Metalloporphyrins are an important class of molecules that are widely distributed in biological systems and play an enormous variety of roles, including catalysis, oxygen and signal transport, energy conversion, and electron transfer.[1–15] The development of new porphyrin compounds and derived materials is a subject of current research interest. New properties and functionalities can be generated by changing the molecular structure, stereochemistry, and interactions, in the context of molecular systems and materials. Particularly promising systems that exhibit remarkable catalytic and electrocatalytic properties[2,6,16–21] associated with high-valence oxygen donor species such as $Mn^{V}$=O[22,23] have been derived from manganese porphyrins.

Supramolecular species containing selected metal complexes attached at the periphery of the metalloporphyrin ring have been found to mimic cytochrome P-450 activity.[24] This is a consequence of the electron-withdrawing/-donating and/or electron-transfer properties of the ancillary complexes, which can also act as cofactors and create new pathways for the oxidation of organic substrates. In this sense, the understanding of their spectroscopic properties, stereochemistry, intramolecular interactions, and redox behavior is of the utmost importance.[25–29] In this work the spectroscopic and electrochemical properties of a new tetraruthenated manganese(III)porphyrin complex, [Mn(3-TRPyP)] (Figure 1), are described. Although this species can form four atropisomers, only a single configuration corresponding to a saddle geometry is inferred from molecular mechanics calculations ($MM^{+}$); this reflects the large steric hindrance of the peripheral bis(bipyridine)chlororuthenium(II) complexes attached at carbon 3 (*meta*) of the bridging pyridyl group (Figure 1).

The catalytic activity of [Mn(3-TRPyP)] in the oxidation of cyclohexane and cyclohexene has been investigated. In addition, the possibility to generate ultrathin supramolecular films of such species has been exploited in electrocatalysis for the oxidation of nitrite and sulfite ions in aqueous solution with the aim of generating new, efficient amperometric sensors.

## Results and Discussion

### Spectroscopic Properties

The insertion of $Mn^{2+}$ ions into the free-base $H_2$(3-TPyP) is very fast and its oxidation to $Mn^{3+}$ can be carried out readily in the presence of air. The resulting [Mn(3-TRPyP)] is soluble in common solvents such as methanol, ethanol, DMF, acetone, acetonitrile, and acetic acid and is sparingly soluble in water as its trifluoromethanesulfonate salt. It should be mentioned that the binding of the ruthenium complexes increases the total molecular charge to +5, thus enhancing its solubility in polar solvents. The $^{1}$H NMR spectrum is complicated by the superimposition of the 2,2′-bipyridine and $Mn^{III}$TPyP peaks, in addition to the low molecular symmetry and to the paramagnetic character of the $Mn^{III}$P center. Accordingly, the structural characterization was carried out by mass spectrometry. The fragmentation profiles of the polymetalated pyridylporphyrins were found to be analogous to those previously found for the derivatives $H_2$(3-TRPyP) and Zn(3-TRPyP).[26,27,30,31] The peak for the [Mn(3-TRPyP)] molecular ion ($[C_{120}H_{88}Cl_4MnN_{24}Ru_4]^{5+}$ = 2467.21 g mol$^{-1}$) was found at *m*/*z* 494 with Δ(*m*/*z*) = 0.20 and *m*/*z* 617 with Δ(*m*/*z*) = 0.25,

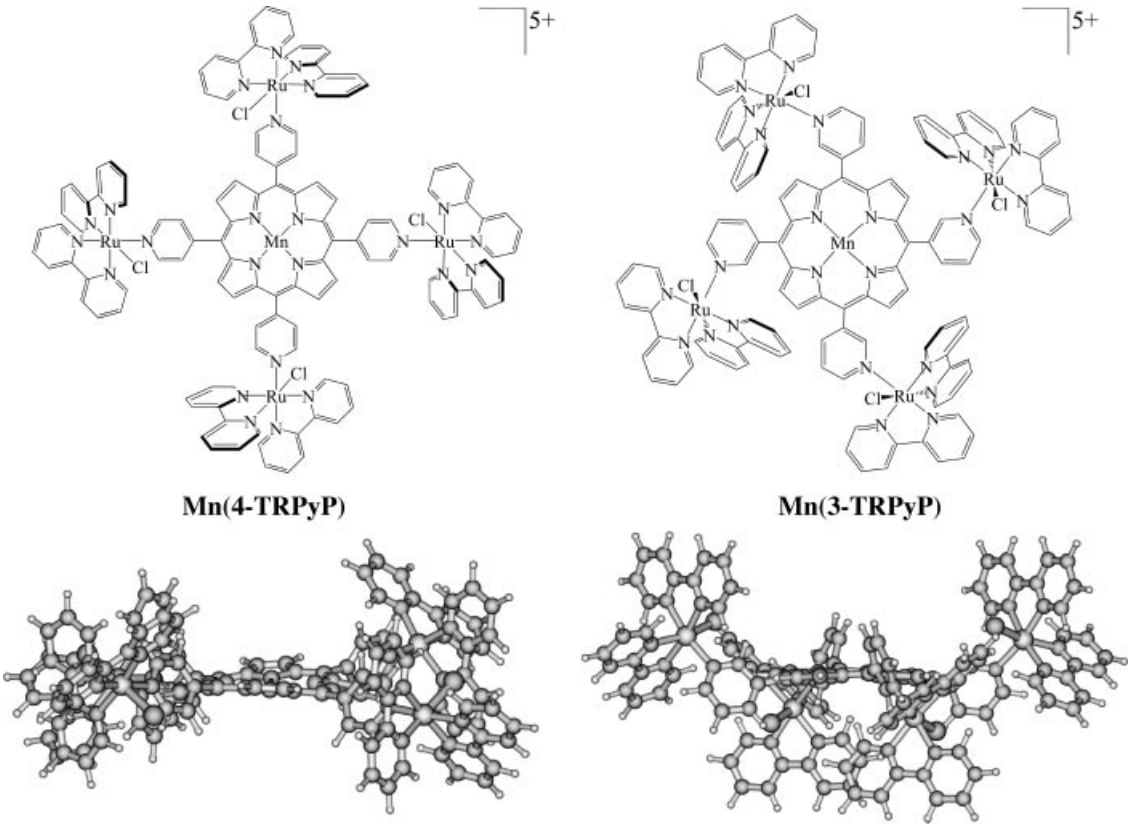

Figure 1. Structures of the tetraruthenated manganese(III) porphyrins [MnTRPyP].

suggesting the occurrence of a $Mn^{III/II}$ redox process in the spray.

[Mn(3-TRPyP)] displays a typical electronic spectrum in methanol,[32] reflecting the strong coupling between the molecular orbitals of the $Mn^{III}$ ion and porphyrin ring.[33,34] The porphyrin bands were found at 464 nm (log $\varepsilon$ = 5.2), attributed to the so-called band V, and 560 (4.3) and 595 nm (3.9), assigned to the IV or $Q_{(1-0)}$ and III or $Q_{(0-0)}$ porphyrin bands, respectively. The MLCT bands of the ruthenium complexes usually found at 360 and 480 nm are hidden by the bands VI (374 nm, log $\varepsilon$ = 4.9) and $V_a$ (399 nm, log $\varepsilon$ = 4.9). The 2,2′-bipyridine intraligand $p\pi \rightarrow p\pi^*$ transitions of the peripheral ruthenium complexes appear at 294 nm (5.3). Finally, the $Mn^{III}$ porphyrin bands II and I appear at 680 (1.6) and 770 nm (1.4) and are assigned to charge-transfer transitions (normally $a_{1u}$ and $a_{2u} \rightarrow d_{xz}$ and $d_{yz}$ transitions, respectively). They tend to become more evident when strongly coordinating ligands such as pyridine, imidazole, and pyrazine are axially coordinated.[35]

## Electrochemistry

The electrochemical behavior of the polymetalated porphyrins was investigated by cyclic voltammetry and spectroelectrochemistry. The voltammograms of a solution of [Mn(3-TRPyP)] in DMF follow the general pattern previously described for the [Mn(4-TRPyP)] isomer.[32] The reversible $Ru^{III/II}$ process is observed at $E_{1/2}$ = 0.93 V (Figure 2), with a cathodic shift of 20 mV in comparison with the *para* isomer.[32] This suggests that the $Mn^{III}$TPyP center is acting as an electron-withdrawing group stabilizing the reduced $[Ru^{II}(bpy)_2(pyP)Cl]$ species. However, no such electronic coupling between the porphyrin ring and the peripheral ruthenium complexes is expected in the case of the *meta* isomer because of the molecular geometry. The porphyrin ring $Mn^{III}P^{+/0}$ redox process was not observed, even at potentials up to 1.50 V.

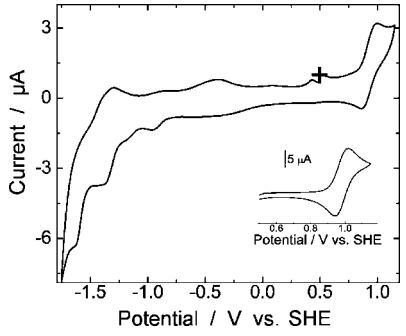

Figure 2. CV of a $2 \times 10^{-3}$ M [Mn(3-TRPyP)] solution in DMF containing 0.1 M $TEAClO_4$ (scan rate: 20 mV $s^{-1}$).

The broad cathodic wave starting around –0.3 V was assigned to the $Mn^{III/II}P$ process and confirmed by spectroelectrochemistry. The waves at $E_{pc}$ = –0.94 and –1.17 V can be tentatively assigned to the successive monoelectronic re-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

duction of the porphyrin ring to the radical anion and dianion (Figure 2), respectively, by comparison with analogous derivatives.[11,32,36–39] However, the possibility of formation of a species with $Mn^{I}P$ character, as in the case of the respective cobalt derivative,[36–39] cannot be discarded. The single-electron reduction of one and two bipyridyl ligands of each peripheral ruthenium complex was observed at $E_{pc}$ = –1.39 and –1.63 V, respectively. All those processes should be coupled to chemical reactions involving the solvent, and the intensity of the wave associated with the reverse anodic process is lower than for the reduction process. The anodic wave at 0.35 V can be assigned to reduced species formed in the cathodic scan because only the reversible $Ru^{III/II}$ pair of waves at $E_{1/2}$ = 0.93 V was found when the scans were limited to the 0.0 to 1.2 V range.

### Spectroelectrochemistry

The spectroeletrochemical behavior of [Mn(3-TRPyP)] in DMF in the –2.2 to +1.1 V range is shown in Figure 3. The most stable form of this supramolecular complex exhibits the transition metal ions as $Mn^{III}$ and $Ru^{II}$ complexes. When the potential was increased from 0.5 to 1.1 V the peripheral ruthenium complex band (bpy, pπ→pπ*) at 297 nm and the MLCT bands at about 490 and 370 nm disappeared, while an absorption band rose at 316 nm. In contrast, the characteristic $Mn^{III}P$ absorption bands (III, IV, V, $V_a$, and VI) remained essentially unchanged. Such spectral changes (Figure 3, A) are characteristic of a reversible $Ru^{II/III}$ process, as suggested by the presence of several isosbestic points. No changes were observed in the 1.1 to 1.5 V range.

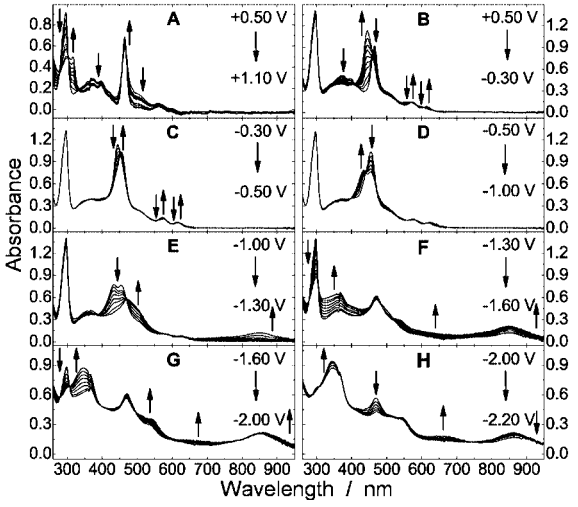

Figure 3. Spectroelectrochemistry of an approx. 80 μM solution of [Mn(3-TRPyP)] in DMF containing 0.10 M $TEAClO_4$ in the 1.1 to –2.2 V range.

The first redox process observed in the 0.5 to –0.3 V range (Figure 3, B), leads to a shift and broadening of the porphyrin Soret band from 464 to 444 nm, characteristic of the reduction of $Mn^{III}P$ to $Mn^{II}P$.[35] Interestingly, a shift of the Soret band maximum to 455 nm was observed at –0.50 V, as a function of time (Figure 3, C), giving a more symmetric and slightly less intense band. This unexpected behavior does not seem to involve a redox process and is probably associated with some axial ligand equilibrium. In this case, the participation of adventitious water molecules[5,6,32] cannot be the cause since quite negative limiting potentials (–2.2 V) could be attained.

When the potential was shifted to –1.0 V a double-peaked Soret band was formed due to the rise of a new absorption band at 433 nm and decrease of the peak at 455 nm (Figure 3, D). This behavior is not consistent with the reduction of the porphyrin ring to the respective radical anion because no characteristic band could be found around 750 nm. An equilibrium involving a face-to-face dimer is another possibility, although this doesn't involve an electron-transfer process. Accordingly, this spectroelectrochemical process was assigned to the formation of a reduced species with $Mn^{I}P$ character, as evidenced by the electrocatalytic activity of GCE modified with films of [Mn(TRPyP)]/[CuTSPc].

The reduction of the porphyrin ring was observed at –1.3 V, where a decay of the double-peaked Soret band and an increase of the absorptions at 500 and 850 nm were observed (Figure 3, E). The next two processes were observed in the ranges –1.3 to –1.6 V (Figure 3, F) and –1.6 to –2.0 V (Figure 3, G) and involve the successive decrease of the bipyridine pπ–pπ* band at 298 nm to half its value, followed by its disappearance, while a broad band rose at 350 nm. Accordingly, they were assigned to the successive single-electron reduction of the first and second bpy ligands of each peripheral ruthenium complex. Interestingly, when the potential was further shifted to –2.2 V the small peak at 470 nm associated with the porphyrin radical anion decreased as the absorbance at 660 nm increased (Figure 3, H). Those changes are typical of the formation of the porphyrin dianion. Generally, this process occurs about 200 mV after the $P^{0/-}$ process, but the reduction of the bpy ligands should shift that redox process to potentials below –2.0 V, as observed in the case of the corresponding [Co(TRPyP)] derivatives.[5,6,32,36,37]

### Electrocatalytic Properties

[Mn(TRPyP)] can form stable ultrathin films of a supramolecular nanomaterial on GCE that, however, exhibit appreciable solubility in aqueous solution. This inconvenience can be eliminated by means of a layer-by-layer electrostatic assembly[32,40] with the structurally complementary tetraanionic sulfonated copper phthalocyanine [CuTSPc]. A remarkable electrochemical activity was observed for the modified electrodes (Figure 4), showing that it is possible to transfer the molecular properties of those tetraruthenated manganese porphyrins to the electrode surface. Typical CVs of GCE modified with [Mn(TRPyP)]/[CuTSPc] films in aqueous solution, at pH 4.7, exhibit a couple of reversible sine-shaped waves at $E_{1/2}$ = 0.95 V assigned to the $Ru^{III/II}$ process. The anodic and cathodic peak current intensities

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

increase linearly as a function of the scan rate, as expected for redox species immobilized on the surface.[9,27,40]

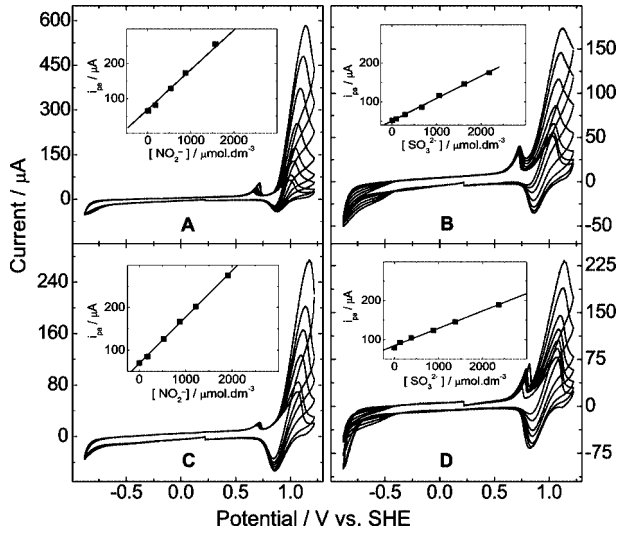

Figure 4. CVs of a GCE modified with layer-by-layer electrostatically assembled films of (A, B) [Mn(4-TRPyP)]/[CuTSPc] ($\Gamma$ = 1.6 and 1.2 nmol cm$^{-2}$) and (C, D) [Mn(3-TRPyP)]/[CuTSPc] ($\Gamma$ = 1.7 and 1.6 nmol cm$^{-2}$) in the presence of increasing concentrations of nitrite (A, C) and sulfite (B, D) in 0.025 M acetate buffer (pH 4.7) and $KNO_3$ (0.5 M). Scan rate: 0.1 V s$^{-1}$. Inset: plot of $i_{pa}$ vs. [substrate].

As aliquots of a stock solution of nitrite and sulfite were added to the electrolyte solution (Figure 4) the anodic wave at 1 V intensified linearly as a function of the concentration of those species. This indicates a relatively fast heterogeneous charge-transfer process mediated by the supramolecular films, in contrast with the bare electrodes, which exhibit broad, irreproducible responses. There is no significant difference in the electrocatalytic properties of the supramolecular nanomaterials obtained with both isomers for the oxidation of sulfite and nitrite. On the other hand, both modified electrodes are ineffective for the reduction of nitrite until –0.85 V. However, this does not seem to be the case for the reduction of sulfite, for which the activity of the *meta* isomer is clearly higher. The broad reduction wave starting at –0.5 V is assigned to the reduction of sulfite directly on the GCE surface.[41,42] This contrasts with the results obtained for [Ni(TRPyP)]/[CuTSPc] and [Co(TRPyP)]/[CuTSPc] films,[43] which exhibit high activity for the reduction of both substrates. This reductive electrocatalytic activity is due to the formation of reduced species with $M^{I}P$ character, such as $Ni^{I}P$ and $Co^{I}P$, which should be responsible for the efficient electron-transfer to nitrite and sulfite. Analogously, this result for the [Mn(TRPyP)]/[CuTSPc] films reinforces our previous assignment of the spectroelectrochemistry event observed at around –1 V to the formation of a species with $Mn^{I}P$ character.

## Catalytic Properties

The catalytic activity of [Mn(3-TRPyP)] species for cyclohexane hydroxylation and cyclohexene epoxidation with iodosylbenzene (PhIO) was evaluated relative to the activity of the [Mn(4-TRPyP)] isomer.[32] [Mn(3-TRPyP)] in acetonitrile solution exhibits bands V, IV, and III at 473, 574, and 616 nm, respectively. Upon adding a PhIO solution in $CH_2Cl_2/CH_3OH/H_2O$ (80:18:2) band V immediately shifts to 427 nm and bands IV and III disappear, giving rise to broad absorptions. These features are characteristic of high-valent $O{=}Mn^{IV}P$ species. However, within about a minute the spectrum of the $Mn^{III}P$ species is regenerated, indicating the consumption of PhIO and the reaction of $O{=}Mn^{IV}P$ with solvent species such as water and methanol. This suggests that the actual catalytically active species ($O{=}Mn^{V}P$) is a much more effective oxidant and oxygen atom donor (Figure 5).

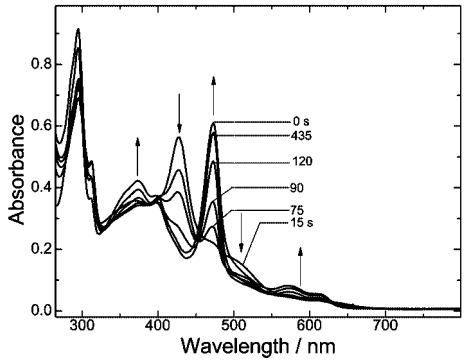

Figure 5. UV/Vis spectra showing the regeneration of $Mn^{III}P$ after reaction of a $4\times10^{-6}$ M acetonitrile solution of [Mn(3-TRPyP)] with a PhIO solution in $CH_2Cl_2/CH_3OH/H_2O$ (80:18:2). [Mn(3-TRPyP)]:[PhIO] = 1:10.

The catalytic activity of [Mn(TRPyP)] for the oxidation of cyclohexane was verified with iodosylbenzene as oxygen donor. Typically, $9.2\times10^{-4}$ mol of cyclohexane, $1.21\times10^{-7}$ mol of catalyst, and $2.7\times10^{-6}$ mol of PhIO were mixed in DCE/ACN (200/80 μL), at 298 K, in a sealed vial. The products were determined by gas chromatography after 15 min and the results are shown in Table 1. Cyclohexanol and cyclohexanone are the main products of the reaction, but small amounts of chlorocyclohexane are also observed. Interestingly, the *meta* isomer exhibits higher selectivity (alcohol/ketone ratio = 3.6 vs. 2.3) and reactivity (44% vs. 34%) than the *para* species.

More clear-cut evidence for the distinct activity of those isomers was obtained when the tetraruthenated manganese porphyrins were used as catalysts for the oxidation of cyclohexene. In general, the *meta* isomer has a significantly higher activity, converting all PhIO into oxygenated products but with a lower epoxide yield. In contrast, the *para* isomer shows a conversion of only about 60%, with a much higher selectivity for epoxide formation (Table 2).

The results described above reveal that [Mn(TRPyP)] has a catalytic activity for the oxidation of cyclohexane by PhIO similar to that of other manganese porphyrins.[44–46] For example, Iamamoto et al.[44] obtained 43% of cyclohexanol and 23% of cyclohexanone (ol/one ratio 2) with [Mn(TPP)-Cl] (chloromanganese tetraphenylporphyrin) in DCM. In general, the lower selectivity in polar solvents (for example

[a] MnP: $1.2\times10^{-7}$ mol; PhIO: $2.7\times10^{-6}$ mol; cyclohexene: $4.9\times10^{-4}$ mol; 1,2-dichloroethane (DCE): 250 μL; acetonitrile (ACN): 44 μL; chlorobenzene as internal standard; all solvents purged with $N_2$; $T$ = 298 K. C-ol = cyclohexen-2-ol, C-one = cyclohexen-2-one, allyl. oxid. = percentage of allylic oxidation products. [b] Based on the initial amount of PhIO. Average error ±3%.

ACN) is associated with the formation of the radical intermediate species $O{=}Mn^{IV}P^{+\cdot}$,[44,47,48] as well as the possible coordination of the solvent molecules to the Mn center. This does not seem to be the case for the [Mn(TRPyP)] complexes, however, which have a higher selectivity in DCE/ACN, in which they are more soluble because of their higher ionic character.

In the case of cyclohexane (Table 1), the higher efficiency suggests that the catalytically active high-valent oxomanganese species formed by [Mn(3-TRPyP)] is more reactive than that formed by [Mn(4-TRPyP)]. Another possibility is the involvement of two different activated species[49] as a consequence of electronic effects or interaction of the oxidant and/or the substrate with the peripheral $[Ru(bpy)_2Cl]^+$ groups. In fact, the ruthenium complexes in [Mn(3-TRPyP)] are positioned above and below the manganese porphyrin center. Accordingly, two pockets of suitable size for interaction with those organic substrates are generated, probably inducing the formation of a structurally more favorable activated complex. In contrast, the *para* isomer has a more symmetric and planar structure, ruling out such a possibility.[32]

The small amount of chlorocyclohexane (Table 1) generated in the oxidation reaction also gives some clues about the role of the peripheral ruthenium complexes in the activated complex. This by-product is likely to be formed when the cyclohexyl radical does not combine with the OH bond at the MnP center and escapes from the "cage". Consequently, its yield should be higher when the peripheral ruthenium complexes are close or interacting with the species participating in the activated complex. This proximity should facilitate the abstraction of a chloro atom from the $[Ru(bpy)_2Cl]$ groups, although the possibility of abstraction from the solvent cannot be discarded. In fact, experiments under similar conditions using another supramolecular species containing four trinuclear ruthenium acetate clusters with no coordinated chloride showed no chlorocyclohexane formation, thus ruling out the hypothesis of chlorine atom abstraction from the solvent. Considering that the redox and electronic properties of both species are similar, the significantly higher amount of chlorocyclohexane generated by the *meta* isomer is strong evidence that its higher catalytic activity can be assigned to the favorable stereochemical effects induced by the peripheral $[Ru(bipy)_2Cl]^+$ groups.

Finally, it is well known that conventional Mn–porphyrin species undergo severe degradation during the catalytic cycles,[44–48] and for this reason new, more-stable catalysts have been pursued, for example involving chlorinated or fluorinated porphyrins. In the case of the [Mn(TRPyP)] catalysts no evidence of decomposition could be detected spectroscopically after at least 10 turnover cycles, or 15 min, corresponding to the time of a typical experiment. Therefore, in spite of their secondary role in catalysis, the peripheral $[Ru(bipy)_2Cl]^+$ groups do provide an important steric protection around the highly reactive $Mn^V{=}O$ site, thereby preventing the degradation of the porphyrin center under such highly oxidizing conditions. Furthermore, they can provide interaction sites for the occurrence of steric effects, inducing changes in the geometry of the activated complex. The last two effects are probably the greatest advantage associated with these [Mn(TRPyP)] catalysts, in addition to their improved selectivity and high solubility in organic solvents.

## Conclusions

A new stereochemically hindered tetraruthenated manganese(III) porphyrin has been obtained and its structural, spectroelectrochemical, catalytic, and electrocatalytic properties investigated. The metalloporphyrin reduction and ruthenium complex oxidation potentials are shifted to more negative potentials in comparison with the planar isomer, suggesting a higher electronic density on the porphyrin ring. Stable and electrocatalytically active ultrathin films of layer-by-layer electrostatic assembled films of [Mn(TRPyP)]/[CuTSPc] can be easily prepared and used as nitrite and sulfite detectors. The activity of the [Mn(3-TRPyP)]/[CuTSPc]-modified GC electrodes for the reduction of sulfite is ascribed to the formation of a reduced species with $Mn^IP$ character at around –0.85 V, as observed by spectroelectrochemistry.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Very significant differences in the P-450 catalytic activity were found for the oxidation of cyclohexene and cyclohexane with iodosylbenzene. In fact, the *meta* isomer is consistently more active than the *para* isomer in both cases, although the selectivity for epoxide is higher for the latter. Such differences are due to steric effects induced by the peripheral [$Ru(bpy)_2Cl$] groups, which are positioned above and below the MnP ring and can therefore direct the activation of the substrates, thus improving the selectivity of the catalytic reactions. In comparison with conventional manganese porphyrins, the great advantage associated with the [Mn(TRPyP)] catalysts is their pronounced stability and improved selectivity in oxygen-transfer reactions.

## Experimental Section

**Materials and Methods:** UV/Vis spectra were recorded with a HP-8453A diode array spectrophotometer, in the 190–1100 nm range, either in $CH_3OH$ or $CH_3CN$. Cyclic voltammograms of [Mn(TRPyP)] in DMF solution were obtained with an AUTOLAB PGSTAT30 potentiostat/galvanostat. A conventional three-electrode cell was employed, consisting of a platinum disk as working electrode, $Ag/Ag^+$ (0.010 M, in $CH_3CN$) as reference electrode, and coiled platinum wire as auxiliary electrode. The solvents were HPLC grade; DMF was dried with anhydrous $CuSO_4$ and distilled under vacuum immediately before use. The electrolyte $[(C_2H_5)_4N]ClO_4$ was prepared by the reaction of $[(C_2H_5)_4N]OH$ with $HClO_4$, recrystallized from water, and dried under vacuum. A similar arrangement, except for the Ag|AgCl|KCl 1.00 M reference electrode, was used in the electrochemical studies using glassy carbon electrodes (GCE) modified with ultrathin electrostatic assembled films of [Mn(3-TRPyP)]/[CuTSPc] or [Mn(4-TRPyP)]/[CuTSPc]. All potentials were converted into the SHE scale by adding 0.503 or 0.222 V to the experimental values in organic or aqueous solution, respectively. Phosphate (25 mM, pH 6.80) and acetate (25 mM, pH 4.70) buffers in 0.50 M $KNO_3$ solution were used as electrolyte. The spectroelectrochemistry data were collected with a previously described homemade thin-layer cell[50] and a PAR model 173 potentiostat/galvanostat in parallel with an HP-8453A spectrophotometer. Electrospray mass spectra were recorded with a Q-Tof (Micromass) mass spectrometer with a quadrupole (Qq) and high-resolution orthogonal time of flight (o-TOF) configuration. The sample was injected with a syringe pump (Harvard Apparatus, Pump 11) at a rate of 10 $\mu L\,min^{-1}$ through an uncoated fused-silica capillary. All samples were dissolved in pure methanol. The ESI mass spectra were acquired at an ESI capillary voltage of 3 kV and a cone voltage of 10 V. Isotopic patterns were calculated using the MassLynx software. The products of the catalytic oxidation reactions were analyzed by gas chromatography using a Shimadzu model GC-17A equipment with flame ionization detector and OV-1701 0.50 micron capillary column (30 m × 0.25 mm). The carrier gas was $N_2$. Acetonitrile (HPLC grade) was dried over 3-Å molecular sieves before use. *n*-Octane was purified with concentrated sulfuric acid, washed with water, and distilled. Dichloromethane was distilled from over $P_2O_5$ and stored over molecular sieves. All other chemicals were reagent grade (1,2-dichloroethane, cyclohexane, methanol, and deuterated cyclohexane with >99% D) and used as received. Iodosylbenzene was prepared from iodobenzene diacetate as described in the literature.[51] All reactions were carried out in a thermostatted 2-mL vial with a septum, containing a magnetic stirring bar, at 25.0 ± 0.1 °C, under argon. 1,2-Dichloroethane, cyclohexane, and *n*-octane (internal reference for GC) were successively syringed into the vial, and $1.14 \times 10^{-5}$ mol of PhIO was added. A suitable volume of acetonitrile stock solution of the catalyst was then introduced in order to obtain the desired concentration.

**Syntheses:** The preparation of the *cis*-dichlorobis(2,2′-bipyridine)-ruthenium(II) complex $[Ru(bpy)_2Cl_2]$ has been described previously.[52] [Mn(3-TPyP)] was obtained by treating 500 mg (0.80 mmol) of the free-base porphyrin $H_2$(3-TPyP) with 147 mg (0.85 mmol) of manganese(II) acetate in refluxing glacial acetic acid for an hour, whilst stirring. The reaction mixture was cooled to room temperature and the solvent removed in a flash evaporator. The solid was washed with water, filtered, and dried under vacuum. Yield: 97%. $C_{40}H_{24}N_8Mn(CH_3COO)\cdot H_2O$ (748.2): calcd. C 67.38, H 3.90, N 14.97; found C 67.76, H 4.12, N 15.98. [Mn(3-TRPyP)] was obtained from the reaction of 101 mg (0.15 mmol) of [Mn(3-TPyP)] with 300 mg (0.62 mmol) of $[Ru(bpy)_2Cl_2]$ in 100 mL of refluxing glacial acetic acid for an hour, whilst stirring. The solvent was removed in a flash evaporator and the residue redissolved in methanol and refluxed for 30 min to assure the coordination of four ruthenium complexes to the peripheral pyridyl nitrogen atoms. The solvent was removed, the solid redissolved in a minimum volume of DMF, and this solution added dropwise to 10 mL of an aqueous lithium trifluoromethanesulfonate solution. The brown amorphous precipitate obtained was filtered, dried under vacuum, purified by successive recrystallization, and finally by neutral alumina column chromatography using a mixture of dichloromethane and ethanol (10:1) as eluent. Yield: 89%. $C_{120}H_{88}Cl_4MnN_{24}Ru_4(CF_3SO_3)_5\cdot 8H_2O$ (3356.7): calcd. C 44.73, H 3.12, N 10.01; found C 44.52, H 3.27, N 9.49.

# Polar Cofacially Fixed Sandwich Complexes: Do They Demonstrate Second Harmonic Generation (SHG)?

**Maik Malessa,[a] Jürgen Heck,*[a] Jürgen Kopf,[a] and M. Helena Garcia[b]**

*Dedicated to Prof. Dr. Wittko Francke on the occasion of his 65th birthday*

**Keywords:** Heterometallic complexes / Sandwich complexes / Donor–acceptor systems / Nonlinear optics / Through-space interaction

For the purpose of possible second harmonic generation (SHG) a cationic and a neutral sandwich unit were cofacially arranged in a three-step synthesis starting from 1,8-diiodonaphthalene. First, 1-cyclopentadienyl-8-iodonaphthalene (**2**) was formed, then the neutral ferrocenyl substituent was fixed in the 8-position by a Negishi cross-coupling reaction. The deprotonation of the cyclopentadienyl substituent, and the subsequent coordination of the half-sandwich fragments ML = $[Fe(\eta^5\text{-}C_5Me_5)]^+$, $[Rh(\eta^5\text{-}C_5Me_5)]^{2+}$, $[Ir(\eta^5\text{-}C_5Me_5)]^{2+}$, $[Ru(\eta^6\text{-}C_6H_6)]^{2+}$ to the cyclopentadienyl anion revealed the desired dinuclear complexes 1-[($\eta^5$-cyclopentadienediyl)-($\eta^5$-pentamethylcyclopentadienyl)iron(II)]-8-ferrocenylnaphthalene (**5**), 1-[($\eta^5$-cyclopentadienediyl)($\eta^5$-pentamethylcyclopentadienyl)rhodium(III)]-8-ferrocenylnaphthalene hexafluorophosphate (**6**$PF_6$), 1-[($\eta^5$-cyclopentadienediyl)($\eta^5$-pentamethylcyclopentadienyl)iridium(III)]-8-ferrocenylnaphthalene hexafluorophosphate (**7**$PF_6$), and 1-[($\eta^6$-benzene)($\eta^5$-cyclopentadienediyl)ruthenium(II)]-8-ferrocenylnaphthalene hexafluorophosphate (**8**$PF_6$). The neutral complex **5** was oxidized to the paramagnetic cation 1-[($\eta^5$-cyclopentadienediyl)-($\eta^5$-pentamethylcyclopentadienyl)iron(III)]-8-ferrocenylnaphthalene hexafluorophosphate (**5**$PF_6$). Compounds **3**, **5**$PF_6$, **6**$PF_6$, and **7**$PF_6$ were characterized by X-ray structure determination; the neutral compound **3** crystallizes in the space group $P2_1/c$, whereas all of the cationic dinuclear complexes crystallize in the chiral space group $C222_1$. A cyclic voltammetry study points to a predominant "through-space" interaction between the cationic sandwich unit and the neutral ferrocene substituent. The compounds **5**$PF_6$, **6**$PF_6$, **7**$PF_6$, and **8**$PF_6$ were subjected to hyper-Rayleigh scattering (HRS) and Kurtz-powder measurements. In both studies no SHG intensity could be observed.

## Introduction

Cofacially stacked arrays of organic and organometallic π-systems are of increasing interest for chemists and physicists, because of novel electrical,[1,2] optical,[2] and magnetic[3] properties. Just recently, theoretical[4] and experimental[5] work has demonstrated that stacked donor–acceptor arrangements of π-systems are suitable for second harmonic generation (SHG) effected by through-space (hyper)polarization (Figure 1).

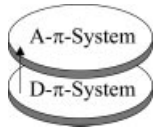

Figure 1. Cofacially stacked arrangement of donor(D)–acceptor(A) π-systems for second harmonic generation (SHG) due to polar "through-space" interaction.

Conventional types of compounds revealing nonlinear optical (NLO) properties, i.e. SHG, are composed of donor and acceptor units linked by conjugated π-bonds, which very often suffer from absorbance in the region of the SHG, and are thus not suitable for practical applications. In contrast, π-stacked donor-acceptor combinations seem to provide a better optical transparency.[6] Our approach to stacked organometallic π-complexes with donor–acceptor combinations, which may call forth SHG, is based on Rosenblum's concept of 1,8-disubstituted naphthalene derivatives containing two sandwich complexes in the *peri* position. Whereas the Rosenblum naphthalene derivatives are symmetrically constructed with the same sandwich complexes in the *peri* position,[7,8] our desired target molecules should contain different sandwich complexes,[9] one of which is a cation, generating an overall dipole moment, which is a possible prerequisite for SHG (Figure 2).

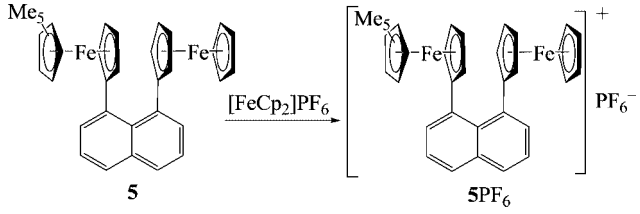
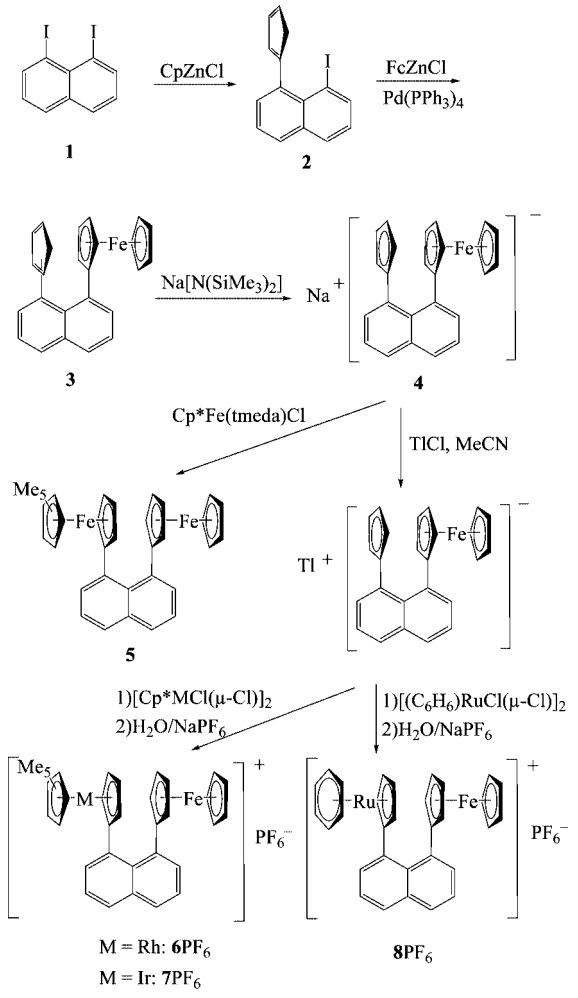
## Results and Discussion

### Synthesis

The assembly of different sandwich complexes in *peri* position of naphthalene requires a stepwise synthesis. Starting with a cross-coupling reaction of 1,8-diiodonaphthalene (**1**) [10] with cyclopentadienylzinc chloride[7a,9a] (Scheme 1), results in the formation of 1-cyclopentadienyl-8-iodonaphthalene (**2**). For the second step, a Pd-catalyzed Negishi cross-coupling reaction with ferrocenylzinc chloride[11,12] was performed, revealing complex **3**, which is composed of the two different isomers **3a** and **3b** (see Exp. Sect.). In order to synthesize the unsymmetrical disandwich-substituted naphthalene derivatives, complex **3** was subjected to a deprotonation by sodium bis(trimethylsilyl)amide to yield **4**, and a consecutive coordination reaction with the proper half-sandwich complexes (Scheme 1). For Rh, Ir, and Ru complexes **6**$PF_6$, **7**$PF_6$, and **8**$PF_6$, the deprotonated complex **4** was treated with thallium chloride in acetonitrile to replace the counterion $Na^+$ with $Tl^+$.[13] This cation exchange is necessary to obtain good yields of the desired dinuclear cationic complexes with Ru, Rh and Ir. In order to achieve the polar structure of the diiron derivative, compound **5** was oxidized to the paramagnetic monocation **5**$PF_6$ by addition of a stoichiometric amount of ferrocenium hexafluorophosphate (Scheme 2), and a dark red-brown crystalline material was obtained. All compounds were fully characterized by elemental analyses, spectroscopic methods and cyclic voltammetry. For compound **3a**, **5**$PF_6$, **6**$PF_6$ and **7**$PF_6$ X-ray structure analyses were determined.



Scheme 2. Oxidation of **5** with ferrocenium hexafluorophosphate.



Scheme 1. Synthesis of polar cofacially fixed sandwich complexes.

### Crystal Structures

The solid-state structures of **3a**, **5**$PF_6$, **6**$PF_6$ and **7**$PF_6$ are displayed in Figures 3, 4, 5 and 6. The mononuclear complex **3a** crystallizes in the monoclinic space group $P2_1/c$, whereas the space group for the dinuclear monocationic species is found to be orthorhombic and chiral with $C222_1$. Not surprisingly, the structural data of the sandwich units are very similar to those of published data for corresponding prototype sandwich complexes (Table 1).[14–17]

[a] Cent: centroid of the corresponding cyclopentadienyl rings.

The most eye-catching feature of all structures under study is the distortion of the compound entities (Figure 7, Table 2); a common occurrence for naphthalene derivatives disubstituted in the 1,8-positions by aromatic moieties.[8,18] The tilt angle between the best plane of the naphthalene-bound Cp ligands and the best planes of the connected six-membered naphthalene rings varies from 45.6(6)° (**5**$PF_6$) to 77.9(8)° (**6**$PF_6$) (Table 2). For the less crowded example **3a**, with only one sandwich unit, intermediate tilt angles of 53.5(2)° and 53.0(2)° are found. Remarkably, the permethylation of one of the distal Cp ligands in the cationic species

does not cause tilt angles that deviate distinctly from those obtained for other comparable naphthalene derivatives,[8,18] which points out that the distortion is not a consequence of the steric hindrance between the positions C2 and C7, and the distal Cp ligands, but rather a result of the steric repulsion of the two-faced Cp units in the *peri* position (compare also data in Table 2). Despite the distortion of the entire *peri*-disubstituted naphthalene derivatives, a projection along the molecular axis of the sandwich complexes still shows an almost complete face-to-face arrangement of the sandwich units (Figure 7). This nicely demonstrates the clamp function of the naphthalene backbone for the purpose of stacking the sandwich units.

## Spectroscopic Properties

The NMR signals of the complexes **3**, **5**, **6**$PF_6$, **7**$PF_6$ and **8**$PF_6$ have been assigned by means of $^1H$, $^{13}C$, $^1H^1H$ COSY, HMQC, ATP and $^1H^1H$ NOESY spectra. For comparison, the symmetrical diferrocenyl-substituted naphthalene congener **9**[8] was studied. The $^1H$ NMR signals of the sandwich units are found in the typical range for the corresponding unsubstituted derivatives. The deviations are difficult to explain, because they are small and probably strongly dominated by the anisotropy effects of the neighboring sandwich complex. The $^{13}C$ NMR shifts, which are less influenced by anisotropy effects compared to the overall shift range, illustrate a slight but distinct low-field shift for the signals of the unsubstituted Cp ligand as well as of the carbon nuclei in 2,5- and 3,4-positions of the naphthalene-bound Cp ligand of the ferrocenyl substituent in the order **5** < **9** < **3** < **8**$PF_6$ < **6**$PF_6$ < **7**$PF_6$. The order may reflect a subtle decrease of the electron repulsion between the ferrocenyl substituent and the neighboring sandwich complex (Table 3).

UV/Vis spectroscopy is a well-tried tool for obtaining initial information about potential nonlinear optical (NLO) behavior in virtue of the solvatochromism of dipolar com-

pounds. If the dipole moments of the ground and an excited state are different, a variation of the solvent polarity will stabilize the two states differently, resulting in a bathochromic or hypsochromic shift of the absorption maximum.[19,20] Therefore, the UV/Vis spectra of the complexes **3**, **5**, **5**$PF_6$, **6**$PF_6$, **7**$PF_6$ and **8**$PF_6$ were recorded in dichloromethane and methanol (Table 4). For both solvents, weak absorption bands can be detected in the region at $\lambda \approx 300$ and 450 nm because of d–d transitions typical for ferrocenes.[21,22] The high-energy d–d transition is superimposed by a strong π–π* transition at $\lambda < 300$ nm, and is thus only observable as a shoulder. The dependence of the absorption maxima on the polarity of the solvent is minor: only a small hypsochromic shift is observed for the low-energy d–d transition. **5**$PF_6$ and **9**$PF_6$ demonstrate additional absorption bands at $\lambda_{max} = 813$ nm ($\varepsilon = 649\ M^{-1}cm^{-1}$) and at about 840 nm ($\varepsilon = 800\ M^{-1}cm^{-1}$),[8a] respectively, which are typical for ferrocenium derivatives, as well as very broad absorption bands at $\lambda_{max} = 1284$ nm ($\tilde{\nu} = 7788\ cm^{-1}$) and $\lambda_{max} = 1500$ nm[8a] ($\tilde{\nu} = 6667\ cm^{-1}$) ($\Delta\tilde{\nu}_{1/2} > 4000\ cm^{-1}$, $\varepsilon < 100\ M^{-1}cm^{-1}$, respectively. The NIR bands are indicative of mixed-valence charge-transfer (MVCT) transitions in mixed-valence compounds of class II.[9a,9b,23a,23b]

## Redox Properties

Cyclic voltammograms were obtained for all of the naphthalene derivatives in this study. For comparison, the redox behavior of the 1,8-diferrocenyl-substituted naphthalene **9** was additionally investigated. As expected, all complexes reveal an electrochemically reversible one-electron oxidation in the range of ferrocene itself (Table 5, Figure 8), and can thus be assigned to the oxidation of the ferrocenyl substituent. The peak-to-peak separations found ($\Delta E_p = E_{pc} - E_{pa}$) are generally larger than the ideal value of 60 mV for a fully reversible one-electron process, which is probably due to the uncompensated solution resistance.

The cyclic voltammograms of the diiron complexes **5** and **9** contain an additional reversible one-electron redox wave due to the oxidation of the second ferrocenyl unit. The permethylation of one of the cyclopentadienyl ligands causes a more pronounced cathodic shift of the first oxidation step for **5** relative to **9**. The rhodium and ruthenium congeners display an irreversible reduction beyond –2000 mV vs. ferrocene/ferrocenium, which is caused by the reduction of the cationic sandwich unit;[24,25] for the iridium derivative **7**$PF_6$ a corresponding reduction was not observed within the accessible range, which seems reasonable, as the reduction potential for the cationic sandwich complex $[CpIr(C_5Me_5)]^+$ is about 500 mV more negatively shifted than for the corresponding rhodium complex.[25] A reduction of the aromatic π-system of the naphthalene unit is not expected within the scan range, because naphthalene reveals a reduction beyond –3 V vs. ferrocene/ferrocenium.[26]

When the oxidation potentials of the ferrocene units of all the monocationic species under study are compared, an increase is observed in the order **5**$PF_6$ < **3** < **7**$PF_6$ < **6**$PF_6$ < **8**$PF_6$ < **9**$PF_6$. It is still under discussion whether the

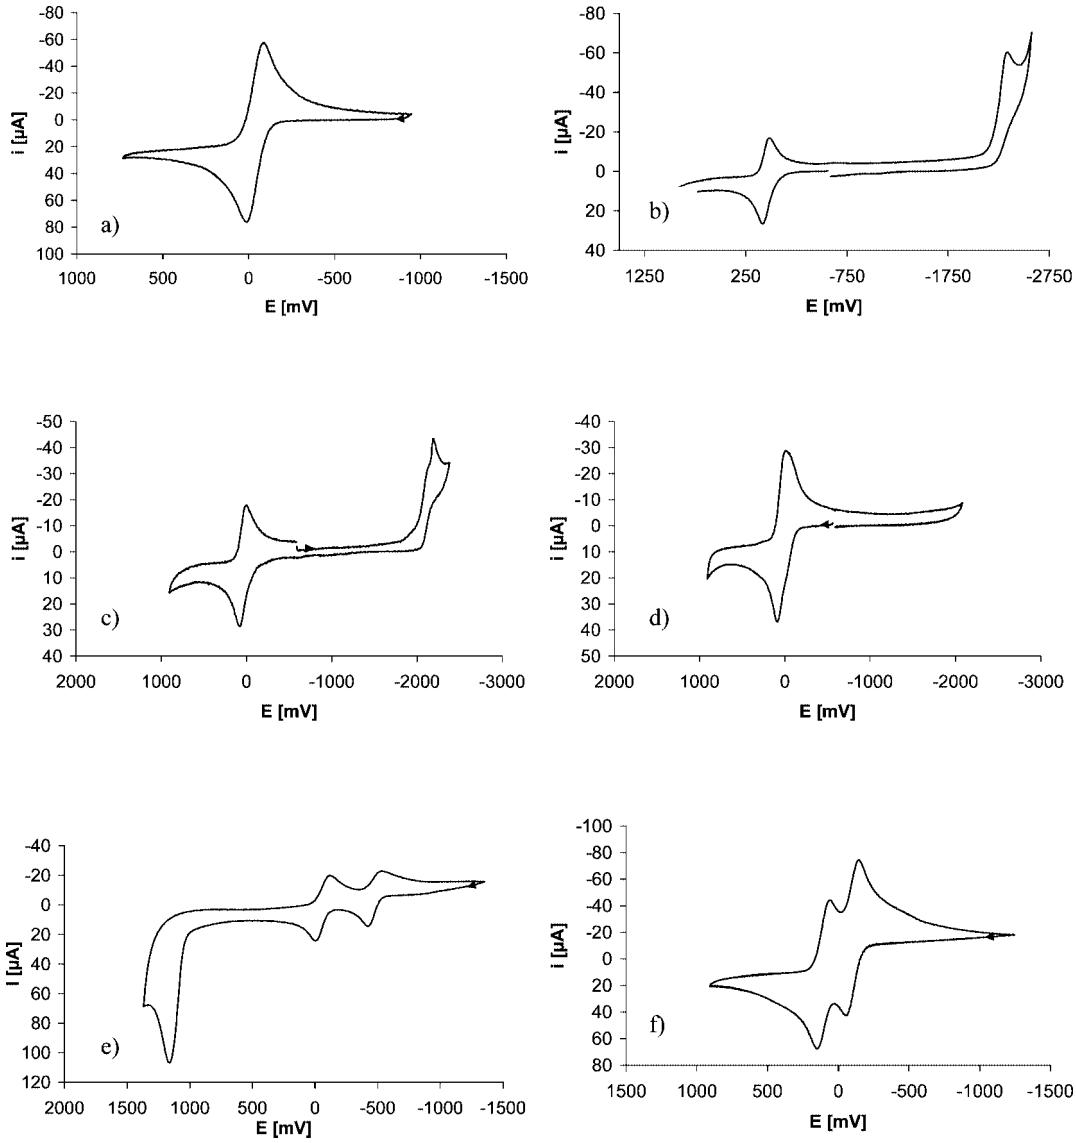

Figure 8. Cyclic voltammograms of **3** (a), **8**$PF_6$ (b), **6**$PF_6$ (c), **7**$PF_6$ (d), **5**$PF_6$ (e), **9** (f) (for more details see Table 5).

oxidation potentials are mainly influenced by a direct "through-space" interaction of the sandwich units, which are in an almost perfect face-to-face arrangement, or by a "through-bond" interaction facilitated by the π-bonding system of the naphthalene core. However, some arguments point to a predominant contribution of the "through-space" interaction: (i) the almost perpendicular conformation of the sandwich substituents with respect to the naphthalene plane hampers the interaction between the sandwich and naphthalene π-bonding systems and (ii) the 1,8-disubstitution of the aromatic naphthalene system disfavours the π-interaction between the substituents. This has been demonstrated by 1,3-diferrocenylated benzene derivatives, which may be regarded electronically similar to the 1,8-diferrocenylated naphthalene species; the benzene compounds reveal a difference in the oxidation potentials for the ferrocene units of less than 100 mV, although the ferrocene substituents rotate around the benzene–ferrocene σ-bond and can thus adopt a coplanar conformation of the ferrocene and benzene π-systems suitable for a proper π-interaction.[27,28] In contrast to this and in accordance with others,[8] a difference in the oxidation potentials of about 200 mV was found for **9**. The interpretation of an important "through-space" interaction in face-to-face stacked sandwich complexes is also in harmony with the explanation of an antiferromagnetic coupling between two paramagnetic trovacene complexes in *peri* position of naphthalene.[18]

## Measurements Concerning Second Harmonic Generation

In order to elucidate the NLO activity of the stacked sandwich compounds with respect to second harmonic generation (SHG), hyper-Rayleigh scattering (HRS) measurements were performed for liquid solution samples of **5**$PF_6$,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**6**$PF_6$, **7**$PF_6$, **8**$PF_6$, and **9**$PF_6$ with a pulsed Nd:YAG laser at $\lambda$ = 1064 and 1500 nm. The measurements were carried out as described in the literature.[29,30] Dichloromethane and acetonitrile were used as solvents. In addition, the Kurtz-powder method[31] was applied for crystalline samples of **5**$PF_6$, **6**$PF_6$ and **7**$PF_6$, because they crystallize in the chiral space group $C222_1$. However, no method could detect a measurable intensity of a frequency-doubled light. One explanation for the lack of SHG of the liquid solution samples is the weak polarizability and thus hyperpolarizability of the polar complexes, which can already be suggested from small solvatochromism. Even for the mixed-valence diferrocenyl species **5**$PF_6$ and **9**$PF_6$, which illustrate broad absorption bands in the NIR region (vide supra), no frequency-doubled signal could be detected, although SHG has been observed for species containing two ferrocene termini, which are separated by a cumulenium bridge.[32] The considerable absorption of **5**$PF_6$ and **9**$PF_6$ at $\lambda < 800$ nm may hamper the recognition of the second harmonic signal by absorption of light over a long range in the visible region. The lack of a SHG of the crystalline phase may be due to the orthorhombic crystal space group $C222_1$, which is a less effective space group for second harmonic generation.[33]

## Conclusions

In order to create second harmonic generation by "through-space" hyperpolarization in two face-to-face, but polar arranged sandwich complexes, four novel disandwich complexes have been synthesized, wherein a ferrocene and a cationic sandwich complex are combined and held together by a naphthalene clamp. The synthesis was performed by two consecutively conducted cross-coupling reactions of cyclopentadienylzinc chloride and ferrocenylzinc chloride, respectively, with 1,8-diiodonaphthalene as starting material. After deprotonation of the free cyclopentadienyl substituent, the coordination of different half-sandwich units revealed the desired dinuclear complexes. In addition, the neutral, but unsymmetrical diferrocenyl derivative **5**, was oxidized to the monocationic dipolar compound **5**$PF_6$. For compounds **3**, **5**$PF_6$, **6**$PF_6$, **7**$PF_6$ the molecular structures have been determined by X-ray structure analysis. Complex **3** crystallizes in the space group $P2_1/c$, whereas the dinuclear species crystallize in the chiral space group $C222_1$. The fixation of the sandwich entities in the *peri* position of the naphthalene backbone causes severe distortion of the entire complex, but warrants an almost linear face-to-face alignment of the two sandwich units. The redox properties of all of these complexes turned out a "through-space" polar interaction, which influences the oxidation potential of the ferrocene unit in **5**$PF_6$, **6**$PF_6$, **7**$PF_6$ and **8**$PF_6$. However, no SHG effect could be detected by means of HRS measurements. Having in mind the chirality of the crystalline material of **5**$PF_6$, **6**$PF_6$ and **7**$PF_6$, the Kurtz-powder method has been applied, but again, no SHG effect could be observed. The lack of SHG in the stacked sandwich entities may raise some doubts about the applicability for SHG in stacked π-systems. To obtain a deeper insight into the "through-space" interaction concerning NLO effects it would be worthwhile to extend the amount of face-to-face stacked sandwich complexes in a polar fashion to make the π-electronic system more polarizable, which is subject of current work.

## Experimental Section

**General:** Manipulations were carried out under dry nitrogen using standard Schlenk technique. Solvents were saturated with nitrogen. Diethyl ether ($Et_2O$), tetrahydrofuran (THF), *n*-hexane and toluene were freshly distilled from the appropriate alkali metal or metal alloy. Dichloromethane ($CH_2Cl_2$) and nitromethane ($MeNO_2$) were dried with calcium hydride. NMR: Varian Gemini 200 BB; Bruker AM 360; measured at 295 K rel. to TMS. UV/Vis: Perkin–Elmer Model 554. IR: KBr pellets; FT-IR Perkin–Elmer Model 325. MS: Finnigan MAT 311 A (EI-MS). Elemental analyses: CHN-O-Rapid, Fa. Heraeus, Zentrale Elementanalytik, Fachbereich Chemie, Universität Hamburg. 1,8-Diiodonaphthalene,[10] di-μ-chlorobis[chloro(η$^5$-pentamethylcyclopentadienyl)rhodium(III)] [Cp*$RhCl_2]_2$,[34] di-μ-chlorobis[chloro(η$^5$-pentamethylcyclopentadienyl)iridium(III)] [Cp*$IrCl_2]_2$,[34] di-μ-chlorobis[chloro(η$^6$-benzene)ruthenium(II)] $[(C_6H_6)RuCl_2]_2$,[35] ferrocenium hexafluorophosphate [FcH]$PF_6$,[36] chloro-(η$^5$-pentamethylcyclopentadienyl)-(tetramethylethylenediamine)iron(II) [Cp*Fe(tmeda)Cl][37] were synthesized according to literature procedures. Zinc chloride was dried by stirring in thionyl chloride unter reflux for several hours. $[Pd(PPh_3)_4]$ was purchased commercially.

**1-Cyclopentadienyl-8-iodonaphthalene (2):** The synthesis was carried out similar to the reaction described in the literature.[7c] Cyclopentadienyllithium (1.82 g, 25.25 mmol) and anhydrous zinc chloride (7.35 g, 53.95 mmol) were stirred in THF (70 mL) at 0 °C for 45 min. 1,8-Diiodonaphthalene (**1**) (4.97 g, 13.08 mmol) was added, the reaction mixture was warmed to room temperature and was stirred for 50 h. The reaction mixture was hydrolyzed with saturated $NH_4Cl$ solution (150 mL), and the products were extracted with $Et_2O$ (total amount 450 mL). The organic layer was dried with $MgSO_4$ and the solvents were evaporated to dryness. Extraction with hexane revealed 1-cyclopentadienyl-8-iodnaphthalene (**2**) as a yellow oil composed of three different isomers (3.55 g, 85.2%). M.p. ca. –10 °C. $^1$H NMR (360 MHz, $CDCl_3$, rel. to TMS, room temp.): $\delta$ = 8.21 (dd, $^3J_{6,7}$ = 7.2, $^4J_{5,7}$ = 3.6 Hz, 1 H, 7-H), 7.86 (dd, $^3J_{5,6}$ = 7.2, $^4J_{5,7}$ = 3.6 Hz, 1 H, 5-H), 7.75–7.79 (m, 1 H, 3-H), 7.44 (d, $^3J_{2,3}$ = 5 Hz, 1 H, 2-H), 7.42 (d, $^3J_{3,4}$ = 5 Hz, 1 H, 4-H), 7.07 ("t", $^3J_{6,7}$ = $^3J_{5,6}$ = 7.2 Hz, 1 H), 6.62–6.70 (m, 3 H, Cp-$H_{vinyl}$), 3.12–3.14 (m, 1 H, sp$^3$-CpH) ppm. IR (KBr): $\tilde{\nu}$ = 3049, 2960, 2927, 2908, 2846, 1927, 1802, 1719, 1595, 1571, 1536, 1498 1437, 1419, 1362, 1352, 1321, 1250, 1221, 1194, 1175, 1139, 1106, 1037, 1001, 950, 928, 890, 860, 826; 815, 764, 726, 681, 641, 606, 581, 557, 522, 505, 466, 419 cm$^{-1}$.

**Monolithioferrocene:** Monolithioferrrocene was prepared similar to the procedure described in the literature.[11] A pentane solution of *t*BuLi (1.48 M, 35 mL, 51.63 mmol) was added dropwise to a solution of ferrocene (10.0 g, 5.37 mmol) in THF (25 mL) at room temperature. After 15 min of stirring, the solution was cooled to –15 °C. The addition of *n*-hexane led to the precipitation of the lithiated products, which contain the monolithiated ferrocene as the main product (3.50 g, 34%). The orange solid material is extremely oxygen- and moisture-sensitive.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**1-Cyclopentadienyl-8-ferrocenylnaphthalene (3):** Anhydrous zinc chloride (2.21 g, 16.2 mmol) was added to a solution of monolithioferrocene (2.317 g, 12,07 mmol) in THF (30 mL) at 0 °C. After stirring for 1 h, the red solution was added to a solution of 1-cyclopentadienyl-8-iodonaphthalene (**2**) (2.57 g, 8.08 mmol) and tetrakis(triphenylphosphane)palladium(0) (0.55 g, 0.48 mmol, 6 mol-%) in THF (10 mL). The reaction mixture was stirred at room temperature for 4 h and poured into a solution of saturated ammonium chloride (200 mL). The mixture was vigorously stirred and extracted with $Et_2O$. The orange-red organic layer was dried with $MgSO_4$. The volume of the solution was reduced to a minimum amount, dissolved in hexane/$Et_2O$ (10:1), filtered through a column of alumina (5% water), and subjected to column chromatography on basic alumina [5% water, hexane/$Et_2O$ (1:0 to 10:1)]. Unreacted ferrocene could be separated first. The second fraction contained the desired compound **3** as an orange-red solid material, consisting of two isomers: 1-(cyclopentadien-1′-yl)-8-(ferrocen-1′′-yl)naphthalene (**3a**) and 1-(cyclopentadien-2′-yl)-8-(ferrocen-1′′-yl)naphthalene (**3b**) (1.90 g, 63%). $C_{25}H_{20}Fe$ (376.28): calcd. C 79.80, H 5.36; found C 79.74, H 5.80. M.p. 122–125 °C; ref.[7c] 134–140 °C. $^1$H NMR (200 MHz, $CDCl_3$, rel. to TMS, room temp.): $\delta$ = 8.18 (d, $^3J_{6,7}$ = 8 Hz, 1 H, 7-H), 7.79 (m, 2 H, H-2, 5-H), 7.50 (t, $^3J_{6,7}$ = $^3J_{5,6}$ = 7.5 Hz, 1 H, 6-H), 7.32–7.42 (m, 2 H, H-3, 4-H), 5.88–6.30 (m, 3 H, Cp-$H_{vinyl}$), 4.30, 4.26 (br. t, 2 H, Fc-$H_{2,5}$, isomer **3a** and **3b**), 4.03 (br. t, Fc-$H_{3,4}$, 1.2 H, isomer **3b**), 3.96 (br. s, 5.8 H, Fc-H, isomer **3a** and **3b**, Fc-$H_{3,4}$ isomer **3a**), 2.89 (br. s, 0.6 H, sp$^3$-CpH, isomer **3b**), 2.68 (br. s, 0.4 H, sp$^3$-CpH, isomer **3a**) ppm. $^{13}$C NMR (50 MHz, $CDCl_3$, rel. to TMS, room temp.): $\delta$ = 137.4, 136.3 (C-1, C-8); 133.2, 132.6, 132.1, 131.9, 129.5, 129.5, 129.20, 128.7, 128.2, 127.8, 125.5, 125.1, 72.1, 70.7 (C-2′′,5′′); 69.9 ($C_5H_5$), 67.2, 66.7 (C-3′′,4′′), 44.7, 41.7 (sp$^3$C-$C_5H_5$) ppm. IR (KBr): $\tilde{\nu}$ = 3076, 3046, 2916, 2897, 2871, 1637, 1591, 1570, 1500, 1478, 1422, 1365, 1105, 1052, 1032, 1022, 999, 952, 894, 824, 810, 773, 673, 485 cm$^{-1}$. MS (EI): *m/z* (%) = 376.3 (100) [M$^+$], 310.3 (59) [M – $C_5H_6$]$^+$, 254 (23) [$C_{10}H_6(C_5H_4)_2^+$], 189 (16) [$C_{10}H_5(C_5H_4)^+$], 121 (16) [FeCp$^+$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 382 (1420, sh), 456 (536 M$^{-1}$cm$^{-1}$) nm; (MeOH): $\lambda_{max}$ ($\varepsilon$) = 295 (ca. 6000), 378 (ca. 800), 458 (ca. 300 M$^{-1}$cm$^{-1}$) nm.

**1-[(η$^5$-Cyclopentadienediyl)(η$^5$-pentamethylcyclopentadienyl)iron(II)]-8-ferrocenylnaphthalene (5):** 1-Cyclopentadienyl-8-ferrocenylnaphthalene (**3**) (0.182 g, 0.48 mmol) was dissolved in THF (10 mL), treated with an Na[N($SiMe_3$)$_2$] solution in THF (1 M, 0.5 mL, 0.5 mmol) at 0 °C and stirred for 90 min. To this solution, which was cooled to –78 °C, [Cp*Fe(tmeda)Cl] (0.412 g, 1.2 mmol) was added. After stirring overnight and warming to room temperature, the reaction mixture was concentrated to dryness. The residue was dissolved in a minimum amount of toluene and filtered through alumina (neutral, 5% water) and the filtrate was purified by column chromatography on alumina (neutral, 5% water). As eluent *n*-hexane/toluene (10:1) was used. The eluate was concentrated to dryness, to yield 1-[(η$^5$-cyclopentadienediyl)(η$^5$-pentamethylcyclopentadienyl)iron(II)]-8-ferrocenylnaphthalene (**5**) (0.18 g, 65%) as an orange crystalline material (Figure 9). $C_{35}H_{34}Fe_2$ (566.35): calcd. C 74.23, H 6.05; found C 73.99, H 6.59. Figure 9. Numbering scheme for the assignment of the NMR signals.

**1-[(η$^5$-Cyclopentadienediyl)(η$^5$-pentamethylcyclopentadienyl)iron(III)]-8-ferrocenylnaphthalene Hexafluorophosphate (5PF$_6$):** 1-[(η$^5$-Cyclopentadienediyl)(η$^5$-pentamethylcyclopentadienyl)iron(II)]-8-ferrocenylnaphthalene (**5**) (0.314 g, 0.55 mmol) was dissolved in $CH_2Cl_2$ (30 mL). Ferrocenium hexafluorophosphate (0.166 g, 0.50 mmol) was added, whereupon the color of the reaction mixture changed form orange-red to dark brown. After stirring at room temperature for 80 min, *n*-hexane (60 mL) was layered on the $CH_2Cl_2$ solution, and the reaction flask was stored at –30 °C for 2 d. The precipitated crystals were filtered off and dried in vacuo. 1-[(η$^5$-Cyclopentadienediyl)(η$^5$-pentamethylcyclopentadienyl)iron(III)]-8-ferrocenylnaphthalene hexafluorophosphate (**5**PF$_6$) was obtained in dark red-brown crystals (0.32 g, 0.45 mmol, 82%). $C_{35}H_{34}Fe_2PF_6{\cdot}(CH_2Cl_2)_{0.66}$ (767.94): calcd. C 55.78, H 4.64; found C 55.98, H 4.70. M.p. 189 °C (dec). $^1$H NMR (360 MHz, [D$_6$]acetone, rel. to TMS, room temp.): $\delta$ = 34.2 (2′,5′-H), 24.9 (2′′,5′′-H), 22.5 (3′′,4′′H), 18.5 (3′,4′-H), 10.9 ($C_5H_5$), 1.87 (4-H, 5-H), –2.22 (6-H), –10.81 (7-H), –25.26 (3-H), –36.55 ($C_5Me_5$), –55.84 (2-H). IR (KBr): $\tilde{\nu}$ = 3121, 3051, 2963, 2916, 1631, 1587, 1502, 1474, 1448, 1423, 1412, 1389, 1314, 1268, 1185, 1133, 1105, 1070, 1032, 1000, 935, 919, 846, 837, 775, 732, 699, 692, 638, 598, 557, 533, 521, 510, 494, 483, 460, 432, 423, 414, 408 cm$^{-1}$. MS (FAB): *m/z* (%) = 566 (100) [M$^+$], 501 (8) [M – Cp]$^+$, 445 (12) [M – FeCp]$^+$, 431 (20) [M – Cp*]$^+$, 310 (44) [M – CpFeCp*]$^+$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 433 (2850, sh), 813 (649), 1284 (122 M$^{-1}$cm$^{-1}$) nm; MeOH: $\lambda_{max}$ ($\varepsilon$) = 304 (24780), 428 (3712, sh), 801 (953 M$^{-1}$cm$^{-1}$) nm.

**1-[(η$^5$-Cyclopentadienediyl)(η$^5$-pentamethylcyclopentadienyl)-rhodium(III)]-8-ferrocenylnaphthalene Hexafluorophosphate (6PF$_6$):** 1-Cyclopentadienyl-8-ferrocenylnaphthalene (**3**) (0.29 g, 0.77 mmol) was dissolved in THF (15 mL), and treated with a solution of Na[N($SiMe_3$)$_2$] in THF (1 M, 0.75 mL, 0.75 mmol) at 0 °C. After stirring for 80 min, the solvent was stripped off in vacuo, and the residue was redissolved in acetonitrile (50 mL), whereupon thallium(I) chloride (0.185 g, 0,77 mmol) was added. The reaction mixture was stirred at room temperature for 3 h and at 40 °C for 18 h. [Cp*RhCl$_2$]$_2$ (0.236 g, 0.38 mmol) was added and the mixture stirred at 45 °C for 3 h and at room temperature for 20 h. The reaction solution was filtered through Celite, and the filtrate was concentrated to dryness. The solid red residue was dissolved in water (60 mL) and, after filtration, $NH_4PF_6$ (0.150 g, 1.03 mmol), dis-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solved in water (5 mL), was added to the filtrate. An orange, voluminous precipitate formed, which was collected on a filter frit, washed with water and $Et_2O$ and dried in vacuo. For recrystallization the orange-red powder of **6**$PF_6$ (0.425 g, 0.57 mmol, 74%) was redissolved in $CH_2Cl_2$ and overlayered with $Et_2O$. $C_{35}H_{34}FeRhPF_6$ (758.37): calcd. C 55.43, H 4.52; found C 56.48, H 4.87. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 463 (960 M$^{-1}$ cm$^{-1}$) nm; (MeOH): $\lambda_{max}$ ($\varepsilon$) = 286 (3758), 461 (190 M$^{-1}$ cm$^{-1}$) nm.

**Cyclic Voltammetry:** Measurements were performed in $CH_2Cl_2$ with 0.4 M [*n*$Bu_4N$]$PF_6$ as supporting electrolyte. An Amel 5000 system was used with a Pt wire as working electrode and a Pt plate (0.6 cm$^2$) as auxiliary electrode. The potentials were measured against Ag/$AgPF_6$ and were referenced to $E_{1/2}$(ferrocene/ferrocenium) = 0 V.

**X-ray Structure Determination:** Crystals of compound **3**, **5**$PF_6$, **6**$PF_6$ and **7**$PF_6$ suitable for an X-ray structure determination were obtained for compound **3** by careful evaporation of the solvent, and for **5**$PF_6$, **6**$PF_6$ and **7**$PF_6$ by slow diffusion of $Et_2O$ into a $CH_2Cl_2$ solution of the complexes at –30 °C. The data were collected with a four-circle diffractometer by Hilger and Watts, Mo-$K_\alpha$, $\lambda$ = 0.71073 Å (Table 6). The structures were solved by direct methods (SHELXS-86)[38a] and the refinements on $F^2$ were carried out by full-matrix least-squares techniques (SHELXL-97).[38b] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined with a fixed isotropic thermal parameter related by a factor of 1.2 to the value of the equivalent isotropic parameter of their carrier atoms. Weights were optimized in the final refinement cycles. Residual electron density was observed for crystals of **5**$PF_6$, **6**$PF_6$, and **7**$PF_6$ pointing out diffuse incorporation of solvent molecules.[39] CCDC-279705 (**3**), -279702 (**5**$PF_6$), -279703 (**6**$PF_6$), and -279704 (**7**$PF_6$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**SHG Measurements:** The efficiency of SHG of the crystalline materials are measured with our experimental setup[40] for the Kurtz powder method.[31] The measurements were performed at 1064 nm laser pulses produced by the Nd:YAG laser at low power (50 mJ per pulse); this laser produces 40-ns pulses with a repetition rate of 10 Hz. The procedure for the measurements is as follows: for crystalline samples, the grain size was not standardized. For this reason signals between individual measurements were seen to vary in some cases by as much as ±20%. The material to be measured was ground to a fine powder and compacted in a mount and installed in the sample holder. In order to compare the new samples with the reference urea, the measurements were averaged over several laser cycles. The voltage from the photomultiplier was measured by an oscilloscope which was triggered by the signal itself. The photomultiplier voltage and the neutral density filter area were optimized to obtain a good signal-to-noise ratio and to prevent the saturation of the photomultiplier. The oscilloscope measures the

[a] GOF = "Goodness-of-fit" = $\{\Sigma[w(F_o^2 - F_c^2)^2]/(n-p)\}^{1/2}$ ($n$ = number of reflections, $p$ = number of parameters). [b] $R_1 = \Sigma||F_o| - |F_c||$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)]\}^{1/2}$.

time integral of the photomultiplier voltage automatically, which is proportional to the SHG efficiency. The oscilloscope also performs the average over several shots automatically. The SHG efficiency measurement for the reference sample was performed under the same experimental conditions as that of the test samples. The SHG efficiency for liquid solutions of the polar compounds was determined by means of hyper-Rayleigh scattering (HRS).[41] The HRS measurements were performed with a pulsed Nd:YAG laser at a wavelength of $\lambda$ = 1064 and 1500 nm. For the experimental setup for $HRS_{1064nm}$, see ref.[28] Solutions of the complexes in dichloromethane and acetonitrile with concentrations in the range of $10^{-4}$ to $10^{-6}$ M were used with *p*-nitroaniline as a reference [$\beta(CH_2Cl_2)_{1064} = 21.6 \cdot 10^{-30}$ esu; $\beta(MeCN)_{1064} = 29.2 \cdot 10^{-30}$ esu].[42] The measurements at 1500 nm wavelength were carried out similar to the setup described in ref.[43] Instead of the third harmonic (355 nm), generated from an Nd:YAG laser with a wavelenghth of 1064 nm, the optical parametric oscillator (OPO)[44] in use was pumped with the second harmonic (532 nm). The signal intensity at 824 nm and the fundamental at 532 nm were removed from the idler by using dichroic mirrors (HR 650–850 and HR 532), a green light and a silicon filter (transparent > 1000 nm). An additional Glan–Taylor polarizer ensured the vertical polarization of the beam into the measurement cell. Measurements were performed with ca. $10^{-4}$–$10^{-6}$ M solutions of **5**, **7** and **8** in $CH_2Cl_2$. Disperse Red 1 (DR1) was used as an external standard with a value of $\beta_{1500}$ (DR1) = $70 \cdot 10^{-30}$ esu. This value was obtained by comparing the slopes of the reference in $CH_2Cl_2$ and $CHCl_3$ to obtain the ratio of $\beta_{solute}$.[45] With the value $\beta(CHCl_3) = 80 \cdot 10^{-30}$ esu[46] the hyperpolarisibility of DR1 in $CH_2Cl_2$ is estimated to be $70 \cdot 10^{-30}$ esu. The effect of the refractive indices of the solvents was corrected using the simple Lorentz local field.[47]

## Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (DFG, HE 1309/3), by the DAAD (Deutsch-Portugiesicher Wissenschaftleraustausch INIDA) and by the European Community (COST D14, TMR FMRX-CT98-0166). We thank the DEGUSSA AG for a donation of $RuCl_3$, the Sartorius GmbH for a donation of microfilters, and Nelson Lopes, GoLP, Centro de Física de Plasmas, Instituto Superior Técnico, Lisboa, Portugal, for performing the Kurtz powder measurements. M. H. G. thanks for financial support by Fundação para a Ciência e Tecnologia, project POCTI/QUI/48443/2002.

## COVER PICTURE

**The cover picture shows** a dendron and two types of dendritic molecules built from dendrons. The shape of these nanometric molecules resembles that of macroscopic entities; the shape of dendrons is similar to that of trees, bis-dendrons can be compared to Janus, the god with two faces, and the multidendritic species shown on the left has the shape of a tropical fish. Details of this chemistry are described in the Microreview by A.-M. Caminade, A. Maraval, and J.-P. Majoral on p. 887 ff.

# Phosphorus-Containing Dendrons: Synthesis, Reactivity, Properties, and Use as Building Blocks for Various Dendritic Architectures

**Anne-Marie Caminade,*[a] Alexandrine Maraval,[a] and Jean-Pierre Majoral*[a]**

**Keywords:** Dendrimers / Phosphorus / Dendrons / Building blocks

Dendrons, also called dendritic wedges, are a special variety of dendrimers possessing one or two functional groups at the core, in addition to the numerous functional end groups. This review is focused on phosphorus-containing dendrons, which are dendrons built with one phosphorus atom at each branching point. Their synthesis, reactivity and properties are described, with emphasis on their use as building blocks for the elaboration of very complex and original dendritic architectures. Electrochemical and catalytic properties, as well as examples in the field of materials are also given.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Dendritic macromolecules constitute the fourth class of macromolecular architectures discovered about two decades ago,[1–3] after the linear, cross-linked, and branched polymers.[4] These hyperbranched architectures are expected to produce new properties and behaviours, and arouse an ever-increasing interest, with more than one thousand publications and more than one hundred patents per year over the last four years. Most of the work concerning hyperbranched architectures is focussed on the most structurally controlled compounds, i.e. dendrimers and dendrons,[5,6] which are

*Anne-Marie Caminade is Director of Research First Class at the CNRS. She received two Ph. D.s in Toulouse (1984 and 1988). She worked as a Post-doc at the Institut Français du Pétrole (1984) and in Pr. M. Veith's group (1988–1989, Saarbrücken, Germany). Since 1985 she has worked at the CNRS with Jean-Pierre Majoral, where she has been Director of Research since 1997. Her research interests centre on the main group elements. She developed several aspects of the chemistry of phosphorus, including low coordinated compounds, coordination of transition metals, reactivity of metallic hydrides, and synthesis of macrocycles. Her current research interest is the synthesis, reactivity and study of the properties of dendrimers and dendritic molecules. She is author of more than 210 publications and 23 patents.*

*Alexandrine Maraval is Doctor in Supramolecular Chemistry. She received her Ph. D. from the Université Paul Sabatier of Toulouse in 2000. Then she worked as a Post-doc with Prof. J. M. Basset at the high school CPE Lyon (2001–2003). Presently, she is working at the CNRS with Jean Pierre Majoral and Anne-Marie Caminade as Ingénieur Valorisation. Her research interest is mainly focused on the main group elements, especially phosphorus chemistry for the preparation of phosphorylated dendrimers. She has also worked with group 3 and 4 elements, their use in organometallic chemistry for the synthesis of new ligands and in catalysis.*

*Jean-Pierre Majoral is Director of Research Exceptional Class at the CNRS. He received his Ph. D. from the Université Paul Sabatier of Toulouse in 1972. Between 1972 and 1973 he worked as a Post-doc with Prof. A. Katritzky (University of East Anglia, Norwich, UK). He became Directeur de Recherche at the Centre National de la Recherche Scientifique in Toulouse in 1978. His research interest is mainly focused on the use of main group elements, especially phosphorus in different areas of chemistry. Presently, he is involved in the preparation and properties of macromolecules such as dendrimers and hyperbranched polymers. Emphasis is also placed on the studies of interactions between heavier main group elements and group 4 elements (titanium, zirconium, and hafnium) with applications in organic and organometallic chemistry. He is a member of the Polish Academy of Sciences and of the Academia Europaea. He is author of more than 370 publications and 31 patents.*

**MICROREVIEWS:** This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

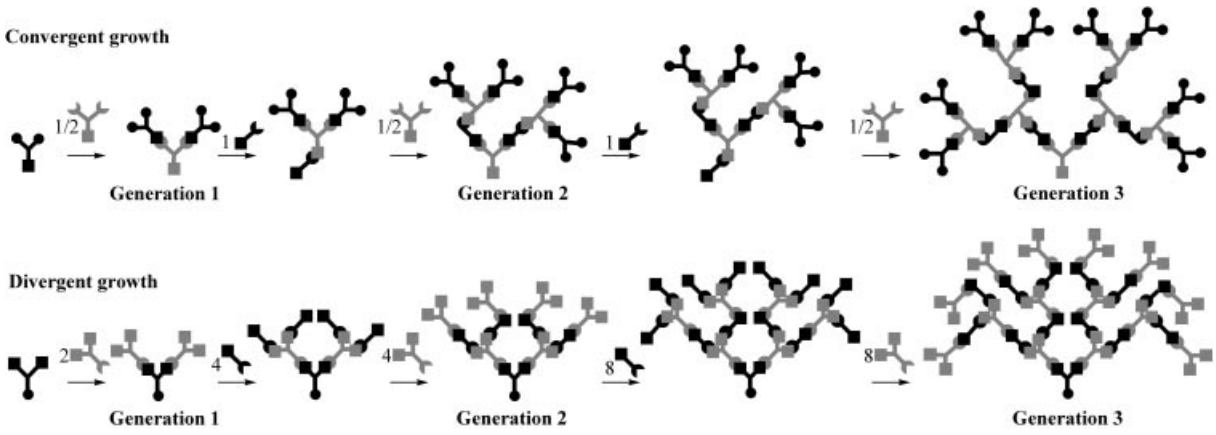


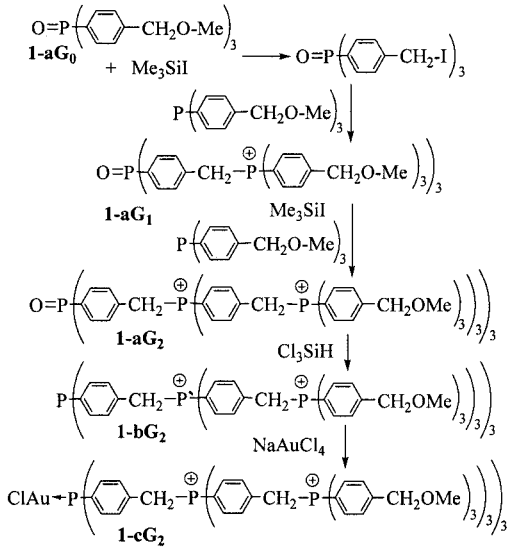
Scheme 1.

synthesised step-by-step (generation after generation) and not with polymerisation reactions. Dendrons,[7] also called dendritic wedges,[8] differ from dendrimers by the presence of one (or a few) functional group(s) located at the core, which are different from the other functional groups located at the periphery; their structure is very reminiscent of that of trees, the function at the core playing the role of the trunk. They are synthesised either by a convergent or a divergent process, generally using two types of monomers, one linear and one branched. In a convergent process, the periphery of the dendron never reacts, and only one reaction occurs at the level of the core; each generation is created by the association of two dendrons with a small molecule. In the divergent process, the periphery reacts at each step, whereas no reaction occurs at the core; each generation is created by the association of several small molecules with one dendron (Scheme 1). In both cases, the main problem is to find five types of functional groups among which one does not react with any of the other four, and four of the functional groups react specifically two-by-two.

The chemical composition of dendrimers and dendrons may be varied infinitely. We proposed about ten years ago a method of synthesis,[9,10] based on the reactivity of phosphorus derivatives, which afforded the highest well-defined generation described to date for any type of dendrimer (generation 12).[11] This method consists of condensation reactions of aldehydes with a phosphorhydrazide, and nucleophilic substitutions of Cl by hydroxybenzaldehyde under basic conditions. This method and its variants are so powerful that we have already published more than 130 papers in this field,[12] and the same method and its variants are also useful for the synthesis of dendrons. The aim of this microreview is to focus on the synthesis, reactivity, properties and use of complex architectures elaborated from dendrons possessing phosphorus at each branching point. Dendrons possessing phosphorus only at the core[13] are considered to be out of the scope of this review.

## Synthesis of Phosphorus-Containing Dendrons

The first phosphorus-containing dendrons **1-G$_n$** ($n$ = 0–2, corresponding to the generation) were synthesised in 1993 by Engel et al.,[14] but they were not recognised as dendrons but classed as dendrimers at that time. The function located at the core is a phosphane oxide, and the growing process consists of an iodination, followed by the quaternarisation of a phosphane. The phosphane oxide can be considered a masked phosphane, thus the dendrimer **1-aG$_n$** can be transformed into the dendron **1-bG$_n$** by reduction with a chlorosilane (Scheme 2). The phosphane located at the core of **1-bG$_n$** is different from all the other functional groups in the molecule, and is truly reactive, as shown by the complexation of gold.

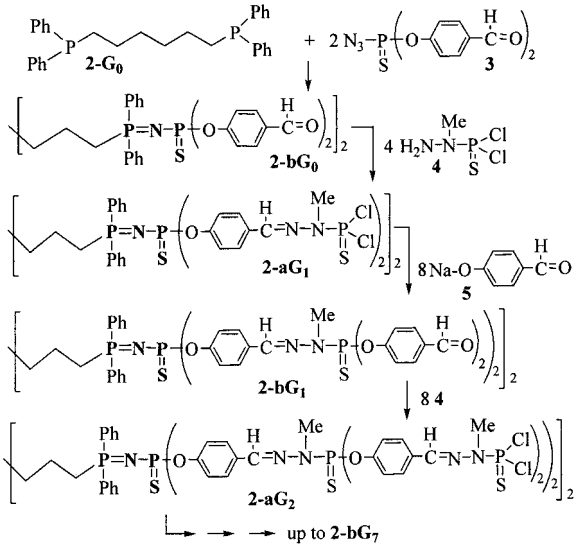


Scheme 2.

We described the second type of phosphorus-containing dendron **2-G$_n$** ($n$ = 0–7), which were also called dendrimers, but they possessed two functional groups at the core, which was different from the others (Scheme 3).[15] Indeed, the P=S groups included in P=N–P=S linkages behave differently from all the other P=S groups, and react easily with electrophiles[16] as will be illustrated later. These linkages are created by a Staudinger reaction between a phosphane such as **2-G$_0$** and a phosphorus azide such as **3**. Then the dendron is grown from the aldehydes with our classical

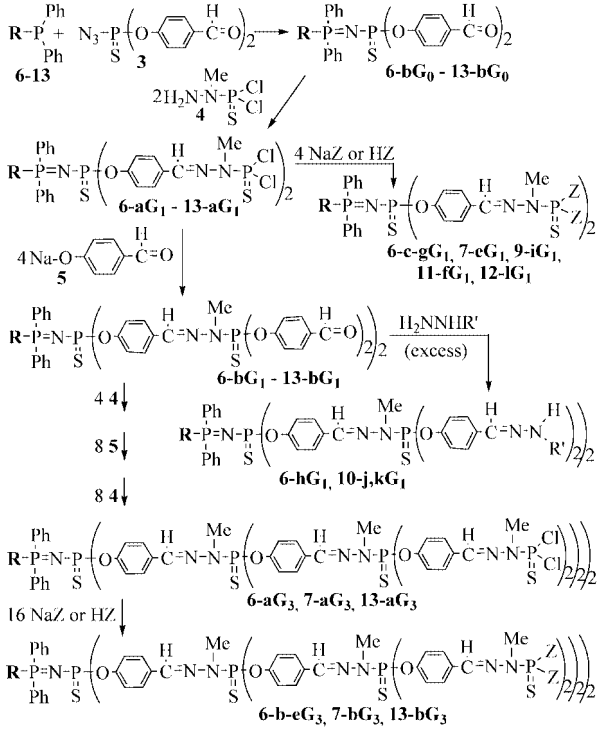
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

method of synthesis of dendrimers, using the phosphorhydrazide **4** in condensation reactions and hydroxybenzaldehyde sodium salt **5** for nucleophilic substitutions.[9–11] It must be emphasised that both reactions can easily be performed at a multi-gram scale. The reiteration of both steps has been carried out up to the obtaining of the seventh generation.



Scheme 3.

The use of Staudinger reactions allowed us to synthesise various types of dendrons possessing an R–$PPh_2$=N–P=S group at the core, starting from variously functionalised phosphanes (Scheme 4). The most often used R substituent is the vinyl group **6**,[17] but an allyl **7**,[18] a styryl **8**,[18] a methyl **9**,[19] a protected benzaldehyde **10**,[19] a triethoxysilane **11**,[20] and a diethoxyphosphonate **12**[21] have also been used as the core of these dendrons (Scheme 4 and Table 1). In addition, dendrons were built by the same process with the bis diphenylphosphanyl ferrocene **13** used as the core.[22] In most cases, the synthesis of the corresponding dendrons has been carried out up to generation 3, using the method already shown in Scheme 3, with the phosphorhydrazide **4** and hydroxybenzaldehyde **5**. Obviously, dendron growth could have been pursued up to higher generations. However, the process was voluntarily stopped at the third generation so as to be able to detect changes that occur at core level when some of these dendrons are used as building blocks for the elaboration of more complex structures. The $^{31}P$ NMR spectrum of the third generation dendron **6-aG$_3$** shows that even the phosphorus atoms located at the core are clearly distinguishable (Figure 1). The synthetic process affords directly as end groups $P(S)Cl_2$ (case a; see Scheme 4 and Table 1) and CHO (case b); various functionalised end groups have also been grafted starting from these functions. The most widely used method for the last step of the synthetic process is the substitution reaction of Cl using phenols (case e)[23] generally functionalised by nitrile (case c),[17] dimethylamine (case d),[17] diphenylphosphane (case f),[20,23] trifluoromethane (case g),[24] and free or complexed iminophosphane (cases l, m).[21] The reaction of a diamine has also been used (case i).[19] In a few cases, condensation reactions of hydrazines with the aldehyde end groups allowed the grafting of other functional groups that were either charged (case h)[25] or not (cases j, k).[19]



Scheme 4.

With aldehydes being one of the repetitively used units in the classical synthesis of our dendrimers and dendrons, any type of compound having at least one aldehyde and another functional group can be used as the core of dendrons, applying the same method. For instance, 4-acetoxybenzaldehyde,[26] pyridine-2,6-dicarboxaldehyde,[18] and ferrocene dicarboxaldehyde[27] have been used as cores of dendrons built by the successive reactions of the phosphorhydrazide and hydroxybenzaldehyde, affording in the final step dendrons **14-bG$_1$**, **15-bG$_2$** and **16-bG$_4$**, respectively (Scheme 5). However, this method of synthesis is not compatible with some kinds of functional groups; in particular for those sensitive to water, the condensation step must be avoided, thus we had to design alternative methods of synthesis.

For instance, the $Si(OEt)_3$ group is readily hydrolysed by traces of moisture, and the dendron **11-aG$_1$** cannot be grown by our traditional method of synthesis. Thus, the sodium salt **17** ($NaOC_6H_4PPh_2$) is used instead of $NaOC_6H_4CHO$ (**5**), then the azide **18** is reacted in a Staudinger reaction, affording directly the third generation **19-aG$_3$** with $P(S)Cl_2$ end groups. Aldehydes were grafted in the last step using the salt **5** (Scheme 6).[20] This method, based on the Staudinger reaction, was also found to be useful for the grafting of other functional groups, such as a pyrene derivative (see for instance dendron **20-G$_2$** in Scheme 6).[20]

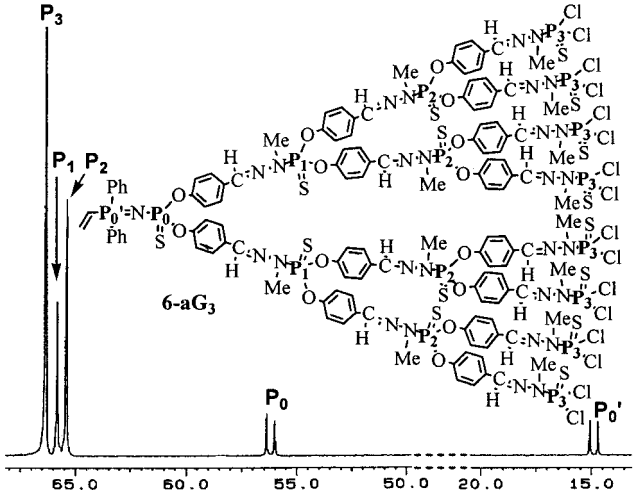

Figure 1. $^{31}$P NMR spectrum of the third generation dendron **6-aG$_3$**.

On the other hand, the presence of chlorine at the core of dendrons is incompatible both with our traditional method of synthesis, in particular with the use of the strong nucleophile **5**, and with the method shown in Scheme 6, because of the use of the salt **17**. Thus, the dendron grown from the chloromethyl phosphane oxide derivative **20-bG$_0$** is built using the repetition of three steps. The first one is the condensation reaction of methylhydrazine with aldehyde; the second is another condensation reaction, between $Ph_2PCH_2OH$ and the secondary hydrazone. The third and last step before the repetition of the three steps is the Staudinger reaction of the phosphane end groups with the azide **3**, which again affords aldehyde end groups. This dendron was grown to the fourth generation **21-bG$_4$** (Scheme 7).[18]

## Reactivity at the Core of Phosphorus-Containing Dendrons

The reactivity at the core of most of the dendrons we have synthesised is related to the presence of a P=N–P=S group. In addition to its own reactivity this group may also enhance the reactivity of other functional groups linked to it. The mesomeric form of the P=N–P=S linkage has a high electron density on sulfur ($P^+$–N=P–$S^-$) which allows the regiospecific complexation of gold, whereas the other P=S groups do not react in this way (Scheme 8).[30] The existence of this mesomeric form also allows the reaction of the P=N–P=S linkage with electrophiles such as methyl triflate. The reaction was first applied to small molecules,[28] then to dendrons.[15] Various functionalised triflates such as allyl or propargyl triflate have also been used.[29] These reactions are easily monitored by $^{31}$P NMR spectroscopy. Indeed, the P=N–P=S linkages give two very characteristic doublets at $\delta \approx 20$ ppm (P=N) and $\delta \approx 52$ ppm (P=S), which move upon *S*-alkylation to $\delta \approx 28$ ppm and $\delta \approx 33$ ppm, respectively. It should be noted that this reaction at the core occurs even for the seventh generation, illustrating the high porosity of these dendrimers, and the specificity of this reaction.[15] Indeed, the numerous other P=S groups consti-

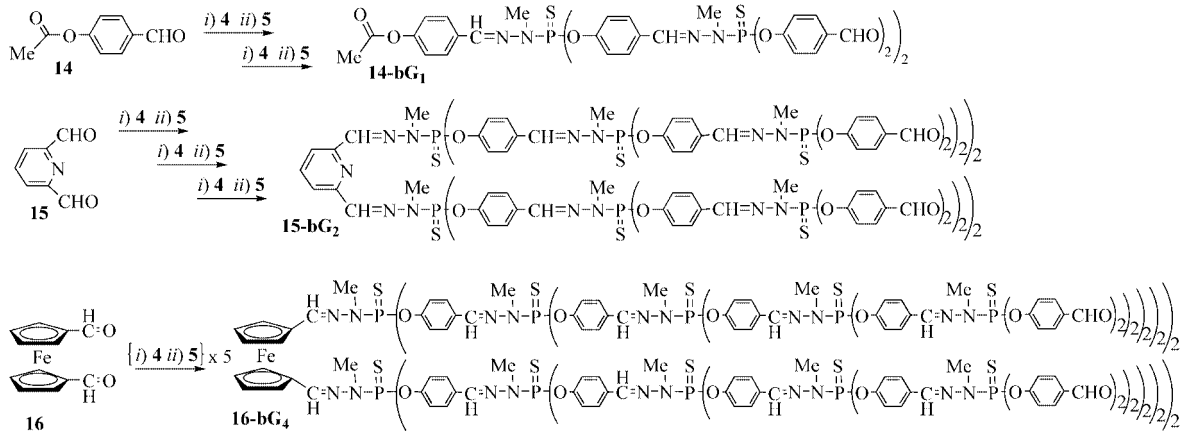
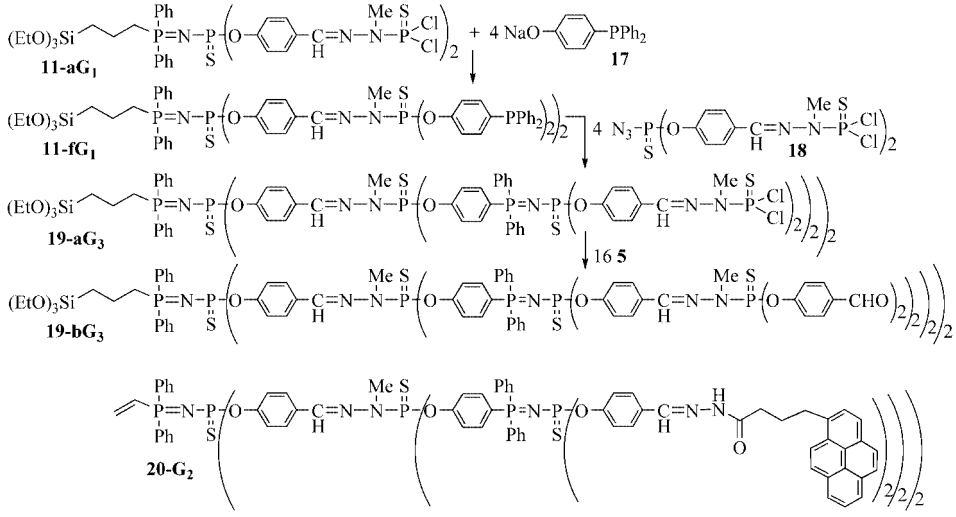
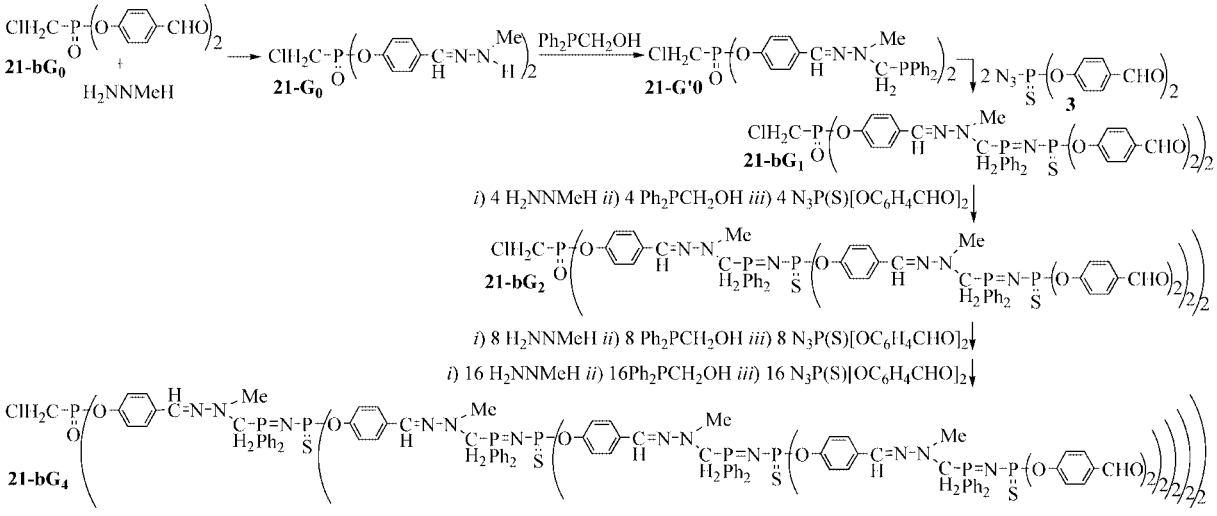


Scheme 5.



Scheme 6.



Scheme 7.

tuting the points of divergence of these dendrons are not alkylated, as shown for one example in Scheme 8, but this type of reaction has been carried out with numerous dendrons.

The alkylation of sulfur is compatible with further modifications of the periphery of the dendrons. In particular, we tried to graft water-solubilising end groups to the cationic dendron **22-aG$_1$**. In order to avoid the formation of triflic

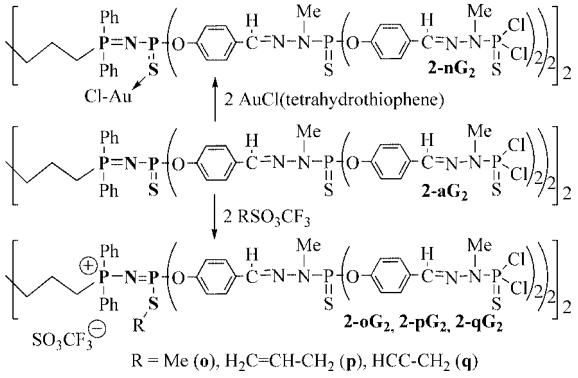
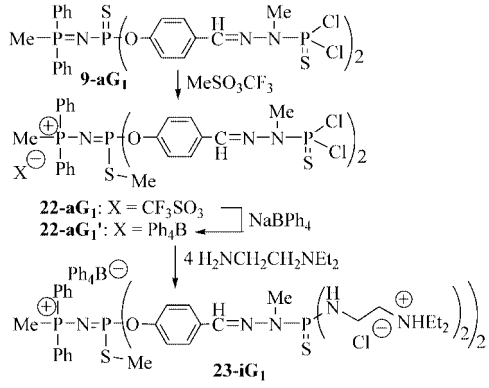


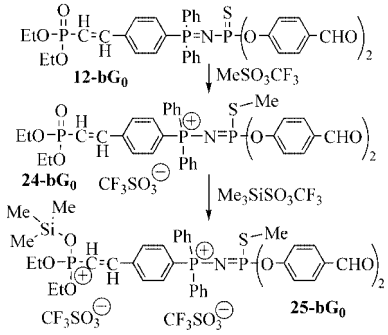
Scheme 8.

acid, which is potentially aggressive for the hydrazone linkage, the triflic counterion of **22-aG$_1$** was first replaced by tetraphenylborane. Then the reaction of 4 equiv. of *N*,*N*-diethylethylenediamine affords cleanly the pentacationic dendron **23-iG$_1$** (Scheme 9).[19]



Scheme 9.

Another illustration of the specificity of the reactivity of the P=N–P=S linkages with alkyl triflates is given by the small dendron **12-bG$_0$** in which only the P=S bond is alkylated by methyl triflate, leading to **24-bG$_0$**. The conjugated P=O bond does not react with methyl triflate, but it reacts with trimethylsilyl triflate, because of the oxophilicity of silicon to afford the dicationic compound **25-bG$_0$** (Scheme 10).[21]



Scheme 10.

The P=N–P=S linkage also induces an electron-withdrawing effect on the functional group linked to the phosphazene, which we exploited particularly when a vinyl group is linked to this phosphorus (series of dendrons **6-G$_n$**). We demonstrated the possibility of performing Diels–Alder additions on this vinyl group,[26] but most of the reactions we carried out were Michael type additions of primary and secondary amines. They were first tested with small compounds possessing one $CH_2$=CH–$PPh_2$=N–$PR_2$=X (X = O, S) linkage,[31] then applied to dendrons. In all cases, we used functionalised amines. The reaction works nicely with primary amines (compounds **26**–**29**) and gave at the core a secondary amine together with an alkyne,[23] a triethoxysilyl group,[20,31] or even a phenol[23] (Scheme 11 and Table 2). In the latter case, the reaction of the amine is specific, no addition of the phenol is observed. Analogous reactions are obtained with secondary amines, such as diallylamine **30** and thiomorpholine **31**.[23] The reactions are carried out either at room temperature or by heating, depending on the rate of the addition, and using either a stoichiometric amount or a slight excess of reagent. The reactions are easily monitored by $^{31}$P NMR, with a deshielding effect on the signal of the P=N group from $\delta$ = 10–12 ppm for **6-G$_n$** to $\delta$ = 17–18 ppm after addition.

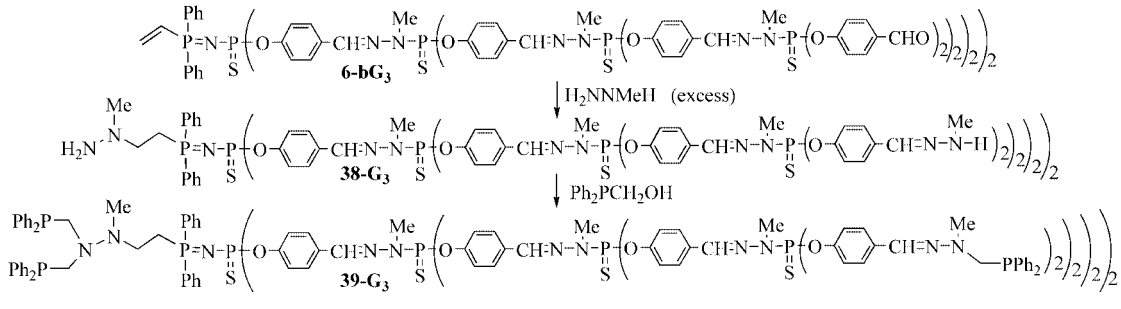
[a] from **20-G$_n$**.

A large excess of reagents must be used with diamines. Two cases can be distinguished: either the diamine possesses two identical primary amino groups, or it possesses one primary and one secondary amino group. In the former case, the use of several hundreds of equivalents prevents the coupling of two dendrons (cases **32** and **33** in Scheme 11 and Table 2), as shown by the loss of symmetry of the diamine, evidenced by $^1H$ and $^{13}C$ NMR spectroscopy.[17,23] The reaction is expected to be more complicated when using nonsymmetrical diamines that have two types of amino groups (primary and secondary). Indeed, besides avoiding the association of two dendrons as for symmetrical diamines, a regiospecific reaction of only one type of amine must be obtained. Such specificity was expected with methylhydrazine (considered to be a special nonsymmetrical diamine), in which the most substituted nitrogen is generally more reactive. The reaction proceeds rapidly at room temperature with an excess of methylhydrazine (30 equiv.) leading to a single product, **34-G$_n$**, corresponding to the exclusive addition of the NMeH group.[17,23,24] The same specificity for the secondary amine is observed with the diamine **35**.[31]

The series of compounds **34-G$_n$** is particularly interesting, due to the wide range of reactions available starting from a $NH_2$ group, which may enlarge the scope of functional groups located at the core of dendrons. It may afford stable hydrazones by condensation reactions with aldehydes, as shown by the synthesis of **36-c,eG$_1$**[31] (Scheme 11). We have also grafted a diphosphane group by reaction with $Ph_2PCH_2OH$ (compounds **37-G$_n$**),[17,19] a type of condensation that we have already used on the periphery of dendrimers.[32,33] A particular case of the reactions shown in Scheme 11 is afforded by dendrons possessing as end groups functions able to react with amines, because both the core and the periphery will react. An example of such a compound is provided by the dendrons **6-bG$_n$**, in which the vinyl group at the core reacts in a Michael type addition, whereas the aldehyde end groups react via condensation reactions. The use of a large excess of methylhydrazine, necessary to prevent a polymerisation reaction between the $NH_2$ of the core and the aldehydes, affords the dendrons **38-G$_n$**. Their subsequent reaction with $Ph_2PCH_2OH$ affords the dendrons **39-G$_n$** that possess a diphosphane at the core and monophosphanes as end groups (Scheme 12).[17]

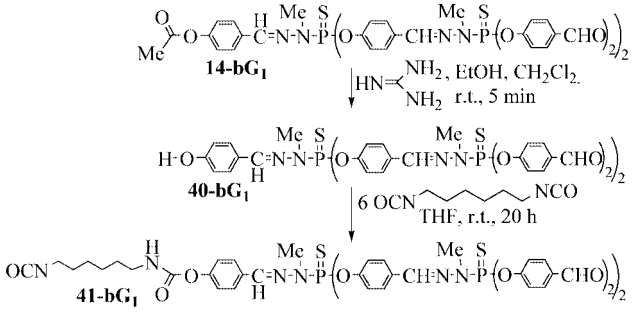
However, the presence of aldehydes as end groups does not necessarily preclude a specific reaction at the core, as shown by dendrons **14-bG$_1$**. The deprotection of the acetyl



Scheme 12.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

group by guanidine occurs cleanly and under very mild conditions to afford the phenol group of **40-bG$_1$**. This phenol is potentially useful for a number of subsequent reactions; we tested the reactivity of diisocyanatohexane, whose addition gives the dendron **41-bG$_1$**, functionalised by an isocyanate and a carbamate at the core (Scheme 13).[26]



Scheme 13.

## Use of Phosphorus-Containing Dendrons for the Elaboration of Complex Dendritic Architectures

Most of the reactions at the core of dendrons described above can be applied to the elaboration of special dendritic architectures. We have been interested in this field for a long time; an example of our work being the growth of dendritic branches inside a pre-existing dendrimer.[34] In most cases, the dendrons used for building special architectures are those issued from the vinyl group at the core, but in one case the alkylated P=N–P=S core of dendron **23-iG$_1$** was used for such a purpose. Indeed, the alkylation of sulfur induces a weakening of the strength of the PS bond, which can be easily cleaved using a nucleophilic phosphane such as P(NMe$_2$)$_3$.[34,35] The dendron **42-iG$_1$** is too sensitive to oxidation to be fully isolated, but it can be directly reacted with the azide **3** to afford the small diblock dendrimer **43-iG$_1$–bG$_0$**, which possesses two types of end groups. The aldehydes can be used to afford other end groups: their reaction with methylhydrazine followed by Ph$_2$PCH$_2$OH affords **44-iG$_1$–G$_0$**, whose phosphane can be used for complexation, as illustrated by the reaction with iron, leading to the cationic complex **45-iG$_1$–G$_0$** (Scheme 14).[19]

Besides this example using the reactivity of the P=N–P=S group, all the other examples of special dendritic architectures that we have described develop from dendrons possessing an amine or phosphane at the core. The simplest type of association consists of using 2 equiv. of dendrons with 1 equiv. of a small molecule. If this molecule possesses another functional group, the resulting bis dendron is itself a dendron, as shown for instance by the condensation of 2 equiv. of the dendrons **32-c,dG$_3$** with 1 equiv. of the azidodialdehyde **3**. The azide remaining at the core of **46-c,d[G$_3$]$_2$** (Scheme 15 and Figure 2)[17] will be used later to afford more elaborate structures. The same methodology was applied to the dendron **32-gG$_1$**, which reacts with the special tetraphosphazene **47**, which possesses four types of functional groups. The reaction occurs as expected only with the aldehydes, leading to the novel type of dendrimeric species **48-g[G$_1$]$_2$**. This compound possesses several types of functional groups at the core constituted by the oligophosphazene linkage, as well as other functional groups within the branches and on the periphery (Scheme 16 and Figure 2).[24]

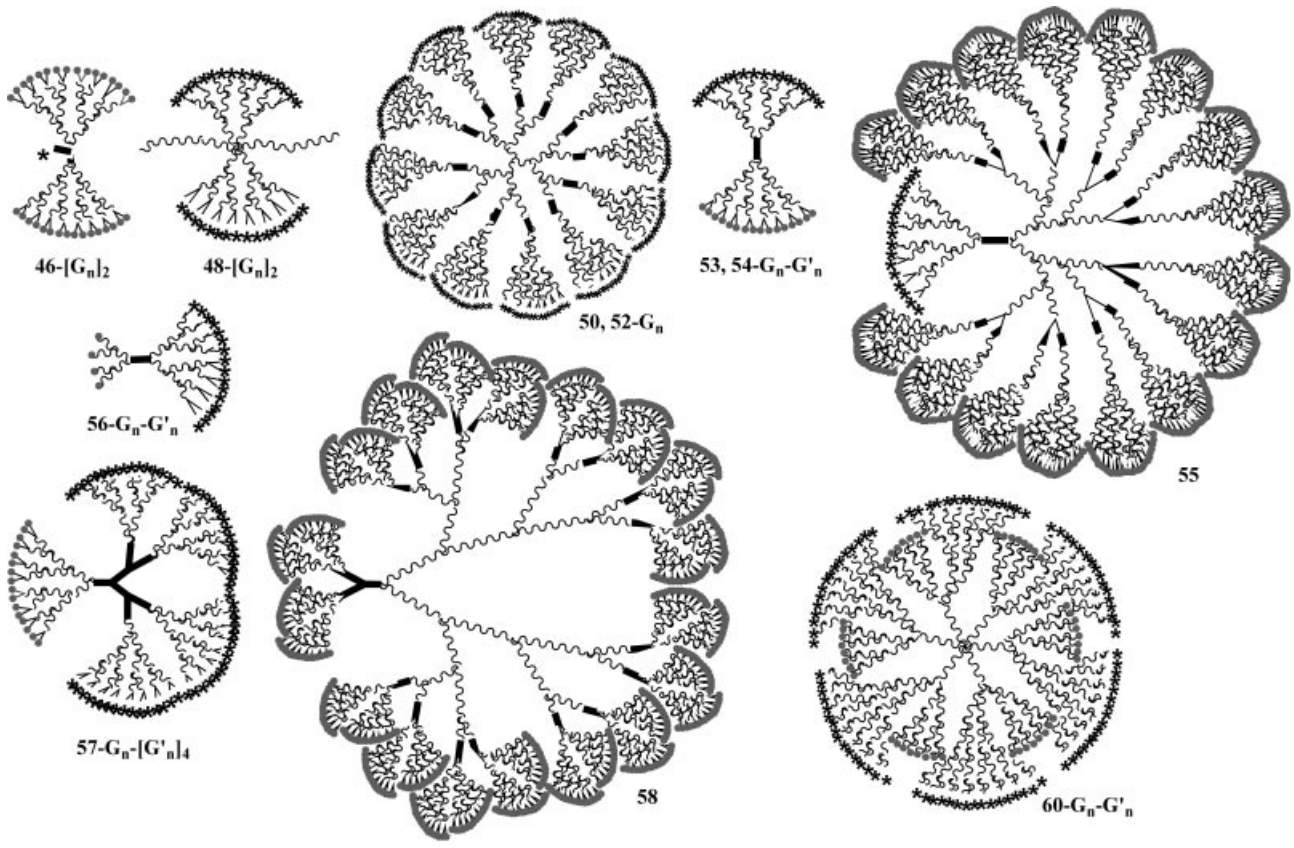

Figure 2. Various schematised special dendritic architectures elaborated from dendrons.

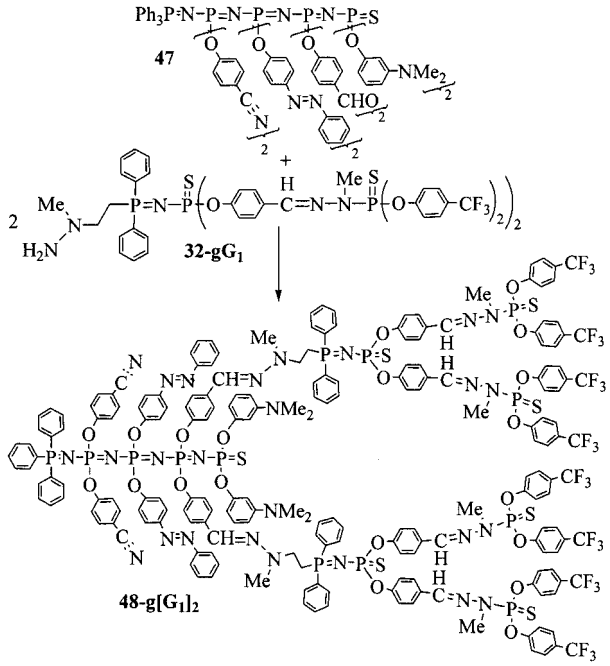


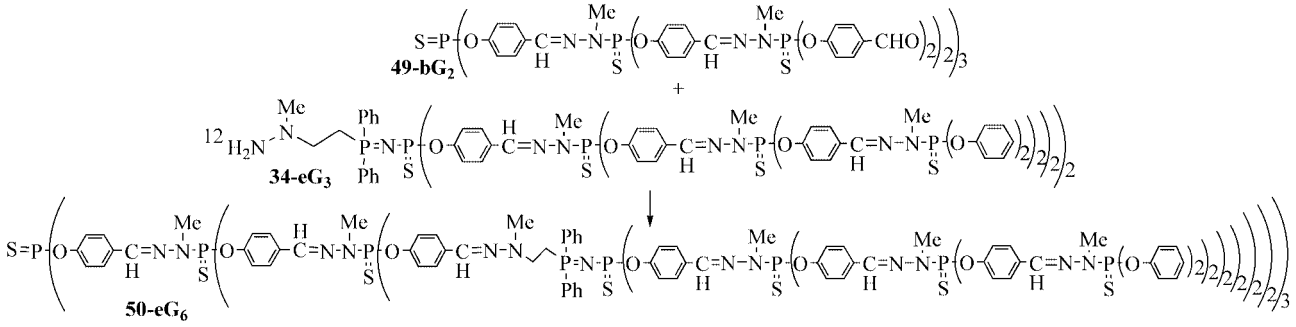
Scheme 16.

Such methodology has been extended to the synthesis in only one step of high generation layered dendrimers. Indeed, the hydrazine function located at the core of the third generation dendron **34-eG$_3$** reacts with the aldehyde end groups of the second generation dendrimer **49-bG$_2$**. The reaction is slow despite the use of an excess of dendrons, and went to completion only after 18 days, as shown with $^1$H NMR data by the disappearance of the aldehydes. Despite its length, this reaction is interesting because it affords the sixth generation of the layered dendrimer **50-eG$_6$** in only one step from the second generation (Scheme 17 and Figure 2).[23] It should be noted that an analogous reaction carried out with the third generation dendrimer **49-bG$_3$** did not continue to completion, even after 40 days. The steric hindrance precludes the insertion of approximately 1 equiv. of dendron among 24, despite the fact that the seventh generation dendrimer, and even higher generations, can be obtained step-by-step using sequentially small molecules instead of dendrons.[11]

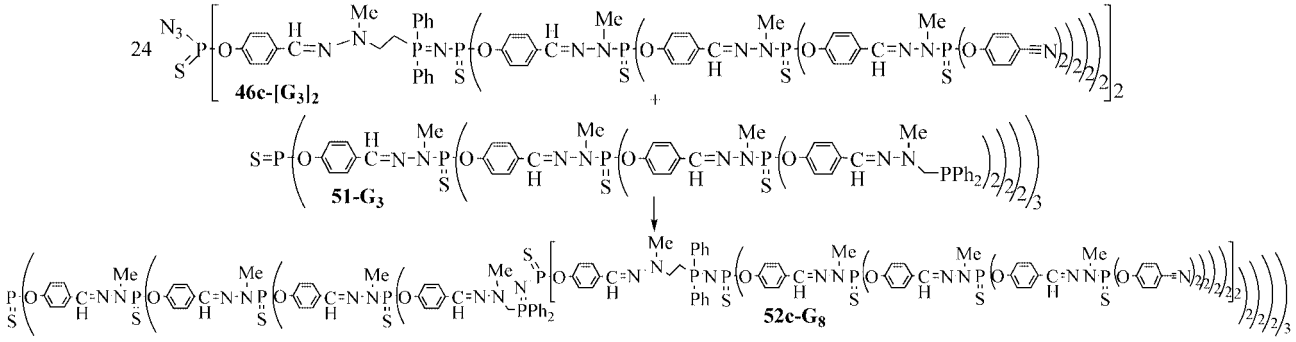
However, the type of reaction used for connecting the dendrons to the dendrimer also has an influence on the highest generation of dendrimer usable. Indeed, the Staudinger reaction of the dendritic azide **46-b[G$_3$]$_2$** with the third generation dendrimer **51-G$_3$** affords the eighth generation of the layered dendrimers **52-cG$_8$** in one step. The P=N–P=S linkages are present only at the level of the fourth and fifth generation (Scheme 18 and Figure 2).[17]

Despite their original dendritic architectures, the compounds shown in the previous schemes possess only one type of end group. However, we have in hand all the tools necessary for synthesising large "Janus" dendrimers that are dendrimers possessing two types of end groups located in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

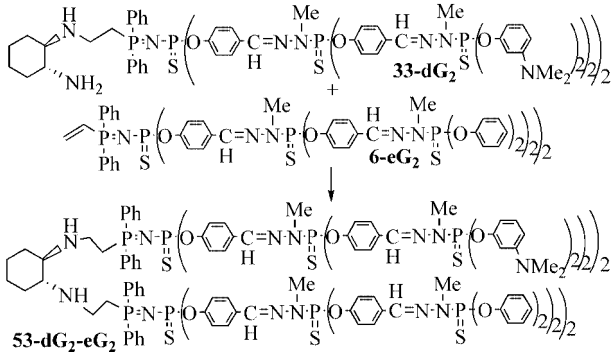


Scheme 17.



Scheme 18.

two different areas of the periphery, obtained in particular by grafting two different dendrons by their core. The first attempt involves the second generation dendrons **6-eG$_2$** and **33-dG$_2$**, which react in a Michael type addition. The resulting unsymmetrical compound **53-dG$_2$–eG$_2$** can also be viewed as a dendron, because of the presence of two NH groups at the centre of the molecule (Scheme 19 and Figure 2).[23]



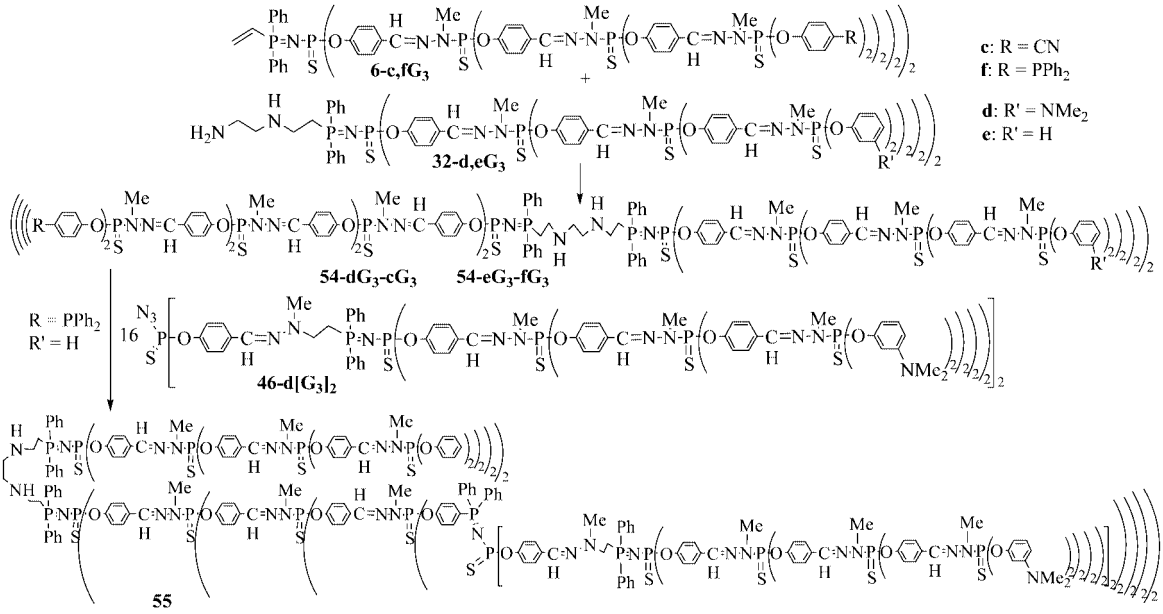
Scheme 19.

Such methodology using Michael type additions can be applied to larger generations. We decided to use compounds no higher than the third generation, in order to be able to detect the modification of the core with a sufficient intensity by NMR spectroscopy. The reaction was carried out with compounds **6-G$_3$** and **32-G$_3$**, leading to compound **54-G$_3$-G$_3$** (Scheme 20 and Figure 2).[17,23] This reaction is compatible with several types of end groups on the periphery of the dendrons, and in particular with phosphanes. This compound (**54-eG$_3$–fG$_3$**) is the precursor of the very special "fish-like" dendritic species **55**. This compound is obtained by the grafting, via a Staudinger reaction, of dendrons **46-d[G$_2$]$_2$** on only half of the periphery of **54-eG$_3$–fG$_3$**, i.e. the face that possesses phosphanes (Scheme 20 and Figure 2).[23] This unsymmetrical compound has 16 phenoxy groups as end groups on one side, two NH "central" functions, 50 P=N–P=S linkages located at four different levels in the ratio 32:16:1:1, and 512 $NMe_2$ as end groups on the other side.

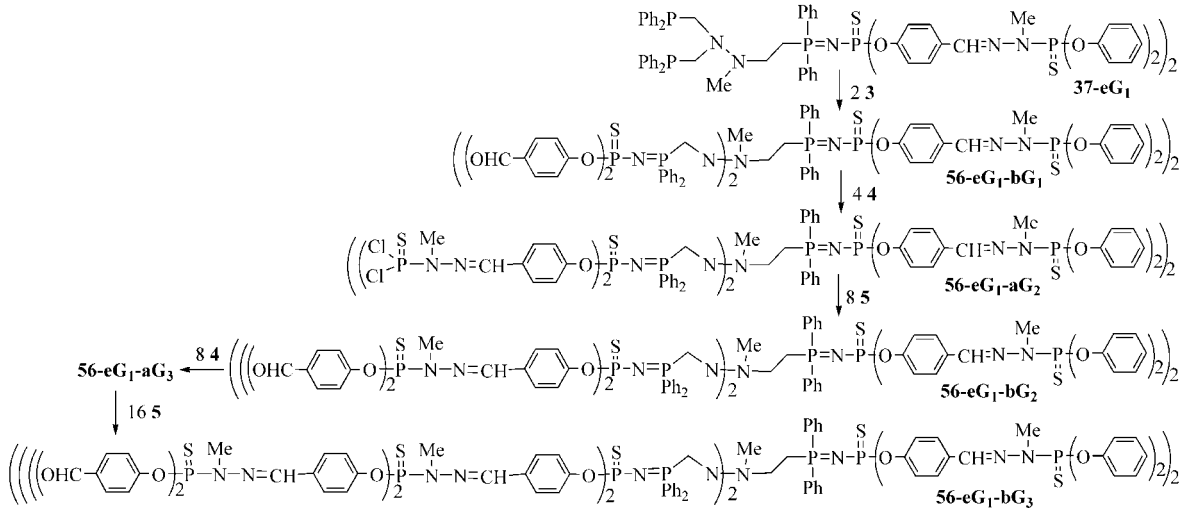
As illustrated above the synthesis of complex dendritic species from dendrons can necessitate several steps, in particular to extend the number of functional groups that are usable. The reaction of the bisaldehyde azide **3** with the core of a dendron such as **37-eG$_1$** affords the possibility of growing new dendritic branches at the core of the dendron; this also allows us to multiply the possible types of functionalisation on one side of this new "Janus" dendritic molecule. Starting from the four aldehyde groups of **56-eG$_1$–bG$_1$**, we applied our classical method for the synthesis of dendrimers, using alternately the phosphorhydrazide **4** and the sodium salt of hydroxybenzaldehyde (**5**). This dendritic species has been grown up to the third generation on one side (compound **56-eG$_1$–bG$_3$**), but it could have been continued to higher generations (Scheme 21 and Figure 2).[19] This compound possesses four end groups on one side and 16 on the other.

However, the shortest method to obtain a different ratio of two types of end group obviously consists of using dendrons that have a different number of end groups. For instance, the reaction of 2 equiv. of **46-c[G$_3$]$_2$** with **37-dG$_3$** af-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 20.

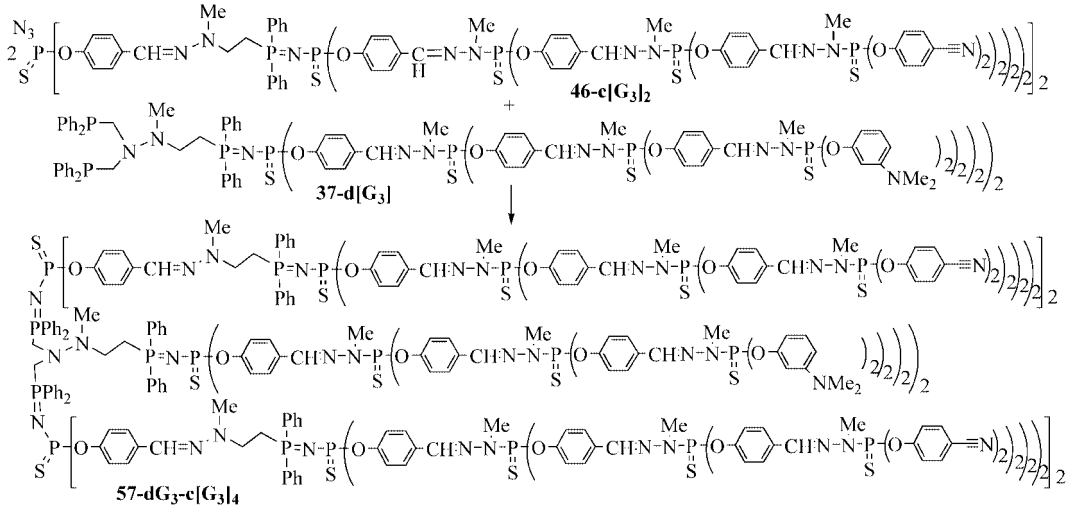


Scheme 21.

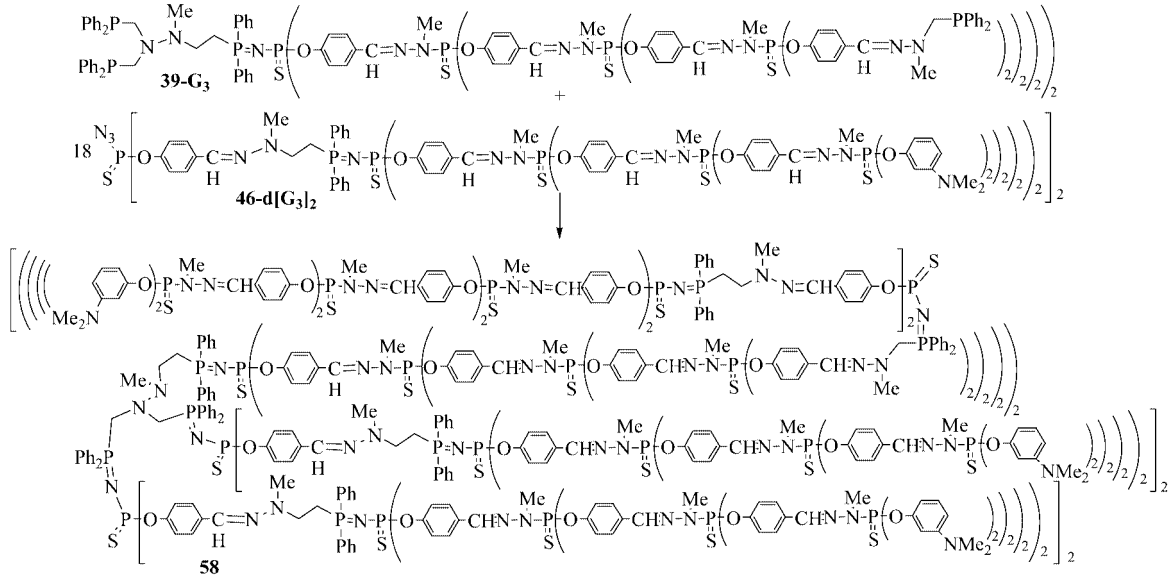
fords the straightforward compound **57-dG$_3$-c[G$_3$]$_4$**, in which the ratio of the end groups is 1:4, i.e. 16 $NMe_2$ and 64 cyano groups (Scheme 22, Figure 2).[17] The same methodology can be envisaged starting from dendron **39-G$_3$** instead of **37-dG$_3$**. The former possesses phosphanes both at the level of the core (2 $P^{III}$) and on the periphery (16 $P^{III}$), which will react in Staudinger reactions with the dendron **46-d[G$_3$]$_2$**. The result is the complex dendritic structure **58**, which is relatively reminiscent of the structure of compound **55**. However, despite its nonsymmetrical internal structure, compound **58** possesses only one type of end group (576 dimethylamino groups). Compound **58** is a kind of layered segment-block dendrimer (Scheme 23 and Figure 2).[17]

A very original distribution of two types of end groups is also obtainable from dendrons. It necessitates a dendrimer possessing reactive internal functions such as **59-eG$_3$–bG$_0$**.[34] The $NH_2$ group located at the core of dendron **34-cG$_2$** is used to react with the internal aldehydes of **59-eG$_3$–bG$_0$**. Obviously, the problem of steric hindrance evoked previously for the layered dendrimer **50-eG$_7$** might be more crucial here, where the reactions must occur inside the dendrimer and not on its periphery. The condensation is relatively slow and requires 10 days to go to completion, but it finally affords compounds **60-eG$_3$–c–G$_4$** (Scheme 24 and Figure 2),[23] confirming the high porosity of our phosphorus dendrimers, already demonstrated by NMR[15] and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 22.



Scheme 23.

fluorescence.[36] However, **34-cG$_2$** is the largest dendron that can be accommodated inside **59-eG$_3$–bG$_0$**; indeed, the reaction of **34-cG$_3$** failed to go to completion.

## Other Properties and Uses of Phosphorus-Containing Dendrons

Besides their usefulness for the synthesis of complex dendritic architectures, dendrons offer other possible uses such as in characterising the special properties of the "dendritic state", for catalysis, or for elaborating new materials, depending on the function located at the core. Dendrons possessing a ferrocene at the core were elaborated with the aim of measuring the influence of the encapsulation of an electroactive function on the electrochemical properties. Dendrons **13-G$_n$** were relatively deceptive, because the wave detected in electrochemistry did not correspond to the oxidation of the ferrocene but of the P=N–P=S linkages. This oxidation is not reversible and induces a polymerisation of the dendron.[22] On the other hand, dendrons **16-G$_n$** do not possess any P=N–P=S linkage, and are usable, therefore, for the detection of any influence on the electrochemical properties, depending on the generation and thus the size of the dendron. Compound **16-bG$_0$** shows the characteristic quasi reversible ($I$pc/$I$pa ≅ 1) single electron oxidation process, whereas **16-bG$_1$** exhibits a slightly more irreversible process ($I$pc/$I$p$a$ = 0.88). This trend is confirmed by the pronounced irreversibility observed for **16-bG$_2$**, which gives a very weak and poorly resolved signal (Figure 3).[27] The core is undetectable presumably because it cannot approach the electrode closely enough because of the steric hindrance induced by the dendritic branches.

The presence of a diphosphanyl group at the core of dendron **37-dG$_3$** prompted us to use it as a ligand for transition metal complexes, in particular for ruthenium. Most ruthenium complexes possess catalytic properties, thus it was

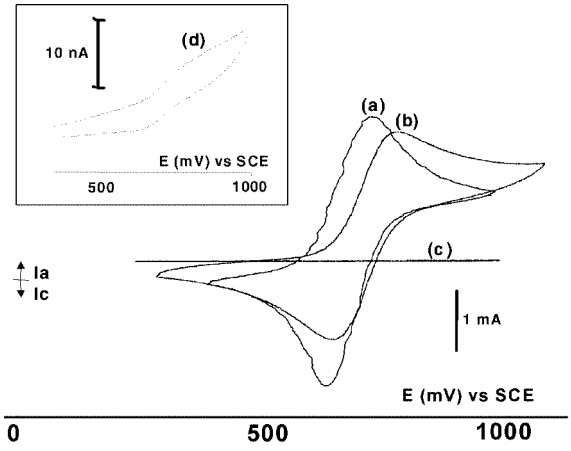

Figure 3. Cyclic voltammograms (scan rate 100 mV·s$^{-1}$) obtained for dendrimers **16-bG$_0$** (a), **16-bG$_1$** (b), **16-bG$_2$** (c), and enlargement for **16-bG$_2$** (d).

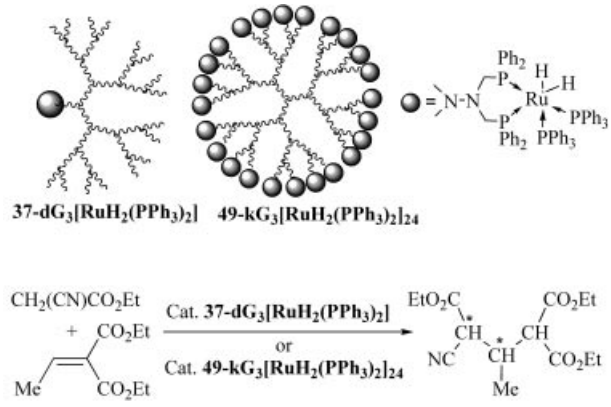


Scheme 25.

tempting to use dendron **37-dG$_3$[RuH$_2$(PPh$_3$)$_2$]** as a catalyst. Indeed, the use of dendritic complexes in catalysis is an area of intense activity, especially for those possessing phosphane complexes,[12b] mainly because of the possibility of recovering the catalyst simply by precipitation or ultra-filtration. Dendron **37-dG$_3$[RuH$_2$(PPh$_3$)$_2$]** was tested in catalysed diastereoselective Michael additions (Scheme 25). The activity of this dendron was compared to that of a third generation dendrimer possessing the same complex as end groups, **49-kG$_3$[RuH$_2$(PPh$_3$)$_2$]$_{24}$**. It was shown that both compounds have the same efficiency at the same mol-% in ruthenium (1%), and that both can be recovered by precipitation and reused twice. It was expected that the steric hindrance around the metallic centre induced by the dendrons might modify the diastereoselectivity of such a reaction, but no change was observed (Table 3).[37]

The triethoxysilyl group connected to the core of dendrons **11-G$_n$**, **27-G$_n$**, and **28-G$_n$** was used for the elaboration of new hybrid organic–inorganic materials. Indeed, the cohydrolysis of these dendrons with Si(OEt)$_4$ (TEOS) in a sol-gel process generally affords the expected functionalised silica.[20] However, the nature of the material and its porosity is highly dependant on the initial ratio of dendron/TEOS, the generation of the dendron, and the length of the linker between the Si(OEt)$_3$ group and the first branching point. It appears that the higher the dendron generation, the greater the required quantity of TEOS for the gelation. Dendron **11-bG$_0$** requires at least 10 equiv. of TEOS, whereas dendron **19-bG$_3$** requires 140 equiv. of TEOS. $^{29}$Si MAS NMR shows that the dendrons are covalently linked to the silica. The porosity of these materials was measured by nitrogen adsorption. Some materials were found to be mesoporous with a narrow or large pore size distribution, others were found to be macroporous or microporous, depending on the length of the linker, the generation of the dendron, the nature of its end groups, and the initial ratio of dendron/TEOS. Elemental and thermal analyses of the materials show that the percentage representing the organic part incorporated in the silica is always high, but inferior to the theoretical percentage.

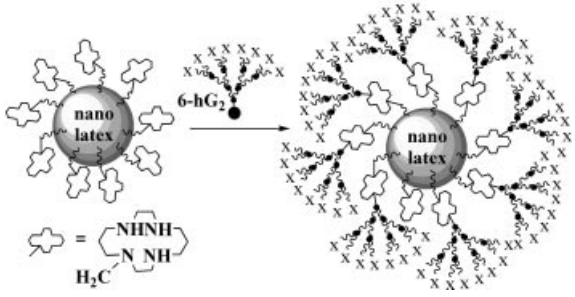
Another way to use dendrons in materials chemistry consists of grafting them to the surface of a pre-existing material, in order to modify its properties. We have used this approach with dendrons **6-hG$_n$**, which has ammonium end groups, to modify by Michael type additions the surface of nanolatexes previously covered by cyclam (Scheme 26). A full coverage of the nanolatexes by the dendrons is observed

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 3. Percentage of conversion and diastereoisomeric ratio for the reaction shown in Scheme 25, using two types of dendritic catalysts (1 mol-% in Ru in all cases). This shows the influence of the recovery and reuse of the catalyst on the efficiency.

| Catalyst | Conversion [%] | Diastereomeric ratio | Catalyst | Conversion [%] | Diastereomeric ratio |
|---|---|---|---|---|---|
| **37-dG$_3$[RuH$_2$(PPh$_3$)$_2$]** first run | 100 | 72:28 | **49-kG$_3$[RuH$_2$(PPh$_3$)$_2$]$_{24}$** first run | 100 | 73:27 |
| **37-dG$_3$[RuH$_2$(PPh$_3$)$_2$]** second run | 100 | 72:28 | **49-kG$_3$[RuH$_2$(PPh$_3$)$_2$]$_{24}$** second run | 100 | 73:27 |
| **37-dG$_3$[RuH$_2$(PPh$_3$)$_2$]** third run | 89 | 72:28 | **49-kG$_3$[RuH$_2$(PPh$_3$)$_2$]$_{24}$** third run | 90 | 73:27 |

in all cases. The number of dendron per nanolatex depends on the generation, but the total number of ammonium groups is practically the same (approximately 600 to 800 ammonium end groups per nanolatex). Interestingly, the suspensions of these modified nanolatexes are stable in water without any surfactant, in contrast to the initial nanolatex. Furthermore, the "dendrigrafted" nanoparticles can be redispersed in water after drying, which is not the case for the initial nanolatex. The dendritic shell also offers a higher thermal stability, and induces the gelation of the water solution after one week at room temperature; about 345000 water molecules were estimated to be gelled by each grafted molecule of **6-hG$_2$**.[25]



Scheme 26.

## Conclusion

This micro-review has demonstrated that phosphorus-containing dendrons are important building blocks for the elaboration of very complex and original dendritic macromolecules. Emphasis has so far been placed on fundamental research, but these dendrons and peculiar dendritic architectures have the potential for development in more applied research. Obviously, there is still considerable work to be done to determine any practical uses of phosphorus-containing dendrons, but some areas of application can be foreseen. For instance, one may consider the modification of the surface of materials, the targeted delivery of drugs, and other types of application in which the presence of two different types of function in a tailored ratio is important.

# Reinecke Anion Derivatives and Homobinuclear Complexes as Tectons in Designing Heteropolymetallic Systems

**Andrei Cucos,[a] Narcis Avarvari,[b] Marius Andruh,*[a] Yves Journaux,*[c] Achim Müller,[d] and Marc Schmidtmann[d]**

**Keywords:** Chromium / Nickel complexes / Thiocyanato complexes / Magnetic properties / Coordination polymers

Two novel $Cr^{III}$–$Ni^{II}$ heteropolynuclear complexes have been obtained through a self-assembly process involving a binuclear $Ni^{II}$ complex with a macrocyclic Robson ligand and Reinecke-type anions (*trans*-$[Cr(NCS)_4(NH_3)_2]^-$, *trans*-$[Cr(NCS)_4(4,4'\text{-bipy})_2]^-$): $[Ni_2(H_2O)_2(fsal\text{-}33)\{Cr(NCS)_4(NH_3)_2\}]\cdot 2H_2O$ (**1**) and $^1{}_\infty[Ni_2(H_2O)_2(fsal\text{-}33)\{Cr(NCS)_4(4,4'\text{-bipy})_2\}]_n\cdot n[Cr(NCS)_4(4,4'\text{-bipy})_2]$ (**2**). The compartmental ligand results from the condensation of 2,6-diformyl-4-methyl-phenol with 1,3-propanediamine. The crystal structure of **1** consists of neutral tetranuclear [CrNiNiCr] species, where each nickel ion is coordinated in one apical position by a Reinecke anion, and in the other one by an aqua ligand. The distances between the metallic centres in **1** are: Ni···Cr = 6.048 and Ni···Ni = 3.133 Å. Compound **2** contains infinite cationic chains constructed from binuclear [Ni–Ni] nodes, connected through *trans*-$[Cr(4,4'\text{-bipy})_2(NCS)_4]$ spacers, and uncoordinated *trans*-$[Cr(NCS)_4(4,4'\text{-bipy})_2]^-$ ions. The $Cr^{III}$ and $Ni^{II}$ ions are connected through 4,4′-bipyridine ligands arising from the Reinecke-type anion. The distance between the nickel and chromium ions within the chain is 11.252 Å. The magnetic properties of **1** have been investigated. Both Ni–Ni and Cr–Ni exchange interactions were found to be antiferromagnetic: $J_{NiNi} = -51.3\ cm^{-1}$; $J_{NiCr} = -22.7\ cm^{-1}$.

## Introduction

The search for new metal-containing building blocks is of current interest in molecular magnetism and in crystal engineering. These are relatively inert anionic complexes with potentially bridging ligands, for example cyano ($[M(CN)_6]^{3-}$,[1] $[M(bipy)(CN)_4]^-$[2]), or oxalato complexes ($[M(C_2O_4)_3]^{3-}$, $[M(bipy)(C_2O_4)_2]^-$[3]), which have been widely employed to design heterospin systems with interesting magnetic properties. It is well known that the thiocyanato anion acts as a bridge between either identical or different metal ions.[4] Nevertheless, the thiocyanato complexes have rarely been used as templates in assembling heteropolynuclear complexes.[5] A very appealing complex in this respect is the anion of the Reinecke salt, $[Cr(NCS)_4(NH_3)_2]^-$, which can interact with the second metal ion through the sulfur atom. For example, a $Cu^{II}$–$Cr^{III}$ heterobinuclear complex has been obtained by reacting the Reinecke anion with a cationic copper(II) complex.[6]

We are currently developing a research project aimed at obtaining heterometallic complexes with interesting structures and magnetic properties, by using homo- or heterobinuclear species as assembling cations. The basic idea of our strategy is to combine the magnetic behaviour of the assembling cation (exhibiting a ferro- or antiferromagnetic coupling between the two metal ions) with that of the anionic building-block. Beyond the individual magnetic behaviour, the two molecular entities may interact through the connecting ligands. This synthetic approach allowed us to obtain complexes with three different spin carriers: 2p-3d-4f,[7] 3d-3d′-4f[8] or high-dimensionality 3d-4f coordination polymers.[9] Apart from our interest in the classical Reinecke anion, we intend to enrich our chemical library with new building blocks, by replacing the $NH_3$ ligands, from the $[Cr(NCS)_4(NH_3)_2]^-$ ion, with organic molecules that can act as bridges. Such building units can be extremely versatile, having both hard and soft coordination sites (e.g. nitrogen donor atoms arising from the organic ligand and sulfur donor atoms from the isothiocyanato ligands).

## Results and Discussion

The first results concerning the synthesis of new heterobimetallics using the Reinecke anion and its derivatives as building blocks are reported herein, and consist of two

$Cr^{III}$–$Ni^{II}$ heteropolynuclear complexes: $[Ni_2(H_2O)_2(fsal\text{-}33)\{Cr(NCS)_4(NH_3)_2\}]\cdot 2H_2O$ (**1**) and $^1{}_\infty[Ni_2(H_2O)_2(fsal\text{-}33)\{Cr(NCS)_4(4,4'\text{-bipy})_2\}]_n\cdot n[Cr(NCS)_4(4,4'\text{-bipy})_2]$ (**2**). Compound **1** is obtained through a self-assembly process involving the Reinecke anion and a binuclear nickel(II) cationic complex, $[Ni_2(H_2O)_2(fsal\text{-}33)]^{2+}$ (fsal-33 is a dianionic macrocyclic binucleating Schiff-base ligand obtained by condensation of 2,6-diformyl-4-methyl-phenol with 1,3-propylenediamine). Compound **2** is obtained using the same nickel(II) complex and a derivative of the Reinecke salt, *trans*-$K[Cr(NCS)_4(4,4'\text{-bipy})_2]$. This Reinecke derivative is obtained by reacting $K_3[Cr(NCS)_6]$ with 4,4′-bypiridine. Its composition and structure are confirmed by chemical analysis, and by the crystal structure of compound **2** (vide infra). The infrared spectrum displays the characteristic bands of the organic ligand, as well as the band of the isothiocyanato group (2067 $cm^{-1}$). The UV/Vis spectrum shows a band with a maximum at 550 nm, which is due to the $^4A_{2g} \rightarrow {}^4T_{2g}$ transition. This transition occurs at lower energy (18180 $cm^{-1}$) than the one observed with the classical Reinecke anion, $[Cr(NCS)_4(NH_3)_2]^-$ (19610 $cm^{-1}$).

The crystal structures of compounds **1** and **2** have been solved. Compound **1** is a neutral tetranuclear $Cr^{III}$–$Ni^{II}$–$Ni^{II}$–$Cr^{III}$ complex. The chromium and nickel ions are connected through one NCS bridge (Figure 1). The two $[Cr(NCS)_4(NH_3)_2]^-$ ions are *trans* disposed with respect to the general plane of the macrocyclic ligand enclosing the nickel ions. Each nickel ion is hexacoordinate, exhibiting an elongated octahedral geometry, with an equatorial $N_2O_2$ macrocyclic donor set, and the aqua ligand and the sulfur atom from the bridge coordinated in the apical positions. The Ni–N and Ni–O distances in the equatorial plane are close and vary between 2.005(2) and 2.0278(15) Å. The apical Ni–aqua and Ni–S distances are, respectively, 2.1138(18) and 2.6057(7) Å. The distances between the metallic centres are Ni···Cr = 6.048 and Ni···Ni = 3.133 Å. The Cr–N distances within the Reinecke anion vary between 1.985(2) and 2.069(2) Å. The analysis of the packing diagram (Figure 2) reveals the formation of layers through intermolecular hydrogen bond interactions established between the aqua ligand and the crystallisation water molecule [O(2)···O(3) = 2.699(3) Å], as well as between the crystallisation water molecule and one sulfur atom from an adjacent tetranuclear unit [O(3)···S(2) = 3.282(3) Å].

The IR spectrum of **1** shows two bands due to the $NCS^-$ ligands (2066, 2104 $cm^{-1}$), in agreement with their different roles: terminal and bridging.

The second compound, $^1{}_\infty[Ni_2(H_2O)_2(fsal\text{-}33)\{Cr(NCS)_4(4,4'\text{-bipy})_2\}]_n\cdot n[Cr(NCS)_4(4,4'\text{-bipy})_2]$ (**2**), contains infinite cationic chains constructed from binuclear [Ni–Ni] nodes, connected through *trans*-$[Cr(NCS)_4(4,4'\text{-bipy})_2]$ spacers, and uncoordinated *trans*-$[Cr(NCS)_4(4,4'\text{-bipy})_2]^-$ ions taking over the charge of the cationic chain (Figure 3). Two chromium complexes acting as spacers are coordinated, through the 4,4′-bipy ligands, above and below the platform formed by the binuclear nickel complex [Ni–N(4,4′-bipy) = 2.139(16) Å] (Figure 3). The equatorial nickel–ligand distances fall in the range 2.008(16)–2.034(15) Å. The sixth coordination site at the nickel ions is occupied by an aqua ligand [Ni–O = 2.241(16) Å]. The intranode Ni···Ni distance is 3.09 Å. The shortest Ni···Cr distance within the chain is 11.25 Å. As far as the chromium building blocks are concerned, the metal ions exhibit an almost perfect octahedral stereochemistry. The Cr–N(NCS) distances (ave, 1.98 Å) are slightly shorter than the Cr–N(4,4′-bipy) ones (ave, 2.08 Å). Selected bond lengths and angles for compounds **1** and **2** are collected in Table 1.

The magnetic properties of complex **1** have been investigated. The $\chi_M T$ versus $T$ curve is represented in Figure 4. The room temperature value of the $\chi_M T$ product (5.30 $cm^3\,mol^{-1}\,K$) is slightly lower than the one corresponding to the four uncoupled metal ions (5.7 $cm^3\,mol^{-1}\,K$). By lowering the temperature, $\chi_M T$ continuously decreases, reaching 0.19 $cm^3\,mol^{-1}\,K$ at 2 K.

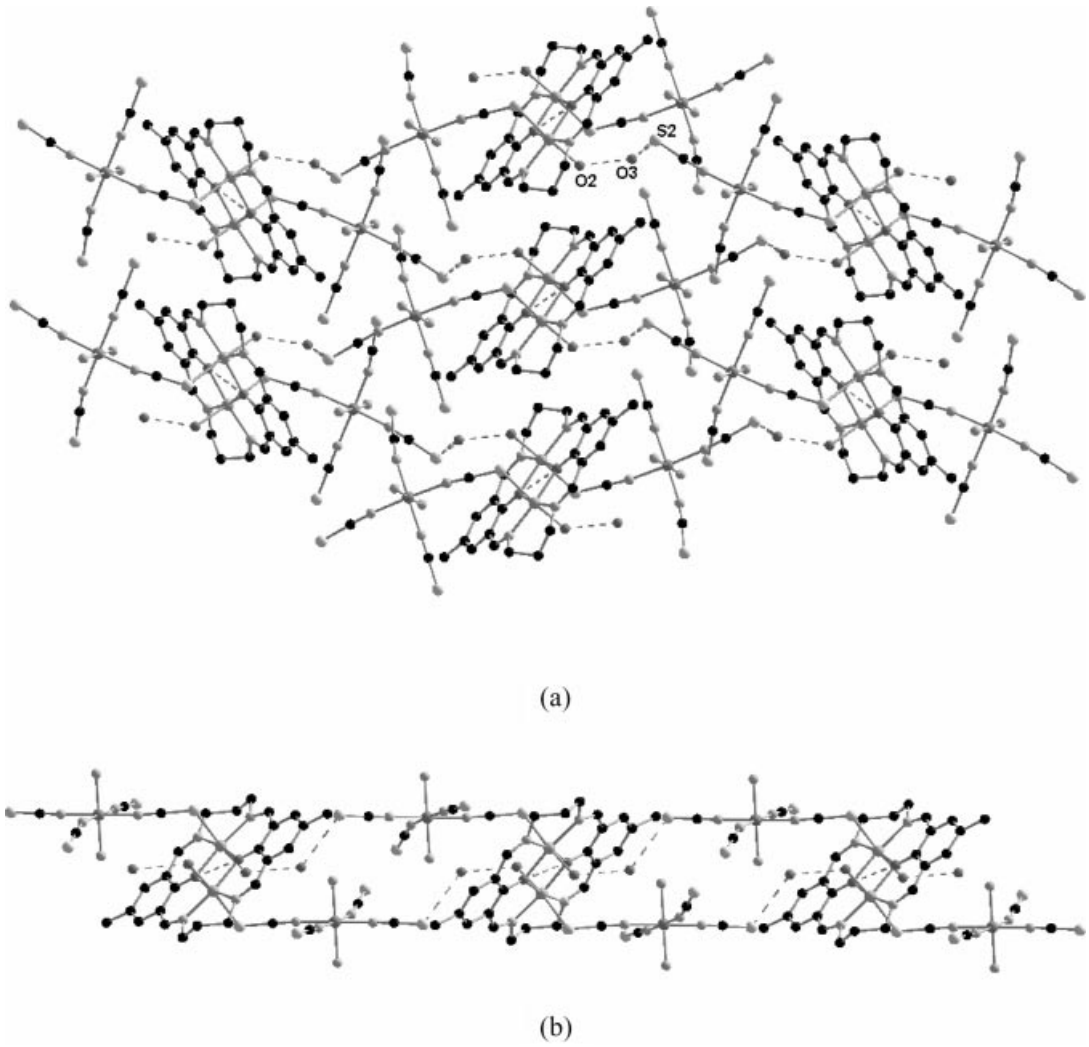

Figure 2. Packing diagram for crystal **1**, showing the formation of the supramolecular layers: a) view along the crystallographic *a* axis; b) side view.

For the centrosymmetric [CrNiNiCr] complex the energies of the low-lying spin states are obtained by using the isotropic Hamiltonian:

$\boldsymbol{H} = -J_{CrNi}(\boldsymbol{S}_{Cr1}\boldsymbol{S}_{Ni1} + \boldsymbol{S}_{Ni2}\boldsymbol{S}_{Cr2}) - J_{NiNi}\boldsymbol{S}_{Ni1}\boldsymbol{S}_{Ni2}$

The full matrix diagonalisation technique was employed to reproduce the experimental data. The best fit to the data led to:

$J_{NiCr} = -22.7\ cm^{-1}$; $J_{NiNi} = -51.3\ cm^{-1}$; $g_{Ni} = 2.2$ (fixed); $g_{Cr} = 1.98$; $R = 2.6\times10^{-4}$ {$R$ is the agreement factor defined as $\Sigma_i[(\chi_M T)_{obsd}(i) - (\chi_M T)_{calcd.}(i)]^2/\Sigma_i[(\chi_M T)_{obsd.}(i)]^2$}.

At first glance, the antiferromagnetic nature of the interaction between $Cr^{III}$ and $Ni^{II}$ is surprising, this pair of ions, both in octahedral stereochemistry, being a classical example of orthogonality of the magnetic orbitals leading to a ferromagnetic coupling. One of the most important factors influencing the sign and the magnitude of the exchange interaction is the bridging angle; more precisely, in our case, the Ni(1)–S(1)–C(13) one [106.03(8)°]. For a [$M_AXM_B$] single bridge system, the ferromagnetic interaction arising from the strict orthogonality of the magnetic orbitals is maximal for a linear $M_A$–X–$M_B$ linkage.[10,11] By decreasing the $M_A$–X–$M_B$ angle, the ferromagnetic interaction decreases also, being finally dominated by the antiferromagnetic one. For example, recent calculations for a related compound, containing the Ni–NC–Cr motif,[11] have shown that the ferromagnetic interaction between $Ni^{II}$ and $Cr^{III}$ ions through a single cyanide bridge is weakened with the bending at the cyanide bridge, becoming antiferromagnetic for values of $a \leq 148°$.

For compound **1**, the deviation from linearity is very important and consequently the relatively strong antiferromagnetic interaction between $Ni^{II}$ and $Cr^{III}$, because of the overlap of the magnetic orbitals, is not surprising. A [NiCr] thiocyanato-bridged cationic coordination polymer, –catena-μ-NCS–Ni(en)$_2$-μ-SCN–Cr(NCS)$_4$–, has recently been described.[5c] The values of the Ni–S–C angles were 93.2 and 105.1° and, accordingly, favoured an antiferromagnetic interaction ($J = -19.9\ cm^{-1}$). As far as the Ni–Ni exchange interaction is concerned, it falls in the range already observed with several other nickel complexes with the same ligand: $Ni^{II}_2L(H_2O)_2(ClO_4)_2$ ($J = -61\ cm^{-1}$),[10] $Ni^{II}_2L(py)_2(BF_4)_2$ (py = pyridine) ($J = -46\ cm^{-1}$)[12] and

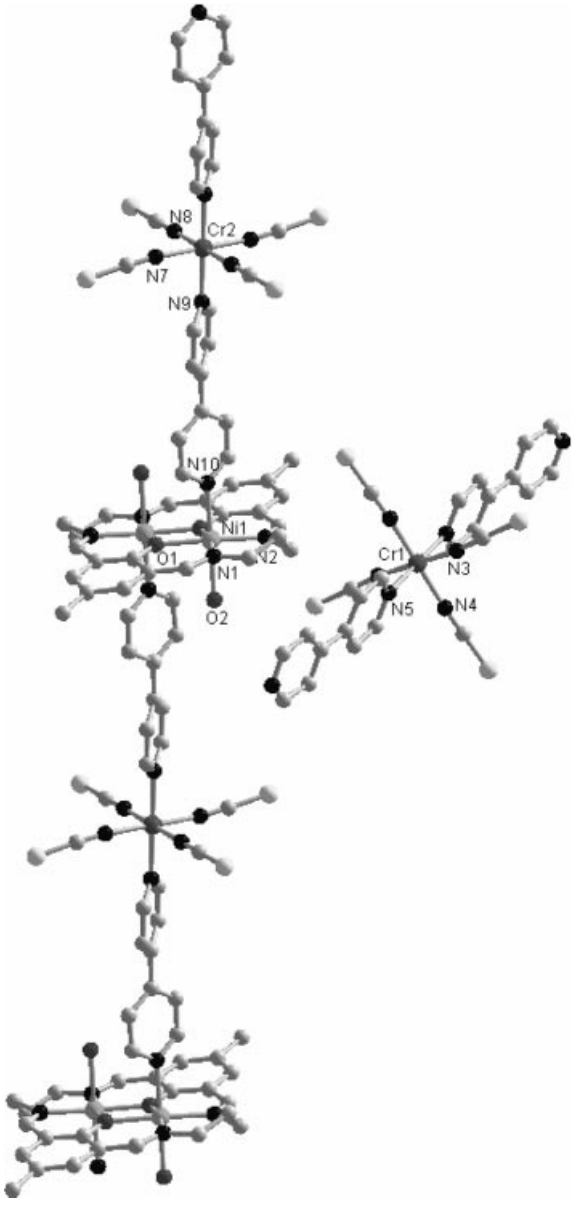

Figure 3. Perspective view of the cationic chain and of the complex anion in **2**, along with the atom-numbering scheme.

$Ni^{II}_2L(H_2O)_2Cl_2$ ($J$ = –72 cm$^{-1}$).[13] In the similar cyano-bridged [CrNiNiCr] complex, the value of the $J_{NiNi}$ parameter is –44.6 cm$^{-1}$.[11]

The functionalisation of the Reinecke anion, by replacing the $NH_3$ groups with potentially bridging ligands, as illustrated by compound **2**, opens interesting perspectives in crystal engineering. Various solid-state architectures can be thus constructed through the selective interaction of the hard (N) and soft (S) donor atoms with appropriate transition-metal ions. Two different metal ions (one hard, the other soft) can be employed simultaneously in order to obtain new solid-state architectures. Moreover, compound **2** illustrates how the building-block approach can be combined with the node-and-spacer approach, to design extended structures.

## Experimental Section

**Synthesis:** K[Cr(NCS)$_4$(4,4′-bipy)$_2$] was prepared by refluxing a *i*PrOH solution of $K_3$[Cr(NCS)$_6$] and 4,4′-bipy (in a 1:2.5 ratio) for 6 h, and isolation of the red solid appeared by cooling. IR (KBr): $\tilde{\nu}$ = 2067 (vs), 1597 (m), 1409 (m), 1218 (m), 1065 (m), 807 (m), 628 (m) cm$^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Compounds **1** and **2** were obtained by reacting the binuclear nickel(II) complex $[Ni_2(fsal\text{-}33)Cl_2]\cdot 2H_2O$[14] (in 1:1 EtOH/water solution) with, respectively, $NH_4[Cr(NCS)_4(NH_3)_2]$ (in $H_2O$) and $K[Cr(NCS)_4(4,4'\text{-bipy})_2]$ (in EtOH), in a 1:2 ratio. In both cases, light red precipitates formed and were isolated by filtration and dried. The first one was dissolved in pure methanol and allowed to evaporate slowly, generating orange needle-like crystals of **1** suitable for X-ray diffraction studies. In the second case, red single crystals of **2** were obtained by dissolving the precipitate in DMF, followed by slow diffusion of ethanol into the resulting solution. Characteristic IR bands due to the NCS ligands (KBr pellets) – **1**: 2066, 2104 $cm^{-1}$; **2**: 2062 $cm^{-1}$.

**Physical Techniques:** The IR spectra (KBr pellets) were recorded with a BIO-RAD FTS 135 spectrophotometer. The electronic spectra (diffuse reflectance technique) were recorded with a UV4 UNICAM spectrophotometer with MgO as a reference.

Magnetic measurements were carried out with a MPMS-5S (Quantum Design) SQUID magnetometer. The diamagnetic corrections for the compounds were estimated using Pascal's constants, and magnetic data were corrected for diamagnetic contributions of the sample holder.

**Crystallography:** Crystal **1** was measured at 183 K with a Bruker AXS SMART diffractometer (Mo-$K_\alpha$ radiation monochromator). Data for crystal **2** were collected at 293 K with a Stoe-IPDS imaging plate system operating with a Mo-$K_\alpha$ X-ray tube with a graphite monochromator. The structures were solved by direct methods and refined by full-matrix least-squares techniques based on $F^2$. Calculations were performed using the SHELX-97 crystallographic software package. The crystallographic data and other pertinent information are collected in Table 2.

CCDC-283332 (for **1**) and CCDC-283333 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# On the Existence of the Elusive Monomethyl Ester of Carbonic Acid [$CH_3OC(O)OH$] at 300 K: $^1H$- and $^{13}C$ NMR Measurements and DFT Calculations

**Angela Dibenedetto,*[a] Michele Aresta,[a] Potenzo Giannoccaro,[a] Carlo Pastore,[a] Imre Pápai,*[b] and Gábor Schubert[b]**

**Keywords:** Carbon dioxide / Density functional calculations / Methylation / NMR spectroscopy

The elusive monomethyl ester of carbonic acid [$CH_3OC(O)OH$] has been prepared at 300 K by protonation of the sodium salt $NaOC(O)OCH_3$ with anhydrous HCl or water and characterized by $^1H$- and $^{13}C$ NMR spectroscopy. The stability of the acid and its reactivity towards hydroxo ions and methylating agents under ambient conditions are discussed. The energetics and the mechanism of the investigated reactions are examined on the basis of density functional calculations. For kinetic and thermodynamic reasons $CH_3OC(O)OH$ is unlikely to be formed by insertion of $CO_2$ into the O–H bond of methanol.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Carbonic acid ($H_2CO_3$, **1**) and its amino [RR′NC(O)OH, **2**] and monoalkyl derivatives [ROC(O)OH, **3**] are elusive species. Their isolation as pure compounds is not trivial as they easily decompose to afford $CO_2$ plus water [Equation (1)], amine [Equation (2)], or alcohol [Equation (3)].

$$\underset{\mathbf{1}}{H_2CO_3} \rightleftharpoons H_2O + CO_2 \quad (1)$$

$$\underset{\mathbf{2}}{RR'N\text{-}C(O)OH} \rightleftharpoons RR'NH + CO_2 \quad (2)$$

$$\underset{\mathbf{3}}{ROC(O)OH} \rightleftharpoons ROH + CO_2 \quad (3)$$

In particular, **1** has never been isolated pure (only its water solutions are known), and **2** was only very recently isolated and characterized as a dimer in the solid state. The X-ray structure shows the existence of H-bonding through the carboxylic moieties [R = $C_6H_5CH_2$, R′ = H; or R,R′ = $PhP(OCH_2CH_2)_2$].[1,2] For **3** only a report of its low-temperature IR spectrum can be found in the literature;[3] no report of its existence at room temperature or information about its stability/reactivity are available. Conversely, the salts of **1** [$MHCO_3$, $M_2CO_3$, $M'CO_3$; M = group 1 metal or ammonia; M′ = group 2 metal], **2** [RR′NC(O)OR″; R″ = ammonium or metal cation], and **3** [ROC(O)OM] or the organic esters of **2** and **3** (R, R′, R″ = alkyl or aryl group) have been known for a long time to be stable compounds at room temperature.

Despite their instability, compounds **1**–**3** are often proposed to be intermediates in reactions in which carbon dioxide is implied. Thus, **2** has been suggested to exist in solutions containing amines and carbon dioxide[4] and **3** has been proposed to be formed by direct interaction of alcohols and $CO_2$,[5] a reaction relevant to the synthesis of organic carbonates by direct carboxylation of alcohols that occurs at temperatures ranging from 330 to 450 K and at a $CO_2$ pressure of 0.1–20 MPa.[7]

In the course of our research on carbon dioxide chemistry, we have synthesized and characterized the first examples of the elusive species **2**.[1,2] We wish to report here the first evidence of the existence of $CH_3OC(O)OH$ at room temperature and describe its reactivity. Density functional calculations have also been carried out to provide a rationale for our experimental findings.

## Results and Discussion

Although it has been suggested that **3** could be formed by direct reaction[5] of ROH with $CO_2$, our $^1H$- and $^{13}C$ NMR measurements run on pressurized (5 MPa) solutions of $CO_2$ in pure, freshly distilled, and absolutely anhydrous methanol did not give any evidence of $CO_2$ insertion into

the O–H bond of methanol to afford $CH_3OC(O)OH$ [**4**; Equation (4)].

$$CH_3OH + CO_2 \rightleftharpoons \underset{\mathbf{4}}{CH_3OC(O)OH} \quad (4)$$

One can argue that reaction 4 may either occur through a direct bimolecular insertion [Equation (4)] or through the generation of a $CH_3O^-$ anion by autoprotolysis of methanol [Equation (5a)], which may attack the electrophilic carbon of $CO_2$ with formation of $CH_3OC(O)O^-$ [Equation (5b)]. The protonation of this latter species would afford **4** [Equation (5c)].

$$CH_3OH + CH_3OH \rightleftharpoons CH_3O^- + CH_3OH_2^+ \quad (5a)$$

$$CH_3O^- + CO_2 \longrightarrow CH_3OC(O)O^- \quad (5b)$$

$$CH_3OC(O)O^- + CH_3OH_2^+ \rightleftharpoons \underset{\mathbf{4}}{CH_3OC(O)OH} + CH_3OH \quad (5c)$$

The abundance of $CH_3O^-$ is very low in pure anhydrous methanol as it is generated by the autoprotolytic dissociation of methanol [Equation (5)], which has an equilibrium constant, $K_{dis}$, of $10^{-16}$.[6] The lack of formation of **4** under these conditions can be explained by taking into consideration the thermodynamics of reaction 4 and its kinetic aspects, as discussed below.

It is worthwhile mentioning that previous theoretical studies[8–11] on the mechanism of carbonic acid formation from $H_2O$ and $CO_2$, a reaction that is analogous to Equation (4), have excluded the possibility of a direct bimolecular insertion because the activation energy predicted for this step is about 50 kcal mol$^{-1}$,[8–10] while the energy barrier decreases substantially (to about 15 kcal mol$^{-1}$)[8] if an additional water molecule is assumed to participate in the hydration process. Our calculations carried out at the B3LYP/6-311++G** level of density functional theory for $CH_3OC(O)OH$ formation involving two $CH_3OH$ molecules (see Figure 1) predict a relatively high energy barrier for this process ($\Delta G^{\ddagger}_{gas}$ = 28.9 and $\Delta G^{\ddagger}_{solv}$ = 22.7 kcal mol$^{-1}$ if solvent effects due to the methanol environment are included), indicating that reaction 4 is likely to be kinetically hindered. Furthermore, $CH_3OC(O)OH$ is found to be thermodynamically unstable with respect to its dissociation products, since the calculations give $\Delta G_{gas}$ = +9.9 kcal mol$^{-1}$ for the gas-phase reaction shown in Figure 1, which decreases to $\Delta G_{solv}$ = +4.4 kcal mol$^{-1}$ in the solvated model [for the isolated $CH_3OC(O)OH$ molecule the calculated dissociation free-energy values are $\Delta G_{gas}$ = +15.1 and $\Delta G_{solv}$ = +11.6 kcal mol$^{-1}$].

Accordingly, **4** has been reported to be a labile species and has only been characterized so far by IR spectroscopy at low temperature.[3] Therefore, it is not likely that it will exist for a long time at temperatures above 273 K. These results suggest that the direct insertion of $CO_2$ into the O–H bond of methanol is quite unlikely to occur under reaction conditions such as those used for the synthesis of organic carbonates,[7] and $CH_3OC(O)OH$ is unlikely to be an intermediate in such a reaction.

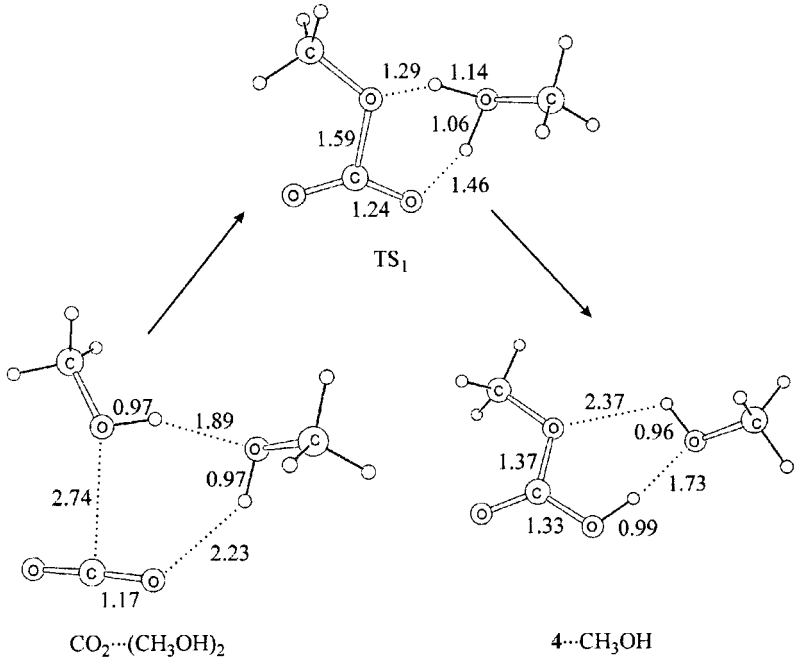

Figure 1. Formation of $CH_3OC(O)OH$ from $CO_2$ and two molecules of methanol. Selected bond lengths obtained from B3LYP/6-311++G** calculations are given in Ångstroms.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

We generated **4** by treating the sodium salt $NaO^{13}C(O)OCH_3$ (**5**) with either anhydrous $HCl/CD_2Cl_2$ or water in a biphasic system. $NaO^{13}C(O)OCH_3$ is easily formed by reaction of sodium methoxide with $^{13}CO_2$ [Equation (6)].

$$CH_3ONa + {}^{13}CO_2 \rightleftharpoons \underset{\mathbf{5}}{NaO^{13}C(O)OCH_3} \quad (6)$$

Compound **5** is a stable, white solid that has already been described.[12] Its IR spectrum shows strong bands at 1631 and 1381 $cm^{-1}$ for the $\nu_{C=O}$ absorption of the carbonate moiety. The reaction of **5** with anhydrous $HCl/CD_2Cl_2$ or water was monitored by carrying out a detailed NMR ($^1H$ and $^{13}C$) study. $^{13}CO_2$ was used in the synthesis of **5** in order to reduce the acquisition time of the $^{13}C$ NMR spectrum, thereby minimizing the risk of decomposition of **4**.

When **5** was suspended in $CD_2Cl_2$ under 0.1 MPa of $^{13}CO_2$, the $^1H$- and $^{13}C$ NMR spectra of the solution did not show any signal that could be attributed to **5** due to its very poor solubility in the solvent. The addition of a sub-stoichiometric amount of either anhydrous $HCl/CD_2Cl_2$ or water to the suspension at 295 K caused the immediate appearance of new signals in the $^1H$- and $^{13}C$ NMR spectra.

The $^1H$ NMR spectrum shows a singlet (1 H) at $\delta$ = 4.76 and a second signal at $\delta$ = 3.38 ppm (3 H; Table 1), which are attributed to the $CD_2Cl_2$-soluble $HO^{13}C(O)OCH_3$ species formed according to reaction 7.

Table 1. Spectroscopic properties of labile $CH_3OC(O)OH$.

| Compound | νCO | νOH | $^1H$ NMR ($\delta$, ppm) | $^{13}C$ NMR ($\delta$, ppm) |
|---|---|---|---|---|
| $CH_3OC(O)OH$ | 1779 | 3484 | 4.76 (1 H, O*H*) | 50.58 (*C*$H_3$) |
| | 1730 | | 3.38 (3 H, C*H*$_3$) | 159.92 (*C*=O) |

$$\underset{\mathbf{5}}{CH_3OC(O)ONa} + HCl\,(H_2O) \rightleftharpoons \underset{\mathbf{4}}{CH_3OC(O)OH} + NaCl\,(NaOH) \quad (7)$$

The $^{13}C$ NMR spectrum confirms the formation of **4**, as demonstrated by the appearance of a signal at $\delta$ = 159.92 ppm due to the carbon atom of the hemicarbonate moiety. Continuing the addition of anhydrous HCl up to a stoichiometric amount produced an increase of the intensity of the signals mentioned above (Figure 2a). The addition of water produces broader peaks (Figure 2b), although they are located at the same positions.

If the NMR tube is left under the same conditions after the addition of the $HCl/CD_2Cl_2$ solution to $NaO(O)COCH_3$ at 295 K, the $^1H$- and $^{13}C$ NMR spectra change: the signals due to **4** slowly disappear while the signals of $CH_3OH$ [$\delta$ = 4.81 (1 H) and 3.42 ppm (3 H)] appear (Figure 2). When $CH_3O^{13}C(O)OH$ is generated using sub-stoichiometric amounts of anhydrous $HCl/CD_2Cl_2$ it has a longer lifetime than when it is generated with water. Therefore aged solutions of **4** show a different behavior according to their preparation. In fact, when anhydrous HCl is used

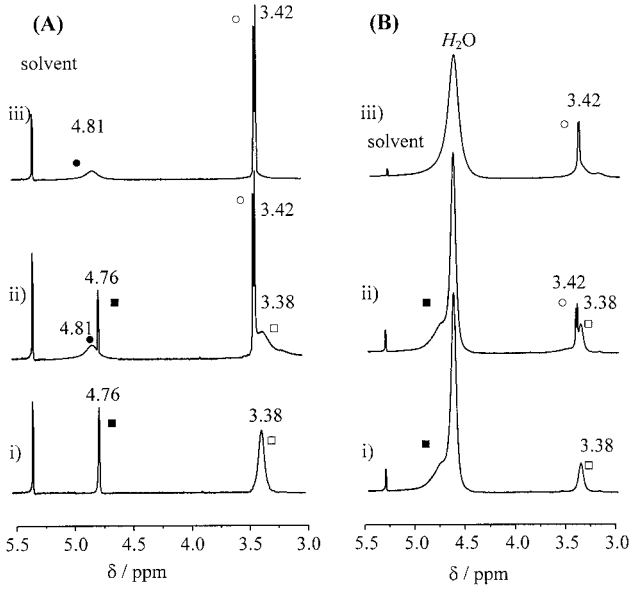

Figure 2. Evolution of the $^1H$ NMR spectrum of $CH_3OC(O)OH$ formed upon addition of (A) $HCl/CD_2Cl_2$ and (B) $H_2O$ to $CH_3OC(O)ONa$ suspended in $CD_2Cl_2$. i) soon after the addition; ii) after 10 min; iii) after 60 min. ■ $CH_3OC(O)OH$; □ $CH_3OC(O)OH$; ● $CH_3OH$; ○ $CH_3OH$.

the signal of free $CO_2$ generated by conversion of **4** is found at $\delta$ = 121.4 ppm. Conversely, when water is used a second signal appears at $\delta$ = 159.62 ppm in the $^{13}C$ NMR spectrum besides the signal at $\delta$ = 159.92 ppm that is attributed to $NaH^{13}CO_3$. In the latter case, the formation of methanol and $NaH^{13}CO_3$ can occur according to two mechanisms:
i) decomposition of $CH_3O^{13}C(O)OH$ into methanol and $^{13}CO_2$ [Equation (8a)] and subsequent reaction [Equation (8b)] of $^{13}CO_2$ with the NaOH formed in reaction 7.

$$CH_3O^{13}C(O)OH \rightarrow CH_3OH + {}^{13}CO_2 \quad (8a)$$

$$^{13}CO_2 + NaOH \rightarrow NaH^{13}CO_3 \quad (8b)$$

ii) direct interaction of the hydroxy moiety $OH^-$ with $CH_3O^{13}C(O)OH$ [Equation (9a)] by attack at the methyl group with formation of methanol and concurrent formation of $NaH^{13}CO_3$ [Equation (9b)].

$$CH_3O^{13}C(O)OH + OH^- \rightarrow CH_3OH + H^{13}CO_3^- \quad (9a)$$

$$H^{13}CO_3^- + Na^+ \rightarrow NaH^{13}CO_3 \quad (9b)$$

The energy barrier obtained for the decomposition of $CH_3OC(O)OH$ via the reverse reaction shown in Figure 1 is $\Delta G^{\ddagger}_{solv}$ = 18.3 kcal mol$^{-1}$ ($\Delta G^{\ddagger}_{gas}$ = 19.0 kcal mol$^{-1}$), whereas the calculations carried out for the methyl-transfer reaction between $CH_3OC(O)OH$ and $OH^-$ (see Figure 3) give a much smaller barrier ($\Delta G^{\ddagger}_{solv}$ = 11.3 and $\Delta G^{\ddagger}_{gas}$ = 4.4 kcal mol$^{-1}$). Moreover, the $S_N2$-type nucleophile substitution depicted in Figure 3 is predicted to be highly exergonic ($\Delta G_{solv}$ = –39.4 and $\Delta G_{gas}$ = –49.5 kcal mol$^{-1}$). These data indicate that reaction 9a is both kinetically and thermodynamically more feasible than the direct decomposition of $CH_3OC(O)OH$. This agrees with the experimental obser-

vation of the stability of **4** in the absence and presence of hydroxy ions.

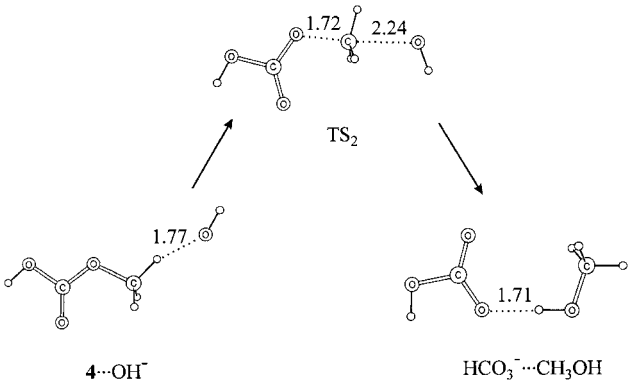

Figure 3. Stationary points located for the methyl-transfer reaction from $CH_3OC(O)OH$ to $OH^-$ forming $HCO_3^-$ and $CH_3OH$. Selected bond lengths obtained from B3LYP/6-311++G** calculations are given in Ångstroms.

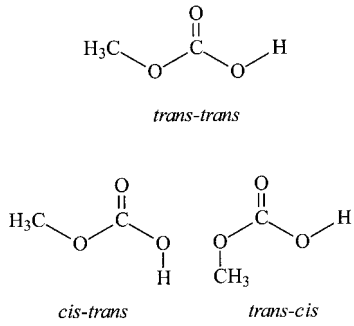
The rate of conversion of **4** into methanol and $CO_2$ in the presence of $OH^-$ is affected by the solvent: an apolar solvent slows the reaction as it does not favor the formation of hydroxy ions in solution from insoluble NaOH. Conversely, when a polar organic solvent or a stoichiometric amount of water is added to $CD_2Cl_2$ containing **5**, **4** is transformed so rapidly that it cannot be detected and only the final products ($CH_3OH$ and $NaHCO_3$) are observed. These experimental data support the direct interaction of **4** with $OH^-$ more than the dissociation of **4** into $CH_3OH$ and $CO_2$ and the subsequent reaction of the latter with NaOH. However, this study gives thermodynamic and kinetic information about **4** and allows us to complete, with the $^1H$- and $^{13}C$ NMR spectra, the characterization of the labile species **4** for which only the low-temperature IR spectrum had been reported so far.

As noted in a previous theoretical study,[13] the global energy-minimum of the $CH_3OC(O)OH$ molecule corresponds to the *trans-trans* orientation of the $CH_3$ and OH groups (see Scheme 1). Our present calculations predict two other conformations that lie only 1.3 (*cis-trans*) and 3.2 kcal mol$^{-1}$ (*trans-cis*) above the most stable isomer to be local minima on the gas-phase potential energy surface. We also estimated the acidity of $CH_3OC(O)OH$ by computing the aqueous p$K_a$ value for the *trans-trans* isomer (see Computational Details) and found that $CH_3OC(O)OH$ is slightly less acidic than $H_2CO_3$. In fact, we calculated a p$K_a$ for $CH_3OC(O)OH$ of 1.7 and for $H_2CO_3$ of 1.1; the experimental p$K_a$ value for $H_2CO_3$ is 3.6. The difference between calculated and experimental p$K_a$ values for $H_2CO_3$ is within the range of typical errors obtained with similar calculations[14] and can be attributed to the simplified solvation model.

Besides the conversion of **4** into methanol and $CO_2$, we also investigated the reactivity of **4** towards a methylating



Scheme 1. Conformations of $CH_3OC(O)OH$.

agent. The interest of reaction 10 lies in the fact that the product is an organic carbonate.

$$CH_3OC(O)OH + SubOR \rightarrow CH_3OC(O)OR + SubOH \quad (10)$$

If $CH_3OC(O)OH$ could be formed from methanol and $CO_2$, reaction 10 would be an effective way to produce DMC, a chemical that has several industrial applications as an alkylating[15] or methoxycarbonylating[16] agent, a precursor of pharmaceuticals and agrochemicals,[17] a solvent,[18] and as an additive to gasoline.[19]

In particular, we investigated the reaction of **4** with the methylating agent *O*-methylisourea (**6**)[20,21] [Equation (11)], which is obtained by treating dicyclohexylcarbodiimide (DCC) with methanol [Equation (12)]. This reagent was preferred to other classical methylating systems (e.g. $BF_3$/$CH_3OH$) as the latter may carry Brønsted acids that decompose **4**.

$$CH_3OC(O)OH + CyN{=}C(OCH_3)(NHCy) \xrightarrow[\mathbf{6}]{} CH_3OC(O)OCH_3 + CyHNC(O)NHCy \quad (11)$$

$$CyN{=}C{=}NCy + CH_3OH \longrightarrow CyN{=}C(OCH_3)(NHCy) \quad (12)$$

(**6**)

When isourea **6** was added to a $CH_2Cl_2$ solution containing $HOC(O)OCH_3$ generated from $NaOC(O)OCH_3$ dimethyl carbonate was immediately formed according to reaction 11. Both products (urea and DMC) were isolated and identified from their NMR spectra ($^1H$ and $^{13}C$) and GC-MS profiles compared with those of authentic samples. When the reaction was carried out in an NMR tube it was possible to follow the disappearance of the signals of **4** and the appearance of new signals due to DMC ($\delta$ = 3.69 ppm, $CH_3$). This reaction both confirms the existence of **4** in solution and underlines the role of **6** as a methylating agent, as already reported in the literature.[20,21] If the isourea is treated with NaOC(O)OMe no methylation reaction occurs, although the addition of a small amount of water allows the reaction to proceed to form urea and DMC as $CH_3OC(O)OH$ is formed.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

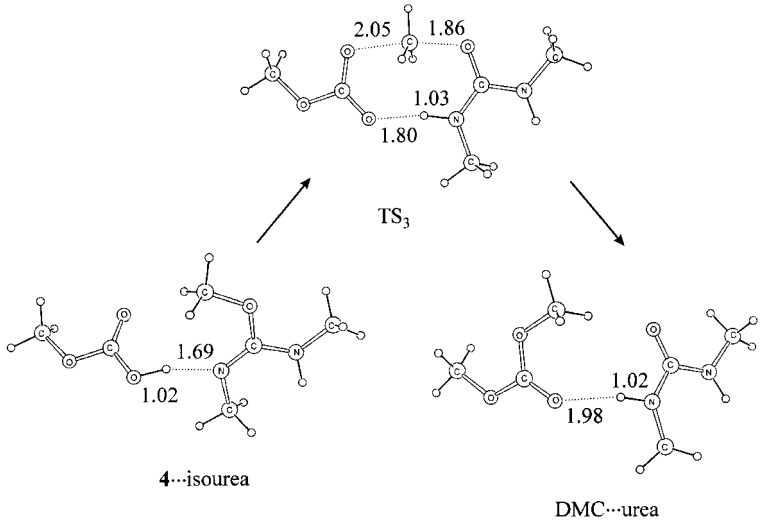


Figure 4. Stationary points located for the $CH_3OC(O)OH + CH_3N{=}C(OCH_3)(NHCH_3) \rightarrow CH_3OC(O)OCH_3 + CH_3HNC(O)NHCH_3$ model reaction. Selected bond lengths obtained from B3LYP/6-311++G** calculations are given in Ångstroms.

In order to explain the mechanism of reaction 12 we carried out DFT calculations on the reaction of **4** with a simplified model of **6** where the cyclohexyl groups have been replaced by methyl moieties (see Figure 4).

The transition state located for the model reaction describes a methyl transfer from isourea to **4**, while the O–H proton of **4** is already transferred to the iminic nitrogen of the isourea. IRC calculations indicate that the reaction takes place in a single step because the H-bonded **4**···isourea minimum is reached directly from the transition state in the reverse direction. The reaction is thermodynamically favored ($\Delta G_{solv}$ = –12.4, $\Delta G_{gas}$ = –11.8 kcal mol$^{-1}$) and the energy barrier is predicted to be $\Delta G^{\ddagger}_{solv}$ = 19.9 kcal mol$^{-1}$ ($\Delta G^{\ddagger}_{gas}$ = 25.5 kcal mol$^{-1}$), which is slightly higher than that found for reaction 13 ($\Delta G^{\ddagger}_{solv}$ = 14.5 kcal mol$^{-1}$).[20]

$$2\ ROH + CO_2 + DCC \rightarrow (RO)_2CO + CyNHC(O)NHCy \qquad (13)$$

It is worthwhile noting that the concentration of **4** in the system generated from **5** and $HCl/CD_2Cl_2$ or water decreases rapidly with an increase of temperature, and above 310 K we were not able to detect the formation of **4** at all. This agrees with the lability of **4**, which converts into methanol and $CO_2$ according to Equation (3), and makes it unlikely that $CH_3OC(O)OH$ is an intermediate in the synthesis of carbonates from alcohols and $CO_2$.

## Conclusions

Our work has demonstrated for the first time the existence of $CH_3OC(O)OH$ (**4**) at room temperature and its stability/lability under the same conditions. Although **4** is very labile, it exists in solution at room temperature for the time necessary to record its $^1$H- and $^{13}$C NMR spectra and to study its conversion with characterization of the products. It can be easily methylated to afford DMC, which is a reaction of potential practical importance. Nevertheless, **4** is not stable at temperatures above 300 K and is not formed for kinetic and thermodynamic reasons at room temperature from alcohols and $CO_2$ [nor in alcohol under 30 MPa of $CO_2$ nor in supercritical $CO_2$ (30 MPa) with added alcohol]. In order for **4** to play a role in the formation of DMC from methanol and $CO_2$, very high pressures of $CO_2$ should most probably be used (likely >>100 MPa).

## Experimental Section

All solvents and starting reagents were RP Aldrich products. Alcohols and solvents were dried, distilled,[22] and stored under dinitrogen. Carbon dioxide was purchased from Rivoira IP (99.999% purity). NMR experiments were carried out with a 300-MHz Bruker apparatus using deuterated CIL solvents. IR spectra were recorded with a FTIR Perkin–Elmer 1710 apparatus. GC-MS analyses were carried out with a Shimadzu 17 A gas chromatograph (capillary column: 30 m; MDN-5S; Ø 0.25 mm, 0.25 μm film) coupled to a Shimadzu QP5050A mass spectrometer. Quantitative determinations on the reaction solutions were recorded using a Hewlett–Packard 6850 GC-FID (capillary column: 30 m; MDN-5S; Ø 0.25 mm, 0.25 μm film).

Methylisourea was prepared as reported in the literature.[20,21]

**Synthesis of the Monomethyl Ester of Carbonic Acid [$CH_3OC(O)OH$] and NMR Studies:** NaOC(O)OMe [or $NaO^{13}C(O)OMe$] (35.0 mg, 0.36 mmol) freshly prepared from MeOH and Na under a $CO_2$ atmosphere was placed in an NMR tube in 0.7 mL of anhydrous $CD_2Cl_2$ and the tube was closed with a silicone stopper. $^1$H- and $^{13}$C NMR spectra were recorded for this sample: no signals were evident besides that of the solvent. Anhydrous HCl in $CD_2Cl_2$ was injected through the stopper in different amounts until the stoichiometric ratio was reached and the $^1$H- and $^{13}$C NMR spectra were recorded after each addition. NMR spectroscopic data are presented and discussed in the main text. Similarly, the reaction was monitored when water was added instead of anhydrous HCl.

**Reaction of 4 with Methylisourea:** $HOC(O)OCH_3$ was generated as described above from sodium methyl carbonate (78.0 mg, 0.8 mmol) and anhydrous $HCl/CD_2Cl_2$ (or water). Once the $^1$H NMR signals of **4** had reached their maximum intensity methyl-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

isourea (200 mg, 0.8 mmol) was added to the solution. After one hour at room temperature the $^1$H NMR signal ($\delta$ = 3.69 ppm) of dimethyl carbonate became evident. The solution was dried under vacuum and the resulting solid suspended in diethyl ether. The ether solution was filtered from the solid. The latter was shown to be urea [CyHNC(O)NHCy]. DMC was isolated from the solution by evaporating the solvent.

**Computational Details:** DFT calculations were carried out at the B3LYP/6-311++G** level[23] in order to obtain information about the structures and relative energies of energy minima and transition states relevant to the reactions investigated. The nature of the stationary points obtained from the geometry optimizations was verified by subsequent vibrational frequency analysis. Intrinsic Reaction Coordinate (IRC) calculations were performed from the located transition states in order to check whether these structures indeed connect the appropriate minima on the proposed reaction pathways. Most of the investigated reactions in the present work involve charged species, therefore we estimated the solvation free-energies using a recent implementation[24] of the Polarizable Continuum Model (PCM).[25] In these calculations, the cavities of the solute molecules were constructed using the atomic radii of the universal force field (UFF)[26] model with individual hydrogen spheres to be able to describe transition states for hydrogen-transfer reactions. The dielectric constant was always chosen according to the solvent used in the experiments ($\varepsilon$ = 8.93 for $CH_2Cl_2$ and 32.63 for methanol). The Gibbs free-energies calculated for the gas phase and solvated models are denoted $\Delta G_{gas}$ and $\Delta G_{solv}$, respectively, in the text, and include the thermal corrections as well. The aqueous p$K_a$ of $CH_3OC(O)OH$ was estimated according to the procedure described by Takano and Houk[14] and using the UAHF cavity model in the PCM calculations to obtain the solvation free-energies. All these calculations were carried out using the Gaussian 03 software package.[27]

# Synthesis and Characterization of a Novel Heteroditopic Macrocyclic System – Monometallic Nickel(II) and Uranyl Complexes and Their Corresponding Heterobimetallic Carbonylrhodium(I) Complexes

**Mauro Bassetti,*[a] Andrea Calenne,[a] Lucilla Mastrofrancesco,[a] Michela Salamone,[a] Gabriele Bocelli,*[b] Andrea Cantoni,[b] and Amos Musatti[b]**

**Keywords:** Heterometallic complexes / Ligand design / Macrocyclic ligands / Metallacycles / Schiff bases

A novel heteroditopic macrocyclic ligand system for selective coordination of two different transition metal ions has been obtained in the form of monometallic salen complexes of $Ni^{II}$ (LNi, **1**) and uranyl ($LUO_2$, **2**). The system is characterized by the presence of a dianionic, tetradentate salen donor system ($N_2O_2$) derived from *cis*-1,2-diaminocyclohexane and of a neutral, tridentate 2,6-bis(alkylthiomethyl)pyridine group ($NS_2$). The two binding sites are connected by two oxyethyl chains. The synthetic procedure involves the coupling of the disodium salt of 2,6-bis(mercaptomethyl)pyridine with two equivalents of 3-(2-bromoethoxy)-2-(2-propenyloxy)benzaldehyde. Removal of the protecting allyl groups from the reaction product (**I**) by palladium catalysis yields the ligand synthon 2,6-bis[2-(3-formyl-2-hydroxyphenyl)oxyethyl]thiomethylpyridine (**II**). The monometallic macrocyclic complexes **1** and **2**, obtained by metal-templated synthesis from *cis*-1,2-diaminocyclohexane, ligson **II**, and the corresponding $Ni^{II}$ or uranyl acetate salts, respectively, in the presence of barium bis(trifluoroacetate), have been fully characterized by spectroscopic techniques in solution and by X-ray diffraction analyses in the solid state. Both complexes react readily at room temperature with $[Rh(CO)_2Cl]_2$ in methanol to form the bimetallic cationic carbonyl complexes $[LNi^{II}Rh(CO)]PF_6$ (**3**) and $[LUO_2Rh(CO)]PF_6$ (**4**) upon addition of $NH_4PF_6$. Two conformers of complex **3** are observed in solution by IR and NMR spectroscopy, in a 5:1 ratio in $[D_2]$dichloromethane, which exhibit a fluxional behavior and are shown to interconvert above room temperature in $[D_3]$acetonitrile. The carbonylrhodium group in the bimetallic systems reacts further with methyl iodide in dichloromethane solution to form oxidative-addition products.

## Introduction

Compartmental ligands characterized by at least two different binding sites are interesting synthetic targets in the field of macrocyclic chemistry[1] as heterobimetallic macrocyclic complexes can be derived from such structures and used as appropriate models in heterogeneous or homogeneous catalysis, in which cooperative effects may arise from the vicinity of two metal centers.[2] Most dinucleating macrocycles available to date contain either one ligand type incorporated into a crown ether ring,[1a,1c,3,4] or the same donor set replicated within the macrocycle,[1a,3,5] which limits, but does not exclude, selectivity toward coordination of different transition-metal ions.[6] Although heteroditopic macrocyclic frames containing nonequivalent ring cavities are a significant advantage in this respect,[7] the introduction of different binding sites implies more elaborate synthetic approaches than those used in the preparation of systems with higher symmetry.[5c,7a,7b,7e,8] Various types of heterobimetallic macrocyclic systems have been reported.[1,5c,9]

We have planned the synthesis of a heterobifunctional macrocyclic structure bearing different donor sites. The choice of the binding units has fallen on systems widely used in catalysis and in coordination chemistry, namely the dianionic tetradentate ($N_2O_2$) salen-type ligand and the neutral tridentate ($NS_2$) 2,6-bis(alkylthiomethyl)pyridine system. The classic salen [*N*,*N*′-ethylenebis(salicylideneaminato)] metal complexes and related derivatives[5a–5c,10] are nowadays finding significant applications, most notably in host–guest chemistry,[1a,8,11] in asymmetric synthesis,[12] and in supramolecular and polymer catalysis.[13] The tridentate, neutral $NS_2$ ligands form complexes with different transition-metal ions[14] and have been used in the preparation of homo- and heterobimetallic macrocyclic structures, including those containing rhodium(I).[15] Square planar rhodium(I) complexes are of special interest in homogeneous catalysis with regard to oxidative addition and carbonylation processes.[16]

The combination of a hard and a soft metal center has driven the design and synthesis of binucleating systems.[17] In the case of metal carbonyl complexes, the proximity of the two metal atoms may activate a carbon monoxide group by interaction of the electrophilic metal center with the oxygen of CO.[18] In this context, we have selected a carbonylrhodium(I) group for coordination to the bis(mercaptomethyl)pyridine ligand and a uranyl or a nickel(II) metal center for the salen binding unit. The electrophilic character of the uranyl system has been well documented, especially its ability to coordinate organic carbonyl groups, such as that of urea, in its planar fifth coordination site,[19] or to act as an electrophilic catalyst for Michael additions[13a] and acyl-transfer reactions.[20] Detection of an intramolecular interaction of the $(NS_2)$Rh–CO group with crown-ether-complexed alkaline metal ions has been attempted.[15b]

## Results and Discussion

### Synthesis of Monometallic Macrocyclic Complexes

The synthetic strategy followed for the preparation of the target structure was directed by the fact that salen $N_2O_2$ type complexes form monometallic macrocyclic systems when a precursor molecular chain appropriately functionalized at both ends undergoes a metal-templated Schiff-base ring-closure reaction in the presence of a diamine partner and the chosen metal ion.[4b] In order to ensure the further coordination within the ring of a second metal ion, an $NS_2$ donor set was incorporated into the molecular chain. Therefore the synthesis of the ligand synthon **II**, which bears two terminal formyl-2-hydroxyaryl groups, was devised (Scheme 1). Following the preparation of monometallic macrocyclic complexes of $Ni^{II}$ and $UO_2$, derived from **II** and *cis*-1,2-diaminocyclohexane, the reaction with $[Rh(CO)_2Cl]_2$ afforded bimetallic $Ni^{II}/Rh^{I}$ and $UO_2/Rh^{I}$ species (Scheme 2). The nickel and uranyl ions were selected for the preparation of the bimetallic carbonylrhodium(I) complexes due to their different electronic and coordinative properties − uranyl is oxophilic whereas nickel(II) is not.

The synthesis of the precursor for the metal-templated ring-closure involves the coupling of the disodium salt of 2,6-bis(mercaptomethyl)pyridine[21] with 3-(2-bromoethoxy)-2-(2-propenyloxy)benzaldehyde,[22] in tetrahydrofuran, to give the allyl protected bis-formyl compound **I** (yield > 50%, Scheme 1). The allyl groups of **I** are then removed by palladium catalysis, following a method described in the literature,[20] to give ligand **II** (yield > 60%), which contains the $NS_2$ donor set, the oxyethyl spacers, and the formyl-2-hydroxyaryl sub-units. Compounds **I** and **II** were purified by column chromatography and characterized by $^1$H NMR, $^{13}$C NMR, and FT-IR spectroscopy, ESI mass spectrometry, and elemental analysis. The chemical shifts of the hydrogen atoms of the aryl rings in compound **II** were identified by a NOESY experiment, which shows correlations between the $OCH_2$ triplet at $\delta$ = 4.17 ppm and the doublet of doublets at $\delta$ = 6.93 ppm, due to the aryl 4-H *ortho* to the oxyethyl chain, as well as between the formyl H atoms at $\delta$ = 10.08 ppm and the doublet of doublets at $\delta$ = 7.20 ppm, due to the aryl 6-H.

The synthesis of the macrocyclic structures was performed by treatment of ligson **II** with *cis*-1,2-diaminocyclohexane, in the presence of $Ba(CF_3SO_3)_2$ as template, followed by transmetalation in situ with the desired metal ace-

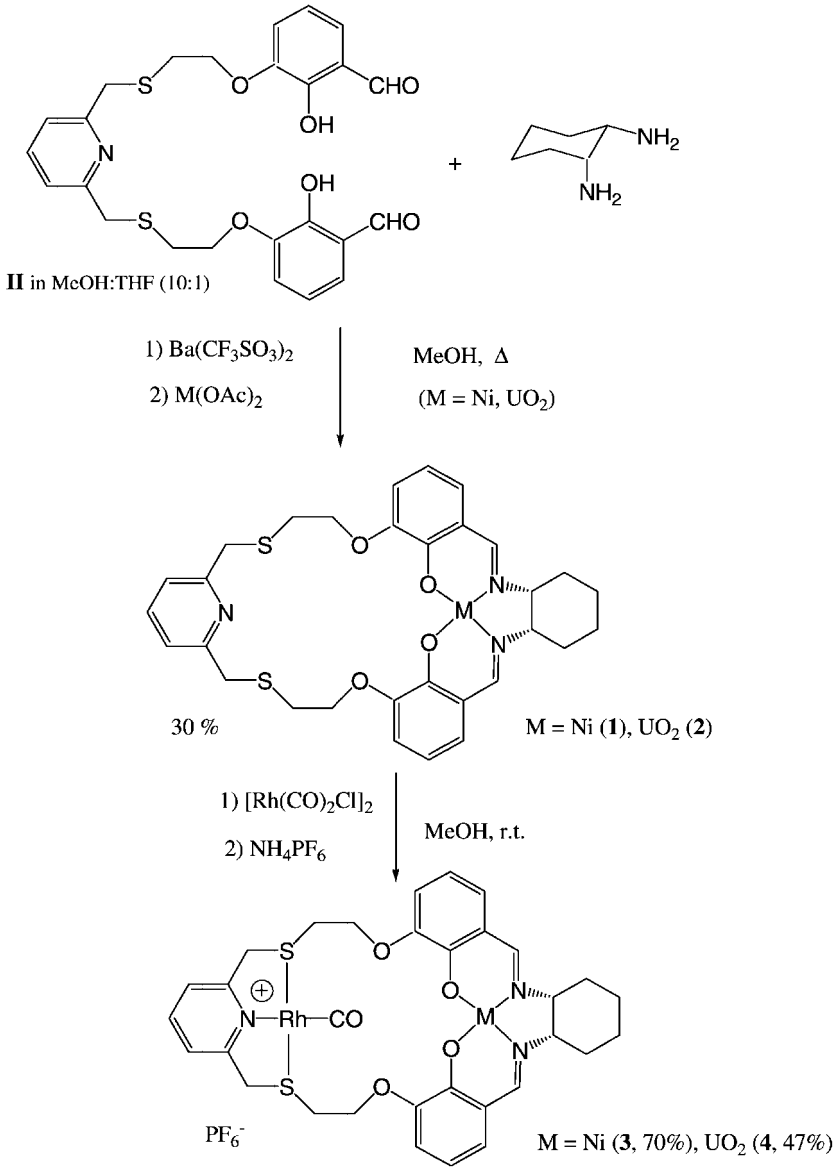

Scheme 2. Template synthesis of monometallic nickel(II) (**1**) and uranyl (**2**) macrocyclic complexes and subsequent formation of heterobimetallic nickel(II)–rhodium(I) (**3**) and uranylrhodium(I) (**4**) complexes.

tate $M(OAc)_2$ (M = Ni, $UO_2$; Scheme 2). Due to the poor solubility of **II**, which is a sticky red oil, in alcoholic solvents, the compound was added to the reaction mixture as a solution in methanol/tetrahydrofuran. The cyclization process involving the dialdehyde, the diamine, and the metal ion entails the formation of a metal–salen structure and affords the desired monometallic macrocyclic complexes **1** and **2**. Both complexes were isolated from their respective reaction mixtures as pure products by column chromatography with yields of around 30%.

The presence of $Ba^{2+}$ as a template cation has been found to be beneficial in cyclization reactions involving a diamine and a precursor containing two formyl-2-hydroxyaryl subunits linked by a polyether chain, affording the corresponding uranyl macrocyclic complexes with yields in the range 35–50% by transmetalation.[19,23] The same template has also been used successfully in the preparation of dissymmetric azamacrocyclic ligands.[7e] However, in the present case, the yields of complexes **1** and **2** were only slightly lower upon performing the reactions in the absence of the barium salt. This fact, along with the relatively low yields of the macrocyclization reactions, may be due to the lower binding ability of the hybrid thioether chain of ligand **II** toward the barium ion with respect to a polyether chain.

Complexes **1** and **2** were characterized by FT-IR, $^1H$ NMR, and $^{13}C$ NMR spectroscopy (see Experimental Section), ESI mass spectrometry, elemental analysis, and single-crystal X-ray diffraction analyses. In the $^1H$ NMR spectrum of complex **1** ([$D_2$]dichloromethane), the hydrogens of the pyridine ring (py) appear as one triplet at $\delta$ = 7.65 ppm (4-H) and one doublet at $\delta$ = 7.26 ppm (3,5-H), while the arene protons appear as two close doublets at $\delta$ = 6.79 and 6.75 ppm, due to 4,6-H, and one apparent triplet at $\delta$ = 6.45 ppm, due to 5-H, thus confirming the presence of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

salen and of the pyridine moieties in the expected ratio. The protons of the linking chains are also clearly identifiable. The fluxional character of the cyclohexane ring (cy) is indicated by the broad shape of the corresponding signals. One significant spectral feature is the presence of the imine CH=N protons, resulting from the coupling of the original aldehyde with the amine groups, at $\delta$ = 7.37 ppm in complex **1**. In the case of the uranyl complex **2**, the same protons appear at higher frequency, $\delta$ = 9.31 ppm, thereby indicating the stronger electron-withdrawing character of the uranyl group with respect to nickel(II). The 7-H protons of the cyclohexyl ring appear at $\delta$ = 3.45 and 4.66 ppm in complexes **1** and **2**, respectively.

In the $^{13}C$ NMR spectra, the imine carbon atoms are observed at $\delta$ = 159.2 and 167.2 ppm for **1** and **2**, respectively, while the infrared frequencies of the CH=N double bonds are virtually unaffected by the metal ion (1616 $cm^{-1}$ in dichloromethane). The electropositive uranyl center affects the rest of the molecule as well, since the $^1H$ NMR chemical shifts of the methylene hydrogens of py$CH_2$S and –S$CH_2CH_2$O– change from $\delta$ = 3.83 and 2.92 ppm in the nickel complex **1** to $\delta$ = 4.57–4.49 and 3.13 ppm, respectively, in complex **2**. The py$CH_2$S hydrogen atoms exhibit AB patterns in the $^1H$ NMR spectra, characterized by $\Delta\nu$ = 7.1 Hz (**1**, $CDCl_3$) and 24 Hz (**2**, $[D_2]$dichloromethane), due to their diastereotopic character,[15] while the same hydrogens of complex **1** appear equivalent in $[D_2]$dichloromethane. In a NOESY spectrum of complex **1** in $CDCl_3$, the absorption at $\delta$ = 6.47 ppm exhibits a cross-peak with the imine proton at $\delta$ = 7.04 ppm and is therefore assigned to the 6-H protons, while the peaks at $\delta$ = 6.71 ppm, due to 4-H, correlate with the $OCH_2$ signal at $\delta$ = 4.08 ppm.

Symmetric macrocyclic ligands containing two tetradentate salen coordination sites formed from *trans*-1,2-diaminocyclohexane, and the corresponding mono- and dinuclear nickel(II) complexes, have been reported.[24] With *trans*-1,2-diaminocyclohexane as the Schiff base counterpart, dissymmetric macrocyclic structures incorporating one nickel(II) salen unit, which acts as an intramolecular redox catalyst, and a 1,4-bis(chloromethylarene) function have been prepared by a multistep synthesis.[25] A macrocyclic compound characterized by the presence of a salen–uranyl moiety opposite a pyridine group and linked by oxyethyl chains has been reported.[23] With 1,2-phenylenediamine or *cis*-1,2-diaminocyclohexane, symmetric, dinuclear salophen or salen $UO_2$ macrocyclic complexes have been described,[26] as well as macrocyclic ligands containing 2,6-bis(alkylthiomethyl) pyridine subunits and the corresponding $[Rh(CO)][PF_6]$ dinuclear complexes.[15d] However, complexes **1** and **2** are the first macrocyclic structures in which a metal–salen unit is faced by an uncomplexed tridentate donor set that is suitable for further coordination of a second transition metal ion.

## X-ray Crystal Structure of Macrocyclic Nickel(II) (1) and Uranyl (2) Complexes

Single crystals of compounds **1** and **2** suitable for X-ray diffraction analysis were obtained by the "liquid diffusion" method from solutions of dichloromethane layered with heptane and kept at room temperature for several days. Selected bond angles and distances are reported in Tables 1 and 2 for complexes **1** and **2**, respectively.

Table 1. Selected bond lengths [Å] and angles [°] for the macrocyclic nickel(II) complex **1**.

### *Geometry of Complex 1*

The nickel atom in the $N_2O_2$ ligand set shows a slightly deformed square-planar conformation (Figure 1) in which the bond angles around the metal range from 85.6(4)° for O(4)–Ni(1)–O(28) to 93.7(5)° for O(4)–Ni(1)–N(13); the maximum out-of-plane deformation of the five atoms of the coordination moiety is 0.06(1) Å. The average Ni–O and Ni–N(13) bond lengths [1.865 and 1.8481 Å, respectively] compare well with the values observed in other monomeric nickel macrocyclic[24] or open complexes[27] formed from *trans*-1,2-diaminocyclohexane. The complex as a whole lies approximately on a plane, with the exception of the cyclohexane and pyridine rings, which are almost orthogonal to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the mean plane of the macrocycle and in a relative *transoid* fashion. In fact, the dihedral angles formed by the mean C(6)–C(11), C(22)–C(27), C(34)–N(39) (py) and C(14)–C(19) (cy) ring planes with that of the coordinative moiety are 7.7(2)°, 2.9(3)°, 82.3(2)°, and 114.5(2)°, respectively. While the chain from O(29) to C(33) is planar and forms a dihedral angle of 4.4(2)° with the coordinative mean plane, the C(42) and C(43) carbon atoms lie 1.02(2) and 1.25(2) Å, respectively, out of the plane formed by the three remaining atoms of the chain. The water molecule is not coordinated to nickel [O(1W)···Ni = 3.99(5) Å] but is hydrogen bonded within the cavity through the oxygen of one ethylene chain [H(1W)···O(29) = 1.94(5) Å] and one of the methylene hydrogens of the opposite one [O(1W)···H(43) = 2.47(5) Å]. Other short contacts are an intramolecular H(1W)···O(28) contact [2.52(2) Å] and an intermolecular H(12)–O(1W)$^{i}$ ($i$ = 1 – $x$, $y$ – 1/2, 3/2 – $z$) contact [2.49(2) Å]. The C(14)–N(13) distance of the cyclohexyl equatorial bond is 1.501 Å, while the C(19)–N(20) distance of the axial bond is 1.506(7) Å. The molecules are connected in the crystal by van der Waals contacts. We have not been able to find other crystal structures of salen–nickel complexes obtained from *cis*-1,2-diaminocyclohexane in the literature. The conformation of the bis(alkylthiomethyl)pyridine ligand set in complex **1** is characterized by the presence of the sulfur atoms oriented outwards with exocyclic lone pairs, with C–S–C bond angles of 98.6(3)° and 103.3(3)°. The C–S bond lengths lie between 1.825 and 1.867 Å, in the usual range observed in macrocyclic structures including this uncomplexed ligand.[15d]

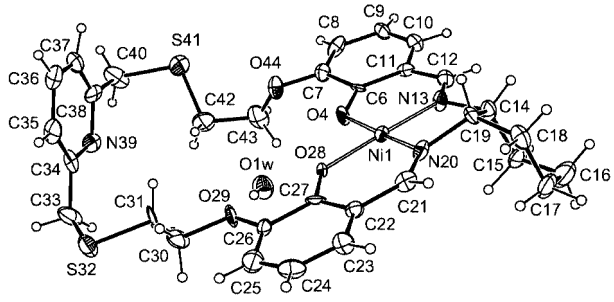

Figure 1. Molecular structure and atom-labelling scheme for the macrocyclic nickel(II) complex **1**.

### *Geometry of Complex 2*

The uranyl moiety in complex **2** exhibits a pentagonal-bipyramidal coordination (Figure 2). Two imine nitrogen atoms [N(20), N(13)], two phenoxy oxygen atoms [O(4), O(28)], and one oxygen from a molecule of water (O5) form the pentagonal base, which is almost planar, while the two uranyl oxygen atoms occupy the apex positions, with out-of-plane deviations of 1.57 and 1.81 Å, respectively. The aromatic rings are planar and the cyclohexane ring adopts the typical chair conformation. This coordinative arrangement compares well with that found for a similar complex containing a coordinated molecule of urea in place of the water molecule.[19] The pyridine ring is oriented in such a way as to form a dihedral angle of 20.7(4)° with respect to the pentagonal planar base. When compared to the S-shaped conformation of the nickel complex **1**, complex **2** can be regarded as lying approximately on a plane including the pyridine and cyclohexyl rings. Since the two phenyl rings C(6)–C(11) and C(22)–C(27) of the salen moiety form a dihedral angle of 47.5(5)° with respect to each other, this part of the complex assumes, as a whole, a butterfly orientation. These two rings are tilted by 28.2(4)° and 19.7(4)°, respectively, with respect to the mean plane formed by the five atoms coordinated by uranium. This conformation, which is due to the relatively large ionic radius of uranium pushing apart the phenyl rings, is typical of uranyl–salen complexes and is similar to that observed in other monomeric macrocyclic uranyl systems[19,28] formed from *cis*-1,2-diaminocyclohexane. The C(14)–N(13) distance of the cyclohexyl axial bond is 1.588 Å, while the C(19)–N(20) distance of the equatorial bond is 1.464 Å. In the crystals the molecules are connected by intra- [H(18a)····N(13) = 2.53(3); O(5)····N(39) = 2.76(2); O(5)····H(40) = 2.90(1) Å], and intermolecular [H(21A)···O(3)$^{i}$ (i = 1/2 – $x$, 1/2 – $y$, –$z$) = 2.33(1); H(30B)···O(5)$^{ii}$ (*ii* = –$x$, –$y$, –$z$) = 2.58(1); H(40B)···O(3)$^{iii}$ (*iii* = 1/2 – $x$, –1/2 – $y$, –$z$) = 2.49(1) Å] van der Waals contacts involving, in particular, the water molecule. The uncomplexed bis(thiomethyl)pyridine group of the uranyl complex **2** has one exocyclic and one endocyclic sulfur atom and is characterized by C–S–C bond angles of 101.9(8)° and 98.0(9)°, respectively, and C–S bond lengths in the range 1.77–1.81 Å.

