_8$](acac) with phthalonitrile by the same procedure.

**Eu(Pc)[Pc(OPh)$_8$] (1):** 56 mg, 28%. $^1$H NMR (300 MHz, $CDCl_3$/[D$_6$]DMSO): $\delta$ = 11.22–11.28 (m, 8 H, Pc-H), 10.67 (s, 8 H, Pc*-H), 9.00–9.06 (m, 8 H, Pc-H), 8.46 (d, $J$ = 7.8 Hz, 16 H, Ph-H$_o$), 8.22 (t, $J$ = 7.8 Hz, 16 H, Ph-H$_m$), 7.80 (t, $J$ = 7.8 Hz, 18 H, Ph-H$_p$) ppm.

**Ho(Pc)[Pc(OPh)$_8$] (2):** 53 mg, 26%. $^1$H NMR (300 MHz, $CDCl_3$/[D$_6$]DMSO): $\delta$ = 4.17 (s, 18 H, Ph-H$_p$), 3.85 (s, 16 H, Ph-H$_m$), 0.34 (s, 16 H, Ph-H$_o$), –1.71 (br. s, 8 H, Pc-H), –8.98 (br. s, 8 H, Pc-H or Pc*-H), –10.26 (br. s, 8 H, Pc-H or Pc*-H) ppm.

**Lu(Pc)[Pc(OPh)$_8$] (3):** 61 mg, 29%. $^1$H NMR (300 MHz, $CDCl_3$/[D$_6$]DMSO): $\delta$ = 9.02 (s, 8 H, Pc-H), 8.39 (s, 8 H, Pc*-H), 8.06 (s, 8 H, Pc-H), 7.74 (s, 16 H, Ph-H$_o$), 7.55 (s, 16 H, Ph-H$_m$), 7.43 (s, 18 H, Ph-H$_p$) ppm.

**Eu(Pc)[Pc(SPh)$_8$] (7):** 64 mg, 30%. $^1$H NMR (300 MHz, $CDCl_3$/[D$_6$]DMSO): $\delta$ = 11.08 (s, 8 H, Pc-H), 10.76 (s, 8 H, Pc*-H), 9.08 (s, 8 H, Pc-H), 8.82 (d, $J$ = 7.8 Hz, 16 H, Ph-H$_o$), 8.29 (t, $J$ = 7.6 Hz, 16 H, Ph-H$_m$), 8.12 (t, $J$ = 7.5 Hz, 18 H, Ph-H$_p$) ppm.

**General Procedure for the Preparation of Homoleptic M[Pc(OPh)$_8$]$_2$ (4–6) and Eu[Pc(SPh)$_8$]$_2$ (8):** A mixture of M(acac)$_3$·$n$H$_2$O (47 mg, 0.10 mmol), 4,5-bis(phenoxy)phthalonitrile (248 mg, 0.80 mmol) or 4,5-bis(thiophenoxy)phthalonitrile (274 mg, 0.80 mmol), and DBU (20 mg, 0.13 mmol) in *n*-pentanol (3 mL) was heated at reflux for 8 h under a slow stream of nitrogen. The volatiles were removed under reduced pressure to give a dark green residue, which was chromatographed with $CHCl_3$ as the eluent. Repeated chromatography followed by recrystallization from $CHCl_3$ and MeOH afforded M[Pc(OPh)$_8$]$_2$ (**4**–**6**) or Eu[Pc(SPh)$_8$]$_2$ (**8**) as darkish-blue crystals with the yield of ca. 40%.

**Eu[Pc(OPh)$_8$]$_2$ (4):** 127 mg,43%. $^1$H NMR (300 MHz, $CDCl_3$/[D$_6$]-DMSO): $\delta$ = 10.79 (s, 16 H, Pc*-H), 8.00 (d, $J$ = 7.8 Hz, 32 H, Ph-H$_o$), 7.75 (t, $J$ = 7.8 Hz, 32 H, Ph-H$_m$), 7.43 (t, $J$ = 7.8 Hz, 16 H, Ph-H$_p$) ppm.

**Ho[Pc(OPh)$_8$]$_2$ (5):** 119 mg, 40%. $^1$H NMR (300 MHz, $CDCl_3$/[D$_6$]DMSO): $\delta$ = 4.65 (s, 16 H, Ph-H$_p$), 4.39 (s, 32 H, Ph-H$_m$), 1.04 (s, 32 H, Ph-H$_o$), –9.74 (s, 16 H, Pc*-H) ppm.

**Lu[Pc(OPh)$_8$]$_2$ (6):** 107 mg, 36%. $^1$H NMR (300 MHz, $CDCl_3$/[D$_6$]DMSO): $\delta$ = 8.58 (s, 16 H, Pc*-H), 7.41 (t, $J$ = 7.7 Hz, 32 H, Ph-H$_o$), 7.19 (t, $J$ = 8.5 Hz, 32 H, Ph-H$_m$), 7.13 (s, 16 H, Ph-H$_p$) ppm.

**Eu[Pc(SPh)$_8$]$_2$ (8):** 135 mg, 42%. $^1$H NMR (300 MHz, $CDCl_3$/[D$_6$]DMSO): $\delta$ = 10.47 (s, 16 H, Pc*-H), 8.24 (d, $J$ = 7.8 Hz, 32 H, Ph-H$_o$), 7.83 (t, $J$ = 7.6 Hz, 32 H, Ph-H$_m$), 7.68 (t, $J$ = 7.3 Hz, 16 H, Ph-H$_p$) ppm.

**Supporting Information** (see footnote on the first page of this article): Molecular structure of Eu[Pc(OPh)$_8$]$_2$ (**4**) from two different perspectives for all non-hydrogen atoms and crystallographic data for Eu[Pc(OPh)$_8$]$_2$ (**4**).

# Syntheses, Structural, and Physical Studies of Basic $Cr^{III}$ and $Fe^{III}$ Benzilates and Benzoates: Evidence of Antisymmetric Exchange and Distributions of Isotropic and Antisymmetric Exchange Parameters

**Vassilios Psycharis,*[a] Catherine P. Raptopoulou,[a] Athanassios K. Boudalis,[a] Yiannis Sanakis,[a] Michael Fardis,[a] George Diamantopoulos,[a] and George Papavassiliou[a]**

*Dedicated to Professor Jean-Pierre Tuchagues on the occasion of his 65th birthday*

**Keywords:** Trinuclear oxo-centered chromium(III) and iron(III) complexes / Magnetic properties / Crystal structures / EPR spectroscopy / Mössbauer spectroscopy

The synthesis, crystal structures, spectroscopic and magnetic properties studies of four trinuclear oxo-centered carboxylate complexes are reported and discussed: $[Cr_3(\mu_3\text{-}O)\{O_2C(OH)Ph_2\}_6(H_2O)_3](NO_3)\cdot 2H_2O\cdot 3Me_2CO$ (**1**·$2H_2O$·$3Me_2CO$), $[Cr_3(\mu_3\text{-}O)(O_2CPh)_6(H_2O)_3](NO_3)\cdot 1.9MeCN\cdot 0.5H_2O$ (**2**·1.9MeCN·$0.5H_2O$), $[Fe_3(\mu_3\text{-}O)\{O_2C(OH)Ph_2\}_6(H_2O)_3](NO_3)\cdot 5.69H_2O$ (**3**·$5.69H_2O$), and $[Fe_3(\mu_3\text{-}O)(O_2CPh)_6(H_2O)_3](NO_3)\cdot 3MeCN$ (**4**·3MeCN). From a crystallographic point of view, the three metal ions form an isosceles triangle in **1** and **3** (benzilato complexes) and an almost equilateral one in **2** and **4** (benzoato complexes). Magnetic susceptibility measurements reveal metal-dependent isotropic exchange, for the $Cr^{III}$ clusters (**1**, **2**), with the "magnetic symmetry" resembling that of an almost equilateral triangle. For the $Fe^{III}$ clusters the "magnetic symmetry" resembles that of an isosceles triangle. Solid-state $^1H$ NMR studies for **1**, through the measurements of the temperature variation of the relaxation rate $1/T_1$, reveal that the first excited spin state with $S_T = 3/2$ is well above (ca. 30 $cm^{-1}$) the ground state with $S_T = 1/2$, consistent with the magnetic susceptibility data. Mössbauer spectroscopic studies give a larger quadrupole splitting, $\Delta E_Q$, value for **3** than for **4**, because of a larger charge asymmetry in **3** attributed to the different nature of the carboxylato ligands. EPR experiments at X-band reveal the presence of antisymmetric exchange within the $Cr^{III}$ clusters and distributions of both isotropic and antisymmetric exchange interactions. In the case of **2** the magnitude and distribution of these interactions are greater. EPR spectroscopy for **3** suggests weak interactions between neighboring units, which could be described assuming a dimer of trimers. For complex **4** the EPR spectra indicate a more complicated picture.

## Introduction

One of the reasons for the extensive study of trinuclear oxo-centered metal carboxylate assemblies (also known as "basic carboxylates") of the general formula $[M^{III}_3O(O_2CR)_6L_3]^+$ (M = 3d metal ion, L = monodentate terminal ligand) is that they serve as simple systems for the study of magnetic and electronic interactions between transition-metal ions.[1–5] Additional interest originates from the fact that they are used as precursors for the synthesis of higher nuclearity clusters exhibiting interesting magnetic properties.[6,7] Such clusters are also studied because they serve as models for the building blocks of polynuclear cores in proteins[8] and in the case of $Cr^{III}$ complexes, for their biological activity.[9]

Magnetic susceptibility studies have been performed for many "basic carboxylates",[3] and at least in the 200–300 K temperature range[1] they are well understood within the framework of the Heisenberg–Dirac–van Vleck (HDvV) isotropic spin Hamiltonian with antiferromagnetic interactions. Kambe[1] has interpreted the magnetic susceptibility data assuming that the exchange interactions within the triangle were all equal (equilateral model) or that one was different from the other two (isosceles model). The crystal structure for many trinuclear complexes reveals an equilateral configuration. Magnetostructural correlations suggest that the equilateral geometry would be appropriate for the description of the magnetic susceptibility data. However, even in highly symmetric cases the magnetic susceptibility measurements require the adoption of the isosceles configuration, in particular for the interpretation of the low-temperature properties of these systems.

The equilateral magnetic model leads to an energy-level diagram with a ground state consisting of two Kramers

doublets. Lowering of the magnetic symmetry to the isosceles configuration indicated by the analysis of the magnetic susceptibility measurements has the consequence that these two doublets differ in energy. Experimental techniques such as heat capacity measurements[10] or inelastic neutron scattering[11,12] have confirmed the lift of the degeneracy of the ground state in consistency with a lower than equilateral geometry. In the case of $Fe^{III}$ complexes, Mössbauer spectroscopy at liquid helium temperatures and in the presence of external magnetic fields has led to the same conclusions; the spectra obtained could not be analyzed within the framework of equilateral configuration. Instead, the spectra were reproduced by assuming lower symmetry and in some cases a scalene configuration was considered more appropriate.[13]

In order to interpret the lifting of the ground-state fourfold degeneracy, a variety of models with different physical origins has been suggested. An early model introduced the concept of the magnetic Jahn–Teller effect, within which the ground state of the system, occupied at low temperatures, adopts an isosceles rather than an equilateral configuration.[14] An isotropic model involving dynamic distortions has been suggested[15] and the results are comparable to those obtained from Kambe's static isosceles model. Other models are based on Hamiltonians that include non-Heisenberg terms and retaining, or not, the $D_3$ symmetry of the cluster. These are biquadratic,[16] anisotropic,[16] and antisymmetric exchange.[2,4,5,17–23] Their appearance is generally associated with spin-orbit coupling and has been adequately described.[20]

Compelling evidence for the role of antisymmetric exchange in trinuclear clusters has been provided by EPR spectroscopy. Within the context of isotropic Heisenberg interactions the $S = 1/2$ ground state would give rise to EPR spectra characterized by the anisotropy of the intrinsic $g$-tensors of the single ions. In the case of $Cr^{III}$ and $Fe^{III}$ complexes this intrinsic anisotropy is small and spectra confined in a narrow region at $g \approx 1.9$–$2.0$ are expected. However, the observed spectra from many clusters exhibit significant $g$-anisotropy, and resonances with $g$ values significantly smaller ($g_{eff} < 1.7$) than those expected are observed.[18,19] Involvement of the antisymmetric exchange term has led to a successful interpretation of this behavior. Similarly, unexpectedly large anisotropies attributed to antisymmetric exchange have been recently observed in trinuclear $Cu^{II}$ complexes[24] and are also frequently encountered in $[3Fe4S]^{1+}$ clusters in proteins.[25]

In some cases analysis of the X-band EPR spectra suggests that, apart from the role of antisymmetric exchange, the role of distributions of the Heisenberg and non-Heisenberg exchange coupling parameters is also of special importance.[25–27] Such distributions have also been implied from Mössbauer studies in the case of $Fe^{III}$ complexes.[13,25,28] Inelastic neutron scattering studies with the spectral characteristics at low temperature have been explained assuming that more than one triangular complex with different degrees of symmetry-lowering are present in the structure.[12]

In the present work, we study the effect of metal and ligand variation ($Cr^{III}$ vs. $Fe^{III}$ and benzilates vs. benzoates) on the structural and electronic (magnetic, spectroscopic) characteristics of "basic metal carboxylates". We present the syntheses and studies of the basic benzilates and benzoates $[Cr_3(\mu_3\text{-}O)\{O_2C(OH)Ph_2\}_6(H_2O)_3](NO_3)\cdot 2H_2O\cdot 3Me_2CO$ (**1**·$2H_2O$·$3Me_2CO$), $[Cr_3(\mu_3\text{-}O)(O_2CPh)_6(H_2O)_3](NO_3)\cdot 1.9MeCN\cdot 0.5H_2O$ (**2**·1.9MeCN·$0.5H_2O$), $[Fe_3(\mu_3\text{-}O)\{O_2C(OH)Ph_2\}_6(H_2O)_3](NO_3)\cdot 5.69H_2O$ (**3**·$5.69H_2O$), and $[Fe_3(\mu_3\text{-}O)(O_2CPh)_6(H_2O)_3](NO_3)\cdot 3MeCN$ (**4**·3MeCN). In particular we present structural, magnetic and X-band EPR data for **1**–**4**, Mössbauer spectroscopic data for **3** and **4** and solid-state NMR spectroscopic data for **1**. This is a continuation of our work on $Cr^{III}$[26] and $Fe^{III}$[27,29–31] complexes exhibiting phenomena like spin frustration, antisymmetric exchange, and $J$-strain, studied with spectroscopic techniques such as EPR.

## Results and Discussion

### Syntheses

Most $Cr^{III}$ "basic carboxylate" complexes have in general been prepared by complicated synthetic routes yielding intractable solids or liquids.[3] $Fe^{III}$ "basic carboxylates" have been prepared by reaction of a $Fe^{III}$ salt with the appropriate sodium carboxylate in aqueous solutions, yielding amorphous solids. In any case, pure crystalline products could not be isolated without recrystallization from organic solvents. Thus, we have reacted $Cr^{III}$ and $Fe^{III}$ salts with the appropriate carboxylic acid or sodium salt directly in organic solvents and we have isolated the corresponding "basic carboxylates" in crystalline form following a straightforward and simple synthetic procedure.

The balanced chemical equations for the synthesis of the "basic benzilates" ($Cr^{III}$: **1**, $Fe^{III}$: **3**) and the "basic benzoates" ($Cr^{III}$: **2**, $Fe^{III}$: **4**) may be written in the forms of Equations (1) and (2) respectively. In every case it is assumed that $H_2O$ from the starting materials and/or the solvent is the source of the $O^{2-}$ ion.

$$3\,M(NO_3)_3\cdot 9\,H_2O + 6\,Ph_2C(OH)COOH \xrightarrow{Me_2CO\,(\mathbf{1}),\,CH_2Cl_2\,(\mathbf{3})} [M_3O\{O_2C(OH)Ph_2\}_6(H_2O)_3](NO_3) + 8\,HNO_3 + 23\,H_2O \quad M = Cr\,(\mathbf{1}),\,Fe\,(\mathbf{3}) \tag{1}$$

$$3\,M(NO_3)_3\cdot 9\,H_2O + 6\,PhCO_2Na \xrightarrow{MeCN\,(\mathbf{2},\mathbf{4})} [M_3O(PhCO_2)_6(H_2O)_3](NO_3) + 6\,NaNO_3 + 2\,HNO_3 + 23\,H_2O \quad M = Cr\,(\mathbf{2}),\,Fe\,(\mathbf{4}) \tag{2}$$

A point of synthetic interest is that for the carboxylates at hand, the use of the carboxylic acid (**1**/**3**) or the sodium carboxylate (**2**/**4**) have both led to the desired complexes.

## Description of the Structures

### *General Remarks*

Compounds **1**–**4**, as members of the large family of "basic carboxylates" containing a central planar $[M_3(\mu_3\text{-}O)]^{7+}$ core and the carboxylato ligands, lie above and below this plane. The monodentate ligands are directed *trans* to the Fe–$O_{oxo}$ bonds. Their structural parameters are typical of "basic carboxylates" and will not be analyzed in detail. In the case of the benzilato complexes **1** and **3**, the triangles formed by the three metal ions are best described as isosceles, while in the benzoato complexes **2** and **4** the triangles formed are equilateral (within a few standard deviations). Selected bond lengths and angles for **1**–**4** are listed in Table 1, and the molecular structure of **1** is selectively shown in Figure 1. The most interesting feature in the structures of **1**–**4** is the presence of intermolecular interactions and the formation of 2D networks, which will be discussed in detail.

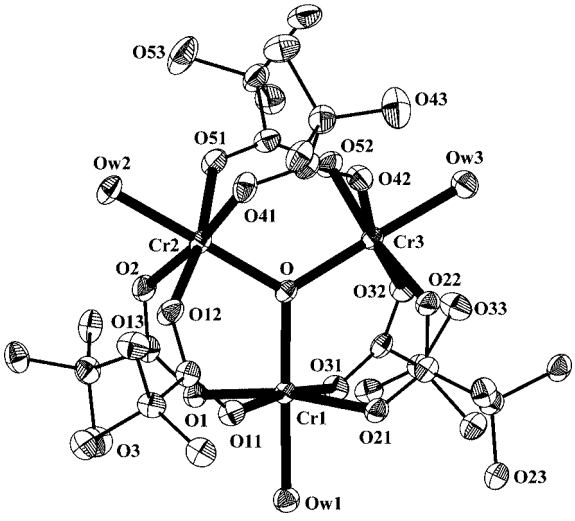

Figure 1. Partially labeled ORTEP plot of the cation of **1** with ellipsoids drawn at the 40% probability level. Only the *ipso* carbon atoms of the benzilato ligands are shown and hydrogen atoms have been omitted for clarity.

### *Lattice Structure of 1·2$H_2O$·3$Me_2CO$*

As shown in Figure 2, the cations of **1** are hydrogen-bonded through their aquo ligands [Ow(1), Ow(2) and Ow(3)] to the nitrate counterions and the solvate molecules [Ow(4), Ow(5) and acetone solvates]. In particular, the water solvate Ow(5) is the intermediate through which the trimers are connected to each other through the hydrogen bonds to Ow(2) and O(53) of one trimer [Ow(5)···O(w2) 2.642 Å, Ow(5)···O(53) 2.977 Å] and O(23) of a neighboring one [Ow(5)···O(23′) 2.809 Å (1 + *x*, *y*, *z*)] forming chains parallel to the *a* axis of the unit cell. The nitrate counterions link trimers belonging to neighboring chains resulting in the formation of layers extended along the *ab* plane [O(33)···O(62″) 3.001 Å (0.5 – *x*, –0.5 + *y*, 0.5 – *z*), Ow(3)···O(62″) 2.741 Å (0.5 – *x*, –0.5 + *y*, 0.5 – *z*), O(3)···O(61‴) 2.885 Å (*x*, –1 + *y*, *z*), Ow(1)···O(61‴) 2.659 Å (*x*, –1 + *y*, *z*)]. The three acetone and the second water solvate molecules are hydrogen-bonded to each other and to coordinated water molecules as well as to the hydroxy group of the benzilato ligands, thus further stabilizing the above-mentioned 2D network.

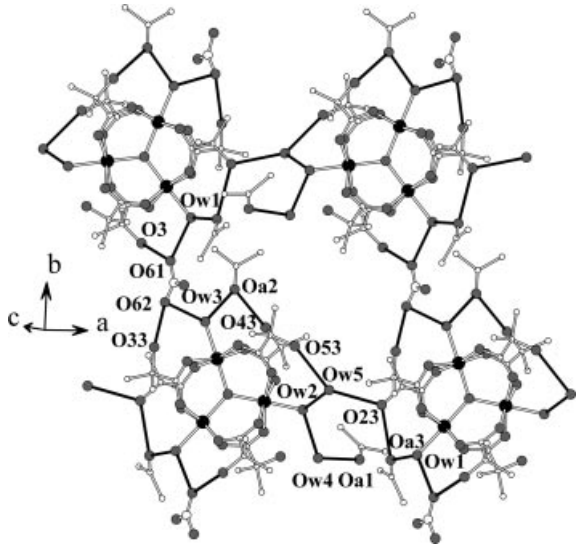

Figure 2. Plot of the 2D polymeric structure of **1** parallel to the *ab* plane. Hydrogen bonds are shown as thick black lines (only the *ipso* carbon atoms of the benzilato ligands are shown). Cr: black circles, O: dark gray, N: large open circles, C: small open circles.

### *Lattice Structure of 2·1.9MeCN·0.5$H_2O$*

The lattice structure of **2** due to hydrogen-bonding interactions is shown in Figure 3. The key feature is the presence of the nitrate counterion, which is hydrogen-bonded to the coordinated water molecules of three different trimers [O(61)···Ow(1′) 2.908 Å (–1 + *x*, *y*, *z*), O(62)···Ow(2″) 2.875 Å (*x*, –1 + *y*, *z*), O(63)···Ow(3) 2.901 Å]. Thus, a 2D network is formed that is parallel to the *ab* plane. The solvate molecules are hydrogen-bonded to each other and to coordinated water molecules but they do not contribute to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the formation of a further polymeric network (these interactions are not shown in Figure 3).

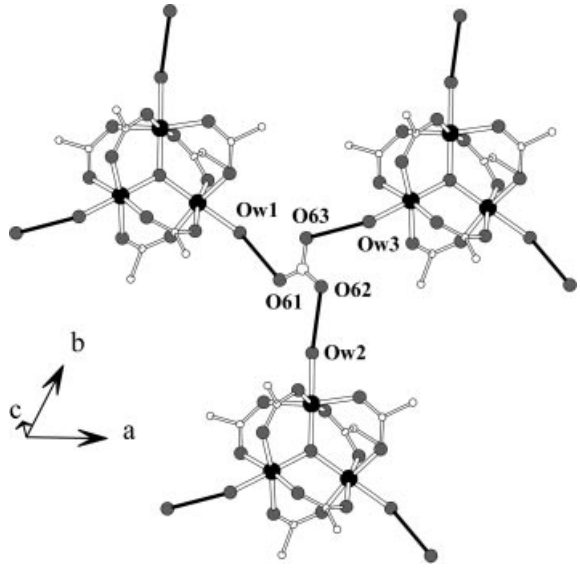

Figure 3. Plot of the 2D polymeric structure of **2** parallel to the *ab* plane. Hydrogen bonds are shown as thick black lines. (only the *ipso* carbon atoms of the benzoato ligands are shown). Cr: black circles, O: dark gray, N: large open circles, C: small open circles.

### *Lattice Structure of 3·5.69$H_2O$*

In the structure of **3**, the X-ray analysis could not reveal the hydrogen atoms of the aquo and benzilato ligands, thus only the intermolecular interactions will be considered for the formation of the lattice structure (Figure 4). Strong intermolecular interactions between O(53) of one trimer and O(13) and Ow(2) of a neighboring trimer [O(53)···O(13′) 2.917 Å (1.5 – *x*, 0.5 – *y*, 1 – *z*), O(53)···Ow(2′) 2.917 Å (1.5 – *x*, 0.5 – *y*, 1 – *z*)] are responsible for the formation of dimers of trimers. The presence of the nitrate counterions and the existence of strong intermolecular interactions [O(61)···Ow(1′′) 2.668 Å (–0.5 + *x*, 0.5 + *y*, *z*) and O(63)···Ow(3′′′) 2.612 Å (1 – *x*, *y*, 0.5 – *z*)] connects the dimers together and the final result is the formation of a 2D polymeric network parallel to the *bc* plane.

### *Lattice Structure of 4·3MeCN*

As in the case of **3**, the X-ray crystal structure analysis of **4** did not reveal the hydrogen atoms of the aquo ligands. Nevertheless, intermolecular interactions less than 3 Å with the nitrate counterions are considered as possible hydrogen-bonding interactions. In particular, the nitrate anions interact with three neighboring trimers [O(61)···Ow(3′) 2.890 Å (1 – *x*, –*y*, 1 – *z*), O(62)···Ow(1′′) 2.680 Å (0.5 – *x*, –0.5 + *y*, 1 – *z*), O(63)···Ow(2′′′) 2.798 Å (0.5 – *x*, 0.5 + *y*, 1 – *z*)], linking the trimers to form a 2D polymeric network parallel to the *ab* plane (Figure 5). The solvent molecules of crystallization also interact intermolecularly with the coordinated water molecules, but they do not contribute to a further development of the lattice structure (these interactions are not shown in Figure 5).

## Mössbauer Spectroscopy

Mössbauer spectra from solid powder samples of **3** and **4** were recorded at zero magnetic field in the 78–300 K temperature range. The spectra at 78 K are shown in Figure 6. Each compound gives rise to one doublet with the following values for the quadrupole interaction ($\Delta E_Q$) and the isomer shift ($\delta$): complex **3**, $\Delta E_Q$ = 0.65 mm s$^{-1}$, $\delta$ = 0.50 mm s$^{-1}$; complex **4**, $\Delta E_Q$ = 0.52 mm s$^{-1}$, $\delta$ = 0.52 mm s$^{-1}$. The values for the isomer shift are consistent with $Fe^{III}$ ($S$ = 5/2) in

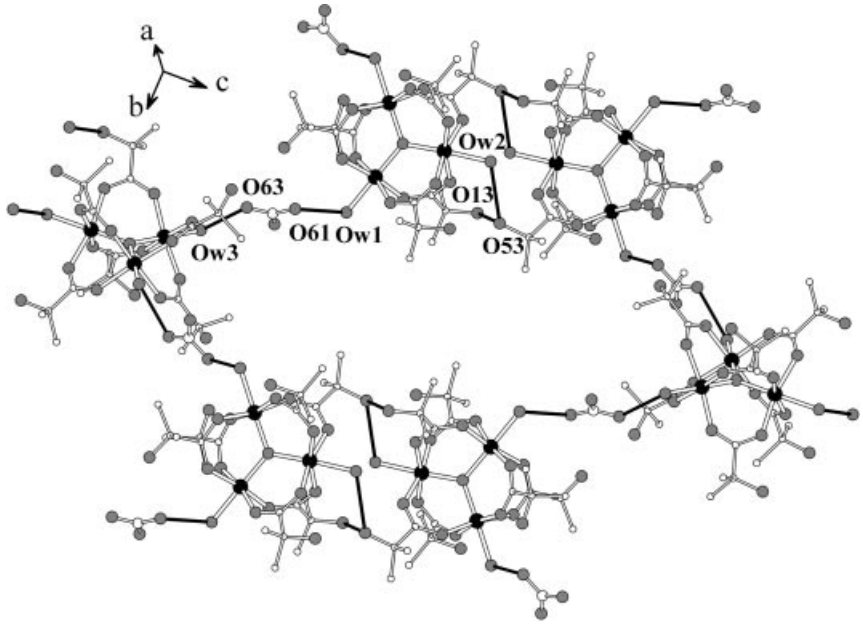

Figure 4. Plot of the 2D polymeric structure of **3** parallel to the *bc* plane. Hydrogen bonds are shown as thick black lines (only the *ipso* carbon atoms of the benzilato ligands are shown). Fe: black circles, O: dark gray, N: large open circles, C: small open circles.

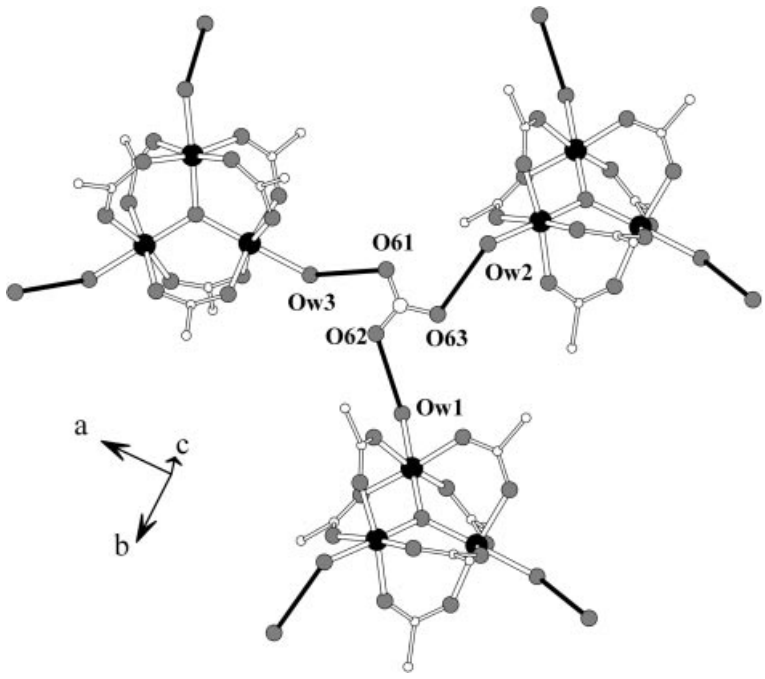

Figure 5. Plot of the 2D polymeric structure of **4** parallel to the *ab* plane. Hydrogen bonds are shown as thick black lines (only the *ipso* carbon atoms of the benzoato ligands are shown). Fe: black circles, O: dark gray, N: large open circles, C: small open circles.

an octahedral environment comprising O donors. The line widths are quite narrow (half width at half maximum 0.20 mm s$^{-1}$), indicating a homogeneous environment around the Fe$^{III}$ ions. Complex **3** is characterized by a larger value for $\Delta E_Q$ than complex **4**, indicating a larger electric field gradient (EFG) for the ferric sites for complex **3**. Inspection of the iron environments for the two compounds suggests that this larger EFG cannot be of geometrical origin; there are no systematic geometrical deviations between **3** and **4** for the ferric octahedra. The larger $\Delta E_Q$ for **3** may suggest, however, a larger charge asymmetry imposed by the different nature of the two carboxylates.

## Magnetic Susceptibility Measurements

### *Cr$^{III}$ Complexes*

The $\chi_M T$ product at 300 K is 4.00 and 3.70 cm$^3$ mol$^{-1}$ K for **1** and **2** respectively, appreciably below the value anticipated for three noninteracting $S$ = 3/2 spins (5.61 cm$^3$ mol$^{-1}$ K), indicative of antiferromagnetic interactions (Figure 7). On cooling, this drops to 0.43 cm$^3$ mol$^{-1}$ K (for **1**) and 0.36 cm$^3$ mol$^{-1}$ K at 2 K (for **2**) not extrapolating to zero at 0 K, thus suggesting the existence of a paramagnetic impurity and/or a magnetic ground state. The $\chi_M$ versus $T$ plots show a gradual increase upon cooling, with a

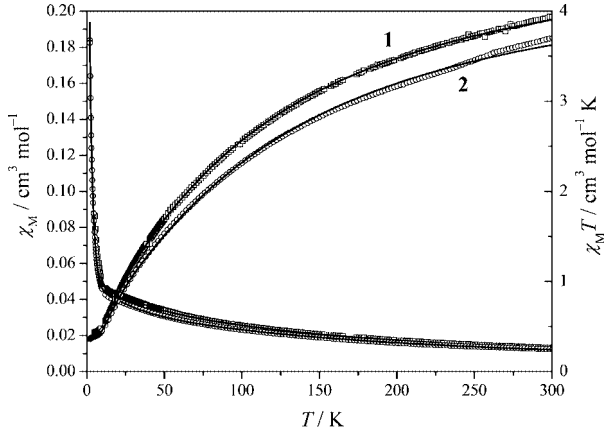

Figure 7. $\chi_M$ vs. $T$ and $\chi_M T$ vs. $T$ experimental data for complexes **1** (□) and **2** (○) and theoretical curves based on the Hamiltonian of Equation (4), using the parameters of solutions **1B** and **2B**, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

more abrupt increase below 12 K, probably attributed to a paramagnetic impurity.

To fit the data, an initial model consisting of three equal $J$ values was considered, with the Hamiltonian being [Equation (3)]:

$$\hat{H} = -2J(\hat{S}_1\hat{S}_2 + \hat{S}_2\hat{S}_3 + \hat{S}_1\hat{S}_3) \quad (3)$$

where $S_i = 3/2$.

Assuming a small fraction of paramagnetic impurities, $\rho$, this model yielded satisfactory solutions with parameters $J = -10.3\ cm^{-1}$, $g = 1.87$, $\rho = 1.0\%$, and $R = 1.5\times10^{-5}$ for **1** (solution **1A**) and $J = -10.2\ cm^{-1}$, $g = 1.79$, $\rho = 0.8\%$, and $R = 3.8\times10^{-4}$ for **2** (solution **2A**). On further examining the system, a 2$J$ model was considered, in order to assess the validity of the previous results. The corresponding Hamiltonian was [Equation (4)]:

$$\hat{H} = -2[J(\hat{S}_1\hat{S}_2 + \hat{S}_1\hat{S}_3) + J'\hat{S}_2\hat{S}_3] \quad (4)$$

An examination of the parameter space for this model indicated the existence of two local minima (Figures S1 and S2, Supporting Information). On examining each, two solutions were obtained for complex **1**, with best-fit parameters $J = -10.6\ cm^{-1}$, $J' = -9.9\ cm^{-1}$, $g = 1.87$, $\rho = 0.98\%$, and $R = 1.3\times10^{-5}$ (**1B**) and $J = -10.1\ cm^{-1}$, $J' = -10.9\ cm^{-1}$, $g = 1.87$, $\rho = 0.98\%$, and $R = 1.3\times10^{-5}$ (**1C**). Similarly, two solutions were obtained for **2**, with best-fit parameters $J = -11.7\ cm^{-1}$, $J' = -9.6\ cm^{-1}$, $g = 1.82$, $\rho = 0.62\%$, and $R = 1.4\times10^{-4}$ (**2B**) and $J = -10.2\ cm^{-1}$, $J' = -12.9\ cm^{-1}$, $g = 1.82$, $\rho = 0.62\%$, and $R = 1.5\times10^{-4}$ (**2C**).

Solutions **1B**, **1C** and **2B**, **2C** are comparable in quality and only marginally better than solutions **1A** and **2A**, respectively. This small improvement of quality in the fits may stem from the fact that the isosceles model is more adequate, but might also be a result of overparametrization. This is further discussed below (see EPR Spectroscopy).

In order to further examine the validity of these results, the $M$ versus $H$ isotherms of **1** and **2** were measured and compared to the calculated ones, for each one of the solutions. In each case the magnetization isotherms were practically superimposable, and verified the data perfectly. Characteristic plots are shown in Figures S3 and S4 in the Supporting Information.

### *$Fe^{III}$ Complexes*

At 300 K the $\chi_M T$ product is 4.69 $cm^3\,mol^{-1}\,K$ for complex **3** and 3.67 $cm^3\,mol^{-1}\,K$ for complex **4**, significantly lower than the theoretically expected value for three noninteracting $S = 5/2$ spins (13.14 $cm^3\,mol^{-1}\,K$), indicating antiferromagnetic interactions (Figure 8). Upon cooling, the $\chi_M T$ product decreases without extrapolating to zero at 0 K, which also agrees with the interplay of antiferromagnetic interactions and a magnetic ground state.

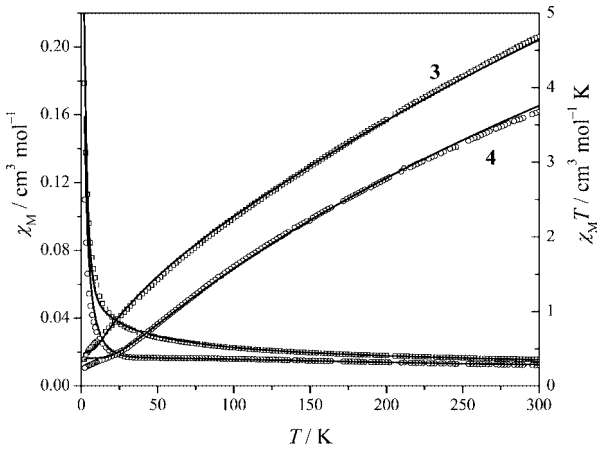

Figure 8. $\chi_M$ vs. $T$ and $\chi_M T$ vs. $T$ experimental data for complexes **3** (□) and **4** (○) and theoretical curves based on the Hamiltonian of Equation (4), using the parameters of solutions **3B** and **4C**, respectively.

Initial attempts to simulate the magnetic properties of complex **3** by considering a single $J$ interaction, viewing the complex as an equilateral triangle [Equation (3)], did not yield satisfactory results, so the Hamiltonian of Equation (4) was considered (with $S_i = 5/2$). From the fitting process two solutions of satisfactory quality were obtained, with a small amount of paramagnetic impurity, with their parameters being $J = -27.5\ cm^{-1}$, $J' = -20.5\ cm^{-1}$, $\rho = 0.36\%$, $g = 2.0$, and $R = 1.0\times10^{-3}$ (**3B**) and $J = -22.5\ cm^{-1}$, $J' = -32.6\ cm^{-1}$, $\rho = 0.35\%$, $g = 2.0$, and $R = 1.1\times10^{-3}$ (**3C**). These two solutions were also located on error contour-plots drawn for various values of $J$ versus $J'$ (Figure S7).

The above-mentioned solutions were further verified by simulations of the $M$ versus $H$ isotherm at 4 K (Figure S7). The experimental data were very well simulated using any set best-fit parameters, which yielded practically superimposable calculated curves.

The behavior of complex **4** could not be accounted for by this model in the low-temperature region, so fits were carried out between 300 and 14 K. These also yielded two solutions, with parameters $J = -34.9\ cm^{-1}$, $J' = -29.3\ cm^{-1}$, $\rho = 0$, $g = 2.0$, and $R = 2.7\times10^{-4}$ (**4B**) and $J = -31.0\ cm^{-1}$, $J' = -38.4\ cm^{-1}$, $\rho = 0$, $g = 2.0$, and $R = 1.7\times10^{-4}$ (**4C**), which were also located on error contour-plots for various $J$ versus $J'$ values (Table 2) (Figure S8). Below 14 K the experimental curve dropped below the theoretically calculated one. This was also evidenced from the magnetization curve, which at 2.5 is significantly lower than the one theoretically calculated based on the best-fit parameters (Figure S10).

Considering that exchange couplings are primarily mediated through the oxide ions,[32] the $J$ values for the $Fe^{III}$ complexes are very close to those derived by applying the formula proposed by Weihe and Güdel[33,34] using the Fe–O distances and the Fe–O–Fe bridging angles. Although for dinuclear $Cr^{III}$ compounds the exchange coupling depends on the same parameters (distances and bringing angles),[35] an analogous magnetostructural correlation scheme has not

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2. Exchange-coupling constants derived for complexes **1**–**4**.

| Best-fit solution | $J$ ($cm^{-1}$) | $J'$ ($cm^{-1}$) | $J_{av}$[a] ($cm^{-1}$) | $g$[b] |
|---|---|---|---|---|
| **1A** | –10.3 | | | 1.87 |
| **1B** | –10.6 | –9.9 | –10.4 | 1.87 |
| **1C** | –10.1 | –10.9 | –10.4 | 1.87 |
| **2A** | –10.2 | | | 1.79 |
| **2B** | –11.7 | –9.6 | –11.0 | 1.82 |

| **4C** | –31.0 | –38.4 | –33.5 | **2.00** |

[a] $J_{av} = (2J + J')/3$. [b] Values in bold were fixed during the fitting process.

yet been obtained for $Cr^{III}$ compounds[36] with nuclearity three and higher. The values obtained for the exchange parameters ($J$, $J'$) are very close to the corresponding values from similar trinuclear oxobridged $Cr^{III}$ and $Fe^{III}$ compounds.[3]

The ligands seem to have no discernible influence on the magnetic properties of the $Cr^{III}$-based complexes. On the contrary, in the case of $Fe^{III}$-based complexes the $J$ values are larger in the case of the benzoate ligand (**4**), as has also been observed in another series of trinuclear iron(III) carboxylate complexes.[37]

Although the number of examples presented herein is hardly sufficient to establish a valid correlation, we may still assume that there is some influence of the carboxylato ligand's electronic parameters on the magnitude of the exchange couplings. This influence should be secondary to that induced by the variation of structural parameters like M···M distances and M–O–M angles, but is probably not negligible. Such an influence has also been observed by Mössbauer spectroscopy, which reveals a larger (ca. 25%) quadrupole splitting for the ferric sites in **3** despite having very similar geometrical environments to the ferric sites in **4**.

In assessing the metal influence on the magnetic properties of the complexes, we first observe that couplings are stronger in iron(III) complexes than in their chromium(III) counterparts, by a factor of about 3. Secondly, we observe that, as in the case of "basic iron(III) carboxylates", "basic chromium(III) carboxylates" present two best-fit solutions of their magnetic susceptibility data within the isosceles model, one with $J > J'$ and one with $J < J'$. However, an important difference is that in the case of chromium(III) complexes these solutions are comparable in quality with the solution derived from the equilateral model ($J = J'$), whereas in the case of iron(III) complexes the latter model fails to satisfactorily reproduce the experimental data. Therefore, although the equilateral model may be insufficient to describe "basic chromium(III) carboxylates", other techniques (like EPR) are necessary to unambiguously prove this.

## Solid-State NMR

Solid-state NMR experiments in magnetic molecular clusters of transition-metal ions probe the magnetic excitations in the electronic spin system of the cluster. In particular, at low temperatures, $T_1$ spin-lattice relaxation measurements are quite sensitive to the low-lying energy levels of the system. The $^1H$ NMR spin-lattice relaxation time $T_1$ was measured at an applied magnetic field $H = 4.7$ T, between room and liquid-helium temperatures. The relaxation rate $1/T_1$ as a function of temperature is shown in Figure 9. At high temperatures the relaxation rate exhibits a weak temperature dependence, while below around 80 K an activated-type dependence is observed. The temperature dependence of $1/T_1$ measured for **1** is analogous to a previously studied trinuclear $Cr^{III}$ complex[26] and has a behavior that has been frequently encountered in previous $^1H$ NMR studies of molecular clusters that include transition-metal ions with low $S$ values, for example $S = 1/2$, 3/2.[38] The NMR $1/T_1$ relaxation data in clusters including metal ions with high $S$ values, such as $S = 5/2$, frequently exhibit a pronounced $1/T_1$ maximum at temperatures of the order of the exchange frequency $J$.[39,40] The absence of a maximum in clusters with metal ions having low $S$ values has not been adequately explained so far and is currently under investigation.

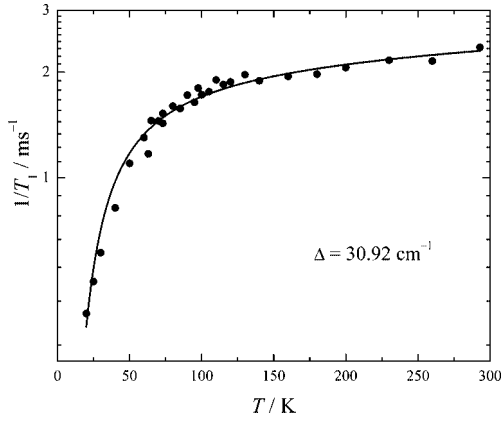

Figure 9. The relaxation rate $1/T_1$ as a function of temperature for **1**.

Using a two-level system and an Orbach-type activation process for the electronic excitation, we have been able to fit the experimental data considering an energy gap consistent with that obtained from the susceptibility data. In this model the NMR relaxation is caused by the local field fluctuations originating from the magnetic excitations from the ground state to the excited state, separated by the energy difference Δ. Assuming that the $Cr^{III}$ spin system remains in the ground state for an average time $\tau_0$ and in the excited state for a lifetime $\tau_1$, during which an effective transverse local field $h_\perp$ appears at the nuclear site, the relaxation rate is expressed as [Equation (5)]:[41]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$\frac{1}{T_1} = (\gamma_N h_\perp)^2 \frac{\tau_1\tau_0}{(\tau_1+\tau_0)^2} \frac{\tau}{(\omega_N\tau)^2+1} \quad (5)$$

where

$$\frac{1}{\tau} = \frac{1}{\tau_0} + \frac{1}{\tau_1}$$

$\gamma_N$ is the proton gyromagnetic ratio, and $\omega_N$ is the Larmor angular frequency.

This model has been frequently employed for the nuclear magnetic relaxation in paramagnets.[38,42,43] For the excitation $1/\tau_0$, we may consider the sum of two processes [Equation (6)]:[44]

$$\frac{1}{\tau_0} = A_0 \coth\left(\frac{g\mu_B H}{2k_B T}\right) + B_0 \exp\left(-\frac{\Delta}{k_B T}\right) \quad (6)$$

The first term is a direct-type process, generally applicable at low temperatures, and the second term is an activation process of the Orbach type because of the presence of the energy level spacing $\Delta$ and is generally applicable at higher temperatures.

For the lifetime $\tau_1$ we consider a temperature-independent term [Equation (7)]:

$$1/\tau_1 = C_1 \quad (7)$$

Setting $\nu_N$ = 200.1 MHz ($H$ = 4.7 T), and using Equations (6) and (7), the experimental NMR points are fitted to Equation (5), shown as a solid line in Figure 13. The influence of the first term in Equation (6), the direct process, is quite small in the experimental determination of $\Delta$. We observe that the line describes the overall experimental features rather well. The value of $\Delta$ determined by the fitting is $\Delta$ = 30.92 $cm^{-1}$. According to the analysis of the magnetic susceptibility measurements for $Cr^{III}$ compounds presented in the previous paragraph, the ground state has $S_T$ = 1/2 (T for total) and the first excited state has $S_T$ = 3/2. For an equilateral exchange interaction model, which is the case (to a good approximation) for the $Cr^{III}$ compounds, $\Delta = 3J$[4] $\approx$ 30 $cm^{-1}$ (for $J \approx$ 10 $cm^{-1}$). Both values for the first excited multiple determined by the analysis of the susceptibility and NMR measurements are in good agreement.

## EPR Spectroscopy

EPR spectroscopy has been proven to be very useful in determining the magnetic properties of the ground state of trinuclear complexes.[2,4,5,17–23]

### *$Cr^{III}$ Complexes*

X-band EPR spectra from powder samples of **1** and **2** recorded at 4.2 K are shown in Figure 10. Both samples give rise to strong signals comprising an absorption peak at $g \approx$ 1.97–1.98 and broad features at higher magnetic fields (Figures 10, left and right). The magnetic susceptibility data indicate an $S_T$ = 1/2 ground state for complexes **1** and **2**. Indeed, the signals of Figure 10 are consistent with an isolated $S_T$ = 1/2 state. In coupled trimers, a relatively large anisotropy in the $g$ tensor for the $S_T$ = 1/2 ground state with a $g_\perp$ value significantly smaller than 2 is usually observed. This anisotropy is the result of antisymmetric exchange interaction [Equation (8)]:

$$\hat{H}_{AE} = \mathbf{d}(\hat{\mathbf{S}}_1 \times \hat{\mathbf{S}}_2 + \hat{\mathbf{S}}_2 \times \hat{\mathbf{S}}_3 + \hat{\mathbf{S}}_3 \times \hat{\mathbf{S}}_1) \quad (8)$$

In the framework of Hamiltonian (8), $g_\parallel \approx g_0$, where $g_0$ is the $g$ value for the $Cr^{III}$ metal ion. $g_\perp$ depends critically on the relationship between $d$ and $\Delta E$, where $\Delta E$ is the energy difference between the two lowest $S_T$ = 1/2 states. In the case of well-isolated $S_T$ = 1/2 doublets with respect to the higher $S$ = 3/2 states and small $d$ values, the dependence

Dashed lines represent theoretical simulations as described in the text. Inset: Distribution of subspectra used to generate the simulations as described in the text. EPR conditions: microwave power 2.0 mW, mod. amplitude, 1.0 mT (left), 0.4 mT (right), microwave frequency 9.42 GHz.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of $g_\perp$ on these parameters is given analytically through the relationship [Equation (9)]:[19]

$$g_\perp = g_{0\perp}\left[1 - \frac{D^2}{\Delta E^2 - (h\nu)^2}\right]^{1/2} \quad (9)$$

$\Delta E$ stands for the separation of the lowest $S = 1/2$ doublets and is given by the relationship [Equation (10)]:

$$\Delta E = (\sigma^2 + D^2)^{1/2} \quad (10)$$

where $D = 4\sqrt{3d}$, and $\sigma = 4|J - J'|$.

From this model the characteristics of the spectra shown in Figure 10 can be understood. The absorption peak observed at $g \approx 1.97$–$1.98$ is attributed to the $g_\parallel$ component, whereas the broad derivative feature corresponds to $g_\perp$. Recently[26] we have observed similar EPR spectra in a $Cr^{III}$ complex similar to **2**. In order to reproduce the line shape of the spectra we follow the same procedure as in that case. Namely, we calculate a large number of axial spectra with $g_\parallel \approx 1.97$–$1.98$ and with smaller $g_\perp$ values, and then by a fitting routine we determine the distribution of the subspectra that reproduce the experimental one. The resulting simulations together with the distributions of the subspectra are shown in the insets in Figure 10.

In both cases the distribution profiles exhibit a maximum at certain $g$ values (1.90 for **1** and 1.53 for **2**). These values are considered as the $g_\perp$ for the $S = 1/2$ ground states. The crystal structure at room temperature revealed an isosceles configuration for **1** and an almost equilateral for **2**. The magnetic susceptibility measurements gave satisfactory results either with an equilateral ($J = J'$) or with an isosceles model ($J \neq J'$). An $S = 1/2$ EPR signal with an axial character cannot arise from a trinuclear system with $J = J'$, because in this case the transition probability corresponding to the $g_\parallel$ component vanishes.[5,13,18]

From the dependence of $g_\perp$ on the antisymmetric exchange parameter $|\mathbf{d}|$, the magnitude of the latter can be determined. For this, knowledge of $g_{0\perp}$ and $\Delta E$ is also required. For $Cr^{III}$ ($S = 3/2$) the intrinsic $\mathbf{g_0}$ tensor is slightly anisotropic with values $g_{0\parallel}$ and $g_{0\perp}$ smaller than 2 and in the 1.98–1.93 range. For the coupled system the $g_\parallel$ parameter does not depend on $|\mathbf{d}|$, therefore we can safely assume that $g_\parallel \equiv g_{0\parallel}$. For the perpendicular component we assume that $g_{0\perp}$ lies in the 1.98–1.93 region.

Although for the description of the magnetic susceptibility data we did not take into account the antisymmetric term, the determined values for $J$ and $J'$ can be used in order to estimate the separation, $\Delta E$ of the two lowest $S = 1/2$ states. We consider also that their average value $J_{av} = (2J + J')/3$ is valid as it satisfactorily reproduces the temperature dependence of the magnetic susceptibility. From Equation (9) and the given values for $\Delta E$ we determine the antisymmetric exchange parameter $|\mathbf{d}|$ for the two solutions (**1B**, **1C** and **2B**, **2C**). From these values we estimate that $|\mathbf{d}| \approx 0.10\ cm^{-1}$ for **1** and $|\mathbf{d}| \approx 1.1\ cm^{-1}$ for **2**. These values fall in the range reported for other carboxylato-bridged trinuclear complexes.[19] $|\mathbf{d}|$ is significantly larger for compound **2**, suggesting that the nature of the carboxylato-bridging ligands affects the magnitude of the antisymmetric exchange interaction.

From Equation (10) we find that $\sigma \approx 3\ cm^{-1}$ for **1** and $\sigma \approx 6\ cm^{-1}$ for **2**. This parameter depicts the splitting of the $S = 1/2$ doublets, which is due to the nonequivalence of the isotropic exchange parameters. We observe that incorporation of antisymmetric exchange through Equation (10) leads to a slightly smaller $\sigma$ compared with the one derived from a purely isotropic exchange Hamiltonian, which was considered in the analysis of the magnetic susceptibility data. From the relationship $\sigma = 4|J - J'|$ we see that the actual $J$ and $J'$ values should be slightly different from those derived from the analysis of the magnetic susceptibility data. This difference is too small to be discernible in the analysis of the temperature dependence of the magnetic susceptibility. Moreover, the magnitude of the antisymmetric exchange parameter $|\mathbf{d}|$ derived from the analysis of the EPR data is not expected to affect this analysis.

The parameter $\sigma$ can be taken as a measure for the lowering of the symmetry because for an equilateral triangle $\sigma = 0$. For compound **1** a non-zero value for $\sigma$ could be anticipated, as the room temperature crystal structure already reveals an isosceles configuration. On the contrary, compound **2** has an equilateral configuration at room temperature. Therefore the finite value of $\sigma$ for this compound (even larger than compound **1**) indicates a lowering of symmetry at low temperatures. The lowering of symmetry is one of the properties of trinuclear complexes that have been the subject of extensive studies during the last few decades, and from this point of view compound **2** belongs to this family of clusters.

The distribution of $g_\perp$ values required to reproduce the EPR spectra of Figure 10 is noteworthy. The distribution is more pronounced for compound **2**. From Equation (9) we observe that $g_\perp$ is extremely sensitive on the ratio $d/\Delta E$. A relatively small distribution on this parameter would lead to a large distribution of the $g$ values, resulting in a severely distorted axial EPR spectrum. This distribution may arise from structural inhomogeneities, resulting for instance from partial solvent loss. Alternatively, this behavior may be connected with the lowering of the symmetry discussed above. We note that, as $\Delta E$ depends on $\sigma$, a small distribution of the isotropic exchange constants would have a prominent effect. These constants are expected to depend on the geometrical characteristics of the clusters. It is probable, therefore, that upon cooling a multitude of geometric configurations are trapped, giving rise to slightly different sets of $J$ values, resulting eventually in a variety of $\sigma$ values. This effect would be more pronounced for compound **2** on going from the equilateral to isosceles configuration upon decrease of temperature.

As the temperature increases, new signals emerge in the lower-field region of the spectra, as shown in Figure 11. The temperature dependence of these signals indicates that they arise from excited states of a paramagnetic system. This is strong evidence against an assignment of these signals to mononuclear $Cr^{III}$ ($S = 3/2$) impurities.[46] On the other hand, they can be very well attributed to excited states with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$S > 1/2$ of the trimeric units, which are gradually populated as the temperature increases. The energy level with $S_T = 3/2$ is the most probable to generate these signals, because it is the first excited state with $S > 1/2$ for the system.

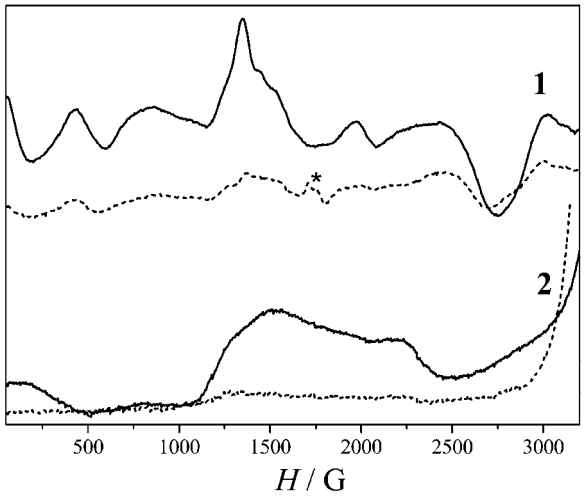

Figure 11. The low magnetic field region of EPR spectra from polycrystalline samples of **1** and **2** at 4.2 K (dotted lines) and 19 K (continuous lines). The asterisk * denotes a weak signal, which is attributed to impurities. EPR conditions: microwave power 2.0 mW, mod. amplitude 1.0 mT, microwave frequency 9.42 GHz.

For an equilateral triangle one has four states with $S_T = 3/2$ with the same energy. For $J \neq J'$ these states differ in energy leading to four separate quartets. Moreover, further splitting may be induced from non-Heisenberg interactions such as single-ion zero-field splitting, dipolar, and antisymmetric exchange. The analysis of the $S_T = 1/2$ signals from the ground state indicates that the magnitude of these interactions is too small to be discernible in the bulk magnetic susceptibility measurements; however they induce very complicated EPR spectra. As is clearly shown in Figure 11, the two complexes differ not only in the EPR spectra obtained from the $S_T = 1/2$ ground state, but also in the EPR spectra from the excited states.

### *$Fe^{III}$ Complexes*

The EPR spectrum recorded at 4.2 K from a polycrystalline sample of compound **3** is shown in Figure 12. Although the analysis of magnetic susceptibility measurements reveals that the ground state for compound **3** has $S_T = 1/2$, as in the case of compounds **1** and **2**, the EPR spectrum for this compound is different. Specifically, a very intense signal is observed at $g \approx 2.0$ and a number of weaker signals are recorded at lower values of the magnetic field. The signal recorded at $g = 2.0$ has a width of about 600 G, and comprises an absorption feature at $g \approx 2.18$, a derivative at $g \approx 1.98$, and a valley at 1.86. These signals are not explained by considering an isolated trinuclear complex as in the case of $Cr^{III}$-based **1** and **2** complexes. Recently, we have observed similar EPR spectra from powdered samples of another trinuclear complex and for their interpretation we suggested inter-trimer interactions leading to weakly coupled dimers of trinuclear units.[31] The crystal structure of **3** reveals intermolecular interactions leading to the formation of dimers of trinuclear centers. In order to reproduce the spectra we have employed the same model as in ref.[31] involving two weakly interacting $S_1 = S_2 = 1/2$ species in the framework of the spin Hamiltonian [Equation (11)]:[20]

$$\hat{H} = \hat{\mathbf{S}}_1\tilde{\mathbf{J}}_{12}\hat{\mathbf{S}}_2 + \hat{\mathbf{S}}_1\mathbf{g}_1\mathbf{B} + \hat{\mathbf{S}}_2\mathbf{g}_2\mathbf{B} \quad (11)$$

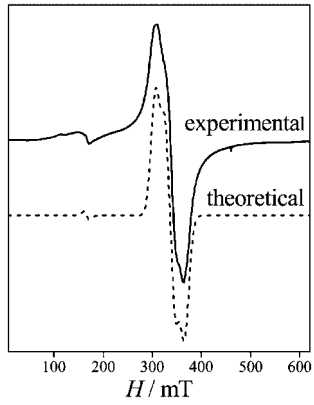

Figure 12. Experimental (solid) and theoretical (dotted) perpendicular-mode X-band EPR spectra from a powdered sample of **3** at 4.2 K. The simulation is obtained as described in the text using an intrinsic line width of 7 mT. EPR conditions: microwave power 2.0 mW, mod. amplitude 0.4 mT, microwave frequency 9.42 GHz.

The exchange interaction is represented by an anisotropic diagonal tensor $\tilde{\mathbf{J}}$. The distance between the trinuclear complexes in a dimer unit is relatively large and the isotropic exchange interaction is expected to be negligible. We find that the spectra are well reproduced for $\mathbf{J} = [0.04, 0.00, -0.04]$ $cm^{-1}$ with $g_1 = g_2 = 2.0$. The interaction of Equation (11) leads to a four-energy-level system.

Within this, manifold "half-field" transitions are expected at $g \approx 4.0$.[47] Indeed, such signals are observed in the EPR spectra of Figure 12. It could be argued that the signals in the $g \approx 4$ region arise from high-spin $Fe^{III}$ impurities which exhibit derivative signals at $g \approx 4.3$. In order to deduce whether the signals in the $g \approx 4.0$ region belong to the exchange coupled system of Equation (11) or arise from $Fe^{III}$ impurities, we have performed EPR spectroscopy in parallel mode (Figure 13). For a high-spin $Fe^{III}$ impurity with a zero-field splitting term $|D| \approx 1$–$2$ $cm^{-1}$, the $g \approx 4.3$ component has no contribution in parallel mode, as it arises from a Kramers doublet. The "half-field" transitions of a system described by Equation (11) involve non-Kramers doublets and the transition probability in parallel mode is finite. The existence of a signal at $g \approx 4.0$ in the parallel mode spectrum provides further evidence for an anisotropic exchange interaction between two neighboring $S = 1/2$ trimers.

The spectra are reproduced assuming isotropic $\mathbf{g}_i$ tensors with $g = 2.00$. From this point of view, complex **3** does not exhibit anisotropic $g$ tensors for the ground $S = 1/2$ state, unlike the Cr analogue complex **1**, for which anisotropic $S = 1/2$ signals are observed (Figure 10). Therefore, there is no indication for antisymmetric exchange in the case of **3**.

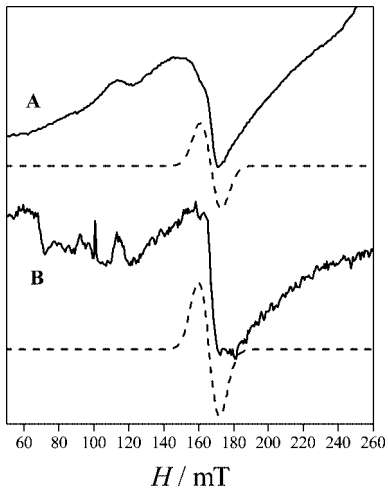

Figure 13. Experimental (solid) and theoretical (dotted) dual-mode X-band EPR spectra from powdered samples of **3** at 4.2 K. A: perpendicular mode; B: parallel mode. Simulations are obtained as described in the text. EPR conditions: A, as in Figure 11; B, microwave power 54 mW, mod. amplitude 0.4 mT, microwave frequency 9.36 GHz.

The anisotropic exchange interaction is mainly of dipolar origin. In the present case, the spin in each trimer delocalizes in three $Fe^{III}$ ions and the size of the triangles is of the same order of magnitude with the distance between the species. In such a case a point-dipole model is not a good approximation. We have observed similar EPR spectra from powdered samples of another trinuclear complex.[31]

Powdered samples from **4** gave rise to complicated EPR spectra at liquid helium temperatures extending several hundreds of mT. We have studied many samples exhibiting identical Mössbauer and IR spectra but each time their EPR spectra showed variations. A representative spectrum is shown in Figure S13. The X-band EPR spectra cannot be interpreted assuming isolated $S = 1/2$ species. The simplified model for intermolecular interactions, adopted in the case of **3**, does not apply to **4** either. Moreover, we note that the magnetic susceptibility data for liquid helium temperatures exhibited significant deviation from the isotropic exchange Hamiltonian [Equations (3) and (4)]. Therefore, it appears that more complicated magnetic interactions have to be taken into account in order to appropriately describe the low-temperature magnetic behavior of **4**.

## Conclusions

Structural, magnetic, and EPR spectroscopic studies have been carried out on two basic chromium(III) and two basic iron(III) carboxylates. In addition, solid-state $^1H$ NMR studies have been carried out on **1** and $^{57}Fe$ Mössbauer studies have been carried out on the ferric complexes **3** and **4**. This allowed us to examine the influence of ligand and metal variation on structural, magnetic, and spectroscopic properties.

From a structural viewpoint benzilato ligands induce a nearly isosceles geometry in **1** and **3**, whereas benzoato ligands induce a nearly equilateral geometry. However, these geometric characteristics are not reflected in the "magnetic symmetry" of the complexes; the magnetic susceptibility data of the chromium(III) complexes can be well described both by the equilateral or isosceles model, whereas those of the iron(III) complexes demand the use of the isosceles model. In the case of the isosceles model, two best-fit solutions are obtained for all complexes. Solid-state $^1H$ NMR studies on **1** reveal that the first excited state is well separated from the ground state and quantitatively confirm the magnetic susceptibility results.

Further information regarding the low-lying spin states of the trimers was obtained by X-band EPR spectroscopy. For **1** and **2** the EPR results favor the isosceles model at least at liquid helium temperatures and confirm the $S_T = 1/2$ ground state. In addition, in **1** and **2** the presence of antisymmetric exchange was revealed along with a distribution of the exchange parameters.

Concerning the iron(III) complexes, the EPR spectrum of **3** is influenced by intermolecular interactions of dipolar origin, whereas that of **4** is too complicated to be analyzed in detail. It is however concluded that antisymmetric exchange is not so important in **3**.

Another point of interest concerns the ligand-induced electronic effects on various magnetic and spectroscopic properties. In particular, it was observed that: (i) isotropic exchange couplings are stronger within benzoato complexes (**2**/**4**) than within benzilato complexes (**1**/**3**), (ii) the electric field gradient is larger for the ferric sites of the "basic iron(III) benzilate" (**3**) than for the sites of the "basic iron(III) benzoate" (**4**), and (iii) the magnitude of the antisymmetric exchange parameter **d** is about 10 times larger for **2** than for **1**.

These differences gain importance with the close structural resemblance of **1**/**2** and **3**/**4**, which does not allow for their simple geometric interpretation. Rather, we assume that electronic factors affect the exchange couplings (isotropic and antisymmetric) and EFG, although this point requires more elaborate studies. Weak intermolecular, metal-dependent interactions may complicate the analysis of the properties of the trinuclear units.

## Experimental Section

**Compound Preparations:** All manipulations were performed under aerobic conditions using materials as received (Aldrich Co). All chemicals and solvents were of reagent grade.

**$[Cr_3(\mu_3\text{-}O)\{O_2C(OH)Ph_2\}_6(H_2O)_3](NO_3)\cdot 2H_2O\cdot 3Me_2CO$ ($1\cdot 2H_2O\cdot 3Me_2CO$):** Solid benzilic acid (0.233 g, 1.01 mmol) was added to a refluxing green-purple solution of $Cr(NO_3)_3\cdot 9H_2O$ (0.204 g, 0.51 mmol) in $Me_2CO$ (15 mL). The reflux continued for 3 days, giving a green solution, which was layered with a mixture of $Et_2O$/*n*-hexane (1:1 v/v %) to afford X-ray-quality green crystals of **1**. The crystals were collected by filtration, and dried in vacuo. (Yield: 0.34 g, ca. 70%.) The resulting powder was analyzed as solvent-free. $C_{84}H_{72}Cr_3NO_{25}$ (1651.47): calcd. C 61.09, H 4.39, N 0.85; found C 60.15, H 4.32, N 0.80. Selected IR data: 3614 [$\nu$(OH)$_{free}$], 1636 [$\nu_{as}$(COO)], 1415 [$\nu_s$(COO)], 600 [$\nu_{as}(Cr_3O)$] $cm^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**$[Cr_3(\mu_3\text{-}O)(O_2CPh)_6(H_2O)_3](NO_3)\cdot 1.9MeCN\cdot 0.5H_2O$ (2·1.9MeCN·0.5$H_2O$):** Solid sodium benzoate (0.373 g, 2.58 mmol) was added to a refluxing green-purple solution of $Cr(NO_3)_3\cdot 9H_2O$ (0.517 g, 1.29 mmol) in MeCN (15 mL). The reflux continued for 2 h, giving a green solution, which upon slow evaporation afforded X-ray-quality green crystals of **2**. (Yield: 0.34 g, ca. 70%.) The crystals of **2** were collected by filtration and dried in vacuo. The resulting powder was analyzed as solvent-free. $C_{42}H_{36}Cr_3NO_{19}$ (1014.73): calcd. C 49.71, H 3.58, N 1.38; found C 48.90, H 3.44, N 1.29. Selected IR data: 1574 [$\nu_{as}$(COO)], 1421 [$\nu_s$(COO)], 620 [$\nu_{as}(Cr_3O)$] $cm^{-1}$.

**$[Fe_3(\mu_3\text{-}O)\{O_2C(OH)Ph_2\}_6(H_2O)_3](NO_3)\cdot 5.69H_2O$ (3·5.69$H_2O$):** Solid benzilic acid (0.228 g, 1.00 mmol) was added to a refluxing solution of $Fe(NO_3)_3\cdot 9H_2O$ (0.202 g, 0.50 mmol) in $CH_2Cl_2$ (20 mL). The color of the solution gradually turned from red to orange and the reflux continued for 2 h. The $NaNO_3$ that precipitated was filtered off and the orange filtrate was layered with *n*-hexane (1:1 v/v %). Orange crystals of **3** suitable for X-ray structure analysis were formed after one week. (Yield: 0.34 g, ca. 70%.) The crystals of **3** were collected by filtration and dried in vacuo. The resulting powder was analyzed as solvent-free. $C_{84}H_{72}Fe_3NO_{25}$ (1663.03): calcd. C 60.67, H 4.36, N 0.84; found C 59.86, H 4.28, N 0.80. Selected IR data: 3603 [$\nu$(OH)$_{free}$], 1612 [$\nu_{as}$(COO)], 1406 [$\nu_s$(COO)], 598 [$\nu_{as}(Fe_3O)$]$cm^{-1}$.

**$[Fe_3(\mu_3\text{-}O)(O_2CPh)_6(H_2O)_3](NO_3)\cdot 3MeCN$ (4·3MeCN):** Solid sodium benzoate (0.144 g, 1.00 mmol) was added to a refluxing solution of $Fe(NO_3)_3\cdot 9H_2O$ (0.202 g, 0.50 mmol) in MeCN (20 mL). The color of the solution gradually turned from red to orange and the reflux continued for 24 h. A white precipitate was filtered off and identified as $NaNO_3$ by FTIR spectroscopy. The orange filtrate was left for slow evaporation and after ca. 1 week, X-ray-quality orange crystals of **4** were formed. (Yield: 0.34 g, ca. 70%.) The crystals of **4** were collected by filtration and dried in vacuo. The resulting powder was analyzed as solvent-free. $C_{42}H_{36}Fe_3NO_{19}$ (1026.28): calcd. C 49.15, H 3.54, N 1.36; found C 48.30, H 3.22, N 1.27. Selected IR data: 1562 [$\nu_{as}$(COO)], 1410 [$\nu_s$(COO)], 573 [$\nu_{as}(Fe_3O)$] $cm^{-1}$.

**Physical Measurements:** Elemental analyses for carbon, hydrogen, and nitrogen were performed on a Perkin–Elmer 2400/*II* automatic analyzer. Infrared spectra were recorded as KBr pellets in the range 4000–500 $cm^{-1}$ with a Bruker Equinox 55/S FTIR spectrophotometer. EPR spectra were recorded with a Bruker ER 200D-SRC X-band spectrometer equipped with an Oxford ESR 9 cryostat in the 4.2–300 K temperature range, an NMR Gaussmeter, an Anritsu frequency counter, and a DM Bruker cavity. Simulations of the EPR spectra were done with home-written routines or software provided to us by Prof. Mike Hendrich, Dept. of Chemistry, Carnegie Mellon University, Pittsburgh, USA. Variable-temperature magnetic susceptibility measurements were carried out with polycrystalline samples of **1**–**4** in the 2.0–300 K temperature range using a Quantum Design MPMS SQUID susceptometer under magnetic fields of 0.1 T (for **1**, **2**) and 1.5 T (for **3**, **4**). Isothermal magnetization measurements were carried out over the 0–5 T magnetic field range. Diamagnetic corrections for the complexes were estimated from Pascal's constants. The calculation of the magnetic susceptibility was accomplished by analytical calculation of the energy levels associated with the spin Hamiltonian using Kambe's spin-coupling approach. Subsequent implementation of the van Vleck equation was done using a home-written routine. For the case of the equilateral model, an analytical expression can also be used.[48] Minimization was carried out with an adapted version of MINUIT.[49] The error factor $R$ is defined as $R = \sum(\chi_{exp} - \chi_{calc})^2/N\chi^2_{exp}$, where $N$ is the number of experimental points. Magnetization $M$ versus applied magnetic field $H$ isotherms were calculated from the best-fit parameters using MAGPACK.[50] Mössbauer spectra for **3** and **4** were recorded with a constant acceleration spectrometer using a $^{57}$Co (Rh) source at room temperature and a variable-temperature Oxford cryostat. The spectra were analyzed with home-written routines. Variable-temperature $^1$H-pulsed NMR experiments for **1** were performed at 4.7 T using a Bruker MSL200 spectrometer operating at 200.145 MHz. An Oxford 1200 CF continuous flow cryostat was employed for measurements in the range 5–300 K. $T_1$ spin-lattice relaxation times were measured using the standard spin-echo pulse sequence combined with the saturation recovery method.[51]

**X-ray Structure Determination:** Green prismatic crystals of **1** ($0.25\times0.35\times0.65$ mm) and **2** ($0.20\times0.30\times0.65$ mm), and orange prismatic crystals of **3** ($0.10\times0.25\times0.50$ mm) and **4** ($0.18\times0.28\times0.50$ mm) were mounted in capillaries with drops of mother liquid. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. Important crystal data and parameters for data collection are reported in Table 3. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11° < 2\theta < 23°$. Intensity data were recorded using a $\theta$–$2\theta$ scan. Three standard reflections monitored every 97 reflections showed less than 3% intensity fluctuation and no decay. Lorentz, polarization, and psi-scan absorption corrections (for **2** and **3** only) were applied using Crystal Logic software. The structures were solved by direct methods using SHELXS-86[52] and refined by full-matrix least-squares techniques on $F^2$ with SHELXL-97.[53] In all cases, the crystals had poor diffraction ability (despite their sufficient size) and the data were collected in increasing $2\theta$ shells, and in each case the data collection was terminated when about 50% of the collected shell data were unobserved. Nevertheless, the quality of the collected data was adequate to establish the structure of the complexes. Further experimental crystallographic details for **1**: $2\theta_{max}$ = 43°, scan speed 1.3° $min^{-1}$; scan range 2.0 + $\alpha_{1\alpha2}$ separation; reflections collected/unique/used, 11108/10817 [$R_{int}$ = 0.0394]/10817; 1200 parameters refined; $(\Delta/\sigma)_{max}$ = 0.011; $(\Delta\rho)_{max}/(\Delta\rho)_{min}$ = 0.811/–0.352 e $Å^{-3}$; $R/R_w$ (for all data), 0.0813/0.1769. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms on the phenyl rings were introduced at calculated positions as riding on bonded atoms; those on the hydroxide and coordinated water molecules were located by difference maps and were refined isotropically. No H atoms for the solvate molecules were included in the refinement. Further experimental crystallographic details for **2**: $2\theta_{max}$ = 45°, scan speed 2.5° $min^{-1}$; scan range 1.7 + $\alpha_{1\alpha2}$ separation; reflections collected/unique/used, 6522/6163 [$R_{int}$ = 0.0255]/6163; 667 parameters refined; $(\Delta/\sigma)_{max}$ = 0.019; $(\Delta\rho)_{max}/(\Delta\rho)_{min}$ = 0.762/–0.625 e $Å^{-3}$; $R/R_w$ (for all data), 0.0836/0.2175. All non-hydrogen atoms were refined anisotropically, except those of the solvate molecules, which were refined isotropically. Hydrogen atoms on the phenyl rings were introduced at calculated positions as riding on bonded atoms; those of the coordinated water molecules were located by difference maps and were refined isotropically. Further experimental crystallographic details for **3**: $2\theta_{max}$ = 42.1°, scan speed 1° $min^{-1}$; scan range 1.75 + $\alpha_{1\alpha2}$ separation; reflections collected/unique/used, 10064/9849 [$R_{int}$ = 0.0421]/9849; 1080 parameters refined; $(\Delta/\sigma)_{max}$ = 0.001; $(\Delta\rho)_{max}/(\Delta\rho)_{min}$ = 0.687/–0.424 e $Å^{-3}$; $R/R_w$ (for all data), 0.1449/0.2373. All non-hydrogen atoms were refined anisotropically, except those of some solvate water molecules that were found to be disordered and were refined isotropically with occupation factors summing one. Hydrogen atoms on the phenyl rings were introduced at calculated positions as riding on bonded atoms; the rest

CCDC-603113 (for **1**), -603114 (for **2**), -603115 (for **3**), and -603116 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Tables S1, S2, S3, and S4 contain selected bond lengths and angles for compounds **1 2**, **3**, and **4** respectively. In Figures S1, S2, S7, and S8, error contour plots of $J$ versus $J'$, in Figures S3, S4, S9, and S10, $M$ versus $H$ isotherms at the appropriate temperature, and in Figures S5, S6, S11, and S12, the energy-level plots for the studied compounds are shown. Every figure of each one of the three groups of four figures given above corresponds to each one of the four studied compounds **1**, **2**, **3**, and **4** correspondingly. In Figure S13 the X-band EPR spectrum of a powdered sample of **4** is shown.

