In this paper we wish to report on a novel $Ru^{II}$ complex, $[Ru(bpy)_2(cpipH)](ClO_4)_2$, in which cpipH was synthesized by grafting an *N*-substituted carbazole group to 2-phenylimidazo[4,5-*f*][1,10]phenanthroline (pip). Attention was paid to the effects of the peripheral carbazole group on the acid-base and DNA binding properties of this complex by comparison with the parent complex, $[Ru(bpy)_2(pip)]^{2+}$. 2,2′-Bipyridine (bpy) was chosen as the ancillary ligand for the complex since the "parent" complex $[Ru(bpy)_3]^{2+}$ was reported to bind extremely weakly to double-stranded DNA.[14] Hence, it is reasonable for us to examine the "inspected" ligand on the DNA binding properties of the complex. We demonstrate here the interesting findings regarding this novel $Ru^{II}$ complex, $[Ru(bpy)_2(cpipH)]^{2+}$, intercalated to the DNA with a binding constant of $(8.2 \pm 0.8) \times 10^5\ M^{-1}$ in buffered 50 mM NaCl, which is greater than that for $[Ru(bpy)_2(pip)]^{2+}$. The excited states of this new complex are 0.7–0.8 p$K_a$ units more basic than those of the ground states.

## Results and Discussion

### Synthesis and Common Spectral Characteristics

The synthetic route to the complex is summarized in Figure 1. CpipH was synthesized by coupling 1,10-phenanthroline-5,6-dione with 4-(carbazol-9-yl)benzaldehyde ac-

cording to protocols reported by Steck and Day.[15] The complex $[Ru(bpy)_2(cpipH)](ClO_4)_2$ was synthesized by direct reaction of $Ru(bpy)_2Cl_2{\cdot}2H_2O$ with cpipH in EtOH/$H_2O$ (4:1, v/v), and purified by column chromatography on silica gel with $CH_3CN/H_2O$/saturated aqueous $KNO_3$ (400:7:1, v/v/v) as eluent. The complex was obtained in satisfactory purity, which was verified by elemental analysis and $^1H$ NMR spectroscopy.

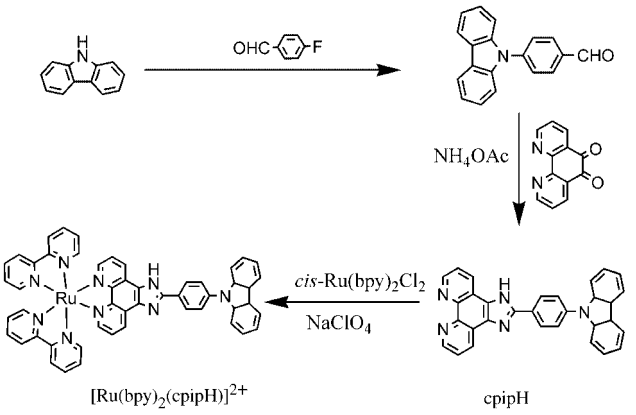

Figure 1. The synthetic route to the $Ru^{II}$ complex.

The complex, in aqueous solution, showed the lowest-energy metal-ligand charge transfer (MLCT) transition absorption band at 462 nm. The energy in the MLCT band increased in the order: $[Ru(bpy)_2(cpipH)]^{2+}$ (462 nm) < $[Ru(bpy)_2(pip)]^{2+}$ (458 nm) < $[Ru(bpy)_2(ip)]^{2+}$(455 nm).[5a] The high-energy absorption bands at 285 and 338 nm are attributed to the intraligand (IL) π-π* transition by comparison with those of $[Ru(bpy)_3]^{2+}$.[16] The order of energies in the IL bands parallels that of the MLCT bands: $[Ru(bpy)_2(cpipH)]^{2+}$ (285 nm) < $[Ru(bpy)_2(pip)]^{2+}$ (283 nm) < $[Ru(bpy)_2(ip)]^{2+}$(280 nm), indicating enhanced π delocalization upon grafting carbazole to $[Ru(bpy)_2(pip)]^{2+}$. The complex, in TRIS buffer at room temperature, was strongly emitting under visible light excitation at 465 nm with emission maxima occurring at 608 nm, which is characteristic of MLCT luminescence,[17] and is assigned to the $^3$MLCT [dπ(Ru) → π* (ligand)] state. An emission quantum yield for the complex in aerated $H_2O$ was determined to be 0.0497 by comparison with $[Ru(bpy)_3]^{2+}$ ($\varphi_{std}$ = 0.033) in aerated aqueous solution.[18,19] The MLCT emission maxima were bathochromically shifted on going from $[Ru(bpy)_2(cpipH)]^{2+}$ to $[Ru(bpy)_2(ip)]^{2+}$: $[Ru(bpy)_2(cpipH)]^{2+}$ ($\lambda_{em}$ = 608 nm) < $[Ru(bpy)_2(pip)]^{2+}$ ($\lambda_{em}$ = 615 nm) < $[Ru(bpy)_2(ip)]^{2+}$($\lambda_{em}$ = 625 nm).[5a]

## DNA-Binding Studies

### *UVIVis Spectra*

The electronic absorption spectra traces of the complex that was titrated with DNA are given in Figure 2. With increasing DNA concentrations, the hypochromisms for the bands at 285, 338 and 462 nm were found to be 54.2%, 37.3% and 23.7%, respectively, and the bathochromisms were found to be 4, 2 and 6 nm, respectively. The hypochromism of 23.7% for the MLCT band for the complex is larger than 15.5% for $[Ru(bpy)_2(ip)]^{2+}$ and 21.9% for $[Ru(bpy)_2(pip)]^{2+}$.[5a] The hypochromism observed for the IL transition of 54.2% (285 nm) for our complex appreciably prevailed over the 3.8% (280 nm) observed for $[Ru(bpy)_2(ip)]^{2+}$ and 20% (283 nm) for $[Ru(bpy)_2(pip)]^{2+}$.[5a] The spectroscopic changes suggest that the complex has a stronger interaction with DNA than $[Ru(bpy)_2(ip)]^{2+}$ and $[Ru(bpy)_2(pip)]^{2+}$.

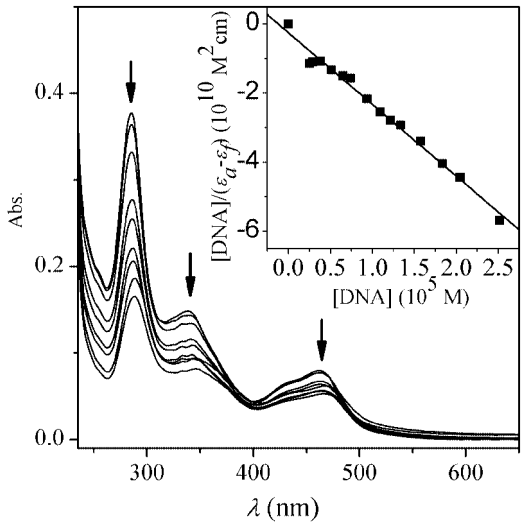

Figure 2. UV/Vis absorption spectra of the $Ru^{II}$ complex (4.6 μM), in the absence and presence of increasing concentrations of ct-DNA (0–25 μM).

To further illustrate the binding strength of the complex quantitatively, the intrinsic DNA binding constant of the complex was determined by monitoring the changes in absorbance at 285 nm with increasing concentrations of DNA, according to Equation (1),[20] where [DNA] is the concentration of DNA in base pairs; the apparent absorption coefficients $\varepsilon_a$, $\varepsilon_f$ and $\varepsilon_b$ correspond to the extinction coefficients at a given DNA concentration, the free complex in solution and the complex that is fully bound to DNA, respectively; and $K_b$ is given by the ratio of the slope to the intercept.

$$[DNA]/(\varepsilon_a - \varepsilon_f) = [DNA]/(\varepsilon_b - \varepsilon_f) + 1/K_b(\varepsilon_b - \varepsilon_f) \quad (1)$$

An intrinsic binding constant was derived to be $(8.2 \pm 0.8) \times 10^5$ M$^{-1}$ for $[Ru(bpy)_2(cpipH)]^{2+}$, and ca. twice that for $[Ru(bpy)_2(pip)]^{2+}$ ($4.7 \times 10^5$ M$^{-1}$).[20] The hypochromism ($H$%) and the intrinsic DNA binding constant of $[Ru(bpy)_2(cpipH)]^{2+}$ are compared with those reported for representative DNA intercalators in Table 1. The $K_b$ value of the complex is larger than those for most of the DNA intercalators collected in Table 1, while smaller than those for the strong DNA intercalators of Δ-$[Ru(phen)(dppz)]^{2+}$ ($3.2 \times 10^6$ M$^{-1}$), Λ-$[Ru(phen)(dppz)]^{2+}$ ($1.7 \times 10^6$ M$^{-1}$)[21] and $[Ru(bpy)_2(ebipcH_2)(bpy)_2Ru]^{2+}$ ($1.3 \times 10^6$ M$^{-1}$).[6a] The $H$% value listed in Table 1 for $[Ru(bpy)_2(cpipH)]^{2+}$ is even larger than those for the typical DNA intercalators mentioned above. The large hypochromism and clear red shifts, as well

[a] ip = imidazo[4,5-*f*][1,10]phenanthroline; pip = 2-phenylimidazo[4,5-*f*][1,10]phenanthroline; taptp = 4,5,9,18-tetraazaphenanthreno[9,10-*b*]triphenylene; ipbp = 3-(1*H*-imidazo[4,5-*f*][1,10] phenanthrolin-2-yl)-4*H*-1-benzopyran-4-one; $ebipcH_2$ = *N*-ethyl-4,7-bis([1,10]phenanthroline[5,6-*f*]imidazo-2-yl)carbazole; dppz = dipyrido[3,2-*a*:2′,3′-*c*]-phenazine. [b] The maximum hypochromism selected from the UV/Vis absorption peaks. [c] *R* is the ratio of the Stern–Volmer quenching constant by using $[Fe(CN)_6]^{4-}$ as the quencher, and obtained from the ratio of the presence of DNA to that obtained in the absence of DNA.

as a relatively large $K_b$ value observed for the interaction of the $Ru^{II}$ complex with the DNA, indicate that complex $[Ru(bpy)_2(cpipH)]^{2+}$ might bind to the DNA by intercalation.

### *Luminescence Studies*

Steady-state emission quenching experiments for the complex, using $[Fe(CN)_6]^{4-}$ as the quencher, further support the intercalation interaction. As illustrated in Figure 3, in the absence of DNA, the emission of $[Ru(bpy)_2(cpipH)]^{2+}$ is efficiently quenched by $[Fe(CN)_6]^{4-}$, resulting in a slope of 92.6 for a linear Stern–Volmer plot, but in the presence of DNA the slope of the quenching plot decreases remarkably to 0.49. The positively charged free complex ions should be readily quenched by $[Fe(CN)_6]^{4-}$, but when bound to DNA, the complex can be protected from the quencher because the highly negatively charged $[Fe(CN)_6]^{4-}$ would be repelled by the negative DNA phosphate backbone, hindering quenching of the emission of the bound complex. A ratio (*R*) of Stern–Volmer quenching constants, using $[Fe(CN)_6]^{4-}$ and obtained from the ratio of the presence of DNA to that of the absence of DNA, can be taken as a measure of the binding affinity. A large *R* value corresponds to a poorer protection and a weaker binding to DNA. As anticipitated, an *R* value of 0.0093 found for the complex we studied in this paper, is smaller than a value 0.051 reported for $[Ru(bpy)_2(pip)]^{2+}$, and 0.25 for $[Ru(bpy)_2(ip)]^{2+}$,[5a] providing further evidence that the binding affinity to the DNA is in the order of $[Ru(bpy)_2(cpipH)]^{2+} > [Ru(bpy)_2(pip)]^{2+} > [Ru(bpy)_2(ip)]^{2+}$,[5a] and the interaction mode between the complex and the DNA is intercalative.

The fluorescence of ethidium bromide (EB) itself in aqueous solution is very weak, but when it intercalates between adjacent DNA base pairs of double-stranded DNA ($K_b = 1.4 \times 10^6$ $M^{-1}$),[22] the fluorescence is greatly enhanced. If a second DNA intercalator is added to the EB–DNA system, it will compete with EB for the DNA binding site, and the fluorescence of the EB–DNA system will be quenched.[23,24] So, the quenching extent of fluorescence of the EB–DNA system can reflect the DNA binding strength of the second molecule. Otherwise, if the second added molecule is not a DNA intercalator, its addition will not

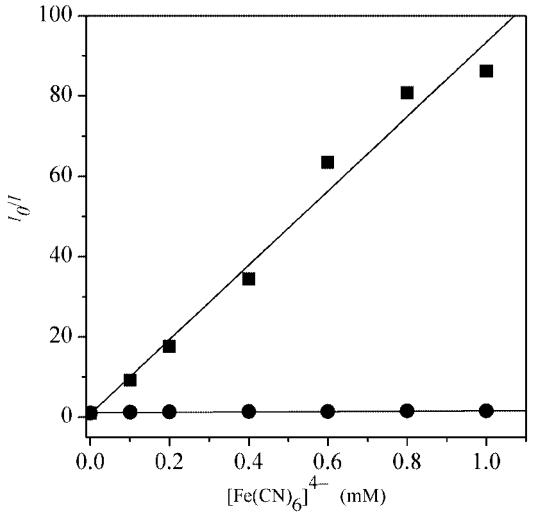

Figure 3. Emission quenching of the $Ru^{II}$ complex with increasing concentrations of $[Fe(CN)_6]^{4-}$ in the absence (■) and presence (●) of ct-DNA:[Ru] = 4.6 μM, [DNA]/[Ru] = 9.

cause the evident reduction in emission intensities of the EB–DNA system. The changes in the emission spectra of the EB–DNA system in the absence and presence of the complex are shown in Figure 4. The emission of the EB–DNA system was efficiently quenched by the complex, resulting in a linear Stern–Volmer plot according to Equation (2), where $I_0$ and $I$ represent the fluorescence intensities in the absence and presence of complex, respectively; $K$ is a linear Stern–Volmer quenching constant dependent on the ratio of the bound concentration of EB to the concentration of DNA; and $r$ is the ratio of the total concentration of the complex to that of DNA ([Ru]/[DNA]).

$$I_0/I = 1 + Kr \quad (2)$$

As shown in the inset of Figure 4, the Stern–Volmer plot has of a slope of $K = 6.17$, which is larger than 2.72 for $[Ru(dmp)_2(obpip)]^{2+}$ (dmp = 2,9-dimethyl-1,10-phenanthroline; obpip = 2-(2-bromophenyl)imidazo[4,5-*f*]-1,10-phenanthroline), and 5.98 for $[Ru(dmp)_2(pbip)]^{2+}$(pbip =2-(4-bromophenyl)imidazo[4,5-*f*]-1,10-phenanthroline),[25] but smaller than a *K* value of 19.3 for [Ru(bpy)-

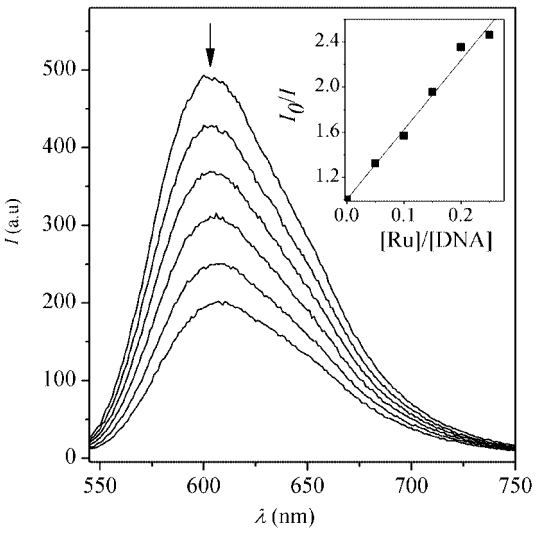

Figure 4. Emission quenching of the EB–DNA system with increasing concentration of the $Ru^{II}$ complex. [EB] = 20 μM, [DNA] = 100 μM, [Ru]:[DNA] = 0–0.25.

$(pp[2,3]p)_2]^{2+}$ (bpy = 2, 2′-bipyridine, pp[2,3]p = pyrido[2′,3′:5,6]pyrazino[2,3-*f*][1,10]phenanthroline), and 31.2 for $[Ru(phen)(pp[2,3]p)_2]^{2+}$ (phen = 1,10-phenanthroline).[13a] From the data in Figure 4, we also know that 50% of EB was replaced by $[Ru(bpy)_2(cpipH)]^{2+}$ from the DNA bound EB at a concentration ratio of [Ru]/[EB] ≈ 0.8. Hence, an apparent DNA binding constant of $1.8 \times 10^6$ M$^{-1}$ was derived [$K_b$(EB)/0.8].

### *Thermal Denaturation Studies*

The thermal melting study of the DNA is a technique used to evaluate the stability of a DNA double helix. When a complex intercalates into DNA base pairs, the base stacking will be more stable and hence the melting temperature of the double-stranded DNA will rise. So the DNA melting temperature ($T_m$) is useful in establishing the extent of intercalation.[26] The melting curves of ct-DNA in the absence and presence of the complex are presented in Figure 5. $T_m$ of ct-DNA was found to be 66.3 °C. In the presence of the complex at a concentration ratio [Ru]/[DNA] = 1:10, $T_m$ of ct-DNA was raised to 73.5 °C. The large increase of 7.2 °C in $T_m$ is comparable to that observed for a classical DNA intercalator.[22–29]

The DNA intrinsic binding constant at 73.5 °C can be obtained from the McGhee equation [Equation (3)], where $T_m^0$ is the melting temperature of ct-DNA alone, $T_m$ is the melting temperature in the presence of the $Ru^{II}$ complex, $\Delta H$ is the enthalpy of DNA (per base pair), $R$ is the gas constant, $K$ is the DNA binding constant at $T_m$, $L$ is the free complex concentration (approximated at the $T_m$ by the total complex concentration), and $n$ is the size of the binding site.

$$1/T_m^0 - 1/T_m = (R/\Delta H)\ln(1 + KL)^{1/n} \quad (3)$$

For the ct-DNA used in these studies, under identical solution conditions, a melting enthalpy of 6.9 kcal mol$^{-1}$ was determined by differential scanning calorimetry.[30]

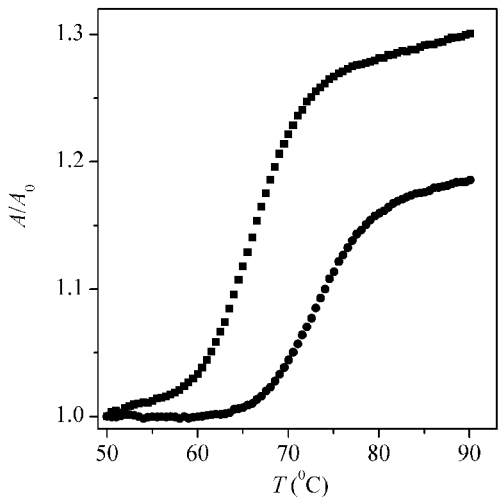

Figure 5. Melting curves of ct-DNA in the absence (■) and presence (●) of the $Ru^{II}$ complex. [Ru] = 5.8 μM, [DNA] = 58 μM.

And on the basis of the neighbor exclusion principle the $n$ value for the complex was assumed to be 2.0 base pairs. As a result $K$ was calculated to be $9.14 \times 10^4$ M$^{-1}$ at 73.5 °C. As the complex binds to ct-DNA, the changes in standard enthalpy, standard entropy and standard free energy can be determined according to Equations (4), (5), and (6), where $K_1$ and $K_2$ are the DNA intrinsic binding constants of the complex at temperature $T_1$ and $T_2$, respectively; $\Delta G°$, $\Delta H°$, and $\Delta S°$ are the corresponding standard free energy change, standard enthalpy change and standard entropy change, respectively.

$$\ln(K_1/K_2) = (\Delta H°/R)(T_1 - T_2)/T_1T_2 \quad (4)$$

$$\Delta G_T^\circ = -RT\ln K \quad (5)$$

$$\Delta G_T^\circ = \Delta H° - T\Delta S° \quad (6)$$

By substituting $K_1 = 8.21 \times 10^5$ M$^{-1}$ ($T_1$ = 298 K) and $K_2 = 9.14 \times 10^4$ M$^{-1}$ ($T_2$ = 346.5 $K$) into Equations (4)–(6), the values of $\Delta H°$, $\Delta G_{298}^\circ$ and $\Delta S°$ were found to be –38.9 kJ mol$^{-1}$, –33.8 kJ mol$^{-1}$ and –17.1 J mol$^{-1}$ K$^{-1}$ at 25 °C, respectively. The negative $\Delta G°$ value suggests that the energy of the adduct is lower than the sum of the energies of the free complex and DNA. The negative $\Delta H°$ suggests that the binding of the complex to DNA at 25 °C is exothermic and enthalpically driven.

## Spectrophotometric pH Titrations

### *UV/Vis Absorption Spectra*

As shown in Figure 6, $[Ru(bpy)_2(cpipH)]^{2+}$ underwent two successive deprotonation processes upon increasing the pH from –0.08 to 11.23. When the pH was increased from 0.10 to 3.73, the bands at 286 and 342 nm increased in intensity and an isosbestic point appeared at 360 nm. These spectral changes resulted from the dissociation of the proton on the protonated imidazole ring. The second depro-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tonation step, which takes place over the pH range of 7.00–10.45, is assigned to the deprotonation of the proton on the neutral imidazole ring, accompanying the following spectral features: the band at 342 nm and the wave valley at 490 nm increase, and the band at 286 nm is red-shifted from 286 nm to 289 nm without any changes in the intensities. The changes in absorbance at the fixed wavelengths as a function of pH are shown in the insets of Figure 6. Two ground-state ionization constants of $pK_{a1} = 0.31 \pm 0.06$, $pK_{a2} = 8.24 \pm 0.03$ were obtained by nonlinear sigmoidal fits of the data, shown in the insets of Figure 6(a) and Figure 6(b). As compared with the two ionization constants of the protonated imidazole ring on some representative $Ru^{II}$ analog complexes, the complex we studied in this paper is more acidic than $[Ru(bpy)_2(ip)]^{2+}$ ($pK_{ai}$ = 1.97, 10.46) and $[Ru(bpy)_2(ebipcH_2)(bpy)_2Ru]^{2+}$ {$ebipcH_2$ = *N*-ethyl-4,7-bis([1,10]phenanthroline[5,6-*f*]imidazo-2-yl)-carbazole} ($pK_{ai}$ = 4.16, 9.65).[6a,10]

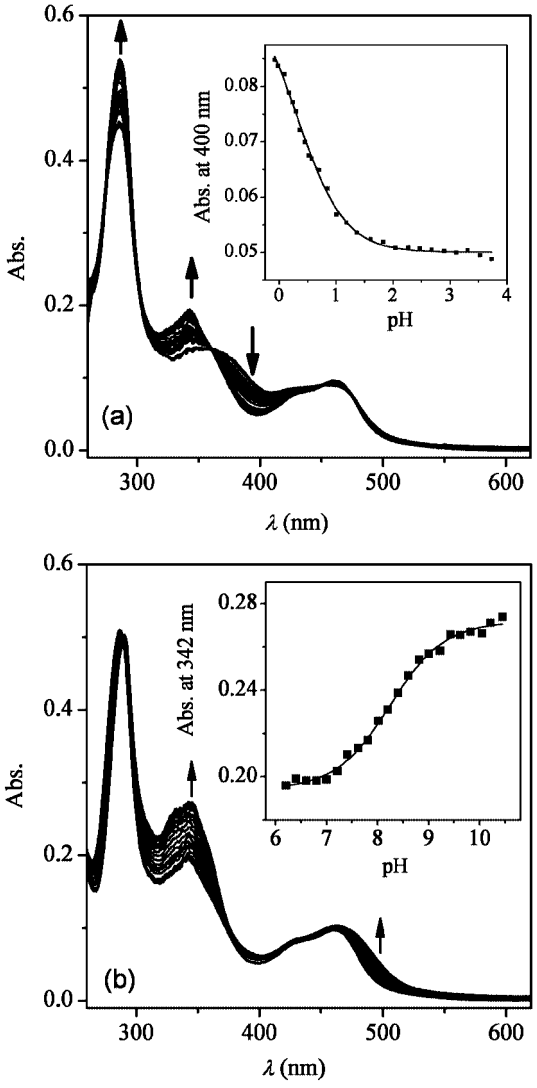

Figure 6. The changes of electronic absorption spectra of the $Ru^{II}$ complex upon raising the pH: (a) pH = –0.08 to 3.73; (b) pH = 6.21 to 10.45.

### *Luminescence Spectroscopic Studies*

As shown in Figure 7, the emission spectra of the complex are sensitive to pH. When the pH is increased from 0.10 to 3.31, the emission maxima are blue-shifted from 628 to 613 nm and the intensities decrease by about 13.9%. As the pH increases from 6.21 to 10.45, the emission maxima become red-shifted from 610 to 622 nm, and the intensities decrease by about 38.1%. The insets of Figure 7, which are the changes of relative emission intensities vs. pH, clearly show that the profiles consist of two sigmoidal curves of opposite gradients, indicative of two deprotonation processes. This is the same result as that described in the section on UV/Vis absorption spectral titrations. The protonation/deprotonation processes are summarized in Figure 8.

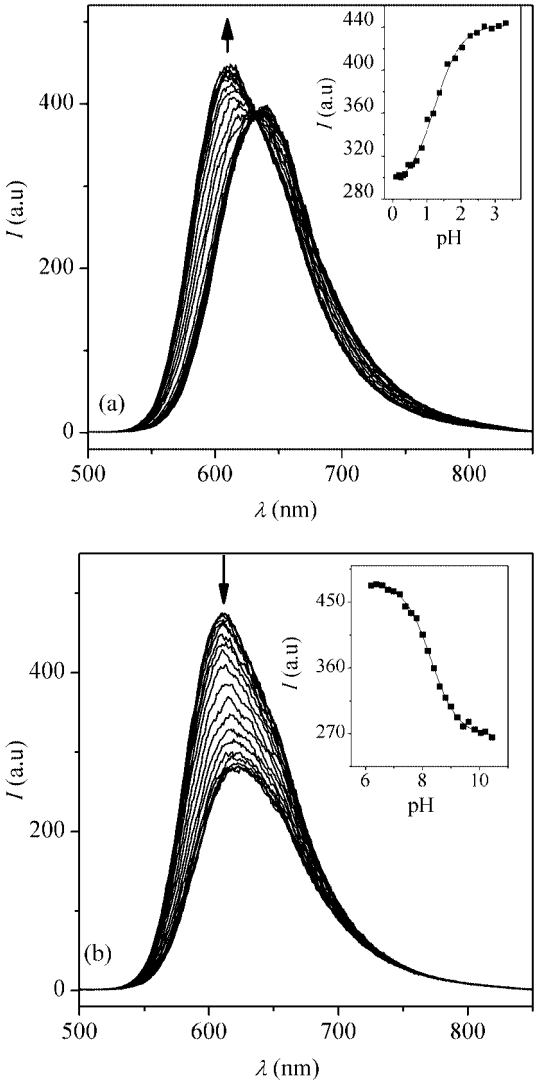

Figure 7. The changes in the emission spectra of the $Ru^{II}$ complex upon raising the pH: (a) pH = 0.10–3.31; (b) pH = 6.21–10.45.

Excited-state ionization constants, $pK_a^*$, could be roughly evaluated on the basis of the Förster cycle,[3] which thermodynamically correlates $pK_a^*$ with $pK_a$ according to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

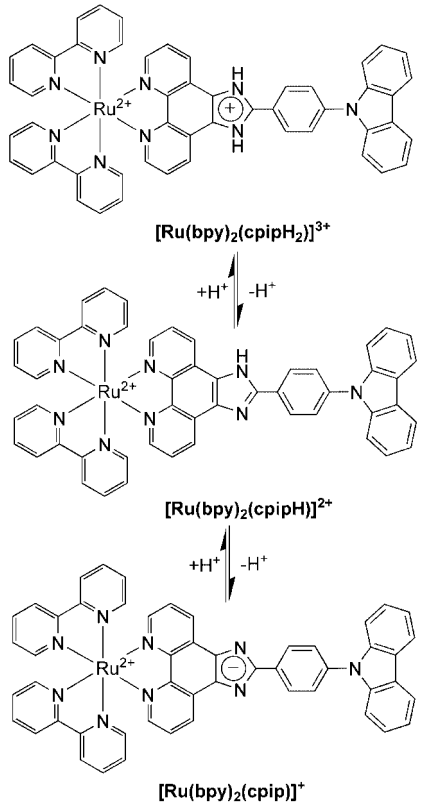

Figure 8. The acid–base equilibria of the $Ru^{II}$ complex.

Equation (7), where $\nu_B$ and $\nu_{HB}$ are pure 0–0 transitions in $cm^{-1}$ for the basic and acidic species, respectively.

$$pK_a^* = pK_a + (0.625/T)(\nu_B - \nu_{HB}) \quad (7)$$

In practice, $\nu_B$ and $\nu_{HB}$ are often difficult or even impossible to obtain. A good approximation is obtained by using the emission maxima for $\nu_B$ and $\nu_{HB}$, since protonation equilibrium is almost certainly established between the $^3$MLCT states.[18]

By using the emission band maxima from both the protonated and deprotonated forms of the ruthenium complex for $\nu_B$ and $\nu_{HB}$ in Equation (7), two $pK_a^*$ values of $pK_{a1}^* = 1.1 \pm 0.1$ and $pK_{a2}^* = 8.9 \pm 0.1$, were obtained. The excited state $pK_a^*$ values are 0.7–0.8 $pK_a$ units more basic than the respective ground-state ones, indicating that the excited electron was delocalized on the cpipH moiety rather than on that of the bpy moiety.

## Conclusions

In summary, a newly synthesized $Ru^{II}$ complex of $[Ru(bpy)_2(cpipH)](ClO_4)_2$ was demonstrated to be a DNA intercalator by evident hypochromism and clear bathochromic shifts of the band at 286 nm, and protection from emission quenching by $[Fe(CN)_6]^{4-}$ upon binding to the DNA, as well as comparable competitive binding to the DNA with the proven DNA intercalator EB and the large increase of 7.2 °C in the melting temperature of the double-stranded DNA at a concentration ratio [Ru]/[DNA] = 1:10. Its interesting DNA-binding and pH responsive spectroscopic properties make it attractive for applications involving molecular optical devices.

## Experimental Section

**Physical Measurements:** Elemental analyses were performed with a Vario EL elemental analyzer. Infrared spectra were measured with a Nicolet–Avatar 360 FT-IR spectrometer using KBr disks. $^1$H NMR spectra were obtained with a Bruker DRX-500 spectrometer. UV/Vis absorption spectra were determined with a GBC Cintra 10e UV/Vis spectrophotometer. Emission spectra were recorded with a Shimadzu RF-5301PC spectrofluorimeter. The interaction of the complex with DNA was conducted in buffer A (5 mM TRIS, 50 mM NaCl, pH = 7.1). A solution of ct-DNA gave ratios of UV absorbance at 260 and 280 nm of about 1.8–1.9:1 indicating that the DNA was sufficiently free of protein. The DNA per nucleotide was determined spectrophotometrically by assuming $\varepsilon_{260}$ = 6600 $M^{-1}cm^{-1}$. Thermal denaturation experiments of the DNA were performed on a GBC Cintra 10e UV/Vis spectrophotometer in Buffer B (1.5 mM $Na_2HPO_4$, 0.5 mM $NaH_2PO_4$, 1 mM $Na_2EDTA$). Using the thermal melting program, the temperature of the cell containing the cuvette was increased from 50 °C to 90 °C and the absorbance at 260 nm was measured every 0.5 °C. The data were smoothed at 0.5 °C intervals with a filter of 5, and the derivative of the resulting curve was taken at a data interval of 0.5 °C. The pH effects on the UV/Vis and emission spectra of the complex were carried out in DMF/Britton–Roberson buffer (4 mM $H_3BO_3$, 4 mM $H_3PO_4$, 4 mM $CH_3COOH$) (1:1, v/v).

**Materials:** 4-(Carbazol-9-yl)benzaldehyde,[31] 1,10-phenanthroline-5,6-dione[32] and *cis*-$Ru(bpy)_2Cl_2 \cdot 2H_2O$[33] were prepared according to literature methods.

**2-[4-(9*H*-Carbazol-9-yl)phenyl]-1*H*-imidazol[4,5-*f*][1,10]phenanthroline (cpipH):**[34] A solution of 1,10-phenanthroline-5,6-dione (0.21 g, 1 mmol), 4-(carbazol-9-yl)benzaldehyde (0.27 g, 1 mmol), and ammonium acetate (1.62 g, 21 mmol) dissolved in acetic acid (30 mL) was refluxed at 110 °C for 5 h under nitrogen. The solution was cooled to room temperature, and $H_2O$ (60 mL) was added. The suspension was then neutralized with concentrated aqueous ammonia. The yellow precipitate that formed was washed with water, dichloromethane and ethanol, and then dried at 100 °C in vacuo. Yield 0.185 g (40%). IR (KBr): $\tilde{\nu}_{max}$ = 3435 (s), 1610 (m), 1525 (m), 1482 (m), 1452 (s), 1352 (m), 739 (s), 720 (m) $cm^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 13.95 (s, 1 H), 9.07 (s, 2 H), 8.98 (d, $J$ = 7.7 Hz, 2 H), 8.59 (d, $J$ = 8.4 Hz, 2 H), 8.30 (d, $J$ = 7.8 Hz, 2 H), 7.94 (d, $J$ = 8.4 Hz, 2 H), 7.88 (m, 2 H), 7.56 (d, $J$ = 8.2 Hz, 2 H), 7.50 (t, $J$ = 7.3 Hz, 2 H), 7.35 (t, $J$ = 7.2 Hz, 2 H) ppm. $C_{31}H_{19}N_5 \cdot 0.2C_2H_5OH$ (470.7): calcd. C 80.13, H 4.29, N 14.87; found C 81.90, H 4.61, N 14.63.

**Caution!** *All the perchlorate salts are potentially explosive and therefore should be handled in small quantities with care.*

**[Ru(bpy)$_2$(cpipH)](ClO$_4$)$_2$:** A mixture of *cis*-$[Ru(bpy)_2Cl_2] \cdot 2H_2O$ (0.052 g, 0.1 mmol), $cpipH \cdot 0.2C_2H_5OH$ (0.046 g, 0.98 mmol), ethanol (8 mL), and $H_2O$ (2 mL) was refluxed at 100 °C for 9 h under nitrogen. The solution was cooled to room temperature and was filtered to remove the insoluble substance. An orange precipitate was obtained by dropwise addition of a fourfold excessive of aqueous $NaClO_4$ solution. The product was purified by column chromatography on silica gel with $CH_3CN/H_2O$/saturated aqueous $KNO_3$ (400:7:1, v/v/v) as eluent followed by reprecipitation with aqueous $NaClO_4$ solution. Red crystals were obtained. Yield

# Ionic Liquids: Synthesis and Characterisation of Triphenylphosphonium Tosylates

**Ludovic G. Bonnet[a] and Benson M. Kariuki*[a]**

**Keywords:** Structure elucidation / Ionic liquids / Solid-state structures / Melting points

Ionic liquids are currently attracting considerable interest from chemists, partly due to their potential as "green" alternatives to volatile molecular organic solvents. Phosphonium ionic liquids have received much less attention than ammonium salts in the past, but the situation is changing. The salts are applied in the liquid state but in this work, salts with higher melting points than is generally the case are investigated. They are solid at room temperature, thus enabling facile separation of liquid reaction products. Nine triphenylphosphonium tosylates have been prepared and characterised; their crystal structures have been determined and their melting points have been scrutinized, showing some sensitivity to the duration of drying. The structural information is expected to be invaluable in the understanding of the properties of the molten state.

## Introduction

Although ionic liquids were first described as long ago as 1914,[1] it is only relatively recently that they have received much attention from chemists.[2–5] The last few decades have witnessed increased application, initially as media for organic synthesis and later on with multiple uses. A number of properties make ionic liquids particularly suited to application as solvents; they have high thermal stability, low vapour pressure and the ability to dissolve a large range of inorganic, organic and polymeric materials. In addition, they have a wide liquid range and are relatively cheap and easy to prepare.

The terms "ionic liquid" and "room temperature ionic liquid" often refer to ionic salts with melting points below ca. 100 °C. Many ionic liquids studied to date fall within this category and, in particular, salts containing quaternary nitrogen cations have been investigated extensively. A number of phosphonium salts also fall within this low melting point class. A factor in the growing interest in these materials is their potential as "green" alternatives to molecular organic solvents; replacement of volatile organic solvents by ionic liquids, which are involatile, would significantly reduce their detrimental impact on the environment. This aspect will undoubtedly become increasingly important as the level of awareness and concern for the habitat intensifies.

Although phosphonium salts have attracted much less interest in the literature than quaternary nitrogen salts to date, their potential as ionic solvents has been recognized for a long time. For example, the first palladium-catalysed reaction in an ionic liquid was carbon–carbon coupling in tributylhexadecylphosphonium bromide.[6] Tetrabutylphosphonium halides (TBPHs) featured prominently in the earlier application of phosphonium salts as ionic solvents. One of the first reported uses of a phosphonium salt as a solvent in an organic reaction was of TBPHs in regioselective *o*-alkylation leading to an efficient and recyclable catalytic system.[7] Several years earlier, in 1981, TBPHs had been used in the ruthenium-catalysed hydrogenation of carbon monoxide to ethyleneglycol.[8] Hydroformylation of olefins in TBPHs and other quaternary phosphonium salts has also been demonstrated.[9,10] Interest in application as alternative solvents and co-catalysts continues to grow.[11]

In this investigation, we consider triphenylphosphonium salts with higher melting points than conventional ionic liquids, focusing exclusively on the tosylates shown in Scheme 1. The efficacy of some of the tosylates has already been demonstrated. The first reported use of a phosphonium molten salt with a tosylate counterion was as the solvent for catalytic hydroformylation of hex-1-ene to heptanal and 2-methylhexanal using **1**, **3**, **5** and **9**.[12] This established that alteration of the substituents in the cation could affect product distribution. Diels–Alder reactions of isoprene with methyl acrylate, but-3-en-2-one and acrylonitrile have also been performed in phosphonium tosylates, including **1**, **3**, **5** and **9**.[13] The results indicate that product selectivity varies with cation substituent and also that the solvents are more suitable for the reactions of oxygen-containing dienophiles than for nitrogenous ones, showing high regioselectivity. Phosphonium salts including **1** and **9** have also been reported to be good co-catalysts for the Baylis–Hillman reac-

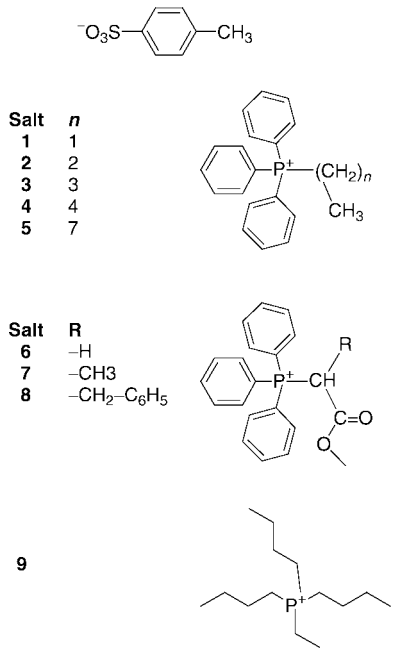
tion with the results showing that neither modification of the cation substituents nor a change in the anion has a major effect on the yield.[14] The tosylates have also been used in rhodium-catalysed transfer hydrogenation of acetophenone.[15]



Scheme 1. The phosphonium tosylates under investigation.

In addition to the general properties of ionic liquids mentioned above, phosphonium salts have a number of other advantages. They can be prepared without halide contamination and therefore be used with no adverse effect on metal catalysts. They are also more thermally stable than quaternary nitrogen salts and thus can be applied under more demanding reaction conditions. The tosylates are relatively inexpensive, easily available, noncorrosive and are stable in air as well as in moisture. A high melting point has been found to be beneficial for the following reason. At the reaction temperature (above the melting point of the salt), the phosphonium salts act as solvents (for catalysts and reagents), allowing homogeneous conditions. On cooling, the salts crystallise out and trap the catalyst thereby enabling easy separation of liquid products. For example, in the hydroformylation,[12] Diels–Alder[13] and hydrogenation[15] reactions mentioned above, product separation involved filtration or decantation of the liquid organic product. The catalyst system or ionic solvent was subsequently reusable.

The growing interest in these materials as well as their potential as alternatives to other ionic and volatile organic solvents makes more fundamental research into their properties imperative. The properties of triphenylphosphonium salts can be affected by a change in the nature of both cation and anion; as a consequence, solvents can be tailor-made for a specific reaction by tuning their properties. For this to be achievable, the correlation between the physicochemical properties of the solvents and the molecular structure needs to be established.[4] This is a sizeable challenge as the number of available cations and anions is immense. Any investigation, therefore, needs to be performed systematically.

Melting points, which are an indication of the lower temperature limit of application of ionic solvents, can be related to the crystal structures and are looked at in some detail in this study. However, ionic salts are applied in the liquid state, where the challenge is to understand properties such as viscosity and ion diffusion. The more ordered crystalline state can provide important information (such as molecular geometry, intra- and intermolecular contacts) to assist in the process of beginning to understand and possibly model the properties of the liquid state. This is a realistic approach as shown by studies of imidazolium ionic liquids in which a correlation has been found between the structural properties of the solid state and those of the liquid state.[16–20] To the best of our knowledge, no structural information has been published for any triphenylphosphonium tosylates. An aim of this study has been to obtain this information, and to this end, the salts shown in Scheme 1 have been synthesised and characterised.

## Results and Discussion

### Melting Points

Melting points are invaluable in the characterisation of materials. In the case of ionic liquids, accurate melting points (along with boiling points and decomposition temperatures) are essential as they give an indication of the range of application. Melting points are also sensitive to the purity of the material – an important consideration as impurities may change the nature of ionic solvents. The melting points determined during this study are shown in Table 1. The "initial" values in the Table were obtained after sample preparation and some showed significant deviations from previously reported values. There were also some

Table 1. Melting points ($T_{mp}$) for the triphenylphosphonium tosylates.

| Salt | *n* | $T_{mp}$ [°C] | | |

discrepancies between the various reports,[12,21–23] and hence further examination was undertaken.

The initial samples were rinsed using a volatile solvent and did not appear to be wet, but additional drying was found to raise the melting points significantly for some. The drying process was repeated until no further change was observed. Thus, for example, the melting point of **1** rose from 118–120 °C to 139–141 °C on storage under vacuum for several days and that of **6** increased from 154–156 °C to 164–166 °C under the same treatment. With the exception of **5**, which is a solvate, none of the analytical techniques indicated the presence of significant amounts of solvent in the initial samples and powder X-ray diffraction confirmed that no observable change in phase or crystallinity occurred during the drying process.

The final values of melting points obtained are also shown in Table 1. One literature value for **3** and that for **9** are significantly higher than the final values from this study, suggesting that even higher melting points might be obtained by further treatment. The final values from this study, along with the literature values for the *n*-alkyltriphenylphosphonium tosylates, are plotted in Figure 1. The need for reliable values is clearly illustrated by **1**. Going by the previously reported melting point, **1** falls within the conventional definition of ionic liquids (i.e. m.p. < 100 °C), whereas a considerably higher value has been obtained during this study. It is noted in passing, however, that **1**, **3** and **5** have been used at temperature as low as 80 °C, 40 °C and 60 °C[13] respectively although the melting points obtained for the pure phases are ca. 140 °C, 133 °C and 130 °C, respectively. This is attributable to the "impurity" effect of the reagents on the ionic solvents.

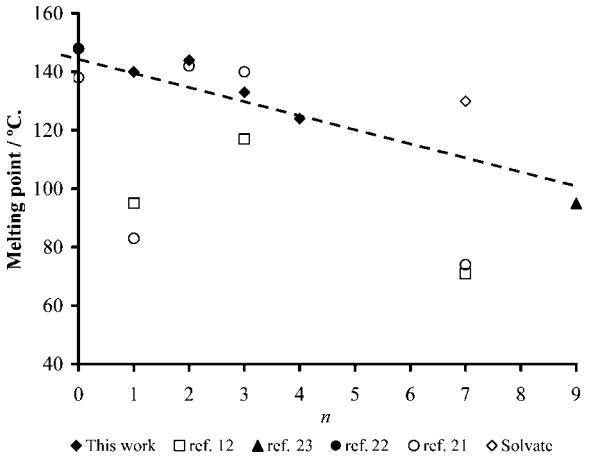

Figure 1. Melting points for the alkyltriphenylphosphonium tosylates.

Incorporation of solvent of crystallisation is clearly a consideration when selecting a salt for use as a solvent. Unlike the other samples investigated, the structure of **5** ($n$ = 7) included the solvent (dichloromethane). Two values have been reported previously for the melting point of **5**, and it is noteworthy that although they are close to each other, the range is quite large for one (8 °C). If an assumption is made that melting points decrease gradually with increasing $n$ for nonsolvated triphenylphosphonium tosylates (the dashed line in Figure 1), then a possible discrepancy is apparent for **5**, with the reported values falling well below that predicted.

The DSC results obtained indicate that endothermic processes occur at temperatures consistent with the melting

points. The peaks are sharp for the alkyltriphenyl compounds (**1**–**4** and **9**), and there is no indication of thermal instability within the timescale and temperature range of the experiment. These salts have high thermal stability, are tolerant toward air and are reusable as solvents.[12,13] On the other hand, DSC shows broader features in the cases of **5**–**7**; loss of the solvent is clearly a factor in **5**, whereas the results may be an indication of thermal transformation close to the melting point for the esters **6** and **7**.

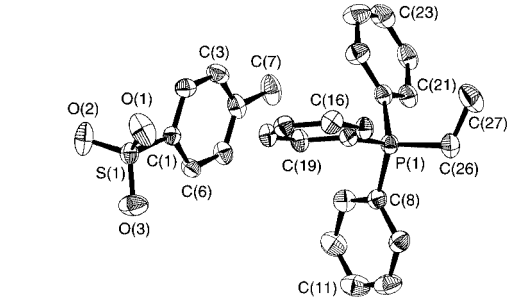
## Structural Characterisation

Crystallographic data for **1**–**5** are shown in Table 2 and data for **6**–**9** are shown in Table 3. The asymmetric units are shown in Figure 2(a) to Figure 10(a).

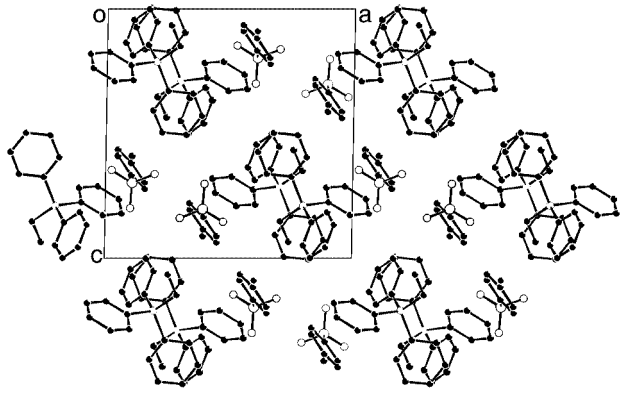
### *Alkyltriphenylphosphonium Tosylates*

In the structure of **1**, tosylate ions are linked by C(3)–H(3)···O(2) interactions (with a H···O distance of 2.4 Å, a C–H···O angle of 170°) to form zigzag chains along the *b*-axis. These chains are arranged side-by-side to form sheets parallel to the (1,0,–1) plane, leading to a layered structure (Figure 2, b). In the structure, a number of edge-to-face interactions with "nonideal" geometry are observed. For example, an aromatic ring of the cation is the donor to two anion rings with planes at ca. 60° and 70° to it and both with CH···π(ring-plane) distances of ca. 3 Å. In the anion, the oxygen closest to the plane of the aromatic ring forms a torsion angle [O(3)–S(1)–C(1)–C(6)] of 16.9(3)°.

For **2**, the propyl chains of the cations are in *trans* conformation relative to the phosphorus atoms to which they are attached. In the crystal, the cations form channels, which run parallel to the *a*-axis and are occupied by pairs of anion chains (Figure 3, c). The two closest C–H···O contacts involve aryl hydrogen atoms [with angles C(26)–H(26B)···O(3) = 160.9(4)° and C(13)–H(13)···O(1) = 164.0(3)° and distances O(3)···H(26B) = 2.39(1) Å and O(1)···H(13) = 2.33(1) Å]. In the crystal structure, pairs of cations are linked by edge-to-face interactions involving all six



(a)



(b)

Figure 2. (a) The asymmetric unit and (b) the crystal structure of **1** viewed down the *b*-axis. Hydrogen atoms have been omitted for clarity.

phenyl rings as shown in Figure 3, (b) and, in addition, close CH···π contact occurs between a proton from a ring of the anion and one cation ring. For these interactions, the C–H···π(ring-plane) distances are in the 2.9–3.3 Å range. The oxygen closest to the plane of the aromatic ring of the anion forms a torsion angle O(2)–S(1)–C(1)–C(2) of –16.2(4)°.

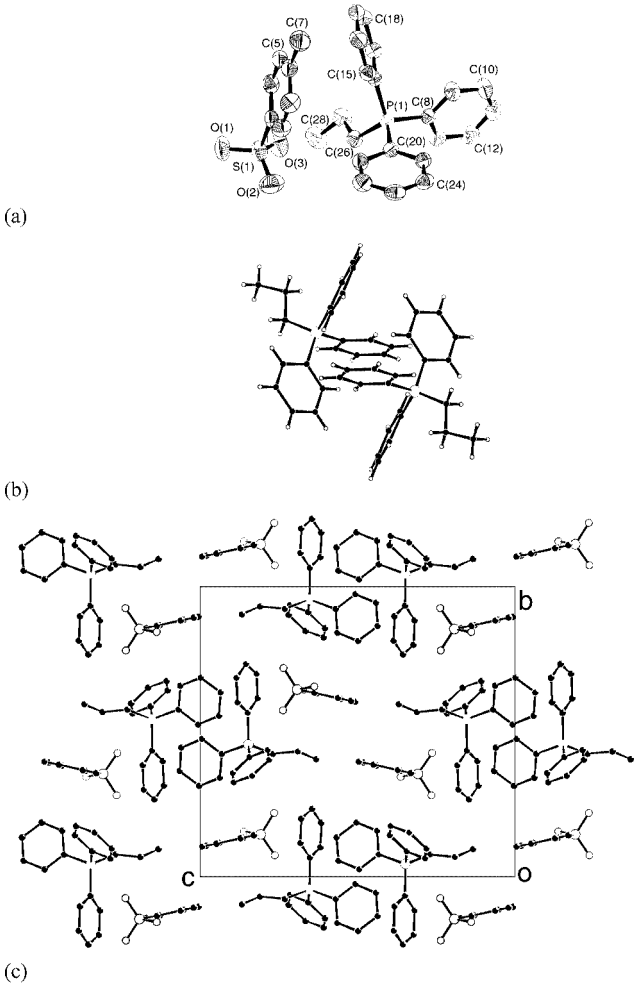

Figure 3. (a) The asymmetric unit, (b) a pair of cations and (c) the crystal structure of **2** viewed down the *a*-axis. Hydrogen atoms have been omitted from (a) and (c) for clarity.

The butyl chain in the crystal structure of **3** is also *all-trans* in conformation. In the structure (Figure 4, c), the tosylate anions are isolated from each other, with no direct contact between them. Pairs of symmetry related cations interact through edge-to-face contacts as shown in Figure 4, b. Each cation acts as both a donor and acceptor, with C–H···π(ring-centre) distance of ca. 2.64 Å. The two ions are also involved in π···π contact with a distance of ca. 3.5 Å between the planes of rings showing ca. 50% overlap. In the structure, a second type of π···π interaction occurs between phenyl rings of neighbouring cations with a separation distance of ca. 4.1 and an overlap of about 1/3 of a ring. The closest C–H···O contacts involve aryl–H and HC–H from the cation [with angles C(16)–H(16)···O(2) = 168.6(5)°, C(24)–H(24)···O(1) = 175.2(5)° and C(26)–H(26B)···O(1) = 173.4(4)° and contact distances O(2)···H(16) = 2.43(1) Å, O(1)···H(26B) = 2.29(1) Å, O(1)···H(24) = 2.37(1) Å]. The oxygen closest to the plane of the aromatic ring of the anion forms a torsion angle O(2)–S(1)–C(1)–C(2) of 12.8(4)°.

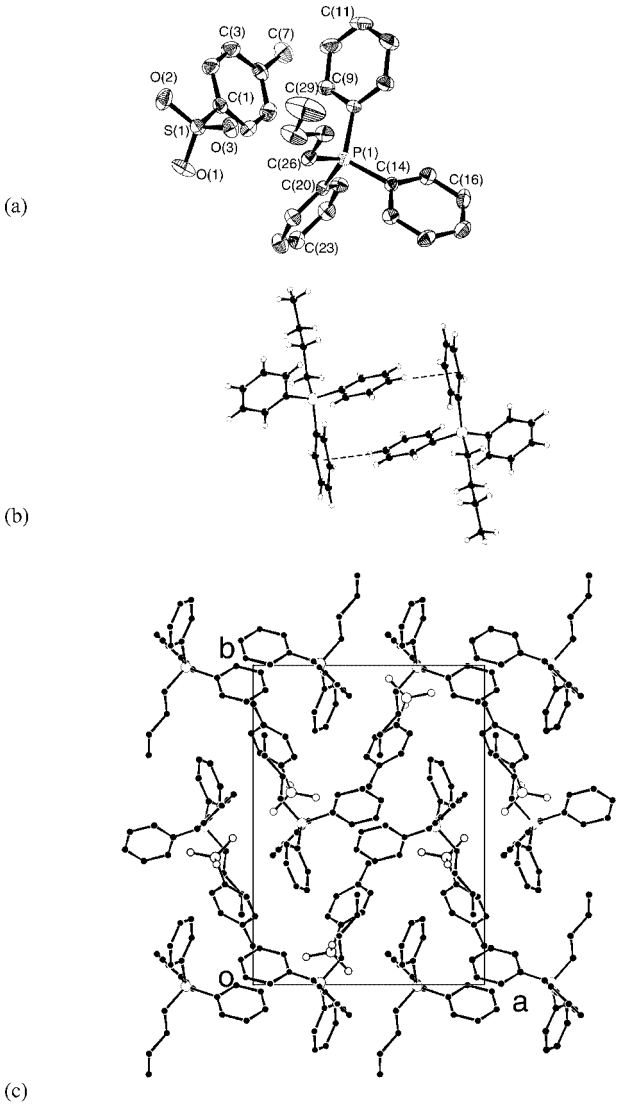

Figure 4. (a) The asymmetric unit of **3**, (b) a pair of cations with the dashed lines showing CH···π contacts and (c) the crystal structure viewed down the *c*-axis. Hydrogen atoms have been omitted from (a) and (c) for clarity.

In the structure of **4**, (Figure 5, c) the pentyl group of the cation is disordered with two components of 63% and 37% occupancy. For the major component, the chain adopts an all-*trans* conformation, except for the terminal methyl group which is *gauche*. As suggested by the similarity in the cell parameters and symmetry, the crystal structures of **3** and **4** are almost identical. Thus pairs of molecules interact in a manner similar to those discussed for **3**, with C–H···π(ring-centre) distance of ca. 2.67 Å and π···π contact interplanar distance of ca. 3.5 Å for rings showing 50% overlap (Figure 5, b). The separation between the planes of the pair of rings involved in the second type of π···π interaction (1/3 ring overlap) is also 4.1 Å. Aryl and $CH_2$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

hydrogen atoms from the cation involved in the closest C–H···O contacts have CH···O distances: O(1)···H(19B) = 2.4(1) Å, O(1)···H(11) = 2.4(1) Å, O(2)···H(19A) = 2.4(1) Å and C–H···O angles: C(11)–H(11)···O(1) = 174.9(5)°, C(19)–H(19B)···O(1) = 170.6(5)°, C(19)–H(19A)···O(2) = 156.9(5)°. The oxygen closest to the plane of the aromatic ring of the anion forms a torsion angle O(3)–S(1)–C(24)–C(29) of 11.5(4)°.

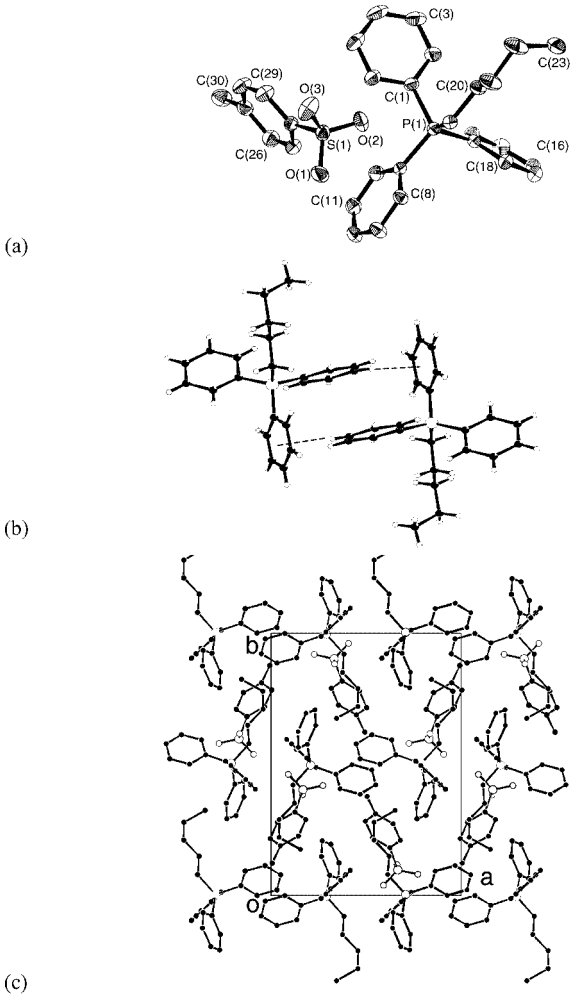

Figure 5. (a) The asymmetric unit of **4**, (b) a pair of cations with the dashed lines showing CH···π contacts and (c) the crystal structure viewed down the *c*-axis. Hydrogen atoms have been omitted from (a) and (c) for clarity.

Unlike the other salts, the crystals of **5** included the dichloromethane solvent (Figure 6, b). The structure consists of channels, parallel to the *a*-axis, which are occupied by the anions. The closest C–H···O contacts have distances: O(1)···H(26B) = 2.2(2) Å, O(1)···H(10) = 2.4(2) Å, O(2)···H(34A) = 2.4(2) Å and C–H···O angles: C(26)–H(26B)···O(1) = 178.7(9)°, C(10)–H(10)···O(1) = 176.0(9)°, C(34)–H(34A)···O(2) = 135.3(9)°. The oxygen closest to the plane of the aromatic ring of the anion forms a torsion angle O(2)–S(1)–C(1)–C(6) = 16.6(9)°. Interactions of π···π type also occur for a pair of cations (Figure 6, b), with an interplanar distance of ca. 3.5 Å for rings showing an overlap of ca. 1/3 of a ring. The rings involved are also donors in C–H···π interactions with –H···π distances of ca. 2.7 Å.

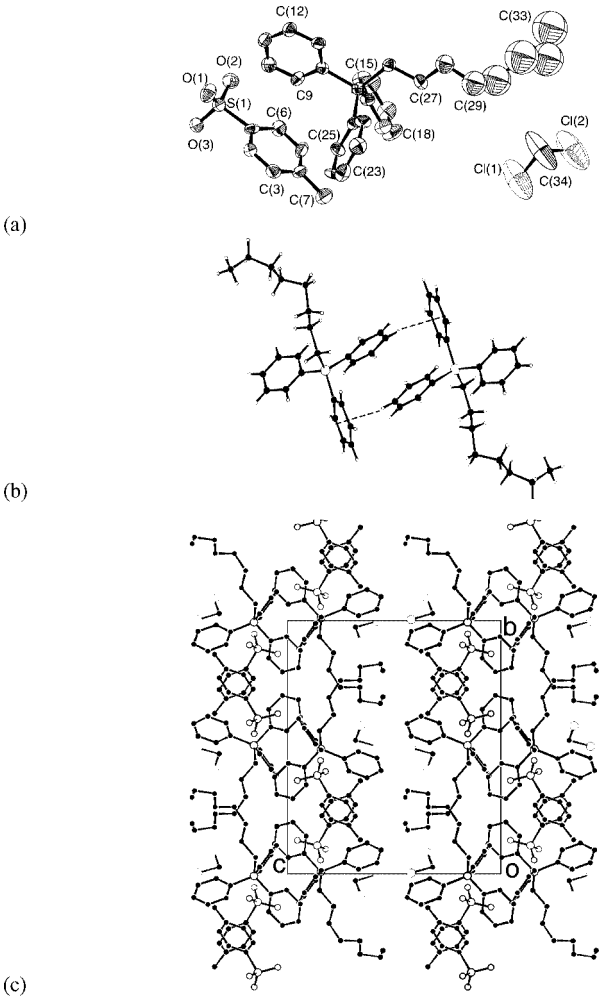

Figure 6. (a) The asymmetric unit, (b) a pair of cations with the dashed lines showing CH···π contacts and (c) the crystal structure of **5** viewed down the *a*-axis. Hydrogen atoms have been omitted from (a) and (c) for clarity.

### *Tosylates of Triphenylphosphonium Esters*

In the crystal structure of **6**, the cations form channels, parallel to the *a*-axis, which are occupied by straight chains of tosylate anions (Figure 7, b). A number of edge-to-face interactions are observed with the tosylate anion as the donor and the cation as the acceptor. However, the planes of the rings involved are not perpendicular. For example, a C–H···π(ring-plane) distance of 2.9 Å is observed between rings with planes oriented ca. 60° relative to each other. The closest CH···O contacts involve cation methylene groups and tosylate oxygen atoms, with distances O(1)···H(26A) = 2.24(1) Å, O(2)···H(26B) = 2.26(1) Å, and angles C(26)–H(26A)···O(1) = 153.3(6)°, and C(26)–H(26B)···O(2) = 164.6(6)°. The oxygen closest to the plane of the aromatic ring of the anion forms a torsion angle O(1)–S(1)–C(1)–C(6) is –19.4(6)°.

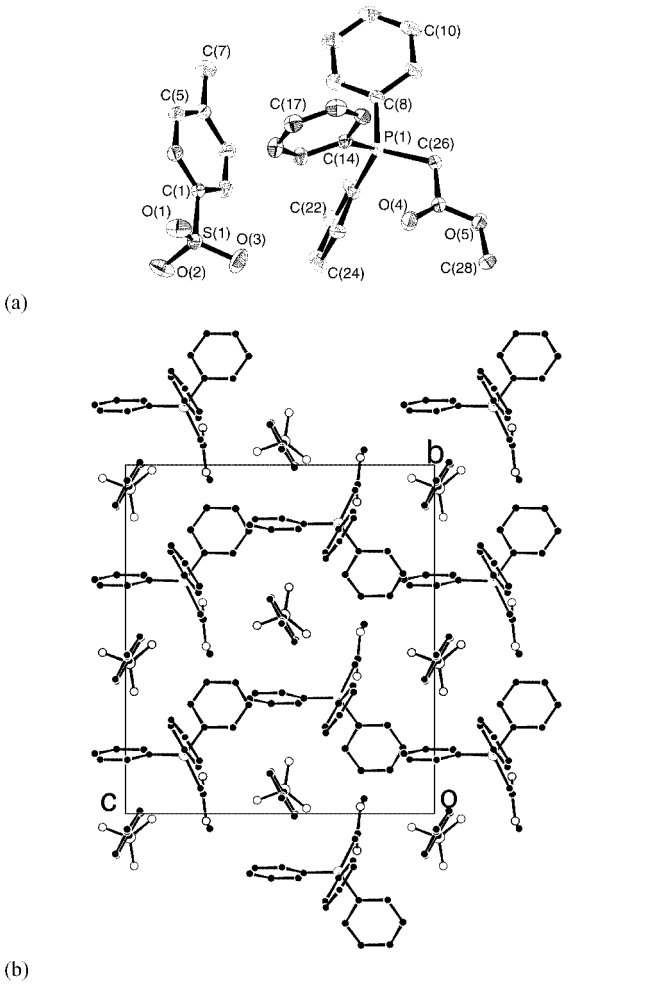

Figure 7. (a) The asymmetric unit and (b) the crystal structure of **6** viewed down the *a*-axis. Hydrogen atoms have been omitted for clarity.

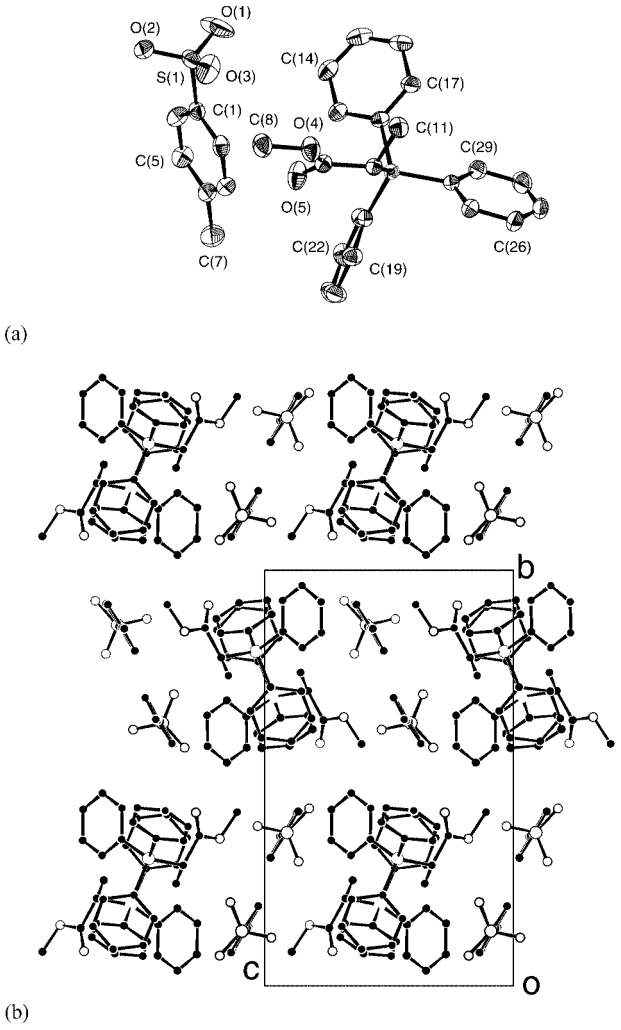

Figure 8. (a) The asymmetric unit and (b) the crystal structure of **7** viewed down the *a*-axis. Hydrogen atoms have been omitted for clarity.

In the crystal structure of **7**, the cations also form channels, running parallel to the *a*-axis (Figure 8, b), which are occupied by zigzag chains of tosylate anions. In the crystal structure, the closest C–H···π distance for an edge-to-face type of interaction involves a cation donor and anion acceptor with a distance of ca. 3.1 Å for rings oriented ca. 100° apart. The shortest C–H···O contact involves the tertiary proton of the cation and one tosylate oxygen with a distance O(2)···H(10) of 2.17(4) Å and angle C(10)–H(10)··· O(2) of 175(3)°. The oxygen closest to the plane of the aromatic ring of the anion forms a torsion angle O(3)–S(1)–C(1)–C(2) of –11.7(4)°.

The crystal structure of **8** (Figure 9, b) does not contain channels. The cations pack in layers, parallel to the *ab* plane, between which isolated anions are located. Edge-to-face interactions are found and involve one cation ring acting as donor to two rings of two neighbouring cations. The two acceptor rings are almost perpendicular to the donor ring, with a C–H···π(ring-plane) distance of ca. 3 Å. The shortest CH···O contact involves an aryl proton and a tosylate oxygen with a distance O(3)···H(17) of 2.40(1) Å and angle C(17)–H(17)···O(3) of 141.5(4)°. The oxygen closest to the plane of the aromatic ring of the anion forms a torsion angle O(2)–S(1)–C(1)–C(2) of –29.2(8)°.

### *Tributyl(ethyl)phosphonium Tosylate*

In the crystal structure of **9**, the methyl group of one butyl chain of the cation is disordered with two components of 60% and 40% occupancy. Considering just the major component, all the alkyl chains adopt *trans* conformation, apart from one, in which the methyl group is *gauche*. In the structure, the tosylate anions are isolated from each other, each being surrounded by cations. The structure can be visualised as being composed of sheets parallel to the *ab* (Figure 10, b), with intermolecular C–H···O contacts occurring within the sheets. The shortest CH···O contacts involve one tosylate oxygen with distances: O(1)···H(18A) = 2.4(3) Å, O(1)···H(12A) = 2.4(2) Å and angles: C(18)–H(18A)···O(1) = 173(1)°, C(12)–H(12A)···O(1) = 153(1)°. The oxygen closest to the plane of the aromatic ring of the anion forms a torsion angle O(1)–S(1)–C(1)–C(2) of –15.1(2)°.

## Conclusions

The observations made during this study show that some care needs to be exercised when determining and using the melting points of these materials. The values obtained suggest that minute amounts of solvent can have a significant effect on the melting points, a possible explanation for the inconsistencies in the previously reported values.

Being ionic, coulombic interactions obviously exist in all these materials. Another feature common to all nine salts is the absence of strong hydrogen-bond donors. There is thus no single strong directional interaction to influence crystal packing. Despite this, a number of structural patterns, which may be valuable when modelling their liquid properties, are evident. In the tosylate anion the angles between the ring and the plane through the C–S–O group containing the oxygen atom closest to the ring fall within the range 11–20° (except for **8** in which the angle is ca. 30°). Apart from **5**, none of the salts contains solvent of crystallisation, a desirable characteristic in ionic solvents. All structures (**1**–**9**) show some degree of C–H···O contact with the tosylate ion acting as the acceptor. In addition, ring edge-to-face C–H···π interactions of variable geometry are also observed (the exception in the C–H···π case is **9**, in which the cation has no phenyl groups). C–H···X interactions (e.g. with X = halide or π) are a recurring theme in the field of ionic liquids and have been described extensively for, for example, imidazolium salts.[16–20]

The cations in the *n*-alkyltriphenylphosphonium salts **1**–**5** tend to pack in pairs (with the exception of **1**, in which the short alkyl chain may allow more favourable alternative packing in the crystal). This motif involving pairs of $(phenyl)_3P$ groups is not unusual and has been observed in, for example, neutral triphenylphosphane oxides.[24] In the structures of **3**–**5**, the pairs of rings involved in C–H···π interactions are almost perpendicular, with interplanar angles of 86°, 85° and 81° respectively. The C–H···π distances (ca. 2.7 Å) in these three structures are also the shortest observed during this study and are similar to the average value obtained in a survey of organometallic materials (2.79 Å).[25] The donor rings in the ion pairs in **3**–**5** are also involved in π···π contacts, clearly leading to a stable motif. Although only a few structures have been determined, some clear differences are observed between the *n*-alkyl salts on the one hand and ester salts on the other. In the case of the esters, cation pairs are not observed and, in addition, the three structures are noncentrosymetric.

We believe that as in the case of imidazolium salts reported before, the structural information from this study will be important in future attempts to gain insight into the structural characteristics of ionic liquids of this type and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

will aid in the understanding of the nature of interactions with solutes.

## Experimental Section

**Techniques:** NMR spectra were recorded with a Bruker AC-300 ($^1$H, 300 MHz; $^{13}$C, 75.5 MHz) and a Bruker AV-300 ($^1$H, 300 MHz; $^{13}$C, 75.5 MHz). Chemical shifts are described in parts per million (ppm) downfield shift from $SiMe_4$ and are reported consecutively as position ($\delta_H$ or $\delta_C$), multiplicity (s = singlet, d = doublet, t = triplet, q = quadruplet, m = multiplet, dd = doublet of doublet), coupling constant (*J*/Hz), relative integral and assignment. Proton NMR spectra were referenced to the chemical shift of residual proton signals ($CHCl_3$ $\delta$ = 7.27 ppm). Carbon spectra were referenced to a $^{13}$C resonance of the solvent ($CDCl_3$ $\delta$ = 77.16 ppm). $^{31}$P NMR spectra were referenced internally on $H_2PO_4$ 5%/$D_2O$ ($\delta$, 0.00). Mass spectra were recorded with a VG Zabspec spectrometer. LSIMS (ceasium ionisation) was performed using 3-nitrobenzyl alcohol as the matrix. DSC results for **1**–**7**, **9** were obtained using a Perkin–Elmer Pyris 1 instrument between 25 and 200 °C at a heating rate of 20°/min with nitrogen purge gas and aluminium sample pans.