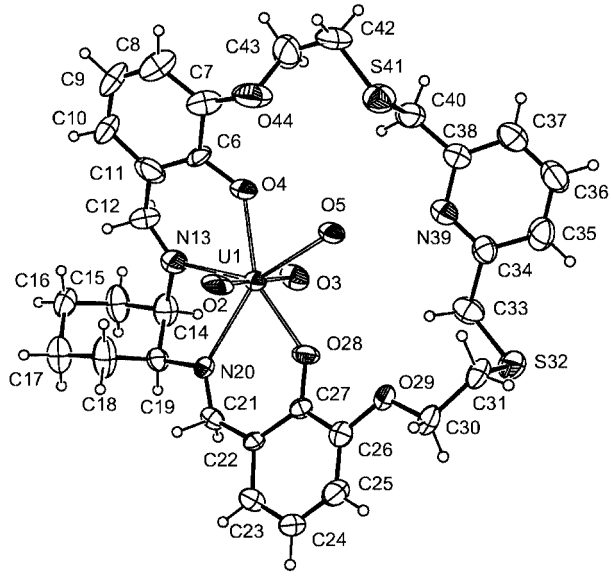

Figure 2. Molecular structure and atom-labelling scheme for the macrocyclic uranyl complex **2**.

### Synthesis of Bimetallic $Ni^{II}$–$Rh^{I}$ (3) and $UO_2$–$Rh^{I}$ (4) Macrocyclic Complexes

A suspension of the monometallic macrocyclic nickel complex **1** in methanol was treated with a methanolic solution of $[RhCl(CO)_2]_2$ (Scheme 2). The mixing of the two

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compounds yielded a clear amber solution which, when analyzed after about 10 min, showed an intense IR band at 2009 $cm^{-1}$ and the disappearance of the absorption bands (2088 and 2014 $cm^{-1}$) of the dicarbonylchlororhodium dimer. Addition of a methanolic solution of $NH_4PF_6$ caused the formation of an orange precipitate, which corresponds to the expected macrocyclic bimetallic $Ni^{II}$–$Rh^{I}$ complex **3** (yield 70%). The monometallic uranyl complex **2** reacts with the dicarbonylchlororhodium dimer in a similar manner (yield 47%). Therefore, the macrocyclic metal–salen structure connected by a relatively short oxyethyl chain does not hinder the coordinative ability of the $NS_2$ ligand set. Both complexes **3** and **4** exhibit good solubility in organic solvents, especially in dichloromethane. This is due, presumably, to the presence of the cyclohexane ring, as a cyclohexyl group is known to increase the solubility of macrocyclic salen complexes with respect to analogous salophen derivatives.[19]

The bimetallic complexes were characterized by FT-IR, $^1H$ NMR, and $^{13}C$ NMR spectroscopy (**3**), FAB mass spectrometry, and elemental analyses. Complexation of the cationic carbonylrhodium group to the tridentate $NS_2$ ligand system is indicated by the presence of a strong split absorption at 2026–2017 $cm^{-1}$ for complex **3** and of a band at 2020 $cm^{-1}$ for complex **4**, both in dichloromethane. The $^{13}C$ NMR chemical shifts of the methylene carbons of py$CH_2$S– and –S$CH_2CH_2O$– move from $\delta$ = 37.7 and 30.0 ppm in the monometallic nickel complex **1** to $\delta$ = 47.0 and 37.3 ppm, respectively, in the bimetallic nickel–rhodium complex **3**. The $^{13}C$ NMR spectrum obtained overnight from a [$D_2$]-dichloromethane solution of the bimetallic uranylrhodium complex **4** is identical to that of the monometallic uranyl complex **2**, which suggests solvolysis of the $(RhCO)^+$ fragment. In analogy, decomposition by loss of CO was observed when monitoring a dichloromethane solution of complex **4** by IR spectroscopy over several hours.

In complex **3**, in addition to the two CO stretching bands in the IR spectrum, broad and split peaks appear in the $^1H$ NMR spectrum, indicating the existence of two isomers in an approximately 5:1 ratio in [$D_2$]dichloromethane. Split peaks are also observed in the $^{13}C$ NMR spectrum. In [$D_3$]-acetonitrile solution, the three methylene groups of py–$CH_2SCH_2CH_2O$– are well separated in the region $\delta$ = 5.2–3.0 ppm (Figure 3). At room temperature, the multiplet due to the py$CH_2$S– methylene groups is better resolved than the broad signals of the –$SCH_2CH_2O$– methylene chain, thus indicating rapid conformational equilibria along the carbon chain spacers and greater flexibility of the macrocyclic structure at these sites. The py$CH_2$S– protons display a distorted AB system ($\delta_{Ha}$ = 4.80, $\delta_{Hb}$ = 4.73 ppm; $\Delta\nu$ = 22 Hz), corresponding to the coordination of the $NS_2$ donor set to the metal ion in a stable configuration. This pattern agrees well with that observed for the open complex [Rh(L)(CO)]$PF_6$ [L = 2,6-bis(benzylthiomethyl)pyridine] in [$D_2$]dichloromethane at –65 °C,[29b] and for the macrocyclic $Rh(CO)^+$ complexes in which a 2,6-bis(thiomethyl)pyridine subunit is linked by a polyether chain.[15c] In addition, the doubled absorptions of the –$SCH_2CH_2O$– groups confirm the presence of the two isomeric species observed in [$D_2$]-dichloromethane. When the temperature is raised, interconversion of these isomers occurs with a coalescence temperature of 44 °C, at which both the chain methylene groups appear as single, broad peaks at $\delta$ = 3.50 and 4.55 ppm, respectively, while the multiplet of the py$CH_2$S– protons is only slightly affected by this temperature change. The observed isomers may arise from the relative position of the metal ions with respect to the mean ligand plane – either opposite or on the same side – and interconvert by conformational changes of the oxyethylene chains, in analogy with what is observed for the symmetric bimetallic $RhCO^+$ macrocyclic complex incorporating two 2,6-bis(alkylthiomethyl)pyridine groups.[15c] Detailed variable-temperature NMR studies involving fluxional processes related to inversion at sulfur[30] and/or conformational equilibria in the macrocyclic frame have been described for mono- and bimetallic carbonylrhodium macrocyclic complexes.[15]

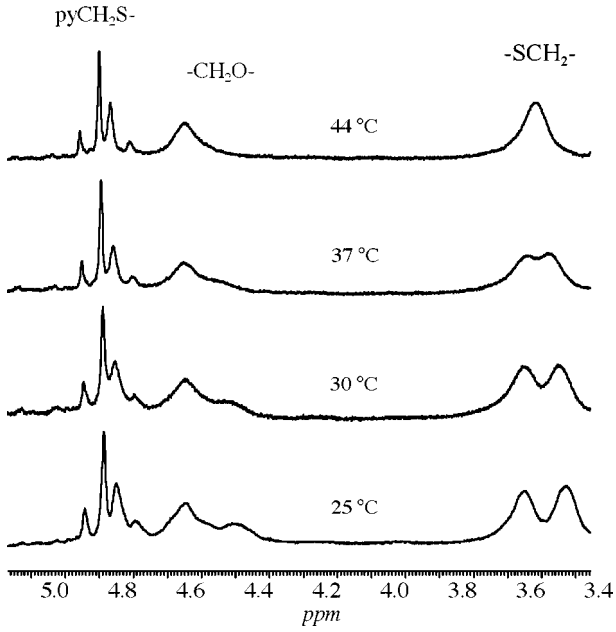

Figure 3. $^1H$ NMR spectra of the heterobimetallic $Ni^{II}$–$Rh^{I}$ complex **3** in [$D_3$]acetonitrile at different temperatures, displaying the methylene groups of the py$CH_2SCH_2CH_2O$ moiety.

The CO stretching band of the complex [Rh(L)(CO)]-$PF_6$, in which L is the "open" $NS_2$ ligand 2,6-bis(benzylthiomethyl)pyridine, is observed at 2019 $cm^{-1}$ in dichloromethane.[29] A comparison with the macrocyclic systems reported here shows that the carbonylrhodium group is not perturbed by the adjacent metal centers. It is worth mentioning that during the synthesis of the bimetallic complexes the intermediate chloride species shows a carbonyl band at 2009 $cm^{-1}$ for the nickel–rhodium complex **3** and 2015 $cm^{-1}$ for the uranylrhodium complex **4**, in methanol, indicating a small effect of the salen–metal ion on the carbonylrhodium group. The dinuclear [2+2] symmetric carbonylrhodium macrocyclic complexes incorporating two 2,6-bis(alkylthiomethyl)pyridine sub-units linked by $(CH_2)_n$ chains ($n$ = 5–10) exhibit CO stretching values in the range

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1991–2009 $cm^{-1}$ (KBr).[15d] The values of 2013 and 2012 $cm^{-1}$ observed in the solid state (KBr) for the heterobimetallic complexes **3** and **4**, respectively, indicate a larger triple-bond character than in the homobimetallic systems. This suggests reduced electron density on rhodium, and hence reduced back-donation from rhodium to carbonyl, rather than an intramolecular CO···M contact in the heterobimetallic complex, which would have lowered the carbonyl stretching frequency.

We have recently described that the monometallic complex $[Rh(L)(CO)]PF_6$ reacts with MeI to give an intermediate methylrhodium(III) iodide species $[Rh(L)(CO)(Me)I]^+$ and an isolable acylrhodium(III) complex $[Rh(L)(COMe)I]PF_6$ as the result of consecutive oxidative addition/migratory insertion reactions.[29a] This was the first report of the organometallic reactivity of a carbonylrhodium complex of the neutral tridentate 2,6-bis(substituted thiomethyl) pyridine system. The product of oxidative addition is observed as a relatively stable intermediate that accumulates in solution and exhibits a strong infrared band at 2106 $cm^{-1}$ (acetonitrile). We therefore tested the reactivity of both complexes **3** and **4** toward methyl iodide (3.5 M) in solution in dichloromethane (Scheme 3). In the case of the nickel–rhodium complex **3**, the reaction solution, when stirred for 5 h at 40 °C, gave an abundant red precipitate, which, analyzed in $[D_3]$acetonitrile, exhibits a strong carbonyl band at 2128 $cm^{-1}$ due to the methylrhodium species, thus indicating the conversion of complex **3** into the product of oxidative addition of methyl iodide. In the case of the macrocyclic uranylrhodium complex **4**, the solution was stirred for 6 h at room temperature in order to minimize the spontaneous loss of CO. After removal of excess MeI and solvent, the spectrum showed the presence of starting material (2001 $cm^{-1}$), the oxidative-addition intermediate (2116 $cm^{-1}$), and the migratory-insertion product at 1676 $cm^{-1}$. Due to the smaller absorptivity of the acyl moiety with respect to the parent terminal $Rh^I$ and $Rh^{III}$ complexes, it can be deduced that the acyl product is more abundant than both the substrate and the methylrhodium(III) intermediate. The presence of the acyl derivative from the bimetallic $UO_2/Rh^I$ complex suggests an easier migratory-insertion reaction than in the corresponding nickel complex. It appears that the IR frequencies of the carbonyl group in the $[Rh(CO)(Me)I]^+$ moiety are affected by the different environments in the two heterobimetallic complexes and in the open system.

## Conclusions

The synthesis of a novel macrocyclic ligand system containing a neutral, tridentate $NS_2$ donor set and a tetradentate, dianionic $N_2O_2$ unity has been described, in particular the isolation and structural characterization of the corresponding monometallic salen complexes of $Ni^{II}$ and of $UO_2$ obtained from *cis*-1,2-diaminocyclohexane. These are the first examples of macrocycles in which a different uncoordinated ligand set ($NS_2$) faces the salen–metal group. Both monometallic compounds react with $[RhCl(CO)_2]_2$ to yield heterobimetallic, cationic complexes characterized by the presence of the $[(NS_2)RhCO]^+$ fragment. This synthetic method allows the sequential and selective coordination of two different metal ions onto a dissymmetric ligand frame using conventional procedures. The uranyl group enhances the lability of the CO ligand with respect to nickel(II). In fact, the $UO_2$–$Rh^I$ complex decomposes slowly by loss of CO and solvolysis of the $Rh(CO)^+$ fragment. The $Ni^{II}$–$Rh^I$ complex, which is more stable, exists in solution as two conformational isomers. The $[Rh–CO]^+$ fragment of both bimetallic complexes undergoes oxidative addition of MeI.

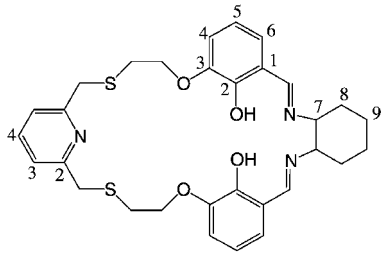
## Experimental Section

**General Methods:** Reactions involving air- and moisture-sensitive compounds were carried out under nitrogen using standard Schlenk line techniques. Tetrahydrofuran was distilled from Na/K alloy, acetonitrile from phosphorus pentoxide, and methanol from magnesium turnings. $^1$H, $^{13}$C, and 2-D NOESY NMR spectra were obtained with a Bruker AM-300 spectrometer. Chemical shifts are reported in ppm relative to tetramethylsilane with (for $^1$H NMR) chloroform ($\delta$ = 7.24 ppm) or dichloromethane ($\delta$ = 5.32 ppm) or (for $^{13}$C NMR) $CDCl_3$ ($\delta$ = 77.0 ppm), [$D_2$]dichloromethane ($\delta$ = 53.1 ppm) or [$D_3$]acetonitrile ($\delta$ = 118.2 ppm) as internal standards. IR spectra were recorded for KBr pellets or in 0.1-mm $CaF_2$ solution cells with a FT-IR Nicolet 510 instrument using the Omnic 4 software. ESI mass spectra were recorded with a Fisons Instruments VG-Platform Benchtop LC-MS (positive ions). FAB mass spectra were obtained with *m*-nitrobenzyl alcohol as matrix on a VG-Quattro Instrument of the University of Tor Vergata, Roma. Elemental analyses were performed by the Servizio di Microanalisi of the Department of Chemistry, Università La Sapienza, Roma. The compounds 3-(2-bromoethoxy)-2-(2-propenyloxy)benzaldehyde[22] and 2,6-bis(mercaptomethyl)pyridine[21,29a] were prepared according to literature procedures. Commercial $[RhCl(CO)_2]_2$ was purified by sublimation before use. Silica gel 60 was used for preparative column chromatography, unless stated otherwise. Other chemicals were used as supplied commercially.



**2,6-Bis{[2-[3-formyl-2-(propenyloxy)phenyl]oxyethyl]thiomethyl}pyridine (I):** Sodium hydride (80% dispersion in mineral oil; 438 mg, 14.6 mmol) was introduced into a 250-mL, three necked flask and washed three times with dry hexane under nitrogen. Tetrahydrofuran (50 mL) and a tetrahydrofuran solution of 2,6-bis(mercaptomethyl)pyridine (1.24 g, 7.3 mmol) were introduced by cannula, and the mixture was stirred for 15 min. 3-(2-Bromoethoxy)-2-(2-propenyloxy)benzaldehyde (4.13 g, 14.5 mmol) was added dropwise to the resulting solution. After 12 h at reflux, the reaction mixture was poured into water and chloroform, and extracted with chloroform (3 × 50 mL). The combined organic layers were washed with 0.5 M NaOH (3 × 30 mL), twice with water, then dried with sodium sulfate. After filtration, evaporation of the solvent under vacuum afforded 3.9 g of crude product, which appeared in a TLC analysis (silica/chloroform) as the most intense spot with a retention factor of 0.11–012, preceded and followed by weaker spots. Purification by column chromatography with chloroform as eluent gave pure **I** as a yellow, sticky oil in 54% yield. $^1$H NMR ($CDCl_3$): $\delta$ = 10.38 (s, 2 H, CHO), 7.60 (t, $J$ = 7.7 Hz, 1 H, py 4-H), 7.38 (pseudo-t, $J$ = 4.7 Hz, 2 H, aryl 5-H), 7.23 (d, $J$ = 7.7 Hz, 2 H, py 3,5-H), 7.05 (pseudo-d, $J$ = 4.7 Hz, 4 H, aryl 4,6-H), 6.08–5.94 (m, 2 H, =CH), 5.34–5.18 (m, 4 H, =$CH_2$), 4.65–4.62 (m, 4 H, $OCH_2$), 4.11 (t, $J$ = 6.7 Hz, 4 H, $OCH_2CH_2S$), 3.85 (s, 4 H, $pyCH_2S$), 2.92 (t, $J$ = 6.5 Hz, 4 H, $OCH_2CH_2S$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 190.17 (CHO), 158.06 (py C-2), 151.72, 151.20 (Ar C-2, C-3), 137.49 (py C-4), 133.03 (CH=), 130.06 (Ar C-1), 123.94, 121.24, 119.15, 118.82 (py C-3 and Ar C-4, C-5, C-6), 119.34 (=$CH_2$), 75.07 ($OCH_2CH=CH_2$), 67.98 ($OCH_2$), 38.01 ($pyCH_2S$), 30.41 ($OCH_2CH_2S$) ppm. FT-IR (dichloromethane): $\tilde{\nu}_{max}$ = 1687 cm$^{-1}$ (C=O). ESI (acetonitrile): $m/z$ = 580.7 [M + 1]$^+$, 602.4 [M + Na]$^+$, 618.8 [M + K]$^+$. $C_{31}H_{33}NO_6S_2\cdot H_2O$ (597.74): calcd. C 62.29, H 5.90, N 2.34, S 10.73; found C 62.62, H 5.64, N 2.64, S 10.82.

**2,6-Bis{[2-(3-formyl-2-hydroxyphenyl)oxyethyl]thiomethyl}pyridine (II):** Formic acid (0.28 mL, 7.5 mmol), triethylamine (freshly distilled from over sodium; 1.0 mL, 7.5 mmol), triphenylphosphane (49 mg, 0.19 mmol), palladium acetate (10 mg, 0.046 mmol), and compound **I** were dissolved in 11 mL of ethanol/water/tetrahydrofuran (5:1:5). The yellow solution was kept under reflux for 2 h, then the solvents were removed in vacuo. The residue was extracted with water (50 mL) and chloroform (3 × 50 mL). The combined extracts were washed with water (3 × 50 mL) and dried with sodium sulfate. Evaporation in vacuo gave 667 mg of crude product as a sticky, red oil. Purification of this material was carried out by column chromatography using a mixture of petroleum ether and acetone (2:1, v/v) to afford pure **II** in 60% yield. Compound **II** appears as the most intense spot in a TLC analysis from hexane/acetone (1:1) with $R_f$ = 0.56. When the reaction was performed under more dilute conditions, the deallylation process was slower and incomplete. On the other hand, longer reaction times produced decomposition of the expected product. $^1$H NMR ($CDCl_3$): $\delta$ = 11.14 (s, 2 H, OH), 10.08 (s, 2 H, CHO), 7.71 (t, $J$ = 7.7 Hz, 1 H, py 4-H), 7.41 (d, $J$ = 8.0 Hz, 2 H, py 3,5-H), 7.20 (dd, $^3J$ = 7.7, $^4J$ = 1.5 Hz, 2 H, Ar 6-H), 6.93 (dd, $^3J$ = 7.8, $^4J$ = 1.3 Hz, 2 H, Ar 4 H), 6.82 (pseudo-t, $J$ = 7.9 Hz, 2 H, Ar 5-H), 4.17 (t, $J$ = 6.2 Hz, 4 H, $OCH_2CH_2S$), 4.01 (s, 4 H, $pyCH_2S$), 2.76 (t, $J$ = 6.1 Hz, 4 H, $OCH_2CH_2S$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 194.50 (CHO), 157.93 (py C-2), 151.56 (Ar C-3), 146.99 (Ar C-2), 137.99 (py C-4), 132.08 (Ar C-1), 128.53 (Ar C-5), 123.31, 122.21, 119.22 (py C-3 and Ar C-4, C-6), 69.99 ($OCH_2$), 37.39 ($SCH_2py$), 29.14 ($OCH_2CH_2S$) ppm. FT-IR (tetrahydrofuran): $\tilde{\nu}_{max}$ = 1658 cm$^{-1}$ (C=O). ESI (acetonitrile): $m/z$ = 500.4 [M + 1]$^+$, 522.3 [M + Na]$^+$. $C_{25}H_{25}NO_6S_2\cdot H_2O$ (517.62): calcd. C 58.01, H 5.26, N 2.71, S 12.39; found C 58.56, H 5.60, N 2.45, S 11.15.

**Nickel(II) Complex 1:** Separate solutions of *cis*-1,2-diaminocyclohexane (0.115 mL, 0.96 mmol) in 70 mL of methanol and dialdehyde **II** (475 mg, 0.95 mmol) in 70 mL of methanol/tetrahydrofuran were added simultaneously, within 1 h, to a refluxing solution of $Ba(CF_3SO_3)_2$ (430 mg, 0.99 mmol) in 250 mL of dry methanol. The solution of **II** was prepared by dissolving compound **II** in 10 mL of tetrahydrofuran, followed by addition of methanol up to the desired volume. After 30 min, $Ni(CH_3COO)_2\cdot 4H_2O$ (249 mg, 1.0 mmol) was added. The solution turned brown and was kept at reflux for 50 min, then cooled to room temperature. The solvent was removed under vacuum, and the residue was extracted with dichloromethane. The organic solution was washed with saturated aqueous solutions of sodium sulfate (3 × 100 mL), sodium hydrogen carbonate (1 × 100 mL), and sodium chloride (1 × 100 mL), then dried with sodium sulfate. After filtration and removal of the solvent under vacuum, the crude product was separated into two equal portions, each of which was purified by column chromatography over alumina deactivated with 3% of water. Initial elution with dichloromethane separated two yellow bands of a material which was not identified. Continued elution with dichloromethane/methanol (at first 150:1, then 100:1) moved a long, brown band, which left the product as a red-brown solid (93 mg from the first portion of crude material and 90 mg from the second; combined yield 30%). $^1$H NMR ([$D_2$]dichloromethane): $\delta$ = 7.65 (t, $J$ = 8 Hz, 1 H, py 4-H), 7.37 (s, 2 H, CH=N); 7.26 (d, $J$ = 8 Hz, 2 H, py 3,5-H), 6.79 (dd, $^3J$ = 8.2, $^4J$ = 1.5 Hz, 2 H, Ar 4-H), 6.75 (dd, $^3J$ = 7.6, $^4J$ = 1.5 Hz, 2 H, Ar 6-H), 6.45 (pseudo-t, $J$ = 7.8 Hz, 2 H, Ar

5-H), 4.05 (t, $J$ = 7.8 Hz, 4 H, –$CH_2$OAr), 3.83 (s, 4 H, py$CH_2$S), 3.45 (br. s, 2 H, cy 7-H), 2.92 (d, $J$ = 7.9 Hz, 4 H, –$CH_2CH_2$S), 2.29 (br. m, 2 H, cy 8-H), 1.93 (s, 2 H, $H_2O$), 1.69 (br. m, 2 H, cy 8-H), 1.41 (m, 4 H, cy 9-H) ppm. $^1$H NMR ($CDCl_3$): $\delta$ = 7.61 (t, $J$ = 7.5 Hz, 1 H, py 4-H); 7.25 (d, $J$ = 8 Hz, 2 H, py 3,5-H), 7.04 (s, 2 H, ArCHN), 6.71 (d, $J$ = 7.4 Hz, 2 H, Ar 4-H), 6.47 (d, $J$ = 7.6 Hz, 2 H, Ar 6-H), 6.30 (pseudo-t, $J$ = 7.7 Hz, 2 H, Ar 5-H), 4.08 (m, 4 H, –$CH_2$OAr), 3.84 and 3.81 (AB system: $\Delta\nu$ = 7.1 Hz, 4 H, py$CH_2$S), 3.56 (br. s, 2 H, cy 7-H), 2.89 (m, 4 H, S$CH_2CH_2$O), 2.32 (s, 2 H, $H_2O$), 2.21 (br. m, 2 H, cy 8-$H_a$), 1.60 (br. m, 2 H, cy 8-$H_b$), 1.35 (br. m, 4 H, cy 9-H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 159.2 (CH=N), 158.6 (py C-2), 155.9, 149.1 (Ar C-2, C-3), 137.6 (py C-4), 125.4, 121.4, 120.8, 117.1, 113.5 (py C-3 and Ar C-1, C-4, C-5, C-6), 67.6 ($CH_2$OAr), 67.4 (br. s, cy C-7), 37.7 (py$CH_2$S), 30.0 ($CH_2$S), 27.32 (C-8), 20.9 (C-9) ppm. ESI (acetonitrile): clusters centered at $m/z$ = 635 [**1** + $H^+$], 657 [**1** + $Na^+$]. FT-IR (KBr): $\tilde{\nu}_{max}$ = 1614 cm$^{-1}$ (vs, C=N), 1572, (py) 1543, 1470, 1446 (vs, Ar), 1322, 1229 (s),1085, 1002, 864, 739 (s). Analytically pure material was obtained by precipitation upon addition of pentane to a solution in dichloromethane. $C_{31}H_{33}N_3NiO_4S_2\cdot H_2O$ (652.45): calcd. C 57.07, H 5.41, N 6.44; found C 57.38, H 4.64, N 6.15.

**Uranyl Complex 2:** Separate solutions of *cis*-1,2-diaminocyclohexane (0.068 mL, 0.576 mmol) in 50 mL of methanol and dialdehyde **II** (288 mg, 0.576 mmol) in 50 mL of methanol/tetrahydrofuran were added simultaneously, within 1 h, to a refluxing solution of $Ba(CF_3SO_3)_2$ (251 mg, 0.576 mmol) in 200 mL of dry methanol. The solution of **II** was prepared by dissolving compound **II** in 5 mL of tetrahydrofuran, followed by addition of methanol up to the desired volume. After 30 min, $UO_2(CH_3COO)_2\cdot 2H_2O$ (244 mg, 0.576 mmol) was added. The solution was kept at reflux for 30 min, then cooled to room temperature. The solvent was removed under vacuum, and the residue was extracted with dichloromethane. The organic solution was washed with saturated aqueous solutions of sodium sulfate (3 × 100 mL), sodium hydrogen carbonate (1 × 100 mL), and sodium chloride (1 × 100 mL), then dried with sodium sulfate. After filtration and removal of the solvent under vacuum, the crude product was purified by column chromatography. Elution was first performed using dichloromethane, which slowly separated a yellow band. Subsequent elution with dichloromethane/methanol (500:1) separated out a second yellow band from the top of the column. Neither of these materials was the expected product and they were not identified. A red band was eluted with dichloromethane/methanol (100:1), and collected as a red powder after removal of solvent. Pure uranyl macrocycle **2** was obtained by precipitation with hexane from a concentrated dichloromethane solution (140 mg, 29% yield). $^1$H NMR ([$D_2$]dichloromethane): $\delta$ = 9.31 (s, 2 H, CH=N), 7.79 (t, $J$ = 7.6 Hz, 1 H, py 4-H), 7.49 (d, $J$ = 7.6 Hz, 2 H, py 3,5-H), 7.24 and 7.22 (two dd, $^3J$ = 6.5, $^4J$ = 1.4 Hz, 2 H + 2 H, Ar 4-H and 6-H), 6.70 (pseudo-t, $J$ = 7.8 Hz, 2 H, Ar 5-H), 4.66 (br. m, 2 H, cy 7-H), 4.57 and 4.49 (AB system, $\Delta\nu$ = 24 Hz, 4 H, py$CH_2$S), 4.48 (t, $J$ = 5.1 Hz, 4 H, –$CH_2$OAr), 3.13 (t, $J$ = 5.1 Hz, 4 H, –$CH_2$S), 2.44 (m, 2 H, cy 8-H), 1.99 (m, 2 H, cy 8-H), 1.75 (m, 4 H, cy 9-H) ppm. $^{13}$C NMR ([$D_2$]-dichloromethane): $\delta$ = 167.2 (CH=N), 159.4 (py C-2), 157.5, 149.7 (Ar C-2, C-3), 138.48 (py C-4), 126.0, 123.3, 122.1, 116.8, 116.0 (py C-3 and Ar C-1, C-4, C-5, C-6), 71.14 (cy C-7), 69.76 (–$CH_2$OAr), 38.32 (py$CH_2$S), 31.58 ($CH_2$S), 27.36 (C-8), 21.42 (C-9) ppm. ESI (methanol): positive, cluster centered at $m/z$ = 847 [**2** + $H^+$]. FT-IR (KBr): $\tilde{\nu}_{max}$ = 1612 cm$^{-1}$ (vs, C=N), 1594 (py), 1522, 1466, 1451, 1309, 1246, 1223, 1086, 898 (s, $UO_2$), 738. FT-IR (dichloromethane): $\tilde{\nu}_{max}$ = 1616 cm$^{-1}$ (vs, C=N), 1597, 1575 (py), 1555, 1456 (vs). $C_{31}H_{33}N_3O_6S_2U\cdot 2H_2O$ (881.80): calcd. C 42.22, H 4.23, N 4.77; found C 42.77, H 4.16, N 4.62.

**$Ni^{II}$–$Rh^{I}$ Complex 3:** In a Schlenk tube, 52.1 mg (0.082 mmol) of the macrocyclic nickel complex **1** was suspended in 3 mL of dry methanol and stirred under argon at room temperature. [$RhCl(CO)_2]_2$ (16 mg, 0.041 mmol) dissolved in 2 mL of methanol was then added with a cannula from another Schlenk tube into the suspension of **3** to afford a clear, amber solution. An infrared analysis of the solution after 10 min showed the presence of an intense peak at 2009 cm$^{-1}$, and the absence of the 2088 and 2014 cm$^{-1}$ bands of the dicarbonylchlororhodium dimer. Addition of a methanolic solution (2 mL) of $NH_4PF_6$ (85 mg) caused the formation of an orange solid, and the mixture was stirred for a few minutes. The solid was then allowed to deposit and the solvent was decanted off. The precipitate was washed twice with cold methanol and vacuum-dried to leave 42 mg of an orange powder. Addition of 0.5 mL of pentane to the reaction solution caused the precipitation of an additional 10 mg of solid. Both materials were characterized by intense infrared absorptions near 2020 cm$^{-1}$ in dichloromethane solution. Overall yield 70%. The compound is moderately air-sensitive, as indicated by the slow decay of intensity of the carbonyl infrared band upon standing in air. $^1$H NMR ([$D_2$]dichloromethane): $\delta$ = 7.98 (t, $J$ = 7 Hz, 4-H py) and 7.86 (m due to the minor isomer, 1 H, py 4-H), 7.59 (d, $J$ = 8 Hz, 2 H, py 3,5-H), 7.31 and 7.38 (2 × s due to the minor isomer, 2 H, CH=N), 6.83 (d, $J$ = 7 Hz, 2 H, Ar 4-H), 6.68 (br. s, 2 H, Ar 6-H), 6.40 (br. s, 2 H, Ar 5-H), 4.72–4.50 (br. m, 8 H, py$CH_2$S and –$CH_2$OAr), 3.47 and 3.68 (2 × m, due to the minor isomer, 4 H, $CH_2$S; 5:1 ratio), 3.22 (br. s, 2 H, cy C-7), 2.24, 1.76, 1.39 (br. m, 8 H, cy 8,9-H) ppm. $^{13}$C NMR ([$D_3$]acetonitrile, peaks of the major isomer): $\delta$ = 161.8 (ArCHN), 161.4 (py C-2), 154.9, 147.8 (Ar C-2, C-3), 140.2 (py C-4), 127.5, 122.1, 121.9, 119.0, 115.3 (py C-3 and Ar C-1, C-4, C-5, C-6), 69.7 (br. s, cy C-7), 68.4 (–$CH_2$OAr), 47.0 (py$CH_2$S), 37.3 (–$CH_2$S), 27.8 (C-8), 21.4 (C-9) ppm. FT-IR (dichloromethane): $\tilde{\nu}_{max}$ 2026, 2017 cm$^{-1}$ (vs, CO), 1618 (s, C=N), 1606 (w, py), 1545, 1470, 1446. FT-IR (KBr): $\tilde{\nu}_{max}$ = 2013 cm$^{-1}$ (CO), 1618 (C=N), 1544, 1444, 1321, 1230, 840, 741, 558. FAB: clusters centered at $m/z$ =765.3 [**3** + $H^+$] and 737 [**3** + $H^+$ – CO]. $C_{32}H_{33}F_6N_3NiO_5PRhS_2\cdot 3H_2O$ (964.36): calcd. C 39.85, H 4.08, N 4.36; found C 39.54, H 3.52, N 4.40.

**$UO_2$–$Rh^{I}$ Complex 4:** The monometallic uranyl complex **2** (60.6 mg, 0.070 mmol) was suspended in 9 mL of methanol in a Schlenk tube and stirred at room temperature. A yellow solution of $[RhCl(CO)_2]_2$ (13.6 mg, 0.035 mmol) in 4 mL of methanol was then added with a cannula and the suspension changed into a clear red-orange solution. After 20 min, the infrared analysis of the solution showed an intense absorption at 2015 cm$^{-1}$ and the absence of the bands due to the starting rhodium dimer. A methanolic solution (3 mL) of $NH_4PF_6$ (155 mg) was added to the reaction flask, causing the immediate formation of a red-brown powder. After stirring for a few minutes the precipitate was allowed to settle, then the solution was decanted off. The solid was washed twice with cold methanol and vacuum-dried to give 17 mg of a brown-red powder. A second crop precipitated out of the mother solution upon standing under argon for a few hours (15 mg). Both crops were characterized by an intense infrared absorption at 2015 cm$^{-1}$ in dichloromethane. Yield: 42%. As in the case of complex **3**, this material is moderately air sensitive. FT-IR (dichloromethane): $\tilde{\nu}_{max}$ = 2020 cm$^{-1}$ (s, CO), 1616 (vs, C=N), 1556, 1453; (KBr): $\tilde{\nu}_{max}$ = 2011 cm$^{-1}$ (CO), 1614 (C=N), 1553, 1450, 1400, 1306, 1230, 1085, 997, 890 ($UO_2$), 844, 745, 558. FAB: clusters centered at $m/z$ = 976.7 [$\mathbf{4}^+$] and 949 [$\mathbf{4}^+$ – CO]. $C_{32}H_{33}F_6N_3O_7PRhS_2U$ (1121.7): calcd. C 34.27, H 2.97, N 3.75; found C 34.32, H 3.67, N 3.32.

**Crystal Structure Determination of the Macrocyclic Nickel Complex 1:** The data were collected on a Philips PW1100 diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71069 Å), controlled by a local pro-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gram.[31] The preliminary cell parameters were obtained from least-squares plots of the ($\theta$,$\chi$,$\varphi$) angular values of 25 reflections ($\theta$ range = 7.3–12.7°) accurately centered on the diffractometer. The intensity of one standard reflection, recorded for every 100, showed a decomposition of about 29%. The recorded data ($\theta$ range = 3–27°) were corrected for this decay, for polarization, and for Lorentz effects. The absorption correction was performed with the method of Walker and Stuart,[32] using a program written by Gluzinski.[33] The low quality of the employed crystal resulted in the low number of observed reflections. The structure was solved by direct methods with SIR97,[34] and refined full-matrix anisotropic least-squares methods with SHELX97.[35] Most of the H atoms were found in a difference Fourier map, and the remainder were put in their theoretical positions, refined by a few cycles with isotropic thermal parameters, and then blocked in the refined positions. The ORTEP drawings were produced with the ORTEP-3 program.[36]

**Crystal Structure Determination of the Macrocyclic Uranyl Complex 2:** The data were collected on a Bruker AXS Smart CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71069 Å) ($\theta$ range = 3–29°). Auto-indexing was performed with an algorithm operating on difference vectors derived from the input reflections. During the data collection the specimen decomposed by about 23%. Data reduction, absorption, and decomposition corrections, structure solution and refinement were all performed with the programs contained in SHELXTL-NT V5.1.[37] The small dimensions of the employed crystal and its low quality resulted in a small number of observed reflections. All the non-hydrogen atoms were refined anisotropically. While most of the hydrogen atoms were found in a difference Fourier map, the remainder ones were put in their geometrical positions, refined by a few cycles with isotropic thermal parameters, and then blocked in the refined positions. The hydrogen atoms of the water molecule were not localized. Experimental crystallographic information for both complexes **1** and **2** are reported in Table 3.

Table 3. Selected crystallographic details for complexes **1** and **2**.

| | **1** | **2** |
|---|---|---|
| Formula | $C_{31}H_{33}N_3NiO_4S_2{\cdot}H_2O$ | $C_{31}H_{33}N_3O_6S_2U{\cdot}H_2O$ |

CCDC-253882 (for **1**) and -253883 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): $^1$H NMR, $^{13}$C NMR, and FT-IR spectra of complexes **1**–**4**. FT-IR spectra of the products of oxidative addition of methyl iodide to complexes **3** and **4**.

## Acknowledgments

We wish to thank Prof. Frank van Veggel for discussions during the early stages of this project, Dr. Valeria van Axel Castelli for many helpful suggestions throughout the work, and Dr. Giovanna Mancini for the 2D NMR measurements. Partial funding from MIUR (projects COFIN1999 "Effetti cooperativi in sistemi organometallici polifunzionali" and COFIN2003 "Effetti cooperativi in nuovi sistemi metallo-ciclopentadienilici polifunzionali") is gratefully acknowledged.

# Synthesis and Structural Characterisation of Palladium and Group-12 Metal Complexes with a Hybrid Phosphanylphosphonate Ferrocene Ligand

**Petr Štěpnička,*[a] Ivana Císařová,[a] and Róbert Gyepes[a]**

**Keywords:** Group 12 metals / Phosphanes / Phosphonate esters / Palladium / Sandwich complexes / Structure eluicidation

Diethyl [1′-(diphenylphosphanyl)ferrocenyl]phosphonate (**1**) was synthesised by stepwise metallation/functionalisation of 1,1′-dibromoferrocene and studied as a ligand for palladium(II) and group-12 metals. Treatment of $[PdCl_2(cod)]$ (cod = $\eta^2$:$\eta^2$-cycloocta-1,5-diene) with **1** in 1:1 or 1:2 molar ratios gave, respectively, the dinuclear, chloride-bridged complex $[\{Pd(\mu\text{-}Cl)Cl(\mathbf{1}\text{-}\kappa P^2)\}_2]$ (**2**) and the mononuclear complex *trans*-$[PdCl_2(\mathbf{1}\text{-}\kappa P^2)_2]$ (**3**), where **1** coordinates exclusively through the phosphane function. The reactions between **1** and group-12 metal bromides $MBr_2$ in a 1:1 molar ratio gave the adducts $[MBr_2(\mathbf{1})]$ [M = Zn (**4**), Cd (**5**), and Hg (**6**)], whose crystal structures change considerably with the metal ion. Thus, whereas **4** is a molecular complex with **1** coordinating as an $O^1,P^2$-chelate, its cadmium(II) analogue is a polymer built up from symmetric $\{CdBr(\mu\text{-}Br)\}_2$ units interconnected by pairs of $O^1,P^2$-bridging phosphanylphosphonate ligands. Finally, the mercury(II) complex **6** is a halide-bridged dimer, $[\{Hg(\mu\text{-}Br)Br(\mathbf{1}\text{-}\kappa P^2)\}_2]$. However, this compound is structurally fluxional in solution (NMR spectra) and, in the crystal, it attains a structure similar to **5** owing to weak interactions between mercury and phosphonate-$O^1$ atoms from adjacent molecules. An isomer to **6**, $[\{HgBr_2(\mathbf{1}\text{-}\kappa^2 O^1,P^2)\}_2]$ (**7**), was isolated from attempted alkylation of **6** and structurally characterised as a dimer, where ligands **1** bridge two $\{HgBr_2\}$ units. All compounds were studied by spectroscopic methods (IR, NMR, mass) and the solid-state structures of **1**, **2**·½$H_2O$, **3**·4 $CHCl_3$, **4**, **5**, **6**·5 $C_6H_6$, and **7** have been determined by single-crystal X-ray diffraction.

## Introduction

Ferrocene donors have attracted considerable attention as valuable ligands for coordination compounds and catalytic applications. Among the numerous multidentate ferrocene donors that have been synthesised during the last few decades, chiral, mixed-donor (typically PN) ligands derived from a 1,2-disubstituted ferrocene backbone have proved to be particularly successful.[1] In contrast, the related unsymmetrical, 1,1′-disubstituted ferrocene derivatives have been studied much less.[2] This applies particularly to donors whose asymmetry arises from the presence of two different phosphorus groups. To date only a few ferrocene diphosphanes $Ph_2PfcPR_2$ {fc = ferrocene-1,1′-diyl; $PR_2$ = PPh(*t*Bu),[3] P(*t*Bu)$_2$,[4] and $P(C_6H_4Y\text{-}4)_2$, Y = OMe, $CF_3$[5]}, phosphanylphosphonites $Ph_2PfcP(OR)_2$,[6] and dppf semi-chalcogenides $Ph_2PfcP(E)R_2$ (E = O,[7] S, and Se[8]) have been reported in the literature, which stands markedly against the vast chemistry of the "popular", symmetric ferrocene diphosphane 1,1′-bis(diphenylphosphanyl)-ferrocene (dppf).[9]

Recent interest in the synthesis and coordination chemistry of ferrocene phosphonate esters and acids[10] led us to design the ferrocene phosphanylphosphonate ligand $Ph_2PfcP(O)(OEt)_2$ (**1**) and study its coordination behaviour. In this contribution, we report the synthesis, characterisation and structures of this ligand and its complexes with palladium(II) and group-12 metals. It should be noted that compound **1** was reported as an intermediate in the synthesis of diphosphanes $Ph_2PfcPH_2$ and $Ph_2PfcPR_2$ [$PR_2$ = (*R*,*R*)-2,5-dimethylphospholan-1-yl] while this work was in progress.[11] However, no investigation into its donor properties was mentioned.

## Results and Discussion

Diethyl [1′-(diphenylphosphanyl)ferrocenyl]phosphonate (**1**) was prepared by lithiation of 1-bromo-1′-(diphenylphosphanyl)ferrocene followed by addition of diethyl chlorophosphate to the formed lithio intermediate, using the general methodology developed by Butler et al.[7a] Subsequent chromatography of the crude product contaminated with (diphenylphosphanyl)ferrocene and some other minor impurities on alumina furnished a good yield of pure **1** as an amber oil, which slowly crystallised upon standing at room temperature (faster at +4 °C) to give an orange, waxy solid. The compound was characterised by standard spectroscopic methods and its structure determined by X-ray diffraction analysis (see Figure 1 and the section dealing with the crystal structures below). It was then studied as a ligand in palladium(II) and group-12 metal complexes.

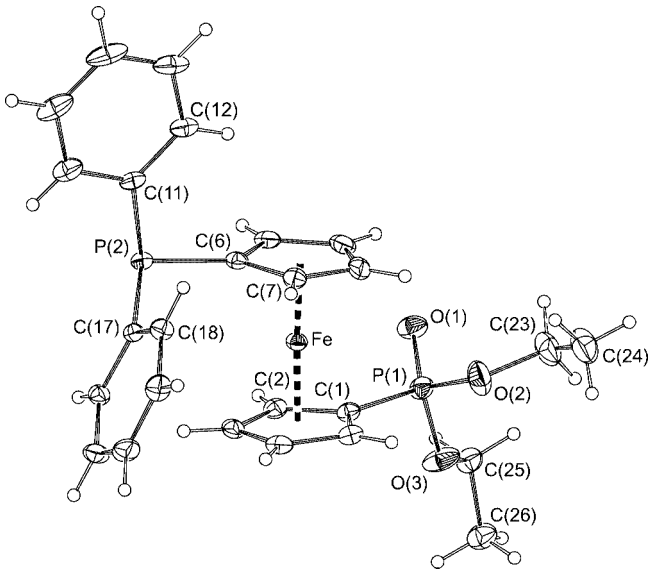

Figure 1. Molecular structure of **1** showing the atom-labelling scheme; for the consecutively numbered ring atoms, only labels of the pivotal atom and its adjacent ring carbon atoms are shown for clarity (note: the atom-numbering scheme adopted for the ligand moieties in all complexes is similar). Displacement ellipsoids are scaled to the 30% probability level. Selected distances [Å] and angles [°]: Fe–Cg(1) 1.6488(9), Fe–Cg(2) 177.00(5), P(1)–O(1) 1.467(2), P(1)–O(2) 1.587(2), P(1)–O(3) 1.572(2), P(1)–C(1) 1.761(2), P(2)–C(6) 1.813(2), P(2)–C(11) 1.838(2), P(2)–C(17) 1.831(2); Cg(1)–Fe–Cg(2) 177.00(5), range of O–P(1)–O angles 105.9(1)–115.7(1), range of C(1)–P(1)–O angles 98.59(9)–117.7(1), range of C–P(2)–C angles: 100.88(9)–102.13(8), ∠ Cp1,Cp2 4.5(1)°, $\tau$[C(1)–Cg(1)–Cg(2)–C(6)] = 155.2(1)°; Cg(1) and Cg(2) are the centroids of the cyclopentadienyl rings C(1–5) (Cp1) and C(6–10) (Cp2), respectively.

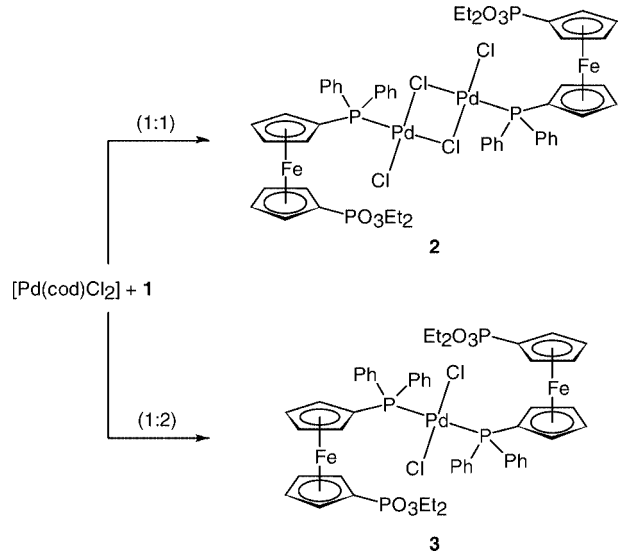

Scheme 1.

## Palladium(II) Complexes

Depending on the stoichiometry, the reaction of [Pd(cod)$Cl_2$] (cod = $\eta^2$:$\eta^2$-cycloocta-1,5-diene) with **1** gives either the chloride-bridged dipalladium(II) complex *trans*-[{Pd(μ-Cl)Cl(**1**-κ$P^2$)}$_2$] (**2**) or the bis(phosphane) complex *trans*-[$PdCl_2$(**1**-κ$P^2$)$_2$] (**3**; Scheme 1). Attempted removal of the chloride ligands from **3** by treatment with $AgClO_4$ gave an intractable, dark-red, oily residue that shows broad signals in the NMR spectra.

The reaction in a 1:1 molar ratio in methanol produced a dark-red, crystalline solid, which was structurally characterised as *trans*-[{Pd(μ-Cl)Cl(**1**-κ$P^2$)}$_2$] (**2**). The spectroscopic data for **2** give no clear signs about the coordination mode of the phosphanylphosphonate ligand and do not allow us to distinguish between two possible isomeric forms, namely **2** and [$PdCl_2$(**1**-κ$^2O^1$,$P^2$)]. For instance, the $^1$H NMR spectra exhibit markedly downfield-shifted ferrocene signals (as compared to **1** and **3**) but practically unaffected signals for the ethoxy groups [$\Delta\delta_H(CH_2) \approx +0.03$ ppm] whilst the $^{31}$P NMR spectra show two distinct signals at $\delta_P$ = 24.6 and 31.1 ppm due to the phosphonate and phosphanyl groups, respectively {coordination shifts [$\Delta\delta_P$ = $\delta_P$(complex) – $\delta_P$(ligand)] of 48.1 ($P^{III}$) and –1.1 ppm ($P^V$), recorded in $CDCl_3$}.

More information about the structure of **2** was obtained from the far-IR spectrum, which contains a strong band at 356 cm$^{-1}$ (with shoulder at 350 cm$^{-1}$), and several bands at 249–256 cm$^{-1}$ attributable to ν(PdCl) stretching vibrations involving the terminal and bridging chloride ligands, respectively. An unambiguous proof of the compound structure came from the X-ray diffraction analysis (Figure 2). Crystals amenable to the diffraction analysis were obtained directly from the reaction mixture. However, since the poor quality of the available crystals (disorder of the phosphonate group and crystal defects) resulted in a relatively low overall quality of the structural data, only the most important structural features will be addressed here.[12]

The structure determination for **2** revealed a doubly halide-bridged dimeric structure with a *sym-trans* geometry. Remarkably, the dihedral angle subtended by the {$PdCl_2P$} least-squares planes is as high as 40.91(5)°, which is rather uncommon for compounds of this type. A search in the Cambridge crystallographic database[13] revealed that the observed tilting of the coordination planes is among the highest observed.[14] As expected, the Pd–Cl bonds to terminal chlorides (2.27 Å) are significantly shorter than those to bridging ones (2.33–2.44 Å). The Pd–P bonds in **2** are about 0.12 Å shorter than those in **3** (see below), which can be ascribed to a lower *trans* influence of the chloride ligand in comparison with the phosphane donor, and possibly also to a less sterically strained structure of **2** where the two bulky phosphanylphosphonate ligands are separated by the Pd(μ-Cl)$_2$Pd core.

For complex **3**, which is formed at a 2:1 ligand-to-metal ratio, the exclusive P-coordination of **1** is clearly manifested by a considerable shift to lower fields for the phosphanyl signal and practically unaffected phosphonate resonance [$\Delta\delta_P(P^{III})$ = 32.3 ppm/$\Delta\delta_P(P^V)$ = –0.6 ppm]. The $^{31}$P coordination shifts for the palladium complexes reflect a relatively higher *trans* influence of the phosphane donor (see also

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

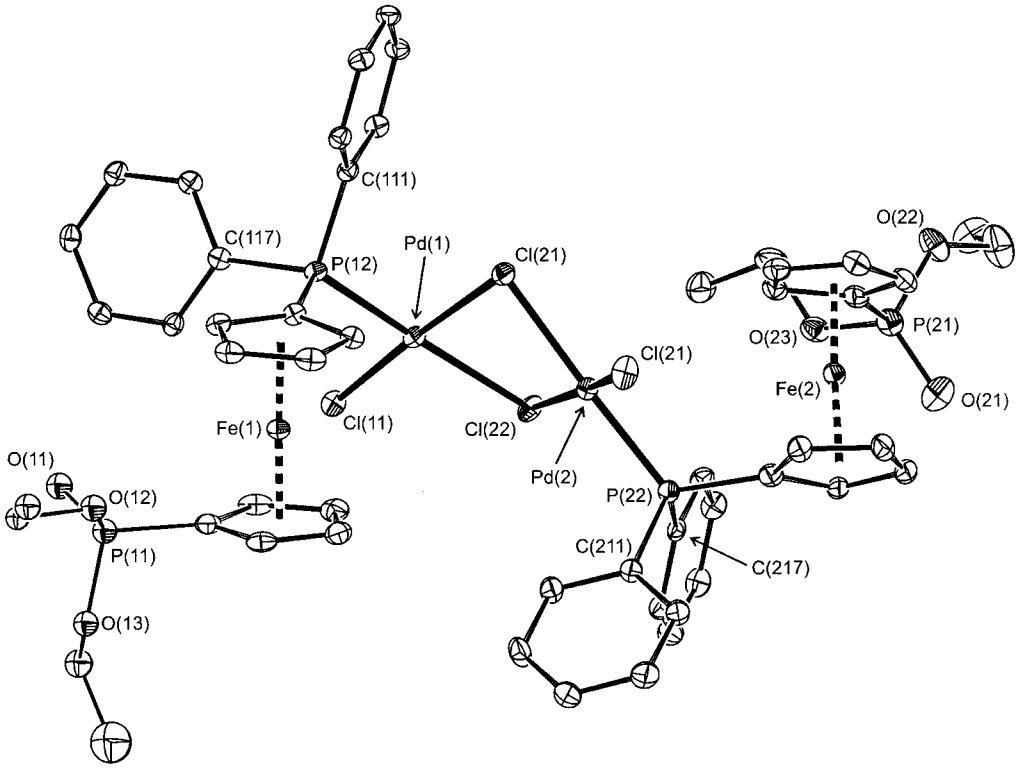

Figure 2. A view of the structure of complex **2** as determined for the solvate **2**·½$H_2O$. For clarity, the solvating water molecule and hydrogen atoms have been omitted and only one orientation of the disordered phosphonate group [the group involving the P(11) atom] is shown. Displacement ellipsoids are drawn at the 20% probability level. The atom-numbering scheme is analogous to that of **1**; the first digit is added to distinguish the symmetrically independent molecular parts. Selected distances [Å] and angles [°]: Pd(1)–Cl(11) 2.273(2), Pd(1)–Cl(12) 2.329(2), Pd(1)–Cl(22) 2.443(2), Pd(1)–P(12) 2.229(2), Pd(2)–Cl(21) 2.273(2), Pd(2)–Cl(12) 2.415(2), Pd(2)–Cl(22) 2.325(2), Pd(2)–P(22) 2.227(2); Cl(11)–Pd(1)–Cl(22) 92.48(5), Cl(11)–Pd(1)–P(12) 93.54(6), Cl(12)–Pd(1)–Cl(22) 83.88(5), Cl(12)–Pd(1)–P(12) 90.06(6), Cl(12)–Pd(2)–Cl(21) 91.70(6), Cl(12)–Pd(2)–Cl(22) 84.58(6), Cl(21)–Pd(2)–P(22) 88.19(7), Cl(22)–Pd(2)–P(22) 95.85(6), Pd(1)–Cl(12)–Pd(2) 89.50(6), Pd(1)–Cl(12)–Pd(2) 88.92(5).

above), which causes the $^{31}P$ NMR resonance to shift to higher field.[16] Simple phosphanes behave similarly; see, for instance, the pair of related complexes *trans*-[{Pd(μ-Cl)-Cl(L)}$_2$] ($\Delta\delta_P$ = 39.5 ppm) and *trans*-[$PdCl_2L_2$] ($\Delta\delta_P$ = 29.4 ppm), where L is tri-*p*-tolylphosphane.[15]

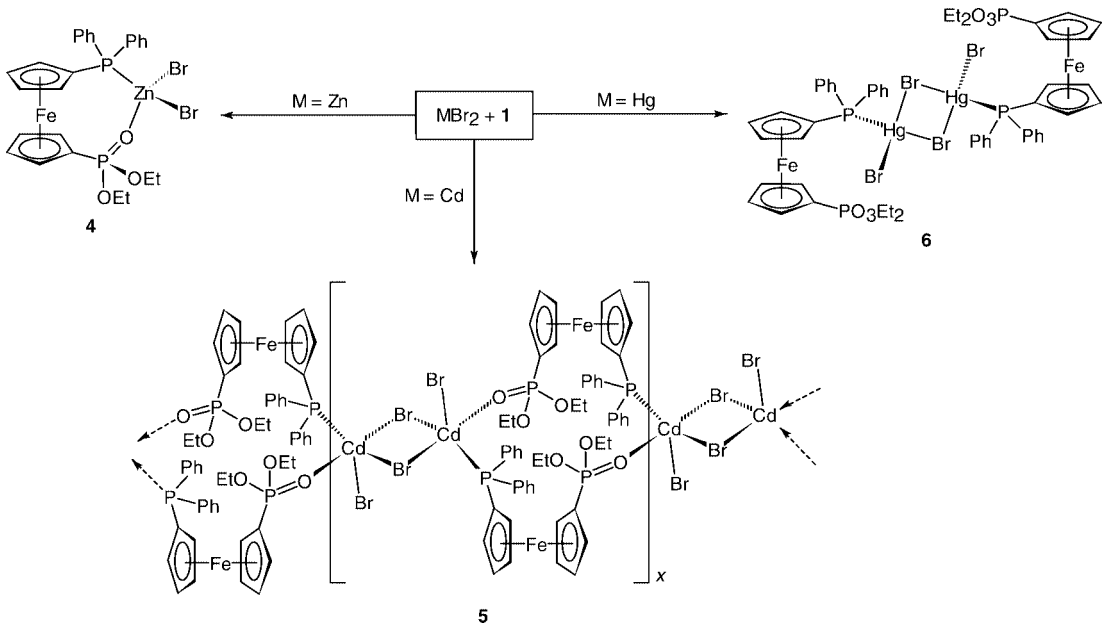
The $^1H$ NMR spectra of **3** spectra exhibit a shift to lower field for all ferrocene signals but virtually no change for the phosphonate ethoxy groups. The $^{13}C$ NMR spectrum displays resonances due to the carbon atoms at the phosphanyl-substituted cyclopentadienyl and phenyl rings as virtually coupled triplets arising from ABX spin systems [$^{12}C$-$^{31}P(A)$-(metal)-$^{31}P(B)$-$^{13}C(X)$] with relatively large $J_{A,B}$ values.[16] Very similar features have been observed for the related complex with P-monodentate 1′-(diphenylphosphanyl)ferrocenecarboxylic acid (Hdpf), *trans*-[$PdCl_2$(Hdpf-κ*P*)$_2$].[17] The solid-state structure of the solvate **3**·4$CHCl_3$ was determined by single-crystal X-ray diffraction analysis (see below).

### Group-12 Metal Complexes

Mixing the phosphanylphosphonate **1** with bromides of divalent group-12 metals in a 1:1 molar ratio in acetone and subsequent crystallisation by diffusion of diethyl ether vapour gave adducts [$MBr_2$(**1**)] [M = Zn (**4**), Cd (**5**), and Hg (**6**)] as air-stable, yellow-orange, crystalline solids.[18] However, the exact formulation for these compounds as based on spectral evidence and crystallographic data (see below) is rather complex and differs for all the members of the series. Thus, whereas compound **4** is a monomeric tetrahedral complex featuring **1** as an *O*,*P*-chelating donor, [$ZnBr_2$(**1**-κ$^2O^1$,$P^2$)], its cadmium analogue is a coordination polymer in which dinuclear {Cd(μ-Br)Br}$_2$ units are linked into infinite chains by means of symmetric pairs of the $O^1$,$P^2$-bridging phosphanylphosphonate ligands (see Scheme 2). This is reflected also by the very poor solubility of **5** compared to the well soluble **4** and **6**.

The $^{31}P$ NMR spectrum of **4** is clearly indicative of *O*,*P*-chelate coordination by showing a pair of doublets at $\delta_P$ = –19.9 and 26.1 ppm ($^3J_{P,P}$ = 5 Hz) assignable to the mutually coupled phosphane and phosphonate phosphorus atoms, respectively. The coordination shifts ($\Delta\delta_P$) of –2.9 ($P^{III}$) and +0.4 ($P^V$) ppm correspond favourably with the shifts observed for [$ZnCl_2$L] complexes with *P*,*P*′-chelating symmetric ferrocene diphosphanes [L/$\Delta\delta_P$ = dppf/–4.5 ppm,[19] and dippf/–6.6 ppm; dippf = 1,1′-bis(diisopropylphosphanyl)ferrocene],[20] and a complex containing two $O^1$-monodentate diethyl ferrocenylphosphonate ligands,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Schematic drawing of structures of the products arising from group-12 metal dibromides and **1**. For compound **5**, the arrows indicate where propagation of the one-dimensional infinite polymeric chain occurs.

$[ZnCl_2\{FcPO_3Et_2\text{-}\kappa O^1\}_2]$ ($\Delta\delta_P$ = +0.7 ppm in $CD_3OD$, Fc = ferrocenyl).[10c] Furthermore, the coordination of the phosphonate group is manifested by a shift of the multiplet due to the $OCH_2$ protons by about 0.3 ppm to lower field in the $^1H$ NMR spectrum.

The IR spectra of **4** and **5** in the region down to about 300 $cm^{-1}$ exhibit mostly bands due to the ligand; useful information about the coordination geometry is provided by the far-IR region. In the case of **4**, two bands attributable to symmetric and antisymmetric ν(ZnBr) stretching vibrations are observed at 219 and 251–254 $cm^{-1}$, respectively, close to the values reported for $[ZnBr_2(PPh_3)_2]$ (236 and 205 $cm^{-1}$).[21] The far-IR spectrum of **5** exhibits a pair of bands as well (at 193 and 158 $cm^{-1}$). The positions of these bands assignable to ν(CdBr) stretching vibrations involving terminal and bridging bromide atoms correspond to those of the binuclear, halide-bridged complex $[\{Cd(\mu\text{-}Br)Br(PCy_3)\}_2]$, which, however, features only tetracoordinate cadmium centres (208 and 169–144 $cm^{-1}$).[22] Notably, the ν(ZnBr)/ν(CdBr) ratios for the band pairs (1.31 and 1.39) correspond well to the expected value obtained from the mass factor: $[A_r(Cd)/A_r(Zn)]^{1/2} \approx 1.31$.

As revealed by X-ray analysis, compound **6** is a symmetric, halide-bridged dimer with the ligand coordinating as a simple phosphane: $[\{Hg(\mu\text{-}Br)Br(\mathbf{1}\text{-}\kappa P^2)\}_2]$ (Scheme 2). The solution NMR spectroscopic data, particularly the relatively large $^1J_{Hg,P}$ coupling constant and the coordination shift $\Delta\delta_P(P^{III})$ of 41.4 ppm, indicate that this structure is most likely retained in solution (cf. the parameters for $[HgBr_2(PPh_3)_2]$ ($^1J_{Hg,P}$ = 4240 Hz/$\Delta\delta_P$ = 27.3 ppm) and $[\{Hg(\mu\text{-}Br)Br(PPh_3)\}_2]$ ($^1J_{Hg,P}$ = 6450 Hz/$\Delta\delta_P$ = 32.6 ppm) recorded in $CDCl_3/CH_2Cl_2$, 1:1[23]). However, a detailed NMR study revealed a fluxional behaviour in solution: the spectra of **6** change with temperature, solvent and also with the sample concentration (see Table 1 and Figures S1 and S2 in the Supporting Information). Upon raising the sample temperature, the signal due to the phosphane group ($P^{III}$) in the $^{31}P$ NMR spectrum shifts to lower fields while the coupling to $^{199}Hg$ increases. In contrast, the phosphonate resonance moves upfield with increasing temperature. In the $^1H$ NMR spectrum the major change occurs in the region of the ferrocene cyclopentadienyl resonances: the signals due to the phosphonate ethoxy groups exhibit practically constant chemical shifts (note that the multiplet of the methylene group is not entirely invariant as it becomes better resolved at *higher* temperatures).

Table 1. Variable temperature (VT) $^{31}P\{^1H\}$ NMR spectroscopic data for **6**.[a]

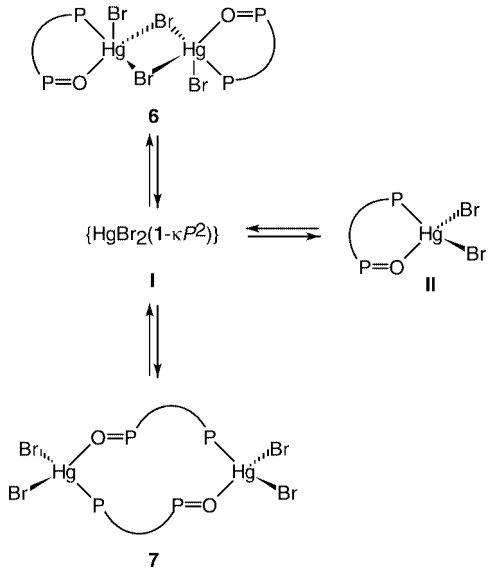
| *T* [°C] | $\delta(P^V)$ [ppm] | $\delta(P^{III})$ [ppm] | $^1J_{Hg,P^{III}}$ [Hz] |
|---|---|---|---|
| +50 | 23.73 | – | –[b] |
| +25 | 23.88 | 24.38 | 6587 |
| 0 | 24.06 | 23.69 | 6702 |
| –25 | 24.22 | 23.52 | 6809 |
| –50 | 24.35 | 23.02 | 6908 |
| +25[c] | 23.88 | 24.56 | 6560 |

[a] The spectra were recorded for a 0.036 M solution in $CDCl_3$. The VT $^1H$ and $^{31}P\{^1H\}$ NMR spectra are available as Supporting Information (see Figures S1 and S2, respectively). Reference data for **1**: $\delta_P$ = –17.0 ($P^{III}$) and 25.7 ppm ($P^V$) (in $CDCl_3$ at 25 °C). [b] Not detected due to signal broadening. [c] Data for a 0.018 M solution.

These spectral characteristics resemble in some respects the solution behaviour of the phosphane complexes $[HgX_2(PR_3)_2]$,[23] and are clearly indicative of structural fluxionality. Considering the NMR and structural data (see below), as well as the donor ability of the ligand, the dynamic processes occurring in solutions of $[HgBr_2(\mathbf{1})]$ may

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

be formulated as shown in Scheme 3. One may expect the hybrid donor **1** to coordinate to the soft mercury atom more strongly through its phosphane group than through the phosphonate oxygen. The inherent weakness of Hg–O bonds would facilitate the formation of tricoordinate species **I** which, in turn, can give rise to intermediate **II** (by closure of the *O*,*P*-chelate ring with the Hg–P bond acting as a pivot) or, by dimerisation, to the halide (**6**) or *O*,*P*-**1**-bridged (**7**) dimers. As mentioned above, the NMR spectroscopic data indicate that the solution equilibrium is shifted in favour of dimer **6**. However, since solvent, concentration and temperature influence the overall distribution, individual components may separate from solutions of [$HgBr_2$(**1**)] depending on their relative solubility in the reaction media (see the structure of **7** below).



Scheme 3. Schematic depiction of the exchange equilibria of [$HgBr_2$(**1**)].

## Crystal Structures

The crystal structure of the solvate **3**·4$CHCl_3$ (Figure 3, Table 2) corroborates the expected *trans* square-planar coordination of the palladium atom. The molecule of the complex is perfectly planar and centrosymmetric due to the imposed crystallographic symmetry. Nevertheless, owing to the steric bulk of the P-bonded (diphenylphosphanyl)ferrocenyl ligands, the interligand angles deviate slightly from the ideal value of 90°. The ferrocene units in **3** are rotated with respect to the coordination plane by approximately 53°, which seems to minimise the steric interactions of the bulky phosphane ligands by bringing the "$PC_3$" moieties of the phosphanylferrocene ligands into a close-to-staggered conformation. This coordination geometry seems to be common to all structurally characterised complexes involving 1′-functionalised ferrocene phosphanes: *trans*-[$PdCl_2$($Ph_2$PfcX-κ*P*)], where X = $CO_2H$,[17] $P(O)Ph_2$,[24] SMe,[25] and (*S*)-4-isopropyl-4,5-dihydrooxazolyl-1-yl.[26]

The ligand phosphonate groups, which do not participate in coordination, are rotated away from the phosphanyl substituent such that the disubstituted ferrocene framework adopts a conformation near to anti-eclipsed with a $\tau$ angle of 136° (cf. the ideal value of 144°). Due to the symmetry of the crystal assembly, the phosphonate groups in individual molecules are inclined towards each other, forming polar domains that accommodate the solvate: each phosphonate moiety binds two solvent molecules by O···H–$CCl_3$ hydrogen bonds to its phosphoryl oxygen atom [C(80)–H(80)···O(1$^i$): C(80)···O(1$^i$) 3.134(5) Å, angle at H(80) 147°; C(90)–H(90)···O(1$^i$): C(90)···O(1$^i$) 3.014(5) Å, angle at H(80) 167°; $i$ ($x$, 1 + $y$, $z$). Consequently, the overall crystal packing can be described as molecular, built up from {**2**$(CHCl_3)_4$} repeating units.

As mentioned above, the solid-state structures of 1:1 complexes involving all group-12 metals [$MBr_2$(**1**)] [M = Zn (**4**), Cd (**5**) and Hg (**6**)] were established by single-crystal X-ray diffraction. Furthermore, an isomer of the latter compound (denoted as **7**, Scheme 3) was also structurally characterised. Crystals of **7** suitable for diffraction analysis were obtained from an attempted alkylation of **6** with iodomethane in methanol, followed by evaporation and crystallisation of the residue from acetone/diethyl ether. Although the IR and solution NMR spectra of the bulk material are virtually identical with the starting material **6**, their crystal structures differ markedly. Structural drawings for **4**–**7** are shown below; selected structural parameters are listed in the appropriate tables.

Clearly, the structures change with the metal and are dictated by a subtle interplay between the hardness of the central atom and the donor abilities of the functional groups available at the ferrocene ligand. With zinc, the smallest and hardest (though polarizable) metal in group 12, the ligand coordinates through both donor groups to form a molecular chelate (Figure 4, Table 3). The unit cell of **4** contains two symmetrically independent but structurally very similar molecules of the complex that differ slightly in the mutual orientation of the ferrocene ligand and the embedded $ZnBr_2$ motif, and further by conformation of the flexible ferrocene, phenyl and ethoxy groups. The coordination spheres around the zinc atoms in both molecules are quite regularly tetrahedral, albeit with rather varying zinc–donor distances: the coordination mode can be described as [3+1] with Zn–Br ≈ Zn–P > Zn–O. The individual bond lengths are comparable with the data reported for

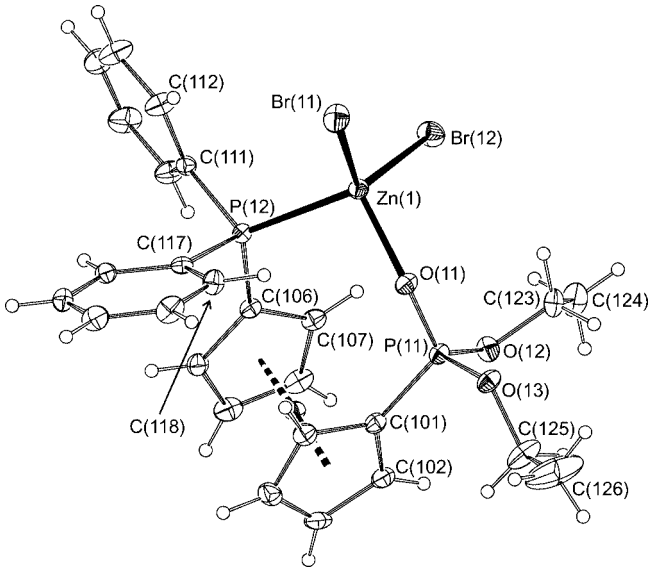

Figure 4. A view of the molecular structure of complex **4** (molecule 1). Displacement ellipsoids enclose 30% probability. Atom labels for molecule 2 (see text) are obtained by adding one to the first digit of the respective atom label in molecule 1.

The solid-state structure of cadmium complex **5** (Figure 5) is relatively complicated (Scheme 2, Table 4). Formally, the "$CdBr_2$" units associate into dimers through two bromide bridges. In addition, each cadmium atom is coordinated to two phosphanylphosphonate ligands (once through P=*O* and once through *P*$Ph_2$) and thus has a coordination number of five. The dicadmium $\{Cd_2Br_4\}$ units are interconnected by means of symmetric ligand pairs to form infinite one-dimensional ribbons (Scheme 2; see also Figure 6).

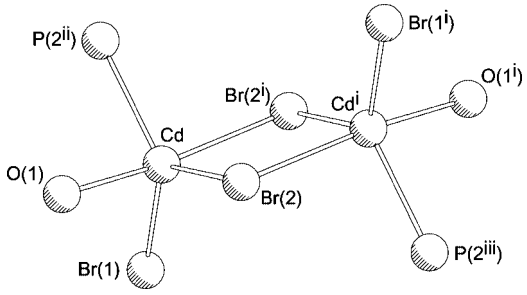

Figure 5. A view of the dicadmium core in **5**. Atomic radii correspond to the isotropic displacement parameters ($U_{iso}$); symmetry codes: *i*: 1 – *x*, 1 – *y*, –*z*; *ii*: 1 – *x*, 1 – *y*, 1 – *z*; *iii*: *x*, *y*, *z* – 1.

The dicadmium core in **5** (Figure 5) is centrosymmetric and its geometry is best described as two identical trigonal bipyramids sharing an edge connecting the axial and equatorial positions. Because of the steric demands of the ligands and the different cadmium–donor distances [Cd–O(1$^i$) < Cd–Br(1) < Cd–P(2$^{ii}$) ≈ Cd–Br(2) < Cd–Br(2$^i$); for symmetry codes, see Figure 5], the trigonal bipyramidal arrangements are markedly distorted. Nonetheless, the structural index parameter proposed by Addison et al.[27] allows us to classify the donor set around the cadmium atoms as trigonal bipyramid rather than a square pyramid (this parameter has a value of 0.76; the values for an idealised trigonal bipyramid and square pyramid are 1 and 0, respectively). It should be noted that pentacoordinate cadmium centres are relatively common, in line with the larger atomic radius of the metal,[28] and has even precedents among structurally characterised complexes featuring simple[29a] and functionalised phosphanes.[29b,29c]

The molecular structure of mercury complex **6** seems, a priori, to be different from **5** as it consists of dimeric $[\{HgBr_2(\mathbf{1}\text{-}\kappa P^2)\}_2]$ units (Figure 7, Table 5) as commonly observed for 1:1 phosphane–mercury(II) halide complexes. However, a closer inspection of the crystal structure reveals the structures to be very similar. The atoms within the cells of both compounds are distributed in a similar manner (see Figure 6), which brings the phosphoryl oxygen O(1) and mercury atoms from neighbouring molecules into proximity [Hg···O = 2.788(2) Å]. Thus, the O(1) atom is capping the {Br(1),Br(2),P(2)} face of a severely distorted tetrahedral donor array formed by phosphane and bromide ligands, although somewhat asymmetrically with respect to the Hg–Br(2$^i$) axis (*i*: 1 – *x*, –*y*, 1 – *z*), being displaced towards the Br(2)···P(2) edge. As a result, the primary donor set around the mercury atom exhibits severe angular deformation. The protrusion of an extra donor into the coordination sphere of mercury leads to a considerable opening of the Br(2)–Hg–P(2) and, mainly, Br(1)–Hg–P(2) angles (up to about 134° in the latter case), which is compensated by closure of the Br(2)–Hg–Br(2$^i$) and Br(2$^i$)–Hg–P(2) angles. It should be noted that in view of the asymmetric "[4+1]" donor environment around the mercury atom, the bonding situation can be described equally well as highly distorted trigonal pyramidal.

The coordination sphere around the mercury atom in **6** is also asymmetric as far as the mercury–donor atom bond lengths are concerned: the three different Hg–Br bond lengths vary by as much as 0.45 Å. As expected, the bond to the terminal bromide Hg–Br(1) is the shortest one while the Hg–Br(2$^i$) distance is the longest. This clearly points to a competition between the O(1) and Br(2$^i$) atoms for the coordination site at the mercury.

The bonding situation in solid **7**, yet another isomer of the $[HgBr_2(\mathbf{1})]$ adduct, is more straightforward. The crystal structure (Figure 8, Table 6) consists of discrete centrosymmetric dimers where two phosphanylphosphonate ligands span two $HgBr_2$ units {i.e., **7** can be formulated as $[(\mu\text{-}1\kappa P^2{:}2\kappa O^1\text{-}\mathbf{1})(\mu\text{-}1\kappa O^1{:}2\kappa P^2\text{-}\mathbf{1})(HgBr_2)_2]$}. The coordination sphere around the mercury centres departs slightly from a regular tetrahedron, most likely due to the presence of the sterically encumbered phosphanylferrocene moiety and its orientation towards the {Hg,Br(1),Br(2)} plane: the P(2)–Hg–Br(1,2) angles are less acute, which, in turn, causes a closure of the O(2$^{ii}$)–Hg–Br(1,2) and O(2$^{ii}$)–Hg–P(1) angles (*i*: –*x*, 2 – *y*, –*z*). However, the deformation is much less pronounced than in **6**. The Hg–Br distances in **7** are very similar and do not differ much from the remaining Hg–

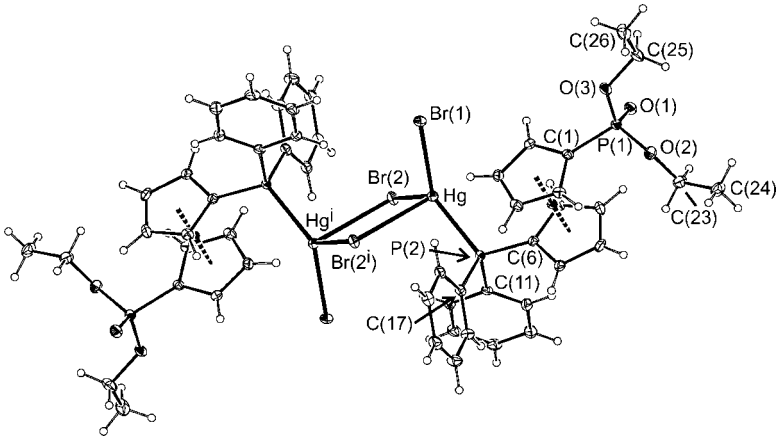

Figure 7. A view of the molecular structure of complex **6** as determined for the solvate **6**·5$C_6H_6$ (solvent molecules have been omitted for clarity). The dimeric molecule is perfectly centrosymmetric due to the imposed symmetry: the halves lie across the crystallographic inversion centre that coincides with the midpoint of the central {$Hg_2Br_2$} ring. Displacement ellipsoids are drawn with 30% probability. Symmetry operations: *i*: 1 – *x*, –*y*, 1 – *z*.

donor bond lengths (compare with **6**). Remarkably, the Hg–O(1$^{ii}$) distance in **7** is only about 5% shorter than that in **6**.[30]

A comparison of the structures determined for the free and several forms of coordinated ligand **1** reveals that coordination of the ligand moiety does not alter its structure in any significant way. The P=O bond lengths are practically identical in all compounds regardless of whether the phosphonate group is free or bonded to a metal (the relative elongation accompanying the coordination is typically less

than 1%). Likewise, the O–P–O angles at the phosphonate group do not change upon coordination; in all the structures determined, the O(1)–P(1)–O(2,3) angles are about 10–15° less acute than the remaining angle O(2)–P(1)–O(3). On the other hand, the coordination of the diphenylphosphanyl moiety leads to a slight opening of the C–P(2)–C angles, which thus approach values closer to the tetrahedral ones, albeit without influencing the P(2)–C bond lengths in any significant manner.

More importantly, coordination causes conformational changes to the ferrocene framework. In the free ligand as well and in the complexes, where it acts as an O,P bridge in a discrete dimer (**7**), a polymeric chain (**5**), and in a supramolecularly interacting assembly (**6**), the 1,1′-disubstituted ferrocene unit adopts a conformation between *syn*-eclipsed ($\tau$ = 144°) and *anti*-staggered ($\tau$ = 180°), with the torsion angles falling in the very narrow range of 155–156°.[31] On the other hand, the $P^2$-monodentate ligands in hydrated **2** and **3**·4 $CHCl_3$ have the donor groups rotated towards each other, as indicated by $\tau$ values of 103/92° (for ligand moieties 1/2) and about 136°, respectively. Chelate coordination of **1** in the zinc(II) complex **4** brings the donor groups even further into proximity, which is reflected by the $\tau$ values of around 53° and 60° for molecules 1 and 2, respectively, indicating an intermediate conformation between *syn*-staggered (36°) and *syn*-eclipsed (72°) for the ferrocene unit.

## Conclusions

In summary, organometallic phosphanylphosphonate **1**, which is accessible in good yield by sequential metallation/functionalisation of 1,1′-dibromoferrocene, is a typical example of a hybrid ligand that is novel to ferrocene chemistry. In palladium(II) complexes it binds predominantly through the phosphanyl group. However, the participation

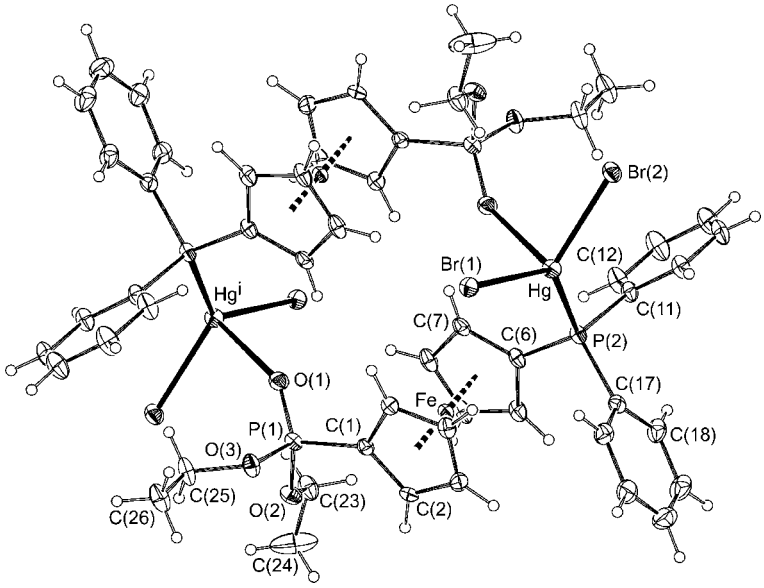

Figure 8. Molecular structure of compound **7**. Similarly to **6**, the parts of the dimeric structure are related by a crystallographic inversion operation. Displacement ellipsoids are shown with 30% probability.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in coordination of the hard phosphonate group can be triggered by increasing the hardness of the ligated metal. This is exemplified by the crystal structures of group-12 metal complexes **4**–**7**, where the increasing hardness of the metal cation results in an increase of the role of $O^1 \rightarrow M$ dative bonding. The hybrid nature of **1** is reflected also by the behaviour of "[$HgBr_2$(**1**)]" in solution: the presence of a weakly coordinating group (phosphonate) renders this adduct structurally fluxional and also allows for isolation of isomeric complexes (**6** and **7**).

It should be pointed out that the direct structural (crystallographic) data discussed in this paper represent the most complete series available thus far for a single phosphanylphosphonate ligand.[32] The data not only demonstrate the flexible nature of **1** as a ligand in the individual molecules of the complexes but also its potential to act as a building block in supramolecular coordination structures. Further investigations into the coordination properties of **1** aimed at new structural motifs are currently underway.

## Experimental Section

**Materials and Methods:** The synthesis of **1** was carried out under argon using tetrahydrofuran (THF) freshly distilled from potassium-benzophenone ketyl. The complexes were synthesised in argon-flushed vessels with exclusion of direct daylight. Chloroform and benzene were dried with anhydrous potassium carbonate and potassium, respectively. Acetone was dried with phosphorus pentoxide, distilled, and stored over activated molecular sieves (4 Å). 1-Bromo-1′-(diphenylphosphanyl)ferrocene was prepared from 1,1′-dibromoferrocene as reported in the literature.[7a] Other chemicals (Lachema, Fluka) and solvents used for crystallisations (methanol, diethyl ether and hexane; Lachema) were used as received.

NMR spectra were recorded with a Varian Unity Inova spectrometer ($^1$H: 399.95; $^{13}$C: 100.58; $^{31}$P: 161.90 MHz) at 25 °C (unless noted otherwise). Chemical shifts ($\delta$, ppm) are given relative to internal tetramethylsilane ($^{13}$C and $^1$H) or to external 85% aqueous $H_3PO_4$ ($^{31}$P). The phosphorus-substituted cyclopentadienyl rings represent AA′BB′X spin systems (A, B = $^1$H, X = $^{31}$P), which give rise to characteristic non-binomial multiplets in the $^1$H NMR spectra. Hence, the multiplicity of the signals of these magnetically nonequivalent protons is given as virtual triplet (vt) or virtual quartet (vq). A similar notation is used for virtual triplets occurring in the $^{13}$C{$^1$H} NMR spectrum of **3**. Note: the $J'$ values given below represent an average of the $^{(n)}J_{P,C}$ and $^{(n+2)}J_{P,C}$ coupling constants in the ABX spin system $^{12}$C-$^{31}$P(*A*)-(metal)-$^{31}$P(*B*)-$^{13}$C(*X*).[16] IR spectra were measured with an FT IR Nicolet Magna 650 (all compounds in the range 4000–400 cm$^{-1}$, the complexes also in the far-IR region: 600–100 cm$^{-1}$). Positive-ion electron impact (EI) and fast atom bombardment (FAB) mass spectra were measured with a ZAB SEQ spectrometer. Electrospray (ESI) mass spectra were recorded with a Bruker Esquire 3000 spectrometer; the samples were dissolved in methanol or firstly in a little chloroform and then diluted with a large excess of methanol.

**Diethyl [1′-(Diphenylphosphanyl)ferrocenyl]phosphonate (1):** Butyllithium (2.4 mL 2.5 M in hexanes, 6 mmol) was slowly added to a stirred solution of 1-bromo-1′-(diphenylphosphanyl)ferrocene (2.25 g, 5.0 mmol) in THF (50 mL) at –80 °C (temperature in bath). The mixture, which darkened somewhat during the addition, was stirred for another 30 min at the same temperature and then treated with diethyl chlorophosphate (0.9 mL, 6 mmol). The resulting yellow-brown solution was stirred for another 15 min at –80 °C and then for 3 h at room temperature. The mixture was evaporated under reduced pressure and the resulting orange-brown oil (containing precipitated LiCl) was purified by column chromatography on alumina with chloroform/diethyl ether (2:3) as the eluent. The first fraction containing mostly (diphenylphosphanyl)ferrocene was discarded and the second, major band was collected and carefully evaporated under vacuum to give **1** as a viscous, amber oil, which crystallised upon standing at +4 °C. Yield: 2.185 g (86%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.30 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, $CH_3$), 4.03–4.14 (m, 4 H, $OCH_2$), 4.21 (vt, 2 H), 4.26 (d of vt, 2 H), 4.39 (vq, 2 H), 4.58 (vt, 2 H) (fc), 7.29–7.38 (m, 10 H, $PPh_2$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 16.44 (d, $^3J_{P,C}$ = 7 Hz, $CH_3$), 61.73 (d, $^2J_{P,C}$ = 6 Hz, $OCH_2$), 67.59 (d, $^1J_{P,C}$ = 215 Hz, $CP^V$ of fc), 72.29 (d, $J_{P,C}$ = 15 Hz), 72.92 (dd, $J_{P,C}$ = 14 and 1 Hz), 73.39 (d, $J_{P,C}$ = 4 Hz), 74.26 (d, $J_{P,C}$ = 14 Hz) (4 × CH of fc), 77.70 (d, $^1J_{P,C}$ = 8 Hz, $CP^{III}$ of fc), 128.19 (d, $J_{P,C}$ = 7 Hz), 128.62, 133.44 (d, $J_{P,C}$ = 20 Hz) (3 × CH of $PPh_2$), 138.60 (d, $^1J_{P,C}$ = 10 Hz, $C_{ipso}$ of $PPh_2$) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = –17.0 ($P^{III}$), +25.7 ($P^V$) ppm. IR (neat): $\tilde{\nu}$ = 3069 (m), 3052 (m), 2981 (s), 2903 (m) ν(C–H); 1478 (s), 1434 (s), 1389 (s), 1369 (m), 1249 (vs), 1188 (s), 1162 (m), 1096 (m), 1050 (vs), 1030 (vs), 961 (vs), 831 (s), 794 (m), 746 (s), 699 (s), 595 (s), 492 (s), 454 (m) cm$^{-1}$. EI MS: *m*/*z* (%) = 507 (25), 506 (100) [$M^{+\cdot}$], 449 (5) [M – $C_4H_9$]$^+$ or [M – $C_2H_5$ – $C_2H_4$]$^+$, 321 (12) (possibly [$FeC_5H_4POPh_2$]$^+$; see ref.[33]), 226 (6), 225 (18), 201 (19), 198 (6), 197 (5), 183 (35), 171 (16), 170 (10), 141 (5), 133 (8), 121 (14), 119 (13), 56 (5). HRMS calcd. for $C_{26}H_{28}{}^{56}FeO_3P_2$: 506.0863; found 506.0860.

**Preparation of *trans*-[{Pd(μ-Cl)Cl(1-κ*P*$^2$)}$_2$] (2):** Solid [$PdCl_2$(cod)] (57 mg, 0.20 mmol) and **1** (107 mg, 0.21 mmol) were mixed with methanol (3 mL). The solids quickly dissolved to give a burgundy-red solution. The mixture was stirred at room temperature for 90 min and then allowed to stand at –18 °C for several days. The separated microcrystalline solid was filtered off, washed with diethyl ether and dried under vacuum. Yield: 105 mg (76%) of dark red-brown solid (the product typically contains traces of **2** detectable in the $^{31}$P NMR spectrum). A crystal selected directly from the reaction mixture (prior to the isolation) was shown to be the solvate **2**·½$H_2O$. $^1$H NMR ($CDCl_3$): $\delta$ = 1.33 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, $CH_3$), 4.07–4.20 (m, 4 H, $OCH_2$), 4.70 (vq, 2 H), 4.76 (vq, 4 H), 4.81 (vq, 2 H), 5.27 (br. s, 2 H) (fc), 7.34–7.65 (m, 10 H, $PPh_2$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 16.49 (d, $^3J_{P,C}$ = 6 Hz, $CH_3$), 62.03 (d, $^2J_{P,C}$ = 6 Hz, $OCH_2$), 68.96 (very br. d, $^1J_{P,C} \approx$ 210 Hz, $CP^V$ of fc), 70.22 (d, $^1J_{P,C}$ = 67 Hz, $CP^{III}$ of fc), 73.59 (d, $J_{P,C}$ = 15 Hz), 74.35 (d, $J_{P,C}$ = 9 Hz), 75.89 (d, $J_{P,C}$ = 13 Hz), approx. 76.97 (d, $J_{P,C} \approx$ 10 Hz, CH of fc; partly obscured by the solvent signal), 128.23 (d, $J_{P,C}$ = 6 Hz, CH of $PPh_2$), 128.34 (d, $^1J_{P,C}$ = 61 Hz, $C_{ipso}$ of $PPh_2$), 134.69 (d, $J_{P,C}$ = 2 Hz), 133.70 (d, $J_{P,C}$ = 12 Hz, CH of $PPh_2$) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = +24.6 ($P^V$), +31.1 ppm ($P^{III}$) (tentative assignment). IR (Nujol): $\tilde{\nu}$ = 1246 (m), 1184 (m), 1166 (m), 1100 (m), 1027 (vs), 969 (m), 956 (m), 842 (w), 753 (m), 692 (m), 594 (m), 545 (m), 522 (m), 480 (s) cm$^{-1}$. Far-IR (polyethene): $\tilde{\nu}$ = 356 (s), 350 (sh), 258 (s), 147 (m), 229 (w), 155 (w) cm$^{-1}$. ESI MS: *m*/*z* = 933, 647 [Pd(**1**)Cl]$^+$. $C_{52}H_{56}Cl_4Fe_2O_6P_4Pd_2$ (1367.3): calcd. C 45.68, H 4.13; found C 45.24, H 4.17.

**Preparation of *trans*-[$PdCl_2$(1-κ*P*$^2$)$_2$] (3):** Neat **1** (112 mg, 0.22 mmol) was added to a suspension of [$PdCl_2$(cod)] (29 mg, 0.10 mmol) in chloroform (4 mL). The yellow complex quickly dissolved to give a red solution, which was allowed to stand for 30 min at room temperature and was then layered with hexane (ca. 10 mL) and allowed to crystallise at 0 °C for several days to afford **2** as an orange, crystalline solid. The complex forms solvates with varying chloroform content: the crystals isolated directly from the mother

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

liquor and immediately analysed by X-ray diffractions were shown to be the solvate **3**·4 $CHCl_3$. The main portion of the crystalline product, which was isolated by filtration, washed with a little hexane and dried in air, was characterised as **3**·3 $CHCl_3$ (114 mg, 74%; orange crystals). $^1H$ NMR ($CDCl_3$): $\delta$ = 1.30 (td, $^3J_{H,H}$ = 7.1, $^4J_{P,H}$ = 0.5 Hz, 6 H, $CH_3$), 4.02–4.15 (m, 4 H, $OCH_2$), 4.58 (vq, 2 H), 4.66 (s, 4 H), 4.89 (d of vt, 2 H) (fc), 7.34–7.62 (m, 10 H, $PPh_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 16.45 (d, $^3J_{P,C}$ = 7 Hz, $CH_3$), 61.85 (d, $^2J_{P,C}$ = 6 Hz, $OCH_2$), 68.33 (d, $^1J_{P,C}$ = 214 Hz, $CP^V$ of fc), 72.83 (vt, $J'$ = 27 Hz, $CP^{III}$ of fc), 72.95 (d, $J_{P,C}$ = 15 Hz, CH of $C_5H_4P^V$), 74.35 (vt, $J'$ = 4 Hz, CH of $C_5H_4P^{III}$), 74.92 (d, $J_{P,C}$ = 13 Hz, CH of $C_5H_4P^V$), 76.70 (m, CH of $C_5H_4P^{III}$; obscured by the solvent signal), 127.84 (vt, $J'$ = 5 Hz), 130.43 (2 × CH of $PPh_2$), 130.90 (vt, $J'$ = 25 Hz, $C_{ipso}$ of $PPh_2$), 134.11 (vt, $J'$ = 6 Hz, CH of $PPh_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = +15.3 ($P^{III}$), +25.1 ($P^V$) ppm. IR (Nujol): $\tilde{\nu}$ = 1248 (s), 1179 (s), 1169 (s), 1096 (m), 1056 (s), 1030 (vs), 965 (vs), 836 (m), 797 (m), 745 (s), 692 (m), 592 (m), 504 (s) $cm^{-1}$. Far-IR (polyethene): $\tilde{\nu}$ = 354 (m), 189 (w) $cm^{-1}$. ESI MS: *m/z* = 1211/1213 $[M + Na]^+$, 1153/1155 $[M - Cl]^+$, 1119/1121 $[Pd(\mathbf{1}) + H]^+$, 861 $[Pd(\mathbf{1})_2 - FeC_5H_4PO_3Et_2]^+$. $C_{52}H_{56}Cl_2Fe_2O_6P_4Pd$·3 $CHCl_3$ (1654.5): calcd. C 42.67, H 3.84; found C 42.71, H 3.82.

**Preparation of [$ZnBr_2$(1-κ$^2O^1$,$P^2$)] (4):** Phosphonate **1** (58 mg, 0.11 mmol) and anhydrous zinc(II) bromide (23 mg, 0.10 mmol) were dissolved in acetone (2 mL). The resulting orange solution was stirred for one day and then allowed to crystallise by diffusion of diethyl ether vapour. Well-developed orange crystals of the product, which formed during several days, were filtered off, washed with hexane and dried under reduced pressure. Yield: 52 mg (71%). $^1H$ NMR ($CDCl_3$): $\delta$ = 1.41 (td, $^3J_{H,H}$ = 7.0, $^4J_{P,H}$ = 0.7 Hz, 6 H, $CH_3$), 4.26–4.37 (m, 4 H, $OCH_2$ and CH of fc), 4.45 (ddq, *J* = 7.8, 9.9 Hz, $^3J_{H,H}$ = 7.0 Hz, 2 H, $OCH_2$), 4.56 (vq, 2 H), 4.65 (d of vt, 2 H), 4.79 (vq, 2 H) (fc), 7.39–7.71 (m, 10 H, $PPh_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 16.19 (d, $^3J_{P,C}$ = 7 Hz, $CH_3$), 64.46 (d, $^1J_{P,C}$ = 223 Hz, $CP^V$ of fc), 64.61 (d, $^2J_{P,C}$ = 6 Hz, $OCH_2$), 69.19 (d, $^1J_{P,C}$ = 42 Hz, $CP^{III}$ of fc), 72.83 (d, $J_{P,C}$ = 15 Hz), 73.37 (d, $J_{P,C}$ = 7 Hz), 73.62 (d, $J_{P,C}$ = 16 Hz), 75.52 (d, $J_{P,C}$ = 11 Hz) (CH of fc), 128.88 (d, $J_{P,C}$ = 7 Hz, CH of $PPh_2$), 129.37 (d, $^1J_{P,C}$ = 38 Hz, $C_{ipso}$ of $PPh_2$), 131.06 (d, $J_{P,C}$ = 2 Hz), 133.74 (d, $J_{P,C}$ = 13 Hz) (CH of $PPh_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = –19.9 (d, $^3J_{P,P}$ = 5 Hz, $P^{III}$), +26.1 (d, $^3J_{P,P}$ = 5 Hz, $P^V$). IR (Nujol): $\tilde{\nu}$ = 1212 (s), 1177 (s), 1100 (m), 1027 (vs), 983 (w), 966 (w), 845 (w), 828 (m), 813 (m), 754 (m), 743 (m), 694 (m), 592 (s), 489 (s), 466 (s) $cm^{-1}$. Far-IR (polyethene): $\tilde{\nu}$ = 356 (m), 317 (m), 317 (m), 2351 (s), 244 (s), 219 (s) $cm^{-1}$. ESI MS: *m/z* = 651 $[Zn(\mathbf{1})Br]^+$, 529 $[\mathbf{1} + Na]^+$. $C_{26}H_{28}Br_2FeO_3P_2Zn$ (731.50): calcd. C 42.69, H 3.86; found C 42.68, H 3.76.

**Preparation of [$CdBr_2$(1-κ$^2O$,$P^2$)] (5):** Phosphonate **1** (56 mg, 0.11 mmol) and $CdBr_2$·4 $H_2O$ (35 mg, 0.10 mmol) were suspended in a mixture of acetone (2 mL) and methanol (1 mL), and the reaction mixture was stirred for 1 d. The solids quickly dissolved to give a clear, orange solution. Crystallisation and isolation as above afforded **5** as an orange, crystalline solid (64 mg, 82%). IR (Nujol): $\tilde{\nu}$ = 1212 (vs), 1178 (vs), 1095 (m), 1067 (m), 1047 (m), 1022 (vs), 982 (m), 964 (m), 837 (w), 795 (w), 751 (s), 697 (s), 591 (s), 498 (s), 486 (m), 458 (w), 442 (w) $cm^{-1}$. Far-IR (polyethene): $\tilde{\nu}$ = 367 (m), 336 (m), 321 (m), 266 (m), 254 (m), 214 (w), 193 (s), 158 (s), 116 (m) $cm^{-1}$. ESI MS: *m/z* = 699 $[Cd(\mathbf{1})Br]^+$, 529 $[\mathbf{1} + Na]^+$. $C_{26}H_{28}CdBr_2FeO_3P_2$ (778.52): calcd. C 40.11, H 3.63; found C 40.04, H 3.62.

**Reaction of $HgBr_2$ with 1 to Form 6:** A mixture of phosphonate **1** (57 mg, 0.11 mmol), $HgBr_2$ (36 mg, 0.10 mmol) and acetone (2 mL) was stirred at room temperature. The solids dissolved quickly to give a clear, orange solution, which immediately deposited a yellow precipitate. After stirring for 30 min, the mixture was transferred to a freezer and allowed to stand at –18 °C overnight. The separated solid was filtered off, washed with diethyl ether (3 × 2 mL) and dried under vacuum. Yield of **6**: 75 mg (87%) of a yellow, powdery solid. A similar reaction in benzene as the solvent (3 mL) gave the microcrystalline solvate **6**·5 $C_6H_6$, which quickly decomposes in air by losing solvent. Crystals suitable for X-ray measurements were taken directly from the reaction and covered with paraffin oil to prevent their decomposition. The selected specimen was fixed onto a glass fibre with wax and transferred to the diffractometer (see also X-ray crystallography below). $^1H$ NMR ($CDCl_3$): $\delta$ = 1.29 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, $CH_3$), 4.00–4.14 (m, 4 H, $OCH_2$), 4.47 (vq, 2 H), 4.69 (d of vt, 2 H), 4.77 (br. vq, 2 H), 4.86 (br. vt, 2 H) (fc), 7.52–7.79 (m, 10 H, $PPh_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 16.42 (d, $^3J_{P,C}$ = 7 Hz, $CH_3$), 62.05 (d, $^2J_{P,C}$ = 6 Hz, $OCH_2$), 68.11 (d, $^1J_{P,C}$ = 60 Hz, $CP^{III}$ of fc), 69.11 (d, $^1J_{P,C}$ = 60 Hz, $CP^V$ of fc), 73.34 (d, $J_{P,C}$ = 15 Hz), 74.30 (d, $J_{P,C}$ = 13 Hz), 75.08 (d, $J_{P,C}$ = 13 Hz), 75.94 (d, $J_{P,C}$ = 9 Hz) (CH of fc), 127.71 (d, $^1J_{P,C}$ = 54 Hz, $C_{ipso}$ of $PPh_2$), 129.55 (d, $J_{P,C}$ = 12 Hz, CH of $PPh_2$), 132.46 (d, $J_{P,C}$ = 3 Hz), 133.53 (d, $J_{P,C}$ = 13 Hz) (CH of $PPh_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 24.3 (s with $^{199}Hg$ satellites, $^1J_{Hg,P}$ = 6610 Hz, $P^{III}$), +23.9 (d, $^3J_{P,P}$ = 5 Hz, $P^V$). Note: the spectra change with the sample concentration (see Table 1). IR (Nujol): $\tilde{\nu}$ = 1225 (s), 1185 (m), 1099 (m), 1065 (m), 1051 (m), 1019 (s), 977 (w), 963 (m), 845 (m), 750 (m), 694 (m), 596 (m), 518 (w), 498 (s), 845 (w), 468 (w) $cm^{-1}$. Far IR (polyethene): $\tilde{\nu}$ = 343 (w), 316 (w), 264 (w), 254 (m), ν(HgBr) 182 (sh), 176 (s) $cm^{-1}$. ESI MS: *m/z* = 787 $[Hg(\mathbf{1})Br]^+$, 529 $[\mathbf{1} + Na]^+$. $C_{26}H_{28}Br_2FeHgO_3P_2$ (866.70): calcd. C 36.03, H 3.26; found C 35.95, H 3.24.

**Attempted Alkylation of 6. Isolation of 7:** Neat methyl iodide (0.31 mL, 5 mmol) was added to a solution of **6** prepared in situ by stirring $HgBr_2$ (36 mg, 0.10 mmol) and **1** (57 mg, 0.11 mmol) in methanol (2 mL) for 15 min. The mixture was stirred for 1 h at room temperature, allowed to stand at 0 °C overnight, and then evaporated under vacuum. The oily residue was dissolved in acetone (ca. 2 mL) and crystallised by gas-phase diffusion of diethyl ether over several days. The crystalline solid formed was filtered off, washed with diethyl ether and dried under vacuum to give **7** as an orange microcrystalline solid. Yield: 81 mg (93%). IR and solution NMR spectra of **7** are identical to those of **6**.

**X-ray Crystallography:** Crystals suitable for single-crystal X-ray diffraction analysis were selected directly from the reaction batch [**1**: orange plate, 0.08 × 0.25 × 0.50 mm; **4**: orange prism, 0.30 × 0.33 × 0.45 mm; **5**: orange block, 0.15 × 0.20 × 0.20 mm, **6**·5 $C_6H_6$: fragment of a yellow plate, 0.08 × 0.08 × 0.28 mm (see preparation of this compound above), **7**: orange prism, 0.05 × 0.08 × 0.08 mm] or grown by recrystallisation from chloroform/hexane (**2**·4 $CHCl_3$: orange plate, 0.10 × 0.30 × 0.43 mm). Full-set diffraction data ($\theta \leq 27.5°$) were collected on a Nonius KappaCCD diffractometer equipped with a Cryostream Cooler (Oxford Cryosystems) using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and analysed with the HKL program package.[34] The data were corrected for absorption by using the routines incorporated in the diffractometer software (**1**, **4**, **5**, and **6**·5 $C_6H_6$: Gaussian correction after indexation of the crystal faces; **2**·4 $CHCl_3$: numerical correction from the indexed crystal shape; **7**: numerical correction based on multiply measured diffractions); transmission factor ranges are given in Table 7. The structures were solved by direct methods (SIR97[35]) and refined by a weighted full-matrix least-squares procedure on $F^2$ (SHELXL97[36]). All non-hydrogen atoms were refined with anisotropic thermal motion param-

[14] A search for structural fragments $\{Pd(\mu\text{-}X)X(P)\}_2$, where X is any halide, furnished 36 hits with *R* below 10%. Most of them are planar molecules (mostly due to imposed symmetry) with the dihedral angle, $\varphi$, equal or close to 0°. Only four structures exhibit $\varphi$ higher than 15°; refcode ($\varphi$, °): NEHVUR (16.2), QAHNOC (29.2), QIVLEM (38.0 and 41.9, two independent fragments), WAVPOY (16.2); $\varphi$ is the dihedral angle subtended by the $\{PdX_2P\}$ planes.
[15] The $\Delta\delta_P$ values were calculated from shifts given in ref.[16] (the complexes) and in: S. O. Grim, A. W. Yanowsky, S. A. Bruno, W. J. Bailey, E. F. Davidoff, T. J. Marks, *J. Chem. Eng. Data* **1970**, *15*, 497 (the ligand).

[28] The ionic radii for divalent metals with coordination number of six are 0.88 (Zn), 1.09 (Cd) and 1.16 Å (Hg). Besides, cadmium(II), like any other metal ion with a $d^{10}$ configuration, has no preferred coordination geometry due to ligand-field stabilisation. Consequently, the coordination geometries are determined chiefly by interplay of electrostatic forces, the nature of the ligands and steric factors. For a reference see, for example: F. A. Cotton, G. Wilkinson, C. A. Murillo, M. Bochmann, *Advanced Inorganic Chemistry*, 6th ed., Wiley, New York, **1999**, chapter 15, p. 598 ff.
[29] The following structures of phosphane–halide complexes featuring pentacoordinate cadmium(II) centres have been retrieved from the Cambridge Crystallographic Database (version 5.26 of November **2004** with updates from February and May **2005**). None of the above compounds is polymeric; a) N. A. Bell, T. D. Dee, I. W. Nowell, *Inorg. Chim. Acta* **1982**, *65*, L87 (code: BIYDIW); b) L. W. Houk, P. K. S. Gupta, M. B. Hossain, D. van der Helm, *Acta Crystallogr., Sect. B* **1982**, *38*, 91 (code: BAZMIY); c) J. T. Mague, J. L. Krinsky, *Inorg. Chem.* **2001**, *40*, 1962 (code: QIWBON).
[30] Notably, the mercury-to-oxygen distances in **6** and **7** fall between the sum of covalent (2.38 Å) and contact (4.02 Å) radii (atomic radii were taken from the Platon program[37]). The flexibility of Hg←O dative bonding can be accounted for by its relative weakness because a variation of the Hg–O distance will result in relatively low energy changes which can, in turn, be compensated by other operating effects, such as steric factors and crystal packing forces.
[31] See also the discussion of conformations adopted by the related ligand 1′-(diphenylphosphanyl)ferrocenecarboxylic acid in the solid state: P. Štěpnička, *Eur. J. Inorg. Chem.* **2005**, 3787.
[32] According to the CSD,[13] the only other structurally characterised ligand is diethyl 2-(diphenylphosphanyl)phenylphosphonate whereas the complexes featuring this and some related donors whose structures were determined are limited exclusively to those with palladium(II) and platinum(II) and just a few examples for each ligand. Representative examples for diethyl 2-(diphenylphosphanyl)phenylphosphonate: a) D. D. Ellis, G. Harrison, A. G. Orpen, H. Phetmung, P. G. Pringle, J. G. de Vries, H. Oevering, *J. Chem. Soc., Dalton Trans.* **2000**, 67 (ligand and Pt complex); for diethyl 2-(diphenylphosphanyl)-ethylphosphonate: b) S. Ganguly, J. T. Mague, D. M. Roundhill, *Inorg. Chem.* **1992**, *31*, 3500 (Pd complex); for diethyl 3-(diphenylphosphanyl)propylphosphonate: c) G. Guerrero, P. H. Mutin, F. Dahan, A. Vioux, *J. Organomet. Chem.* **2002**, *649*, 113 (Pd and Pt complexes).

# Another Example of the Instability of a Keggin-Type Heteropolyanion in the Presence of Aqueous Hydrogen Peroxide: From $[AsW_{12}O_{40}]^{3-}$ to Low-Nuclearity Oxoperoxotungstates – Crystal Structure of $[(n\text{Hex})_4N]_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$

**Jean-Yves Piquemal,*[a] Laurent Salles,[b] Geneviève Chottard,[c] Patrick Herson,[c] Chehrazed Ahcine,[b] and Jean-Marie Brégeault*[b]**

**Keywords:** Oxidation / Hydrogen peroxide / Peroxo ligands / Catalysis / Tungsten

The Keggin dodecatungstoarsenato anion of $HNa_2[AsW_{12}O_{40}]$ is inherently unstable in aqueous hydrogen peroxide and is mainly degraded to $[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]^{3-}$, $[HAsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]^{2-}$ and $[\{WO(O_2)_2(H_2O)\}_2(\mu\text{-}O)]^{2-}$. These anions were isolated as salts and identified by elemental and spectroscopic analyses. The salt with the formula $[(n\text{C}_6\text{H}_{13})_4]_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ was obtained from the reaction of tungstic acid, "$H_2WO_4$" (or $HNa_2[AsW_{12}O_{40}]\cdot n\text{H}_2\text{O}$), with aqueous hydrogen peroxide, $HNa_2[AsO_4]\cdot 7\text{H}_2\text{O}$ and $[(n\text{C}_6\text{H}_{13})_4\text{N}]\text{Cl}$. The structure was refined with $R_1 = 0.058$ and $wR_2 = 0.067$ [monoclinic $C2$ (no. 5); $a = 20.516(6)$ Å, $b = 15.923(4)$ Å, $c = 14.902(2)$ Å, $\beta = 91.64(1)°$, $Z = 2$]. The vibrational spectra (IR and Raman) suggest that the overall structure is maintained in organic solvents. The close relation between the phosphate- and arsenate-based complexes indicates that fluxional behaviour may exist for all these di- and tetranuclear complexes. Fluxionality may play a key role in the transfer of active oxygen (from peroxo groups) to organic substrates via $\{WO(O_2)_2\}$ units. It is shown that the heteroligand $[XO_p]^{n-}$ (X = As, HAs, MeAs, P, HP, etc.) has a marked effect on the stoichiometric and regioselective epoxidation of (*R*)-(+)-limonene to 1,2-epoxide at ambient temperature, for a given pH of the aqueous phase. The oxodiperoxo complexes can be used to carry out epoxidation stoichiometrically and regioselectively with (*R*)-(+)-limonene, but can also be employed in a catalytic process in a two-phase mixture at room temperature.

## Introduction

Heteroligand peroxo-transition-metal complexes possess coordination spheres composed of one to three peroxo groups, and one or more monodentate or polydentate ligands. The stability of the peroxo complex can be enhanced and the reactivity of the coordinated peroxo group changed by specific heteroligand combinations.[1–7] A novel class of heteropolyoxoperoxometalate complexes has attracted attention.[1–14] Representatives of this class are the tetranuclear complexes $Q_3[PO_4\{M_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ (denoted "$PM_4$"; compound **1**: M = Mo and $Q^+$ = amino-2 pyridinium[8] or $Q^+ = [(n\text{Hex})_4\text{N}]^+$;[9] compound **2**: M = W and $Q^+ = [(n\text{Hex})_4\text{N}]^+$[10–12]) and the parent dinuclear complexes $[(n\text{Bu})_4\text{N}]_2[REO_3\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]\cdot x\text{H}_2\text{O}$ (compound **3**: R = OH and E = P[13] with $x = 0$; compound **4**: R = OH and E = As[14] with $x = 0$; compound **5**: R = $CH_3$ and E = As[14] with $x = 1$).

The dimeric moiety $[M_2O_2(\mu\text{-}O_2)_2(O_2)_2]$ is a building block for these five anions. To the best of our knowledge, it has not been observed in peroxotungsten complexes with oxo,[15] oxalate[16] and carbonate[17] or in oxoperoxomolybdates[18,19] with molybdate as assembling ligands, $[\{MoO(O_2)_2\}_2(\mu\text{-}MoO_4)\{\mu\text{-}O\}]^{4-}$ and $[\{\{MoO(O_2)_2\}_2(\mu\text{-}O)\}_2(\mu_4\text{-}MoO_4)]^{6-}$. Complexes with[20] and without[20,21] the dimeric moiety $[M_2O_2(\mu\text{-}O_2)_2(O_2)_2]$ have been synthesised with sulfate as the assembling ligand.

On the one hand, it was shown that both the "$H_3[PW_{12}O_{40}]\cdot n\text{H}_2\text{O}/(H_2O_2/H_2O)$" and the "$H_2WO_4/H_3PO_4/(H_2O_2/H_2O)$" systems involve common species, $[PW_xO_y]^{w-}$, $x = 1$–4. The Keggin-type heteropolyoxometalate (POM) is degraded by $H_2O_2$ to form a variety of phosphatooxoperoxo complexes. These, along with other pure oxoperoxotungstates,[13,22,23] for example $[\{WO(O_2)_2(H_2O)\}_2(\mu\text{-}O)]^{2-}$, have been characterised by IR, Raman, $^{31}$P and $^{183}$W NMR spectroscopy. In contrast with $H_4[SiW_{12}O_{40}]\cdot n\text{H}_2\text{O}$, more drastic conditions (70% $H_2O_2$ in water) have to be used to degrade the Keggin-type polyanionic structure.[23] On the other hand, a new lacunary heteropolyoxotetraperoxotungstate, related to the Keggin structure

$[(Co^{II}O_4)W_{11}O_{31}(O_2)_4]^{10-}$, has been characterised by single-crystal X-ray diffraction.[24] The authors underlined that the different reactivities of lacunary and saturated Keggin complexes (i.e. $[PM_{12}O_{40}]^{3-}$ where M = Mo or W) towards aqueous $H_2O_2$ may be related to the longer M=O bonds of the terminal oxygen atoms of *cis*-$W(O)_2$ groups around the vacancy that lead to *cis*-$W(O)(O_2)$. The conversion of $H_3[PM_{12}O_{40}]\cdot nH_2O$ in the presence of hydrogen peroxide should also require the intervention of lacunary precursors, but in equilibrium with $\{MO_2(OH)\}^+$ or $\{MO_2\}^{2+}$ species, which are converted to $\{MO(O_2)_2(H_2O)_2\}$ moieties.[6,13,25] Recent review articles focus on $H_2O_2$-based epoxidation catalysed by lacunary polyoxometalates,[7] e.g. $[\gamma\text{-}SiW_{10}O_{34}(H_2O)_2]^{4-}$. The nonlacunary heteropolyoxoperoxometalates $[PTiW_{11}O_{39}(O_2)]^{5-}$ and $[PTi_2W_{10}O_{38}(O_2)_2]^{7-}$ have also been reported.[26,27] In these compounds, the peroxo ligands are probably bonded to the Ti atom (statistical disorder makes it impossible to locate the Ti atoms and the peroxo ligands). These substituted polyoxometalates are moderately active for olefin epoxidation with the use of 30% $H_2O_2$ ($O_{peroxo}$/catalyst = 1200:2 mol/mol). It is inferred that there is no degradation of the Keggin-structured framework at 50 °C over 24 h,[27] although synergy may exist between the tungsten and titanium centres. The retention of the Keggin unit of this Ti–POM was reinvestigated,[28] but in some systems the isolable species are often not those that lie along the principal reaction coordinates for the catalysis.[6,25]

Although it was formerly accepted that the O–O bond lengths are fairly constant and do not depend on the nature of the metal ligands, we were interested in a systematic study of the heteroligand effect. This is of major importance for catalysis in homogeneous[6,29] or two-phase-medium[6,9,13,22,23,30,31] conditions, for grafting onto (or inserting in) polymeric supports[6,30,32–38] or for the comprehensive study of the synthesis of transition-metal-containing mesostructured materials from peroxo species.[39,40] We report here the synthesis and structural characterisation of $[(n\text{Hex})_4N]_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ (**6**). Salts of the anion have been prepared by several groups;[11–12,41–43] despite many attempts to show that **1**, **2** and **6** are isomorphous, it was previously difficult to isolate single crystals of **6** suitable for X-ray measurements. The profiles of the Raman and infrared spectra of **6** are compared with those of tetra-*n*-butylammonium (μ-hydrogenoarsenato)bis(μ-peroxo)bis-(oxoperoxotungstate)(2–) (**4**)[14] and with those of the methylarsenato analogue (**5**).[14] Moreover, it is shown that the interaction of excess $H_2O_2$ (30%) with an aqueous solution of $[AsW_{12}O_{40}]^{3-}$ leads to the degradation of the Keggin unit and to the formation of a less-condensed oxoperoxo species in the same way as $H_3[PW_{12}O_{40}]\cdot nH_2O$ in the presence of $H_2O_2$. These complexes are active oxygen-to-olefin transfer agents at room temperature and are active catalysts in the oxidation of model organic substrates using 30% $H_2O_2$ in water in a two-phase medium.

## Results and Discussion

### Syntheses of 6: Peroxide-Mediated Decomposition of $[AsW_{12}O_{40}]^{3-}$ or Reaction of $H_2O_2$ with Tungstic Acid in the Presence of Arsenate

The synthesis of $[(n\text{Hex})_4N]_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ (**6**) from "$H_2WO_4$" is based on methods that generate oxoperoxo species,[44] mainly $[WO(O_2)_2(H_2O)_2]$, $[WO(OH)(O_2)_2]^-$ and $[\{WO(O_2)_2H_2O\}_2(\mu\text{-}O)]^{2-}$ [with peroxide/tungsten(VI) > 2] which are subsequently coordinated by the assembling anion $[AsO_4]^{3-}$. Another procedure can be developed with the use of $Na_2H[AsW_{12}O_{40}]\cdot NaCl\cdot 30H_2O$, which is degraded by excess $H_2O_2$ (Scheme 1); these results compare well with previously reported data,[22,23] and spectroscopic evidence shows that the "$H_3[PW_{12}O_{40}]\cdot nH_2O/H_2O_2/H_2O$" and "$H_2WO_4/H_3PO_4/H_2O_2/H_2O$" systems give the same oxoperoxo species.[4,6,10,13,22,23] To precipitate one of the anions formed from $[AsW_{12}O_{40}]^{3-}$ and excess $H_2O_2$, we added tetra-*n*-butylammonium chloride and isolated the complex $[(n\text{Bu})_4N]_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$, and subsequently added potassium chloride to give $K_2[\{WO(O_2)_2(H_2O)\}_2(\mu\text{-}O)]$. Therefore, the appropriate choice of counteranions allowed us to obtain the two oxoperoxo salts selectively (Scheme 1). The products have been fully characterised by an active oxygen assay, elemental analysis and vibrational studies (IR and Raman spectra, vide infra). The isolation of **6** led to structural X-ray data.

### Structure of the Tetranuclear Complex $[(n\text{Hex})_4N]_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ (6)

The arsenic atom of $[AsO_4]^{3-}$ and one of the nitrogen atoms, N(2), lie on a binary axis. The neutral moiety, $\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}$, and the other nitrogen atom, N(1), are in general positions, while the other two locations are generated by the binary axis.

Single-crystal X-ray analyses show that **1**,[9] **2**[10] and **6** (this work) are isomorphous and are structurally very similar. The anion of **6** (Figure 1) consists of a slightly distorted tetrahedral assembling anion, $[AsO_4]^{3-}$, and two neutral units, $\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}$, in which the tungsten(VI) atoms are coordinated by seven oxygen atoms in a pentagonal-bipyramidal arrangement (PBPY-7, IUPAC Nomenclature). The four oxygen atoms of the anion are corner sharing with the four different basal planes of the pentagonal bipyramids. Atoms O(3) and O(4) of the arsenate bridge two tungsten atoms within a dinuclear unit. The geometry about the arsenic atom does not deviate significantly from that of a tetrahedral arrangement (Table 1), with a mean bond angle of 109.5°. The As–O bond lengths average 1.66 Å, in agreement with those of **4**, **5**[14] and many tungsten(VI) arsenates containing heteropolyanions, and with values found for arsenates and organoarsenates.[45,46] The tungsten atoms have two differently bound peroxo ligands: one is in the $\eta^2$-side-bound configuration, [W(1)–O(11)–O(12) and W(2)–O(21)–O(22)] (Figure 1), and the other is in the $\mu_2$-$\eta^2$:$\eta^1$ mode (or unsymmetrical bridging). Thus, in **6**, the tungsten atoms are connected in pairs not only by the $[AsO_4]^{3-}$ group, but also by the unique $\mu_2$-$\eta^2$:$\eta^1$ peroxo bridges, and the two pentagonal bipyramids associated in this way share one edge of the nonbasal plane, O(13)···O(23). It is important to note that a similar unit exists only in the anion of **1**[9] and **2**[10], and in the dinuclear complexes that have recently been isolated: **3**,[13] **4**,[14] **5**[14] and $[P(C_6H_5)_4]_2[(C_6H_5)_2SiO_2\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]$ (**7**).[39] The least-squares planes for the anion of **6** are such that the pentagonal bipyramids of the oxygen atoms surrounding the two tungsten atoms are almost identical. Each pentagonal girdle is generated by two peroxo groups and one oxygen atom of the arsenate group. A summary of bond lengths and angles of the anion is presented in Table 1. One of the axial positions is occupied by a terminal oxo ligand $O^{2-}$ (W=O: 1.77, 1.70 Å) and the other by an oxygen atom of a bridging unsymmetrical peroxo group with a notably long bond (W–O: 2.42, 2.37 Å), similar to those found for **4**, **5**[14] and **7**.[39] The oxygen atoms that define the equatorial plane are coplanar to within 0.004–0.143 Å. As is the case for octahedral coordination in polyoxometalates, W(1) and W(2) are located outside the mean plane defined by the five equatorial O atoms (0.37 Å and 0.40 Å, respectively). These distances are also found for the other structural units in **3**, **4**, **5** and **7**.[13,14,39] In the $\eta^2$-peroxo groups, O(11)–O(12) and O(21)–O(22) are nearly symmetrically coordinated to W(1) and W(2), respectively [W(1)–O(11) and W(1)–O(12) have bond lengths of 1.92 and 1.90 Å, respectively]. The O(11)–O(12) and O(21)–O(22) bond lengths (1.49 and 1.48 Å, respectively) are in the usual range (1.40–1.50 Å),[1–4] and the corresponding three-membered –W–O–O– rings are nearly isosceles. In contrast to these structural data, the bridging peroxo groups $\mu_2$-$\eta^2$:$\eta^1$ [O(13)–O(14) and O(23)–O(24)] are dissymetrically coordinated to W(1) and W(2), which results in a relatively long W–O bond with the bridging oxygen atoms [W(1)–O(13) and W(2)–O(23) are 2.06 and 2.00 Å, respectively] and a shorter bond with the second oxygen atom (1.93 and 1.90 Å, respectively), similar to those found for the side-bound peroxo group. The OWO angles are unchanged (about 45°), whereas the peroxo bond lengths lie between 1.48 and 1.52 Å. It is well known that the addition of suitable ancillary ligands (hexamethylphosphorotriamide, HMPA,[47] or pyridine *N*-oxide, pyO)[48] to "$H_2WO_4$" ("$WO_3{\cdot}H_2O$") or tungsten powder in 30% $H_2O_2$ in water leads to the formation of well-characterised molecular complexes: $[WO(O_2)_2L^1L^2]$ where $L^1$ = HMPA, $L^2$ = $H_2O$,[47] or $L_1$ = $L_2$ = pyO.[48] The dinuclear anion, $[\{WO(O_2)_2(H_2O)\}_2(\mu\text{-}O)]^{2-}$, can also be formed at an early stage of the reaction; it seems likely that the anions of **4**, **5** and **6** are obtained by reactions of the molecular complexes

($L^1$ = $L^2$ = $H_2O$) and/or of dinuclear species with $H_{3-\varepsilon}$-$[AsO_4]^{\varepsilon-}$ species in the same way as that for the phosphatooxoperoxotungstate species for which, according to NMR spectroscopic studies, there are several equilibria.[6,13,22,23]

### Infrared and Raman Spectra: Correlation of Vibrational Data with the Structure of Complexes 4, 5 and 6

Attempts to measure the Raman spectra of **1**, **2** and **6** in a benzene solution were unsuccessful,[42] but the solid state and acetonitrile solutions show common features in the 500–1000 $cm^{-1}$ region, which suggests that the structures of the anions of **4**, **5** and **6** are maintained in some organic solvents (here acetonitrile) at room temperature, as proposed in a preliminary structural study.[14] The IR and Raman spectra of **6** are presented in Figure 2 and the attributions of the main infrared and Raman vibrations are given in Table 2.

The infrared and Raman spectra of arsenate-containing complexes show strong bands in the 960–990 $cm^{-1}$ region assigned to $\tilde{\nu}$(W=O) of the terminal oxo group (see Table 2). For tetrahedral $XO_4$ compounds, four vibrations are expected: $\tilde{\nu}_1(A_1)$, $\tilde{\nu}_2(E)$, $\tilde{\nu}_3(F_2)$ and $\tilde{\nu}_4(F_2)$. With free $[AsO_4]^{3-}$, these maxima are at about 878 ($\tilde{\nu}_3$), 837 ($\tilde{\nu}_1$), 463 ($\tilde{\nu}_4$) and 349 ($\tilde{\nu}_2$) $cm^{-1}$.[49] Although all of them are Raman-active, only $\tilde{\nu}_3$ and $\tilde{\nu}_4$ are infrared-active for $T_d$ symmetry.[50] We propose that the two strong infrared and Raman bands in the 915–865 $cm^{-1}$ region be attributed to vibrations of the arsenato ligand, i.e. As–O stretches (see Table 2). For "$Na_3[AsW_{12}O_{40}]\cdot nH_2O$"[51] (reformulated as $Na_2H[AsW_{12}O_{40}]\cdot NaCl\cdot 30H_2O$ – see Experimental Section), an infrared band located at 911 $cm^{-1}$ is attributed to the $\tilde{\nu}_{asym}$(As–O) vibration.[51] Two infrared bands at 892 and 875 $cm^{-1}$ are also tentatively attributed to the $\tilde{\nu}(AsO_4)$ stretches of the arsenato-containing tetranuclear species.[50]

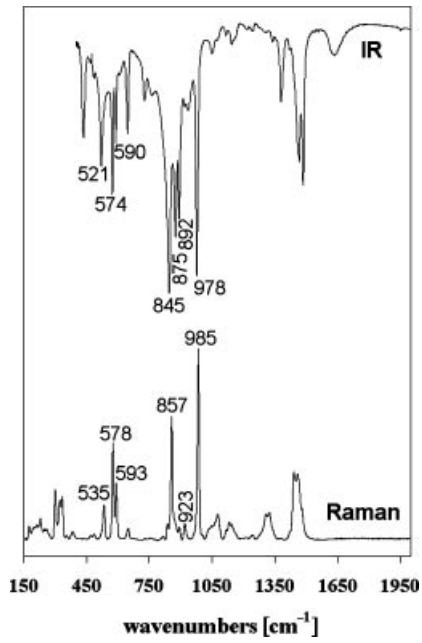

Figure 2. Infrared and Raman spectra of solid samples of $[(n\text{Hex})_4N]_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ (**6**).

The bands at 857–861 $cm^{-1}$ (Raman spectra) and at 843–849 $cm^{-1}$ in the IR spectra are related to the Raman- and infrared-active $\tilde{\nu}$(O–O) vibrations of the peroxo ligands. These values are in agreement with previously obtained values for tungsten oxoperoxometalates involving other assembling anions and $\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}$ units,[9,13,14,20,22,23] and also with those from the Raman spectra of many unactivated organic peroxides. We propose to limit the wavenumber region expected for the $\tilde{\nu}$(O–O) to 830–885 $cm^{-1}$. Thus, we observed the O–O stretch at 876 $cm^{-1}$ in the spectrum of hydrogen peroxide (30% $H_2O_2$ in water). Barium peroxide ($BaO_2$), which is registered in

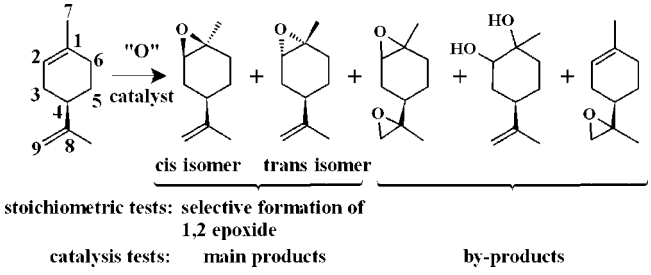
the "peroxide class" of ionic compounds with isolated $[O_2]^{2-}$ ions, presents a Raman band at 842 $cm^{-1}$ that is unambiguously assigned to $\tilde{\nu}$(O–O).[52] Hence, spectroscopic data cannot differentiate all the ionic peroxide from the iono-covalent transition-metal complexes. In contrast, the peroxide function has a marked influence on the asymmetric and a less-marked influence on the symmetric stretches of the $\{W(O_2)_2\}$ moieties; their attributions, according to literature data,[50] are given in Table 2 for **4**, **5** and **6**. Two maxima are observed for $\tilde{\nu}_{asym}[W(O)_2]$ that correspond to the structural data (vide supra).

### Stoichiometric Epoxidation of (*R*)-(+)-Limonene

The reaction is highly chemoselective and regioselective, i.e. no bis-epoxides, no diols and no 8,9-epoxides were obtained (Scheme 2). Limonene oxide (0.7:1 to 1:1 mixtures of *cis* and *trans* 1,2-epoxide) was characterised and isolated.[13,30] Figure 3 shows that half of the peroxide oxygen is transferred to the olefinic substrate at room temperature, a result which differs from that of the MTO/$H_2O_2$ systems.[29,53] Comparative experiments with "$CH_3ReO_3$ + $2H_2O_2$/solvent" show complete transfer of the peroxide oxygen.



Scheme 2. Oxidation products of (*R*)-(+)-limonene.

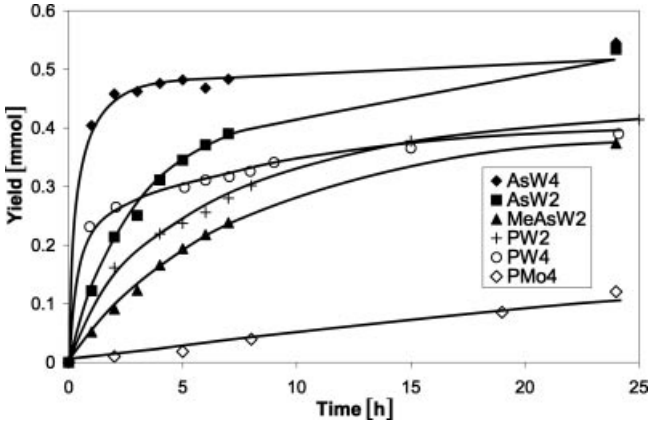


Figure 3. Stoichiometric epoxidation of (*R*)-(+)-limonene. $[(nBu)_4N]^+$ salts, 0.25 mmol for $XW_2$ and 0.125 mmol for $XW_4$ or $XMo_4$; active oxygen content due to oxoperoxo complex = 1 mmol; (*R*)-(+)-limonene: 1.5 mmol; 20 °C; solvent: dry $CH_2Cl_2$ (5 mL); $N_2$ ($P \approx 0.1$ MPa), internal standard: *n*-decane.

The kinetic curves also show that $[AsW_4O_{24}]^{3-}$ is more efficient than $[HAsW_2O_{14}]^{2-}$ and that there is a dramatic change from $[PMo_4O_{24}]^{3-}$ to $[AsW_4O_{24}]^{3-}$, which can be correlated with $\tilde{\nu}$(O–O).[13] It appears that the assembling ligand and the metal have a marked influence on the activity of these species, which all initially contain bridging $\mu$-$\eta^2$:$\eta^1$ peroxo ligands.

It was demonstrated by variable-temperature $^{31}P$ NMR spectroscopy that $[PM_4O_{24}]^{3-}$ species (M = Mo, W) and even the $[HPW_2O_{14}]^{2-}$ complex are fluxional.[25,43] In these anionic complexes, tridentate peroxo can also bind in a bidentate mode. The rearrangement involves the well-known seven-coordinate and six-coordinate tungsten moieties that were recently characterised;[40] at room temperature, the phosphate anion conserves its tetradentate character of a $\mu_4$-assembling ligand. We cannot run these same NMR spectroscopic experiments with the arsenato analogues, but the structural and spectrometric data related to **2**[10] and **6**, and also to **3**,[13] **4** and **5**,[14] lead us to consider that the phosphatooxoperoxotungstate species and the arsenato analogues behave similarly. Thus, rigid models are only a first approach for the transfer of active oxygen (from peroxo species) to olefinic substrates.[25,43] Rapid equilibria exist between anionic structures with tridentate ($\mu$-$\eta^2$:$\eta^1$-$O_2^{2-}$) and bidentate ($\eta^2$-$O_2^{2-}$) modes of coordination for the two kinds of peroxo groups of the $\{M_2O_2(\mu\text{-}O_2)_2(O_2)_2\}$ moieties, which play a key role in the activation and transfer of the oxygen of the peroxo groups, probably in the form of $\{\equiv As\text{–}OMO(O_2)_2\}$ and even free $\{MO(O_2)_2\}$ moieties.

### Catalysis Tests

Alkene epoxidation catalysed by "$AsW_4$" peroxo complexes has been investigated by several groups.[11,30,42,43,54] The Arquad 2HT® salts of complexes "$AsW_4$" and "$AsW_2$" are active precursors and catalysts in olefin oxidation, and form epoxides in the range 20–60 °C in two-phase "$H_2O_2$/$H_2O$/$CHCl_3$ or toluene" systems under phase-transfer catalysis (PTC) conditions (see Table 3, Entries 2 to 4). They transfer active oxygen to (*R*)-(+)-limonene to mostly give the monoepoxides, which are known to be acid-sensitive.[55–57] Complete optimisation must consider the effects of the organic solvent, the nature of $Q^+$, the assembling ligand X and the anionic species ($Cl^-$, $Br^-$, $HSO_4^-$, etc.), the pH of the aqueous phase, the presence of $Na^+Cl^-$ and the W/X/$Q^+$ ratios, and these factors have been analysed in detail by several groups.[30,58,59] For example, it has recently been shown that under PTC, a system such as W/$[PO_4]^{3-}$/$Q^+$ = 2:1:0.4 was more effective than the system 2:1:2 or 4:1:3 corresponding to the onium salts of "$PW_2$" and "$PW_4$", respectively.[31] The use of a large excess of $Q^+$ leads to low yields and turnover numbers, as shown previously.[30] If a tetra-*n*-hexylammonium cation is used instead of Arquad 2HT®, the conversion is very low (see Table 3, Entry 1).

Comparative studies for the recycling of different catalytic systems for epoxidation are under investigation by our group, and limitations exist for all of them except for the non-chlorinated solvents. Inexpensive buffer systems are

[a] General PTC procedure: organic solvent (5 mL, 15%); $H_2O_2$ (4 mL, 19.6 mmol); Teflon-coated bar driven externally by a magnetic stirrer (1200 rpm); limonene (6.2 mmol). [W]/[limonene] = 2%. [b] Conversion based on (*R*)-(+)-limonene was determined by GC using *n*-decane as an internal standard. [c] The selectivity is defined as S = [mol. *cis*- and *trans*-limonene oxide]/[mol. of converted limonene]. [d] See Scheme 2. [e] Catalysis test with **6**.

now easily used and recycled, as well as solid catalysts that are highly resistant to leaching. Note that the use of toluene as the organic solvent instead of $CHCl_3$ leads to a similar conversion but to a lower selectivity towards mono-epoxides (*cis* and *trans*).

Controlled addition of more appropriate weak bases ($Na_2[HAsO_4]$ is used here) to generate a buffer mixture [$pK_a$ ($H_2AsO_4^-/HAsO_4^{2-}$) = 6.95] leads to very high selectivity (>97%), but with a higher reaction time (e.g. 12 h for 99% conversion of limonene at room temperature).

It is clear that certain Keggin-type polyoxometalates can be stable under certain reaction conditions.[26–28] Parameters to consider in this context are solvent, concentrations, pH (more generally the acidity function), temperature, counterions, etc. In this paper, all the species of the catalyst pool, using the dodecatungstate anion as the catalyst precursor, have not been identified. To the best of our knowledge, it is not possible to find spectrometric evidence for all the oxoperoxo complexes. Unfortunately, we cannot perform kinetics or time-resolved studies, and the true catalytic species may be present only at low concentrations and are not amenable to characterisation. It was against this backdrop that we published refs.[25,43]. The catalyst of Noyori et al.[58] is not isolable.

## Conclusion

The addition of arsenate to oxoperoxotungstate species (peroxide/tungsten > 2), as well as the use of polyoxometalates such as the Keggin dodecatungstoarsenate anion of $Na_2H[AsW_{12}O_{40}]\cdot nH_2O$ or "$AsW_{12}$", give, with excess aqueous hydrogen peroxide, arsenatooxoperoxotungstate complexes: $Q_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ or "$AsW_4$", $Q_2[HAsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]$ or "$AsW_2$", etc. isolated with $Q^+$ = onium cation and $Q'_2[\{WO(O_2)_2(H_2O)\}_2(\mu\text{-}O)]$. All these anionic species are highly effective for epoxidation procedures (complete optimisation must consider the effects of the nature of $Q^+$ or $Q'^+$, the organic solvent, the assembling ligand X, the pH of the aqueous phase and the $W/X/Q^+$ ratios, as we showed previously).[6,9,30,31] Thus, the heteropolyanion can only be a precursor of the true catalysts (e.g. "$AsW_4$", "$AsW_2$", etc.). The "$AsW_n$" complexes, which have no coordinated water, are lipophilic and are easily transferred into an organic phase with selected $Q^+$. The facile transfer of active oxygen from these peroxo species to olefinic substrates can be related to their structure and their fluxionality. We propose that the lack of solvolytic stability of "$AsW_{12}$" and of its analogues in aqueous hydrogen peroxide can be attributed to the equilibria between Keggin and lacunary heteropolyanions and $\{WO_2(OH)\}^+$; this mononuclear group subsequently reacts with $H_2O_2$ to generate the well-known Mimoun species, $[WO(O_2)_2(H_2O)_2]$, and with X, thus forming "$AsW_4$", "$AsW_2$", etc. On the contrary, as shown recently,[7] $[\{WO(O_2)_2(H_2O)\}_2(\mu\text{-}O)]^{2-}$ is a preferred catalyst in water for the epoxidation of various allylic alcohols. The crystal structures of "$AsW_4$", "$AsW_2$" and of their methylarsenato analogue show that they contain the unique $\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}$ moieties of the Venturello complex.

## Experimental Section

### Syntheses

**$Na_2H[AsW_{12}O_{40}]\cdot NaCl\cdot 30H_2O$:** This sodium salt was prepared according to the previously described procedure in which concentrated aqueous HCl (12 M) is used.[51] Note that we found chlorine in the final product, which corresponds to a monohydrogenodisodium salt (yield 72%). $H_{61}AsClNa_3O_{70}W_{12}$ (3566.98): calcd. As 2.10, Cl 0.99, Na 1.93, W 61.85; found As 1.99, Cl 0.84, Na 2.09, W 62.58.

**$[(n\text{Hex})_4N]_3[AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ (6) and $K_2[\{WO(O_2)_2(H_2O)\}_2(\mu\text{-}O)]\cdot 2H_2O$:** This complex was first prepared from the "$H_2WO_4/H_2O_2/H_2O/Na_2H[AsO_4]\cdot 7H_2O/[(n\text{Hex})_4N]Cl$" systems. The synthesis was adapted from methods previously described for the preparation of **6**[60] and **1**, **2**.[9,11] Tungstic acid, "$H_2WO_4$", (2.5 g, 10 mmol) was added to a 30% aqueous solution of hydrogen peroxide (7 mL, 69 mmol). After 40 min of stirring at 60 °C, and then cooling to room temperature and centrifugation (15 min at 2000 rpm), the supernatant liquid (solution A) was added to an aqueous solution of $Na_2H[AsO_4]\cdot 7H_2O$ (2 mL, 0.78 g, 2.5 mmol). After 15 min of stirring, a solution of $[(n\text{Hex})_4N]Cl$ (1.56 g, 4 mmol) in toluene (25 mL) was slowly added. After 60 min of vigorous stirring, the white precipitate formed at the interface was filtered off, washed thoroughly with distilled water (10 mL), toluene (10 mL) and diethyl ether (10 mL) and dried with $P_4O_{10}$ (yield: 2.82 g, 50%). $C_{72}H_{156}AsN_3O_{24}W_4$ (2258.37): calcd. C 38.29, H 6.96, As 3.32, N 1.86, W 32.56; found C 38.07, H 7.10, As 3.15, N 1.75, W 32.16. IR and Raman spectroscopy: see Table 2. Although tetra-*n*-butylammonium and bis(triphenylphosphoranylidene) ammonium salts were prepared in powder or microcrystalline forms, only the tetra-*n*-hexylammonium salts gave single crystals of an appropriate size from acetonitrile solutions in the presence of a slight excess of hydrogen peroxide, otherwise Keggin salts are

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

formed. Compound **6** was also synthesised from "$Na_2H[AsW_{12}O_{40}]$·$NaCl$·$30H_2O/H_2O_2/H_2O/[(n\text{Hex})_4]Cl$ or $[(n\text{Bu})_4N]Cl$" systems. Aqueous hydrogen peroxide (30%, 100 mmol; 10 mL) was slowly added to a solution of the $[AsW_{12}O_{40}]^{3-}$ salt (vide supra, 0.5 mmol, 1.57 g) in water (1 mL). After 30 min of stirring at room temperature, an aqueous solution of tetra-*n*-butylammonium chloride (3 mL, 1.6 mmol, 0.45 g) was slowly added. The white precipitate was filtered off, washed with water (2 × 10 mL) and then dried with $P_4O_{10}$ (yield: 0.47 g, 41.5% based on As). Higher yields (≥90%) were obtained when an excess of $Na_2H[AsO_4]$·$7H_2O$ was added to the aqueous phase. Excess potassium chloride (7 mmol) can also be added to the recovered filtrate. A few millilitres of ethanol were added to the solution that was cooled to 5 °C until a snow-white precipitate appeared. After filtration and washing with ethanol, the precipitate, $K_2[\{WO(O_2)_2(H_2O)_2\}(\mu\text{-}O)]$·$2H_2O$, was air dried (yield 60% based on the initial precursor). See Scheme 1 for the appropriate choice of counteranions in order to obtain the two oxoperoxo salts selectively.

**$[(n\text{Bu})_4N]_2[HAsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]$ (4):** Solution A (vide supra) and a solution of $Na_2H[AsO_4]$·$7H_2O$ (1.59 g; 5.1 mmol) in water (2 mL) were mixed at room temperature. After 20 min of stirring, an aqueous solution of $[(n\text{Bu})_4N]Cl$ (2.78 g, 10 mmol in 10 mL) was slowly added while slow stirring was maintained. The white precipitate was filtered off on a fritted glass disc, washed thoroughly with cold water (10 mL) and diethyl ether (10 mL) and dried with $P_4O_{10}$ (yield: 4.46 g, 77%). $C_{32}H_{73}AsN_2O_{14}W_2$ (1152.56): calcd. C 33.34, H 6.38, As 6.50, N 2.43, W 31.90; found C 33.49, H 6.45, As 6.15, N 2.55, W 30.92. IR and Raman spectroscopy: see Table 2. (Compound **4** can also be prepared from $[AsW_{12}O_{40}]^{3-}$, but it is more convenient to use a direct method).

**$[(n\text{Bu})_4N]_2[CH_3AsO_3\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]$ (5):** This was prepared in a similar manner. $Na_2[CH_3AsO_3]$·$6H_2O$ (1.49 g, 5.1 mmol), dissolved in water (2 mL), was added to solution A. After 30 min of stirring $[(n\text{Bu})_4N]Cl$ (2.78 g in 7.5 mL water) was slowly added. Well-formed crystals suitable for X-ray measurements were obtained by slow evaporation of acetonitrile/$H_2O_2$ solutions of the microcrystalline precipitates of **4** and **5**.[14]

**Structure Determinations:** Single crystals of **6** were grown from $CH_2Cl_2/(C_2H_5)_2O/H_2O_2$ (2:1:0.1), or better from $CH_3CN/H_2O_2/H_2O$ mixtures, by slow evaporation at +5 °C. Although highly precise crystal structure analyses are not easily obtained with the tetra-*n*-hexylammonium cation[9,10] (a result of the flexibility of the long alkyl chain, solvent molecules that are incorporated in the crystals and disorder for some of the cations[61]), X-ray measurements were undertaken, because, at least, the structure of the anion could be elucidated, which would provide valuable information for the chemistry of heteropolyanions containing the $[AsO_4]^{3-}$ assembling ligand and for the relationship of some Keggin anions and Venturello–Ishii systems.

**$[(n\text{Hex})_4N][AsO_4\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}_2]$ (6):** $C_{72}H_{156}AsN_3O_{24}W_4$, $M_r$ = 2258.37, monoclinic, space group *C*2 (no. 5); $a$ = 2051.6(6), $b$ = 1592.3(4), $c$ = 1490.2(2) pm, $\beta$ = 91.64(1)°, $V$ = 4.866(1) nm$^3$, $Z$ = 2, $\rho_{calcd.}$ = 1.54 Mg m$^{-3}$, $F(000)$ = 2260, $\lambda$ = 71.073 pm, $T$ = 293 K, $\mu$(Mo-$K_\alpha$) = 0.5112 mm$^{-1}$, crystal dimensions 0.1 × 0.3 × 0.4 mm (parallelepiped), 2° ≤ 2$\theta$ ≤ 50°, 13697 measured reflections, 7412 were unique, 206 parameters refined in full-matrix, $R_1$ = 0.058 with 5318 reflections [$I > 3\sigma(I)$], $wR_2$ = 0.067, $w \neq 1$ [weighting scheme of the form $w = w'[1 - \{(||F_o| - |F_c||)/6\sigma(F_o)\}^2]^2$ with $w' = 1/\Sigma_r A_r T_r(X)$ with coefficients 0.417, 0.302 and 0.177 for a Chebyshev series for which $X = F_c/F_{c(max)}$].[62] Min./max. residual electron density –127/153 e mm$^{-3}$. Goodness of fit: 0.93. The data were collected with a KAPPACCD-Enraf Nonius automated diffractometer at room temperature. (At low temperature the crystal collapsed.) Unit cell dimensions with estimated standard deviations were obtained from least-squares refinements of the setting angles of 35 well-centered reflections. Corrections were made for Lorentzian and polarization effects; an absorption correction (sadabs) was also applied. The structure was solved by direct methods (SHELX-86 program)[63] and subsequent Fourier difference techniques. Some of the carbon atoms of the ammonium counterions showed high thermal parameters as a result of the flexibility of the long alkyl chain and were not refined, even with reduced occupancy. Only 34 carbon atoms could be well located in the difference Fourier map. These problems probably arise from low-solvent content and from the fact that the crystal decomposes slowly. Computations were performed using CRYSTALS,[64] adapted to a PC computer. Atomic form factors for neutral C, N, As, O and W were taken from ref.[65] Refinements were carried out by minimising the functions $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $Rw^* = [\Sigma w(||F_o| - |F_c||)^2/\Sigma wF_o^2]^{1/2}$, where $F_o$ and $F_c$ are the observed and calculated structure factors, respectively. A representation of the anion was drawn with CAMERON[66] (see Figure 1).

CCDC-276917 for **6** contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**General:** The solvents were purified by standard procedures for the stoichiometric and catalytic tests. Commercial, stabilised 30% w/v aqueous solutions of hydrogen peroxide (pH ≈ 1.5) either contained a phosphorus(V) concentration lower than 1.5 mM or were without phosphates (Aldrich) in order to avoid the formation of phosphatooxoperoxotungstate species. Tungstic acid, "$H_2WO_4$" was supplied by Eurotungstène. $Na_2H[AsO_4]$·$7H_2O$ and $Na_2[CH_3AsO_3]$·$6H_2O$ were obtained from Prolabo/VWR. The onium salts are marketed by Aldrich and Lancaster Synthesis. (*R*)-(+)-Limonene (Lancaster) was shown to be more than 97% pure by GC and NMR analyses. GC analyses were carried out with a Girdel chromatograph (FID) fitted with a SPB™ 1701 capillary column with helium as the carrier gas. Analyses were performed at temperatures ranging from 70 to 200 °C (5 °C min$^{-1}$, $P_{He}$: 0.16 MPa). GC–MS analyses were performed with a GC apparatus coupled with a mass spectrometer (Girdel 30/Delsi-Nermag and Trace GC 2000 series-Thermofinnigan) coupled to a Trace MS mass spectrometer (EI or CI/$NH_3$). $^1H$ and $^{13}C$ NMR spectra were recorded at ambient temperature with a Fourier transform apparatus (Bruker AC 200), using $CDCl_3$ as the solvent and TMS as the internal reference. IR spectra (resolution: 2–4 cm$^{-1}$) were measured with a Fourier transform apparatus (Bruker IFS 45 or Equinox 55) in Nujol suspension, either between two caesium bromide plates or KBr pellets. Solution spectra of **4**, **5** and **6** in acetonitrile (0.05 M) were recorded at room temperature with a standard sodium chloride cell (0.1 mm thickness). Acetonitrile has a window between 500–910 cm$^{-1}$, which is suitable for studying $\tilde{\nu}$(O–O), $\tilde{\nu}_{sym}[W(O_2)]$ and $\tilde{\nu}_{asym}[W(O_2)]$ bands.

Raman spectra were recorded at room temperature with a Jobin–Yvon U1000 spectrometer with a resolution of 4 cm$^{-1}$. Solid samples of the complexes were mounted on a disc rotating at about 1000 rpm in order to avoid decomposition and/or photoreduction by the laser beam (excitation line, 514.5 nm of an $Ar^+$ laser; source power, 30–50 mW; scanning time, ca. 2 h). Solutions of **6** (0.25 M), **4** (0.5 M) and **5** (0.5 M) were studied. Elemental analyses (C, H, As, N and W) were carried out at the Service Central d'Analyses CNRS, Vernaison.

**Stoichiometric Regioselective Epoxidation with Six Oxoperoxo Complexes:** These were conducted under dinitrogen using Schlenk

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

techniques and deaerated solvents. (*R*)-(+)-Limonene (1.5 mmol) was rapidly added to a thermostatted (20 °C) solution of the complex (0.25 mmol for $XW_2$ and 0.125 mmol for $XW_4$ or $XMo_4$, active oxygen content, i.e. $[O_2]^{2-}$: 1 mmol) in dry $CH_2Cl_2$ (5 mL). The solution was stirred under dinitrogen. GC analyses were performed periodically with *n*-decane as internal standard. (*R*)-(+)-Limonene oxide (mixture of *cis* and *trans*) was obtained and isolated. It was identified by MS and by $^1H$ and $^{13}C$ NMR spectroscopy.[13]

**Catalysis Tests:** Our previous procedure[13,23] was followed. "$H_2WO_4$" was treated with 15% $H_2O_2$ (4 mL, 19.6 mmol). After 15 min of stirring (necessary for the precursor to react completely at 60 °C) and cooling at room temperature, $Na_2H[AsO_4]\cdot 7H_2O$ was added (see Table 3). $Q^+Cl^-$, dissolved in the organic solvent, was then added with the substrate (6.2 mmol). The two-phase mixture was stirred vigorously (1200 rpm) for 6 h at 20 °C under dinitrogen. The organic extract was analysed by GC and/or GC–MS and in some cases by $^1H$ NMR spectroscopy.

## Acknowledgments

We thank Dr. John Lomas for constructive discussions and for correcting the manuscript, and Mme F. Sarrazin for preparing the text.

# Reactivity of the Pyrazolatopalladium(II) Complexes $[Pd(dmpz)_2(Hdmpz)_2]$ and $[Pd_2(\mu\text{-}dmpz)_2(dmpz)_2(Hdmpz)_2]$ towards Carboxylic Acids: Hydrogen Bonds as the Driving Force That Determines the Nature of the Final Products

**Irene Ara,[a] Juan Forniés,*[a] Roberto Lasheras,[b] Antonio Martín,[a] and Violeta Sicilia*[b]**

**Keywords:** Carboxylate ligands / Heterometallic complexes / Hydrogen bonds / N ligands / Palladium

The compound $[Pd(Hdmpz)_4](O_2CCH_2NHCOCH_3)_2$ (**1**; (Hdmpz = 3,5-dimethylpyrazole) has been obtained by treatment of $[Pd(dmpz)_2(Hdmpz)_2]$ (**A**) with two equivalents of *N*-acetylglycine ($HO_2CCH_2NHCOCH_3$). The X-ray study on a crystal of **1** revealed that the *N*-acetylglycinate anion links to the cationic complex $[Pd(Hdmpz)_4]^{2+}$ through the carboxylate group by charge assisted $N–H^{(+)}\cdots O^{(-)}$ hydrogen bonds. Additionally, the remaining N–H and C=O groups allow the *N*-acetylglycinate anions to self-assemble through N–H···O hydrogen bonds to generate infinite chains. The compounds $[Pd_2(\mu\text{-}dmpz)_2(O_2CCH_2NHCOCH_3\text{-}\kappa O)_2(Hdmpz)_2]$ (**2**) and $[Pd_2(\mu\text{-}dmpz)_2(O_2CC_6H_4\text{-}R\text{-}\kappa O)_2(Hdmpz)_2]$ [R = *m*-$NO_2$ (**3a**), *p*-$N(CH_3)_2$ (**3b**), *p*-$NH_2$ (**3c**), *p*-$OCH_3$ (**3d**), *p*-OH (**3e**)] have been obtained by treatment of $[Pd_2(\mu\text{-}dmpz)_2(dmpz)_2(Hdmpz)_2]$ (**B**) with two equivalents of the monocarboxylic acids *N*-acetylglycine ($HO_2CCH_2NHCOCH_3$) and the benzoic derivatives $HO_2CC_6H_4R$ [R = *m*-$NO_2$, *p*-$N(CH_3)_2$, *p*-$NH_2$, *p*-$OCH_3$, *p*-OH] respectively. The X-ray study on complexes **3d** and **3e** shows that in these complexes the carboxylate anion bonded to one Pd atom and the terminal Hdmpz group bonded to the other one have the right arrangement to establish an N–H···O hydrogen bond. The H···O and N···O distances are in the range of those corresponding to charge-assisted $N–H^{(+)}\cdots O^{(-)}$ interactions. In complexes **3a**–**3e**, the H atoms of the terminal Hdmpz groups can be replaced by $Ag^+$ to give the mixed-metal complexes $[Pd_2Ag_2(\mu\text{-}dmpz)_4(\mu\text{-}O_2CC_6H_4\text{-}R\text{-}\kappa O)_2(Hdmpz)_2]$ [R = *m*-$NO_2$ (**4a**), *p*-$N(CH_3)_2$ (**4b**), *p*-$NH_2$ (**4c**), *p*-$OCH_3$ (**4d**), *p*-OH (**4e**)]. Compounds **4a**–**4e**, which exhibit a transoid conformation of the carboxylate groups with respect to the Pd···Pd line, isomerise to the cisoid species (**4a′**–**4e′**). The X-ray structure of the DMSO adduct of **4d′** is also reported.

## Introduction

The coordination chemistry of neutral pyrazole (HRpz) or anionic pyrazolate (Rpz) ligands has been intensively developed over many years[1] and has been thoroughly reviewed.[2–5] Recently, unprecedented compounds showing new bonding modes for pyrazolate ligands have been reported.[6–10] In spite of this, the number of palladium and platinum compounds is rather low. Only a few examples of mono- ($[Pt(pz)_2(Hpz)_2]$,[11,12] $[Pt(Hpz)_4]Cl_2$,[11] $[Pd(Hpz)_4]Cl_2$,[12] $[Pd(dmpz)_2(Hdmpz)_2]$[13]), di- {$[Pd_2(\mu\text{-}dmpz)_2(dmpz)_2(Hdmpz)_2]$,[14] $[Pd_2(\mu\text{-}3\text{-}t\text{Bupz})_2(3\text{-}t\text{Bupz})_2(H_3\text{-}t\text{Bupz})_2]$,[12] $[Pd_2(\mu\text{-}pz)_2(Hpz)_4](BF_4)_2$[15]} or trinuclear ($[\{Pt(\mu\text{-}pz)_2\}_3]$,[12,16] $[\{Pd(\mu\text{-}pz)_2\}_3]$,[12] $[\{Pd(\mu\text{-}4\text{-}Mepz)_2\}_3]$,[12] $[\{Pd(\mu\text{-}3\text{-}Phpz)_2\}_3]$[17]) compounds containing only pyrazoles (HRpz) and/or pyrazolates (Rpz) as ligands have been reported up to now, one of them, $[Pd_2(\mu\text{-}dmpz)_2(dmpz)_2(Hdmpz)_2]$ having been published recently by us.[14] This kind of compound often contains inter-[11–13] or intramolecular[12,14] N–H···N hydrogen bonds involving neutral pyrazole (HRpz) and anionic pyrazolate (Rpz) groups, and the protons of the coordinated pyrazoles can be replaced by metal ions as $Cu^I$, $Ag^I$ and $Au^I$ to give heterometallic polynuclear complexes.[12–14]

The mono- and dinuclear complexes $[Pd(dmpz)_2(Hdmpz)_2]$ (**A**)[13] and $[Pd_2(\mu\text{-}dmpz)_2(dmpz)_2(Hdmpz)_2]$ (**B**)[14] have terminal dmpz and Hdmpz ligands bonded to each palladium centre, that is, on each side of both complexes there is a dmpz group, which is a hydrogen-bond acceptor, and an Hdmpz ligand, which is a hydrogen-bond donor. We therefore considered it of interest to use these compounds as starting materials to obtain organic–organometallic hydrogen-bonded networks by reaction of both complexes with carboxylic acids. A carboxylic acid group (COOH) can form complementary hydrogen bonds with the dmpz and Hdmpz ligands on the same side of each complex (Figure 1a) or transfer its proton to the dmpz ligand. Should this be the case, charge-assisted $N–H^{(+)}\cdots O^{(-)}$ hydrogen bonds would be formed between complex cations and

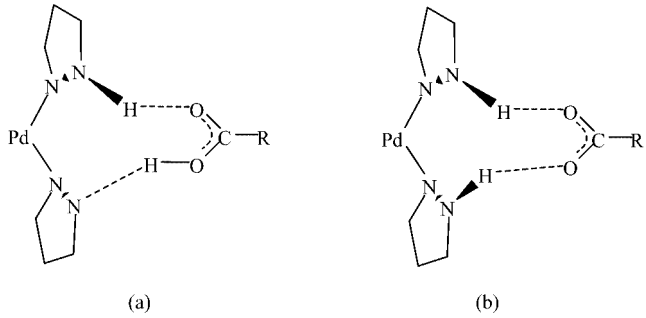
carboxylate anions yielding a heteromeric synthon of type $R_2(10)$[18,19] (Figure 1b). Additionally, the substitution of dmpz by carboxylate groups could also take place.



(a) (b)

Figure 1. a) Complementary hydrogen bonds between the neutral carboxylic group and the "*cis*-Pd(dmpz)(Hdmpz)" fragment. b) Charge-assisted $N–H^{(+)}\cdots O^{(-)}$ hydrogen bonds between a carboxylate anion and the cationic "*cis*-$Pd(Hdmpz)_2$" fragment.

In this paper we report the reactivity of complexes $[Pd(dmpz)_2(Hdmpz)_2]$ (**A**) and $[Pd_2(\mu\text{-}dmpz)_2(dmpz)_2(Hdmpz)_2]$ (**B**) towards monocarboxylic acids such as *N*-acetylglycine ($HO_2CCH_2NHCOCH_3$) and benzoic acid derivatives [$HO_2CC_6H_4$-R, R = *m*-$NO_2$, *p*-$N(CH_3)_2$, *p*-$NH_2$, *p*-$OCH_3$, *p*-OH]. Some of these carboxylic acids contain an additional functional group that is able to form an extra molecular hydrogen bond. As a result, a new mononuclear complex and new dinuclear heteroleptic compounds containing pyrazolate and carboxylate ligands in the same molecule have been obtained. Replacement of the protons of coordinated Hdmpz in the dinuclear complexes by $Ag^I$ gives new heteropolynuclear Pd-Ag ones.

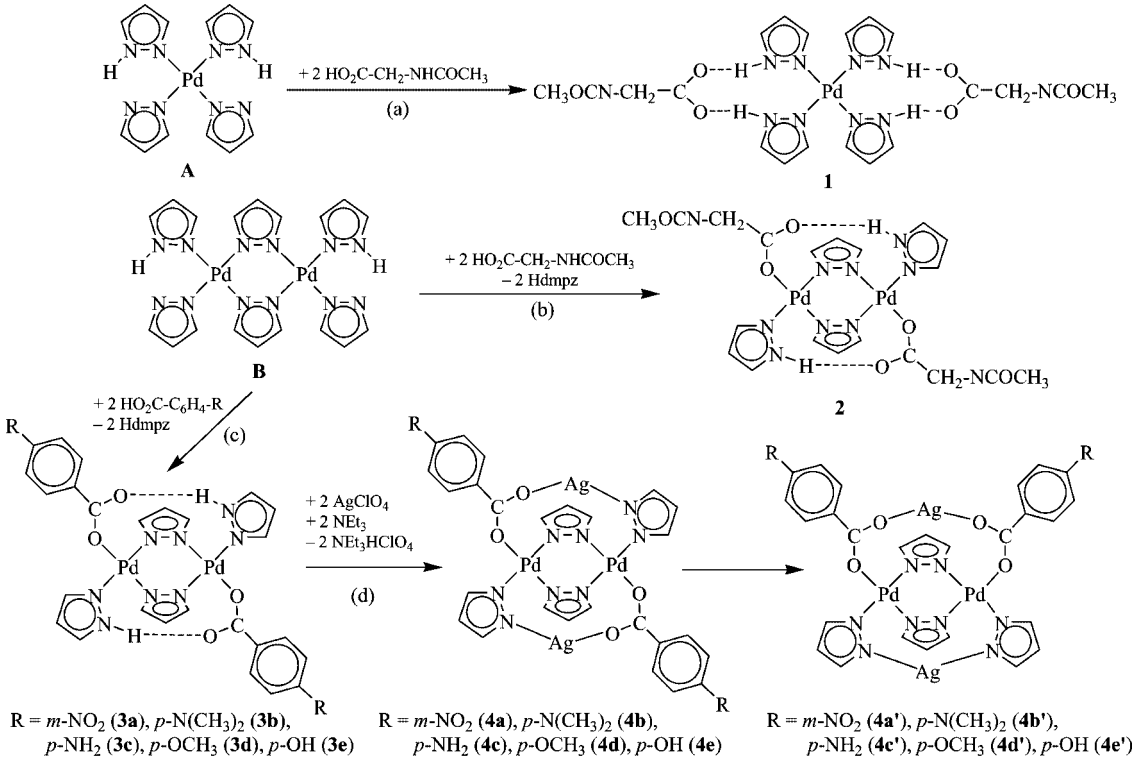
## Results and Discussion

### Reactivity of $[Pd(dmpz)_2(Hdmpz)_2]$ (A) towards the Monoprotic Weak Acids *N*-Acetylglycine and $HO_2CC_6H_4$-R [R = *m*-$NO_2$, *p*-$N(CH_3)_2$, *p*-$NH_2$, *p*-$OCH_3$, *p*-OH]

$[Pd(dmpz)_2(Hdmpz)_2]$ (**A**) reacts with two equivalents of *N*-acetylglycine in dichloromethane/methanol solution to give $[Pd(Hdmpz)_4](O_2CCH_2NHCOCH_3)_2$ (**1**) as a pure compound in a very high yield (path a in Scheme 1) by selective protonation of the anionic monodentate dmpz ligands. The X-ray study of a crystal of **1** revealed that the *N*-acetylglycinate anion interacts with the cationic complex $[Pd(Hdmpz)_4]^{2+}$ through N–H···O hydrogen bonds.

The reactions of $[Pd(dmpz)_2(Hdmpz)_2]$ (**A**) with the benzoic derivatives $HO_2CC_6H_4$-R [R = *m*-$NO_2$, *p*-$N(CH_3)_2$, *p*-$NH_2$, *p*-$OCH_3$, *p*-OH] under similar conditions do not give rise to pure compounds: their $^1H$ NMR spectra seem to indicate that species of stoichiometry $[Pd(Hdmpz)_4](O_2CC_6H_4\text{-}R)_2$ [R = *m*-$NO_2$, *p*-$N(CH_3)_2$, *p*-$NH_2$, *p*-$OCH_3$, *p*-OH] could be present in all mixtures, but we have not been able to separate and characterise them.

Elemental analyses and the IR and $^1H$ NMR spectroscopic data of $[Pd(Hdmpz)_4](O_2CCH_2NHCOCH_3)_2$ (**1**) (see Experimental Section) are in agreement with this stoichiometry, which was confirmed later by an X-ray diffraction



(note: Me groups of the 3,5-dmpz or 3,5-Hdmpz have been omited for clarity)

Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

study. The $^1$H NMR spectrum of **1** in solution reveals the equivalence of the four Hdmpz ligands since only one set of signals is observed [$\delta$ = 15.45 (s, 4 H, N–H), 5.72 (s, 4 H, H$^4$), 2.49 (s, 12 H, $CH_3$), 2.25 (s, 12 H, $CH_3$) ppm]. The two *N*-acetylglycinate anions also give only one set of signals [$\delta$ = 6.56 (s, 2 H, N–H), 4.05 (d, $^3J_{H,H}$ = 3.74 Hz, 4 H, $CH_2$), 2.06 (s, 6 H, $CH_3$) ppm].

The molecular and supramolecular structures of compound **1** are shown in Figures 2 and 3, respectively. Table 1 lists a selection of intra- and intermolecular bond distances and angles.

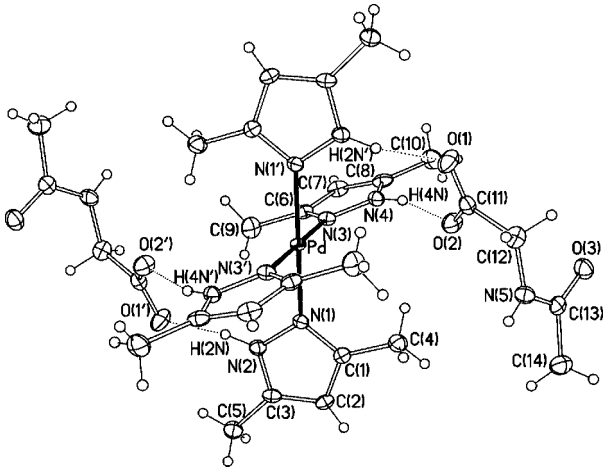


Figure 2. Molecular structure of **1** (50% probability ellipsoids).

In the $[Pd(Hdmpz)_4]^{2+}$ part of the complex the Pd centre shows an almost square-planar coordination environment with all the Pd–N bond lengths in the range of those found in palladium complexes with this kind of ligand.[6,11–13,15–17,20,21] Each pair of mutually *trans* Hdmpz groups are coplanar to each other (interplanar angle of 0° between planes 2 and 2′ and planes 3 and 3′. See Table 1 for the definition of the planes used in this discussion) and almost perpendicular to the other pair of Hdmpz groups [interplanar angle of 86.6(1)°]. All Hdmpz ligands are almost perpendicular to the best least-squares coordination plane of the metal centre (plane 1), since the interplanar angles are 80.9(1)° [planes 1 and 2 (2′)] and 76.7(1)° [planes 1 and 3 (3′)].[22] The Hdmpz groups are turned in such a way that the N–H bonds of the two Hdmpz ligands in the *cis* positions point roughly to the same side of the palladium coordination plane.

The *N*-acetylglycinate anions are bonded to the cation through hydrogen bonds. The two N–H groups pointing to the same side of the palladium coordination plane form N–H···O hydrogen bonds with the two oxygen atoms of the same carboxylate group. These N–H···O hydrogen bonds seem to be quite strong as the H···O and N···O distances are perceptibly shorter than those involved in neutral molecules[23,24] and are even at the lower end of the range observed for charge-assisted N–H$^{(+)}$···O$^{(-)}$ hydrogen bonds.[24–30] According to these structural data, the C–O distances within the $COO^-$ moieties indicate that the carboxylic acid does not retain its acidic hydrogen, which has been transferred to the monodentate dmpz groups[31] such that the complex cations and the carboxylate anions are joined by a heteromeric synthon of type $R_2(10)$[18,19] (Figure 1b). Compound **1** is a new example in which the N–H···O interaction is reinforced by an electrostatic one, the

H-bond acceptor being a carboxylate anion and the H-bond donor an organometallic cation containing N–H groups.

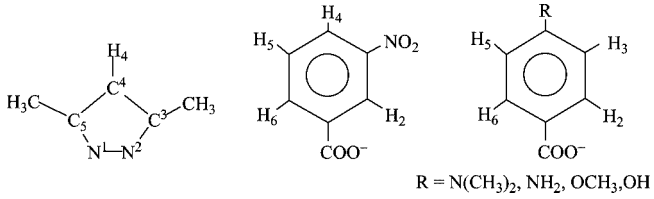
In addition, the *N*-acetylglycinate anions self-assemble through N–H···O links to generate infinite chains. The H···O and N···O distances are longer than those involving the carboxylate group, but within the range observed for this kind of interaction between neutral molecules.[23,25] The supramolecular architecture of compound **1** is a 2D network which can be described as being formed by infinite chains of *N*-acetylglycinate anions ($CH_3CONHCH_2COO^-$) linked through the carboxylate group ($COO^-$) to the $[Pd(Hdmpz)_4]^{2+}$ cations by charge-assisted $N–H^{(+)}\cdots O^{(-)}$ hydrogen bonds.

### Reactivity of $[Pd_2(\mu\text{-dmpz})_2(dmpz)_2(Hdmpz)_2]$ (B) towards the Monoprotic Weak Acids *N*-Acetylglycine and $HO_2CC_6H_4$-R [R = *m*-$NO_2$, *p*-$N(CH_3)_2$, *p*-$NH_2$, *p*-$OCH_3$, *p*-OH]

$[Pd_2(\mu\text{-dmpz})_2(dmpz)_2(Hdmpz)_2]$ (**B**) reacts with the monocarboxylic acids *N*-acetylglycine and the benzoic derivatives $HO_2CC_6H_4$-R [R = *m*-$NO_2$, *p*-$N(CH_3)_2$, *p*-$NH_2$, *p*-$OCH_3$, *p*-OH] in a 1:2 molar ratio, but in a different way to $[Pd(dmpz)_2(Hdmpz)_2]$ (**A**). In these cases selective protonation of the monodentate dmpz groups (one from each palladium atom), their elimination as Hdmpz, and their further displacement by the carboxylate anions generated takes place. These carboxylate groups interact with the palladium atoms in a monodentate way to give compounds $[Pd_2(\mu\text{-dmpz})_2(O_2CCH_2NHCOCH_3\text{-}\kappa O)_2(Hdmpz)_2]$ (**2**) and $[Pd_2(\mu\text{-dmpz})_2(O_2CC_6H_4\text{-R-}\kappa O)_2(Hdmpz)_2]$ [R = *m*-$NO_2$ (**3a**), *p*-$N(CH_3)_2$ (**3b**), *p*-$NH_2$ (**3c**), *p*-$OCH_3$ (**3d**), *p*-OH (**3e**)] (paths b and c in Scheme 1).

The IR absorptions corresponding to the carboxylate groups (see Experimental Section) are in agreement with the monodentate coordination mode of these anions,[32] as confirmed by the X-ray structures of compounds **3d** and **3e**.

According to the symmetry of these compounds ($C_2$), their $^1H$ NMR spectra show a set of signals corresponding to one half of each complex, namely "Pd(μ-dmpz)($O_2CC_6H_4$-R-κ*O*)(Hdmpz)" (see Experimental Section, Scheme 2). The methyl signals corresponding to bridging dmpz or terminal Hdmpz groups were unambiguously assigned by NOE experiments.



Scheme 2.

A common way to synthesise pyrazolate complexes is by treating carboxylate derivatives with the neutral pyrazole (HRpz) in the presence of $NEt_3$. These reactions proceed with elimination of the carboxylic acid and coordination of the pyrazolate anion $Rpz^-$ to the metal centre.[33,34] The substitution of $Rpz^-$ anions by carboxylate groups has seldom been used as carboxylate complexes are much easier to make than pyrazolates. As far as we know, only $[Ru_2(\mu\text{-}O_2CR)_2(Hpz)_2(CO)_4]$ has been prepared in such a way;[35] the carboxylic acid is added in a large excess to induce protonation of all Rpz groups in the starting material. However, in the synthesis of complexes **2** and **3a**–**3e** the carboxylic acids are added to compound **B** in a stoichiometric manner (1:2) and selective protonation of the terminal dmpz groups takes place. Thus, the selectivity of this process is the key to synthesising mixed-ligand complexes.

An X-ray study was performed on complexes **3d** and **3e** to try to ascertain if the OH groups of the carboxylate anions of different complexes are involved in hydrogen-bonding interactions to generate supramolecular structures. Unfortunately, no supramolecular aggregates were found and both complexes show discrete dinuclear structures. The molecular structures of complexes **3d** and **3e** are shown in Figures 4 and 5, respectively, and a selection of bond lengths and angles is given in Tables 2 and 3.

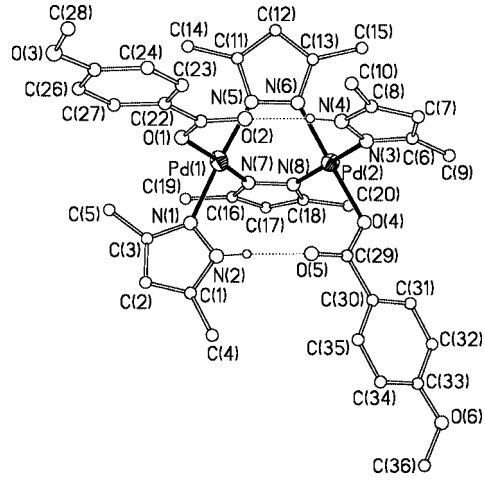


Figure 4. Molecular structure of **3d**.

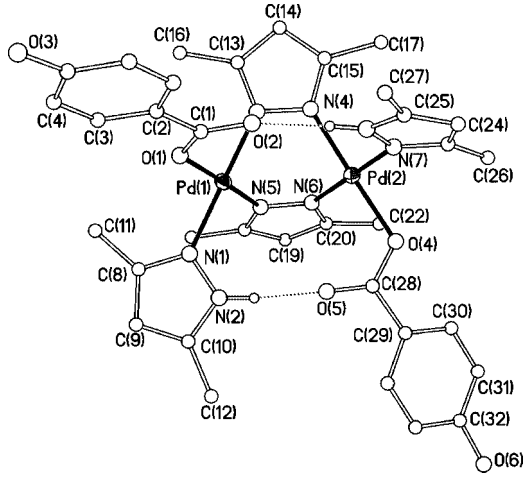

Figure 5. Molecular structure of **3e**.

Complexes **3d** and **3e** are dinuclear species of $Pd^{II}$ with two 3,5-dmpz groups bridging the two metal atoms, which

are located at 3.269 (**3d**) and 3.272 Å (**3e**). The $Pd_2N_4$ ring shows a typical boat-like conformation, the dihedral angle between both Pd–N–N–Pd fragments being 73.5(1)° (**3d**) and 72.9(1)° (**3e**).[22] In addition, each Pd atom is bonded to a nitrogen of a neutral, monodentate 3,5-dimethylpyrazole and to an oxygen of the carboxylate anion to complete a square-planar coordination environment. The angles defined by two ligands in *cis* positions and the metal centre are close to 90°. The Pd–N distances are in the range of distances found in other complexes with this kind of ligand.[6,11–17,20,21,36] No significant differences are observed in the Pd–N distances corresponding to terminal Hdmpz or bridging dmpz groups. The Pd–O bond lengths (ca. 2.00 Å) are similar to those observed in palladium complexes with monodentate carboxylate groups.[37–43] The two Pd–O–C angles are surprisingly different to each other: while one of them is smaller than 120° [C(29)–O(4)–Pd(2): 116.6° (**3d**); C(28)–O(4)–Pd(2): 118.2° (**3e**)] and similar to those found in other complexes with this type of ligand, such as $[Pd(phen)(MeCO_2)_2]$ (Pd–O–C: 114.3° and 118.5°),[37] $[Pd\{3,3'\text{-}[CH_2CH(COOEt)_2]\text{-}2,2'\text{-byp-}\kappa N,N'C^{\beta}\}(O_2CCH_3)]$ (Pd–O–C: 116.9°–119.9°),[38] the other is, unusually, greater than 120° [C(21)–O(1)–Pd(1): 122.9° (**3d**); C(1)–O(1)–Pd(1): 124.3° (**3e**)]. The C–O distances within the $COO^-$ moieties (1.232–1.292 Å) indicate that the carboxylic acid molecules do not retain their acidic hydrogen, which has been transferred to the monodentate dmpz groups to generate Hdmpz ones.[31]

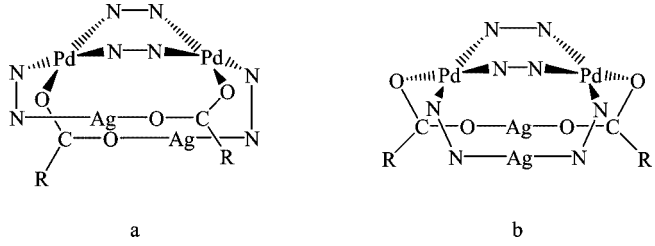
The monodentate carboxylate anion bonded to a Pd atom and the terminal Hdmpz group bonded to the other Pd atom have an adequate arrangement to establish an N–H···O hydrogen bond. The H···O and N···O distances are in the range of those corresponding to charge-assisted $N\text{–}H^{(+)}\cdots O^{(-)}$ bonds. In addition, the N–H···O angles are in the range observed for these kinds of interactions.[24–30]

### Reactivity of $[Pd_2(\mu\text{-dmpz})_2(O_2CC_6H_4\text{-R-}\kappa O)_2(Hdmpz)_2]$ [R = *m*-$NO_2$ (3a), *p*-$N(CH_3)_2$ (3b), *p*-$NH_2$(3c), *p*-$OCH_3$ (3d), *p*-OH (3e)] towards $AgClO_4$

The reactions of $[Pd_2(\mu\text{-dmpz})_2(O_2CC_6H_4\text{-R-}\kappa O)_2(Hdmpz)_2]$ [R = *m*-$NO_2$ (**3a**), *p*-$N(CH_3)_2$ (**3b**), *p*-$NH_2$ (**3c**), *p*-$OCH_3$ (**3d**), *p*-OH (**3e**)] with $AgClO_4$ in a 1:2 molar ratio in the presence of $NEt_3$ produce the deprotonation of the terminal Hdmpz groups and formation of $[Pd_2Ag_2(\mu\text{-dmpz})_4(O_2CC_6H_4\text{-R-}\kappa O)_2]$ [R = *m*-$NO_2$ (**4a**), *p*-$N(CH_3)_2$ (**4b**), *p*-$NH_2$(**4c**), *p*-$OCH_3$ (**4d**), *p*-OH (**4e**)]. In these reactions the $NHEt_3ClO_4$ by-product is eliminated by washing with methanol, where compounds **4a**–**4e** are insoluble.

This method has previously been used in the synthesis of the Pd-Ag pyrazolate complexes $[Pd_2Ag_4(dmpz)_8]$[13] and $[Pd_2Ag_2(dmpz)_6]$[14] from $[Pd(dmpz)_2(Hdmpz)_2]$ and $[Pd(\mu\text{-dmpz})_2(dmpz)_2(Hdmpz)_2]$, respectively.

Elemental analysis and IR and $^1H$ NMR spectroscopic data (Experimental Section, Scheme 2) are in agreement with the stoichiometry proposed and presented in Scheme 1. With the exception of the signal corresponding to the acidic N–H protons, the number of signals observed in the $^1H$ NMR spectra of compounds **4a**–**e** is the same as that observed in the spectra of the starting complexes (**3a**–**3e**). We thus propose the molecular structure represented in Scheme 3a for compounds **4a**–**e**, in which the two acidic H atoms of complexes **3a**–**3e** have been replaced by Ag ones, keeping the carboxylate groups in a transoid conformation with respect to the Pd···Pd axis. If acetone solutions of compounds **4a**–**4e** are left at room temperature until the solvent has completely evaporated the resulting solids exhibit different $^1H$ NMR spectra (Experimental Section, Scheme 2) to those shown by the starting compounds (**4a**–**4e**), revealing a change in the molecular structure to give the isomers **4a′**–**4e′** (Scheme 3b). The $^1H$ NMR spectra of these complexes display two signals corresponding to the $H^4$ atoms



Scheme 3.

of the $Pd_2(\mu\text{-dmpz})_2$ groups. A cisoid arrangement of the carboxylate groups with respect to the Pd···Pd axis could account for these two signals.

Single crystals of $[Pd_2Ag_2(\mu\text{-dmpz})_4(p\text{-}O_2CC_6H_4OCH_3\text{-}\kappa O)_2(DMSO)]$ were obtained from a solution of **4d** in DMSO. Its $^1H$ NMR spectrum is similar to that of **4d′** in DMSO, indicating that the structure of the skeleton of both complexes is the same. The X-ray study of a single crystal allowed us to unambiguously establish the structure proposed for these compounds. The molecular structure of $[Pd_2Ag_2(\mu\text{-dmpz})_4(p\text{-}O_2CC_6H_4OCH_3\text{-}\kappa O)_2(DMSO)]$ is shown in Figure 6, and Table 4 contains a selection of bond lengths and angles in the complex.

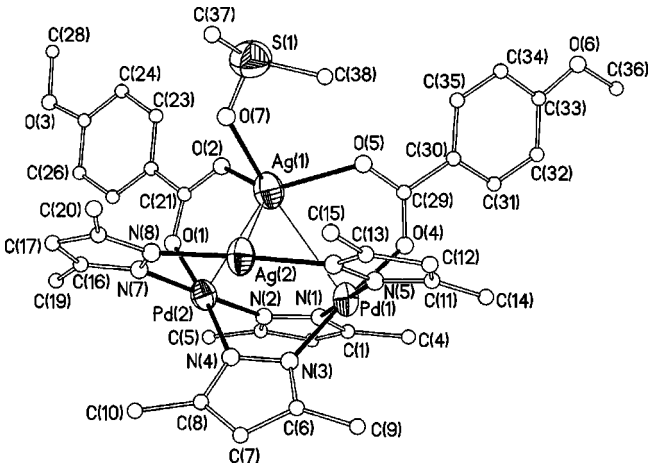

Figure 6. Molecular structure of $[Pd_2Ag_2(\mu\text{-dmpz})_4(\mu\text{-}O_2CC_6H_4OCH_3)_2(DMSO)]$.

Table 4. Bond lengths [Å] and angles [°] for $[Pd_2Ag_2(\mu\text{-dmpz})_4(O_2CC_6H_4OCH_3\text{-}\kappa O)_2(DMSO)]$ from **4d′**.

$[Pd_2Ag_2(\mu\text{-dmpz})_4(p\text{-}O_2CC_6H_4OCH_3\text{-}\kappa O)_2(DMSO)]$ is a palladium/silver tetranuclear compound with both palladium atoms bridged by two 3,5-dmpz groups in such a way that the $Pd_2N_4$ ring shows a typical boat-like conformation, the dihedral angle between both Pd–N–N–Pd fragments being 70.5(2)°.[22] Both palladium atoms complete their square-planar coordination environments by bonding to one nitrogen of another 3,5-dmpz group and one oxygen of the carboxylate anion. In this complex the two 3,5-dmpz groups outside the $Pd_2N_4$ ring are in cisoid positions with respect to the Pd···Pd axis, as are both carboxylate groups, although in the starting complex $[Pd_2(\mu\text{-dmpz})_2(O_2CC_6H_4\text{-}OCH_3\text{-}\kappa O)_2(Hdmpz)_2]$ (**3d**) transoid positions are observed. The Pd–N[6,11–17,20,21,36] and Pd–O[44,45]distances are in the range of those found in palladium compounds with the same kind of ligands.

One of the silver atoms, Ag(2), is bonded to two 3,5-dmpz groups in an almost linear coordination environment [N(8)–Ag(2)–N(6) = 176.9(3)°]. The 3,5-dmpz groups bridging Ag(2) and both palladium atoms are almost coplanar [interplanar angle of 4.7(3)°] and the dihedral angles between them and the coordination planes of the corresponding palladium atoms are 52.3(3)° [Pd(1)] and 51.5(3)° [Pd(2)].[22] The Ag–N distances are similar to those found in other silver pyrazolate complexes.[13]

The other silver atom, Ag(1), is coordinated to two oxygen atoms, one from each carboxylate group, which act as a bridge between this atom] and both palladium atoms. Ag(1) completes its coordination environment with the oxygen of one molecule of DMSO used as crystallisation solvent. All Ag–O distances are in the range of those observed in silver complexes with these kinds of ligands.[44–49] Ag(1) also contacts with Ag(2), the Ag(1)···Ag(2) distance being 2.9208(12) Å, which is similar to distances found in other complexes with Ag···Ag interactions.[50–53] In addition, Ag(1) contacts with Pd(1) [Ag(1)···Pd(1) = 3.0652(12) Å] and Pd(2) [Ag(1)···Pd(2) = 2.9586(12) Å] and the Ag–Pd vectors are nearly perpendicular to the square coordination planes of the Pd(1) and Pd(2) centres [9.2(1)° and 9.7(1)° respectively]. Both facts indicate weak Pd···Ag interactions.[54,55]

The planar "C–$CO_2$" fragment from the carboxylate group bonded to Pd(1) forms angles of 69.8(3)° and 72.3(4)° with the palladium coordination plane and the 3,5-dmpz group outside the $Pd_2N_4$ ring, respectively.[22] The same parameters for Pd(2) are 86.6(3)° and 87.1(4)°. The interplanar angle between both "C–$CO_2$" fragments is 68.1(4)°.

## Conclusion

In summary, *N*-acetylglycine reacts with $[Pd(dmpz)_2(Hdmpz)_2]$ (**A**) in a 2:1 molar ratio to give $[Pd(Hdmpz)_4](O_2CCH_2NHCOCH_3)_2$ (**1**) by selective protonation of the anionic monodentate dmpz ligands. The cationic complex $[Pd(Hdmpz)_4]^{2+}$ is bonded to the *N*-acetylglycinate anion through charge-assisted $N–H^{(+)}\cdots O^{(-)}$ hydrogen bonds. *N*-acetylglycine also reacts with $[Pd_2(\mu\text{-dmpz})_2(dmpz)_2(Hdmpz)_2]$ (**B**) in a 2:1 molar ratio, but in this case, the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

selective protonation of the monodentate dmpz groups (one from each palladium atom) is followed by their displacement by the carboxylate anions generated and their elimination as Hdmpz. In the resulting compound, $[Pd_2(\mu\text{-dmpz})_2(O_2CCH_2NHCOCH_3\text{-}\kappa O)_2(Hdmpz)_2]$ (**2**), the monodentate carboxylate groups exhibit a transoid conformation with respect to the Pd···Pd axis. The benzoic derivatives, $HO_2CC_6H_4$-R [R = *m*-$NO_2$, *p*-$N(CH_3)_2$, *p*-$NH_2$, *p*-$OCH_3$, *p*-OH] react with **B** in the same way that *N*-acetylglycine does to give compounds $[Pd_2(\mu\text{-dmpz})_2(O_2CC_6H_4\text{-R-}\kappa O)_2(Hdmpz)_2]$ [R = *m*-$NO_2$ (**3a**), *p*-$N(CH_3)_2$ (**3b**), *p*-$NH_2$ (**3c**), *p*-$OCH_3$ (**3d**), *p*-OH (**3e**)]. In the complexes **3a**–**3e**, the H atoms of the terminal Hdmpz groups can be replaced by $Ag^+$ to give $[Pd_2Ag_2(\mu\text{-dmpz})_4(\mu\text{-}O_2CC_6H_4\text{-R-}\kappa O)_2(Hdmpz)_2]$ [R = *m*-$NO_2$ (**4a**), *p*-$N(CH_3)_2$ (**4b**), *p*-$NH_2$ (**4c**), *p*-$OCH_3$ (**4d**), *p*-OH (**4e**)], keeping the carboxylate groups in a transoid conformation. Compounds **4a**–**4e** isomerise in acetone solution at room temperature to the cisoid species **4a′**–**4e′**.

## Experimental Section

**General Procedures and Materials:** $[Pd_2(\mu\text{-dmpz})_2(dmpz)_2(Hdmpz)_2]$[14] and $[Pd(dmpz)_2(Hdmpz)_2]$[13] were prepared as described elsewhere. All reagents were commercially available and used as received from Aldrich. Elemental analyses were performed with a Perkin–Elmer 240-B microanalyser. IR spectra were recorded with a Perkin–Elmer 599 spectrophotometer (Nujol mulls between polyethylene plates in the range 400–4000 $cm^{-1}$). NMR spectra were recorded with a Varian Unity-300 spectrometer using standard references.

**$[Pd(Hdmpz)_4](O_2CCH_2NHCOCH_3)_2$ (1):** *N*-acetylglycine (0.12 g, 1.0227 mmol) was added to a solution of $[Pd(dmpz)_2(Hdmpz)_2]$ (**A**; 0.250 g, 0.5113 mmol) in $CH_2Cl_2$/MeOH (25:5 mL). The mixture was stirred at room temperature for 2 h and then the solvent was evaporated to dryness. Addition of $Et_2O$ (5 mL) to the residue yielded **1** (0.3436 g, 93%). $C_{28}H_{44}N_{10}O_6Pd$ (723.12): calcd. C 46.51, H 6.13, N 19.36; found C 46.63, H 5.90, N 19.07. IR: $\tilde{\nu}_{max}$ = 3450–3000 $cm^{-1}$ (s, br), 1667 (m), 1628 (vs), 1583 (s), 1376 (s), 1287 (s), 1068 (m), 1035 (m), 783 (m, sh), 650 (m), 597 (m), 555 (m), 517 (m).

**$[Pd_2(\mu\text{-dmpz})_2(O_2CCH_2NHCOCH_3)_2(Hdmpz)_2]$ (2):** A solution of *N*-acetylglycine (0.06 g, 0.51 mmol) in methanol (10 mL) was added to a solution of $[Pd_2(\mu\text{-dmpz})_2(dmpz)_2(Hdmpz)_2]$ (**B**; 0.200 g, 0.2546 mmol) in $CH_2Cl_2$ (50 mL). The mixture was stirred at room temperature for 2 h and the solution was then filtered through celite and the solvent evaporated to dryness. Addition of $Et_2O$ (5 mL) to the residue yielded **2** (0.110 g, 51%). $C_{28}H_{42}N_{10}O_6Pd_2$ (721.11): calcd. C 40.64, H 5.12, N 16.92; found C 40.71, H 5.08, N 16.60. IR: $\tilde{\nu}_{max}$ = 3450–3000 $cm^{-1}$ (s, br), 1627 (vs), 1583 (vs), 1376 (s), 1282 (s), 1175 (m), 1035 (m), 814 (m), 775 (m), 660 (w). $^1H$ NMR (300 MHz, $CDCl_3$, 23 °C): $\delta$ = 1.80 (s, 6 H, $CH_3$, dmpz), 1.86 (s, 6 H, $CH_3$, *N*-acetylglycine), 2,18 (s, 6 H, $CH_3$, Hdmpz), 2.26 (s, 6 H, $CH_3$, dmpz), 2.64 (s, 6 H, $CH_3$, Hdmpz), 3.74 ($\nu_A$, $^2J_{H,H}$ = 4.0 Hz, 2 H, $CH_2$, acetylglycine), 3.76 ($\nu_B$, 2 H, $CH_2$, acetylglycine), 5.41 (s, 2 H, 4-H, dmpz), 5.80 (s, 2 H, 4-H, Hdmpz), 5.99 (s, 2 H, N-H, acetylglycine), 13.07 (s, 2 H, N-H, Hdmpz) ppm.

**$[Pd_2(\mu\text{-dmpz})_2(O_2CC_6H_4NO_2\text{-}\kappa O)_2(Hdmpz)_2]$ (3a):** A solution of *m*-nitrobenzoic acid (0.1067 g, 0.638 mmol) in methanol (3 mL) was added to a yellow solution of **B** (0.2496 g, 0.318 mmol) in $CH_2Cl_2$ (35 mL). The mixture was stirred at room temperature for 2 h and the solvent was then evaporated to dryness. Addition of diethyl ether (12 mL) to the residue gave **3a** as a yellow solid, which was filtered off and dried (0.055 g, 32% yield). $C_{34}H_{38}N_{10}O_8Pd_2$ (927.54): calcd. C 44.03, H 4.13, N 15.09; found C 43.93, H 4.27, N 14.83. IR: $\tilde{\nu}_{max}$ = 1631 $cm^{-1}$ (vs), 1586 (s), 1531 (s), 1378 (vs), 1348 (s), 1155 (m), 1072 (m), 820 (m), 782 (m), 760 (m). $^1H$ NMR (300 MHz, [D$_6$]acetone, 23 °C): $\delta$ = 1.94 (s, 6 H, $CH_3$, dmpz), 2.36 (s, 6 H, $CH_3$, Hdmpz), 2.40 (s, 6 H, $CH_3$, dmpz), 2.93 (s, 6 H, $CH_3$, Hdmpz), 5.47 (s, 2 H, 4-H, dmpz), 6.10 (s, 2 H, 4-H, Hdmpz), 7.70 (t, $^3J_{H,H}$ = 7.7 Hz, 2 H, 5-H), 8.33 (d, $^3J_{H6,H5}$ = 7.7 Hz, 2 H, 6-H), 8.40 (d, $^3J_{H4,H5}$ = 7.7 Hz, 2 H, 4-H), 8.80 (s, 2 H, 2-H), 13.78 (s, 2 H, N-H, Hdmpz) ppm.

**$[Pd_2(\mu\text{-dmpz})_2\{O_2CC_6H_4N(CH_3)_2\text{-}\kappa O\}_2(Hdmpz)_2]$ (3b):** Prepared similarly to **3a** from **B** (0.3000 g, 0.382 mmol) and *p*-dimethylaminobenzoic acid (0.1262 g, 0.764 mmol). Addition of methanol (7 mL) to the residue gave **3b** (0.2904 g, 82%). $C_{38}H_{50}N_{10}O_4Pd_2$ (923.68): calcd. C 49.41, H 5.46, N 15.16; found C 49.15, H 5.45, N 15.17. IR: $\tilde{\nu}_{max}$ = 1609 $cm^{-1}$ (vs), 1589 (s), 1543 (s), 1525 (s), 1356 (vs), 1307 (s), 1230 (m), 1194 (vs), 1140 (m), 1063 (m), 946 (m), 837 (m), 810 (m), 778 (vs). $^1H$ NMR (300 MHz, [D$_6$]DMSO, 23 °C): $\delta$ = 1.83 (s, 6 H, $CH_3$, dmpz), 2.25 (s, 6 H, $CH_3$, Hdmpz), 2.30 (s, 6 H, $CH_3$, dmpz), 2.78 (s, 6 H, $CH_3$, Hdmpz), 2.92 (s, 12 H, $NMe_2$), 5.45 (s, 2 H, 4-H, dmpz), 6.07 (s, 2 H, 4-H, Hdmpz), 6.65 (d, $^3J_{H2,H3}$ = $J_{H5,H6}$ = 8.8 Hz, 4 H, 3-H, 5-H), 7.71 (d, $^3J_{H2,H3}$ = $J_{H5,H6}$ = 8.8 Hz, 4 H, 2-H, 6-H), 14.00 (s, 2 H, N-H, Hdmpz) ppm.

**$[Pd_2(\mu\text{-dmpz})_2(O_2CC_6H_4NH_2\text{-}\kappa O)_2(Hdmpz)_2]$ (3c):** Prepared similarly to **3a** from **B** (0.2027 g, 0.258 mmol) and *p*-aminobenzoic acid (0.071 g, 0.516 mmol). Yield: 0.2017 g (90%). $C_{34}H_{42}N_{10}O_4Pd_2$ (867.58): calcd. C 47.07, H 4.88, N 16.14; found C 46.76, H 4.72, N 15.83. IR: $\tilde{\nu}_{max}$ = 3386 $cm^{-1}$ (m), 3329 (m), 3176 (m), 3125 (m), 1642 (m), 1600 (vs), 1548 (m), 1513 (m), 1376 (vs), 1297 (s), 1174 (s), 1066 (m), 849 (m), 813 (m), 782 (m), 649 (m), 505 (m). $^1H$ NMR (300 MHz, [D$_6$]acetone, 23 °C): $\delta$ = 1.94 (s, 6 H, $CH_3$, dmpz), 2.36 (s, 12 H, $CH_3$, dmpz, Hdmpz), 2.89 (s, 6 H, $CH_3$, Hdmpz), 4.98 (s, 4 H, $NH_2$), 5.41 (s, 2 H, 4-H, dmpz), 6.00 (s, 2 H, 4-H, Hdmpz), 6.60 (m, 4 H, 3-H, 5-H), 7.77 (m, 4 H, 2-H, 6-H), 14.34 (s, 2 H, N-H, Hdmpz) ppm.

**$[Pd_2(\mu\text{-dmpz})_2(O_2CC_6H_4OCH_3\text{-}\kappa O)_2(Hdmpz)_2]$ (3d):** Prepared similarly to **3a** from **B** (0.2995 g, 0.381 mmol) and *p*-methoxybenzoic acid (0.1161 g, 0.763 mmol). The addition of methanol (8 mL) to the residue gave **3d** as a yellow solid (0.2165 g, 63%). $C_{36}H_{44}N_8O_6Pd_2$ (897.60): calcd. C 48.17, H 4.94, N 12.48; found C 47.87, H 4.82, N 12.35. **X-ray Structure Determination:** Crystal data and other details of the structure analysis are presented in Table 5. Single crystals of **1** were obtained by slow diffusion of *n*-hexane into a solution of **1** in chloroform at room temperature. Single crystals of **3d** and **3e** were obtained by slow diffusion of *n*-hexane into their respective solutions in acetone at room temperature. Single crystals of **4d′** were obtained by slow diffusion of diethyl ether into a solution of **4d** in DMSO at room temperature. For **3d·$Me_2CO$**, the acetone solvent molecule was found to be disordered over two sets of positions that were refined with partial occupancy 0.50:0.50. A common set of anisotropic parameters was used for each pair of homologous atoms. For **3e·2$Me_2CO$**, one of the acetone solvent molecules was modelled as disordered over two positions with partial occupancy 0.75:0.25, with the central C atom (C38) being common for the two sets. For **4d′·0.7$Me_2SO$**, the sulfur atom of the $Me_2SO$ molecule coordinated to Ag(1) was disordered over two positions [S(1)/S(1′)] refined with partial occupancy 0.80:0.20. For this molecule, all the

# One-Pot Synthesis and Structure of Organochalcogen Halides with Mixed Valence States

**Ernesto Schulz Lang,*[a] Gleison Antônio Casagrande,[a] Gelson Manzoni de Oliveira,[a] Gabriela Nanci Ledesma,[a] Sebastião S. Lemos,[b] Eduardo Ernesto Castellano,[c] and Ulrich Abram[d]**

**Keywords:** Halides / Secondary bonding / Selenium / Tellurium

Treatment of the diorganodichalcogenides PhEEPh (E = Se, Te) with one equivalent of elemental halogen (bromine or iodine) in methanol followed by addition of a sulfur donor and one more equivalent of the corresponding organochalcogen trihalide $PhTeX_3$ affords the mixed-oxidation-state organochalcogen halides $[PhE^{II}(L)PhE'^{IV}X_4]$ (E = Se, Te; E′ = Te; X = Br, I; L = thiourea, tetramethylthiourea) in a one-pot procedure. The X-ray structural analyses of these compounds suggest a strong dependence of the formation of supramolecular assemblies on the nature of the halogen bonded to the tellurium atom. The halogen can induce intramolecular and intermolecular secondary interactions among the heavy atoms simultaneously and, in addition to Te···X and X···X secondary bonds, intramolecular interactions of the type Te···$\eta^6$-$\pi$-aryl can be formed.

## Introduction

The chemistry of organochalcogen halides is also the chemistry of secondary bonds and as such is the subject of considerable current interest. The bonding in these compounds eludes simple description, and concepts like hypervalence, multicenter bonding, charge-transfer interactions, and secondary bonds have been invoked to understand their structural and chemical properties.[1–9] Intermolecular bonding of the type E···X and X···X (E = Se, Te; X = Cl, Br, I) of various strengths leads to the formation of polymeric chains, dimeric structures, or monomers with fairly strong intermolecular interactions. Many of these halogen compounds lie close to the ionic/covalent borderline, and several identified species have been found to be dependent on the substituents R, the donor atom, the identity of the halogen, and, in some cases, also on the dielectric constant of the solvent in which they have been prepared.[10–12]

Recently, as part of our research on the coordination of organotellurium compounds, we have reported the syntheses and the molecular structures of organotellurium trihalides[13,14] and organotellurium monohalides,[11,15,16] as well as several studies involving structures of phenyltellurate halides stabilized by different cations.[17–19] Most of the crystal structures reported for the $RTeX_3$ species show that the occurrence of intra- and intermolecular interactions (secondary bonding), together with the nature of the organic groups bonded to the tellurium atoms, exert influence on the geometry around the tellurium(IV) center and consequently define the structural patterns of these compounds.[14,20–26] The apparent bisphenoidal coordination sphere of the central tellurium atom is extended by the presence of intermolecular Te···X and X···X secondary interactions. It has been assumed that for $RTeX_3$ compounds there is a tendency for the chlorides to be polymeric, the bromides either polymeric or dimeric, the iodides dimeric, and, if R is particularly bulky, monomeric structures would be the norm. Here, the size of the halogen should be the other determining factor, with dimeric structures preferred as the halogen size increases.[27,28] A comparison of the structure of $[(2,4,6\text{-}Ph_3C_6H_2)TeI_3]$ with the bonding situation in other organotellurium(IV) triiodides suggests a strong dependence of the formation of supramolecular assemblies on the nature of the organic substituents.[14]

More recently, we have extended our studies to investigate the reaction conditions needed to obtain and isolate the corresponding mono-iodide of the more bulky substituted ditellurides $(MesTe)_2$ or $(2,4,6\text{-}Ph_3C_6H_2Te)_2$. The presence of the methyl or phenyl groups on the aromatic rings probably prevents the formation of stable tetrameric subunits similar to $(PhTeI)_4$.[11] Attempts to crystallize the corresponding aryltellurenyl mono-iodide (RTeI) were un-

successful as it decomposes to other aryltellurium derivatives.[11,15,16] Thus, for example, $(MesTe)_2$ [Mes = 2,4,6-$(CH_3)C_6H_2$] reacts with iodine to produce [MesTeI], which disproportionates to [$MesTeI_3$], elemental tellurium, and [$MesTe(TeMes_2)I$].[16] When the same reaction is carried out with [(2,4,6-$Ph_3C_6H_2$)Te]$_2$, the compound [(2,4,6-$Ph_3C_6H_2$)-$TeI_3$][14] is formed as a result of a disproportion reaction under inert atmosphere or an oxo-bridged tellurium(IV) compound in the presence of air.[15] We are investigating this process further as it seems to have not only a steric influence but also an electronically directed behavior. The compound [$MesTe(TeMes_2)I$] is a representative example of a wider class of compounds of general formula [RTe(L)X] (where L is a neutral donor ligand), which were reported for the first time in the pioneering work of Foss and Huseby.[29] More recently, Godfrey,[12] Sadekov et al.,[30] and Singh et al.[31,32] have reported new examples.

Taking into account the unexpected reactivity and the interesting structural arrays previously obtained for several organochalcogen halides, we have turned our attention to the possibility of preparing organochalcogen halides with chalcogen atoms presenting mixed valence states in the same molecule.

There are only a few examples of this class of compounds in the literature. One of these is [$(DMSeU)_2Te_2Br_6$] (DMSeU = *N*,*N*-dimethylselenourea), which was obtained during the preparation of thin films of Te–Se alloys.[33] This compound contains both $Te^{IV}$ and $Te^{II}$ in the same molecule and there are no previously reported cases of such structures involving tellurium. Recently the synthesis and structural elucidation of [$Me_2TeCCTeMe$]I, the first alkynyltelluronium species, was reported.[34] A further search in the Cambridge Crystallographic Database reveals one more structure showing the coexistence of $Ph_3TeI$ and MesTeI in a ratio of 4:2 in the same compound.[3,35] The iodine atoms bridge the $Te^{IV}$ and $Te^{II}$ atoms to build blocks containing six molecules.

In the light of these previous results and to expand our studies on the molecular structures and intermolecular bonding in organotellurium derivatives, we have prepared organic models which should allow the study of the interaction processes of tellurium(II) cations with tellurolate anions. In this paper we report the synthesis and the structural characterization of the four new complexes [(TMTU)-PhTe(μ-Br)$TeBr_3Ph]_2$ (**1**), [(TU)PhTe(μ-I)$TeI_3Ph]_2$ (**2**), [PhSe(TU)][$PhTeI_4$] (**3**), and [PhSe(TU)][$PhTeBr_4$] (**4**).

## Results and Discussion

The reactions between diaryl dichalcogenides and an equivalent amount of halogen in methanol at room temperature afford the corresponding arylchalcogen halides stabilized by a sulfur donor. The arylchalcogenide trihalide was added to the mixture and stirred at slow reflux for 2 h. The final solution was filtered and crystals suitable for X-ray analysis were achieved by slow evaporation of the solvent. Compounds **1**–**4** were obtained in yields of 63–85 % [Equation (1)].

$$1/2\ (PhE)_2 \xrightarrow{1/2\ X_2} PhEX \xrightarrow{L} PhE(L)X \xrightarrow{PhE'X_3} PhE(L)PhE'X_4 \quad (1)$$

E = Se, Te; E′ = Te; X = Br, I; L = $(Me_2N)_2CS$ (TMTU), $(H_2N)_2$-CS (TU)

Several attempts to recrystallize **1**–**4** in order to obtain compounds with a high purity resulted in disproportionation to yield mainly $Ph_2TeX_2$ and $PhEX_3$ (E = Se, Te; X = Br, I).[11,16] Besides elucidating the structures of **1**–**4**, we were also interested in the structure of similar compounds containing chlorine. Attempts to obtain PhTeCl[36] by treatment of $(PhTe)_2$ with $SO_2Cl_2$ and then [PhE(L)PhE′$Cl_4$] according to Equation (1) failed; the analysis of the final material revealed merely the presence of [PhTe(TU)Cl][18] and the starting materials $PhTeCl_3$ or $PhSeCl_3$.

### X-ray Crystallography

The X-ray studies showed that the asymmetric units of compounds **1** and **2** (Figures 1 and 2, respectively) present the general formula [PhTe(L)$PhTeX_4$] [**1**: L = TMTU (tetramethylthiourea), X = Br; **2**: L = TU (thiourea), X = I] Since the Te2–Br2 and Te2–I4 distances in **1** and **2** [3.1757(13) and 3.1687(8) Å] are similar to the Te1–Br2 and Te1–I4 distances, but much smaller than the Te1–Br3′ and Te1–I4′ bond lengths of 3.8471(13) and 3.7602(12) Å. According to Alcock's concept of secondary bonds,[1] the latter bonds are examples of this type of interaction. Thus, it is plausible to state that the asymmetric units are neutral monomers connected by secondary Te···X interactions into dimers with the formula [LPhTe(μ-X)$TeX_3Ph]_2$. The crystal structures of compounds **3** and **4** (Figures 3 and 4, respectively) are built up of discrete $[PhTeX_4]^-$ anions (**3**: X = I; **4**: X = Br) and the corresponding $[PhSe(TU)]^+$ cations. Considering the E···X secondary bonds, the complex salts **3** and **4** should be classified as pseudo-dimeric (**3**) or polymeric (**4**) assemblies.

The two PhTe(TMTU)$PhTeBr_4$ units in complex **1** are related by a center of inversion in the center of the rectangle formed by the atoms Te1, Br3, Te1′, and Br3′ (Figure 1). The Br3 and Br3′ atoms form secondary bonds to the Te1′ and Te1 atoms, respectively, thereby closing the dimeric arrangement. The geometry around the $Te^{IV}$ atom (Te1) may be described as distorted octahedral with bonds to five bromine atoms (Br1, Br2, Br3, Br4, and Br3′) and to one aromatic carbon atom (C11). The geometry around the $Te^{II}$ atom (Te2) presents a T-shape and involves a bromine atom (Br2), a sulfur atom, and an aromatic carbon (C21). The Br2 atom is shared by both tellurium atoms located in the same asymmetric unit, thereby suggesting the occurrence of a charge-transfer compound. The sum of the van der Waals radii of Te and Br is 4.0 Å.[37] The Te2–S bond length of 2.455(3) Å agrees with similar examples in the literature containing a Br–Te–S arrangement.[29] An intramolecular contact is observed between $Te^{II}$ and the π-system of the phenyl ring C11–C16, resulting in a relatively short distance

between $Te^{II}$ and C12 [3.577(23) Å] in the solid-state structure of **1**. The distance between the $Te^{II}$ atom and the centroid of the phenyl ring is 3.935(18) Å and can be interpreted as a Te–$\eta^6$-π-interaction.[38]

The PhTe(TU)PhTe$I_4$ units in complex **2** are also related by a center of inversion in the middle of the rectangle formed by the atoms Te1, I4, Te1′, and I4′. The dimer is connected through the I4 and I4′ atoms. The geometry around the Te1 atom may also be described as distorted octahedral, with bonds to five iodine atoms (I1, I2, I3, I4, and I4′) and to one aromatic carbon atom (C11). The Te1–I3 bond [2.7953(7) Å] is shorter than the *trans* Te1–I4 [3.2651(7) Å] and the Te2–I4 [3.1687(8) Å] bonds, probably due to the bridging role of the I4 atom,. The I4 atom is shared by both tellurium atoms located in the same asymmetric unit, which also suggests the occurrence of a charge-transfer process as in compound **1**.

In a recent work Aragoni et al.[6] discussed the ionic {[RSeCN]$^+$I$^-$} or "T-shaped" hypervalent {R(I)SeCN} features of an ICN adduct with a selenium donor. Density functional theory (DFT) calculations, among other studies, have accounted for the strong polarity of the Se–I bond as being due to the selenium atom having a partial hypervalent state. These results allowed the authors to conclude that the compound can be described as the product of a donor–acceptor interaction between I and the selenium atom of the organic cation [RSeCN]$^+$. This evidence can also be used to support our molecular interpretation of the monomeric fragments LPhTe(μ-X)Te$X_3$Ph of compounds **1** and **2**, although with a reasonably strong polarization of the bonds Br2–Te2 in **1** and I4–Te1 in **2**. The [PhTeS(R)]$^+$ fragment of **1** and **2** would correspond to the organic cation [RSeCN]$^+$ of Aragoni and co-workers.[6] The dimerization

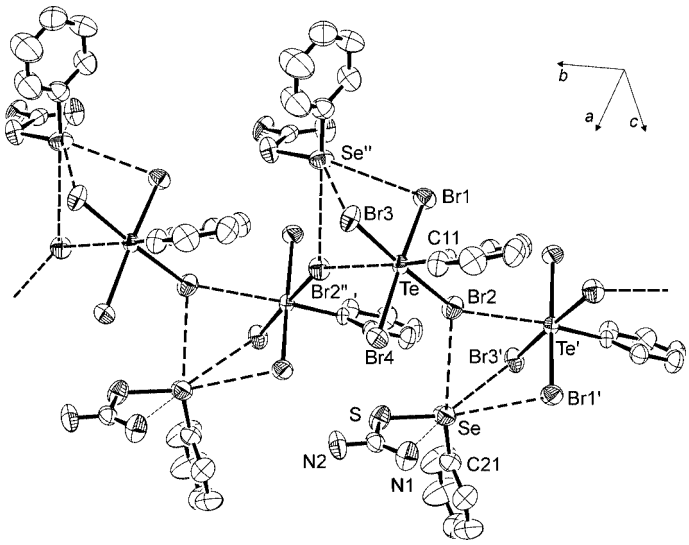

Figure 4. Crystal structure of **4** (hydrogen atoms omitted). Ellipsoids are drawn at 50 % probability. Selected bond lengths [Å] and angles [°]: Te–Br1 2.6535(12), Te–Br2 2.7688(12), Te–Br3 2.6163(12), Te–Br4 2.7309(12), Br2–Te′ 3.5775(13), Te–C11 2.148(9), Se–Br1′ 3.7113(18), Se–Br2 3.6853(16), Se–Br3′ 3.9395(17), Se–S 2.196(4), Se–C21 1.930(11), Se–N1 3.1681(97); Br1–Te–Br2 87.29(4), Br1–Te–Br3 89.69(4), Br1–Te–Br4 176.28(4), C11–Te–Br1 92.3(2), C11–Te–Br2 90.2(2), C11–Te–Br3 89.4(2), Te–Br1–Se′′ 94.02(4), Te–Br2–Se 124.00(5), Te–Br3–Se′′ 89.53(4), Br2–Se–S 93.87(10), Br2–Se–C21 156.1(3), C21–Se–S 100.3(4). Symmetry transformation used to generate equivalent atoms (′): $-x$, $y - 0.5$, $-z + 1$; (′′): $-x$, $y + 0.5$, $-z + 1$.

of the compounds through secondary Te···X bonds indicates the presence of a partial positive charge on the Te atom, as expected in hypervalent adducts with halogens. However, complexes **1** and **2** cannot be classified as charge-transfer (CT) complexes. Indeed, based on their structures and literature precedents[4,6] they should be considered CT-type compounds where the donor–acceptor interaction occurs from the μ-Br2 and μ-I4 atoms of the octahedral $[PhTeX_4]$ fragment, which acts as donor, to the empty σ* molecular orbital located on the S–Te axis of the $[PhTeS(R)]^+$ moiety.