# First Example of a Gold(I) *N*-Heterocyclic-Carbene-Based Initiator for the Bulk Ring-Opening Polymerization of L-Lactide

**Lipika Ray,[a] Vimal Katiyar,[a] Mustafa J. Raihan,[a] Hemant Nanavati,[a] Mobin M. Shaikh,[a] and Prasenjit Ghosh*[a]**

**Keywords:** Carbenes / Functionalized NHC / Ring-opening polymerization (ROP) / Organometallic catalysis / Silver–NHC complex / Gold–NHC complex

Synthesis, structure, and catalysis studies of two Au- and Ag-based initiators, namely, [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AuCl (**1c**) and [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AgCl (**1b**), for the bulk ring-opening polymerization of L-lactide are reported. Specifically, gold complex **1c** was obtained from silver complex **1b** by the transmetalation reaction with $(SMe_2)AuCl$. Silver complex **1b** was synthesized by the treatment of 3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazolium chloride (**1a**) with $Ag_2O$. Compound **1a** was synthesized directly from the reaction of *N*-*tert*-butyl-2-chloroacetamide, cyclohexene oxide, and imidazole. The molecular structures of **1a**, **1b**, and **1c** have been determined by X-ray diffraction studies. The formation of neutral monomeric complexes with linear geometries at the metal centers was observed for both **1b** and **1c**. The Au and Ag complexes **1c** and **1b** successfully catalyzed the bulk ring-opening polymerization of L-lactide at elevated temperatures under solvent-free melt conditions to produce moderate to low molecular weight polylactide polymers with narrow molecular weight distributions.

## Introduction

The long-standing notion of gold being an expensive and unreactive coinage metal with limited utility is gradually changing. Various new applications of $Au^I$ complexes in pharmaceuticals,[1] chemical vapor depositions,[2] and in homogeneous catalysis[3] have been recently reported. Compared to the other coinage metals (i.e. Cu and Ag), Au has seen relatively few applications and poses a formidable challenge in utility-oriented research. Quite significantly, a recent report detailed the use of a $Au^I$ complex supported over a sterically demanding *N*-heterocyclic carbene (NHC) ligand as a catalyst for the ethyl diazoacetate-assisted carbene-transfer reaction;[3] this represents an important breakthrough in this field of chemistry and adds further promise to the use of gold in chemical catalysis. The growing utility of NHCs in homogeneous catalysis is now well-recognized, and a plethora of NHC-based catalysts have been developed in recent years for a wide variety of transformations, such as C–C coupling reactions,[4,5] olefin metatheses,[6] hydrogenations,[7,8] hydroformylations,[9] hydrosilylations,[10] CO-ethylene copolymerizations,[11] hydroboration[12] reactions, and so forth. Interestingly enough, despite the numerous NHC-transition metal complexes that exist, the Au–NHC complexes are surprisingly few in number and have seldomly been employed in catalysis.[13]

A growing number of new applications have appeared lately for the $Ag^I$–NHC counterparts however, and their catalytic utility has just begun to unfold.[14,15] Specifically, the $Ag^I$–NHC complexes have been found to be active catalysts for several chemical transformations, such as, ethyl diazoacetate (EDA)-assisted carbene-transfer reactions,[16] catalytic preparation of 1,2-bis(boronate) esters,[17] transesterification reactions, and ring-opening lactide polymerization reactions.[18] It is noteworthy that even though the applications of $Ag^I$–NHC complexes in chemical catalysis is a recent phenomenon, they are long-known for their use as transmetalation agents for the synthesis of other transition metal–NHC complexes.[14,15] Like its heavier congener, the Au analogue, biomedical applications, particularly with regard to antimicrobial activities, have recently been reported for $Ag^I$–NHC complexes.[19,20] Thus far, the popularity of Ag–NHC complexes can be ascribed to their broadly based applications, to their synthetic accessibility, and to their air and moisture stabilities, which make them user-friendly and hence convenient to handle.[14,15]

As the catalytic utility of Au–NHC complexes remains largely unexplored and that of the Ag–NHC complexes is just beginning to emerge, we became interested in the design of Au and Ag complexes for their potential application in homogeneous catalysis. In particular, we were interested in

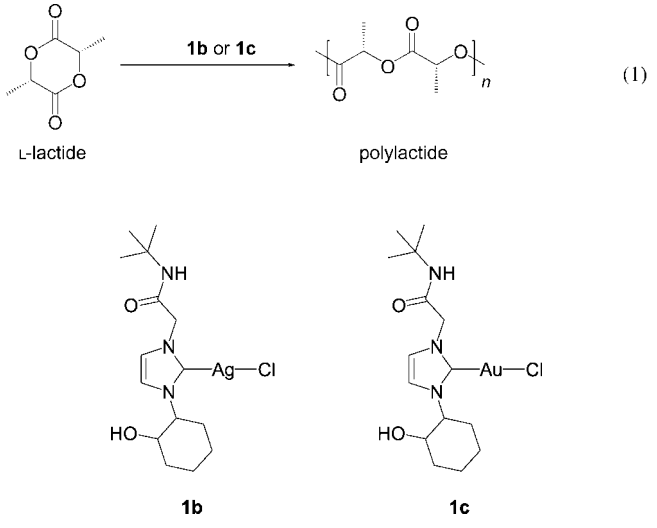
the design of Au–NHC and Ag–NHC based initiators for the ring-opening polymerization (ROP) of L-lactide. In this regard, we have recently reported a Ag–NHC complex as an initiator for the bulk ROP of L-lactide.[21] Although there exists a few reports on the use of $Ag^{I}$–NHC complexes for the ROP of L-lactides,[18,21] we are unaware of any such report in the case of the $Au^{I}$–NHC complexes.

Of late, the ROP of L-lactide has attracted considerable attention by virtue of its eco-friendliness. Not only is the polylactide polymer (PLA) biodegradable, but the lactide monomer can also be generated from renewable resources by a corn fermentation process or from agricultural starch wastes.[22,23] Because of their good mechanical properties and biocompatibility, PLAs have found wide utility in medical and pharmaceutical applications.[24,25] Various metals, such as Zn, Al, and Sn, have been extensively utilized for the synthesis of PLAs.[22a] The specific objective of our program is centered around the design of novel initiators for the bulk polymerization of L-lactides, which are often used for the large-scale production of PLAs. It is interesting to note that even though PLAs can be synthesized by both solution polymerization[26] and bulk polymerization,[27] solution polymerization suffers from certain disadvantages such as being susceptible to impurity levels and to various unwanted reactions, namely, racemization and transesterification, and hence is not conducive for the large-scale production of PLAs.[28] Our approach towards the design of initiators for bulk polymerization involved the utilization of functionalized NHCs as we rationalized that the presence of functional groups would enhance the solubility of the initiators in the monomer melt.

Here in this contribution, we disclose the first example of $Au^{I}$–NHC-based initiator **1c** along with $Ag^{I}$–NHC-based initiator **1b** for the bulk ROP of L-lactide (Figure 1). Specifically, both the gold and the silver complexes, namely, [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AuCl (**1c**) and [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AgCl (**1b**), effectively catalyze the ROP of L-lactide at elevated temperatures under solvent-free melt conditions to afford polylactide polymers of moderate to low molecular weights with narrow molecular weight distributions [Equation (1)]. We also disclose the synthesis and structural characterizations of both the Au (**1c**) and Ag (**1b**) complexes supported over a novel difunctionalized *N*-heterocyclic carbene ligand, 3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene.

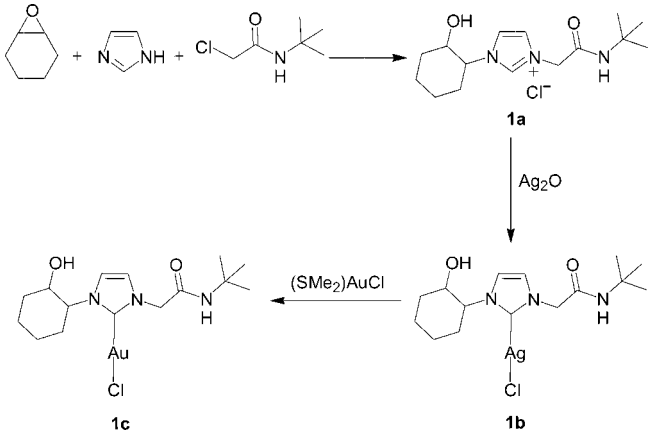


(1)

Figure 1. The complexes [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AgCl (**1b**) and [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AuCl (**1c**).

## Results and Discussion

A difunctionalized *N*-heterocyclic carbene ligand, 3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene, with two functionalized imidazolyl *N*-substituents, a 2-hydroxycyclohexyl moiety and an *N*-*tert*-butylacetamido moiety, was synthesized by a modified procedure reported by Arnold and coworkers.[29] Specifically, the NHC precursor, 3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazolium chloride (**1a**), was obtained from the direct reaction of *N*-*tert*-butyl-2-chloroacetamide, cyclohexene oxide, and imidazole in 96% yield (Scheme 1). The formation of imidazolium salt **1a** was confirmed by the appearance of the diagnostic (NC*H*N) resonance at $\delta$ = 9.31 ppm in the $^{1}$H NMR spectrum and the corresponding carbon resonance (N*C*HN) at $\delta$ = 136.3 ppm in the $^{13}$C NMR spectrum. The most interesting aspect of the $^{1}$H NMR spectrum is the diastereotopic nature of the two bridging methylene proton (-C$H_2$-) resonances which appear as two doublets at $\delta$ = 5.16 ppm and 4.96 ppm and display a geminal coupling between the two protons ($^{2}J_{H,H}$ = 15 Hz). For example, similar diastereotopic hydrogens for the bridging methylene moiety (-C$H_2$-) have been reported for Ir complexes with a 1-*n*-butyl-3-(2-pyridylmethyl)imidazol-2-ylidene ligand.[30] The carbonyl moiety (-*C*ONH-) appeared at $\delta$ = 163.8 ppm in the $^{13}$C NMR spectrum and at 1671 cm$^{-1}$ ($\nu_{co}$) in the infrared spectrum. In the electrospray mass spectrum the 3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazolium cation appeared as a peak at *m*/*z* = 280 and was further substantiated by HRMS results.



Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The imidazolium halide salt **1a** has been structurally characterized by X-ray diffraction studies (Figure 2). The N1–C9 and N2–C9 bond lengths are 1.326(6) Å and 1.314(6) Å, respectively, and the N2–C9–N1 angle is 107.9(5)° for **1a** and is comparable with other imidazolium halide salts. For example, in a CN-functionalized imidazolium salt, 1-$CH_2$CN-3-methylimidazolium chloride, the C–N bond lengths are 1.348(3) Å and 1.336(3) Å and the N–C–N angle is 107.6°.[31]

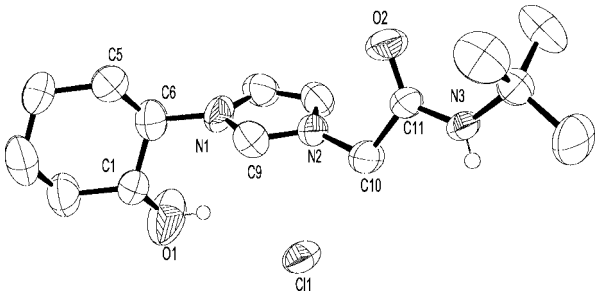


Figure 2. ORTEP drawing of **1a** with thermal ellipsoids drawn at 50% probability level. Selected bond lengths [Å] and angles [°]: N1–C9 1.326(6), N2–C9 1.314(6), N2–C9–N1 107.9(5).

The silver complex, [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AgCl (**1b**), was synthesized by the reaction of 3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazolium chloride (**1a**) with $Ag_2O$ in dichloromethane at room temperature in 86% yield with the convenient methodology developed by Lin and coworkers.[32] The $^1$H NMR spectrum of **1b** confirmed the absence of the reactant imidazolium (NC*H*N) peak in the ca. 9 ppm region. The $^{13}$C NMR spectrum showed a new peak at $\delta$ = 181.6 ppm, which corresponds to the silver-bound carbene (N*C*N) resonance; the peak at $\delta$ = 136.3 ppm attributable to reactant **1a** (N*C*HN) was absent as a result of its deprotonation by $Ag_2O$ and is indicative of the formation of **1b**. The two diastereotopic protons of the bridging methylene (-C$H_2$-) group appeared shifted as two doublets at $\delta$ = 4.94 ppm ($^2J_{H,H}$ = 15 Hz) and 4.82 ppm ($^2J_{H,H}$ = 15 Hz), respectively, compared to that of **1a**. The carbon resonance of the bridging methylene (-*C*$H_2$-) group appeared at $\delta$ = 54.4 ppm in the $^{13}$C NMR spectrum. In the infrared spectrum, the amide carbonyl (-CONH-) appeared at 1673 cm$^{-1}$ while the hydroxy group appeared as a broad peak at 3302 cm$^{-1}$.

The definitive proof for the structure of **1b** came from X-ray diffraction studies (Figure 3), which revealed a neutral monomeric complex bearing a 1:1 (NHC ligand/metal) stoichiometry. The silver center of **1b** was found to be two-coordinate, displays a linear geometry [∠ C1–Ag1–Cl1 = 172.66(11)°], and is consistent with the most common geometry displayed by $d^{10}$ silver(I) ions.[33] The Ag–$C_{carb}$ (Ag1–C1 = 2.066(4) Å) bond length of **1b** is shorter than the sum of the individual covalent radii of Ag and C (2.111 Å),[34a] but is comparable to that observed in other related (NHC)AgCl-type complexes. For example, a Ag–$C_{carb}$ bond length of 2.056(7) Å was observed in the case of [1,3-*bis*(mesityl)imidazol-2-ylidene]AgCl,[35] while that of 2.098(2) Å was observed in another functionalized NHC complex, [1-(2-benzylideneamino-3,5-di-*tert*-butylbenzyl)-3-(*tert*-butyl)imidazol-2-ylidene]AgCl.[36] However, it is to be noted that the extent of π-backbonding in Group 11 metal–NHC (Cu, Au, Ag) complexes still remains a matter of debate with independent theoretical calculations carried out by Frenking[37] and Meyer,[38] who propose opposing views. In addition, a recent study by Cundari[39] concluded that a shortening of the metal–carbene bond up to 4% can be attributed to the change in hybridization state of the carbene carbon as a consequence of the enhanced *s*-character of the in-plane carbene lone pair σ-bonded to the metal in the metal–NHC complexes. The Ag1–Cl1 bond length of 2.3264(11) Å in **1b**, however, matches more closely with the sum of individual covalent radii of Ag and Cl (2.329 Å)[34a] and is in agreement with a single-bond character.

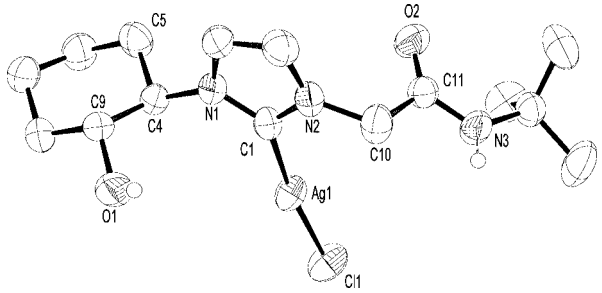

Figure 3. ORTEP drawing of **1b** with thermal ellipsoids drawn at 50% probability level. Selected bond lengths [Å] and angles [°]: Ag–C1 2.066(4), Ag–Cl1 2.3264(11), N1–C1 1.350(4), N2–C1 1.345(5), C1–Ag–Cl1 172.66(11), N2–C1–N1 110.9(3).

Another notable structural feature of **1b** is that both of the *N*-substituents, that is, the 2-hydroxycyclohexyl and the *N*-*tert*-butylacetamido moieties, are disposed *trans* to each other with respect to the plane that contains the central imidazole ring and the silver center. The 2-hydroxy cyclohexyl O atom (O1···Ag1 = 4.176 Å) and the *N*-*tert*-butylacetamido O atom (O2···Ag1 = 4.199 Å) are located equidistant from the central Ag atom but in approximately diagonally opposite directions (*trans* orientation). Furthermore, the 2-hydroxycyclohexyl and the *N*-*tert*-butylacetamido moieties are perpendicular to the imidazole ring where the dihedral angle is 111.2° (C9–C4–N1–C1) and 85.6° (C1–N2–C10–C11), respectively.

The treatment of silver complex **1b** with ($SMe_2$)AuCl yielded the gold complex, [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AuCl (**1c**), along with the precipitation of off-white AgCl in 77% yield. It is interesting to note that there are several methods available for the synthesis of Au–NHC complexes: (1) cleavage of electron-rich olefins,[40] (2) carbene transfer from Group 6 carbonyl complexes,[41] (3) reactions of azolium salts or free NHCs with $Au^I$ precursors,[42] (4) protonation or alkylation of gold azolyl complexes,[43] and (5) transmetalation by the reaction of $Ag^I$–NHC complexes with $Au^I$ precursors.[32] The popularity of the transmetalation method is primarily a result of the fact that the generation of free carbenes from the imidazolium salts with the use of strong bases often

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

promotes decomposition reactions, and also the generated free carbenes are often difficult to handle because of their air and moisture sensitivities.[13] The $^1$H NMR spectrum of **1c** shows two diastereotopic bridging methylene protons (-C$H_2$-) that appear as two sets of doublets at $\delta$ = 5.01 ppm ($^2J_{H,H}$ = 15 Hz) and 4.40 ppm ($^2J_{H,H}$ = 15 Hz). The Au-bound carbene (N*C*N) peak appears slightly shifted at $\delta$ = 170.2 ppm compared to the Ag-bound carbene (N*C*N) resonance at $\delta$ = 181.6 ppm in the $^{13}$C NMR spectrum. In the infrared spectrum, the carbonyl peak of the amido (-CONH-) moiety appears at 1676 cm$^{-1}$ while the cyclohexyl hydroxy peak appears at 3439 cm$^{-1}$.

The X-ray diffraction study revealed that the molecular structure of gold complex **1c** (Figure 4) is isomorphous with silver complex **1b**. The *N*-substituents, 2-hydroxycyclohexyl and *N*-*tert*-butylacetamido, were found to be perpendicular to the imidazole ring, and the dihedral angles between each of these two moieties and the imidazolium ring is 112.1(5)° (C9–C4–N2–C1) and 83.7(6)° (C11–C10–N1–C1), respectively. Notably, the 2-hydroxycyclohexyl O atom and the *N*-*tert*-butylacetamido O atom are disposed *trans* to each other with respect to the central imidazole ring and they also point away from the Au atom in diagonally opposite directions. The O1···Au1 (2-hydroxycyclohexyl O atom) and the O2···Au1 (*N*-*tert*-butylacetamido O atom) distances are 4.082 Å and 4.109 Å, respectively. Consistent with a shorter covalent radii of Au compared to Ag,[34] the Au1–C1 bond [1.969(5) Å] in **1c** was indeed shorter than the corresponding Ag1–Cl bond [2.066(4) Å] in **1b**. Another noticeable difference is that the N1–C1–N2 angle [105.2(4)°] in **1c** is slightly greater than the value seen in **1b** [104.3(3)°].

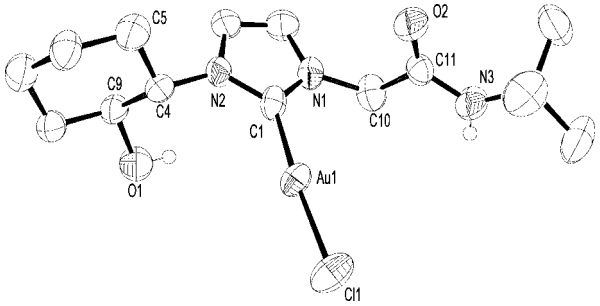

Figure 4. ORTEP drawing of **1c** with thermal ellipsoids drawn at 50% probability level. Selected bond lengths [Å] and angles [°]: Au–C1 1.969(5), Au–Cl1 2.2845(13), N1–C1 1.332(6), N2–C1 1.355(5), C1–Au–Cl1 175.30(15), N2–C1–N1 111.3(4).

It is worth noting that compared to the numerous Ag$^I$–NHC complexes that are known, the Au$^I$–NHC complexes are surprisingly few in number. Correspondingly, the structural diversity exhibited by Ag$^I$–NHC complexes are more varied and diverse[35,36,44,45] when compared to their gold counterparts,[46–48] which commonly exhibit neutral monomeric (NHC)AuX (X = halide) and cationic [(NHC)$_2$Au]$^+$ type structures.[13] In this regard, Nolan and coworkers[49] have recently reported a series of neutral monomeric gold complexes, [1,3-bis(R)imidazol-2-ylidene]AuCl (R = mesityl, 2,6-di-*i*-propylphenyl, cyclohexyl and adamentyl); the bond lengths and bond angles of which are comparable to that observed in **1c**.

Because of their synthetic ease and air and moisture stabilities, there is a growing emphasis on the catalytic utility of Au and Ag complexes of the (NHC)MX (M = Au, Ag, X = halide) type. Research in this area may facilitate their use as precursors in the preparation of other important compounds.

Quite significantly, both Au and Ag complexes **1c** and **1b** efficiently catalyze the bulk ROP of L-lactide under solvent-free melt conditions at elevated temperatures. To the best of our knowledge, **1c** represents the first example of a Au$^I$–NHC based initiator for the ROP of L-lactide. Even though there exists a report of solution polymerization[18] and a report of the bulk polymerization[21] of L-lactide by Ag$^I$–NHC complexes, we are not aware of any such polymerization by Au$^I$–NHC complexes. Bulk polymerization exhibits certain advantages over solution polymerization: (1) no solvent is required, (2) it is less vulnerable to impurity levels and unwanted side reactions, (3) it is often useful for the large-scale production of PLAs.[28]

Specifically, a typical polymerization experiment would involve the heating of L-lactide and the catalyst, **1b** or **1c**, for a given monomer to catalyst ratio in a sealed vessel under vacuum at a designated temperature for a specific period of time. Under these conditions, the reaction mixture would form a monomer melt in which the polymerization would occur. The variation of the [M]:[C] ratio (M = monomer, C = catalyst) showed that the maximum molecular weight in the case of **1b** (Entry 2: $M_n = 5.1 \cdot 10^3$, Table 1) as well as in **1c** (Entry 2: $M_n = 5.4 \cdot 10^3$, Table 2) were obtained at [M]:[C] ratio 100:1 for a 4 h run at 160 °C. The molecular weight distributions are almost similar for both catalysts **1b** (PDI = 1.10–1.53) and **1c** (PDI = 1.07–1.35). Interesting would be the comparison of the polymerization results of **1b** and **1c** with that of the other reported Au and Ag–NHC complexes. As we are unaware of any Au–NHC complex known for the ROP of L-lactide, such a comparison can only be drawn for the Ag–NHC complexes.[18,21] For example, for a cationic 2:1 (NHC ligand/metal) silver-NHC complex supported over a mono-functionalized NHC ligand re-

cently reported by us[21] for the bulk polymerization of L-lactide under analogous melt conditions, higher molecular weight polymers were obtained as compared to that of **1b** and **1c**. However, it should be noted that in the present study neutral monomeric (NHC)MCl (M = Ag and Au) type complexes, supported over a different difunctionalized NHC ligand, were examined as initiators for lactide polymerizations.

Table 2. Melt polymerization of L-lactide by **1c**.

| 14 | 100 | 160 | 8 | $5.1\cdot10^3$ | 1.35 | 90 |

The time-dependence study showed that the average molecular weight ($M_n$) of the polymer increased with time for the first 6 h in the case of **1b** and for the first 4 h in the case of **1c**, after which it reached saturation. The temperature-dependence study was carried out in the range 120–180 °C and showed that for both **1b** and **1c** the molecular weight increased steadily with the temperature till 160 °C after which point it started to decrease. The decrease in molecular weight may be attributed to the depolymerization that takes place at higher temperatures. A similar decrease in the molecular weight at higher temperatures has been reported by Liao[27a] and by Albertson and Varma.[24] Detailed mechanistic studies are underway to establish the nature of the active species responsible for the catalysis. In this regard, it is worth mentioning that there have been reports of both metal-mediated polymerization[21] as well as carbene-mediated lactide polymerization.[52]

It is interesting to note that despite the fact that the Au–$C_{carb}$ bond energy (76.3 kcal/mol) is significantly stronger than the Ag–$C_{carb}$ bond energy (53.1 kcal/mol) in (NHC)-MCl (M = Ag and Au) complexes,[37] comparable polymer molecular weights were observed in the case of **1b** ($M_n$ = $3.0–5.1\cdot10^3$) and **1c** ($M_n$ = $2.0–5.4\cdot10^3$). At this juncture, it will be worthwhile to compare the activity of **1c**, with representative examples of other metal-based catalysts for the bulk ROP of L-lactide. For example, the zinc complexes of the picolyl carbene ligand, namely, ethyl zinc iodide·1-mesityl-3-picolylimidazol-2-ylidene adduct and its bis-ligand adduct gave PLAs with $M_n$ = $(6.1–20)\cdot10^3$, when the polymerization was carried out at 140 °C.[26b] The molecular weight distributions (PDI = 1.78–2.45) for PLAs obtained from these picolylcarbene-based zinc complexes are, however, higher as compared to that of **1b** or **1c**. Similarly, the Co, Ni, Cu, and Zn complexes of a Schiff base ligand derived from salicylidene and L-aspartic acid, also yielded PLAs with a viscosity average molecular weight in the order of $(4.86–11.1)\cdot10^3$ at 130 °C over a period of 24 h.[53] Furthermore, PLAs with a relatively narrow molecular weight distribution (PDI = 1.12–1.32) have been obtained with $M_n$ = $(1.93–2.3)\cdot10^4$ with the use of Red-Al as a catalyst in the temperature range of 110–135 °C.[27b] In addition, a series of titanatranes with varying ring sizes have been successfully employed to achieve molecular weights [$M_n$ = $(1.6–3.36)\cdot10^4$] with PDI in the range of 1.42–1.97 at 130 °C.[27c] Recently, various ferric alkoxides [$Fe(OR)_3$; R = Et, Pr, *i*Pr, Bu] have been reported for moderate molecular weight PLAs [$M_n$ = $(1.78–13.97)\cdot10^4$] with PDI = 1.60–1.98; however, the polymerization have been carried out up to 72 h at 130–150 °C.[27a] We believe that, as a first example of a Au-based initiator for the bulk polymerization of L-lactide, the Au–NHC complex **1c** would encourage further research in the utility of gold in this area.

## Conclusion

In summary, two new silver and gold complexes, namely, [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AgCl (**1b**) and [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AuCl (**1c**), supported over a difunctionalized *N*-heterocyclic carbene ligand have been synthesized. The **1a**, **1b**, and **1c** complexes have been structurally characterized by X-ray diffraction studies. The comparison of structures **1b** and **1c** show the formation of neutral monomeric complexes that have a 1:1 (NHC ligand/metal) stoichiometry. Notably, in neither structure **1b** nor structure **1c** was the chelation of the functionalized sidearms to the metals observed. This is in agreement with the two-coordinated $d^{10}$ configurations of the $Au^I$ and $Ag^I$ ions that prefer linear geometries. The gold and silver complexes **1c** and **1b** effectively catalyze the ROP of L-lactide under solvent-free melt conditions to produce the polylactide polymer of moderate to low molecular weight with a narrow molecular weight distribution. Gold complex **1c** represents the first example of a $Au^I$–NHC based initiator for the ROP of L-lactide.

## Experimental Section

**General Procedures:** All manipulations were carried out with a glove box and/or standard Schlenk techniques. Solvents were purified and degassed by standard procedures. $Ag_2O$ was purchased from SD-fine chemicals (India) and used without any further purification. $(SMe_2)AuCl$[50] and *N*-*tert*-butyl-2-chloroacetamide[51] were synthesized according to literature procedures. $^1H$- and $^{13}C\{^1H\}$ NMR spectra were recorded in $CDCl_3$ with a Varian 400 MHz NMR spectrometer. $^1H$ NMR peaks are labeled as singlet (s), doublet (d) and multiplet (m). Infrared spectra were recorded with a Perkin–Elmer Spectrum One FTIR spectrometer. Mass spectrometry measurements were performed with a Micromass Q-Tof spectrometer. Polymer molecular weights were determined with a Waters GPC (Waters 2414 RI Detector) and with PL-

gel, 5μ Mixed-D (2 × 300 mm) column, with polystyrene standards in chloroform, with a covered molecular weight range of l40 to $4{\cdot}10^5$. X-ray diffraction data for **1b** was collected with a NONIUS-MACH3 diffractometer and that of **1a** and **1c** was collected on Oxford diffraction XCALIBUR-S instrument. The crystal data collection and refinement parameters are summarized in Table 3. The structures were solved by direct methods and standard difference map techniques and were refined by full-matrix least-squares procedures on *F*2 with SHELXTL (Version 6.10). CCDC-606428 (**1a**), CCDC-606429 (**1b**), and CCDC-606427 (**1c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of 3-(*N*-*tert*-Butylacetamido)-1-(2-hydroxycyclohexyl)-imidazolium Chloride (1a):** Cyclohexene oxide (0.656 g, 6.69 mmol) and imidazole (0.455 g, 6.69 mmol) were heated at 60 °C for 12 h and the resulting sticky brown solid was dissolved in acetonitrile (ca. 20 mL). *N*-*tert*-Butyl-2-chloroacetamide (1.00 g, 6.69 mmol) was added to the solution and the reaction mixture was heated at 90 °C for 2 h. A white precipitate was collected by filtration and was recrystallized from acetonitrile (ca. 10 mL) and dried under vacuum to give the product **1a** as a white solid (2.02 g, 96%). $^1$H NMR ($CDCl_3$, 400 MHz, 25 °C): $\delta$ = 9.31 (s, 1 H, NC*H*N), 8.19 (br., 1 H, N*H*), 7.44 (br., 2 H, NC*H*CHN), 5.16 (d, $^2J$ = 15 Hz, 1 H, C$H_2$), 4.96 (d, $^2J$ = 15 Hz, 1 H, C$H_2$), 4.12–4.00 (m, 1 H, $C_6H_{10}$), 3.62–3.56 (m, 1 H, $C_6H_{10}$), 2.12–1.98 (m, 4 H, $C_6H_{10}$), 1.78–1.68 (m, 4 H, $C_6H_{10}$), 1.30 [s, 9 H, C(C$H_3$)$_3$] ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 100 MHz, 25 °C): $\delta$ = 163.8 (*C*O), 136.3 (N*C*HN), 123.1 (N*C*HCHN), 120.1 (NCH*C*HN), 51.8 (*C*H$_2$), 34.3 ($C_6H_{10}$), 31.2 ($C_6H_{10}$), 30.9 [*C*(CH$_3$)$_3$], 28.5 [C(*C*H$_3$)$_2$], 24.5 (2C, $C_6H_{10}$), 23.9 (2C, $C_6H_{10}$) ppm. IR (KBr): $\tilde{\nu}$ = 3213 (br, OH), 1671 (s, CO) cm$^{-1}$. LRMS (ES): *m*/*z* (%) = 280 [100, (NHC–Ligand)$^+$]. HRMS (ES): calcd. for (NHC–Ligand)$^+$ 280.2025; found 280.2022.

**Synthesis of [3-(*N*-*tert*-Butylacetamido)-1-(2-hydroxycyclohexyl)-imidazol-2-ylidene]AgCl (1b):** A mixture of 3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazolium chloride **1a** (2.98 g, 9.53 mmol) and $Ag_2O$ (1.11 g, 4.77 mmol) in dichloromethane (ca. 25 mL) was stirred at room temperature for 6 h. The reaction mixture was filtered and the solvent was removed under vacuum to give the product **1b** as a white solid (3.46 g, 86%). $^1$H NMR ($CDCl_3$, 400 MHz, 25 °C): $\delta$ = 8.19 (br., 1 H, N*H*), 7.03 (br., 2 H, NC*H*CHN), 4.94 (d, $^2J$ = 15 Hz, 1 H, C$H_2$), 4.82 (d, $^2J$ = 15 Hz, 1 H, C$H_2$), 4.25–4.20 (m, 1 H, $C_6H_{10}$), 3.68–3.55 (m, 1 H, $C_6H_{10}$), 2.13–2.04 (m, 4 H, $C_6H_{10}$), 1.80–1.70 (m, 4 H, $C_6H_{10}$), 1.34 [s, 9 H, C(C$H_3$)$_3$] ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 100 MHz, 25 °C): $\delta$ = 181.6 (N*C*N–Ag), 166.6 (*C*O), 123.0 (N*C*HCHN), 117.8 (NCH*C*HN), 54.4 (*C*H$_2$), 34.4 ($C_6H_{10}$), 32.9 ($C_6H_{10}$), 32.3 [*C*(CH$_3$)$_3$], 28.6 [C(*C*H$_3$)$_2$], 24.9 (2 C, $C_6H_{10}$), 24.4 (2 C, $C_6H_{10}$) ppm. IR (KBr): $\tilde{\nu}$ = 3302 (br, OH), 1673 (s, CO) cm$^{-1}$. LRMS (ES): *m*/*z* = 386 (NHC–Ag)$^+$, 667 (NHC)$_2$Ag]$^+$.

**Synthesis of [3-(*N*-*tert*-Butylacetamido)-1-(2-hydroxycyclohexyl)-imidazol-2-ylidene]AuCl (1c):** A mixture of [3-(*N*-*tert*-butylacetamido)-1-(2-hydroxycyclohexyl)imidazol-2-ylidene]AgCl **1b** (0.277 g, 0.651 mmol) and ($SMe_2$)AuCl (0.193 g, 0.651 mmol) in dichloromethane (ca. 15 mL) was stirred at room temperature for 6 h, when the formation of an off-white AgCl precipitate was observed. The reaction mixture was filtered and the solvent was removed under vacuum to obtain the product **1c** as a white solid (0.259 g, 77%). $^1$H NMR ($CDCl_3$, 400 MHz, 25 °C): $\delta$ = 9.12 (br., 1 H, N*H*), 7.12 (br., 1 H, NC*H*CHN), 6.93 (br., 1 H, NC*H*CHN), 5.01 (d, $^2J$ = 15 Hz, 1 H, C$H_2$), 4.40 (d, $^2J$ = 15 Hz, 1 H, C$H_2$), 4.35–4.29 (m, 1 H, $C_6H_{10}$), 3.76–3.70 (m, 1 H, $C_6H_{10}$), 2.07–2.01 (m, 4 H, $C_6H_{10}$), 1.80–1.67 (m, 4 H, $C_6H_{10}$), 1.30 [s, 9 H, C(C$H_3$)$_3$] ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 100 MHz, 25 °C): $\delta$ = 170.2 (N*C*N–Au), 165.7 (*C*O), 123.6 (N*C*HCHN), 117.7 (NCH*C*HN), 54.4 (*C*H$_2$), 41.0 ($C_6H_{10}$), 34.0 ($C_6H_{10}$), 32.4 [*C*(CH$_3$)$_3$], 29.7 [C(*C*H$_3$)$_2$], 24.9 (2 C, $C_6H_{10}$), 24.3 (2 C, $C_6H_{10}$) ppm. IR (KBr): $\tilde{\nu}$ = 3439 (br, OH), 1676 (s, CO) cm$^{-1}$.

**Polymerization Experiments:** Bulk polymerizations of L-lactide were carried out in vacuo-sealed glass ampoules. Firstly, the glass ampoule was charged with monomer (L-lactide) and dried for a period of two hours under high vacuum at 50 °C. Subsequently, the catalyst (**1b** or **1c**) was then added with the monomer to catalyst ratio in the range of 50–300. The ampoule was sealed under high vacuum and immersed in an oil bath. Polymerizations were carried out in the temperature range 120–180 °C. After a predetermined time (1–8 h) the glass ampoule was removed and subsequently the molten reactive polymer mixture was cooled while the sealed ampoule was immersed in liquid nitrogen to stop the polymerization, and thereafter the samples were removed for analysis. The analyses were performed on the crude reaction mixture; no precipitation was executed in order to avoid fractionation of the sample.

## Acknowledgments

We thank the Department of Science and Technology (Grant No: SR/S1/IC-25/2003) for financial support of this research. We are grateful to the National Single Crystal X-ray Diffraction Facility at IIT Bombay, India, for the crystallographic results. LR thanks IIT Bombay, Mumbai, for a research fellowship.

# A Comparative Study of the Optical and Electroluminescent Properties of $Eu^{III}$ Complexes with TTA and 2-(2′-Pyridyl)azoles: The Crystal Structure of $[Eu(TTA)_3(PBO)]$

**Li-Hua Gao,[a,b] Min Guan,[c] Ke-Zhi Wang,*[a] Lin-Pei Jin,[a] and Chun-Hui Huang[c]**

**Keywords:** X-ray diffraction / Luminescence / Chelates / N,O ligands / Lanthanides

Two $Eu^{III}$ mixed-ligand complexes, namely $[Eu(TTA)_3(PBO)]$ and $[Eu(TTA)_3(PBT)]$ [TTA = 1,1,1-trifluoro-3-(2-thenoyl)acetonato, PBO = 2-(2′-pyridyl)-1,3-benzoxazole, and PBT = 2-(2′-pyridyl)-1,3-benzothiazole], have been synthesized. $[Eu(TTA)_3(PBO)]$ has been structurally characterized by single-crystal X-ray diffraction analysis. The complex crystallizes in the monoclinic space group $C2/c$. The lattice parameters are $a$ = 41.346(4), $b$ = 10.0538(8), $c$ = 20.3793(16) Å, $\beta$ = 110.922(2)°, $Z$ = 8. The $Eu^{III}$ ion is eight-coordinate, with three bidentate $TTA^-$ anions and one bidentate N,O-chelated PBO molecule. A comparative study by UV and emission spectroscopy was carried out and electroluminescent properties of the related complexes $[Eu(TTA)_3(PBO)]$ and $[Eu(TTA)_3(PBT)]$ are reported as well.

## Introduction

$Eu^{III}$ complexes have attracted tremendous interest due to their highly monochromic red emission with large Stokes shifts and long emission lifetimes of up to a few milliseconds.[1] These materials have found widespread applications in chemical and earth sciences as well as bioinorganic chemistry, ranging from DNA binding properties to antibody labels in immunoassays.[1–3] A particularly important class of complexes is that of lanthanide β-diketonates, which have recently attracted attention in the development of new materials based on red, near-infrared, and white-light photo-conversion and switching/sensing molecular devices,[4] sol–gel glasses,[5] liquid crystals,[6] red-emitting electroluminescent devices,[7–9] supramolecular assemblies,[10] polymers,[11] and Langmuir–Blodgett (LB) and self-assembled ultrathin films.[12–14]

As far as $Eu^{III}$ β-diketonates developed for electroluminescent devices are concerned, [Eu(β-diketonate)$_3$L]-type complexes (L = bidentate neutral heterocyclic ligand) have played a very important role. It has been demonstrated that the introduction of L to replace the two coordinated water molecules in [Eu(β-diketonate)$_3$(H$_2$O)$_2$] is imperative to obtain vapor volatility for vacuum deposition film-based electroluminescent devices.[15] However, as almost all of the bidentate neutral heterocyclic ligands are α-diimines such as 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen), or their substitutional derivatives, in addition to 2,2′-bipyridine *N*-oxide and 1,10-phenanthroline *N*-oxide,[16] novel types of complexes are limited.[1–8] We have reported a series of [Eu(β-diketonate)$_3$(α-diimine)]-type complexes for electroluminescent devices,[8] and introduced amphiphilic complexes of this kind into Langmuir–Blodgett films.[13] To promote rapid development of these research fields, it is important to develop novel examples of such complexes.

In addition to the great interest in functional metal complexes based on bpy and phen derivatives, structurally analogous 2-(2′-pyridyl)azoles such as 2-(2′-pyridyl)-1,3-benzoxazole (PBO), 2-(2′-pyridyl)-1,3-benzothiazole (PBT), and 2-(2′-pyridyl)benzimidazole (PBI), which are structurally similar to 2,2′-bipyridine or 1,10-phenanthroline *N*-oxide,[16] have attracted special attention for use in electroluminescent devices, as radiopharmaceuticals based on metal complexes of $[Re^{I}(CO)_3(L)X]$ (X = halide),[17] when attached to $Re^{V}O^{3+}$ and $Tc^{V}O^{3+}$ cores,[18] for complexation with $Ru^{II}$,[19] $Pt^{II}$,[20] $Rh^{III}$ and $Pd^{II}$,[20b] $Mo^{V}$,[21] $Sn^{II}$,[22] and $Co^{II}$, $Zn^{II}$ and $Cu^{II}$ etc.,[23] and because of their structural and physicochemical properties. We have reported the electroluminescence properties of $Eu^{III}$ complexes with PBI,[8c,8i] but so far little attention has been paid to lanthanide complexes with 2-(2′-pyridyl)azoles.[24] Here, we present a comparative study of the optical and electroluminescent

cence properties of $Eu^{III}$ complexes of $[Eu(TTA)_3(L)]$ [TTA = 1,1,1-trifluoro-3-(2-thenoyl)acetonato; L = PBO, PBT, and PBI], and a single-crystal X-ray structural characterization of $[Eu(TTA)_3(PBO)]$.

## Results and Discussion

### Synthesis

2-(2′-Pyridyl)-1,3-benzoxazole (PBO), 2-(2′-pyridyl)-1,3-benzothiazole (PBT), and 2-(2′-pyridyl)benzimidazole (PBI), and their $Eu^{III}$ complexes $[Eu(TTA)_3(PBO)]$, $[Eu(TTA)_3(PBT)]$, and $[Eu(TTA)_3(PBI)]$ were prepared according to the reactions shown in Figure 1. The three 2-(2′-pyridyl)azoles were obtained by direct condensation of picolinic acid with 2-aminophenol, 2-aminothiophenol, and 1,2-phenylenediamine, respectively, in a 1:1 molar ratio in the presence of polyphosphoric acid,[25] although there have been reports of the synthesis of PBO based on the oxidation of the appropriate Schiff bases by $Ag_2O$[26a] and by the palladium-catalyzed carbonylation and condensation of aromatic halides and *o*-aminophenols.[27] Single crystals of PBT suitable for X-ray diffraction analysis were obtained by recrystallization from $CH_2Cl_2$/hexane; its structure and lattice parameters are consistent with those reported previously.[26b] The reaction of $[Eu(TTA)_3(H_2O)_2]$ with L (L = PBO, PBT and PBI) in a 1:1 molar ratio in refluxing ethanol for 1 h, and then washing of the filtered product with hot ethanol, yielded satisfactorily pure $[Eu(TTA)_3(L)]$. $[Eu(TTA)_3(PBO)]$ was also structurally characterized by single-crystal X-ray diffraction.

### Crystal Structure

A molecular view and the crystal packing of $[Eu(TTA)_3(PBO)]$ are shown in Figures 2 and 3, respectively; selected bond parameters are listed in Table 1. As expected, the PBO ligand coordinates to the $Eu^{III}$ ion in an unusual N,O-chelation mode. The complex crystallizes in the monoclinic space group $C2/c$ with lattice parameters $a$ = 41.346(4), $b$ = 10.0538(8), $c$ = 20.3793(16) Å, $\beta$ = 110.922(2)°, and $Z$ = 8. The complex is mononuclear and the $Eu^{III}$ ion is eight-coordinate, with six oxygen atoms of three bidentate $TTA^-$

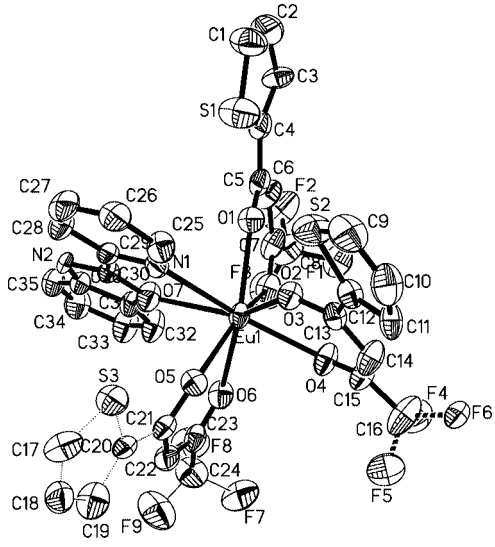

Figure 2. Asymmetric unit of $[Eu(TTA)_3(PBO)]$ with atom numbering scheme and thermal ellipsoids (30%).

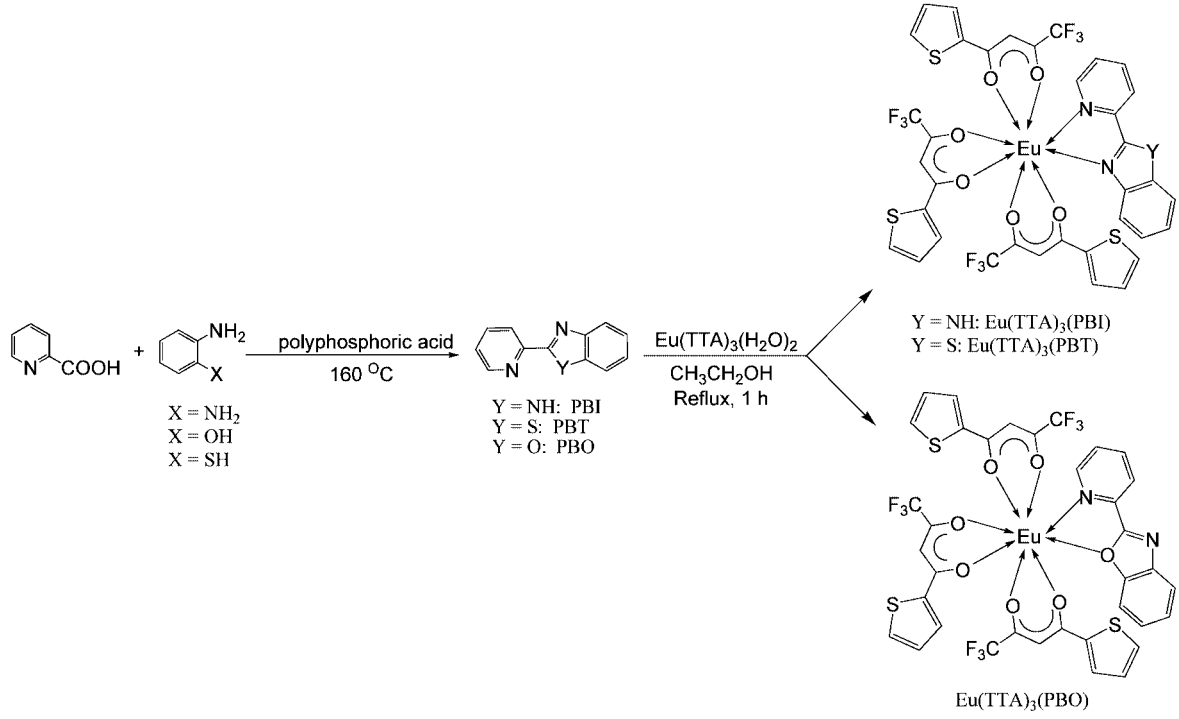

Figure 1. The synthetic routes to the $Eu^{III}$ complexes.

anions and one oxygen atom and one nitrogen atom of a bidentate PBO ligand. These atoms lie at the apices of a slightly distorted square antiprism. One of the two planes of the square antiprism is formed exclusively by oxygen atoms [O(1)–O(4)] and the other one by one nitrogen atom and three oxygen atoms [N(1) and O(5)–O(7)]. The two square planes are almost parallel to each other, as shown by the dihedral angle of 1.3°. The average bond lengths and angles of the $TTA^-$ ligands are similar to those reported for other TTA complexes.[28] The Eu–O bond lengths range from 2.33(2) to 2.58(2) Å, and the mean Eu–O(TTA) bond [2.36(2) Å] is 0.22 Å shorter than the average Eu–O(PBO) bond [2.58(2) Å], thus indicating that TTA has a stronger coordinating ability than PBO. The Eu−O bond in PBO of $[Eu(TTA)_3(PBO)]$, however, is stronger than the Eu−N bonds found in $[Eu(TTA)_3(PBO)]$, $[Eu(DBM)_3(pip)]$ (DBM = dibenzoylmethanato; pip = 2-phenylimidazo[4,5-*f*]1,10-phenanthroline),[8h] and $[Eu(DBM)_3(edapip)]$ {edapip = 3-ethyl-2-[4′-(dimethylamino)phenyl]imidazo[4,5-*f*]1,10-phenanthroline}.[8d] Interestingly, as shown in Figure 3, there is a π···π stacking interaction between two PBO molecular planes in two adjacent $[Eu(TTA)_3(PBO)]$ molecules, with an interplanar distance of 3.354(1) Å and a dihedral angle of 0° between them.

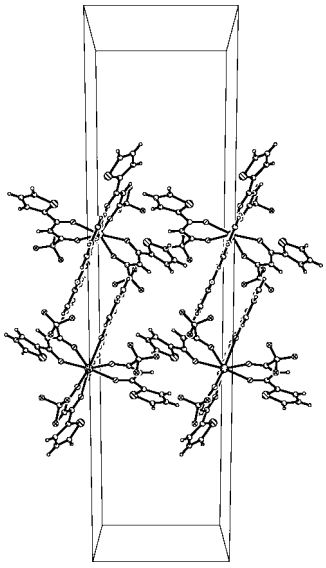

Figure 3. The molecular packing of $[Eu(TTA)_3(PBO)]$ along the *a*-axis. Hydrogen atoms have been omitted for clarity.

## UV Spectra

The UV absorption spectrum of $[Eu(TTA)_3(PBO)]$ is compared with those of $[Eu(TTA)_3(H_2O)_2]$ and PBO in Figure 4. There is one principle π–π* absorption peak at 300 nm in the spectrum of PBO and two peaks at 266 and 338 nm in that of $[Eu(TTA)_3(H_2O)_2]$, while a new shoulder centered at 318 nm appears in the spectrum of $[Eu(TTA)_3(PBO)]$ in addition to one peak at 302 nm due to PBO and two peaks at 266 and 336 nm to $[Eu(TTA)_3(H_2O)_2]$, thus indicating the complexation of PBO to the $Eu(TTA)_3$ moiety.

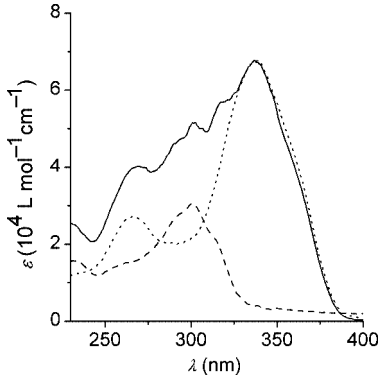

Figure 4. UV absorption spectra of PBO (dashed line), $[Eu(TTA)_3(H_2O)_2]$ (dotted line), and $[Eu(TTA)_3(PBO)]$ (solid line) in $CH_3CN$.

As shown in Figure 5, the complexation of PBT to $Eu(TTA)_3$ results in profound changes in the UV spectra: the π–π* absorption bands at 338 and 266 nm of $[Eu(TTA)_3(H_2O)_2]$ are blue-shifted to 330 and 251 nm, respec-

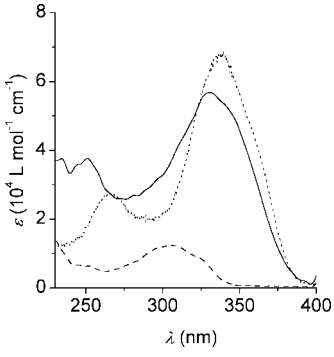

Figure 5. UV absorption spectra of PBT (dashed line), $[Eu(TTA)_3(H_2O)_2]$ (dotted line), and $[Eu(TTA)_3(PBT)]$ (solid line) in $CH_3CN$.

tively, for $[Eu(TTA)_3(PBT)]$ and the molar extinction coefficient for the former is decreased as the coordination reaction takes place. Furthermore, the broad band at 305 nm for PBT disappears in the spectrum of $[Eu(TTA)_3(PBT)]$.

In the spectrum of $[Eu(TTA)_3(PBI)]$ (Figure 6), the dominant absorption feature for $Eu(TTA)_3$ is also blue-shifted to 323 nm relative to $[Eu(TTA)_3(H_2O)_2]$; no absorption feature for PBI is observed (308 nm).

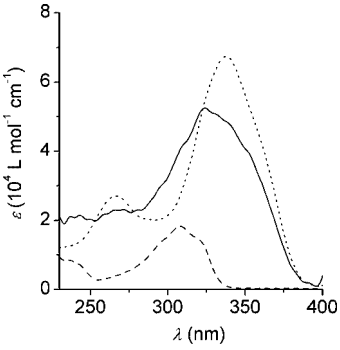

Figure 6. UV absorption spectra of PBI (dashed line), $[Eu(TTA)_3(H_2O)_2]$ (dotted line), and $[Eu(TTA)_3(PBI)]$ (solid line) in $CH_3CN$.

### Photo- and Electroluminescent Properties

The excitation spectra for PBO, PBT, and PBI in $CH_3CN$ show maximum excitation wavelengths at 300, 305, and 308 nm, respectively; these correspond well to their corresponding maximum UV absorption peaks. However, the excitation spectra for $[Eu(TTA)_3(PBO)]$, $[Eu(TTA)_3(PBT)]$, and $[Eu(TTA)_3(PBI)]$ in $CH_3CN$ show maximum excitation wavelengths at 341, 341, and 339 nm, respectively, which correspond well to the maximum UV absorption peak at 338 nm for $[Eu(TTA)_3(H_2O)_2]$, thus indicating that $TTA^-$ rather than neutral 2-(2′-pyridyl)azoles (PBO, PBT and PBI) is mainly involved in intramolecular energy transfer from the excited triplet of $TTA^{-}$* to the $^5D_0$ state of $Eu^{III}$.[1] The emission spectra of the three complexes show a similar pattern in the $Eu^{III}$ region, with sharp characteristic emission peaks at 595, 613, 654, and 702 nm due to $^5D_0 \rightarrow {}^7F_J$ ($J$ = 1, 2, 3, and 4) transitions, respectively, with the electric dipole transition ($^5D_0 \rightarrow {}^7F_2$) being the strongest. The emission quantum yields of $[Eu(TTA)_3(PBO)]$, $[Eu(TTA)_3(PBT)]$, and $[Eu(TTA)_3(PBI)]$ in $CH_3CN$ were determined to be 1.22-, 0.51-, and 0.54-times that of $[Eu(TTA)_3(H_2O)_2]$ in the same solvent, respectively.

By using *N*,*N*′-bis(3-methylphenyl)-*N*,*N*′-diphenyl-1,1′-biphenyl-4,4′-diamine (TPD) as hole-transporting material, 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP) as hole-blocking material, and tris(8-quinolinolato)aluminium ($Alq_3$) as electron-transporting material, we fabricated four-layer electroluminescence (EL) devices with the configuration ITO/TPD (20 nm)/$Eu^{III}$ complex (40 nm)/BCP (10 nm)/$Alq_3$ (40 nm)/$Mg_{0.9}$:$Ag_{0.1}$ (200 nm)/Ag (80 nm). Figure 7 shows the chemical structures of the materials and the configuration of the EL devices. As exemplified in Figure 8 for the electroluminescence spectrum of $[Eu(TTA)_3(PBO)]$, the two devices give similar features of an $Eu^{III}$ characteristic emission with good red-emitting purity centered at 613 nm, which corresponds to the $^5D_0 \rightarrow {}^7F_2$ transition. Figures 9 and 10 show current density/luminance/voltage curves for the devices ITO/TPD (20 nm)/$[Eu(TTA)_3(PBO)]$ (40 nm)/BCP (10 nm)/$Alq_3$ (40 nm)/$Mg_{0.9}$:$Ag_{0.1}$ (200 nm)/Ag (80 nm) and ITO/TPD (20 nm)/$[Eu(TTA)_3(PBT)]$ (40 nm)/BCP (10 nm)/$Alq_3$ (40 nm)/$Mg_{0.9}$:$Ag_{0.1}$ (200 nm)/Ag (80 nm), respectively. The $[Eu(TTA)_3(PBO)]$-based device has a turn-on voltage (the voltage at which the device gives a luminance of 1 cd m$^{-2}$) of about 10 V, which is comparable to the voltage of about 10.5 V for an $[Eu(TTA)_3(PBT)]$-based device. However, the maximum red-emitting brightness of 18 cd m$^{-2}$ achieved at 15 V and 4.3 mA cm$^{-2}$ for the $[Eu(TTA)_3(PBO)]$-based device is much lower than the value of 30 cd m$^{-2}$ observed at 15 V and 165 mA cm$^{-2}$ for an $[Eu(TTA)_3(PBT)]$-based device and much higher than the value of 0.43 cd m$^{-2}$ observed at 26 V and 1.6 mA cm$^{-2}$ for an $[Eu(TTA)_3(PBI)]$-based device;[8i] it is half that (36 cd m$^{-2}$) observed for an $[Eu(TTA)_3(HEPB)]$

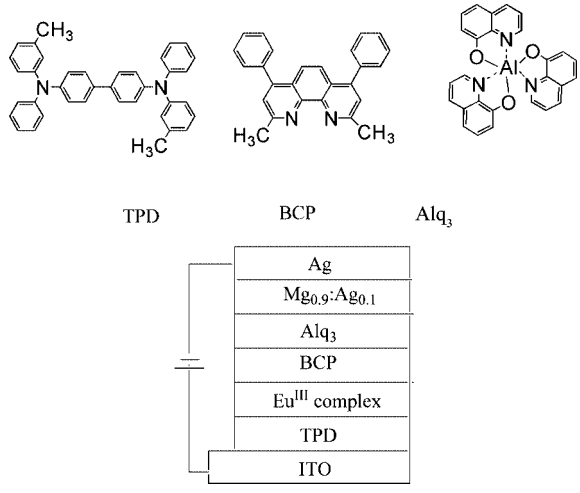

Figure 7. Chemical structures of the materials and the configuration of the EL device.

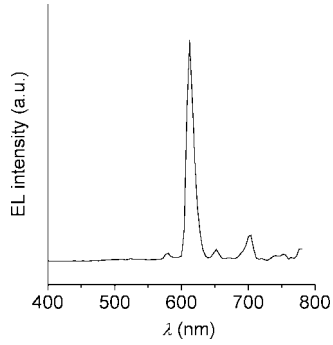

Figure 8. Electroluminescence spectrum of the $[Eu(TTA)_3(PBO)]$-based device ITO/TPD (20 nm)/$[Eu(TTA)_3(PBO)]$ (40 nm)/BCP (10 nm)/$Alq_3$ (40 nm)/$Mg_{0.9}$:$Ag_{0.1}$ (200 nm)/Ag (80 nm).

[EPBM = 1-ethyl-2-(2′-pyridyl)benzimidazole] based device.[8c] The poor EL performance observed for the $[Eu(TTA)_3(PBI)]$-based device is mainly attributed to the poor vacuum volatility of $[Eu(TTA)_3(PBI)]$ due to the presence of the strongly polar NH group on PBI.

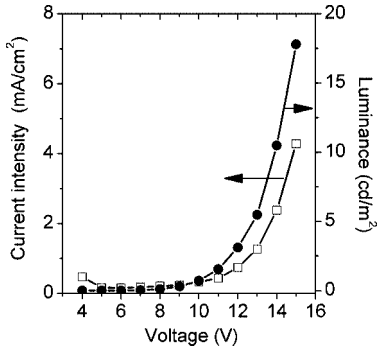

Figure 9. Current/voltage (*I*/*V*) and luminance/voltage (*L*/*V*) characteristics for the EL device ITO/TPD (20 nm)/$[Eu(TTA)_3(PBO)]$ (40 nm)/BCP (10 nm)/$Alq_3$ (40 nm)/$Mg_{0.9}$:$Ag_{0.1}$ (200 nm)/Ag (80 nm).

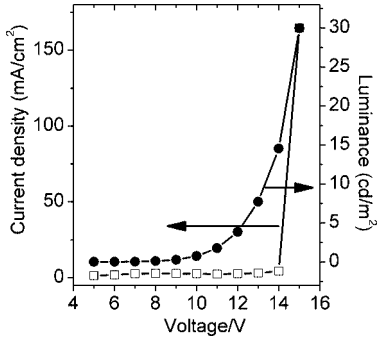

Figure 10. Current/voltage (*I*/*V*) and luminance/voltage (*L*/*V*) characteristics for EL device ITO/TPD (20 nm)/$[Eu(TTA)_3(PBT)]$ (40 nm)/BCP (10 nm)/$Alq_3$ (40 nm)/$Mg_{0.9}$:$Ag_{0.1}$ (200 nm)/Ag (80 nm).

## Conclusions

We have synthesized two $Eu^{III}$ mixed-ligand complexes with TTA and PBO or PBT. The N,O-bidentate coordination to $Eu^{III}$ by PBO in $[Eu(TTA)_3(PBO)]$ has been demonstrated by single-crystal X-ray diffraction. The N,N-Bidentate coordination to $Eu^{III}$ by PBT and PBI in $[Eu(TTA)_3(PBT)]$ and $[Eu(TTA)_3(PBI)]$ causes more evident changes in the UV spectra than in the N,O-bidentate coordinated $[Eu(TTA)_3(PBO)]$. However, the photoluminescence quantum yield of N,O-coordinated $[Eu(TTA)_3(PBO)]$ is the highest and follows the order: $[Eu(TTA)_3(PBO)] > [Eu(TTA)_3(PBI)] \approx [Eu(TTA)_3(PBT)]$. The maximum red-emitting EL brightness follows the order $[Eu(TTA)_3(PBT)] > [Eu(TTA)_3(PBO)] >> [Eu(TTA)_3(PBI)]$. The low brightness of only 0.43 cd m$^{-2}$ observed for the $[Eu(TTA)_3(PBI)]$-based EL device is most probably due to the poor vacuum volatility of $[Eu(TTA)_3(PBI)]$, since we noticed serious thermal decomposition during the vacuum deposition of $[Eu(TTA)_3(PBI)]$.

## Experimental Section

**Physical Measurements:** C, H, N elemental analyses were performed with a Vario EL elemental analyzer. IR spectra were measured with a Nicolet Avatar 360 FT-IR spectrometer as KBr disks. $^1$H NMR spectra were obtained with a Bruker DRX-500 spectrometer. UV absorption spectra were determined with a GBC Cintra 10e UV/Vis spectrophotometer. Emission spectra were recorded with a Shimadzu RF-5301PC spectrofluorimeter. The PL quantum yields of $CH_3CN$ solutions of the complexes were calculated using Equation (1),[29] where $\varphi_s$ and $\varphi_{std}$ are the quantum yields of unknown and standard $[Eu(TTA)_3(H_2O)_2]$, $A_s$ and $A_{std}$ ($< 0.1$) are the solution absorbance at the excitation wavelength, $I_s$ and $I_{std}$ are the integrated emission intensities, and $n_s$ and $n_{std}$ are the refractive indices of the solvents.

$$\varphi_s = \varphi_{std}(A_{std}/A_s)(I_s/I_{std})(n_s/n_{std})^2 \quad (1)$$

The EL devices were fabricated by sequentially depositing organic layers in one run under high vacuum ($<8\times10^4$ Pa) thermal evaporation onto a pre-cleaned indium/tin oxide glass substrate with a sheet resistance of 15 Ω/cm$^2$, which was kindly supplied by China Southern Glass Holding Co., Ltd as a gift. A shadow mask with 5-mm-diameter openings was used to define the cathode of a 200-nm thick $Mg_{0.9}$:$Ag_{0.1}$ alloy layer, with an 80-nm thick Ag cap. The thickness of the deposited layer and the evaporation speed of the individual materials were monitored in vacuo with quartz crystal monitors. The deposition rates were maintained to be 0.1–0.3 nm s$^{-1}$ for organic materials and 1.0–1.3 nm s$^{-1}$ for $Mg_{0.9}$:$Ag_{0.1}$ alloy. All electrical testing and optical measurements were performed under ambient conditions. The EL spectra were measured with a Spectrascan PR650 photometer. The current/voltage (*I*/*V*) and luminance/voltage (*L*/*V*) characteristics were measured with a computer-controlled Keithley 2400 Sourcemeter unit with a calibrated silicon diode.

**Materials:** $[Eu(TTA)_3(H_2O)_2]$[30] [TTA = 1,1,1-trifluoro-3-(2-thenoyl)acetonato] was prepared by a literature method. 2-(2′-Pyridyl)benzimidazole (PBI) and $[Eu(TTA)_3(PBI)]$ were synthesized as described previously.[8c,8i] The other materials were commercially available and were used without further purification.

**2-(2′-Pyridyl)-1,3-benzoxazole (PBO):** A mixture of powdered 2-picolinic acid (12.3 g, 0.1 mol), 2-aminophenol (10.9 g, 0.1 mol), and syrupy phosphoric acid (50 mL) was stirred at 160 °C for 4 h. The blue slurry was then poured into vigorously stirred cold water (500 mL). Aqueous ammonia was then added up to a pH of about 7. The resulting pink solid product was filtered off and recrystallized from $CH_2Cl_2$/hexane. Yield: 8.6 g (43.9%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 8.86 (d, $J$ = 4.60 Hz, 1 H), 8.40 (d, $J$ = 7.90 Hz, 1 H), 7.94 (m, 1 H), 7.86 (m, 1 H), 7.71 (d, $J$ = 4.60 Hz, 1 H), 7.50 (m, 1 H), 7.44 (m, 2 H) ppm. IR (KBr): $\tilde{\nu}$ = 3058 (w), 1583 (m), 1552 (m), 1454 (vs), 1437 (s), 1347 (m), 1242 (m), 1076 (s), 809 (m), 742 (vs), 704 (m) cm$^{-1}$. $C_{12}H_8N_2O$ (196.21): calcd. C 73.50, H 4.10, N 14.30; found C 73.70, H 4.20, N 14.10.

**2-(2′-Pyridyl)-1,3-benzothiazole (PBT):** This was synthesized as described above for PBO except that 2-aminothiophenol was used instead of 2-aminophenol. Yield: 6.0 g (30.6%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 8.72 (d, $J$ = 4.70 Hz, 1 H), 8.42 (d, $J$ = 7.91 Hz, 1 H), 8.13 (d, $J$ = 8.13 Hz, 1 H), 8.00 (d, $J$ = 7.94 Hz, 1 H), 7.89 (m, 1 H), 7.54 (m, 1 H), 7.44 (m, 2 H) ppm. IR (KBr): $\tilde{\nu}$

= 3052 (w), 1583 (m), 1562 (m), 1509 (m), 1456 (s), 1432 (vs), 1316 (s), 1292 (m), 1265 (m), 1233 (m), 996 (m), 978 (s), 783 (s), 758 (s), 739 (s), 725 (s), 618 (s) $cm^{-1}$. $C_{12}H_8N_2S$ (212.21): calcd. C 67.90, H 3.80, N 13.20; found C 68.00, H 3.85, N 13.15.

**[Eu(TTA)$_3$(PBO)]:** PBO (0.0785 g, 0.4 mmol) and [Eu(TTA)$_3$-($H_2O$)$_2$] (0.3408 g, 0.4 mmol) were refluxed in ethanol (10 mL) for 1 h. The solid product formed upon cooling was filtered off, washed with hot ethanol, and then vacuum-dried. Yield: 0.29 g (71.6%). UV ($CH_3CN$): $\lambda$ ($\varepsilon$) = 266 (4.03), 302 (5.18), 318 (5.70), 336 ($6.80\times10^4$ $M^{-1}cm^{-1}$) nm. IR (KBr): $\tilde{\nu}$ = 1598 (s), 1578 (m), 1541 (m), 1508 (w), 1463 (w), 1413 (m), 1359 (w), 1311 (s), 1250 (w), 1230 (w), 1189 (m), 1136 (s), 1085 (w), 1062 (w), 935 (w), 858 (w), 787 (m), 748 (m), 720 (m), 681 (w), 642 (w), 581 (w), 457 (vw) $cm^{-1}$. $C_{36}H_{20}EuF_9N_2O_7S_3$ (1011.7): calcd. C 42.74, H 1.99, N 2.77; found C 42.66, H 2.06, N 2.96.

**[Eu(TTA)$_3$(PBT)]:** This complex was synthesized as described above for [Eu(TTA)$_3$(PBO)] except that PBT was used instead of PBO. UV ($CH_3CN$): $\lambda$ ($\varepsilon$) = 234 (3.73), 251 (3.77), 330 ($5.69\times10^4$ $M^{-1}cm^{-1}$) nm. IR (KBr): $\tilde{\nu}$ = 1625 (m), 1598 (s), 1578 (m), 1540 (m), 1508 (w), 1464 (w), 1413 (m), 1357 (w), 1308 (s), 1248 (w), 1231 (w), 1187 (m), 1142 (s), 1083 (w), 1065 (m), 995 (w), 935 (w), 855 (w), 788 (m), 762 (w), 718 (m), 681 (w), 644 (m), 577 (m), 496 (vw), 461 (vw) $cm^{-1}$. $C_{36}H_{20}EuF_9N_2O_6S_4$ (1027.8): calcd. C 42.07, H 1.96, N 2.73; found C 41.77, H 2.11, N 2.76.

**X-ray Crystallographic Study:** Yellow single crystals with approximate dimensions suitable for X-ray structural analysis were obtained by recrystallization from $CH_2Cl_2$/$CH_3CN$. The data were collected at 294(2) K with a CCD area detector Bruker SMART 2000 X-ray diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) in the $\omega$-2$\theta$ scan mode (2$\theta$ range: 5.52–52.48°). The coordinates of all non-hydrogen atoms and anisotropic thermal parameters were refined by full-matrix least squares. The data were processed with a Pentium PC using the Bruker SHELXTL software package.[16] Further details of the data collection and refinement are given in Table 2. CCDC-296449 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Affinity of Polypyridines Towards $Cd^{II}$ and $Co^{II}$ Ions: a Thermodynamic and DFT Study

**Silvia Del Piero,[a] Plinio Di Bernardo,[b] Rosalisa Fedele,[a] Andrea Melchior,*[a] Pierluigi Polese,[a] and Marilena Tolazzi*[a]**

**Keywords:** Cadmium(II) / Cobalt(II) / Pyridine complexes / Thermodynamics / Density functional calculations

$Cd^{II}$ and $Co^{II}$ complex formation with pyridine (py), 2,2′-bipyridine (bipy), 2,2′6′,2′′-terpyridine (terpy), 2-(aminomethyl)pyridine (amp), and bis[(2-pyridyl)methyl]amine (dpma) was studied at 298 K in the aprotic solvent dimethyl sulfoxide (DMSO) and in an ionic medium set to 0.1 mol dm$^{-3}$ with $Et_4NClO_4$ in anaerobic conditions. Potentiometric, UV/Vis spectrophotometric, and calorimetric measurements were carried out to obtain the thermodynamic parameters of the systems investigated. Enthalpy-stabilized mononuclear $ML_j$ complexes are formed, whereas entropy changes counteract complex formation. These results are discussed in terms of different basicities, steric requirements, and solvation, of both the ligands and the resulting complexes. Density functional theory (DFT) calculations were carried out in order to obtain structural information and binding energies in vacuo. The DFT results are correlated with the solution studies.

## Introduction

In recent years, a variety of polyamine N-donor ligands have been investigated in water[1–7] and nonaqueous solvents[8–12] with the aim of studying the influence of basicity and steric effects on selectivity patterns in metal coordination. Examples of the attractive properties and applications of these ligands are their potential use as building blocks of sequestering agents for metals of environmental importance, such as Cd or Pb,[4] fluorescent chemosensors,[3e] catalysts,[3f] or models for small molecule carriers, as in $Cu^{I}$ or $Co^{II}$ dioxygen complexes.[13–18]

In this context, some of our published papers concerning the complexation of transition-metal ions like $Cd^{II}$ and $Co^{II}$[11] have shown that steric effects and N-methylation strongly influence not only the stoichiometry and nature of all metal ion complexes formed, but also the selectivity of these ligands toward metal ions. Systematic studies confirm that different N-alkylation of polyamines, or merely the substitution of only one amine with one alcohol group, causes important differences in the dioxygen affinity of $Co^{II}$ complexes:[11b,11e] this affinity greatly depends on the electron density at the central metal ion, which, in turn, is affected by the electron donor and steric properties of the coordinated ligands.

As an extension of previous works, we report here the results of research on quantifying the complexing ability of pyridine functions toward $Cd^{II}$ and $Co^{II}$ metal ions in DMSO. The $sp^2$ hybridized N can exert high ligand field strength, even though its basicity may be less significant than that of $sp^3$ hybridized nitrogens.[19–21] Moreover, their lower σ-donor ability, greater rigidity with respect to linear polyamines, and their ability to give rise to π backbonding makes them suitable to tune the electronic and steric effects that govern ligand affinity for metal ions.[22,23] Pyridine functions are often found in multifunctional compounds with desirable or predictable properties such as luminescence, electrochemical, or catalytic activity.[22,23]

The model ligands chosen were: pyridine (py), 2,2′-bipyridine (bipy), and 2,2′6′,2′′-terpyridine (terpy). In order to highlight the subtle interplays between steric and electronic effects, intermediate 2-(aminomethyl)pyridine (amp) and bis[(2-pyridyl)methyl]-amine (dpma) ligands were also studied. The latter possess potentially interesting and versatile ways of binding, and may also give rise to polymetallic complexes with luminescent properties or favor spin-crossover phenomena.[24–27]

The stability constants for $Cd^{II}$ were determined by direct potentiometric titration techniques, and UV/Vis spectroscopic measurements were employed for the $Co^{II}$ systems. Enthalpy values were obtained by direct calorimetric titration.

To obtain a gas-phase picture of metal–ligand interactions, the study was completed with calculations using den-

sity functional theory (DFT). DFT provides an excellent framework, yielding structural information and a number of chemical reactivity indices about ligands and their complexes, and gives results of quality comparable to those obtainable by correlated ab initio calculations. DFT has previously been used to study the influence of N-methylation on structural properties of transition-metal complexes with cyclic polyaza ligands[11g,28] and to describe the properties of polyamines, such as their basicity in both gas-phase[29] and solvent models.[30]

## Results

### Solution Thermodymamics

Computer treatment of the potentiometric, spectrophotometric, and calorimetric experimental data shows that the best fit is obtained when only mononuclear $ML_j$ species are considered. The overall stability constants and thermodynamic functions obtained, together with the corresponding limits of error, are listed in Table 1. For the $Co^{II}$–bipy system, stability constants in DMSO have been previously given[31] and are in good agreement with the data reported here.

For the $Co^{II}$–amp and –dpma systems, some experimental details must be given to explain why thermodynamic data for $Co^{II}$–amp are not reported. The color of the solutions turns from pink to deep blue as titration proceeds with both amp and dpma, as clearly shown in Figure 1, in which absorbances at increasing times are reported for the $Co^{II}$–dpma systems at $R_c = C_L/C_M$ (the total ligand-to-metal ratio) of 1. This spectral change had already been observed in basic aqueous solutions in the presence of $O_2$ and explained by catalytic oxidative dehydrogenation of the ligand, with the transformation of the amine to imine.[32,33] Evidently, this reaction also occurs in our case, although the concentrations of water and $O_2$ were very low in our experimental conditions. The Co–imine product was expected to be present in very low amounts; nevertheless, its very high molar extinction coefficients in the visible range prevented the use of d-d $Co^{II}$ bands to follow aminopyridine complexation. The rate of the undesired reaction was influenced by $C_L/C_M$: the lower this ratio, the slower the reaction. The inset in Figure 1 shows absorbance at 588 nm ($A_{588}$) as a function of time for various $R_c$. At a $C_L/C_M$

value ≤0.7, this process does not occur within a reasonable interval of time, sufficient to collect reliable spectrophotometric titration point data. This was not the case when amp was used, as this secondary reaction was much faster and also not prevented at very low $C_L/C_M$ ratios.

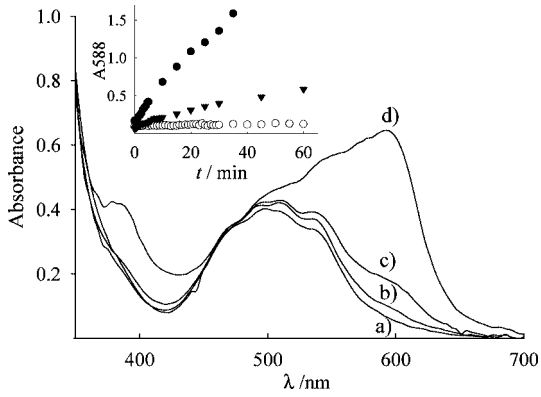

Figure 1. Spectral changes of a Co/dpma solution ($C_L/C_M$ = 1) at increasing times: a) 5 s; b) 30 s; c) 5 min; d) 75 min. Time evolution (small graph) of absorbance at $\lambda$ = 588 nm in case of different Co/dpma ratios: (○) $C_L/C_M$ = 0.7; (▼) $C_L/C_M$ = 1; (●) $C_L/C_M$ = 1.5.

Figure 2 and Figure 3 show $\Delta h_v$, the total molar enthalpy change, as a function of $R_c$ for $Cd^{2+}$- and $Co^{2+}$-ligand systems. The fit between experimental and calculated curves (full lines in the figures) is good, and their shapes are fully consistent with the information obtained from analysis of potentiometric and spectrophotometric data.