Single crystals were obtained by slow diffusion of diethyl ether into a dichloromethane solution of the salt. Single-crystal diffraction data for **1**–**3**, **6**–**9** were recorded at ca. 296 K with a Rigaku R-axis II diffractometer equipped with a molybdenum rotating anode source and an image plate detector system. Data for **4** and **5** were recorded with a Bruker Smart 6000 diffractometer equipped with a CCD detector and a copper-tube source. Structures were solved and refined using SHELXL.[26] During final refinement, aromatic C–H atoms were riding on the atoms they are bonded to with a bond length of 0.93 Å. Powder diffraction data confirm that the crystal structures obtained are representative of the bulk samples, except for **8**, where the amount of crystalline material obtained was too small for powder diffraction.

CCDC-277854 to -277862 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Syntheses:** All manipulations were performed under argon using standard Schlenk techniques. All solvents were dried with the appropriate drying agent and distilled under dinitrogen: sodium benzophenone ketyl (diethyl ether, toluene) or calcium hydride (dichloromethane). Unless otherwise stated, all reagents were purchased from Aldrich, Acros or Lancaster and used as supplied. All the *p*-toluenesulfonates were obtained in good yield and high purity using known literature methods.[27]

The same method was used for all salts. Salts **1**–**5** were obtained by refluxing a 1:1 molar ratio solution of the alkyl *p*-toluenesulfonate (ca. 4 g) and triphenylphosphane (ca. 5 g) in toluene (ca. 50 mL) for 18 hours under argon. The solvent was then removed under reduced pressure and the residual was washed with diethyl ether. The resulting solid was recrystallised from dichloromethane/diethyl ether to a crystalline white solid.

The appropriate methoxycarbonylalkyl *p*-toluenesulfonate was used for **6** and **7**. The recrystallised product obtained for **6** had a pale brown colouration. For **8**, methyl 3-phenyl-2-(tolyl-4-sulfonyloxy)propionate was used and the solution was refluxed for 42 hours. The final recrystallised product was pale yellow in colour. A solution of ethyl *p*-toluenesulfonate and tributylphosphane was refluxed as described above to yield **9**.

**Ethyltriphenylphosphonium Tosylate (1):** Ethyl *p*-toluenesulfonate (3.8 g, 19.0 mmol) and triphenylphosphane (5.0 g, 19.1 mmol) afforded a crystalline white solid (8.1 g, 92%). M.p. 139–141 °C (ref.[21] 82–83 °C, ref.[12] 94–95 °C). FAB+: *m*/*z* (%) = 291 (100) $[M - C_7H_7SO_3]^+$, 753 (8) $[2M - C_7H_7SO_3]^+$. $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 1.34 (dt, $^3J_{H,H}$ = 7.4, $^3J_{P-H}$ = 20.1 Hz, 3 H, $CH_2CH_3$), 2.31 (s, 3 H, $CCH_3$), 3.60 (m, 2 H, $CH_2$), 7.08 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, $^{tosylate}$Ar-*H*), 7.63–7.79 (m, 17 H, Ar-*H*) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 75.5 MHz): $\delta$ = 5.6 (d, $^2J_{P,C}$ = 5.2 Hz, $CH_2CH_3$), 14.8 (d, $^1J_{P,C}$ = 52.3 Hz, $CH_2$), 20.3 ($CCH_3$), 116.8 (d, $^1J_{P,C}$ = 86.2 Hz, $^{phosphonium}$Ar-$C_{ipso}$), 125.1, 127.3 ($^{tosylate}$Ar-*C*H), 129.4, 129.5, 132.4, 132.5, 134.0 ($^{phosphonium}$Ar-*C*H), 137.6, 143.5 ($^{tosylate}$Ar-$C_{ipso}$) ppm. $^{31}$P NMR ($D_2O$, 121 MHz): $\delta$ = 26.3 ($^{phosphonium}P$) ppm.

**Triphenyl(propyl)phosphonium Tosylate (2):** Propyl *p*-toluenesulfonate (4.0 g, 18.7 mmol) and triphenylphosphane (4.9 g, 18.7 mmol) afford a crystalline white solid (8.4 g, 94%). M.p. 143–145 °C (ref.[21] 141–143 °C). FAB+: *m*/*z* (%) = 305 (100) $[M - C_7H_7SO_3]^+$, 781 (5) $[2M - C_7H_7SO_3]^+$. $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 1.18 (m, 3 H, $CH_2CH_3$), 1.61 (m, 2 H, $CH_2CH_3$), 2.33 (s, 3 H, $CCH_3$), 3.52 (m, 2 H, $PCH_2$), 7.04 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, $^{tosylate}$Ar-*H*), 7.62–7.84 (m, 17 H, Ar-*H*) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 75.5 MHz): $\delta$ = 14.7 (d, $^3J_{P,C}$ = 17.2 Hz, $CH_2CH_3$), 16.0 (d, $^2J_{P,C}$ = 4.0 Hz, $CH_2CH_3$), 20.9 ($CCH_3$), 23.1 (d, $^1J_{P,C}$ = 50.6 Hz, $PCH_2$), 117.9 (d, $^1J_{P,C}$ = 85.6 Hz, $^{phosphonium}$Ar-$C_{ipso}$), 125.8, 127.8 ($^{tosylate}$Ar-*C*H), 130.0, 130.2, 133.0, 133.2, 134.5 ($^{phosphonium}$Ar-*C*H), 137.8, 144.5 ($^{tosylate}$Ar-$C_{ipso}$) ppm. $^{31}$P NMR ($D_2O$, 121 MHz): $\delta$ = 23.9 ($^{phosphonium}P$) ppm.

***n*-Butyltriphenylphosphonium Tosylate (3):** *n*-Butyl *p*-toluenesulfonate (3.5 g, 15.3 mmol) and triphenylphosphane (4.0 g, 15.3 mmol) afforded a crystalline white solid (7.0 g, 93%). M.p. 132–134 °C (ref.[21] 139–140 °C, ref.[12] 116–117 °C). FAB+: *m*/*z* (%) = 319 (100) $[M - C_7H_7SO_3]^+$, 809 (11= $[2M - C_7H_7SO_3]^+$. $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 0.86 (t, $^3J_{H,H}$ = 7.1 Hz, 3 H, $CH_2CH_3$), 1.52 (m, 4 H, $CH_2CH_2CH_3$), 2.28 (s, 3 H, $CCH_3$), 3.50 (m, 2 H, $PCH_2$), 7.01 (d, $^3J_{H,H}$ = 7.9 Hz, 2 H, $^{tosylate}$Ar-*H*), 7.57–7.79 (m, 17 H, Ar-*H*) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 75.5 MHz): $\delta$ = 13.3 ($CH_2CH_3$), 20.9 ($CCH_3$), 21.3 (d, $^1J_{P,C}$ = 50.6 Hz, $PCH_2$), 23.2 (d, $^2J_{P,C}$ = 16.7 Hz, $PCH_2CH_2$), 24.5 (d, $^3J_{P,C}$ = 4.0 Hz, $CH_2CH_3$), 118.0 (d, $^1J_{P,C}$ = 85.6 Hz, $^{phosphonium}$Ar-$C_{ipso}$), 125.9, 127.8 ($^{tosylate}$Ar-*C*H), 130.1, 130.2, 133.1, 133.2, 134.6 ($^{phosphonium}$Ar-*C*H), 137.9, 144.5 ($^{tosylate}$Ar-$C_{ipso}$). $^{31}$P NMR ($D_2O$, 121 MHz): $\delta$ = 24.2 ($^{phosphonium}P$) ppm.

***n*-Pentyltriphenylphosphonium Tosylate (4):** *n*-Pentyl *p*-toluenesulfonate (3.8 g, 15.6 mmol) and triphenylphosphane (4.1 g, 15.6 mmol) afforded a crystalline white solid (6.9 g, 87%). M.p. 123–125 °C. # A Theoretical Study on $Pd^{II}$ Complexes Containing Hemilabile Pyrazole-Derived Ligands

**Albert Rimola,[a] Mariona Sodupe,*[a] Josep Ros,[a] and Josefina Pons*[a]**

**Keywords:** $Pd^{II}$ complexes / Pyrazole / Hemilabile ligands / Density functional theory

The properties of $Pd^{II}$ complexes containing hemilabile pyrazole-derived ligands (L) of the form BPz-$(CH_2)_x$-$A(CH_2)_yA(CH_2)_x$-PzB, with A being a donor atom and B a substituent group at the pyrazole ring, have been investigated through quantum-chemical calculations. The geometries of the $[PdLCl_2]$ and $[PdL]^{2+}$ complexes have been optimized and the reaction free energy of $[PdLCl_2] \rightarrow [PdL]^{2+} + 2\ Cl^-$ computed for 32 different ligands, using the hybrid B3LYP density functional method. The formation of the tetracoordinate $[PdL]^{2+}$ complexes is more favorable for the longer (eight- and nine-membered) chains than for the shorter (six- and seven-membered) ones. Moreover, results show the nature of the donor atom A influences significantly the formation of $[PdL]^{2+}$, the process becoming more favorable according to the order PH > NH > S > O. Finally, electron-donor substituents at the pyrazole ring enhance the formation of $[PdL]^{2+}$, whereas electron-acceptor groups hinder the process.

## Introduction

The study of hemilabile ligands has received an increasing interest in recent years. The main reason for this attention is the capability of hemilabile ligands to generate vacant coordination sites and to stabilize reaction intermediates which result in promising chemical properties. The relevance and utility of this concept gave rise to the publication of excellent reviews which cover all the aspects of these ligands.[1] The term "hemilabile" was first introduced by Jeffrey and Rauchfuss in 1979, and it refers to polidentate coordination ligands which possess at least one substitutionally labile donor function.[2] There are several examples in the literature about the influence of transition-metal complexes with hemilabile ligands in the activation of small molecules[3–6] and in the activity of homogeneous catalysis.[7–9] Furthermore, hemilability probably occurs also in other disciplines such as bioinorganic chemistry or surface phenomena. A very useful classification of hemilabile situations was reported by Braunstein and Naud in an excellent review.[10] According to these authors three general types of hemilability can be visualized (see Scheme 1). Hemilability of type I is found when the labile donor group coordinates and decoordinates spontaneously. In hemilability of type II there is an intramolecular competition between the donor groups in the same ligand (a) or between donor groups of two identical ligands (b). Finally, hemilability of type III refers to a situation where there is a competition between a labile donor center and an external solvent molecule. Although this phenomenon was first studied in mononuclear complexes, it has been expanded to dinuclear[11] and polynuclear ones, particularly to metal clusters.[12] It should be pointed out that, although homofunctional bidentate ligands such as $R_2N(CH_2)_nNR_2$ or $R_2P(CH_2)_nPR_2$ could coordinate in monodentate or bidentate forms, they are not considered hemilabile since their coordination mode depends on the metal center and the effects of the coordinated ligands. In fact, hybrid ligands containing very different do-

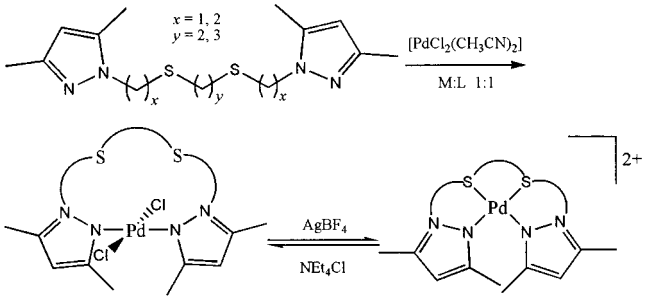
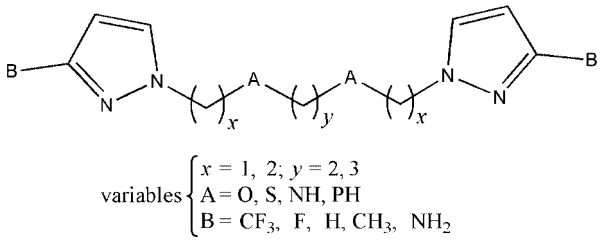
nor functions, such as hard and soft donor atoms, are the basis of most of hemilabile ligands.

Pyrazole-derived ligands are potential hemilabile ligands since steric and electronic properties of both the pyrazole and the ancillary donor groups can be easily tuned.[13] In recent years our research group has reported the synthesis, the characterization and the coordinating properties of pyrazolic ligands containing additional donor groups: N,N,[14] N,O,[15] N,P[16] and N,S.[17] NMR studies of complexes in solution have shown that some of them display hemilability; pyrazole is the stronger (inert) donor group, except in the case of N,P and N,S for which it can also behave as a labile group. Previous studies with Pz-$(CH_2)_x$S$(CH_2)_y$S$(CH_2)_x$-Pz tetradentate ligands and $Pd^{II}$ have shown that both N,N bicoordination and N,S,S,N tetracoordination are obtained and can be interconverted in solution (see Scheme 2).[17c] Moreover, the formation of the N,S,S,N coordinating mode in $Pd^{II}$ complexes appears to be controlled by the geometry imposed by the PdNNCS ring in such a manner that ligands Pz-$(CH_2)_x$S$(CH_2)_y$S$(CH_2)_x$-Pz with $x$ = 1 did not lead to the formation of the tetradentate coordination. However, the N,S,S,N complex was obtained for different lengths of the alkyl chain between S atoms ($y$ = 1, 2). This interesting observation can be visualized as a recognition phenomenon of the planar $Pd^{II}$ ion by the N,S,S,N ligand which would act as a chemical receptor. Given that the selective metal ion recognition plays a fundamental role in the search of chemical and biochemical sensors[18] the combination of both strong and weak donor centers found in the same pyrazole–thioether receptor might open new perspectives in the applications of hemilabile ligands. Some molecular recognition processes involving $Pd^{II}$ complexes were described in the literature.[19,20]



Scheme 2.

The main goal of this paper is to perform a comprehensive theoretical study on the properties of pyrazole-containing ligands (L) of the form BPz-$(CH_2)_x$A$(CH_2)_y$A$(CH_2)_x$-PzB, with A being a donor atom and B a substituent group at the pyrazole ring, through quantum-chemical calculations (Scheme 3). For that, we have optimized the geometry of the $[PdCl_2L]$ and $[PdL]^{2+}$ complexes and computed the reaction free energy of $[PdCl_2L] \rightarrow [PdL]^{2+} + 2\ Cl^-$, for 32 different ligands. This study has allowed us to analyze the influence of the number of $–CH_2–$ groups that join the two pyrazole rings, the nature of donor atoms directly bonded to Pd in the products, and the electronic effects induced by substituent groups at the pyrazole rings.



Scheme 3.

## Results and Discussion

As mentioned, the labile behavior of the ligands exposed in the introduction is given by the thioether groups, the inert groups being the pyrazole rings. This labile behavior varies depending on the number of $–CH_2–$ groups that join the two pyrazole rings (variables $x$ and $y$), but it can also be modified by other factors, such as the nature of the donor atom that is directly bonded to Pd in the products (variable A), and the electronic effects induced by substituent groups at the pyrazole rings (variable B). All these variables, labeled in Scheme 3, affect the electronic and the structural properties of the complexes and, consequently, the hemilabile equilibrium $[PdCl_2L] \rightleftarrows [PdL]^{2+} + 2\ Cl^-$. Free-energy calculations for this reaction with all ligands built with these variables show that there is a clear relationship between the energetic results and the structural factors.

### I. Chain Length

Ligands with different chain lengths have been built by changing the values of variables $x$ and $y$. We have considered six- ($x$ = 1, $y$ = 2), seven- ($x$ = 1, $y$ = 3), eight- ($x$ = 2, $y$ = 2), and nine-membered ($x$ = 2, $y$ = 3) chains. To make the discussion less tedious, hereafter, these systems will be referred to as hexane-, heptane-, octane-, and nonane-chain systems. In all cases, the other variables have been kept fixed to A = S and B = $CH_3$. Since the length of the chain mainly influences the geometry of the reaction products, only the optimized structures of $[PdL]^{2+}$ complexes are shown in Figure 1.

It can be observed that the bond lengths of the newly formed Pd–S bonds show significant deviations (about 0.06 Å) upon increasing the chain length. More importantly, the square-planar coordination of Pd in $[PdL]^{2+}$ can be significantly distorted depending on the length of the ligand. In particular, it is observed that hexane- and heptane-chain systems present N–Pd–N *cis* angles (102°–108°) that are much larger than the N–Pd–S *cis* ones (81°–82°), whereas in octane and nonane structures the computed N–Pd–N *cis* angles (90°–95°) are much closer to the N–Pd–S ones (88°–89°). On the other hand, the N–Pd–S *trans* angles tend to 180° and the deviation from planarity decreases[21]

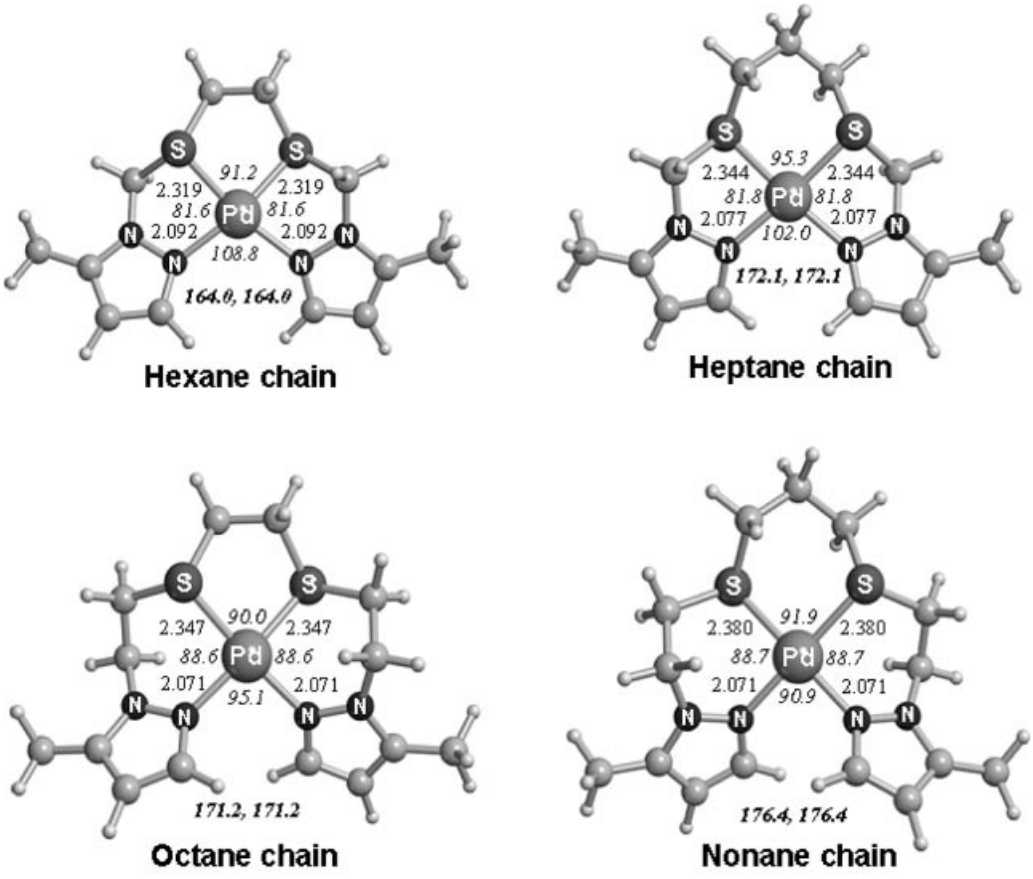

Figure 1. Main geometry parameters optimized at the B3LYP level. Distances are in Å and angles in degrees. Standard numbers correspond to distances, italic numbers to *cis* angles, and bold and italic numbers to *trans* angles.

as the chain length is increased. Therefore, we can conclude that, compared to the ideal square-planar geometry, products with six- and seven-membered chains are more distorted than those with eight- and nine-membered chains. This can be related to the type of rings formed in products. In the hexane-chain products, we obtain three five-membered rings, in the heptane-chain ones two five-membered rings and one six-membered ring, in the octane-chain complexes one five and two six-membered rings and, finally, in nonane-chain products all three rings are six-membered. These results seem to suggest that formation of five-membered rings introduce important strain in the complex that leads to quite distorted structures with respect to the ideal square-planar geometry. Computed structural parameters are in a good agreement with the crystallographic data of related complexes synthesized.[17c]

Reaction free energies have been calculated both in the gas phase and in solution. Calculations in solution have been performed using the conductor-like COSMO continuum model[27] with three different solvents: $CH_3OH$ ($\varepsilon$ = 32.63), acetone ($\varepsilon$ = 20.70), and $CH_2Cl_2$ ($\varepsilon$ = 8.93). Results are given in Figure 2. As expected, the computed free energy of the $[PdLCl_2] \rightarrow [PdL]^{2+} + 2\ Cl^-$ reaction is much smaller in solution than in the gas phase and decreases when the dielectric constant of the solvent increases due to the enhanced stability of the charged species. Nevertheless, in all cases the trends observed upon enlarging the chain length are the same; i.e the reaction is favored from the hexane- to the nonane-chain ligand, the reaction energy decreasing by 23–29 kcal/mol. Since product complexes are the ones that suffer larger structural changes due to the length of the chain, the reaction free energies are expected to be governed by the stability of the products. In principle, it is possible to distinguish two different groups: i) the six-

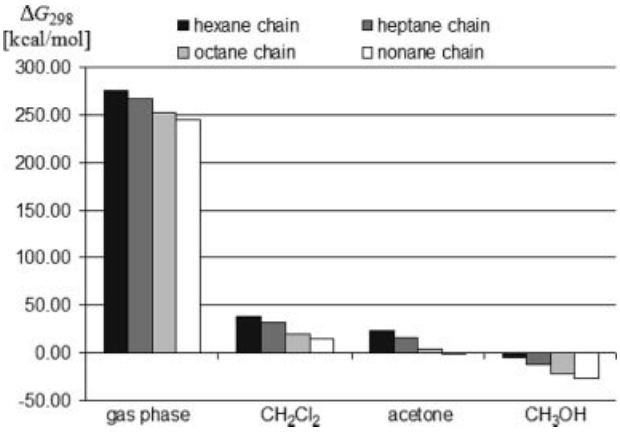

Figure 2. Computed reaction free energies ($\Delta G_{298}$) of $[PdLCl_2] \rightarrow [PdL]^{2+} + 2\ Cl^-$ in the gas phase and in solution. In kcal/mol. Effect of chain length.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and seven-membered chain complexes, and ii) the eight- and nine-membered ones, the reaction energies for the latter species being energetically more favorable. These two groups are the same observed when the structural factors were considered. So, there is a clear trend: the more distorted the products are, the more the equilibrium favors the reactants. These theoretical results agree with the experimental data which show that product complexes with octane- and nonane-chain ligands can be synthesized, whereas those with hexane- and heptane-chain ligands are not observed[17c].

### II. Donor Atom

The changes produced on the structural parameters have been analyzed for four different donor atoms A = O, S, NH, and PH. We have optimized all the structures built with the values $x$ = 1, 2; $y$ = 2, 3; and B = $CH_3$. Table 1 shows the optimized Pd–$N_{azine}$ and Pd–A distances, both for reactants and products.

For reactants, all Pd–$N_{azine}$ distances are similar (2.06–2.07 Å). This is not surprising considering that the chain length does not affect the Pd–NH interaction and that the donor atoms are not interacting with Pd in the reactant complexes [$PdLCl_2$]. In contrast, the Pd–$N_{azine}$ distances range from 2.01 to 2.15 Å in the product complexes $[PdL]^{2+}$. The longest Pd–$N_{azine}$ distances appear for species with PH, followed by those with S, NH, and finally O, which shows the shortest distance. Furthermore, for ligands with PH and S, the Pd–$N_{azine}$ bond lengths increase as the reaction proceeds, whereas for ligands with NH and O, these distances decrease. That is, the formation of the two new Pd–A bonds weakens the Pd–$N_{azine}$ interaction for A = PH and S and strengthens it for A = O and NH. The other structural parameters such as *cis* and *trans* angles are not affected by the effects of the different donor atoms.

In order to obtain a deeper insight into the hemilabile character of these ligands we have used Bader's theory of "Atoms in Molecules".[22] In this work we have computed the values of $\rho(r)$ (electron charge density at the bond critical point, bcp), the values of $\nabla^2\rho(r)$ (Laplacian of the electron charge density at the bcp that coincides with the sum of the three curvatures of the Hessian matrix), and the ratio $|\lambda_1/\lambda_3|$ ($\lambda_i$ being the curvatures of the Hessian matrix) at the Pd–$N_{azine}$ and Pd–A bcp. According to this theory, values of $\nabla^2\rho(r) < 0$ address regions where the charge density is concentrated. In contrast, regions in which $\nabla^2\rho(r) > 0$, the charge density is depleted. The ratio of $|\lambda_1/\lambda_3|$ is a measure of the covalency between two atoms. Ratios greater than unity indicate covalent or polar interactions, usually referred to as shared interactions. Ratios lower than 0.2 imply closed-shell interactions, such as those given in noble gas repulsive states, in ionic bonds, in hydrogen bonds, and in van der Waals molecules.[22b]

The $\rho(r)$ values at the Pd–$N_{azine}$ bcp, both in reactants and products, are shown in Figure 3. In agreement with the computed Pd–$N_{azine}$ distances, the computed electron density values in the reactants remain similar (between 0.093 and 0.096), regardless of the donor atom. However, in the products these values range from 0.111 to 0.081 and follow the sequence O > NH > S > PH. On the other hand, it can be observed in Figure 3 that when S is a donor atom, the electron density value at the Pd–$N_{azine}$ bcp is similar in reactants and products. Considering that in the reactants the Pd–$N_{azine}$ bond is in *trans* position with another Pd–$N_{azine}$ bond, and that in the products the Pd–$N_{azine}$ bonds are in *trans* position with the newly formed Pd–S bonds, this seems to suggest that the $N_{azine}$ and S donor atoms have a similar donor character and that the Pd–$N_{azine}$ and Pd–S bonds are similar in strength. For NH and O, the electron density values of Pd–$N_{azine}$ at the bond critical points increase as the reaction proceeds. Therefore, the $N_{azine}$ atoms exert a *trans* influence on NH and O donor atoms. In contrast, when PH acts as donor atom, the electron density values of Pd–$N_{azine}$ bond critical points decreases along the reaction because PH exerts a *trans* influ-

Table 1. Pd–$N_{azine}$ and Pd–A distances in [$PdLCl_2$] and $[PdL]^{2+}$. Distances are in Å.

ence on $N_{azine}$. According to these results, the strength of the Pd–A bonds seems to follow the order Pd–PH > Pd–S > Pd–NH > Pd–O.

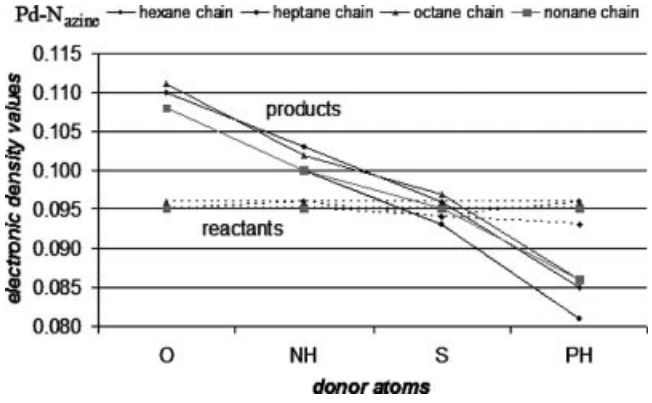

Figure 3. $\rho(r)$ density values at the Pd–$N_{azine}$ bond critical points in reactants, $PdLCl_2$, and products, $PdL^{2+}$. Effect of donor atoms.

The computed values of $\rho(r)$, $\nabla^2\rho(r)$, and $|\lambda_1/\lambda_3|$ at the Pd–$N_{azine}$ and Pd–A bond critical points as well as the net atomic charge of $Pd^{II}$ for nonane-chain products are summarized in Table 2. The fact that the values obtained for $\nabla^2\rho(r)$ at the bcp for Pd–$N_{azine}$ are positive and relatively large evidence a closed-shell interaction. This fact is reinforced by the values of $|\lambda_1/\lambda_3|$, which are lower than 0.2. Regarding the Pd–A bcp, it is worth to note an interesting tendency in the nature of the interaction. From the beginning to the end of the series O, NH, S, PH, the values of $\nabla^2\rho(r)$ decrease and the $|\lambda_1/\lambda_3|$ ratio increases. This fact means that the shared interaction between Pd and the donor atoms follows the order Pd–O < Pd–NH < Pd–S < Pd–PH. This tendency is confirmed by the values of the net atomic charge of Pd, which indicate that the charge transfer from the donor atoms to Pd increases according to the same order. These results agree with the trends observed by the *trans* influence. According to them one would expect that the formation of the new Pd–A bonds would become energetically more favorable as we go from O to NH, from NH to S, and from S to PH.

Table 2. Electron density, $\rho(r)$, Laplacian, $\nabla^2\rho(r)$ and $|\lambda_1/\lambda_3|$ values at the Pd–$N_{azine}$ and Pd–A bond critical points, and Pd net atomic charge.

| | Pd–$N_{azine}$ | | | Pd–A | | | Charge |
|---|---|---|---|---|---|---|---|
| | $\rho$ | $\nabla\rho^2$ | $\lambda_1/\lambda_3$ | $\rho$ | $\nabla\rho^2$ | $\lambda_1/\lambda_3$ | $q_{Pd}$ |

The computed reaction free energies of $[PdLCl_2] \rightarrow [PdL]^{2+} + 2\ Cl^-$ are given in Figure 4. We only report the values in the gas phase since both results in the gas phase and in solution follow the same trends (see above). It can be observed that the computed free energies do not follow the expected order as shown in Figure 4: $\Delta G(O) > \Delta G(S) > \Delta G(NH) > \Delta G(PH)$. That is, the reaction appears to be more favorable for ligands with NH than for those with S. To obtain a deeper insight into the reaction driving force, we have split the reaction energy ($\Delta E_{reaction}$) in two terms: i) the difference between the interaction energies in reactants and products ($\Delta E_{int}$) and ii) the reorganization energy ($\Delta E_{reorg}$) of the ligand. The interaction energy in the reactants ($E_{int(REACT)}$) corresponds to $E(PdLCl_2) - E(Pd^{II}) - E(L) - 2\ E(Cl^-)$, whereas that in the products ($E_{int(PROD)}$) is $E(PdL^{2+}) - E(Pd^{II}) - E(L)$. The term $\Delta E_{reorg}$ can be understood as the energy cost associated to the conformational change of the ligand along the reaction, and corresponds to the energy difference between single-point calculations of the ligand at the geometry of reactants and products. The values of these terms are shown in Table 3 for the nonane chains. Since $E_{int(REACT)}$ is quite constant for all systems and variations in $\Delta E_{reorg}$ are small, the main contribution on the reaction energy comes from $E_{int(PROD)}$, which follows the same trend of $\Delta E_{reaction}$ and $\Delta G_{298}$ (see Figure 4). It is worth noting that the largest reorganization energy is obtained for PH ligands. This is probably related to the higher barrier for inversion at P. Despite that, reactions with this donor atom are the most favored ones. The order obtained for the interaction energies in the products (PH > NH > S > O; in absolute values) is the same as that found for the interaction between $Pd^{II}$ and the smallest donor-atom-containing entities $H_2O$, $H_2S$, $NH_3$, and $PH_3$ (–141.6, –180.5, –192.1, and –211.8 kcal/mol, respectively) and arises from different factors: electrostatic interaction, metal–ligand repulsion, and charge transfer. As expected, population analysis indicates that the charge transfer from the ligand to Pd is larger for S and PH species than for O and NH ones. However, a point-charge model assuming a 2+ charge at the Pd position shows that the electrostatic stabilization is larger for $NH_3$ and $PH_3$ than for $H_2O$ and $H_2S$. As a consequence, the preference of $Pd^{II}$ to interact with donor atoms follows the order PH > NH > S > O. These results agree with the experimental fact that the inert groups of hemilabile ligands contain P atoms while the labile ones contain O atoms.[1]

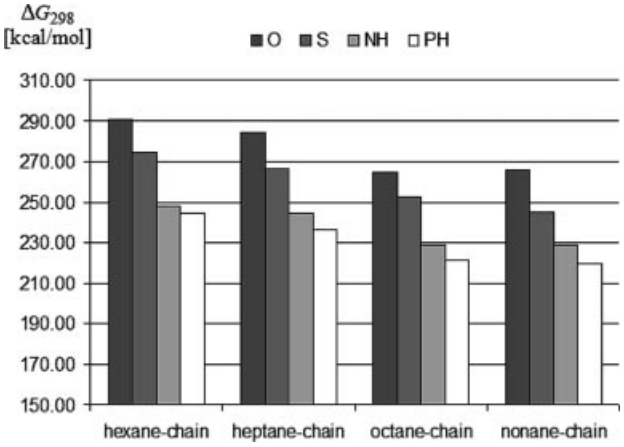

Figure 4. Computed reaction free energies ($\Delta G_{298}$) of $PdLCl_2 \rightarrow PdL^{2+} + 2\ Cl^-$ in the gas phase. In kcal/mol. Effect of donor atoms.

Table 3. Contribution of metal-ligand interaction energies and reorganization energy of the ligand to the $[PdLCl_2] \rightarrow [PdL]^{2+} + 2\ Cl^-$ reaction energy. In kcal/mol.

| | $E_{int(REACT)}$[a] | $E_{int(PROD)}$[b] | $\Delta E_{int}$[c] | $\Delta E_{reorg}$[d] | $\Delta E_{reaction}$ |
|---|---|---|---|---|---|
| O | –692.3 | –437.4 | 254.9 | 25.5 | 280.4 |
| S | –692.1 | –454.5 | 237.6 | 22.8 | 260.4 |
| N | –692.6 | –478.4 | 214.2 | 25.9 | 240.0 |
| P | –692.6 | –501.3 | 191.4 | 40.8 | 232.2 |

[a] $E_{int(REACT)} = E(PdLCl_2) - E(Pd^{II}) - E(L) - 2\ E(Cl^-)$. [b] $E_{int(PROD)} = E(PdL^{2+}) - E(Pd^{II}) - E(L)$. [c] $\Delta E_{int} = E_{int(PROD)} - E_{int(REACT)}$. [d] $\Delta E_{reorg} = E(L)_{PROD} - E(L)_{REACT}$.

### C. Ring Substituents

Substituents with different electronic properties (B = $CF_3$, F, H, $CH_3$, and $NH_2$) are introduced at position 5 of pyrazole rings in order to analyze their influence on the structural parameters of Pd complexes and on the $[PdLCl_2] \rightarrow [PdL]^{2+} + 2\ Cl^-$ reaction. Calculations have been performed for different chain lengths ($x$ = 1, 2 and $y$ = 2, 3) and assuming S as donor atom. Table 4 shows the optimized Pd–$N_{azine}$ bond lengths, both for reactants and products.

It can be observed that changing the substituent at the pyrazole ring does not induce a significant variation on the Pd–$N_{azine}$ bond length of the reactant complexes. This is due to the fact that ring pyrazoles are in the *trans* configuration, and thus the electronic effects of the substituents are mutually compensated. However, the Pd–$N_{azine}$ bond lengths in the products are longer when substituents have a global electron-withdrawing character. The contrary occurs if substituents have a global electron-donor character, the Pd–$N_{azine}$ distances becoming shorter. Nevertheless, the Pd–S bonds are not affected by the type of substituent.

We have also calculated the electron density values of the Pd–$N_{azine}$ bond critical points in the products, and the results are shown in Figure 5. The observed trends agree with the observed changes on the Pd–$N_{azine}$ distances; that is, products with electron-withdrawing substituents (and longer Pd–$N_{azine}$ bonds), present smaller electron density values at the bond critical points than product complexes with electron-donor substituents (and shorter Pd–$N_{azine}$ distances). Based on these results the variation on the Pd–$N_{azine}$ bond strength, due to the effects of substituents, is expected to follow the order $CH_3 > NH_2 > H > F > CF_3$.

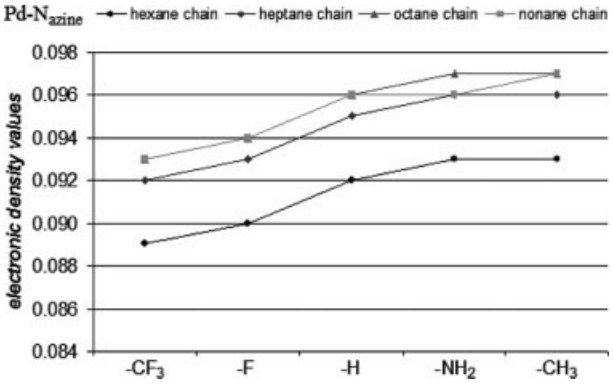

Figure 5. $\rho(r)$ density values at the Pd–$N_{azine}$ bond critical points in products, $[PdL]^{2+}$. Effect of ring substituent.

The induced structural and electronic changes will influence the stability of the products and consequently, the $[PdLCl_2] \rightarrow [PdL]^{2+} + 2\ Cl^-$ reaction energy. Gas-phase reaction free energies calculated for the different ligands considered are given in Figure 6. As expected, reactions are more favored when substituents have an electron-donor character, in agreement with the changes observed for the Pd–$N_{azine}$ bond lengths and electron density values at the bond critical point. However, the trends on Pd–$N_{azine}$ bond length or electron density values do not perfectly agree with the observed trends in reaction free energies. That is, whereas with $CH_3$ as substituent the Pd–$N_{azine}$ distances are shorter than with $NH_2$, the reaction is more favorable if the substituent is $NH_2$. This may be understood considering that, in addition to the σ-donor electronic character, $NH_2$ has a π-donor resonant character that enhances more the global stability of the products. It is worth noting that the reaction free energy can change by as much as 27–29 kcal/mol by introducing substituents of different character in the pyrazole ring.

Table 4. Pd–$N_{azine}$ distances in $[PdLCl_2]$ and $[PdL]^{2+}$. Distances are in Å.

## Conclusions

The properties of $Pd^{II}$ complexes containing pyrazole-derived hemilabile ligands BPz-$(CH_2)_x$A$(CH_2)_y$A$(CH_2)_x$-PzB (with $x$ = 1,2; $y$ = 2,3; A = O, NH, S and PH; and B = $CF_3$, F, H, $CH_3$, $NH_2$) have been investigated through quantum-chemical calculations. Optimal geometries for $[PdLCl_2]$ and $[PdL]^{2+}$ complexes and the reaction free energy of $[PdCl_2L] \rightarrow [PdL]^{2+} + 2\ Cl^-$ have been determined for 32 different ligands using the hybrid B3LYP density functional method. Compared to the ideal square-planar geometry, products with six- ($x$ = 1, $y$ = 2) and seven-membered ($x$ = 2, $y$ = 3) chains are more distorted than those with eight- ($x$ = 2, $y$ = 2) and nine-membered ($x$ = 2, $y$ = 3) chains. Thus, formation of tetracoordinate $[PdL]^{2+}$ complexes is more favorable for the longer chains. This is in agreement with the experimental results, which show that only octane and nonane ligand complexes can be isolated and characterized. Results for different donor atoms A show that the $[PdCl_2L] \rightarrow [PdL]^{2+} + 2\ Cl^-$ reaction is favoured according to the order PH > NH > S > O. This seems to contradict the electron density analysis which shows a larger $L \rightarrow Pd^{II}$ charge transfer for A = S than for A = NH. The reaction energy decomposition and point charge calculations show, however, that the electrostatic + polarization stabilizing term is larger when A = NH. Finally, the introduction of substituents at the pyrazole ring can modulate the strength of the Pd–$N_{azine}$ bond and modify the reaction energy, the electron-donor substituents enhancing the formation of $[PdL]^{2+}$.

## Theoretical Details

Molecular geometries were optimized using the non-local hybrid three-parameter B3LYP[23] density functional method with the Gaussian98 program package.[24] Frequency calculations were also performed to confirm that each stationary point is an actual minimum. For Pd we used the quasi-relativistic effective core potential (ECP) of Hay and Wadt[25] to represent the 28 innermost electrons of the palladium atom. The basis set used for the valence and outermost core orbitals is the standard double-ζ LANL2DZ set associated to the ECP. For atoms directly attached to the metal atom (Cl, $N_{azine}$, and the heteroatoms O, N, S, and P from the ligand chain) we used the 6-31++G(d,p) basis,[26] whereas the remaining atoms were described with the smaller 6-31G basis.[27] In order to analyze the influence of further enlarging the basis set on the $PdLCl_2 \rightarrow PdL^{2+} + 2\ Cl^-$ reaction energy, we have also performed (for a few cases) single-point calculations by adding an f function to the Pd basis,[28] and using the 6-311++G(2d,2p) basis sets for the atoms directly bonded to the metal center. Results showed that the reaction energies differ by less than 1 kcal/mol and thus, we expect computed reaction energies with the small basis set to be reasonably accurate. Thermodynamic corrections have been obtained by standard statistical methods, assuming the harmonic/rigid rotor approximation.[29] Solvent effects have been introduced using the Conductor-like Screening Model (COSMO) method,[30] by performing single-point calculations at the gas-phase-optimized geometries. Net atomic charges have been obtained using the natural population analysis (NPA) method of Weinhold et al.[31] while the topological properties of the electron density have been studied employing Bader's theory of "Atoms In Molecules" (AIM)[22] by means of the Xaim software.[32]

# Cyclohexylbis(hydroxymethyl)phosphane: A Hydrophilic Phosphane Capable of Forming Novel Hydrogen-Bonding Networks

**Miriam Gonschorowsky,[b] Klaus Merz,[b] and Matthias Driess*[a]**

**Keywords:** (Hydroxymethyl)phosphanes / Phosphane conjugates / Phosphane sulfides / Hydrogen bonds

The cyclohexyl-substituted (hydroxymethyl)phosphane CyP-$(CH_2OH)_2$ (**1**) has been prepared by reaction of the corresponding primary phosphane $CyPH_2$ with aqueous formaldehyde. Compound **1** has been used as building block for the synthesis of new functionalized water-soluble phosphorus compounds. Thus, Mannich-type condensation of **1** with excess glycine affords the air-stable amino acid phosphane conjugate $CyP[CH_2N(H)CH_2COOH]_2$ (**2**). Simple oxidation of **1** with hydrogen peroxide and elemental sulfur leads to the crystalline chalcogenide derivatives $CyP(O)(CH_2OH)_2$ (**3**) and $CyP(S)(CH_2OH)_2$ (**4**). X-ray diffraction analyses of the latter revealed distinct intermolecular hydrogen bonding motifs and possess different types of hydrogen bond networks to each other due to the different proton acceptor ability of the chalcogen atom X of the P=X group (X = O, S): while the oxygen atom of the P=O moiety in **3** serves as proton acceptor, affording a P=O–HO bifurcated network, the sulfur atom of the P=S group denies hydrogen bonding interactions. In addition, the ligand ability of **1** has been studied towards Pt(+2) and Cu(+1) ions: Reaction of **1** with $Pt(COD)Cl_2$ (COD = cycloocta-1,5-diene) furnishes the air-stable complex *cis*-$[PtCl_2\{CyP(CH_2OH)_2\}_2]$ (**5**), while the crystalline dimeric Cu(+1) complex $[CuI\{CyP(CH_2OH)_2\}_2]_2$ (**6**) results from the reaction of CuI with two molar equivalents of **1**. The complex **6** shows a intermolecular hydrogen bonding pattern different from that of **1**, **3** and **4**, respectively. The new coordination compounds **5** and **6** represent metal-phosphane labelled alcohols which are promising building blocks for the synthesis of metal-based drugs.

## Introduction

(Hydroxymethyl)phosphanes $[P(CH_2OH)_xR_{3-x}$; R = H, alkyl, aryl; $x$ = 1, 2, 3] constitute an important class of functionalized hydrophilic phosphanes, which have gained considerable prominence in recent years. They are accessible by insertion of formaldehyde into the P–H bonds of secondary and primary phosphanes or $PH_3$ and combine the chemical properties of common organophosphane donor ligands with that of hydrophilic alcohols. In other words, such phosphanes are excellent precursors for the synthesis of a variety of water-soluble organic and organometallic phosphorus compounds. Since the P–$CH_2OH$ moieties can easily be re-transformed into P–H bonds by liberation of formaldehyde molecules, (hydroxymethyl)phosphanes can be considered as masked primary or secondary organophosphanes ($RPH_2$, $R_2PH$; R = alkyl, aryl) which are less sensitive against air but more water-soluble in contrast to the latter. Therefore (hydroxymethyl)phosphanes can participate in a number of chemical reactions, which are typical of $PH_3$ or organophosphanes, including oxidation reactions,[1,2] nucleophilic substitution and addition reactions to activated multiple bonds[1,3] or formation of phosphonium salts via nucleophilic addition to alkylhalides.[2] Another well established type of reactions of (hydroxymethyl)phosphanes represents the Mannich-type condensation with amino-functionalized compounds like amines,[4] amino acids[5] or enzymes,[6] which leads to the formation of (aminomethyl)phosphanes containing a >P–$CH_2$–N< moiety. As Henderson and co-workers have demonstrated, the Mannich-type condensation is, for example, a feasible method for the immobilization of phosphanes to amino-functionalized polymer supports[7] and also render covalent linkage of enzymes to insoluble supports by using multifunctional (hydroxymethyl)phosphanes like $P(CH_2OH)_3$ as coupling reagent.[6] Such immobilized supports are of high interest for the development of a new class of catalysts,[6] which may find diverse application, for imagine. In this context, metal complexes of phosphane-derived biomolecules[8] as well as the coordination chemistry of water-soluble (hydroxymethyl)phosphane ligands have attracted considerable interest in the last decade for the design and development of new water-soluble catalysts[9] or metal-based drugs.[8] (Hydroxymethyl)phosphane ligands, especially the parent system $P(CH_2OH)_3$, have been employed to synthesize stable water-soluble complexes with catalytic active metals (e.g. Rh and Ir)[10] – for their use in biphasic catalysis[11] –

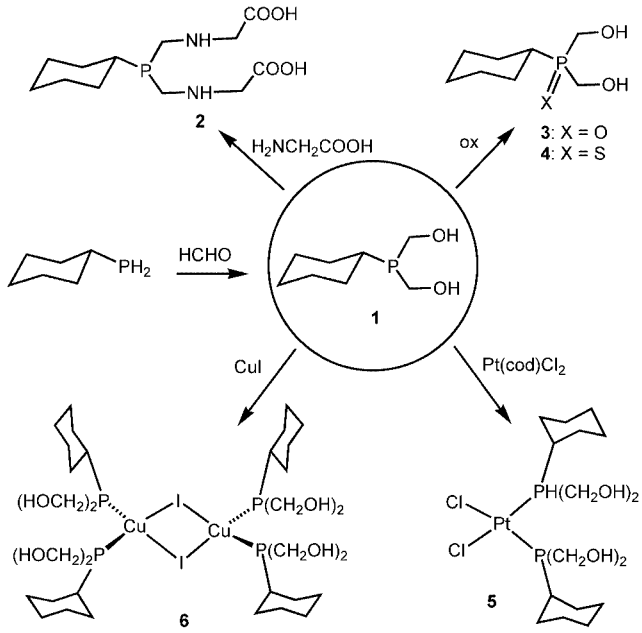
or with cytotoxic transition metals such as Pt and Au[12] for potential medical application. In addition, hydroxymethyl-functionalized phosphanes deserve not only attention as versatile phosphane ligands but also as versatile candidates for crystal engineering studies. Especially multifunctional bis(hydroxymethyl)phosphanes $RP(CH_2OH)_2$ and their chalcogenide derivatives $RP(X)(CH_2OH)_2$ (X = O, S) appear as potential building blocks for different hydrogen bonding pattern in solid state. However, there are only a few examples known, demonstrating that (hydroxymethyl) phosphanes and their chalcogenides[1] are able to form intermolecular hydrogen bonds. To our surprise, structural investigations are rather rare and only available for $(HOCH_2)_2P–CH_2CH_2–P(CH_2OH)_2$,[13] ferrocenyl (Fc)-substituted (hydroxymethyl)phosphanes,[2,14,15] and their derivatives $FcP(X)(CH_2OH)_2$ (X = O, S),[14,15] $FcCH_2P(S)(CH_2OH)_2$[2] and $FcCH(CH_3)P(S)(CH_2OH)_2$,[16] respectively. We report here the synthesis and characterization of a variety of new cyclohexyl-derived bis(hydroxymethyl) phosphane compounds. The versatile chemistry of the readily accessible phosphane $CyP(CH_2OH)_2$ (**1**) is demonstrated by several characteristic reactions, including Mannich-type condensation with glycine to form the amino acid phosphane conjugate **2** and simple oxidation reactions of the phosphorus atom with $H_2O_2$ and elemental sulfur, affording the new phosphane chalcogenides $CyP(X)(CH_2OH)_2$ (**3**) (X = O) and **4** (X = S), respectively. Additionally, initial studies on the coordination chemistry of ligand **1** were carried out towards Pt(+2) and Cu(+1) ions which lead to the new complexes **5** and **6** and represent metal-phosphane modified alcohols as potential precursors for metal-based drugs. In order to learn more about the molecular association of different bis(hydroxymethyl) phosphorus moieties with and without P=X functions (X = O, S) via hydrogen bonds, the structures of **1**, **3**, **4** and **6** were also established by X-ray diffraction analyses.

## Results and Discussion

### Synthesis and Characterization of 1–6

All reactions described in this work, that include the preparation of the starting compound $CyP(CH_2OH)_2$ (**1**) as well as the various syntheses performed with this precursor, are summarized in Scheme 1. A general procedure for the synthesis of hydroxymethyl-functionalized phosphanes involves hydrophosphanylation of the formyl group by addition of primary or secondary phosphanes to formaldehyde.[17] For the preparation of the title compound **1** we used $CyPH_2$[17] as starting material, which can easily be synthesized from commercially available and inexpensive chemicals. The formylation reaction of $CyPH_2$ with slight excess of aqueous formaldehyde solution (36.5%) at room temperature produced the bis(hydroxymethyl)phosphane (**1**) in almost quantitative yield (Scheme 1). The isolation of compound **1** can easily be achieved by removal of the solvent and excess formaldehyde in vacuo. The latter synthesis turned out to be much more efficient than the reported patent procedure,[18] by which **1** was obtained from the corresponding phosphonium salt by treatment with a base at 50 °C. However, no data concerning characterization of **1** were previously reported.



Scheme 1. Synthesis and reactions of $CyP(CH_2OH)_2$ **1**.

$CyP(CH_2OH)_2$ is an air-stable crystalline solid with an unpleasant odour, which is soluble in organic solvents as well as in water, due to its amphiphilic character. It was characterized by mass spectrometry, elemental analysis, NMR spectroscopy and X-ray diffraction analysis. The EI mass spectrum revealed the $[M]^+$ peak at $m/z$ = 176 (19%) and respective fragment ions due to the elimination of formaldehyde and decomposition of the cyclohexyl group. The $^{31}P$–NMR spectrum of **1** shows a broad singlet at $\delta$ = –11.4 ppm similar to the chemical shifts observed for related hydroxymethyl-functionalized phosphanes.[4] As expected, the $^1H$-NMR spectrum of **1** reveals that the $CH_2$ protons of the $PCH_2OH$ groups are chemically inequivalent (diastereotopic) and represent the AB part of an ABX spin system (A, B = $^1H$; X = $^{31}P$). The inequivalence of the methylene protons is caused by the pyramidally coordinated, prochiral phosphorus center. Simulation of the AB region of the $^1H$ NMR spectrum of **1** confirmed the observed eight-line pattern of higher order with partially overlapping signals for the $CH_2$ protons and their geminal coupling of $J_{AB}$ = 13 Hz and two different $^2J_{P,H}$ coupling constants of 5.4 (P,A) and 3.9 Hz (P,B), respectively (Figure 1). Similar coupling patterns were also observed for other bis(hydroxymethyl) phosphanes like cam-$P(CH_2OH)_2$ (cam = 8-camphanyl)[19] and $FcP(CH_2OH)_2$,[14] which exhibit bulky groups directly bonded to the phosphorus atom.

As suggested previously[15] the close proximity of these bulky groups may cause restricted rotation around the P–$CH_2$ and/or $CH_2$–O bonds. The ability of **1** to associate via hydrogen bonds was confirmed by an X-ray diffraction analysis, showing that the molecules constitute a two-di-

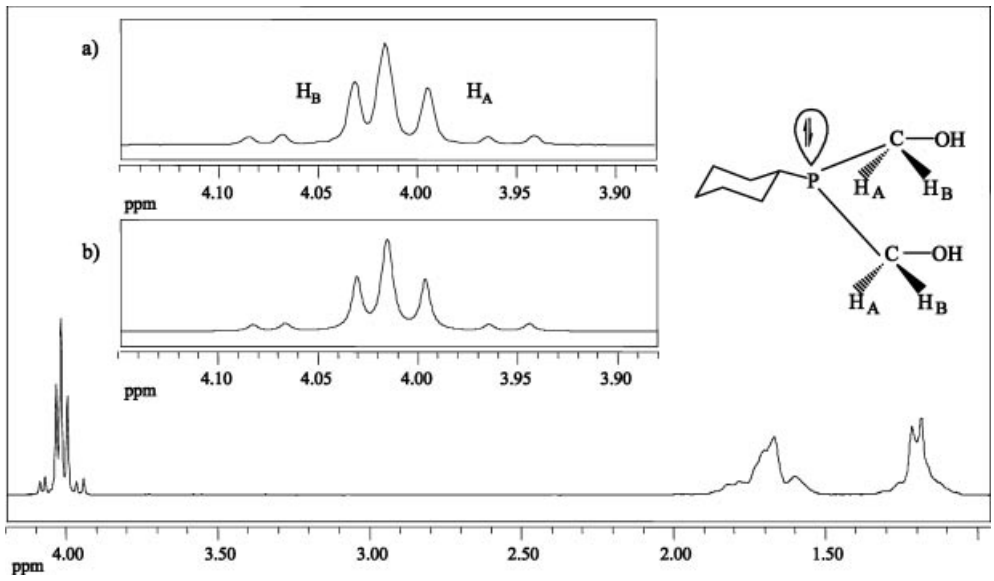

Figure 1. $^1$H NMR-spectrum of **1**; a) measured; b) simulated.[20]

mensional hydrogen bond network with the OH groups serving as proton donors and acceptors (see next section). The apparently activated OH group of the hydroxymethyl-functionalized phosphane **1** can be used to synthesize various new phosphorus ligands in biomedical applications. Since phosphanyl-containing amino acids or peptides represent new carrier ligands for the development of novel metal-containing drugs, the synthesis of bio-compatible phosphorus compounds is of increasing interest. A possible synthetic route to such systems offers the Mannich-type condensation of the OH groups in (hydroxymethyl)phosphanes with the $NH_2$ groups in amino acids and peptides, respectively.[5] In fact, the Mannich-type condensation of CyP-$(CH_2OH)_2$ with 3.5-fold excess of glycine in oxygen-free water/ethanol at room temperature affords the phosphane-glycine conjugate CyP$[CH_2N(H)CH_2COOH]_2$ (**2**), in which each hydroxymethyl group was reacted with one glycine molecule (Scheme 1). Addition of excess molar amounts of glycine was necessary in order to prevent disubstitution reactions at the nitrogen centers. The glycine-derived phosphane **2** was obtained as an air-stable, colorless crystalline solid, which is moderately soluble in water, but insoluble in organic solvents. Due to the expected protonation of the amino functions and deprotonation of the COOH groups, **2** shows excellent solubility in aqueous Brønstedt acids and bases. The new conjugate **2** was characterized by NMR spectroscopy and ESI mass spectrometry. Solutions of *N*-protonated **2** in $DCl/D_2O$ show one $^{31}$P NMR resonance signal at $\delta$ = –24.4 ppm, similar to the values observed for related amino acid-functionalized phosphanes in acidic solutions.[5] The $^1$H NMR spectrum exhibits two different sets of methylene protons: one for the methylene protons of the P–C*H*$_2$–N part and one for the $NH_2^+$–C*H*$_2$–COOH moiety. The first represents the AB part of an ABX spin system (A, B = $^1$H; X = $^{31}$P; $J_{AB}$ = 14.1, $^2J_{P,A}$ = 1.0 and $^2J_{P,B}$ = 2.2 Hz), while the other is an AB spin system without $^{31}$P coupling with a geminal A,B coupling of 17.2 Hz. In basic aqueous solutions ($NaOD/D_2O$), **2** is converted into the corresponding carboxylate with chemical equivalent methylene protons for the NH–$CH_2$–COO- moiety due to fast inversion of configuration at the nitrogen atom on the NMR time scale. However, this does not affect the AB pattern for the methylene protons of the P–$CH_2$–N moiety. The composition of **2** is proven by ESI mass spectrometry, recorded in negative mode, showing the $[M - H^+]$-ion peak at *m*/*z* = 289.3 as base-peak.

Oxidation of the phosphorus atom in **1** furnished the new crystalline chalcogenides CyP(X)$(CH_2OH)_2$ (**3**) (X = O) and (**4**) (X = S). The phosphane oxide **3** results by controlled oxidation of **1** with one equimolar amount of hydrogen peroxide in 81% yield (Scheme 1). The preparation of the phosphane sulfide homolog **4** was achieved in quantitative yield by stirring a solution of **1** in toluene with elemental sulfur at room temperature (Scheme 1). Both compounds are colorless crystalline solids, which are soluble in water and protic organic solvents like alcohols, but insoluble in apolar organic solvents in contrast to the parent phosphane **1**. The chalcogenides **3** and **4** were characterized by means of NMR spectroscopy and mass spectrometry. Their molecular structures were additionally confirmed by single-crystal X-ray diffraction analyses (see next section). As expected, the $^{31}$P NMR chemical shifts of **3** ($\delta$ = 55.7 ppm) and **4** ($\delta$ = 54.5 ppm) are quite similar to values of related phosphane chalcogenides,[2,15] which usually appear at relatively low field. The $^1$H NMR spectra of both compounds show unresolved overlapping multiplets for the methylene protons of the $PCH_2OH$ groups, which indicate the expected chemical inequivalence (AB part of an ABX spin system; A, B = $^1$H; X = $^{31}$P) of the latter. The $^{13}$C nucleus of the $PCH_2OH$ groups exhibits a doublet in the $^{13}C\{^1H\}$ NMR spectra of **3** and **4**, respectively, with characteristically large $^1J$(P,C) coupling constants (**3**: 75.6 Hz; **4**: 66.7 Hz) for phosphane chalcogenides.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In order to probe the coordination ability of **1**, the monodentate phosphane ligand was allowed to react with Pt(+2) and Cu(+1) compounds, since such metal complexes are of interest because of their important cytotoxic properties. In fact, the well established precursor $Pt(COD)Cl_2$ reacts with **1** in the molar ratio of 1:2 in dichloromethane at 25 °C, affording solely *cis*-$[PtCl_2\{CyP(CH_2OH)_2\}_2]$ (**5**) which can be isolated in 82% yield (Scheme 1). Complex **5** is an air-stable colorless crystalline solid, which is soluble in alcohols and moderate soluble in water. Its characterizations are based on multi-nuclear NMR spectroscopy, ESI-mass spectrometry and combustion analysis. Especially diagnostic is the $^{195}Pt\{^1H\}$ NMR spectrum of **5**, which shows one triplet at $\delta$ = –4523 ppm according to the coupling of the platinum nucleus with two chemically equivalent phosphorus atoms. The resulting $^1J_{Pt,P}$ coupling constant of 3490 Hz clearly indicates that the platinum atom has the *cis*-configuration.[21] This is evident by the fact that the corresponding *trans*-isomers of similar Pt complexes exhibit $^1J_{Pt,P}$ coupling constants which are around 1000 Hz lower than the values for *cis* complexes (e.g., *cis*-$[Pt\{P(CH_2OH)_3\}_2I_2]$: $^1J_{Pt,P}$ = 3227 Hz vs. *trans*-$[Pt\{P(CH_2OH)_3\}_2I_2]$: $^1J_{Pt,P}$ = 2162 Hz).[21] This trend can be simplified explained by the higher *trans*-influence of phosphorus compared to halide ligands, which weakens a Pt–P bond and hence lowers the Pt,P coupling constant. The $^{31}P$ NMR spectrum of complex **5** in $CD_3OD$ shows one resonance signal at $\delta$ = 15.8 ppm for the two equivalent phosphorus nuclei. Additionally, $^{195}Pt$-satellites can be observed, with the identical $^1J_{Pt,P}$ coupling constant as already observed in the corresponding $^{195}Pt$ NMR spectrum. In the $^{13}C\{^1H\}$ NMR spectrum of complex **5** two unresolved multiplets were observed at $\delta$ = 36.0 ppm and $\delta$ = 54.8 ppm. Due to potential coupling with the adjacent phosphorus and platinum nuclei these signals are assigned to the carbon atoms, which are directly bonded to the phosphorus (C1–Cy and $CH_2OH$). As expected and similar to the "free" ligand **1** and its chalcogenides **3** and **4**, the methylene protons of the $PCH_2OH$ groups of the complex **5** are chemically inequivalent. Thus, the $^1H$ NMR spectrum of **5** exhibits two broad multiplets at $\delta$ = 4.43 and 4.67 ppm for the inequivalent $CH_2$ protons, showing geminal coupling of 14 Hz and $^3J_{Pt,H}$ coupling constants of 18.6 Hz and 29.4 Hz, respectively, for the respective $^{195}Pt$-satellites. The ESI mass spectra show the characteristic peak for the $[M - Cl]^+$ ion at $m/z$ = 583.8 in positive mode and one for the $[M + Cl]^-$ ion peak at $m/z$ = 653.8 in negative mode, which are typical for related platinum chloride complexes (e.g. *cis*-$[PtCl_2\{P(FcCH_2)(CH_2OH)_2\}_2]$).[15]

Similar reaction of $CyP(CH_2OH)_2$ ligand **1** with CuI in molar ratio of 1:2 in dichloromethane at room temperature (Scheme 1) furnished air-stable, colorless crystals of **6**, which are soluble in alcohols and moderate soluble in water. According to an X-ray structure analysis, compound **6** forms a dimer with two iodo-bridges between the Cu atoms and the dimers are associated via hydrogen bonds in a different motif than **1**, **3** and **4** (see next section). Complex **6** was also characterized by NMR spectroscopy, mass spectrometry and elemental analysis. Its $^{31}P$ NMR spectrum in $CD_3OD$ shows one resonance signal at $\delta$ = –7.9 ppm for the four chemically equivalent phosphorus atoms which is broadened ($h_{1/2}$ ca. 25 Hz) due to the presence of the $^{63/65}Cu$-quadrupole nuclei. Broadening of the resonance signals is also observed in the $^1H$ NMR spectrum of **6** which limits stereochemical information. While ESI-MS investigations of **6** were in contrast to **5** unsuccessful, FAB mass spectromeric measurements revealed at least the fragmention $[Cu\{CyP(CH_2OH)_2\}_2]^+$ at $m/z$ = 415.2 as the largest fragment.

### X-ray Crystal Structure Determinations

Crystal structure elucidations were performed for the compounds **1**, **3**, **4** and **6**. Because hydroxymethyl-functionalized phosphorus compounds represent oligoalcohol molecules, they have a large tendency to associate via hydrogen bonding which makes them to versatile building blocks for the construction of new architectures by molecular recognition for crystal engineering. In fact, the compounds show a different variety of hydrogen bonding networks. Single crystals of **1** suitable for an X-ray diffraction analysis were grown in EtOH/$n$Bu$_2$O. (Table 1). However, the hydrogen-bonding network of **1** could not be analyzed by X-ray diffraction studies due to the moderate crystal quality. The compound crystallizes monoclinic with two independent molecules **1A** and **1B** in the unit cell (Figure 2). Their atomic distances and angles are practically identical and resemble the respective values observed for the related bis(hydroxymethyl) phosphanes $(Fc\text{-}P(CH_2OH)_2$,[15] $FcCH_2P(CH_2OH)_2$[2] or $(HOCH_2)_2P\text{–}CH_2CH_2\text{–}P(CH_2OH)_2$[13].

Table 1. Selected bond lengths [Å] and angles [°] for $CyP(CH_2OH)_2$ (**1**).

| Molecule **1A** | | Molecule **1B** | |
|---|---|---|---|
| lengths [Å] | | | |

| O(3)···O(4) | 2.584 | | |
| O(4)···O(2) | 2.651 | | |

In contrast to the limited geometrical analysis of **1**, the crystal structure determinations of the phosphane derivatives $CyP(O)(CH_2OH)_2$ **3** and $CyP(S)(CH_2OH)_2$ **4** afforded better data sets (see Table 5) suitable for a topological analysis of the hydrogen-bonding networks. The latter revealed other types of hydrogen-bonding networks than that of the related ferrocenyl-substituted compounds $[FcP(X)(CH_2OH)_2$ (X = O, S),[15] $FcCH_2P(S)(CH_2OH)_2$,[2] and

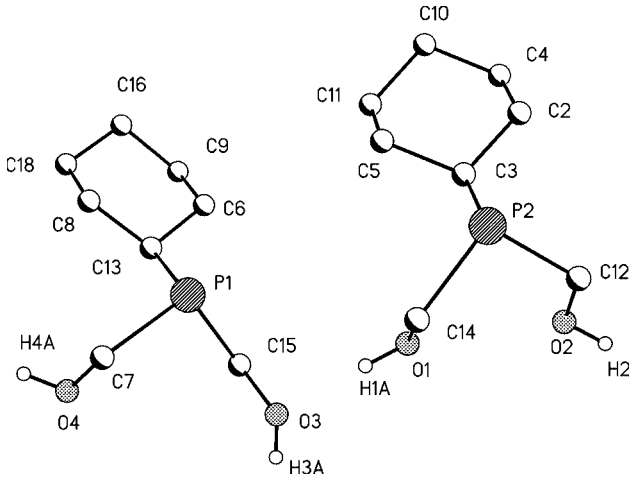

Figure 2. Molecular structure (without hydrogen atoms) of the two independent molecules of $CyP(CH_2OH)_2$ **1** in the unit cell.

$FcCH(CH_3)P(CH_2OH)_2$[16]] and presumably that of **1**. The molecular structures of compounds **3** and **4** are shown in the Figure 3 and Figure 6, respectively, while selected bond lengths and angles are given in the Table 2 and Table 3, respectively. The P–O bond length of 1.512 (4) Å in **3** is identical with that in $FcP(O)(CH_2OH)_2$ [1.510 (1) Å],[15] which represents the hitherto only known structure for this class of compounds. (Hydroxymethyl)phosphane oxides exhibit P=O groups which are favorable hydrogen-bond acceptors and therefore are predestined to form hydrogen bonds with proton donors like hydroxy groups. The hydrogen-bonding arrangement of compound **3** is shown in Figure 4, while Figure 5 depicts the crystal packing. In **3** each P=O group forms bifurcated hydrogen bonding interactions to the O–H groups of one neighboring molecule, with distances between hydrogen bonded oxygen atoms of 2.717 (6) Å for O(3)···O(1A) and 2.709 (6) Å for O(2)···O(1A), respectively. This leads to an arrangement of linked molecules via P=O···HO hydrogen bonds, where each molecule has solely two connected neighbors. As it is shown in the crystal packing of **3** (Figure 5), the one-dimensional chains are not linked to each other. The P=O···HO motif was also observed for the related compound $FcP(O)(CH_2OH)_2$.[15] but in contrast to **3**, $FcP(O)(CH_2OH)_2$ possesses a hydrogen-bonding network between three neighboring molecules, where each P=O unit forms hydrogen bonds to OH groups of different adjacent molecules.

As expected, the distances and angles around the P atom in the phosphane sulfide **4** (Table 3) are identical with that of the related compound $FcP(S)(CH_2OH)_2$.[7] The structure of **4** (Figures 6 and 7) shows a completely different hydrogen-bonding pattern compared to that of the oxide **3**. The hydrogen-bonding network and crystal packing of the sulfide **4** are presented in Figure 7 and Figure 8, respectively. Interestingly and in contrast to the oxygen atom in **3**, the sulfur atom in **4** is not involved in hydrogen-bonding. Hydrogen bonds are formed exclusively between the hydroxy groups, with each OH functionality acting as a donor in one and as an acceptor in another hydrogen bond. This

for the sulfur-free phosphane $FcP(CH_2OH)_2$[15] and reminiscent of that in the related sulfide $FcP(S)(CH_2OH)_2$.[15] In contrast to **4**, the hydrogen bonds in $FcP(S)(CH_2OH)_2$ are formed between three neighboring molecules with a network of alternating eight- and twelve-membered rings. However, in contrast to the sulfide **4** and $FcP(S)(CH_2OH)_2$, the structures of other related ferrocenyl-derived compounds $FcCH_2P(S)(CH_2OH)_2$[2] and $FcCH(CH_3)P(CH_2OH)_2$[16] show a hydrogen-bonding pattern with hydrogen bonds formed between the sulfur atom and hydroxy groups as well as between OH groups. The formation of O–H···S hydrogen bonds in $FcCH_2P(S)(CH_2OH)_2$ and $FcCH(CH_3)P(CH_2OH)_2$ on the one hand and the lack of O–H···S interactions in $FcP(S)(CH_2OH)_2$ and **4** on the other hand is rather peculiar. As already suggested previously,[15] the proximity of the bulky groups to the phosphorus centers in $FcP(S)(CH_2OH)_2$ and **4** may effectively shield the sulfur atoms and prevent hydrogen bonding interactions of the P=S group. Additionally, the sulfur atom of the P=S group is a much weaker hydrogen-bond acceptor compared to the P=O functionality.

As shown in the crystal packing diagrams of the compounds **3** (Figure 5) and **4** (Figure 8), the hydrophobic cyclohexyl groups have also an important influence on the aggregation behaviour of the molecules. Due to van der Waals interactions, the cyclohexyl groups are effectively stacked on each other, which leads to the formation of alternating hydrophobic and hydrophilic regions in the crystal packing.

The structural elucidation of the copper complex **6** revealed another new type of hydrogen-bonding network. The molecular structure and the hydrogen-bonding pattern of complex **6** are represented in the Figure 9 and Figure 10, respectively, while selected distances and angles are given in Table 4. The centrosymmetric complex **6** is a dimer and possesses two iodo-bridges in a planar $Cu_2I_2$ ring. There are other CuI–phosphane complexes known, having a four-membered $Cu_2I_2$ core and terminal coordinated monodentate phoshane ligands (e.g. $[CuI(PPh_2Me)_2]_2{\cdot}SO_2$,[22] $[CuI(PH_2Ph)_2]_2$[23] and $[CuI(PMe_3)_2]_2$[24]). Complex **6** represents the first example of a Cu(+1) complex containing functionalized monodentate phosphane ligands coordinated to a CuI dimer. The distances and angles of compound **6** are unexceptional and similar to that of $[CuI(PMe_3)_2]_2$.[24]

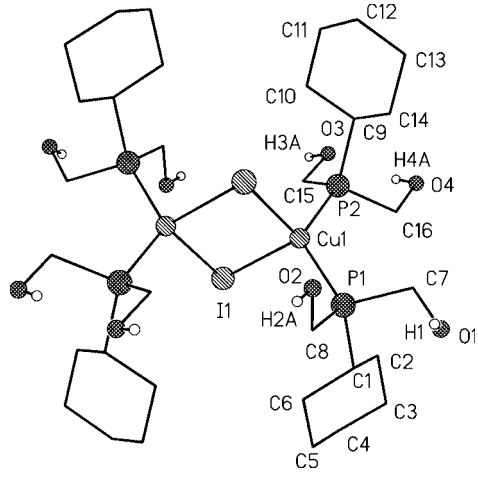

Figure 9. Molecular structure of $[CuI\{CyP(CH_2OH)_2\}_2]_2$ (**6**).

As expected, the crystal structure of **6** shows intermolecular hydrogen bonding interactions due to the presence of OH groups in the phosphane ligand. There exist two dif-

| O(1)···O(4B) | 2.702(8) | O(1)–H(1)···O(4B) | 155.9(4) |
| O(3A)···O(1) | 2.684(8) | O(3A)–H(3A)···O(1) | 164.2(4) |

ferent types of intermolecular hydrogen bonds with the distances between the hydrogen bonded oxygen atoms O(1)···O(4B) of 2.702(8) Å and O(3A)···O(1) of 2.684(8) Å, respectively (Figure 10). The hydroxy group O(1)–H(1) of phosphane ligand 1 [with P(1)] acts as a donor in one hydrogen bond and as an acceptor in a second hydrogen bond with two adjacent molecules **6**. The hydroxy groups O(3)–H(3) and O(4)–H(4) of phosphane ligand 2 [with P(2)] are each involved in only one hydrogen bonding with two neighboring molecules. At least each dimer molecule is associated via six hydrogen bonds with four adjacent molecules, with the neighboring dimers are oriented about 90° to the observed molecule. This leads to the formation of two-dimensional networks, which are parallel stacked on each other.