The crystal structure of complex **3** is built up of $[PhTeI_4]_2^{2-}$ anions stabilized by two $[PhSeTU]^+$ cationic units. The I3 and I3′ atoms connect the $[PhTeI_4]^-$ anionic units and the I2 and I2′ atoms present a weak interaction with the Se and Se′ atoms of cationic $[PhSeTU]^+$ units. The geometry around the Te atom can be described as distorted octahedral as it is bonded to five halogen atoms (I1, I2, I3, I4 and I3′) and to one aromatic carbon atom (C11). The geometry around the Se atom shows a distorted T-shaped form; the Se atom is bonded to one sulfur atom, one aromatic carbon atom (C21), and weakly bonded to one iodine atom [Se–I2 = 3.9485(12) Å]. The ionic formulation of compound **3** is supported by the fact that the Se–I bond length is much longer than analogous bond lengths in previously reported structures [Se–I = 2.564(1)–2.720(1) Å].[39,40] The structure of **3** is quite different from that of compound **1** with regards to the coordination sphere of the $Te^{II}$ and $Se^{II}$ atoms. The $Te^{II}$ atom in **1** has a tendency to form an intramolecular bond of the type Te···$\eta^6$-π-aryl, while for **3** the $Se^{II}$ atom coordinates preferentially to iodide atoms. Weak $Se^{II}$···I secondary interactions link the neighboring molecules into a chain along the crystallographic *b* axis. Also of interest in the structure of **3** is the presence of four identical weak I···I secondary interactions [3.7128(8) Å] with adjacent molecules to give a polymeric, double-zigzag chain along the crystallographic *a* axis. As in **2** and in other organotellurium triiodides,[14] intramolecular I···I and Te···I secondary interactions contribute to the formation of continuous supramolecular chains in the crystal packing.

The crystal structure of complex **4** is built up of discrete cationic $[PhSeTU]^+$ and anionic $[PhTeBr_4]^-$ units, with halogen atoms bridging secondary adjacent tellurium atoms to give a single zigzag polymeric chain along the crystallographic *b* axis. The chain character is additionally reinforced by three secondary bonds from cationic selenium atoms to the bromine ligands of the surrounding anionic units (Figure 4). The geometry around the Te atom, which is bonded to five bromine atoms (Br1, Br2, Br3, Br4, and Br2′′) and to one aromatic carbon atom (C11), may be described as distorted octahedral. The Se atom shows a highly distorted octahedral geometry, with secondary bonds to three bromine atoms (Br1, Br2′′, Br3) and primary bonds with one aromatic carbon atom (C21) and the sulfur/nitrogen atoms of the thiourea ligand. The interionic Se···Br secondary bonds of **4**, with distances varying from 3.6853(16) (Se–Br2) to 3.9395(17) Å (Se–Br3′) can be considered weak interactions when compared with the Se–Br bond lengths of 2.3331(8) Å in $2\text{-}Me_2NCH_2C_6H_4SeBr$,[32,41] for example. The Se–N1 bond length of 3.1681(97) Å in **4** is also a very weak interaction when compared with Se–N bond lengths of other compounds such as $2\text{-}Me_2NCH_2C_6H_4SeX$: [X = Cl: Se–N = 2.135(4) Å; Br: 2.143(6) Å; I: 2.172(3) Å].[42]

### $^{125}$Te and $^{77}$Se NMR Spectroscopy

Attempts to study the title complexes in noncoordinating solvents by means of NMR spectroscopy were unsuccessful

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

due to their poor solubility. Since compounds **1**–**4**, as expected, do not show many significant features in their $^{1}H$ or $^{13}C$ NMR spectra, our attention turned to $^{125}Te$ and $^{77}Se$ NMR spectroscopy. A mixture of [$D_6$]acetone and [$D_6$]-DMSO (9:1 by volume) was employed for the NMR studies. The two signals detected for **1** at $\delta$ = 1203.3 and 828.8 ppm (for **2** only one broad signal is observed at $\delta$ = 946 ppm) appear very close to the two peaks observed at $\delta$ = 1202.3 and 824.8 ppm for $PhTeBr_3$, whose spectrum was recorded under the same conditions for comparison purposes. The dissolution of $PhTeBr_3$ presumably produces the ionic species shown in Equation (2).

$$2\ PhTeBr_3 \xrightarrow{DMSO} [PhTe^{IV}Br_2]^+ + [PhTe^{IV}Br_4]^- \quad (2)$$

The major signal of compound **1** at $\delta$ = 1203.3 (s) ppm should correspond to the ionic form $[PhTe^{IV}Br_4]^-$, which occurs at $\delta$ = 1199.8 ppm for the standard compound $(NEt_4)[PhTeBr_4]$. This result allows also us to conclude that the dissolution of compound **1** (and probably also of **2**) leads to the cleavage of all the bonds represented by dotted lines in Figure 1 (e.g., the secondary Te1–Br3′ and the primary Te2–Br2 bonds). This also supports the assumption that the second signal of compound **1** [$\delta$ = 828.8 (s) ppm] should correspond to the cationic species $[PhTe(L)]^+$.

The selenium derivatives **3** and **4** seem to exhibit a different behavior in solution. While compound **4** presents only a sharp $^{125}Te$ resonance at $\delta$ = 1230.2 ppm, compound **3** does not show any NMR signal even though different windows were investigated. Furthermore, in the case of **4** two sharp $^{77}Se$ resonances are found at $\delta$ = 655.9 and 446.5 ppm in an approximate proportion of 1:1. This result supports the hypothesis of a partial disruption of the polymer according to Equation (3).

$$\{[PhSe(TU)][PhTeBr_4]\}_n \rightarrow n/2\ \{PhSe(TU)[PhTeBr_4]_2\}^- + n/2\ [PhSe(TU)]^+ \quad (3)$$

The anionic species might be fluxional and variable-temperature studies would be needed to characterize such a system. Unfortunately, we could not do this because of the limited solubility of all compounds in solvents adequate for low-temperature studies.

## Conclusions

A good familiarity with the coordination chemistry and reactivity of organyl chalcogen compounds in the single oxidation states +2 and +4 is required and desirable for the adequate planning of different syntheses (one pot) to give good yields of organyl chalcogenides derivatives with mixed valence states.

The X-ray analytical data of the structures of compounds **1**–**4** show a strong tendency to dimerize for **1** and **2** and suggest that the formation of supramolecular assemblies depends on the nature of the halogen bonded to the tellurium atom. The halogen can induce simultaneous intra- and intermolecular secondary interactions among the heavy atoms and, in addition to Te···X and X···X secondary bonds, intramolecular interactions of the type Te···$\eta^6$-π-aryl can be formed. Secondary bonds are usually not strong enough to remain in solution, especially in coordinating solvents, but they can have spectacular effects in the building of a crystal by creating the secondary structure that defines the supramolecular arrangement in the solid state.[43,44] These findings also suggest further investigations of the steric influence of the organic substituents on the final architecture of the compounds.

## Experimental Section

**General Procedure:** All manipulations were conducted under dinitrogen, using standard Schlenk techniques. Methanol was dried with sodium and distilled prior to use. Diphenyl diselenide and diphenyl ditelluride were prepared according to literature methods.[45,46]

**X-ray Structural Determination:** The structures were solved by direct methods using SHELXS-97.[47] Subsequent Fourier-difference map analyses yielded the positions of the non-hydrogen atoms. Refinements were carried out with the SHELXL-97 package.[47] All refinements were made by full-matrix least-squares on $F^2$ with anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were included in the refinement in calculated positions. Crystal data and more details of the data collections and refinements are contained in Table 1.
CCDC-286671–286674 (**1**–**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**NMR Spectroscopy:** All NMR spectra were recorded with a Varian Mercury plus spectrometer (7.05 T) operating at 94.74 MHz for $^{125}Te$ and 57.23 MHz for $^{77}Se$. $^{125}Te$ and $^{77}Se$ NMR spectra were acquired in a mixture of [$D_6$]acetone and [$D_6$]DMSO (9:1 by volume) and were externally referenced to $Me_2Te$ and $Me_2Se$ checked against $Te_2Ph_2$ in $CDCl_3$ ($\delta$ = 450.0 ppm)[48] and $Se_2Ph_2$ in $CDCl_3$ ($\delta$ = 461.0 ppm),[49] respectively. The sample temperature was maintained at 300 K during the acquisitions.

**General Procedure for the Synthesis of PhE(L)PhE′$X_4$. PhTe(TU)-$PhTeI_4$:** Iodine (1 mmol, 0.2538 g) was added to a solution of diphenyl ditelluride (1 mmol, 0.4092 g) in methanol at room temperature. The mixture was stirred for 10 min until the color changed from red to black. Thiourea (2 mmol, 0.1522 g) was then added to the mixture − the color of the solution changed from black to red − and soon afterwards $PhTeI_3$ (2 mmol, 1.1706 g) was added. The solution was kept at slow reflux for 2 h. The final solution was filtered at room temperature and crystals suitable for X-ray analysis were grown by slow evaporation.
**1:** Yield: 1.0141 g (65 %). M.p. 189–192 °C. $C_{17}H_{22}Br_4N_2STe_2$: calcd. C 23.71, H 2.57, N 3.25; found C 24.44, H 2.81, N 3.89. $^{125}Te$ NMR: $\delta$ 1203.3 (s), 828.8 (s) ppm.
**2:** Yield: 1.2907 g (63 %). M.p. 147–149 °C; $C_{13}H_{14}I_4N_2STe_2$: calcd. C 15.72, H 1.42, N 2.82; found C 16.00, H 1.47, N 2.73. $^{125}Te$ NMR: $\delta$ = 946 ppm (br).
**3:** Yield: 1.2840 g (68 %). M.p. 168–170 °C; $C_{13}H_{14}I_4N_2SSeTe$: calcd. C 16.53, H 1.49, N 2.97; found C 16.82, H 1.42, N 2.89.
**4:** Yield: 1.2853 g (85 %), Melting point: 178–180 °C; $C_{13}H_{14}Br_4N_2SSeTe$: calcd. C 20.64, H 1.87, N 3.70; found C 19.42, H 2.05, N 3.88. $^{125}Te$ NMR: $\delta$ = 1230.2 ppm (s). $^{77}Se$ NMR: $\delta$ = 655.9 (s), 446.5 (s) ppm.

# Synthesis, Structure and Reactivity in Styrene Polymerization by Heterocyclic Alkoxy- and Thiolatotitanium(IV) Complexes

**Pedro J. Aragón,[a] Fernando Carrillo-Hermosilla,[a] Elena Villaseñor,[a] Antonio Otero,*[a] Antonio Antiñolo,[a] and Ana M. Rodríguez[a]**

**Keywords:** Heterocyclic ligands / Polymerization / Structure elucidation / Titanium

The reaction of $[Ti(OiPr)_4]$ or $[TiCl_4(THF)_2]$ with two equivalents of pyridyl alcohols or pyridyl or pyrimidinyl thiols has proven to be a good preparative method to obtain a variety of non-metallocene diisopropoxo- or dichlorotitanium(IV) complexes. The complexes $[Ti(X)_2\{2\text{-}(OCH_2)\text{-}6\text{-}R\text{-}(C_5H_3N)\}_2]$ were found to be dynamic at room temperature, with the heterocyclic alkoxy ligand dissociating and recoordinating in a $\kappa^2$-N,O chelate fashion, as revealed by a single-crystal X-ray analysis of $[Ti(OiPr)_2\{2\text{-}(OCH_2)(C_5H_4N)\}_2]$ (**1**). The dynamic behavior of some of the resulting thiolato complexes was also studied and the single-crystal X-ray analysis of $[Ti(OiPr)_2\{2\text{-}S\text{-}4,6\text{-}Me_2\text{-}(C_4HN_2)\}_2]$ (**5**) revealed a $\kappa^2$-N,S system for these complexes. These complexes show catalytic activity in the polymerization of styrene upon activation with methylaluminoxane.

## Introduction

The coordination chemistry of the transition metals has experienced significant developments during the last three decades and at present constitutes an area of great importance due to its theoretical interest and diverse applications in organic synthesis and catalytic processes. The chemistry of the group 4 elements is dominated by complexes that contain cyclopentadienyl ligands or their derivatives. This is due to the fact that in recent years this field has undergone a significant expansion aimed at exploiting applications of these complexes as catalysts in olefin polymerization, hydrogenation, and hydrosilylation reactions. Nevertheless, increasing interest is being shown in the use of alternative ligands, such as alkoxy or amido derivatives, that are capable of stabilizing metal complexes in high oxidation states. In this way, it is possible to design ligands that can stabilize active species in certain catalytic processes so that they can be used instead of Cp ligands.[1]

In this paper we describe the synthesis and characterization of new alkoxy- and thiolatotitanium(IV) complexes bearing heterocyclic rings in the ligands. In addition, the activity of these complexes as styrene polymerization catalysts has been studied.

## Results and Discussion

The new complexes $[Ti(X)_2\{2\text{-}(OCH_2)\text{-}6\text{-}R\text{-}(C_5H_3N)\}_2]$ [X = O*i*Pr, R = H (**1**); X = Cl, R = H (**2**); X = Cl, R = Me (**3**)], $[Ti\{2,6\text{-}(OCH_2)_2(C_5H_3N)\}_2]$ (**4**), $[Ti(X)_2(SR)_2]$ [X = O*i*Pr, SR = 2-S-4,6-$Me_2$-$(C_4HN_2)$ (**5**); X = Cl, SR = 2-S-4,6-$Me_2$-$(C_4HN_2)$ (**6**); X = O*i*Pr, SR = 2-S-$(C_4H_3N_2)$ (**7**); X = Cl, SR = 2-S-$(C_4H_3N_2)$ (**8**); X = O*i*Pr, SR = 2-S-$(C_5H_4N)$ (**9**)], and $[TiCl_2\{2\text{-}S\text{-}(C_5H_4N)\}\{O(CH_2)_4Cl\}]$ (**10**) were prepared by reaction of the corresponding alcohol or thiol with $[Ti(OiPr)_4]$ or $[TiCl_4(THF)_2]$ (Scheme 1).

Complexes **1**–**3** were isolated as white, air-sensitive solids. Complex **1** is very soluble in THF but complexes **2** and **3** are only sparingly soluble in this solvent.

The presence of two isopropoxide or chloride groups and two alkoxypyridine ligands means that several stereochemical configurations are possible, with the possibility of $\kappa^2$-O,N coordination of the latter ligands to the metal center. A single-crystal X-ray analysis of compound **1** was carried out in order to provide precise structural details of this compound and the related complexes **2** and **3**. The structure of complex **1** is shown in Figure 1, together with the atom-numbering scheme. The bond lengths and angles for this structure are given in Table 1. Complex **1** crystallizes in the monoclinic space group $P2_1/n$. The Ti atom has a markedly distorted pseudoctahedral geometry, with the alkoxypyridine ligands occupying four sites in a chelate fashion. This arrangement is consistent with the $^{13}C$ NMR spectra of complexes **1**–**3**, in which the signals assigned to the C2 and C6 atoms of the pyridine moiety are shifted to slightly lower field in comparison with those in the free ligand. In this way, each ligand is bonded to the metal center through both

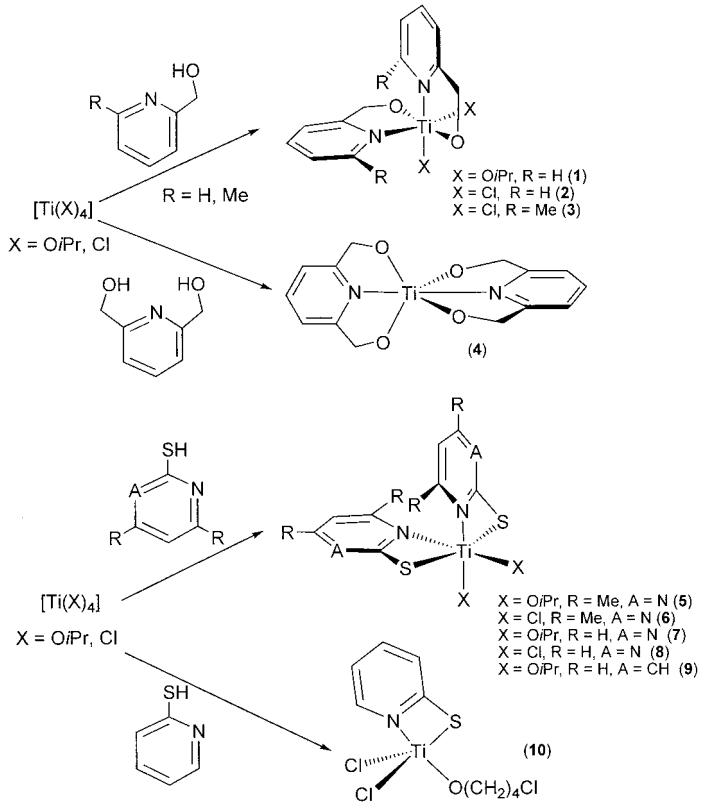

Scheme 1.

the nitrogen and the oxygen atoms. The Ti–O1 and Ti–O2 distances are slightly longer than those found in [Ti($\eta^5$-$C_5H_5$){2-(OC*i*Pr$_2$)-($C_5H_4$N)}Cl$_2$] [1.8267(9) Å],[2] which may indicate low O(pπ)–Ti(dπ) donation to the metal. In contrast, the Ti–N distances are similar in both complexes.

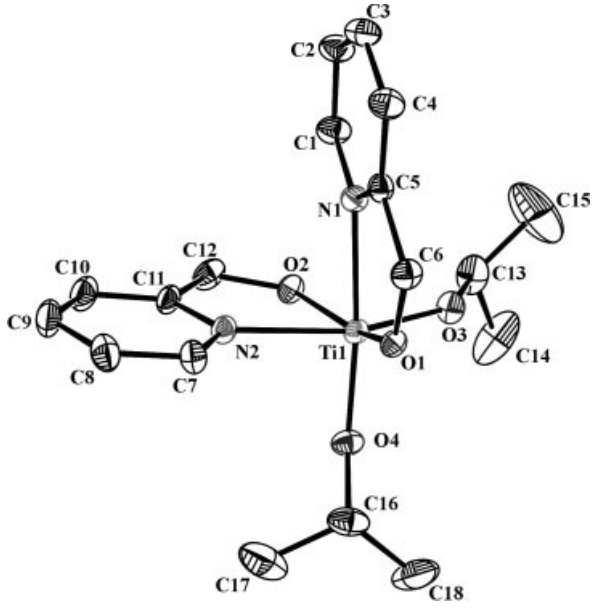

Figure 1. An ORTEP drawing of **1** with the numbering scheme.

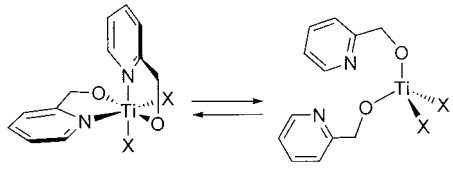
It is worth noting that this configuration makes the two hydrogen atoms in the methylene groups inequivalent. In contrast, the $^1$H NMR spectrum of complex **1** shows one single peak for these hydrogen atoms at room temperature. This behavior can be explained in terms of a dynamic process in solution for this molecule. In this process, the alkoxypyridine ligands probably change their $\kappa^2$-N,O coordination to a $\kappa^1$-O coordination through a rupture of the metal–nitrogen bonds (Scheme 2). A similar behavior has been observed in zirconium complexes with oxypyridine and oxypyrimidine ligands.[3]



Scheme 2.

A variable-temperature $^1$H NMR study was also carried out on the complexes. When the $^1$H NMR spectrum of complex **1** was recorded at 213 K, an AB spin system ($\delta_A$ = 5.92, $\delta_B$ = 5.89 ppm; $J_{AB}$ = 18.55 Hz) was observed for the inequivalent methylene protons, indicating that, at this temperature, the alkoxypyridine ligands are coordinated in a chelate fashion [$\Delta G^{\ddagger}$ = 54.5(6) kJ mol$^{-1}$], as found in the X-ray structure. In addition, two signals for the methyl groups of the isopropoxide ligands were found, indicating that free rotation does not occur at this temperature [$\Delta G^{\ddagger}$ = 51.2(5) kJ mol$^{-1}$]. A similar behavior was observed for complex **2**. The low solubility of complex **3** prevented us from

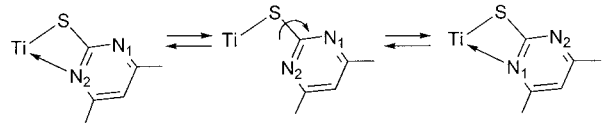
obtaining conclusive results for this complex, although one would expect a similar situation to occur in all three cases.

Attempts to obtain a complex of the type $[Ti(X)_2\{2,6\text{-}(OCH_2)_2\text{-}(C_5H_3N)\}]$ were unsuccessful. In all cases, $[Ti\{2,6\text{-}(OCH_2)_2\text{-}(C_5H_3N)\}_2]$ (**4**) was obtained as a very insoluble white solid.

The $^{13}C$ NMR spectrum of complex **1** is consistent with a disposition in which the dialkoxide ligand shows tridentate coordination and is bonded to the metal atom in a "pincer" fashion.[4]

Similarly, it was not possible to obtain the analogous compound of complex **3** with isopropoxide ligands − a complex mixture of unidentified compounds was obtained in all cases. A possible explanation for this behavior involves the high level of steric hindrance associated with the ligands on the metal center in comparison with the less-crowded chloride complex **3**.

Thiolato complexes **5**–**10** were obtained as yellow (**5**–**9**) or pale-orange (**10**) very air-sensitive solids, with the chloride complexes **6**, **8**, and **10** being only sparingly soluble in THF. The $^1H$ NMR spectrum of **5** shows a broad singlet at $\delta$ = 2.42 ppm due to the thiolato methyl groups, indicating that fluxional behavior may be occurring in the molecule. This behavior is probably due to an interchange in the positions of the nitrogen atoms of the pyrimidine groups in the coordination sphere of the titanium atom by rotation around the S–C bonds (see Scheme 3).[3,5] Kempe[6] has described similar complexes with isolobal aminopyridinato ligands. These complexes undergo a dynamic process that implies an interchange between the aminopyridinato ligands. This exchange proceeds via a tetrahedral transition state similar to that we postulate for the exchange in the thiolato complexes



Scheme 3.

A variable-temperature $^1H$ NMR study was carried out on this complex. When the $^1H$ NMR spectrum was recorded at 223 K, two signals corresponding to the methyl groups of the pyrimidine fragments were observed, indicating that rotation around the S–C bond is hindered [$\Delta G^{\ddagger}$ = 60.5(2) kJ mol$^{-1}$] for both thiolate ligands, which act as chelate ligands. As the temperature increases, the rotation becomes easier and at temperatures above 293 K only one signal is observed, corresponding to the free rotation of the two equivalent ligands. A similar behavior was observed for complex **7**. The lack of solubility of complexes **6** and **8** prevented us from obtaining results for these compounds, although the $^{13}C$ NMR spectra indicate that some chelate interaction is present in **6** but not in **8** at room temperature.

A single-crystal X-ray analysis of complex **5** was carried out in order to obtain more precise structural information for this compound and analogous complexes **6**–**10**. The structure of complex **5** is shown in Figure 2, and bond lengths and angles for this structure are given in Table 1.

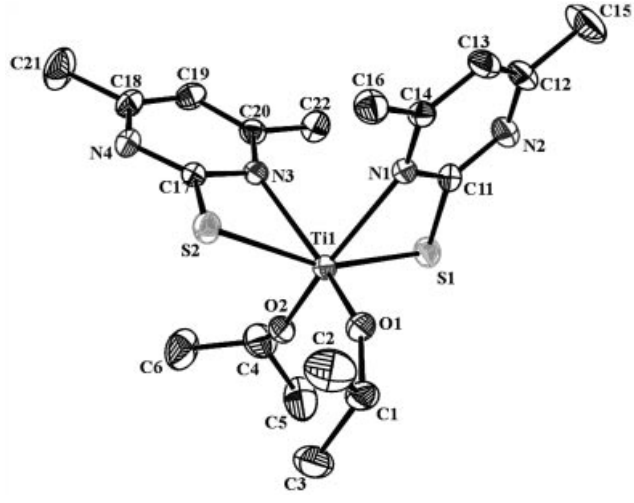


Figure 2. An ORTEP drawing of **5** with the numbering scheme.

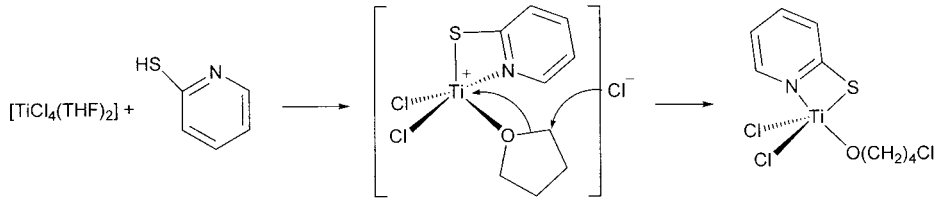
To the best of our knowledge, only three structurally characterized titanium thiolatopyridine or -pyrimidine complexes have been described,[7a–7c] and two of these contain cyclopentadienyl ligands. Complex **5** crystallizes in the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4.

monoclinic space group $P2_1/n$. The Ti atom shows a highly distorted pseudooctahedral geometry, with two isopropoxide ligands occupying two sites and the other four sites occupied by the thiolatopyrimidine ligands in a chelate fashion. The bonding of the didentate thiolate to the metal center can be considered as being intermediate between the pyridine-2-thiolate form and the canonic amide-thione. The Ti–S distances are longer than those found in cyclopentadienyl and noncyclopentadienyl titanium complexes with thiolato ligands.[7,8] This suggests weaker Ti–S bonds in complex **5**. The Ti–N distances are even longer than those found in the aminopyridinate complexes described above,[6] in accordance with the lability of the Ti–N(pyridine) bonds.

Whereas the reaction of 2-HS-($C_5H_4N$) with [Ti(O*i*Pr)$_4$] gives rise to the complex [Ti(O*i*Pr)$_2${2-S-($C_5H_4N$)}$_2$] (**9**), the reaction with [$TiCl_4(THF)_2$] gives a complex in which the opening of a THF molecule was observed, i.e., [$TiCl_2${2-S-($C_5H_4N$)}{$O(CH_2)_4Cl$}] (**10**), as deduced from the $^1$H NMR spectrum. A similar reactivity has been described previously by some of us[1f,9] in heteroscorpionate complexes of titanium. The formation of this complex can be envisaged as being the result of a nucleophilic THF ring-opening reaction of the intermediate cationic species [$TiCl_2$(THF){2-S-($C_5H_4N$)}]Cl, which itself results from the coordination of a thiolate ligand and subsequent loss of a chloride ligand (Scheme 4).

Chelate coordination of the pyridinethiolate ligand can be proposed for both complexes **9** and **10** on the basis of the $^{13}$C NMR spectra.

Finally, the catalytic activities of some of the complexes obtained were investigated for styrene polymerization in the range 273–363 K in the presence of 2000 equivalents of methylaluminoxane (MAO) in toluene (Table 2). In all cases, the fraction that was insoluble in 2-butanone contained the majority of the resulting polymer (>98%). In addition, the $^{13}$C NMR spectrum in $CDCl_2CDCl_2$ at 393 K contains the characteristic peaks of syndiotactic polystyrene.[10] As can be seen from Table 2, for the alkoxypyridine complexes the activity increases with reaction temperature. In contrast, thiolato complexes show higher activities at low temperature, where they are probably more stable. In any case, the activities are similar to that found for the complex [Ti(O*i*Pr)$_4$] (140 Kg PS/mol Ti/h at 293 K).

## Conclusions

The results reported here show that a range of diisopropoxy- or dichlorotitanium(IV) complexes bearing alkoxy or thiolato heterocyclic ligands can be easily prepared by reaction of the simple precursors [Ti(O*i*Pr)$_4$] and [$TiCl_4(THF)_2$] with the corresponding alcohols or thiols. The molecular structures of **1** and **5**, as determined by X-ray diffraction, show hexacoordination around the titanium atom, with two chelate heterocyclic substituents. These compounds, as well as some of their analogs, have a dynamic bonding process in solution. Finally, these new complexes, which do not contain cyclopentadienyl units, exhibit moderate activities in styrene polymerization in conjunction with MAO.

## Experimental Section

**General Remarks:** All operations were performed under an inert atmosphere using standard vacuum-line (Schlenk) techniques or an MBRAUN glove-box. Solvents were purified by distillation from the appropriate drying agents before use. Titanium precursors and different alcohols and thiols were purchased from Aldrich, stored under an inert atmosphere, and deoxygenated before use. NMR spectra were obtained with a Varian Inova FT-500 instrument.

**Preparation of [Ti(O*i*Pr)$_2${2-(OCH$_2$)(C$_5$H$_4$N)}$_2$] (1):** [Ti(O*i*Pr)$_4$] (1 mL, 3.26 mmol) was added to a solution of 2-(hydroxymethyl) pyridine (0.65 mL, 6.52 mmol) in $CH_2Cl_2$ (50 mL) and the reaction mixture was stirred for 2 h at room temperature. The resulting colorless solution was evaporated to dryness to give complex **1** as a white solid, which was purified by washing with hexane (yield: 1.22 g, 98%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.01 (d, $J$ = 6.1 Hz, 12 H, C$H_3$ isopropoxide), 4.61 (sept, $J$ = 6.1 Hz, 2 H, C*H*O isopropoxide), 5.55 (s, 4 H, C$H_2$ pyridine), 7.13 (dd, $J_{5,6}$ = 4.6 Hz, $J_{5,4}$ = 8 Hz, 2 H, 5-H pyridine), 7.15 (d, $J$ = 8 Hz, 2 H, 3-H pyridine), 7.61 (dd, $J_{4,5}$ = 8 Hz, $J_{4,3}$ = 8 Hz, 2 H, 4-H pyridine), 8.61 (d, $J$ = 4.6 Hz, 2 H, 6-H pyridine) ppm. $^{13}$C NMR (500 MHz, $CDCl_3$): $\delta$ = 25.66 (*C*H$_3$ isopropoxide), 74.30 (*C*H$_2$ pyridine), 75.30 (*C*HO isopropoxide), 118.91 (C-5 pyridine), 121.78 (C-3 pyridine), 137.45 (C-4 pyridine), 147.19 (C-6 pyridine), 166.06 (C-2 pyridine) ppm. $C_{24}H_{26}N_2O_4Ti$ (453.86): calcd. C 56.55, H 6.86, N 7.33; found C 56.31, H 6.56, N 7.95.

**Preparation of [Ti(Cl)$_2${2-(OCH$_2$)(C$_5$H$_4$N)}$_2$] (2):** 2-(Hydroxymethyl)pyridine (0.30 mL, 3.01 mmol) was added to a solution of [TiCl$_4$(THF)$_2$] (0.50 g, 1.50 mmol) in THF (25 mL) and the resulting white suspension was stirred for 16 h at room temperature. A white precipitate formed and when the sedimentation was complete the solution was filtered and the white precipitate washed with THF (50 mL) at 60 °C and filtered again. The two solutions were combined and the solvent was evaporated to give complex **2** as a pale-brown solid (yield: 0.20 g, 41%). $^1$H NMR (500 MHz, [D$_6$]-DMSO): $\delta$ = 4.86 (s, 4 H, C$H_2$ pyridine), 7.85 (dd, $J_{5,4}$ = 8 Hz, $J_{5,6}$ = 6 Hz, 2 H, 5-H pyridine), 7.96 (d, $J$ = 8.5 Hz, 2 H, 3-H pyridine), 8.47 (dd, $J_{4,5}$ = 8 Hz, $J_{4,3}$ = 8.5 Hz, 2 H, 4-H pyridine), 8.75 (d, $J$ = 6 Hz, 2 H, 6-H pyridine) ppm. $^{13}$C NMR (500 MHz, [D$_6$]-DMSO): $\delta$ = 59.96 (*C*H$_2$ pyridine), 123.93 (C-3 pyridine), 124.95 (C-5 pyridine), 141.76 (C-6 pyridine), 144.96 (C-4 pyridine), 157.27 (C-2 pyridine) ppm. $C_{12}H_{12}Cl_2N_2O_2Ti$ (334.86): calcd. C 43.02, H 3.61, N 8.36; found C 42.81, H 3.56, N 8.95.

**Preparation of [Ti(Cl)$_2${2-(OCH$_2$)-6-Me-(C$_5$H$_3$N)}$_2$] (3):** 6-Methyl-2-pyridylmethanol (0.18 mL, 1.49 mmol) was added to a solution of [TiCl$_4$(THF)$_2$] (0.25 g, 0.75 mmol) in THF (25 mL) and the resulting white suspension was stirred for 16 h at room temperature. A gray precipitate formed and when sedimentation was complete the solution was filtered to give complex **3** as a gray solid. The solid was washed with hexane (50 mL) and dried under vacuum (yield: 0.27 g, 87%). $^1$H NMR (500 MHz, [D$_6$]DMSO): $\delta$ = 2.72 (s, 6 H, C$H_3$ pyridine), 4.83 (s, 4 H, C$H_2$ pyridine), 7.72 (d, $J$ = 7.8 Hz, 2 H, 5-H pyridine), 7.79 (d, $J$ = 7.8 Hz, 2 H, 3-H pyridine), 8.37 (t, $J$ = 7.8 Hz, 2 H, 4-H pyridine) ppm. $^{13}$C NMR (500 MHz, [D$_6$]-DMSO): $\delta$ = 20.01 (*C*H$_3$ pyridine), 60.29 (*C*H$_2$ pyridine), 121.98 (C-3 pyridine), 126.14 (C-5 pyridine), 145.75 (C-4 pyridine), 157.49, 154.04 (C-2, C-6 pyridine) ppm. $C_{14}H_{16}Cl_2N_2O_2Ti$ (362.86): calcd. C 58.54, H 7.37, N 6.83; found C 58.15, H 7.52, N 6.91.

**Preparation of [Ti{2,6-(OCH$_2$)$_2$(C$_5$H$_3$N)}$_2$] (4):** [Ti(O*i*Pr)$_4$] (1 mL, 3.26 mmol) was added to a solution of 2,6-bis(hydroxymethyl)pyridine (0.93 g, 6.52 mmol) in $CH_2Cl_2$ (50 mL) and the reaction mixture was stirred for 4 h at room temperature. The resulting colorless solution was evaporated to dryness to give complex **4** as a white solid. The solid was purified by washing with hexane (yield: 1.00 g, 95%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 5.85 (s, 8 H, C$H_2$ pyridine), 7.32 (d, $J$ = 7.7 Hz, 4 H, 3-H, 5-H pyridine), 7.88 (t, $J$ = 7.7 Hz, 2 H, 4-H pyridine) ppm. $^{13}$C NMR (500 MHz, $CDCl_3$): $\delta$ = 78.75 (*C*H$_2$ pyridine), 116.60 (C-3, C-5 pyridine), 140.52 (C-4 pyridine), 168.44 (C-2, C-6 pyridine) ppm. $C_{14}H_{14}N_2O_4Ti$ (321.80): calcd. C 52.20, H 4.38, N 8.70; found C 51.64, H 5.01, N 8.37.

**Preparation of [Ti(O*i*Pr)$_2${2-S-4,6-Me$_2$-(C$_4$HN$_2$)}$_2$] (5):** [Ti(O*i*Pr)$_4$] (1 mL, 3.26 mmol) was added to a solution of 2-mercapto-4,6-dimethylpyrimidine (0.92 g, 6.52 mmol) in $CH_2Cl_2$ (50 mL) and the reaction mixture was stirred for 2 h at room temperature. The resulting yellow solution was evaporated to dryness to give complex **5** as a yellow, crystalline solid, which was washed with hexane (yield: 1.17 g, 81%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.26 (d, 12 H, C$H_3$ isopropoxide), 2.42 (broad signal, 12 H, C$H_3$ pyrimidine), 4.81 (sept, $J$ = 6.2 Hz, 2 H, C*H*O isopropoxide), 6.50 (s, 2 H, 5-H pyrimidine) ppm. $^{13}$C NMR (500 MHz, $CDCl_3$): $\delta$ = 23.80, 26.23 (*C*H$_3$ C$_4$, *C*H$_3$, C$_6$ pyrimidine), 25.36 (*C*H$_3$ isopropoxide), 81.64 (*C*HO isopropoxide), 115.17 (C-5 pyrimidine), 168.71 (C-4 pyrimidine), 164.25 (C-6 pyrimidine), 179.20 (C-2 pyrimidine) ppm. $C_{18}H_{28}N_4O_2TiS_2$ (307.52): calcd. C 48.64, H 6.35, N 12.61, S 14.14; found C 49.10, H 5.89, N 12.10, S 13.85.

**Preparation of [TiCl$_2${2-S-4,6-Me$_2$-(C$_4$HN$_2$)}$_2$] (6):** A solution of 2-mercapto-4,6-dimethylpyrimidine (0.42 mL, 3.00 mmol) in THF (10 mL) was added dropwise to a solution of [TiCl$_4$(THF)$_2$] (0.50 g, 1.50 mmol) in THF (25 mL) and the resulting brown-red suspension was stirred for 16 h at room temperature. Complex **6** was obtained as a pale-yellow solid after sedimentation, subsequent filtration, and drying under vacuum (yield: 0.46 g, 78%). $^1$H NMR (500 MHz, [D$_6$]DMSO): $\delta$ = 2.41 (s, 12 H, C$H_3$ pyrimidine), 6.95 (s, 2 H, 5-H pyrimidine) ppm. $^{13}$C NMR (500 MHz, [D$_6$]DMSO): $\delta$ = 23.85 (*C*H$_3$ pyrimidine), 118.45 (C-5 pyrimidine), 167.86 (C-4, C-6 pyrimidine), 168.53 (C-2 pyrimidine) ppm. $C_{12}H_{14}ClN_2S_4Ti$ (396.60): calcd. C 36.29, H 3.55, N 14.11, S 16.15; found C 36.46, H 3.22, N 14.45, S 16.52.

**Preparation of [Ti(O*i*Pr)$_2${2-S-(C$_4$H$_3$N$_2$)}$_2$] (7):** [Ti(O*i*Pr)$_4$] (1 mL, 3.26 mmol) was added to a solution of 2-mercaptopyrimidine (0.75 g, 6.52 mmol) in $CH_2Cl_2$ (50 mL) and the reaction mixture was stirred for 2 h at room temperature. The resulting yellow solution was evaporated to dryness and complex **7** was obtained as a yellow, crystalline solid, which was washed with hexane. (yield: 1.24 g, 98%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.24 (d, $J$ = 6 Hz, 12 H, C$H_3$ isopropoxide), 4.70 (sept, $J$ = 6 Hz, 2 H, C*H*O isopropoxide), 6.79 (t, $J$ = 5 Hz, 2 H, 5-H pyrimidine), 8.47 (d, $J$ = 5 Hz, 4 H, 4-H, 6-H pyrimidine) ppm. $^{13}$C NMR (500 MHz, $CDCl_3$): $\delta$ = 25.60 (*C*H$_3$ isopropoxide), 81.54 (*C*HO isopropoxide), 114.73 (C-5 pyrimidine), 151.70 (C-4 pyrimidine), 159.92 (C-6 pyrimidine), 179.82 (C-2 pyrimidine) ppm. $C_{14}H_{20}N_4O_2S_2Ti$ (387.86): calcd. C 43.30, H 5.19, N 14.43, S 16.51; found C 43.85, H 5.85, N 14.01, S 16.01.

**Preparation of [TiCl$_2${2-S-(C$_4$H$_3$N$_2$)}$_2$] (8):** A solution of 2-mercaptopyrimidine (0.27 mL, 2.40 mmol) in THF (10 mL) was added dropwise to a solution of [TiCl$_4$(THF)$_2$] (0.40 g, 1.20 mmol) in THF (50 mL) and the resulting yellow suspension was stirred for 5 h at room temperature. Complex **8** was obtained as a pale-yellow solid after sedimentation, subsequent filtration, and drying under vacuum (yield: 0.37 g, 91%). $^1$H NMR (500 MHz, [D$_6$]DMSO): $\delta$ = 6.89 (t, $J$ = 5.3 Hz, 2 H, 5-H pyrimidine), 8.33 (d, $J$ = 5.3 Hz, 4 H, 4-H, 6-H pyrimidine) ppm. $^{13}$C NMR (500 MHz, [D$_6$]DMSO): $\delta$ = 119.84 (C-5 pyrimidine), 159.26 (C-4, C-6 pyrimidine), 168.51

(C-2 pyrimidine) ppm. $C_8H_6Cl_2N_4S_2Ti$ (340.70): calcd. C 28.17, H 1.77, N 16.43, S 18.80; found C 28.40, H 1.54, N 16.68, S 19.23.

**Preparation of [Ti(O*i*Pr)$_2${2-S-(C$_5$H$_4$N)}$_2$] (9):** [Ti(O*i*Pr)$_4$] (1 mL, 3.26 mmol) was added to a solution of 2-mercaptopyridine (0.73 g, 6.52 mmol) in $CH_2Cl_2$ (50 mL) and the reaction mixture was stirred for 2 h at room temperature. The resulting yellow solution was evaporated to dryness and complex **9** was obtained as a yellow solid, which was washed with hexane (yield: 1.19 g, 95%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.20 (d, $J$ = 5.9 Hz, 12 H, C$H_3$ isopropoxide), 4.70 (sept, $J$ = 5.9 Hz, 2 H, C$H$O isopropoxide), 6.72 (dd, $J_{5,6}$ = 6 Hz, $J_{5,4}$ = 7.8 Hz, 2 H, 5-H pyridine), 7.11 (d, $J$ = 8.1 Hz, 2 H, 3-H pyridine), 7.39 (dd, $J_{4,5}$ = 7.8 Hz, $J_{4,3}$ = 8.1 Hz, 2 H, 4-H pyridine), 8.35 (d, $J$ = 8.1 Hz, 2 H, 6-H pyridine) ppm. $^{13}$C NMR (500 MHz, $CDCl_3$): $\delta$ = 25.56 (*C*H$_3$ isopropoxide), 80.34 (*C*HO isopropoxide), 116.97 (C-5 pyridine), 126.54 (C-3 pyridine), 137.94 (C-4 pyridine), 144.31 (C-6 pyridine), 170.74 (C-2 pyridine) ppm. $C_{16}H_{22}N_2O_2S_2Ti$ (385.70): calcd. C 49.74, H 5.74, N 7.25, S 16.60; found C 49.21, H 5.25, N 6.87, S 16.21.

**Preparation of [TiCl$_2${2-S-(C$_5$H$_4$N)}{O(CH$_2$)$_4$Cl}] (10):** A solution of 2-mercaptopyridine (0.33 g, 3.00 mmol) in THF (10 mL) was added dropwise to a solution of [$TiCl_4(THF)_2$] (0.50 mL, 1.50 mmol) in THF (25 mL). The resulting orange suspension was stirred for 16 h at room temperature. Complex **10** was obtained as a pale-orange solid after sedimentation, subsequent filtration, and drying under vacuum (yield: 0.38 g, 76%). $^1$H NMR (500 MHz, [D$_6$]DMSO): $\delta$ = 1.78 [m, 4 H, (C$H_2$)$_2$], 3.22 (m, 2*H* C$H_2$Cl), 4.73 (t, $J$ = 5.8 Hz, 2 H, C$H_2$O), 7.20 (m, 1 H, 5-H pyridine), 7.40 (d, $J$ = 8.4 Hz, 1 H, 3-H pyridine), 7.75 (m, 1 H, 4-H pyridine), 8.46 (d, $J$ = 6.4 Hz, 1 H, 6-H pyridine) ppm. $^{13}$C NMR (500 MHz, [D$_6$]-DMSO): $\delta$ = 30.19, 32.27 [(*C*H$_2$)$_2$], 60.78 (*C*H$_2$Cl), 85.37 (*C*H$_2$O), 120.09 (C-5 pyridine), 122.33 (C-3 pyridine), 137.96 (C-4 pyridine), 148.20 (C-6 pyridine), 157.89 (C-2 pyridine) ppm. $C_9H_{12}Cl_3NOSTi$ (332.50): calcd. C 32.12, H 3.59, N 4.16, S 9.53; found C 32.41, H 4.00, N 4.32, S 9.14.

**Styrene Polymerizations:** Polymerizations of styrene using the various catalyst precursors were carried out by adding a suspension of the titanium precursor (6 μmol) in toluene to a 100-mL flask, under an inert atmosphere, containing styrene (2 mL, previously dried with alumina) and a solution of 10% MAO (12 mmol) in toluene. The final volume of the resulting mixture was 12 mL. Polymerization reactions were run for 90 min at different temperatures and quenched by the addition of 10% HCl/methanol mixture (50 mL). The resulting polymers were filtered off, washed with methanol, and dried. The bulk polymers were extracted by refluxing in 2-butanone (35 mL) at 80 °C for four hours. The resulting polymers were dried and weighed.

**X-ray Crystal-Structure Determinations:** Single crystals of a colorless block of **1** and a yellow prism of **5** were placed in a cooled nitrogen gas stream at 200 and 230 K, respectively, on a NONIUS-MACH3 diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å). Table 3 summarizes the crystal data, data collection, and structural solution and refinement parameters for both compounds. Intensity data were collected by using an $\omega/2\theta$ scan technique. Data were corrected for Lorentz and polarization effects and absorption correction was not necessary. The structures were solved by direct methods using the SHELXS computer program,[11] completed by subsequent difference Fourier syntheses, and refined by full-matrix least-squares procedures (SHELXL97)[12] on $F^2$. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were placed using a "riding model" and included in the refinement at calculated positions.

CCDC-283896 (**1**) and -283897 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free

*Dedicated to Professor Victor Riera on the occasion of his 70th birthday[‡]*

**Keywords:** Metallocenes / Zirconium / Homogeneous catalysis / Polymerization / Ethylene

The *ansa*-indene ligands {1-$Me_2Si$(3-$C_9H_6R)_2$} [R = Me (**1**), *n*Pr (**2**), *n*Bu (**3**), and Bz (**4**)] were prepared by alkylation of the unsubstituted *ansa*-indene. These ligands were converted, by reaction with *n*BuLi, to the di-lithium compounds [$Li_2$1-$Me_2Si$(3-$C_9H_5R)_2$}] [R = Me (**5**), *n*Pr (**6**), *n*Bu (**7**), and Bz (**8**)]. *ansa*-Zirconocenes, [Zr{1-$Me_2Si$(3-$\eta^5$-$C_9H_5R)_2$}$Cl_2$] [R = Me (**9**), *n*Pr (**10**), *n*Bu (**11**), and Bz (**12**)], have been prepared by the reaction of $ZrCl_4$ with **5**–**8** in diethyl ether/toluene at –78 °C. The molecular structure of *meso*-[Zr{1-$Me_2Si$[3-$\eta^5$-$C_9H_5(CH_3)]_2$}$Cl_2$] (**9**) and *rac*-[Zr{1-$Me_2Si$[3-$\eta^5$-$C_9H_5$-$(CH_2CH_2CH_3)]_2$}$Cl_2$] (**10**) have been determined by single-crystal X-ray diffraction studies. Ethylene polymerization catalysis has been studied for complexes **9**–**12** as a mixture of *meso* and *rac* isomers in the presence of methylaluminoxane (MAO) as cocatalyst. Complexes **9**–**12** exhibit high activities and give rise to polyethylene with low molecular weights without the introduction of molecular hydrogen. In addition, active species from these complexes were found to be very stable in comparison with unsubstituted analogues.

## Introduction

A large number of new catalysts for olefin polymerization, classified as metallocene catalysts, have been prepared during the last decade.[1] The majority of these catalysts consist of a zirconium complex with the general formula LL′$ZrCl_2$ and these systems are activated by methylaluminoxane (MAO). The ligands L and L′ are typically equal or different dienyl ligands that may be linked together by a bridge. A major evolution has been achieved in the field of polypropylene, which can now be produced with different types and degrees of stereoregularity.[2] In fact, a new class of catalysts based on $C_2$-symmetric metallocenes, with *ansa*-bis(indenyl) ligands, produce almost isotactic polypropylenes. The best-known example is Brintzinger's *rac*-[Zr{1-$(C_2H_4)$($\eta^5$-$C_9H_6)_2$}$Cl_2$].[3] Although the introduction of an alkyl substituent in the cyclopentadienyl fragment of the indenyl group has been studied,[4] few examples of *ansa*-bis-indenyl complexes, bearing $SiMe_2$ bridges, have been described[5–9] and, to the best of our knowledge, there is not a complete structural characterization of these complexes. The target for these catalysts was to study the influence of the metallocene structure in the performance of propylene polymerization. Less attention has been paid to the study of the influence on the properties of the polyethylene obtained with these catalysts, i.e., on the molecular weight of the obtained polymer. Usually, this parameter can be controlled during the polymerization by either adjusting the temperature of the polymerization or by adding molecular hydrogen, which acts as a chain transfer agent.[10]

With this in mind, and as part of our continued interest in this field,[11] we have developed new examples of *ansa*-zirconocene catalysts of the general formula [Zr{1-$Me_2Si$(3-$\eta^5$-$C_9H_5R)_2$}$Cl_2$]. These catalysts have proved to be very active and are able to produce polyethylene with low molecular weight without introducing molecular hydrogen to control the process. It was of particular interest to compare the results with the analogous unsubstituted complex [Zr{1-$Me_2Si$($\eta^5$-$C_9H_6)_2$}$Cl_2$].[12]

Here we provide the details of the preparation and polymerization behavior of four members of this class of catalysts [Zr{1-$Me_2Si$(3-$\eta^5$-$C_9H_5R)_2$}$Cl_2$] [R = Me (**9**), *n*Pr (**10**), *n*Bu (**11**), and Bz (**12**)]. The activities of these systems in the polymerization of ethylene and the molecular weights

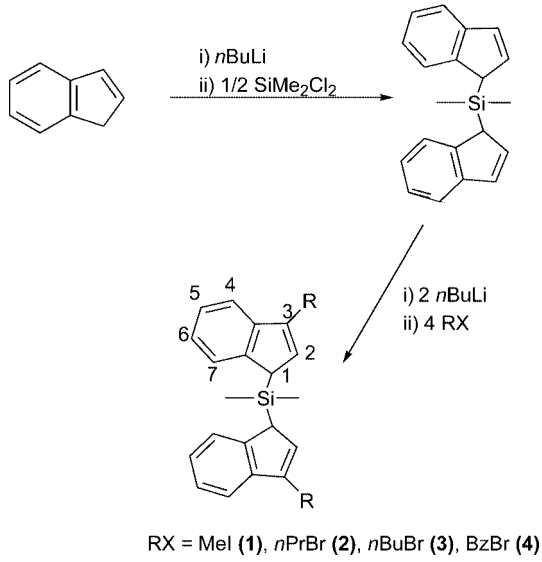
of the resulting polymers are discussed. In addition, the molecular structures of *rac*-**10** and *meso*-**9** have been determined by X-ray diffraction methods.

## Results and Discussion

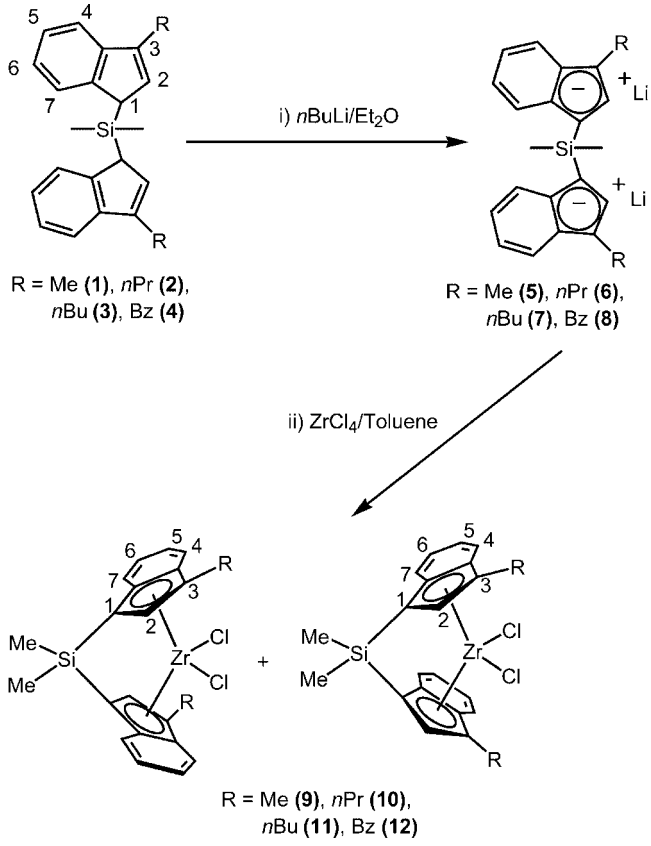
The preparation of the substituted *ansa*-indene precursors {1-$Me_2Si$(3-$C_9H_6R)_2$} [R = Me (**1**), *n*Pr (**2**), *n*Bu (**3**) and Bz (**4**)] was achieved by alkylation of the dilithium salt of {1-$Me_2Si$(3-$C_9H_7)_2$}, generated with *n*BuLi in $Et_2O$, with a large excess of RX (X = I and R = Me for **1**, X = Br and R = *n*Pr for **2**, X = Br and R = *n*Bu for **3**, and X = Br and R = Bz for **4**) (Scheme 1). Column chromatography was used to purify the ligands **1**–**4**.



Scheme 1.

This is the preferred route because of the very simple synthesis and purification of the intermediate {1-$Me_2Si(C_9H_7)_2$} and because of its intrinsic versatility. In fact, {1-$Me_2Si(C_9H_7)_2$} is a convenient starting material for the synthesis of a series of different 3-alkyl- and 3-silyl-*ansa*-bisindenyl ligands.[13] The $^1$H NMR spectra show the *meso*-isomer as the major isomer for derivatives **1**–**4**, with two singlets for the *ansa*-bridge methyl groups, a doublet for H1, a doublet for H2, and four multiplets corresponding to the protons of the $C_6$ ring of the indenyl moiety. In addition, the corresponding signals were observed for the pendant alkyl chain (see Exp. Sect.).

As shown in Scheme 2, the deprotonation of **1**–**4** with *n*BuLi gave the lithium salts [$Li_2${1-$Me_2Si$(3-$C_9H_5R)_2$}] [R = Me (**5**), *n*Pr (**6**), *n*Bu (**7**), and Bz (**8**)]. The subsequent reaction of the lithium salts with $ZrCl_4$, in diethyl ether/toluene, gave the corresponding zirconocene complexes [Zr{1-$Me_2Si$(3-$\eta^5$-$C_9H_5R)_2$}$Cl_2$] [R = Me (**9**), *n*Pr (**10**), *n*Bu (**11**), and Bz (**12**)]. The orange solids obtained are sensitive towards air and moisture and are soluble in polar solvents.



Scheme 2.

While the total yield of this last step is satisfactory, a random *rac*/*meso* ratio is obtained. In general, the *rac*/*meso* ratio ranges from 0.6:1 (**10**) to 1.86:1 (**12**). For complex **9**, samples of the pure *meso* diastereomer and a product enriched in the *rac* isomer (11.5:1) were obtained by careful recrystallization from $CH_2Cl_2/Et_2O$.

The $^1$H NMR spectra for the *meso* isomers of the complexes **9**–**12** show the following signals: two singlets for the *ansa*-bridge methyl groups, a singlet for the proton of the indenyl $C_5$ ring, and four multiplets corresponding to the protons of the $C_6$ ring of the indenyl moiety. In addition, the appropriate signals were observed for the pendant alkyl chain (see Exp. Sect.). Furthermore, the following signals were observed for the *rac* isomers of the complexes **9**–**12**: a singlet for the *ansa*-bridge methyl groups, a singlet for the proton of the indenyl $C_5$ ring, and four multiplets corresponding to the protons of the $C_6$ ring of the indenyl moiety. In addition, several signals were observed for the pendant alkyl chain (see Exp. Sect.).

$^1$H NMR nuclear Overhauser effect (NOE) difference spectroscopy allowed unambiguous identification of each isomer. Irradiation of the signal due to H2 in the *meso* isomer (which appears as a singlet in the NMR spectrum) led to measurable enhancement of the protons of the C3-alkyl substituent and the protons in one of the methyl groups of the $SiMe_2$ bridge. However, a similar irradiation in the *rac* isomer led to enhancement of the corresponding signals due to the C3-alkyl and the silicon methyl groups as well as the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

aromatic proton H7 on the opposite indenyl ring (Figure 1). In the *meso* isomer, these $SiMe_2$ methyl groups are located in very different chemical environments (one is sandwiched between the two $C_6$ aromatic rings, and the other is only flanked by the Cp rings), while in the *rac* isomer the two methyl groups are equivalent.

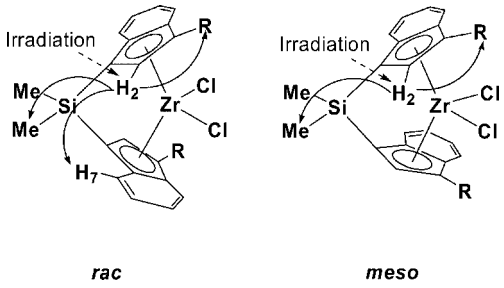


Figure 1. $^1H$ NOE difference experiments provide information on the spatial proximity between protons.

The carbon signal assignments were made following a procedure on the basis of $^1H$ and $^{13}C$ NMR correlated spectroscopy (HETCOR) (see Exp. Sect.). For the *meso* isomer of these compounds **9**–**12**, the $^{13}C$ analysis showed two signals for the *ansa*-bridge methyl groups, a signal for the carbon C2 of the indenyl $C_5$ ring, and four signals corresponding to the carbons (C4–C7) of the $C_6$ ring of the indenyl moiety. For the *rac* isomers, only one signal was found for the ansa-bridge methyl groups. In addition, a signal of the carbon C2 of the indenyl $C_5$ ring was observed, and four signals corresponding to the carbons (C4–C7) of the $C_6$ ring of the indenyl moiety. The corresponding signals were observed for the pendant alkyl chain for both isomers (see Exp. Sect.).

### X-ray Molecular Structures of Complexes *meso*-9 and *rac*-10

Single crystals of *meso*-**9** and *rac*-**10** that were suitable for X-ray diffraction were obtained from $CH_2Cl_2$/ether and toluene. Their molecular structures, as determined by the crystallographic analysis, are depicted in Figure 2.

The *meso*-**9** complex crystallizes in the triclinic space group $P\bar{1}$. The crystal structure reveals the existence of one unique isomer. The *rac*-**10** complex crystallizes in the monoclinic space group $P_2/c$ with a solvate toluene molecule. The crystal structure reveals the existence of two racemic enantiomers. The bonding parameters for *meso*-**9** and *rac*-**10** are summarized in Table 1. The mutual arrangement of the indenyl fragments corresponds to $C_2$ symmetry for *rac* and $C_s$ for *meso*.

In both cases the zirconium atom is in a pseudotetrahedral environment formed by the two chloride ligands and two $\eta^5$-coordinated indenyl ligands. The Zr–C bond lengths of five-membered rings range between 2.448(6) and 2.662(6) Å. These values are close to that found in other *ansa*-bis(indenyl) zirconocene complexes (2.5 Å).[14] The Zr–Cl distances for these complexes are within the range

observed previously for other bis(indenyl)-zirconium dichlorides [2.407(1)–2.465(2) Å].[15–20]

The angles between some relevant planes are collected in Table 2 along with the geometrical parameters described in Figure 3 for compounds *meso*-**9**, *rac*-**10**, and the unsubstituted parent *rac*-[Zr{1-$Me_2Si(\eta^5$-$C_9H_6)_2$}$Cl_2$].[12] As usual for bent metallocenes, the overall coordination environment is best described by the set of parameters depicted in Figure 3, which describes the metal accessibility. In particular, the smaller the "bite angle" $\beta$ and the larger the Cp–M–Cp′ $\alpha$ angle, the more the metal is tucked into the ligand envelope.

The main geometrical difference of *meso*-**9** and *rac*-**10** from *rac*-[Zr{1-$Me_2Si(\eta^5$-$C_9H_6)_2$}$Cl_2$] is associated with the angle $\beta$ and the range of Zr–$C_{Cp}$ bond lengths. $\beta$, in *meso*-**9** (63.9°) and *rac*-**10** (62.9°), is increased compared to that of *rac*-[Zr{1-$Me_2Si(\eta^5$-$C_9H_6)_2$}$Cl_2$] (60.2°). The range of $Zr–C_{Cp}$ for both complexes (0.21 Å for *meso*-**9** and 0.20 Å for *rac*-**10**) is similar to that in *rac*-[Zr{1-$Me_2Si(\eta^5$-$C_9H_6)_2$}$Cl_2$] (0.20 Å).

These differences are, likely, caused by the bulky R substituents at C(3) of both indenyl fragments. This conclusion is supported by significant displacements of the C(3)–R bonds from the planes of the parent cyclopentadienyl rings opposite to Zr (4.1° and 4.5° for *meso*-**9**, and 4.2° for *rac*-**10**).

It can be seen from Figure 2 that, for the structures of the complexes *meso*-**9** and *rac*-**10**, both $C_5$ rings are eclipsed, including, in the case of *meso*-**9**, the methyl-substituent in position 3. In *meso*-**9**, it can be observed that one of the chloride ligands is very close to the $C_6$ aromatic rings, whereas the other one is in an intermediate location between the methyl-substituents. In the case of *rac*-**10**, each

chloride ligand is between a ring and an alkyl substituent. This situation could give rise to a great influence of the rings and their alkyl substituents on the positions occupied by the active sites of the catalysts. These features could be established to control the molecular weight of the polymers obtained.

### Polyethylene Polymerization using Complexes 9–12

Complexes **9**–**12**, used as *rac*/*meso* mixtures, after being activated with methylaluminoxane (MAO), are very active

catalysts for the polymerization of ethylene. In the present study, we used a 10% solution of MAO in toluene, which contains about 20–30% of $AlMe_3$. In all polymerization experiments, Al(*i*Bu)$_3$ was used to scavenge possible impurities in the monomer. The polymerization results are compared with those of one of the best zirconocene catalysts, i.e., [Zr{1-$Me_2Si(\eta^5$-$C_9H_6)_2$}$Cl_2$].[12] The polymerization results and the available polymer characterization data are shown in Table 3.

Complexes **9**–**12** show similar or higher activities than the reference complex and, moreover, these new catalysts produced lower molecular weight polyethylene than the reference catalyst. Although it is not possible to establish any relation between the size of the substituent and the polymer molecular weight, we suggest that this low molecular weight arises due to the steric influence of the substituents. The activities of complexes **9**–**12** decrease as the bulk of the substituent in position 3 increases.

In addition, the melting points of all the polymers were determined (see Table 3). The catalysts **9**–**12** produced crystalline materials with relatively high melting points (near 130 °C).

The stability of metallocene complexes is one of the most important variables for its future industrial use. The activities of activated forms of complexes **9**–**12** were tested after 12 h of contact between the complexes and MAO solution. It is worth noting that these complexes maintained a reasonable level of activity after this contact time. In contrast, the reference complex ([Zr{1-$Me_2Si(\eta^5$-$C_9H_6)_2$}$Cl_2$]) did not give any reaction with ethylene after the same time of contact with MAO. It therefore appears that an increase in the volume of the substituent in the 3-position leads to an increase in the stability of the catalyst.

## Conclusions

We have carried out the synthesis of new examples of *ansa*-bis-indenylzirconocene complexes, bearing a $SiMe_2$ bridge, with alkyl substituents in the 3 position. The presence of these groups allows stable and very active catalysts to be obtained in ethylene polymerization, producing polyethylenes of low molecular weight, in comparison with the unsubstituted analogue. In addition, complexes *meso*-[Zr{1-$Me_2Si$[3-$\eta^5$-$C_9H_5(CH_3)]_2$}$Cl_2$] and *rac*-[Zr{1-$Me_2Si$[3-$\eta^5$-$C_9H_5(CH_2CH_2CH_3)]_2$}$Cl_2$] have been characterized by X-ray diffraction methods.

## Experimental Section

**General Remarks:** All reactions were carried out using standard Schlenk-tube and glove-box techniques in dry nitrogen. Solvents were distilled from appropriate drying agents and degassed before use. $ZrCl_4$, indene, $SiMe_2Cl_2$, $ICH_3$, $BrCH_2CH_2CH_3$, $BrCH_2CH_2CH_2CH_3$, and $BrCH_2Ph$ were purchased from Aldrich and used directly. $^1H$ and $^{13}C$ spectra were recorded with Varian GEMINI FT-400 and Varian INNOVA FT-500 spectrometers and referenced to the residual deuterated solvent. Microanalyses were carried out with a Perkin–Elmer 2400 microanalyzer. Mass spectrometry was performed with a Hewlett–Packard 5988A (*m*/*z* = 50–1000) (electron impact) spectrometer.

**Preparation of {1-$Me_2Si$[3-$C_9H_6(CH_3)]_2$} (1):** *n*BuLi (1.60 M in hexane) (38.00 mL, 60.74 mmol) was added over 15 min to a cooled (–78 °C) solution of [$Me_2Si(C_9H_7)$] (7.30 g, 25.31 mmol) in $Et_2O$ (100 mL) in a 250-mL Schlenk tube. At the end of the addition the solution was allowed to reach room temperature and stirred for 4 h, cooled again to –78 °C, and MeI (14.37 g, 101.24 mmol) was added. The reaction mixture was allowed to reach room temperature and stirred for 16 h. The solvent was removed in vacuo and hexane (100 mL) was added. Water (200 mL) was added, the organic product was extracted with hexane, the aqueous layer was washed with hexane (3 × 50 mL), the organic layers combined, dried with $MgSO_4$, filtered and the solvent removed from the filtrate under reduced pressure to yield the title compound as a yellow oil. Compound **1** was purified by column chromatography ($Et_2O$/hexane, 1:9) (yield 7.05 g, 88%). $^1H$ NMR (400 MHz, $CDCl_3$) (for the predominant isomer): $\delta$ = 0.10 and 0.14 (2 s, each 3 H, $SiMe_2$), 0.82 (m, 6 H, $CH_3$), 3.56 (d, $J$ = 1.8 Hz, 2 H, 1-H), 6.82 (d, $J$ = 1.8 Hz, 2 H, 2-H), 7.11–7.37 (m, 8 H, 4-H–7-H) ppm. MS electron impact: *m*/*z* (%) = 316 (3) [M, {1-$Me_2Si$[3-$C_9H_6(CH_3)]_2$}]$^+$, 187 (100) [M – (3-Me – $C_9H_6$)]$^+$, 129 (56) [M – $Me_2Si$]$^+$.

**Preparation of {1-$Me_2Si$(3-$C_9H_6(CH_2CH_2CH_3))_2$} (2):** The synthesis of **2** was carried out in an identical manner to **1**. [$Me_2Si(C_9H_7)$] (7.30 g, 25.31 mmol), *n*BuLi (1.60 M in hexane) (38.00 mL, 60.74 mmol), and $BrCH_2CH_2CH_3$ (12.45 g, 101.24 mmol). Yield 8.48 g (89%). $^1H$ NMR (400 MHz, $CDCl_3$) (for the predominant isomer): $\delta$ = 0.19 and 0.32 (2 s, each 3 H, $SiMe_2$), 0.95 (m, 6 H, $CH_2CH_2CH_3$), 1.39–2.73 (m, 8 H, -$CH_2CH_2CH_3$), 3.50 (d, $J$ = 1.8 Hz, 2 H, 1-H), 6.98 (d, $J$ = 1.8 Hz, 2 H, 2-H), 7.10–7.50 (m, 8 H, 4-H–7-H) ppm. MS electron impact: *m*/*z* (%) = 372 (3) [M, {1-$Me_2Si$(3-$C_9H_6(CH_2CH_2CH_3))_2$}]$^+$, 216 (100) [M – (3-Pr – $C_9H_6$)]$^+$, 156 (23) [M – $Me_2Si$]$^+$.

**Preparation of {1-$Me_2Si$(3-$C_9H_6(CH_2CH_2CH_2CH_3))_2$} (3):** The synthesis of **3** was carried out in an identical manner to **1**. [$Me_2Si(C_9H_7)$] (7.30 g, 25.31 mmol), *n*BuLi (1.60 M in hexane) (38.00 mL, 60.74 mmol), and $BrCH_2CH_2CH_2CH_3$ (13.87 g, 101.24 mmol). Yield 9.13 g (90%). $^1H$ NMR (400 MHz, $CDCl_3$) (for the predominant isomer): $\delta$ = 0.22 and 0.08 (2 s, each 3 H,

$SiMe_2$), 0.95–2.73 (m, 18 H, -$CH_2CH_2CH_2CH_3$), 3.80 (d, $J$ = 1.8 Hz, 2 H, 1-H), 6.89 (d, $J$ = 1.8 Hz, 2 H, 2-H), 7.10–7.50 (m, 8 H, 4-H–7-H) ppm. MS electron impact: $m/z$ (%) = 400 (3) [M, {1-$Me_2Si(3\text{-}C_9H_6(CH_2CH_2CH_3))_2$}]$^+$, 228 (100) [M – (3-Bu-$C_9H_6$)]$^+$, 59 (55) [M – $Me_2Si(C_9H_6)$]$^+$.

**Preparation of {1-$Me_2Si(3\text{-}C_9H_6(CH_2C_6H_5))_2$} (4):** The synthesis of **4** was carried out in an identical manner to **1**. [$Me_2Si(C_9H_7)$] (7.30 g, 25.31 mmol), *n*BuLi (1.60 M in hexane) (38.00 mL, 60.74 mmol), and $BrCH_2C_6H_5$ (8.66 g, 50.62 mmol). Yield 5.34 g (45%). $^1$H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): $\delta$ = 0.16 and 0.13 (2s, each 3 H, $SiMe_2$), 2.72–3.00 (m, 4 H, -$CH_2C_6H_5$), 3.54 (d, $J$ = 1.8 Hz, 2 H, 1-H), 6.78 (d, $J$ = 1.8 Hz, 2 H, 2-H), 7.14–7.39 (m, 18 H, 4-H–7-H, $CH_2C_6H_5$) ppm. MS electron impact: $m/z$ (%) = 468 (2) [M, {1-$Me_2Si(3\text{-}C_9H_6(CH_2C_6H_5))_2$}]$^+$, 264 (83) [M – (3-Bz-$C_9H_6$)]$^+$, 91 (100) [M – $Me_2Si(C_9H_6)$]$^+$.

**Preparation of $Li_2${1-$Me_2Si(3\text{-}C_9H_5(CH_3))_2$} (5):** *n*BuLi (1.60 M in hexane) (23.79 mL, 37.92 mmol) was added dropwise over 15 min to a cooled (–80 °C), stirred solution of {1-$Me_2Si(3\text{-}C_9H_6(CH_3))_2$} (**1**) (5.00 g, 15.80 mmol) in $Et_2O$ (80 mL) in a 250-mL Schlenk tube. The solution was warmed up to room temperature and stirred for 4 h. An increasing turbidity developed and this finally led to the formation of a yellow-orange suspension. The solvent was removed in vacuo to give a yellow solid, which was washed with hexane (2 × 50 mL) and dried under vacuum to yield **5** as a free flowing yellow solid (yield 3.94 g, 76%). $C_{22}H_{22}Li_2Si$ (328.28): calcd. C 80.47, H 6.75; found C 80.53, H 6.80.

**Preparation of $Li_2${1-$Me_2Si(3\text{-}C_9H_5(CH_2CH_2CH_3))_2$} (6):** The synthesis of **6** was carried out in an identical manner to **5**. {1-$Me_2Si(3\text{-}C_9H_6(CH_2CH_2CH_3))_2$} (**2**) (5.00 g, 13.28 mmol), *n*BuLi (1.60 M in hexane), and (19.91 ml, 31.85 mmol). Yield 4.48 g (87%). $C_{26}H_{30}Li_2Si$ (384.48): calcd. C 81.22, H 7.86; found C 81.43, H 7.93.

**Preparation of $Li_2${1-$Me_2Si(3\text{-}C_9H_5(CH_2CH_2CH_2CH_3))_2$} (7):** The synthesis of **7** was carried out in an identical manner to **5**. {1-$Me_2Si(3\text{-}C_9H_6(CH_2CH_2CH_2CH_3))_2$} (**3**) (5.00 g, 12.48 mmol) and *n*BuLi (1.60 M *in* hexane) (18.72 mL, 29.95 mmol). Yield (4.37 g, 85%). $C_{28}H_{34}Li_2Si$ (412.54): calcd. C 81.52, H 8.31; found C 81.43, H 8.40.

**Preparation of $Li_2${1-$Me_2Si(3\text{-}C_9H_5(CH_2C_6H_5))_2$} (8):** The synthesis of **8** was carried out in an identical manner to **5**. {1-$Me_2Si(3\text{-}C_9H_6(CH_2C_6H_5))_2$} (**4**) (5.00 g, 10.67 mmol) and *n*BuLi (1.60 M in hexane) (16.00 mL, 26.21 mmol). Yield 4.10 g (80%). $C_{34}H_{30}Li_2Si$ (480.57): calcd. C 84.97, H 6.29; found C 84.83, H 6.34.

**Preparation of [Zr{1-$Me_2Si(3\text{-}\eta^5\text{-}C_9H_5(CH_3))_2$}$Cl_2$] (9):** A cooled (–78 °C) slurry of $ZrCl_4$ (2.79 g, 12.00 mmol) in toluene (80 mL) was rapidly added to a cooled (–78 °C) solution of $Li_2${1-$Me_2Si(3\text{-}C_9H_5(CH_3))_2$} (**5**) (3.94 g, 12.00 mmol) in $Et_2O$ (80 mL) in a 250-mL Schlenk tube. The reaction mixture was stirred for 30 min at –20 °C and then overnight at room temperature (16 h). The orange suspension was filtered through a G4 frit with Celite. The filtrate was evaporated to dryness under reduced pressure to yield a sticky dark-orange product. The product was washed with $Et_2O$ (30 mL) and the residue was dried to give an orange solid (0.86 g, 15%). *rac*/*meso* = 55:45. For this complex, samples of the pure *meso* diastereomer and a product enriched in the *rac* isomer (11.5:1) were obtained by careful recrystallization from $CH_2Cl_2$/$Et_2O$.

***meso* Isomer:** $^1$H NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 0.80 [s, 3 H, $Si(CH_3)$ *exo*], 1.27 [s, 3 H, $Si(CH_3)$ *endo*], 2.35 (s, 6 H, $CH_3$), 5.50 (s, 2 H, 2-H), 6.83 and 7.09 (2t, $J$ = 8.8 Hz, each 2 H, *5-H*, 6-H), 7.32 and 7.44 (2d, $J$ = 8.8 Hz, each 2 H, 4-H, 7-H) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CD_2Cl_2$): $\delta$ = 13.03 [$Si(CH_3)$ *exo*], 13.62 [$Si(CH_3)$ *endo*], 43.62 ($CH_3$), 76.78, 86.00 (C1, C3), 118.40 (C2), 123.21 and 125.11 (C5, C6), 126.15, 126.48 (C4, C7) ppm.

***rac* Isomer:** $^1$H NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 1.09 [s, 6 H, $Si(CH_3)_2$], 2.22 (s, 6 H, $CH_3$), 5.68 (s, 2 H, 2-H), 6.97 and 7.23 (2t, $J$ = 8.8 Hz, each 2 H, 5-H, 6-H), 7.35 and 7.38 (2d, $J$ = 8.8 Hz, each 2 H, 4-H, 7-H) ppm. $^{13}$C NMR (125 MHz, $CD_2Cl_2$): $\delta$ = –1.44 ppm [$Si(CH_3)_2$], 13.34 ($CH_3$), 78.04, 86.40 (C1, C3), 119.32 (C2), 124.25 and 125.06 (C5, C6), 126.55 and 126.85 (C4, C7) ppm.

**Both Isomers:** $C_{22}H_{22}Cl_2SiZr$ (476.6): calcd. C 55.44, H 4.65; found C 55.63, H 4.68.

**Preparation of [Zr{1-$Me_2Si[3\text{-}\eta^5\text{-}C_9H_5(CH_2CH_2CH_3)]_2$}$Cl_2$] (10):** The synthesis of **10** was carried out in an identical manner to **9**. $Li_2${1-$Me_2Si[3\text{-}C_9H_5(CH_2CH_2CH_3)]_2$} (**6**) (4.48 g, 11.65 mmol) and $ZrCl_4$ (2.72 g, 11.65 mmol). Yield 1.61 g (26%). *rac*/*meso* = 38:62.

***meso* Isomer:** $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.04 [s, 3 H, $Si(CH_3)$ *exo*], 1.51 [s, 3 H, $Si(CH_3)$ *endo*], 1.07 (t, 6 H, $J$ = 7.9 Hz, $CH_2CH_2CH_3$), 1.74 (m, 4 H, $CH_2CH_2CH_3$), 2.98 (m, 4 H, $CH_2CH_2CH_3$), 5.73 (s, 2 H, 2-H), 7.07 and 7.32 (2t, $J$ = 8.8 Hz, each 2 H, 5-H, 6-H), 7.57 and 7.65 (2d, $J$ = 8.8 Hz, each 2 H, 4-H, 7-H) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CDCl_3$): $\delta$ = –2.45 [$Si(CH_3)$ *exo*], –0.71 [$Si(CH_3)$ *endo*], 14.46 ($CH_2CH_2CH_3$), 23.62 ($CH_2CH_2CH_3$), 30.78 ($CH_2CH_2CH_3$), 77.30, 80.10 (C1, C3), 117.27 (C2), 124.36 and 126.04 (C5, C6), 126.30 and 126.47 (C4, C7) ppm.

***rac* Isomer:** $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.25 [s, 6 H, $Si(CH_3)_2$], 1.03 (t, 6 H, $J$ = 7.9 Hz, $CH_2CH_2CH_3$), 1.65 (m, 4 H, $CH_2CH_2CH_3$), 2.84 (m, 4 H, $CH_2CH_2CH_3$), 5.91 (s, 2 H, *2-H*), 7.19 and 7.47 (2t, $J$ = 8.8 Hz, each 2 H, 5-H, 6-H), 7.57 and 7.65 (2d, $J$ = 8.8 Hz, each 2 H, 4-H, 7-H) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CDCl_3$): $\delta$ = –1.12 ppm [$Si(CH_3)_2$], 14.34 ($CH_2CH_2CH_3$), 23.54 ($CH_2CH_2CH_3$), 30.49 ($CH_2CH_2CH_3$), 77.40, 85.31 (C1, C3), 117.27 (C2), 124.55 and 124.92 (C5, C6), 126.62 and 126.72 (C4, C7) ppm.

**Both Isomers:** $C_{26}H_{30}Cl_2SiZr$ (532.73): calcd. C 58.62, H 5.68; found C 58.71, H 5.69.

**Preparation of [Zr{1-$Me_2Si[3\text{-}\eta^5\text{-}C_9H_5(CH_2CH_2CH_2CH_3)]_2$}$Cl_2$] (11):** The synthesis of **11** was carried out in an identical manner to **9**. $Li_2${1-$Me_2Si[3\text{-}C_9H_5(CH_2CH_2CH_2CH_3)]_2$} (**7**) (4.37 g, 10.59 mmol) and $ZrCl_4$ (2.47 g, 10.59 mmol). Yield 2.08 g (35%). *rac*/*meso* = 59:41.

***meso* Isomer:** $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 0.87 [s, 3 H, $Si(CH_3)$ *exo*], 1.36 [s, 3 H, $Si(CH_3)$ *endo*], 0.89 (t, $J$ = 7.9 Hz, 6 H, $CH_2CH_2CH_2CH_3$), 1.34 (m, 4 H, $CH_2CH_2CH_2CH_3$), 1.51 (m, 4 H, $CH_2CH_2CH_2CH_3$), 2.72 (m, 4 H, $CH_2CH_2CH_2CH_3$), 5.58 (s, 2 H, 2-H), 6.91 and 7.16 (2t, $J$ = 8.8 Hz, each 2 H, 5-H, 6-H), 7.41 and 7.49 (2d, $J$ = 8.8 Hz, each 2 H, 4-H, 7-H) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CDCl_3$): $\delta$ = –2.69 [$Si(CH_3)$ *exo*], –0.96 [$Si(CH_3)$ *endo*], 13.95 ($CH_2CH_2CH_2CH_3$), 22.77 ($CH_2CH_2CH_2CH_3$), 28.24 ($CH_2CH_2CH_2CH_3$), 32.29 ($CH_2CH_2CH_2CH_3$), 77.10, 84.81 (C1, C3), 116.88 (C2), 123.98 and 125.77 (C5, C6), 126.03, 126.19 (C4, C7) ppm.

**Both Isomers:** $C_{28}H_{34}Cl_2SiZr$ (560.79): calcd. C 59.97, H 6.11; found C 60.21, H 6.19.

**Preparation of [Zr{1-Me$_2$Si[3-η$^5$-C$_9$H$_5$(CH$_2$C$_6$H$_5$)]$_2$}Cl$_2$] (12):** The synthesis of **12** was carried out in an identical manner to **9**. $Li_2${1-$Me_2Si[3$-$C_9H_5(CH_2C_6H_5)]_2$} (**8**) (4.10 g, 8.53 mmol) and $ZrCl_4$ (2.00 g, 8.53 mmol). Yield 2.15 g (40%). *rac*/*meso* = 65:35.

***meso* Isomer:** $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.01 [s, 3 H, Si($CH_3$) *exo*], 1.29 [s, 3 H, Si($CH_3$) *endo*], $\delta_A$ = 4.28, $\delta_B$ = 4.22 (AB, $J_{AB}$ = 21.6 Hz, 4 H, $CH_2C_6H_5$), 5.77 (s, 2 H, *2-H*), 7.02–7.48 (m, 8 H, 4-H–7-H), 7.02–7.48 (m, 10 H, $CH_2C_6H_5$) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CDCl_3$): $\delta$ = –1.40 [Si($CH_3$) *exo*], –0.99 [Si($CH_3$) *endo*], 34.22 ($CH_2C_6H_5$), 65.84, 85.90 (C1, C3), 118.12 (C2), 124.06 and 125.85 (C5, C6), 126.12 and 126.14 (C4, C7), 118.04–140.17 ($CH_2C_6H_5$) ppm.

***rac* Isomer:** $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 0.79 [s, 6 H, Si($CH_3$)], $\delta_A$ = 4.17, $\delta_B$ = 4.04 (AB, $J_{AB}$ = 19.6 Hz, 4 H, $CH_2C_6H_5$), 5.59 (s, 2 H, 2-H), 7.02–7.48 (m, 8 H, 4-H–7-H), 7.02–7.48 (m, 10 H, $CH_2C_6H_5$) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CDCl_3$): $\delta$ = –2.85 [Si($CH_3$)$_2$], 34.58 ($CH_2C_6H_5$), 65.94, 86.32 (C1, C3), 118.04 (C2), 124.25 and 124.74 (C5, C6), 126.57 and 126.78 (C4, C7), 118.04–140.17 ($CH_2C_6H_5$) ppm.

**Both Isomers:** $C_{34}H_{30}Cl_2SiZr$ (628.82): calcd. C 64.94, H 4.81; found C 65.02, H 4.86.

**Polymerization Experiments:** Polymerizations (three runs for catalyst) were carried out in a 250 mL glass reactor using toluene as a solvent (100 mL). Catalysts (6 μmol) were treated with the appropriate quantity (Al/Zr = 2000) of a commercial (CROPTOM) solution of MAO in toluene (10% Al) for 15 min. Toluene (80 mL), Al($i$Bu)$_3$ scavenger (2 mL), and activated catalyst were introduced, in this order, into the reactor and the temperature was maintained at 343 K. The nitrogen atmosphere was removed and a continuous flow of ethylene (1.5 bar) was introduced over 30 min. The reaction mixture was then quenched by the addition of acidified methanol. The polymer was collected by filtration, washed with methanol, and dried under vacuum at room temperature for 24 h.

**Polymer Analysis Procedures:** $M$w, $M$n, and $M$w/$M$n were measured with an Alliance GPC-2000 high temperature GPG device from Waters Corp., Milford, MA, USA. The mobile phase was 2,4,5-trichlorobenzene (HPLC grade, J. T. Baker Ltd.) at 150 °C. Prior to use as a mobile phase, TCB was filtered through a 0.2-μ fiberglass filter (PALL Corp.). The GPC device was completed with 3 Styragel® columns (Waters Corp.) and an additional GARD column. All columns were placed in an oven and heated to 150 °C. The RI detector at 150 °C was used for MW determination by the relative method. Data processing was performed using Millennium® ver. 4.2 Software (Waters Corp.). The sample (0.020 g) was dissolved in 2,4,5-trichlorobenzene (10.0 mL) (HPLC grade, J. T. Baker Ltd.) at 150 °C over 7 h. The solution was stirred four times during this period. The hot solution (7 mL) of each sample was placed into the metal vial equipped with a mechanism for automatic filtration through 0.2-μ metal filters prior to injection. The vials were immediately placed in an autosampler heated continually at 150 °C. The sample was stirred for 15 min in the autosampler prior to injection. 12 PS narrow standards in the range of $M_W$ from 2430 Dalton to 1.800.000 Dalton (Aldrich) were used for the calibration of the GPC device. The standards were prepared analogous to the sample preparation. The concentrations of standard solutions were calculated according the recommendations of Aldrich. The calibration curve is linear in all range of $M_W$ and indicates the good working order of the device and especially the columns.

**X-ray Crystal Structure Determination of *meso*-9 and *rac*-10:** Intensity data were collected with a Nonius-MACH3 diffractometer equipped with a graphite monochromator and a Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) using a $\omega/2\theta$-scan technique. The final unit cell parameters were determined from 25 well-centered reflections and refined by least-squares methods. Data were corrected for Lorentz and polarization effects and a semi-empirical absorption correction (Psi-scans) was made.[21]

The structures were solved using direct methods,[22] completed by subsequent difference Fourier syntheses, and refined by full-matrix least-squares procedures on $F^2$.[23] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were placed using a "riding model" and included in the refinement at calculated positions. Weights were optimized in the final cycles. Crystallographic data are given in Table 4.

Table 4. Crystal data and structure refinement for *meso*-**9** and *rac*-**10**.

| | *meso*-**9** | *rac*-**10** |
|---|---|---|
| Empirical formula | $C_{22}H_{22}Cl_2SiZr{\cdot}CH_2Cl_2$ | $C_{26}H_{30}Cl_2SiZr{\cdot}0.5C_7H_8$ |
| Formula weight | 561.53 | 578.78 |

# Synthesis of New Tripodal Tri-Functionalized Hydrotris(indazol-1-yl)borate Ligands and X-ray Structures of Their Cyclopentadieneruthenium Complexes

**Alexandre Carella,[a] Guillaume Vives,[a] Tara Cox,[a] Joël Jaud,[a] Gwénaël Rapenne,*[a] and Jean-Pierre Launay*[a]**

**Keywords:** Tripodal ligands / Ligand design / Ruthenium / Indazole / Stacking interactions

Two new tripodal ligands designed to anchor complexes onto surfaces have been synthesized. They integrate ester or thioether functions at the 6-position of the indazoles. Potassium hydrotris[6-(ethoxycarbonyl)indazolyl]borate and potassium hydrotris{6-[(ethylsulfanyl)methyl]indazolyl}borate exhibit three pendant groups oriented to anchor complexes onto an oxide and a metallic surface, respectively. Their complexation with $[RuCp(CH_3CN)_3]PF_6$ yielded two piano-stool-shaped complexes that were characterized by X-ray diffraction. Comparison with the synthesized unfunctionalized analog showed that the three 6-substituted functions do not interfere with the coordination site and are particularly well oriented for surface deposition.

## Introduction

In the last decade, the continuous improvement of near-field microscopy techniques such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM) has led to the imaging and the study of physicochemical properties of various molecules.[1] These techniques allow the visualization and manipulation of only one molecule and therefore the electrical[2] and mechanical properties[3] of a single molecule deposited on a surface can be investigated. As single-molecule experiments require the control of the shape of the molecule deposited, the design and the synthesis of rigid ligands able to be covalently attached on surfaces with a minimum number of degrees of freedom is an active field of research.[4] In particular, the movement of a molecule can be efficiently restricted by attaching the molecule to a surface with a tripod,[5] which prevents translation. Some rigid organic molecules with three points of attachment have already been used in AFM or STM studies.[6] However, the absence of coordination sites restricts their field of application. Therefore, a structurally rigid bifunctional molecule combining coordinating sites and anchoring groups is of special interest. It would allow the covalent attachment of coordination complexes on a surface, for instance giving rise to surface-mounted molecular gears or motors.[6,7]

Since their discovery by Trofimenko in the late 1960s,[8] the trispyrazolylborate ligands, also known as scorpionate ligands, have been used increasingly in bioinorganic, organometallic, and coordination chemistry.[9] This last aspect has been extensively developed with a particular interest in the modification of the functional groups connected to the pyrazolyl moiety in order to control or modify the steric and electronic environment surrounding the metal center. However its analogue, hydrotris(indazolyl)borate ($Tp^{4Bo}$), has not stimulated intense studies since its synthesis in 1995.[10] Nevertheless tris(indazolyl)borate bears two advantages over trispyrazolylborate. First it is larger, but the increase in size is not accompanied by a decrease in the rigidity of the molecule. Furthermore, by withdrawing the metal away from the surface, it allows interferences caused by metal–surface interactions to be minimized, which is particularly important for near-field microscopy experiments. The rigidity of its indazolyl fragments, conjugated with its tripodal shape, should make it a good candidate for surface deposition of metal complexes onto surfaces.

Here we report the synthesis of two new scorpionate ligands incorporating functional groups on the indazole, designed to interact with metallic or oxide surfaces. The functionalized borate ligands were designed to have three functional groups pointing in the opposite direction of the coordination site in order not to interfere sterically with it. Each of the three legs of the tripodal unit bears a functional group connected at the 6-position of indazole, which should be the optimal orientation for anchoring on a surface. The ester function has been found to strongly interact with oxide surfaces,[11] spontaneous deprotection yielding carboxylic groups that covalently bind the metallic oxide. In order to interact with a metallic surface, the thioether function was chosen to alleviate the problem encountered with oxidatively unstable thiols. Acetyl-protected thiols were also

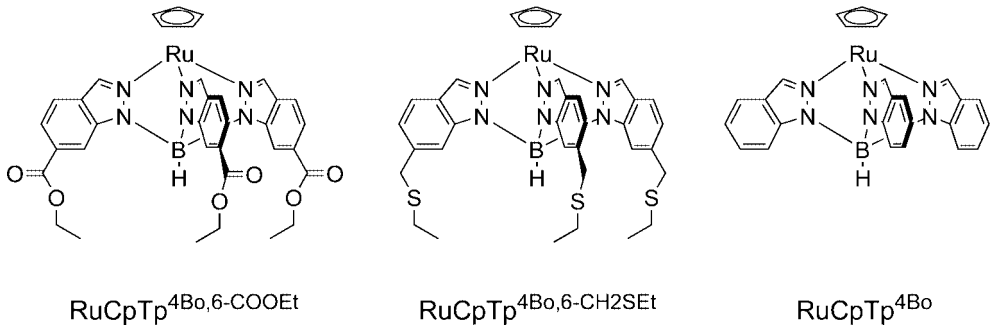

Figure 1. Structure of the triester-functionalized, trithioether-functionalized, and unfunctionalized ruthenium(II) complexes.

good candidates because of their spontaneous deprotection on a gold surface,[12] but preliminary experiments showed their incompatibility with the last step of the synthesis of the borate ligand, which requires sodium borohydride, yielding the reduction of the acetyl-protected thiol. The thioether group is stable in a wider range of conditions and is also known to interact strongly with a gold surface.[13] The synthesis of the hydrotris[6-(ethoxycarbonyl)indazol-1-yl]borate ligand incorporating three ester functions and the hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borate ligand with three pendant thioether arms is described, followed by the preparation and X-ray structures of the corresponding $\eta^5$-cyclopentadienylruthenium complexes with both functionalized tripodal ligands and also with the unfunctionalized ligand. Following Trofimenko's scorpionate nomenclature,[9] the 6-functionalized ligands can be noted as $KTp^{4Bo,6\text{-}COOEt}$ for the ester-functionalized and $KTp^{4Bo,6\text{-}CH2SEt}$ for the thioether-functionalized ligand, and similarly the ruthenium complexes can be noted as $RuCpTp^{4Bo,6\text{-}COOEt}$, $RuCpTp^{4Bo,6\text{-}CH2SEt}$, and $RuCpTp^{4Bo}$ (Figure 1).

## Results and Discussion

### Ligand Syntheses

The strategy we followed consisted in the synthesis of a functionalized indazole in a first step, and its subsequent reaction with potassium borohydride to yield the potassium hydrotris(indazol-1-yl)borate ligand. Purification methods used in classical organic chemistry, such as column chromatography, are not suited to the purification of salts. Trituration with an apolar solvent can selectively dissolve the indazole precursor, and an additional sublimation step provides pure material. Potassium hydrotris[6-(ethoxycarbonyl)indazol-1-yl]borate ($KTp^{4Bo,6\text{-}COOEt}$) was synthesized in three steps starting with 3-amino-4-methylbenzoic acid (**1**) (Scheme 1). The esterification of **1** in ethanol mediated by thionyl chloride[14] afforded ethyl 3-amino-4-methylbenzoate (**2**) quantitatively. The conversion of **2** into ethyl indazole-6-carboxylate (**3**) was performed using the Jacobson procedure[15] by reaction of **2** with potassium acetate, acetic anhydride, and isopentyl nitrite in refluxing toluene to give ethyl 1-acetylindazole-6-carboxylate, which was deprotected with HCl, affording **3** in 64% yield.

The formation of the indazolyl ring was demonstrated by $^1$H NMR where the NH proton resonates with a characteristic signal at $\delta$ = 11 ppm. Reaction of **3** at 180 °C for 5 h with potassium borohydride gave the triester-functionalized $KTp^{4Bo,6\text{-}COOEt}$ in 68% yield after purification by repetitive trituration with hot toluene and sublimation of the unreacted ethyl indazole-6-carboxylate. It is noteworthy that by conducting the reaction at 150 °C instead of 180 °C, the bis(indazolyl)borate was mainly obtained. As known from the literature,[16] the signal of the BH proton is very broad and difficult to find but very informative to differentiate the

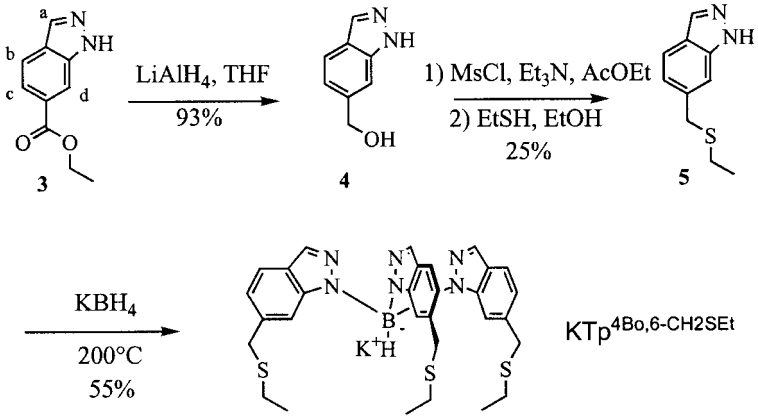

Scheme 2. Synthesis of potassium hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borate.

bis (signal near 3.5 ppm) and tris ($\delta$ = 5 ppm) indazolylborates.

Concerning the regiochemistry of the reaction, Trofimenko has shown on the hydrotris(indazol-1-yl)borate ligand[10] that the interplay of steric and electronic factors tilts in favor of the latter, giving a product that is sterically hindered around the boron atom but not on the coordination side. Similarly, we obtained exclusively the product resulting from the fusion of the benzo ring at the 4–5-position (giving the $Tp^{4Bo}$ product) in which the boron atom is bound to the more hindered nitrogen atom and no trace of the 3–4 fusion product ($Tp^{3Bo}$). This regiospecificity is maintained with ester groups at the 6-position of the indazole, as confirmed by the X-ray structure of the ruthenium complex.

The synthesis of 6-[(ethylsulfanyl)methyl]indazole (**5**) was achieved in two steps from **3** (Scheme 2). Reduction of the ethyl ester function using $LiAlH_4$ gave 6-(hydroxymethyl)-indazole (**4**) with a very good yield. Mesylation of the alcohol followed by reaction with thioethanol allowed the thioether-substituted indazole **5** to be obtained in a one-pot procedure. The same procedure used to obtain $KTp^{4Bo,6\text{-}COOEt}$ was applied to **5**, yielding potassium hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borate ($KTp^{4Bo,6\text{-}CH2SEt}$).

### Complex Formation and Characterization

The coordination chemistry of the two ligands was consistent with the absence of steric hindrance on the metal coordination face. Complexation of $KTp^{4Bo}$, $KTp^{4Bo,6\text{-}COOEt}$, and $KTp^{4Bo,6\text{-}CH2SEt}$ with $[RuCp(CH_3CN)_3]PF_6$ was performed by heating the scorpionate ligand with 1 equiv. of ruthenium complex in anhydrous and degassed acetonitrile. The $\eta^5$-cyclopentadienylruthenium(II) complexes of each tripodal ligand were obtained; $\eta^5$-cyclopentadienyl(hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borato)ruthenium(II) ($RuCpTp^{4Bo,6\text{-}CH2SEt}$) and $\eta^5$-cyclopentadienyl(hydrotris[6-(ethoxycarbonyl)indazol-1-yl]-borato)ruthenium(II) ($RuCpTp^{4Bo,6\text{-}COOEt}$) were obtained with a lower yield compared to the complex formed with the unfunctionalized ligand. For solubility reasons, the synthesis of $RuCpTp^{4Bo,6\text{-}COOEt}$ required the use of anhydrous DMF as cosolvent. The three complexes were fully characterized.

The cyclic voltammogram of the unfunctionalized complex exhibits a reversible metal-centered oxidation at 0.49 V/SCE, that is 100 mV higher than the pyrazolyl analog in the same conditions (Table 1). This shows that ruthenium(II) is more stabilized in $RuCpTp^{4Bo}$ than in its pyrazolyl analog synthesized by Mann et al.,[17] which can be explained by the more pronounced $\pi$-acceptor character of the hydrotris(indazolyl)borate compared to its pyrazolyl analog. In the ruthenium complex $RuCpTp^{4Bo,6\text{-}COOEt}$, which incorporates the triester-functionalized ligand, oxidation occurs at a higher potential: 0.63 V/SCE, the ethoxycarbonyl electron-withdrawing groups stabilizing the ruthenium(II) state further. The ester substituents decrease the $\sigma$-donor character and increase the $\pi$-acceptor character of the scorpionate ligand. The combination of this low $\sigma$-donor character and solubility problems could explain the moderate yield of the coordination step. The coordinating nitrogen of the ester-functionalized scorpionate ligand being less donor than its unfunctionalized analog, is thus less efficient in the displacement of the acetonitrile ligands of the ruthenium precursor. In the ruthenium complex $RuCpTp^{4Bo,6\text{-}CH2SEt}$, which incorporates the thioether functions, oxidation occurs at a slightly lower potential of 0.48 V/SCE, the slightly electron-donating (ethylsulfanyl)-methyl groups destabilizing the ruthenium(II) state.

Variable temperature $^1$H NMR experiments have shown that the rotation of the Cp ligand in the complexes is fast compared to the NMR timescale down to at least –90 °C in deuterated dichloromethane, indicating that the coordination site is not sterically affected by the ethoxycarbonyl or (ethylsulfanyl)methyl substituents.

### Crystal Structures of the Complexes

Crystals suitable for X-ray diffraction were grown by the slow diffusion of methanol over a dichloromethane solution of the complex. The ORTEP representations with atom numbering are shown in Figure 2, while selected bond lengths and angles are listed in Table 2.

$RuCpTp^{4Bo,6\text{-}COOEt}$ and $RuCpTp^{4Bo}$ crystallized in the *Pccn* space group while $RuCpTp^{4Bo,6\text{-}CH2SEt}$ crystallized in the $P\bar{1}$ group. The triester-functionalized complex cocrystallized with molecules of methanol (0.5 equiv. per ruthenium complex), which are located on a symmetry axis and are highly disordered. In line with the $^1$H NMR spectroscopic data, the three complexes have a piano stool shape where the scorpionate ligand binds the ruthenium center in a facial tripodal mode (i.e. $\kappa^3$-*N*,*N*′,*N*′′), as shown by Trofimenko for scorpionate complexes. The crystal structure of complexes with the triester- and (ethylsulfanyl)-methyl-functionalized ligands confirmed the regiochemistry of the scorpionate formation, which is the expected $Tp^{4Bo}$ isomer. Moreover, the functional groups at the 6-position of indazole are well oriented, pointing in the opposite direction of the coordination site, which is thus free of any steric hindrance as seen in solution by a variable temperature $^1$H NMR experiment. The lack of interference between the coordination site and the attaching groups suggests that this molecule can be expected to be truly bifunctional, acting both as ligand and anchor to fix metal complexes onto a surface.

significant conformations can be defined (Figure 3). The first one can be considered as an eclipsed conformation in which one of the dihedral angles between a CH bond of the cyclopentadienyl ligand and one indazole of the scorpionate ligand is 0°. In the second one, the staggered conformation, two of these dihedral angles are equal to 12°. Because of the symmetry of each ligand, a rotation of 24° is invariant. A 12° rotation of one ligand with respect to the other allows the interconversion between staggered and eclipsed conformations.

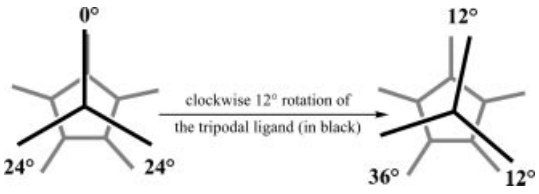

Figure 3. Eclipsed (left) and staggered (right) conformations of a complex containing both $C_3$- and $C_5$-symmetry ligands. Interconversion occurs upon a 12° rotation. For symmetry reasons, the staggered conformation appears every 24°.

On purely steric grounds, the staggered conformer is expected to be the most stable, as obtained in the case of the pyrazolyl analog RuCpTp.[15] On the contrary, RuCpTp$^{4Bo}$ adopts an almost eclipsed conformation in the solid state, with a dihedral angle between the C(24)–H(24) bond and the plane of the N(1)-containing indazole equal to 0.3° (Figure 2, bottom view). An explanation for a favored eclipsed conformation must be found in the crystal packing and in the intermolecular forces involved in the solid state. A careful examination of the crystal packing of the unfunctionalized and both functionalized complexes showed π-stacking interactions between the two indazoles of neighboring complexes. As shown for the unfunctionalized complex in Figure 4, the two indazoles face each other in a head-to-tail mode, the electron-rich part of one indazole being exactly above the electron-poor part of the other indazole, which provides further stabilization by donor–acceptor interactions. The distance between the planes of two consecutive indazoles is ideal for stacking: 3.62 Å for the triester complex, 3.59 Å for the tris (ethylsulfanyl)methyl complex, and 3.56 Å for the unfunctionalized complex.

Moreover, average Ru–C distances of 2.15 Å (for cyclopentadienyl) and Ru–N bond lengths of 2.11 Å (for trisindazolylborate) are found in the three complexes, showing that the coordination of the tripodal ligand is not influenced by the presence of the functional groups at the 6-position of the indazole rings. The moderate reactivity of the triester-functionalized ligand towards complexation with $[RuCp(CH_3CN)_3]PF_6$ is thus justified purely by electronic considerations, while steric hindrance due to the ester groups can be ruled out.

## Conclusions

In summary, we have described the preparation and coordination of two new tripodal ligands that bear functional groups suitable for surface deposition. The orientation of the three anchoring groups, as shown by the X-ray structures, seems to be ideal for surface deposition of organometallic complexes. Work is underway to anchor these complexes on surfaces and integrate the triester-functionalized ligand into molecular machines such as a molecular rotary motor[7] designed to be studied as a single molecule deposited on an oxide surface.

## Experimental Section

All commercially available chemicals were of reagent grade and were used without further purification. $[RuCp(CH_3CN)_3]PF_6$ was purchased from Strem. Potassium hydrotris(indazol-1-yl)borate ($KTp^{4Bo}$) was prepared according to a literature procedure.[10] NMR spectra were recorded with Bruker AM 250 or Avance 500 spectrometers and full assignments were made using COSY, ROESY, HMBC, and HMQC methods when necessary. The numbering scheme for the indazol derivatives is given in molecule **3** (see Scheme 1 and Scheme 2). Chemical shifts are defined with respect to TMS = 0 ppm for $^1H$ and $^{13}C$ NMR spectra and were measured relative to residual solvent peaks. UV/Vis spectra were recorded with a Shimadzu UV-3100 spectrometer. FAB and DCI mass spectrometry was performed using a Nermag R10–10. The melting points were measured on a Kofler Reichert apparatus and are not corrected.

**Ethyl 3-Amino-4-methylbenzoate (2):** 3-Amino-4-methylbenzoic acid (**1**) (2.00 g, 13.3 mmol, 1 equiv.) was dissolved in absolute eth-

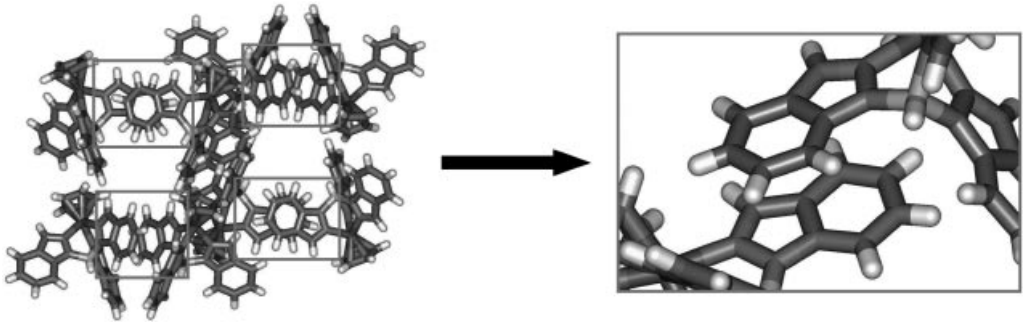

Figure 4. Stabilization in the crystal structure of RuCpTp$^{4Bo}$ by π-stacking interactions between neighboring indazolyl pairs. Zooming in shows the donor–acceptor interactions between two indazolyl groups positioned in a head-to-tail arrangement with an interplane distance of 3.56 Å.

anol (50 mL). Thionyl chloride (2 mL, 27.4 mmol, 2 equiv.) was added dropwise and the reaction mixture was heated at reflux overnight, during which the color of the solution turned from purple to pink. Ethanol was removed under reduced pressure, and the residual oil was dissolved in ethyl acetate (50 mL) and washed with a saturated sodium carbonate solution (3 × 20 mL). The combined aqueous phases were extracted with ethyl acetate (20 mL). Then the combined organic phases were dried with $MgSO_4$ and the solvent removed under reduced pressure to afford ethyl 3-amino-4-methylbenzoate (**2**) (2.33 g, 13.0 mmol, 98%) as a pink oil which was used without further purification. DCI-MS ($NH_3$): *m*/*z* (%) = 180 [M + H]$^+$, 197 [M + $NH_4$]$^+$. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 7.26–7.30 (m, 2 H, H$^{c-d}$), 6.92 (d, $^3J$ = 7.8 Hz, 1 H, H$^b$), 4.31 (q, $^3J$ = 6.9 Hz, 2 H, C$H_2$CH$_3$), 3.91 (broad s, 2 H, $NH_2$), 2.00 (s, 3 H, Me), 1.21 (t, $^3J$ = 6.9 Hz, 3 H, CH$_2$C$H_3$) ppm.

**Ethyl 1*H*-Indazole-6-carboxylate (3):** In a three-necked round-bottomed flask, ethyl 3-amino-4-methylbenzoate (**2**) (2.30 g, 12.8 mmol, 1 equiv.), potassium acetate (1.3 g, 13.2 mmol, 1.1 equiv.), and acetic anhydride (4.4 mL, 47 mmol, 3.6 equiv.) were suspended in toluene (50 mL). Isopentyl nitrite (3.6 mL, 24.6 mmol, 2.1 equiv.) was added dropwise to this suspension over a 15-min period. The gelatinous mixture was heated at reflux overnight giving an orange solution, which was evaporated to dryness. HCl (5 M, 10 mL) and concentrated HCl (5 mL) were added and the red solution was heated at 50 °C for 1 h followed by 10 min at 60 °C. After cooling down, the acid layer was extracted twice with toluene (20 mL) to remove neutral compounds. The red combined organic phases were washed three times with concentrated HCl. The acid phase was then carefully neutralized with ammonia, causing precipitation of the compound. After filtration, the product was dissolved in dichloromethane then dried with $MgSO_4$ and the solvent removed under reduced pressure to afford **3** (1.56 g, 8.2 mmol, 64%) as a brown solid. The product can be sublimed (0.1 Torr, 160 °C) or used without further purification. DCI-MS ($NH_3$): *m*/*z* (%) = 191 [M + H]$^+$. High resolution LSI calculated [M + H]$^+$: 191.0821 ($C_{10}H_{11}N_2O_2$); found: 191.0827 (100% [M + H]$^+$). M.p. 125 °C. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 11.15 (s, 1 H, NH), 8.27 (d, $^4J$ = 1 Hz, 1 H, H$^a$), 8.14 (s, 1 H, H$^d$), 7.88–7.77 (m, 2 H, H$^{b-c}$), 4.42 (q, 2 H, $^3J$ = 7.0 Hz, C$H_2$CH$_3$), 1.44 (t, 3 H, $^3J$ = 7.2 Hz, CH$_2$C$H_3$) ppm. $^{13}$C NMR (63 MHz, $CDCl_3$): $\delta$ = 166.8 (CO), 139.5, 135.0 (C$^a$), 129.0, 125.7, 121.6 (C$^c$), 120.7 (C$^b$), 112.1 (C$^d$), 61.3 ($CH_2$), 14.4 ($CH_3$) ppm. $C_{10}H_{10}N_2O_2$: calcd. C 63.2, H 5.30, N 14.7; found: C 62.8, H 5.11, N 14.5.

**Potassium Hydrotris[6-(ethoxycarbonyl)indazol-1-yl]borate (KTp$^{4Bo,6-COOEt}$):** Ethyl indazole-6-carboxylate (**3**) (700 mg, 3.68 mmol, 3.5 equiv.) and potassium borohydride (56 mg, 1.05 mmol, 1 equiv.) were ground up in a mortar then dried under vacuum and the vessel was filled with argon. The mixture was heated in a sand bath at 180 °C until the gas evolution had ceased (5–6 h). The reaction was then quenched by addition of toluene. The solid was filtered off and purified by trituration with hot toluene, which dissolved the unreacted **3**. After drying under vacuum, the solid was ground in a mortar and any remaining unreacted indazole was removed by sublimation, by heating the sample at 160 °C under vacuum. By repeating alternating trituration and sublimation, potassium hydrotris[6-(ethoxycarbonyl)indazol-1-yl]borate (KTp$^{4Bo,6-COOEt}$) (440 mg, 0.712 mmol, 68%) was obtained as a pale yellow solid. FAB-MS (MeOH, Gly-Thio, negative mode): *m*/*z* (%) = 579 [M – K]$^-$. High resolution LSI calculated [M – K]$^-$: 578.2085 ($C_{30}H_{27}BN_6O_6$); found: 578.2099 (100% [M – K]$^-$). $^1$H NMR (250 MHz, [D$_6$]DMSO): $\delta$ = 8.20 (s, 3 H, H$_a$), 8.15 (d, $^4J$ = 1 Hz, 3 H, H$^d$), 7.81 (d, $^3J$ = 8.5 Hz, 3 H, H$^c$), 7.59 (dd, $^3J$ = 8.5 Hz, $^4J$ = 1 Hz, 3 H, H$^b$), 4.33 (q, $^3J$ = 7 Hz, 6 H, C$H_2$CH$_3$), 1.34 (t, $^3J$ = 7 Hz, 9 H, CH$_2$C$H_3$) ppm. $^{13}$C NMR (63 MHz, [D$_6$]-DMSO): $\delta$ = 166.3 (CO), 144.3, 133.0 (C$^a$), 126.3, 123.2, 120.6 (C$^c$), 120.3 (C$^b$), 112.7 (C$_d$), 61.0 ($CH_2$), 14.3 ($CH_3$).

**$\eta^5$-Cyclopentadienyl(hydrotris[6-(ethoxycarbonyl)indazol-1-yl]borato)ruthenium(II) (RuCpTp$^{4Bo,6-COOEt}$):** Potassium hydrotris[6-(ethoxycarbonyl)indazol-1-yl]borate (KTp$^{4Bo,6-COOEt}$) (62 mg, 0.1 mmol, 1 equiv.) was dissolved in dry DMF (2 mL), dry acetonitrile was added (20 mL), and the mixture was purged with argon. [RuCp(CH$_3$CN)$_3$]PF$_6$ (43 mg, 0.1 mmol, 1 equiv.) was added to this solution, which was then refluxed overnight. Evaporation of the solvent followed by a purification by column chromatography ($SiO_2$: cyclohexane/ethanol 0–20%) afforded $\eta^5$-cyclopentadienyl-[hydrotris[6-(ethoxycarbonyl)indazol-1-yl]borato]ruthenium(II) (RuCpTp$^{4Bo,6-COOEt}$) (39 mg, 0.052 mmol, 52%) as a yellow solid. DCI-MS ($NH_3$): 747 [M + H]$^+$, 764 [M + $NH_4$]$^+$. High resolution LSI calculated [M + H]$^+$: 747.1676 ($C_{35}H_{34}BN_6O_6Ru$); found: 747.1700 (100% [M + H]$^+$). M.p. 212 °C dec. $^1$H NMR (250 MHz, $CD_2Cl_2$): $\delta$ = 8.66 (d, $^4J$ = 0.9 Hz, 3 H, H$^a$), 8.62 (d, $^4J$ = 1.2 Hz, 3 H, H$^d$), 7.69 (dd, $^3J$ = 8.5 Hz, $^4J$ = 1.2 Hz, 3 H, H$^c$), 7.62 (dd, $^3J$ = 8.5 Hz, $^4J$ = 0.9 Hz, 3 H, H$^b$), 4.63 (s, 5 H, Cp), 4.42 (q, $^3J$ = 7 Hz, 6 H, C$H_2$CH$_3$), 1.43 (t, $^3J$ = 7.2 Hz, 9 H, CH$_2$C$H_3$) ppm. $^{13}$C NMR (63 MHz, $CD_2Cl_2$): $\delta$ = 167.6 (CO), 143.1, 140.2 (C$^a$), 129.2, 126.8, 122.0 (C$^c$), 119.7 (C$^b$), 114.6 (C$^d$), 72.8 (Cp), 62.0 ($CH_2$), 15.0 ($CH_3$) ppm. $E_{Ru^{II}:Ru^{III}}$ (V/SCE): +0.63 rev (sweep rate: 100 mV s$^{-1}$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$ in L mol$^{-1}$ cm$^{-1}$) = 222 (60300), 256 (14000), 334 (12800), 418 nm (6900).

**$\eta^5$-Cyclopentadienyl[hydrotris(indazol-1-yl)borato]ruthenium(II) (RuCpTp$^{4Bo}$):** A solution of potassium hydrotris(indazol-1-yl)borate (KTp$^{4Bo}$) (81 mg, 0.2 mmol, 1 equiv.) in acetonitrile (20 mL) was purged with argon and [RuCp(CH$_3$CN)$_3$]PF$_6$ (87 mg, 0.2 mmol, 1 equiv.) was added. The solution was refluxed for 1.5 h. The solution, initially yellow, turned to orange-brown. Upon cooling to room temperature, an orange precipitate appeared. Recrystallization from chloroform/methanol gave pure RuCpTp$^{4Bo}$ (70 mg, 0.132 mmol, 65%) as an orange microcrystalline product. DCI-MS ($NH_3$): *m*/*z* (%) = 548 [M + $NH_4$]$^+$, 531 [M + H]$^+$. High resolution LSI calculated [M + H]$^+$: 531.1042 ($C_{26}H_{22}BN_6Ru$); found: 531.1061 (100% [M + H]$^+$). M.p. 222 °C dec. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 8.61 (s, 3 H, H$_a$), 7.90 (d, $^3J$ = 8.75 Hz, 3 H, H$^b$), 7.6 (d, $^3J$ = 7.25 Hz, 3 H, H$_d$), 7.32 (t, $^3J$ = 7.25 Hz, 3 H, H$^c$), 7.05 (t, $^3J$ = 7.25 Hz, 3 H, H$^6$), 4.56 (s, 5 H, Cp) ppm. $^{13}$C NMR (63 MHz, $CDCl_3$): $\delta$ = 138.9 (C$^a$), 125.9, 123.7, 120.5 (C$^c$), 119.2 (C$^b$), 111.5 (C$^d$), 70.7 (Cp) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$ in L mol$^{-1}$ cm$^{-1}$) = 231 (21400), 298 (15000), 307 (12200), 325 (9700), 388 nm (4600). CV ($CH_3CN$, $Bu_4NPF_6$) $E_{Ru^{II}:Ru^{III}}$ (V/SCE): +0.49 rev (sweep rate: 100 mV s$^{-1}$).

**6-(Hydroxymethyl)-1*H*-indazole (4):** $LiAlH_4$ (1.6 g, 42.5 mmol, 4 equiv.) was added carefully in portions to a solution of **3** (2 g, 10.5 mmol, 1 equiv.) in freshly distilled THF (100 mL) at 0 °C. After 2 h of vigorous stirring, TLC analysis showed a complete disappearance of the starting material and the presence of a single product. The reaction mixture was carefully quenched with water (1.6 mL) followed by a 15% NaOH solution (1.6 mL) and then water (4 mL). The mixture was filtered through Celite and the filter cake was washed several times with dichloromethane. The filtrate was dried with $MgSO_4$ and the solvent was removed under reduced pressure, affording 6-(hydroxymethyl)indazole (**4**) (1.45 g, 9.8 mmol, 93%). This compound was used without further purification. ESI-MS: *m*/*z* (%) = 149 [M + H]$^+$. M.p. 159 °C. $^1$H NMR (250 MHz, [D$_6$]DMSO): $\delta$ = 12.97 (s, 1 H, NH), 8.00 (s, 1 H, H$^a$), 7.65 (d, $^3J$ = 8.4 Hz, 1 H, H$^d$), 7.46 (s, 1 H, H$^b$), 7.04 (d, $^3J$ = 8.4 Hz, 1 H, H$_c$), 5.28 (br. s, 1 H, OH), 4.61 (d, $^3J$ = 5.9 Hz, 2 H, $CH_2$).

**6-[(Ethylsulfanyl)methyl]-1*H*-indazole (5):** Mesyl chloride (0.65 mL, 8.4 mmol, 1 equiv.) was added dropwise to a solution of 6-(hydroxymethyl)indazole (**4**) (1.24 g, 8.4 mmol, 1 equiv.) and triethylamine (2.5 mL) in ethyl acetate (170 mL) at 0 °C. The mixture was stirred at room temperature for 12 h, the organic phase was washed three times with water (50 mL), and the combined aqueous phases were extracted once with ethyl acetate. The combined organic phases were dried with $MgSO_4$ and the solvent removed under reduced pressure, giving a pale yellow solid that was used without purification in the next step. The mesylate yellow solid was dissolved in dry THF (75 mL) and added dropwise to a solution of ethane thiol (0.62 mL, 8.4 mmol, 1 equiv.) in ethanol (75 mL) with KOH (0.7 g, 12.5 mmol, 1.5 equiv.). The solvent was removed under reduced pressure and the crude material was purified by column chromatography ($SiO_2$, cyclohexane/$Et_2O$ 40%) to give 6-[(ethylsulfanyl)methyl]indazole (**5**) (400 mg, 2.08 mmol, 25%) as a white solid. DCI-MS ($NH_3$): *m*/*z* (%) = 193 $[M + H]^+$. High resolution LSI calculated $[M + H]^+$: 193.0799 ($C_{10}H_{13}N_2S$); found: 193.0804 (100% $[M + H]^+$). M.p. 61 °C. $^1H$ NMR (250 MHz, $CD_2Cl_2$): $\delta$ = 11.35 (s, 1 H, NH), 8.01 (s, 1 H, $H^a$), 7.68 (d, $^3J$ = 8.3 Hz, 1 H, $H^d$), 7.44 (s, 1 H, $H^b$), 7.08 (d, $^3J$ = 8.3 Hz, 1 H, $H^c$), 3.86 (s, 2 H, $CH_2$), 2.39 (q, $^3J$ = 7.3 Hz, 2 H, $CH_2CH_3$), 1.15 (t, $^3J$ = 7.3 Hz, 3 H, $CH_2CH_3$) ppm. $^{13}C$ NMR (63 MHz, $CD_2Cl_2$): $\delta$ = 140.4, 138.0 ($C^a$), 134.4, 122.7 ($C^c$), 120.8 ($C^b$), 109.6 ($C^d$), 36.3 ($CH_2S$), 25.4 ($CH_2$), 14.3 ($CH_3$) ppm. $C_{10}H_{12}N_2S$: calcd. C 62.5, H 6.29, N 14.6; found C 62.2, H 6.14, N 14.5.

**Potassium Hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borate ($KTp^{4Bo,6\text{-}CH2SEt}$):** 6-[(Ethylsulfanyl)methyl]indazole (**5**) (300 mg, 1.56 mmol, 3.4 equiv.) and potassium borohydride (25 mg, 46 mmol, 1 equiv.) were ground up in a mortar, dried under vacuum and the vessel was filled with argon. The mixture was heated in a sand bath at 200 °C; 5 h were needed until the gas evolution had ceased. The solid was ground in a mortar and any remaining unreacted indazole was removed by sublimation, by heating the sample at 160 °C under vacuum. By repeating alternating trituration with toluene and sublimation, potassium hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borate ($KTp^{4Bo,6\text{-}CH2SEt}$) (160 mg, 0.25 mmol, 55%) was obtained as a pale yellow sticky solid. FAB-MS (MeOH, Gly-Thio, negative mode): *m*/*z* (%) = 584 $[M - K]^-$. High resolution LSI calculated $[M - K]^-$: 584.2022 ($C_{30}H_{33}BN_6S_3$); found: 584.2042 (100% $[M - K]^-$). $^1H$ NMR (250 MHz, $[D_6]$-DMSO): 7.82 (d, $^4J$ = 1 Hz, 3 H, $H^a$), 7.52 (d, $^3J$ = 8.0 Hz, 3 H, $H^c$), 6.92 (s, 3 H, $H^d$), 6.84 (dd, $^3J$ = 8.0 Hz, $^4J$ = 1 Hz, 3 H, $H^b$), 3.57 (s, 2 H, $CH_2S$), 2.05 (q, $^3J$ = 7.4 Hz, 6 H, $CH_2CH_3$), 0.97 (t, $^3J$ = 7 Hz, 9 H, $CH_2CH_3$), 5.73 (br. s, 1 H, B*H*) ppm. $^{13}C$ NMR (63 MHz, $[D_6]$DMSO): $\delta$ = 143.8, 133.3 ($C^a$), 131.9, 121.9, 120.0 ($C^c$), 119.5 ($C^b$), 112.6 ($C^d$), 35.2 ($CH_2S$), 24.0 ($CH_2$), 14.2 ($CH_3$) ppm. $^{11}B$ NMR (160 MHz, $[D_6]$DMSO): –2.57 (s, 1 H) ppm.

**$\eta^5$-Cyclopentadienyl(hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borato)ruthenium(II) ($RuCpTp^{4Bo,6\text{-}CH2SEt}$):** Potassium hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borate ($KTp^{4Bo,6\text{-}CH2SEt}$) (62 mg, 0.1 mmol, 1 equiv.) was dissolved in dry acetonitrile (20 mL) and the mixture was purged with argon. $[RuCp(CH_3CN)_3]PF_6$ (43 mg, 0.1 mmol, 1 equiv.) was added to this solution and it was then refluxed for 2 h. Evaporation of the solvent followed by a purification by column chromatography ($SiO_2$: cyclohexane/dichloromethane 0–50%) afforded $\eta^5$-cyclopentadienyl(hydrotris{6-[(ethylsulfanyl)methyl]indazol-1-yl}borato)ruthenium(II) ($RuCpTp^{4Bo,6\text{-}CH2SEt}$) (10 mg, 0.013 mmol, 13%) as a yellow solid. DCI-MS ($NH_3$): 753 $[M + H]^+$. High resolution LSI calculated $[M + H]^+$: 753.1613 ($C_{35}H_{40}BN_6RuS_3$); found: 753.1637 (100% $[M + H]^+$). M.p. 206 °C dec. $^1H$ NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 8.57 (s, 3 H, $H^a$), 7.78 (s, 3 H, $H^d$), 7.55 (d, 3 H, $^3J$ = 8.3 Hz, $H^b$), 7.08 (d, 3 H, $^3J$ = 8.3 Hz, $H^c$), 4.55 (s, 5 H, Cp), 3.87 (s, 6 H, $CH_2$), 2.15 (q, 6 H, $^3J$ = 7.3 Hz, $CH_2CH_3$), 1.22 (t, 9 H, $^3J$ = 7.3 Hz, $CH_2CH_3$) ppm. $^{13}C$ NMR (126 MHz, $CD_2Cl_2$): $\delta$ = 143.0, 138.9 ($C^a$), 136.9, 122.7, 122.3 ($C^c$), 119.3 ($C^b$), 111.0 ($C^d$), 70.7 (Cp), 36.4 ($CH_2S$), 25.2 ($CH_2$), 14.3 ($CH_3$) ppm. $E_{Ru^{II}:Ru^{III}}$ (V/SCE): +0.49 rev (sweep rate: 100 mV s$^{-1}$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$ in L mol$^{-1}$ cm$^{-1}$) = 231 (30500), 309 (14700), 327 (13500), 390 nm (6200).

**X-ray Crystallographic Study:** Crystal data for $\eta^5$-cyclopentadienyl(hydrotris[6-(ethoxycarbonyl)indazol-1-yl]borato)ruthenium(II) ($RuCpTp^{4Bo,6\text{-}COOEt}$). Orange prismatic crystals suitable for X-ray analysis were obtained by slow evaporation of a solution of the complex in a pentane/methanol (1:1) mixture. $C_{35}H_{33}BN_6O_6Ru\cdot 0.5CH_3OH$: $M_r$ = 1523.17, orthorhombic, space group *Pccn*, *a* (Å) = 22.682(6), *b* (Å) = 15.0415(13), *c* (Å) = 19.813(3), *V* (Å$^3$) = 6760(2), *Z* = 4, $\rho_{calcd.}$ = 1.497 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) (mm$^{-1}$) = 0.521. Data were collected on a Nonius-Kappa CCD diffractometer using Mo-$K_\alpha$ graphite-monochromated radiation ($\lambda$ = 0.71073 Å) at 200 K; 3983 reflections having $I > 2\sigma(I)$ were used for structure determination (4.06° < $\theta$ < 27.00°). For all computations the Bruker maXus software package was used. Final results: $R(F)$ = 0.0507, $Rw(F)$ = 0.1004, Gof = 1.032.

**Crystal Data for $\eta^5$-Cyclopentadienyl[hydrotris(indazol-1-yl)borato]-ruthenium(II) ($RuCpTp^{4Bo}$):** Orange prismatic crystals suitable for X-ray analysis were obtained by dissolution of the compound in dichloromethane and slow liquid diffusion of methanol. $C_{26}H_{21}BN_6Ru$: $M_r$ = 529.377, orthorhombic, space group *Pccn*, *a* (Å) = 13.2676(12), *b* (Å) = 18.891(2), *c* (Å) = 19.4177(13), *V* (Å$^3$) = 4866.8(7), *Z* = 8, $\rho_{calcd.}$ = 1.445 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) (mm$^{-1}$) = 0.67. Data were collected on a Nonius-Kappa CCD diffractometer using Mo-$K_\alpha$ graphite-monochromated radiation ($\lambda$ = 0.71073 Å) at 298 K; 2103 reflections having $I > 3\sigma(I)$ were used for structure determination (0° < $\theta$ < 35.00°). For all computations the Bruker maXus software package was used. Final results: $R(F)$ = 0.047, $Rw(F)$ = 0.108, Gof = 1.055.

**Crystal Data for $\eta^5$-Cyclopentadienyl(hydrotris{6-[(ethylsulfanyl)-methyl]indazol-1-yl}borato)ruthenium(II) ($RuCpTp^{4Bo,6\text{-}CH2SEt}$):** Yellow prismatic crystals suitable for X-ray analysis were obtained by dissolution of the compound in dichloromethane and slow liquid diffusion of methanol. $C_{35}H_{39}BN_6RuS_3$: $M_r$ = 751.81, triclinic, space group $P\bar{1}$, *a* (Å) = 9.883(3), *b* (Å) = 14.032(3), *c* (Å) = 14.889(4), *V* (Å$^3$) = 1802.7(7), *Z* = 2, $\rho_{calcd.}$ = 1.385 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) (mm$^{-1}$) = 0.642. Data were collected on a Nonius-Kappa CCD diffractometer using Mo-$K_\alpha$ graphite-monochromated radiation ($\lambda$ = 0.71073 Å) at 298 K; 3927 reflections having $I > 2\sigma(I)$ were used for structure determination (0° < $\theta$ < 27.00°). For all computations the Bruker maXus software package was used. Final results: $R(F)$ = 0.072, $Rw(F)$ = 0.131, Gof = 1.064.

CCDC-254040 (for $RuCpTp^{4Bo}$), -254041 (for $RuCpTp^{4Bo,6\text{-}COOEt}$), and -284359 (for $RuCpTp^{4Bo,6\text{-}CH2SEt}$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electrochemistry:** The voltammetric experiments were measured with an AUTOLAB PGSTAT 100 potentiostat using a Pt disc (1 mm diameter) as working electrode and a Pt counter electrode. The reference electrode used was the saturated calomel electrode (SCE). Tetra-*n*-butylammonium hexafluorophosphate ($Bu_4NPF_6$, 0.1 M) acted as the electrolyte. All solutions were degassed thoroughly for at least 15 min with argon and an inert gas blanket was maintained over the solution during the measurements.

# A Cyclic Fc–Histidine Conjugate: Synthesis and Properties – Interactions with Alkali Metal Ions

**Somenath Chowdhury,[a] Gabriele Schatte,[b] and Heinz-Bernhard Kraatz*[a]**

**Keywords:** Ferrocene / Ferrocenophane / Peptide / Bioinorganic chemistry

The synthesis of the novel $N,N^{\pi}$-(ferrocenophane-1,1′-diyldicarbonyl)-bridged histidine methyl ester **1** and of the acyclic bis(histidine methyl ester) derivative **3** are reported. The structure of **1** was studied in the solid state and in solution. The single-crystal structure of **1** shows that both proximal ferrocenyl (Fc) carbonyl groups are *syn* with respect to each other, which is a new structural motif for Fc–amino acid conjugates. This new *syn* conformation allows effective binding to alkali metal cations. Binding is evaluated by cyclic voltammetry monitoring the halfwave potential of the Fc group. Cation binding causes a shift to lower potential ($Na^+ > Li^+ > K^+$, $Cs^+$). Upon binding, compound **1** shows selectivity towards $Na^+$ ions.

## Introduction

With the increased interest in chemical sensor technology, redox-based sensing of molecular recognition events in host–guest systems has received considerable attention in recent years.[1] Binding of the guest to a host can affect the structure of the host and/or its electronic properties, which can be detected by a suitable redox-active probe, such as ferrocene (Fc). In this regard, specifically designed macrocycles have been studied to electrochemically recognize cationic or anionic species in polar solvents and in some cases neutral molecules.[2–4] Cyclic amides, a class of natural macrocycles are well known for their biological activities as antibiotics and ion-transport regulators in membranes.[5] These properties are attributed to their capability to capture and release metal ions.[6] However, it is recognized that to achieve good artificial cyclopeptide ionophores, a decrease of the conformational freedom is beneficial and can be achieved by introducing some constraints to the cyclic skeleton.[7] Recently, Cheng and co-workers used 1,*n*′-Fc-labelled cyclopeptides to recognize alkali ions,[8] in which the metal ions are thought to bind to the amide carbonyl groups. However, no structural details were provided, although it is proposed that the binding of the ions to the 1,*n*′-dicarbonyl groups proximal to the Fc unit are largely responsible for the changes in the half-wave potential upon metal ion binding. Various studies show that in acyclic[9–10] as well as in cyclic[11] 1,*n*′-dipeptide-substituted Fc conjugates both the carbonyl groups directly attached to the Fc unit adopt an *anti* conformation. Herein, we report the synthesis, characterization and electrochemical studies of a novel histidine-containing ferrocenophane, where both Fc-carbonyl groups adopt a *syn* conformation, which generates a recognition site for metal ions. As part of this study, we compare the binding properties of this new cyclic ferrocene conjugate with its acyclic 1,1′-bis(histidine methyl ester) derivative, which is prepared as part of this study.

## Results and Discussions

The target ferrocenophane **1** was synthesized from 1,1′-ferrocenedicarboxylic acid and histidine methyl ester at very high dilutions in order to avoid oligomerization (Scheme 1). After purification by column chromatography, a reddish, crystalline solid was obtained in 38% yield.

The product was characterized by standard spectroscopic methods. The $^1$H NMR spectrum shows the presence of an amide resonance at $\delta$ = 7.57 ppm, and seven resonances in a 1:1:1:1:1:1:2 intensity ratio in the region of $\delta$ = 4.86–4.36 ppm. The α-H is observed as a multiplet at $\delta$ = 4.88 ppm. The $^{13}$C NMR spectrum reveals three signals at $\delta$ = 172.3, 172.2, and 169.5 ppm from carbonyl groups, the first of which is assigned to the ester C=O group, while the latter two are amide carbonyl groups. The IR spectrum shows the expected ester carbonyl band at 1731 cm$^{-1}$ and a strong peak at 1652 cm$^{-1}$ due to the amide group. Like most Fc–peptide derivatives, compound **1** exhibits a weak and broad absorbance in the visible region at $\lambda_{max}$ = 449 nm. This band does not show a sizeable Cotton effect in the CD spectrum (Figure 4). Because the rotation about the Cp–Fe–Cp axis is restricted by the two substituents, the Fc unit

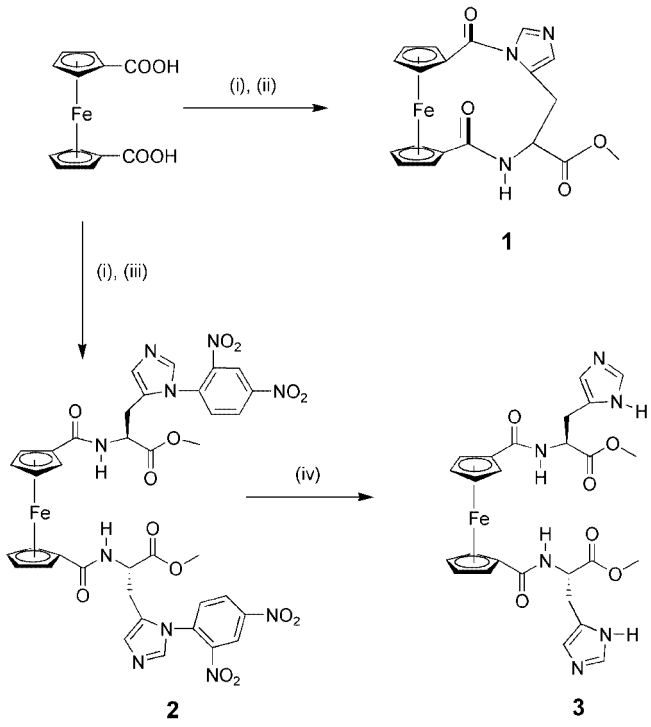

Scheme 1. Synthesis of of ferrocene–histidine conjugates **1** and **3**: (i) activation by EDC/HOBt, (ii) addition of a solution of histidine methyl ester and triethylamine at very high dilution at 0 °C after 30 min and stirring at room temperature for 12 h, (iii) addition of a solution of triethylamine and H-His(DNP)-OMe (cooling with ice bath), (iv) stirring with 10-fold molar excess of thiophenol in methanol at room temperature.

should show helical chirality.[9a,10a] As for other L-amino acids, we would have expected a strong positive band indicating a (*P*)-helical isomer. However, in the absence of a large database for CD spectra, two possibilities have to be considered: (a) compounds of this type display weak CD bands in the Fc region or (b) the absence of an intramolecular H-bond prevents the formation of a single conformation in solution and potentially both (*P*)- and (*M*)-helical isomers are formed in equimolar amounts. DFT calculations by Heinze have shown that (*P*)-helical conformations are energetically preferred for 1,1′-disubstituted Fc–L-amino acid conjugates.[12]

The acyclic compound **3** was prepared in order to compare its properties to those of the ferrocenophane **1**. Compound **3** was synthesized from ferrocenedicarboxylic acid by coupling with 2 equiv. of L-histidine(DNP) methyl ester in dichloromethane, followed by the deprotection of the imidazole group in methanol.[13] The desired compound **3** was obtained in 72% and was characterized spectroscopically. As shown in Figure 4, compound **3** displays a strong positive band in the CD spectrum in the Fc region indicating (*P*) helicity and a "Herrick-type" conformation of the system, as would be expected from an L-amino acid conjugate.[10a] This is in contrast to the very weak signal of the cyclic compound **1**.

Compound **1** was readily crystallized to yield rod-like red crystals by slow diffusion of hexanes into a dilute solution of compound **1** in chloroform. The structural presentation of compound **1** is given in Figure 1 and shows that one Fc unit is linked through the two carbonyl groups to the α-amino group as well as to the $N^{\pi}$ atom of the imidazole group.

Figure 2 shows a packing diagram of compound **1** indicating the formation of a supramolecular helical structure in the absence of intermolecular H-bonding, reminiscent of Hirao's chirality assembly.[10a] The Fe–C(Cp) distances fall into the expected range of 2.033(3)–2.061(3) Å.

The two Cp rings are parallel [angle between the two Cp planes: 2.5(2)°]. The Cp–CO bond lengths are significantly different. The Cp ring attached to the α-N atom of His exhibits a Cp–CO distance of 1.485(4) Å, whereas the Cp–CO distance of the Cp ring connected to the $N^{\pi}$ atom of the imidazole ring is shortened to 1.469(4) Å. This has also been observed in the structure of $Fc(CO–His–OMe)_2$.[14] The shortening of the Cp–CO distance is probably because of a greater electronic interaction of this Cp ring with the imidazole ring. As already observed in the structure of $Fc(CO–His–OMe)_2$ the Cp ring and the imidazole ring are not coplanar. However, the twist angle of 49.2(1)° is much larger than in $Fc(CO–His–OMe)_2$ (twist angle of 36.5°). The Cp–amide twist angle of 11.9(2)° is identical to the Cp–amide twist angle in $Fc(CO–His–OMe)_2$ (11.8°). The range of Cp–amide angles for Fc–amides and –peptides is between 5 and 20°.

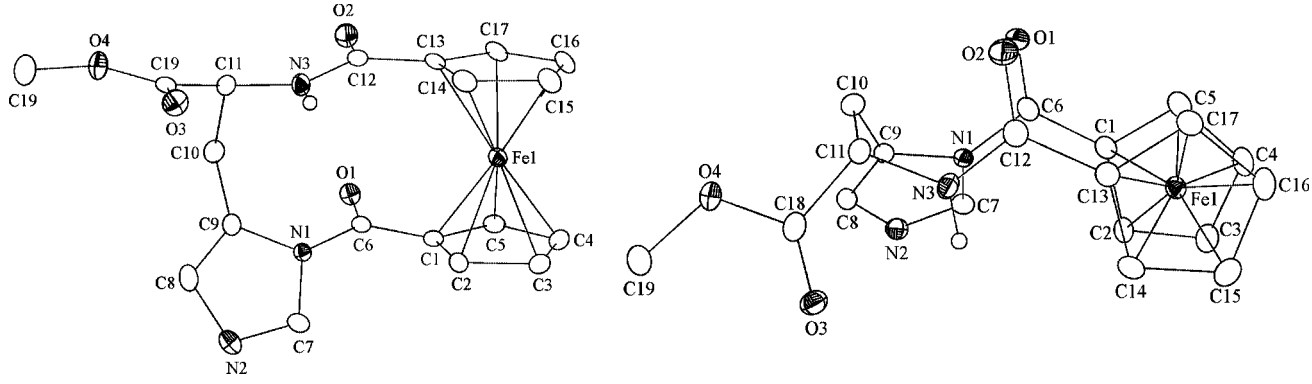

Figure 1. Two ORTEP diagrams of compound **1** showing all non-hydrogen atoms. Both C=O groups proximal to the Fc group are *syn* with respect to each other. All atoms are shown at the 30% probability level.

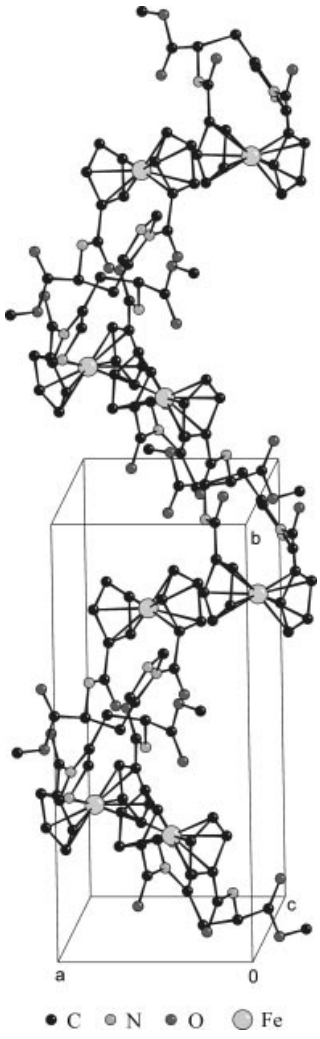

Figure 2. Helical intermolecular arrangement of compound **1**; view along the *c*-axis.

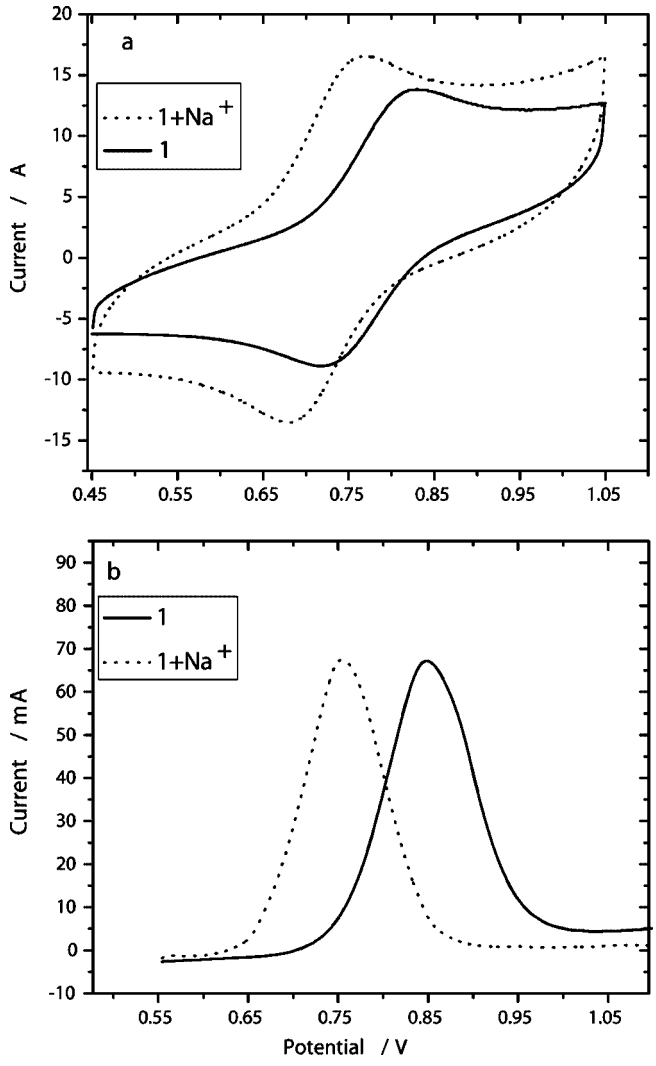

Figure 3. (a) Cyclic voltamogram at a scan rate of 0.1 V and (b) differential pulse voltamogram at a pulse width of 0.05 s of compound **1** before (——) and after (·····) the addition of $NaClO_4$ to the solution (1 mM solute in MeCN) using TBAP (0.1 M) as supporting electrolyte. Glassy carbon was used as working electrode, Ag/AgCl as reference and Pt as counter electrode.

Electrochemical studies [cyclic voltammetry (CV) and differential pulse voltammetry (DPC)] of compounds **1** and **3** were carried out in acetonitrile solutions with TBAP (0.1 M) as the supporting electrolyte. The CVs and DPVs for the compounds **1** and **3** are shown in Figure 3. Both compounds show quasi-reversible behavior ($i_a/i_c$ = 1.1, and 1.09) with a halfwave potential 794 and 751 mV, for **1** and **3**, respectively.

In comparison, the monosubstituted compound Fc(CO–His–OMe) shows a reversible one-electron oxidation at 630 mV. $Fc(CO–His–OMe)_2$, having an addition Fc group linked to the $N^{\pi}$ atom of the Im ring of His exhibits an additional wave at 762 mV.[14]

In the presence of alkali metal ions, some shifts in the $E_{1/2}$ value for compound **1** are noticeable. The halfwave potentials for the compounds **1** and **3** before and after addition of alkali metal ions are summarized in Table 1. Whereas the shift in the halfwave potential of **1** in the presence of $Li^+$ is shifted by 46 mV to lower potential, the presence of $Na^+$ causes a shift of 100 mV, making it significantly easier to oxidize the Fc group. The presence of other alkali metal ions does not cause any significant shifts in the halfwave potential.

We rationalize these potential shifts by the direct interaction of the metal ions with the two proximal *syn* carbonyl groups on the Fc unit. Association of $ClO_4^-$ anions with the Fc unit will result in a lower redox potential as bound metal ions are very close to the Fc unit and surrounded by $ClO_4^-$. The larger metal ions $K^+$ and $Cs^+$ may not fit into the cavity provided by the two carbonyl groups and thus do not affect the electrochemical properties of the Fc group.

For compound **3** on the other hand, the addition of alkali ions causes no electrochemical change but only minor effects, as in the case of $Cs^+$. Here, the two proximal C=O groups are *anti*, and binding occurs through the ester carbonyl group and/or the imidazole nitrogen atom, which both are far away from the Fc moiety. Cation binding to

Table 1. Half-wave potentials [mV] (±5) of ferrocene conjugates **1** and **3** with or without alkali metal ions.[a]

| Composition | **1** | **3** |
|---|---|---|
| Pure | 794 | 751 |
| Li | 748 | 751 |
| Na | 695 | 748 |
| K | 772 | 754 |
| Cs | 772 | 773 |

[a] Measured by differential pulse voltammetry using glassy carbon as working vs. Ag/AgCl as reference, and Pt as counter electrode. Compounds **1** and **3** were at 1 mM concentration in $CH_3CN$ containing 0.1 M TBAP. The $E_{1/2}$ value of the $Fc/Fc^+$ couple under the experimental conditions is 448(±5) mV (vs. Ag/AgCl). Halfwave potential recorded for pure compound and upon addition of 10 mol-equiv. of $MClO_4$ (M = Li, Na, K, Cs).

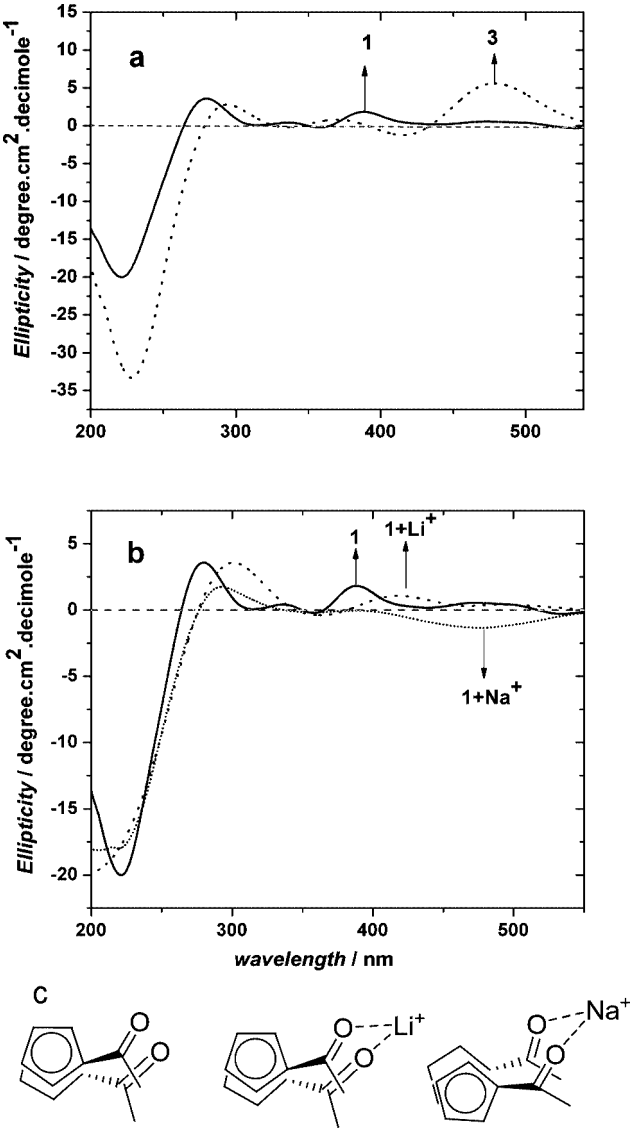

Figure 4. CD spectra in 1 mM solution in acetonitrile of (a) **1** and (b) **3** in the absence and presence of 10 equiv. of alkali metal (Li and Na) perchlorate salts and (c) schematic representation of change in conformation of the Fc entity of **1** with the addition of alkali metal salts.

the carbonyl groups causes the cathodic shift in the redox potential. Association of the $ClO_4^-$ anion with the alkali cation does not appear to influence the redox potential of the Fc group.

We postulated that binding of the ions to the two proximal *syn* C=O group may in fact cause small structural changes in the Fc core. We decided to investigate compound **1** in the presence of alkali metal ions by CD spectroscopy, which allows us to evaluate if structural changes occur involving the helicity of the ferrocene. Figure 4 shows the CD spectra of compounds **1** and **3** and changes of conformation of Fc in **1** upon addition of alkali metal salts. In comparison to **3**, the Fc-based CD band of compound **1** around 400–450 nm is very weak, which indicates weak helical chirality.

However, in the presence of alkali metals, there are noticeable changes occurring in this region. Figure 4 shows the CD spectra of compound **1** in the presence of $Li^+$ and $Na^+$. $Li^+$ causes a bathochromic shift and the band broadens. The conformation of the Fc unit is not affected. The larger $Na^+$ ion, which in the electrochemistry studies shows the largest effect, causes an apparent change in the conformation of the Fc unit. The Fc band now has an apparent negative Cotton effect. Assuming coordination of the metal ion to the two proximal *syn* carbonyl groups, the smaller $Li^+$ will fit into the "binding site" established by compound **1** with only minor adjustment, whereas the larger $Na^+$ requires that the Cp rings slightly rotate towards (*M*) helicity (Figure 4). Interestingly, for compound **3**, only $Cs^+$ causes a sizeable effect in the halfwave potential. The CD spectrum of compound **3** in the presence of $Cs^+$ clearly shows that the intensity of the Fc band indicating (*P*) helicity decreases drastically, corroborating a structural argument for the influence of alkali metal binding on these Fc conjugates (Figure S1).

## Conclusion

In conclusion, we provide details of the synthesis of a novel ferrocenophane, which displays an unusually *syn* conformation of the two proximal carbonyl groups, having the two Cp rings in an 1,1′-conformation. To the best of our knowledge this is the first example of an Fc–amino acid or –peptide conjugate that deviates from the classic Herrick conformation in such a drastic fashion. This conformation has consequences for the metal-recognition properties of this complex. The ferrocenophane **1** has the ability to recognize specific alkali elements, and displays the strongest change in the halfwave potential in the presence of $Na^+$ ions. The change in the halfwave potential is related to small structural changes that take place upon binding of the alkali metal ion to the proximal ferrocenyl C=O groups and small rotations of the two Cp rings of the metallocene.

## Experimental Section

**Synthesis and Characterization:** All syntheses were carried out in air unless otherwise indicated. $CH_2Cl_2$ (BDH; ACS grade) used for

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

synthesis was dried with $CaH_2$ and distilled prior to use. $CDCl_3$ (Aldrich) was dried with $CaH_2$, and stored over molecular sieves (8–12 mesh; effective pore size 4 Å; Fisher) before use. EDC·HCl, HOBt (Quantum), BOP (Advanced Chemtech), $MgSO_4$, and $NaHCO_3$ (VWR) were used as received. For column chromatography, a column (i.d. 2.7 cm; length 45 cm) was packed 18–22 cm high with 230–400 mesh silica gel (VWR). For TLC, aluminum plates coated with silica gel 60 $F_{254}$ (EM Science) were used. NMR spectra were recorded with a Bruker Avance 500 MHz spectrometer using a 5-mm broadband probe operating at 500.134 MHz ($^1$H) and 125.766 MHz ($^{13}$C{$^1$H}). Peak positions in both $^1$H and $^{13}$C NMR spectra are reported in ppm relative to TMS. The $^1$H NMR spectra are referenced to the residual $CHCl_3$ signal at $\delta$ = 7.27 ppm. All $^{13}$C{$^1$H} spectra are referenced to the $CDCl_3$ signal at $\delta$ = 77.23 ppm. Mass spectrometry was carried out with a VG Analytical 70/20 VSE instrument. Infrared spectra were obtained in KBr and recorded with a Perkin–Elmer model 1605 FT-IR (resolution: 4 cm$^{-1}$). 1,1′-Ferrocenedicarboxylic acid was synthesized from diacetylferrocene, which was synthesized from ferrocene by a known procedure.[15]

**Synthesis of 1:** 1,1′-Ferrocenedicarboxylic acid (0.0558 g, 0.2 mmol) was suspended in dichloromethane (100 mL). Diisopropylethylamine (DIPEA, 1 mL) was added to the solution at 0 °C. His-OMe·2HCl was added (0.048 g, 0.2 mmol) and stirring was continued. After 30 min, $CH_2Cl_2$ was added to the solution up to a total volume of 2 L. The reaction mixture was cooled to 0 °C (ice bath) for 15 min, followed by the addition of BOP (0.8 g, 2 mmol). After stirring at room temperature for 24 h, the volume of the solution was reduced to 400 mL by roto-evaporation. The organic solution was sequentially washed with saturated aqueous $NaHCO_3$, 10% aqueous citric acid, saturated $NaHCO_3$, and finally water. Traces of water were removed using anhydrous $Na_2SO_4$. After concentration, the crude product was purified by flash column chromatography using a chloroform/methanol solvent mixture (93:7, v/v; $R_f$ = 0.35). The solvents were removed under reduced pressure. Compound **1** was obtained as a red crystalline solid in 32% yield (0.032 g). HRMS (ES): calcd. for $C_{19}H_{17}FeN_3O_4$ 407.1449; found 407.1410 [M]$^+$. FT-IR (KBr): $\tilde{\nu}$ = 3530 (br., s, N–H, w), 1731 (s, C=O, ester) 1652 (s, C=O, amide I), 1538 (s, amide II) cm$^{-1}$. UV/Vis ($CH_3CN$): $\lambda$ ($\varepsilon$) = 449 (254 M$^{-1}$ cm$^{-1}$) nm. $^1$H NMR ($CDCl_3$): $\delta$ = 7.68 (s, 1 H, *o*-H of imidazole ring), 7.57 (br., s, 1 H, amide NH), 6.89 (s, 1 H, *m*-H of imidazole ring), 4.88 (m, 1 H, *α*-H of His), 4.86 (s, 1 H, *o*-H of Cp to Im ring), 4.80 (s, 1 H, *o*-H of Cp to Im ring), 4.77 (s, 1 H, *o*-H of Cp to CONH), 4.71 (s, 1 H, *o*-H of Cp to CONH), 4.48 (s, 1 H, *m*-H of Cp to Im ring), 4.46 (s, 1 H, *m*-H of Cp to Im ring), 4.36 (s, 2 H, *m*-H of other Cp attached to CONH), 3.82 (3 H, $CH_3$ of methyl ester), 3.24 (m, 2 H, β-H of His) ppm. $^{13}$C{$^1$H}NMR ($CDCl_3$): $\delta$ = 172.3, 172.2, 169.5, 135.4, 135.0, 73.6, 73.5, 72.7, 72.5, 72.3, 72.0, 71.9, 70.5, 70.0, 53.0, 52.7, 29.3 ppm.

**Synthesis of 2:** To a solution of ferrocenedicarboxylic acid (0.274 g, 1 mmol), dissolved in dry $CH_2Cl_2$ (50 mL), was added HOBt (0.38 g, 2.5 mmol), and EDC·HCl (0.48 g, 2.5 mmol). The reaction mixture was stirred for 0.5 h and then cooled to 0 °C (ice bath). H–His(DNP)–OMe (0.67 g, 2 mmol) was dissolved in dichloromethane (40 mL) and $Et_3N$ (0.5 mL, ca. 6 mmol) was added at 0 °C. The mixture was stirred at room temperature for 12 h. Workup was identical to that described for compound **1**. The crude product was purified by flash column chromatography using chloroform ($R_f$ = 0.28) and afforded a reddish yellow solid of **2** (0.70 g, 77%). $^1$H NMR ($CDCl_3$): $\delta$ = 8.84 (s, 1 H, 3-H of DNP), 8.04 (d, $J_{HH}$ = 9 Hz, 1 H, 5-H of DNP), 7.86 (d, $J_{HH}$ = 9 Hz, 1 H, 6-H of DNP), 7.85 (d, $J$ = 9 Hz, 1 H, NH of amide), 7.60 (s, 1 H, *o*-H of imidazole), 6.91 (s, 1 H, *m*-H of imidazole), 4.89 (m, 1 H, α-H of His), 4.69 (s, 1 H, *o*-H of Fc), 4.66 (s, 1 H, *o*-H of Fc), 4.41 (s, 1 H, *m*-H of Fc), 4.36 (s, 1 H, *m*-H of Fc), 3.70 (3 H, $CH_3$ of methyl ester), 3.18 (m, 2 H, β-H of His) ppm.

**Synthesis of 3:** Compound **2** (0.45 g, 0.5 mmol) was dissolved in methanol (20 mL) and thiophenol (1.2 g, 10 mmol) was added. After stirring of the reaction mixture at room temperature for 7 h, methanol was removed and the product was purified by flash chromatography ($CHCl_3$/MeOH, 80:20; $R_f$ = 0.27). The final product was obtained as an orange solid in 65% yield (0.19 g). HRMS (ES): calcd. for $C_{26}H_{28}FeN_6O_6$ 576.2214; found 576.2191 [M]$^+$. FT-IR (KBr): $\tilde{\nu}$ = 3540 (br., s, N–H), 1731 (s, C=O, ester), 1639 (s, C=O, amide I), 1533 (s, amide II) cm$^{-1}$. UV/Vis ($CH_3CN$): $\lambda$ ($\varepsilon$) = 442 (240 M$^{-1}$ cm$^{-1}$) nm. $^1$H NMR $CDCl_3$): $\delta$ = 7.84 (d, $J$ = 8 Hz, 1 H, NH of amide), 7.54 (s, 1 H, *o*-H of imidazole), 6.87 (s, 1 H, *m*-H of imidazole) 4.89 (m, 1 H, α-H of His), 4.69 (s, 1 H, *o*-H of Fc), 4.66 (s, 1 H, *o*-H of Fc), 4.41 (s, 1 H, *m*-H of Fc), 4.36 (s, 1 H, *m*-H of Fc), 3.70 (3 H, $CH_3$ of methyl ester), 3.18 (m, 2 H, β-$CH_2$ of His) ppm. $^{13}$C{$^1$H}NMR ($CDCl_3$): $\delta$ = 173.3, 171.2, 135.5, 135.4, 131.4, 98.0, 72.2, 72.1, 71.3, 70.4, 53.4, 53.3, 28.8 ppm.

**CD Measurements:** CD spectra of $CH_3CN$ solutions with a concentration of $1.0\cdot10^{-3}$ M were recorded under argon at 25 °C with a PiStar-180 spectropolarimeter (Applied Biophysics) using a quartz cell (path length 1 cm).

**X-ray Crystallography:** An orange plate-like crystal of compound **1** ($C_{19}H_{17}Fe_1N_3O_4$) (Table 2) with the approximate dimensions of 0.08 × 0.05 × 0.05 mm, coated with oil (Paratone 8277, Exxon), was mounted onto a nylon fiber of a CryoLoop™ device (diameter of the nylon fiber: 10 microns; loop diameter 0.1–0.2 mm; Hampton

Research, USA) under a microscope. The crystal was then mounted onto the goniometer head, which was quickly transferred to the cold stream of the X-ray diffractometer. All measurements were made with a Nonius KappaCCD 4-Circle Kappa FR540C diffractometer using monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at –100 °C. An initial orientation matrix and cell was determined from 10 frames using $\varphi$ scans.[16] The X-ray data were measured using $\varphi$- and $\omega$-scans.[16] Data reduction was performed with the HKL DENZO and SCALEPACK software,[17] which corrects for beam inhomogeneity, possible crystal decay, Lorentz and polarization effects. A multi-scan absorption correction was applied (SCALEPACK).[17] The structure was solved by direct methods (SHELXS-97)[18] and refined by full-matrix least-squares methods on $F^2$ with SHELXL97-2.[19] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions (C–H bond lengths 0.95/0.98/1.00 Å, N–H bond lengths 0.88 Å) and were not refined. The isotropic thermal parameters of the hydrogen atoms were fixed at 1.2 times that of the preceding carbon atom. CCDC-285760 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electrochemical Measurements:** The electrochemical experiments were carried out at room temperature with a CV-50W voltammetric analyzer. A gold electrode (diameter 50 μm) was used as the working electrode. 1 mM $CH_3CN$ solutions of compounds **1** and **3** were prepared containing 0.1 M tetrabutylammonium perchlorate (TBAP). The measurements were carried out in a low scan rate of 100 and 10 mV/s for cyclic voltammetry (CV) and differential pulse voltammetry (DPV), respectively. A platinum wire (1 mm) was used as the counter electrode. The reference electrode was Ag/AgCl (BAS). The $E_{1/2}$ value of the $Fc/Fc^+$ couple under the experimental conditions was 448(± 5) mV (vs. Ag/AgCl).

# Reassignment, Isolation, Spectral and X-ray Characterization of Diastereoisomers of the Macrocyclic Ligand 3,10-*meso*-3,5,7,7,10,12,14,14-Octamethyl-1,4,8,11-tetraazacyclotetradecane and their $Ni^{II}$ and $Cu^{II}$ Complexes

**Yung-Chan Lin,*[a] Tarun Kumar Misra,[b] Tian-Huey Lu,[c] Maddirala Shambabu Joseph,[d] and Chung-Sun Chung*[d]**

**Keywords:** Diastereoisomers / Macrocyclic ligands / X-ray crystallography / Coordination modes

Reduction of the macrocyclic ligand, 3,10-*meso*-3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetraazacyclotetradecane-4,11-diene dihydroperchlorate (L), with sodium borohydride yielded three [$L_b$ (**1**), $L_c$ (**2**), and $L_d$ (**3**)] of four possible diastereoisomers. The diastereoisomeric macrocycles and their $Ni^{II}$ and $Cu^{II}$ complexes have been characterized and confirmed by IR, UV/Vis, and NMR spectroscopy as well as X-ray crystallography. The chiral carbon centers and methyl groups at the 5 and 12 positions of **1**, **2** and **3** have the 5*S*,12*R*-C-*meso*, 5*S*,12*S*-C-*racemic*, and 5*R*,12*R*-C-*racemic* configurations, respectively. In accordance with the X-ray structure determination, the geometry around the $Ni^{II}$ ion in the complexes is approximately square-planar and the $Cu^{II}$ ion has an octahedral geometry. The N–H configuration of $[NiL_c](ClO_4)_2(H_2O)_{0.5}$ (**5**) is *trans*-II, different from the most thermodynamically stable *trans*-III configuration that is found in $[NiL_b](ClO_4)_2$ (**4**), $[CuL_b(H_2O)_2](ClO_4)_2$ (**7**), and $[CuL_d(ClO_4)_2]$ (**8**). UV/Vis spectra reveal that $Ni^{II}$ complexes exhibit almost 100 % planar species in aqueous solution resulting from steric effects produced by numerous methyl groups, especially axial orientations and distorted structures. In six coordinate $Cu^{II}$ complexes, acetonitrile acts as a better axial donor than the water molecule; the weaker axial bonding is a result of steric interactions that lead to stronger in-plane coordinations.

## Introduction

The 14-membered tetraazacyclotetradecane macrocyclic ligands have been exploited extensively in different fields of research such as catalysis, bioinorganic, biomimetic, building blocks in supramolecular, and coordination chemistry.[1] These ligands have provided the ideal coordination sites for many metal ions and have been used as metal ion binding sites in medical techniques such as MRI and radioimmunotherapy.[2] Many of these metal complexes can be used as catalysts in redox reactions.[3] For instance, nickel complexes are used to produce CO through the photochemical and electrochemical reduction of $CO_2$.[4]

The stereochemistry of the 14-membered tetraazacyclotetradecane macrocyclic ligands and their metal complexes is very rich because of the presence of several asymmetric carbons and four N–H groups on their skeleton.[5] One such macrocyclic ligand can have numerous diastereoisomeric forms.[5] The macrocyclic molecule 3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetraazacyclo-tetradecane-4,11-diene, $Me_8$-[14]diene, which has two chiral centers at the 3 and 10 positions, exhibits three noninterconvertible diastereoisomers, 3*S*,10*R*-*meso*- $Me_8$[14]diene (L), 3*R*,10*R*-*racemic*-$Me_8$[14]-diene, and 3*S*,10*S*-*racemic*-$Me_8$[14]diene (Scheme 1). Nickel(II) complexes of these ligands were obtained from a template reaction of tris[(±)-1,2-propanediamine]nickel(II) perchlorate, tris[(+)-1,2-propanediamine]nickel(II) perchlorate, or tris[(–)-1,2-propanediamine]nickel(II) perchlorate with acetone and were characterized by proton NMR spectroscopy.[6] In addition, the Nickel(II) complex of 3,10-*meso*-$Me_8$[14]diene was confirmed by X-ray crystallography.[6a,7] In a different approach, the reaction of (±)-1,2-propanediamine hydroperchlorate with acetone yields stereospecifically only the crystalline 3,10-*meso*-$Me_8$[14]-diene·$2HClO_4$.[6a,8] Failure to isolate any C-*rac* isomer apparently results from a higher solubility of the C-*rac* salt. Treatment of (–)-1,2-propanediamine hydroperchlorate with

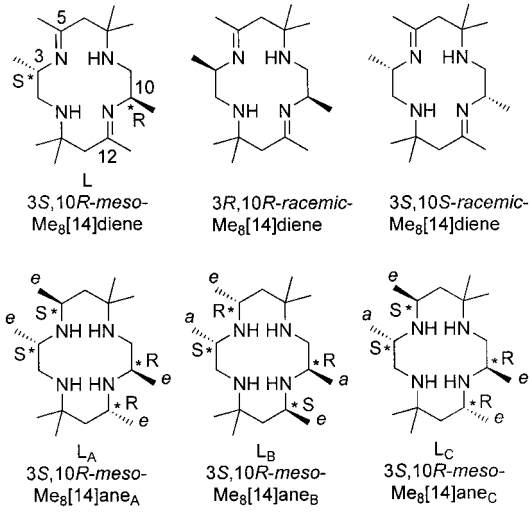
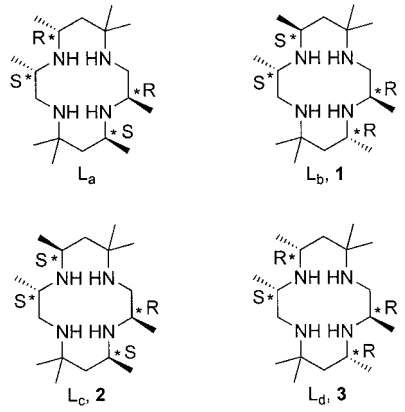
acetone yields no crystalline product under these conditions.[6a] The configuration of 3,10-*meso* is designated as 3*S**,10*R**-*meso*. Reduction of 3,10-*meso*-$Me_8$[14]diene with $NaBH_4$ generates another two chiral centers at the 5 and 12 positions and gives an isomeric mixture of the corresponding saturated macrocycles, 3,10-*meso*-$Me_8$[14]anes.[8] These molecules and their *N*-alkylated derivatives have been characterized and studied in the field of kinetics, coordination chemistry, and environmental monitoring.[9] The $Cr^{III}$ complexes of these ligands have been used as sensor materials, artificial ionophores, and in membrane electrodes.[10] Antimicrobial activity of these ligands and their complexes have been investigated.[11] Despite their huge importance and usefulness in different fields of science, proper assignment of these diastereoisomeric ligands and their complexes has been lacking.



Scheme 1.

Although the assignment of diastereoisomeric forms of macrocyclic ligands and their complexes are an arduous problem, Bembi et al.[8] argued that the reduction of 3,10-*meso*-$Me_8$[14]diene would give three isomeric 3,10-*meso*-$Me_8$[14]anes. These were isolated and denoted as 3,10-*meso*-$Me_8$[14]$ane_A$ ($L_A$), 3,10-*meso*-$Me_8$[14]$ane_B$ ($L_B$) and 3,10-*meso*-$Me_8$[14]$ane_C$ ($L_C$) (Scheme 1). Bembi and coworkers characterized these ligands and their complexes by either NMR spectroscopy on its own or by both NMR spectroscopy and X-ray crystallography. In this context we have found two main flaws with their assignment and characterization of these ligands and their complexes: (i) The basis on which they have assigned the ligands $L_A$–$L_C$ is nebulous. The *RS*-configuration of the chiral methyls of $L_A$ and $L_C$ are the same. $L_C$ differs from $L_A$ in having one chiral methyl at the axial position. Thus, $L_C$ is nothing but a conformer of $L_A$. The methyl orientations (axial or equatorial) of ligand $L_A$ (or $L_C$) in its complexes with metals match those of $L_b$ rather than those of $L_A$ (or $L_C$), although they have the same *RS*-configuration, i.e., $L_A$ and $L_C$ are conformers of $L_b$. (ii) Ligand $L_B$ and its $Ni^{II}$ complex, $[NiL_{B\alpha}](ClO_4)_2$, were characterized by X-ray crystallography,[8,9h] but if one undertakes a critical investigation it can be seen that in both cases crystal structures of the ligand moiety appeared as the conformer of $L_A$ and not $L_B$. Thus, proper assignment of the diastereoisomers obtained from the reduction reaction of 3,10-*meso*-$Me_8$[14]diene is very much needed and important. In this paper we describe the reassignment, isolation, spectral and X-ray characterization of diastereoisomers of 3,10-*meso*-3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetraazacyclotetradecane and their $Ni^{II}$ and $Cu^{II}$ complexes. The assignment of diastereoisomers has been performed on the basis of *RS*-configuration. Thus, reduction of 3,10-*meso*-$Me_8$[14]diene would give four diastereoisomeric macrocycles, $L_a$ (*SRRS*), $L_b$ (**1**, *SSRR*), $L_c$ (**2**, *SSRS*) and $L_d$ (**3**, *SRRR*) (Scheme 2). Over the course of reduction, the configurations of chiral methyls at position 3 (3*S*) and 10 (10*R*) remain intact. $L_a$ and **1** have mesomeric configuration whereas **2** and **3** are enantiomers of one another. Isomers were separated by fraction crystallization from a methanol/water mixture. The solubility of the *meso* isomers is lower and hence they separated first. Isomer $L_a$ cannot be isolated following the experimental methods described in the text, but we have still assigned it as 3*S*,10*R*-C-*meso*-5*R*,12*S*-C-*meso*-$Me_8$[14]ane. According to the results from NMR spectroscopy and X-ray crystallography studies, the structures of isomers **2** and **3** are indeed different from the literature reports. The square-planar $Ni^{II}$ and elongated octahedral $Cu^{II}$ complexes have also been characterized by UV/Vis spectroscopy in order to study the behavior of the d–d transitions and axial additions.



Scheme 2.

## Results and Discussion

### Synthesis

Reduction of L with $NaBH_4$ gave an isomeric mixture of the corresponding saturated macrocycles, 3*S*,10*R*-*meso*-$Me_8$[14]anes. 3*S*,10*R*-C-*meso*-$Me_8$[14]ane exists as four diastereoisomeric isomers, two 5,12-C-*meso* ($L_a$, **1**) and two 5,12-C-*racemic* (**2**, **3**) forms. By using the partial crystallization method, the *meso* and *racemic* isomers could easily be separated. Although the isomer $L_a$ could not be isolated following the experimental methods described in the text, we have assigned it as 3*S*,10*R*-C-*meso*-5*R*,12*S*-C-*meso*-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Me_8$[14]ane. The two *rac* forms are enantiomers of each other and are difficult to separate completely because of their similar chemical properties. To date no effective method has been found to separate isomeric C-*rac*-macrocycles, e.g. a (7*S*,14*S*)/(7*R*,14*R*)-C-*rac*-$Me_6$[14]ane (tet b) or (5*S*,12*S*)/(5*R*,12*R*)-C-*rac*-$Me_2$[14]ane mixture. Crystals of **1** and **2** were obtained from ether solutions. The reactions of isomeric ligands with nickel acetate tetrahydrate in a refluxing methanol solution produced green nickel(II) complexes. After adding lithium perchlorate trihydrate, the yellow square-planar nickel(II) complexes were obtained. The complexes were crystallized from acetonitrile or a water/methanol mixture. Reacting copper perchlorate hexahydrate with the isomeric ligands provided the octahedral $Cu^{II}$ complexes. Crystals were obtained from the methanol/water mixture.

## $^1$H NMR Spectroscopy

Although the one-dimensional $^1$H NMR spectra of macrocycles and their $Ni^{II}$ complexes are not well resolved, they present some key features that can be used to assign their configurations. From the $^1$H NMR spectra the chiral and geminal methyl groups can easily be identified as well as the equatorial and axial methyls. The splitting pattern of the signals for the chiral methyls is a doublet whereas for the geminal methyls a singlet signal is seen. Thus geminal dimethyl groups give two singlet signals, one for the equatorial and the other for the axial methyl group. The number of chiral methyl signals varies depending on their axial and equatorial positions. The singlet at the higher field is assigned to the signal for the equatorial methyl protons and the remaining intense singlet to the axial group.[6b,8,9c,9h,12] In the case of **1** and **4**, $^1$H NMR spectra (Table 1) show four signals; two for the geminal dimethyls and the remaining two for the chiral methyls. This reveals that the molecules **1** and **4** have centrosymmetric symmetry. In the case of **2** and **5** eight signals are observed, four for the geminal dimethyls and the remaining four for the chiral methyls. This reveals that the molecules **2** and **5** are asymmetric.

Table 1. Selected $^1$H NMR spectroscopic data of ligands **1**–**2** and $Ni^{II}$ complexes **4**–**5**.[a]

| Ligands / Complexes | Geminal dimethyl | Methyl on chiral carbon atoms |
|---|---|---|
| **1** | 1.05 s (*e*, 6 H) | 0.96 d (*e*, 6 H) |
| | 1.11 s (*a*, 6 H) | 1.01 d (*a*, 6 H) |
| **2** | 0.98 s (*e*, 3 H) | 0.91 d (*e*, 3 H) |
| | 0.99 s (*e*, 3 H) | 0.97 d (*a*, 3 H) |
| | 1.03 s (*a*, 3 H) | 1.01 d (*a*, 3 H) |
| | 1.06 s (*a*, 3 H) | 1.02 d (*a*, 3 H) |
| **4** | 1.20 s (*e*, 6 H) | 1.15 d (*e*, 6 H) |
| | 1.81 s (*a*, 6 H) | 1.60 d (*a*, 6 H) |

| | 1.27 s (*e*, 3 H) | 1.19 d (*e*, 3 H) |
| | 2.29 s (*a*, 3 H) | 1.50 d (*a*, 3 H) |
| | 2.49 s (*a*, 3 H) | 1.93 d (*a*, 3 H) |

[a] s = singlet, d = doublet, *a* = axial, *e* = equatorial.

### *Ligand 1 and Complex 4*

In both cases, the methyl signals appear as two singlets and two doublets corresponding to six protons each. This requires the structure to have centrosymmetric symmetry, since the methyl groups are clearly pair-wise equivalent. In the case of **1**, two singlets at $\delta$ = 1.05 and 1.11 ppm can be assigned to the geminal dimethyl groups at the 7 and 14 positions. The upfield singlet at $\delta$ = 1.05 ppm can be assigned to equatorial methyl groups and the downfield singlet at $\delta$ = 1.11 ppm to axial methyl groups. The upfield doublet at $\delta$ = 0.96 ppm is due to two equatorially oriented methyl groups, whereas the downfield doublet at $\delta$ = 1.01 ppm is assigned to two axially oriented methyl groups. Similar observations have also been found in the case of **4**, two singlets at $\delta$ = 1.20 and 1.81 ppm can be assigned to geminal dimethyl groups at the 7 and 14 positions. The upfield singlet at $\delta$ = 1.20 ppm can be assigned to equatorial methyl groups and the downfield singlet at $\delta$ = 1.81 ppm to axial methyl groups. The 1.15 ppm ($J_{HH}$ = 5.75 Hz) doublet is assigned to two equatorially oriented methyl groups, while the 1.60 ppm ($J_{HH}$ = 6.71 Hz) doublet is assigned to two axially oriented methyl groups. A diequatorial-diaxial arrangement for the four chiral methyl groups is possible in **1** and **4**.

### *Ligand 2 and Complex 5*

Differing greatly from **1**, the spectra of **2** and **5** show that the methyl signals give four singlets and four doublets, where each signal corresponds to three protons. In the case of **2**, the singlets at 0.98, 0.99, 1.03, and 1.06 ppm can be assigned to geminal dimethyl groups at the 7 and 14 positions and the doublets at 0.91, 0.97, 1.01, and 1.02 ppm can be assigned to four chiral methyl groups at the 3, 5, 10, and 12 positions. Two upfield singlets at $\delta$ = 0.98 and 0.99 ppm appear due to two equatorially oriented methyl groups, while the downfield doublet at $\delta$ = 1.03 and 1.06 ppm is assigned to two axially oriented methyl groups. The doublet at the highest field can be assigned to an equatorially oriented methyl group and another doublet at $\delta$ = 0.97 ppm to an axially oriented methyl group. The similar chemical shifts and coupling constants of the two remaining doublets at $\delta$ = 1.01 and 1.02 ppm indicate that the two chiral methyl groups have a similar chemical environment. Therefore, the two doublets at the lower field should be assigned to axial oriented methyl groups. Thus an equatorial-triaxial arrangement for the four chiral methyl groups is possible in the structure. In the case of **5**, the methyl signals also give four singlets and four doublets, where each signal corresponds to three protons. The singlets at 1.17, 1.27, 2.29, and 2.49 ppm can be assigned to the 7,7,14,14-tetramethyl groups. Two upfield singlets at $\delta$ = 1.17 and 1.27 ppm appear due to two equatorially oriented methyl groups and the downfield doublets at $\delta$ = 2.29 and 2.49 ppm are due to two axially oriented methyl groups. The doublets at 1.14 ($J_{HH}$ = 6.46 Hz), 1.19 ($J_{HH}$ = 5.75 Hz), 1.50 ($J_{HH}$ = 7.21 Hz), and 1.93 ($J_{HH}$ = 7.43 Hz) ppm can be assigned to four chiral methyl groups, where the two doublets at higher field can be assigned to equatorially oriented methyl groups

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and the other two doublets to the axially oriented methyl group. A diequatorial-diaxial arrangement for the four chiral methyl groups is possible in the structure. The different results of the methyl orientations in **2** and **5** are because of the nitrogen inversions.

### $^{13}C$ NMR Spectroscopy

On the basis of $^{13}C$ NMR spectra, the symmetric and asymmetric macrocyclic ligands and their nickel(II) complexes can clearly be distinguished. Each stereochemically distinct carbon atom displays a separate resonance. However, most resonances cannot be assigned to corresponding carbons by using $^{13}C$ NMR spectra alone. Even so, there is enough evidence to define whether the structures are symmetric or asymmetric from the $^{1}H$ NMR, $^{13}C$ NMR and X-ray spectral studies. The $^{13}C$ NMR spectra of **1** and **4** show nine peaks as a result of pair-wise equivalence of the carbon atoms, while eighteen peaks are seen in the case of **2** and **5** because of the eighteen nonequivalent carbon atoms. On the basis of DEPT-135 experiments, the peaks in the range from 15 to 30 ppm can be assigned to eight carbon atoms of peripheral methyl groups and the remaining peaks in the range from 40 to 60 ppm correspond to ring carbon atoms. The results are supported by similar observations for C-*meso*-$Me_8$[14]diene and $Me_4$[14]denen. Both complexes, [Ni(*Aα*-$Me_4$[14]denen)]$^{2+}$ (symmetry) and [Ni(*Bβ*-$Me_4$[14]denen)]$^{2+}$ (asymmetry), containing fourteen carbon atoms show fourteen and seventeen peaks, respectively.[13] Similar observations have also been found in the case of two isomeric *trans*-[Co([15]ane)$Cl_2$]$^{+}$ complexes.[14] In the case of symmetric C-*meso* and C-*rac*-$Me_6$[22]ane, twelve peaks are seen owing to the pair-wise equivalence of the carbon atoms.[15]

$Cu^{II}$ complexes (**7** and **8**) are NMR inactive. Hence, these were confirmed by X-ray crystallography.

### Crystal Structures

The crystal structures of ligands and complexes are shown in Figures 1, 2, 3, 4, 5, and 6, which are drawn with ORTEP at the 30% probability level. Structural configurations and methyl orientations are shown in Scheme 3. Selected bond lengths and bond angles are listed in Tables 2, 3, and 4. The geometry around the nickel(II) ion in the complexes is approximately square-planar and around the copper(II) ion it is octahedral.

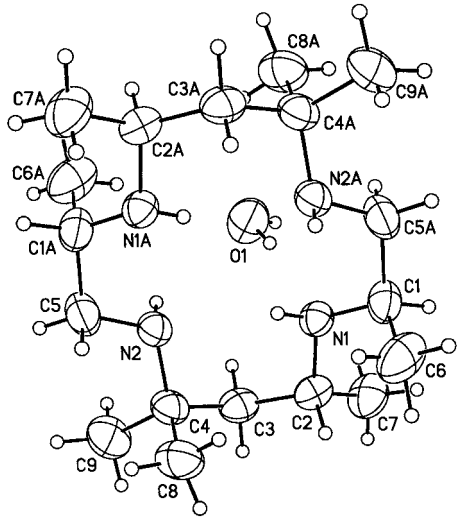

Figure 1. An ORTEP view of ligand **1**.

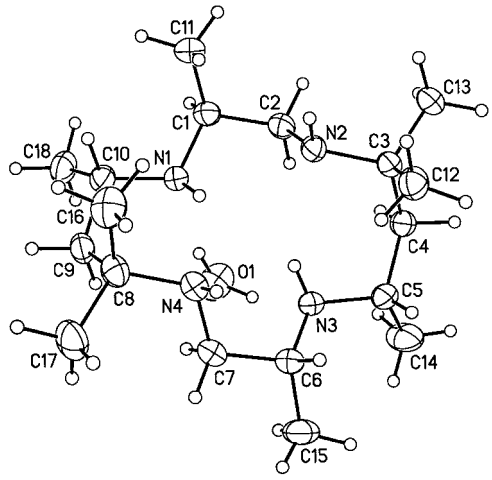

Figure 2. An ORTEP view of ligand **2**.

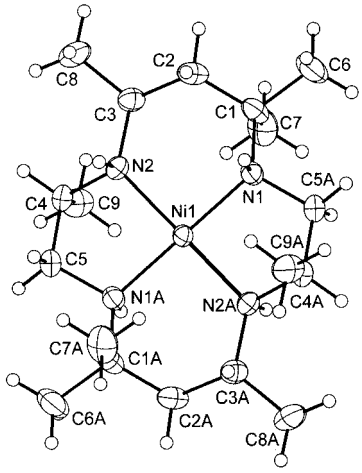

Figure 3. An ORTEP view of complex **4**.

#### *Ligand 1*

An inversion center is present in the molecule. The structure determination indicates that the ring lies in a zigzag shape with tetramine equatorial positions. The configurations of the four chiral carbon centers are 3*S*, 5*S*, 10*R*, and 12*R*. The 3,10-dimethyl groups occur on opposite sides of the ring in a *meso* configuration and have an axial orientation. Moreover, the 5,12-dimethyl groups also occur on opposite sides of the ring in a *meso* configuration but have an equatorial orientation. All distances and angles fall within the normal ranges. The H(1) atom of the water molecule forms an O–H···N hydrogen bond with a length of 2.129(1) Å with the N(1) atom of the secondary amine. The other distance, between the water H(1) atom and the amine

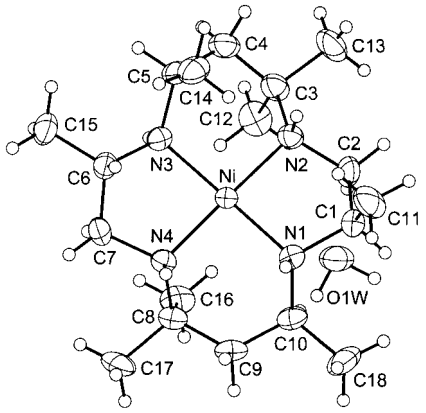

Figure 4. An ORTEP view of complex **5**.

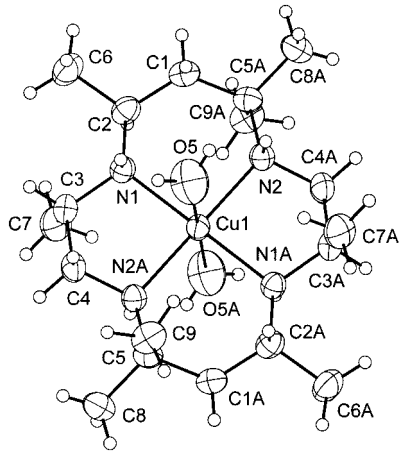

Figure 5. An ORTEP view of complex **7**.

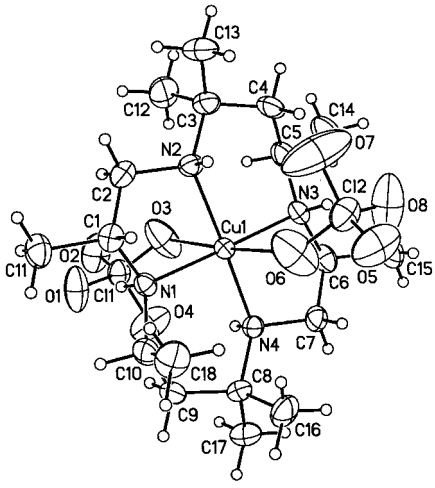

Figure 6. An ORTEP view of complex **8**.

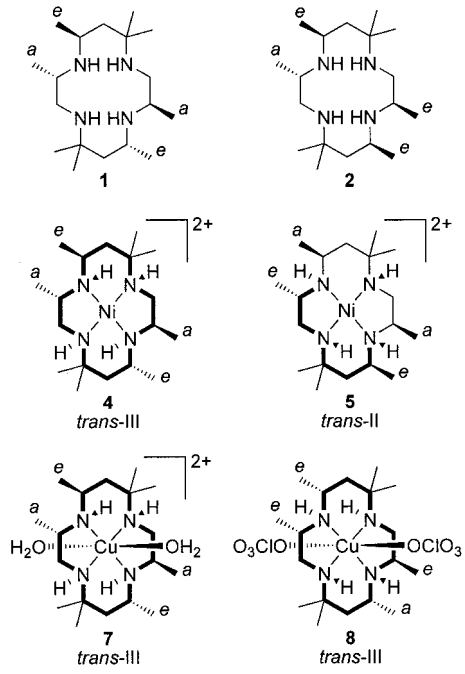
N(2) atom, is 2.993(2) Å. The distance, 2.619(2) Å, between the O(1) atom and the H(2A) atom shows that the water O(1) atom is also slightly hydrogen bonded to the amine H(2A) atom. A diequatorial-diaxial arrangement for the four chiral methyl groups is observed in the structure, where the methyl groups at the 5 and 12 positions occupy a *meso* configuration.



Scheme 3. *gauche* conformations of the five-membered chelate rings and chair conformations of the six-membered chelate rings are indicated by heavier lines.

### *Ligand 2*

The 14-membered ring has a noncentrosymmetric and folded structure where two diagonal nitrogen atoms point up and the other two down, and a water molecule is located on a crystallographic two-fold center. The configurations of the four chiral carbon centers are 3*S*, 5*S*, 10*R*, and 12*S*. All four NH groups and the 3-methyl group lie on the same side of the ring, while the water molecule and 5,10,12-trimethyl groups are on the other side. The 3-methyl group retains an axial orientation and the 5,10,12-trimethyl groups have an equatorial orientation with 3,10-dimethyl in a *meso* configuration and 5,12-dimethyl in a *racemic* configuration. The distances of the intermolecular O(1)–H(1A)···N(1) and O(1)–H(1B)···N(3) hydrogen bonds are 2.218(1) and 2.052(1) Å, respectively. An equatorial-triaxial arrangement for the four chiral methyl groups is possible in the structure, where the methyl groups at the 5 and 12 positions occupy a *racemic* configuration.

### *Complex 4*

The X-ray analysis reveals that the $Ni^{II}$ ion is located on a center of inversion and coordinated by four nitrogen atoms in equatorial positions to form a distorted square-planar geometry. The 14-membered ring consists of two six-membered chelate rings in chair conformations and two five-membered chelate rings in *gauche* conformations. The complex has a 1*R*,4*S*,8*S*,11*R* configuration of the four N chiral centers. The most thermodynamically stable nitrogen configuration is supposed to be the *trans*-III (–++–)[5a] configuration. The four chiral carbon centers are in the

is hydrogen bonded to pairs of adjacent N–H groups with normal N···O distances of 2.983 and 3.151 Å.

### *Complex 5*

The $Ni^{II}$ ion is four-coordinate in a distorted square-planar geometry with the four N-atoms of **2**. The complex cation is a noncentrosymmetric structure and has a 1*S*,4*R*,8*S*,11*S* configuration of the four chiral nitrogen centers in the *trans*-II (+–++) configuration, different from the most thermodynamically stable *trans*-III. The chiral carbon centers and 3,5,10,12-tetramethyl groups are in configurations of 3*S*,10*R*-C-*meso* and 5*S*,12*S*-C-*racemic*, where 3,12-dimethyl groups occupy an equatorial orientation and 5,10-dimethyl groups an axial orientation. The five-membered chelate ring, Ni, N(3), C(6), C(7), N(4), has a thermodynamically stable *gauche* conformation with the equatorial methyl group in the one structure and a distorted eclipsed conformation with the axial methyl group in the other. The six-membered chelate ring, Ni, N(4), C(8), C(9), C(10), N(1), has a chair conformation with the equatorial methyl group in the one structure and a twist-boat conformation with the axial methyl group in the other. The 3-methyl group and the neighboring amine group are found on the same side of the coordination plane *trans* to the other methyl and amine groups. A diequatorial-diaxial arrangement of the four chiral methyl groups is observed in the structure.

The Ni–N bond lengths in the range 1.925(4) to 1.949(4) Å are shorter than the values found in **4**, but similar to those found in [Ni(3,10-C-*rac*-5,12-C-*rac*-$Me_8$[14]ane)]$(ClO_4)_2$ [1.926(2) and 1.931(2) Å],[17] where the four N–H groups are on the same side and the 14-membered ring has a basket configuration. The N–Ni–N bond angles of the *gauche* and chair chelate rings are 86.79(16) and 91.97(15)°, respectively, smaller than those found in the eclipse [87.46(16)°] and twist-boat chelate rings [94.23(16)°]. In the second perchlorate ion [Cl(2)], three oxygen atoms are found to be disordered over two positions. The abnormal O–Cl(2)–O bond angles of the perchlorate ions, ranging from 52.2(8) to 135.9(9)°, suggest further complicated disorder. Hydrogen bonds between water molecules, perchlorate ions, and amine groups help to stabilize the crystal structure. The water molecule is placed between two perchlorate ions to form HO–H···O–$ClO_3$ hydrogen bonds in the range 2.094 to 2.628 Å. The distances of the hydrogen bonds between the perchlorate O atom and the amine H atom are in the range 2.063 to 2.508 Å.

### *Complex 7*

The copper(II) ion is coordinated by four nitrogen atoms in equatorial positions and two oxygen atoms in *trans* axial positions from water to form a distorted octahedron. The complex cation has a 1*R*,4*S*,8*S*,11*R* configuration of the four chiral nitrogen centers in the *trans*-III (–++–) configuration with both six-membered chelate rings in chair conformations and both five-membered chelate rings in *gauche* conformations. Each of the two methyl groups on the five-membered chelate rings has an axial orientation *trans* to the H atom of the neighboring amine group. Four of the six methyl groups at the 5, 7, 12, and 14 positions on the six-membered chelate rings are in a stable equatorial plane and lie away from the metal ion center. A diequatorial-diaxial arrangement for the four chiral methyl groups is observed in the structure.

The Cu–O (axial) bond is considered to be very weakly coordinated, since the Cu–O(5) distance of 2.816(4) Å is longer than the typical values for $Cu^{II}$ complexes and is significantly longer than the four Cu–N (equatorial) distances, 2.035(3) and 2.038(3) Å. In fact, the axial bonds of most six-coordinate $Cu^{II}$ complexes are often elongated as a result of the Jahn–Teller effect. These facts support the complex belonging to a six-coordinate (4 + 2) geometry.[18] The axial Cu–O bond length is compared to those in [Cu(3,10-C-*meso*-5,12-C-*meso*-$Me_8$[14]ane)$(H_2O)_2$]$(NO_3)_2$,[9d] [Cu(C-*meso*-1,5,8,12-tetramethyl-1,4,8,11-tetraazacyclotetradecane)$(H_2O)_2$]$(NO_2)_2$,[19a] and [Cu(C-*meso*-5,12-dimethyl-1,4,8,11-tetraazacyclotetradecane)$(H_2O)_2$]$Cl_2$-$(H_2O)_2$.[19b] Each of the water molecules forms intramolecular hydrogen bonds with one H atom of an amine group and one O atom of the perchlorato group, as well as an intermolecular hydrogen bond with the perchlorate O atom of a neighboring molecule. The N(1)–H(1)···O(5) distance is 2.428 Å and the N(2)–H(2)···O(5) distance 2.713 Å. The distances between the coordinated water H(5B) atom and the perchlorate O atoms are in the range 2.097 to 2.973 Å.

### *Complex 8*

The complex has a distorted octahedral coordination geometry with the macrocyclic tetradentate amine N atoms in equatorial positions and two O atoms of two perchlorato groups in *trans* axial positions with the angle O(6)–Cu–O(3) equal to 176.07(10)°. The four N atoms of the macrocyclic ligand form a square plane. The largest deviation from the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

least-squares plane is 0.0044(10) Å. The deviation of the Cu atom from the relevant plane is 0.0507(10) Å. The tetradentate ligand adopts its most stable conformation with two six-membered chelate rings in chair conformations and two five-membered chelate rings in *gauche* conformations. The complex has a 1*S*,4*R*,8*R*,11*S* configuration of the four chiral N centers in the *trans*-III (+—+) configuration. The configurations of the four chiral carbon centers are 3*S*, 5*R*, 10*R*, and 12*R* with 3,5,10-trimethyl groups in equatorial positions and the 12-methyl group in an axial position. The axial methyl group on the six-membered chelate ring makes the chair conformation unstable while the methyl group on the other six-membered chelate ring is in the stable equatorial position. A triequatorial-axial arrangement for the four chiral methyl groups is observed in the structure.

The Cu–O(3) distance [2.731(3) Å] is longer than the other axial Cu–O(6) distance [2.570(4) Å] and the four Cu–N distances [2.015(2)–2.047(2) Å]. This result shows that $[CuL_d(ClO_4)_2]$ forms an unusual six-coordinate (4 + 1 + 1′) structure in which the complex has four strongly coordinated atoms, one weakly coordinated atom and one very weakly coordinated atom. The Cu–O bond lengths are compared to those in [Cu(1,4,7,11-tetraazacyclotetradecane)$(ClO_4)_2$][20a] and [Cu(C-*meso*-1,5,8,12-tetramethyl-1,4,8,11-tetraazacyclotetradecane)$(ClO_4)_2$].[20b] The N–Cu–N angles of five- and six-membered rings are in the expected range. Hydrogen bonds between amine hydrogen atoms and O atoms of perchlorato groups help to stabilize the crystal structure. The distances are N(1)–H(1B)···O(1) 2.146 Å, N(2)–H(2C)···O(7) 2.645 Å, N(3)–H(3A)···O(8) 2.211 Å, and N(4)–H(4C)···O(4) 2.491 Å.

### Spectra and Properties

The infrared spectra of the $Ni^{II}$ and $Cu^{II}$ complexes show a sharp NH stretching vibration of secondary amines around 3200 $cm^{-1}$ with a broad strong band at about 1100 $cm^{-1}$ resulting from the perchlorate anions.

The UV/Vis spectra of the $Ni^{II}$ complexes, **4** and **5**, show strong absorption bands of the planar chromophore at 469 and 455 nm, respectively. For low-spin nickel(II) tetramine complexes the energy of the d–d band is a measure of the energy of the equatorial Ni–N interactions. The single absorption band of **4** at 469 nm (21,322 $cm^{-1}$) is assigned to the $^1A_{1g} \rightarrow {}^1E_g$ transition of the square planar nickel(II) complex and is approximately 656 $cm^{-1}$ lower in frequency than that of **5** at 455 nm (21,978 $cm^{-1}$), establishing that **4** exerts weaker metal-donor atom interactions than its diastereoisomeric complex **5**. Similar observations have been found with $[Ni(tet\ a)]^{2+}$ (*meso*) and $[Ni(tet\ b)]^{2+}$ (*racemate*).[21] In aqueous solution, $Ni^{II}$ complexes of 14-membered tetrazamacrocyclic ligands exist as an equilibrium mixture of low-spin square planar (yellow, planar) and high-spin pseudooctahedral (blue, *cis*-diaqua and *trans*-diaqua) complex cations.[22] The *cis*-diaqua form is much more unstable than the low-spin square-planar and *trans*-diaqua high-spin pseudooctahedral complex cations. The equilibrium can be affected by various factors: addition of salts, temperature, solvent, ionic strength, pH value, and steric effect, etc.[23] In addition, the proportion of planar species also increases by an increase in the number of methyl groups on the macrocyclic ligand.[24] In nitromethane (a noncoordinating solvent), **4** and **5** have molar extinction coefficients of $\varepsilon$ = 77.9 and 90.6 $dm^3 mol^{-1} cm^{-1}$ in 100% planar species, respectively.[25] The values are almost equal to those found in aqueous solution over a range of temperatures. This result shows that the intensities of the bands are temperature-independent and axial additions are not observed. In other words, **4** and **5** exhibit almost 100% planar species in aqueous solution, which may result from the steric effect produced by numerous methyl groups, especially axial orientations and the distorted structures.

Both $Cu^{II}$ complexes, **7** and **8**, exhibit two bands, one falls in the visible region and the other falls in the ultraviolet region. Previous studies show that the most $Cu^{II}$ complexes are six-coordinate tetragonal with long axial bonds. The higher energy band (≈270 nm) in the ultraviolet region is assigned to ligand-metal charge-transfer transitions associated with the nitrogen donors.[26] The lower d–d transition in the visible region of the spectrum is believed to be a combination of the three possible transitions $d_{xy}$, $d_{xz}$, $d_{yz} \rightarrow d_{x^2-y^2}$ and is characteristic of many $Cu^{II}$ complexes.[26] The expected $d_{z^2} \rightarrow d_{x^2-y^2}$ transition appearing at the lowest energy (near-IR region), indicative of the splitting of the $e_g$ (in $O_h$) caused by the tetragonal distortion (Jahn–Teller), was not observed in the visible region. Cheng and Chung reported that the rod-like acetonitrile is coordinated more strongly than $H_2O$ in the axial position of $[Ni(tet\ b)]^{2+}$ because of steric interactions, even though the donor ability of $H_2O$ is greater than acetonitrile,[26d] indicating that acetonitrile is a better axial donor. As the axial bond weakens, the copper atom becomes more positive, and attracts the in-plane ligands more strongly. Some interesting results are provided in the visible spectra where the visible band of **7** at 511 nm (19,569 $cm^{-1}$) in acetonitrile is some 391 $cm^{-1}$ lower in frequency than that at 501 nm (19,960 $cm^{-1}$) in aqueous solution, while the bands of **8** are observed at 528 nm (18,939 $cm^{-1}$) in both acetonitrile and aqueous solution. These results indicate that the axial donor is more strongly bound in **8** than that found in **7**, as seen from the crystal structures, resulting in weaker in-plane coordinations.[26a] In this work, the axial coordination is largely affected by the steric interactions between the axial donor and the axial methyl groups. When **7** is dissolved in aqueous solution, the entire band envelope shifts to the blue region, indicating that water molecules are more weakly bound or unbound since the axial methyl groups almost sterically congest the axial sites.

## Conclusions

In summary, four diastereoisomers of 3,10-*meso*-3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetraazacyclotetradecane were distinguished by the *RS*-configurations of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chiral methyls at the 5 and 12 positions. Ligands **1**, **2**, and **3** were isolated and assigned as 5*S*,12*R*-C-*meso*, 5*S*,12*S*-C-*racemic* and 5*R*,12*R*-C-*racemic*, respectively. The isomer $L_a$ could not be isolated following the experimental methods described in the text, and we assigned it as 5*R*,12*S*-C-*meso*-$Me_8$[14]ane. Spectral studies show that **1** is centrosymmetric whereas **2** and **3** are noncentrosymmetric. Nickel(II) and copper(II) complexes of these ligands were isolated. In accordance with the X-ray structure determination, the geometry around the $Ni^{II}$ ion in the complexes is approximately square-planar and the $Cu^{II}$ ion octahedral. The configuration of **5** is *trans*-II, different from the most thermodynamically stable *trans*-III complex as shown in **4**, **7**, and **8**. In complexes **7** and **8** unusual six-coordinate (4 + 2) and (4 + 1 + 1′) geometries, respectively, were formed because of the longer Cu–O distances compared with the equatorial Cu–N distances. UV/Vis spectra show that both $Ni^{II}$ complexes exhibit almost 100% planar species in aqueous solution as a result of the steric effect produced by numerous methyl groups, especially axial orientations and the distorted structures. In six coordinate $Cu^{II}$ complexes, acetonitrile turns out to be a better axial donor than the water molecule, and the weaker axial bonding is a result of the steric interactions producing stronger in-plane coordinations.

## Experimental Section

**Physical Measurements:** A Bruker DMX-600 MHz or AC300 MHz spectrometer was used to obtain $^1H$ and $^{13}C$ NMR spectra that are referenced to the solvent. Infrared spectra were recorded with a Perkin–Elmer System 2000 FT-IR spectrophotometer as KBr pellets. UV/Vis spectra were recorded with a Hitachi Model U-3300 spectrophotometer. High-resolution mass spectra were obtained using a MAT-95XL mass spectrometer. Microanalysis (C, H, N) was performed using a Heraeus CHNOS Rapld F002 elemental analyzer.

**Synthesis of Ligands and Complexes:** All the chemicals used were of reagent grade and were not purified further. The reaction of (±)-1,2-propanediamine with acetone in perchloric acid yielded stereospecifically only the crystalline 3,10-*meso*-$Me_8$[14]diene·$2HClO_4$.[6a,8]

***Caution!*** Although no problem was encountered in this work, the transition metal perchlorate is potentially explosive. It should be prepared in small quantities and handled with care.

**$L_b$ (1):** Ligand L (73.0 g, 143 mmol) was suspended in methanol (300 mL) and stirred. An aqueous solution of sodium hydroxide (25.0 g of NaOH in 250 mL of $H_2O$) was then added until the ligand L completely dissolved. Thereafter sodium borohydride (43.0 g, 1.14 mol) was added pinchwise to the solution until no more bubbles appeared. The mixture was then refluxed for 3.0 h. After the mixture had cooled to room temperature, an aqueous solution of sodium hydroxide (16.0 g of NaOH in 400 mL of $H_2O$) was added and stirred for 30 min; a white precipitate subsequently appeared. This precipitate, a mixture of isomers 3*S*,10*R*-C-*meso*-$Me_8$[14]anes (34.5 g, 77%), was washed with cold water and dried. The isomer **1** was separated by the partial crystallization method: a mixture of isomers of 3*S*,10*R*-C-*meso*-$Me_8$[14]anes (30.0 g, 96.1 mmol) was dissolved in boiling methanol (400 mL) and filtered while hot. Deionized water (400 mL) was added to the hot filtrate and stirred until the solution had cooled to room temperature. A white precipitate of **1** was formed, which was filtered and recrystallized from hot ether. Yield 18.2 g (61%). M.p. 125 °C (from ether). $C_{18}H_{40}N_4$ (312.54): calcd. C 69.17, H 12.90, N 17.93; found C 69.02, H 12.82, N 17.85. FT-IR (KBr disk): $\tilde{\nu}$ = 3265, 2966, 2910, 2826, 1475, 1185 $cm^{-1}$. $^1H$ NMR (600 MHz, $CDCl_3$): $\delta$ = 0.96 (d, $J$ = 6.14 Hz, 6 H), 1.01 (d, $J$ = 6.44 Hz, 6 H), 1.05 (s, 6 H), 1.11 (s, 6 H), 1.22 (d, $J$ = 2.58 Hz, 1 H), 1.25 (d, $J$ = 2.57 Hz, 1 H), 1.62 (m, 2 H), 2.57 (m, 2 H), 2.64 (m, 2 H), 2.99 (m, 2 H), 3.08 (m, 2 H) ppm. $^{13}C$ NMR (125 MHz, $CDCl_3$): $\delta$ = 16.6 ($CH_3$), 20.4 ($CH_3$), 25.7 ($CH_3$), 29.1 ($CH_3$), 45.4 (CH), 47.4 (CH), 47.6 ($CH_2$), 48.7 ($CH_2$), 52.9 (C) ppm. HRMS ($EI^+$, $m/z$): calcd. for $C_{18}H_{40}N_4$ 312.3253, found 312.3253. The filtrate ($F_1$) was kept for further treatment.

**$L_c$ (2):** Deionized water (200 mL) was added to the above filtrate ($F_1$) and continuously stirred for 30 min. A small amount of white precipitate containing a mixture of the isomers was removed. The filtrate ($F_2$) was then evaporated on a rotary evaporator and gave a mixture of *rac* isomers, $L_c$ and $L_d$. Yield 10.4 g (35%). This mixture was then dissolved in ether and partial crystals of **2** were obtained in the first fraction by slow evaporation at room temperature. M.p. 91 °C (from ether). $C_{18}H_{40}N_4{\cdot}H_2O$ (330.56): calcd. C 65.40, H 12.81, N 16.95; found C 65.29, H 12.73, N 16.88. FT-IR (KBr disk): $\tilde{\nu}$ = 3246, 2966, 2930, 2837, 1500, 1174 $cm^{-1}$. $^1H$ NMR (600 MHz, $CDCl_3$): $\delta$ = 0.91 (d, $J$ = 6.11 Hz, 3 H), 0.97 (d, $J$ = 6.76 Hz, 3 H), 1.01 (d, $J$ = 2.88 Hz, 3 H), 0.98 (s, 3 H), 0.99 (s, 3 H), 1.01 (d, $J$ = 2.88 Hz, 3 H), 1.02 (d, $J$ = 2.44 Hz, 3 H), 1.03 (s, 3 H), 1.04 (d, $J$ = 2.83 Hz, 1 H), 1.06 (s, 3 H), 1.08 (d, $J$ = 2.56 Hz, 1 H), 1.67 (m, 2 H), 2.44 (m, 3 H), 2.63 (m, 1 H), 2.76 (m, 2 H), 2.97 (m, 2 H) ppm. $^{13}C$ NMR (125 MHz, $CDCl_3$): $\delta$ = 16.2 ($CH_3$), 20.5 ($CH_3$), 21.5 ($CH_3$), 25.3 ($CH_3$), 27.1 ($CH_3$), 27.6 ($CH_3$), 29.1 ($CH_3$), 29.5 ($CH_3$), 43.5 ($CH_2$), 45.9 (CH), 46.0 ($CH_2$), 47.2 (CH), 47.4 ($CH_2$), 49.4 ($CH_2$), 50.8 (CH), 52.3 (C), 53.1 (C), 54.4 (CH) ppm. HRMS ($EI^+$, $m/z$): calcd. for $C_{18}H_{40}N_4$ 312.3253, found 312.3253. After removing all the crystals, the filtrate ($F_3$) was kept for further treatment.

**$L_d$ (3):** The above filtrate ($F_3$) was air-dried and a white damp residue ($R_1$) was obtained with no crystals. We had hoped it contained a small amount of **2** but only the predominant form of 3 was present. Since these two *racemic* forms are enantiomers of each other and have identical chemical properties it was very difficult to separate them completely and characterize them separately by spectral studies. An X-ray study was the ideal tool for a unique characterization of **3** and was therefore obtained for $[CuL_d(ClO)_2]$ to provide the necessary evidence.

**$[NiL_b](ClO_4)_2$ (4):** A methanol solution (20 mL) of **1** (0.520 g, 1.66 mmol) was added to a boiling methanol solution (20 mL) of nickel acetate tetrahydrate (0.411 g, 1.65 mmol). The solution was heated over a steam bath for 2.0 h and the volume was reduced to 30 mL. After adding lithium perchlorate trihydrate (0.610 g, 3.80 mmol), the reaction mixture was again heated for 5 min and then cooled to room temperature. A bright orange-yellow precipitate was filtered off and washed with methanol followed by ether. The solid was then dissolved in a hot acetonitrile solution. Slow evaporation of the solvent at room temperature gave an orange-yellow crystalline complex **4** that was filtered off and air-dried. Yield 0.634 g (67%). $C_{18}H_{40}Cl_2N_4NiO_8$ (570.13): calcd. C 37.92, H 7.07, N 9.83; found C 37.75, H 7.03, N 9.78. UV/Vis ($CH_3NO_2$): $\lambda$ ($\varepsilon$) = 469 nm (77.9 $dm^3\,mol^{-1}\,cm^{-1}$). FT-IR (KBr disk): $\tilde{\nu}$ = 3541, 3245, 3026, 2975, 1438, 1086 $cm^{-1}$. $^{13}C$ NMR (75 MHz, $CD_3NO_2$): $\delta$ = 13.1 ($CH_3$), 16.2 ($CH_3$), 21.2 ($CH_3$), 24.7 ($CH_3$), 45.5 (CH), 46.4 ($CH_2$), 49.1 ($CH_2$), 50.4 (CH), 53.5 (C) ppm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**$[NiL_c](ClO_4)_2(H_2O)_{0.5}$ (5):** A methanol solution (20 mL) of **2** (1.49 g, 4.78 mmol) was added to a boiling methanol solution (20 mL) of nickel acetate tetrahydrate (1.19 g, 4.78 mmol). The pH of this solution was adjusted between 11 and 12 with sodium hydroxide. After stirring for 3.0 h, lithium perchlorate trihydrate (1.49 g, 9.29 mmol) was added and the solution was cooled to room temperature. The pH of the solution was adjusted to neutrality with perchlorate acid. Yellow crystals were obtained by slow evaporation of the water/methanol mixture. The bright yellow complex **5** was filtered off and washed with methanol and ether. Yield 1.66 g (61%). $C_{18}H_{41}Cl_2N_4NiO_{8.50}$ (579.14): calcd. C 37.33, H 7.14, N 9.67; found C 37.15 H 7.08, N 9.60. UV/Vis ($CH_3NO_2$): $\lambda$ ($\varepsilon$) = 455 nm (90.6 $dm^3 mol^{-1} cm^{-1}$). FT-IR (KBr disk): $\tilde{\nu}$ = 3430, 3195, 2975, 2873, 1635, 1462, 1115 $cm^{-1}$. $^{13}C$ NMR (75 MHz, $CD_3NO_2$): $\delta$ = 9.84 ($CH_3$), 16.9 ($CH_3$), 17.1 ($CH_3$), 19.9 ($CH_3$), 21.5 ($CH_3$), 24.3 ($CH_3$), 26.6 ($CH_3$), 27.3 ($CH_3$), 43.7 ($CH_2$), 44.3 (CH), 47.5 ($CH_2$), 48.0 ($CH_2$), 48.4 (CH), 49.2 ($CH_2$), 51.5 (CH), 53.7 (C), 54.6 (CH), 56.1 (C) ppm.

**$[NiL_d](ClO_4)_2\ x{\cdot}H_2O$ (6):** This complex was synthesized by following the same method as used for **5**, except ligand **3** was used instead of **2**. Spectral data are not given because they are identical to those of **5**. Unfortunately we were unable to obtain single crystals of this compound.

**$[CuL_b(OH_2)_2](ClO_4)_2$ (7):** A methanol solution (20 mL) of copper perchlorate hexahydrate (2.73 g, 7.38 mmol) was added to a methanol solution (20 mL) of **1** (2.18 g, 6.98 mmol). The mixture was refluxed for 1.0 h and then cooled to room temperature. The pink solid that precipitated was separated by filtration and washed several times with methanol and ether. The solid was then dissolved in a hot methanol/water mixture. Slow evaporation of the solvent at room temperature gave the purplish red crystalline complex **7**, which was filtered off and air-dried. Yield 4.02 g (84%). $C_{18}H_{44}Cl_2CuN_4O_{10}$ (611.01): calcd. C 35.38, H 7.26, N 9.17; found C 35.18, H 7.21, N 9.11. UV/Vis ($H_2O$): $\lambda$ ($\varepsilon$) = 279 (10464), 501 nm (131 $dm^3 mol^{-1} cm^{-1}$). FT-IR (KBr disk): $\tilde{\nu}$ = 3463, 3152, 2971, 2880, 1147, 1088 $cm^{-1}$.

**$[CuL_d(ClO_4)_2]$ (8):** Copper perchlorate hexahydrate (0.593 g, 1.60 mmol) was added to a methanol solution (20 mL) of $R_1$ (0.501 g, 1.60 mmol). The mixture was refluxed for 1.0 h and cooled to room temperature. The red precipitate was filtered off and washed with methanol and ether. Red crystals of **8** were obtained by slow evaporation of the methanol/water mixture. Yield 0.791 g (86%). $C_{18}H_{40}Cl_2CuN_4O_8{\cdot}H_2O$ (574.98): C 37.60, H 7.01, N 9.74; found C 37.41, H 6.96, N 9.69. UV/Vis ($H_2O$): $\lambda$ ($\varepsilon$) = 275 (6956), 527 nm (151 $dm^3 mol^{-1} cm^{-1}$). FT-IR (KBr disk): $\tilde{\nu}$ = 3183, 2967, 2893, 1146, 1090 $cm^{-1}$.

**$[CuL_c(ClO_4)_2]$ (9):** The complex was synthesized by following the same method used for **8**, except ligand **2** was used instead of **3**. Spectral data are not given because these are identical to those of **8**. Unfortunately we were unable to obtain single crystals of this compound.