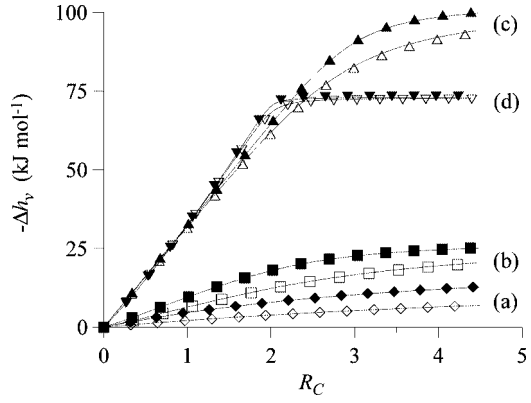

Figure 2. Total molar enthalpy changes $\Delta h_v$ as a function of $R_c$ = $C_L/C_M$ for $Cd^{II}$ complex formation in DMSO. (a) bipy, (◊) 5.05, (♦) 15.01 mmol dm$^{-3}$ in $Cd^{2+}$; (b) terpy, (□) 5.04, (■) 15.10 mmol dm$^{-3}$ in $Cd^{2+}$; (c) amp, (△) 4.98, (▲) 14.97 mmol dm$^{-3}$ in $Cd^{2+}$; (d) dpma, (▽) 5.07, (▼) 14.93 mmol dm$^{-3}$ in $Cd^{2+}$. Solid lines calculated from values of $\beta_j$ and $\Delta H°_{\beta j}$, Table 1.

Some considerations may be made: (*i*) differentiation of curves of the complexation of Cd with bipy and terpy at various $C_M$ indicates the formation of complexes of low stability; (*ii*) for Co with bipy, differentiation after $R_c$ = 1 is explained by the formation of a very stable mononuclear ML complex, followed by other $ML_j$ species of lower stability; (*iii*) the linear trend of the curve for the Co–terpy and –dpma systems up to $R_c$ = 2 and the absence of heat

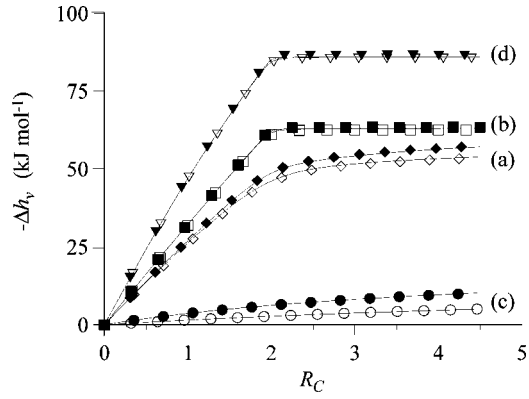

Figure 3. Total molar enthalpy changes $\Delta h_v$ as a function of $R_c$ = $C_L/C_M$ for $Co^{II}$ complex formation in DMSO. For (a), (b), and (d), see legend of Figure 2 for same (a), (b), and (d) systems. In this case, (c) refers to py, (○) 15.05, (●) 45.01 mmol dm$^{-3}$ in $Co^{2+}$.

evolving beyond this value are consistent with the formation of ML and $ML_2$ complexes of comparable stability; (*iv*) as regards Co–dpma, the presence of an equivalent point at exactly $R_c$ = 2 is in good agreement with the hypothesis that the secondary reaction is negligible from a calorimetric point of view.

Calorimetric data show that a very small thermal effect occurs between Cd and py, even at high metal concentrations ($C_M$ = 50 mmol dm$^{-3}$). For this reason, no $\Delta H°_{\beta j}$ are reported, and only a rough value of $\log\beta_1$ ($\log\beta_1$ = 0.5 ± 0.2) could be calculated from potentiometric measurements. A similar trend was found for $Co^{II}$, but the higher thermal effects due to metal–ligand interaction allow the calculation of reliable values for $\log\beta_1$ and $\Delta H°_{\beta 1}$ by treatment of calorimetric data.

For the sake of comparison, Table 1 lists the available stability constants and thermodynamic functions for complex formation in water.[34–38] The set of data presented are the most complete in the literature, independently of the fact that some of them[36] refer to 20 °C. The choice seems to be reasonable, as the stability constants available at 25 °C, for which enthalpy data are not given,[39,40] are very close to those reported at 20 °C.

## Computational Results

The M–N distances of complexes $[CdL]^{2+}$ and $[CoL]^{2+}$, whose geometries were optimized in vacuo, are listed in Table 2. A comprehensive list of bond lengths and angles is given as supporting information also for the free ligands (Supporting Information, Tables S1–S6): the results are in good agreement with experimental X-ray data.[41] To check the reliability of model chemistry in predicting the structural features of the compounds, the geometry of the structurally known[42] $[Co(terpy)_2]^{2+}$ was optimized (Supporting Information, Table S7) and also in this case the match between calculated and experimental data is good.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2. M–N distances in Å.

| |  |  |  | |
|---|---|---|---|---|
| | $d_{M-N}$ | $d_{M-N}$ | $d_{M-Nin}$ | $d_{N-Nex}$ |
| $Co^{2+}$ | 1.782 | 1.853 | 1.871 | 1.936 |
| $Cd^{2+}$ | 2.169 | 2.205 | 2.205 | 2.267 |

In all cases, the M–N bond lengths appear to be shorter than in crystal structures;[41,43] this is of course due to the approximate models used and to the absence of other electrodonating ligands. The qualitative result of longer Cd–N distances of 0.33–0.39 Å with respect to Co–N is consistent with experimental structures, although in the last case the gap is in the range 0.18–0.31 Å. Table 3 lists total binding energies, $E_{bind}$, calculated for the formation of ML adducts. Energies for σ donation from the nitrogen lone pair to the metal, $E_{LP(N) \rightarrow M}$, calculated by using natural bond orbital (NBO) analysis,[44] are also listed in Table 3. In order to provide some indication of the role of π acceptor pyridine units in ligand–metal bonds, the NBO charges of the N atoms and metals in the compounds are calculated and listed in Table 4.

Table 3. Binding energies ($E_{bind}$) and strengths of N lone pair → metal interactions from NBO analysis ($E_{LP(N)\rightarrow M}$) in kJ mol$^{-1}$ for formation of $ML^{2+}$ complexes. $\Delta E = E^{Co^{2+}} - E^{Cd^{2+}}$.

| | $E_{bind}$ | | |
|---|---|---|---|
| | py | bipy | terpy |
| $Co^{2+}$ | –615.0 | –1007.9 | –1341.8 |

## Discussion

### General Remarks on Solvent Role

All complexes form in highly exothermic reactions, whereas entropy terms oppose reactions (Table 1), with the exception of the $Cd^{II}$–terpy system, for which a small positive entropy value was found. Negative enthalpy and entropy values are typical of reactions involving complexation of metal ions by neutral ligands in aprotic solvents.[8–12]

Pyridine complexes are characterized by higher stabilities in water than in DMSO: the trend is opposite to that found for simple primary and secondary aliphatic amines, in which the greater solvation of ligands in water through strong hydrogen bonds[45,46] overcomes the greater solvation[11a,47] of metal ions in DMSO. In the present case, the role of ligand solvation is evidently of minor importance, and the stability constants follow the trend expected on the basis of metal ion solvation. As regards amp and dpma, higher stability is still observed in water although it is much less marked. This higher stability in the case of dpma systems, for which all the thermodynamic functions are available in the two solvents, is essentially entropic in origin, as enthalpy terms are more favorable in DMSO. This indicates that the desolvation effects of the amino group, more important in water than in DMSO, play a major role in determining the stability trend in the two solvents.

### Pyridine Ligands

Pyridine shows a much lower affinity for $Cd^{2+}$ and $Co^{2+}$ ions with respect to monoamines ($\log K_1^{n\text{-butylamine}} = 2.6$ and 1.91 for Cd and Co, respectively):[11a,11b] this point is certainly due to the lower basicity of pyridine nitrogen when compared with amines in DMSO.[45,46] Steric effects may also be considered, as *ortho* hydrogens on pyridine rings produce steric hindrance once coordinated to a metal ion.[2]

The higher stabilities and more negative enthalpy and entropy data for the $Co^{II}$–bipy system, as compared with py, fit the formation of chelated complexes, although some steric strain, due to hydrogens in 3,3′-positions, occurs in the *cis*-conformer allowing coordination to metal ion.[2]

Certainly, the entry of the third bipy molecule causes unfavorable electronic and steric effects due to the other two ligands, and this explains the lower stability and enthalpy gain for the third complexation step. This fits crystallographic data, which show that, in the solid state, a distorted octahedron is formed by three bipy molecules around $Co^{II}$.[48]

When $[Co(terpy)]^{2+}$ (and $[Co(terpy)_2]^{2+}$) is formed, the ligand behaves as a terdentate: the low gain in the enthalpy term with respect to $[Co(bipy)]^{2+}$ complex formation ($\Delta\Delta H^{\circ}_{\beta_1}{}^{Co(terpy)\rightarrow Co(bipy)} = -4$ kJ mol$^{-1}$) is mainly due to extensive desolvation effects that come into play when this rigid terdentate ligand coordinates. This is confirmed by the low unfavorable entropy term associated with the same complexation step for the two ligands ($\Delta T\Delta S^{\circ}_{\beta_1}{}^{Co(terpy)\rightarrow Co(bipy)} = +5$ kJ mol$^{-1}$). Extra energy should also be considered for terpy rearrangement in the preorganized planar conformer with convergent nitrogen atoms. Lastly, strain is also produced by the resulting two fused five-membered chelate rings.

Analysis of thermodynamic data on $Cd^{2+}$ reactions suggests some preliminary considerations: (*i*) the positive in-

crease in the stability constants of $Co^{II}$ complexes on going from py to bipy and terpy (in both solvents) is not observable in the $Cd^{II}$ systems; (*ii*) the lower affinity for $Cd^{II}$ than for $Co^{II}$ is a peculiarity of all the pyridine ligands examined here. This effect is connected to the intrinsic nature of the ligands and the size of the metal ions, and not to the different solvation of central ions, as this was presumed to be larger for $Co^{II}$ than for $Cd^{II}$,[11c] which would give an opposite trend in stability.

The calculated M–N distances (Table 2) show that, in the gas phase, this higher affinity for $Co^{II}$ is also present: bond lengths are always longer for $Cd^{II}$– than for $Co^{II}$–pyridine systems, these differences being more marked for the less stable $M^{II}$–py complexes (0.387 Å longer in $Cd^{II}$–py than in $Co^{II}$–py). It is noteworthy that the difference in M–$N_{in}$ bond lengths calculated with DFT in $Cd^{II}$– and $Co^{II}$–terpy complexes (0.334 Å) is slightly higher than that of the M–$N_{ex}$ bond (0.331 Å): this is in agreement with previous studies which found that small cations are able to better interact with the central nitrogen, due to the steric constraint of this rigid ligand.[49]

As regards the binding energies (Table 3), the high values found (549–1542 kJ mol$^{-1}$) cannot be compared with experimental ones, as solvation effects were not taken into account in calculations. However, they are important because they show relative trends equal to those experimentally determined: even in this case, the affinity of pyridine ligands is higher for $Co^{II}$ than for $Cd^{II}$. Certainly, one of the main factors influencing this trend is the higher charge density on $Co^{II}$, which causes this smaller ion to be a harder acid than $Cd^{II}$.

The π backbonding does not appear to be important as far as these bipositive metal ions are concerned. In fact, the trend in total binding energies ($E_{bind}$ in Table 3) is parallel to that found in $E_{LP(N)\rightarrow M}$, that is σ donation plays a dominant role in ligand–metal bond stabilization. The calculated NBO charges on metal ions and nitrogens in the compounds (Table 4) give the same indications. The addition of π-acceptor units (from py to terpy) leads to a decrease in metal charges (and a simultaneous increase in N charges), showing that electron transfer mainly goes from the ligand to the metal by σ donation. An opposite trend in the positive metal charge was observed when the number of pyridine units was increased in complexes where π backbonding played an important role.[50]

The stability of $Co^{II}$ complexes increases much more than that of $Cd^{II}$ ones on going from bidentate bipy to terdentate terpy ($\Delta\Delta G^{\circ}_{Cd(terpy-bipy)}$ = 0.7; $\Delta\Delta G^{\circ}_{Co(terpy-bipy)}$ = 1.7). This indicates that, whereas the affinity of the ligands towards $Co^{II}$ becomes larger and larger on increasing the number of pyridine donors, the stability of $Cd^{II}$ complexes is not so affected by the increase of binding sites in the ligand. This is also confirmed by the total binding energy values (Table 3), which show that $\Delta E_{bind}$ (= $E_{bind}{}^{Co^{2+}}$ – $E_{bind}{}^{Cd^{2+}}$) increases on going from py to terpy, particularly for terpy, clearly indicating more marked selectivity for $Co^{2+}$.

The results of this terpy complexation with $Cd^{II}$ are difficult to explain solely by desolvation and steric effects, already discussed for $Co^{II}$. An attempt to explain these data is that the ligand behaves as a terdentate one, and this is achieved by structural rearrangement in the metal ion coordination sphere, giving rise to a pentacoordinate species. A certain misfit between the size of the large cadmium ion and the steric requirements of the ligand lies at the origin of this behavior. Also in the solid state, some preference for pentacoordination has already been highlighted in Cd–terpy compounds with crowded anions.[43a] Reaction enthalpies, lower for $[Cd(terpy)]^{2+}$ than for $[Cd(bipy)]^{2+}$, and especially the favorable entropy term for the formation of the terpyridyl complex, compared with the unfavorable entropy of formation of the bipyridyl complex, fit this hypothesis.

### Aminopyridine Ligands

The thermodynamic data, when compared with those obtained for mono- and bidentate aliphatic amines[11a,11b] and with py, suggest the involvement of all the N atoms in metal complex formation with amp and dpma. In order to support this hypothesis, some $^1H$ NMR spectra of solutions of $Cd^{II}$ and dpma at various $R_c$ values were recorded. In particular, the spectrum of $[Cd(dpma)_2]^{2+}$ in [D$_6$]DMSO solution (Figure S1, Supporting Information) shows that the multiplet centered at $\delta$ = 8.49 ppm in the free ligand, assigned to *ortho* pyridine protons, is shifted by 0.38 ppm ($\delta$ = 8.11 ppm) after complexation. This effect, together with the symmetric pattern of the given spectrum, reflects the binding of all pyridine nitrogens to $Cd^{II}$ atoms in complex formation. The weak, broad signal due to the proton of the secondary -NH- amino group is also shifted by about 2 ppm on complex formation (from about 3.2 to 5.1 ppm). Another proof of the coordination of the amino group of dpma comes from FTIR spectra, recorded for a DMSO solution with a dpma-to-cadmium ratio of 2, where no bands for free secondary amino groups (at 3305 cm$^{-1}$) can be detected, whereas only the band due to bonded amine (at 3192 cm$^{-1}$) was observed.

Amp complexes with Cd are characterized by much higher stabilities with respect to bipy ($\Delta\log\beta_1$ = 2.56 and $\Delta\log\beta_2$ = 5.14), especially as regards the second complexation step. This is mainly due to the higher affinity for metal ions of amines compared with pyridines in DMSO.[45,46] More favorable steric and solvational effects certainly also play an important role, as indicated by the large gain in stability produced when the more crowded $[Cd(amp)_2]^{2+}$ is formed. At the origin of this large stability gain, there is a considerable and favorable increase in enthalpy that largely overcomes the parallel unfavorable decrease in entropy. This may reflect greater solvation of amp complexes in which the hydrogens of amines bonded to the metal ion can organize the solvent molecules near the metal complex by forming hydrogen bonds. This explanation is also in agreement with the formation of $[Cd(amp)_3]^{2+}$, a stable M/L = 1:3 species, which is not formed by the more rigid and less solvent-ordering bipy with the cadmium ion. When the third com-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plexation step is examined, desolvation effects are already over, as indicated by the higher negative stepwise enthalpy and entropy values. The same trend in desolvation effects, to an even more marked extent, is observed when examining the second complexation step with dpma.

When a pyridine ring is added to amp, a trend similar to that found on going from bipy to terpy is obtained for $Cd^{II}$ amp and dpma complexation. The gain in stability is very small, due to a less unfavorable entropy term, whereas the $\Delta H°_{\beta_1}$ value is even less favorable than for amp: the enthalpy gain due to the additional $Cd–N_{py}$ bond is overcome by the enthalpy spent during desolvation. As dpma donor atoms are undoubtedly all bonded to $Cd^{II}$, this result clearly confirms the low affinity of the pyridine moiety for $Cd^{II}$, which is even more enhanced when more py units are part of a more complex structural frame, as in dpma (and terpy).

From another point of view, as regards differences in complex stability between one metal ion with terpy and dpma, it should be noted that the gain in stability is much more significant for $Cd^{II}$ ($\Delta\log\beta_1^{dpma–terpy} = 2.22$) than for $Co^{II}$ ($\Delta\log\beta_1^{dpma–terpy} = 0.64$), that is, the relative selectivity towards $Co^{II}$ is decreased. This evidences the great influence of structural constraints in governing metal–ligand affinity: substitution of the central pyridine unit with a flexible amino group relaxes ligand structural requirements and decreases the particular misfit cited for Cd–terpy systems. Obviously, as two pyridines are still inserted in the ligand frame, residual strains still occur, and also contribute to the low gain in stability with respect to the Cd–amp system (see above).

When comparing analogous bidentate and tridentate aliphatic ligands, such as primary ethylenediamine (en), diethylenetriamine (dien), and secondary *N*,*N*′-dimethylethylenediammine (dmen) and *N*,*N*′′-dimethyldiethylenetriamine (dmdien), much higher stability and exothermicity are found,[11c,11d,11e] due to the higher basicity of the aliphatic ligands. The opposite occurs with the corresponding tertiary *N*,*N*,*N*′,*N*′-tetramethylethylenediammine (tmen) and *N*,*N*,*N*,′*N*′,*N*′′-pentamethyldiethylenetriamine (pmdien) although the basicity order in DMSO is still $R_3N > py$.[45,46] In this case, steric hindrance due to the methyl groups of the ligands in the complexes evidently explains this reverse behavior.

### Dioxygen Affinity

Reversible dioxygen-binding properties were found for $[Co(bipy)(terpy)]^{2+}$ mixed complexes in nonaqueous low-coordinating media, such as acetonitrile or nitrobenzene, and μ-peroxo adducts were isolated.[51] In order to verify if oxygen binding also occurs in DMSO, $O_2$ was bubbled in solutions containing the mixed complex $[Co(terpy)(bipy)]^{2+}$ {the stability constant for the reaction $Co^{2+}$ + terpy + bipy ⇌ $[Co(terpy)(bipy)]^{2+}$ was also evaluated by spectrophotometric titration and its value was $\log K = 8.9(0.1)$}. No changes in UV/Vis spectra were observed in the range 300–650 nm, thus showing that no $O_2$ absorption occurred. Fitting the dissociative mechanism at the basis of dioxygen coordination,[52] higher activation energy is probably required for the bond breaking necessary for $O_2$ coordination, when the $[Co(terpy)(bipy)]^{2+}$ species is solvated by the more-coordinating solvent DMSO.

## Conclusions

Much lower affinities are shown by pyridine ligands for $Cd^{II}$ than for $Co^{II}$: this is due to the poorer acid properties of the former ion, confirmed by the calculated binding energies of the complex and by longer M–N lengths in $Cd^{2+}$ complexes. No important π backbonding seems to be involved as far as these bipositive metal ion–ligand systems are concerned, as evidenced by DFT calculations on model systems. This selectivity increases with the number of pyridine units in the ligands: when the larger $Cd^{II}$ with rigid planar terpy is considered, a misfit between ion size and ligand structural requirement is invoked to explain the results. This point is also confirmed by the huge gain in the stability of the $Cd^{II}$ complex when one py unit is substituted with an amino group in dpma. This extra stability, especially with respect to cobalt systems, is not explained only in terms of the higher σ-donor properties of the amino group, but also by taking into account the particular relaxation introduced into the Cd–ligand system when the central py is substituted with an aliphatic moiety. A comparison with data available in water shows that the desolvation effects of the amino group, more important in water than in DMSO, play a crucial role in determining the stability trend in the two solvents, especially for aminopyridine ligands.

## Experimental Section

**General Remarks:** Solvated salts, $Co(ClO_4)_2·6DMSO$ and $Cd(ClO_4)_2·6DMSO$, ligands, and solvents were prepared and purified as described previously.[11a,11b,11c] All experiments in anaerobic conditions were carried out at room temperature in a MB Braun 150 glovebox under a controlled atmosphere containing less than 1 ppm of water and less than 1 ppm of oxygen.

**Potentiometric Measurements:** In a typical titration, known volumes of ligand solutions ($50 < C°_L < 400$ mmol dm$^{-3}$) were added to $Cd^{II}$ solutions (20 mL) ($2 < C°_{Cd} < 20$ mmol dm$^{-3}$) at 298.1 ± 0.1 K. The equilibrium concentrations of cadmium(II), necessary to calculate stability constants, were obtained from the emf data of a galvanic cell similar to that reported previously.[11a] Emf data were ascertained with an Amel 338 pHmeter equipped with a Weiss WCD1001 Cd ion-selective electrode as working electrode and a Methrom 6.0718.000 silver electrode as reference. The Nernstian response of Cd electrodes was checked in the range $10^{-7} <$ metal $< 10^{-2}$ mmol dm$^{-3}$. Equilibrium was typically reached in 2–5 min. The Hyperquad[53] minimization program was used to calculate stability constants.

**Spectrophotometric Measurements:** UV/Vis spectra were recorded with a Varian Cary 50 spectrophotometer, using optic fiber probes connected directly with the cell inside the glovebox. The concentra-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tions of cobalt(II) and ligands were in the range $2 < C°_{Co} < 20$ mmol dm$^{-3}$ and $50 < C°_{L} < 400$ mmol dm$^{-3}$, respectively. Data were recorded over the wavelength range 300–650 nm. The absorption maximum for $Co(ClO_4)_2$ in DMSO occurs at 535 nm, with an extinction molar coefficient of $\varepsilon = 11.9$ mol$^{-1}$ dm$^3$ cm$^{-1}$.[11a] Maximum absorption of $CoL_j$ complexes is shifted to lower wavelengths (Supporting Information, Figure S2 as an example), in line with an increase in ligand field strength. In the case of dpma with $Co^{II}$, UV/Vis data were collected in the presence of $Cd^{II}$ as a competitive ion, in order to obtain more reliable values for the stability constants.

The absorbance data at about 20 different wavelengths in the range 450–550 nm were analyzed and the formation constants of $CoL_j$ complexes were determined, together with the molar extinction coefficients of the complexes at each relevant wavelength, using the Hyperquad program.[53] UV/Vis measurements for dioxygen uptake were carried out on similar apparatus by means of 1-cm optic fiber probes (Hellma) dipped directly into the reaction vessel.

**Calorimetric Measurements:** A Tronac model 87-558 precision calorimeter was employed to measure reaction heats. The calorimeter was checked by titration of tris(hydroxymethyl)aminomethane (Tham) with a standard solution of HCl in water. The experimental value of the neutralization heat of Tham was $\Delta H° = -47.59$ kJ mol$^{-1}$, in good agreement with the accepted value of $-47.53 \pm 0.13$ kJ mol$^{-1}$.[1]

Calorimetric titrations were performed at 298.00 ± 0.02 K by adding known volumes of ligand solutions ($50 < C°_{L} < 400$ mmol dm$^{-3}$) to 20 mL of metal (metal = $Cd^{II}$, $Co^{II}$) solutions ($2.00 < C°_{metal} < 50.0$ mmol dm$^{-3}$).

For each titration run, the experimental values of the total heat produced in the reaction vessel were calculated as a function of the added titrant. These values were corrected only for the dilution heat of the titrant, which was determined separately. The dilution heat of the titrate was found to be negligible in the metal concentration range used.

Quantity $\Delta h_v$, total heat per mole of metal ion, was defined and calculated by dividing the net reaction heat by the number of moles of metal ion in the calorimetric vessel. The Letagrop Kalle[54] least-squares computer program was used to calculate enthalpy changes.

**NMR Measurements:** $^1$H NMR spectra were recorded at 298 K with a Bruker AC-200 spectrometer. Measurements were performed on [$D_6$]DMSO solutions containing metal ions (ca. 30 mmol dm$^{-3}$) and the dpma ligand in the molar ratio $R_c = 1$ or 2. Analogous measurements were carried out on solutions containing only the ligand concerned.

**FTIR Spectroscopy:** FTIR spectra were obtained on a Bio-Rad FTS 40 spectrometer (maximum resolution 4 cm$^{-1}$; 16 scans). A cell with barium fluoride windows (thickness 25 μm) was used. Cells were filled, closed in a glovebox, and quickly transferred to the spectrometer. $C°_{Cd}$ and $C°_{L}$ in the DMSO solutions were about 50 mmol dm$^{-3}$.

**Computational Procedure:** DFT calculations on $ML^{2+}$ complexes (M = Co, Cd; L = py, bipy, terpy) were performed using Gaussian03[55] with the B3LYP three-parameter hybrid density functional.[56] For the $Co^{2+}$ complexes the unrestricted formalism was employed with three unpaired electrons ($S = 4$). The split valence basis set 6-31G(d) was employed for the atoms of the ligands, and a 3-21G basis was applied for the metal ions. The use of the small 3-21G basis set was due to the observation that sometimes the application of ECPs with $Co^{2+}$ gave convergence problems with open-shell SCF in DFT calculations. Nevertheless, the choice of this basis set for the metal ions does not affect the qualitative trend of the results.

All geometries were optimized by symmetry constraints. After optimization, equilibrium points were characterized by calculating vibrational frequencies, in order to confirm that they were local minima.

Binding energies were corrected for zero-point energy and basis set superposition error (BSSE) by the counterpoise correction ($E_{bind} = E_{ML^{2+}} - E_{M^{2+}} - E_L + E_{BSSE}$).[57] NBO analysis was performed by the NBO3.1 program included in Gaussian.

**Supporting Information** (see footnote on the first page of this article): Figure S1 shows $^1$H NMR spectra for the Cd–dmpa system in [$D_6$]DMSO. Figure S2 shows spectral changes, in terms of molar absorption of *j* species versus wavelengths, for the Co–bipy species. Tables S1–S7 list DFT-optimized distances and angles of py, bipy, and terpy, their ML (M = $Cd^{II}$, $Co^{II}$) and $Co(terpy)_2$ complexes, and the numbering scheme.

**Keywords:** Bioinorganic chemistry / Platinum / Amino acids / Sulfur / Selenium

Dichloro[(1*R*,2*R*)-*trans*-diaminocyclohexane]platinum(II) was activated with $Ag_2CO_3$ and then treated with (*S*)-methionine, *S*-methyl-(*S*)-cysteine, (*S*)-selenomethionine and *Se*-methyl-seleno-(*S*)-cysteine. The *N*,*S*- and *N*,*Se*-chelated platinum(II) species were isolated as hexafluorophosphate salts and characterized by multinuclear NMR spectroscopy, ESI-MS, IR, elemental analyses and, in the case of the (*S*)-methionine and (*S*)-selenomethionine complexes, by X-ray crystallography.

## Introduction

Modern anticancer chemotherapy makes use of a variety of drugs, including metal-based agents. Cisplatin, *cis*-diamminedichloroplatinum(II), is one of the most effective anticancer drugs known to date.[1] It is widely used in the treatment of several solid tumors, including metastatic testicular germ-cell cancer, which has become a curable disease in more than 90% of cases.[2] In order to overcome the severe toxic side-effects of cisplatin-based therapy (nephrotoxicity, neurotoxicity, nausea, and vomiting), the second-generation platinum drug carboplatin, diammine(1,1-cyclobutanedicarboxylato)platinum(II), has been developed and approved for worldwide clinical use.[3,4]

Synthetic variations in the coordinating ligands have led to platinum complexes with 1,2-diaminocyclohexane (DACH) ligands.[5] The most prominent representative of this new class of third-generation platinum complexes is oxaliplatin (Figure 1), which was found to be active in primarily cisplatin- and carboplatin-resistant cell lines and tumors.[6] Recently, oxaliplatin (Eloxatin) has been approved in more than 60 countries all over the world for the treatment of metastatic colorectal cancer, which is the second most frequent cause of cancer death in developed countries.[7]

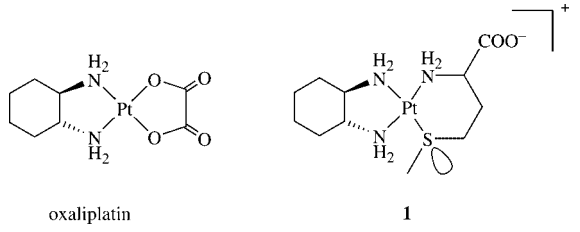

Figure 1. Chemical structures of oxaliplatin and of one of its metabolites (**1**) found in the plasma ultrafiltrate of cancer patients, both of which contain an (*S*)-methionine ligand.

It is widely accepted that cellular DNA is the crucial target for platinum anticancer drugs,[8] but how the drug reaches DNA is still puzzling. Platinum compounds display a high affinity for sulfur, in agreement with the hard/soft acid/base (HSAB) principle, therefore sulfur-containing biomolecules such as amino acids, peptides and proteins in the blood stream, the cytosol, and the nucleus should prevent anticancer platinum drugs from reaching the DNA.[9]

In plasma ultrafiltrate of rats and cancer patients treated with oxaliplatin, different kinds of metabolites, including those with (*S*)-methionine, have been detected in substantial amounts.[10,11] Whether these (*S*)-methionine species are produced from the organism just for detoxification and excretion purposes only, or themselves are involved in the anticancer process, is still a matter of some controversy. This is rather astonishing for a drug that is routinely used in

clinical practice and which has reached blockbuster status. Consequently, we have focused on finding an appropriate synthetic procedure for the synthesis of the (*S*)-methionine derivative, which has also been used and extended to other sulfur- and selenium-containing amino acids. Interestingly, it is worthwhile to mention that (*S*)-selenomethionine as well as *Se*-methylseleno-(*S*)-cysteine are currently being evaluated in preclinical[12] and clinical settings[13,14] as chemopreventive agents (also called cytoprotective or rescue agents). Therefore, syntheses of [(1*R*,2*R*)-*trans*-diaminocyclohexane]platinum(II) coordinated to (*S*)-selenomethionine and *Se*-methylseleno-(*S*)-cysteine are of great interest in order to provide these complexes for evaluation of their pharmacological properties in the future.

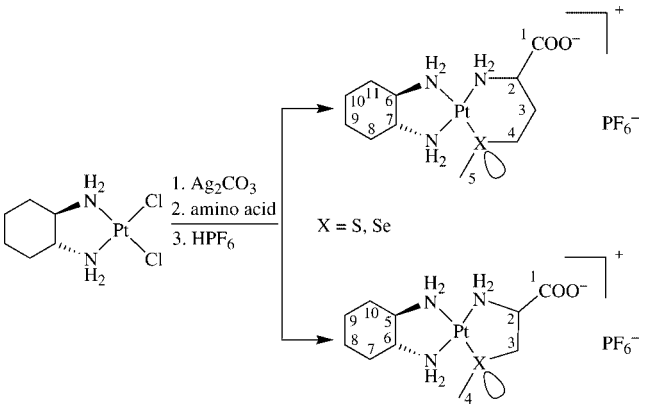

Figure 2. Syntheses of [(1*R*,2*R*)-*trans*-diaminocyclohexane]platinum(II) complexes containing (*S*)-methionine (**1**·$PF_6$), *S*-methyl-(*S*)-cysteine (**2**·$PF_6$), (*S*)-selenomethionine (**3**·$PF_6$), and *Se*-methylseleno-(*S*)-cysteine (**4**·$PF_6$) as amino acid ligands (stereochemistry at 2-C and X are omitted).

## Results and Discussion

There are several reports in the literature dealing with the characterization of complexes like **1** (Figure 1), but in nearly all cases the target complexes were synthesized in small amounts in an NMR tube without isolation. In only one case was the synthesis of **1** described based on several laborious isolation steps, including two HPLC separations.[15] Additionally, the yield was very low (1.2%). In the present work, synthesis of the amino acid platinum(II) complex [(1*R*,2*R*)-*trans*-diaminocyclohexane][(*S*)-methionine-$\kappa^2$*N*,*S*]platinum(II) (**1**·$PF_6$) started from $K_2PtCl_4$ and (1*R*,2*R*)-*trans*-diaminocyclohexane. The resulting complex dichloro[(1*R*,2*R*)-*trans*-diaminocyclohexane]platinum(II) was treated with silver carbonate in order to remove the chloro ligands (Figure 2). Direct addition of (*S*)-methionine to the activated platinum species afforded a yellow crude product after lyophilization. After dissolution and addition of aqueous $HPF_6$, the target compound **1**·$PF_6$ was isolated as a white solid in moderate yield. The decisive steps towards the improved preparation of **1** are the use of $Ag_2CO_3$ for the activation of the dichloro[(1*R*,2*R*)-*trans*-diaminocyclohexane]platinum(II) complex and the addition of aqueous $HPF_6$ to this raw product. $HPF_6$ efficiently removes the carbonate counterions, while $PF_6^-$ is known to be a beneficial partner in the crystallization process. The (*S*)-methionine complex **1**·$PF_6$ was intensively studied and characterized by $^1$H, $^{13}$C, $^{15}$N, $^{31}$P, and $^{195}$Pt NMR spectroscopy, X-ray diffraction analysis, elemental analysis, IR spectroscopy, and ESI MS.

The $^1$H NMR spectrum of **1**·$PF_6$, which was measured in $H_2O/D_2O$ (9:1), can be divided into three spectral regions (Figure 3). The signals deriving from the cyclohexane ring (6-H to 11-H) are found in the upfield region ($\delta$ = 1.0–2.3 ppm). The signals of the diastereotopic protons of the $CH_2$ groups display a marked splitting of up to nearly 0.8 ppm, as could be deduced from the $^1$H,$^{13}$C-COSY NMR spectrum. The 2-H, 3-H, and 4-H resonances of the coordinated (*S*)-methionine are found between $\delta$ = 2.1 and 3.5 ppm. All N*H* signals are detected most downfield ($\delta$ = 4.8–5.8 ppm) and are partly superimposed by the HDO resonance, which was suppressed by pre-saturation. Significant downfield shifts are observed for the signals of protons 4-H and 5-H. In uncoordinated (*S*)-methionine, 4-H and 5-H resonate at $\delta$ = 2.58 and 2.07 ppm, respectively. In the target complex, however, two sets of signals at $\delta$ = 2.87/2.94 (4-H) and 2.45/2.46 (5-H) ppm are detected. On the contrary, an upfield shift from $\delta$ = 3.80 ppm in the free ligand to $\delta$ = 3.35/3.44 ppm was found for the signal of the α-proton 2-H. Deconvolution of the $^1$H NMR spectrum in the region at $\delta \approx$ 2.45 ppm allowed us to estimate the ratio between the two sets of signals: under the experimental conditions (298 K), a ratio of 2:3 was found.

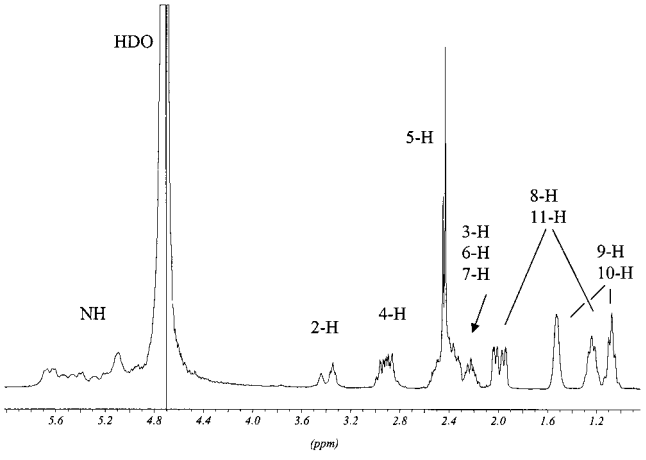

Figure 3. $^1$H NMR spectrum of **1**·$PF_6$ with the HDO signal suppressed by pre-saturation.

The coordination sphere around the central platinum ion could be determined on the basis of the $^{195}$Pt and $^{15}$N chemical shifts. The $^{195}$Pt NMR spectrum of **1**·$PF_6$ displays two signals at $\delta$ = –3313 and –3335 ppm for the two diastereoisomers (Figure 4), which is in accordance with a $PtN_3S$ configuration. Deconvolution and integration resulted in the same ratio of 2:3. For $PtN_3S$-type complexes, $^{195}$Pt chemical shifts in the range of $\delta$ = –3000 to –3300 ppm are expected,[16,17] whereas $PtN_2SO$ and $PtN_2S_2$ complexes

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

resonate in the region af $\delta \approx -2700$ and $-3700$ ppm,[18] respectively. Besides $^{195}$Pt NMR investigations, the $^{15}$N chemical shifts were used to characterize the structure of the platinum complexes. Two-dimensional $^{1}$H,$^{15}$N-correlated spectroscopy at natural abundance of the $^{15}$N nuclei (spin 1/2, 0.37% natural abundance) has proven to be a powerful tool since the $^{15}$N chemical shift of the nitrogen atom is diagnostic for ligands coordinated in *trans* position. Three $^{15}$N chemical shifts could be detected for **1**·$PF_6$: the $^{1}$H,$^{15}$N shift correlation peak at $\delta = -45$ ppm can be assigned to the 2-C*N*$H_2$ group of (*S*)-methionine *trans* to the nitrogen atom of the DACH ligand,[19] whereas the resonance at $\delta = -14$ ppm can be assigned to 7-C*N*$H_2$ *trans* to the nitrogen atom of the (*S*)-methionine ligand; the cross peak of 6-C*N*$H_2$ *trans* to the coordinated thioether group could be detected at $\delta = -4$ ppm.

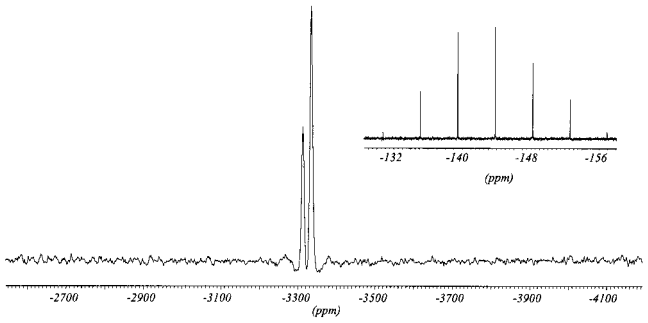

Figure 4. $^{195}$Pt and $^{31}$P (small inset) NMR spectra of **1**·$PF_6$.

The two sets of resonances for the (*S*)-methionine ligand in the $^{1}$H NMR spectrum as well as two $^{195}$Pt signals for **1**·$PF_6$ are a consequence of the coordination of (*S*)-methionine to the platinum(II) center through the sulfur and nitrogen atoms. As a result, another stereocenter which undergoes slow isomerization at the sulfur atom is formed. When the temperature was raised, the epimerization at the chiral sulfur center became faster, and at 333 K only one signal for the methyl protons 5-H was observed. This process was reversible (Figure S1, Supporting Information). In the case of the cyclohexane protons, the isomerization process seems to have no detectable influence on the proton signals. In the $^{13}$C NMR spectra of the free and coordinated (*S*)-methionine ligand, the resonances of the carbonyl carbon atom C-1 are found in close proximity at $\delta = 174.6$ and 176.3/176.8 ppm, respectively. However, a distinct downfield shift of the signal of the *S*-methyl group from $\delta = 14.3$ to 19.6/19.7 ppm was detected. These features are in accordance with an *N*,*S* coordination of (*S*)-methionine to the platinum(II) center as well. The hexafluorophosphate counterion signal appears at $\delta = -143.9$ ppm in the $^{31}$P NMR spectrum (Figure 4). Due to the coupling of the phosphorus nucleus with the six fluorine atoms, it appears as a septet with a coupling constant of 710 Hz.

X-ray diffraction quality single crystals were grown by slow concentration of a methanol solution of the complex. The structure of **1**·$PF_6$ consists of a complex cation **1** (Figure 5) and a complex anion $[PF_6]^-$, which interacts weakly through contacts of the type N−H···F (N1···F6 2.935, N2···F4 3.123, N2···F5 3.352, N2···F6 3.303 Å). The platinum(II) ion has a square-planar coordination geometry as it is chelated by two ligands: (1*R*,2*R*)-*trans*-diaminocyclohexane and (*S*)-methionine. (1*R*,2*R*)-*trans*-DACH acts as a neutral ligand and coordinates to the platinum(II) ion through nitrogen atoms N1 and N2 [Pt–N1 2.051(2), Pt–N2 2.051(2) Å]. These bond lengths are intermediate between those found in oxaliplatin [Pt−N1 2.06(2), Pt−N2 2.04(2) Å].[20] The second ligand, which is negatively charged due to the presence of the ionized carboxyl group, is bound to the platinum(II) ion through the nitrogen atom N3 and the thiomethyl sulfur atom S1. Coordination of the latter to the platinum(II) ion creates a new stereogenic center at the S atom, i.e. (*R*), in addition to the opposite configuration at atom C7. The Pt−N3 [2.062(2) Å] and Pt−S1 [2.2607(6) Å] bonds are markedly longer than the corresponding bonds in two independent molecules of dichloro[(*S*)-methionine-κ$^2$*N*,*S*)platinum(II)[21] [2.047(8), 2.029(8) and 2.246(2), 2.247(2) Å]. The deviation of the coordinated atoms from the mean plane through PtN1N2N3S1 does not exceed ±0.023 Å. The five-membered chelate ring has a distorted envelope conformation with a clear tendency towards a zigzag arrangement of C1 (+0.55 Å) and C6 (–0.14 Å). The torsion angle $\Theta_{N1–C1–C6–N2}$, which serves as a measure of the deviation of the chelate ring from planarity, is –54.3°. The cyclohexane ring adopts a chair conformation with the amino groups in equatorial positions.

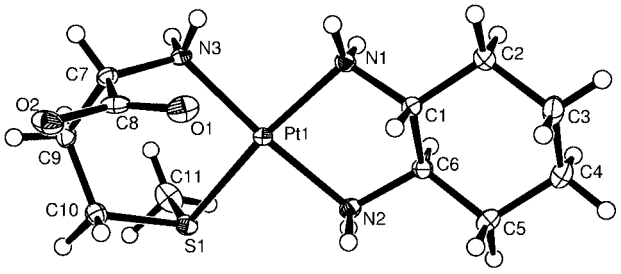

Figure 5. Structure of the cation in **1**·$PF_6$ with thermal ellipsoids at the 50% probability level. Selected bond lengths [Å] and angles [°]: Pt–N1 2.051(2), Pt–N2 2.051(2), Pt–N3 2.062(2), Pt–S1 2.2607(6), C10–S1 1.810(3), S1–C11 1.805(3), C8–O1 1.235(3), C8–O2 1.276(3); N1–Pt–N2 82.79(10), N3–Pt1–S1 95.35(7), C11–S1–C10–C9 –62.8, N3–C7–C8–O1 –2.2.

The six-membered metallocycle has a chair conformation, which is distorted because of the presence of heteroatoms. The methyl substituent at S1 and the $COO^-$ group are placed on opposite sides of the $PtN_3S$ plane. The orientation of the carboxylato group can be described by the torsion angle $\Theta_{N3–C7–C8–O1}$ (–2.2°). This angle is comparable with that observed on coordination of (*S*)-methionine to the palladium(II) ion in [$PdCl_2$(*S*-met)] (3.7°).[22]

The derivative **2**·$PF_6$, which contains an *S*-methyl-(*S*)-cysteine ligand, was synthesized in analogy to **1**·$PF_6$, thereby demonstrating the applicability of this reaction

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pathway (Figure 2). Characterization was performed by elemental analysis, mass spectrometry, and IR, $^1$H, and $^{13}$C NMR spectroscopy. Besides the fact that one methylene unit is missing in **2**·$PF_6$, the $^1$H and $^{13}$C NMR spectra show a similar resonance pattern with respect to the (*S*)-methionine counterpart. The diastereoisomer ratio was found to be nearly 1:1. In **2**·$PF_6$, the proton signals are shifted to lower field in the amino acid ligand by 0.1 to 0.5 ppm. Comparison with the diastereoisomers of **1**·$PF_6$ revealed chemical shift differences smaller than 0.1 ppm. These differences are more pronounced in **2**·$PF_6$, with $\Delta\delta$ values of between 0.1 and 0.2 ppm. Remarkable $\Delta\delta$ values were observed especially in the case of the *S*-Me protons (**1**·$PF_6$: 0.01 ppm; **2**·$PF_6$: 0.1 ppm), thereby reflecting the change from the six-membered to the more strained five-membered platinacycle. The latter observation was also confirmed in the $^{13}$C NMR spectrum, in which the *S*-Me carbon resonances are found at $\delta$ = 19.6 and 19.7 ppm for **1**·$PF_6$ and at $\delta$ = 20.6 and 21.8 ppm for the *S*-methyl-(*S*)-cysteine analog **2**·$PF_6$.

As mentioned in the introduction, (*S*)-selenomethionine and *Se*-methylseleno-(*S*)-cysteine are currently being evaluated as cytoprotective agents during the treatment with platinum-based anticancer complexes. Administration of either selenium agent results in a decreased platinum-induced toxicity without affecting the tumor-inhibiting properties of the platinum complexes. In the case of cis- and carboplatin (two monodentate ammine ligands), in-depth NMR spectroscopic and ESI-MS studies have been performed.[23,24] These showed that one or both ammine ligands are released from the platinum center upon coordination of (*S*)-selenomethionine. It is widely accepted that such types of complexes are not further involved in the anticancer process.[24] In contrast, for oxaliplatin, which contains the bidentate DACH ligand, release of the coordinated diamine is not expected due to the chelate effect. Therefore, the anticancer-active [(1*R*,2*R*)-*trans*-diaminocyclohexane]-platinum(II) fragment will still remain intact, thus opening up the possibility to selectively synthesize these types of metabolites and study their pharmacological properties.

Synthesis of the (*S*)-selenomethionine complex **3**·$PF_6$ was performed in analogy to the (*S*)-methionine counterpart (Figure 2). A comparable peak pattern to **1**·$PF_6$ as well as analogous shift differences with respect to the uncoordinated ligand were observed in the $^1$H and $^{13}$C NMR spectra of **3**·$PF_6$. The signals of protons 4-H and 5-H are significantly shifted to lower field in the complex, whereas the signal of the 2-H protons displays an upfield shift (e.g. the methyl resonances in **3**·$PF_6$ at $\delta$ = 2.31 and 2.34 ppm occur in the free ligand at $\delta$ = 1.93 ppm). The $^{13}$C NMR resonances of **3**·$PF_6$ are equivalent to those observed for the (*S*)-methionine analog: the resonances for the carboxylate group in **3**·$PF_6$ appear at $\delta$ = 176.8 and 176.5 ppm and are slightly shifted in comparison to the free ligand ($\delta$ = 174.5 ppm); a distinct downfield shift of the signal of the *Se*-methyl group from $\delta$ = 3.6 ppm to $\delta$ = 11.7/11.6 ppm was also observed. The diastereoisomer ratio deduced from the $^1$H NMR spectrum by deconvolution and integration was 2:3, which is the same as for the (*S*)-methionine analog. Comparison of the $^1$H and $^{13}$C NMR spectra of the *Se*-methylseleno-(*S*)-cysteine complex **4**·$PF_6$ with those of **3**·$PF_6$ revealed the same pattern as described above for **1**·$PF_6$ and **2**·$PF_6$. The $^1$H chemical shift differences of the diastereoisomers (with respect to the amino acid ligand) were small in the case of **3**·$PF_6$ ($\Delta\delta < 0.05$ ppm), whereas the $\Delta\delta$ values of **4**·$PF_6$ were found to be between 0.05 and 0.16 ppm. This general behavior was also confirmed in the $^{13}$C NMR spectra, in which the *Se*-Me carbon atom resonates at $\delta$ = 11.7 and 11.6 ppm in the case of **3**·$PF_6$ and at $\delta$ = 12.6 and 13.5 ppm for the *Se*-methylseleno-(*S*)-cysteine analog **4**·$PF_6$. For the latter, a converted diastereoisomer ratio of 3:2 with respect to **3**·$PF_6$ was found. As explained above, $^{195}$Pt and $^{15}$N NMR resonances are very indicative of the coordination sphere around the platinum center. Both the $^{195}$Pt (Figure 6) and $^{15}$N chemical shifts of **3**·$PF_6$ [$^{195}$Pt NMR: $\delta$ = –3381, –3351 ppm; $^{15}$N NMR: $\delta$ = –48.0 (2-$CNH_2$), –18.0 (7-$CNH_2$), 3.5 (6-$CNH_2$) ppm] are similar to those observed for the (*S*)-methionine analog **1**·$PF_6$ ($^{195}$Pt NMR: $\delta$ = –3335, –3313 ppm;$^{15}$N NMR: $\delta$ = –45.2 (2-$CNH_2$), –14.0 (7-$CNH_2$), 4.0 (6-$CNH_2$) ppm] and are therefore in agreement with the structure presented in Figure 2.

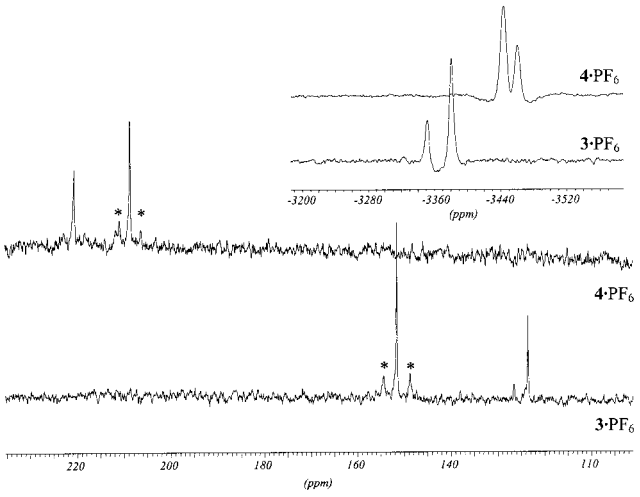

Figure 6. $^{77}$Se and $^{195}$Pt (small inset) NMR spectra of **3**·$PF_6$ and **4**·$PF_6$; $^{195}$Pt satellites are marked with asterisks. In the case of the less intense signals, $^{195}$Pt satellites could not unequivocally be detected.

From the analytical point of view, the selenium complexes offer an advantage since the selenium atom itself can be investigated by NMR spectroscopy ($^{77}$Se, spin 1/2, 7.6% natural abundance), thereby ultimately proving coordination of the selenium atom to the platinum center. Besides a remarkable downfield shift in comparison to the free ligand, coordination of the selenium atom is also reflected by the appearance of platinum satellites due to a $^1J_{^{77}Se,^{195}Pt}$ coupling (Figure 6).[25] In **3**·$PF_6$ and **4**·$PF_6$, the $^{77}$Se chemical shifts of the diastereoisomers appear at $\delta$ = 123.5/151.5 and 208.6/220.5 ppm, respectively; the uncoordinated amino acids resonate at $\delta$ = 84.8 and 51.2 ppm, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Coupling of $^{77}$Se with the $^{195}$Pt central ion in the (*S*)-selenomethionine complex **3**·$PF_6$ (435 Hz) is thereby significantly larger than in the *Se*-methylseleno-(*S*)-cysteine analog **4**·$PF_6$ (355 Hz).

Finally, the structure of **3**·$PF_6$ in the solid state was determined by X-ray crystallography. Single crystals were grown by slow concentration of a methanol solution of the complex. The structural motif of the complex cation **3** is very similar to that of complex **1**. Again, the methyl and carboxylate groups are positioned on opposite sides of the $PtN_3Se$ plane. However, it is worth noting that the Pt–Se distance [2.3777(10) Å] is more than 0.1 Å longer than the corresponding Pt–S distance in **1**. The Pt–Se bond length is comparable to that in dichloro[*O*-methyl-(*S*)-selenomethionine]platinum(II) [2.3697(8) Å].[26] Remarkably, the *Se*-methyl and COOMe groups lie on the same side of the $PtCl_2NSe$ plane in this complex (Figure 7).

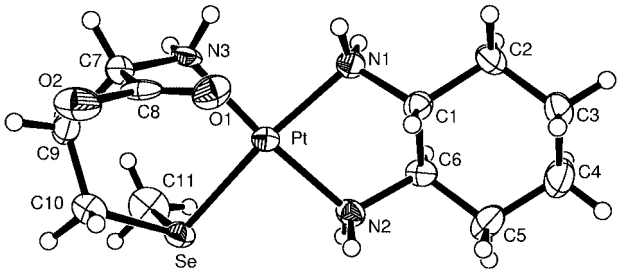

Figure 7. Structure of the cation in **3**·$PF_6$ with thermal ellipsoids at the 50% probability level. Selected bond lengths [Å] and angles [°]: Pt–N1 2.056(7), Pt–N2 2.061(7), Pt–N3 2.079(7), Pt–Se1 2.377(10), C10–Se1 1.948(9), Se1–C11 1.920(11), C8–O1 1.225(12), C8–O2 1.297(10); N1–Pt–N2 82.80(3), N3–Pt1–Se1 95.20(19), C11–Se1–C10–C9 –60.1, N3–C7–C8–O1 0.50.

## Conclusions

[(1*R*,2*R*)-*trans*-Diaminocyclohexane]platinum(II) complexes with coordinated (*S*)-methionine, *S*-methyl-(*S*)-cysteine, (*S*)-selenomethionine, and *Se*-methylseleno-(*S*)-cysteine ligands have been synthesized and characterized by multinuclear NMR spectroscopy, ESI-MS, IR spectroscopy, and elemental analysis. The (*S*)-methionine (**1**·$PF_6$) and (*S*)-selenomethionine (**3**·$PF_6$) complexes were also studied by X-ray crystallography. The synthetic procedure resulting in the (*S*)-methionine complex by activation of the dichloro[(1*R*,2*R*)-*trans*-diaminocyclohexane]platinum(II) species with $Ag_2CO_3$ and isolation of the resulting complex as its hexafluorophosphate salt can also be extended to other sulfur- and selenium-containing amino acids. This is of central interest since three out of the four complexes synthesized are metabolites in cancer patients treated with oxaliplatin. These metabolites can now be evaluated with respect to their pharmacological properties.

## Experimental Section

**General:** All chemicals and solvents used were obtained from commercial suppliers and were used as received. (*S*)-Methione was purchased from Roth and (*S*)-selenomethionine from Acros. *S*-Methyl-(*S*)-methionine, *Se*-methylseleno-(*S*)-cysteine, and $HPF_6$ (71% in water) were purchased from Fluka, and potassium tetrachloroplatinate(II) was obtained from Johnson Matthey. Dichloro[(1*R*,2*R*)-*trans*-diaminocyclohexane]platinum(II) was prepared according to a standard literature procedure.[27] The synthetic procedures were carried out in a light-protected environment in doubly distilled water and under argon using standard Schlenk-line techniques. Elemental analyses were performed by the microanalytical laboratory at the University of Vienna. $^1$H, $^{13}$C{$^1$H}, $^{31}$P{$^1$H}, $^1$H,$^1$H-COSY, $^1$H,$^{13}$C-COSY, $^1$H,$^{15}$N-COSY, $^{195}$Pt, and $^{77}$Se NMR spectra were recorded in $D_2O$ or $H_2O/D_2O$ (9:1) with a Bruker Avance DPX 400 instrument (UltraShield Magnet) using standard pulse programs at 400.13 ($^1$H), 162.0 ($^{31}$P), 100.63 ($^{13}$C), 85.99 ($^{195}$Pt), 76.32 ($^{77}$Se), and 40.55 ($^{15}$N) MHz. Two-dimensional spectra were measured in a gradient-enhanced mode. Chemical shifts were measured relative to the solvent peak ($\delta$ = 4.71 ppm), to external 85% $H_3PO_4$, to external $^{15}NH_4Cl$, to external $Ph_2Se_2$ at $\delta$ = 464 ppm, or to external $K_2[PtCl_4]$ at $\delta$ = –1630 ppm. Mass spectra (ESI-MS) were recorded with a Bruker ESQUIRE$_{3000}$ ion trap mass spectrometer. Infrared spectra (4000–400 cm$^{-1}$) were recorded in KBr pellets using a Perkin–Elmer FTIR instrument.

**(*SP*-4-3)-[(1*R*,2*R*)-*trans*-Diaminocyclohexane][(*S*)-methionine-κ$^2$*N*,*S*]platinum(II)·Hexafluorophosphate (1·$PF_6$):** Silver carbonate (355 mg, 1.29 mmol) was added in one portion to a suspension of dichloro[(1*R*,2*R*)-*trans*-diaminocyclohexane]platinum(II) (500 mg, 1.32 mmol) in 100 mL of water and the mixture was stirred at room temperature overnight. Silver chloride precipitated and was filtered off. (*S*)-Methionine (188 mg, 1.26 mmol) was then added to the bright-yellow solution and the mixture was stirred at room temperature for 8 h. Thereafter, the solution was lyophilized to give a slightly yellow crude product. The solid was dissolved in 5 mL of water in a 10-mL plastic vial and a solution of $HPF_6$ (146 μL, 1.26 mmol) in 1 mL of water was added. The mixture was lyophilized and the solid was washed with small portions of methanol. The target platinum(II) complex was obtained after filtration by removal of the solvent under reduced pressure and drying over $P_2O_5$. Yield: 380 mg (50%) [based on the amount of (*S*)-methionine]. $C_{11}H_{24}F_6N_3O_2PPtS$ (602.44): calcd. C 21.93, H 4.02, N 6.98, S 5.32; found C 21.62, H 4.05, N 6.76, S 5.30. **Structure Determination:** X-ray diffraction measurements were performed with Nonius Kappa CCD diffractometers. Single crystals were positioned at 35 and 29.1 mm from the detector and 591 and 256 frames were measured, each for 20 s over a 1.5 and 1.0° scan width (for complexes **1**·$PF_6$ and **3**·$PF_6$, respectively). The data were processed using the Denzo-SMN software package.[28] Crystal data,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

data collection parameters, and structure-refinement details for **1**·$PF_6$ and **3**·$PF_6$ are given in Table 1. The structures were solved by direct methods and refined by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. H atoms of **1**·$PF_6$ were located on difference Fourier maps and isotropically refined. All hydrogen atoms of **3**·$PF_6$ were included at calculated positions with fixed thermal parameters. Computer programs: structure solution: SHELXS-97;[29] refinement: SHELXL-97;[30] molecular diagrams: ORTEP;[31] computer: Pentium II; scattering factors.[32] CCDC-606533 (**1**·$PF_6$) and -606879 (**3**·$PF_6$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# $Co^{III}$ Complexes with Square-Planar $N_2S_2$- and $N_2(SO_2)_2$-Type Ligands as An Active Site Structural Model for Nitrile Hydratase – Biological Implications of an Amidate Coordination

**Takuma Yano,[a] Hidekazu Arii,[a] Syuhei Yamaguchi,[a] Yasuhiro Funahashi,[a] Koichiro Jitsukawa,[a] Tomohiro Ozawa,*[a] and Hideki Masuda*[a]**

**Keywords:** Nitrile hydratase / Cobalt / Amidate ligand / Electrophilic interactions / Lewis acids

In an attempt to understand the unique active site structure of nitrile hydratase, four $Co^{III}$ complexes with square-planar $N_2S_2$- or $N_2(SO_2)_2$-type donor sets, Na[$Co^{III}$(**L:$N_2S_2$**)] (**1**-Na), $PPh_4$[$Co^{III}$(**L:$N_2S_2$**)] (**1**-$PPh_4$), $PPh_4$[$Co^{III}$(**L:$N_2S_2$**)(*t*BuNC)$_2$] (**2**), and $PPh_4$[$Co^{III}${**L:$N_2(SO_2)_2$**}(*t*BuNC)$_2$] (**3**) were synthesized and characterized on the basis of electronic absorption spectroscopy, IR spectroscopy, cyclic voltammetry, and X-ray structural analysis. Both of the crystal structures of complexes **1**-Na and **1**-$PPh_4$ revealed a square planar structure with $N_2S_2$ donating atoms, and **2** exhibited an octahedral structure coordinated with two *tert*-butylisocyanide (*t*BuNC) molecules at the axial sites of complex **1**-$PPh_4$. Complex **3**, which showed an octahedral structure with sulfinate sulfur atoms equatorially coordinated to the center, was synthesized by the treatment of **2** with a suitable oxidant. The reduction potential values from $Co^{III}$ to $Co^{II}$ for complex **3** in solution demonstrated a larger positive shift when compared with those of complexes **1**-$PPh_4$ and **2**, which indicates that the oxygenation of the sulfur atoms increased the Lewis acidity of the $Co^{III}$ center. Interestingly, the coordination equilibrium, the C=O stretching frequency, and the redox potential for **1**-$PPh_4$ were all closely related to the acceptor number (AN) of the solvents. Furthermore, the coordination of monodentate *t*BuNC to the axial position of **1**-$PPh_4$ was dependent on the solvents used. These findings indicate that an electrophilic interaction between the carbonyl oxygen atoms and the solvent molecules control the Lewis acidity of the metal ion. On the other hand, such a solvent dependence was not detected in the S=O stretching frequency of sulfinates **3**. We have concluded that the increase in the redox potential/Lewis acidity of the metal center is a result of the oxygenation of sulfur, and that this increase is controlled by the interaction of the amidate carbonyl oxygen with the secondary coordination sphere. As demonstrated in previous mutation studies, this study suggests that the interaction of the nitrile hydratase active site with the functional groups from the peptide backbone is essential for the catalytic activity of the complex.

## Introduction

Nitrile Hydratase (NHase) is an enzyme that hydrates a nitrile compound to the corresponding amide. Because of its high conversion ability, this enzyme has been employed for the industrial production of acrylamide from acrylonitrile under mild conditions.[1] The NHases are largely classified into $Fe^{III}$-type and $Co^{III}$-type families.[2–4] *Rhodococcus rhodochrous* J1, which is a bacterium with the typical $Co^{III}$-type NHase, has been used to produce several kilotons of acrylamide per year.[3–5] The common amino acid sequence (C–**X**–**Y**–C–S–C) of the peptide in the $Fe^{III}$-type and the $Co^{III}$-type NHase has been proposed as the metal binding ligand on the basis of the similarity between the EXAFS and its pre-edge spectra[6,7] in addition to homology in significant amino acid sequences.[8]

Recent X-ray structure analysis of both NHase types revealed that the metal centers are surrounded by two amide nitrogen atoms and two cysteine sulfur atoms in the equatorial plane with a cysteine sulfur and an oxygen atom ($H_2O$ or $OH^-$), or a cysteine sulfur and a NO group, at the axial sites for the $Co^{III}$- or $Fe^{III}$-types, respectively.[9–12] Interestingly, two equatorially coordinated cysteine sulfur atoms are oxygenated to a sulfenate and a sulfinate, respectively, and the two nitrogen atoms contribute as an amidate ligand. Such a unique structure is very interesting in relation to its hydration mechanism in biological systems.

In such a hydration enzyme, a higher Lewis acidity of the metal center should be required, although M–$OH^-$ (or M–$OH_2$) or M–NCR are proposed as possible active intermediates. On the basis of the HSAB rule, the $N^-$ and $S^-$ ions employed in the enzymes may stabilize the higher oxidation state of the metal center, and the attached electron-withdrawing carbonyl group along with the sulfenyl and sulfinyl

oxygen atoms may reduce the electron density on the metal center to induce a higher acidity. It is quite apparent that both functional groups are very important for the enzymatic reaction. However, the use of the mutant Fe-type NHases that did not contain oxygenated sulfur atoms did not show any hydration reaction, which indicates that the oxygenated sulfur atoms are essential for the enzymatic activity.[13]Most studies that use model complexes have focused on the effect of the oxidation of sulfur. For example, several $Co^{III}$ and $Fe^{III}$ complexes with pentadentate ligands that contain an imine,[14] an amide,[15,16] or an amine[17] group and sulfur atoms have been synthesized and studied. Among them, Mascharak and coworkers[15a] have prepared the complex [Co(PyPS)(CN)] with the use of the amide-type ligand, which was easily replaced by a $H_2O$ molecule. The coordinated water molecule catalytically hydrated acetonitrile to acetamide at pH = 9.5. The addition of an oxidant to the solutions of the complexes afforded the corresponding sulfur-oxidized species.[15b] For the $Co^{III}$ mononuclear complex, the $Co^{III}$ species with a sulfinate was isolated. Hydration of acrylonitrile with this sulfonate–$Co^{III}$ complex proceeded three times faster than that of the complex with two unoxidized sulfur atoms even in acidic media (pH = 8.0). They concluded that the oxygenation of sulfur would make the acidity of the coordinated $H_2O$ molecule increase. Other groups have prepared and characterized the $Co^{III}$ and $Fe^{III}$ complexes with tetradentate planar ligands that contain two amide nitrogen atoms and two thiolate sulfur atoms in the same coordination environment as the NHase active sites,[18,19] and they also succeeded in the generation of sulfinate and sulfenate species by the oxidation of the coordinated sulfur atoms.[18a,18b,19a,19b] However, all of them showed octahedral structures with two monodentate ligands at the axial positions.[18a,18b,19a,19b] Recently, Artaud and coworkers reported that in the synthesis of the $N_2(SO_2)_2$-type $Co^{III}$ complex with a $CN^-$ ion at the apical position, the octahedral complex with a hydroxo ion at another axial position was derived.[20] Thus, the oxygenation of sulfur in the equatorial plane has been described to be one of the important factors that leads to an octahedral geometry.

Few have paid attention to the amidate group. However, a mutation study of Fe-containing NHase demonstrated that βR56K, whose Arg56 residue is replaced by lysine and coordinated to the sulfinate and sulfenate oxygen atoms through a hydrogen bond, demonstrated only ca. 1% of the reactivity of the native species.[21] For the βY68F mutant of the $Co^{III}$-type NHase, the enzymatic activity drastically decreased, although it was positioned at a distance from the active site.[22] Moreover, the OH group of tyrosine in βTyr68 is linked to the carbonyl oxygen of the active site through water molecules and the hydrogen bond network around βArg56. βArg56 is, itself, also connected to βTyr68. These facts indicate that the hydrogen-bonding interactions of the coordinating functional groups with the outer sphere strongly contribute to the appearance of the NHase activity. Therefore, we focused on the biological role of the amidate carbonyl group and synthesized two $Co^{III}$ complexes with $N_2S_2$-type ligands, *N*,*N*′-bis(2-mercapto-2-methylpropionyl)-1,3-diaminopropane ($H_4$**L**) and the corresponding sulfinic acid derivative [**L**:$N_2(SO_2)_2$; the two sulfur atoms of $H_4$**L** are oxygenated to sulfinates]. In order to evaluate the influence of the outer sphere, the coordination behaviors of the axial sites of the $Co^{III}$ complex with *tert*-butylisocyanide (*t*BuNC) were evaluated. Isocyanides such as isobutylisocyanide[23] and cyclohexylisocyanide[24] are often employed because of their well-known ability to act as coordinative monodentate ligands for NHase.

## Results and Discussion

### Crystal Structures of Na[Co(L:$N_2S_2$)]3$H_2O$ (1-Na), $PPh_4$[$Co^{III}$(L:$N_2S_2$)]$H_2O$ (1-$PPh_4$), $PPh_4$[$Co^{III}$(L:$N_2S_2$)$_2$-(*t*BuNC)$_2$] (2), and $PPh_4$[$Co^{III}${L:$N_2(SO_2)_2$}(*t*BuNC)$_2$]-EtOH (3)

The $N_2S_2$-type ligand, $H_4$**L**, which provides electron-donating atoms similar to the equatorial coordination environment of the NHase active center, was used for the construction of the model complexes. The $Co^{III}$ complex with **L**, Na[Co(**L**:$N_2S_2$)] (**1**-Na), was prepared by the air-oxidation of the corresponding $Co^{II}$ complex derived from the reaction of $CoCl_2$ and $H_4$**L** in DMF. Recrystallization of the compound from an acetonitrile/diethyl ether solution afforded a single crystal suitable for X-ray analysis, whose

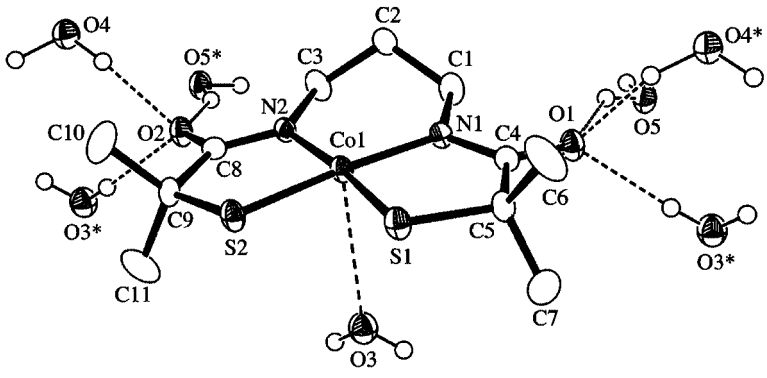

Figure 1. An ORTEP view of Na[Co(**L**:$N_2S_2$)] (**1**-Na) with solvated water molecules, which shows 50% probability ellipsoids. H atoms are omitted for clarity except for those of the water molecules.

crystal data and molecular structure are shown in Table 2 and Figure 1, respectively. Two $[Co^{III}(\mathbf{L}:N_2S_2)]^-$ and two $Na^+$ ions are included together with six water molecules in a unit cell (Figure S1). Selected bond lengths and angles are listed in Table 1. Complex **1**-Na has a square-planar geometry with $N_2S_2$ donor atoms as well as the equatorial coordination in the active site of NHase.[9–12] The bond lengths around the metal center [Co1–N1 = 1.919(3), Co1–N2 = 1.918(3), Co1–S1 = 2.141(1), Co1–S2 = 2.142(1) Å] are comparable to those of the $Co^{III}$ complexes with amide (Co–N = 1.86–1.90 Å) and thiolate coordinations (Co–S = 2.13–2.14 Å) that were previously reported.[18c,19c] Each carbonyl oxygen of the ligand **L** was significantly coordinated to three water molecules [$O_{carbonyl}\cdots O_{water}$ = 2.84–2.91 Å] in the crystal. Furthermore, one water molecule also weakly approaches the $Co^{III}$ ion with a bond length of 3.20 Å at the axial position, which is very similar to the case of Co-type NHase.[11]

One more $Co^{III}$ complex with **L**, $PPh_4[Co(\mathbf{L}:N_2S_2)]$ (**1**-$PPh_4$), was also prepared by the ion-exchange of **1**-Na in an aqueous solution of $PPh_4Cl$. Complex **1**-$PPh_4$ was obtained as a single crystal suitable for X-ray analysis, whose crystal data and molecular structure are shown in Table 2 and Figure 2, respectively. Four $[Co^{III}(\mathbf{L}:N_2S_2)]^-$ anions and four $PPh_4^+$ cations are included together with four water molecules in a unit cell (Figure S2). Selected bond lengths and angles are listed in Table 1. The molecular structure of complex **1**-$PPh_4$ was essentially the same as that of **1**-Na. The bond lengths around the metal center [Co1–N1 = 1.902(3), Co1–N2 = 1.896(3), Co1–S1 = 2.138(1), Co1–S2 = 2.144(1) Å] are in the range of those of the $Co^{III}$ complexes with amide (Co–N = 1.86–1.90 Å) and thiolate coordinations (Co–S = 2.13–2.14 Å) that were previously reported.[18c,19c] However, a detailed comparison of those of **1**-Na and **1**-$PPh_4$ indicated that the Co–N bonds of **1**-$PPh_4$ were significantly different from those of **1**-Na, although the Co–S bonds was almost the same as those of **1**-Na. This behavior is apparently influenced by the number of hydrogen bonds between water molecules and the amidate carbonyl oxygen atoms. The two carbonyl oxygen atoms of **1**-$PPh_4$ are hydrogen-bonded with one water molecule each. However, each carbonyl oxygen of **1**-Na is coordinated to three water molecules of a water–sodium cluster. The C=O [1.250(4), 1.243(4)], $C_{amide}$–N [1.341(4), 1.348(4)], and Co–N [1.902(3), 1.896(3)] bond lengths of **1**-$PPh_4$ with one water molecule for one carbonyl oxygen demonstrated significant alternations of shorter, longer, and shorter lengths in comparison with those of **1**-Na, C=O [1.263(4), 1,257(4)], $C_{amide}$–N [1.330(4), 1.332(3)], and Co–N [1.919(3), 1.918(3)], with three hydrogen bonds for each carbonyl oxygen. This alternation in bond lengths provides evidence for the fact that the amidate carbonyl oxygen is affected by the interaction of the secondary sphere.

An octahedral $Co^{III}$ complex, $PPh_4[Co^{III}(\mathbf{L}:N_2S_2)(t\text{BuNC})_2]$ (**2**), where two of the axial positions of **1** are occupied by *tert*-butylisocyanide (*t*BuNC) molecules, was also isolated from an ethanol solution that contained a large amount of *t*BuNC as a red-colored single-crystal suitable for X-ray analysis. Crystal data is listed in Table 2 and the ORTEP view of the anion moiety of **2** is shown in Figure 3. Four $[Co^{III}(\mathbf{L}:N_2S_2)(t\text{BuNC})_2]^-$ anions and four

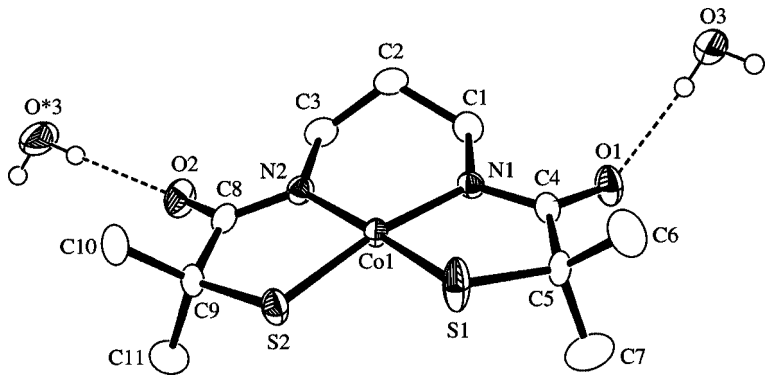

Figure 2. An ORTEP view of $[Co(\mathbf{L{:}N_2S_2})]^-$ anion part of complex **1** with solvated water molecules, which shows 50% probability ellipsoids. H atoms are omitted for clarity except for those of the water molecules.

$PPh_4^+$ cations are included in a unit cell. Selected bond lengths and angles are listed in Table 1. The *tert*-butyl group of the axial ligands and the propylene group of the equatorial ligand are disordered. The octahedral coordination formed by the axial binding of *t*BuNC ligands to **1** induces longer $Co–N_{amide}$ and Co–S bonds in comparison with those of **1**, although the average bond lengths of Co–S [2.2491(8) Å] and $Co–N_{amide}$ [1.973(2) Å] are within the range of those of the previously reported octahedral $Co^{III}$ complexes with thiols and/or amides (Co–S = 2.22–2.27 Å, Co–N = 1.91–2.00 Å).[18a,19a,19b,19d] The detailed examination of the bond lengths around the Co center indicate that the Co–N and Co–S bonds are clearly elongated in comparison with those of complexes **1**-$PPh_4$ and **1**-Na, which is explained by the coordination of the *t*BuNC molecules.

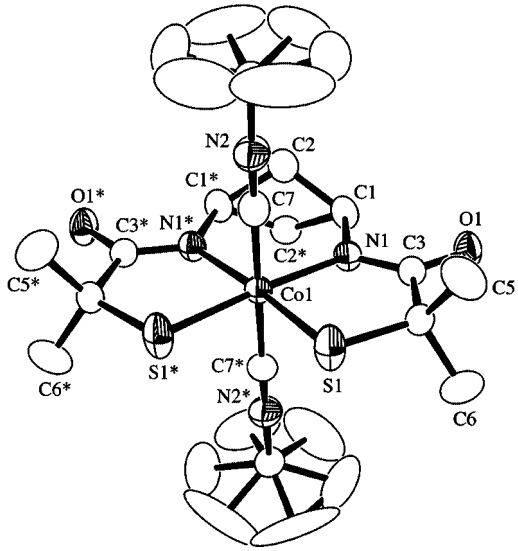

Figure 3. An ORTEP view of $[Co(\mathbf{L{:}N_2S_2})(t\text{BuNC})_2]^-$ anion part of complex **2**, which shows 50% probability ellipsoids.