## Conclusion

The amphiphilic cyclohexyl (hydroxymethyl)phosphane **1** is a valuable building block for designing novel hydrogen bonding networks. Using the versatile reactivity of phosphane **1** a variety of functionalized phosphorus compounds can be synthesized. Thus, Mannich-type condensation of **1** with glycine produced the air-stable amino acid functionalized phosphane **2**, and the crystalline derivatives **3** and **4** were prepared by simple oxidation reactions. The X-ray crystal structure diffraction analyses revealed completely different hydrogen bonding pattern for the oxide **3** and the sulfide **4**. While **3** shows intermolecular bifurcated hydrogen bonding interactions between the strong P=O acceptor and the O–H donor groups, the sulfur atom of **4** was not involved in any hydrogen bond. The hydrogen bonding network in **4** was exclusively formed by O–H···O–H interactions and was similar to that observed for the related phosphane $FcP(CH_2OH)_2$.[14,15] In addition, the coordination chemistry of **1** was studied which led to the air-stable complexes *cis*-$[PtCl_2\{CyP(CH_2OH)_2\}_2]$ (**5**) and $[CuI\{CyP(CH_2OH)_2\}_2]_2$ (**6**), respectively. The crystal structure of the latter revealed another new type of hydrogen-bonding network where one OH group of phosphane ligand 2 [with P(2)] is not involved in any hydrogen bond.

## Experimental Section

**General Remarks:** All manipulations were performed under dry and oxygen-free argon. Solvents were dried according to standard methods and saturated with argon or degassed, respectively. The NMR spectra were recorded on a Bruker Avance DPX 250 MHz spectrometer at room-temperature. Chemical shifts $\delta$ are given in ppm and were referenced against $Me_4Si$ ($^1H$, $^{13}C$; using residual protonated solvent peak or the carbon resonance, respectively), 85% $H_3PO_4$ ($^{31}P$) and $H_2PtCl_6$ in $D_2O$ ($^{195}Pt$). ESI-mass spectrometric analysis were performed in the positive and the negative mode using a Bruker Esquire 3000 instrument. The EI- and FAB-mass spectra were recorded at a VG instruments Autospec/EBEE spectrometer. Elemental analyses were carried out on a VarioEL (CHN) elemental analyzer. $CyPH_2$[25] and $PtCl_2(COD)$[26] were prepared according to published procedures. All other chemicals used as starting materials were obtained commercially and without further purification.

**Preparation of $CyP(CH_2OH)_2$ (1):** Aqueous formaldehyde (36.5%, 4.23 mL, 56.0 mmol) was placed in oxygen-free ethanol (10 mL) and purged with argon at room temperature for 30 min. Then a solution of $CyPH_2$ (2.60 g, 22.4 mmol) in 10 mL of oxygen-free ethanol was added dropwise and the mixture was stirred overnight at 25 °C. After removal of the solvent in vacuo the residual colorless solid is recrystallized from ethanol/di-*n*-butyl ether at –15 °C. Yield: 3.86 g, (98%). $C_8H_{17}O_2P$ (176.2): calcd. C 54.6, H 9.7; found C 54.4, H 10.1. $^1H$ NMR (250.13 MHz, $D_2O$): $\delta$ = 1.00–1.40 (m, 5 H, Cy), 1.44–1.98 (m, 6 H, Cy), 3.98 (dd, $^2J_{P,H}$ = 5.4, $^2J_{H,H}$ = 13.0 Hz, 2 H, $PCH_2$), 4.05 (dd, $^2J_{P,H}$ = 3.9, $^2J_{H,H}$ = 13.0 Hz, 2 H, $PCH_2$) ppm. $^{13}C$ NMR (62.90 MHz, $D_2O$): $\delta$ = 26.2 (s, C4-Cy),

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

26.4 (d, $^3J_{P,C}$ = 10.6 Hz, C3-, C5-Cy), 29.2 (d, $^2J_{P,C}$ = 12.0 Hz, C2-, C6-Cy), 29.4 (d, $^1J_{P,C}$ = 13.8 Hz, C1-Cy), 57.3 (d, $^1J_{P,C}$ = 10.4 Hz, $PCH_2$) ppm. $^{31}P$ NMR (101.25 MHz, $D_2O$): $\delta$ = –11.4 (br. s) ppm. EI-MS: *m/z* (%) = 176 [$M^+$ (19)], 146 [$M^+ - CH_2O$ (18)], 115 [$CyPH^+$ (17)], 83 [$Cy^+$ (70)], 55 [$C_4H_7^+$ (100)] 41 [$C_3H_5^+$ (74)].

**Preparation of $CyP[CH_2N(H)CH_2COOH]_2$ (2):** A solution of glycine (0.83 g, 11.38 mmol) in degassed water (3.5 mL) was added via a syringe to phosphane **1** (0.57 g, 3.24 mmol) in 1.5 mL oxygen-free ethanol and stirred overnight at 25 °C. The formed solid was filtered off and the filtrate evaporated giving the product as a colorless crystalline solid. Yield: 808 mg (86%). $^1H$ NMR (250.13 MHz, DCl/$D_2O$): $\delta$ = –0.92 to –0.80 (m, 5 H, Cy), –0.31 to –0.05 (m, 6 H, Cy), 1.61 (br. d, $^2J_{H,H}$ = 14.1 Hz, 2 H, $PCH_2$), 1.76 (dd, $^2J_{P,H}$ = 2.2, $^2J_{H,H}$ = 14.1 Hz, 2 H, $PCH_2$), 2.16 (d, $^2J_{H,H}$ = 17.2 Hz, 2 H, $CH_2COOH$), 2.20 (d, $^2J_{H,H}$ = 17.2 Hz, 2 H, $CH_2COOH$) ppm. $^{13}C$ NMR (62.90 MHz, DCl/$D_2O$): $\delta$ = 24.9 (s, C-4-Cy), 25.9 (d, $^3J_{P,C}$ = 11.3 Hz C-3-, C-5-Cy), 27.8 (d, $^2J_{P,C}$ = 10.8 Hz, C-2-,C-6-Cy), 32.8 (d, $^1J_{P,C}$ = 4.6 Hz, C-1-Cy), 43.6 (d, $^1J_{P,C}$ = 18.8 Hz, $PCH_2$), 48.4 (d, $^3J_{P,C}$ = 7.6 Hz, $CH_2COOH$), 168.0 (s, COOH) ppm. $^{31}P$ NMR (101.25 MHz, DCl/$D_2O$): $\delta$ = –24.4 (br. s) ppm. ESI-MS (negative mode): 289.3 [$M - H^+$].

**Preparation of $CyP(O)(CH_2OH)_2$ (3):** Aqueous hydrogen peroxide (0.3%, 6 mL) was added to a solution of compound **1** (100 mg, 0.568 mmol) in 20 mL methanol and stirred in air for 10 min. The solvent was removed at a rotor vapour, co-evaporated twice with water (2 × 10 mL) and washed with dry ether (10 mL). After drying in vacuo the product **3** was obtained as colorless crystalline solid. Yield: 87 mg (81%). $C_8H_{17}O_3P$ (192.2): calcd. C 50.0, H 8.9; found C 50.4, H 9.3. $^1H$ NMR (250.13 MHz, $D_2O$): $\delta$ = 1.10–1.41 (m, 4 H, Cy), 1.58 –1.85 (m, 6 H, Cy) 1.98 (m, 1 H, H1–Cy) 4.02 (m, 4 H, $PCH_2$) ppm. $^{13}C$ NMR (62.90 MHz, $D_2O$): $\delta$ = 24.4 (d, $^4J_{P,C}$ = 1 Hz, C-4-Cy), 25.7 (d, $^3J_{P,C}$ = 3.4 Hz, C3-, C-5-Cy), 25.9 (d, $^2J_{P,C}$ = 12.7 Hz, C-2,C-6-Cy), 32.2 (d, $^1J_{P,C}$ = 61.8 Hz, C-1 Cy), 54.8 (d, $^1J_{P,C}$ = 75.6 Hz, $PCH_2$) ppm. $^{31}P$ NMR (101.25 MHz, $D_2O$): $\delta$ = 55.7 (br. s) ppm. ESI-MS (negative mode): 191.3 [$M - H^+$].

**Preparation of $CyP(S)(CH_2OH)_2$ (4):** Elemental sulfur (86 mg, 2.670 mmol) was added to a solution of phosphane **1** (470 mg, 2.670 mmol) in 10 mL toluene at room temperature. While stirring for 30 min the sulfur disappeared and a colorless solid was formed. After evaporation of the solvent the residue was re-dissolved in ethanol (8 mL) and filtered. The solvent was again partly removed in vacuo and diethyl ether was added causing the product to precipitate. The solid was filtered off and dried in vacuo yielding **4** as a colorless crystalline solid. Yield: 555 mg (100%). $C_8H_{17}O_2SP$ (208.2): calcd. C 46.15, H 8.23; found C 45.9, H 8.15. $^1H$ NMR (250.13 MHz, $D_2O$): $\delta$ = 1.10–1.81 (m, 11 H, Cy), 4.18 (m, 4 H, $PCH_2$) ppm. $^{13}C$ NMR (62.90 MHz, $D_2O$): $\delta$ = 25.1 (s, C-4 Cy), 25.5 (d, $^3J_{P,C}$ = 3.8 Hz, C3-, C5-Cy), 26.5 (d, $^2J_{P,C}$ = 16.7 Hz, C-2,C-6 Cy), 32.8 (d, $^1J_{P,C}$ = 52.3 Hz, C-1Cy), 58.1 (d, $^1J_{P,C}$ = 66.7 Hz, $PCH_2$) ppm. $^{31}P$ NMR (101.25 MHz, $D_2O$): $\delta$ = 54.5 (s) ppm. EI-MS: *m/z* (%) = 208 [$M^+$ (69)], 178 [$M^+$-$CH_2O$ (9)], 127 [$M^+ - Cy + H$ (47)], 126 [$M^+ - Cy + 2H$ (38)], 108 [$M^+ - Cy - OH$ (100)], 83 [$Cy^+$ (39)], 78 [$HP(S)CH_2^+$ (84)], 55 [$C_4H_7^+$ (82)], 41 [$C_3H_5^+$ (70)].

**Preparation of *cis*-$[PtCl_2\{CyP(CH_2OH)_2\}_2]$ (5):** Phosphane **1** (218 mg, 1.236 mmol) and $Pt(COD)Cl_2$ (231 mg, 0.618 mmol) were dissolved in $CH_2Cl_2$ (10 mL) and stirred for 2 h at room temperature. After standing for another 4 h at 25 °C the formed solid was filtered off and dried in vacuo giving the product as a colorless crystalline solid, which may be recrystallized from hot methanol. Yield: 313 mg (82%). $C_{16}H_{34}Cl_2O_4P_2Pt$ (618.4): calcd. C 31.1, H 5.5; found C 31.2, H 5.8. $^1H$ NMR (250.13 MHz, [$D_4$]MeOH): $\delta$ = 1.21 –1.79 (m, 12 H, Cy-H3,–H4,–H5), 1.83 (br. m, 4 H, Cy-H2,-H6), 2.21 (br. m, 4 H, Cy-H2,-H6), 2.58 (br. m, 2 H, Cy-H1), 4.43 (m, $^2J_{H,H}$ = 14.0, $^2J_{P,H}$ = 0.8, $^3J_{Pt,H}$ = 18.6 Hz, 4 H, $PCH_2$), 4.67 (m, $^2J_{H,H}$ = 14.0, $^2J_{P,H}$ = 2.0, $^3J_{Pt,H}$ = 29.4 Hz, 4 H, $PCH_2$) ppm. $^{13}C$ NMR (62.90 MHz, [$D_4$]MeOH): $\delta$ = 26.2 (br. s, C-4 Cy), 27.2/27.4 (d, $^3J_{P,C}$ = 6.0 Hz, C-3, C-5 Cy), 29.8 (br. s, C2-,C6-Cy), 36.0 (m, C-1 Cy), 54.8 (m, $PCH_2$) ppm. $^{31}P$ NMR (101.25 MHz, [$D_4$]-MeOH): $\delta$ = 15.8 [s; Pt-satellites (d), $^1J_{Pt,P}$ = 3490 Hz] ppm.

$^{195}$PtNMR (53.52 MHz, [D$_4$]MeOH): $\delta$ = –4523 (t, $^1J_{Pt,P}$ = 3502 Hz) ppm. ESI-MS (positive mode): 583.8 [M – Cl]. ESI-MS (negative mode): 653.8 [M + Cl].

**Preparation of [CuI{CyP(CH$_2$OH)$_2$}$_2$]$_2$ (6):** A solution of phosphane **1** (107 mg, 0.61 mmol) in 3 mL of $CH_2Cl_2$ was added dropwise to a suspension of CuI (58 mg, 0. 305 mmol) in 3 mL of $CH_2Cl_2$ at room temperature. After stirring for 4 h at 25 °C the solvent was removed under reduced pressure and the solid re-dissolved in 2 mL hot degassed methanol. Colorless crystals of product **6** were formed during 1 day standing at 25°, which were filtered off and dried in vacuo. Yield: 152 mg (92%). $C_{32}H_{68}Cu_2I_2O_8P_4$ (1085.7): calcd. C 35.4, H 6.3; found C 34.9, H 6.0. $^1$H NMR (250.13 MHz, [D$_4$]MeOH): $\delta$ = 1.10–1.88 (m, 40 H, Cy), 2.01–2.20 (m, 4 H, 1-H Cy), 4.11 (br. s, 16 H, PCH$_2$) ppm. $^{31}$P NMR (101.25 MHz, [D$_4$]MeOH): $\delta$ = –7.97 (br. s, $w_{1/2}$ = 35 Hz) ppm. FAB-MS: *m*/*z* (%) = 415.2 [Cu{CyP(CH$_2$OH)$_2$}$_2^+$ (30)], 239.3 [CuCyP(CH$_2$OH)$_2^+$ (24)], 176.2 [CyP(CH$_2$OH)$_2^+$ (34)].

**X-ray Crystallographic Study:** Crystals of **1**, **3**, **4** and **6** were mounted on top of a thin glass fiber. Data were collected with a a Bruker-AXS SMART1000 diffractometer with graphite-monochromated Mo-*Kα* radiation ($\lambda$ = 0.71073 Å). The crystal data are summarized in Table 5. Structures were solved by direct methods (SHELX-97) and refined (SHELXL-97) by full-matrix least-squares methods. Except for **1**, the positions of the O–H hydrogen atoms were localized in the difference Fourier map and refined. All other hydrogen atoms were introduced at calculated positions (riding model), included in structure factor calculations, and not refined. CCDC-260936 to -260938 (for **3**, **4**, **6**) and -283461 (for **1**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Reaction of the Heteronuclear Cluster $[Cp^*IrRu_3(\mu\text{-}H)_2(CO)_{10}]$ with Alkynes: Stereoselective Binding

**Padmamalini Srinivasan[a] and Weng Kee Leong*[a]**

**Keywords:** Heterometallic complexes / Ruthenium / Iridium / Alkynes / Stereoselectivity

The reaction of the heteronuclear cluster $[Cp^*IrRu_3(\mu\text{-}H)_2(CO)_{10}]$ (**1**) with the symmetrical alkynes RCCR (R = Ph, Et) afforded the butterfly clusters $[Cp^*IrRu_3(CO)_9(RCCR)]$ (**2**) and the trinuclear clusters $[Cp^*IrRu_2(CO)_7(RCCR)]$ (**3**) and $[Ru_3(CO)_8(C_4R_4)]$ (**4**). The clusters **2** and **3** have the alkyne aligned parallel to an Ru–Ir bond. The reaction of **1** with unsymmetrical alkynes also afforded stereoselective binding of the alkyne such that the bulkier substituent was pointing away from the $Cp^*Ir$ moiety; with PhCCH, however, all three stereoisomers were obtained. With the bis-silylated alkynes (R = $SiMe_3$, $SiEt_3$), loss of one trialkylsilyl group occurred to give $[Cp^*IrRu_3(CO)_9(HCCR)]$ and $[Ru_3(CO)_9(\mu\text{-}H)(CCR)]$ (**5**).

## Introduction

Mixed-metal alkyne clusters have been of interest because of their catalytic potential in hydrogenation reactions,[1] as models for the carbon–carbon triple bond activation on metal surfaces and for chemisorption of small molecules on metal surfaces,[2] as well as precursors to bimetallic particles.[3] The reaction of tetrahedral clusters with alkynes often results in cluster opening to give "butterfly" structures,[4] where the $M_3M'$ skeleton takes the form of a butterfly and the alkyne $C_2$ unit binds to the metal framework in a $\mu_4$-$\eta^2$ fashion to form a quasi-octahedral $M_3M'C_2$ skeleton.[5] The total electron count for these clusters are best considered using the Wade's system, i.e., as octahedral $M_3M'C_2$ clusters, with each CR unit donating three electrons to the skeletal bonding. They are therefore 62-electron "electron precise" butterfly or 14-electron *closo* octahedral clusters;[6] use of the EAN rule predicts unsaturation, which is not in agreement with their reactivity and hence discouraged.[7]

Three isomers are possible for the $M_3M'C_2$ skeleton and for the coordinated alkynes (Figure 1). The alkyne can be disposed parallel to a heterometallic MM′ bond (a) or to a homometallic MM bond (b); these are related as hinge-apex isomers. The orientation of the alkyne with respect to the hinge bond can also be different, such as in (a) and (c), which are related as (*cis*,*trans*) alkyne isomers.

Most reactions of heterometallic tetrahedral clusters with alkynes afforded butterfly clusters exhibiting either hinge-apex or alkyne, or both types of isomerism. In some cases, however, the reactions were found to be highly stereoselective. For example, the reaction of $[CpMRu_3(CO)_{12}]^-$ (M = W, Mo), $[IrRu_3(\mu\text{-}H)(CO)_{13}]$ and $[IrRu_3(CO)_{13}]^-$ towards internal alkynes afforded ‖M–Ru (M = W, Mo and Ir) clusters with alkyne insertion into the Ru–Ru bond as the only product.[8] However, the reaction of $[CpMRu_3(CO)_{12}]^-$ (M = W, Mo) clusters with phenyl acetylene afforded ‖M–Ru *cis* and *trans* isomers,[8a] while the reaction of $[FeRu_3(\mu\text{-}H)_2(CO)_{13}]$ with alkynes afforded hinge-apex as well as alkyne isomers; isomerisation of the ‖Fe–Ru to the ‖Ru–Ru isomer occurred on heating.[9] In the reaction of $[Cp^*RhRu_3(\mu\text{-}H)_4(CO)_9]$ with alkynes, the isomer with the heterometal atom at the wingtip (‖Ru–Ru) was obtained as the only isomer, while the Cp analogue afforded both hinge-apex isomers (‖Rh–Ru and ‖Ru–Ru). However, it was observed that the ‖Rh–Ru isomer converted into the ‖Ru–Ru isomer during purification of the product on TLC plates.[10] In both the FeRu and RhRu systems, the reverse isomerisation was not facile. This suggested that for these two systems, the isomer with the heterometal atom in the hinge was the kinetically favored product and that with the heterometal atom in the wingtip was the thermodynamically more stable product.

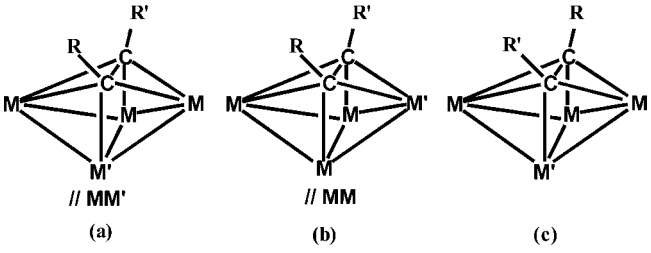

Figure 1. Isomers in $M_3M'C_2$ clusters.

Heterometallic clusters like the previously reported $[CpRhRu_3(\mu\text{-}H)_4(CO)_9]$ are attractive as they allow for the study of site selectivity in the binding of alkynes, particularly unsymmetrical alkynes; the Cp serves as a ligand which allows for stereoelectronic influence on the cluster.

However, this cluster was known to fragment readily under the reaction conditions,[10] and we thus sought to examine the reactivities of some heavier relatives, viz., $[Cp^*IrM_3(\mu\text{-}H)_2(CO)_{10}]$ [M = Ru (**1**) or Os], which we have recently synthesised,[24] in the hope that the third-row elements would lend stability to the cluster core. Our investigations with the cluster **1** are reported here.

## Results and Discussion

**Reactions of 1 with Alkynes:** The thermal reaction of **1**, with the symmetrical alkynes RCCR (R = Ph, Et) in hexane afforded a dark red solution from which three compounds, viz., $[Cp^*IrRu_3(CO)_9(RCCR)]$ (**2**), $[Cp^*IrRu_2(CO)_7(RCCR)]$ (**3**), and $[Ru_3(CO)_8(C_4R_4)]$ (**4**) were isolated (Scheme 1).

All the products have been completely characterised, including by single-crystal X-ray crystallographic studies. The clusters **4a** and **4b** have been reported previously,[11] including the X-ray crystal structure in the case of the former.[12] The ORTEP plots for **2a**, **3a** and **4b** are shown in Figure 2, Figure 3 and Figure 4, respectively. The alkyne butterfly clusters **2** have the alkyne C≡C bond parallel to an Ru–Ir hinge; their structural discussion will follow later.

The gross structural features of **4b** are very similar to those of **4a**.[11a] As has been observed there, the $Ru_3C_4$ unit is in an approximately pentagonal bipyramidal arrangement, the Ru–Ru bonds are rather short and attributable to the two bridging carbonyl groups, and the double bonds of the butadiene-1,4-diyl moiety are delocalised over the three C–C bonds although the central bond is marginally longer. However, the asymmetry observed in **4b** is statistically more significant than those observed in **4a** because of the lower e.s.d.s. Thus the two Ru–Ru bonds are different and the difference in bond lengths between the central C–C bond of the butadiene-1,4-diyl moiety compared to the other two is now statistically significant.

A common atomic numbering scheme and selected bond parameters for **3a** and **3b** are given in Table 1. Both the clusters **3** are $Ru_2Ir$ clusters with an electron count of 48; their structural features are similar. There is an asymmetrical carbonyl bridge, and the alkyne ligand is coordinated in a $\mu_3$-$\eta^2$ fashion over the $Ru_2Ir$ triangle, with the alkyne C–C bond parallel to the Ru–Ir bond bridged by the carbonyl. This type of bonding mode of an alkyne has been observed in a number of clusters.[13] The longest metal–metal bond

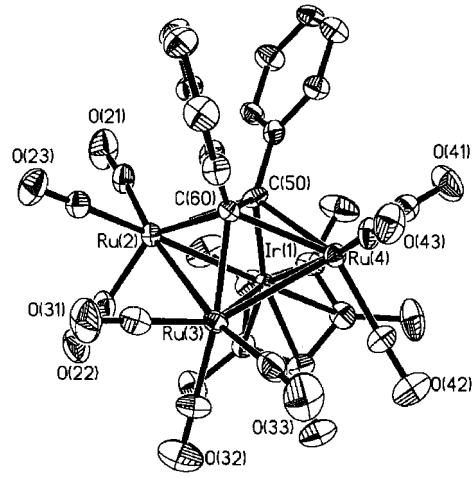

Figure 2. ORTEP diagram of **2a**. Thermal ellipsoids are drawn at the 50% probability level. The phenyl hydrogen atoms are omitted for clarity.

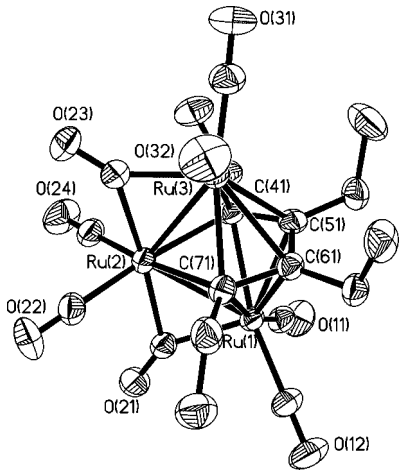

Figure 4. ORTEP diagram and selected bond parameters of **4b**. Thermal ellipsoids are drawn at 50% probability level. Organic hydrogen atoms are omitted for clarity. Ru(1)–Ru(2) = 2.6646(4) Å; Ru(2)–Ru(3) = 2.6741(4) Å; Ru(1)–C(41) = 2.275(3) Å; Ru(1)–C(51) = 2.297(3) Å; Ru(1)–C(61) = 2.300(3) Å; Ru(1)–C(71) = 2.317(3) Å; Ru(2)–C(41) = 2.192(3) Å; Ru(2)–C(71) = 2.188(3) Å; Ru(3)–C(41) = 2.315(3) Å; Ru(3)–C(51) = 2.363(3) Å; Ru(3)–C(61) = 2.352(3) Å; Ru(3)–C(71) = 2.252(3) Å; C(41)–C(51) = 1.440(5) Å; C(51)–C(61) = 1.479(5) Å; C(61)–C(71) = 1.444(5) Å; Ru(1)–Ru(2)–Ru(3) = 88.967(11)°.

is Ir(1)–Ru(2), which is bridged by the carbonyl and is also parallel to the alkyne C–C bond; this bond is significantly longer than the other two. The alkyne C–C bond lengths at ca. 1.40 Å have clearly lost their triple bond character; the bond order is less than two.[14]

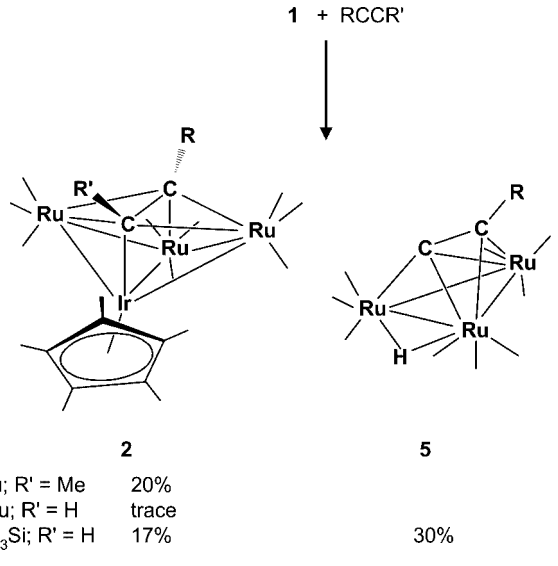
The yields of the clusters **3** increased at the expense of that for clusters **2** when the reaction time was prolonged. This suggested that **3** were derived from the butterfly alkyne clusters **2**. This was also supported by the observation that thermolyses of **2a** and **2b** afforded **3a** and **3b**, respectively. Furthermore, we have also found that the UV photolyses of solutions of **2** yielded **3**. Thus the butterfly alkyne clusters were not very stable at high temperatures or under photolytic conditions, and were prone to undergo fragmentation to yield the stable triangular clusters. However, neither thermolysis nor photolysis yielded the triruthenium clusters **4**, which indicated that **2** were not the precursors. Similarly, we have found that $[Cp^*Ir(CO)_2]$ did not react with **4a** or **4b** under thermolytic or photolytic conditions. Thus the formation of clusters **4** involved a different pathway from that leading to **2** and **3**.

The reaction of **1** with the unsymmetrical alkynes *t*BuCCMe, 1-hexyne and $Me_3SiCCH$, however, gave only very low yields of the alkyne butterfly clusters **2** (Scheme 2). The reaction with 1-hexyne was particularly poor, and the amount of material obtained was very little, although the IR spectral profile suggested that it had a similar structure to **2c**.[15] For $Me_3SiCCH$, the known triruthenium cluster $[Ru_3(CO)_9(\mu\text{-}H)(C_2SiMe_3)]$ (**5a**) was also obtained.[16] With the exception of **2d**, the molecular structures of all the products have been determined by single-crystal X-ray crystallographic studies, albeit that for **5a** has already been reported.[17,18] The ORTEP plot for **2c** is shown in Figure 5, and it shows that the C≡C bond of the alkyne is again parallel to an Ru–Ir hinge, and the less bulky group of the alkyne is *cis* to the Cp*Ir. The $^1$H NMR spectrum of **2c** did not show the presence of isomers. Hence the binding of the unsymmetrical alkyne appeared to be highly stereoselective. Monitoring of the reaction using infrared spectroscopy showed that strong peaks attributable to $[Cp^*Ir(CO)_2]$ were formed, suggesting fragmentation of the cluster.



Scheme 2.

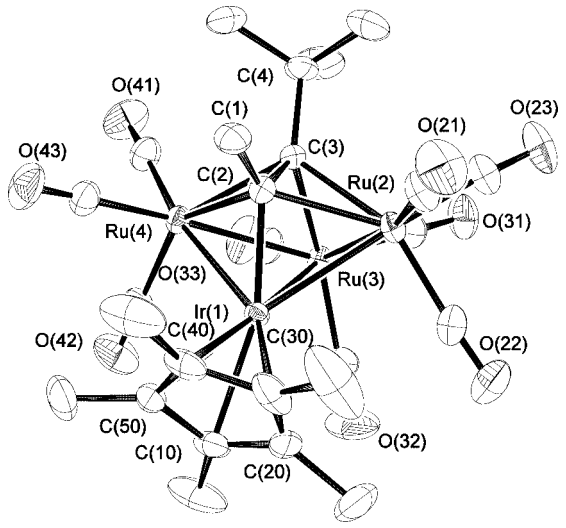

Figure 5. ORTEP diagram of **2c**. Thermal ellipsoids are drawn at 50% probability level. Organic hydrogen atoms are omitted for clarity.

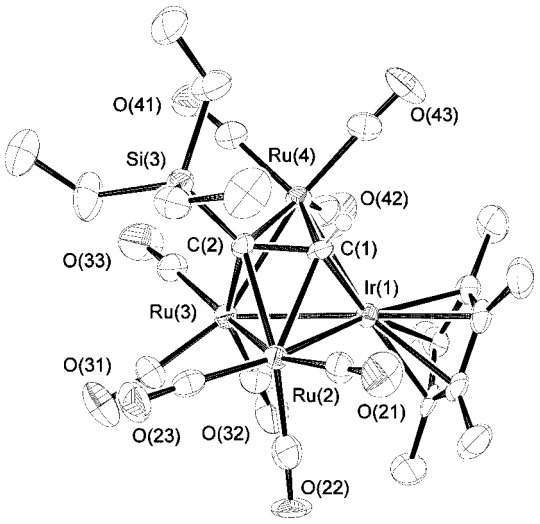

Figure 6. ORTEP diagram of **2f**. Thermal ellipsoids are drawn at 50% probability level. Organic hydrogen aotms are omitted for clarity.

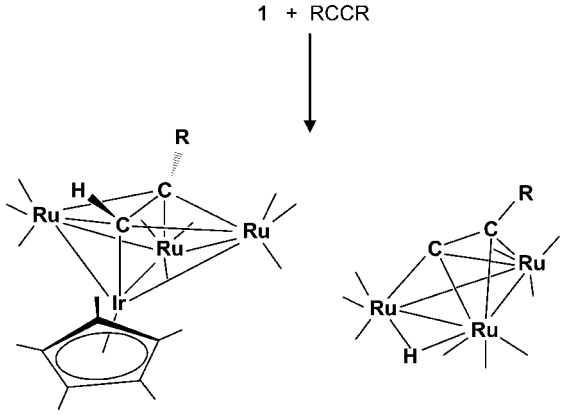
Somewhat surprisingly, the thermal reaction of **1** with the bis-silylated alkynes $R_3SiCCSiR_3$ (R = Me, Et) in hexane afforded two products which were analogous (or identical for R = Me) to those for $Me_3SiCCH$ (Scheme 3). The identity of the clusters **2e** and **2f** have been confirmed by complete characterisation, including by single-crystal X-ray crystallographic studies; the ORTEP plot for **2f** is shown in Figure 6.



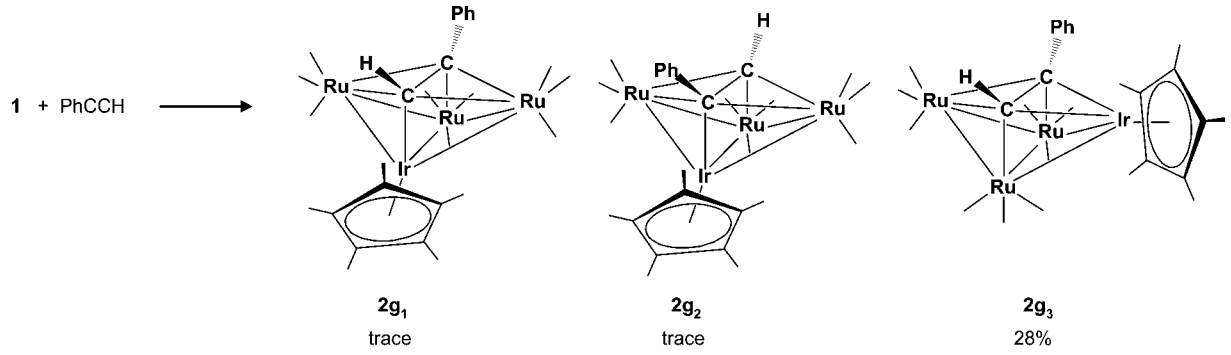
Scheme 3.

The replacement of one trialkylsilyl group by hydrogen was also clearly supported by the $^1$H NMR and FAB MS data; the singlets at $\delta \approx 10.5$ ppm corresponded to the alkenic hydrogen atoms on the alkynes and were in agreement with similar compounds reported in the literature.[18] Monitoring of the reaction with $Me_3SiCCSiMe_3$ by $^1$H NMR spectroscopy showed that the trimethylsilyl group was lost during the reaction and not during workup. GC analysis of an aliquot of the crude reaction mixture suggested that the trimethylsilyl group was lost as octamethyltrisiloxane, which suggested that the hydrogen may have originated from trace amounts of water. However, the desilylation product was observed in almost similar yields even when the reaction was carried out with thoroughly dried solvents and glassware. Since [Cp*Ir(CO)$_2$] is known to bring about C–H activation of hydrocarbons, it is also possible that the Cp*Ir(CO) fragment in these clusters may be responsible for the hydride exchange with $SiMe_3$ group.

Desilylation has been reported by Schneider and co-workers in their attempt to synthesize Fe–Ni heteronuclear clusters by the vaporisation of nickel atoms into a solution of (bistrimethylsilyl)acetylene and [Fe(CO)$_5$]; the reaction had unexpectedly afforded the cluster [Fe$_3$(CO)$_9$(μ-H)(C≡CSiMe$_3$)], and it was suggested that cleavage might have occurred during chromatographic work-up.[19] Vahrenkamp and co-workers have also reported desilylation in the reaction of [RuCo$_2$(CO)$_{11}$] with $Me_3SiC{\equiv}CMe$. The initial product, [RuCo$_2$(CO)$_9$(μ$_3$-$Me_3SiC{\equiv}CMe$)], formed in the reaction underwent subsequent desilylation to give [RuCo$_2$(CO)$_9$(μ$_3$-HC≡CMe)].[20]

In contrast to the highly stereoselective reactions with the other unsymmetrical alkynes above, the reaction of **1** with phenylacetylene afforded three isomeric alkyne butterfly clusters as red crystalline products (Scheme 4). The major product, obtained in 28% yield, was identified as [Cp*IrRu$_3$(CO)$_9$(PhCCH)] (**2g$_3$**); it has been characterised spectroscopically and analytically, as well as by a single-crystal X-ray structure analysis. The ORTEP plot of **2g$_3$** is shown in Figure 7, and it shows that the alkyne C≡C bond is parallel to an Ru–Ru hinge. The other two products were obtained in very low yields. A single-crystal X-ray structural study on **2g$_2$** showed it to be a hinge-apex isomer of **2g$_3$** in which the bulkier Ph group of the alkyne is oriented *cis* to the Cp*Ir; the ORTEP plot for **2g$_2$** is shown in Figure 8. The IR spectrum of the third product, **2g$_1$**, shows a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4.

pattern similar to that of **2a**–**f**. The $^1$H NMR characteristics are consistent with the assumption of a cluster-bound PhCCH. The multiplet between $\delta$ = 7.00 and 7.77 ppm is due to aromatic protons, the singlet at $\delta$ = 1.82 ppm can be assigned to Cp* methyl protons, and the singlet at $\delta$ = 10.58 ppm corresponds to the alkyne C–H. The MS is also consistent with structures like those observed for $\mathbf{2g_2}$ and $\mathbf{2g_3}$. Based on these spectroscopic characteristics it was thus tentatively identified as a third isomer in which the alkyne C≡C bond is parallel to an Ru–Ir hinge, and the bulkier Ph group of the alkyne is *trans* to the Cp*Ir, i.e., similar to **2c**–**f**.

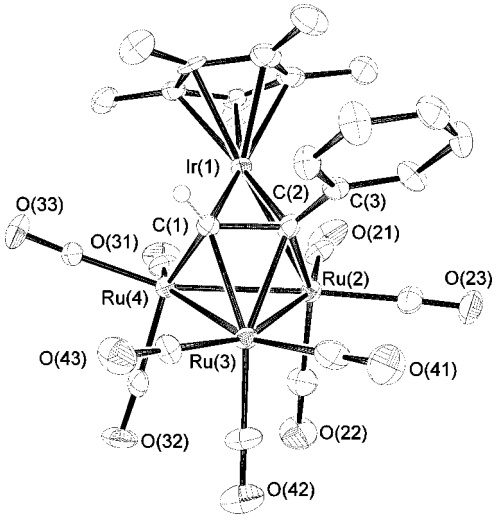


Figure 7. ORTEP diagram of $\mathbf{2g_3}$. Thermal ellipsoids are drawn at 50% probability level. Organic hydrogen atoms are omitted for clarity.

In the reaction of **1** with internal alkynes, only the ‖Ru–Ir isomers were observed; prolonged heating of this isomer did not lead to isomerisation but to cluster fragmentation instead. In contrast, the reaction with phenylacetylene yielded the ‖Ru–Ru isomer $\mathbf{2g_3}$ as the major product; the ‖Ru–Ir *cis* and ‖Ru–Ir *trans* isomers were obtained as minor products. It was observed by IR spectroscopy that a solution of $\mathbf{2g_3}$ converted slowly to $\mathbf{2g_1}$ and $2g_2$ on standing. Likewise, monitoring of a deuterated benzene solution of

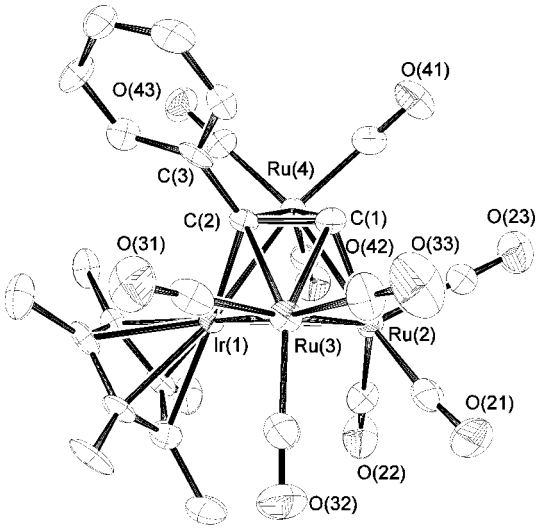

Figure 8. ORTEP diagram of $\mathbf{2g_2}$. Thermal ellipsoids are drawn at 50% probability level. Organic hydrogen atoms are omitted for clarity.

$\mathbf{2g_3}$ by $^1$H NMR at ambient temperature indicated the slow formation of two new singlets at $\delta$ = 1.82 and 1.87 ppm, assignable to the Cp* signals of $\mathbf{2g_1}$ and $\mathbf{2g_2}$, respectively, as well as singlets at $\delta$ = 10.58 and 11.37 ppm, due to the respective C–H protons of the phenylacetylene. However, complete conversion to either $\mathbf{2g_1}$ or $\mathbf{2g_2}$ was not observed even after a month. Prolonged heating of $\mathbf{2g_3}$ finally afforded a 1.2:1.0:5.4 equilibrium mixture of $\mathbf{2g_1}$/$\mathbf{2g_2}$/$\mathbf{2g_3}$. This indicated clearly that the equilibrium lies towards the ‖Ru–Ru isomer $\mathbf{2g_3}$, i.e., that it was the thermodynamically most stable isomer. This is in agreement with the earlier observations on the $[FeRu_3(\mu\text{-}H)_2(CO)_{13}]$ and $[Cp/Cp^*RhRu_3(\mu\text{-}H)_4(CO)_9]$ systems.[9,10]

As a natural extension from the above reactions with alkynes, we attempted the reaction of **1** with 1-hexene to see if cluster-olefin complexes may be prepared, but none could be isolated. Instead, we found that the cluster-catalysed isomerisation of 1-hexene gave a mixture of 2- and 3-hexenes. However, we have monitored the reaction by $^1$H NMR spectroscopy and found that complete isomerisation was not achieved even after many hours.

### Structural Discussions on 2

The clusters **2** have been studied crystallographically; selected bond parameters using a common atomic numbering scheme were presented in Table 2. With the exception of **2g$_3$**, the alkyne is disposed parallel to the hinge heterometallic bond, with the torsion angle between the carbon–carbon backbone and the Ir(1)–Ru(3) edge close to 0° [torsion angles ranging between –0.7 to 1.9°]. This hinge Ir–Ru bond is also the longest of the metal–metal bonds, as has been generally found in $M_4C_2$ butterfly clusters.[21] The Ir–Ru bond lengths in general are, however, comparable to Ir–Ru bond lengths reported in the literature [Ir–Ru = 2.4972–2.9882 Å].[22] Also evident is the loss of multiple-bond character in the alkyne C–C bond; this length is surprisingly consistent across the different clusters, averaging 1.45 Å and with the range of values well within the experimental errors, despite the variation in substituents. However, there is a clear trend that the alkyne is closer to the iridium than to the ruthenium, as has been observed for clusters **3** above; this is consistent with the difference in the metal–metal bond lengths of [Ir$_4$(CO)$_{12}$] and [Ru$_3$(CO)$_{12}$] (mean of 2.693 and 2.853 Å, respectively).[23] The effect of asymmetry in the alkyne is also evident in the $M_{wingtip}$–$C_{alkyne}$ bond lengths; the M–C distance to the $C_{alkyne}$ carrying the bulkier substituent is longer than that to the $C_{alkyne}$ carrying the less bulky group. This difference ranges from 0.04 to 0.08 Å, with the exception of **2c**, while for the symmetrical alkynes **2a** and **2b**, the difference in this bond length is less than 0.03 Å. The effect of asymmetry in the alkyne is also apparent in **2g$_3$**.

## Conclusions

The cluster [Cp*IrRu$_3$(μ-H)$_2$(CO)$_{10}$] reacts with alkynes under thermal activation to yield butterfly clusters of the general formulae [Cp*IrRu$_3$(CO)$_9$(RCCR′)], but with substantial cluster fragmentation. The reactions did not proceed under photochemical or chemical activation with TMNO (trimethylamine *N*-oxide). However, the thermal activation also led to cluster fragmentation to [Cp*Ir(CO)$_2$] and alkyne substituted triruthenium clusters such as **4** and **5**, or the iridium-diruthenium clusters **3**. The yields of these decomposition products can be quite high; over 50% in the case of the combined yields of **3a** and **4a**, and accounted for the observed low yields of the clusters **2**.

The binding of the alkyne also appears to be highly stereoselective, with a general preference towards the stereoisomer in which the alkyne is aligned parallel to an Ru–Ir hinge, and with the bulkier substituent oriented away from the Cp*Ir moiety in the case of unsymmetrical alkynes. A notable exception is observed in the case of phenylacetylene, for which all three possible isomers are observed to be in equilibrium, with the isomer in which the alkyne is aligned parallel to an Ru–Ru hinge being the thermodynamically most stable.

Our results thus represent a map of the possibility of stereoselective binding of alkynes in such heteronuclear clusters. The high stereoselectivity exhibited in some cases suggests that such clusters may be useful in the stereocontrol of reactions with alkynes, and our future work will be directed towards that.

## Experimental Section

All reactions were carried out using standard Schlenk techniques under nitrogen. Solvents used in reactions were of AR grade, and were dried, distilled and kept under argon in flasks fitted with Teflon valves prior to use. The products were generally separated by thin-layer chromatography (TLC), using plates coated with silica gel 60 F254 of 0.25 mm or 0.5 mm thickness and extracted with hexane or dichloromethane. Infrared spectra were recorded as hexane solutions unless otherwise stated with a Bio-Rad FTS 165 FTIR spectrometer at a resolution of 1 $cm^{-1}$ using a solution cell with NaCl windows of path length 0.1 mm. NMR spectra were acquired with a Bruker ACF 300 MHz as $CDCl_3$ solutions unless otherwise stated. Chemical shifts reported are referenced to residual protons of the solvent. Mass spectra were collected using the Fast Atom Bombardment (FAB) technique and were carried out with a Finnigan MAT95XL-T mass spectrometer normally with 3-nitrobenzyl alcohol matrix at the National University of Singapore mass spectrometry laboratory. Microanalyses were carried out by the microanalytical laboratory at the National University of Singapore. GC analyses were carried out with an Agilent GC-MS consisting of a GC 6890 MS 5973 equipped with an HP-1 column (300 mm × 0.25 mm × 0.25 μm). In photochemical reactions, UV irradiation was performed with a Hanovia 450 W UV lamp ($\lambda_{max}$ = 254 nm). The cluster **1** was prepared according to published procedures.[24]

**Reaction of 1 with Alkynes:** In a typical reaction, cluster **1** (10.0 mg, 10.0 μmol), PhCCPh (2.5 mg, 10 μmol) and hexane (20 mL) were placed in a Carius tube fitted with a teflon valve, and the solution degassed by three freeze-pump-thaw cycles. The reaction was then heated in an oil-bath at 90 °C for 6 h. After removal of the solvent and volatiles under reduced pressure, the residue was redissolved in a minimum volume of dichloromethane and chromatographed on silica-gel TLC plates with 100% hexane as eluent. The analytical and spectroscopic data for the products are given in Table 3. Diffraction quality crystals were grown from hexane by slow cooling.

**Thermolysis of 2a and 2b:** Cluster **2a** (6.7 mg, 6.0 μmol) and hexane (20 mL) were placed in a Carius tube fitted with a Teflon valve, and the reaction mixture degassed by three freeze-pump-thaw cycles. The mixture was then heated at 90 °C for 7 h. Chromatographic separation of the mixture on silica-gel TLC plates using hexane as eluent afforded three bands. These were, in order of elution, unreacted **2a** (2.0 mg, 30%), **3a** (2.5 mg, 40%), and **1** (0.5 mg, 8%), identified by their IR spectra.

Heating **2b** (8.4 mg, 8.0 μmol) under the same conditions followed by a similar work-up afforded **2b** (3.3 mg, 40%), **3b** (2.4 mg, 35%), and **1** (0.6 mg, 7%).

**Photolysis of 2a and 2b:** A hexane solution of **2a** (6 mg, 6.0 μmol) was photolysed in a quartz Carius tube under UV light for 7 h. Chromatographic separation of the mixture on silica-gel TLC

alkene. The infrared spectrum of the reaction mixture showed that cluster **1** remained mainly unchanged.

**X-Ray Crystal Structure Determinations:** Crystals were mounted on quartz fibres. X-ray data were collected with a Bruker AXS APEX system, using Mo-$K_\alpha$ radiation, at 223 K with the SMART suite of programs.[25] Data were processed and corrected for Lorentz and polarisation effects with SAINT,[26] and for absorption effects with SADABS.[27] Structural solution and refinement were carried out with the SHELXTL suite of programs.[28] Crystal and refinement data are summarised in Table 4 and Table 5.

The structures were solved by direct methods to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. All non-hydrogen atoms were generally given anisotropic displacement parameters in the final model. Organic hydrogen atoms were placed in calculated positions and refined with a riding model. Compound $\mathbf{2g_3}$ was refined as a racemic twin.

CCDC-283339 to -283350 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Fluorinated β-Diketones for the Extraction of Lanthanide Ions: Photophysical Properties and Hydration Numbers of Their $Eu^{III}$ Complexes

**Anne-Sophie Chauvin,[a] Frédéric Gumy,[a] Izuru Matsubayashi,[b] Yuko Hasegawa,*[b] and Jean-Claude G. Bünzli*[a]**

**Keywords:** Lanthanide / Luminescence / β-diketonate / Hydration number / Extraction

Tris(β-diketonato)europium(III) with a series of variably fluorinated ligands derived from 3,5-heptanedione were synthesised with the aim of determining their hydration state under extraction conditions. The number of coordinated water molecules was determined by measuring the lifetime of the $Eu(^5D_0)$ excited level in water and deuterated water. The hydration gain ($\Delta q = q - q_0$) after shaking chloroform solutions during 10 min with 0.1 M $NaClO_4$ aqueous solutions depends on the fluorination extent of the diketonates: fluorination of one methyl group leads to a decrease in $\Delta q$ of ca. 0.5 unit, while fluorination of one ethyl group results in a decrease of ca. 1.3 units. Highly fluorinated complexes (i.e with hexafluoroacetylacetonate and related ligands) display a hydration number close to one while poorly fluorinated compounds (or nonfluorinated ones, such as the acetylacetonate complex) have a hydration state close to two. Photophysical properties of the $Eu^{III}$ β-diketonates are also described and the synthesis of the fluorinated β-diketones is re-investigated and discussed in details.

## Introduction

Tris and tetrakis (β-diketonato)lanthanides(III) are the most widely studied complexes of the 4f-element series because of their potential use in several applications,[1] from NMR shift reagents to electroluminescent materials for light-emitting diodes, trace analysis, and separation/extraction systems.[2,3] Lanthanide β-diketonates are easily synthesised from the parent β-diketones, they possess large thermodynamic stability and, in addition, some of them are commercially available. The introduction of fluorine substituents on β-diketones produces large changes in the properties of the resulting $Ln^{III}$ complexes. For instance, while the separation factor between $La^{III}$ or $Pr^{III}$ and $Lu^{III}$ by solvent extraction drops from almost $4{\cdot}10^7$[4] with acetylacetone (Hacac) to 3000[5,6] with 2-thenoyltrifluoroacetone (Htta), and less than 100 with hexafluoroacetylacetone (Hhfa),[7] the complexes become more volatile and can be used to separate trivalent lanthanide ions by gas chromatography.[8,9] Moreover, due to the heavy atom effect,[10] which facilitates intersystem crossing, the metal-centred luminescent properties are enhanced, for instance in the case of $Sm^{III}$ and $Eu^{III}$ electroluminescent devices.[11] As a consequence, ternary complexes of the tris(β-diketonato)$Ln^{III}$ with tta and 1,10 phenanthroline are routinely used to produce luminescent resins[12] and liquid crystals.[13]

The stability of lanthanide β-diketonates in aqueous solutions decreases with fluorination since the electron-withdrawing effect of the fluorine atoms reduces the charge density on the oxygen atoms. This decrease in stability could influence the extraction and separation efficiency of lanthanides with β-diketones. The relationship between extractability and stability of aqueous complexes is presently investigated in one of our laboratories.[7] On the other hand, synergistic extraction of lanthanides(III) with β-diketonate and a Lewis base improves the extractability and also depends on the fluorination of β-diketonates. For instance, in $CHCl_3$ [$Eu(acac)_3$] forms a 1:1 ternary complex with tributylphosphate (tbp) having $\log\beta_1 = 1.90$, while trifluoroacetonate (tfa) forms both 1:1 and 1:2 ternary complexes with $\log\beta_1$ and $\log\beta_2$ equal to 3.32 and 4.64, respectively, where $\beta_n = [EuA_3(tbp)_n]_O/[EuA_3]_O[tbp]^n_O$ with A = β-diketonate ion while the subscript O indicates concentrations in the organic solvent.[14] Similarly, benzoylacetonate forms only the 1:1 adduct ($\log\beta_1 = 1.60$) but benzoyltrifluoroacetonate leads to both 1:1 and 1:2 ternary complexes ($\log\beta_1 = 3.64$ and $\log\beta_2 = 5.28$).[14]

Two opposite effects will compete as far as the hydration state of the tris(β-diketonates) is concerned: the smaller complexation power of the fluorinated ligands is expected to foster interaction with water whereas the presence of the fluorine substituents will create a protective, repulsive shell around the metal centre. We determine here the hydration state $q$ of the europium β-diketonates with the fluorinated ligands depicted in Scheme 1, using the luminescent lifetime method, to unravel the relationship between $q$ and the extent of fluorination. We also re-investigate the synthesis of

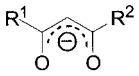
the fluorinated β-diketones since published literature procedures are sometimes imprecisely described. The acronyms used here for β-diketonates (see Scheme 1) are relative to partially fluorinated methyl (acac, hfa) or ethyl groups ($F_5H_3$, $F_5H_5$, $F_5F_5$, $F_3H_5$, $F_3F_5$); β-diketones are indicated by an additional H in front of the acronym.



acac : $R^1 = R^2 = CH_3$

hfa : $R^1 = R^2 = CF_3$

$F_5H_3$ : $R^1 = C_2F_5$ $R^2 = CH_3$

$H_5H_5$ : $R^1 = R^2 = C_2H_5$

$F_5H_5$ : $R^1 = C_2F_5$ $R^2 = C_2H_5$

$F_5F_5$ : $R^1 = R^2 = C_2F_5$

$F_3H_5$ : $R^1 = CH_2CF_3$ $R^2 = C_2H_5$

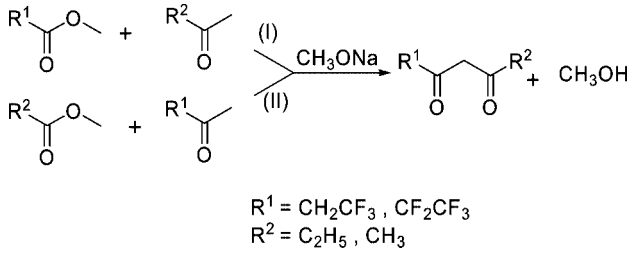
$F_3F_5$ : $R^1 = CH_2CF_3$ $R^2 = C_2F_5$

Scheme 1. Ligands used in this study. Acronyms refer to the number of fluorine atoms present in the β-diketonates.

## Results and Discussion

### Syntheses of the Ligands

Two different pathways can be envisaged for the synthesis of fluorinated β-diketones. The most common synthetic route consists in methoxide-mediated acylation of the appropriate ketones with fluorinated esters (route I, see Scheme 2), for which the yields are generally good because fluorinated esters have electrophilic carbonyl moieties that are highly reactive in Claisen condensations. On the other hand, there are few reported examples of the condensation of alkyl perfluoroalkyl ketones with nonfluorinated esters under basic conditions (route II, see Scheme 2), due to the lack of reactivity or even the decomposition of the reactants. The presence of fluorine atoms is known to reduce intermolecular interactions (van der Waals forces and hydrogen bonding) and therefore fluorinated β-diketones are highly volatile (as well as their complexes, used in the chromatographic separation of lanthanides).[1,8] As a consequence, special care has to be exercised during the synthesis and subsequent isolation of the fluorinated β-diketones which are easily lost by co-evaporation with the solvent: several ketones form azeotropes with the reaction solvent [for example $H(F_3F_5)$ or $H(F_5F_5)$, either in ether, THF, or hexane] or extraction solvent ($CHCl_3$) after acidic treatment. Surprisingly, experimental details pertaining to the synthesis of some of the ligands used in this study could not be found in the literature, even though complexes have been isolated. In other cases, the reported synthesis could not be reproduced and/or the starting materials used are no more commercially available. For instance, the synthesis of $H(F_5F_5)$ reported in the literature simply refers to that of 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione H(fod), without any experimental detail nor characterisation of the final $H(F_5F_5)$ product.[15] For these reasons and because lanthanide β-diketonates are presently stirring a renewed interest,[1,12,13] we discuss in detail the synthesis of all the ligands described in Scheme 1.



Scheme 2. Pathways for the synthesis of fluorinated β-diketones.

S. N. Misra et al. have reported the synthesis of 1,1,1-trifluorohexane-2,4-dione, $H(F_3H_5)_5$, in hexane and its subsequent isolation by distillation.[16] We found, however, that an azeotropic mixture forms upon carrying out the reaction in hexane or ether. Therefore, this ligand was isolated as its sodium salt. Further treatment to convert it into its neutral form was unsuccessful. After a methanolic solution of the sodium salt was passed through an ion exchange column (Amberlite 120), subsequent distillation yielded a colourless oily liquid. Although the latter displayed $^{19}F$ NMR signals, elemental analysis showed it to contain only 5% of carbon. 1,1,1,2,2-Pentafluoro-3,5-heptanedione $H(F_5H_5)$ was synthesised by addition of the enolate of 2-butanone to methyl pentafluoropropionate (route I). To ensure that all the 2-butanone was converted under its enolate form, more than two equivalents of base were added; otherwise, the 2-butanone enolate reacts with the fluorinated ketone, the enolate ion of which is formed preferentially if only one equivalent of base is added.[17,18] The synthesis can be conducted either in ether or in THF, but a higher yield is obtained with the former solvent. Moore et al.[19] reported an analogous synthesis, in which the ketone was added to a mixture of sodium methoxide and methyl pentafluoropropionate. However, the product was only characterised by IR so that we report its full analytical data. Two reports describe the isolation of the hydrated form of 1,1,1,2,2,6,6,7,7,7-decafluoro-3,5-heptanedione, $H(F_5F_5)$, by distillation.[20,21] Again, we observed the formation of azeotropic mixtures when ether or $CH_2Cl_2$ were used as solvents, as mentioned for $H(F_3H_5)$. As a consequence, this ligand has been isolated as its sodium salt. Alternatively, for large scale synthesis, removal of $H(F_5F_5)$ from the reaction mixture can be achieved by complexation with $Cu^{II}$, the metal being then released under acidic conditions and the ligand purified by distillation.[22] The synthesis of 1,1,1,2,2,7,7,7-octafluoro-3,5-heptanedione, $H(F_3F_5)$, was the most troublesome. First attempts using either route I or II were unsuccessful, the product being only isolated in trace amounts. In case of route I, this possibly arises from

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the low boiling point of the starting ketone $CF_3CH_2COCH_3$ (41 °C), which can be easily evaporated from the reaction mixture either by the $N_2$ flux used to keep the conditions anhydrous or because deprotonation of this ketone is exothermic, which favours evaporation. The reaction was consequently conducted in presence of an excess of ketone and in a sealed tube. Finally, it was found that treating the resulting sodium salt $Na(F_3F_5)$ with sulfuric acid led to a partial decomposition of the product into $CF_3CF_2COCH_2COCH_3$. Therefore, $F_3F_5$ was also isolated in the form of its sodium salt $Na(F_3F_5)$. The yield of the reaction remains low, although it can be somewhat improved by using diethyl ether as solvent instead of hexane (37 vs. 25%, respectively).

The absence of spectroscopic feature, such as the single carbonyl vibration band in the spectral range 1740–1780 $cm^{-1}$, the $^1H$ NMR signal in the range 5.6–6.2 ppm arising from the CH=C proton, and the $^{13}C$ NMR resonances occurring for both *C*=CO and *C*=O, point to all the ligands, except $Na(F_3F_5)$, being exclusively under the enol form. This was expected in view of the presence of the electron-withdrawing $CF_2$ and $CF_3$ groups:[23] indeed, literature data based on $^1H$ NMR evidences show that the only detected form for β-diketones with more than four fluorine atoms is the enol isomer. A noticeable exception is 1,1,1,5,5,5-hexafluoro-3-(trifluoromethyl)pentane-2,4-dione, which is reported to exist under its keto form.[24] In our case, $Na(F_3F_5)$, which features a nonfluorinated α-carbon, has structural similarity with the latter compound. An enol-ketone equilibrium was found, displaced in favour of the enol form, 70%. The occurrence of the keto form for these two diketones is however difficult to explain.

## Syntheses of the Complexes

The neutral ligand was deprotonated (alternatively, its sodium salt was used) and the resulting β-diketonate easily reacted with europium acetate, giving in most cases a solid or a viscous oil which could be recrystallised either in methanol or in a mixture of methanol and water. The complexes were characterised by elemental analyses and in most cases they were found to be mono- or di-hydrated. Since the β-diketonates are hygroscopic, all the solutions for the luminescence studies were prepared in a glove-box and care was taken to keep them free of water. In the case of $EuF_3H_5$, the microanalysis was not reproducible, with a very low proportion of carbon (less than 10 percent), which is probably due to the high volatility of the β-diketone. For the same reasons, care had to be taken when preparing the $10^{-5}$ M solutions to avoid evaporation of the compound upon weighting. The tris(β-diketonates) were all studied in chloroform, the usual extraction solvent, for comparison reasons.

## Photophysical Properties

Absorption data for some of the ligands (in chloroform), their sodium salts (in water) and their $Eu^{III}$ complexes (in chloroform) are reported in Table 1. The ligands, except $H(F_5H_3)$, and the sodium salts feature one main absorption band located in the range 32500–39000 $cm^{-1}$ which is assigned to π→π* transitions. According to calculations performed with the CAChe Pro 6.0 program package for Microsoft Windows® (Fujitsu Ltd., 2000–2002), the enol forms should yield π→π* transitions located at lower energy than the bands arising from the keto form (> 40000 $cm^{-1}$). In addition, $Na(F_5H_3)$ displays a shoulder at 26620 $cm^{-1}$. For the neutral ligands, shifts of the maximum of the main absorption band seem to depend on two factors, the length of the alkyl substituent and the extent of fluorination. For instance, $H(F_5H_5)$ has one more carbon atom compared with $H(F_5H_3)$, and the resulting inductive effect materialises in a bathochromic shift of ca. –3250 $cm^{-1}$. On the other hand, fluorination induces hypsochromic shifts: +2670 $cm^{-1}$ for the replacement of the two methyl groups of acac by trifluoromethyl groups in hfa, while fluorination of an ethyl group of $H(H_5H_5)$ leads to a small shift of +490 $cm^{-1}$ only. These trends are inverted for the sodium salts in water. A small hypsochromic shift (+550 $cm^{-1}$) occurs in going from $Na(F_5H_3)$ to $Na(F_5H_5)$ while fluorination leads to bathochromic shifts: –1560 $cm^{-1}$ between Na(acac) and Na(hfa), –400 $cm^{-1}$ and –2180 $cm^{-1}$ in going from $Na(H_5H_5)$ to $Na(F_5H_5)$ and $Na(F_5F_5)$, respectively. Substitution of the ethyl group in $Na(F_3H_5)$ by a pentafluoroethyl group in $Na(F_3F_5)$ unexpectedly results in quite a large energy shift (–2890 $cm^{-1}$). Even larger red

shifts are observed when fluorinating the methylene group in $Na(F_3H_5)$ to yield $Na(F_5H_5)$, –5000 $cm^{-1}$ or in $Na(F_3F_5)$ to generate $Na(F_5F_5)$, –3890 $cm^{-1}$. Upon complexation with trivalent europium, both batho- and hypso-chromic shifts are seen with respect to the de-protonated ligands (Figure 1). The coordinated ligands are under their enol form, as ascertained by IR data. In addition to the shift undergone by the main absorption band, most of the $Eu^{III}$ complexes display a shoulder located at smaller energy, in the range 30400–30900 $cm^{-1}$.

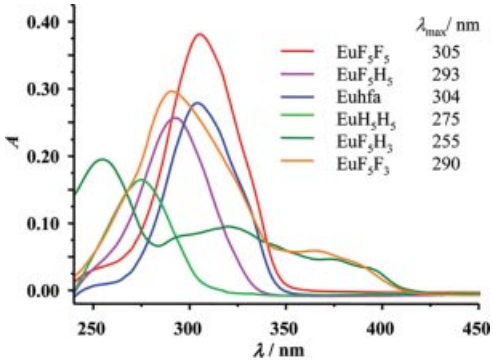

Figure 1. UV/Vis absorption spectra of europium complexes $10^{-5}$ M in chloroform.

Excitation of $Eu^{III}$ β-diketonates either into the f-f or ligand-centred absorption bands at room temperature results in a line-like emission characteristic of the $Eu(^5D_0)$ level. At lower temperature (77 K) and upon enforcement of a time delay, no broad emission band corresponding to a triplet state of the ligand is seen, thus reflecting an efficient ligand-to-metal energy transfer. Spectra are very similar whatever the ligand is, pointing to a similar structure for all the complexes; the $^5D_0 \rightarrow {}^7F_1$ emission band is comprised of three regularly spaced components, indicative of a low symmetry of the metal ion environment in solution. Two typical spectra are presented in Figure 2 and relative intensities of the $^5D_0 \rightarrow {}^7F_J$ transitions ($J$ = 1–4), are compared in Table 2.

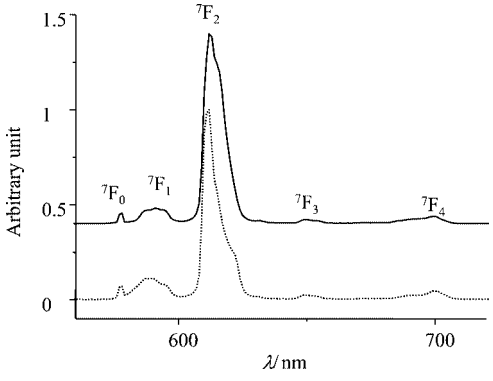

Figure 2. Luminescence spectra of $Eu(F_5F_5)_3$ (black line) and $Eu(F_5H_5)_3$ (dotted line) $10^{-5}$ M in $CHCl_3$, at 295 K, without time delay, with excitation at 32785 $cm^{-1}$ and 31130 $cm^{-1}$, respectively.

### Hydration Numbers in Water-Saturated Chloroform

In solvent extraction systems, the aqueous solutions containing the lanthanide ions are mixed with a nonmiscible organic solvent, e.g. chloroform containing the organic ligand. Therefore the organic phase is saturated with water which interacts directly with the europium complex, affecting the hydration number of the extracted species.[25,26] In order to determine the efficiency of the β-diketonate complexes towards extraction of $Eu^{III}$, the number of water molecules present in the first coordination sphere, $q$, has been determined under extraction conditions (see Exp. Section). Results are listed in Table 3. To make sure that the calculated $q$ values are connected with the extraction process, hydration of the complexes was also measured before putting the chloroform solution in contact with the aqueous solution ($q_0$). In all cases, the hydration $q_0$ was found to be less than 1.

The hydration gains ($q - q_0$) upon shaking the solutions during ten minutes with the aqueous solution of sodium perchlorate are plotted vs. the number of fluorine atoms in Figure 3. As expected, ligands bearing fluorine atoms pro-

vide complexes with a smaller increase in the number of coordinated water molecules than, for instance, $H_5H_5$. The data reported in Figure 3 allow us to differentiate three types of compounds. The first series comprises the complexes with ligands having one completely hydrogenated ethyl substituent, $H_5H_5$, $F_3H_5$ and $F_5H_5$. Fluorination of the methyl group corresponds to a decrease of 0.5 in ($q$ – $q_0$) and complete fluorination of the ethyl substituent to a decrease of 1.3. A similar behaviour is seen in the second series, having one completely fluorinated ethyl substituent, with a decrease in ($q$ – $q_0$) of 0.4 between the complexes with $F_3F_5$ and $F_5F_5$. In the last series, with hfa and $F_5H_3$, $q$ – $q_0$ = –0.5. Altogether, the highest fluorinated complex with $F_5F_5$ tends to remain non hydrated ($\Delta q = 0.2 \pm 0.2$) while the nonfluorinated compound with $H_5H_5$ tends to acquire two water molecules ($\Delta q = 1.7 \pm 0.1$), in line with the usual composition [$Ln(L)_3 \cdot 2H_2O$] exhibited by lanthanide tris(β-diketonates).[1] However, larger hydration numbers have sometimes been reported, for instance for [$Ln(tta)_3$] and [$Ln(pta)_3$] (pta: pivaloyltrifluoroacetone) in $CHCl_3$,[27] and for [$Eu(tta)_3$] in benzene ($q$ = 3).[28] The water uptake does not vary linearly with the number of fluorine atoms and steric effects also play an important role, as seen for the complexes with hfa and $F_5H_3$ which display a larger hydration increase upon shaking the chloroform solution with aqueous sodium perchlorate than the other complexes with ligands bearing two $C_2$ substituents.

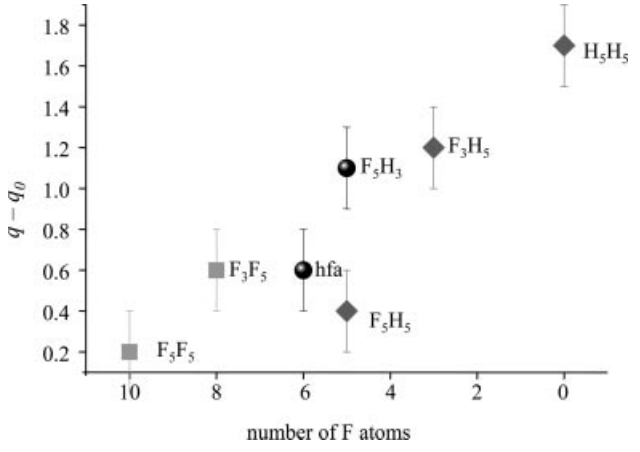

Figure 3. Increase in the number of water molecules in the inner coordination sphere ($q$ – $q_0$) of the europium tris(β-diketonates) upon shaking the solution with aqueous $NaClO_4$.

Furthermore, 1,10-phenanthroline was added to the solutions after the extraction processes, and the lifetimes were measured again: the corresponding $q$ values were in the range 0–0.1. In the case of $Eu(H_5H_5)_3$, further mixing of the phenanthroline-containing solution with aqueous sodium perchlorate resulted in a $q$ value equal to 0.3, confirming the strength of the *o*-phen-Eu interaction.

## Conclusion

From the results reported in this paper, the extent of β–diketone fluorination changes the ratio between the keto and enol forms. Increasing fluorination favours the presence of the keto form in organic solvent. It may be one of the reasons why more fluorinated β-diketones form more stable ternary complexes with Lewis bases in organic solvents. On the other hand, the hydration number of the "extracted" species in $CHCl_3$ decreases with fluorination, which seems to be in contradiction with the previous statement. Our understanding is that fluorine substituents form a repulsive shell around the metal centre reducing, via potentially strong F···H bonds, the metal–water interaction.

## Experimental Section

**Synthesis and Characterisations:** Starting materials were purchased from Narchem, Apollo Scientific, Acros, or Fluka and were of analytical grade. Reactions were conducted under inert atmosphere with standard Schlenk and dry box techniques. Tetrahydrofuran and diethyl ether were freshly distilled from sodium and benzophenone, respectively. Elemental analyses were performed by Dr. Eder. (Microchemical Laboratory, University of Geneva). When fluorinated compounds were analyzed, $CeO_2$ was added to the samples to avoid evaporation and to improve burning conditions; the ratio of oxygen introduced into the burner was also increased. $^1H$ NMR and $^{13}C$ NMR spectra were recorded on a Bruker Avance DRX 400 spectrometer at 298 K and their assignment was based on $^1H$ coupling. Chemical shifts are given in part par million with respect to TMS. $^{19}F$ NMR spectra were recorded at 298 K on a Bruker AV 200 MHz. ES-MS spectra of $10^{-5}$–$10^{-4}$ M solutions in acetonitrile or MeOH/$H_2O$ were obtained with a Finningan SSQ 710C spectrometer using a capillary temperature of 200 °C, an acceleration potential of 4.5 kV and an ion spray voltage of 4.6 kV. The instrument was calibrated using the horse myoglobin standard and the analyses were conducted in positive mode. Analyses by MALDI-Tof MS were performed in the positive ion mode on an Axima CFR plus mass spectrometer (Kratos, Manchester, UK) equipped with a 337 nm nitrogen laser and pulsed extraction. Analyses were carried out in the reflectron mode at a mass range of $m/z$ = 600–3000 with an accelerating voltage of 20 kV. The instrument was externally calibrated with a mixture of Angiotensin II and ACTH (18–39). The resulting compounds were loaded onto the target plate by mixing 1μL of sample solution with the same volume of a matrix solution (10 mg/mL α-cyano-4-hydroxycinnammic acid in 50% 0.1% TFA plus 50% acetonitrile) and left to dry in the drying box at room temperature. Electron impact ionisation spectra were recorded on a Nermag R10–10C mass spectrometer with an ionisation potential of 70 V. IR spectra were recorded in ATR mode with a Perkin–Elmer FT-IR Spectrum One spectrometer fitted with a universal ATR sampling accessory featuring a diamond/ZnSe crystal. UV/Vis absorption spectra were measured on a Perkin–Elmer Lambda 900 spectrometer using quartz Suprasil® cells of 0.1 and 1 cm path length.