**Crystallography:** Single crystals of ligands were obtained by slow evaporation of either ether solutions, methanol/water mixtures, or acetonitrile solutions. Intensity data were collected with a Siemens Smart CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data reduction and empirical absorption corrections were performed with the XTAL package or NRCVAX programs.[27] Structures were solved by the heavy atom method with SHELXS 97 and refined by full-matrix least-squares analysis on $F^2$ with SHELXL.[28] All the non-hydrogen atoms were refined anisotropically and the hydrogen atoms fixed at calculated positions and refined using a riding model. A summary of the crys-

# Reactions of Ruthenium–Aminophosphane Complexes with Diynes: P–N Bond Activation and Formation of Novel Phosphaallyl, Azaallyl, and Aminocarbene Complexes

**Sonja Pavlik,[a] Florian Jantscher,[a] Georg Dazinger,[a] Kurt Mereiter,[b] and Karl Kirchner*[a]**

**Keywords:** Ruthenium / Phosphaallyl complexes / Azaallyl complexes / Density functional calculations

The aminophosphane complexes $[RuCp(PPh_2NRR'_2)(CH_3CN)_2]^+$ and $[RuCp^*(PPh_2NRR'_2)(CH_3CN)_2]^+$ (NRR′ = NH*n*Pr, $NEt_2$, $NC_5H_5$) react with 1,6-heptadiyne and 1,7-octadiyne to yield novel $\eta^3$-phosphaallyl–$\eta^2$-vinylamine complexes of the types $[RuCp\{\eta^3\text{-}(P,C,C)\text{-}PPh_2CH{=}C{-}(CH_2)_n{-}\eta^2\text{-}(C,C){-}C{=}CHNRR'_2\}]^+$ and $[RuCp^*\{\eta^3\text{-}(P,C,C)\text{-}PPh_2CH{=}C{-}(CH_2)_n{-}\eta^2\text{-}(C,C)\text{-}C{=}CHNRR'_2\}]^+$ ($n$ = 3, 4). These complexes are the kinetic products but eventually form the $\eta^1$-phosphaallyl–$\eta^3$-azaallyl complexes $[RuCp\{\eta^1\text{-}(P)\text{-}PPh_2CH{=}C{-}(CH_2)_n{-}\eta^3\text{-}(C,C,N)\text{-}CCHNRR'_2\}]^+$ and $[RuCp^*\{\eta^1\text{-}(P)\text{-}PPh_2CH{=}C{-}(CH_2)_n{-}\eta^3\text{-}(C,C,N)\text{-}CCHNRR'_2\}]^+$, respectively. With $n$ = 3 elevated temperatures are required, while with $n$ = 4 this conversion takes places already at room temperature. The only exception is $[RuCp^*(PPh_2NH{n}Pr)(CH_3CN)_2]^+$ where amido butadiene complexes $[RuCp^*\{\eta^1\text{-}(N)\text{-}N{n}PrPPh_2\text{-}\eta^4\text{-}CH{=}C(CH_2)_nCH{=}CH_2\}]PF_6$ ($n$ = 3, 4) are obtained instead. In the case of $[RuCp\{\eta^1\text{-}(P)\text{-}PPh_2CH{=}C{-}(CH_2)_3{-}\eta^3\text{-}(C,C,N)\text{-}CCHNRR'_2\}]^+$ with NRR′ = $NEt_2$ and $NC_5H_5$, a further rearrangement took place at elevated temperatures affording the aminocarbenes $[RuCp\{{=}C(NRR')\text{-}\eta^2\text{-}(C,C)\text{-}C(CH_2)_3C{-}CH_2{-}(\eta^1\text{-}(P)\text{-}PPh_2)\}]^+$. Representative X-ray structures are presented. Moreover, conceivable mechanisms for all these reaction sequences are established by means of DFT/B3LYP calculations.

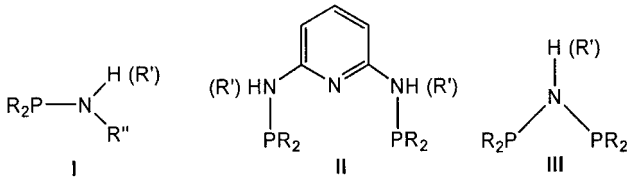
## Introduction

Aminophosphanes that contain one or more direct $P^{III}$–N bonds have received considerable attention in recent years as ligands for transition metals.[1] They are accessible in large quantities through the use of relatively simple condensation processes from inexpensive starting materials, that is, primary or secondary amines and $PR_2Cl$ compounds which contain dialkyl or diaryl substituents as well as achiral and chiral P–O- and P–N-containing phosphane units. Accordingly, variations of electronic, steric, and stereochemical parameters may be achieved in a very facile fashion. The most common structural types of such ligands contain either one P–N unit (e.g. **I**),[2] two or more P–N units which are not directly bound (e.g. **II**),[3,4] or a P–N–P framework (e.g. **III**).[5,6] It should be noted that in some cases $P^{III}$–N bonds were found to be sensitive towards acid- or base-catalyzed hydrolysis during complexation reactions.[7] However, by choosing appropriate substituents on both phosphorus and nitrogen centers, P–N bond cleavage can be avoided.



I II III

We have recently started to investigate the chemistry of RuCp, RuCp*, and RuTp complexes that contain one or two aminophosphane ligands of the most simple $PR_2NHR'$ type, **I**. In these compounds coordination takes place exclusively through the phosphorus donor leaving the N-site available for further reactions. We have shown, for instance, that in the vinylidene and allenylidene complexes $[RuCp(PPh_2NHR)_2\{{=}C{=}(C)_n{=}CHR'\}]^+$ and $[RuTp(PPh_2NHR)_2\{{=}C{=}(C)_n{=}CHR'\}]^+$ ($n$ = 0, 1; R = Ph, *n*Pr; R′ = alkyl, aryl) an intramolecular addition of the NHR′ moiety to the α-carbon of the cumulene moiety takes place, resulting in the formation of novel four-membered aza-phospha-carbenes.[8] Complexes of the types $[RuCp(PPh_2NHPh)(CH_3CN)_2]^+$ and $[RuCp^*(PR_2NHR')(CH_3CN)_2]^+$ (R = Ph, *i*Pr, R′ = Ph, $C_6F_5$) have been found to react with terminal alkynes and diynes to give amido butadiene complexes.[9,10] In all these reactions, the N–H bond but not the P–N bond is cleaved unless larger amounts of water are present. Recently, when we switched over to a complex where the aminophosphane lacks a N–H bond viz. [RuCp-

$(PPh_2NEt_2)(CH_3CN)_2]^+$, we discovered that it reacts with diynes to afford unusual and unprecedented phosphaallyl complexes which readily rearrange to give azaallyl complexes.[11] This process formally constitutes an insertion of an unsaturated carbon C4 chain into the P–N bond, that is, in the course of this reaction the P–N bond is cleaved. The present work is intended to investigate in detail the formation of phosphaallyl complexes and their conversion to azaallyl complexes and we report here the reaction of $[RuCp(PPh_2NRR')(CH_3CN)_2]PF_6$ and $[RuCp^*(PPh_2NRR')(CH_3CN)_2]PF_6$ (NRR′ = NH*n*Pr, $NEt_2$, $NC_5H_{10}$) with diynes. The mechanistic considerations will be supported by DFT/B3LYP calculations.

## Results and Discussion

### Starting Materials

The starting complexes **1a**–**c** were obtained in highly isolated yields by reacting $[RuCp(CH_3CN)_3]PF_6$ with 1 equiv. of the respective aminophosphane $PPh_2NRR'$ (NRR′ = NH*n*Pr, $NEt_2$, $NC_5H_{10}$) at room temperature. The analogous RuCp* complexes were obtained in a similar fashion by reacting $[RuCp^*(CH_3CN)_3]PF_6$ with $PPh_2NRR'$ affording complexes **2a**–**c**. All these complexes are stable to air in the solid state but decompose slowly in solutions on exposure to air. Complexes **1a**–**c** and **2a**–**c** exhibit a singlet resonance in the $^{31}P\{^1H\}$ NMR spectrum in the range of 83–102 ppm. Structural views of **1a** and **2c** are shown in Figure 1 and Figure 2 with selected bond lengths given in the captions.

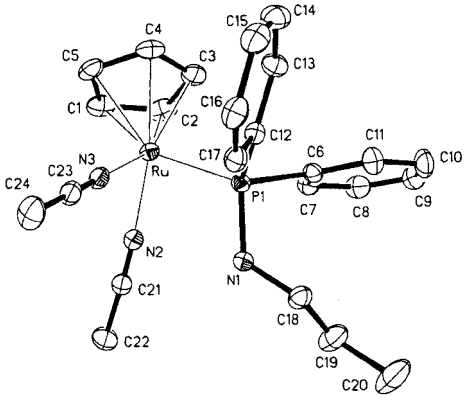

Figure 1. Structural view of $[RuCp(PPh_2NH{\it n}Pr)(CH_3CN)_2]PF_6$ (**1a**) showing 50% thermal ellipsoids ($PF_6^-$ omitted for clarity). Selected bond lengths [Å]: Ru–C(1–5)$_{av}$ 2.187(2), Ru–N(2) 2.064(2), Ru–N(3) 2.064(2), Ru–P(1) 2.2823(5), P(1)–N(1) 1.657(2).

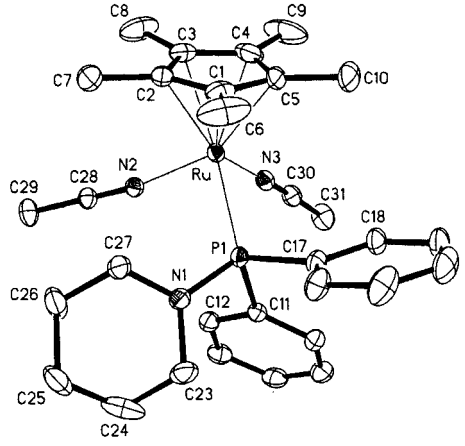

Figure 2. Structural view of $[RuCp^*(PPh_2NC_5H_{10})(CH_3CN)_2]PF_6$ (**2c**) showing 20% thermal ellipsoids ($PF_6^-$ omitted for clarity). Selected bond lengths [Å]: Ru–C(1–5)$_{av}$ 2.191(2), Ru–P(1) 2.3322(5), Ru–N(2) 2.064(2), Ru–N(3) 2.059 (2), P(1)–N(1) 1.668(2).

### Reaction of $[RuCp(PPh_2NRR')(CH_3CN)_2]^+$ (NRR′ = NH*n*Pr, $NEt_2$, $NC_5H_{10}$) with Diynes

Within a few minutes, treatment of **1a**–**c** with 1,6-heptadiyne results in the formation of the $\eta^3$-phosphaallyl–$\eta^2$-vinylamine complexes $[RuCp\{\eta^3\text{-}(P,C,C)\text{-}PPh_2CH{=}C\text{–}(CH_2)_3\text{-}\eta^2\text{-}(C,C)\text{–}C{=}CH\text{–}NH{\it n}Pr\}]^+$ (**3a**), $[RuCp\{\eta^3\text{-}(P,C,C)\text{-}PPh_2CH{=}C\text{–}(CH_2)_3\text{–}\eta^2\text{-}(C,C)\text{-}C{=}CH\text{–}NEt_2\}]^+$ (**3b**), and $[RuCp\{\eta^3\text{-}(P,C,C)\text{-}PPh_2CH{=}C\text{–}(CH_2)_3\text{–}\eta^2\text{-}(C,C)\text{-}C{=}CH\text{–}NC_5H_{10}\}]^+$ (**3c**) in high yields (Scheme 1).[12,13] It is interesting to note that despite the fact that the aminophosphane ligand of **1a** bears a NH proton, a phosphaallyl complex rather than an amido butadiene complex is formed, as has been observed recently for $[RuCp(Ph_2PNHPh)(CH_3CN)_2]^+$. This may be attributed to the lower acidity of the NH proton (in other words, a stronger N–H bond) in $PPh_2NH{\it n}Pr$ as compared to the NH bond in $PPh_2NHPh$. Accordingly, P–*N* rather than N–H bond activation is favored. The phosphaallyl composition proved not to be the most stable one. In fact, if a solution of **3a**–**c** is kept at 90 °C for several hours, further rearrangement takes place, leading eventually to the thermodynamically more stable $\eta^1$-phosphaallyl–$\eta^3$-azaallyl complexes $[RuCp\{\eta^1\text{-}(P)\text{-}PPh_2CH{=}C\text{–}(CH_2)_3\text{–}\eta^3\text{-}(C,C,N)\text{-}C{=}CH\text{–}NH{\it n}Pr\}]^+$ (**4a**), $[RuCp\{\eta^1\text{-}(P)\text{-}PPh_2CH{=}C\text{–}(CH_2)_3\text{–}\eta^3\text{-}(C,C,N)\text{-}C{=}CH\text{–}NEt_2\}]^+$ (**4b**), and $[RuCp\{\eta^1\text{-}(P)\text{-}PPh_2CH{=}C\text{–}(CH_2)_3\text{–}\eta^3\text{-}(C,C,N)\text{-}C{=}CH\text{–}NC_5H_{10}\}]^+$ (**4c**) in essentially quantitative yields (Scheme 1).[14] On the other hand, with **1a** and 1,7-octadiyne no $\eta^3$-phosphaallyl–$\eta^2$-vinylamine complex could be observed and the $\eta^1$-phosphaallyl–$\eta^3$-azaallyl **4d** was obtained directly. In the case of **1b** and **1c** the respective $\eta^3$-phosphaallyl–$\eta^2$-vinylamine complexes **3d** and **3e** could be observed spectroscopically but rearranged rapidly at room temperature to afford the corresponding $\eta^1$-phosphaallyl–$\eta^3$-azaallyl complexes **4e** and **4f**. All compounds, which are air-stable both in solution and in the solid state, were fully characterized by $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy as well as elemental analysis.

The $^1H$ NMR spectroscopic data for **3a** include characteristic resonances at 4.14 (d, $J_{HP}$ = 4.4 Hz) and 3.99 ppm (d, $J_{H,P}$ = 7.6 Hz, 1 H) assignable to the protons $H^1$ and $H^4$ of the $\eta^3$-phosphaallyl and $\eta^2$-vinylamine units, respectively. In the $^{13}C\{^1H\}$ NMR spectrum the characteristic resonance of the coordinated $sp^2$ carbon atoms $C^1$, $C^2$, $C^3$, and $C^4$ of the $\eta^3$-phosphaallyl–$\eta^2$-vinylamine moiety exhi-

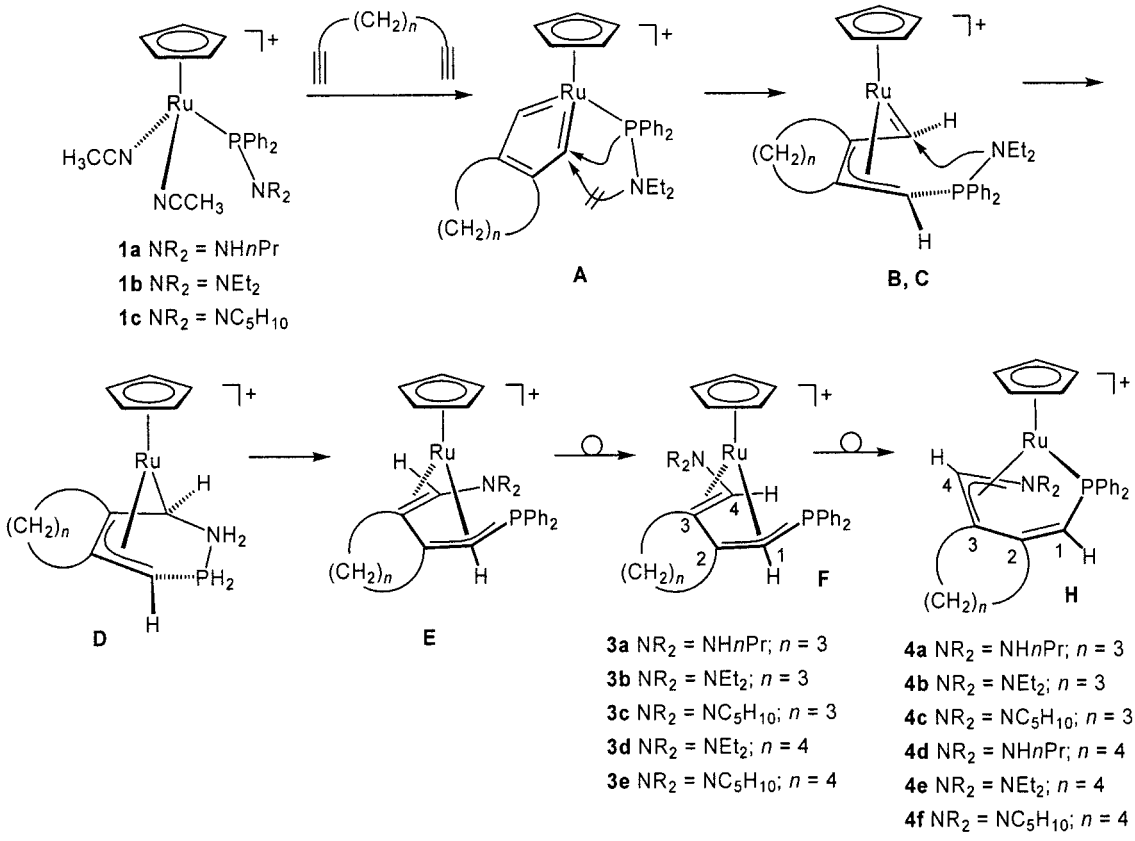

Scheme 1.

bit resonances at 41.6 (d, $J_{CP}$ = 24.5 Hz), 82.1, 116.8 (d, $J_{CP}$ = 3.8 Hz), and 106.9 ppm (d, $J_{CP}$ = 6.1 Hz), respectively. In the $^{31}P\{^1H\}$ NMR spectrum the phosphaallyl ligand exhibits a singlet at 9.3 ppm. Concurrent NMR spectra are observed for **3b**–**e**.

The NMR spectroscopic data of **4a**–**f** are quite different from those of **3a**–**e**. As the overall spectroscopic features are very similar, we describe here only those of **4a**. The $^1H$ NMR spectrum exhibits resonances at 5.98 (d, $J_{HP}$ = 10.1 Hz) and 6.02 ppm, which can be assigned to the olefinic hydrogen atom $H^1$ and the allyl proton $H^4$. The most characteristic features in the $^{13}C\{^1H\}$ NMR spectrum are a low-field doublet resonance at $\delta$ = 170.1 ppm (d, $J_{CP}$ = 29.1 Hz) and doublet resonances at 111.9 (d, $J_{CP}$ = 47.2 Hz), 85.8 (d, $J_{CP}$ = 1.9 Hz), and 74.4 ppm assignable to the terminal allyl carbon atom $C^3$, the two olefinic carbon atoms $C^1$ and $C^2$, and the central allyl carbon atom $C^4$ bearing the NH*n*Pr unit. In the $^{31}P\{^1H\}$ NMR spectrum the $\eta^1$-(P)-phosphaallyl ligand exhibits a singlet at $\delta$ = 70.3 ppm (cf. 9.3 ppm in **3a**).

The solid-state structures of **3a**, **3c**, and **4f** were determined by single-crystal X-ray diffraction. ORTEP diagrams are depicted in Figure 3, Figure 4, and Figure 5 with selected bond lengths given in Table 1. The structures of **3a** and **3c** can be described as a three-legged piano stool geometry with the $\eta^3$-phosphaallyl moiety and the C=C bond of the vinylamine unit as the legs. The $\eta^3$-phosphaallyl functionality is nearly symmetrically bonded to the metal with the Ru–P, Ru–C(18), and Ru–C(19) bond lengths being 2.2763(5), 2.241(2), and 2.220(2) Å in **3a** and 2.2505(4), 2.239(2), and 2.203(2) Å in **3c**, respectively. The olefin part of the vinylamine moiety is strongly asymmetrically bonded to the metal center with the Ru–C bonds to the carbon

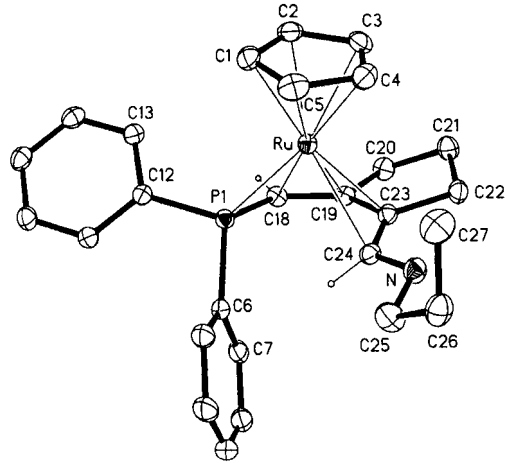

Figure 3. Structural view of [RuCp{$\eta^3$-(P,C,C)-$PPh_2CHC–(CH_2)_3$–$\eta^2$-(C,C)-CCHNH*n*Pr}]$PF_6$ (**3a**) showing 40% thermal ellipsoids ($PF_6^-$ omitted for clarity). Selected bond lengths [Å]: Ru–C(1–5)$_{av}$ 2.197(2), Ru–P(1) 2.2763(5), Ru–C(18) 2.241(2), Ru–C(19) 2.220(2), Ru–C(23) 2.236(2), Ru–C(24) 2.490(2), P(1)–C(18) 1.768(2), C(18)–C(19) 1.4129(34), C(19)–C(23) 1.437(3), C(23)–C(24) 1.396(3), C(24)–N 1.344(2).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms C(23) and C(24) being 2.236(2) and 2.490(2) Å in **3a** and 2.219(2) and 2.551(2) Å in **3c**, respectively. Strong alteration of olefin binding by π-donor substituents has also been observed in $[FeCp(CO)_2(H_2C{=}CHNMe_2)]^+$ where the vinylamine is essentially $\eta^1$-bound [the nonbonded Fe···C separation is 2.823(11) Å].[15] In turn, the C(24)–N bonds in **3a** and **3c** exhibit already double bond character being 1.344(2) and 1.359(2) Å, respectively. The bonding situation of the –C=CHNH*n*Pr and $-C{=}CHNC_5H_{10}$ units might be described as intermediate between the limiting vinylamine and imine forms or alternatively perhaps even as $\eta^1$-(C)-azaallyl. Accordingly, rotation about the C(23)–C(24) bond is expected to be facile, putting the amine moiety rapidly in a *syn*-conformation for steric reasons (conversion **D** to complexes **3** in Scheme 1).

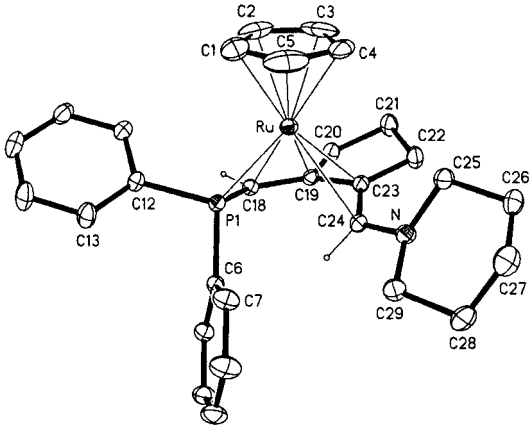

Figure 4. Structural view of $[RuCp\{\eta^1\text{-}(P)\text{-}PPh_2CH{=}C\text{–}(CH_2)_3\text{–}\eta^3\text{-}(C,C,N)\text{-}CCHNC_5H_{10}\}]PF_6$ (**3c**) showing 40% thermal ellipsoids ($PF_6^-$ omitted for clarity). Selected bond lengths [Å]: Ru–C(1–5)$_{av}$ 2.182(2), Ru–P(1) 2.2505(4), Ru–C(18) 2.239(2), Ru–C(19) 2.203(2), Ru–C(23) 2.219(2), Ru–C(24) 2.551(2), P(1)–C(18) 1.774(2), C(18)–C(19) 1.415(2), C(19)–C(23) 1.438(2), C(23)–C(24) 1.406(2), C(24)–N 1.359(2).

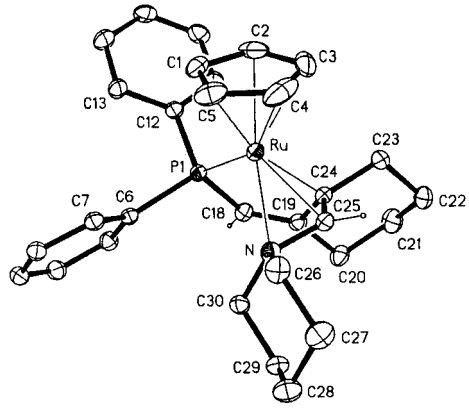

Figure 5. Structural view of $[RuCp\{\eta^1\text{-}(P)\text{-}PPh_2\text{-}CH{=}C(CH_2)_4\text{-}\eta^3\text{-}(C,C,N)\text{-}CH\text{-}NC_5H_{10}\}]PF_6$ (**4f**) showing 40% thermal ellipsoids ($PF_6^-$ omitted for clarity). Selected bond lengths [Å]: Ru–C(1–5)$_{av}$ 2.210(2), Ru–N 2.186(2), Ru–C(25) 2.089(2), Ru–C(24) 2.204(2), Ru–P(1) 2.2791(5), P(1)–C(18) 1.796(2), C(18)–C(19) 1.336(2), C(19)–C(24) 1.505(2), C(24)–C(25) 1.418(2), C(25)–N 1.415(2).

The structure of **4f** also adopts a three-legged piano stool conformation with the $\eta^3$-azaallyl moiety and the P atom as the legs. The $\eta^3$-azaallyl unit, being *exo*-oriented with respect to the phosphane moiety, is asymmetrically bonded

to the metal with the Ru–C bond length to the central allyl carbon atom C(25) [2.089(2) Å] distinctly shorter than the Ru–N and Ru–C(24) bonds to the terminal allyl atoms N and C(24) [2.186(2) and 2.204(2) Å, respectively].

Upon keeping a $CH_3CN$ solution of **4b** at 90 °C for 12 h, an unexpected rearrangement took place affording the aminocarbene $[RuCp\{=C(NEt_2)\text{-}\eta^2\text{-}(C,C)\text{-}C(CH_2)_3CCH_2\text{-}(\eta^1\text{-}(P)\text{-}PPh_2)\}]^+$ (**5a**) in essentially quantitative yield (71% isolated yield) as monitored by $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy (Scheme 2). The same isomerization reaction was observed for **4c** yielding $[RuCp\{=C(NC_5H_{10})\text{-}\eta^2\text{-}(C,C)\text{-}C(CH_2)_3CCH_2\text{-}(\eta^1\text{-}(P)\text{-}PPh_2)\}]^+$ (**5b**) but the reaction was not quantitative. Attempts to isolate **5b** in pure form were unsuccessful and only mixtures of **4c** and **5b** were obtained. All other azaallyl complexes turned out to be thermally stable and there was no evidence for the formation of an aminocarbene. In the course of this process, the hydrogen of the central allyl carbon atom $C^4$ is transferred onto the olefinic carbon $C^1$. It is interesting to note that this reaction takes place only in the coordinating solvent $CH_3CN$, but not in $CH_3NO_2$. It may be speculated that such a formal 1,4 hydrogen shift reaction proceeds most likely by a metal mediated C–H activation step and the intermediacy of a hydride species (Scheme 2). Addition of the coordinating solvent may cause a hapticity change of the $\eta^3$ azaallyl moiety to give a $\eta^2$ vinylamine, thereby providing a latent vacant coordination site for a subsequent C–H bond activation step. Insertion of the noncoordinated olefin moiety into the Ru–H bond may then afford the aminocarbene complex. The conversion of activated olefins to heteroatom-stabilized carbenes is well documented.[16]

Characteristic features of **5a** and **5b** comprise, in the $^{13}C\{^1H\}$ NMR spectrum, a low-field doublet resonance in the range of 225.2 (d, $J_{CP}$ = 13.0 Hz) and 222.9 (d, $J_{CP}$ = 12.3 Hz) ppm, respectively, assignable to the carbene carbon atoms. The $sp^3$ carbon atom $C^1$ gives rise to a doublet resonance at 37.9 (d, $J_{CP}$ = 35.3 Hz) and 36.7 (d, $J_{CP}$ = 35.3 Hz). The $^{31}P\{^1H\}$ NMR spectrum reveals an unusually high-field shifted resonance at –34.3 and –37.8 ppm (cf. 9.3 and 4.3 ppm in **3b** and **3c**, and 74.1 and 73.3 ppm in **4b** and **4c**) with a small coupling constant of 36 Hz. The structural identity of **5a** was unequivocally proven by X-ray crystallography. The result is depicted in Figure 6 with important bond lengths given in the caption. Overall, **5a** adopts a typical three-legged piano stool conformation with $PPh_2$, the

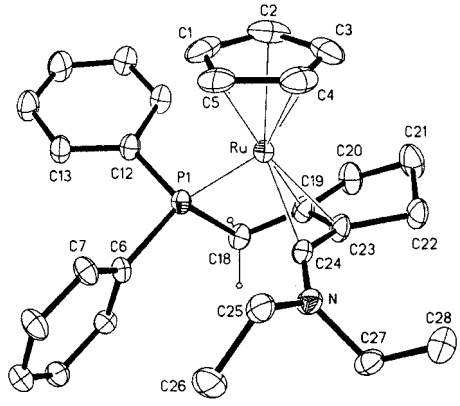

Figure 6. Structural view of $[RuCp\{=C(NEt_2)\text{-}\eta^2\text{-}(C,C)\text{-}C(CH_2)_3\text{-}C\text{–}CH_2\text{-}(\eta^1\text{-}(P)\text{-}PPh_2)\}]PF_6$ (**5a**) showing 20% thermal ellipsoids ($PF_6^-$ omitted for clarity). Selected bond lengths [Å]: $Ru\text{–}C(1\text{–}5)_{av}$ 2.204(9), Ru–C(24) 2.006(7), Ru–C(23) 2.201(7), Ru–C(19) 2.444(8), Ru–P(1) 2.263(2), P(1)–C(18) 1.818(7), C(18)–C(19) 1.493(12), C(19)–C(23) 1.421(12), C(23)–C(24) 1.508(11), C(24)–N 1.147(9).

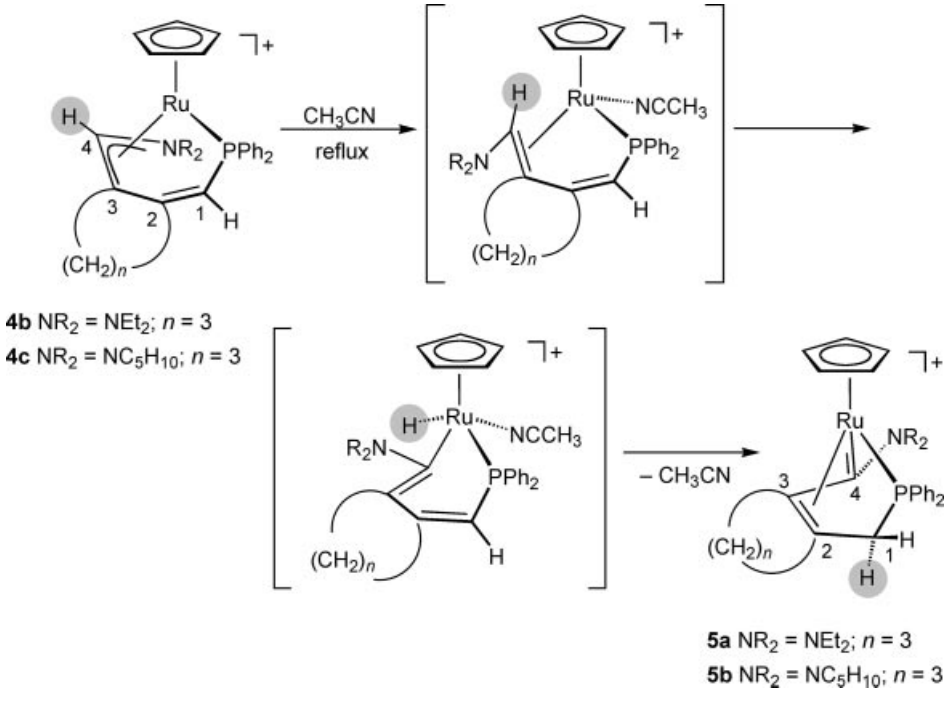


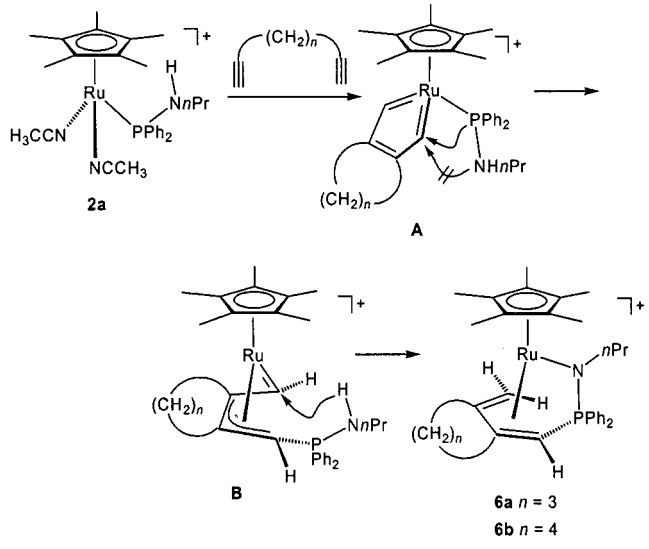
Scheme 2.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

two C=C bonds of the vinyl moiety and the carbene carbon atom as the legs. The most notable feature is the comparatively short Ru–C(24) bond length of 2.006(7) Å reflecting metal carbon double bond character which is typical for aminocarbenes. The $\eta^2$-vinyl unit is asymmetrically bonded to the metal center with Ru–C(23) and Ru–C(19) bond lengths of 2.201(7) and 2.444(8) Å, respectively.

### Reaction of $[RuCp^*(PPh_2NRR')(CH_3CN)_2]^+$ (NRR′ = NH*n*Pr, $NEt_2$, $NC_5H_5$) with Diynes

Given the previously observed behavior differences between $[CpRu(PR_3)(CH_3CN)_2]^+$ and the homologous $[Cp^*Ru(PR_3)(CH_3CN)_2]^+$ complexes with respect to the C–H activation processes,[17] we have addressed the question of whether P–N bond activation occurs also in the case of the Cp* aminophosphane complexes **2a**–**c**. In contrast to **1a**–**c**, the reaction of **2a** both with 1,6-heptadiyne and 1,7-octadiyne results in the clean formation of the amido butadiene complexes $[RuCp^*\{\eta^1\text{-}(N)\text{-}NnPrPPh_2\text{-}\eta^4\text{-}CH{=}C(CH_2)_3CH{=}CH_2\}]PF_6$ (**6a**) and $[RuCp^*\{\eta^1\text{-}(N)\text{-}NnPrPPh_2\text{-}\eta^4\text{-}CH{=}C(CH_2)_4CH{=}CH_2\}]PF_6$ (**6b**) in high yields (Scheme 3). There was no evidence that phosphaallyl or azaallyl complexes were formed. The same reaction has been found for $[RuCp(PPh_2NHPh)(CH_3CN)_2]^+$ and $[RuCp^*(PR_2NHR')(CH_3CN)_2]^+$ (R = Ph, *i*Pr, R′ = Ph, $C_6F_5$).[10,11] Compounds **6a** and **6b** are air-stable both in solution and in the solid state and were characterized by $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy as well as elemental analysis.



Scheme 3.

As these compounds exhibit similar spectroscopic features to the RuCp $\eta^4$-butadiene amido complexes already described recently,[10,11] they are not discussed here. The solid-state structures of **6a** and **6b** were determined by single-crystal X-ray diffraction. ORTEP diagrams are depicted in Figure 7 and Figure 8 with selected bond lengths reported in the captions.

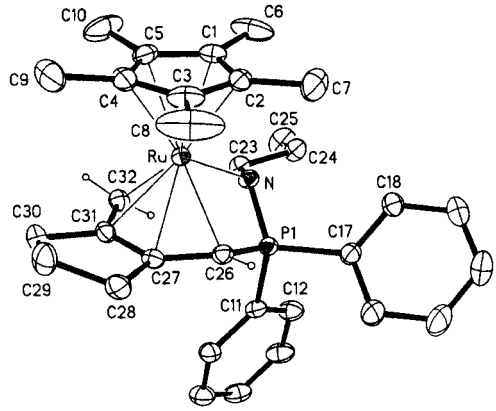


Figure 7. Structural view of $[RuCp^*\{\eta^1\text{-}(N)\text{-}NnPrPPh_2\text{-}\eta^4\text{-}CH{=}C(CH_2)_3CH{=}CH_2\}]PF_6$ (**6a**) showing 40% thermal ellipsoids ($PF_6^-$ omitted for clarity). Selected bond lengths [Å]: $Ru\text{–}C(1\text{–}5)_{av}$ 2.207(3), Ru–N = 2.183(2), Ru–C(26) 2.222(2), Ru–C(27) 2.232(2), Ru–C(31) 2.227(2), Ru–C(32) 2.204(2), P(1)–N 1.600(2), P(1)–C(26) 1.769(2), C(26)–C(27) 1.416(3), C(27)–C(31) 1.432(3), C(31)–C(32) 1.401(3).

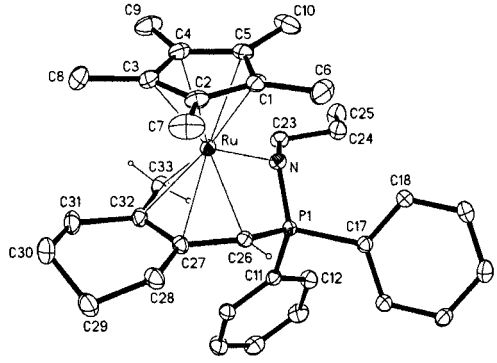

Figure 8. Structural view of $[RuCp^*\{\eta^1\text{-}(N)\text{-}NnPrPPh_2\text{-}\eta^4\text{-}CH{=}C(CH_2)_4CH{=}CH_2\}]PF_6$ (**6b**) showing 20% thermal ellipsoids ($PF_6^-$ omitted for clarity; only the first of three independent Ru complexes is shown). Selected bond lengths [Å]: $Ru\text{–}C(1\text{–}5)_{av}$ 2.220(2), Ru–N 2.184(2), Ru–C(26) 2.191 (2), Ru–C(27) 2.249(2), Ru–C(32) 2.244(2), Ru–C(33) 2.172(2), P(1)–N 1.600(2), P(1)–C(26) 1.771(2), C(26)–C(27) 1.423(3), C(27)–C(32) 1.436(3), C(32)–C(33) 1.406(4).

In similar fashion to the RuCp complexes **1a**–**c**, with 1,6-heptadiyne, 1,7-octadiyne, **2b**, and **2c**, the $\eta^1$-phosphaallyl–$\eta^3$-azaallyl complexes $[RuCp^*\{\eta^1\text{-}(P)\text{-}PPh_2\text{–}CH{=}C(CH_2)_3\text{-}\eta^3\text{-}(C,C,N)\text{-}CCHNEt_2\}]PF_6$ (**8a**), $[RuCp^*\{\eta^1\text{-}(P)\text{-}PPh_2\text{–}CH{=}C(CH_2)_3\text{-}\eta^3\text{-}(C,C,N)\text{-}CCHNC_5H_{10}\}]PF_6$ (**8b**), $[RuCp^*\{\eta^1\text{-}(P)\text{-}PPh_2\text{–}CH{=}C(CH_2)_4\text{-}\eta^3\text{-}(C,C,N)\text{-}CCHNEt_2\}]PF_6$ (**8c**), and $[RuCp^*\{\eta^1\text{-}(P)\text{-}PPh_2\text{–}CH{=}C(CH_2)_4\text{-}\eta^3\text{-}(C,C,N)\text{-}CCHNC_5H_{10}\}]PF_6$ (**8d**), respectively, are obtained in high isolated yields (Scheme 4). While in the case of 1,6-heptadiyne the intermediacy of $\eta^3$-phosphaallyl–$\eta^2$-vinylamine complexes **7a** and **7b** could be observed by NMR spectroscopy, in the case of 1,7-octadiyne no intermediates were detected. Again, all compounds were fully characterized by a combination of $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy and elemental analysis. Overall, the spectroscopic features of complexes **7** and **8** are very similar to those of complexes **3** and **4** and are thus not discussed here. In ad-

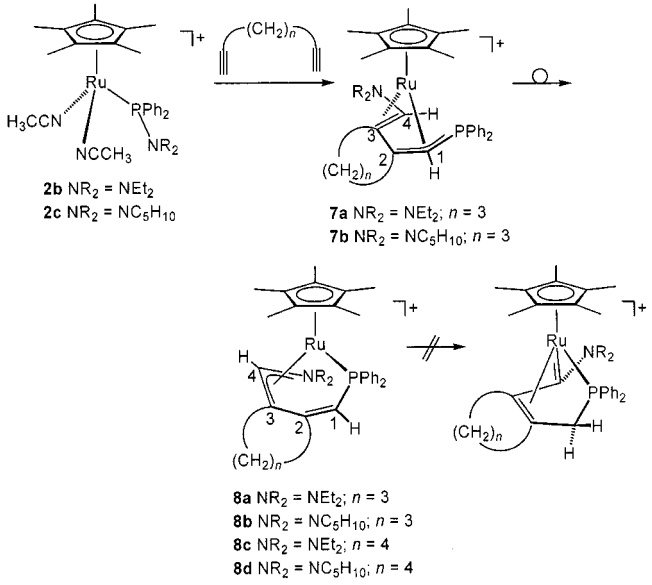
dition, the solid-state structures of **8c** and **8d** were determined by single-crystal X-ray diffraction. ORTEP plots are depicted in Figure 9 and Figure 10 with selected bond lengths reported in the captions.



Scheme 4.

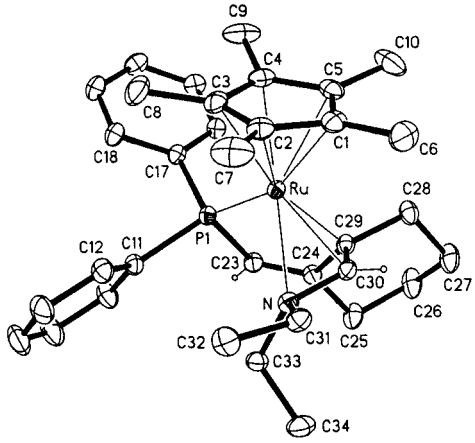


Figure 9. Structural view of [RuCp*{$\eta^1$-(P)-$PPh_2CH{=}C(CH_2)_4$-$\eta^3$-(C,C,N)-C=CH–$NEt_2$}]$PF_6{\cdot}CH_2Cl_2$ (**8c**·$CH_2Cl_2$) showing 30% thermal ellipsoids ($PF_6^-$ and solvent omitted for clarity). Selected bond lengths [Å]: Ru–$C(1–5)_{av}$ 2.239(2), Ru–P(1) 2.3020(6), Ru–C(29) 2.253(2), Ru–C(30) 2.092(2), Ru–N 2.243(2), P(1)–C(23) 1.795(2), C(23)–C(24) 1.325(3), C(24)–C(29) 1.510(3), C(29)–C(30) 1.425(3), N–C(30) 1.421(3).

Finally, as part of our ongoing effort to investigate the chemistry of complexes with ligands which possess direct $P^{III}$–N bonds towards alkynes, we set out here to prepare a complex with a diphenylphosphanylhydrazide ligand, that is, a ligand having a $P^{III}$–N–N unit. It should be noted that transition-metal complexes with $R_2PNHNR'_2$ ligands are comparatively rare. With respect to late transition metals, they have been found to coordinate either as monodentate or bidentate ligands in $\kappa^1$-P and $\kappa^2$-P,N fashion, respectively.[18] Accordingly, treatment of [RuCp$(CH_3CN)_3$]$PF_6$ with 1 equiv. of $PPh_2NHNMe_2$ in $CH_2Cl_2$ as the solvent

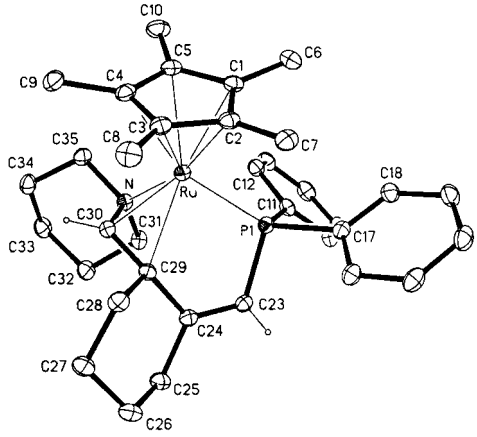

Figure 10. Structural view of [RuCp*{$\eta^1$-(P)-$PPh_2CH{=}C(CH_2)_4$-$\eta^3$-(C,C,N)-C=CH–$N(CH_2)_5$}]$PF_6$ (**8d**) showing 30% thermal ellipsoids ($PF_6^-$ omitted for clarity). Selected bond lengths [Å]: Ru–$C(1–5)_{av}$ 2.228(2), Ru–P(1) 2.2978(5), Ru–C(29) 2.252(2), Ru–C(30) 2.090(2), Ru–N 2.233(2), P(1)–C(23) 1.796(2), C(23)–C(24) 1.326(3), C(24)–C(29) 1.508(3), C(29)–C(30) 1.418(3), N–C(30) 1.418(2).

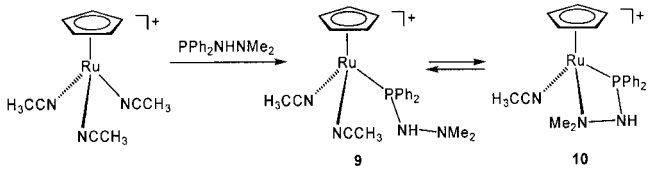
at room temperature yields, upon workup, a 5:1 mixture of [RuCp{$\kappa^1$(P)-$PPh_2NHNMe_2$}$(CH_3CN)_2$]$PF_6$ (**9**) and [RuCp{$\kappa^2$(P,N)-$PPh_2NHNMe_2$}$(CH_3CN)$]$PF_6$ (**10**) where the $PPh_2NHNMe_2$ ligand is attached to the metal center in the $\kappa^1$-P and $\kappa^2$-P,N mode, respectively (Scheme 5). Complex **9** is obtained in pure form, when the reaction is performed in the presence of 1 equiv. of $CH_3CN$. Both complexes were characterized by means of $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy and elemental analysis in the case of **9**. Crystals of **10** could be grown by diffusion of diethyl ether into a $CH_2Cl_2$ solution of a reaction mixture containing both **9** and **10**. A structural view of **10** is depicted in Figure 11 with selected bond lengths and angles reported in the caption.



Scheme 5.

Complexes **9** and **10** exhibit singlet resonances in the $^{31}P\{^1H\}$ NMR spectrum at 90.6 to 61.4 ppm, respectively. In the case of **10** where the $PPh_2NHNMe_2$ ligand is bound in $\kappa^2$-P,N fashion the $^1H$ and $^{13}C\{^1H\}$ NMR spectra show the two methyl groups to be inequivalent, giving rise to two signals at $\delta$ = 3.35 and 2.82 ppm and 63.9 and 57.8 ppm, respectively [cf. complex **9** exhibits one singlet at $\delta$ = 2.27 ppm and a doublet centered at $\delta$ = 49.9 ppm ($J_{CP}$ = 3.4 Hz)].

Unfortunately, in contrast to the clean reactions of complexes **1** and **2** with diynes, the reaction of **9** with 1,6-heptadiyne and 1,7-octadiyne afforded only mixtures of intractable materials. Thus as yet no further reactions have been performed with **9**.

Selected bond lengths [Å] and angles [°]: Ru–$C(1–5)_{av}$ 2.173(2), Ru–P(1) 2.2915(2), Ru–N(2) 2.216(2), Ru–N(3) 2.050(2), P(1)–N(2) 1.688(2), N(1)–N(2) 1.456(2), P(1)–Ru–N(2) 67.03(4).

### Mechanistic Aspects

For the present conversion of **1** and **2** to the respective phosphaallyl complexes **4**, unfortunately, no intermediate products could be detected spectroscopically. From previous experimental data[19] it is reasonable to assume that the formation of the $\eta^3$-phosphaallyl–$\eta^2$-vinylamine proceeds via the intermediacy of the cationic metallacyclopentatriene **A** and the $\eta^3$-allyl carbene complex **B**. The formation of the latter involves migration of the $\kappa^1$(P) coordinated $PPh_2NRR'$ ligand to one of the two electrophilic carbene carbon atoms of **A**.[19] Accordingly, we have chosen **B** (in the form of the two model complexes $[CpRu\{=CH\text{–}(\eta^3\text{-}CHCHCH\text{–}PH_2NH_2)\}]^+$ and $[CpRu\{=CH\text{-}(\eta^3\text{-}CHCHCH\text{–}PMe_2NHMe)\}]^+$) as the starting point of our theoretical mechanistic investigation based on DFT/B3LYP calculations. The energy profile for the conversion of **B** to the $\eta^3$-phosphaallyl–$\eta^2$-vinylamine complexes **4** is shown in Figure 12. The models of **4** with $PH_2NH_2$ and $PMe_2NHMe$ will be called **F** (in Figure 12 the energy values in parentheses refer to $PMe_2NHMe$). The reliability of the computational method (details in Experimental Section) is supported by the good agreement between the calculated geometries of **F** with the X-ray structures of the related complexes (e.g. **3a** and **3c**).

The first step **B** to **C** constitutes a rotation of the aminophosphane substituent about the C–P bond, which is required to place the amine moiety in a position suitable for nucleophilic attack at the carbene carbon atom. This process is slightly endothermic by 3.2 kcal/mol and possesses a small activation barrier (6.7 kcal/mol). Subsequent nucleophilic attack of the amine moiety at the carbene carbon atom of **C** yields intermediate **D**, which features an unusual six-membered aza-phosphacycle. The transition state for this process, $\mathbf{TS_{CD}}$, is very similar to the structure of **D**, indicating that the transition state structure occurs quite late along the reaction coordinate and is merely 0.3 kcal/

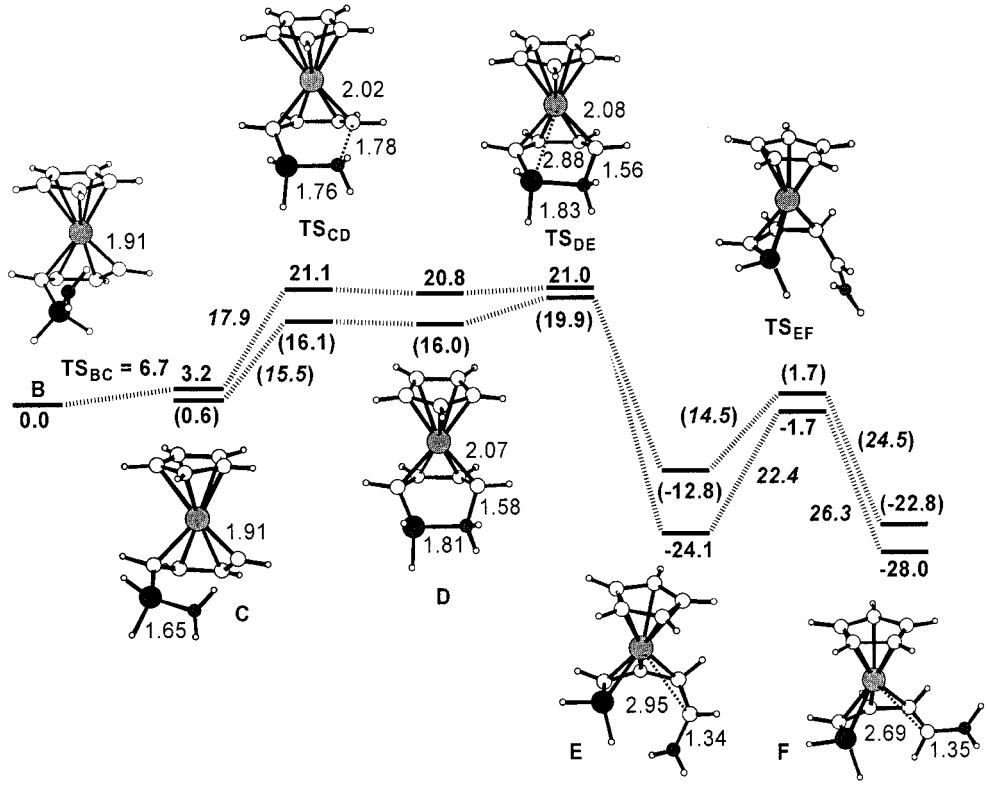

Figure 12. Energy profile (in kcal/mol, relative to **B**) for the conversion of **B** to **F** with $PH_2NH_2$ as model aminophosphane ligand. The numbers in parentheses refer to $PMe_2NHMe$ as the model ligand.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mol higher in energy than **D**. In the course of this reaction, a new N···C bond starts to form. It is 1.78 Å in $\mathbf{TS_{CD}}$ and finally reaches 1.58 Å in species **D**. This process requires an activation energy of 17.9 kcal/mol. The P–N bond in **D** is rather weak as judged from the long P–N bond length of 1.81 Å. Accordingly, this bond is readily cleaved, yielding the $\eta^3$-phosphaallyl–$\eta^2$-vinylamine complex **E**. This transformation is strongly exothermic, releasing 44.9 kcal/mol. The transition state connecting **D** and **E** is reached at an early stage and thus its structure is very similar to **D**. In fact, the only noticeable change from **D** to $\mathbf{TS_{DE}}$ is a weak but apparently important Ru···P interaction of 2.88 Å. In **E** the Ru–P bond is fully developed (2.30 Å), while the Ru–$C^4$ bond becomes very weak or almost nonbonding (2.95 Å). On going from **D** to **E**, the amino substituent is initially placed in an *anti* position, that is, pointing towards the phosphane moiety, which is sterically unfavorable, especially if the amine is mono- or even disubstituted (repulsive interactions) such as in **3b**, **3c**, **3d**, or **3e**. Rotation of the amine unit about the $C^3$–$C^4$ bond yields the experimentally observed and isolated *syn* isomer **F**. Surprisingly, despite the fact that the Ru–$C^4$ bond is rather long (2.95 Å), the activation barrier for this rotation is relatively high, requiring 22.4 kcal/mol. However, in the case of the more realistic model ligand $PMe_2NHMe$, the activation barrier becomes significantly smaller (14.5 kcal/mol) and unfavorable steric interactions are better taken into account (Figure 12, numbers in parentheses).

Experimentally it has been observed that $\eta^3$-phosphaallyl–$\eta^2$-vinylamine complexes (**F**) are the kinetic products but isomerize (in some cases already at room temperature) to the thermodynamically more stable $\eta^1$-phosphaallyl–$\eta^3$-azaallyl complexes **H**. The energy profiles for this conversion are presented in Figures 12 (**F** → **E**) and 13 (**E** → **H**). In agreement with experimental data, the overall process is thermodynamically favored. This rearrangement exhibits a *syn–anti* isomerization of the $NH_2$ substituent and thus proceeds most likely again via the intermediacy of **E** (Figure 12). This first step needs an activation energy of 26.3 kcal/mol for the parent $PH_2NH_2$ ligand and 24.5 kcal/mol for $PMe_2NHMe$ and is thus rate determining. Once **E** is re-formed, the subsequent processes are facile. Complex **E** proceeds through transition state $\mathbf{TS_{EG}}$ to afford the metallacycle **G**. This reaction is energetically slightly unfavorable by 6.7 kcal/mol with an activation energy of 12.1 kcal/mol. These values, however, are comparatively small taking into account that in the course of this reaction two Ru–C bonds are broken, which are counterbalanced only by one weak Ru–C interaction (2.65 Å). Moreover, as a consequence of that ongoing from **E** by $\mathbf{TS_{EG}}$ to **G**, the C4 chain experiences a severe distortion, as is apparent from the changes of the respective torsion angles C–C–C–C being 39.2, 58.1, and finally 111.5°, respectively. This may also explain why the formation of azaallyl complexes is far more facile in the case of 1,7-octadiyne where the phosphaallyl complexes contain a six-membered ring system than with 1,6-heptadiyne where these complexes feature a more rigid five-membered ring. The subsequent conversion of **G** to the $\eta^1$-phosphaallyl–$\eta^3$-azaallyl complexes **H** requires merely 0.4 kcal/mol activation energy and is energetically very favorable, releasing 18.5 kcal/mol (Figure 13).

Finally, we also looked for a plausible mechanism of the formation of amido-butadiene complexes (**I**) from allyl carbene complexes (**B**). This reaction is obviously restricted to aminophosphane ligands possessing NH protons. An energetically feasible pathway with the model complexes [CpRu{=CH-($\eta^3$-CHCHCH–$PH_2NH_2$)}]$^+$ and [CpRu{=CH-($\eta^3$-CHCHCH–$PMe_2NHMe$)}]$^+$ (**A**) is shown in Figure 14. Accordingly, the N–H proton in **B** is transferred to the carbene carbon atom by transition state $\mathbf{TS_{HI}}$ without any involvement of the metal center. This reaction has an activation barrier of 17.7 kcal/mol (18.1 kcal/mol for $PMe_2NHMe$) and is exothermic releasing 8.4 kcal/mol (11.0 kcal/mol for $PMe_2NHMe$). Therefore, in the case of complexes with

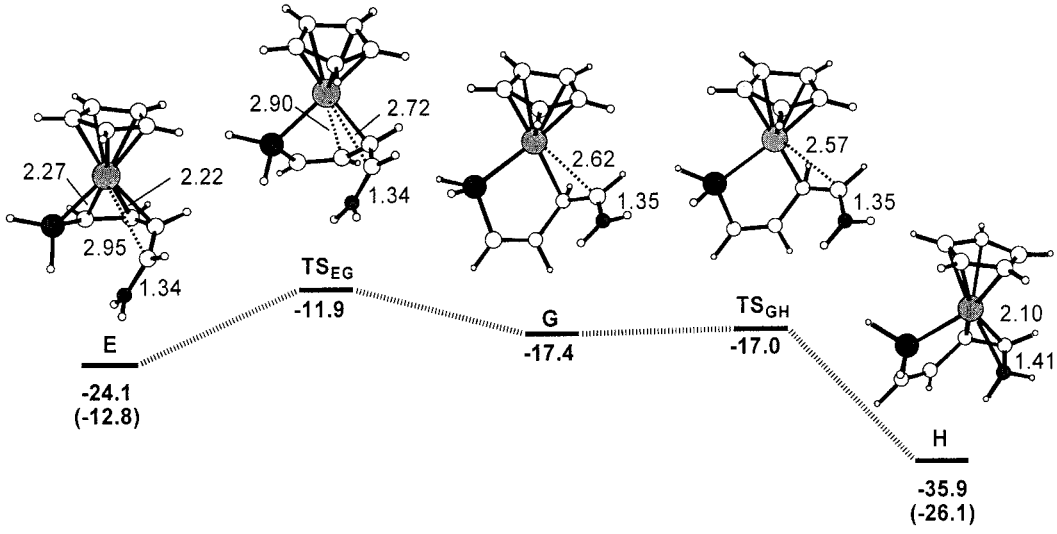

Figure 13. Energy profile (in kcal/mol, relative to **B**) for the conversion of **E** to **H** with $PH_2NH_2$ as model aminophosphane ligand. The numbers in parentheses refer to $PMe_2NHMe$ as the model ligand.

aminophosphanes that contain N–H bonds, this pathway becomes competitive with the formation of phosphaallyl (**F**) and azaallyl complexes (**H**). It should be noted that we were unable to find an alternative pathway to obtain amido butadiene complexes by oxidative addition of the N–H bond to the metal center.

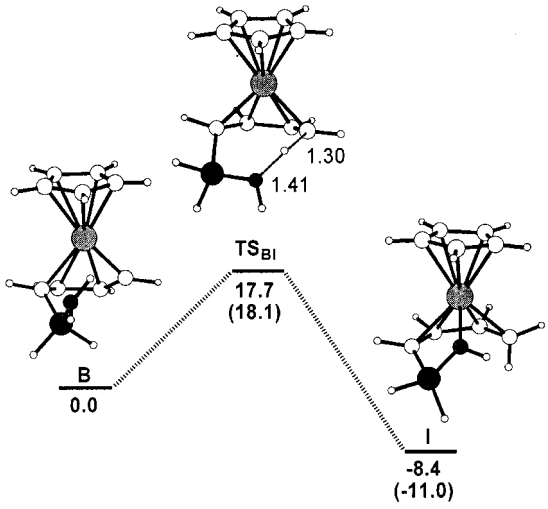

Figure 14. Energy profile (in kcal/mol, relative to **B**) for the reaction of **B** to **I** with $PH_2NH_2$ as model aminophosphane ligand. The numbers in parentheses refer to $PMe_2NHMe$ as the model ligand.

## Experimental Section

**General:** Manipulations were performed under inert purified argon by using Schlenk techniques and/or a glovebox. All chemicals were standard reagent grade and used without further purification. The solvents were purified according to standard procedures.[20] The deuterated solvents were purchased from Aldrich and dried with 4 Å molecular sieves. $[RuCp(CH_3CN)_3]PF_6$,[21] $[RuCp^*(CH_3CN)_3]PF_6$,[22] and $PPh_2NHNMe_2$[23] were prepared according to the literature. $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded with Bruker Avance-250 and -300 spectrometers and were referenced to $SiMe_4$ and $H_3PO_4$ (85%), respectively. $^1H$ and $^{13}C\{^1H\}$ NMR signal assignments were confirmed by $^1H$-COSY, 135-DEPT, and HSQC($^1H$-$^{13}C$) experiments.

**$[RuCp(PPh_2NH$*n*$Pr)(CH_3CN)_2]PF_6$ (1a):** $PPh_2NH$*n*Pr (185 mg, 0.76 mmol) was added to a solution of $[RuCp(CH_3CN)_3]PF_6$ (300 mg, 0.69 mmol) in $CH_2Cl_2$ (10 mL) and the mixture was stirred for 2 h at room temperature. After removal of the solvent, a yellow powder was obtained which was collected on a glass frit, washed with $Et_2O$ (3 × 10 mL), and dried under vacuum. Yield: 421 mg (95%). $C_{24}H_{29}F_6N_3P_2Ru$ (636.52): calcd. C 45.29, H 4.59, N 6.60; found C 45.23, H 4.79, N 6.74. $^1H$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 7.69–7.42 (m, 10 H, Ph), 4.43 (s, 5 H, Cp), 2.85–2.66 (m, 2 H, *n*Pr), 2.50–2.32 (m, 1 H, N*H**n*Pr), 2.20 (d, $J_{HP}$ = 1.4 Hz, 6 H, $CH_3CN$), 1.51 –1.30 (m, 2 H, *n*Pr), 0.80 (t, $J_{HH}$ = 7.4 Hz, 3 H, *n*Pr) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 136.1 (d, $^1J_{CP}$ = 48.7 Hz, Ph$^1$), 131.6 (d, $^2J_{CP}$ = 11.9 Hz, Ph$^{2,6}$), 130.0 (d, $^4J_{CP}$ = 1.9 Hz, Ph$^4$), 128.2 (d, $^3J_{CP}$ = 10.0 Hz, Ph$^{3,5}$), 126.7 ($CH_3CN$), 76.6 (d, $J_{CP}$ = 2.3 Hz, Cp), 45.8 (d, $J_{CP}$ = 8.0 Hz, $CH_2$), 24.9 (d, $J_{CP}$ = 5.8 Hz, $CH_2$), 11.0 ($CH_3$), 3.7 ($CH_3CN$) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 86.0 ($PPh_2$), –143.0 ($^1J_{FP}$ = 708.3 Hz, $PF_6$) ppm.

**$[RuCp(PPh_2NEt_2)(CH_3CN)_2]PF_6$ (1b):** This complex has been prepared analogously to **1a** with $[RuCp(CH_3CN)_3]PF_6$ (300 mg, 0.69 mmol) and $PPh_2NEt_2$ (179 mg, 0.69 mmol) as starting materials. Yield: 416 mg (93%). $C_{25}H_{31}F_6N_3P_2Ru$ (650.55): calcd. C 46.16, H 4.80, N 6.46; found C 46.10, H 4.72, N 6.55. $^1H$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 7.61–7.30 (m, 10 H, Ph), 4.26 (s, 5 H, Cp), 3.42–3.20 (m, 4 H, Et), 2.22 (6 H, $CH_3CN$), 0.96 (t, $J_{HH}$ = 7.1 Hz, 3 H, Et) ppm. $^{13}C\{^1H\}$ NMR ($\delta$, $CD_2Cl_2$, 20 °C): 137.4 (d, $^1J_{CP}$ = 46.0 Hz, Ph$^1$), 131.4 (d, $^2J_{CP}$ = 11.5 Hz, Ph$^{2,6}$), 129.7 (d, $^4J_{CP}$ = 1.9 Hz, Ph$^4$), 128.0 (d, $^3J_{CP}$ = 9.6 Hz, Ph$^{3,5}$), 127.3 ($CH_3CN$), 77.4 (d, $J_{CP}$ = 2.3 Hz, Cp), 42.4 (d, $J_{CP}$ = 6.5 Hz, $CH_2$), 13.6 (d, $J_{CP}$ = 2.3 Hz, $CH_3$), 3.7 ($CH_3CN$) ppm. $^{31}P\{^1H\}$ NMR ($\delta$, $CD_2Cl_2$, 20 °C): 102.1 ($PPh_2$), –143.0 ($^1J_{FP}$ = 711.8 Hz, $PF_6$) ppm.

**$[RuCp(PPh_2NC_5H_{10})(CH_3CN)_2]PF_6$ (1c):** This complex has been prepared analogously to **1a** with $[RuCp(CH_3CN)_3]PF_6$ (374 mg, 0.86 mmol) and $PPh_2NC_5H_{10}$ (232 mg, 0.86 mmol) as starting materials. Yield: 500 mg (88%). $C_{26}H_{31}F_6N_3P_2Ru$ (662.56): calcd. C 47.13, H 4.72, N, 6.34; found C 46.66, H 4.89, N 6.51. $^1H$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 7.66–7.26 (m, 10 H, Ph), 4.23 (s, 5 H, Cp), 3.30–3.01 (m, 4 H, $NC_5H_{10}$), 2.20 (d, $J_{HP}$ = 1.0 Hz, 6 H, $CH_3CN$), 1.72–1.36 (m, 6 H, $NC_5H_{10}$) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 136.6 (d, $^1J_{CP}$ = 46.0 Hz, Ph$^1$), 131.2 (d, $^2J_{CP}$ = 11.1 Hz, Ph$^{2,6}$), 129.7 (d, $^4J_{CP}$ = 1.9 Hz, Ph$^4$), 128.1 (d, $^3J_{CP}$ = 9.6 Hz, Ph$^{3,5}$), 127.3 ($CH_3CN$), 77.4 (d, $J_{CP}$ = 2.3 Hz, Cp), 50.1 (d, $J_{CP}$ = 3.4 Hz, $CH_2$), 27.0 (d, $J_{CP}$ = 5.4 Hz, $CH_2$), 24.4 ($CH_2$), 3.7 ($CH_3CN$) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 98.8 ($PPh_2$), –143.0 ($^1J_{FP}$ = 710.5 Hz, $PF_6$) ppm.

**$[RuCp^*(PPh_2NH$*n*$Pr)(CH_3CN)_2]PF_6$ (2a):** $PPh_2NH$*n*Pr (145 mg 0.60 mmol) was added to a solution of $[RuCp^*(CH_3CN)_3]PF_6$ (300 mg, 0.60 mmol) in $CH_2Cl_2$ (5 mL) and the mixture was stirred for 2 h at room temperature. The volume of the solution was then reduced to about 1 mL and $Et_2O$ (5 mL) was added. A yellow precipitate was formed, which was washed with $Et_2O$ (2 × 5 mL) and dried under vacuum. Yield: 336 mg (80%) $C_{29}H_{39}F_6N_3P_2Ru$ (706.66): calcd. C 49.29, H 5.56, N 5.95; found: C 48.94,; H 6.09, N 5.59. $^1H$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 7.65–7.40 (m, 10 H, Ph), 3.09–2.85 (m, 1 H, NH), 2.74 (m, $J_{HH}$ = 6.9 Hz, 2 H, $CH_2$), 2.23 (d, $J_{HP}$ = 1.3 Hz, 6 H, $CH_3CN$), 1.49 (d, $J_{HP}$ = 1.7 Hz, 15 H, Cp*), 1.27–1.21 (m, 2 H, $CH_2$), 0.84 (t, $J_{HH}$ = 7.5 Hz, 3 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 135.4 (d, $^1J_{CP}$ = 43.7 Hz, Ph$^1$), 132.0 (d, $^2J_{CP}$ = 11.5 Hz, Ph$^{2,6}$), 129.7 (Ph$^4$), 128.0 (d, $^3J_{CP}$ = 9.2 Hz, Ph$^{3,5}$), 124.7 ($CH_3CN$), 86.8 (Cp*), 46.0 (d, $J_{CP}$ = 9.2 Hz, $CH_2$), 25.0 (d, $J_{CP}$ = 6.1 Hz, $CH_2$), 10.5 ($CH_3$), 9.1 (Cp*), 3.8 ($CH_3CN$) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 82.9 ($PPh_2$), –144.5 ($^1J_{FP}$ = 710.2 Hz, $PF_6$) ppm.

**$[RuCp^*(PPh_2NEt_2)(CH_3CN)_2]PF_6$ (2b):** This complex has been prepared analogously to **2a** with $[RuCp^*(CH_3CN)_3]PF_6$ (300 mg, 0.60 mmol) and $PPh_2NEt_2$ (153 mg 0.60 mmol) as starting materials. Yield: 350 mg (82%) $C_{30}H_{41}F_6N_3P_2Ru$ (720.68): calcd. yellow precipitate was formed, which was collected on a glass frit, washed with $Et_2O$ (3 × 10 mL), and dried under vacuum. $^1H$ NMR spectroscopy revealed that **9** and **10** were formed in an approximately 5:1 ratio. If the same reaction was performed in the presence of acetonitrile (40 μL, 0.77 mmol), complex **9** was exclusively obtained. Yield: 398 mg (84%). $C_{23}H_{28}F_6N_4P_2Ru$ (637.51): calcd. C 43.33, H 4.43, N 8.79; found C 42.98; H 4.50, N 8.61. $^1H$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 7.74–7.54 (m, 4 H, Ph), 7.53–7.39 (m, 6 H, Ph), 4.45 (s, 5 H, Cp), 3.51 (d, $^2J_{HP}$ = 34.1 Hz, 1 H, N*H*), 2.27 (6 H, $CH_3$), 2.26 (d, $J_{HP}$ = 1.3 Hz, 6 H, $CH_3CN$) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 136.2 (d, $^1J_{CP}$ = 51.7 Hz, $Ph^1$), 132.6 (d, $^2J_{CP}$ = 12.1 Hz, $Ph^{2,6}$), 130.2 (d, $^4J_{CP}$ = 2.3 Hz, $Ph^4$), 127.9 (d, $^3J_{CP}$ = 9.8 Hz, $Ph^{3,5}$), 127.0 ($CH_3CN$), 76.4 (d, $J_{CP}$ = 2.9 Hz, Cp), 49.9 (d, $J_{CP}$ = 3.4 Hz, $CH_3$) 3.8 (d, $J_{CP}$ = 1.2 Hz, $CH_3CN$) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 90.6 ($PPh_2$), –142.9 ($^1J_{FP}$ = 710.8 Hz, $PF_6$) ppm. All attempts to grow crystals of **9** were unsuccessful. Crystals of **10** were grown by diffusion of diethyl ether into a $CH_2Cl_2$ solution of the reaction mixture containing **9** and **10**. **10**: $^1H$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 7.72–7.36 (m, 10 H, Ph), 4.48 (s, 5 H, Cp), 3.35 (s, 3 H, Me), 2.82 (s, 3 H, Me), 2.14 (d, $J_{HP}$ = 1.6 Hz, $CH_3CN$) ppm. The NH proton could not be detected. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 132.9–128.5 (Ph), 128.1 ($CH_3CN$), 73.0 (Cp), 63.9 ($CH_3$), 57.8 ($CH_3$), 3.85 ($CH_3CN$) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 61.4 ($PPh_2$), –142.9 ($^1J_{FP}$ = 711.5 Hz, $PF_6$) ppm.

**X-ray Structure Determination:** Crystals of **1a**, **2a**, **3c**, **3f**, **4a**, **5a**, **6a**, **6b**, **8c·$CH_2Cl_2$**, **8d**, and **10** were obtained by diffusion of $Et_2O$ or pentane into $CH_2Cl_2$ solutions. Crystal data and experimental details are given in Table 1 and Table 2. X-ray data were collected with a Bruker Smart APEX CCD area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and 0.3° $\omega$-scan frames covering mostly complete spheres of the reciprocal space. Corrections for absorption (multi-scan method), $\lambda/2$ effects, and crystal decay were applied.[24] The structures were solved by direct methods using the program SHELXS97.[25] Structure refinement on $F^2$ was carried out with the program SHELXL97.[24] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were inserted in idealized positions and were refined riding with the atoms to which they were bonded, except for N-bound hydrogen atoms, which were refined in *x*,*y*,*z* if permitted by data quality.[26] Compound **6b** crystallizes in the acentric triclinic space group *P*1 (no. 1) with three independent Ru complexes in the unit cell. Two of these three complexes adopt a pseudocentric arrangement (pseudo space group $P\bar{1}$) while the third complex does not comply with this symmetry. In Figure 8 only the first of these three complexes is shown as a representative example.

CCDC-286740 to -286750 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** All calculations were performed using the Gaussian98 software package on the Silicon Graphics Origin 2000 of the Vienna University of Technology.[27] The geometry and energy of the model complexes and the transition states were optimized at the B3LYP level[28] with the Stuttgart/Dresden ECP (SDD) basis set[29] to describe the electrons of the ruthenium atom. For the C, N, P, and H atoms the 6-31g** basis set was employed.[30] A vibrational analysis was performed to confirm that the structures of the model compounds have no imaginary frequency. Transition state optimizations were performed with the Synchronous Transit-Guided Quasi-Newton Method (STQN) developed by Schlegel et al.[31] Frequency calculations were performed to confirm the nature of the stationary points, yielding one imaginary frequency for the transition states and none for the minima. The vibrational eigenvectors corresponding to the reaction coordinate (with imaginary frequency) of all transition states were visually checked to confirm the connectivity of transition states with the reactants and the products. Crucial transition states have been confirmed by IRC calculations. All geometries were optimized without symmetry constraints.

Table 2. Details for the crystal structure determinations of complexes **6a**, **6b**, **8c·$CH_2Cl_2$**, **8d**, and **10**.

# Mono- versus Binuclear Copper(II) Complexes in Phosphodiester Hydrolysis

**Katalin Selmeczi,[a,c] Michel Giorgi,[c] Gábor Speier,[a,b] Etelka Farkas,[d] and Marius Réglier*[c]**

**Keywords:** Catalysis / Dinuclear copper(II) complex / Enzyme mimics / Phosphate ester hydrolysis / Tripodal ligands

Mono- and dinuclear copper(II) complexes [Cu(**L$^1$OH**)]-$(CF_3SO_3)_2$ (**1**) and [$Cu_2$(**L$^2$O**)]$(CF_3SO_3)_3$ (**2**) have been synthesized and characterized by X-ray crystallography. Complexes **1** and **2** were then tested as catalysts for the hydrolysis of bis(*p*-nitrophenyl)phosphate (BNPP). At pH 6, the dinuclear complex **2** was found to be 20-fold more active than complex **1** and the reaction up to 600-fold faster than the un-promoted reaction. On the basis of potentiometric studies, we were able to demonstrate that the bis(aqua)copper complex was the active species by the formation of a ternary complex in which one copper atom binds to a hydroxide and the second, to the substrate. We also propose that BNPP reacts with the bis(aqua)copper complex to give a stable, hydrolytically inactive BNPP-**2** complex (**3**).

## Introduction

During the last decade, there has been increasing interest in the development of metal complexes which promote the hydrolysis of phosphate ester linkages.[1,2] The main approach developed in this domain concerns the design of functional models for hydrolytic metalloenzymes. Beside their important roles in the understanding of their mechanisms, the development of hydrolytic metalloenzyme mimics are of great importance in biotechnology for the design of synthetic nucleases which could be used as artificial restriction enzymes. On the other hand, since a number of phosphate esters and related phosphorus(V) compounds are used in agriculture as pesticides or, unfortunately, as potent nerve agents in chemical weaponry (mustard gases), the development of catalytic systems able to hydrolyze and destroy such compounds is of considerable environmental and medicinal importance.

Among the metalloenzymes which catalyze the hydrolysis of the phosphate ester linkage, metallonucleases are important because they are ubiquitous and essential for living organisms.[3] Certainly, due to its high natural abundance and good Lewis acid properties, $Mg^{2+}$ is the most important metal encountered in nuclease active sites. Multinuclear transition metal centers with $Zn^{2+}$, $Mn^{2+}$ and $Fe^{2+}$ are often present too. As examples, in enzymes which hydrolyze phosphodiesters into phosphomonoesters, the active site of alkaline phosphatase contains a dinuclear $Zn^{2+}$ core,[4] while the active site present in purple acid phosphatases (PAPs) contains one $Fe^{3+}$ associated to a $Fe^{2+}$ (or $Zn^{2+}$, $Mn^{2+}$).[5] In the commonly disclosed mechanism, one of the metal ions (the one with the highest Lewis acidity) favors the formation and co-ordination of a hydroxide ion at physiological pH, while the second one activates the phosphate ester group for intramolecular nucleophilic attack by the adjacent hydroxide. On the basis of this mechanism, nuclease mimics incorporating dinuclear metal centers with Co,[6,7] Ln,[8,9] Zn[10,11] and Fe[12] were recently published as efficient bioinspired catalysts for phosphoester hydrolysis.

While the copper ion has never been identified as a cofactor in natural nucleases, $Cu^{2+}$ exhibits some interesting features rendering it attractive for artificial nucleases: (*i*) $Cu^{2+}$ is substitutionally labile and at the same time a strong Lewis acid necessary for the activation of the phosphodiester bond towards nucleophilic attack and (*ii*) $Cu^{2+}$ lowers the p$K_a$ of coordinated water, thereby providing metal-bound hydroxide at near-neutral pH. That is why binuclear[13,14] complexes of $Cu^{2+}$ have also been described as efficient bioinspired catalysts in phosphoester hydrolysis.

The importance of nuclearity (mononuclear vs. dinuclear) was clearly demonstrated for $Fe^{3+}$.[12] The situation is less clear for copper since mononuclear $Cu^{2+}$ complexes were also reported in the literature as agents with good activity.[15,16] We report in this paper the kinetics of BNPP hydrolysis by the dinuclear [$Cu_2$(**L$^2$O**)]$(CF_3SO_3)_3$ (**2**), in order to study the influence of the nuclearity of copper com-

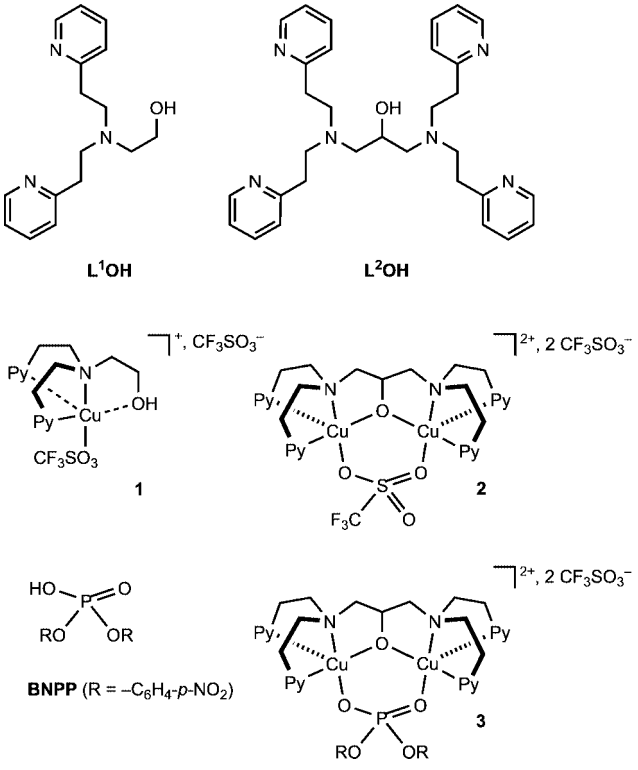
plexes, including a quantitative comparison with the mononuclear parent complex [Cu(**L$^1$OH**)](CF$_3$SO$_3$)$_2$ (**1**).

## Results and Discussion

**Synthesis:** Michael addition of 2-ethanolamine or 1,3-diamino-2-hydroxypropane to freshly distilled 2-vinylpyridine in methanol/acetic acid leads to ligands **L$^1$OH** and **L$^2$OH**, respectively.[17] The corresponding copper(II) complexes **1** and **2** were obtained in good yields by treatment with 1 equiv. of ligands **L$^1$OH** and **L$^2$OH** in dichloromethane with 1 and 2 equiv. of copper(II) triflate, respectively.[18] Complex **3** was prepared by mixing 1 equiv. of complex **2** in water with 1 equiv. of BNPP in methanol at room temperature (Scheme 1).



Scheme 1.

**Crystal Structures:** Crystal data for complexes **1** and **3**, together with details of the X-ray diffraction experiment, are reported in Table 5.

Single crystals of [Cu(**L$^1$OH**)](CF$_3$SO$_3$)$_2$ (**1**) suitable for X-ray diffraction analysis were obtained by slow diethyl ether vapor diffusion into a saturated acetone solution of the copper complex **1**. [Cu(**L$^1$OH**)](CF$_3$SO$_3$)$_2$ (**1**) is a mononuclear complex with a five-coordinate copper(II) cation (Figure 1). The geometry around the copper(II) ion is clearly a quite perfect square pyramid as it can be seen from the geometric parameters and the $\tau$ factor which is equal to 0.04.[19] The equatorial positions are occupied by one pyridine N atom (N3) and the nitrogen N1 and oxygen O19 of the ethanolamine moiety. The fourth equatorial ligand is the oxygen atom of a triflate counterion. The nitrogen N2 of the second pyridine occupies the axial coordination site at a distance equal to 2.171(4) Å from the copper, which is typically somewhat longer than the equatorial copper to pyridine distance [$d_{Cu–N3}$ = 1.979(4) Å]. The deviation of the copper atom from the mean basal plane defined by atoms N1, N3, O1 and O19 is equal to 0.291 Å.

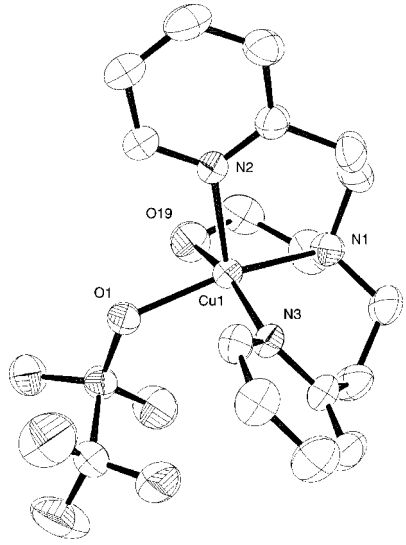


Figure 1. ORTEP perspective view of copper(II) complex [Cu(**L$^1$OH**)](CF$_3$SO$_3$)$_2$ (**1**). The H atoms and one CF$_3$SO$_3^-$ counterion are omitted for clarity. Bond lengths are in Å: Cu–N1 2.044(4), Cu–N2 2.171(4), Cu–N3 1.979(4), Cu–O1 2.042(3), Cu–O19 1.973(4). Bond angles are in °: N1–Cu–N2 96.93(16), N3–Cu–O1 88.51(15), N3–Cu–N2 100.28(19), N3–Cu–N1 95.26(17), O1–Cu–N2 98.14(15), O19–Cu–N1 84.54(18), O19–Cu–N2 98.4(2), O1–Cu–N1 163.55(16), O19–Cu–O1 86.77(17), O19–Cu–N3 161.21(18). Numbers in parentheses are the estimated standard deviation in the least significant digits.

For the complex **2**, suitable crystals for X-ray diffraction analysis were obtained by slow diethyl ether vapor diffusion into a saturated dichloromethane solution. The structure of [Cu$_2$(**L$^2$O**)](CF$_3$SO$_3$)$_3$ (**2**), already described in a previous paper,[18] consists of a binuclear complex with two tetragonally coordinated Cu$^{II}$ ions bridged in the equatorial positions by the alkoxide and triflate ligands (Figure 2). The Cu–Cu distance was found to be 3.699(3) Å. This is somewhat longer than that found e.g. in the similar [Cu$_2$(**L$^2$O**)(OMe)](PF$_6$)$_2$ [2.995(2) Å].[20] The two positions in the basal plane of the copper ions are occupied by one of the pyridine nitrogen atoms and the aliphatic nitrogen of the ligand **L$^2$OH**. The other two equatorial positions are occupied by the oxygen atoms O1 of the ligand **L$^2$OH** and O2 of the triflate anion. As in complex **1**, the geometry around both coppers is a square pyramidal ($\tau$ = 0.11) and the distance of the Cu–atoms to the mean plane defined by atoms O1, O2, N1 and N2 is equal to 0.308 Å. The axial pyridine N3 donor, which is bound to the Cu$^{II}$ atom at a distance of 2.179(4) Å, is a bit longer than the equatorial pyridine donor N2 [Cu1–N2 2.009(3) Å]. The bond lengths

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and bond angles of **2** shows similarities to other dicopper complexes with ligands derived from 1,3-diamino-2-hydroxypropane.[20–22]

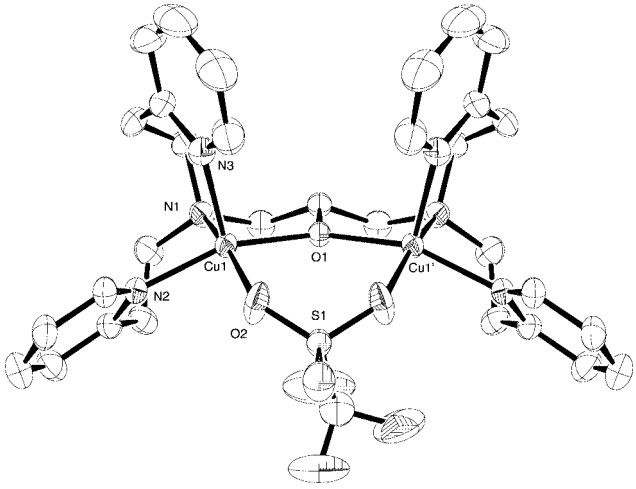

Figure 2. ORTEP perspective view of the copper(II) complex $[Cu(\mathbf{L^2O})](CF_3SO_3)_2$ (**2**). The H atoms and 2 $CF_3SO_3^-$ counterion are omitted for clarity. Bond lengths are in Å: Cu1–O1 1.9695(12), Cu1–N2 2.009(3), Cu1–N1 2.032(3), Cu1–O2 2.047(3), Cu1–N3 2.179(4). Bond angles are in °: O1–Cu1–N2 159.45(14), O1–Cu1 N1 87.04(12), N2–Cu1–N1 94.17(12), O1–Cu1–O2 90.54(12), N2–Cu1–O2 83.10(13), N1–Cu1–O2 165.31(15), O1–Cu1–N3 104.69(11), N2–Cu1–N3 95.40(10), N1–Cu1–N3 98.93(14), O2–Cu1–N3 95.71(16). Numbers in parentheses are the estimated standard deviation in the least significant digits.

Slow solvent evaporation of a solution of $[Cu_2(\mathbf{L^2O})(BNPP)](CF_3SO_3)_2$ (**3**) (Figure 3) gave deep blue crystals suitable for X-ray diffraction analysis. The structure of **3** consists of a binuclear copper(II) complex in which the Cu atoms are bridged together through the BNPP in a bidentate coordination and the alkoxide of the ligand $\mathbf{L^2OH}$. The geometries of the metals are approximately distorted square pyramidal, the $\tau$ parameter is equal to 0.14 and 0.26 for Cu1 and Cu2, respectively. As in complex **2**, the equatorial positions are occupied by the N atom from a pyridine, the nitrogen and the O atoms of the ethanolamine moiety, as well as the O atom of the BNPP ligand. The apical positions are taken by the nitrogen atoms of the remaining pyridines. The copper to nitrogen distances are slightly longer than in complex **2**: Cu1–N3 2.2432(4) Å and Cu2–N5 2.1864(4) Å. As for **2**, the bases of both pyramids, defined by atoms O1, O3, N1, N2 and O1, O4, N4, N6, respectively, are close to planarity and the out of plane distances of the copper atoms are equal to 0.25 Å and 0.27 Å for Cu1 and Cu2, respectively. The distance between the two copper ions is equal to 3.7252(2) Å which is slightly longer than that observed for complex **2**. This can be explained by the nature of the BNPP ligand which is coordinated to the complex by the two nitrophenyl rings and shows a stabilizing interaction with the $\mathbf{L^2OH}$ ligand which is not observed in complex **2**. The phenyl ring of the BNPP ligand, defined by the atoms C38–C43, is involved in a π-stacking interaction with the pyridine, defined by atoms N6, C20–C24. On the another hand, the second nitrophenyl ring of the BNPP ligand is involved in a CH-π contact with the two apical pyridines of the $\mathbf{L^2OH}$ ligand (the distances between the centroid of the ring, defined by the atoms C32–C37 and the H atoms of C16 and C30, are equal to 3.46 Å and 3.73 Å, respectively). Consequently, the distance between the centroid of the axial pyridines is longer than in complex **2** [$d$ = 5.4236(5) Å for **3** and $d$ = 4.958(4) for **2**] and the dihedral angle between both aromatic rings increases from 77° in **2** to 84.18° in **3**.

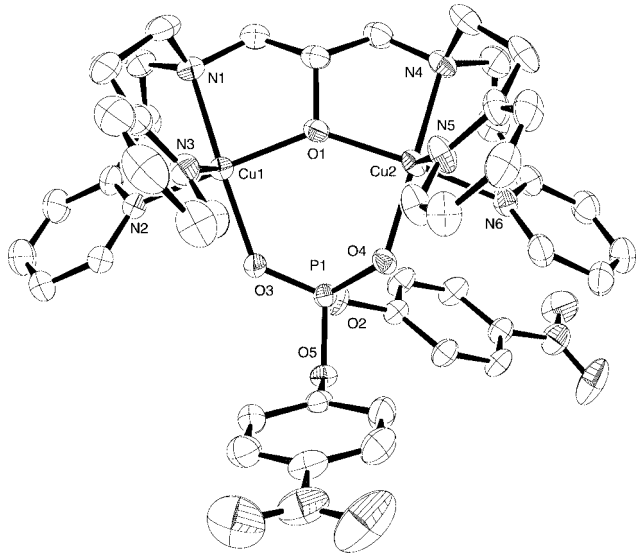

Figure 3. ORTEP perspective view of the copper(II) complex $[Cu_2(\mathbf{L^2O})(BNPP)](CF_3SO_3)_2$ (**3**). The H atoms and 2 $CF_3SO_3^-$ counterion are omitted for clarity. Bond lengths are in Å: Cu1–O1 1.9823(3), Cu1–O3 1.9854(3), Cu1–N1 2.0628(4), Cu1–N2 2.0116(4), Cu1–N3 2.2432(4), Cu2–O1 1.9874(3), Cu2–O4 1.9733(3), Cu2–N4 2.0595(4), Cu2–N5 2.1864(4), Cu2–N6 2.0230(4). Bond angles are in °: O1–Cu1–O3 92.409(13), O1–Cu1–N1 86.28(2), O1–Cu1–N2 161.41(2), O1–Cu1–N3 102.662(14), O3–Cu1–N1 169.72(2), O3–Cu1–N2 86.358(15), O3–Cu1–N3 94.77(2), N1–Cu1–N2 91.63(2), N1–Cu1–N3 95.47(2), N2–Cu1–N3 95.92(2), O1–Cu2–O4 92.451(12), O1–Cu2–N4 86.62(2), O1–Cu2–N5 106.976(14), O1–Cu2–N6 157.079(15), O4–Cu2–N4 172.71(2), O4–Cu2–N5 91.56(2), O4–Cu2–N6 86.104(15), N4–Cu2–N5 95.63(2), N4–Cu2–N6 91.93(2), N5–Cu2–N6 95.93(2). Numbers in parentheses are the estimated standard deviation in the least significant digits.

**Acid-Base Equilibrium Determination:** The distribution of different species in an aqueous solution is essential for understanding the activity of the complexes in phosphate ester hydrolysis. The protonation constants of the ligands $\mathbf{L^1OH}$ and $\mathbf{L^2OH}$ (Table 1), as well as the stability constants of their copper complexes and the p$K_a$ values of their copper-bound water molecules (Table 2), were determined by potentiometric titration in 0.2 M aqueous KCl at 40 °C.

In the case of $\mathbf{L^1OH}$, three protonation steps were found in the 2–11 pH range. The p$K_a$ values of 2.82(2) and 3.89(2) are assigned to the deprotonation of the pyridine N atoms and the third at 7.71(1) to that of the tertiary amine. Deprotonation of the OH group does not occur in the detectable pH range.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 1. Protonation constants of the ligands at 40 °C [$I$ = 0.2 M (KCl)].

| Species | p$K$ | |
|---|---|---|
| | **L$^1$OH** | **L$^2$OH** |
| $[LH_6]^{6+}$ | | <<2 |
| $[LH_5]^{5+}$ | | 2.66(2) |
| $[LH_4]^{4+}$ | | 3.41(5) |
| $[LH_3]^{3+}$ | 2.82(2) | 4.25(5) |
| $[LH_2]^{2+}$ | 3.89(2) | 5.83(7) |
| $[LH]^{+}$ | 7.71(1) | 7.92(1) |

Table 2. Overall stability constants (log$\beta$) and stepwise deprotonation constants (p$K$) of the copper complexes at 40 °C [$I$ = 0.2 M (KCl)].

| Species | **L$^1$OH** | | **L$^2$OH** | |
|---|---|---|---|---|
| | log$\beta$ | p$K$ | log$\beta$ | p$K$ |
| $\{[\mathbf{L^1OH_2}]Cu(H_2O)\}^{3+}$ (**C**) | 11.48(8) | | | |
| $\{[\mathbf{L^1OH}]Cu(H_2O)\}^{2+}$ (**A**) | 9.02(3) | 2.46 | | |
| $\{[\mathbf{L^1O}]Cu(H_2O)\}^{+}$ (**B**) | 2.91(5) | 6.11 | | |
| $\{[\mathbf{L^2OH}]Cu_2(H_2O)_2\}^{4+}$ (**D**) | | | 17.88(2) | |
| $\{[\mathbf{L^2O}]Cu_2(H_2O)_2\}^{3+}$ (**E**) | | | 14.14(6) | 3.74 |
| $\{[\mathbf{L^2O}]Cu_2(H_2O)(OH)\}^{2+}$ (**F**) | | | 8.0(6) | 6.14 |

In the case of **L$^2$OH**, three additional deprotonation steps were observed; the first is estimated to occur at a pH less than 2 which is out of the detectable range. In the following steps one proton is removed from each pyridine N atom and the p$K_a$ values at 5.83(7) and 7.92(1) correspond to the deprotonation of the two tertiary amines. Again, the proton of the OH group is not removed up to pH 11.

Titration of the ligands in the presence of various equivalents of $Cu^{2+}$ was also analyzed (Figure 4). In aqueous solution it is reasonable to assume that the bridging triflate anions in **1** and **2** are replaced by water molecules. For the [**L$^1$OH**]:[$Cu^{2+}$] 1:1 system, at a pH higher than 8 and for the [**L$^1$OH**]:[$Cu^{2+}$] 1:2 system at a pH higher than 4, precipitation of copper hydroxide was observed, and neither the mononuclear species at pH > 8 nor the dinuclear species could be determined. Equilibrium modeling from the titration results indicate that two predominant species $\{[\mathbf{L^1OH}]Cu(H_2O)\}^{2+}$ (**A**) and $\{[\mathbf{L^1O}]Cu(H_2O)\}^{+}$ (**B**) are formed in addition to a small amount of the species (**C**) (Scheme 2), where one pyridine N atom is protonated. At a p$K_a$ of 6.11 the ligand OH group in **A** is deprotonated to give the species $\{[\mathbf{L^1O}]Cu(H_2O)\}^{+}$ (**B**). The formation of this species was confirmed by spectrophotometric titration (Figure 5) where an important increase in $\varepsilon$ was observed at 374 nm in the pH range 5.5–7 this was attributed to the formation of the RO–Cu$^{II}$ LMCT band ($\varepsilon$ = 60 M$^{-1}$cm$^{-1}$ at pH 5.5 and $\varepsilon$ = 570 M$^{-1}$cm$^{-1}$ at pH 7). No formation of binuclear species in the pH range examined was observed by ESR spectroscopy.

In the case of **L$^2$OH**, no precipitation of copper hydroxide occurs, and the formation of a dinuclear species starts at a relatively low pH value. The deprotonation of the ligand OH in **D** is observed at acidic pH (p$K$ = 3.74) which is in agreement with the spectrophotometric titration in this pH range (Figure 6). A distinct peak forms at 365 nm ($\varepsilon$ =

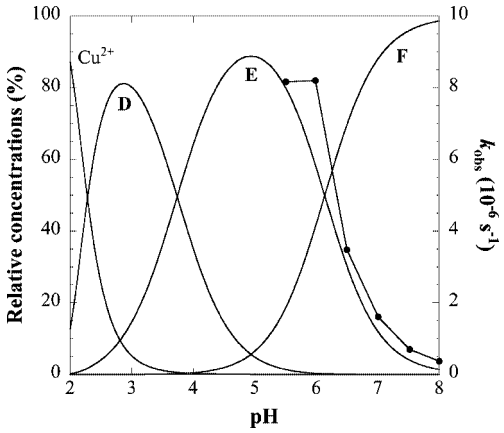

Figure 6. Species distribution of the complexes of **L²OH** (5 mM) with 2 equiv. $Cu^{2+}$ in 0.2 M KCl at 40 °C and pH/rate profile for BNPP hydrolysis promoted by **2**; [**2**] = 0.488 mM, [BNPP] = 0.192 mM at 40 °C.

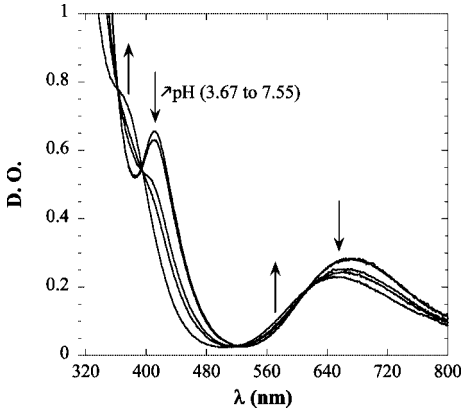

Figure 7. UV/Vis spectra of **2** at various pH values (3.67, 4.53, 5.77, 6.11 and 7.55).

2100 $M^{-1}cm^{-1}$) when the pH is raised and it can be assigned as the RO–$Cu^{II}$ LMCT band. A p$K_a$ of 6.14 for {[**L²O**]-$Cu_2OH(H_2O)$}$^{2+}$ signifies that the metal-bound water is deprotonated. At this pH, the UV/Visible absorption spectrum shows some variations, the peak at 365 nm becomes a weak shoulder with an important decrease in intensity (Figure 7; $\varepsilon$ = 1030 $M^{-1}cm^{-1}$). Similar UV/Visible features have been previously observed for several related (μ-phenoxo)dicopper(II) complexes.[23,24] This probably indicates the formation of the double bridged (μ-alkoxo)(μ-hydroxo)-dicopper(II) complex **G**. ESR silent spectra observed at a pH higher than 7, seem to confirm this proposal.

**Phosphate Hydrolysis:** The efficiency of [$Cu_2$(**L²O**)]($CF_3SO_3$)$_3$ (**2**) was studied in the 5.5–8 pH range with respect to BNPP hydrolysis and compared to the activity of the parent complex [Cu(**L¹OH**)]($CF_3SO_3$)$_2$ (**1**) (Scheme 3, Table 3). Since, the hydrolysis of BNPP by **1** or **2** proceeds cleanly to give *p*-nitrophenol (PNP) and *p*-nitrophenyl phosphate (MNPP), as revealed by thin-layer chromatography, the progress of the reaction was monitored by the visible absorbance change at 400 nm due to the release of 4-nitrophenolate anion.

Values for the observed initial rate ($V_i$) and the first-order rate ($k_{obs}$ = $V_i$/[BNPP]) constants for the appearance of the *p*-nitrophenolate anion are listed in Table 4 and Table 5 as a function of the pH (Figure 8). While an important effect of pH on the BNPP hydrolysis was observed for **2** (Table 4), the mononuclear complex **1** exhibited only a slight pH effect (Table 5). For **2**, we observed the maximal activity in the 5.5–6 pH range.

In order to find the reactive species, the pH dependence of the initial rate was measured and compared with the species distributions. The plots of $k_{obs}$ vs. pH give a sigmoidal curve and follow the distribution of the complex {[**L²O**]-$Cu_2(H_2O)_2$}$^{3+}$ (**E**) which must be the active species in the

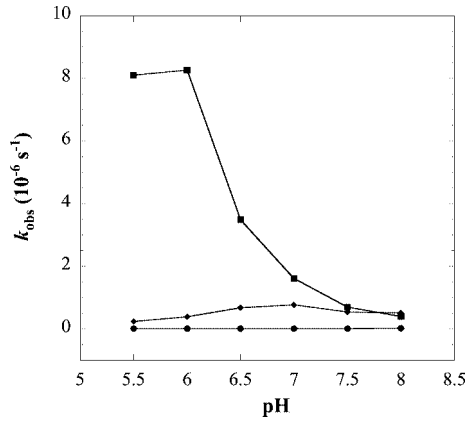

Figure 8. pH dependence on $k_{obs}$ for BNPP hydrolysis promoted by copper complexes **1** (filled diamond) and **2** (filled square) and un-promoted (filled circle).

hydrolysis (Figure 5). For this case the second order constants $k_2$ (M$^{-1}$s$^{-1}$) can be obtained taking into account the quantities of species **E** ($k_2$[2] = $k_{obs}$/[**E**]) (Table 4).

From these kinetic data, it becomes apparent that: (*i*) **2** is more efficient in promoting the hydrolysis of BNPP than the mononuclear copper complex **1** (Table 5, ratio $k_{obs}$[2]/$k_{obs}$[1] > 20) and (*ii*) the rate of the **2**-promoted reaction is up to 600 times faster than the unpromoted reaction. This

means that the copper complex **2** is a good catalyst for phosphate ester hydrolysis in the pH range 5.5–6.0.

In order to gain a better insight into the mechanism, the initial rate was measured as a function of **2** and BNPP concentrations. The rate of BNPP hydrolysis shows a first order dependence on the concentration of the complex **2** (Figure 9). This means that one molecule of **2** is involved in the BNPP hydrolysis. The same result was obtained for complex **1**.

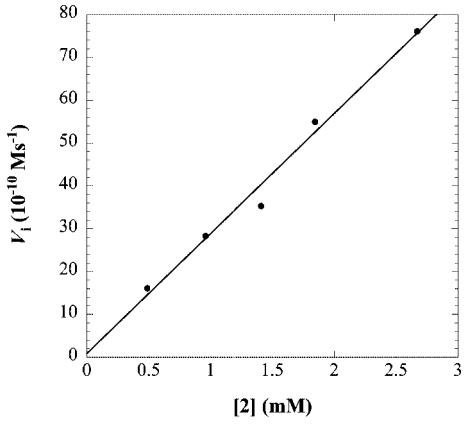

Figure 9. $V_i$ vs. [**2**] of hydrolysis of BNPP. Each reaction mixture contained 50 mM MES/0.1 M KCl, pH 6 at 40 °C and 0.192 mM BNPP. The plotted lines are the computer-generated best fit with $R = 0.9920$.

As shown in Figure 10, saturation was observed when the concentration of BNPP was 1 mM. This indicates a pre-equilibrium related to the formation of the active complex (**2**/substrate) followed by the rate-determining transformation of the substrate with the complex. The treatment of the data, using the Michaelis–Menten model, showed the following constants: $K_M = 0.17$ mM and $k_{cat} = 11.2 \cdot 10^{-6}$ s$^{-1}$. For the complex **1** (0.5 mM) at pH 7, $K_M = 0.65$ mM

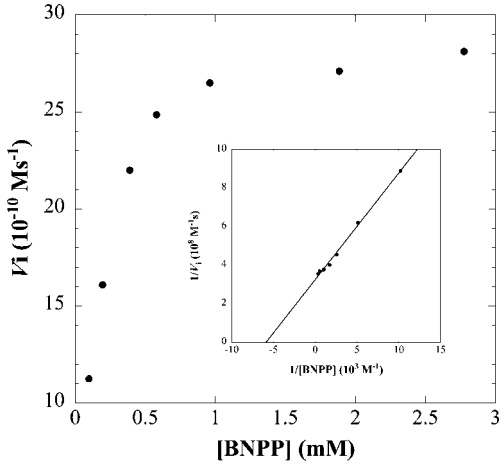

Figure 10. Saturation kinetics of copper complex **2** by BNPP. Each reaction mixture contained 50 mM MES/0.1 M KCl, pH 6 at 40 °C and 0.5 mM **2**. Inset: Lineweaver–Burk plot, the plotted line is the computer-generated best fit ($R = 0.9978$) according to $1/V_i = K_M/(V_{max}[BNPP]) + 1/V_{max}$, where $K_M = 0.17$ mM, $V_{max} = 3.07 \cdot 10^{-9}$ M s$^{-1}$ and $k_{cat} = 11.2 \cdot 10^{-6}$ s$^{-1}$, $\{[\mathbf{L^2O}]Cu_2(H_2O)_2\}^{3+} = 0.55$[**2**].

and $k_{cat} = 1.38 \cdot 10^{-6}$ s$^{-1}$ were obtained taking $[\{[\mathbf{L^1O}]Cu(H_2O)\}^{+}] = 0.89$[**1**].

On the basis of the potentiometric titration study and kinetic data we assume that the bis(aqua)copper complex $\{[\mathbf{L^2O}]Cu_2(H_2O)_2\}^{3+}$ (**E**) is responsible for the BNPP hydrolysis (Figure 5) according to a double Lewis acid activation mechanism. As shown in Scheme 4, the cleavage process may involve the following steps: (*i*) the phosphodiester BNPP coordinates to one copper ion as a monodentate ligand by replacing one water molecule (**E** → **H**); (*ii*) deprotonation of the second water ligand by a phosphate group and the subsequent nucleophilic attack of the phosphate by hydroxide leads to a pentavalent intermediate (**H** → **I**). Nucleophilic attack by free water molecule (Scheme 4, pathway b) can be excluded since the dinuclear complex **2** is more efficient in promoting hydrolysis of BNPP than the mononuclear complex **1** (Table 4, ratio $k_{obs}^{[2]}/k_{obs}^{[1]} > 20$); (*iii*) the P–O bond breaks to give *p*-nitrophenolate followed by the formation of the monoester complex (**I** → **J**); (*iv*) replacement of MNPP by water leads to the active species (**J** → **E**). This mechanism is in good agreement with the results described in the literature. It is generally believed that one of the metal ions serves to reversibly bind the phosphoester substrate whereas the second ion serves to activate a hydroxide ion at a physiological pH. The second metal ion also serves to increase the electrophilic susceptibility of the substrate and neutralizes the anionic substrate, thus moderating the electrostatic repulsion of the attacking nucleophile. The reaction then consists of an intramolecular nucleophilic attack of the adjacent hydroxide at the substrate (P–O bond cleavage).

Other pathways that should be considered are the formation of a bridged phosphate complex **3** (**K**). Due to an appropriate Cu–Cu distance, the formation of these complexes is favorable and stabilizes the phosphate ester. Indeed, complex **3** was prepared independently and under the reaction conditions (40 °C, 50 mM MES pH 6) it was not hydrolysed into *p*-nitrophenol and *p*-nitrophenyl phosphate even after 3 h. The easy formation and stability of such intermediates limits the performance of the catalyst. The copper(II) complex **2** behaves like ribonuclease which, in addition to a correct enzyme-substrate complex, also forms non-reactive enzyme-substrate complexes that do not form products but inhibit the reactions.

## Conclusion

We have demonstrated that the dinuclear complex **2** hydrolyzes the activated phosphodiester BNPP 20-fold faster than the mononuclear complex **1** and up to 600-fold faster than the un-promoted reaction at a slightly acidic pH (pH 6). The mechanism for the hydrolysis of BNPP appears to be classic according to a double Lewis acid activation. Our results are interesting for the design of more efficient copper catalysts for hydrolysis of phosphodiesters. What should be solved next is (*i*) the stabilization of the species **F** in preventing the formation of a double bridged (μ-alk-

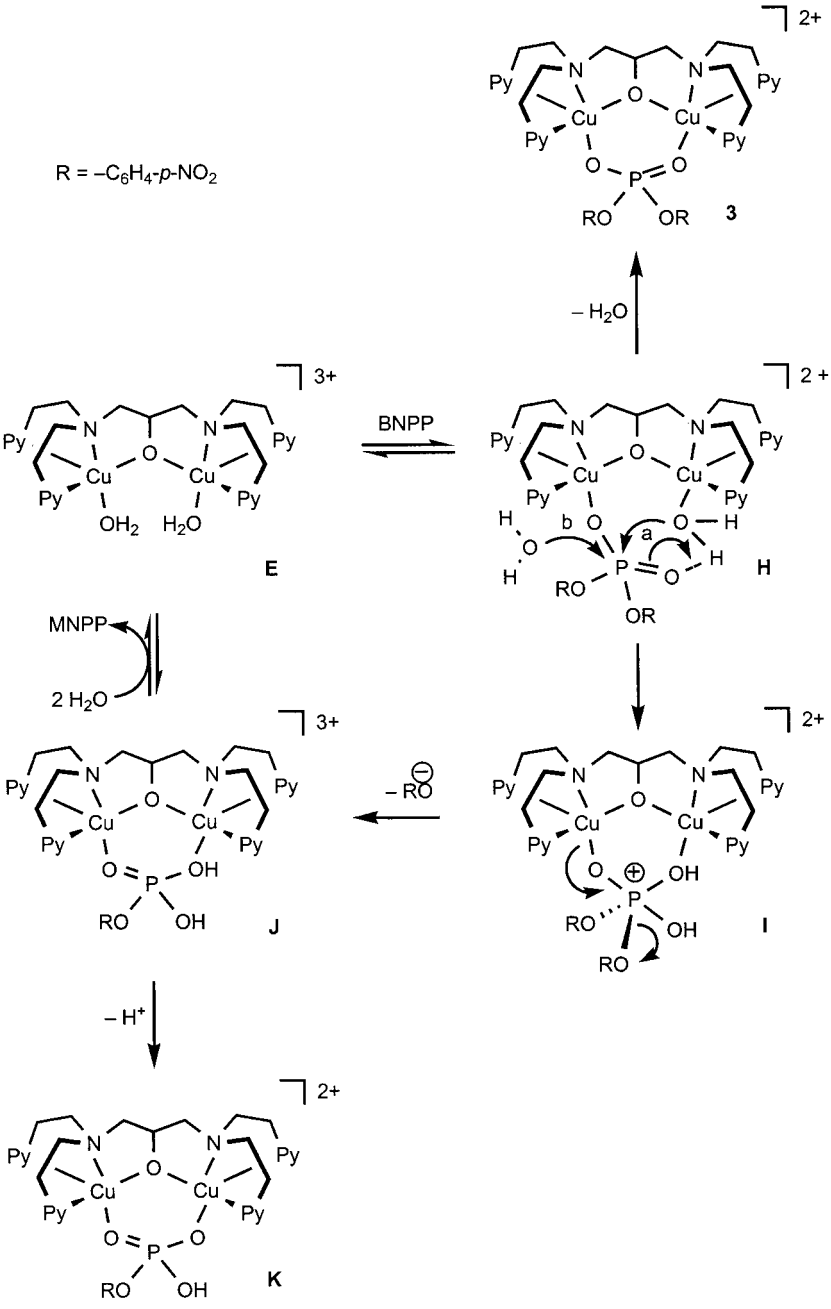

Scheme 4. Proposed mechanism for BNPP hydrolysis promoted by the copper complex **2**.

oxo)(μ-hydroxo)dicopper(II) complex **G** which seems not reactive in the hydrolysis of BNPP; (*ii*) to solve the problem of product (substrate) inhibition in preventing the formation of species such as **K** (**3**). Ligands, which could solve these problems, are currently under investigation in our laboratory.

## Experimental Section

**General Remarks:** NMR spectra were recorded at 25 °C in $CDCl_3$ using a Bruker AC-300 spectrometer. Chemical shifts are reported in ppm as $\delta$ values downfield from an internal standard of TMS. Infrared spectra were measured using neat films or KBr pellets using a Specord M80 (Carl Zeiss Jena) instrument. UV/Vis absorption spectra were recorded in $CH_2Cl_2$ using a Shimadzu UV-120A spectrometer. Elemental analyses were measured using a C, H, N, S Carlo Erba EA 1108 analyzer.

**Materials:** Solvents were freshly distilled under Ar (MeOH/Mg, $Et_2O$/Na-benzophenone ketyl, acetone/$CaH_2$ and $CH_2Cl_2/P_2O_5$). Commercial starting materials were used without purification, except for 2-vinylpyridine which was chromatographed using silica gel prior to use. Ligand **L²OH** was prepared by the Michael addition of 1,3-diamino-2-hydroxypropane to 2-vinylpyridine.[17] Complex $[Cu_2(\mathbf{L^2O})](CF_3SO_3)_3$ (**2**) was prepared by the reaction of $Cu(CF_3SO_3)_2$ with the ligand **L²OH** in $CH_2Cl_2$.[18]

***N*,*N*-Bis[2-(2-pyridyl)ethyl]ethanolamine (L¹OH):** 2-Ethanolamine (1.83 g, 1.81 mL, 30 mmol) and 2-vinylpyridine (25.2 g, 25.9 mL,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.24 mol) were heated under reflux in MeOH (150 mL) with acetic acid (4.41 g, 4.2 mL, 73.5 mmol) for 5 days. Methanol was evaporated under vacuum. The resulting brown mixture was dissolved in $CH_2Cl_2$ (100 mL), washed with 15% aqueous NaOH (2 × 50 mL) and brine (2 × 50 mL). The organic layer was dried with $Na_2SO_4$. The solvent was removed by rotary evaporation to give an oil. This oil was dried under vacuum (ca. 0.01 Torr) at 40 °C to remove excess 2-vinylpyridine. The residue was chromatographed on silica gel ($CH_2Cl_2$/MeOH, 85:15) to yield the pure ligand **L¹OH**. Yield: 6.18 g, 76%. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 2.60 (t, $J$ = 5.1 Hz, 2 H), 2.70–2.90 (m, 8 H), 3.40 (t, $J$ = 5.1 Hz, 2 H), 6.85–7.0 (m, 4 H), 7.40 (td, $J$ = 5.8 Hz and $J$ = 1.7 Hz, 2 H), 8.40 (dd, $J$ = 3.1 Hz and $J$ = 1.0 Hz, 2 H) ppm. $^{13}$C NMR (50 MHz, $CDCl_3$): $\delta$ = 35.8 ($CH_2$), 53.9 ($CH_2$), 55.9 ($CH_2$), 59.4 ($CH_2$), 121.0 ($CH_{py}$), 123.3 ($CH_{py}$), 136.2 ($CH_{py}$), 148.9 ($CH_{py}$), 160.3 ($C_{py}$) ppm. IR (neat film): $\tilde{\nu}$ = 3300 ($\nu_{OH}$), 3010 ($\nu_{C-H}$ aromatic), 2900 ($\nu_{C-H}$ aliphatic), 1600, 1570, 1480, 1440 ($\nu_{C-C}$ pyridine ring), 1055 ($\nu_{C-O}$), 770, 756 ($\gamma_{C-H}$, $\gamma_{C-C}$ aromatic) cm$^{-1}$. UV/Vis (MeOH): $\lambda_{max}$/nm ($\varepsilon$/M$^{-1}$ cm$^{-1}$) = 230 (4200), 260 (7700).

**[Cu(L¹OH)](CF$_3$SO$_3$)$_2$ (1):** Ligand **L¹OH** (590 mg, 2 mmol) dissolved in $CH_2Cl_2$ (10 mL) was added dropwise to a suspension of $Cu(CF_3SO_3)_2$ (723.4 mg, 2 mmol) in $CH_2Cl_2$ (10 mL). After stirring at room temperature for 2 h, a deep blue oil was formed. This oil was allowed to settle and washed with $Et_2O$ until the formation of a solid. Drying under vacuum afforded the copper(II) complex **1**. Yield: 786 mg, 63%. IR (KBr): $\tilde{\nu}$ = 3450 ($\nu_{O-H}$), 3020 ($\nu_{C-H}$ aromatic), 2920 ($\nu_{as\ C-H}$ aliphatic), 1615, 1500, 1450, ($\nu_{C-C}$ pyridine), 770, 740 ($\gamma_{C-H}$ aromatic, $\gamma_{C-C}$), 1270, 1035, 640, 518 ($\nu_{triflate}$) cm$^{-1}$. UV/Vis (MeOH): $\lambda_{max}$/nm ($\varepsilon$/M$^{-1}$ cm$^{-1}$) = 215 (4130), 262 (9650), 381 (220), 690 (120). $C_{18}H_{21}N_3CuF_6O_7S_2$ (633.02): calcd. C 34.20, N 6.65, H 3.32, Cu 10.95; found C 34.85, N 6.42, H 3.24, Cu 10.25.

**[Cu$_2$(L²O)(BNPP)](CF$_3$SO$_3$)$_2$ (3):** To a solution of the complex **2** (54.2 mg, 0.05 mmol) in $H_2O$ (10 mL) was added BNPP (17 mg, 0.05 mmol) dissolved in MeOH (5 mL). After stirring at room temperature for 2 h, the solvent was allowed to evaporate in air. Deep blue crystals suitable for X-ray diffraction were grown within a few days. Yield: 44 mg, 69%. IR (KBr): $\tilde{\nu}$ = 3120, 3080 ($\nu_{C-H}$ aromatic), 2920 ($\nu_{as\ C-H}$ aliphatic), 2880 ($\nu_{s\ C-H}$ aliphatic), 1610, 1590, 1490 ($\nu_{C-C}$ pyridine), 1520 ($\nu_{as\ NO2}$), 1355 ($\nu_{s\ NO2}$), 1220 ($\nu_{as\ P-O-C}$ aromatic), 1150 ($\nu_{C-O}$), 770–750 ($\gamma_{C-H}$, $\gamma_{C-C}$ aromatic), 1265, 1034, 640, 518 ($\nu_{triflate}$) cm$^{-1}$. $C_{45}H_{45}N_8Cu_2O_{15}F_6S_2P$ (1273.08): calcd. C 42.40, N 8.80, H 3.53, Cu 9.98; found C 41.95, N 8.58, H 3.27, Cu 10.42.

**pH Potentiometric Titration:** The pH potentiometric titrations were conducted at 40.0 ± 0.1 °C at an ionic strength of 0.2 M KCl. Calibration of the electrode and pH meter was performed using a 0.05 M KH/phthalate buffer and a p$K_w$ of 13.294 at 40 °C. Solution of ligands **L¹OH** and **L²OH** (5 mM) in 0.2 M KCl, acidified with HCl (0.2008 M), were titrated in an $N_2$ atmosphere with KOH solution (0.1941 M) at 40 °C in the presence and absence of $Cu_2(CF_3SO_3)_2$. The initial concentration of $Cu_2(CF_3SO_3)_2$ was varied between 4–10 mM. The titrations of the free ligands were run between pH 2 and 11.5, with added metal solution between pH 2 and 8 for the ligand **L¹OH** and between pH 2 and 11 for the ligand **L²OH**. To calculate the deprotonation constants and $Cu^{II}$ association constants from the titration data a multiparameter curve fitting program based on SUPERQUAD[25] and PSEQUAD[26] was used.

**Kinetics:** Hydrolysis of BNPP was monitored by following the visible absorption change at 400 nm ($\varepsilon$ = 18500 M$^{-1}$ cm$^{-1}$) due to the release of *p*-nitrophenolate anion (PNPate). Conversion from absorbance to concentration was performed by using the Lambert–Beer law [Equation (1)]. In order to take into account the concentration change of the PNPate as a function of pH, the $[PNPate]_{tot}$ was calculated following equations (2) and (3), where the p$K_a$ of PNP (7.15) was determined using the above condition. The activity of the complex was determined by the initial rate method.

$$[PNPate]_{meas} = O.\,D./18500 \quad (1)$$

$$pH = 7.15 + \log([PNPate]_{meas}/[PNP]) \quad (2)$$

$$[PNPate]_{tot} = [PNPate]_{meas} + [PNP] \quad (3)$$

In a typical kinetic experiment, freshly prepared phosphate ester stock solution in water (12 μL, 50 mM) was added to a solution of copper(II) complex (**1**: 75 μL, 20 mM; **2** 60 μL, 25 mM) at 40 °C. The copper complex solutions were buffered with MES (pH 5.5–6.5), HEPES (pH 7–8) and the ionic strength was maintained with 0.1 M KCl. The final volume was 3 mL. The pseudo-first-order rate constants for un-promoted reactions ($k_{uncat}$, s$^{-1}$) were measured by following the increase in absorbance from a 1.92 mM BNPP solution.

**X-ray Crystallographic Studies:** All the measurements were performed using a Bruker–Nonius KappaCCD diffractometer.[27] The cell determinations and data integrations were performed using the software Denzo-Scalepak.[28] The structure solutions were obtained using Sir92[29] and the refinements were carried out using SHELXL-97,[30] except for complex **3**, which was refined using the software MaXus (Table 5).[31]

CCDC-283857 (for **1**), -283855 (for **2**) and -283856 (for **1**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Keywords:** Aluminum / Chirality / N ligands / Titanium / Tripodal ligands

$Al^{III}$ and $Ti^{IV}$ complexes of $C_3$-symmetric tetradentate trisamidoamine ligands with trigonal bipyramidal coordination geometry, containing chlorine or dialkylamido groups, or with a free coordination site in the apical position, have been synthesised by salt metathesis and amine elimination. Products with threefold symmetry were generally obtained for tetravalent titanium, whereas for the aluminium complexes either asymmetric structures with two of the three podand arms taking part in coordination to the metal or symmetric arrangements possessing the full threefold symmetry were formed depending on the steric properties of the ligands.

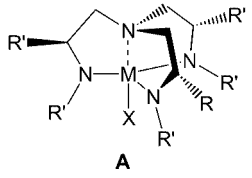
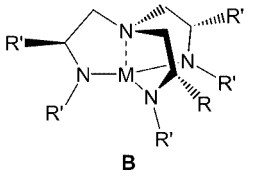
## Introduction

The preparation of chiral ligands capable of efficient chirality transfer is crucial for successful asymmetric metal catalysis.[1,2] Several factors need to be considered in the design of new ligands, including steric and electronic effects, kinetic properties, hapticity and bite angles.[3,4] Another factor that occasionally plays an important role is symmetry. $C_2$-Symmetric ligands have, in many situations, proven to offer advantageous properties over those lacking symmetry, and such ligands have been extensively employed in asymmetric catalysis and various processes involving chiral recognition.[5] $C_3$-Symmetric ligands, however, have been considerably less investigated,[6] although extensive studies have been performed on achiral ligands possessing threefold rotational axes. Particularly detailed studies have been performed by the groups of Verkade[7,8] and Schrock[9] on complexes with derivatives of tris(2-aminoethyl)amine (TREN) most of them bearing bulky substituents such as trialkylsilyl or pentafluorophenyl groups on nitrogen. Metal complexes with TREN or its derivatives have also been used in several applications. Some recent examples include nitrogen activation by $Mo^{IV}$ complexes with *N*,*N*′*N*′′-aryl-substituted TREN ligands,[10] alkene epoxidation by $Mn^{III}$ and $Fe^{III}$ complexes,[11] phosphoester hydrolysis[12] and $CO_2$ fixation[13] by $Zn^{II}$ complexes, and thiosulfate oxidation by $Cu^{II}$ complexes.[14] Furthermore, a $Cu^{II}$ complex has been shown to react reversibly with oxygen,[15] and $Cu^{II}$ and $Ni^{II}$ complexes to bind nucleobases.[16]





Triamidoamines usually serve as tetradentate ligands, forming rigid trigonal bipyramidal (**A**) or, in the absence of an apical ligand, trigonal monopyramidal (**B**) complexes with a variety of transition metals and main-group elements.[7,9,17] The M–$N_{ap}$ distances vary significantly, occasionally resulting in complexes lacking a transannular bond, thus leading to tridentate coordination.[7–17] Other coordination modes are possible, however, as shown by the recently determined structures of $[Ni(tren)(abpt)](NO_3)_2$ [abpt = 4-amino-3,5-bis(pyrid-2-yl)-1,2,4-triazole],[18] $[Ni(tren)Sb_2S_4]$,[19] $[Co(tren)(amino\ acidato\text{-}N,O)]X_2$,[20] and $[Co(tren)(N_3)_2]Br$,[21] which exhibit octahedral coordination.

Several methods have been employed for metal complex formation of TREN derivatives. Usually the ligand is treated with a base such as butyllithium prior to reaction with a transition metal salt,[22] although ligands with acidic protons on nitrogen may react directly with the metal com-

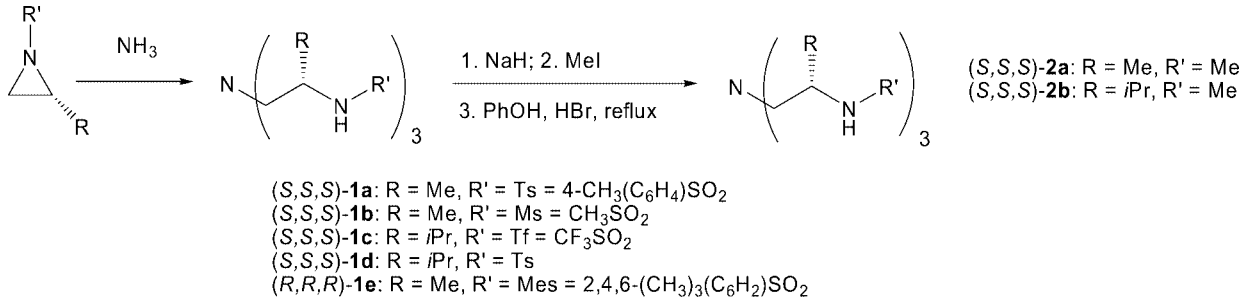


Scheme 1. Synthesis of the $C_3$-chiral TREN ligands **1a**–**1e** and **2a**,**b**.

pound.[23] Metal halides and metal amide complexes are the most commonly used metal sources.

A few chiral tetradentate TREN analogues with the chirality residing in the ligand backbone[24–27] or in substituents on the equatorial nitrogen atoms,[28] as well as tridentate ligands lacking an apical nitrogen,[29] have been prepared. Upon metal complex formation, a chiral pocket with a $C_3$-symmetric environment is created in the apical position, a favourable situation for asymmetric catalysis.[30] Some of the chiral ligands, notably those by Gade, have indeed been assessed in asymmetric reactions and were found to induce moderate to high enantioselectivity in stoichiometric[30a] and catalytic[30c] alkylations of aryl aldehydes. Proazaphosphatranes have been shown to serve as excellent catalysts in a vast number of base-mediated[31] and metal-catalysed[32] processes, but their chiral analogues[26,28,33] have not yet been applied in catalysis. Titanatranes have been employed in asymmetric ring-opening of *meso* epoxides and enantioselective oxidation of sulfides,[34] but no reports on the use of azatitanatranes, first described in 1991,[35] have appeared.

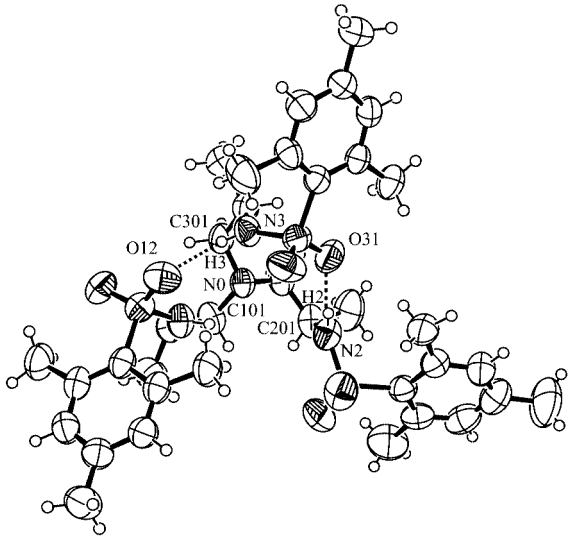
Since we have access to a versatile method for the preparation of chiral TREN derivatives,[24] we initiated a study of the formation of amido metal complexes[36,37] for potential use in asymmetric catalysis.

## Results and Discussion

### Ligand Preparation

Ligands (*S*,*S*,*S*)-**1a**–**c**[24] and -**1d**[38] were prepared as described previously, starting from the appropriate enantiopure aziridine and ammonia. Ligand (*R*,*R*,*R*)-**1e** was prepared analogously in 60% overall yield. Compounds (*S*,*S*,*S*)-**2a** and (*S*,*S*,*S*)-**2b** were obtained from (*S*,*S*,*S*)-**1a** and (*S*,*S*,*S*)-**1d**, respectively, by N-methylation followed by deprotection of the tosyl groups with HBr[24b] (Scheme 1).

Upon crystallisation by vapour-diffusion from chloroform/hexane, ligand (*R*,*R*,*R*)-**1e** afforded suitable crystals for X-ray analysis (Figure 1). Interestingly, the molecular structure of (*R*,*R*,*R*)-**1e** deviates only slightly from threefold symmetry. Two hydrogen bonds between NH functions and sulfonylic oxygen atoms (Figure 1, dashed lines) hold the ligand structure in a bent conformation which is similar to that observed upon coordination to metal ions (azametallatranes **A** and **B**). The TREN structure is approximately $C_3$-symmetric, with the angles centred around the bridgehead nitrogen atom being almost identical (Figure 1). The TREN arm labelled as **III** in Figure 1 participates in two hydrogen bonds involving carboxamide proton H3, which interacts with the sulfonyl oxygen atom in arm **I** (O12), whereas its sulfonyl unit forms a hydrogen bond with H2(N2). Both hydrogen bonds have similar metric parameters (N–H···O = 0.86 Å, N–H–O = 170°–175°).



Selected bond lengths (Å) and angles (deg) for crystal structure of **1e**

| H Bonds, Å | | | N–H···O Angles (deg) | N0-Centered Angles (deg) | |
|---|---|---|---|---|---|
| | ***N-H*** | ***H···O*** | | C201-N0-C301 | 110 |
| N2-H2···O31 | 0.86 | 2.11 | 175 | C201-N0-C101 | 111 |
| N3-H3···O12 | 0.86 | 2.19 | 170 | C301-N0-C101 | 114 |

Figure 1. ORTEP view of the molecular structure of (*R*,*R*,*R*)-**1e** (30% thermal ellipsoids). Dashed lines indicate hydrogen bonds. The hydrogen atoms were included at calculated positions with fixed thermal parameters.

The ligands **1a**–**e** bearing electron-withdrawing substituents on the nitrogen atoms possess relatively acidic NH protons and were found to react directly with metal amides in a transamination reaction. On the other hand, coordination of the *N*-alkylated TREN derivatives (*S*,*S*,*S*)-**2a** and (*S*,*S*,*S*)-**2b** required initial metallation with *n*BuLi and subsequent reaction with $M^{(n)}Cl_n{\cdot}(THF)_m$ in a salt metathesis step.

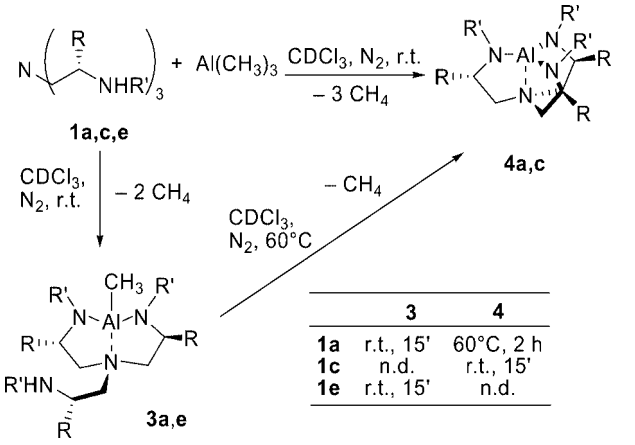
### Metal Complex Formation: Aluminum(III) Complexes

Complex formation between ligands (*S*,*S*,*S*)-**1a**,**c** and (*R*,*R*,*R*)-**1e** and suitable $Al^{III}$ precursors was initially studied whilst monitoring the course of the reactions by $^1H$ NMR spectroscopy. Addition of one equivalent of $Al(OiPr)_3$ did not afford any new $Al^{III}$ complex, even upon prolonged heating at 100 °C. However, the addition of one equivalent of $AlMe_3$ to (*S*,*S*,*S*)-**1a** (Scheme 2) was accompanied by instantaneous gas evolution.



Scheme 2. Synthesis of $Al^{III}$ complexes of ligands **1a**, **1c** and **1e**.

The $^1H$ NMR spectrum recorded after 15 minutes at room temperature is consistent with the quantitative formation of a new metal complex containing three diastereotopic ligand arms and thus being devoid of threefold symmetry (Figure 2, spectrum b). The presence of one N*H* (doublet at $\delta$ = 4.70 ppm) and one Al–C$H_3$ signal (singlet at $\delta$ = –0.39 ppm) suggested the new species to be **3a** (R = Me, R′ = Ts), with a structure similar to a complex obtained from a dipodal analogue of **1** and trimethylaluminium.[39] This assumption was corroborated by the modifications observed upon heating at 60 °C. Further evolution of gas was detected, followed by the slow formation (2 h) of the symmetrical species **4a** (Scheme 2). The disappearance of the N*H* signal and the accompanying downfield shift of almost all the signals in the spectrum of **4a** with respect to those of the uncomplexed ligand (Figure 2, spectrum c) provided evidence that the coordination of (*S*,*S*,*S*)-**1a** to aluminium had occurred. A particularly evident deshielding effect ($\Delta\delta \approx 0.5$ ppm) was observed for one of the diastereotopic C$H_2$ resonances (doublet of doublets, from $\delta$ = 2.13 ppm in **1a** to $\delta$ = 2.60 ppm in **4a**).

The same experiment was repeated with (*R*,*R*,*R*)-**1e**. With this sterically more demanding ligand no symmetrical complex was obtained, and only the formation of **3e** (R = Me, R′ = Mes) was observed even after heating at 60 °C for 48 h (Scheme 1). In contrast, reaction of trimethylaluminium with the more reactive triflate derivative (*S*,*S*,*S*)-**1c** afforded **4c** (R = *i*Pr, R′ = Tf) directly without detection of any intermediate complex of type **3** (Scheme 2). The monomeric nature of **4a** and **4e** is supported by the single set of resonances in their NMR spectra ($^1H$, $^{13}C$ and $^{19}F$ in the case of complex **4e**), which reflect the $C_3$ symmetry of the complex. Verkade and co-workers provided analogous symmetry considerations derived from the NMR spectral pattern to demonstrate the monomeric nature of their *N*-trimethylsilylazaalumatrane.[40]

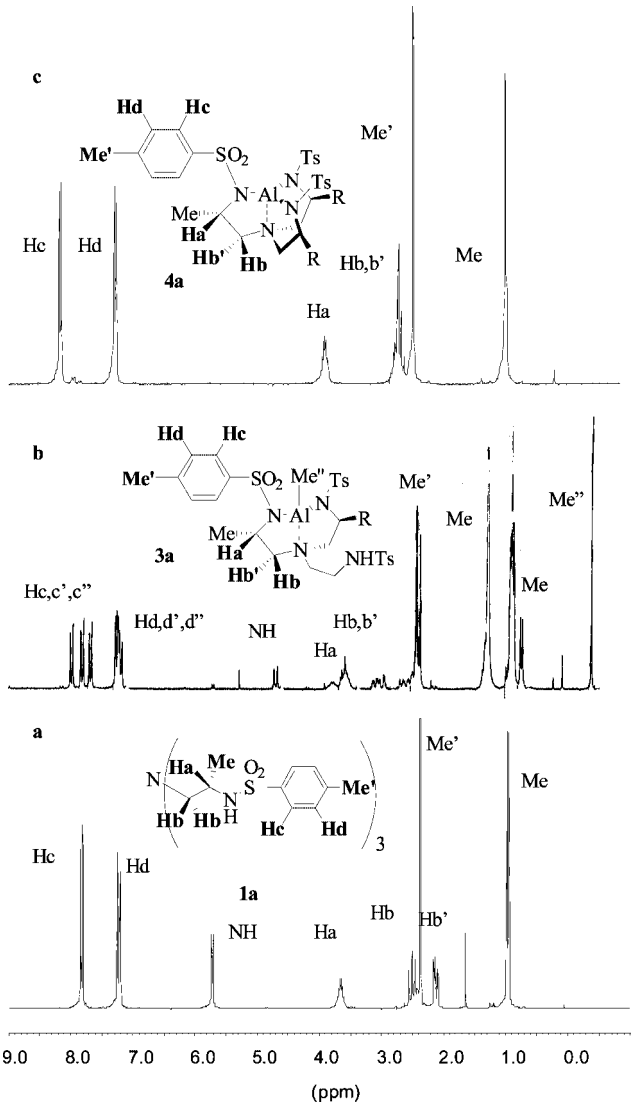


Figure 2. Reaction of $AlMe_3$ (0.020 M) with (*S*,*S*,*S*)-**1a** (0.020 M) in $CDCl_3$ under nitrogen monitored by $^1H$ NMR spectroscopy (250 MHz): a) (*S*,*S*,*S*)-**1a**; b) addition of $AlMe_3$ (1 equiv.), room temp., 15 min; c) after heating at 60 °C, 2 h: **4a**.

A synthetic procedure that allowed the preparation of **4a** on a one-gram scale was achieved by carrying out the reaction of Scheme 1 under slightly modified conditions. Complex **4a** was obtained in 99% yield by adding trimethylaluminium to a saturated solution of (*S*,*S*,*S*)-**1a** in dry THF and refluxing the reaction mixture under nitrogen until a white precipitate separated from the colourless solution. Isolation of pure **4a** was possible by washing with dry pentane and centrifugation. Despite its tendency to afford dendritic precipitates, layering of a concentrated solution of **4a** in dichloromethane with a 1:1 mixture of dichloromethane/diethyl ether and with pure diethyl ether allowed the growth

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of colourless single crystals suitable for X-ray diffraction analysis.

The crystal structure of **4a** is depicted in Figure 3 along with the principal bond lengths and angles.

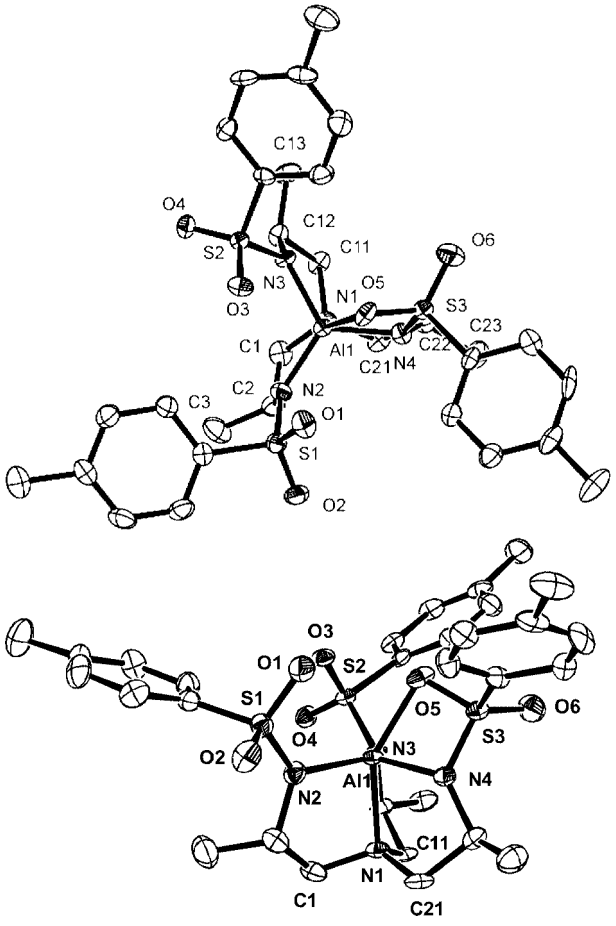

Figure 3. ORTEP views of (*S*,*S*,*S*)-**4a** (50% probability level thermal ellipsoids). Principal bond lengths [Å] and angles [°]: Al–N(1) 2.042(4), Al–N(2) 1.861(5), Al–N(3) 1.872(4), Al–N(4) 1.897(4), Al–O(5) 2.054(4), S(1)–O(1) 1.445(4), S(1)–O(2) 1.433(4), S(2)–O(4) 1.442(3), S(2)–O(3) 1.450(4), S(3)–O(5) 1.495(4), S(3)–O(6) 1.423(4); N(2)–Al–N(3) 117.5(2), N(2)–Al–N(4) 116.8(2), N(3)–Al–N(4) 122.2(2), C(1)–N(1)–C(11) 112.0(4), C(1)–N(1)–C(21) 113.3(4), C(11)–N(1)–C(21) 110.1(4), N(2)–Al–N(1) 86.4(2), N(3)–Al–N(1) 84.8(2), N(4)–Al–N(1) 80.4(2), N(1)–Al–O(5) 120.7(2), Al–O(5)–S(3) 93.9(2). All hydrogen atoms have been omitted for clarity.

Azaalumatrane **4a** crystallises in the space group $P2_12_12_1$ with a dichloromethane molecule present in the unit cell. The complex is monomeric and approximately $C_3$-symmetric, as is evident from the observed $N_{eq}$–Al–$N_{eq}$ angles (116.8–122.2°), which is in accordance with the structural features derived from the NMR spectroscopic data recorded in solution. The five-coordinate aluminium complex possesses a highly distorted trigonal-bipyramidal coordination geometry, the metal centre being slightly displaced above the equatorial plane [N(1)–Al–$N_{eq}$ = 80.4–86.4°]. The equatorial N–Al bond lengths (1.861–1.897 Å) are comparable to those reported for analogous azaalumatranes[17,41,42] and to nitrogen–aluminium distances in five-coordinate $Al^{III}$/amido complexes (1.897–1.976 Å).[43] The transannular interaction in **4a** [N(1)–Al = 2.042(4) Å] is stronger than in the *N*-methyl-substituted azaalumatrane **4f** [R = H and R′ = Me; 2.124(6) Å], which is a dimer bearing a trigonal-bipyramidal geometry around the five-coordinate aluminium.[43] On the other hand a considerably stronger transannular bond [1.983(6) Å] is found in the *N*-trimethylsilyl-substituted analogue **4g** (R = H and R′ = $SiMe_3$), in which the bulky $SiMe_3$ groups prevent dimerisation and leave a coordinatively unsaturated aluminium.[42] Interestingly, the transannular interaction observed in **4a** lies within the range found in the analogous $Al^{III}$/trialkanolamine complexes.[44] Distortion of the bipyramidal geometry is due to the coordination of one of the sulfonyl oxygen atoms belonging to a tosyl group to aluminium, the angle along the axial direction deviating considerably from 180° [N(1)–Al–O(5) = 120.7°]. This Al–O(5) interaction results in a bond length [2.054(4) Å] which is comparable to that of the transannular bond [2.042(4) Å]. As a consequence, both the sulfur–oxygen covalent bond [S(3)–O(5) = 1.495(4) Å, compared to an average S–O distance of 1.439 Å] and the $N_{eq}$–Al bond [N(4)–Al = 1.897(4) Å compared 1.861–1.872 Å for the remaining two Al–N bonds] are elongated.

As mentioned above, achiral azaalumatranes have been prepared and studied previously by Verkade.[41–43] For the monomeric complexes an interconversion between the λ and δ chelate ring conformations was observed, which was rapid on the NMR timescale down to –95 °C.[42] On the other hand, interconversion between the spiral diastereomers of **4a** was not observed at room temperature, which implies that the presence of the ring-methyl substituents of ligand **1a** increases the interconversion barrier and prevents such a conformational twist. Moreover, it is evident from the molecular structure of **4a** (Figure 3, horizontal view) that these methyl substituents play a crucial structural role and appear to determine the orientation of the N–$SO_2$–Ar moieties. This implies that the chirality of the $C_3$ cavity around the metal centre (the "chiral pocket") is determined by the orientation of the methyl groups and thus by the absolute configuration of the ligand.

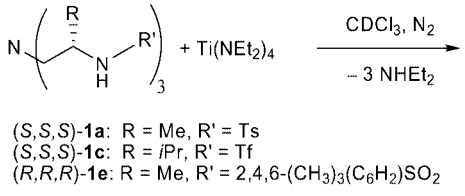
The use of azaalumatranes as precursors for the synthesis of a variety of transition metal or main group element azatranes by transmetallation has been reported.[43] However, the potential of this type of complex to serve as a Lewis acid, and thus to increase the coordination number by apical coordination, is as yet essentially unexplored, although Al complexes of dipodal analogues have been employed as chiral Lewis acid catalysts.[45] We note that achiral Al complexes have in fact been used as Lewis acid catalysts in the ring-opening polymerisation of heterocycles,[39] and chiral analogues may be of interest for controlling the tacticity of the polymers.

### Metal Complex Formation: Titanium(IV) Complexes

The reaction of ligand **1a** with [Ti($NEt_2$)$_4$] in a 1:1 stoichiometry was initially performed in $CDCl_3$ in an NMR

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tube and monitored by $^1$H NMR spectroscopy (Scheme 3). Whereas a poorly resolved spectrum was recorded after 15 min, which indicated the presence of fluxional species of low symmetry in solution, the spectral patterns simplified and sharpened up over a period of three days at ambient temperature. The highly resolved spectrum recorded at that stage is consistent with the formation of a monomeric complex with threefold symmetry (**5a**) possessing one residual diethylamido group. Complex formation was further supported by the liberation of diethylamine and the observation that the methylene proton resonances of the $Et_2N$ ligand give an AB system ($\delta$ = 4.36 and 4.51 ppm respectively). The reaction was accompanied by a change of colour from yellow to reddish-brown. An analogous complex was formed from ligand **1e** and [Ti(NEt$_2$)$_4$] within six days at room temperature or within six hours upon heating at 60 °C; **1c** exhibits higher reactivity, undergoing instantaneous complex formation (Scheme 3).



(*S*,*S*,*S*)-**1a**: R = Me, R' = Ts
(*S*,*S*,*S*)-**1c**: R = *i*Pr, R' = Tf
(*R*,*R*,*R*)-**1e**: R = Me, R' = 2,4,6-(CH$_3$)$_3$(C$_6$H$_2$)SO$_2$

(*S*,*S*,*S*)-**5a**
(*S*,*S*,*S*)-**5c**
(*R*,*R*,*R*)-**5e**

Scheme 3. Synthesis of Ti$^{VI}$ complexes of ligands **1a**, **1c** and **1e**.

The $^1$H NMR spectra of azatitanatranes **5a**, **5c** and **5e** are all consistent with the formation of highly symmetric monomeric species. In all cases the resonances of the triamidoamine ligands have undergone significant shifts with respect to the uncomplexed ligand (see Table 1).

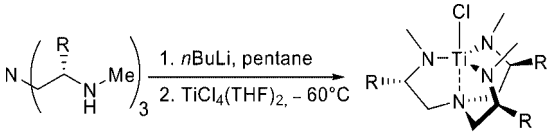
Table 1. Selected $^1$H NMR spectroscopic data [ppm] for ligands **1a**, **1c** and **1e** and complexes **5a**, **5c** and **5e**.

| | NC*H*$_2$CHR–N | | Ti–N(C*H*$_2$Me)$_2$ | |
|---|---|---|---|---|
| Ti(NEt$_2$)$_4$ | – | – | 3.46 | 3.46 |
| (*S*,*S*,*S*)-**1a** | 2.13 | 2.50 | – | – |
| (*S*,*S*,*S*)-**5a** | 2.52 | 3.05 | 4.36 | 4.50 |
| (*S*,*S*,*S*)-**1c** | 2.24 | 2.90 | – | – |
| (*S*,*S*,*S*)-**5c** | 2.62 | 3.30 | 4.24 | 4.80 |
| (*R*,*R*,*R*)-**1e** | 2.17 | 2.83 | – | – |
| (*R*,*R*,*R*)-**5e** | 3.47 | 4.63 | 3.48 | 3.92 |

A different behaviour is observed for complex **5e** and complexes **5a** and **5c**. Thus, in complex **5e** a remarkable deshielding (ca. 1 ppm) of the signals of the methylene protons of the TREN moiety is observed (from $\delta$ = 2.52 and 3.05 ppm in **5a** and $\delta$ = 2.63 and 3.30 ppm in **5c** to $\delta$ = 3.50 and 4.63 ppm in **5e**) due to a shielding of the protons of the apical diethylamido group ($\delta$ = 3.48 and 3.92 ppm vs. $\delta$ = 4.36 and 4.50 ppm for **5a** and $\delta$ = 4.24 and 4.80 ppm for **5c**). The observed difference in $\delta$ values very likely originates from a more open structure of complex **6e** compared to the other two, which is caused by the more hindered nature of the mesitylene groups. The bulkier substituents on the external part of the ligand remove the sulfonyl moieties from the inner part of the cavity, thus moving the aromatic rings closer to the methylene groups of the TREN backbone. This fact diminishes the magnetic anisotropy effect of the S=O groups on the apical ligand and increases the effect of the peripheral aromatic ring on the protons of the TREN backbone. $^1$H NOESY experiments on complexes **5a** and **5c** were in agreement with such hypothesis. In fact, a significant difference in the distances between the aromatic *meta* protons and the hydrogen atoms in the methyl group of the ligand backbone was found (3.00 and 2.25 Å for **5a** and **5e**, respectively).

A synthetic protocol allowing the preparation of Ti$^{IV}$ complex **5a** on a gram scale was worked out as well. Azatitanatrane **5a** was prepared in 95% yield and high NMR purity by carrying out the reaction in a 3:1 pentane/THF mixture at room temperature from a concentrated solution of the reactants (0.2 M); it was isolated as a yellowish solid by filtration.

Finally, the Ti complexes of **2a** and **2b** (**6a** and **6b**) were prepared as previously reported for the achiral analogue [{(MeNCH$_2$CH$_2$)$_3$N}TiCl][46] by salt metathesis of the lithium salt of the triamidoamine ligands and [TiCl$_4$(THF)$_2$] as metal source (Scheme 4). The $^1$H and $^{13}$C NMR spectra are consistent with the assumed threefold symmetry of the complexes. Unfortunately, attempts to obtain single crystals for X-ray structure determination failed.



(*S*,*S*,*S*)-**2a**: R = Me
(*S*,*S*,*S*)-**2b**: R = *i*Pr

(*S*,*S*,*S*)-**6a**: R = Me
(*S*,*S*,*S*)-**6b**: R = *i*Pr

Scheme 4. Synthesis of Ti$^{VI}$ complexes of ligands **2a** and **2b**.

All attempts to displace the apical amido ligand in the N-sulfonated azatitanatranes **5a**–**c** with both O- and N-based nucleophiles only yielded mixtures or led to complex degradation, as was established upon monitoring the reactions by $^1$H NMR spectroscopy.

Several examples of reactivity studies performed with the tris-tosyl azatitanatrane **5a** are summarised in Scheme 5. Upon addition of *tert*-butyl hydroperoxide (from 1 to 10 equiv.) no formation of peroxoazatitanatrane complexes was observed (Scheme 5, path a); a complete decomposition of the starting complex occurred with concurrent slow oxidation of the free diethylamine.[47] This behaviour is in contrast to the previously established oxygenation behaviour of titanatrane complexes.[48] In the same way, treatment with racemic 2-octanol resulted, again, in complete decomposi-

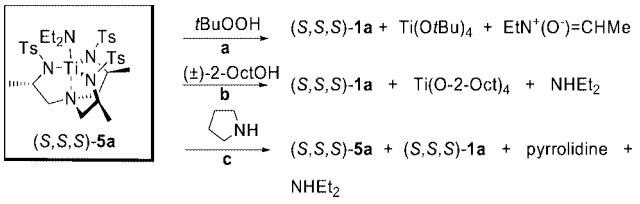
tion of the complex with formation of ligand **1a** and titanium alkoxides (Scheme 5, path b). The oxophilic nature of titanium(IV) compounds is well documented[49] and this argument can be invoked to explain the high reactivity towards oxygen-containing species observed for **5a**. Verkade has reported that attempts to displace an apical $NMe_2$ group from an achiral azatitanatrane (R′ = Me, L = $NMe_2$) with *tert*-butyl alcohol give only a mixture of starting material, titanium alkoxide and alcoholysis products, with no detectable evidence for the displacement product.[50] Similar results were obtained in the attempted exchange of the apical diethylamido ligand for N-based nucleophiles. Addition of up to 10 equivalents of pyrrolidine to **5a** in $CDCl_3$ only returned the unreacted starting materials, and additional heating resulted in partial decomposition of the complex (Scheme 5, path c).[51]



Scheme 5. Reactivity of complex **5a** with O- and N-based nucleophiles.

From these preliminary results it seems clear that the apical diethylamido ligand in complex **5a**, in analogy with the previously reported azatitanatranes,[35] is not easily displaced and this limits its use as a catalyst by the activation of apical substituents. Since apical chloro ligands can be replaced by alkylation to yield the corresponding alkyltitanium compounds[22a,52] or, alternatively, may be abstracted by treatment with silver salts to generate, for example, triflate derivatives,[49] or replaced by a siloxyl ($R_3SiO$) group by reaction with sodium siloxide,[53] such azatrane derivatives may be more suitable for use as Lewis acid catalysts. Such work is currently in progress.

## Conclusion

Enantiopure $C_3$-symmetric $Al^{III}$ and $Ti^{IV}$ complexes have been obtained from chiral trisamidoamine derivatives with threefold symmetry. Further studies are needed in order to ascertain whether the complexes have the key properties required for catalysis, such as a sufficiently large cavity for substrate binding, fast exchange of coordinated substrate, and efficient transfer of chirality from the chiral complex to the substrate undergoing reaction.

## Experimental Section

**General Remarks:** All metal-containing compounds were prepared under dry nitrogen on a high vacuum line using standard Schlenk techniques or in a glove box. All reaction flasks were heated prior to use and solvents and solutions were transferred by needle/septum techniques. Separation of solids from suspensions was performed by centrifugation with a Rotina 48 centrifuge (Hettich Zentrifugen, Tuttlingen, Germany) equipped with a specially designed Schlenk tube rotor.[54] Solvents were dried according to standard procedures and used under nitrogen: diethyl ether, THF, toluene and pentane were distilled from sodium/benzophenone and stored over a potassium mirror, except for diethyl ether, which was stored over activated 4-Å molecular sieves. Dichloromethane was distilled from calcium hydride and stored over activated 4-Å molecular sieves. The deuterated solvents used for NMR experiments were dried with activated 4-Å molecular sieves. Deuterated chloroform was additionally treated with a small amount of dry potassium carbonate. Pellets and powdered 4-Å molecular sieves were purchased from Aldrich and activated before use. The $^1H$ and $^{13}C$ NMR spectra were recorded with Bruker AC 200 SY ($^1H$: 200.13 MHz; $^{13}C$: 50.32 MHz), AC 250 ($^1H$: 250.18 MHz; $^{13}C$: 62.90 MHz), DRX 300 ($^1H$: 300.13 MHz; $^{13}C$: 75.46 MHz) and Bruker Avance 400 ($^1H$: 400.00 MHz; $^{13}C$: 100.58 MHz) instruments and referenced to the residual signals from $CDCl_3$ ($^1H$: $\delta$ = 7.26 ppm; $^{13}C$: $\delta$ = 77.2 ppm) and $C_6D_6$ ($^1H$: $\delta$ = 7.20 ppm) ppm. $^{19}F$ NMR spectra were recorded with the Bruker DRX 300 spectrometer using $CFCl_3$ as internal reference ($^{19}F$: 282.35 MHz; $CFCl_3$ $\delta$ = 0 ppm). Melting points are uncorrected and were determined withy a Reichert Austria apparatus. Optical rotations were measured with a Perkin–Elmer 241 polarimeter ($\lambda$ = 589 nm, sodium D-line) at 25 °C using a quartz cell (10 cm). Chromatographic separations were performed with Macherey–Nagel silica gel (70–230 mesh). Flash chromatography was performed as described in the literature[55] using Macherey–Nagel 60 silica gel (0.040–0.063 mm, 230–400 mesh). TLC analyses were run using Macherey–Nagel POLYGRAM®SIL G/$UV_{254}$ silica pre-coated plastic sheets (40 × 80 mm, 0.2 mm thickness). $Al(CH_3)_3$ (2.0 M solution in heptane) was purchased from Aldrich. The ligands used for the preparation of metal complexes were dried under vacuum and stored over $P_2O_5$ or under nitrogen. All other chemicals were obtained commercially and used without further purification.

**Ligand (*R*,*R*,*R*)-1e:** (*R*,*R*,*R*)-**1e** was obtained in 60% yield (0.99 g) following the procedure previously described for **3a**.[24] M.p. 177–178 °C, $[\alpha]_D^{20}$ = –82.6 (*c* = 1.2, $CHCl_3$). $^1H$ NMR (250.18 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.91 (d, *J* = 6.2 Hz, 9 H), 2.17 (dd, *J* = 12.7 and 4.5 Hz, 3 H), 2.27 (s, 9 H), 2.67 (s, 18 H), 2.83 (dd, *J* = 12.6 and 11.1 Hz, 3 H), 3.68–3.91 (m, 3 H), 5.88 (d, *J* = 7.2 Hz, 3 H), 6.91 (s, 6 H) ppm. $^{13}C$ NMR (62.90 MHz, $CDCl_3$, 25 °C): $\delta$ = 19.6 [$CH_3$, 3 C, –CH(*C*$H_3$)], 20.8 ($CH_3$, 3 C, *p*-*C*$H_3$), 23.0 ($CH_3$, 6 C, *o*,*o*′-*C*$H_3$), 45.9 (CH, 3 C, $CH_2$*C*HMeN), 57.3 ($CH_2$, 3 C, N*C*$H_2$CHMe-), 131.7 (CH, 6 C, *C*H arom.), 135.8 ($C_q$, 3 C, CH*C*MeCH arom.) 138.8 ($C_q$, 6 C, -$SO_2$*C*CMeCH- arom.), 141.6 ($C_q$, 3 C, $SO_2$*C* arom.) ppm. $C_{36}H_{54}N_4O_6S_3$ (735): calcd. C 58.83, H 7.40, N 7.62; found C 58.95, H 7.42, N 7.60.

**Synthesis of $Al^{III}$ Complexes of Ligands (*S*,*S*,*S*)-1a and (*S*,*S*,*S*)-1c in situ:** Ligand **1** (0.020 mmol) was added to a 1-mL volumetric flask and dissolved in $CDCl_3$. Trimethylaluminium (2.0 M in heptane, 0.010 mL, 0.020 mmol) was then added and the solution (0.500 mL) was transferred into a screw-cap NMR tube, which was sealed under nitrogen and kept at room temperature. The reaction was followed by $^1H$ NMR spectroscopy. Once the complete formation of the complex was observed, the sample was kept at 0 °C in the refrigerator.

**Complex (*S*,*S*,*S*)-3a:** Upon addition of ligand (*S*,*S*,*S*)-**1a** (13.02 mg) to $AlMe_3$, formation of **3a** (colourless solution) was quantitative after 15 min. $^1H$ NMR (250.18 MHz, $CDCl_3$, 25 °C): $\delta$ = –0.39 (s, 3 H), 0.72 (d, *J* = 6.6 Hz, 3 H), 0.86 (d, *J* = 5.3 Hz, 3 H), 0.87 (d, *J* = 5.3 Hz, 3 H), 2.35 (s, 3 H), 2.40 (s, 3 H), 2.42 (s, 3 H), 2.47 (dd, *J* = 13.6 and 12.3 Hz, 1 H), 2.62 (dd, *J* = 16.7 and 10.1 Hz, 1

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

H), 2.98 (dd, $J$ = 15.4 and 2.2 Hz, 1 H), 3.08 (dd, $J$ = 13.6 and 4.4 Hz, 1 H), 3.69–3.42 (m, 1 H), 3.91–3.69 (m, 1 H), 4.72 (d, $J$ = 10.5 Hz, 1 H), 7.20 (d, $J$ = 8.3 Hz, 2 H), 7.27 (d, $J$ = 8.3 Hz, 4 H), 7.69 (d, $J$ = 8.3 Hz, 2 H), 7.83 (d, $J$ = 8.3 Hz, 2 H), 7.99 (d, $J$ = 8.3 Hz, 2 H) ppm.

**Complex (*R*,*R*,*R*)-3e:** This complex was prepared from $AlMe_3$ and ligand (*R*,*R*,*R*)-**1e** (14.70 mg). Quantitative formation occurred in 15 min; colourless solution. $^1$H NMR (250.18 MHz, $CDCl_3$, 25 °C): $\delta$ = –0.41 (s, 3 H), 0.56 (d, $J$ = 5.9 Hz, 3 H), 0.73 (d, $J$ = 5.6 Hz, 3 H), 0.90 (d, $J$ = 6.6 Hz, 3 H), 2.25 (s, 3 H), 2.29 (s, 3 H), 2.31 (s, 3 H), 2.36 (dd, $J$ = 14.4 and 2.9 Hz, 1 H), 2.50–2.71 (m, 2 H), 2.62 (s, 6 H), 2.67 (s, 6 H), 2.74 (s, 6 H), 3.04 (dd, $J$ = 7.9 and 4.3 Hz, 1 H), 3.20 (dd, $J$ = 14.3 and 2.9 Hz, 1 H), 3.38–3.53 (m, 1 H), 3.54–3.69 (m, 2 H), 3.70–3.91 (m, 1 H), 4.53 (d, $J$ = 10.3 Hz, 1 H), 6.87 (s, 2 H), 6.94 (s, 2 H), 6.98 (s, 2 H) ppm.

**Complex (*S*,*S*,*S*)-4a:** This complex was prepared from $AlMe_3$ and ligand (*S*,*S*,*S*)-**1a** (13.02 mg). The solution was heated at 60 °C for 15 d, resulting in 100% conversion to (*S*,*S*,*S*)-**4a**. The solution was colourless. $^1$H NMR (250.18 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.87 (d, $J$ = 6.0 Hz, 9 H), 2.37 (s, 9 H), 2.43–2.76 (m, 6 H), 3.73–3.90 (m, 3 H), 7.25 (d, $J$ = 8.3 Hz, 6 H), 8.15 (d, $J$ = 8.3 Hz, 6 H) ppm. $^{13}$C NMR (62.90 MHz, $CDCl_3$, 25 °C): $\delta$ = 19.1 [$CH_3$, 3 C, –CH(*C*$H_3$)–N–], 21.5 ($CH_3$, 3 C, *C*$H_3$ arom.), 46.4 (CH, 3 C, $CH_2$C*H*MeN), 55.8 ($CH_2$, 3 C, NC*H*$_2$CHMe), 128.1 (CH, 6 C, CH arom.), 129.2 (CH, 6 C, CH arom.), 139.3 ($C_q$, 3 C, CH arom.), 142.6 ($C_q$, 3 C, CH arom.) ppm.

**Complex (*S*,*S*,*S*)-4c:** This complex was prepared from $AlMe_3$ and ligand (*S*,*S*,*S*)-**1c** (13.37 mg). Full conversion to colourless **4c** was observed after 2 h at 60 °C. $^1$H NMR (250.18 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.96 (d, $J$ = 7.0 Hz, 9 H), 1.00 (d, $J$ = 7.0 Hz, 9 H), 2.02–2.90 (m, 3 H), 2.23 (dd, $J$ = 13.2 and 4.8 Hz, 3 H), 2.88 (dd, $J$ = 13.2 and 10.8 Hz, 3 H), 3.65–3.79 (m, 3 H) ppm. $^{13}$C NMR (62.90 MHz, $CDCl_3$, 25 °C): $\delta$ = 17.1 ($CH_3$, 9 C, CH*C*$H_3$), 17.9 ($CH_3$, 9 C, CH*C*$H_3$), 31.0 [CH, 3 C, –*C*H($CH_3$)$_2$], 53.1 (CH, 3 C, –$CH_2$*C*H*i*Pr), 56.9 (CH, 3 C, –*C*$H_2$CH*i*Pr), 119.2 ($C_q$, $J_{C,F}$ = 320.9 Hz, 3 C, $CF_3$) ppm. $^{19}$F NMR (282.35 MHz, $C_6D_6$, 28 °C): $\delta$ = –77.95 ppm.

**Complex (*S*,*S*,*S*)-4a:** Ligand (*S*,*S*,*S*)-**3a** (1.042 g, 1.60 mmol) was placed in a 100-mL Schlenk-tube. Dry THF (10 mL) was added followed by trimethylaluminium (2.0 M in heptane, 0.800 mL, 1.60 mmol) while stirring under nitrogen. After gently heating up to reflux, gas evolution was observed from the colourless solution. The reaction mixture was heated at 60 °C for 2 h and formation of a white precipitate was observed. Complex (*S*,*S*,*S*)-**5a** (1.069 g, 1.59 mmol, 99% yield) was isolated as a white solid after centrifugation and washing with dry THF (2 × 10 mL) and pentane (2 × 10 mL). $^1$H and $^{13}$C NMR as reported above. $C_{30}H_{39}AlN_4O_6S_3$ (675): calcd. C 53.39, H 5.82, N 8.30; found C 53.52, H 5.89, N 8.47.

**Synthesis and Characterisation of $Ti^{IV}$ Complexes of Ligands (*S*,*S*,*S*)-1a, (*S*,*S*,*S*)-1c and (*R*,*R*,*R*)-1e in situ:** Ligand **1** (0.027 mmol) was added to a 1-mL volumetric flask and dissolved in $CDCl_3$. Tetrakis(diethylamino)titanium (0.010 mL, 0.028 mmol) was then added and the solution (0.500 mL) was transferred into a screw-cap NMR tube, which was sealed and kept at room temperature. The reaction was followed by $^1$H NMR spectroscopy. Once the complex was observed, the volatile diethylamine was removed under vacuum and the sample was kept in solution at 0 °C in the refrigerator.

**Complex (*S*,*S*,*S*)-5a:** Ligand (*S*,*S*,*S*)-**5a** (17.6 mg) gave the complex quantitatively after 3 d, during which time the solution turned reddish-brown. $^1$H NMR (250.18 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.03 (d, $J$ = 6.5 Hz, 9 H), 1.21 (t, $J$ = 7.4 Hz, 6 H), 2.38 (s, 9 H), 2.52 (dd, $J$ = 12.1 and 5.0 Hz, 3 H), 3.05 (dd, $J$ = 12.1 and 11.6 Hz, 3 H), 4.12–4.36 (m, 3 H), 4.36 (dq, $J$ = 11.1 and 7.4 Hz, 2 H), 4.50 (dq, $J$ = 11.1 and 7.4 Hz, 2 H), 7.23 (d, $J$ = 8.3 Hz, 6 H), 8.00 (d, $J$ = 8.3 Hz, 6 H) ppm. $^{13}$C NMR (62.90 MHz, $CDCl_3$, 25 °C): $\delta$ = 13.0 [$CH_3$, 3 C, $NCH_2$(*C*$H_3$)], 19.5 [$CH_3$, 3 C, –CH(*C*$H_3$)–N–], 21.5 ($CH_3$, 3 C, *C*$H_3$ arom.), 49.8 ($CH_2$, 6 C, N*C*$H_2$Me), 53.1 [CH, 3 C, $NCH_2$*C*H($CH_3$)–], 60.7 [$CH_2$, 3 C, N*C*$H_2$CH($CH_3$)], 127.7 (CH, 3 C, CH arom.), 129.1 (CH, 3 C, CH arom.), 141.1 ($C_q$, 3 C, CH arom.), 142.2 ($C_q$, 3 C, CH arom.) ppm.

**Complex (*S*,*S*,*S*)-5c:** Ligand (*S*,*S*,*S*)-**1c** (18.1 mg) gave the complex immediately with a 100% conversion; the solution turned dark brown. $^1$H NMR (250.18 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.93 (d, $J$ = 7.2 Hz, 9 H), 1.03 (d, $J$ = 7.2 Hz, 9 H), 1.14 (t, $J$ = 7.2 Hz, 6 H), 2.22–2.42 (m, 3 H), 2.62 (dd, $J$ = 13.2 and 6.1 Hz, 3 H), 3.30 (dd, $J$ = 13.2 and 12.1 Hz, 3 H), 4.05–4.22 (m, 3 H), 4.24 (dq, $J$ = 14.8 and 7.2 Hz, 2 H), 4.80 (dq, $J$ = 14.8 and 7.2 Hz, 2 H) ppm. $^{13}$C NMR (62.90 MHz, $CDCl_3$, 25 °C): $\delta$ = 14.1 [$CH_3$, 3 C, $NCH_2$(*C*$H_3$)], 16.6 ($CH_3$, 9 C, CH*C*$H_3$), 20.2 ($CH_3$, 9 C, CH*C*$H_3$), 31.2 [CH, 3 C, –*C*H($CH_3$)$_2$], 52.8 ($CH_2$, 6 C, N*C*$H_2$Me), 55.7 (CH, 3 C, –$CH_2$*C*H*i*Pr), 64.5 (CH, 3 C, –*C*$H_2$CH*i*Pr), 120.1 ($C_q$, $J$ = 326.2 Hz, 3 C, *C*$F_3$) ppm. $^{19}$F NMR (282.35 MHz, $C_6D_6$, 28 °C): $\delta$ = –72.53 ppm.

**Complex (*R*,*R*,*R*)-5e:** Ligand (*R*,*R*,*R*)-**1e** (19.9 mg) was used. After 6 d at room temperature followed by 6 h of heating at 60 °C, a dark-yellow solution was obtained, which according to $^1$H NMR contained 90% of complex **5e**. $^1$H NMR (250.18 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.97 (d, $J$ = 7.1 Hz, 9 H), 1.35 (t, $J$ = 7.1 Hz, 6 H), 2.32 (s, 9 H), 2.71 (s, 18 H), 3.47 (dd, $J$ = 12.5 and 10.9 Hz, 3 H), 3.38–3.63 (m, 2 H), 3.78–4.03 (m, 2 H), 4.38–4.55 (m, 3 H), 4.63 (dd, $J$ = 12.8 and 4.8 Hz, 2 H), 7.00 (s, 6 H) ppm. $^{13}$C NMR (62.90 MHz, $CDCl_3$, 25 °C): $\delta$ = 14.5 [$CH_3$, 3 C, N–$CH_2$(*C*$H_3$)], 18.4 [$CH_3$, 3 C, –CH(*C*$H_3$)–N–], 21.1 ($CH_3$, 3 C, *p*-*C*$H_3$), 23.9 ($CH_3$, 6 C, *o*,*o*-*C*$H_3$), 43.6 ($CH_2$, 6 C, N*C*$H_2$Me), 57.5 (CH, 3 C, $CH_2$*C*HMeN), 61.3 ($CH_2$, 3 C, N*C*$H_2$CHMe-), 132.6 (CH, 6 C, *C*H arom.), 132.9 ($C_q$, 3 C, CH*C*MeCH arom.), 140.9 ($C_q$, 6 C, -$SO_2$C*C*MeCH-arom.), 145.3 ($C_q$, 3 C, $SO_2$*C* arom.) ppm.

**Complex (*S*,*S*,*S*)-5a:** Ligand (*S*,*S*,*S*)-**1a** (1.048 g, 1.62 mmol) was placed in a 100-mL Schlenk-tube. Dry toluene (50 mL) was added and the mixture was stirred until the ligand was completely dissolved upon gently heating. Tetrakis(diethylamino)titanium (0.600 mL, 1.60 mmol) was then added while stirring under nitrogen. The reaction mixture turned from colourless to brown and it was refluxed for 4 h. The solvent was then evaporated under vacuum and the resulting brown powder was washed with dry pentane (2 × 20 mL). Pure **5a** (1.221 g, 1.59 mmol, 98% yield) was obtained as a brown powder. $^1$H and $^{13}$C NMR as reported above. $C_{34}H_{49}N_5O_6S_3Ti$ (768): calcd. C 53.18, H 6.43, N 9.12; found C 52.99, H 6.15, N 9.01.

**Complex (*S*,*S*,*S*)-6a:** Ligand (*S*,*S*,*S*)-**2a** (0.300 g; 1.29 mmol) was added with a syringe to a Schlenk flask followed by pentane (19 mL). The flask was cooled to –50 °C and *n*BuLi (2.5 M in hexanes, 1.51 mL, 3.78 mmol) was added dropwise during 15 min. The temperature was allowed to reach 0 °C during 30 min and the flask was then allowed to stand at room temperature for 2 h. The flask was cooled to –60 °C and [$TiCl_4$(THF)$_2$] (0.429 g, 1.26 mmol) was added under a stream of argon. The flask was slowly allowed to reach room temperature overnight and was then stirred for another 48 h. The flask was centrifuged and the dark-red solution was transferred with a transfer needle to a Schlenk flask. Most of the pentane was removed in vacuo and a crystalline material formed at –30 °C after a few days (0.227 g, 57% yield). $^1$H NMR

**Complex (*S*,*S*,*S*)-6b:** The complex with ligand (*S*,*S*,*S*)-**2b** (0.395 g; 1.26 mmol) was prepared in an identical manner in 64% yield (0.318 g). $^1$H NMR (200.13 MHz, $C_6D_6$, 25 °C): $\delta$ = 0.67 (d, $J$ = 7.0 Hz, 9 H), 0.79 (d, $J$ = 8.5 Hz, 9 H), 1.73 (m, 3 H), 2.13 (dd, $J$ = 11.7 and 5.6 Hz, 3 H), 2.84 (dd, $J$ = 10.5 and 10.5 Hz, 3 H), 3.12 (m, 3 H), 3.28 (s, 9 H) ppm. $^{13}$C NMR (50.32 MHz, $C_6D_6$, 25 °C): $\delta$ = 14.2 ($CH_3$, 3 C, CH*C*H$_3$), 18.3 ($CH_3$, 3 C, CH*C*H$_3$), 26.6 [CH, 3 C, C*H*(C$H_3$)$_2$], 43.0 ($CH_3$, 3 C, NC$H_3$), 53.6 (CH, 3 C, –$CH_2$*C*H*i*Pr), 71.7 ($CH_2$, 3 C, –*C*H$_2$CH*i*Pr) ppm. $C_{18}H_{39}ClN_4Ti$ (395): calcd. C 46.39, H 8.76, N 18.03; found C 46.21, H 8.73, N 17.98.

**X-ray Diffraction**

**(*R*,*R*,*R*)-3e:** Crystallized from chloroform/hexane by vapour diffusion. Diffraction data were measured at the Istituto di Chimica Biomolecolare of CNR (Padova), with a Philips PW1100 diffractometer by using graphite-monochromated Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å) at 293(2) K in the $\theta$–2$\theta$ scan mode up to $\theta$ = 60°. Formula: $C_{36}H_{54}N_4O_6S_3$. Monoclinic, space group $P2_1$. Unit cell parameters: $a$ = 8.496(2), $b$ = 16.355(3), $c$ = 14.374(3) Å, $\beta$ = 98.33(4)°. $V$ = 1976.2(3) Å$^3$. $Z$ = 2. $D_{calcd.}$ = 1.235 g cm$^{-3}$. $\mu$ = 2.095 mm$^{-1}$. 3176 Collected reflections, 3053 of which were independent ($R_{int}$ = 0.029). The structure was solved by direct methods of the SHELXS 97 program[56] and refined by full-matrix block least-squares on $F^2$, using all data, with the SHELXL 97 program.[57] A planarity restraint was applied to each of the three phenyl rings. Hydrogen atoms were calculated at idealised positions and refined as riding. Data/restraints/parameters: 3053/10/455. Final $R$ indices: $R_1$ = 0.038 and $wR_2$ = 0.097 [$I > 2\sigma(I)$]; $R_1$ = 0.039 and $wR_2$ = 0.101 (all data). Goodness of fit (on $F^2$): 1.063. Max. and min. residual in the final $\Delta F$ map: +0.182 and –0.223 e Å$^{-3}$.

**(*S*,*S*,*S*)-5a:** Crystals of **5a** were grown by layering a concentrated solution of the pure compound in dichloromethane with diethyl ether, and allowing slow diffusion at room temperature. Diffraction data were collected at the Laboratoire de Chimie Organométallique et de Catalyse (Institut Le Bel, Université Louis Pasteur, Strasbourg) using a Nonius–Kappa CCD diffractometer equipped with a molybdenum source [$\lambda$(Mo-$K_\alpha$) = 0.71073 Å] at 174 K. Formula: $C_{30}H_{39}AlN_4O_6S_3{\cdot}CH_2Cl_2$. Orthorhombic, space group $P2_12_12_1$. Unit cell parameters: $a$ = 7.6495(1), $b$ = 21.4914(3), $c$ = 22.3149(4) Å. $V$ = 3668.5(1) Å$^3$. $Z$ = 4. $D_{calcd.}$ = 1.380 g cm$^{-3}$. $\mu$ = 0.418 mm$^{-1}$. 10747 Collected reflections, 6021 of which were independent ($R_{int}$ = 0.06). The Nonius OpenMoleN software package was used for all calculations.[58] The refinement was carried out by least-squares methods against $F^2$. The hydrogen atoms were included at calculated positions with fixed thermal parameters. Data/restraints/parameters: 3641/0/424. Final $R$ indices: $R_1$ = 0.051 and $wR_2$ = 0.071 [$I > 2\sigma(I)$]. Goodness of fit (on $F^2$): 1.292. Max. and min. residual in the final $\Delta F$ map: +0.679 and –0.161 e·Å$^{-3}$.

CCDC-277426 and -278811 contain the supplementary crystallographic data for (*R*,*R*,*R*)-**3e** and (*S*,*S*,*S*)-**5a**, respectively. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): 2D NMR spectra of complex **5a** (NOESY) and **5e** (TOCSY and NOESY).

# Synthesis of Novel S-Bridged Heterotrinuclear Complexes Containing Six-Membered Chelate Rings: Structural, Spectroscopic, and Electrochemical Properties of $[Co\{Rh(apt)_3\}_2]^{3+}$ (apt = 3-Aminopropanethiolate)

**Nagina Amir,*[a] Masaru Motonishi,[a] Mitsuharu Fujita,[a] Yoshitaro Miyashita,*[a] Kiyoshi Fujisawa,[a] and Ken-ichi Okamoto*[a]**

**Keywords:** 3-Aminopropanethiolate / Heterometallic complexes / Crystal structures / Six-membered chelate rings / Spectroscopy / Electrochemistry

A bidentate ligand, 3-aminopropanethiolate (apt), was synthesized and treated with $RhCl_3 \cdot 3H_2O$ in basic water to yield a novel mononuclear complex, *fac*(*S*)-$[Rh(apt)_3]$ (**1**), which was characterized by spectroscopic methods. Furthermore, the reaction of **1** with $CoCl_2 \cdot 6H_2O$ in water formed the linear-type, S-bridged trinuclear complexes $\Delta\Lambda$-$[Co\{Rh(apt)_3\}_2]^{3+}$ (**2a**) and $\Delta\Delta/\Lambda\Lambda$-$[Co\{Rh(apt)_3\}_2]^{3+}$ (**2b**), which were characterized by stereochemical, spectrochemical, and electrochemical methods. **2a** and **2b** are stable and exhibit trivalency in water. X-ray crystallographic analysis of **2a** and **2b** showed that all of the bridging sulfur atoms are fixed in the *R* configuration for the $\Delta$ unit and in the *S* configuration for the $\Lambda$ unit, and each complex has six six-membered chelate rings, all of which are in the chair conformation. The crystal structure of the corresponding 2-aminoethanethiolate (aet) trinuclear complex $\Delta\Lambda$-$[Co\{Rh(aet)_3\}_2]^{3+}$ (**4a**) was also determined. The structures of **2a** and **2b** have some differences from that of **4a** as a result of the six-membered chelate rings. The Co···Rh distances in **2a** and **2b** [3.0490(4) and 3.063(1) Å] are significantly longer than this distance in the aet complex **4a** [2.9139(2) Å]. The UV/Vis absorption spectra of **2a** and **2b** indicate a shift to higher energies as compared with **4a** and $\Delta\Delta/\Lambda\Lambda$-$[Co\{Rh(aet)_3\}_2]^{3+}$ (**4b**). The chemical shifts for the $NCH_2$ and $SCH_2$ carbon atoms in **2a** and **2b** are shifted to higher fields than those for **4a** and **4b** in the NMR spectra. The $Co^{III/II}$ redox potential values are –0.56 V (**2a**) and –0.57 V (**2b**) compared with –0.35 V (**4a**) and –0.36 V (**4b**). This shows that the $Co^{III}$ state is more stable in **2a** and **2b** than it is in **4a** and **4b**.

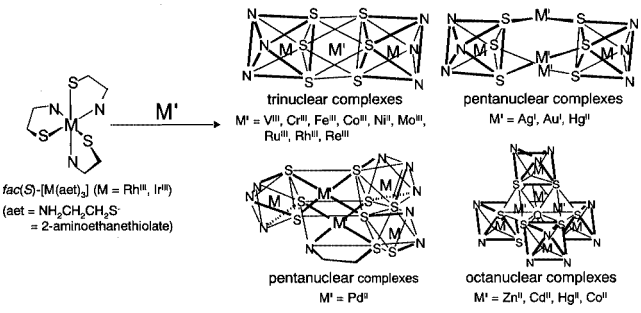
## Introduction

The chemistry of sulfur-bridged metal complexes has attracted much interest because of the importance of coordinated thiolato groups in a variety of systems ranging from inorganic to organic and biological chemistry. It has been recognized that, because of their high Lewis basicity, coordinated thiolato groups have an affinity to form S-bridged polynuclear structures with transition-metal ions. Therefore, mononuclear complexes, *fac*(*S*)-$[M(aet)_3]$ (M = $Co^{III}$, $Rh^{III}$, $Ir^{III}$; aet = 2-aminoethanethiolate), could function as metalloligands to other transition-metal ions, using sulfur atoms.[1] The polynuclear complexes obtained so far have shown unique stereochemical, spectrochemical, and electrochemical properties, depending highly upon the nature of the central metal ions and the metal ions in the terminal building blocks (Scheme 1).[1–5]



Scheme 1.

The complex $[Co(tn)_3]^{3+}$ (tn = 1,3-propanediamine) containing an additional methylene group shows some interesting differences in properties when compared with the corresponding complex $[Co(en)_3]^{3+}$ (en = ethylenediamine).[6–13] For example, six-membered chelate rings give rise to a larger bite angle (N···N distances in chelates) than five-membered rings.[6–9] It was reported that both the conformational flexibility and the structural bulkiness are larger in $[M(tn)_3]^{3+}$ than in $[M(en)_3]^{3+}$ (M = $Co^{III}$ or $Cr^{III}$

ion).[10,11] It was also observed that the ring–ring interactions, which give rise to the energy differences between conformations, are more severe and more numerous in the six-membered chelate ring complexes than in five-membered systems.[10] Moreover, the absorption maxima in the first d–d transition region in the tn complexes shift to lower energies than those in the corresponding en complexes.[12,13]

Similar to the complexes $[Co(tn)_3]^{3+}$ and $[Co(en)_3]^{3+}$ with N–N donor ligands, complexes containing five- and six-membered chelate rings with N–S donor ligands also show interesting differences in properties. For example, an additional methylene group led to differences in reactivity: all the attempts to synthesize $[Co(apt)_3]$ (apt = 3-aminopropanethiolate) were unsuccessful, unlike the corresponding complex $[Co(aet)_3]$, which was obtained easily.[14] Similarly, $[Ni(apt)_2]$ was obtained under more drastic conditions than $[Ni(aet)_2]$. Moreover, differences in chemical properties were also observed: $[Ni(apt)_2]$ gave $[Ni\{Ni(apt)_2\}_2]^{2+}$ when dissolved in polar solvents, whereas $[Ni(aet)_2]$ remained practically insoluble. The aqueous solutions of $[Ni\{Ni(apt)_2\}_2]^{2+}$ were less stable than those of the homologous trinuclear complex $[Ni\{Ni(aet)_2\}_2]^{2+}$.[15] The solubility of complexes with six-membered chelate rings, e.g. $[Ni\{Ni(apt)_2\}_2]^{2+}$, was lower than that of complexes with five-membered chelate rings, e.g. $[Ni\{Ni(aet)_2\}_2]^{2+}$.[16] As far as structure was concerned, the most striking difference resulting from the presence of an additional methylene group was found to be the opening of the dihedral angle by 30°. This can be attributed to the steric requirements of the enlargement of the chelate ring. The electronic properties are also influenced by the additional methylene group, which could be explained in terms of different bond lengths and angles of the chromophores in these complexes.[15]

It has been well explained in the literature that the variations in the bridging ligands provide remarkable control over the electronic structures and photophysics of complexes. In one of the reports it was found that bpa dimers [bpa = 1,2-bis(4-pyridyl)ethane] exhibit a broad, low-energy emission from a metal-centered $^3$LF excited state, whereas the bpe and bpy dimers [bpe = *trans*-1,2-bis(4-pyridyl)ethylene, bpy = 4,4′-bipyridyl] exhibit structured emission from the lowest pyridyl-centered $3(\pi–\pi^*)$ excited state.[17] In another report, complexes of 4-pyridine thiolate with $Co^{II}$, $Ni^{II}$, $Zn^{II}$, $Cd^{II}$, $Hg^{II}$, $Pt^{II}$, $Sn^{IV}$, and $Bi^{III}$ involve bonding through sulfur rather than nitrogen,[18] while complexes of 2-(2-mercaptoethyl)pyridine with $Co^{II}$, $Ni^{II}$, $Pd^{II}$, and $Pt^{II}$ involve bonding through sulfur as well as nitrogen.[19] It can therefore be demonstrated that the modifications of the bridging ligand provide exquisite control over the electronic structures and photophysics of the compounds, including the orbital character of the lowest emissive state. It is also assumed that the complexes using apt, which has an additional methylene group as compared with aet, can lead to somewhat different structural, spectrochemical, or electrochemical properties, which might be quite interesting.

No doubt metal complexes of aet ligands have been widely studied, many of them form stable chelates, but those of apt have received little attention up to now. Only a few $Co^{III}$, $Ni^{II}$, $Zn^{II}$, $Cd^{II}$, $Hg^{II}$, and $Fe^{III}$ complexes have been reported.[14,15,20,21] The polynuclear complexes obtained were homopolynuclear complexes only, and to the best of our knowledge, there is no report of heteropolynuclear complexes. The choice of apt is based on the simplicity of the ligand and the fact that the ligand had been poorly studied. Turning to six-membered rings in the mononuclear unit, we are interested in the effects of changes in the three-dimensional structure on the metal, spectroscopic, and electrochemical properties.

In this paper, we report on the stepwise synthesis of aptH·HCl from 3-aminopropanol following literature methods with some modifications.[22–24] After synthesis, aptH·HCl was treated with the $Rh^{III}$ ion to obtain a mononuclear complex *fac*(*S*)-$[Rh(apt)_3]$ (**1**), which reacts with the $Co^{II}$ ion to form heterotrinuclear complexes $[Co\{Rh(apt)_3\}_2]^{3+}$ in *meso* (**2a**) and *racemic* (**2b**) forms. Crystal structural analysis and spectrochemical characterization have been described comparatively for the corresponding aet complexes. Electrochemical measurements were also performed.

## Results and Discussion

### Synthesis of Ligand

The ligand aptH·HCl was prepared by modified literature methods.[22–24] There was only a very simple description for the synthesis of the aminoalkanethiol series in the literature. Therefore, the synthesis of aptH·HCl was examined in detail and improved. The ligand was obtained by the three-step reaction shown in Scheme 2. Each compound was characterized by elemental analysis and NMR spectroscopy.

The first step of the reaction was vigorous and was therefore carried out in an ice bath. From this step, the compound 1-amino-3-propylsulfate (**I**) was obtained. The second step gave tetrahydro-1,3-thiazine-2-thione (**II**) with the ring-formation reaction of **I** and carbon disulfide. Compound **II** is a thione-thiol tautomer that consists of tetrahydro-1,3-thiazine-2-thione and 5,6-dihydro-1,3-thiazine-2-thiol (Figure 1). The X-ray crystal structure of **II** is shown in Figure 2, and bond lengths and angles are listed in Table 1. The six-membered ring is not a planar structure because of the $sp^3$ carbon atoms C1 and C2, and the $sp^3$ sulfur atom S1, although the C1, S1, C4, N1, C3, and S2 atoms are almost on the same plane. The S2–C4 distance [1.692(3) Å] is shorter than the length of the single bond S1–C1 [1.814(4)] and S1–C4 [1.729(3) Å]. It is reported that the length of the single bond S–C of typical thiol compounds is 1.82 Å, and that of typical thione compounds is 1.56 Å.[25–28] Similarly, the N1–C4 distance [1.321(4) Å] is shorter than the length of the single bond N1–C3 [1.471(5) Å], which suggests multibonding. Thus, the C4 atom is in an $sp^2$ hybridized state. The S1–C4 distance in **II** is similar to the corresponding S–C distance [1.722(7) Å] in *N*,*N*′-trimethylenethiourea.[29]

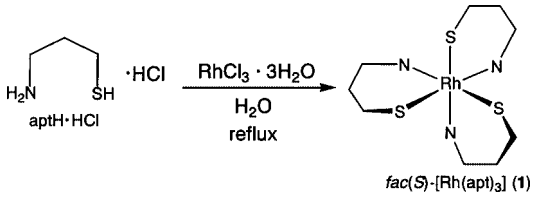
The third step in the reaction of **II** gave aptH·HCl as a result of ring opening. This ligand is hygroscopic and soluble in water, methanol, ethanol, and acetone, and less soluble in other solvents. The overall process was carried out in a manner similar to that of the synthesis of 1-Meaet (1-Meaet = 1-amino-2-propanethiolate).[30]

### Syntheses of Complexes

Preparation of the apt mononuclear complex *fac*(*S*)-[Rh(apt)$_3$] (**1**) (Scheme 3) was carried out by a modified method of the synthesis of the aet mononuclear complex, *fac*(*S*)-[Rh(aet)$_3$] (**3**).[31,32] The difference between the syntheses was the order in which the starting materials were added. For the synthesis of the aet mononuclear complex, $RhCl_3 \cdot 3H_2O$ was added to a basic aqueous solution containing the ligand, and the mixture was heated to reflux under nitrogen. However, in this work, the apt was added at the end and gave a higher yield than a similar method for synthesizing the aet mononuclear complex. The resulting yellow powder was found to be **1**. This neutral complex is not soluble in general solvents, but soluble in acidic water following the protonation of the sulfur atoms of the coordinated thiolato group. Complex **1** was obtained more easily and in a purer form than the complexes *fac*(*S*)-[Co(apt)$_3$] and *trans*(*S*)-[Ni(apt)$_2$], which were obtained under more drastic conditions.[15]



Scheme 3.

The trinuclear complexes ΔΛ-[Co{Rh(apt)$_3$}$_2$](NO$_3$)$_3$ [**2a**(NO$_3$)$_3$] and ΔΔ/ΛΛ-[Co{Rh(apt)$_3$}$_2$]Br$_3$ (**2b**Br$_3$) were synthesized by the reported procedure, but using aptH instead of aetH.[33] It was found that, in the case of **2a**(NO$_3$)$_3$ and **2b**Br$_3$, the reaction gave the trivalent Co$^{III}$ complexes under nitrogen or air. This result is different from the case of ΔΛ-[Co{Rh(aet)$_3$}$_2$](NO$_3$)$_3$ [**4a**(NO$_3$)$_3$] and ΔΔ/ΛΛ-[Co{Rh(aet)$_3$}$_2$]Br$_3$ (**4b**Br$_3$), which gave divalent Co$^{II}$ complexes under such conditions, in which case $H_2O_2$ was used for oxidation.[33] This difference in reactivity can be related to the difference in the redox potential of the Co$^{III}$ ion in trinuclear structures (vide infra). Complexes **2a** and **2b** (Scheme 4) were obtained both in *meso* and *racemic* forms similar to **4a** and **4b**. Selective crystallization using suitable counter anions was achieved. This is different from the case of the Co$^{III}$ complexes in which [Co{Co(aet)$_3$}$_2$]Cl$_3$ gave both *meso* and *racemic* forms while [Co{Co(apt)$_3$}$_2$]Cl$_3$ gave only the *meso* form.[14,21]

### Crystal Structures of Complexes 2a, 2b, and 4a

The results of the ICP analysis and elemental analysis confirmed that the ratio of Co to Rh was 1:2 in **2a** and **2b**. The values obtained for the molar conductivity in aqueous solution for the apt complexes **2a** and **2b** (329 and 363 S·cm$^2$·mol$^{-1}$, respectively) are comparable to the values of the aet complexes **4a** and **4b** (384 and 401 S·cm$^2$·mol$^{-1}$, respectively). These values are also within the range normally observed for other trivalent trinuclear complexes containing *fac*(*S*)-[Rh(aet)$_3$] units (323–404 S·cm$^2$·

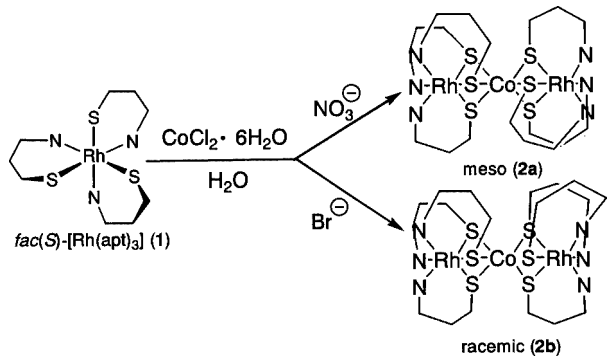

Scheme 4.

mol$^{-1}$).[2,3,34,35] The structures of **2a**, **2b**, and **4a**, determined by X-ray structural analysis, are shown in Figures 3, 4, and 5, respectively. The crystal structure of **4a** was determined for purposes of comparison. The selected bond lengths and angles are summarized in Table 2 and Table 3. Compounds **2a** and **2b** consist of two approximately octahedral *fac*(*S*)-[Rh(apt)$_3$] units and one Co atom, forming the completely linear-type, S-bridged trinuclear structures, ΔΛ-[Co{Rh(apt)$_3$}$_2$]$^{3+}$ (for **2a**) and ΔΔ/ΛΛ-[Co{Rh(apt)$_3$}$_2$]$^{3+}$ (for **2b**). Only the ΛΛ configuration of **2b** is shown in Figure 4. All of the bridging sulfur atoms in **2a** and **2b** have the *R* configuration for the Δ unit and the *S* configuration for the Λ unit, which corresponds to the results in all of the reported trinuclear structures. Each complex has six six-membered chelate rings in a molecule, and all of the rings are in the chair conformation.

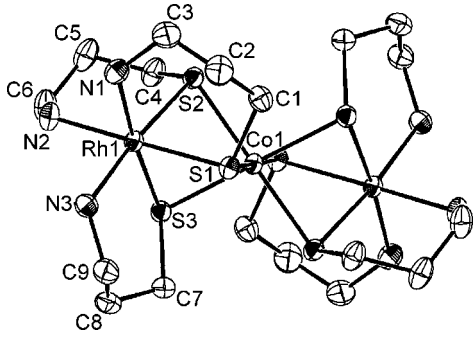

Figure 3. Crystal structure of **2a**.

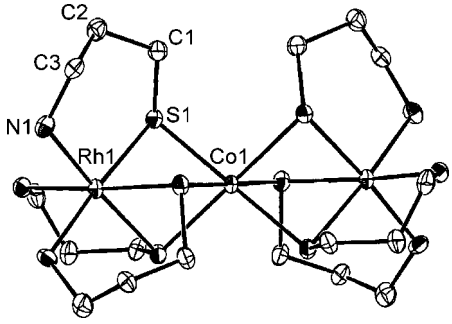

Figure 4. Crystal structure of **2b**.

The Co···Rh distances in apt complexes **2a** and **2b** [3.0490(4) and 3.063(1) Å] are significantly longer than that in the aet complex **4a** [2.9139(2) Å]. The Rh–S [av. 2.322(1) Å], Rh–N [av. 2.133(5) Å], and Co–S [av. 2.291(1) Å] distances in **2a** are slightly longer than those in **4a** [av. 2.306(8), av. 2.121(3), and av. 2.290(9) Å]. The S–Rh–S (av. 80.43(4)°), N–Rh–N [av. 88.2(2)°], and S–Co–S [av. 81.71(4)°] angles in **2a** are more acute than those in **4a** [av. 83.75(3), av. 96.2(1), and av. 84.45(3)°] while Co–S–Rh angles [av. 82.73(4)°] in **2a** are more obtuse than those in **4a** [av. 78.67(3)°]. These differences in the bond lengths and angles are attributed to the presence of six-membered chelate rings that are formed between the metal and ligands in the case of apt complexes **2a** and **2b** compared with the five-membered chelate rings found in the case of aet complex **4a**. It can be concluded that increasing the number of methylene groups in the chelate rings influences the stereochemistry of the complexes. Six-membered chelate rings give rise to a larger bite angle than five-membered rings, which is very clearly observed in the present case. The S–Rh–N bite angles in **2a** [av. 96.0(1)°] and **2b** [98.5(3)°] are significantly larger than those in **4a** [av. 87.0(1)°].

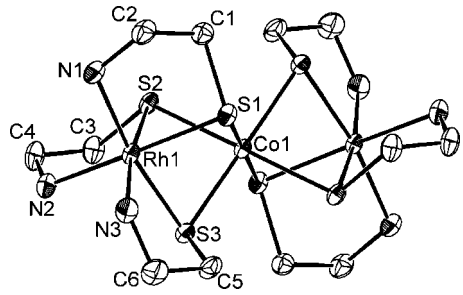

Figure 5. Crystal structure of **4a**.

## Spectroscopic Properties

### *UV/Visible Spectra*

Diffuse reflectance (DR) spectra of **1** and **3** were measured in the solid state, since the neutral mononuclear complexes are sparingly soluble in water. Both complexes exhibit the characteristic intense bands at ca. $40\times10^3$ cm$^{-1}$. These bands may be due to charge transfer (CT) transitions from the sulfur atoms to the Rh$^{III}$ ion. This suggests that **1** is the apt mononuclear complex *fac*(*S*)-[Rh(apt)$_3$] with the same geometry as **3**.

UV/Vis absorption (AB), DR, and circular dichroism (CD) spectra of **2a** and **2b** are shown in Figure 6. It was found that **2a** and **2b** exhibit characteristic AB and CD spectra of the trinuclear structure just as for complexes **4a** and **4b** with some shift towards the higher energy side.[33] The observed AB peaks arise from d–d transitions and CT transitions from the sulfur atoms to the metal ions. The peaks observed at about $40–50\times10^3$ cm$^{-1}$ are due to CT transitions from the sulfur atoms to the Rh$^{III}$ ion. DR and AB spectra show similar patterns, and therefore it is believed that the symmetry of **2a** and **2b** is not altered in solution. Furthermore, AB did not change with time. This means that **2a** and **2b** are stable for a long time in solution.

[a] Symmetry code: $1 - y, x - y, z$.

When comparative studies were performed, it was found that there was no significant difference between the electronic spectra of the aqueous solutions of **2a**, **2b** and **4a**, **4b**. This trend is similar to that of $[Co\{Co(aet \text{ or } apt)_3\}_2]^{3+}$ [14,21], whereas it is different from that of $[Ni\{Ni(aet \text{ or } apt)_2\}_2]^{2+}$, in which important differences were observed.[15] The AB peaks in **2a** and **2b** were observed at higher energy levels compared with those in the corresponding $Co^{III}$ and $Ni^{II}$ complexes. It is therefore concluded that the addition of another methylene group to the chelate ring in octahedral trinuclear complexes does not cause important modifications in the chromophores, and the structures are very similar in both cases.

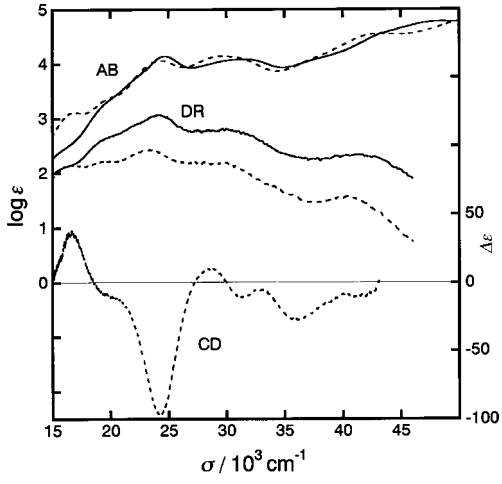

Figure 6. UV/Vis AB (log $\varepsilon$), DR (arbitrary scale), and CD ($\Delta\varepsilon$) spectra of **2a** (———) and $(-)^{CD}_{412}$-**2b** (- - - - -).

The CD spectrum of **2b**, which was optically resolved with an SP-Sephadex C-25 column, shows bands in the region $15–40 \times 10^3$ cm$^{-1}$. These CD bands correspond well to the d–d and CT bands for $[Co\{Rh(apt)_3\}_2]^{3+}$ in the AB spectra. It seems that $(-)^{CD}_{412}$-**2b** is the ΛΛ isomer and $(+)^{CD}_{412}$-**2b** is the ΔΔ isomer. The CD spectrum of **2b** is also in agreement with that of **4b**. In the CD spectra, no significant changes were observed with time over several hours. This illustrates that the trinuclear structures are fairly stable, retaining their oxidation state even under aerobic conditions.

### *IR and Far-IR Spectra*

The IR and far-IR spectra of **I**, **II**, and aptH·HCl show all the characteristic bands for the vibration and bending modes of the $NH_2$ and $CH_2$ groups (Figure S1). The overall IR spectral pattern of **1** is in good agreement with that of **3**.[35] The IR spectral patterns of **2a**$(NO_3)_3$ and **2b**$Br_3$ are similar to each other, reflecting the similarity between the isomers (Figure S2). Moreover, these spectral patterns are typical for linear-type, S-bridged trinuclear complexes in the range 4000–400 cm$^{-1}$.[2,3,35–38] The IR spectra of **1**, **2a**$(NO_3)_3$, and **2b**$Br_3$ show characteristic bands in the range 3500–2800 cm$^{-1}$, corresponding to the vibration modes of the $NH_2$ and $CH_2$ groups. The bands for the bending mode of the $NH_2$ and $CH_2$ groups are observed at 1700–1000 cm$^{-1}$. The IR spectra show similar patterns in the range 3500–2800 cm$^{-1}$, but in the range 1700–1000 cm$^{-1}$, there are small differences between the spectrum of the mononuclear complex **1** and those of the trinuclear complexes **2a**$(NO_3)_3$ and **2b**$Br_3$. The bands at ca. 1100 cm$^{-1}$ in **1** are shifted to higher energies in **2a**$(NO_3)_3$ and **2b**$Br_3$, which reflects the change from mononuclear to trinuclear geometry. The same trend is observed in the case of $Co^{II}$, $Ni^{II}$, $Zn^{II}$, $Cd^{II}$, and $Hg^{II}$ complexes with apt.[14,15,20,21] The similarity between the IR spectral patterns of **1** and those of the trinuclear **2a**$(NO_3)_3$ and **2b**$Br_3$ shows that the terminal units retain their structure during the formation of S-bridged complexes. The absence of bands in the range 2550–2600 cm$^{-1}$ (υS–H) is characteristic of coordinated sulfur. The far-IR spectra of **1**, **2a**$(NO_3)_3$, and **2b**$Br_3$ are quite complicated, but show little difference in the region 500–420 cm$^{-1}$ be-

tween the mononuclear complex **1** and the two trinuclear complexes **2a**$(NO_3)_3$ and **2b**$Br_3$ (Figure S2). Because the far-IR spectra were complicated, it was difficult to assign the bands for the shifts resulting from the vibrations of the Co–S bonds.

### *NMR Spectra*

The $^1$H- and $^{13}$C NMR spectra were measured for each product during the synthesis of ligands **2a** and **2b**. The ligand aptH·HCl as well as **I** and **II** show three sharp signals for the C$H_2$ protons and three sharp signals for the *C*$H_2$ carbons. The proton signals in the $^{13}$C-$^1$H heteronuclear multiple-bond correlation spectrum (HMBC) of aptH·HCl show coupling with the corresponding carbon signals (Figure S3). Moreover, the proton signals in the $^1$H-$^1$H correlation spectroscopy (COSY) indicate coupling between the corresponding proton signals. Both **2a** and **2b** also exhibit three sets of sharp proton signals and three carbon signals resulting from the six apt ligands (Figure S4). This means that the $S_6$ or $D_3$ symmetrical, S-bridged, trinuclear structures observed in the crystals are retained in aqueous solution. The details of the NMR spectroscopic data are shown in Table 4. In **2a** and **2b**, the chemical resonances in the $^1$H NMR spectra show shifts to lower fields for the NC$H_2$ protons and to higher fields for the SC$H_2$ protons. Moreover, the splitting pattern for the protons is also different from that observed in **4a** and **4b**.[35] It is worth noting that the chemical shifts for the N*C*$H_2$ and S*C*$H_2$ carbon atoms in **2a** and **2b** show shifts to higher fields than those for **4a** and **4b**.

### Electrochemical Properties

Cyclic voltammetry experiments were performed for **2a** and **2b**. The cyclic voltammogram obtained for **2b** is shown in Figure 7. For the already reported complexes of apt with $Co^{III}$, $Ni^{II}$, $Zn^{II}$, $Cd^{II}$, and $Hg^{II}$, there is no information about the electrochemical properties.[14,15,20,21] Therefore, to the best of our knowledge, this is the first report on the electrochemistry of S-bridged complexes containing apt. Each of the voltammograms displays a quasi-reversible redox couple in the negative potential region. In analogy to the characterized electrochemistry of the $[Co\{M(aet)_3\}_2]^{3+}$ (M = $Rh^{III}$, $Co^{III}$) system,[33,39–41] this redox process is assigned as the redox couple corresponding to $Co^{III/II}$. The redox couples of the apt complexes **2a** (–0.56 V) and **2b** (–0.57 V) are more negative than those of the aet complexes **4a** (–0.35 V) and **4b** (–0.36 V).[33,39] This means that the $Co^{III}$ state in apt complexes is more stable than that in **4a** and **4b**. A possible reason for this might be the difference in nucleophilicity of sulfur or structural differences of the $Co^{III}$ ion resulting from the additional methylene group in apt, which forms six-membered chelates rather than five-membered ones, as is the case for aet. Since the difference in reduction potential resulting from the difference in the configuration of complexes is very slight, the $E_{1/2}$ value for the *meso* isomer **2a** is only 0.01 V more positive than that for the corresponding *racemic* isomer **2b**. A profound difference was observed when the ligand was changed from *fac*(*S*)-[Rh(aet)$_3$] to *fac*(*S*)-[Rh(apt)$_3$], where **2b** is reduced (0.21 V) more easily than **4b**. The redox process of **2b** is reversible, as with **4a** and **4b**. However, in the case of **2a**, the observed peak separation was too broad to establish whether the redox process is reversible. The difference in electrochemical properties of **2a**, **2b** and **4a**, **4b** could be related to the difference of reactivity explained in the synthetic part, where it was found that, in the case of **2a** and **2b**, the reaction under nitrogen or air gave the trivalent $Co^{III}$ complexes as compared with the case of **4a** and **4b**, where $H_2O_2$ was used for oxidation.

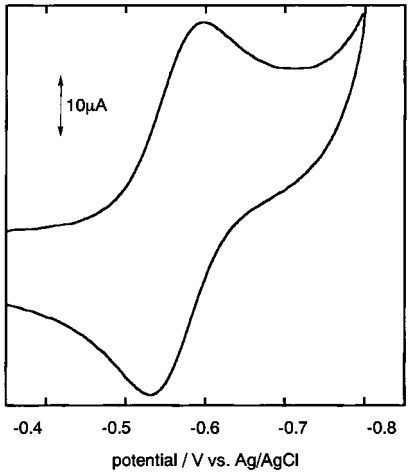

Figure 7. Cyclic voltammogram of **2b**.

## Conclusions

A novel mononuclear complex *fac*(*S*)-[Rh(apt)$_3$] (**1**) was synthesized and characterized by spectroscopic methods. The reaction of **1** with $CoCl_2 \cdot 6H_2O$ in water formed linear-type, S-bridged trinuclear complexes ΔΛ-[Co{Rh(apt)$_3$}$_2$]$^{3+}$ (**2a**) and ΔΔ/ΛΛ-[Co{Rh(apt)$_3$}$_2$]$^{3+}$ (**2b**), unlike ΔΛ-[Co{Rh(aet)$_3$}$_2$]$^{3+}$ (**4a**) and ΔΔ/ΛΛ-[Co{Rh(aet)$_3$}$_2$]$^{3+}$ (**4b**) where an oxidizing agent was required. The complexes were characterized by stereochemical, spectrochemical, and electrochemical techniques. The Co···Rh, Rh–S, and Rh–N distances in **2a** and **2b** are longer than those of **4a**. The differences in bond lengths and angles are due to the presence of six-membered chelate rings in **2a** and **2b**, rather than the five-membered chelate rings in **4a**. The absorption bands in **2a** and **2b** are shifted to higher energies than those of **4a**. The results of IR and far-IR spectra indicate that the terminal units retain their structure during the formation of S-bridged complexes. NMR spectra of **2a** and **2b** show that the chemical shift values in $^{13}C$ NMR are shifted to higher fields as compared to **4a** and **4b**. In addition, the $Co^{III}$ oxidation state in **2a** and **2b** is more stable than that in **4a** and **4b**. It can be concluded that the properties of complexes are greatly influenced by increasing the number of methylene groups in the chelate rings.

## Experimental Section

### Materials

The aet complexes *fac*(*S*)-[Rh(aet)$_3$] (**3**), ΔΛ-[Co{Rh(aet)$_3$}$_2$](NO$_3$)$_3$ [**4a**(NO$_3$)$_3$], and ΔΔ/ΛΛ-[Co{Rh(aet)$_3$}$_2$]Br$_3$ (**4b**Br$_3$) were prepared by procedures similar to those in the literature.[31–33] All reagents were purchased from Wako Pure Chemical Ind. Ltd. All chemicals were of reagent grade and were used without further purification.

### Preparation of Ligand

The ligand was prepared by literature methods with some modifications as follows.[22–24]

**1-Amino-3-propylsulfate (I):** A mixture of 3-amino-1-propanol (75.1 g, 1.0 mol) and carbon tetrachloride (200 cm$^3$) was cooled in an ice bath. Chlorosulfonic acid (116.5 g, 1.0 mol) was slowly added to the mixture. The reaction mixture was kept overnight, and carbon tetrachloride was removed in vacuo. The crude solid was crushed with methanol (400 cm$^3$), and isolated by filtration. A pure white powder of 1-amino-3-propylsulfate was obtained by recrystallization from water/methanol. Yield: 123.5 g, 79%. $C_3H_9NO_4S$ (155.17): calcd. C 23.35, H 5.66, N 9.15; found C 22.87, H 5.57, N 8.88.

**Tetrahydro-1,3-thiazine-2-thione (II):** To a suspension containing 1-amino-3-propylsulfate (252.2 g, 1.62 mol) and carbon disulfide (150.0 g, 1.94 mol) in ethanol (50%, 700 cm$^3$) was added slowly in an ice bath NaOH (141.8 g, 3.56 mol) in ethanol (50%, 300 cm$^3$). After the reaction mixture was heated to reflux for 30–40 min the ethanol was removed by evaporation. Colorless crystals of tetrahydro-1,3-thiazine-2-thione were obtained by recrystallization from hot water. Yield: 149.0 g, 70%. $C_4H_7NS_2$ (133.22): calcd. C 36.06, H 5.30, N 10.51; found C 35.40, H 5.06, N 10.34.

**3-Aminopropanethiol Hydrochloride (aptH·HCl):** A suspension of tetrahydro-1,3-thiazine-2-thione (149.0 g, 1.12 mol) in conc. HCl (800 cm$^3$) was heated to reflux for 3 weeks. After evaporating until an oil remained, a white precipitate of aptH·HCl was obtained by the addition of ethanol/ether. Yield 133.0 g, 95%. $C_3H_{10}ClNS$ (127.63): calcd. C 28.23, H 7.89, N 10.97; found C 29.05, H 6.67, N 10.30.

### Preparation of Complexes

***fac*(*S*)-[Rh(apt)$_3$] (1):** To a solution containing NaOH (0.61 g, 15 mmol) in water (10 cm$^3$) was added $RhCl_3 \cdot 3H_2O$ (0.10 g, 0.38 mmol). A solution of aptH·HCl (1.10 g, 8.6 mmol) in water (40 cm$^3$) was then added to this mixture . The mixture gave a yellow precipitate after slight heating and was then heated to reflux for a further 1–1.5 h. The yellow precipitate was collected by filtration and washed with water, methanol, and acetone. Yield of **1**·2H$_2$O: 0.075 g, 53%. $C_9H_{28}N_3O_2RhS_3$ (409.42): calcd. C 28.05, H 6.63, N 10.90; found C 28.02, H 6.11, N 10.34. Reflectance maxima ($\sigma$/$10^3$ cm$^{-1}$): 13.5, 28.5, 34.1 sh, 40.4.

**ΔΛ-[Co{Rh(apt)$_3$}$_2$](NO$_3$)$_3$ [2a(NO$_3$)$_3$] and ΔΔ/ΛΛ-[Co{Rh(apt)$_3$}$_2$]Br$_3$ (2bBr$_3$):** To a suspension containing **1** (0.20 g, 0.55 mmol) in water (10 cm$^3$) was added a solution containing $CoCl_2 \cdot 6H_2O$ (0.65 g, 2.7 mmol) in water (5 cm$^3$). The mixture was stirred at room temperature for 30 min and filtered. A saturated aqueous solution of $NaNO_3$ (5 cm$^3$) was added to the dark brown filtrate, and the resulting dark red crystals [**2a**(NO$_3$)$_3$·2H$_2$O] were collected by filtration. A saturated aqueous solution of NaBr (5 cm$^3$) was added to the filtrate, and the resulting dark red crystals (**2b**Br$_3$·3.5H$_2$O) were collected by filtration. Crystals suitable for X-ray crystallography were obtained by recrystallization of **2a**(NO$_3$)$_3$·2H$_2$O and **2b**Br$_3$·3.5H$_2$O from the aqueous solutions containing $NaNO_3$ and NaCl. Yield of **2a**(NO$_3$)$_3$·2H$_2$O: 0.065 g, 12%. $C_{18}H_{52}CoN_9O_{11}Rh_2S_6$ (1027.77): calcd. C 21.04, H 5.10, N 12.27; found C 21.19, H 4.98, N 11.89. Absorption maxima [$\sigma$/$10^3$ cm$^{-1}$ (log $\varepsilon$/mol$^{-1}$·dm$^3$·cm$^{-1}$)]: 14.5 (2.11), 20.9 (3.49), 24.7 (4.14), 31.5 (4.08 sh), 38.6 (4.13 sh), 48.7 (4.78). Reflectance maxima ($\sigma$/$10^3$ cm$^{-1}$): 15.3, 19.0, 24.2, 29.6 sh, 41.1. Yield of **2b**Br$_3$·3.5H$_2$O: 0.045 g, 7.9%. $C_{18}H_{55}Br_3CoN_6O_{3.5}Rh_2S_6$ (1100.49): calcd. C 19.50, H 5.00, N 7.58; found: C 19.73, H 5.08, N 7.96. Absorption maxima [$\sigma$/$10^3$ cm$^{-1}$ (log $\varepsilon$/mol$^{-1}$·dm$^3$·cm$^{-1}$)]: 16.7 (3.11), 18.3 (3.14), 24.3 (4.06), 29.7 (4.14 sh), 40.2 (4.35 sh), 51.0 (4.80). Reflectance maxima ($\sigma$/$10^3$ cm$^{-1}$): 16.5, 19.1, 23.4, 29.5 sh, 40.3.