Furthermore, treatment of complex **2** with 30% $H_2O_2$ according to a previously-reported procedure[19b] with some modifications successfully afforded the corresponding complex, $PPh_4[Co\{\mathbf{L{:}N_2(SO_2)_2}\}(t\text{BuNC})_2]$ (**3**), of which the two thiolate groups were oxygenated to sulfinates. The crystal data of a single crystal obtained from an EtOH/ether solution is listed in Table 2, and the molecular structure revealed the formation of complex **3**, as depicted in Figure 4. Selected bond lengths and angles are listed in Table 1. The bond lengths around the metal center [Co1–N1 = 1.996(2), Co1–N2 = 1.986(3), Co1–S1 = 2.1830(7), Co1–S2 = 2.1723(7) Å] lay within the range of those of the previously reported $Co^{III}$ complexes with amide and sulfinate groups (Co–N = 1.94–2.00 Å, Co–S = 2.21–2.23 Å).[18a,19b] The Co–N and Co–S bond lengths of **3** are longer than those of **1**-$PPh_4$ and **1**-Na, which is reasonably explained by the coordination of the *t*BuNC molecules. The oxygenation of sulfur in complexes **2** and **3** induced the lengthening of the Co–N bonds and the shortening of the Co–S bonds, although it did not influence the Co–C(*t*BuNC) bond lengths. The carbonyl oxygen atoms of the ligand $\mathbf{L{:}N_2(SO_2)_2}$ were also significantly coordinated to an ethanol molecule. Such a hydrogen bond was not found around the sulfinate oxygen atoms.

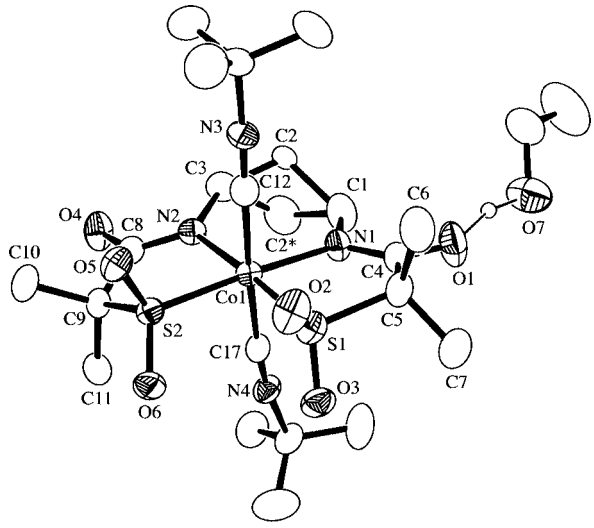

Figure 4. An ORTEP view of $[Co\{\mathbf{L{:}N_2(SO_2)_2}\}(t\text{BuNC})_2]^-$ anion part of complex **3**, which shows 50% probability ellipsoids. H atoms are omitted for clarity.

### Coordination Equilibrium of *t*BuNC to 1 in Solution

The electronic absorption spectrum of complex **1** showed a ligand-to-metal charge transfer (LMCT) band around 600 nm ($\varepsilon$ = 3800 $M^{-1}cm^{-1}$), which is characteristic of a square planar $Co^{III}$ complex with sulfur atoms.[18c,19c] The coordination behavior of the monodentate ligands at the axial positions of **1** was studied with anionic ligands, such as sodium phenolate, sodium thiophenolate, tetraethylammonium thiocyanate ($Et_4NSCN$), and tetraphenylphosphonium cyanide ($PPh_4CN$), and with neutral ligands, such as water, 4-phenylpyridine, and *tert*-butylisocyanide (*t*BuNC). Significant spectral changes were observed only when $PPh_4CN$ or *t*BuNC was added to a solution of **1** at ambient temperature. For $PPh_4CN$ and *t*BuNC, the absorption spectra had a change in the isosbestic point at 301 nm and 317 nm in EtOH, respectively (Figure S3). It is clear that both the monodentate ligands coordinate at the axial sites of **1**. In the case of *t*BuNC, such a spectral change in the isosbestic point of the LMCT band was also observed in other solvents, which indicates that the $Co^{III}$ complex reacted with *t*BuNC to form octahedral complex **2**.[18a,19c] Formation of the octahedral complex was also supported by the fact that the finally obtained spectrum was in good agreement with that of **2**. The axial coordination of *t*BuNC in complex **2** is also clear from the fact that complexes **1** and **2** show a paramagnetism and a diamagnetism, respectively, in their $^1H$ NMR spectra (Figure S4). It should be noted that the octahedral coordination of **2** was maintained without any release of the axial ligands in an aqueous solution, although the coordination of the ligands was not conserved in organic solvents (Figure S5). Therefore, we can conclude that the octahedral structure of complex **2** is maintained in water, which is comparable to the effect of the oxygenation of the sulfur atoms.

For the complete formation of octahedral species in acetone, the addition of a 1000-fold excess of *t*BuNC in methanol was required. The electrostatic effect on the metal center that is caused by the interaction between the coordinated amide groups and the solvent is best understood through the examination of the equilibrium experiment with complex **1** for the following reasons: (1) the sulfur atoms of the tetradentate ligand are not easily air-oxidized in the preparation of complex **1**; therefore, direct interactions of the oxygenated sulfinate oxygen atoms with the solvent molecules of the secondary coordination sphere can be eliminated, (2) the solvation of the neutral monodentate ligand *t*BuNC that is coordinated to the complex can be excluded, (3) the axial coordination of the ligands to the square-planar complex induces a higher lability of the complex. Therefore, we investigated the effect of solvents on the equilibrium constant ($K_s$) [Equation (1)].

$$[Co^{III}(\mathbf{L}{:}\mathbf{N_2S_2})]^- + 2\ t\text{BuNC} \overset{K}{\rightleftharpoons} [Co^{III}(\mathbf{L}{:}\mathbf{N_2S_2})(t\text{BuNC})_2]^- \quad (1)$$

With the use of the intensity change in the LMCT band (700 nm), the equilibrium constants for the reaction have been estimated. Equation (2) was derived on the basis of Equation (1) with material balances taken into account.

$$\log\{(A_0-A)/A\} = 2\log[C_{Bu}-\{2(A_0-A)/A_0\}C_{CoL}] + \log K_s \quad (2)$$

Here, $A_0$ and $A$ represent the absorption intensities of the $[Co^{III}(\mathbf{L}{:}\mathbf{N_2S_2})]^-$ solution and that of the mixed solution of $[Co^{III}(\mathbf{L}{:}\mathbf{N_2S_2})]^-$ and $[Co^{III}(\mathbf{L}{:}\mathbf{N_2S_2})(t\text{BuNC})_2]^-$, respectively. $C_{Bu}$ and $C_{CoL}$ are the total concentrations of *t*BuNC and the $[Co^{III}(\mathbf{L}{:}\mathbf{N_2S_2})]^-$ solutions, respectively. The relationship between the absorbance term of the complex versus the concentration term of added *t*BuNC was plotted according to Equation (1) and showed a linear relationship with a slope of 2, within experimental error. This indicates that two *t*BuNC molecules are coordinated to the $Co^{III}$ complex in all of the solvents. This result was also confirmed from the similarity in the absorption spectrum of **2** as described above. The equilibrium constant, $K_s$, clearly showed the solvent dependence (Table S1); they gradually decreased as follows: $H_2O$/MeOH (3:7) > $H_2O$/MeOH (1:9) > methanol > ethanol > 2-PrOH > dichloromethane > acetone. The constant, $K_s$, demonstrated a linear relationship only for the acceptor number (AN)[25–28] of solvents which is an index of electrophilicity[28,29] [Figure 5 (■)]. $K_s$ did not show this relationship for any other physical parameters such as a donor number[29,30] or a dielectric constant. This result indicates that an interaction of the electrophilic solvent with **1** makes the axial coordination of *t*BuNC easier.

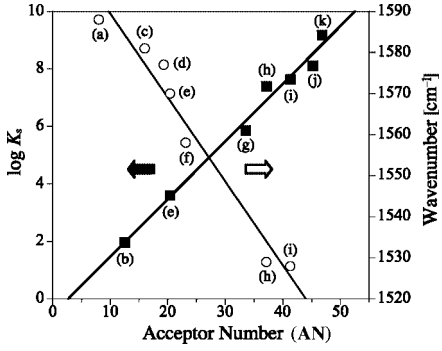

Figure 5. Plots of log$K_s$ values (■) and C=O stretching vibration values (○) for complex **1** versus ANs of organic solvents. (a) THF; (b) acetone; (c) DMF; (d) MeCN; (e) $CH_2Cl_2$; (f) $CHCl_3$; (g) 2-propanol; (h) EtOH; (i) MeOH; (j) $H_2O$/MeOH [1:9 (v/v)]; (k) $H_2O$/MeOH [3:7 (v/v)].

### Infrared Spectra of 1 and 3 in Organic Solvents

As described above, the coordination of *t*BuNC at the axial sites of **1** depends on the electrophilic solvents, whose solvent dependence should be considered to be caused by the interaction of complex **1** with the solvent molecules. The electron-rich carbonyl oxygen atoms of the ligand **L** can also interact with the electrophilic solvent. Therefore, IR spectra were obtained for **1** and **3** in order to identify the interaction site of the complexes with the solvent molecules.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The IR spectra of sample solutions without the $Co^{III}$ complex were measured as a base line. A difference spectrum between the solution of **1** and the base line was then adopted. Interestingly, the frequencies assigned to the stretching vibration of C=O are dependent on the solvents within the range of 1520–1590 $cm^{-1}$ as listed in Table S2. The C=O stretching vibrations are linearly dependent on the ANs as shown in Figure 5 (○), which suggests that the axial coordination is predominantly controlled by the interaction of the solvent molecules with the carbonyl oxygen atoms.

The solvent-dependent shift of the C=O stretching frequency was also observed for **3**, and the C=O stretching vibration for **3** (Table S3) showed a similar shift to that of **1**, as shown in Figure 6 (■). However, in the same solvents the absorption bands in **3** appeared in a higher energy region compared with those of **1**. An increase in the C=O bond strength of **3** compared with that of **1** induced a decrease in the Co–N bond strength, which may be explained in terms of the coordination saturation and strong *trans* influence of $SO_2$.[15c] On the other hand, remarkably, the stretching frequency of the S=O group, which is considered as another possible interaction site for the solvents, did not show any significant shift [Figure 6 (○), Table S4]. The vibration responsible for N≡C in **3** is also linearly dependent on the ANs of the solvents (Figure S6, Table S5). The linear relationship indicates that the interaction of the carbonyl oxygen atoms with the solvent molecules causes a change in the N≡C vibration, while the sulfinate oxygen did not show any interaction with the solvents as described above. The N≡C vibration showed a significantly higher energy shift with an increase in AN, which is similar to the case of the oxidized sulfur atoms.[18a] This result suggests that the attractive interaction of the carbonyl oxygen atoms with the solvent molecules causes an increase in the Lewis acidity of the $Co^{III}$ center.

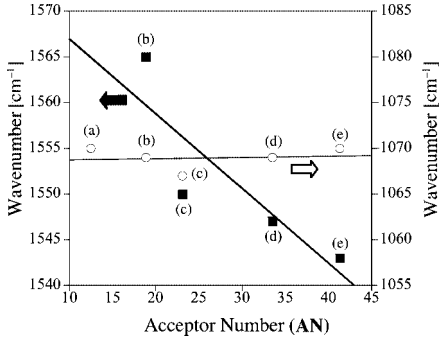

Figure 6. Plots of C=O (■) and S=O stretching vibration values (○) for complex **3** versus ANs of organic solvents. (a) Acetone; (b) MeCN; (c) $CHCl_3$; (d) 2-PrOH; (e) MeOH.

## Redox Behaviors of 1, 2 and 3 in Organic Solvents

The solvent dependence of the C=O stretching vibrations that appeared for complexes **1** and **3** must also influence the acidity of the metal center, so the electrochemical properties of the complexes was investigated with the use of cyclic voltammetry with an $Ag/Ag^+$ reference electrode. The voltammogram of **1** exhibited only one quasi reversible redox wave assignable to $Co^{III}/Co^{II}$ with $\Delta E \approx 100$ mV and $i_p/i_c \approx 1.0$ within the experimental potential range (–1.7 V to –1.1 V). The electrochemical parameters are listed in Table S5, in which the redox potentials have been standardized to the $Fc/Fc^+$ potential. The redox potential is high enough to maintain the Co center in the 3+ oxidation state and is consistent with those of previously reported $N_2S_2$-type Co complexes that contain two amidate nitrogen atoms and two sulfur atoms as coordinating atoms.[31–33] The redox potential in methanol is clearly much higher than that in acetone, which is in agreement with the tendencies for the equilibrium constant $K_s$ and the C=O stretching vibrations. The solvent dependence of the results led us to expect that the Lewis acidity of the $Co^{III}$ center could effectively be controlled by the interaction of **1** with the solvent molecules. The redox potential value ($E_{1/2}$) assignable to $Co^{III}/Co^{II}$ of **1**, as expected, exhibited a solvent dependency with a linear relation to the AN values of the solvents; that is, –1.12 V versus $Fc/Fc^+$ in MeOH (AN = 41.3) and –1.73 V in THF (AN = 8.0), respectively (Figure 7, Table S6). The redox potential values showed a significantly larger positive shift with an increase in AN, which suggests that the attractive interaction of the carbonyl oxygen atoms with the solvent molecules causes an increase in the Lewis acidity of the $Co^{III}$ center and promotes the axial coordination of a monodentate ligand. On the basis of such a linear relation, the ideal redox potential values of **1** in an aqueous solution (AN = 54.8) and in a noninteracting solvent (AN = 0) were estimated to be –0.93 and –1.89 V, respectively, which implies that the interaction of the amidate carbonyl group with the water molecules causes a shift in the redox potential for the $Co^{III}$ complex by ca. 1 V in comparison with that of a noninteracting solvent.

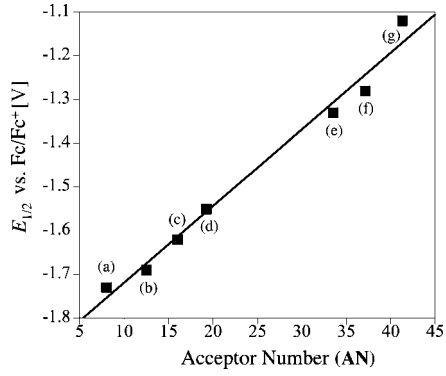

Figure 7. Plots of $E_{1/2}$ for complex **1** versus ANs of organic solvents. (a) THF; (b) acetone; (c) DMF; (d) MeCN; (e) 2-PrOH; (f) EtOH; (g) MeOH.

Furthermore, the reduction potential of complex **3** in MeOH was observed at –1.27 V and that of **2** in the presence of a large amount of *t*BuNC in a MeOH solution was detected at –2.18 V, which indicates that the oxygenation of the sulfur atoms raises the reduction potential of the $Co^{III}$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complex by ca. 0.9 V. The octahedral structure of complex **2** that is maintained in water is comparable to the effect of the oxygenation of the sulfur atoms. These findings indicate that the attractive interaction between the carbonyl oxygen atoms and the water molecules can control the Lewis acidity of the metal ion as well as the effect of the oxygenation of the sulfur atoms. Consequently, complex **2**, as described above, can maintain the octahedral structure in an aqueous solution (AN = 54.8) without the release of the axial ligands.

### Biological Implications

In the crystal structures of both the Co- and Fe-containing NHases,[9–12] the sulfenate and the sulfinate oxygen atoms interact with the arginine residue through hydrogen bonds as described above, and the amidate carbonyl oxygen atoms are coordinated to water molecules. Moreover, the water molecules form a hydrogen bonded network with other water molecules that starts from the tyrosyl oxygen (βTyr68 in $Co^{III}$-type NHases, Figure 8). It has recently been reported by Miyanaga et al. that the mutant of $Co^{III}$-type NHase, βY68F, where the hydrogen bonded network is destroyed by the replacement of tyrosine by phenylalanine, does not show significant hydratase function.[22] Miyanaga et al. have explained it on the basis of the crystal structures as follows: βTyr68 contributes to the capture of a substrate or an imidate intermediate through the hydrogen bonds.[22] With the consideration of this report[22] and our results, we can propose that a higher Lewis acidity of the central metal ion is required for the axial coordination of the ligands, which is important for the enzymatic reaction, and may finely be regulated by the hydrogen bonded network from tyrosine to the amidate oxygen atoms through water molecules. From the fact that the S=O group did not show an electrophilic interaction,[28,29] we can conclude that the sulfinate oxygen atoms do not contribute to the control of the Lewis acidity of the central metal. If the Lewis acidity of the central metal can be sensitively controlled by these hydrogen bonding interactions, the reaction will rapidly proceed and the reaction product will also be rapidly released from the central metal ion. In the crystal structures of **1**-$PPh_4$, **1**-Na, and **3** the carbonyl oxygen atoms of the ligands **L** and **L:$N_2(SO_2)_2$** are coordinated to water and ethanol molecules, respectively. Furthermore, as shown in the crystal structure of complex **1**-Na, three hydrogen bond interactions with three water molecules for each carbonyl oxygen influenced the Co–*N*–C–O bonding system. However, such an interaction was not found in the sulfinyl oxygen atoms of **3**, which may suggest that the sulfinyl oxygen groups do not significantly interact with the solvent molecules.

In conclusion, this paper describes that the hydration reaction in NHase is significantly controlled by the amidate groups as well as the oxygenated sulfur groups.

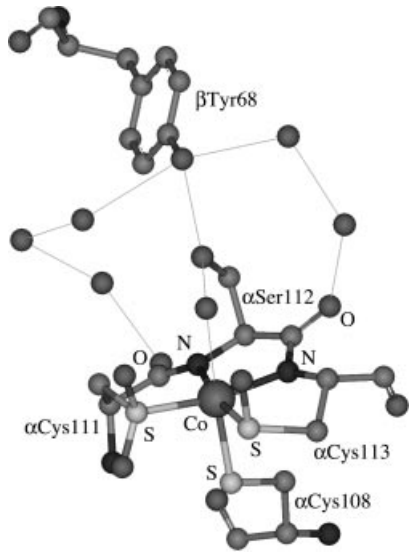

Figure 8. Hydrogen bonding networks near the active site of NHase: hydroxy oxygen of βTyr68 hydrogen-bonded to amide carbonyl oxygen atoms by water molecules.

## Experimental Section

**Reagents and Technique:** All manipulations were performed with Schlenk technique under an Ar atmosphere or in a glove box. Reagents in this study were purchased in reagent grade from Wako Pure Chemical Industries Ltd. or Tokyo Kasei Kogyo Co. Ltd. and used without further purification. Solvents in reagent grade were purchased from Wako Pure Chemical Industries Ltd. and Kanto Kagaku Co. Inc. and distilled twice prior to use.

**Synthesis of $H_4$L:** 2-benzylthio-2-methylpropionic acid chloride was synthesized as described previously.[34] The acid chloride (12.77 g, 50.00 mmol) was added dropwise to a THF solution containing 1,3-diaminopropane (1.85 g, 25.00 mmol) and triethylamine (5.06 g, 50.00 mmol). After filtration, a 1 M HCl aqueous solution was added to the filtrate and evaporated. Addition of diethyl ether to the concentrated solution afforded a white powder which was identified as an *S*-benzylated **L** by $^1$H NMR spectroscopy, whose powder (2.00 g, 4.36 mmol) was dissolved in THF (20 mL) and treated with liquid ammonia at –78 °C. To this solution was added sodium (1.91 g, 82.95 mmol), which was stirred vigorously for 30 min. After the excess ammonia was removed by evaporation at room temperature, the solution was adjusted to pH 3 with 1 M $KHSO_4$. The product was extracted with ethyl acetate and the solvent evaporated. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 1.63 (s, 12 H), 1.70 (m, 2 H), 2.29 (s, 2 H), 3.28 (q, 4 H), 7.83 (s, 2 H) ppm.

**Preparation of Na[Co(L:$N_2S_2$)] (1-Na) and $PPh_4$[Co(L:$N_2S_2$)] (1-$PPh_4$):** Na[Co(**L**:$N_2S_2$)] (**1**-Na) was prepared according to the literature with some modifications.[18,19] Recrystallization of the compound from acetonitrile/diethyl ether afforded a single crystal in atmosphere. Addition of $PPh_4Cl$ (269.4 mg, 0.72 mmol) to an aqueous solution (20 mL) of the sodium salt (256.3 mg, 0.72 mmol) afforded a single crystal of $PPh_4$[Co(**L**:$N_2S_2$)] (**1**-$PPh_4$). $C_{35}H_{40}CoN_2O_3PS_2$ (690.74): calcd. C 60.86, H 5.84, N 4.06; found C 60.93, H 5.77, N 4.03. Electronic absorption spectra ($CHCl_3$): $\lambda_{max}$ [$\varepsilon$ ($M^{-1}$ $cm^{-1}$)] = 312 (7300), 443 (sh), 640 (2600) nm.

**Preparation of $PPh_4$[Co(L:$N_2S_2$)(*t*BuNC)$_2$] (2):** Monodentate ligand, *t*BuNC, (200 μL, 1.76 mmol) was added to an acetonitrile solution (150 μL) containing $PPh_4$[Co(**L**:$N_2S_2$)] (3 mg,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$0.43 \cdot 10^{-2}$ mmol). A red crystal was isolated by the slow diffusion of diethyl ether into the solution at 0 °C. $C_{45}H_{56}CoN_4O_2PS_2$ (838.99): calcd. C 64.42, H 6.73, N 6.68; found C 64.14, H 6.60, N 6.47. Selected IR bands (KBr): $\tilde{\nu}$ = 2176 (s, CN), 1535 (s, CO) $cm^{-1}$. $^1H$ NMR (300 MHz,$D_2O$): $\delta$ = 1.36 (s, 12 H, $CH_3$), 1.49 (s, 18 H, *t*Bu), 1.75 (t, 2 H, $CH_2$), 3.79 (t, 4 H, $CH_2$), 7.72 (m, 20 H, Ph) ppm. Electronic absorption spectra ($H_2O$): $\lambda_{max}$ [$\varepsilon$ ($M^{-1}cm^{-1}$)] = 294 (12800), 360 (sh) nm.

**Preparation of $PPh_4$[Co{L:$N_2(SO_2)_2$}(*t*BuNC)$_2$] (3):** To an ethanol solution (1 mL) containing $PPh_4$[Co(**L:$N_2S_2$**)] (83 mg, 0.12 mmol) was added *t*BuNC (191 μL, 1.44 mmol). After the solution was stirred for 10 min, 30% $H_2O_2$ (0.62 mL, 5.45 mmol) was added dropwise to the ethanol solution at –10 °C. The solution was left to stand for 3 h at –10 °C. A crude compound was obtained by the addition of diethyl ether into the solution. Recrystallization of the compound from ethanol/diethyl ether afforded a single crystal suitable for X-ray analysis. $C_{47}H_{64}CoN_4O_8PS_2$ (967.07): calcd. C 58.37, H 6.67, N 5.79; found C 58.14, H 6.50, N 6.00. Selected IR bands (KBr) : $\tilde{\nu}$ = 2199 (s, CN), 1552 (s, CO), 1214 and 1071 (s, SO) $cm^{-1}$. $^1H$ NMR (300 MHz, [$D_6$]DMSO): 1.15 (s, 12 H, $CH_3$), 1.34 (s, 18 H, *t*Bu), 3.16 (t, 6 H, $CH_2$), 7.83 (m, 20 H, Ph) ppm. Electronic absorption spectrum (EtOH): $\lambda_{max}$ [$\varepsilon$ ($M^{-1}cm^{-1}$)] = 273 (9700), 313 (21400), 400 (sh) nm. ESI-MS ([$Co^{III}$(**L:$N_2(SO_2)_2$**)(*t*BuNC)$_2$]$^-$): *m*/*z* (%) = 563.

**X-ray Structural Analysis:** Crystals suitable for X-ray diffraction measurements were mounted on glass fibers. The diffraction data were collected with a Rigaku Mercury diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation at –100 °C with the oscillation technique. Crystal data and experimental details are listed in Table 2. All structures were solved by a combination of direct methods and Fourier techniques. Non-hydrogen atoms were anisotropically refined by full-matrix least-squares calculations. Hydrogen atoms were included but not refined. Refinements were continued until all shifts were smaller than one-tenth of the standard deviations of the parameters involved. Atomic scattering factors and anomalous dispersion terms were taken from the International Tables for X-ray Crystallography.[35] All calculations were carried out with a Japan SGI workstation computer with the teXsan crystallographic software package.[36] CCDC-606977, CCDC-252730, CCDC-606976, and CCDC-281586 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

### Other Physical Measurements

Elemental analysis was performed with a Perkin–Elmer 2400II CHNS/O full-automatic analyzer. All mass spectra were acquired with a LCT mass spectrometer equipped with an ionspray interface (Micromass Limited, Manchester, UK). Instrument settings, data acquisition, and data processing were controlled by a computer with Windows NT operating system. Samples were introduced with a single syringe pump (KD scientific Inc., USA) fitted with Hamilton syringes (Hamilton Co, Reno, NE). The samples for all spectral measurements were prepared in MeCN or MeOH. $^1H$ NMR spectra were recorded with a Varian Gemini-300 FT-NMR instrument. Electronic absorption spectra were measured with a JASCO V-550 or V-570 spectrophotometer in the wavelength range of 900 – 250 nm. A match paired quartz cell was used with a 10 mm length. Infrared spectral measurements were carried out with a JASCO FT/IR 410 spectrophotometer. Solid samples were prepared with a pressure greater than 5 tons in KBr powder. Spectra in solution were measured with the use of a double-piled $CaF_2$ or KBr cell with 0.1 mm thick walls for the C=O and S=O stretching frequencies of the sulfinates. Differential spectra between the sample and the corresponding solvent were used to verify the spectral features. Electrochemical measurements were performed with a BAS BIOANALYTICAL Systems model CV-50W or with a ALS/CH Instruments Electrochemical Analyzer Model 600A. Pt electrodes were adopted as the working- and counter-electrode and an Ag/$Ag^+$ electrode was used as a reference. Cyclic voltammograms were collected in a glove box under an Ar atmosphere. The potential values were revised on the $Fc/Fc^+$ standard.

### Determination of Equilibrium Constants

Equilibrium constants were spectrophotometrically determined by means of spectral changes of **1** upon the addition of a suitable

Table 2. Crystallographic data and experimental details for Na[Co(**L:$N_2S_2$**)] (**1**-Na), $PPh_4$[Co(**L:$N_2S_2$**)] (**1**-$PPh_4$), $PPh_4$[Co(**L:$N_2S_2$**)(*t*BuNC)$_2$] (**2**) and $PPh_4$[Co{**L:$N_2(SO_2)_2$**}(*t*BuNC)$_2$] (**3**).

# Synthesis, Characterisation and Properties of *As*-Monohalogenated Dibenzoarsocines $S(C_6H_4S)_2AsHal$ (Hal = Cl, Br, I) – A Study of the Transannular Interaction S→As

**Simplicio González-Montiel,[a] Noemí Andrade-López,[a] and José G. Alvarado-Rodríguez*[a]**

**Keywords:** Arsenic complexes / Main group elements / Hypervalent compounds / Structure elucidation

Addition of $AsCl_3$ to $S(C_6H_4SH)_2$ in benzene solution leads to the formation of the stable compound $S(C_6H_4S)_2AsCl$ (**1**). The $S(C_6H_4S)_2AsHal$ [Hal = Br (**2**), I (**3**)] compounds have been synthesised by halogen exchange from **1** and the corresponding potassium halide. X-ray structure determinations of complexes **1**–**3** reveal that the arsenic atom acts as an acceptor atom exhibiting an intramolecular transannular interaction with the thioether-like sulfur atom. The geometry of the tetracoordinate As atom in the title compounds is described as distorted pseudo-trigonal-bipyramidal with a stereochemically active lone pair and 66–63 % trigonal-bipyramidal character. The transannular interaction influences the conformation of the dibenzotrithiarsocine system, adopting the central eight-membered ring with a boat–boat conformation and $C_s$ symmetry.

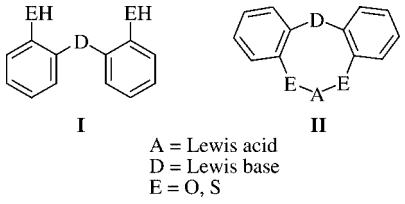
## Introduction

We have been interested in the coordination chemistry of dithio ligands that can increase the coordination number around an acidic Lewis atom A, where A is a heavy p-block element. Some of these ligands, in particular $D(CH_2CH_2S)_2^{2-}$ with the donor atom D = O, S and NR, are quite flexible and led to the atom A expanding its coordination number through an *intramolecular transannular* interaction D→A. In these metallocanes, the conformational diversity is very large.[1] In addition, in these compounds the interaction is a stabilising factor in comparison with the cyclooctane ring and can be envisaged as a tool for controlling stabilities and conformations. The strength of this interaction spans over a wide range. In some cases it is very strong; for example in arsocanes the cross-ring bond has been claimed as being responsible for the stabilisation of discrete arsenium cations.[2] On the other hand, the more constrained ligands of type **I** (Scheme 1) have been explored for several groups in the coordination chemistry of transitional metals as well as light p-block elements; in these type **II** complexes the transannular interaction can also take place.[3] In particular, we have studied some *Sb*-monohalogenated dibenzometallocines and we have shown by means of X-ray crystallographic and DFT studies the acidic behaviour of the antimony atom acting as a Lewis acceptor toward sulfur in the decreasing order I > Br > Cl. These results prompt us to expand our studies to arsenic, a lighter group 15 element.



Scheme 1.

Here we report the synthesis and structural study of type **II** complexes with arsenic(III) as the acceptor atom. These compounds are good models for further understanding of the nature of the S→As interaction. After the description of the synthesis of dibenzoarsocines, IR and Raman spectra, mass spectra, NMR and X-ray crystallographic data are presented and discussed.

## Results and Discussion

### Synthesis of $S(C_6H_4S)_2AsHal$ (Hal = Cl, Br, I)

The ligand $S(C_6H_4SH)_2$ was prepared according to a reported method.[4] Treatment of $S(C_6H_4SH)_2$ with $AsCl_3$ in benzene yielded $S(C_6H_4S)_2AsCl$ (**1**) as colourless crystals (see Scheme 2). $S(C_6H_4S)_2AsBr$ (**2**) and $S(C_6H_4S)_2AsI$ (**3**) were obtained from a halogen-exchange reaction as reported for antimony complexes[3] between **1** and an excess of KBr/HBr or KI in hot benzene, respectively, yielding colourless crystals for **2** and pale yellow crystals for **3** (see

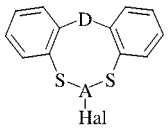
Scheme 2.

## Vibrational Spectra

The Raman spectrum of each compound in the solid state was obtained for light scattered from the 1579.8 nm line of an argon ion laser. Under these conditions, compounds **1** and **2** experienced photodecomposition by the laser. The IR spectrum of each solid compound pressed on a CsI disk was collected in the 4000–200 $cm^{-1}$ range. The Raman spectrum of the iodo complex is shown in Figure 1.

Besides the expected benzene group bands, there are several bands below 400 $cm^{-1}$. In the 400–300 $cm^{-1}$ region we found two very intense bands assignable to the asymmetric and symmetric stretching vibration modes of the S–As–S group. In order to confirm the assignment of these bands, we compared these data with those exhibited by the antimony analogue complexes previously reported (see Scheme 3). The data are listed in Table 1. In the case of the arsenic complexes, the $\nu_{asym} - \nu_{sym}$ difference ($\Delta$) is $59 \pm 3$ $cm^{-1}$, whereas in antimony complexes with sulfur as the donor atom, $\Delta$ is $46 \pm 4$ $cm^{-1}$.



A = As, Sb

Scheme 3.

In the IR spectra of complexes **1** and **2** we assigned the 392 and 280 $cm^{-1}$ bands to the As–Cl and As–Br stretching bands, respectively.[5] In order to establish the presence of the As–I group frequency band, we used the Varshni ap-

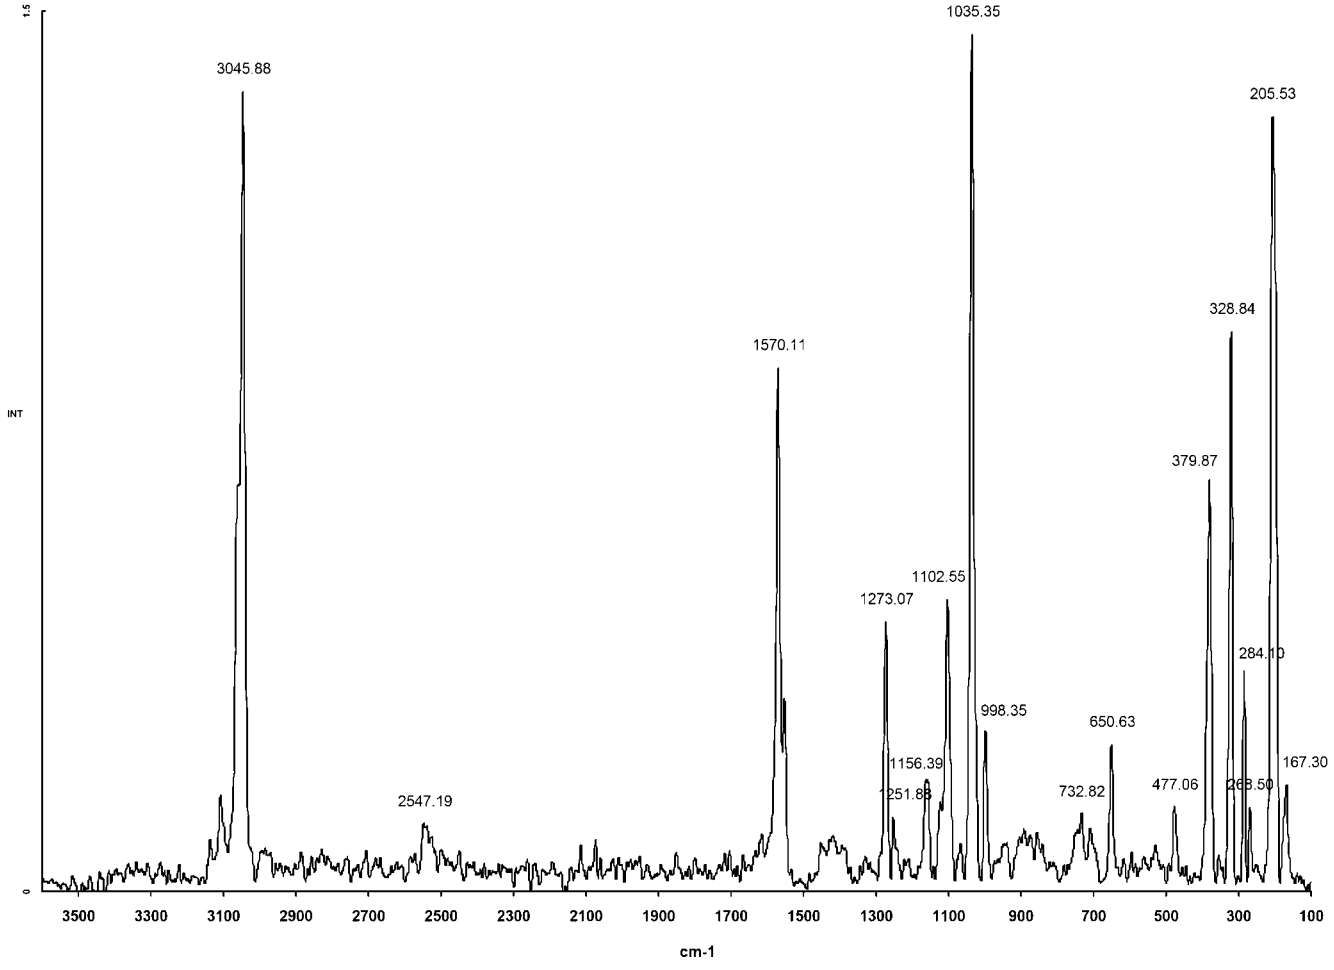


Figure 1. Raman spectra of $S(C_6H_4S)_2AsI$ (**3**).

| | | Raman | 370 | 311 | 59 |

[a] For the data of antimony complexes see ref.[3] [b] Not measured.

proach reported for a series of metallocanes containing As, Sb and Bi linked to halide ligands, in conjunction with the As–I bond length found in complex **3**.[6] By using this treatment, we calculated the stretching frequency at 172 $cm^{-1}$. However, we did not observe any significant band at this frequency. Therefore the intense band at 205 $cm^{-1}$ has been assigned to the As–I stretching frequency.[5] In this sense, Draeger et al. stated that the most intense bands in their series studied belong to the iodo complexes.[6] The vibrational data analysis has shown the usual tendency that the higher the mass of the halogen ligand, the lesser the frequency of the stretching As–Hal group band.

## Mass Spectra

The EI mass spectra were obtained at 70 eV. In **1** and **2** the molecular ion was observed as a low-intensity peak with the appropriate isotopic ratio; for **3** the molecular ion was not observed. In all cases the intense ion fragment in $m/z$ = 323 is assigned to the loss of the halogen atom in the compounds, yielding an $S(C_6H_4S)_2As$ tricyclic moiety, confirming the binding of arsenic to sulfur atoms and the stability of the dibenzotrithiarsocine system. In all the spectra there are peaks corresponding to the $S(C_6H_4S)_2$, $S(C_6H_4)S$ and $S(C_6H_4)_2$ fragments. No more peaks could be assigned.

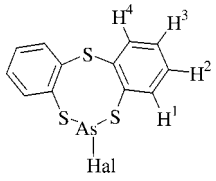
## NMR Spectroscopy

The NMR spectra of the three complexes were recorded in $CDCl_3$ solution at room temperature and the chemical shifts are relative to TMS. The assignments of these complexes were made by two-dimensional heteronuclear and homonuclear correlation experiments (coloc and hetcor).

$^1H$ NMR spectra of complexes **1**–**3** each displayed four signals in an ABCD pattern (see Table 2, Scheme 4). In these spectra the disappearance of the signal of the SH proton at $\delta$ = 4.10 ppm indicated that the arsenic complexes were formed. In solution the two $S(C_6H_4SAs)$ halves are equivalent. In all complexes the signals of the protons 2-H, 3-H and 4-H are shifted towards high frequencies with respect to those of the free neutral ligand.[4]

Table 2. $^1H$ NMR chemical shift ($\delta$ values [ppm]) for **1**–**3**.

| | Hal | 1-H | 2-H | 3-H | 4-H |
|---|---|---|---|---|---|
| **1** | Cl | 7.53 | 7.29 | 7.21 | 7.56 |
| **2** | Br | 7.53 | 7.29 | 7.21 | 7.54 |
| **3** | I | 7.48 | 7.28 | 7.21 | 7.52 |

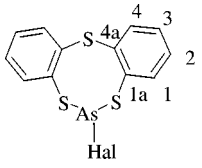


Scheme 4.

The $^{13}C$ NMR spectra of complexes **1**–**3** in $CDCl_3$ each show an important paramagnetic effect from the arsenic atom to the *ipso* carbon atom C-1a, causing chemical shift variations in the order of 8.6, 7.9 and 7.3 ppm at higher frequencies with respect to the free neutral ligand.[4] Similar shifts have been reported in dibenzostibocine analogues.[3] Another interesting feature was the observation of a small deshielding of the C-1a atom due to the increment of the electronegativity of the halogen ligand (see Table 3, Scheme 5).

Table 3. $^{13}C$ NMR chemical shift ($\delta$ values [ppm]) for **1**–**3**.

| | Hal | C-1 | C-1a | C-2 | C-3 | C-4 | C-4a |
|---|---|---|---|---|---|---|---|
| **1** | Cl | 134.7 | 143.6 | 130.0 | 127.7 | 130.9 | 131.7 |
| **2** | Br | 134.9 | 142.9 | 130.0 | 127.6 | 130.7 | 131.6 |
| **3** | I | 135.3 | 141.6 | 129.9 | 127.7 | 130.7 | 131.9 |



Scheme 5.

## X-ray Structures of Compounds 1–3

The structures in the crystalline solid state of all complexes were definitely determined by single-crystal X-ray diffraction analyses. The molecular structure drawings are depicted in Figure 2 and selected bond lengths, angles and torsion angles are given in Table 4. Compounds **1** and **3** crystallise with mirror symmetry in space groups $Pmn2_1$ and *Pnma*, respectively; the two $S(C_6H_4SAs)$ halves are related by a mirror plane containing the S2–As–Hal plane.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

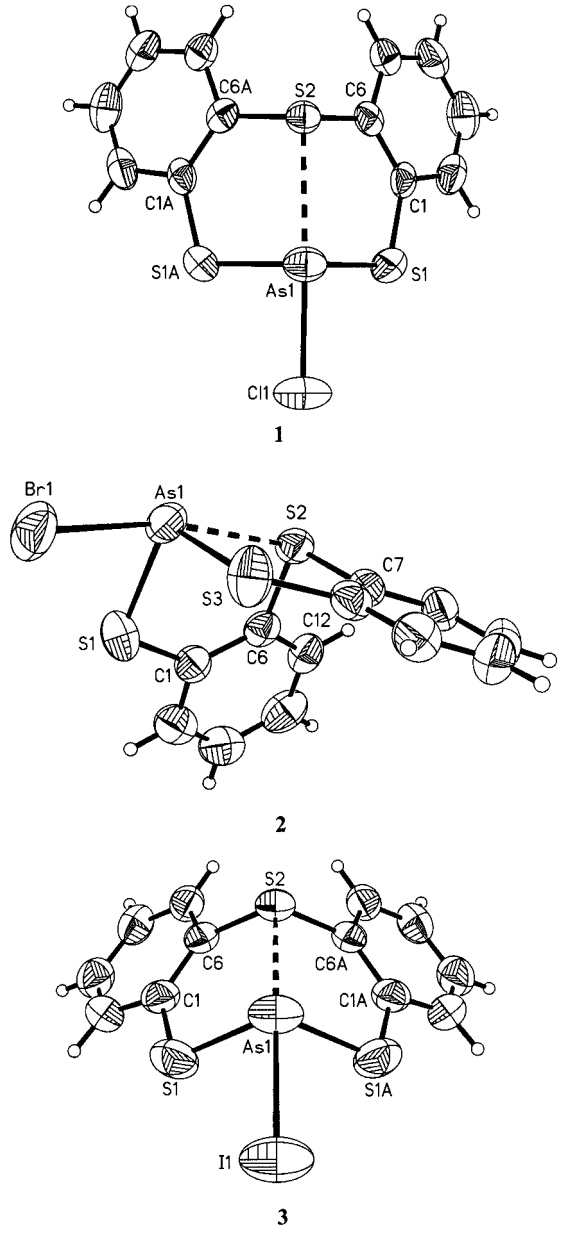


Figure 2. ORTEP diagrams of $S(C_6H_4S)_2AsCl$ (**1**), $S(C_6H_4S)_2AsBr$ (**2**) and $S(C_6H_4S)_2AsI$ (**3**) (50% probability ellipsoids).

In all complexes **1**, **2** and **3** the As–S distances are in good agreement with the covalent radii sum [$\Sigma r_{cov}$(As,S) = 2.22 Å][7] and with those reported in other heterocycles with arsenic–sulfur bonds.[8–19] The As–Hal distances (Hal = Cl, Br, I) are 5–7% longer than the corresponding covalent radii sum [($\Sigma r_{cov}$(As,Cl) = 2.19 Å; $\Sigma r_{cov}$(As,Br) = 2.34 Å; $\Sigma r_{cov}$(As,I) = 2.53 Å][5] and are similar to other distances in several heterocycles containing As–Hal bonds.[1,2,8,9,11,16,20,21] The angles around the arsenic atom can be divided in two sets. The larger angles are the endocyclic S–As–S ones, the largest found in the iodo complex [102.84(11), 103.22(9) and 104.30(7)° in **1**, **2** and **3**, respectively]. On the other hand, the angles involving the halogen atom are on average substantially smaller [87.00(8), 87.71(6) and 87.70(3)° in **1**, **2** and **3**, respectively]. At first glance, the local geometry of the tricoordinate arsenic atom could be described as pyramidal.

| C12–S3–As–S1 | – | 83.4(3) | – |

In addition to the covalent bonds of the arsenic atom, a transannular interaction S2→As1 within the eight-membered rings was observed (see Figure 2). The S2→As1 bond lengths in **1**, **2** and **3** are 2.705(3), 2.698(2) and 2.740(1) Å, respectively, which are 22, 21 and 24% longer than the covalent radii sum of As and S but significantly shorter than the van der Waals radii sum [$\Sigma r_{vdW}$(As,S) = 3.65 Å],[7] prompting us to propose the existence of a secondary bonding.[22] These S2→As1 distances in **1**, **2** and **3** are significantly longer than those reported for the two crystallographic different cations in $[S(CH_2CH_2S)_2As][GaCl_4]$[2] [2.347(10) and 2.391(9) Å] and are similar to those reported for $S(CH_2CH_2S)_2AsCl$[9] [2.719(3) Å], $S(CH_2CH_2S)_2AsBr$[1] [2.70 Å], $S(CH_2CH_2S)_2AsI$[1] [2.77 Å], $[AsCl_3(9)aneS_3]$[20] [2.715(3) Å], $[AsBr_3\{MeS(CH_2)_2SMe\}]$[20] [2.725(3) Å] and $[AsI_3\{MeS(CH_2)_2SMe\}]$[20] [2.697(2) Å] for neutral tetra- and hexacoordinate arsenic complexes, but significantly shorter than those reported for $[AsCl_3(14)aneS_4]$[20] [2.8709(9) and 2.9655(9) Å] $[AsBr_3\{MeS(CH_2)_2SMe\}]$[20] [2.876(3) Å], $[AsI_3\{MeS(CH_2)_2SMe\}]$[20] [2.792(2) Å], $[S(CH_2CH_2S)_2AsS_2CN(CH_2CH)_2]$[1] [3.170(2) and 3.113(2) Å], $S(CH_2CH_2S)_2AsS_2CNEt_2$[12] [3.172(2) Å], $S(CH_2CH_2S)_2AsS_2PPh_2$[10] [2.881(4) Å], $S(CH_2CH_2S)_2AsS_2P(OMe)_2$[11] [2.911(1) Å] and $S(CH_2CH_2S)_2AsS_2P[OCH(Me)]_2CH_2$[1] [2.942(11) Å]. In the title compounds it can be clearly seen that the transannular interaction (S2→As1) decreases in the order Br > Cl > I with the shortest distance in the bromo compound. A similar phenomenon has been observed in the arsocanes.[1]

If the transannular interaction S→As is taken into account, the geometry of the coordination sphere of the arsenic atom can be described as pseudo-trigonal-bipyramidal, where the halogen and thioether-like sulfur atoms are in

Table 5. Comparison of S→As–Hal geometrical bond parameters, bond lengths [Å], bond angles [°], and % TBP and BO in **1**–**3** complexes.

| | Hal | S→As | S→As–Hal | % TBP | $\Delta d$[a] | BO[b] S→As |
|---|---|---|---|---|---|---|
| **1** | Cl | 2.705(3) | 166.4(1) | 66.1 | 0.485 | 0.207 |
| **2** | Br | 2.698(2) | 168.36(6) | 66.6 | 0.478 | 0.212 |
| **3** | I | 2.740(1) | 166.96(3) | 63.7 | 0.520 | 0.185 |

[a] Bond widening, $\Delta d = (d_{exp} - \Sigma r_{cov})$ according to standard bond lengths $d$(As,S) = 2.22 Å.[7] [b] Mode of calculation BO = $10^{-(1.41 \cdot \Delta d)}$.[26–28]

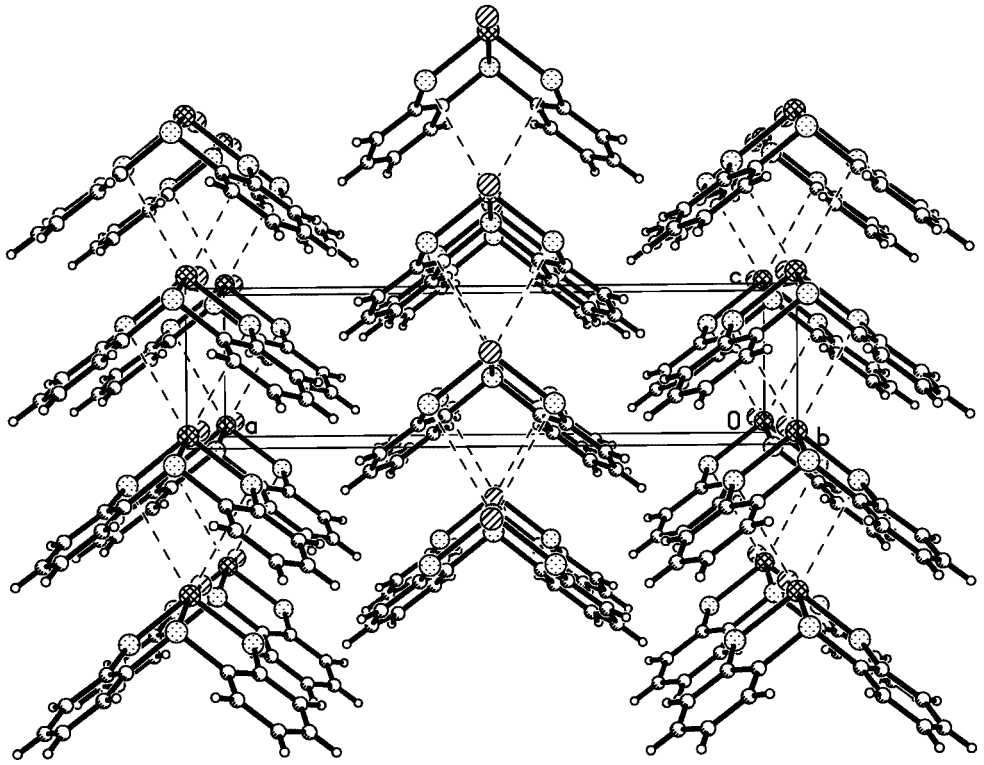

Figure 3. View of the As···S intermolecular interactions in the crystal structure of **1**.

axial positions; meanwhile the equatorial positions are occupied by the two thiolate-like sulfur atoms and the stereochemically active lone pair of the arsenic(III) atom.

The influence of the S→As interaction on the local geometry of the arsenic atom from pyramidal to trigonal-bipyramidal (TBP) can be evaluated. In this regard, we used the method of Holmes based upon donor–acceptor atom bond length.[23–25] Likewise, in order to establish the magnitude of the interaction, we calculated the Pauling-type bond order (BO) for all compounds.[26–28] The results are presented in Table 5. The displacement at geometry and bond order are related to bond lengths.

The percentages of TBP in the title compounds are slightly smaller than those reported for the antimony analogues, in spite of the smaller angles S→As–Hal to the ideal linear *trans* angle in comparison with the same S→Sb–Hal data. With regard to the BO, these values are relatively smaller than those observed for the trithiarsocanes $S(CH_2CH_2S)_2AsHal$ (Hal = Cl, Br, I) despite the apparent rigidity of the dibenzoarsocine system, and are also smaller than those calculated for the $S(C_6H_4S)_2SbHal$ analogues (0.308, 0.287 and 0.274 for Hal = I, Br and Cl, respectively).

The transannular interaction also influences the eight-membered ring conformation, which can be described as boat–boat ($C_s$ symmetry).[29] This conformation was also found in the iodo–antimony analogue with the shortest transannular interaction for that series and the arsenium cation $[S(CH_2CH_2S)_2As]^+$, which displays the largest BO in the series of arsocanes.

In the crystal the packing is mainly due to As···S intermolecular weak interactions, as is shown in Figure 3 for the chloro compound. These As···S distances are 3.602(2), 3.595(3)–3.662(3) and 3.711(2) Å for **1**, **2** and **3**, respectively; the increase in these distances can be ascribed to the increasing halogen atom sizes.

## Conclusions

In order to gain a better insight into the nature of the D→A interactions and their relation to the geometrical features in the dibenzometallocine systems containing heavier p-block elements, $S(C_6H_4S)_2AsHal$ compounds **1**–**3** have been synthesised and structurally fully characterised. All

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compounds exhibit a pseudo-bipyramidal-trigonal local geometry of the arsenic atom with intramolecular weak As···S interactions in the crystal structure.

The title compounds exhibit a relatively strong S→As transannular interaction, where the distances are 21–23% longer than the covalent radii sum. All compounds have shown relatively high TBP displacement values, with Pauling-type bond orders similar to the more flexible arsocane systems. However, these BO values are smaller than those calculated for the antimony analogues, suggesting a much poorer Lewis acidity of $As^{III}$ in comparison to the heavier antimony atom.

## Experimental Section

**General Methods:** Unless noted otherwise, all reactions and operations were carried out under argon at room temperature with use of standard Schlenk techniques. Solvents were dried and distilled before use. Melting points were determined with a Melt-Temp II instrument and are uncorrected. Spectra were recorded with the following instruments. Mass spectra: EI, 70 eV, Hewlett Packard MS-598 mass spectrometer. Elemental analysis: Perkin–Elmer Series II CHNS/O Analyzer. IR spectra: 4000–400 $cm^{-1}$ range, Perkin–Elmer System 2000 FTIR spectrometer, as KBr pellets and 400–200 $cm^{-1}$ range, Bruker Tensor 27 spectrometer, as CsI pellets. Raman spectra: In the solid state, 4000–100 $cm^{-1}$ range, Perkin–Elmer Spectrum GX NIR FT-RAMAN spectrometer with 10–280 mW laser power and 4 $cm^{-1}$ resolution. NMR: Jeol Eclipse 400 spectrometer, residual protio-solvent signal used as reference for $^1H$ NMR spectra; $^{13}C\{^1H\}$ NMR spectra referenced through the solvent peaks; chemical shifts quoted on the $\delta$ scale (downfield shifts positive) relative to tetramethylsilane ($^1H$, $^{13}C\{^1H\}$); spectra recorded at 25 °C; $^1H$, 399.78 MHz; $^{13}C\{^1H\}$, 100.53 MHz. $AsCl_3$, KBr, HBr and KI were obtained commercially and used as received. $S(C_6H_4SH)_2$ was prepared as reported.[4]

**$S(C_6H_4S)_2AsCl$ (1):** $AsCl_3$ (1.38 g, 7.55 mmol) was added to a solution containing $S(C_6H_6SH)_2$ (1.76 g, 7.59 mmol) in benzene (25 mL). The yellow solution was stirred for 30 min, during which the colour changed to green, and then was refluxed for 24 h. The solution was cooled to room temperature and dried by means of a column of Celite and $Na_2SO_4$. Slow concentration of the benzene solution afforded colourless crystals of **1**, which were washed with hexanes (40 mL) and filtered by suction. Yield: 2.18 g (80%). M.p. 124–126 °C. MS (EI): *m*/*z* (%) = 358 (30) [$M^{\cdot+}$], 323 (70) [$M^{\cdot+}$ – Cl], 248 (10) [$S(C_6H_4S)_2^{\cdot+}$], 216 (100, base peak) [$S(C_6H_4S)^{\cdot+}$]. $C_{12}H_8AsClS_3$ (358.76): calcd. C 40.17, H 2.25; found C 40.29, H 2.28. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.21 (ddd, $^3J_{3\text{-H},2\text{-H}} = {}^3J_{3\text{-H},4\text{-H}}$ = 7.68 Hz, $^4J_{3\text{-H},1\text{-H}}$ = 1.48 Hz, 2 H, 3-H), 7.29 (ddd, $^3J_{2\text{-H},1\text{-H}} = {}^3J_{2\text{-H},3\text{-H}}$ = 7.68 Hz, $^4J_{2\text{-H},4\text{-H}}$ = 1.48 Hz, 2 H, 2-H), 7.53 (dd, $^3J_{1\text{-H},2\text{-H}}$ = 7.68 Hz, $^4J_{1\text{-H},3\text{-H}}$ = 1.48 Hz, 2 H, 1-H), 7.56 (dd, $^3J_{4\text{-H},3\text{-H}}$ = 7.68 Hz, $^4J_{4\text{-H},2\text{-H}}$ = 1.48 Hz, 2 H, 4-H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 127.7, 130.0, 130.9, 131.7, 134.7, 143.6 ppm. IR (KBr): $\tilde{\nu}$ = 3049, 1567, 1447, 1417, 1255, 1032, 732 $cm^{-1}$.

**$S(C_6H_4S)_2AsBr$ (2):** $S(C_6H_4S)_2AsCl$ (**1**, 200 mg, 0.56 mmol), KBr (400 mg, 3.32 mmol) and HBr (48%, 4 mL) were suspended in benzene (25 mL) and the mixture was refluxed for 24 h. The water was removed from the resulting colourless solution by means of a Dean–Stark trap. The yellow solution obtained was dried by means of a column of Celite and $Na_2SO_4$. Slow concentration of the benzene solution afforded colourless crystals of **2**, which were washed with hexanes (40 mL) and filtered by suction. Yield: 160 mg (71%). M.p. 138–140 °C. MS (EI): *m*/*z* (%) = 402 (7) [$M^{\cdot+}$], 323 (100, base peak) [$M^{\cdot+}$ – Br], 248 (20) [$S(C_6H_4S)_2^{\cdot+}$], 215 (30) [$S(C_6H_4S)^{\cdot+}$ – 1], 184. $C_{12}H_8AsBrS_3$ (403.22): calcd. C 35.74, H 2.00; found C 36.14, H 2.06. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.21 (ddd, $^3J_{3\text{-H},2\text{-H}} = {}^3J_{3\text{-H},4\text{-H}}$ = 7.50 Hz, $^4J_{3\text{-H},1\text{-H}}$ = 1.48 Hz, 2 H, 3-H), 7.29 (ddd, $^3J_{2\text{-H},1\text{-H}} = {}^3J_{2\text{-H},3\text{-H}}$ = 7.50 Hz, $^4J_{2\text{-H},4\text{-H}}$ = 1.48 Hz, 2 H, 2-H), 7.53 (dd, $^3J_{1\text{-H},2\text{-H}}$ = 7.50 Hz, $^4J_{1\text{-H},3\text{-H}}$ = 1.48 Hz, 2 H, 1-H), 7.54 (dd, $^3J_{4\text{-H},3\text{-H}}$ = 7.50 Hz, $^4J_{4\text{-H},2\text{-H}}$ = 1.48 Hz, 2 H, 4-H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 127.6, 130.0, 130.7, 131.6, 134.9, 142.9 ppm. IR (KBr): $\tilde{\nu}$ = 3042, 1551, 1444, 1415, 1252, 1033, 741 $cm^{-1}$.

**$S(C_6H_4S)_2AsI$ (3):** $S(C_6H_4S)_2AsCl$ (**1**, 200 mg, 0.56 mmol) and KI (550 mg, 3.32 mmol) were suspended in benzene (25 mL) and the mixture was refluxed for 24 h. The yellow solution obtained was dried by means of a column of Celite and $Na_2SO_4$. Slow concentration of the benzene solution afforded pale yellow crystals of **3**,

C 32.01, H 1.79; found C 31.29, H 1.86. $^1$H NMR ($CDCl_3$): $\delta$ = 7.21 (ddd, $^3J_{3\text{-H},2\text{-H}} = {}^3J_{3\text{-H},4\text{-H}}$ = 7.48 Hz, $^4J_{3\text{-H},1\text{-H}}$ = 1.46 Hz, 2 H, 3-H), 7.28 (ddd, $^3J_{2\text{-H},1\text{-H}} = {}^3J_{2\text{-H},3\text{-H}}$ = 7.48 Hz, $^4J_{2\text{-H},4\text{-H}}$ = 1.46 Hz, 2 H, 2-H), 7.48 (dd, $^3J_{1\text{-H},2\text{-H}}$ = 7.48 Hz, $^4J_{1\text{-H},3\text{-H}}$ = 1.46 Hz, 2 H, 1-H), 7.52 (dd, $^3J_{4\text{-H},3\text{-H}}$ = 7.48 Hz, $^4J_{4\text{-H},2\text{-H}}$ = 1.46 Hz, 2 H, 4-H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 127.7, 129.9, 130.7, 131.9, 135.3, 141.6 ppm. IR (KBr): $\tilde{\nu}$ = 3044, 1550, 1445, 1414, 1251, 1032, 751 $cm^{-1}$.

**X-ray Crystallography:** Suitable single crystals of all complexes were grown by slow concentration of benzene solutions. X-ray diffraction data on **1**–**3** were collected at room temperature with a CCD Smart 6000 diffractometer through the use of Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å, graphite monochromator). The data were integrated, scaled, sorted and averaged using the SMART software package. The structures were solved by direct methods, using SHELXTL NT Version 5.10 and refined by full-matrix least squares against $F^2$.[30] An empirical absorption correction based on the multiple measurement of equivalent reflections was applied by using the program SADABS.[31] The displacement parameters of non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were kept fixed with a common isotropic displacement parameter. Selected crystallographic data are given in Table 6. CCDC-600909 (**1**), -600910 (**2**) and -600911 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Product Diversity in the Reaction of [(norbornadiene){CpP(*i*Pr)$_2$}Rh] with Alkyl Iodides

**Esteban Ortega,[a] Nina Kleigrewe,[a] Gerald Kehr,[a] Gerhard Erker,*[a] and Roland Fröhlich[a]**

**Keywords:** Rhodium / Phosphonium salts / Dimetallic complexes / Cyclopentadienyl ligands / Phosphorus ylides

The reagents [(CpPR$_2$)Li] [R = *i*Pr (**2b**), cyclohexyl (**2c**)] react with [(nbd)RhCl] (nbd = norbornadiene) dimer [(**1a**)$_2$] to yield the respective mononuclear complexes [(nbd)Rh(CpPR$_2$)] (**3b**,**c**). Subsequent treatment of **3b** with a large excess of MeI led to the formation of the stable organometallic phosphonium salt [(nbd)Rh{CpP(*i*Pr)$_2$Me}]I (**4b**). The analogous reaction of **3b** with the slightly more bulky EtI or *n*PrI resulted in the formation of the dinuclear [μ-CpP(*i*Pr)$_2$]-bridged dirhodium complex [(nbd)Rh{CpP(*i*Pr)$_2$}Rh(nbd)I] (**5b**) and the corresponding ylides C$_5$H$_4$P(*i*Pr)$_2$R$^1$ [R$^1$ = Et (**6b**), *n*Pr (**6c**)]. The rhodium complexes **3b**, **4a** and **5b** were characterised by X-ray crystal-structure analyses.

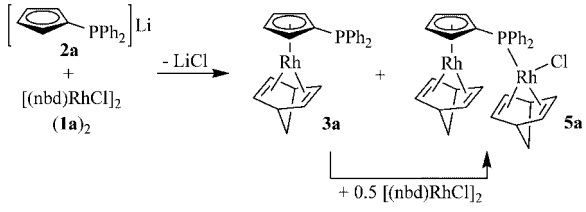
## Introduction

[CpRh(L)$_n$] complexes have been of increasing interest lately due to some remarkable reactivities, for example their ability to catalyse selective C–H activation processes in conjunction with R$_2$B–BR$_2$ reagents.[1] It may be of interest to use Rh cyclopentadienides that bear functional groups at their Cp rings in order to potentially facilitate such currently high activation energy C–H cleavage reactions by precoordination of suitable substrates in a second coordination sphere around the catalytically active metal centre. For that reason, we have prepared a couple of (dialkylphosphanyl)-cyclopentadienyl-containing rhodium(I) complexes[2] and have encountered some unexpected features with regard to their reactions with alkyl iodides. This will be described and discussed in this article.

## Results and Discussion

### Synthetic Developments

The (diphenylphosphanyl)cyclopentadienide anion was prepared by treatment of CpLi with ClPPh$_2$ followed by deprotonation with *n*-butyllithium/hexane in toluene.[3] When we wanted to attach this simple functionalised ligand to an Rh(diene) framework, we encountered the same difficulties that had previously been observed by Poilblanc et al.[2] For example, treatment of the (nbd)RhCl (nbd = norbornadiene) dimer [(nbd)RhCl]$_2$ [(**1a**)$_2$][4] with [(CpPPh$_2$)Li] (**2a**) always resulted in the formation of a mixture of the desired mononuclear complex **3a** and its dinuclear adduct **5a** containing an unreacted monomeric (nbd)RhCl unit from the starting material (**1a**)$_2$. These two products could not be separated with sufficient ease, nor were we able to convert **5a** back to the desired **3a**, for example by treatment with additional **2a** (Scheme 1).



Scheme 1.

Therefore, we made a variety of changes in our synthetic scheme and slightly changed the substituents and reagents to eventually achieve a clean formation of mononuclear Rh$^I$ complexes of the desired type. The reagents [{CpP(*i*Pr)$_2$}Li] (**2b**) and [(CpPCy$_2$)Li] (**2c**; Cy = cyclohexyl) were prepared as described in the literature.[5,6] The reaction of [(nbd)-RhCl]$_2$ [(**1a**)$_2$] with **2b** was carried out in THF at room temperature. Removal of the solvent and extraction of the residue with pentane cleanly gave the mononuclear complex [(nbd)Rh{CpP(*i*Pr)$_2$}] (**3b**; 85% isolated yield). Complex **3b** was characterised by X-ray diffraction. Single crystals were obtained from pentane. The structure shows a typical disturbed trigonally planar coordination geometry around the rhodium atom made up by the pair of norbornadiene C=C double bonds [C=C(centroid)–Rh–C=C(centroid) = 70.7°] and the substituted Cp ring [Cp(centroid)–Rh–C=C(centroid) = 144.4° and 144.9°]. The norbornadiene ligand is almost symmetrically bonded to the metal atom through its

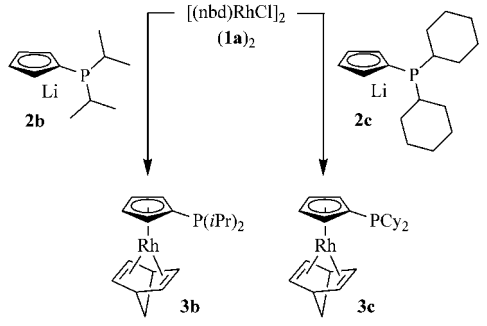
*endo* face [Rh–C14/C15 = 2.119(2), 2.127(2) Å; Rh–C18/C17 = 2.127(2), 2.135(2) Å]. The diisopropylphosphanyl-substituted Cp ring is rather uniformly $\eta^5$-coordinated to the rhodium atom, with Rh–C(Cp) distances being in a narrow range between 2.214(2) and 2.290(2) Å.[7] In the crystal, a metal complex conformation is found that has the bulky P(*i*Pr)$_2$ substituent rotated toward one side of the coordinated nbd ligand, with the C1–P vector almost bisecting the C15–Rh–C17 angle in the respective projection. The phosphorus centre in complex **3b** is three-coordinate and prochiral [C1–P–C7 = 103.1(1)°; C1–P–C6 = 99.7(1)°; C7–P–C6 = 101.9(1)°].

In solution, rotation around the Rh–Cp[P] vector is fast. Consequently, complex **3b** shows only one norbornene olefinic $^1$H NMR multiplet ($\delta$ = 3.24 ppm) representing four protons plus a signal for the two bridgehead hydrogen atoms ($\delta$ = 3.22 ppm). The methyl groups of the isopropyl substituents at the prochiral phosphorus atom are pairwise diastereotopic, as expected ($^{13}$C: $\delta$ = 19.7/20.4 ppm). The $^1$H NMR signals of the pairs of Cp hydrogen atoms are observed at $\delta$ = 4.93 (2 H) and 5.20 (2 H) ppm. The corresponding $^{31}$P NMR resonance of **3b** occurs at $\delta$ = –3.2 ppm.

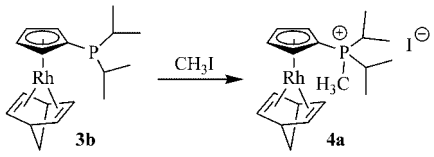
The reaction of dimer (**1a**)$_2$ with [(CpPCy$_2$)Li] (**2c**) took place analogously. The product [(nbd)Rh(CpPCy$_2$)] (**3c**) was isolated in 68% yield. It was characterised spectroscopically and by C,H elemental analysis (for details see the Experimental Section and Scheme 2).



Scheme 2.

## Reactions with Alkyl Iodides

We expected that the CpPR$_2$ subunit in complex **3b**, for example, should show a typical reactivity pattern of a phosphorus nucleophile. Treatment with suitable alkyl electrophiles might, therefore, yield the respective quaternized phosphonium salts at the organometallic backbone. This was actually observed when we treated complex **3b** with methyl iodide. Treatment of **3b** with a large excess of MeI in pentane rapidly led to the formation of the organometallic phosphonium salt **4a** (Scheme 3), which precipitated from the solution and was obtained as a slightly beige-coloured solid in 92% yield.[8] Slow diffusion of pentane vapour into a solution of **3b** in dichloromethane gave single crystals that were suitable for an X-ray crystal structure analysis. The structure of phosphonium salt **4a** is very similar to that of phosphane complex **3b** as it features the same framework structure (see Figure 1 and Table 1). This similarity even extends to the overall characteristics of the favoured conformational orientation of the Cp[P] ring system. The C1–P bond in **4a** is shorter [1.767(5) Å] than in **3b** [1.822(2) Å] and the phosphorus centre is tetracoordinate (Figure 2).



Scheme 3.

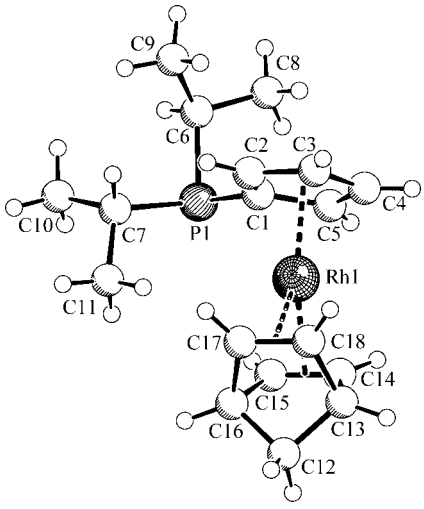


Figure 1. View of the molecular structure of [(nbd)Rh{CpP(*i*Pr)$_2$}] (**3b**).

Table 1. Comparison of selected structural parameters of complexes **3b**, **4a** and **5b**.[a]

[a] Bond lengths [Å].

In solution, complex **4a** features a typical phosphonium-type $^{31}$P NMR chemical shift ($\delta$ = +35.1 ppm).[9,10] Again, the system is conformationally equilibrated in solution. The isopropyl methyl groups at the prochiral phosphorus atom are pairwise diastereotopic [$^{13}$C NMR: $\delta$ = 16.6/16.7 ($CH_3$), 22.8 (d, $^1J_{P,C}$ = 49.7 Hz, CH) ppm] and there is an additional $CH_3$ group bonded to the phosphorus centre [$^1$H NMR: $\delta$ = 2.24 ($^2J_{P,H}$ = 12.5 Hz) ppm; $^{13}$C NMR: $\delta$ = 4.3 ($^1J_{P,C}$ = 54.4 Hz) ppm].

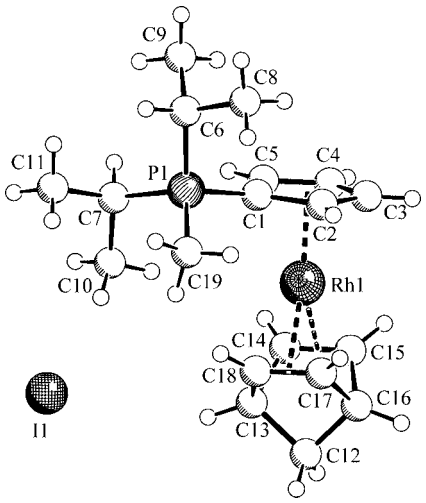

Figure 2. Molecular structure of [(nbd)Rh{CpP(*i*Pr)$_2$Me}]I (**4a**).

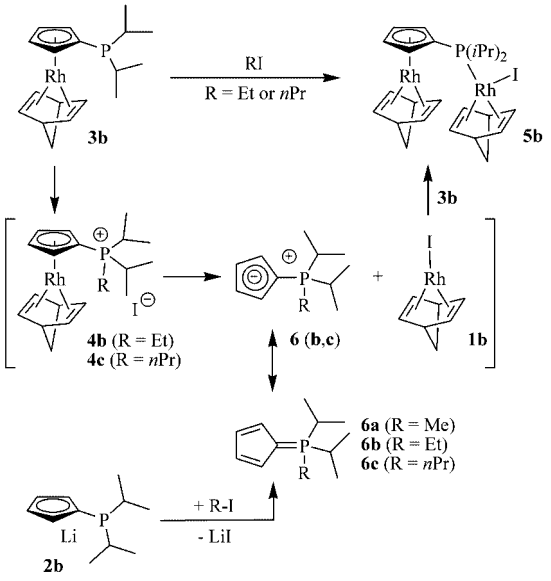
The reaction of complex **3b** with excess ethyl iodide under similar conditions gave a different reaction product. After removal of the volatiles in vacuo, we isolated the dinuclear [μ-CpP(*i*Pr)$_2$]-bridged dirhodium complex **5b** in good yield (86%; Scheme 4). This product was characterised spectroscopically, by C,H elemental analysis and by X-ray diffraction (single crystals were obtained from a pentane solution at –30 °C).



Scheme 4.

The X-ray crystal structure analysis of **5b** shows the presence of an [(nbd)Rh{CpP(*i*Pr)$_2$}] subunit that is structurally very similar to that found in **3b** or **4a** (see above and Table 1). The phosphorus atom of this unit coordinates to the Rh centre of an (nbd)RhI subunit. The norbornadiene ligand is again *endo*-coordinated through both its C=C double bonds. The rhodium centre Rh2 is distorted square-planar coordinated by this pair of C=C double bonds and P1 and I1 are *cis* to each other [Rh2–I1 = 2.6624(4), Rh2–P1 = 2.2992(7) Å; I1–Rh2–P1 = 95.76(2)°]. The resulting bond angle at the phosphorus atom (Rh2–P1–C1) is 119.24(9)° (Figure 3).

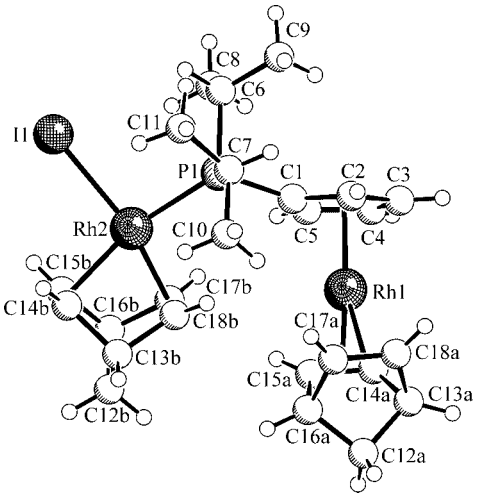


Figure 3. Molecular structure of complex **5b**.

In solution, there is again a rapid rotation around the Rh1–Cp[P] vector, resulting in the observation of a single $^1$H NMR =CH resonance [$\delta$ = 3.09 (4 H) ppm] for the nbd-1 ligand. In contrast, nbd-2, which is bonded to the distorted square planar Rh2 centre, exhibits a clearly differentiated pair of HC=CH $^1$H/$^{13}$C NMR features of the double bonds *cis* to I and *cis* to P1 [$^1$H NMR: $\delta$ = 3.83/5.36 (each 2 H) ppm; $^{13}$C NMR: $\delta$ = 51.0/78.4 ppm], respectively. Again, the isopropyl groups at the prochiral phosphorus atom are pairwise diastereotopic, as expected ($^1$H NMR: $\delta$ = 1.12/1.36 ppm; $^{13}$C NMR: $\delta$ = 19.7/20.1 ppm). The $^{31}$P NMR resonance of complex **5b** is located at $\delta$ = +40.1 ppm.

Although the complete mechanistic elucidation of the unexpected formation of the dinuclear product **5b** must await further detailed studies, we would like to propose a tentative scheme for the possible formation of this product. It may be assumed that the formation of the unexpected product **5b** might also be initiated by phosphonium salt formation. The resulting intermediates (**4b**, **4c**) seem not to be stable under the applied reaction conditions but rather undergo a nucleophilic displacement of the respective (C$_5$H$_4$)P(*i*Pr)$_2$R moiety (**6b**, **6c**) by iodide. Substitution of the Cp-phosphonium ylides **6b**, **6c** might be facilitated by their higher steric bulk as compared to the [P]-CH$_3$ derivative **6a** in **4a**. In the case of **4b** and **4c** the nucleophilic substitution reaction probably leads to the formation of the ethyl- or *n*-propyl-substituted phosphonium salts **6b** or **6c**, respectively, which must be assumed to be slightly more bulky than their methylphosphonium analogue **6a**. Apparently, the reaction in the cases **4b** and **4c**, in contrast to the more persistent **4a**, proceeds with cleavage of the Cp ligand bearing the bulky phosphonium substituent from the rhodium atom, with the possible formation of (nbd)RhI (**1b**). Under the applied reaction conditions, this monomeric species seems never to reach a high enough concentration to give rise to observable dimer formation, but is apparently

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

efficiently trapped by the neutral starting material **3b** to yield the $CpPR_2$-bridged dinuclear product **5b**.[5,11] We have only observed this unexpected reaction pathway in the case of treatment of **3b** with ethyl iodide or *n*-propyl iodide but so far not with methyl iodide, which only gave the organometallic phosphonium salt **4a** that is stable under the applied reaction conditions.