Low-resolution luminescence data (spectra and lifetimes) were recorded at room temperature (298 ± 0.1 K) with a Fluorolog FL3–22 spectrometer from Horiba-Jobin–Yvon-Spex using 1-cm path length quartz Suprasil® cells. The temperature was kept constant by using a FL-1027 thermostated cell holder. Emission and excitation spectra were corrected for the instrumental function. The complexes were dissolved in $CHCl_3$ or $CDCl_3$, the concentration being adjusted to $1 \cdot 10^{-5}$ M. Phosphorescence lifetimes of frozen solutions at 77 K in quartz capillaries or in 1-cm Suprasil® cells were determined with the instrument in time-resolved mode. Solutions for the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

determination of the number of coordinated water molecules were prepared as follows. The organic $CHCl_3$ phase containing the Eu β-diketonate (3.3 mL, $10^{-5}$ M) was mixed with the aqueous phase (0.1 M $NaClO_4$, 0.1 mL) and stirred during 10 minutes before extraction (this span of time is necessary to get a constant lifetime value). A similar solution in $CDCl_3/D_2O$ was prepared in parallel in a glove-box to avoid moisture contamination. The solutions were then centrifuged and the organic phase was recovered and further analysed by luminescence enforcing a 0.03–0.05 ms delay to avoid interference with fluorescence emission from the ligand. Lifetimes were determined upon ligand excitation and monitoring the $^5D_0 \rightarrow {}^7F_2$ and the $^5D_0 \rightarrow {}^7F_4$ transitions; they are the average of at least three independent measurements. All luminescence decays proved to be single exponential and were analysed using Origin 7.0®. The number of coordinated water molecules was determined by using Horrock's equation $q = 1.11\ (\Delta k\ -0.31)$.[29]

**Syntheses of the Ligands:** 1,1,1,5,5,5-Hexafluoropentane-2,4-dione H(hfa), and heptane-3,5-dione $H(H_5H_5)$ were commercial products (Aldrich).

**Synthesis of 5,5,6,6,6-Pentafluorohexane-2,4-dione $H(F_5H_3)$:** Sodium methoxide (2.16 g, 39 mmol) was suspended in hexane (10 mL). Methyl pentafluoropropionate (1.78 g, 10 mmol) was added with stirring and cooling to 0 °C. After further stirring during 1 h under $N_2$, acetone (0.4 g, 7 mmol) was added dropwise which resulted in an orange solution. The mixture was further stirred during 3 days, then the solution was cooled to 0 °C and sulfuric acid (7.0 mL, 6.0 M) was slowly added. Two phases formed, which were separated, the hexane phase being orange. The aqueous phase was washed 5 times with hexane and the combined organic phases were dried with $Na_2SO_4$ before distillation of the solvent. The residue was further distilled to give the desired product as pale oil (580 mg, yield: 40%). IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 738, 798, 845, 942, 1019, 1117, 1166, 1198, 1329 (aliphatic C–F), 1411, 1440, 1596, 1653, (C=C), 1745 (C=O), 2854, 2963, 3130 ($sp^3$ C–H). $^1H$ NMR (400 MHz, $CDCl_3$): $\delta_H$ = 3.77 (s, 3 H, $–CH_3$), 6.14 (s, 1 H, –CH) ppm. $^{13}C$ NMR (400 MHz, $CDCl_3$): $\delta_H$ = 44.9 ($–CH_3$), 99.0 (–CH=C), 110–130 ($CF_x$), 166 (C=O) 176.0 (C=C–O) ppm. $^{19}F$ NMR (200 MHz, $CDCl_3$): $\delta_F$ = –82.08 (3F, $-CF_3$), –123.40 (2F, $–CF_2$) ppm. Maldi-MS (negative mode): *m/z* = 203.55 $[(F_5H_3)^-$, calcd. 203.01]. CI-MS ($CHCl_3$): *m/z* = 84 $[CH_3COCHC^+(OH)]$, 119 $[CF_3CF_2^+]$, 189 $[CF_3CF_2COCHC^+(OH)]$. $C_6H_5F_5O_2 \cdot 0.3H_2O$ (209.4): calcd. C 34.40, H 2.69; found C 34.34, H 2.67.

**Sodium Salt of 1,1,1-Trifluoro-3,5-heptanedione $Na(F_3H_5)$:** Sodium methoxide (0.78 g, 15 mmol) was dissolved in diethyl ether (2 mL) and introduced into a tube equipped with a magnetic stirrer. Propanoic acid methyl ester (0.62 g, 7.00 mmol) was added with stirring and the solution was cooled to 0 °C. 4,4,4-Trifluorobutane-2-one (1.06 g, 8.4 mmol) was added dropwise to the stirred mixture and an orange solution resulted. The tube was sealed and the mixture was further stirred during 3 days. The ether was removed by rotary evaporation and a deep orange residue was obtained (570 mg, yield: 36%). IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 668, 742 815, 912 1039, 1133, 1144, 1200, 1257, 1320, 1361 (aliphatic C–F), 1378, 1408, 1437, 1530, 1633, (C=C), 1712 (C=O), 2840, 2956, 2997 ($sp^3$ C–H). $^1H$ NMR (400 MHz, $CDCl_3$ + DCl 0.1 M, 10 μL): $\delta_H$ = 0.96 (s, 3 H, $–CH_3$), 2.28 (q, 2 H, $–CH_3CH_2$), 3.57 (s, 2 H, $–CF_3CH_2$), 5.67 (s, 1 H, –CH), 8.33 (s, OH) ppm. $^{19}F$ NMR (200 MHz, $D_2O$): $\delta_F$ = –121.0 ppm. Maldi-MS (negative mode, 34 mV): *m/z* = 181.44 $[(F_3H_5)^-$, calcd. 181.14].

**1,1,1,2,2-Pentafluoro-3,5-heptanedione ($F_5H_5$):** Sodium methoxide (1.98 g, 33 mmol) was suspended in diethyl ether (40 mL). 2-Butanone (1.08 g, 15 mmol) was added to the mixture which was stirred during 1 h under $N_2$ at room temp., whereupon a white slurry resulted. A solution of methyl pentafluoropropionate (1.60 g, 9 mmol) in diethyl ether (25 mL) was added whilst stirring, which resulted in the formation of a pale pink slurry. The mixture was further stirred during 16 h, then sulfuric acid (100 mL, 1.5 M) was slowly added whilst stirring and the ether phase turned orange. The aqueous phase was extracted with freshly distilled diethyl ether (4× 100 mL), and the resulting organic phases were dried with $Na_2SO_4$. The solvent was partially removed and the product was purified by distillation at 133 °C to give a colourless yellow liquid (880 mg, yield 45%). IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 738, 815, 889, 984, 1021, 1064, 1120, 1168, 1203, 1329, 1384 (aliphatic C–F) 1417, 1459, 1594, (C=C), 1779, (C=O) 2890, 2988, 2949 ($sp^3$ C–H). $^1H$ NMR (400 MHz, $CDCl_3$): $\delta_H$ = 1.20 (t, 3 H, *J* = 7.6 Hz, $–CH_3$), 2.55 (q, 2 H, *J* = 7.6 Hz, $–CH_2$), 5.99 (s, 1 H, –CH) ppm. $^{13}C$ NMR (400 MHz, $CDCl_3$): $\delta_C$ = 9.55 ($–CH_3$), 32.19 ($–CH_2$), 80–130 ($–CF_x$),176–180 (C=C–O, –CH=C), 199.0 (C=O) ppm. $^{19}F$ NMR (200 MHz, DMSO): $\delta_F$ = –81.4, –81.6 ($–CF_3$), –120.0, –122.3 ($–CF_2$) ppm. CI-MS ($CHCl_3$): *m/z* = 99 $[CH_3CH_2COCHC(OH)]^+$, 119 $[CF_3CF_2]^+$, 189 $[CF_3CF_2COCHC(OH)]^+$, 218.46 $[(F_5H_5 + H)^+$, calcd. 218.04]. $C_7H_7F_5O_2 \cdot 0.3H_2O$ (223.4): calcd. C 37.62, H 3.43; found C 37.82, H 3.43.

**Sodium Salt of 1,1,1,2,2,7,7,7-Octafluoro-3,5-heptanedione $Na(F_3F_5)$:** Sodium methoxide (0.78 g, 15.4 mmol) was placed with diethyl ether (2 mL) in a tube containing a magnetic stirrer. Methyl pentafluoropropionate (1.25 g, 7.00 mmol) was added with stirring and cooling to 0 °C. 4,4,4-Trifluorobutane-2-one (1.06 g, 8.40 mmol) was added to the stirred mixture dropwise and an orange solution resulted. After sealing the tube, the mixture was further stirred during 3 days. The ether was removed by rotary evaporation and an orange residue was obtained (756 mg, yield: 37%). IR ($cm^{-1}$, ATR, as Na salt): $\tilde{\nu}$ = 742, 813, 874, 924, 943, 959, 994, 1040, 1066, 1113, 1032, 1149, 1174, 1208, 1265, 1319, 1362 (aliphatic C–F), 1407, 1438, 1600, 1669, 1713, 1743 (C=O), 2958, 3008 ($sp^3$ C–H) ppm. $^1H$ NMR (400 MHz, $D_2O$): $\delta_H$ = 2.34 (s, 2 H, $CH_2COCH_2CF_3$), 3.70 (s, 2 H, $CH_2COCH_2CF_3$), 4.02 (s, 2 H, $CH_2CF_3$), 5.88 (s, 1 H, CH=C) ppm. $^{19}F$ NMR (200 MHz, DMSO): $\delta_F$ = –81.14 ($–CF_3$), –82.32 ($–CF_3$), –119.71 ($–CF_2$) ppm. Maldi-MS (positive mode): *m/z* = 252.4 $[(NaF_3F_5 – NaF)^+$, calcd. 252.00]; 294.1 $[(NaF_3F_5)^+$, calcd. 293.99].

**Sodium Salt of 1,1,1,2,2,6,6,7,7,7-Decafluoro-3,5-heptanedione $Na(F_5F_5)$:** Sodium methoxide (0.76 g, 14.2 mmol) was suspended in diethyl ether (40 mL). 3,3,4,4,4-Pentafluorobutane-2-one (1.13 g, 7.00 mmol) was added and the mixture was stirred at room temp. during 1 h under $N_2$ atmosphere, whereupon a colourless solution resulted. A solution of methyl pentafluoropropionate (1.25 g, 7.00 mmol) in diethyl ether (10 mL) was added whilst stirring, which resulted in a pale orange solution. After further stirring during 16 h the mixture turned orange. The ether was removed by distillation and a brown residue was obtained together with an oily liquid. The latter was removed and the residue was washed 5 times with dichloromethane. The resulting brown powder was dried under vacuum (960 mg, yield 42%). IR ($cm^{-1}$, ATR, Na salt): 736, 821, 922, 1019, 1103, 1139, 1165, 1192, 1322, 1368 (aliphatic C–F), 1427, 1521, 1582, 1661, (C=O), 2967 ($sp^3$ C–H). $^1H$ NMR (400 MHz, $CDCl_3$ + DCl 0.1 M, 10 μL): $\delta_H$ = 5.03 (s, 1 H, –CH). $^{13}C$ NMR (400 MHz, $D_2O$): $\delta_C$ = 90.0 (–CH=C), 110–130 (broad bands due to coupling with $^{19}F$), 170–175 (C=O), 177.00 (C=C–O) ppm. $^{19}F$ NMR (200 MHz, DMSO): $\delta_F$ = –80.81 ($–CF_3$), –81.17 ($–CF_3$), –117.71 ($–CF_2$), –121.14 ($–CF_2$) ppm. Maldi-MS (negative mode): *m/z* = 307.59 $[(F_5F_5 + H)^-$, calcd. 307.08].

**Synthesis of the Europium Complexes:** Europium acetate solutions were prepared just before being used, by dissolution of europium

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

oxide (0.16 g, 0.45 mmol) in $CH_3COOH$ (3 mL, 0.9 M). After stirring during 1 h, the solutions were filtered and the resulting filtrate cooled to 0 °C.

**Tris(hexafluoroacetonato)europium(III), $Eu(hfa)_3·3H_2O$:** A solution of hfa (0.30 g, 1.44 mmol) in methanol (3 mL) was added dropwise at 0 °C to the europium acetate solution. After stirring overnight, a white yellow precipitate formed, which was removed by filtration, and recrystallised from methanol, giving $Eu(hfa)_3·3H_2O$ (280 mg, yield: 70%) as a pale yellow solid. IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 659, 677, 742, 772, 804, 855, 956, 1011, 1104, 1133, 1194, 1211, 1252, 1351 (aliphatic C–F), 1464, 1532, 1561, 1613, 1650, (C=O), 2968 ($sp^3$ C–H), 3160, 3314, 3642 (O–H). $^{19}F$ NMR (200 MHz, DMSO): $\delta_F$ = –75.35 (–$CF_3$) ppm. $C_{15}H_3EuF_{18}O_6·3H_2O·0.5MeOH$ (843.99): calcd. C 22.08, H 1.32; found C 22.07, H 1.68.

**Tris(3,5-heptanedionato)europium(III), $Eu(H_5H_5)_3·2H_2O$:** A solution of $H_5H_5$ (0.19 g, 1.44 mmol) in methanol (3 mL) was added dropwise to at 0 °C to the europium acetate solution. After a few minutes, a precipitate formed. The pH of the mixture, which was 4, was then adjusted at 6.5 by addition of NaOH 1 M. After stirring overnight, the mixture was filtered. The resulting precipitate was recrystallised from methanol yielding $Eu(H_5H_5)_3·2H_2O$ as white yellow powder (160 mg, yield: 60%). IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 759, 806, 854, 898, 947, 980, 1005, 1068, 1175 (C=O), 1219, 1243, 1306, 1330 (=C–O), 1371, 1398, 1511 (C=C), 1587, (C=O), 2877, 2936, 2968 ($sp^3$ C–H), 3079, 3346, 3576 (O–H). $C_{21}H_{33}EuO_6·2H_2O$ (570.17): calcd. C 44.29, H 6.55; found C 44.79, H 6.59.

**Tris(1,1,1,2,2-pentafluoro-3,5-heptanedionato)europium(III), $Eu(F_5H_5)_3·3.8H_2O$:** A solution of $F_5H_5$ (0.31 g, 1.44 mmol) in methanol (5 mL) was added dropwise at 0 °C to the europium acetate solution. After stirring overnight, a white powder was filtered and recrystallised from methanol to provide $Eu(F_5H_5)_3·3.8H_2O$ (185 mg, yield 44%). IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 679, 721, 753, 811, 943, 1021, 1067, 1133, 1157, 1191, 1325 (aliphatic C–F), 1408, 1461, 1512, 1627 (C=O), 2983 ($sp^3$ C–H), 3301 (O–H). $^{19}F$ NMR (200 MHz, DMSO): $\delta_F$ = –82.46 (–$CF_3$), –82.75 (–$CF_3$), –125.76 (–$CF_2$), –125.95 (–$CF_2$) ppm. $C_{21}H_{24}EuF_{15}O_6·3.8H_2O$ (894.53): calcd. C 28.93, H 2.96; found C 28.95, H 2.81.

**Tris(1,1,1,2,2,6,6,7,7,7-decafluoro-3,5-heptanedionato)europium(III), $Eu(F_5F_5)_3·2H_2O$:** The sodium salt of $F_5F_5$ (0.3 g, 0.91 mmol) was introduced into a flask in which water (10 mL) and methanol (1 mL) were added and the solution warmed at 60 °C until complete dissolution. The europium acetate solution was then added dropwise, which induced a precipitate. After stirring overnight, the mixture was filtered and the filtrate recrystallised from methanol to give $Eu(F_5F_5)_3·2H_2O$ (140 mg, yield: 43%). IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 658, 744, 766, 796, 924, 1027, 1121, 1145, 1175, 1195, 1289, 1327 (aliphatic C–F), 1476, 1520, 1542 (C=C), 1646 (C=O), 3388 (O–H). $^{19}F$ NMR (200 MHz): $\delta_F$ = –78.49 (–$CF_3$), –82.52 (–$CF_3$), –121.13 (–$CF_2$) ppm. $C_{21}H_3EuF_{30}O_6·2H_2O$ (1109.19): calcd. for C 22.74, H 0.64; found C 22.96, H 0.44.

**Tris(5,5,6,6,6-pentafluoro-2,4-hexanedionato)europium(III), $Eu(F_5H_3)_3$:** A solution of 5,5,6,6,6-pentafluoro-2,4-hexanedione (0.3 g, 1.44 mmol) in methanol (5 mL) was added dropwise at 0 °C to the europium acetate solution. A white precipitate formed and, after stirring overnight, methanol was removed to give a yellow oily residue which was recrystallised from methanol/water (50:50 v/v) to give $Eu(F_5H_3)_3$ (153 mg, yield: 42%). IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 738, 798, 845, 942, 1019, 1118, 1166, 1198, 1329 (aliphatic C–F), 1411, 1440, 1596, 1653 (C=C), 1745 (C=O), 2854, 2963 ($sp^3$ C–H), 3130 (O–H). $^{19}F$ NMR (200 MHz, $CDCl_3$): $\delta_F$ = –82.90 (–$CF_3$), –126.96 (–$CF_2$) ppm. $C_{18}H_{12}EuF_{15}O_6$ (761.96): calcd. for C 28.67, H 1.84; found C 28.40, H 1.59.

**Tris(1,1,1,2,2,7,7,7-octafluoro-3,5-heptanedionato)europium(III), $Eu(F_3F_5)_3$:** The sodium salt of $F_3F_5$ (0.2 g, 0.67 mmol) was dissolved in a mixture water (5 mL) and methanol (1 mL). The europium acetate solution was then added dropwise at 0 °C. After stirring overnight, the product was extracted with 3 × 20 mL of dichloromethane then the solvent was removed to give a solid which was recrystallised from water/methanol (50:50 v/v) to provide a pale yellow compound (80 mg, yield: 37%). IR ($cm^{-1}$, ATR): $\tilde{\nu}$ = 681, 743, 771, 789, 844, 872, 896, 960, 998, 1024, 1049, 1067, 1084, 1120, 1156, 1185, 1206, 1267, 1328, 1370, (aliphatic C–F), 1439, 1521, 1576, 1626, 1664 (C=C), 1732 (C=O), 2854, 2958, 3003 ($sp^3$ C–H). $^{19}F$ NMR (200 MHz, $CDCl_3$): $\delta_F$ = –81.36 (–$CF_3$), –82.72 (–$CF_3$), –119.78 (–$CF_2$) ppm.

**Tris(1,1,1-trifluoro-3,5-heptanedionato)europium(III), $Eu(F_3H_5)_3$:** This compound was synthesised similarly to $Eu(F_3F_5)_3$, but starting from the sodium salt of $F_3H_5$ (0.3 g, 0.97 mmol). $Eu(F_3H_5)_3$ was obtained as a pale yellow solid (92 mg, yield: 38%). IR ($cm^{-1}$, ATR, as Na salt): $\tilde{\nu}$ = 753, 833, 869, 945, 989, 1114, 1167, 1210, 1249, 1278, 1325, 1389 (aliphatic C–F), 1427, 1498, 1630, 1699, 1725, 1748 (C=O), 2968, 3037 ($sp^3$ C–H). $^{19}F$ NMR (200 MHz, DMSO): $\delta_F$ = –121.9 (–$CF_3$) ppm.

# Syntheses, Crystal Structures and Magnetic Properties of Carboxylato-Bridged Polymeric Networks of $Mn^{II}$

**Subal Chandra Manna,[a] Ennio Zangrando,[b] Michael G. B. Drew,[c] Joan Ribas,*[d] and Nirmalendu Ray Chaudhuri*[a]**

**Keywords:** Manganese(II) / Carboxylate / Crystal structure / Magnetic behavior

Three new carboxylato-bridged polymeric networks of $Mn^{II}$ having molecular formula $[Mn(ox)(dpyo)]_n$ (**1**), $\{[Mn_2(mal)_2(bpee)(H_2O)_2]\cdot 0.5(bpee)\cdot 0.5(CH_3OH)\}_n$ (**2**) and $\{[Mn_3(btc)_2(2,2'\text{-bipy})_2(H_2O)_6]\cdot 4H_2O\}_n$ (**3**) [dpyo, 4,4′-bipyridine *N*,*N*′-dioxide; bpee, *trans*-1,2 bis(4-pyridyl)ethylene; 2,2′-bipy, 2,2′-bipyridine; ox = oxalate dianion; mal = malonate dianion; btc = 1,3,5-benzenetricarboxylate trianion] have been synthesized and characterized by single-crystal X-ray diffraction studies and low temperature magnetic measurements. Structure determination of complex **1** reveals a covalent bonded 2D network containing bischelating oxalate and bridging dpyo; complex **2** is a covalent bonded 3D polymeric architecture, formed by bridging malonate and bpee ligands, resulting in an open framework with channels filled by uncoordinated disordered bpee and methanol molecules. Whereas complex **3**, comprising btc anions bound to three metal centers, is a 1D chain which further extends its dimensionality to 3D via π-π and H-bonding interactions. Low temperature magnetic measurements reveal the existence of weak antiferromagnetic interaction in all these complexes.

## Introduction

Metal-organic frameworks (MOFs) containing paramagnetic metal ions represent a new class of materials for their intriguing network topologies and for their potential applications in the area of catalysis, separation, sorption, sensors, but also as electronic and magnetic devices.[1,2] Moreover, such MOFs have compositional/structural diversities which may be tuned by the suitable choice of ligands as well as metal ions. Thus, the construction of target molecules with the properties mentioned above is a challenge for synthetic chemists.[3] To achieve the desired networks, various carboxylates have been used due to their wide variety of coordination modes,[4] resulting in efficient superexchange pathways. Several groups as well as our labs[5–8] reported the syntheses and characterizations of a large number of carboxylato-bridged multidimensional networks. Oxalate, malonate, succinate, fumarate, maleate, terephthalate, 1,3,5-benzenetricarboxylate etc. are among the more employed carboxylates to build up the framework. Moreover, combination of nitrogen donor co-/bridging- ligands i.e. pyrazine, piperazine, 1,2-bis(4-pyridyl)ethane, 4,4′-trimethylenedipyridine, 4,4′-bipyridyl disulphide, hexamethylenetetramine etc. with carboxylates may enhance the dimensionality of the molecular frameworks.[7] But evaluation of magnetic interaction of these coordination polymers as a function of geometry and electronic configuration of the individual metal ion is the most important issue in the current research.[9,10] Manganese-carboxylates are well recognized from the magnetic point of view[11,12] as these systems often possess a large number of unpaired electrons. Literature survey reveals[13] that there are several manganese-containing networks showing single molecular magnetism, ability of individual molecules to function as magnetizable magnets in the absence of an external magnetic field and with no long-range ordering from intermolecular interactions. Due to these novel properties, increasing attention has been devoted to the construction of manganese–carboxylate frameworks in order to assess the correlation between structure and magnetism.

While manganese–oxalate frameworks are rare,[14] there are some reports[15] on the molecular-based magnets formed by bimetallic three-dimensional oxalate networks. On the other hand, there are some reports by our group using malonate,[6] showing antiferromagnetic coupling only, besides interesting networks. Our studies till date did not investigate the effect of coligand on the magnetic property in the manganese-malonate frameworks. In addition, metal carboxylates, alone and in combination with nitrogen donor

coligands, are of particular interest for the possibility to form open-framework structures[4b] besides the existence of magnetic interactions. The above mentioned facts have driven us to pursue the design and syntheses of manganese–carboxylates varying the carboxylate anion as well as the coligand.

The present contribution reports the syntheses, crystal structures and low-temperature magnetic measurements of three new carboxylato-bridged polymeric architectures of manganese(II) using three different carboxylates, $[Mn(ox)(dpyo)]_n$ (**1**), $\{[Mn_2(mal)_2(bpee)(H_2O)_2]\cdot 0.5(bpee)\cdot 0.5(CH_3OH)\}_n$ (**2**) and $\{[Mn_3(btc)_2(2,2'\text{-bipy})_2(H_2O)_6]\cdot 4H_2O\}_n$(**3**) [dpyo = 4,4′-bipyridine *N*,*N*′-dioxide; bpee = *trans*-1,2-bis(4-pyridyl)ethylene; 2,2′-bipy = 2,2′-bipyridine; ox = oxalate dianion; mal = malonate dianion; btc = 1,3,5-benzenetricarboxylate trianion].

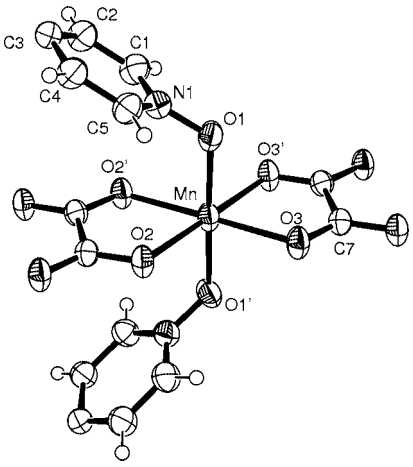

Figure 2. ORTEP drawing of the manganese coordination sphere in complex **1**. The metal is located on a twofold axis passing in between the oxalate C–C bond.

## Results and Discussion

### Description of the Structures

#### *Complex 1*

The X-ray diffraction analysis of complex **1** displays a 2D layered structure of composition $[Mn(ox)(dpyo)]_n$, as depicted in Figure 1. In the framework of (4,4) topology, the manganese ions occupy the 4-connecting nodes while double chelating oxalate and dpyo ligands form the rhomboid grid, with the latter spacers arranged in a herringbone pattern with respect to the –Mn–ox– arrays. The metals are separated by 5.657(2) Å (axis b) along the oxalate and by 12.537(3) Å through the dpyo linkers. Each manganese(II) center is arranged on a twofold axis and the coordination sphere comprises of *trans*-located dpyo oxygen atoms and four oxalate donors in the equatorial plane (Figure 2). All the Mn–O bond lengths are comparable in length within their e.s.d.'s. (Table 1). The dpyo ligand, positioned on a center of symmetry, presents coplanar pyridine rings and is connected to the metal with a N(1)–O(1)–Mn angle of 119.8(2)°.

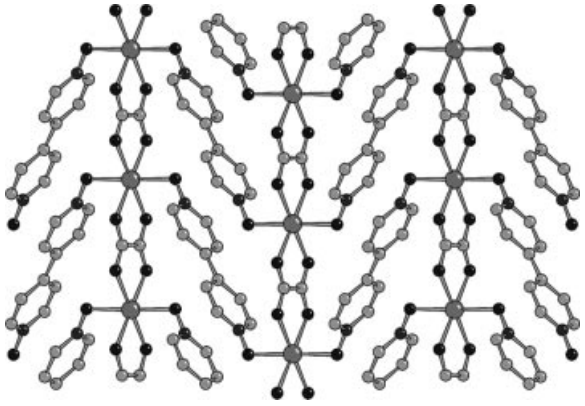

Figure 1. Ball and stick drawing of the 2D sheet of complex **1**.

Table 1. Selected coordination bond lengths [Å] and angles [°] of complex **1**.

| | | | |
|---|---|---|---|
| Mn–O(3) | 2.175(2) | Mn–O(2) | 2.185(2) |
| Mn–O(1) | 2.180(2) | O(1)–N(1) | 1.332(4) |
| O(2)–Mn–O(2′) | 75.64(11) | O(3)–Mn–O(1) | 87.63(9) |
| O(3′)–Mn–O(3) | 77.40(12) | O(3)–Mn–O(2) | 103.48(8) |
| O(1)–Mn–O(1′) | 178.60(14) | O(3)–Mn–O(2′) | 179.12(9) |
| O(1)–Mn–O(2) | 88.81(9) | C(7)–O(2)–Mn | 115.70(19) |
| O(1′)–Mn–O(2) | 92.30(9) | C(7′)–O(3)–Mn | 113.49(19) |
| O(3′)–Mn–O(1) | 91.28(9) | N(1)–O(1)–Mn | 119.8(2) |

The packing shows well-separated layers and the shortest intermetallic distance is 7.648(2) Å. The shortest contact of 3.315(4) is detected between C(1) and O(2) that can be interpreted as a CH···O interaction.

#### *Complex 2*

The structure of **2** reveals covalently bonded $[Mn(mal)(H_2O)]_n$ layers connected by bpee ligands to form a 3D polymer (Figure 3 and Figure 4). The malonate anion, in its frequently found coordination mode[6,16,17] acts as a chelating and a bis(monodentate) ligand towards three metal ions. A selection of bond lengths and angles is reported in Table 2, and the metal coordination sphere with atom labeling Scheme is shown in Figure 5. The octahedral coordination geometry of the metal atom consists of four planar equatorial carboxylate oxygen atoms [range of Mn–O bond lengths of 2.165(3)–2.183(3) Å], while the axial positions are occupied by a water molecule and a bpee nitrogen donor with slightly longer bond lengths [Mn–O(1w) 2.263(3), Mn–N(21) 2.297(3) Å, Table 2].

In the (4,4) square grid (Figure 3) of side dimensions 5.419 × 5.614 Å (Mn–Mn distances), the coordinated water molecule forms two intra-layer hydrogen bonds with oxygen atoms of the neighboring chelating anions [O(1w)–O(17) 2.719(5) Å, O(1w)–O(11) 2.748(4) Å].

Symmetry operations: (′) ½ + *x*, ½ – *y*, ½ + *z*, (′′) ½ + *x*, ½ – *y*, ½ – *z*

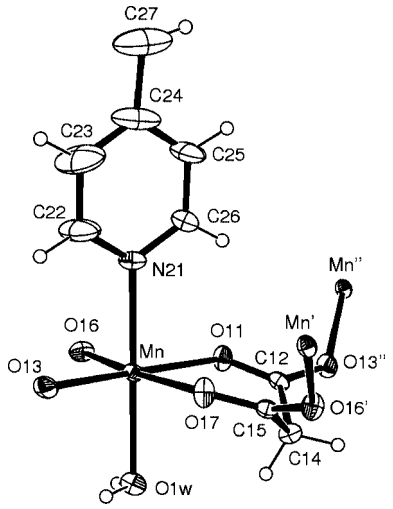

Figure 5. ORTEP drawing showing the coordination pattern of malonate anion in complex **2**.

The present structure is close comparable to those detected in analogous derivatives $[Mn_2(mal)_2(4,4\text{-bipy})(H_2O)_2]_n$,[6a] and $[Mn_2(mal)_2(hmt)(H_2O)_2]_n$,[6b] where $[Mn(mal)(H_2O)]_n$ layers are connected by 4,4′-bipy and hmt spacers, respectively. However, in the present complex **2**, the sheets are separated by 11.944 Å (half *b* axis), a longer value than that measured in closer packed layers of the 4,4′-bipy and hmt derivatives (9.386 and 8.029 Å, respectively). The intermetallic distance spaced by the bpee ligand is 14.052 Å, which is evidently longer than the value of 11.727 Å found in the 4,4′-bipy derivative.

A view of the packing along axis *a* evidences channels, accounting for 26.2% of the unit cell,[18] that are filled by disordered uncoordinated bpee and methanol molecules.

### *Complex 3*

Complex **3**, of composition $[Mn_3(btc)_2(bipy)_2(H_2O)_6]\cdot 4(H_2O)$, forms a ladder-like ribbon built up of $Mn(H_2O)(bipy)$ and $Mn(H_2O)_4$ units bridged by btc anions as depicted in Figure 6. Of the two crystallographically independent manganese ions, Mn(1) possesses a distorted trigonal bipyramid coordination geometry (Figure 7). The equatorial plane encloses bipy nitrogen N(2) and btc oxygen donors O(2), O(4) [coordination distances of 2.289(8), 2.203(6), 2.204(6) Å, respectively], while bipy N(1) and aqua O(1w) are located at the axial sites [Mn(1)–N(1) = 2.242(9), Mn(1)–O(1w) = 2.132(7) Å]. However, oxygens O(1) and O(3) from different btc carboxylate groups at longer distance [Mn–O of 2.513(6), 2.528(6) Å] appear also to interact with the metal. This epta coordination pattern observed for Mn(1) is not novel, and, among other structures, it was reported in various Mn(EDTA) derivatives.[19] On the other hand, Mn(2) is located on a center of symmetry and attains the usual octahedral coordination geometry through four aqua ligands [Mn–$OH_2$ of 2.189(7),

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2.206(8) Å] and two btc oxygens [Mn–O 2.156(6) Å]. A selection of coordination bond lengths and angles is reported in Table 3. Thus each btc ligand bridges three metal ions and the $Mn_3$ triangle have dimensions 10.096(4) Å along the Mn(1)–Mn(1) edge, 8.594(3) and 10.450(3) Å for the Mn(1)–Mn(2) edges. All the atoms of btc are coplanar within ± 0.14 Å, and the max deviation of metal ions from the best-fit-plane through the dianion is displayed by Mn(2) (Figure 6), being displaced by 0.34 Å. The distance measured between the btc centroids forming the (btc)-$Mn(H_2O)_4$-(btc) rungs of the stairlike chain is 11.59 Å.

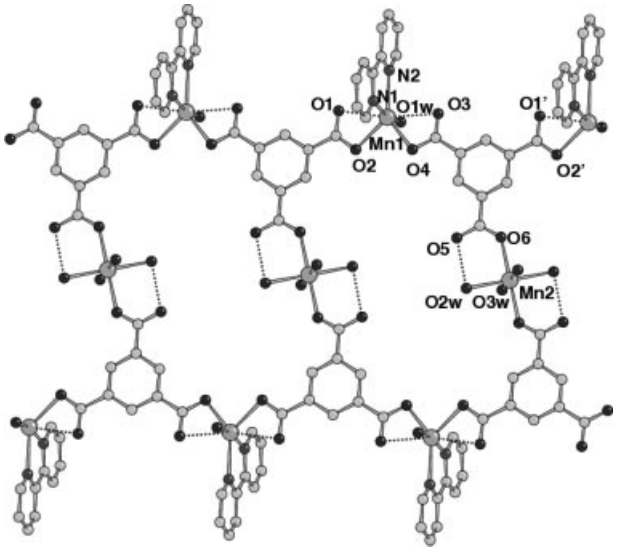

Figure 6. Double-stranded chain of complex **3** viewed down axis *c*. O(2w) forms an intrachain hydrogen bond, dotted lines Mn(1)–O(1) and Mn(1)–O(3) represent long coordination distances.

In the crystal packing the 1D chains are connected by a H-bonding Scheme that occurs among coordinated and lattice water molecules with carboxylate groups (Table 4). The shortest interchain Mn–Mn distance is 6.306(2) Å. The framework is locked through π-π interactions between the peripheral bipyridine ligands (Figure 8), enhancing the dimensionality of the complex to 3D. The $[Mn_3(btc)_2(bipy)_2(H_2O)_6]$ framework shows an accessible porosity that accounts for 20.4% of the unit cell volume (Platon program[18]): this space is occupied by lattice water molecules (four per metal unit). The present compound is isomorphous with that of cobalt derivative,[8k] where the uncoordinated water molecules were found disordered over different locations.

## Magnetic Properties

### *Complex 1*

Although the structure is two-dimensional, from a magnetic point of view the system can be considered as one-dimensional owing to the long Mn–Mn distance created by the linker dpyo, for which we can assume a negligible overlap between the magnetic orbitals of the $Mn^{II}$ ions.

The temperature dependence of $\chi_M T$ ($\chi_M$ being the magnetic susceptibility for one $Mn^{II}$ ion) for complex **1** is shown in Figure 9 (from 300 K to 2 K). At 300 K $\chi_M$ is 0.018 $cm^3$ $mol^{-1}$, and decreasing the temperature the $\chi_M$ value increases in a monotonous form up to 0.13 $cm^3$ $mol^{-1}$ at 18 K, where the curve presents a maximum, and then decreases to 0.09 $cm^3$ $mol^{-1}$ at 2 K. The value of $\chi_M T$ at 300 K is 4.6 $cm^3$ $mol^{-1}$ K, which is as expected for an "isolated" $Mn^{II}$ ion (Figure 9). Decreasing the temperature $\chi_M T$ gradually decreases reaching 0.2 $cm^3$ $mol^{-1}$ K at 2.00 K. The shape of these curves is characteristic of the occurrence of antiferromagnetic interactions between the $Mn^{II}$ centers and the presence of a maximum in the $\chi_M$ curve (Figure 9) indicates that the AF coupling is not negligible. The plot of the reduced magnetization ($M/N\beta$) at 2 K from 0 to 5 T is also indicative of the antiferromagnetic coupling (Figure 9, inset). The curve reaches the value of 1.2 $N\beta$, instead of 5.0 for an isolated $S = 2.5$ ion at 2 K, assuming $g = 2.00$. The X-band powder EPR spectrum at room temperature gives an isotropic signal centered at $g = 2.00$, typical for manganese(II) ions (Figure 1S).

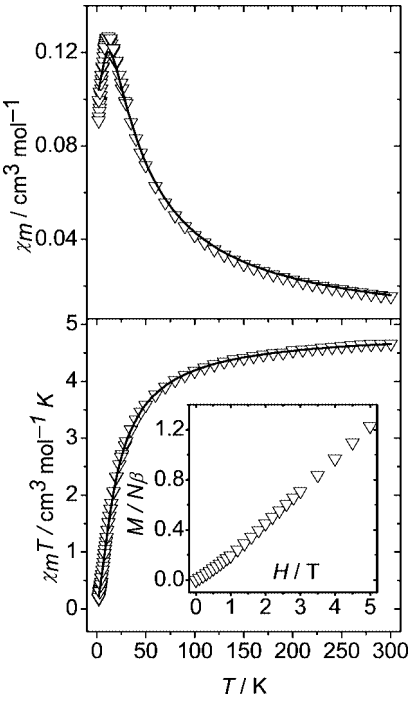

Figure 9. Plots of $\chi_M$ and $\chi_M T$ vs. T for complex **1**. Solid lines represent the best fit by using the expression cited in the text. Inset: plot of the reduced magnetization at 2 K.

This kind of magnetism for one-dimensional $Mn^{II}$ system has been theoretically studied mainly by Fisher.[20] His approach allows to analyze the magnetic data by means of an analytical expression assuming an infinite number of classical spins ($S = 5/2$).[20] The best fit was obtained for $J = -1.89 \pm 0.01$ $cm^{-1}$, $g = 2.00 \pm 0.004$ and $R = 5.4 \times 10^{-5}$ ($R$ is the agreement factor defined as $\Sigma_i[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2 / \Sigma_i[(\chi_M T)_{obs}]^2$). The value of $g = 2.00$ perfectly agrees with that expected for a manganese(II) ion ($S = 5/2$).

Scarce $J$ data for manganese ions bridged by the oxalate ligand have been reported. In an excellent paper of Glerup et al.,[14] comparing the coupling in μ-oxalate complexes with manganese, iron, cobalt, and nickel, the mean value of $J$ for three different Mn–oxalato complexes is –2.14 $cm^{-1}$, analogous to that found in complex **1**.

### *Complex 2*

Before describing the features of complex **2**, we would like to recall that carboxylate functionality is among the most widely used bridging groups for designing polynuclear

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complexes with interesting magnetic properties. Its versatility as a linker is illustrated by the variety of its coordination modes while acting as a bridge,[21] the most common being indicated as *syn-syn*, *syn-anti* and *anti-anti*. Usually the exchange coupling through the carboxylate moiety is highly dependent on the conformation of the bridge between the interacting metal centers.[22] The *syn-anti* bridge for carboxylate ligands appears to be a rather common binding mode for $Mn^{II}$ complexes,[23] and a little is known about the magnetic properties of such complexes. In general, these bridges induce much smaller $J$ values because of the expanded metallic core and the mismatch in the orientation of magnetic orbitals.[23] The magnetic properties for *syn-anti* $Mn^{II}$-carboxylato bridged complexes have been studied for some two-dimensional polymers such as $[Mn(MCPA)_2(H_2O)_2]_n$ (MCPA = 2-methyl-4-chlorophenoxyacetic acid),[24] for some one-dimensional polymers such as $[Mn(\mu\text{-}3\text{-}ClPhCOO)_2(2,2'\text{-bipy})_2]_n{\cdot}nH_2O$,[25] with two *syn-anti* carboxylate bridges and for discrete $Mn^{II}$ homodinuclear complexes involving either only one *syn-anti* carboxylate bridge, $[Mn(2,2'\text{-bipy})_2(H_2O)_2(Me_2NCH_2COO)](ClO_4)$[26] or two *syn-anti* carboxylate bridges, $[Mn_2(\mu\text{-}PhCOO)_2(2,2'\text{-bipy})_4](ClO_4)_2$.[25] The antiferromagnetic coupling is always very small. In the presence of two carboxylate bridges[25] the coupling parameter $J$ is slightly greater than that derived for a single bridge.[25,26] All these exchange coupling constants are of the same order (between –0.5 and –2 $cm^{-1}$).

The temperature dependence of $\chi_M T$ ($\chi_M$ being the magnetic susceptibility for one $Mn^{II}$ ion) for complex **2** is shown in Figure 10 (top; from 300 K to 2 K). At 300 K $\chi_M$ is 0.0012 $cm^3\ mol^{-1}$ (Figure 2S) and it increases in a monotonous form to 0.65 $cm^3\ mol^{-1}$ at 2 K as the temperature is lowered. At 300 K $\chi_M T$ is 4.35 $cm^3\ mol^{-1}$ K, a value which is as expected for an "isolated" $Mn^{II}$ ion. $\chi_M T$ is almost invariable up to 100 K and gradually decreases on cooling to reach the value of 1.3 $cm^3\ mol^{-1}$ K at 2.00 K. The shape of these curves is characteristic of the occurrence of weak antiferromagnetic interactions between the $Mn^{II}$ centers. The lack of a maximum in the $\chi_M$ curve (Figure 2S) indicates that the AF coupling is very small. The plot or the reduced magnetization ($M/N\beta$) at 2 K from 0 to 5 T is also indicative of small antiferromagnetic coupling (Figure 10, bottom). The curve reaches the value of 4.7 $N\beta$, but the shape is different from the Brillouin function for an isolated $S = 2.5$ ion at 2 K, assuming $g = 2.00$.

Taking into account the structure of **2** in which Mn(mal) layers are linked together by the long bpee ligands, the susceptibility data were fitted by the expansion series of Lines[27] for a $S = 5/2$ antiferromagnetic quadratic layer, based on the exchange Hamiltonian $H = -\Sigma_{nn} J S_i S_j$, where $\Sigma_{nn}$ runs over all pairs of nearest-neighbor spins $i$ and $j$, Equation (1).

$$Ng^2\beta^2/\chi|J| = 3\theta + (\Sigma C_n/\theta^{n-1}) \quad (1)$$

$\theta = kT/|J|S(S+1)$, $C_1 = 4$, $C_2 = 1.448$, $C_3 = 0.228$, $C_4 = 0.262$, $C_5 = 0.119$, $C_6 = 0.017$ and $N$, $g$ and $\beta$ in Equation (1) have their usual meanings. The best fit is obtained for the superexchange parameters $J = -0.20 \pm 0.02$ $cm^{-1}$ and $g = 2.00 \pm 0.003$ (Figure 10) with $R = 2.6 \times 10^{-4}$.

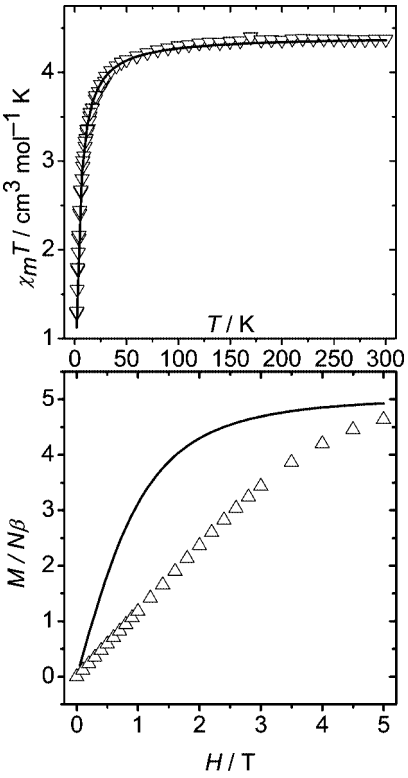

Figure 10. Top: plot of the $\chi_M T$ vs. $T$ for complex **2**. Solid line represents the fit with the expression given in the text. Bottom: plot of the reduced magnetization at 2 K. Solid line represents the Brillouin function for $S = 2.5$ and $g = 2.00$.

The magnetic properties of **2** may be compared with those observed of other two-dimensional manganese(II) systems showing low antiferromagnetic coupling and for which possible antiferromagnetic ordering is not yet achieved at the lowest limit of the measurement temperature. For example, in $[\{Mn(SCN)_2(EtOH)_2\}_2]$,[27b] the superexchange parameter $J$ was reported to be –1.22 $cm^{-1}$ and the low-temperature EPR spectra show an increase in the line width at low temperature, but the susceptibility plot does not show important deviations from the theoretical two-dimensional susceptibility plot even not at low temperature. Room temperature X-band EPR spectrum (Figure 3S) shows an isotropic signal centered at $g = 2.00$, typical for manganese(II) ions.

### *Complex 3*

Plot of $\chi_M T$ vs. $T$ for complex **3** is shown in Figure 11 (top). At 300 K $\chi_M T$ starts at 4.36 $cm^3\ mol^{-1}$ K, which is the typical value for one isolated $Mn^{II}$ ion ($g = 2.00$). This value is almost constant up to 50 K, then it decreases rapidly to 3.62 $cm^3\ mol^{-1}$ K at 2 K, a trend indicative of very weak antiferromagnetic coupling among the manganese(II) ions. The reduced magnetization curve ($M/N\beta$) vs. $H$ at 2 K corroborates this very weak antiferromagnetic coupling. The experimental data are slightly smaller than those corresponding to the Brillouin function for $S = 5/2$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and $g$ = 2.00 (Figure 11, bottom). This almost negligible antiferromagnetic coupling is due to the extended benzenetricarboxyalate bridging ligand, which cannot create any significant coupling.[28]

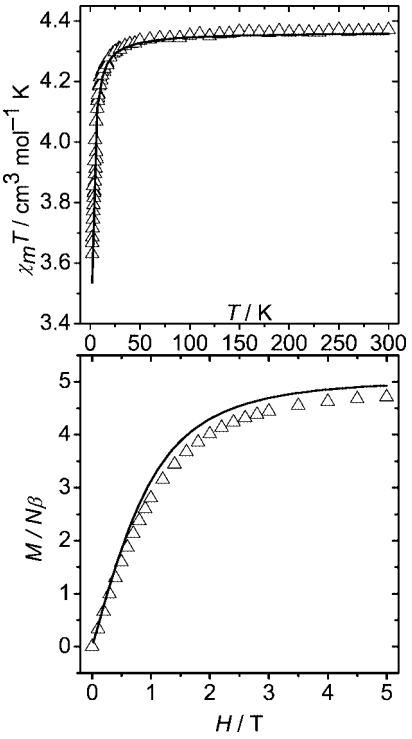

Figure 11. Top: plot of $\chi_M T$ vs. $T$ for complex **3** with the best fit calculation represented by the solid line. Bottom: plot of the reduced magnetization vs. $H$ at 2 K. Solid line corresponds to the Brillouin function for $g$ = 2.00.

The magnetic fit for complex **3** is impracticable, due to its intrinsic complication. Considering the structure as a pseudo-one-dimensional $Mn^{II}$ systems ($S$ = 5/2) it is possible to try to fit the experimental susceptibility data by using the formula given by Fisher for a model with classical spin.[20,22] The best fit parameters were $J$ = –0.05 cm$^{-1}$, $g$ = 2.00 and $R = 1.8 \times 10^{-3}$. However, $J$ value must be taken cautiously, being the one-dimensionality only a drastic estimate, and thus the Fisher's formula would not be completely valid. Furthermore, the asymmetry of one of the manganese ions could give a $g$ value different from 2.00, likely indicative that the hypothesis of the $g$ = 2.00 in the reduced magnetization is not fully accurate, and the AF coupling is even lower than –0.05 cm$^{-1}$. The X-band powder EPR spectrum at room temperature shows an isotropic signal centered at $g$ = 2.00. (Figure 4S).

### Thermal Analysis

Complex **1** upon heating does not show any mass change up to 300 °C and on further heating its frame work gradually collapses. The thermogravimetric analysis of complex **2** shows desolvation within the temperature range of 70–200 °C (Figure 5S). The behavior suggests the loss of lattice methanol and dehydration of coordinated water molecules (vide infra) takes place in sequence without showing any intermediate species. This also corroborates the involvement of H-bonding between the malonate oxygens and water molecules. The lattice bpee cannot leave the system upon heating up to 200 °C, then the framework of the complex collapses. On the other hand complex **3**, that comprises of ten water molecules per trinuclear unit, loses water in multi steps upon heating (Figure 6S). The first step (60–125 °C) accounts for the release of four guest water as well as two coordinated water molecules. This upon further heating starts to lose coordinated water molecules showing a non isolable intermediate at ca. 200 °C and then the framework appears to collapse on continuation of heating. Through careful heating we have been able to isolate the intermediate, $[Mn_3(btc)_2(2,2'\text{-bipy})_2(H_2O)_4]$ (**3a**) which reverts on exposure to humid atmosphere (≈ 70%) for 2–3 hours. The formation of **3a** is not unlikely as elimination of one water molecule from each terminal metal center results in a six coordinated geometry for Mn(1) (see Figure 7), but further elimination of coordinated water molecules leads to an unstable system and to the collapse of the metal organic framework. Thus the thermal analyses of these three complexes hint that the MOF of **1** is thermally more stable than those of **2** and **3**.

## Conclusions

In this paper we have presented the syntheses, the crystal structures, variable temperature magnetic studies and thermal behaviors of three carboxylato-bridged polymeric networks of manganese(II). The above discussion shows that the use of different carboxylates, namely oxalate, malonate and 1,3,5-benzenetricarboxylate, in combination with neutral coligands, dpyo, bpee, and 2,2′-bipy, has made feasible the construction of coordination polymers of different dimensionality. Complexes **2** and **3** are 3D open frameworks, the former contains channels filled up by disordered uncoordinated bpee and methanol and the latter is achieved through π-π and H-bonding interactions. On the other hand, complex **1** is a covalent bonded 2D network.

## Experimental Section

**Materials:** High purity manganese chloride tetrahydrate; 4,4′-bipyridyl *N*,*N*′-dioxide; 2,2′-bipyridine and *trans*-1,2-bis(4-pyridyl)ethylene were purchased from Aldrich chemical Company. All other chemicals used were of analytical grade.

**Physical Measurements:** Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer elemental analyzer. IR spectra (4000–600 cm$^{-1}$) were taken in KBr pellets using a Jasco FT-IR (model 300E). The magnetic measurements were carried out on polycrystalline samples with a Quantum Design MPMS SQUID magnetometer (applied field 0.1 T) working in the temperature range 300–2 K. Diamagnetic corrections were estimated from Pascal's tables. EPR spectra were recorded on powder samples at X-band frequency with a BRUKER 300E automatic spectrometer, varying the temperature between 4–300 K. Thermal analysis were done on a Pyris Diamond system.

**Crystallographic Data Collection and Refinement:** Crystal data and details of data collections and refinements for the structures reported are summarized in Table 5. Diffraction data set of complex **1** was carried out on a Nonius DIP-1030H system with Mo-$K_\alpha$ radiation. For complexes **2** and **3**, reflections were collected on a STOE four–circle diffractometer equipped with MAR–research image plate system and Mo-$K_\alpha$ radiation. Cell refinement, indexing and scaling of the data sets were carried out using Denzo and Scalepack,[29] and XDS.[30] All the structures were solved by Patterson and Fourier analyses[31] and refined by the full-matrix least-squares method based on $F^2$ with all observed reflections.[31] Two lattice water molecules were detected in the ΔF map of complex **3**. Disordered peaks in the electron-density map of complex **2** were interpreted as a bpee ligand and a methanol (both arranged over a center of symmetry), each accounting for 0.25 molecule per metal unit. The contribution of H atoms at calculated positions were included in the final cycles of refinement, except those of lattice water and disordered molecules. All the calculations were performed using the WinGX System 1.64.05.[32]

**[Mn(ox)(dpyo)]$_n$ (1):** A methanolic solution (10 mL) of 4,4′-bipyridine *N*,*N*′-dioxide (1 mmol, 0.188 g) was added dropwise to an aqueous solution (5 mL) of $MnCl_2{\cdot}4H_2O$ (1 mmol, 0.197 g) with constant stirring for 10 min. To the resulting reaction mixture an aqueous solution of disodium oxalate (1 mmol, 0.134 g) was added whilst stirring condition. After 30 minutes a bright red compound separated. Single crystals suitable for X-ray analysis were obtained by diffusing a methanolic solution (10 mL) of $MnCl_2{\cdot}4H_2O$ and 4,4′-bipyridine *N*,*N*′-dioxide on an aqueous solution (10 mL) of disodium oxalate in a tube. Bright red crystals deposited at the junction of two solutions after one week. Yield: 80%. $C_{12}H_8MnN_2O_6$ (331.14): C 43.48, H 2.41, N 8.45; found C 43.47, H 2.42, N 8.46. IR: $\tilde{\nu}$ = 3114 (w), 3085 (w), 2929 (vw), 1619 (vs), 1468 (s), 1222 (s), 1176 (w), 844 (w), 792 (vw), 553 (vw) cm$^{-1}$.

**{[Mn$_2$(mal)$_2$(bpee)(H$_2$O)$_2$]·0.5(bpee)·0.5(CH$_3$OH)}$_n$ (2):** An aqueous solution (5 mL) of disodium malonate (1 mmol, 0.148 g) was added to an aqueous solution (5 mL) of $MnCl_2{\cdot}4H_2O$ (1 mmol, 0.197 g) whilst stirring condition. To this reaction mixture a methanolic solution (10 mL) of *trans*-1,2-bis(4-pyridyl)ethylene (1 mmol, 0.182 g) was added. The resultant reaction mixture was stirred for 1 h and filtered. The filtrate was kept in a desiccator ($CaCl_2$) and after a few days bright yellow single crystals of X-ray diffraction quality were obtained. Yield 75%. $C_{24.50}H_{25}Mn_2N_3O_{10.50}$ (639.35): C 45.98, H 3.91, N 6.56; found C 46.01, H 3.90, N 6.57. IR: $\tilde{\nu}$ = 3436-3190 (s, v br), 1675 (w), 1611 (vs), 1558 (vs), 1467 (w), 1436 (s), 1372 (vs), 1314 (w), 1104 (w), 1016 (w), 830 (w), 761 (s), 731 (s), 628 (w), 542 (w) cm$^{-1}$.

**{[Mn$_3$(btc)$_2$(2,2′-bipy)$_2$(H$_2$O)$_6$]·4H$_2$O}$_n$ (3):** An aqueous solution (5 mL) of $MnCl_2{\cdot}4H_2O$ (1 mmol, 0.197 g) was added to a methanolic solution of (10 mL) of 2,2′-bipyridine (1 mmol, 0.156 g) dropwise whilst stirring condition. The resultant yellow colored solution was mixed to an aqueous solution (5 mL) of btc (0.66 mmol, 0.184 g) and stirred for 1 h and filtered. The filtrate was kept in a desiccator ($CaCl_2$). After one week bright yellow crystals suitable for X-ray diffraction were obtained. Yield 70%. $C_{38}H_{42}Mn_3N_4O_{22}$ (1071.58): C 42.55, H 3.91, N 5.22, found C 42.57, H 3.93, N 5.20. IR: $\tilde{\nu}$ = 3475–3025 (s, v br) 1671 (w), 1611 (vs), 1557 (vs), 1437 (s), 1372 (s), 1314 (w), 1247 (w), 1157 (w), 1016 (w), 932 (w), 761 (s), 731 (s), 650 (w), 541 (w) cm$^{-1}$.

CCDC-276231, -276232 and -276233 (for complexes **1**, **2** and **3**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): X-band EPR spectra for complexes **1**–**3**, the $\chi_M$ plot vs. T for **2**, and the thermogravimetric analysis of **2** and **3** (Figures 1S–6S).

## COVER PICTURE

**The cover picture shows** the self-assembly of a tetranuclear $Co^{III}$ metallacycle from the reaction of a bis(benzene-*o*-dithiolato) ligand and $Co^{II}$ after aerial oxidation. Two differently coordinated metal centres (*syn* and *anti*) are observed in the metallacycle even though a ligand with two identical donor sites has been used. This unusual structural motif is formed in order to avoid strong steric interactions between the *ortho*-sulfur atoms, which would result in a hypothetical dinuclear complex. Details are discussed in the article by F. E. Hahn et al. on p. 535ff.

# Structural Diversity of Host–Guest and Intercalation Complexes of Fullerene $C_{60}$

**Mohamed Makha,[a] Ariaan Purich,[a] Colin L. Raston,*[a] and Alexandre N. Sobolev[a]**

**Keywords:** Fullerenes / Crystal structures / Packing models / Host–guest interactions

Pristine fullerene $C_{60}$ has a *fcc* structure. Crystallisation of the fullerene in a variety of solvents can lead to inclusion complexes, as well as discrete host–guest complexes in the presence of cavitands and porphyrins, and related molecules. The complexes retain varying degrees of fullerene···fullerene interactions at the van der Waals limit, except in a limited number of cases where the fullerenes are completely shrouded by one or more included/host molecule. Analysis of the fullerene···fullerene interactions in these complexes reveals a diverse structural arrangement of the fullerenes. They can be organised into dimers, single linear columns or zigzag chains, double columns, spectacular fivefold Z-shaped columnar arrays, hexagonal close-packed layers, corrugated sheets, honeycomb motifs, non-close-packed layers and complex three-dimensional networks. Disorder of the fullerenes in the solid state is common, although structures with close-packed planar arrangements of $C_{60}$ molecules and/or with symmetry matching between the host molecule and the fullerene (two-, three- and fivefold symmetry) tend to have less disorder of the fullerene.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Icosahedral fullerene $C_{60}$ readily forms intercalation complexes affording materials that contain small molecules such as haloforms[1,2] through to larger molecules like ferrocene,[3] curved- or bowl-shaped receptor molecules including modified calixarenes,[4] cyclotriveratrylene and related molecules,[5] porphyrins and metal macrocycles.[6] Some of these complexes have the fullerene completely shrouded by other molecules whereby the structures are devoid of fullerene···fullerene interactions, although most of them have fullerene···fullerene interactions to varying degrees. Herein, we analyse the structures of these complexes that were previously established using X-ray diffraction techniques, focusing on the nature of the fullerene···fullerene interactions (closest contacts), on any geometrical alignment of the polyhedral faces from adjacent fullerenes and on any disorder of the fullerenes. Such aspects of the structures are often overlooked or oversimplified despite their fundamental importance in developing the supramolecular chemistry of $C_{60}$ and, ultimately, in devising ways of controlling the interplay of $C_{60}$ molecules as a paradigm in crystal engineering in building up new materials with novel function. Indeed, the supramolecular chemistry of fullerenes has been used to control the interplay of fullerenes in the solid state, and fullerenes have been covalently linked under high pressure and temperature[7] and advances have been made in the building up of arrays of $C_{60}$ that involve complexation with calix[5]arene.[8] Typically, the structure determination of fullerene complexes is carried out at ca. 150 K with no distinction between dynamic or static disorder.

General aspects of the supramolecular chemistry of fullerenes feature in various review articles;[9] these reviews include aspects of chemically modified $C_{60}$, which is beyond the scope of this review, although it is noteworthy that there have been some spectacular findings. The organization of the potassium salt of a pentasubstituted fullerene into ≈17-nm spherical bilayer vesicles,[10] the assembling of fullerenes on surfaces,[11] the binding of porphyrins[12] and assembling of 64 $C_{60}^-$ anions on the surface a dendrimer with terminal ferricinium moieties[13] are particular noteworthy. Dendrimers can also bind fullerenes within their internal cavities;[14] these include porphyrin-containing systems.[15] In addition, self-assembly processes can stabilise nanoparticles of fullerenes, such as a diblock polymer shrouding, which involves approximately $10^{10}$ fullerene molecules.[16] Fuller-

enes can also be taken up in the pores of mesoporous silica, with aggregation of the fullerenes in the presence of cavitand molecules. This process is the basis of a qualitative test for host–guest chemistry between the fullerene and cavitands in solution,[17] and confinement of the fullerene can be used to form hydrated $C_{60}$ at 350 °C, i.e. by controlling the synthesis in a confined space.[18] Fullerenes, including metallofullerenes such as $Sm@C_{82}$,[19] and $C_{60}O$ can also be drawn inside carbon nanotubes.

The formation of inclusion complexes of $C_{60}$ with small molecules such as solvent molecules has limited scope in building up new arrays since the relatively large fullerene molecules can still interact with several fullerenes, and fullerene···fullerene interactions dominate the extended structure. Inclusion complexes involving larger molecules tend to have less fullerene···fullerene interactions because the molecules can cover a larger part of the surface of the fullerene. The limiting case is when the fullerene is completely shrouded by other molecules, and clearly the greater the attraction between other molecules and the electron deficient $C_{60}$, the less likelihood of multiple fullerene···fullerene interactions or any such interactions. Optimising the complementarity of curvature and size of $C_{60}$ with host molecules such as bowl-shaped cavitands and saddle-shaped molecules has been used to good effect in forming assemblies of host–guest complexes as part of extended structures with fullerene···fullerene interactions, although the origins of such work relate to the use of cavitand molecules as a means of purifying the fullerene through host–guest/molecular-recognition chemistry.[4]

Matching the curvature of $C_{60}$ with that of potential host molecules is not an essential strategy for forming complexes, since planar porphyrins readily form complexes in the solid state with spheroidal fullerenes, often with the structures possessing fullerene···fullerene interactions.[20] In addition, the choice of solvent can effect the formation of host–guest complexes, tipping the balance from complexation to complexation with aggregation of the fullerenes through to little or no complexation. Even the presence of $C_{70}$ can affect the nature of the host–guest complex of $C_{60}$ with a host molecule.[23] Figure 1 summarises the main types of "host" molecules that have been used for the for-

*Dr. Mohamed Makha completed his BSc at the University Mohammed V (Morocco) and then gained a government scholarship to China for a Chinese literature diploma and a Masters degree in industrial chemistry. He also was awarded a Monash University postgraduate scholarship and completed his Ph.D. in 2001 under the supervision of Prof. Colin Raston. He then embarked on a postdoctoral fellowship at the University of Leeds (UK), and since 2004 he has been appointed to the University of Western Australia following his ARC Australian Postdoctoral Fellowship Award. His research interests are centred on macrocyclic chemistry, green chemistry, biopolymers and nanomaterials.*

*Ariaan Purich was born in Perth, Australia in 1984. She is currently completing a double degree in Science and Engineering at the University of Western Australia. She completed the science component of her degree in 2004, majoring in Chemistry. As her third year project, she researched the relationship between fullerene $C_{60}$ arrangements within different compounds and the distances between these fullerene molecules. She enjoys skiing, bungee jumping and going to the beach. Ariaan is currently completing the engineering component of her degree, majoring in Environmental Engineering.*

*Professor Colin Raston is an Australian Research Council Professorial Fellow at the University of Western Australia, being appointed to the University in 2003. He completed a Ph. D. under the guidance of Professor Allan White, and after postdoctoral studies with Professor Michael Lappert at the University of Sussex, he was appointed as Lecturer at the University of Western Australia (1981) then to the Chair of Chemistry at Griffith University (1988), being awarded a DSc there in 1993, Monash University (1995) and Leeds (2001). His research interests cover aspects of nanochemistry, supramolecular chemistry, crystal engineering and green chemistry.*

*Dr. Alexandre N. Sobolev has M.Sc. and Ph.D. degrees (1972, 1988) in "small-molecule" crystallography from the Laboratory of Crystal Chemistry and Structure Analysis at the L. Karpov Physico-Chemical Research Institute, Moscow. He moved to the University of Western Australia in 1992 to participate in advanced projects involving structural studies on a number of series of chemical compounds in various areas. Currently, the emphasis has been on the crystal chemistry of the macromolecular complexes.*

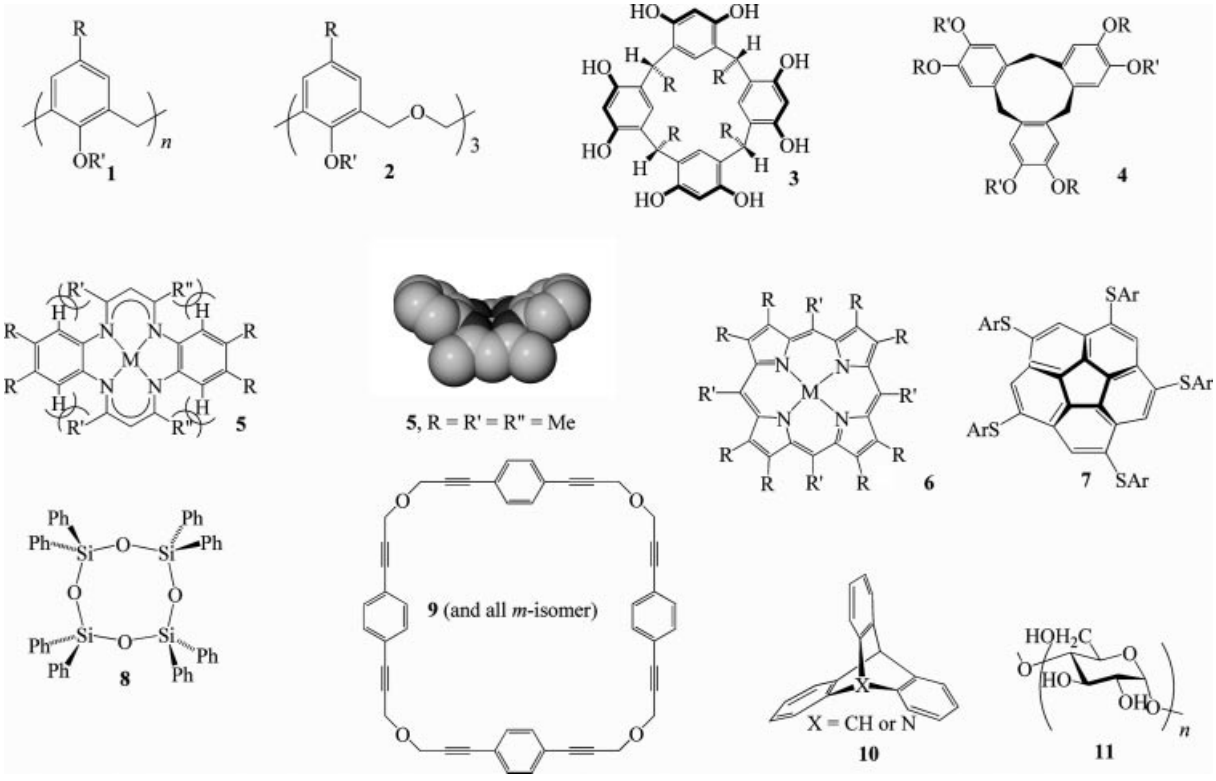

Figure 1. Types of molecules that form complexes with fullerenes with a specific example for **5** shown in space filling.

mation of complexes of $C_{60}$ and includes cavitands **1**–**4**, **7**[21] and **9**,[22] saddle-shaped molecules **5**, porphyrins **6**, siloxanes **8**, curved-faced tryptophanes **10**,[23] and β- and γ-cyclodextrins ($n$ = 7, 8) **11**, although not all of these lead to crystalline material and structure authentication by using diffraction data. When complexation is not prevalent, the addition of other synthons can be effective. For example, group 1 ions bind to modified calixarenes (R′ = ester), resulting in the complexation of $C_{60}$.[24] Seemingly, most molecules with aromatic-ring systems and electron-rich moieties can form complexes with $C_{60}$, including benzene and extended aromatic systems and tetrathiafulvalenes,[25] but the conditions to effect complexation can vary.

While the solid-state structures of many fullerene host–guest complexes of $C_{60}$ have been determined, the focus of the structures has usually been on the nature of the host–guest interplay, often with little regard to the nature of the extended structure dealing with fullerene···fullerene interactions and to the nexus to the structure of *fcc* $C_{60}$. In analysing the extended structures, the indicator for fullerene···fullerene interactions is any centroid-to-centroid distance that is close to 10.0 Å (the van der Waals limit of

Table 1. Structural types for the arrangement of $C_{60}$ molecules in the solid state.

| Structural types | Number of examples | Number of structures with ordered $C_{60}$ | Number of fullerenes with close contacts | Closest centroid···centroid fullerene distances [Å] |
|---|---|---|---|---|
| Pure $C_{60}$[26] | 8 | 0 | 12 | 9.940 |

the fullerene). Fullerene $C_{60}$ molecules can be positioned with different combinations of five- and six-membered rings facing each other, an edge facing a ring face, or two edges facing each other. The type of positioning affects the closest carbon-to-carbon distance – and to a certain extent the centroid···centroid distance. In general, for fullerene molecules at the van der Waals limit, the closest carbon-to-carbon distances are between 3.1–3.4 Å, depending on how the fullerene molecules are oriented. Thus, analysing different $C_{60}$ arrangements also involves considering the state of order/disorder of the fullerenes. Table 1 summarises the salient information, including the number of compounds that exhibit a particular arrangement of $C_{60}$ molecules, the proportion of each arrangement in which $C_{60}$ is ordered and the proportion of each arrangement in which fullerene centroid···centroid distances are $<10.30$ Å. While this is slightly beyond the van der Waals limit, it nevertheless is a guide for the packing of the fullerenes in building up continuous structures.

## The Extreme Cases – Pristine *fcc* and Encapsulated $C_{60}$

In pure *fcc* $C_{60}$ (Figure 2), the centroid···centroid distance is 9.94 Å, and this is a reference point to compare centroid···centroid distances with complexes of the fullerene. Pure $C_{60}$ contains disordered molecules, which is not surprising given the spheroidal nature of the fullerene in the absence of any directional contacts beyond the 12 fullerene···fullerene interactions for each fullerene.[26]

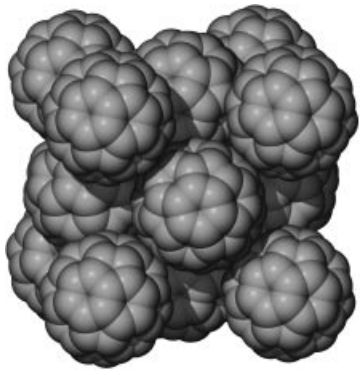

Figure 2. Space filling *fcc* for pristine $C_{60}$.[26]

In some complexes, each $C_{60}$ molecule is completely encapsulated with no intimate contact with other $C_{60}$ molecules, for example, in complexes of calix[5]arenes with *p*-substituted pendant arms (phenyl or benzyl) in which two calixarenes shroud each fullerene. For calix[5]arenes, the complementarity of size and shape of the fullerene with the cavity defined by the phenol moieties is striking. Calix[5]arene with H atoms in the *p*-positions can also form a complex in which two calixarenes interact with a central fullerene, but there is still enough room on the surface of the fullerene to allow close contacts with other fullerenes. This is part of a one-dimensional array of five columns of close-packed fullerenes in a Z-shaped array (see below).[8] This is a spectacular example of a simple change in substitution of calixarene that dramatically changes the nature of the complex.