### Column Chromatography

Column chromatography was also performed with an SP-Sephadex C-25 column ($Na^+$ form). When the reddish brown filtrate was

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

eluted with a NaCl solution (0.5 M), two bands were obtained: a reddish brown band followed by a greenish brown band. The UV/Vis absorption spectra of the bands showed that the reddish brown band contains **2a** and the greenish brown band contains **2b**. The purity of the isomers that had been obtained by fractional precipitation, was confirmed by column chromatography [SP-Sephadex C-25 column ($Na^+$ form)].

**Optical Resolution of 2b**

Compound **2b** was optically resolved with an SP-Sephadex C-25 column ($K^+$ form). An aqueous solution of **2b** was charged onto the column and adsorbed. The column was first eluted with an aqueous solution of $K_2[Sb_2(R,R\text{-tartrato})_2]\cdot 5H_2O$ (0.15 M), whereupon two distinct greenish brown bands were separated. The bands were finally eluted and collected by an aqueous solution of KCl (0.5 M). The CD spectra of the two bands were measured, which had a positive or negative CD sign at 412 nm. The CD spectra of two bands were just opposite to each other. The $\Delta\varepsilon$ values of each eluent containing the $(+)_{412}^{CD}$ and $(-)_{412}^{CD}$-**2b** isomers were evaluated on the basis of the absorption spectroscopic data of **2b**$Br_3\cdot 3.5H_2O$. CD extrema [$\sigma/10^3$ $cm^{-1}$ ($\Delta\varepsilon$/$mol^{-1}\cdot dm^3\cdot cm^{-1}$)]: **2b** (lower) 16.73 (–41.06), 24.26 (+99.62), 28.62 (–11.27), 31.38 (+10.65), 35.94 (+28.10), 42.05 (+10.96); **2b** (upper) 16.62 (+38.24), 24.19 (–96.92), 28.80 (+10.45), 31.46 (–11.07), 36.23 (–27.98), 41.87 (–10.12).

**Measurements**

Elemental analysis (C, H, and N) was performed by the Department of Chemistry in the University of Tsukuba. The concentrations of Co and Rh in the complexes were determined with a NIPPON Jarrell-Ash ICPA-575 spectrometer. UV/Vis absorption spectra were recorded with a JASCO V-560 spectrophotometer and solid-state diffuse reflectance spectra were recorded with a JASCO V-570 spectrophotometer equipped with an integrating sphere apparatus (JASCO ISN-470) using powder samples diluted with MgO. IR and far-IR spectra were recorded with a JASCO FT/IR-550 spectrometer using KBr disks in the range 4000–400 $cm^{-1}$ and Nujol mulls between polyethylene pellets in the range 650–50 $cm^{-1}$. $^1H$ and $^{13}C$ NMR spectra were recorded with a BRUKER AM500 and AM600 NMR spectrometer in $D_2O$ using sodium 4,4-dimethyl-4-silapentane-1-sulfonate (DSS) as an internal reference or $CDCl_3$ using tetramethylsilane (TMS) as an internal reference. The molar conductance of the complexes was measured with a HORIBA conductivity meter (DS-14). Electrochemical experiments were performed with a CV-50W voltammetry analyzer, Bioanalytical Systems, Inc. (BAS) with a platinum-working electrode (BAS, Pt). In the electrochemical experiments an aqueous Ag/AgCl/NaCl (3 $mol\cdot dm^{-3}$) (BAS, RE-1B) and platinum wire were used as the reference and auxiliary electrodes, respectively. All the measurements were carried out at room temperature in an aqueous solution, which was bubbled with $N_2$ gas, and contained $Na_2SO_4$ (0.1 $mol\cdot dm^{-3}$) as a supporting electrolyte.

**X-ray Crystal Structure Determinations**

Single-crystal X-ray data collections were performed with a Rigaku AFC-7S Mercury CCD area detector with a graphite monochromatized Mo-$K_\alpha$ (0.71070 Å) radiation using the CrystalClear (Rigaku) program package. Crystallographic data of **II** and complexes **2a**$(NO_3)_3\cdot 2H_2O$, **2b**$Cl_3$, and **4a**$(NO_3)_3\cdot 3H_2O$ are listed in Table 5. The positions of Rh, Co, and non-hydrogen atoms were determined by direct methods (SHELX 97 **2a**, **4a**)[42] or (SIR97 **II**, **2b**),[43] and some remaining atom positions were found by successive difference Fourier techniques (DIRDIFF-99).[44] The structures were refined by full-matrix least-squares techniques using anisotropic thermal parameters for non-hydrogen atoms. All hydrogen atoms except for those of **II** were included in calculated positions but not refined. The CrystalStructure (Rigaku) program package was used for the calculations.[45]

CCDC-279990–CCDC-279993 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): IR and far-IR spectra of **I**, **II**, and aptH·HCl (Figure S1); IR and far-IR spectra of complexes **1**, **2a**, and **2b** (Figure S2); $^1H$-$^1H$

# Theoretical Studies on Metal–Metal Interaction and Intrinsic $^{1,3}$[σ*(d)σ(s/p)] Excited States of Dinuclear d$^{10}$ Complexes with Bridging Phosphane Ligands

Qing-Jiang Pan,[a,b] Hong-Xing Zhang,*[a] Hong-Gang Fu,[b] and Hai-Tao Yu[b]

**Keywords:** Metallophilicity / Excited states / Dinuclear d$^{10}$ complexes / Electronic structure / Solvent effects

To explore the metal–metal interaction and spectroscopic properties, the ground- and excited-state structures of $[M_2(dpm)_2]^{2+}$ [M = Ag (**2**), Cu (**3**), dpm = bis(diphosphanyl)-methane] and their solvated species $[M_2(dpm)_2]^{2+}\cdot(MeCN)_2$ were optimized by the MP2 and CIS methods, respectively. In the ground states, the calculated M–M distances and their corresponding M–M stretching frequencies for **2** and **3** indicate the presence of metallophilic attraction; there is strong N→Cu/Ag coordination in acetonitrile, which is different from the case in previous studies of $[Au_2(dpm)_2]^{2+}$ (**1**). CIS calculations show that **2** and **3** have $^{1,3}[\sigma^*(d)\sigma(s/p)]$ as their lowest-energy excited state, as is also the case for **1**, confirmed by unrestricted MP2 calculations. On the basis of the CIS-optimized structures, the TD-DFT (B3LYP) method was employed to calculate the emission spectra of such complexes. For **3**, the phosphorescent emissions were calculated at 424 and 514 nm in the solid state and acetonitrile, which is comparable to the experimental data of 475 and 480 nm, respectively. The comparison between the gas-phase and solution emissions for **1**–**3** reveals that the N→M coordination results in a large red-shift of the emission wavelength. Taking previous studies into account , we found that the M–M distances are linearly correlated with the M–M stretching frequencies for the dinuclear d$^{10}$ complexes.

## Introduction

Despite the fact that two closed-shell metal cations would normally be expected to repel each other, a larger number of inorganic and organometallic complexes have been described whose structures indicate strong metal–metal interactions.[1–5] Among these interactions, the Au$^{I}$–Au$^{I}$ interaction has been intensively investigated both experimentally[6–11] and theoretically,[2–4,12–17] and coined as "aurophilicity" by Schmidbaur.[18] The energy of the aurophilic attraction in the solid state and solution was estimated to be 7–15 kcal/mol,[3] comparable to that of hydrogen bonds. Pyykkö et al.[1–4] have attributed the attraction to correlation effects that are strengthened by relativistic effects.

The Au–Au aurophilic attractions often result in unusual photochemical and photophysical properties for the Au$^{I}$ complexes.[6–11] It was found that their unique spectroscopic features in the absorption and emission spectra clearly relate to the presence of the Au–Au interactions. The luminescence of Au$^{I}$ complexes was assigned as a metal-centered (MC) transition or a metal–metal-to-ligand charge-transfer (MMLCT) transition.[12–17] Recently, we calculated the aurophilic interactions and excited-state properties of model complexes $[Au_2(dpm)_2]^{2+}$ (**1**),[12,13] $[Au_2(dpm)(i\text{-}mnt)]$ (**4**),[16] and $[(AuPH_3)_2(i\text{-}mnt)]$ (**5**)[16,17] [dpm = bis(diphosphanyl)-methane and i-mnt = i-malononitriledithiolate]. The results revealed that the 507-nm phosphorescent emission of **1** in acetonitrile has the σ[s(Au$_2$)]→σ*[d(Au$_2$)] (MC) transition property,[13] while the 512 and 495-nm emissions in the $CH_2Cl_2$ solution for **4** and **5**, respectively, arise from the Au–Au to i-mnt charge-transfer (MMLCT) transition.[16] The Au$^{I}$–Au$^{I}$ interaction is strengthened in these emissive excited states, resulting from the formation of a σ single bond between the Au$^{I}$ centers upon excitation.

Though aurophilic attraction between gold(I) atoms is widely acknowledged,[1–20] the development of silver–silver (argentophilicity)[21,22] and copper–copper (cuprophilicity)[22–24] bonding interactions remains in its infancy. Che and coworkers[25–32] have structurally characterized a series of luminescent dinuclear d$^{10}$ complexes with bridging phosphane ligands. The d$^{10}$–d$^{10}$ metallophilicity in these complexes was confirmed by Raman spectroscopy. For $[M_2(dcpm)_2](X)_2$ [M = Au, Ag, and Cu; X = counteranion; dcpm = bis(dicyclohexylphosphanyl)methane], with metal–metal distances of 2.939, 2.960, and 2.731 Å, respectively, the 88, 80, and 104-cm$^{-1}$ fundamental bands were assigned to the M–M stretching vibrations.[27–29] These d$^{10}$ complexes exhibit intense luminescence either in the solid state or in solution, which is experimentally attributed to the σ[(*n* + 1)p]→σ*(*n*d) transitions.

Apart from the above fundamental interest, the existing and/or potential applications based on d$^{10}$ coinage metal

complexes such as optical materials, photocatalysts, biosensors, and molecular pharmacology have also received the attention of many researchers.[6,22–24,33–37] For example, it has been suggested that the therapeutic action of gold drugs for rheumatoid arthritis is related to the ability of the $Au^I$ complexes to quench the singlet oxygen $^1\Delta_g$ state at 7752 $cm^{-1}$.[37] Such applications of the $d^{10}$ complexes are clearly pertinent to their excited-state properties. Therefore, the theoretical investigation of the electronic structures of the ground- and excited states of the complexes is also of practical significance.

So far, computational methods are sufficiently advanced to allow calculation of ground- and excited states of relatively large molecular complexes.[38] At the same time, experiments provide wide and accurate information that can serve as a test for the computational methods. In theory these make both the systematic investigations of the M–M interactions and the luminescence of the $d^{10}$ coinage metal complexes possible. Since the presence of a bridging ligand facilitates the intramolecular interaction,[4] the series of complexes, $[M_2(P–P)_2]^{2+}$ [M = Au, Ag, and Cu; P–P = dmpm, dppm, and dcpm; dmpm = bis(dimethylphosphanyl)methane and dppm = bis(diphenylphosphanyl)methane], with eight-membered-ring conformation,[24–31,38–44] are ideal candidates for such investigations.

Here, we use the second-order Møller–Plesset perturbation (MP2)[46] and single excitation configuration interaction (CIS)[38] methods to fully optimize the ground- and excited-state structures of model complexes $[M_2(dpm)_2]^{2+}$ [M = Ag (**2**) and Cu (**3**)] and their solvated species $[M_2(dpm)_2]^{2+}\cdot(MeCN)_2$, respectively. On the basis of the MP2- and CIS-optimized structures, the absorption and emission spectra of such complexes were obtained from TD-DFT (time-dependent density functional theory)[47–49] calculations, respectively. Combined with the previous studies on **1**, the calculated M–M distances (3.03–3.16 Å) and their corresponding M–M stretching frequencies (69–89 $cm^{-1}$) for **1**–**3** indicate the presence of metallophilic attraction in the ground states. Complexes **1**–**3** give rise to the metal-centered $\sigma(s, p_z)\rightarrow\sigma^*(d_{x^2-z^2}, d_{y^2})$ emissions, both in the gas phase and in solution, revealing that the dinuclear $d^{10}$ complexes with bridging phosphane ligands have the intrinsic $^{1,3}[\sigma^*(d)\sigma(s/p)]$ excited states (the $M_2P_4$ unit lies in the *xz* plane and the *z* axis goes through the two metal atoms).

## Computational Details and Theory

It has been found that the complexes, $[M_2(P–P)_2]^{2+}$ (M = Au, Ag, and Cu; P–P = dmpm, dppm, and dcpm), form a series of discrete dinuclear M(I) dimers in the crystalline phase, i.e. no intermolecular M(I)–M(I) interactions.[25–30,40–45] There are close cation–anion contacts of 2.692 and 2.687 Å (M···O) in the crystal lattices of $[Ag_2(dcpm)_2]\cdot(CF_3SO_3)_2$[28] and $[Cu_2(dcpm)_2]\cdot(ClO_4)_2$,[29] respectively, but such interactions are not apparent in the X-ray structure of the gold(I) congener $[Au_2(dcpm)_2]\cdot(ClO_4)_2$ (closest Au···$OClO_3$, 3.362 Å).[25,26] Therefore, these types of complexes can be modeled by $[M_2(dpm)_2]^{2+}$ and $[M_2(dpm)_2]\cdot(ClO)_2$, which reflect the behaviors in the gas phase and solid state, respectively. To save the computational resources, the hydrogen was used to replace methyl, phenyl, cyclohexyl and other heavy substituents in the ab initio studies. A similar model has been applied in many studies.[12–17,50,51]

In this work, we employed the $C_i$ symmetry to settle the ground- and excited-state conformations of $[M_2(dpm)_2]^{2+}$ [M = Ag (**2**) and Cu (**3**)], which are consistent with the results from the X-ray diffraction study of $[M_2(dcpm)_2]\cdot(X)_2$ (X = counteranion).[28–30] Because the solvent affects the luminescence of the complexes,[12,13,16,17,25–32,40] we used the solvated species $[M_2(dpm)_2]^{2+}\cdot(MeCN)_2$ to establish the solvent effects of acetonitrile.

All the calculations were carried out using the GAUSSIAN03 program package.[52] The ground- and excited-state structures of **2** and **3** and their solvated species were fully optimized by the MP2[46] and CIS[38] methods, respectively. On the basis of such optimized structures, the TD-DFT (B3LYP)[47–49] method was performed to calculate the absorption and emission spectra of the complexes.

In the calculations, quasi-relativistic pseudopotentials of the Ag, Cu, and P atoms proposed by Hay and Wadt[53,54] with 19, 19, and 5 valence electrons, respectively, were employed, and the LanL2DZ basis sets associated with the pseudopotential were adopted. In order to describe the $d^{10}$–$d^{10}$ metallophilic attraction and the molecular properties precisely, one additional function was implemented for Ag ($\alpha_f$ = 0.22), Cu ($\alpha_f$ = 0.24), and P ($\alpha_d$ = 0.34).[2–4] The basis sets were taken as Ag(8s6p4d1f/3s3p2d1f), Cu(8s5p5d1f/3s3p2d1f), P(3s3p1d/2s2p1d), N(10s5p/3s2p), C(10s5p/3s2p), and H(4s/2s). Thus, 152 basis functions and 80 electrons for **2** and **3** and 218 basis functions and 124 electrons for **2**·$(MeCN)_2$ and **3**·$(MeCN)_2$ were included in the calculations.

## Results and Discussion

### Ground-State Structures

We used the MP2 method to fully optimize the ground-state structures of **2** and **3** and solvated species **2**·$(MeCN)_2$ and **3**·$(MeCN)_2$. Their structures are depicted in Figure 1. Under the $C_i$ symmetry, these complexes have $^1A_g$ ground states. The main optimized geometry parameters are listed in Table 1 and Table 2, together with the data from X-ray crystal diffraction studies for $[M_2(dcpm)_2]\cdot(X)_2$ (M = Ag, X = $CF_3SO_3^-$; M = Cu, X = $ClO_4^-$).[28,29] For **2** and **3**, the $d^{10}$ metal atoms take on a nearly linear two-coordinate geometry; the calculated P–M–P angles are 178.9° and 179.1°, comparable to the experimental values of 172.4° and 162.5°, respectively, as shown in Table 1. In the crystalline structure, the cation–anion interactions (M···O = 2.692 and 2.687 Å for the Ag and Cu complexes, respectively) result in a large difference between the calculated and experimental results.

[a] Experimental values of $[Ag_2(dcpm)_2]\cdot(CF_3SO_3)_2$ and $[Cu_2(dcpm)_2]\cdot(ClO_4)_2$ are from ref.[27] and ref.[28], respectively.

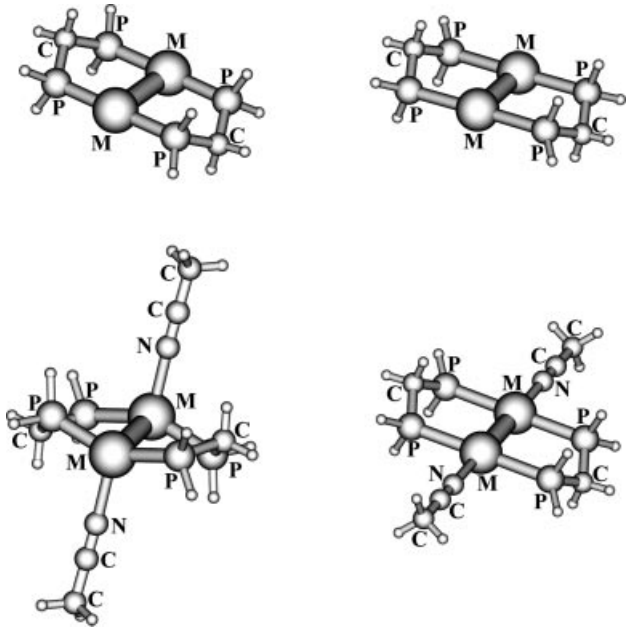

Figure 1. Ground- (left side) and excited- (right side) state structures for $[M_2(dpm)_2]^{2+}$ [M = Ag (**2**) and Cu (**3**)] and their weakly solvated species $[M_2(dpm)_2]^{2+}\cdot(MeCN)_2$.

The calculated 180.0° dihedral angles of P–M–M–P for **2** and **3** indicate that the $M_2P_4$ unit is coplanar. However, the interaction between the M(I) atom and acetonitrile in **2**·$(MeCN)_2$ and **3**·$(MeCN)_2$ results in $M_2P_4$ distortion from the original planarity, which is reflected by the calculated P–M–M–P dihedral angles of 151.3° and 138.4° (Table 2). The M–N distances are 2.380 and 1.976 Å for **2**·$(MeCN)_2$ and **3**·$(MeCN)_2$, respectively, which are very close to the experimental distances of 2.382 and 2.029 Å for $[Ag_2(dppa)_2(MeCN)_2]\cdot(PF_6)_2$ (dppa = $Ph_2PNHPPh_2$)[22] and $[Cu_2(dcpm)_2(MeCN)_2]\cdot(Y)_2$ ($Y^-$ = $ClO^-$ and $BF_4^-$)[29,30] and similar to the distances of 2.116 and 1.886 Å for $[M_2(form)_2]$ [M = Ag and Cu, form = (*p*-$CH_3C_6H_4$)NCHN(*p*-$CH_3C_6H_4$)].[55] In previous studies,[13] the calculated Au–N distance in **1**·$(MeCN)_2$ is 2.600 Å (Table S1 of the Supporting Information), which is much longer than the Au–N distance of 2.090 Å in $[Au_2(dpim)_2]\cdot(ClO_4)_2$ [dpim = 2-(diphenylphosphanyl)-1-methylimidazole].[56] Our calculated M–N distances for **1**–**3** in acetonitrile suggest that the M···N interactions are strong enough to form an M–N single bond for the Ag and Cu complexes, but very weak in the Au complex. The M–N bonding energies in (**1**–**3**)·$(MeCN)_2$ were estimated by using the Counterpoise method at the MP2 level. They are approximately 18.9, 27.0, and 36.5 kcal/mol, respectively. The present studies substantiate the previous conclusion that the $Au^I$ atom favors a linear two-coordinate arrangement, while the $Ag^I$ and $Cu^I$ atoms have the formal three coordination.[57]

The M(I)–M(I) separations that were calculated are 3.033, 3.160, and 3.061 Å for **1**–**3** in the ground states, which correspond to the experimental data of 2.939, 2.960, and 2.731 Å, respectively.[26,28,29] There is a large difference, especially for the Ag and Cu complexes. The following two reasons may be responsible for this. First, the choice of basis sets may cause such a difference. Hence, the SDD basis set, which is larger than the LanL2DZ basis set, was used to optimize **1**–**3** in order to judge the basis-set effect. The calculated results show that the Ag–Ag distance is shortened by about 0.1 Å but the Au–Au and Cu–Cu distances are nearly unchanged upon increasing the basis sets as shown in Table S2 of the Supporting Information. Second, in our calculations we used the model complex $[M_2(dpm)_2]^{2+}$ to replace the real complex $[M_2(P–P)_2]^{2+}$ (P–P = dmpm, dppm, and dcpm). This substituent approximation may affect the geometry parameters of the complexes. In Table S2,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

we list the optimized geometry parameters of $[M_2(dmpm)_2]^{2+}$ (M = Au, Ag, and Cu) and the data for $[M_2(P–P)_2](X)_2$ (M = Au, Ag, and Cu; P–P = dmpm, dppm, and dcpm; X = counteranion) that were determined from experiments.[22,26,28,29,40–45] One can see that the calculated results have now improved. The M–M distances of $[M_2(dmpm)_2]^{2+}$ (M = Au, Ag, and Cu) are 2.985, 3.021 and 2.818 Å, respectively and approach the experimental values. Table S2 of the Supporting Information indicates that although the use of the larger basis sets (SDD) and heavy substituent on the phosphorous atoms (e.g. dmpm ligand) in the calculations presents results that are closer to the experimental values, the calculated results for $[M_2(dpm)_2]^{2+}$ with the LanL2DZ basis sets can also describe the essential characteristics of real complexes.

The natural bond orbital (NBO) analysis[58–60] using the MP2 density shows that the M atoms of **1**–**3** have net electronic charges of +0.31, +0.56, and +0.56, respectively, while electronic charges residing on the P atoms are +0.39, +0.28, and 0.27. This indicates that the electrons of the P atoms transfer to the original $(n + 1)$s and $(n + 1)$p empty orbitals of M(I). Consequently, the closed-shell electronic configurations, $nd^{10}(n + 1)s^0$, are no longer kept in **1**–**3** but become $5d^{9.76}6s^{0.87}6p^{0.03}4f^{0.03}$ (Au), $4d^{9.89}5s^{0.52}5p^{0.02}4f^{0.01}$ (Ag), and $3d^{9.86}4s^{0.56}4p^{0.02}4f^{0.01}$ (Cu) instead. Because the relativistic effects are stronger on Au than on Ag and Cu,[61] there is more 5d→6(s, p) population transfer for the Au atom. Such a destruction of metal closed-shell structures may be one of the predominant driving forces in causing metallophilic attraction.

### Absorption Spectra

According to the vertical electron-transition mechanism in the absorption process, the optimized ground-state structures of (**1**–**3**)·$(MeCN)_2$ were kept, while TD-DFT (B3LYP) calculations were performed in order to calculate the excited states related to the absorption. With respect to the $^1A_g$ ground state under the $C_i$ point group, the $^1A_g$→$^1A_u$ transition is spin-dipole-allowed. We obtained low-lying dipole-allowed transitions of (**1**–**3**)·$(MeCN)_2$ that represent the possible absorptions of **1**–**3** in acetonitrile. Transition energies (eV/nm) of these absorptions are presented in Table 3, together with the corresponding oscillator strengths and experimental values available.[8,25,28,29,31,32,39] In order to conveniently assign the calculated electronic absorptions, the electron density diagrams of the frontier molecular oribitals involved in the transitions are displayed in Figure 2.

For **1**·$(MeCN)_2$, we obtained three low-lying absorptions from the TD-DFT calculations. In Figure 2, one can see that the orbitals involved in the transitions are mainly Au in character. The analyses of the wave functions of **1**·$(MeCN)_2$ suggest that the $29a_u$ (HOMO–3), $30a_u$ (HOMO–2), $31a_u$ (HOMO), and $32a_g$ (LUMO) orbitals mainly have σ(Au–P), $\sigma^*(d_{y^2-z^2})$, $\sigma^*(s, d_{z^2})$, and $\sigma(sp_z)$ character, respectively (the $Au_2P_4$ unit lies in the *xz* plane and the *z* axis goes through the two Au atoms).

The lowest-energy absorption of **1** in acetonitrile was calculated at 291 nm, which results from the $31a_u$→$32a_g$ (HOMO→LUMO) configuration with the largest CI coefficient of 0.673 in the wave functions (Table 3). We attributed this absorption to a metal-centered $\sigma^*(s, d_{z^2})$→$\sigma(sp_z)$ transition. It has been found that $[Au_2(P–P)_2]^{2+}$ (P–P = dmpm, dppm, and dcpm)[8,25,31,32,39] display intense absorption bands at 269, 292, and 278 nm in acetonitrile, respectively. These absorptions correspond to the calculated 291-nm absorption and also arise from a $\sigma^*(s, d_{z^2})$→$\sigma(sp_z)$ transition. The $B^1A_u$ excited state of **1**·$(MeCN)_2$ gives the absorption at 237 nm, which corresponds to the experimental absorption at 239–267 nm (in Table 3).[8,25,31,32,39] The absorption also has the nature of a MC transition, a $\sigma^*(d_{y^2-z^2})$→$\sigma(sp_z)$ transition. There is much contribution from the phosphane ligands for the $X^1A_g$→$C^1A_u$ transition, which is intuitively reflected in Figure 2. We assigned the 224-nm absorption to a σ(Au–P)→$\sigma(sp_z)$ transition.

With respect to analogous Ag and Cu complexes, we obtained three and four low-lying electronic transitions in ace-

Table 3. Calculated absorptions of $[Au_2(dpm)_2]^{2+}$·$(MeCN)_2$, $[Ag_2(dpm)_2]^{2+}$·$(MeCN)_2$, and $[Cu_2(dpm)_2]^{2+}$·$(MeCN)_2$ at the TD-DFT (B3LYP) level.

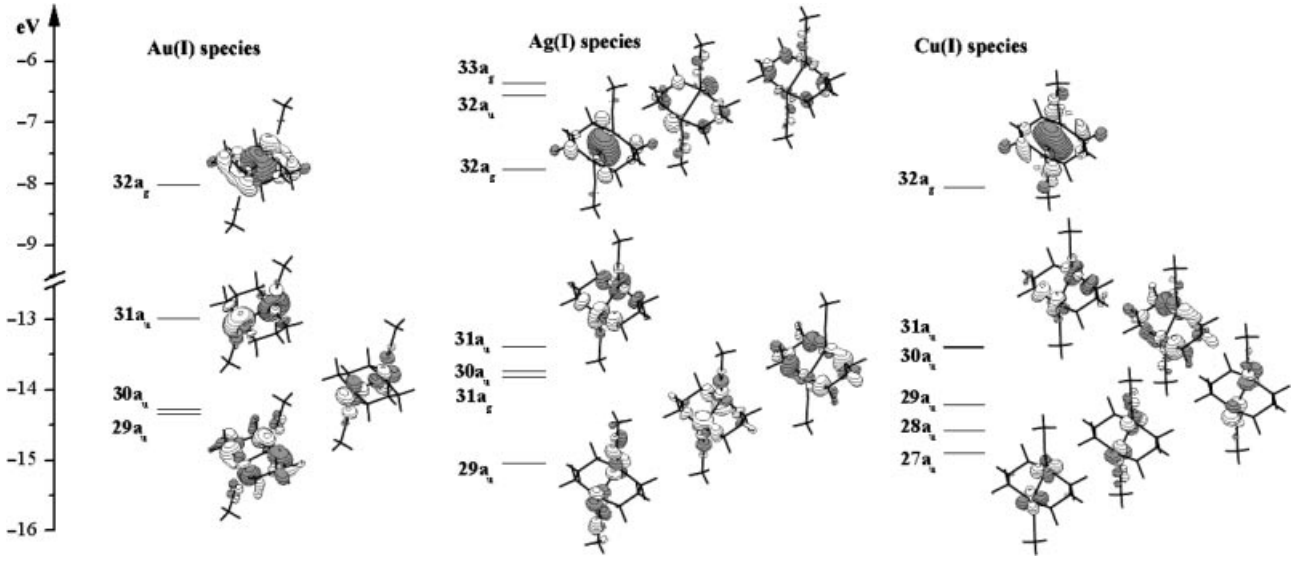

Figure 2. Frontier molecular diagrams of $[M_2(dpm)_2]^{2+}\cdot(MeCN)_2$ (M = Au, Ag, and Cu) in the TD-DFT (B3LYP) calculations.

tonitrile, respectively. By combining the information from Table 3 and Figure 2, one can see that **2** and **3** have relatively more complicated transitions than **1**. The calculated lowest-energy absorption of 256 nm for **2** in acetonitrile was assigned to a $\sigma^*(s, d_{z^2})\rightarrow\sigma(sp_z)$ transition, with a maximum oscillator strength of 0.132; we relate this to the 261-nm absorption band of $[Ag_2(dcpm)_2]^{2+}$ recorded in acetonitrile.[28] The lowest-energy absorption of 283 nm for **3** in acetonitrile is not a pure metal-centered $\sigma^*(s, d_{z^2})\rightarrow\sigma(sp_z)$ transition, which is different from those of **1** and **2**. The absorption (Table 3) results from the $31a_u\rightarrow32a_g$ (HOMO→LUMO) and $30a_u\rightarrow32a_g$ (HOMO–1→LUMO) configurations and is attributed to the mixture of $\sigma^*(s, d_{z^2})\rightarrow\sigma(sp_z)$ and $\sigma(Cu–P)\rightarrow\sigma(sp_z)$ transitions. Our calculated absorptions agree well with the experimental observations and provide more detailed information about the transition properties of the absorptions.

Such analyses show that relativistic effects play a significant role in the electronic transitions of **1**–**3** in acetonitrile, especially for the lowest-energy HOMO→LUMO transitions. As far as **1**–**3** are concerned, relativistic effects destabilize the $\sigma^*[nd_{z^2}(M_2)]$ orbital but stabilize the $\sigma[(n + 1)sp_z(M_2)]$, which result in the net effect of a decrease in the HOMO–LUMO energy gap. Because the later-row transition metals have stronger relativistic effects, **1** has a smaller HOMO–LUMO gap (Figure 2) and lower-energy HOMO→LUMO absorption than **2** and **3** (Table 3). Since the relativistic effects of Ag are larger than those of Cu, **2** should have a lower HOMO→LUMO absorption in acetonitrile. However, this is not the case in the present calculations (Table 3). We think that the M–M interactions are also one of the more important factors that affect the transition energies for **2** and **3**. Table 2 shows that the M–M distance of 2.875 Å for **3** is much shorter than that of 3.069 Å for **2**, which greatly facilitates the lower-energy transition for the Cu complex. It could be said[1] that among the coinage metals (Au, Ag, and Cu), only silver is "normal". As already mentioned, gold is anomalous because of its large relativistic effects. As the underlying nodeless d shell of copper is more compact than that of silver or gold, copper is often seen to behave differently. This suggestion has been, to some extent, reflected in such studies on the electronic absorptions of **1**–**3**. Additionally, it is worth noting that the spin-orbit interactions are an important influence on the transition moments, even if they are perhaps quenched in the molecular field.

In addition, we also calculated the absorptions of **1**–**3** in the acetonitrile solution using the CIS method. Their lowest-energy absorptions mainly feature the HOMO→LUMO transitions and the $\sigma^*(s, d_{z^2})\rightarrow\sigma(sp_z)$ characters, as do those from the TD-DFT calculations. However, the transition energies of 5.60, 6.66, and 6.68 eV for **1**–**3**, respectively, from the CIS calculations were severely overestimated relative to the experimental values. The TD-DFT calculations yield a better estimation of transition energies of absorptions than the CIS method.

### Excited-State Structures

To describe the luminescent properties of **2** and **3**, the CIS method was used to optimize the excited-state structures, both in the gas phase and in acetonitrile. Their structures are shown in Figure 1 and the main optimized geometry parameters are listed in Table 1 and Table 2.

With respect to the $^1A_u/^3A_u$ excited states of **2** and **3**, the optimized structures show significant changes compared with those of their corresponding $^1A_g$ ground states as can be seen in Table 1. The M(I)–M(I) distances are shortened from 3.160 and 3.061 Å to 2.981/3.056 and 2.667/2.704 Å for **2** and **3**, respectively. The bonding interactions between the two M(I) atoms in the $^1A_u/^3A_u$ excited states weaken the P→M dative bonds.

In solution, the acetonitrile molecules coordinate to the metal atoms of **2** and **3** with N–M–M angles of 109.5° and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

113.9° in the $^1A_g$ ground states, respectively; in the $^1A_u/^3A_u$ excited states, the N–M–M angles are close to 180° (Table 2). The M–N interactions in **2**·$(MeCN)_2$ and **3**·$(MeCN)_2$ are slightly weaker in the $^1A_u/^3A_u$ excited states than in the ground states, thus elongating by ca. 0.02/0.06 and 0.03/0.07 Å, respectively. However, the interaction between the $Au^I$ and N atoms in acetonitrile is greatly enhanced in the excited states since the Au–N distances of the $^1A_u/^3A_u$ excited states are about 0.17/0.22 Å shorter than that of the $^1A_g$ ground state (Table S1 of Supporting Information). Our previous studies on **1** showed that the N→Au coordination in acetonitrile results in about a 200-nm red-shift of the emission wavelength in the $^3A_u$ excited state.[13] Thus, we conjecture that the influence of acetonitrile on emissions of **2** and **3** is not as significant as on **1**.

To certify the validity of the CIS-optimized geometries, we used the unrestricted MP2 method (UMP2) to optimize the lowest-energy triplet excited states of **1**–**3**. The main optimized geometry parameters of the $^3A_u$ excited states are given in Table 4. The wave functions of the excited states demonstrate that the HOMOs are the σ bonding orbitals, mainly contributed to by the metal $(n + 1)(sp_z)$ atomic orbitals, and the LUMOs possess $\sigma^*(nd_{z^2})$ character. The $^3A_u$ excited state from the UMP2 calculations has orbital character that is very similar to that of the $^3A_u$ excited state from the CIS calculations for each complex. Thus, the $^3[\sigma^*(d)\sigma(sp)]$ states from the UMP2 calculations correspond to those from the CIS calculations. In comparison with those optimized by the CIS method, the geometry parameters of the $^3A_u$ excited states from the UMP2 method are more unrelaxed (Table 1 and Table 4). This is because the latter includes more electron correlation effects.[2–4] Despite some differences between the UMP2 and CIS methods in optimized geometry parameters for **1**–**3**, the two methods can reasonably predict the excited-state properties of the complexes.

Table 4. Optimized geometry parameters of the lowest-energy $^3A_u$ triplet excited states by the UMP2 method for $[Au_2(dpm)_2]^{2+}$ (**1**), $[Ag_2(dpm)_2]^{2+}$ (**2**), and $[Cu_2(dpm)_2]^{2+}$ (**3**).

[a]. The results of the $^3A_u$ triplet excited state of $[Au_2(dpm)_2]^{2+}$ (**1**) are from ref.[13]

We have performed the frequency calculations on **1**–**3** at the MP2 level for the ground and triplet excited states. No imaginary frequencies available indicate that these ground- and excited structures are minimum points. The calculated M–M stretching frequencies (Table 5) are ca. 89, 69, and 69 $cm^{-1}$ for **1**–**3** in the ground states, which are comparable to the experimental data of 88, 80, and 104 $cm^{-1}$ for $[Au_2(dcpm)_2]\cdot(ClO_4)_2$,[27] $[Ag_2(dcpm)_2]\cdot(CF_3SO_3)_2$,[28] and $[Cu_2(dcpm)_2]\cdot(ClO_4)_2$,[29] respectively. Keeping the experimental M–M distances from the MP2 calculations, we optimized the structures of **1**–**3** and present the calculated M–M frequencies in Table 5. The M–M stretching frequencies provide evidence for weak metallophilic attraction between the two $d^{10}$ metal atoms in the ground states.

Relative to those in the ground states, the M–M stretching frequencies greatly increase in the $^3A_u$ excited states. The 144, 142, and 170 $cm^{-1}$ M–M stretching frequencies of **1**–**3** correspond to 175, 180, and 150 $cm^{-1}$ frequencies estimated by Raman Resonance spectroscopy, respectively.[27–29] Such MP2 calculations suggest that the M–M interaction is weak in the ground state (mean M–M dis-

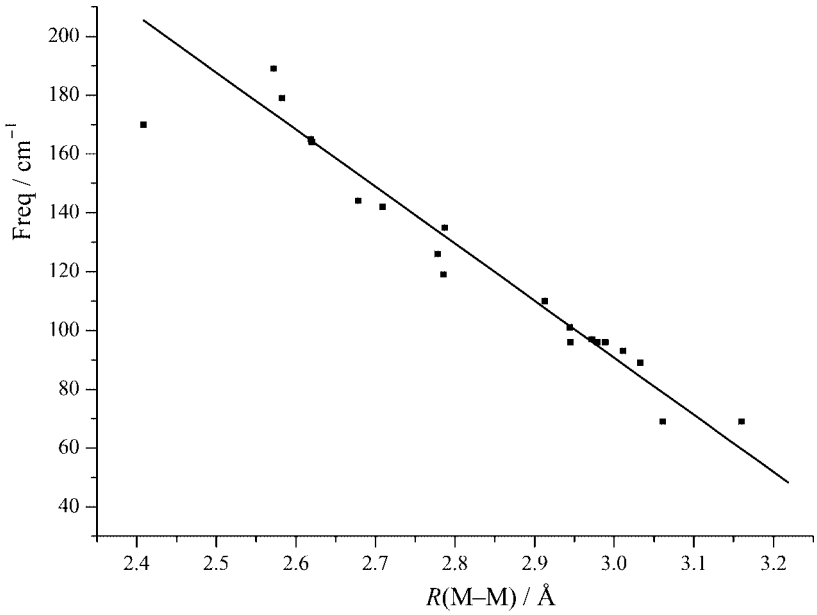

Figure 3. Plot of M–M distances versus stretching frequencies in the ground and lowest-energy triplet excited states for a series of dinuclear $d^{10}$ complexes, **1**–**10**, from the MP2 and UMP2 calculations, respectively.

tance: 3.10 Å, and M–M stretching frequency: 80 $cm^{-1}$), but is strongly enhanced in the triplet excited state (mean M–M distance: 2.60 Å, and M–M stretching frequency: 150 $cm^{-1}$).

In Table 5, we summarize the calculated M–M distances and stretching frequencies in the ground and lowest-energy triplet excited states for a series of dinuclear $d^{10}$ complexes, **1**–**10**, from MP2 and UMP2 calculations, respectively.[13,16] The plot of the M–M distances versus stretching frequencies in Figure 3 intuitively illustrates that the M–M distances are linearly correlated with the M–M stretching frequencies for the dinuclear $d^{10}$ complexes.

## Emission Spectra

It has been found that the CIS excited-state geometries are more accurate than the CIS transition energies as indicated in the literature.[62,63] The large deviations in the excitation energies are caused by an unbalanced description of the ground- and excited states. TD-DFT calculations, based on linear-response theory, have recently been reformulated to yield better transition energies than the CIS method.[63–66] Since the CIS method can present the accurate excited-state geometry and potential-energy surface, and the TD-DFT calculations can reasonably predict the

Table 6. Calculated emissions of $[Au_2(dpm)_2]^{2+}$ (**1**), $[Ag_2(dpm)_2]^{2+}$ (**2**) and $[Cu_2(dpm)_2]^{2+}$ (**3**) in the gas phase, solid state and acetonitrile solution at the CIS and TD-DFT (B3LYP) levels.

[a] The emissions of $[M_2(dcpm)_2]^{2+}$ (M = Au, Ag, and Cu) in acetonitrile are from ref.[24,25], ref.[27] and ref.[28,29], respectively. The results of $[Au_2(dmpm)_2]^{2+}$ are from ref.[8] and those of $[Au_2(dppm)_2]^{2+}$ from ref.[30,31,38]. [b] The results from $[M_2(dpm)_2]\cdot(ClO)_2$ (M = Au, Ag, and Cu) with fixed experimental M···O distances of 3.362, 2.692, and 2.687 Å, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

transition energies, the combination of the benefits of the two methods is a practical approach to describe the excited-state properties of molecules.

In this paper, we have used the CIS method to optimize the lowest-energy singlet and triplet excited states for **2** and **3** and their solvated species. On the basis of these optimized structures, the TD-DFT (B3LYP) method was performed to calculate the emission spectra of **2** and **3** in the gas phase and in solution. The calculated emissions are listed in Table 6, together with the experimental values for $[M_2(dcpm)_2]\cdot(X)_2$ (M = Ag, X = $CF_3SO_3^-$; M = Cu, X = $ClO_4^-$).[28–30]

From the TD-DFT calculations, the $^1A_u/^3A_u$ excited states of **2** and **3** give rise to the 302/356 and 328/397-nm emissions in the gas phase, and 366/424 and 435/514-nm emissions in acetonitrile, respectively. According to the analyses of the wave functions of these excited states, we attribute the emissions to the metal-centered σ(s, $p_z$)→σ*($d_{x^2-z^2}$, $d_{y^2}$) transitions, as is the case for those of **1** in previous studies.[13] The detailed information on the electronic structures of the $^3A_u$ excited states for **1**–**3** are presented in Table S3 of the Supporting Information, contributing to our understanding of such MC transitions. Compared with those in the gas phase, the calculated emissions in acetonitrile are red shifted by about 64/68 and 107/117 nm for the $^1A_u/^3A_u$ excited states of **2** and **3**, respectively. The interactions between cation and solvent molecules result in a large red shift. Since the lowest-energy emissions of **1**–**3** arise from the metal-centered σ(s, $p_z$)→σ*($d_{x^2-z^2}$, $d_{y^2}$) transitions, either in the gas phase or in solution, we think that the dinuclear $d^{10}$ complexes with bridging phosphane ligands have the intrinsic $^{1,3}$[σ*(d)σ(s/p)] excited states.

In the crystalline phase of $[Ag_2(dcpm)_2]\cdot(CF_3SO_3)_2$[28] and $[Cu_2(dcpm)_2]\cdot(ClO_4)_2$,[29] very close cation-anion contacts were determined by X-ray crystal diffraction [2.692 and 2.687 Å (M···O), respectively]. The presence of anions near the $[M_2(dcpm)_2]^{2+}$ cations affects the solid-state emission. In previous studies of **1**,[12] the less bulky $ClO^-$ anion was used to replace the original $ClO_4^-$ anion in the $[Au_2(dcpm)_2]\cdot(ClO_4)_2$ crystalline phase, i.e. **1**·$(ClO)_2$ was applied to simulate the solid-state behaviors of the Au complex. Similar models, **2**·$(ClO)_2$ and **3**·$(ClO)_2$, were used in the calculations in order to represent the real complexes, $[Ag_2(dcpm)_2]\cdot(CF_3SO_3)_2$ and $[Cu_2(dcpm)_2]\cdot(ClO_4)_2$, respectively. When the *R*(M–OCl) distance changes from 5.5 to 2.5 Å, the corresponding phosphorescent emission varies in the ranges 382–535, 398–440, and 356–370 nm for the Au, Ag and Cu complexes, respectively. Figure 4 clearly reflects the correlation between the emission wavelength and *R*(M–OCl) for **1**–**3**·$(ClO)_2$. The emission of **1**·$(ClO)_2$ is very sensitive to the *R*(M–OCl) distance, especially when *R*(M–OCl) < 3.5 Å, while those of **2**·$(ClO)_2$ and **3**·$(ClO)_2$ are relatively insensitive. When *R*(M–OCl) > 4.0 Å, the anion slightly affects the emissions of the complexes. Keeping the experimental M···O distances 3.362, 2.692, and 2.687 Å in the calculations on $[M_2(dpm)_2]\cdot(ClO)_2$ (M = Au, Ag, and Cu), respectively, we obtained the emissions of **1**–**3** in the solid state. The calculated phosphorescent emissions are 402, 366, and 424 nm, which are comparable to the experimental emissions of 368, 417, and 475 nm in the solid state, respectively.[28,29]

From Table 6, one can see that the CIS method overestimates the emission energies by ca. 2 eV with respect to the experimental values for the Ag and Cu complexes, while those predicted by TD-DFT are closer to the experimental values. For **3**, the phosphorescent emissions were calculated at 4.81 eV (258 nm) and 4.41 eV (281 nm) in the solid state and acetonitrile, respectively, while the experimental values were severely overestimated [2.61 eV (475 nm) and 2.58 eV (480 nm)] for $[Cu_2(dcpm)_2]\cdot(ClO_4)_2$.[29,30] TD-DFT calculations were carried out at the CIS-optimized excited-state

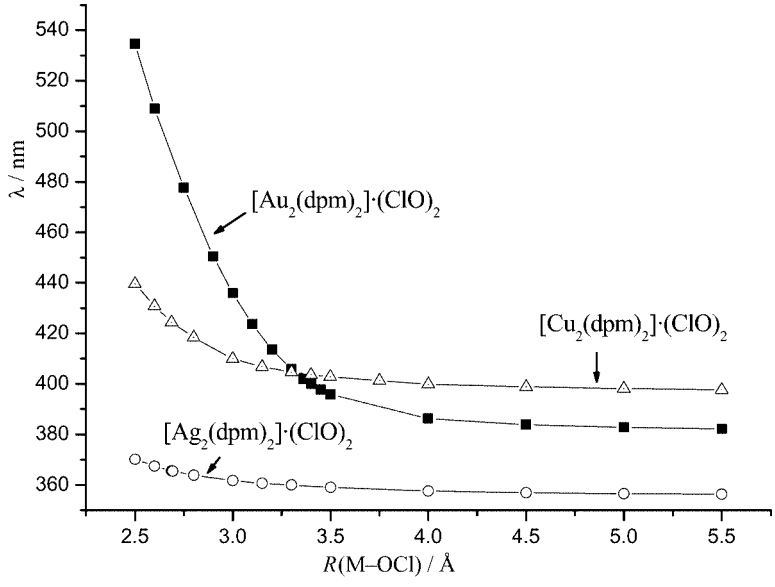

Figure 4. Plot of emission wavelength versus *R*(M–OCl) (distance between M atom and $ClO^-$ anion) for $[M_2(dpm)_2]^{2+}\cdot(ClO)_2$ (M = Au, Ag, and Cu) in the TD-DFT (B3LYP) calculations.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structure to obtain more accurate estimates of the emission energies. With TD-DFT, the phosphorescent emission energies were predicted to be 2.92 eV (424 nm) and 2.41 eV (514 nm) in the solid state and in acetonitrile, respectively, which are much closer to the experimental observations. However, with respect to the Au complex, the CIS and TD-DFT calculations over- and underestimated the emission energies, respectively, relative to the available experimental data.[8,25,26,31,32,39]

## Conclusions

In the paper, we used theoretical methods to study the electronic structures and spectroscopic properties of **2** and **3** and their solvated species. Taking previous studies into account on **1**,[13] we have come to the following conclusions.

For the dinuclear $d^{10}$ complexes of **1**–**3**, the calculated M–M distances (3.03–3.16 Å) and their corresponding M–M stretching frequencies (69–89 $cm^{-1}$) at the MP2 level indicate the presence of metallophilic attraction in the ground states. This is also supported by the NBO analysis on the electronic configurations of the metal atoms. In acetonitrile, the N→M coordination is strong enough to form a σ single bond in the Ag and Cu species, but is very weak in the Au analog. This agrees with the usual coordinated geometries of the Au, Ag, and Cu atoms.

In the excited states of **1**–**3**, the M–M interactions are strengthened, resulting from the promotion of electrons from the σ*(d) antibonding orbital to the σ(s/p) bonding orbital upon excitation. These complexes give rise to the metal-centered $\sigma(s, p_z)\rightarrow\sigma^*(d_{x^2-z^2}, d_{y^2})$ emissions, both in the gas phase and in solution, revealing that the dinuclear $d^{10}$ complexes with bridging phosphane ligands have the intrinsic $^{1,3}[\sigma^*(d)\sigma(s/p)]$ excited states. The comparison between the gas-phase and solution emissions for **1**–**3** shows that the N→M coordination results in a large red shift of the emission wavelength.

Taking previous studies into account, we found that the M–M distances are linearly correlated with the M–M stretching frequencies for the dinuclear $d^{10}$ complexes in the ground and lowest-energy triplet excited states.

In comparison with experimental values, the CIS calculations severely overestimate the transition energies of the Ag and Cu complexes, but the TD-DFT calculations reasonably predict their transition energies. However, with respect to the Au analog, the CIS and TD-DFT methods over- and under-estimate the transition energies, respectively.

# Absence of Dichroism in Dinuclear Rhenium Complexes with Sterically Hindered $\mu_2$-($\eta^2$-*N*,*O*)-Nitrosobenzene Ligands

**Christoph Krinninger,[a] Stefan Wirth,[a] Peter Klüfers,[a] Peter Mayer,[a] and Ingo Peter Lorenz*[a]**

**Keywords:** Dichroism / Dinuclear complexes / N ligands / Rhenium / Structure elucidation

The substitution reactions of $[Re(CO)_5X]$ (X = Cl, Br) with 2,6-dihalo-substituted nitrosobenzene derivatives $C_6H_2YZ_2NO$ (Y = H, Cl, Br; Z = Cl, Br) leads to the formation of dinuclear $\mu_2$-$\eta^2$-*N*,*O*-nitrosobenzene-bridged complexes of the type $[\{(CO)_3Re(\mu\text{-}X)\}_2ONC_6H_2YZ_2]$ (**6a**,**b**, **7a**,**b**, **8a**,**b**, **9a**). The turquoise coloured solutions of the complexes in $CH_2Cl_2$ show only one UV/Vis absorption of medium intensity in the region 670–710 nm, depending on the halogen bridges X and substituents Z. Single crystals of the complexes do not exhibit any dichroic properties. This may be due to the almost perpendicular orientation of the phenyl ring towards the Re–O–N–Re plane. The molecular structures of six compounds, as determined by single-crystal X-ray analyses, show two face-joined octahedra with Re centres that are bridged by two halogens X and one NO group. NO coordinates in a nonsymmetrical $\eta^2$-like fashion with N- or O-linkage to each Re centre. The phenyl rings do not lie within the symmetry plane containing the atoms Re, N and O, but are almost perpendicular to this (torsion angle O–N–C–C = 83.5–85.4°) because of the 2,6-dihalogen substituents Z.

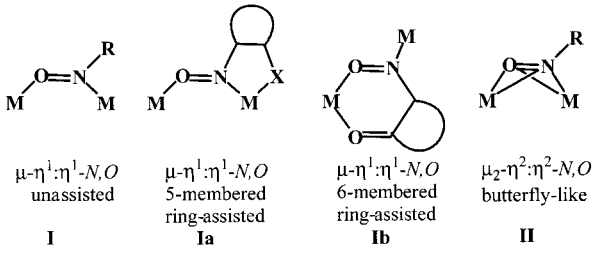
## Introduction

The coordination chemistry of organic RNO nitroso compounds has been extensively investigated,[1] and their many different coordination modes have been summarised in schemes in previous accounts of our work, as well as by others.[2,3] The dominant bonding mode bridging two metal centres is of the type $\mu$-$\eta^1$-*N*, $\mu$-$\eta^1$:$\eta^2$-*N*,*O*, $\mu$-$\eta^1$:$\eta^1$-*N*,*O* or $\mu$-$\eta^2$:$\eta^2$-*N*,*O* (Scheme 1), although the unassisted ligand function $\mu$-$\eta^1$:$\eta^1$-*N*,*O* (type I) with a simple bridging coordination mode is less common. Co-assisted ligand functions, that is those with additional coordination by a further donor system (e.g. amido or carbonyl groups), have been verified in most examples and form additional five- (type Ia)[4] or six-membered rings (type Ib).[5] Furthermore, type I has been only observed in a unique neutral complex of platinum[6] and in a dinuclear rhodium cation with thiolato bridges.[7]

We have recently published a series of complexes[2,3] that are the first simple, neutral and dinuclear *C*-nitroso complexes to exhibit this rare, unassisted $\mu$-$\eta^1$:$\eta^1$-*N*,*O* ligand function (type I), and contain only single atoms, X, as additional bridges (X = Cl, Br, I). All of these complexes show dichroic properties and form deep-blue solutions. In the UV/Vis spectra, one very intense broad absorption is found at $\lambda$ = 600–650 nm (log $\varepsilon$ > 30000), which is due to a solvochromic ligand-to-metal CT band ([NO–Re$^I$]). Light reflected from microcrystalline powders of the substances shines with different colours (like shells). Visual inspection of suitable crystals with polarized light under a microscope clearly showed a polarisation-dependent absorption. In the case of $[\{(CO)_3Re(\mu\text{-}Br)\}_2ONC_6H_4NEt_2]$ sufficiently large single crystals showed a pronounced linear dichroism.[3] We were able to correlate this dichroism with the arrangement of the molecules in the unit cells, which show alignment of the RNO units along a crystal plane. It is worthwhile to note that the dihedral angles Re–O–N–Re and O–N–C–C (phenyl ring) are less than 5° and 3°, respectively. This means that the NO group and the phenyl ring (together with the $NR_2$ substituent)[2,3] lie almost within the symmetry plane of the dinuclear complexes. To prove this correlation, we decided to synthesise analogous complexes with nitrosobenzene ligands that are sterically hindered in both *ortho* positions. Our aim was, therefore, to twist the phenyl



Scheme 1. Bonding modes of *C*-nitroso compounds bridging two metals ($\mu$-$\eta^2$-*N*,*O*).

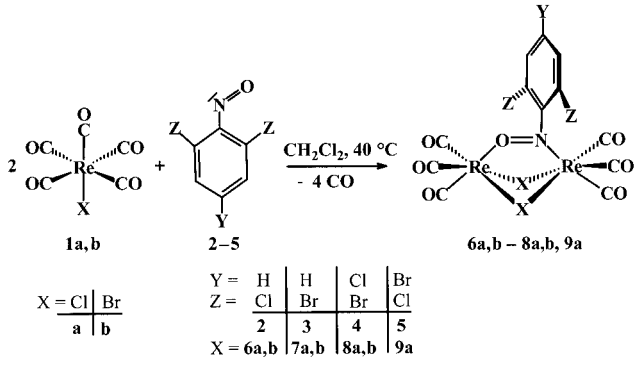
ring out of the plane and to observe the effect this had on the dichroism. We undertook the reaction of 2,6-dihalo-substituted nitrosobenzenes with $[Re(CO)_5X]$ (X = Cl, Br), and obtained the corresponding dinuclear complexes $[\{(CO)_3Re(\mu\text{-}X)\}_2ONC_6H_2YZ_2]$, which exhibit the same nitroso ligand function $\mu_2$-$\eta^1$:$\eta^1$-*O*, but with a perpendicular orientation of the phenyl ring towards the plane formed by the atoms Re, O, N and Re. As a consequence of this, the dichroism is lost.

## Results and Discussion

The reaction of $[Re(CO)_5X]$ (X = Cl, Br) (**1a**,**b**) with the sterically hindered *C*-nitroso compounds 4-Y-2,6-$Z_2C_6H_2NO$ [Y = H, Z = Cl (**2**), Br (**3**); Y = Cl, Z = Br (**4**); Y = Br, Z = Cl (**5**)] leads to the dinuclear complexes **6a**,**b**–**8a**,**b** and **9a** (Scheme 2). All reactions were carried out in boiling $CH_2Cl_2$. Whereas **9a** was obtained in good yield (65%), **9b** could not be isolated under the same reaction conditions. It is interesting to note that using boiling toluene as solvent resulted in the dimeric halo complexes $[(CO)_4ReX]_2$ (X = Cl, Br); no reaction occurred when $[Re(CO)_5I]$ was used as the starting material.



Scheme 2. Synthesis of sterically hindered $\mu_2$-($\eta^2$-*N*,O)-nitrosobenzene complexes **6**–**9**.

Compounds **6a**,**b**–**8a**,**b** and **9a** were obtained as dark-green crystals that are stable in air for some days. The complexes are soluble in THF, acetone, $CHCl_3$, $CH_2Cl_2$, and even in toluene, but nearly insoluble in pentane or hexane. The turquoise solutions formed in these solvents can be kept in air for several days without decomposition. In the UV/Vis spectra ($CH_2Cl_2$) two broad absorptions are observed, one lies consistently at about $\lambda_1$ = 375–380 nm, whereas the second, which originates from a ligand-to-metal CT (NO–$Re^I$), is observed over a larger range at $\lambda_2$ = 670–710 nm. It is shifted to lower frequency with respect to the corresponding π–π*-NO electronic transition of the free ligands. It is noteworthy that they are also observed at lower frequencies and with smaller intensities than those of the corresponding nitrosoaniline complexes published previously,[2,3] where the NO group, phenyl ring and the $NR_2$ substituent lie exactly within the symmetry plane of the dinuclear complexes. In spite of the frequency range of $\lambda_2$, there is no dependence of its spectral position on either the halogen bridges or substituents.

The X-ray structure analyses of **6a**,**b**–**8a**,**b** show that the phenyl ring with both halo substituents in the *ortho* positions is orientated perpendicular to the symmetry plane. As is therefore expected, the light reflected from crystalline powders of these complexes does not shine in different colours and neither does it show any polarisation-dependent absorption of the type mentioned above.[2,3] Therefore, they do not exhibit any significant dichroic properties.

The IR spectra of **6a**,**b**–**8a**,**b** and **9a** show five ν(CO) absorptions. As the NO group is bonded by N and O to different Re centres, the electronic situation at both Re centres is different. This normally results in two different *fac*-$Re(CO)_3$ fragments, each with local $C_{3v}$ symmetry. However, because of the bulky substituents in the *ortho* position of the nitrosobenzenes, the local symmetry of the $Re(CO)_3$ fragment at N is reduced to $C_s$. Therefore, three bands of the type 2A′ + A′′ are detected. Due to electronic reasons the *N*-bonded $Re(CO)_3$ moiety should be more electron rich and act as a better π-donor for the CO ligands than the O-bonded one. Therefore, the absorptions at higher wavenumbers with varying intensities have been assigned to the $\{(CO)_3Re\text{–}O\}$ fragment [$\tilde{\nu}$ = 2086–2091 ($A_1$), 2006–2012 $cm^{-1}$ (E)] and the three absorptions at lower wavenumbers and similar intensities to the $\{(CO)_3Re\text{–}N\}$ fragment [$\tilde{\nu}$ = 2024–2058 (A′), 1961–1970 (A′), 1913–1949 $cm^{-1}$ (A′′)]. Because several bands lie very close together it is not possible to draw any conclusions about the halogens as substituents or bridges. The ν(NO) band of the complexes is found at 1329–1350 $cm^{-1}$, which is a shift to lower frequency of about 115 $cm^{-1}$ with respect to the free *C*-nitroso ligand and of about 50 $cm^{-1}$ compared with other complexes.[2,3]

The $^1H$ NMR spectrum of **6a** shows three separate doublets at $\delta$ = 7.40, 7.42 and 7.44 ppm. In the case of **6b**, only a multiplet between $\delta$ = 7.38–7.44 ppm can be detected. In the spectra of **7a** two doublets for the ring protons in the 3,5-positions are detected at $\delta$ = 7.26 and 7.37 ppm, and one triplet for the proton in the 4-position at $\delta$ = 7.67 ppm. Complex **7b** exhibits a triplet at $\delta$ = 7.27 ppm, a doublet at $\delta$ = 7.38 ppm and a multiplet at $\delta$ = 7.61–7.64 ppm, whereas **8a** only shows one broad signal at $\delta$ = 7.66 ppm, and **8b** and **9a** exhibit singlets at $\delta$ = 7.64 and 7.60 ppm, respectively. It is noteworthy that in spite of the mirror symmetry in the $Re_2NO$ plane compounds **6a**,**b** and **7a**,**b** with the benzene ring substituted in 2,6-positions exhibit different signals for the three protons in the 3,4- and 5-positions. Compounds **8a**,**b**, and **9a**, however, show only one resonance for the 3,5-protons.

In the $^{13}C$ NMR spectra of **6a**,**b**–**8a**,**b** and **9a** the signals for the phenyl groups are detected at $\delta$ = 124.1–140.9 ppm. Here, we observe three signals for the three different types of C-atoms in the 2,6-, 3,5- and 4-positions. The *N*-bonded quaternary carbon is observed at $\delta$ = 160.2–164.5 ppm and the signals corresponding to the CO ligands at the Re centres appear at $\delta$ = 181–192 ppm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The parent peaks as well as peaks corresponding to fragments resulting from the successive loss of up to six CO ligands are observed in the mass spectra (DEI-MS) of **6a**,**b**–**8a**,**b** and **9a**.

The compositions and structures of complexes **6a**,**b**–**8a**,**b** were confirmed by X-ray structure analysis (see Table 2). Single crystals of complexes **6a**,**b**–**8a**,**b** were obtained by the diffusion of pentane into solutions of the complexes in $CHCl_3$. The molecular structures and selected bond lengths and angles are given in Figures 1 (**6a**), 2 (**6b**), 3 (**7a**), 4 (**7b**), 5 (**8a**) and 6 (**8b**). They show two face-joined octahedra with two halogens and the NO group as bridging ligands. The N–O distances are approximately 1.299 Å, similar to the values for analogous complexes,[1–3] but significantly longer than the average N–O distances of free *C*-nitroso compounds (1.21 Å).[8] There is no significant dependence of the NO lengths upon varying the halo bridges. In all cases, and in contrast to the recently published analogous complexes,[2,3] the Re–O bonds (approx. 2.10 Å) are significantly longer than the Re–N bonds (approx. 1.99 Å), whereas all the bridging Re–X bonds in the complexes are similar in length. For better comparison, the most important structural parameters of all complexes are summarised in Table 1.

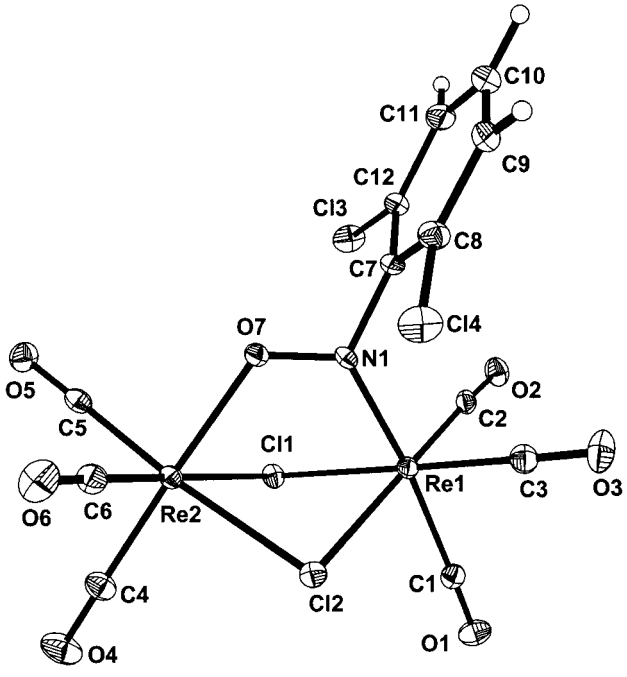


Figure 1. Molecular structure of **6a**. Selected bond lengths [Å] and angles [°]: Re(1)–N(1) 1.994(4), Re(2)–O(7) 2.124(4), Re(1)–Cl(1) 2.4914(14), Re(1)–Cl(2) 2.4726(14), Re(2)–Cl(1) 2.5024(14), Re(2)–Cl(2) 2.5056(14), O(7)–N(1) 1.282(6), N(1)–C(7) 1.457(6), Re(1)–C(1) 2.031(6), Re(1)–C(2) 1.952(6), Re(1)–C(3) 1.917(7), Re(2)–C(4) 1.928(6), Re(2)–C(5) 1.902(6), Re(2)–C(6) 1.908(6); N(1)–O(7)–Re(2) 120.2(3), O(7)–N(1)–Re(1) 123.9(3), O(7)–Re(2)–Cl(2) 82.82, O(7)–Re(2)–Cl(1) 82.82(11), N(1)–Re(1)–Cl(1) 84.52(13), N(1)–Re(1)–Cl(2) 85.96(13), Cl(2)–Re(1)–Cl(1) 80.83(5), Cl(1)–Re(2)–Cl(2) 79.98(5), O(7)–N(1)–C(7) 110.3(4), O(7)–N(1)–C(7)–C(8) 84.74.

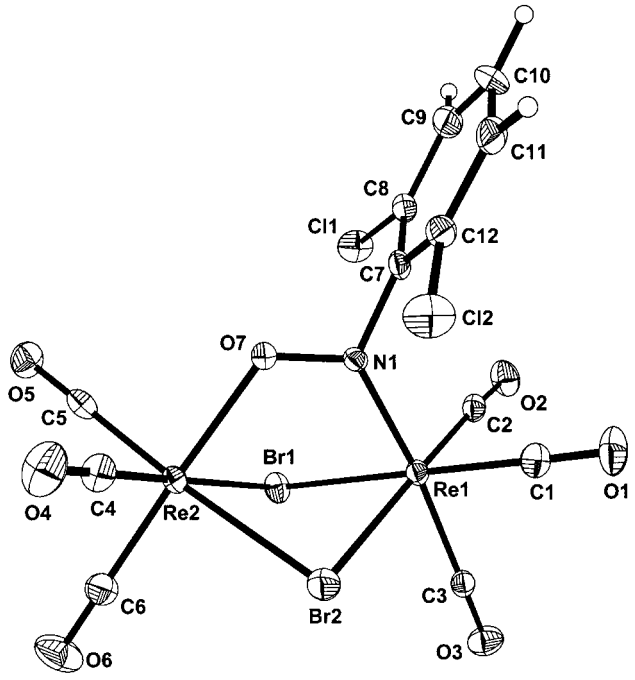

Figure 2. Molecular structure of **6b**. Selected bond lengths [Å] and angles [°]:Re(1)–N(1) 1.990(6), Re(2)–O(7) 2.116(5), Re(1)–Br(1) 2.6115(13), Re(1)–Br(2) 2.5965(11), Re(2)–Br(1) 2.6199(10), Re(2)–Br(2) 2.6305(12), O(7)–N(1) 1.299(8), N(1)–C(7) 1.451(9), Re(1)–C(1) 1.923(9), Re(1)–C(2) 1.936(9), Re(1)–C(3) 2.020(9), Re(2)–C(4) 1.902(8), Re(2)–C(5) 1.891(9), Re(2)–C(6) 1.907(9); N(1)–O(7)–Re(2) 121.8(4), O(7)–N(1)–Re(1) 126.5(5), O(7)–Re(2)–Br(2) 84.25(14), O(7)–Re(2)–Br(1) 83.58(4), N(1)–Re(1)–Br(1) 85.84(17), N(1)–Re(1)–Br(2) 86.73(17), Br(2)–Re(1)–Br(1) 82.89(4), Br(1)–Re(2)–Br(2) 82.07(4), O(7)–N(1)–C(7) 109.7(5), O(7)–N(1)–C(7)–C(12) 85.44.

The dihedral angles Re–O–N–$C_{Ph}$ of all complexes are smaller than 1.4°. The main difference between these complexes compared to those recently published[2,3] is that the dihedral angles O(7)–N(1)–C(7)–C(8/12) lie between 83.5–85.4°. This means that there is a near perpendicular orientation of the phenyl ring towards the plane formed by the atoms Re, O, N and Re. The consequence of this is the loss of dichroism. No Re–Re interaction is observed in any of the compounds, although the Re–Re distance varies with the size of the halogen bridges [Re(1)–Re(2) ≈ 3.47 (**6a**, **7a**, **8a**) and 3.54 Å (**6b**, **7b**, **8b**)].

It is worthwhile to emphasise that the orientation of the molecules described in this paper within the lattice is similar to that reported earlier[3] for the dichroic molecules. The triclinic crystal system is observed in both cases, although the packing of the dichroic molecules is closer, in particular with respect to the parallel phenyl rings of adjacent molecules, and the π-delocalisation is more widespread. Both effects lead to the significant anisotropy that is necessary for dichroism. Such close contact between the phenyl rings of the present molecules is not possible and the π-delocalisation is less. Therefore, it can be concluded that the absence of dichroism in **6a**,**b**–**8a**,**b** and **9a** is a result of the non-planar arrangement of the phenyl rings with respect to the

$Re_2NO$ plane. In addition, it is interesting to note that this is the only structural parameter that changes in comparison with the dichroic complexes.[3]

In summary, we have synthesised a novel series of analogous[2,3] neutral and dinuclear Re complexes with *C*-nitroso ligands. They also contain an unassisted $\mu_2$-$\eta^1$:$\eta^1$-*N*,O bridge (type I, Scheme 1) and only single atoms (X = Cl, Br) as additional bridges. However, the complexes do not possess any dichroic properties. This is a result of the different orientation of the *C*-nitroso ligand, which is almost perpendicular to the Re–O–N–Re symmetry plane. This is caused by the two substituents (Z) in the two *ortho* positions of the phenyl ring. A considerably different reaction pathway has been found for the reaction of $[Re(CO)_5X]$ (X = Cl, Br, I) with more sterically demanding *C*-nitroso ligands (e.g. 1-nitroso-2-naphthol), whereby HX or $CO_2$ elimination has been observed, and quite different mononuclear products have been obtained.[9]

## Experimental Section

All operations were carried out under argon in dry solvents.[10] $[Re(CO)_5X]$ (X = Cl, Br),[11] 2,6-dibromonitrosobenzene, 2,6-dichloronitrosobenzene, 2,6-dibromo-4-chloronitrosobenzene and, 4-bromo-2,6-dichloronitrosobenzene were prepared according to a literature procedure.[12] NMR spectra were recorded with a Jeol Ex 400 ($^1$H: 399.78 MHz; $^{13}$C: 100.54 MHz) or a Jeol Eclipse 270 MHz spectrometer ($^1$H: 270.17 MHz; $^{13}$C: 67.94 MHz) in $CDCl_3$. Mass spectra were obtained with a Jeol Mstation JMS 700. IR and UV/Vis spectra were measured with a Perkin–Elmer Spectrum One FT-IR or Perkin–Elmer Lambda 16 spectrometer. Elemental analyses were performed with a Heraeus Elementar Vario EL. For X-ray data see Table 2.

**Synthesis of 6–9 from 1a,b. General Procedure:** $[Re(CO)_5X]$ (X = Cl, Br) (**1a**,**b**) and 4-Y-2,6-$Z_2C_6H_2NO$ [Y = H, Z = Cl (**2**), Z = Br (**3**); Y = Cl, Z = Br (**4**); Y = Br, Z = Cl (**5**)] were dissolved in 20 mL of dichloromethane and heated for 40 h under reflux, whereby the solution turned green. The solvent was then evaporated and the green residue was purified by column chromatography ($CH_2Cl_2$).

**$\mu_2$-($\eta^2$-*N*,*O*-2,6-Dichloronitrosobenzene)bis[$\mu$-chlorotricarbonylrhenium(I)] (6a):** Synthesised from 116 mg (0.321 mmol) of **1a** and 42.4 mg (0.240 mmol) of **3**. Yield: 51.7 mg (0.066 mmol, 41%) green crystals, m.p. 145 °C (dec.). $^1$H NMR (399.78 MHz, $CDCl_3$): $\delta$ = 7.40 (d, $^3J$ = 6.54 Hz, 1 H, $CH_{arom.}$), 7.42 (d, $^4J$ = 0.66 Hz, 1 H, $CH_{arom.}$), 7.44 (d, $^4J$ = 2.04 Hz, 1 H, $CH_{arom.}$) ppm. $^{13}$C NMR (100.53 MHz, $CDCl_3$): $\delta$ = 124.1 ($CH_{arom.}$), 129.2 ($CH_{arom.}$), 131.5 ($CH_{arom.}$), 161.3 (ON-$C_q$), 185.1 (CO), 192.2 (CO) ppm. # New Ligands for Rh-Catalysed Hydroformylation of 1-Octene in Supercritical Carbon Dioxide – X-ray Structure of $[Rh\{PPh_2(OC_9H_{19})\}_4]PF_6$

**Marta Giménez-Pedrós,[a] Ali Aghmiz,[a] Núria Ruiz,[a] and Anna M. Masdeu-Bultó*[a]**

**Keywords:** Alkenes / Hydroformylation / P ligands / Rhodium / Supercritical fluids

The new P-donor ligands $PPh_{3-n}(OC_9H_{19})_n$ ($n$ = 3, 2, 1) containing branched alkyl chains were synthesised and their coordination to $Rh^I$ and $Pd^{II}$ studied. The X-ray structure of $[Rh\{PPh_2(OC_9H_{19})\}_4]PF_6$ was determined. Reaction of the $[Rh(acac)(CO)_2]/PPh_{3-n}(OC_9H_{19})_n$ systems with $CO/H_2$ at 5 atm and 80 °C in toluene led to the formation of $[RhH(CO)\{PPh_{3-n}(OC_9H_{19})_n\}_3]$ as the main species. The Rh-catalysed hydroformylation of 1-octene with these ligands was investigated in supercritical carbon dioxide ($scCO_2$) and toluene as solvents. Although the catalytic systems are not soluble in $scCO_2$, they are active. The activities are higher in toluene than in $scCO_2$ but the selectivities for aldehydes in the case of the phosphonite derivative are higher in the supercritical medium than in toluene.

## Introduction

In the last few years supercritical carbon dioxide ($scCO_2$) has received growing attention as an alternative reaction medium for homogeneous catalysis[1] as it is an environmentally friendly and cheap solvent. More important, however, are its gas-like properties, especially in reactions in which the reactants are gases. $scCO_2$ is highly miscible with gases such as hydrogen and carbon monoxide (it can therefore avoid the gas–liquid mass transfer) and is highly compressible. It also has a low viscosity and therefore a high diffusivity. Moreover, its ability as an extraction solvent has proved useful for separating the products from the catalysts without the need for harsher conditions such as those used for the distillation of higher alkenes.[2]

The catalytic hydroformylation of long-chain alkenes is an interesting reaction for transforming alkenes into aldehydes using carbon monoxide and hydrogen.[3] The aldehydes obtained allow the synthesis of oxo alcohols used in the detergent industry and as plasticizers in the polymer industry. Rhodium catalysts associated with P-donor ligands are the most successful system for the hydroformylation of alkenes under mild conditions. Water can be used as a "green" solvent in this reaction, but this process is limited to short-chain alkenes (propene and 1-butene) because a certain degree of solubility of the alkene in water is required.[4] $scCO_2$ is a non-polar solvent in which alkenes are soluble, but ligand modification is often needed to increase the solubility of the catalytic systems. The most successful approach is to introduce perfluoroalkyl chains in the ligand.[5] However, the synthesis of perfluorinated ligands is difficult and expensive.

Cole-Hamilton and co-workers obtained good activities when they used alkylated phosphanes such as $[Rh_2(OAc)_4]/PEt_3$ systems, which are soluble in $scCO_2$, in the hydroformylation of 1-hexene, but the *n*/*iso* ratios were modest (2.1–2.6).[6] Ligands containing alkyl groups, preferably branched, with a chain length of eight carbon atoms have reportedly shown high solubility in supercritical carbon dioxide.[7] In the case of alkylphosphanes, such as $P(C_8H_{17})_3$, the Rh systems were not soluble under the conditions studied and the turnover frequency (TOF) was low (3–7 $h^{-1}$, 8–20% conversion in 2 h), although the *n*/*iso* ratios were high (up to 3.9).[6] When linear alkylated groups were introduced into the aromatic rings $[P(C_6H_4C_6H_{13})_3$, $P(C_6H_4C_{10}H_{21})_3$, and $P(C_6H_4C_{16}H_{33})_3]$, the corresponding rhodium systems, which are partially soluble in $scCO_2$, showed activities in the hydroformylation of 1-hexadecene with average TOFs of 150, 350 and 20 $h^{-1}$, respectively. This correlated with a maximum solubility of the $C_{10}H_{21}$ derivative.[5c] Other $scCO_2$-insoluble systems, such as $P(OPh)_3$, $P(p\text{-}OC_6H_4\text{-}C_9H_{19})_3$ and $PPh_2[CH_2CH(CO_2C_{16}H_{33})CH_2\text{-}CO_2C_{16}H_{33}]$, have been reported to show good activity in the hydroformylation of 1-hexene. The advantage of insoluble systems is that the products can be flushed away from the insoluble catalyst system by taking advantage of the excellent extraction ability of $scCO_2$.[8]

The incorporation of *tert*-butyl substituents into the alkyl chains of P-donor ligands has been reported to increase their solubility in $scCO_2$.[7,9] Introducing branched chains in surfactants derived from sodium bis(2-ethyl-1-hexyl)sulfosuccinate increases their solubility in $scCO_2$.[10]

In this paper we present the synthesis of three new P-donor ligands with nine-carbon, branched alkyl substituents (Figure 1) and their application to the rhodium-catalysed hydroformylation of 1-octene in $scCO_2$ and in toluene as solvents. Phosphite (**1**), phosphonite (**2**) and phosphinite (**3**) ligands were selected because the introduction of oxy groups has a positive effect on activity and regioselectivity.[3b,11] Bulky monophosphonite ligands have shown very high activities in the isomerisation/hydroformylation of octene.[11] We also studied the coordination of the new ligands to rhodium(I) and palladium(II).

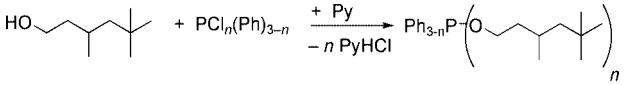
Figure 1. P-donor ligands.

## Results and Discussion

### Synthesis of Ligands

Ligands **1**–**3** were prepared from the commercially available alcohol 3,5,5-trimethylhexanol by reaction with phosphorus trichloride or the corresponding chlorophenylphosphane in diethyl ether in the presence of pyridine (Scheme 1). The ligands were purified by flash chromatography on basic alumina eluting with hexane under an inert gas and obtained as air- and moisture-sensitive colourless oils in good yields (56–80%). The $^1H$ NNMR spectra show the methylene (-$OCH_2$-) signals at $\delta = 3.8$ ppm, the methylene and methine signals between $\delta = 1.6$ and 1.0 ppm, and the methyl doublet and singlet from the *tert*-butyl group at $\delta = 0.9$ ppm. The signals were assigned by means of COSY and HETCOR experiments. The $^{31}P\{^1H\}$ NMR singlet signals appear at $\delta = 139.9$, 156.6 and 112.5 ppm for **1**–**3**, respectively, which are typical values for this kind of phosphorus compounds.[12]

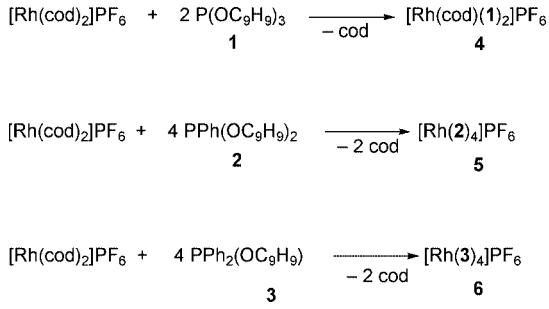


**1**: $n = 3$
**2**: $n = 2$
**3**: $n = 1$

Scheme 1. Synthesis of **1**–**3**.

### Synthesis of Complexes

To explore the coordination chemistry of the P-donor ligands **1**–**3** we decided to study their reactivity with rhodium(I) and palladium(II) complexes. We chose $[Rh(cod)_2]PF_6$ (cod = 1,5-cyclooctadiene) as a model for cationic complexes (Scheme 2). The reaction of ligands **1**–**3** with $[Rh(cod)_2]PF_6$ in anhydrous dichloromethane at room temperature should proceed by displacement of the 1,5-cyclooctadiene ligand, followed by coordination of two P-donor ligands. With tris(3,5,5-trimethylhexyl) phosphite (**1**) in a P/Rh molar ratio of 2:1, the complex $[Rh(cod)(\mathbf{1})_2]PF_6$ (**4**) was obtained as a relatively air-stable, yellow oil in high yield. Several attempts to solidify the complex were unsuccessful. Its $^{31}P\{^1H\}$ NMR spectrum shows a doublet at $\delta = 116.1$ ppm ($J_{P,Rh} = 244.0$ Hz), which corresponds to the coordinated phosphite ligand, and the characteristic septuplet of the $PF_6^-$ counteranion at $\delta = -143.2$ ppm ($J_{P,F} = 711.5$ Hz). The presence of coordinated cyclooctadiene was confirmed by the $^1H$ NMR spectrum, which shows signals at $\delta = 4.05$ ppm (HC=CH) and 2.57 and 2.36 ppm (-$CH_2$-). The $^1H$ NMR signals corresponding to the coordinated ligand are shifted slightly with respect to those of the free ligand. The mass spectrum shows a signal at $m/z = 1129.5$ corresponding to the $[Rh(cod)(\mathbf{1})_2]^+$ fragment.



Scheme 2. Syntheses of **4**–**6**.

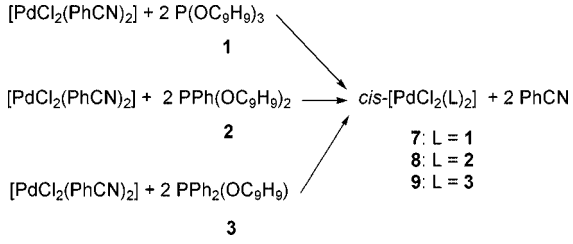
However, upon treatment of the same precursor complex $[Rh(cod)_2]PF_6$ with the same P/Rh molar ratio but using phosphonite **2**, the $^{31}P\{^1H\}$ NMR spectrum shows two doublets in the region of coordinated phosphorus atoms at $\delta = 146.0$ ($J_{P,Rh} = 165.9$ Hz) and 138.5 ($J_{P,Rh} = 170.8$ Hz) ppm and the $^1H$ NMR spectrum shows signals corresponding to coordinated cyclooctadiene (at $\delta = 4.0$ and 2.5–2.7 ppm). When the P/Rh molar ratio is 4:1, the $^{31}P\{^1H\}$ NMR spectrum shows only the signal at $\delta = 146.0$ ppm. There was no evidence of coordinated COD in the $^1H$ NMR spectrum, and only signals attributable to the coordinated ligand were detected. In this case, a relatively air-stable, yellow, oily solid was obtained in 76% yield. The mass spectrum of the isolated product has a signal $m/z = 1679.7$ corresponding to the cationic fragment $[Rh(\mathbf{2})_4]^+$. We propose that, at a P/Rh ratio of 2:1, a mixture of $[Rh(cod)(\mathbf{2})_2]PF_6$ and $[Rh(\mathbf{2})_4]PF_6$ (**5**) is formed and the totally substituted species **5** is formed at a P/Rh ratio of 4. Similar $[RhL_4]^+$ species have been obtained with $PPh(OCH_3)_2$,[13] with similar $^{31}P$ NMR spectroscopic data ($\delta = 148$ ppm, $J_{P,Rh} = 170$ Hz).[14]

In the reaction of $[Rh(cod)_2]PF_6$ with ligand **3** only one doublet is observed in the $^{31}P\{^1H\}$ NMR spectrum at P/Rh ratios of 2:1 and 4:1 [$\delta = 132.3$ ppm ($J_{P,Rh} = 162.2$ Hz)], which agrees with the data reported for $[Rh\{PPh_2(OR)\}_4]^+$ (R = Me: $\delta = 132.2$ ppm, $J_{P,Rh} = 159$ Hz; R = Et: $\delta = 130.5$ ppm, $J_{P,Rh} = 156$ Hz),[15] along with a septuplet signal for $PF_6^-$ at $\delta = -143.1$ ppm ($J_{F,P} = 712.6$ Hz). In the $^1H$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

NMR spectrum there are only signals corresponding to the coordinated ligand **3**. A relatively air-stable, yellow solid was isolated in 73% yield. The X-ray crystal structure (see below) shows that this complex is $[Rh(\mathbf{3})_4]PF_6$ (**6**).

To prepare neutral palladium complexes, we chose $[PdCl_2(PhCN)_2]$ as a model precursor. The reaction of ligands **1**–**3** with $[PdCl_2(PhCN)_2]$ in anhydrous dichloromethane at room temperature proceeds by the displacement of two molecules of PhCN followed by the coordination of two P ligands to afford $[PdCl_2(\mathbf{1}–\mathbf{3})_2]$ (**7**–**9**, Scheme 3), which were obtained as relatively air-stable, yellow oils in good yields, with mass spectra in agreement with a mononuclear formulation. The $^1H$ NMR spectra of **7**–**9** show signals corresponding to the coordinated ligands. The $^{31}P\{^1H\}$ NMR spectra show only one singlet at $\delta$ = 94.2 (**7**), 122.2 (**8**) and 110.2 ppm (**9**), which indicates that only one of the two possible isomers (*cis* or *trans*) is formed. The difference between the $^{31}P$ NMR signal of the complex and that of the free ligand, known as the coordination chemical shift, $\Delta$ (= $\delta_{coord} - \delta_{free}$), for similar palladium(II) complexes is indicative of the stereochemistry of these complexes. The lowest (negative) values of $\Delta$ are found for *cis* isomers containing ligands with Tolman angles, $\Theta$, of less than 140°, and high values (positive) of $\Delta$ are found for *trans* isomers containing ligands with Tolman angles higher than 140°.[16] Based on this observation, since the values of $\Delta$ for complexes **7** and **8** are –45.7 and –34.4 ppm, respectively, we propose that the *cis* isomers are present in these complexes. In the case of complex **9** the value of $\Delta$ is –2.3 ppm. Taking into account that the estimated value of $\Theta$ from the X-ray structure is 128° (see below), we also propose the formation of the *cis* isomer for complex **9**.



Scheme 3. Syntheses of **7**–**9**.

### X-ray Structure of 6

The crystal structure of complex **6** was solved with crystals obtained by slow diffusion of diethyl ether into a dichloromethane solution of the complex. The X-ray structure is shown in Figure 2 and selected bond lengths and angles are given in Table 1.

This cationic rhodium complex contains four coordinated phosphinite ligands **3**, as observed in solution. The Rh–P bond lengths [2.2848(6) Å] are in the range reported for other $Rh^I$ complexes with phosphinite ligands.[17] The cation has a slightly tetrahedrally distorted square-planar geometry [*trans* P–Rh–P angles of 166.64(3)°] due to intramolecular ligand repulsion. A similar distortion, but to a greater extent, has been reported for $[Rh(PMe_3)_4]^+$ (*trans* P–Rh–P angles of 148.29 and 151.46°).[18] The C–P–Rh angles [115.75(8) and 118.97(8)°] deviate from the ideal tetrahedral value, as observed in coordinated P-donor ligands. The estimated Tolman angle for **3**, calculated in accordance with the reported method,[19] is 128°. The alkoxy chains are in a staggered arrangement above and below the coordination plane in order to minimise repulsion. There is a disorder in the *t*Bu fragments. The $PF_6^-$ anions are located in the cavities formed between the four *t*Bu groups from two different cationic units.

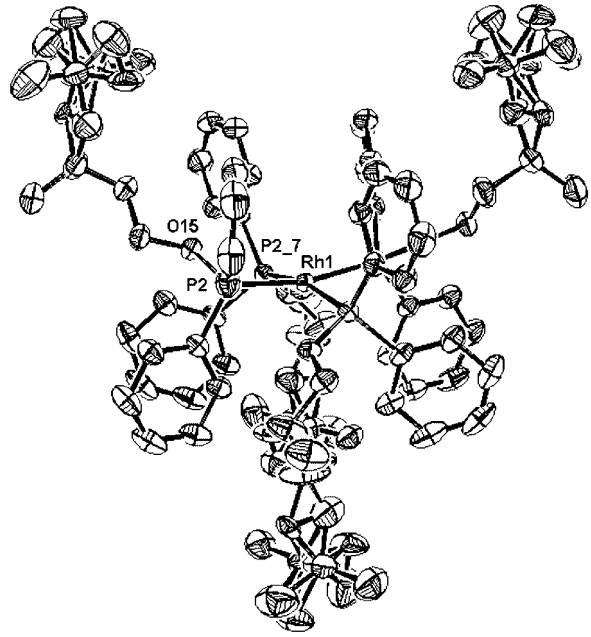


Figure 2. ORTEP drawing of complex **6**. $PF_6^-$ and hydrogen atoms have been omitted for clarity.

Table 1. Selected bond lengths [Å] and angles [°] of complex **6**.[a]

### Reactivity of [Rh(acac)(CO)$_2$]/1–3 with CO and $H_2$

The reactivity of the systems $[Rh(acac)(CO)_2]$/**1**–**3** with CO and $H_2$ was analysed by high-pressure NMR (HPNMR) and IR (HPIR) spectroscopy. The $^{31}P\{^1H\}$ and $^1H$ NMR spectra were recorded for the complex $[Rh(acac)(CO)_2]$ in the presence of 4 equiv. of ligand **1**–**3** in $[D_6]$toluene ($[Rh] = 2\times10^{-2}$ M) with stepwise addition of $H_2$ and CO. As the IR technique is more sensitive, the IR spectra could be recorded at concentrations closer to the catalytic value ($2–5\times10^{-3}$ M) in methyltetrahydrofuran under

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the same conditions. A list of identified species is given in Table 2.

Table 2. Identified species for [Rh(acac)(CO)$_2$]/**1**–**3** (P/Rh = 4) systems at 5 atm CO/H$_2$ (1:1) after 1 h at 80 °C.

[a] n.d. = not detected.

Upon addition of 4 mol-equiv. of **1** to [Rh(acac)(CO)$_2$] in toluene, the $^{31}$P{$^1$H} spectrum shows a major, broad doublet signal at $\delta$ = 140 ppm, attributed to a mixture of the species [Rh(acac)(CO)$_n$(**1**)$_{2-n}$], along with a small multiplet at $\delta$ = 80 ppm and a singlet at $\delta$ = 0 ppm due to decomposed ligand. Addition of 2.5 atm of H$_2$ to this solution caused two new doublet signals to appear in the $^{31}$P{$^1$H} NMR spectrum at $\delta$ = 158.9 ppm ($J$ = 212.3 Hz) and $\delta$ = 157.9 ppm ($J$ = 207.8 Hz). Two new signals also appear in the hydride region of the $^1$H NMR spectrum at $\delta$ = –10.7 ppm (quint, $J$ = 7.8 Hz) and $\delta$ = –11.8 ppm (dq, $J$ = 33.7, 9.4 Hz). After further addition of 2.5 atm of CO (5 atm total pressure) and heating of the system at 80 °C for 1 h, the doublet signal in the $^{31}$P{$^1$H} NMR spectrum at $\delta$ = 157.9 ppm, the multiplet signal at $\delta$ = 80 ppm and the hydride signal at $\delta$ = –11.8 ppm in the $^1$H NMR spectrum disappear and new signals are observed at $\delta$ =154.6 (d, $J_{Rh,P}$ = 194.6 Hz), 140.8 (dd, $J$ = 273.6, 164.7 Hz), 138.1 (s, free **1**) and 70.2 (dt, $J$ = 273.4, 94.3 Hz) ppm. We assigned the signals at $\delta$ = 157.9 ppm and the hydride doublet of quintuplets at $\delta$ = –11.8 ppm to the species [RhH(**1**)$_4$] (**10**) by comparison with published data for the analogous species [RhH{P(OPh)$_3$}$_4$] [$\delta_P$ = 129.7 ($J_{Rh,P}$ = 232.8 Hz) ppm; $\delta_H$(hydride) = –10.6 ($J_{Rh,H}$ = 44, $J_{P,H}$ = 7 Hz) ppm].[20] We assigned the major doublet signal at $\delta$ = 158.9 ppm in the $^{31}$P{$^1$H} NMR spectrum together with the quintuplet at $\delta$ = –10.7 ppm in the $^1$H NMR spectrum to [RhH(CO)(**1**)$_3$] (**11**). The multiplicity of the hydride signal (quintuplet) is explained by the accidentally identical values of $^1J_{Rh,H}$ and $^2J_{P,H}$, as was also reported for [RhH(CO){P(OPh)$_3$}$_3$] [$\delta_P$ = 141.1 ($J_{Rh,P}$ = 240 Hz) ppm; $\delta_H$(hydride) = –10.9 ($J_{Rh,H}$ = $J_{P,H}$ = 3 Hz) ppm].[20] The minor signal at $\delta$ = 154.6 ($J_{Rh,P}$ = 194.6 Hz) ppm is attributed to the dicarbonyl species [RhH(CO)$_2$(**1**)$_2$] (**12**), whose hydride signal is not detected in the $^1$H NMR spectrum due to its low concentration. The signals at $\delta$ = 140.8 and 70.2 ppm could correspond to mixed complexes with phosphite/phosphonate and carbon monoxide ligands formed by the partially decomposed ligand. Coordination of phosphonates to rhodium complexes has been described in the literature[21] and the chemical shifts observed here correlate with those reported for mixed species. At the end of the experiment, the pressure was released and water was added to decompose the remaining ligand. The signals at $\delta$ = 140.8 and 70.2 ppm disappeared and new signals appeared, which could correspond to species with only phosphonate ligands.

The HPIR spectra of [Rh(acac)(CO)$_2$]/**1** at 5 atm CO/H$_2$ (1:1) in the ν(CO) region initially show signals at 2049, 2025, 2005, 1980 and 1960 cm$^{-1}$. By comparison with published data for [RhH(CO){P(OPh)$_3$}$_3$] [ν(CO) = 2060 (m) cm$^{-1}$],[22] the band at 2025 cm$^{-1}$ was assigned to **11**. The absorptions at 2049 and 1980 cm$^{-1}$ could correspond to the equatorial/equatorial isomer **ee-12** and those at 2005 and 1960 cm$^{-1}$ could correspond to the equatorial/axial isomer **ea-12**. The bands reported for ee-[RhH(CO)$_2${P(OPh)$_3$}$_2$] appear at 2053 and 2018 cm$^{-1}$ and for the isomer ea-[RhH(CO)$_2${P(OPh)$_3$}$_2$] at 2034 and 1992 cm$^{-1}$.[23] After 2 h at 80 °C, bands appeared at 1991 and 1828 cm$^{-1}$ attributed to rhodium species with bridging carbonyl ligands.

The $^{31}$P{$^1$H} and $^1$H NMR spectra of the [Rh(acac)(CO)$_2$]/**2** system (P/Rh = 4) in toluene under 5 atm of CO/H$_2$ (1:1), after heating at 80 °C for 1 h, show signals assigned to [RhH(CO)(**2**)$_3$] (**13**) and [RhH(CO)$_2$(**2**)$_2$] (**14**; Table 2); the hydride signals could not be detected in the $^1$H NMR spectrum. The signal of the remaining unreacted species [Rh(acac)(CO)$_n$(**2**)$_{2-n}$] appears at $\delta$ = 156 ppm. The slow reaction rate of similar precursors containing phosphite ligands with CO/H$_2$ has been reported.[24] The broad doublet at $\delta$ = 144.1 ($J_{Rh,P}$ = 168.7 Hz) ppm is better resolved at –60 °C and could correspond to dimeric Rh$^0$ complexes [Rh$_2$(CO)$_6$(**2**)$_2$] or [Rh$_2$(CO)$_4$(**2**)$_4$], as has been observed for other P-donor–rhodium systems.[25] The broad multiplets at $\delta$ = 120 and 82 ppm were attributed to mixed phosphonite/phosphonate species.

The HPIR spectrum, after 1 h under these reaction conditions, shows several absorptions in the 2200–1800 cm$^{-1}$ region that were difficult to assign. The band at 2065 could correspond to compound **13** and the ones at 2073 and 2029 cm$^{-1}$ and 2042 and 1991 cm$^{-1}$ could correspond to the ee and ea isomers of **14**, respectively. The absorptions around 1800 cm$^{-1}$ could correspond to the Rh$^0$ dimeric species.

The $^{31}$P{$^1$H} NMR spectrum of [Rh(acac)(CO)$_2$]/**3** (P/Rh = 4) at 5 atm CO/H$_2$ (1:1), after 1 h at 80 °C, shows a major signal at $\delta$ = 138.1 ppm, which, together with a hydride signal at $\delta$ = –9.4 ppm, was attributed to the species [RhH(CO)(**3**)$_3$] (**15**) by comparison with published data.[26] A minor, partially overlapped doublet at $\delta$ = 136.8 ppm, together with a hydride doublet of triplets at $\delta$ = –9.1 ppm,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

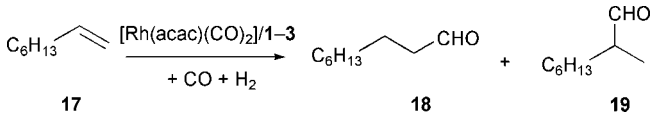
was attributed to the species $[RhH(CO)_2(\mathbf{3})_2]$ (**16**). In comparison, $[RhH(CO)\{PPh_2(OPh)\}_3]$ shows signals at $\delta_P$ = 142 ($J_{P,Rh}$ = 169 Hz) ppm and $\delta_H$ = –9.4 (dq, $J_{H,P}$ = 13, $J_{H,Rh}$ = 3 Hz) ppm and $[RhH(CO)_2\{PPh_2(OPh)\}_2]$ shows signals at $\delta_P$ = 145 ($J_{P,Rh}$ = 165 Hz) ppm and $\delta_H$ = –9.5 ppm.[27] The signals at $\delta$ = 130.8 and 84.9 ppm in the $^{31}P\{^1H\}$ spectrum may correspond to mixed phosphinite/phosphonate species, as proposed for the other systems.

The IR spectrum of $[Rh(acac)(CO)_2]$/**3**, under the same conditions, initially shows only one band at 1987 $cm^{-1}$ in the 2200–1800 $cm^{-1}$ region. After 1 h of stirring at 80 °C, five absorptions are present at 2044, 2025, 2006, 1966 and 1918 $cm^{-1}$. The band at 2025 $cm^{-1}$ was assigned to **15**, the absorptions at 2044 and 1966 $cm^{-1}$ were attributed to isomer **ee-16**, since they are similar to ones reported for the equatorial/equatorial isomer of $[RhH(CO)_2\{PPh_2(OPh)\}_2]$ (2045, 1970 $cm^{-1}$),[27] the ones at 2006 and 1918 $cm^{-1}$ could correspond to the isomer **ea-16**.

In summary, the study of the reactivity of $[Rh(acac)(CO)_2]$/**1**–**3** with CO and $H_2$ at 5 atm ($CO/H_2$ = 1:1) and 80 °C has shown that the precursors $[RhH(CO)(\mathbf{1}–\mathbf{3})_3]$ are formed as the main species in all cases.

## Hydroformylation of 1-Octene

We studied the hydroformylation of 1-octene (**17**) to obtain the corresponding linear (**18**) and branched (**19**) aldehydes (Scheme 4) in toluene as a model solvent and in $scCO_2$.



17 18 19

Scheme 4. Hydroformylation of 1-octene using different $[Rh(acac)(CO)_2]$/**1**–**3** systems.

### *Hydroformylation of 1-Octene in Toluene*

Table 3 (Entries 1–7) shows the results of 1-octene hydroformylation in toluene using $[Rh(acac)(CO)_2]$/**1**–**3** as the catalyst precursor. The products obtained were the isomeric aldehydes *n*-nonanal (**18**) and isononanal (**19**) and the isomerised products 2-octene [(*E*) and (*Z*)], (3*E*)-3-octene and (4*E*)-4-octene. No hydrogenated products were observed. The selectivity towards isomerised products is also listed.

Hydroformylation with $[Rh(acac)(CO)_2]$/**1** in toluene (Entry 1, Table 3) shows high activity (conversion = 98%) with a high selectivity for aldehydes at a P/Rh molar ratio of 4, although isomerised octenes were also formed. The *n*/*iso* ratio is relatively high (3.5), as is observed for other rhodium/phosphite systems.[3b] When the P/Rh ratio was reduced to 2, the conversion, and especially the selectivity, decreased (Entry 2, Table 3).

The catalyst precursors with ligands **2** and **3** provided very low selectivity for the aldehydes and produced octene isomers as the main products (Entries 3–7, Table 3). Since these poor donor ligands tend to form rhodium species with a high number of coordinated ligands per rhodium atom (see synthesis section above), which can inhibit hydroformylation,[28] we performed an experiment with a lower

Table 3. Hydroformylation of 1-octene using $[Rh(acac)(CO)_2]$/**1**–**3** catalyst precursors in $scCO_2$.[a]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

P/Rh ratio (Entry 6, Table 3); the selectivity for aldehydes decreased dramatically.

The low selectivity for aldehydes has been attributed to the nonformation of the active species $[RhH(CO)(L)_3]$. Our HPIR experiments showed that, in the case of systems with **2** and **3**, an activation time is needed before these species are detected. The system $[Rh(acac)(CO)_2]$/**2** was therefore preactivated in toluene at 5 atm ($CO/H_2$ = 1) and 80 °C for 1 h. 1-Octene was then added, the system was pressurised and again heated to 80 °C, and the reaction started. The conversion was slightly higher and the selectivity for aldehydes increased from 21 to 47% (Entry 4, Table 3). Similar results were obtained when the preactivated catalyst precursor with ligand **3** was used (Entry 7, Table 3).

Rhodium catalysts with phosphonite ligands have been shown to have very high activity in the isomerisation/hydroformylation of internal alkenes.[11] When we used $[Rh(acac)(CO)_2]$/**2** under the same conditions as for the hydroformylation of (2*E*)-2-hexene, 17% total conversion was obtained with a selectivity of 45% for aldehydes and a 1-heptanal/2-methylhexanal/3-ethylpentanal ratio of 24:54:22, which indicates that the isomerisation rate is slower than the hydroformylation rate for these systems.

### *Hydroformylation of 1-Octene in Supercritical $CO_2$*

The solubility of the catalyst precursors in $scCO_2$ was studied using a Thar autoclave equipped with sapphire windows. The purged autoclave was charged with $[Rh(acac)(CO)_2]$/**1**–**3** (P/Rh = 4), filled with $CO/H_2$ at 5 atm ($CO/H_2$ = 1:1) and pressurised with $CO_2$ up to 240 atm at 80 °C. Visual inspection through the windows showed that the supercritical phase is colourless, which indicates that there is no apparent solubility of these systems.

The catalytic experiments using $scCO_2$ with systems $[Rh(acac)(CO)_2]$/**1**–**3** are summarised in Table 3 (Entries 9–19). A reference experiment with the system $[Rh(acac)(CO)_2]$/**1** without solvent provided lower conversion and selectivity than when toluene was used as a solvent (Entry 8, Table 3).

As expected due to the low solubility of the catalyst precursors, the conversions with $scCO_2$ were lower than for the toluene systems under similar conditions. However, conversion was good with the catalyst system $[Rh(acac)(CO)_2]$/**1** (Entry 9, Table 3), although the selectivity for aldehydes fell to 25%. This led the linear/branched ratio to increase to 4.2. We optimised the conditions with this system by modifying the P/Rh ratio (Entry 10, Table 3), partial $CO/H_2$ pressure (Entry 11, Table 3), temperature (Entry 12, Table 3) and total pressure (Entry 13, Table 3). Under the best conditions (P/Rh = 6, $CO/H_2$ = 20 atm, $T$ = 100 °C, total pressure 250 atm), we achieved high conversion (82%) and high selectivity for aldehydes (89%; Entry 13, Table 3) probably because of the greater solubility of this system in $scCO_2$. Under these conditions, the linear/branched ratio was similar to that of the toluene system.

When the system $[Rh(acac)(CO)_2]$/**2** was used in $scCO_2$, the selectivity for aldehydes increased from 47% to 76%, although the conversion was lower (Entry 14 vs. Entry 4, Table 3). To favour the formation of the active species in one of the experiments (Entry 15, Table 3), the system was preactivated in diethyl ether at 5 atm ($CO/H_2$ = 1) at 80 °C for 1 h. The solvent was then evaporated and 1-octene was added. The system was pressurised and heated again to 80 °C and the reaction started. In this case the conversion and selectivity decreased considerably and decomposition of the catalyst was observed at the end of the reaction. Under the optimised conditions, we obtained high selectivity for aldehydes (94%) and a conversion of 70%.

When the system $[Rh(acac)(CO)_2]$/**3** (Entries 17–19, Table 3) was used, the best results were also obtained under the optimised conditions (selectivity for aldehydes 79% and conversion of 24%).

In summary, the catalyst precursors formed with $[Rh(acac)(CO)_2]$/**1**–**3** are active in the hydroformylation of 1-octene in $scCO_2$. In the catalyst system with the phosphite **1**, similar conversion and selectivities to those of the toluene reaction can be achieved by optimising the reaction conditions. The selectivity for aldehyde of the rhodium catalyst precursors with ligands **2** and **3** increases, especially with ligand **2**, when $scCO_2$ is used as the reaction medium instead of toluene.

## Conclusions

We have synthesised new P-donor ligands **1**–**3** with branched substituents and studied their coordination to $Rh^I$ and $Pd^{II}$. We have characterised complexes $[Rh(cod)(\mathbf{1})_2]PF_6$, $[Rh(\mathbf{2},\mathbf{3})_4]PF_6$ and $[PdCl_2(\mathbf{1}–\mathbf{3})_2]$. We have determined the X-ray structure of $[Rh(\mathbf{3})_4]PF_6$ and confirmed the formation of the tetrakis(phosphite) complex. The reactivity of $[Rh(acac)(CO)_2]$/**1**–**3** with $CO/H_2$ at 5 atm ($CO/H_2$ = 1) and 80 °C indicates that $[RhH(CO)(\mathbf{1}–\mathbf{3})_3]$ is the main species formed in solution. The solubility of the catalyst precursors $[Rh(acac)(CO)_2]$/**1**–**3** in $scCO_2$ is low but they are active in the hydroformylation of 1-octene in $scCO_2$. In this solvent, the catalyst precursor with ligand **1** gives similar activities and selectivities to those in toluene. Catalyst precursors with ligands **2** and **3** give lower conversions than in toluene but the aldehyde selectivity is higher.

## Experimental Section

**General:** All reactions were carried out under nitrogen using standard Schlenk techniques. Solvents were distilled and degassed prior to use. $^1H$, $^{13}C\{^1H\}$, $^{19}F$ and $^{31}P\{^1H\}$ NMR spectra were recorded with Varian Gemini spectrometers operating at 300 or 400 MHz ($^1H$), 75.43 or 100.57 MHz ($^{13}C$), 376.3 MHz ($^{19}F$) or 121.44 or 161.92 MHz ($^{31}P$). Chemical shifts are reported relative to tetramethylsilane for $^1H$ and $^{13}C\{^1H\}$ as internal reference, 85% $H_3PO_4$ for $^{31}P\{^1H\}$ and $CFCl_3$ for $^{19}F$. Mass spectrometry was performed with either an AUTOSPEC (EI-HR) or an AUTOFLEX spectrometer (MALDI-TOF). High-pressure NMR experiments (HPNMR) were carried out in a 10-mm-diameter sapphire tube with a titanium cap equipped with a Teflon/polycarbonate protection.[29] High-pressure IR experiments were performed in situ with an infrared autoclave.[30] Gas chromatography analyses were per-

formed with a Hewlett–Packard 5890A apparatus in an HP-5 (5% diphenylsilicone/95% dimethylsilicone) column (25 m × 0.2 mm) for the separation of the products.

**Catalysis:** Hydroformylation experiments were carried out in a Parr autoclave (25 mL) with magnetic stirring. The autoclave was equipped with a liquid inlet, a gas inlet, a $CO_2$ inlet and a thermocouple. An electric heating mantle kept the temperature constant.

**Standard Hydroformylation Experiment in Toluene:** The reactions in toluene were carried out in the same Parr autoclave. The complex [Rh(acac)(CO)$_2$] (0.024 mmol) and the ligand (0.096 mmol) in toluene (10 mL) were stirred at room temperature for 1 h. The substrate (4.8 mmol) was then added and the resulting solution was introduced into the evacuated autoclave. The system was pressurised and heated. When thermal equilibrium was reached, more gas mixture was introduced until the desired pressure was attained. After the required reaction time, the autoclave was cooled to room temperature and depressurised. The products were identified by GC/MS.

**Standard Hydroformylation Experiment in scCO$_2$:** The complex [Rh(acac)(CO)$_2$] (0.06 mmol) and the ligand (0.24 mmol) in diethyl ether (2 mL) were stirred at room temperature for 30 min. The resulting solution was introduced into the evacuated autoclave, and the solvent was removed in vacuo. 1-Octene (12 mmol) was then added. The system was pressurised with 5 atm of CO/H$_2$ (1:1), and liquid $CO_2$ was introduced until a total pressure of 60 bar was reached. The autoclave was heated to the desired temperature. When thermal equilibrium was reached, the total pressure was adjusted with a Thar syringe pump. After the reaction time, the autoclave was cooled down to –10 °C and depressurised. The final mixture was analysed by GC. The products were identified by GC/MS.

**Solubility Studies:** The solubility studies were carried out in a Thar reactor (100 mL) equipped with sapphire windows and magnetic stirring. The autoclave was charged with a solution of the ligand (0.220 mmol) and [Rh(acac)(CO)$_2$] (0.055 mmol) in diethyl ether. The solvent was removed in vacuo, the reactor was pressurised with syn-gas and $CO_2$, the system was heated to 80 °C, and the total pressure was adjusted to 240 atm. Solubility was monitored by visual inspection through the sapphire windows with a mirror due to safety requirements.

**HPNMR:** In a typical experiment, the NMR tube was filled under $N_2$ with a solution of [Rh(acac)(CO)$_2$] (0.04 mmol), the ligand **1**–**3** (0.16 mmol) and [D$_8$]toluene (2 mL). The tube was pressurised to 5 atm of CO/H$_2$ (1:1) and left at 80 °C for 1 h. The NMR spectra were then recorded.

**HPIR:** In a typical experiment, the HPIR cell was filled under $N_2$ with a solution of [Rh(acac)(CO)$_2$] (0.036 mmol), the ligand **1**–**3** (0.144 mmol) and methyltetrahydrofuran (15 mL). The cell was pressurised to 5 atm of CO/H$_2$ (1:1) and left at 80 °C for 1 h. The IR spectra were then recorded.

**Preparation of Tris(3,5,5-trimethylhexyl) Phosphite (1):** A solution of phosphorus trichloride (0.87 g, 6.3 mmol) in 6.5 mL of diethyl ether was added dropwise to a solution of 3,5,5-trimethylhexanol (2.74 g, 0.019 mol) and pyridine (1.50 g, 0.019 mol) in 12 mL of diethyl ether at –10 °C. The solution was stirred at room temperature for 2 h. The solution was filtered and the solvent was removed. The resulting colourless oil was purified by flash chromatography on basic alumina eluting with hexane. Yield: 2.33 g (80%) (colourless oil). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 3.74 (q, $J_{H,P}$ = $J_{H,H}$ = 7.1 Hz, 6 H, POC$H_2$), 1.57 (m, 6 H, POCH$_2$C*H*H + C*H*CH$_3$) 1.36 (m, 3 H, POCH$_2$CH*H*), 1.15 [dd, $^2J_{H,H}$ = 14.0 Hz, $^3J_{H,H}$ = 3.4 Hz, 3 H, CH(CH$_3$)C*H*H], 1.00 [dd, $^2J_{H,H}$ = 14.0 Hz, $^3J_{H,H}$ = 6.0 Hz, 3 H, CH(CH$_3$)CH*H*], 0.86 [d, $^3J_{H,H}$ = 6.4 Hz, 9 H, CH(C*H*$_3$)], 0.82 [s, 27 H, C(C*H*$_3$)$_3$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 60.49 (d, $^2J_{P,C}$ = 10.6 Hz, PO*C*H$_2$), 51.21 [s, CH(CH$_3$)*C*H$_2$], 40.52 (d, $^3J_{P,C}$ = 4.6 Hz, POCH$_2$*C*H$_2$), 31.11 [s, *C*(CH$_3$)$_3$], 29.99 [s, C(*C*H$_3$)$_3$], 25.91 [s, *C*H(CH$_3$)], 22.53 [s, CH(*C*H$_3$)] ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 139.9 ppm. EIMS: *m*/*z* = 461 [M + H]$^+$. High-resolution EIMS: 461.4120 ($C_{27}H_{58}O_3P$).

**Preparation of Bis(3,5,5-trimethylhexyl) Phenylphosphonite (2):** A solution of dichloro(phenyl)phosphane (1.79 g, 0.010 mol) in 6.5 mL of diethyl ether was added dropwise to a solution of 3,5,5-trimethylhexanol (2.88 g, 0.02 mol) and pyridine (1.58 g, 0.02 mol) in 12 mL of diethyl ether at –10 °C. The solution was stirred at room temperature for 7 h and then filtered. After all the solvent had been removed under reduced pressure, the resulting colourless oil was purified by flash chromatography on basic alumina eluting with hexane. Yield: 2.21 g (56%) (colourless oil). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.59 (m, 2 H, Ph), 7.38 (m, 3 H, Ph), 3.87 (m, 2 H, POC*H*H), 3.75 (m, 2 H, POCH*H*), 1.64 (m, 4 H, POCH$_2$C*H*H + C*H*CH$_3$), 1.43 (m, 2 H, POCH$_2$CH*H*), 1.19 [m, 2 H, CH(CH$_3$)C*H*H], 1.05 [m, 2 H, CH(CH$_3$)CH*H*], 0.91 [d, $^3J_{H,H}$ = 8.4 Hz, 6 H, CH(C*H*$_3$)], 0.87 [s, 18 H, C(C*H*$_3$)$_3$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 141.25 (d, $^1J_{P,C}$ = 19.2 Hz, C$_i$ Ph), 129.84 (s, C$_p$ Ph), 129.65 (d, $^3J_{P,C}$ = 2.3 Hz, C$_m$ Ph), 128.08 (d, $^2J_{C,P}$ = 4.5 Hz, C$_o$ Ph), 65.04 (d, $^2J_{P,C}$ = 9.2 Hz, PO*C*H$_2$), 64.99 (d, $^2J_{P,C}$ = 8.4 Hz, PO*C*H$_2$), 51.26 [s, CH(CH$_3$)*C*H$_2$], 51.22 [s, CH(CH$_3$)*C*H$_2$], 40.77 (d, $^3J_{C,P}$ = 4.6 Hz, POCH$_2$*C*H$_2$), 40.72 (d, $^3J_{C,P}$ = 4.3 Hz, POCH$_2$*C*H$_2$), 31.1 [s, *C*(CH$_3$)$_3$], 29.97 [s, C(*C*H$_3$)$_3$], 25.92 [s, *C*H(CH$_3$)], 22.54 [s, CH(*C*H$_3$)], 22.48 [s, CH(*C*H$_3$)] ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 156.6 ppm. EIMS: *m*/*z* = 394.3 [M]$^+$. High-resolution EIMS: 394.2991 ($C_{24}H_{43}O_2P$).

**Synthesis of 3,5,5-Trimethylhexyl Diphenylphosphinite (3):** A solution of chlorodiphenylphosphane (1.00 g, 4.6 mmol) in 6.5 mL of diethyl ether was added dropwise to a solution of 3,5,5-trimethylhexanol (0.66 g, 4.6 mmol) and pyridine (0.36 g, 4.6 mmol) in 12 mL of diethyl ether at –10 °C. The solution was stirred at room temperature for 2 h and then filtered. After all the solvent had been removed under reduced pressure, the resulting colourless oil was purified by chromatography on basic alumina eluting with hexane. Yield: 1.01 g (67%) (colourless oil). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.40 (m, 4 H, Ph), 7.22 (m, 6 H, Ph), 3.78, (m, 2 H, POC$H_2$), 1.64 (m, 1 H, POCH$_2$C*H*H), 1.55 [m, 1 H, C*H*(CH$_3$)], 1.40 (m, 1 H, POCH$_2$CH*H*), 1.13 [dd, $^2J_{H,H}$ = 13.8 Hz, $^3J_{H,H}$ = 3.8 Hz, 1 H, CH(CH$_3$)CH*H*], 0.96 [dd, $^2J_{H,H}$ = 14.2 Hz, $^3J_{H,H}$ = 6.8 Hz, 1 H, CH(CH$_3$)C*H*H], 0.82 [d, $^3J_{H,H}$ = 6.2 Hz, 3 H, CH(C*H*$_3$)], 0.77 [s, 9 H, C(C*H*$_3$)$_3$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 142.28 (d, $^2J_{P,C}$ = 18.8 Hz, C$_i$ Ph), 130.54 (d, $^2J_{P,C}$ = 7.6 Hz, C$_o$ Ph), 130.33 (d, $^2J_{P,C}$ = 7.6 Hz, C$_o$ Ph), 129.12 (d, $^3J_{P,C}$ = 5.3 Hz, C$_m$ Ph), 128.26 (s, C$_p$ Ph), 128.19 (s, C$_p$ Ph), 68.50 (d, $^2J_{P,C}$ = 19,1 Hz, PO*C*H$_2$), 51.21 [s, CH(CH$_3$)*C*H$_2$], 40.83 (d, $^3J_{P,C}$ = 7.6 Hz, POCH$_2$*C*H$_2$) 31.08 [s, *C*(CH$_3$)$_3$], 29.99 [s, C(*C*H$_3$)$_3$] 29.95 [s, C(*C*H$_3$)$_3$], 25.92 [s, *C*H(CH$_3$)], 22.50 [s, CH(*C*H$_3$)] ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 112.5 ppm. EIMS: *m*/*z* = 328.2 [M]$^+$. High-resolution EIMS: 328.1961 ($C_{21}H_{29}OP$).

**Preparation of [Rh(C$_8$H$_{12}$)(1)$_2$]PF$_6$ (4):** Ligand **1** (221 mg, 0.48 mmol) was added to a solution of [Rh(cod)$_2$]PF$_6$ (93 mg, 0.20 mmol) in 2 mL of anhydrous dichloromethane. The solution turned yellow immediately and was stirred for 1 h. The solvent was then evaporated in vacuo and the product washed with cold methanol. The product was obtained as a yellow oil. Yield: 219 mg (86%). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 4.05 (m, 16 H,

$POCH_2$ + CH= cod), 2.57 (m, 4 H, $CH_2$ cod), 2.36 (m, 4 H, $CH_2$ cod), 1.60 (m, 18 H, $POCH_2CH_2$ + $CHCH_3$), 1.22 [dd, $^2J_{H,H}$ = 14.0 Hz, $^3J_{H,H}$ = 3.6 Hz, 6 H, $CH(CH_3)CHH$], 1.14 [dd, $^2J_{H,H}$ = 14.0 Hz, $^3J_{H,H}$ = 6.0 Hz, 6 H, $CH(CH_3)CHH$], 0.97 [d, $^3J_{H,H}$ = 6.4 Hz, 18 H, $CH(CH_3)$], 0.90 [s, 54 H, $C(CH_3)_3$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 106.2 (m, CH= cod), 65.2 (d, $J_{C,P}$ = 6.1 Hz, $POCH_2$), 51.3 [s, $CH(CH_3)CH_2$], 39.8 (d, $POCH_2CH_2$), 31.1 [s, $C(CH_3)_3$], 29.9 [s, $C(CH_3)_3$] 26.1 [s, $CH(CH_3)$], 22.5 [s, $CH(CH_3)$] ppm. $^{19}$F NMR (376.3 MHz, $CDCl_3$, 20 °C): $\delta$ = –73.11 (d, $J_{P,F}$ = 715.4 Hz) ppm. $^{31}P\{^1H\}$ NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 116.1 (d, $J_{Rh,P}$ = 244.0 Hz), –143.2 [sept, $J_{F,P}$ = 711.5 Hz] ppm. MS (MALDI-TOF): *m*/*z* = 1129.54 [M – $PF_6$ – 3 H]$^+$, 1003.45 [M – $PF_6$ – $C_9H_{20}$ – H]$^+$.

**Preparation of [Rh(2)$_4$]PF$_6$ (5):** Ligand **2** (316 mg, 0.80 mmol) was added to a solution of $[Rh(cod)_2]PF_6$ (46.5 mg, 0.20 mmol) in 2 mL of anhydrous dichloromethane. The solution turned yellow immediately and was stirred for 1 h. The solvent was evaporated and the residue washed with cold methanol and dried in vacuo overnight to give the product as a yellow oily solid. Yield: 277 mg (76%). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.5 (m, 20 H, Ph), 3.47 (br. m, 8 H, POC*H*H), 3.16 (br., 8 H, POCH*H*), 1.38 (br. m, 24 H, $POCH_2CH_2$ + $CHCH_3$), 1.02 [br. m, 16 H, $CH(CH_3)CH_2$], 0.85 [d, $^3J_{H,H}$ = 5.6 Hz, 24 H, $CH(CH_3)$], 0.87 [s, 72 H, $C(CH_3)_3$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 137.74 (br., $C_i$ Ph), 131.47 (s, $C_o$ Ph), 130.33 (s, $C_m$ Ph) 128.34 (s, $C_p$ Ph), 66.00 (br., $POCH_2$) 51.19 [s, $CH(CH_3)CH_2$], 39.91 (s, $POCH_2CH_2$), 31.01 [s, $C(CH_3)_3$], 29.90 [s, $C(CH_3)_3$], 26.21 [s, $CH(CH_3)$], 22.65 [s, $CH(CH_3)$] ppm. $^{19}$F NMR (376.3 MHz, $CDCl_3$, 20 °C): $\delta$ = –74.32 (d, $J_{F,P}$ = 710.8 Hz) ppm. $^{31}P\{^1H\}$ NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 146.0 (d, $J_{P,Rh}$ = 169.7 Hz), –143.2 (sept, $J_{P,F}$ = 711.5 Hz) ppm. MS (MALDI-TOF): *m*/*z* = 1679.7 [M – $PF_6$ – 2 H]$^+$ 1285.56 [M – $PF_6$ – 4 H]$^+$.

**Preparation of [Rh(3)$_4$]PF$_6$ (6):** Ligand **3** (158 mg, 0.47 mmol) was added to a solution of $[Rh(cod)_2]PF_6$ (80 mg, 0.20 mmol) in 2 mL of anhydrous dichloromethane. The solution turned yellow immediately and was stirred for 1 h. Diethyl ether was then added to the solution to afford a yellow solid. Yield: 228 mg (73%). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.2–7.3 (m, 40 H, Ph), 2.78 (br. m, 8 H, $POCH_2$), 0.80 [m, 12 H, $POCH_2CH_2CH(CH_3)$], 0.67 [dd, $^2J_{H,H}$ = 13.8 Hz, $^3J_{H,H}$ = 5.6 Hz, 4 H, $CH(CH_3)CHH$], 0.60 [s, 36 H, $C(CH_3)_3$], 0.54 [dd, $^2J_{H,H}$ = 14.0 Hz, $^3J_{H,H}$ = 3 Hz, 4 H, $CH(CH_3)CHH$], 0.42 [d, $^3J_{H,H}$ = 6.4 Hz, 12 H, $CH(CH_3)$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 133.25 (br., $C_i$ Ph), 133.01 (s, $C_o$ Ph), 131.06 (s, $C_m$ Ph), 128.27 (s, $C_p$ Ph), 66.53 (s, $POCH_2$), 51.08 [s, $CH(CH_3)CH_2$], 37.85 (s, $POCH_2CH_2$), 31.06 [s, $C(CH_3)_3$], 29.83 [s, $C(CH_3)_3$], 26.02 [s, $CH(CH_3)$], 22.86 [s, $CH(CH_3)$] ppm. $^{31}P\{^1H\}$ NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 132.3 (d, $J_{P,Rh}$ = 162.2 Hz), –143.1 (sept. $J_{P,F}$ = 712.6 Hz) ppm.

**Preparation of [PdCl$_2$(1)$_2$] (7):** Ligand **1** (120 mg, 0.26 mmol) was added to a solution of $[PdCl_2(PhCN)_2]$ (50 mg, 0.13 mmol) in 2 mL of anhydrous dichloromethane. The solution was stirred for 1 h, then the solvent was evaporated in vacuo and the product was washed with cold methanol and dried under vacuum overnight. The product was obtained as a light-yellow oil. Yield: 124 mg (87%). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 4.15 (m, 12 H, $POCH_2$) 1.64 (m, 6 H, $POCH_2CHH$), 1.55 (m, 6 H, $CHCH_3$), 1.46 (m, 6 H, $POCH_2CHH$), 1.44 [dd, $^2J_{H,H}$ = 14.0 Hz, $^3J_{H,H}$ = 3.6 Hz, 6 H, $CH(CH_3)CHH$], 1.03 [dd, $^2J_{H,H}$ = 14.0 Hz, $^3J_{H,H}$ = 6.4 Hz, 6 H, $CH(CH_3)CHH$], 0.88 [d, $^3J_{H,H}$ = 3.2 Hz, 18 H, $CH(CH_3)$], 0.83 [s, 54 H, $C(CH_3)_3$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 66.60 (s, $POCH_2$), 51.35 [s, $CH(CH_3)CH_2$], 39.77 (s, $POCH_2CH_2$), 31.29 [s, $C(CH_3)_3$], 30.18 [s, $C(CH_3)_3$], 26.15 [s, $CH(CH_3)$] 22.67 [s, $CH(CH_3)$] ppm. $^{31}P\{^1H\}$ NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 94.2 (s) ppm. MS (MALDI-TOF): *m*/*z* = 1063.7 [M – Cl]$^+$, 1026.7 [M – 2 Cl]$^+$.

**Preparation of [PdCl$_2$(2)$_2$] (8):** Ligand **2** (51 mg, 0.12 mmol) was added to a solution of $[PdCl_2(PhCN)_2]$ (25 mg, 0.06 mmol) in 2 mL of anhydrous dichloromethane. The solution was stirred for 1 h, then the solvent was evaporated in vacuo and the product was washed with cold methanol and dried under vacuum overnight. The product was obtained as a yellow oil. Yield: 47 mg (81%). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.75 (m, 4 H, Ph), 7.45 (m, 6 H, Ph), 4.20 (br. m, 4 H, POC*H*H), 3.95 (br. m, 4 H, POCH*H*), 1.71 (br. m, 4 H, $POCH_2CHH$), 1.54 (br. m, 8 H, $POCH_2CH$H + $CHCH_3$), 1.13 [br. m, 8 H, $CH(CH_3)CH_2$], 0.90 [d, $^3J_{H,H}$ = 6.4 Hz, 12 H, $CH(CH_3)$] 0.87 [s, 36 H, $C(CH_3)_3$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 140.70 (br., $C_i$ Ph), 132.55 (s, $C_o$ Ph), 131.74 (s, $C_m$ Ph), 129.07, (s, $C_p$ Ph), 67.83 (s, $POCH_2$), 50.93 [s, $CH(CH_3)CH_2$], 39.22 (s, $POCH_2CH_2$), 30.88 [s, $C(CH_3)_3$], 29.77 [s, $C(CH_3)_3$], 25.82 [s, $CH(CH_3)$], 22.26 [s, $CH(CH_3)$] ppm. $^{31}P\{^1H\}$ NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 122.2 (s) ppm. MS (MALDI-TOF): *m*/*z* = 929.4 [M – Cl]$^+$, 894.4 [M – 2 Cl]$^+$.

**Preparation of [PdCl$_2$(3)$_2$] (9):** Ligand **3** (85.63 mg, 0.26 mmol) was added to a solution of $[PdCl_2(PhCN)_2]$ (50 mg, 0.13 mmol) in 2 mL of anhydrous dichloromethane. The solution was stirred for 1 h, the solvent was evaporated in vacuo and the residue was washed with methanol. The product was obtained as a yellow oil. Yield: 98 mg (91%). $^1$H NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.81 (m, 8 H, Ph), 7.46 (m, 12 H, Ph), 3.63 (m, 4 H, $POCH_2$), 1.31–1.19 [m, 6 H, $POCH_2CH_2$ + $CH(CH_3)$ + $CH(CH_3)CH_2$], 0.92 [d, $^3J_{H,H}$ = 4.4 Hz, 6 H, $CH(CH_3)$], 0.78 [s, $C(CH_3)_3$] ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 20 °C): $\delta$ = 140.4 (br. $C_i$ Ph), 132.58 (d, $^2J_{P,C}$ = 6.1 Hz, $C_o$ Ph), 132.52 (d, $^2J_{P,C}$ = 6.1 Hz, $C_o$ Ph), 131.75 (br., $C_m$ Ph), 128.20 (br., $C_p$ Ph), 67.86 (s, $POCH_2$), 50.93 [s, $CH(CH_3)CH_2$], 39.22 ($POCH_2CH_2$), 30.87 [s, $C(CH_3)_3$], 29.76 [s, $C(CH_3)_3$], 25.81 [s, $CH(CH_3)$], 22.26 [s, $CH(CH_3)$] ppm. $^{31}$P NMR (161.9 MHz, $CDCl_3$, 20 °C): $\delta$ = 110.21 (s) ppm. MS (MALDI-TOF): *m*/*z* = 796.9 [M – Cl]$^+$, 762.0 [M – 2 Cl]$^+$.

**Crystal Data for Complex 6:** Suitable crystals of complex **6** were grown by slow diffusion of diethyl ether into a solution of the complex in dichloromethane and mounted on a glass fibre. The measurements were taken at 120 K with a Bruker SMART CCD1000 diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å). Data collection and processing were carried out with Smart and Saint from Bruker. Complex **6** ($C_{84}H_{112}O_4P_4Rh{\cdot}PF_6$) crystallised in a tetragonal *P*4/*n* space group with *a* = 18.021 (2), *c* = 13.431 (3) Å, *V* = 4361.8 (12) Å$^3$, *M* = 1557.50, *Z* = 2, $\rho_{calcd.}$ = 1.186 mg m$^{-3}$, $\mu$ = 0.345 mm$^{-1}$. The yellow crystal was prismatic and of dimensions 0.6 × 0.52 × 0.48 mm. The $\theta$ range for measurement was 1.52–26.37° and 4471 unique reflections were measured at 120 K ($R_{int}$ = 0.0381). The structure was solved by direct methods (SHELXS-97)[31] and refined on $F^2$ by full-matrix least squares (SHELXL-97)[32] of 278 parameters. All non-hydrogen atoms were refined anisotropically. The data were corrected for absorption effects with SADABS.[33] The final parameters were $R = \sum||F_o| - |F_c||/\sum|F_o|$ = 0.0393 for 3571 reflections with $F_o^2 > 2\sigma(F_o^2)$ and $wR_2 = [\sum w(F_o^2 - F_c^2)/\sum w(F_o^2)^2]^{1/2}$ = 0.1178. Goodness-of-fit = 1.1. The ORTEP diagram was generated with ORTEP-3.[34] CCDC-270199 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Keywords:** Fluorine / Sulfur / Pincer ligands / Thioether / Palladium compounds

Metathesis reactions employing lead fluorothiolates and $C_6H_4$-1,3-$(CH_2Br)_2$ afford the corresponding pincer-type dithioether ligands $C_6H_4$-1,3-$(CH_2SR_f)_2$ [$R_f$ = $C_6H_4F$-2 (**L1**), $C_6H_4F$-3 (**L2**), $C_6H_4F$-4 (**L3**), $C_6H_4CF_3$-2 (**L4**), $C_6H_4CF_3$-3 (**L5**), and $C_6H_4CF_3$-4 (**L6**)]. A series of $Pd^{II}$ pincer-type complexes [PdCl($\kappa^3$-**Ln**)], **1** to **6**, were prepared and fully characterized. The X-ray diffraction molecular structures of $C_6H_4$-1,3-$[CH_2S(C_6H_4F$-4$)]_2$ (**L3**), [PdCl(SCS–$C_6H_4F$-2)] (**1**), [PdCl(SCS–$C_6H_4F$-3)] (**2**), [PdCl(SCS–$C_6H_4F$-4)] (**3**), [PdCl{SCS–$C_6H_4(CF_3)$-2}] (**4**), and [PdCl{SCS–$C_6H_4(CF_3)$-4}] (**6**) are also reported.

## Introduction

Pincer-type palladacycles are one of the most popular and well-investigated classes of cyclometalated compounds.[1,2] They have found application in diverse areas from efficient catalyst precursors[3] to molecular materials for crystalline switches and sensors.[4] In particular, SCS pincer-type palladium compounds have been widely studied as catalyst precursors, either as low-molecular-weight or PEG-supported polymers,[2a,5] for $Pd^{II}$-catalyzed Heck[6] and Suzuki[2d,7] cross-coupling reactions.[8–10] SCS pincer-type palladium compounds have also been the focus of interesting structural and conformational studies such as isomeric exchange[11] and dimer formation.[12] Macromolecular and self-assembled supramolecular chemistry have also profited from the useful properties of SCS pincer-type compounds for the construction of polymetallic complexes,[13] macrocycles,[14] large metallodendrimers,[15] functionalized polymers,[16] mixed Pd–Au nanoparticles,[17] polypincer-porphyrin compounds,[18] and supramolecular arrays of palladium.[19]

The possibility of fine tuning the steric and electronic properties of the metal center by simply changing the donor groups or their substituents is one of the features that makes this anionic, terdentate, six-electron donor ligand so flexible and amenable to a plethora of applications.[20] In particular, fluorine-containing pincer-type complexes are relatively rare.[21] The fluorous SCS pincer-type palladium complex with a SCS–$C_6H_4$-*p*-$C_6F_{13}$ ligand has recently been synthesized and shown to be catalytically active under both microwave and thermal heating.[22] The fluorinated PCP pincer-type complexes [RuCl{$C_6H_3$-2,6-$[CH_2P(C_6F_5)_2]_2$}-($PPh_3$)],[23a] [PdCl{$C_6H_3$-2,6-$[CH_2P(C_6F_5)_2]_2$}], and [Pd-($NCCH_3$){$C_6H_3$-2,6-$[CH_2P(C_6F_5)_2]_2$}]$BF_4$ have also recently been described.[23b]

As part of our interest in fluorinated sulfur-containing ligands,[24] we have synthesized a series of SCS pincer-type ligands with several fluorinated substituents at the sulfur atoms.[25] In this paper, we report on the synthesis and characterization of the pincer-type dithioether ligands $C_6H_4$-1,3-$(CH_2SR_f)_2$ [$R_f$ = $C_6H_4F$-2 (**L1**), $C_6H_4F$-3 (**L2**), $C_6H_4F$-4 (**L3**), $C_6H_4(CF_3)$-2 (**L4**) $C_6H_4(CF_3)$-3 (**L5**), and $C_6H_4(CF_3)$-4 (**L6**)] and the corresponding $Pd^{II}$ complexes [PdCl(**Ln**)], **1** to **6**, and include the X-ray diffraction structures of $C_6H_4$-1,3-$(CH_2SC_6H_4F$-4$)_2$ (**L3**), [PdCl(SCS–$C_6H_4F$-2)] (**1**), [PdCl(SCS–$C_6H_4F$-3)] (**2**), [PdCl(SCS–$C_6H_4F$-4)] (**3**), [PdCl{SCS–$C_6H_4(CF_3)$-2}] (**4**), and [PdCl{SCS–$C_6H_4(CF_3)$-4}] (**6**).

## Results and Discussion

### SCS Pincer-Type Ligands

Lead fluorothiolates, $Pb(SR_f)_2$, react with $C_6H_4$-1,3-$(CH_2Br)_2$ to give the corresponding dithioether compounds $C_6H_4$-1,3-$(CH_2SR_f)_2$ [$R_f$ = $C_6H_4F$-2 (**L1**), $C_6H_4F$-3 (**L2**), $C_6H_4F$-4 (**L3**), $C_6H_4(CF_3)$-2 (**L4**), $C_6H_4(CF_3)$-3 (**L5**), and $C_6H_4(CF_3)$-4 (**L6**)] as clear dense oils (**L1**, **L2**, **L4**, and **L5**)

or crystalline white solids (**L3** and **L6**), in very good yields (see Scheme 1).

The mass spectra of all compounds show the signals corresponding to the molecular ion $[M]^+$ with significant intensities (75–90%). The $^1H$ NMR spectra of compounds **L1**–**L6** exhibit a singlet for the benzylic $CH_2$ protons. All other signals appear in the aromatic region as multiplets. The $^{13}C$ NMR spectra show quartets for the carbon atoms of the $CF_3$ groups, whereas the signals for all aromatic carbon atoms with fluorine atoms appear as doublets as a result of their magnetic coupling with the fluorine nuclei. The remaining signals have been assigned with the aid of two-dimensional HETCOR experiments. As expected, the $^{19}F$ NMR spectra for all compounds show only one signal. IR, $^1H$ and $^{19}F$ NMR spectroscopy as well as EI-MS data (reported in the Experimental Section) confirm the identity of each ligand.

The X-ray structure of $C_6H_4$-1,3-$(CH_2SC_6H_4F$-4$)_2$ (**L3**) is shown in Figure 1 and Figure 2, and the principal bond lengths and angles are reported in Table 1. The solid-state structure analysis of compound **L3** corresponds to the results obtained from $^1H$, $^{13}C$, and $^{19}F$ NMR spectroscopy, observed in solution.

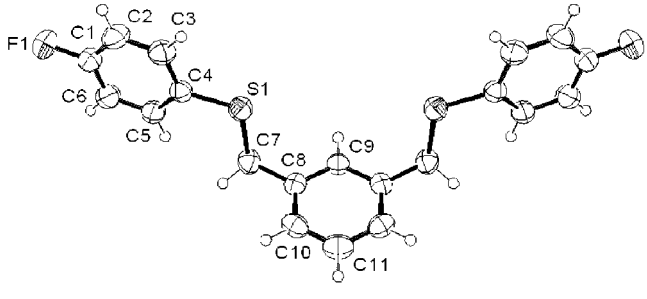

Figure 1. ORTEP drawing of compound $C_6H_4$-1,3-$(CH_2SC_6H_4F$-4$)_2$ (**L3**).

In contrast with the structure of $C_6H_4$-1,3-$(CH_2SC_6F_5)_2$,[25] in which the $SR_f$ groups are positioned on opposite sides of, and almost parallel to, the central aromatic ring, the molecular structure of **L3** has a *syn* configuration where the sulfur substituents point in the same direction as and are almost perpendicular to the central aromatic ring.

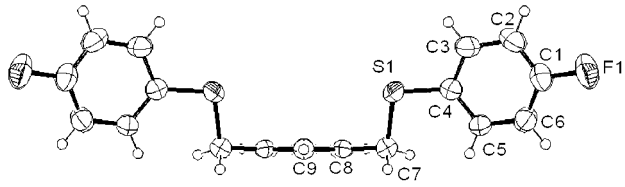

Figure 2. ORTEP drawing of compound **L3**, view along the C9–C11 axis.

## Pincer-Type Palladacycles

In our experiments, the reaction of the highly fluorinated pincer-type ligands $C_6H_4$-1,3-$(CH_2SC_6F_5)_2$ or $C_6H_4$-1,3-$(CH_2SC_6HF_4$-4$)_2$[25] with either $[PdCl_2(NCCH_3)_2]$ or $[Pd(NCCH_3)_4](BF_4)_2$ failed to produce the expected palladacycle derivatives. $SC_6F_5$ or $SC_6HF_4$-4 are much poorer donors than the corresponding protioaryl systems and, in contrast to phosphanes, they are not considered to be particularly good π acceptors.[26] Both of these effects contribute to a weaker S–Pd bond than the competing Pd–$NCCH_3$ interactions and prevent the formation of the Pd pincer-type compounds. This lack of reactivity emphasizes the importance of sulfur coordination as a preliminary step to C–Pd bond formation.

In contrast, the reaction of ligands **L1**–**L6** with $[PdCl_2(NCCH_3)_2]$ yielded the corresponding SCS pallada-

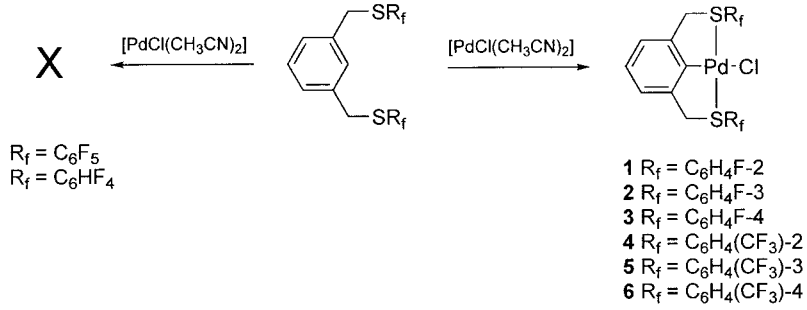

Scheme 2. Synthesis of palladium compounds **1**–**6**.

cycle compounds shown below as air-stable, yellow, crystalline solids. The yields are noticeably different for compounds bearing monofluorinated rings (**1**: 96, **2**: 81, **3**: 68%) from those with the bulkier $C_6H_4CF_3$ moiety (**4**: 79, **5**: 36, **6**: 44%), probably because they are influenced by steric factors (Scheme 2).

The $^1H$ NMR spectra of compounds **1**–**6** in $CD_3CN$ show a broad singlet for the $CH_2SR_f$ protons in the $\delta \approx$ 4.2–4.7 ppm range, probably because of a combination of *syn–anti* isomer exchange and the conformational interconversion of the $Pd^{II}$-containing five-membered rings.[27] The signal for the proton at ca. 7 ppm (C1–H) is absent, indicating complete cyclopalladation. With the exception of compound **4**, for which the low solubility precluded its measurement, the C1 shielding, as a result of cyclopalladation for the rest of the complexes, is also diagnostic of palladation at C1. The ($\delta^{13}$C1–H – $\delta^{13}$C1–Pd) values are as follows: **1** 28.29; **2** 30.74; **3** 33.57; **5** 30.37; and **6** 30.91 ppm. Likewise, the parameters defined as $\Delta_{Ln} = \delta^{13}C1 - \delta^{13}C4$ for the ligands and $\Delta_n = \delta^{13}C1 - \delta^{13}C4$ for the palladium complexes have the following values: $\Delta_{L1} = 0.74$, $\Delta_1 = 34.08$; $\Delta_{L2} = 0.57$, $\Delta_2 = 35.86$; $\Delta_{L3} = 0.87$, $\Delta_3 = 37.09$; $\Delta_{L5} = 0.63$, $\Delta_5 = 35.3$; and $\Delta_{L6} = 0.44$, $\Delta_6 = 35.87$ ppm.

$^{19}F\{^1H\}$ NMR spectra of compounds **1**–**3** and **4**–**6** exhibit a single, sharp resonance in the fluoro-aromatic region (–108.89, –113.69, –114.6 ppm) or in the $CF_3$-aromatic region (–56.56, –62.99, –62.60 ppm), respectively. Thus, isomers arising from substituent orientation relative to the square plane are not detected, which suggests that, in these complexes, sulfur inversion is either absent or faster than the NMR time scale. Palladium complexes of related thioethers exhibit relatively low energies for the process involving the inversion of configuration at the sulfur atoms ($\Delta E \approx 50$–$70$ kJ mol$^{-1}$), which is probably also true in these cases.[28]

## Molecular Structures

An X-ray structural study of compounds **1**–**3** provided solid-state evidence verifying the solution results and confirming, for all cases, the terdentate-binding mode of the SCS ligands. ORTEP drawings of [PdCl(SCS–$C_6H_4$F-2)] (**1**), [PdCl(SCS–$C_6H_4$F-3)] (**2**), and [PdCl(SCS–$C_6H_4$F-4)] (**3**) are shown in Figure 3, Figure 4 and Figure 5, respectively, and selected bond lengths and angles are reported in Table 2.

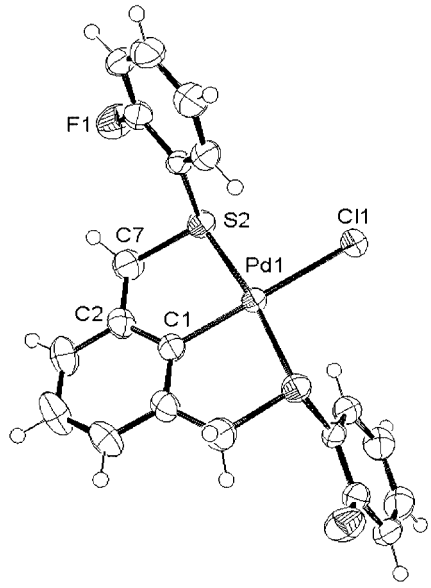

Figure 3. ORTEP drawing of compound [PdCl(SCS–$C_6H_4$F-2)] (**1**).

The Pd atoms are in slightly distorted square-planar environments: S(1)–Pd(1)–S(2), **1** 171.94(6); **2** 170.84(3); **3** 170.28(2)° and Cl(1)–Pd(1)–C(1), **1** 180.00(1); **2** 177.83(10); **3** 179.03(7)°. The bonding parameters of Pd are very similar to those observed for the complexes [PdCl{2,6-$C_6H_3$-($CH_2S$*t*Bu)$_2$}],[29] Pd–S 2.308(2); Pd(1)–Cl(1) 2.406(3); and Pd–C(1) 1.998(11) Å; [PdCl{2,3,5,6-$C_6H$-($CH_2S$*t*Bu)$_4$}],[19f] Pd–S(1) 2.297(3); Pd(1)–S(2) 2.302(3); Pd(1)–Cl(1) 2.408(3); Pd–C(1) 1.994(9) Å; and [Pd{4-(*n*BuO)-2,6-$C_6H_2$-($CH_2$SPh)$_2$}($NCCH_3$)]$^+$,[30] Pd–S(1) 2.2992(8); Pd–S(2) 2.2961(9); Pd–C(1) 1.975(2) Å.

The $C_6H_4$F-2 and $C_6H_4$F-3 groups attached to the metal-bound sulfur atoms in **1** and **2** are oriented in an *anti* fashion with respect to the square plane; a common conformation observed in these type of compounds,[19f,29–31] which allows for minimization of any steric repulsions between the aromatic rings. In contrast, the $C_6H_4$F-4 groups attached to the metal-bound sulfur atoms in **3** are oriented in a *syn* fashion with respect to the square plane; this allows for maximization of intermolecular aromatic π-stacking inter-

171.54(2); **6** 165.99(4)° and Cl(1)–Pd(1)–C(1), **4** 178.46(7); **6** 176.82(13)°. The bonding parameters for Pd are comparable with those observed for complexes **1**–**3** and analogous compounds.[19f,29–31] The $C_6H_4(CF_3)$-*n* (*n* = 2 or 4) groups attached to the metal-bound sulfur atoms are oriented in an *anti* fashion with respect to the square plane, as is the case for **1** and **2**.

## Summary and Conclusions

Pincer-type ligands of the SCS class can be prepared with partially fluorinated aromatic substituents. However, only those with a single F or $CF_3$ group will undergo facile palladation reactions to give the corresponding palladacycle. When the number of F atoms is increased, the resulting electronic effect on the S donor is such that coordination to palladium is too weak to allow for metallation to occur.

The solid-state structures show no unusual steric effects that would prevent these complexes from being used in a variety of catalytic reactions. We are currently testing these complexes as catalysts for the Suzuki coupling of aromatic groups. The results showing the effect of these electron-withdrawing substituted SCS pincers will be reported in due course.

## Experimental Section

**General:** All reactions were carried out under inert conditions using conventional Schlenk glassware. The solvents were dried by using established procedures and distilled under nitrogen immediately prior to use. TLC (Merck, $2 \times 5$ cm$^2$ Kieselgel 60 F254) was used to monitor the progress of the reaction under study with hexane/ethyl acetate (9:1) as the eluent. The IR spectra were measured with a Nicolet Avatar FT-IR spectrometer. $^1$H-, $^{13}$C-, and $^{19}$F NMR spectra were recorded with a Varian Unity Inova 300 spectrometer operating at 300 MHz. Chemical shifts are relative to TMS $\delta = 0$ ($^1$H, $^{13}$C) and $CFCl_3$ $\delta = 0$ ($^{19}$F) using $CD_3CN$ as the solvent. Electron impact mass spectra were recorded with a Jeol JMSSX102A mass spectrometer. Elemental analyses were determined using a Fisons EA1108 instrument. The starting material 1,3-bis(bromomethyl)benzene was obtained from Aldrich Chemical Co. and used without further purification. $C_6H_3$-1,3-$(CH_2SC_6F_5)_2$, $C_6H_3$-1,3-$(CH_2SC_6HF_4$-4$)_2$,[25] and $Pb(SR_f)_2$[32] ($R_f$ = $C_6H_4$F-2, $C_6H_4$F-3, and $C_6H_4$F-4) were prepared according to published procedures.

**Preparation of Compounds L1–L6:** $C_6H_4$-1,3-$(CH_2SC_6H_4F$-*n*$)_2$ (**L1**–**L3**) and $C_6H_4$-1,3-$[CH_2SC_6H_4(CF_3)$-*n*$]_2$ (**L4**–**L6**).

In all reactions, stoichiometric quantities of reactants were used, and since all preparations were similar, only a typical procedure is described.

$Pb(SC_6H_4F$-*n*$)_2$ or $Pb[SC_6H_4(CF_3)$-*n*$]_2$ (0.41 mmol) was added to a mixture of 1,3-bis(bromomethyl)benzene (0.113 g, 0.41 mmol) in acetonitrile (30 mL). The stirred mixture was maintained under reflux for 24 h. After this time, $PbBr_2$ was filtered off, the solvent was removed under vacuum, and the residue purified by column chromatography (silica gel; hexane/ethyl acetate 9:1).

Spectroscopic parameters follow the numbering scheme shown in the following diagram.

**General Procedure for the Preparation of Palladium(II) Complexes 1–6:** Dichloropalladium(II) (0.216 g, 1.22 mmol) in acetonitrile (25 mL) was heated under reflux for 1 h. Silver tetrafluoroborate (0.495 g, 2.54 mmol) was added to this solution. Silver chloride was separated from the suspension by filtration through Celite. The ligand (**L1**–**L6**) (0.435 g, 1.22 mmol) was dissolved in warm acetonitrile (10 mL) and added to the filtrate. The solution immediately turned orange and was heated under reflux for 4 h. The reaction mixture turned yellow, and excess NaCl (0.189 g, 3.23 mmol) was added. The suspension was stirred overnight. The yellow precipitate was filtered off and washed three times with water and two times with ethanol. The products were obtained as yellow powders.

**[PdCl{$C_6H_3$-1,3-$(CH_2SC_6H_4F$-2)$_2$}] (1):** Yellow crystals; yield: 0.583 g, 96%. M.p. 187 °C. IR (KBr): $\tilde{\nu}$ = 750, 1470, 1449, 1221, 1262, 724, 818, 1061, 1029, 2900, 2976, 3046 cm$^{-1}$. **Crystal Data:** Crystallographic data, solution and refinement parameters for the single crystal structure determinations of compounds **L3**, **1**, **2**, **3**, **4**, and **6** are reported in Table 4. Single crystals of all compounds were obtained from slow evaporation of saturated acetonitrile solutions. X-ray diffraction data for compounds **L3** and **1** were collected at 298 K with a Siemens P4 automatic diffractometer and analyzed using graphite-monochromated Mo-$K_\alpha$ X-ray radiation ($\lambda$ = 0.71073 Å). X-ray diffraction data for compounds **2**, **3**, **4**, and **6** were collected at 173 K with a Bruker APEX CCD single crystal diffractometer with Mo-$K_\alpha$ X-ray radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods using SHELXS 97–2.[33] Least-squares refinement based on $F^2$ was carried out by a full-matrix method with SHELXL 97–2.[33] All non-hydrogen atoms were refined with anisotropic thermal parameters. The location of hydrogen atoms was generated geometrically and included in the refinement with an isotropic fixed thermal parameter using a "riding" model. Neutral atom scattering factors and anomalous dispersion corrections were taken from International Tables for Crystallography.[34] Molecular structure drawings were generated using ORTEP3 for Windows.[35]

CCDC-251029 (**L3**), -251028 (**1**), -254754 (**2**), -281816 (**3**), -281832 (**4**), and -281831 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Characterisation of Alkali Metal and Thallium Polyfluoroantimonates, $ASb_nF_{5n+1}$ ($n$ = 2, 3)

**Primož Benkič,[a] H. Donald Brooke Jenkins,[b] Maja Ponikvar,[a] and Zoran Mazej*[a]**

**Keywords:** Alkali metals / Antimony / Fluorides / Lewis acids / Superacidic systems

Reactions of AF (A = K, Rb, Tl) with excess liquid $SbF_5$ in anhydrous HF (or $SO_2$) at room temperature give products having the composition $ASb_2F_{11}$. The reaction between CsF and a small excess of $SbF_5$ in anhydrous HF (0.76 mmol of CsF + 4.19 mmol of $SbF_5$ in 4 mL of aHF) yields $CsSb_2F_{11}$, whereas the reaction with a large excess of $SbF_5$ (0.79 mmol of CsF + 23 mmol of $SbF_5$ in 10 mLof aHF) yields the salt $CsSb_3F_{16}$. Efforts to prepare similar compounds using the monofluorides of Li and Na led only to the already known $ASbF_6$ compounds. Reactions of AF (A = Na, K, Rb, Cs) with liquid $SbF_5$ at 85 °C in the absence of solvents yield the products $NaSbF_6$, $ASb_2F_{11}$ (A = K, Rb) and $CsSb_3F_{16}$, respectively. A single-crystal X-ray diffraction study on the salt $KSb_2F_{11}$ [orthorhombic, at 250 K, *Pbca*, with $a$ = 1141.65(8), $b$ = 1279.96(9), $c$ = 3948.5(3) pm, $V$ = 5.7699(7) nm$^3$ and $Z$ = 24] has shown it to be isostructural with $AgSb_2F_{11}$. $CsSb_2F_{11}$, on the other hand, is monoclinic at 250 K [$P2_1/n$, with $a$ = 774.10(14), $b$ = 1425.41(17)m, $c$ = 951.30(15) pm, $\beta$ = 113.226(6)°, $V$ = 0.9646(3) nm$^3$ and $Z$ = 4]. $RbSb_2F_{11}$ and $TlSb_2F_{11}$ belong to yet a third structural type. Crystals of $CsSb_3F_{16}$ are orthorhombic at 200 K [$Pca2_1$, with $a$ = 2207(3), $b$ = 772.6(11), $c$ = 1605(3) pm, $V$ = 2.737(8) nm$^3$ and $Z$ = 8]. The vibrational spectra of $Sb_2F_{11}^-$ salts are consistent with the above crystallographic assignments, showing that $Sb_2F_{11}^-$ anions deviate strongly from $D_{4h}$ symmetry in having no symmetry at all (point group $C_1$). The vibrational spectra of $CsSb_3F_{16}$ confirm the presence of $Sb_3F_{16}^-$ anions, which adopt a *cis*-fluorine-bridged geometry consistent with the crystal structure.

## Introduction

Compounds of the type $ASbF_6$ (A = monovalent cation) are well known and established.[1] In contrast to $ASbF_6$ salts, reports concerning the formation of $ASb_2F_{11}$ and $ASb_3F_{16}$ compounds are scarce. $CsSb_2F_{11}$ has been prepared from CsF and $SbF_5$ in $SO_2$ solution and investigated by $^{19}F$ NMR spectroscopy.[2] Its (incomplete) vibrational spectrum was also reported.[3,4] The salt $AgSb_2F_{11}$ has been studied and its synthesis, crystal-structure determination and vibrational spectra have been published recently.[5] In the case of the $Sb_3F_{16}^-$ salts of alkali metal fluorides only the caesium compound has been reported to exist.[6]

The tendency of alkali metal fluorides to form stable, complex fluoro or oxofluoro anion salts with covalent metal fluorides or oxofluorides decreases from $Cs^+$ to $Li^+$.[7] However, the cut-off limit for salt formation in the view of the size (volume) of the $A^+$ cation appears to vary somewhat from one system to another.[7] The aim of this work was a systematic investigation of reactions between monofluorides of alkali metals (including thallium) and antimony pentafluoride [with and without the presence of solvents such as $SO_2$ and anhydrous HF (aHF)] to find out how the size of the cations influences the composition of the final products. In other words, which compounds with general formula $ASb_nF_{5n+1}$ ($n$ = 1, 2, 3) should exist for a specific cation.

## Results and Discussion

### Syntheses

Reactions of AF (A = K, Rb, Tl) with an excess of $SbF_5$ in anhydrous HF or $SO_2$ at room temperature yield products having the composition $ASb_2F_{11}$ [Equation (1)].

$$AF + 2SbF_5 \xrightarrow[298\ K]{aHF/SO_2,\ SbF_5} ASb_2F_{11}\ (A = K, Rb, Tl) \quad (1)$$

The reaction between CsF and a small excess of $SbF_5$ in anhydrous HF (0.76 mmol of CsF + 4.19 mmol of $SbF_5$ in 4 mL of aHF) yields $CsSb_2F_{11}$ whilst, in contrast, the reaction with a large excess of $SbF_5$ (0.79 mmol of CsF + 23 mmol of $SbF_5$ in 10 mL of aHF) yields $CsSb_3F_{16}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The course of the reaction between KF and $SbF_5$ (the starting molar ratio KF/$SbF_5$ being 1:2) in $SO_2$ is in agreement with previous findings for Cs salts.[2] $KSb_2F_{11}$ is similar to $CsSb_2F_{11}$ in being relatively soluble in $SO_2$.

Efforts to prepare similar compounds starting from the monofluorides of Li and Na led only to already known $ASbF_6$[1] compounds [Equation (2)].

$$AF + SbF_5 \xrightarrow[298\ K]{aHF/SO_2,\ SbF_5} ASbF_6 \quad (A = Li, Na) \tag{2}$$

The reaction between NaF and $SbF_5$ in $SO_2$ yields only $NaSbF_6$ which, like the corresponding $CsSbF_6$, is rather insoluble[2] in $SO_2$ (see Experimental Section).

The previously reported vibrational spectra of products obtained by heating equimolar mixtures of $SbF_5$ and the corresponding alkali metal fluoride under $F_2$ at 280 °C exhibited no evidence at all for the presence of polyfluoroantimonates.[8] Our results, however, show that when the reaction mixture of a sample of alkali fluoride (AF, A = Na, K, Rb, Cs) and an excess of liquid $SbF_5$ is heated at 85 °C $NaSbF_6$, $ASb_2F_{11}$ (A = K, Rb) and $CsSb_3F_{16}$ are isolated as the final products.

## Crystal Structures

Single crystals of $ASb_2F_{11}$ (A = K, Cs) were prepared by slow evaporation (over two months) of the volatiles from saturated solutions of the corresponding $ASb_2F_{11}$ salts in aHF acidified with a large excess of $SbF_5$. A similar procedure using NaF yields only single crystals of $NaSbF_6$. These results suggest that the products of the reaction between AF (A = Li, Na) and an excess of $SbF_5$ [Equation (2)] are not the result of kinetic control.

The crystal structures of $ASb_2F_{11}$ compounds can be divided into three groups. The first group corresponds to $ASb_2F_{11}$ compounds having similarly sized cations (A = $K^+$, $H_3O^+$, $Ag^+$). Crystals of $KSb_2F_{11}$ are orthorhombic at 250 K (see Experimental Section) and are isostructural to $AgSb_2F_{11}$[5] and also structurally related to $H_3OSb_2F_{11}$.[9] The complex structure of $KSb_2F_{11}$ reveals three crystallographically nonequivalent $Sb_2F_{11}^-$ anions that are highly distorted from ideal $D_{4h}$ symmetry (Figure 1). Distortions of $Sb_2F_{11}$ units are usually expressed in terms of the bridge angle $\alpha$ (bending of $F_5Sb$–F–$SbF_5$ about bridging fluorine) and the torsion angle $\psi$ (torsion of two planar $SbF_{4,eq}$ groups from eclipsed to staggered conformation). In $KSb_2F_{11}$ three different bridge (149.2°, 150.4° and 146.1°) and three corresponding dihedral (20.2°, 21.2° and 32.6°) angles for three crystallographically nonequivalent $Sb_2F_{11}$ units were identified. The bridging and dihedral angles found in $KSb_2F_{11}$ are close to the values found for the anion in the isostructural $AgSb_2F_{11}$ ($\alpha$ = 148.3°, 151.8° and 143.5°; $\psi$ = 22.5°, 18.0° and 37.1°).[5] The Sb–$F_t$ bonds are, as expected, shorter (181.2–186.4 pm) and show a wider spread than the Sb–$F_b$ bonds (202.4–204.1 pm; Table 1). The $F_{eq}$–Sb–$F_{ax}$ Bond angles are slightly greater than 90°, while the $F_{eq}$–Sb–$F_b$ are more acute by 3–7° (Table 2).

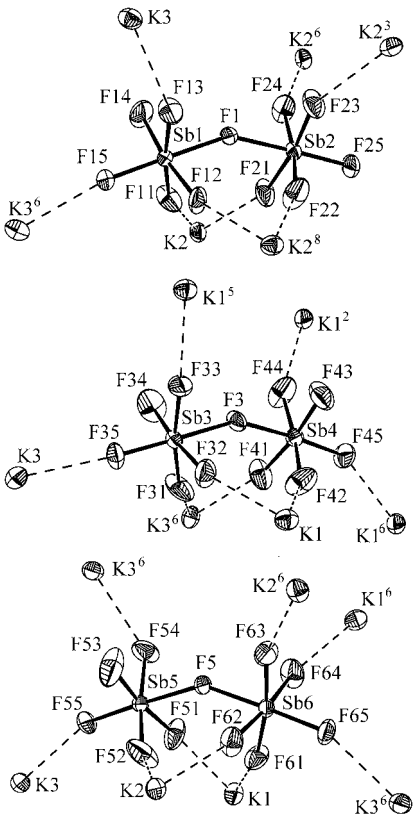

Figure 1. Three crystallographically nonequivalent $Sb_2F_{11}$ units and their interactions with $K^+$ cations in the crystal structure of $KSb_2F_{11}$ (thermal ellipsoids are drawn at 40% probability level). Superscripted numbers: symmetry operations used for generation of equivalent atoms: [1] $x, y, z$; [2] $x + ½, -y + ½, -z$; [3] $-x, y + ½, -z + ½$; [4] $-x + ½, -y, z + ½$; [5] $-x, -y, -z$; [6] $-x + ½, y + ½, z$; [7] $x, -y + ½, z + ½$; [8] $x + ½, y, -z + ½$.

There are also three crystallographically nonequivalent $K^+$ cations in the crystal structure of $KSb_2F_{11}$. The K–F bond lengths span a wide range of values (260.1–289.8 pm). By comparison, in $KSbF_6$ eight fluorine atoms, which form a slightly distorted dodecahedron, surround the K atoms at distances of between 261.8 and 320.4 pm.[10] The coordination number of the potassium atoms in $KSb_2F_{11}$ can be written as 8 for K1 and K3 and 9 for K2.

$CsSb_2F_{11}$ crystallises in the monoclinic space group $P2_1/n$ (no. 14) with the unit-cell parameters and the crystal and structure refinement data given in the Experimental Section. Selected bond lengths and angles are summarised in Tables 3 and 4, respectively. The packing diagram is depicted in Figure 2.

The structure of the $Sb_2F_{11}^-$ anion and its interactions with $Cs^+$ cations, along with the numbering scheme adopted, are given in Figure 3. The structure of $CsSb_2F_{11}$ is ionic and consists of discreet $Sb_2F_{11}^-$ anions and

$Cs^+$ cations in a simple packing arrangement. As in the case of $KSb_2F_{11}$, the $Sb_2F_{11}^-$ anion in $CsSb_2F_{11}$ is highly distorted from ideal $D_{4h}$ symmetry ($\alpha$ = 146.0°, $\psi$ = 33.9°; Figure 3). The Sb–F bond lengths (Table 3) and F–Sb–F bond angles (Table 4) in $CsSb_2F_{11}$ are comparable to those found for $KSb_2F_{11}$ (Tables 1 and 2).

Taking the coordination number as the number of nearest neighbour atoms[9] then Cs is surrounded by 12 fluorine atoms at distances of between 307.0(4) and 355.2(4) pm. In

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

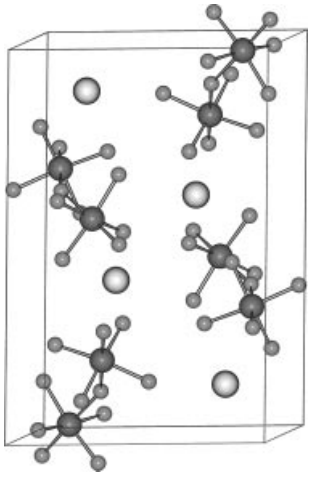

Figure 2. Packing diagram of $CsSb_2F_{11}$.

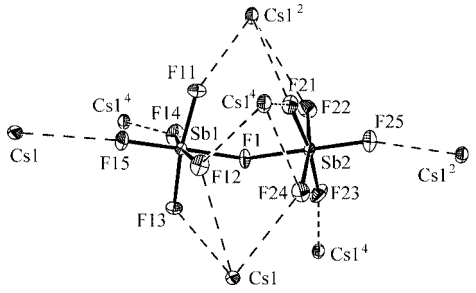

Figure 3. $Sb_2F_{11}$ unit and interacting $Cs^+$ cations in $CsSb_2F_{11}$ (thermal ellipsoids are drawn at 40% probability level). Superscripted numbers: symmetry operations used for generation of equivalent atoms: [1] $x, y, z$; [2] $-x + ½, y + ½, -z + ½$; [3] $-x, -y, -z$; [4] $x + ½, -y + ½, z + ½$.

$CsSbF_6$ twelve fluorine atoms again surround the Cs atom with six close contacts (311.6 pm) and six long contacts (338.3) pm.[11]

The X-ray powder-diffraction photographs indicate that $RbSb_2F_{11}$ and $TlSb_2F_{11}$ are isostructural and different from $KSb_2F_{11}$ or $CsSb_2F_{11}$. Their isostructurality is consistent with the close similarity shown by the ionic radii of Rb and Tl (Shannon: Rb = 175 pm, Tl = 173 pm for C.N. = 8;[12] Goldschmidt: Rb = Tl = 149 nm[13]) or their volumes [$V(Rb^+) = V(Tl^+) = 0.014$ nm$^3$].[14]

Examples of crystal structures of $Sb_3F_{16}^-$ salts are rare. The $Sb_3F_{16}^-$ anion adopts a *cis*-fluorine-bridged geometry in the crystal structures of $[OsO_3F][Sb_3F_{16}]$,[15] $[OCNCO][Sb_3F_{16}]$,[16] $[XeN(SO_2F)_2][Sb_3F_{16}]$[17] and $[Cl_3][Sb_3F_{16}]$,[18] whereas a *trans*-fluorine-bridged $Sb_3F_{16}^-$ anion has been reported in the crystal structure of $[Br_2][Sb_3F_{16}]$.[19] $CsSb_3F_{16}$ crystallises in the orthorhombic space group $Pca2_1$ (no. 29). The unit-cell parameters and the crystal and structure refinement data are given in the Experimental Section. Selected bond lengths and angles are summarised in Tables 5 and 6, respectively. The packing diagram is depicted in Figure 4.

The crystal structure of $CsSb_3F_{16}$ reveals two crystallographically nonequivalent $Sb_3F_{16}^-$ anions adopting a *cis*-fluorine-bridged geometry. The structure of the $Sb_3F_{16}^-$ anions and their interactions with $Cs^+$ cations, along with the numbering scheme adopted, are given in Figure 5. The Sb–$F_t$ bond lengths (Table 5) in $CsSb_3F_{16}$ are comparable to those found for $KSb_2F_{11}$ and $CsSb_2F_{11}$ (Tables 1 and 3).

The corresponding pairs of Sb–$F_b$ bond lengths in the $F_5Sb–F_b–SbF_5$ units of $KSb_2F_{11}$ [Sb1–F1 = 204.1(5), F1–

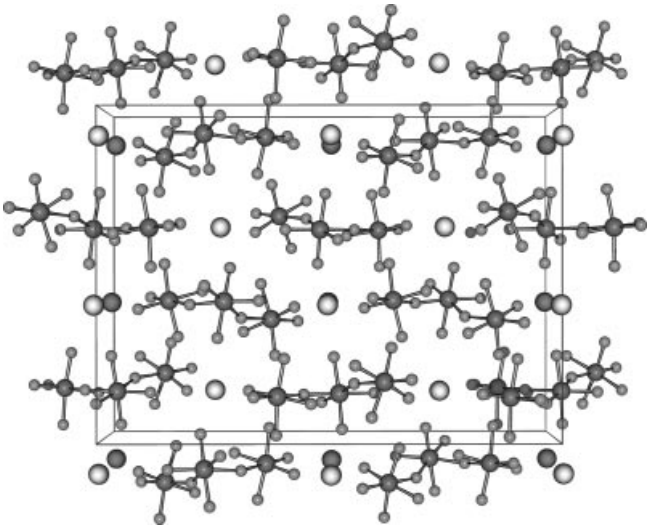

Figure 4. Packing diagram for $CsSb_3F_{16}$.

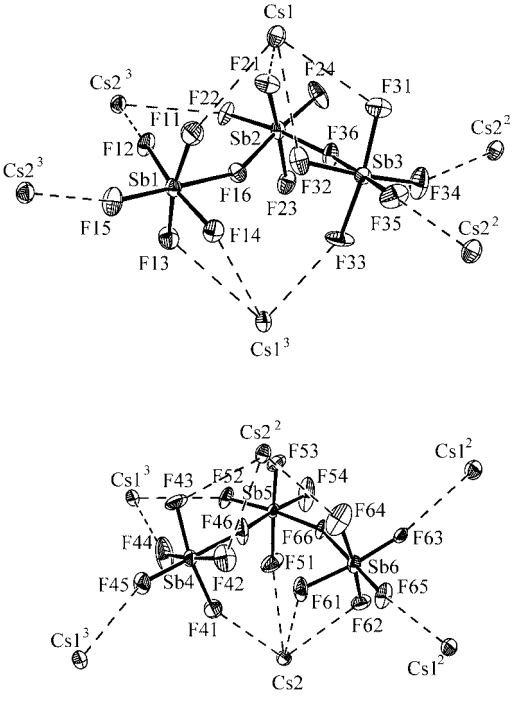

Figure 5. Two crystallographically nonequivalent $Sb_3F_{16}$ units and their interactions with $Cs^+$ cations in the crystal structure of $CsSb_3F_{16}$ (thermal ellipsoids are drawn at 40% probability level). Superscripted numbers: symmetry operations used for generation of equivalent atoms: [1] *x*, *y*, *z*; [2] –*x*, –*y*, *z* + ½; [3] –*x* + ½, *y*, *z* + ½; [4] *x* + ½, –*y*, *z*.

Sb1 = 202.4(5); Sb3–F3 = 203.4(5); F3–Sb4 = 202.8(5); Sb5–F5 = 203.8(5), F5–Sb6 = 202.4(5) pm] and $CsSb_2F_{11}$ [Sb1–F1 = 203.9(3), F1–Sb2 = 203.9(3) pm] are much closer than the corresponding pairs of Sb–$F_b$ bond lengths in the $F_5Sb–F_b–SbF_4–F_b–SbF_5$ units of $CsSb_3F_{16}$. The Sb–$F_b$ bond lengths (Sb2–F16, Sb2–F36 and Sb5–F46, Sb5–F66) between $F_b$ and the central Sb atom are much shorter [196(8)–199.6(17) pm] than the corresponding bond lengths between $F_b$ and the terminal Sb atoms (F16–Sb1, F36–Sb3 and F46–Sb4, F66–Sb6), which are in the range 207(2)–209.5(9) pm.

There are also two crystallographically nonequivalent $Cs^+$ cations in the crystal structure of $CsSb_3F_{16}$. On a similar basis to the assignment of the coordination number made in the case of $CsSb_2F_{11}$, these cations are surrounded by 12 fluorine atoms at distances of between 304(12) and 366(5) pm.

### Vibrational Spectra

The Raman and IR spectra of $ASb_2F_{11}$ (A = K, Rb, Cs, Tl) and $CsSb_3F_{16}$ are shown in Figures 6 and 7, respectively, with additional details given in Tables 7 and 8.

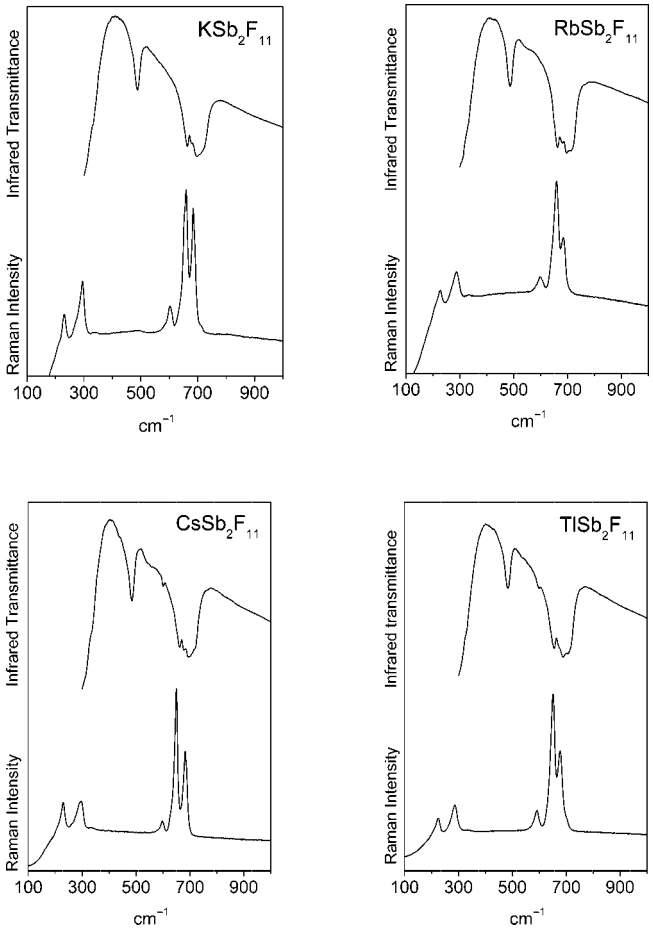

Figure 6. Infrared and Raman spectra of $ASb_2F_{11}$ (A = K, Rb, Cs, Tl).

The IR spectra (Figure 6, Table 7) were taken for powdered samples obtained from the synthesis [Equation (1)] and also for powdered samples obtained by grinding selected single crystals of $ASb_2F_{11}$ (A = K, Cs). They were found to be identical. Raman spectra taken for powdered samples obtained from the synthesis [Equation (1)] and Raman spectra taken for single crystals of $ASb_2F_{11}$ (A = K, Cs) were also identical. Small differences in the observed wavenumbers and relative intensities of some of the Raman and infrared bands of these salts arise as a consequence of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

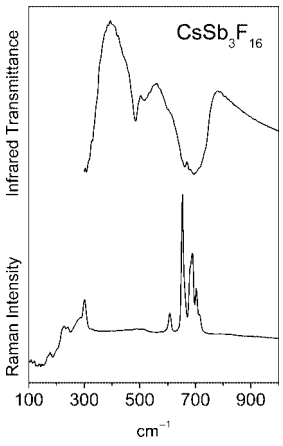

Figure 7. Infrared and Raman spectra of $CsSb_3F_{16}$.

the fact that some bands are broad, which makes the precise estimation of particular band positions difficult. A further factor contributing to these small differences are the crystal effects.

$Sb_2F_{11}^-$ anions deviate strongly from ideal $D_{4h}$ symmetry and, in fact, possess no symmetry at all (point group $C_1$). A partial assignment of the spectra of the $Sb_2F_{11}^-$ anions was made on the basis of comparison with $[M(CO)_4(Sb_2F_{11})_2]$ (M = Pd, Pt),[20] which contain two crystallographically nonequivalent and highly distorted $Sb_2F_{11}^-$ anions (Table 7, Figure 6). The bands in the regions 592–698 $cm^{-1}$ and 702–719 $cm^{-1}$ are assigned to Sb–$F_{eq}$ and Sb–$F_{ax}$ stretches, respectively, meanwhile bands around 500 $cm^{-1}$ are typical for Sb–F–Sb bridging. Bands below 300 $cm^{-1}$ were assigned to bending deformations.

[a] Intensities are given in parentheses; w = weak, mw = medium weak, m = medium, ms = medium strong, s = strong, vs. = very strong, sh = shoulder. [b] ν = Stretching mode, δ = deformation mode.

The vibrational spectrum of $CsSb_3F_{16}$ is similar but not identical to that for $CsSb_2F_{11}$. The $Sb_3F_{16}^-$ anion in $CsSb_3F_{16}$ exhibits very complex Raman and infrared spectra (Figure 7, Table 8). Reported vibrational data for the $Sb_3F_{16}^-$ anion are scarce. $[OsO_3F][Sb_3F_{16}]$,[15] $[ClCO][Sb_3F_{16}]$,[22] $[OCNCO][Sb_3F_{16}]$,[16] $[XeN(SO_2F)_2][Sb_3F_{16}]$,[17] $[ReF_6][Sb_3F_{16}]$[23] and $[PF_4][Sb_3F_{16}]$[24] have

been characterised by Raman spectroscopy and $[ClO_2][Sb_3F_{16}]$[25] by IR spectroscopy. These data vary significantly as the nature of the cation changes. The bands attributed to the $Sb_3F_{16}^-$ anion in $CsSb_3F_{16}$ show most correspondence with those found in $[ClCO][Sb_3F_{16}]$,[22] where $Sb_3F_{16}^-$ was found to exhibit a common *cis*-fluorine-bridged $Sb_3F_{16}^-$ anion consistent with the crystal structure analysis made for $CsSb_3F_{16}$.

## Conclusions

Smaller cations such as $Li^+$ [$V(Li^+)$ = 0.002 nm$^3$][14] and $Na^+$ [$V(Na^+)$ = 0.004 nm$^3$][14] yield $ASbF_6$ compounds, whereas larger $A^+$ cations (A = $Ag^+$, $H_3O^+$, $K^+$) prefer to form $ASb_2F_{11}$ salts. These latter ions, with volumes $V(Ag^+)$ = 0.006 nm$^3$,[5] $V(H_3O^+)$ = 0.008 nm$^3$[5] and $V(K^+)$ = 0.010 nm$^3$,[14] lead to salts which crystallise in an identical structural type. The coordination of the three crystallographically nonequivalent $A^+$ cations can be approximately regarded as being 5+3, (C.N. = 8), 6+3 (C.N. = 9) and 6+2 (C.N. = 8), respectively. X-ray powder diffraction patterns indicate that $RbSb_2F_{11}$ and $TlSb_2F_{11}$ are isostructural, which, as was alluded to above, is not surprising in light of their similar volumes. The larger $Cs^+$ cation [$V(Cs^+)$ = 0.019 nm$^3$][14] yields $CsSb_2F_{11}$, which represents the third structural type with the highest coordination number (C.N. = 12) found for the cation $A^+$.

In all crystal structures determined for $ASb_2F_{11}$ compounds the $Sb_2F_{11}$ units are observed to have a high degree of distortion. The bridge angle $\alpha$ and torsion angle $\psi$ in the $Sb_2F_{11}$ units may have some cation-dependence, although these values are mostly influenced by long interionic contacts in the solid state.

Only the largest of the alkali metal cations ($Cs^+$) is capable of stabilizing the weakly fluoro-basic $Sb_3F_{16}^-$ anion.

A summary of known compounds with general formula $ASb_nF_{5n+1}$ (A = monovalent metal cation; $n$ = 1, 2, 3) is shown in Table 9.

Table 9. Compounds with general formula $ASb_nF_{5n+1}$ (A = monovalent metal cation; $n$ = 1, 2, 3).

## Experimental Section

### Techniques

The infrared spectra, with a resolution of 4 cm$^{-1}$, of powdered samples sandwiched between AgCl windows in a leak-tight brass cell were recorded (5 scans) with a Perkin–Elmer FTIR 1710 spectrometer. Raman spectra, with a resolution of 1 cm$^{-1}$, were recorded (10–20 scans) with a Renishaw Raman Imaging Microscope System 1000, with the 632.8-nm exciting line of a He-Ne laser.

X-ray powder diffraction patterns were obtained using the Debye–Scherrer technique with Ni-filtered Cu-$K_\alpha$ radiation. Samples were loaded into quartz capillaries (0.3 mm) in a dry-box. Intensities were estimated visually.

### Reagents and Apparatus

Volatile materials were manipulated using an all-PTFE vacuum line equipped with PTFE valves. The manipulation of the non-volatile solids was accomplished under a dry argon atmosphere in a dry-box (M. Braun, Germany). The residual water in the atmosphere within the dry-box never exceeded 1 ppm. All reactions were carried out in FEP (Polytetra, Germany) reaction vessels (height: 300 mm; inner diameter: 15.5 mm; outer diameter: 18.75 mm) equipped with PTFE valves[31] and PTFE-coated stirring bars. All reaction vessels were pretreated with $F_2$ prior to use.

LiF (Merck, 99.9%), NaF (Merck, 99%), KF (Ventron, 99.9%), RbF (Aldrich, 99%), CsF (Ventron, 99.9%), $SO_2$ (Messer Griesheim, 99.9%) and fluorine (Solvay) were used as supplied. TlF was prepared by reaction between $Tl_2CO_3$ (Merck, P.A.) and aqueous HF. $SbF_3$ (Alfa Aesar, 99%) was treated with aHF in order to remove possible traces of $Sb_2O_3$. $SbF_5$ was prepared by fluorination of $SbF_3$ in a flow reaction. Its purity was checked by Raman spectroscopy. Anhydrous HF (Fluka, Purum) was treated with $K_2NiF_6$ for several hours prior to use.

### Reactions between AF and an Excess of $SbF_5$

In a dry-box a sample of the fluoride AF (A = Li – Cs, Tl) was loaded into the FEP reaction vessel. An excess of $SbF_5$ and the solvent (aHF or $SO_2$) were condensed onto the solid fluoride salt at 77 K. The reaction mixtures were left stirring for several days at room temperature. The details of the reaction conditions are given in Table 10. Clear colourless solutions were obtained in the case of reactions between NaF or KF and $SbF_5$ in aHF. However, in the case of the reaction between AF (A = Li, Rb, Cs and Tl) and $SbF_5$ in aHF, a clear, colourless liquid phase was visible above an insoluble white solid, which always formed. The reaction between KF and $SbF_5$ (molar ratio = 1:2) in $SO_2$ as solvent, yielded a clear, colourless solution. In the case of the reaction between NaF and $SbF_5$ (molar ratio = 1:2) in $SO_2$ *two* liquid phases were observed. In this latter case a clear, colourless solution was visible above a milky suspension.

Volatiles were slowly pumped off at room temperature over a few hours to leave behind white solids. The chemical analyses of the resulting isolated $ASb_2F_{11}$ salts (A = K, Rb, Cs) are given in Table 11. The Raman spectra of the products of reactions between AF (A = Li, Na) and $SbF_5$ in aHF or $SO_2$ showed only the bands [Li: 669(100), 569(10), 295(80); Na: 672(100), 581(10), 279(50)] that can be assigned to $ASbF_6$ salts.[32]

In further experiments a sample of alkali metal fluoride (AF, A = Na, K, Rb, Cs) was loaded into the FEP reaction vessel and an excess of liquid $SbF_5$ was condensed onto the solid fluoride salt at 77 K. The reaction mixture was warmed up to 85 °C. The details

| $CsSb_3F_{16}$[f] | – | 45.53 | 37.90 | – | 45.0 | 37.7 |

[a] The chemical analyses are given in mass percent. [b] A = alkali metal. [c] Prepared in aHF. [d] Prepared in aHF with a small excess of $SbF_5$. [e] Prepared in aHF with a large excess of $SbF_5$. [f] Prepared at 85 °C without aHF.

of the reaction conditions are given in Table 12. On the basis of the final masses of the solidified isolated solids and comparison of their vibrational spectra with the vibrational spectra obtained for the products in AF/$SbF_5$/aHF system it was concluded that the final products were $ASbF_6$ (A = Na), $ASb_2F_{11}$ (A = K, Rb) and $ASb_3F_{16}$ (A = Cs). The chemical analysis of the latter salt is given in Table 11.

Table 12. Reaction conditions for the reactions of AF (A = Na, K, Rb, Cs) with an excess of $SbF_5$ at 85 °C.

| Starting materials | | | | | Reaction time | Mass balance | | Final product |
|---|---|---|---|---|---|---|---|---|
| AF[a] | | $SbF_5$ | | | | calcd. | found | |
| AF | [g] | [mmol] | [g] | [mmol] | [d] | [g] | [g] | |
| NaF | 0.012 | 0.29 | 0.400 | 1.85 | 5 | 0.075[b] | 0.070 | $NaSbF_6$ |
| KF | 0.060 | 1.03 | 5.000 | 23.07 | 9 | 0.507[c] | 0.480 | $KSb_2F_{11}$ |
| RbF | 0.091 | 0.87 | 1.600 | 7.38 | 5 | 0.466[c] | 0.461 | $RbSb_2F_{11}$ |
| CsF | 0.158 | 1.04 | 1.250 | 5.77 | 5 | 0.834[d] | 0.823 | $CsSb_3F_{16}$ |

[a] A = alkali metal. [b] Calculated for $ASbF_6$. [c] Calculated for $ASb_2F_{11}$. [d] Calculated for $ASb_3F_{16}$.

### Preparation of Single Crystals of $ASb_2F_{11}$ (A = K, Cs) and $CsSb_3F_{16}$

Preparations were carried out in a double T-shaped apparatus consisting of two FEP tubes (19 mm o.d., and 6 mm o.d.). CsF or $KSb_2F_{11}$ (ca. 0.2 mmol of each) were loaded into the wider of the two tubes in a dry-box. $SbF_5$ (ca. 7 mmol) and aHF (ca. 4 mL) were then condensed onto the starting material at 77 K. The reaction mixtures were then brought up to room temperature. After one day the clear solutions that had developed were transferred into the narrower tube. The evaporation of the solvent from these solutions was carried out by maintaining a temperature gradient corresponding to about 10 K between both tubes for one month, and later increasing this further to about 50 K for an additional month. The effect of this treatment was to enable aHF and the excess of $SbF_5$ to be slowly evaporated from the narrower into the wider tube, leaving colourless crystals of $ASb_2F_{11}$ (A = K, Cs). A similar procedure was adopted with NaF but this yielded only single crystals of $NaSbF_6$. Crystals were selected from the compounds in a dry-box and these were then placed inside 0.3-mm quartz capillaries, which were heat-sealed and mounted on the goniometer head of the diffractometer.

When the final product of the reaction between CsF and liquid $SbF_5$ at 85 °C was checked under a microscope it was found to consist of small regular blocks. Single crystals were immersed in perfluorinated oil (ABCR, FO5960) in the dry-box, selected under the microscope and then transferred into the cold nitrogen stream of the diffractometer.

Table 13. Crystal data and structure refinement for $KSb_2F_{11}$, $CsSb_2F_{11}$ and $CsSb_3F_{16}$.

| Empirical formula | $KSb_2F_{11}$ | $CsSb_2F_{11}$ | $CsSb_3F_{16}$ |

### Chemical Analyses

The alkali metal content (A) was determined by flame atomic emission spectrometry.[33] The total fluoride content (F) was determined following complete decomposition of the sample with Devarda alloy in alkaline media by direct potentiometry using a fluoride ion selective electrode.[34] The antimony content was, in turn, determined potentiometrically by redox titration with $KBrO_3$ after prior reduction of the antimony with alumina powder in acidic media.[35] The results of analysis of the isolated K, Rb, and Cs polyfluoroantimonate products are given in Table 11.

### X-ray Structure Determination of $ASb_2F_{11}$ (A = K, Cs) and $CsSb_3F_{16}$ Salts

Single-crystal data of $ASb_2F_{11}$ (A = K, Cs) and $CsSb_3F_{16}$ were collected using a Mercury CCD area detector coupled with a Rigaku AFC7S diffractometer with a graphite-monochromated Mo-$K_\alpha$ radiation source. Data were corrected for Lorentz, polarisation and absorption effects and processed using the Rigaku Crystalclear software suite.[36] The structures were solved by direct methods[37] and then expanded using Fourier techniques. The salt $CsSb_3F_{16}$ crystallizes in an acentric space group ($Pca2_1$), so the Flack parameter[38] was refined. The latter converged to a twin ratio of 0.75(7). Some details of the single-crystal data collection and data processing and refinement for $ASb_2F_{11}$ (A = K, Cs) and $CsSb_3F_{16}$ are given in Table 13.

Further details of the crystal-structure investigation may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-415752 ($KSb_2F_{11}$), -415751 ($CsSb_2F_{11}$) and -415750 ($CsSb_3F_{16}$).

## Acknowledgments

The authors (Z. M., P. B. and M. P.) gratefully acknowledge the Slovenian Research Agency (ARRS) for the financial support of the present study within the research program P1-0045 Inorganic Chemistry and Technology. We are also grateful to Prof. Jack Passmore for a careful reading of the manuscript and helpful comments.

## COVER PICTURE

**The cover picture shows** the crystal structure of the cationic organometallic π-conjugated push–pull chromophore combining the mixed sandwich acceptor group $[CpFe(\eta^6\text{-}p\text{-}MeC_6H_4)]^+$, associated with the 2-*tert*-butyl-4*H*-chromen-4-ylidene donor through the asymmetric hydrazone spacer −NH−N=CH−. This dipolar chromophore exhibits solvatochromic properties, low-lying intramolecular charge-transfer transition and enhanced second-order NLO properties ($\mu\beta$), as measured with the EFISH technique at 1.907 μm. The scientific cooperation between researchers from the Southern Hemisphere (Chile) and the Northern Hemisphere (France) is symbolised not only by the Southern Cross but also by the NaCl crystals of the salt desert El Salar de Atacama. Details are discussed in the article by C. Manzur, D. Carrillo, B. Caro, J.-R. Hamon et al. on p. 1131 ff.

# Block Copolymer Assemblies as Templates for the Generation of Mesoporous Inorganic Materials and Crystalline Films

**Bernd Smarsly[a] and Markus Antonietti*[a]**

**Keywords:** Block copolymers / Mesoporous materials / Self-assembly / Sol–gel processes

This Microreview presents the synthesis of mesoporous, crystalline inorganic materials using self-assembled block copolymer mesostructures as templates. The advances in this field are discussed in light of the progress in the development of suitable polymer templates. Particular emphasis is placed on the special conditions and demands to transform the primary sol–gel films into mesoporous, aligned crystalline films for functional applications.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

In the past ten years scientists have learned to develop and use appropriate amphiphilic block copolymers (soft matter) as templates to generate inorganic films and multicrystals with controlled porosity on the nanometer scale (hard matter). Such inorganic materials with a nanoscale structural set-up and large specific surfaces had not been accessible before and may play important roles in sorption, catalysis, photoconversion, or piezo- and ferroelectric devices.

[a] Max-Planck Institute of Colloids and Interfaces, Am Mühlenberg, 14476 Potsdam-Golm, Germany

This Microreview will introduce the concept of "true liquid-crystal templating",[1,2] i.e. the idea of converting a self-assembled block copolymer mesophase into its inorganic counterpart with liquid precursors (e.g. providing mesoporous silica, metal oxides, and metals), which is also termed "nanocasting".[3] We will delineate the special effects for a number of oxide crystalline systems with special functions in detail.

The field of mesoporous oxides made by templates is, of course, much bigger, and for a general overview of ordered mesoporous oxides we refer the reader to the review article by Schüth.[4] This review will be centered around the generation of mesoporous inorganic structures using block copolymers as templates, putting special emphasis on the con-

*Bernd Smarsly studied chemistry and physics at the University of Marburg, Germany, and Innsbruck, Austria, and received a Masters degree of Natural Science in 1998. He completed his PhD studies in 2001 at the Max Planck Institute of Colloids and Interfaces. Afterwards, from 2002–2003 he worked as a postdoctoral researcher at the Advanced Materials Laboratory of the University of New Mexico at Albuquerque, USA. Since 2003 he has been working as group leader at the MPI of Colloids and Interfaces. His main research interests now focus on the preparation of functional, mesostructured metal oxides, their physico-chemical properties, and the development of novel characterization techniques, especially using X-ray scattering.*

*Markus Antonietti studied chemistry in Mainz and did his doctorate with Hans Sillescu. His habilitation about nanostructured polymer gels in 1990 filled him with enthusiasm for complex materials. After his Professorship of Chemistry at the University of Marburg, he was appointed Director of the Department of Colloid Chemistry at the Max Planck Institute of Colloids and Interfaces in 1993. Markus Antonietti's contributions to the chemical community are manifold, but first of all he is interested in the creativity in research. He loves to share and impart this passion. He also likes cooking with his family and loud music.*

ditions of crystalline metal-oxide formation and the observed textural properties. While most of the research is focused on oxide materials, a separate paragraph is reserved for the interesting emerging field of mesoporous metals.

## 1. General Mechanism

The general idea of using block copolymers as templates is based on the fact that amphiphilic block copolymers self-assemble in certain solvents to give robust, very regular superstructures that feature structural motifs on the nanometer scale (lyotropic liquid-crystalline phases). Typically, the constituting entities are spherical or cylindrical micelles or lamellar sheets with a characteristic cross-section of 5–100 nm.

The block copolymer self-assembly technique is probably the best examined mode of self-organization[5] and is governed by the microphase separation dictated by the mutual incompatibility of the different blocks, one being soluble and the other being insoluble in the solvent to be used ("amphiphilic" polymers). In most cases, aside from classical nonionic surfactants, which can be regarded as small block oligomers composed of an oligoethylene and oligo(ethylene oxide), diblock or triblock copolymers are used that feature polystyrene,[2a] polybutadiene,[6] and poly(propylene oxide) as the hydrophobic block,[7] and poly(ethylene oxide) or poly(vinylpyridines)[8] as hydrophilic blocks. Recently, a semi-commercial family of "KLE" block copolymers [KLE = *K*raton-*L*iquid-*b*-poly(*e*thylene oxide)] was introduced, which combines good chemical accessibility and high mesophase robustness with a superb application profile.[9] Kraton liquid is a hydrogenated poly(ethylene-*co*-butylene) hydrophobic block with a low glass transition. In principle, block copolymers self-assemble or microphase-separate in a variety of solvents, in particular water, but also alcohols or THF, which enables a certain width of chemistry for inorganic framework generation. This is contrary to low molecular weight surfactants, which usually rely on water and the hydrophobic effect for self-assembly.

In a typical block copolymer templating procedure (see Figure 1), such regularly ordered mesostructures of amphiphiles in water are converted into their 1:1 replica (their "negative") by solidifying the hydrophilic or solvatophilic domains between the micelles. This is done by replacing the majority of the solvent by a metal or metal oxide precursor with similar polarity and condensing this precursor around the aggregates. An especially suitable precursor for this procedure is, for instance, hydrated silicic acid, which shows a very similar polarity and proton-bridging behavior as water, such that the final assembly patterns are very similar to the ones found in water. Depending on the final material of choice, this precursor can be a hydrolysable metal species such as metal–orthoesters, but can also be a metal salt (metal chlorides, etc.), and the final structure can be made out of metal oxides, metal chalcogenides, or even the elemental metals. The organic template can also be regarded as a place holder that prevents the inorganic reaction from occurring and becomes void space upon removal either by extraction or thermal decomposition.

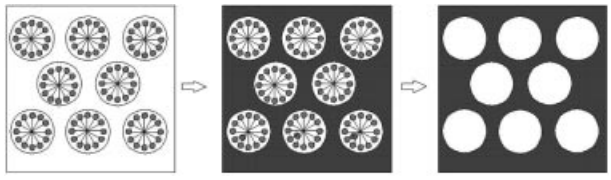

Figure 1. Illustration of the typical block copolymer templating procedure ("nanocasting"). A soft matter complex fluid is surrounded with a high concentration of inorganic precursor (left), and the continuous phase is solidified (middle). After solidification of the inorganic phase, the template is removed to give a solid negative replica ("hardcopy") of the original phase.

Figures 2 and 3 show examples of mesostructures that can be obtained by varying the polymers.[6b]

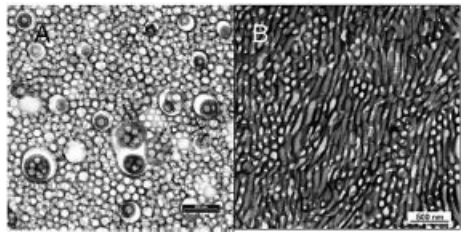

Figure 3. TEM of two mesoporous silicas obtained from PB-*b*-PEO templates,[6] illustrating the wide range of accessible structures. **A** presents a micellar phase at the borderline to a lamellar phase, which contains some vesicles as precursor structures (scale bar: 200 nm), while **B** shows the bicontinuous sponge-like $L_3$-phase (scale bar: 500 nm).

One main advantage of block copolymers over low molecular weight surfactants is their significantly higher molecular weight and their variability in size and composition, which enable a rich diversity of structures (hexagonal, cu-

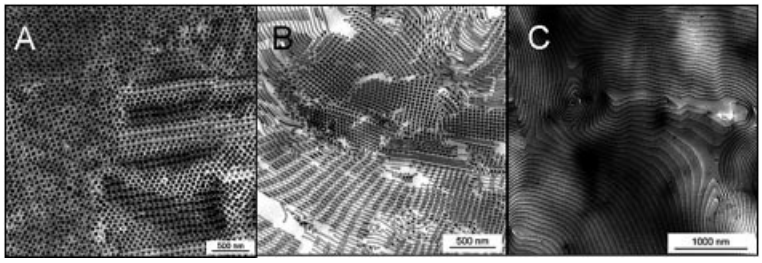

Figure 2. Microtomed films of lyotropic phases of block copolymers, as used for nanocasting. **A**: BCC phase; **B**: hexagonal phase; **C**: lamellar phase (taken from refs.[6b,6c]).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bic, etc.) and a wider range of accessible pore sizes, currently up to about 80 nm.[6] Initial work was pioneered by Göltner et al. using PS-*b*-PEO[2] or PS-*b*-PVP block copolymers.[8] Later, presumably independently, this work was extended by Stucky towards Pluronics block copolymers[7] and by Wiesner et al.[10] towards organically modified aluminosilica hybrids.

The assumption that the final silica mesostructure represents a 1:1 copy of the lyotropic phase was later proven by comparing the replicas with species obtained by cross-linking of lyotropic phases with γ-radiation.[11] An unusual case is shown in Figure 4, where a branched lamellar phase is replicated and compared with the original phase. The two TEM images show the original lyotropic phase (Figure 4, A) and the templated, porous silica (Figure 4, B), and it is nicely seen that one is the "negative" of the other.

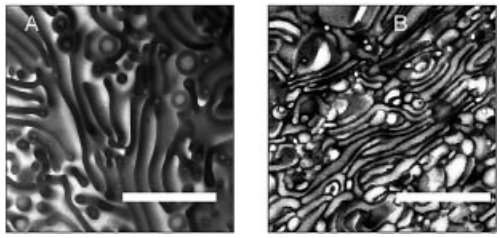

Figure 4. Original or copy? **A** represents the lyotropic phase (TEM obtained from thin cuts) leading to the corresponding silica (**B**) shown in Figure 3. This example illustrates the similarity between the original block copolymer mesophase and the silica replica. Terminal ends of lamellae, branching points, vesicles, membrane, and pores are replicated with about the same abundance and fine structural features. The scale bars represent 1000 nm.

The quality of replication plus the homogeneity has also been proved by small angle X-ray scattering. Already in the original paper by Göltner et al.[2c] the authors showed that after solidification and removal of the template the diffractogram is only shifted to slightly higher angles, while the pattern stays unaltered. This means that the material shrinks slightly but does not change its local structure. A case for quantitative fitting of the scattering curve is shown in Figure 5.

In this case (using KLE polymers as a template), TEM shows that the mesoporous silica contains a regular packing of spherical mesopores about 13 nm in diameter, which are located on the sites of a face-centered cubic arrangement. Evidently, not only are the single mesopores extremely uniform in shape and size, but the 3D arrangement is also nearly undisturbed over large areas of up to several square micrometers. This example illustrates the amazing order and control of the materials' structure that can be achieved by the nanocasting procedure, in spite of the mechanical stresses during the condensation of the matrix. Small-angle X-ray scattering (SAXS) is usually applied to provide an overall, averaged characterization of mesoporous materials. In this case (Figure 5, b), the presence of distinct SAXS patterns with pronounced maxima and minima confirms the high regularity of the mesostructure and the mesopore size and lattice type.

In the case of metal oxides the ultimate composition is readily obtained by heat-treatment in air or oxygen to give the amorphous or crystalline oxide form, and mesoporous metals are obtained by an in situ or final reduction step, either electrochemically or chemically.

## 2. Evaporation-Induced Self-Assembly for the Generation of Organized Thin Films

The general concept of nanocasting was originally developed for thick specimens (monoliths or powders), although it also holds true for the generation of bulk materials and thin films. The latter was remarkably improved and simplified by introduction of the technique of "evaporation-induced self-assembly" (EISA).[12] EISA proceeds along a different methodology, but the underlying templating mechanism is identical to nanocasting. The practical difference lies in the fact that one starts from a homogeneous solution with a significantly larger amount of volatile solvents with low viscosity.

Taking this low viscosity, which means less organized precursor solutions, coatings of excellent macroscopic

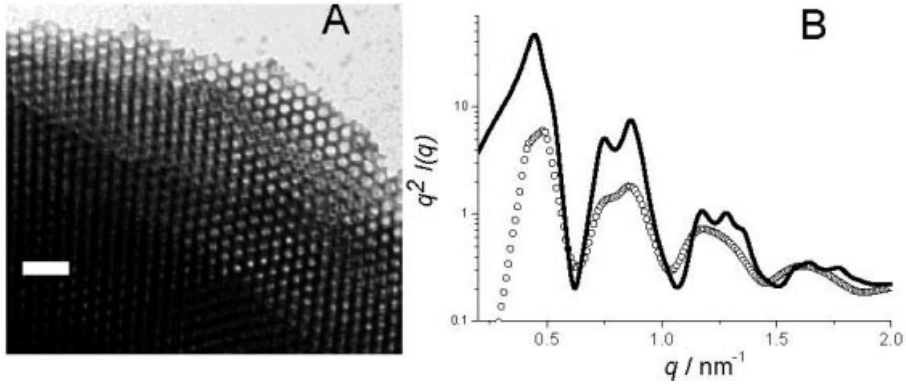

Figure 5. Mesoporous silica featuring spherical mesopores (size of about 13 nm) obtained from the KLE block copolymer [poly(ethylene-*co*-butylene)-*b*-poly(ethylene oxide)].[9a] The TEM image (**A**) reveals a highly ordered structure of spherical mesopores arranged on a fcc lattice. The scale bar is 80 nm. **B**: Small-angle X-ray scattering curve of the mesoporous silica (circles) and a fitting (solid line) based on a model of spherical mesopores with a certain polydispersity and lattice distortions[9a] In the present case, the relative polydispersity of the pore radius is only 5% (including the deviations from spherical shape).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

homogeneity can be generated by standard coating techniques, i.e. dip-coating, spin-coating, doctor-blading, or spraying. After evaporation of the volatile solvent, a high-concentration template phase is regained. This is the return to the situation of nanocasting, although already shaped in a defined coating geometry. It must be mentioned, however, that throughout drying, large scale orientation of the otherwise unorganized lyotropic phase can be promoted to a very high extent. For EISA in thin films, the strong interaction with the substrate in the interplay with a directional drying pressure (e.g. in dip coating) usually leads to a high degree of preferred orientation, much higher than in the bulk materials.[13] An orientation is usually established that provides a maximum degree of interaction with the substrate via the densest lattice plane.[14]

For the generation of inorganic materials discussed below, low molecular weight inorganic precursors or salts are usually taken. Recent papers, however, have shown that similar constructions can also be achieved by EISA using preformed inorganic nanoparticles of sizes of only a few nanometers for structure build-up, e.g. $TiO_2$[15] or $CeO_2$,[16] as illustrated in Figure 6.

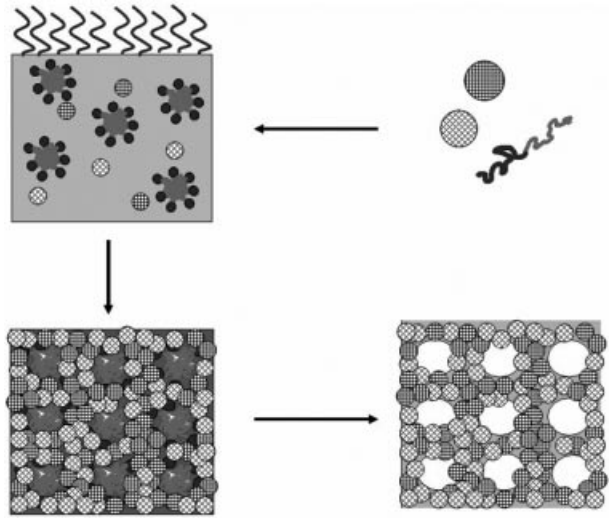

Figure 6. Block copolymer templating to generate a mesoporous scaffold starting from inorganic nanoparticles, using the EISA process. The scheme illustrates the more complicated case where two different nanoparticles ("bricks"), cross-hatched with vertical/horizontal and diagonal lines, respectively, are used for structure set-up to generate binary contacts.

It is evident that this approach faces different obstacles, for instance the colloidal stability of the initial sol, and only recently has a novel procedure for the synthesis of nanoparticles provided particles which could be sufficiently dispersed at high concentrations.[17] On the other hand, there are also benefits due to the building block approach, as the material is already crystallized and does not shrink.[16] Binary systems (i.e. two different nanoparticles) can also be easily made, thus leading to interesting binary contacts.

While the overall principle of block copolymer templating for inorganic chemistry seems to be surprisingly straightforward, it is worthwhile to highlight some key features of this process:

· Such high area interfaces between two materials can only be generated if all of the involved interfacial energies throughout the process are lowered. This compatibilization is provided by the special chemical character of the appropriate block copolymer. If a new inorganic substance is to be made porous, a block copolymer with the right binding moieties along the backbone of one block has to be chosen.

· As the formation of microphase-separated block copolymer phases is a thermodynamic phenomenon, templating is substantially governed by numerous physical parameters. Together with solvent effects, it is difficult to predict pore structures a priori, hence optimal templating conditions were found by trial-and-error experiments in many cases. In addition to these thermodynamic parameters, templating is further aggravated by strong kinetic effects, as some intermediary structures might turn out to be metastable. For instance, Gibaud et al. have shown that the rate of evaporation of the volatile solvent, even when all the other parameters are kept the same, can dramatically change the final mesophase structure.[14]

· A general problem of true liquid-crystalline sol–gel templating is the simultaneous occurrence of condensation of the inorganic species and the self-assembly process. Experimental procedures are usually needed that delay the condensation significantly until completion of micelle formation. Robust self-assembly of amphiphilic copolymers into micelles, which is the best choice for systems with higher segregation strength (or incompatibility between the two blocks), is certainly favorable for this purpose. The use of block copolymers towards larger sizes is limited for the same reason by their increasingly reduced mobility. Hence, the upper limit for block copolymer templating is, under practical conditions, currently at about 80 nm in structural size.[6]

· The solvating block is sometimes tightly bound and molecularly mixed into the inorganic phase, bringing some organic character to it, as found for PEO and silica.[18] This can result, after template removal, in extensive extra microporosity (pore size below 2 nm), as reported by various studies.[18–24] While physisorption techniques gave no unambiguous conclusion, detailed small-angle X-ray and neutron scattering (SAXS, SANS) analyses of PS-*b*-PEO-templated silicas provided a quantification of the microporosity[21–23] and showed that the micropores are actually located between the mesopores.

## 3. Synthesis of Mesoporous, Crystalline Metal Oxides

While work in the first years of block copolymer templating has been mainly focused on amorphous silica as a model case, one of the current scientific challenges is the creation of mesoporous metal oxides whose pore walls are entirely nanocrystalline. The reason for this is essentially driven by their potential applications: crystalline oxides are chemically, thermally, and mechanically more robust. In addition, oxide materials possess inherently interesting func-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tionality, which is improved or is accessible by the introduction of mesopores. For instance, mesoporous, crystalline $TiO_2$ could be beneficial for various applications like solid-state solar cells ("the Grätzel cell")[25] or photocatalysis.[26] In these applications, organized porosity would be helpful to improve the contact between the oxide and other species (e.g. the anode in case of solar cells). Another target is heterogeneous catalysis, where it would be desirable to generate mesoporous metal oxides such as $CeO_2$, $ZrO_2$, or $V_2O_5$.

The necessity of a high crystallinity imposes a severe problem. It is evident that the soft, self-assembled structures of amphiphilic block copolymers (ABC) are not very stable at the high temperatures needed for many crystallization processes of oxides. The use of preformed, soluble metal oxide nanoparticles for casting evidently has certain elegance because of the absence of a separate nucleation step for the oxide, but is still restricted to some readily dispersable oxides.[16] This is why the most frequently employed strategy starts from molecular metal precursors such as metal chlorides or alkoxides (e.g. $TiCl_4$, $CeCl_3{\cdot}7H_2O$, etc.). Many metal oxide precursors are indeed available that are amenable to sol–gel templating and are soluble in common solvents.

These precursors are then condensed, and nucleation and crystallization as well as the removal of the template occur concurrently and have to be dynamically balanced. This is not simple, as crystal growth can severely disrupt the fragile, soft ABC mesostructure, which would lead to pore collapse and loss of mesostructural order. Therefore, usually quite delicate and tedious heat-treatment procedures have to be used to avoid mesostructural breakdown and to balance condensation, crystallization, and calcination of the template.

Previous experiments with classical templates gave highly crystalline mesoporous oxides in only a few cases, in particular for $TiO_2$.[27–30] In the majority of these studies the materials showed either moderate crystallinity or significant damage to the mesostructural regularity (pore shape and porosity). A clever optimization of all these processes was presented by Grosso et al., who developed an in situ experiment to study the morphological changes by simultaneous small- and wide-angle X-ray scattering (SAXS/WAXS), leading to an improved understanding of the crystallization and its interference with the imprinted mesostructure.[30c] Using that technique, crystalline mesoporous anatase became accessible with traditional templates.

Novel amphiphilic block copolymer templates helped to improve the preparation of mesoporous $TiO_2$ films[31] and to extend these results also to other oxides of high chemical relevance. This is on the one hand due to the ability of these systems to self-assemble in a broader range of solvent systems: poly(ethylene-*co*-butylene)-*b*-poly(ethylene oxide) ("KLE polymers") is more robust and has more hydrophobic "contrast" than the commonly applied polymers of the Pluronics family.[31b] Poly(isobutylene)-*b*-poly(ethylene oxide) (PIB-*b*-PEO)[31a] is a similar template system with improved templating properties and good accessibility.

Secondly, due to their larger and chemically variable molecular weight, the pore structure can be adopted to match organic process parameters and properties, such as the nanocrystal size. If an inorganic system shows a small nucleation and fast growth-rate, the nanocrystals get rather big under standard conditions and the targeted pore size has to match the size of the accessible tectonic elements to form the structure. In other cases, the desired physical properties rely on a certain structural size, such as the exciton or plasmon size. Anatase just keeps its favorable indirect semiconductor properties at a size larger than 10 nm, and making the structure finer does not contribute to performance. For all those systems, the targeting of slightly larger pore sizes (ca. 20 nm) is advised.

Thirdly, the chemical functionality of the inorganic-binding block can also, in principle, be adjusted, for example by introduction of acetylacetoxy groups[32] or a variety of other metal-complexing moieties, following the hard-soft-acid-base (HSAB) principle.[33] Up to know, however, it has been possible to address all practical questions with the simple PEO binding block.

The final crystalline films are very homogeneous, crack-free, and flat on the scale of some nanometers over macroscopic dimensions. This is nicely illustrated by high resolution SEM of the surface of such an optimized anatase film (Figure 7). The depicted pores have a size of about 13 nm, are open to the surface, and at some positions even the three openings towards the lower cubic pore layer are visible. The overall flatness of this film (excluding pores) is lower than 2 nm, as determined by atomic force microscopy (AFM). It should be emphasized that these films show a rather homogeneous spherical pore shape. The structure resembles highly ordered inverse opal structures with respect to the perfection of the mutual arrangement, thus proving that crystal-like packing can also be achieved with block copolymers.

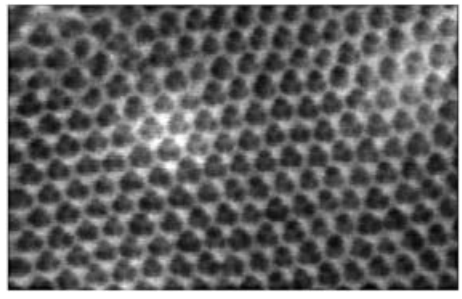

Figure 7. HRSEM of a mesoporous crystalline anatase film indicating the typical lyotropic liquid-crystalline arrangement of pores. The pores have a cross-section of about 13 nm. Note that in some pores the three entries to the lower layer of the cubically packed pores are visible.

With these improved templates, various metal oxides could be applied as highly crystalline coatings with high structural regularity of the mesopores (spherical, size larger than 12 nm).[34–36]

Beside the technically highly relevant anatase, $ZrO_2$, $CeO_2$, and a variety of mixed intermediary ternary oxide

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mixtures of the two metals have also been synthesized (see Figure 8).[34]

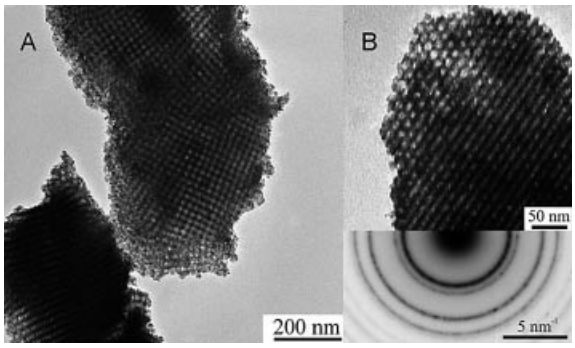

Figure 8. Crystalline, mesoporous $CeO_2$ films prepared from molecular precursors (**A**),[34b] and mesoporous powder obtained from preformed $CeO_2$ nanoparticles (**B**).[16a] The selected-area electron diffraction pattern (bottom part of **B**) proves the crystallinity of the mesopore walls.