In order to further support the proposed reaction course, we treated **2b** with methyl iodide, ethyl iodide and *n*-propyl iodide. The corresponding trialkyl(Cp)phosphonium ylide products (**6a**–**c**) were isolated as pale-yellow solids and characterised spectroscopically. The resulting ylide **6a** features a $^{31}P$ NMR signal at $\delta$ = 24.7 ppm and a $^{13}C$ NMR resonance for the adjacent C1 ring carbon atom at $\delta$ = 74.0 ppm with a very characteristic $^1J_{P,C}$ coupling constant of 104 Hz [C=P(*i*Pr)$_2$Me].[12,13] The ethyl-substituted CpP(*i*Pr)$_2$Et ylide **6b** shows an analogous $^{13}C$ NMR feature at $\delta$ = 74.3 ppm ($^1J_{P,C}$ = 101 Hz). This signal was detected in the crude reaction mixture obtained by treatment of complex **2b** with ethyl iodide to eventually yield **5b**.

## Conclusions

The reaction of [(nbd){CpP(*i*Pr)$_2$}Rh] (**3b**) with simple alkyl iodides shows some remarkably different outcomes depending on the bulk of the alkyl group of the RI reagent used. The reaction with methyl iodide leads to the formation of a stable phosphonium salt **4a**, whereas the analogous reaction of **3b** with either EtI or *n*PrI rapidly results in the formation of the dinuclear product **5b**. The experimental characteristics of these reactions led us to assume that in the latter cases the corresponding phosphonium salts might also have been formed initially. However, these slightly more bulky systems seem to be unstable with regard to CpP(*i*Pr)$_2$R ylide dissociation,[14] a pathway that eventually leads to the formation of **5b**. For the less bulky [(nbd){CpP(*i*Pr)$_2$Me}Rh]I system this pathway seems not to be readily available under our typical reaction conditions. This specific alkyl group dependent behaviour makes the **3b** + RI reaction system a remarkable example of an observed borderline behaviour along a threshold determined by rather subtle differences in steric bulk.

## Experimental Section

**General:** All reactions involving air- or moisture-sensitive compounds were carried out under an inert gas using Schlenk-type glassware or in a glove box. Solvents were dried and distilled prior to use. The following instruments were used for physical characterisation of the compounds: Melting points: DSC 2010 TA-instruments; elemental analyses: Foss-Heraeus CHNO-Rapid; MS: Micromass Quattro LC-Z electrospray mass spectrometer; NMR: Bruker AC 200 P ($^1H$: 200 MHz; $^{13}C$: 50 MHz), ARX 400 ($^1H$: 400 MHz; $^{13}C$: 100 MHz), Varian 500 INOVA ($^1H$: 500 MHz; $^{13}C$: 125 MHz) or Varian UNITY plus 600 ($^1H$: 600 MHz; $^{13}C$: 151 MHz). The complex [(nbd)RhCl]$_2$ (**1a**)[4] and the reagents [{CpP(*i*Pr)$_2$}Li] (**2b**)[5] and [{CpPCy$_2$}Li] (**2c**)[5] were prepared according to literature procedures.

**X-ray Crystal-Structure Determinations:** Data sets were collected with a Nonius KappaCCD diffractometer equipped with a rotating anode generator. Programs used: data collection COLLECT (Nonius B.V., **1998**), data reduction Denzo-SMN (Z. Otwinowski, W. Minor, *Methods in Enzymology* **1997**, *276*, 307–326), absorption correction SORTAV (R. H. Blessing, *Acta Crystallogr., Sect. A* **1995**, *51*, 33–37; R. H. Blessing, *J. Appl. Crystallogr.* **1997**, *30*, 421–426) and Denzo (Z. Otwinowski, D. Borek, W. Majewski, W. Minor, *Acta Crystallogr., Sect. A* **2003**, *59*, 228–234), structure solution SHELXS-97 (G. M. Sheldrick, *Acta Crystallogr., Sect. A* **1990**, *46*, 467–473), structure refinement SHELXL-97 (G. M. Sheldrick, University of Göttingen, **1997**), graphics SCHAKAL (E. Keller, University of Freiburg, **1997**). CCDC-600987 to -600989 (for **3b**, **4a** and **5b**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Reaction of [{CpP(*i*Pr)$_2$}Li] (2b) With [(nbd)RhCl]$_2$ [(1a)$_2$]. Formation of Complex 3b:** A solution of **2b** (94 mg, 0.50 mmol) in THF (3 mL) was added to a solution of (**1a**)$_2$ (115 mg, 0.25 mmol) in THF (3 mL) at ambient temperature and the suspension was stirred at room temperature overnight. Subsequently, the solvent was removed in vacuo and the crude product was extracted through Celite with pentane (4 mL) five times. Evaporation of the solvent yielded the rhodium complex **3b** as a yellow powder (160 mg, 0.43 mmol, 85%). Crystals suitable for X-ray crystal structure analysis were obtained by slow evaporation of the solvent from a concentrated pentane solution at ambient temperature. $^1H$ NMR (500 MHz, $C_6D_6$, 298 K): $\delta$ = 0.95 (t, $J$ = 1.5 Hz, 2 H, $CH_2^{nbd}$), 1.13 (dd, $J$ = 14.6, 7.1 Hz, 6 H, Me$^{iPr}$), 1.25 (dd, $J$ = 10.8, 6.8 Hz, 6 H, Me$^{iPr}$), 1.90 (dsept, $J$ = 7.0, 0.9 Hz, 2 H, CH$^{iPr}$), 3.22 (m, 2 H, CH$^{nbd}$), 3.24 (m, 4 H, =CH$^{nbd}$), 4.93 (m, 2 H, Cp), 5.20 (m, 2 H, Cp) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $C_6D_6$, 298 K): $\delta$ = 19.7 (d, $J$ = 9.3 Hz, Me$^{iPr}$), 20.4 (d, $J$ = 17.5 Hz, Me$^{iPr}$), 23.8 (d, $J$ = 12.8 Hz, CH$^{iPr}$), 30.5 (d, $J$ = 10.5 Hz, =CH$^{nbd}$), 47.0 (d, $J$ = 2.8 Hz, CH$^{nbd}$), 57.4 (d, $J$ = 7.0 Hz, $CH_2^{nbd}$), 86.3 (m, Cp), 89.0 (m, Cp), 94.7 (Cp; detected by $^1H/^{13}C$ ghmbc experiment) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$, 81 MHz, 298 K): $\delta$ = –3.2 (s, P*i*Pr$_2$) ppm. $C_{18}H_{26}PRh$ (376.27): calcd. C 57.45, H 6.96; found C 57.49, H 6.92.

**X-ray Crystal Structure Analysis of 3b:** $C_{18}H_{26}PRh$, $M$ = 376.27, colourless crystal 0.30 × 0.30 × 0.05 mm, $a$ = 5.875(1), $b$ = 10.749(1), $c$ = 13.870(1) Å, $\alpha$ = 104.53(1), $\beta$ = 90.22(1), $\gamma$ = 93.37(1)°, $V$ = 846.3(2) Å$^3$, $\rho_{calcd.}$ = 1.477 g cm$^{-3}$, $\mu$ = 1.093 mm$^{-1}$, empirical absorption correction ($0.735 \leq T \leq 0.947$), $Z$ = 2, triclinic, space group $P\bar{1}$ (no. 2), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$- and $\varphi$-scans, 8037 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sin$\theta$)/$\lambda$] = 0.67 Å$^{-1}$, 4102 independent ($R_{int}$ = 0.034) and 3745 observed reflections [$I \geq 2\sigma(I)$], 185 refined parameters, $R$ = 0.027, $wR_2$ = 0.070, max. (min.) residual electron density 0.41 (–1.06) e Å$^{-3}$, hydrogen atoms calculated and refined as riding atoms.

**Reaction of [(CpPCy$_2$)Li] (2c) with [(nbd)Rhcl]$_2$ [(1a)$_2$]. Formation of Complex 3c:** According to the procedure described for the formation of **3b**, **3c** was obtained as a yellow powder (54 mg, 0.118 mmol, 68%) from **2c** (46 mg, 0.173 mmol) in THF (2 mL) and (**1a**)$_2$ (40 mg, 0.087 mmol) in THF (1 mL). The crude product was extracted three times through Celite with pentane (2 mL). $^1H$ NMR (400 MHz, $C_6D_6$, 298 K): $\delta$ = 0.97 (m, 2 H, $CH_2^{nbd}$), 1.11–1.47 (m, 12 H, Cy), 1.65 (dm, $J$ = 11.9 Hz, 2 H, Cy), 1.78 (dm, $J$ = 11.2 Hz, 2 H, Cy), 1.85 (m, 2 H, Cy), 1.93 (dm, $J$ = 11.7 Hz, 2 H, Cy), 2.31 (dm, $J$ = 11.7 Hz, 2 H, Cy), 3.25 (m, 4 H, =CH$^{nbd}$), 3.24 (m, 2 H, CH$^{nbd}$), 4.95 (m, 2 H, Cp), 5.18 (m, 2 H, Cp) ppm. $^{13}C\{^1H\}$ NMR (100.6 MHz, $C_6D_6$, 298 K): $\delta$ = 27.0 (s, Cy), 27.6

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(d, $J$ = 7.8 Hz, Cy), 27.8 (d, $J$ = 11.5 Hz, Cy), 30.4 (broad d, $J$ = 10.6 Hz, Cy), 30.4 (d, $J$ = 8.7 Hz, Cy), 30.6 (d, $J$ = 15.2 Hz, =CH$^{nbd}$), 34.1 (d, $J$ = 12.8 Hz, Cy), 47.1 (d, $J$ = 2.1 Hz, CH$^{nbd}$), 57.4 (d, $J$ = 6.8 Hz, CH$_2^{nbd}$), 86.5 (m, Cp), 89.3 (dd, $J$ = 14.6, $J$ = 3.3 Hz, Cp), 95.1 (dd, $J$ = 23.5, $J$ = 4.6 Hz, Cp) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$, 298 K): $\delta$ = –11.2 (s, PCy$_2$) ppm. $C_{24}H_{34}$PRh (456.39): calcd. C 63.16, H 7.51; found C 63.55, H 7.62.

**Reaction of 3b with Methyl Iodide. Formation of the Organometallic Phosphonium Salt 4a:** A large excess of methyl iodide (0.25 mL, 4.00 mmol) was added to a solution of **3b** (35 mg; 0.09 mmol) in pentane (5 mL). Precipitation occurred immediately and the tawny suspension was stirred at ambient temperature for 2 h. The supernatant was removed by filtration in air and the resulting beige filter cake was washed carefully with pentane (1 mL). Subsequently, the residue was dried in vacuo and **4a** was obtained as a brown powder (44 mg, 0.085 mmol, 92%). Crystals suitable for X-ray crystal structure analysis were obtained by slow diffusion of pentane into a concentrated solution of **4a** in dichloromethane. $^1$H NMR (500 MHz, $CDCl_3$, 298 K): $\delta$ = 1.06 (t, $J$ = 1.6 Hz, 2 H, CH$_2^{nbd}$), 1.43 (dd, $J$ = 9.7, 7.1 Hz, 6 H, Me$^{i\mathrm{Pr}}$), 1.47 (dd, $J$ = 9.5, 7.1 Hz, 6 H, Me$^{i\mathrm{Pr}}$), 2.24 (d, $J$ = 12.5 Hz, 3 H, Me), 3.03 (m, 2 H, CH$^{i\mathrm{Pr}}$), 3.36 (broad s, 2 H, CH$^{nbd}$), 3.53 (m, 4 H, =CH$^{nbd}$), 5.19 (m, 2 H, Cp), 5.79 (m, 2 H, Cp) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CDCl_3$, 298 K): $\delta$ = 4.3 (d, $J$ = 54.4 Hz, Me), 16.6 (d, $J$ = 2.5 Hz, Me$^{i\mathrm{Pr}}$), 16.7 (d, $J$ = 2.9 Hz, Me$^{i\mathrm{Pr}}$), 22.8 (d, $J$ = 49.7 Hz, CH$^{i\mathrm{Pr}}$), 35.2 (d, $J$ = 10.1 Hz, =CH$^{nbd}$), 46.7 (d, $J$ = 2.6 Hz, CH$^{nbd}$), 58.4 (d, $J$ = 6.9 Hz, CH$_2^{nbd}$), 72.8 (dd, $J$ = 90.6, 6.0 Hz, Cp) 87.7 (dd, $J$ = 11.6, 4.2 Hz, Cp), 92.4 (dd, $J$ = 10.1, 3.7 Hz, Cp) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$, 121.5 MHz, 298 K): $\delta$ = 35.1 (s, P$i$Pr$_2$) ppm. MS (ESI): $m/z$ calcd. 391.105 [M–I]$^+$; found 391.00. $C_{19}H_{29}$IPRh (518.20): calcd. C 44.03, H 5.64; found C 43.94, H 5.50.

**X-ray Crystal-Structure Analysis of 4a:** $C_{19}H_{29}$IPRh·$CH_2Cl_2$, $M$ = 603.13, yellow crystal 0.30×0.10×0.03 mm, $a$ = 15.973(1), $b$ = 10.887(1), $c$ = 26.453(1) Å, $V$ = 4600.1(5) Å$^3$, $\rho_{calcd.}$ = 1.742 g cm$^{-3}$, $\mu$ = 2.389 mm$^{-1}$, empirical absorption correction (0.534 ≤ $T$ ≤ 0.932), $Z$ = 8, orthorhombic, space group $Pbca$ (no. 61), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$- and $\varphi$-scans, 22987 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.66 Å$^{-1}$, 5470 independent ($R_{int}$ = 0.060) and 4556 observed reflections [$I \geq 2\sigma(I)$], 231 refined parameters, $R$ = 0.045, $wR_2$ = 0.146, max. (min.) residual electron density 1.75 (–0.82) e Å$^{-3}$ close to iodine, hydrogen atoms calculated and refined as riding atoms.

**Reaction of 3b with Ethyl Iodide. Formation of Complex 5b:** A large excess of ethyl iodide (0.25 mL, 3.10 mmol) was added to a solution of **3b** (30 mg; 0.08 mmol) in toluene (3 mL) at room temperature. After the reaction mixture had been stirred at ambient temperature overnight, all volatiles were removed in vacuo. The obtained yellow oil was washed twice with pentane (1 mL) and dried in vacuo. The pure product was obtained as a yellow solid (48 mg, 0.07 mmol, 86%). Crystals suitable for X-ray crystal structure analysis were obtained from a pentane solution at –30 °C. $^1$H NMR (600 MHz, $C_7D_8$, 298 K): $\delta$ = 0.90 (br., 2 H, CH$_2^{nbd1}$), 1.10/1.14 (each dm, $J$ = 8.5 Hz, each 1 H, CH$_2^{nbd2}$), 1.12 (dd, $J$ = 14.5, 7.1 Hz, 6 H, Me$^{i\mathrm{Pr}}$), 1.36 (dd, $J$ = 15.8, 7.0 Hz, 6 H, Me$^{i\mathrm{Pr}}$), 2.46 (dsept, $J$ = 7.9, 7.1 Hz, 2 H, CH$^{i\mathrm{Pr}}$), 3.09 (m, 4 H, =CH$^{nbd1}$), 3.08 (m, 2 H, CH$^{nbd1}$), 3.36 (br., 2 H, CH$^{nbd2}$), 3.83 (m, 2 H, =CH$^{nbd2}$), 4.41 (m, 2 H, Cp), 5.07 (m, 2 H, Cp), 5.36 (m, 2 H, =CH$^{nbd2}$) ppm. $^{13}$C{$^1$H} NMR (150 MHz, $C_7D_8$, 298 K): $\delta$ = 19.7 (Me$^{i\mathrm{Pr}}$), 20.1 (d, $J$ = 4.7 Hz, Me$^{i\mathrm{Pr}}$), 27.9 (d, $J$ = 24.1 Hz, CH$^{i\mathrm{Pr}}$), 31.9 (d, $J$ = 10.2 Hz, =CH$^{nbd1}$), 47.1 (d, $J$ = 2.4 Hz, CH$^{nbd1}$), 51.0 (dd, $J$ = 2.3, 1.6 Hz, CH$^{nbd2}$), 52.2 (d, $J$ = 11.7 Hz, =CH$^{nbd2}$), 57.7 (d, $J$ = 6.7 Hz, CH$_2^{nbd1}$), 65.1 (dd, $J$ = 4.9, 2.1 Hz, CH$_2^{nbd2}$), 78.4 (dd, $J$ = 11.4, 5.5 Hz, =CH$^{nbd2}$), 87.2 (dd, $J$ = 6.1, 4.2 Hz, Cp), 88.0 (dd, $J$ = 7.6, 3.9 Hz, Cp). 89.1 (Cp, detected by $^1$H/$^{13}$C ghmbc experiment) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$, 298 K): $\delta$ = 40.1 (d, $J$ = 163.4 Hz, P$i$Pr$_2$) ppm. $C_{25}H_{34}$IPRh$_2$ (698.23): calcd. C 43.00, H 4.91; found C 43.03, H 5.26.

**X-ray Crystal-Structure Analysis of 5b:** $C_{25}H_{34}$IPRh$_2$, $M$ = 698.21, red crystal 0.20×0.20×0.10 mm, $a$ = 10.097(1), $b$ = 17.498(1), $c$ = 13.770(1) Å, $\beta$ = 92.85(1)°, $V$ = 2429.8(2) Å$^3$, $\rho_{calcd.}$ = 1.909 g cm$^{-3}$, $\mu$ = 2.704 mm$^{-1}$, empirical absorption correction (0.614 ≤ $T$ ≤ 0.774), $Z$ = 4, monoclinic, space group $P2_1/n$ (no. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$- and $\varphi$-scans, 16579 reflections collected (±$h$, ±$k$, ±$l$), [(sin$\theta$)/$\lambda$] = 0.67 Å$^{-1}$, 5968 independent ($R_{int}$ = 0.030) and 5230 observed reflections [$I \geq 2\sigma(I)$], 267 refined parameters, $R$ = 0.026, $wR_2$ = 0.059, max. residual electron density 1.47 (–1.62) e Å$^{-3}$ close to iodine, hydrogen atoms calculated and refined as riding atoms.

**Reaction of 3b with *n*-Propyl Iodide. Formation of Complexes 5b and 6c:** *n*-Propyl iodide (7.8 μL, 13.5 mg, 0.08 mmol) was added to a solution of **3b** (30 mg, 0.08 mmol) in $C_6D_6$ (1 mL) at room temperature. The reaction mixture was transferred into an NMR tube and the reaction was monitored by NMR spectroscopy.

**Reaction of [{CpP(*i*Pr)$_2$}Li] (2a) with Methyl Iodide. Generation of 6a:** Methyl iodide (99.30 μL, 227 mg, 1.60 mmol) was added to a solution of **2a** (300 mg, 1.60 mmol) in toluene (40 mL) at room temperature. After the reaction mixture had been stirred at ambient temperature overnight, all volatiles were removed in vacuo. The product was obtained as a bright yellow solid (310 mg, 0.94 mmol, 59%). M.p. 96 °C (DSC). $^1$H NMR [400 MHz, $C_6D_6$/TDF (4:1), 298 K]: $\delta$ = 6.66, 6.31 (each m, each 2 H, $C_5H_4$), 1.83 (dsept, $J_{H,H}$ = 6.8, $J_{P,H}$ = 10.0 Hz, 2 H, CH$^{i\mathrm{Pr}}$), 1.08 (d, $J_{P,H}$ = 12.0 Hz, 3 H, Me), 0.82 (dd, $J_{P,H}$ = 16.2, $J_{H,H}$ = 6.8 Hz, 6 H, Me$^{i\mathrm{Pr}}$), 0.70 (dd, $J_{P,H}$ = 15.8, $J_{H,H}$ = 6.8 Hz, 6 H, Me$^{i\mathrm{Pr}}$) ppm. $^{13}$C{$^1$H} NMR [100 MHz, $C_6D_6$/TDF (4:1), 298 K]: $\delta$ = 113.9 (d, $J$ = 16.3 Hz, $C_5H_4$), 113.3 (d, $J$ = 13.8 Hz, $C_5H_4$), 74.0 (d, $J$ = 104.2 Hz, C=P), 22.7 (d, $J$ = 52.9 Hz, CH$^{i\mathrm{Pr}}$), 15.6 (d, $J$ = 1.8 Hz, Me$^{i\mathrm{Pr}}$), 15.4 (d, $J$ = 2.1 Hz, Me$^{i\mathrm{Pr}}$), 0.6 (d, $J$ = 56.9 Hz, Me–P) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $C_6D_6$, 298 K): $\delta$ = 24.7 (s, P$i$Pr$_2$) ppm. MS (ESI): $m/z$ calcd. 197.1459 [M + H]$^+$; found 197.1446. $C_{12}H_{21}$P·LiI (330.12): calcd. C 43.66, H 6.41; found C 42.61, H 6.52.

**Reaction of [{CpP(*i*Pr)$_2$}Li] (2a) with Ethyl Iodide. Generation of 6b:** According to the procedure described for the generation of **6a**, **6b** was obtained as a colourless powder (435 mg, 1.26 mmol, 79%) from the reaction of **2a** (300 mg, 1.60 mmol) with ethyl iodide (129 μL, 249 mg, 1.60 mmol) in toluene (40 mL). M.p. 144 °C (DSC). $^1$H NMR [600 MHz, $C_6D_6$/TDF (4:1), 298 K]: $\delta$ = 6.59, 6.28 (each m, each 2 H, $C_5H_4$), 1.99 (dsept, $J_{P,H}$ = 10.6, $J_{H,H}$ = 7.0 Hz, 2 H, CH$^{i\mathrm{Pr}}$), 1.77 (dq, $J_{P,H}$ = 12.7, $J_{H,H}$ = 7.7 Hz, 2 H, $CH_2$), 0.90 (dd, $J_{P,H}$ = 15.4, $J_{H,H}$ = 7.0 Hz, 6 H, Me$^{i\mathrm{Pr}}$), 0.86 (q, $J_{P,H}$ = $J_{H,H}$ = 7.7 Hz, 3 H, $CH_3$), 0.80 (dd, $J_{P,H}$ = 15.4, $J_{H,H}$ = 7.0 Hz, 6 H, Me$^{i\mathrm{Pr}}$) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $C_6D_6$/TDF, 4:1, 298 K): $\delta$ = 113.7 (d, $J$ = 16.7 Hz, $C_5H_4$), 113.3 (d, $J$ = 13.3 Hz, $C_5H_4$), 73.1 (d, $J$ = 103.5 Hz, P=C), 22.0 (d, $J$ = 51.8 Hz, CH$^{i\mathrm{Pr}}$), 16.2 (d, $J$ = 1.8 Hz, Me$^{i\mathrm{Pr}}$), 16.0 (d, $J$ = 1.9 Hz, Me$^{i\mathrm{Pr}}$), 11.7 (d, $J$ = 52.9 Hz, $CH_2$), 7.5 (d, $J$ = 4.8 Hz, $CH_3$) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $C_6D_6$, 298 K): $\delta$ = 24.7 (s, P$i$Pr$_2$) ppm. MS (ESI): $m/z$ calcd. 211.1616 [M + H]$^+$; found 211.1. $C_{13}H_{23}$P·LiI (344.15): calcd. C 45.37, H 6.74; found C 44.45, H 6.73.

**Reaction of [{CpP(*i*Pr)$_2$}Li] (2a) with *n*-Propyl Iodide. Generation of 6c:** According to the procedure described for the generation of **6a**, **6c** was obtained as a colourless powder (470 mg, 0.76 mmol, 82%) from the reaction of **2a** (300 mg, 1.60 mmol) with *n*-propyl

## COVER PICTURE

**The cover picture shows** the Alhambra in Granada, the home town of the Spanish author of this paper. The Moors in their desert dreamt of palaces abundant with water, and that is why they built the Alhambra. Likewise, the water-soluble encapsulating pyrazolylborate ligand, shown as an (aqua)zinc complex set in one of Alhambra's gardens, is the realization of a long-standing dream of the Freiburg group, whose biomimetic zinc complex chemistry was previously confined by the hydrophobicity of the model complexes, typically the zinc hydroxide complex shown in the background. The abundance of red (carbonyl oxygen) and green (amide nitrogen) atoms in the foreground complex visualizes its hydrophilicity due to the carboxamide substituents on the tripod ligand. Details are discussed in the article by H. Vahrenkamp et al. on p. 3869 ff.

# Clues to Dimetallohydrolase Mechanisms from Studies on Pyrazolate-Based Bioinspired Dizinc Complexes – Experimental Evidence for a Functional $Zn–O_2H_3–Zn$ Motif

**Franc Meyer*[a]**

**Keywords:** Bioinorganic chemistry / Hydrolases / Metalloenzymes / Enzyme models / Zinc

Various hydrolytic metalloenzymes contain two adjacent zinc ions within their active site that work synergistically during substrate turnover. While structural biology, biochemical investigations, and quantum chemical calculations have provided much insight into those cocatalytic sites, crucial details of the catalytic mechanisms have remained under debate. Valuable contributions to further our understanding of the functional role of the zinc ions in a specific coordination environment can be obtained from the study of simple biomimetic synthetic complexes that emulate features of the natural systems. To this end, a series of highly preorganized pyrazolate-based dizinc complexes has been developed, which are particularly amenable to fine-tuning of the dimetallic core. These bioinspired dizinc complexes have made possible the investigation of systematic effects of factors such as the zinc–zinc separation on hydrolytic activity and substrate binding. The present microreview summarizes findings relevant to dimetallohydrolases that have been obtained from studies of the pyrazolate-based synthetic analogues, including experimental support for a functional role of the $Zn–O_2H_3–Zn$ motif and clues to the binding and hydrolytic cleavage of phosphodiester and β-lactam substrates.

## 1. Introduction

Numerous biological functions rely on enzymes that promote the hydrolytic cleavage of biological substrates such as phosphate esters, peptides or amides, and these enzymes often contain two or even three cooperating metal ions within their active site.[1–4] Although specific mechanisms are involved for the individual metalloenzymes, crucial roles of the metal ions are believed to comprise the generation of a hydroxide nucleophile at physiological pH by lowering the $pK_A$ of water, the Lewis acid activation and orientation of the substrate through metal coordination, as well as the stabilization of intermediates and leaving groups.[2,4,5] Since $Zn^{2+}$ is a strong Lewis acid with rapid ligand exchange and a flat coordination hypersurface that allows the coordination number und geometry to be changed easily, it fulfils all these requirements while, at the same time, lacking undesired redox activity.[6] Hence, zinc is found very often in hydrolytic enzymes, although other metals such as $Mg^{2+}$ or $Mn^{2+}$, or even $Ni^{2+}$ in urease may be preferred in certain cases.

## 2. Oligozinc Hydrolases: Phosphatases, Metallo-β-lactamases, and Aminopeptidases as Examples

Prominent hydrolases that incorporate two proximate zinc ions include some metallo-β-lactamases,[7,8] several aminopeptidases,[9] phosphotriesterase,[10] and alkaline phosphatase.[11,12] Similarly, human phosphodiesterase features two divalent metal ions, at least one of which is $Zn^{2+}$ (the second is probably $Mg^{2+}$).[13,14] Enzymes that hydrolyze phosphodiesters are of prime importance to the manipula-

*Franc Meyer was born in 1965 in Hamburg and studied chemistry at RWTH Aachen. He earned his doctorate with Professor P. Paetzold in 1993 and was a postdoctoral fellow with Professor P. B. Armentrout in Salt Lake City until 1995. After his Habilitation with Professor G. Huttner in Heidelberg in 2000 and a visiting professorship at the University of Vienna he became full professor of inorganic chemistry at the Georg-August-University Göttingen in 2001. His research focuses on cooperative effects in bimetallic and multimetallic complexes, with particular interests in bioinorganic chemistry, bioinspired catalysis and magnetochemistry. His awards include a Dozentenstipendium from the Fonds der Chemischen Industrie and the Karl-Freudenberg prize of the Heidelberg Academy of Sciences and Humanities.*

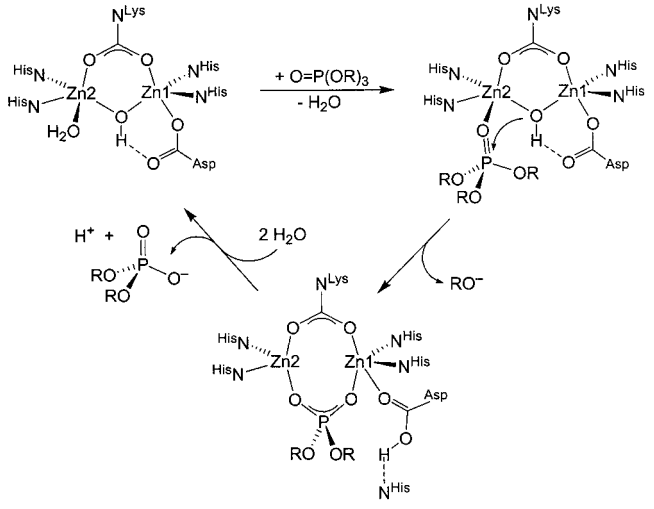
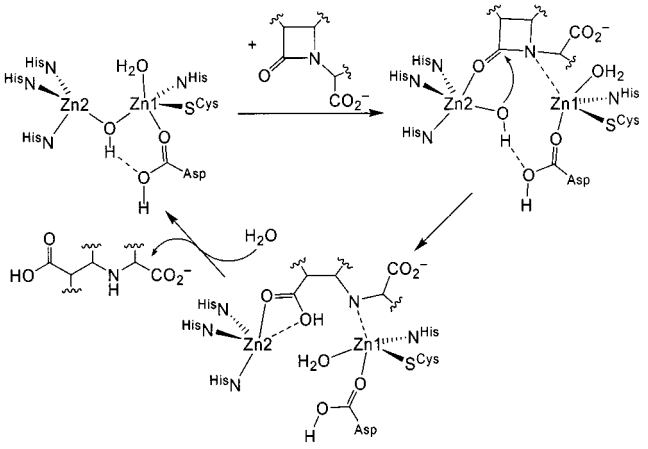
tion of DNA and RNA because of their involvement in replication, transcription, recombination, and DNA repair. It is through the synergistic Lewis acid activation of the substrate, the nucleophile, and the leaving group in these processes that the $10^{16}$-fold rate enhancement can be achieved that is needed to hydrolyze DNA on the biological time scale.[3] A representative example illustrating the role of two active-site zinc ions in phosphoester hydrolysis is phosphotriesterase (PTE).[10] PTE efficiently degrades highly toxic organophosphate triesters by the proposed mechanism outlined in Scheme 1.[15] Similar to various other oligozinc enzymes, the crystallographically characterized form of PTE has a bridging O atom, which most likely is a bridging hydroxide in agreement with the experimental p*K*a value of 5.8.[16] It is assumed that the substrate enters the scene to replace a water at Zn2, followed by nucleophilic attack of the μ-OH onto the substrate-P and ejection of the leaving group. Proton transfer away from the active site, assisted by a nearby histidine residue, gives a phosphate anion which spans the two metal ions, and solvent molecules finally move in to regenerate the original state upon product release.



Scheme 1. Proposed mechanism of phosphotriesterase.[15]

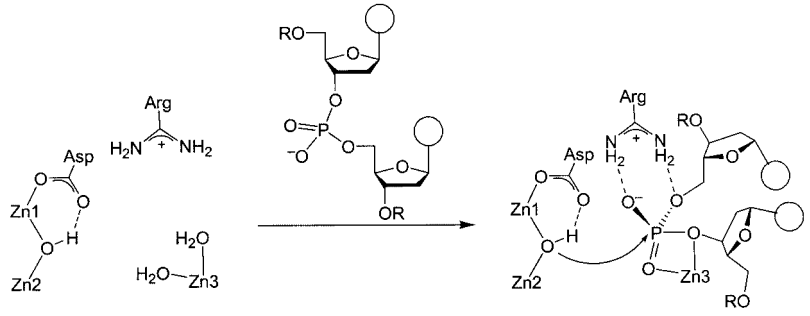
Even more than two metal ions may be involved in phosphoester cleavage; an example is the P1 nuclease, which degrades single-stranded RNA and DNA into 5′-mononucleotides. P1 nuclease features a trinuclear zinc site sketched in Scheme 2, where a hydroxide bridging Zn1 and Zn2 is assumed to attack the phosphate substrate that binds to Zn3 in a bidentate fashion.[17]

Despite manifold investigations, details of the mode of action of these and other metallohydrolases remain controversial. One important aspect under debate is the identity and the exact binding mode of the nucleophile.[18,19] Since a hydroxide spanning two zinc ions has been detected crystallographically in the majority of dimetallohydrolases, this μ-OH is usually considered to be the active nucleophile. Computational evidence for a catalytic bridging hydroxide in a phosphodiesterase site has indeed been reported.[19] On the other hand, the hydroxide can be suspected to exhibit a rather low nucleophilicity in this tightly bridging form. It has thus been suggested in an alternative picture that a shift of the bridging hydroxide to a terminal position occurs upon substrate binding prior to attack on the coordinated substrate.[20] A similar scenario is also assumed for the dizinc-β-lactamase mechanism depicted in Scheme 3.



Scheme 3. Proposed simplified mode of action of dizinc metallo-β-lactamase CcrA from *B. fragilis*.[18,21]

β-Lactamases are enzymes that efficiently hydrolyze and cleave the four-membered ring of β-lactams.[22] This β-lactam motif is a crucial functionality in antibiotics derived from the penicillin, cephalosporin, and carbapenem families. Expression of β-lactamases capable of inactivating this motif and thus inactivating these drugs has become a standard bacterial defense mechanism. Among the four classes (A, B, C, and D),[23,24] of β-lactamases, enzymes of the most recently discovered class B depend on one or two zinc ions



Scheme 2. Proposed mechanism of P1 nuclease.[17]

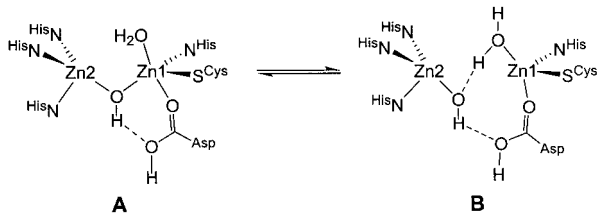
within their active site.[8,25] Unfortunately, clinically useful inhibitors are not yet available for those metallo-β-lactamases, in contrast to the serine-based β-lactamases of classes A, C, and D.[26] Bacterial resistance caused by metallo-β-lactamases now represents a serious clinical threat, and a spread of these enzymes to pathogenic bacteria has raised the concern of the biomedical community.[27] Current efforts thus focus on gathering a detailed picture of the mechanism of action within the active site of the metallo-β-lactamases,[8,28] which is not only of fundamental interest but may also contribute to the development of effective mechanism-based inhibitors.[29]

Molecular structures of several dizinc metallo-β-lactamases have been determined,[30–36] but mechanistic studies have concentrated on CcrA from *B. fragilis* and BcII from *B. cereus II*. While intimate details of the active-site structures vary, common features of dizinc metallo-β-lactamases comprise one tetrahedral {$(His)_3Zn(\mu\text{-}OH)$} motif (Zn2 in Scheme 3) in which the hydroxide serves as a bridge to the second zinc (Zn1). The latter is found in a distorted trigonal bipyramidal environment as a {$(His)(Asp)(X)Zn(H_2O)(\mu\text{-}OH)$} center, where X is His or Cys. From stopped-flow kinetic investigations in combination with theoretical studies, a mechanism has been postulated[18,21,37] that starts by docking the substrate to Zn2 by means of its ring carbonyl group. This polarizes the lactam unit and allows the N-atom to interact with Zn1, inducing conformational changes with rupture of the Zn–OH–Zn bridge and activation of the hydroxide for nucleophilic attack.[38] Zn1 then stabilizes the negative charge on the nitrogen leaving group, which is released upon rate-determining proton transfer.[18] Bringing in water from the medium finally regenerates the initial active-site state (Scheme 3).

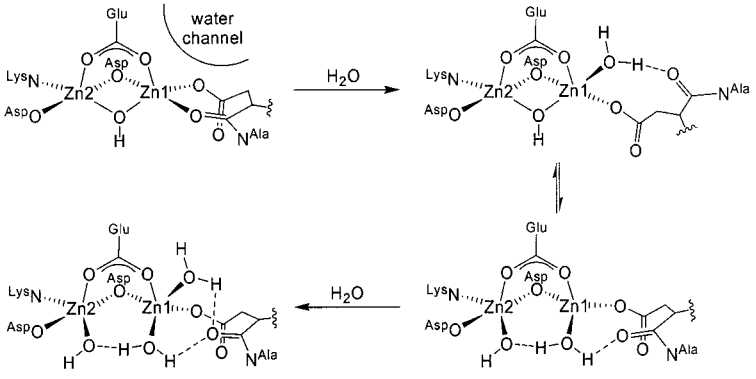
Recent DFT, Hartree–Fock, and molecular dynamics studies have revealed a somewhat refined picture, suggesting that the active site can easily assume different conformations.[39] When the Asp residue is neutral, the dizinc core may readily interchange between a tightly bridged state **A** and a loosely bridged state **B** with changes of coordination number at Zn1 (Scheme 4). The more flexible state **B** can be described as an $O_2H_3$ unit between the two metal ions. Evidence for different active-site conformation is also available from experimental studies,[37] but details such as the protonation state of the Asp residue remain controversial.[40,41] It is obvious, however, that solid-state structures obtained crystallographically do not provide the whole story.



Scheme 4. Interconversion of tightly and loosely bridged active site forms of CcrA from *B. fragilis* as predicted by calculations.[39]

A Zn–(H)OHO(H)–Zn motif reminiscent of the situation in **B** has indeed been observed in bioinspired synthetic model complexes, and from those findings the bridging $O_2H_3$ unit has been proposed as a structural and possibly functional unit in oligozinc hydrolases.[42,43] Some further corroboration comes from a most recent DFT study on the dizinc active site of bovine lens leucine aminopeptidase (*bl*LAP).[44] This widespread enzyme preferably hydrolyzes the peptide bond of N-terminal leucine in a peptide chain and plays a central role in the degradation and modification of proteins.[9a,45,46] Most proposed catalytic mechanisms have assumed that the terminal amino group of the peptide binds to Zn2 and that the OH acts as the nucleophile,[46,47] but a QM/MM study predicted an unreasonably high calculated barrier for nucleophilic attack.[48] A more recent DFT study then demonstrated that an additional water molecule can be introduced by way of the water channel above Zn1 and may undergo facile insertion into the Zn–OH–Zn unit to result in an $O_2H_3$ bridge (Scheme 5). Since an additional water molecule may be spontaneously incorporated at Zn1, this scenario has been described as the formation of a water sluice in the *bl*LAP active site, providing a plausible mechanism for the continual generation of an active nucleophile (Scheme 5).[44]

In view of this accumulating body of evidence for the relevance of a bridging $O_2H_3$ in dizinc hydrolases, it appeared particularly desirable to experimentally test the hydrolytic efficiency of this motif relative to the related Zn–OH–Zn unit.



Scheme 5. Generation of a water sluice in the active site of *bl*LAP according to recent DFT calculations.[44]

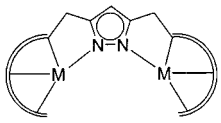
## 3. Relevance of Synthetic Model Complexes

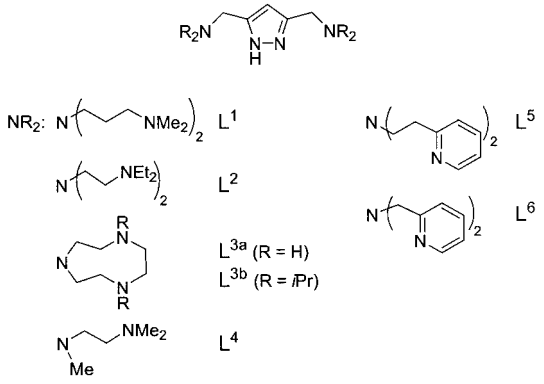
Synthetic hydrolase models have been very useful in providing information about basic functional principles and mechanistic aspects of enzyme action.[49,50] This is particularly true for the role of active-site metal ions in a specific biological donor environment, and most recent examples of hydrolase mimics even aim at elucidating second-sphere effects such as hydrogen-bonding patterns at metal-bound substrates.[51,52] As an advantage over their enzyme counterparts, small molecule synthetic analogues allow for easy systematic investigations of substituent effects, and it becomes possible to examine a variety of factors that influence reactivity.[50] Apart from the fundamental insights obtained from those biomimetic studies regarding structural, spectroscopic, and mechanistic features, there is hope that artificial nucleases for biomimetic hydrolysis of DNA or RNA will eventually lead to beneficial applications in biotechnology and medicine.[53] This has stimulated considerable efforts directed towards the development of well-designed metal complexes that mediate the hydrolytic cleavage of DNA or RNA or phosphodiester model substrates.[4,54,55] One should keep in mind, however, that no synthetic models have yet been developed that at the same time mimic all aspects of the natural enzymes, i.e., active-site structure, function and mechanism. As has been emphasized recently,[50] many structural models lack functional equivalence, while many functional models bear little structural resemblance to the enzyme active sites – a more elaborate combination of both properties in new synthetic compounds certainly is a demanding task. This is even more true for the emulation of additional factors provided by the protein matrix, such as regulation of activity, site-specific reactivity, and many more. These aspects are still far from being included in current model systems.

Successful strategies for obtaining (in a targeted manner) stable and well-defined di- and multinuclear complexes generally rely on compartmental ligand scaffolds that provide distinct binding pockets for the metal ions.[4,56] This may be achieved by incorporating proper donor sites within a single macrocyclic framework or by linking two (or more) individual ligand subunits by means of a more or less rigid spacer. The spacer itself may contain built-in donor atoms to reduce the flexibility and increase preorganization of the dinucleating scaffold; phenolate-based systems are certainly the most abundant among these. Attractive metal–metal distances usually range from 3 to 5 Å. This report will highlight a particular class of model complexes for di- and oligonuclear metallohydrolase active sites, where compartmental pyrazolate-based ligands are used as dinucleating scaffolds for nesting two metal ions (**C**).[57] The central pyrazolate unit is a reasonable compromise for mimicking bridging carboxylate donors that are widely found in nature but are difficult to incorporate into a polydentate compartmental ligand framework: just like a bridging carboxylate group, the pyrazolate provides a single negative charge and it supports a similar range of metal–metal distances.



**C**

The scope of modulating electronic and geometric characteristics of the dimetallic core by varying the ligand side arms attached to the 3- and 5-positions of the heterocycle is an attractive option for this class of ligands. Important variations comprise the type and number of side-arm donor atoms as well as the lengths of the chelate arms (Scheme 6). While the former allows for the modification of the coordination numbers and electronic structures of the metal ions, the latter controls the properties of the dimetallic pocket, including the metal–metal distance.[58–63]



Scheme 6. Selection of dinucleating pyrazolate ligands.

The comparative experimental studies summarized in this microreview focus on dizinc complexes of ligands $L^1$–$L^6$ that provide two metal-ion-binding pockets each, either tridentate ($L^4$) or tetradentate ($L^1$–$L^3$, $L^5$, $L^6$). The primary intention behind this approach is to elucidate how the mutual arrangement of two metal ions determines their cooperative reactivity. It is not aimed at exactly reproducing any biological coordination environment, but emphasis is laid on the question how two (or more) metals may work in concert in order to bind and transform biorelevant substrates. Inter alia, studies on this assortment of ligands have provided experimental evidence for the less favorable reactivity of a tightly bridging hydroxide in the clamp of a dimetal site as compared with a more loosely bridging $O_2H_3$ unit. The results also reveal some general structure–activity correlations for bioinspired di- and oligozinc hydrolase mimics. In the long term, it is anticipated that such findings will contribute to the development of two-center catalysis not only in the biomimetic but also in a broader sense.

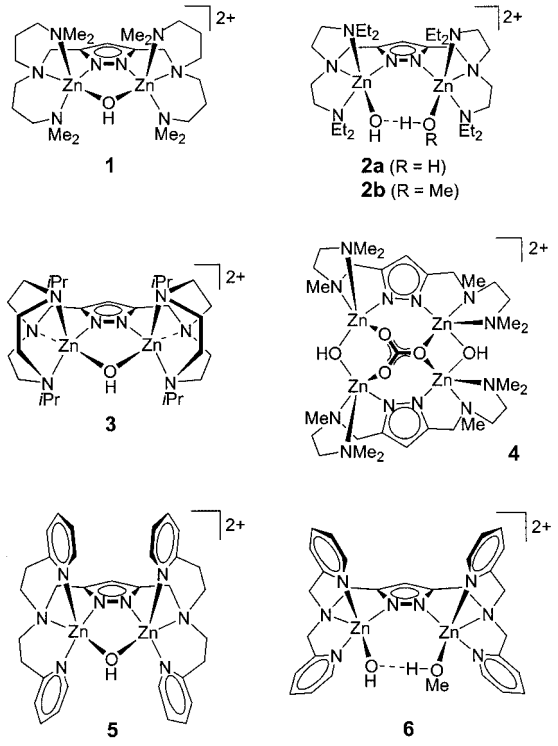
## 4. Zinc Coordination Chemistry of the Pyrazolate-Based Scaffolds

### (i) Dizinc Complexes with OH versus $O_2H_3$ Bridges

As outlined above, a dimetallic arrangement with a bridging $O_2H_3^-$ group can be described as a combination

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of both a $Zn–OH_2$ and a Zn–OH function, and hence as a hydrated form of an active terminal Zn–OH. A comparative evaluation of the hydrolytic activity of a Zn–O(H)–Zn relative to that of a Zn–(H)OHO(H)–Zn species in synthetic model chemistry was achieved with the highly preorganized dizinc complexes **5** and **6** (Scheme 7), where the metal–metal separation is controlled by the lengths of the chelating side arms.[64] Complementing information was obtained from complexes **1** and **2** that are based on the related aliphatic ligand scaffolds, but in this case the system with long side arms (forming six-membered chelate rings in **1**) exhibits rather weak $Zn^{2+}$-binding capabilities in aqueous solution, which precludes any conclusive evaluation of its hydrolytic efficiency under the appropriate conditions.[65]



Scheme 7. Assortment of crystallographically characterized pyrazolate-based zinc complexes.[64,65]

In **1** and **5** the zinc ions may come rather close together (≈3.5 Å) and allow for a bridging position of a hydroxide coligand within the dimetallic pocket. In contrast, the shorter ligand side arms in **2a/b** and **6** pull the two zinc ions back and apart, thus enforcing much longer Zn···Zn distances (>4 Å). This prevents the small hydroxide from spanning the two metal ions and induces incorporation of an additional solvent molecule, water or MeOH, to give an $O_2H_3$ (**2a**) or $O_2H_2Me$ (**2b**, **6**) bridging unit, respectively. Differences in reactivity for these species are apparent, since in acetone solution **2a** gradually absorbs $CO_2$ from air to give a carbonato-bridged complex while **1** does not.[43] Stopped-flow studies on the dinickel(II) analogues of **2a/2b** have revealed that exchange of water and methanol in these complexes is very rapid with $k_{obs} > 10^3\ s^{-1}$ at room temperature.[66] The lability of the $Zn–H_3O_2–Zn$ bridge has been corroborated by extensive DFT calculations on the mechanism of the replacement of water by methanol in pyrazolate-based complexes of types **2** and **6** to successively give the Zn-bound HO–H–OMe and MeO–H–OMe functionalities (by an endothermic process).[67] The replacement can occur through two fundamentally different substitution mechanisms: an addition-elimination, controlled by the metal ions, and a direct exchange in which the metal ions serve as a template. Since the steric bulk and the stiffness of the ligands in **2a** and **6** prevent an easy expansion of the coordination sphere, only the direct exchange mechanism is possible for these systems. Nevertheless, barriers for the conversion of the HO–H–OH, HO–H–OMe, and MeO–H–OMe bridges are low enough (lower for **6** than for **2**) to enable a rapid equilibrium under experimental conditions. Comparing the different functionalities, the HO–H–OH form is clearly less nucleophilic than the methoxide form MeO–H–OMe, but the hydroxide in the mixed species HO–H–OMe is more nucleophilic than the methanol component.[67]

Fewer short side arms provided by the ligand in **4** allow for greater flexibility of the Zn···Zn distance and offer additional coordination sites for substrate binding. At neutral to basic pH, the dizinc complex **4′** formed in situ from $L^4$ and $Zn(ClO_4)_2$ was found to readily absorb $CO_2$ from air to give tetranuclear **4**, where two $\{L^4H_{-1}Zn_2\}$ subunits are linked by two hydroxide bridges and the resulting rectangle of four zinc ions is capped by a $\mu_4$-carbonate.[68]

Unexpectedly, a bridging hydroxide was detected crystallographically in **3**,[65] despite the short ligand side arms that were assumed to induce a situation similar to the corresponding dinickel(II) complex **2a**. This can be traced to the ability of zinc(II) to adopt a {4+1} coordination with two significantly elongated backside bonds between zinc and the bridgehead-N in **3**. However, the dinuclear scaffold in **3** appears to be somewhat strained and it is assumed that the bridging hydroxide in **3** more easily adopts a semibridging or even nonbridging position in solution than the tightly bound hydroxide in **1** and **5**. Unfortunately, no crystallographic information is yet available for $[L^{3a}Zn_2(OH)(H_2O)_x]^{2+}$.

### (ii) p$K_a$ of the Zn-Bound Water

While the X-ray crystallographic results provide structural insight for the various complexes, knowledge of the species distribution in aqueous solution is crucial for understanding their hydrolytic reactivity. Species distributions of ligands $L^1$–$L^6$ in the presence of $Zn^{2+}$ have been determined by potentiometric titrations and have revealed the existence of various mononuclear and dinuclear complexes depending on the pH, except for the case of $L^1$, where only mononuclear species are formed in the pH range 4–7 and precipitation of zinc hydroxide is observed at higher pH.[64,65,69,70] As expected, ligands that form six-membered chelate rings generally provide lower complex stability than the corresponding systems that form five-membered chelate

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rings, and complexes with pyridyl-containing ($L^5$, $L^6$) or triazacyclononane-derived ligands ($L^{3a}$, $L^{3b}$) give more stable complexes than the corresponding open-chain aliphatic scaffolds ($L^1$, $L^2$, $L^4$). The species distribution diagram of $L^{3a}/Zn^{2+}$ differs somewhat from that of the system $L^{3b}/Zn^{2+}$, supporting a significant effect of the outer side-arm substituents.[65,70] For all ligands except $L^1$, the dominant species above pH ≈ 8 is $[(LH_{-2})Zn_2]^{2+}$, which most likely represents the complex structures **2a**, **3**, **5**, or **6** observed in the solid state. The species $[(LH_{-2})Zn_2]^{2+}$ is thus better described as $[(LH_{-1})Zn_2(OH)]^{2+}$ or $[(LH_{-1})Zn_2(O_2H_3)]^{2+}$. The $pK_A$ of the zinc-bound water can be extracted from the titration data, and values obtained for $[(LH_{-1})Zn_2(OH_2)_x]^{3+}$ (L = $L^2$ – $L^6$) are collected in Table 1.

Table 1. $pK_A$ values for the deprotonation of Zn-bound water in dizinc complexes $[(LH_{-1})Zn_2(OH_2)_x]^{3+}$ to give $[(LH_{-1})Zn_2(OH)(OH_2)_{x-1}]^{2+}$.[64,65,69,70]

| Species | $L^1$ | $L^2$ | $L^{3a}$ | $L^{3b}$ | $L^4$ | $L^5$ | $L^6$ |
|---|---|---|---|---|---|---|---|
| $pK_A$ | – | 7.57 | 8.29 | 8.04 | 7.66 | 7.96 | 7.60 |

All $pK_A$ values are clearly lower than the $pK_a$ of $[Zn(H_2O)_6]^{2+}$ (8.96)[71] and lower than most $pK_A$ values of zinc-bound water in five-coordinate mononuclear zinc complexes with tetradentate tripodal ligands. The $pK_A$ values 8.29, 8.04, and 7.96 for $[(L^{3a}H_{-1})Zn_2]^{3+}$, $[(L^{3b}H_{-1})Zn_2]^{3+}$, and $[(L^5H_{-1})Zn_2]^{3+}$, respectively, appear to be relatively high for bridging water in dinuclear zinc(II) complexes, which is often found to have $pK_a$ values below 8. However, a similar $pK_A$ of 8.0 for metal-bound water has been determined for the dizinc complex of the dinucleating ligand comprising two tacn subunits tethered by a bridging alkoxide.[72] The mononuclear complex $[(Me_3tacn)Zn(OH_2)_3]^{2+}$ ($Me_3tacn$ = 1,4,7-trimethyl-1,4,7-triazacyclononane) is much less acidic ($pK_A$ ≈ 10.8), which has to be attributed (at least in part) to its higher coordination number.[73] Comparison is more straightforward for the system $L^6/Zn^{2+}$, since $[(tpa)Zn(OH_2)]^{2+}$ {tpa = tris(pyridylmethyl)amine} can be viewed as a mononuclear analogue of $[(L^6H_{-1})Zn_2(OH_2)_x]^{3+}$.[60] The $pK_a$ of $[(tpa)Zn(OH_2)]^{2+}$ is 8.03,[74] clearly indicating a certain increase in acidity due to the dinuclear arrangement in **6** that induces formation of the $O_2H_3$ bridge.

As the most interesting result of these considerations, it should be noted that involvement in strong hydrogen bonding (such as in the $O_2H_3$ bridge) can cause an even more drastic decrease in the $pK_A$ of Zn-bound water than incorporation of the resulting hydroxide in a bridging position between two zinc ions, as is evident from a comparison of the values of $pK_A$ = 7.60 for $[(L^6H_{-1})Zn_2(OH_2)_x]^{3+}$ and $pK_A$ = 7.96 for $[(L^5H_{-1})Zn_2(OH_2)_x]^{3+}$.[64] The same holds true for the corresponding pyrazolate systems with aliphatic N-donor side arms, where $pK_A$ = 7.57 for $[(L^2H_{-1})Zn_2(OH_2)_x]^{3+}$, $pK_A$ = 8.29 for $[(L^{3a}H_{-1})Zn_2(OH_2)_x]^{3+}$, and $pK_A$ = 8.04 for $[(L^{3b}H_{-1})Zn_2(OH_2)_x]^{3+}$.[65,69,70] These findings clearly demonstrate that a bridging position of water (or the resulting hydroxide) is *not* required for sufficiently lowering its $pK_A$ to give a zinc-bound hydroxide at physiological pH, since this increase in acidity may well be achieved by the appropriate hydrogen-bonding pattern such as that found in the intramolecular $O_2H_3$ bridge.[64,65] Similar conclusions have also been reached for the influence of hydrogen bonding in mononuclear zinc hydroxide systems.[75] This observation supports the view that the $O_2H_3$ unit is an attractive structural and possibly functional motif in oligozinc enzyme chemistry.[42,43,64]

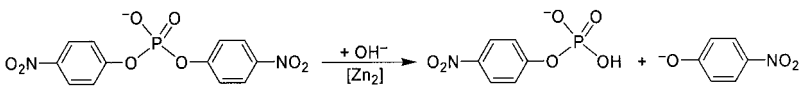
## 5. Models for Oligozinc Phosphatases

Despite the manifold studies on zinc-containing model phosphatases, there is still only limited knowledge about the intrinsic factors that govern hydrolytic activity and a lack of general structure–reactivity correlations.[72,76] The assortment of dizinc complexes described above appeared to be a promising set of systems for gaining further clues on the cooperative action of two proximate zinc atoms in biomimetic hydrolytic reactions.

### (i) Structure–Activity Correlations in Phosphate Diester Hydrolysis

Phosphatase activities of the various pyrazolate-based dizinc complexes have been evaluated in 1:1 DMSO/aqueous buffer (or pure water in the case of the $L^{3a}/Zn^{2+}$ system[77]), by using sodium bis(4-nitrophenyl) phosphate (sodium bnpp) as a test substrate (Scheme 8). Differences among the series of complexes gave valuable insights into structure–activity correlations and allowed for the experimental assessment of the hydrolytic efficiency of a bridging versus pseudo-terminal Zn-bound hydroxide.[64,65] Instead of crystallographically characterized **4**, dinuclear species $\{L^4H_{-1}Zn_2\}$ (**4′**) prepared in situ from $L^4$ and 2 equiv. $Zn(ClO_4)_2 \cdot 6H_2O$ was used without isolation of the complex in order to avoid any possible active-site inhibition by the carbonate.

Since **1** is not stable in aqueous solution, results for this complex are not meaningful. For all other systems (**2**, **3**, **4′**, **5**, **6**), the rate of BNPP hydrolysis was linearly dependent on complex concentration, in agreement with pyrazolate-based dizinc active species. Pseudo-first-order rate constants $k_{obs}$ (defined by $v_0 = k_{obs} \cdot [complex]_0$) at pH 8.28 are collected in Figure 1, showing drastic differences between the complexes. Except for **2**, inspection of the pH-depen-



Scheme 8. Phosphodiesterase model reaction with BNPP test substrate.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dence of $k_{obs}$ revealed that the sigmoidal increase in hydrolysis rate at higher pH generally coincides with the formation of species $[LH_{-1}Zn_2(OH)(H_2O)_x]^{2+}$ featuring the Zn-bound hydroxide. This clearly established that deprotonation of the $Zn–OH_2$ function is required for hydrolytic activity, in accordance with findings for other phosphatase model systems. Only in the case of **2** did the species $[LH_{-1}Zn_2(OH)(H_2O)_x]^{2+}$ turn out to be inactive, which was interpreted in terms of a bidentate substrate binding within the dimetallic pocket that replaces the Zn-bound hydroxide and leaves no accessible coordination sites for activation of the water nucleophile (compare also results for phosphate ester binding summarized below).[65] Taking into account the individual species distributions and the predominance of the active species at the relevant pH, a more reliable comparison with reference to the true second-order rate constants $k_{bim}$ that included the percentage factor for the $[LH_{-1}Zn_2(OH)(H_2O)_x]^{2+}$ species at pH 8.28 is also given (Figure 1). Trends are qualitatively similar to those for the $k_{obs}$ values, with the order of activity **4′** > **6** > **5** > **3**.

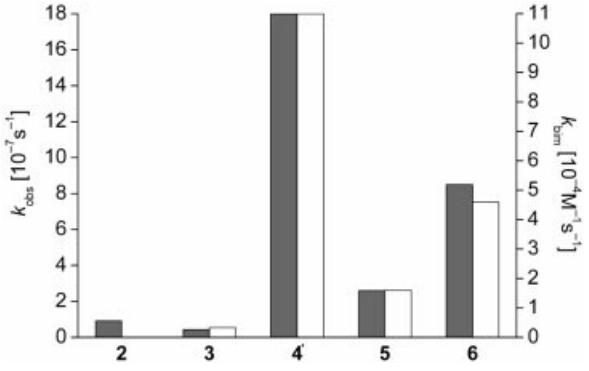


Figure 1. Comparison of rate constants $k_{obs}$ (dark) and $k_{bim}$ (light) for BNPP hydrolysis at pH 8.28 mediated by the different pyrazolate-based dizinc complexes.

Direct comparison of **5** and **6** proved most insightful and allowed us to draw valuable conclusions regarding the relative hydrolytic efficiencies of the Zn–OH–Zn and Zn–$O_2H_3$–Zn functions, since both **5** and **6** are fully stable under the experimental conditions and have closely related dimetallic core structures. The effect of substrate concentration on the initial hydrolysis rate suggested a substrate-binding pre-equilibrium, and a Michaelis–Menten type analysis gave almost identical $K_M$ values of 51 ± 5 mM and 56 ± 4 mM, but very distinct $k_{cat}$ values of $(0.49 \pm 0.04) \times 10^{-5}$ $s^{-1}$ and $(2.3 \pm 0.1) \times 10^{-5}$ $s^{-1}$ for **5** and **6**, respectively. Evidently, it is not the initial substrate binding, but the subsequent intrinsic reactivity at the dizinc core that makes the difference, leading to an almost fivefold higher hydrolytic activity for **6**. Although any further interpretation was hampered by the lack of structural information for the intermediate {complex–substrate} adducts, these data strongly support the view of the Zn–$O_2H_3$–Zn moiety as a favorable functional unit in dizinc enzyme chemistry.

After a single turnover, BNPP hydrolysis by any of the dizinc complexes **3**–**6** became much slower or even stopped completely. This has to be attributed to inhibition by the formed phosphate monoester (which is a much stronger ligand), and structural insight for the phosphate inhibited dizinc sites was obtained from isolated product-bound complexes (see below). In methanol, however, catalytic transesterification was observed to sequentially give the mixed diester methyl 4-nitrophenyl phosphate and dimethyl phosphate (dmp).[64] While the first transesterification step again occurred much faster when mediated by **6** as compared to **5**, the opposite was true for the second step. Apparently, complex **6** is intrinsically more active, but on the other hand, inhibition is also more pronounced for the system with the larger Zn···Zn distance. On the basis of structural insight for the two dizinc complexes with bound DMP as well as NMR studies, the differences in inhibition could be rationalized and traced to stronger DMP binding in the dimetallic clamp of **6**: while the larger Zn···Zn separation enforced by the ligand scaffold $L^6$ is perfectly suited to accommodate the bridging O–P–O moiety of DMP, ligand $L^5$ favors much shorter Zn···Zn distances.[64] Hence the pyrazolate-based dizinc arrangement in **5** has to be distorted drastically to host the DMP bridge (Figure 2), resulting in a much decreased DMP binding affinity. This may hint towards a suitable strategy to avoid the latent problem of product inhibition in synthetic dizinc hydrolase models.

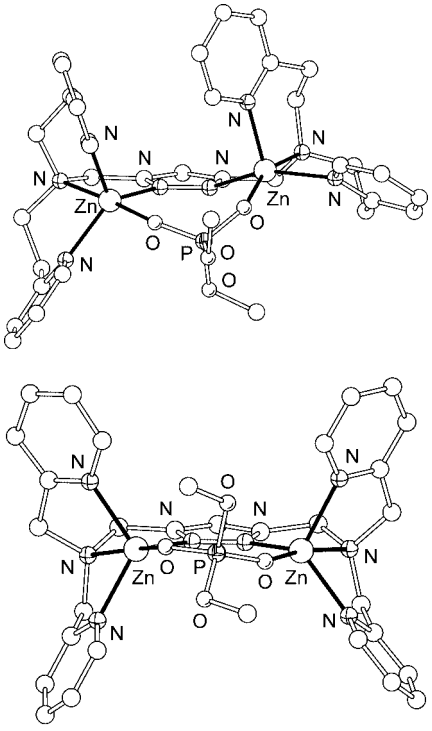

Figure 2. Molecular structures of $[L^5H_{-1}Zn_2(dmp)]^{2+}$ (top) and $[L^6H_{-1}Zn_2(dmp)]^{2+}$ (bottom) illustrating the much greater distortion of the dizinc scaffold in the former case.

As was also stated for the related complex $[L^{3a}H_{-1}Zn_2(OH)(H_2O)_x]^{2+}$,[77] it can be concluded that the pyrazolate-based dizinc complexes show many typical features of a metalloenzyme, such as formation of a substrate complex, activation of the substrate through coordination, preorganiza-

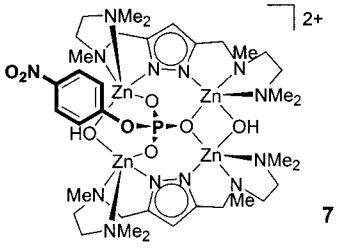
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion of the substrate and the nucleophile, and inhibition by the product.

### (ii) Dizinc Scaffolds with Bound Phosphate

The same *O*,*O*′-bridging DMP coordination mode shown in Figure 2 has been detected crystallographically in complexes $[L^2H_{-1}Zn_2(dmp)]^{2+}$, $[L^4H_{-1}Zn_2(dmp)(NO_3)_2]^{2+}$, $[L^5H_{-1}Zn_2(dmp)]^{2+}$, and $[L^6H_{-1}Zn_2(dmp)]^{2+}$, with Zn···Zn distances between 4.2 and 4.4 Å.[64,65] A similar binding mode was also observed for diphenyl phosphonate (dpp) in the related dicopper(II) complex $[L^{3a}H_{-1}Cu_2(dpp)]^{2+}$, while a $\mu_4$-κ*O*:κ*O*′:κ*O*′′:κ*O*′′′ phosphate was found in $[(L^{3a}H_{-1}Cu_2)_2(PO_4)]^{3+}$.[70] It should be noted that structures with bidentate bridging DMP are reminiscent of the proposed phosphate ester binding in the dizinc active sites of various metallohydrolases[78] and mimic a crucial intermediate in the phosphotriesterase mechanism (compare Scheme 1).[15]

ESI mass spectrometry confirmed the weak binding of BNPP, but significantly stronger coordination of the first hydrolysis product 4-nitrophenyl phosphate (npp), as well as of DMP. Active-site inhibition of the most active complex **4**′ by NPP was visualized in the structure of the complex $[(L^4H_{-1}Zn_2)_2(OH)_2(npp)]^{2+}$ (**7**; Scheme 9), where the NPP caps a rectangle of four zinc ions and blocks all accessible coordination sites.[65] Accordingly, only 0.5 equiv. BNPP is hydrolyzed per $\{L^4H_{-1}Zn_2\}$ (**4**′).



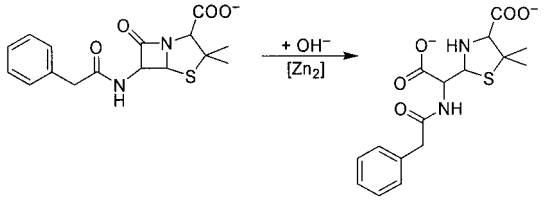
Scheme 9. Complex derived from inhibition of **4**′ by 4-nitrophenyl phosphate.[65]

## 6. Models for Dizinc Metallo-β-lactamases

Despite the extensive work on synthetic metallohydrolase models, very few studies have employed preorganized dinuclear zinc(II) complexes as functional mimics of metallo-β-lactamases.[79–81] Such model studies may contribute valuable insights into the mechanistic roles and cooperative effects of the proximate metal ions in that important class of enzymes and the identity of the active nucleophile. Furthermore, isolated adducts between synthetic dizinc scaffolds and β-lactam compounds or their ring-opened derivatives should provide clues to possible substrate binding modes.

### (i) Penicillin G Hydrolysis

Several pyrazolate-based dizinc complexes turned out to be active mediators for the hydrolytic cleavage of penicillin G. Following the time course of penicillin G hydrolysis promoted by **1**, **2a**, **5**, and **6** with in situ FTIR spectroscopy revealed drastic differences in activity (Scheme 10, Figure 3).[80]



Scheme 10. Hydrolytic cleavage of penicillin G mediated by the dizinc complexes.

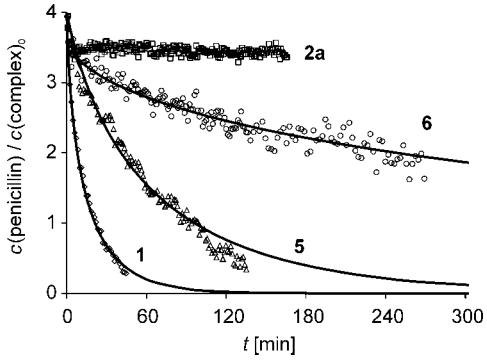


Figure 3. Time course of penicillin G hydrolysis in DMSO/water (9:1) in the presence of the different dizinc complexes.[80]

Unexpectedly, hydrolytic efficiency is much greater for systems **1** and **5**, which feature a shorter Zn···Zn separation and a bridging hydroxide in their resting state, while complex **2a** is not active at all, and **6** is still less efficient than free $Zn^{2+}$. Mass spectrometry in combination with NMR and IR spectroscopy indicated predominant coordination of the β-lactam antibiotics through their carboxylate group, whereas involvement of the β-lactam C=O in metal coordination could not be unambiguously deduced from the spectroscopic data, in agreement with findings for other dizinc metallo-β-lactamase model systems.[79] NMR experiments of the reaction mixtures suggested an explanation for the much greater hydrolytic activity of **1** and **5** relative to **2a** and **6**: after substrate binding through the carboxylate anchor with replacement of the Zn-bound hydroxide (compare the structure of **9** shown below), only in the case of the six-membered chelate rings in **1** and **5** do the labile side-arm N-donors tend to dissociate to generate an accessible coordination site and to allow for the binding and activation of the water nucleophile. In contrast, the five-membered chelate rings in **2a** and **5** impart much higher stability, rendering any detachment of the ligand side arms less likely. Hemilability of the longer side arms in related pyrazolate-based dimetal complexes could also be confirmed structurally in several cases.[59a,62a,80] These observations underline the necessity for the activation of both the substrate and the nucleophile through zinc coordination, which requires suitably designed dimetallic scaffolds that offer sufficient and properly oriented binding sites.

### (ii) Structural Characterization of Dizinc β-Lactam Adducts

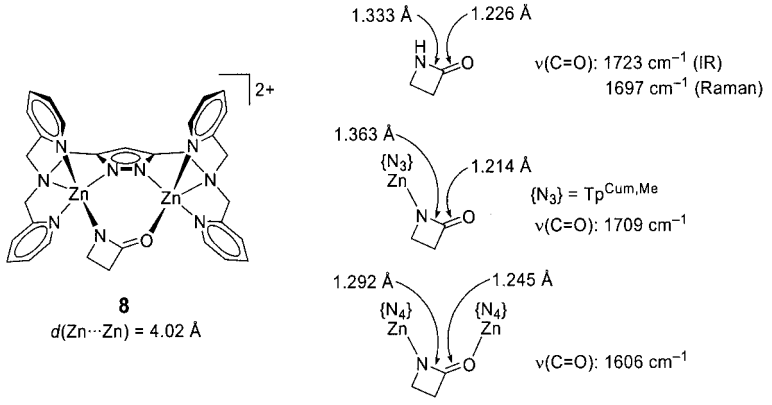
Unfortunately, it was not possible to isolate any adduct between a dizinc complex and the penicillin substrate or its ring-opened product in crystalline form suitable for X-ray diffraction. In order to obtain structural insight into β-lactam binding at dizinc sites, we therefore turned to smaller substrate analogues featuring different levels of structural simplification as compared to penicillin. The most simple choice is 2-azetidinone, which is readily incorporated into the dimetallic pocket of some of the pyrazolate-based dizinc complexes, giving lactamide-bridged complexes such as **8** (Scheme 11).[82]

Comparison of the IR spectroscopic and metric characteristics of the N-deprotonated lactamide with those of free azetidinone,[83,84] and the β-lactamide subunit of a mononuclear $Tp^{Cum,Me}$Zn(β-lactamido) complex [Scheme 11; $Tp^{Cum,Me}$ = tris(3-cumyl-5-methylpyrazolyl)borate][85] was informative: in the latter system the β-lactamide is solely bound by its N atom to a single zinc ion, which reduces conjugation within the amide moiety and hence leads to lengthening of the C–N bond and a slight shortening of the C=O bond. Binding of a second zinc ion to the β-lactamide-O as observed in complex **8** reverses this trend, i.e. the C–N bond is shortened and the C=O bond is clearly elongated. In line with these structural findings, the β-lactam ν(C=O) stretch in $Tp^{Cum,Me}$Zn(β-lactamido) at 1709 $cm^{-1}$ is barely shifted from those of free 2-azetidinone, while the ν(C=O) vibration of **8** appears at much lower frequency. These findings underline the particular ability of highly preorganized dinuclear scaffolds to accommodate and polarize small substrate molecules within their dimetallic binding pocket, which is quite distinct from activation at a single metal ion.

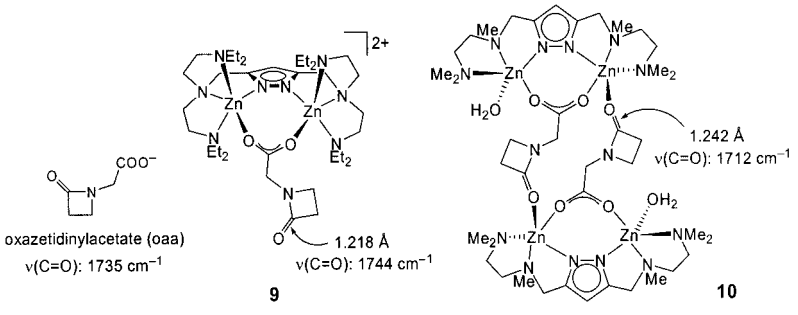
2-Azetidinone is apparently unsuited as a model substrate with regard to penicillin binding at a dizinc site because coordination of the deprotonated β-lactam-*N* is undesired. N-substituted oxazetidinylacetate (oaa; Scheme 12) proved more appropriate, since that also incorporates the carboxylate group in an α position to the β-lactam-*N*. The carboxylate of penicillin G was identified spectroscopically as the primary anchoring group for substrate binding at the dizinc scaffolds, and the same applies to complexes of oaa, e.g. in structurally characterized **9**.[80]

Interestingly, additional coordination of the β-lactam-*O* does occur if the ligand scaffold provides fewer side arms and hence leaves accessible sites at the metal ion. The tetrametallic complex **10** represents the first system for which binding of a β-lactam-*O* has been verified crystallographically. The C=O bond in **10** is markedly lengthened relative to **9**, and the ν(C=O) stretch is found at a significantly lower frequency (Scheme 12). Such polarization is usually assumed to activate the amide moiety for nucleophilic attack.

While the structural findings confirm that for β-lactam antibiotics (or related β-lactam derivatives) binding of zinc to the carboxylate group is favored over binding to the β-lactam function, coordination of the β-lactam amide-O may still be induced under suitable circumstances or upon proper orientation of the substrate within the binding



Scheme 11. (β-lactamido)zinc systems.



Scheme 12. Binding of oxazetidinylacetate (oaa).[80]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pocket, and this leads to significant changes of the internal geometry of the β-lactam moiety, which are likely to facilitate subsequent hydrolytic ring cleavage. It is plausible that electrostatics contributes significantly to the preferential binding of an anionic carboxylate to the highly charged pyrazolate-based dizinc scaffolds $\{LZn_2\}^{3+}$, but a lower positive charge of the dizinc arrangement or involvement of the carboxylate in interactions with positively charged protein residues or in strong hydrogen bonding within the enzyme active site may well alter the binding preference in favor of the neutral β-lactam amide moiety.

## Concluding Remarks

The studies summarized above demonstrate how the investigation of well-designed synthetic model complexes may afford clues to the understanding of substrate transformations at metalloenzyme active sites. The compartmental pyrazolate-based ligand scaffolds have the distinct advantage of easy tuning of essential parameters in the dimetallic core – such as the metal–metal separation – which have a decisive effect on reactivity. A bridging position of water (or the resulting hydroxide) between the two zinc ions is not required for sufficiently lowering its p$K_a$, but proper hydrogen bonding of the pseudo-terminal Zn–OH, such as the one in the $Zn–O_2H_3–Zn$ function, does the job and at the same time may result in higher nucleophilicity of the Zn-bound hydroxide. Comparative functional studies on the phosphodiesterase activity of an assortment of pyrazolate-based dizinc complexes provided experimental support for a possible functional role of the $Zn–O_2H_3–Zn$ motif and structural insight into phosphate ester binding at dimetal sites. Similarly, some structure–activity correlations could be deduced for penicillin hydrolysis at bioinspired dizinc sites, and first crystallographic evidence for coordination and activation of a β-lactam could be obtained. Future directions in the development of synthetic analogues of dizinc enzymes will comprise, inter alia, the incorporation of functional groups that emulate mechanistically important protein residues in the vicinity of the active site.

## Acknowledgments

Our work in the field of metallohydrolase models has been supported by the DFG, the German Academic Exchange Service (DAAD) and COST D21. Close collaborations with Dr. E. Farkas (Debrecen/Hungary) within the working group 0001 of the COST D21 program has been particularly beneficial for these studies.

# Kinetics and Thermodynamics of Halide and Nitrite Oxidation by Mammalian Heme Peroxidases

**Jürgen Arnhold,[a] Enrico Monzani,[b] Paul G. Furtmüller,[c] Martina Zederbauer,[c] Luigi Casella,[b] and Christian Obinger*[c]**

**Keywords:** Bioinorganic chemistry / Peroxidases / Halides / Nitrites / Thermodynamics / Kinetics

The human heme peroxidases myeloperoxidase (MPO), eosinophil peroxidase (EPO) and lactoperoxidase (LPO) are able to oxidise (pseudo)halides and nitrite to reactive species that participate in host defence against foreign microorganisms as well as in immunomodulation and tissue degradation in certain pathologies. The heme in EPO and LPO is covalently linked to the apoprotein by two ester bonds, whereas in MPO it is additionally linked by a unique sulfonium ion bond to a methionine residue. As a consequence, the prosthetic group in MPO is significantly distorted from a planar conformation. These structural differences are reflected by distinct spectral and redox properties as well as reactivities toward chloride, bromide, iodide, thiocyanate and nitrite, which function as endogenous two- and one-electron donors for these enzymes in vivo. Standard reduction potentials at pH 7 have been determined for all redox couples involved in the halogenation and peroxidase cycle of MPO and LPO and partially of EPO. A detailed thermodynamic analysis of the formation of reactive halide species by MPO and EPO was also performed. Thus, for the first time, a comprehensive analysis of reactions catalysed by human heme peroxidases is presented that allows a better understanding of their role in physiological and pathophysiological processes.