*p*-Benzylcalix[5]arenes **1** form a 2:1 complex with $C_{60}$ in which the fullerene is shrouded by two staggered *trans* host molecules in the cone conformation with dangling benzyl groups [Figure 3(a)].[38,39] Interestingly, the symmetry axis of the calixarene is aligned with a $C_5$ symmetry-element of $C_{60}$. However, in the case of the related $C_{60}$ complex of *p*-phenylcalix[5]arene,[40] the rigid extended arms interdigitate in one hemisphere of the 2:1 supermolecule such that symmetry matching for both calixarenes is not possible, and the "confused" fullerene is now completely disordered.[40] Other authenticated structures in which $C_{60}$ is encapsulated by two calix[5]arenes such that there are no interfullerene contacts include a calix[5]arene complex with three methyl and two iodo groups (1,3-disposition) in the *p*-positions of the upper rim.[41]

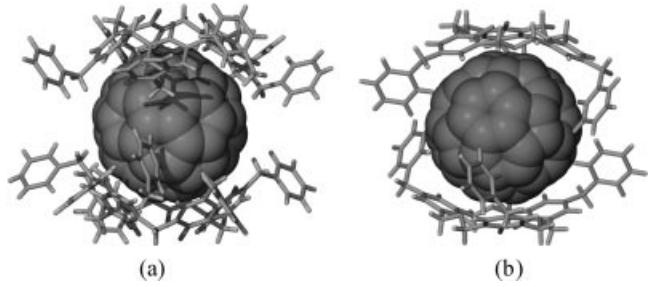

Figure 3. Encapsulation of single fullerene $C_{60}$. Structure of (a) [$C_{60}$⊂{*p*-benzylcalix[5]arene}$_2$] and (b) [$C_{60}$⊂{*p*-benzyloxacalix[3]arene}$_2$].[38]

Oxacalix[3]arenes **2** also have complementarity of curvature with $C_{60}$, and *p*-benzyloxacalix[3]arene similarly forms a 2:1 complex in which two calixarenes shroud the fullerene. Here, a $C_3$ symmetry-axis of $C_{60}$ lines up with the symmetry axis of the two host molecules in the *trans* arrangement, i.e. the fullerene is not disordered at the temperature at which the diffraction data were acquired, ca. 173 K.[38] The benzyl groups are edge-on to the fullerene, with C–H···fullerene interactions [Figure 3(b)], rather than face-on for π···π interactions, or the benzyl groups are directed away from the fullerene such as in the structure of the analogous *p*-benzylcalix[5]arene complex.[38] Clearly, symmetry matching is a worthwhile endeavour to afford ordered fullerene molecules in the solid state, at least at low temperature (ca. 173 K).

## Dimeric Arrangement of $C_{60}$ Molecules

In a few cases, $C_{60}$ molecules are confined as pairs at the van der Waals limit (9.93–10.20 Å).[28] Only one compound has ordered fullerenes at the temperature of the X-ray diffraction studies. A striking feature of the 1:1 *p*-bromohomooxocalix[3]arene $C_{60}$ complex is the relatively small

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

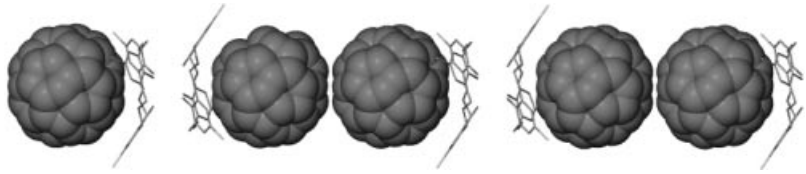

Figure 4. Inclusion complex $C_{60}$ as van der Waals dimers sandwiched by two *p*-bromo-homooxocalix[3]arene molecules.[43]

calixarene that disrupts the interfullerene interactions. Isolated pairs of fullerenes have π···π interactions with the calixarenes, with distances between the centroids within the pairs of fullerenes of 9.93 Å. The cup shape of the calixarene and possible polarization effects from the bromine substituents presumably impact on the overall structure, which consists of the stacking of the dimeric columns as represented by the top view projection with no other fullerene···fullerene close contact other than that of the dimers, Figure 4.[43] While a trimeric aggregate of $C_{60}$ molecules have been proposed for the structure of the 1:1 complex of $C_{60}$ with *p*-*t*Bu-calix[8]arene,[42] its solid-state structure authentication remains elusive, and the same can be said of higher arrays. For the dimeric arrangement, there are only a couple of structures in which the fullerene molecules are ordered.

## Single Linear Columns

A common arrangement of $C_{60}$ molecules is as single linear columns with each fullerene in close contact to two fullerenes and the dihedral angle set at 180°. All structures have disordered fullerene molecules, and the fullerenes are at the van der Waals limit (10.1 Å) (Figure 5).[44]

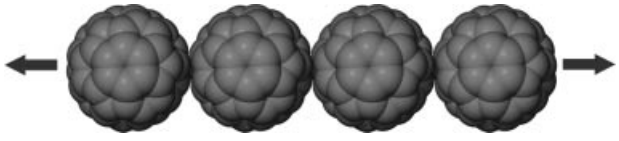

Figure 5. Single column arrays of $C_{60}$ found in the structure of bis(1,3,5-triphenylbenzene)chlorobenzene clathrate; fullerene centroid-to-centroid distances: 10.10 Å.[44]

## Zigzag Chains

$C_{60}$ molecules can be organised into continuous zigzag chains, with varying $C_{60}$–$C_{60}$ close contacts (9.90–10.20 Å). These chains are similar to linear columns, but with the $C_{60}$ molecules offset with respect to each other and with the dihedral angle <180°. The dihedral angle ranges from 118 to 172° thus presenting the intermediate structures between linear-chains and double-column arrangements. There are more zigzag-chain structures than linear-column structures of $C_{60}$, and the proportion of ordered structures is much higher (Table 1). It is interesting that the zigzag chains (and corrugated sheets, see below) contain higher proportions of $C_{60}$ centroid-to-centroid distances that are at the lower end of the van der Waals limits than linear columns and planar layers. This suggests that the zigzag arrangement of fullerenes encourages fullerene···fullerene interactions more than the linear counterparts.

The 1:1 complex between $C_{60}$ and CTV (cyclotriveratrylene; **4**, R = R′ = Me), and the recent structure of the 1:1 complex of calix[5]arene and $C_{60}$ (Figure 6), form zigzag structures. It is interesting to note that the CTV complex forms in toluene in the presence of a saturated solution of CTV (approximately 20-fold excess of CTV relative to the fullerene), whereas a fivefold excess of CTV gives a 3:2 complex that is rich in $C_{60}$ and the fullerenes are arranged in close-packed, hexagonal sheets (see below).

## Double Columns (Close Packed)

A few examples of $C_{60}$ complexes crystallising with the fullerenes arranged into two close-packed columns have been authenticated. This is the limiting case for zigzag chains in which the dihedral angle between the fullerenes is 60° and each fullerene is in close contact with four other

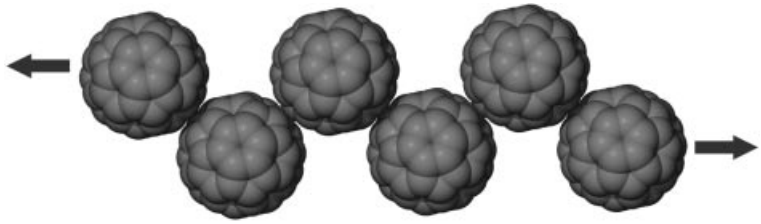

Figure 6. Zigzag fullerene arrangement in the structure of [$C_{60}${calix[5]arene}]; fullerene centroid-to-centroid distances: 10.03 Å.[8]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fullerenes rather than with two (Figure 7). All of the complexes have some level of disorder, and the fullerene arrangement is depicted for the siloxane/$C_{60}$-fullerene complex in which each fullerene is surrounded by four others with centroid···centroid distances of 9.85–10.10 Å.[45]

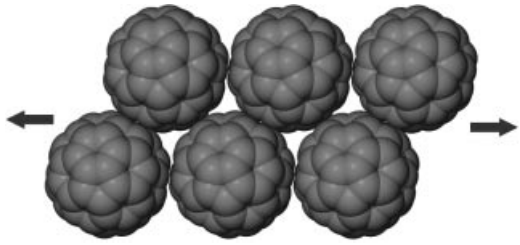

Figure 7. The double-columnar array in a siloxane/$C_{60}$-fullerene complex; centroid···centroid distances: 9.85–10.1 Å.[45]

## Fivefold Z-Shaped Columns (Close Packed)

Calix[5]arene **1**, $n$ = 5, R = R′ = H, forms a unique complicated complex with $C_{60}$, $[(C_{60})_5\{\text{calix[5]arene}\}_4]$,[32] in which the fullerenes assemble into five columns in a Z-arrangement [Figure 8(a)], which are surrounded by a sheath of calixarenes. The fullerenes are close packed in the columns with three different fullerene environments [Figure 8(b)]: (i) those on the outer columns, and each fullerene is in contact with four other fullerenes (cf. the environment the fullerene in the double-column arrangement, Figure 7), (ii) those in the two nearest columns of the bend of the "Z" shape, where the fullerenes have six close contacts, and (iii) the central column where each fullerene also has six close fullerenes, albeit now in a flat hexagonal arrangement. On the basis of analytical data, prior to the structure determination, the complex was thought to be a 1:1 complex rather than a 5:4 complex, and in this context, care needs to be exercised in establishing the stoichiometry of fullerene host–guest complexes in the absence of structural elucidation. Moreover, the presence of other fullerenes, and other globular molecules in solution, dramatically changes the nature of the complex that crystallises from solution. In the presence of $C_{70}$, which is the other major fullerene in fullerite, a 1:1 calixarene: $C_{60}$ complex forms (see above).[8] Remarkably no $C_{70}$ is incorporated into the structure, but it still predetermines the nature of the $C_{60}$ complex formed. This is despite the solution binding constants that favour $C_{70}$ complexation over that of $C_{60}$, and thus crystal packing forces must be more important. The same 1:1 complex involving $C_{60}$ also forms in the presence of $C_{84}$ and 1,2-dicarborane ($1,2\text{-}C_2B_{10}H_{12}$), an icosahedral molecule, which in the absence of $C_{60}$ is drawn into the cavity of the calixarene.[46]

## Close-Packed Layers

The structure of these 2D arrays takes on some aspects of the structure of *fcc* for pure $C_{60}$. Hexagonal close packing of the fullerene molecules occurs in several structures with fullerene···fullerene centroid-to-centroid distances of 10.0–10.2 Å (Figure 9). In comparison to other $C_{60}$ arrangements, the proportion of structures in this category is relatively low, despite the fact that hexagonal close packing is a common arrangement for two-dimensional arrays of spheroidal moieties. Within these structures, the $C_{60}$ molecules tend to be ordered, and in some cases, this relates to the interplay of the fullerenes with inclusion/host molecules on either side of the hexagonal arrays, as in the complex with CTV (see below).[47]

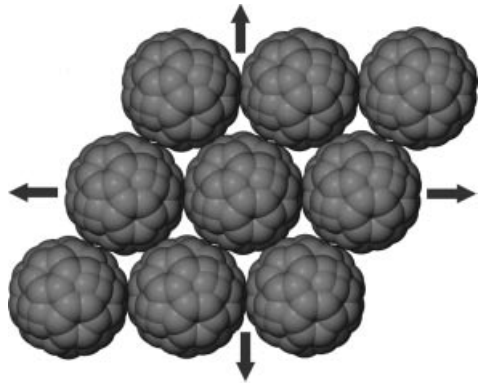

Figure 9. Hexagonal close-packed $C_{60}$ fullerenes in $(C_{60})_{1.5}$(CTV); centroid-to-centroid distances: 10.00 –10.2 Å.[47]

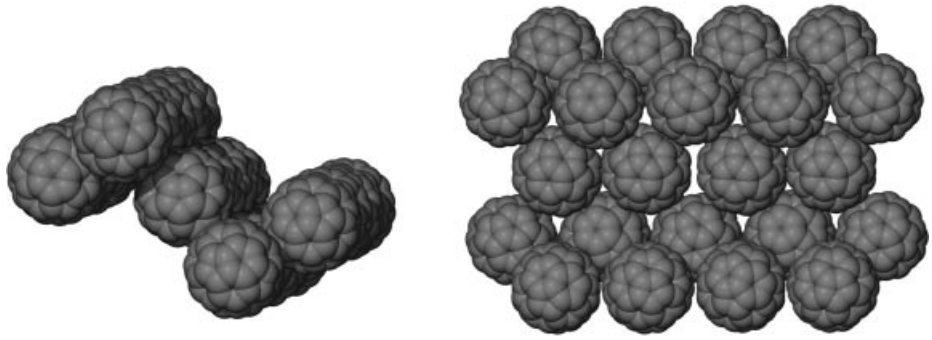

(a) (b)

Figure 8. (a) Projection of the fivefold Z-shaped arrangement of fullerenes in $[(C_{60})_5\{\text{calix[5]arene}\}_4]$, and (b) the projection normal to this; closest centroid-to-centroid distances: 9.88 Å.[32]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Complexation of $C_{60}$ in toluene solutions of CTV (**4**, R = R′ = Me) results in polymeric structures in the solid state, with either a fullerene-rich phase $(C_{60})_{1.5}$(CTV) or a 1:1 phase $(C_{60})$(CTV)[47,48] (Figure 9); both complexes were studied electrochemically (solution and solid state). The structures are dominated by fullerene···fullerene interactions, and each CTV has a $C_{60}$ that is associated within the cavity of the CTV as a "ball and socket" nanostructure. For $(C_{60})_{1.5}$(CTV), the fullerenes collectively comprise a two-dimensional, close-packed array with half of the fullerenes devoid of CTV (Figure 9).[47] Disorder is found for the fullerenes that are not capped by CTV, while the fullerenes included in the cavity of CTV are stabilised and show order. Solvated host–guest species of (CTV)$(C_{60})$ are formed first in solution, and this results in the polarisation of the fullerene that promotes aggregation, which is evident by a resonant interfullerene transition band as 475 nm. Interestingly, $C_{70}$ does not form an isolable complex with CTV, yet remarkably in the presence of 1,2-dicarborane, a ternary complex forms, with each fullerene in the cavity of a CTV molecule and with each of these supermolecules linked by bifurcated H-bonding to two carborane molecules, thus forming a helical arrangement. Therefore, additional synthons can encourage host–guest chemistry.[49]

## Corrugated Sheets

$C_{60}$ molecules can also form corrugated sheets in a manner that is similar to layering. In this arrangement, the $C_{60}$ molecules form layers, but these layers are not planar. From a side-on view, these sheets look like zigzag arrangements. Corrugated sheets are also a common arrangement for $C_{60}$ molecules, and a very high proportion of the compounds that exhibit this structure exhibit fullerene···fullerene close contacts, and this fact indicates that these molecules are at the van der Waals limits. Hence, it can be concluded that when $C_{60}$ molecules are arranged in corrugated layers, as opposed to planar layers, close contact between the fullerenes is encouraged. Corrugated-sheet structures also have a high proportion of ordered compounds.

Non-aromatic macrocycles **5** have two divergent concave surfaces in a saddle-shape arrangement that arises from the otherwise unfavourable interactions between the methyl groups and the adjacent H-atoms on the aromatic rings. This arrangement can act as a divergent heterotopic receptor towards $C_{60}$. In the structure of $(C_{60})$Ni(TMTAA) (**5**, R = H, R′ = R′′ = Me), two host molecules shroud the fullerene such that a fullerene is in the saddle of one Ni(TMTAA) molecule with the methyl groups directed towards it and in the opposite saddle of another Ni(TMTAA) molecule; the overall host–guest contacts form a continuous zigzag array in which the fullerenes form a corrugated two-dimensional sheet (Figure 10).[50] $Cu^{II}$ and $Zn^{II}$ TMTAA molecules bind $C_{60}$ in a similar fashion and are isostructural with the $Ni^{II}$ analogue. OMTAA (**5**, R = Me) forms a 1:1 complex with $C_{60}$ in which the extended supramolecular array is based on linear chains of close-contact $C_{60}$ molecules and on linear chains of π-stacked alternating molecules of $C_{60}$ and Ni(OMTAA) in which the adjacent chains run in opposite directions and thus cancel out the dipole moments. The same macrocycle forms a 1:1 complex with $C_{70}$, which is isostructural with the $C_{60}$ complex of Ni(TMTAA). In all of these $Ni^{II}$ macrocyclic structures, there are no significant contacts between the metal centres and the fullerenes. As in other systems, there is evidence for the formation of 1:1 solvated supermolecules in solution, which then go on to form micelle-like species.[50] The unsymmetrical macrocycle **5** (R = H, R′ = Me, R′′ = Ph) also forms a 1:1 complex with $C_{60}$.[51]

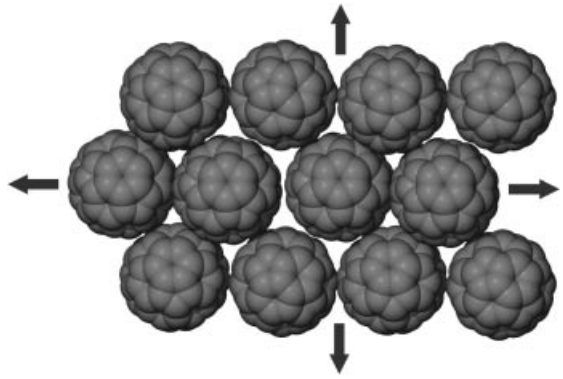

Figure 10. The corrugated array of fullerenes in the Ni(TMTAA)/$C_{60}$ complex; centroid-to-centroid distances: 9.99 to10.07 Å.[50]

## Honeycomb Motif

An unusual arrangement of the $C_{60}$ molecules is one in which the fullerene molecules form a honeycomb motif as shown in Figure 11.[52] Few compounds exhibit this type of arrangement, and in most cases, these structures have disordered fullerenes.[36]

Figure 11. The honeycomb arrangement of $C_{60}$ molecules in 5,10,15,20-tetraphenylporphyrin bis($C_{60}$-fullerene) benzene solvate; centroid-to-centroid distances: 9.98 Å.[52]

## 3D Continuous Networks of $C_{60}$

The arrangement of fullerenes in fullerene-$C_{60}$ complexes can have continuous three-dimensional networks. Some are

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

simply analogues of the *fcc* packing of pristine $C_{60}$. Indeed, the simplest structure is one in which the *fcc* packing is maintained and small molecules are included in the interstices, for example ethene (Figure 12).[53] For larger molecules, other arrangements are possible. Alternatively, other close-packed arrangements can result, notably *bcc* packing found in the ethane complex.[53]

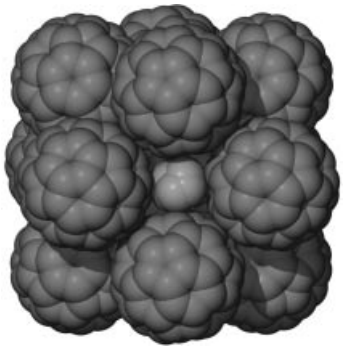

Figure 12. The *fcc* arrangement in the ethene inclusion complex with $C_{60}$; centroid-to-centroid distances: 10.03 Å.[53]

Other continuous three-dimensional arrangements are more complex, often, with more included molecules, for example, the carbon disulfide complex $C_{60}{\cdot}1.5CS_2$ (Figure 13).[54]

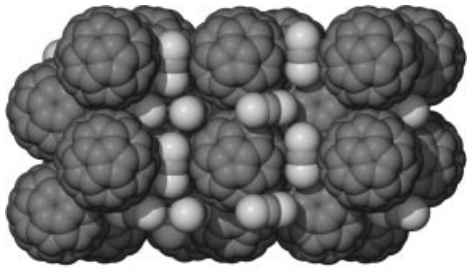

Figure 13. Continuous array in the $C_{60}$-fullerene carbon disulfide solvate ($C_{60}{\cdot}1.5CS_2$); closest centroid-to-centroid distances: 9.96 Å.[54]

From Table 1, it is evident that three-dimensional arrangements are more prevalent and by their very nature have more interfullerene contacts at the van der Waals limits. Intersecting sheets of fullerenes with moderately sized molecules creating channels are possible; this is exemplified by the structures in Figure 14.[55]

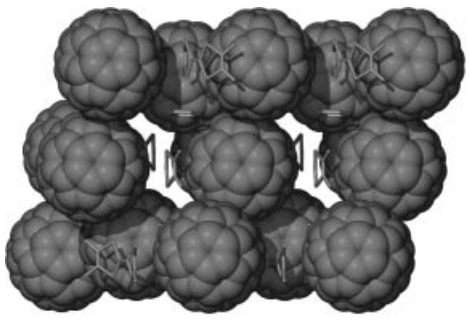

Figure 14. Structure of $C_{60}$-fullerene/tetramethyltetraselenafulvalene benzene solvate; centroid-to-centroid distances: 9.80 Å.[55]

## Higher Complexity Structural Motifs

The structures here are based on complexes containing large host/included molecules. The fullerene rich calix[6]arene complexes, $(C_{60}/C_{70})_2$calix[6]arene, have been structurally authenticated as isomorphous complexes,[56] and exhibit the calixarene in a double-cone conformation and a fullerene perched in each of the shallow cavities – this arrangement resembles the jaws of a pincer acting on two adjacent cage molecules; the extended structures have continuous three-dimensional interplay of the fullerenes that is close to the van der Waals limit. In the case of the $C_{70}$ complex, the principle axis of the fullerene is aligned such that the end of the fullerene that is close to this axis, where the curvature of the cage is similar to that of $C_{60}$, resides in the cavity.

Calix[4]arenes and Calix[4]resorcinarenes have cavities that are too small to accommodate fullerenes. Nevertheless, some calix[4]arenes have been shown to form stable crystalline complexes with $C_{60}$ with the fullerene *exo* to the calixarene cavity, and include: (i) *p*-phenyl-calix[4]arene, which has a toluene molecule in the cavity; the overall structure is dominated by fullerene–fullerene and *exo*-calixarene–fullerene interactions,[57] (ii) *p*-bromo-calix[4]arene propyl ether – the structure shows very close interfullerene contacts in a columnar structure, which most likely results in opposing induced dipoles from the unidirectionally aligned calixarenes,[58] and (iii) *p*-iodo-calix[4]arene benzyl ether – the fullerenes are ordered without appreciable interfullerene interactions.[59] There is also calix[4]resorcinarene **3** (R = $CH_2CH_2Ph$), which has a molecular capsule derived from head-to-head hydrogen bonding of two resorcinarene and propan-2-ol molecules – the fullerenes are also arranged in columns.[60] Biscalix[4]resorcinare is effective in binding $C_{60}$ (cf. biscalixarenes, Figure 4),[61] and calix[4]resorcinarenes (**3**) that bear dithiocarbamate groups between the oxo groups, with R = alkyl chains and with methylene groups between adjacent oxo groups form torus-shaped complexes that comprise three calixarenes with divalent cadmium and zinc ions, which effectively bind $C_{60}$.[62]

The fourfold symmetry of calixarenes and resorcinarenes relates to complexation of siloxane **8** with $C_{60}$ in toluene.[49,59,60] Here, the fullerenes are arranged in double-columnar arrays and are shrouded by edge-on siloxanes – the siloxanes are interlocked by one of the phenyl groups of one molecule residing in the cavity of another.

Bulky groups incorporated into porphyrin **6** [R = H, R′ = $C_6H_3$-3,5-($t$Bu)$_2$] result in a 1:1 complex with $C_{60}$, but there is a fullerene on either side of the porphyrin such that the continuous structure has the fullerene encapsulated.[63]

## Conclusion and Prospects

Structural analysis reveals a diverse range of structures; in some cases, these structures appear regularly, whilst others are represented by a single example. Even with prior knowledge on the composition of fullerene $C_{60}$ complexes, it is difficult to predict the arrangement of fullerenes given the inherently weak interactions between the components

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and the delicate balance between fullerene···fullerene interactions and host···fullerene interactions. Predicting the outcome of crystallization with respect to host/guest ratios and the arrangement between the components is even more problematic, and this is compounded by the effect of other solutes on the complexes formed that are still not an integral part of the structure. Greater structural diversity is anticipated along with higher complexity of the structures, although full characterization of such complexes using diffraction data will be a major challenge. Compounds in which the $C_{60}$ molecules are arranged in planar layers contain the highest levels of order of the fullerenes, and, in general, structures in which there is symmetry matching between the host and the fullerene reduces the disorder of the fullerene at low temperature. Arrays of fullerenes can be completely shrouded by a sheath of host molecules. The reverse is possible whereby the "host molecules" can reside in channels formed by a continuous array of fullerenes at the van der Waals limit. Clearly designing host molecules to bind fullerenes in cavities is now well established, but unless the fullerene is completely shrouded by host molecules, predicting the interplay of the fullerenes has serious limitations.

## Acknowledgments

# Bundle of Nanobelts Up to 4 cm in Length: One-Step Synthesis and Preparation of Titanium Trisulfide ($TiS_3$) Nanomaterials

**Jingjing Ma,[a] Xiaoyang Liu,*[a] Xuejing Cao,[a] Shouhua Feng,[a] and Michael E. Fleet[b]**

**Keywords:** One dimensional / Nanostructures / Layered compounds / Titanium / Sulfides / CVT / One-step synthesis

One-dimensional (1D) titanium trisulfide ($TiS_3$) nanobelt bundles up to 4 cm in length have been successfully synthesized through an easy and common chemical vapor transition (CVT) process. The as-synthesized samples were characterized by X-ray powder diffraction (XRD), polarized light microscopy, scanning electron microscopy (SEM), and transmission electron microscopy (TEM). All microscopic observations indicated a belt-like morphology. Powder XRD patterns showed that $TiS_3$ crystallized in the monoclinic system with $a = 4.958(1)$ Å, $b = 3.393(1)$ Å, $c = 8.793(3)$ Å and $\beta = 97.27(5)°$. TEM images revealed a nanostructure with an interplanar spacing of 0.87 nm. The ED pattern and HRTEM images confirmed the [014] elongated direction and the [001] dilated direction of the bundle of $TiS_3$ nanobelts. Its tensile strength (TS) was further examined with a universal testing machine with 20 N as the biggest strength: the maximum stress and the break strain were 111.027 MPa and 97.1 %, respectively. Because the $TiS_3$ nanocrystals are up to 4 cm in length and flexible enough to be cut into small pieces, they should be used directly in electrical and electronic applications. Also, these nanomaterials are synthesized and prepared by a simple one-step process.

## I. Introduction

Recently, there is a growing interest in the synthesis, characterization, and application of one-dimensional (1D) nanomaterials such as nanobelts, nanowires, etc. because of their low dimensionality and high aspect ratio, as well as their unusual physical properties. The synthesis and functionality of 1D nanomaterials have become one of the most highly energized research areas. During the past two decades, various sulfide nanomaterials have been synthesized.[1–12] However, the preparation of sulfide nanobelts remains poorly studied, and only a few successful examples have been reported. For example, ZnS nanobelts with wurtzite structure have been prepared by simple thermal evaporation of ZnS powder in the presence of Au catalysts at 970 °C.[13] PbS nanobelts have been successfully synthesized in the mixed solution of $PbCl_2$ and $Na_2S_2O_3$.[14]

Titanium trisulfide $TiS_3$ is of interest to us because of its potential application in CuO-based cathodes of non-aqueous alkali metal batteries. Measurements of the electrical conductivity and the Hall coefficient at 15–300 K and of the thermal EMF at 80–400 K indicate that $TiS_3$ is semiconducting with extrinsic n-type conductivity. The mobility of the carriers is approximately 30 $cm^2/V$ at room temperature, and increases up to approximately 100 $cm^2/V$ at 100 K, and then drops at lower temperatures.[15] Thin films of $TiS_3$ have been prepared by thermal chemical vapor deposition (CVD), by reacting $TiCl_4$ and a series of sulfur sources,[16] but the nanoscale synthesis of $TiS_3$ has few successful results reported. Only Dong-Kyun Seo synthesized the $TiS_3$ material in the same size with $TiO_2$ powder and the mixtures of boron and sulfur as starting materials by a solid-gas metathetical reaction,[17] but there was neither SEM nor TEM image to indicate its nanosize. Furthermore, the boron powder could not adsorb all the oxygen completely during this oxidation–deoxidization process, and the remained $TiO_2$ would reduce the purity of the sample, some other peaks of the mixture from its XRD pattern also confirmed that.

It is well known that the synthesis and preparation generally require two separate steps in the fabrication of functional materials, e.g., firstly the phase is obtained in powder form using different synthesis methods, and then the powder product is processed into different functional forms according to specific applications, with hot pressing being the most common method used to work the powders. However, for nanomaterials, the particle size increases when the nanopowders are hot-pressed, which results in the loss of physical properties associated with the small-size effect (high specific surface area, surface conductivity, etc.). The retention of small particle size while processing the powders into different shapes is a very important issue in the field of nanomaterials. We presently report the synthesis and preparation of high-purity $TiS_3$ with nanobelt structure by an easy and

common one-step CVT process, which yields a product that can be used directly in electrical and electronic applications.

## II. Results and Discussion

The products were characterized by X-ray diffraction (XRD, with a SIEMENS D5005 diffractometer with a graphite monochromator), scanning electron microscopy (SEM JEOL.LTD JSM-6700F), transmission electron microscopy (TEM, Jeol Ltd., JEM-3010), polarized-light microscopy (Olympus BX51), universal testing machine (Shimadzu AG-I).

The XRD pattern of the bulk samples (e.g., Figure 1) was consistent with pure $TiS_3$ (JCPDS No. 36–1337). The product crystallized in the monoclinic system with $a$ = 4.958(1) Å, $b$ = 3.393(1) Å, $c$ = 8.793(3) Å and $\beta$ = 97.27(5)°. The structure calculations were optimized by least-squares refinement. The diffraction peaks were sharp and strong, confirming that the products were well crystallized. This XRD pattern also proved that the [001] direction should be the direction of growth of $TiS_3$ nanobelts bundle either elongated direction or dilated direction. Using polarized-light microscopy, the $TiS_3$ crystals were seen to be dark grey with a metallic shine and belt-like habit (Figure 2). The nanocrystals were up to 4 cm in length and, thus, apparently suitable without further treatment as functional material in electrical devices. Figure 2 (c and d) reveal a layered structure in agreement with the strong preferred orientation indicated by the bulk XRD pattern (Figure 1) and the habit of $TiS_3$ crystals deduced in previous studies.[18,19]

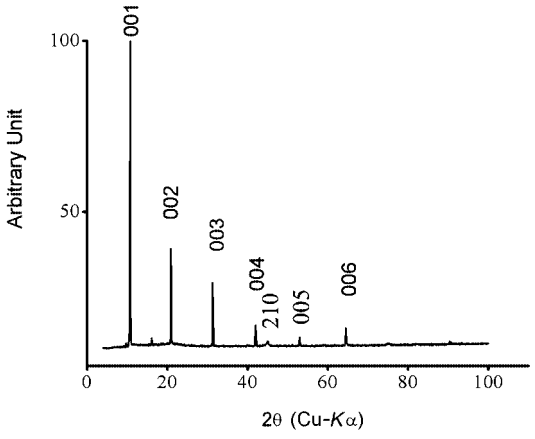

Figure 1. Bulk XRD pattern of the bundle of $TiS_3$ nanobelts. The numbers above the peaks are the Miller indices for the monoclinic structure.

The morphology of the nanobelt crystals was further investigated by SEM. A typical SEM image of the $TiS_3$ products (Figure 3, a) shows smooth laminar crystal faces and a layered structure. Figure 3 (b, c and d), shows a more massive habit with individual $TiS_3$ nanobelts up to 100 μm in length.

TEM images (Figure 4) provide further insight into the morphology of these materials. $TiS_3$ nanobelts with length

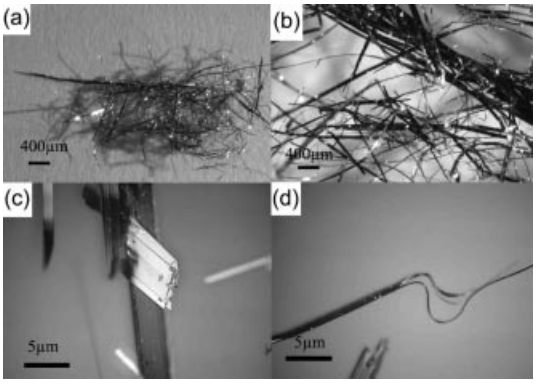

Figure 2. The appearance of the bundle of $TiS_3$ nanobelts in polarized-light microscopy (Olympus BX51). a) and b) show the dark grey belt-like appearance. c) and d) reveal the layered microstructure.

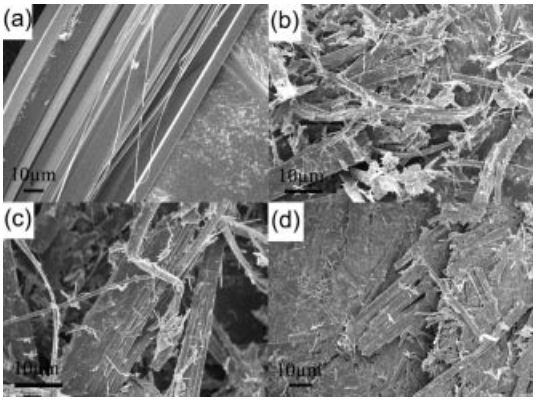

Figure 3. Low-magnification SEM images of $TiS_3$ nanobelt bundles synthesized by a simple CVT process of Ti and S at 600 °C; a) is taken from the centre of a $TiS_3$ nanobelt bundle; b) shows the typical appearance of $TiS_3$ nanobelt bundles; c) and d) show details of massive nanobelts.

up to 4 cm were first comminuted by grinding in ethanol, then the mixed solution was pulsed by ultrasonic cleaner for ca. 10 min. In order to sample the smallest size fraction of $TiS_3$ crystals, the clear solution on top of the sedimented column was pipetted onto a holey carbon grid, and the ethanol allowed to evaporate. Typical TEM images at low magnification (Figure 4, a and b) show that the ground crystal products are nanobelts, and that the yield of nanobelts is quite high (>95%). The selected-area electron diffraction pattern taken from a single $TiS_3$ nanobelt confirms the single-crystal nature of the sample and can be indexed on a monoclinic unit cell, consistent with the powder XRD results presented above (JCPDS No. 36–1337). The [014] direction of the ED pattern is parallel to the elongated axis of the belt, showing that the elongated growth might occur along the [014] direction. Furthermore, the [001] direction of the ED pattern is parallel to the dilated axis of the belt, showing that the dilated growth might occur along the [001] direction which corresponds to the XRD result. High-resolution TEM images (Figure 4, c and d) show that the nanobelts are single crystals and free of dislocations and defects.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

From Figure 4 (c), we can see that the nanobelts are structurally uniform with an interplanar spacing of 0.87 nm; it should be elongated along the [014] direction and dilated along the [210] direction which is consonant with the ED pattern. The $TiS_3$ nanobelts were not sensitive to electron beam irradiation during the HRTEM investigation.

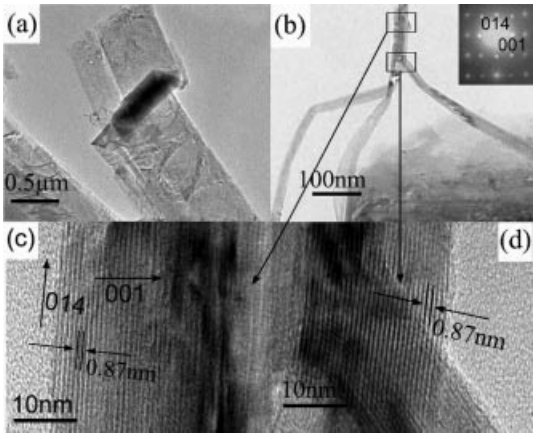

Figure 4. TEM and HRTEM images of the $TiS_3$ nanobelts revealing details of their geometry; a) and b) are images of several overlapped $TiS_3$ nanobelts, (inset) The corresponding electron diffraction pattern confirms the single-crystal nature of the sample and can be indexed to a monoclinic unit cell consistent with the XRD results presented above; c) and d) are HRTEM images of a $TiS_3$ nanobelt, showing that the nanobelts are single crystals and free from dislocations and defects, also, the nanobelts are structurally uniform with an interplanar spacing about 0.87 nm.

Figure 5 shows that in the structure of monoclinic titanium trisulfide $TiS_3$, two of the three S atoms per formula unit are present as a single-bonded disulfide ion ($S_2^{2-}$; S–S = 2.04 Å), and the third S atom is formally sulfide ($S^{2-}$).[16] The Ti atom is in irregular eightfold coordination with S atoms. Six shorter Ti–S distances (2.45 to 2.49 Å) form $TiS_6$ trigonal prisms, which are linked through shared faces into an infinite chain parallel to the *b*-axis, that makes the structure quasi one-dimensional. Neighboring chains are offset by *b*/2 and connected laterally by longer Ti–S bonds (2.63 and 2.64 Å) into sheets parallel to the crystal face (001). Individual (001) sheets are bounded above and below by a layer of disulfide groups, and held together in the resulting two-dimensional structure by only van der Waals' forces. Extensive bulk and powder XRD[16,18] (Figure 1) and microfocus single-crystal XRD[18] show that the acicular (needle-shaped) and blade- or belt-like crystals of $TiS_3$ are elongated in a gradient direction, and that the layer surface (i.e., the prominent growth surface) is (001), which is also concluded from HRTEM images and ED pattern. In addition, the $TiS_3$ nanobelts bundle can be broken into 1D needles, having a parting or cleavage parallel to the (100) direction. This parting is believed to be responsible for the belt-like morphology of the nanocrystals shown in Figure 2 (d) and Figure 4, and requires the severing of the long (2.63 and 2.64 Å) Ti–S bonds. Thus, the broad surface of the nanobelts (Figure 4, a) is a cleavage or parting surface populated by broken bonds, although the strong bonds of the monoclinic $TiS_3$ structure remain in tact. The nanobelts tend to separate into 1D needles by cleavage along (001), which requires the breaking of the weak van der Waals' bonds. On the basis of this orientational relationship, one would expect that the lattice fringes of Figure 4 (c and d) should correspond to the interlayer spacing $d_{001}$ (0.8706 nm). The 1D $TiS_3$ needles should get widen layer by layer along the [100] direction which is consistent with the HRTEM results.

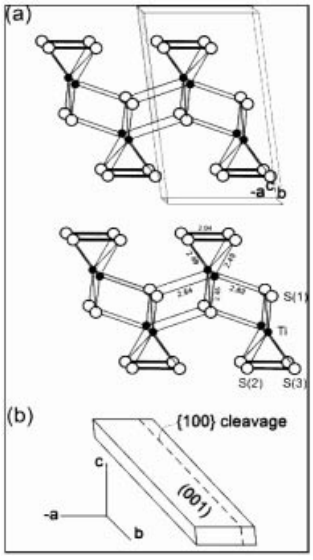

Figure 5. Structure of titanium trisulfide $TiS_3$; (a) monoclinic structure of titanium trisulfide $TiS_3$ shows that the Ti atom is in irregular eightfold coordination with S atoms. Six shorter Ti–S distances (2.45 to 2.49 Å) form $TiS_6$ trigonal prisms, which are linked by shared faces into an infinite chain parallel to the *b*-axis, making the structure quasi one-dimensional; (b) schematic pattern of the layer structure of titanium trisulfide ($TiS_3$) shows that the crystals of $TiS_3$ are elongated in the *b*-axis direction and that the layer surface is (001). Also, the crystals have a cleavage parallel to (100).

In order to prove that these bundles of $TiS_3$ are not extremely fragile, we use an universal testing machine with 20 N as the biggest strength to examine the tensile strength of this material. Figure 6 showed that the maximum stress was 111.027 MPa, the break strain 97.1% and the average stress 100–110 MPa. The maximum stress value of a bundle of $TiS_3$ is nearly the same with that of aluminum (≈ 100 MPa),[20] and much higher than those of some widely used engineering plastics such as PVC (≈ 25 MPa), poly(propylene) (25.48 MPa)[21] and poly(vinyl acetate) (29.4 MPa),[21] even some films used in conducting application. For example, a poly(*p*-phenylene) (PPP) film was electrochemically deposited onto a stainless steel electrode surface by direct oxidation of benzene in $BF_3$–diethyl ether solution at an applied potential of 1.7 V (vs. Ag/AgCl), and the as-grown PPP film had a tensile strength of 53.9–63.7 MPa;[22] a crystalline polythiophene (Pth) film was electrochemically deposited onto a nickel substrate from freshly distilled $BF_3$–diethyl ether (BFEE) solution containing 15 mM thiophene, and the crystalline film had a tensile

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

strength of 73.5–83.3 MPa.[23] So we believe these $TiS_3$ nanobelts bundles should be flexible enough to be used in applications directly.

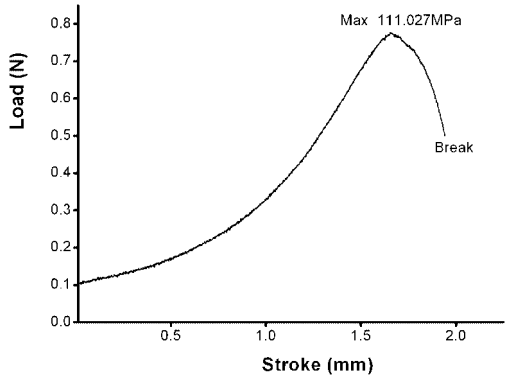

Figure 6. Tensile strength (TS) of the $TiS_3$ nanobelts bundle.

## III. Conclusions

Nanobelt crystals of $TiS_3$ with sufficient length (≈ 4 cm) and tensile strength (the average stress is 100–110 MPa) to be used directly in electrical devices without further treatment have been produced by a one-step reaction process. The successful synthesis of $TiS_3$ nanobelts encourages us to investigate the synthesis and preparation of other nanostructured metal sulfides by this easy and common CVT method, which does not require the use of organic (organic sulfur, organometallic) reagents. For the synthetic process, reaction temperature and length of the quartz-glass tube are of great importance. Therefore, establishing these parameters and the relationship between them are key points to the synthesis of metal sulfides with nanostructures. Moreover, the $TiS_3$ semiconductor nanobelts are expected to present more novel physical properties and applications in practice, and further research is now in progress in our laboratory.

## IV. Experimental Section

$TiS_3$ nanobelt crystals were prepared by the direct reaction of titanium and sulfur within evacuated sealed quartz-glass tubes with a diameter of 10 mm and a length of 130 mm. In order to ensure the purity of the sample, titanium sponge (99.7%; Alfa Aesar) and sulfur sublimate (99.99%; Aldrich) instead of oxides were used as the titanium and sulfur sources, respectively. Charges, consisting of about 1 g of starting composition in the stoichiometric proportion of $TiS_3$, were loaded in a quartz-glass tube closed at one end using a long-stemmed funnel. Then the tube with the starting materials was evacuated and sealed, and heated in a horizontal-tube furnace. The synthesis was achieved by establishing a temperature gradient of 80–100 °C along the tube with the starting mixture at the hot end. $TiS_3$ fibers were obtained at the cool end when charges were heated at 600 °C for 15 days. When the temperature was set below 600 °C, the sulfur did not react completely with titanium, and an excess amount of it was deposited at the cool end. Temperatures above 600 °C tended to produce unwanted powder and crystals of $TiS_2$: $TiS_3$ undergoes peritectic decomposition (to $TiS_2$ + native sulfur) at 632 °C, 8.95 atm. The optimum reaction duration was 15 days.

# Pyrophosphate and ATP as Stabilizing Ligands for High-Valent Nickel Complexes

**Dror Shamir,[a] Israel Zilbermann,*[a,b] Eric Maimon,[a,b] Alexander I. Shames,[d] Haim Cohen,[a,c] and Dan Meyerstein*[a,c]**

**Keywords:** ATP / Cyclam / High-valent transition metal complexes

ATP stabilizes trivalent nickel complexes which suggests that another plausible role of ATP in biological systems is the stabilization of high-valent transition metal complexes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

Anionic ligands, which are hard acids e.g. $SO_4^{2-}$ or $CH_3CO_2^-$, are known to stabilize, through axial coordination, $Ni^{III}$ complexes with tetraazamacrocyclic ligands, e.g. (cyclam)$Ni^{III}$ (cyclam = 1,4,8,11-tetraazacyclotetradecane).[1–4] Thus, good stabilizing anionic ligands are needed in order to synthesize stable high-valent nickel complexes. It has been observed that phosphate[4] and its derivatives are good axial ligands and therefore the effect of $P_2O_7^{4-}$ as a ligand was studied. The electrochemical results (CV) of the oxidation of $Ni^{II}L^{2+}$ in the presence of pyrophosphate on a glassy carbon electrode (Figure 1) point out that pyrophosphate forms a very stable complex; the formation constant of the pyrophosphate complex $Ni^{III}L(P_2O_7)_2^{5-}$ at pH = 7.0 is calculated from the intercept of the line in the inset of Figure 1 (Nernst equation) to be $K_{eq} = 9.6\cdot10^{10}$ M$^{-2}$ {the stability constants were calculated using the total concentration of pyrophosphate in the solution, relative to $E_{1/2}[NiL(H_2O)_2^{3+}/NiL^{2+}]$ at pH = 2.0[4b]}. One obtains $E_{1/2}$ = 0.44 V (vs. SCE), for the $Ni^{III/II}L$ couple in solutions containing 0.016 M pyrophosphate (as p$K_{a4}$ of $H_4P_2O_7$ is 8.66, it is reasonable to assume that at pH = 7.0, due to the inductive effect of the central $Ni^{III}$ ion,[4] the ligand is $P_2O_7^{4-}$). The electrochemical results are independent of the presence of dioxygen in the solution. Furthermore, the cyclic voltammogram at pH = 3.0, consists of two pseudo-reversible oxidation waves (Figure 1). The first wave is the oxidation of divalent nickel to trivalent nickel (one-electron oxidation) and the second wave might be attributed to the oxidation of trivalent nickel to tetravalent nickel. In order to characterize the electrochemical oxidation product, preparative electrolysis at 640 mV (vs. SCE) was performed and the resulting oxidized complex was characterized by EPR. The results point out that it is indeed a trivalent nickel complex (the measured $g$ values are typical for trivalent (cyclam)nickel: $g_\perp$ = 2.220; $g_\parallel$ = 2.022; $g_{av}$ = 2.154, at 200 K).[5] In order to determine whether an $Ni^{IV}$ complex is formed during the second oxidation wave, a second preparative electrolysis (vs. SCE) was performed by applying a controlled voltage of 800 mV to a solution containing $Ni^{III}L(P_2O_7)_2^{5-}$, and the resulting oxidized solution was characterized by EPR. However, formation of tetravalent (cyclam)nickel was not observed, probably due to the fast decomposition of the unstable $Ni^{IV}$ complex. A similar result was obtained when a CV experiment was performed using the electrolyzed solution, beginning the cycle at +0.9 V. The electrochemical results were corroborated by pulse radiolysis experiments which show that $Ni^{IV}L(P_2O_7)_n^{4-4n}$ ($n$ = 1 or 2) can be formed, but indeed is short-lived. The reaction of $Ni^{III}L(P_2O_7)_2^{5-}$ with the $N_3^{\cdot}$ radical, which is an outer-sphere oxidizing agent[6] with $E^0$ = 1.3 vs. NHE,[6] was studied by pulse radiolysis: $Ni^{III}L(P_2O_7)_2^{5-}$ was prepared by oxidation of $Ni^{II}L^{2+}$ with $Na_2S_2O_8$ at pH = 3.0[7] in a solution containing 0.016 M $Na_4P_2O_7$. To this solution 0.1 M $NaN_3$ was added, which did not affect the spectrum of the $Ni^{III}L(P_2O_7)_2^{5-}$ complex. Upon exposure to ionizing radiation, $N_3^{\cdot}$ radicals were formed accoding to Equations (1), (2) and (3) in less then 5 μs.

$$H_2O \xrightarrow{e^-,\,\gamma} {}^{\cdot}OH,\ H^{\cdot},\ e^-_{aq},\ H_2,\ H_2O_2,\ H_3O^+,\ OH^-$$
$$G({}^{\cdot}OH) = 2.65;\ G(H^{\cdot}) = 0.60;\ G(e^-_{aq}) = 2.65;\ G(H_2) = 0.45;\ G(H_2O_2) = 0.75[8] \quad (1)$$

$$e^-_{aq} + N_2O + H_2O \rightarrow {}^{\cdot}OH + OH^- + N_2;\ k = 9.1\cdot10^9\ M^{-1}s^{-1}[9] \quad (2)$$

$${}^{\cdot}OH + N_3^- \rightarrow {}^{\cdot}N_3;\ k = 1.0\cdot10^{10}\ M^{-1}s^{-1}[10] \quad (3)$$

The reaction of $^{\cdot}N_3$ with $Ni^{III}L(P_2O_7)_2^{5-}$ results in the formation of an intermediate with a strong absorption band shifted to the red (450 nm relative to that of $Ni^{III}L$-

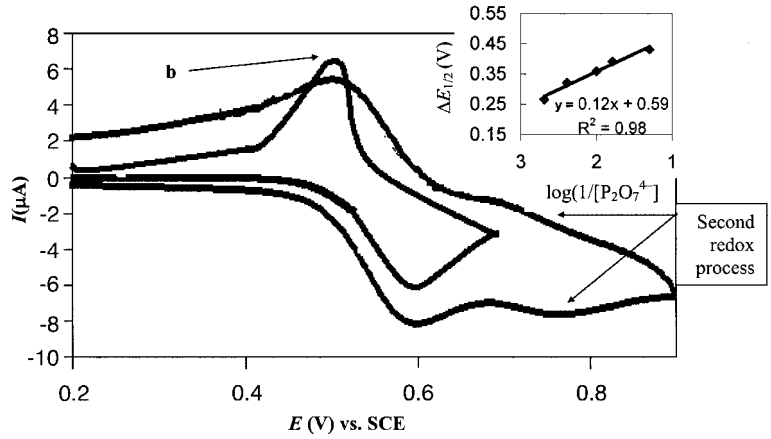

Figure 1. Electrochemical oxidations of $Ni^{II}L^{2+}$ in the presence of $Na_4P_2O_7$. Solution composition: 0.1 M $NaClO_4$, pH = 3.0, 0.001 M $Ni^{II}L^{2+}$, 0.016 M pyrophosphate, scan rate 50 mV/s; b: the same performed only for the 1st oxidation wave. Inset: Dependence of $\Delta E_{1/2}$ on log (1/[$P_2O_7^{4-}$]), where $\Delta E_{1/2}$ is the difference between $E_{1/2}$ for $NiL^{2+}$ in the absence of $P_2O_7^{4-}$ and the measured $E_{1/2}$.

$(P_2O_7)_2^{5-}$ at 380 nm; Figure 2), which plausibly represents the $Ni^{IV}L$ complex. The kinetics of formation of the intermediate obey a pseudo-first-order rate law, i.e. the observed rate is proportional to $[Ni^{III}L(P_2O_7)_2^{5-}]$. The rate of the reaction is independent of (i) $[N_3^-]$, (ii) $[N_2O]$, (iii) pH in the range 6–11 and wavelength, and the rate constant is $k\{LNi^{III}(P_2O_7)_2^{5-} + N_3^{\cdot}\} = (3.1 \pm 0.4) \times 10^8\ M^{-1}\,s^{-1}$. Thus, it is suggested that the reaction observed occurs between the trivalent nickel complex and the azide radical to produce the tetravalent nickel complex according to Equation (4).

$$[LNi^{III}(P_2O_7)_2]^{5-} + N_3^{\cdot} \rightarrow [LNi^{IV}(P_2O_7)_2]^{4-} + N_3^- \quad (4)$$

The formation of the transient is followed by three time-separated processes which obey first-order rate laws. The first two are probably isomerisation processes, with rate constants of ca. $2 \cdot 10^3$ and 90 $s^{-1}$ respectively; similar rates were reported for the isomerisation reactions of $Ni^{III}L$ complexes.[1] The third reaction is the decomposition of the tetravalent complex in which the absorption spectrum due to the transient disappears. The suggestion that the transient is $[LNi^{IV}(P_2O_7)_2]^{4-}$ is corroborated by its long life time (Figure 2). The rate of decomposition of the transient is ca. 0.25 $s^{-1}$ and is nearly independent on pH, in the range $6 < pH < 10$, complex concentration and the presence of dioxygen; all these properties point out that the transient formed is not a ligand-based radical.

As $P_2O_7^{4-}$ was found to stabilize the $Ni^{III}L$ complexes, it was decided to study the effect of ATP as a ligand, which might form the stable complex $Ni^{III}L(ATP)_2^{5-}$. It is indeed observed that ATP reacts with $Ni^{III}L(H_2O)_2^{3+}$ to form a stable $Ni^{III}L(ATP)_2^{5-}$ complex. From the electrochemical results (Figure 3), which point out that ATP forms a very stable complex, one calculates the formation constant of the ATP complex $Ni^{III}L(ATP)_2^{5-}$ to be $K_{eq} = 1.2 \cdot 10^{11}\ M^{-2}$ and $E_{1/2} = 0.41$ V (vs. SCE) for the $Ni^{III/II}L$ couple in solutions containing 0.016 M ATP (the stability constants were calculated using the total concentration of ATP in the solution). As expected, the electrochemical results also point out that the cathodic shift (compared to $Ni^{II}L$) at pH = 7.0 is higher than that at pH = 5.0 ($K_{eq} = 2.0 \cdot 10^8\ M^{-2}$ and $E_{1/2} = 0.51$ V

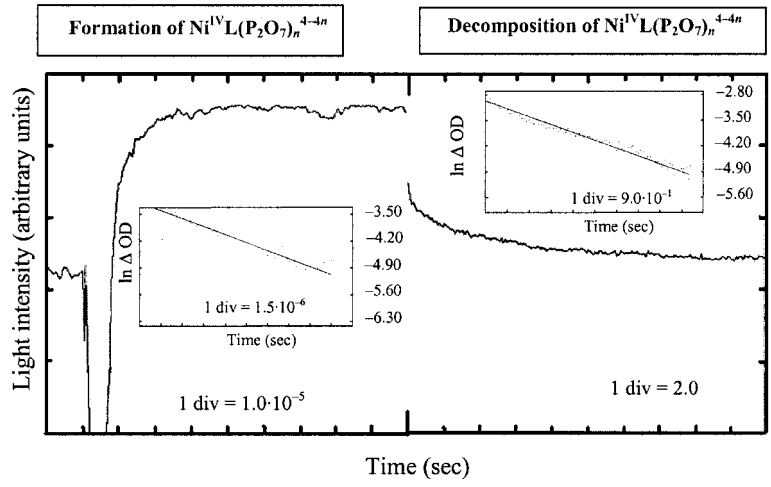

Figure 2. Pulse radiolysis of $Ni^{III}L^{2+}$ in the presence of $Na_4P_2O_7$. Solution composition: $4 \cdot 10^{-4}$ M $Ni^{III}L(SO_4)_2^-$, 0.1 M pyrophosphate, 0.02 M $NaN_3$, pH = 8.0; $\lambda_{max}$ = 450 nm.

for the $Ni^{III/II}L$ couple in solutions containing 0.016 M ATP at pH = 5.0). This pH effect is attributed to the $pK_a$ values of ATP ($pK_{a1}$ = 1.77; $pK_{a2}$ = 3.96; $pK_{a3}$ = 6.24).[11] Preparative electrolysis of a solution containing $Ni^{II}L$ in the presence of ATP at 420 mV (vs. SCE) yields an $Ni^{III}L(ATP)_2^{5-}$ complex which is stable for hours in Ar- or air-saturated solutions (as in the $P_2O_7^{4-}$ system it is assumed that due to the inductive effect of the central $Ni^{III}$ ion the ligand is $ATP^{4-}$). The EPR spectrum at 200 K ($g_\perp$ = 2.209; $g_\parallel$ = 2.025; $g_{av}$ = 2.148, 200 K) is in agreement with this assignment. However, the electrochemical oxidation of $Ni^{II}L^{2+}$ in aerated solutions containing ATP is an irreversible process (Figure 3). This observation suggests that the $Ni^{III}L(ATP)_2^{5-}$ complex formed is synergistically oxidized by the electrode and by $O_2$ causing a decomposition of the complex. The results demonstrate that pyrophosphate and ATP stabilize high-valent transition metal complexes. Thus, it is reasonable to suggest that another role of ATP in biological systems is the stabilization of high-valent transition metal complexes, e.g. $Fe^{III}$ and $Mn^{III}$.

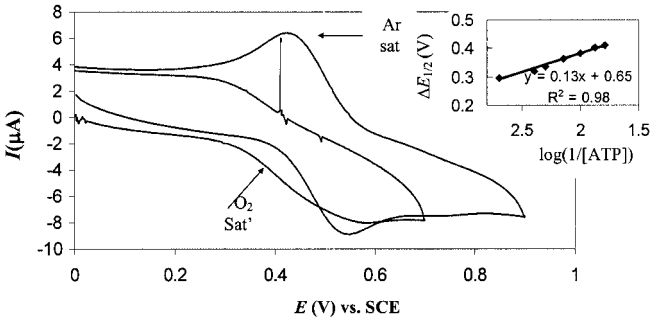

Figure 3. Electrochemistry of $Ni^{II}L^{2+}$ in the presence of ATP. Solution composition: 0.1 M $NaClO_4$, pH = 6.0; a: Ar-saturated; 0.01 M ATP, 0.001 M $Ni^{II}L^{2+}$; b: $O_2$-saturated; 0.01 M ATP, 0.001 M $Ni^{II}L^{2+}$; scan rate 50 mV/s. Inset: Dependence of $\Delta E_{1/2}$ on log (1/[ATP]), where $\Delta E_{1/2}$ is the difference between $E_{1/2}$ for $NiL^{2+}$ in the absence of ATP and the measured $E_{1/2}$.

# Inclusion of Metal Complexes into Cavities of 2D Coordination Networks Built from *p*-Sulfonatothiacalix[4]arene Tetranuclear Clusters

**Mingyan Wu,[a] Daqiang Yuan,[a] Lei Han,[a] Benlai Wu,[a] Yanqing Xu,[a] and Maochun Hong*[a]**

**Keywords:** *p*-Sulfonatothiacalix[4]arene / Supramolecular chemistry / Coordination polymer / Inclusion

Reactions of the *p*-sulfonatothiacalix[4]arene salt ($Na_4H_4TCAS$) and $MSO_4$ (M = Co, Cu) in the presence of 2,2′-bipyrazine (2,2′-bpz) generated 2D coordination networks formed by tetranuclear cluster subunits, namely $\{[Co(2,2'\text{-bpz})(H_2O)_4]^{2+}\subset[Co_4(TCAS)(\mu_4\text{-}SO_4)(H_2O)_4]^{2-}\cdot 10.75H_2O\}_n$ (**1**) and $\{[Cu(2,2'\text{-bpz})(H_2O)_3]^{2+}\subset[Cu_4(TCAS)(\mu_4\text{-}SO_4)(H_2O)_4]^{2-}\cdot 16H_2O\}_n$ (**2**). X-ray diffraction analyses reveal that both these complexes include metal–2,2′-bipyrazine complexes into the hydrophobic cavities of *p*-sulfonatothiacalix[4]arenes as guests through supramolecular interactions. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Recently, both the fields of host–guest chemistry and coordination polymers have seen rapid progress and continue to receive wide attention in the chemical sciences.[1,2] The overlapping of these two diverse fields occurs when host molecules are employed as building blocks to construct coordination polymers.[3] The incorporation of host molecules into coordination frameworks, which have well-documented inclusion properties, brings out a number of special aspects not necessarily achievable with conventional ligands, such as multiple inclusion behaviors, unusual topologies, and a vast range of intermolecular interactions. In addition, the coordination polymers formed from host molecules may lead to the development of useful chemoselective materials. Water-soluble calixarenes, which show a wide variety of inclusion properties and coordination abilities to both main-group and transition-metal ions,[4–5] are potentially versatile synthons for the syntheses of coordination polymers. Though there are several examples of coordination polymers constructed from water-soluble calixarenes exhibiting the inclusion of large guest molecules, such as [2.2.2]cryptand and crown ether,[3a,3b] coordination polymers of calixarenes incorporating transition-metal complexes as guests are rarely reported.[3g] Recently, *p*-sulfonatothiacalix[4]arene (TCAS), a new member of the calixarene family, has attracted considerable interest in the broad field of supramolecular chemistry.[6] Like its classic counterpart *p*-sulfonatocalix[4]arene (CAS), *p*-sulfonatothiacalix[4]arene possesses strongly hydrophilic upper and lower rims and a strongly hydrophobic conelike cavity that is bound by four phenyl rings. It can change its conformation from $C_{4v}$ to a cleftlike $C_{2v}$ symmetry while keeping a cone conformation to better accommodate many kinds of ionic and neutral guests. However, the introduction of four sulfur atoms into the calix[4]arene skeleton leads to at least two significant changes. Firstly, the electron-rich cavity of thiacalix[4]arene is larger than that of the classic calix[4]arene. Thus, regardless of electron-density effects, *p*-sulfonatothiacalix[4]arene shows a higher inclusion ability to encapsulate aromatic moieties than classic calix[4]arene, which suggests that the size of the cavity is more important in determining the inclusion ability.[7] Secondly, *p*-sulfonatothiacalix[4]arene can bind metal ions not only at the upper and lower rims but also at the linker positions,[8] which makes it a good candidate for constructing polymers. As reported previously, it tends to form tetranuclear bivalent anions with transition metal ions, capture small guests such as water and the pyridinium cation in its hydrophobic pocket, and further extend its structure through metal–sulfonate oxygen bonds into a 2D layer.[9] Based on the above discussion, we reason that divalent metal complexes with aromatic ligands such as 2,2′-bipyrazine are likely to be incorporated into the 2D cavities of thiacalixarenes for the balance of the charge and interactions with aromatic rings,[10] as shown in Scheme 1. Herein, we wish to report two coordination polymers derived from *p*-sulfonatothiacalix[4]arenes, 2,2′-bipyrazine (2,2′-bpz), and $MSO_4$ (M = Co, Cu), namely, $\{[Co(2,2'\text{-bpz})(H_2O)_4]^{2+}\subset[Co_4(TCAS)(\mu_4\text{-}SO_4)(H_2O)_4]^{2-}\cdot 10.75H_2O\}_n$

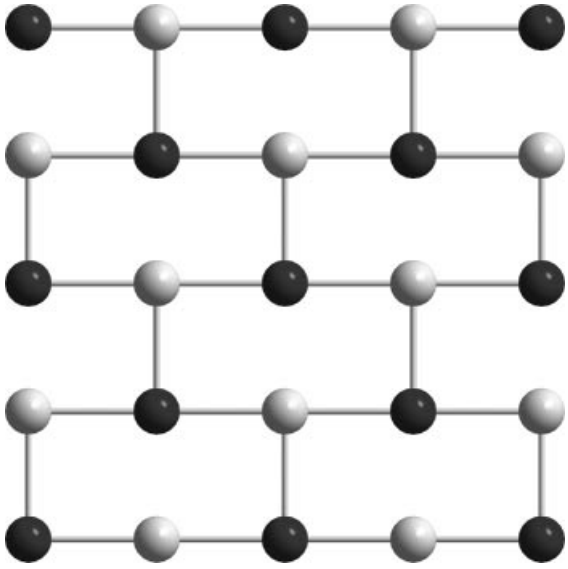
## Results and Discussion

Crystals of complexes **1** and **2** suitable for X-ray diffraction were obtained by slow diffusion of an MeOH solution of 2,2′-bpz into an aqueous solution of $Na_4H_4TCAS$ and $CoSO_4$, and $Na_4H_4TCAS$ and $CuSO_4$, respectively. Complexes **1** and **2** crystallize in space group *C*2/*c* and $P2_1/c$, respectively. They display a very similar structure of a 2D, up–down bilayer arrangement built from $[M_4(TCAS)(\mu_4\text{-}SO_4)]^{2-}$(M = Co for **1**, Cu for **2**) subunits, with inclusion of metal–2,2′-bpz cations into the cavities of the *p*-sulfonatothiacalix[4]arenes as counterions.

In the bowl-like anion subunit, a trapezoid-like tetranuclear cluster is sandwiched between one TCAS unit and one sulfate ligand (Figure 1). The fully deprotonated $TCAS^{8-}$ unit maintains a conventional cone conformation and utilizes its phenoxy groups as $\mu_2$-phenoxy bridges to bind four $M^{II}$ ions. The average $M\text{–}O_{(phenoxy)}$ distances are 2.105 Å in **1** and 2.072 Å in **2**. Interestingly, at the lower rim of $TCAS^{8-}$, the $SO_4^{2-}$ anion binds to the four $M^{II}$ ions in a rare tridentate coordination mode to complete the base of the bowl.[9] Two oxygen atoms of the sulfate anion ligate to two metal centers and one acts as a bridge linking the other two metal centres. All of the four cobalt(II) ions in **1** and three of the copper(II) ions (Cu1, Cu2, Cu3) in **2** are in an $O_5S$ octahedral geometry. The oxygen atoms from aqua ligands and the sulfonate groups of adjacent *p*-sulfonatothiacalix[4]arenes complete the six-coordination spheres. Exceptionally, in **2**, Cu4 is in an $O_4S$ square-pyramidal geometry, with an aqua ligand in the equatorial plane. Notably, each $[M_4(TCAS)(\mu_4\text{-}SO_4)]^{2-}$ subunit acts as a three-connector and extends the structure of **1** or **2** into an interesting molecular brick-wall architecture (Scheme 2). Though the aggregation of the tetranuclear clusters in both complexes is directed by the coordination of the sulfonate groups of



Scheme 2. Schematic representation of the brick-wall networks of **1** and **2**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$TCAS^{8-}$, there is a slight difference in the coordination modes. In **1**, two sulfonate groups monodentately link the subunits into an infinite chain along the crystallographic *b* axis (Figure 2). Along the crystallographic *a* axis, two sulfonate groups adopt an O,O′-$\eta^1$:$\eta^1$:$\mu_2$ bridging bidentate mode to connect the two adjacent linear chains into an up–down bilayer structure (Figure 2). In **2**, one sulfonate group adopts an O,O′-$\eta^1$:$\eta^1$:$\mu_2$ bridging bidentate mode (Figure 3) to join the subunits into an infinite chain along the crystallographic *b* axis. Along the crystallographic *c* axis, two sulfonate groups bind in a monodentate coordination mode and act as chain linkers (Figure 3). Along the third crystallographic axis (*c* axis for **1**, *a* axis for **2**), the layers lie directly above one another to give 1D channels. Large numbers of lattice water molecules (10.75 and 16 in the asymmetric units of **1** and **2**, respectively) fill the channels and interstices between the layers (Figure S1 and Figure S2 in the Supporting Information).

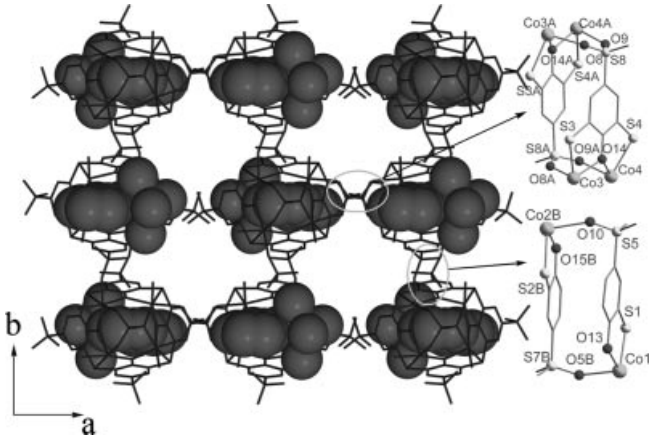

Figure 2. The extended structure of **1** with the incorporation of cobalt–2,2′-bpz cations into the cavities of *p*-sulfonatothiacalix[4]-arenes.

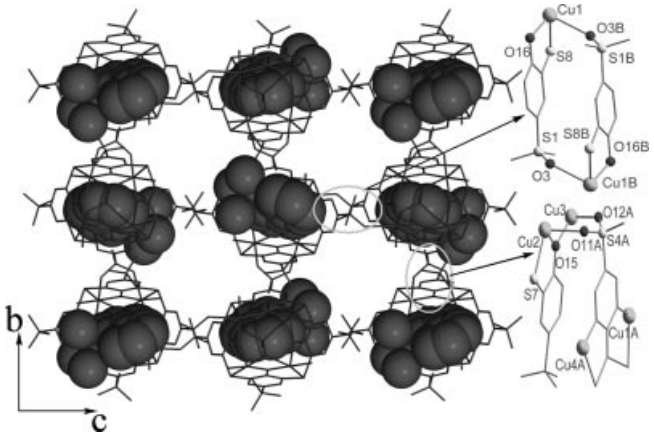

Figure 3. The extended structure of **2** with the incorporation of copper–2,2′-bpz cations into the cavities of *p*-sulfonatothiacalix[4]-arenes.

Despite being fixed by the four metal centers and the $SO_4^{2-}$ anion at the lower rim, the *p*-sulfonatothiacalix[4]arene shows versatility in displaying various conformations and splays its opposite aromatic rings into a cleftlike $C_{2v}$ symmetry to accommodate the guest. Comparatively, the separation distance between the opposite phenyl ring centroids of each *p*-sulfonatothiacalix[4]arene in **1** is much larger (7.5 Å) than that of **2** (6.2 Å). Accordingly, the dihedral angles between the aromatic rings and the plane of the phenolic oxygen atoms are 137.9° (in **1**) and 136.9° (in **2**), which are larger than that of the corresponding coordination polymer that encapsulates the pyridinium cation (133.8°).[9a] The metal–2,2′-bpz cation, as expected, is precariously held in the shallow hydrophobic pocket of the $TCAS^{8-}$ anion as the counterion (Figure 1) by cooperative supramolecular interactions. In **1**, the $[Co(2,2'\text{-bpz})(H_2O)_4]^{2+}$ moiety is held by two CH···π interactions, one involving a *meta* pyridyl hydrogen atom and a phenyl ring of the *p*-sulfonatothiacalix[4]arene with a C–H···Ar centroid distance of 2.926 Å, and the other involving a *para* pyridyl hydrogen atom and the same phenyl ring of the *p*-sulfonatothiacalix[4]arene with a C–H···Ar centroid distance of 3.164 Å, as shown in Figure 1 left. However, in **2**, the $[Cu(2,2'\text{-bpz})(H_2O)_3]^{2+}$ cation uses one of its *meta* pyridyl hydrogen atoms to form a CH···π interaction with a phenyl ring of the *p*-sulfonatothiacalix[4]arene, with a C–H···Ar centroid distance of 2.700 Å (Figure 1 right). Additionally, other intermolecular interactions such as electrostatic attractions, hydrophobic–hydrophobic interactions, and hydrogen bonding may also play important roles in the recognition process between metal–2,2′-bpz cations and $TCAS^{8-}$ anions. The closest O···O separations of the aqua ligands in the metal–2,2′-bpz cations and the oxygen atoms of the sulfonate groups are 2.703 Å in **1** and 2.705 Å in **2**, which shows rather strong hydrogen-bonding interactions between the hosts and guests.

In summary, we have successfully synthesized two tetranuclear cluster coordination polymers, which both include metal–2,2′-bpz complexes as guests through a combination of supramolecular interactions. It further demonstrates that *p*-sulfonatothiacalix[4]arene is a good host molecule with the flexibility to accommodate a range of guests through self-adjustment and that it is a good ligand to construct coordination polymers. Because of the thermal stability of the skeleton, the layer coordination networks built from tetranuclear clusters may prove to be of high interest in separation/absorption applications.[11] Further research is under way and systematic results will be reported later.

## Experimental Section

**Syntheses of Complexes 1 and 2:** A solution of 2,2′-bipyrazine (8 mg, 0.05 mmol) in $CH_3OH$ (4 $cm^3$) was carefully layered on a solution of $Na_4H_4TCAS$ (45 mg, 0.05 mmol) and $CoSO_4{\cdot}6H_2O$ (66 mg, 0.25 mmol) or $CuSO_4{\cdot}5H_2O$ (63 mg, 0.25 mmol) in water (4 $cm^3$, pH = 3.8) using an $H_2O/CH_3OH$ (3 $cm^3$) buffer. Over a period of about three weeks, red (**1**) or orange (**2**) prism crystals formed, which were suitable for X-ray diffraction analyses. Yield: 26 mg for **1** (30.67%, based on $Na_4H_4TCAS$) or 24 mg for **2** (26.95%, based on $Na_4H_4TCAS$). **1**, $C_{32}H_{51.50}Co_5N_4O_{38.75}S_9$ (1695.46): calcd. C 22.67, H 3.06, N 3.30; found C 22.81, H 2.98,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

N 3.36%. **2**, $C_{32}H_{46}Cu_5N_4O_{43}S_9$ (1780.97): calcd. C 21.58, H 2.60, N 3.15; found C 21.69, H 2.53, N 3.19%.