Those ceria/zirconia systems are interesting for various applications. Compared to other metal oxides, ceria and zirconia are chemically and thermally extraordinarily stable and are therefore used as catalyst supports and in ceramic membranes for sensing and catalysis. Ceria has just one polymorph (fluorite structure), and can switch easily between $Ce^{4+}$ and $Ce^{3+}$, balancing the charge difference with oxygen vacancies. This distinct property makes cerium oxide in the form of mesoporous layers an interesting candidate for solid-oxide fuel cells.

Porous crystalline films with very high thermal stability and related crystallization temperatures, such as $Al_2O_3$[35a] and $HfO_2$,[35b] have also been made. The case studies on $HfO_2$ had the advantage that removal of the template and crystallization are thermally clearly separate processes. Here, it could be demonstrated that the transformation of the initial self-assembled composite, consisting of the block copolymer and weakly condensed metal oxyhydrates, into the final mesoporous, crystalline metal oxide proceeds through the steps of inorganic condensation, template removal, and final crystallization. WAXS/SAXS experiments performed in situ during the heat treatment revealed that the crystallization has to be adjusted to be a solid–solid transformation from an almost completely dry, water-free, amorphous metal oxide into its crystalline counterpart. It is essential that the BC template is stable enough to support the mesostructure up to a temperature (350–400 °C under nitrogen) where the anhydrous and amorphous condensed metal oxide species is formed.

As shown for $Al_2O_3$, a slightly higher structural size is also favorable for the mechanical stability of the intermediary amorphous thin pore walls and the final thermal stability. Well organized $\gamma$-$Al_2O_3$ films were only accessible when the pore size was increased to about 20 nm[35a] (Figure 9).

Furthermore, even such complex materials as perovskites (e.g. $BaTiO_3$, $SrTiO_3$, and their substitution products) can now be obtained as mesoporous films,[36] which is particularly interesting for a number of reasons (Figure 10). First, such materials are more difficult to accomplish in the desired stoichiometric composition by ordinary sol–gel methods. Secondly, the class of perovskites is linked to properties such as ferroelectricity, piezoelectricity, adjustable bandgaps, or even high-temperature superconductivity.[37]

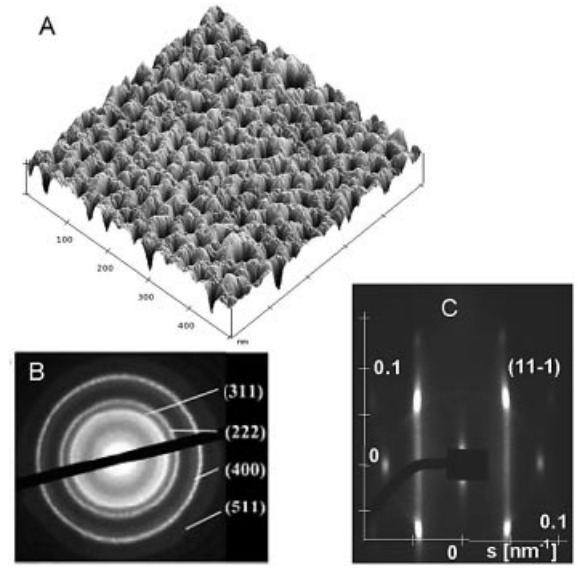

Figure 9. Crystalline, mesoporous films of $\gamma$-$Al_2O_3$, heat-treated at 900 °C.[35a] **A**: Atomic force microscopy image. **B**: Selected-area electron diffraction, underlining the polycrystalline character. **C**: 2D SAXS pattern obtained at a low angle of incidence with respect to the substrate, proving the close to perfect orientation of the mesostructure in the *z*-direction.

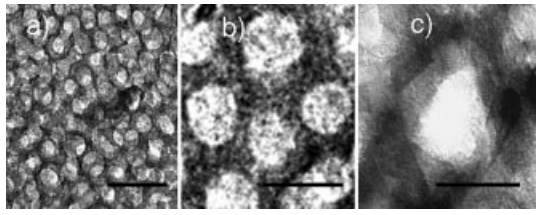

Figure 10. Structural changes in mesoporous $SrTiO_3$ perovskite films upon transformation from the amorphous (a and b) to the crystalline phase. The walls, in spite of the complex composition, are nevertheless homogeneous and single crystalline. Scale bars from left to right: 50 nm, 20 nm, and 10 nm.

For other oxide systems, such as $Nb_2O_5$, a newly emerging dynamic effect sets in. On a mesoscpic scale, these films look quite similar to all the other previously described ones (Figure 11). Both WAXS and electron diffraction, however, show that the structure is built up by aligned single nanoparticles, that is, the nanoparticles "sense" their mutual organization and orient together in one energetically favorable direction.[38] This effect also occurs for dense sol–gel films made by similar protocols and has been called "soft epitaxy". It might become the basis for the generation of oriented films by simple chemical coating means.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

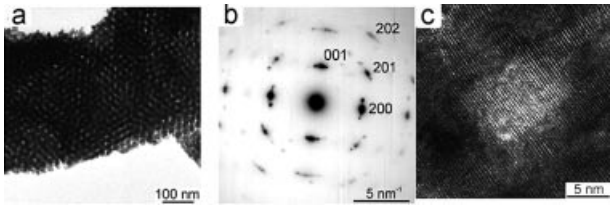

Figure 11. Soft epitaxy of mesoporous niobium oxide made by nanocasting: a) TEM of a porous film; b) electron diffraction of the same area, indicating an epitaxial alignment of the formed nanoparticles to the surface and each other; c) HRTEM of one single pore supporting the rather high degree of mutual organization.

The special functionality of crystalline oxide films has been explored both for $SnO_2$[39] and $WO_3$.[40] In the case of $SnO_2$, it was shown that the resulting porous thin-films are conducting, which is a prerequisite for their use as sensors and as electrodes. For $WO_3$, reversible electrochromism, which is the reversible change of the transparency of those films with applied electric fields, has also been observed (Figure 12). The switching time in these films is much shorter than classical thin-films analogous to this structure (already applied in switchable rear mirrors) as electrons only have to be moved from the walls to the pore interior (Figure 12).

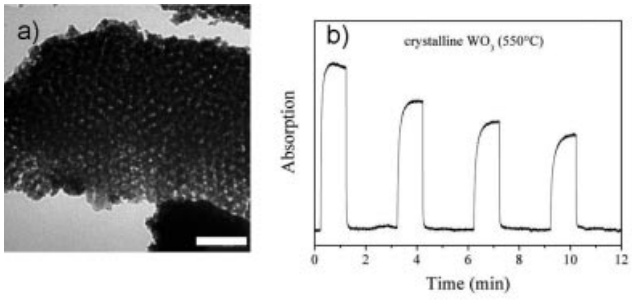

Figure 12. Mesoporous $WO_3$ (TEM, a) prepared with KLE block copolymers shows improved electrochromic switching. b) The absorption at 450 nm as a function of applied voltage. The mesoporous, crystalline mesostructure with its much higher surface area and short transport paths leads to a much faster coloration and decoloration than previous materials.

Very recently, some new approaches have been developed that extend nanocasting in a even more general frame and bypass some of the aforementioned problems. For instance, in the method of Holmes and Watkins the films are exposed to solutions of metal oxide precursors in supercritical $CO_2$.[41] This procedure has the advantage that capillary forces are absent and that the films have higher temperature stability because of the supercritical conditions. In separate work, Chmelka et al. first cross-linked the mesophases of block copolymers featuring additional double bonds,[42] and then the inorganic precursor was infiltrated. This approach reduces the disruption of the BC mesophase upon condensation of the metal salts.

Wiesner and Gruner et al.[43] have used extended amphiphilic dendrimers as templates, the self assembly of which is also expected to be rather robust against variations of the environment. Another interesting approach was introduced by Domen:[44] first, an amorphous mesoporous oxide is prepared, which is then followed by carbon deposition inside the pores, which acts as a temperature-stable scaffold. The material is then crystallized at elevated temperature, where the carbon prevents mesostructural collapse. Finally, the carbon is oxidized by calcination in oxygen to generate the pure inorganic scaffold.

## 4. Mesoporous Metals and Other Semiconductors

Aside from mesoporous metal oxides, mesoporous elemental metals, e.g. Pt, Pd, and Ni, have also been obtained by block copolymer templating. In principle, mesoporous metals are also accessible through the schematic principle depicted in Figure 1. Similar to mesoporous oxides, in the first step, reducible metal salts ($PdCl_2$, $H_2PtCl_6$, etc.) are distributed around the block copolymer domains. The preparation of the corresponding metals is more delicate because of the additional reduction step, which can be performed by electrodeposition (for instance on gold electrodes) or chemically, for example with metallic Zn. A second problem of these strategies is the high densification of matter throughout metal formation.

The Attard group has reported the electrochemical preparation of mesoporous metal electrodes (Figure 13, A),[45] which could be interesting for various applications such as fuel cells (Ni) or electrochemical hydrogenation of organic species (Pd, Pt). Yamauchi et al.[46] have described the generation of mesostructured particles of Ni (Figure 13) and Ni–Co alloys, partly by electroless methods, especially by using organic reducing agents such as dimethylaminoborane or sodium borohydride. Furthermore, Kucernak has demonstrated that it is possible to obtain mesostructures of otherwise inaccessible mesoporous "alloys" such as Pt/Ru.[47] Such two-phase, mesostructured metal blends show high promise for catalytic applications, such as in fuel cells.

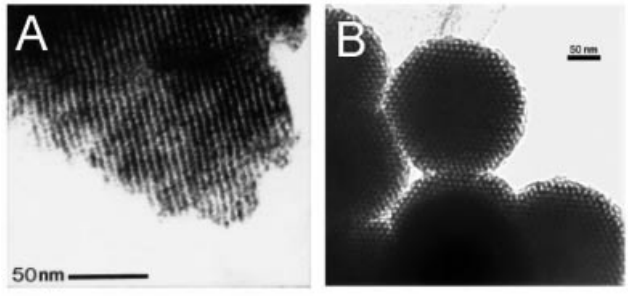

Figure 13. Mesoporous Pt[45a] (**A**) and mesoporous Ni[46a] particles (**B**).

Using oligomeric nonionic surfactants, even non-oxidic semiconductors have been made. Stupp et al.[48] have been able to mesostructure thin films of CdS, CdSe, and ZnS, while for $Ag_2S$, CuS, HgS, and PbS the same methodology only resulted in compound films without mesoscopic features. Nandhakumar et al.[49] have extended this approach

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to synthesize mesostructuted CdTe films with excellent optical properties. As these experiments were already possible with rather short oligomeric structures, it is expected that the advantages of block copolymer templates can also be transferred to these classes of inorganic materials.

## Conclusion and Outlook

Nanocasting with block copolymer templates has turned into a powerful instrument for generating inorganic materials with mesostructure, porosity, and a high surface area, as documented by the broad variety of new materials described above. In nanocasting, the self-assembly of "soft", fragile matter is literally hard-copied into inorganic hard matter, with all the advantageous properties resulting from the inorganic world. Through the hard-copy approach, the inorganic films are fitted out with the properties that make them valuable for different areas of materials science, e.g. chemical sensing, piezoelectricity, catalysis, electrochromism, solar cells, light-emitting diodes, etc. All these applications benefit from an optimized mesostructure, conduction pathways, or addressed binary interface contacts.

It is our personal view that these new materials are the first case where self-assembly will have a significant impact on nanosciences, especially for diverse electrochemical applications where complex metal oxides are needed with high surface areas. It is also very likely that various fields such as electrochromism, batteries, and electrode materials will benefit dramatically from progress in the preparation of mesoporous inorganic materials and metals. However, there are still some important challenges that hinder a broader application of block copolymer templated mesostructures in technical devices. For instance, for catalysis and electrodes it would be desirable to prepare crystalline, mesoporous metal oxides in the form of macroscopic monoliths, which can also be obtained in arbitrary shapes. Moreover, although various mesostructures have been obtained as high quality thin films with thicknesses of up to several micrometers, the preparation of much thicker layers is still a problem. Such geometries are, however, needed for various applications, for example for catalytically active coatings.

Another point of exploration and interest are hierarchical mesostructures with their expectedly superior transport properties, because larger pores could serve as transport pores, reduce back-pressure, and enhance diffusion. Such hierarchical structures could, in principle, be obtained by mixing the corresponding block copolymer micelles of different sizes. However, this build-up of hierarchically arranged micelles is not a trivial task because block copolymers tend to form either mixed micelles or phase-separate macroscopically.[50,51]

Furthermore, new types of block copolymer could open up a new chapter in templating. So far, self-assembly has mainly been carried out in close-to-aqueous systems. If templates were available that form self-organized lyotropic structures in a variety of solvents, this would dramatically facilitate processing and allow broader synthetic access to other porous materials, in particular for substances which are sensitive to water.

Evidently, in spite of the huge progress in the field of block copolymer self-assembly, there are still fascinating new opportunities for inorganic and materials chemistry, which will, in our opinion, keep this area very active for the next few years.

# Analysis of the Synergistic Effect of Carbonylplatinum Complexes on the Iridium-Catalysed Carbonylation of Methanol to Acetic Acid

**Samuel Gautron,[a,b] Nicolas Lassauque,[a] Carole Le Berre,[a] Philippe Serp,[a] Laurent Azam,[a] Roberto Giordano,[a] Gábor Laurenczy,[c] Daniel Thiébaut,[b] and Philippe Kalck*[a]**

**Keywords:** Homogeneous catalysis / Carbonylation / Iridium / Platinum / Reaction mechanism

High-pressure NMR mechanistic investigations into the promoting role of dicarbonyldiiodoplatinum complex in the iridium-catalysed carbonylation of methanol to acetic acid are consistent with iodide abstraction from the $[IrI_3(CH_3)(CO)_2]^-$ resting state species by $[PtI_2(CO)_2]$, unbolting the rate-limiting migratory CO insertion step. A new [Ir–Pt] heterodimetallic complex, which presumably represents the key species involved in the abstraction of $I^-$, has been characterised by NMR in tandem with FAB-MS.

## Introduction

Carbonylation of methanol is the major route to the production of acetic acid, and the worldwide industrial manufacture associated with this homogeneous catalytic process reaches $6 \cdot 10^6$ tons/year [Equation (1)]. This reaction involves a complex mixture of reactants consisting of water, acetic acid, methyl iodide, methyl acetate, hydroiodic acid, and traces of propionic acid, from which methanol is absent as it is immediately converted by HI into $CH_3I$. Many efforts have been aimed at the substitution of iridium for rhodium since the former tolerates low levels of water during the reaction, saving operating costs in the separation step of water from acetic acid.

$$CH_3OH + CO \xrightarrow[3\ MPa,\ 180°C]{Cat} CH_3COOH \quad (1)$$

Moreover, in the active species $H[IrI_2(CO)_2]$ (**1**) the metal centre is more nucleophilic than that in the homologous rhodium precursor used in the Monsanto process,[1] so that the rate of the first step of the catalytic cycle, the oxidative addition of $CH_3I$ affording $[IrI_3(CH_3)(CO)_2]^-$ (**2**), is largely enhanced.[2] The subsequent step, the migratory CO insertion leading to an Ir–acetyl species is so slow[3] that a process based on iridium cannot be suitable for industrial applications. In 1994, Watson et al. discovered that addition of ruthenium promoters to the iridium catalyst resulted in a dramatic increase in catalytic activity,[4] and very recent reports[5,6] have shown that this is due to the abstraction of an iodo ligand from **2**, allowing the rapid migratory insertion of CO into the Ir–$CH_3$ bond. The authors have proposed an intermediate [Ir–Ru] heterodimetallic complex, which has not been detected. In 1998, we patented the promoting effect of platinum,[7] which gives performances comparable to the iridium/ruthenium system in terms of turnover frequencies (2500 $h^{-1}$ for Ir–Pt and 2800 $h^{-1}$ for Ir–Ru, respectively, expressed with regard to Ir). For the two dimetallic systems, maximum activities are found for water concentrations close to 5 wt.-%, whereas the corresponding value approaches 14 wt.-% for the Monsanto process.

We envisaged that in both cases the catalytic cycles could present some common features. Thus, we undertook investigations on the [Ir–Pt] system in order to obtain a deeper insight into the nature of the intermediates that are formed and are responsible for the iodide abstraction from **2**. At first, we decided to study the catalytic complex mixtures by high-pressure NMR spectroscopy under conditions that closely resemble those used in the industrial process. Relevant pieces of information arise from the use of $^{13}C$-enriched reactants, such as $^{13}CO$, $^{13}CH_3{}^{13}COO{}^{13}CH_3$, and $^{13}CH_3I$ in $^{13}C$ and $^{195}Pt$ NMR spectroscopy. Thus, we were able to focus on every part of the catalytic cycle, using a procedure that leads to the detection of the transition metal complexes bearing carbonyl and methyl or acyl ligands. We

present here our first mechanistic results based on high-pressure NMR ($^{13}C$, $^{1}H$, $^{195}Pt$) experiments. Moreover, in order to characterise the short-lived complexes involved in this process, we used the bis(triphenylphosphoranylidene) $[PPN]^+$ stabilising counterion and made observations at room temperature by NMR in tandem with FAB-MS. The new heterodimetallic species $[IrI(CH_3)(CO)_2(\mu\text{-}I)_2PtI_2(CO)]^-$ has been identified and its evolution monitored in solution.

The iridium complex **1** alone, initially studied by Forster[2] and Pannetier et al.,[8] is known to slowly catalyse the carbonylation of methanol to acetic acid. In mixtures similar to those employed industrially,[9] under 3 MPa and at 95 °C, we observed by high-pressure $^{13}C$ NMR spectroscopy (100.6 MHz) the spontaneous formation of the methyliridium complex $H[Ir(^{13}CH_3)I_3(^{13}CO)_2]$ (**2**) together with small amounts of the acyl species $H[Ir(^{13}CO^{13}CH_3)I_3(^{13}CO)_2]$ (**4**) (see Table 1). As previously proposed by Forster from IR observations,[2] we confirm that under these conditions the resting state is the methyl complex **2**, which is characterised by signals at $\delta$ = 157.1 (s, CO), –15.2 [q, $^1J$(C,H) = 141 Hz, $CH_3$] ppm. These NMR values are very close to those for $[PPN][Ir(CH_3)I_3(CO)_2]$, which was characterised by X-ray crystallography.[10] Small amounts of $CO_2$ were also detected, resulting from the water gas shift side reaction (WGSR). In addition, some $CH_4$ was detected. Evidence of occurrence of the WGSR was provided by the presence of $H[IrHI_3(CO)_2]$ and $H[IrI_4(CO)_2]$, as shown by the relevant NMR spectroscopic data. The low activity of **2** was also shown by the low consumption of $^{13}CO$ and

Table 1. NMR spectroscopic data for the species involved in the methanol carbonylation reaction.

| Complex | $^{13}C$ NMR ($\delta$/ppm) | Products | $^{13}C$ NMR ($\delta$/ppm) |
|---|---|---|---|
| $PPN[IrI_2(CO)_2]$ (**1**) | 169.9 (s, CO) | AcOH | 177.3 (s), 21.1 (q) |

$^{13}CH_3I$.[11] Thus, in the absence of any stabilising counterion, we have established the nature of the catalytic species that present the longest life-times.

Subsequently, our studies focused on the accelerating effect of platinum promoters on the iridium system. Under 3 MPa ($^{13}CO/^{12}CO$ = 1:3) and at 95 °C in a high-pressure NMR sapphire tube, addition to the catalytic iridium mixture of $[PtI_2(CO)_2]$ (**5**), which is the stable species formed from $[Pt_2I_2(\mu\text{-}I)_2(CO)_2]$ under CO, led to a significant increase in the carbonylation rate. In batch experiments using a Hastelloy® reactor, we obtained a carbonylation rate (based on the transformation of AcOMe into acetic acid) of 16 mol $L^{-1}$ $h^{-1}$ with iridium alone, compared to 35 mol $L^{-1}$ $h^{-1}$ after addition of $[PtI_2(CO)]_2$ (Pt/Ir = 3:7). $^{13}C$ NMR spectra led to observe the change in the concentration of the organic compounds during the catalytic runs

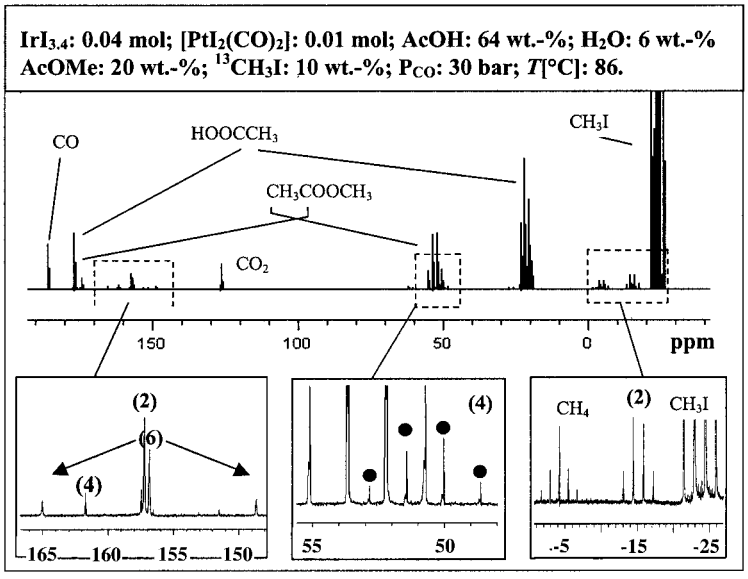

Figure 2. $^{13}C$ NMR spectroscopic data for the [Ir–Pt]/methanol carbonylation system.

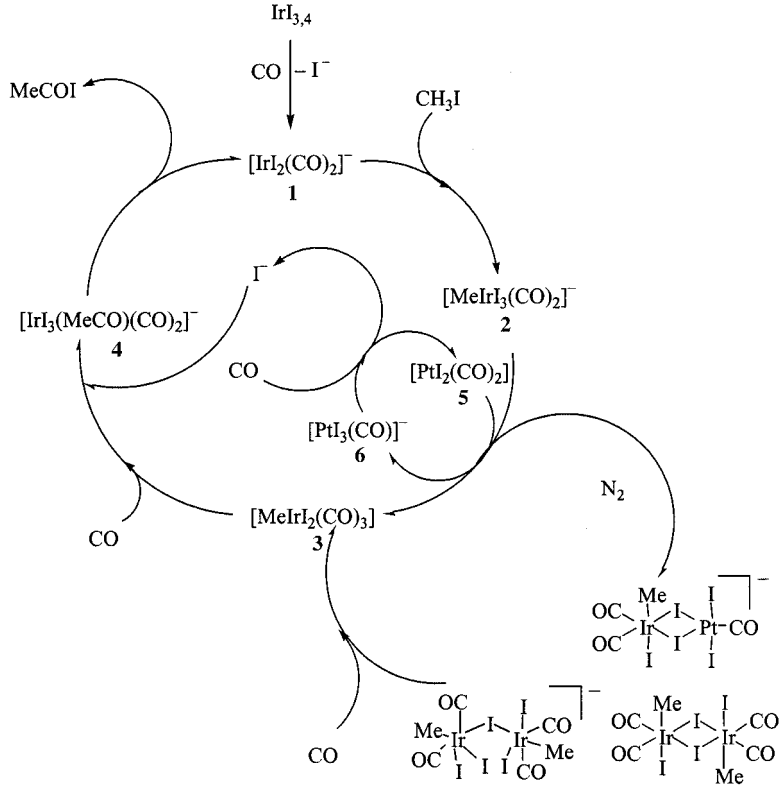

Figure 3. Proposed catalytic cycle for the [Ir–Pt] system.

and particularly the intensity ratio between the signals of acetic acid and methyl iodide. We have charged two high-pressure NMR tubes with $IrI_{3.4}$, $^{13}CH_3I$ (10 wt.-%), AcOMe (20 wt.-%), $H_2O$ (6 wt.-%) and AcOH (64 wt.-%) under 30 bar of a mixture of $^{13}CO/^{12}CO$, one tube containing only $IrI_{3.4}$ salt (a) and the other containing the mixture of $IrI_{3.4}$ and $[PtI_2(CO)]_2$ (b). After 3 h at 86 °C, we can compare (Figure 1) the relative intensity ratios of the two signals of $^{13}CH_3I$/AcOH and conclude that a larger amount (around two times) of $^{13}CH_3I$ was consumed[11] with the [Ir–Pt] system than with the iridium catalyst only. Under these conditions, we observed the presence of $H[PtI_3(CO)]$ (**6**) and the signals corresponding to the iridium complexes **2** and **4** in significant amounts[12] (Figure 2).

The role of platinum is mainly to assist the formation of the species $[IrI_2(CH_3)(CO)_3]$ (**3**), in which the electron density on the iridium atom is reduced; migratory CO insertion can then occur more rapidly to produce **4**. In separate experiments we checked that platinum indeed acts as a real co-catalyst, since application of 3 MPa of CO exerted on **6** provides **5** again, whereas such a platinum species alone does not catalyse the carbonylation reaction. Finally, reductive elimination of acyl iodide from **4** regenerates **1** (Figure 3).

In order to obtain a clear view of this dimetallic process, we decided to decrease the reaction rate by performing the experiments under ambient conditions and by using the $[PPN]^+$ stabilising counterion under nitrogen. A number of $^1H$ NMR (250 MHz, $CD_2Cl_2$, 25 °C) spectra were recorded while varying the Ir/Pt molar ratio. Addition of $[Pt_2I_2(\mu\text{-}I)_2(CO)_2]$ to a dichloromethane solution of **2-PPN** provided several signals at $\delta$ = 2.36, 2.28, 2.14, 2.09, 1.90 and 1.85 ppm (Figure 4). At low platinum concentrations (Ir/Pt = 9.5:1), the signal at $\delta$ = 2.14 ppm is assigned to unreacted **2-PPN**. We may tentatively assign the peak at $\delta$ = 2.09 ppm to the solvated neutral species $[IrI_2(CH_3)(CO)_2(solv)]$, in which the coordinated solvent could be $CD_2Cl_2$. Indeed, iridium(III) complexes containing coordinated $CH_2Cl_2$ have been reported previously.[13] At higher platinum concentrations (Ir/Pt = 5.3:1), significant amounts of the two isomers of $[Ir_2I_2(\mu\text{-}I)_2(CH_3)_2(CO)_4]$ were detected at $\delta$ = 1.90 and 1.85 ppm.[10]

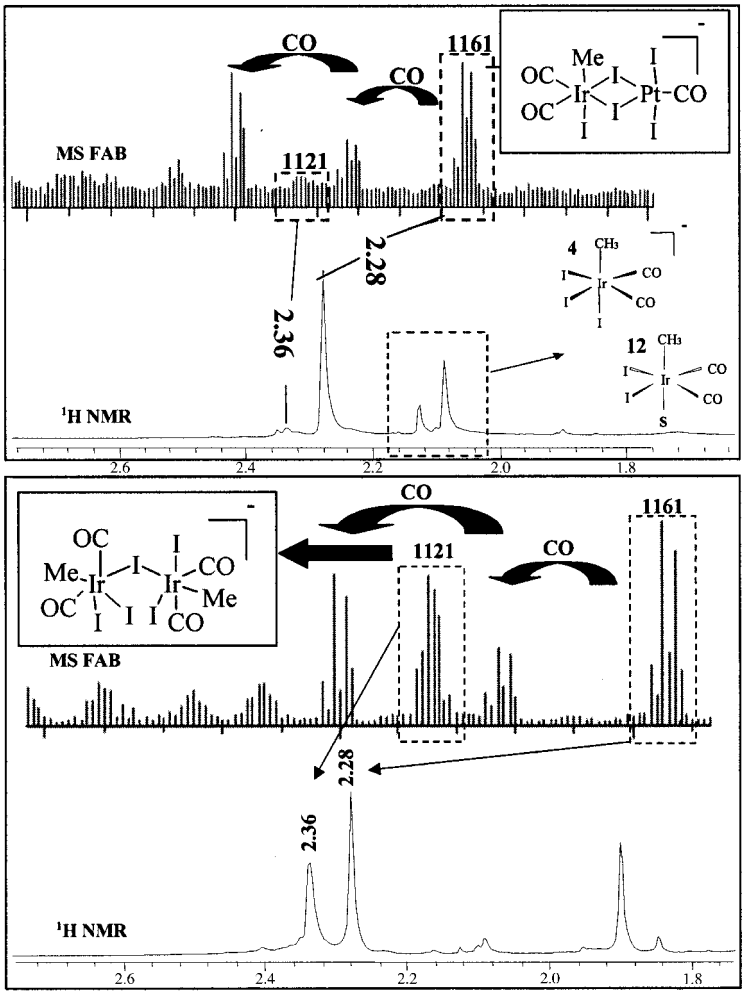

Figure 4. Detection of $[IrI(CH_3)(CO)_2(\mu\text{-}I)_2PtI_2(CO)]^-$ and $[Ir_2I_4(\mu\text{-}I)(CH_3)_2(CO)_4]^-$ by tandem NMR and FAB/MS experiments: top (Ir/Pt = 9.5:1), bottom (Ir/Pt = 5.3:1).

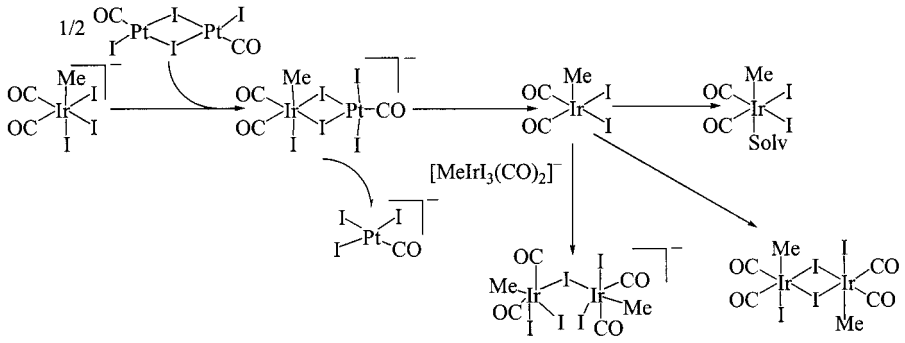
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. Reaction route leading to $Ir_2$-bridged species through the intermediate formation of an [Ir–Pt] dimetallic moiety (from **2** and $[Pt_2I_2(\mu\text{-}I)_2(CO)_2]$).

As already stated, two additional $^1H$ NMR signals appeared at $\delta$ = 2.36 and 2.28 ppm, whose relative intensities vary with the Ir/Pt molar ratio. In order to assign these two signals, for the given Ir/Pt ratios, we recorded $^1H$ NMR spectra in tandem (analysed from the same sample) with FAB/MS experiments. Representative examples are shown in Figure 4. For an Ir/Pt = 5.3:1 molar ratio, two anionic complexes were detected at *m*/*z* = 1121 and 1161. The former molecular peak corresponds to the anionic heterodimetallic complex $[IrI(CH_3)(CO)_2(\mu\text{-}I)_2PtI_2(CO)]^-$. The latter is consistent with the formulation $[Ir_2I_4(\mu\text{-}I)(CH_3)_2(CO)_4]^-$, which was previously suggested as an intermediate in the [Ir–Ru] system.[5] In a second representative run, for an Ir/Pt = 9.5:1 molar ratio, the peak at *m*/*z* = 1121 in the FAB/MS spectra, as well as the signal at $\delta$ = 2.36 ppm in the $^1H$ NMR spectra disappeared nearly completely. Thus, the signal at $\delta$ = 2.28 ppm can be unambiguously assigned to the complex $[Ir_2I_4(\mu\text{-}I)(CH_3)_2(CO)_4]^-$. Additionally, $^{13}C$ NMR spectra reveal the signals of $[Ir_2I_4(\mu\text{-}I)(CH_3)_2(CO)_4]^-$ at $\delta$ = 154.68 ppm (s, CO), –14.83 ppm (q, $J_{C,H}$ = 141 Hz, $CH_3$) and two new carbonyl signals that correspond to $[IrI(CH_3)(CO)_2(\mu\text{-}I)_2PtI_2(CO)]^-$. The CO ligand coordinated to Pt gives a signal at $\delta$ = 154.9 ppm (s, CO) with its satellites characterised by a doublet ($^1J_{Pt,C}$ = 1650 Hz, CO). The other carbonyl signal at $\delta$ = 155.4 ppm (no coupling constant) is assigned to the two CO ligands coordinated to the iridium atom. The quadruplet at $\delta$ = –14.2 (q, $^1J_{C,H}$ = 141 Hz, $CH_3$) ppm shows no coupling between $^{13}C$ and $^{195}Pt$ and is presumably due to the $CH_3$ ligand coordinated to the iridium atom. The $^{195}Pt$ NMR spectra show a new signal at $\delta$ = –5462 (s, + satellites d, $^1J_{Pt,C}$ = 1650 Hz, CO) ppm, together with a signal of $[PtI_3(CO)]^-$ at $\delta$ = –5460 (s, + satellites d, $^1J_{Pt,C}$ = 1759 Hz, CO) ppm. Scheme 1 summarises the reaction pathway for the formation and the evolution of the mixed [Ir–Pt] complex. Under CO, the [Ir–Pt] system leads very quickly to the two complexes **3** and **6**.

This work presents circumstantial evidence that the main role of the platinum promoter during the iridium-catalysed carbonylation of methanol is to abstract an iodo ligand from $[IrI_3(CH_3)(CO)_2]^-$ (**2**) through the formation of the heterodimetallic $[IrI(CH_3)(CO)_2(\mu\text{-}I)_2PtI_2(CO)]^-$ intermediate species.

## Experimental Section

**Synthesis of the Iridium Complexes:** The synthesis of the iridium complexes has been previously reported.[10]

**Synthesis of the Platinum Complexes**

**$[PtI_2(CO)_2]$ (5) and $[PtI_2(CO)]_2$ (5′):** $[Pt(CO)_2I_2]$ was prepared by addition of $PtI_2$ (2 g, 4.45 mmol) in an autoclave containing hexane (125 mL). The mixture was pressurised with CO (12 bar) and stirred at 75 °C for 1 h. The solution was cooled in the reactor under CO (1 bar). 1.69 g (80% yield) of a red solid was obtained and dried under reduced pressure, which corresponds to $[PtI_2(CO)]_2$. Under CO, this compound leads to $[PtI_2(CO)_2]$ in 100% yield. $[PtI_2(CO)]_2$: IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2111 (CO) $cm^{-1}$. $^{13}C$ NMR ($CD_2Cl_2$): $\delta$ = 154.5 (s, $^1J_{Pt-C}$ = 1843 Hz, CO) ppm. $^{195}Pt$ NMR ($CD_2Cl_2$): $\delta$ = –5328 ($^1J_{Pt-C}$ = 1843 Hz) ppm. $[PtI_2(CO)_2]$: IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2127 (CO) $cm^{-1}$. $^{13}C$ NMR ($CD_2Cl_2$): $\delta$ = 166 (s, $^1J_{Pt-C}$ = 1466 Hz, CO) ppm. $^{195}Pt$ NMR ($CD_2Cl_2$): $\delta$ = –5790 ($^1J_{Pt-C}$ = 1466 Hz) ppm.

**[PPN][$PtI_3(CO)$] (6-PPN):** $[PtI_2(CO)]_2$ (1 g, 1.05 mmol) was dissolved in dichloromethane (50 mL), and HI (0.26 g, 2.10 mmol) was added to give rapidly, at room temperature, the complex $H[PtI_3(CO)]$. Then, [PPN]Cl (1.20 g, 2.10 mmol) was added to the solution. The solvent was removed under vacuum to give a yellow product. Crystallisation of this compound in $CH_2Cl_2$/hexane (1:1) gave yellow crystals of $[PPN][PtI_3(CO)]$ (1.08 g, 45%). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2075 (CO) $cm^{-1}$. $^{13}C$ NMR ($CD_2Cl_2$): $\delta$ = 152.8 (s, $^1J_{Pt-C}$ = 1759 Hz, CO) ppm. $^{195}Pt$ NMR ($CD_2Cl_2$): $\delta$ = –5460 ($^1J_{Pt-C}$ = 1759 Hz). MS ($FAB^-$): *m*/*z* = 603.

# Atom Assignment in Solid-State Structures on the Basis of X-ray Crystallography and DFT Calculations – A Case Study on a Molecular Cu–Sb Alloy

**Reinhart Ahlrichs,[a] Dieter Fenske,*[b,c] Alexander Rothenberger,*[b,c] Claudia Schrodt,[c] and Stephan Wieber[c]**

*Dedicated to Professor Hansgeorg Schnöckel on the occasion of his 65th birthday*

**Keywords:** DFT calculations / Molecular alloys / Sb ligands

The structure determination of the molecular Cu-Sb alloy $[Cu_{28}Sb_{12}(PEt_3)_{12}\{Sb(SiMe_3)_2\}_2]$ was performed by DFT-assisted X-ray crystallography, a powerful combination of methods, widely applicable.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Recently, some of our interests have been focused on the synthesis of Cu–Sb clusters and their structural analysis.[1,2] For the synthesis of conventional $Cu^I$–Sb complexes, $Cu^I$ salts are treated with tertiary stibane ligands to produce coordination compounds analogous to thoroughly investigated $[Cu^IX{\cdot}PR_3]$ (R = organic group, X = anion) complexes.[3] A remarkable achievement in the area of Cu–Sb compounds represents the synthesis of the thermally unstable first copper(I) antimonide complex $[Mes_2SbCu(PMe_3)_2]_2$ (Mes = 2,4,6-trimethylphenyl) by the metathesis reaction of $Mes_2SbLi$ with CuCl.[4] A different approach to the syntheses of copper(I) antimonides involves the reaction of $Sb(SiMe_3)_3$ with $Cu^I$ salts in the presence of tertiary phosphanes. As results from these studies, a series of Cu–Sb cluster complexes {e.g., $[Cu_{10}(Sb_3)_2(SbSiMe_3)_2(dppm)_6]$, $[Cu_{17}Sb_8(dppm)_7]$, and $[Cu_{20}Sb_{10}(PCy_3)_8]$ [dppm = 1,2-bis(diphenylphosphanyl)methane, Cy = cyclohexyl]} was obtained and structurally characterised.[1,2] A common feature of the majority of clusters produced in these reactions are the unexpected ratios of Cu/Sb. This is illustrated by $[Cu_{20}Sb_{10}(PCy_3)_8]$, where physical measurements showed that the concept of oxidation numbers can no longer be applied and that they are instead best described as molecular sections of Cu–Sb alloys.[1] Investigations in this field so far showed a preference for copper–antimony compounds with Cu/Sb = 2:1, a ratio which is observed in the η-phase of the rather complex Cu–Sb phase diagram.[5,6] The structural analysis of these complexes has proven to be impossible by X-ray crystallography alone, but the solid-state structure of $[Cu_{45}Sb_{16}(PEt_2Me)_{16}]$, the largest representative of molecular Cu–Sb alloys, was possible by a combined approach of DFT calculations and X-ray crystallography.[2]

## Results and Discussion

Here we describe the so far best example of DFT-assisted X-ray crystallography in the Cu–Sb alloy system, which is, due to the structural diversity, predestined for future discoveries in this field. The reaction of CuOAc and $Sb(SiMe_3)_3$ (ratio 1:1) in the presence of $PEt_3$ produces the Cu–Sb cluster $[Cu_{28}Sb_{12}(PEt_3)_{12}\{Sb(SiMe_3)_2\}_2]$ (**1**) (Scheme 1).

$$CuOAc + Sb(SiMe_3)_3 \xrightarrow[Et_2O]{PEt_3} [Cu_{28}Sb_{12}(PEt_3)_{12}\{Sb(SiMe_3)_2\}_2]\cdot 2Et_2O\ (\mathbf{1})$$

Scheme 1. Synthesis of **1**.

The initial X-ray structural analysis of black crystals of **1** led to problems with the atom assignment of Cu(5,10,17) and Sb(6,8,10) and their symmetry equivalents, indicated by unusual thermal parameters. All other atoms could be unequivocally identified. Figure 1 represents the refined structural model of **1** based on results obtained from DFT calculations.

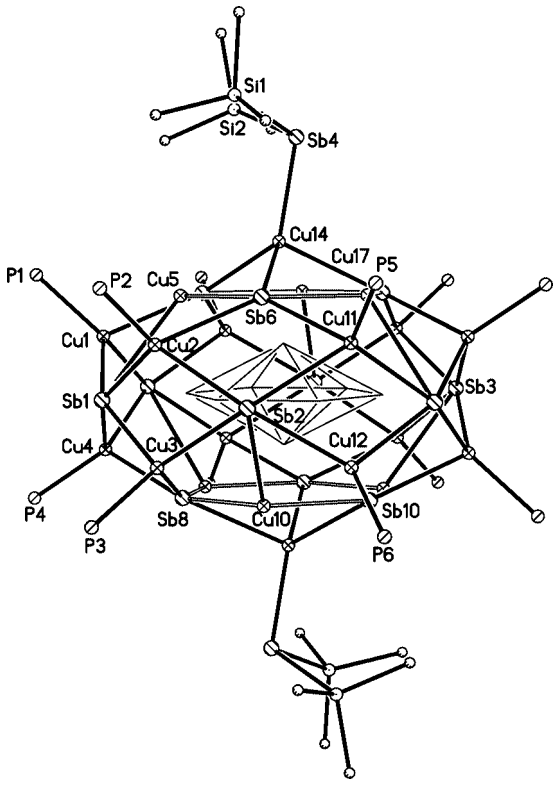

Figure 1. Molecular structure of **1**. Et groups and bonds to the inner $[Cu_8]$ unit and solvent have been omitted for clarity. Selected ranges of bond lengths [Å]: Cu–Sb 2.5322(11)–3.109(11), Cu–P 2.213(2)–2.228(2), Sb(4)–Si(1) 2.542(3), Sb(4)–Si(2) 2.547(3), short Cu–Cu distances observed in the inner $[Cu_8]$ unit 2.410(1), 2.476(1).

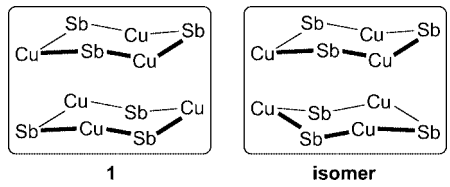
The DFT study was carried out to allow reliable assignment of atom types to the positions in question [Cu(5,10,17), Sb(6,8,10) and symmetry equivalents]. All calculations were performed with the TURBOMOLE program package[7] by employing the BP86 functional with the very efficient MARI-J approximation,[8] and recently developed TZVP basis sets.[9] For P–Me and –Et smaller basis sets were used. The number of contracted basis functions is as follows: Sb [6s5p3d2f], Cu [6s4p4d1f], Si [5s5p2d1f], P [5s5p2d1f], C [5s3p1d], and H [2s]. The core electrons 1s to 3d of Sb (28 electrons) were modeled by a small-core ECP (Effective Core Potential), taking into account scalar relativistic effects.[10] The results of these calculations give a clear preference to six-membered $[CuSb]_3$ rings (indicated by open bonds in Figure 1) over $Cu_6$, $Sb_6$, $Cu_4Sb_2$, $Cu_2Sb_4$, and permutations thereof. $[CuSb]_3$ rings, however, can be in different orientations relative to each other (Scheme 2).

The calculated structures of **1** and a conformer (generated by the exchange of all Cu and Sb positions within slightly puckered six-membered rings) are equally stable ($\Delta$ = 4 kJ/mol) and fit with a structure solution of X-ray crystallographic data, based on these DFT suggestions. The calculated structure of the acentric isomer of **1** (Scheme 2, right) is 28 kJ/mol more stable than calculated **1** but shows larger deviations of Cu–Sb bond lengths and would require lower crystallographic symmetry. Although an acentric structure of **1** was initially ruled out when refinement of a



Scheme 2. Relative arrangement of $[CuSb]_3$ rings in **1** and its isomer.

structural model in the space group $P2_1$ did not indicate a preference for Cu or Sb on any site in the highlighted six-membered $[CuSb]_3$ rings (Figure 1; Scheme 2, right), the findings of DFT calculations and X-ray crystallographic results are not contradictory and point towards individual acentric cluster molecules with a 50:50 distribution. This results in a pseudo-centrosymmetric solid-state structure of **1** representing the average composition rather than an individual molecule. Based on these considerations, the structure of **1** and its conformer was solved and refined in the space group $P2_1/n$. Atomic positions within the six-membered rings were refined with 50% occupancy of both Cu and Sb. The solid-state structure of **1** (Figure 1) consists of a central hexagonal-bipyramidal arrangement of Cu atoms surrounded by a distorted icosahedral arrangement of Sb atoms and an additional layer of a capped hexagonal prism of 14 Cu atoms (Figure 2).

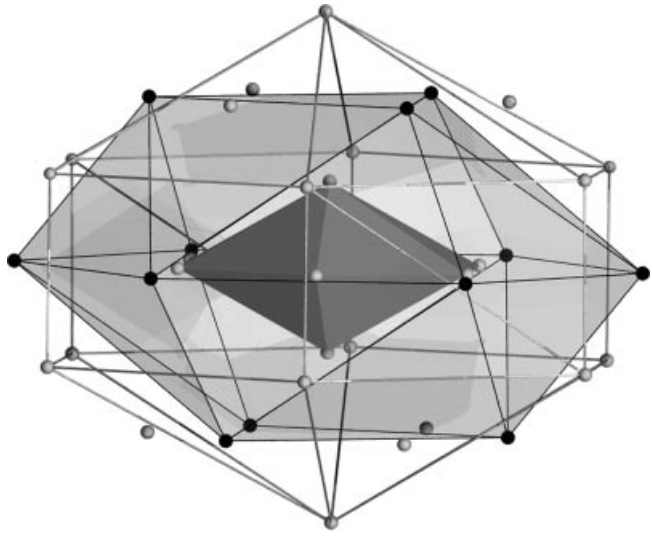


Figure 2. Polyhedral model of the cluster core found in **1** (Sb black, Cu grey).

Over six of the twelve trigonal faces of the hexagonal-prismatic arrangement Cu atoms are located, which form the crucial six-membered $[CuSb]_3$ rings together with two $Sb_3$ faces of the icosahedral arrangement of the Sb atoms (Figures 1 and 2). Cu atoms in the hexagonal prism are coordinated by P atoms of $PEt_3$ ligands [Cu–P 2.213(2)–2.228(2) Å], whilst two $[Sb(SiMe_3)_2]$ ligands coordinate the two capping Cu atoms [Cu(14) and its symmetry-equivalent atom].

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

## Conclusion

The exchange of lattice positions in other copper–transition metal compounds is well known.[11] Indications for statistical occupation of atomic positions in a molecular Cu–Sb alloy (resulting here in the cocrystallisation of two conformers), however, are in this case to the best of our knowledge observed for the first time. An increasing number of copper and antimony atoms in metal clusters could lead to even more challenging structural analyses of these species and will propagate the use of DFT methods where conventional X-ray crystallography on its own fails to give convincing results.

## Experimental Section

**General Remarks:** All operations were carried out under purified nitrogen. Hexane and diethyl ether were dried with $LiAlH_4$ and freshly distilled. $PEt_3$, $Sb(SiMe_3)_3$, and CuOAc were prepared according to published procedures.[12]

**Synthesis of 1:** CuOAc (0.24 g, 2.00 mmol) was dissolved in $Et_2O$ (8 mL) and $PEt_3$ (0.56 mL, 4.00 mmol). The yellow solution was cooled to –78 °C and $Sb(SiMe_3)_3$ (2.91 mL, 2.00 mmol, 0.31 M in hexane) was added. The brown reaction mixture was stored at –78 °C for 12 h and was then warmed up to –8 °C and stored for four weeks. Black crystals of **1** were isolated (0.08 g, 21%), but decomposed at room temperature, precluding elemental analysis. **1** is insoluble in ethereal solvents and hydrocarbons.

**X-ray Crystallographic Study of 1:** Crystallography data for the compound were collected with a Stoe IPDS II diffractometer by using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structure was solved by direct methods and refined by full-matrix least squares on $F^2$ (all data) using the SHELXTL software package.[13] Hydrogen atoms were placed in calculated positions, non-hydrogen atoms were assigned anisotropic thermal parameters. $C_{92}H_{238}Cu_{28}O_2P_{12}Sb_{14}Si_4$; $M$ = 5342.42; monoclinic, space group $P2_1/n$; $Z$ = 4; $a$ = 19.0392(5) Å, $b$ = 22.0502(6) Å, $c$ = 19.4760(5) Å, $\beta$ = 97.145(2)°; $V$ = 8112.9(4) Å$^3$; $T$ = 120(2) K; $F(000)$ = 5132; $D_{calcd.}$ = 2.187 g cm$^{-3}$; 52524 reflections measured, of which 17705 were unique ($R_{int}$ = 0.0689); 455 parameters; final $wR_2$ = 0.1572 (all data); $R_1$ = 0.0588 [$I > 2\sigma(I)$]; largest difference peak/hole = 3.554/–3.273°e·Å$^{-3}$; disordered components were refined with isotropic thermal parameters. A numerical absorption correction was performed. CCDC-281468 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Dipolar Organoiron Pyranylideneacetaldehyde Hydrazone Complexes: Synthesis, Characterization, Crystal Structure, Linear and Nonlinear Optical Properties

**Lorena Millán,[a] Mauricio Fuentealba,[a] Carolina Manzur,*[a] David Carrillo,*[a] Nadège Faux,[b] Bertrand Caro,*[b] Françoise Robin-Le Guen,[b] Sourisak Sinbandhit,[c] Isabelle Ledoux-Rak,[d] and Jean-René Hamon*[e]**

**Keywords:** Donor–acceptor systems / Iron / Pyranylideneacetaldehyde / Nonlinear optics / Sandwich complexes

New cationic organoiron(II) pyranylideneacetaldehyde hydrazone complexes were prepared in high yields through condensation reactions of the organometallic hydrazine precursor $[CpFe(\eta^6\text{-}p\text{-}MeC_6H_4NHNH_2)]^+PF_6^-$ with differently substituted α- and γ-pyranylideneacetaldehydes. The mononuclear hydrazones were stereoselectively obtained as their (*E*) isomers about the N=C double bond. All the new compounds were thoroughly characterized by a combination of elemental analysis and spectroscopic techniques ($^1H$ and $^{13}C$ NMR, IR, and UV/Vis), and by a single-crystal X-ray diffraction analysis of the 2-*t*Bu-chromene derivative **5**. The spectroscopic data suggest that these complexes have a partial pyrylium character due to the electron-accepting ability of the cationic organometallic fragment and to the electron-releasing properties of the methylenepyran-based donor. The crystal structure of **5** shows that the $\eta^6$-coordinated tolyl ring and the pyran ring are coplanar (dihedral angle 3.2°), a favorable situation that allows conjugation between the intracyclic oxygen atom and the cationic iron center through the entire hydrazone backbone. Compounds **4**–**6** are strongly polarized D–π–A systems that exhibit solvatochromic properties, low-lying intramolecular charge-transfer bands in their electronic absorption spectra, and enhanced second-order NLO properties ($\mu\beta$), as measured by the EFISH technique at 1.907 μm.

## Introduction

The electron-donating and -accepting capabilities of organoligand–metal fragments have been successfully applied in the design and development of highly efficient dipolar chromophores in order to achieve high second-order nonlinear optical (NLO) responses.[1] This has led to a growing development of organometallic push–pull rod-shaped oligomers, mainly ferrocene-based donor–acceptor materials,[2] and, in particular, those incorporating a cationic acceptor subunit have demonstrated good second-harmonic generation (SHG) efficiency.[3,4] The potentially attractive NLO properties of ferrocene-based complexes are coupled with good thermal and photochemical stability,[5] excellent donor capability,[6] and redox-switching abilities.[7] On the other hand, the cationic isolobal electron-acceptor counterparts of ferrocene, namely the robust mixed-sandwich derivatives $[CpFe(\eta^6\text{-arene})]^+$,[8] have also been the subject of intense investigations within the domains of arene functionalization,[9] electron transfer and redox processes,[10] photochemistry,[11] and, in one case, as an organometallic chromophore to achieve second-order NLO responses.[12] Along this line, some of us have thoroughly investigated organometallic dipolar chromophores in which the electron-withdrawing cationic organometallic fragment $[CpFe(\eta^6\text{-arene})]^+$ (A) is connected to a potent donating organic[13] or ferrocenyl[14] subunit (D) by an asymmetric –NR–N=CR– (R = H, Me) hydrazone conjugated bridge (π), and have shown that in such D–π–A-type systems an effective electron delocalization or electronic interaction between the electron-donating and -accepting termini takes place through the entire hydrazone skeleton. Others of us have recently reported on donor–acceptor pentacarbonylmetal methylenepyran Fischer-type methoxycarbene complexes (metal = Cr, W).[15]

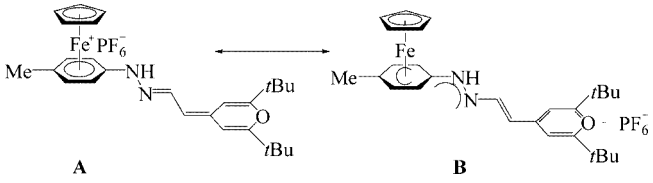
These complexes, which have a pyrylium character owing to the π-electron-accepting ability of the carbene fragment and to the electron-releasing properties of the methylenepyran core, exhibit a large first hyperpolarisability $\mu\beta$, as measured by the electric-field-induced-second-harmonic (EFISH) generation technique.[16] These facts, and the results of a recent theoretical study, which focused attention on the importance of pyrylium–methylenepyran duality for NLO purposes,[17] prompted us to investigate new push–pull structures that combine an ionic iron acceptor with a methylenepyran group, which should act as electron donors because of the aromaticity gain upon electron delocalization of the heterocyclic oxygen lone-pair (Scheme 1).



Scheme 1. Resonance forms for the methylenepyran–pyrylium mesomers.

For this purpose, we have chosen three archetypal pyranylideneacetaldehyde-type structures where the pyranyl ring is substituted at positions 2,6 (**1**) and 4,6 (**3**), or fused with a six-membered ring (**2**), as depicted in Figure 1. The present contribution reports on the preparation and full spectroscopic characterization (IR, UV/Vis, $^1$H, and $^{13}$C NMR) of

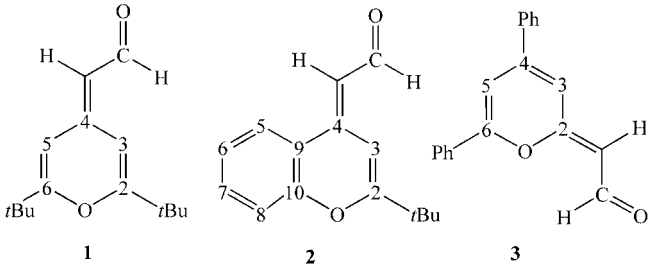


Figure 1. Substituted α- and γ-pyranylideneacetaldehydes used in this work and their labelling scheme.

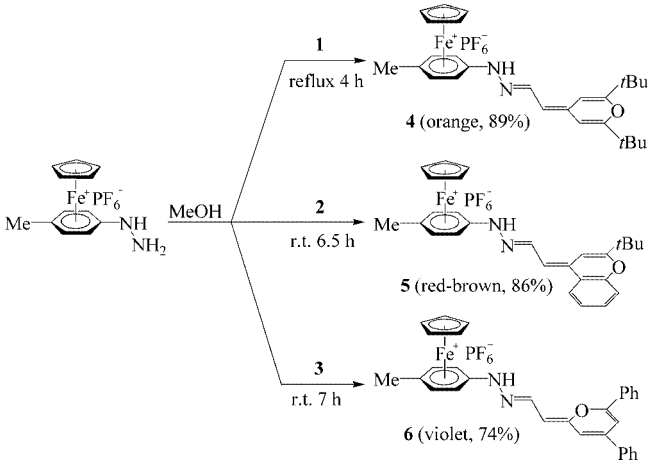

Scheme 2. Preparation of complexes **4**–**6**.

the resulting new mononuclear complexes **4**–**6**, in which a substituted α- or γ-methylenepyran fragment is attached to a [CpFe(η$^6$-*p*-tolylhydrazone)]$^+$ moiety (the structural formulae of complexes **4**–**6** are given in Scheme 2), the crystal and molecular structures of the benzopyran derivative **5** to gain insight into influence of the electron-withdrawing organometallic group on the geometry of D–π–A systems, and finally the second-order NLO properties of these three compounds by measuring the second-harmonic generation efficiency, $\mu\beta$, by the EFISH generation technique.

## Results and Discussion

### Syntheses and Spectroscopic Characterization

The new mononuclear chromophores **4**–**6** were successfully prepared by a condensation reaction of the ionic organometallic hydrazine precursor [CpFe(η$^6$-*p*-MeC$_6$H$_4$-NHNH$_2$)]$^+$PF$_6^-$ with the γ-pyranylideneacetaldehydes **1** and **2**, and the α-pyranylideneacetaldehyde **3** (see Figure 1), respectively, in ethanol solution (Scheme 2). The three complexes were isolated as orange (**4**), reddish-brown (**5**), and dark-violet (**6**) microcrystalline solids, in excellent yields of between 74 and 89% after recrystallization from a dichloromethane/diethyl ether mixture. All three mononuclear species display good thermal stability in air. Compound **6** has the same intense dark color as the methylenepyran Fischer-type carbene derivatives.[15a] Complexes **4**–**6** exhibit a good solubility in common polar organic solvents, but are insoluble in diethyl ether, hydrocarbons, and water. Their structures were inferred from satisfactory elemental analysis, $^1$H and $^{13}$C NMR, IR, and UV/Vis spectroscopy, and additionally, in the case of complex **5**, by an X-ray diffraction analysis (vide infra).

The solid-state IR spectra of compounds **4**–**6** exhibit the three typical features we have previously observed for related mononuclear organometallic hydrazones.[13] These are: (i) a weak to medium ν(N–H) stretching vibration at about 3320 cm$^{-1}$, (ii) a sharp intense band at about 1565 cm$^{-1}$ attributed to the asymmetric ν(C=N) stretching vibration, and (iii) a splitting of the very strong ν(PF$_6$) band at about 845 and 828 cm$^{-1}$ and a sharp and strong $\delta$(P–F) band at around 557 cm$^{-1}$. In addition, the IR spectra show weak bands in the 1640–1590 cm$^{-1}$ region assigned to the ν(C=C) stretching mode of the methylenepyran fragment.[18]

Interestingly, the organoiron hydrazones **4**–**6** are formed stereoselectively as the sterically less hindered (*E*) isomer (about the N=C double bond), as indicated by the unique set of signals in their $^1$H and $^{13}$C NMR spectra (see Exp. Sect.), and definitively assigned from the structural analysis of complex **5** (see below). In the $^1$H NMR spectra of all the compounds, the sandwich moiety [CpFe(η$^6$-*p*-MeC$_6$H$_4$–)]$^+$ is clearly identified by the characteristic sharp singlets of the Cp and *p*-methyl tolyl proton resonances observed at $\delta \approx 5.00$ and 2.48 ppm, respectively. In addition, the upfield-shifted signals of the aromatic protons of the coordinated C$_6$ ring ($\delta \approx 6.20$ ppm), the doublet ($\delta$ = 8.15–8.37, $^3J_{H,H}$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

≈ 10 Hz) assigned to the deshielded imine proton, and the low-field position ($\delta$ = 9.21–9.48 ppm) of the acidic benzylic N–H signal appear in their expected regions.[13,14] On the other hand, the vinylic 3-H resonance of the methylenepyran core (see Figure 1 for labelling scheme), which is common to the three compounds under investigation, appears as a doublet ($^4J_{H,H}$ = 2.0 Hz) for **4** and as a singlet for **5** and **6**, at $\delta$ = 6.24, 6.38, and 6.85, respectively. Like the 3-H signal, 5-H also appears as a singlet, which strongly indicates that compound **6** is isolated as a single isomer about the C-2=C(exocyclic) double bond, even though the starting pyranic aldehyde **3** is a mixture of (*Z*) and (*E*) isomers.[19] However, the formation of a minor isomer, the population of which is too low to be detected by 300 MHz NMR spectroscopy, cannot be ruled out. It should be noted that the $^1$H NMR spectrum was recorded after recrystallization of the compound and that both isomers have indeed been spectroscopically characterized for a related Fischer-type carbene complex derived from the same mixture of aldehydes.[20]

Consistent with the proposed structure, the $^{13}$C NMR spectra of complexes **4**–**6** exhibit the expected characteristic sharp resonances for the $C_5$ ring and the *p*-Me substituent of the sandwich fragments at $\delta \approx$ 76 and 19 ppm, respectively. The two carbon atoms linked to a nitrogen atom appear as broad signals at lower field, with the imine carbon signal at $\delta \approx$ 143 ppm and the coordinated $C_{ipso}$ signal at $\delta \approx$ 120 ppm. This latter value suggests a partial C–N multiple-bond character, in agreement with the findings of the crystallographic study (see below). The carbon signals of the coordinated $C_6$ ring are shifted upfield relative to those of the free benzo and phenyl rings of compounds **5** and **6**, respectively. In addition, the three types of methylenepyran frameworks exhibit five resonances assigned to five types of skeletal carbon atoms. Molecule **4**, for example, shows the quaternary C-2, C-4, and C-6 carbon atoms as peaks at $\delta$ = 164.67, 134.86, and 163.91 ppm, respectively, with the vinylic C-3 and C-5 signals at $\delta$ = 98.04 and 104.35 ppm, respectively, and the exocyclic carbon signal at $\delta$ = 106.45 ppm. Moreover, the *tert*-butyl carbon atoms show up as two sets of two closely spaced singlets at $\delta$ = 27.09 and 27.13 and 35.16 and 35.47 ppm for the methyl and the quaternary carbon atoms, respectively.

The $^1$H NMR chemical shift of the 3-H proton has previously been taken as a criterion for the degree of pyrylium character.[21] In general, as the contribution of the pyrylium resonance form contributes more to the ground-state structure of a compound, the chemical shift of the signal of the hydrogen atom in the 3-position tends to shift downfield. Thus, from comparison of the observed 3-H chemical-shift values of compounds **4**–**6** with those, more deshielded (see Exp. Sect. and Tables S1 and S2), of unsaturated Fischer-type carbene complexes bearing an α- and γ-methylenepyran or γ-methylenebenzopyran group, namely [$(OC)_5$-W=C(OMe)$(CH=CH)_n$CH=(pyran)] ($n$ = 0–2),[15,20] it seems that the sandwich molecules **4**–**6** have a lower pyrylium or benzopyrylium character. This trend is also confirmed by the $^{13}$C NMR spectroscopic data (Tables S1 and S2). This would suggest that the [CpFe(η$^6$-*p*-tolyl)]$^+$ moieties have a lower electron-withdrawing ability than the [$(OC)_5$W=C(OMe)] carbene fragment. However, a decrease of the electronic transmission between the ends of the molecule through the NH–N=CH spacer should also be considered.

### X-ray Crystal Structure

The molecular structure of the cationic organometallic moiety **5**$^+$, along with the atom-labelling scheme, is presented in Figure 2. Selected bond lengths and angles are listed in Table 1, and details of data collection and refinement are provided in the Exp. Sect. Compound **5** crystallizes in the monoclinic space group $P2_1/n$ with four molecules in the unit cell. In the mixed-sandwich fragment, the iron atom is coordinated to the cyclopentadienyl ring at a ring centroid–iron distance of 1.654 Å, and to the tolyl ring at a ring centroid–iron distance of 1.554 Å. The carbocyclic rings coordinated to the iron center are essentially parallel to one another (deviation of 4.10°), which gives rise to a ring centroid–iron–ring centroid angle of 177.2°. These metrical parameters, together with those listed in Table 1, are similar to those we have already reported for related mononuclear hydrazone complexes,[13] and are typical of an η$^5$-Fe$^{II}$-η$^6$ metallocene-type coordination.[22] More interestingly, the coordinated tolyl ring and the pyran ring, as well as the two six-membered rings of the benzopyran subunit, are coplanar (dihedral angles 3.2° and 1.4°, respectively), a situation which allows conjugation between the intracyclic oxygen atom and the cationic iron center through the entire hydrazone backbone.

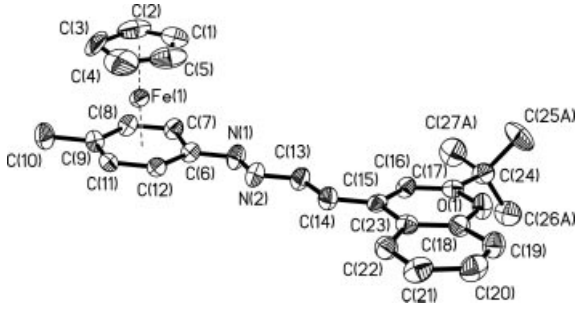

Figure 2. Molecular structure and atom-numbering scheme for **5**·$CH_2Cl_2$. Hydrogen atoms, the $PF_6^-$ counteranion, one of the disordered positions of the *tert*-butyl substituent, and the solvent molecule have been omitted for clarity. Displacement ellipsoids are at the 30% probability level.

A close inspection of Table 1 reveals characteristic structural features provoked by the electron-withdrawing CpFe$^+$ moiety on the η$^6$-coordinated arylhydrazone ligand. Thus, the Fe(1)–C(6) bond [2.198(6) Å] is longer than the mean value of the other five Fe(1)–C($C_6$ ring) bonds (2.048 Å). This elongation (0.15 Å) is a consequence of a partial delocalization of the benzylic nitrogen electron lone-pair toward the cationic mixed-sandwich moiety, and is reflected by (i) a depyramidalization of the N(1) atom, with idealized bond angles at this sp$^2$-hybridized nitrogen atom [C(6)–N(1)–

N(2) = 120.7(5)°], (ii) a C(6)–N(1) bond length of 1.342(7) Å, which is intermediate between a single and a double carbon–nitrogen bond,[22] and (iii) a very weak cyclohexadienyl character of the coordinated phenyl ring, with a folding dihedral angle of 3.3° about the C(7)–C(12) axis. Moreover, this cyclohexadienyl character is exemplified by two long C(6)–C(7) and C(6)–C(12) distances of 1.410(8) Å, while the remaining four other C–C bonds are significantly shorter and fall in the interval 1.366(8)–1.398(8) Å (Table 1), thus emphasizing the weight of the iminocyclohexadienyl mesomeric form (Scheme 1).[8a,13a] On the benzomethylenepyran side, we observe that the exocyclic bond C(14)–C(15) is 1.354(8) Å long, which suggests a weak benzopyrylium character. In fact, for comparison, the exocyclic bond lengths 1.393(8),[15c] 1.389(10),[23] and 1.40(1) Å[15a] measured for γ-methylenepyran Fischer-type carbene complexes have more single-bond character, in accordance with a large conjugation between the intracyclic oxygen lone-pair and the strongly electron-withdrawing carbene fragment. It is worth remarking that these findings fully corroborate the observed NMR spectroscopic data (see above). In addition, it should be noted that NMR studies have shown that the presence of a fused benzene ring decreases the electron-donating ability of the pyran heterocycle.[16]

### Linear and Nonlinear Optical Properties

The UV/Vis spectra of the three complexes under study are similar in that the spectra consist of two intense and broad absorption bands in the visible region. As expected from its dark-violet color, the low-energy absorption band of compound **6** is red-shifted relative to those of **4** and **5**. The origin of the high-energy absorption band in the range 300–380 nm is assumed to be an intra-ligand charge-transfer (ILCT) transition, and the low-energy absorption band in the region 380–550 nm is assigned to a metal-to-ligand charge-transfer (MLCT) transition.[12,13b,24] Deconvolution of the spectra with Gaussian curves gives rise to three or four absorption bands for these two CT transitions (Figure 3 and Table 2). The data of Table 2 indicate that the linear-optical properties (i.e. the energies and intensities of the absorption bands corresponding to the above-mentioned CT transitions) of **4**–**6** are in agreement with those reported for other D–π–A systems having the same $[CpFe(\eta^6\text{-arene})]^+$ fragment as electron acceptor linked to an organic electron-donating group.[12,13b] The broadening of the low-energy band is probably the result of the overlap of broad d–d visible bands of the $[CpFe(\eta^6\text{-arene})]^+$ fragment.[10a,11,25] For compounds **4** and **6**, the two characteristic CT bands exhibit bathochromic shifts when the solvent polarity is increased, thus indicating increased polarity in the excited state. The solvatochromism is much larger for **4** than for **6**, whereas the solvent influence is negligible for compound **5**. Nevertheless, solvatochromic effects can hint at the magnitude of the expected nonlinear optical properties, since they reflect the polarizability of a chromophore.[26]

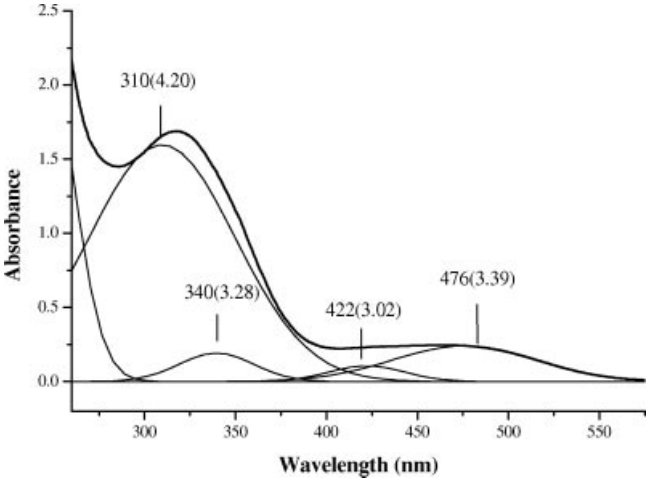

Figure 3. Deconvoluted UV/Vis spectrum of compound **5** recorded in $CH_2Cl_2$. The first number is the wavelength ($\lambda$) and the value in parentheses is log$\varepsilon$ (see Table 2).

Table 2. Electronic absorption and EFISH data.

| Compound | $\lambda$ [nm] (log$\varepsilon$) $CH_2Cl_2$ | $\lambda$ [nm] (log$\varepsilon$) DMSO | $\Delta\lambda$ [nm] | $\mu\beta$ ($\times 10^{-48}$) [esu] $CH_2Cl_2$ |
|---|---|---|---|---|
| **4** | 369 (4.48) | 382 (4.55) | +23 | 154 ± 20 |
| | 396 (3.80) | 452(3.27) | +56 | |
| | 451 (4.07) | 486 (3.69) | +35 | |
| **5** | 310 (4.20) | 309 (4.11) | –1 | 149 ± 10 |
| | 340 (3.28) | 348 (3.66) | +8 | |
| | 422 (3.02) | 415 (2.92) | –7 | |
| | 476 (3.39) | 469 (3.34) | –7 | |
| **6** | 369 (4.17) | 374 (4.05) | +5 | 83 ± 40 |
| | 453 (3.86) | 483 (3.65) | +30 | |
| | 486 (3.62) | 498 (2.94) | +12 | |
| | 523 (4.05) | 531 (3.75) | +8 | |

The second-order NLO properties of compounds **4**–**6** were investigated using the electric-field-induced second-harmonic (EFISH) generation technique, which provides information about the scalar product, $\mu\beta$, of the vectorial part of the first hyperpolarisability tensor, $\beta$, and the dipole

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

moment vector, $\mu$.[27] Compounds **4**–**6** exhibit reasonable $\mu\beta$ values (Table 2), although they remain significantly weaker than those reported for organic hydrazone molecules ($\mu\beta$ = $100–640 \times 10^{-48}$ esu).[28] However, these compounds contain a longer conjugated moiety containing two phenyl rings and are substituted with a very strong acceptor group ($NO_2$) and a good alkoxy donor substituent. The $\mu\beta$ values reported in the present work are comparable to the values of $74 \times 10^{-48}$ and $310 \times 10^{-48}$ esu determined for two Fischer-type methoxycarbene complexes bearing an identical methylenepyran donor fragment to that in **4** and **5** (Table S3).[20] This clearly indicates that the hydrazone and the methylenepyran fragments act as a good π-conjugated spacer and electron donor, respectively, and that the $[CpFe(\eta^6\text{-arene})]^+$ group, which can be functionalized by easy, $CpFe^+$-induced transformations at the coordinated arene ring,[9] could be used as a strong electron-acceptor substituent in molecular engineering for quadratic NLO.[29] Finally, it is interesting to note that the $\mu\beta$ values of **4** and **5** are practically identical, whereas that of **6** is only half as large. This behavior can be attributed to the fact that the spacer is located at the α-position of the electron-donating pyran ring in compound **6**, whereas in **4** and **5** it is located at the γ-position. As a consequence, the internal charge transfer responsible for the $\beta$ value should be smaller and the $\mu\beta$ scalar product is also reduced by the fact that $\mu$ and $\beta$ are probably not parallel to one another.

## Concluding Remarks

In summary, three new organometallic π-conjugated push-pull chromophores have been prepared in high yields by condensation reactions of cyclopentadienyliron(II)-complexed *p*-tolylhydrazines with differently substituted archetypal pyranylideneacetaldehydes. Their original design combines an organometallic acceptor group, namely the cationic mixed-sandwich fragment $[CpFe(\eta^6\text{-}p\text{-}MeC_6H_4)]^+$, associated with an α- and γ-methylenepyran donor through the asymmetric hydrazone spacer NH–N=CH. Single-crystal X-ray diffraction analysis of compound **5** has shown a favorable electronic structure resulting from the coplanarity of the coordinated tolyl ring and the pyran ring, as well as the two six-membered rings of the benzopyran subunit, thus allowing conjugation between the intracyclic oxygen atom and the cationic iron center through the entire hydrazone backbone. As such, the organometallic hydrazones described in this work can be defined as type-I non-rod-shaped dipolar chromophores,[30] and have been proven to favor electronic delocalization along the conjugated chain. Finally, compounds **4**–**6** are strongly polarized D–π–A systems that exhibit solvatochromic properties and have low-lying intramolecular charge-transfer bands in their electronic absorption spectra and enhanced second-order NLO properties ($\mu\beta$). Theoretical computations are obviously required before discussing the electronic structures of the complexes and the electronic transitions giving rise to the NLO properties in more detail; these are currently underway and will be published in due course.

## Experimental Section

**General Procedures:** Unless otherwise noted, all reactions and manipulations were performed at room temperature under dinitrogen using standard Schlenk-line techniques. Solid IR spectra were obtained from KBr disks with a Perkin–Elmer Model Spectrum One FT IR spectrophotometer. Electronic spectra were collected with a Spectronic Genesys 2 spectrophotometer. $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker Advance DPX 300, 400 Digital or a DPX 500 spectrometer, as noted within the text. All NMR spectra are reported in ppm ($\delta$) relative to tetramethylsilane, with the residual solvent proton resonance and carbon resonances used as internal standards. Coupling constants are reported in Hz. $^1H$ and $^{13}C$ NMR chemical shift assignments are supported by data obtained from $^1H$-$^1H$ COSY, $^1H$-$^{13}C$ HMQC, and $^1H$-$^{13}C$ HMBC NMR experiments, and are given according to the numbering scheme of Figure 1. Melting points were determined in evacuated capillaries and are not corrected. Microanalytical data were obtained by the Institut de Chimie de Rennes Microanalysis Service with a Thermo-FINNIGAN Flash EA 1112 CHNS/O analyzer.

**Materials:** Solvents were dried and distilled under dinitrogen by standard methods prior to use. Reagents were purchased from commercial suppliers and used without further purification. The organometallic hydrazine precursor $[CpFe(\eta^6\text{-}p\text{-}CH_3C_6H_4NHNH_2)]^+\text{-}PF_6^-$ was synthesized as described previously,[13e] and the γ-pyranylideneacetaldehydes **1**–**3** (see Figure 1) were also prepared according to published procedures.[19,31]

**($\eta^5$-Cyclopentadienyl)[(2,6-di-*tert*-butyl-4*H*-pyran-4-ylidene)acetaldehyde ($\eta^6$-*p*-tolyl)hydrazone]iron Hexafluorophosphate (4):** A Schlenk tube was charged with a magnetic stirring bar, $[CpFe(\eta^6\text{-}p\text{-}CH_3C_6H_4NHNH_2)]^+PF_6^-$ (105 mg, 0.271 mmol), (2,6-di-*tert*-butyl-4*H*-pyran-4-ylidene)acetaldehyde (**1**; 63.0 mg, 0.269 mmol), and ethanol (15 mL). The reaction mixture was refluxed for 4 h, then cooled to room temperature and stored at –30 °C overnight. The orange precipitate was filtered off, washed with diethyl ether ($2 \times 5$ mL), and dried under vacuum. It was then dissolved in a minimum amount of $CH_2Cl_2$ and the solution was layered with an equivalent volume of diethyl ether. Compound **4** was isolated as an orange, microcrystalline solid. Yield: 145 mg (89%). M.p. 212 °C (dec.). $C_{27}H_{35}F_6FeN_2OP$ (604.39): calcd. C 53.66, H 5.84, N 4.64; found C 53.53, H 6.02, N 4.85. **X-ray Crystal-Structure Determination for 5·$CH_2Cl_2$:** A red-orange plate of complex **5** with dimensions 0.18 × 0.11 × 0.10 mm was mounted on a glass fiber in a random orientation. Data collection was performed at room temperature with a Bruker Smart Apex diffractometer equipped with a two-dimensional CCD detector and a graphite-monochromated Mo-$K_\alpha$ radiation (λ = 0.71073 Å) source, with a nominal crystal-to-detector distance of 6.3 cm. A hemisphere of data was collected on the basis of four ω-scans runs (starting ω = 28°) at φ values of 0°, 120°, 240°, and 0°, with the detector at 2θ = 28°. In each of these runs, frames (600, 600, 600, and 50, respectively) were collected at 0.3° intervals and for 10 s per frame. The diffraction frames were integrated using the SAINT package,[32] and corrected for absorption with SADABS.[33] The positions of the heavy atoms were determined by direct methods, and successive difference electron density maps were produced with the SHEXTL 6.14 software package[34] to locate the remaining atoms. Refinement was performed by the full-matrix least-squares method based on $F^2$. The *tert*-butyl group was disordered over two positions, with an occupation multiplicity, μ, of 0.71/0.29. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in their calculated positions, assigned fixed isotropic thermal parameters, and allowed to ride on their respective parent atoms. $C_{27}H_{29}F_6FeN_2OP{\cdot}CH_2Cl_2$, $M_r$ = 683.27, *a* = 10.1473(10), *b* = 18.7529(19), *c* = 16.2043(16) Å, β = 95.395(2)°, *V* = 3069.9(5) $Å^3$, monoclinic, $P2_1/n$, *Z* = 4, $D_{calcd.}$ = 1.478 $g cm^{-3}$, μ = 0.779 $mm^{-1}$, SADABS absorption correction applied, *F*(000) = 1400, *T* = 299(2) K, $2\theta_{max}$ = 28.08°, reflections collected/unique 25343/6916 [$I > 2\sigma(I)$], data/restraints/parameters 6916/126/459, $R/R_{w2}$ [$I > 2\sigma(I)$] = 0.0923/0.1923, $R/R_{w2}$ (all data) = 0.2394/0.2485, GOF = 0.962, $[\Delta\rho]_{min}/[\Delta\rho]_{max}$ = –0.346/0.476. CCDC-272776 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**EFISH Measurements:** The principle of the EFISH technique has been described elsewhere.[35,36] In order to avoid reabsorption of the generated second harmonics, the data were recorded using 1.907-μm, 10-ns incident laser pulses produced by a hydrogen Raman shifter pumped by an Nd:YAG laser at 1.06 μm at a repetition rate of 10 Hz. The centrosymmetry of the solution was broken by dipolar orientation of the chromophores with a high-voltage pulse (8 kV applied on 3 mm during 1 μs) synchronized with the laser pulse. The compounds were dissolved in dichloromethane at various concentrations ($10^{-3}$ to $10^{-2}$ M) and the solutions were introduced into the measurement cell where the high-voltage was applied during SHG measurements. NLO measurements were calibrated with pure dichloromethane as a reference. Acquisition and data processing were performed using a computerized home-made system.

**Supporting Information** (see footnote on the first page of this article): Tables S1 and S2 compare selected $^1H$ and $^{13}C$ NMR chemical shifts of compounds **4** and **5** with those of pentacarbonyltungsten methylenepyran Fischer-type methoxycarbene complexes, and Table S3 lists the EFISH data of these same pentacarbonyltungsten methylenepyran Fischer-type methoxycarbene complexes.

## Acknowledgments

Financial support from the Fondo Nacional de Desarrollo Científico y Tecnológico [FONDECYT, Chile; grant no. 1010318 (D. C. and C. M.)], the CNRS-CONICYT agreement no. 16771 (C. M., D. C., and J.-R. H.), the Pontificia Universidad Católica de Valparaíso, the Université de Rennes 1, and the Ministère de l'Education Nationale de la Recherche et de la Technologie (MENRT, grant to N. F.) is gratefully acknowledged.

# Density-Functional Calculation of the $^{183}W$ and $^{17}O$ NMR Chemical Shifts for Large Polyoxotungstates

**Jose Gracia,[a] Josep M. Poblet,*[a] Jochen Autschbach,[c] and Leonid P. Kazansky*[b]**

**Keywords:** Density-functional calculations / NMR spectroscopy / Tungsten / Oxygen / Polyoxometalates

A phosphane sulfate relativistic DFT method (ZORA) has been used to calculate the $^{183}W$ and $^{17}O$ NMR chemical shifts for large polyoxotungstates, including $W_6O_{19}^{2-}$, $CH_3OTiW_5O_{18}^{3-}$, $W_5O_{18}W^{II}NO^{3-}$, $W_{10}O_{32}^{4-}$, α-δ-γ-$XW_{12}O_{40}^{n-}$, β-$PW_9O_{28}Br_6^{3-}$, $P_2W_{18}O_{62}^{6-}$, $PW_2O_{14}^{3-}$, and $W_7O_{24}^{6-}$, based on their optimized molecular structures. Despite sizeable deviations between the calculated and experimental values, the calculations correctly reproduce the trends in the change of the chemical shift for both nuclei. As expected, the diamagnetic term is almost constant throughout the whole series. The change in the chemical shifts is shown to be determined by the paramagnetic term, which depends on the electronic structure of the whole anion under study and, in particular, on the local geometry around a given tungsten atom. On the other hand, there is no correlation between the chemical shift and HOMO–LUMO gap, showing that deeper occupied levels and several unoccupied orbitals play an important role in the paramagnetic term. However, analysis of the components of the paramagnetic shielding has shown that the most significant transitions determining the change of both $^{183}W$ and $^{17}O$ NMR chemical shifts for anions consisting of tungsten and oxygen atoms are the occupied–occupied and not the occupied–virtual ones.

## Introduction

NMR spectroscopy is one of the powerful techniques for studying the problems of the chemistry of polyoxometalates (POM) formed by V, Mo, W, and other metals in high oxidation states[1] as it can be used to characterize them both in solution and in the solid state. POMs are usually built of metal–oxygen octahedra that form $M_nO_m^{z-}$ isopolyanions or $XM_nO_m^{z-}$ heteropolyanions. In many cases all nuclei can be observed in the NMR spectra, which helps to elucidate the chemical environment of the nucleus under study.

Several resonance lines may be observed in the NMR spectra depending on the complexity of an anion and its symmetry, and assigning each line to a particular atom sometimes presents a problem. The nature of the chemical shifts is therefore still to be revealed.

As a matter of fact there have been several attempts to understand the nature of the chemical shifts for POMs, and particularly for polyoxotungstates (POTs). The first such study attempted to explain the trend in the change of the $^{183}W$ NMR chemical shifts in lacunary POTs by the charge delocalization resulting from the removal of one W=O group from the Keggin anion $X^{x+}W_{12}O_{40}^{x-8}$.[2] Further, there have also been attempts to correlate the $^{17}O$ and $^{183}W$ chemical shifts with the wavelength of the lowest charge-transfer (LCT) band (the electronic transition from the MO localized mainly on the oxygen atoms to a virtual MO localized mainly on the metals),[3,4] with bond lengths,[5,6] with the inverse sum of the energy separations,[7,8] and with the calculated charges on atoms[9] obtained from EHMO calculations. However, the calculation of the actual chemical shielding for different nuclei is still to be attained.

The first attempts to calculate $^{183}W$ NMR chemical shifts were limited to small and simple molecules like $WO_{4-x}S_x^{2-}$, $W(CO)_6$, $WF_6$, and $WCl_6$, and a practically linear correlation between calculated and experimental shifts was found.[10,11] Calculation of the $^{17}O$ NMR chemical shifts in metal oxide anions $MO_4^{n-}$ has been carried out by different methods with different degrees of accuracy.[12,13]

The first calculation of the $^{183}W$ chemical shift in a large Keggin anion using DFT was not so successful, and large discrepancies have been found by Bagno and co-workers even for small molecules.[14] Later, more reasonable calculated values of the $^{183}W$ NMR chemical shifts were obtained by the same authors.[15] A number of reviews of theoretical calculations of NMR chemical shifts in transition metal compounds have been published, including the results of $^{183}W$ chemical shift calculations by first-principles meth-

ods (relativistic Hartree–Fock and DFT).[16] However, those previous calculations were limited to comparatively small systems and no exhaustive theoretical study of chemical shifts in large heavy-metal POMs has yet been reported.

In the present work we have calculated the $^{183}W$ and $^{17}O$ nuclear magnetic shielding for several POTs using DFT methods with the goal of elucidating the relationship between the shielding and the geometric characteristics as well

as the influence of the latter on the chemical shifts. DFT methods have been shown to be adequate to rationalize many different aspects of the electronic structure,[17,18] magnetism,[19] and bonding[20] in POMs, and a summary of the most illustrative results can be found in a recent review.[21]

The first part of this study discusses several types of POTs (represented in Figures 1 and 2), namely the Lindqvist anion $W_6O_{19}^{2-}$ and its derivatives $CH_3OTiW_5O_{18}^{3-}$, $W_5O_{18}W^{II}NO^{3-}$, and $W_{10}O_{32}^{4-}$ (structural type I, characterized by edge sharing of $WO_6$ octahedra having a symmetry close to $C_{4v}$), the Keggin anions of general formula $XW_{12}O_{40}^{n-}$, their β and γ forms, and a bromide derivative (structural type II, with octahedra having two edge- and two corner-shared oxygen atoms), and the Dawson anion $P_2W_{18}O_{62}^{6-}$ (structural type III, where $W_bO_6$ octahedra have three corner-shared oxygen atoms). The octahedra in all these anions may be assigned as having local axial symmetry close to $C_{4v}$, with one terminal W=O bond. Finally,

the peroxo complex $PW_2O_{14}^{3-}$ (structural type IV) represents a POT where the tungsten has a formal coordination number of 7, with the lowest chemical shift, and the heptatungstate $W_7O_{24}^{6-}$ (structural type V) has three types of W, each of which has two terminal oxygen atoms.

The second part of the study will describe the results of the DFT calculations of the $^{183}W$ and $^{17}O$ chemical shifts for the corresponding reduced polyoxotungstates with delocalized, unevenly delocalized, and localized electrons.

### Calculation of the Chemical Shielding

We used the ADF 2003.01 package[22] to compute the geometries of the molecules. The DFT calculations are characterized by the local density approximation featuring the *Xα* model for exchange with Becke's gradient-corrected functional,[23] and the VWN parameterization for correlation[24] corrected with Perdew's functional.[25] The basis functions for describing the valence electrons of all the atoms are Slater-type orbitals of triple-ζ+ polarization quality. The internal or core electrons are described by a relativistic core potential generated with the auxiliary program DIRAC.[22] The valence orbitals in this approach are kept orthogonal to the core orbitals by means of a single-ζ Slater-type core-orthogonalization basis set. We applied quasi-relativistic corrections to the valence shell by means of the zeroth-order relativistic approximation (ZORA). The NMR shielding tensors were computed from a parallel version of the NMR module.[26a] Although some previous studies have shown that all-electron basis sets reproduce the chemical shifts in some transition metal oxides better,[26b] we found no improvement in our results when this type of basis set was used for large POTs.

Generally, the W–O bonds in the optimized configurations are slightly longer than those observed in the X-ray structure determinations of the corresponding POTs. However, if we take the same anion but in different X-ray structures we sometimes see large discrepancies in the bond lengths. Even in a single crystal there may be two slightly different configurations with the same overall symmetry. Optimizing a structure results in a unique configuration for the given POT because, despite possible different initial coordinates, the program will end up delivering unique atomic coordinates, and although this may lead to an overestimation or underestimation of the calculated chemical shifts, such an approach is justified for comparison of the chemical shifts for different POTs, especially when accurate X-ray-determined coordinates are not available.

As usual, the calculated chemical shift, $\delta_{cal}$, is determined as the difference between the total shielding of the reference molecule, $\sigma_r$, and the shielding of the molecule under study, $\sigma_x$. For each nucleus the total shielding tensor, $\sigma_t$, is calculated as the sum of the paramagnetic ($\sigma_p$) and diamagnetic ($\sigma_d$ ) contributions and therefore:

$$\delta_{cal} = \sigma_r - \sigma_x$$

where $\sigma_x$ is the isotropic average of the shielding tensor for the nucleus in an anion and $\sigma_r$ is the shielding of the reference compound.

The simplest oxoanion, $WO_4^{2-}$, is usually used as a reference for $^{183}W$ NMR chemical shifts and the resonance line of water is used as a reference for $^{17}O$ NMR chemical shifts. For convenience, the absolute shielding of liquid water, $\sigma_t$, is accepted to be equal to +291 ppm.[27]

The experimental values of $^{183}W$ chemical shifts may vary slightly depending on the spectrometer (sometimes by up to 10 ppm, and the chemical shifts of POTs are usually more positive in organic media. On the contrary, protonation of POT generally results in a negative shift of the resonance. Moreover, it should be noted that solvation effects are not included in these theoretical studies even though they can considerably influence the calculated chemical shift, which is assumed to refer to the gaseous state of a single molecule. Hence, we can only estimate a general trend in the chemical shifts from these calculations and, at best, to make an assignment of the resonances for a complex anion with nonequivalent nuclei.

## Results

### The $^{183}W$ NMR Chemical Shift

Table 1 gives the calculated paramagnetic, diamagnetic, and total shielding along with calculated and experimental $^{183}W$ NMR shifts for the POTs shown in Figures 1 and 2. (Table S1 in the Supporting Information shows the difference in the calculated parameters for the experimental and optimized structures of $W_6O_{19}^{2-}$ as an example).

It can be seen that the chemical shift decreases as the number of corner-sharing oxygen atoms increases (structures I→II→III) and that the most positive shift for $W^1$ in $W_7O_{24}^{4-}$, which formally has no terminal oxygen atoms, and the most negative shift for $PW_2O_{14}^{3-}$ are correctly predicted by the calculations. For the bromide derivative, the resonance assigned to the six $W_b$ tungstens linked to bromide, observed at $\delta$ = +192 ppm, and the other line corresponding to $W_a$, observed at $\delta$ = –123 ppm, are also correctly predicted by the calculations. As expected, a soft ligand induces a large positive shift for the corresponding tungsten.

The order of the computed resonances corresponds to the observed one for both β-$SiW_{12}O_{40}^{4-}$ and for γ-$SiW_{12}O_{40}^{4-}$, and only the shift of $W_c$ is rather exaggerated, probably due to an inadequate geometry.

In general, for anions consisting of $WO_6$ octahedra with an axial symmetry and a single W=O bond, including the peroxo anion, we observe a nice linear correlation between the calculated and experimental shifts for the POTs studied (Figure 3). The most notable deviations from this linear trend are observed for anions with the Keggin structure, which was shown by a more detailed analysis to be due to the structure-optimization process (as will be presented elsewhere). Briefly, the results of the latter depend strongly on the overall anionic charge, although for anions with the same negative charge, for example $XW_{12}O_{40}^{5-}$ (X = $B^{III}$, $Al^{III}$, and $Ga^{III}$), the observed and calculated shifts increase regularly with an increase of the inner tetrahedron.

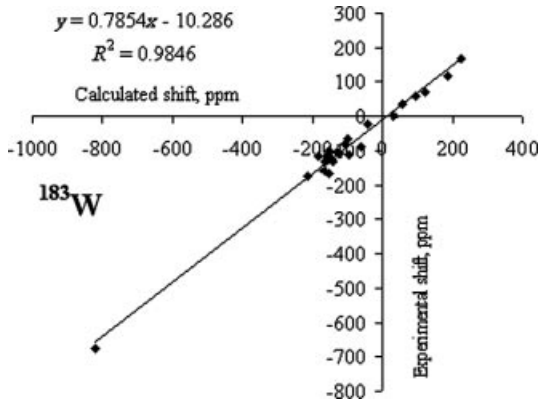

Figure 3. Correlation of the experimental and calculated $^{183}W$ NMR chemical shifts.

### The $^{17}O$ NMR Chemical Shift

The $^{17}O$ NMR shifts depend strongly on the type of bonding (terminal or bridging) and the calculated values follow the experimental trend well (Table 2). A comparison of the calculated and experimental chemical shifts shows that the magnitude of the calculated shifts is overestimated for the bridging oxygen atoms and slightly underestimated for the terminal ones (Figure 4).

In the cases where the POT contains equal numbers of slightly different bridging oxygen atoms it is impossible to assign closely spaced resonances unequivocally in the experimental spectra. However, according to the calculations, the larger chemical shift for $CH_3OTiW_5O_{18}^{3-}$ ($\delta$ = 390 ppm) can be assigned to the bridging oxygen, $O_c$, linking two different tungsten atoms, and that at $\delta$ = 380 ppm to $O_e$ (Table 2).

In the case of $W_{10}O_{32}^{4-}$, according to the calculations the two resonances at $\delta$ = 434 and 421 ppm observed in the experimental NMR spectrum should be attributed to the bridging oxygen, $O_c$, which links $W_a$ and $W_b$ and $O_d$, which is bound to two identical $W_b$ lying in a square plane. For the oxygen atoms ($O_e$) in the linear bridges the calculated shift is the lowest, although it is observed between $O_c$ and $O_d$ in the experimental spectrum.

The bridging oxygen atoms in the Keggin anions $XW_{12}O_{40}^{n-}$ give two closely spaced resonances with equal intensity in the range $\delta$ = 440–390 ppm. Using a special method, which involves replacing three tungstens by molybdenum atoms, Shum and Klemperer[43b] have shown that the line with the larger chemical shift is due to the edge-sharing oxygens ($O_b$). According to the DFT calculations, the resonance with the larger chemical shift should be assigned to the edge bridging oxygen atoms $O_b$, which fully confirms the conclusions drawn from the experiment.

The rotation of a triplet in β-$SiW_{12}O_{40}^{4-}$ should formally result in the inequivalence of the oxygen atoms, with a corresponding weight ratio (according to the atom labels) of 3:6:3 for the terminal oxygen atoms and 3:6:3:3:6:3 for the bridging ones. However, only four lines are observed in the $^{17}O$ NMR spectrum, which were assigned[43b] as follows: the highest chemical shift was assigned to the terminal oxygen atoms, the line with intensity 3 to the edge-bridging $O_c$ in the six-membered ring, the line with intensity 9 to the edge-bridging $O_b$ and $O_f$, the line with intensity 12 to the corner bridging $O_a$, $O_d$, and $O_e$, and, finally, the less-intense line was assigned to the internal oxygens $O_g$ and $O_h$. Our

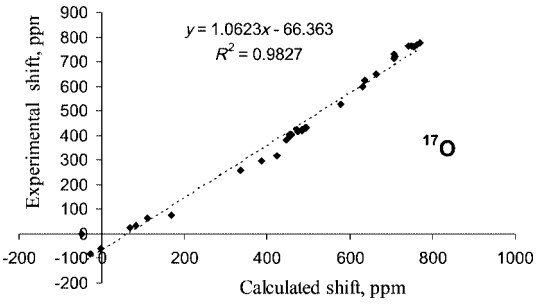

Figure 4. Correlation of the experimental and calculated $^{17}O$ NMR chemical shifts.

calculations fully confirmed the observed pattern, with the largest chemical shift for the bridging oxygen atoms $O_c$ in the ring.

For $W_7O_{24}^{4-}$ the range of the $^{17}O$ NMR chemical shifts is fairly well reproduced by the calculations; a possible assignment of the lines is given in Table 2.

In general, a rather good linear correlation between the calculated and experimental $^{17}O$ NMR chemical shifts for POTs may be seen in Figure 4.

### General Results

Taking into account all the calculated values for both $^{183}W$ and $^{17}O$ NMR chemical shifts, we have obtained good correlations between calculated and experimental values even though the NMR spectra were measured in different solvents in some cases. This shows that calculations adequately reflect the changes in chemical shifts depending on the structure. The discrepancies observed in some cases may result from the inadequacy of the optimized geometry, and the deviation of the slope from unity may be due to the basis sets used in the calculations.

## Discussion

According to the present calculations the diamagnetic shielding (Tables 1 and 2) for both $^{183}W$ and $^{17}O$ is essentially unaffected by the geometry (the chemical environment). This can be understood from the fact that the diamagnetic shielding contains the unperturbed, zero-order density. The largest contributions are due to the core shells at $^{183}W$ and $^{17}O$ nuclei. Such core shells should not change on going from one chemical environment to another and therefore yield constant diamagnetic shielding contributions that cancel out in relative chemical shifts. Thus, we will consider only the paramagnetic contribution. In the following sections we discuss the analysis of the paramagnetic shielding tensors in a gauge-including atomic orbitals (GIAO) basis where a gauge-origin independent division into a paramagnetic and a diamagnetic contribution can be achieved.[26c]

### The $^{183}W$ Paramagnetic Shielding

The paramagnetic contribution is determined by the magnetically perturbed MOs,[10] while the most important one is considered to be due to the coupling of the occupied ($\Psi_a$) and virtual ($\Psi_i$) MOs under the applied magnetic field. The magnitude of the coupling coefficients, $u_{ai}$, are given as[10]

$$u_{ai} \approx -\frac{1}{2(\varepsilon_i^0 - \varepsilon_a^0)}\langle \Psi_i | M | \Psi_a \rangle$$

where $\varepsilon_i^0$ and $\varepsilon_a^0$ are the orbital energies of the virtual and occupied MOs. We will refer to the "u-tensor" in conjunction with nuclear shielding contributions arising from these coefficients and note that inverse occupied–virtual MO energy differences enter these terms. Thus, common knowledge often relates the magnitude of the paramagnetic shielding to the size of the HOMO–LUMO gap, for example.

The paramagnetic shielding is determined by the sum of all magnetically active transitions and by atomic orbital coefficients forming the corresponding MOs. For the large anions, which consist of tungsten and oxygen atoms, so many MOs are formed that it is rather difficult to show which transitions are the most important in the paramagnetic shielding. However, a preliminary analysis of the paramagnetic shielding for $W_6O_{19}^{2-}$ shows that the largest contributions (about 15%) come from two transitions from rather deep bonding MOs ($5t_{1g}$), involving p and d orbitals of the bridging oxygen and tungsten atoms, respectively, not to the LUMO but to upper virtual orbitals ($a_{1g}$ and $e_g$), consisting of W-$d_{z^2}$ and p- and s-oxygen orbitals. Moreover, terms involving pairs of occupied orbitals should be also taken into account. In the paramagnetic shielding, this is a term, from now on dubbed "*s*-tensor", that is specific to the computation of the nuclear shielding in a GIAO basis, where the external magnetic field will change the overlap between the basis functions (atomic orbitals or AOs). In the case of $^{183}W$ shielding it can attain 15% of the total paramagnetic term, which is mostly due to the occupied–virtual transitions ("*u*-tensor"). For the paramagnetic contribution of the terminal oxygen atom in the case of the Lindqvist anion, for example, 163 occupied–occupied ("*s*-tensor") and 238 occupied–virtual (*u*-tensor) couplings should be taken into account, and for the latter less than 50 transitions exceed 10 ppm. For the bridging oxygen the number of transitions increases to 488 and 744, respectively, and some transitions contribute with opposite signs.

Two points should be mentioned. First of all, the lowest charge transfer, determined as the HOMO–LUMO gap, $E_{LCT}$, is by no means the principal contributor otherwise we should observe a correspondence between $1/E_{LCT}$ and the $^{183}W$ chemical shifts (see Table S2 in the Supporting Information). Usually, the HOMO is a nonbonding orbital consisting of the p-orbitals of the bridging oxygen atoms, especially of the inner oxygen atoms, and even for simpler complexes the transitions from deeper MOs, involving several metallic orbitals, make the largest contributions.

As already mentioned, the paramagnetic shielding includes not only the *u*-term, which involves the occupied and virtual MO coupling and plays a dominant role in the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

change of the chemical shift, but also the occupied–occupied MO coupling (*s*-tensor) and additional "paramagnetic gauge terms". The latter are also related to the GIAO formalism (they are negligibly small in the present study, see discussion on the components of the paramagnetic shielding[44] and Table 3). In frozen-core calculations there is, in addition, a frozen-core term (dubbed "*b*-tensor" here) that stems from the change of the valence-core orthogonalization under the external magnetic-field perturbations. As for POTs, the magnitudes of the changes in the *s*- and *b*-tensors may be comparable with the *u*-term and therefore they demand more consideration in detail:

1. For anions with octahedra having only *edge-shared* oxygen atoms (the first four, Figures 1a–c) and the internal oxygen linking six and five tungsten atoms, for a span of the experimental shifts of 334 ppm (span of the calculated shifts: 380 ppm), increasing the mean $R_{WO}$ results in a negative shift (–135 ppm) due to the *b*-term but in positive shifts due to the *s*-term (338 ppm) and the *u*-term (only 210 ppm). The total shift therefore increases with $R_{WO}$.
2. As opposed to the Lindqvist-type anions, α-Keggin anions (Figure 1d), with their narrow range (89 ppm) of calculated shifts (66 ppm for experimental ones), and with two corner and two edge-shared oxygen atoms and the inner oxygen linking three W atoms and the central atom, an increase of the mean $R_{WO}$ in the optimized structures corresponds to a general decrease of the chemical shift due to a decrease in the *b*-term (213 ppm) and the *u*-term (277 ppm; both of which correspond to an increase in the chemical shift), which is outweighed by the negative shift due to the *s*-term (–579 ppm); a fine interplay of these components therefore determines the total chemical shift.

For the β-γ Keggin isomers and $P_2W_{18}O_{62}^{6-}$ a decrease of the *b*-term from 237 to 8 ppm ($\Delta$ = –229 ppm) and the *u*-term from –6534 to –6999 ppm ($\Delta$ = –465 ppm, for a total of –694 ppm) is close to the increase of the *s*-term from –521 to 134 ppm ($\Delta$ = 655 ppm).

The second point is that the absolute values of the *s*-term for the Lindqvist-type anions are almost twice as large as for the Keggin anions. On the other hand, the pentacoordination of $W_a$ in γ-$SiW_{12}O_{40}^{4-}$ (Table 3, Figure 1e) results in a rather small magnitude of the *s*-term; this is probably characteristic for pentacoordination.

It is noteworthy that the *u*-term for $W_a$ in $P_2W_{18}O_{62}^{6-}$ is the lowest of all $WO_6$ octahedra, which is difficult to explain as the local symmetry around $W_a$ is almost the same as in the Keggin system. However, despite substantial differences in the components of the paramagnetic shielding, the calculated $^{183}W$ chemical shifts for the Keggin anion and for $W_a$ of the Dawson anion proved to be almost the same, reflecting the similarity of the local geometry.

Some unusual values of the *b*- and *u*-terms for the Dawson anion may be explained by the correlations of the *b*- and *s*- against the *u*-term as the largest component (anions α-$XW_{12}O_{40}^{n-8}$, β-$SiW_{12}O_{40}^{4-}$, γ-$SiW_{12}O_{40}^{4-}$, $X_2W_{18}O_{62}^{6-}$) shown in Figure 5. It is clearly seen that three components are interrelated, but only for similar types of anions.

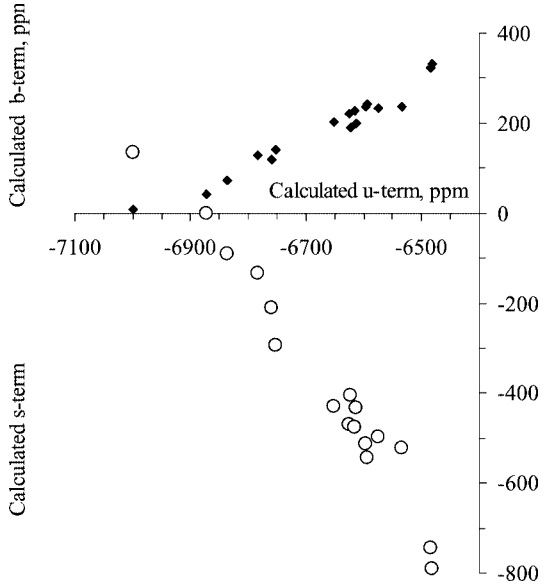

Figure 5. Interrelation between paramagnetic *u*- and *b*- (♦) and *s*- (○) terms for POTs (α-$XW_{12}O_{40}^{n-8}$, β-$SiW_{12}O_{40}^{4-}$, γ-$SiW_{12}O_{40}^{4-}$, $X_2W_{18}O_{62}^{6-}$).

In general, we can observe that increasing $R_{WO}$ results in a corresponding absolute increase in the *u*-term (the more negative the shielding the more positive the chemical shift)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

determined by the occupied–virtual MO transitions (see Figure S1 in the Supporting Information) That, in turn, depends on the bonding system (edge, corner, inner oxygen atoms, and angles between bonds) and determines the change of the *b* and *s* shielding components. In any case, the *s*-term changes in a broader range than the *u*-term, which is usually considered as the most important. For POTs, where tungsten is surrounded only by oxygen atoms as ligands, we can suggest that the change of the chemical shift is determined by the total paramagnetic contribution, in which the occupied–occupied transitions have proved to be the most important, and a fine interplay of the components (*s*- and *u*-terms) of the paramagnetic shielding variable in quite a large range will determine the total chemical shift. Nevertheless, the calculation adequately represents the general trend in the chemical shifts.

It should be noted that the *u*- and *s*-terms decrease with $R_{WO}$ for the anions built with octahedra linked by edge-shared oxygens and therefore a close correlation between the experimental shifts and the sum of the inversed energies of the electronic transitions between d and d* orbitals calculated by the EHMO method is observed.[8]

### The $^{17}O$ Paramagnetic Shielding

For the terminal oxygen atoms the *s*-term makes no more than 5% contribution to the paramagnetic *u*-term and the core *b*-term is much lower (Table 4). For the inner oxygen the *s*-term may reach 30% and moreover is of opposite sign, therefore it makes a sizeable contribution. Only for $W_6O_{19}^{2-}$ is the *s*-term for $O_c$ negative as it binds six tungsten atoms. For $W_{10}O_{32}^{4-}$, where the inner oxygen atoms $O_f$ bind five W atoms, and for $O_d$ in the Keggin anion, which binds four atoms, the *s*-term becomes positive.

Table 4. Components of the $^{17}O$ paramagnetic shielding for some POTs.

| Anion | Atom | *b*-term [ppm] | *s*-term [ppm] | *u*-term [ppm] | PGT [ppm] | $R_{W-O}$ av. [Å] |
|---|---|---|---|---|---|---|
| $W_{10}O_{32}^{4-}$ | $O_a$ | 1 | –36 | –787 | 1 | 1.756[a] |
| | $O_c$ | –2 | –9 | –596 | –15 | 1.938, 1.969[a] |
| | $O_f$ | –7 | 114 | –276 | 8 | 2.288, 2.354[a] |
| | $O_b$ | 0 | 7 | –868 | –2 | 1.739[b] |
| | $O_d$ | –3 | –7 | –594 | –5 | 1.942[b] |
| | $O_e$ | –4 | –82 | –521 | 7 | 1.923[b] |
| $W_6O_{19}^{2-}$ | $O_a$ | 1 | –1 | –880 | 0 | 1.730 |
| | $O_b$ | –2 | –15 | –573 | –7 | 1.953 |

| | $O_c$ | –4 | –23 | –556 | 2 | 1.930 |
| | $O_d$ | –8 | 121 | –355 | 23 | 2.469 |

[a] Distance to $W_a$. [b] Distance to $W_b$.

Depending on the type of oxygen atom (corner- or edge-shared), the absolute value of the *s* component is larger for the corner one. However, because the bond length in corner sharing is usually shorter than that for an edge-sharing oxygen, the absolute *u*-term is less, making more negative shift for the corner oxygen that links two equivalent tungsten atoms having the same chemical shift. If it binds two tungsten atoms with different chemical shifts (as $O_c$ in $W_{10}O_{32}^{4-}$), the magnitude becomes unpredictable.

However, from Figure 6 (taking into account data for anions $W_6O_{19}^{2-}$, $W_{10}O_{32}^{4-}$, $CH_3OTiW_5O_{18}^{3-}$, α-$PW_{12}O_{40}^{3-}$, α-$SiW_{12}O_{40}^{4-}$, and β-$SiW_{12}O_{40}^{4-}$) the interrelation between the *u*-term and the *s*-term for three types of oxygen atoms − terminal, bridging, and inner − is clearly seen. A certain similarity between this plot and the one given in Figure 5 may be noted.

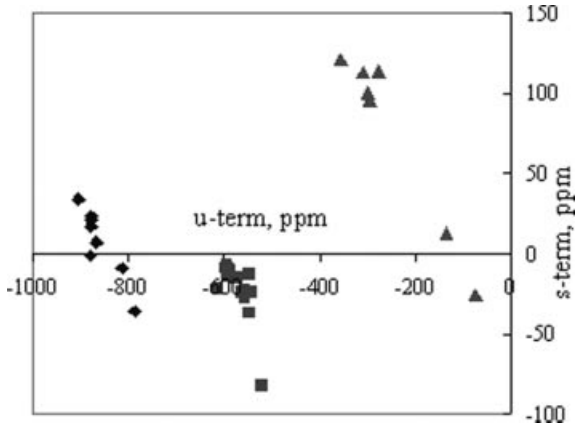

Figure 6. Interrelation of the *u*- and *s*-terms in the $^{17}O$ paramagnetic shielding for POT. ♦: terminal oxygen atoms; ■: bridging oxygen atoms; ▲: inner oxygen atoms.

For all POTs the most deshielded ones proved to be the terminal oxygen atoms. Although the shorter bond length leads to increased $\Delta E$, it is possible that an increase of the numerator exceeds the effect of decreasing $1/\Delta E$ (see formula above).

## Conclusions

Having considered the results of calculations of the $^{183}W$ and $^{17}O$ NMR chemical shifts we can come to the following conclusions: 1) Generally, the calculations reproduce the patterns of the chemical shifts for both nuclei for several types of tungsten and oxygen atoms. However, when the range of the chemical shifts is rather narrow, prediction of the chemical shifts will depend on the chosen geometric parameters, and a fine interplay of the different components of the paramagnetic shielding may result in discrepancies between the calculated and experimental chemical shifts, as, for example, for γ-$SiW_{12}O_{40}^{4-}$. 2) The accuracy of the calculated chemical shifts is far from what would be desirable and, in principle, a complete compatibility between calculated and observed chemical shifts is still not possible for such polyoxotungstate complexes because of inaccuracies in the geometric characteristics obtained by X-ray diffraction studies. Sometimes, even for rather simple peroxotungstates with overall $C_2$ symmetry, two tungstens are crystallographically not identical and their different local geometry may

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

easily give rise to differences of 200 ppm or more in the calculated chemical shifts. Therefore, for sake of consistency, the optimized structures, despite some inadequacy, may be an adequate approach for the calculation of the NMR shielding. 3) For POTs consisting of tungsten and oxygen atoms the change in the chemical shifts is determined by an interplay of the components of the paramagnetic shielding, in which the main contributor has been shown to be the *s*-term (the occupied–occupied MO coupling) along with the change in the *u*-term (the occupied–virtual MO transitions). Apparently, such a behavior of the paramagnetic shielding is characteristic, as shown by our preliminary results, for other polyoxometalates involving vanadium or molybdenum. 4) From the accumulated data the reverse task may, in principle, become possible, namely deducing the geometry from the observed chemical shifts, if the nature of the nuclear shielding is completely understood. 5) At present, the reliable assignment of the several resonance lines observed in the NMR spectra to specific atoms may be made only in the case of widely separated NMR shifts. The fine details of the anion geometry must therefore be taken into account to be able to assign the resonances correctly. 6) It is rather well known[10,11,45] that taking into account the spin-orbit coupling during calculation of the chemical shift of heavy elements notably increases the correspondence between the calculated and experimental shifts. This is especially true when the ligands around the coordinating cation are quite different and heavy. However, although our preliminary calculations for POTs where the ligand atoms are only oxygen atoms, obtained by including the SO coupling term, give slightly more reasonable values in terms of magnitude, they do not give the correct order of the resonances for the Keggin anions and even violate the sequence of the lines for β- and γ-$SiW_{12}O_{40}^{4-}$.

Thus, to improve the accuracy of computed NMR chemical shifts in polyoxometalates is not simple and will require effort in several areas, most notably to incorporate exact exchange functionals in the DFT calculations, to consider the spin-orbit coupling, and to use larger basis sets. The reader must bear in mind that the calculation of the shielding tensors for *one* atom of the Dawson anion $P_2W_{18}O_{62}^{6-}$ needs more than ten days of computer time.[46] Therefore, it will be necessary to further improve the codes of NMR calculations for large systems, and probably for clusters with relatively large *q*/*m*, where *q* is charge and *m* the number of metals, to introduce the effect of the solvent.[47]

**Supporting Information** (see also footnote on the first page of this article): Influence of the geometric parameters on calculated shieldings for $W_6O_{19}^{2-}$ and HOMO–LUMO separation for several POTs are given in Tables S1 and S2. The correlation between calculated paramagnetic shielding and mean bond length, $R_{W-O}$, in Keggin anions is given in Figure S1.

# DFT Calculations of the $^{183}W$ NMR Chemical Shifts in Reduced Polyoxotungstates

**Jose Gracia,[a] Josep M. Poblet,*[a] Jorge A. Fernández,[a] Jochen Autschbach,[c] and Leonid P. Kazansky*[b]**

**Keywords:** Density-functional calculations / NMR spectroscopy / Tungsten / Oxygen / Polyoxometalates

A relativistic DFT method (ZORA) is used to calculate the $^{183}W$ and $^{17}O$ NMR chemical shifts for the reduced polyoxotungstates $W_5O_{18}W^{II}NO^{3-}$, $\gamma$-$SiW_{12}O_{40}^{6-}$, $P_2W_{18}O_{62}^{8-}$, and $W_{10}O_{32}^{6-}$ with different degrees of (de)localization of the electrons introduced. Despite some discrepancies in the calculated and experimental data, the calculations adequately describe the changes in the chemical shifts upon reduction. The reduction of a fully oxidized anion is accompanied by an expansion of the geometry. The effect of the charge localization and change in geometry on the chemical shift is evaluated. The shift of the resonance of the tungsten atoms largely depends on the reduced charge acquired upon reduction. On the other hand, those tungsten atoms that do not increase the electron density upon reduction have a negative shift. The calculations also reproduce the negative shifts of all the $^{17}O$ NMR resonances upon reduction of the polyoxotungstates.

## Introduction

Because of the well-known ability of polyoxometalates (POM) consisting of $V^V$, $Mo^{VI}$, and $W^{IV}$ to be reversibly reduced by one, two, or more electrons, they have attracted much attention in catalysis and other fields where redox reactions are quite important.[1–4] Depending on the molecular structure, electrons delocalize over the whole of the coordination sphere or just a part of it. EPR[1,5,6] and, subsequently, $^{17}O$ NMR spectroscopy[7] have proved that a single electron can be delocalized and that this delocalization can be "frozen out" at quite low temperatures (several degrees kelvin).

The second electron introduced by a certain mechanism generally pairs with the first one. $^{17}O$ NMR[7,8] and then $^{183}W$ NMR[9–11] spectroscopy have shown that the electron pair formed is completely delocalized in the Keggin anion $SiW_{12}O_{40}^{6-}$, partly in the Dawson anion $P_2W_{18}O_{62}^{8-}$, in $W_{10}O_{32}^{6-}$ or $\gamma$-$SiW_{12}O_{40}^{6-}$, and resides completely on specific atoms in $\gamma$-$SiW_{10}W^V_2S_2O_{38}^{6-}$,[12] $\gamma$-$SiMo^V_2W_{10}O_{40}^{6-}$,[10] and $P_2W_{15}Mo_3O_{62}^{8-}$ (delocalization of the electron pair over three Mo atoms),[13] or, in the case of six electrons, in $XW_9W_3^{IV}O_{40}H_6^{x-}$ (localization of six electrons in triplet forming metal–metal bonding).[14,15] In some specific cases, the introduction of two electrons entails the localization of one electron on one atom while the second electron partially delocalizes over the tungsten atoms adjacent to the first reduced atom (for example $P_2W_{17}Mo^VO_{62}^{8-}$).[13]

Several cases, however, should be considered separately. In the nitrosyl complexes $W_5O_{18}W^{II}NO^{3-}$ with the Lindqvist-type structure,[16] $PW_{11}W^{II}NO_{40}^{8-}$, and the corresponding Ru complexes with the Keggin structure,[17–19] the electron density of the cation introduced delocalizes onto the neighboring tungsten atoms.

In all the examples mentioned above, the degree of delocalization was monitored by NMR spectroscopy and estimated by the characteristic positive shift of the resonance lines attributed to the tungstens accepting the electron density. At the same time, some resonances undergo negative shift which, depending on the structure and position of the most important atom in it, may be rather significant.

In this paper we report DFT calculations of the $^{183}W$ and $^{17}O$ chemical shifts for several reduced POMs.

## Computational Details

We used the ADF 2003.01 package[20] to compute the geometries of the molecules reported here. The density-functional theory (DFT) calculations are characterized by the local density approximation featuring the *Xa* model for exchange with Becke's gradient-corrected functional,[21] and the VWN parameterization for correlation[22] corrected

with Perdew's functional.[23] The basis functions for describing the valence electrons of all the atoms are Slater-type orbitals of triple-ζ+ polarization quality. The internal or *core* electrons are described by means of single Slater functions and were generated with the auxiliary program DIRAC.[20] Quasi-relativistic corrections − *zeroth-order relativistic approximation* (ZORA) − were performed with corrected core potentials. The NMR shielding tensors were computed from a parallel version of the NMR module.[24]

The calculated chemical shift, $\delta_{cal}$, is determined as the difference between total shielding of the reference molecule, $\sigma_r$, and the shielding, $\sigma_x$, of the molecule being studied:

$\delta_{cal} = \sigma_r - \sigma_x$

For each nucleus, the total shielding tensor, $\sigma_t$, is calculated as the sum of the paramagnetic ($\sigma_p$) and diamagnetic ($\sigma_d$) contributions. The simplest oxoanion, $WO_4^{2-}$, is usually used as a reference for $^{183}W$ NMR spectroscopy (calculated $\sigma_t$ is 2663 ppm).[25] The $^{17}O$ NMR chemical shift is measured relative to pure water ($\delta$ = 0 ppm) for which the absolute shielding, $\sigma_t$, is 291 ppm.[26]

It is well known that when electrons are added to the structure the framework swells somewhat (i.e. some bonds are elongated).[15,27–30] Thus, in all cases, for both the parent oxidized POM and its reduced counterparts, the structures used were the optimized ones before and after the two electrons had been introduced.

## Results and Discussion

### $W_5O_{18}WNO^{3-}$

This anion is a derivative of the Lindqvist anion that contains one tungsten atom in the formal oxidation state 2+ with an NO group in place of the terminal oxygen atom. Formally, NO has a charge of 1+.[16] The oxidized anion has no counterpart and for purposes of comparison the Lindqvist anion is used. Although the X-ray geometry of this anion was not determined because the lattice cells are very similar, the atomic coordinates were inferred from the general description of the related anion $Mo_5O_{18}MoNO^{3-}$ and by comparison with the Lindqvist molybdate and tungstate anions. The symmetry of the anion is $C_{4v}$, which leads to three types of tungsten atoms (Figure 1). Three resonances are observed in the $^{183}W$ NMR spectrum with an intensity ratio of 1:4:1, the first of which is substantially shifted to low field (Table 1) and assigned to the reduced tungsten linked to NO. It should be noted that the experimental shift for $W_c$ is markedly lower than the expected one for a $W(d^4)$ configuration. Due to the back-donation from tungsten to the nitrosyl group less electron density is left on tungsten, which results in a smaller chemical shift. The $^{183}W$ and $^{17}O$ NMR chemical shifts calculated for the optimized structure are given in Table 1.

The calculations correctly describe the pattern of the $^{183}W$ chemical shifts, although the value for $W_c$ is considerably underestimated. The HOMO with *e* symmetry shows a π interaction between the W metal and the NO group (see Figure 1).

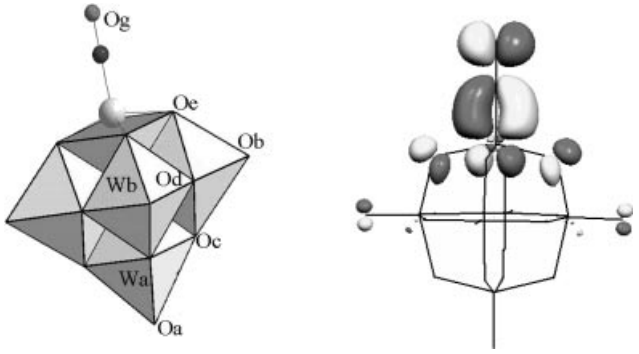

Figure 1. Structure and HOMO of $W_5O_{18}WNO^{3-}$.

Table 1. Calculated parameters and experimental $^{183}W$ and $^{17}O$ NMR shifts for $W_5O_{18}WNO^{3-}$.

| | $W_c$ | $W_b$ | $W_a$ | $O_a$ | $O_b$ | $O_c$ | $O_d$ | $O_e$ | $O_f$ |
|---|---|---|---|---|---|---|---|---|---|
| $\delta_{cal}$ [ppm] | 488 | 225 | 197 | 699 | 717 | 456 | 438 | 517 | –27 |
| $\delta_{exp}$ [ppm] | 653 | 168 | 117 | 728 | 734 | 402 | 399 | 448 | |

The $^{17}O$ NMR chemical shifts calculated for several oxygen atoms enable the lines observed for both the terminal and bridging ($O_c$ and $O_d$, respectively) atoms to be assigned. It should be pointed out that the chemical shift for the bridging $O_e$ is larger than for the other bridging atoms. This may be due to an interaction with the cation with the lowest oxidation state ($W_c$)[16] or the influence of the passing electron density. However, the oxygen atoms of this type have a higher shift[25] in $CH_3OTiW_5O_{18}^{3-}$, where no delocalization occurs. It should be noted that, as before, the chemical shifts calculated for the bridging oxygen atoms are overestimated and for the terminal ones they are underestimated.[25] Nevertheless, if compared with $W_6O_{19}^{2-}$, the computed $^{17}O$ chemical shifts correctly represent the marked decrease in the experimental shifts for all the oxygen atoms in $W_5O_{18}W_cNO^{3-}$.

### γ-$SiW_{12}O_{40}^{n-}$

The structure of this anion, determined by Tézé et al.,[10] is the result of two triplet groups ($W_a$–$W_b$–$W_b$) rotated by 60° along two $C_3$ axes of the Keggin anion (Figure 2). This structure gives rise to four resonances with a 2:1:2:1 intensity pattern. The most shielded atoms in the $^{183}W$ NMR spectrum proved to be the $W_a$ tungstens in rather a peculiar position (Table 2).[10]

According to the $^{183}W$ NMR spectrum, the two-electron-reduced form reveals an uneven distribution of the electron density over the coordination sphere. The most deshielded atoms proved to be $W_d$, which acquire the largest portion of the electron density, and the least shielded are $W_c$. Experimentally, the assignment of the resonance lines for the reduced species is ambiguous because the quality of the spectrum did not allow the spin–spin coupling to be determined. However, the present calculations unambiguously show that $W_d$ is reduced first because the LUMO that acquires two electrons mainly consists of $W_d$ $d_{xy}$ orbitals and,

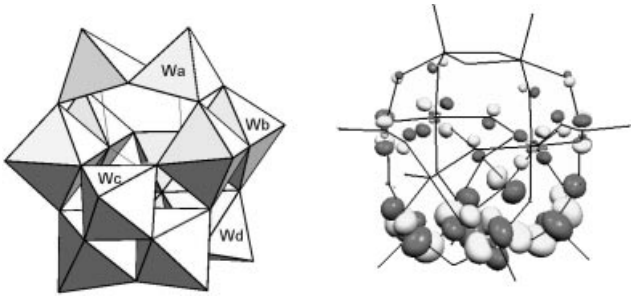

Figure 2. Structure and HOMO of the two-electron-reduced $\gamma$-$SiW_{12}O_{40}^{6-}$.

Table 2. Calculated and experimental $^{183}W$ NMR chemical shifts [ppm] for the oxidized $\gamma$-$SiW_{12}O_{40}^{4-}$ and 2e-reduced $\gamma$-$SiW_{12}O_{40}^{6-}$ anions.

| | $W_a$ | $W_b$ | $W_c$ | $W_d$ |
|---|---|---|---|---|
| $\delta^{ox}{}_{exp}$[a] | –160 | –105 | –117 | –127 |
| $\delta^{ox}{}_{cal}$[b] | –170 | –130 | –184 | –158 |
| $\delta^{red}{}_{exp}$[a] | –131 | –63 | –124 | 489 |
| $\delta^{red}{}_{cal}$[b] | –47 | –2 | –65 | 471 |
| $\delta^{*}{}_{cal}$[c] | –63 | –63 | –98 | –32 |
| $\Delta\delta_{geom}$[d] | +107 | +67 | +86 | +126 |
| $\Delta\delta_{elect}$[d] | +16 | +61 | +33 | +503 |

[a] Observed NMR chemical shifts for the fully oxidized ($\delta^{ox}{}_{exp}$) and 2e-reduced ($\delta^{red}{}_{exp}$) anions. [b] Computed NMR chemical shifts for the fully oxidized ($\delta^{ox}{}_{cal}$) and 2e-reduced ($\delta^{red}{}_{cal}$) anions in their optimal structures. [c] $\delta^{*}{}_{cal}$ is the shift computed for the oxidized anion but with the structure of the reduced anion. [d] $\Delta\delta_{geom} = \delta^{*}{}_{cal} - \delta^{ox}{}_{calc}$ represents the shift induced by the geometrical change and $\Delta\delta_{elect} = \delta^{red}{}_{cal} - \delta^{*}{}_{calc}$ the shift resulting from the incorporation of the electron density in the already deformed anion (see text for more details).

to a lesser extent, $W_b$ tungsten atoms; $W_a$ and $W_c$ are reduced afterwards. Nevertheless, in the observed spectrum of the reduced anion one of the resonance lines ($\delta$ = –131 ppm) is negatively shifted with respect to the lines of the oxidized anion. The notable positive calculated shifts (>100 ppm) of the lines assigned to $W_a$ and $W_c$ for the reduced anion will be discussed below.

It should also be noted that, despite an increase in the electron population on the reduced tungsten, the diamagnetic shielding does not differ much ($\delta$ = 5 ppm) from the diamagnetic shielding for nonreduced tungstens.

## $P_2W_{18}O_{62}^{6-}$

This is the largest anion considered in this paper (Figure 3). Its $^{183}W$ NMR spectrum completely corresponds to the two expected resonance lines with an intensity ratio of 1:2, the first of which is assigned to the cap tungsten atoms ($W_a$) (Table 3).[9] It should be noted that $W_b$ is linked to other tungsten atoms with three corner- and one edge-shared oxygen atoms, unlike $W_a$, which is linked by two corner- and two edge-shared oxygen atoms as in the Keggin anion.

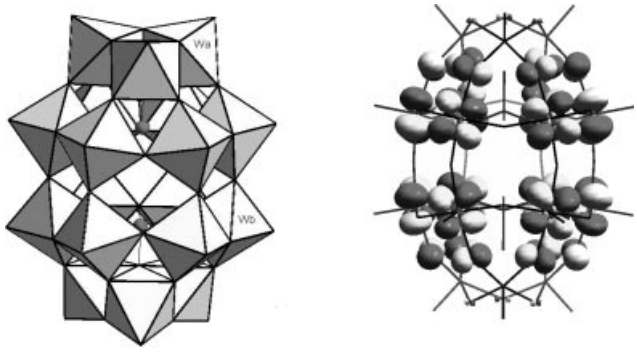

Figure 3. Structure and HOMO of the two-electron-reduced $P_2W_{18}O_{62}^{8-}$.

Table 3. Calculated and observed $^{183}W$ NMR chemical shifts [ppm] for the oxidized $P_2W_{18}O_{62}^{6-}$ and 2e-reduced $P_2W_{18}O_{62}^{8-}$ anions.[a]

| | $W_a$ | $W_b$ |
|---|---|---|
| $\delta^{ox}{}_{exp}$ | –127 | –173 |
| $\delta^{ox}{}_{cal}$ | –146 | –215 |
| $\delta^{red}{}_{exp}$ | –299 | –51 |
| $\delta^{red}{}_{cal}$ | –193 | –143 |
| $\delta^{*}{}_{cal}$ | –105 | –134 |
| $\Delta\delta_{geom}$ | 41 | 81 |
| $\Delta\delta_{elect}$ | –88 | –9 |

[a] See Table 2 for definitions of the chemical shifts.

Reducing the anion with two electrons completely delocalizes the electron pair over 12 $W_b$ atoms. As shown by different calculation approaches, the HOMO (Figure 3), which contains two electrons, is composed of symmetry-adapted $W^5$ $d_{xy}$ orbitals of the belt tungsten atoms $W_b$. This is clear from the marked positive shift of the more intense resonance line. At the same time, the resonance assigned to the cap tungsten atoms $W_a$ undergoes a substantial negative shift.

Despite the notable discrepancy between the calculated and experimental chemical shifts, and although the calculated absolute shifts upon reduction are markedly less than the observed ones (Table 3), the DFT calculation adequately reflects how the chemical shifts tend to change upon reduction.

## $W_{10}O_{32}^{4-}$

Like the Dawson anion $P_2W_{18}O_{62}^{6-}$ considered above, this decatungstate may be viewed as a combination of two fragments of the initial anion, in this case the Lindqvist anion (Figure 4). $W_{10}O_{32}^{4-}$ also gives two resonance lines in the $^{183}W$ NMR spectrum at $\delta$ = –23 and –165 ppm, with an intensity ratio of 4:1, both of which are shifted to high field with respect to the parent anion ($\delta$ = +59 ppm).[11] In contrast to the Dawson anion, two-electron reduction of $W_{10}O_{32}^{4-}$ induces positive shifts in both resonances. However, the second line shifts by only 16 ppm, while the first one shifts by 330 ppm, strongly indicating that the electron pair is delocalized over eight tungsten atoms of the $W_b$ type.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

This is also confirmed by the nature of the HOMO, which consists of symmetry-adapted $d_{xy}$ orbitals of $W_b$ (Figure 4).

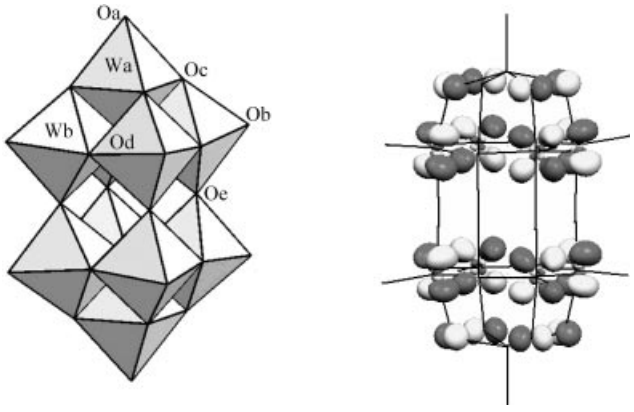

Figure 4. Structure and HOMO of the two-electron-reduced $W_{10}O_{32}^{6-}$.

A slight positive shift in the line assigned to $W_a$ might indicate the delocalization of electron density on these atoms, as was observed in $\gamma$-$SiW_{12}O_{40}^{6-}$. However, this may be misleading. We should bear in mind that when an anion is reduced, it "swells" because the bond lengths increase. According to the X-ray structure determination of the oxidized and reduced species[30] of the decatungstate, both types of $WO_6$ octahedron increase in size slightly, which is confirmed by the structures computed for oxidized and reduced anions. The geometry changes most in the belt octahedra (see the bond lengths in Table 4).

Table 4. Observed and calculated NMR shieldings for $W_{10}O_{32}^{n-}$.[a]

[a] See Table 2 for definitions of the chemical shifts.

The calculated charge on the $W_b$ atoms decreases upon reduction, and there is practically no change in $W_a$.[31] In other words, the positive shift for $W_a$ is caused by a geometrical change in the cap octahedron due to the reduction of the vicinal tungstens.

Unlike in the $^{183}W$ NMR spectrum, all the $^{17}O$ NMR resonances shift to high field upon reduction. These negative shifts may be the result of the delocalization of the electron density, the shielding of the nuclei, or the exclusion of the HOMO (LUMO before reduction) from the transitions that determine the paramagnetic term. From the calculated charges, only the $O_c$ atoms seem to reveal some increase in their negative charge upon reduction. Thus, the substantial negative shifts may be assumed to be due to an increase in the paramagnetic shielding. It should be noted that the $^{17}O$ resonance line assigned to the $O_e$ linking two fragments undergoes the least negative shift, despite delocalization of the electron pair over $W_b$. Once again, if the shifts calculated for $W_{10}O_{32}^{4-}$ and $W_{10}O_{32}^{6-}$ are compared using the geometry for the reduced anion, we see that the decrease in the shifts is larger.

It should be noted that despite localization of the electron density over the eight $W_b$ atoms, the terminal oxygen atom $W_a$ feels the presence of the electron pair in the HOMO, which is probably excluded from the principle transitions that determine the paramagnetic shielding. On the other hand, $O_e$ does not react to the presence of the electron density on the nearest $W_b$ tungsten atoms. Presumably because of selection rules, the HOMO does not participate in the transitions that determine the paramagnetic contribution of these oxygen atoms.

Electronic and geometric factors also influence the calculated chemical shifts. For example, the reduction of a tungsten ion *always* induces a positive shift in the $^{183}W$ NMR resonance in polytungstates. The present DFT calculations reproduce this phenomenon fairly well and show that the greater the electron density on a given nucleus the greater the chemical shift. It increases from the Dawson anion (2 e per 12 $W_b$), to decatungstate (2 e per 8 $W_b$), and then to the $\gamma$-Keggin anion (2 e per 4 $W_d$ and partially on another 4 $W_b$).

The incorporation of one electron into a nonbonding metal orbital is associated with a small enlargement in the reduced octahedron. By analyzing the chemical shift in several geometries we managed to separate the electronic factors from the geometric factors causing this positive shift. For some of the anions discussed above we calculated the chemical shifts for the oxidized parent anions but using the optimized geometry for the reduced form. In all cases, substantial positive shifts of the calculated values $\delta^{*}_{cal}$ were found, therefore $\Delta\delta_{geom}$ ($\delta^{*}_{cal} - \delta^{ox}_{cal}$) will be considered as the geometry factor due to the enlargement of the anion as a result of reduction. On the other hand, the shift due to incorporation of the electron density, $\Delta\delta_{elec}$, is given by $\delta^{red}_{cal} - \delta^{*}_{cal}$, where calculated values refer to the optimized structure of the reduced form. The importance of the electronic effect increases as the charge density on the reduced center increases. Hence, in the $\gamma$-$SiW_{12}O_{40}^{6-}$ anion the electronic term for $W_d$ was estimated to be four times larger than the geometric term. For $W_b$ in $W_{10}O_{32}^{6-}$ the two terms are of similar weight. The electronic effect must be much less important in the case of the Dawson anion, where the two extra electrons are shared by 12 centers, therefore the positive shift is due to enlargement of the anion (see Table 3).

We will now discuss the case of $W_{10}O_{32}^{4-}$ in some detail. The 2e-reduction shifts the signal associated to the reduced belt tungstens ($W_b$) by +330 ppm. The corresponding computed value is +290 ppm. By calculating the chemical shift of the oxidized anion with the geometry of the reduced

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

partner, we estimate that the geometrical effect is +150 ppm ($\Delta\delta_{geo}$). Thus, the addition of two electrons to the already adapted (enlarged) framework shifts the signal by a further +140 ppm ($\Delta\delta_{elec}$). For the nonreduced $W_a$, the calculated shift is +97 ppm, a very high value in comparison with the experimental value of +16 ppm. The DFT calculations probably overestimate the deformation of the cap octahedra ($\Delta\delta_{geo}$ = +116 ppm) due to the reduction of a belt site.

As mentioned above, the two added electrons in $\gamma$-$SiW_{12}O_{40}^{6-}$ are shared mainly by four tungstens. Consequently, the electronic term is much more important. $\Delta\delta_{elec}$ for $W_d$ was computed to be +503 ppm, whereas the corresponding $\Delta\delta_{geo}$ contribution is only +126 ppm. As for $W_{10}O_{32}^{4-}$, the relatively large $\Delta\delta_{geo}$ values for the nonreduced centers seem to be the cause of their large positive shift.

Figure 5 compares the calculated and experimental $^{183}W$ chemical shifts for the reduced and parent anions, and gives important data for $W_5O_{18}W_cNO^{3-}$. From the position of the points, it can be assumed that the values calculated for the reduced anions are slightly overestimated, because the linear trend seems to be positively shifted. This shows that the increase in the chemical shifts is not only due to the reduction but also because the additional electrons lead to an enlargement of the structure. The positive shift of 65 ppm of the trend may assume that the optimization of the structure in the reduced state slightly overestimates the bond lengths.

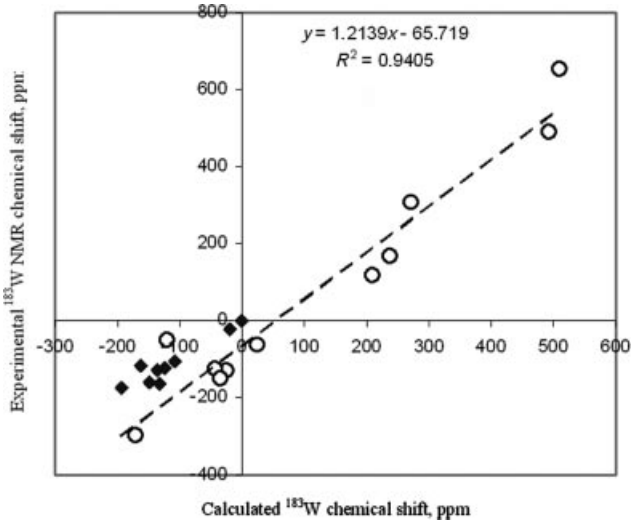

Figure 5. Correlation of the experimental and calculated $^{183}W$ chemical shifts for reduced and parent anions: ♦ oxidized anions, o reduced anions.

Analysis of the transitions responsible for the paramagnetic shielding of different tungsten atoms may clarify the situation for those atoms for which the resonances with less-positive shifts are assigned.

## Conclusions

DFT calculations have been carried out to analyze the effect of reduction on the $^{183}W$ and $^{17}O$ chemical shifts in several prototypic polyoxotungstates. In general, the experimental trends are well reproduced, although significant discrepancies were found between some computed and observed values. This deviation is especially important for the $W^{II}$ ion in the Lindqvist derivative $W_5O_{18}W^{II}NO^{3-}$, probably due to the inability of DFT methods to properly describe the interaction between the $W^{II}$ ion and the NO ligand.

The incorporation of one electron in a nonbonding metal orbital produces an enlargement of the reduced octahedron. By analyzing the chemical shift in several geometries we have been able to separate the electronic factors from the geometric factors that cause the positive shift. The importance of the electronic effect increases with the charge density on the reduced center, hence in the $\gamma$-$SiW_{12}O_{40}^{6-}$ anion the electronic term has been estimated to be three times larger than the geometric term, whereas for $W_{10}O_{32}^{6-}$ the two terms have similar weight. The electronic effect must be much less relevant in the Dawson anion, where the two extra electrons are shared by 12 centers. This means that the small positive shift should be mainly attributed to a change in the geometry as a consequence of the reduction. The present calculations have not allowed us to rationalize the extremely negative shift of the resonance line assigned to the cap $W_a$ in reduced $P_2W_{18}O_{62}^{8-}$.

The $^{17}O$ NMR lines are negatively shifted upon reduction, in contrast to the positive shifts resulting from placing the electron density on the tungsten atoms. The large negative shift of the resonance of $O_a$ in $W_{10}O_{32}^{6-}$, which is rather far away from the delocalized electron pair, is especially surprising. Further analysis of the calculated $^{17}O$ NMR chemical shifts may clarify this situation.

# Iodine Attack on the Metalloligand [{Ti($\eta^5$-$C_5Me_5$)($\mu$-NH)}$_3$($\mu_3$-N)]: Surprising Formation of the [$Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3(NH_3)]^+$ Cation

**Keywords:** Indium / Iodine / N ligands / Nitrido complexes / Titanium

The reactivity of the trinuclear imido-nitrido complex [{Ti($\eta^5$-$C_5Me_5$)($\mu$-NH)}$_3$($\mu_3$-N)] (**1**) and derivatives thereof with iodine has been investigated. Treatment of the indium(I) adduct [IIn{($\mu_3$-NH)$_3$Ti$_3$($\eta^5$-$C_5Me_5$)$_3$($\mu_3$-N)}] (**2**) with $I_2$ (1 equiv.) in benzene afforded the indium(III) complex [$I_3$In{($\mu_3$-NH)$_3$Ti$_3$($\eta^5$-$C_5Me_5$)$_3$($\mu_3$-N)}] (**3**), but with excess of iodine the precipitation of orange crystals of the ionic complex [$Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3(NH_3)][InI_4]$ (**4**) takes place. Analogous treatment of the metalloligand **1** with $I_2$ in toluene gave initially the iodine(I) derivative [I{($\mu_3$-NH)$_3$Ti$_3$($\eta^5$-$C_5Me_5$)$_3$($\mu_3$-N)}][$I_3$] (**5**). Surprisingly, toluene solutions of **5** at room temperature produced crystals of the ionic complex $[Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3(NH_3)][I_3]\cdot C_7H_8$ (**6**·$C_7H_8$). The trinuclear titanium cation $[Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3(NH_3)]^+$ of complexes **4** and **6** has been structurally characterized by a combination of X-ray and DFT studies.

## Introduction

Transition metal nitrido complexes have received considerable attention over the last decades.[1,2] Compounds of group 6–8 metals usually bear the nitrido ligand as a terminal functionality [M]≡N and the study of its reactivity is an area of increasing activity.[1,3] The analogous early transition metal derivatives have not received the same treatment due to their difficult characterization and, perhaps more importantly, the lack of a systematic method of synthesis. This could be related with the tendency of the nitrido ligand to bridge two or more early-transition metal centers, which produces singular and very often unpredictable polynuclear structures.[2,4]

The imido-nitrido complex [{Ti($\eta^5$-$C_5Me_5$)($\mu$-NH)}$_3$($\mu_3$-N)] (**1**)[5,6] shows a cyclic [$Ti_3(\mu$-$NH)_3$] system, which resembles that of other triazamacrocycles such as 1,4,7-triazacyclononanes,[7] and especially 1,3,5-triazacyclohexanes,[8] whose extensive coordination chemistry is known. In fact, we have recently shown the capacity of **1** to act as a preorganized tridentate ligand with transition,[4,9,10] and main group metals.[11] The great versatility of **1** is also confirmed by the possibility of preparing complexes with metals in low [e.g. $Mo^0$, $Ir^I$] or high oxidation states [e.g. $Ti^{IV}$, $Ta^V$]. Although the main driving force in the coordination of **1** is the electron donation of the nitrogen atom lone pair to the incorporated metals, theoretical calculations performed on adducts of **1** with transition metals in low oxidation states have shown that the presence of $Ti^{IV}$ centers in the metalloligand produces an additional stabilization through metal–metal coupling.[9]

We have recently shown the formation of indium(I) and indium(III) iodide adducts [$I_x$In{($\mu_3$-NH)$_3$Ti$_3$($\eta^5$-$C_5Me_5$)$_3$($\mu_3$-N)}] [$x$ = 1 (**2**), $x$ = 3 (**3**)] through the reaction of **1** with the corresponding metal halides,[12] and were interested in performing the oxidation reactions directly on the metallocubane system, for example preparing **3** from the indium(I) complex **2**. Here we present the results obtained in this reaction, including the opening of the metalloligand **1** in the presence of excess iodine to give ionic complexes containing the singular unprecedented cation [$Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3(NH_3)]^+$, which has been structurally characterized by X-ray and DFT studies.

## Results and Discussion

The objective of this work was to evaluate the possibility of performing oxidation processes on inorganic fragments incorporated into the preorganized metallocubane ligand [{Ti($\eta^5$-$C_5Me_5$)($\mu$-NH)}$_3$($\mu_3$-N)] (**1**). In this way, we tried to obtain the indium(III) iodide adduct [$I_3$In{($\mu_3$-NH)$_3$-Ti$_3$($\eta^5$-$C_5Me_5$)$_3$($\mu_3$-N)}] (**3**) from the indium(I) analogue [IIn{($\mu_3$-NH)$_3$Ti$_3$($\eta^5$-$C_5Me_5$)$_3$($\mu_3$-N)}] (**2**) via oxidation with iodine. In a NMR experiment, complex **3** was quanti-

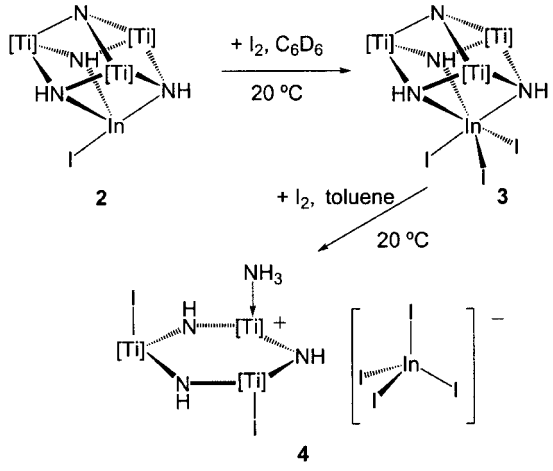
tatively formed within minutes by oxidation of **2** using a solution of $I_2$ in [$D_6$]benzene (Scheme 1). However, an excess of iodine in the reaction produced the consumption of **3**.



Scheme 1. Reaction of **2** with iodine. [Ti] = Ti($\eta^5$-$C_5Me_5$).

In a preparative scale reaction, a toluene solution of **3** was layered with a solution containing an excess of iodine (3 equiv.) in toluene to afford orange crystals of the ionic complex [$Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3(NH_3)$][$InI_4$] (**4**) in 49% yield. The X-ray analysis of **4** confirms the structure proposed in Scheme 1, containing a tetraiodoindiate(III) anion and a trinuclear titanium cation (see Figure 1). The $InI_4^-$ moiety found in **4** shows an average bond length for In–I of 2.703(2) Å and bond angles I–In–I of 109.5(6)°, typical for this tetrahedral fragment[13] (vide infra discussion about the cation structure). Complex **4** is not soluble in benzene or toluene and decomposes immediately in [$D_8$]tetrahydrofuran, [$D_5$]pyridine, [$D_1$]chloroform, or [$D_2$]dichloromethane, precluding its characterization by NMR spectroscopy. The IR (KBr) spectrum shows several bands in the range 3304–2942 $cm^{-1}$ and one at 1587 $cm^{-1}$ that are similar to those found for the Ti–$NH_3$-containing complex [{$Ti_2(\eta^5$-$C_5Me_5)_2Cl_3(NH_3)$}($\mu$-N)].[6] The latter absorption is assigned to the $NH_3$ bending mode.[14]

Since the metalloligand **1** coordinated to indium was affected in the reaction with $I_2$, we have also investigated the reaction of "free" **1** with iodine in toluene (Scheme 2). Treatment of **1** with excess of iodine leads to precipitation of a dark brown solid in 64% yield. Spectroscopic and analytical data are consistent with the iodine(I) derivative [I{($\mu_3$-$NH)_3Ti_3(\eta^5$-$C_5Me_5)_3(\mu_3$-N)}][$I_3$] (**5**). This complex is slightly soluble in [$D_6$]benzene and soluble in [$D_2$]dichloromethane. The $^1H$ and $^{13}C\{^1H\}$ NMR spectra show resonances for equivalent $\eta^5$-$C_5Me_5$ ligands. The *ipso* carbon resonances of the $C_5Me_5$ ligands are shifted to a lower field with respect to those of **1**, in a similar tendency to that found for our previously reported adducts [$X_nM$·**1**].[12] Resonances due to the $\mu$-NH ligands were not detected in the $^1H$ NMR spectrum, but the presence of those groups was confirmed in the IR (KBr) spectrum with two $\nu_{NH}$ absorptions at 3340 and 3218 $cm^{-1}$.

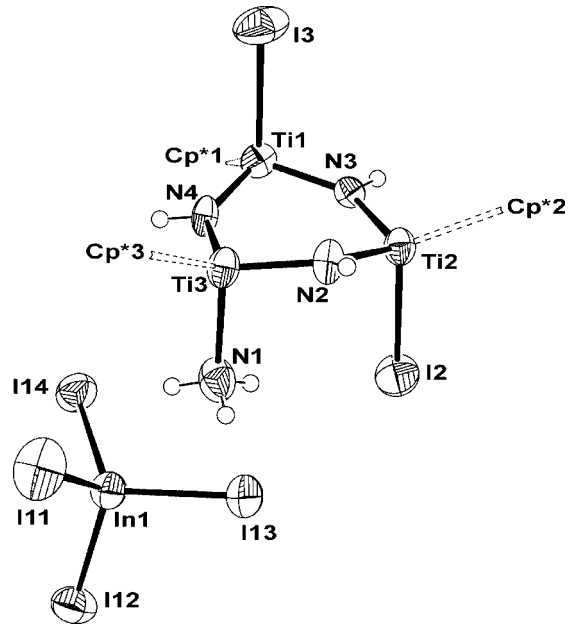


Figure 1. Simplified view of the complex [$Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3$-($NH_3$)][$InI_4$] (**4**) with thermal ellipsoids at the 50% probability level. The pentamethylcyclopentadienyl ligands are not shown for clarity.

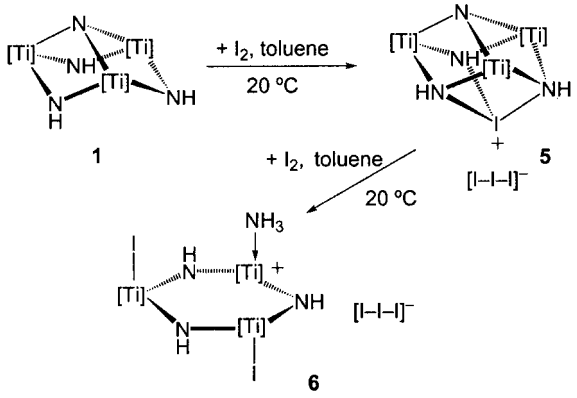

Scheme 2. Reaction of **1** with iodine. [Ti] = Ti($\eta^5$-$C_5Me_5$).

Analogous disproportionation reactions of $I_2$ in the presence of tetraazamacrocyclic or cryptand ligands to give coordination compounds of iodine(I) have been previously reported.[15] Attempts to grow suitable crystals of **5** for a X-ray crystal structure determination failed, but saturated toluene solutions of **5** at room temperature afforded orange crystals of [$Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3(NH_3)$][$I_3$]·$C_7H_8$ (**6**·$C_7H_8$) in poor yields.[16] Complex **6** is not soluble in unreactive solvents and its IR (KBr) spectrum is essentially identical to that of **4**.

The X-ray crystal structure determination of **6** shows a triiodide anion and the same trinuclear titanium cation [$Ti_3(\eta^5$-$C_5Me_5)_3I_2(\mu$-$NH)_3(NH_3)$]$^+$ found for **4** (see Figure 2). While **4** crystallizes as a solvent-free compound, crystals of **6** bear one toluene solvent molecule per complex. The $I_3^-$ ion in **6** is asymmetric [I–I distances are

2.867(1) and 3.000(1) Å, I–I–I 179.0(1)°] as determined in many other crystalline structures with such an anion.[17] Selected distances and angles of the cation structures are shown in Table 1.

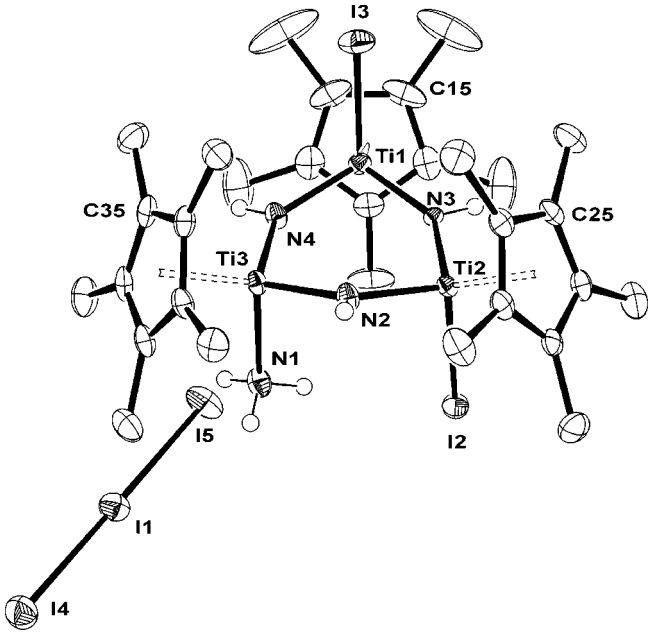

Figure 2. Perspective view of the $[Ti_3(\eta^5\text{-}C_5Me_5)_3I_2(\mu\text{-}NH)_3(NH_3)][I_3]$ (**6**) with thermal ellipsoids at the 50% probability level. Solvent molecule is not shown for clarity.

The cation of both **4** and **6** is a cyclic trinuclear complex, with three $Ti(\eta^5\text{-}C_5Me_5)L$ moieties held together by bridging (μ-NH) imido ligands. Each titanium atom has a classical three-legged piano-stool arrangement, where the legs are occupied by one iodine and two imido groups for Ti(1) and Ti(2), and one ammonia and two imido ligands for Ti(3). With respect to the plane formed by the three titanium atoms, I(3) is located above while I(2) and the ammonia molecule are below the plane. This structural disposition (two below, one above) of the ligands resembles that of the oxotitanium complexes $[\{Ti(\eta^5\text{-}C_5Me_5)L\}_3(\mu\text{-}O)_3]$ (L = Me,[18] Cl,[19] Br,[20] $CH_2CH{=}CH_2$[21]). The titanium–iodine distances of 2.677(av.) Å are in the normal range[22] and the titanium–nitrogen (ammonia) bond lengths [2.167(11) for **4** and 2.149(4) Å for **6**] are very similar to the unique crystallographic documented titanium organometallic complex with ammonia $[\{Ti_2(\eta^5\text{-}C_5Me_5)_2Cl_3(NH_3)\}(\mu\text{-}N)]$ (2.158 Å).[6] This distance is longer than that found for the Ti–$OH_2$ bonds in aquotitanium(IV) derivatives.[23] Surprisingly, only seven other examples of metal–ammonia interactions are found for groups 3, 4, and 5 when a search is performed in the CSD.[24] The bridging imido ligands are characterized by titanium–nitrogen bond lengths in the range 1.790(3)–1.918(3) Å [av. 1.85 Å], which are slightly shorter than those found in **1** [av. 1.92 Å], and angles Ti–N–Ti clearly wider 125.8(2)–138.3(2)° than those of complex **1** (93.2° av.) where the $\mu_3$-nitrogen apical atom constrains the geometry. On the other hand, distances from N(1) to I(2) of 3.661(1) in **4** and 3.623(3) Å in **6** could be indicative of the existence of an intramolecular hydrogen bonding interaction between them (sum of the van der Waals' radii 3.650 Å).[25]

DFT calculations were conducted to characterize the trinuclear fragment $[Ti_3(\eta^5\text{-}C_5Me_5)_3I_2(\mu\text{-}NH)_3(NH_3)]^+$. The optimized geometry coincides quite well with the X-ray ones, as can be seen in Table 1. Calculated distances are slightly longer than the experimental and some of the angles differ by a small number of degrees. Especially significant is the distance Ti(3)–N(1) 2.191 Å, which is only ≈0.02 and ≈0.04 Å longer than those found in complexes **3** and **6**, respectively. The cation $[Ti_3(\eta^5\text{-}C_5Me_5)_3I_2(\mu\text{-}NH)_3(NH_3)]^+$ displays a relatively large HOMO–LUMO gap of 1.88 eV, a fact that is a signal of its relative stability.

Although all the three metal atoms in the titanium complex are formally in their highest oxidation state, the Mulliken population analysis suggests that the Ti atom bonded to $NH_3$ carries a larger positive charge (+1.42 e) than the other two titaniums [computed charge for Ti(1) + Ti(2) = +0.92 e]. The LUMO is a nonbonding orbital with a larger participation of Ti(3) (Figure 3). As a matter-of-fact, the monoreduction of $[Ti_3(\eta^5\text{-}C_5Me_5)_3I_2(\mu\text{-}NH)_3(NH_3)]^+$ hardly induces changes in the geometry of the cluster, the additional metal electron being mainly localized on the Ti bonded to ammonia [spin density on Ti(3) of ≈0.5 e,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

whereas the other two Ti share ≈0.6 e]. All these results are in concordance with the drawings proposed for the trinuclear titanium cation in Schemes 1 and 2.

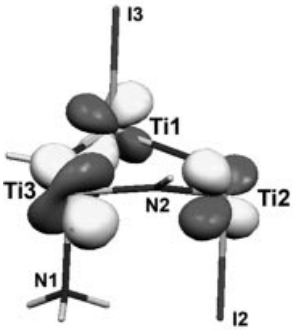

Figure 3. 3D representation of the LUMO for $[Ti_3(\eta^5\text{-}C_5Me_5)_3I_2(\mu\text{-}NH)_3(NH_3)]^+$.

In summary, the heterometallocubane $[IIn\{(\mu_3\text{-}NH)_3Ti_3(\eta^5\text{-}C_5Me_5)_3(\mu_3\text{-}N)\}]$ (**2**) allows the oxidation with iodine of the supported InI, under mild conditions, to cleanly give the expected indium(III) derivative $[I_3In\{(\mu_3\text{-}NH)_3Ti_3(\eta^5\text{-}C_5Me_5)_3(\mu_3\text{-}N)\}]$ (**3**). However, an excess of iodine in the solution produces the rupture of the preorganized structure of $[\{Ti(\eta^5\text{-}C_5Me_5)(\mu\text{-}NH)\}_3(\mu_3\text{-}N)]$ (**1**) to give the singular cation $[Ti_3(\eta^5\text{-}C_5Me_5)_3I_2(\mu\text{-}NH)_3(NH_3)]^+$. This complex is also accessible through the reaction of **1** with an excess of iodine. DFT studies support the cationic nature of the unprecedented ammonia adduct.

## Experimental Section

**General Considerations and Starting Materials:** All manipulations were carried out under argon using Schlenk line or glovebox techniques. Hexane was distilled from Na/K alloy just prior to use. Toluene was freshly distilled from sodium. NMR solvents were dried with Na/K alloy ($C_6D_6$) or calcium hydride ($CD_2Cl_2$) and vacuum-distilled. Oven-dried glassware was repeatedly evacuated with a pumping system (ca. $1\cdot10^{-3}$ Torr) and subsequently filled with inert gas. Iodine was purchased from Aldrich and sublimed under vacuum prior to use. $[\{Ti(\eta^5\text{-}C_5Me_5)(\mu\text{-}NH)\}_3(\mu_3\text{-}N)]$ (**1**),[6] $[IIn\{(\mu_3\text{-}NH)_3Ti_3(\eta^5\text{-}C_5Me_5)_3(\mu_3\text{-}N)\}]$ (**2**),[12] and $[I_3In\{(\mu_3\text{-}NH)_3Ti_3(\eta^5\text{-}C_5Me_5)_3(\mu_3\text{-}N)\}]$ (**3**)[12] were prepared according to published procedures.

Samples for infrared spectroscopy were prepared as KBr pellets. $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Varian Unity-300 spectrometer. Chemical shifts ($\delta$) are given relative to residual protons or to carbon of the solvent. Microanalyses (C,H,N) were performed with a Heraeus CHN-O-Rapid microanalyzer.

**Oxidation Reaction of 2 with Iodine:** A 5-mm valved NMR tube was charged with **2** (10 mg, 0.012 mmol), $I_2$ (3.0 mg, 0.012 mmol) and [$D_6$]benzene or [$D_8$]toluene (1.00 mL). The course of the reaction was monitored by $^1H$ NMR spectroscopy. After 5 min at room temperature the spectrum shows the complete consumption of **2** along with resonances due to complex **3**.[12]

**$[IIn\{(\mu_3\text{-}NH)_3Ti_3(\eta^5\text{-}C_5Me_5)_3(\mu_3\text{-}N)\}]$ (2):** $^1H$ NMR (300 MHz, $C_6D_6$, 20 °C): $\delta$ = 12.87 (br. s, 3 H, NH), 2.01 (s, 45 H, $C_5Me_5$) ppm.

**$[I_3In\{(\mu_3\text{-}NH)_3Ti_3(\eta^5\text{-}C_5Me_5)_3(\mu_3\text{-}N)\}]$ (3):** $^1H$ NMR (300 MHz, $C_6D_6$, 20 °C): $\delta$ = 11.58 (br. s, 3 H, NH), 1.95 (s, 45 H, $C_5Me_5$) ppm.

**Synthesis of $[Ti_3(\eta^5\text{-}C_5Me_5)_3I_2(\mu\text{-}NH)_3(NH_3)][InI_4]$ (4):** A solution of $I_2$ (0.062 g, 0.24 mmol) in toluene (10 mL) was carefully added to $[I_3In\{(\mu_3\text{-}NH)_3Ti_3(\eta^5\text{-}C_5Me_5)_3(\mu_3\text{-}N)\}]$ (**3**) (0.090 g, 0.08 mmol) in toluene (30 mL). The system was allowed to react without any stirring for 5 days to yield **4** as orange crystals suitable for X-ray analysis. The resultant red solution was concentrated in volume under vacuum until ca. 15 mL and allowed to stand at room temperature to give a second crop of crystals. The combined yield of **4** was 0.059 g (49%). IR (KBr) $\tilde{\nu}$ = 3304 (m), 3261 (m), 3192 (w),

C 24.22, H 3.45, N 3.77; found C 24.85, H 3.39, N 2.69.

**Synthesis of [I{(μ3-NH)3Ti3(η5-C5Me5)3(μ3-N)}][I3] (5):** A solution of $I_2$ (0.75 g, 2.96 mmol) in toluene (30 mL) was carefully added to **1** (0.40 g, 0.66 mmol) in toluene (30 mL). The system was allowed to react without any stirring for 3 days. After decantation, the resultant dark brown crystals were vacuum-dried to afford **5** (0.47 g, 64%). IR (KBr) $\tilde{\nu}$ = 3340 (m), 3218 (m), 2911 (s), 1486 (m), 1426 (s), 1376 (s), 1021 (w), 762 (s), 717 (s), 660 (vs), 638 (vs), 594 (s), 467 (m) $cm^{-1}$. $^1H$ NMR (300 MHz, $C_6D_6$, 20 °C): $\delta$ = 1.88 (s, 45 H, $C_5Me_5$) ppm. $^1H$ NMR (300 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 2.10 (s, 45 H, $C_5Me_5$) ppm, NH resonance was not detected. $^{13}C\{^1H\}$ NMR (75 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 123.8 ($C_5Me_5$), 12.3 ($C_5Me_5$) ppm. $C_{30}H_{48}I_4N_4Ti_3$ (1115.94): calcd. C 32.29, H 4.33, N 5.02; found C 31.18, H 4.23, N 4.52.

**Synthesis of [Ti3(η5-C5Me5)3I2(μ-NH)3(NH3)][I3] (6):** A saturated solution of **5** in toluene at room temperature for 5 days gave orange crystals (0.050 g) of **6**·$C_7H_8$ suitable for X-ray crystallographic studies. IR (KBr) $\tilde{\nu}$ = 3301 (m), 3234 (m), 3116 (m), 2909 (s), 2852 (w), 1587 (m), 1493 (m), 1428 (m), 1377 (s), 1271 (s), 1021 (m), 798 (vs), 753 (s), 729 (s), 710 (vs), 622 (m), 494 (w), 465 (w), 432 (m) $cm^{-1}$. $C_{37}H_{59}I_5N_4Ti_3$ (1338.08): calcd. C 33.21, H 4.44, N 4.19; found C 32.67, H 4.37, N 3.67.

**X-ray Crystal Structure Determination of Complexes 4 and 6:** Orange crystals of compounds **4** and **6** were obtained from toluene solutions at room temperature. Crystals of **4** were mounted in a glass capillary in a random orientation and transferred to an Enraf–Nonius CAD4 diffractometer for characterization and data collection at room temperature. Complex **6** crystallized with one molecule of toluene, so the crystals were removed from the Schlenk and covered with a layer of viscous perfluoropolyether (Fomblin®Y). A suitable crystal was selected with the aid of a microscope, attached to a glass fiber, and immediately placed in the low temperature nitrogen stream of the diffractometer. The intensity data sets were collected at 150 K with a Bruker–Nonius KappaCCD diffractometer equipped with an Oxford Cryostream 700 unit. Crystallographic data for all the complexes are presented in Table 2. The structures were solved, using the WINGX package,[26] by direct methods (SHELXS-97) and refined by least-squares against $F^2$ (SHELXL-97).[27] All non-hydrogen atoms of **4** and **6** were anisotropically refined. All the hydrogen atoms were positioned geometrically and refined by using a riding model except those attached to N(1) and N(2) in complex **6** which were directly located in the difference Fourier map and refined isotropically. The largest residual density peaks are located at 0.88 Å of I(14) in compound **4** and at 0.83 Å of I(4) in compound **6**. The refinement of the crystal structure of complex **6** was also performed substituting the ammonia molecule by water and the result was a decrease of the quality of the study, increased *R* values, poorer temperature factors for the oxygen atom and always the appearance of the third hydrogen atom in the difference Fourier map, excluding the existence of a water molecule.

CCDC-283509 and -283510 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** All DFT calculations were carried out with the ADF program[28] by using triple-ζ and polarization Slater basis sets to describe the valence electrons of C and N. For titanium, a frozen core composed of the 1s, 2s, and 2p orbitals was described by double-ζ Slater functions, the 3d and 4s orbitals by triple-ζ functions, and the 4p orbital by a single orbital. Hydrogen atoms were described by triple-ζ and polarization functions. The geometries and binding energies were calculated with gradient corrections. We used the local spin density approximation, characterized by the electron gas exchange (Xα with $a$ = 2/3) together with Vosko–Wilk–Nusair parametrization[29] for correlation. Becke's nonlocal corrections[30] to the exchange energy and Perdew's nonlocal corrections[31] to the correlation energy were added. Quasirelativistic corrections were employed by using the ZORA formalism with corrected core potentials. The quasirelativistic frozen core shells were generated with the auxiliary program DIRAC.[28]

**Supporting Information** (see footnote on the first page of this article): The $^1H$ and $^{13}C\{^1H\}$ NMR spectra of complex **5** are provided as Supporting Information.

# Redox Chemistry in the Reaction of Oxovanadium(V) with Thiolate-Containing Ligands: the Isolation and Characterization of Non-Oxo Vanadium(IV) Complexes Containing Disulfide and Thioether Groups

**Hua-Fen Hsu,*[a] Chia-Ling Su,[a] Neeruganti O. Gopal,[b] Chi-Chin Wu,[a] Wei-Cheng Chu,[a] Yi-Fang Tsai,[a] Ya-Ho Chang,[a] Yi-Hung Liu,[c] Ting-Shen Kuo,[d] and Shyue-Chu Ke*[b]**

**Keywords:** Vanadium / S ligands / Bioinorganic chemistry / EPR spectroscopy

The reactions of $V^{V}O(O\text{-}iPr)_3$ with $[PS3']H_3$ and $[PS3]H_3$ {$[PS3']H_3$ = $P(C_6H_3\text{-}5\text{-}Me\text{-}2\text{-}SH)_3$, $[PS3]H_3$ = $P(C_6H_4\text{-}2\text{-}SH)_3$} led to the formation of $[V^{IV}(L)]$ [L = P2S4′ (**1a**), P2S4 (**1b**)], where L was formed by the oxidative coupling of two PS3′ or PS3 ligands by a disulfide bond. When the reaction of $V^{V}O(O\text{-}iPr)_3$ with $[PS3']H_3$ was conducted in the presence of methoxide followed by the addition of a cation, $[V^{IV}(PS3')(PS2S^{Me'})]X$ [X = $N(C_2H_5)_4$ (**2a**), $N(C_2H_5)_3(CH_2Ph)$ (**2b**)] was isolated, where $PS2S^{Me'}$ is a bis(benzenethiolato)phenylmethylthioetherphosphane ligand generated from the methylation of one thiolate group in PS3′. The structures of complexes **1a**,**b** and **2a**,**b**, determined by X-ray crystallography, contain six- and seven-coordinate non-oxo vanadium(IV) centers, respectively, with an octahedral geometry for **1a**,**b** and a pentagonal-bipyramidal geometry for **2a**,**b**. The electronic, magnetic, and electrochemical properties of these complexes were determined by UV/Vis and EPR spectroscopy, SQUID measurements, and cyclic voltammetry.

## Introduction

Vanadium has been shown to have an important role in biological systems and therefore its complexes are worth investigation.[1] In particular, the interactions of high-valent vanadium species with sulfur-containing bioligands, such as cysteine and glutathione, are essential subjects in various biological and medical topics.[1a,2] Vanadate interacts with the Cys residue in the catalytic site of the protein-tyrosine phosphatase (PTP), inhibiting the activity of the enzyme that might be associated with the insulin-mimetic behavior of vanadium compounds.[3] Some ascidians sequester $V^{V}$ species from seawater and reduce it to $V^{III}$ which is accumulated in high concentration in vacuoles of the blood cells.[4] The mechanism for this redox conversion is still unknown. In addition to tunichrome and NADPH, glutathione and cysteine might be candidates to act as reductants in the cell.[5] A natural vanadium(IV) complex, amavadin, was isolated from *Amanita* mushrooms.[6] Even though the structure of this complex is known, its function is still not well understood.[7] It has been suspected that amavadin might be involved in the defensive system of the mushrooms through the specific oxidation of some thiols to disulfide.[8] The toxicity of vanadium in biological systems is not well understood, however, it has been shown that the injection of vanadate in mice decreased the cellular level of glutathione, an essential antioxidant in the cell.[9] Vanadium complexes with S-donor ligands have been shown to have insulin-mimetic antidiabetic activity.[10]

From this information, efforts have been made to understand the fundamental chemistry of high-valent vanadium complexes with thiolate ligands that have similar functional groups to those in cysteine and glutathione.[11] Among those studies, the interaction of $VO^{3+}$ species with thiolate-containing ligands has not been intensively investigated.[11b,11d] Therefore, in this paper we focus on the chemistry of $VO^{3+}$ reacting with the tris(benzenethiolato)phosphane ligands, $[PS3]H_3$ and $[PS3']H_3$. The reactions led to the reduction of vanadium(V) to vanadium(IV) with the formation of the two new types of ligands, L (L = P2S4 and P2S4′) and $PS2S^{Me'}$ (see Scheme 1). The former was created by the oxidative coupling of two PS3 ligands by way of a disulfide linkage, and the latter resulted from the methylation of one thiolate group in the PS3′ ligand. We verified this chemistry by isolating the reaction products, $[V^{IV}(L)]$ [L = P2S4′ (**1a**), P2S4 (**1b**)] and $[V^{IV}(PS3')(PS2S^{Me'})]X$ [X

= $N(C_2H_5)_4$ (**2a**), $N(C_2H_5)_3(CH_2Ph)$ (**2b**)] (Scheme 2). Notably, **1a**,**b** and **2a**,**b** belong to a limited set of non-oxo (or "bare") vanadium complexes.[12] The interest in non-oxo vanadium species stems from amavadin and vanadium nitrogenase that contain an eight-coordinate non-oxo vanadium center and a [V(μ-S)$_3$(His)(homocitrate)] site, respectively. Herein, we describe the syntheses, structures, spectroscopy, and magnetic properties of **1a**,**b** and **2a**,**b**, as well as the significance of the chemistry provided in this work.

## Results and Discussion

### Syntheses and X-ray Structures

The reaction of 1 equiv. [PS3′]$H_3$ in ether with 1 equiv. $V^VO(O\text{-}iPr)_3$ in *i*PrOH generated a purple solid that was recrystallized from dichloromethane/hexane to give the crystalline form of [$V^{IV}$(P2S4′)] (**1a**). The synthetic procedure of [$V^{IV}$(P2S4)] (**1b**) was similar to that of **1a** except [PS3]$H_3$ was used and the compound was recrystallized from benzene/ether. When $V^VO(O\text{-}iPr)_3$ in *i*PrOH was added to equimolar amounts of [PS3′]$H_3$ in methanol with the presence of sodium methoxide, a transient brown solution was produced which gradually changed to a purple color in one hour. After addition of the counterion, X, the purple crystalline solid of [$V^{IV}$(PS3′)(PS2S$^{Me\prime}$)]X [X = $N(C_2H_5)_4$ (**2a**), $N(C_2H_5)_3(CH_2Ph)$ (**2b**)] precipitated from the solution by the next day. When the reactions were performed with $V^VO(O\text{-}iPr)_3$ and the ligands in a molar ratio of 1:2, there were no appreciable gains in the yields of compounds **1a**,**b** and **2a**,**b**. The solid forms of these complexes were stable in the air, however, the solution forms decomposed within minutes of exposure to the air.

The structure of **1a** was obtained by X-ray crystallography, but it was poorly refined as a result of the weak intensity of the data. Compound **1b** afforded X-ray crystallographic data of better quality and its ORTEP diagram is shown in Figure 1. It consists of a $V^{IV}$ ion coordinated to a hexadentate ligand, P2S4, with a nine-membered chelate ring containing a S–S bond. The vanadium(IV) center adopts a distorted octahedral geometry by binding to two phosphane atoms and four thiolate groups of P2S4, with the two P donor atoms in *cis* positions. The generation of P2S4 by the reaction was a consequence of the oxidative coupling of two PS3 ligands by formation of a disulfide linkage. Similar chemistry was also found in the reaction of $Os^{II}$ with the PS3 ligand, however, two disulfide linkages were formed.[13] Redox chemistry of $V^V/V^{IV}$ coupled with $RS^-$/RSSR, as demonstrated by the isolation of **1a**,**b**, is unprecedented, although the chemistry of $V^{IV}/V^{III}$ coupled with $RS^-$/RSSR has been reported.[11e,11g] To the best of our knowledge, hexadentate P2S4 and P2S4′ ligands containing two phosphane and four thiolate donor atoms have not been presented in the literature. Selected bond lengths and angles of **1b** are listed in Table 1. The V–S distances of 2.307–2.335 Å in **1b** are in the range of those for reported $V^{IV}$-thiolate complexes.[11a,11d–11h] The S atoms of the disulfide linkage remain uncoordinated, and the S–S distance of 2.055 Å is similar to those in characterized disulfide-containing compounds.[11d,11f]

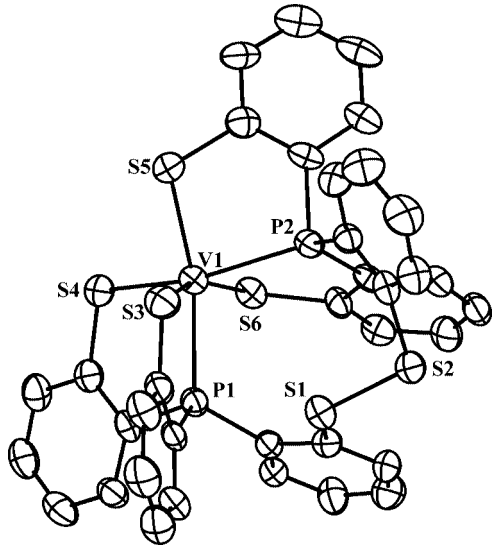

Figure 1. ORTEP diagram of **1b** shown with 35% thermal ellipsoids. All hydrogen atoms are omitted for clarity.

The structures of **2a** and **2b** were determined by X-ray crystallography and their anions are very similar (see Figure S1 and Figure 2, respectively). However, **2b** provides a better quality of X-ray crystallographic data and is discussed here. The anion of **2b** consists of a seven-coordinate $V^{IV}$

center by binding to PS3′ and $PS2S^{Me\prime}$, where $PS2S^{Me\prime}$ is a bis(thiolato)thioetherphosphane ligand. Interestingly, during the reaction a thiolate group in the PS3′ ligand was methylated to yield the $PS2S^{Me\prime}$ ligand. The S(2)–C(10) distance of 1.763(5) Å is close to those found in methylphenyl thioether-containing compounds,[14] but is different from the reported S–O and S–OH distances found in sulfoxide and sulfenic acid, respectively.[15] The S atom of the thioether group in $PS2S^{Me\prime}$ remains uncoordinated. The structure adopts a distorted pentagonal-bipyramidal geometry with two P atoms in the equatorial plane. Seven-coordinate $V^{IV}$ complexes are unusual and the only reported example is $[V(S_2)_2(terpy)]$.[16] Selected bond lengths and angles of **2a** and **2b** are listed in Table S1 and Table 2, respectively. The distances of V–S bonds occur in a large range (2.374 to 2.551 Å). The axial V–S distances (2.374 and 2.386 Å) are comparable to those in **1b** and other reported $V^{IV}$-thiolate complexes.[11a,11d–11h] However, the equatorial V–S bond lengths (2.444, 2.434, and 2.551 Å) are much longer than those in reported $V^{IV}$-thiolate compounds, but are close to those in seven-coordinate vanadium(III)-thiolate complexes.[17]

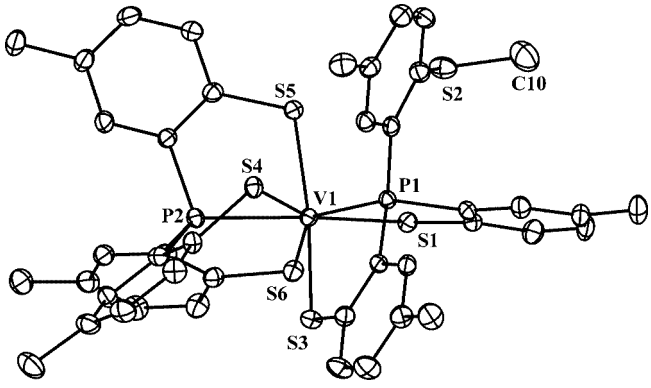

Figure 2. ORTEP diagram of **2b** shown with 35% thermal ellipsoids. The cation and all hydrogen atoms are omitted for clarity.

### Spectroscopic, Electrochemical, and Magnetic Studies

The patterns of the bands in the UV/Vis spectra of **1a**,**b** are similar to each other, but are dissimilar to that of **2a**, clearly delineating the different coordination sites of **1a**,**b** and **2a** in solution state (Figure 3). The absorptions of **1a** are slightly red-shifted relative to those of **1b** as a result of the methyl substituents of the ligand in **1a**. The intense bands appearing in these spectra are very likely caused by the ligand-to-metal charge transfers that mask d-d transitions. Cyclic voltammograms (CVs) of complexes **1a**,**b** and **2a** were measured under nitrogen with ferrocene (Fc) as an external standard. The potentials are referenced versus the $Fc^+$/Fc couple as summarized in Table 3. The CVs of **1a** and **2a** display two well-separated reversible waves of equal size as one-electron-reduction and one-electron-oxidation processes (Figure 4). The reduction processes should be interpreted as metal-centered reductions to $V^{III}$ species since the thiolate ligands are unlikely to be reduced in this potential range. Although the possibility of ligand-based oxidations should not be excluded, we are inclined to speculate that the oxidation processes are related to metal-centered oxidations since the oxidation of thiolate to thiyl radical is usually irreversible and at higher potential.[12e,12i] The potentials ($E_{1/2}$) of **1a** are much higher than the corresponding potentials of **2a**. Presumably, this is related to the six-coordinate metal center in **1a** compared with the seven-coordinate metal center in **2a**; this is in agreement with lower-coordinate complexes stabilized at lower oxidation states. The differences in potentials of these two complexes are 689 mV for the $V^{III}/V^{IV}$ couple and 498 mV for the $V^{IV}/V^{V}$ couple, indicating that the effect of the coordination number on the stabilization of the oxidation state is more pronounced for the former than the latter couple. Indeed, the potentials of redox couples of **1a** are closer to those of the corresponding couples in a six-coordinate non-oxo vanadium(IV) complex, $V^{IV}L^{P}_2$, in which $L^P$ is a tridentate bis(phenolato)phosphane ligand (Table 3).[12p] The potentials of **1a** are slightly higher than those in $V^{IV}L^{P}_2$ since the reduced form is more stable in a P2S4 environment compared with a P2O4 environment. The cyclic voltammogram of **1b** displays an irreversible reduction wave at –0.818 V and an irreversible oxidation wave at 0.149 V, presumably related to the redox processes to $V^{III}$ and $V^{V}$, respectively. The potentials of **1b** are higher than those of **1a**, consistent with the electron-donating nature of the methyl substituent in the ligand of **1a**. Some irreversible oxidized waves are observed in the potential range of 0.2 to 0.8 V for **1a**,**b** and

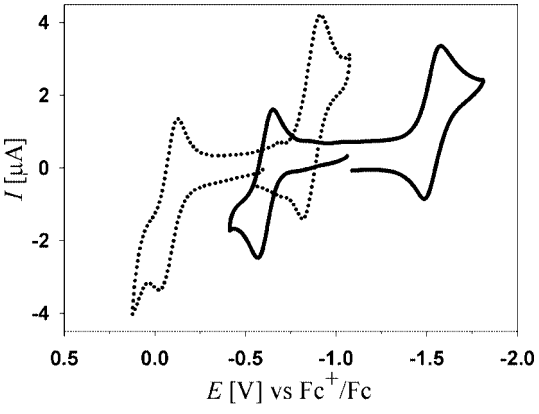

Figure 4. Cyclic voltammograms of complexes **1a** (dotted line) and **2a** (solid line) in $CH_2Cl_2$ solutions (scan rate: 100 mV s$^{-1}$).

The magnetic properties of the complexes were studied by SQUID measurements over the temperature range 5–300 K. The temperature-independent magnetic moments of **1a** and **2a** are 1.78±0.10 and 1.68±0.04 $\mu_B$, respectively, close to the spin-only value of one unpaired electron ($\mu_{eff}$ = 1.73 $\mu_B$). These results are consistent with a $V^{IV}$ ion that has a $S$ = 1/2 ground state. The $^1$H NMR spectra of **1a** and **2a** in $CD_2Cl_2$ exhibit broadened resonance signals in the range of –10 to 20 ppm, in agreement with paramagnetic species in the solution state. The EPR spectra of **1a**,**b** and **2a** in frozen $CH_2Cl_2$ solutions are presented in Figure 5. The spectra of **1a**,**b** are not highly resolved, which is probably a result of the bad quality of glass samples. Attempts to obtain better resolved spectra by preparing the samples under various conditions did not succeed. These spectra exhibit an eight-line pattern with hyperfine splitting of $108.01 \cdot 10^{-4}$ and $103.55 \cdot 10^{-4}$ cm$^{-1}$ for **1a**,**b** and **2a**, respectively, centered at $g_z \cong 1.97$ that is caused by coupling of the unpaired electron with the $^{51}$V nuclear spin ($I$ = 7/2). Spin quantification of the EPR signals account for almost 100% of all three complexes. These results confirm $S$ = 1/2 $d^1$ electronic configuration assignments of the vanadium ions. As shown in Figure 5, each member of the octet is further split into a 1:2:1 triplet of lines, indicating that the electron is coupled to two equivalent $^{31}$P nuclei ($I$ = 1/2) with a superhyperfine splitting of 2.8 and 3.2 mT for **1a**,**b** and **2a**, respectively. The magnetic parameters of the $x$ and $y$ components could not be determined directly from these spectra because of considerable overlapping of lines. We have attempted to simulate these spectra based on $S$ = 1/2 rhombic models with two equivalent coordinating phosphorus nuclei. Notably, we have assumed that the principal axis systems for the $g$, $A^V$, and $A^P$ tensors are collinear for simplicity, which may not be justified for non-oxo vanadium(IV) complexes as described by Chaudhuri and coworkers.[12p] Satisfactory fits are presented in Figure 5 and the derived EPR parameters are presented in Table 4. The EPR parameters of six-coordinate **1a**,**b** exhibit $g_z < g_{x,y} < 2$ and $A_z >> A_x$, $A_y$ characteristic of a $(d_{xy})^1$ ground state configuration.[12e,12p,18] The study of complex **2a** is the first reported EPR study of a seven-coordinate non-oxo vanadium(IV) complex with approximately $D_{5h}$ symmetry. For an ideal pentagonal-bipyramidal ($D_{5h}$) symmetry, simple crystal-field considerations place the $e_1''$ ($d_{xz}$ and $d_{yz}$) the lowest. The $a_1'$ ($d_{z^2}$) and $e_2'$ ($d_{xy}$, $d_{x^2-y^2}$) lie relatively high above $e_1''$, and the ordering of $e_2'$ and $a_1'$ depends on the relative field strength of the equatorial and the axial ligands. The system is subject to Jahn–Teller distortion. Complex **2a** adopts a pseudo $D_{5h}$ pentagonal-bipyramidal geometry with S1, P1, S4, P2, and S6 atoms forming the pentagon. The spin-Hamiltonian parameters (Table 4) are such that $g_z < g_{x,y} < 2$ and $A_z >> A_x$, $A_y$. These results are consistent with the unpaired electron being in a nondegenerate $d_{xz}$ ground state expected for a pentagonal-bipyramidal complex with a $d^1$ electron configuration. The fact that the observed $g$ anisotropy is relatively small suggests a considerable energy difference between the $d_{xz}$ and $d_{yz}$ orbitals, even though these orbitals are strongly coupled by spin-orbit interactions.

From the observed spin-Hamiltonian parameters, the Fermi contact term ($k$) at the $^{51}$V nucleus has been calculated.[19] A large value of $k$ indicates a large contribution to the hyperfine coupling constant by the unpaired electron. The values of the Fermi contact term obtained in the present work ($k$ = 0.53, 0.53, and 0.51 for **1a**, **1b**, and **2a**, respectively) indicate the moderate hyperfine coupling from the $^{51}$V nucleus. The observed spectral features, the obtained

| Compound | $g_x$ | $g_y$ | $g_z$ | $A_x$ [$10^{-4}$ cm$^{-1}$] | $A_y$ [$10^{-4}$ cm$^{-1}$] | $A_z$ [$10^{-4}$ cm$^{-1}$] |
|---|---|---|---|---|---|---|
| **1a** | 1.999(9) | 1.989(9) | 1.976(9) | 18.68 | 29.73 | 108.01[a] |
| **1b** | 1.999(2) | 1.989(6) | 1.976(9) | 18.67 | 29.72 | 108.01[a] |
| **2a** | 1.997(9) | 1.989(2) | 1.979(9) | 17.26 | 26.00 | 103.55 |

[a] The parameter for compounds **1a** and **1b** is only accurate to $\pm 0.9 \cdot 10^{-4}$ cm$^{-1}$, because the spectra of **1a** and **1b** are not as well-resolved as **2a** in the high-field region.

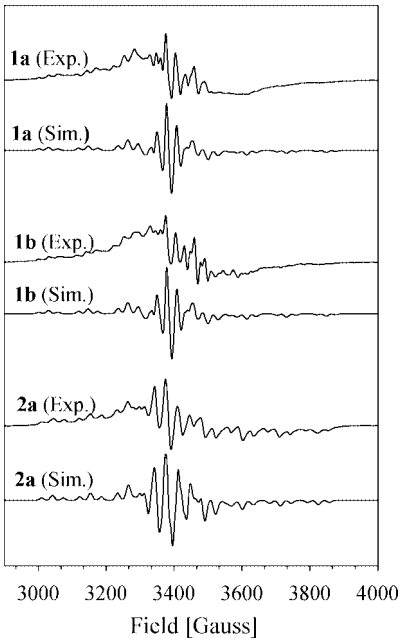

Figure 5. Experimental and simulated EPR spectra of **1a**,**b** and **2a**. Instrument settings: microwave frequency, 9.5192 GHz for **1a**, 9.5158 GHz for **1b**, 9.5152 GHz for **2a**; modulation amplitude, 8 G at 100 kHz; temperature, 5 K; microwave power, 5 mW.

spin-Hamiltonian parameters with low $k$ values, and the isotropic superhyperfine coupling from the two equivalent phosphorus nuclei signify the delocalization of the unpaired electron density away from the $V^{IV}$ metal center.

### The Disulfide Formation and the Alkylation of Coordinated Thiolate

Ligand-based reactions of metal-thiolate complexes are well-known.[11b,15a,20] The reactions include alkylation, metalation, and oxygenation of bound sulfur centers. The formation of disulfide along with the reduction of metal ions has also been seen in metal-thiolate chemistry.[11e,11g,13,21] However, it has never been reported that $V^V$ species mediate the disulfide formation and the alkylation of thiolate, as presented in this work. The mechanism of forming the thioether group contained in **2a**,**b** is less clear. The alkylation of coordinated thiolate groups is mostly limited to late-transition-metal complexes such as $Ni^{II}$, $Ru^{II}$, $Fe^{II}$, and $Zn^{II}$ thiolates, where bound sulfur atoms tend to react with electrophiles like carbonium sources.[20a,20d,20g,22] The nucleophilicity of bound sulfur atoms has been attributed to a four-electron repulsion between a sulfur lone pair and electrons in filled metal d-orbitals. However, in the case of high-valent vanadium thiolates, the electron repulsion stemming from the metal–sulfur dπ-pπ interactions is undermined by the electron deficiency of the metal center. Thus, an electrophilic attack of bound sulfur to carbon in methoxide leading to the formation of **2a**,**b** is less likely, but cannot be excluded. More likely, the methylation of thiolate might involve the homolytic cleavage of the C–O bond in methoxide by a bound thiyl radical generated by the reaction of $V^V$ with thiolate.[23] In this case, the initial step possibly involved the reduction of $V^V$ to $V^{IV}$ and the oxidation of thiolate to thiyl radical.[24] Thus, a $V^{IV}(RS\cdot)(OCH_3)$ species might be proposed as an intermediate.

## Conclusions

This work describes the redox chemistry that occurs in the reactions of vanadium(V) with thiolate groups, leading to the formation of two types of non-oxo vanadium(IV) complexes: one with disulfide- and the other with thioether-containing ligands, as shown by **1a**,**b** and **2a**,**b**, respectively. The chemistry here contrasts with the reported reactions of $VO^{3+}$ with thiolate-containing ligands, NS3 and $btap^{3-}$ {NS3 = $[N(CH_2CH_2S)_3]^{3-}$, $btap^{3-}$ = 2-[bis(ethylthiolato)-amino]-4-methylphenolate}, in which redox chemistry was not involved and oxovanadium(V) complexes binding with the title ligands were obtained.[11b,11d] Compared with NS3 and $btap^{3-}$ ligands, the PS3 system might be attributed to a better driving force of the redox process between $V^V/V^{IV}$ and $RS^-/RS\cdot$ couples, consequently generating a $V^{IV}$–RS· intermediate that might be a key species for forming **1a**,**b** and **2a**,**b**.

## Experimental Section

**General Considerations:** Manipulations were performed under nitrogen by standard Schlenk techniques or in a nitrogen-filled glove box. $[P(C_6H_4\text{-}2\text{-}SH)_3]$, $[P(C_6H_3\text{-}5\text{-}Me\text{-}2\text{-}SH)_3]$,[25] and $VO(i\text{PrO})_3$[26] were synthesized according to literature procedures. Solvents were dried, distilled, and degassed using standard techniques. All other starting materials were obtained commercially and used without further purification.

**Physical Methods:** Electronic spectra were recorded in the range of 300–1100 nm on a Hewlett Packard 8453 spectrophotometer. Electrochemical studies were performed at ambient temp. under nitrogen with a CHI 600A electrochemical analyzer. Cyclic voltammograms were obtained by using a three-component system consisting of a platinum-disk working electrode, a platinum-wire auxiliary electrode, and a $Ag/Ag(NO_3)$ (0.01 M in $CH_3CN$) reference electrode. The experiments were performed in $CH_2Cl_2$ by using tetrabutylammonium tetrafluoroborate (0.05 M) as the supporting

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

electrolyte. The ferrocenium/ferrocene ($Fc^+/Fc$) couple was measured as an external standard. Under our experimental conditions, the $Fc^+/Fc$ couple was at $E_{1/2}$ ($\Delta E_p$) = 0.161 ± 0.01 V (130 mV) vs. $Ag/Ag(NO_3)$ (0.01 M in $CH_3CN$). The $^1H$ NMR spectra were recorded with a BRUKER AMX-400 at ambient temp. EPR spectra were obtained at X-band using a Bruker EMX spectrometer equipped with a Bruker TE102 cavity and an Advanced Research System continuous-flow cryostat (3.2–200 K). The microwave frequency was measured with a Hewlett–Packard 5246L electronic counter. The instrument settings are shown in the Figure caption. SQUID magnetic measurements were performed with a QUANTUM DESIGN MPMS-7 with a field of 5000 G. The measurements were taken over the following temp. ranges with the indicated increments: 5–10 K (one data point every 1 K), 12–20 K (one data point every 2 K), 23–50 K (one data point every 3 K), 55–100 K (one data point every 5 K), 110–300 K (one data point every 10 K). Diamagnetic contributions were estimated for each compound by using Pascal's constants.

**Synthesis of [$V^{IV}$(P2S4′)] (1a):** An *i*PrOH solution of $VO(iPrO)_3$ (0.061 g, 0.25 mmol) was added to an ether solution of $[PS3']H_3$ (0.100 g, 0.25 mmol) to generate a bluish-purple solution. After stirring for 1 h, a bluish-purple solid precipitated. The solid was filtered in the air and was followed by recrystallization from $CH_2Cl_2$ and hexane in anaerobic conditions to yield the crystalline form of **1a** [0.040 g, 0.047 mmol, ca. 19% based on $VO(iPrO)_3$]. $C_{42}H_{36}P_2S_6V$ (846.01): calcd. C 59.63, H 4.29, S 22.74; found C 59.42, H 4.28, S 22.53. UV/Vis in $CH_2Cl_2$ ($\lambda$, nm; $\varepsilon$, $M^{-1}cm^{-1}$): 438 ($6.02\cdot10^3$), 531 ($6.92\cdot10^3$), 764 ($3.21\cdot10^3$), 918 ($2.40\cdot10^3$).

**Synthesis of [$V^{IV}$(P2S4′)] (1b):** An *i*PrOH solution of $VO(iPrO)_3$ (0.068 g, 0.28 mmol) was added to an ether solution of $[PS3]H_3$ (0.100 g, 0.28 mmol) to generate a bluish-purple solution. After stirring for 1 h, a bluish-purple solid precipitated. The solid was filtered in the air and was followed by recrystallization from benzene and ether in anaerobic conditions to yield the crystalline form of **1b** [0.017 g, 0.023 mmol, ca. 8.2% based on $VO(iPrO)_3$]. $C_{36}H_{24}P_2S_6V$ (761.85): calcd. C 56.75, H 3.18, S 25.25; found C 56.21, H 3.17, S 24.40. UV/Vis in $CH_2Cl_2$ ($\lambda$, nm; $\varepsilon$, $M^{-1}cm^{-1}$): 513 ($6.93\cdot10^3$), 747 ($3.33\cdot10^3$), 890 ($2.41\cdot10^3$).

**Synthesis of [$V^{IV}$(PS3′)(PS2$S^{Me'}$)][$N(C_2H_5)_4$] (2a) and [$V^{IV}$(PS3′)-(PS2$S^{Me'}$)][$N(C_2H_5)_3(CH_2Ph)$] (2b):** An *i*PrOH solution of $VO(iPrO)_3$ (0.060 g, 0.25 mmol) was added to a methanol solution of $[PS3']H_3$ (0.100 g, 0.25 mmol) and $CH_3ONa$ (0.040 g, 0.75 mmol) to generate a brown solution. The reaction mixture changed to a purple color after stirring for 30 min. After filtering through Celite, the solution was concentrated and layered with $(C_2H_5)_4NBr$ (0.050 g, 0.24 mmol) in methanol to give a purple crystalline solid of **2a** [0.020 g, 0.02 mmol, ca. 8% based on $VO(iPrO)_3$]. $C_{51}H_{59}NP_2S_6V$ (991.23): calcd. C 61.79, H 6.00, N 1.41, S 19.41; found C 60.99, H 6.19, N 1.33, S 18.73. UV/Vis in $CH_2Cl_2$ ($\lambda$, nm; $\varepsilon$, $M^{-1}cm^{-1}$): 443 ($4.53\cdot10^3$), 562 ($4.92\cdot10^3$), 677 ($2.98\cdot10^3$). The procedure for the synthesis of **2b** is the same except $(C_2H_5)_3(CH_2Ph)NBr$ was used for the cation. **2b**, $C_{56}H_{61}NP_2S_6V$ (1053.38): calcd. C 63.85, H 5.85, N 1.33, S 18.27; found C 62.99, H 6.05, N 1.32, S 17.82.

### Crystallographic Structure Determination

Each crystal was mounted on a glass fiber and quickly coated in epoxy resin. Diffraction measurements were carried out at 295(2) K for **1b** and 150(2) K for **2b** with a Bruker SMART 1000 CCD diffractometer with graphite-monochromated Mo-$K\alpha$ radiation ($\lambda$ = 0.7107 Å). Least-squares refinement of the positional and anisotropic thermal parameters for the contribution of all non-hydrogen atoms and fixed hydrogen atoms was based on $F^2$. A SADABS absorption correction was made.[27] The SHELXTL structural refinement program was employed.[28] All non-hydrogen atoms were refined with anisotropic displacement factors. All hydrogen atoms were calculated using the riding model. Detailed data and refinement parameters are summarized in Table 5 (**1b** and **2b**) and Table S2 (**2a**).

Table 5. Crystallographic data for compounds **1b** and **2b**.

| | **1b**·$2C_6H_6$ | **2b**·$CH_3OH$ |
|---|---|---|
| Formula | $C_{48}H_{36}P_2S_6V$ | $C_{57}H_{65}NOP_2S_6V$ |
| $M$ [g mol$^{-1}$] | 918.01 | 1085.34 |
| $T$ [K] | 295(2) | 150(2) |
| Crystal system | Monoclinic | Monoclinic |
| Space group | $P2_1/a$ | $P2_1/n$ |
| $a$ [Å] | 18.0270(10) | 12.58000(10) |
| $b$ [Å] | 13.8510(9) | 33.6470(3) |
| $c$ [Å] | 19.1040(11) | 14.25500(10) |

# Oxidative Addition of $Cl_2$, HClO to Square-Planar $Pt^{II}$ Complexes: Synthesis and Structural Characterization of Platinum(II) and Platinum(IV) Bis(amidate) Complexes

**Fenghui Liu[a] and Wanzhi Chen*[a]**

**Keywords:** Platinum / Amidates / Amines

New bis(amidate)platinum(II) complexes with the general formula *cis*-[Pt(RNH$_2$)$_2$(NHCO*t*Bu)$_2$] were prepared by the hydrolysis of the corresponding *cis*-[Pt(RNH$_2$)$_2$(*t*BuCN)$_2$]$^{2+}$ complex. The bis(amidate)platinum(IV) complexes with the formula *trans*,*cis*,*cis*-[PtCl$_2$(RNH$_2$)$_2$(NHCO*t*Bu)$_2$] (**5**: R = H, **6**: R = Et), *trans*,*cis*,*cis*-[PtCl(OH)(RNH$_2$)$_2$(NHCO*t*Bu)$_2$] (**8**: R = H, **9**: R = Et, and **10**: 2R = 1,2-*c*Hex), and mono(amidate) complex *mer*-[PtCl$_3$(DACH)(NHCO*t*Bu)$_2$] (**7**, DACH = *trans*-1,2-diaminocyclohexane) have been generated selectively by the oxidative addition of $Cl_2$ and HClO to the corresponding platinum(II) complexes, [Pt(RNH$_2$)$_2$(NHCO*t*Bu)$_2$], in water. All the prepared compounds were characterized by elemental analyses and $^1$H and $^{195}$Pt NMR spectroscopy. The structures of *trans*,*cis*,*cis*-[PtCl$_2$(NH$_3$)$_2$(NHCO*t*Bu)$_2$] (**5**), *trans*,*cis*,*cis*-[PtCl$_2$(EtNH$_2$)$_2$(NHCO*t*Bu)$_2$] (**6**), *mer*-[PtCl$_3$-(DACH)(NHCO*t*Bu)] (**7**), and *trans*,*cis*,*cis*-[PtCl(OH)(DACH)-(NHCO*t*Bu)$_2$] (**10**) have been confirmed by X-ray diffraction analyses. The structures of these platinum(IV) complexes adopt an octahedral geometry. The Pt–N, Pt–O, and Pt–Cl distances are in the expected ranges. These complexes are rare examples of bis(amidate)- and mono(amidate)platinum(IV) complexes.

## Introduction

Since the discovery of the antitumor activity of *cis*-Pt(NH$_3$)$_2$Cl$_2$ by Rosenberg and co-workers[1] a large number of platinum(II) and platinum(IV) complexes containing *cis*-(NH$_3$)$_2$Pt or *cis*-(RNH$_2$)$_2$Pt units have been prepared and characterized.[2,3] Numerous efforts have been made to develop new antitumor compounds that do not show cross-resistance with *cis*-platin. *cis*-[Pt(RNH$_2$)$_2$(amidate)$_2$] complexes, derived from *cis*-Pt(RNH$_2$)Cl$_2$ have proved to be useful building blocks to assemble homo- and heteronuclear dimeric,[3] oligomeric,[4] and polymeric complexes.[5] The two mutually *cis* amidate ligands play a critical role in favoring the association of the platinum units and other metal ions such as in the biologically active "platinum blues".[6] The amidate-bridged dimeric platinum complex [Pt$_2$(NH$_3$)$_4$(NHCO*t*Bu)L$_2$]$^{2+}$, where L is $NO_3^-$ or solvent molecules, has been found to activate C–H bonds of ketones[7] and to catalyze the ketonation of alkynes, epoxidation, and dihydroxylation of terminal olefins.[8]

It is well known that the $Pt^{IV}$ species are involved in the activation of C–H bonds such as the Shilov system, which consists of aqueous solutions of $Pt^{II}$ and $Pt^{IV}$ salts that convert alkanes to the corresponding chlorides and alcohols under mild conditions.[9] Taking into account the fascinating chemistry of bis(amidate)platinum(III) complexes, the amidatoplatinum(IV) complexes may also be useful for such types of organic transformation processes. Furthermore, although most of the platinum centered antitumor drugs are platinum(II) compounds, in recent years a number of platinum(IV) complexes have also been found to be active for antitumor treatment with improved pharmacological properties.[10] However, so far no bis(amidate)- and mono(amidate)platinum complexes having a $Pt^{IV}$ center have been reported. Here we report for the first time the preparation, $^1$H and $^{195}$Pt NMR spectra, and structural characterization of the platinum(IV) complexes *mer*-[PtCl$_3$(DACH)-(NHCO*t*Bu)] (DACH = *trans*-1,2-diaminocyclohexane), *trans*,*cis*,*cis*-[PtCl$_2$(RNH$_2$)$_2$(NHCO*t*Bu)$_2$], and *trans*,*cis*,*cis*-[PtCl(OH)(RNH$_2$)$_2$(NHCO*t*Bu)$_2$] (R = H, Et; and 2R = 1,2-cHex). These platinum(IV) complexes were prepared by oxidative addition of $Cl_2$ and HClO to their corresponding platinum(II) complexes, *cis*-[Pt(RNH$_2$)$_2$(NHCO*t*Bu)$_2$], in high yields.

## Results and Discussion

### Synthesis and NMR Characterization

The [Pt(RNH$_2$)$_2$(NHCO*t*Bu)$_2$] complexes are easily prepared in high yield by basic hydrolysis of their corresponding platinum(II)-nitrile complexes, [Pt(RNH$_2$)$_2$(*t*BuCN)$_2$]$^{2+}$. This procedure has been employed to prepare [Pt(NH$_3$)$_2$-

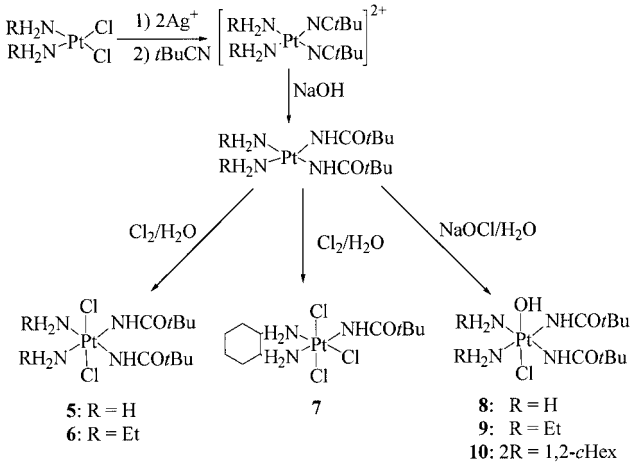
$(NHCOtBu)_2]$ and *cis*-$[Pt(DACH)(NHCOtBu)_2]$. *cis*-$[Pt(EtNH_2)_2(NHCOtBu)_2]$ and *cis*-$[Pt(DACH)(NHCOtBu)_2]$ were similarly obtained. The synthetic strategy for making the platinum(II) as well as platinum(IV) complexes described below is shown in Scheme 1. These platinum(II) complexes are isolated as stable colorless crystalline solids, and they are soluble in acetone, ethanol, and chloroform. The neutral square-planar complexes, *cis*-$[Pt(NH_3)_2(NHCOtBu)_2]$ and *cis*-$[Pt(EtNH_2)_2(NHCOtBu)_2]$, react with an equimolar amount of $Cl_2$ (0.3% in water) at room temperature to give the bis(amidate)platinum(IV) complexes, *trans*,*cis*,*cis*-$[PtCl_2(NH_3)_2(NHCOtBu)_2]$ (**5**) and *trans*,*cis*,*cis*-$[PtCl_2(EtNH_2)_2(NHCOtBu)_2]$ (**6**), as yellow crystals, respectively. However, *mer*-$[PtCl_3(DACH)(NHCOtBu)]$ (**7**) was generated as the sole isolated product when *cis*-$[Pt(DACH)(NHCOtBu)_2]$ was dissolved in $Cl_2/H_2O$ under the same conditions. The reactions proceeded in good yields. The initially formed $[PtCl_2(DACH)(NHCOtBu)_2]$ probably further reacted with HCl to lose one molecule of $tBuCONH_2$ and yield the final product, **7**. The isolated crystals of **5**–**7** are poorly soluble in common organic solvents, but are moderately soluble in dimethyl sulfoxide. Their $^{195}Pt$ NMR spectra exhibit a singlet at –35, –30.6, and –289 ppm, respectively, indicative of typical platinum(IV) compounds.



Scheme 1.

Sodium hypochlorite has proved to be a convenient oxygen source for olefin epoxidation catalyzed by transition-metal complexes.[11] We found that it also acts as a $Cl^-$ and $HO^-$ source for the preparation of (chloro)(hydroxo)platinum(IV) complexes. The platinum(II) complexes *cis*-$[Pt(NH_3)_2(NHCOtBu)_2]$, *cis*-$[Pt(EtNH_2)_2(NHCOtBu)_2]$, and *cis*-$[Pt(DACH)(NHCOtBu)_2]$ easily dissolved in an aqueous solution of NaOCl (available $Cl_2$ 5%) at room temperature and yielded *trans*,*cis*,*cis*-$[PtCl(OH)(RNH_2)_2(NHCOtBu)_2]$ {R = H, **8**; R = Et, **9**; $(RNH_2)_2$ = DACH, **10**} in moderate yields. All these chloro(hydroxo)platinum(IV) complexes were isolated as yellow solids. The $^{195}Pt$ NMR spectra of **8**–**10** in $[D_6]$acetone exhibit singlets at –134, –146, and 189 ppm, respectively, which are typical of $Pt^{IV}$ species. The $^{195}Pt$ NMR spectrum of **10** measured immediately upon dissolving in $[D_6]$DMSO shows two singlets at 189 and –193 ppm. The downfield signal disappeared and the upfield signal was intensified after the solution stood in an NMR tube for 24 h. After this time the $^1H$ NMR spectrum also became simpler. Thus the upfield signal at $\delta$ = –193 ppm is assigned to the solvated species $[Pt(OH)(DMSO)(DACH)(NHCOtBu)_2]Cl$.

The general synthetic route to platinum(IV) complexes is the oxidation of platinum(II) complexes by hydrogen peroxide or halogens.[12] The oxidative addition of HOCl with NaOCl provides a convenient route for the preparation of chloro(hydroxo)platinum(IV) complexes.

## Structural Description

The structures of compounds **4**–**7** and **10** have been determined by X-ray diffraction. A summary of the crystallographic data can be found in Table 1. Colorless crystals of **4** were obtained by slow evaporation of its acetone/water solution. Compound **4** crystallizes in a chiral orthorhombic space group $P2_12_12$, and the chiral configuration is predetermined by the diamine, 1*R*,2*R*-*trans*-diaminocyclohexane. The structure of **4** established by X-ray diffraction analysis is shown in Figure 1. As expected, the central platinum is tetra-coordinated to four nitrogen atoms in a square-planar geometry. The shortness of the C–O and C–N bond lengths illustrates the $sp^2$ character of the related atoms. The structure of **4** is the first crystal structure of a platinum(IV) complex of the type $[Pt(RNH_2)_2(trans\text{-}Cl_2)(amidate)_2]$ in which the chlorine atoms occupy the axial positions of an octahedral geometry.

Although compounds **5** and **6** crystallize in different noncentrosymmetric space groups *C*2 and *Pc*, respectively, they display the same structure. The structure of **5** is depicted in Figure 2 and the structure of compound **6** is given as Supporting Information. There are two independent molecules in the asymmetric crystallographic unit of compound **6**, which have essentially the same structure. Therefore, only one of the two molecules is shown in the Supporting Information. The coordination polyhedrons of the complexes are distorted octahedrons for both **5** and **6**. The two amine and two amidate ligands are in mutual *cis* positions, and the two chloride ions are in mutual *trans* positions. The sum of the angles of the neighboring nitrogen atoms around Pt is 359.8° for **5** and 360.5° for **6**, indicating their coplanarity. The Pt–Cl bond lengths [2.324(8) and 2.328(7) Å for **5**, 2.311(2) and 2.319(2) Å for **6**] are in good agreement with other structurally characterized platinum chloride compounds.[13] The $NH_3$ and $NH_2$ groups in **5** and **6** are involved in intra- and intermolecular hydrogen bonding. The Cl–Pt–Cl angles [179.24(8)° for **5** and 177.01(6)° for **6**] are close to 180°.

The trichloroplatinum(IV) complex **7** crystallizes in an orthorhombic space group *Pbca*. Its unit cell contains eight molecules of $[PtCl_3(DACH)(NHCOtBu)_2]$ and eight molecules of acetone. The structure of **7** consists of an octahe-

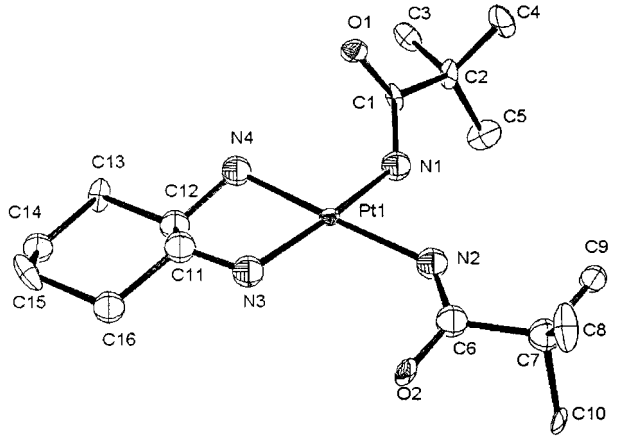

Figure 1. Molecular structure of $[Pt(DACH)(NHCOtBu)_2]$ (**4**). Selected bond lengths and angles: Pt(1)–N(1) 2.055(11), Pt(1)–N(2) 2.098(15), Pt(1)–N(3) 2.062(12), Pt(1)–N(4) 2.051(15), N(4)–Pt(1)–N(1) 93.5(5), N(4)–Pt(1)–N(3) 80.6(6), N(1)–Pt(1)–N(3) 173.2(7), N(4)–Pt(1)–N(2) 178.3(6, N(1)–Pt(1)–N(2) 85.1(5 N(3)–Pt(1)–N(2) 100.9(6).

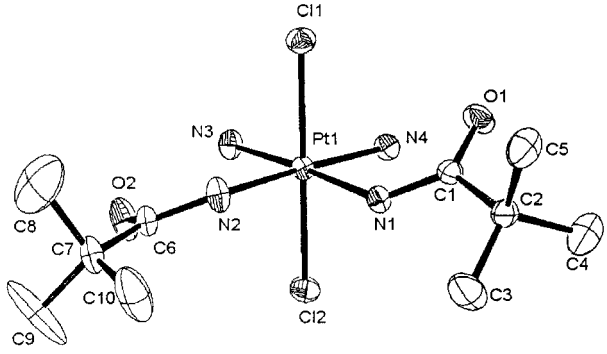

Figure 2. Molecular structure of *trans,cis,cis*-$[PtCl_2(NH_3)_2(NHCOtBu)_2]$ (**5**). Selected bond lengths [Å] and angles [°]: Pt(1)–Cl(1) 2.316(2), Pt(1)–Cl(2) 2.300(2), Pt(1)–N(1) 2.016(6), Pt(1)–N(2) 1.991(7), Pt(1)–N(3) 2.070(7), Pt(1)–N(4) 2.059(6), N(2)–Pt(1)–N(1) 86.6(3), N(2)–Pt(1)–N(4) 176.8(3), N(1)–Pt(1)–N(4) 90.7(3), N(2)–Pt(1)–N(3) 92.4(3), N(1)–Pt(1)–N(3) 177.0(3), N(4)–Pt(1)–N(3) 90.1(3), N(2)–Pt(1)–Cl(2) 89.3(2), N(1)–Pt(1)–Cl(2) 87.54(19), N(4)–Pt(1)–Cl(2) 88.8(2), N(3)–Pt(1)–Cl(2) 89.6(2), N(2)–Pt(1)–Cl(1) 91.3(2), N(1)–Pt(1)–Cl(1) 93.0(2), N(4)–Pt(1)–Cl(1) 90.6(2), N(3)–Pt(1)–Cl(1) 89.9(2), Cl(2)–Pt(1)–Cl(1) 179.24(8).

drally coordinated platinum(IV) center in which the platinum atom is surrounded by three nitrogen and three chlorine atoms in a meridional fashion. The structure is depicted in Figure 3. The cyclohexyl ring exhibits pseudoplanarity as a consequence of the racemic mixture and disorder. The Pt–Cl bond lengths are not unusual, but the chlorine atom *trans* to the nitrogen atom has a rather longer Pt–Cl distance [2.329(2) Å] than the other two in mutually *trans* positions [2.311(2) and 2.319(2) Å]. However, it should be pointed out that an opposite trend has been observed in *cis*-$[PtCl_4\{NH{=}C(Et)OMe\}_2]$.[14] All other bond lengths and angles are as expected and agree perfectly with the values already reported for bis(amidate) platinum complexes.[15]

Compound **10** crystallizes in the noncentrosymmetric space group $P2_1$, and the chirality is predetermined by the ligand 1*R*,2*R*-*trans*-1,2-diaminocyclohexane. Figure 4 depicts the molecular structure of **10** with an atomic labeling scheme. The $PtN_4$ moiety maintains its *cis*-arrangement. The chloride and hydroxide groups are located in axial positions with normal Pt–O and Pt–Cl distances. The Pt–O distance [2.043(16) Å] is consistent with those found in other platinum hydroxide complexes,[16] and the O–Pt–Cl angle is 179.1(5)°. One of the two C=O groups is oriented toward the $NH_2$ group as shown in Figure 4. The N(3)···O(3) distance is 2.71 Å, indicating intramolecular hydrogen bonding.