## Heme Peroxidases

Peroxidases are iron-containing enzymes that have been used in a great number of analytical and technical applications[1] since they are able to catalyze one- and two-electron oxidation reactions of inorganic and organic compounds with hydrogen peroxide. Physiologically, these enzymes are not only responsible for protection against harmful side-effects of oxygen metabolism but are also involved in a variety of biosynthetic and degradative functions related to the consumption of hydrogen peroxide. Today we know, as result of gene and genome sequencing and increasing data deposited in protein data banks, of two heme-containing peroxidase superfamilies, namely the superfamily of plant, fungal and bacterial peroxidases[2] and the superfamily of animal peroxidases.[3] The physiological importance of these metalloenzymes is underlined by the fact that higher organisms often contain a high number of genes encoding peroxidases. For example, in *Arabidopsis thaliana*, the first plant for which the whole genome has been sequenced, 73 full-length genes encoding classical plant peroxidases[4] and several genes encoding so-called ascorbate peroxidases[5] have been identified in the genome. Moreover, the diversity in structure and function can be further increased by variations in gene transcription and translation resulting in the fact that one single gene can encode several multiple forms of a protein or enzyme.

In the human genome there are only four genes encoding for homologous heme peroxidases known as myeloperoxidase (MPO), eosinophil peroxidase (EPO), lactoperoxidase (LPO) and thyroid peroxidase (TPO), which are members of the animal peroxidase superfamily. MPO, EPO and LPO are functionally homologous enzymes closely involved in host defence. MPO is secreted at inflammatory sites from stimulated polymorphonuclear leukocytes and also monocytes,[6] while EPO is released from activated eosinophils.[7] LPO is found in mucosal surfaces and exocrine secretions such as milk, tears and saliva.[8] In contrast, TPO is involved in the biosynthesis of the thyroid gland hormones thyroxine and triiodothyronine.[9]

Closely related with the physiological role is the nature of the substrates oxidized by human peroxidases. These enzymes prefer small anionic molecules as electron donors, such as halides (chloride, bromide, iodide), thiocyanate and nitrite. The corresponding oxidation products, for example

hypohalous acids or nitrogen dioxide, are responsible for killing microorganisms[6,10] or in iodination of tyrosine residues of thyroglobulin in hormone syntheses.[9] However, since many of these reaction products are (strong) halogenating and nitrating oxidants, they also contribute to tissue injury in certain inflammatory diseases.[11] Moreover, certain products of the halogenating activity of peroxidases are known to function as immunomodulators such as taurine chloramine[12] and hypothiocyanite.[13]

These functional features are closely related with the peculiar structural and redox properties of these heme proteins. Recently, the standard reduction potentials of the redox couple compound I/ferric enzyme for MPO, EPO and LPO, as well as compound II/ferric enzyme and compound I/compound II for MPO and LPO have been determined.[14–16] With this knowledge, it is now possible to relate much better data on (pseudo)halide and nitrite oxidation to the structural and functional properties of perox-

*Juergen Arnhold graduated from the Biophysical Department of the Biological Faculty of the Lomonossow State University Moscow in 1974. Since that time he has been working at the Institute of Medical Physics and Biophysics of the University of Leipzig, Germany, where he got his PhD degree in 1982 and habilitated in 1997. In 2003, he obtained the degree of an associate professor. His research interests concern the study of chemical processes during oxidative stress in biological systems, lipid peroxidation reactions, as well as chemistry and biochemistry of myeloperoxidase and other heme peroxidases. He is also a specialist for the physiology of neutrophilic granulocytes and oxidative damage of biomaterials during inflammation. Prof. Arnhold's studies have resulted in about 150 scientific publications.*

*Enrico Monzani was born in Locate Triulzi (Milano). He received his degree in Industrial Chemistry at the University of Milano in 1991 and his Ph.D degree in Chemistry at the University of Pavia in 1994. He did post-university training at the enzymology laboratory of the "Istituto di Ricerche Farmacologiche Mario Negri", Milano. From 1997 he obtained a permanent position as Research Associate in Inorganic Chemistry at the University of Pavia. His research interest is in the field of Bioinorganic chemistry, in particular on the structural and functional characterization of heme and copper proteins, covering both studies on the macromolecules and on the low molecular weight model systems.*

*Paul G. Furtmüller was born in 1965. He studied Biotechnology and Food Sciences at the University of Natural Resources and Applied Life Sciences in Vienna and obtained his M.Sc. degree in 1997. Then he reached his Ph.D. in Biochemistry in 2000 with Prof. Obinger at the same University, where he got in 2001 a position as a Research Assistant. During his Ph.D, in 1999, he was a Visiting Scientist at the University of Alberta with Prof. H. Brian Dunford, where he studied halide oxidation by myeloperoxidase. His main scientific interests are structure-function relationships of heme peroxidases.*

*Martina Zederbauer was born in Klagenfurt in 1967. After working as designer she studied Food Sciences and Biotechnology at the BOKU – University of Natural Resources and Applied Life Sciences in Vienna. At the moment she is finishing her PhD on "The Role of Heme to Protein Linkages in Catalysis of Human Myeloperoxidase".*

*Luigi Casella was born in Milano in 1947. He obtained his degree in Chemistry from the University of Milano in 1973. In the period 1978-1979 he was a postdoc with J.A. Ibers at Northwestern University, Evanston (USA) with a CNR-NATO fellowship. Since 1990 he is full professor of Inorganic Chemistry at the Faculty of Sciences of the University of Pavia. He has been the Chairperson of the European COST Chemistry Action D21 "Metalloenzymes and chemical biomimetics". His scientific interest is the chemistry of metal enzymes containing heme or copper cofactors involved in oxidative processes. He is the author of more than 150 papers in international chemical and biochemical journals and an international patent.*

*Christian Obinger was born in Salzburg in 1962. He obtained his degree in Chemistry and Biochemistry from the University of Vienna in 1988 and his Ph.D degree in 1992. In 1992 he obtained a position as research assistence at the Department of Chemistry at BOKU – University of Natural Resources and Applied Life Sciences. In 1995 he did postdoc training with Peter Nicholls at the Brock University in Canada and got his habilitation in 1999. He is associate professor in biochemistry and interested in the enzymology of iron- and copper-containing enzymes. He hosted two meetings on plant-type and mammalian peroxidases and was coordinator of a COST group within the Action D21 "Metalloenzymes and chemical biomimetics". He is the author of more than 90 papers in international journals.*

idases. This review summarises the present knowledge on halide and nitrite oxidation by MPO, EPO and LPO from the viewpoint of biophysical chemistry and compares their halogenation and nitration activity with respect to the modification of functional sites in proteins.

## Active Site of Mammalian Peroxidases

Among the mammalian peroxidases only the 3D structure of MPO is known. The structure of human MPO at 2.3 Å resolution was obtained and this structure has been refined at 1.8 Å, using X-ray data recorded at –180 °C.[17] Each half of dimeric MPO contains one iron, which is present as covalently bound heme. Besides differences in the overall structure, the mode of heme binding in animal peroxidases is the most significant structural difference to plant-type peroxidases, which have the heme not covalently attached to the protein. In MPO and other animal peroxidases, the methyl groups on pyrrole rings A and C of the protoporphyrin IX derivative are modified to allow formation of ester linkages with the carboxyl groups of Glu242 and Asp94. In addition, the β-carbon of the vinyl group on pyrrole ring A in MPO forms a covalent bond with the sulfur atom of Met243, giving rise to a sulfonium ion linkage (Figure 1, A).[17] The heme porphyrin ring is considerably distorted from planarity. Although pyrrole rings B and D are nearly coplanar, ring A and, to a lesser extent, ring C are tilted toward the distal side, resulting in a bow-shaped structure of the heme.

Unlike the two acidic residues, Met243 has no obvious equivalent in EPO, LPO or TPO,[18] although there is biochemical and biophysical evidence for a heme linkage through esters in EPO,[19] LPO[20] and TPO.[21] The uncommon manner of heme binding is responsible for the peculiar spectroscopic features[18] and redox properties of mammalian peroxidases. MPO has the largest red shift of the maximum of the Soret band in the visible spectrum among peroxidases and the highest values for standard reduction potentials of redox couples where compound I is involved. The MPO-specific sulfonium ion linkage could have the following roles: first, it serves as an electron-withdrawing substituent due to its positive charge, and, second, together with its neighbouring residue Glu242 (Figure 1, A), it appears to be responsible for the lower symmetry of the heme group and distortion from the planar conformation. The spectral properties of EPO, LPO and TPO are very similar, thereby underlining that they share an identical way of heme binding by two ester bonds.[18] All other active site residues, i.e. the proximal histidine (His336) and the heme distal site residues histidine (His95 in MPO), arginine (Arg239) and glutamine (Gln91; see Figure 1) are highly conserved in mammalian peroxidases. Moreover, the overall structure of the four representative proteins seems to be similar. There are only a small number of insertions/deletions and modelling suggests that almost all the regions corresponding to helices in MPO are well conserved in the other members of this protein superfamily.[18]

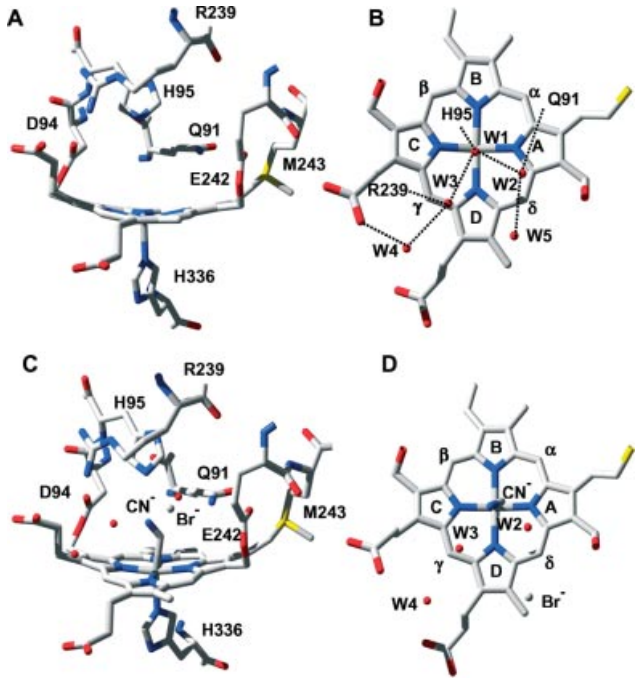

Figure 1. (A) The non-planar porphyrin ring in MPO and its covalent attachments to the protein through two ester bonds (Asp94 and Glu242) and one sulfonium linkage (Met243). The catalytic residues His95, Arg239 and Gln91 are also shown, the latter of which is important in halide binding. (B) The locations of the five water molecules in the distal heme cavity of ferric high-spin MPO. This figure was constructed using the coordinates deposited in the Protein Data Bank (accession code 1CXP). (C) The structure of the myeloperoxidase-cyanide-bromide double complex (MPO complexed with cyanide and bromide). The view in (D) is approximately normal to the heme plane. Please note that in the MPO–bromide complex the halide binds at W2, which is positioned above the δ-methine bridge carbon (i.e. the potential electron donation site of both nitrite and halides) between pyrrole rings A and D. This figure was constructed using the coordinates deposited in the Protein Data Bank (accession code 1D7W).

## Nitrite and Halide Binding

Cyanide and nitrite bind very tightly to the active site of mammalian peroxidases and convert the protein into a low-spin species. The pH dependency of cyanide binding resembles that of $H_2O_2$ in compound I formation (see below), since both require the deprotonated form of a group with a p$K_a$ of 4.0–4.3, which seems to be the distal histidine.[22–24] Following deprotonation of HCN by the distal histidine, the cyanide anion binds to the heme iron to produce an $S = 1/2$ low-spin complex. The crystal structure of the MPO–cyanide complex[25] shows that the orientation of the cyanide ion is determined by the formation of three hydrogen bonds between its nitrogen atom and the distal histidine as well as water molecules W2 and W3 (see C and D in Figure 1). Water W1 is displaced by cyanide and the heme iron moves about 0.2 Å into the plane of the heme during the transition of high-spin MPO to its low-spin form. No significant protein conformational changes are associated with cyanide binding.[25]

Similar to cyanide, nitrite binding converts ferric high-spin to low-spin MPO.[24,26] The structure of the MPO–

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$NO_2^-$ complex is unknown. However, because of the large spectral changes, one would expect that nitrite also binds directly to $Fe^{III}$ through the nitrogen atom [Equation (1)], with $PorFe^{III}$–$NO_2^-$ being the peroxidase nitrite complex.

$$PorFe^{III} + NO_2^- \leftrightarrows PorFe^{III}–NO_2^- \quad (1)$$

The pH dependency of nitrite binding resembles that of halide binding to MPO (see below). In contrast to cyanide binding, nitrite and halide binding is favoured at acidic pH and needs protonation of the distal histidine. This is shown by a significant decrease of the dissociation constant of bound nitrite upon decreasing the pH from 7.0 (2.3 mM) to 5.0 (31 μM).[24] LPO shows a much reduced affinity toward nitrite, with a dissociation constant of about 45 mM at neutral pH.[28] From the pH dependence of $NO_2^-$[24] and chloride binding,[27] the p$K_a$ value of the distal histidine was found to be around 4.3.

Halides do not bind directly to the heme iron. The structure of the MPO–bromide complex[25] demonstrates that bromide binds at the position of water molecule W2 (Figure 1, B), which is hydrogen bonded to the amide nitrogen of Gln91. Bromide binding is accompanied by small shifts of the side-chains of His95 and the heme-ester-linked Glu242 as well as of water molecules W1 and W5. Possible electrostatic interactions occur between the bromide and water molecules W1 and W5, the Nε of His95 and the amide nitrogen of Gln 91.[25] The closest heme atom to the bromide is the δ-methylene bridge carbon between pyrrole rings A and D (Figure 1). Thus, halides are typical high-spin ligands in contrast to the low-spin ligands cyanide or nitrite. As a consequence, spectral changes upon halide binding are relatively small.[18]

## The Redox Couple Compound I/Native Enzyme

Hydrogen peroxide is known to convert resting ferric heme peroxidases ($PorFe^{III}$) into compound I ($^{\cdot+}PorFe^{IV}$=O),[29] which is a porphyrin π-cation radical with an oxygen atom coupled by a double bond to iron(IV) [Equation (2)].[30]

$$PorFe^{III} + H_2O_2 \rightarrow {}^{\cdot+}PorFe^{IV}=O + H_2O \quad (2)$$

In this redox reaction, the reduction of hydrogen peroxide to water is coupled with the oxidation of ferric heme. The oxidation and reduction steps of this redox reaction consist of the two half reactions (both written as reduction process) given in Equations (3) and (4).

$$^{\cdot+}PorFe^{IV}=O + 2e^- + 2H^+ \rightarrow PorFe^{III} + H_2O \quad (3)$$

$$H_2O_2 + 2e^- + 2H^+ \rightarrow 2H_2O \quad (4)$$

As the absorption of the Soret band of heme peroxidases shows a marked hypochromicity upon formation of compound I, it is possible to monitor this fast conversion by stopped-flow spectroscopy. By monitoring the resulting absorbance change at the wavelength for which the extinction coefficient of native enzyme and corresponding compound I are known, and taking into account the standard reduction potential, $E'°$, of 1.32 V at pH 7 for the redox couple $H_2O_2/2H_2O$,[31] equilibrium concentrations of all reactants and standard reduction potentials of the couples compound I/ferric enzyme have been determined for human heme peroxidases using the Nernst equation [Equation (5)] (Table 1). An alternative approach to generate compound I of peroxidases is the use of peroxyacetic acid, which is reduced to acetate and water. The redox couple peroxyacetic acid/acetate, $H_2O$ has a standard reduction potential of 1.14 V at pH 7.[16]

$$E' = E'^{o} + (RT/nF) \ln(a_{ox}/a_{red}) \quad (5)$$

Table 1. Standard reduction potentials ($E'°$) at pH 7 of all redox couples of the peroxidase cycle of human heme peroxidases.

| Redox couple | MPO | EPO | LPO |
|---|---|---|---|
| Compound I/native enzyme | 1.16 V[14] | 1.10 V[14] | 1.09 V[16] |
| Compound I/compound II | 1.35 V[37] | n.d.[a] | 1.14 V[16] |
| Compound II/native enzyme | 0.97 V[37] | n.d.[a] | 1.04 V[16] |

[a] n. d.: not determined.

In Equation (5) $E'$ is the reduction potential of any redox couple and $E'^{o}$ is the standard reduction potential that is referred to a concentration of 1 M or a pressure of 101.3 kPa in the case of gases. The gas constant $R$ is equal to 8.31 $JK^{-1}mol^{-1}$. The temperature $T$ is conventionally set to 298 K and $n$ represents the number of electrons transferred in a single reaction step by the redox couple. The Faraday constant $F$ is 96485 $A{\cdot}s\,mol^{-1}$ and $a_{ox}$ and $a_{red}$ are the activities of the oxidised and reduced species, respectively. This method has been applied since a direct electrochemical determination of the reduction potential of the compound I/native enzyme couple is not possible due to the very high instability of compound I.

The highest $E'°$ value for the compound I/ferric enzyme couple was found to be 1.16 ± 0.01 V for MPO[14] followed by EPO and LPO, with $E'°$ values of 1.10 ± 0.01 V[14] and 1.09 ± 0.01 V,[16] respectively. These differences are apparently caused by the mode of heme-to-protein linkages described above: only in MPO, in addition to the two ester linkages that are also present in EPO and LPO, is there the unique sulfonium ion linkage at Met243 (see A and C in Figure 1), which, besides its electron-withdrawing properties, will provoke an additional distortion of the prosthetic group with the consequence of a pronounced out-of-plane structure of the iron in the resting state.[17] This uncommon way of heme binding is also responsible for the red-shift of the Soret band in MPO (430 nm), EPO (413 nm) and LPO (412 nm) compared to proteins with a more coplanar heme such as ferric hemoglobin and horseradish peroxidase (HRP).[18] The critical role of Met243 in the heme–protein interaction is underlined by site-directed mutagenesis studies. Replacement of Met243 in mutant MPO strongly affects the physical properties, substrate binding, substrate specificity and substrate oxidation of the corresponding mutants.[32] In general, Met243 variants exhibit spectral and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

catalytic properties similar to LPO and EPO, the heme of which is linked only by two ester bonds to the apoprotein.

## The Redox Couples Compound I/Compound II and Compound II/Ferric Enzyme

Compound I of heme peroxidases can be reduced by two consecutive one-electron steps to the ferric enzyme via the intermediate complex compound II [$PorFe^{IV}=O$], whereby numerous small molecular substrates, including aromatic amino acids, nitrite, indole derivatives and others, are oxidised by abstracting one electron.[24,33,34] For example, the generally accepted mechanism of nitrite oxidation involves the intermediates compound I and compound II [Equations (6) and (7)].

$$^{\cdot+}PorFe^{IV}=O + NO_2^- \rightarrow PorFe^{IV}=O + {}^{\cdot}NO_2 \quad (6)$$

$$PorFe^{IV}=O + NO_2^- + 2H^+ \rightarrow PorFe^{III} + {}^{\cdot}NO_2 + H_2O \quad (7)$$

These reactions, together with the oxidation of the ferric enzyme by hydrogen peroxide [Equation (2)], form the peroxidase cycle.

The oxidation of nitrite to nitrogen dioxide [$E'°({}^{\cdot}NO_2/NO_2^-) = 1.04$ V at pH 7][35] as well as of tyrosine to tyrosyl radical [$E'°$(tyrosyl radical/tyrosine) = 0.94 V at pH 7][36] has been used to convert compound II of MPO or LPO to the ferric enzyme and to calculate the standard reduction potentials of the redox couple compound II/ferric enzyme of these peroxidases (Table 1). Finally, the standard reduction potentials of the couple compound I/compound II have been calculated from the two other experimentally determined potentials of the peroxidase cycle (Table 1). Experimental details and calculations are described elsewhere.[15,16,37]

Significant differences were observed in the oxidation of indole derivatives by compound I and II of MPO and LPO. The rates of reduction of compound II to ferric peroxidase were similar, which is reflected by the fact that the standard reduction potentials of the redox couple compound II/ferric enzyme for MPO and LPO differ by only 0.07 V.[16,37] Higher differences, however, were found in one-electron substrate oxidation for reactions catalysed by compound I. The highest standard reduction potential of couple compound I/compound II ($1.35 \pm 0.01$ V at pH 7) was obtained for MPO.[37] The potential for this couple for LPO ($1.14 \pm 0.02$ V) is considerably lower,[16] and the corresponding potential for EPO is still unknown. As EPO exhibits more similarities to LPO than to MPO in its redox properties, it is assumed that the couple compound I/compound II of EPO has a similar $E'°$ value to LPO.

Thus, compound I of MPO is able to oxidise substrates with a reduction potential around 1.2 V and higher with sufficient rates,[38] thus underlining its extraordinary role in substrate oxidation during bacterial killing. A partial reduction of compound I of MPO to compound II is even observed in the presence of 250 mM hydrogen carbonate.[39] The redox couple $CO_3^{\cdot-}/HCO_3^-$ has a standard reduction potential at pH 7 equal to 1.78 V.[40] Assuming a very low concentration for the unstable carbonate radical, it follows from the Nernst equation [Equation (5)] that compound I of MPO is readily able to oxidise high concentrations of hydrogen carbonate.

The formation of isomeric compound I, where the radical function is transferred from the porphyrin ring to the protein moiety, is still under discussion.[18,41] The conversion from porphyryl to protein radical has been shown in MPO[42,43] and LPO[43] in the absence of good one- or two-electron donors. Apparently, this conversion can be neglected when considering the composition of the medium at inflammatory sites containing a high number of substrates being oxidised by peroxidases.

## Nitrite Oxidation by Mammalian Peroxidases

The oxidation of nitrite by its reaction with either compound I or compound II requires the formation of nitrogen dioxide [Equations (6) and (7)].[44] As has been demonstrated above, both compound I and compound II are able to perform the one-electron reaction of nitrite. Some of the rate constants for these reactions have been determined for mammalian peroxidases. Table 2 also includes, for comparative purpose, data for the plant model enzyme HRP.[44,45] Brück et al.[46] have reported that LPO compound I reacts with nitrite in a two-electron process to produce nitrate and the resting enzyme directly due to the lack of observation of the spectral features of compound II when compound I was mixed with nitrite in a stopped-flow apparatus. However, this could be due to the high rate of LPO compound II reduction by nitrite, which would prevent accumulation of compound II. Normally, the compound II spectrum dominates in a peroxidase cycle that consists of Equations (2), (6) and (7). In fact, with a sequential-mixing stopped-flow apparatus with millisecond mixing time, we have been able to observe the transient formation of LPO compound II (unpublished results) when compound I was mixed with nitrite. Unfortunately, the reaction rate constant for the reduction of EPO compound I by nitrite has not been obtained yet, although it is assumed to be much higher than that of compound II.[44k]

Table 2. Second-order rate constants for the reduction of the peroxidase intermediates by nitrite.

| Enzyme | Intermediate | pH | $k$ ($M^{-1}s^{-1}$) |
|---|---|---|---|
| LPO | compound I | 7.2 | $2.2 \times 10^7$ [46] |
| | compound II | 7.2 | $3.5 \times 10^5$ [46] |
| | compound II | 7.0 | $6.8 \times 10^4$ [16] |
| MPO | compound I | 7.0 | $(2.2 \pm 0.2) \times 10^6$ [24] |
| | compound II | 7.0 | $(5.5 \pm 0.1) \times 10^2$ [24] |
| | compound I | 5.0 | $(1.1 \pm 0.2) \times 10^7$ [24] |
| | compound II | 5.0 | $(8.9 \pm 0.6) \times 10^4$ [24] |
| EPO | compound II | 7.4 | $(5.6 \pm 0.2) \times 10^3$ [44k] |
| HRP | compound I | 6.93 | $6.7 \times 10^2$ [45a] |
| | compound II | 7.5 | $(6.6 \pm 0.4)$[44e] |
| | compound II | 7.0 | 13.3[45b] |

Generally, reduction of compound I [Equation (6)] is faster than that of compound II [Equation (7)], and this is

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

reflected by the higher redox potential for the compound I/compound II couple with respect to the compound II/native enzyme couple (Tables 1 and 2). Nevertheless, the same trend occurs with HRP (Table 2), which has a standard reduction potential of about 0.9 V for both redox intermediates.[47] This suggests that, besides the thermodynamic frame, kinetic aspects have to be taken into account. Considering Equations (6) and (7), according to the Marcus theory, there are significant differences in complexity. In compound I reduction the porphyrin cation radical has to be quenched; the rigid and highly delocalised aromatic skeleton of the macrocycle facilitates the electron transfer. In the case of MPO, it has been demonstrated that the δ-meso carbon of the porphyrin π-cation radical of compound I is most likely the electron donation site in compound I since it is located adjacent to the positively charged sulfonium ion linkage to the vinyl group attached to pyrrole ring A (Figure 1).[18,48] By contrast, reduction of the oxoiron(IV) species in compound II requires a more pronounced rearrangement; in fact, Equation (7) requires two protons for the formation of a water molecule from the oxoiron(IV) group. Furthermore, formation of the native enzyme includes a low-spin to high-spin shift that restores the out-of-plane disposition of $Fe^{III}$. The need for protons in compound II reduction by nitrite is also shown by the effect of pH on the reaction rates determined in the case of MPO (Table 2). Both reductions of compound I and compound II are controlled by an amino acid residue with a p$K_a$ value of $4.3 \pm 0.3$,[24] most likely the distal histidine, and the rates are higher at acidic pH. Reduction of compound I is approximately fivefold higher at pH 5 with respect to pH 7, whereas for compound II the ratio of the reaction rate constants at the two pH values increases by a factor of 160, thus indicating a much larger dependence on the proton concentration in the latter reaction.

## Redox Chemistry of (Pseudo)halide Oxidation by Peroxidases

Human heme peroxidases are unique among human enzymes in their ability to oxidise (pseudo)halides to (pseudo)hypohalous acids with concomitant reduction of compound I in a two-electron step to the ferric enzyme form. The overall reaction is given in Equation (8)

$$^{\cdot+}PorFe^{IV}{=}O + X^- + H^+ \rightarrow PorFe^{III} + HOX \quad (8)$$

where X denotes $Cl^-$, $Br^-$, $I^-$ or $SCN^-$. This redox process can be divided into two half-reactions, where the reduction of compound I [Equation (3)] is coupled with the (pseudo)halide oxidation ([Equation (9)], written as a reduction process.

$$XOH + 2e^- + H^+ \rightarrow X^- + H_2O \quad (9)$$

Standard reduction potentials for the redox couple XOH/$X^-$, $H_2O$ are given for pH 0 and pH 7 in Table 3. At pH 7, HOCl, HOBr and HOI exist predominantly in the undissociated form according to their p$K_a$ values (see also Table 3). Standard reduction potentials for HOCl, HOBr and HOI were originally described at pH 0. The reduction potentials of these couples decrease between pH 0 and pH 7 by about 0.03 V with increasing pH unit, as two electrons and one proton are involved in the corresponding half-reaction. Thus, the standard reduction potentials of the couples HOCl/$Cl^-$, $H_2O$, HOBr/$Br^-$, $H_2O$, and HOI/$I^-$, $H_2O$ are 1.28, 1.13 and 0.77 V, respectively, at pH 7. A further data set exists in the literature for these standard reduction potentials at pH 7;[31,49] they are about 0.20 V lower than those indicated in Table 3. These data were also originally determined from standard values at pH 0 by using, unfortunately, a wrong coefficient to consider the pH dependence.

Table 3. Standard reduction potentials [V] for two-electron oxidation of (pseudo)halides and p$K_a$ values of (pseudo)hypohalous acids.

| $X^-$ | p$K_a$ (HOX) | $E'°$(HOX/$X^-$, $H_2O$) pH 0 | pH 7 | $E'°$($X_2$/2 $X^-$) |
|---|---|---|---|---|
| $Cl^-$ | 7.53[50] | 1.49[51] | 1.28 | 1.39[52] |
| $Br^-$ | 8.8[53] | 1.33[54] | 1.13 | 1.09[55] |
| $I^-$ | 10.0[56] | 0.99[57] | 0.78 | 0.54[58] |
| $SCN^-$ | 5.3[59] | 0.82[a] | 0.56[a] | 0.72[a] |

[a] This work.

The standard reduction potential for the couple HOSCN/$SCN^-$, $H_2O$ can be calculated from the equilibrium constant of the following redox reaction [Equation (10)].

$$H_2O_2 + SCN^- \rightarrow OSCN^- + H_2O \quad (10)$$

An equilibrium constant of $3.7 \times 10^3$ $M^{-1}$ has been obtained for this reaction.[60] However, a critical re-evaluation yielded a totally different value of $5.65 \times 10^{25}$ $M^{-1}$.[61] With the latter value and $E'° = 1.32$ V at pH 7 for the couple $H_2O_2$/2 $H_2O$,[31] the unknown standard reduction potential for the couple $OSCN^-$/$SCN^-$, $H_2O$ can be determined to be 0.56 V at pH 7. With the p$K_a$ value of HOSCN (5.3),[59] a standard value of 0.82 V is obtained for this redox couple at pH 0.

Thus, the ease of oxidation of (pseudo)halide ions is the following: $SCN^- > I^- > Br^- > Cl^-$ (Table 3). In conversion of compound I to the ferric enzyme form by (pseudo)halide ions studied by rapid scan spectroscopy, the same order of sequence for the interacting (pseudo)halide has been obtained (Table 4). Only MPO compound I is able to react with chloride at pH 7.0 at reasonable rates.[42,62] It has been suggested that the experimental data for the interaction of chloride with compound I can be fitted best by a mechanism that includes a compound I–chloride complex.[62b] At low chloride concentration, the formation of the compound I–chloride complex is rate limiting, whereas at high chloride concentration its transition to ferric MPO and release of hypochlorous acid (HOCl) is rate controlling.[62b]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 4. Apparent second-order rate constants for the reactions between compound I of MPO, EPO and LPO with (pseudo)halide at pH 7 and 15 °C.

| | MPO[42] $\times 10^4$ ($M^{-1} s^{-1}$) | EPO[65] $\times 10^4$ ($M^{-1} s^{-1}$) | LPO[66] $\times 10^4$ ($M^{-1} s^{-1}$) |
|---|---|---|---|
| Chloride | 2.5 | 0.31 | – |
| Bromide | 110 | 1900 | 4.1 |
| Iodide | 720 | 9300 | 12000 |
| Thiocyanate | 960 | 10000 | 20000 |

At acidic pH compound I reduction is accelerated significantly, which is also reflected by an increase in the steady-state chlorination activity of MPO.[63] At pH 5 EPO compound I is also an oxidant of chloride (Table 4). At acidic pH, chloride binds to a protonated amino acid close to the ferryl oxygen since there is a halide-dependent change in the EPR spectrum at acidic pH.[64] Supported by the crystal structure of the MPO–bromide but not the MPO–cyanide–bromide double complex,[25] which can be regarded as a model of the compound I–halide complex, it is likely that the distal histidine, upon protonation, allows such direct interaction between chloride (but not bromide or iodide) and ferryl oxygen. In the native enzyme, bromide replaces water molecule W2, which is hydrogen bonded to the amide of Gln91 in the proximity of the Nε atom of His95 (Figure 1, B), but in the cyanide complex W2 is not displaced and bromide binds in place of W5, thereby preventing a direct H-bond interaction with protonated His95 (Figure 1, C and D).[25] Maybe the W2 site is inaccessible for larger anions like bromide or iodide when cyanide is bound to the iron. Although no crystallographic studies are available for chloride binding in the distal cavity of MPO, it is possible that the W2 position could accommodate this ion equally well in both native MPO and its cyanide complex, since chloride (1.81 Å) is significantly smaller than bromide (1.96 Å) or iodide (2.2 Å). The steric hindrance of $Br^-$ and $I^-$ to bind at the W2 position seems to be reflected by the fact that with increasing radii of the anionic substrates the increase of the rate of compound I reduction by the halide is less pronounced (Table 4).

It is important to note that EPO compound I is a much better oxidant of bromide, iodide and thiocyanate than MPO (Table 4),[65] which suggests some differences in substrate access and binding sites. LPO has been shown to have barely detectable activity with bromide at neutral pH but oxidizes iodide and thiocyanate very efficiently (Table 4).[66] Thus, in addition to redox thermodynamic properties, other factors such as anion size, anion binding and topological effects determine the effect of pH and substrate specificity of compound I reduction directly to ferric peroxidase.[18]

It has also been proposed that MPO is able to oxidise chloride to chlorine, bromide to bromine or to form the interhalogen bromine chloride (BrCl). The formation of $Cl_2$ and BrCl in myeloperoxidase-driven reactions and neutrophil suspensions has been reported in several publications.[67] In these cases, the reduction of compound I to the ferric enzyme [Equation (8)] would be coupled with halide oxidation by one of the following half-reactions [Equations (11), (12) and (13), all written as reduction process].

$$Cl_2 + 2e^- \rightarrow 2Cl^- \quad (11)$$

$$Br_2 + 2e^- \rightarrow 2Br^- \quad (12)$$

$$BrCl + 2e^- \rightarrow Br^- + Cl^- \quad (13)$$

The standard reduction potentials of the couples $Cl_2/2Cl^-$, $Br_2/2Br^-$ and $I_2/2I^-$ are given in Table 3. They are independent of pH. The redox couple $BrCl/Br^-$, $Cl^-$ has a standard reduction potential of 1.21 V.[68] Whether other halogenated oxidation products, including interhalogens, can result from (pseudo)halide oxidation by peroxidases is purely speculative. Due to the low iodide concentration (<1 μM[69]) in blood and most tissues (with the exception of the thyroid gland), iodide oxidation by MPO, EPO and LPO is of little importance. The redox chemistry of $SCN^-$ oxidation by peroxidases is rather complex. In addition to the formation of hypothiocyanite ($OSCN^-$), further oxidation products such as cyanate ($OCN^-$) and $(SCN)_2$ have been reported.[61,70] Hypothiocyanous acid (HOSCN) and $SCN^-$ are the hydrolysis products of $(SCN)_2$ with a hydrolysis constant of $5.7 \times 10^{-4}$ M².[61] From this constant and the values for the standard reduction potential of the couple $HOSCN/SCN^-$, $H_2O$ (Table 3), the unknown potential for the couple $(SCN)_2/2SCN^-$ (0.72 V) can be calculated.

In general, it follows from thermodynamic rules that the oxidation of a (pseudo)halide by compound I of peroxidases is only possible if the actual reduction potentials for (pseudo)halide oxidation [$E'(HOX/X^-, H_2O)$ or $E'(X_2/2X^-)$] are lower than the reduction potential for the reduction of compound I $E'$[compound I/PorFe$^{III}$] [Equations (14) and (15)].

$$E'(HOX/X^-, H_2O) < E'[\text{compound I/PorFe}^{III}] \quad (14)$$

$$E'(X_2/2X^-) < E'[\text{compound I/PorFe}^{III}] \quad (15)$$

The reduction potential of any redox couple depends on reactant concentrations and pH value and can be determined by means of the Nernst equation [Equation (5)]. As the redox couples involved in halide oxidation by peroxidases possess different dependencies on pH, certain pH threshold values depending on halide concentration exist for a given peroxidase − only below this pH threshold value is the halide oxidation thermodynamically favourable.[68] The reduction potential of the couple compound I/ferric enzyme declines by –0.059 V per increasing pH unit at neutral and slightly acidic pH values. The potential of the couple $HOX/X^-$, $H_2O$ is diminished by –0.0295 V per pH unit if the pH is lower than the p$K_a$ value of the corresponding hypohalous acid. At pH values higher than the p$K_a$ value, the slope will change by –0.059 V per pH unit. The redox couple $X_2/2X^-$ is independent of pH.

A selected example for the calculation of pH threshold values is presented for the formation of HOCl and HOBr by MPO and EPO assuming equimolar concentrations for compound I and the ferric enzyme form as well as concen-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trations of $10^{-6}$ M for HOCl, $10^{-1}$ M for $Cl^-$, $10^{-6}$ M for HOBr and $10^{-4}$ M for $Br^-$ (Figure 2). Under these conditions, clear pH thresholds are found for the formation of HOCl and HOBr by EPO at pH 5.75 and 7.6, respectively. The formation of HOBr by MPO would be possible at all pH values indicated in Figure 2, while the formation of HOCl is unlikely at pH values higher than 7.5. Both reduction potentials of both couples are nearly identical in this pH range. It is necessary to point out that these considerations are influenced by uncertainties about the knowledge of the real concentration values of all reactants.

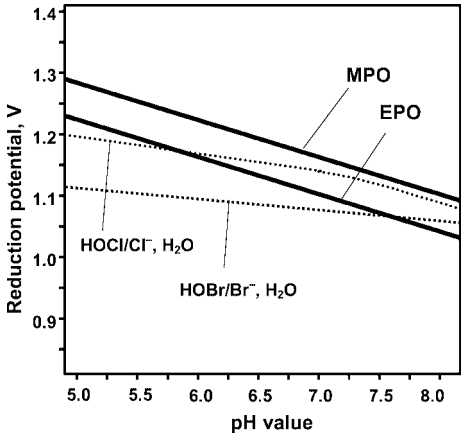

Figure 2. Selected example for the determination of pH threshold values below which the formation of HOBr or HOCl would be thermodynamically possible by the MPO (or EPO)-hydrogen peroxide-halide system. Reduction potentials of the redox couples compound I/ferric enzyme are given for MPO and EPO as a function of pH (solid lines) using equimolar concentrations of compound I and the ferric enzyme form. The reduction potentials of the couples $HOCl/Cl^-$, $H_2O$ and $HOBr/Br^-$, $H_2O$ (dotted lines) are indicated in the same pH range for $10^{-6}$ M HOCl, $10^{-1}$ M $Cl^-$, $10^{-6}$ M HOBr and $10^{-4}$ M $Br^-$.

Calculated pH thresholds for the chloride and bromide oxidation by MPO and EPO have been compared with experimentally determined pH threshold values for the formation of chloro- and bromohydrins from unsaturated phosphatidylcholines by these peroxidases at varying halide concentrations. This analysis revealed that chlorine, bromine and bromine chloride are the favoured chloride and bromide oxidation products by MPO, whereas hypochlorous and hypobromous acid will primarily be formed by EPO.[68]

The inability to induce MPO effects at 0.1 M $Cl^-$ and neutral pH values and the existence of certain pH threshold values by lowering the pH was also evidenced in other investigations on lipids, such as the formation of lysophospholipids from highly unsaturated phosphatidylcholines[71] or the accumulation of diene conjugates in low-density lipoproteins.[72] In contrast, when using taurine or monochlorodimedon as detection system, the chlorinating activity of MPO has been reported at neutral pH values up to pH 8.[73] Taurine is known to bind to MPO and be modified by the MPO–$H_2O_2$–$Cl^-$ system by so-called enzyme-bound hypochlorous acid but not by free HOCl, as revealed by kinetic studies at low pH.[74] Similarly, the chlorination of monochlorodimedon by chloroperoxidase occurs clearly by enzyme-bound HOCl.[75] Thus, the mechanism of chlorination of taurine and monochlorodimedon by MPO at neutral pH values remains unknown from the viewpoint of redox chemistry.

For MPO and chloride, it has been shown that chloride forms a reversible complex with compound I, the absorbance of which is in between those of compound I and native MPO.[62b] At pH 7 it was impossible to reconstitute the ferric enzyme form completely from compound I of MPO by adding chloride or bromide in the stopped-flow experiment.[42,74] Apparently, only the complex between compound I and $Cl^-$ or $Br^-$ was formed without inducing the halide oxidation; only at pH 5 did a complete reconstitution of ferric MPO from compound I take place.[28,76] How the addition of taurine facilitates the reconstitution of ferric MPO in halide oxidation at neutral pH values remains unknown.

## Protein Modification by Peroxidase Products

Reactive halide and nitrogen species produced by heme peroxidase contribute to the modification of functional sites of proteins and other biomolecules. Hypochlorous acid, hypobromous acid and nitrogen dioxide in particular have been investigated for their ability to induce post-translational modifications in proteins. As a result of the action of hypohalous acid, most of all, oxidation of sulfhydryl and methionine residues as well as halogenation of aromatic amino acid residues have been reported.[77] Although the chlorination of tyrosine residues in protein by the MPO–$H_2O_2$–$Cl^-$ system has been reported,[78] the formation of 3-chlorotyrosine is an unfavourable reaction for HOCl.[77a] Only 2% of HOCl produced by MPO or neutrophils is used to convert tyrosine residues in albumin to chlorotyrosines.[78a] A substantial bromination of tyrosine residues of albumin is observed at physiological concentrations of chloride and bromide at a pH higher than 7.[79]

Nitration of proteins is often observed during pathophysiological situations when oxidative and nitrative stress conditions are simultaneously produced and, in particular, both nitrite and hydrogen peroxide concentrations in cells increase.[80] The MPO–$H_2O_2$–nitrite system causes both nitration and nitrosylation of selected tyrosine and tryptophan residues in proteins, for example in human serum albumin.[79b] The most commonly detected marker of biological nitration is 3-nitrotyrosine, and different mechanisms, which are probably simultaneously active, have been proposed for its formation in vitro.[80e]

Nitrogen dioxide is derived from the one-electron oxidation of nitrite by compound I and compound II of heme peroxidases (see above). Dimerisation of two $^{\cdot}NO_2$ species in a reversible reaction generates $N_2O_4$, which forms symmetrical ($O_2N$–$NO_2$) and asymmetrical (ON–$NO_3$) tautomers that are able to produce nitrated and nitrosated tryptophan derivatives.[81]

Formation of 3-nitrotyrosine is also thought to occur by coupling of nitrogen dioxide with the phenoxy radical

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[Equation (16)], which is also produced by one-electron oxidation of tyrosine residues in proteins mediated by the peroxidase intermediates compound I and compound II.

$$^{\cdot}NO_2 + Ph–O^{\cdot} \rightarrow O_2N–Ph–OH \quad (16)$$

Since the Tyr$^{\cdot}$/Tyr standard reduction potential at pH 7 is 0.94 V,[36] the phenoxy radical can be generated by oxidation of the phenol by both nitrogen dioxide or the peroxidase intermediates compound I and compound II.

Even though the dominant mechanism for nitration by peroxidases in the presence of nitrite and hydrogen peroxide considers the formation of nitrogen dioxide by the classical enzyme intermediates, several data show that another active species with chemical properties similar to those of peroxynitrite can be generated by mammalian peroxidases. This alternative species has been proposed for LPO based on kinetic analysis and product distribution in nitration/oxidation experiments of *p*-cyanophenol, phenylacetic acid[44d,44e] and tryptophan derivatives[44f] as mechanistic probes. For the enzymatic reactions, the importance of this second nitrating species becomes dominant as the nitrite concentration in solution increases. The generation of an oxidant species with the chemical properties of peroxynitrite by MPO and EPO in the presence of nitrite has been proposed in vivo, through the use of EPO- and MPO-knockout mice, from the detection of hydroxylated targets.[44h] It has been shown that while the major reacting nitrogen species generated by peroxidase catalysis is nitrogen dioxide, a further minor, but not negligible, contribution produces products typical of $ONOO^-$ reactivity.

The formation of the enzyme nitrating species with peroxynitrite reactivity can be explained by considering that, after coordination of nitrite to the iron, the nitrite adduct can undergo oxidation by hydrogen peroxide according to the following reaction [Equation (17)][44d–44f]

$$PorFe^{III}–NO_2^- + H_2O_2 \rightarrow PorFe^{III}–N(O)OO^- + H_2O \quad (17)$$

where the $PorFe^{III}–N(O)OO^-$ species is assumed to be an iron-bound peroxynitrite coordinated through the nitrogen donor atom. This assumption is based on its chemical properties and on the similarities between the spectral features of $PorFe^{III}–NO_2^-$ and the intermediate formed as a transient species upon treatment of LPO with hydrogen peroxide in the presence of an excess of nitrite.[44e]

The characterisation of this intermediate is complicated by its high reactivity, which causes a quick degradation by reaction with nearby amino acid residues of the protein. In addition, the lifetime of the heme-bound peroxynitrite may be reduced through the fast conversion to nitrate. In fact, the catalytic effect of heme complexes in the dismutation of (O-bound) peroxynitrite is well known,[82] and a similar activity can also be exerted with the N-bound species. For these reasons, the redox properties of the $PorFe^{III}–N(O)OO^-$ intermediate are not known. The species generated by LPO shares several reactivity features with free peroxynitrite, such as a certain preference to produce *N*-nitrosotryptophan rather than *N*-nitrotryptophan, and the capability of reacting with aromatic residues to give both nitration and hydroxylation of the ring.[44f] The latter activity indicates a strong oxidising property for $PorFe^{III}–N(O)OO^-$, although the relative relevance of the one-electron (radical) reactions with respect to the two-electron oxidations promoted by this species is still unclear. The lack of effect of $CO_2$ on the observed reactivity of the $PorFe^{III}–N(O)OO^-$ intermediate[44e] indicates that the reactivity is not, or is only partly, due to free peroxynitrite generated by the dissociation of the adduct; thus, the reactions observed occur within the protein active site and are due to the protein iron-bound peroxynitrite.

It has to be mentioned that MPO and EPO are strong cationic proteins with p$K_a$ values around 10. LPO, however, has a p$K_a$ value of about 7.5. The formation of complexes with acidic proteins is known for MPO. The binding and uptake of MPO to endothelial cells is mediated by MPO–albumin complexes.[83] After endocytosis by the endothelial, MPO becomes associated with fibronectin-rich fibrils.[84] Other proteins known to interact with myeloperoxidase are apoprotein A-1, ceruloplasmin and antitrypsin,[85] although the physiological meaning of these findings is unclear. Regarding the antimicrobial role of these enzymes, however, the combination of adhesion to pathogens with the biochemical capacity to generate strong oxidants seems to be a general strategy in unspecific immune defence that developed very early in evolution.

## Conclusion

Here we have demonstrated how the functional features of human peroxidases to use small anionic one- and two-electron donors are closely related with their peculiar structural and redox properties and how the corresponding products contribute to the modification of functional sites of proteins and other biomolecules. This knowledge will help in the rational design of new potent and specific inhibitors that will dampen inflammation without precipitating infectious diseases.

## Acknowledgments

# New Dimeric Copper(II) Complex $[Cu(5\text{-}MeOsal)_2(\mu\text{-}nia)(H_2O)]_2$ with Magnetic Exchange Interactions through H-Bonds

**Dušan Valigura,*[a] Jan Moncol,[a] Maria Korabik,[b] Zuzana Púčeková,[a] Tadeusz Lis,[b] Jerzy Mroziński,[b] and Milan Melník[a]**

**Keywords:** Copper / Carboxylate ligands / Nicotinamide / Dimer / Structure / Magnetic properties

The synthesis and characterization (elemental analysis, IR, electronic and EPR spectra as well as magnetization measurements over the temperature range 1.8 K–300 K) of solid complex $[Cu(5\text{-}MeOsal)_2(\mu\text{-}nia)(H_2O)]_2$ (**1**; 5-MeOsal = 5-methoxysalicylate, nia = nicotinamide) is reported together with the crystal structure. In blue–green complex **1**, two $Cu(5\text{-}MeOsal)_2(H_2O)$ units are held together by a pair of bidentate nonchelating nicotinamide ligands, which form a $(CuNC_3O)_2$ ring. Each Cu atom adopts a distorted square-pyramidal geometry. The oxygen atoms from two unidentate 5-MeOsal anions occupy the *trans* position, a water molecule and the pyridine N atom of nicotinamide build the basal plane and a carboxamide O atom occupies the apical position. The separation between two Cu atoms within the centrosymmetric dimer is 6.940(2) Å. The dimeric units are self-assembled across a centre of symmetry by the formation of two pairs of strong hydrogen bonds, which create a one-dimensional polymeric structure with the interdimer Cu···Cu separation 4.901(2) Å. It is believed that these hydrogen bonds between the copper(II) atoms are responsible for the unique magnetic properties of compound **1**. The magnetic susceptibility of complex **1** exhibits a maximum at 6 K. A satisfactory explanation was found with the Bleaney–Bowers equation for Cu–Cu interaction through carboxylato groups and H-bond bridges ($2J = -6.83$ cm$^{-1}$). An additional molecular field correction that was used to characterize the interaction across the nia bridges is assumed to be extremely weak ($zJ' = -0.28$ cm$^{-1}$).

## Introduction

For quite some time, copper complexes with various organic ligands have been a subject of intense study because of their interesting properties which include biomedical activities. Nicotinamide (also known as a niacin derivative or vitamin $B_3$) is a nitrogen donor ligand that has been used in the treatment of various skin diseases (atopic eczema,[1,2] psoriasis and skin cancer[3–5]), and the biological activity of its copper complexes have also been studied.[6] In addition, the biological activity of different salicylic acid derivatives and their copper(II) complexes is well known.[7–10] Meanwhile, salicylatocopper(II) complexes that contain nicotinamide are rarely studied in spite of their possible structural diversities. There are only two examples (out of 26 known structures)[6,11] of polymeric copper(II) complexes where nicotinamide acts as a bridging ligand – $[Cu_2(CH_3COO)_4(\mu\text{-}nia)]_n$ and $\{[Cu(sacharinato)_2(\mu\text{-}nia)(H_2O)]\cdot H_2O\}_n$.

With the purpose to obtain and study the properties of all possible products that could be prepared by the reactions under study, we report the synthesis, structural characterisation and properties of the unusual dimeric complex $[Cu(5\text{-}MeOsal)_2(\mu\text{-}nia)(H_2O)]_2$ (**1**), which exhibits rare intradimer and/or interdimer interactions that result in magnetic properties that are of interest.

## Results and Discussion

The molecular structure of **1** (Figure 1) consists of dimeric $[Cu(5\text{-}MeOsal)_2(\mu\text{-}nia)(H_2O)]_2$ molecules that are located at a centre of symmetry. Two equivalent $Cu(5\text{-}MeOsal)_2(H_2O)$ moieties are connected by a pair of bidentate nonchelating nicotinamide ligands, which creates a twelve-membered metallocyclic $(CuNC_3O)_2$ ring. Each Cu atom adopts a distorted square-pyramidal geometry with the oxygen atoms of two unidentate 5-MeOsal anions in the *trans* position [Cu–O12 = 1.945(2) Å]. A water molecule [Cu–O1W = 1.989(2) Å] and the pyridine N atom of nicotinamide [Cu–N1 = 2.030(3) Å] build the basal plane; a carboxamide O atom of the bridging nicotinamide assumes the apical position [Cu–O1 = 2.267(2) Å]. The copper atom is displaced from the basal plane towards the carboxamide O atom by 0.047(1) Å. The $\tau$ value[12] of 0.066 implies an almost perfect square-pyramidal geometry. The separation between Cu···Cu$^{i}$ ($1-x$, $1-y$, $1-z$) within the dimeric molecule is 6.940(2) Å(Figure 1). The amide H atoms of the apically coordinated carboxamide group are linked to the co-

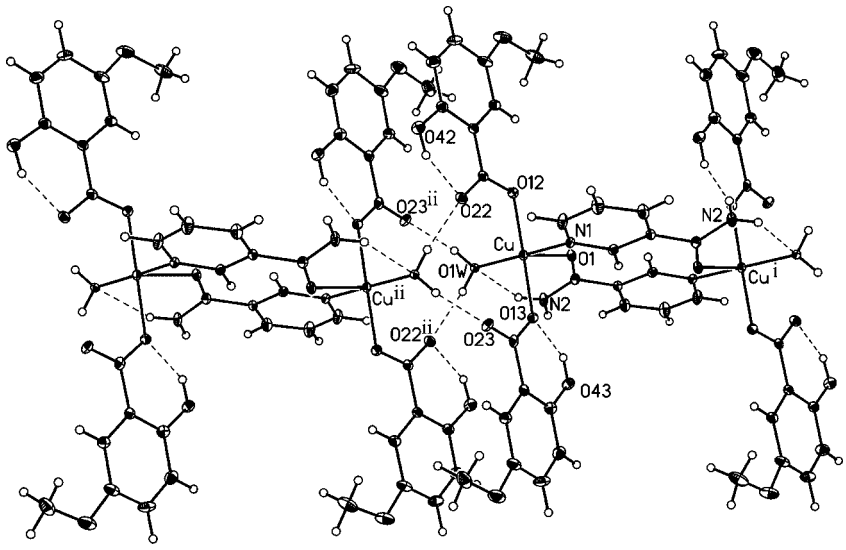

Figure 1. Perspective view of $[Cu(5\text{-}MeOsal)_2(\mu\text{-nia})(H_2O)]_2$, with the atom numbering scheme. Thermal ellipsoids are drawn at the 30% probability level. Selected bond lengths [Å] and angles [°]: Cu–O13 = 1.945(2), Cu–O12 = 1.952(2), Cu–N1 = 2.030(3), Cu–O1W = 1.989(2), Cu–O1 = 2.267(2), O13–Cu–O12 = 177.05(9), O1W–Cu–N1 = 173.09(10), O13–Cu–O1W = 87.35(9), O13–Cu–O1 = 86.67(9), O12–Cu–O1W = 90.27(9), O12–Cu–O1 = 91.73(9), O13–Cu–N1 = 92.14(10), O1W–Cu–O1 = 93.32(9), O12–Cu–N1 = 90.42(10), N1–Cu–O1 = 93.52(9), symmetry codes: (i) $1-x$, $1-y$, $1-z$, (ii) $1-x$, $-y$, $1-z$.

ordinated (in the equatorial position) water O atoms (O1W) by hydrogen bonds N2–H2A···O1W$^{i}$ ($1-x$, $1-y$, $1-z$) with interatomic distances N2···O1W$^{i}$ of 3.129(4) Å. These hydrogen bonds create six-membered metallocyclic rings ($CuO_2NCH$) and stabilize the molecular structure of the dimeric unit of **1**. The other short intramolecular hydrogen bonds are formed by the salicylato hydroxy H atoms (H43O and H42O) to the carboxylate O atoms (O13 and O22) and create six-membered cyclic rings ($O_2C_3H$) that stabilize the molecular structure as well.

The unusual dimeric structure of **1** prompted the study of its magnetic properties within the temperature range 1.8–300 K and the measurement of its EPR spectrum. The EPR spectrum (Figure 2) at room temperature is of axial symmetry and simulation of its shape[13] gave $g_{\perp}$ = 2.061 and $g_{\parallel}$ = 2.345 ($g_{av}$ = 2.156). When the temperature is decreased to –196 °C (liquid nitrogen), the spectrum becomes pseudo-isotropic in shape with $g$ = 2.133, and no information concerning the mutual interaction between the paramagnetic centres within the dimer could be drawn from these spectra (Figures 2 and 3).

Magnetization measurements showed that **1** exhibits maximum magnetic susceptibility at 6 K (Figure 3). The magnetic data of the complex were fit with the Bleaney–Bowers equation,[14] to characterize the intradimer interaction,

$$\chi_m = \frac{N\beta^2 g^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1}$$

(where N is Avogadro's number, $g$ is the spectroscopic splitting factor, $\beta$ is the Bohr magneton, k is Boltzmann's con-

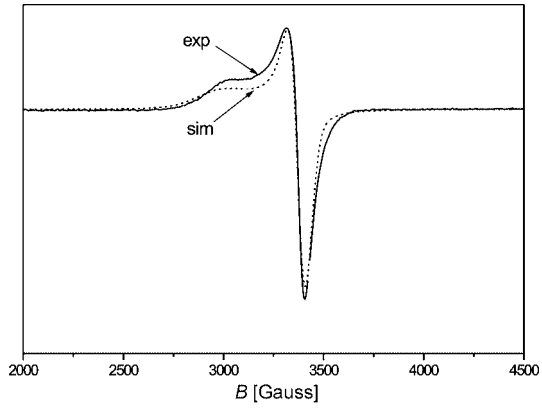

Figure 2. EPR spectrum of **1** at room temperature.

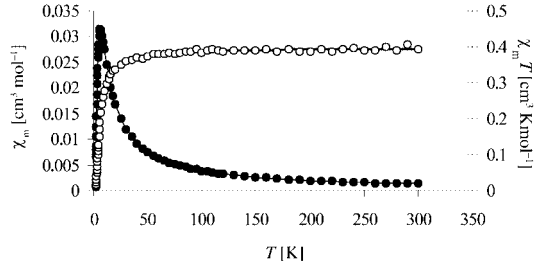

Figure 3. The plot of the $\chi_m$ and $\chi_m T$ product versus temperature [$\chi_m$ – the molar magnetic susceptibility calculated per one copper(II) centre]. The solid line was generated from the best-fit magnetic parameters.

stant and $J$ is the exchange parameter) together with the application of a molecular field model to the calculation of the present magnetic data of complex **1** to obtain characteristics of interdimer magnetic interactions.[15]

$$\chi_m^{corr} = \frac{\chi_m}{1 - \frac{2zJ'\chi_m}{Ng^2\beta^2}}$$

where $\chi_m$ is the molar susceptibility given by the Bleaney–Bowers equation, $zJ'$ is the molecular exchange parameter, $z$ is number of the nearest neighbours and $R$ is the agreement factor defined as

$$R = \sum_{i=1}^{n} \frac{(\chi_i^{exp}T - \chi_i^{calc}T)^2}{(\chi_i^{exp}T)^2}$$

Satisfactory least-squares fit to the experimental results was obtained for $g$ = 2.06, $2J$ = –6.83 cm$^{-1}$, $zJ'$ = –0.28 cm$^{-1}$, and $R$ = 9.99·10$^{-5}$. The small differences between the $g$ values obtained from the least-squares fit procedure and $g_{av}$ from the EPR spectra is often observed and can be attributed to the unresolved axial anisotropy of the EPR spectra and the fact that the $g$ values obtained from the magnetic data are only refined isotropically.[16]

This magnetic behaviour of **1** is surprising because the magnetic centres are bridged by a nicotinamide ligand (the shortest pathway covers a five-atom bridge) which includes the aromatic pyridine ring and the carboxamide side chain. The π-system of the pyridine ring is probably not the actual mode of interaction [the C31–C71 bond length of 1.506(4) Å is much longer than the average bond length of 1.385(4) Å within the pyridine ring]. The pyridine ring and the carboxamide group are not coplanar (ring plane to carboxamide group plane angle is 14.2°); thus, the structural data support the notion that there is no possibility for the π-system to be involved in the magnetic interaction. The σ-bonds involved in the intradimer magnetic interaction by nicotinamide ligands can be ruled out on the basis of our recently published results.[17] The 3-pyridylmethanol bridging ligand shows[17] the same number of σ-bonds and a very weak ferromagnetic interaction (Weiss constant $\Theta$ = +1.1 K). Consequently, the model for the magnetic interaction between the $Cu^{2+}$ ions within the dimeric molecule can be ruled out as well, and another interaction that is responsible for the magnetic properties of **1** should be found.

The strongest interdimer interactions are illustrated Figure 1 as a system of O–H···O hydrogen bonds between dimeric units of **1** that create a supramolecular chain of dimers along the $b$ axis with an interdimer copper-to-copper distance [distance Cu···Cu$^{ii}$ (1 – $x$, –$y$, 1 – $z$) of 4.901(2) Å] shorter than the distance Cu···Cu$^{i}$ within the dimeric units. The H atoms of the water molecules are linked to uncoordinated carboxyl O atoms (O12$^{ii}$ and O22$^{ii}$) of the neighbouring 5-methoxysalicylate anions by hydrogen bonds O1W–H1W···O22$^{ii}$ and O1W–H2W···O23$^{ii}$ (1 – $x$, –$y$, 1 – $z$) with interatomic distances O1W···O22$^{ii}$ of 2.695(3) Å and O1W···O23$^{ii}$ of 2.658(3) Å, respectively. The interdimer interactions could cause magnetic interactions because the pairs of $Cu^{2+}$ ions are, in this case, bridged by four carboxylato groups [similar to "paddle-wheel" copper(II) acetate structures], but one water molecule is inserted into each pair of carboxylato groups (Figure 4). This water molecule insertion into the bis-carboxylato bridge induces a greater distance between the polyhedra basal planes, a greater Cu···Cu distance and a longer path for the magnetic interaction compared with regular carboxylato dimers. This explanation needs further evidence based either on similar structures or the analysis of magnetic orbital interactions to be validated. Both of these topics are currently under investigation in our lab. Data which show that hydrogen bonds could cause antiferromagnetic interactions between copper(II) centres were found in literature,[18–22] but unfortunately most of the examples involve a completely different types of ligand.

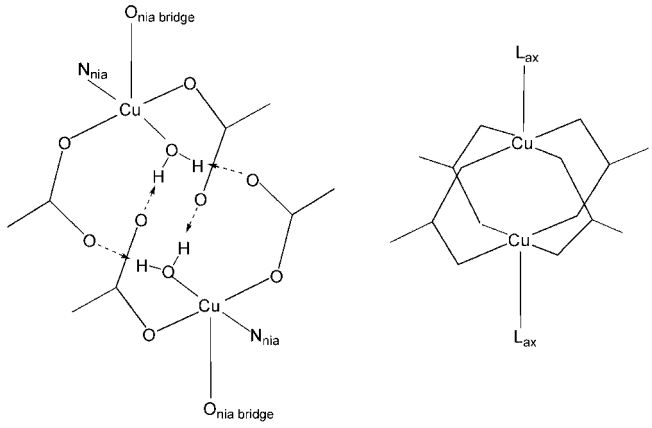

Figure 4. Schematic comparison of interdimer Cu···Cu interactions in **1** and in regular "paddle-wheel" carboxylatocopper(II) structures.

As mentioned above, the crystal structure of **1** can be compared with polymeric complexes[6,11] $[Cu_2(CH_3COO)_4(\mu\text{-nia})]_n$ and $\{[Cu(sacharinato)_2(\mu\text{-nia})(H_2O)]\cdot H_2O\}_n$ where each Cu atom has a square-pyramidal environment. In the former complex, the $Cu_2(CH_3COO)_4$ moieties form dimer units, and in the latter complex, the Cu(sacharinato)$_2$($H_2O$) units are connected by bidentate nonchelating nicotinamide ligands by N and O donor sites. The Cu–N (N atom of nia pyridine ring), Cu–O (O atom of carboxamide group of nia ligand) and finally Cu···Cu (neighbouring Cu atoms bridged by nia ligands) distances are 2.002, 2.315 and 7.547 Å, respectively, for $[Cu_2(CH_3COO)_4(\mu\text{-nia})]_n$, 2.158, 2.146 and 7.056 Å, respectively, for $\{[Cu(sacharinato)_2(\mu\text{-nia})(H_2O)]\cdot H_2O\}_n$ and 2.030(3), 2.268(2) and 6.939(2) Å, respectively, for complex **1**. The shorter Cu···Cu separation could be explained by a pair of nia bridging ligands and probably by additional hydrogen bond interaction with N–H···O (see above).

In $[CuCl_2(\mu\text{-denia})(denia)]_2$,[23] where a pair of denia ligands also serve as a bridge between two equivalent $CuCl_2$(denia) moieties, the Cu···Cu separation is about 0.762 Å longer than that found in **1**. The Cu–N (N atom of the pyridine ring of the bridging *N*,*N*-diethylnicotinamide molecule) of 2.012(3) Å compares well with the bond length Cu–N1 of complex $[Cu(5\text{-MeOsal})_2(\mu\text{-nia})(H_2O)]_2$, but Cu–

O (O atom from amide group of bridging *N*,*N*-diethylnicotinamide molecule) of 2.475(2) Å is about 0.207 Å longer than that found in **1**. These complexes, however, were not magnetically characterized.

## Conclusions

In conclusion, we have prepared and characterized a novel dimeric molecular complex that contains nicotinamide as a bridging ligand. These dimers are linked into a chain structure by strong hydrogen bonds that give interdimer copper-to-copper distances that are shorter than those found in intradimers. The nature of the bridging ligands (four carboxylic groups of salicylato anions) that are involved in the formation of the interdimer hydrogen bonds are probably the reason for the unusual magnetic behaviour of this dimeric substance.

## Experimental Section

**Materials:** All used chemicals were of analytical grade (Aldrich, or Sigma) and used without further purification.

**Physical Measurements:** Carbon, hydrogen and nitrogen elemental analyses were carried out with a CHNSO FlashEA 1112 (Thermo-Finnigan) elemental analyzer. The copper content of the complex was determined by the electrolysis of a water solution obtained by the mineralization of the sample in a mixture of sulfuric acid and potassium peroxodisulfate. Infrared spectra were measured with a Nicolet MAGNA 750 IR spectrometer with both KBr pellet and nujol suspension techniques for the 4000–400 $cm^{-1}$ region and a polyethylene pellet for the 400–100 $cm^{-1}$ region. Electronic spectra (190–1100 nm) of the complexes were measured in Nujol suspensions with a SPECORD 200 (Carl Zeiss Jena) spectrophotometer. Magnetization measurements in the temperature range of 1.8–300 K were carried out on powdered samples of the complexes with a magnetic field strength of 0.5 T and with a Quantum Design SQUID Magnetometer (type MPMS-XL5). Corrections for the diamagnetism of the constituting atoms were calculated with Pascal constants,[24] the value of $60 \cdot 10^{-6}$ $cm^3 mol^{-1}$ was used as the temperature-independent paramagnetism of the copper(II) ion. EPR spectra of the powdered samples were recorded at room temperature with a spectrometer Bruker ESP 300 operating at X-band equipped with an ER 035M Bruker NMR gaussmeter and a HP 5350B Hewlett Packard microwave frequency counter.

**Synthesis of 1:** Nicotinamide (122 mg, 1.0 mmol) was added to an ethanol solution (30 mL) of copper(II) acetate (200 mg, 1 mmol) while stirring. After several minutes, 5-methoxysalicylic acid (336 mg, 2 mmol) was added to the dark blue solution. The reaction mixture was stirred for a few days at ambient temperature. The blue–green powder product which precipitated from the solution was filtered off (150 mg, 56%), and the mother liquid was left to crystallize at ambient temperature. The dark blue–green crystals were separated and dried at ambient temperature. $C_{44}H_{44}Cu_2N_4O_{20}$ (1075.93): calcd C 49.03, H 4.30, Cu 11.79, N 5.19; found C 48.63, H 4.21, Cu 12.19, N 5.49. IR (KBr): $\tilde{\nu}$ = 1635 $\nu_{as}(COO^-)$, 1432 $\nu_s(COO^-)$ $cm^{-1}$. ES (Nujol): 244 (CT band), 323 (CT band), 671 (*d*←*d* band) nm.

**X-ray Structural Studies:** Data collection and cell refinement of complex **1** were carried out with a Kuma KM4-CCD difractometer with graphite monochromated Mo *Kα* radiation and the use of the *CrysAlis* software package.[25] Intensity data were corrected for Lorenz and polarization factors; absorption correction was applied as well. The structures of the complexes were solved by direct methods with *SHELXS-97*[26] and refined by the full-matrix least-squares procedure with *SHELXL-97*. Geometrical analyses were performed with *SHELXL-97*.[27] The structures were drawn with *XP* in *SHELXTL*.[28] Crystallographic data for $C_{44}H_{44}Cu_2N_4O_{20}$ (**1**): $M_r$ = 1075.93, dark green plate, 0.09 × 0.20 × 0.20 mm, monoclinic, *C*2/*c*, *a* = 21.805 (6), *b* = 11.735 (3), *c* = 17.585 (5) Å, *β* = 104.72 (3)°, *V* = 4352 (2) $Å^3$, *Z* = 4, $D_c$ = 1.642 $Mg \cdot m^{-3}$, $\mu$ = 1.07 $mm^{-1}$, *F*(000) = 2216, *T* = 100(2) K. Of the 15711 reflections, 5122 were unique ($R_{int}$ = 0.066), 3248 observed [$F_2 > 2.0\sigma(F^2)$], which refined to *R* = 0.058, *wR* = 0.091.

CCDC-603094 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Preparation of ZnO Nanowires in a Neutral Aqueous System: Concentration Effect on the Orientation Attachment Process

Ming Yang,[a] Guangsheng Pang,*[a] Jixue Li,[a] Linfeng Jiang,[a] and Shouhua Feng*[a]

**Keywords:** Zinc oxide / Orientation attachment / Self-assembly / Nanostructures

ZnO nanowires with diameters in the range of 10 to 30 nm and lengths of ca. several micrometers are prepared with the use of ZnO nanoparticles as building blocks. The length and diameter of the ZnO nanowires can be controlled by the variation of the concentration of the nanoparticles in the orientation attachment process. A plausible mechanism for the concentration-controlled orientation attachment process is suggested.

## Introduction

The preparation of nanostructures with control of their size, shape, and crystalline structure has been one of the main objectives in the chemistry of nanomaterials.[1–5] Nanoparticles can be used as building blocks to obtain well-defined assemblies and superstructures, which can lead to novel and unique properties that are not found in the individual components.[6–7] Orientation attachment has attracted increased interest in recent years as a new means for the fabrication and self-organization of nanocrystalline materials.[8] Recent work has shown the universality of the orientation attachment in the formation and growth of nanocrystals.[9–14] To find a facile method that can precisely control the morphology of low dimensional nanostructures through the mastery of the orientation attachment process is still a challenge.

ZnO is an environmentally friendly transparent semiconductor with a large bandgap of 3.37 eV and it exhibits various distinct properties.[15–17] One-dimensional (1D) ZnO is a focused material, which allows it to possess excellent optical properties.[18] Various methods have been successfully utilized to synthesize 1D ZnO.[19–27] For the reported solution method, a basic environment is necessary to induce 1D growth of the ZnO particles in the nanoscale range.[14,24,27–32] Generally, the common formation mechanisms of 1D ZnO involve the vapor–liquid–solid (VLS) growth model,[26] and the Oswald ripening growth model.[27] The VLS process seems to be the most successful for the generation of 1D structures among all of the vapor-based methods. The Oswald ripening phenomenon is a classical crystal-growth method which describes the growth of the crystal in terms of the Gibbs-Thompson equation. The formation of ZnO nanorods on the basis of the orientation attachment process has only recently been demonstrated.[14] Other metal oxide (e.g. $TiO_2$ and CuO) nanorods have also been prepared by the orientation attachment of nanoparticles.[33–34] In this work, we provide an easy method for the preparation of ZnO nanowires in a neutral aqueous system by the careful control of the orientation attachment of the ZnO nanoparticles. A mechanism for the formation and growth of the low-dimensional nanostructure, which is critical to understand in order to achieve control over the morphology of the nanostructure, and the properties of the structure at the nanoscale level are discussed.

## Results and Discussion

Figure 1 shows the SEM image of 1D ZnO obtained by the hydrothermal treatment of ZnO colloidal nanoparticles at a concentration of 0.8 g/L. The ZnO nanowires are several micrometers in length and vary in diameter from 10 to 30 nm. The curvature of the wire implies that there is some flexibility in the backbone of the ZnO nanowires. Figure 1B shows the TEM image of an individual ZnO nanowire with a diameter of ca. 15 nm and a length of ca. 2.3 μm. The inset in Figure 1C displays the selected area electron diffraction (SAED) pattern of an individual ZnO nanowire. The SAED pattern reveals the single-crystalline nature of the ZnO nanowires. Figure 1D shows the HRTEM image of the ZnO nanowire that is shown in Figure 1C. The image indicates that the preferred direction of growth of the ZnO nanowires is [0001]. The morphology of 1D ZnO is strongly dependent on the concentration of the ZnO colloidal nanoparticles. When the concentration of the ZnO nanoparticles is increased to 4 g/L, ZnO nanorods with lengths that vary from 200 to 800 nm and diameters

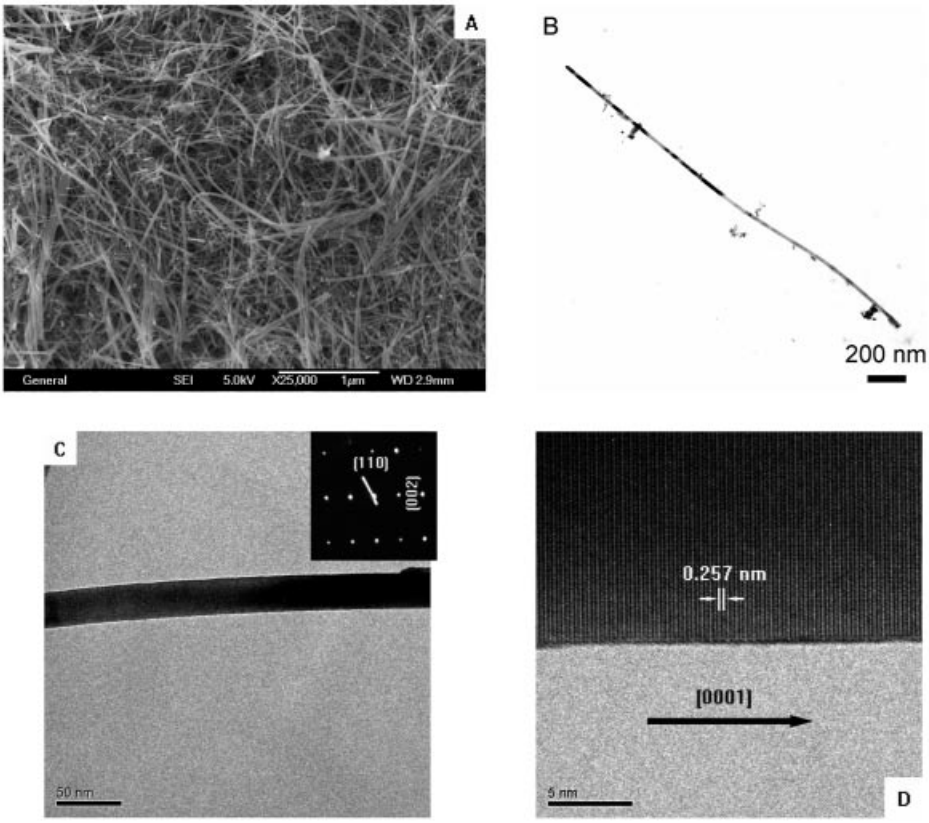

Figure 1. (A) SEM image of ZnO nanowires, (B) and (C) TEM images of ZnO nanowires (inset displays SAED pattern), (D) HRTEM of ZnO nanowires.

that vary from 20 to 40 nm are obtained (see Supporting Information). When the concentration is increased to 16 g/L, ZnO nanorods with smaller aspect ratios are obtained. The diameters of these nanorods vary from 30 to 50 nm and the lengths vary from 60 to 200 nm (see Supporting Information). The narrow distribution of the diameter of the ZnO nanowires is also indicated by the X-ray diffraction (XRD) line broadening. Figure 2 shows the XRD patterns for 1D ZnO obtained at different concentrations of the nanoparticles. All diffraction peaks can be well-indexed to hexagonal phase zinc oxide (JCPDC card No. 36–1451). The diameters estimated from the Debey-Scherrer formula on the basis of the full width of the peak at half-maximum height are 21.0 nm, 28.9 nm, and 48.2 nm obtained by the hydrothermal treatment of 0.8 g/L, 4.0 g/L, and 16.0 g/L ZnO colloidal nanoparticles, respectively. These values are consistent with the SEM observation.

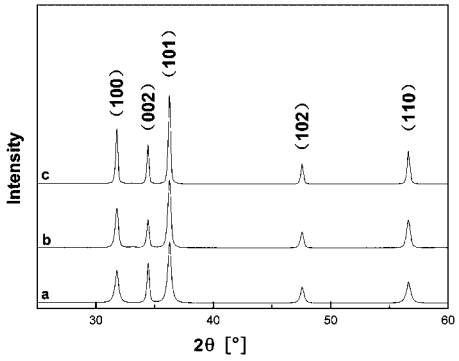

Figure 2. XRD patterns for 1D ZnO obtained by the hydrothermal treatment of (a) 0.8, (b) 4.0, and (c) 16.0 g/L ZnO colloids.