**X-ray Structure Determination:** Crystal data for **1**: $C_{32}H_{51.50}Co_5N_4O_{38.75}S_9$ (1695.46), monoclinic, space group *C*2/*c*, $T$ = 173(2) K, $a$ = 22.764(4), $b$ = 18.334(4), $c$ = 30.170(6) Å, $\beta$ = 95.057 (7), $V$ = 12543(4) Å$^3$, $Z$ = 8, $d_{calcd.}$ = 1.796 Mg m$^{-3}$, $F$(000) = 6884, $\mu$ (Mo-$K_\alpha$) = 1.695 mm$^{-1}$, red, 0.20 × 0.13 × 0.06 mm, $\theta$ range 3.05–27.49°, 46748 reflections collected, 14025 unique ($R_{int}$ = 0.0381). Final *GooF* = 1.074, $R_1$ = 0.0546, $wR_2$ = 0.1301, $R$ indices based on 12226 reflections with $I > 2\sigma(I)$ (refinement on $F^2$), 838 parameters, $(\Delta\rho)_{max}$ = 1.802, $(\Delta\rho)_{min}$ = –0.767 e/Å$^{-3}$. Crystal data for **2**: $C_{32}H_{46}Cu_5N_4O_{43}S_9$ (1780.97), monoclinic, space group $P2_1/c$, $T$ = 173(2) K, $a$ = 14.981(3), $b$ = 18.407(4), $c$ = 23.447(5) Å, $\beta$ = 100.571(2), $V$ = 6356(2) Å$^3$, $Z$ = 4, $d_{calcd.}$ = 1.861 Mg m$^{-3}$, $F$ (000) = 3596, $\mu$ = 2.049 mm$^{-1}$, orange, 0.40 × 0.15 × 0.60 mm, $\theta$ range 2.32–27.48°, 47791 reflections collected, 14314 unique ($R_{int}$ = 0.0457), Final *GooF* = 1.161, $R_1$ = 0.0659, $wR_2$ = 0.1342, $R$ indices based on 12550 reflections with $I > 2\sigma(I)$ (refinement on $F^2$), 895 parameters, $(\Delta\rho)_{max}$ = 1.495, $(\Delta\rho)_{min}$ = –0.848 e/Å$^{-3}$. Data collections for the two compounds were performed with a Rigaku Mercury-CCD diffractometer with graphite-monochromated Mo-*K*α radiation ($\lambda$ = 0.71073 Å). The data sets were collected at 173(2) K ($\omega$-scan mode). The structures of the two compounds were solved by direct methods and refined by full-matrix least-squares techniques with the *SHELXTL*-97 program package.[12] All non-hydrogen atoms were refined anisotropically except for several disordered solvent molecules. The organic hydrogen atoms were located at geometrically calculated positions and refined using a riding model [C–H = 0.95 Å $U_{iso}$(H) = 1.2$U_{eq}$(C)]. The hydrogen atoms on the water molecules were located in difference density maps and were refined as riding using the instruction AFIX 3,[12] and no attempt was made to locate the hydrogen atoms of disorder water molecules.

CCDC-266331 and CCDC-266330 (for **1** and **2**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

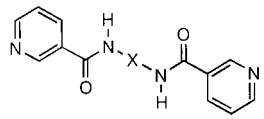
# Entrapment of a Hexamer of Nitrobenzene Molecules between the Layers of (4,4)-Coordination Networks Containing Intra-β-Sheet Hydrogen Bonds

**Madhushree Sarkar[a] and Kumar Biradha*[a]**

**Keywords:** Coordination networks/ Hydrogen bonds/ Aggregation / Host-guest systems

Two *exo*-bidentate pyridyl ligands containing diamides as spacers were shown to form non-interpenetrated 2D-coordination networks of (4,4)-geometry upon treatment with $Cu(NO_3)_2$ and NaSCN. The crystal structures reveal that both structures contain intralayer β-sheet hydrogen bonds. In one of these structures nitrobenzene occupies 60 % of the crystal volume included between the coordination networks. The nitrobenzene molecules form a layer which has the hexameric C–H···O hydrogen bonded aggregate as a basic building block.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

The design and syntheses of novel coordination networks is currently an interesting area of research in chemistry as it offers novel materials with functional properties.[1] One of the interesting aspects of coordination networks is that they offer intriguing possibilities for the inclusion and aggregation of guest molecules. The exploration of the geometry of such aggregates of small molecules in different surroundings is the most significant aspect as it helps in delineating and updating the principles of crystal engineering and supramolecular chemistry. The structure and characteristic properties of those aggregates are distinctly different from the properties of the parent molecules.[2] There are several instances in which weak intermolecular interactions have led to the formation of a variety of aggregations of small molecules in different surroundings.[2] We report here the C–H···O hydrogen-bonded hexameric aggregate of nitrobenzene that is trapped between the layers of a (4,4)-metal-organic network formed by $Cu^{II}$ and bis(3-pyridylcarboxamido)ethane (**1**). Ligand **1** contains two pyridine moieties for the formation of extended coordination networks, an alkyl moiety for providing the flexibility and two amide moieties for the formation of N–H···O hydrogen bonds.[3] Recently, ligand **1** was shown by us to form doubly interpenetrated and non-interpenetrated (4,4)-coordination networks upon reaction with CuI.[4] In both cases the networks are propagated by CuI clusters, secondary building units, and are joined together by β-sheet hydrogen bonds. Here we report another interesting variation of a (4,4)-network which is formed by the reaction of ligand **1** with $Cu(SCN)_2$. The salient feature of the network is that the β-sheet hydrogen bonds exist within the layer of the (4,4)-network but not between the layers. As a result, the (4,4)-networks have no cavities and the aromatic guest molecules are included between the layers. The Cambridge Structural Database (CSD)[5] analysis on nitrobenzene complexes reveals that the C–H···O hydrogen-bonded nitrobenzene aggregate observed here is unique and unprecedented.



**1**: X= -$CH_2$-$CH_2$- **2**: X= -$C_6H_4$-

The careful layering of an MeOH solution of $Cu(NO_3)_2$ and NaSCN onto a nitrobenzene solution of ligand **1** resulted in single crystals of complex $\{Cu(\mathbf{1})_2(SCN)_2 \cdot 6(\text{nitrobenzene})\}_n$ (**3**). An X-ray structure analysis reveals that complex **3** exhibits a (4,4)-coordination network and includes six nitrobenzene molecules per metal atom. The asymmetric unit of **3** contains a Cu atom with half occupancy (on inversion center), two half units of **1**, one SCN anion and three nitrobenzene molecules. Furthermore, the Cu atom has a highly distorted octahedral geometry as four units of **1** occupy the equatorial positions [Cu–N: 2.048(5) Å and 2.642(5) Å] and two SCN [Cu–N: 1.953(5) Å] anions occupy the axial positions. Each loop of the (4,4)-network has a rhomboidal shape with two Cu–Cu diagonal distances of 31.2 and 10 Å (Figure 1a). The ligands in the sheet recognize each other through β-sheet hydrogen bonds [N–H···O: 2.989(7) Å, 164°; 2.933(7) Å, 157°] and edge-to-edge aromatic C–H···π interactions. The interlayer separation between the coordination networks is as high as 11 Å as one layer of nitrobenzene molecules occupies the space between the layers (Figure 1b).

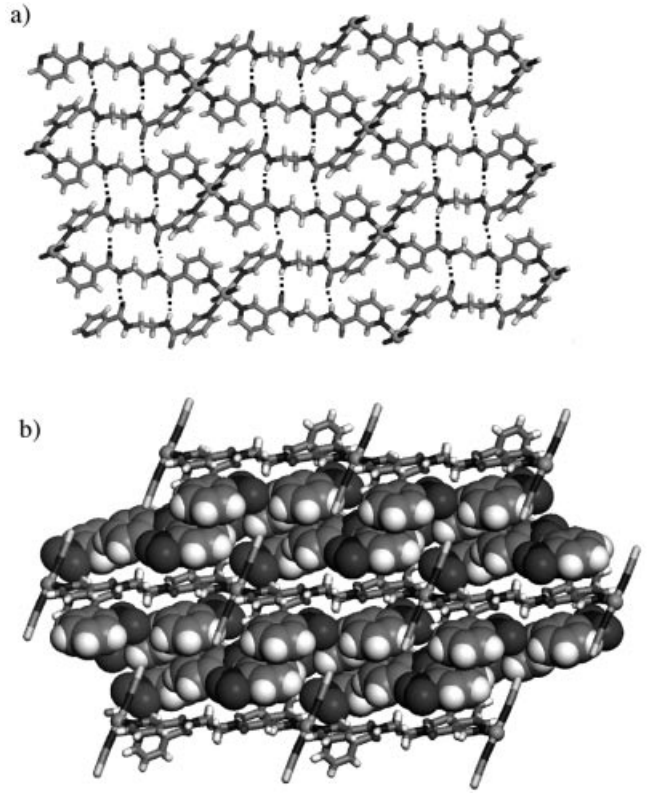

Figure 1. a) (4,4)-Network in the crystal structure of **3**. Note the intralayer β-sheet hydrogen bonds; b) entrapment of a nitrobenzene layer between (4,4)-coordination networks (view along the short diagonal).

The layer of nitrobenzene consists of C–H···O hydrogen-bonded hexameric aggregates of nitrobenzene molecules (Figure 2a). In the aggregate all the molecules lie in a plane and interact with each other through six C–H···O hydrogen bonds [C···O, C–H···O: 3.221(12) Å, 144°; 3.340(18) Å, 132°; 3.303(15) Å, 129°]. Furthermore, the aggregate has a distorted hexagon shape with the length and width dimensions of 25.8 and 11.4 Å, respectively. These aggregates stack on each other in a slipped fashion through aromatic π–π interactions to form a layer which interacts with the host framework through C–H···O hydrogen bonds and aromatic interactions (Figure 2b).

The repetition of the reaction by using other aromatic guests such as benzene, xylene, toluene, naphthalene and benzoic acid in place of nitrobenzene resulted in precipitates but not single crystals. Furthermore, the change of spacers from ethyl to butyl/hexyl/octyl did also not result in single-crystal formation. However, use of bromobenzene instead of nitrobenzene resulted in single crystals in very low yield (5%) which are very unstable for data collection.[6]

In **3**, nitrobenzene occupies as much as 61% of the unit-cell volume. The analysis of the CSD shows that this aggregate is the first of its kind among the 135 nitrobenzene solvates that are present in the database. However, the structural motif **I**, which is part of the aggregate, was found to exist in 23 structures out of the 4607 structures of the nitroaromatic derivatives.

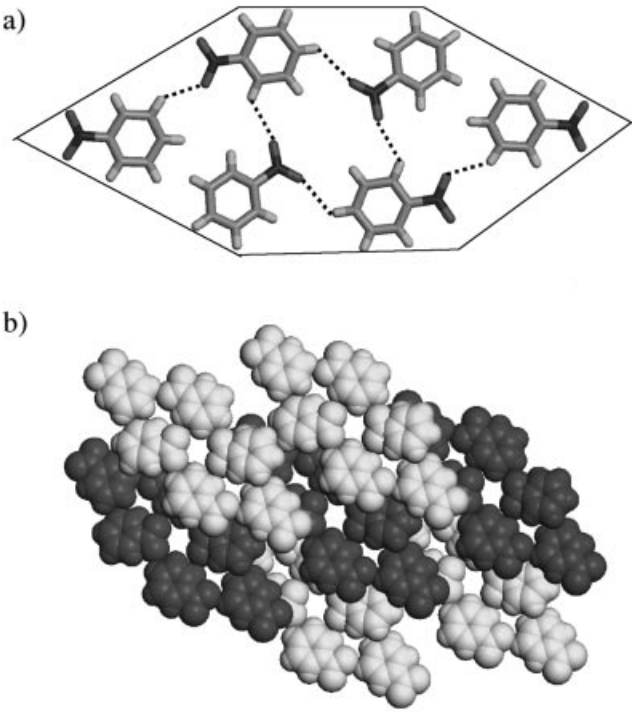

Figure 2. a) C–H···O hydrogen-bonded hexameric aggregate of nitrobenzene molecules; b) layer of hexameric aggregates formed through π–π interactions.

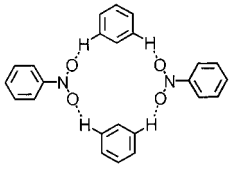

**I**

In TGA, a gradual weight loss (8%) of **3** occurred from 50–96 °C which may correspond to the loss of one of the nitrobenzene molecules bound by only one C–H···O hydrogen bond in the hexamer. From 90–141 °C, 40% weight loss occurred which corresponds to five nitrobenzene molecules. The network is stable up to 260 °C. Guest exchange reactions were tried by immersing crystals of **3** in benzene, toluene or naphthalene in $CHCl_3$. TLC of these crystals indicated the absence of nitrobenzene. From the elemental and powder X-ray diffraction analysis of the immersed crystals, it can be concluded that the nitrobenzene molecules are expelled, but the new guest molecules are not included. The TGA plots and XRPD spectra are included in the Supporting Information.

Ligand **2** was then considered as it has a phenyl spacer which makes the host network self-sufficient to interact with neighboring layers. The layering of an MeOH solution of $Cu(NO_3)_2$ and NaSCN onto a nitrobenzene solution of ligand **2** resulted in single crystals of the complex $\{Cu(\mathbf{2})_2(SCN)_2\}$ (**4**). The X-ray diffraction analysis revealed that complex **4** also contains a (4,4)-network similar to **3**. The unit-cell contents are the same as for **3** but without nitrobenzene molecules, and the coordination geometry of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Cu atom is a distorted octahedron [Cu–N: 2.060(4), 2.494(4) Å; Cu–NCS: 1.965(4) Å]. Within the (4,4)-network the ligands recognize each other through β-sheet hydrogen bonds [N–H···O: 2.924(5) Å, 150°; 3.154(5) Å, 152°] as well as aromatic edge-to-face interactions which form between the phenyl spacers and also between the pyridyl groups of adjacent ligands (Figure 3). The Cu atoms in the network are joined together by ligand **2** with a distance of 17.272 Å and each loop has a rhomboidal shape with diagonal-to-diagonal distances of 33.7 and 10.5 Å. These layers stack on each other with an interlayer separation of 5.2 Å which suggests strong aromatic edge-to-face interactions between the layers. The use of other solvents, such as $CHCl_3$ or toluene, in place of nitrobenzene also resulted in single crystals of complex **4**, which indicates that the crystallization of complex **4** does not depend on the nature of the solvents. These reactions emphasize the fact that the host–host (aromatic) interactions are robust enough to allow crystal formation of complex **4**.

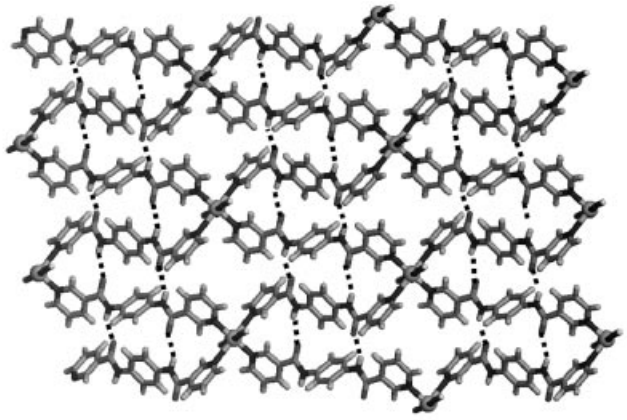

Figure 3. (4,4)-Coordination network of crystal structure **4**. Note the intralayer β-sheet hydrogen bonds and edge-to-face aromatic interactions between the ligands.

## Experimental Section

**General:** FTIR spectra were recorded with an NEXUS-870 instrument, Thermo Nicolet Corporation. UV/Vis spectra were recorded with a Shimadzu UV-1601. Elemental analyses were obtained with a Perkin Elmer instrument, series II, CHNS/O analyzer 2400. TGA data were recorded with a Perkin Elmer instrument, Pyris Diamond TG/DTA (air). Powder XRD data were recorded with a Philips PW 1710 diffractometer.

**Synthesis of Complex 3:** Methanol (1.0 mL) was layered onto a nitrobenzene (5.0 mL) solution of *N*,*N*′-bis(3-pyridinecarboxamido)-1,2-ethane (**1**) (40.0 mg, 0.148 mmol). Onto this solution was layered a $Cu(SCN)_2$ solution, which was obtained by mixing a methanolic solution (0.5 mL) of $Cu(NO_3)_2$ (17.8 mg, 0.074 mmol) and a methanolic solution (0.5 mL) of NaSCN (11.9 mg, 0.148 mmol). Green crystals formed in 70% yield (300 mg) after 3–4 d. $C_{66}H_{58}CuN_{16}O_{16}S_2$ (1458.94): calcd. C 54.33, H 3.97, N 15.35; found C 53.48, H 3.71, N 15.02. IR: $\tilde{\nu}$ = 3317 (N–H stretch), 3071 (aromatic C–H stretch), 2064 (thiocyanate CN stretch), 1632 (amide C=O stretch), 1601(amide II), 1519 (asym. N–O stretch), 1342 (sym. N–O stretch), 849.46 (C–N stretch) $cm^{-1}$. UV: $\lambda_{max}$ ($\varepsilon$) = 205.67 (816097), 260.27 (616248 $dm^3 mol^{-1} cm^{-1}$) nm.

**Synthesis of Complex 4:** A methanolic solution of $Cu(SCN)_2$, formed by addition of an MeOH (0.5 mL) solution of $Cu(NO_3)_2$ (15.2 mg, 0.063 mmol) to an MeOH (0.5 mL) solution of NaSCN (10.2 mg, 0.126 mmol), was carefully layered onto an ethanol (1 mL)/$CHCl_3$ (5.0 mL) solution (6 mL) of 1,4-bis(3-pyridinecarboxamido)benzene (**2**) (40.0 mg, 0.126 mmol). Light-green crystals formed in 20% yield (40.8 mg) after a week. $C_{38}H_{28}CuN_{10}O_4S_2$ (816.36): calcd. C 55.9, H 3.4, N 17.1; found C 55.0, H 2.9, N 16.8. IR: $\tilde{\nu}$ = 3326 (N–H stretch), 3066 (aromatic C–H stretch), 2068 (thiocyanate, CN), 1645 (C=O stretch), 1610 (amide) $cm^{-1}$. UV: $\lambda_{max}$ ($\varepsilon$) = 204 (45314), 295.71 (27043 $dm^3 mol^{-1} cm^{-1}$) nm.

**X-ray Structure Analysis of Complexes 3 and 4:** The single-crystal data sets were collected at room temperature for both complexes with a Bruker-Nonius Mach3 CAD4 X-ray diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) in the ω-scan mode. The crystals of complex **3** were immersed in oil and covered with glue in order to prevent loss of guest molecules. The structure was solved by direct methods and refined by least-squares methods on $F^2$ using SHELX-97.[7] Non-hydrogen atoms were refined anisotropically and hydrogen atoms were fixed at calculated positions and refined using a riding model. In complex **4**, the S atom of the NCS anion was disordered over two sites and hence the occupancies were refined (61 and 39%). Crystal data for **3**: Triclinic, $P\bar{1}$, $a$ = 9.967(2), $b$ = 12.950(3), $c$ = 14.945(3) Å, $\alpha$ = 106.90(3), $\beta$ = 102.94(3), $\gamma$ = 102.11, $V$ = 1718.9(6) $Å^3$, $Z$ = 1, $D_{calcd.}$ = 1.409 $g cm^{-3}$, 3111 reflections out of 5858 unique reflections with $I > 2\sigma(I)$, 1.50° < $\theta$ < 25.06°, final $R$ values: $R_1$ = 0.0778, $wR_2$ = 0.1724. Crystal data for **4**: Triclinic, $P\bar{1}$, $a$ = 8.259(2), $b$ = 9.613(2), $c$ = 12.656(3) Å, $\alpha$ = 85.70(3), $\beta$ = 74.66(3), $\gamma$ = 71.18, $V$ = 917.1(3) $Å^3$, $Z$ = 1, $D_{calcd.}$ = 1.478 $g cm^{-3}$, 2292 reflections out of 3231 unique reflections with $I > 2\sigma(I)$, 1.67° < $\theta$ < 25.00°, final $R$ values: $R_1$ = 0.0522, $wR_2$ = 0.1177. CCDC-286845 (**3**) and -286846 (**4**), contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Preparative procedures for **1**–**4**, TGA measurement of **3**, powder spectra of guest-exchanged materials of **3**, ORTEP drawings of **3** and **4**, and IR and UV spectra of complexes and ligands.

# Self-Assembly of a Tetranuclear $Co^{III}$-Metallacycle from the Reaction of a Bis(benzene-*o*-dithiolato) Ligand with $Co^{II}$ and Subsequent Aerial Oxidation

**F. Ekkehardt Hahn,*[a] Thorsten Kreickmann,[a,b] and Tania Pape[a]**

**Keywords:** Cobalt / S ligands / Metallacycles / Self-assembly

The bis(benzene-*o*-dithiol) ligand [$(HS)_2$-2,3-$C_6H_3$–$CH_2$–$C_6H_3$-2,3-$(SH)_2$] ($H_4$-**1**) reacts, after deprotonation with $Li_2CO_3$, with $CoCl_2{\cdot}6H_2O$. Aerial oxidation in methanol gives the tetranuclear metallacycle $Li_4[Co_4(\mathbf{1})_4]$. The X-ray structure analysis of $(PNP)_4[Co_4(\mathbf{1})_4]$ (**7**) reveals a cyclic structure in which each of the bis(benzene-*o*-dithiolato) ligands forms a bridge between two cobalt centers. Two differently coordinated cobalt atoms (*syn* and *anti*) are observed in the tetranuclear complex.

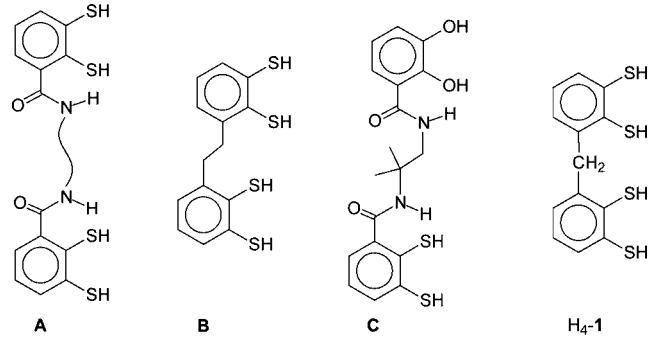
## Introduction

The combination of polydentate organic ligands and transition metals has led to supramolecular complexes.[1] Metal-directed self-assembly has been used to form different supramolecular architectures like helicates,[2] boxes,[3] squares,[4] molecular containers,[5] and other structural motifs.[6] Among those, metal helicates have attracted special interest owing to their presence in nature.[2] The first triple-stranded helicate $[Fe_2(RA)_3]$ (RA = rhodotorulic acid), containing exclusively oxygen donor functions from hydroxamate groups, was isolated and characterized by Raymond et al.[7] The early helicate chemistry, however, was dominated by nitrogen donor ligands like oligobipyridines.[2,8] Later, triple-stranded helical complexes with catecholato donor groups were prepared.[2,9] The coordination chemistry of dicatechol ligands has been reviewed.[10] Double-stranded helical structures built from ligands with an unsymmetrical spacer (directional ligands) have been reported.[11] Even the triple-stranded helicate of a catecholato/aminophenolato ligand has been described.[12]

Much less is known about helicates containing benzene-*o*-dithiolato or other dithiolene donor groups. We have described a method for the *o*-functionalization of benzene-1,2-dithiol, which gives 2,3-dimercaptobenzoic acid[13] or 2,3-dimercaptobenzyl alcohol.[14] These building blocks were used to synthesize bis(benzene-*o*-dithiol) ligands of type **A**,[15,16] **B**,[16] and the benzene-*o*-dithiol/catechol ligand **C**[17] (Scheme 1). Non-helical mono- and dinuclear complexes have been obtained with ligands **A** and **B**, while ligand **C** reacts with $Ti^{IV}$ to give a triple-stranded helicate with a parallel ligand orientation.



Scheme 1. Ligands containing the benzene-*o*-dithiol donor group.

However, no dinuclear triple-stranded helicates have been obtained so far from bis(benzene-*o*-dithiol) ligands such as **A** and **B**. Albrecht et al. have shown that methylene-bridged dicatecholato[18] and catecholato/aminophenolato[12] ligands are capable of forming triple-stranded helicates with $Ti^{IV}$ and $Ga^{III}$. In our search for helicates built exclusively from sulfur donors, we have therefore prepared the novel methylene-bridged bis(benzene-*o*-dithiol) ligand $H_4$-**1** (Scheme 1). Here we present the preparation of ligand $H_4$-**1** and its coordination chemistry with $Co^{III}$.

## Results and Discussion

Ligand $H_4$-**1** was prepared as depicted in Scheme 2. 1,2-Bis(isopropylmercapto)benzene (**2**) was synthesized as described previously.[14,16] Deprotonation of **2** with *n*BuLi/TMEDA in hexane yielded the organolithium compound **3**. Compound **3** was not isolated but immediately transformed into 2,3-bis(isopropylmercapto)benzaldehyde (**4**) by reaction with *N*,*N*-dimethylformamide followed by an acidic

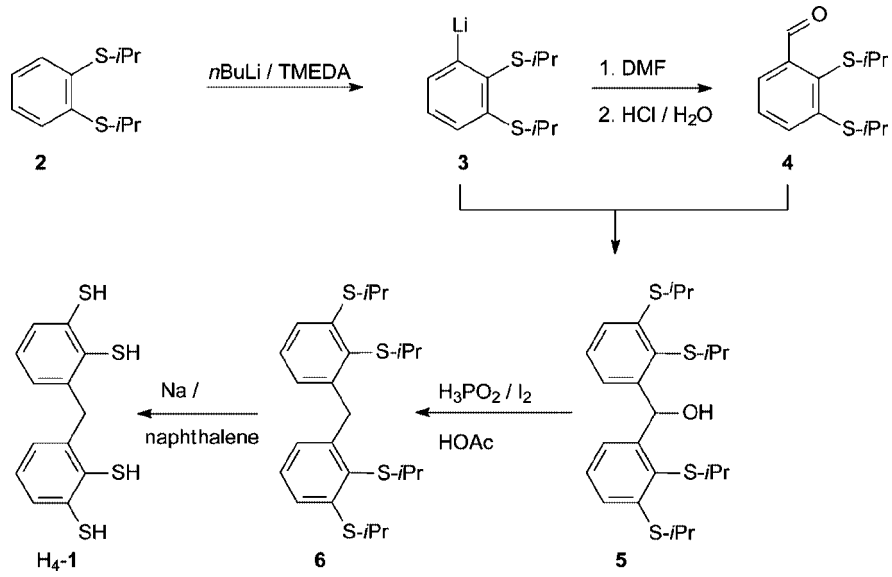

Scheme 2. Synthesis of the bis(benzene-*o*-dithiol) ligand $H_4$-**1**.

workup. Reaction of equimolar amounts of **3** and **4** in hexane yielded the alcohol **5** after acidification. Alcohol **5** was deoxygenated with hypophosphorous acid in the presence of a catalytic amount of iodine in acetic acid.[19] Removal of the *S*-protection groups in ligand precursor **6** with sodium/naphthalene in THF liberated ligand $H_4$-**1**, which was isolated after hydrolysis in approximately 85% yield (relative to **2**).

Reaction of equimolar amounts of $H_4$-**1** and $CoCl_2 \cdot 6H_2O$ in methanol at ambient temperature in the presence of two equivalents of $Li_2CO_3$ yielded a brown solution. We assume that this solution contained $Co^{II}$ complexes with benzene-*o*-dithiolato ligands. Upon aerial oxidation, the brown solution immediately turned deep blue, which indicates the formation of a $Co^{III}$–benzene-*o*-dithiolato complex. Addition of PNPCl [$PNP^+$ = bis(triphenylphosphoranylidene)ammonium] led to the precipitation of a blue solid, which was isolated and dried. The composition of the blue solid was established by ESI mass spectroscopy (Figure 1, negative ions). No peaks for a double-stranded complex of composition $[Co_2(\mathbf{1})_2]^{4-}$ are observed. Instead, three peaks are found at *m*/*z* = 351, 648, and 1241. These are assigned to the ions $[Co_4(\mathbf{1})_4]^{4-}$, $\{(PNP)[Co_4(\mathbf{1})_4]\}^{3-}$, and $\{(PNP)_2[Co_4(\mathbf{1})_4]\}^{2-}$. These assignments were corroborated by matching isotope patterns. Thus, the reaction of ligand $H_4$-**1** with $CoCl_2$ followed by aerial oxidation and precipitation with PNPCl does not yield a dinuclear complex, as was expected, but instead a tetranuclear complex of composition $(PNP)_4[Co_4(\mathbf{1})_4]$ (**7**).

To establish the molecular structure of the $[Co_4(\mathbf{1})_4]^{4-}$ anion, crystals suitable for an X-ray analysis were grown by slow vapour diffusion of pentane into a solution of **7** in dichloromethane. The molecular structure of tetraanion $[Co_4(\mathbf{1})_4]^{4-}$ is shown in Figure 2. The complex anion contains four $[Co(S_2C_6H_3R)_2]$ units arranged in a cyclic fashion. Each $\mathbf{1}^{4-}$ ligand bridges two cobalt atoms. Each of the cobalt atoms is coordinated by two benzene-*o*-dithiolato

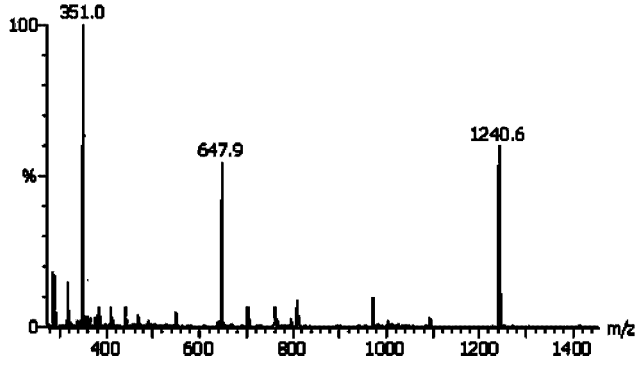

Figure 1. ESI mass spectrum (negative ions) of $(PNP)_4[Co_4(\mathbf{1})_4]$ (**7**).

units from different ligands in a square-planar fashion. The Co–S and C–S distances in **7** are normal and match those reported for the mononuclear complex $(AsPh_3Me)[Co(S_2C_6H_3CH_3)_2]$.[20] Cobalt(III) complexes with electron-poor benzene-*o*-dithiolato ligands [$S_2C_6Cl_4$ or $S_2C_6H_2(CN)_2$] have been reported to dimerize.[21] In such dimers the $[Co(bdt)_2]^-$ (bdt = substituted benzene-*o*-dithiolate) units lie parallel to one another such that the cobalt atom of each $[Co(bdt)_2]^-$ unit is directly opposite a sulfur atom belonging to the second unit. This arrangement leads to the formation of two new Co–S bonds and a tetragonal-pyramidal coordination environment for each cobalt atom.

No such extra Co–S interactions are observed in the anion $[Co_4(\mathbf{1})_4]^{4-}$. The $[Co_4(\mathbf{1})_4]^{4-}$ anions are well separated in the solid state, and no intramolecular Co–Co (shortest separation about 9 Å) and Co–S (shortest separation about 7 Å) or intermolecular Co–Co (shortest separation longer than 9 Å) and Co–S (shortest separation longer than 7 Å) contacts are found.

In contrast to the recently reported dinuclear nickel complex with an ethylene bridged bis(benzene-*o*-dithiolato) ligand (Scheme 1, **B**),[16] the tetranuclear complex $(PNP)_4$-

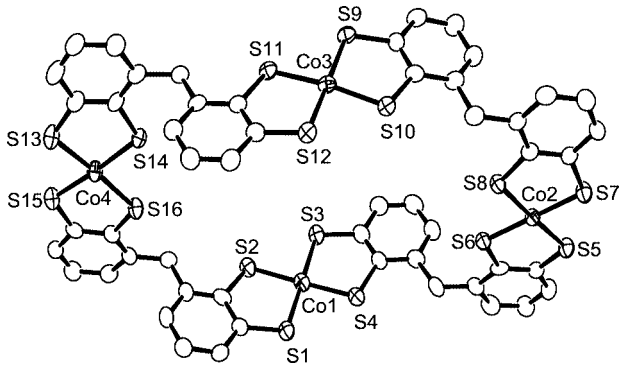

Figure 2. Molecular structure of the $[Co_4(\mathbf{1})_4]^{4-}$ anion of **7**. Hydrogen atoms and cations have been omitted for clarity. Selected ranges for bond lengths [Å] and bond angles [°]: Co–S 2.157(2)–2.176(2), C–S 1.746(6)–1.769(6), S–Co–S (intra ligand) 91.08(7)–91.84(7), Co–S–C 104.4(2)–105.9(2).

$[Co_4(\mathbf{1})_4]$ contains two metal centers with a slightly different coordination environment. Two cobalt atoms (Co1 and Co3) are coordinated by benzene-*o*-dithiolato units and the alkyl substituents are arranged in *anti* positions, while the other two cobalt atoms (Co2 and Co4) are coordinated by benzene-*o*-dithiolato units that have their alkyl substituents arranged in a *syn* fashion. This leads to two different $C_2$ axes along the two metal–metal connection lines Co1–Co3 and Co2–Co4 (Figure 3). The distances between the equivalent cobalt atoms are 9.661 Å (Co1–Co3) and 15.933 Å (Co2–Co4). A large internal cavity is formed by this arrangement. Two benzene rings of the $PNP^+$ cations partly fill this cavity without any interaction with the metallacycle. Complex **7** is, to the best of our knowledge, the first metallosupramolecular assembly that contains two differently coordinated metal centers even though a ligand with two identical donor sites has been used.

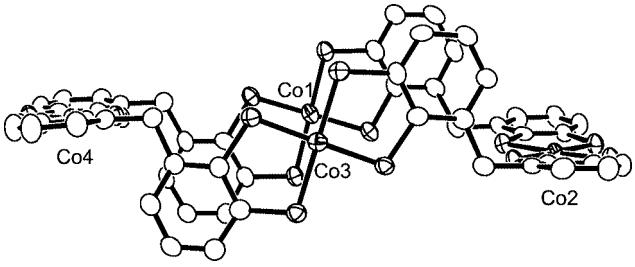

Figure 3. View along the Co1–Co3 axis showing the *syn* (Co2, Co4) and *anti* (Co1, Co3) arrangement of the substituted benzene-*o*-dithiolato ligands.

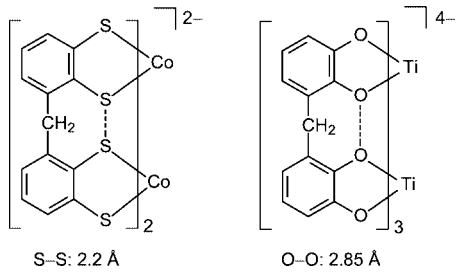
Although a tetranuclear complex $[Co_4(\mathbf{1})_4]^{4-}$ is entropically less favorable than two dinuclear complexes $[Co_2(\mathbf{1})_2]^{2-}$, the larger compound is exclusively formed. We believe that this occurs because of a strong steric interaction between the two sulfur atoms in the 2-positions of the aromatic rings that would occur in a hypothetical dinuclear complex $[Co_2(\mathbf{1})_2]^{2-}$ (Scheme 3, left). Albrecht et al. prepared a dicatechol ligand, with the same topology as $H_4$-**1**, that forms a dinuclear triple-stranded helicate with $Ti^{IV}$ (Scheme 3, right).[18] In this complex, no repulsion between the oxygen atoms in the 2-positions is observed (intraligand O···O distance 2.85 Å). In addition, possible repulsion between these oxygen atoms is also compensated by coordination to hard lithium cations. This coordination is not possible and was not observed with the soft sulfur donor atoms. In a hypothetical dinuclear complex with benzene-*o*-dithiol ligands, steric interaction between the sulfur atoms in the 2-position would occur owing to the longer C–S bonds (1.76 Å versus 1.35 Å for the C–O bonds) and the larger intraring C–C–S angles (119° versus 114° for the C–C–O angles). On the basis of these parameters, the S···S distance in a dinuclear complex $[Co_2(\mathbf{1})_2]^{2-}$ would be around 2.2 Å, which is far too short for a nonbonding interaction (typically S–S bond lengths are 2.0 Å). Consequently, strong repulsion between the sulfur atoms must occur in the hypothetical $[Co_2(\mathbf{1})_2]^{2-}$ complex in which two cobalt atoms are coordinated in a square-planar fashion by two $CH_2$-bridged bdt ligands. In order to avoid this unfavourable repulsion, one benzene-*o*-dithiolato group of each $\mathbf{1}^{4-}$ ligand is rotated by about 90° around the Ar–$CH_2$ axis, which, in turn, leads to the formation of the tetranuclear metallacycle.



Scheme 3. Hypothetical complex $[Co_2(\mathbf{1})_2]^{2-}$ (left) and triple-stranded helicate (right).

## Experimental Section

If not stated otherwise, all manipulations were carried out under dry argon by using standard Schlenk techniques. Hexane, tetrahydrofurane, and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) were freshly distilled from sodium/benzophenone prior to use. The starting material 1,2-bis(isopropylmercapto)benzene (**2**) was prepared as described before.[16]

**2,3-Bis(isopropylmercapto)benzaldehyde (4):** A sample of *n*-butyllithium (12.16 mL of a 2.5 M solution in hexane) was added dropwise to a solution of TMEDA (4.56 mL, 30.4 mmol) and 1,2-bis(isopropylmercapto)benzene (**2**, 6.9 g, 30.4 mmol) in hexane (100 mL) at 0 °C. After 30 min, the ice bath was removed, and the stirring was continued for 3 h at ambient temperature, which resulted in the formation of an off-white slurry. Dry *N*,*N*-dimethylformamide (3.53 mL, 45.6 mmol) was added, and the solution was stirred for 12 h. Water (100 mL) and hydrochloric acid (37%, 20 mL) were added, and the aqueous solution was extracted with diethyl ether (3 × 50 mL). The combined organic layers were dried with $MgSO_4$, and the solvent was removed in vacuo. Column chromatography ($SiO_2$, $Et_2O$/petroleum ether, 1:3) gave a yellow oil (7.33 g, 28.8 mmol, 95%). $^1H$ NMR ($CDCl_3$, 300.1 MHz): $\delta$ = 10.8 (s, HC=O), 7.67 (dd, 1 H, Ar-H), 7.49–7.35 (m, 2 H, Ar-H), 3.54–3.32 (m, 2 H, SCH), 1.39 (d, $^3J$ = 7.0 Hz, 6 H, $CH_3$), 1.23 (d, $^3J$ = 7.0 Hz, 6 H, $CH_3$) ppm. $^{13}C$ NMR ($CDCl_3$, 75.5 MHz): $\delta$ = 193.4

(C=O), 146.5, 139.7, 136.4, 131.4, 129.2, 124.3 (Ar-C), 40.9 (SCH), 36.0 (SCH), 23.0 ($CH_3$), 22.6 ($CH_3$) ppm. GC/MS (EI, 70 eV): *m/z* (%) = 254 (66) $[M]^+$, 211 (10) $[M - C_3H_7]^+$, 179 (5) $[M - SC_3H_7]^+$, 41 (100) $[C_3H_5]$. $C_{13}H_{18}OS_2$ (254.40): calcd. C 61.38, H 7.13, S 25.20; found C 61.47, H 7.36, S 24.87.

**Bis[2,3-bis(isopropylmercapto)phenyl]methanol (5):** A sample of *n*-butyllithium (3.00 mL of a 2.5 M solution in hexane) was added dropwise to a solution of TMEDA (1.15 mL, 7.50 mmol) and 1,2-bis(isopropylmercapto)benzene **2** (1.7 g, 7.50 mmol) in hexane (30 mL) at 0 °C. After 30 min, the ice bath was removed, and the stirring was continued for 3 h at ambient temperature, which resulted in the formation of an off-white slurry. 2,3-Bis(isopropylmercapto)benzaldehyde (**4**, 1.91 g, 7.50 mmol) dissolved in hexane (10 mL) was added dropwise, and the solution was stirred for 12 h. Acidification with hydrochloric acid (37%) yielded a yellow precipitate, which was isolated by filtration, washed with hexane, and dried in vacuo to give **5** as a white powder (3.46 g, 7.20 mmol, 96%). $^1$H NMR ($CDCl_3$, 300.1 MHz): $\delta$ = 7.26–7.18 (m, 4 H, Ar-H), 7.01 (s, 1 H, C*H*–OH), 7.00 (dd, 2 H, Ar-H), 3.66 (sept, 2 H, SCH), 3.50 (sept, 2 H, SCH), 1.37 (d, 12 H, $CH_3$), 1.24 (d, 12 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$, 75.5 MHz): $\delta$ = 148.3, 144.9, 131.4, 128.7, 126.3, 124.5 (Ar-C), 72.0 (CH–OH), 39.1 (SCH), 36.1 (SCH), 25.5 ($CH_3$), 25.1 ($CH_3$) ppm. IR (KBr): $\tilde{\nu}$ = 3457 (br., O–H), 3050 (s, Ar-H), 2960, 2923, 2863 (s, $CHMe_2$), 1557 (m, Ar-C=C), 1443 (s, CH) $cm^{-1}$. MS (EI, 70 eV): *m/z* (%) = 480 (64) $[M]^+$, 437 (73) $[M - C_3H_7]^+$, 405 (100) $[M - SC_3H_7]^+$. $C_{25}H_{36}OS_4$ (480.16): calcd. C 62.45, H 7.55, S 26.68; found C 62.51, H 7.47, S 26.44.

**Bis[2,3-bis(isopropylmercapto)phenyl]methane (6):** Iodine (80 mg, 0.31 mmol) and bis[2,3-bis(isopropylmercapto)phenyl]methanol (**5**, 1.50 g, 3.10 mmol) were dissolved in concentrated acetic acid (60 mL). Hypophosphorous acid (1.60 mL, 50% solution by weight in water) was added, and the solution was stirred at 60 °C for 24 h. Water (100 mL) was added at ambient temperature, and the aqueous phase was extracted with hexane (3 × 50 mL). The combined organic layers were washed with saturated $NaHCO_3$ solution (2 × 20 mL) and dried with $MgSO_4$, and the solvent was removed in vacuo. Column chromatography ($SiO_2$, $Et_2O$/hexane, 1:5) gave **6** as a white powder (1.41 g, 3.04 mmol, 98%). $^1$H NMR ($CDCl_3$, 300.1): $\delta$ = 7.20–7.15 (m, 4 H, Ar-H), 6.80–6.75 (dd, 2 H, Ar-H), 4.72 (s, 2 H, $CH_2$), 3.54 (m, 4 H, SCH), 1.45 (d, 12 H, $CH_3$), 1.30 (d, 12 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$, 75.5 MHz): $\delta$ = 149.1, 147.4, 134.3, 130.9, 128.6, 126.6 (Ar-C), 42.5 ($CH_2$), 41.3 (SCH), 38.1 (SCH), 25.5 ($CH_3$), 25.1 ($CH_3$) ppm. IR (KBr): $\tilde{\nu}$ = 3048 (Ar-H), 2960, 2923, 2863 (s, $CHMe_2$), 1443 (s, $CH_2$) $cm^{-1}$. MS (EI, 70 eV): *m/z* (%) = 464 (8) $[M]^+$, 421 (5) $[M - C_3H_7]^+$, 389 (100) $[M - SC_3H_7]^+$, 357 (53) $[M - S_2C_3H_7]^+$. $C_{25}H_{36}S_4$ (464.17): calcd. C 64.60, H 7.81, S 27.59; found C 64.47, H 7.87, S 27.72.

**Bis(2,3-dimercaptophenyl)methane ($H_4$-1):** Compound **6** (3.80 g, 8.19 mmol) and naphthalene (5.20 g, 41.0 mmol) were dissolved in tetrahydrofurane (80 mL), and pieces of sodium (1.90 g, 82 mmol) were added. The mixture was stirred for 12 h at ambient temperature, and degassed methanol (15 mL) was then added dropwise. After 10 min, the solvent was removed in vacuo, and the residue was dissolved in degassed water (30 mL). The aqueous phase was washed with degassed diethyl ether (3 × 20 mL), filtered, and acidified with hydrochloric acid (37%). The product was extracted with dichloromethane (3 × 20 mL), the combined organic layers were dried with $MgSO_4$, and the solvent was removed in vacuo to give $H_4$-**1** as an off-white powder (2.33 g, 7.78 mmol, 96%). $^1$H NMR ($CDCl_3$, 300.1 MHz): $\delta$ = 7.34 (dd, $^3J$ = 7.9, $^4J$ = 1.3 Hz, 2 H, Ar-H), 7.00 (t, $^3J$ = 7.9 Hz, 2 H, Ar-H), 6.78 (dd, $^3J$ = 7.9, $^4J$ = 1.3 Hz, 2 H, Ar-H), 4.18 (s, 2 H, $CH_2$), 3.84 (s, 2 H, SH), 3.81 (s, 2 H, SH) ppm. $^{13}$C NMR ($CDCl_3$, 75.5 MHz): $\delta$ = 141.5, 134.7, 133.2, 131.5, 129.7, 128.3 (Ar-C), 43.3 ($CH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3050 (s, Ar-H), 2894 (m, C–H), 2525 (m, S–H), 1443, 717 (C–H) $cm^{-1}$. MS (EI, 70 eV): *m/z* (%) = 296 (76) $[M]^+$, 263 (85) $[M - SH]^+$, 230 (100) $[M - 2SH]^+$, 197 (47) $[M - 3SH]^+$. $C_{13}H_{12}S_4$ (295.98): calcd. C 52.67, H 4.08, S 43.25; found C 53.22, H 3.88, S 43.82.

**$(PNP)_4[Co_4(1)_4]$ (7):** A solution of $H_4$-**1** (50 mg, 0.169 mmol) and $Li_2CO_3$ (25 mg, 0.34 mmol) in methanol (10 mL) was added to a solution of $CoCl_2 \cdot 6H_2O$ (40 mg, 0.169 mmol) in methanol (10 mL). The mixture was stirred for 12 h, exposed to air for 10 min, and filtered. Addition of bis(triphenylphosphoranylidene)ammonium chloride (PNPCl) (97 mg, 0.169 mmol) to the filtrate gave a blue precipitate of **7**, which was isolated by filtration, washed with methanol, and dried in vacuo (110 mg, 0.031 mmol, 74%). MS (ESI, negative ions): *m/z* (%) = 351.0 $[Co_4(\mathbf{1})_4]^{4-}$, 648 $[(Co_4(\mathbf{1})_4)^{4-} + PNP^+]^{3-}$, 1241 $[(Co_4(\mathbf{1})_4)^{4-} + 2\,PNP^+]^{2-}$. $C_{196}H_{152}N_4P_8S_{16}Co_4$ (3559.7): calcd. C 66.13, H 4.30, N 1.57, S 14.41; found C 65.77, H 4.42, N 1.48, S 14.28.

**X-ray Crystallographic Study of 7:** A suitable crystal of **7** (0.15 × 0.10 × 0.08 mm) was mounted on a Bruker AXS APEX diffractometer equipped with a rotating molybdenum anode ($\lambda$ = 0.71073 Å), cooling device, and graphite monochromator. $(PNP)_4[Co_4(\mathbf{1})_4]$, $C_{196}H_{152}N_4P_8S_{16}Co_4$, $M$ = 3559.7, triclinic $P\bar{1}$, $a$ = 18.473(7), $b$ = 19.797(7), $c$ = 24.497(9) Å, $\alpha$ = 80.724(7), $\beta$ = 89.026(7), $\gamma$ = 79.787(7)°, $V$ = 8701(6) Å$^3$, $Z$ = 2, $\rho_{calcd.}$ = 1.359 g $cm^{-3}$, $\mu$ = 0.696 $mm^{-1}$. 54025 Structure factors ($-19 \le h \le 19$, $-21 \le k \le 21$, $-26 \le l \le 26$, $2\theta$ range 2.1–55.0°) were collected at 123(2) K. An empirical absorption correction was applied ($T_{min}$ = 0.903, $T_{max}$ = 0.947) before merging gave 22725 unique intensities ($R_{int}$ = 0.069). Structure solution with SHELXS[22] and subsequent refinement of 2053 parameters against $F^2$ of 22725 unique intensities [13118 observed intensities $I > 2\sigma(I)$] using SHELXL[23] with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were added to the structure model on calculated positions. Final residues $R$ = 0.0591, $wR$ = 0.1186. CCDC-284858 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Hydride Transfer Reactivity of $Mo(L)(H)(depe)_2$ (L = N, $NBEt_3$)

**Johan Cugny,[a] Helmut W. Schmalle,[a] Thomas Fox,[a] Olivier Blacque,[a] Montserrat Alfonso,[a] and Heinz Berke*[a]**

**Keywords:** Hydride complexes / Hydride transfer reaction / Insertion reaction / Nitride complexes / Phosphane complexes / Molybdenum

Starting from $Mo(N_2)_2(depe)_2$ (**1**), the nitrido complex Mo(N)$(N_3)(depe)_2$ (**2**) was obtained by the reaction of **1** with $Me_3SiN_3$. Subsequent reaction of **2** with HCl in $CH_3OH$ afforded the cationic imido chloride **3**, which could be converted into the nitrido chloride **4** with sodium bis(trimethylsilyl)amide. From **3** and **4** the hydrido complexes of the type Mo(H)(L)$(depe)_2$ [L = N (**7**), $NBEt_3$ (**8**)] were obtained by the reaction with the hydride reagents $LiBH_4$ and $NaHBEt_3$. The hydridic character of the $L_nM$–H bond of **8** was determined by DQCC measurements (bond ionicity $i$ = 81%). Hydride reactivity studies were carried out on **7** and **8**; however, only **8** underwent hydride transfer reactions. **8** reacted with 4,4′-dichlorobenzophenone and acetophenone to afford the corresponding alkoxide complexes Mo$(NBEt_3)$(OCHRR′)$(depe)_2$ [R, R′ = $C_6H_4Cl$ (**10**); R = Me, R′ = Ph (**11**)]. The high propensity of **8** to undergo carbonyl insertion was documented further by reactions with $CO_2$ and carbonylmetal compounds. Conversion with $CO_2$ led to formation of the formato complex Mo(N$BEt_3$)(OCHO)$(depe)_2$ (**9**) and reactions with $Fe(CO)_5$ and $Re_2(CO)_{10}$ resulted in the formation of Mo[(μ-OCH)Fe$(CO)_4$]$(NBEt_3)(depe)_2$ (**12**) and Mo[(μ-OCH)$Re_2(CO)_9$]$(NBEt_3)$(depe)$_2$ (**13**). X-ray diffraction studies were carried out on **1**–**4**, **6**, **8**–**10** and **12**–**14**.

## Introduction

For various homogeneous catalyses the activation of $L_nM$–H bonds[1–13] (M = transition metal) plays a decisive role. Insertion reactions of these bonds with unsaturated molecules are strongly dependent on the ancillary ligand sphere.[14] An increasing number of strongly σ-donating *cis*-phosphane substituents are expected to enhance the electron density on the metal center and on the hydrido ligand.[15] The ligand *trans* to the hydrido ligand is attributed a crucial *trans* influence. In a DFT study[16] the three complexes $LW(H)(dmpe)_2$ with L = NO, CH and N were compared and analyzed according to their various *trans* influences. The $L_nM$–H bond strength was found to decrease in the order NO > CH > N suggesting in this order increasing hydride transfer activity.

The nitrido ligand ($N^{3-}$)[21–23] is regarded as a strong *trans*-influence ligand and a very strong π-donor; similar in this property may only be the isoelectronic oxo ligand. A combined experimental and theoretical study[24] has compared the Cr–L bonds with L = $O_{oxo}$, $N_{nitrido}$ and $C_{carbyne}$. From a natural bond orbital analysis, bond lengths and topological analyses of the total electron density, the bond order and the total binding interaction of this multiple bond is in the order Cr–N > Cr–O > Cr–C. The nitrido moiety is therefore expected to display an additional nucleophilic behaviour for early and middle transition metal complexes in high oxidation states.[25] The reactivity patterns of related hydrido complexes with *trans* ligands L = NO and CMes were reported earlier so that it remains to study the influence of the nitrido ligand.[14,17–20]

We describe here the synthesis of molecules based on nitrido ligands such as $Mo(H)(L)(depe)_2$ (L = N and $NBEt_3$) and we present also reactivity studies carried out with the $Mo(H)(NBEt_3)(depe)_2$ complex.

## Results and Discussion

### Hydrido Nitrido Complexes

A common route to access nitrido complexes consists of the decomposition of (azido)metal complexes. The synthetic route described in this paper was thus largely inspired by the initial work of Chatt and Dilworth[26] with some modifications developed in the group of Pickett.[27] For the synthesis of $Mo(N_2)_2(depe)_2$ (**1**) we applied the procedure described by George and Noble[28] which utilizes the reduction of $MoCl_5$ with sodium amalgam followed by the addition of the phosphane ligand under dinitrogen. The bis(dinitrogen) species **1** was obtained in 69% yield and characterized by an X-ray diffraction study (crystallographic data for **1** in the Supporting Information). The de-

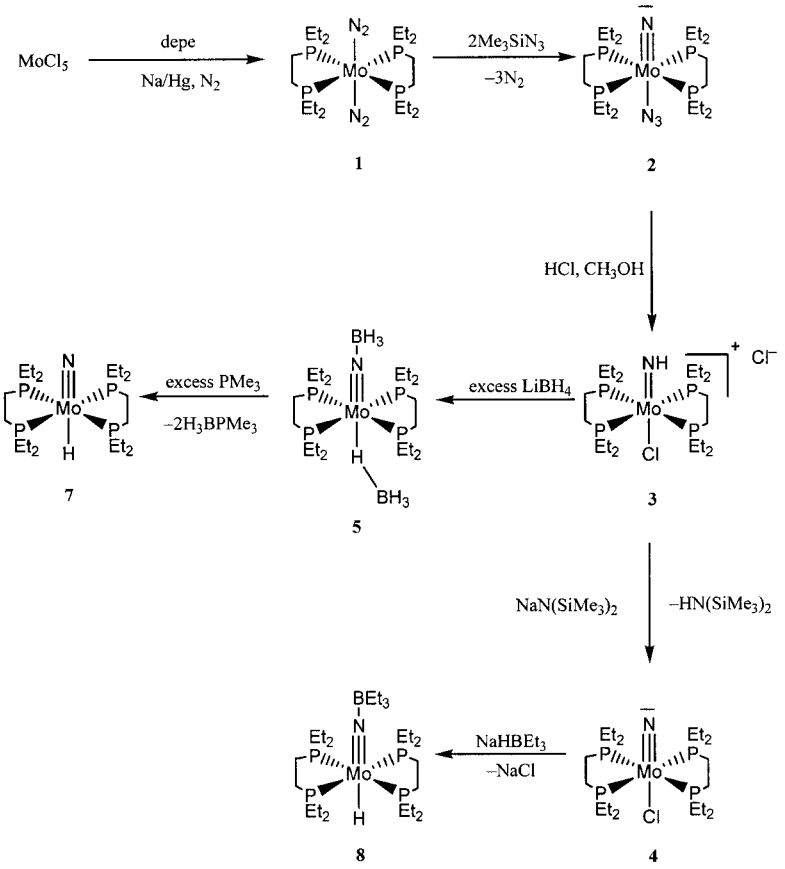
sired nitrido function was formed by treatment of **1** with trimethylsilyl azide[29,30] to yield the known compound Mo(N)(N$_3$)(depe)$_2$ (**2**). The imido derivative [Mo(Cl)(NH)(depe)$_2$][Cl] (**3**) was then produced by protonation of **2**, dissolved in methanol, with a small amount of aqueous concentrated hydrochloric acid in $CH_3OH$.

Suitable crystals of **2** and **3** for X-ray diffraction studies were grown from a saturated THF solution at –30 °C (crystallographic data for both complexes are available in the Supporting Information).

According to literature[26,31,32] the imido group can be deprotonated by a suitable base. In this study sodium bis(trimethylsilyl)amide in toluene was used, which prevents side reactions and leads to higher yields[32] of the nitrido species Mo(Cl)(N)(depe)$_2$ (**4**) (Scheme 1).

The structure of **4** was additionally confirmed by an X-ray diffraction analysis (Figure 1) using a single crystal obtained by cooling of a saturated toluene solution to –30 °C. Three independent molecules were found in the asymmetric unit. For all of which a pseudooctahedral geometry was observed with the two depe ligands in equatorial and the chloride ion and nitrido group in *trans* positions. The average of the Mo–N bonds of 1.699(5) Å is slightly shorter than those observed in similar (R$_2$P–CH$_2$–CH$_2$–PR$_2$)$_2$(X)-Mo≡N complexes [1.79(2) Å for R = Ph, X = N–N≡N,[33] 1.704(6) Å for R = Ph, X = N≡C–C(CN)=C(O)(CH$_3$)[34] and 1.704(3) Å for R = Ph, X = N≡C–C(H)=C(O)(Ph)[35]] which confirms the triple bond character of this unit. The *trans* influence of the nitride group is demonstrated by a long Mo–Cl distance [average value 2.772(2) Å], which is by more than 0.3 Å longer in comparison with the unweighted mean value of 2.410 Å reported in the literature.[36]

The preparation of two types of hydrido nitrido complexes was achieved. Starting from **3**, the borohydride Mo($\eta^1$-HBH$_3$)(NBH$_3$)(depe)$_2$ (**5**) was obtained when an excess of LiBH$_4$ in THF was applied. The $^1$H NMR spectrum of **5** in [D$_8$]THF revealed a broad quadruplet at $\delta$ = –2.90 ppm with a characteristic $^{11}$B coupling ($^1J_{HB}$ = 88 Hz), which was assigned to the protons of the tetrahydroborate moiety. The $^{11}$B NMR spectrum furthermore showed a quadruplet at $\delta$ = –15.9 ppm ($^1J_{HB}$ = 82 Hz) for the BH$_3$ unit on the nitrido group, and a quintuplet at $\delta$ = –44.6 ppm ($^1J_{HB}$ = 82 Hz) for the BH$_4$ unit. Presumably, the reaction to **5** proceeded via the intermediate Mo(Cl)(NBH$_3$)(depe)$_2$ (**6**), since the reaction of **3** with just 1 equiv. of LiBH$_4$ indeed yields **6**. In the $^1$H NMR spectrum a broad signal appeared at $\delta$ = 2.4 ppm, which was attributed to the NBH$_3$ moiety. The $^{11}$B NMR spectrum of **6** revealed one quadruplet at $\delta$ = –13.5 ppm for the NBH$_3$ unit and its $^{31}$P{$^1$H} NMR spectrum displayed a singlet at $\delta$ = 49.0 ppm indicating the presence of the four chemically equivalent phosphorus nuclei. A unique crystal of **6** suitable for an X-ray diffraction analysis was obtained from a saturated THF solution at –30 °C. Figure 2 shows the molecular



Scheme 1.

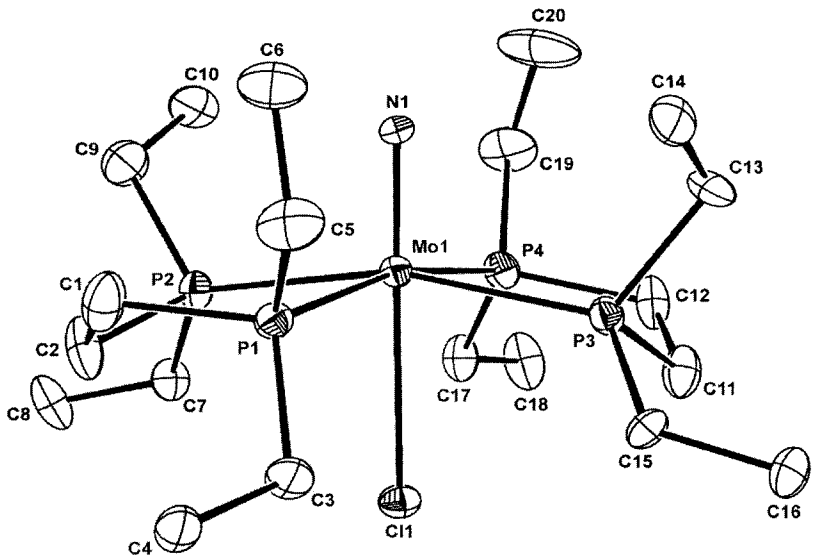

Figure 1. Molecular structure of **4**; only one of the three independent molecules is shown. Selected bond lengths [Å] and angles [°]: Mo1–N1 1.690(5), Mo1–Cl1 2.7901(19), N1–Mo1–Cl1 177.6(2) (molecule 1), Mo2–N2 1.684(5), Mo2–Cl2 2.7406(17), N2–Mo2–Cl2 175.06(18) (molecule 2) and Mo3–N3 1.722(5), Mo3–Cl3 2.7859(19), N3–Mo3–Cl3 174.23(19) (molecule 3). The displacement ellipsoids are of 20% probability and all hydrogen atoms have been omitted for clarity.

structure of **6**. Disorder was recognized between the $NBH_3$ and Cl groups, which prevented an accurate comparison of the bond parameters of **4** and **6**. On a rough scale, however, a significantly shorter Mo–Cl bond of 2.621(2) Å seems to be present in **6**, which speaks for a weaker *trans* influence of the $NBH_3$ unit in **6** with respect to that of the nitrido group in **4**.

Treatment of the borohydride species **5** with an excess of $PMe_3$ in toluene at 120 °C for 11 d resulted in the formation of the desired hydride Mo(H)(N)(depe)$_2$ (**7**). The $^1$H NMR spectrum of **7** in $C_6D_6$ displayed at room temperature, among other resonances, that of the hydrido ligand as a quintuplet at $\delta$ = –5.99 ppm ($^2J_{HP}$ = 30 Hz). The $^{31}$P{$^1$H} NMR spectrum reveals a singlet at $\delta$ = 80.6 ppm.

The $NBEt_3$-substituted hydrido complex **8** was obtained from the nitrido chloride **4** by treatment with a slight excess of the hydride reagent $NaHBEt_3$ in THF at room temperature for 15 h. Due to the considerable basicity of the ter-

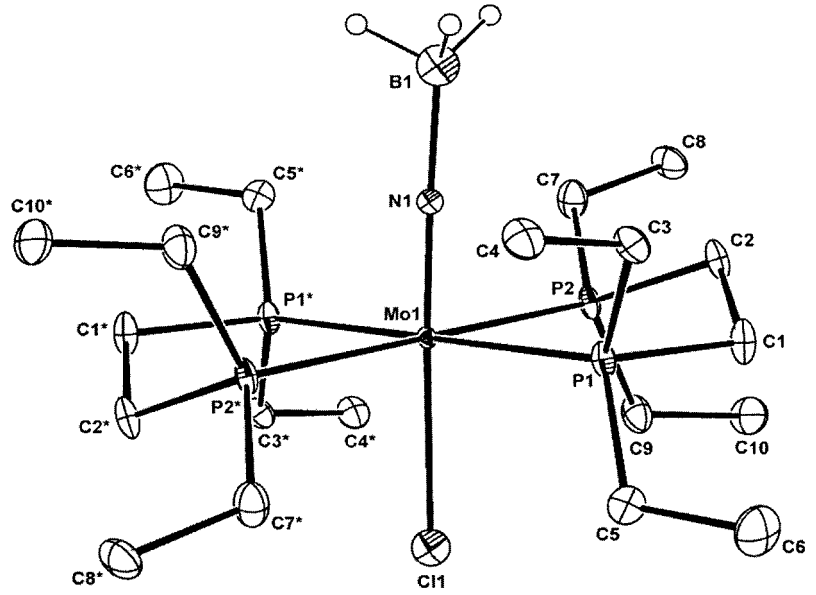

Figure 2. Molecular structure of **6** (ellipsoids are drawn at the 30% probability level). Selected bond lengths [Å] and angles [°]: Mo1–N1 1.656(4), Mo1–Cl1 2.621(2), N1–B1 1.62(1); N1–Mo1–Cl1 177.49(13), B1–N1–Mo1 177.9(4). The molybdenum center lies on a special position (inversion center) and half of the molecule is reproduced by the symmetry operation 1 – *x*, 1 – *y*, 1 – *z* (the symmetry-related atoms are labeled with an asterisk). The hydrogen atoms of the $BH_3$ group have been refined with soft B–H distance restraints. The $NBH_3$/Cl disorder and selected hydrogen atoms have been omitted for clarity.

minal nitrido group the "leftover" $BEt_3$ moiety is scavenged after $H^-$ transfer to the Mo center. The $^1H$ NMR spectrum of **8** shows a characteristic resonance for the hydrido ligand as a quintuplet at $\delta$ = –6.23 ppm ($^2J_{HP}$ = 36 Hz). The presence of the *N*-bound $BEt_3$ group was confirmed by a $CH_2$ resonance in the $^1H$ NMR spectrum appearing as a 1:3:3:1 quadruplet at $\delta$ = 0.86 ppm ($^3J_{HH}$ = 8 Hz) and a triplet for the Me groups at $\delta$ = 1.36 ppm ($^3J_{HH}$ = 8 Hz). In the $^{13}C$ NMR spectrum the signal of the $CH_2$ groups of the $BEt_3$ moiety could not be detected. Their chemical shift at $\delta$ = 18.9 ppm could only be extracted from a C–H correlation spectrum of **8**.

The molecular structure of **8** was confirmed by an X-ray diffraction analysis. It exhibits pseudooctahedral coordination of the Mo center with the two depe ligands in equatorial positions and the hydrido ligand and the $NBH_3$ group *trans* to each other (Figure 3). The hydride atom was found in the difference electron density map. It could be refined isotropically (0.022 Å$^2$). The Mo–H bond length of 1.85(2) Å compares well with that observed for the Mo(H)(CO)(NO)(PMe$_3$)$_3$ complex [1.84(3) Å].[19] The Mo–N bond of 1.7571(14) is longer than in **4** [1.698(5) Å], presumably due to the attached $BEt_3$ group which apparently reduces the strength of the metal–nitrogen triple bond.

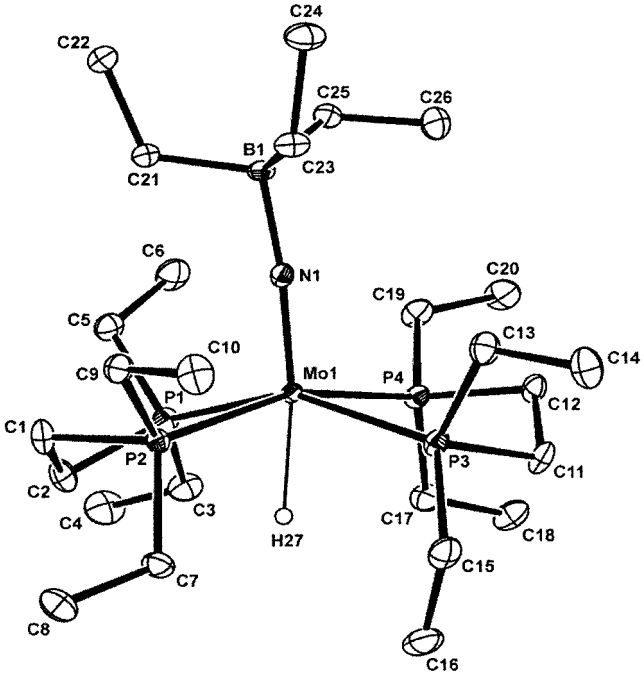

Figure 3. Molecular structure of **8** (ellipsoids are drawn at the 30% probability level). Selected bond lengths [Å] and angles [°]: Mo1–N1 1.7571(14), Mo1–H27 1.85(2), N1–B1 1.568(2), N1–Mo1–H27 171.2(7), B1–N1–Mo1 173.69(14). All hydrogen atoms have been omitted for clarity, except the hydrido atom H27 for which the positional parameters were freely refined.

### Hydridic Character of the *trans*-Mo(H)(NBEt$_3$)(depe)$_2$ Complex 8

Different approaches to classify the L$_n$M–H bond in terms of its hydridic character are based either on kinetic or thermodynamic studies of hydride transfer reactions. Cheng and Bullock[37] determined kinetic hydridicities by the reaction of L$_n$M–H bonds (M = transition metal) with the trityl cation. The work of Sarker and Bruno[38] rely on the equilibration of both types of species to establish a thermodynamic scale of hydridicities. Bond ionicities may also be taken as an indicator for the hydridic character of the L$_n$M–H bond. We used $^2H$ NMR spectroscopy to determine the deuterium quadrupole coupling constant (DQCC) of the D nucleus by measuring the temperature-dependent $T_{1min}$ relaxation time in [H$_8$]toluene[39,40] and also by calculation of the DQCC from the "Pake doublet" appearing in the static solid-state NMR spectrum, preferably at low temperatures. For these experiments the deuterium derivative Mo(D)(NBEt$_3$)(depe)$_2$ (**8a**) had to be prepared using LiDBEt$_3$ instead of NaHBEt$_3$. According to the $T_{1min}$ method, the DQCC of the deuteride **8a** was calculated to be 43 ± 1 kHz. The ionicity of the Mo–D(H) is thus 81.0 ± 0.4% and stresses the strong polarity of the Mo–D bond in **8a**. This bond ionicity belongs to the largest ionicities reported for transition metal hydrides.[41] From the solid-state $^2H$ NMR spectra a Δ value of the "Pake doublet" of 31.1 kHz is obtained, from which the DQCC was calculated to be 42 ± 1 kHz corresponding to a bond ionicity of 81.7 ± 0.5% very close to the value obtained by the $T_{1min}$ method.

### Hydride Transfer Reactions of Mo(H)(N)(depe)$_2$ (7) and *trans*-Mo(H)(NBEt$_3$)(depe)$_2$ (8)

Very much to our surprise, the hydride **7** turned out to be very unreactive. It did not react with ketones or carbonylmetal compounds and produced a mixture of unidentified products in the presence of $CO_2$. The reason for this is yet unclear, especially in view of the fact that the very related derivative **8**, distinguished from **7** by an additional Lewis acid bound to the nitrido ligand, showed various hydride transfer reactions.

The Mo–H bond of **8** was shown to be highly polarized and at least in a kinetic sense this complex seemed to be prone to undergo hydride transfer reactions, i.e. insertions with a wide variety of unsaturated compounds such as $CO_2$,[42–48] ketones and carbonylmetal compounds (Scheme 2). Reaction of **8** with an excess of $CO_2$ (450 mbar at –196 °C) in [D$_8$]toluene indeed proceeded smoothly at room temeperature. The reaction was complete after a few minutes and the *O*-formate product Mo(OCHO)(NBEt$_3$)(depe)$_2$ (**9**) was isolated in 70% yield as analytically pure yellow crystals after recrystallisation from diethyl ether solution. The formate group of **9** displayed a singlet resonance at $\delta$ = 8.04 ppm in the $^1H$ NMR spectrum and a singlet resonance at $\delta$ = 166.0 ppm in the $^{13}C$ NMR spectrum. The IR spectrum of **9** revealed two intense bands at 1611 and 1320 cm$^{-1}$ for the formate ligand, in accordance with other $\eta^1$-formate complexes reported in the literature.[49,50] The structure of **9** was finally confirmed by an X-ray diffraction analysis (Figure 4).

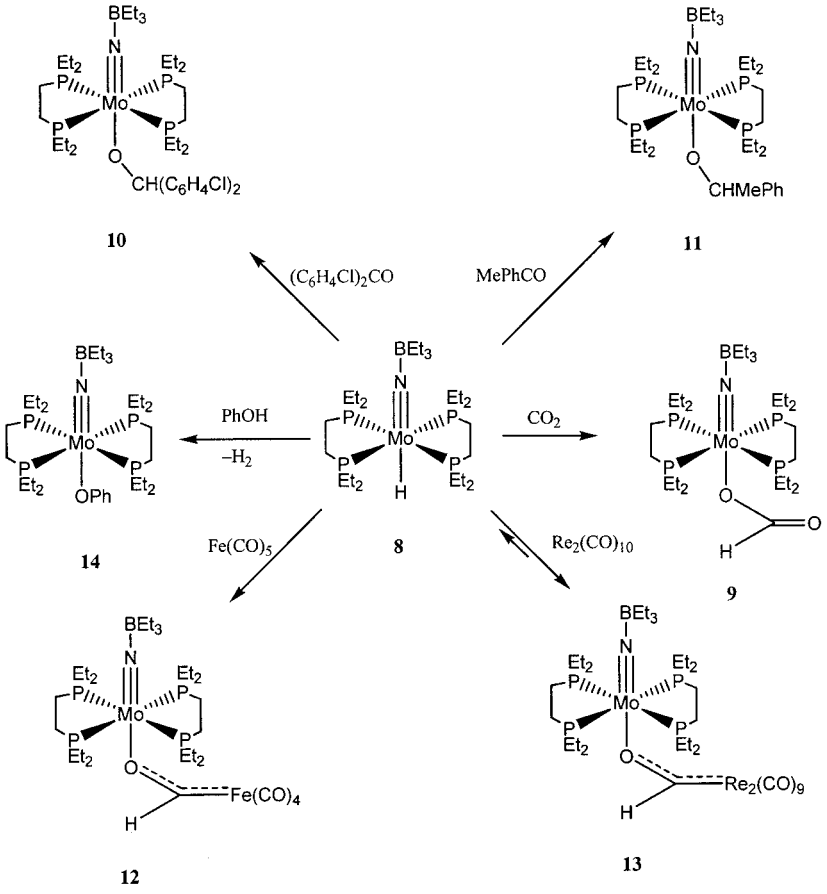

Scheme 2.