In summary, oxidative addition of chlorine or HOCl to the neutral [$Pt(RNH_2)_2$(NHCO*t*Bu)$_2$] complexes in water yielded a number of bis(amidate) and mono(amidate) platinum(IV) complexes. Complexes **5**–**10** represent the first fully characterized examples of platinum(IV) mono(amidate) and bis(amidate) complexes derived from oxidative addition. The present study also provides a convenient synthetic route for chloro(hydroxo)platinum(IV) complexes using NaClO as the source of the chloride and hydroxide ions. Furthermore, these complexes may potentially be precursors for the preparation of some $Pt^{IV}$ compounds since the Cl atoms can easily be replaced by other anions.

## Experimental Section

**General Remarks:** *cis*-$Pt(EtNH_2)_2Cl_2$,[17] $Pt(DACH)Cl_2$ (DACH = *trans*-1,2-diaminocyclohexane),[18] *cis*-[$Pt(NH_3)_2$(NHCO*t*Bu)$_2$]·$2H_2O$,[19] and *cis*-[Pt(DACH)(NHCO*t*Bu)$_2$]·$4H_2O$[19] were prepared according to previously published procedures. $Cl_2/H_2O$ (available chlorine 0.3%), NaClO/$H_2O$ (available $Cl_2$ 5.0%), and other chemicals were purchased from commercial sources and used as received. The elemental analyses were performed with a Perkin–Elmer PE 2400II analyzer. The $^1H$ and $^{195}Pt$ NMR spectra were recorded with a Bruker 500 MHz spectrometer. The NMR chemical shifts are given in ppm relative to TMS ($^1H$) and $K_2PtCl_4$ ($^{195}Pt$), and referenced either to residual solvent signals ($^1H$) or externally ($^{195}Pt$).

CAUTION! Perchlorate salts of metal complexes are potentially explosive and should be handled with great care.

***cis*-[Pt(EtNH$_2$)$_2$(NC*t*Bu)$_2$](ClO$_4$)$_2$ (1):** A suspension of *cis*-$Pt(EtNH_2)_2Cl_2$ (0.36 g, 1.0 mmol) in water (10 mL) was treated with $AgClO_4$ (0.41 g, 2.0 mmol), and the mixture was stirred overnight in the dark. After the removal of AgCl, *t*BuCN (1.0 g, 12.0 mmol) was added to the filtrate. The resulting white precipitate was separated and washed with $H_2O$, EtOH, and $Et_2O$, and dried in vacuo. Yield: 0.53 g (82%). $C_{14}H_{32}Cl_2N_4O_8Pt$ (650.41): calcd. C 25.85, H 4.96, N 8.61; found C 25.81, H 4.87, N 8.50. $^1H$ NMR (500 MHz, [$D_6$]acetone): 2.62 (q, $J_{HH}$ = 7.0 Hz, $CH_2CH_3$, 4 H), 1.52 (s, $C(CH_3)_3$, 18 H), 1.10 (t, $CH_2CH_3$, 6 H) ppm. $^{195}Pt$ NMR (107.30 MHz, [$D_6$]acetone): $\delta$ = –2857 ppm.

***cis*-[Pt(EtNH$_2$)$_2$(NHCO*t*Bu)$_2$]·H$_2$O (2):** A suspension of **1** (1.30 g, 2.0 mmol) in water (10 mL) was treated with NaOH (0.20 g, 5.0 mmol). The mixture was stirred overnight at room temperature. The resulting white solid was collected by filtration, washed with cold water and dried in vacuo. Condensing the filtrate and cooling at 5 °C afforded the second crop of the product. Yield: 0.88 g (87%). $C_{14}H_{34}N_4O_2Pt·H_2O$ (503.54): calcd. C 33.39, H 7.21, N 11.13; found C 33.29, H 7.31, N 11.12. $^1H$ NMR (500 MHz, [$D_6$]-acetone): $\delta$ = 6.24 (br. s. $NH_2$, 4 H), 4.89 (s, NH, 2 H), 2.75 (q, $J_{HH}$ = 6.8 Hz, $CH_2$, 4 H), 1.17 (t, $CH_2CH_3$, 6 H), 1.10 (s, $C(CH_3)_3$, 18 H) ppm. $^{195}Pt$ NMR (107.00 MHz, [$D_6$]acetone): $\delta$ = –2564 ppm.

**X-ray Crystallographic Study:** Single crystals of the complexes **4**–**7**, and **10** were grown by slow evaporation of solutions from the above-described preparations. In each case, suitable crystals were mounted on a glass fibre; the hemispheres of X-ray intensity data were collected with a Bruker Smart-*CCD* diffractometer equipped with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The first 50 frames were recollected at the end of the process to monitor crystal decay. The raw frame data were integrated into the SHELX-format reflection files and corrected for Lorentz and polarization effects using SAINT.[20] All structures were solved by direct methods and refined against $F^2$ by full-matrix least-squares techniques.[21] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced into their calculated positions. Compounds **6**–**8** crystallize in noncentrosymmetric space groups. The absolute configurations were determined by refinement of the Flack *x* parameters. Details of the X-ray experiments and crystal data are summarized in Table 1.

CCDC-285359 (for **4**), -195437 (for **5**), -195438 (for **6**), -195439 (for **7**), and -195440 (for **10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Direct Preparation of [Ru($\eta^2$-$O_2CO$)($\eta^6$-arene)(L)] Carbonate Complexes (L = Phosphane, Carbene) and Their Use as Precursors of [$RuH_2$(*p*-cymene)($PCy_3$)] and [Ru($\eta^6$-arene)(L)($MeCN)_2$][$BF_4]_2$: X-ray Crystal Structure Determination of [Ru($\eta^2$-$O_2CO$)(*p*-cymene)($PCy_3$)]·1/2$CH_2Cl_2$ and [Ru($\eta^2$-$O_2CO$)($\eta^6$-$C_6Me_6$)-($PMe_3$)]·$H_2O$

**Bernard Demerseman,*[a] Mbaye Diagne Mbaye,[a] David Sémeril,[a] Loïc Toupet,[a] Christian Bruneau,[a] and Pierre H. Dixneuf[a]**

**Keywords:** Arene ligands / Hydrides / O ligands / Reactive intermediates / Ruthenium

[$RuCl_2$($\eta^6$-arene)($PR_3$)] complexes react with $K_2CO_3$ in the presence of water to afford the carbonatoruthenium(II) derivatives [Ru($\eta^2$-$O_2CO$)($\eta^6$-arene)($PR_3$)] (**2**; arene = *p*-cymene, R = Cy, Ph, or Me; arene = hexamethylbenzene, R = Me) involving a planar Ru($\eta^2$-$O_2CO$) moiety as shown by X-ray crystal structure determination of **2a** (*p*-cymene, $PCy_3$) and **2d** (hexamethylbenzene, $PMe_3$). The complex [Ru($\eta^2$-$O_2CO$)(*p*-cymene)($PCy_3$)] is cleanly converted in hot methanol into the dihydride [$RuH_2$(*p*-cymene)($PCy_3$)]. The related complexes [Ru($\eta^2$-$O_2CO$)($\eta^6$-arene)(IMes)] [arene = *p*-cymene or hexamethylbenzene, IMes = 1,3-bis(2,4,6-trimethylphenyl)imidazol-2-ylidene] are straightforwardly prepared by treating [$RuCl_2$($\eta^6$-arene)$]_2$ precursors with 1,3-bis(2,4,6-trimethylphenyl)imidazolium chloride and $K_2CO_3$ in THF at reflux. The removal of the carbonato ligand from complexes **2** with $HBF_4$ in the presence of acetonitrile leads to the dicationic derivatives [Ru($\eta^6$-arene)(L)($MeCN)_2$][$BF_4]_2$ (L = $PR_3$ or IMes).

## Introduction

The formation of metal catalysts in situ from a metal complex and an alkali metal carbonate salt, introduced as a base, is receiving growing attention. This is the case with a variety of cross-coupling and Heck reactions catalysed by palladium complexes.[1,2] Recently, the generation of ruthenium catalysts for ring-closing enyne metathesis[3,4] or sequential alkene isomerisation/Claisen reactions,[5] by treatment of [$RuCl_2$($\eta^6$-arene)$]_2$ with an imidazolium salt and $Cs_2CO_3$ in situ, has provided other useful examples. In this case, $Cs_2CO_3$ was expected to generate an imidazolylidene carbene by deprotonation of the imidazolium salt, as was fully demonstrated by Arduengo[6] and Çetinkaya.[7] However, the question was raised whether the carbonate anion acts solely as a proton acceptor or might additionally enter into the coordination sphere of the ruthenium centre. Indeed, there are already examples of carbonatoruthenium(II) complexes, although such complexes were most often depicted as unexpected or undesired side-products. Their formation has been observed during the course of various processes, including metathetical exchange between an alkali metal carbonate and a ruthenium halide or cationic ruthenium precursor,[8–11] reaction of carbon dioxide with an oxaruthenacyclobutane,[8] hydrolysis of carbamato ligands,[12] oxidation of coordinated carbon monoxide,[13–18] and reactions involving a formal reduction of carbon dioxide ($2\ CO_2 + 2e^- \rightarrow CO + CO_3^{2-}$).[19,20] From a structural point of view, mononuclear carbonatoruthenium(II) complexes contain an Ru($\eta^2$-$O_2CO$) fragment, whereas the carbonate dianion is a bridging ligand in the dinuclear [$Ru_2$(μ-$O_2CO)_4]^{3-}$ anion[21–23] and in polynuclear, heteroleptic ruthenium complexes.[9,24,25]

The involvement of carbonatoruthenium complexes in organometallic synthesis is still uncommon but, remarkably, the carbonato complex [Ru($\eta^2$-$O_2CO$)(bipy)$_2$] has been shown to react with terminal alkynes under aqueous acidic conditions to conveniently produce [Ru(alkyl)(CO)(bipy)$_2]^+$ and [Ru(acyl)(CO)(bipy)$_2]^+$ derivatives.[26–28] We wish to report here the direct synthesis of [Ru($\eta^2$-$O_2CO$)($\eta^6$-arene)($PR_3$)] carbonatoruthenium(II) derivatives starting from [$RuCl_2$($\eta^6$-arene)($PR_3$)] precursors and $K_2CO_3$, and of related [Ru($\eta^2$-$O_2CO$)($\eta^6$-arene)(IMes)] complexes, where IMes is an imidazolylidene ligand, from [$RuCl_2$($\eta^6$-arene)$]_2$ precursors and an imidazolium salt in the presence of $K_2CO_3$. The present account illustrates the usefulness of the carbonato ligand as a protecting group for ruthenium centres that favours the access to valuable ruthenium hydride derivatives, such as the dihydride complex [$RuH_2$-

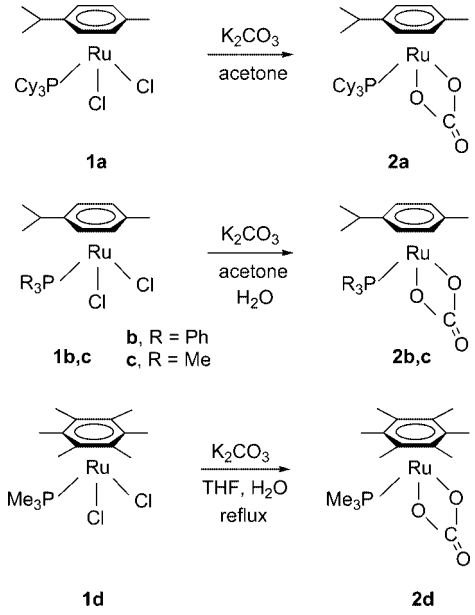
(*p*-cymene)($PCy_3$)], and to dicationic [Ru(η⁶-arene)(L)-$(MeCN)_2$][$BF_4$]$_2$ derivatives.

## Results and Discussion

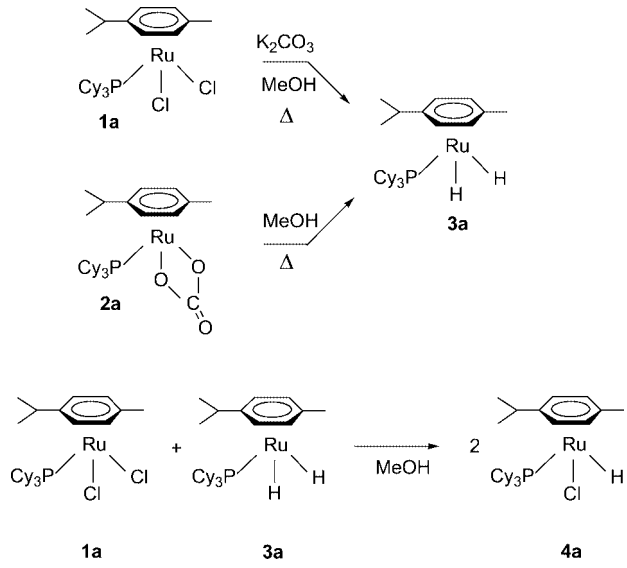
### Synthesis of [Ru(η²-$O_2CO$)(η⁶-arene)(L)] Complexes

Upon stirring at room temperature, a red slurry consisting of [$RuCl_2$(*p*-cymene)($PCy_3$)] (**1a**) and $K_2CO_3$ in acetone as solvent gradually (2 d) turned yellow. Subsequent workup afforded orange-yellow crystals of the new carbonato complex [Ru(η²-$O_2CO$)(*p*-cymene)($PCy_3$)] (**2a**) in 78% yield (Scheme 1).



Scheme 1. Synthesis of the new carbonatoruthenium complexes **2a**–**d**.

No reaction was detected under similar conditions starting from [$RuCl_2$(*p*-cymene)($PR_3$)] precursors **1b**,**c** (**b**: R = Ph; **c**: R = Me) without the addition of a small amount of water to the reaction mixture (ca. 2 wt.-% relative to acetone) to promote the expected reaction and the formation of complexes **2b**,**c** (Scheme 1). Complexes **2b**,**c** were isolated as orange solids in 97 and 95% yield, respectively. Since very long reaction times (10 d starting from **1c**) were required, the use of methanol (instead of acetone) as a polar solvent to facilitate the cleavage of ruthenium–chloride bonds was attempted. Starting from **1b**,**c**, an obvious decomposition was observed at room temperature, whereas **1a** still led to **2a** but also gave minor amounts of the dihydride [$RuH_2$(*p*-cymene)($PCy_3$)] (**3a**) and the chloro hydride [RuCl(H)(*p*-cymene)($PCy_3$)] (**4a**), as determined by $^{31}P\{^1H\}$ NMR spectroscopy. When the yellow reaction mixture in methanol was additionally heated at reflux for 1 h, the dihydride **3a** was obtained selectively (Scheme 2). The dihydride complex **3a** was isolated as a colourless solid in yields of up to 81%. As expected, **3a** was also obtained when a solution of pure **2a** in methanol was heated at reflux (Scheme 2).



Scheme 2. Synthesis of the ruthenium hydride complexes **3a** and **4a**.

The formation of a metal alkoxide intermediate that spontaneously undergoes a β-elimination process is among the most usual routes allowing the transformation of metal–halide into metal–hydride bonds. Evidence for such a mechanism was first obtained from the study of the reaction of [RuCl(Cp)($PPh_3$)$_2$] with NaOMe,[29] and the synthesis of [RuH(Cp)($PPh_3$)$_2$] has since been more conveniently achieved using $K_2CO_3$ in methanol.[30] The formation of the hydride derivatives **3a** and **4a** that occurs in methanol can be rationalised in the same way. The use of acetone as solvent precludes the formation of any ruthenium methoxide intermediate and thus allows selective formation of **2a**. The conversion of **2a** into the dihydride complex **3a** that occurs in methanol at reflux might result from the reaction of the carbonato ligand with two molecules of methanol to generate methoxide groups along with carbon dioxide and water. Finally, the second minor compound, identified as the chloro hydride [RuCl(H)(*p*-cymene)($PCy_3$)] (**4a**), was alternatively synthesised by mixing equimolar amounts of **1a** and **3a** in methanol as solvent (Scheme 2). The synthesis of the parent complex [RuCl(H)(η⁶-benzene)($PCy_3$)] has recently been achieved by treating [$RuCl_2$(η⁶-benzene)($PCy_3$)] with sodium formate.[31]

As with the reaction with **1c**, the conversion of the more robust precursor [$RuCl_2$(hexamethylbenzene)($PMe_3$)] (**1d**) into the corresponding carbonato complex [Ru(η²-$O_2CO$)(η⁶-$C_6Me_6$)($PMe_3$)] (**2d**) needed a reaction time longer than 10 d at room temperature. The synthesis of **2d** was more rapidly (24 h) achieved by treating **1d** with $K_2CO_3$ in THF at reflux, although addition of a small amount of water was also required to reach completion of the reaction (Scheme 1).

The new complexes **2a**–**d**, **3a** and **4a** were characterised by $^1H$, $^{13}C$, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectroscopy and elemental analysis. The $^1H$ and $^{31}P\{^1H\}$ NMR spectra accounted for the coordination of the phosphane besides the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

arene ligand. More specific and characteristic were the high-field $^1$H NMR resonances corresponding to the RuH protons in **3a** and **4a**. The presence of the carbonato ligand in **2a**–**d** was confirmed by $^{13}$C and $^{13}$C{$^1$H} NMR spectroscopy as a resonance between $\delta$ = 165.6 and 166.8 ppm with a small coupling constant ($^3J_{P,C} < 2.9$ Hz). The two complexes **2a**·1/2$CH_2Cl_2$ and **2d**·$H_2O$ were further characterised by an X-ray crystal structure analysis. Crystallographic data are summarised in the Exp. Sect., and ORTEP drawings of **2a** and **2d** are shown in Figures 1 and 2, respectively; selected bond lengths and angles are given in the captions.

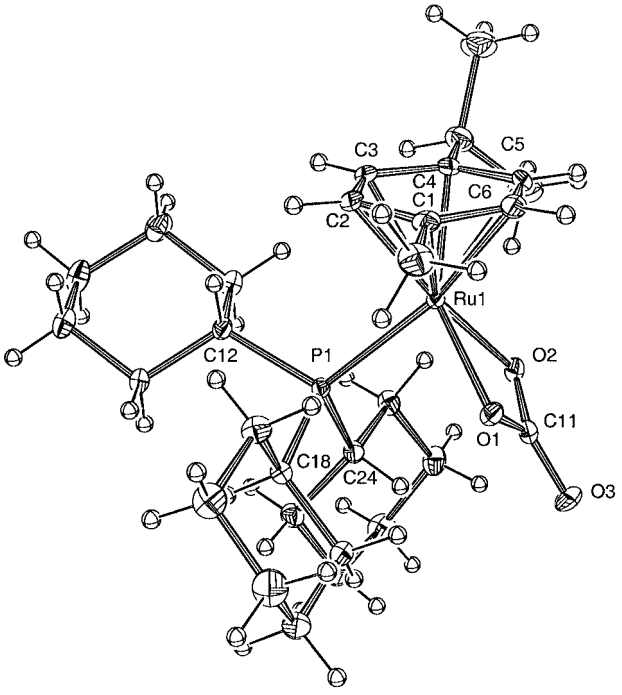


Figure 1. ORTEP drawing of **2a**·1/2$CH_2Cl_2$ showing 50% probability thermal ellipsoids. The $CH_2Cl_2$ molecule has been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–O1 2.079(2), Ru1–O2 2.087(2), O1–C11 1.323(3), O2–C11 1.315(3), O3–C11 1.232(3), Ru1–P1 2.3779(6); O1–Ru1–O2 62.90(7), C11–O1–Ru1 93.02(1), C11–O2–Ru1 92.90(1), O1–C11–O2 111.0(2), O1–C11–O3 124.5(2), O2–C11–O3 124.5(2), O1–Ru1–P1 86.92(5), O2–Ru1–P1 88.09(5).

Figures 1 and 2 show mononuclear species containing a carbonate dianion $\eta^2$-*O*,*O*-coordinated to the ruthenium centre. The two Ru–O bond lengths are almost identical, although they are slightly longer in **2d** [2.104(2) and 2.091(2) Å in **2d** vs. 2.087(2) and 2.079(2) Å in **2a**]. The two Ru–O bonds form a small angle [62.90(7)° in **2a**; 62.81(8)° in **2d**]. The exocyclic C=O bond in **2a** or **2d** [1.232(3) and 1.239(4) Å, respectively] is significantly shorter than the two endocyclic C–O bonds [1.323(3) and 1.315(3) Å in **2a**; 1.325(4) and 1.315(4) Å in **2d**]. It is worth noting the planar arrangement of the Ru($\eta^2$-$O_2$CO) fragment, as indicated by the sum of the angles of the four-membered ring, and around the carbon atom, both of which are very close to 360° (359.8° and 360.0° for **2a** and 359.9° and 360.0° for **2d**, respectively). This plane is approximately perpendicular

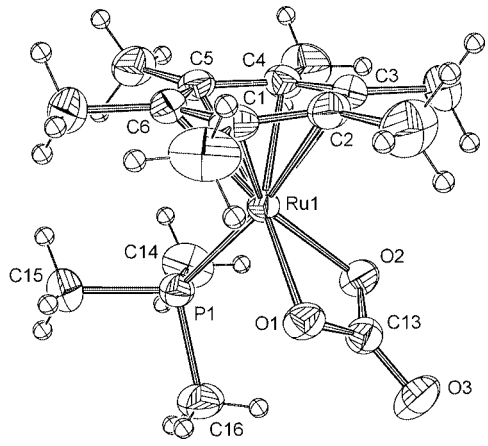

Figure 2. ORTEP drawing of **2d**·$H_2O$ showing 50% probability thermal ellipsoids. The $H_2O$ molecule has been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–O1 2.104(2), Ru1–O2 2.091(2), O1–C13 1.325(4), O2–C13 1.315(4), O3–C13 1.239(4), Ru1–P1 2.343(1); O1–Ru1–O2 62.81(8), C13–O1–Ru1 92.2(2), C13–O2–Ru1 93.1(2), O1–C13–O2 111.8(2), O1–C13–O3 123.7(3), O2–C13–O3 124.5(3), O1–Ru1–P1 88.61(7), O2–Ru1–P1 84.25(7).

to the Ru–P bond [**2a**: O1–Ru1–P1 = 86.92(5)°, O2–Ru1–P1 = 88.09(5)°; **2d**: O1–Ru1–P1 = 88.61(7)°, O2–Ru1–P1 = 84.25(7)°]. The Ru–P bond lengths in **2a** and **2d** are also similar [2.3779(6) and 2.343(1) Å, respectively]. Finally, these main structural features for the Ru($\eta^2$-$O_2$CO) fragment in **2a** and **2d** are in good agreement with those arising from the study of the distinct complex [Ru($CO_3$)($PPh_3$)$_2$($CO$)$_2$], obtained by hydrolysis of the carbamato ligands in [Ru($O_2CN$*i*Pr$_2$)$_2$($PPh_3$)$_2$($CO$)$_2$].[12]

The observed need for water to generate the carbonato complexes **2** suggests a lack of reactivity of the $CO_3^{2-}$ dianion. Furthermore, attempts to synthesise **2d** using $KHCO_3$ instead of $K_2CO_3$ also showed the same need for addition of water to trigger the reaction. Note that the related complex [Ru($CO_3$)($\eta^6$-$C_6Me_6$)(*i*Pr$_2$PCH$_2$CH$_2$OMe)] has been fortuitously synthesised from [RuCl($\eta^6$-$C_6Me_6$)($\eta^2$-*P*,*O*-*i*Pr$_2$PCH$_2$CH$_2$OMe)][$PF_6$] upon treatment with aqueous $Na_2CO_3$.[10] The addition of water might be expected to result in the additional presence of the more reactive hydroxide anion, and this suggested the formation of a Ru–OH bond in a chloride ligand substitution reaction as the first step in this reaction. As depicted in Scheme 3, subsequent reaction between the basic hydroxide intermediate and the acidic $HCO_3^-$ anion completes the formation of the carbonato complexes.

An insertion of carbon dioxide into the Ru–OH bond might also be considered. Indeed, the stable bicarbonato derivative [Ru($\eta^1$-$OCO_2H$)(Me)($\eta^6$-$C_6Me_6$)($PMe_3$)] has been previously been obtained by treating the hydroxide complex [Ru(OH)(Me)($\eta^6$-$C_6Me_6$)($PMe_3$)] with carbon dioxide.[32]

The reaction between $K_2CO_3$ and an imidazolium salt such as 1,3-bis(2,4,6-trimethylphenyl)imidazolium chloride has been shown to generate reactive imidazol-2-ylidene species that can be trapped with sulfur.[6] This process appeared attractive to synthesise organometallic (vs. sulfide)

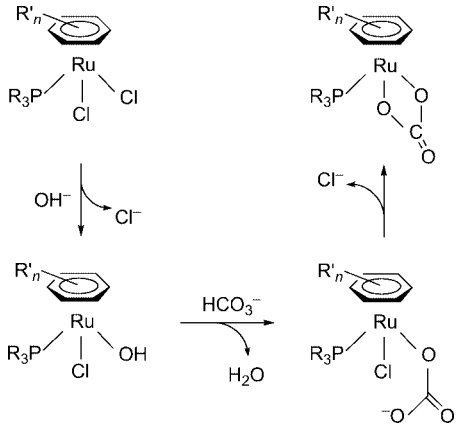
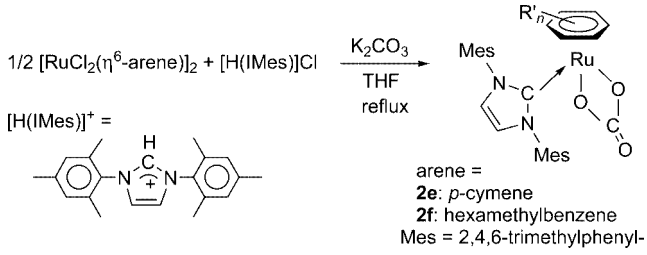


Scheme 3. Rationale accounting for the formation of complexes **2** catalysed by water.

derivatives under similar conditions. Thus, treatment of a 2:1 [H(IMes)]Cl/[$RuCl_2$(η⁶-arene)]$_2$ mixture with an excess of $K_2CO_3$ in THF at reflux led to the new carbonato complexes **2e** and **2f**, which were isolated as dark-orange solids in 79 and 46% yield, respectively (Scheme 4).



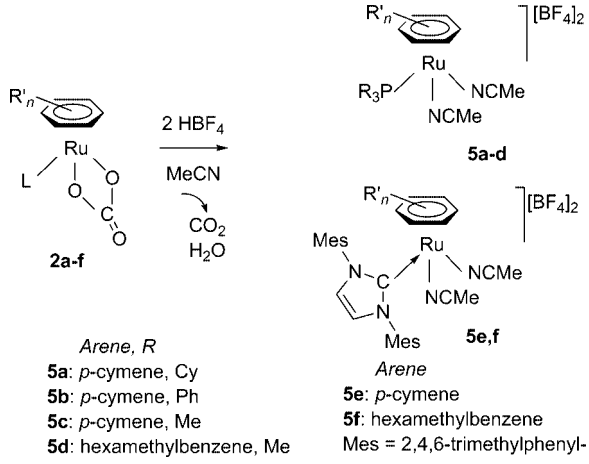
Scheme 4. Synthesis of the carbonatoruthenium complexes [Ru(η²-$O_2CO$)(η⁶-arene)(IMes)] (**2e** and **2f**).

Complexes **2e** and **2f**, which only differ from the carbonato complexes **2a**–**d** by the presence of the 1,3-bis(2,4,6-trimethylphenyl)imidazol-2-ylidene ligand instead of a phosphane, were characterised by $^1$H, $^{13}$C and $^{13}$C{$^1$H} NMR spectroscopy and elemental analysis. The $^{13}$C NMR resonance corresponding to the carbene carbon nucleus in **2e** and **2f** is located at $\delta$ = 180.5 and 183.6 ppm, respectively. The assignment of the $^{13}$C NMR resonance corresponding to the carbonato ligand in **2e** and **2f** ($\delta$ = 166.4 and 166.2 ppm, respectively) was inferred by comparison with **2a**–**d**.

The formation of the carbonato complexes [Ru(η²-$O_2CO$)(η⁶-arene)(IMes)] sheds new light on the preparation of catalysts for enyne metathesis and *O*-allyl isomerisation reactions, which were generated in situ by heating a mixture of [$RuCl_2$(*p*-cymene)]$_2$, imidazolium salt and an excess of $Cs_2CO_3$ in toluene.[3–5] The transient formation of [$RuCl_2$(*p*-cymene)(IMes)], which releases a reactive [$RuCl_2$(IMes)] moiety, was postulated. The fact that the catalytic species may arise from an [Ru($CO_3$)(*p*-cymene)(IMes)] species rather than the [$RuCl_2$(*p*-cymene)(IMes)] intermediate must now be considered.

### Synthesis of Dicationic [Ru(η⁶-arene)(L)(MeCN)$_2$][$BF_4$]$_2$ Derivatives

As previously reported for the reactivity study of the carbonato complex [Ru(η²-$O_2CO$)(bipy)$_2$],[26] double protonation of the carbonato ligand in complexes **2a**–**f** easily occurs under acidic conditions to generate carbon dioxide, water, and to formally release a 14-electron [Ru(η⁶-arene)(L)]$^{2+}$ fragment. The derivatives [Ru(η⁶-arene)(L)(MeCN)$_2$][$BF_4$]$_2$ (**5a**–**f**) were isolated in high yield (84–99%) after treating **2a**–**f** with 2 equiv. of $HBF_4$ (as its dimethyl ether adduct) in acetonitrile as solvent (Scheme 5).



Scheme 5. Synthesis of the dicationic derivatives [Ru(η⁶-arene)(L)(MeCN)$_2$][$BF_4$]$_2$ (**5a**–**f**).

Complexes **5a**–**f** are robust yellow compounds that are highly soluble in acetonitrile. They were characterised by $^1$H, $^{13}$C, $^{13}$C{$^1$H} and $^{31}$P{$^1$H} NMR spectroscopy and elemental analysis. Remarkably, the $^{13}$C NMR resonance corresponding to the carbene carbon nucleus in **5e** and **5f** ($\delta$ = 163.7 and 164.1 ppm, respectively) is shifted upfield relative to **2e** and **2f** ($\delta$ = 180.5 and 183.6 ppm, respectively). This observation likely indicates a reduced back-donation from the metal atom in **5e** and **5f** as compared to **2e** and **2f**, which results in an enhanced imidazolium (vs. imidazolylidene) character.[33] A study of analogous [Ru(η⁶-benzene)(L)(MeCN)$_2$]$^{2+}$ complexes obtained by treatment of [Ru(η⁶-benzene)(MeCN)$_3$][OTf]$_2$ with a phosphane has recently been reported and emphasises the potential of such complexes.[34]

## Conclusions

The easy formation of carbonatoruthenium complexes on reaction of $K_2CO_3$ with $L_nRuCl_2$ precursors in the presence of water constitutes a convenient method to remove the chloride ligands and to use the carbonato ligand as a protecting group for transition metal centres. Under acidic conditions, a clean elimination of the carbonato ligand takes place to formally generate a coordinatively unsaturated dicationic moiety. Thus, the transformation of [$RuCl_2$(η⁶-arene)(L)] precursors into dicationic [Ru(η⁶-arene)(L)(MeCN)$_2$][$BF_4$]$_2$ derivatives is achieved without any

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

involvement of strong chloride scavengers such as silver or thallium salts. The carbonato ligand also allows a convenient route to useful dihydride complexes upon reaction with methanol. Finally, the formation of carbonatoruthenium intermediates may interfere in processes where a ruthenium catalyst is generated in situ from a ruthenium dichloride complex and an alkali metal carbonate as base.

## Experimental Section

**General:** The reactions were performed according to Schlenk-type techniques. Commercial solvents (99+% grade) were used without further purification except diethyl ether and dichloromethane, which were distilled under an inert gas after drying according to conventional methods. NMR spectra were recorded at 297 K with AC 200 FT and AC 300 Bruker instruments and referenced internally to the solvent peak. Elemental analyses were performed by the "Service de Microanalyse du CNRS", Vernaison, France. Complexes **1a**–**d** were obtained by treating the appropriate phosphane with dimeric $[RuCl_2(\eta^6\text{-arene})]_2$ ruthenium complexes in dichloromethane as solvent, as described in the literature.[35] For the convenience of this work, **1a** was prepared as its acetone adduct. The preparation of 1,3-bis(2,4,6-trimethylphenyl)imidazolium chloride has been described elsewhere.[36]

**$[RuCl_2(p\text{-cymene})(PCy_3)]\cdot$acetone (1a):** Stoichiometric amounts of $[RuCl_2(p\text{-cymene})]_2$ (8.07 g, 13.2 mmol) and $PCy_3$ (7.39 g, 26.4 mmol) were mixed in dichloromethane (60 mL) as reported previously.[37] After stirring for 2 h, the mixture was concentrated to dryness and acetone (60 mL) was added to the residue. The mixture was stirred to obtain a red precipitate that was collected by filtration. Yield: 16.1 g (95%). The product retains 1 equiv. of acetone per Ru, as indicated by $^1$H NMR spectroscopy.

**$[Ru(\eta^2\text{-}O_2CO)(p\text{-cymene})(PCy_3)]\cdot 1/2CH_2Cl_2$ (2a):** A mixture consisting of a sample of **1a** (6.00 g, 9.30 mmol), $K_2CO_3$ (2.00 g, 14.5 mmol) and acetone (50 mL) was stirred for 2 d. The volatiles were then removed under vacuum to leave a yellow solid, whicht was extracted with dichloromethane (50 mL). The solution was filtered and the filtrate was covered with acetone (20 mL) and then with diethyl ether (160 mL) to afford orange-yellow crystals. Yield: 4.51 g (78%). $^1$H NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 1.25 (d, $^3J_{H,H}$ = 6.9 Hz, 6 H, CH$Me_2$), 1.16–1.89 (m, 33 H, Cy), 2.12 (s, 3 H, Me), 2.52 (m, 1 H, C$H$Me$_2$), 5.26 (d, $^3J_{H,H}$ = 6.2 Hz, 2 H, $C_6H_4$), 5.34 (d, $^3J_{H,H}$ = 6.2 Hz, 2 H, $C_6H_4$) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, $CD_2Cl_2$): $\delta$ = 18.7 (s, $Me$C$_6$H$_4$), 23.3 (s, CH$Me_2$), 27.0 (s, Cy, 1 C), 28.3 (d, $J_{P,C}$ = 10.2 Hz, Cy, 2 C), 29.9 (s, Cy, 2 C), 32.6 (s, $C$HMe$_2$), 35.4 (d, $^1J_{P,C}$ = 18.9 Hz, Cy, 1 C), 85.4 (d, $^2J_{P,C}$ = 3.8 Hz, $C_6H_4$, 2 CH), 86.6 (d, $^2J_{P,C}$ = 4.2 Hz, $C_6H_4$, 2 CH), 94.5 (s, $C$Me, *p*-cymene), 103.7 (s, $Ci$Pr, *p*-cymene), 165.6 (d, $^3J_{P,C}$ = 2.6 Hz, $CO_3$) ppm. $^{31}$P{$^1$H} NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 37.8 ppm (s). $C_{29}H_{47}O_3PRu\cdot 1/2CH_2Cl_2$ (618.21): calcd. C 57.32, H 7.66, Cl 5.73, P 5.01; found C 57.24, H 7.82, Cl 5.52, P 5.18.

**$[Ru(\eta^2\text{-}O_2CO)(p\text{-cymene})(PPh_3)]$ (2b):** A mixture consisting of a sample of **1b** (2.71 g, 4.77 mmol), $K_2CO_3$ (1.50 g, 10.9 mmol), acetone (40 mL) and water (0.50 mL) was stirred for 3 d. The resulting yellow slurry was concentrated to dryness and the remaining solid was extracted with dichloromethane (40 mL). Acetone (10 mL) was added to the orange filtrate and this mixture was slowly concentrated to leave a crystalline orange-yellow solid, which was found to be pure by $^1$H and $^{31}$P{$^1$H} NMR spectroscopy. Yield: 2.57 g (97%). Orange crystals were obtained by recrystallisation from hot acetonitrile. $^1$H NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 1.18 (d, $^3J_{H,H}$ = 6.7 Hz, 6 H, CH$Me_2$), 2.00 (s, 3 H, $Me$C$_6$H$_4$), 2.49 (m, 1 H, C$H$Me$_2$), 5.12 (d, $^3J_{H,H}$ = 6.1 Hz, 2 H, $C_6H_4$), 5.20 (d, $^3J_{H,H}$ = 6.2 Hz, 2 H, $C_6H_4$), 7.37–7.54 (m, 15 H, Ph) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, $CD_2Cl_2$): $\delta$ = 18.6 (s, $Me$C$_6$H$_4$), 22.9 (s, CH$Me_2$), 31.8 (s, $C$HMe$_2$), 87.1 (d, $^2J_{P,C}$ = 5.4 Hz, $C_6H_4$, 2 CH), 87.8 (d, $^2J_{P,C}$ = 4.4 Hz, $C_6H_4$, 2 CH), 96.3 (s, $C$Me, *p*-cymene), 106.8 (s, $Ci$Pr, *p*-cymene), 128.8 (d, $^2J_{P,C}$ = 9.9 Hz, Ph, *ortho*), 131.1 (s, Ph, *para*), 131.5 (d, $^1J_{P,C}$ = 44.8 Hz, Ph, *ipso*), 134.5 (d, $^3J_{P,C}$ = 9.7 Hz, Ph, *meta*), 165.1 (s, $CO_3$) ppm. $^{31}$P{$^1$H} NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 33.0 ppm (s). $C_{29}H_{29}O_3PRu$ (557.60): calcd. C 62.47, H 5.24, P 5.55; found C 62.33, H 5.30, P 5.30.

**$[Ru(\eta^2\text{-}O_2CO)(p\text{-cymene})(PMe_3)]$ (2c):** A mixture consisting of a sample of **1c** (1.50 g, 3.92 mmol), $K_2CO_3$ (1.00 g, 7.24 mmol), acetone (40 mL) and water (0.50 mL) was stirred for 10 d. The resulting yellow slurry was concentrated to dryness and the remaining solid was extracted with dichloromethane (40 mL). The solution was filtered and the orange filtrate was slowly concentrated to leave an orange, crystalline solid, which was found to be pure by $^1$H and $^{31}$P{$^1$H} NMR spectroscopy. Yield: 1.38 g (95%). Recrystallisation from an acetone/acetonitrile mixture afforded dark-orange crystals. $^1$H NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 1.17 (d, $^3J_{H,H}$ = 6.9 Hz, 6 H, CH$Me_2$), 1.34 (d, $^2J_{P,H}$ = 10.3 Hz, 9 H, $PMe_3$), 2.05 (s, 3 H, $Me$C$_6$H$_4$), 2.51 (m, 1 H, C$H$Me$_2$), 5.38 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, $C_6H_4$), 5.46 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, $C_6H_4$) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, $CD_2Cl_2$): $\delta$ = 14.9 (d, $^1J_{P,C}$ = 28.4 Hz, $PMe_3$), 18.9 (s, $Me$C$_6$H$_4$), 23.2 (s, CH$Me_2$), 32.2 (s, $C$HMe$_2$), 86.1 (s, $C_6H_4$, 2 CH), 86.6 (s, $C_6H_4$, 2 CH), 94.9 (s, $C$Me, *p*-cymene), 103.9 (s, $Ci$Pr, *p*-cymene), 166.7 (d, $^3J_{P,C}$ = 2.9 Hz, $CO_3$) ppm. $^{31}$P{$^1$H} NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 8.3 ppm (s). $C_{14}H_{23}O_3PRu$ (371.38): calcd. C 45.28, H 6.24, P 8.34; found C 45.18, H 6.29, P 8.30.

**$[Ru(\eta^2\text{-}O_2CO)(\text{hexamethylbenzene})(PMe_3)]\cdot H_2O$ (2d):** A mixture consisting of a sample of **1d** (2.00 g, 4.87 mmol), $K_2CO_3$ (1.50 g, 10.9 mmol), acetone (40 mL) and water (0.60 mL) was stirred for 10 d. The resulting yellow slurry was concentrated to dryness and the remaining solid was extracted with dichloromethane (40 mL). Acetone (10 mL) was added to the orange filtrate and this mixture was slowly concentrated to leave an orange, crystalline solid, which was found to be pure by $^1$H and $^{31}$P{$^1$H} NMR spectroscopy. Yield: 1.87 g (92%). Alternatively, a mixture consisting of a sample of **1d** (1.00 g, 2.44 mmol), $K_2CO_3$ (1.00 g, 7.2 mmol), THF (40 mL) and water (0.50 mL) was heated at reflux for 24 h, then treated as above. Yield: 0.55 g (54%). Recrystallisation by diffusion of THF into a concentrated solution of the compound in dichloromethane afforded orange-red crystals. $^1$H NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 1.22 (d, $^2J_{P,H}$ = 10.2 Hz, 9 H, $PMe_3$), 2.04 (s, 18 H, $C_6Me_6$) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, $CD_2Cl_2$): $\delta$ = 13.7 (d, $^1J_{P,C}$ = 28.0 Hz, $PMe_3$), 16.2 (s, $C_6Me_6$), 95.1 (d, $^2J_{P,C}$ = 3.4 Hz, $C_6$Me$_6$), 166.8 (d, $^3J_{P,C}$ = 2.6 Hz, $CO_3$) ppm. $^{31}$P{$^1$H} NMR (121.50 MHz, $CD_2Cl_2$): $\delta$ = 4.7 ppm (s). $C_{16}H_{27}O_3PRu\cdot H_2O$ (417.45): calcd. C 46.04, H 7.00, P 7.42; found C 45.86, H 6.92, P 7.45.

**$[Ru(\eta^2\text{-}O_2CO)(p\text{-cymene})(IMes)]$ (2e):** A mixture consisting of a sample of $[RuCl_2(p\text{-cymene})]_2$ (2.00 g, 3.27 mmol), 1,3-bis(2,4,6-trimethylphenyl)imidazolium chloride (2.27 g, 6.66 mmol), $K_2CO_3$ (3.00 g, 21.7 mmol), THF (40 mL) and dichloromethane (10 mL) was stirred overnight then heated at reflux for 20 h. The resulting slurry was concentrated to dryness and the remaining solid was extracted with dichloromethane (30 mL). The solution was filtered and the filtrate was concentrated under vacuum to leave a brown solid, which was found to be pure by $^1$H NMR spectroscopy. Yield: 3.60 g (79%). Recrystallisation from hot toluene afforded dark-orange crystals of **2e**·1/4$C_7H_8$ in 77% yield relative to crude **2e**. $^1$H

**X-ray Crystallography:** A selected crystal of **2a**·1/2$CH_2Cl_2$ was studied with a NONIUS Kappa CCD diffractometer equipped with a graphite monochromator. The cell parameters were obtained with Denzo and Scalepack,[38] and data collection with NONIUS KappaCCD software.[39] Data reduction was carried out with Denzo and Scalepack.[38] A selected crystal of **2d**·$H_2O$ was studied with a NONIUS CAD 4 automatic diffractometer equipped with a graphite monochromator.[40] After Lorenz and polarisation corrections (**2d**),[41] the structures were solved with SIR-97, which revealed the non-hydrogen atoms.[42,43] After anisotropic refinement, many hydrogen atoms might be found with Fourier difference calculations. The whole structures were refined with SHELXL-97 by full-matrix least-squares methods on $F^2$ ($x$, $y$, $z$, $\beta_{ij}$ for Ru, P, Cl,

# Boron–Nitrogen Adducts of 1,3,5-Triaza-7-phosphaadamantane (PTA): Synthesis, Reactivity, and Molecular Structure

**Brian J. Frost,*[a] Charles A. Mebi,[a] and Phillip W. Gingrich[a]**

**Keywords:** Borane adducts / Boroxine / N,P ligands / Coordination modes / Structure elucidation

Addition of $BH_3$ to 1,3,5-triaza-7-phosphaadamantane (PTA) leads to the formation of the first coordination complex of PTA in which a nitrogen and not the phosphorus of PTA is involved in the bonding. Multinuclear NMR spectroscopy, X-ray crystallography, and computational chemistry are utilized in the characterization of the products. Crystal structures of PTA–$BH_3$ (**1**) and O=PTA–$BH_3$ (**2**) adducts are described. In addition a coordination polymer, $[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n$ (**3**), resulting from Lewis acid–base adduct formation between the PTA ligands of $CpRu(PTA)_2Cl$ and the product of the cyclocondensation of phenylboronic acid is described. The polymeric compound **3** was also characterized by X-ray crystallography.

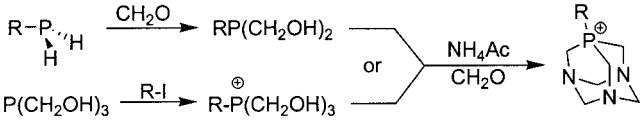
## Introduction

The coordination chemistry and catalytic activity of metal complexes containing aminophosphane ligands has been explored extensively in recent years.[1] Much of the interest in this class of ligand arises from the variety of coordination modes possible (i.e. *N*-bound, *P*-bound, or N–P chelate). Particularly important for catalytic applications is the hemilabile nature of the hard nitrogen donor.[2] Our group,[3–5] and others,[6] have been interested in the chemistry of the heterocyclic phosphane 1,3,5-triaza-7-phosphaadamantane (PTA), which was first synthesized by Daigle in the 1970s (Figure 1).[7,8] The attractive properties of PTA are its resistance to oxidation, small size, strong binding ability, and water solubility. Although PTA is an aminophosphane, the adamantane-like structure excludes the possibility of P–N chelate formation. PTA coordinates to metal atoms through the phosphorus atom, with only one known example of a PTA complex containing a nitrogen–metal dative bond; a polymeric structure formed through the coordination of a nitrogen of a ruthenium-bound PTA ligand to silver.[9] Because metals preferentially bind to the phosphorus of PTA, the amine functionalities of PTA are the preferred site of alkylation and protonation.[7,10] We have been interested in the coordination chemistry of PTA and, specifically, why transition metals bind to the phosphorus site and other Lewis acids, such as $H^+$ and $R^+$, bind preferentially, although not exclusively, to the nitrogen sites. Methylation of PTA with MeI leads to *N*-methylated PTA (PTA-Me) with a small amount, $< 5\%$, of the *P*-methylated PTA (Me-PTA).[10,11] The synthesis of *P*-alkylated PTA derivatives may be accomplished by starting with phosphane sources such as R-$PH_2$ or $P(CH_2OH)_3$, Scheme 1.[12,13]

Figure 1. PTA.



Scheme 1.

Herein we present experimental and theoretical data on the addition of $BH_3$ to PTA and O=PTA, affording the first coordination complex of PTA involving only nitrogen coordination. Also described is an extended polymeric structure, $[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n$, held together by B–N coordination of a PTA nitrogen to triphenylboroxine.

## Results and Discussion

$BH_3$ complexes of PTA and O=PTA, **1** and **2** respectively, have been synthesized in good yield by addition of $BH_3$–THF to PTA or O=PTA. In both cases, addition of $BH_3$ leads to the formation of a N–B coordination complex, Scheme 2. As it is not surprising that such complexes are formed, compound **1** is, to the best of our knowledge, the first example of a coordination complex of PTA in which only nitrogen of PTA is involved in bonding. Peruzzini et al. recently reported the first example of a coordination

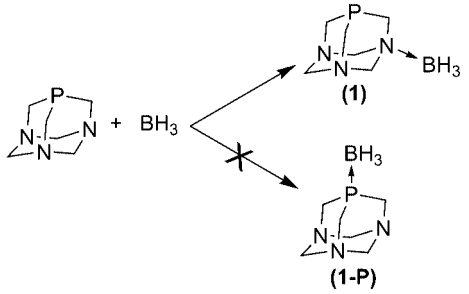
complex involving binding of a nitrogen of PTA to another metal;[9] in this case the phosphorus of PTA is already coordinated to ruthenium. There are still no examples in the literature of a nitrogen-bound PTA–metal complex in which the phosphorus is not also coordinated to a metal.



Scheme 2.

The site of $BH_3$ binding has been determined by: X-ray crystallography, computational chemistry, IR spectroscopy, $^1H$, $^{31}P$, and $^{11}B$ NMR spectroscopy, all of which indicate that addition of $BH_3$ results in preferential B–N and *not* B–P bond formation. No evidence of P–B bond formation was observed by any spectroscopic method including $^{11}B$ or $^{31}P$ NMR spectroscopy.[14,15]

Addition of $BH_3$ to PTA or O=PTA results in a slight shift of the $^{31}P$ NMR resonances with respect to PTA and O=PTA. The complexes **1** and **2** exhibit $^{31}P$ NMR resonances at –88.4 and –9.8 ppm, respectively, compared to –98.3 and –2.5 ppm for PTA and O=PTA.[7,8] These shift values are similar to those observed for the methylation of PTA; $PTA(Me)^+$ exhibits a $^{31}P$ NMR resonance at –86.1 ppm.[6] The $^{11}B$ NMR spectra of **1** and **2** were obtained with resonances at –10.8 ppm for **1** (quartet, $^1J_{BH}$ = 98 Hz) and –12.2 ppm for **2** (quartet, $^1J_{BH}$ = 95 Hz). These values compare well with other $^{11}B$ chemical shifts of other $H_3B–NR_3$ compounds. For example, the $^{11}B$ NMR chemical shift of the borane adducts of 1,3,5-trimethyl-1,3,5-triazacyclohexane[16] and 3,5-dimethyl-1,3,5-thiadiazacyclohexane[17] were found to be –12.6 ppm (q, $^1J_{BH}$ = 96 Hz) and –11.1 ppm (q, $^1J_{BH}$ = 97 Hz), respectively.

The solid-state structures of **1** and **2** were determined by X-ray crystallography. Crystals suitable for X-ray analysis were obtained by slow diffusion of hexanes into a THF solution of the complex at room temperature over 3 days.

### Structure of $PTA–BH_3$ (1)

A thermal ellipsoid representation of complex **1** is depicted in Figure 2, along with the atomic numbering scheme. Selected bond lengths and angles may be found in Table 1. The overall structure including bond lengths and angles is practically identical to that of PTA. Noteworthy is that the B–N bond length [1.58(2) Å] in **1** is similar to that found in the DABCO adduct, $N(CH_2CH_2)_3N–BH_3$ (B–N = 1.598 Å),[18] and is slightly shorter than the B–N bond in the hexamethylenetetramine–borane adduct [B–N = 1.661(7) Å].[19] Also of note is that the (B)N–C(N) bond length, 1.505(9) Å, is longer than the other N–C(N) bond lengths, 1.458(9) Å, consistent with other PTA complexes

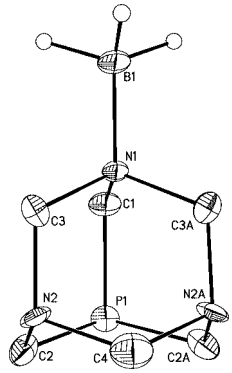


Figure 2. Thermal ellipsoid plot of $PTA–BH_3$ showing the atomic numbering scheme; hydrogen atoms have been omitted for clarity; thermal ellipsoids are plotted at 50% probability.

in which one nitrogen atom of PTA has been protonated or alkylated.[20] Table 2 compares the bond lengths and angles of **1** with PTA and other PTA complexes.

### Structure of O=PTA–$BH_3$ (2)

A thermal ellipsoid representation of complex **2** is depicted in Figure 3, along with the atomic numbering scheme. Selected bond lengths and angles may be found in Table 3. The P–O bond length in **2** [1.4903(11) Å] is slightly longer than found in O=PTA (P–O = 1.476 Å).[21,22] Noteworthy is that the B–N bond length in **2** [1.616(2) Å] is slightly longer than the B–N distance in **1** [1.58(2) Å], presumably due to the more positive nature of the formally $P^V$ oxidation state of the phosphorus. Comparison of bond lengths and angles in **2** with O=PTA may be found in Table 2.

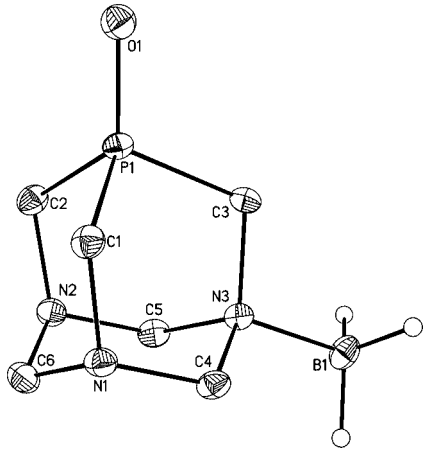

Figure 3. Thermal ellipsoid plot of O=PTA–$BH_3$ showing the atomic numbering scheme; hydrogen atoms have been omitted for clarity; thermal ellipsoids are plotted at 50% probability.

### Theoretical Calculations

In an attempt to gain insight into the reactivity differences between the nitrogen and phosphorus sites of PTA, calculations were performed modeling the alkylation and $BH_3$ addition to PTA. Density Functional Theory (DFT) calculations (B3LYP/LANL2DZ) were performed on **1**, **1-P**, PTA, PTA-Me, and Me-PTA as described in the experimental section. From these calculations we predict an energy difference of 53.6 kJ/mol between **1** and **1-P**, with **1** being the more stable isomer. This is consistent with calculations comparing the alkylation of PTA at the nitrogen atom (PTA-Me) or phosphorus (Me-PTA), which predict that nitrogen is the preferred site of alkylation by ca. 39.1 kJ/mol. These results are in agreement with those obtained by Darensbourg et al.[10] Table 4 contains comparisons of calculated geometries for **1**, **1-P**, **2**, PTA, and O=PTA. The bond lengths and angles in Table 4 correspond well that those found in the crystal structures of **1**, **2**, PTA, and O=PTA.

### Reactivity of 1 and 2

Complexes of **1** and **2** are susceptible to hydrolytic cleavage of the boron–nitrogen bond in both the solid state and in solution. $BH_3$ may also be cleanly and easily removed from **1** or **2** by addition of excess diazobicyclooctane (DABCO) to an acetone solution of **1** or **2** at 50° C. One of the unusual features of **1** is that the phosphorus is now much more vulnerable to oxidation than PTA, $PTA(H)^+$, or $PTA(Me)^+$. Solids of PTA–$BH_3$ were stable in air for weeks, whereas solutions of PTA–$BH_3$ show signs of oxidation to O=PTA–$BH_3$ over the course of days, Scheme 3. In contrast, PTA, $PTAH^+$, and $PTAMe^+$ are indefinitely stable towards air oxidation in the solid state or solution. Both **1** and **2** must be stored under dry conditions, and **1** must be stored under nitrogen to prevent oxidation.

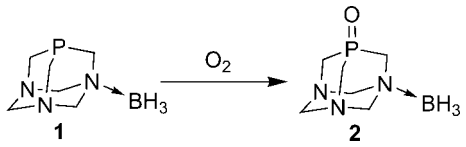
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

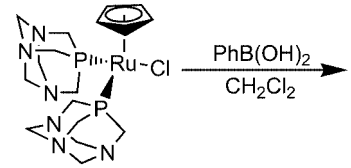


Scheme 3.

Addition of $BH_3$ appears to activate the phosphorus to alkylation as well as oxidation; addition of methyl iodide to PTA–$BH_3$ results in the formation of ca. 20% of the phosphorus-methylated product (Me-PTA) and ca. 80% of the nitrogen-methylated product (PTA-Me). Compared to the alkylation of PTA with MeI, which results in >95% PTA-Me and <5% Me-PTA the phosphorus in **1** is activated with respect to alkylation. This may open up new synthetic pathways towards high-yield synthesis of phosphorus-alkylated PTA compounds important in the further development of the chemistry of PTA and PTA derivatives. Currently phosphorus-alkylated PTA is synthesized by first alkylating $P(CH_2OH)_3$ followed by reaction with $NH_4OAc$ and formaldehyde (Scheme 1).[12,13]

### Synthesis of $[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n \cdot 1/2CH_2Cl_2$

We have previously reported the solid-state structure of $CpRu(PTA)_2Cl$.[4] In an attempt to access the cationic $CpRu(PTA)_2S^+$ complexes (where S = solvent; $CH_3CN$, $H_2O$), recently described,[23] we reacted $NaBPh_4$ with $CpRu(PTA)_2Cl$ in the presence of 1-propanol. Instead of the desired product, $[CpRu(PTA)_2S][BPh_4]$, we obtained crystals of the polymeric complex $[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n \cdot 3CH_2Cl_2$ in low yield (< 10%). The yield from this reaction is very low; the product is likely obtained due to small amounts of $Ph_3B_3O_3$ impurities in the $NaBPh_4$, or from adventitious water reacting with the tetraphenylborate anion generating triphenylboroxine. This complex was obtained in moderate yields (48%) by reaction of $CpRu(PTA)_2Cl$ with three equivalents of phenylboronic acid in dichloromethane, which affords large orange crystals of $[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n \cdot 1/2CH_2Cl_2$ (**3**). The polymer forms as a result of the cyclocondensation of phenylboronic acid, to triphenylboroxine, followed by formation of a Lewis acid–base adduct with the PTA ligands of $CpRu(PTA)_2Cl$ (Scheme 4); similar to the PTA–$BH_3$ complexes described above. Adducts of boroxines with amines have been reported;[24–30] however, compound **3** is the first involving PTA. Perzzuni et al. have described elsewhere the first heterobimetallic complex in which PTA exhibits both P and N coordination. In this case, $CpRu(PTA)_2Cl$ was treated with AgOTf leading to a polymeric structure in which PTA is bound to both ruthenium (by phosphorus) and silver (by nitrogen).[9] Complex **3** and the complexes described by Peruzzini are the only verifiable examples of PTA complexes in which the nitrogen sites of PTA are involved in dative bonding to another atom. It is now apparent that the nitrogen sites of PTA may be far from benign in the chemistry of PTA complexes. Unlike the water-soluble organometallic polymers of Peruzzini et al.,[9] compound **3** does not appear to remain polymeric in aqueous solution, presumably due to ring-cleavage hydrolysis of the coordinated $Ph_3B_3O_3$.



$[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n + 3n\ H_2O$

**3**

Scheme 4.

The $^{31}P$ NMR of the polymeric **3** in dichloromethane exhibits a broad singlet at –21.9 ppm, relative to the $^{31}P$ NMR chemical shift of –25.6 ppm for the parent $CpRu(PTA)_2Cl$. The $^1H$ NMR spectrum of **3**, in $CD_2Cl_2$, contains a sharp resonance attributed to the Cp protons at $\delta$ = 4.59 ppm an upfield shift of 0.16 ppm, relative to $CpRu(PTA)_2Cl$, indicating shielding of the protons by the phenyl groups of the boroxine as confirmed by the crystal structure. The N$CH_2$N protons of the PTA ligands in **3** exhibit an AB pattern centered at $\delta$ = 4.53 ppm ($^2J_{(HAHB)}$ = 13 Hz). The P$CH_2$N protons of the PTA ligands also exhibit an AB pattern centered at $\delta$ = 3.98 ppm ($^2J_{(HAHB)}$ = 15 Hz). The PTA protons are shifted downfield due to the deshielding effect of the N–B bonding. Two distinct resonances for the phenyl rings of the boroxine are observed, 8.07 ppm (5 H) and 7.5 ppm (10 H), indicating two different environments for the phenyl rings. $^{11}B$ NMR spectroscopy of **3** in acetone reveals two different boron environments with $^{11}B$ chemical shifts of 29.3 and 21.3 ppm indicative of unbound and bound boron nuclei, respectively.[31] This suggests that **3** remains polymeric in acetone with two of the boron atoms of triphenylboroxine coordinated to a PTA and remaining boron uncoordinated.

### Structure of $[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n \cdot 1/2CH_2Cl_2$

The solid-state structure of **3** was determined by X-ray crystallography. Large orange crystals suitable for X-ray diffraction were obtained by slow diffusion of hexanes into a concentrated solution of **3** in $CH_2Cl_2$. A thermal ellipsoid representation of complex **3** is depicted in Figure 4, along with the atomic numbering scheme. Selected bond lengths and angles may be found in Table 5. The structure consists of $CpRu(PTA)_2Cl$ molecules linked together in linear chains by $Ph_3B_3O_3$, cocrystallized with half a molecule of $CH_2Cl_2$. The polymeric structure is obtained through formation of a Lewis acid–base adduct from one nitrogen atom on each PTA to a boron atom of triphenylboroxin. Two of the three boron atoms in triphenylboroxin form N–B bonds, which affords a linear polymer, with the geometry about the coordinated boron sites significantly distorted

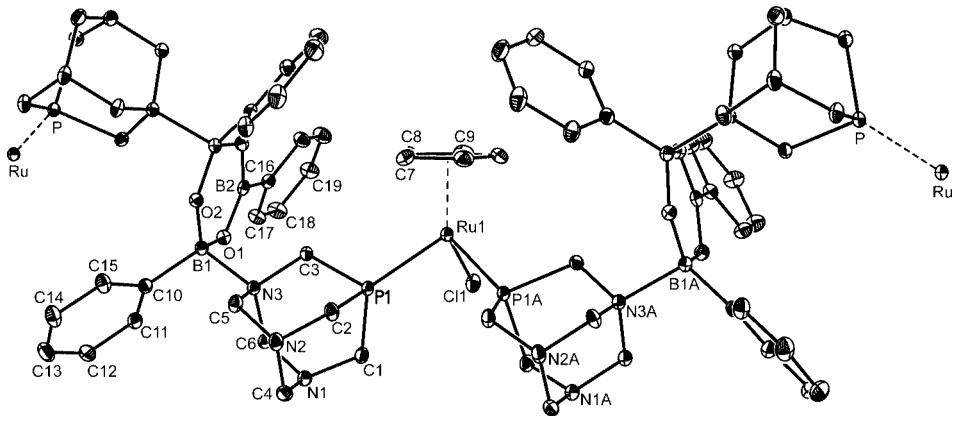

Figure 4. Thermal ellipsoid plot of **3** showing the atomic numbering scheme; hydrogen atoms have been omitted for clarity; thermal ellipsoids are plotted at 50% probability.

from planar towards tetrahedral with O–B–O angles of 115.8(2)° and N–B–C angles of 107.46(18)°. The boron atom, which is not coordinated to nitrogen is nearly planar with a O–B–O angle of 122.3(3)°. The B–N bond lengths are 1.737(3) Å, significantly longer than the N–B distances in compounds **1** and **2**, but comparable to other nitrogen-coordinated boroxin complexes which have B–N distances of 1.73–1.84 Å.[28–30] Comparison of the structure of **3** with the parent complex $CpRu(PTA)_2Cl$ and the diprotonated form $[CpRu(PTAH)_2Cl]^{2+}$, previously reported by us,[3,4] reveals that the core organometallic portion of **3** is largely unchanged, Table 6. The P–Ru–P angle is slightly less obtuse and the Ru–P bond lengths are elongated slightly (≈ 0.01 Å) in **3** vs. the other two complexes. The biggest change is in the (N)C–N distances within the PTA ligand, which have been utilized to determine when a PTA ligand has been protonated [on average the (N)C–N distance increases from ca. 1.46 to ca. 1.53 Å upon protonation].[20]

## Conclusions

We have presented here the synthesis and characterization of three boron-coordinated PTA complexes. Peruzzini et al. published the first report of a PTA complex in which a metal is bound to a nitrogen of the PTA ligand.[9] Here we reported the second such complex, in which a nitrogen of a ruthenium-bound PTA serves as a Lewis base coordinating to the Lewis basic boron of triphenylboroxin. It should be noted that in both of these complexes the phosphorus atom of PTA is *already bound to a metal*. To the best of our knowledge, there are still no substantiated cases in the literature in which PTA serves only as a nitrogen donor ligand to a metal center. We reported here the closest example of such a structure; complex **1** represents the first coordination complex of PTA in which *only* the nitrogen of the PTA ligand is coordinated to another atom through a dative bond. Finally, it should be noted that the nitrogen sites of PTA may become involved in coordination chemistry and are not necessarily innocent bystanders. Complex **3** and the complexes previously reported by Peruzzini[9] may serve as a beginning for the use of PTA as a ligand in the building of extended structures, utilizing the ability of both the phosphorus and nitrogen sites of PTA to serve as Lewis bases.

## Experimental Section

**Materials and Methods:** Unless otherwise noted all manipulations where performed on a double-manifold Schlenk vacuum line under nitrogen or in a nitrogen-filled glovebox. Nitrogen was purified by passing the gas through a column of molecular sieves (Lind 13X), calcium chloride, potassium hydroxide, and dryrite. Tetrakis-(hydroxymethyl)phosphonium chloride was obtained from Cytec and used as received. Ruthenium trichloride hydrate, $D_2O$, KOH, $PPh_3$, phenyl boronic acid, dicyclopentadiene, cyclooctadiene (COD), and $BH_3$–etherate were purchased from commercial sources and used as received. 1,3,5-Triaza-7-phosphaadamantane (PTA),[7,8] 1,3,5-triaza-7-phosphaadamatane oxide (O=PTA),[7] and $CpRu(PTA)_2Cl$[4,32] were prepared according to the literature procedures. Solvents were freshly distilled from standard drying reagents or dried with activated molecular sieves. Water was distilled and deoxygenated prior to use. NMR spectra were recorded with either a Varian Unity Plus 500 FT-MNR spectrometer, a GN 300 FT-NMR/Scorpio spectrometer, or a QE 300 FT-NMR/Aquarius spectrometer. Proton spectra were referenced to residual solvent relative to TMS with the exception of aqueous spectra, which were referenced to an external standard of sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS). Phosphorus chemical shifts are relative to an external reference of 85% $H_3PO_4$ in $D_2O$ with positive values downfield of the reference. $^{11}B$ chemical shifts are relative to an external reference of $BF_3$ in diethyl ether, with positive values downfield from the reference.

**Synthesis of PTA–$BH_3$ (1):** PTA (1.0 g, 6.4 mmol) was dissolved in a minimum amount of dichloromethane. The solution was then cooled in an ice bath and 1.1 equiv. of 1.0 M borane tetrahydrofuran complex was added via syringe (7 mL). The solution was stirred for 2 h, after which time the solvent was removed under vacuum leaving 1.01 g of a fine white solid (93% yield). $^1H$ NMR (300 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 4.50–4.25 (m, 6 H, NC$H_2$N), 3.88–3.66 (m, 6 H, PC$H_2$N), 1.17 (q, $^1J_{BH}$ = 98 Hz, 3 H, $BH_3$) ppm. $^{11}B$ NMR (160 MHz, [$D_6$]acetone, 25 °C): $\delta$ = –10.8 (q, $^1J_{BH}$ = 98 Hz) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, [$D_6$]acetone, 25 °C): $\delta$ = –88.4 (s) ppm. IR (KBr): $\tilde{\nu} = \upsilon_{(BH)}$: 2365 (s), 2312 (m), 2263 (m) $cm^{-1}$; $\upsilon_{(BN)}$: 1174 (s) $cm^{-1}$. IR ($CH_2Cl_2$): $\tilde{\nu} = \upsilon_{(BH)}$: 2370 (s), 2305 (m), 2271 (m) $cm^{-1}$; $\upsilon_{(BN)}$: 1172 (s) $cm^{-1}$. $C_6H_{15}BN_3P$: calcd. C 42.15, H 8.84, N 24.57; found C 42.20, H 8.90, N 25.02. X-ray quality crystals were grown by slow diffusion of hexanes into a concentrated THF solution of **1**, yielding colorless needles over the course of a week. A crystal suitable for X-ray diffraction was selected and mounted under oil on a glass fiber. Crystallographic data and data collecting parameters are listed in Table 7.

**Synthesis of O=PTA–$BH_3$ (2):** The borane complex of PTA oxide (O=PTA) was synthesized in a manner analogous to the PTA–borane complex described above. PTA=O (50 mg, 0.29 mmol) was dissolved in $CH_2Cl_2$ (20 mL) and $BH_3$–THF (1.0 mL, 1.0 M) was added at room temperature with stirring. The resultant solution turned cloudy and was stirred for an additional 1 h, after which time the product was collected by filtration. O=PTA–$BH_3$ was obtained as a fine white powder in 37% yield (20 mg). $^1H$ NMR (300 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 4.5–3.8 (m, PTA), 1.47 (q, $^1J_{BH}$ = 95 Hz, $BH_3$) ppm. $^{11}B$ NMR (160 MHz, [$D_6$]acetone, 25 °C): $\delta$ = –12.2 (q, $^1J_{BH}$ = 95 Hz) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, [$D_6$]-acetone, 25 °C): $\delta$ = –9.8 ppm. IR (KBr): $\tilde{\nu} = \upsilon_{(BH)}$: 2389 (s), 2325 (m), 2283 (m) $cm^{-1}$. $C_6H_{15}BN_3OP$: calcd. C 38.54, H 8.09, N 22.47; found C 38.92, H 8.51, N 22.56. Colorless X-ray quality crystals were obtained after approximately one week by layering a dilute solution of **2** in THF with hexane. A crystal suitable for X-ray diffraction was selected and mounted under oil on a glass fiber. Crystallographic data and data collecting parameters are listed in Table 7.

**Synthesis of $[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n \cdot 1/2CH_2Cl_2$ (3):** A Schlenk flask was charged with $CpRu(PTA)_2Cl$ (50 mg, 0.097 mmol) and

$PhB(OH)_2$ (36 mg, 0.295 mmol); the solids were dissolved in a minimum volume (≈ 5 mL) of dichloromethane and stirred under nitrogen for 10 h. Addition of hexanes afforded 38 mg (48%) $[CpRu(PTA)_2Cl(Ph_3B_3O_3)]_n$·1/2 $CH_2Cl_2$ (**3**) as orange crystals. $^1H$ NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 8.0–8.1 (m, 5 H, ArH), 7.35–7.45 (m, 10 H, ArH), 4.4–4.6 (AB spin system, $^2J_{(HAHB)}$ = 13 Hz, 17 H, Cp, $NCH_2N$), 3.9–4.1 (AB spin system, $^2J_{(HAHB)}$ = 15 Hz, 12 H, $PCH_2N$) ppm. $^{11}B$ NMR (160 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 29.3 (s, $B_{uncoordinated}$), 21.3 (br. s, *B*–N) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = –21.9 (br. s, Ru–PTA) ppm. IR (KBr): $\tilde{\nu} = \upsilon_{(BO)}$: 1387, 1344, 1310 $cm^{-1}$. $C_{36}H_{45}B_3Cl_2N_6O_3P_2Ru$: calcd. C 49.35, H 5.18, N 9.59; found C 50.51, H 5.14, N 9.42. Dark orange X-ray quality crystals were grown by slow diffusion of hexanes into a $CH_2Cl_2$ solution of **3** over the course of 4 days. A crystal suitable for X-ray diffraction was selected and mounted under oil on a glass fiber. Crystallographic data and data collecting parameters are listed in Table 7.

**Computational Details:** Theoretical calculations were performed in an attempt to obtain insight into the differential reactivity of the phosphorus and nitrogen nuclei of PTA. All calculations were run on a Beowulf cluster of 16 dual processor computers operating under Linux. Theoretical calculations were performed using the Gaussian 03 program package employing the LANL2DZ basis set of Wadt and Hay[33,34] as implemented in Gaussian 03.[35] Density functional (DFT) calculations were carried out on all complexes using Becke's three-parameter hybrid method[36] coupled to the correlation functional of Lee, Yang, and Parr (B3LYP).[37] Frequency calculations were performed on all optimized structures in order to establish the nature of the extrema and to calculate values for $\Delta H$ and $\Delta G$. Full geometry optimizations were performed on **1**, **1-P**, PTA, PTA-Me, and Me-PTA starting from the crystal structures of each compound.

CCDC-288665 to -288667 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

The authors would like to thank Brady Janes and Lauren Volz for their help on this project. PWG would like to thank the NSF-EPSCoR program (EPS-0132556) for a summer fellowship and UNR for an undergraduate research award supporting this project. We thank Cytec for the generous gift of $P(CH_2OH)_4Cl$. Financial support from the National Science Foundation is acknowledged for funding for the X-ray diffractometer (CHE-0226402).

# Programmed Helicity in Self-Assembled Hydrogen-Bonded Chains of Chiral Copper(II) Complexes

David G. Lonnon,[a] Stephen B. Colbran,*[a] and Donald C. Craig[a]

**Keywords:** Hydrogen bonds / Supramolecular / Self-assembly / Copper / Helical structures

The copper(II) complexes $[Cu(H_2L^1)Cl_2]_2[CuCl_4]\cdot CH_3CN\cdot H_2O$ ($HL^1$ = *N*-6-(4-hydroxyphenyl)-2-pyridylmethyl-*N*,*N*′,*N*′-trimethylethylenediamine), $[Cu(HL^2)Cl_2]$ ($HL^2$ = *N*-4-hydroxybenzylmethyl-*N*,*N*′,*N*′-trimethylethylenediamine) and $[Cu_2(\mu\text{-}L^3)_2(H_2O)(ClO_4)]ClO_4\cdot H_2O$ ($HL^3$ = *N*-2-hydroxybenzylmethyl-*N*,*N*′,*N*′-trimethylethylenediamine) were prepared and characterised in acetonitrile solution (by ESI-MS, EPR and UV/Vis-NIR spectroscopy) and in the solid state (by X-ray crystallography). Each copper(II) complex is chiral and has a potential inter-complex hydrogen-bond donor group. Upon crystallisation, all three copper(II) complexes undergo spontaneous enantioselective self-assembly into hydrogen-bond-linked helices.

## Introduction

Self-assembly into spiral structures is inherent in nature, from the grandest scale – e.g. spiral galaxies[1] – through everyday structures – e.g. the aesthetically pleasing spiral seashell – to the molecular scale – e. g. the structures of biological macromolecules such as proteins[2] and nucleic acids.[3] The self-organisation of the latter molecules into specific structures is, of course, vital to their function and so to all life, and has inspired the recent interest into molecules that aggregate into regular spiral topologies.[4–8] Metal coordination complexes proffer a vast array of useful catalytic, magnetic and optical properties and so, not surprisingly, helical coordination polymers are synthetic targets for emergent applications in asymmetric catalyses, in enantioselective separations and as magnetic/optical materials.[7,8] The design and construction of coordination polymers with helical topologies thus presents a contemporary challenge that spans coordination, supramolecular and materials chemistry.

In the majority of those helical coordination polymers reported in the literature, ditopic ligands are employed to bridge and link two adjacent metal centres.[7,8] Herein, we demonstrate that molecular helicity can be predictably programmed into the solid-state structures of simple copper(II) coordination complexes by judicious introduction of molecular chirality through ligand design in combination with a noncovalent recognition element that induces aggregation and hence self-organisation into a spiral arrangement upon crystallisation. The natures of the new complex species in solution were also investigated by the use of a combination of electrospray ionisation mass, UV/Visible-NIR and X-band EPR spectroscopy.

## Results and Discussion

Three ligands $HL^1$–$HL^3$ were targeted. All three are chiral and, although isolated as the racemate, upon coordination to a metal ion the chirality of the individual ligand molecule must transfer to the complex species thus formed. In $HL^1$ and $HL^2$ the positioning of the phenolic 4-OH groups prevents intramolecular hydrogen bonding interactions, but is ideal for inter-complex hydrogen bonding; therefore, these OH groups should act as a recognition element for inter-complex aggregation through hydrogen bonding. Thus, overall, simple metal complexes of $HL^1$ and $HL^2$ should be chiral and aggregate into strands through inter-complex hydrogen bonding. In contrast, the *ortho*-OH groups in $HL^3$ are ideally positioned for binding to a metal ion, because this was assumed that it would curtail the involvement of these groups in inter-complex aggregation. To test these predictions the three ligands were made, and their reactions with cupric chloride and cupric perchlorate studied.

### Syntheses

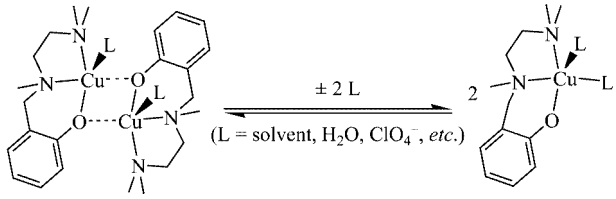
The ligands $HL^1$–$HL^3$ were prepared by direct reductive amination reactions of *N*,*N*,*N*′-trimethylethylenediamine with the appropriate aldehyde. For $HL^1$, tetrahydropyran (THP) protected 4-phenol-6-pyridylaldehyde was used and the THP protecting group was removed with pyridinium tosylate in 95% ethanol. Three crystalline materials were obtained from the reactions of the ligands with the cupric salts: A green powder was obtained from $HL^1$ and $CuCl_2$ in methanol/ether that afforded clear, gold-brown platelets of $[Cu(HL)Cl_2]_2[CuCl_4]\cdot MeCN\cdot 2H_2O$ upon recrystallisation from acetonitrile/methanol, green crystalline $[Cu(HL^2)Cl_2]$ deposited from solution of $HL^2$ and $CuCl_2$ in methanol/ether, and dark green-black $[Cu_2(L^3)_2(H_2O)(ClO_4)]ClO_4\cdot H_2O$ crystallised from an alkaline (pH 9) aqueous solution of cupric perchlorate and $HL^3$.

### Solution Physicochemical Properties

Positive-mode ESI-MS, X-band EPR (at 77 K) and UV/Vis-NIR spectra were acquired to give information about the species in acetonitrile solutions; the data are listed in the Experimental Section and spectra are shown in the supporting information, Figure S1 and Figure S2 (for supporting information see also the footnote on the first page of this article). The ESI-MS spectrum of $[Cu(H_2L^1)Cl_2]_2[CuCl_4]$ shows only peaks for the $[Cu(H_2L^1)Cl_2]^+$ ion (at *m*/*z* 419; calcd. *m*/*z* 419.06) suggesting that this is the only cationic species in solution. The EPR spectrum of the frozen acetonitrile solution at 77 K reveals overlaid axial subspectra for two nonequivalent copper(II) centres, a four/five-coordinate tetragonally distorted ion [$g_\parallel \approx 2.26$ ($A_\parallel \approx 156$ G) >> $g_\perp \approx 2.07$] and a distorted tetrahedral species [$g_\parallel \approx 2.39$ ($A_\parallel \approx 120$ G) >> $g_\perp \approx 2.09$], which is attributed to $[CuCl_3(MeCN)_x]^-$ (in acetonitrile solution, $[CuCl_4]^{2-}$ is only observed at high chloride concentrations[11]). The UV/Vis-NIR spectrum shows a broad asymmetric band at 676 nm with a long low-energy tail, distinctive for a tetragonally distorted ion; the lowest energy transition for $[CuCl_3(MeCN)_x]^-$ is reported at 405 nm and is hidden in the intense UV tail.[11]

The ESI-MS spectrum of $[Cu(HL^2)Cl_2]$ was very weak until 1% acetic acid was added to the carrier solvent; in the presence of the acetic acid, $[Cu(HL^2)Cl]^+$ (at *m*/*z* 306; calcd. *m*/*z* 306.06) was observed along with peaks for the protonated ligand, $(H_2L^2)^+$, and ions that result from chloride–acetate exchange. The results are consistent with $[Cu(HL^2)Cl_2]$ persisting into acetonitrile solution. The EPR spectrum of the complex in acetonitrile solution at 77 K is axial and thus indicative for a tetragonally-distorted species with a $d_{x^2-y^2}$ ground-state and the UV/Vis-NIR spectrum shows a broad asymmetric visible band at 676 nm with distinct tail to low energy (identically with $[Cu(H_2L^1)Cl_2]^+$); these spectra are consistent with $[Cu(HL^2)Cl_2]$ dissolving unchanged in acetonitrile.

The main peak in the ESI-MS spectrum of $[Cu_2(L^3)_2(H_2O)](ClO_4)_2$ at *m*/*z* 270 corresponds to the monomeric species $[Cu(L^3)]^+$ (calcd. *m*/*z* 270.08). The solid complex is EPR silent indicative for antiferromagnetic coupling between the two copper(II) centres relayed by the phenolate bridges in the dimeric $[Cu_2(L^3)_2(H_2O)]^{2+}$ cation. The EPR spectrum of a frozen acetonitrile solution of the complex at 77 K shows a strong axial signal [$g_\parallel = 2.25$ ($A_\parallel = 165$ G) >> $g_\perp = 2.06$] for a tetragonal monomer suggesting that the dimer dissociates in solution according to:



The UV/Vis-NIR spectrum differs from those of the other two complexes: It shows a relatively sharp and intense σ-phenolate → Cu$^{II}$ charge-transfer band at 430 nm[12,13] plus a weaker visible (*d*-*d*) band at 625 nm; these two bands are blue shifted by ca. 30 and 85 nm, respectively, as a 1:1 EtOH/water solution is made alkaline (pH raised from 7 to 10). The EPR and UV/Vis-NIR spectra are very similar to those of other copper(II) dimers of chelating ligands with a phenolate sidearm that break up in donor solvents to monomeric species.[12,13]

### Crystal Structures

**$[Cu(HL)Cl_2]_2[CuCl_4]\cdot CH_3CN\cdot 2H_2O$:** The crystal structure confirms the identity of the complex salt as $[Cu(H_2L^1)Cl_2]_2[CuCl_4]$. The structure of the $[Cu(H_2L^1)Cl_2]^+$ ion is illustrated in Figure 1. Immediately obvious is that the terminal tertiary amine of $HL^1$ is protonated and "dangling" in the $[Cu(H_2L^1)Cl_2]^+$ ion. This is expected: the tertiary amine is a relatively weak donor to a metal ion due to steric effects but is strongly basic and, therefore, protonation is favoured over coordination to a metal ion under the weakly acidic conditions in solutions of simple metal salts. As it must be, the $[Cu(H_2L^1)Cl_2]^+$ complex cation is chiral, with $HL^1$ wrapped about the copper centre, which is bound by the pyridyl and the adjacent chiral, tertiary amine donors (nitrogen atoms N1 and N2, respectively). Within the crystal, both enantiomers of $[Cu(H_2L^1)Cl_2]^+$ appear and are related by crystallographic inversion; see below. The Cu–N and Cu–Cl distances in the $[Cu(H_2L^1)Cl_2]^+$ ion are listed in the caption to Figure 1 and are indicative for a copper(II) centre.[13–17] The two largest angles about the copper ion, the *transoid* angles Cl1–Cu1–N2 [132.5(2)°] and Cl2–Cu1–Nl [152.2(2)°], give $\beta = 71.2°$ and $\omega = 51.4°$ [where $\beta = 90°$ and $\omega = 0°$ for square-planar geometry ($D_{4h}$) and $\beta = 54.7°$ and $\omega = 90°$ for tetrahedral geometry ($T_d$)], thus revealing the geometry of Cu1 is near to midway between ideal square-planar and ideal tetrahedral. The $[CuCl_4]^{2-}$ counteranions exhibit a much less flattened tetrahedral geometry, which is commonplace for this ion:[14] the *transoid* equatorial angles Cl3–Cu2–Cl3* [124.3(1)°] and Cl4–Cu2–Cl4* [138.7(3)°] yield $\beta = 60.3°$ and $\omega = 77.9°$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

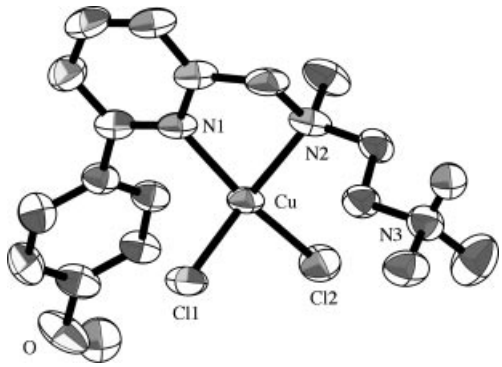


Figure 1. View of the $[Cu(S\text{-}H_2L^1)Cl_2]^+$ complex ion (50% thermal ellipsoids at 295 K are shown; hydrogen atoms on carbon are omitted for clarity). Key metric data – bond lengths [Å]: Cu1–Cl1 2.256(2), Cu2–Cl3 2.257(2), Cu1–Cl2 2.192(2), Cu2–Cl4 2.208(3), Cu1–N1 1.965(5), Cu1–N2 2.054(5); bond angles [°]: Cl1–Cu1–Cl2 101.82(7), Cl3–Cu2–Cl3* 124.3(1), Cl1–Cu1–N1 97.9(2), Cl3–Cu2–Cl4 102.2(1), Cl1–Cu1–N2 132.5(2), Cl3–Cu2–Cl4* 96.83(9), Cl2–Cu1–N1 152.2(2), Cl4–Cu2–Cl4* 138.7(3), Cl2–Cu1–N2 98.9(2), N1–Cu1–N2 81.5(2).

As predicted, homochiral $[Cu(H_2L^1)Cl_2]^+$ ions self-assemble along the *y* axis into helical chains that are held together by hydrogen bonding between the phenol OH group (O1) and the chloride co-ligand Cl1 ($H_{O1}\cdots Cl1$ 2.163 Å), Figure 2. The helices, in which the adjacent cations are inter-related by a $2_1$ crystallographic screw, are quite open with large grooves, Figure 2 (b). The helices interweave to afford layers parallel to the *yz* plane, Figure 2 (c). Within a layer all cations have the same chirality and, therefore, all helices identical (*M or P*) handedness, but adjacent helices within the layers run in the opposite direction; the *S*-enantiomer, i.e. $[Cu\{(S)\text{-}H_2L^1\}Cl_2]^+$, affords the left-handed (*M*) helices. The helices alternate in chirality parallel to the *x*-axis so adjacent layers contain cations and helices of opposite chirality. The $[CuCl_4]^{2-}$ anions are interspersed between the cation layers and each forms a $Cl\cdots H\text{–}^+NHR$ hydrogen bond (Cl3···N3 3.290 Å) to the nearest cation in the two adjacent layers. The lattice acetonitrile and water molecules fill voids in $[CuCl_4]^{2-}$ anion layers; notably each water (W) is well-positioned to form hydrogen bonds with the nearest $[Cu(H_2L^1)Cl_2]^+$ ion ($O_W\cdots$Cl2 3.259 Å) and the adjacent $[CuCl_4]^{2-}$ anion ($O_W\cdots$Cl4 3.391 Å).

**$[Cu(HL^2)Cl_2]$:** Figure 3 presents a view of the complex molecule. The copper(II) centre is four coordinate, bound by the two amine nitrogen atoms of $HL^2$ and two chloride co-ligands with Cu–N and Cu–Cl distances that are typical of those of other copper(II) chloride complexes of ethylenediamine derivatives (e.g. $[Cu(ethylenediamine)Cl_2]$[15]

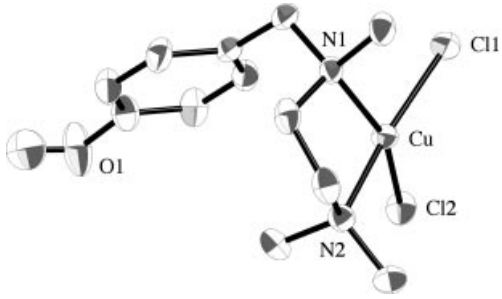

Figure 3. View of the $[Cu(R\text{-}HL^2)Cl_2]$ complex molecule (50% thermal ellipsoids at 295 K are shown; hydrogen atoms on carbon are omitted for clarity). Key metric data – bond lengths [Å]: Cu–Cl1 2.263(1), Cu–Cl2 2.269(1), Cu–N1 2.086(3), Cu–N2 2.045(3); bond angles [°]: Cl1–Cu–Cl2 93.0(1), Cl1–Cu–N1 92.9(1), Cl1–Cu–N2 171.1(1), Cl2–Cu–N1 157.7(1), Cl2–Cu–N2, 91.7(1), N1–Cu–N2 85.5(1).

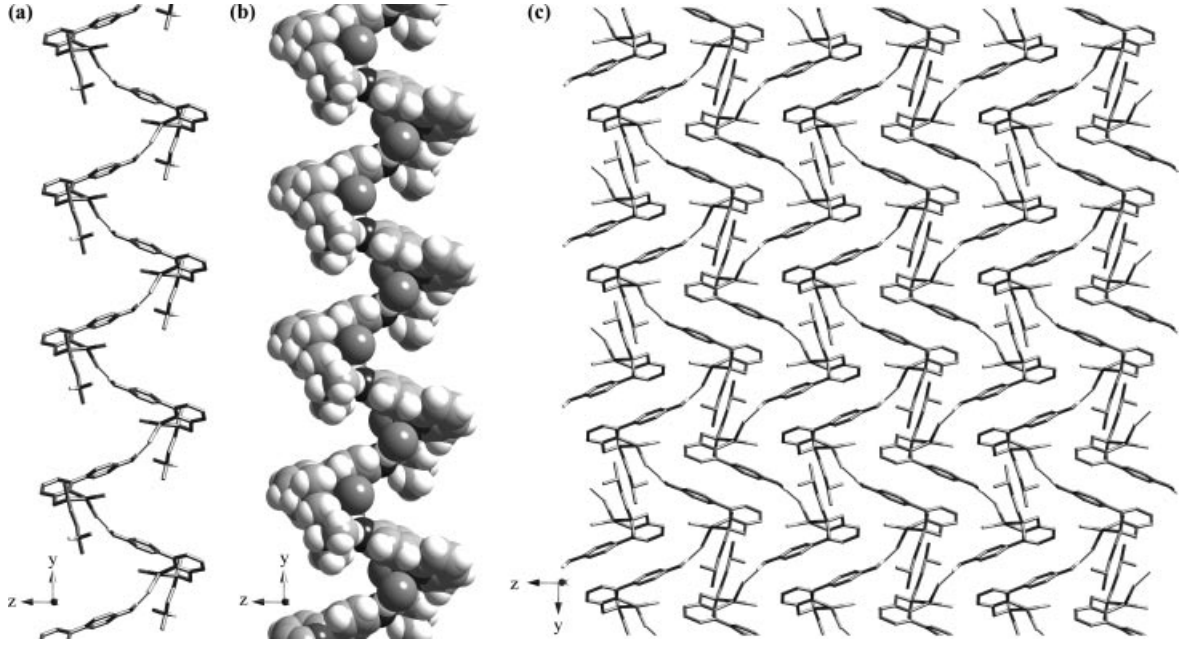

Figure 2. $[Cu(H_2L^1)Cl_2^{2+}]_\infty$ helices: (a) stick view of a *M*-helix, (b) spacefilling view (CPK van der Waal's radii) of a *M*-helix from the same perspective as (a); (c) view of a layer illustrating the antiparallel packing of the helices, all of which have the same (*M*) handedness. For clarity, those hydrogen atoms not involved in hydrogen bonding are omitted from views (a) and (c).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

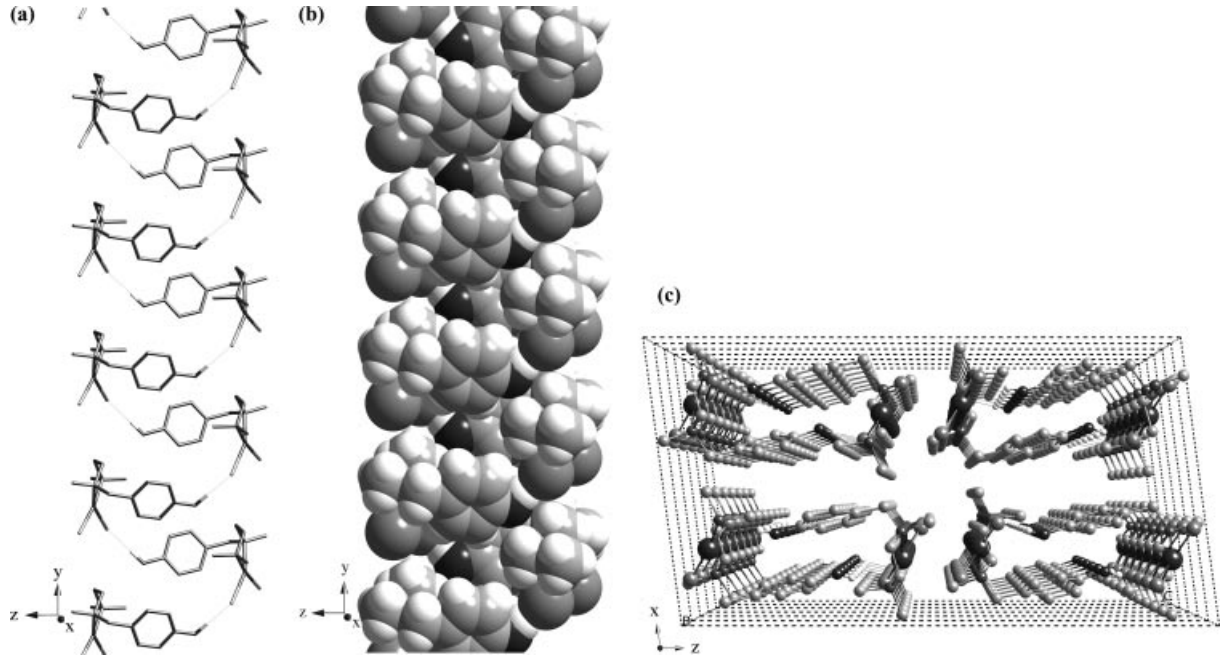

Figure 4. $[Cu(HL^2)Cl_2]_\infty$ helices: (a) view of a single *P*-helix (with carbon-bound hydrogen atoms omitted for clarity); (b) spacefilling view (CPK van der Waal's radii) showing the tight packing of complex molecules in a *P*-helix drawn from the same perspective as (a); (c) ball-and-stick perspective view of the crystal structure showing the packing of the helices of opposite chirality along the *y* axis (the top left and bottom right helices are left-handed, the others right-handed).

Cu–N 2.010 and 2.017 Å, Cu–Cl 2.286 and 2.301 Å; [Cu(*trans*-*N*,*N*,*N*′*N*′-tetramethylcyclohexane-1,2-diamine)$Cl_2$][16] Cu–N 2.052 Å, Cu–Cl 2.247 Å). The *transoid* angles about copper, N2–Cu–Cl1 171.1(1)° and N1–Cu–Cl2 157.7(1)°, give $\beta$ = 82.2° and $\omega$ = 21.9° indicative for moderate tetrahedral distortion away from square-planar geometry.

The hydroxy group of $HL^2$ is, as predicted, involved in intermolecular hydrogen bonding. The enantiomers of $[Cu(HL^2)Cl_2]$ separate and self-assemble into helices parallel to the *y* axis, Figure 4. Within each helix, the $[Cu(HL^2)Cl_2]$ molecules all have the same handedness and adjacent complexes are linked by hydrogen bonding between the chloride co-ligand (Cl2) on one and the hydroxy group of $HL^2$ on the other (Cl···H 2.103 Å), Figure 4(a). The crystal is the racemate in which the *P*-helices are comprised of the $[Cu(R\text{-}HL^2)Cl_2]$ enantiomer (i.e. from the *R*-enantiomer of the ligand). Comparison of the space-filling representations of the $[Cu(H_2L^1)Cl_2^+]_\infty$ helix, Figure 2 (b), and the $[Cu(HL^2)Cl_2]_\infty$ helix, Figure 4 (b), shows the grooves in the latter helices to be considerably more tightly packed and shallow. Thus, whereas the $[Cu(H_2L^1)Cl_2^+]_\infty$ helices interweave in the crystal (see Figure 2, c), each $[Cu(HL^2)Cl_2]_\infty$ helix packs largely independently of the others, Figure 4 (c); there are no significant interactions with the four nearest-neighbour helices, which have opposite chirality (because the chirality of the helices alternates along both the *x* and *z* axes).

**$[Cu_2(\mu\text{-}L^3)_2(H_2O)(ClO_4)]ClO_4\cdot H_2O$:** The $[Cu_2(L^3)_2(H_2O)(ClO_4)]^+$ cation, Figure 5, consists of two independent five-coordinate copper(II) centres, Cu1 and Cu2. Both copper ions are bound by the same enantiomer of $L^3$ (so the dimers are the chiral *R*,*R*- and *S*,*S*-enantiomers) and exhibit

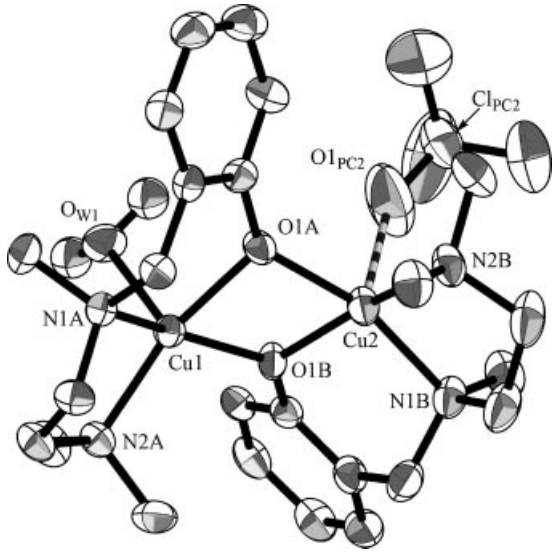

Figure 5. View of the $[Cu_2(S\text{-}L^3)_2(H_2O)(ClO_4)]^+$ complex ion (50% thermal ellipsoids at 295 K are shown;W = water, PC = perchlorate). Key metric data – bond lengths [Å]: Cu1–O1A 1.987(3), Cu2–O1A 1.955(3), Cu1–N1A 2.032(4), Cu2–O1B 1.940(3), Cu1–N2A, 2.046(4), Cu2–N1B 2.023(4), Cu1–O1B 1.995(3), Cu2–N2B, 2.034(4), Cu1–OW1, 2.223(3), Cu2···O1Pc2 2.580(3); bond angles [°]: O1A–Cu1–N1A 92.3(1), O1B–Cu2–N1B 92.6(1), O1A–Cu1–N2A 163.8(2), O1A–Cu2–N1B 163.1(2), O1A–Cu1–O1B 74.4(1), O1A–Cu2–O1B 76.3(1), O1A–Cu1–OW1 95.0(1), O1A–Cu2–O1Pc2 93.8(1), N1A–Cu1–N2A 86.5(2), N1B–Cu2–N2B 87.3(2), N1A–Cu1–O1B 156.4(1), O1B–Cu2–N2B 167.0(2), N1A–Cu1–OW1 101.1(2), N1B–Cu2–O1Pc2 99.1(2), N2A–Cu1–O1B 100.8(2), N2B–Cu2–O1Pc2 102.4(2), N2A–Cu1–OW1 101.1(1), O1A–Cu2–N2B 100.6(2), O1B–Cu1–OW1 99.4(1), O1B–Cu2–O1Pc2 90.5(1), Cu1–O1A–Cu2 101.2(1).

square-pyramidal geometries (trigonality indices:[17] Cu1, $\tau$ = 0.12; Cu2, $\tau$ = 0.07). The two amine nitrogen atoms and the phenolate oxygen atom of $L^3$ are equatorially bound, and each phenolate group also bonds to the fourth equatorial position of the other copper, thereby producing a phenolate-bridged dimer with Cu1···Cu2 3.047 Å. The equatorial Cu–O/N distances at 2.00 ± 0.5 Å are indicative for copper(II).[13–17] An axial water (W1) completes the coordination sphere of Cu1 [Cu1–$O_{W1}$ = 2.223(3) Å] and a weakly bound, axial perchlorate [PC2: Cu2–$O1_{Pc2}$ = 2.580(3) Å] that of Cu2; the axial water and the perchlorate ligands lie to the same side of the equatorial $Cu_2O_2$ plane and are hydrogen-bonded to a lattice water (W2).

Given that the phenol group of $L^3$ becomes involved in binding to the copper(II) ions as anticipated (see above), it was a surprise to find that the homochiral $[Cu_2(L^3)_2(H_2O)(ClO_4)]^+$ ions also self-assemble along with the (second) perchlorate counterion and a lattice water into $2_1$ helices parallel to the *y* axis, Figure 6. Spiral hydrogen-bond-linked chains comprised of the axial water ligand (W1), a perchlorate (PC1), and a lattice water (W2) form the helix cores; see Figure 6 (c). The hydrogen bond lengths in the spiral $[(H_2O)_2(ClO_4)^-]_\infty$ core are given in the Supporting Information (Figure S3). The dicopper(II) ions do not directly hydrogen bond with each other, but rather water W1, the axial ligand to Cu1, forms the link between each copper(II) dimer and the spiral core. The crystal is the racemate containing *M* and *P* helices; the chirality of the helices derives from the copper dimers with the *S,S*-enantiomer producing the *P*-helix (that shown in Figure 6, a–c). Figure 6 (d) illustrates the packing of the helices in the crystal. Helices of the same handedness align parallel to the *x*-axis and helices

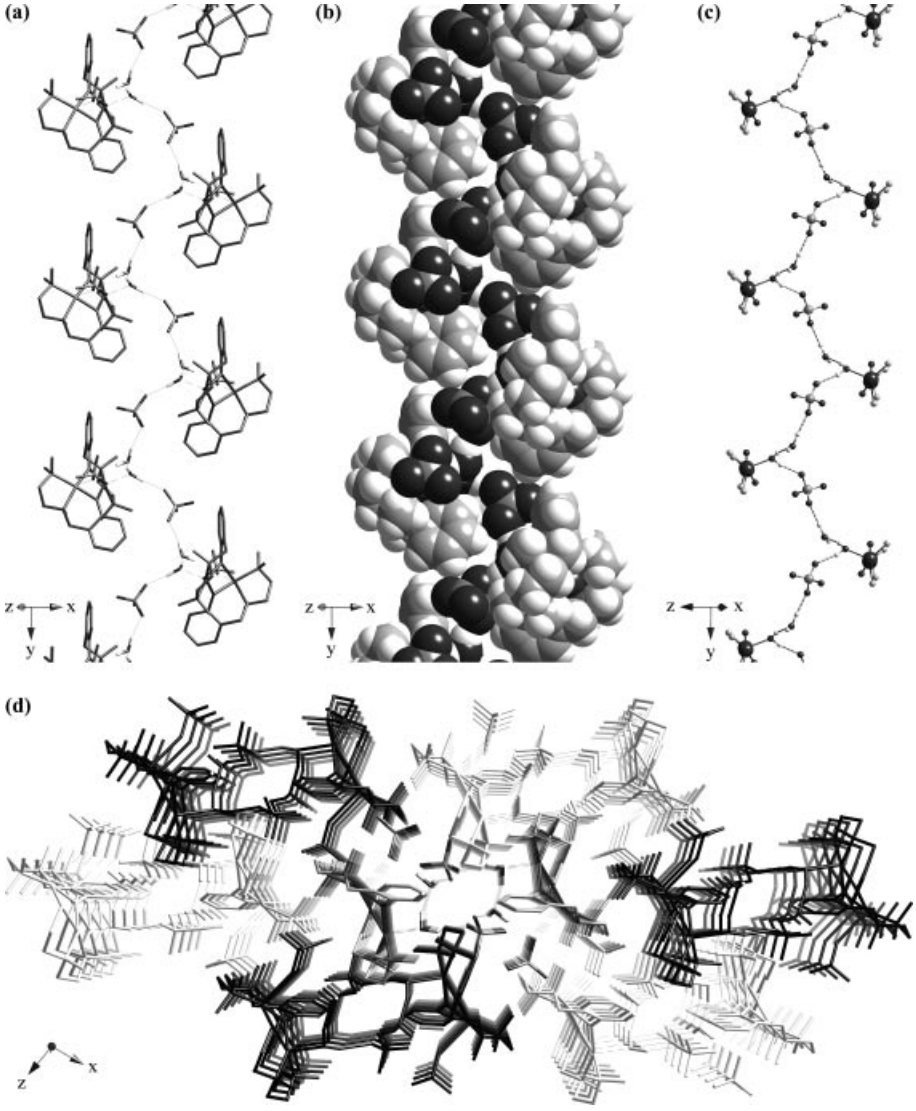

Figure 6. $[Cu_2(\mu\text{-}L^3)_2(H_2O)(ClO_4)](ClO_4)\cdot(H_2O)]_\infty$ helices: (a) view of a *P*-helix, (b) spacefilling view (CPK van der Waal's radii) of a *P*-helix from the same perspective as (a); (c) view of a *P*-helix core illustrating the spiral $[(H_2O)_2(ClO_4)^-]_\infty$ chain (with carbon atoms, the hydrogen atoms attached to these and the perchlorate ligand (PC2) all omitted for clarity); (d) perspective view down a *P*-helix showing the packing of the six surrounding helices. For clarity, the neighbour helices are alternatively shaded light and dark in view (d) and those hydrogen atoms not involved in hydrogen bonding are omitted from views (a) and (d).

alternate in handedness parallel to the *z*-axis, so that each helix is surrounded by six neighbours, two of the same handedness and four of the opposite handedness.

## Conclusion

Three new helical copper(II) coordination polymers have been prepared and characterised. These examples serve to demonstrate that a weak inter-ion, noncovalent recognition element, hydrogen bonds involving a phenol or water OH group within the complex species, in concert with the chiral twist of the complex cation is perfectly sufficient to cause aggregation into spirals. Zigzag chains[7,8] of hydrogen-bonded complexes alternating in chirality were not observed in this work. In the three crystal structures, the spontaneous enantioselective self-assembly of the complexes within each helix suggests a self-recognition process must play a role in each crystallisation just as hydrogen bonding between complimentary bases dictates DNA double strand formation. Notably, the adjacent copper(II) complexes are crystallographically inter-related by a $2_1$ screw. Given the weak directionality of the phenol OH···Cl–Cu or Cu–$OH_2$···O ($H_2O$ or $ClO_4^-$) hydrogen bonds, this is not surprising – it is the simplest possible symmetry relationship between the adjacent hydrogen-bonded complexes in a helix. Likewise, a majority of the recently reported coordination polymer helices[7,8] align along a twofold screw axis. The obvious implication, of course, is that a recognition element(s) of greater complexity with inbuilt directionality in the non-covalent interaction – i.e. more information content – is necessary for predictable self-assembly of helices of higher symmetry.

## Experimental Section

**General:** $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded at 300 K with a Bruker AC 300F spectrometer (300 MHz) operating at 300.13 MHz. Electrospray Ionisation (ESI) mass spectra were acquired with a VG Quattro mass spectrometer operating with a capillary voltage of 4 kV and a cone voltage of 30 V at 60 °C with a feed solvent of $CH_3CN$/water (1:1, v/v). Electronic spectra of the complexes were recorded between 220 and 2000 nm with a CARY 5 spectrometer in the dual beam mode; solution spectra were recorded in sealed 1-cm quartz cuvettes and solid-state spectra were recorded in reflectance mode on powdered samples. X-band EPR spectra of both solids and frozen solutions and were recorded at 77 K (using a liquid nitrogen dewar) with a Bruker EMX 10 EPR spectrometer. Elemental analyses for C, H and N were carried out at the Australian National University Microanalytical Laboratory. Prior to being sent for analysis, samples were dried at 40 °C for 48 h under vacuum (0.2 Torr) over phosphorus pentoxide.

***Caution:*** Although no problems were encountered in the course of this work, perchlorate salts are potentially explosive materials and appropriate precautions should be taken when handling them.

***N*-[6-(4-Hydroxyphenyl)-2-pyridylmethyl]-*N*,*N*′,*N*′-trimethylethylenediamine ($HL^1$):** A solution of *N*,*N*,*N*′-trimethylethylenediamine (363 mg, 3.55 mmol) in 1,2-dichloroethane (15 $cm^3$) was added to a 1,2-dichloroethane (10 $cm^3$) solution of 6-(2-tetrahydropyranyl-4-phenoxyl)-2-pyridinecarbaldehyde (1.000 g, 3.54 mmol) followed by the addition of solid sodium triacetoxyborohydride (0.902 g, 4.25 mmol). The resulting white suspension was stirred for 12 h under nitrogen to give a yellow suspension, which was washed twice with a saturated $NaHCO_3$ solution (≈ 10 $cm^3$), dried with magnesium sulfate and the solvent remove under vacuum to give the tetrahydropyranyl (THP)-protected precursor, THP-$L^1$, as a viscous yellow-brown oil (1.130 g). $^1H$ NMR ($CDCl_3$): $\delta$ = 7.93 (d, 2 H, Ar), 7.67 (d, 1 H, py), 7.54 (t, 1 H, py), 7.33 (d, 1 H, py), 7.12 (d, 2 H, Ar), 5.49 (m, 1 H, $CH_2$), 3.92 (m, 2 H, $CH_2$), 3.77 (s, 2 H, $CH_2$), 3.62 (m, 2 H, $CH_2$), 2.60 (m, 2 H, $CH_2CH_2$), 2.49 (m, 2 H, $CH_2CH_2$), 2.35 (s, 3 H, $CH_3$), 2.23 (s, 6 H, 2 $CH_3$), 2.08 (m, 2 H, $CH_2$), 1.90 (m, 2 H, $CH_2$) ppm. ESI-MS: *m*/*z* (%) = 370 (100) [(THP)-$L^1$ + H]$^+$, 286 (10) $[H_2L]^+$. Removal of the THP protecting group was effected by heating pyridinium *p*-toluenesulfonate (75.3 mg, 0.30 mmol) and THP-$L^1$ (1.105 g, 3.00 mmol) in ethanol (50 $cm^3$) at 60 °C for 6 h. The solvent was removed and the resulting solid purified by column chromatography on silica gel with dichloromethane as the eluent; the main yellow band afforded the product, a clear light golden oil (0.810 g, 95%; > 98% purity by $^1H$ NMR spectroscopy). $^1H$ NMR ($CDCl_3$): $\delta$ = 7.90 (d, 2 H, Ar), 7.68 (d, 1 H, py), 7.55 (t, 1 H, py), 7.33 (d, 1 H, py), 7.15 (d, 2 H, Ar), 3.88 (m, 2 H, $CH_2$), 2.70 (m, 4 H, $CH_2CH_2$), 2.38 (s, 9 H, $CH_3$) ppm. ESI-MS: *m*/*z* (%) = 286 (100) $[H_2L^3]^+$. UV ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$/$dm^3mol^{-1}$ $cm^{-1}$) = 263 (12400), 284 nm (13400).

***N*-4-(Hydroxybenzyl)methyl-*N*,*N*′,*N*′-trimethylethylenediamine ($HL^2$):** The literature method[9] was adapted as follows. A mixture of *N*,*N*,*N*′-trimethylethylenediamine (1.502 g, 14.73 mmol), 4-hydroxybenzaldehyde (1.800 g, 14.73 mmol), and sodium triacetoxyborohydride (3.751 g, 17.70 mmol), in 1,2-dichloroethane (70 $cm^3$) was stirred overnight for 16 h under nitrogen. The solvent was removed to give an orange oil that partially dissolved in acetonitrile (≈ 2 × 20 $cm^3$) leaving an off-white solid that was removed by filtering the solution through a short silica plug. Removal of the solvent in vacuo gave the product as an orange-yellow oil (2.822 g, 92%; ≈ 95% purity by $^1H$ NMR spectroscopy). $^1H$ NMR ($CDCl_3$): $\delta$ = 7.10 (d, 2 H, Ar), 6.80 (d, 2 H, Ar), 3.59 (s, 2 H, $CH_2$), 2.92 (t, 2 H, $CH_2CH_2$), 2.79 (t, 2 H, $CH_2CH_2$), 2.52 (s, 6 H, $CH_3$), 2.32 (s, 3 H, $CH_3$); $\delta_C$ ($CDCl_3$) 157.9 (Ar), 131.8 (Ar), 126.7 (Ar), 116.3 (Ar), 62.1 ($CH_2$), 54.7 ($CH_2CH_2$), 52.0 ($CH_2CH_2$), 44.3 ($CH_3$), 41.9 ($CH_3$) ppm. ESI-MS: *m*/*z* (%) = 209 (100) $[H_2L^2]^+$. UV ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$/$dm^3mol^{-1}$ $cm^{-1}$) = 278 (6200), 283 (5900), 314 nm (2900).

***N*-2-Hydroxybenzylmethyl-*N*,*N*′,*N*′-trimethylethylenediamine ($HL^3$):**[10] A mixture of *N*,*N*,*N*′-trimethylethylenediamine (1.530 g, 15.00 mmol), 2-hydroxybenzaldehyde (1.832 g, 14.99 mmol), and sodium triacetoxyborohydride (3.820 g, 18.03 mmol), in 1,2-dichloroethane (40 $cm^3$) was stirred for 16 h under nitrogen. Workup as for $L^1$ afforded $HL^2$; a straw-coloured oil (2.780 g, 89%; > 98% purity by $^1H$ NMR spectroscopy). $^1H$ NMR ($CDCl_3$): $\delta$ = 7.16 (t, 1 H, Ar), 7.00 (d, 1 H, Ar), 6.83 (d, 1 H, Ar), 6.77 (t, 1 H, Ar), 3.68 (s, 2 H, $CH_2$), 2.74 (m, 4 H, $CH_2CH_2$), 2.42 (s, 6 H, $CH_3$), 2.32 (s, 3 H, $CH_3$) ppm $^{13}C$ NMR ($CDCl_3$): $\delta$ = 158.2 (Ar), 129.7 (Ar), 122.5 (Ar), 119.8 (Ar), 117.0 (Ar), 61.2 ($CH_2$), 56.1 ($CH_2CH_2$), 53.3 ($CH_2CH_2$), 44.7 ($CH_3$), 42.6 ($CH_3$) ppm. ESI-MS: *m*/*z* (%) = 209 (100) $[H_2L^3]^+$. UV ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$/$dm^3mol^{-1}$ $cm^{-1}$) = 277 (6400), 330 nm (600).

**$[Cu(HL^1)Cl_2]_2[CuCl_4]$:** Methanol solutions, 5 $cm^3$ each, of $HL^1$ (140 mg, 0.49 mmol) and $CuCl_2$ (66 mg, 0.49 mmol) were stirred overnight. The resulting dark green solution when placed under diethyl ether produced a green precipitate, which was twice recrystallised, firstly from dichloromethane/acetonitrile (3:1) under diethyl ether and then from methanol/acetonitrile (1:1). This pro-

duced X-ray quality, brown, plate-like crystals of $[Cu(HL^1)Cl_2]_2[CuCl_4]$ (82 mg, 16%). $C_{34}H_{48}Cl_8Cu_3N_6O_2\cdot CH_3CN\cdot 2H_2O$: calcd. C 38.46, H 4.93, N 8.72; found C 38.16, H 4.75, N 8.82. ESI-MS (MeCN): *m*/*z* (%) = 384 (100) $[Cu(HL^1)Cl]^+$, 286 (30) $[H_2L^1]^+$. UV ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$/dm$^3$mol$^{-1}$ cm$^{-1}$) = 268 (12400), 288 (13400), 460 (1100), 677 (275), 775 sh (240) nm. UV (solid): $\lambda_{max}$ ($\varepsilon$/dm$^3$mol$^{-1}$ cm$^{-1}$) = 690 nm. EPR ($CH_3CN$ glass, 77 K): $g_\parallel$ = 2.29, $g_\perp$ = 2.09, $A_\parallel$ = 156 G, $g_\parallel$ = 2.26, $g_\perp$ = 2.08, $A_\parallel$ = 120 G; EPR (powder, 77 K) $g_{iso}$ = 2.10.

**$[Cu(HL^2)Cl_2]$:** To $HL^2$ (100 mg, 0.48 mmol) in methanol (10 cm$^3$) was added $CuCl_2$ (65 mg, 0.48 mmol) to give a dark blue solution that was stirred for 2 h. The solution was then reduced to half volume and placed under diethyl ether. After two days standing a green precipitate formed which was collected by filtration and dried under vacuum to give $[Cu(HL^2)Cl_2]$ (128 mg, 78%); a portion of this solid was recrystallised from methanol under diethyl ether to give green crystals of sufficient quality for X-ray crystallographic analysis. All data obtained from the powder and crystals were identical. $C_{12}H_{20}Cl_2CuN_2O$: calcd. C 42.05, H 5.88, N 8.17; found C 41.76, H 5.78, N 8.20. ESI-MS (1% HOAc in $CH_3CN$): *m*/*z* (%) = 674 (10) $[Cu_2(HL^2)_2Cl_2(OAc)]^+$, 331 (40) $[Cu(HL^2)(OAc)]^+$, 306 (10) $[Cu(HL^2)Cl]^+$, 209 (100) $[H_2L^2]^+$. UV ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$/dm$^3$mol$^{-1}$ cm$^{-1}$) = 282 (6200), 379 (1000), 678 (205), 770 sh (190) nm. UV (powder): $\lambda_{max}$ = 685. EPR ($CH_3CN$ glass, 77 K): $g_\parallel$ = 2.25, $g_\perp$ = 2.09, $A_\parallel$ = 153 G; EPR (powder) $g_{iso}$ = 2.12.

**$[Cu_2(L^3)_2(H_2O)](ClO_4)_2$:** Aqueous solutions of $L^3$ (135 mg, 0.65 mmol, in 5 mL) and $Cu(ClO_4)_2\cdot 6H_2O$ (240 mg, 0.65 mmol, in 5 mL) were combined to give a black green solution (pH = 5). NaOH (ca. 0.6 mL, 5 M) was added dropwise until a precipitate began to form (pH = 9). The mixture was stirred for 20 h, and then the solid collected by filtration and washed with ethanol, then diethyl ether and dried under vacuum to give the product as a dark green powder (124 mg, 26%). Further product was obtained from the filtrate, which was reduced to half volume then left to slowly evaporate in air. Black, block-shaped crystals (26 mg, 5%) of X-ray analysis quality were obtained. The crystals and the powder exhibited identical spectroscopic data. $C_{24}H_{38}Cl_2Cu_2N_4O_{10}\cdot 2H_2O$: calcd. C 37.12, H 5.45, N 7.21; found C 37.18, H 5.31, N 7.47. ESI-MS (MeCN): *m*/*z* (%) = 560 (15) $[Cu_2(L^3)_2(H_2O)]^{2+}$, 271 (100) $[Cu(L^3)]^+$, 209 (30) $[H_2L^3]^+$. UV ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$/dm$^3$mol$^{-1}$ cm$^{-1}$) = 233 (6800), 278 (6300), 428 (2000), 639 (315). UV (water/ethanol, 1:1, pH = 7): $\lambda_{max}$ ($\varepsilon$/dm$^3$mol$^{-1}$ cm$^{-1}$) = 418 (1900), 673 (430) nm. UV (water/ethanol, 1:1, pH = 10): $\lambda_{max}$ ($\varepsilon$/dm$^3$mol$^{-1}$ cm$^{-1}$) = 389 (1800), 588 (532) nm; $\lambda_{max}$ (powder) = 627 nm. EPR ($CH_3CN$ glass, 77 K): $g_\parallel$ = 2.25, $g_\perp$ = 2.06, $A_\parallel$ = 165 G; EPR (powder, 77 K): silent.

**X-ray Crystallography:** Relevant crystal, data collection and refinement data for the X-ray crystal structures of $[Cu(H_2L^1)Cl_2]_2[CuCl_4]\cdot CH_3CN\cdot 2H_2O$, $[Cu(HL^2)Cl_2]$ and $[Cu_2(\mu\text{-}L^3)_2(H_2O)(ClO_4)]ClO_4\cdot H_2O$ are summarised in Table 1.

CCDC-290947–290949 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article). Plots of EPR (at 77 K) and UV/Vis-NIR spectra for all complexes in the solid state and in acetonitrile solution; a figure of a $[Cu_2(L^3)_2(H_2O)(ClO_4)](ClO_4)\cdot(H_2O)]_\infty$ helix showing hydrogen bond lengths.

# Charge-Transfer Phase Transition and Ferromagnetism of Iron Mixed-Valence Complexes ($n$-$C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6; dto = $C_2O_2S_2$)

**Miho Itoi,*[a] Yuuki Ono,[b] Norimichi Kojima,*[b] Kenichi Kato,[c,d] Keiichi Osaka,[c,d] and Masaki Takata[c,d]**

**Keywords:** Mixed-valence compounds / Iron / Magnetic properties / Charge transfer

The iron mixed-valence complex, ($n$-$C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$ (dto = dithiooxalato) shows a charge-transfer (CT) phase transition at $T_{CT}$ = 122.4 K. In the vicinity of $T_{CT}$, the spin state changes from $Fe^{II}$ ($S$ = 2) – $Fe^{III}$ ($S$ = 1/2) (high-temperature phase: HTP) to $Fe^{II}$ ($S$ = 0) – $Fe^{III}$ ($S$ = 5/2) (low-temperature phase: LTP) accompanied by a charge transfer between $Fe^{II}$ and $Fe^{III}$. This complex also undergoes a ferromagnetic transition at 7 K in the LTP. In order to investigate the mechanism of the CT phase transition and the ferromagnetism, we have systematically synthesized ($n$-$C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6), and have investigated their physical properties by magnetic susceptibility, powder X-ray diffraction measurements, and ESR spectroscopy. The compounds ($n$-$C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6) display ferromagnetic phase transitions at 7 K, 7 K (& 13 K), 19.5 K, and 22 K, respectively. For $n$ = 3 and 4, the CT phase transitions take place at $T_{CT} \approx$ 120 K and $T_{CT} \approx$ 140 K, respectively. For $n$ = 5 and 6, on the other hand, the CT phase transition does not occur, and the spin configuration of $Fe^{II}$ ($S$ = 2) and $Fe^{III}$ ($S$ = 1/2) corresponding to the HTP for $n$ = 3 and 4 is stable between 2 K and 300 K. The cation size of ($n$-$C_nH_{2n+1})_4N^+$ ($n$ = 3–6) acts as an effective internal pressure which induces the CT phase transition and the ferromagnetic ordering in the $[Fe^{II}Fe^{III}(dto)_3]^-_\infty$ layer. We also discuss the mechanism of the CT phase transition and the ferromagnetism induced by the charge-transfer interaction between $Fe^{II}$ and $Fe^{III}$.

## Introduction

Transition-metal complexes with $d^4$-$d^7$ configuration have a possibility of a spin transition between a low-spin (LS) state and a high-spin (HS) state. The spin-crossover phenomenon has gained a renewed importance through the discovery of Light Induced Excited Spin State Trapping (LIESST) for $[Fe(ptz)_6](BF_4)_2$ (ptz = 1-propyltetrazole)[1] and the thermally induced spin-crossover transition with a large thermal hysteresis around room temperature in a triazole-bridged iron(II) complex.[2,3]

One expects mixed-valence complexes with spin states situated in the spin-crossover region to display several new types of conjugated phenomena, coupled with spin and charge, between neighboring metal ions, that minimize the free energy in the whole system. To explore this possibility, we have synthesized iron mixed-valence complexes whose spin states are situated in that region. It is well-known that tris(dithiocarbamato) iron(III) complexes show the spin-crossover transition.[4] In these complexes, the $Fe^{III}$ atom is coordinated by six S atoms. Taking account of these particulars, we have synthesized dithiooxalato-bridged iron mixed-valence complexes. (Hereafter, dithiooxalato is denoted as dto.)

Heterometal dto complexes were first synthesized by Ōkawa et al., who described the ferromagnetism of ($n$-$C_3H_7)_4N[M^{II}Cr^{III}(dto)_3]$ ($M^{II}$ = Fe, Co, Ni)[5] and compared their ferromagnetic properties with those of ($n$-$C_4H_9)_4N[M^{II}Cr^{III}(ox)_3]$ ($M^{II}$ = Mn, Fe, Co, Ni, Cu, ox = oxalato).[6] The structures and magnetic properties of $A[M^{II}Cr^{III}(dto)_3]$ [$A^+$ = $Ph_4P^+$, ($C_nH_{2n+1})_4N^+$, $n$ = 3–5; $M^{II}$ = Mn, Fe, Co] complexes were investigated by J. M. Bradly et al.,[7] who confirmed that all the complexes were ferromagnets with Curie temperatures between 5 and 16 K except for the $[Mn^{II}Cr^{III}(dto)_3]$ complex, which did not show a long-range ordering above 2 K.

Recently, we have discovered a new type of first-order phase transition at $T_{CT} \approx$ 120 K for ($n$-$C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$, where the thermally induced charge-transfer between the $Fe^{II}$ and $Fe^{III}$ is reversible.[8,9] This phase transition is schematically shown in Figure 1. In the high-temperature phase (HTP), the $Fe^{III}$ ($S$ = 1/2) and $Fe^{II}$ ($S$ = 2) sites are coordinated by six S atoms and six O atoms, respectively. On the other hand, in the low-temperature

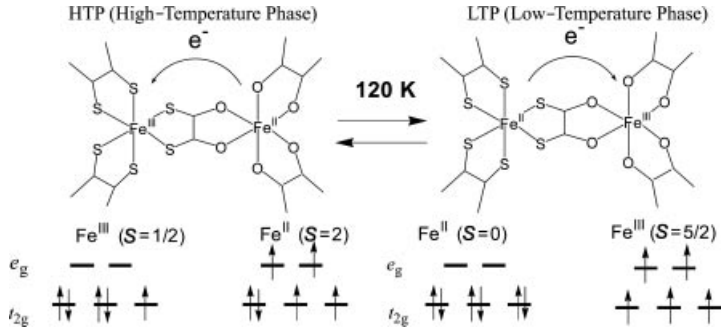

Figure 1. Schematic representation of a charge-transfer phase transition in $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$.

phase (LTP), the $Fe^{III}$ ($S$ = 5/2) site is coordinated by six O atoms, and the $Fe^{II}$ ($S$ = 0) site by six S atoms. Moreover, we have found a ferromagnetic transition at 7 K. The ferromagnetic interaction takes place over a long distance involving $Fe^{III}$ ($S$ = 5/2) – $S_2C_2O_2$ – $Fe^{II}$ ($S$ = 0) – $O_2C_2S_2$ – $Fe^{III}$ ($S$ = 5/2). The ferromagnetic ordering is presumably induced by the charge-transfer interaction between $Fe^{II}$ and $Fe^{III}$.

In order to investigate the mechanism of the CT phase transition and the ferromagnetism induced by the charge-transfer interaction between $Fe^{II}$ and $Fe^{III}$ for $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$, we have synthesized iron mixed-valence complexes, $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6), and investigated their crystal structures and physical properties by powder X-ray diffraction, magnetic susceptibility measurements, and ESR spectroscopy. In this paper, we report our results concerning the CT phase transition and the ferromagnetic phase transition for $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6; the complex is hereafter denoted as $n$ = 3–6). In addition, we discuss the mechanism of the CT phase transition and the ferromagnetism induced by the charge-transfer interaction between $Fe^{II}$ and $Fe^{III}$.

## Results

### Structural Characterization

The crystal structure of $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$ has already been determined by single-crystal X-ray diffraction analysis.[10] In this compound, $Fe^{II}$ and $Fe^{III}$ are alternately bridged by dithiooxalato molecules, which forms the 2-D honeycomb network structure of $[Fe^{II}Fe^{III}(dto)_3]^-_\infty$. The $(n\text{-}C_3H_7)_4N^+$ cation layer is intercalated between two $[Fe^{II}Fe^{III}(dto)_3]^-_\infty$ layers. This structure is common in heterometal oxalato and dithiooxalato complexes.[11,12] The space group of $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$ is $P6_3$.

Single crystals of $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 4–6) have not yet been obtained. However, crystals of $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 4–6) appear to have honeycomb structures that are restricted to the *ab* plane. For these crystals, the lattice parameter $c$ increases with the number of carbon atoms in $(n\text{-}C_nH_{2n+1})_4N^+$, a relationship based on results from the analogous complexes $(n\text{-}C_nH_{2n+1})_4N[M^{II}Cr^{III}(dto)_3]$ (M = Mn, Fe, Co, Ni; $n$ = 3–5) and $A[Mn^{II}Fe^{III}(dto)_3]$ [A = $N(C_nH_{2n+1})_4$ ($n$ = 3–5) and $P(C_6H_5)_4$].[7,13] In support of this suggestion, note that the infrared spectra of all the complexes show dto-ligand vibration bands; the ν(CO) stretching mode of the dithiooxalato molecule appears around 1500 $cm^{-1}$, (1490.91 $cm^{-1}$, 1496.0 $cm^{-1}$, 1490.5 $cm^{-1}$, and 1490.5 $cm^{-1}$ for $n$ = 3–6, respectively). In the case of the parent compounds $K_2(C_2O_2S_2)$ and $KBa[Fe^{III}(dto)_3]\cdot 3H_2O$, the ν(CO) vibration modes appear at higher energies (1516 $cm^{-1}$ and 1528 $cm^{-1}$). The low values of ν(CO) of the $n$ = 3–6 complexes indicate that the dto molecule acts as a bridging ligand to form the 2-D network.

The structural characteristics of $(n\text{-}C_nH_{2n+1})[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6) were investigated by powder X-ray diffraction (PXD) using synchrotron radiation. Figure 2 shows the X-ray diffraction patterns for $n$ = 3–6 taken over 1 h at room temperature. The profiles are broad, and several peaks are only observed below $2\theta > 20°$. For the title complexes, the thermal vibration of $(n\text{-}C_nH_{2n+1})_4N^+$ appears to be quite large. A PXD measurement at low temperatures was carried out so that thermal vibration of the cation might be prevented; however, the diffraction profiles were still broad.

The sharpest peak can be attributed to the (002) reflection, which generally moves to a higher angle with decreasing temperature. The (002) reflections for $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ systematically shift to lower angle as shown in Figure 2(a). These results suggest that the interlayer spacing becomes larger as the number of carbon atoms in the alkyl chains increases.

The unit cell parameters of $n$ = 3 and 4 were estimated by the Rietveld method as shown in Figure 2(b) and (c). For the refinement of $n$ = 4, we used the coordination of $(n\text{-}C_4H_9)_4N[Mn^{II}Fe^{III}(ox)_3]$ with the space group $P6_3$.[12] The cell parameters $a$ are 10.06 Å ($n$ = 3) and 10.09 Å ($n$ = 4). The lattice parameters $c$ are 16.18 Å ($n$ = 3) and 18.14 Å ($n$ = 4). The $c$ parameter determined by PXD differs from the result of a single-crystal X-ray diffraction (SXD) study, since the $h$ $k$ $l$ reflections obtained by the Rietveld analysis cover the range $h$ = 0–3, $k$ = 0–2, $l$ = 0–4, a data range that is much smaller than that of the single-crystal analysis ($h$ = 0–12, $k$ = –12 to 10, $l$ = –16 to 15). The error in the cell parameters in the PXD thus becomes larger than that in the SXD.

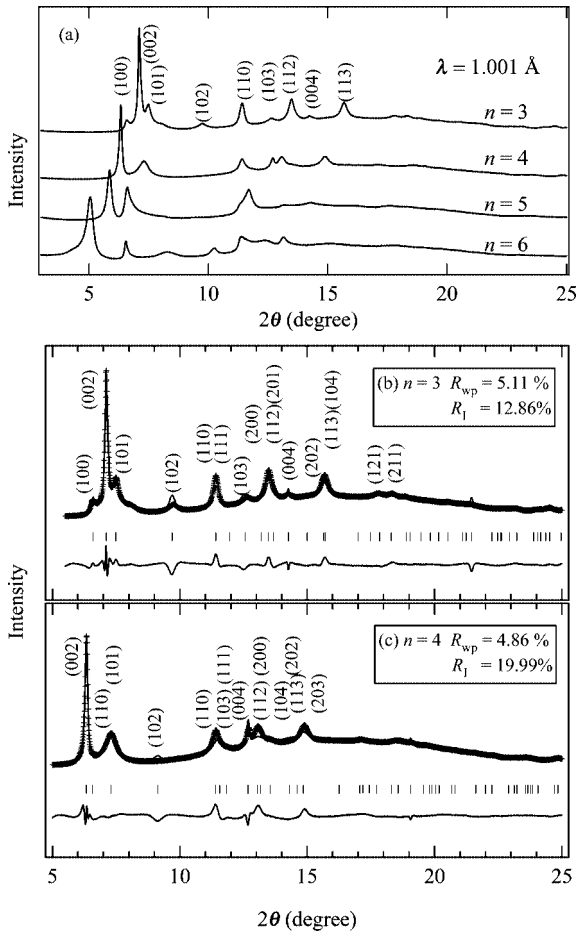

Figure 2. (a) Powder X-ray diffraction patterns for $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6) at room temperature. (b) Result of the Rietveld refinement for $n$ = 3, and (c) for $n$ = 4. $R_{wp}$ and $R_I$ are expressed as $\{[\Sigma_i w_i(y_i - y_{i,calc})^2/\Sigma_i w_i y_i^2]^{1/2}\}$ and $\{[\Sigma_K|I_{K,calc} - I_K|/\Sigma_K I_{K,calc}]\}$, respectively.

In the cases of $n$ = 5 and 6, the cell parameter could not be determined by the Rietveld method. The estimated parameters of $c$ are 19.67 Å and 22.71 Å, respectively. The lattice parameters for $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ are listed in Table 1.

Table 1. Lattice parameters for $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$.

| $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ | $a$ [Å] | $c$ [Å] | $R^*$, $R_{WP}$** |
|---|---|---|---|
| $n$ = 3 | 10.06[a] | 16.04[a] | 0.091[a]* |
| | 10.06[b] | 16.18[b] | 0.051[b]** |
| $n$ = 4 | 10.09[b] | 18.14[b] | 0.049[b]** |
| $n$ = 5 | | 19.67[c] | |
| $n$ = 6 | | 22.71[c] | |

[a] Value obtained from single-crystal structure analysis. [b] Refined value obtained by using the Rietveld method. [c] Calculated from the position of the (002) peak. $R_{wp}$ is expressed as $\{[\Sigma_i w_i(y_i - y_{i,calc})^2/\Sigma_i w_i y_i^2]^{1/2}\}$.

## Magnetic Properties

The static magnetic susceptibilities of $n$ = 3–6 were measured in an external magnetic field of 5000 G. Figure 3 shows the $\chi T$ and the inverse magnetic susceptibility ($\chi^{-1}$) as a function of temperature for $n$ = 3–6. The magnetic susceptibilities for $n$ = 5 and 6 obey the Curie–Weiss law [$\chi^{-1} = (T - \theta)/C$] in the range 50–300 K. However, for $n$ = 3 and 4, the magnetic susceptibilities do not obey the Curie–Weiss law over this range. The change of slope is at around 100 K on the $\chi^{-1}$ curves showing a thermal dependence. The Weiss constants are +12 K ($T_{CT} < T$: 120–300 K) and +20 K ($T_{CT} > T$: 30–98.4 K) for $n$ = 3, +18 K ($T_{CT} < T$: 140–300 K), and +27 K ($T_{CT} > T$; 39.7–100 K) for $n$ = 4. Those of $n$ = 5 and 6 are +23 K and +21 K, respectively.

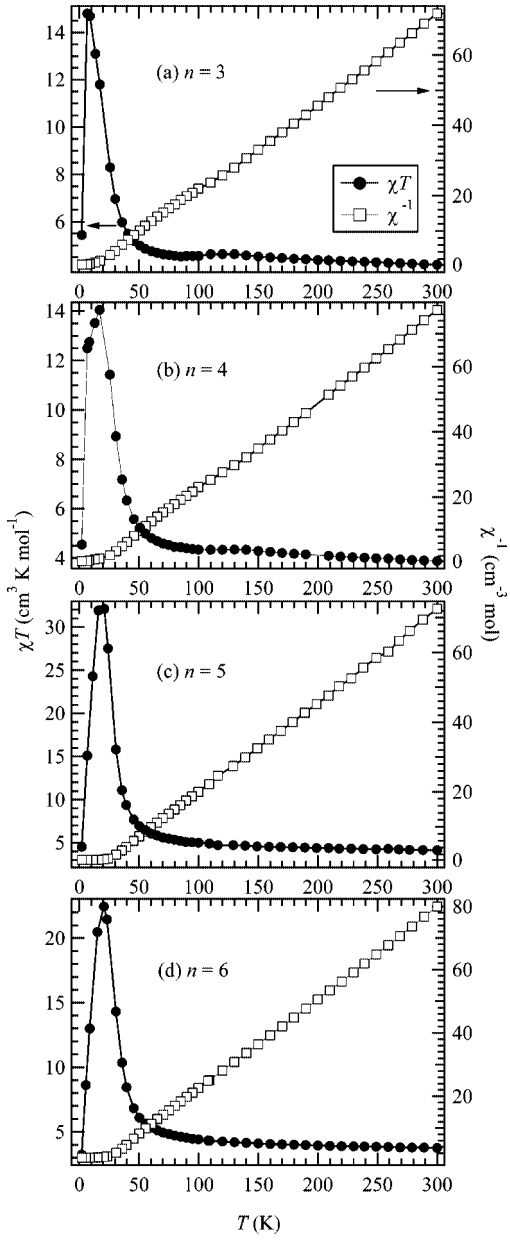

Figure 3. Temperature dependence of the magnetic susceptibility multiplied by temperature ($\chi T$) and the inverse susceptibility ($\chi^{-1}$) of $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

All these positive Weiss constants imply the existence of a ferromagnetic interaction between $Fe^{II}$ and $Fe^{III}$. At room temperature, the effective moments, $\mu_{eff}$, are 5.87 $\mu_B$ ($n$ = 3), 5.58 $\mu_B$ ($n$ = 4), 5.94 $\mu_B$ ($n$ = 5), and 5.48 $\mu_B$ ($n$ = 6). When $kT>>|J|$, the effective moment of HTP with $Fe^{II}$ ($S$ = 2) and $Fe^{III}$ ($S$ = 1/2) is calculated as 5.91 $\mu_B$ ($g$ = 2.00).

In order to confirm the ferromagnetic phase transition, we investigated the field-cooled magnetization (FCM), the remanent magnetization (RM) and the zero-field cooled magnetization (ZFCM) for $n$ = 3–6, the results of which are shown in Figure 4. The FCM curve was obtained on cooling with an external magnetic field of 30 G. After the FCM measurement, the magnetic field was switched off at 2 K; then, the RM was measured from 2 K to 35 K. After cooling from 300 K to 2 K in zero external field, an external field of 30 G was switched on at 2 K. Then, the ZFCM was measured from 2 K to 35 K.

Figure 4(a) displays the FCM, RM, and ZFCM as a function of temperature for $n$ = 3. The FCM curve shows a rapid increase below 8 K, as well as a tendency to saturate below 6 K. The RM vanishes at about 7 K. Below 7 K, the ZFCM is smaller than the FCM, a result which is due to the fact that the applied magnetic field of 30 G is too weak to move the magnetic domain walls below the ferromagnetic temperature. The ZFCM and FCM curves overlap at 7 K, where the magnetic hysteresis disappears. From these results, we estimate the Curie temperature to be 7 K. The FCM and ZFCM curves for $n$ = 4, provided in Figure 4(b), are different from those for $n$ = 3. The FCM has a shoulder at 13 K and the ZFCM has two peaks at 7 K and 13 K. The RM vanishes at 13 K, where the ZFCM and FCM meet each other. The ZFCM of $n$ = 4 implies that two ferromagnetic phases with $Tc$ = 7 K and 13 K coexist, which we can regard as a mixture of HTP and LTP at a low temperature. The coexistence of HTP and LTP is consistent with the ESR data. Figure 4(c) and (d) show the temperature dependences of the magnetizations for $n$ = 5 and 6. The FCM steeply increases at 23 K and 26 K for $n$ = 5 and 6, respectively, and the RM disappears at 19 K and 25 K for $n$ = 5 and $n$ = 6, respectively, where the ZFCM and FCM curves meet each other. The Curie temperatures for $n$ = 3–6 were evaluated at 7 K, 7 K (&13 K), 19.5 K and 22 K, respectively, from heat capacity measurements (for $n$ = 3 and 4),[14,15] and by an *Arrott plot*,[16] i.e. $M^2 - H/M$ ($1/\chi$) plot (for $n$ = 5 and 6). The Curie temperatures for $n$ = 3–6 are listed in Table 2.

Reflecting the CT phase transition, a small bump appears in the $\chi T$ curve and the slope of $\chi^{-1}$ changes around 120 K ($n$ = 3) and 140 K ($n$ = 4). We carefully measured the magnetic susceptibility for $n$ = 3 and 4 with a sweep rate of 0.1 K min$^{-1}$ on heating and cooling, the results of which are shown in Figure 5. A thermal hysteresis loop appears between 60 K and 130 K for $n$ = 3, and between 50 K and 150 K for $n$ = 4. The $\chi T$ curve for $n$ = 4 changes by about 4% between 50 K and 150 K. This value is smaller than that for $n$ = 3, which drops by about 7% between 60 K and 130 K.

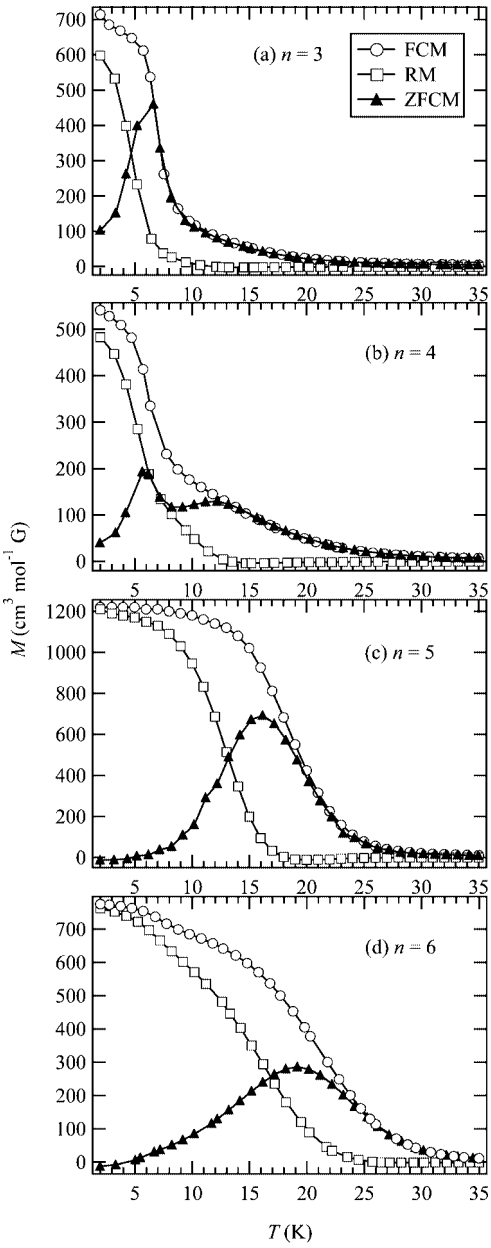

Figure 4. Temperature dependence of the field cooled magnetization (FCM:○), the remnant magnetization (RM:□), and the zero-field cooled magnetization (ZFCM:▲) for $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6). Applied magnetic field $H$ = 30 G.

## ESR Spectroscopy

In order to investigate the CT phase transition and the spin state of the Fe atom, we obtained the ESR spectra for $n$ = 3–6 between 4 K and 300 K. The experimental conditions are as described in ref.[17]

Figure 6 shows the temperature dependence of the ESR signal of the $n$ = 3 complex. When the temperature was lowered from room temperature, an ESR signal corresponding to the $Fe^{III}$ site with $S$ = 5/2 appeared below 105 K, and its intensity strengthened with decreasing temperature. On heating, the ESR signal vanished above 130 K. The $g$ value of the ESR signal at the center of the 3200-G

* $T_{CT\uparrow}$ and $T_{CT\downarrow}$ denote, respectively, the upper-limit and the lower-limit of the thermal hysteresis loop for the charge-transfer phase transtion.
** Curie constants were estimated in the high-temperature phase (HTP).
*** Curie temperatures of $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ were determined by heat capacity measurements (for $n$ = 3, 4) and by Arrott plots (for $n$ = 5, 6).

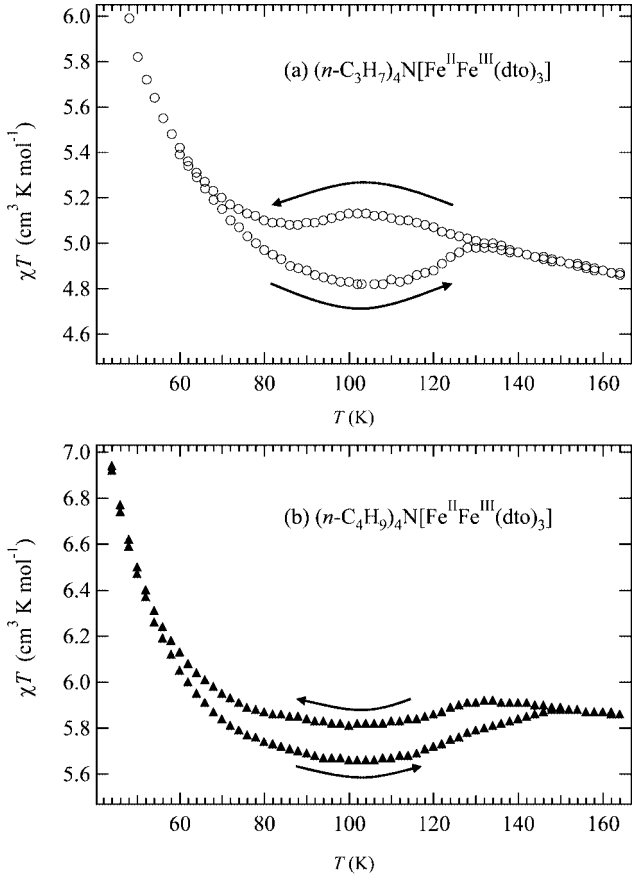

Figure 5. Temperature dependence of the magnetic susceptibility for $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$ and $(n\text{-}C_4H_9)_4N[Fe^{II}Fe^{III}(dto)_3]$. Temperature sweep rate is 0.1 K $min^{-1}$; (→) and (←) denote heating and cooling, respectively.

field is 2.10, which is consistent with that of the HS state ($^6A_{1g}$) of $Fe^{III}$, whose spin-orbit interaction is negligibly small. The half width ($\Delta H_{pp}$) has an almost constant value of $\Delta H_{pp}$ = 1470 G between 60 K and 120 K. In the case of $n$ = 4, as shown in Figure 7, a similar ESR signal corresponding to the HS state ($^6A_{1g}$) of $Fe^{III}$ appeared below 105 K in the cooling mode. On heating, the ESR signal almost disappeared above 145 K. The $\Delta H_{pp}$ for $n$ = 4 has an almost constant value of 1600 G between 50 and 140 K. In addition to the ESR signal due to the HS state ($^6A_{1g}$) of $Fe^{III}$, a weak signal is observed at 1600 G, whose $g$ value is 4.1. This weak signal should be attributed to the HTP fraction, i.e. the HS state ($S$ = 2; $^5T_{2g}$) of the $Fe^{II}$ and/or the LS state ($S$ = 1/2; $^2T_{2g}$) of the $Fe^{III}$. For $n$ = 5 and 6, a similar ESR signal appears at about 1600 G. Therefore, the HTP coexists with the LTP at 20 K for $n$ = 4, a finding which could account for the existence of the two peaks in the ZFCM.

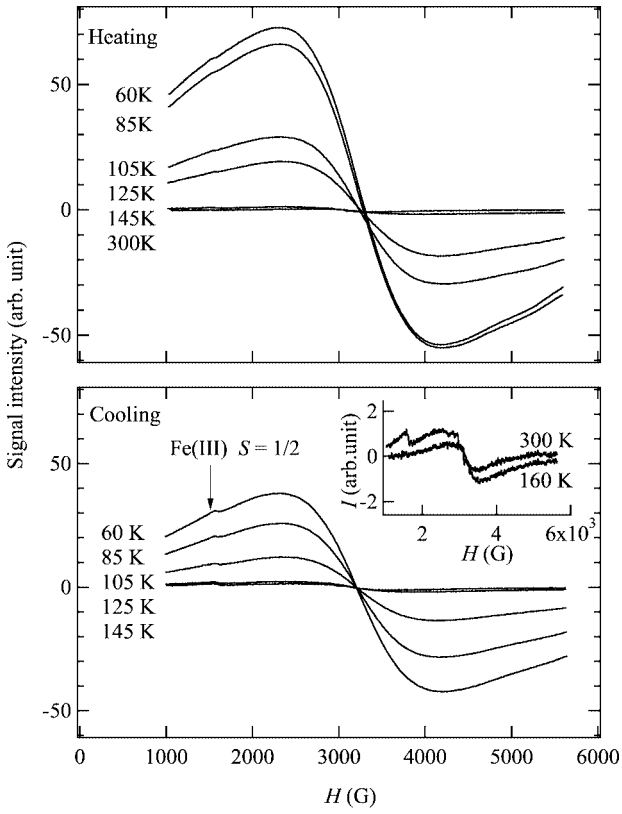

Figure 7. Temperature dependence of the ESR spectra on heating and cooling for $(n\text{-}C_4H_9)_4N[Fe^{II}Fe^{III}(dto)_3]$. Inset denotes the ESR signal corresponding to the $Fe^{III}$ ($^2T_{2g}$, $S$ = 1/2) of the HTP at 160 K and room temperature.

We estimated the spin susceptibilities corresponding to the HS state ($^6A_{1g}$) of the $Fe^{III}$ atom for $n$ = 3 and 4. The spin susceptibility is expressed as $\chi_{spin} = A(I(H) \times \{\Delta H_{PP}\}^2)$, where A is a constant value, $I(H)$ is the signal intensity, and $\Delta H_{PP}$ is the half width.[18] The spin susceptibilities for $n$ = 3 and $n$ = 4 are shown in Figure 8. The large thermal hysteresis loop in $\chi_{spin}$ for $n$ = 4 is in good agreement with that of the dc magnetic susceptibility; however, the thermal hysteresis loop in $\chi_{spin}$ for $n$ = 3 is narrower than that of the dc magnetic susceptibility.

In the cases of $KBa[Fe^{III}(dto)_3]\cdot 3H_2O$ and $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 5 and 6), the ESR spectra are completely different from those of $n$ = 3 and 4. For $n$ = 5 and 6, we could not observe a drastic signal change caused by the CT phase transition such as we noted for $n$ = 3 and 4. The ESR signals of $n$ = 5 and 6 are shown in Figure 9. The ESR spectra of the parent complex, $KBa[Fe^{III}(dto)_3]\cdot 3H_2O$, is shown in Figure 9(a). The paramagnetic spin of $KBa[Fe^{III}(dto)_3]\cdot 3H_2O$ has been already reported as the $Fe^{III}$ LS state ($S$ = 1/2) on the basis of magnetic susceptibility and Mössbauer spectroscopy results.[11,19,20]

The $KBa[Fe^{III}(dto)_3]\cdot 3H_2O$ complex has two ESR signals: a strong signal at 1600 G, and a weak signal at 3200 G. The $g$ values of the ESR signals at 1600 G and 3200 G are estimated at 4.10 and 2.01 and are attributed to the $g_\perp$ and $g_\parallel$ of $Fe^{III}$ ($S$ = 1/2), respectively. However, the ESR signal with $g$ = 2.01 persisted at room temperature, even though

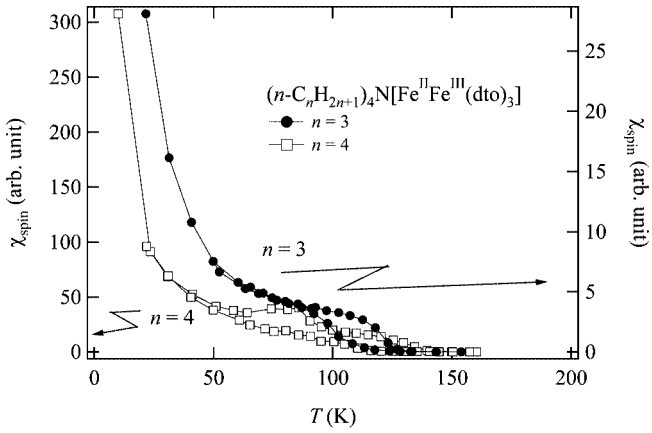

Figure 8. Temperature dependence of the spin susceptibility for $(n\text{-}C_nH_{2n+1})N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3 and 4).

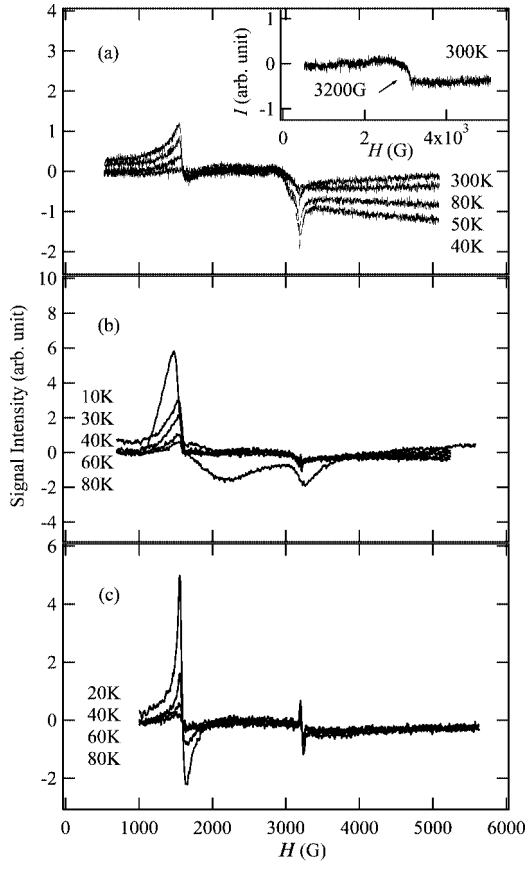

Figure 9. The ESR spectra at several temperatures for (a) $KBa[Fe^{III}(dto)_3]\cdot 3H_2O$; (b) $(n\text{-}C_5H_{11})_4N[Fe^{II}Fe^{III}(dto)_3]$; and (c) $(n\text{-}C_6H_{13})_4N[Fe^{II}Fe^{III}(dto)_3]$.

the strong signal with $g$ = 4.10 disappeared above 90 K. Therefore, we suggest that the HS state ($S$ = 5/2) of the $Fe^{III}$ atom caused by linkage isomerization ($Fe^{III}O_4S_2$ and / or $Fe^{III}O_6$) is responsible for this appearance of the ESR signal around 3200 G at room temperature. The $^{57}Fe$ Mössbauer spectrum for $KBa[Fe^{III}(dto)_3]\cdot 3H_2O$ did not enable us to distinguish the minor fraction of the $Fe^{III}$ HS state ($S$ = 5/2) caused by linkage isomerization from the LS state ($S$ = 1/2), because these Mössbauer spectra appear at almost

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the same velocities. Therefore, the ESR signal due to the $Fe^{III}$ HS state ($S$ = 5/2) is presumably superposed on the ESR signal with $g_{\parallel}$ = 2.01 corresponding to the $Fe^{III}$ LS state ($S$ = 1/2).

For $n$ = 5 and 6, the ESR spectra were quite similar to those of $KBa[Fe^{III}(dto)_3]\cdot 3H_2O$. A strong signal at 1580 G and a weak signal at 3260 G were observed. The $g$ values of the ESR signals at 1580 G and 3260 G are estimated at 4.10 and 2.01, respectively, which are attributed to the $g_{\perp}$ and $g_{\parallel}$ of the LS state ($S$ = 1/2) of $Fe^{III}$. The signal with $g$ = 2.01 persisted at room temperature, so that an ESR signal due to the HS state ($S$ = 5/2) of the $Fe^{III}$ atom caused by linkage isomerization ($Fe^{III}O_4S_2$ and /or $Fe^{III}O_6$) appeared around 3260 G. Note that the ratio of the linkage isomer $Fe^{II}O_4S_2$ ($S$ = 2) can be estimated easily by Mössbauer spectroscopy. The percentages of the linkage isomer of $Fe^{II}O_4S_2$ are about 8% at 60 K for $n$ = 3, 14% at 25 K for $n$ = 4, 4% at 25 K for $n$ = 5, and 11% at 30 K for $n$ = 6. The $Fe^{II}O_4S_2$ persists at low temperatures without creating charge-transfer.[21]

In the cases of $n$ = 5 and 6, the ESR signals of the LS state ($S$ = 1/2) of the $Fe^{III}$ atom decrease with increasing temperature and then almost disappear above 90 K; the latter change takes place because of rapid spin-lattice relaxation. The ESR signal of the HS state ($^5T_{2g}$) of $Fe^{II}$ and the LS state ($^2T_{2g}$) of $Fe^{III}$ could not be observed in the high-temperature region. From the analysis of the ESR spectra, we conclude that the CT phase transition does not take place for $n$ = 5 and 6, in which the spin configurations of $Fe^{II}$ ($S$ = 2) and $Fe^{III}$ ($S$ = 1/2) are stable between 4 K and 300 K.

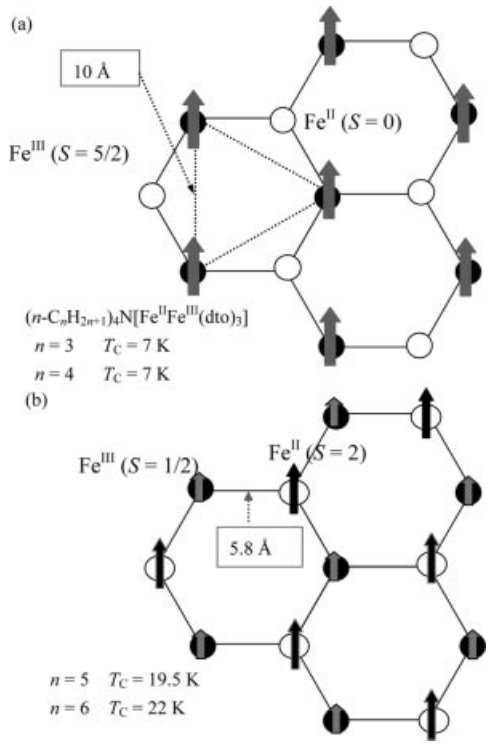

Figure 10. Schematic representation of ferromagnetic ordering for $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6). (a) The ferromagnetic ordering for $n$ = 3 and $n$ = 4 takes place in the LTP with the spin configuration $Fe^{II}$ ($S$ = 0) and $Fe^{III}$ ($S$ = 5/2). (b) The ferromagnetic ordering for $n$ = 5 and $n$ = 6 takes place in the HTP with the spin configuration $Fe^{II}$ ($S$ = 2) and $Fe^{III}$ ($S$ = 1/2).

## Discussion

The spin state in the paramagnetic-ferromagnetic region and the existence of the charge-transfer phase transition of $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 3–6) are revealed by magnetic susceptibility measurements and ESR spectroscopy. The appearance of the CT phase transition and the mechanism of the ferromagnetism in an iron mixed-valence tris-dithiooxalato complex critically depend on the cation size $(n\text{-}C_nH_{2n+1})_4N^+$ ($n$ = 3–6). The CT phase transitions are observed for $n$ = 3 (120 K) and 4 (140 K), and then the $Fe^{II}$ ($S$ = 0) – $Fe^{III}$ ($S$ = 5/2) spin combination causes the ferromagnetic transition at 7 K. On the other hand, the CT phase transition is not apparent for $n$ = 5 and $n$ = 6; $Fe^{II}$ ($S$ = 2) – $Fe^{III}$ ($S$ = 1/2) spins are stable between 2 K and 300 K. The spin configuration corresponding to the HTP of $n$ = 3 and 4 is responsible for the ferromagnetic transitions at 19.5 K ($n$ = 5) and 22 K ($n$ = 6), respectively. The ferromagnetically ordered states and several parameters for $n$ = 3–6 are schematically shown in Figure 10 and Table 2.

Due to the effect of the cation size, the $[Fe^{II}Fe^{III}(dto)_3]$ layers are separated by an increment corresponding to the length of the alkyl chain from $n$ = 3 to $n$ = 6. The bulkier $(n\text{-}C_nH_{2n+1})_4N^+$ cations probably expand or distort slightly the $[Fe^{II}Fe^{III}(dto)_3]$ honeycomb ring. The cell parameter $a$ of the analogous complexes, $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(ox)_3]$ ($n$ = 3–5)[22] tends to expand slightly as $n$ increases. For $n$ = 4, the slight expansion or distortion of the 2-D honeycomb ring ($\Delta a$ = 0.03 Å) might be expected to lead to an inhibition of CT between the Fe atoms; thus, the HTP spin partially remains at low temperature. We should note that $n$ = 5 shows a CT phase transition under 0.5 GPa, and the ferromagnetic transition temperature changes from 19.5 K to 7 K. In other words, the spin configuration changes from $Fe^{II}$ ($S$ = 2) – $Fe^{III}$ ($S$ = 1/2) (HTP) to $Fe^{II}$ ($S$ = 0) – $Fe^{III}$ ($S$ = 5/2) (LTP).[23] There is a limiting size of the honeycomb ring between $n$ = 4 and $n$ = 5 where the CT does not occur. Unfortunately, we could not obtain information on the crystal structure of the $(n\text{-}C_nH_{2n+1})_4N[Fe^{II}Fe^{III}(dto)_3]$ ($n$ = 5, 6) complexes by PXD. A single crystal X-ray analysis of the $n$ = 4–6 and an X-ray diffraction measurement taken under pressure are necessary to quantitatively clarify the cation size effects on the $[Fe^{II}Fe^{III}(dto)_3]^-$ layer.

The mechanism of the magnetic interaction in the iron tris-dithiooxalato complexes is dramatically changed according to whether a CT phase transition exists. Here, we will discuss the origin of the magnetic interaction in the title complexes. The ferromagnetic ordering for $n$ = 3 and 4 is considered to be established by the charge-transfer interaction between $Fe^{II}$ and $Fe^{III}$, the same mechanism as in $Fe^{III}_4[Fe^{II}(CN)_6]_3\cdot 15H_2O$ ($T_C$ = 5.5 K),[24,25] as shown in Fig-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ure 11(a). In contrast, for $n$ = 5 and 6, the spin configuration of $Fe^{II}$ ($S$ = 2) and $Fe^{III}$ ($S$ = 1/2) is the ground state between 2 K and 300 K. The ferromagnetic ordering for $n$ = 5 and 6 is schematically shown in Figure 11(b); each $Fe^{III}$ site in the LS state ($S$ = 1/2) accepts a $t_2$ electron with a down-spin from the neighboring $Fe^{II}$ site in the HS state ($S$ = 2). Therefore, the coupling between the ground configuration $\varphi_i[Fe^{III}(t_2^5)]\varphi_j[Fe^{II}(t_2^4e^2)]$ and the charge-transfer configuration $\varphi_i[Fe^{II}(t_2^6)]\varphi_j[Fe^{III}(t_2^3e^2)]$ stabilizes the ground state, a situation favoring ferromagnetic ordering. In the ground configuration of $\varphi_i[Fe^{III}(t_2^5)]\varphi_j[Fe^{II}(t_2^4e^2)]$, in addition to the charge-transfer interaction, the potential exchange interaction due to the orbital orthogonality between the $t_2$ electron with an up-spin $Fe^{III}$ and the $Fe^{II}$ electrons with up-spins (in $e$ orbitals and one $t_2$ orbital) induces ferromagnetic ordering, which is presumably responsible for the ferromagnetic transition with a high $T_C$ in $n$ = 5 and 6.

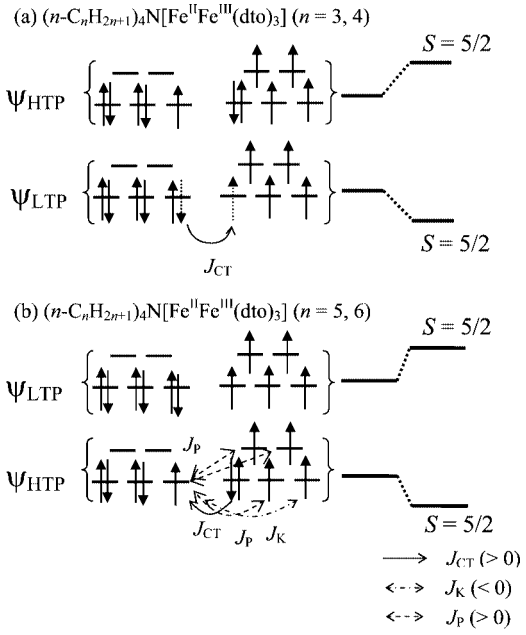

Figure 11. (a) Ferromagnetism induced by the charge-transfer interaction between $Fe^{II}$ ($S$ = 0) and $Fe^{III}$ ($S$ = 5/2) for ($n$-$C_nH_{2n+1}$)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] ($n$ = 3, 4). (b) Ferromagnetism induced by the charge-transfer interaction as well as the potential exchange interaction between $Fe^{II}$ ($S$ = 2) and $Fe^{III}$ ($S$ = 1/2) for ($n$-$C_nH_{2n+1}$)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] ($n$ = 5, 6). Solid line arrow: charge transfer interaction ($J_{CT} > 0$); dash-dotted line arrow: kinetic exchange interaction ($J_K < 0$); short-dashed line arrow: potential exchange interaction ($J_P > 0$).

Next, to quantify the ferromagnetic interaction between the iron atoms of ($n$-$C_nH_{2n+1}$)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] ($n$ = 3–6), we will estimate the exchange interaction $J$ in a 2-D layer by means of the simplest Hamiltonian,

$$H = -J\sum_{<i,j>}\vec{S}_i\cdot\vec{S}_j - gh\sum_i S_i^Z .$$

Here, $h$ is the external magnetic field. For $n$ = 3 and 4, the LTP spin state with $Fe^{III}$($S$ = 5/2) – $Fe^{II}$($S$ = 0) appears via a CT phase transition, and the states produce large triangular interactions in the 2-D plane [Figure 10(a)]. In the case of the triangular lattice, the number of nearest neighbors of the $Fe^{III}$ ($S$ = 5/2) site is 6. The molar susceptibility of the triangular lattice, calculated by a high-temperature expansion up to the second order, is given by [Equation (1)]:[26]

$$\chi = \frac{NS(S+1)}{3}\beta(g\mu_B)^2 + \frac{2N\beta^2\mu_B^2g^2}{3}JS^2(S+1)^2 \qquad (1)$$

Here $\beta$ is $1/kT$, $N$ is Avogadro's number, and $\mu_B$ is the Bohr magneton. After substituting $S$ = 5/2 and $g$ = 2.00 into (1), we estimate the exchange coupling by the least-squares method. The fitting curves are shown in Figure 12(a). The range analyzed in the LTP is from 20 to 122 K for $n$ = 3, and from 20 to 140 K for $n$ = 4. The values obtained are $J$ = 3.12 K for $n$ = 3, and 2.39 K for $n$ = 4.

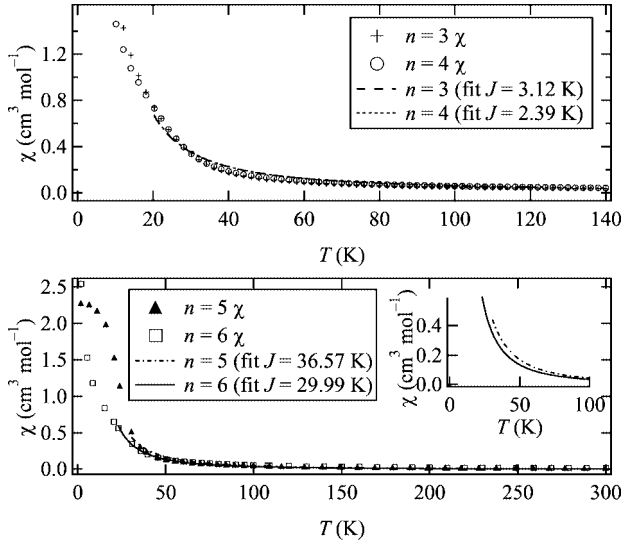

Figure 12. Temperature dependences of $\chi$ for $n$ = 3–6 with high-temperature expansion fitting. (a) dashed line: fitting for $n$ = 3; short-dashed line: fitting for $n$ = 4 in LTP spin configuration ($Fe^{III}$ $S$ = 5/2 – $Fe^{II}$ $S$ = 0) on triangular lattice. Molar susceptibility for $n$ = 3 and 4 is indicated by plus (+) and circle (○) symbols, respectively. (b) dash-dotted line: fitting for $n$ = 5; solid line: fitting for $n$ = 6 in HTP spin configuration ($Fe^{III}$ $S$ = 1/2 – $Fe^{II}$ $S$ = 2) on hexagonal lattice. Molar susceptibility for $n$ = 5 and 6 is indicated by the solid triangle (▲) and square (□) symbols, respectively.

On the other hand, for $n$ = 5 and 6, there is no CT phase transition, and the $Fe^{III}$ ($S$ = 1/2) – $Fe^{II}$ ($S$ = 2) interaction takes place on hexagonal rings [Figure 10(b)]. In the case of a hexagonal lattice, the number of nearest neighbors is 3. For $n$ = 5 and 6, the $Fe^{II}$ ($S$ = 2) atom is connected with three $Fe^{III}$ ($S$ = 1/2) atoms. The high-temperature expansion of the susceptibility for a hexagonal lattice is calculated by the same procedure as (1), and we get the molar susceptibility as follows [Equation (2)]:

$$\chi = \frac{N\beta\mu_B^2}{6}(g_AS_A(S_A+1)+g_BS_B(S_B+1)) + \frac{N\beta^2\mu_B^2}{3}g_Ag_BJS_A(S_A+1)S_B(S_B+1) \qquad (2)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

After substituting $S_A$ = 1/2 and $S_B$ = 2 into (2), we estimated the exchange coupling and g values by the least-squares method. The range analyzed is from 31 to 300 K for $n$ = 5, and from 21 to 300 K for $n$ = 6. Then, we obtained $J$ = 36.57 K for $n$ = 5 and $J$ = 29.99 K for $n$ = 6, with $g_{1/2}$ = $g_2$ = 4.00 values, which were in agreement with the $T_C$ and g values obtained by the ESR spectra. The fitting curves are shown in Figure 12(b). The ferromagnetic interactions $J$ for $n$ = 3 and 4 are considerably lower than those for $n$ = 5 and 6.

## Conclusion

We have synthesized ($n$-$C_nH_{2n+1}$)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] ($n$ = 3–6), and have investigated the cation-size effect on the CT phase transition and the ferromagnetic transition in these compounds. The result of our PXD measurement confirmed that the 2-D honeycomb network layer [$Fe^{II}Fe^{III}$(dto)$_3$]$^-$ is increasingly well separated with increases in the number $n$ of the ($n$-$C_nH_{2n+1}$)$_4$N cations. We have also determined, by magnetic susceptibility and ESR spectroscopy measurements, the spin states of the $Fe^{II}$ and $Fe^{III}$ sites for $n$ = 3–6 between 2 and 300 K. The ($n$-$C_nH_{2n+1}$)$_4$N$^+$ cation size affects the existence or nonexistence of the CT phase transition and the ferromagnetic interaction $J$ between the $Fe^{II}$ and $Fe^{III}$ sites. For $n$ = 3 and 4, we observed the thermally induced charge transfer between $Fe^{II}$ and $Fe^{III}$ around 120 K ($n$ = 3) and 140 K ($n$ = 4). The spin configuration changes from $Fe^{II}$ ($S$ = 2) – $Fe^{III}$ ($S$ = 1/2) (HTP) to $Fe^{II}$ ($S$ = 0) – $Fe^{III}$ ($S$ = 5/2) (LTP) in the vicinity of the CT phase transition temperature ($T_{CT}$). Furthermore, the $Fe^{III}$ ($S$ = 5/2) spin, which is located on a large triangular lattice, is ferromagnetically ordered at 7 K. On the other hand, for $n$ = 5 and 6, the CT phase transition did not occur, and the spin configuration of the HTP for $n$ = 3 and 4 dominated over the whole temperature range. The $Fe^{II}$ ($S$ = 2) – $Fe^{III}$ ($S$ = 1/2) spin configurations located on a hexagonal lattice produce the ferromagnetic transitions at 19.5 K ($n$ = 5) and 22 K ($n$ = 6), respectively.

## Experimental Section

### Syntheses

**$K_2C_2O_2S_2$:** Potassium dithiooxalate, $K_2C_2O_2S_2$, was prepared by the reaction of potassium hydrogensulfide KHS (14.57 g, 0.20 mol) and di-*n*-pentyl dithiooxalate ($n$-$C_5H_{11}$)$_2$($C_2O_2S_2$) (0.10 mol) in methanol. The di-*n*-pentyl dithiooxalate was obtained by the reaction of oxalyl dichloride $(COCl)_2$ (8.61 mL, 0.10 mol) and 1-pentanethiol $CH_3(CH_2)_4SH$ (25 mL, 0.20 mol). After filtration, the $K_2C_2O_2S_2$ was washed well with methanol to remove the KHS and, because $K_2C_2O_2S_2$ is highly hygroscopic,[27,28] it was dried in vacuo. $C_2K_2O_2S_2$ (198.35): calcd. C 12.11, S 32.33; found C 12.28, S 32.54.

**KBa[$Fe^{III}$(dto)$_3$]·3$H_2O$:** $Fe(NO_3)_3$·10$H_2O$ (2.10 g, 5.61·10$^{-3}$ mol) was treated with $K_2C_2O_2S_2$ (3.00 g, 15.1 mmol) in cold water (25 mL), and the solution was filtered to remove iron sulfide. Then $BaBr_2$·2$H_2O$ (2.50 g, 0.17 mol) was added to the dark purple solution, and KBa[$Fe^{III}$(dto)$_3$]·3$H_2O$ precipitated. The salt was recrystallized from water and dried for one day.[20,29,30] $C_6H_6BaFeKO_9S_6$ (646.8): calcd. C 11.14, H 0.94, S 29.75; found C 11.39, H 1.20, S 29.66.

**($n$-$C_nH_{2n+1}$)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] ($n$ = 3–6):** The title complexes were synthesized in a way similar to the preparation of ($n$-$C_3H_7$)$_4$N-[$M^{II}Cr^{III}$(dto)$_3$] (M = Fe, Co, Ni, Zn).[5]

A solution of KBa[Fe(dto)$_3$]·3$H_2O$ (0.5 g, 0.77 mmol) in a 3:2 methanol/water mixture (20 mL) was stirred. To this was added slowly a solution of $FeCl_2$·4$H_2O$ (0.24 g, 0.77 mmol) and ($n$-$C_nH_{2n+1}$)$_4$NBr ($n$ = 3–6) (1.15 mmol) in a 3:2 methanol/water mixture (20 ml), whereupon a black powdered crystal precipitated. The compounds ($n$-$C_nH_{2n+1}$)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] ($n$ = 3–6) were separated as powdered crystals by suction filtration and washed first with a 1:1 methanol/water mixture and then with methanol and diethyl ether. The compounds ($n$-$C_nH_{2n+1}$)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] ($n$ = 7, 8) could not be obtained as crystalline powders. The elemental analysis for the precipitated crystal that had been stirred at 30–40 °C for 12 h was in good agreement with the calculated one; the results are listed in Table 3.

Table 3. Elemental analysis of C, H, N, and S in ($n$-$C_nH_{2n+1}$)$_4$N-[$Fe^{II}Fe^{III}$(dto)$_3$] ($n$ = 3–6).

| ($n$-$C_nH_{2n+1}$)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] | C | H | N | S |
|---|---|---|---|---|
| $n$ = 3 found (calc) | 32.88 (32.83) | 4.46 (4.29) | 2.34 (2.13) | 29.40 (29.22) |
| $n$ = 4 | 36.73 (36.98) | 5.14 (5.08) | 1.76 (1.96) | 27.33 (26.92) |
| $n$ = 5 | 40.71 (40.52) | 5.93 (5.75) | 1.64 (1.82) | 24.72 (24.96) |
| $n$ = 6 | 43.78 (43.58) | 6.58 (6.34) | 1.64 (1.69) | 23.23 (23.27) |

**Measurements:** The powder X-ray diffraction data was taken at the BL02B2 beam line of SPring-8.[31] The as-grown powdered sample was sealed in a Lindemann capillary having a diameter of 0.3 mm, which gave a homogeneous intensity distribution in the Debye–Scherrer ring. The wavelength of the X-ray was 1.001 Å, and the exposure time at 300 K was 1 h. The static magnetic susceptibility was measured with a Quantum Design MPMS5 SQUIID magnetometer. Powdered crystals (10 mg) were wrapped in a polyethylene film and held in a plastic straw. The magnetic susceptibility obtained was corrected for the background and the core diamagnetism. The diamagnetic correction for constituting atoms was carried out using Pascal's constants.[32] The diamagnetic Pascal's corrections are as follows: –4.18·10$^{-4}$ cm$^3$ mol$^{-1}$ ($n$ = 3), –4.66·10$^{-4}$ cm$^3$ mol$^{-1}$ ($n$ = 4), –5.13·10$^{-4}$ cm$^3$ mol$^{-1}$ ($n$ = 5), and –5.60·10$^{-4}$ cm$^3$ mol$^{-1}$ ($n$ = 6). The ESR spectra for the powdered crystals were obtained with a JEOL JES-TE300 X-band ESR spectrometer. The magnetic field was monitored with an Echo Electronics ES-FC5 field meter.

## Acknowledgments

The authors wish to thank Prof. K. Asai, Prof. Y. Uwatoko, Prof. F. Varret, Prof. K. Boukheddaden, Prof. C. Itoi, Dr. Y. Kobayashi, and Dr. M. Enomoto for many helpful discussions. This work was supported by a Grant-in-Aid for Scientific Research and a Grant-in-Aid from the 21st Century COE (Center of Excellence) Program (Research Center for Integrated Science) of the Japanese Ministry of Education, Science, Sports, and Culture. The synchrotron-radiation X-ray powder experiments were performed at the SPring-8 BL02B2 with approval of the Japanese Synchrotron Radiation Research Institute (JASRI). One of the authors (M. Itoi) was sup-

# Two New $Cu^{II}$ Coordination Polymers: Studies of Topological Networks and Water Clusters

**Jin Yang,[a] Jian-Fang Ma,*[a] Ying-Ying Liu,[a] Ji-Cheng Ma,[a] Heng-Qing Jia,[b] and Ning-Hai Hu[b]**

**Keywords:** Coordination polymers / Copper / Materials science / Topology / Water clusters

Two new $Cu^{II}$ coordination polymers, namely $[Cu_2(BDC)_2(L)_4(H_2O)_2]\cdot 14H_2O$ (**1**) and $[Cu_{1.5}(BTC)(L)_{1.5}(H_2O)_{0.5}]\cdot 2H_2O$ (**2**), where L = 1,1′-(1,4-butanediyl)bis(imidazole), BDC = 1,4-benzenedicarboxylate, and BTC = 1,3,5-benzenetricarboxylate, have been synthesized at room temperature. Complex **1** exhibits an unusual, square-planar, four-connected 2D $^{2}_{6}4$ net, which has been predicated by Wells. Interestingly, three types of water clusters, namely $(H_2O)_6$, $(H_2O)_8$, and $(H_2O)_{10}$, are observed in the hydrogen-bonded layers constructed by the BDC ligands and water molecules. The BTC anion in compound **2** is coordinated to the $Cu^{II}$ cation as tetradentate ligand to form a $(6^6)_2(4^26^48^4)_2(6^4810)$ net containing three kinds of nonequivalent points. Thermogravimetric analyses (TGA) and IR spectra for **1** and **2** are also discussed in detail. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

During the past few years much attention has been paid to theoretical and experimental studies of small water clusters due to their unusual properties and importance in many physical, chemical, and biological processes.[1] A detailed understanding of the numerous possible structures and stabilities of isolated water clusters in diverse surroundings can help us study the nature of water–water interactions in bulk water or ice.[2] For example, the water hexamer is the building block of ice $I_h$ and appears to be relevant to liquid water as well.[3] Several different isomers for the water hexamer, such as book, bag, ring, cage, and prism topologies, have been found from theoretical calculations.[4] Thus, the search for experimental models of these small water clusters is very important to improve our study of the structures and characteristics of liquid water and ice.

On the other hand, understanding the structure of coordination polymers is an important aspect to achieve a true advance in the synthesis and design of new materials for practical applications.[5] The analysis of network topology is a particularly useful tool for reducing multidimensional structures to simple node-and-connection reference nets. Wells has listed a large number of topologies in his classic monographs on networks,[6] and numerous fascinating archetypal structures, including diamond ($6^6$), $SiO_2$ ($6^48^2$-b), $SrSi_2$ ($10^3$-a), α-$ThSi_2$ ($10^3$-b), and PtS ($4^28^4$) have been reported[7] that are of fundamental importance in structural design and in the understanding of structure–property correlations. In this work we report two new $Cu^{II}$ coordination polymers, namely $[Cu_2(BDC)_2(L)_4(H_2O)_2]\cdot 14H_2O$ (**1**), which contains an unusual, square-planar, four-connected $^{2}_{6}4$ net and three types of water clusters, and $[Cu_{1.5}(BTC)(L)_{1.5}(H_2O)_{0.5}]\cdot 2H_2O$ (**2**), which possesses a $(6^6)_2(4^26^48^4)_2(6^4810)$ net [L = 1,1′-(1,4-butanediyl)bis(imidazole),[8] BDC = 1,4-benzenedicarboxylate, BTC = 1,3,5-benzenetricarboxylate; Scheme 1].

## Results and Discussion

### Crystal Structures

The synthesis of complexes **1** and **2** is described in the Experimental Section. Selected bond lengths and angles for compounds **1** and **2** are listed in Table 1. Part of the structure of $[Cu_2(L)_4(H_2O)_2]\cdot(BDC)_2\cdot 14H_2O$ (**1**) is shown in Figure 1 (a). There are two crystallographically unique $Cu^{II}$ cations in the asymmetric unit. Each $Cu^{II}$ cation adopts a distorted square-pyramidal geometry by coordinating to four nitrogen atoms from four L molecules and one water molecule. Four nitrogen atoms (N1, N5, N9, and N8A for Cu1; N4, N11, N13, and N16A for Cu2) form the base of the pyramid and one water molecule (Ow1 for Cu1; Ow2 for Cu2) occupies the apical position, with respective Cu–O distances of 2.380 and 2.464 Å. The BDC anion acts as a counter-anion and structure-directing reagent, indicating that the coordination of L to the $Cu^{II}$ cation is stronger than that of the BDC anion in this case.

The structure of **1** consists of an unusual, 2D, square-planar, four-connected $^2_6$4 net, which has been predicated by Wells.[6] In this net the $Cu^{II}$ cation acts as a four-connected node and L acts as the edge of every circuit (Figure 1, b). This $^2_6$4 net is entirely different from the square-planar four-connected ($8^6$) net first reported by Tong et al. and us, which was not mentioned by Wells.[5g,8c] It is well known that when square-planar, four-connected building blocks self-assemble into extended structures, 2D (4,4) square grids are favored.[9] This observation shows that formation of a $^2_6$4 net may be attributed to the effects of the flexible L and the BDC anion. Moreover, if two of the L molecules act as each of two opposite edges, a single L molecule acts as each of the other four edges, and every $Cu^{II}$ cation can be seen as a three-connected node, the structure of **1** can be regarded as a 2D (6,3) network.

Table 1. Selected bond lengths [Å] and angles [°] for compounds **1** and **2**.

[a] Symmetry codes for **1**: $^{\#1}$ $-x+1, -y, -z-1$; $^{\#2}$ $-x, -y+1, -z$. [b] Symmetry codes for **2**: $^{\#1}$ $-x+1.5, -y+1.5, -z+1$; $^{\#2}$ $x, y+1, z$; $^{\#3}$ $x, -y+1, z-0.5$; $^{\#4}$ $x, y-1, z$; $^{\#5}$ $-x+1, y, -z+1.5$.

In addition, a notable feature within complex **1** is the presence of three types of water clusters, namely $(H_2O)_6$, $(H_2O)_8$, and $(H_2O)_{10}$, in the hydrogen-bonded layer of BDC anions and water molecules (Figure 2, a). The hydrogen-bonding parameters are outlined in Table 2. Within the $(H_2O)_6$ cluster, two water molecules (OW2 and OW2A) act as two hydrogen-bond donors with OW4 and OW4A as hydrogen-bond acceptors to form a cyclic water tetramer (Figure 2, b).[10,11] Interestingly, the cyclic water tetramer is hydrogen-bonded to two neighboring free water molecules, OW6 and OW6A, yielding a water hexamer. Furthermore, the oxygen atoms O2, O2A, O5, O5A, O7, and O7A from the BDC ligands are involved in hydrogen bonds with water molecules OW4, OW4A, OW6, and OW6A to stabilize the $(H_2O)_6$ cluster. Within the $(H_2O)_{10}$ cluster, four water molecules (OW7, OW7A, OW16, and OW16A) act as both hydrogen-bond donors and acceptors (Figure 2, c). Four water molecules (OW13, OW13A, OW15, and OW15A) play the role of hydrogen-bond donors, while another two water molecules (OW14 and OW14A) only act as hydrogen-bond acceptors. Four water molecules (OW15, OW15A, OW16, and OW16A) form a cyclic water tetramer through hydrogen bonds, which is further hydrogen-bonded by water molecules OW7, OW13, OW14, OW7A, OW13A, and OW14A, leading to an $(H_2O)_{10}$ cluster. Moreover, the $(H_2O)_{10}$ cluster is stabilized by oxygen atoms O1, O1A, O3, O3A, O6A, and O6B from BDC ligands. It is of interest that the four water molecules of the cyclic water tetramer in the $(H_2O)_6$ or $(H_2O)_{10}$ clusters are completely coplanar without regard to the connectivity of the hydrogen atoms. The hydrogen-bond lengths are 2.818(4) [OW15–H(15C)···OW16], 2.879(4) [OW15–H(15D)···OW16$^{\#8}$], 2.812(4) [OW2–H(2D)···OW4], and 2.809(4) Å [OW2–H(2C)···OW4$^{\#4}$], and are slightly longer than the average hydrogen-bond length of liquid water tetramer (2.718 Å).[4a,12] In the $(H_2O)_8$ cluster, the lattice water molecules (OW8A, OW8B, OW5, and OW5A) and the coordinated water molecules (OW1 and OW1A) of the $[Cu_2(L)_4(H_2O)_2]^{4+}$ cation are associated by hydrogen bonds to form a cyclic centrosymmetric water hexamer (Figure 2, d). The average OW···OW distance is about 2.80 Å, which is slightly longer than the corresponding value in ice $I_h$ (2.759 Å) and the calculated value of 2.718 Å for cyclic water hexamer.[3] However, they are shorter than those observed in liquid water (2.854 Å).[3] The cyclic water hexamer is hydrogen-bonded to two neighboring water molecules (OW10A and OW10B), yielding a $(H_2O)_8$ cluster. It is worthwhile to note that two water molecules of the $(H_2O)_8$ cluster bind to the $Cu^{II}$ cations. Meanwhile, four water molecules are involved in hydrogen bonds with the oxygen atoms from the carboxylate groups of the

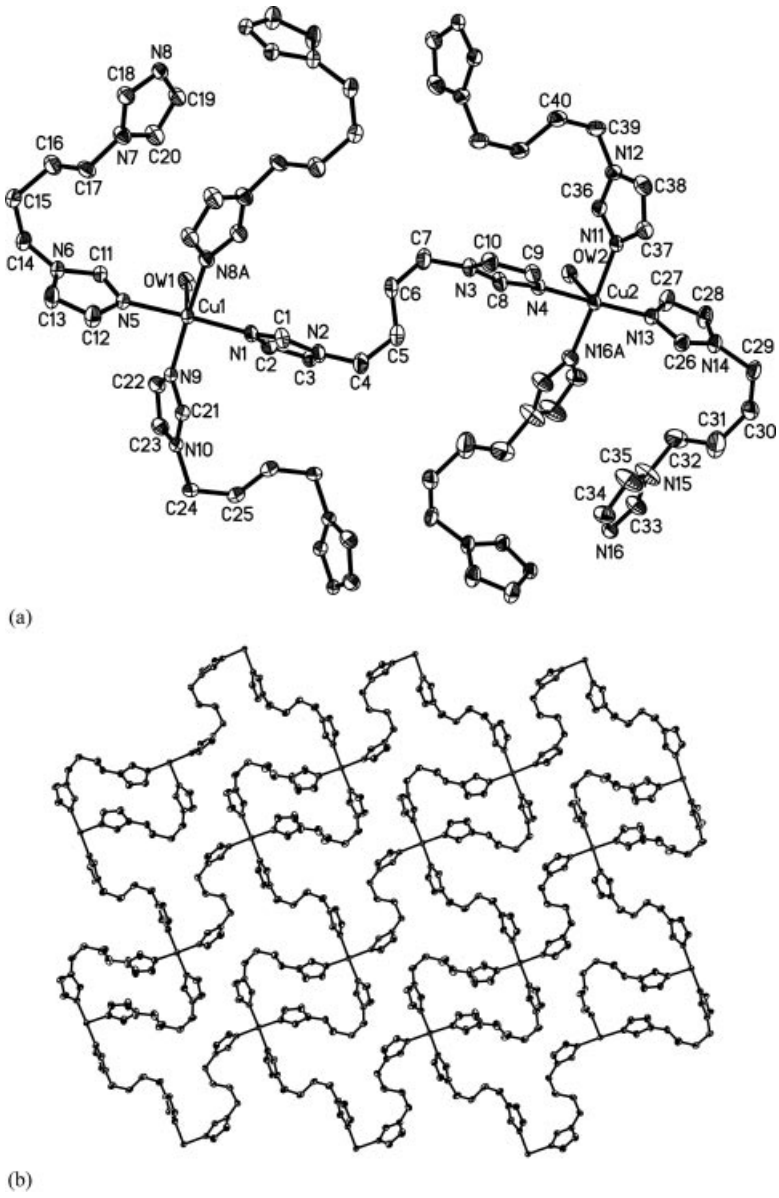

Figure 1. (a) An ORTEP view of complex **1** showing 30% thermal probability ellipsoids. (b) The square-planar, four-connected 2D $^{2}_{6}4$ network.

BDC ligands. This indicates that the $(H_2O)_8$ cluster is stabilized not only by hydrogen bonds but also by coordination interactions. The water molecule, the organic BDC anion, and the $Cu^{II}$ cation play a crucial role in the formation of the water clusters. Furthermore, the square-planar, four-connected $^{2}_{6}4$ net and the hydrogen-bonded layer are further connected through the coordinating water molecules to form 3D supramolecular structures. Figure 3 (a) displays the packing structure of compound **1**. The H-bonding layers act as a "glue" to reinforce the coordination polymeric $^{2}_{6}4$ sheet, forming an overall 3D structure. Each H-bonding layer links two polymeric sheets, and each polymeric sheet is also attached to two H-bonding layers through OW1 and OW2 molecules (Figure 3, b). Here, both water–sheet and water–water interactions are important for the stability of the overall structure.

It should be pointed out that the angles between two neighboring carboxylate groups of BDC and BTC anions are 180° and 120°, respectively, which suggests that the BTC anion may be superior to the BDC anion when it comes to meeting the configurations of $[Cu(L)_n]^{2+}$ ($n$ = 1 or 2) cations, and to coordinate to the $Cu^{II}$ cation (Scheme 1). Thus, during the construction of **2** the multi-carboxylate ligand BTC was chosen as organic anion.

The structure of **2** contains two crystallographically unique $Cu^{II}$ cations, two unique L molecules, and one unique BTC anion. As shown in Figure 4 (a), the Cu1 cation is five-coordinate in a distorted square-pyramidal ge-

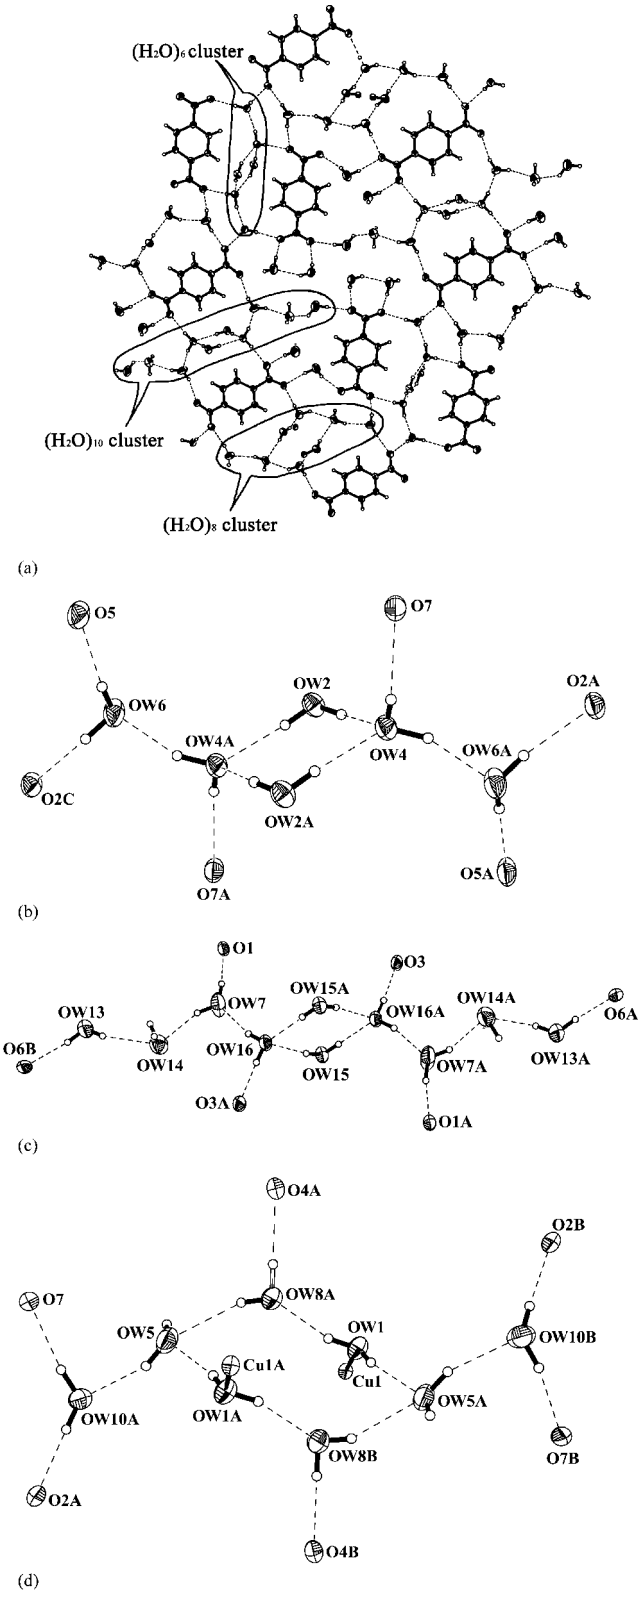

Figure 2. (a) The hydrogen-bonded layer of BDC and water molecules. (b) An ORTEP view showing the $(H_2O)_6$ cluster and its coordination environment. (c) An ORTEP view showing the $(H_2O)_{10}$ cluster and its coordination environment. (d) An ORTEP view showing the $(H_2O)_8$ cluster and its coordination environment.

ometry by coordinating to two nitrogen atoms (N3 and N6A) from two L molecules and three oxygen atoms (O1, O2A, and O3A) from three BTC molecules. The Cu2 center also has a distorted square-pyramidal coordination sphere defined by two carboxylate oxygen atoms (O5 and O5A), one water molecule (OW1), and two nitrogen atoms (N1 and N1A) from two L molecules. The BTC anions bridge the $Cu^{II}$ cations to form 2D networks, which are further connected through the L ligands to form a 3D framework structure, see Figure 4 (b) and Figure 4 (c). In addition, there are some hydrogen-bonded water molecules in the framework of **2**. These water molecules are stabilized by both hydrogen bonds and coordination interactions (OW1 coordinates to Cu2). The hydrogen-bonded water molecules not only fill the voids in the supramolecular framework but also contribute to the total lattice energy. The framework host sufficiently affects the hydrogen bonds of the water molecules and the water molecules maybe also influence the arrangement of the framework host.

If, for reasons of classifying the net, we define the BTC anion as a single point, then it can be considered as a four-connected node (Scheme 1). Thus, there are three kinds of nodes in the structure of **2**: a five-connected node for Cu1, a four-connected node for Cu2, and a four-connected node for the BTC anion. There are some unique four-, six-, eight-, and ten-membered circuits through the nodes in **2** (see Figures S1–S13 in the Supporting Information). For the four-connected BTC anion, each of six sets of links is contained in six-membered circuits (see Figures S1 and S2). Thus, the four-connected BTC anion has the Schäfli symbol $6^6$ (Figure 5, a). For the five-connected Cu1 node, ten sets of links are contained in four six-membered circuits (Figures S3–S5), two four-membered circuits (Figure S6), and four eight-membered circuits (Figures S7–10), therefore this node has the Schäfli symbol $(4^26^48^4)$ (Figure 5, b). For the four-connected Cu2 node, four sets of links are contained in a six-membered circuit (Figure S11), while the other two sets of links are contained in an eight-membered circuit (Figure S12) and a ten-membered circuit (Figure S13), respectively, therefore the four-connected Cu2 node has the Schäfli symbol $(6^4810)$ (Figure 5, c). The molar ratio of these three kinds of nodes is 2:2:1 (BTC/Cu1/Cu2), thus the structure of **2** can be symbolized as a $(6^6)_2(4^26^48^4)_2(6^4810)$ net with three kinds of nonequivalent points (Figure 5, d).[6] The topological analysis of this net was performed with OLEX.[13] The present case indicates that topological analysis is a useful tool for the description and comparison of natural and artificial networks in crystal engineering.[14]

From the above descriptions, the choice of anion is clearly critical in determining the molecular structures of the final compounds. In this work, both planar two-carboxylate anion and three-carboxylate anion were chosen to study the variation of the structures for **1** and **2**. The topological difference between **1** and **2** should therefore result from the structural features of the BDC and BTC anions. The BDC anion in **1** is not coordinated to the $Cu^{II}$ cation but acts as a counter-anion and template reagent, whereas the BTC anion in **2** meets the configuration of $[Cu(L)_n]^{2+}$

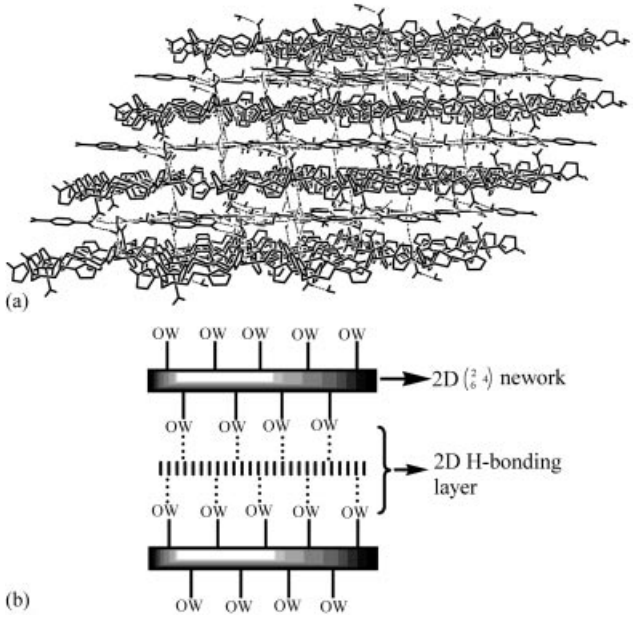

Figure 3. (a) The 3D H-bonding structure of **1**. (b) A schematic representation of the 3D H-bonding structure.

($n$ = 1 or 2) cations and coordinates to the $Cu^{II}$ cation as a four-coordinate ligand. Although different Cu/L ratios (1:1, 1:2, 1:3, and 1:4) were used in the preparations, only **1** and **2** were isolated as the products. Thus, the formation of these different frameworks is due to the effects of different organic anions.

## IR Spectra and TGA

The solid-state IR spectra of **1** and **2** in the region 4000–400 $cm^{-1}$ exhibit characteristic bands for BDC, BTC, and L ligands (see Figure S14 in the Supporting Information). The IR spectrum of **1** shows a broad band centered around 3427 $cm^{-1}$ attributable to the O–H stretching frequency of the water cluster. The IR spectrum of ice shows the O–H stretch at 3220 $cm^{-1}$, while this stretching vibration in liquid water appears at 3490 and 3280 $cm^{-1}$.[15] This indicates that the water cluster in **1** has an O–H stretching vibration similar to that of liquid water, and the slight difference is attributable to the environment that the clusters are in.[16] The peaks around 1600, 1560, 1400, and 1350 $cm^{-1}$ for **1** and **2** can be attributed to the asymmetric and symmetric vibrations of the carboxylate groups.[17]

In order to characterize the compounds **1** and **2** more fully in terms of thermal stability, we studied them by TGA. Compounds **1** and **2** were heated from 35 to 780 °C under $N_2$. As expected, the TGA curves of compounds **1** and **2** exhibit three similar weight-loss stages. The first weight loss, corresponding to the water molecules, is observed over the wide temperature range 35–90 °C (observed 18.6%, calculated 19.1%) for **1** and 35–93 °C (observed 6.7%, calculated 7.1%) for **2**. The second weight loss is 52.4% (calculated 50.6%) for **1** in the range 238–350 °C and 46.4% (calculated 45.1%) for **2** in the range 239–344 °C, and is assigned to the release of L molecules. Drastic weight losses corre-

sponding to the removal of BDC and BTC were observed from 420 to 528 °C for **1** and from 423 to 524 °C for **2**, respectively.

## Conclusions

Two new $Cu^{II}$ coordination polymers with different topologies have been obtained due to the effects of different organic anions on the final frameworks' formation. When the BDC anion was chosen as the dicarboxylate anion, a coordination polymer **1** with an unusual, square-planar, four-connected $^2_6$4 net and three types of water clusters was obtained. In **2**, the BTC anion coordinates to the $Cu^{II}$ cation as a tetradentate ligand to form a $(6^6)_2(4^26^48^4)_2(6^4810)$ net with three kinds of nonequivalent points.

## Experimental Section

**Materials and Methods:** All reagents and solvents for syntheses were purchased from commercial sources and used as received. A Perkin–Elmer 240 elemental analyzer was used to collect microanalytical data, and the FT-IR spectrum was recorded from KBr pellets in the range 4000–400 $cm^{-1}$ on a Mattson Alpha-Centauri spectrometer. TGA was performed with a Perkin–Elmer TG-7 analyzer under nitrogen.

**Synthesis of 1,1′-(1,4-Butanediyl)bis(imidazole) (L):** A mixture of imidazole (3.4 g, 50 mmol) and NaOH (2.0 g, 50 mmol) in DMSO (10 mL) was stirred at 60 °C for 1 h, and then 1,4-dichlorobutane (3.2 g, 25 mmol) was added. The mixture was cooled to room temperature after stirring at 60 °C for 2 h and then poured into 200 mL of water. A white solid formed immediately, which was isolated by filtration in 86% yield (4.1 g) after drying in air. $C_{10}H_{14}N_4$ (190.25): calcd. C 63.16, H 7.37, N 29.47; found C 63.11, H 7.42, N 29.31.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Synthesis of $[Cu_2(L)_4(H_2O)_2]\cdot(BDC)_2\cdot 14H_2O$ (1):** A mixture of $CuCl_2\cdot 2H_2O$ (0.171 g, 1 mmol), NaOH (0.080 g, 2 mmol), and $H_2BDC$ (0.166 g, 1 mmol) in water was stirred for 10 min at 60 °C, then 1,1′-(1,4-butanediyl)bis(imidazole) (L; 0.190 g, 1 mmol) was added to the mixture. After stirring for 30 min, the blue precipitate was collected and dissolved in a minimum amount of ammonia (14 M). Suitable blue single crystals of **1** were obtained by slow evaporation of this solution at ambient temperature in 73% yield (109.8 mg). $C_{56}H_{96}Cu_2N_{16}O_{24}$ (1504.6): calcd. C 44.66, H 6.38, N 14.89; found C 44.89, H 6.60, N 14.49.

**Synthesis of $[Cu_{1.5}(BTC)(L)_{1.5}(H_2O)_{0.5}]\cdot 2H_2O$ (2):** Compound **2** was prepared in the same way as for **1**, but with 1,3,5-benzenetricarboxylic acid ($H_3BTC$), in 53% yield (33.5 mg). $C_{24}H_{29}Cu_{1.5}N_6O_{8.5}$ (632.84): calcd. C 45.51, H 4.58, N 13.27; found C 45.22, H 4.51, N 13.79.

**X-ray Crystallography:** Single-crystal X-ray diffraction data for complexes **1** and **2** were recorded with a Rigaku RAXIS-RAPID image plate diffractometer and a Bruker-AXS Smart CCD diffractometer, respectively, using the ω-scan technique with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). All the structures were solved by direct methods with SHELXS-97[18] and refined by full-matrix least-squares techniques using the SHELXL-97 program.[19] Non-hydrogen atoms were refined with anisotropic temperature parameters the and the hydrogen atoms of the ligands were refined as rigid groups. The hydrogen atoms of the water molecules for **1** and **2** were located from the difference Fourier maps. Further details of the structural analysis are summarized in Table 3.

Table 3. Summary of X-ray crystallographic data for compounds **1** and **2**.

# Synthesis, Structures, and Luminescent Properties of Aluminum Complexes with Chelating Anilido-Imine Ligands

Xiaoming Liu,[a] Hong Xia,[a] Wei Gao,[a] Ling Ye,[a] Ying Mu,*[a] Qing Su,[a] and Yi Ren[a]

**Keywords:** Aluminum / N ligands / Luminescence

The syntheses of a number of four-coordinate aluminum complexes, *ortho*-$C_6H_4(NAr')(CH{=}NAr'')AlCl_2$ [Ar′ = Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**2a**); Ar′ = 2,6-*i*$Pr_2C_6H_3$, Ar′′ = 2,6-$Me_2C_6H_3$ (**2b**); Ar′ = Ar′′ = 2,6-$Me_2C_6H_3$ (**2c**); Ar′ = *p*-$MeC_6H_4$, Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**2d**)], are described. Complexes **2a**–**2d** were synthesized from the reaction of $AlCl_3$ with lithium salt of the corresponding ligand at room temperature. All complexes were characterized by $^1H$ and $^{13}C$ NMR spectroscopy and molecular structures of complexes **2a**, **2b**, and **2d** were determined by X-ray crystallography. Luminescent properties of complexes **2a**–**2d** in both solution and the solid state were studied.

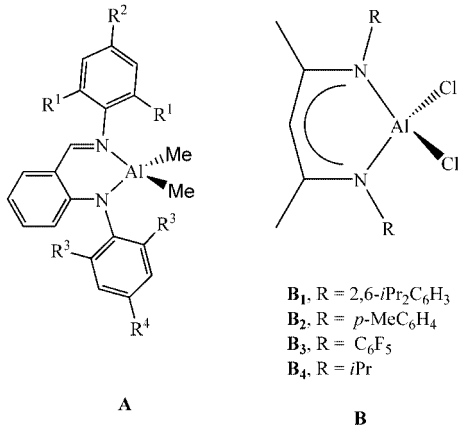
## Introduction

Luminescent metal complexes have attracted increasing attention because of their potential application in areas of chemistry, medicine, and material science.[1] Many luminescent complexes of main group and transition metals, such as $Al^{III}$,[2] $Zn^{II}$,[3] $Pt^{II}$,[4] $Ir^{III}$,[5] and $Re^{I}$,[6] have been designed and synthesized in recent years. Particularly, chelated aluminum complexes have attracted much attention because of their low cost, and good luminescent and electron-transporting properties. As the well-known tris(8-hydroxyquinolinyl)aluminum ($Alq_3$) was found to be a good emitter, and a highly efficient electron-transporting material and host material in organic electroluminescence devices,[7–9] a large number of its derivatives with modified 8-hydroxyquinoline ligands have been investigated.[1b,2,10] Aluminum complexes with nitrogen-containing ligands have also been reported,[11] while the luminescent properties of coordinative unsaturated aluminum complexes have not been extensively explored, probably because of their instability to air and moisture.[12,13] We have recently focused our attention on the synthesis of aluminum complexes of this type. As a continuation of our studies on the luminescent alkylaluminum complexes with chelating anilido-imine ligands (Scheme 1 A),[14d] herein we report the syntheses, characterization, and fluorescent properties of a number of aluminum dichloride complexes with anilido-imine ligands, *ortho*-$C_6H_4(NAr')(CH{=}NAr'')AlCl_2$ [Ar′ = Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**2a**); Ar′ = 2,6-*i*$Pr_2C_6H_3$, Ar′′ = 2,6-$Me_2C_6H_3$ (**2b**); Ar′ = Ar′′ = 2,6-$Me_2C_6H_3$ (**2c**); Ar′ = *p*-$MeC_6H_4$, Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**2d**)].



Scheme 1.

## Results and Discussion

### Ligand Synthesis

Free ligands, *ortho*-$C_6H_4(NHAr')(CH{=}NAr'')$ [Ar′ = Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**1a**); Ar′ = 2,6-*i*$Pr_2C_6H_3$, Ar′′ = 2,6-$Me_2C_6H_3$ (**1b**); Ar′ = Ar′′ = 2,6-$Me_2C_6H_3$ (**1c**); Ar′ = *p*-$MeC_6H_4$, Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**1d**)], were synthesized by a literature procedure.[15] Of these free ligands, compounds **1a**, **1c**, and **1d** are known, while **1b** is a new compound. The new ligand **1b** was prepared by the reaction of *ortho*-$C_6H_4F(CH{=}NC_6H_3Me_2\text{-}2,6)$ with LiN(H)Ar (Ar = 2,6-*i*$Pr_2C_6H_3$) (Scheme 2) in good yield (72% isolated yields). The reaction was carried out in THF and the crude product

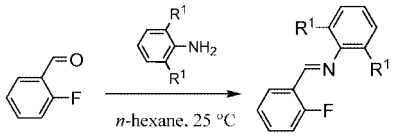
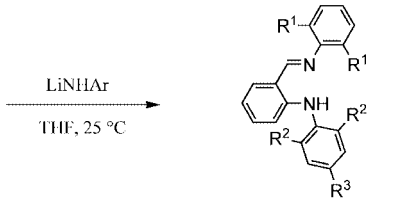
was purified by crystallization from methanol. Compound **1b** was characterized by $^1$H and $^{13}$C NMR spectroscopy along with elemental analysis. The $^1$H NMR spectrum of **1b** exhibits resonance at $\delta$ = 8.39 ppm for the imino CH proton, with the corresponding $^{13}$C NMR resonance at $\delta$ = 166.25 ppm. The NH resonance appears at characteristically low field ($\delta$ = 10.5 ppm). The infrared absorption band of the imine C=N stretch occurs in the region 1617 cm$^{-1}$. Those data are similar to the corresponding values of **1a**, **1c**, and **1d**.[14d]



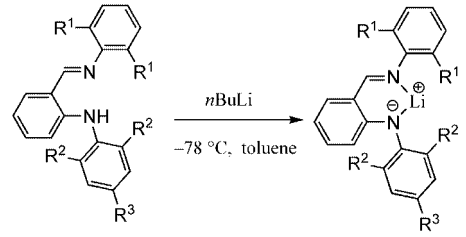


**1a** $R^1 = R^2 = i$Pr, $R^3$ = H
**1b** $R^1$ = Me, $R^2 = i$Pr, $R^3$ = H
**1c** $R^1 = R^2$ = Me, $R^3$ = H
**1d** $R^1 = i$Pr, $R^2$ = H, $R^3$ = Me

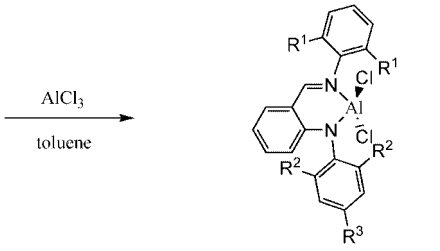
Scheme 2. Synthetic procedure of ligands **1a**–**1d**.

## Complex Synthesis

The aluminum dichloride complexes **2a**–**2d** were synthesized in reasonable yields (68–75%) by reaction of $AlCl_3$ with the lithium salt of the corresponding ligand that was generated in situ by treating the free ligand with *n*BuLi in hexanes at –78 °C (Scheme 3). All complexes are well soluble in toluene, dichloromethane, diethyl ether, and THF, but sparingly soluble in saturated hydrocarbon solvents. Complexes **2a**–**2d** were all characterized by elemental analyses, $^1$H and $^{13}$C NMR spectroscopy, and satisfactory analytic results were obtained for all compounds. In the $^1$H NMR spectra of these complexes, the resonances for the imino CH protons ($\delta$ = 7.32–7.90 ppm) shift about 1 ppm towards high field compared to the corresponding signals of the free ligands. However, the resonances ($\delta$ = 173.5–174.5 ppm) for the imino CH carbons in the $^{13}$C NMR spectra shift to low field in comparison with the corresponding ones of the free ligands and the dialkylaluminum complexes.[14d] The N–H signals of the free ligands disappear in the $^1$H NMR spectra of complexes **2a**–**2d**, which is indicative of formation of an Al–N bond in these compounds. The two methyl groups of the isopropyl units in complexes **2a**, **2b**, and **2d** are inequivalent, as the coordination of the anilido-imine ligands to the aluminum center causes rotation about the N–aryl bond to become slow on the NMR timescale.[16] In addition, $^1$H and $^{13}$C NMR spectra reveal that these complexes all have $C_s$-symmetric structures in solution. All complexes are more stable than the corresponding alkylaluminum complexes in solution; they have pretty good thermal stability and can be heated in boiling toluene for several hours without obvious decomposition.



**1a** $R^1 = R^2 = i$Pr, $R^3$ = H
**1b** $R^1$ = Me, $R^2 = i$Pr, $R^3$ = H
**1c** $R^1 = R^2$ = Me, $R^3$ = H
**1d** $R^1 = i$Pr, $R^2$ = H, $R^3$ = Me



**2a** $R^1 = R^2 = i$Pr, $R^3$ = H
**2b** $R^1$ = Me, $R^2 = i$Pr, $R^3$ = H
**2c** $R^1 = R^2$ = Me, $R^3$ = H
**2d** $R^1 = i$Pr, $R^2$ = H, $R^3$ = Me

Scheme 3. Synthetic procedure of complexes **2a**–**2d**.