The orientation attachment of the ZnO nanoparticles in the preparation of the ZnO nanowires is observed after 1 h of hydrothermal treatment. Two primary nanoparticles attach to each other along the *c*-axis as shown in Figure 3A and Figure 3B. The nanoparticles may attach to each other along other axes as demonstrated by Pacholski and coworkers,[14] although we did not observe such a phenomenon. The orientation attachment is fundamentally driven by the high surface-energy (3.5 nm) of the ZnO nanoparticles. However, a decrease in the high surface-energy is observed upon the formation of 1D ZnO because there is a reduction in the surface-to-volume ratio. An important characteristic of ZnO is its polar surface. The oppositely charged ions produce positively charged Zn-(001) and negatively charged O-(00–1) polar surfaces, which results in a normal dipole moment and spontaneous polarization along the *c*-axis.[20] The electric dipole moments along the *c*-axis favor the orientation attachment in this direction. According to the model proposed by Penn,[35] the stability constant for the particle encounter complex ($K_{os}$) can be used to estimate the rate of crystal growth by the orientation attachment. High values of $K_{os}$ tend to favor the orientation attachment process. In a previous report,[14] a high concentration of the ZnO colloid was necessary to form

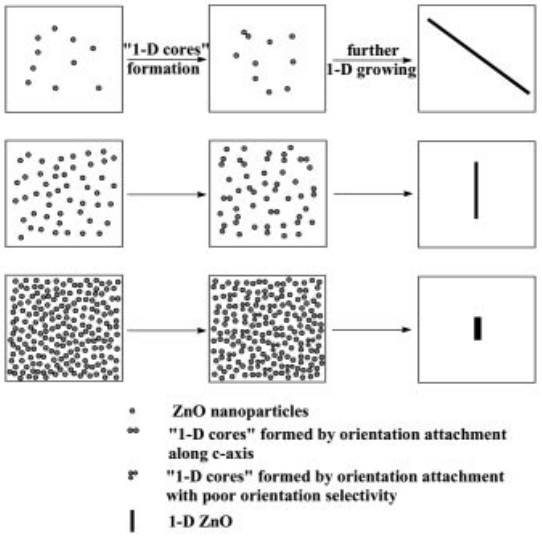
nanorods in a basic ethanol/water environment. Because ZnO nanoparticles are highly charged in the basic environment, an increase in the surface potential was observed. As the surface potential increased, the stability constant decreased. This means that the orientation attachment process was relatively slow in basic environments and a higher concentration of the nanoparticles was needed to accelerate it. In the neutral aqueous system we report here, the electrostatic repulsion from stabilizers such as $OH^-$ is avoided, which results in an overcompensation of the electric-dipole attractions between the nanoparticles. In other words, the value of $K_{os}$ is much larger in neutral aqueous solutions than it is in basic alcoholic solutions, which allows the orientation attachment of the nanoparticles to occur under much lower concentrations. Our results confirm that orientation attachment can occur at relatively low concentrations of the nanoparticles; in fact, this was found to occur at concentrations as low as 0.8 g/L (0.01 M), which is 10 times lower than the reported value.[14] However, there is also a critical concentration that must be met in order to produce 1D ZnO in neutral aqueous systems. If the concentration of the ZnO nanoparticles is less than 0.4 g/L, the orientation attachment of the ZnO nanoparticles is completely inhibited, and only ZnO nanoparticles that are larger in size relative to the starting nanoparticles are obtained.

Adjustments in the orientation attachment process can be realized by the variation of the concentration of the ZnO nanoparticles in the neutral aqueous system. At a certain concentration, there is a possibility that two primary particles collide and merge into a "1D (nanorod) core". These "1D cores" can continue to grow into nanorods or nanowires. Figure 3C and Figure 3D show that individual nanoparticles and "1D cores" can fuse together by the orientation attachment process, which results in additional 1D growth of the "1D cores". On the basis of our observations, we can speculate that the length of the nanowires can be influenced by the alteration of the number of viable "1D cores". The number of initially merged "1D cores" is related to the concentration of the nanoparticles. Large amounts of "1D cores" form when the concentration is high, whereas only small amounts of "1D cores" form when the concentration is low. In a certain colloidal stock, the number of ZnO nanoparticles is constant. If the number of "1D cores" was reduced, a greater share of nanoparticles would be available for continued 1D growth. It is understandable that fewer "1D cores" will result



Scheme 1. Simplified illustration of the concentration-controlled orientation attachment process.

in an increase of the length of the nanorods. At the same time, if the concentration is high, the orientation attachment will occur with poor orientation selectivity and continued growth will result in ZnO nanorods with large diameters and small aspect ratios. Scheme 1 shows a simplified illustration of the concentration-controlled orientation attachment process. The irregular surface of the 1D ZnO nanostructures can be smoothed and should follow the conventional mechanism of dissolution and growth (Oswald ripening), which finally results in a single crystalline nanowire.

## Conclusions

In summary, ZnO nanowires have been obtained with the use of ZnO nanoparticles as building blocks by the concentration-controlled orientation attachment process in a neutral aqueous system. The concentration of the nanoparticles is found to influence the orientation attachment process, and therefore, the continued growth of the ZnO nanowires can be controlled. Our results suggest that the orientation attachment process is similar to the conventional crystal growth process if the nanoparticle colloid is viewed as an ion in solution.

## Experimental Section

**Physical Methods:** Powder X-ray diffraction (XRD) analysis was performed with a Rigaku D/MAX 2500/PC diffractometer with graphite-filtered Cu-$K_\alpha$ radiation. XRD data were collected over 25–60° with a step interval of 0.02° and a preset time of 1.2 s per step at room temperature. Scanning electron microscope (SEM) was performed with a JSM-6700F electron microscope. High resolution transmission electron microscope (HRTEM) was performed with a JEM-3010 electron microscope. The ZnO nanowires will break into shorter ZnO nanorods under strong ultrasonic treatment. If samples are to be observed by HRTEM, prolonged ultrasonic treatment of the samples should be avoided.

**Preparation of ZnO Nanoparticles:** ZnO nanoparticles are prepared by a conventional sol-gel method.[36–37] In a typical synthesis, zinc acetate dehydrate (2.195 g) is dissolved in ethanol (100 mL) and heated at reflux for 2 h. The solution is then cooled to room temperature and lithium hydroxide hydrate (0.588 g) is added. The suspension is then placed in an ultrasonic bath in order to solubilize the weakly soluble powder. After 30 min, the suspension is filtered through a glass fiber (0.1 μm) frit to remove the insoluble solids and then cyclohexane (300 mL) is added into the as-obtained ZnO colloids to precipitate the ZnO nanoparticles.

**Preparation of 1D ZnO:** Different amounts of ZnO nanoparticles (0.02 g, 0.10 g, 0.40 g) were dissolved in distilled water (25 mL) and then transferred to a 40-mL Teflon-lined stainless steel autoclave and heated at 160 °C for 12 h. The obtained precipitates were washed with distilled water and then dried at 60 °C for 2 h.

**Supporting Information** (see footnote on the first page of this article): SEM images of 1D ZnO obtained by hydrothermal treatment of 4.0 g/L and 16.0 g/L ZnO colloidal nanoparticles and TEM image of ZnO nanoparticles.

# Genotoxic Potential of *N*-(Benzothiazolyl)sulfonamide Copper(II) Complexes on Yeast Cells Transformed with YEGFP Expression Constructs Containing the RAD54 or RNR2 Promoter

**Marta González-Álvarez,[a] Gloria Alzuet,[a] Lucas del Castillo,[b] Joaquín Borrás,*[a] and Malva Liu-González[c]**

**Keywords:** Copper complexes / DNA damage / Genotoxicity / yEGFP expression

Four ternary complexes $[Cu(L)_2(phen)]$ where L is an *N*-(benzothiazol-2-yl)sulfonamide derivative have been prepared and their ability to cleave DNA has been studied. The complexes were structurally characterized with the aid of single-crystal X-ray crystallography. Whereas the molecular structure of the $[Cu(L1)_2(phen)]$ (**1**) [HL1 = *N*-(6-chlorobenzothiazol-2-yl)benzenesulfonamide] and $[Cu(L3)_2(phen)]$ (**3**) [HL3 = *N*-(benzothiazol-2-yl)benzenesulfonamide] complexes can best be described as having a distorted square-planar geometry, that of the $[Cu(L4)_2(phen)]$ (**4**) [HL4 = *N*-(benzothiazol-2-yl)toluenesulfonamide] complex shows a strictly square-planar geometry. The $[Cu(L2)_2(phen)MeOH]$ (**2**) [HL2 = *N*-(6-chlorobenzothiazol-2-yl)toluenesulfonamide] complex displays an axially elongated square-pyramidal coordination geometry in which the phen ligand binds at the basal plane. Viscosity and fluorescence measurements indicated that $[Cu(L4)_2(phen)]$ (**4**) has a propensity for binding calf thymus DNA. The four complexes were found to be efficient chemical nucleases, with ascorbate/$H_2O_2$ activation giving rise to hydroxyl and superoxide radicals as active cleaving species. The nuclease activity of **4** is not only the highest of the four complexes, but also much higher than that of the copper–phenanthroline complex. The ability of the complexes to cleave DNA within cells has been tested by monitoring the expression of the yEGFP gene containing reporter plasmid. The significant induction of fluorescence by complex **4** indicates that it is able to cleave DNA inside the cell.

## Introduction

The mechanism of metal carcinogenesis has been widely studied since a number of metals are known to have carcinogenic potential. In 1986, for example, Kawanishi et al.[1] proposed the hypothesis that metal carcinogenesis involves the generation of endogenous reactive oxygen species (ROS). These same researchers subsequently reported that various carcinogenic metal compounds are capable of causing oxidative DNA damage in the presence of $H_2O_2$.[2–5] Indeed, metals are considered to act not only as carcinogens, but also as cocarcinogens that activate carcinogenic chemicals, since a large number of weak, nonmutagenic carcinogens have been found to act through metal-mediated oxidative DNA damage. Endogenous metals ions such as copper and iron seem to play a particularly important role in ROS generation from various carcinogens, which in turn leads to DNA damage. It has been shown, for example, that in phosphate buffer $Cu^{II}/H_2O_2$ induces DNA damage at the thymine and guanine positions by generating ROS.[6] Moreover, copper has a dual role in oxidative DNA damage: it generates ROS through autoxidation of carcinogens and also activates $H_2O_2$ to form a reactive $Cu^{I}$–hydroperoxo complex.

In recent years the interaction of transition metal complexes with nucleic acids has attracted attention because of their relevance in the development of new reagents for biotechnology and medical research. Interest in the rational design of novel transition metal complexes that bind and cleave duplex DNA with high sequence or structure selectivity has been especially keen. Indeed, there is already a considerable amount of literature that deals with the practical use of transition metal complexes as chemical nucleases. The redox activity of copper complexes of 1,10-phenanthroline as artificial nucleases, for instance, is well known.[7,8] Meunier et al.[9] even developed the Clip-Phen series containing two phen moieties linked through tethers in order to favor the stoichiometry of two phen units per copper. These authors showed that the DNA cleavage activity of copper Clip-Phen complexes increased dramatically in relation to that of the phen parent compound. They then went on to determine the cytostatic activity of these

complexes.[10] Our group has previously reported[11] several copper ternary complexes of *N*-substituted sulfonamides and phen with the ability to damage DNA in the presence of various reducing agents.

A great number of chemical substances are known to possess in vitro biocatalytic activity, emulating different enzymatic processes. Among these chemicals, copper-coordinated compounds have shown superoxide dismutase and/or DNAsa activities, depending on the type of ligand present. However, in vitro activity occurs under conditions that are usually not equivalent to the physiological environment in the cell. This is an important consideration in evaluating research in this field, as, in order to have any effect, the chemical product in question needs to penetrate within the cell itself. Once the substance is in the cytoplasm, the different mechanisms of cell detoxification can reduce or even prevent its activity, either through degradation or extrusion out of the cell or to intracellular compartments.

In the past, yeast has been used as a model for understanding physiological processes in superior eukaryotes and it is still considered to be an ideal organism for in vivo studies on the activity of biological compounds. Our group has used an *S. cerevisiae* strain deficient in superoxide dismutase for in vivo evaluation of the SOD-like activity of various copper complexes.[12,13] Induction of different yeast genes in response to exposure to DNA-damaging agents represents an important and promising approach for developing genotoxicity tests. Induction of RAD54 and RNR2, two promoters that control the expression of damage-inducible genes, has already been used successfully to evaluate DNA damage.[14–17] We have gone one step further and developed reporter plasmids that express the green fluorescent protein yEGFP gene.[18] The expression of this gene in cells containing the reporter plasmid in response to the exposure to DNA-damaging agents is thus monitored by noting the presence of its characteristic green fluorescence.

Scheme 1. *N*-(Benzothiazolyl)sulfonamide ligands.

In this paper we describe the synthesis, characterization, and biological activity assays of four copper ternary complexes with *N*-substituted sulfonamides and *o*-phenanthroline. The sulfonamide ligands selected for this study (Scheme 1) possess two main features that facilitate the synthesis of copper(II) complexes with nuclease activity; both a benzothiazole ring and an aromatic ring (benzene or toluene) able to intercalate between the DNA bases, as well as a sulfonamido group that can interact with DNA through hydrogen bonds. In addition, the benzenesulfonamido group has been suggested to be a functional element that facilitates various biological activities such as the inhibition of tumor cell growth.[19] The biological activity studies include evaluations of DNA binding ability, nuclease activity, and the ability to damage DNA in yeast cells transformed with yEGFP expression constructs containing either the RAD54 or the RNR2 promoter.

## Results and Discussion

### Spectroscopic and Structural Aspects

Ternary copper(II) complexes $[Cu(L)_2phen]$ (L = L1, L2, L3, and L4) were prepared and characterized with the aid of analytical, spectroscopic, and X-ray diffraction data.

All the complexes had the same infrared spectrum pattern, and the most significant feature was a shift of the characteristic band of the benzothiazole ring from 1550 $cm^{-1}$ in the free ligands to 1460 $cm^{-1}$ in the complexes. As for the sulfonamidato group, the bands assigned to $\nu(SO_2)_{as}$ and $\nu(SO_2)_s$ are shifted to slightly lower frequencies while the $\nu$(S–N) vibration appears at slightly higher frequencies than those of the uncoordinated ligands. In general, the IR spectra are similar to those observed for other copper *N*-sulfonamide derivatives[20,21] with the modifications noted above being mainly because of the ligand deprotonation at the sulfonamide group.

The diffuse reflectance spectra of complexes **1**, **3**, and **4** exhibit a d–d shoulder in the range of 652 to 671 nm while that of complex **2** shows two well-defined d–d bands at 543 and 702 nm. The room temperature magnetic moments of complexes **1** ($\mu_{eff}$ = 1.73 BM), **2** ($\mu_{eff}$ = 1.75 BM), **3** ($\mu_{eff}$ = 1.82 BM), and **4** ($\mu_{eff}$ = 1.77 BM) are consistent with the presence of a single unpaired electron. The EPR spectra of the complexes are axial with $g_{\|}$ ranging from 2.22 to 2.30 and $g_{\perp}$ around 2.05.

The complexes have been structurally characterized with the aid of single-crystal X-ray diffraction techniques. ORTEP drawings of the complexes, including the atomic numbering schemes, are shown in Figure 1, Figure 2, Figure 3, and Figure 4. Selected bond lengths and angles are listed in Table 1.

The crystal structures of compounds **1**, **3**, and **4** consist of a discrete monomeric copper(II) species surrounded by

four N atoms belonging to a phenanthroline molecule and two deprotonated *N*-sulfonamide ligands in a distorted square-planar geometry. In complexes **1** and **3** the tetrahedrality value of 15.51° and 18.79°, respectively, indicates that the copper ion adopts a distorted square-planar geometry.[22] The metal ion in complex **4** is located at an inversion symmetry center, hence its coordination polyhedron is strictly square planar. The Cu–N bond lengths lie in the range 1.949(4) to 2.027(12) Å, which are normal lengths for Cu–Nphen and Cu–N-benzothiazole coordination bonds.[11,13,23]

The copper(II) ion in complex **2** is five-coordinate with a distorted square-pyramidal geometry. The basal plane is defined by the benzothiazole N atoms of two deprotonated sulfonamide ligands and the two N atoms of a phenanthroline molecule. The Cu–N bond lengths are similar to those found in complexes **1**, **3**, and **4**. The oxygen atom of a coordinated methanol molecule occupies the axial position with a bond length of 2.353 Å. The changes in bond length are described by tetragonality ($T^5$); in this case, the tetragonality value of 0.85 fits into the range expected for square-pyramidal complexes with mixed nitrogen-oxygen ligands.[24] The in-plane angular distortion described by the ratio $\tau$ represents the percentage of trigonal distortion in a square-pyramidal geometry.[25] The $\tau$ value of 0.20 found here thus indicates the presence of a slight distortion.

The coordination mode of the sulfonamide as a monodentate ligand that binds through the benzothiazole N atom in complexes **1**, **2**, **3**, and **4** is the same as that usually found in other $Cu^{II}$ complexes with *N*-substituted sulfonamide analogs.[12,13,23]

## DNA Binding Properties

The mode of and propensity for binding of the complexes to calf thymus DNA (CT-DNA) has been studied with the aid of different techniques.

### *Viscosity Measurements*

Viscosity measurements were carried out on CT-DNA by varying the concentration of the complexes. Hydrodynamic measurements that are sensitive to length changes are regarded as the least ambiguous and the most critical tests of binding in solution. One classic intercalation model results in the lengthening of the DNA helix as the base pairs are separated to accommodate the binding ligand, thus leading to the increase of DNA viscosity. In contrast, complexes that bind exclusively in DNA grooves by means of partial and/or nonclassic intercalation under the same conditions typically cause either a less pronounced (positive or negative) or no change in DNA solution viscosity.[26] The results obtained with our compounds reveal that while complex **4** (Figure 5) interacts with DNA in a classic intercalative mode, the presence of complexes **1**, **2**, or **3** (data not shown) has no effect on the relative viscosity of CT-DNA. This indicates that the interaction of these complexes follows the general pattern of other complexes that bind in DNA grooves by either a partial or nonclassic intercalation.

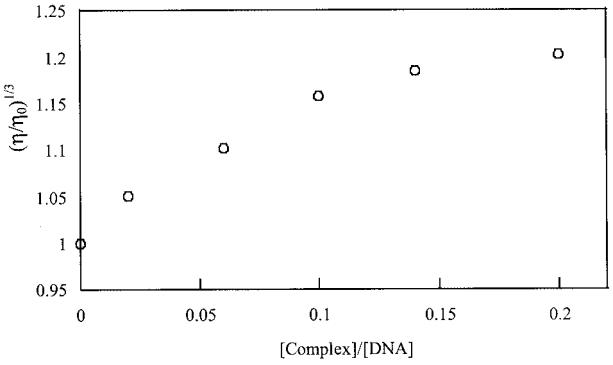

Figure 5. Effect of increasing amounts of the $[Cu(L4)_2(phen)]$ (**4**) complex on the relative viscosity of CT-DNA.

The different behavior exhibited by complex **4** may be attributable to its strictly square-planar geometry; in the other complexes, the distortion of the coordination polyhedron may prevent the intercalation between the bases of the DNA.

### *Effect of the Complexes on the Emission Spectra of the DNA-EB System*

To corroborate the findings from the viscometry results on the mode of DNA interaction, we carried out competitive ethidium bromide (EB) binding studies. Since EB shows a reduced emission intensity in buffers because of the quenching by the solvent molecules and a significantly enhanced intensity when bound to DNA, the emission intensity of this compound is often used as a spectroscopic probe.[27] Binding of the complexes to DNA decreases the emission intensity of EB and the extent of the emission intensity reduction actually gives a measure of the DNA binding propensity of the complexes in question. The results in Figure 6 (a) show that the fluorescence intensity of CT-DNA–EB decreases remarkably with the addition of complex **4**, which indicates that the complex binds to DNA, replacing the EB from the CT-DNA. Such a result is common in intercalative DNA interactions and is consistent with the results obtained from the viscosity measurements.

The fluorescence quenching of EB bound to DNA by complex **4** is in agreement with the classic linear Stern–Volmer equation[27]

$$I_{F0}/I_F = 1 + k_q[Q],$$

where $I_{F0}$ is the emission intensity in the absence of quencher, $I_F$ is the emission intensity in the presence of quencher, $k_q$ is the quenching constant, and $[Q]$ is the quencher concentration. This concordance can be observed by comparing the fluorescence quenching curve of $I_{F0}/I_F$ to the concentration of complex **4** (Figure 6, b). It may thus be concluded that complex **4** binds to DNA mainly by means of intercalation. The value of $K_{app}$ is $1.72 \times 10^6$ $M^{-1}$, which corresponds to the copper(II) complex concentration [Q] = 58.1 μM that causes a 50% quenching of the initial EB fluorescence. This finding suggests that the interaction of **4** with DNA is quite strong.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

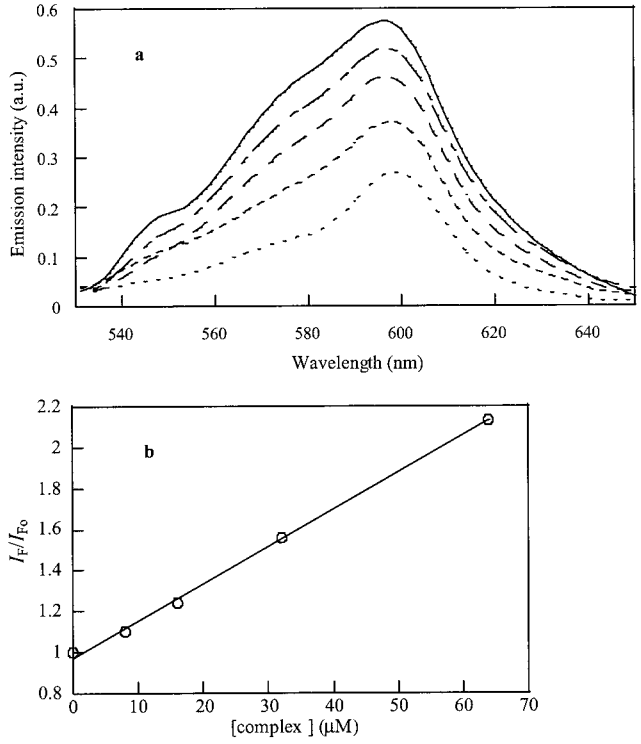

Figure 6. (a) Emission spectra of the DNA–EB system (100 μM CT-DNA base pairs and 10 μM ethidium bromide) $\lambda_{ex}$ = 500.0 nm $\lambda_{em}$ = 530–650 nm, in the absence (continuous line) and in the presence (discontinuous lines) of increasing amounts of complex **4** (0–64 μM). (b) Emission quenching of DNA–EB system upon addition of [Cu(L4)$_2$(phen)] (**4**).

The presence of complexes **1**, **2**, or **3** (data not shown) has no effect on the emission spectra of the DNA–EB system under the same conditions.

### *Thermal Denaturation Results*

The binding of complexes **1**–**4** to CT-DNA was then studied from the thermal denaturation profile of DNA. While complexes **1** and **2** produced no increase in the melting temperature ($T_m$) upon their addition to DNA (CT-DNA $T_m$ = 57 °C), complexes **3** and **4** increased the $T_m$ to 75 and 71 °C, respectively. These results suggest a groove binding for complexes **1** and **2** and intercalation for complexes **3** and **4**, thereby explaining the resulting increased duplex stabilization.[28]

The behavior of complex **3** is noteworthy, especially since the thermal denaturation experiments indicate that this compound can intercalate with DNA while fluorescence and viscosity results do not agree with this result. One possible explanation for the duplex stabilization that is effected by complex **3** is that specific hydrogen-bonding interactions are present between the *N*-(benzothiazolyl)sulfonamide ligands and the bases or phosphate backbone of the DNA. Another possibility is that deformations in the double-helix structure that occur upon binding of the complexes result in additional interstrand interactions.[29]

### pUC18 Cleavage

We then went on to study the activity of the complexes as chemical nucleases using supercoiled (SC) pUC18 DNA in cacodylate buffer (pH = 6.0) with ascorbate/$H_2O_2$ activation. The efficiency of the complexes has been compared with that of both copper salt and the bis(*o*-phenanthroline)-copper complex under the same conditions.

The results shown in Figure 7 indicate that the DNA cleavage activity order is **4** > **2** > **1** > **3**. The results also reveal that the DNA scission mediated by the compounds depends on complex concentration, with the cleavage being more efficient at higher concentrations.

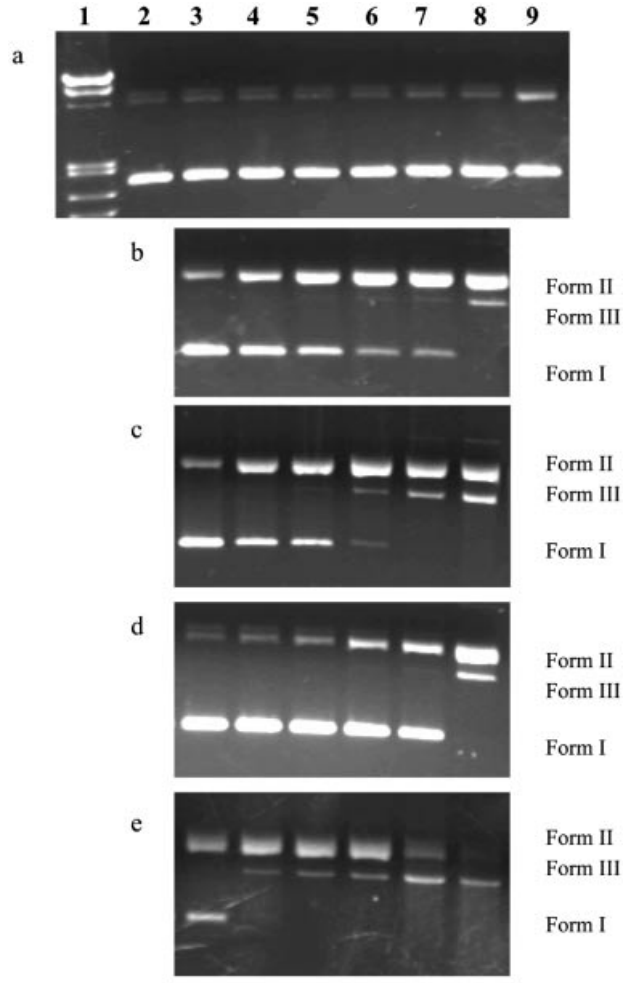

Figure 7. Agarose gel electrophoresis of pUC18 plasmid DNA treated with copper salt, the complexes, or bis(*o*-phenanthroline)-copper(II). [Ascorbate/$H_2O_2$]:[tested compound] = 1:1. Incubation time: 30 min (37 °C). (a) $CuSO_4$ (b) [Cu(L1)$_2$(phen)] (**1**) complex, (c) [Cu(L2)$_2$(phen)MeOH] (**2**) complex, (d) [Cu(L3)$_2$(phen)] (**3**) complex, (e) [Cu(L4)$_2$(phen)] (**4**) complex.

Marker, 3; lane 2: supercoiled DNA; lane 3: copper salt (a) or complexes (b–e) 1.5 μM; lane 4: copper salt (a) or complexes (b–e) 3 μM; lane 5: copper salt (a) or complexes (b–e) 4.5 μM; lane 6: copper salt (a) or complexes (b–e) 6 μM; lane 7: copper salt (a) or complexes (b–e) 7.5 μM; lane 8: copper salt (a) or complexes (b–e) 9 μM; lane 9: [Cu(phen)$_2$]$^{2+}$ complex 9 μM.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Complexes **1** and **2** at 3 and 4.5 μM (see parts b and c in Figure 7, lanes 4 and 5) produced supercoiled DNA cleavage, which was transformed into circular DNA (Form II). Linearized DNA was not observed under these conditions. This latter finding suggests that cleavage may occur randomly over the DNA since a significant portion of the plasmid already appears to be converted to Form II without concurrent formation of Form III. For its part, Form III resulted from multiple cleavage of Form II and appeared only when full cleavage of Form I was practically achieved (Figure 7, part b, lane 8 and part c, lane 6).

At low concentrations of complex **3** (1.5, 3, and 4.5 μM, lanes 3, 4, and 5 in Figure 7, d) the plasmid remained supercoiled. In contrast to the reactivity of **1** and **2**, complex **3** was unable to mediate the conversion of supercoiled DNA (Form I) at 3 and 4.5 μM (Figure 7, part d, lanes 4 and 5). Upon increasing the concentration of **3** to 6 and 7.5 μM, the supercoiled DNA was partially transformed into open circular DNA (Figure 7, part d, lanes 6 and 7) whereas at 9 μM, DNA Form I was fully converted into Form II and Form III (Figure 7, part d, lane 8).

Complex **4** was the most reactive of the complexes (Figure 7, e), proving to be a very efficient chemical nuclease. At the very low concentration of 1.5 μM, the compound was capable of mediating the conversion of supercoiled DNA to its open circular form (lane 3 in Figure 7, e). In the concentration range from 3 to 6 μM, complex **4** induced complete degradation of the plasmid to yield the open circular and linear forms (Figure 7, part e, lanes 4–6) while at 7.5 μM, the supercoiled DNA was converted into Form II, Form III and small linear fragments that appeared as a smear on the gel (Figure 7, part e, lane 7). At a concentration of 9 μM, only the linear Form III and small linear fragments were observed (Figure 7, part e, lane 8). These products are inconsistent with a mechanism of concerted cleavage of both strains of the plasmid.

As no cleavage was found for $CuSO_4$ under the same conditions (lanes 3–8 of Figure 7, a), the DNA cleavage activity of the compounds can be ascribed to the cooperative effect between $Cu^{II}$ and its ligands.

Since our compounds contain *o*-phenanthroline as a ligand, we have compared their nucleolytic activity with that of bis(*o*-phenanthroline)copper complex, which is a well-known and very efficient chemical nuclease. A comparison of lane 8 of Figure 7, part b (**1**, 9 μM), part c (**2**, 9 μM), part d (**3**, 9 μM), and part e (**4**, 9 μM) with lane 9 of Figure 7 (a) ($[Cu(phen)_2]^{2+}$, 9 μM) clearly indicates that these complexes present considerably higher nuclease activity than the bis(*o*-phenanthroline)copper complex. Under these conditions, bis(*o*-phenanthroline)copper complex was only able to transform a small quantity of SC DNA into its open circular form while the complexes mediated the full conversion of the plasmid Form I to the Forms II and III, with complex **4** producing small linear fragments. It is thus clear that the presence of an *N*-sulfonamide ligand increases nuclease activity.

The existence of diffusible radical species in the nuclease mechanism can be inferred by monitoring the quenching of DNA cleavage in the presence of alternative H-atom donors, which should scavenge radicals (such as $OH^{\cdot}$) in solution. To this end, we included standard scavengers of reactive oxygen intermediates in the electrophoretic process (Figure 8).

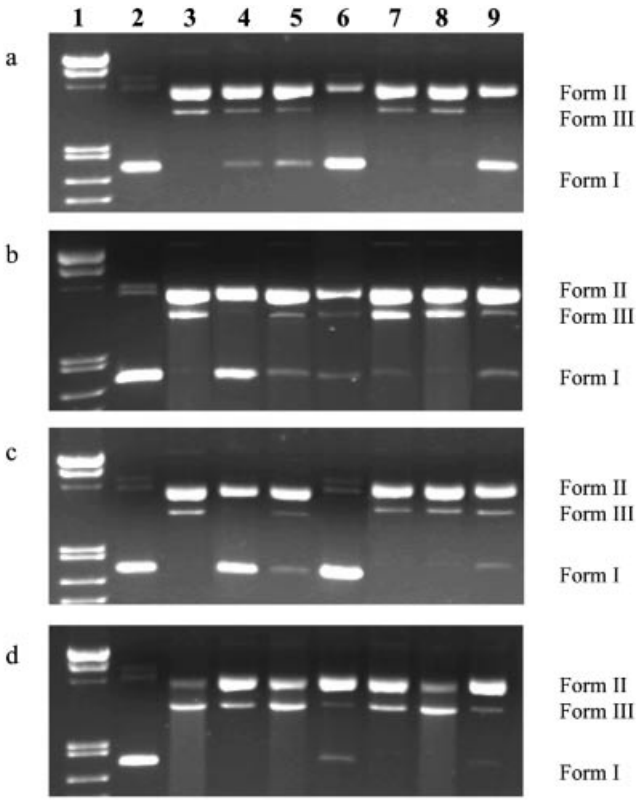

Figure 8. Agarose gel electrophoresis of pUC18 plasmid treated with 9 μM complexes and 9 μM ascorbate/$H_2O_2$ in the presence of potential inhibitors. Incubation time 30 min (37 °C). (a) $[Cu(L1)_2$-(phen)] (**1**) complex, (b) $[Cu(L2)_2$(phen)MeOH] (**2**) complex, (c) $[Cu(L3)_2$(phen)] (**3**) complex, (d) $[Cu(L4)_2$(phen)] (**4**) complex. Lane 1: DNA/EcoRI + Hind III. Marker, 3; lane 2: supercoiled DNA; lane 3: complex without inhibitors; lane 4: complex + DMSO (1 M); lane 5: complex + *tert*-butyl alcohol (1 M); lane 6: complex + $NaN_3$(100 mM); lane 7: complex + 2,2,6,6 tetramethyl-4-piperidone (100 mM); lane 8: complex + distamycin (8 μM); lane 9: complex + SOD (15 units).

The presence of the hydroxyl radical scavengers dmso and *tert*-butyl alcohol (lanes 4 and 5 of Figure 8a–d) significantly inhibited the chemical nuclease activity of the complexes. This suggests a cleavage pathway involving the formation of the reactive hydroxyl radical.

Sodium azide (lane 6 of Figure 8, a–d) inhibited DNA cleavage by the compounds to some extent, a finding that points to the participation of $^1O_2$ in the reaction. However, except in the case of **4**, 2,2,6,6-tetramethyl-4-piperidone, another singlet oxygen scavenger, had no observable effect on the cleavage reaction (lanes 7), which clearly contradicts the initial result. This may be resolved by taking into account that since the azide ion can act as a ligand of copper(II), inhibition of the nuclease reaction probably occurs not by radical quenching, but rather by blocking the coordination site on copper that is involved in radical formation. We can

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thus conclude that $^1O_2$ is most likely not involved in the reaction.[30]

Lane 9 of Figure 8 (a–d) shows a significant reduction of the DNA cleavage of the complexes in the presence of the SOD enzyme, which indicates that $O_2^-$ is one of the reactive species that actually breaks the DNA.

In the presence of the minor groove binder distamycin (lanes 8), the complexes displayed no apparent inhibition of DNA damage. This suggests that there are no minor binding preferences for the complexes.[31]

The mechanism of the DNA strand scission of bis(*o*-phenanthroline)copper(II) in the presence of reducing agents indicates that upon its reduction, the copper(II) complex binds to DNA, thereby liberating a phenanthroline.[32] Hydrogen peroxide then forms a copper–oxene reactive species that attacks the C1–H of the D-ribose. However, for complexes **1**, **2**, **3**, and **4**, $OH^{\cdot}$ and $O_2^-$ are the active oxygen species involved in the reaction. The involvement of these ROS excludes the formation of a copper–oxene such as that proposed by Sigman for bis(*o*-phenanthroline)copper(II).[32]

Because of the presence of hydroxyl and superoxide radicals and taking into account that the complexes are not able per se to induce any effect on the double stranded DNA, but that the cleavage process can be induced with the addition of activating agents at very low concentrations, we propose that the DNA damage can occur either through a Fenton-type reaction:

$$Cu^{II}(L) + e^- \rightarrow Cu^{I}(L)$$

$$Cu^{I}(L) + H_2O_2 \rightarrow Cu^{II}(L) + OH^- + OH^{\cdot}$$

or a Haber–Weiss reaction:

$$Cu^{II}(L) + e^- \rightarrow Cu^{I}(L)$$

$$Cu^{I}(L) + O_2 \rightarrow Cu^{II}(L) + O_2^-$$

$$O_2^- + H_2O_2 \rightarrow O_2 + OH^- + OH^{\cdot}$$

The proposed mechanism for our compounds is similar to that for the related Cu–*N*-quinolinsulfonamide-*o*-phenanthroline complex.[11]

In summary, the four complexes are very efficient chemical nucleases at low concentrations and in the presence of a low concentration of $H_2O_2$/ascorbate. In particular, $[Cu(L4)_2(phen)]$ (**4**) is a promising compound with much higher activity than that exhibited by the paradigmatic bis(*o*-phenanthroline)copper(II) complex. The high efficiency of **4** is probably due to the fact that its intercalation binding to DNA permits ROS formation near the deoxyribose moiety. Studies with inhibiting reagents suggest that the cleavage mechanism for these compounds is different from that proposed by Sigman for the bis(*o*-phenanthroline)copper(II) complex.

## Genotoxicity Assay in Yeast Cells

### *Sensitivity of the RAD54-yEGFP and RNR2-yEGFP Reporter System to EMS at Different Incubation Times*

Previous studies have shown that the brightness of the fluorescence signal obtained from yeast strains carrying the RAD54-yEGFP promoter-reporter construct on the plasmid correlates with exposure to increasing concentrations of MMS (methyl methane sulfonate).[15] EMS (ethyl methane sulfonate) and MMS are alkylating agents that can act on DNA and lead to damage and mutagenesis. EMS is regularly used as the reference substance for assessing the mutagenic and DNA-damaging potential of chemicals.[14] In order to test the sensitivity of the various transformed

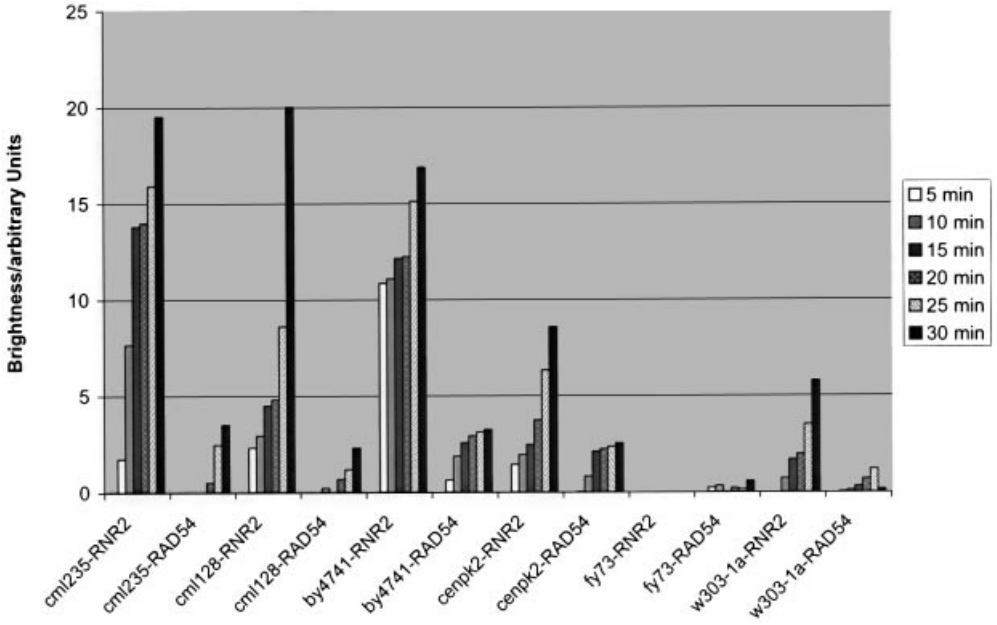

Figure 9. Comparison of EMS-dependent fluorescence in different *Saccharomyces cerevisiae* strains carrying the RAD54-yEGFP or the RNR2-yEGFP constructs. Intensity of the fluorescence signal is dependent on incubation time (0, 5, 10, 15, 20, 25, or 30 min; 0 min is represented as the background). The fluorescence signal displayed has been normalized for cell density.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

strains to this paradigmatic mutagenic substance, we have performed fluorescence measurements in response to EMS treatment with yeast cell cultures carrying the RAD54-yEGFP or RNR2-yEGFP constructs. These assays have also been carried out with the aim of selecting the most sensitive transformed stain for subsequent evaluation of the genotoxicity of copper(II) complexes.

The results, shown in Figure 9, demonstrate that after treatment with EMS, only a weak increase in fluorescence is observed with the various RAD54-yEGFP constructions.

As an alternative sensor system, the RAD54 promoter was replaced by the promoter of the RNR2 gene. RNR2, a small subunit of ribonucleoside diphosphate reductase essential for the synthesis of nucleotide precursors, was shown to be induced by MMS treatment.[15] EMS was also able to induce measurable levels of yEGFP fluorescence driven by RNR2, where the fluorescence signal obtained with the RNR2 promoter was stronger than that observed with the RAD54 promoter. This result is consistent with data presented by Jelinsky and Samson[33] and Afanassiev et al.[14] The best results were obtained with the CML128-RNR2 strain, which was consequently chosen to test the ability of the copper compounds to cause DNA damage.

### *Sensitivity of the CML128-RNR2-yEGFP Reporter System to Copper Compounds at Different Concentrations*

The induction of a fluorescence signal driven by promoters that respond to DNA damage in the yeast *S. cerevisiae* provides a system to monitor the activity of substances that possess mutagenic potential at low concentrations. This method not only allows for the recognition of mutagenic agents that are able to produce DNA damage to living systems, but it can also be used to determine the biologically active concentrations of these substances, since the yeast system provides all the typical features of eucaryotic cell architecture and metabolism.

We thus tested the ability of compounds **1**, **2**, **3**, and **4**, previously shown to be strong DNA-cleaving agents, to induce a fluorescence signal in the selected CML128-RNR2-yEGFP system. The response obtained in the presence of $CuCl_2$ or $[Cu(phen)_2]^{2+}$ was studied for comparative purposes while EMS was used as a positive control. Figure 10 shows the intensity of the fluorescence signals induced by EMS, compounds **1**–**4**, and $CuCl_2$ and bis(*o*-phenanthroline)copper(II) over the system after 20 hours of incubation.

As can be seen in Figure 10, complexes **3** and **4** induced fluorescence. In particular, complex **4**, which had been found to be the most efficient chemical nuclease, showed a significant induction of the fluorescence reporter system, which indicates that this compound is able to produce DNA cleavage inside the cell. The signal was much stronger than that of complex **3**. Other substances that have been described in the literature as having induced fluorescence signals over similar systems include cisplatin (a strong DNA cleaving agent), camptothecin (an inhibitor of topoisomerase I), aphidicolin (an inhibitor of DNA polymerases α and δ), and actinomycin D (an intercalator that inhibits mainly transcription, but also replication to some extent).[14]

Complexes **1**, **2**, and bis(*o*-phenanthroline)copper(II), which possesses strong DNA cleaving activity, did not activate the RNR2 promoter-driven yEGFP expression Also, the results show that $CuCl_2$ was unable to induce a fluorescence signal. These negative results observed with complexes **1**, **2**, and bis(*o*-phenanthroline)copper(II), all of which are able to produce pUC18 DNA cleavage, could be because of enzymatic inactivation, lack of cell penetration, detoxification, or other specific properties of the yeast. Some substances known to have mutagenic or DNA-damaging potential, including psoralen, benzpyrene, tetracycline, colchicine, bleomycin, and mitomycin C, are unable to induce activity in similar systems.[14]

Because of the high genotoxic potential of **4**, our next task will be to evaluate the therapeutic use of this compound. With this aim, the potential antitumor activity of **4** will be tested on human tumor cell lines.

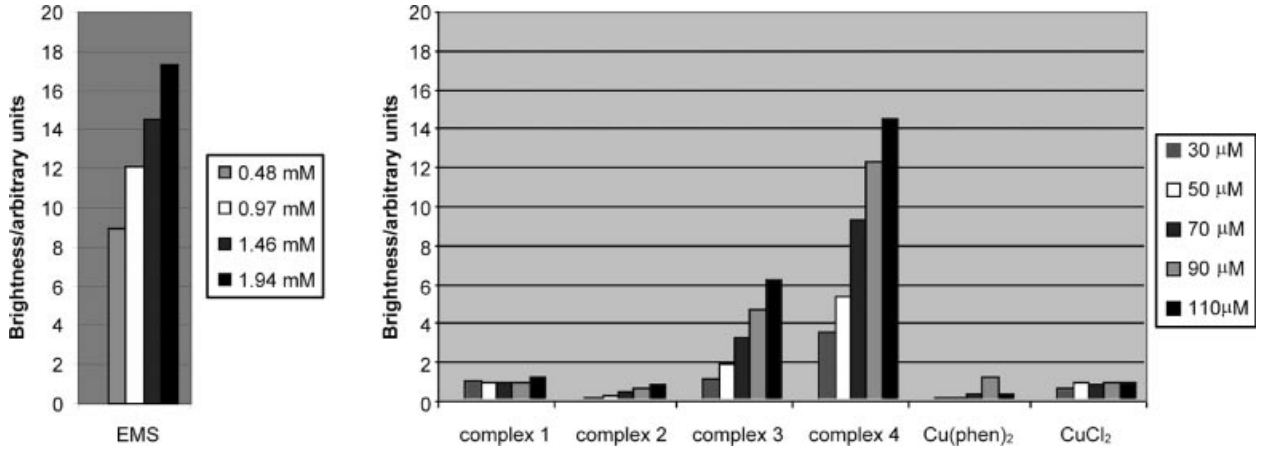

Figure 10. Fluorescence response profiles after treatment of CML128-RNR2-yEGFP with increasing concentrations of EMS, complexes **1**, **2**, **3**, or **4**, $[Cu(phen)_2]^{2+}$, or $CuCl_2$. Diagrams show the dose response of fluorescence after 20 h of incubation (0 M is represented as the background).

## Conclusions

Ternary copper(II) complexes with *N*-substituted sulfonamide ligands and *o*-phenanthroline have been prepared and structurally characterized with the aid of X-ray crystallography. The DNA cleavage activities of these complexes have been studied and compared with that of bis(*o*-phenanthroline)copper(II). All the complexes act as efficient chemical nucleases and their activities were found to be higher than that of the paradigmatic bis(*o*-phenanthroline)copper(II) complex. The most active cleaving agent was found to be $[Cu(L4)_2(phen)]$(**4**), which was able to mediate DNA scission at very low concentrations (1.5 μM) in the presence of low concentrations of activating agents. The significant activity of this complex can be ascribed to its efficient binding to DNA, as deduced from viscosity, fluorescence, and thermal denaturation studies. The sensitivity of the CML128-RNR2-yEGFP reporter system to copper compounds was tested to evaluate the genotoxic potential (i.e., the potential to inflict DNA damage) of the compounds at the cellular level. The significant induction of fluorescence by complex **4** indicated a high genotoxic potential for this compound. This fact makes **4** a very promising DNA damaging agent for further studies on human tumor cell lines.

## Experimental Section

**Materials:** Reagents and solvents were commercially available and were used without further purification. pUC18 was purchased from Roche Diagnostics. Calf thymus DNA (CT-DNA) was supplied by Sigma–Aldrich.

**Physical Methods:** Elemental analyses (C,H,N,S) were performed with a Carlo–Erba AAS instrument. IR spectra (KBr disks) were obtained with a Mattson satellite FT-IR in the range 4000–400 $cm^{-1}$. Fast atomic bombardment (FAB) mass spectra were obtained with a VG Autospec spectrometer with 3-nitrobenzyl alcohol as the matrix. Diffuse reflectance spectra (nujol mulls) of the complexes were carried out with a Shimadzu UV-2101 PC spectrophotometer. Electronic Paramagnetic Resonance (EPR) spectra were taken at the X-band frequency at room temperature with a Bruker ELEXSYS Spectrometer.

### Synthesis of the Ligands

***N*-(Benzothiazol-2-yl)benzenesulfonamide (HL3) and *N*-(Benzothiazol-2-yl)toluenesulfonamide (HL4):** A solution containing 2-aminobenzothiazole (1 g) and benzenesulfonyl chloride (2.5 g) or toluenesulfonyl chloride (2.5 g) in pyridine (6 mL) was heated at reflux for 1 h. The mixture was added to cold water (10 mL) and stirred for several minutes. The resulting solid was recrystallized from ethanol. After several weeks, slow evaporation of the filtrate gave rise to single crystals suitable for X-ray diffraction.

***N*-(Benzothiazol-2-yl)benzenesulfonamide (HL3):** Yield: 1.89 g, 98.9%. $C_{13}H_{10}N_2S_2O_2$ (290.35): calcd. C 53.77; H 3.47; N 9.65; S 20.08; found C 53.88; H 3.26; N 9.69; S 20.05. IR (KBr): $\tilde{\nu}$ = 1561 (thiazole); 1317–1304, 1146 $\nu(SO_2)$; 959 $\nu$(S–N) $cm^{-1}$. FAB: *m*/*z* = 291 [$M^+$]. UV: $\lambda_{max}$ = 309 (π→π*) nm.

***N*-(Benzothiazol-2-yl)toluenesulfonamide (HL4):** Yield: 1.88 g, 93.0%. $C_{14}H_{12}N_2S_2O_2$ (304.38): calcd. C 55.24; H 3.97; N 9.20; S 21.07; found C 55.11; H 3.97; N 9.26; S 21.14. IR (KBr): $\tilde{\nu}$ = 1560 (thiazole); 1314, 1146 $\nu(SO_2)$; 960 $\nu$(S–N) $cm^{-1}$. FAB: *m*/*z* = 305 [$M^+$]. UV: $\lambda_{max}$ = 302 (π→π*) nm.

***N*-(6-Chlorobenzothiazol-2-yl)benzenesulfonamide (HL1) and *N*-(6-Chlorobenzothiazol-2-yl)toluenesulfonamide (HL2):** These compounds were obtained and characterized as previously reported.[23,34]

### Synthesis of the Complexes

**$[Cu(L1)_2(phen)]$ (1), $[Cu(L2)_2(phen)MeOH]$ (2), $[Cu(L3)_2(phen)]$ (3), and $[Cu(L4)_2(phen)]$(4):** Aqueous NaOH (0.5 M, 2 mL) was added to a solution of the ligand (1 mmol) in methanol (40 mL). A suspension of $CuSO_4$ (0.5 mmol) and 1,10-phenanthroline monohydrate (0.5 mmol) in methanol was then added, and the resulting mixture was stirred for ca. 30 min at 40 °C. After cooling, the mixture was filtered to remove the precipitate that formed. Well-shaped crystals of **1**, **3**, and **4** were obtained from the filtrate by slow evaporation at room temperature for several months. Crystals of complex **2** were also formed, but they were not of sufficiently high quality for structural determination. Reaction in methanol by means of slow diffusion afforded good quality crystals of **2** after several days. Crystals of all the complexes were isolated by means of filtration, washed with MeOH, and dried under vacuum.

**Complex 1:** Yield: 0.142 g, 32%. $C_{38}H_{26}Cl_2CuS_4N_6O_4$: calcd. C 51.09, H 2.93, N 9.41, S 14.36; found C 51.15, H 2.96, N 9.39, S 14.28. IR (KBr): $\tilde{\nu}$ = 1465 (thiazole); 1279, 1129 $\nu(SO_2)$; 961 $\nu$(S–N) $cm^{-1}$. Solid UV/Vis: $\lambda_{max}$ = 355 (π→π*), 652 sh (d–d) nm.

**Complex 2:** Yield: 0.124 g, 26%. $C_{41}H_{32}Cl_2CuS_4N_6O_5$: calcd. C 51.76, H 3.39, N 8.83 S 13.48; found C 51.65, H 3.42, N 8.91 S 13.28. IR(KBr): $\tilde{\nu}$ = 1462 (thiazole); 1295, 1139 $\nu(SO_2)$; 968 $\nu$(S–N) $cm^{-1}$. Solid UV/Vis: $\lambda_{max}$ = 338 (π→π*), 543, 702 (d–d) nm.

**Complex 3:** Yield: 0.152 g, 37%. $C_{38}H_{26}CuS_4N_6O_4$: calcd. C 55.49, H 3.19 N 10.22 S 15.60; found C 55.32, H 3.15 N 10.10 S 15.67. IR (KBr): $\tilde{\nu}$ = 1432 (thiazole); 1276, 1144 $\nu(SO_2)$; 968 $\nu$(S–N) $cm^{-1}$. Solid UV/Vis: $\lambda_{max}$ = 371 (π→π*), 671 sh (d–d) nm.

**Complex 4:** Yield: 0.115 g, 27%. $C_{40}H_{30}CuS_4N_6O_4$: calcd. C 56.49 H 3.56 N 9.88 S 15.08. found C 56.53 H 3.42 N 9.88 S 15.08. IR(KBr): $\tilde{\nu}$ = 1489–1441 (thiazole); 1276, 1134 $\nu(SO_2)$; 967 $\nu$(S–N) $cm^{-1}$. Solid UV/Vis: $\lambda_{max}$ = 337 (π→π*), 665 sh (d–d) nm.

**X-ray Crystallography:** A green crystal measuring 0.04 × 0.04 × 0.08 mm (**1**), a blue crystal measuring 0.2 × 0.08 × 0.24 mm (**2**), a brown crystal measuring 0.04 × 0.1 × 0.2 mm (**3**), and a dark blue crystal measuring 0.14 × 0.12 × 0.08 mm (**4**), and either a triclinic space group $P\bar{1}$ (**1**) or a monoclinic space group *P*21/*c* (**2**, **3**, and **4**) (as determined from systematic absences) were used. Data collection was performed at 293 K with a Nonius Kappa-2000 single crystal diffractometer, with Cu-$K_\alpha$ radiation ($\lambda$ = 1.54184 Å) for complexes **1**, **3**, and **4** or with a Nonius Kappa CCD single crystal diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) for complex **2**. The crystal-detector distance was fixed at 35 mm (**1**, **3**, and **4**) or 32.1 mm (**2**) and a total of 106 (**1**), 228 (**2**), 430 (**3**), and 91 (**4**) images were collected by means of the oscillation method, with a scan angle per frame of 2° (**1**, **3**, and **4**) or 1.7° (**2**) oscillation and 20 s (**1**), 15 s (**2**), 26 s (**3**), and 2 s (**4**) exposure time per image. The data collection was carried out and calculated with the program Collect.[35] Data reduction and cell refinements were performed with the programs HKL Denzo and Scalepack.[36]

Unit cell dimensions were determined from 295 (**1**), 10423 (**2**), 3916 (**3**), and 597 (**4**) reflections between $\theta$ = 0.999° and 39.973° (**1**),

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.998° and 28.7° (**2**), 0.999° and 63.691° (**3**), and 0.99° and 36.05° (**4**). Multiple observations were averaged: for complex **1** ($R_{merge}$ = 0.0000) this resulted in 1712 unique reflections of which 1189 were observed with $I > 2\sigma(I)$, for complex **2** ($R_{merge}$ = 0.030) this resulted in 10601 unique reflections of which 6891 were observed with $I > 2\sigma(I)$, for complex **3** ($R_{merge}$ = 0.0000) this resulted in 4086 unique reflections of which 2439 were observed with $I > 2\sigma(I)$, and for complex **4** ($R_{merge}$ = 0.0000) this resulted in 879 unique reflections of which 732 were observed with $I > 2\sigma(I)$. Final mosaicity was 0.35(**1**), 0.43 (**2**), 0.50 (**3**), and 0.509 (**4**). All data completeness was 74.2% (**1**), 98.2% (**2**), 84.0% (**3**), and 95.5% (**4**).

Crystal structures were solved by direct methods, either with the program SIR-97 (**1**, **2**, and **3**) or SHELXS-86 (**4**).[37] Anisotropic least-squares refinements were carried out with SHELXL-97.[38] All non-hydrogen atoms were anisotropically refined while hydrogen atoms were located geometrically. The final cycle of full-matrix least-squares refinement based on 1712 (**1**), 10601 (**2**), 4086 (**3**), and 879 (**4**) reflections and 494 (**1**), 536 (**2**), 561 (**3**), and 284 (**4**) parameters converged to a final value of $R_1$ [$F^2 > 2\sigma(F^2)$] = 0.052, $wR_2$ [$F^2 > 2\sigma(F^2)$] = 0.130, $R_1$ ($F^2$) = 0.082, $wR_2$ ($F^2$) = 0.150 for complex **1**; $R_1$ [$F^2 > 2\sigma(F^2)$] = 0.046, $wR_2$ [$F^2 > 2\sigma(F^2)$] = 0.127, $R_1$ ($F^2$) = 0.090, $wR_2$ ($F^2$) = 0.170 for complex **2**; $R_1$ [$F^2 > 2\sigma(F^2)$] = 0.044, $wR_2$ [$F^2 > 2\sigma(F^2)$] = 0.094, $R_1$ ($F^2$) = 0.092, $wR_2$ ($F^2$) = 0.112 for complex **3**; and $R_1$ [$F^2 > 2\sigma(F^2)$] = 0.036, $wR_2$ [$F^2 > 2\sigma(F^2)$] = 0.097, $R_1$ ($F^2$) = 0.045, $wR_2$ ($F^2$) = 0.105 for complex **4**. Final difference Fourier maps showed no peaks higher than 0.261 e/Å$^3$ nor deeper than –0.397 e/Å$^3$ for complex **1**, no peaks higher than 0.678 e/Å$^3$ to 1.06 Å to H14d nor deeper than 1.5 e/Å$^3$ to 0.85 Å to Cu for complex **2**, no peaks higher than 0.197 e/Å$^3$ to 1.14 Å to N1c nor deeper than –0.405 e/Å$^3$ to 0.98 to Cu1 for complex **3**, and no peaks higher than 0.411 e/Å$^3$ nor deeper than –0.167 e/Å$^3$ for complex **4**. Semi-empirical absorption correction was applied using the program XABS2[39] for complex **1**. Geometrical calculations were made with PARST.[40] The crystallographic plots were made with ORTEP.[41] A summary of crystallographic data of the complexes is given in Table 2.

The supplementary crystallographic data for this paper is contained in CCDC-299259, -299260, -299261, and -299262. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Metal Complexes–DNA Interactions**

**Viscosity Measurements:** Viscosity experiments were carried out with a Cannon 25 L97 viscosimeter immersed in a Julabo thermostatted water bath maintained at 25.0 ± 0.1 °C. Solutions of the complexes (1–10 μM) in cacodylate buffer (pH = 6.0) were added to a calf thymus DNA (50 μM base pairs) solution in cacodylate buffer. The flow times were measured with a digital stopwatch. The flow measurements were performed in triplicate. Data were presented as $(\eta/\eta_0)^{1/3}$ vs. the ratio of the concentration of complex and DNA, where $\eta$ is the viscosity of DNA in the presence of the complex and $\eta_0$ is the viscosity of DNA alone. Viscosity values were calculated from the observed flow time of a DNA-containing solution corrected from the flow time of buffer alone ($t_0$), $\eta = t - t_0$.

**Fluorescence Quenching of Ethidium Bromide Intercalated to DNA by Interaction of the Copper Complexes with DNA:** The fluorescence spectra were recorded with a JASCO FP-6200 spectrofluorimeter at room temperature. The experiments were conducted by adding copper(II) complex solutions at various concentrations (0–64 μM) to samples containing 100 μM calf thymus DNA base pairs and 10 μM ethidium bromide in cacodylate buffer (pH = 6.0). All the samples were excited at 500 nm and emission was recorded at 530–650 nm.

**Thermal Denaturation Experiments:** DNA-melting experiments were carried out by monitoring the absorbance (260 nm) of CT-DNA (100 μM base pairs) at different temperatures in the absence and presence of the complexes in a 4:1 DNA/complex ratio. Measurements were performed with an Agilent 8453 UV/Vis spectrophotometer equipped with a Peltier temperature controlled sample cell and driver (Agilent 89090A). The solution containing the ternary complex and CT-DNA in phosphate buffer (1 mM phosphate, 2 mM NaCl, pH = 7.2) was continuously stirred and heated with a rate of temperature increase of 1 °C/min. The temperature interval studied ranged from 25 to 90 °C.

**pUC18 DNA Cleavage:** A typical reaction for complexes was undertaken by mixing a cacodylate buffer (0.1 M, 7 μL, pH 6.0), pUC18 (1 μL, 0.25 μg/μL), a solution of the tested complex (6 μL) at increasing concentrations between 1.5 μM and 9 μM, ascorbate (3 μL), and a $H_2O_2$ (3 μL) twofold molar excess relative to the concentration of the complex in cacodylate buffer. The mixtures were allowed

Table 2. Crystal data and structure refinement for [Cu(L1)$_2$(phen)] (**1**), [Cu(L2)$_2$(phen)MeOH] (**2**), [Cu(L3)$_2$(phen)] (**3**), and [Cu(L4)$_2$-(phen)] (**4**).

to stand for 30 min at 37 °C. After that, a quench buffer solution (3 μL) consisting of bromophenole blue (0.25%), xylene cyanole (0.25%), and glycerol (30%) were added. The solution was then subjected to electrophoresis on a 0.8% agarose gel in 0.5×TBE buffer (0.045 M Tris, 0.045 M boric acid, and 1 mM EDTA) containing 2 μL/100 mL of a solution of ethidium bromide (10 mg/mL) at 80 V for about 2 h. The gel was photographed on a capturing gel printer plus TDI.

To test for the presence of reactive oxygen species (ROS) generated during strand scission, various reactive oxygen intermediate scavengers were added to the reaction mixtures. The scavengers used were superoxide dismutase (15 units), DMSO (1 M), *tert*-butyl alcohol (1 M), sodium azide (100 mM), and 2,2,6,6-tetramethyl-4-piperidone (100 mM). An assay in the presence of the minor groove binder distamycin (8 μM) was also performed. Samples were treated as described above.

**Genotoxicity Assays**

**Construction of a Plasmid Containing yEGFP Under the Transcriptional Control of the RNR2 or RAD54 Promoter:** PCR was used to amplify the RNR2 and RAD54 promoters from genomic *Saccharomyces cerevisiae* DNA with the primers shown in Table 3. pUG35 plasmid was digested with Sal I and Sac I to remove the original promoter of yEGFP. The PCR products were digested with the same restriction enzymes and were ligated into the pUG35 to produce pUG35-RNR2 or pUG35-RAD54. The yeast strains used in this study, listed in Table 4, were grown on a YNB medium (1.68 g of YNB without aa and without salts, 5 g of ammonium sulfate, and 20 g of glucose per liter) with the required amino acids.

**Sensitivity of the RAD54-yEGFP and RNR2-yEGFP Reporter Systems to EMS:** Liquid YNB (10 mL; 1.68 g of YNB without aa and without salts, 5 g of ammonium sulfate, and 20 g of glucose per liter) with the suitable requirements were inoculated into a fresh sample of the yeast strain to give approximately $1\times10^6$ cells/mL. The cultures were incubated overnight at 28 °C with vigorous shaking. The cultures were then washed twice in 50 mM potassium phosphate buffer (pH = 7.0) and resuspended in this buffer to a final concentration of $5\times10^7$ cells/mL. EMS (30 μL) was added to 1 mL of cells and incubated for 30 min at 30 °C. 100 μL samples were obtained at different times (0, 5, 10, 15, 20, 25, and 30 min) during the incubation. The EMS mutagenesis was stopped in each cell suspension by adding an equal volume of a freshly made 10% (w/v) filter-sterilized solution of sodium thiosulfate. The suspensions were then mixed well and centrifuged, after which the cells were collected and washed twice with sterile water. The cells were then inoculated in liquid medium and incubated at 28 °C for 20 h on an orbital shaker. For cell fluorescence measurements, the cell cultures were diluted (1:10 in sterile distilled water) and transferred directly to cuvettes. Samples with cell cultures with no mutagenic agents were taken as blanks. Fluorescence measurements were performed with a Jasco FP-6200 spectrofluorometer. The excitation and emission wavelengths were set to 488 and 511 nm, respectively, with a slit width of 10 nm. Fluorescence values were normalized for the absorption values of each cell. The normalized fluorescence values were then plotted against the substance concentration and incubation time. All calculations and plots were made with MS Excel.

**Evaluation of Genotoxicity Produced by the Complexes:** Single colonies of the selected transformed yeast strains grown on selective medium were used to inoculate 5 mL of medium and then grown to mid log phase (0.4 AU at 600 nm). The cells were resuspended in fresh medium to a final concentration of 0.1 AU. Solutions of EMS, the copper salt, or the test compounds at increasing concentrations were distributed in parallel. The tubes were incubated at 28 °C for 20 h on an orbital shaker at 120 rpm. Fluorescence measurements were performed as described above except that, in this case, the first measurement was taken at 0 h and repeated at 4, 16, and 20 h of incubation.

## Acknowledgments

J. B. and G. A. acknowledge financial support from the Spanish CICYT (CTQ2004-03735). M. G.-A. wishes to thank the city government of Valencia (Spain) for a Carmen and Severo Ochoa postdoctoral fellowship.

# Modelling the Electron-Transfer Complex Between Aldehyde Oxidoreductase and Flavodoxin

**Ludwig Krippahl,[a] P. Nuno Palma,[a][‡] Isabel Moura,[a] and José J. G. Moura*[b]**

**Keywords:** Bioinorganic chemistry / Electron transfer / Molybdenum / Enzyme models

Three-dimensional protein structures of the xanthine oxidase family show different solutions for the problem of transferring electrons between the flavin adenine dinucleotide (FAD) group and the molybdenum cofactor. In xanthine oxidase all the cofactors lie within domains of the same protein chain, whereas in CO dehydrogenase the Fe–S centres, FAD and Mo cofactors are enclosed in separate chains and the enzyme exists as a stable complex of all three. In aldehyde oxidoreductase, only Fe–S and Mo co-factors are present in a single protein chain. Flavodoxin is docked to aldehyde oxidoreductase to mimic the flavin component on the intramolecular electron transfer chain of aanthine oxidase and CO dehydrogenase and, remarkably, the main features of the electron-transfer pathway are observed.

## Introduction

Molybdenum and tungsten are found in a mononuclear form in the active site of a diverse group of enzymes that catalyze, in general, oxygen-atom transfer and are distinct from the nitrogenase enzyme that contains a complex FeSMo cluster. Mononuclear Mo-enzymes have been classified into three main groups, called the xanthine oxidase (XO), dimethyl sulfoxide reductase (DMSOR) and sulfite oxidase (SO) families.[1,2] The active site of these enzymes contains the metal atom coordinated to one or two pyranopterin molecules and to a variable number of ligands containing atoms such as oxygen (oxo, hydroxo, water, serine, and aspartic acid), sulfur (cysteines) and selenium (selenocysteines). Pyranopterin is an organic ligand that can be either in the monophosphate form or have a nucleotide molecule attached by a pyrophosphate link. In addition, these proteins may have other redox cofactors such as iron-sulfur (Fe–S) centres, hemes and flavin groups, which are involved in intra- and intermolecular electron-transfer processes.[1–3]

There are a few known crystal structures of molybdenum hydroxylases from the XO family. These include aldehyde oxidoreductase (AOR) from *Desulfovibrio gigas*,[4–6] xanthine oxidoreductase (XO) from *Bos taurus*[7] and Xanthine dehydrogenase (XDH) from *Rhodobacter capsulatus*.[8] There are also two known crystal structures of similar proteins containing Mo, namely CO dehydrogenase (CODH) from *Oligotropha carboxidovorans*, which catalyzes the oxidation of CO to $CO_2$ without cleavage of a C–H bond,[9,10] and 4-hydroxybenzoyl-CoA Reductase (4-HBCR) from *Thaurea aromatica*, which catalyzes reductive removal of an aromatic hydroxy group.[11,12]

Despite their similarity, these proteins show three different sequence arrangements for the active sites participating in electron transfer between the FAD group: the two [2Fe-2S] centres and the Molybdenum cofactor.[1,2,7–14] In general, all the cofactors in XO and XDH lie within domains of the same protein chain, although some exceptions are found in prokaryotic XDHs such as the one isolated from *Rhodobacter capasulatus.* In CODH and 4-HBCR, two [2Fe-2S] centres, one FAD and one Mo cofactor are enclosed in separate chains and the enzyme exists as a stable complex of all three. In AOR only the two [2Fe-2S] centres and Mo cofactor are present in a single and shorter polypeptide chain (Figure 1).

Although the arrangement of the 4-HBCR subunits containing the FAD group, the molybdenum cofactor and the two intermediary [2Fe-2S] centres is similar to that of CODH, 4-HBCR is significantly different from CODH. The gene sequences for the three subunits of 4-HBCR in *Rhodopseudomonas palustris*[15] and *T. aromatica*[13] reveal significant differences between these proteins, and 4-HBCR consists of three subunits of $(\alpha\beta\gamma)_2$ composition.[16,17] Each monomer contains a [4Fe-4S] centre[16] in addition to the prosthetic groups shared with CODH. The additional [4Fe-4S] centre is coordinated to conserved cysteinyl residues in a unique stretch of approximately 40 amino acids in the β subunit.[12,19] Nevertheless, for the purposes of this work the important features of 4-HBCR are shared with CODH,

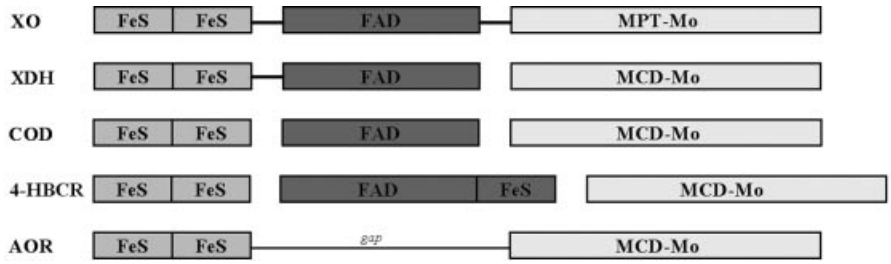

Figure 1. Schematic representation of the domain sequence for the three enzymes XO, CODH, 4-HBCR (that includes an extra elongation of the β-subunit that binds, in addition to the FAD moiety, the [4Fe-4S] center) and AOR (homologies among molybdenum hydroxylases). The FAD domain is absent in the *D. gigas* aldehyde oxidoreductase. In the *R. capsulatus* Xanthine dehydrogenase and the *Bos Taurus* XO, the iron-sulphur and flavin-binding portions of the protein constitute one subunit (XdhA), and the molybdenum-binding portion a second (XdhB). In the *O. carboxydovorans* CO dehydrogenase, the iron–sulphur centres are together in one subunit (CoxS), the flavin in a second (CoxM) and the molybdenum in a third subunit (CoxL). A comparison with the *R. capsulatus* XDH domain sequence is also included (a variation of the XO domain theme).

namely the electron-transfer pathway involving the FAD, the two [2Fe-2S] centres and the Mo cofactor.

The molybdenum [iron-sulfur] protein, first isolated from *Desulfovibrio gigas* (*Dg*AOR),[18] was later shown to mediate the electronic flow from salicylaldehyde to a suitable electron acceptor, and its 2,6-dichlorophenolindophenol (DCPIP)-dependent aldehyde oxidoreductase activity was studied in detail[19] using a wide range of aldehydes and analogues. A steady-state kinetic analysis ($K_M$ and $V_{max}$) was performed for acetaldehyde, propionaldehyde, benzaldehyde and salicylaldehyde in the presence of a suitable electron acceptor (DCPIP), and a simple Michaelis–Menten model was shown to be applicable as a first kinetic approach. Xanthine, purine, allopurinol and *N*1-methylnicotinamide (NMN), however, could not be utilized as enzyme substrates. DCPIP and ferricyanide were shown to be capable of cycling the electronic flow, whereas other cation and anion dyes [$O_2$ and $NAD(P)^+$] were not active in this process. This molybdenum hydroxylase was later shown to be part of an electron-transfer chain that is capable of linking the oxidation of aldehydes to the reduction of protons and involves flavodoxin.[20]

The FAD domain, which is present in XO and CODH but absent in AOR, and the evidence for in vitro electron transfer between AOR and flavodoxin, led to the reasonable assumption that flavodoxin can play the role of a reaction partner for AOR that replaces the missing domain. Our hypothesis was that the interaction between AOR and flavodoxin should mimic the arrangement of the domains or subunits of the other similar proteins, therefore to test this hypothesis we attempted to model the AOR-flavodoxin complex using the BiGGER docking algorithm.[21,22]

## Results and Discussion

Our hypothesis was thus that if flavodoxin assumed the role of the missing FAD domain, the complex of flavodoxin with AOR should be similar to the structures of CODH and XO, and should be consistent with the experimental data available.[20]

### The Nature of the Electron-Transfer Complex

The interaction between AOR and flavodoxin seems to be driven mostly by electrostatics, since both partners are highly charged and flavodoxins have high dipolar moments (approx. 400 Debye). Both AOR and flavodoxin are acidic, but the reaction rate of electron transfer, as measured using aldehydes as electron donor through AOR and following the formation of flavodoxin semiquinone state at 590 nm (Figure 2) (experimental conditions as in ref.[20]; see also caption to Figure 2), increased with increasing ionic strength up to 0.1 M. Although the strong ionic-strength dependency of the reaction kinetics for the electron transfer between AOR and flavodoxin from *D. gigas* indicates that the interaction is driven mostly by electrostatics, it was intriguing that the reaction rate increased with increasing ionic strength. However, the docking results (see below) helped to explain this observation and called our attention to the effect of ionic strength on the electrostatic field generated

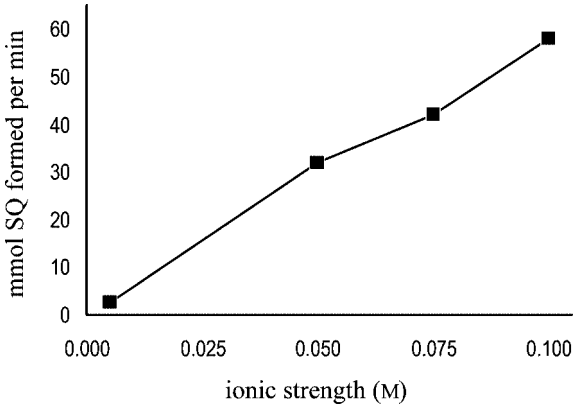

Figure 2. Dependency of the AOR-flavodoxin reaction rate on ionic strength. The reaction rate was measured by the formation of the semiquinone form of FAD, which was followed by spectroscopy at 590 nm. Anaerobic formation of flavodoxin semiquinone was followed at 580 nm, using benzaldehyde as electron donor, varying the media ionic strength (adjusted with NaCl). The experiments were conducted at 20 °C and pH 7.6 (Tris-HCl buffer). AOR was 2 μM, flavodoxin 24 μM and substrate 100 μM. General procedures as detailed indicated in ref.[20]

by AOR at the suggested interaction site, near the more exposed [2Fe-2S] moiety. Figure 3 shows the electrostatic field in this region at an ionic strength of 0.0, 0.1 and 0.5 M. The electrostatic field was calculated by solving the linearised Poisson–Boltzmann equation with a multi-grid finite difference solver,[23] with a grid resolution of 2 Å. The simplifying assumptions (equal concentrations and radii for positive and negative ions and linearisation of the hyperbolic sine term) and the finite difference solution limit the precision of the calculations, but this is not important for the qualitative result that explains the effects of ionic strength on this reaction. At higher ionic strength the overall negative charge of AOR has less influence near the positive patch surrounding the exposed [2Fe-2S] cluster, thus allowing a positive region of the field to project farther from the surface and possibly helping to guide the negatively charged flavodoxin. This explains both the reaction kinetics data and how these two strongly acidic proteins may interact despite their large negative charge.

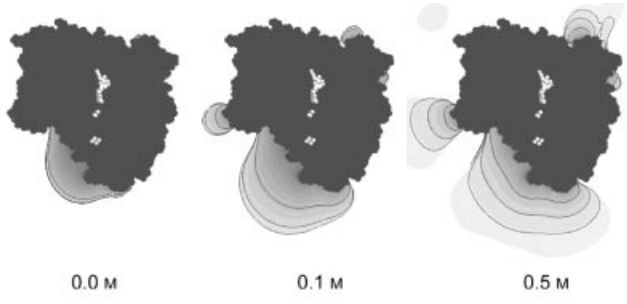

Figure 3. The three panels show the positive regions of the electrostatic field projected by AOR at 0.0, 0.1 and 0.5 M of ionic strength. The isopotential lines are for 0.1, 0.01 and 0.001 kcal mol. Only the positive regions of the electrostatic field are shown. The more exposed [2Fe-2S] cluster is shown on the lower part of each panel, and the projecting positive region of the field corresponds to the most likely docking site (Figure 4).

### AOR-Flavodoxin Complex: Docking Model

We used the BiGGER[21,22] docking algorithm both with the default soft docking parameters and with the hard docking option for all docking runs. The first stage of the docking algorithm was to select a set of 5000 solutions from all possible configurations and generate candidate complexes by shifting one of the partners relative to the other in steps of 1 Å of translation for each 15°-step in rotation. This exhaustive search generated billions of possibilities, most of which were excluded by eliminating excessive overlap and by keeping only those with the highest surface contact areas.

The soft docking algorithm[22] is a general docking algorithm applicable to cases ranging from tightly binding enzyme-inhibitor complexes to transient electron-transfer interactions, and so must take into account the effects of side-chain flexibility, which is potentially essential in strong interactions. This algorithm models side-chain flexibility implicitly by allowing some interatomic clashes involving selected regions of flexible side-chains at the surface of the protein. The downside is an increase in the fraction of incorrect models retained in those cases where side-chain flexibility is not a relevant factor. In such cases, which are common for weak interactions, the hard docking alternative tends to provide clearer results. Our approach was to use both alternatives to take advantage of the best features of each. Agreement between hard docking and soft docking results indicated that it was not necessary to account for side-chain conformation changes. In such cases we can use the hard docking results, which are generally clearer and easier to interpret. If the results of the two alternatives disagree, then we should use the soft docking models because this suggests side-chain conformation changes may be an important factor in the formation of the complex. In the case of the AOR-flavodoxin complex studied here, the results of hard docking agreed with those of soft docking − both approaches gave similar clusters of models among the highest ranking − so all results presented here are for hard docking. This agreement of the six different docking simulations, with different conditions and partners, shows the simulations to be reliable. Furthermore, in all cases there are structures with the configuration predicted by our hypothesis among the highest scoring models when ranked by the electrostatic interaction score.