The molybdenum centre adopts a pseudooctahedral geometry, with the $NBEt_3$ moiety and the $\eta^1$-formato ligand *trans* to each other. The structure revealed an Mo–O bond length of 2.214(2) Å.[18,50,51] The Mo–N and N–B bond lengths of 1.713(3) Å and 1.609(5) Å, respectively, are similar to those of **10** and **14**.

Reactions of **8** with 4,4′-dichlorobenzophenone and acetophenone were completed at 60 °C in 1 d and at room temperature in 3 d, respectively, to afford the corresponding alkoxide complexes *trans*-$Mo(OCHRR')(NBEt_3)(depe)_2$ [R = R′ = *p*-$C_6H_4Cl$ (**10**); R = Ph, R′ = Me (**11**)]. 4,4′-Dichlorobenzophenone was chosen as a model reagent for disubstituted aromatic ketones, because of difficulties faced in the reaction of **8** with the parent benzophenone where two products were obtained, which could not be separated. In the $^1H$ NMR spectrum compound **10** shows a singlet at $\delta$ = 4.68 ppm and a characteristic signal at $\delta$ = 83.1 ppm in the $^{13}C$ NMR spectrum, both being attributed to the Mo–OCH moiety. In a similar manner, the OCH moiety of complex **11** was identified by a quadruplet at $\delta$ = 4.11 ppm ($^3J_{HH}$ = 6.3 Hz) in the $^1H$ NMR spectrum and by a singlet at $\delta$ = 75.1 ppm in the $^{13}C$ NMR spectrum. Single crystals of **10** suitable for X-ray diffraction analysis were obtained by cooling a concentrated solution of **10** in diethyl ether to –30 °C.

As shown in Figure 5, the molybdenum center of **10** exhibits a pseudooctahedral coordination environment similar to that of the complexes mentioned before. This structure shows an Mo–O bond length of 2.1781(16) Å, in the range of those reported in related structures.[19,52] The Mo1–N1 bond length of 1.733(2) Å falls into the range of those observed for **8** and **9**, while the N1–B1 bond length of 1.612(4) is similar to that in **9**.

The insertion of CO into an activated $L_nM$–H bond could result in the formation of a formyl species. This reaction has been proposed to be a key step in the homogeneous hydrogenation of CO. However, the direct product of CO insertion into an $L_nM$–H bond to give a metal-bound formyl group has only rarely been observed,[53–57] because in most cases this step is thermodynamically not favourable. Despite this, metal-bound CO was found to insert into strongly polar $L_nM$–H bonds. Insertion of **8** with $Fe(CO)_5$ and $Re_2(CO)_{10}$ was thus attempted affording the μ-formyl complexes *trans*-$Mo[(\mu\text{-}OCH)Fe(CO)_4](NBEt_3)(depe)_2$ (**12**) and *trans*-$Mo[(\mu\text{-}OCH)Re_2(CO)_9](NBEt_3)(depe)_2$ (**13**). Compound **12** was isolated as yellow crystals after recrystallisation from a saturated toluene solution. In contrast to the reaction with $Fe(CO)_5$, the reaction with $Re_2(CO)_{10}$ in toluene reaches an equilibrium after 2 d which is strongly shifted to the formyl side. Analytically pure

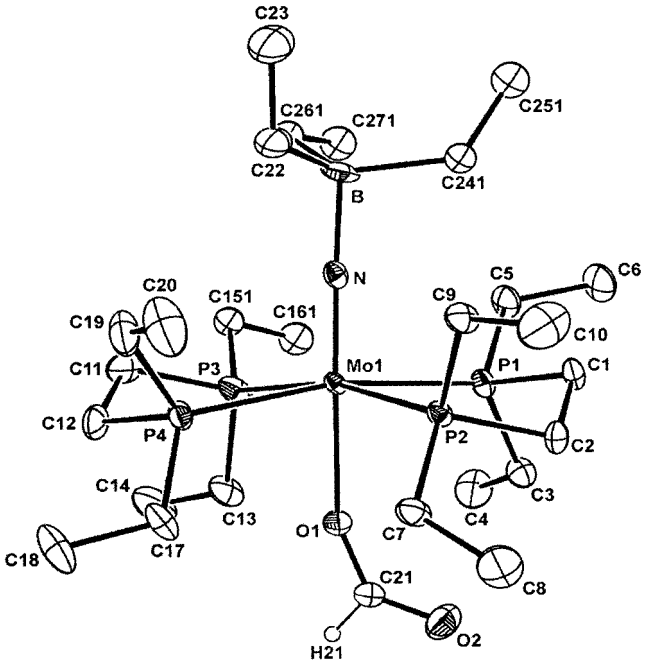

Figure 4. Molecular structure of **9** (ellipsoids are drawn at the 30% probability level). Selected bond lengths [Å] and angles [°]: Mo1–N 1.713(3), Mo1–O1 2.214(2), N–B 1.609(5), O1–C21 1.234(4), Mo1–*N*–B 177.5(3), N–Mo1–O1 179.07(13), Mo1–O1–C21 157.6(3). Selected hydrogen atoms and the disordered ethyl groups on the phosphorus atom P3 and on the boron atom have been omitted for clarity.

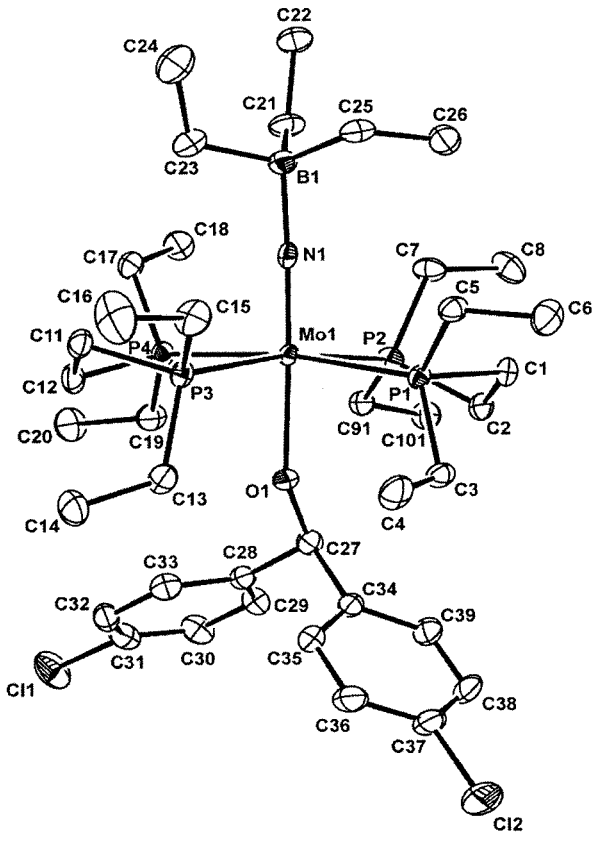

Figure 5. Molecular structure of **10** (ellipsoids are drawn at the 30% probability level). Selected bond lengths [Å] and angles [°]: Mo1–N1 1.732(2), N1–B1 1.612(4), Mo1–O1 2.1781(16), Mo1–N1–B1 177.1(2), N1–Mo1–O1 177.39(8), Mo1–O1–C27 147.98(16). All hydrogen atoms and the disordered ethyl group of the phosphorus atom P2 have been omitted for clarity.

orange crystals of **13** were obtained by crystallization from toluene. Among other resonances, the $^1$H NMR spectra of **12** and **13** show characteristic $H_{formyl}$ signals at $\delta$ = 13.78 ppm and at $\delta$ = 14.91 ppm in a typical chemical shift region reported for similar complexes.[14,17,19,52] The $^{31}$P NMR spectrum displays a singlet for the four equivalent phosphorus nuclei at $\delta$ = 52.2 ppm and at $\delta$ = 54.4 ppm for **12** and **13**, respectively. In the low-field region the $^{13}$C NMR spectra consist of a broad signal for the $C_{formyl}$ atom at $\delta$ = 293.2 ppm and $\delta$ = 289.5 ppm for **12** and **13**, respectively. In the IR spectrum of **12** the ν(CO) bands of the $Fe(CO)_4$ moiety appear at 2020, 1966 and 1870 cm$^{-1}$ and in the IR spectrum of **13** seven bands at 2094, 2070, 2025, 2007, 1969, 1935 and 1902 cm$^{-1}$ are found, which were assigned to the ν(CO) vibrations of the $Re_2(CO)_9$ unit.

The X-ray structures of **12** and **13** are presented in Figures 6 and 7. Both coordination geometries around the Mo centers possess a distorted octahedral arrangement. The μ-formyl bond lengths in **12** [1.219(3) Å] and **13** [1.250(4) Å] are noticeably different, with a longer separation in the rhenium complex **13** indicating a stronger π-donation of the $Re_2(CO)_9$ fragment.

The potential for hydrogenations using **8** was tested by the reaction of the hydride with acetone in the presence of a proton donor (PhOH) simulating a stoichiometric "ionic hydrogenation". The reaction of **8** with the phenol alone was so fast that instantaneous formation of $H_2$ and the phenoxy complex **14** was observed (signal at $\delta$ = 4.45 ppm in the $^1$H NMR spectrum). A crystal of **14** suitable for an X-ray analysis was obtained from a saturated diethyl ether solution at –30 °C. The molecular structure of **14** shows the molybdenum atom in pseudo-octahedral environment with the phenoxy[58] group and the $Et_3BN$ ligand *trans*-disposed to each other (Figure 8).

The hydrogenation of cyclohexene was also attempted using **8** without the presence of an acidic substrate. A Young NMR tube was pressurized with 1700 mbar $H_2$ in the presence of complex **8** (1%). After 12 d at 110 °C, 94% of the cyclohexene was found to be hydrogenated to cyclohexane. The $^1$H NMR spectrum of the reaction mixture showed that the typical signals of the cyclohexene starting material ($\delta$ = 5.59, 1.85, 1.46 ppm) decreased, while the characteristic resonance for cyclohexane ($\delta$ = 1.34 ppm) appeared. The presence of the cyclohexane was further confirmed by GC-MS. However, **8** could not be recovered. The $^{31}$P NMR showed the presence of the free depe phosphane ($\delta$ = –17.9 ppm) among several unidentified signals indicating that **8** is a precursor to the irreversibly formed catalytically active species, which presumably coordinates only one depe ligand.

All hydrogen atoms, except H1, and the co-crystallized solvent molecule of toluene have been omitted for clarity.

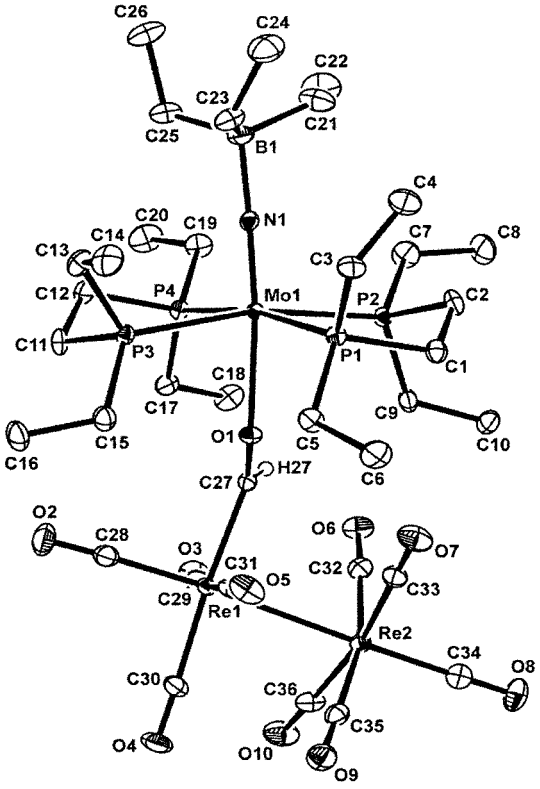

Figure 7. Molecular structure of **13** (ellipsoids are drawn at the 40% probability level). Selected bond lengths [Å] and angles [°]: Mo1–N1 1.712(3), Mo1–O1 2.350(2), N1–B1 1.625(5), C27–O1 1.250(4), Re1–C27 2.137(4), Re1–Re2 3.0511(3), Mo1–O1–C27 139.4(2), Re1–C27–O1 130.6(3), C27–Re1–Re2 91.26(10), N1–Mo1–O1 173.63(12), Mo1–N1–B1 176.0(3). All hydrogen atoms, except H27, have been omitted for clarity.

## Conclusion

Two transition metal hydride complexes of the type $Mo(H)(L)(depe)_2$ [L = N (**7**), $NBEt_3$ (**8**)] were prepared. Since a high propensity for insertion reactions was found for **8**, but not for **7**, hydridicity and reactivity of **8** were investigated in detail. Even though this difference in chemical behaviour is yet unexplained, it indicates that slight alterations in the coordination sphere may cause rather pronounced reactivity changes of the $L_nM$–H bond; an important circumstance for any hydride tuning efforts.

## Experimental Section

**General:** Reagent grade benzene, toluene, pentane, diethyl ether and tetrahydrofuran were dried and distilled from sodium benzophenone ketyl prior to use. MeOH was dried and distilled from Mg. Literature procedures were used to prepare the following compounds: 1,2-bis(diethylphosphanyl)ethane (depe)[59] and $PMe_3$.[60] Other reagents were purchased and used without further purification. All the manipulations were carried out under nitrogen using Schlenk techniques or a dry glovebox. IR spectra were obtained with a Bio-Rad FTS-45 instrument and Raman spectra were obtained with a Renishaw Labram Raman spectrometer. Mass spectra were obtained with a Finnigan-MAT-8400 spectrometer. Gas chromatography-mass spectra (GC-MS) were recorded with a Varian-Chrompack CP-3800 gas chromatograph equipped with a Saturn 2000 electron impact mass spectrometer (EI-MS). The samples were carried by an He flow through a CP-SIL 8 CB-MS FS 30 × 25 (.25) column; flow: 1 mL/ min, split: 100:1, EI: 70 eV, isothermal method at 30 °C. NMR spectra were measured with a Varian Mercury 200 spectrometer at 81.0 MHz for $^{31}P\{^1H\}$, with a Varian Gemini 300 spectrometer at 300.1 MHz for $^1H$, 121.5 MHz for $^{31}P\{^1H\}$, 75.4 MHz for $^{13}C\{^1H\}$ and 96.2 MHz for $^{11}B\{^1H\}$ and with a Bruker-DRX-500 spectrometer at 500.2 MHz for $^1H$, 202.5 MHz for $^{31}P\{^1H\}$, 125.8 MHz for $^{13}C\{^1H\}$, 36.2 MHz for $^{14}N$ and 32.5 MHz for $^{95}Mo$. Chemical shifts for $^1H$ and $^{13}C$ are given in ppm relatively to TMS ($SiMe_4$), the $^{31}P\{^1H\}$ NMR spectra were referenced to 98% external $H_3PO_4$, $^{11}B$ relative to $Et_2O{\cdot}BF_3$, $^{14}N$ relative to $CH_3NO_2$ and $^{95}Mo$ relative to $MoO_4^{2-}$. Elemental analyses: Leco CHN(S)-932 instrument.

**Preparation of *trans*-$Mo(N_2)_2(depe)_2$ (1):** Ligand depe (0.744 g, 3.61 mmol) was added dropwise to 20 mL of a THF suspension of 1% Na amalgam under nitrogen. Then sublimed $MoCl_5$ (0.410 g, 1.5 mmol) was added and the brown solution was stirred for 18 h. The solution was filtered twice through Celite which was then rinsed with toluene. The solvent was removed under vacuum and the resulting precipitate dissolved in 30 mL of toluene. The solution was filtered further twice through Celite, and brought to a volume of 12 mL under vacuum; 24 mL of MeOH was added to precipitate the product at –30 °C within 15 h. The orange needles were filtered off, washed with MeOH and then dried under vacuum. Yield of **1**:

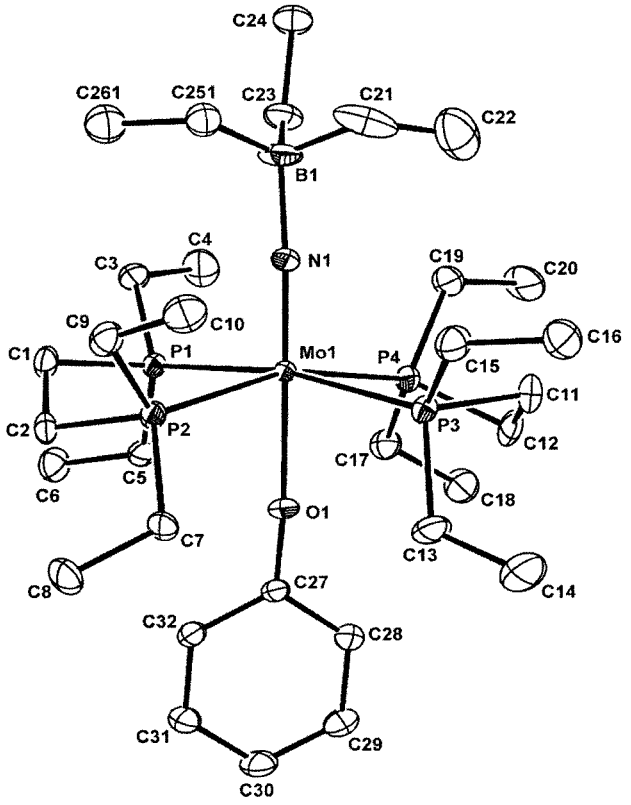

Figure 8. Molecular structure of **14** (ellipsoids are drawn at the 30% probability level). Selected bond lengths [Å] and angles [°]: Mo1–N1 1.719(2), Mo1–O1 2.1656(18), N1–B1 1.603(4), Mo1–O1–C27 175.43(19), N1–Mo1–O1 178.05(10), Mo1–N1–B1 176.8(2). All hydrogen atoms and the disordered ethyl group on the boron atom have been omitted for clarity.

0.592 mg, 1.04 mmol, 69%. $^1$H NMR ($C_6D_6$, 298 K, 300.1 MHz): $\delta$ = 1.83 (m, 16 H, PC$H_2$CH$_3$), 1.35 [m, 8 H, P(C$H_2$)$_2$P], 1.09 (m, 24 H, PCH$_2$C$H_3$) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$, 298 K, 121.5 MHz): $\delta$ = 56.7 (s) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, 298 K, 75.4 MHz): $\delta$ = 23.7 [m, P(*C*H$_2$)$_2$P], 21.4 (m, P*C*H$_2$CH$_3$), 8.7 (m, PCH$_2$*C*H$_3$) ppm. IR (KBr): $\tilde{\nu}$ = 1921 [$\nu_{asym}$(N$_2$)] cm$^{-1}$. Raman: $\tilde{\nu}$ = 1997 [$\nu_{sym}$(N$_2$)] cm$^{-1}$. $C_{20}H_{48}MoN_4P_4$ (564.45): calcd. C 42.56, H 8.57, N 9.93; found C 42.86, H 8.44, N 9.88.

**Preparation of *trans*-Mo(N)(N$_3$)(depe)$_2$ (2):** Complex **1** (0.507 mg, 0.90 mmol) was dissolved in 30 mL of THF in a round-bottomed flask and trimethylsilyl azide (0.32 mL, 2.43 mmol) was added. The mixture was refluxed for at least 1 h. The reddish solution was filtered through Celite and concentrated under vacuum. The solid was rinsed with pentane and dried under vacuum to afford a brown solid. Yield of **2**: 0.449 mg, 0.79 mmol, 88%. $^1$H NMR ($C_6D_6$, 293 K, 300.1 MHz): $\delta$ = 2.11–1.73 (m, 16 H, PC$H_2$CH$_3$), 1.52 [br. m, 4 H, P(CH$_2$)$_2$P], 1.36 [br. m, 4 H, P(CH$_2$)$_2$P], 1.20 (m, 12 H, PCH$_2$C$H_3$), 1.02 (m, 12 H, PCH$_2$C$H_3$) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$, 293 K, 121.5 MHz): $\delta$ = 59.2 (br. s) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, 293 K, 75.4 MHz): $\delta$ = 22.2 [m, P(*C*H$_2$)$_2$P], 21.8 (m, P*C*H$_2$CH$_3$), 19.0 (m, P*C*H$_2$CH$_3$), 8.5 (s, PCH$_2$*C*H$_3$), 7.5 (s, PCH$_2$*C*H$_3$) ppm. IR (ATR): $\tilde{\nu}$ = 2022 [$\nu_{asym}$(N$_3$)], 977 [$\nu$(Mo≡N)] cm$^{-1}$. Raman: $\tilde{\nu}$ = 1342 [$\nu_{sym}$(N$_3$)] cm$^{-1}$. $C_{20}H_{48}MoN_4P_4$ (564.45): calcd. C 42.56, H 8.57, N 9.93; found C 42.92, H 8.45, N 9.56.

**Preparation of *trans*-[Mo(Cl)(NH)(depe)$_2$][Cl] (3):** Compound **2** (0.412 g, 0.73 mmol) was dissolved in 15 mL of MeOH and a few drops of 32% aqueous HCl were added. A darkening of the red solution was observed. The solution was stirred for 15 min and then the solvent was removed under vacuum. The precipitate was dissolved in THF, the solution filtered through Celite, concentrated under vacuum, and the residue washed three times with pentane and dried under vacuum to yield a red powder. Yield of **3**: 349 mg, 0.59 mmol, 80%. $^1$H NMR ([D$_8$]THF, 295 K, 500.2 MHz): $\delta$ = 2.07 (m, 16 H, PC$H_2$CH$_3$), 1.92 [br. m, 8 H, P(C$H_2$)$_2$P], 1.21 (m, 24 H, PCH$_2$C$H_3$) ppm. $^{31}$P{$^1$H} NMR ([D$_8$]THF, 295 K, 202.5 MHz): $\delta$ = 47.5 (s) ppm. $^{13}$C{$^1$H} NMR ([D$_8$]THF, 295 K, 125.8 MHz): $\delta$ = 23.2 [m, P(*C*H$_2$)$_2$P], 19.0 (m, P*C*H$_2$CH$_3$), 8.3 (s, PCH$_2$*C*H$_3$) ppm. $C_{20}H_{49}Cl_2MoNP_4$ (594.35): calcd. C 40.42, H 8.31, N 2.36; found C 40.03, H 7.97, N 2.07.

**Preparation of *trans*-Mo(Cl)(N)(depe)$_2$ (4):** Compound **3** (203.6 mg, 0.34 mmol) was suspended in 15 mL of toluene and a 0.6 M solution of NaN(SiMe$_3$)$_2$ in toluene (1.14 mL, 0.68 mmol) was added. The precipitate was dissolved and the solution stirred overnight. The brown solution was filtered through Celite and concentrated under vacuum. Then **4** was extracted with pentane and the solution concentrated under vacuum to yield a brown powder. Yield of **4**: 123.5 mg, 0.22 mmol, 64%. $^1$H NMR ($C_6D_6$, 293 K, 500.2 MHz): $\delta$ = 2.38 (m, 4 H, PC$H_2$CH$_3$), 1.88 (m, 4 H, PC$H_2$CH$_3$), 1.80 (m, 4 H, PC$H_2$CH$_3$), 1.75 (m, 4 H, PC$H_2$CH$_3$), 1.64 [br. m, 4 H, P(C$H_2$)$_2$P], 1.41 [br. m, 4 H, P(C$H_2$)$_2$P], 1.27 (m, 12 H, PCH$_2$C$H_3$), 1.04 (m, 12 H, PCH$_2$C$H_3$) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$, 293 K, 121.5 MHz): $\delta$ = 56.0 (s) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, 293 K, 125.8 MHz): $\delta$ = 22.4 [m, P(*C*H$_2$)$_2$P], 21.7 (m, P*C*H$_2$CH$_3$), 19.4 (m, P*C*H$_2$CH$_3$), 9.0 (s, PCH$_2$*C*H$_3$), 7.8 (s, PCH$_2$*C*H$_3$) ppm. IR (KBr): $\tilde{\nu}$ = 984 [$\nu$(Mo≡N)] cm$^{-1}$. Raman: $\tilde{\nu}$ = 915 [$\nu$(Mo≡N)] cm$^{-1}$. MS (EI): *m*/*z* = 560 [M$^+$], 353 [M$^+$ – 1 depe]. $C_{20}H_{48}ClMoNP_4$ (557.88): calcd. C 43.06, H 8.67, N 2.51; found C 43.35, H 8.53, N 2.63.

**Preparation of *trans*-Mo($\eta^1$-HBH$_3$)(NBH$_3$)(depe)$_2$ (5):** Complex **3** (1.0192 g, 1.71 mmol) was mixed with LiBH$_4$ (28.8 mg, 8.59 mmol), dissolved in 50 mL of THF. Evolution of gas, assumed to be H$_2$, was observed and the mixture was stirred overnight. The solution was filtered through Celite and concentrated under vacuum. The precipitate was dissolved in toluene, the solution filtered through Celite twice and concentrated under vacuum to afford a brown powder. Yield of **5**: 502 mg, 0.91 mmol, 53%. $^1$H NMR ([D$_8$]THF, 293 K, 500.2 MHz): $\delta$ = 2.17–1.93 (m, 16 H, PC$H_2$CH$_3$), 1.83 [br. m, 8 H, P(C$H_2$)$_2$P], 1.44 (br., 3 H, B$H_3$), 1.25 (m, 12 H, PCH$_2$C$H_3$), 1.18 (m, 12 H, PCH$_2$C$H_3$), –2.9 (q, 4 H, *H*B$H_3$, $^1J_{HB}$ = 82 Hz) ppm. $^{31}$P{$^1$H} NMR ([D$_8$]THF, 293 K, 202.5 MHz): $\delta$ = 47.0 (s) ppm. $^{13}$C{$^1$H} NMR ([D$_8$]THF, 293 K, 125.8 MHz): $\delta$ = 22.5 [m, P(*C*H$_2$)$_2$P], 19.8 (m, P*C*H$_2$CH$_3$), 19.4 (m, P*C*H$_2$CH$_3$), 9.1 (s, PCH$_2$*C*H$_3$), 8.6 (s, PCH$_2$*C*H$_3$) ppm. $^{11}$B NMR ([D$_8$]THF, 293 K, 160.5 MHz): $\delta$ = –15.9 (q, 1 B, N*B*H$_3$, $^1J_{HB}$ = 88 Hz), –44.62 (quint, 1 B, H*B*H$_3$, $^1J_{HB}$ = 82 Hz) ppm. IR (ATR): $\tilde{\nu}$ = 2290 [$\nu$(B–H)] cm$^{-1}$. $C_{20}H_{55}B_2MoNP_4$ (551.11): calcd. C 43.59, H 10.06, N 2.54; found C 43.27, H 10.35, N 2.24.

**Preparation of *trans*-Mo(Cl)(NBH$_3$)(depe)$_2$ (6):** Compound **3** (50.7 mg, 0.085 mmol) was mixed with LiBH$_4$ (1.85 mg, 0.085 mmol), dissolved in 15 mL of THF. H$_2$ gas evolution was observed and the mixture was stirred overnight. The solution was filtered through Celite and concentrated under vacuum; the precipitate was dissolved in toluene, the solution filtered twice again through Celite and concentrated under vacuum to yield a yellow powder. Yield of **6**: 39.2 mg, 0.069 mmol, 80%. $^1$H NMR ($C_6D_6$, 293 K, 300.1 MHz): $\delta$ = 2.4 (q, 3 H, B$H_3$, $^1J_{HB}$ = 85 Hz), 2.17–1.93 (m, 16 H, PC$H_2$CH$_3$), 1.83 [br. m, 8 H, P(C$H_2$)$_2$P], 1.18 (m, 12 H, PCH$_2$C$H_3$), 0.95 (m, 12 H, PCH$_2$C$H_3$) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$, 293 K, 121.5 MHz): $\delta$ = 49.0 (s) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, 293 K, 75.4 MHz): $\delta$ = 21.7 [m, P(*C*H$_2$)$_2$P], 19.3 (m, P*C*H$_2$CH$_3$),

18.1 (m, P*C*H$_2$CH$_3$), 9.1 (s, PCH$_2$*C*H$_3$), 8.2 (s, PCH$_2$*C*H$_3$) ppm. $^{11}$B NMR ([H$_8$]THF, 293 K, 96.2 MHz): $\delta$ = –13.5 (q, 1 B, N*B*H$_3$, $^1J_{HB}$ = 95 Hz) ppm. IR (ATR): $\tilde{\nu}$ = 2287 [ν(B–H)] cm$^{-1}$. $C_{20}H_{51}BClMoNP_4$ (571.72): calcd. C 42.01, H 8.99, N 2.45; found C 41.88, H 8.95, N 2.23.

**Preparation of *trans*-Mo(H)(N)(depe)$_2$ (7):** A mixture of **5** (502 mg, 0.91 mmol) with an excess of PMe$_3$ (1.41 mL, 13.6 mmol) was dissolved in 40 mL of toluene in an autoclave. The autoclave was placed in an oil bath at 120 °C for 11 d. The solution was concentrated under vacuum; **7** was extracted into pentane, the solution filtered through Celite and concentrated under vacuum to yield a red oil. Yield of **7**: 347.5 mg, 0.66 mmol, 73%. $^1$H NMR (C$_6$D$_6$, 293 K, 500.2 MHz): $\delta$ = 1.54 [br. m, 24 H, P(C*H*$_2$)$_2$P, PC*H*$_2$CH$_3$], 1.14 (br. m, 24 H, PCH$_2$C*H*$_3$), –5.99 (quint, 1 H, Mo–*H*, $^2J_{PH}$ = 30 Hz) ppm. $^{31}$P{$^1$H} NMR (C$_6$D$_6$, 293 K, 202.5 MHz): $\delta$ = 80.6 (s, $^1J_{PMo}$ = 102 Hz) ppm. $^{13}$C{$^1$H} NMR (C$_6$D$_6$, 293 K, 125.8 MHz): $\delta$ = 28.2 [br., P*C*H$_2$CH$_3$, P(*C*H$_2$)$_2$P], 9.3 (br., PCH$_2$*C*H$_3$) ppm. $^{14}$N{$^1$H} NMR (C$_6$D$_6$, 293 K, 36.2 MHz): $\delta$ = –71.6 (s) ppm. $^{95}$Mo NMR (C$_6$D$_6$, 293 K, 32.5 MHz): $\delta$ = –2062 (quint, $^1J_{PMo}$ = 102 Hz) ppm. MS (EI): *m*/*z* = 526 [M$^+$]. $C_{20}H_{49}MoNP_4$ (523.4): calcd. C 45.89, H 9.44, N 2.68; found C 45.66, H 9.62, N 2.71.

**Preparation of *trans*-Mo(H)(NBEt$_3$)(depe)$_2$ (8):** Complex **4** (291.8 mg, 0.52 mmol) was dissolved in THF (40 mL) and a 1 M solution of NaHBEt$_3$ in THF (0.54 mL, 0.54 mmol) was added. The reaction mixture was stirred at room temperature for 1 d. The solvent was removed under vacuum and the precipitate was extracted into pentane, the solution filtered through Celite and concentrated under vacuum. The crude product was recrystallised from a saturated diethyl ether solution by cooling to –30 °C to afford yellow-orange crystals. Yield of **8**: 385.5 mg, 0.48 mmol, 92%. $^1$H NMR (C$_6$D$_6$, 293 K, 500.2 MHz): $\delta$ = 2.18 (br. m, 8 H, PC*H*$_2$CH$_3$), 1.65 (br. m, 4 H, PC*H*$_2$CH$_3$), 1.48 [br. m, 4 H, P(C*H*$_2$)$_2$P], 1.37 [br. m, 4 H, P(C*H*$_2$)$_2$P], 1.36 (t, 9 H, BCH$_2$C*H*$_3$, $^3J_{HH}$ = 7.5 Hz), 1.25 (br. m, 4 H, PC*H*$_2$CH$_3$), 1.17 (m, 12 H, PCH$_2$C*H*$_3$), 0.77 (m, 12 H, PCH$_2$C*H*$_3$), 0.68 (q, 6 H, BC*H*$_2$CH$_3$, $^3J_{HH}$ = 7.5 Hz), –6.23 (quint, 1 H, Mo–*H*, $^2J_{PH}$ = 36 Hz) ppm. $^{31}$P{$^1$H} NMR (C$_6$D$_6$, 293 K, 202.5 MHz): $\delta$ = 65.5 (s) ppm. $^{13}$C{$^1$H} NMR (C$_6$D$_6$, 293 K, 125.8 MHz): $\delta$ = 24.8 (m, P*C*H$_2$CH$_3$), 23.6 [m, P(*C*H$_2$)$_2$P], 23.5 (m, P*C*H$_2$CH$_3$), 18.9 (br., B*C*H$_2$CH$_3$), 12.7 (s, BCH$_2$*C*H$_3$), 9.2 (s, PCH$_2$*C*H$_3$), 8.1 (s, PCH$_2$*C*H$_3$) ppm. $^{11}$B{$^1$H} NMR (C$_6$D$_6$, 293 K, 160.5 MHz): $\delta$ = –1.7 (s, 1 B, N*B*Et$_3$) ppm. IR (ATR): $\tilde{\nu}$ = 1417 [ν(Mo–H)] cm$^{-1}$. $C_{26}H_{64}BMoNP_4$ (621.43): calcd. C 50.25, H 10.38, N 2.25; found C 50.18, H 10.49, N 2.22.

**Preparation of *trans*-Mo(D)(NBEt$_3$)(depe)$_2$ (8a):** Complex **8a** was obtained by an analogous procedure as for **8**, using LiDBEt$_3$ instead of NaHBEt$_3$. $^2$H NMR ([H$_8$]toluene, 293 K, 76.79 MHz): $\delta$ = –6.51 (br.) ppm. $^{31}$P{$^1$H} NMR ([H$_8$]toluene, 293 K, 202.5 MHz): $\delta$ = 65.1 (t, $^2J_{PD}$ = 5.4 Hz) ppm.

**Preparation of *trans*-Mo[$^1$η-OC(O)H](NBEt$_3$)(depe)$_2$ (9):** The hydrido complex **8** (42.4 mg, 0.068 mmol) was dissolved in 0.5 mL of [D$_8$]toluene in a Young NMR tube, which was put under 450 mbar of CO$_2$ at 77 K. The reaction mixture was warmed to room temperature. The solution became light orange and after 30 min the solvent and the excess of CO$_2$ were removed under vacuum. The compound was extracted into Et$_2$O and the solution filtered through Celite. Recrystallisation from Et$_2$O at –30 °C afforded yellow crystals. Yield of **9**: 31.9 mg, 0.048 mmol, 70%. $^1$H NMR (C$_6$D$_6$, 293 K, 300.1 MHz): $\delta$ = 8.04 (s, 1 H, OC*H*O), 2.2 [br. m, 4 H, P(CH$_2$)$_2$P], 2.10 (br. m, 8 H, PC*H*$_2$CH$_3$), 1.64 [br. m, 4 H, P(CH$_2$)$_2$P], 1.51 (br. m, 8 H, PC*H*$_2$CH$_3$), 1.19 (t, 9 H, BCH$_2$C*H*$_3$, $^3J_{HH}$ = 7.3 Hz), 1.11 (m, 12 H, PCH$_2$C*H*$_3$), 0.87 (m, 12 H, PCH$_2$C*H*$_3$), 0.55 (q, 6 H, BC*H*$_2$CH$_3$, $^3J_{HH}$ = 7.3 Hz) ppm. $^{31}$P{$^1$H} NMR (C$_6$D$_6$, 293 K, 121.5 MHz): $\delta$ = 52.3 (s) ppm. $^{13}$C{$^1$H} NMR (C$_6$D$_6$, 293 K, 125.8 MHz): $\delta$ = 166.0 (s, O*C*HO), 21.6 [m, P(*C*H$_2$)$_2$P], 21.4 (m, P*C*H$_2$CH$_3$), 19.5(br., B*C*H$_2$CH$_3$), 18.0 (m, P*C*H$_2$CH$_3$), 12.6 (s, BCH$_2$*C*H$_3$), 9.3 (s, PCH$_2$*C*H$_3$), 7.9 (s, PCH$_2$*C*H$_3$) ppm. $^{11}$B{$^1$H} NMR (C$_6$D$_6$, 293 K, 96.2 MHz): $\delta$ = 0.3 (br., 1 B, N*B*Et$_3$) ppm. IR (ATR): $\tilde{\nu}$ = 1611 [$\nu_{asym}$(COO)], 1320 [$\nu_{sym}$(COO)] cm$^{-1}$. $C_{27}H_{64}BMoNP_4O_2$ (665.44): calcd. C 48.73, H 9.69, N 2.11; found C 48.91, H 9.75, N 2.15.

**Preparation of *trans*-Mo[$^1$η-OCH(PhCl)$_2$](NBEt$_3$)(depe)$_2$ (10):** 15.4 mg (0.061 mmol, 1.1 equiv.) of 4,4′-dichlorobenzophenone was added to a [D$_8$]toluene solution (0.7 mL) of Mo(H)(NBEt$_3$)-(depe)$_2$ (34 mg, 0.055 mmol). After 1 d at 60 °C, the solvent was removed under vacuum to afford a light orange powder. The precipitate was washed with pentane and then the product was extracted with diethyl ether. Crystallization from diethyl ether at –30 °C gave yellow single crystals. Yield of **10**: 37.9 mg, 0.043 mmol, 80%. $^1$H NMR ([D$_8$]toluene, 293 K, 500.2 MHz): $\delta$ = 6.92 (d, 4 H, Ph, $^3J_{HH}$ = 8.4 Hz), 6.78 (d, 4 H, Ph, $^3J_{HH}$ = 8.4 Hz), 4.68 (s, C*H*O), 2.12–2.00 [br., 8 H, P(C*H*$_2$)$_2$P], 1.48 (br., 8 H, PC*H*$_2$CH$_3$), 1.29 (br., 8 H, PC*H*$_2$CH$_3$), 1.06 (m, 12 H, PCH$_2$C*H*$_3$), 1.04 [t, 9 H, B(CH$_2$C*H*$_3$)$_3$, $^3J_{HH}$ = 7.7 Hz], 0.79 (m, 12 H, PCH$_2$C*H*$_3$), 0.35 [q, 6 H, B(C*H*$_2$CH$_3$)$_3$, $^3J_{HH}$ = 7.4 Hz] ppm. $^{31}$P{$^1$H} NMR ([D$_8$]toluene, 293 K, 121.5 MHz): $\delta$ = 48.15 (s, 4 P) ppm. $^{13}$C{$^1$H} NMR ([D$_8$]toluene, 293 K, 125,8 MHz): $\delta$ = 150.8 (s, *i*-Ph), 131.5 (s, *p*-Ph), 129.0 (t, Ph), 128.0 (t, Ph), 83.1 (s, O*C*H), 21.8–21.6 [m, P(*C*H$_2$)$_2$P and P*C*H$_2$CH$_3$], 20.9–20.1 [br., B(*C*H$_2$CH$_3$)$_3$], 19.9 (P*C*H$_2$CH$_3$), 12.9 [s, B(CH$_2$*C*H$_3$)$_3$], 9.1 (s, PCH$_2$*C*H$_3$), 8.4 (s, PCH$_2$*C*H$_3$) ppm. $^{11}$B NMR ([D$_8$]toluene, 293 K, 96.2 MHz): $\delta$ = 3.5 [br., *B*(C*H*$_2$CH$_3$)$_3$] ppm. $C_{39}H_{72}BCl_2MoNOP_4$ (872.54): calcd. C 53.68, H 8.32, N 1.61; found C 53.67, H 8.36, N 1,63.

**Preparation of *trans*-Mo[$^1$η-OCH(Me)Ph](NBEt$_3$)(depe)$_2$ (11):** Complex **8** (36.8 mg, 0.059 mmol) was dissolved in 0.5 mL of C$_6$D$_6$ in a Young NMR tube. Then acetophenone (6.9 μL, 0.059 mmol) was added by a micro-syringe. After 3 d of standing at room temperature, the solution was concentrated under vacuum and the solid was dissolved in diethyl ether, the solution filtered through Celite and put in a refrigerator at –30 °C where yellow crystals were obtained. Yield of **11**: 40.5 mg, 0.054 mmol, 92%. $^1$H NMR (C$_6$D$_6$, 293 K, 300.1 MHz): $\delta$ = 7.11–6.97 (m, 5 H, Ph), 4.11 [q, 1 H, OC*H*(Me)Ph, $^3J_{HH}$ = 6.3 Hz], 2.20 (br. m, 8 H, PC*H*$_2$Me), 1.75 [br. m, 4 H, P(CH$_2$)$_2$P], 1.60–1.54 (br. m, 8 H, PC*H*$_2$Me), 1.38 [br. m, 4 H, P(CH$_2$)$_2$P], 1.25 (t, 9 H, BCH$_2$C*H*$_3$, $^3J_{HH}$ = 7.5 Hz), 1.18 (m, 12 H, PCH$_2$C*H*$_3$), 0.96 (d, 3 H, OCHC*H*$_3$Ph, $^3J_{HH}$ = 6 Hz), 0.92 (m, 12 H, PCH$_2$C*H*$_3$), 0.52 (q, 6 H, BC*H*$_2$Me, $^3J_{HH}$ = 7.5 Hz) ppm. $^{31}$P{$^1$H} NMR (C$_6$D$_6$, 293 K, 121.5 MHz): $\delta$ = 48.1 (s) ppm. $^{13}$C{$^1$H} NMR (C$_6$D$_6$, 293 K, 125.8 MHz): $\delta$ = 128.0–126.7 (m, Ph), 75.1 (s, O*C*HMePh), 30.3 [s, OCH(*C*H$_3$)Ph], 21.8 [m, P(*C*H$_2$)$_2$P], 21.4 (m, PC*H*$_2$CH$_3$), 19.9 (br., B*C*H$_2$Me), 17.3–17.6 (m, PC*H*$_2$Me), 13.1 (s, BCH$_2$*C*H$_3$), 9.5 (s, PCH$_2$*C*H$_3$), 8.2 (s, PCH$_2$*C*H$_3$) ppm. $^{11}$B{$^1$H} NMR (C$_6$D$_6$, 293 K, 96.2 MHz): $\delta$ = –2.5 (s, 1 B, N*B*Et$_3$) ppm. $C_{34}H_{72}BMoNP_4O$ (741.58): calcd. C 55.07, H 9.79, N 1.89; found C 55.25, H 10.01, N 1.90.

**Preparation of *trans*-Mo(NBEt$_3$)[(μ-OCH)Fe(CO)$_4$](depe)$_2$ (12):** 6.74 μL (0.05 mmol) of pentacarbonyliron was added to a [D$_8$]toluene solution (0.7 mL) of hydride **8** (13 mg, 0.05 mmol). After 30 min at room temperature, the solution was filtered through Celite and the solvent was removed under vacuum to afford a light orange powder. Then the product was extracted with toluene. Crystallization from toluene at –30 °C gave yellow single crystals. Yield of **12**: 35.7 mg, 0.044 mmol, 88%. $^1$H NMR ([D$_8$]toluene,

**Preparation of *trans*-Mo(OPh)(NBEt$_3$)(depe)$_2$ (14):** Complex **8** (34 mg, 0.055 mmol) was dissolved in 0.4 mL of [D$_8$]toluene in a Young NMR tube and phenol (6 mg, 0.064 mmol) was added. The reaction occurred instantaneously. The solvent was removed under vacuum and the residue was extracted into diethyl ether and the solution filtered through Celite. The product **14** crystallized from diethyl ether at –30 °C to afford yellow crystals. Yield of **14**: 24 mg, 0.034 mmol, 61%. $^1$H NMR (C$_6$D$_6$, 293 K, 300.1 MHz): $\delta$ = 7.08 (d, 2 H, *m*-Ph, $^1J_{HH}$ = 7.5 Hz), 6.54 (t, 1 H, *p*-Ph, $^1J_{HH}$ = 7.8 Hz), 5.91 (d, 2 H, *o*-Ph, $^1J_{HH}$ = 8.1 Hz), 2.23 (br. m, 4 H, PC$H_2$CH$_3$), 2.14 (br. m, 4 H, PC$H_2$CH$_3$), 1.70 (br. m, 4 H, PC$H_2$CH$_3$), 1.63 [br. m, 8 H, P(CH$_2$)$_2$P], 1.38 (br. m, 4 H, PC$H_2$CH$_3$), 1.22 (t, 9 H, BCH$_2$C$H_3$, $^3J_{HH}$ = 7.5 Hz), 1.18 (m, 12 H, PCH$_2$C$H_3$), 0.83 (m, 12 H, PCH$_2$C$H_3$), 0.55 (q, 6 H, BC$H_2$CH$_3$, $^3J_{HH}$ = 7.5 Hz) ppm. $^{31}$P{$^1$H} NMR (C$_6$D$_6$, 293 K, 121.5 MHz): $\delta$ = 52.4 (s) ppm. $^{13}$C{$^1$H} NMR (C$_6$D$_6$, 293 K, 125.8 MHz): $\delta$ = 129.0 (s, *m*-Ph), 119.5 (s, *o*-Ph), 114.0 (s, *p*-Ph), 21.8 [m, P(*C*H$_2$)$_2$P], 21.5 (m, PC$H_2$CH$_3$), 19.5 (br., BC$H_2$CH$_3$), 17.3 (m, PC$H_2$CH$_3$), 12.9 (s, BCH$_2$C$H_3$), 9.6 (s, PCH$_2$C$H_3$), 7.8 (s, PCH$_2$C$H_3$) ppm. $^{11}$B{$^1$H} NMR (C$_6$D$_6$, 293 K, 96.2 MHz): $\delta$ = –0.9 (br., 1 B, N*B*Et$_3$) ppm. IR (ATR, 22 °C): $\tilde{\nu}$ = 1309 [$\nu$(OPh)] cm$^{-1}$. $C_{32}H_{68}BMoNP_4O$ (713.53): calcd. C 53.86, H 9.61, N 1.96; found C 53.71, H 9.33, N 1.84.

**Attempt of Stoichiometric "Ionic Hydrogenation" of Acetone by 8 in the Presence of Phenol:** Compound **8** (6.3 mg, 0.01 mmol) was dissolved in 0.4 mL of [D$_8$]THF in a Young NMR tube. Then 0.73 μL of acetone (0.58 mg, 0.01 mmol) and PhOH (1 mg, 0.01 mmol) were added. Formation of complex **14** was detected by NMR spectroscopy. A product of hydrogenation could not be observed.

**Hydrogenation of Cyclohexene:** To a [D$_8$]toluene solution (0.7 mL) of Mo(H)(NBEt$_3$)(depe)$_2$ (**8**) (3.8 mg, 0.006 mmol) was added 66 μL (0.65 mmol) of cyclohexene in a Young NMR tube. The reaction mixture was degassed in 3 freeze-pump-thaw cycles. H$_2$ (1400 mbar) was applied at 77 K. The catalytic reaction was carried out at 110 °C. After 24 h, cyclohexane (8%) could be detected spectroscopically. In the $^{31}$P NMR spectrum characteristic signals of the free phosphane ligand were observed. After an additional period of 31 h, the amount of cyclohexane was 25% and it had hardly changed after 45 h. Another flush of H$_2$ (1739 mbar) was then introduced at 77 K to the solution mixture. After 9 d at 110 °C, the amount of cyclohexane had reached 94%. Cyclohexane: $^1$H NMR ([D$_8$]toluene, 300 MHz, 20 °C): $\delta$ = 1.34 (s, 6 H). GC-MS: $t_r$ = 1.63 min; $m/z$ = 83 [M$^+$].

**X-ray Crystal Structure Analyses:** Crystallographic data for compounds **4**, **6**, **8**–**10** and **12**–**14** are collected in Tables 1 and 2. All crystals were embedded in polybutene oil within a glove box, mounted on glass fibers and fixed by a cold N$_2$ stream of an Oxford Cryogenic System at the diffractometer. Measurement temperatures of 153(2) K for compound **6**, 173(2) K for compound **4** and 183(2) K for the remaining compounds were used. An imaging plate detector system (Stoe IPDS) with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) was used for the exposure of 222, 176, 200, 182, 200, 236, 300 and 187 images at constant times of 3.5, 3.0, 1.6, 8.0, 4.0, 6.0, 4.0 and 3.0 min per image.[61] The crystal-to-image distances were set to 50 mm for **6**, **8**, **9**, **10**, **12** and **14**, to 64 mm for **13** and to 70 mm for **4**; φ-rotation (for **6** and **8**) and φ-oscillation modes (for **4**, **9**, **10**, **12**, **13** and **14**) were necessary for the increments of 1.7 and 1.1° or of 0.9, 1.0, 1.0, 1.1, 0.7 and 1.0° per exposure in each case. The intensities were integrated by using a dynamic peak profile analysis, and an estimated mosaic spread (EMS) check was performed to prevent overlapping intensities. For the cell parameter refinements, 7998 (**4**, **12** and **14**), 8000 (**8** and **9**) and 8001 reflections[61] (**6**, **10** and **13**) were selected out of the whole limiting spheres with intensities $I > 6\sigma(I)$. A total of 59134, 12588, 43658, 37490, 53007, 33565, 43402 and 23754 reflections were collected, of which 16225, 3869, 9585, 10353, 12539, 11856, 10343 and 11186 were unique after performing absorption correction and data reduction ($R_{int}$ = 16.02, 5.62, 8.57, 11.06, 8.70, 7.43, 4.99 and 8.77%). A total of 12, 10, 10, 11, 12, 12, 10 and 15 indexed crystal faces were used for the numerical absorption corrections.[62] The structures were solved with the merged unique data set after checking for correct space groups. The Patterson method was used to solve the crystal structures by applying the software options of the program SHELXS-97.[63] The structure refinements were performed with the program SHELXL-97.[63] The programs PLATON[64] and PLUTON[65] were used to check the results of the X-ray analyses. The crystal structure of compound **4** showed a superstructure with three independent complexes in the asymmetric unit of the monoclinic cell (space group $P2_1/c$). A complete check with PLATON[64] did not suggest a higher symmetry system or space group. Compound **6** crystallized in the centrosymmetric triclinic space group $P\bar{1}$. The Mo atoms of the structure lie on centers of inversion; thus, only half of the molecule had to be refined. As a consequence, a disorder between the NBH$_3$ and Cl ligands was observed. The hydrogen atoms of the BH$_3$ group were located by difference electron density calculations. The geometry of the BH$_3$ group has been corrected by using B–H and H···H distance restraints and the coordinates of the H atoms were finally fixed dur-

ing the last refinement. For compound **8** the position of the hydride atom H27 was also located by difference electron density calculations but all its parameters were freely refined while the other positions of hydrogen atoms were calculated after each refinement cycle. Compound **9** crystallized in the centrosymmetric monoclinic space group $P2_1/n$. Large anisotropic displacement parameters were observed for two ethyl groups on the boron atom and for one ethyl group on the phosphorus atom P3. The disorder refinement for these ethyl groups done with distance restraints improved significantly the result, the atomic splitting was kept and the corresponding carbon atoms were refined isotropically. For compound **10** one ethyl group on the phosphorus atom P2 was treated for disorder and isotropically refined. Compound **12** crystallized in the triclinic space group $P\bar{1}$. One toluene solvent molecule cocrystallized with the structure and is located near a center of inversion leading to a disorder. Many FREE instructions were necessary to calculate the positions of H atoms of the disordered toluene, and the corresponding carbon atoms were refined isotropically. One ethyl group on the boron atom B1 in compound **14** was found to be positionally disordered. All structures in this paper crystallize in centrosymmetric triclinic or monoclinic space groups, except the structure of **2** given in the Supporting Information. CCDC-280778 to -280788 and CCDC-249319 (for **1**–**4**, **6**, **8**–**10** and **12**–**14**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): ORTEP representations and crystallographic details of compounds **1**, **2** and **3**.

# The First Coordination Polymers Based on Octahedral Hexahydroxo Rhenium Cluster Complexes $[Re_6Q_8(OH)_6]^{4-}$ (Q = S, Se) and Alkaline Earth Metal Cations

**Yuri V. Mironov,[a,b] Vladimir E. Fedorov,*[a] Hyunjin Bang,[b] and Sung-Jin Kim*[b]**

**Keywords:** Rhenium / Synthesis / Luminescent properties / Cluster compounds

Seven novel octahedral cluster compounds $[\{Mg(H_2O)_5\}_2Re_6S_8(OH)_6]\cdot 6H_2O$ (**1**), $[\{Ca(H_2O)_3\}_2Re_6S_8(OH)_6]$ (**2**), $[\{Ca(H_2O)_3\}_2Re_6Se_8(OH)_6]$ (**3**), $[\{Sr_2(H_2O)_{10}\}Re_6S_8(OH)_6]\cdot 6H_2O$ (**4**), $[\{Sr_2(H_2O)_{10}\}Re_6Se_8(OH)_6]\cdot 6H_2O$ (**5**), $[\{Ba_2(H_2O)_8\}Re_6S_8(OH)_6]$ (**6**), and $[\{Ba_2(H_2O)_8\}Re_6Se_8(OH)_6]$ (**7**) were prepared by the direct reaction of $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ and $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ with the cations of the elements of main group II. All compounds have been characterized by single crystal X-ray diffraction. Compound **1** has a discrete molecular structure, compounds **4** and **5** have a one-dimensional chain structure, and compounds **2**, **3**, **6**, and **7** crystallize in two different types of two-dimensional layered structure. This sulfur containing series has been characterized by luminescent spectroscopy.

## Introduction

Octahedral rhenium clusters present an attractive class of structural and functional building blocks for the design of solids including coordination polymers and supramolecular constructions.[1] Coordination polymer compounds based on rhenium chalcohalide[2] and chalcogenide[3] clusters have been known for a long time. Others were obtained quite recently. One of the most developed building blocks is the octahedral rhenium chalcogenide cluster complexes of general formula $Re_6Q_8L_6$ where Q = S, Se, Te and L = an acido ligand or an organic donor group. There are two groups of terminal ligand, L, that are suitable for inclusion in such complexes with the appropriate partners. Firstly, there is the ambidentate CN ligand; in this case the $[Re_6Q_8(CN)_6]^{4-/3-}$ building blocks act with the transition or post-transition metals forming cyano-bridged inorganic polymeric structures.[4] Secondly, it is possible to use specific organic molecules that can function as a bidentate-bridge, and in this case mixed organic/inorganic polymers are formed.[5]

Very recently[6] two novel cluster complexes $K_4[Re_6Q_8(OH)_6]\cdot 8H_2O$ (Q = S, Se) were synthesized and characterized. In a preceding contribution, we presented the cluster anions $[Re_6Q_8(OH)_6]^{4-}$ as promising new building blocks for the construction of coordination polymers. In the present work a series of crystalline solids **1**–**7** are prepared by the direct reaction of $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ and $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ with the cations of the elements of main group II.

$[\{Mg(H_2O)_5\}_2Re_6S_8(OH)_6]\cdot 6H_2O$ (**1**)
$[\{Ca(H_2O)_3\}_2Re_6S_8(OH)_6]$ (**2**)
$[\{Ca(H_2O)_3\}_2Re_6Se_8(OH)_6]$ (**3**)
$[\{Sr_2(H_2O)_{10}\}Re_6S_8(OH)_6]\cdot 6H_2O$ (**4**)
$[\{Sr_2(H_2O)_{10}\}Re_6Se_8(OH)_6]\cdot 6H_2O$ (**5**)
$[\{Ba_2(H_2O)_8\}Re_6S_8(OH)_6]$ (**6**)
$[\{Ba_2(H_2O)_8\}Re_6Se_8(OH)_6]$ (**7**)

Simple synthetic methods produce these complexes on a large scale. All seven structures were elucidated by single-crystal X-ray diffraction. Compound **1** has a discrete molecular structure, and compounds **4** and **5** are isostructural and form a one-dimensional chain structure. Compounds **2** is isostructural with **3**, and **6** is isostructural with **7**; these compounds form two types of two-dimensional layered structure.

To date, only the ionic alkaline earth aqua complexes $[Ca(H_2O)_7][Re_6Q_6Cl_8]\cdot 3H_2O$ (Q = S, Se), $[Ca(H_2O)_8][Re_6S_6Cl_8]$, and $Mg(H_2O)_6[Re_6S_6Cl_8]\cdot 2H_2O$ have been reported.[7]

## Results

### Structures

Compounds **1**–**7** contain hexahydroxo cluster anions $[Re_6Q_8(OH)_6]^{4-}$ (Q = S or Se) coordinated to $M^{2+}$ cations, where M = Mg, Ca, Sr, Ba. The structures of the $[Re_6-$

$Q_8(OH)_6]^{4-}$ (Q = S, Se) cluster anions are similar to those observed in the starting materials, and to the well known octahedral complexes of type $[Re_6Q_8L_6]^{4-}$ with L = $Cl^-$, $Br^-$, $I^-$, $CN^-$. The $Re_6$ octahedron that resides inside a cube of $Q_8$ (S, Se) forms a system of Re–Re and Re–($\mu_3$-Q) bonds. Six terminal $OH^-$ ligands are coordinated to the Re atoms with Re–O bond lengths in the following ranges: 2.090(6)–2.093(6) Å (**1**), 2.100(4) Å (**2**), 2.124(3) Å (**3**), 2.077(7)–2.096(6) Å (**4**), 2.080(6)–2.110(5) Å (**5**), 2.059(9)–2.093(11) Å (**6**) and 2.083(7)–2.100(8) Å (**7**). The structures of complexes with $M^{2+}$ demonstrate a strong dependence on the atomic size of the metal used.

Compound **1** has a discrete molecular structure (Figure 1) where the cluster anion $[Re_6S_8(OH)_6]^{4-}$ is coordinated to by two aqua cationic $[Mg(H_2O)_5]^{2+}$ complexes in a *trans* arrangement about the OH bridges. In this way each Mg atom is coordinated to by 5 water molecules, with Mg–O distances in the range of 2.052(7)–2.216(7) Å, and by the O atom of the OH ligand of the cluster anion. The Mg–O(OH) distance is equal to 2.046(7) Å, and the ∠Re–O–Mg is equal to 138.0(3)°.

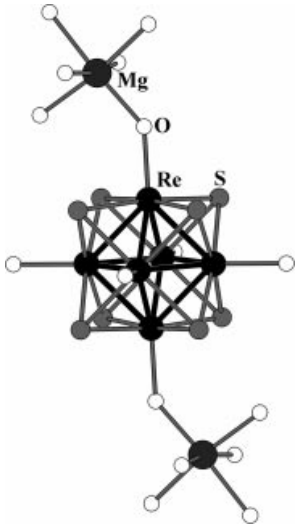

Figure 1. Structure of molecular complex $[\{Mg(H_2O)_5\}_2Re_6S_8(OH)_6]$ in (**1**).

Compounds **2** and **3** have a two-dimensional layered structure (Figure 2). Each Ca atom of compounds **2** and **3** is coordinated to by three water molecule O atoms with Ca–O distances of 2.377(5) Å, and by three O atoms from the OH ligands of three different cluster anions with Ca–O distances of 2.338(4) Å. This results in the formation of the *fac*-isomer. Whereas each Ca atom is coordinated to by three cluster anions, and each cluster anion is coordinated to by six Ca atoms giving a Ca/cluster anion ratio of 2:1. Interlayer distances are in the range excepted for hydrogen bonds between the O atoms of the water molecules coordinated to the Ca atoms and the O atoms of the OH groups of the cluster anions in an adjacent layer (2.745 Å in **2** and 2.804 Å in **3**).

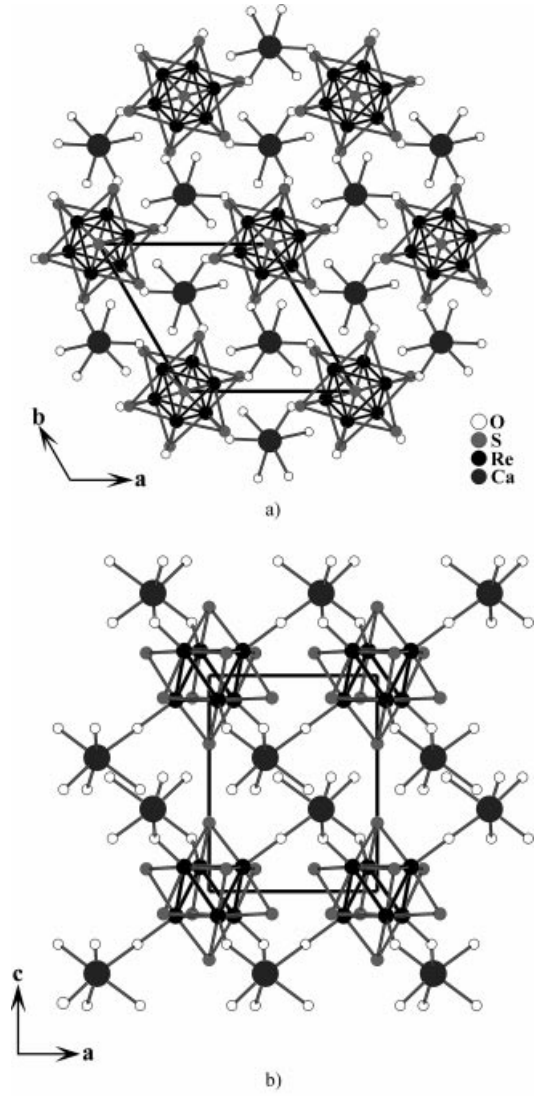

Figure 2. Structure of $[\{Ca(H_2O)_3\}_2Re_6S_8(OH)_6]$ (**2**): a) view along the *c*-axes; b) view along the *b*-axes.

Compounds **4** and **5** form one-dimensional chain-like structures (Figure 3). In these compounds cluster anions are bonded by cationic dimers $[Sr_2(H_2O)_{10}]^{4+}$. Two Sr atoms are bridged by two water molecules to form a dimer with an Sr–Sr separation of 4.3140(19) Å in **4** and 4.3016(16) in **5** and Sr–O distances of 2.675(8) Å and 2.680(8) Å in **4** and 2.666(6) Å and 2.686(7) Å in **5**. Additionally each Sr atom is coordinated to by 4 terminal water molecules (Sr–O distances are in the ranges of 2.555(8)– 2.603(9) Å in **4** and 2.551(7)–2.622(7) Å in **5**) and two O atoms of the OH ligands of the cluster anion [Re–O(OH) distances equal 2.532(7) Å in **4** and 2.547(6) Å in **5**]. Each Sr atom is connected to the Q atom of the cluster anion with Sr–Q distances equal to 3.260(3) Å (**4**) and 3.3649(12) Å (**5**).

In compounds **6** and **7** (Figure 4) the Ba atoms also form dimers but of a different type to the Sr dimers: two O atoms of the OH ligands of the cluster anions bridge the Ba atoms. The Ba–Ba distances in these compounds are equal to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

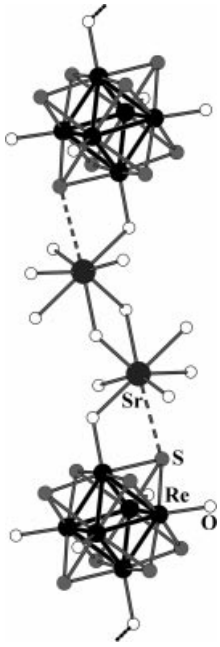

Figure 3. Structure of fragment of the $[\{Sr_2(H_2O)_{10}\}Re_6S_8(OH)_6]_n$ chain in (**4**).

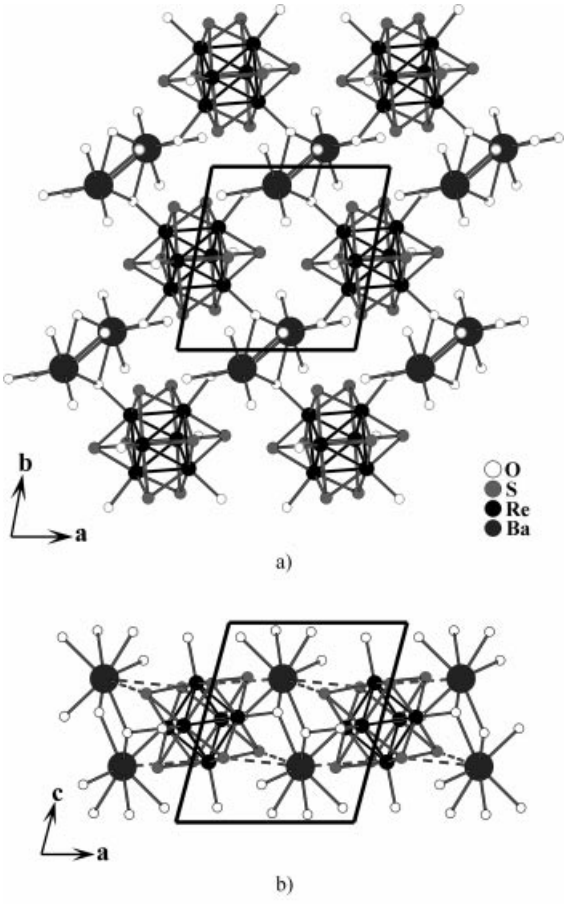

Figure 4. Structure of $[\{Ba_2(H_2O)_8\}Re_6S_8(OH)_6]$ (**6**): a) view along the *c*-axes; b) view along the *b*-axes.

4.352(2) Å in **6** and 4.4016(16) Å in **7**, the Ba–O distances for the bridged OH ligands are equal to 2.724(10) Å and 2.795(11) Å for **6**, 2.708(7) Å and 2.799(7) Å for **7**. Additionally each Ba atom is coordinated to by four water molecule O atoms [Ba–O distances are in range of 2.761(12)–2.86(3) Å (**6**) and 2.809(12)–2.92(2) Å (**7**)], and one atom of a OH ligand of a cluster anion [Ba–O distances are equal to 2.648(11) Å in **6** and 2.632(8) Å in **7**]. The coordination spheres of the Ba atoms are expanded by three Q atoms of the cluster core [Ba–S distances in **6** are 3.537(4), 3.660(3) and 3.878(4) Å, and the Ba–Se distances in **7** are 3.5715(14), 3.7457(13) and 3.7883(14) Å]. In this way each Ba dimer is coordinated to four cluster anions resulting in the formation of two-dimensional layered structures. Finally, in compounds **6** and **7** four OH ligands coordinated to the Ba atoms are associated with the anion clusters, whereas the other two are terminal and are in a *trans* arrangement about the dimer unit. The terminal OH groups are hydrogen bonded to the O atoms of water molecules coordinated to Ba atoms in an adjacent layer causing close packing of the layers. The closest interlayer distances are $O(H_2O)$–O(OH) = 2.748 Å in **6** and 2.813 Å in **7**.

Thus, the coordination numbers of the metal atoms in these compounds vary from 6 for Mg and Ca to 8 for Sr, and 10 for Ba.

### Luminescence

The luminescent properties of the starting cluster compound $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ and the thio complexes **1**, **2**, **4**, **6** were studied. All compounds show similar behavior; for example, upon excitation at 440 nm, the solid sulfur containing samples $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ and **1**, **2**, **4** and **6** displayed photoluminescence maxima at 618, 621, 618, 619 and 625 nm, respectively (Figure 5). These results are consistent with those previously reported for sulfide rhenium clusters.[5f,6] Figure 6 shows a comparison of the emission spectra for the rhenium sulfide (**2**) and selenide (**3**) cluster compounds. The emission maximum of the selenide

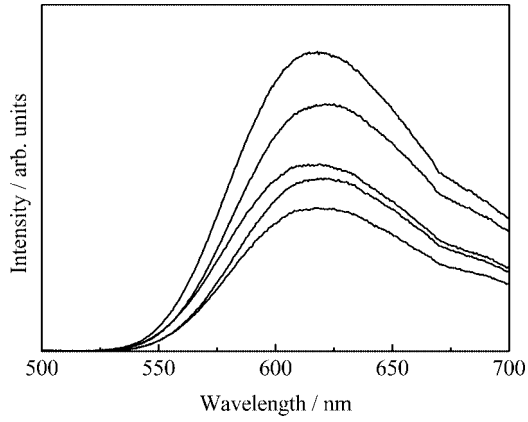

Figure 5. Solid-state emission ($\lambda_{exc}$ = 440 nm) spectra of the compounds $K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ and **1**, **2**, **4**, **6** (from top to bottom). The maxima are observed at 618, 621, 618, 619 and 625 nm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cluster is shifted by about 40 nm to a longer wavelength relative to the sulfide cluster, which is consistent with previous reports.[5f,8]

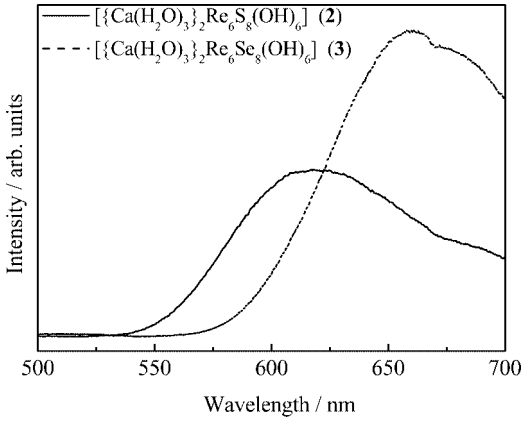

Figure 6. Solid-state emission ($\lambda_{exc}$ = 440 nm) spectra of compounds $[\{Ca(H_2O)_3\}_2Re_6S_8(OH)_6]$ (**2**) and $[\{Ca(H_2O)_3\}_2Re_6Se_8(OH)_6]$ (**3**). The maxima are observed at 619 and 659 nm.

## Experimental Section

$K_4[Re_6S_8(OH)_6]\cdot 8H_2O$ and $K_4[Re_6Se_8(OH)_6]\cdot 8H_2O$ were prepared as previously described.[6] All other reagents were commercially available products of reagent grade quality, and were used as obtained. All experiments were not performed under controlled atmospheric conditions.

All compounds were obtained in 70–90% yield by mixing an aqueous solution of $K_4[Re_6Q_8(OH)_6]\cdot 8H_2O$ with the chloride or nitrate salt of the corresponding metal. Crystals of compound **1** were obtained in the presence of 1,3,5-trioxane. The formation of compounds **2**–**5** may be forced by adding a few drops of DMF to the reaction mixture.

**Luminescence Measurements:** The emission spectra of solid samples of **1**, **2**, **3**, **4**, **6** were recorded in the wavelength range of 500 nm to 700 nm using a UV-Spectrofluorimeter equipped with a ORIEL 77200 monochromator and a Hamamatsu R928 PMT detector. The Xe lamp (ORIEL photomax, 75 W) was used as a light source, which emitted intense and relatively stable radiation in a continuous range of 200 nm to 800 nm. The excitation slit width was 1.56 mm, and the emission slit width was 60 μm.

**X-ray Crystallography:** Single crystal X-ray diffraction data were collected on $[\{Mg(H_2O)_5\}_2Re_6S_8(OH)_6]$ (**1**), $[\{Ca(H_2O)_3\}_2Re_6Q_8(OH)_6]$ where Q = S (**2**), Se (**3**), $[\{Sr_2(H_2O)_{10}\}Re_6Q_8(OH)_6]$ where Q = S (**4**), Se (**5**), and $[\{Ba_2(H_2O)_8\}Re_6Q_8(OH)_6]$ where Q = S (**6**), Se (**7**). Data were collected with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 170 K (**1**, **3**) and 293 K (**2**, **4**, **5**, **6**, **7**) with a Bruker Smart APEX CCD diffractometer with the operating program SMART. A face-indexed absorption correction was performed numerically with the use of XPREP. The program SADABS was then employed to perform incident beam and decay corrections. All structures were solved by direct methods and refined (full-matrix least-squares on $F^2$) with the SHELX-97 program suite.[9]

# Platinum-Group Chelate Complexes with 9-Hydroxyphenalenone Derivatives: Synthesis, Structures, Spectroscopic Properties and Cytotoxic Activities

Tomoyuki Mochida,*[a,b] Reiko Torigoe,[a] Takeo Koinuma,[a] Chika Asano,[a] Tadaaki Satou,[c] Kazuo Koike,[c] and Tamotsu Nikaido[c]

**Keywords:** Platinum / Rhodium / Palladium / O ligands / Metal–metal interactions

The following platinum-group chelate complexes with 5-R-9-hydroxyphenalenone ($L^1$: R = H; $L^2$: R = Me; $L^3$: R = Pr) have been prepared: $[Rh^I(L)(CO)_2]$ (**1a**: L = $L^1$; **1b**: L = $L^2$; **1c**: L = $L^3$), $[Pd^{II}(L)_2]$ (**2a**: L = $L^2$; **2b**: L = $L^3$), $[Pt^{II}(L^1)(NH_3)_2](NO_3)$ (**3**), and $(Bu_4N)[Pt^{II}(L^1)(Cl)_2]$ (**4**). Compounds **1a** and **1b** are different colors in the solid state: yellow and deep red, respectively. X-ray analysis revealed that **1a** has a regular π–π stacking structure while **1b** has a dimer-like arrangement with a $Rh^I$–$Rh^I$ distance of 3.2336(6) Å. Both solids were luminescent at 77 K. Compounds **2a** and **2b** are planar extended π-conjugated complexes, which exhibit two-dimensional stacking modes in the crystal. The solid-state structure of complex **3** is hydrogen-bonded in a polar arrangement. The cytotoxic activities of **1a**, **3**, and **4**, evaluated in vitro against HL60 human acute myeloid leukemia cell lines, were comparable to that of cisplatin.