## Crystal Structure

The molecular structures of the complexes **2a**, **2b**, and **2d** were determined by X-ray crystallographic analysis. Crystals of all three complexes suitable for X-ray crystal structure determination were grown from *n*-hexane at room temperature. The ORTEP drawings of molecular structures of **2a**, **2b**, and **2d** are shown in Figure 1 (top), Figure 2, and Figure 3, respectively. Selected bond lengths and angles for these complexes are given in Table 1. The X-ray analysis reveals that all three complexes adopt a distorted tetrahedral geometry with the metal center chelated by the bidentate ligand through the imine and amido nitrogen atoms. The N–Al–N bite angle in **2b** [99.27 (6)°] is larger than those in **2a** [97.59 (8)°] and **2d** [97.82 (8)°], but similar to the one in the related β-diketiminato aluminum complex [Scheme 1; $\mathbf{B_1}$ 99.36 (4)°, $\mathbf{B_2}$ 99.41(12)°],[17a,17b] which contains a similar six-membered $C_3N_2Al$ metallacycle. In these three complexes, the six-membered chelating rings are nearly planar with the aluminum atom lying 0.5017, 0.0963, and 0.3065 Å out of the plane, respectively. The imino C=N bonds in these complexes retain their double bond character, being 1.303(2), 1.303(2), and 1.310(3) Å for **2a**, **2b**, and **2d**, respectively. The Al–N (amido) distances [1.8327(19) Å

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for **2a**, 1.8397(14) Å for **2b**, 1.826(2) Å for **2d**] are much shorter than the Al–N (imine) distances [1.894(2) Å for **2a**, 1.8927(15) for **2b**, 1.8937(19) Å for **2d**] because the anionic amido nitrogen can also π-donate to the aluminum, whereas the neutral imine nitrogen does not have an available lone pair for π-donation. The Al–N (imine) distances (1.893 Å average) are shorter than the values (1.953 Å average) previously reported for *ortho*-$C_6H_4(NAr')(CH{=}NAr')AlMe_2$[14d] because of the more electrophilic aluminum center in the dichloro aluminum compounds, but larger than the one [1.850(2) Å] in $(TTP)AlCl_2$.[17b] The Cl–Al–Cl angles (109.40° average) in **2a** and **2d** are close to the ideal tetrahedral angle of 109.47°, and they are similar to that of the reported diketiminatolaluminum complex (Scheme 1; B).[17] In addition, X-ray diffraction analysis reveals that intermolecular π–π interaction appears in the solid state of complex **2a** (Figure 1, bottom). One phenyl ring in the ligand of **2a** stacks together with the corresponding one in an adjacent molecule by the π–π interaction with a distance of 3.6 Å.[18]

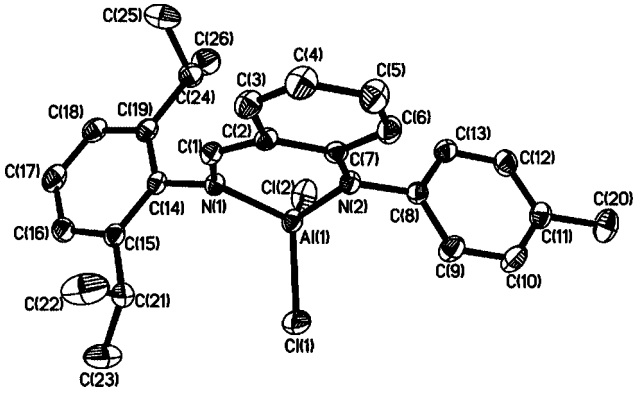

Figure 3. Molecular structure of complex **2d** (thermal ellipsoids are drawn at the 30% probability level).

## Fluorescent Properties

Table 2 summarizes the UV/Vis and fluorescent properties of compounds **1a**–**1d** and **2a**–**2d** determined in both solution and the solid state. In solution, the free ligands **1a**–**1d** have a weak emission band at $\lambda_{max}$ = 419, 420, 423, and 430 nm, respectively. When these ligands were bound to an aluminum center, strong green luminescence was observed. The observed luminescence of the complexes could be attributed to a π*–π transition of their chelated anilido-imine conjugated ligands. As shown in Figure 4, in contrast to the free ligands, each of complexes **2a**–**2d** in solution gives a broad emission band (bandwidth at half-height = 70–90 nm) with $\lambda_{max}$ = 512, 510, 505, and 554 nm, respectively. The emission energies of these complexes are significantly red-shifted in comparison with the free ligands. The role of the aluminum atom in the luminescence of **2a**–**2d** should be twofold, as pointed out in the literature for coordination complexes.[19] First, the formation of covalent bonds between the Al and N atoms by the donation of lone pairs of the N atom to the Al atom changes the emission energy, owing to the lowering of the energy gap between π* and π. Second, after coordination with the Al atom, the ligand becomes more rigid, which can reduce the loss of energy by vibrational motions and increase the emission efficiency. The emission maxima of complexes **2a**–**2c** in solution are

close to each other, while the emission maximum of **2d** is red-shifted about 40 nm compared to other complexes. This result could be attributed to the differences in the number and size of the *ortho*-substituents on the rotatable aryl rings of their ligands, which might affect the conjugated extent of these complexes.[14a–14d] In addition, the lower basicity and lower electron density of the anilide may also be responsible for the emission red shift in **2d**.[14e] The quantum yields of these compounds are low in solution. Complexes **2a**–**2d** all emit bright fluorescence in the solid state when irradiated by exciting light. The emission spectra of complexes **2a**–**2d** in the solid state are shown in Figure 5. Complexes **2b**, **2c**, and **2d** each have a relatively narrow band (bandwidth at half-height: 60–70 nm) in the solid state with $\lambda_{max}$ = 497, 498, and 544 nm, respectively. The emission

maxima of these complexes in the solid state are blue shifted compared to their corresponding emission maxima in solution, which probably resulted from the reduced conjugated extent of the three complexes, as the free rotation of the aryl rings in these complexes is blocked in the solid state. The emission maximum of complex **2a** ($\lambda_{max}$ = 540 nm) in the solid state is red shifted compared to its corresponding emission maximum in solution, which is normal considering that red shifting of the emission maximum can be observed for most fluorescent compounds in the solid state, probably because of π–π stacking of aromatic rings in the molecules (see Figure 1, bottom). This result also implies that the rotation of 2,6-*i*$Pr_2$Ph groups about the N–aryl bond in complex **2a** is slow in solution, which is consistent with the $^1$H NMR experimental result.

## Conclusion

Our research results indicate that the chelating bidentate anilido-imine conjugated ligands are well suited for synthesizing the four-coordinate aluminum complexes by a salt metathesis reaction of $AlCl_3$ with the lithium salt of corresponding ligands at room temperature. $^1$H and $^{13}$C NMR spectra reveal that these aluminum complexes have $C_s$-symmetric structures in solution and X-ray diffraction analysis indicates that the six-membered chelating ring in these complexes is nearly planar with the aluminum lying slightly out of the plane. These complexes produce bright fluorescence in both solution and the solid state, and the emission color in solution can be tuned by the *ortho* substituents on the rotatable aryl rings of the ligands. The four-coordinate aluminum complexes are a new class of luminescent material with potential applications in optoelectronic devices.

## Experimental Section

All reactions were performed using standard Schlenk techniques in high-purity nitrogen or glovebox techniques. Toluene, *n*-hexane, THF, and diethyl ether were dried by refluxing over sodium and benzophenone and distilled under nitrogen prior to use. $C_6D_6$ was dried with activated 4 Å molecular sieves and vacuum-transferred to a sodium-mirrored air-free flask. $CDCl_3$ was dried with $CaH_2$ for 48 h and vacuum-transferred to an air-free flask. $AlCl_3$ and *n*BuLi were purchased from Aldrich and used as received. NMR spectra were measured using a Varian Mercury-300 NMR spectrometer. The elemental analysis was performed with a Perkin–Elmer 2400 analyzer. UV/Vis absorption spectra were recorded with a UV-3100 spectrophotometer. Fluorescence measurements were carried out on an RF-5301PC.

***ortho*-$C_6H_4$[NH($C_6H_3$*i*$Pr_2$-2,6)](CH=N$C_6H_3Me_2$-2,6) (1b):** A solution of *n*BuLi (30.32 mL, 48.5 mmol) in hexanes was added to a solution of 2,6-diisopropylaniline (8.1 mL, 48.5 mmol) in THF (30 mL) at –78 °C. The mixture was allowed to warm to room temperature and stirred overnight. The resulting solution of LiNHAr was transferred into a solution of *ortho*-$C_6H_4F$(CH=N$C_6H_3Me_2$-2,6) (11.0 g, 48.5 mmol) in THF (40 mL) at 25 °C. After stirring for 2 h, the reaction was quenched with $H_2O$ (25 mL), extracted with *n*-hexane, and the organic phase was evaporated to dryness in vacuo to give the crude product as a yellow solid. Pure product (13.4 g, 72%) was obtained as yellowish-green crystals by recrystallization from ethanol at –20 °C. $C_{27}H_{32}N_2$ (384.56): calcd. C 84.33, H 8.39, N 7.28; found C 84.28, H 8.48, N 7.24. $^1$H NMR (300 MHz, $CDCl_3$, 293 K): $\delta$ = 1.15, 1.17 [d, $J$ = 6.6 Hz, 2×6 H, CH(C$H_3$)$_2$], 2.21 (s, 6 H, C$H_3$), 3.22 [sept, $J$ = 6.6 Hz, 2 H, C$H$(CH$_3$)$_2$], 6.30 (d, $J$ = 8.1 Hz, 1 H, Ph-*H*), 6.71 (t, $J$ = 6.6 Hz, 1 H, Ph-*H*), 6.98 (t, $J$ = 7.2 Hz, 1 H, Ph-*H*), 7.09–7.38 (m, 7 H, Ph-*H*), 8.39 (s, 1 H, C*H*=NAr), 10.53 (s, 1 H, N*H*) ppm. $^{13}$C{$^1$H} NMR (300 MHz, $CDCl_3$, 293 K): $\delta$ = 18.7 (*C*H$_3$), 23.2 [CH(*C*H$_3$)$_2$], 25.0 [CH(*C*H$_3$)$_2$], 28.8 [*C*H(CH$_3$)$_2$], 112.2, 115.3, 116.5, 124.0, 127.7, 127.9, 128.3, 132.5, 134.7, 134.8, 147.7, 150.2, 151.1 (Ph), 166.2 (*C*H=NAr) ppm.

***ortho*-$C_6H_4N(C_6H_3$*i*$Pr_2$-2,6)(CH=N$C_6H_3$*i*$Pr_2$-2,6)$AlCl_2$ (2a):** A solution of *n*BuLi in hexanes (0.28 mL, 0.45 mmol) was added dropwise to a stirred toluene solution of *ortho*-$C_6H_4$NH($C_6H_3$*i*$Pr_2$-2,6)(CH=N$C_6H_3$*i*$Pr_2$-2,6) (0.20 g, 0.45 mmol) at –78 °C. After the addition, the reaction mixture was warmed to room temperature and stirred overnight. The resulting mixture was added dropwise to a toluene suspension solution of $AlCl_3$ (0.06 g, 0.45 mmol) at –78 °C with stirring. The mixture was warmed to room temperature and stirred for 12 h, and the solution was evaporated to dryness in vacuo. The solid residue was extracted with *n*-hexane (30 mL). Insoluble materials were removed by filtration through Celite. The yellow filtrate was concentrated to about 20 mL and kept at –20 °C overnight to let the product crystallize. The product was obtained as yellow-green crystals (0.18 g, 75%). $C_{31}H_{39}Al_2Cl_2N$ (537.54): calcd. C 69.27, H 7.31, N 5.21; found C 69.20, H 7.40, N 5.25. $^1$H NMR (300 MHz, $C_6D_6$, 293 K): $\delta$ = 0.93, 1.00 [d, $J$ = 6.9 Hz, 2×6 H, CH(C$H_3$)$_2$], 1.38, 1.46 [d, $J$ = 6.9 Hz, 2×6 H, CH(C$H_3$)$_2$], 3.53 [sept, $J$ = 6.9 Hz, 2×2 H, C$H$(CH$_3$)$_2$], 6.25 (t, $J$ = 6.1 Hz, 1 H, Ph-*H*), 6.41 (d, $J$ = 8.8 Hz, 1 H, Ph-*H*), 6.70 (t, $J$ = 6.6 Hz, 2 H, Ph-*H*), 7.07–7.12 (m, 6 H, Ph-*H*), 7.92 (s, 1 H, *H*C=N) ppm. $^{13}$C{$^1$H} NMR (300 MHz, $C_6D_6$, 293 K): $\delta$ = 22.9, 24.7, 25.4, 25.7 [4×CH(*C*H$_3$)$_2$], 28.7, 29.0 [2×*C*H(CH$_3$)$_2$], 115.1, 117.1, 119.3, 124.7, 125.2, 129.0, 136.9, 137.2, 137.6, 141.1, 143.5, 146.7, 158.0 (Ph), 173.5 (*C*H=NAr) ppm.

***ortho*-$C_6H_4N(C_6H_3$*i*$Pr_2$-2,6)(CH=N$C_6H_3Me_2$-2,6)$AlCl_2$ (2b):** A solution of *n*BuLi in hexanes (0.33 mL, 0.52 mmol) was added dropwise to a stirred toluene solution of *ortho*-$C_6H_4$NH($C_6H_3$*i*$Pr_2$-2,6)(CH=N$C_6H_3Me_2$-2,6) (0.20 g, 0.52 mmol) at –78 °C. After the addition, the reaction mixture was warmed to room temperature and stirred overnight. The resulting mixture was added dropwise to a toluene suspension solution of $AlCl_3$ (0.07 g, 0.52 mmol) at –78 °C with stirring. The mixture was warmed to room temperature and stirred for 12 h, and the solution was evaporated to dryness in vacuo. The solid residue was extracted with *n*-hexane (30 mL). Insoluble materials were removed by filtration through Celite. The yellow filtrate was concentrated to about 20 mL and kept at –20 °C overnight to let the product crystallize. The product was obtained as yellow-green crystals (0.18 g, 70%). $C_{27}H_{31}AlCl_2N_2$ (481.44): calcd. C 67.36, H 6.49, N 5.82; found C 67.30, H 6.44, N 5.91. $^1$H NMR (300 MHz, $C_6D_6$, 293 K): $\delta$ = 0.99 [d, $J$ = 6.6 Hz, 6 H, CH(C$H_3$)$_2$], 1.42 [d, $J$ = 6.6 Hz, 6 H, CH(C$H_3$)$_2$], 2.67 (s, 6 H, C$H_3$), 3.48 [sept, $J$ = 6.6 Hz, 2 H, C$H$(CH$_3$)$_2$], 6.27 (t, $J$ = 6.0 Hz, 1 H, Ph-*H*), 6.38 (d, $J$ = 8.7 Hz, 1 H, Ph-*H*), 6.60 (d, $J$ = 8.1 Hz, 1 H, Ph-*H*), 6.72 (t, $J$ = 6.6 Hz,1 H, Ph-*H*), 6.81–7.19 (m, 6 H, Ph-*H*), 7.35 (s, 1 H, C*H*=NAr) ppm. $^{13}$C{$^1$H} NMR (300 MHz, $C_6D_6$, 293 K): $\delta$ = 18.8 (*C*H$_3$), 24.6 [CH(*C*H$_3$)$_2$], 25.5 [CH(*C*H$_3$)$_2$], 28.6 [*C*H(CH$_3$)$_2$], 115.3, 116.7, 119.3, 125.2, 129.3, 132.7, 137.2, 137.3, 143.9, 146.7 (Ph), 173.8 (*C*H=NAr) ppm.

**X-ray Structure Determinations of 2a, 2b, and 2d:** Single crystals of **2a**, **2b**, and **2d** suitable for X-ray structural analysis were obtained from *n*-hexane. Diffraction data were collected at 293 K with a Rigaku R-AXIS RAPID IP diffractometer equipped with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) for **2a**, **2b**, and **2d**. Details of the crystal data, data collections, and structure refinements are summarized in Table 3. The structures were solved by direct methods[20] and refined by full-matrix least-squares on $F^2$. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in idealized positions. All calculations were performed using the SHELXTL[21] crystallographic software packages.

CCDC-279167 (for **2a**), -279168 (for **2b**), and -279169 (for **2d**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 3. Crystal data and structural refinement details for **2a**, **2b**, and **2d**.

| | **2a** | **2b** | **2d** |
|---|---|---|---|
| Empirical formula | $C_{31}H_{39}AlCl_2N_2$ | $C_{27}H_{31}AlCl_2N_2$ | $C_{26}H_{29}AlCl_2N_2$ |
| Formula mass | 537.5 | 481.42 | 467.39 |

# Optical Properties of the Perovskite Solid Solution $LaTiO_2N$–$ATiO_3$ (A = Sr, Ba)

François Cheviré,[a] Franck Tessier,*[a] and Roger Marchand[a]

**Keywords:** Oxynitrides / Perovskites / Solid solution / Optical properties

Starting from the colored oxynitride $LaTiO_2N$, new perovskite-type solid solutions have been evidenced in the systems $La_{1-x}A_xTiO_{2+x}N_{1-x}$ (A = Sr, Ba) by ammonolysis at 950 °C of the corresponding oxide precursors prepared by the molten salt route. The color of the resulting powders varies progressively from the brown of $LaTiO_2N$ to the white of the oxide with a decrease in both the nitrogen and lanthanum contents. The optical absorption was characterized by diffuse reflectance. The nonlinear variation of the optical bandgap may result from the competition between the variation of the inductive effect between lanthanum and strontium, structural changes, and the difference in electronegativity between nitrogen and oxygen. For the compounds with a low nitrogen content the observed green shade is attributed to the presence of a nitrogen-rich secondary phase: $TiO_xN_y$ in which titanium presents a mixed-valence state. Taking advantage of a chimie douce process, the amorphous citrate route, the highest oxidation state of titanium was stabilized until $x = 0.9$ in the $La_{0.1}Sr_{0.9}Ti(O,N)_3$ phase giving the powder a bright yellow color ($Eg$ = 2.49 eV).

## Introduction

The progressive insertion of nitrogen, a less electronegative element compared with oxygen, within an oxide network involves an increase in the covalency of the bonding. A lower optical gap value, $Eg$, and consequently a modification of the absorption properties of the compound results from this substitution. Whereas many oxides are white, the corresponding oxynitrides are often colored. For example, considering the following cross-substitution: $M^{n+} + O^{2-} = M^{(n+1)+} + N^{3-}$, $ZrO_2$ (baddeleyite) and $BaTiO_3$ (perovskite) give rise to the isostructural colored oxynitrides TaON (yellow, $Eg$ = 2.5 eV) and $BaTaO_2N$ (red brown, $Eg$ = 2.0 eV), respectively. Over the last few years, nitride-type materials have largely been studied for their optical potential as nontoxic colored pigments (see below), as novel inorganic UV absorbers,[1] or as visible light-driven photocatalysts.[2–5]

The first colored oxynitride perovskites were obtained by substituting titanium in $BaTiO_3$ by a +5 oxidation-state element, such as tantalum or niobium. Numerous novel oxynitride phases were and are still obtained by applying this substitution principle at both the 12- and 6-fold-coordinated cationic sites. This is a key principle at the origin of a rich chemistry. $ATaO_2N$ (A = Ca, Sr, Ba) and $ANbO_2N$ (A = Sr, Ba) manifest dielectric properties.[6,7] $BaTaO_2N$ and $BaNbO_2N$ crystallize in a cubic unit cell and $SrTaO_2N$ in a tetragonal one.[8–10] The substitution of barium by a lanthanide element results in the oxynitrides $RTiO_2N$ (R = La, Nd),[11] where the +4 oxidation state of titanium is stabilized by the inductive effect of the rare earth element on the Ti-(O,N) bond.[12,13] This well-known effect is based on the capacity of an electropositive element (alkaline earth or rare earth) to share some electrons with the closest transition metal–nitrogen (oxygen) bond to enhance its covalent character, and thus to stabilize it. $NdTiO_2N$ is an orthorhombic $GdFeO_3$-type perovskite, while $LaTiO_2N$ crystallizes in a unit cell with triclinic symmetry.[14] The simultaneous substitution of both barium and titanium enables access to the white phase $LaZrO_2N$, which also presents a deformed $GdFeO_3$-type perovskite structure,[14] or to the oxynitride family $RTaON_2$ (R = La → Dy) and $LaNbON_2$.[11]

On the basis of one of the specific features of nitrogen, i.e. $\chi_N < \chi_O$, we were very interested in working with oxynitride solid-solution domains as a suitable means to tune the optical properties by the progressive modification of the composition. Jansen et al. have shown the possibility of adjusting the color of oxynitride pigments in the perovskite-type system $Ca_{1-x}La_xTaO_{2-x}N_{1+x}$.[15,16] The hue varies from yellow ($CaTaO_2N$) to brown ($LaTaON_2$) through orange and red intermediate colors as a result of the nitrogen content. Grins et al. obtained similar results in the system $AZr_{1-x}Ta_xO_{3-x}N_x$ with powders evolving from the white of $AZrO_3$ to the yellow, red, or brown of $ATaO_2N$, where A corresponds to Ca, Sr, and Ba, respectively.[17] Recently, Diot has evidenced solid-solution domains in the perovskite systems $A(A,Ta)(O,N,\square)_3$ (A = Ca, Sr, Ba) and

$Sr(Sr,Nb)(O,N,\square)_3$ giving rise to a range of colored pigments from pale yellow to orange brown.[18] Her research has also shown the interest in using defect fluorite rare earth tungstates $R_6WO_{12}\square_2$ and $R_{14}W_4O_{33}\square_3$ (R = rare earth) to isolate oxynitride powders $R_6W(O,N,\square)_{14}$ and $R_{14}W_4(O,N,\square)_{36}$, the color of which changes progressively from the white of the oxides to bright yellow with increasing nitrogen substitution. While with large rare earth elements the ammonolysis reaction of $RTaO_4$ tantalates provides either perovskite phases $RTaON_2$[11] or pyrochlore phases $R_2Ta_2O_5N_2$,[19] Maillard et al. identified defect fluorite solid solutions $RTa(O,N,\square)_4$ with small rare earths ($r_{R3+} \leq r_{Gd3+}$).[20] Colored oxynitride solid-solution domains have also been obtained in other structure types; for example, orange $Ta_{3-x}Zr_xN_{5-x}O_x$ ($0 \leq x \leq 0.60$) isostructural with $Ta_3N_5$ and pale yellow $Ta_{1-x}Zr_xN_{1-x}O_{1+x}$ ($0 \leq x \leq 0.28$) isostructural with TaON.[21]

This study was motivated, in part, by the preparation of light-colored oxynitride powders, for which an absorption edge located at exactly 400 nm will allow the absorption of all UV radiations. Our objective was to evidence a solid-solution domain $La_{1-x}A_xTiO_{2+x}N_{1-x}$ between the colored oxynitride $LaTiO_2N$ (brown, gap = 2.0 eV[22]) and the titanate $ATiO_3$ (A = Sr, Ba; gap > 3.1 eV) absorbing in the UV range.[1] $LaTiO_2N$ crystallizes in a distorted perovskite-type structure (Figure 1), as determined by neutron diffraction refinement, with a triclinic unit cell ($I\bar{1}$, $a$ = 5.6097 Å, $b$ = 7.8719 Å, $c$ = 5.5772 Å, $\alpha$ = 90.199°, $\beta$ = 90.154°, $\gamma$ = 89.988°).[14] The structure reveals two distinct $Ti(O,N)_6$ octahedra and no nitrogen/oxygen ordering in the anionic network.

## Results and Discussion

Firstly, we have considered the preparation of oxide precursors by molten salt synthesis. When $x$ = 0, $La_2Ti_2O_7$ (layered-perovskite structure) is clearly identified by X-ray diffraction. In the case of substituted compositions $La_{1-x}A_xTiO_y$, oxide precursors correspond generally to a mixture of ternary phases $La_aA_bTi_cO_d$ with variable composition. However, for $x$ values close to 1, single-phase powders present a perovskite structure close to that of the corresponding $ATiO_3$ titanate. Interestingly, the reaction of these precursors under ammonia leads systematically to the formation of single-phase perovskite-type oxynitrides, even in the case of a mixture of multinary oxides ($x < 1$). Figure 2 clearly illustrates this observation with the example of the composition $x$ = 0.5.

Table 1 details the experimental parameters of the ammonolysis experiments that were performed. All the compositions have a perovskite-structure type for which the position of the diffraction peaks continuously shifts from $LaTiO_2N$ to (Ba/Sr)$TiO_3$, as observed, for example, in the case of strontium (Figure 3). Although the structure of $LaTiO_2N$ was refined in a triclinic unit cell using neutron diffraction, the diffraction lines of the corresponding X-ray diffraction pattern can be indexed in a cubic perovskite unit cell [$a$ = 3.939(2) Å]. The asymmetry of some peaks, previously reported,[11] indicates that the real unit cell is not cubic. However, the distortion is quite weak relative to that observed for $NdTiO_2N$ and is not strong enough to determine the unit cell unambiguously by this technique. Here, it was not our purpose to refine all compositions of the solid solution by neutron diffraction. Using the cubic unit cell is an easy way to verify the linear evolution of the cell parameter and to prove the formation of the solid solution. Corresponding cubic unit-cell parameters have been plotted vs. $x$ in Figure 4. The trend follows a linear relation, in both cases, in agreement with Vegard's law. The opposite variation of the parameters, towards higher and lower values for Ba- and Sr-substitution, respectively, is explained if we compare the size of the cations in the 12-fold coordination (from Shannon:[23] La, 1.36 Å; Ba, 1.61 Å; Sr, 1.44 Å). There is a larger difference between La and Ba than there is for La and Sr, which should be balanced by the substitution of nitrogen by oxygen with increasing $x$ values. The resulting effect of such a competition within the lattices leads to the observed trend.

The brown color of the Ba-containing oxynitrides slightly lightens when increasing the alkaline earth metal amount from $x$ = 0.3 to 0.5. But the composition with $x$ = 0.75 presents a dark green shade that we attribute to a partial reduction of titanium. A decrease in the reaction temperature to 900 °C does not modify the green aspect of the color. In the case of Sr-containing oxynitrides, we observe a different color range strongly related to the substitution of a smaller cation (Table 1). A study performed by Eng et al.[24] in the perovskite system $ATiO_3$ (A = Sr, Ca) attributes the formation of a narrow conduction band leading to a higher value of the bandgap (+0.2 eV) mainly to the distortion of the linear M–O–M bonds from Sr (180°) to Ca (156°). This effect becomes more detectable with Ta than with Ti compounds because of the formation of larger conduction bands. This study just focuses on the effect of the tilting of the octahedra and does not take into account

either inductive effects or octahedral distortions. While changing the alkaline earth metal, similar color and also bandgap modifications have been observed in many phases, for example, in the perovskite-type oxynitrides, $CaTaO_2N$ (yellow), $SrTaO_2N$ (orange red), and $BaTaO_2N$ (red brown).[7,8,10,25–27] In this series, the atomic ratio O/N is constant and the modifications in the optical properties can only be explained by any changes in the structure and/or in the inductive effect relative to the choice of the alkaline earth metal. The characteristics of these phases are the following: $BaTaO_2N$ [cubic, bandgap = 1.8 eV; Ta–(O,N)–Ta = 180°], $SrTaO_2N$ [tetragonal, bandgap = 2.1 eV; Ta–(O,N)–Ta = 180° and 173.8°], $CaTaO_2N$ [orthorhombic, bandgap = 2.4 eV; Ta–(O,N)–Ta = 153.9°]. The linear evolution of the bandgap from $BaTaO_2N$ to $CaTaO_2N$ does not parallel a linear change in the Ta–(O/N)–Ta angles. As $BaTaO_2N$ and $SrTaO_2N$ display similar bond angles we expect similar bandgaps for both of them, which is not the

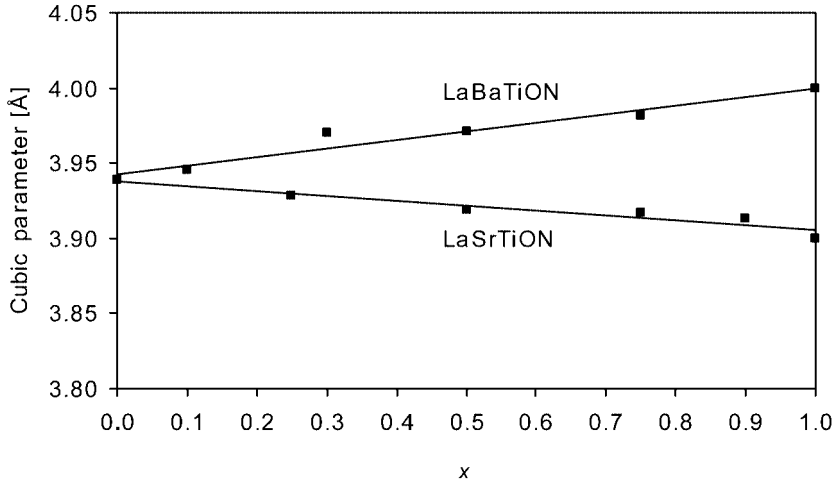

Figure 4. Variation of the unit-cell parameter in the $La_{1-x}Ba(Sr)_xTi(O,N)_3$ solid solutions.

case. Thus, the evolution of the bandgap value, and also the color, cannot only be the consequence of the deviation from linearity of the M–O–M bonds. The color change is due to several parameters including structure changes and the influence of the weaker inductive effect of strontium compared to that of barium, leading to a less covalent compound.

According to ref.,[24] the bandgap variation between $SrTiO_3$ (180°) and $CaTiO_3$ (156°) reaches 0.2 eV. However, the bond angles of $LaTiO_2N$ (160–167°) are closer to 180° than those of $CaTiO_3$, so we can expect a lower influence on the bandgap and a more diluted one for each of the intermediate compositions in the solid solution La–Sr–Ti–O–N. Between the two end members, $LaTiO_2N$ and $SrTiO_3$, the only visible effect in the bandgap position comes from the N/O substitution. The main consequence is an important red shift of the absorption edge. Thus, compared to the Ba-based system, for the same value of $x$, the absorption of the Sr-containing compositions is shifted towards lower wavelengths resulting in red and orange powders for $x$ = 0.25 and $x$ = 0.50, respectively, instead of the brown powders observed for the Ba-containing compositions. In the present system, the color of the powders varies progressively from the brown of $LaTiO_2N$ to the white of the oxide $SrTiO_3$ with the decrease in the nitrogen content. However, the $x$ = 0.9 composition is also characterized by a bright green shade close to apple-green. This greenish color of the powder may be a consequence of the combination of a yellow hue and a black component. It is effectively known that a black-unsaturated yellow appears green, then khaki, and finally black.

We ascribe the black shade to the presence of a mixed-valent-state for titanium ($Ti^{III}/Ti^{IV}$). The origin of this phenomenon may be clarified according to two hypotheses. First, the reduction of titanium may occur directly in the oxynitride product. It is then necessary to take account of a decrease in the formal cationic charge and consequently of a smaller nitrogen content in the structure, as illustrated by the following formulations with $x$ = 0.9:

$(La_{1-x}Sr_x)Ti^{IV}O_{2+x}N_{1-x} \rightarrow (La_{1-x}Sr_x)(Ti^{IV}_{1-y}Ti^{III}_y)O_{2+(x+y)}N_{1-(x+y)}$

$(La_{0.1}Sr_{0.9})Ti^{IV}O_{2.9}N_{0.1} \rightarrow (La_{0.1}Sr_{0.9})(Ti^{IV}_{1-y}Ti^{III}_y)O_{2.9+y}N_{0.1-y}$

Secondly, some reduced titanium may be present in a secondary black phase, $TiO_xN_y$. The powder then contains a mixture of a nitrogen-rich titanium oxynitride phase and a yellow $La_{0.1}Sr_{0.9}Ti(O,N)_3$ oxynitride. However, no secondary phase was detected by XRD analyses (Figure 3). From experience, it is well known that a very small amount of impurity, even indiscernible by XRD, may be sufficient to alter completely the color of the product and to overestimate nitrogen titration results. In order to avoid any reduction of titanium, ammonolysis experiments were carried out at lower temperatures (until 850 °C), but this did not allow for the stabilization of the higher oxidation state of titanium since a green shade was still observed. Grins et al. have reported similar color changes within the oxynitride solid solutions $AZr_xTa_{1-x}O_{2+x}N_{1-x}$ (A = Ca–Ba) without describing the hue progression.[16]

Nitrogen determination of the samples leads to the formulations listed in Table 2. Experimental contents are slightly higher than the calculated values (≈2%). In the case of the most greenish composition (A = Ba and $x$ = 0.75), the observed deviation (≈4%) is more important and seems to validate the hypothesis of a nitrogen-rich secondary phase. In the strontium-based oxynitride series, the black component in the apple-green shade is not very marked and suggests an extremely low amount of titanium oxynitride $TiO_xN_y$, which does not considerably affect the measured nitrogen amount.

The optical characterization of $La_{1-x}Sr_xTi(O,N)_3$ oxynitrides by diffuse reflectance highlights several significant points (Figure 5). The plot of the corresponding spectra between the two end members of the solid solution confirms the shift of the absorption edge towards higher wavelengths with increasing nitrogen content. However, this shift is not progressive. Between the oxide $SrTiO_3$ and the oxynitride $La_{0.1}Sr_{0.9}Ti(O,N)_3$ the absorption edge moves from 375 to 500 nm – a shift of 125 nm – whereas it stays between 525 and 590 nm for the lanthanum-rich compositions. In an at-

tempt to explain this nonlinearity, and despite the difficulty in calculating the band structure due to nitrogen/oxygen disorder, it is realistic to involve the following effects. Basically, the element located in the 12-fold coordination site does not directly influence the bandgap between the 2p(O) and 3d(Ti) bands, but rather it engenders an inductive effect on the Ti-(O,N) bond. Besides the effect of the large cation, nitrogen/oxygen substitutions modify the position of the valence band in a precise manner, so that the position of the absorption edge moves towards higher wavelengths. As nitrogen is less electronegative than oxygen, the energy level difference between the oxygen and nitrogen 2p orbitals [$E_{2p}$(O) = –14.8 eV, $E_{2p}$(N) = –13.4 eV (top of the valence band[28])] can simply explain the decrease in the bandgap between the valence and conduction bands. Also, as discussed above, by substituting La for Sr the decrease in the bond angles from 180° causes a small increase in the bandgap value that can act as a minor counter effect to the red shift (coupled with inductive effect variation) to explain parts of the nonlinearity of the bandgap values along the solid solution. By comparison with the oxide $SrTiO_3$, the absorption edge profile appears less steep and the spectral selectivity lower (Table 3), which is mainly a consequence of a lower crystallization state. We have already observed that the crystallization state of the powder influences the steepness of the diffuse reflectance spectrum in oxide systems. Thus, the absorption edge becomes steeper with an increasing crystallization state. This is probably linked to the better homogeneity of the environments of titanium. The average octahedron is $TiO_{4+2x}N_{2-2x}$, but because of the O/N disorder we consent that a large variety of O/N environments, with slightly different absorption properties, should exist around the titanium atoms, leading to the spreading of the absorption edge. Moreover, the level of the reflection plateau dramatically decreases with increasing nitrogen content. We have already observed, and not yet explained, such a phenomenon in several systems.[29,30] In the case of the composition $x$ = 0.9 the absorption edge – located at 500 nm – should correspond to a yellow color although the powder appears "apple green". This result provides further confirmation of the presence of a black component. Thus, the alteration of the expected color is effectively due to the existence of partially reduced titanium, which is no longer totally stabilized under the reducing ammonia synthesis conditions used.

A more reactive oxide precursor was synthesized by the amorphous citrate route in order to stabilize the +4 oxidation state of titanium in the $La_{0.1}Sr_{0.9}Ti(O,N)_3$ oxynitride phase. This chimie douce process allows very fine and chemically homogeneous powders to be obtained rapidly. These powders are potentially able to manifest an enhanced reactivity with ammonia at lower temperatures.[31,32] Experimental data are listed in Table 4 for both the $x$ = 0.9 and 1.0 compositions. A bright yellow powder is obtained after ammonolysis of the $x$ = 0.9 precursor at 950 °C. Reduction phenomena did not occur with longer reaction times. The corresponding diffuse reflectance spectra, shown in Figure 6, reveal an absorption domain at the same wavelengths as that for the absorption of the greenish product obtained from the molten salt precursor. Moreover, a slight gain is noticed in the maximum value of the diffuse reflectance, in possible relation with the disappearance of the black component discussed previously. In addition, the experimental nitrogen content of this phase reaches 0.81 wt.-%, in excellent agreement with the calculated content (0.74 wt.-%), and corresponds to the following formulation $La_{0.10}Sr_{0.90}TiO_{2.89}N_{0.11}$. All these results confirm the hypothesis of the presence of a small amount of titanium oxynitride as an impurity in the former results, since the use of a more chemically homogeneous precursor solves the problem. Nevertheless, the green shade appears again for the composition $x$ = 0.05, and the powder becomes yellowish green. In this case, a very small amount of dopant is present and hence it is difficult to come to a conclusion on the origin of the reduced titanium giving the green shade and also on the nature of the "impurity" phase. Many possibilities are of interest, such as the presence of a $TiO_xN_y$ or $SrTi(O,N,\square)_3$ secondary phase. When the reaction is carried out under ammonia at 750 °C a pale green powder, without any marked yellow hue, is produced. It seems that under usual ammonolysis conditions the reduction of titanium occurs before the maximum nitrogen content is obtained.

To conclude, we have synthesized new oxynitride solid solutions for the systems $La_{1-x}A_xTiO_{2+x}N_{1-x}$ (A = Sr, Ba), where it is possible to tune progressively the color of the powders from brown ($LaTiO_2N$), to red, orange, yellow, and finally white ($SrTiO_3$) with the variation of both nitrogen and lanthanum contents. The green shade observed in the presence of low nitrogen contents is attributed to mixed-

valent titanium present in a black nitrogen-rich phase, $TiO_xN_y$. An attenuation of this reduction phenomenon is detected when using more chemically homogeneous and reactive precursors prepared by the amorphous citrate route. Such processes create suitable solutions to optimize the properties of (oxy)nitride materials for optical applications (colored pigments, visible-light photocatalysts). Avoiding such parasitic colors is a major synthetic problem in the preparation of light-colored materials for promising appli-

cations such as novel UV absorbers. Nevertheless, the interest in oxynitride solid-solution domains relies on the ability to tune the absorption edge position towards 400 nm, which is the limit between the UV and the visible ranges.

## Experimental Section

**Synthesis of Oxide Precursors:** Lanthanum-modified titanates were obtained using both a modified ceramic route and by taking advantage of the amorphous citrate route, a chimie douce method, which gives the oxide precursors an enhanced homogeneity and reactivity towards ammonia.

**Solid-State Route:** $La_{1-x}A_xTiO_{3.5-x/2}$ precursors ($x$ = 0, 0.25, 0.5, 0.75, 0.9) were prepared by heating a stoichiometric mixture of $La_2O_3$ (99.99%, Alfa Aesar), $BaCO_3$ (99%, Acros), $SrCO_3$ (99%, Alfa Aesar), and $TiO_2$ (Degussa, P25) in a molten salt medium. The melt content, corresponding to the eutectic mixture 50 mol-% NaCl and 50 mol-% KCl, was determined to form 50 wt.-% of the total reactants weight.[33] The corresponding mixture was heated at 1000 °C for 15 h in a muffle furnace. The resulting products were washed using distilled water and absolute ethyl alcohol, and then dried at 150 °C.

**Amorphous Citrate Route:** Among numerous chimie douce type processes that have been developed to prepare oxide powders in order to improve their quality (purity, chemical homogeneity, etc.) and their reactivity the process involving citric acid as a complexing agent has been preferentially used. It is not, strictly speaking, a classic sol-gel process in the usual sense in that the gel is not formed by a metal–oxygen–metal network, but rather from calcination of metal–organic complexes, thus producing ultra fine reactive powders with an excellent chemical homogeneity.[34] In order to characterize any influence of the synthesis route, the $x$ = 0.9 precursor for A = Sr was also prepared using this route. Lanthanum oxide ($La_2O_3$, 99.99%, Alfa Aesar), strontium carbonate ($SrCO_3$, 99%, Alfa Aesar), and titanium tetrabutoxide ($C_{16}H_{36}O_4Ti$, 99%, Acros) were used as starting materials and dissolved in a diluted nitric acid solution. Citric acid ($C_6H_8O_7$, Merck, > 99%) dissolved in a minimum amount of water was added to the solution in the proportion of one mole per cation valence, the addition being followed by a 30 min stirring step at 120 °C. Since the complexation of cations by citric acid is improved at pH ≥ 7, the acidic solution was neutralized by an ammonia solution (25%, Merck),[35] then stirred at 150 °C for 15 min to promote chelate formation. The liquid was progressively heated to 250 °C, leading after 15 h to an expanded black solid residue. This solid was finally ground and calcined at 600 °C in an alumina crucible until total elimination of carbon had occurred.

**Thermal Ammonolysis:** Nitridation reactions were carried out in alumina boats placed inside an electric furnace through which ammonia gas flowed at 40–50 $L\,h^{-1}$. The temperature was raised to 950–1000 °C with a heating rate of 10 °C $min^{-1}$. After a reaction time of 15 h the furnace was switched off and the nitrided powders were cooled to room temperature under a pure nitrogen atmosphere.

**X-ray Diffraction:** XRD powder patterns were recorded using a Philips PW3710 diffractometer operating with Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å). X′PERT software – Data Collector, Graphics, and Identify – were used for recording, analysis, and phase matching of the patterns, respectively. The lattice parameters were refined using Dicvol04.[36]

**Elemental Analysis:** Nitrogen and oxygen contents were determined with a LECO TC-436 analyzer using the inert gas fusion method. Nitrogen was detected as $N_2$ by thermal conductivity and oxygen as $CO_2$ by infrared detection. The apparatus was calibrated using $N_2$ and $CO_2$ gas (purity ≥ 99.95%) as well as ε-TaN as a nitrogen standard.[37]

**UV/Vis Spectrophotometry:** Diffuse reflectance spectra were collected using a Varian Cary 100 Scan spectrometer equipped with the Varian WinUV software and the integrating sphere Labsphere (DRC-CA-30I). Prior to measurements, the absolute reflectance of the samples was calibrated with a certified "spectralon" standard (Labsphere Cie). Experimental data were collected within the 250–800 nm range with a 1 nm step and 0.5 s integration time. The position of the absorption edge was determined graphically at the inflection point of the curve and the value of the optical gap using the theory of Kubelka–Munk.[38]

# Synthesis, Characterization, and Properties of Some Copper(II) Complexes of 2-Pyridineformamide Thiosemicarbazone (HAm4DH)

**María del Carmen Aguirre,[a] Joaquín Borrás,[b] Alfonso Castiñeiras,*[a] José M. García-Monteagudo[c] Isabel García-Santos,[a] Juan Niclós,[d] and Douglas X. West[e]**

**Keywords:** Thiosemicarbazones / Copper complexes / One-dimensional chains / Cyclic voltammetry / DNA cleavage

Reactions between different copper(II) salts and 2-pyridineformamide thiosemicarbazone (HAm4DH) in neutral ethanolic media led to the formation of complexes with the formulae $[Cu(HAm4DH)X_2]$ (X = Cl or Br) (**1**, **2**) and $[Cu(HAm4DH)_2]X_2$ (X = $NO_3$ or $ClO_4$) (**3**, **4**). The same reactions carried out in the presence of triethylamine gave rise to new complexes with the general formulae [Cu(Am4DH)X] (X = Cl, Br, AcO, or $NO_3$) (**5**–**8**), $[Cu(H_2O)(Am4DH)](ClO_4)$ (**9**), and $[Cu(Am4DH)_2]$ (**10**), many of which were isolated with different molecules of crystallization and contain a deprotonated thiosemicarbazone (Am4DH). These complexes were characterized by elemental analysis, and different spectroscopic and magnetic techniques. The thermal and redox behavior of the complexes was also evaluated. Complexes **1**, **2**, **5**, and **6** show better nuclease activity than $[Cu(phen)_2]^{2+}$. In addition, crystals were isolated in the cases of $[Cu(HAm4DH)Cl_2]_2$ (**5a**), $^1_\infty$[Cu(Am4DH)Cl] (**5b**), $^1_\infty$[Cu(Am4DH)Br] (**6a**), and $[Cu(HAm4DH)(H_2O)(ClO_4)_2]\cdot MeOH\cdot H_2O$ (**9a**) and these structures were analyzed by X-ray diffraction. Compound **5a** has a dimeric structure with chlorine bridges and shows weak antiferromagnetism ($J$ = –12.2 $cm^{-1}$). Complexes **5b** and **6a** are one-dimensional polymers formed through halogen bridges and the deprotonated thiosemicarbazone in the thiolate form. In compound **9a** the copper(II) is in a distorted octahedral environment with two $ClO_4$ units coordinated to the metal center.

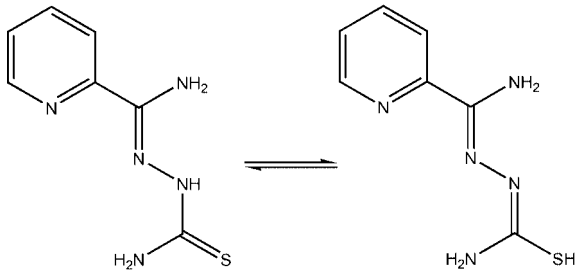
## Introduction

In general, thiosemicarbazones are obtained by condensation of the corresponding thiosemicarbazide with aldehydes or ketones.[1] However, an alternative method of synthesis involves the use of nitriles as starting materials.[2] In this case, the resulting thiosemicarbazones contain an additional amino group (Scheme 1), which gives improved water solubility. This in turn can improve the biological activity of these compounds and their metal complexes. Furthermore, this amino group is undoubtedly able to participate in hydrogen bond formation, which can favor the formation of supramolecular species.



**Ia** **Ib**

Scheme 1.

Thiosemicarbazones in the solid state are in an approximately planar arrangement with a *Z* configuration around the C=N bond and the terminal thioamide sulfur atom in a *trans* disposition with respect to the azomethine nitrogen (**Ia** in Scheme 1). The fact that this system undergoes *thione–thiol* tautomerism makes the thiosemicarbazones versatile ligands for a wide range of metal ions both in the neutral and anionic forms (Scheme 1).

Thiosemicarbazones generally coordinate to metal centers through the sulfur and azomethine nitrogen atoms to give a five-membered chelate ring with the metal. The resulting complexes are usually mononuclear,[3] dinuclear,[4,5]

or polynuclear in conjunction with an additional ligand such as a halogen.

The ability of these ligands to be deprotonated in a suitable basic medium frequently leads to the formation not only of neutral mononuclear species but also polynuclear entities in which the thiosemicarbazone acts as a bridging ligand − generally through the thiolate sulfur atom.[6–8]

Although complexes of a number of metals with 2-pyridineformamide thiosemicarbazone (HAm4DH)[9–12] or its $^4N$-substituted derivatives[13–21] have been studied, the coordination of these ligands with copper(II) has scarcely been investigated hitherto.[16,22,23] To explore their versatility further, in the work described here we prepared a number of copper(II) complexes of HAm4DH and determined their thermal, magnetic, and redox properties, the X-ray crystal structures of the complexes $[Cu(HAm4DH)Cl_2]_2$ (**5a**), $^1_\infty$[Cu(Am4DH)Cl] (**5b**), $^1_\infty$[Cu(Am4DH)Br] (**6a**), and $[Cu(HAm4DH)(H_2O)(ClO_4)_2]\cdot MeOH\cdot H_2O$ (**9a**), and the in vitro nuclease activities of a selection of these compounds.

## Results and Discussion

The reactions between different copper(II) salts and HAm4DH, in neutral or slightly basic ethanolic media, gave a series of complexes with the general formulae $[Cu(HAm4DH)X_2]$ (X = Cl or Br) (**1**, **2**), $[Cu(HAm4DH)_2]X_2$ (X = $NO_3$ or $ClO_4$) (**3**, **4**), [Cu(Am4DH)X] (X = Cl, Br, AcO, or $NO_3$) (**5**–**8**), $[Cu(H_2O)(Am4DH)](ClO_4)$ (**9**), and $[Cu(Am4DH)_2]$ (**10**). These compounds generally have melting points above 200 °C and are soluble in DMF and DMSO, partially soluble in methanol, but insoluble in other commonly used organic solvents. The mass spectra of the complexes (FAB) in some cases show the molecular ion peak, although the most significant peaks correspond to the fragments $[Cu(HAm4DH)_2]^+$, $[Cu(HAm4DH)X]^+$, and $[Cu(HAm4DH)]^+$, where X is the corresponding anion. These fragmentation patterns involve the addition or loss of a hydrogen atom from the fragments.

The molar conductivities of freshly prepared solutions of the complexes in DMF are in the range $\Lambda_m$ = 23–63 $S\cdot cm^2\cdot mol^{-1}$, which indicates that the compounds are neutral. However, $[Cu(Am4DH)(H_2O)](ClO_4)$ is a 1:1 electrolyte ($\Lambda_m$ = 96 $S\cdot cm^2\cdot mol^{-1}$). The molar conductivity values for $[Cu(HAm4DH)_2](NO_3)_2\cdot EtOH$ and $[Cu(HAm4DH)_2](ClO_4)_2$ are 152 and 168 $S\cdot cm^2\cdot mol^{-1}$, respectively, and these values correspond to 1:2 electrolytes.[24]

Single crystals of the complexes $[Cu(HAm4DH)Cl_2]_2$ (**5a**), $^1_\infty$[Cu(Am4DH)Cl] (**5b**), $^1_\infty$[Cu(Am4DH)Br] (**6a**), and $[Cu(HAm4DH)(H_2O)(ClO_4)_2]\cdot MeOH\cdot H_2O$ (**9a**) suitable for X-ray diffraction were obtained by the slow evaporation of $[Cu(Am4DH)Cl]\cdot 0.5\,EtOH$ (**5**), $[Cu(Am4DH)Br]\cdot 0.5\,EtOH$ (**6**), or $[Cu(Am4DH)(H_2O)](ClO_4)$ (**9**) solutions in 1:1 mixtures of MeOH/$CCl_4$, MeOH/$CH_3CN$, or MeOH/$CCl_4$, respectively, in air at room temperature.

### Crystal Structure of $[Cu(HAm4DH)Cl_2]_2$ (5a)

It can be seen from Figure 1 that **5a** is a centrosymmetric binuclear species. Each copper(II) center is bonded to a neutral HAm4DH molecule through the thione sulfur, azomethine nitrogen, and pyridinic nitrogen atoms. Three chlorine atoms are also bound to the metal − one terminal chlorine and the other two as bridges between the metal centers. This arrangement gives rise to an octahedral environment in such a way that the dimer is formed by two octahedra that share an edge consisting of the dimeric skeleton Cu(μ-Cl)$_2$Cu. The most significant bond lengths and angles are shown in Table 1.

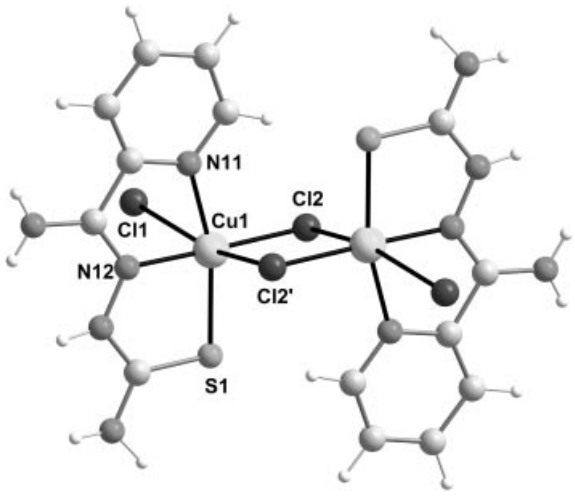

Figure 1. Perspective view of **5a** (symmetry code i: $-x + 2$, $-y$, $-z + 1$).

The formation of dimers is not unusual in copper(II) complexes of thiosemicarbazones.[4,25] However, the majority of such compounds have the formula $[Cu(L)Cl]_2$, where the bridging atom is either the sulfur or the chlorine atom, which gives rise to a coordination number of five around the metal center. In the case where L is 2-pyridinecarboxaldehyde thiosemicarbazone it was possible to obtain both structures,[4] each with a pyramidal geometry; that is, the copper(II) centers are joined either by two thiolate bridges from the thiosemicarbazone or by two chloro bridges. In contrast, compound **5a** has a coordination mode and geometry that is completely different, where the Cu(μ-Cl)$_2$-Cu skeleton has the two copper centers joined through two chloro bridges that have markedly different bond lengths: 2.219(1) Å (Cu1–Cl2$^i$, i: $-x + 2$, $-y$, $-z + 1$) and 3.139(1) Å (Cu1–Cl2). This gives rise to a rhomboidal geometry, with Cu–Cu and Cl–Cl distances of 3.837(1) and 3.850(2) Å, respectively, and Cl–Cu–Cl and Cu–Cl–Cu angles of 90.20(3) and 89.90(3)°, respectively. The existence of one weak and one strong Cu–Cl interaction is a characteristic feature in dimeric species with halogen bridges.[26,27] However, the second Cu–Cl distance in **5a** is at the higher limit of the sum of the van der Waals radii (3.15 Å), but is equal to or less than the order of magnitude for these bonds found in other copper(II) dimers with chloro bridges.[28] The three coordination positions around the copper center are occupied by the sulfur and two nitrogens of HAm4DH, with values of 2.027(2) and 1.941(2) Å for the Cu–Npyri-

[a] Symmetry transformation used to generate equivalent atoms i: $-x + 2, -y, -z + 1$; X3 = Cl2$^{i}$. [b] i: $-x - 1/2, y - 1/2, z$; X3 = Cl1$^{i}$. [c] i: $-x + 1/2, y - 1/2, z$; X3 = Br1$^{i}$. [d] X1, X2, and X3 are O11, O21, and O1 for molecule 1, and O31, O41, and O2 for molecule 2, respectively.

dine and Cu–Nazomethine, respectively, and 2.296(1) Å for the Cu–S distance. On the other hand, the Cu–Cl1 terminal distance is 3.132(1) Å, which is longer than those found in similar compounds[29,30] and is also at the higher limit of the sum of van der Waals radii (as is Cu–Cl2), a situation that confers significant ionic character to this chlorine atom.

On the basis of the information discussed above and on the assumption that each Cu is hexacoordinate, the *trans* angles N11–Cu1–S1, N12–Cu1–Cl2$^{i}$, and Cl1–Cu1–Cl2 [164.1(1), 178.6(1), and 165.2(1)°, respectively] and the distances discussed above suggest that each metal center has an octahedral coordination geometry with a growing tetragonal distortion of the 4+2 type, and a $CuCl_3N_2S$ chromophore in which the equatorial plane defined by the atoms S1, N12, N11, and Cl2$^{i}$ contains the copper(II) centers (Table 2). This plane forms a dihedral angle of 1.8(1)° with the average plane corresponding to the thiosemicarbazone chain, which in turn forms an angle of 6.0° with the pyridine ring. This situation confirms that the HAm4DH ligand is almost planar in the coordination arrangement.

The bonding parameters for the thiosemicarbazone in the complex are close to those in the free ligand − apart from the N13–N12–C16 angle, which increases from 116.7(2)° to 120.1(2)° as a consequence of the involvement of N12 in coordination with the copper center.

In the crystal packing the dimeric units interact with one another through Cl1, which participates in hydrogen bonding to form chains along the [100] direction, as shown in Figure 2. Each dimeric unit is bonded to its neighbor

Table 2. Best least-squares planes for **5a**, **5b**, **6a**, and **9a**.[a]

ter is coordinated to a deprotonated thiosemicarbazone through the thiolate sulfur atom and the azomethine and pyridine nitrogen atoms, a situation that is common with this type of ligand. The structure of the 1D coordination polymers is formed by the asymmetric halogen bridges between the metal centers, which gives rise to pentacoordination around each copper(II) center (Figure 3). In both complexes the Cu–S, Cu–Nazomethine, and Cu–Npyridine distances (Table 1) are very similar and the most marked difference (0.008 Å) is in the Cu–S bond of **5b**. This in turn is associated with the largest deviation (0.039 Å), which is not particularly significant in comparison with that in **5a**.

The Cu–Cl distances in **5b** are 2.247(2) and 2.945(2) Å and, although these are significantly different, they are more similar to one another than those found in the dimer **5a** (differences of 0.920 Å vs 0.694 Å). The shortest distance is slightly longer than those found in other copper(II) complexes with thiosemicarbazone ligands and chloro bridges[25] and the longest distance is in the range found in other systems with chloro bridges between copper centers (2.70–3.19 Å).[31,32]

In **6a** both Cu–Br bond lengths are also significantly different. However, in this case the difference is 0.582 Å, which represents the smallest difference of the three complexes under discussion. However, the bond lengths are shorter and longer, respectively, than those found in $[Cu(dmamhp)Br_2]_2$ (dmamhp = 2-dimethylaminomethyl-3-hydroxypyridine), a dimer that contains asymmetric bromo bridges with Cu–Br distances of 2.439(2) and 2.805(2) Å.[33]

The $\tau$ values found in the two complexes[34] are 0.039 for **5b** and 0.031 for **6a**, and these are consistent with the copper(II) atoms having a tetragonal pyramidal coordination environment ($\tau = 0$) with a distortion towards trigonal bipyramidal ($\tau = 1$). In this arrangement the basal plane is defined by N11, N12, S1, and X1, all of which are coplanar [maximum deviations of 0.088(3) and 0.104(2) Å in N12 for **5b** and **6a**, respectively], and the copper center is located 0.170(3) Å above this plane in **5b** and 0.173(1) Å above it in **6a** (Table 2). This basal plane forms angles of 10.1(2) and 9.4(1)° with the plane of the thiosemicarbazone chain, which in turn forms angles of 4.5(3) and 3.3(2)°, respectively, with the best least-squares plane of the pyridine ring.

The axial position is occupied by the neighboring halogen atom that forms the bridge (symmetry code: $-x - 1/2$, $y - 1/2$, $z$) and this gives rise to angles in the range 86.9(2)–98.7(1) Å in **5b** and 87.5(1)–99.0(1) Å in **6a** (Table 1). The chains develop along the [010] direction and in these chains the Cu···Cu separations are 4.158(1) and 4.249(1) Å for **5b** and **6a**, respectively. This level of separation is sufficiently large that magnetic interactions can take place between the metal centers.

In contrast to the situation in **5a**, a number of significant changes are apparent in **5b** and **6a** in terms of the bonding parameters of HAm4DH when compared to the data for the free ligand. These changes are due to deprotonation of the ligand and mainly affect the bond lengths and angles around C17. This situation gives rise to elongation of the S1–C17 and N14–C17 bonds from average values of 1.698(2) and 1.316(3) Å to 1.741(6) and 1.363(6) Å, respectively. On the other hand, the N13–C17 bond decreases in length from 1.340(2) to 1.305(8) Å. Some bond angles also experience significant changes on complexation and this is due to the presence of the thiolate form of the ligand; S1–C17–N14 and C17–N13–N12 are modified from average values of 123.0(2) and 118.3(2)° in HAm4DH to 116.8(5) and 111.3(5)°, respectively, while S1–C17–N13 changes form 120.3(2) to 125.4(5)°. These changes are clearly a result of changes in the electronic delocalization in the thiosemicarbazone chain on conversion to the thiol form of the ligand and subsequent deprotonation in the basic medium.

A number of hydrogen bonds are formed in the crystal packing arrangement. The most significant of these occur between the amino donor groups and the imine nitrogen atoms of neighboring chains, which act as acceptors (Table 3). These interactions give rise to a three-dimensional supramolecular network.

### Crystal Structure of $[Cu(HAm4DH)(H_2O)(ClO_4)_2]\cdot MeOH\cdot H_2O$ (9a)

The asymmetric unit consists of two complex molecules that are crystallographically independent (I and II), and are separated by a Cu···Cu distance of 9.687(2) Å. In each molecule the copper(II) center is hexacoordinate by a neutral thiosemicarbazone molecule through the sulfur atoms and the usual nitrogen atoms, an oxygen atom from a water molecule, which occupies the equatorial positions, and two oxygen atoms from the perchlorate ligands, which occupy the axial positions. Figure 4 is a diagram of molecule I.

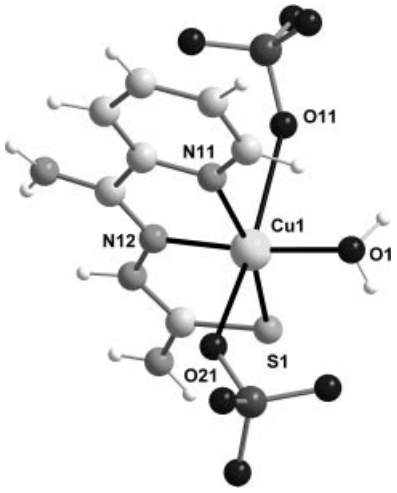

Figure 4. Representation of molecule I of **9a**.

In the equatorial plane the metal–ligand distances in the two molecules range from 1.919(3) Å for the Cu–Nazomethine distance in the second molecule to 2.278(1) Å for the Cu–S distance in the first molecule (Table 1). The axial Cu–O distances are different and this gives rise to a 4+1+1 distortion in the coordination polyhedron. One of the Cu–O distances is around 2.5 Å and the other around 2.8 Å. These distances are considerably longer than the equatorial Cu–Owater distance, which has an average value of 1.965(2) Å, but are of the same order of magnitude as those found in other copper(II) complexes with coordinated perchlorate groups.[5,26,35–37]

Another indication of the magnitude of the distortion is given by the *trans* angles in the equatorial plane, which have average values of 166.1(1)° for N11–Cu1–S1 and 173.8(1) for N12–Cu1–O1. However, the clearest evidence of distortion is provided by the *trans* angle between the axial positions, with values of 168.6(1)° in the first molecule and 162.2(1)° in the second. These bond angle values are comparable to those found in other copper(II) complexes with coordinated perchlorate ligands but are larger than the value of 155.9(2)° found in $[Cu(HL)(H_2O)(ClO_4)_2]$, where HL is 2-formylpyridine thiosemicarbazone.[5] In both molecules the equatorial plane containing each Cu atom is approximately coplanar with the corresponding thiosemicarbazone plane [dihedral angles are 2.4(1) and 2.6(1)°] (Table 2), which in turn form angles of 4.5(2) and 5.7(2)° with the best least-squares plane of the pyridine ring.

Once again in this complex − as in the case of **5a** − only the N13–N12–C16 angle changes and this angle has values of 120.7(3) and 120.2(3)° in the two molecules in the complex.

Numerous hydrogen-bonding interactions occur in the crystal packing arrangement (Table 3) and it is not only the amine and imine groups of HAm4DH that take part but also the water and ethanol molecules and the noncoordinated oxygen atoms of the perchlorate ligands.

### Spectral Studies

The IR spectra of the $Cu^{II}$ complexes contain bands in the range 3473–3158 $cm^{-1}$ and these correspond to $\nu$(NH) and, in cases where the complex contains solvent molecules, $\nu$(OH). Bands are also observed between 1610 and 1568 $cm^{-1}$ and these are due to $\nu$(CN+CC).

The C=S vibration modes are seen for the ligand HAm4DH at 853 $cm^{-1}$ and this band is observed at lower frequencies in the complexes, which shows that coordination of the thio donor to the copper center has taken place. In the free ligand the band corresponding to $\nu$(NN) is observed at 999 $cm^{-1}$, while in all of the complexes this band appears at higher frequencies because of coordination of the metal center through the sulfur and azomethine nitrogen atom.

The diffuse reflectance spectra of all of the complexes show three broad bands in the visible region. The intense band, which has the high energy, appears at 26350–26724 $cm^{-1}$ and has a shoulder on the highest energy side. This band is due to ligand transitions: $n \rightarrow \pi^*$ (main band) and $\pi \rightarrow \pi^*$ (shoulder). A second band is observed between 22624 and 24232 $cm^{-1}$ and this has various components that must correspond to metal–ligand charge-transfer processes (MLCT), probably $\sigma(S) \rightarrow d_{x^2-y^2}$ ($Cu^{II}$) or $\pi \rightarrow d_{x^2-y^2}$ ($Cu^{II}$). In contrast to other copper(II) complexes, in this case there does not seem to be a clear correlation between the position of the maximum of this band and the coordination geometry or the nature of the ligand coordinated to the metal. The band that is observed in the lower energy region of the spectrum has two components at 15244–16353 and 14245–15785 $cm^{-1}$ and these correspond to a d–d transition.[38]

The EPR spectra of polycrystalline samples, measured at room temperature, are axial and isotropic. The spectra of complexes **1** and **8** are practically identical and show an axial nature (Figure 5, a) and very similar EPR parameters for the two complexes, a situation that suggests the same coordination polyhedron around copper(II). Given that $g_{\|} > g_{\perp}$, the unpaired electron is located in a $d_{x^2-y^2}$ orbital and this is characteristic of a distorted tetragonal structure. Complex **7** gives rise to an axial spectrum that is slightly rhombic, as can be seen in Figure 5 (b). The EPR parameters of this complex are practically identical to those of the two complexes discussed above. The complexes are also quasi-isotropic.

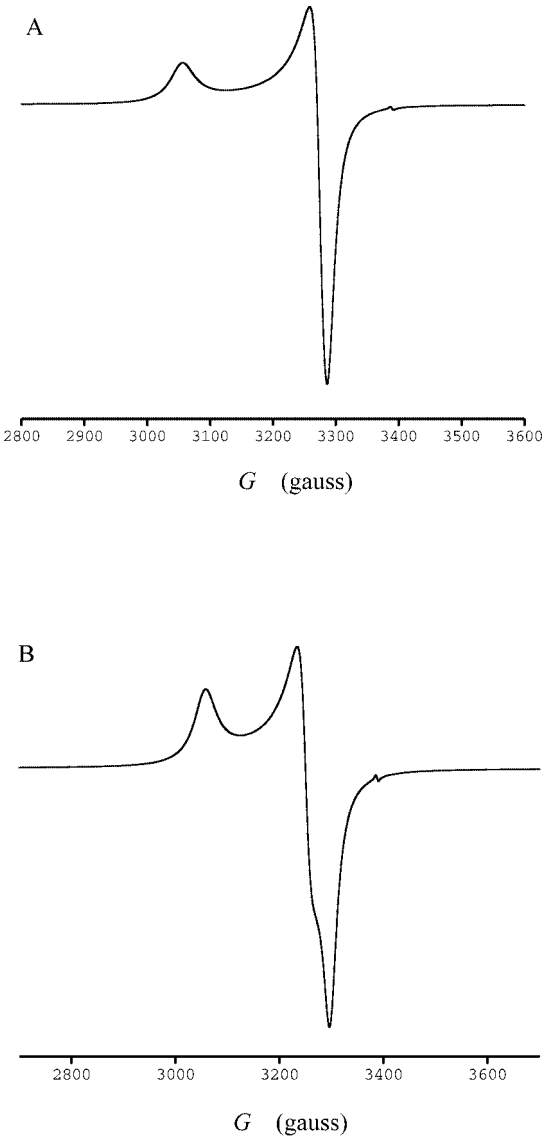

Figure 5. ESR spectra of **1** (A) and **7** (B) at room temperature.

## Magnetic Behavior

The magnetic moments of the complexes were measured at room temperature (298 K) and the majority are in the range 1.75–2.20 BM, which is characteristic of mononuclear copper(II) complexes. However, in compound **5a**, $[Cu(HAm4DH)Cl_2]_2$, the value is 1.24 BM and this is lower than the expected spin-only value, which clearly indicates antiferromagnetic coupling between the copper(II) ions. This behavior is very similar to that found in binuclear copper(II) complexes containing chloro bridges. In order to determine the extent of the magnetic interaction between the two metal ions and to elucidate the difference in the singlet–triplet energy values, the magnetic susceptibility was measured in the temperature range 2–150 K. The variation in the magnetic susceptibility with temperature is shown in Figure 6. It can be seen that the magnetic susceptibility increases to a maximum at 15 K on cooling and then falls rapidly on decreasing the temperature further. The experimental magnetic susceptibility values (corrected for diamagnetism) were adjusted using the Bleaney–Bowers equation[39] for a coupled dinuclear copper(II) species:

$$\chi_M = \{(Ng^2\beta^2)/kT[3 + \exp(-J/kT)]\}^{-1}(1 - \rho) + \rho Ng^2\beta^2/4kT + \chi_{TIP}$$

which results from considering the same values of $H = -2JS_1S_2$ and where the symbols have the accepted meanings. A nonlinear least-squares adjustment program was used to calculate $-J$ and $g$ and excellent agreement was obtained when $J = -12.2$ cm$^{-1}$, $g = 2.17$, $\chi_{TIP} = 124\times10^{-6}$, $\rho = 0.035$, and $R = 1.2\times10^{-3}$. The coupling constant calculated for the singlet–triplet exchange clearly shows that antiferromagnetic interactions exist between the copper(II) ions in **5a** in the solid phase.

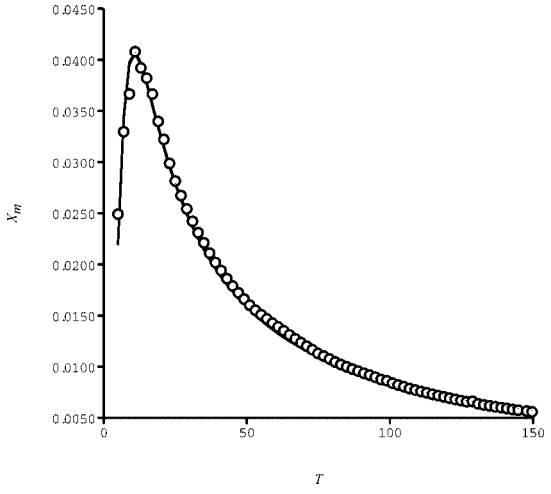

Figure 6. Temperature [K] dependence of the magnetic susceptibility $\chi_M$ (cm$^3$·mol$^{-1}$) of **5a**. The solid line represents the least-squares fit equation and the parameters described in the text.

In contrast to copper(II) complexes containing hydroxy bridges, which have equivalent Cu–O (bridge) distances, dimers with chloro bridges frequently have different Cu–Cl (bridge) distances and the singlet–triplet splitting depends on the length of the bridging bonds and the Cu–Cl–Cu angle of the bridge.[40]

Correlation studies were carried out on the magnetic and structural properties of a diverse range of dinuclear copper(II) species − particularly compounds with two chloro bridges between the metal centers and trigonal pyramidal or square-pyramidal coordination geometries. Reasonable consistency was found in that the singlet–triplet splitting and, consequently, the isotropic interaction parameter ($2J$) correlate reasonably well with the $\varphi/r$ ratio between the bridging angle Cu–Cl–Cu′ ($\varphi$) and the longest Cu–Cl distance from the basal plane ($r$). The $\varphi/r$ values between 32.5 and 34.75 °/Å correspond to ferromagnetic interaction while values outside this range correspond to antiferromagnetic behavior.[41] The $\varphi/r$ value found for compound **5a** is 28.6 °/Å and this is consistent with the correlation.

However, this situation contrasts with that found for $[(dpt)Cu(\mu\text{-}Cl)_2Cu(dpt)]Cl_2$ (dpt = dipropylenetriamine, $\varphi/r$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

= 35.9 °/Å), where each copper(II) ion is in a trigonal bipyramidal environment and the compound shows ferromagnetic coupling between the copper(II) ions ($J$ = 42.9 $cm^{-1}$) and an interdimeric antiferromagnetic coupling ($J'$ = –3.92 $cm^{-1}$).[42] Another similar example is [(depc)(Cl)Cu(μ-$Cl)_2$Cu(Cl)(depc)] (depc = diethyl pyridine-2,6-dicarboxylate, $\varphi/r$ = 40.9 °/Å), in which each copper(II) ion is in a distorted octahedral environment and coupling constants of $J$ = 39.9 $cm^{-1}$ and $J'$ = –0.59 $cm^{-1}$ are found.[43]

## Thermochemistry

The pyrolysis of the compounds subjected to thermogravimetric analysis (**1**–**3**, **5**–**8**, **10**) occurred in four or five stages, with overall evolution of $H_2O$, $CO_2$, CO, $NH_3$, NO, $NO_2$, and $SO_2$ in all cases except that of compound **7**, for which only three stages and the evolution of only $H_2O$, $CO_2$, NO, $NO_2$, and $SO_2$ were detected (Table 4). In keeping with their observed crystal structures, compounds **1** and **7** gave off no solvent molecules, and these compounds were stable up to 226 °C and 174 °C, respectively. The remaining compounds, which are all solvated, lost solvent molecules even at room temperature, because of which the number of solvent molecules included in the working empirical formula of the starting material was calculated as that which gave the best agreement with the experimental weight loss during the first decomposition stage, assuming this stage to involve only solvent loss; for example, for compounds **3** and **10** this procedure afforded the working empirical formulae $[Cu(HAm4DH)_2](NO_3)_2 \cdot 0.52\,EtOH$ and $[Cu(Am4DH)_2] \cdot 1.27\,H_2O$, respectively. Note that the final residue of compound **7**, the only compound not to give off ammonia as well as $SO_2$ and nitrogen oxides, was $Cu(NO_3)_2$, and that for all compounds except compound **7** the final residue accounted for a greater percentage of the initial mass than would correspond to its consisting entirely of CuO, the difference being quite substantial in some cases; this suggests that in these cases, too, the residue may have contained $Cu(NO_3)_2$, or perhaps a copper(II) oxy-nitrate, even though only CuO was detected.

## Cyclic Voltammetry Studies

The reduction peak potentials for $Cu^{II}$ are shown in Table 5 along with the corresponding reoxidation peaks for $Cu^{I}$. It can be seen that the more negative the cathodic peak, the more stable the complex (for a variation in potential of 0.02 $V \cdot s^{-1}$).

Table 5. Reduction peak potentials for $Cu^{II}$ and the corresponding peaks for the reoxidation of $Cu^{I}$.

[a] $V$ vs. SCE.

In all cases a well-defined cathodic peak was observed and, based on the position of the peak on the potential scale (–0.4 to –0.8 V vs SCE) and its absence in the reverse measurements on the ligands, this can be attributed to the reduction of copper(II) according to the equation:

$$Cu^{2+} + e^- \leftrightarrows Cu^+$$

In the majority of the complexes the corresponding anodic peak is also observed ($E_a$) (Figure 7), although in some cases the appearance of the peak depends on the experimental conditions (e.g. potential range and length of time after preparation of the solution). The peak shapes and the separation between the cathodic and anodic peaks (when they are observed) demonstrate the irreversible nature of the electrode process.

Voltammograms were also obtained over a larger potential range and these showed a cathodic peak at around –2 V versus SCE, which is also present in the voltammograms obtained for the ligand (Figure 8). This peak can be assigned to reduction of the ligand from the thione to the thiol, as proposed by other authors for similar conditions.[44] An anodic peak was also observed in the potential range 0.5–0.6 V versus SCE (Figure 9) and the origin of this peak is not clear because of its changeable behavior.

In complexes **3**, **8**, **9**, and **10** the peak due to the reduction of copper(II) is split into two very close peaks that

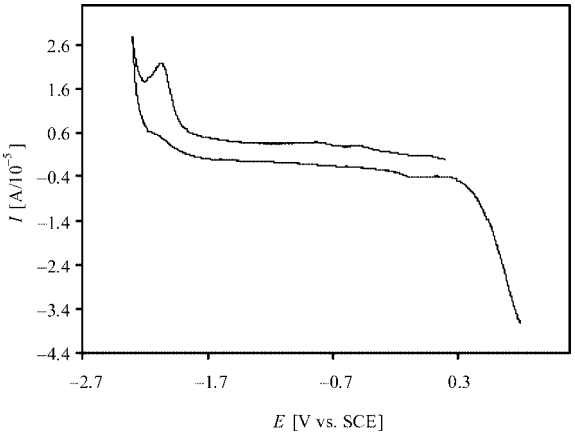

Figure 8. Cyclic voltammogram (scan rate 0.2 V·s$^{-1}$) of a 1 mM solution in DMF of HAm4DH.

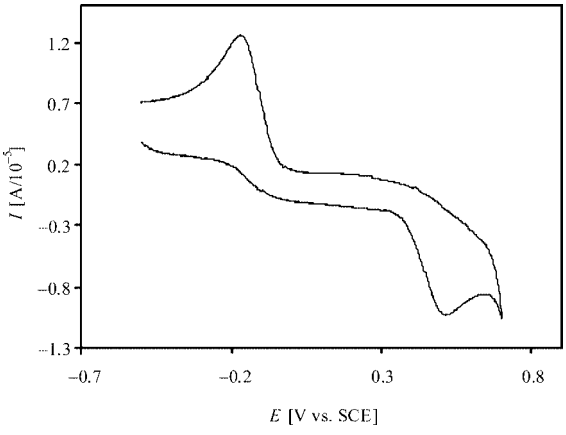

Figure 9. Cyclic voltammogram (scan rate 0.2 V·s$^{-1}$) of a 1 mM solution in DMF of **1**.

practically overlap (Figure 10) − these peaks are due to the presence of two chemically very similar species in solution. In the case of complex **9** this splitting becomes more marked as the length of time after preparation of the solution increases. This change indicates a progressive change in the structure of the ligand. Complexes **1** and **7** also show splitting of the cathodic peak because of the reduction of copper(II) (Figure 11) but, given the characteristic shape of one of the peaks, this splitting can be attributed to the fact that a proportion of the electrochemical reaction takes place at the surface.

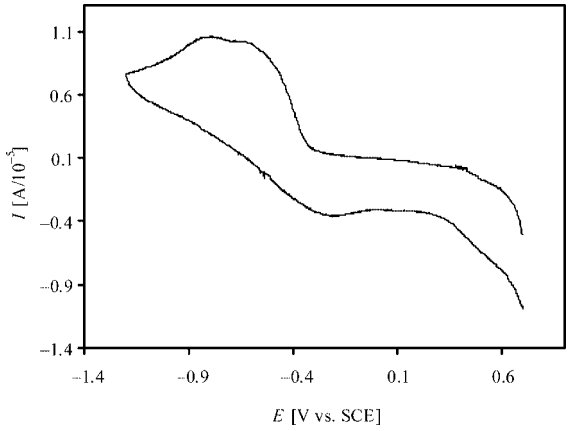

Figure 10. Cyclic voltammogram of complex **10** in $10^{-3}$ M DMF (scan rate 0.2 V·s$^{-1}$).

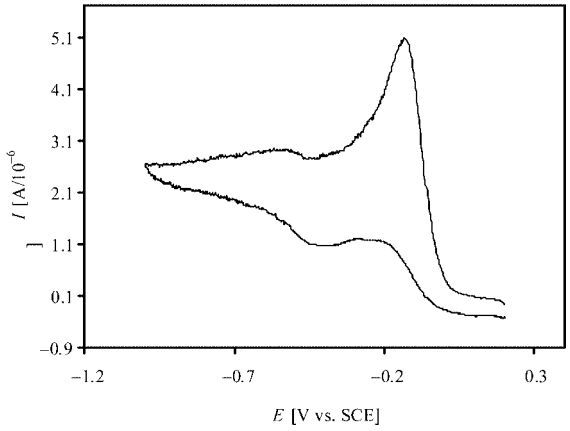

Figure 11. Cyclic voltammogram of complex **1** in $10^{-3}$ M DMF (scan rate 0.2 V·s$^{-1}$).

Similar splitting − albeit less marked − was observed in the anodic peak associated with the reoxidation of copper(I).

### The Activity of Thiosemicarbazone/Copper Complexes as DNA Nucleases

The electrophoresis studies carried out on complexes **1**, **2**, **5**, and **6** (Figure 12) show that these materials have nuclease activity because a significant proportion of the DNA, which is initially supercoiled (lane 2), appears in a circular form when incubated in the presence of 12 μM of complex (lanes 5, 7, 9, and 11, respectively). It can also be seen that the nuclease capacity of the four complexes under investigation is dependent on the concentration, as the digestion observed on incubating the DNA with 24 μM of the complex is higher than that produced with 12 μM for all four complexes.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

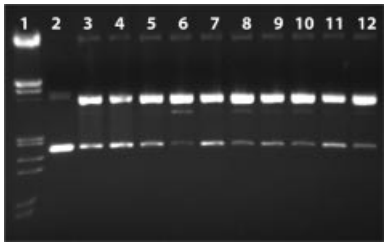

Figure 12. Agarose gel electrophoresis of pUC18 plasmid DNA treated with complexes **1**, **2**, **5** and **6** or $CuSO_4$ in the presence of 50 equiv. $H_2O_2$/ascorbate tandem. Incubation time 1 h (37 °C). Lane 1, λDNA/EcoR1 + HindIII Marker; lane 2, supercoiled DNA (control); lane 3, $Cu(SO_4)$ 40 μM; lane 4, $Cu(SO_4)$ 80 μM; lane 5, complex **2** 12 μM; lane 6, complex **2** 24 μM; lane 7, complex **6** 12 μM; lane 8, complex **6** 24 μM; lane 9, complex **1** 12 μM; lane 10, complex **1** 24 μM; lane 11, complex **5** 12 μM; lane 12, complex **5** 24 μM. Incubation time 1 h (37 °C).

It is known that copper has nuclease activity in its own right and, for this reason, the digestion produced by $CuSO_4$ under the same conditions was also determined. It can be seen from Figure 12 that the presence of $CuSO_4$ causes a proportion of the DNA to change to the circular form upon digestion (lanes 3 and 4). Complexes **1**, **5**, and **6** show practically identical nuclease activity to that shown by copper under the same conditions (cf. lanes 3–4 with 7–8, 9–10 and 11–12). The activity of these complexes must therefore be due to the presence of copper. In contrast, at a concentration of 24 μM complex **2** causes complete digestion of the supercoiled plasmid to give the circular form and a small quantity of the linear form. This complex clearly shows higher activity than $CuSO_4$ under the same experimental conditions (lanes 4 and 6).

In an effort to determine the mode of action of the nuclease process associated with complex **2**, we assessed the influence of different agents that could potentially inhibit reactive oxygen species (ROS). These compounds included hydroxy radical scavengers (DMSO and *tert*-butyl alcohol), singlet oxygen scavengers (sodium azide and 2,2,6,6-tetramethyl-4-piperidone), and superoxide radical scavengers (SOD). Finally, distamycin was tested as a species that bonds to DNA in the minor groove. Comparison of lanes 4 and 5 (Figure 13), which represent assays with DMSO and *tert*-butyl alcohol, respectively, with lane 3 (absence of inhibitor) shows that these additives do inhibit the process. This observation indicates the participation of the hydroxy radical in the DNA digestion process. Sodium azide (lane 6) and 2,2,6,6-tetramethyl-4-piperidone (lane 7) also inhibit the nuclease activity of the complex. This finding shows that singlet oxygen − or a species that behaves in a similar way − is also involved in the nuclease process. It is worth highlighting that azide can form complexes with copper and in this case the inhibition is markedly higher than that observed with 2,2,6,6-tertramethyl-4-piperidone. The presence of distamycin in the reaction mixture did not lead to changes in the activation of the complex, as can be seen in lane 8. This observation shows that the complex does not interact with DNA through the minor groove. The SOD enzyme, on the other hand, increased the nuclease activity and lane 9 shows total degradation of the plasmid. The dismutation process of the superoxide ion probably gives rise to a greater proportion of hydroxy radicals, which are produced by decomposition of hydrogen peroxide produced in the dismutation process.

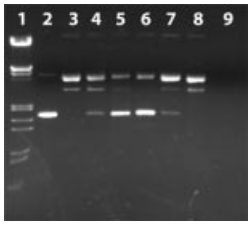

Figure 13. Agarose gel electrophoresis of pUC18 plasmid DNA treated with 24 μM of complex **2** and different inhibitors in the presence of $H_2O_2$/ascorbate (50 times more concentrated than the complex). Incubation time 1 h (37 °C). Lane 1, λDNA/EcoR1 + HindIII Marker; lane 2, supercoiled DNA (control); lane 3, complex without inhibitor; lane 4, complex + 1 M DMSO; lane 5, complex + 1 M *tert*-butyl alcohol; lane 6, complex + $NaN_3$ (100 mM); lane 7, complex + 2,2,6,6-tetramethyl-4-piperidone (100 mM); lane 8, complex + distamycin (8 μM); lane 9, complex + SOD (15 units).

These results imply that the $OH^{\cdot}$ radicals take part in the nucleic acid digestion process in the same way as singlet oxygen (or a species with similar behavior). The following mechanism can be proposed for the process:

1. reduction of $Cu^{II}$ to $Cu^{I}$;
2. interaction of the $Cu^{I}$ complex with DNA, possibly through the major groove;
3. reaction between hydrogen peroxide or oxygen with the $Cu^{I}$ to form the reactive oxygen species;
4. reaction of the hydroxy radical and singlet oxygen with DNA and destruction of the strands.

If the reactive species are not generated in the immediate vicinity of the DNA they can diffuse and be neutralized. For this reason the structures of the complexes and the nature of the ligand govern the DNA recognition process and determine the level of chemical damage.

The fact that the complex does not intercalate with the minor groove of the double helix possibly means that the reduction of $Cu^{II}$ to $Cu^{I}$ and the production of reactive oxygen species capable of attacking the DNA do not take place in the vicinity of the DNA. For this reason the digestion process is not as effective as that in cases where the complexes act by intercalation, for example, $[Cu(phen)_2]^{2+}$. This could be the reason why complex **2** shows a higher nuclease activity than the other compounds synthesized in this study.

## Experimental Section

**General:** Elemental analyses were carried out with a Carlo–Erba Model 1108 and Perkin–Elmer 240B microanalyzer. IR spectra were recorded with a Bruker IFS-66 V spectrophotometer as KBr disks (4000–400 $cm^{-1}$) or polyethylene-sandwiched Nujol mulls (500–100 $cm^{-1}$). Mass spectra were obtained with a Hewlett Packard HP598A spectrometer. Electronic spectra were obtained with a Shimadzu UV-3101PC spectrophotometer equipped with a reflectance accessory. X-band EPR spectra of the complexes were obtained in 3 mm Pyrex tubes with a Bruker EMX spectrometer using

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a conventional Dewar insert at liquid nitrogen temperature and $Cr^{II}$ as the reference. Room temperature magnetic moments were determined on a DSM-8 magnetic susceptibility balance, and the instrument was calibrated using nickel metal. Variable-temperature (5–293 K) magnetic susceptibility measurements on a polycrystalline sample of **5a** were carried out with a Quantum Design SQUID susceptometer using an applied magnetic field of 2000 G over the whole temperature range. All data were corrected for diamagnetism of the ligands as estimated from Pascal's constants. The conductivity measurements were carried out with a CRISON digital conductivity bridge model MicroCM 2202 using freshly prepared $10^{-3}$ M solutions of the complexes in DMF. Thermogravimetric analysis from 20 to 950 °C was performed in a Shimadzu TGA-DGT 50H thermobalance using a constant 100 mL/min air flow. Evolved gases were identified from between 21 and 24 IR spectra of the gaseous products that were recorded at appropriate times during the analysis using a coupled Nicolet Magma 550 FTIR spectrophotometer; in each spectrum, the characteristic bands of the various gases were unequivocally identified by comparison with spectra in the Sigma–Aldrich FTIR library. Cyclic voltammograms were obtained on a 273 EG&G Princeton Applied Research electrochemical analyzer. The measurements were carried out at 50 mV·s$^{-1}$ under oxygen-free conditions using a three-electrode cell with a glassy carbon electrode. Tetra(*n*-butyl)ammonium perchlorate (TBAP) was used as the supporting electrolyte.

All chemicals and solvents were of analytical grade and were used as received. The TBAP used as the supporting electrolyte in electrochemical measurements was purchased from Fluka and recrystallized from hot methanol.

***Caution! Perchlorates are potentially explosive and care should be taken in handling these compounds.***

**Preparation of HAm4DH:** The ligand, HAm4DH, 2-pyridineformamide thiosemicarbazone was prepared according to a literature procedure.[2]

**Synthesis of [Cu(HAm4DH)Cl$_2$] (1):** An ethanolic solution (20 mL) of HAm4DH (0.25 g, 1.28 mmol) was added to a stirred solution of $CuCl_2 \cdot 2H_2O$ (0.22 g, 1.28 mmol) in ethanol (20 mL). The mixture was stirred for 7 days; the resulting suspension was filtered off and the bluish-green solid was washed with ethanol and dried with calcium chloride. Yield: 0.38 g (90%). $C_7H_9Cl_2CuN_5S$ (329.70): calcd. C 25.5, H 2.8, N 21.2, S 9.7; found C 25.6, H 2.8, N 21.0, S 9.5. Selected IR data: $\tilde{\nu}_{max}$ = 3437–3165 (NH), 1639–1578 (C=N + C=C), 1020 (NN), 793 (C=S), 463 (Cu–N), 349 (Cu–S), 319, 264 (Cu–Cl) cm$^{-1}$. FAB$^+$ MS [*m*/*z*, assignment]: 258 [Cu(HAm4DH)]. UV/Vis ($\lambda_{max}$, nm): 26738, 24154, 15244, 14245. EPR (X-band, solid sample): $g_{\parallel}$ = 2.19, $g_{\perp}$ = 2.04, $g_{av}$ = 2.05, $G$ = 4.75. $\mu_{eff}$ = 2.05 MB. Conductance ($\Lambda_m$/S·cm$^2$·mol$^{-1}$) in DMF: 28.

**Synthesis of [Cu(HAm4DH)Br$_2$]·0.5 EtOH·0.5 H$_2$O (2):** A solution of HAm4DH (0.20 g, 1.02 mmol) in ethanol (20 mL) was added to a solution of $CuBr_2$ (0.46 g, 2.05 mmol) in ethanol (20 mL). The mixture was stirred for one week and the resulting dark brown solid was filtered off, washed with ethanol, and dried under vacuum. Yield: 0.92 g (99%). $C_8H_{13}Br_2CuN_5OS$ (545.64): calcd. C 21.3, H 2.9, N 15.5, S 7.1; found C 22.2, H 2.3, N 15.0, S 6.5. Selected IR data: $\tilde{\nu}_{max}$ = 3408, 3324 (NH), 1562, 1515 (C=N, C=C), 1015 (NN), 789 (C=S), 464 (Cu–N2), 324 (Cu–S), 254 (Cu–Br) cm$^{-1}$. FAB$^+$ MS [*m*/*z*, assignment]: 338, [Cu(Am4DH)Br]; 257, [Cu(Am4DH)]. UV/Vis ($\lambda_{max}$, nm): 26693, 24232, 15253, 14271 cm$^{-1}$. EPR (X-band, solid sample): $g_{iso}$ = 2.04. $\mu_{eff}$ = 2.16 MB. Conductance ($\Lambda_m$/S·cm$^2$·mol$^{-1}$) in DMF: 34.6.

**Synthesis of [Cu(HAm4DH)$_2$](NO$_3$)$_2$·EtOH (3):** A solution of $Cu(NO_3)_2 \cdot 3H_2O$ (0.25 g, 1.02 mmol) and HAm4DH (0.40 g, 2.05 mmol) in ethanol (20 mL) was stirred for one week. A dark green precipitate formed and this was filtered off, washed with ethanol, and dried under vacuum. Yield: 0.25 g (40%). $C_{16}H_{24}CuN_{12}O_7S_2$ (624.11): calcd. C 30.8, H 3.9, N 26.9, S 10.3; found C 31.5, H 3.5, N 26.2, S 11.8. Selected IR data : $\tilde{\nu}_{max}$ = 3422–3171 (NH), 1599–1519 (C=N, C=C), 1384 ($NO_3$), 1016 (NN), 840 (C=S), 467 (Cu–N2), 338 (Cu–S) cm$^{-1}$. FAB$^+$ MS [*m*/*z*, assignment]: 453, [Cu(HAm4DH)$_2$]; 322, [Cu(H$_3$Am4DH)(NO$_3$)]; 259, [Cu(H$_2$Am4DH)]. UV/Vis ($\lambda_{max}$, nm): 26378, 22676, 21459, 16326, 15588. EPR (X-band, solid sample): $g_{iso}$ = 2.08. $\mu_{eff}$ = 2.16 MB. Conductance ($\Lambda_m$/S·cm$^2$·mol$^{-1}$) in DMF: 125.6.

**Synthesis of [Cu(HAm4DH)$_2$](ClO$_4$)$_2$ (4):** A solution of HAm4DH (0.25 g, 1.28 mmol) in ethanol (20 mL) was added to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.47 g, 1.28 mmol) in ethanol (20 mL). The mixture was stirred for 7 days and the resulting black solid was filtered off, washed with ethanol and dried with calcium chloride. Yield: 0.64 g (76%). $C_{14}H_{18}Cl_2CuN_{10}O_8S_2$ (652.93): calcd. C 23.5, H 2.3, N 19.6, S 9.0; found C 23.9, H 2.4, N 19.3, S 9.0. Selected IR data: $\tilde{\nu}_{max}$ = 3421–3189 (NH), 1619–1518 (C=N, C=C), 1118, 936, 632 [$\nu_3$, $\nu_1$, $\nu_4$ ($ClO_4$)], 1019 (NN), 847 (C=S), 488 (Cu–N2), 363 (Cu–S) cm$^{-1}$. FAB$^+$ MS [*m*/*z*, assignment]: 258, [Cu(HAm4DH)]. UV/Vis ($\lambda_{max}$, nm): 26364, 22655, 15593, 14290. EPR (X-band, solid sample): $g_{\parallel}$ = 2.19, $g_{\perp}$ = 2.04, $g_{av}$ = 2.08, $G$ = 4.75. $\mu_{eff}$ = 1.97 MB. Conductance ($\Lambda_m$/S·cm$^2$·mol$^{-1}$) in DMF: 152.4.

**Synthesis of [Cu(Am4DH)Cl]·0.5 EtOH (5):** A solution of HAm4DH (0.20 g, 1.02 mmol) in ethanol was added to a stirred solution of $CuCl_2 \cdot 2H_2O$ (0.18 g, 1.02 mmol) in ethanol (20 mL). After a few drops of triethylamine (0.14 mL, 1.02 mmol) were added, the mixture was stirred for 7 days, just to complete precipitation of a dark green solid which was filtered off, washed with ethanol, and dried. Yield: 0.30 g (92%). $C_8H_{11}ClCuN_5O_{0.5}S$ (316.27): calcd. C 30.4, H 3.5, N 22.1, S 10.1; found C 30.2, H 3.5, N 21.7, S, 9.4. Selected IR data: $\tilde{\nu}_{max}$ = 3473–3158 (NH), 1625–1515 (C=N, C=C), 1020 (NN), 783 (C=S), 467 (Cu–N2), 350 (Cu–S), 313 (Cu–Cl) cm$^{-1}$. FAB$^+$ MS [*m*/*z*, assignment]: 294, [Cu(H$_2$Am4DH)Cl]; 259, [Cu(H$_2$Am4DH)]. UV/Vis ($\lambda_{max}$, nm): 26385, 22989, 16247, 15662 cm$^{-1}$. EPR (X-band, solid sample): $g_{iso}$ = 2.08. $\mu_{eff}$ = 2.04 MB. Conductance ($\Lambda_m$/S·cm$^2$·mol$^{-1}$) in DMF: 47.8. Recrystallization from MeOH/$CCl_4$ or EtOH/$H_2O$ gave green prismatic crystals of [Cu(HAm4DH)Cl$_2$]$_2$ (**5a**) and green needles of $^1_\infty$[Cu(Am4DH)Cl] (**5b**), respectively, that were suitable for X-ray diffraction.

**Synthesis of [Cu(Am4DH)Br]·0.5 EtOH (6):** A solution of HAm4DH (0.20 g, 1.02 mmol) in ethanol (20 mL) was added to a solution of $CuBr_2$ (0.23 g, 1.02 mmol) in ethanol (20 mL). Triethylamine (0.14 mL, 1.02 mmol) was added and the mixture was stirred for one week. The resulting dark green solid was filtered off, washed with ethanol, and dried under vacuum. Yield: 0.31 g (84%). $C_8H_{11}BrCuN_5O_{0.5}S$ (360.72): calcd. C 26.6, H 3.1, N 19.4, S 8.9; found C 26.7, H 3.0, N 19.2, S 6.2. Selected IR data: $\tilde{\nu}_{max}$ = 3521–3159 (NH), 1613–1514 (C=N, C=C), 1017 (NN), 844 (C=S), 468 (Cu–N2), 329 (Cu–S), 255 (Cu–Br) cm$^{-1}$. FAB$^+$ MS [*m*/*z*, assignment]: 338, [Cu(Am4DH)Br]; 257, [Cu(Am4DH)]. UV/Vis ($\lambda_{max}$, nm): 26350, 23068, 16247, 15698 cm$^{-1}$. EPR (X-band, solid sample): $g_{iso}$ = 2.07. $\mu_{eff}$ = 1.98 MB. Conductance ($\Lambda_m$/S·cm$^2$·mol$^{-1}$) in DMF: 62.6. X-ray quality crystals of $^1_\infty$[Cu(Am4DH)Br] (**6a**) were obtained as blue prisms by recrystallization from MeOH/acetonitrile.

**Synthesis of [Cu(Am4DH)(OAc)] (7):** A solution of HAm4DH (0.20 g, 1.02 mmol) in ethanol (20 mL) was added to a solution of $Cu(CH_3OO)_2 \cdot H_2O$ (0.20 g, 1.02 mmol) in ethanol (20 mL) and triethylamine was added (0.14 mL, 1.02 mmol). The mixture was

stirred for 7 days and the resulting green solid was filtered off, washed with ethanol, and dried under vacuum. Yield: 0.26 g (80%). $C_9H_{11}CuN_5O_2S$ (316.83): calcd. C 34.1, H 3.5, N 22.1, S 10.1; found C 34.4, H 3.5, N 21.8, S 10.0. Selected IR data: $\tilde{\nu}_{max}$ = 3427–3183 (NH), 1596, 1515 (C=N, C=C, $CH_3COO$), 1407 ($CH_3COO$), 1018 (NN), 846 (C=S), 442 (Cu–N2), 409 (Cu–O), 351 (Cu–S) $cm^{-1}$. $FAB^+$ MS [*m*/*z*, assignment]: 257, [Cu(Am4DH)]. UV/Vis ($\lambda_{max}$, nm): 26399, 23364, 16155, 15662, 14358 $cm^{-1}$. EPR (X-band, solid sample): $g_{\parallel}$ = 2.20, $g_{\perp}$ = 2.04, $g_{av}$ = 2.06, $G$ = 5. $\mu_{eff}$ = 2.10 MB. Conductance ($\Lambda_m$/S·cm²·mol⁻¹) in DMF: 33.7.

**Synthesis of [Cu(Am4DH)(NO$_3$)]·0.5 EtOH (8):** A solution of HAm4DH (0.20 g, 1.02 mmol) in ethanol was added to a stirred solution of $Cu(NO_3)_2{\cdot}3H_2O$ (0.25 g, 1.02 mmol) in ethanol (20 mL). After adding a few drops of triethylamine (0.14 mL, 1.02 mmol), the mixture was stirred for 7 days and, a dark brown solid was isolated that was filtered off, washed with ethanol, and dried with calcium chloride. Yield: 0.27 g (77%). $C_8H_{13}CuN_6O_{3.5}S$ (342.82): calcd. C 28.0, H 3.2, N 24.5, S 9.4; found C 27.5, H 2.9, N 24.8, S 10.2. Selected IR data: $\tilde{\nu}_{max}$ = 3424–3172 (NH), 1598–1523 (C=N, C=C), 1384, 1101 ($NO_3$), 1016 (NN), 841 (C=S), 465 (Cu–N2), 333 (Cu–S) $cm^{-1}$. $FAB^+$ MS [*m*/*z*, assignment]: 320, [Cu(HAm4DH)($NO_3$)]; 257, [Cu(Am4DH)]. UV/Vis ($\lambda_{max}$, nm): 26406, 23474, 21186, 16353, 15785 $cm^{-1}$. EPR (X-band, solid sample): $g_{\parallel}$ = 2.20, $g_{\perp}$ = 2.04, $g_{av}$ = 2.05, $G$ = 5. $\mu_{eff}$ = 2.15 MB. Conductance ($\Lambda_m$/S·cm²·mol⁻¹) in DMF: 40.2.

**Synthesis of [Cu(Am4DH)(H$_2$O)](ClO$_4$) (9):** A solution of HAm4DH (0.20 g, 1.02 mmol) in ethanol was added to a stirred solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (0.38 g, 1.02 mmol) in ethanol (20 mL). After adding a few drops of triethylamine (0.14 mL, 1.02 mmol), the mixture was stirred for 7 days and the brown solid formed was filtered off, washed with ethanol, and dried. Yield: 0.16 (43%). $C_7H_{10}ClCuN_5O_5S$ (375.25): calcd. C 22.4, H 2.7, N 18.7, S 8.5; found C 22.2, H 2.4, N 16.2, S 7.8. Selected IR data: $\tilde{\nu}_{max}$ = 3429–3175 (NH), 1608–1518 (C=N, C=C), 1109, 926, 627 [$\nu_3$, $\nu_1$, $\nu_4$ ($ClO_4$)], 1016 (NN), 791 (C=S), 466 (Cu–N), 350 (Cu–S) $cm^{-1}$. $FAB^+$ MS [*m*/*z*, assignment]: 255, [Cu(Am4DH-2 H)]. UV/Vis ($\lambda_{max}$, nm): 26716, 23252, 15964, 15431. $\mu_{eff}$ = 2.19 MB. Conductance ($\Lambda_m$/S·cm²·mol⁻¹) in DMF: 90.3. Dark green prismatic crystals of [Cu(HAm4DH)($H_2O$)($ClO_4$)$_2$]·MeOH·$H_2O$ (**9a**) suitable for X-ray diffractometry were obtained after a few days by slow evaporation of a mixture of MeOH/$CCl_4$ at room temperature.

**Synthesis of [Cu(Am4DH)$_2$]·4 H$_2$O (10):** $Cu(CH_3OO)_2{\cdot}H_2O$ (0.20 g, 1.02 mmol) and HAm4DH (0.4 g, 2.05 mmol) were dissolved in ethanol (20 mL); some triethylamine was added (0.28 mL, 2.05 mmol) and the mixture was stirred for a week. The dark green precipitate was filtered off, washed with ethanol, and dried under vacuum. Yield: 0.35 (42%). $C_{14}H_{24}CuN_{10}O_4S_2$ (524.08): calcd. C 32.1, H 4.6, N 26.7, S 11.2; found C 32.1, H 3.3, N 25.2, S 13.7. Selected IR data: $\tilde{\nu}_{max}$ = 3423–3174 (NH), 1598–1520 (C=N, C=C), 1016 (NN), 845 (C=S), 470 (Cu–N2), 337 (Cu–S) $cm^{-1}$. $FAB^+$ MS [*m*/*z*, assignment]: 452, [Cu(HAm4DH)(Am4DH)]; 257, [Cu(Am4DH)]. UV/Vis ($\lambda_{max}$, nm): 26724, 22624, 15649, 14409 $cm^{-1}$. EPR (X-band, solid sample): $g_{iso}$ = 2.08. $\mu_{eff}$ = 2.13 MB. Conductance ($\Lambda_m$/S·cm²·mol⁻¹) in DMF: 32.7.

**X-ray Crystallography:** Crystals were mounted on glass fibers and these samples were used for data collection. Data for **5b** and **6a** were collected with a Nonius CAD4 automatic diffractometer and for **5a** and **9a** with a Bruker SMART CCD 1000 diffractometer. Cell constants and an orientation matrix were obtained from data collection of $2.03 < \theta < 26.48°$ for **5a**, $15.69 < \theta < 45.59°$ for **5b**,

Table 6. Crystal data and structure refinement for **5a**, **5b**, **6a**, and **9a**.

$1.56 < \theta < 26.43°$ for **6a** and $4.37 < \theta < 72.98°$ for **9a**. The data for **5b** and **6a** were processed with SAINT[45] and corrected for absorption using SADABS.[46] The structures were solved by direct methods,[47] which revealed the position of all non-hydrogen atoms. These atoms were refined on $F^2$ by a full-matrix least-squares procedure using anisotropic displacement parameters.[48] The hydrogen atoms were located from difference syntheses or in their calculated positions (C–H, 0.93–0.97 Å), and were refined using a riding model. Atom scattering factors were taken from the International Tables for Crystallography.[49] Crystal and refinement data are listed in Table 6.

**Cleavage of pUV18 by Thiosemicarbazone/Copper:** The interaction of the copper(II) complexes with DNA was studied using the plasmid pUC18 in the presence of $H_2O_2$, with the resulting fragments analyzed by electrophoresis in agarose. Plasmid pUC18 has a size of 2686 base pairs at a concentration of 0.25 mg·mL$^{-1}$ in TE buffer (pH = 8, Tris 10 mM, EDTA 1 mM). The assay carried out involved digesting plasmid pUC18 with the copper complexes in the presence of a reducing agent. The copper(II) complexes are insoluble in the buffer solutions commonly used in DNA degradation processes. For this reason DMF was employed as a solvent and the method reported by Reddy[50] was used for studies in this solvent. A typical assay was carried out as follows: 7 μL of 0.1 M cacodylate buffer (pH = 6.0), 1 μL of DNA pUC18 (0.25 μg·μL$^{-1}$), 6 μL of a solution of the copper(II) complex (or copper) (40 or 80 μM) in 0.1 M cacodylate buffer (pH = 6.0), 3 μL of $H_2O_2$ (0.4 or 0.8 mM) in 0.1 M cacodylate buffer, and 3 μL ascorbate (0.4 or 0.8 mM). The samples were incubated at 37 °C for 60 min. After this time 3 μL of charge buffer (0.25% bromophenol, 0.25% xylene cyanol, and 30% glycerol) was added and the electrophoresis was carried out immediately at 80 V in 0.8% agarose gel [containing 2 μL/100 mL of a solution of ethidium bromide (10 mg·mL$^{-1}$)] using 0.5×TBE as a buffer (0.045 M Tris, 0.045 M boric acid, and 1 mM EDTA) for 2–2.5 h. The gel was photographed using a Gel printer Plus TDI system. Assays involving the various inhibitors were carried out in the same way as above but the agents under investigation were added as follows: *tert*-butyl alcohol (1 M) and DMSO (1 M) for their ability to scavenge OH· radicals, sodium azide (100 mM), and 2,2,6,6-tetramethyl-4-piperidone (100 mM), which are characterized by their ability to scavenge singlet oxygen; distamycin (8 mM), which intercalates between the nucleobases of the minor groove of the double helix of DNA and superoxide dismutase (15 units) for its ability to quench the superoxide radical. It is known that copper(II) shows nuclease activity in its own right and therefore comparative electrophoresis was carried out for a range of incubation times in order to determine whether the complex showed higher, lower or equivalent activity to the copper(II) salts.

CCDC-277157 (for $[Cu(HAm4DH)Cl_2]_2$), CCDC-277158 (for $^1_\infty[Cu(Am4DH)Cl]$), CCDC-277159 for ($^1_\infty[Cu(Am4DH)Br]$), and CCDC-277160 for ($[Cu(HAm4DH)(H_2O)(ClO_4)_2]$·MeOH·$H_2O$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

Financial support from ERDF (EU)-DGI-MCYT (Spain) (Projects BQU2002-04523-C02 and CTQ2004-03735) and the Xunta de Galicia (Project PGIDIT03PXIC20302PN) is gratefully acknowledged.

# Novel Metallosupramolecular Networks Constructed from $Cu^{II}$, $Ni^{II}$, and $Cd^{II}$ with Mixed Ligands: Crystal Structures, Fluorescence, and Magnetism

**Miao Du,*[a] Xiu-Juan Jiang,[a] Xiao-Jun Zhao,[a] Hua Cai,[a] and Joan Ribas[b]**

**Keywords:** Coordination polymers / Inclusion complexes / Supramolecular chemistry / Noncovalent interactions

Reactions of mixed ligands succinic acid ($H_2$suc) and bent dipyridines, such as 2,5-bis(3-pyridyl)-1,3,4-oxadiazole (3-bpo) and its 4-*N*-donor analog (4-bpo), with inorganic $Cu^{II}$, $Ni^{II}$, and $Cd^{II}$ salts yield three new metal-organic coordination frameworks $\{[Cu(suc)(3\text{-bpo})(H_2O)_2]\cdot(H_2O)_{1.75}\}_n$ (**1**), $\{[Ni(suc)(4\text{-bpo})(H_2O)_2]\cdot(H_2O)_5\}_n$ (**3**), and $\{[Cd_2(suc)_2(3\text{-bpo})_2(H_2O)_2]\cdot(H_2O)_{6.75}\}_n$ (**4**), in which the metal centers are linked by bridging ligands 3-bpo/4-bpo and $suc^{2-}$ along two directions to form 2D infinite networks. The corrugated 2D nets of **1** and **4**, obtained under hydrothermal conditions, align in an interdigitated manner with the presence of significant aromatic-stacking interactions to result in similar 3D architectures. The 2D sheets in **3** are extended by interlayer hydrogen bonds to afford a 3D structure. However, when succinic acid is replaced by fumaric acid ($H_2$fum) in the reaction with 3-bpo and $Cu^{II}$ salt, a metallacyclophane $[Cu(Hfum)_2(3\text{-bpo})(H_2O)]_2\cdot(3\text{-bpo})_2\cdot(H_2O)_6$ (**2**) is generated. The binuclear coordinated motifs are hydrogen-bonded to the lattice water chains to furnish a unique 3D channel-like framework, in which the guest 3-bpo molecules are accommodated. The thermal stabilities of these new materials were investigated by thermogravimetric analysis (TGA) of mass loss. The magnetic coupling in complexes **1**–**3** is antiferromagnetic and very small, which is as expected considering the long organic bridges between the paramagnetic centers. The solid-state luminescence properties of **4** reveal an intense fluorescence emission at 378 nm.

## Introduction

Research on metal-organic supramolecular chemistry has rapidly developed to produce new materials with interesting structural features and potential applications, and is also one of the most active branches in current coordination chemistry.[1,2] By self-assembly of well-designed organic ligands and metal ions under appropriate conditions, a variety of novel metallosupramolecular architectures, such as coordination polymers and host-guest compounds, have been achieved so far.[1,2] Previous reports have revealed that bifunctional building blocks such as dicarboxylate and dipyridine can bind and bridge metal centers well,[3] and to some extent, it is now possible to predict the target materials based on such ligands containing specific structural and functional information. On the other hand, metal-carboxylate complexes are of great interest in several fields including bioinorganic chemistry,[4] molecular magnetism,[5] and crystal engineering.[6]

Nowadays, the combination of two or more predetermined organic building blocks within a structure has proven to be a powerful synthetic approach to generate functional metal-organic frameworks.[2b,7] Succinic acid ($H_2$suc) is an effective linking ligand that has been extensively used, together with 4,4′-bipyridine (bipy), to construct mixed-ligand polymeric arrays such as a 1D chain [Zn(suc)(bipy)],[8a] a 3D open framework $[Cu(suc)(bipy)(H_2O)_2]\cdot 2H_2O$,[8a] a 3D pillar-layered network $[Mn(suc)(bipy)(H_2O)]\cdot 0.5bipy$,[8b] a twofold interpenetrated 3D pillar-layered structure $[Cd(suc)(bipy)]\cdot 0.25H_2O$,[8c] and a unique twisting chiral net $[Co(suc)(bipy)(H_2O)_2]\cdot 2H_2O$.[8d] Recently, a dipyridyl *exo*-bidentate heterocyclic ligand, somewhat structurally similar to bipy but with a bent backbone, 2,5-bis(4-pyridyl)-1,3,4-oxadiazole (4-bpo) and its 3-*N*-donor analog (3-bpo) have been involved considerably in our investigations, and a series of interesting discrete/infinite coordination frameworks[9] and organic cocrystalline materials[10] have been generated utilizing their advantage as linking units with the potential ability for coordination, hydrogen-bonding, and/or aromatic-stacking interactions. As an extension of this research, our current work has been focused on simultaneous employment of such N-donor ligands in cooperation with dicarboxylates to assemble new coordination frameworks.[11] In this context, we describe here the preparation, crystal structures, and properties of the mixed-ligand systems $\{[Cu(suc)(3\text{-bpo})(H_2O)_2]\cdot(H_2O)_{1.75}\}_n$ (**1**), $[Cu(Hfum)_2(3\text{-bpo})(H_2O)]_2\cdot(3\text{-bpo})_2\cdot(H_2O)_6$ (**2**), $\{[Ni(suc)(4\text{-bpo})(H_2O)_2]\cdot(H_2O)_5\}_n$ (**3**), and $\{[Cd_2(suc)_2(3\text{-bpo})_2$-

$(H_2O)_2]\cdot(H_2O)_{6.75}\}_n$ (**4**), where $H_2$fum refers to fumaric acid. Complexes **1**, **3**, and **4** are 2D coordination polymers, while the dinuclear metallacyclophane **2** represents an unusual inclusion compound containing 1D water chains. The magnetic and fluorescence properties of these new materials were also studied.

## Results and Discussion

### Preparation and Thermal Stabilities of Complexes 1–4

Coordination polymers **1** and **4** were obtained by hydrothermal synthesis, and complexes **2** and **3** were prepared under ambient conditions. In the case of **3**, suitable crystals for X-ray diffraction were achieved by diffusion method in order to facilitate the slow growth of larger single crystals. During the preparation of coordination polymers **1**, **3**, and **4**, the pH environments of the reaction systems were adjusted by triethylamine to promote the complete deprotonation of succinic acid. As a consequence, in the resultant crystalline materials, the succinate dianions act as the bridging blocks to extend the 1D metal-bpo arrays to 2D infinite frameworks. Notably, in the dinuclear complex **2** with the unusual 3D inclusion architecture, the fumaric acid is found in its uncommon mono-deprotonation form and adopts the unprecedented terminal coordination mode with copper. This result is probably related to the fact that the reaction system leading to the generation of **2** does not include a sufficiently strong base. Presumably, the level of deprotonation of the dicarboxylic acid is of great relevance to the final structure of **2**. All complexes are air-stable and insoluble in common organic solvents and water, which is consistent with their polymeric and neutral nature. Thermogravimetric experiments were carried out to explore their thermal stabilities. The TGA curve of **1** shows an obvious weight loss of 6.33% in the range of 46–148 °C (peak: 123 °C), corresponding to the release of the lattice water molecules (calculated: 6.68%). The decomposition of the residuary $[Cu(suc)(3\text{-bpo})(H_2O)_2]$ moiety starts at 187 °C, and then there are three consecutive steps of weight losses ending at 396 °C (peaks: 253, 273, and 358 °C). Further heating to 800 °C reveals no weight loss. Complex **2** remains intact until heating to ca. 100 °C, and then there are three consecutive steps of weight losses (peaks: 182, 260, and 282 °C) concluding at 370 °C. Further heating to 800 °C reveals a continuous and slow weight loss. The TGA curve of **3** suggests that the first weight loss of 17.88% in the range 110–159 °C (peak: 133 °C) corresponds to the expulsion of the lattice water molecules (calculated: 17.14%). Then the coordination framework starts to decompose beyond 195 °C with a series of complicated weight losses, and does not end until heating to 800 °C. For complex **4**, the first step of weight loss (15.59%) in the 62–122 °C range correlates to the elimination of coordinated and lattice water molecules (calculated: 14.82%). The remaining substance does not lose weight upon further heating until two consecutive weight losses (peaks: 276 and 422 °C) occur in the temperature range of 196–478 °C. Further heating to 800 °C reveals no weight loss.

### Structural Analysis of Complexes 1–4

#### *{[Cu(suc)(3-bpo)(H$_2$O)$_2$]·(H$_2$O)$_{1.75}$}$_n$ (1)*

Single-crystal X-ray diffraction analysis reveals that complex **1** is a 2D metal-organic coordination network in which the metal centers are linked by bidentate $suc^{2-}$ and 3-bpo ligands. Each $Cu^{II}$ atom, located at an inversion center, has an octahedral geometry by virtue of two $suc^{2-}$ oxygen atoms, two 3-bpo nitrogen atoms, and two aqua ligands [Figure 1 (a)], and as expected, the geometry shows Jahn–Teller elongation with two $Cu–O_{water}$ bond distances

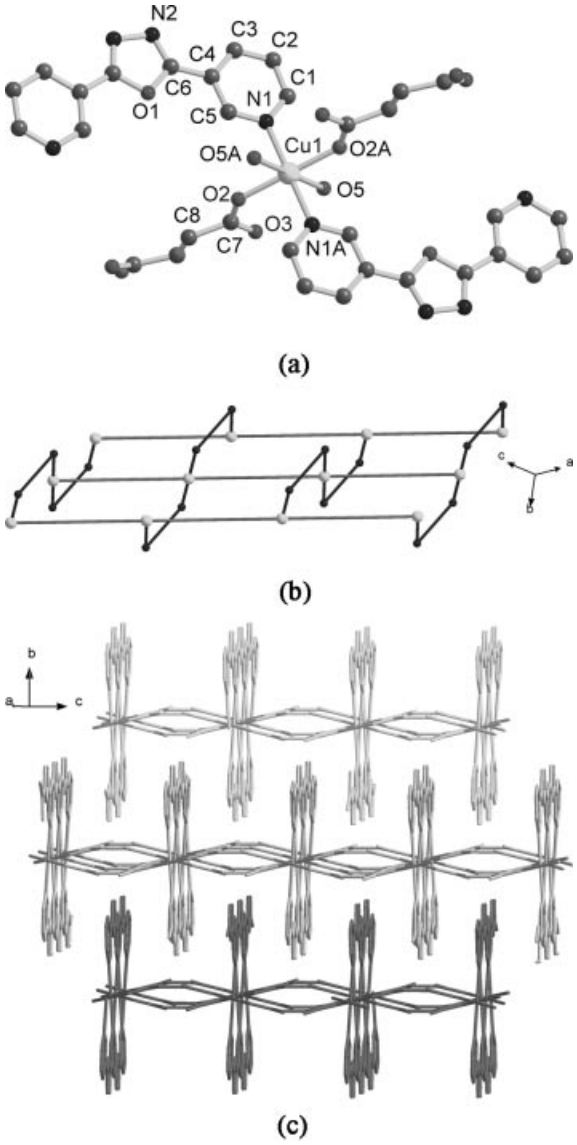

Figure 1. (a) A portion view of **1** with atom labeling of the asymmetric unit and the coordination sphere of copper (all hydrogen atoms are omitted for clarity). (b) A perspective view of the 2D $Cu^{II}$ network with mixed ligands $suc^{2-}$ and 3-bpo, which are simplified as rods and flexuous motifs, respectively. (c) A packing diagram of **1** showing the interdigitation of the 2D networks.

[2.621(7) Å] being significantly longer than those of the other four Cu–O/Cu–N bond lengths [1.947(2)/2.030(3) Å]. The carboxylate group is binding to copper through O(2) in a monodentate fashion, resulting in a longer bond length of C(7)–O(2) than that of C(7)–O(3). Detailed bond parameters are listed in Table 1. Both 3-bpo and $suc^{2-}$ bridging components adopt a *trans* arrangement around copper. As depicted in Figure 1 (b), the 3-bpo molecules connect the $Cu^{II}$ ions to produce a 1D sinusoidal chain, and a similar motif is also observed in $\{[Cu_2(3\text{-bpo})_2(H_2O)_6(SO_4)_2](H_2O)_6\}_n$.[9b] The adjacent chains are arranged in an A(-A) A(-A) sequence and are further interlinked by $suc^{2-}$ ligands in a *trans* bi-monodentate manner to generate a 2D (4,4) network. The distances between the $Cu^{II}$ centers separated by 3-bpo and $suc^{2-}$ are 8.302(3) and 9.499(2) Å, respectively. There also exist intralayer O–H···O hydrogen bonds [O(5)–H(5A)···O(3), H···O and O···O distances: 1.87 and 2.726(4) Å, O–H···O angle: 164°; O(5)–H(5B)···O(3)$^{i}$ (i = $-x + 3/2, -y + 1/2, -z + 1$), H···O and O···O distances: 2.06 and 2.904(5) Å; O–H···O angle: 158°], which further stabilize this framework.

Table 1. Selected bond lengths [Å] and angles [°] for complex **1**.[a]

| Bond lengths | | | |
|---|---|---|---|
| Cu(1)–O(2) | 1.947(2) | Cu(1)–N(1) | 2.030(3) |
| Cu(1)–O(5) | 2.621(7) | O(2)–C(7) | 1.277(4) |
| O(3)–C(7) | 1.231(4) | | |
| **Bond angles** | | | |
| O(2)–Cu(1)–N(1) | 89.29(10) | O(2)–Cu(1)–N(1A) | 90.71(10) |
| O(2)–Cu(1)–O(5) | 81.51(10) | O(2)–Cu(1)–O(5A) | 98.49(10) |
| N(1)–Cu(1)–O(5A) | 87.89(11) | N(1)–Cu(1)–O(5) | 92.11(11) |

[a] Symmetry codes: A: $-x + 3/2, -y + 1/2, -z$.

The most interesting structural feature of **1** is the packing mode of the 2D networks. As illustrated in Figure 1 (c), the 3-bpo segments lie up and down each 2D sheet, and as a consequence, these 2D arrays are interdigitated with the presence of interlayer π–π stacking interactions between the adjacent 3-bpo molecules. The center-to-center and center-to-plane distances of two antiparallel oxadiazole rings are 4.14 and 3.65 Å, respectively, and those for the pyridyl planes (with a dihedral angle of 4.7°) are 4.15 and 3.70/3.60 Å, respectively. Similar examples with such interdigitation alignment have been documented, which suggest that the stacking interactions can play an important role in extending the structural dimensionality of metallosupramolecular networks.[12]

### *[Cu(Hfum)$_2$(3-bpo)(H$_2$O)]$_2$·(3-bpo)$_2$·(H$_2$O)$_6$ (2)*

When succinic acid was replaced by the more rigid fumaric acid under different reaction conditions, a distinct complex **2** was produced. It consists of a centrosymmetrical binuclear unit $[Cu(Hfum)_2(3\text{-bpo})(H_2O)]_2$, two 3-bpo guests, and lattice water molecules. As shown in Figure 2 (a), in the binuclear entity, each $Cu^{II}$ atom is in a distorted square-pyramidal geometry with a $\tau$ parameter of 0.244.[13] Two 3-bpo nitrogen atoms and two carboxylate oxygen atoms of $Hfum^-$ occupy the basal plane, and a water ligand is located at the axial position with a significantly longer Cu–O bond distance of 2.219(3) Å. Selected bond lengths and angles for **2** are listed in Table 2. The two Cu atoms are linked by a pair of 3-bpo molecules to afford a bimetallic ring motif with an intramolecular Cu···Cu distance of 8.385(3) Å. Similar bimetallic macrocycles $[Cu_2(3\text{-bpo})_2(H_2O)_6](ClO_4)_4(H_2O)_4$ and $[Cu(3\text{-bpo})(NO_3)_2]_2(CH_3CN)_2$ were reported recently.[9b] Remarkably, the mono-deprotonated fumaric acid moieties coordinate to $Cu^{II}$ in a unidentate fashion and locate above and below the metallocycle plane. In most documented cases, fumaric acid serves as a dianionic fum bridge using both carboxylate groups,[14] and thus such a unidentate coordination mode of $Hfum^-$ and/or $fum^{2-}$ is quite unique.[15,16] In this structure, as expected, the C–O bonds of the carboxylate groups binding to copper

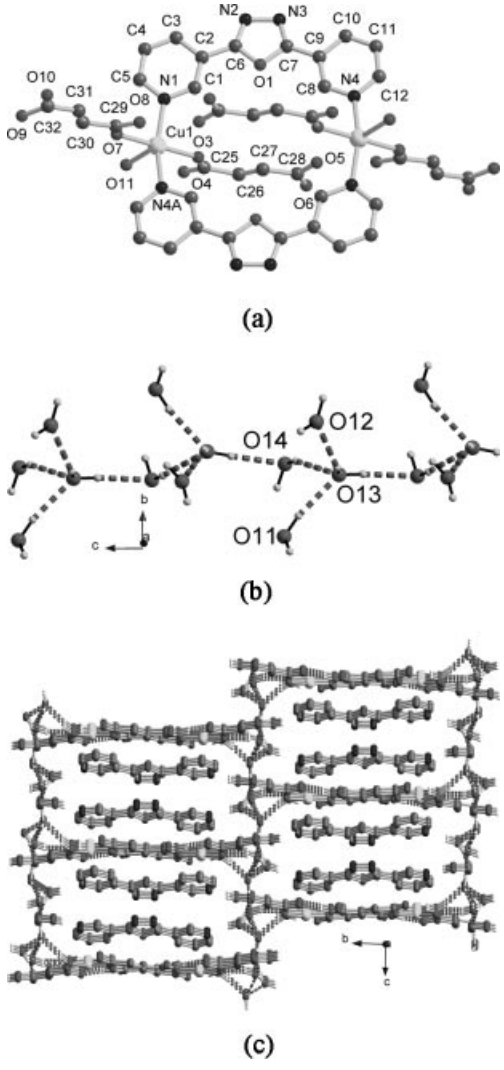

Figure 2. (a) Bimetallic macrocycle of **2** with atom labeling of the asymmetric unit and the coordination sphere of copper (all hydrogen atoms, guest 3-bpo, and lattice water molecules are omitted for clarity). (b) A representation of the 1D water chain linked by water-water interactions. (c) A perspective view of the 3D channel-like hydrogen-bonded network with the accommodation of guest 3-bpo molecules.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

have longer lengths than those of the carboxylate groups not binding to copper, and the C–O bonds connecting with the hydrogen atoms of the carboxyl groups are also significant longer (see Table 2 for details). Another unique structural feature of **2** is that the 3-bpo molecules adopt the different *cisoid*-I and *cisoid*-II conformations[9a,17] when present as the bridging ligand and free guest molecule, respectively.

Table 2. Selected bond lengths [Å] and angles [°] for complex **2**.[a]

| Bond lengths | | | |
|---|---|---|---|
| Cu(1)–O(3) | 1.935(3) | Cu(1)–O(7) | 1.966(3) |
| Cu(1)–O(11) | 2.219(3) | Cu(1)–N(1) | 2.043(4) |
| Cu(1)–N(4A) | 2.034(4) | O(3)–C(25) | 1.263(5) |

[a] Symmetry codes: A: $-x$, $1-y$, $1-z$.

Interestingly, the O(14)–H(14B)···O(13) and O(13)–H(13B)···O(14) hydrogen bonds between the lattice water molecules result in the formation of a 1D water chain along the *c* axis [see Figure 2 (b)], around which the lattice O(12) and coordinated O(11) water molecules are fixed by additional O(13)–H(13A)···O(12) and O(11)–H(11B)···O(13) interactions. Detailed hydrogen-bonding geometries are listed in Table 3. The binuclear subunits and the water chains are extended to a 2D layered structure along the crystallographic (011) plane by O(14)–H(14A)···O(7) and above water–water [O(11)···O(13)] interactions, and the structure is also stabilized by the O(11)–H(11A)···O(4) and O(5)–H(5)···O(8) bonds within each binuclear macrocycle. As shown in Figure 2 (c), these 2D arrays are further linked to afford a 3D channel-like network by interlayer O(12)–H(12B)···O(10) interactions, among which the guest 3-bpo entities are accommodated. Hydrogen-bonding interactions such as O(9)–H(9)···N(5) and O(12)–H(12A)···N(8) can be detected between the guest molecules and the host framework. Additionally, significant π–π stacking interactions exist between the adjacent 3-bpo moieties of the dimeric units within each 2D hydrogen-bonded layer, as well as between the neighboring guest 3-bpo molecules located in the cavities, with center-to-center and center-to-face separations of the aromatic rings in the range of 3.27–4.01 and 3.26–3.57 Å, respectively. Presumably, these supramolecular forces could consolidate this interesting host-guest inclusion system.

The significant structural difference between complexes **1** and **2** may be attributed to the intrinsic structural features of the $suc^{2-}$ and $Hfum^{-}$ ligands. We have clearly demonstrated that the structures of $Cu^{II}$ complexes with 3-bpo are solely dependent on the nature of the inorganic counteranions (for example, $ClO_4^-$, $NO_3^-$, $SO_4^{2-}$, and $OAc^-$),[9b] which afford two types of coordinated motifs such as the 1D sinusoidal chain and binuclear macrocycle (being similar to the cases of **1** and **2**, respectively) when 3-bpo takes the *cisoid*-I conformation. In this work, we can extend this conclusion to organic anions, which are also critical in determining the molecular assembly of the resultant polymeric networks.

### *{[Ni(suc)(4-bpo)(H$_2$O)$_2$]·(H$_2$O)$_5$}$_n$ (3)*

The 2D-layered polymeric network of complex **3** was revealed by X-ray single-crystal diffraction determination. As illustrated in Figure 3 (a), each $Ni^{II}$ center lies on an inversion site and is six-coordinate by binding to a pair of unidentate $suc^{2-}$ ligands, two aqua molecules, and two 4-bpo nitrogen atoms. Important bond lengths and angles are listed in Table 4. Two C–O bond lengths of the monodentate carboxylate group are similar, probably a result of the formation of hydrogen bonds as described later. The octahedral $Ni^{II}$ atoms are interconnected by 4-bpo ligands to afford a wavelike 1D chain running along the crystallographic [010] direction. Adjacent chains are further held together by *trans* bis-monodentate suc dianions, leading to the generation of a 2D undulating (4,4) layer, with the dimensions of the rectangle grid unit of $13.756(1)\times 8.934(1)$ Å$^2$ [see Figure 3 (b)]. As illustrated in Figure 3 (c), intralayer O(4)–H(4B)···O(3)$^{i}$ (i = $-x$, $-y+1$, $-z+1$) and interlayer O(4)–H(4A)···O(3)$^{ii}$ (ii = $-x+1/2$, $-y+1$, $z-1/2$) interactions between the aqua ligands and uncoordinated carboxylate oxygen atoms are observed.

Table 3. Hydrogen bond geometries in the crystal structure of complex **2**.

| D–H···A | D···A [Å] | H···A [Å] | D–H···A [°] | Symmetry codes |
|---|---|---|---|---|
| O(5)–H(5)···O(8) | 2.555(5) | 1.74 | 176 | $-x$, $-y+1$, $-z+1$ |
| O(9)–H(9)···N(5) | 2.627(5) | 1.81 | 171 | |
| O(11)–H(11A)···O(4) | 2.679(5) | 1.86 | 162 | |
| O(11)–H(11B)···O(13) | 2.796(6) | 1.96 | 169 | $x-1$, $y$, $z$ |
| O(12)–H(12A)···N(8) | 2.863(6) | 2.02 | 173 | $-x+1$, $-y+2$, $-z+1$ |
| O(12)–H(12B)···O(10) | 2.967(8) | 2.15 | 160 | |
| O(13)–H(13A)···O(12) | 2.697(7) | 1.99 | 140 | |
| O(13)–H(13B)···O(14) | 2.803(7) | 1.96 | 175 | $x$, $-y+3/2$, $z+1/2$ |
| O(14)–H(14A)···O(7) | 2.864(5) | 2.04 | 164 | $x+1$, $y$, $z$ |
| O(14)–H(14B)···O(13) | 2.815(6) | 2.04 | 152 | |

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

These afford two types of 6-membered and 13-membered hydrogen-bonded rings, with H···O/O···O distances of 1.85/2.659(4) and 1.87/2.711(4) Å, respectively, and O–H···O angles of 159 and 170°, respectively. Further analysis of the crystal packing indicates that these 2D waved layers take the parallel stacking mode with some offset, and are further linked to afford a 3D network by interlayer hydrogen bonds as stated earlier. Notably, allowing for the volume of the included disordered water molecules in this 3D open framework, there still remains 190.0 $Å^3$ of void space in the unit cell.[18]

### *{[$Cd_2$(suc)$_2$(3-bpo)$_2$($H_2O$)$_2$]·($H_2O$)$_{6.75}$}$_n$ (4)*

Complex **4** is also a 2D network, constructed from $Cd^{II}$ and the mixed bridging ligands $suc^{2-}$ and 3-bpo. The local coordination environments around two crystallographically independent $Cd^{II}$ centers are similar, and can be best described as a pentagonal-bipyramidal geometry ($CdN_2O_5$). The equatorial plane is composed of two chelating carboxylate groups from a pair of $suc^{2-}$ ligands and one oxygen-donor aqua ligand [Cd–O: 2.259(6)–2.485(6) Å], and the axial positions are occupied by two 3-bpo nitrogen atoms [Cd–N: 2.345(8)–2.382(8) Å], as shown in Figure 4 (a). Important bonds lengths and angles are listed in Table 5. Most of the C–O bond lengths of the carboxylate groups are nearly equivalent as a result of their chelated coordination. Similar to the structure of complex **1**, the $Cd^{II}$ ions are connected by 3-bpo and $suc^{2-}$ ligands to furnish a 2D framework with common (4,4) topology [see Figure 4 (b)], and these 2D motifs interdigitate to result in a 3D crystal packing managed by aromatic stacking between 3-bpo moieties [see Figure 4 (c)]. The center-to-center and center-to-face distances between the neighboring 3-bpo molecules are in the range of 3.65–3.78 and 3.35–3.58 Å, respectively. Also, intralayer O(11)–H(11A)···O(4)$^i$ (i = $-x$ + 1, $-y$, $-z$ + 1) and O(12)–H(12B)···O(6) bonds [H···O/O···O distances: 1.95/2.795(9) and 1.89/2.732(8) Å, O–H···O angles: 169 and 172°] can be detected between the aqua ligands and carboxylate groups to further support this structure. However, the arrangement of 3-bpo in **4** is somewhat flexuous, rather than the complanate style as in **1** [see Figure 4 (c)]. This can be attributed to the dissimilar coordination tendency of bpo to $Cu^{II}$ and $Cd^{II}$ metal centers, reflected by the difference in N–M–N angles of 180° for **1** and 168.0(2)/168.1(3)° for **4**.

[a] Symmetry codes: A: $x$ – 1, $y$ + 1, $z$; B: $-x$, $-y$ + 1, $-z$ + 1.

A comparison of the three 2D suc/bpo-bridged coordination polymers **1**, **3**, and **4** also reveals the different alignment fashions of the 1D metal–bpo chains. As described earlier, such polymeric chains array in antiparallel [A(-A) A(-A), for **1**] and parallel [AAAA, for **3**] sequences in the resultant 2D networks by further linkage of suc dianions. However, the 1D structures take an A(-A)(-A′)A′ manner in the 2D framework of **4** [see Figure 4 (b)], due to its lower crystallographic symmetry.

### Magnetic Properties of Complexes 1–3

The magnetic properties of **1** are shown in Figure 5 (a). The $\chi_M T$ value ($\chi_M$ is the molar magnetic susceptibility for one $Cu^{II}$ ion) at 300 K is 0.40 $cm^3 mol^{-1} K$, which is as expected for one magnetically quasi-isolated spin doublet ($g > 2.00$). Starting from room temperature, $\chi_M T$ values smoothly decrease to 50 K and then quickly decrease to 0.09 $cm^3 mol^{-1} K$ at 2 K. The overall trend is characteristic of weak antiferromagnetic interactions. The reduced molar

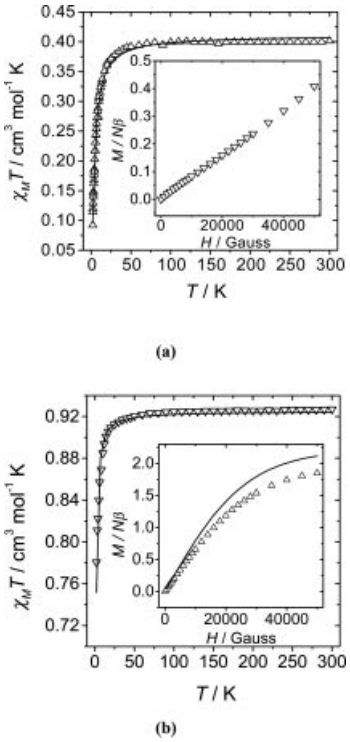

Figure 5. Plot of $\chi_M T$ vs. $T$ for (a) complex **1** and (b) complex **2**. Solid line represents the best fit. Inset: Plot of the reduced magnetization ($M/N\beta$) at 2 K for (a) complex **1** and (b) complex **2** (solid line represents the Brillouin function for $g$ = 2.22).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

magnetization at 2 K [see inset in Figure 5 (a)] clearly indicates that the antiferromagnetic coupling is not negligible. The $M/N\beta$ value at 5 T is close to 0.5 electrons and the shape of the curve does not follow the Brillouin law.

Complex **1** is actually a 2D entity in which the $Cu^{II}$ ions are linked by $suc^{2-}$ and 3-bpo ligands. Both ligands are very long, and thus a small antiferromagnetic coupling is expected. Layers can be considered as pseudoquadratic. Considering these structural features, we have fitted the susceptibility data by the expression given by Rushbrooke and Wood for a Heisenberg square-planar system.[19] The expression was deduced by taking into account the $S = ½$ value for the $Cu^{II}$ ion, based on the spin Hamiltonian $H = -2J\Sigma_{ij}S_iS_j$.

$$\chi_M T = \frac{Ng^2\beta^2}{4k}\left[1-\frac{2}{x}+\frac{2}{x^2}-\frac{1.333}{x^3}+\frac{0.25}{x^4}+\frac{0.4833}{x^5}+\frac{0.003797}{x^6}\right]^{-1}$$

In this expression $x = kT/J$, and $N$, $\beta$, and $k$ have the usual meanings. The values obtained for the exchange parameters are $J = -1.06 \pm 0.01$ cm$^{-1}$, $g = 2.10 \pm 0.01$, and $R = 4 \times 10^{-5}$ ($R$ is the agreement factor defined as $\Sigma_i[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2/\Sigma[(\chi_M T)_{obs}]^2$ in this and the subsequent cases). This small $J$ value can be interpreted as a consequence of the weak overlap between the $Cu^{II}$ ions through the long organic ligands.

The magnetic properties of **2** as a $\chi_M T$ versus $T$ plot ($\chi_M$ is the molar magnetic susceptibility for two $Cu^{II}$ ions) and the reduced magnetization ($M/N\beta$ versus $H$, inset) are shown in Figure 5 (b). The value of $\chi_M T$ at 300 K is 0.93 cm$^3$ mol$^{-1}$ K, which is as expected for two isolated $Cu^{II}$ ions without coupling ($g > 2.00$). Starting from room temperature, $\chi_M T$ values are practically constant to 50 K, and below 50 K they quickly decrease to 0.78 cm$^3$ mol$^{-1}$ K at 2 K. This feature is characteristic of very weak antiferromagnetic interactions between the $Cu^{II}$ ions, which is also clearly corroborated by the reduced molar magnetization at 2 K. The $M/N\beta$ value at 5 T is close to 1.8 electrons and the curve is below the theoretical Brillouin function for $g = 2.22$. The fit of the susceptibility data of the dinuclear $Cu^{II}$ complex **2** was carried out by application of the Bleaney–Bowers formula.[20] The best-fit parameters obtained are $J = -0.90 \pm 0.01$ cm$^{-1}$, $g = 2.22 \pm 0.01$, and $R = 6.1 \times 10^{-5}$. The small $J$ value can be interpreted as a consequence of the almost nil overlap between the two $Cu^{II}$ ions through the long 3-bpo bridging ligand.[9]

On comparison of the $\chi_M T$ curves for complexes **1** and **2**, it is worth noting their quite different scales [see Figure 5 (a) and (b), respectively]. The $\chi_M T$ range (300–2 K) for **1** is approximately 0.4 to 0.1 cm$^3$ mol$^{-1}$ K, whereas the range for **2** is only 0.93 to 0.78 cm$^3$ mol$^{-1}$ K. This feature corresponds to the different behaviors of the reduced magnetization for both complexes, indicating that the antiferromagnetic coupling is smaller in complex **2**.

The plot of $\chi_M T$ versus $T$ for one $Ni^{II}$ ion (complex **3**) is shown in Figure 6 (a). From room temperature to 50 K, $\chi_M T$ values are constantly close to ca. 1.20 cm$^3$ mol$^{-1}$ K, which is typical for one isolated $Ni^{II}$ ion with $g > 2.00$. There is a small decrease down to 40 K, and then to 0.75 cm$^3$ mol$^{-1}$ K at 2 K, indicating a very small antiferromagnetic coupling or the logical existence of the zero-field splitting (ZFS) of $Ni^{II}$ ions. The plot of the reduced magnetization ($M/N\beta$) for **3** is also shown in the inset in Figure 6 (a). The expected value of reduced magnetization for two unpaired electrons at saturation would be 2.3 (assuming $g = 2.15$, which is the $g$ value obtained from magnetic measurements, see later). The experimental value is close to 1.8 electrons at 2 K and 50000 Gauss. In the same figure we have represented the Brillouin function for $S = 1$ and $g = 2.15$. The experimental data are below the theoretical curve, indicating either the presence of weak antiferromagnetic interactions or, most likely, the signature of single-ion ZFS ($D$) of $Ni^{II}$.

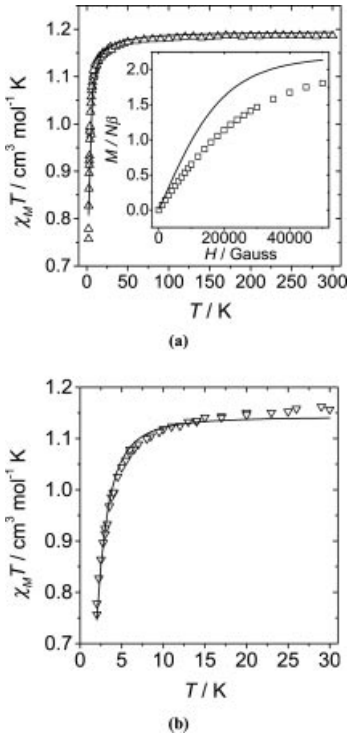

Figure 6. (a) Plot of $\chi_M T$ vs. $T$ for complex **3**. Solid line represents the best fit. Inset: Plot of the reduced magnetization ($M/N\beta$) at 2 K (solid line represents the Brillouin function at 2 K for $g = 2.15$). (b) Plot of the low temperature $\chi_M T$ region, assuming isolated $Ni^{II}$ ions with zero-field splitting ($D$ parameter). Solid line represents the best fit.

The structure of **3** is also a 2D case, which is difficult to fit, mainly due to small $J$ values. Therefore, in the first approach, we can assume that the long 3-bpo ligand does not create any coupling, and thus the small experimental coupling is due to the $suc^{2-}$ ligand. With this hypothesis, we can assume that complex **3** behaves as a 1D system. For systems of this kind, isotropic 1D $S = 1$, the temperature-dependence of the susceptibility extrapolated from calculations performed on ring systems of increasing length has been given by Weng,[21] which is valid only for antiferromagnetic coupling. Neither ZFS nor the Haldane gap effect[22] is taken into account in this expression. The best-fit parameters for **3** are $J = -0.38 \pm 0.01$ cm$^{-1}$, $g = 2.14 \pm 0.01$,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and $R = 2.0 \times 10^{-4}$. As indicated earlier, the small decrease in $\chi_M T$ values from 40 to 2 K could also be attributed to the typical single-ion ZFS for isolated $Ni^{II}$ ions, which is usually very great and of the order of 4–6 $cm^{-1}$.[23] For this reason we have also fitted the low temperature region assuming isolated $Ni^{II}$ ions (without any coupling), applying the formula given by Kahn for this $S = 1$ case.[20] It is important to emphasize that with this method it is only possible to calculate the absolute value of $D$, that is $|D|$, not its sign.[20] With this hypothesis, the best fit was obtained with the parameters $|D| = 3.9\ cm^{-1}$ and $g = 2.14$ [see Figure 6 (b)]. The calculated $D$ value lies in the order of magnitude typical for isolated $Ni^{II}$ ions, as indicated earlier.[23]

As a conclusion, we must emphasize that the two phenomena (small coupling and single-ion ZFS) may be active in this type of nickel complex. It is impossible to separate both components with these standard measurements. In any case, the antiferromagnetic coupling must be very small, as expected for the length of the bridging ligands.

### Luminescence Study of Complex 4

Solid-state luminescence properties of the polymeric $Cd^{II}$ ($d^{10}$ metal) complex **4** with the aromatic ligand 3-bpo were investigated ($\lambda_{ex} = 320$ nm). The free 3-bpo molecule displays an emission maximum at 364 nm, whereas a broad and intense emission band at 378 nm is observed for complex **4**. Hence, the fluorescence wavelength of 3-bpo is considerably affected by the incorporation of metal-coordination interactions. This significant red-shift phenomenon may be assigned to the ligand-to-metal charge transfer (LMCT). The intense fluorescence emission also shows that the coordination polymer **4** could have roles as potential photoactive inorganic-organic hybrid material.

## Conclusions

Three 2D metal-organic coordination polymers and a unique 3D metallosupramolecular inclusion complex have been achieved through self-assembly of metal ions and mixed organic ligands under different conditions. These new crystalline materials also display such useful properties as magnetism and fluorescence. This study clearly indicates that 3-bpo/4-bpo and $suc^{2-}$ ligands could act as excellent bridging spacers to construct programmed coordination polymers, and such a mixed-ligand synthetic strategy may further flourish this attractive chemistry. Further studies of the design and preparation of new metal-organic coordination frameworks with the bent *exo*-dipyridyl building blocks and other organic carboxylic acids (for example, the commonly used terephthalic, trimesic, and pyromellitic acids) are underway in our laboratory.

## Experimental Section

**General Materials and Methods:** All the reagents and solvents for synthesis and analysis were commercially available and used as received, except for 3-bpo and 4-bpo, which were prepared according to literature procedures.[24] FTIR spectra (KBr pellets) were recorded with an AVATAR-370 (Nicolet) spectrometer. Carbon, hydrogen, and nitrogen analyses were performed with a CE-440 (Leemanlabs) analyzer. TGA experiments were carried out with a Dupont thermal analyzer from room temp. to 800 °C under nitrogen at a heating rate of 10 °C/min. Fluorescence spectra were recorded with a Cary Eclipse spectrofluorimeter (Varian) equipped with a xenon lamp and quartz carrier at room temp.

**Magnetic Studies:** The variable-temp. magnetic susceptibilities were measured in the "Servei de Magnetoquímica (Universitat de Barcelona)" on polycrystalline samples (30 mg) with a Quantum Design SQUID MPMS-XL susceptometer, operating in the temp. range of 2–300 K and a magnetic field of 0.1 T. The diamagnetic corrections were evaluated from Pascal's constants for all constituent atoms.

**Syntheses of the Complexes**

**$\{[Cu(suc)(3\text{-bpo})(H_2O)_2]\cdot(H_2O)_{1.75}\}_n$ (1):** A mixture of succinic acid (17.2 mg, 0.15 mmol), $Cu(OAc)_2\cdot H_2O$ (23.5 mg, 0.12 mmol), 3-bpo (26.4 mg, 0.12 mmol), and triethylamine (0.2 mL) in water (10 mL) was sealed in a Teflon-lined stainless steel vessel (20 mL), which was heated at 140 °C for 5 d and then cooled to room temp. at a rate of 5 °C/h. Blue prism crystals were collected in 42% yield (24.0 mg, based on 3-bpo). $C_{16}H_{19.5}CuN_4O_{8.75}$ (471.40): calcd. C 40.76, H 4.17, N 11.88; found C 40.50, H 3.55, N 11.47. IR (KBr): $\tilde{\nu}$ = 3407 (br), 1616 (vs), 1556 (vs), 1482 (s), 1417 (vs), 1390 (vs), 1338 (s), 1284 (m), 1230 (s), 1194 (m), 1127 (m), 1083 (m), 1052 (m), 964 (m), 825 (s), 732 (s), 690 (vs) $cm^{-1}$.

**$[Cu(Hfum)_2(3\text{-bpo})(H_2O)]_2\cdot(3\text{-bpo})_2\cdot(H_2O)_6$ (2):** A mixture of fumaric acid (59.6 mg, 0.51 mmol) and $Cu(OAc)_2\cdot H_2O$ (38.9 mg, 0.19 mmol) in $CH_3OH/H_2O$ (10 mL, v:v = 1:1) was stirred for 10 min and the resultant blue precipitate was filtered. A solution of 3-bpo (23.6 mg, 0.10 mmol) in $CH_3OH$ (10 mL) was added to the filtrate with constant stirring for 30 min and then left to stand at room temp., producing blue block crystals after a period of 1 week in 12% yield (5.1 mg, based on 3-bpo). $C_{64}H_{60}Cu_2N_{16}O_{28}$ (1628.36): calcd. C 47.20, H 3.71, N 13.76; found C 47.42, H 3.84, N 13.72. IR (KBr): $\tilde{\nu}$ = 3432 (s), 3074 (s), 1720 (s), 1600 (vs), 1481 (m), 1413 (s), 1390 (vs), 1330 (s), 1282 (vs), 1251 (s), 1201 (s), 1164 (s), 1081 (m), 1042 (m), 975 (s), 829 (m), 730 (s), 695 (vs), 652 (s) $cm^{-1}$.

**$\{[Ni(suc)(4\text{-bpo})(H_2O)_2]\cdot(H_2O)_5\}_n$ (3):** The pH of a $CH_3OH/H_2O$ (5 mL, v:v = 1:1) solution containing succinic acid (14.5 mg, 0.12 mmol) and $Ni(ClO_4)_2\cdot 6H_2O$ (47.5 mg, 0.13 mmol) was adjusted to 7 with triethylamine. The resultant mixture was then carefully layered onto a buffer of glycol (2 mL), below which a solution of 4-bpo (23.4 mg, 0.11 mmol) in $CHCl_3$ (2 mL) was placed in a straight glass tube. Upon slow evaporation of the solvents over 2 weeks, green lamellar single crystals suitable for X-ray analysis were obtained in 26% yield (15.0 mg, based on 4-bpo). $C_{16}H_{26}N_4NiO_{12}$ (525.12): calcd. C 36.59, H 4.99, N 10.67; found: C 35.98, H 4.07, N 11.15. IR (KBr): $\tilde{\nu}$ = 3100 (br), 1546 (vs), 1489 (s), 1420 (vs), 1278 (w), 1224 (m), 1120 (w), 1063 (m), 1017 (w), 970 (w), 842 (s), 753 (s), 716 (s), 677 (s), 511 (m) $cm^{-1}$.

**$\{[Cd_2(suc)_2(3\text{-bpo})_2(H_2O)_2]\cdot(H_2O)_{6.75}\}_n$ (4):** The same hydrothermal procedure as for **1** was used except that $Cu(OAc)_2\cdot H_2O$ was replaced by $Cd(OAc)_2\cdot 2H_2O$, affording colorless block crystals of **4** in 58% yield (37.2 mg, based on 3-bpo). $C_{32}H_{41.5}Cd_2N_8O_{18.75}$ (1063.03): calcd. C 36.15, H 3.94, N 10.54; found: C 35.55, H 4.04, N 10.04. IR (KBr): $\tilde{\nu}$ = 3412 (br), 1581 (vs), 1548 (s), 1466 (m), 1415 (vs), 1292 (s), 1233 (w), 1192 (m), 1084 (m), 1029 (m), 900 (m), 815 (m), 732 (s), 692 (s), 639 (m) $cm^{-1}$.

***Caution!*** Perchlorate complexes of metal ions in the presence of organic ligands are potentially explosive. Only a small amount of material should be handled and with care.

**X-ray Crystallography:** Single-crystal X-ray diffraction data for complexes **1**–**4** were collected with a Bruker Apex II CCD diffractometer at 293(2) K with Mo-*Kα* radiation ($\lambda$ = 0.71073 Å) by $\omega$ scan mode. There was no evidence of crystal decay during data collection. A semiempirical absorption correction was applied using the SADABS program, and the program SAINT was used for integration of the diffraction profiles.[25] The structures were solved by direct methods using the SHELXS program of the SHELXTL package and refined with SHELXL.[26] The final refinement was performed by full-matrix least-squares methods with anisotropic thermal parameters for all non-hydrogen atoms on $F^2$. Hydrogen atoms bonded to carbon were placed geometrically and allowed to ride during subsequent refinement with an isotropic displacement parameter fixed at 1.2 times $U_{eq}$ of the parent atoms. Hydrogen atoms of the aqua ligands in all structures and the lattice water molecules in **2** were first located in difference Fourier maps, and then placed at calculated positions and included in the final refinement. The lattice water in the structures of **1**, **3**, and **4** were treated using the disordered model and their hydrogen atoms not located. Starting positions for carboxyl hydrogen atoms in the structure of **2** were located in difference syntheses, and refinement was performed using rigid O–H groups allowed to rotate but not tip, with the bond length of 0.82 Å. Further crystallographic data and structure refinement parameters of complexes **1**–**4** are summarized in Table 6.

CCDC-284066 to -284069 (for **1**–**4**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Atmospheric Pressure Chemical Vapour Deposition of $NbSe_2$ Thin Films on Glass

Nicolas D. Boscher,[a] Claire J. Carmalt,[a] and Ivan P. Parkin*[a]

**Keywords:** Chemical vapour deposition / Metal selenide / Thin film

Atmospheric pressure chemical vapour deposition (APCVD) of niobium selenide films on glass substrates was achieved by reaction of di-*tert*-butyl selenide with $NbCl_5$ at 250–600 °C. X-ray diffraction showed that the $NbSe_2$ films were crystalline and of the $2H_a$ poly-type with cell constants close to those expected ($a$ = 3.44 Å; $c$ = 12.58 Å). Marked preferred orientation along either (101) or (200) was noted at higher deposition temperature and this unexpectedly varied depending on distance from the reactor inlet. The films produced at 600 °C showed exactly the Nb/Se ratio expected for $NbSe_2$ by energy dispersive analysis by X-rays. The films deposited at the substrate temperatures of 500 °C or less were selenium rich with a niobium to selenium ratio of 1:2.5. The films produced at 600 °C were dark-green, powdery and poorly adhesive. The films produced at 500 °C and below were dark-brown matte in appearance, they passed the Scotch tape test, but could be scratched with a steel scalpel. SEM showed that the films were composed of plate-like crystals, which become longer and thicker with increasing deposition temperature.

## 1. Introduction

Niobium diselenide ($NbSe_2$) is an important material because of its wide range of interesting physical properties, such as the presence of both a charge density wave transition and a superconducting transition. The structure of this low dimensionality layered material is hexagonal ($P6_{3/mmc}$) and composed of strongly bonded molecular layers stacked in a close-pack manner – with weak van der Waals interactions between the layers – which leads to highly anisotropic properties. Like all the layered group V transition-metal dichalcogenide, $NbSe_2$ has many different crystallographic poly-types, for example $2H_a$-, $2H_b$-, 3R-, $4H_a$-, $4H_{d1}$- and $4H_{d2}$-$NbSe_2$, depending on how the molecular layers stack-up and in turn the specific poly-type determines the physical properties of the materials. The poly-types $2H_a$- or $2H_b$-, and $4H_a$-$NbSe_2$ are superconducting with a transition temperature of $T_c$ = 7.2 K and $T_c$ = 6.3 K, respectively.[1,2] A charge-density wave is present in all the $NbSe_2$ polytypes. Moreover, an incommensurate charge-density wave is present in 2H-$NbSe_2$ below $T_c$ = 33.3 K. Its structure remains incommensurate through the superconducting transition.[3] Even though the phase diagram of the niobium–selenium system is not fully known, many forms of niobium selenide, apart from $NbSe_2$, have been observed, such as $Nb_5Se_4$, $Nb_3Se_4$, $NbSe_2$, $NbSe_3$ and $NbSe_4$.[2,4–6]

Similar to most of the transition-metal dichalcogenides, $NbSe_2$ has been cited for use as an electrical conductor and as a solid lubricant at high temperature. $NbSe_2$ is also a good intercalation host. It has been shown that the growth of hydrogen intercalated in $H_xNbSe_2$ results in changes in the conductivity type from metallic to semiconducting.[7] Therefore, due to this sensitivity to intercalated molecules, niobium diselenide films may, as titanium diselenide films, find application as hosts for sensor materials.

The most common method to grow crystals of $NbSe_2$ is the vapour-phase-transport of prereacted polycrystalline $NbSe_2$ with iodine as a transport agent. $NbSe_2$ thin films have been grown using van der Waals epitaxy (VDWE) and pulsed-laser deposition (PLD).[7,8] To the best of our knowledge a CVD route to $NbSe_2$ has not been reported to date.

Here we present the CVD of $NbSe_2$ thin films. The motivation for this work was to produce niobium selenide films on glass and to use precursors other than $H_2Se$. One interesting feature of this work was the unexpected variation in preferred orientation that was noted depending on the position of analysis on the substrate.

## 2. Results and Discussion

### Synthesis and Characterisation

Atmospheric pressure CVD reactions of $NbCl_5$ with $tBu_2Se$ were studied on glass substrates at 250–650 °C. The deposition was observed on both top plate and substrate. The extent of the film coverage was dependent on the deposition temperature. Only the six first centimetres of the substrate were coated for a deposition temperature of 600 °C,

[a] Department of Chemistry, University College London, 20 Gordon Street London, UK

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

whilst the whole substrate was coated with uniform thickness at 300 °C. This indicates that the deposition is mass-transport-limited at the highest temperature, whereas the deposition is surface-reaction-limited at the lowest temperature. At a deposition temperature of 600 °C, the films produced from $t$Bu$_2$Se and NbCl$_5$ were dark-green and powdery. They failed the Scotch tape test and the scratch test but were insoluble in the common organic solvents, they only slowly decomposed in diluted nitric acid or diluted bleach, and were stable in air for over six months. At a deposition temperature at or below 500 °C, the films had a dark-black matt appearance; they passed the Scotch tape test, but were scratched with a steel scalpel.

Due to the porous nature of the films grown from NbCl$_5$ and $t$Bu$_2$Se at all the different reaction temperatures, the contact-angle measurement for water droplets was exceptionally small less than 10°. The films did not show photo-induced hydrophilic properties. This means that the surface of the niobium selenide films is unlikely to be oxide-terminated as niobium oxide shows a photo-induced reduction in the contact angle. Furthermore, this low contact-angle measurement means that water readily permeates the film and is related to high porosity.

The SEM images for the films deposited at the onset deposition temperature (300 °C) show ca. 0.2 μm plates in a perpendicular orientation to the substrate (Figure 1). The SEM images for the films deposited between 300 and 600 °C show a series of hexagonal platelets, which become longer and thicker with increasing deposition temperature. The average length of the platelets was 0.2 μm for the films deposited at 400 °C, up to 0.6 μm at 600 °C. This change in platelet size can be related to faster growth kinetics and smaller numbers of nucleation sites at the higher temperatures.

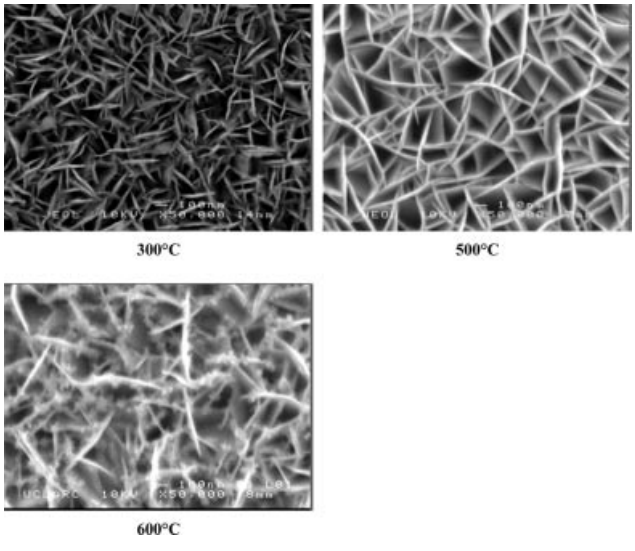

Figure 1. Scanning electron micrographs of the films produced from the APCVD of NbCl$_5$ and $t$Bu$_2$Se at substrate temperatures of 300, 500 °C and 600 °C.

The films produced at a deposition temperature of 600 °C showed exactly the Nb/Se ratio expected for NbSe$_2$ by EDAX [Nb$_{1.00(3)}$Se$_{2.00(3)}$]. No chlorine, carbon or other contamination was found by the EDAX in these films. The films deposited at substrate temperatures below 500 °C were selenium rich with a niobium to selenium ratio of 1:2.5 at 350, 450 and 500 °C. This could indicate the co-formation of NbSe$_3$ or NbSe$_4$ or elemental selenium which would raise the selenium content. No chlorine contamination was found in the films except those produced at the very lowest deposition temperature (300 °C), and then it was at trace levels ca. 1 atom%.

An X-ray photoelectron spectrum of the niobium 3d peak for the film from di-*tert*-butyl selenide and NbCl$_5$ revealed the presence of two different environments in the film (Figure 2). The peaks at 203.2 eV and 205.9 eV can be respectively assigned to the Nb 3d$_{5/2}$ and Nb 3d$_{3/2}$ peaks of the niobium diselenide. The peaks at 207.3 eV and 210.0 eV can be assigned to the Nb 3d$_{5/2}$ and Nb 3d$_{3/2}$ peaks of niobium oxide Nb$_2$O$_5$. This data suggest that the uppermost surface is partially oxidised. The XPS of the selenium 3d peak for the same NbSe$_2$ film shows that there are also three selenium environments present (Figure 3). The peaks at 52.9 eV and 53.8 eV can be respectively assigned to the Se 3d$_{5/2}$ and Se 3d$_{3/2}$ peaks of the niobium diselenide. The doublet peaks at 54.1 eV, 55.0 eV and 54.6 eV, 55.5 eV can be respectively assigned to selenium and selenium dioxide. These assignments are a little tentative because a range of different curve fittings could be employed.

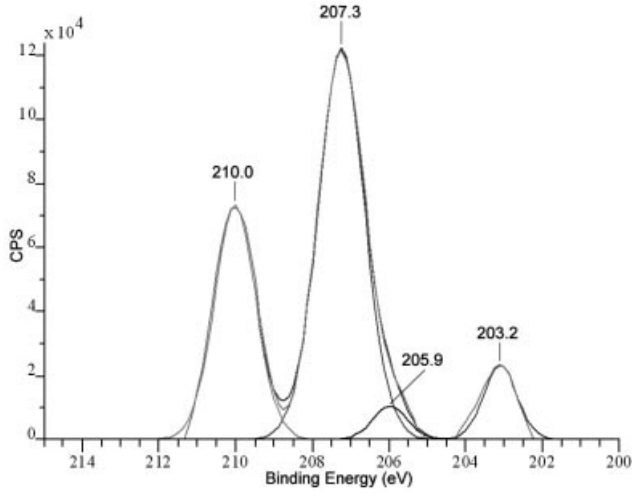

Figure 2. X-ray photoelectron spectrum of the Nb 3d peaks from the surface of a film deposited from the reaction of NbCl$_5$ and $t$Bu$_2$Se at 600 °C.

Glancing-angle X-ray powder diffraction of the films showed that the reflections matched the reference spectrum for 2H$_a$-NbSe$_2$ (JCPDS File No. 018–0923) (Figure 4). The films produced at 600 °C were highly crystalline. Interestingly, measuring the XRD pattern sequentially from the leading edge of the film until the back of the film showed that the preferred orientation became significantly more pronounced with distance from the reactor inlet. The preferential orientation in the first centimeter of the coating from the reactor inlet showed some (101) texturing, al-

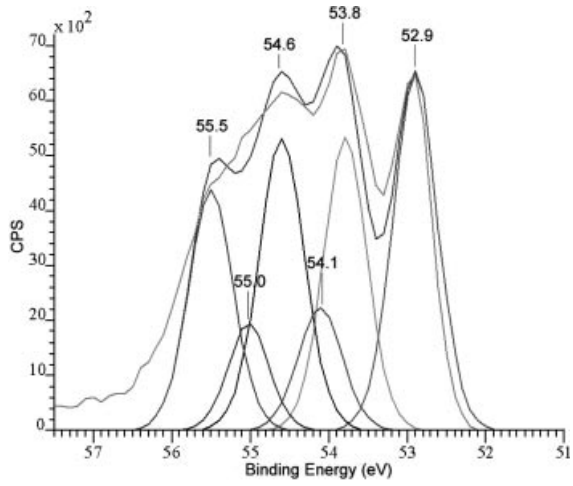

Figure 3. X-ray photoelectron spectrum of the Se 3d peaks from the surface of a film deposited from the reaction of $NbCl_5$ and $tBu_2Se$ at 600 °C. Outermost line is the actual data.

though the diffraction peaks were similar to the intensity stick pattern found in the literature. Very strong preferential growth along the (002) direction was shown in the next centimeter. Notably no preferential orientation was noticed in the films grown at lower substrate temperature. The indexed cell constants found for the films grown at 600 °C, $a$ = 3.44 Å and $c$ = 12.58 Å, compare well with the literature for hexagonal $NbSe_2$ $a$ = 3.44 Å and $c$ = 12.55 Å. The films grown at lower substrate temperatures all matched the literature diffraction patterns for 2H-$NbSe_2$ with the anticipated intensities and peak positions – however a detailed analysis of the cell constants indicated that they all tended to have slightly smaller $a$ values than stoichiometric $NbSe_2$.

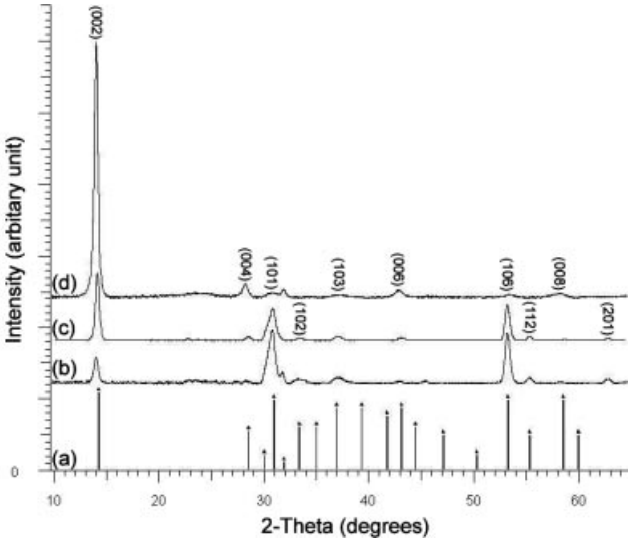

Figure 4. XRD pattern obtained for the film formed on glass from the APCVD of $NbCl_5$ and $tBu_2Se$ at 600 °C [(a) JCPDS reference file; (b) 0.5 cm, (c) 2 cm and (d) 4 cm from the front of the substrate].

Raman analysis of the films produced at 600 °C was identified as the distinctive 2H-$NbSe_2$ Raman pattern from the literature with a wide peak at 180 $cm^{-1}$ and a strong peak at 228 $cm^{-1}$ with a shoulder at 238 $cm^{-1}$ (Figure 5).[9–12] Raman analysis of the films produced at a substrate temperature of 500 °C or below show a similar Raman pattern with two strong bands around 182 $cm^{-1}$ and 245 $cm^{-1}$ and a smaller peak at 310 $cm^{-1}$ (Figure 6). This pattern is different to the one formed at higher temperature, the peaks are broader and an additional peak is seen at 309 $cm^{-1}$.

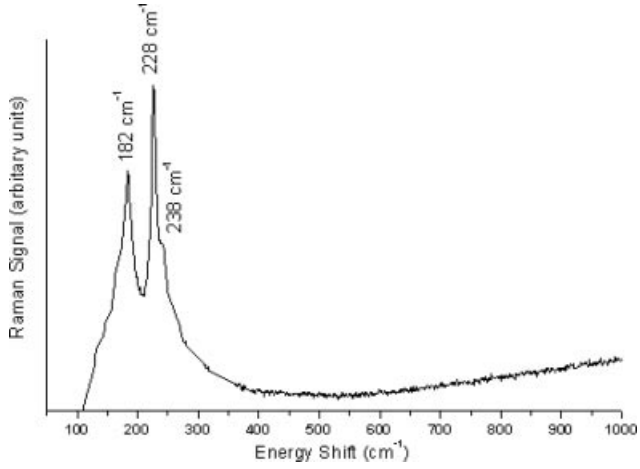

Figure 5. Raman pattern obtained for the film formed on glass from the APCVD of $NbCl_5$ and $tBu_2Se$ at 600 °C.

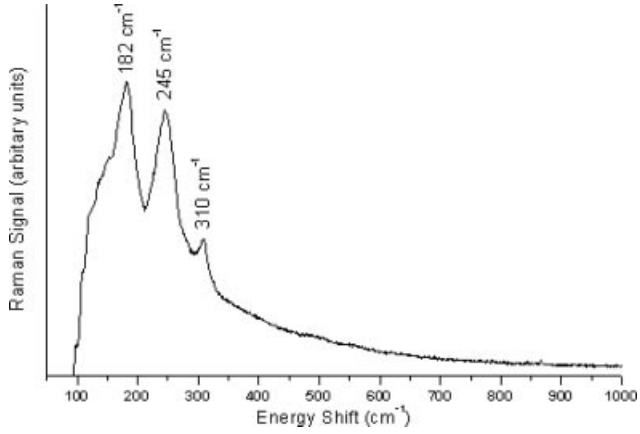

Figure 6. Raman pattern obtained for the film formed on glass from the APCVD of $NbCl_5$ and di-*tert*-butyl selenide at 300 °C.

### Preferred Orientation with Pathlength

The detection of changes in preferred orientation for the $NbSe_2$ thin film grown at 600 °C with deposition position along the substrate is highly unusual for a CVD process. The substrate was made of the same glass along its length and the substrate temperature was independently checked with an external thermocouple at different points on the glass and shown to be uniform. Thus the differences in preferred orientation cannot be attributed to temperature or substrate effects. Notably, the changes in preferred orientation only occurred at the highest deposition temperature and became more noticeable with distance along the sub-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

strate. At 600 °C the deposition was only ca. 6 cm along the substrate, and the reaction had changed over from a surface-reaction-limited regime as seen at 500 °C, to a mass-transport-limited regime. Thus, along the length of the reactor the reaction becomes depleted in precursor. This depletion, therefore, has an effect on the growth of the crystallites – with growth in one particular direction being favoured under more dilute precursor conditions. Additionally, the diffusion effects of reactants and exhaust products through the boundary layer change with position along the reactor. This change over in preferred orientation is in part a consequence of the reactor design. A 'shower head' design reactor where multiple channels of reactants are used perpendicular to the substrate would be unlikely to show this effect.

### A New Superstoichiometric $NbSe_{2+x}$ Phase?

We have previously studied the analogous formation of $NbS_2$ films from the reaction of $NbCl_5$ and $tBu_2Se$ and *tert*-butylthiol.[13] In this case crystalline films were only found at substrate temperature above 500 °C, whereas the films formed in this study were crystalline at 300 °C and above. Furthermore, under some conditions EDX revealed that superstoichiometric $NbS_{2.4}$ was formed. This superstoichiometric material had similar principle Raman bands and intensity distribution (187, 242 and 298 $cm^{-1}$) to those formed in this study for the superstoichiometric $NbSe_2$ films.[14]

The films grown at substrate temperatures of 300–550 °C were all superstoichiometric – $NbSe_{2+x}$ ($x$ = 0.4–0.6) by EDX analysis. X-ray powder diffraction, Raman and spot EDX analysis did not detect any free selenium metal in these films. Furthermore, none of these techniques showed the presence of higher niobium phases such as $NbSe_3$ or $NbSe_4$. No other elements were found in the films – save for a slight surface oxidation (first few nanometres). As the films grown at 300–550 °C were all exceptionally similar if not the same as the 2H-$NbSe_2$ poly-type by X-ray diffraction, with the expected intensity pattern and peak positions, it is logical to assume that the excess selenium is embedded and intercalated within the structure, especially as these are layered structures with van der Waals interactions between neighbouring sheets. These films had a slightly different unit cell size with the *a* and *c* axis slightly smaller than the literature values, the difference is right at the margin for differentiation based on the 3σ criterion. Intuitively though one would expect a large increase in the cell parameters with excess selenium incorporation. A further explanation is that an amorphous phase is present with a higher selenium content that does not show up on the XRD, Raman or XPS analysis; however, given the breadth of analysis completed, this seems unlikely. Interestingly the Raman patterns were quite revealing and supportive of a similar structure type – having a slightly different pattern to that seen for the films grown at 600 °C – which matched exactly the literature pattern for 2H-$NbSe_2$. The Raman pattern of the films made at lower substrate temperatures most closely resembled that seen for our previous CVD studies of $NbS_{2.4}$.[13,14] Hence, the lower-temperature films were consistent with the formation of the 2H-$NbSe_2$ structure with some incorporated selenium. We have not found evidence of any literature reference on this type of material being reported previously.

## 3. Conclusion

Niobium selenide films were deposited on glass from the APCVD reaction of $NbCl_5$ and $tBu_2Se$. Between 300 and 500 °C, the films were crystalline and selenium rich with a niobium to selenium ratio of 1:2.5 at 350, 450 and 500 °C. The films produced at a deposition temperature of 600 °C showed exactly the Nb/Se ratio expected for $NbSe_2$. No chlorine, carbon or other contamination was found by the EDAX in these films. The films produced at 600 °C were highly crystalline with a preferential growth either along (101) or the (002) direction. The preferred orientation effects were more marked with distance from the reactor inlet and suggest that depletion in reagents leads to a slightly altered growth mechanism. The $NbSe_2$ films were stable in air, insoluble in the common organic solvents, and were only slowly decomposed in nitric acid. The films grown at 300–550 °C best fit the $2H_a$-$NbSe_2$ structural type with some excess intercalated selenium.

## 4. Experimental Section

***Caution:*** It should be noted that the CVD of $NbSe_2$ could produce $H_2Se$, which is highly toxic and malodorous. All the experiments should be conducted in a fume cupboard and the gas from the CVD process treated with bleach (with an associated copper sulfate indicator bubbler, to check the bleach is working) to destroy the possible presence of $H_2Se$. After the CVD synthesis the $NbSe_2$ films were treated as air sensitive although subsequent analysis showed that they were indefinitely air stable.

**Chemical Vapour Deposition Studies:** Depositions experiments were carried out under dinitrogen (99.99%) on glass substrates using a horizontal-bed cold-wall APCVD reactor. The glass substrate was a $SiO_2$-precoated (ca. 50 nm thick $SiO_2$ barrier layer) standard float glass (Pilkington, UK) 15 cm × 4 cm × 0.3 cm. The substrate was heated by a graphite block and the nitrogen carrier gas was preheated to 110 °C by being passed along 2 m lengths of coiled stainless-steel tubing inside a tube furnace.

Niobium pentachloride was obtained from Aldrich Chemical Co. and di-*tert*-butyl selenide was supplied by Epichem. They were both used without further purification. The di-*tert*-butyl selenide and $NbCl_5$ were placed into two different stainless-steel bubblers, which were both heated by a jacket. They were both introduced into the gas streams by passing hot $N_2$ through the bubblers. The bubbler temperatures and flow rates were kept constant to 90 °C and 0.5 L·$min^{-1}$ (67.4 mmol·$min^{-1}$) for the $tBu_2Se$ bubbler and to 210 °C and 2.0 L· $min^{-1}$ (47.8 mmol·$min^{-1}$) for the niobium pentachloride bubbler (Table 1). The flow rate through the mixing chamber was between 1.9 and 4.6 L·$min^{-1}$ for all depositions.

Table 1. EDAX, Raman and X-ray diffraction data for the films produced by APCVD reaction of $tBu_2Se$ with $NbCl_5$.

| Deposition temperature | XRD (lattice constant in Å+/– 0.01 Å) | Raman | EDAX |
|---|---|---|---|
| 250 °C | – | – | No film |
| 300 °C | 2H-$NbSe_2$; $a$ = 3.36, $c$ = 12.47 | 182 + 245 + 310 | $NbSe_{2.4}$ |
| 350 °C | 2H-$NbSe_2$; $a$ = 3.37, $c$ = 12.59 | 183 + 248 + 309 | $NbSe_{2.5}$ |
| 400 °C | 2H-$NbSe_2$; $a$ = 3.42, $c$ = 12.56 | 184 + 248 + 310 | $NbSe_{2.6}$ |
| 450 °C | 2H-$NbSe_2$; $a$ = 3.36, $c$ = 12.63 | 183 + 247 + 309 | $NbSe_{2.5}$ |
| 500 °C | 2H-$NbSe_2$; $a$ = 3.41, $c$ = 12.63 | 183 + 246 + 309 | $NbSe_{2.5}$ |
| 600 °C | 2H-$NbSe_2$; $a$ = 3.44, $c$ = 12.58 | 2H-$NbSe_2$ | $NbSe_2$ |

The reaction of $tBu_2Se$ and $NbCl_5$ was studied in the temperature range from 250–600 °C. The deposition time for all experiments was 1 min. At the end of the deposition, the bubbler line was closed and the substrate was cooled under nitrogen in the reactor. Then the substrates were handled briefly in air before storage under dry, oxygen-free nitrogen in a glove box. Analyses were performed for each sample on a 2 cm × 4 cm band cut 2 cm from the front of the substrate.

**Film Analysis:** X-ray diffraction patterns were measured with a Bruker X-pert diffractometer using monochromated Cu-$K_{\alpha 1}$ radiation ($K_{\alpha 1}$ = 1.5406 Å). The system had a focus and movable $x$-$y$ stage to analyse various portions of the film. The diffractometer used glancing incident radiation (1.5°). The samples were indexed using unit cell and compared to database standards. EDAX was obtained with a Philips XL30ESEM instrument and SEM was obtained with a JEOL 6301 instrument. UV/Vis-NIR spectra were recorded in the range 190–1100 nm using a Helios double-beam instrument. Reflectance and transmission spectra were recorded between 300 and 1200 nm with a Zeiss miniature spectrometer. Reflectance measurements were standardised relative to a rhodium mirror and transmission relative to air. Raman spectra were acquired with a Renishaw Raman System 1000 using a helium-neon laser of wavelength 632.8 nm. The Raman system was calibrated against the emission lines of neon. X-ray photoelectron spectroscopy was undertaken with a VG ESCALAB 220I XL instrument with focussed (300 μm spot) monochromatic Al-$K_\alpha$ radiation at a pass energy of 20 eV. Scans were acquired with steps of 50 meV. A flood gun was used to control charging. Binding energies were referenced to an adventitious C 1s peak at 284.6 eV (this peak is due to residual pump oil used in the XPS high vacuum system- but is removed on the first argon ion etching). Argon sputtering was used for approximately 1 minute in a rastering mode in order to remove surface contamination.

## Acknowledgments

Dr. G. Reid, Prof. W. Levason and Dr. A. Hector are thanked for useful discussions on related projects. The EPSRC is thanked for financial support.

# Counteranion-Induced Formation of *cis* and *trans* Singly and Doubly $H_2$biim-Bridged Di-, Hexa-, and Polymeric Ag–$H_2$biim Complexes

**Rui-Li Sang[a] and Li Xu*[a]**

**Keywords:** Crystal engineering / Luminescence / Metal–metal interactions / N ligands / Silver

A series of *cis* and *trans* singly and doubly $H_2$biim-bridged di-, hexa-, and polymeric complexes of silver(I) ($H_2$biim = 2,2′-biimidazole), namely $[Ag_2(\mu\text{-}H_2biim)_2]SO_4\cdot 2H_2O$ (**1**), $[Ag_2(\mu\text{-}H_2biim)_2(\mu\text{-ox})]_n$ (**2**), $[Ag_6(\mu\text{-}H_2biim)_5(H_2biim)_2](ClO_4)_4(CH_3CO_2)_2\cdot 2H_2O$ (**3**), and $[Ag(\mu\text{-}H_2biim)(nicotinate)]_n$ (**4**) have been synthesized and characterized by X-ray crystallography and IR and photoluminescence spectroscopy. The structural topology of the Ag–$H_2$biim system is determined by the charge of the counteranions. Thus, dianionic counterions facilitate the formation of dimeric structures driven by the charge-balance requirement, whereas a monoanionic counterion favors the formation of helical structures. Counteranions of larger size lead to either finite helical structures or a *trans* arrangement of the coordinating nitrogen atoms because of steric requirements. Organic counteranions with a strong coordination ability bind to the $Ag^+$ ions while inorganic counteranions are uncoordinated. The argentophilic attraction is not dominant in this system. Examination of the luminescent properties of $H_2$biim and compounds **1**–**4** indicates that the fluorescence emission of $H_2$biim is effectively shifted upon metal coordination.

## Introduction

The substitution reaction is one of the most important chemical reactions and is widely employed in the preparation of new chemical materials, especially supramolecular polymer materials. The general strategy is to use multifunctional organic ligands to replace inorganic ligands of simple starting metal complexes to build functional supramolecular architectures.[1–3] Crystal formation depends on many factors, including metal–ligand, metal–metal, ligand–ligands, hydrogen bonding, and π stacking interactions. Covalent metal–ligand interactions are the strongest and thus dominate crystal formation. Interactions between open metal ions, known as metal–metal bonds, are comparable in strength to metal–ligand bonds and are the driving force in the formation of metal clusters. However, interactions between closed metal ions, typically coinage ones, which are intermetallic attraction in nature,[4,5] are comparable to hydrogen bonds in strength. Thus, the aggregation of closed metal ions is flexible and depends on other factors, such as weak interactions and charge balance. Although metal coordination requirements are dominant in the global architecture, other auxiliary factors such as charge balance and weak, noncovalent requirements play a significant role due to the multiple bonding modes of the ligand and the variety of geometries available for some metal ions. Many metal complexes, especially those with neutral ligands, appear as cationic species and thus anionic counterparts are usually present for charge balance. The role of these counteranions has been the subject of several reports.[6–8] Recent research results have indicated that the coordinating ability, shape, and size of counteranions have a significant influence on the global structures through either metal coordination or crystal-packing effects when noncoordinated.[7,8] In the present work, we will describe the Ag–$H_2$biim system with various counteranions of different charge, size, and coordinating ability to compare their competitive power. $Ag^+$ is an appropriate probe as it has varied coordination geometries and is able to aggregate through argentophilic attractions.[6,7] 2,2′-Biimidazole is an evergreen ligand that has attracted constant interest in supramolecular chemistry,[9] biochemistry,[10] cluster science,[11] and antitumor drugs.[12] The Ag–$H_2$biim system is able to adopt multiple coordinating modes and a variety of geometries, and can thus serve as a probe to examine the role of the above counteranion characteristics in crystal-structure formation. Four new supramolecular complexes, namely $[Ag_2(\mu\text{-}H_2biim)_2]SO_4\cdot 2H_2O$ (**1**), $[Ag_2(\mu\text{-}H_2biim)_2(\mu\text{-ox})]_n$ (**2**), $[Ag_6(\mu\text{-}H_2biim)_5(H_2biim)_2](ClO_4)_4(CH_3CO_2)_2\cdot 4H_2O$ (**3**), and $[Ag(\mu\text{-}H_2biim)(nicotinate)]_n$ (**4**) have been synthesized and characterized and the influences of the competing counteranion characteristics (charge, coordinating ability, and size) in the crystal-structure formation will be discussed.

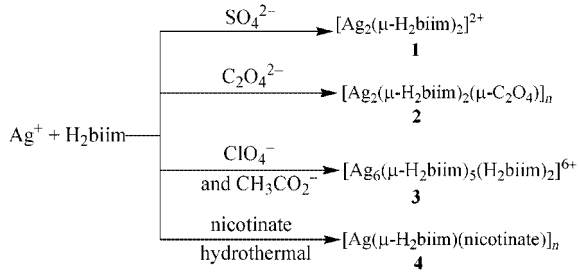
## Results and Discussion

### Syntheses of the Complexes

The syntheses of complexes **1**–**4** are summarized in Scheme 1. It is obvious that the complexation of $Ag^+$ and $H_2$biim depends on the charge, size, and coordination ability of the counteranions: organic counteranions of strong coordination ability, such as oxalate and nicotinate, become coordinated to produce the neutral reaction products **2** and **4**, whereas inorganic counteranions, such as $ClO_4^{2-}$ and $SO_4^{2-}$, are uncoordinated, yielding charged, polynuclear Ag–$H_2$biim complexes. It seems that dianionic counterions facilitate the formation of dimeric structures, presumably as a consequence of the charge-balance requirement, as suggested by the formation of the dimers **1** and **2**. In contrast, monoanionic counterions tend to favor the formation of helical structures, as suggested by **3**, **4**, and the previously reported complex $[Ag(\mu\text{-}H_2biim)]NO_3$.[10b] The use of larger $ClO_4^-$ instead of $NO_3^-$ leads to the formation of the finite helical complex **3**.



Scheme 1. Syntheses of compounds **1**–**4**.

### Crystal Structures

#### *$[Ag_2(\mu\text{-}H_2biim)_2]SO_4{\cdot}2H_2O$ (1)*

The structure of the dicationic dimer of **1** is given in Figure 1 (a). The two Ag atoms are doubly bridged by $H_2$biim, forming a dicationic dimeric structure. Such a dimeric structure facilitates the charge balance through an alternating arrangement of the dimer and $SO_4^{2-}$ in the resulting infinite chain (Figure 1, b). Each $Ag^+$ ion is coordinated to the two nitrogen atoms from the different $H_2$biim moieties [Ag–N1 = 2.149(6), Ag–N3 = 2.130(5) Å] in an almost linear arrangement [N1–Ag–N3 = 170.6(2)°] as in the case of $[\{Ru(pap)_2(Biim)\}_2Ag_2](ClO_4)_2$ (179°)[5a] and $[Ag_2(napy)_2](ClO_4)_2$ (168°).[5d] The distance between the two Ag atoms is 2.818(1) Å, slightly shorter than in the doubly bridged $[\{Ru(pap)_2(Biim)\}_2Ag_2](ClO_4)_2$ [2.890(2) Å],[5a] $[Ag_2(dpim)_2(CH_3CN)_2](ClO_4)_2$ [2.9932(9) Å],[5b] and $[Ag_2(Ph_2PCH_2SPh)_2](ClO_4)_2$ [2.9501(8) and 2.9732(9) Å][5c] but comparable to that in $[Ag_2(napy)_2](ClO_4)_2$[5d] [2.748(2) Å]. The $H_2$biim ligands are slightly twisted, with a dihedral angle of 14.6°. The two biimidazole ligands are nearly perpendicular to each other (the angle between their least-squares planes is 77.1°). The two neighboring $[Ag_2(H_2biim)_2]^{2+}$ units are linked together by weak Ag···$O_{sulfate}$ interactions into a one-dimensional chain with a pitch of 10.32 Å running along the *c* axis (Figure 1, b).

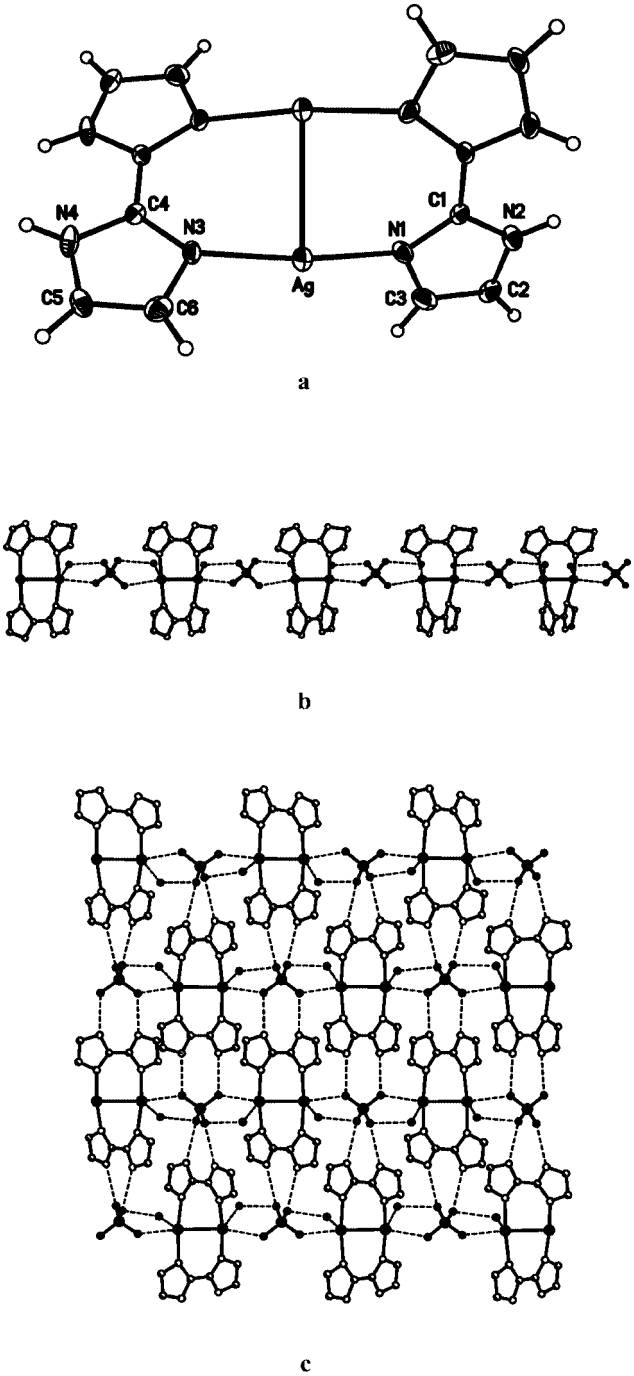


Figure 1. (a) ORTEP drawing of the $[Ag_2(H_2biim)_2]^{2+}$ moiety of **1** with 30% probability thermal ellipsoids. (b) Infinite chain showing $Ag^+$–$SO_4^{2-}$ and $Ag^+$–$H_2O$ interactions. (c) Hydrogen-bonded sheet structure.

The water molecules interact weakly with the Ag atoms [2.756(2) Å] and sulfate (2.861 Å). The staggered arrangement of $H_2$biim of the neighboring chains allows for the formation of interchain N–$H_{biim}$···$O_{sulfate}$ hydrogen bonds (N4···O1 = 2.722, N2···O2 = 2.770 Å) in the resultant sheet structure, as shown in part c of Figure 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### *[Ag$_2$(μ-H$_2$biim)$_2$(μ-ox)] (2)*

As shown in part a of Figure 2, compound **2** has a similar, doubly bridged dimeric structure to that of **1** although their counteranions are remarkably different in size, shape, and coordinating ability, thus indicating that the dimeric structure results from the charge, rather than the other characteristics such as coordinating ability, size, and shape, of the counteranions. Different from the inorganic counteranion $SO_4^{2-}$, the organic counteranion oxalate coordinates more strongly and acts as a didentate bridging ligand to link the dimers into an infinite chain [Ag–$O_{ox}$ = 2.392(4) Å; Figure 2, b]. The Ag–Ag separation [2.8437(9) Å] is not significantly changed by the oxalate coordination. Nevertheless, the binding of oxalate to $Ag^+$ apparently changes the geometric parameters of the dimer, as indicated by the considerably smaller N–Ag–N angle [132.95(16)°] and longer Ag–N distances [2.236(4) and 2.203(4) Å] than those in **1**.

Additionally, the direct coordination of oxalate also accounts for the absence of lattice water molecules in the crystals. The $H_2$biim ligands are slightly twisted, and their dihedral angle of 28.2° is larger than that (14.6°) in **1**. As opposed to **1**, the least-squares planes of the two biimidazole ligands are nearly parallel to each other. The atoms Ag, N1, N3, and O1 are nearly coplanar. In spite of these changes, the crystal structures of **1** and **2** are somewhat similar to each other: both have a one-dimensional, chain-like structure formed by either Ag–$O_{ox}$ bonds or Ag···$O_{sulfate}$ interactions and hydrogen-bonded sheet structures due to interchain N–H···$O_{sulfate}$ or N–H···$O_{ox}$ (2.722, 2.746 Å) hydrogen bonds, as indicated in Figures 1 (c) and 2 (b), respectively.

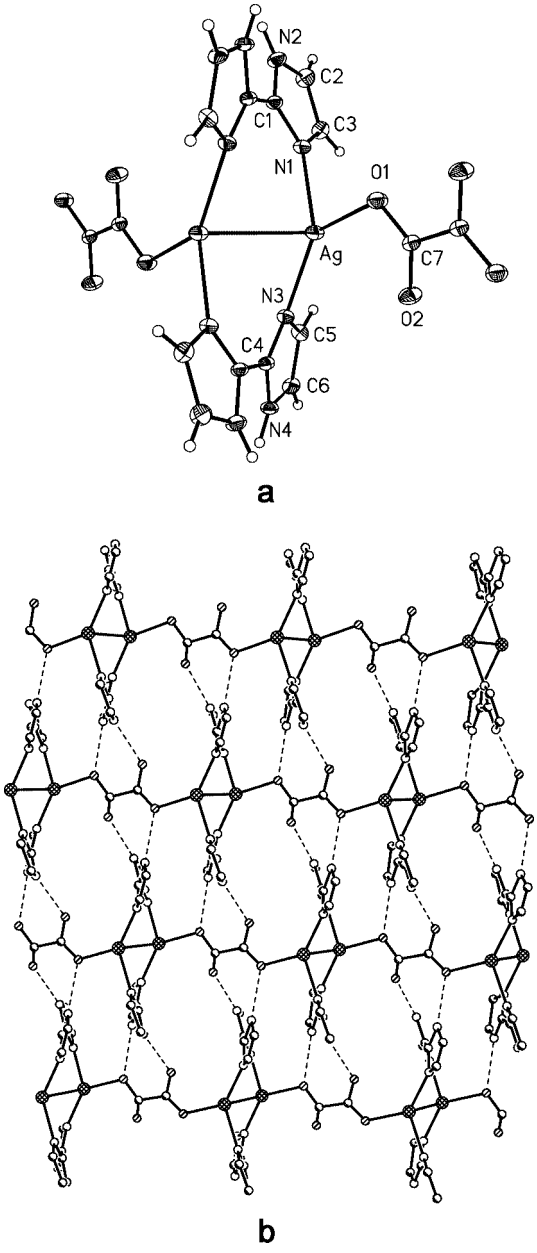

Figure 2. (a) ORTEP drawing of **2** with 30% probability thermal ellipsoids. (b) Sheet structure showing interchain $C_2O_4^{2-}$···$H_2$biim hydrogen bonds.

### *[Ag$_6$(μ-$_2$biim)$_5$(H$_2$biim)$_2$](ClO$_4$)$_4$(CH$_3$CO$_2$)$_2$·4H$_2$O (3)*

Complex **3** contains a mixture of monoanionic inorganic and organic anions and consequently adopts the hexanuclear helical structure $[Ag_6(\mu\text{-}H_2biim)_5(H_2biim)_2]^{6+}$, as shown in Figure 3 (a), instead of a dimeric structure, similar

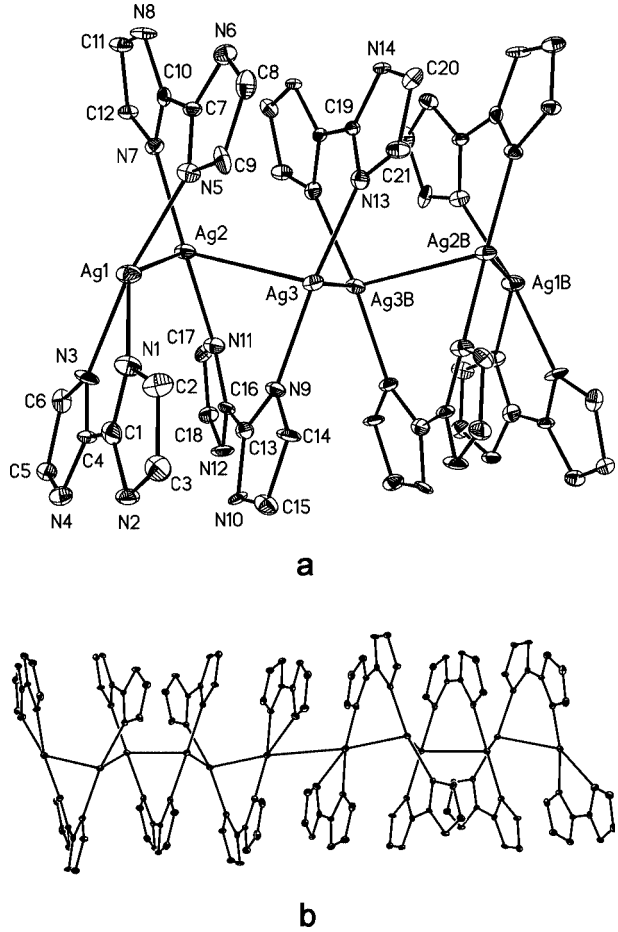

Figure 3. (a) ORTEP drawing of $[Ag_6(\mu\text{-}H_2biim)_5(H_2biim)_2]^{6+}$(**3**). (b) 1D Ag chain.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to that reported for [Ag($H_2$biim)$NO_3$].[10b] In this helical structure, the counteranion lies alongside the $Ag^+$ chain[10b] rather than between the $Ag^+$ ions to facilitate the charge balance. The hexameric structure has $C_2$ symmetry, with the twofold axis bisecting the Ag3–Ag3a bond. As opposed to **1** and **2**, the neighboring $Ag^+$ in **3** is singly bridged by the five $H_2$biim ligands through the *cis* nitrogen atoms, yielding a hexameric helix with Ag–N bonds ranging from 2.112(2) to 2.157(2) Å. The middle $Ag^+$ atoms (Ag2, Ag3) have an almost linear coordination geometry [N–Ag–N = 164.8(2)° and 172.6(2)°] that is stabilized by Ag···$O_{perchlorate}$ interactions (Ag2···O = 2.912, Ag3···O = 2.879 Å). The helix ends at Ag1 as it is chelated by $H_2$biim. It is notable that the Ag1–N1 distance of 2.543(7) Å is comparable to the above Ag···$O_{perchlorate}$ separations but considerably longer than the Ag1–N3 bond [2.163(5) Å], and is responsible for the almost linear N3–Ag1–N5 angle [170.4(2)°]. The Ag–Ag distances [Ag1–Ag2 = 2.9335(18), Ag2–Ag3 = 3.0093(16), Ag3–Ag3′ = 3.078(2) Å] are significantly longer than in **1** and **2** but similar to those reported previously.[10,11] Compound **3** adopts a hexameric helical structure rather than an infinite helical structure similar to the reported nitrate derivative[10b] as a consequence of the chelating instead of bridging $H_2$biim ligands that terminate the growth of the helix. This observation may be attributed to the steric requirement of perchlorate, which is larger than the nitrate in 1D [Ag(μ-$H_2$biim)]$NO_3$,[10b] and is thus unable to allow for the presence of counteranions surrounding the terminal Ag atoms (Ag1). This leads to the structural evolution whereby two sevenths of the bridging $H_2$biim ligands in the one-dimensional helical [Ag(μ-$H_2$biim)]$NO_3$[10b] become chelated in the present hexanuclear compound to compensate for the missing Ag1–O interaction that is needed to stabilize the linear coordination. The acetate groups are involved in hydrogen bonding with $H_2$biim (2.7–2.8 Å) and water (2.79 Å) rather than with the Ag atoms.

The preference of carboxylate groups to form hydrogen bonds with $H_2$biim rather than coordinate to metal ions has been demonstrated in the complexes [$M(H_2biim)_2(H_2O)_2$]-$(RCO_2)_2$.[9f] The chelating $H_2$biim is twisted to a lesser extent (the dihedral angle is 10.8°) than the bridging ones (22–25°). The helix is also characteristic of an approximately parallel arrangement of neighboring $H_2$biim ligands, with the dihedral angles and the distances between the ring atoms and the least-square planes ranging from 8–12° and 2.8–3.6 Å, respectively, due to π-stacking interactions between the aromatic imidazole rings. As shown in Figure 3 (b), the hexamers are connected by an unsupported Ag1–Ag1′ attraction [3.317(2) Å] and π-stacking interactions between the imidazole rings into a 1D Ag chain. The π-stacking interactions between the hexanuclear silver units are similar to those within the hexameric spiral. Other interactions in **2** are hydrogen bonds between lattice water molecules and uncoordinated nitrogen atoms, with separations between O and N of 2.722 (O1w–N10) and 2.728 Å (O2w–N6).

### *[Ag(μ-$H_2$biim)(nicotinate)]$_n$ (4)*

Compound **4** has a monoanionic, organic counterion that is believed to account for the formation of an infinite helical structure (Figure 4), as in the case of **3** and [Ag($H_2$-biim)]$NO_3$.[10b] Interestingly, unlike the nitrate analogue [Ag($H_2$biim)]$NO_3$,[10b] **4** has the coordinating nitrogen atoms *trans* to each other, which leads to a considerably longer Ag···Ag separation (ca. 6 Å) than in **3** and [Ag($H_2$-biim)]$NO_3$ (ca. 3 Å)[10b] due to the steric requirement of the bound nicotinate. This indicates that Ag–Ag attractions are not dominant in the Ag–$H_2$biim system. The Ag–$N_{nicotinate}$ distance [2.534(6) Å] is significantly longer than the Ag–$N_{biim}$ distance [av. 2.188(5) Å]. The three N atoms around $Ag^+$ are approximately in a T-shaped arrangement with the N–Ag–N angles being 159.3°, 110.3° and 89.4°, respectively. The bridging $H_2$biim is twisted, with a dihedral angle of about 30°. The helices are held together through Ag···$O_{nicotinate}$ interactions (Ag1···O1 = 2.843, Ag1···O2 = 2.957 Å) and N–H···$O_{nicotinate}$ hydrogen bonds (N2···O1 = 2.689 Å) to form a sheet structure, as illustrated in Figure 5. The pyridyl rings of two nicotinate groups separated by about 3.6 Å are almost parallel to each other, which suggests significant π-stacking interactions.

## Luminescent Properties

Metal complexes are promising luminescent materials for applications such as light-emitting materials owing to their ability to enhance, shift, and quench luminescent emission of organic ligands by metal coordination. Although numerous biimidazole complexes have been reported, their photophysical properties have been investigated only very re-

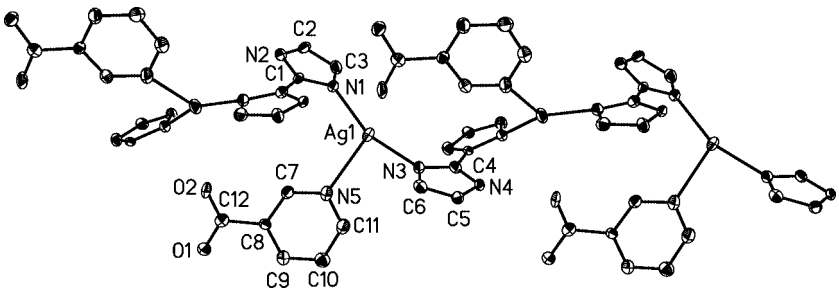

Figure 4. ORTEP drawing of [Ag($H_2$biim)$_2$(nicotinate)]$_n$ (**4**) with 30% probability thermal ellipsoids.

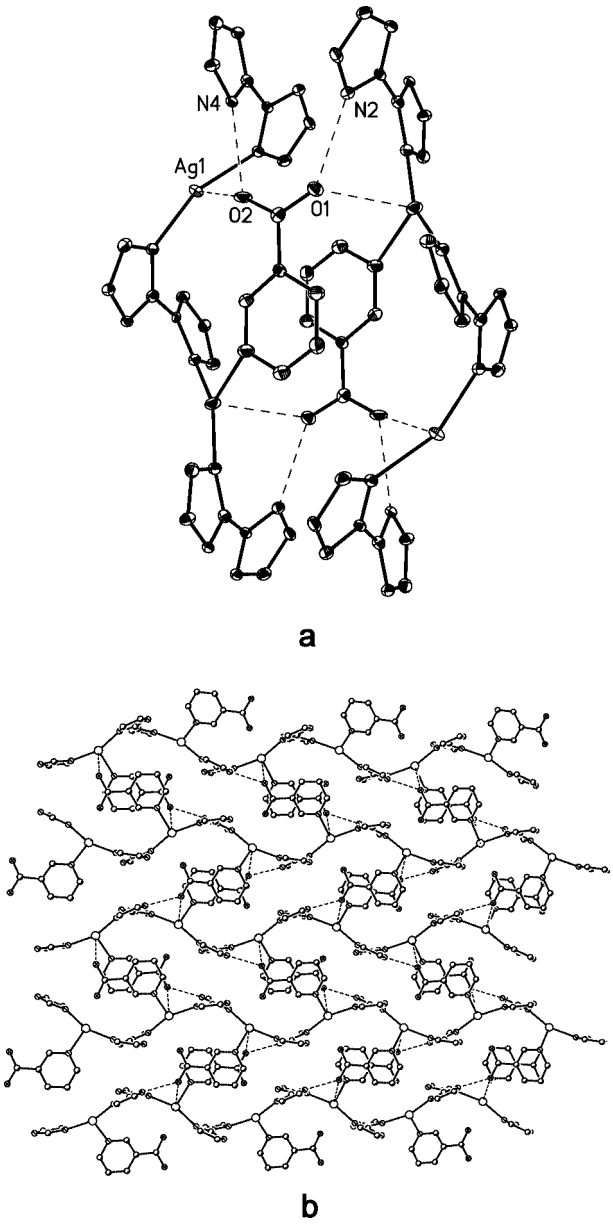

Figure 5. (a) Interhelix interactions and (b) multiple helices interconnected by nicotinate in **4**.

cently.[9a] The solid-state emission spectra of compounds **1**–**4** are shown in Figure 6. The free $H_2$biim ligand displays an emission maximum at 431 nm when excited at 334 nm in the solid state at ambient temperature. A violet-fluorescent emission band at 439 nm was observed for **1** upon excitation at 360 nm, attributable to the ligand-centered emission. Moreover, compound **1** exhibits violet-fluorescent emission bands at 346 nm and a yellowish-green radiation emission at lower energy (576 nm) upon excitation at 260 nm.

Upon excitation at a slightly longer wavelength (298 nm), compound **2** emits only one violet luminescence at 349 nm; the other one is probably quenched by oxalate. Excitation at 370 nm leads to greenish-blue photoluminescence with an emission maximum at 512 nm for **3**, similar to that in

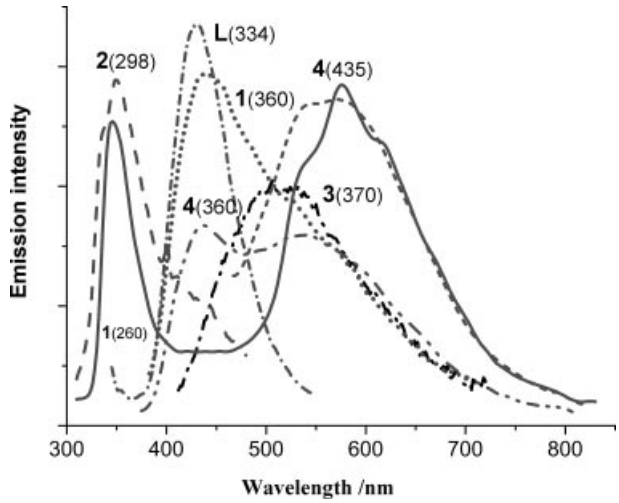

Figure 6. Luminescence emission spectra of **1**–**4** and **L** ($H_2$biim).

$[Ag(Me_2\text{-imy})_2][Ag\text{-}Cl_2]$ (544 nm), which possesses extended Ag–Ag interactions.[15] Compound **4** exhibits similar violet-fluorescent emission bands at 437 nm upon excitation at 360 nm. However, one more yellowish-green radiation emission of **4** was observed at 539 nm, presumably due to the aromatic nicotinate group. A similar yellowish-green fluorescent emission band at 571 nm was also observed for **4** upon excitation at 435 nm.

## Conclusion

The structural topology of the Ag–$H_2$biim system is determined by the charge of the counteranions. Thus, dianionic counterions facilitate the formation of dimeric structures driven by the charge-balance requirement, whereas a monoanionic counterion favors the formation of helical structures. Larger counteranions lead to either finite helical structures or a *trans* arrangement of the coordinating nitrogen atoms because of steric requirements. Organic counteranions with a strong coordination ability bind to the $Ag^+$ ions while inorganic counteranions remain uncoordinated. The argentophilic attraction is not dominant in the Ag–$H_2$biim system. The fluorescence emission of $H_2$biim is effectively shifted upon coordination of the ligand to $Ag^+$.

## Experimental Section

**General Remarks:** $H_2$biim was synthesized in accordance with a published procedure.[13] The reagents and solvents employed were commercially available and used as received without further purification. The C, H, and N microanalyses were carried out with a Vario EL III elemental analyzer. IR spectra were recorded with a Magna 750 FT-IR spectrometer photometer as KBr pellets in the range 4000–400 $cm^{-1}$. Fluorescent spectra were measured with an Edinburgh FLS920 analytical instrument.

***CAUTION**! Perchlorate salts are potentially explosive and should be handled with care and in small amounts.*

**$[Ag_2(H_2biim)_2]SO_4 \cdot 2H_2O$ (1):** $Ag_2O$ (0.056 g, 0.25 mmol) was dissolved in 20 mL of aqueous $H_2SO_4$ (0.05 M) and $H_2$biim (0.067 g,

half an hour then a water solution (20 mL) containing oxalic acid (0.032 g, 0.25 mmol) was added. The resulting solution was stirred at 80 °C for two hours and then filtered off. The filtrate was left in air to evaporate to form crystals of **2** after one day. The crystals were collected by filtration, washed with ethanol, and dried in air (0.093 g, 65% yield based on Ag). $C_{14}H_{12}Ag_2N_8O_4$ (572.06): calcd. C 29.39, H 2.12, N 19.59; found C 29.36, H 2.34, N 19.44. IR (KBr): $\tilde{\nu}$ = 3435 s $cm^{-1}$, 3142 w, 3076 m, 2999 m, 2898 m, 2807 m, 1597 s, 1545 s, 1435 w, 1406 s, 1384 m, 1334 w, 1310 s, 1218 w, 1105 s, 940 m, 886 m, 761 m, 747 m, 735 m, 689 m.

**$[Ag_6(\mu\text{-}H_2biim)_5(H_2biim)_2](ClO_4)_4(CH_3CO_2)_2\cdot 4H_2O$ (3):** An aqueous solution (10 mL) of $NaClO_4\cdot H_2O$ (0.70 g 0.5 mmol) was added to a well-stirred suspension of $H_2$biim (0.067 g, 0.5 mmol) and $Ag(CH_3COO)$ (0.083 g, 0.5 mmol) in 50 mL of water. The suspension was then refluxed for 2 h. After cooling, the resulting suspension was filtered off. The filtrate was left in air to evaporate the solvent and crystals were obtained after a few days. The product was collected by filtration, washed with ethanol, and dried in vacuo (0.078 g, 43% yield based on Ag). $C_{46}H_{56}Ag_6Cl_4N_{28}O_{24}$ (2174.2): calcd. C 25.41, H 2.60, N 18.04; found C 25.49, H 2.67, N 18.11. IR (KBr): $\tilde{\nu}$ = 3449 m $cm^{-1}$, 3176 w, 3143 w, 3076 m, 3002 m, 2898 m, 2807 m, 1631 w, 1546 m, 1436 w, 1406 m, 1384 s, 1333 m, 1218 w, 1144 m, 1121 s, 1106 s, 1084 s, 940 m, 887 m, 747 m, 689 m, 626 w.

**$[Ag_2(H_2biim)_2(nicotinate)_2]_n$ (4):** A mixture of $AgNO_3$ (0.042 g, 0.25 mmol), $H_2$biim (0.333 g, 0.25 mmol), and nicotinic acid (0.308 g, 0.25 mmol) in $H_2O$ (16 mL) was heated at 165 °C for 3 d under autogenous pressure. After cooling, the resulting solution was filtered off. The filtrate was left in air to evaporate the solvent and crystals were obtained after a few days. The product was collected by filtration, washed with ethanol, and dried in vacuo (0.042 g, 46% yield based on Ag). $C_{12}H_{10}AgN_5O_2$ (364.12): calcd. C 39.58, H 2.77, N 19.24; found C 39.53, H 2.85, N 19.16. IR (KBr): $\tilde{\nu}$ = 3435 m $cm^{-1}$, 3109 m, 3067 m, 2991 m, 2896 m, 2806 m, 1594 s, 1547 s, 1406 m, 1384 s, 1334 m, 1219 w, 1191 w, 1152 w, 1105 m, 1030 w, 993 w, 940 w, 915 w, 774 m, 749 mw, 691 m.

**X-ray Crystallographic Study:** Suitable single crystals of complexes **1**–**4** were mounted on a Siemens Smart CCD diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) at 298 K. All absorption corrections were performed with the SADABS program. All structures were solved by direct methods and refined by full-matrix least-squares fitting on $F^2$ with SHELXTL-97.[14] All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were located at geometrically calculated positions and treated as riding on their parent atoms. Crystallographic data and structural refinements for compounds **1**–**4** are summarized in Table 1. Selected bond lengths and hydrogen bonds are summarized in Tables 2 and 3, respectively. CCDC-285100 (**1**), -285101 (for **2**), -262860 (for **3**), and -285012 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis, Structure and Stability of New $Pt^{II}$–Bis(N-Heterocyclic Carbene) Complexes

**Sebastian Ahrens,[a] Eberhardt Herdtweck,[b][‡] Sigrid Goutal,[a][‡‡] and Thomas Strassner*[a]**

**Keywords:** Carbene ligands / NMR spectroscopy / Platinum / Synthesis / Ligand design / Solid state structure

The use of metal acetates has allowed the synthesis of NHC complexes without isolation of the free carbene. This route is very useful in cases where the metal acetates are readily available and has been used, for example, for the synthesis of bis(N-heterocyclic carbene) complexes of palladium(II). In the case of platinum, however, the corresponding acetate is not commercially available and is difficult to synthesize. Previously published syntheses require either an external base (e.g. NaOAc or KO*t*Bu) or a transmetalation step. Here we present a new general synthetic pathway for platinum–bis(carbene) complexes using platinum(II) acetylacetonate as a commercially available metal precursor. Aromatic substituents greatly enhance the stability of the metal complexes against acidic media.

## Introduction

In the last decade N-heterocyclic carbene (NHC) complexes of transition metals have found applications in many fields of chemistry. Metal complexes of imidazoline-2-ylidenes have recently been shown to be extremely versatile and stable catalysts for a wide range of reactions, including C–C coupling reactions,[1,2] olefin metathesis,[3–6] hydroformylation,[7,8] and, most recently, CH activation.[9,10] The key for this development has been the number of improved synthetic methods for the preparation of NHC complexes, which have been summarized in recent reviews.[11–13]

Metal acetates allow the synthesis of NHC complexes without isolation of the free carbene. Palladium(II) acetate in wet dimethyl sulfoxide (DMSO) at elevated temperatures directly forms carbene complexes with imidazolium salts. Even methylene-bridged bis(imidazolium) salts can be converted into the corresponding bis(carbene) complexes in high yields (85–90%).[14–16] We and others have been particularly interested in these chelate ligands as a way of extending the area to more complex ligands and more stable complexes.[17–23] Here we present a new general synthetic pathway towards platinum–bis(carbene) complexes with aromatic substituents, which greatly enhance the stability of the corresponding platinum carbene complexes.