The second stage of BiGGER is the ranking stage, in which the 5000 models are evaluated according to electrostatics, solvent exclusion, and surface complementarity and amino acid contacts. The global scoring function included in BiGGER is also designed for general applicability by combining these different factors to give a single score optimised to separate correct models from incorrect models over a broad range of complexes. This is the best option when no information is available regarding the interaction being studied. However, BiGGER also provides the hydrophobicity and electrostatic scores for those cases in which it is possible to estimate if the interaction is driven mainly by solvation effects or by electrostatics.[21,22] Since this was one such case, we chose to use the electrostatic score to rank the most likely models. Nevertheless, the global score also placed high scoring models in the same region (including the highest ranking model).

The choice of the electrostatic interaction score was dictated by experimental data on the ionic-strength dependency of the electron-transfer reaction between flavodoxin and AOR (both form *D. gigas*), and by the large charge of the partners, which suggested electrostatics to be the main driving force in this interaction. Furthermore, the docking simulations also suggested that the interaction between AOR and flavodoxin is strongly driven by electrostatics, since the electrostatic score value was high, with an estimated enthalpy for the electrostatic interaction of approximately 100 kcal mol$^{-1}$. This is an approximate value due to the fact that it is calculated from a simple Coulombic model and the docking models generated by BiGGER are not very precise as the translation search is in steps of 1 Å and the side-chain placement was not optimised for each model. However, these simplified calculations are the only practical

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

way of dealing with thousands of candidate models without excessive computational demands, and the results do not require precise energy estimates, as all six simulations were in agreement and the estimated energy contributed by electrostatics was one to two orders of magnitude greater than that for hydrophobicity. Overall, all the simulation results and experimental data agree that the interaction between these proteins is essentially due to electrostatics.

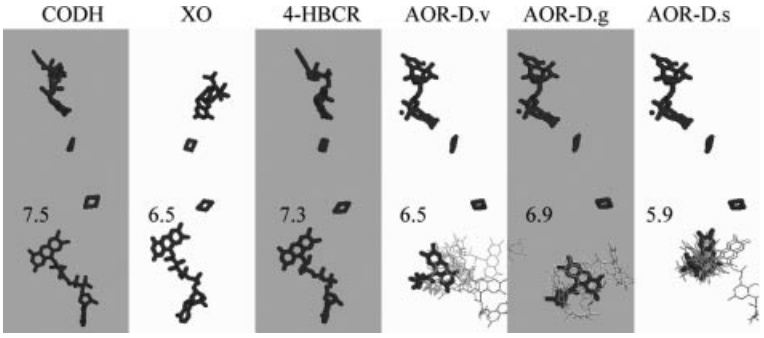

Figure 4. The relative positions of the FAD prosthetic groups for COD, XO, and 4-HBCR (first three panels) and the best models for the AOR-flavodoxin complex using the *D. vulgaris*, *D. gigas* and *D. salexigens* flavodoxins (last three panels). For the docking models the highest ranking configuration is shown in thick lines, and other high ranking configurations in thin lines. The numbers indicate the distances (in Å) between the cofactors. For the AOR-flavodixin complexes, the smallest distance of the fifteen highest ranking models is shown.

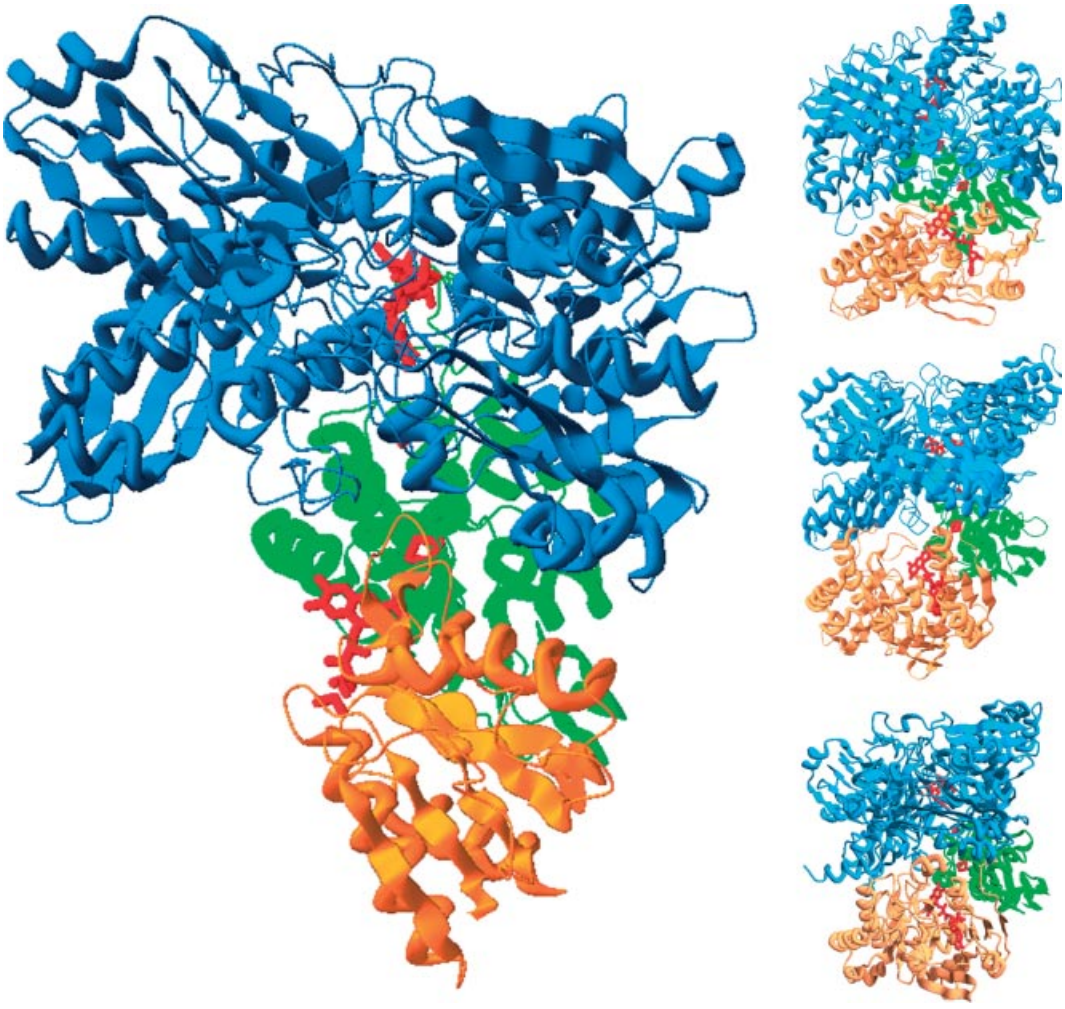

Figure 5. One possible docking configuration for *D. gigas* flavodoxin and AOR (left panel) compared with the structures of XO (top right), COD (centre right) and 4-HBCR (bottom right). The colours correspond to the sequence homology schemes shown in Figure 1, green for the FeS regions, orange for the FAD and flavodoxin, and blue for the MCD-Mo or MPT-Mo regions.

In short, all the docking results presented are for hard docking with electrostatic scoring. To model the complex between the flavodoxin and aldehyde oxidoreductase (AOR) from *Desulfovibrio gigas* we used the following structures:

– the X-ray structure for AOR (PDB code 1hlr, after correcting the transformation matrix to generate the dimer),[4,6]

– a homology model for the *D. gigas* flavodoxin using the Swiss-PROT sequence Q01095[24] and the structure from the *D. vulgaris* flavodoxin (PDB code 1fx1),[25]

– a homology model for the *D. salexigens* flavodoxin based on the *D. vulgaris* flavodoxin structure 1fx1,

– the *D. vulgaris* flavodoxin structure 1fx1.

Our goal was to model the *D. gigas* complex, although flavodoxins from *D. vulgaris* and *D. salexigens* also form productive complexes in vitro (unpublished data). Since the structure for the *D. gigas* flavodoxin was a model generated by homology, the other two − one a crystallographic structure and the other also a homology model − could be used to check the consistency of the results and verify that the *D. gigas* flavodoxin model was appropriate for our purposes. This was indeed the case, with the docking results for *D. salexigens* and *D. vulgaris* flavodoxin complexes being virtually identical to those obtained for the *D. gigas* flavodoxin.

We cannot give one unique model for the MOP-flavodoxin complex, and the interaction is most likely dynamic and cannot be represented by a single structure. However, these results indicate that flavodoxin interacts by docking near the exposed Fe–S cluster in a configuration resembling the structures of Xanthine oxidase (Figures 4 and 5). The distances between the FAD and [2Fe-2S] groups are similar in all three cases, with the shortest distance in the fifteen highest ranking models ranging between 6 and 7 Å, values similar to those of CODH, XO and 4-HBCR. Although not evident from the figure, in the models with the shortest distances among the highest ranking the dimethylbenzene part of the isoalloxazine ring is pointing towards the [2Fe-2S] centre in a manner analogous to CODH, XO and 4-HBCR. Despite this structural similarity, the contact surface of the flavodoxin in the AOR-flavodoxin models is less than half the contact surface of the FAD domain in XO. The contact surface area for flavodoxin, calculated with the DSSP program,[26] was no higher than 930 Å$^2$ (value for the model with largest surface contact among the highest ranking models), whereas the contact surface for the corresponding domain in XO is 2250 Å$^2$. This may explain why the XO complex is stable while AOR-flavodoxin is a transient complex.

## Conclusions

AOR was previously shown to be part of an electron-transfer chain comprising four different soluble proteins from *D. gigas*, namely:

AOR → flavodoxin → Cyt $c_3$ (4 hemes) → (NiFe) Hydrogenase

comprising a total of 11 discrete redox centres, which is capable of linking the oxidation of aldehydes to the reduction of protons to hydrogen and involves a flavodoxin-FMN semiquinone state.[22] The intramolecular electron-transfer process within AOR will follow, in the presence of substrate, the electron flow from Mo to the proximal [2Fe-2S] centre and then to the distal [2Fe-2S] centre and the redox partner, modelled here as flavodoxin.

Molybdenum hydroxylases (XO family) are a remarkable example of how biology finds a wide range of structural solutions to build up a required electron-transfer array of redox centres. Different arrangements of the building blocks (protein chains and domains) give rise to similar 3D placements of the redox cofactors participating in this optimised ET reaction. The docking results for the AOR-flavodoxin complex support the hypothesis of structural and functional equivalence to the active-site arrangements found in CODH and XO, and the smaller contact surface suggests an explanation for the AOR-flavodoxin complex being less stable than the otherwise similar XO.

This modular construction of complex enzymes by rearrangement of sub-domains and sub-units is a general observation. Superoxide reductases are also a good example,[27,28] but not unique. Relatively exposed sub-domains with characteristic structures that are recognized in simple electron-transfer proteins are, in most cases, used as docking sites for electron-transfer partners (i.e. ferredoxin folding in hydrogenase,[29] plant-type ferredoxin folding in AOR (see ref.[4] and this work) and Fd-NADPH reductase[30]).

A more complex situation was found for the structural homologue 4-HBCR,[12] which contains an additional iron-sulfur centre, whereby a low-potential ferredoxin serves as in vivo electron donor for the enzyme.[11,16] The redox potentials of the FAD$^{\cdot}$/FADH and $Mo^{V/IV}$ transitions are exceptionally low, thus making 4-HBCR the only member of the XO family whose function is to catalyze the reduction of the substrate and suggesting an inverted electron flow. But, even so, a conserved architecture is also maintained for the three key redox sites (Mo, 2 [2Fe-2S] centres and FAD).

# Identification of the Dinuclear and Tetranuclear Air-Oxidized Products Derived from Labile Phenolate-Bridged Dimanganese(II) Pyridyl-Chelate Compounds

**Frank Bartnik Larsen,[a] Astrid Boisen,[a] Kevin J. Berry,[b] Boujemaa Moubaraki,[c] Keith S. Murray,[c] Vickie McKee,[d] Robert C. Scarrow,[e] and Christine J. McKenzie*[a]**

**Keywords:** Manganese / O ligands / Chelates / Bond valence sum analysis / Oxidation

Dioxygen-sensitive dinuclear manganese complexes of the phenoxo-hinged dinucleating ligand 2,6-bis{[*N*,*N*′-bis(2-picolyl)amino]methyl}-4-*tert*-butylphenolato (bpbp$^-$) containing exogenous labile THF, water and perchlorato ligands are described. The manganese(II) complexes $[Mn_2(bpbp)(ClO_4)_2(THF)]^+$ (**1**) and $[Mn_2(bpbp)(ClO_4)(H_2O)_2]^{2+}$ (**2**) have been isolated as the salts **1**·$ClO_4$·THF·$3H_2O$, **1**·$B(C_6H_5)_4$·4THF and **2**·$(ClO_4)_2$·$H_2O$. Complexes **1** and **2** are spontaneously oxidised in air in solution and the solid state. The reaction products of the air oxidation in THF, water and methanol solutions are labile dinuclear $Mn^{II}$–$Mn^{III}$, $Mn^{III}_2$ and $Mn^{III}$–$Mn^{IV}$ complexes containing water- and methanol-derived exogenous ligands. In addition, a $Mn_4$ complex has been isolated. Magnetic susceptibility data confirm the $Mn^{II}$–$Mn^{III}$ oxidation state assignment with an $S = 2/S = 5/2$ model with weak antiferromagnetic coupling ($J = -3.7$ cm$^{-1}$) in $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ [**3**·$(ClO_4)_2$]. A tetranuclear complex, $[Mn_4(O)_{4-n}(OH)_n(bpbp)_2](ClO_4)_4$ [$n$ = 1 or 2; **7**·$(ClO_4)_4$], recovered from THF shows a $Mn_4O_6$ adamantane-type core with the O bridges furnished by the two phenolato groups and four hydroxide/oxide bridges. We have arrived at two feasible formulations for the core metal oxidation states and oxo-bridge protonation states, namely $[Mn^{III}_4(O)_2(OH)_2(bpbp)_2]^{4+}$ and $[Mn^{III}_3Mn^{IV}(O)_3(OH)(bpbp)_2]^{4+}$, for **7**, on the basis of a bond valence sum analysis of the crystal structure, elemental analysis and XANES. Thus, complex **7** is at least two oxidation state levels lower than known complexes with the $Mn_4O_6$ adamantane core structure. The magnetism of **7** was fitted well to an $Mn^{III}_4$ three-*J* model. Complex cations related to **3** by homology, and to **7** by hydration/solvation, have been identified by ESI mass spectrometry. The $[Mn_2(bpbp)(OH)_2(H_2O)_2]^{2+}$ ion (**4**) present in aqueous solutions on dissolution of **1**·$ClO_4$·THF·$3H_2O$ in air or by simple dissolution of **3** in water-containing solvent is isoelectronic to **3**. In the presence of significant amounts of water the $Mn^{II}$–$Mn^{III}$ complexes **3** and **4** are susceptible to further metal oxidation and concomitant aquo ligand deprotonation to give ions assignable to $[Mn^{III/IV}_2(bpbp)O(OCH_3)_2(H_2O)]^{2+}$ (**5**) and $[Mn^{III}_2(bpbp)(OH)_3(H_2O)]^{2+}$ (**6**). ESI mass spectra of water or methanol solutions of **1**, **2**, **3** and **7** show predominantly an ion assignable to the oxide $[Mn_2(bpbp)(O)]^{2+}$ (**8**). Cation **8** is most likely not present in solution. Using mild source conditions and MS-MS techniques, the gas-phase fragmentation pathways to generate **8** have been mapped.

## Introduction

Dinuclear manganese compounds are of considerable interest due to their potential as catalysts for oxidation reactions in which hydrogen peroxide or, better, dioxygen are used as the terminal oxidant.[1] We have discovered that a dimanganese complex of the dinucleating ligand 2,6-bis{[*N*,*N*′-bis(2-picolyl)amino]methyl}-4-*tert*-butylphenolato (bpbp$^-$) (Scheme 1) promotes an $O_2$-dependent oxidative cleavage of ketones.[2] The product carboxylates from this reaction are trapped as bridging ligands in isolated $Mn^{II}$–$Mn^{III}$ complexes. For reactions in acetone this results in a mixture of three formate/actetate-bridged $Mn^{II}$–$Mn^{III}$ complexes $[Mn_2(bpbp)(RCO_2)(R'CO_2)](ClO_4)_2$ (R = R′ = H, R = H R′ = $CH_3$ and R = R′ = $CH_3$). $^{13}$C-Labelling experiments show that the one- and two-carbon fragments of the formate and acetate bridges, respectively, are derived from acetone. The putative reactive oxidizing species derived from the combination of the $[Mn_2(bpbp)]^{n+}$ core and dioxygen has not yet been identified for this system and the present study represents a further attempt to elucidate the oxygenation reaction mechanism. Here we report several species based on the $[Mn_2(bpbp)]^{n+}$ core containing water-,

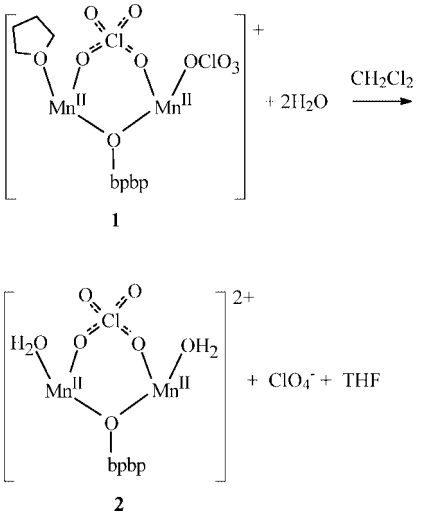
## Results and Discussion

### Air-Sensitive $Mn^{II}_2$ Complexes

The reaction of manganese(II) perchlorate with bpbpH in THF under an inert atmosphere gives a white compound formulated as $[Mn_2(bpbp)(ClO_4)_2(THF)](ClO_4)\cdot THF\cdot 3H_2O$ (**1**·$ClO_4$·THF·$3H_2O$). The cation was structurally characterised as its tetraphenylborate salt, $[Mn_2(bpbp)(ClO_4)_2(THF)][B(C_6H_5)_4]\cdot 4THF$ [**1**·$B(C_6H_5)_4$·4THF], which was obtained by recrystallisation of **1**·$ClO_4$·THF·$3H_2O$ in THF under $N_2$ in the presence of sodium tetraphenylborate. Recrystallisation of **1**·$ClO_4$·THF·$3H_2O$ in the noncoordinating solvent dichloromethane under $N_2$ resulted in replacement of the THF and terminal perchlorate ligands with adventitious water to give the complex $[Mn_2(bpbp)(ClO_4)(H_2O)_2](ClO_4)_2\cdot H_2O$ [**2**·$(ClO_4)_2$·$H_2O$].[2] The core structures of the $Mn^{II}_2$ complexes **1** and **2** are depicted in in Scheme 2 and the X-ray structures of cations **1** and **2** in Figure 1. Important bond lengths and angles are listed in Table 1. The metal coordination environments for each of the manganese ions in **1** and **2** are geometrically different. In the case of **1** this is further accentuated by the fact that the donor set on each metal ion is different. One of the tridentate 2,6-bis{[*N*,*N*′-bis(2-picolyl)amino]methyl} arms is coordinated in a facial mode while the other shows a meridional coordination geometry in both structures. The asymmetrical coordination of the bridging perchlorate is most pronounced in **2** [Mn1–O1 = 2.651(3) and Mn2–O2 = 2.334(2) Å] with a bond-length difference significantly larger than for **1** [Mn1–O7 = 2.185(18) and Mn2–O8 = 2.296(16) Å]. According to the Cambridge Crystallographic database,[3] these structures are the first reports of dimanganese complexes with a $\mu_2$-perchlorato-*O*,*O*′ bridge. Only one other example exists where a perchlorate bridges two



Scheme 2. Ligand-substitution reaction and core structure of the $Mn^{II}_2$ complexes **1** and **2**. For simplicity only the hinging donor O atom of the dinucleating ligand is shown. Not depicted are the three remaining N donors to each Mn ion from the heptadentate ligand.

manganese atoms, but in this case the perchlorate acts as a one-atom bridge ($\mu_2$-perchlorato-*O*,*O*).[4]

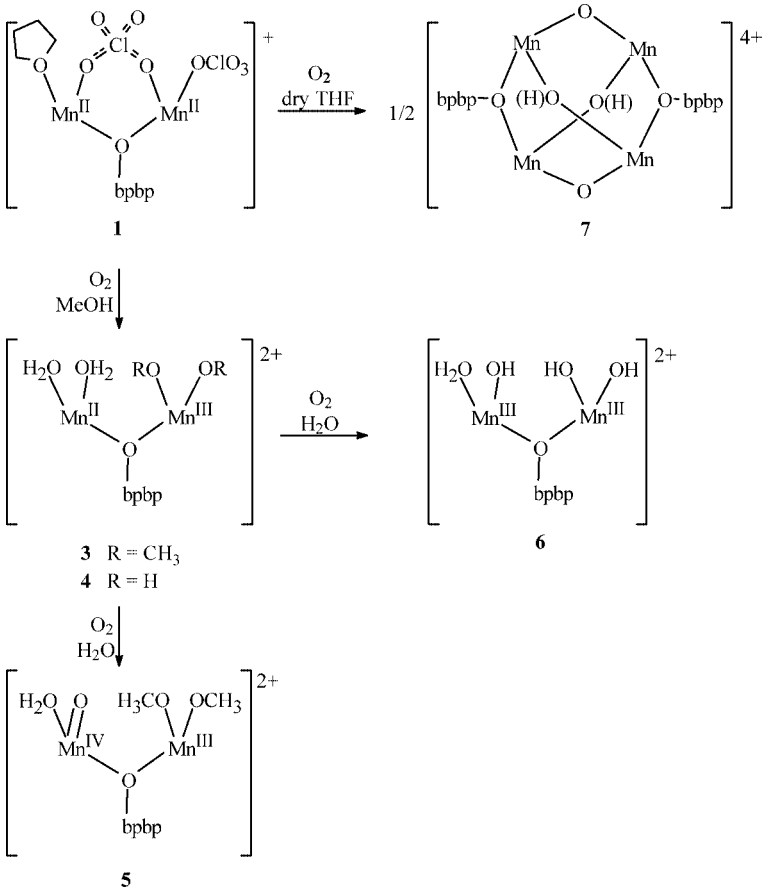
## Air Oxidation of the $Mn^{II}_2$ Complexes

Solutions of complexes **1** and **2** in water, methanol, acetone and THF darken within minutes on exposure to air. In acetone, this occurs with concomitant acetone oxidation.[2] The species we have now identified when air oxidation of **1** is carried out in water, methanol or THF are summarised in Scheme 3. The dinuclear, mixed-valence $Mn^{II}$–$Mn^{III}$ complex $[Mn_2(bpbp)(CH_3O)_2(H_2O)_2](ClO_4)_2$ [**3**·$(ClO_4)_2$] and the tetranuclear complex $[Mn_4(O)_{4-n}(OH)_n(bpbp)_2](ClO_4)_4$ ($n$ = 1 or 2) [**7**·$(ClO_4)_4$], were isolated from methanol and THF, respectively, as their perchlorate salts. Exposure of the salts of **1** and **2** as solid compounds to air results in them turning brown within hours. We have not determined the nature of this solid-state reaction.

## The Solid-State Characterisation

### *X-ray Structures*

The dark-green crystals obtained from the air oxidation of **1** in methanol are the mixed-valence $Mn^{II}$–$Mn^{III}$ complex **3**·$(ClO_4)_2$ (Figure 2). This complex is identical to the product of the methanol reaction of manganese perchlorate with bpbpH in air without isolating an intermediate $Mn^{II}$–$Mn^{II}$ complex.[5] The two exogenous H-bonded methoxo-aquo "bridging groups" span the metal ions. The complex is unsymmetrical and the valence trapping unambiguous: the two methoxide ligands are coordinated to the $Mn^{III}$ ion with an average $Mn^{III}$–O distance of 1.876 Å, while the two $Mn^{II}$–$OH_2$ distances are an average of 0.279 Å longer.



Scheme 3. The core structures of the starting compound **1** and the complexes isolated or identified by ESI MS.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

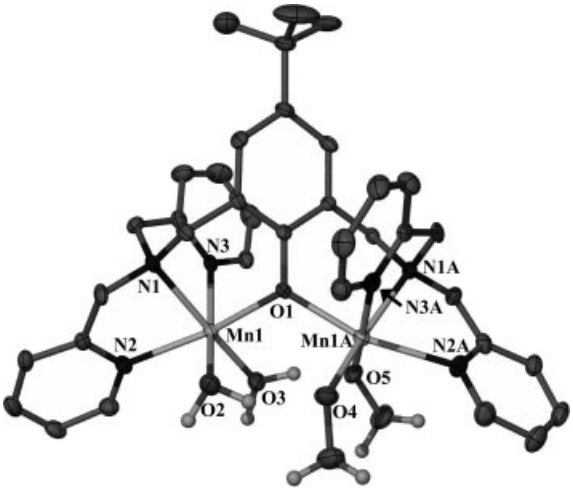


Figure 2. The X-ray crystal structure of the cation in **3**.

Solutions of **1** in THF turn dark in minutes and deposit brown-black solids in good yields over some hours. Addition of *tert*-butylhydrogen peroxide to the reaction results in an instant colour change and precipitation of a dark solid. The products isolated by these two synthetic routes give identical elemental analyses consistent with two $ClO_4^-$ ions per $[Mn_2(bpbp)]^{n+}$ unit. These products look to be amorphous and give no detectable powder XRD pattern. However, on one occasion crystals were obtained by the complete evaporation of the THF from a very dilute solution in a flask with a large surface area at the base. We have not been successful in growing better crystals under a variety of more appropriate conditions. The structure of these small ($0.20 \times 0.10 \times 0.02$ mm), weakly diffracting brown crystals was determined by synchrotron X-ray crystallography to be a tetranuclear, adamantane-type manganese complex [**7**·$(ClO_4)_4$; Figure 3]. The data are of low quality, although the core topology is clear. Bond lengths and angles are listed in Table 2. A definitive oxidation-state assignment cannot be made from the X-ray structure alone since the poor data quality precludes conclusive determination of the protonation state of the cation. The charge of the cation (4+) is without doubt, however, and the overall oxidation state can therefore in theory range from $Mn^{III}_2Mn^{IV}_2$ (only oxide bridges) down to $Mn^{II}_2Mn^{III}_2$ (only hydroxide bridges); lower oxidation-state assignments would require $H_2O$ as bridging ligand or protonation of the bridging phenolate, both of which are unfeasible.

We eliminated the lower oxidation-state formulations $[Mn^{II}Mn^{III}_3(O)(OH)_3(bpbp)_2]^{4+}$ and $[Mn^{II}_2Mn^{III}_2(OH)_4(bpbp)_2]^{4+}$ on the basis of a comparison of metric parameters with known compounds (see below). This leaves three possible assignments depending on the number of hydroxide bridges, namely $[Mn^{III}_4(O)_2(OH)_2(bpbp)_2]^{4+}$, $[Mn^{III}_3Mn^{IV}(O)_3(OH)(bpbp)_2]^{4+}$ and $[Mn^{III}_2Mn^{IV}_2(O)_4(bpbp)_2]^{4+}$. Notably, the structure of complex **7** is very similar to its $Fe^{III}_4$ counterpart $[(bpbp)_2Fe^{III}_4(\mu\text{-}O)_2(\mu\text{-}OH)_2](ClO_4)_4$,[6] thus implying that an isostructural **7** might also contain two hydroxide bridges and hence the same metal oxidation state, i.e. $Mn^{III}_4$. Both complexes have identical metal–$O_{phenoxo}$ distances [Fe–$O_{phenoxo}$ = 2.092(4), Mn–$O_{phenoxo}$ = 2.095(7) Å], although the average Fe–$O_{oxo/hydroxo}$ distance [1.893(5) Å] is slightly longer than

the equivalent distance in **7** [Mn–$O_{oxo/hydroxo}$ = 1.846(11) Å].

Jahn–Teller distortions are commonly observed in pseudo-octahedral high-spin $Mn^{III}$ ($d^4$) complexes; these distortions usually take the form of axial elongations or compressions. In the case of the manganese in complex **7**, the principal distortion is caused by the shorter bond lengths on one octahedral face due to the anionic oxygen-based ligands. In addition, there is an axial elongation in that the longest Mn–O bond is *trans* to the longest Mn–N bond. These effects are, however, too subtle to be used for oxidation,state assignment.

The majority of $Mn_4$ adamantane-type complexes with which **7** can be compared have been prepared using neutral tridentate capping ligands [e.g. 1,4,7-triazacyclononane, tris-(aminomethyl)ethane or *N*,*N*-bis(2-pyridylmethyl)ethylamine] and the oxygen atom bridging groups are all non-protonated oxides rather than hydroxides.[7,8] The strength of the $Mn^{IV}$–oxo bond typically yields robust adamantane $Mn^{IV}_4O_6$ cores with more or less unambiguous spectroscopic signatures. Two singly protonated[7d] complexes and two one-electron-reduced[7e,8] complexes derived from the $Mn^{IV}_4O_6$ core have been structurally characterised. Ligand-exchange reactions have furthermore yielded neutral bis-ligand complexes containing two *N*,*N*-bis(2-pyridylmethyl)-ethylamine ligands and two *N*-substituted iminodiacetate ligands.[7f] Typical geometrical parameters for these complexes are $Mn^{IV}$–O ≈ 1.80, $Mn^{IV}$–OH ≈ 1.95, $Mn^{III}$–O ≈ 1.83 Å and Mn–O–Mn ≈ 128–130°. Only small differences in the Mn–O bond length arise from reduction of $Mn^{IV}$ to $Mn^{III}$, while protonation induces significant changes. Only one other $Mn_4$ complex with an adamantane core incorporating bridging alkoxides/phenoxides as in **7** is known.[8] Armstrong and co-workers have shown that the mixed-valence complex $[(tphpn)_2Mn^{III}Mn^{IV}{}_3(\mu\text{-}O)_4](OTf)_2(ClO_4)_3$ [Htphpn = *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)-2-hydroxypropane-1,3-diamine] is formed by a core rearrangement induced by a one-electron oxidation of the $[\{(tphpn)Mn^{III}Mn^{IV}(\mu\text{-}O_2)\}_2]^{4+}$ dimer-of-dimers complex.[8] The complex contains four oxide and two alkoxide bridges and the average Mn–$O_{oxo}$ bond length is 1.805(8) Å, which corresponds well to a 3:1 mixture of $Mn^{IV}$ and $Mn^{III}$ with all oxide bridges. The analogous average Mn–$O_{oxo/hydroxo}$ bond length for **7** is 1.846(11) Å, which is slightly longer and therefore consistent with a lower average oxidation state in **7**.

### *Oxidation-State Assignment by Bond Valence Sum (BVS) Analysis*

To further assess the possible oxidation states of Mn in **7**, we employed Bond Valence Sum (BVS) analysis,[9] which uses all of the metal–ligand bond lengths to indicate the likely oxidation state. Each bond length is used to calculate a bond valence from the expression BV = exp[($r_0$ – $r_{MX}$)/0.37 Å], where $r_0$ depends on the identity of M and X. The traditional but cumbersome approach[9] to oxidation-state determination by BVS assumes that the $r_0$ values also depend on the oxidation state of M, and these $r_0$ values are selected so that, for complexes with unambiguous oxidation states, the BVS is approximately equal to the oxidation state. This approach requires a separate calculation for each possible oxidation state and is unsuited for mixed-valence complexes. An alternative, and simpler, approach[10] uses the BVS calculated with oxidation-state-independent $r_0$ but allows that it may deviate for some specific donors. For example, the parameters $r_0$(M–O) = 1.759, $r_0$(M–N) = 1.831 and $r_0$(M–S) = 2.151 Å can distinguish between complexes of high-spin iron(II) (BVS = 2.30 ± 0.14), high-spin iron(III) (BVS = 3.04 ± 0.12), and low-spin iron [BVS = 4.2 ± 0.3 for low-spin iron(II or III)].

Calculations of BVSs using data from mononuclear manganese complexes found in a search of the Cambridge Structural Database[3] indicate that the same $r_0$ parameters previously used for iron can be used to distinguish high-spin manganese oxidation states (Figure 4). The BVSs for mononuclear manganese complexes with oxidation states specified in the CSD name show a clear separation between manganese(II), (III) and (IV) complexes. About 5% of the "manganese(II)" complexes have BVSs greater than 2.5 (i.e. closer to values expected for $Mn^{III}$ or $Mn^{IV}$), but upon consulting the original literature these were found either to be misnamed in the CSD (NOTGUY, HOSTUE, WAQDEX, RULNER), oxidation-state ambiguous (SEVWOF), or likely intermediate-spin (HODTUP, MNPHCY02, TOGPEK) or low-spin (NTPOMN, NTPIPM10, LAHCUS, GOGBEJ, YEXWAZ, WEGQII, LIHBEJ) complexes. Excluding these from the manganese(II) data results in 279 complexes with BVS = 1.92 ± 0.17. Thus, we conclude that high-spin $Mn^{II}$, $Mn^{III}$ and $Mn^{IV}$ complexes have a BVS of approximately 1.9, 3.1 and 4.1 ± 0.2, respectively, when using the $r_0$ values previously used for iron complexes.

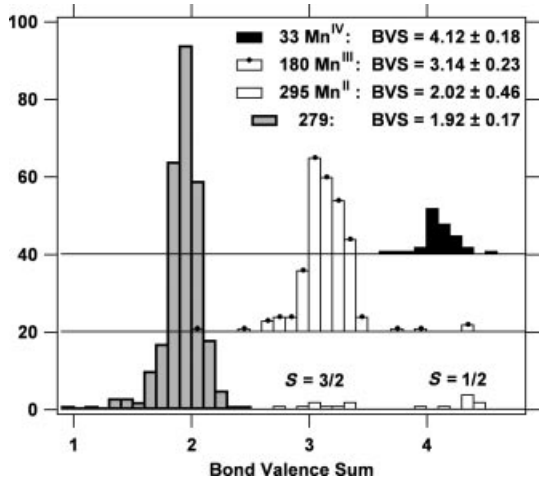

Figure 4. BVSs calculated from bond lengths in the Cambridge Structure Database (April 2001 release) for mononuclear manganese complexes (crystallographic $R < 0.10$) with only N, O and S coordination in which the oxidation state of the manganese (II, III or IV) is specified in the name field. BVS analyses in this paper use $r_0$ values of 1.759, 1.831 and 2.151 Å for Mn–O, Mn–N and Mn–S bonds, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Figure 5 shows that most binuclear manganese complexes in the CSD have BVSs that are within 0.2 of the average BVS expected from the assigned oxidation states. Most of the outliers shown in Figure 5 (those with CSD codes shown) can be explained as due to errors in oxidation state naming or differences in spin state, as explained in the figure caption.

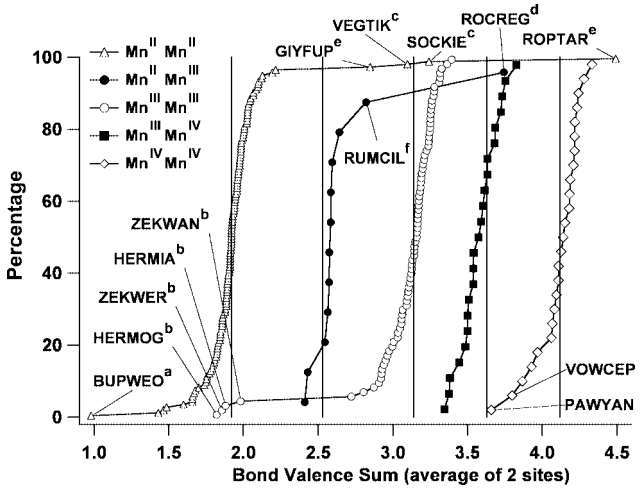

Figure 5. BVSs calculated for dinuclear manganese complexes where the oxidation states are specified by the name in the Cambridge Structure Database (April 2001 release) plotted vs. the percentile within each class. The five solid lines indicate, from left, the BVSs expected for (II,II), (II,III), (III,III), (III,IV) and (IV,IV) dinuclear complexes. CSD codes are indicated for structures with especially large deviations from the expected BVS. In most cases, the large deviations were explained upon inspection of the CSD record: (a) only 42% occupancy of manganese atoms; (b–d) misassigned oxidation states in name should be (b) $Mn^{II}Mn^{II}$, (c) $Mn^{III}Mn^{III}$ and (d) $Mn^{III}Mn^{IV}$; (e) probable low- or intermediate-spin $Mn^{III}$; ambiguous oxidation state due to presence of cobalt atom in cluster (assigned as $Co^{2+}$).

Using the same oxidation-state-independent $r_0$ values, the BVSs of the $Mn^{II}_2$ complexes **1**·$ClO_4$·THF·$3H_2O$ and **2**·$ClO_4$·$H_2O$ as well as the $Mn^{II}$–$Mn^{III}$ complex **3**·$(ClO_4)_2$ were calculated; they are listed in Table 3. There is excellent agreement with the values expected based on the data of Figures 4 and 5. From the BVSs of the individual Mn atoms of **3** it is clear that they are valence-trapped as a $Mn^{II}$ and $Mn^{III}$. The BVS of complex **7**·$(ClO_4)_4$, when compared to the values obtained by analysis of three X-ray structures of closely related $Mn^{III}Mn^{IV}_3$ and $Mn^{IV}_4$ adamantane core complexes, shows that **7** clearly has a much lower overall oxidation state. The average BVS (3.25) is equally consistent with a $Mn^{III}_4$ (expected $3.14 \pm 0.2$) or $Mn^{III}_3Mn^{IV}$ (expected $3.38 \pm 0.2$) core. The possibility of a $Mn^{III}_2Mn^{IV}_2$ dimer (expected BVS = $3.63 \pm 0.2$) is, however, much less likely.

### *Oxidation-State Assignment by XANES*

XANES of **1**·$ClO_4$·THF·$3H_2O$ and **7**·$(ClO_4)_4$ supports these oxidation-state assignments (see Figure 6). The edge energy, which we consider to be the energy at which the XANES spectrum intensity = 0.5, for **1**·$ClO_4$·THF·$3H_2O$ is almost identical to the energy recorded for $Mn^{II}(acac)_2$, thus confirming the oxidation-state assignment. The edge energy for **7**·$(ClO_4)_4$ is very close to that measured for $Mn^{III}(acac)_3$, thus indicating that the overall oxidation state of **7**·$(ClO_4)_4$ might be $Mn^{III}_4$. Furthermore, the edge energy is markedly lower than that found in the mixed-valent manganese(III,IV) complex $[tpa_2Mn_2O_2](ClO_4)_3$ [tpa = tris(2-pyridylmethyl)amine; lower by 1.5 eV] and the manganese(IV) complex $[(Me_3tacn)_2Mn_2O_3][PF_6]_2$ ($Me_3tacn$ = 1,4,7-trimethyl-1,4,7-triazacyclononane; lower by 3.0 eV). The large difference between the edge energy of **7**·$(ClO_4)_4$ and the mixed-valence tpa-manganese(III,IV) complex discounts a $Mn^{III}_2Mn^{IV}_2$ oxidation-state assignment for **7**·$(ClO_4)_4$. The difference in edge energy between a $Mn^{III}_3Mn^{IV}$ and a $Mn^{III}_4$ complex is, however, probably too small to be discerned by XANES, and these two oxidation-state assignments can therefore not be excluded for **7**·$(ClO_4)_4$.

Assignment of an oxidation state of $Mn^{III}_2Mn^{IV}_2$, and thus oxo bridges, for **7** has inherent problems due to its lack of solution stability, as indicated by the lack of Mn–O CT absorptions and $Mn_4$ ions in the ESI mass spectrum (see below). This contrasts with the data for the counterpart $Fe^{III}_4$ complex,[6] for which, for example, an ion assignable to the singly deprotonated species $[(bpbp)_2Fe^{III}_4(O)_3(\mu\text{-}OH)]^{3+}$ is easily observed. This is contradictory to the typical stability of oxo-bridged manganese complexes. The presence of hydroxo bridges, which typically are weaker than oxo bridges, can account for the instability of **7**·$(ClO_4)_4$ along with the fact that $Mn^{III}$–O bonds are believed to be more labile than $Mn^{IV}$–O bonds due to Jahn–Teller effects.[7e] Armstrong and co-workers have further shown that

Table 3. Values obtained for the oxidation state assignment from a BVS analysis of **1**, **2**, **3** and **7**.

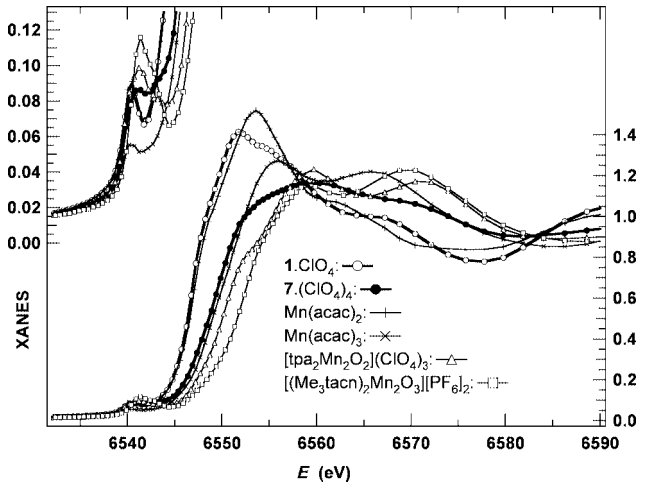

Figure 6. Comparison of Mn K-edge XANES spectra for **1**·$ClO_4$ and **7**·$(ClO_4)_4$ with those of $Mn^{II}$ and $Mn^{III}$ complexes of acetylacetonate (acac), a $Mn^{III}Mn^{IV}$ mixed-valence di-oxo-bridged complex of tris(2-pyridylmethyl)amine (tpa), and a $Mn^{IV}$ dimeric tri-oxo-bridged complex of 1,4,7-trimethyl-1,4,7-triazacyclononane ($Me_3tacn$).

the effective basicity of the oxo bridges in $[Mn_4O_6(bpea)_4]^{4+}$ increases by 17.5 orders of magnitude upon one-electron reduction.[7e] Thus, the presence of one or two hydroxo bridges in **7** is very feasible.

On the basis of the crystal structure (BVS analysis), elemental analysis and XANES of **7**·$(ClO_4)_4$, we therefore propose that the complex might be $[Mn_4(O)_{4-n}(OH)_n(bpbp)_2]^{4+}$ ($n$ = 1 or 2) and contain either three or four $Mn^{III}$ centres.

## The Structural Formulation of the Solution- and Gas-Phase Species Derived from Hydroxylic Solvents by Analysis of ESI Mass Spectra

Tractable products were not isolated after the air oxidation of **1** in water or in methanol containing significant amounts of water. Analyses of fragmentation pathways in ESI mass spectrometric studies of reaction solutions indicate that aqueous solutions contain the homologue of **3**, the $Mn^{II}$–$Mn^{III}$ $[Mn_2(bpbp)(OH)_2(H_2O)_2]^{2+}$ ion (**4**), and higher oxidation state $Mn^{III}_2$ and $Mn^{III/IV}_2$ solvent-derived species. The presence of methoxide vs. hydroxide most likely facilitates the isolation of **3**. Terminal methoxide ligands are more commonly characterised for $Mn^{III}$ and $Fe^{III}$ complexes than hydroxide ligands, presumably because proton-transfer interactions between the hydroxide ligand and solvent (non-coordinated) water are blocked. Mn compounds with terminal hydroxide ligands are usually characterised only when the hydroxide is found in cavities and other well-shielded environments.[11] A comparison of the ESI mass spectra of **3**·$(ClO_4)_2$ using both methanol and water as spray solvent is shown in Figure 7. Figure 7(a) and (e) show that similar spectra are obtained for **3**·$(ClO_4)_2$ in methanol and water, respectively, under standard source conditions. Through a series of Collision Activation Dissociation (CAD) experiments we were able to show that the ion at $m/z$ 348.8, which is observed as essentially the only species in both these mass spectra, can be assigned to the $Mn^{II}$–$Mn^{III}$ oxide $[Mn_2(bpbp)(O)]^{2+}$ (**8**). Cation **8** is, however, most likely *not* found solution. This ion corresponds to the loss of the mass equivalent of two water molecules and one dimethyl ether molecule from **3**, or the loss of the mass equivalent of three water molecules from **4**, to give **8**. The gas-phase fragmentation pathway to **8** could be mapped from spectra recorded using very mild source conditions [Figure 7(b) and (f)]. We assigned the higher oxidation state species $[Mn^{III}_2(bpbp)O(OH)_2]^{2+}$ ($m/z$ 357.2) and $[Mn^{III/IV}_2(bpbp)O(OH_2)(OCH_3)_2]^{2+}$ (**5**) ($m/z$ 388.7) to the ions generated from the water solutions under mild source conditions. Coordinated water ligands are retained by cations **3** and **4** in the spectra in Figure 7(b) and (f), which show also that methoxide ligands can be substituted by hydroxides. Assignments for the various ions are listed under the spectra. Only neutral species can be lost from cations in gas-phase CAD experiments: coordinated water loss is facile, and the mass equivalents of hydroxyl and methoxyl radicals and dimethyl ether can also be lost, ultimately to produce cation **8**. The pathways are delineated in the scheme under the spectra in Figure 7. We have previously noted the facile gas-phase formation of (sometimes novel) metal oxide ions from metal carbonates by loss of neutral $CO_2$.[12] The present cases showing mass losses equivalent to the neutral fragments $H_2O$, $CH_3OCH_3$, $HO^{\cdot}$ and $CH_3O^{\cdot}$ serve as another example.

## Magnetic Susceptibility

The magnetic susceptibility of **3**·$(ClO_4)_2$ was measured in the temperature range 4.2 to 300 K at an applied field of 1 T. The data are generally indicative of weak antiferromagnetic coupling occurring within $Mn^{II}/Mn^{III}$ pairs via the endogenous bridging phenolate group of $bpbp^-$. The strong H-bonding between the two aqua ligands of the $Mn^{II}$ and the two methoxide ligands of the $Mn^{III}$ may also contribute a superexchange pathway. Least-squares fitting of the susceptibility data to Heisenberg exchange models ($-2J\ S_1 \cdot S_2$) for $S$ = 5/2:4/2 pairs, assuming the $g$ values for $Mn^{II}$ and $Mn^{III}$, are the same and give the best fit parameters $g = 1.97 \pm 0.02$ and $J = -3.7 \pm 0.02\ cm^{-1}$. The experimental and calculated plots are shown in Figure 8. The $J$ value is similar to those found for other dinuclear $Mn^{II}$–$Mn^{III}$ μ-phenoxo complexes but does not agree with the structural correlation found by Latour et al.[13] for μ-phenoxo, bis-μ-carboxylato compounds, largely because the $Mn^{II}$–O and $Mn^{III}$–O(phenoxo) lengths are so similar in the present compound.

Magnetic susceptibility and variable-field magnetisation measurements on samples of the bulk materials of **7**·$(ClO_4)_4$ were also carried out. The plot of effective magnetic moment ($\mu_{eff}$) vs. temperature, measured in a field of 1 T, is shown in Figure 9, while the isothermal magnetisation data are given in Figure S1 (Supporting Information). A stronger magnetic coupling is evident from the overall

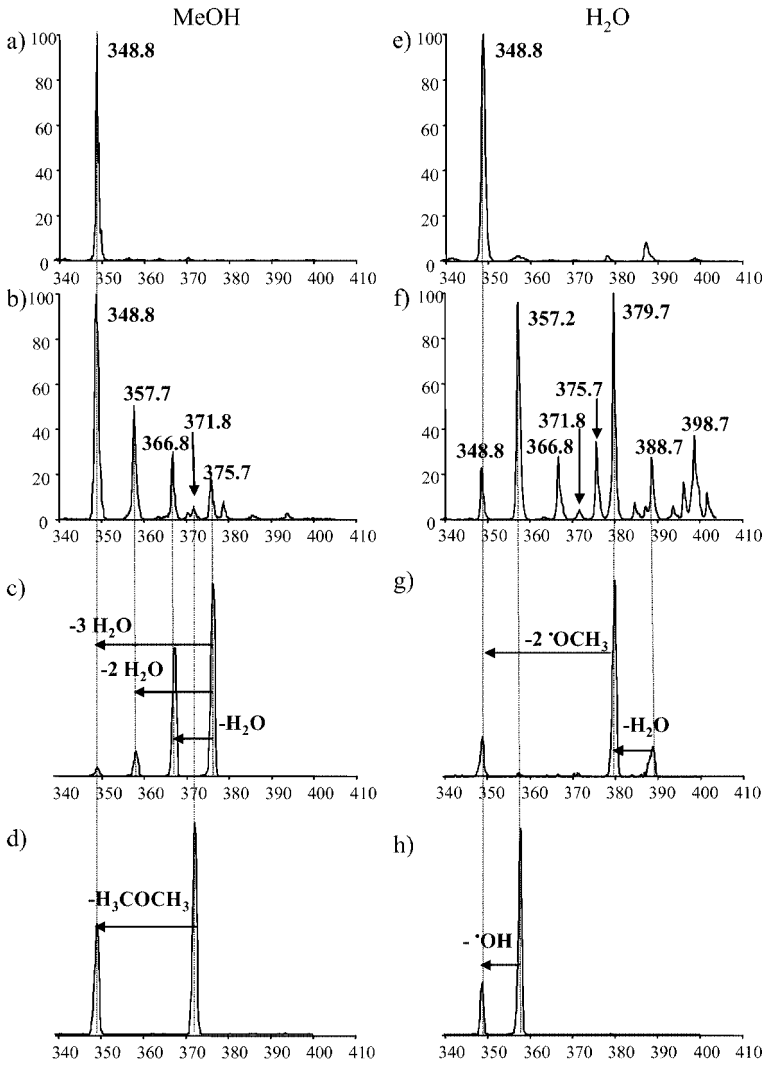

Figure 7. ESI mass spectra of **3**·$(ClO_4)_2$ in methanol (a and b) and in water (e and f). Spectra (a) and (e) were recorded with a tube lens potential of 100 V (normal source conditions); spectra (b) and (f) were recorded with a tube lens potential of 20 V (mild source conditions). Collision-Activated Dissociation (CAD) spectra (c, d and g, h) were recorded by mass selection from spectra (b) and (f), respectively. Mass selected for CAD: (c) *m*/*z* 375.7; (d) *m*/*z* 371.8; (g) *m*/*z* 388.7; (h) *m*/*z* 357.2. Peak assignment and CAD pathways are show below spectra.

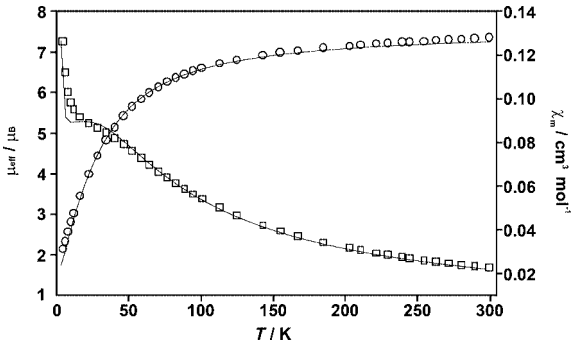

Figure 8. Plots of magnetic susceptibility () and moment (O) per molecule for complex **3**·$(ClO_4)_2$. The solid lines are the calculated values with the $S$ = 5/2:4/2 model and parameters given in the text.

lower magnetic moment per manganese ion in bulk samples of **7**·$(ClO_4)_4$ compared with **3**·$(ClO_4)_2$. This suggests a superexchange pathway that is more efficient than that in **3** and is consistent with the presence of oxo bridges, although in the absence of more a definitive oxidation state assignment from the X-ray crystal structure and XANES measurements a precise analysis cannot be made. We interpret the data as follows. At 300 K, a $\mu_{eff}$ value of 8.2 $\mu_B$ per $Mn_4$ is obtained, and this decreases gradually to reach 7.7 $\mu_B$ at 30 K, followed by a rapid decrease to reach 5.6 $\mu_B$ at 2 K, from where it continues to decrease. Four uncoupled $Mn^{III}$ $S$ = 2 centres would give a $\mu_{eff}$ of 9.8 $\mu_B$ ($g$ = 2.0), thus medium strength antiferromagnetic coupling is indicated. Except for the beginning of the region of rapid decrease (10–5 K), the $\mu_{eff}$ vs. temperature data can be fitted well to a three-$J$ ($S$ = 2) tetramer ($-2JS_1 \cdot S_2$) model[14] [for atoms Mn(1), Mn(2), Mn(3) and Mn(4), where Mn(3) is Mn(2′) and Mn(4) is Mn(1′) in Figure 3], with $g$ = 1.94 and $J_{12}$ = –8, $J_{13}$ = –38 and $J_{24}$ = 23 $cm^{-1}$. The $J_{13}$ and $J_{24}$ values could be positive or negative for a similar $J_{12}$ value to that shown (see Figure 9, dotted line). This is not the same as using a two-$J$ model with $J_{13} = J_{24}$ as such a model does not give a good fit of the data. Comparison of these $J$ values to those previously reported for $Mn^{III}$–O–$Mn^{III}$- (angular) and $Mn^{III}$–(OPh)–$Mn^{III}$-bridged systems unfortunately does not give an unambiguous assignment of the individual $J$ values to particular bridges in the adamantane core. This is because the $J$ values found for such bridges often overlap in size and are not as clearly defined as in analogous $Fe^{III}$ systems. In support of the fitting using three $J$ values, it should be noted that the best fit to the data for the isostructural, and possibly isovalent, $Fe^{III}_4$ complex was a three-$J$ value fit.[6] In that case they were readily assigned to the three types of bridge. The magnetisation isotherm for **7**·$(ClO_4)_4$, at 2 K (Figure S1), did not reach saturation in $M$ at the highest field of 5 T, but gave a value of 7.65 $\mu_B$, which is somewhere between $S$ = 3 and $S$ = 4 ground-state values. The best-fit parameter set, given above, gave a calculated $M$ value, at 2 K and 5 T, of 6.9 N$\mu_B$, which is less than the observed value. This discrepancy may be related to the heterogeneity of the sample used. The energy levels calculated from this parameter set show $S$ = 3 lower, but only by 4 $cm^{-1}$, than $S$ = 4, with other $S$ values greater than 100 $cm^{-1}$ above. It was also possible to obtain reasonable fits to the data of Figure 9 using a $Mn^{II}Mn^{III}Mn^{II}Mn^{III}$ model with spins {5/2, 2, 5/2, 2}, and a similar ground $S$ = 3 state and nearby $S$ = 4, but this formulation is unlikely in view of the XANES data.

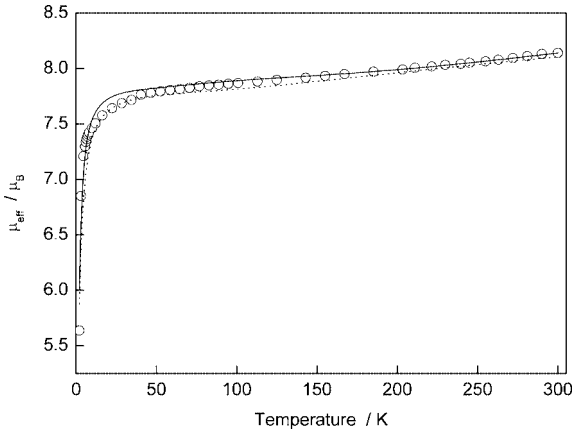

Figure 9. Plot of magnetic moment, $\mu_{eff}$, (open circles) vs. temperature, per $Mn_4$, for **7**·$(ClO_4)_4$. The solid line is that calculated using the parameters for the $Mn^{III}_4$ model, with $g$ = 1.94, $J_{12}$ = –8 $cm^{-1}$, $J_{13}$= –38 $cm^{-1}$ and $J_{24}$ = 23 $cm^{-1}$. The dotted line uses parameters, also for the $Mn^{III}_4$ model, with $g$ = 1.93, $J_{12}$ = –14 $cm^{-1}$, $J_{13}$ = 66 $cm^{-1}$ and $J_{24}$ = –67 $cm^{-1}$.

## Conclusions

Dioxygen-sensitive dimanganese(II) complexes of a pentadentate, phenoxide-hinged, dinucleating ligand with labile solvent-derived and perchlorate exogenous ligands have been structurally characterised. In previous work we have shown that the $[Mn^{II}_2(bpbp)]^{3+}$ cation can activate dioxygen in an as-yet-unknown mechanism to form an oxidant capable of oxidative ketone cleavage. Using other solvents we show here that reactions with $O_2$ yield a series of dinuclear $Mn^{II}$–$Mn^{III}$, $Mn^{III}_2$ and $Mn^{III}$–$Mn^{IV}$ complexes and one tetranuclear manganese complex. However, we cannot propose that any of these species is the pertinent $[Mn^{II}_2(bpbp)]^{3+}/O_2$-derived oxidant. The use of "anhydrous" conditions was crucial for obtaining the crystals of **1**, **2**, **3** and **7**. The structures of the solution species **4**, **5** and **6** have been predicted on the basis of the information provided by the crystal structures of the other members of the series and through a careful analysis of tandem MS experiments. The ESI MS studies indicate facile formation of a gas-phase oxide species **8**. Without the analysis of MS/MS under mild source conditions here, and knowledge of the solid-state structures of the precursors, such a species might otherwise have been mistaken as being present in solution.

The range of oxidation states attainable for an adamantane $Mn_4O_6$ core has been extended to a lower oxidation state in complex **7**. By comparison with known oxo-bridged, tetramanganese adamantane core complexes, as well as the use of BVS analysis and XANES measurements, the overall oxidation state of complex **7** has been narrowed

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

down to two possible assignments – $[Mn^{III}_4(O)_2(OH)_2(bpbp)_2]^{4+}$ and $[Mn^{III}_3Mn^{IV}(O)_3(OH)(bpbp)_2]^{4+}$. The difficulty in obtaining solution spectroscopic data, and thus further oxidation-state evidence, can be attributed to the expected reactivity of the $Mn^{III}$–OH–$Mn^{III}$ moieties and serve as further circumstantial evidence that **7** is not the oxide–phenoxide-bridged $Mn^{III}_2Mn^{IV}_2$ species $[Mn_4(O)_4(bpbp)_2](ClO_4)_4$. Although no definitive assignment can be made, **7** still represents the lowest overall oxidation state for a structurally characterised tetranuclear manganese complex with an adamantane core – it is either two or three oxidation levels lower, for example, than $[(tphpn)_2Mn^{III}Mn^{IV}_3(\mu\text{-}O)_4](OTf)_2(ClO_4)_3$.[8] Based on the very small differences of the metric parameters of **7** with the higher oxidation state $Mn_4O_6$ adamantane core compounds in the literature, it can be envisaged that a relatively wide range of oxidation and protonation states may be accessible for $Mn_4O_6$ adamantane core systems without a major structural deformation. A study of the redox chemistry of **7** and its reduced/oxidised and protonated/deprotonated counterparts would be particularly interesting with respect to modelling biological water and oxygen metabolism reactions. This has so far proved impossible in our hands due to solution instability.

## Experimental Section

Elemental analyses were performed at the Chemistry Department II at Copenhagen University, Denmark, and Atlantic Microlab, Inc., Norcross, Georgia 30091, USA. UV/Vis spectra were recorded with a Shimadzu UV-3100 spectrophotometer. ESI mass spectra were obtained using a Finnigan TSQ 700 triple quadrupole instrument equipped with a Finnigan API source in the nanoelectrospray mode. 2,6-Bis{[bis(2-pyridylmethyl)amino]methyl}-4-*tert*-butylphenol (bpbpH),[15] $[tpa_2Mn_2O_2](ClO_4)_3$ [tpa = tris(2-pyridylmethyl)amine],[16] and $[(Me_3tacn)_2Mn_2O_3][PF_6]_2$[7b] were synthesised following literature procedures. $Mn(acac)_2$ and $Mn(acac)_3$ were purchased from Aldrich Chemical company.

***CAUTION!*** *Although no problems were encountered in the preparation of the perchlorate salt, suitable care should be taken when handling such potentially hazardous compounds.*

**$[Mn_2(bpbp)(ClO_4)_2(THF)](ClO_4)\cdot THF\cdot 3H_2O$ ($1\cdot ClO_4\cdot THF\cdot 3H_2O$):** Triethylamine (28.8 μL, 0.21 mmol) was added to a solution of bpbpH (119.2 mg, 0.21 mmol) in degassed THF (3 mL). $Mn(ClO_4)_2\cdot 6H_2O$ (150.1 mg, 0.42 mmol) was then added to give a clear, colourless solution. Air-sensitive white microcrystals of the product deposited over 24 h. Yield: 230.8 mg (92%). $C_{40}H_{47}Cl_3Mn_2N_6O_{14}\cdot C_4H_8O\cdot 3H_2O$: calcd. C 44.85, H 5.22, N 7.13, Cl 9.03; found C 44.89, H 5.16, N 7.15, Cl 9.29. ESI MS ($CH_3CN$): *m*/*z* (%) 390.1 (100) $[(bpbp)Mn_2(ClO_4)]^{2+}$, 879.2 (50) $[(bpbp)Mn_2(ClO_4)_2]^{+}$.

**$[Mn_2(bpbp)(ClO_4)_2(THF)][B(C_6H_5)_4]\cdot 4THF$ ($1\cdot B(C_6H_5)_4\cdot 4THF$):** $1\cdot ClO_4\cdot THF\cdot 3H_2O$ and approx. 4 equiv. of $NaB(C_6H_5)_4$ were dissolved in degassed THF. Slow evaporation under $N_2$ gave very air-sensitive crystals as colourless blocks after a few days.

**$[Mn_2(bpbp)(ClO_4)(H_2O)_2](ClO_4)_2\cdot H_2O$ ($2\cdot (ClO_4)_2\cdot H_2O$):** A solution of $1\cdot ClO_4\cdot THF\cdot 3H_2O$ in degassed $CH_2Cl_2$ (approx. 50 ppm $H_2O$) was allowed to evaporate under $N_2$. Air-sensitive crystals formed as colourless blocks overnight.

**$[Mn_2(bpbp)(OCH_3)_2(H_2O)_2](ClO_4)_2$ ($3\cdot (ClO_4)_2$):** Triethylamine (113 mg, 1.11 mmol) was added to a pale-green solution of $Mn(ClO_4)_2\cdot 6H_2O$ (862 mg, 2.38 mmol) and bpbpH (599 mg, 1.05 mmol) in methanol (14 mL). The initially colourless solution changed to red brown. Dark-purple crystals of the product deposited over 24 h. Yield: 320 mg (31%). $C_{38}H_{49}Cl_2Mn_2N_6O_{13}$: calcd. C 46.64, H 5.05, N 8.59, Cl 7.25; found C 45.79, H 5.10, N 8.68, Cl 7.36. ESI MS (mild source conditions, $CH_3OH$): *m*/*z* (%) 348.8 (100) $[(bpbp)Mn_2O]^{2+}$, 357.7 (50) $[(bpbp)Mn_2(OH)_2]^{2+}$, 366.8 (30) $[(bpbp)Mn_2(OH)_2(H_2O)]^{2+}$, 371.8 (5) $[(bpbp)Mn_2(OCH_3)_2]^{2+}$, 375.7 (20) $(bpbp)Mn_2(OH)_2(H_2O)_2]^{2+}$. UV/Vis ($CH_3OH$): $\lambda_{max}$, ($\varepsilon$) = 309 nm (17200 L mol$^{-1}$ cm$^{-1}$), 258 (4560).

Alternatively, recrystallisation of $1\cdot ClO_4\cdot THF\cdot 3H_2O$ from dry MeOH in air gave $3\cdot (ClO_4)_2$.

**$[Mn_4(O)_2(OH)_2(bpbp)_2](ClO_4)_4$ ($7\cdot (ClO_4)_4$):** A solution of $1\cdot ClO_4\cdot THF\cdot 3H_2O$ (25 mg, 0.021 mmol) in dry THF (50 mL) was treated with 2 equiv. of *tert*-butylhydrogen peroxide (6 M in decane). The solution turned black. The mixture was allowed to stand in an open flask until dryness and the very small brown crystals used for the structural analysis were recovered. All other preparations of this material resulted in dark amorphous powders which give no XRPD pattern. Thus, the homogeneity of the bulk sample of this compound is not clear despite the fact that elemental analyses are consistent with the proposed formulation. $C_{72}H_{80}Cl_4Mn_4N_{12}O_{22}$: calcd. C 47.33, H 4.41, N 9.2, Cl 7.76; found (average) C 46.99, H 4.36, N 9.15, Cl 7.50.

**X-ray Crystallography:** Analysis of $1\cdot B(C_6H_5)_4\cdot 4THF$ was done at 180(2) K on a Bruker Nonius X8-APEXII instrument at the University of Southern Denmark. The structure was solved by direct methods and refined against all $F^2$ data using software incorporated in WinGX ver. 1.70.[17] The geometry of all solvent THF molecules was restrained and each THF molecule was refined with one isotropic displacement parameter. The O-position of one solvent THF could not be determined. Two of the remaining solvent THF molecules as well as the coordinated THF and the perchlorates were all refined with isotropic displacement parameters as disordered over two positions with equal occupancy, except for the position of the non-bridging perchlorate, which was refined with 33/66% occupancy. The chloride in the bridging perchlorate as well as all remaining non-hydrogen atoms were refined with anisotropic atomic displacement parameters, and hydrogen atoms bonded to carbon were inserted at calculated positions using a riding model. Crystals of $7\cdot (ClO_4)_4$ were too weakly diffracting for data collection using a standard laboratory sealed-tube source and so the data were collected at 150 K at Station 9.8 of the Synchrotron Radiation Source at Daresbury.[18] The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELXTL package.[19] The cation has a twofold axis passing through the two phenolic oxygen atoms, there is disorder of the two *tert*-butyl groups and in one of the perchlorate anions these were both modelled with equal occupancy of two positions. All non-hydrogen atoms were refined with anisotropic atomic displacement parameters and hydrogen atoms bonded to carbon were inserted at calculated positions using a riding model; hydrogen atoms bonded to oxygen were not located and were not included in the model. Since the crystals were formed by complete evaporation of a reaction mixture, the high *R*-value might be ascribed to crystal defects caused by solvent loss. Voids remain in the structure ($4\times 204$ Å$^3$ per unit cell) but because of the weak diffraction data SQUEEZE[20] could not be used to estimate the electron density and it can therefore not be excluded that diffuse solvent molecules are located in these voids. Data collection and structure refinement details are summarised in Table 4.

**Magnetochemistry:** A Quantum Design MPMS5 Squid magnetometer was used to obtain magnetic susceptibility in a field of 1 T. Samples with a mass of about 20 mg were contained in a calibrated gelatine capsule which was held in the centre of a plastic drinking straw fixed to the sample oval. The instrument was calibrated by use of a standard palladium sample supplied by Quantum Design Inc. Magnetisation isotherms (2–20 K and 0–5 T fields) were obtained on a sample of **7**·(ClO$_4$)$_4$ dispersed in a Vaseline mull in order to prevent torquing of crystallites and production of anomalous data.

**XANES:** Complexes were diluted with boron nitride and data were obtained in fluorescence mode on beamlines X9B or X18 of the National Synchrotron Light Source, using the inflection point of a Mn foil spectrum at 6539.0 eV as the energy calibration. The general procedures for obtaining XANES spectra (which are normalised to the edge height) from the fluorescence data were similar to those used previously for iron and cobalt compounds.[10,21]

**Supporting Information** (see footnote on the first page of this article): Isothermal magnetisation data for **7**·(ClO$_4$)$_4$.

## Acknowledgments

Support from the Danish Technical and Natural Science Research Council (grant, 26-02-0192), DANSYNC and COST project no. D21/0010/01 is gratefully acknowledged. V.M. is grateful to the EPSRC for access to Station 9.8 of the SRS at Daresbury. X-ray beam time for the EXAFS and XANES study was provided at beam lines X9B and X18B through the General Users Program of the National Synchrotron Light Source, which is supported by the US Department of Energy, Divisions of Materials Science and Chemical Science (DOE contract number DE-AC02-76CH00016). K.S.M. thanks the Australian Research Council for support for the magnetic studies.

# Zinc(II) Complexation Behaviour of Sulfonamide-Based Enzyme Inhibitors

**Sílvia Chaves,[a] Sérgio M. Marques,[a] Anabela Cachudo,[b] M. Alexandra Esteves,[b] and M. Amélia Santos*[a]**

**Keywords:** MMP inhibitors / Carbonic-anhydrase inhibitors / Hydroxamate / Hydroxypyrimidinone / Sulfonamido-based inhibitors / Sulfonamides

Sulfonamide derivatives containing extrafunctional groups, such as hydroxamic acids, hydroxypyrimidinones and carboxylic acids, have been recently identified as inhibitors towards several zinc-containing enzymes, such as the matrix metalloproteinases (MMPs) and/or carbonic anhydrases (CAs). Since these inhibitors are supposed to bind the zinc ion at the active site, it was decided to study the zinc(II) complexation with a set of representative compounds in order to identify the most probable coordination modes and to find eventual relationships with the inhibitory properties. These studies were performed in aqueous solution, by potentiometry and $^1$H NMR spectroscopy, and in the solid phase, by infrared spectroscopy. The solution equilibrium studies indicate that these compounds present similar affinity for zinc (pZn ≈ 6). Under stoichiometric conditions, the formation of 1:1 metal complex species involves a preferential (*O*,*O*) coordination via the hydroxamic or hydroxypyrimidinone moieties, while the coordination via the sulfonamide groups could mainly be achieved under zinc excess conditions.

## 1. Introduction

Matrix metalloproteinases (MMPs) and some carbonic anhydrase (CA) isoenzymes are known to be involved in carcinogenesis and tumour invasion processes.[1–3] Therefore, both types of zinc-containing enzymes became the targets for drug design and specific inhibitors for each type of enzymes are well known. In particular, many inhibitors of CAs containing aromatic/heteroaromatic sulfonamides have been used in the treatment of several diseases; concerning the MMP inhibitors, hydroxamate derivatives have been widely developed as possible anti-tumour/metastatic agents.[1,4]

Since these two families of inhibitors bind the zinc at the enzyme active sites, efforts have already been made to explore connections between CA and MMP inhibitors and eventual "cross-reactivity" or synergic effects.[5,6] Following the current trend of exploring potential dual inhibitors for those metalloenzymes,[7] we have recently identified a set of potent enzyme inhibitors,[8,9] some of them containing sulfonamide moieties inserted in diverse scaffolds bearing the usual zinc-binding groups in matrix metalloproteinase inhibitors (MMPi), namely: carboxylic and primary hydroxamic groups as well as, more recently, the hydroxypyrimidinones (heterocyclic hydroxamic acids).[10]

Direct comparison of the previously described compounds showed a clear trend towards an increased inhibitory activity of the sulfonamide derivatives. In the absence of X-ray structures of the enzyme-inhibitor adducts, some modelling studies have already been performed to simulate the inhibition of some MMPs and to aid the understanding of those results.[8] Aimed at shedding some extra light on the rationalization of the enzyme inhibition results, a set of four representative compounds ($H_iL^n$, $n$ = 1–4, see Scheme 1) was selected and their Zn complexation behaviour was studied to identify the 1:1 zinc-binding mode preferences of the diverse bifunctional compounds, in order to establish eventual zinc-binding affinity/inhibitory activity relationships. Results with some model compounds (e.g. $H_2L^5$ and $HL^6$) were also analysed for comparison purposes.

The zinc complexation studies were mainly performed in aqueous solution, using potentiometric and $^1$H NMR spectroscopic methods, although a brief analysis of solid zinc complexes was also carried out by infrared spectroscopy.

## 2. Results and Discussion

### 2.1. Acid Base Properties of the Ligands

The fully protonated form of the ligands under study has three ($H_2L^n$, $n$ = 1, 2, 4) or two ($H_2L^3$) dissociable protons. The determination of the corresponding protonation constants was mainly performed by potentiometry but, for $H_2L^2$, $\log K_3$ (<2) was calculated by $^1$H NMR spectroscopy. Table 1 shows the stepwise protonation constants ($\log K_i$) calculated for the sulfonamide derivatives under study ($H_2L^n$, $n$ = 1–4) and also the values previously determined for $H_2L^5$ and $HL^6$ (used for comparison purposes).

$^1$H NMR titration was also used to determine the protonation sequence for compounds containing a primary sulfonamide group ($H_2L^n$, $n$ = 1, 2, 4). In fact, for $H_2L^1$ and $H_2L^4$, the protonation sequence is more difficult to predict than for the remaining compounds, because both the sulfonamide anions and the hydroxamate hydroxy groups are protonated at nearby high pH ranges. $H_2L^2$ was also analysed by $^1$H NMR titration due to its analogy to $H_2L^1$, to aid the discussion of the coordination modes for the corresponding zinc complexes. Analysis of the titration curve profiles (Figure 1) suggests that, for ligands $H_2L^1$ and $H_2L^2$, the sulfonamide anion ($SO_2NH^-$) is the first group to be protonated. In fact, for both ligands, at pD ca. 10–11, peaks 1, 5 and 6 are downfield shifted. Regarding $H_2L^1$, the chemical shift profiles of the nonlabile protons nearby the sulfonamide group, indicate that the protonation successively occurs on the hydroxamate group (downfield shifts of peaks 3 and 4 at pD ≈ 8.5) and the *N*-amine group (at pD ca. 2 large deshielding effect on peaks 2, 3, 4).

Table 1. Stepwise protonation constants ($\log K_i$) of $H_iL^n$ ($i$ = 1, 2, $n$ = 1–6) as well as the global formation constants ($\log\beta$) of the corresponding $Zn^{2+}$ complexes ($I$ = 0.1 M KCl, $t$ = 25.0±0.1 °C).

| Ligand | $H_iL$ $\log K_i$ | Protonated centre | $Zn_mH_hL_l$ $(m,h,l)$ $\log\beta$ |
|---|---|---|---|
| $H_2L^1$ | 10.28(2) | [b] | (1,1,1) 15.14(5) |
| | 8.75(3) | [b] | (1,2,2) 30.09(7) |

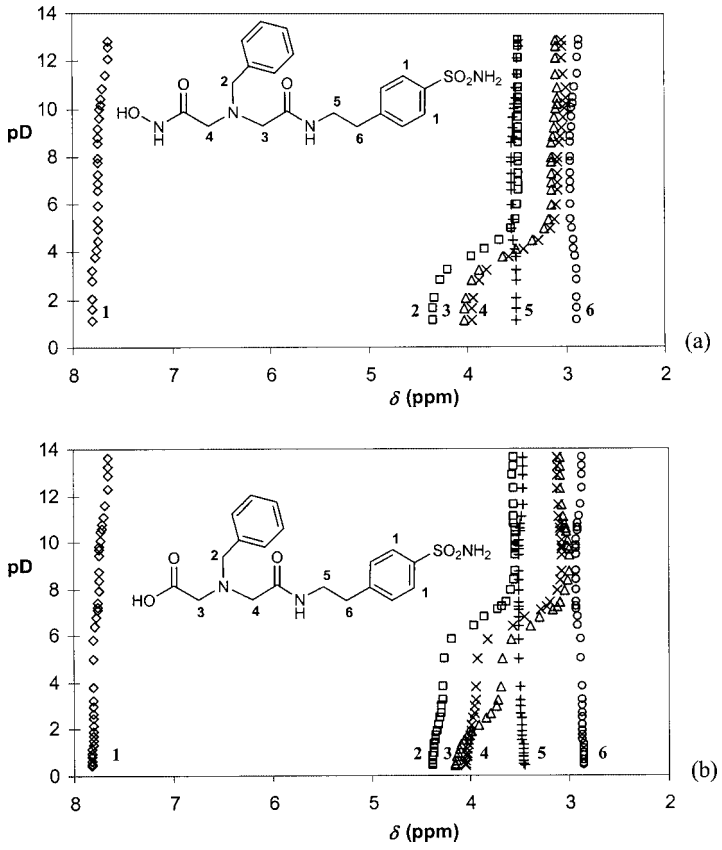

Figure 1. $^1$H NMR titration curves of (a) $H_2L^1$ and (b) $H_2L^2$.

For $H_2L^2$, Figure 1, b) illustrates that the second and third protonation occur in the *N*-amine (large downfield shifts of peaks 2, 3 and 4 at pD ≈ 5) and carboxylate (at pD ≈ 1 large downfield shift of peak 3) groups, respectively.

Concerning the hydroxypyrimidinone derivative, $H_2L^4$, Figure 2 shows the following protonation sequence: sulfonamide group (at pD ca. 11 downfield shift of peaks 2 and 3); hydroxy group (downfield shift of peaks 1 and 4 at pD ca. 7); *N*-imine group (downfield shift of all peaks at pD ca. 2). As found for the $HL^6$ analogue,[11] all the protons feel the protonation of the *N*-imine group, probably due to the enamine-imine equilibrium.