## Introduction

Platinum-group metal complexes with various ligands have attracted growing attention in recent decades because of their unique photochemical[1] and electronic properties.[2] Here we report the use of hydroxyphenalenone as an extended π-conjugated ligand to explore a novel type of complex. The phenalenyl system is an odd-alternant hydrocarbon,[3,4] the unique properties of which have been widely investigated. Haddon has reported the interesting properties of spiro-biphenalenyl radicals, which exhibit electronic-switching phenomena in the solid state.[5] Several transition-metal complexes of phenalenyl derivatives have been reported: a neutral palladium complex with a $\eta^3$-phenalenyl ligand was prepared by Nakasuji,[6] and some transition-metal complexes with phenalenone-related ligands were prepared in the 1970s.[7,8] More recently, metal chelate complexes with 9-hydroxyphenalenones have been prepared, including aluminum complexes for multilayer light-emitting devices[9] and a luminescent europium complex.[10] However, no examples of phenalenone chelate complexes with platinum-group metals have been reported. We are interested in the antitumor potential of such complexes because their planar π-conjugated nature might allow intercalation into DNA to enhance cytotoxic activity.

In this study, we prepared chelate complexes of platinum-group metals with 9-hydroxyphenalenone ($HL^1$), its 5-methyl derivative ($HL^2$), and a 5-propyl derivative ($HL^3$) (Scheme 1). Use of the 5-alkyl derivatives improved the solubility of the complexes. We also tried, unsuccessfully, to prepare a 5-*tert*-butyl ligand by a Friedel–Crafts or similar condensation reaction. Here we report the preparation and properties of $[Rh^I(L)(CO)_2]$ (**1a**: L = $L^1$; **1b**: L = $L^2$; **1c**: L = $L^3$), $[Pd^{II}(L)_2]$ (**2a**: L = $L^2$; **2b**: L = $L^3$), $[Pt^{II}(L^1)(NH_3)_2](NO_3)$ (**3**), and $(Bu_4N)[Pt^{II}(L^1)(Cl)_2]$ (**4**). The molecular structures were confirmed crystallographically, and the remarkable difference in color between **1a** and **1b** was rationalized in terms of metal–metal interactions. Furthermore, the cytotoxic activities of **1a**, **3**, and **4** against human acute myeloid leukemia cells were evaluated.

## Results and Discussion

### Preparation and Spectroscopic Properties

Reaction of the 9-hydroxyphenalenone derivatives ($HL^1$, $HL^2$, and $HL^3$) with various metal sources in the presence of base produced chelate complexes (Scheme 1). We prepared the neutral complexes **1a**–**c** and **2a**–**b**, the anionic complex **3**, and the cationic complex **4** using methods analogous to the known preparations of chelate complexes of platinum-group metals with acetylacetonate derivatives.[11–15] We could not obtain platinum analogs of **2**; similar procedures afforded uncharacterizable black precipi-

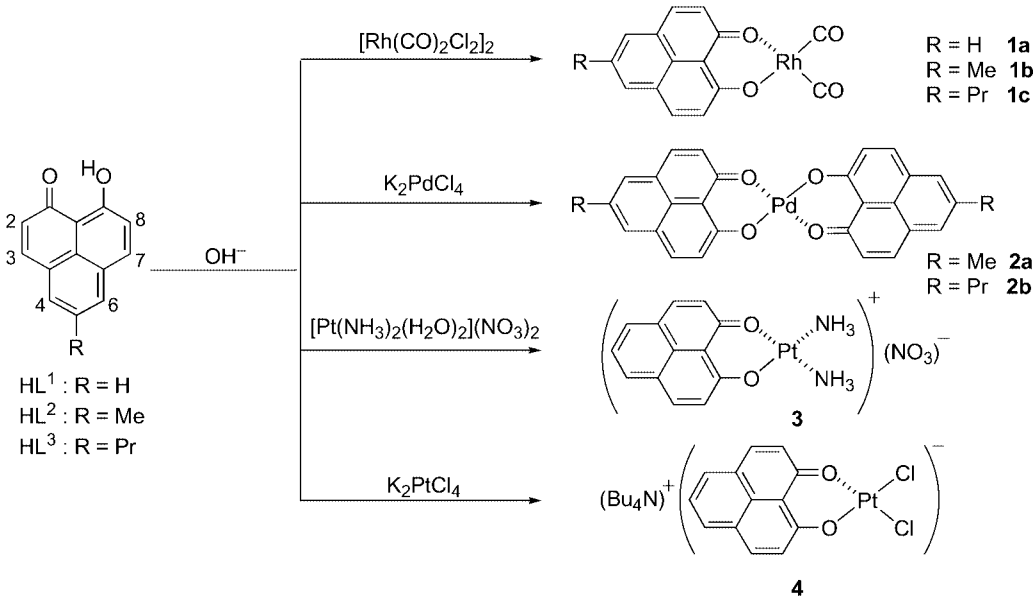

Scheme 1.

tates. Attempted syntheses of Magnus-type complexes using **3** and **4** failed.

The $^1$H NMR spectroscopic data for compounds **1**–**4** are listed in Table 1 alongside the infrared stretching frequencies of C=O and other characteristic vibrations. In **1a**–**c** and **2b**, the signals for $H^2$ and $H^4$ exhibited downfield shifts, while $H^3$ was shifted upfield relative to their free ligand values. In **3** and **4**, the ring protons showed slight upfield shifts. The ligand C=O stretching bands were observed at frequencies slightly lower than those of the free ligand. In DMF solution, the lowest energy UV/Vis absorption bands for $HL^1$, $HL^2$, and $HL^3$ appeared at $\lambda_{max}$ = 449, 449, and 438 nm, respectively. The lowest energy absorption bands for the metal complexes were found at lower energies than those of the ligands: $\lambda_{max}$ = 498 (**2a**), 497 (**2b**), 477 (**3**), and 461 nm (**4**) in DMF, and at around $\lambda_{max}$ = 460 nm for **1a**–**c** in dichloromethane. Compounds **1a**–**c** decomposed[16] when heated in DMF or DMSO.

In the following sections, the structures and solid-state properties of the individual complexes are described. Crystal data, data collection parameters, and analysis statistics are listed in Table 2, and selected bond lengths and bond angles given in Table 3. ORTEP[17] drawings of the molecular structures of **1a**, **2a**, **3**, and **4**, as well as the packing diagrams of **2b** and **4**, have been deposited as supporting information.

### [Rh$^I$(L$^1$)(CO)$_2$] (1a) and [Rh$^I$(L$^2$)(CO)$_2$] (1b)

The rhodium ion in these complexes is coordinated by the phenalenone ligand and two CO ligands in a square planar arrangement. The molecular geometries of **1a** and

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

**1b** were almost identical; the structure of **1b**, determined by X-ray crystallography, is shown in Figure 1. Comparing the intramolecular bond lengths of these complexes with those of [Rh$^I$(acac)(CO)$_2$] (acac = acetylacetone)[13] shows that the Rh–O and C≡O distances are shorter in the phenalenone complexes (by about 0.04 and 0.1 Å, respectively), while the Rh–C(CO) distances are longer (by about 0.09 Å). This suggests that the bonds between Rh and the chelating ligand are somewhat stronger in the phenalenone complexes.

The packing diagram of **1a** is shown in Figure 2. The crystal structure has a polar space group ($P2_1$), in which the molecules are arranged in a column along the stacking (*b*) axis. There is no intermolecular metal–metal bonding: the intermolecular Rh···Rh distance is 4.587 Å. The packing of **1b** is different from that of **1a** and is shown in Figure 3. An intermolecular Rh–Rh interaction [Rh–Rh: 3.2336(6) Å] forms dimers, which have a staggered configuration. In the crystal, the long molecular axes are located within the *a*–*c* plane, and interdimer face-to-face stacking interactions form columns along the *b* axis. The molecules in adjacent columns are arranged such that their long axes are orthogonal.

It is known that d$^8$ metal complexes can associate through metal–metal interactions in the solid state.[2a,18] In [Rh$^I$(acac)(CO)$_2$],[13] the molecules form one-dimensional arrays with Rh···Rh distances of 3.26 Å. The Rh–Rh distance in **1b** is comparable to that in Rh$^I$ 1D chain complexes and bridged dinuclear Rh$^I$ complexes.[19–21]

Solutions of **1a** and **1b** were yellow and exhibited almost identical absorption spectra, but **1b** formed intense deep red crystals while **1a** remained yellow in the crystalline state. Similar structure-dependent color change has been observed previously in some platinum complexes.[22] Figure 4 (a) and (b) show the absorption and emission spectra of powder samples of **1a** and **1b**, respectively. Solid lines represent room temperature absorption spectra, obtained by applying a Kubelka–Munk conversion to reflectance spectra. The absorption edge of **1a** appears at around 500 nm while that for **1b** appears at around 600 nm; the lower energy of **1b**'s absorption is consistent with its intense color. The broken lines in Figure 4 represent the emission spectra at 77 K. Compound **1a** exhibited red emission, with two bands at $\lambda_{max}$ = 600 nm and $\lambda_{max}$ = 648 nm. Compound **1b** exhibited a weak, broad band at $\lambda_{max}$ = 658 nm. These complexes were emissive at 77 K but not room temperature, and not in solution.

The low-energy absorption in **1b** is a consequence of metal–metal interactions. DFT calculations were carried out using the crystallographically determined geometries of **1a** and **1b**, and the frontier orbitals are plotted in Figure 5. In **1a**, the HOMO (–6.22 eV) and LUMO (–2.69 eV) are of predominantly ligand character with only a small contribution from the metal d orbitals. The d orbitals' contribution is more significant for the HOMO and therefore the lowest energy excitation is predominantly π–π* mixed with an MLCT character. In contrast to **1a**, the HOMO of **1b** (–5.48 eV) consists of metal d$z^2$ orbitals; the d–d interaction raises the energy level of the Rh$^I$–Rh$^I$ σ-antibonding orbital above that of the ligand orbital. The LUMO (–2.53 eV) is a ligand-based orbital. Therefore, the intense color of **1b** is attributed to MLCT. Electronic absorptions from metal-centered ($4d_{z^2}$ to $5p_z$) transitions in binuclear rhodium complexes are mostly found between 550 and 600 nm,[20] but the transition in **1b** is of a different character because the conjugation of the ligand lowers the π* level. The crystal structure of **1c** could not be determined but its yellow color suggests that it has no metal–metal interactions.

[a] Carbonyl groups (C≡O).

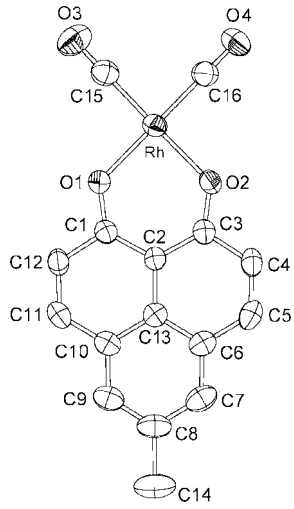

Figure 1. ORTEP drawing of the molecular structure of **1b** with the atom-numbering scheme. The counterions are omitted. Displacement ellipsoids are shown at the 50% probability level. The numbering of the phenalenyl moiety is the same in the other complexes.

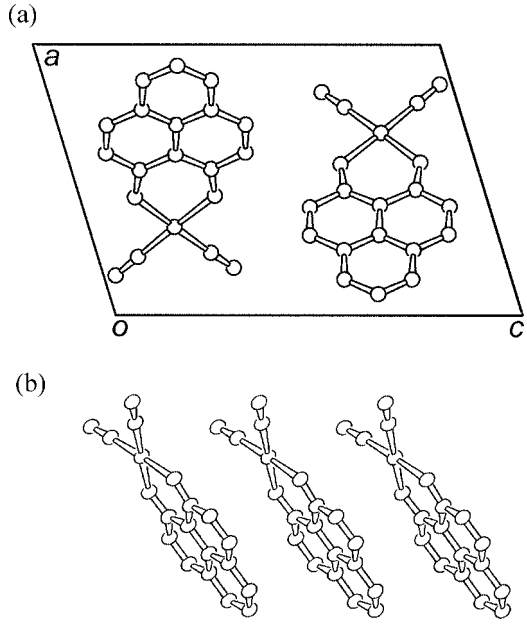

Figure 2. (a) Packing diagram of **1a** viewed along the *b* axis. (b) Stacking arrangement of **1a**.

Mononuclear $Rh^I$ complexes are known to emit from MLCT or π–π* intraligand excited states.[23] The emission from **1a** is assigned to vibronic progressions from the π–π* excited state mixed with some MLCT character. Consistent with this, a long emission lifetime of 2.0 ms was observed for this band. Solid $[Rh^I(acac)_2(CO)_2]$ also exhibits weak π–π* emission as a structured band in the 430–530 region.[16] Dinuclear $Rh^I$ complexes often exhibit a strong red emission between 650 and 850 nm because of metal–metal interactions,[21] but, in the case of **1b**, the emission was very weak. This might be a consequence of the highly conjugated nature of the ligand.

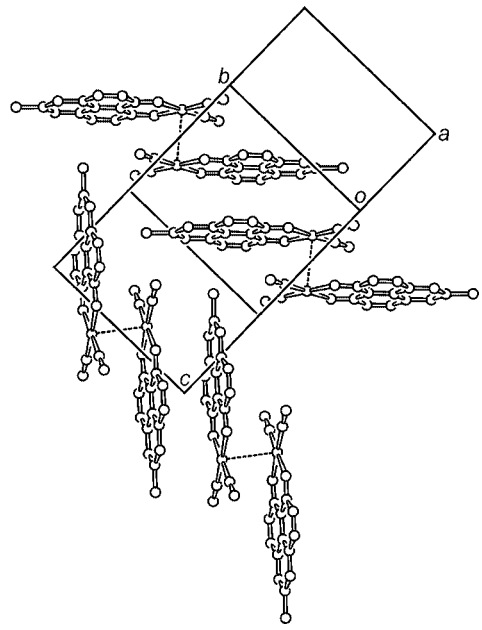

Figure 3. Packing diagram of **1b**. The hydrogen atoms are omitted for clarity. The dashed lines represent Rh–Rh interactions.

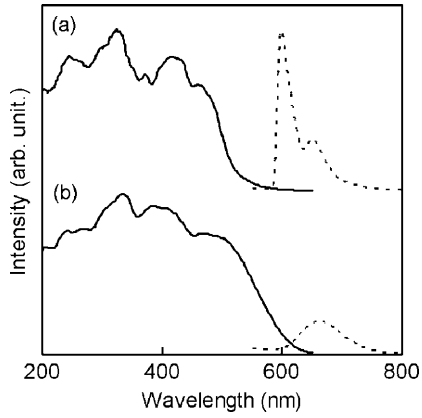

Figure 4. UV/Vis absorption spectra at room temperature (solid lines) and emission spectra at 77 K (dashed lines) for solid samples of (a) **1a** and (b) **1b**.

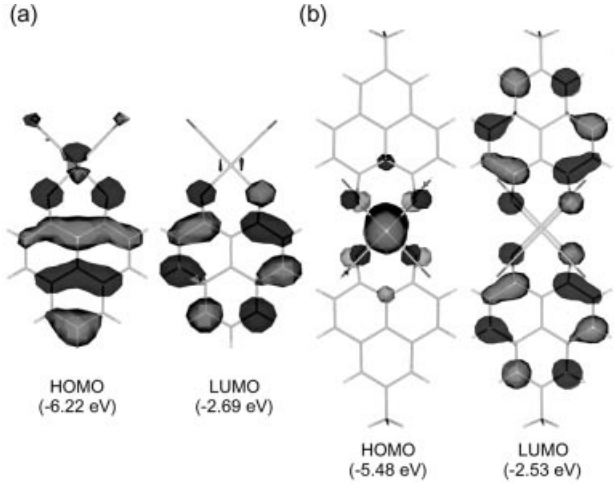

Figure 5. Frontier orbitals for (a) **1a** and (b) **1b** (dimer) derived from DFT calculations.

### $[Pd^{II}(L^2)_2]$ (2a) and $[Pd^{II}(L^3)_2]$ (2b)

The molecular structures of **2a** and **2b**, determined by X-ray crystallography, are almost identical. The coordination of the palladium atom in each case is square planar, forming an extended π-conjugated planar complex. The Pd–O distances are comparable to those in the chelate complex $[Pd(acac)_2]$.[12] The packing diagram of **2a** is shown in Figure 6 (a), and the structure of **2b** is almost identical, except that the *b* axis is elongated (by 1.2 Å) because of the longer

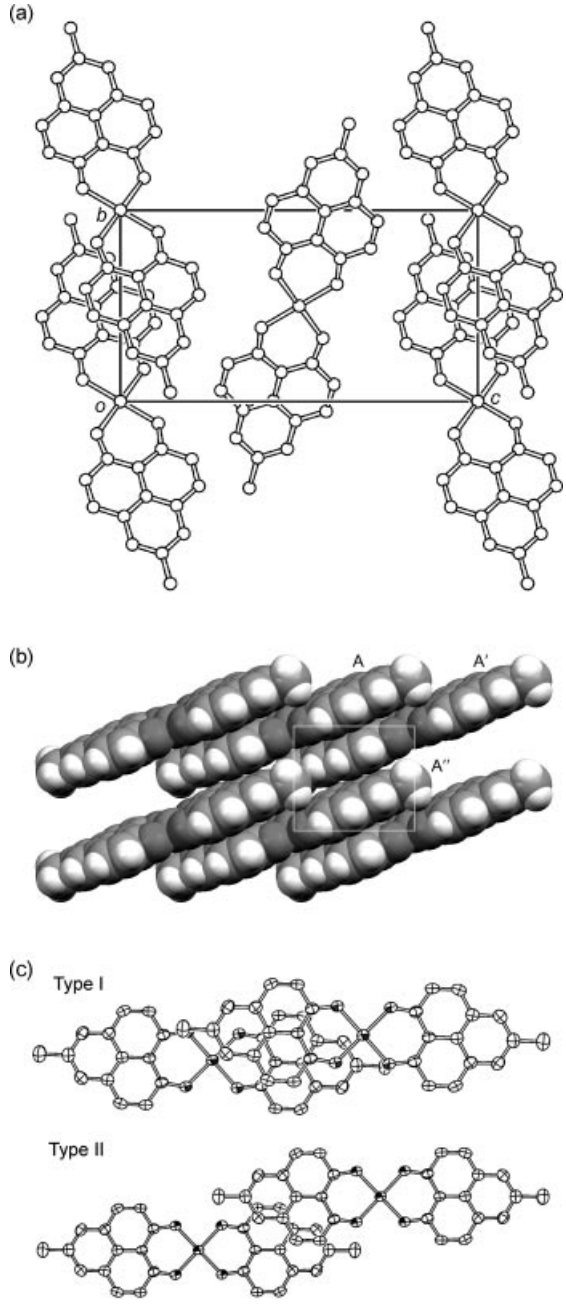

Figure 6. (a) Packing diagram of **2a** viewed along the *a* axis. The hydrogen atoms are omitted for clarity. (b) Space-filling representation of the sheet structure of **2a** within the *ab* plane. (c) ORTEP drawing of the overlapping modes of **2a**, viewed along the molecular plane.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

alkyl group. The packing diagram of **2b** has been deposited as supporting information. In both crystals, the palladium atoms are located on the origin of the crystal lattice, and the closest distances between palladium atoms are equal to the *a* axis length: 7.439 Å for **2a** and 7.566 Å for **2b**. The complexes form two-dimensional layered structures, consisting of stacking of the planar molecules along the *a* axis. The layered structure of **2a** is shown in Figure 6 (b) as a space-filling model. There are two stacking modes, as shown in Figure 6 (c): type I stacking is formed between molecules A and A′ in Figure 6 (b), the symmetry code for A′ being $x$, $1 + y$, $z$, and type II stacking is formed between molecules A′ and A′′, the symmetry code for A′′ being $1 + x$, $1 + y$, $z$. The overlap between phenalenyl rings is larger for type I than type II. The stacking modes of **2a** and **2b** are similar, although the overlap of stacking type II is slightly more significant in **2b**, which results in stronger intermolecular interactions. It is interesting to note that the stacking structures of these complexes resemble those of polycyclic aromatic compounds.

### $[Pt^{II}(L^1)(NH_3)_2](NO_3)$ (3) and $(Bu_4N)[Pt^{II}(L^1)(Cl)_2]$ (4)

Complex **3** shows an approximate $C_{2v}$ structure. The distances C(1)–C(2), C(2)–C(3), and C(3)–C(4) are about 1.42 Å, and Pt–O(1) and Pt–O(2) are about 1.96 Å. These bond lengths are similar to the corresponding distances in the chelate compounds $[Pt(acac)_2]$[24] and $[PtCl_2(acac)]$.[14] Figure 7 shows the packing diagram. This complex has a layered structure, with hydrogen-bonded sheets and hydrophobic phenalenone layers arranged alternately along the *a* axis. The two ammine ligands are involved in intermolecular hydrogen bonding with the nitrate counteranions (N–H···O distances: 2.89 and 3.03 Å) to form a two-dimensional zigzag hydrogen-bond network within the *b*–*c* plane. Within the phenalenone layer, the aromatic rings have a herring-bone-like arrangement. Furthermore, this crystal has a polar space group (*Pc*), which is associated with a hydrogen-bond-assisted arrangement of the phenalenone complex, as seen in Figure 7. The face-to-face distance between the neighboring phenalenone planes along the *b* axis is 4.5 Å. The intermolecular distance between the neighboring platinum atoms is 5.9 Å; no direct metal–metal interactions are observed.

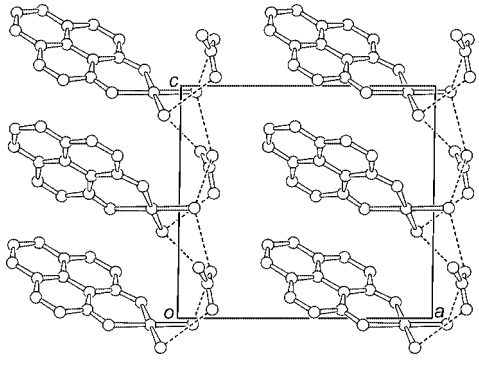

Figure 7. Packing diagram of **3** viewed along the *b* axis. The hydrogen atoms are omitted for clarity. The dashed lines represent hydrogen bonds.

In complex **4**, the lengths of the C–C and Pt–O bonds are almost the same as those found in **3**. The Pt–Cl distances are about 2.30 Å, which is comparable to the value found in $[PtCl_2(acac)]$.[14] The tetrabutyl ammonium cation and phenalenone complex anion are paired and arranged alternately in the crystal. The distance between neighboring platinum atoms is 8.73 Å; again, there were no metal–metal interactions. The molecular structure and packing diagram of **4** are deposited as Supporting Information.

### Cytotoxic Activities

Antitumor activity, as typified by cisplatin (*cis*-$[PtCl_2(NH_3)_2]$), is an important feature of platinum-group metal complexes.[25] In this study, we have evaluated the cytotoxic activities of **1a**, **3**, and **4** against human acute myeloid leukemia (HL60) cells. The concentration of the metal complexes giving a growth inhibition of 50% ($IC_{50}$) was evaluated in vitro by the MTT assay. The $IC_{50}$ values (estimated standard deviations) for **1a**, **3**, and **4** were 3.12 (0.37), 1.69 (0.51), and 3.62 (0.46) μmol/L, respectively. The observed activities were of the same order, although **3** seems to be somewhat more active than the others. Under the same experimental conditions, the $IC_{50}$ for cisplatin was 3.16 (0.50) μmol/L (control for **1a**) and 2.19 (0.59) μmol/L (control for **3** and **4**). Thus, the present compounds have the same order of cytotoxic activity as cisplatin. However, the activity is possibly due to the ligand, and, therefore, the cytotoxicity of 9-hydroxyphenalenone needs to be evaluated for discussion of the cytotoxicity of the metal complexes.

## Conclusions

We have prepared a series of platinum-group metal complexes with hydroxyphenalenone derivatives and investigated their structures, properties, and cytotoxic activities. In the solid state, the colors of the rhodium complexes **1a** and **1b** are very different; we attribute the intense color of the latter to metal–metal interactions. These compounds were emissive at 77 K in the solid state, but the highly conjugated ligands might not be favorable for emission. In the crystals of these rhodium complexes, change of ligand led to a different packing arrangement, but no corresponding change in packing was seen in the palladium complexes **2a** and **2b**. Complexes **2a** and **2b** exhibited interesting packing arrangements. No metal–metal interactions were seen in these complexes, but incorporation of a sterically hindered substituent at the 5-position of the ligand might lead to a staggered molecular arrangement and shortened metal–metal distances. The rhodium and platinum complexes exhibit noteworthy cytotoxic activity. Future research into phenalenone complexes might focus on the construction of one-dimensional complexes with metal–metal interactions, and, furthermore, use a redoxed ligand (that is, a phenalenyl radical), which could interact with the one-dimensional electronic system.

## Experimental Section

**General Remarks:** NMR spectra were recorded with a JEOL JNM-ECL-400 spectrometer. Infrared spectra were recorded as KBr pellets on a JASCO FTIR 230 spectrometer. UV/Vis spectra were recorded with a JASCO V-570 UV/Vis/NIR spectrometer. Solid-state electronic absorption spectra were measured with the same spectrometer equipped with an integrating sphere for diffuse reflectance spectroscopy, Kubelka–Munk conversion being applied to the resultant spectra. Emission spectra were recorded with a JASCO FP-6500 spectrometer. DFT calculations were performed with Gaussian 98[26] software at the B3LYP level using a Lanl2DZ basis set.

**Cytotoxic Studies:** The direct growth-inhibition effects of **1a**, **3**, and **4** were examined in vitro against HL60 human acute myeloid leukemia cells. These cells were obtained from the RIKEN Cell Bank, Japan. The HL60 cells were washed and suspended in the culture medium at a concentration of $3 \times 10^4$ cells/mL, and this suspension was incubated in 5% $CO_2$/air for 24 h at 37 °C. To this suspension was added the metal complex dissolved in ethanol and water. Cisplatin was used as control. These cells were further incubated for 72 h, and cell growth evaluated using a modified 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay.[27] After termination of the cell culture, MTT in phosphate-buffered saline was added to each well and incubated for 4 h in 5% $CO_2$/air at 37 °C. After adding DMSO, the plates were examined using a microplate reader at 550 nm.

**X-ray Crystallographic Study:** X-ray diffraction data for single crystals were collected on a Rigaku Mercury or a Bruker APEX CCD diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by the direct method (SHELXS 97[28]) and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were inserted at the calculated positions and allowed to ride on their respective parent atoms.

CCDC-259428 (for **1a**), -259427 (for **1b**), -259429 (for **2a**), -259430 (for **2b**), -259431 (for **3**), and -259432 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Ligands:** The syntheses of 9-hydroxyphenalenone ($HL^1$) and 9-hydroxy-5-methylphenalenone ($HL^2$) were carried out according to published methods,[29] and 9-hydroxy-5-propylphenalenone ($HL^3$) was prepared from 6-methoxy-2-propylnaphthalene[30] in the same way as $HL^2$. The crude product was purified by sublimation under vacuum followed by recrystallization from hexane to give a yield of 44%.

**$[Rh^I(L^1)(CO)_2]$ (1a):** To a stirred DMF solution (1 mL) of $[Rh(CO)_2Cl]_2$ (15 mg, $3.9 \times 10^{-5}$ mol), which was cooled in an ice bath, 9-hydroxyphenalenone ($HL^1$) (16 mg, $8.1 \times 10^{-5}$ mol) was added, dissolved in a methanol solution of potassium hydroxide ($9.3 \times 10^{-5}$ mol). A lustrous red powder precipitated immediately, which was collected by filtration, washed with dichloromethane, and dried under vacuum to afford a yellow powder; 57% yield (16 mg). Yellow plate-like crystals suitable for X-ray crystallography were obtained by recrystallization from dichloromethane/pentane. $\lambda_{max}$/nm (DMF): 266, 352, 368, 428, 452. $C_{15}H_7O_4Rh$ (354.11): calcd. C 50.88, H 1.99; found: C 50.62, H 2.13.

**$[Rh^I(L^2)(CO)_2]$ (1b):** This compound was prepared in the same way as **1a**, using 15 mg ($8.5 \times 10^{-5}$ mol) of 9-hydroxy-5-methylphenalenone ($HL^2$). Red powder, 84% yield (24 mg). Red needle-like crystals suitable for X-ray crystallography were obtained by recrystallization from dichloromethane/hexane. $\lambda_{max}$/nm (DMF): 266, 356, 372, 436, 462. $C_{32}H_{18}O_8Rh_2$ (736.26): calcd. C 52.20, H 2.46; found C 51.92, H 2.60.

**$[Rh^I(L^3)(CO)_2]$ (1c):** This compound was prepared in the same way as **1a**, using $[Rh(CO)_2Cl_2]$ (22 mg, ($5.7 \times 10^{-5}$ mol), 9-hydroxy-5-propylphenalenone ($HL^2$) (26 mg, $1.1 \times 10^{-4}$ mol), and potassium hydroxide in methanol ($1.0 \times 10^{-4}$ mol), and stirring for 30 min. A yellow powder was obtained in a quantitative yield. $\lambda_{max}$/nm ($CH_2Cl_2$): 369, 435, 462. $C_{18}H_{13}O_4Rh$ (396.18): calcd. C 54.57, H 3.31; found C 54.75, H 3.56.

**$[Pd^{II}(L^2)_2]$ (2a):** 9-Hydroxy-5-methylphenalenone ($HL^2$) (22 mg, $1.1 \times 10^{-4}$ mol) and a methanol solution of potassium hydroxide ($1.6 \times 10^{-4}$ mol) were added to a stirred aqueous solution (1 mL) of $K_2PdCl_4$ (15 mg, $4.6 \times 10^{-5}$ mol). An orange precipitate was generated immediately, which was collected by filtration, washed with dichloromethane, and dried under vacuum. Orange needles, 92% yield (22 mg). Single crystals suitable for X-ray crystallography were obtained by slow cooling of a hot DMF solution. $\lambda_{max}$/nm (DMF): 367, 385, 498. $C_{28}H_{18}O_4Pd$ (524.82): calcd. C 64.07, H 3.46; found C 62.13, H 3.62.

**$[Pd^{II}(L^3)_2]$ (2b):** This compound was prepared in the same way as **2a**, using $K_2PdCl_4$ (16 mg, $4.8 \times 10^{-5}$ mol), 9-hydroxy-5-propylphenalenone ($HL^3$) (22 mg, $9.2 \times 10^{-5}$ mol), and potassium hydroxide ($1.2 \times 10^{-4}$ mol), and heating for 30 min at 50 °C. Red-orange powder, 80% yield (22 mg). Single crystals were obtained by recrystallization from DMF. $\lambda_{max}$/nm (DMF): 271, 369, 384, 466, 497. $C_{32}H_{26}O_4Pd$ (580.93): calcd. C 66.16, H 4.51; found C 65.94, H 4.59.

**$[Pt^{II}(L^1)(NH_3)_2](NO_3)$ (3):** Silver nitrate (44 mg, $2.6 \times 10^{-4}$ mol) was added to a solution of *cis*-$Pt(NH_3)_2Cl_2$ (40 mg, $1.3 \times 10^{-4}$ mol) in methanol/water (1:3 v/v, 1 mL) . This solution was stirred in the dark at 60 °C for 3 h, and then the AgCl was removed by filtration (Celite plug). 9-Hydroxyphenalenone ($HL^1$) (26 mg, $1.3 \times 10^{-4}$ mol) and a methanol solution of potassium hydroxide ($1.3 \times 10^{-4}$ mol) were added to this solution of *cis*-$[Pt(NH_3)_2(H_2O)_2](NO_3)_2$. After stirring for 3 h at 60 °C, the solvent was removed by vacuum evaporation. Orange powder, 54% yield (31 mg). Orange needle-like crystals suitable for X-ray crystallography were obtained by recrystallization from DMF/diethyl ether. $\lambda_{max}$/nm (DMF): 378, 395, 452, 477. $C_{13}H_{13}N_3O_5Pt$ (486.36): calcd. C 32.11, H 2.69, N 8.64; found C 31.95, H 2.72, N 8.71.

**$(Bu_4N)[Pt^{II}(L^1)(Cl)_2]$ (4):** A 10% tetrabutylammonium hydroxide/methanol solution (250 mg, $9.6 \times 10^{-4}$ mol) was added to a stirred methanol solution (0.3 mL) of 9-hydroxyphenalenone ($HL^1$) (9.7 mg, $4.9 \times 10^{-5}$ mol). This solution was transferred to a test tube, and a methanol solution (2 mL) of $K_2PtCl_4$ (20 mg, $4.8 \times 10^{-5}$ mol) and 18-crown-6 (60 mg, $2.3 \times 10^{-5}$ mol) was layered over the solution and allowed to react slowly by diffusion. Over a few days, the color of the solution changed from orange to red, and a black powder was gradually deposited. The powder was removed by filtration, and the filtrate concentrated to a small volume on a rotary evaporator. After adding a small amount of water, the solution was cooled in an ice bath for about 1 h. A red powder precipitated, which was collected by filtration, washed with dichloromethane, and dried under vacuum. Red powder, 26% yield (8.8 mg). Needle-like crystals suitable for X-ray crystallography were obtained by recrystallization from DMF/diethyl ether. $\lambda_{max}$/nm (DMF): 350, 414, 438, 461. $C_{29}H_{43}Cl_2NO_2Pt$ (703.64): calcd. C 49.50, H 6.16, N 1.99; found C 48.95, H 6.07, N 2.06.

**Supporting Information:** (see footnote on the first page of this article) ORTEP drawings of the molecular structures of **1a**, **2a**, **3**, and **4**, and packing diagrams of **2b** and **4** are provided.

# Reactivity of Carboranylacetylenes towards Cobalt Complexes

**Avijit Goswami,[a] Yong Nie,[a] Thomas Oeser,[b] and Walter Siebert*[a]**

*Dedicated to Professor Herbert Schumann on the occasion of his 70th birthday*

**Keywords:** Carboranes / Carboranylacetylenes / Cobalt / (Cyclobutadiene)cobalt complexes / (Cyclopentadienone)cobalt complexes

The reaction of 1,6-diiodo-$C_4B_2$ *nido*-carborane derivative **1** with $RC_2Li$ (R = Me, SPh) yields the corresponding carboranylacetylenes **2b**,**c**. Treatment of the $PPh_2$-substituted *nido*-carborane **3a** with $PhC_2ZnCl$ in the presence of a catalytic amount of $Pd(PPh_3)_4$ leads to the known basal-substituted *nido*-carboranylacetylene **2a**. The synthesis of apical-substituted compound **4b** is achieved by the substitution of **3b** by a $Pd^0$-catalyzed Nigishi-type cross-coupling reaction; the basal boron atom is blocked by the *n*-butyl group. The 1,3-dicarboranyl-substituted ($\eta^4$-cyclobutadiene)cobalt complexes **5a**,**c** are obtained from the reactions of **2a**,**c** with stoichiometric amounts of $CpCo(C_2H_4)_2$. The 1,6-dialkynyl carborane **6** reacts regioselectively at the basal acetylene group with a stoichiometric amount of $CpCo(CO)_2$ to give 1,3-dicarboranyl-substituted (cyclobutadiene)cobalt complex **7**. The dicarboranyl-substituted (cyclopentadienone)cobalt complex **8** is formed by the reaction of compound **4b** with $CpCo(CO)_2$. The new compounds are characterized by NMR spectroscopy, mass spectrometry, and by X-ray crystal structure analyses for **5a** and **8**.

## Introduction

Over the past decades numerous functionalized carboranes were synthesized,[1] and their properties have been extensively investigated by both theoretical[2] and experimental analyses.[3] A large number of carborane derivatives are used in medicinal and pharmaceutical applications.[4] The reactivity of carboranylacetylenes towards transition-metal complexes has received relatively little attention. In 1973, Hawthorne et al.[5] reported the first generation of 1,2,4-tris(*closo*-1,2-$C_2B_{10}H_{11}$-1-yl)benzene by the reaction of 1-ethynyl-1,2-carborane with a catalytic amount of bis(acrylonitrile)nickel(0). Michl et al.[6] presented a convenient route to synthesize tris(1,12-carboranyl)-substituted benzene derivatives by a palladium-catalyzed cross-coupling of three 1,12-dicarba-*closo*-dodecaboranyl units to a 1,3,5-trihalobenzene. In 1982, a series of σ-1-*ortho*- and σ-1-*meta*-carboranylacetylenides of copper, silver, palladium, platinum, and iron were synthesized by Zakharkin and his coworkers.[7] In 2003, Grimes[8] published an account on cluster formation between a 1,3,5-tris(carboranylacetylene)benzene and $Co_2(CO)_8$. Very recently, we reported cobalt-mediated dimerization reactions of apically alkynyl-substituted *closo*-$C_2B_5$ carboranes with cobalt complexes.[9] While the inherent scope and reaction efficiencies are found to be limited, the study introduces the attractive prospect that small alkynyl-substituted carboranes might be utilized for metal-mediated dimerization reactions. Here we report the synthesis of functionalized *nido*-$C_4B_2$ carboranes and the reactions of some of the alkynyl-substituted derivatives with cobalt complexes.

## Results and Discussion

### Preparation and Characterization of $C_4B_2$ *nido*-Carboranylacetylenes 2b,c

Because of the easy accessibility and high stability of the peralkylated 2,3,4,5-tetracarba-*nido*-hexaboranes(6)[10] (in comparison with the parent $C_4B_2H_6$[11]), their reactivity has drawn special attention.[12,13] To investigate substitution reactions of $C_4B_2$ *nido*-carboranes, functional groups other than alkyl or aryl groups are needed at the boron atom(s). Wrackmeyer et al.[12] and more recently our group[14] noticed that nucleophilic substitutions proceeded smoothly at the basal boron atom to give the corresponding carboranes with organyl, stannyl, diphenylphosphanyl, N-bonded (μ-NS)$Fe_2(CO)_6$ groups, as well as with the [$CpFe(CO)_2$] group. However, even the presence of an excess of nucleo-

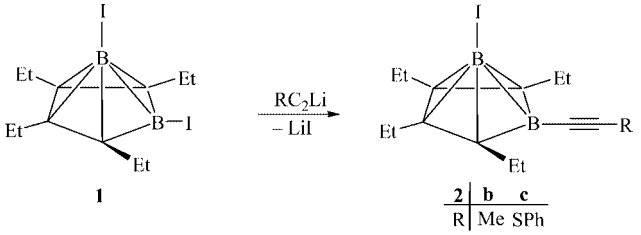
 InterScience © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phile was not enough to achieve substitution at the apical boron atom.[12,14]

Analogously, nucleophilic substitution reactions of 2,3,4,5-tetraethyl-1,6-diiodo-2,3,4,5-tetracarba-*nido*-hexaborane(6) (**1**) with $RC_2Li$ (R = Me, SPh) led to the corresponding basal-substituted carborane derivatives **2b**,**c** in high yields (Scheme 1). In agreement with the findings of Wrackmeyer et al.[12] and our recent results,[14] an excess of lithium acetylides did not effect additional substitution at the apical boron atom. Compounds **2b**,**c** (light yellow oils) were characterized by $^1$H-, $^{13}$C-, and $^{11}$B NMR spectroscopy, as well as by mass spectrometry. The *nido*-$C_4B_2$ framework is retained, and little difference is found in the $^1$H- and $^{13}$C NMR spectra in comparison to that of compound **1**. In the $^{11}$B NMR spectra of **2b**,**c** the basal boron atoms give signals at $\delta$ = 10–12 ppm, which are only slightly shifted downfield from that of **1** ($\delta$ = 5.5 ppm), while the shifts of the signals for the apical boron atoms are the same as that of the starting carborane **1** ($\delta$ = –52.7 ppm).

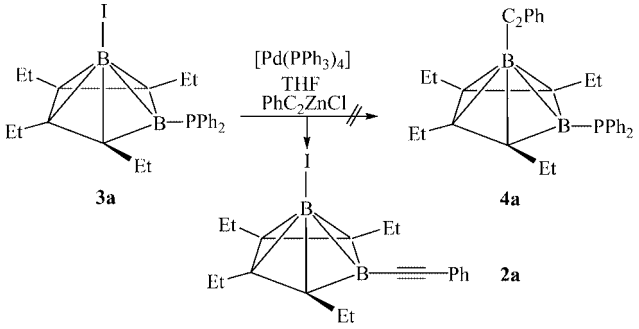


Scheme 1.

The $^1$H NMR spectrum of **2b** exhibits the signals ($\delta$ = 1.2–2.4 ppm) for the ethyl groups, in addition to the methyl resonance ($\delta$ = 1.98 ppm). In the $^{13}$C NMR spectrum, a signal ($\delta$ = 112.4 ppm) is found for the skeletal carbon atoms nonadjacent to the basal boron atom, whereas the signals for the boron-bound carbon atoms and for the acetylene carbon atoms are not observed. Similarly, the $^1$H NMR spectrum of **2c** shows the signals ($\delta$ = 1.3–2.4 ppm) for the ethyl groups along with the multiplets ($\delta$ = 7.2–7.6 ppm) for the aryl protons. The $^{13}$C NMR spectrum features a signal at $\delta$ = 113.0 ppm for the skeletal carbon atoms nonadjacent to the basal boron atom; however, the signals for the boron-bound carbon atoms and the acetylene carbon atoms are not detected. EI-MS data confirm the identity of carboranes **2b**,**c** through the appearance of the molecular ion peaks with the correct isotopic pattern.

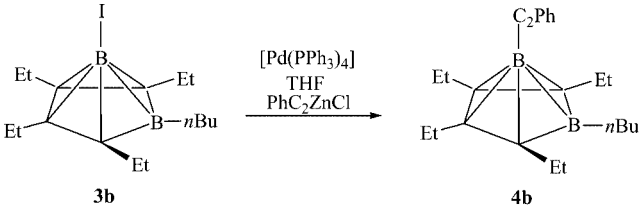
### Substitution Reactions at the Apical Boron Atom of 3a

In most of the cases, the apical boron–halogen bonds are found to be inert;[12,14] however, substitution reactions can be achieved by $Pd^0$-catalyzed Nigishi-type cross-coupling reactions.[15] Analogously, an attempt to prepare the carborane **4a** by the reaction of **3a** with $PhC_2ZnCl$ in the presence of a catalytic amount of $Pd(PPh_3)_4$ was not successful, as the known carborane **2a**[14] was obtained by the substitution of $PPh_2$ at the basal boron atom (Scheme 2).



Scheme 2.

On the other hand, treatment of compound **3b** with $PhC_2ZnCl$ in the presence of a catalytic amount of $Pd(PPh_3)_4$ led to the expected carborane **4b** in moderate yield (Scheme 3). Compound **4b** (yellow oil) was characterized by $^1$H-, $^{13}$C-, and $^{11}$B NMR spectroscopy, as well as by mass spectrometry. The $^{11}$B NMR signal of the substituted apical boron atom is shifted only slightly downfield to $\delta$ = –50.5 ppm, whereas the chemical shift for the basal boron atom remains the same as that for **3b** ($\delta$ = 19 ppm). In the EI mass spectrum of **4b**, the molecular ion peak appears at *m*/*z* = 344 with the expected isotopic distribution.



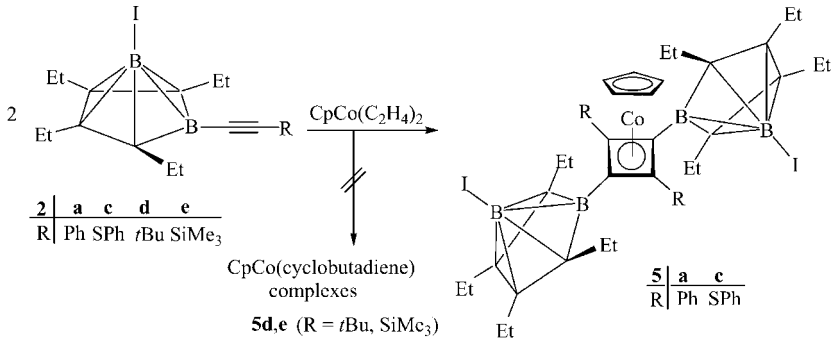
Scheme 3.

### Formation of Bis(carboranyl)cyclobutadiene Cobalt Complexes 5 and 7

No reaction was observed between carboranylacetylene derivatives **2** with catalytic and stoichiometric amounts of $CpCo(CO)_2$ in refluxing toluene for several days, as monitored by $^{11}$B NMR spectroscopy. However, adding $CpCo(C_2H_4)_2$ to the reaction mixture and refluxing for an additional two days, followed by column chromatography afforded the 1,3-dicarboranyl-substituted $CpCo(\eta^4$-cyclobutadiene) complexes **5a**,**c** (Scheme 4). No reaction was observed with **2d**,**e**.

The *trans*-1,3-isomers are sterically favored, as confirmed by the solid-state structure of **5a**. However, several known complexes have *cis*-bis(trimethylsilyl)cyclobutadiene ligands.[16] The stereochemistry problem was resolved unequivocally by the analysis of the major peaks in the mass spectra with respect to the degradation of the cyclobutadiene ring. In general, three different acetylene molecules are released from the molecular ion of the *cis* isomer, whereas only one acetylene molecule is released from the *trans* isomer.[17] Here, in both of **5a** and **5c**, only a single acetylene molecule was released from the molecular ion. Therefore,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4.

the mass spectra clearly provide evidence for *trans* isomers. The $^{11}$B NMR signals of **5a**,**c** for the basal boron atoms are shifted downfield to $\delta$ = 18 ppm, while the chemical shifts for the apical boron atoms remain the same as those for in the starting carboranes ($\delta$ = –52 ppm). The $^{1}$H NMR spectra of **5a**,**c** show the multiplets ($\delta$ = 7.1–7.6 ppm) for the aryl hydrogen atoms in addition to the Cp resonances ($\delta$ = 4.95 and 5.10 ppm). In the $^{13}$C NMR spectra, the signals ($\delta$ = 84–86 ppm) for the Cp–C are observed, but the signals for the four quaternary carbon atoms of the cyclobutadiene ring are not found.

The structure of **5a** was characterized by performing a single-crystal X-ray diffraction analysis. Two independent molecules were found in the asymmetric unit with very similar distances and angles; the structure of one molecule is shown in Figure 1. It reveals almost equal C–C bond lengths within the cyclobutadiene ring, and none of the phenyl groups lie in the $C_4$ plane. The conformation is highly influenced by the bulky $C_4B_2$ *nido*-carboranyl groups, which are oriented away from the metal center.

Regioselective reactivity of the carboranylacetylene derivative **6**[14] towards cobalt complexes $CpCoL_2$ (L = CO, $C_2H_4$) was observed. In the reactions of $CpCoL_2$ with the $C_4B_2$ *nido*-carborane **6** containing two acetylene moieties at the boron atoms, only the basal boron-substituted acetylene unit undergoes cyclobutadiene ring formation to give **7** (Scheme 5). The $^{11}$B NMR spectrum of complex **7** exhibits signals at $\delta$ = 15 and –50.4 ppm; the latter value for the apical boron atom is shifted slightly downfield relative to that of the starting carborane **6**. The mass spectrum shows the molecular ion peak with the expected isotopic pattern.

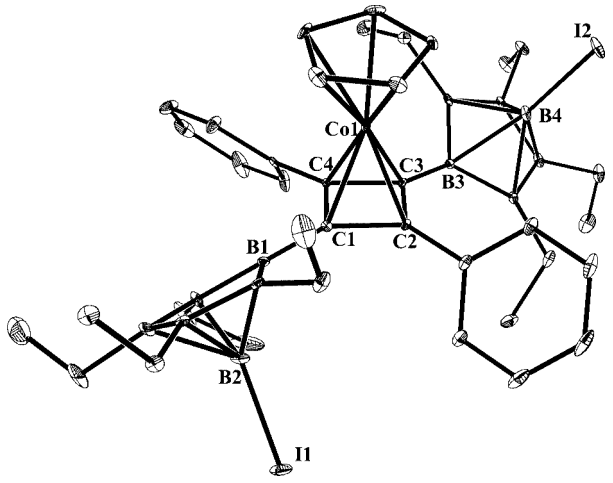


Figure 1. Molecular structure of **5a** in the solid state; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and bond angles [°]: C1–B1 1.559(6), C3–B3 1.549(6), C1–C2 1.471(5), C2–C3 1.480(5), C3–C4 1.465(5), C4–C1 1.466(5), B2–I1 2.131(5), B4–I2 2.114(5), B1–B2 1.943(6), B3–B4 1.820(6), C1–C2–C3 91.2(3), C2–C3–C4 88.2(3), C3–C4–C1 92.0(3), C4–C1–C2 88.5(3), B1–B2–I1 144.5(3), B3–B4–I2 141.6(3). Only one of the two independent molecules is shown to provide a better overview.

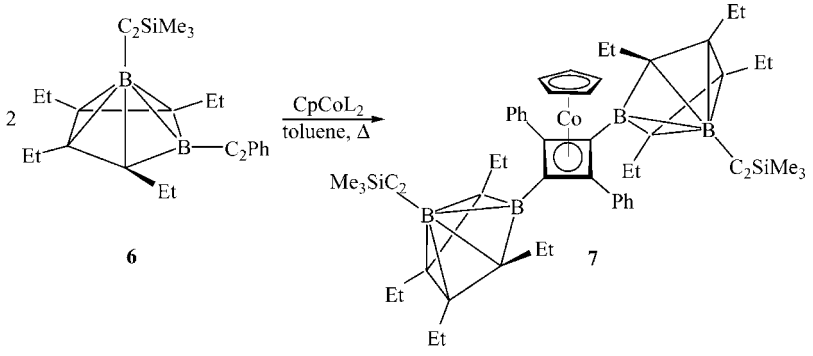
### ($\eta^5$-Cyclopentadienyl)($\eta^4$-2,5-bis-carboranyl)(cyclopentadienone)cobalt Complex 8

To investigate the reactivity of the apical boron-bound acetylene group, the carboranylacetylene derivative **4b** was prepared (see earlier), in which the basal boron atom is blocked by the *n*-butyl group. Interestingly, the reaction of compound **4b** with a stoichiometric amount of CpCo-



Scheme 5.

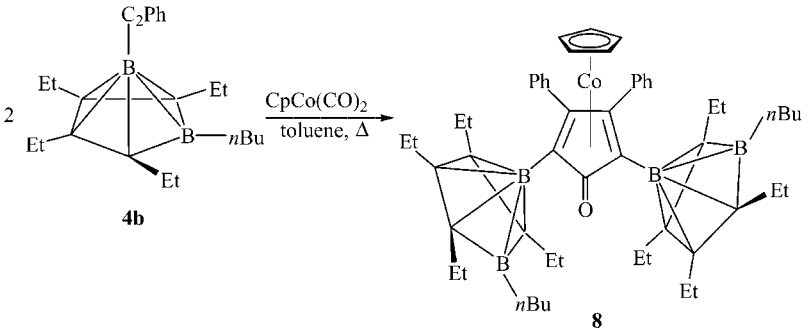

Scheme 6.

$(CO)_2$ led to the 2,5-dicarboranyl-substituted ($\eta^4$-cyclocyclopentadienone)cobalt complex **8** in good yield (Scheme 6). It was characterized by $^1$H-, $^{13}$C-, and $^{11}$B NMR spectroscopy, mass spectrometry, and X-ray crystal structure analysis. As expected, the $^{11}$B NMR signal of the apical boron atom is shifted downfield to $\delta$ = –44.4 ppm. The $^1$H NMR spectrum of **8** shows a singlet at $\delta$ = 4.95 ppm for $C_5H_5$, in addition to the phenyl group resonances ($\delta$ = 6.90–7.63 ppm). In the $^{13}$C NMR spectrum, the signals for the Cp–C and carbonyl groups are observed at $\delta$ = 81.7 and 188.1 ppm, respectively, while the signals for the cyclopentadienone ring are not found. The IR spectrum of **8** shows a band at $\tilde{\nu}$ = 1593 cm$^{-1}$, and the appearance of the molecular ion peak with the correct isotopic distribution in the EI-MS data confirms the identity.

The solid-state structure of **8** was characterized by performing a single-crystal X-ray diffraction analysis (Figure 2). Four molecules of **8** crystallized with one hexane molecule. As expected,[18] the structure reveals that the bulky carboranyl groups are bound to α-carbon atoms of the cyclopentadienone ring to reduce the steric strain.

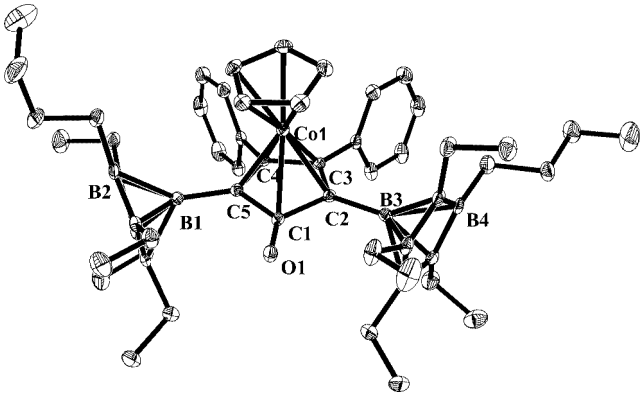

Figure 2. Molecular structure of **8** in the solid state; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and bond angles [°]: C5–B1 1.549(5), C2–B3 1.560(5), C1–C2 1.490(5), C2–C3 1.427(5), C3–C4 1.452(5), C4–C5 1.447(5), C5–C1 1.488(5), C1–O1 1.241(4), B1–B2 1.878(6), B3–B4 1.851(6), C1–C2–C3 108.0(3), C2–C3–C4 108.6(3), C3–C4–C5 109.3(3), C4–C5–C1 106.7(3), C5–C1–C2 106.3(3), O1–C1–C5 126.5(3), O1–C1–C2 126.9(3).

## Conclusions

The reactions of carboranylacetylenes with catalytic and stoichiometric amounts of cobalt complexes $CpCoL_2$ (L = CO, $C_2H_4$) have been studied. Reactions in the presence of catalytic amounts of $[CpCoL_2]$ with carboranylacetylenes **2**, **4b**, and **6** do not lead to benzene derivatives, which can be explained on steric grounds. The ($\eta^4$-1,3-dicarboranylcyclobutadiene)cobalt complexes **5a**,**c** are formed by the reactions of **2a**,**c** with stoichiometric amounts of $CpCo(C_2H_4)_2$. Regioselective reactions occur between $CpCoL_2$ and the $C_4B_2$ *nido*-carborane **6**. Only the basal-substituted borylacetylene moiety of compound **6** is involved in cyclobutadiene ring formation, whereas the apical-substituted borylacetylene unit remains unreacted. The reaction of carboranylacetylene **4b**, carrying an *n*-butyl group at the basal boron atom, with $CpCo(CO)_2$ leads to the (cyclopentadienone)cobalt complex **8**. The cobalt complexes **5**, **7**, and **8** are stable at room temperature and are resistant to light, oxygen, and moisture.

## Experimental Section

**General:** All reactions were performed under nitrogen using standard Schlenk techniques. Solvents were dried with the appropriate drying agents and distilled under nitrogen. Glassware was dried with a heat gun under high vacuum. $^1$H-, $^{13}$C- and $^{11}$B NMR spectra were recorded with a Bruker AC 200 spectrometer. $^1$H- and $^{13}$C NMR spectra were referenced to $(CH_3)_4Si$, and $^{11}$B NMR spectra were referenced to $F_3B{\cdot}OEt_2$. IR spectra were recorded with a Bruker IFS 28 FT spectrometer. Mass spectra were obtained with Finnigan MAT 8230 plus spectrometers using the EI technique. Melting points (uncorrected) were obtained with a Büchi apparatus, using capillaries that were filled under nitrogen and sealed. The *nido*-carboranes **1**,[19] **2a**,**d**,**e**,[14] **3a**,[14] **6**,[14] and $CpCo(C_2H_4)_2$[20] were prepared according to literature procedures. $CpCo(CO)_2$ was purchased from Aldrich®.

**General Procedure for Basal Boron-Substituted Carboranylacetylenes 2b,c**

An appropriate solution of lithium acetylide in hexane (30 mL) was cooled to –40 °C and added by syringe to a solution of the *nido*-carborane **1** in hexane (20 mL) at –78 °C. The mixture was warmed to room temp. and stirred for 2 d. After filtration, the light yellow solution was dried in vacuo to give a yellow oil.

**6-Butyl-2,3,4,5-tetraethyl-1-iodo-2,3,4,5-tetracarba-*nido*-hexaborane(6) (3b):** A solution of *n*BuLi (1.7 mL, 4.2 mmol) was very slowly added to a solution of *nido*-carborane **1** (0.92 g, 2.1 mmol) in hexane (50 mL) at –78 °C. The mixture was warmed to room temp. and was stirred for 20 h. After filtration, the slightly yellow filtrate was dried in vacuo and distilled at 43 °C/0.04 mbar to give a yellow oil. Yield: 0.70 g (90%). $^1H$ NMR (200.1 MHz, $CDCl_3$): $\delta$ = 0.89, 1.45, 1.95 (m, 9 H, *n*Bu), 1.19, 1.40 (t, 2×6 H, $CH_2CH_3$), 2.08, 2.36 (m, 2×4 H, $CH_2CH_3$) ppm. $^{13}C$ NMR (50.3 MHz, $CDCl_3$): $\delta$ = 13.7, 14.2 ($CH_3$), 18.5, 19.0 ($CH_2$), 16.0, 17.6, 25.9, 26.6 (*n*Bu), 112.9 (skeletal carbon atoms nonadjacent to the basal boron) ppm. $^{11}B$ NMR (64.2 MHz, $CDCl_3$): $\delta$ = 19 (br., $B_{basal}$), –52.6 (s, $B_{apical}$) ppm. MS (EI, 70 eV): *m*/*z* (%) = 370 (100) [$M^+$], 243 (10) [$M^+$ – I].

**Attempt to Prepare 2,3,4,5-Tetraethyl-1-phenylethnyl-6-diphenylphosphanyl-*nido*-carborane (4a):** To lithium phenylacetlylide (0.54 g, 5.0 mmol) in THF (15 mL) at room temp. was added $ZnCl_2$ (0.68 g, 5.0 mmol), and the solution was stirred for 3 h. The solution was then added to a mixture of **3a** (1.24 g, 2.5 mmol) and $Pd(PPh_3)_4$ (0.04 g, 0.034 mmol), and the resulting yellow mixture was heated at reflux for 10 d. The solvent was removed under high vacuum, the black residue was extracted with hexane (2×20 mL) and filtered. The yellow filtrate was dried in vacuo to give a yellow viscous oil. Yield: 0.51 g (49%) **2a**. NMR and mass spectroscopic data were in agreement with the previously reported result.[19]

**6-Butyl-2,3,4,5-tetraethyl-1-phenylethynyl-2,3,4,5-tetracarba-*nido*-hexaborane(6) (4b):** To lithium phenylacetlylide (0.54 g, 5.0 mmol) in THF (30 mL) at room temp. was added $ZnCl_2$ (0.68 g, 5.0 mmol), and the solution was stirred for 3 h. The solution was then added to a mixture of **3b** (0.85 g, 2.3 mmol) and $Pd(PPh_3)_4$ (0.04 g, 0.034 mmol) in THF (30 mL). The resulting yellow mixture was heated at reflux for 6 d. After evaporation of the solvent, the black residue was extracted with hexane (2×20 mL) and filtered. The yellow filtrate was dried in vacuo to give a yellow oil. Yield: 0.5 g (63%). $^1H$ NMR (200.1 MHz, $CDCl_3$): $\delta$ = 0.95, 1.52, 2.02 (m, 9 H, *n*Bu), 1.19, 1.25 (t, 2×6 H, $CH_2CH_3$), 2.10, 2.45 (m, 2×4 H, $CH_2CH_3$), 7.22–7.35 (m, 5 H, Ph) ppm. $^{13}C$ NMR (50.3 MHz, $CDCl_3$): $\delta$ = 14.1, 15.4, 22.6, 26.3 (*n*Bu), 17.4, 18.5 ($CH_3$), 29.7, 30.5 ($CH_2$), 112.1 (skeletal carbon atoms nonadjacent to the basal boron), 127.7, 128.0, 131.9 (Ph) ppm. $^{11}B$ NMR (64.2 MHz, $CDCl_3$): $\delta$ = 20 (br., $B_{basal}$), –50.5 (s, $B_{apical}$) ppm. MS (EI, 70 eV): *m*/*z* (%) = 344 (100) [$M^+$].

**General Procedure for Cobalt Complexes 5a,c**

To an appropriate solution of carboranylacetylene in toluene was added a portion of $CpCo(CO)_2$ at room temp. The deep-red mixture was heated at reflux and monitored by $^{11}B$ NMR spectroscopy, indicating that no reaction took place. After 4 d, one portion of $CpCo(C_2H_4)_2$ was added, and the resulting mixture was again heated at 120 °C for another 2 d. After completion of the reaction, the solvent was removed to dryness, and the crude product was purified by column chromatography on silica gel to give two fractions. Using hexane as the eluant, unreacted $CpCo(CO)_2$ and $CpCo(C_2H_4)_2$ were obtained. The second fraction (toluene) contained the corresponding (cyclobutadiene)cobalt complex.

**{η⁴-Bis[2,3,4,5-tetraethyl-1-iodo-2,3,4,5-tetracarba-*nido*-hexaboranyl]diphenyl(cyclobutadiene)}(η⁵-cyclopentadienyl)cobalt(I) (5a):** Starting materials: compound **2a** (0.50 g, 1.2 mmol), $CpCo(CO)_2$ (0.10 g, 0.6 mmol), and $CpCo(C_2H_4)_2$ (0.10 g, 0.6 mmol). Yield: 0.40 g (76%), yellow crystals, m.p. 124–125 °C. Compound **5a** was recrystallized from a solution of toluene at –20 °C. $^1H$ NMR (200.1 MHz, $CDCl_3$): $\delta$ = 1.3 (m, 24 H, $CH_3$), 2.3 (m, 16 H, $CH_2$), 5.10 (s, 5 H, Cp–H), 7.25, 7.55 (m, 10 H, Ph) ppm. $^{13}C$ NMR (50.3 MHz, $CDCl_3$): $\delta$ = 13.4, 14.3 ($CH_3$), 18.4, 19.8 ($CH_2$), 84.5 (Cp–C), 113.0 (skeletal carbon atoms nonadjacent to the basal boron), 127.6, 128.0, 131.7 (Ph) ppm; quaternary carbon atoms were not found. $^{11}B$NMR (64.2 MHz, $CDCl_3$): $\delta$ = 18 (br., $B_{basal}$), –52.0 (s, $B_{apical}$) ppm. MS (EI, 70 eV): *m*/*z* (%) = 952 (100) [$M^+$], 538 (10) [$M^+$ – $Et_4C_4B_2I(C_2Ph)$]. MS (HR-EI, 70 eV): *m*/*z* = 952.2087 [$M^+$], $^{12}C_{45}{}^{1}H_{55}{}^{11}B_4{}^{59}Co^{127}I_2$: 952.2097; $\Delta$mmu = –1.0.

**{η⁴-Bis[2,3,4,5-tetraethyl-1-iodo-2,3,4,5-tetracarba-*nido*-hexaboranyl]diphenylthio(cyclobutadiene)}(η⁵-cyclopentadienyl)cobalt(I) (5c):** Starting materials: compound **2c** (0.40 g, 1.2 mmol), $CpCo(CO)_2$ (0.10 g, 0.6 mmol), and $CpCo(C_2H_4)_2$ (0.10 g, 0.6 mmol). Yield: 0.25 g (54%), brown-red oil. $^1H$ NMR (200.1 MHz, $CDCl_3$): $\delta$ = 1.26, 1.35 (t, 2×12 H, $CH_3$), 2.10, 2.35 (m, 2×8 H, $CH_2$), 4.95 (s, 5 H, Cp–H), 7.15–7.55 (m, 10 H, SPh) ppm. $^{13}C$ NMR (50.3 MHz, $CDCl_3$): $\delta$ = 13.6, 15.7 ($CH_3$), 19.1, 19.7 ($CH_2$), 85.4 (Cp–C), 115.5 (skeletal carbon atoms nonadjacent to the basal boron), 125.0, 128.8, 131.0 (SPh) ppm; skeletal carbon atoms adjacent to the basal boron and quaternary carbon atoms were not found. $^{11}B$NMR (64.2 MHz, $CDCl_3$): $\delta$ = 18 (br., $B_{basal}$), –52.1 (s, $B_{apical}$) ppm. MS (EI, 70 eV): *m*/*z* (%) = 1016 (70) [$M^+$], 570 (5) [$M^+$ – $Et_4C_4B_2I(C_2SPh)$]. MS (HR-EI, 70 eV): *m*/*z* = 1016.1550 [$M^+$], $^{12}C_{45}{}^{1}H_{55}{}^{11}B_4{}^{59}Co^{127}I_2{}^{32}S_2$: 1016.1538; $\Delta$mmu = 1.2.

**CpCo[Bis(carboranyl)cyclobutadiene] (7):** To a solution of **6** (0.053 g, 0.14 mmol) in toluene (8 mL) was added a portion of $CpCo(CO)_2$ (0.04 g, 0.22 mmol) at room temp. The deep-red reaction mixture was heated at reflux for 9 d. The brown reaction mixture was cooled and filtered through a pad of sea sand; the yellow-brown filtrate was dried in vacuo to give a brown oil. Yield: 0.056 g (89%). $^{11}B$ NMR (64.2 MHz, $CDCl_3$): $\delta$ = 15 (br, $B_{basal}$), –50.4 (s, $B_{apical}$) ppm. MS (EI, 70 eV): *m*/*z* (%) = 892 (100) [$M^+$]. MS (HR-EI, 70 eV): *m*/*z* = 892.4999 [$M^+$], $^{12}C_{55}{}^{1}H_{73}{}^{11}B_4{}^{59}Co^{28}Si_2$: 892.4955; $\Delta$mmu = 4.4.

**(η⁵-Cyclopentadienyl)(η⁴-2,5-bis-carboranyl-3,4-diphenylcyclopentadienone)cobalt(I) (8):** Carboranylacetylene **4b** (0.45 g, 1.3 mmol) and (η⁵-cyclopentadienyl)(dicarbonyl)cobalt(I) (0.11 g, 0.65 mmol) were dissolved in toluene (30 mL). The resulting dark-red mixture was stirred at 120 °C for 3 d. After cooling, the solvent was removed under high vacuum, and the black residue was purified by column chromatography ($SiO_2$, hexane). Cobalt complex **8** was recrystallized from a solution of hexane at –20 °C. Yield: 0.4 g (73%), brown solid, m.p. 133–136 °C. $^1H$ NMR (200.1 MHz, $CDCl_3$): $\delta$ = 1.20 (m, 2×12 H, $CH_2CH_3$), 0.90, 1.85, 2.12 (m, 2×9

**X-ray Crystal Structure Determinations of 5a and 8:** Crystal data and details of the structure determinations are listed in Table 1. Reflections were collected with Bruker SMART APEX (**5a**) and Bruker-AXS SMART 1000 (**8**) diffractometers (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, graphite monochromator, $\omega$-scan). Empirical absorption corrections were applied. The structure was solved by direct methods and refined by least-square methods based on $F^2$ with all measured reflections (SHELXTL 6.12).[21] All non-hydrogen atoms were refined anisotropically. CCDC-276980 (**5a**) and CCDC-276981 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Probing the Dinucleating Behaviour of a Bis-Bidentate Ligand: Synthesis and Characterisation of Some Di- and Mononuclear Cobalt(II), Nickel(II), Copper(II) and Zinc(II) Complexes of 3,5-Di(2-pyridyl)-4-(1*H*-pyrrol-1-yl)-4*H*-1,2,4-triazole

**Marco H. Klingele,[a] Peter D. W. Boyd,[b] Boujemaa Moubaraki,[c] Keith S. Murray,[c] and Sally Brooker*[a]**

**Keywords:** 1,2,4-Triazoles / Bridging ligands / N ligands / Copper complexes / Cobalt complexes / Nickel complexes / Zinc complexes / Magnetic properties

As a probe of the dinucleating ability of the known but little studied bis-bidentate ligand 3,5-di(2-pyridyl)-4-(1*H*-pyrrol-1-yl)-4*H*-1,2,4-triazole (pldpt) its reactivity towards $MX_2{\cdot}6H_2O$ (M = $Co^{II}$, $Ni^{II}$ and $Zn^{II}$; X = $ClO_4^-$ and $BF_4^-$) as well as $Cu(ClO_4)_2{\cdot}6H_2O$, in a 1:1 metal-to-ligand molar ratio in MeCN, has been investigated. In the case of $Co^{II}$, $Ni^{II}$ and $Zn^{II}$, these reactions gave dinuclear complexes $M^{II}_2(pldpt)_2X_4(MeCN)_m(H_2O)_n$, whereas for $Cu^{II}$ initially the mononuclear complex $[Cu^{II}(pldpt)_2(ClO_4)_2]$ was isolated, followed by the dinuclear complex $[Cu^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$. The use of the strongly polar aprotic co-solvent DMF resulted in the partial breakdown of the initial dinuclear entities in the case of $Co^{II}$ and $Ni^{II}$ but not in the case of $Zn^{II}$. In all five of the structurally characterised dinuclear complexes the $(N',N^1,N^2,N'')_2$ double-bridging coordination mode is realised with distorted octahedral $N_4Y_2$-coordinated metal centres (Y = DMF, $H_2O$ or MeCN). The two mononuclear complexes feature the common *trans*-$(N',N^1)_2$ coordination mode with axial DMF or $ClO_4^-$ co-ligands. The near-perpendicular orientation [82.4(3)–88.8(1)°] of the π-electron-rich 4-(1*H*-pyrrol-1-yl) substituent with respect to the triazole ring of pldpt, observed in all of these structures, means that no π-interactions are expected between these rings so any electronic interaction is likely to be small. Whether a di- or mononuclear complex of pldpt forms is therefore primarily determined by a number of other factors, including the reaction stoichiometry, the nature of the counterions and the solvent, as well as the relative solubility of the various possible products. Clearly the nature of the $N^4$ substituent can have a major impact on the last of these factors. Magnetic studies carried out on the dinuclear complexes revealed that the triazole bridges mediate relatively weak antiferromagnetic coupling between the two metal centres.

## Introduction

The utilisation of 1,2,4-triazole derivatives as bridging ligands in transition-metal complexes is currently of considerable interest.[1–3] The 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles are bis-bidentate so they are potentially dinucleating ligands that should be capable of bridging two metal ions by means of the $N_2$ unit of the central triazole ring.[2] Quite a large range of such ligands have been used for the preparation of transition-metal complexes (Figure 1). In the resulting di- and mononuclear complexes a variety of coordination modes have been observed of which the dinuclear $(N',N^1,N^2,N'')_2$ double bridging and the mononuclear $(N',N^1)_2$ coordination mode are the most common and most important ones (Figure 2).[2] For octahedral complexes featuring the latter mode, the *trans* type is frequently encountered. Here, the pyridine–triazole moieties of the two ligands are coordinated to the metal centre in a common plane with axially *trans*-positioned co-ligands. In contrast, there is only one example in the literature where the isomeric *cis* type is realised.[4]

Within this ligand class the reactivity of 4-amino-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole ($NH_2$dpt, **2**) (Figure 1) towards transition-metal salts and the properties of the resulting di- and mononuclear complexes have been studied quite extensively over the last 20 years.[5–29] From an electronic point of view the presence of the strongly electron-donating amino group on $N^4$ should facilitate the formation of dinuclear complexes of this ligand. However, of this family only two dinuclear complexes, namely $[Ni^{II}_2(NH_2dpt)_2(H_2O)_2Cl_2]Cl_2{\cdot}4H_2O$[5] and $[Cu^{II}_2(NH_2dpt)(H_2O)_4(SO_4)_2]{\cdot}H_2O$,[12] have been structurally characterised

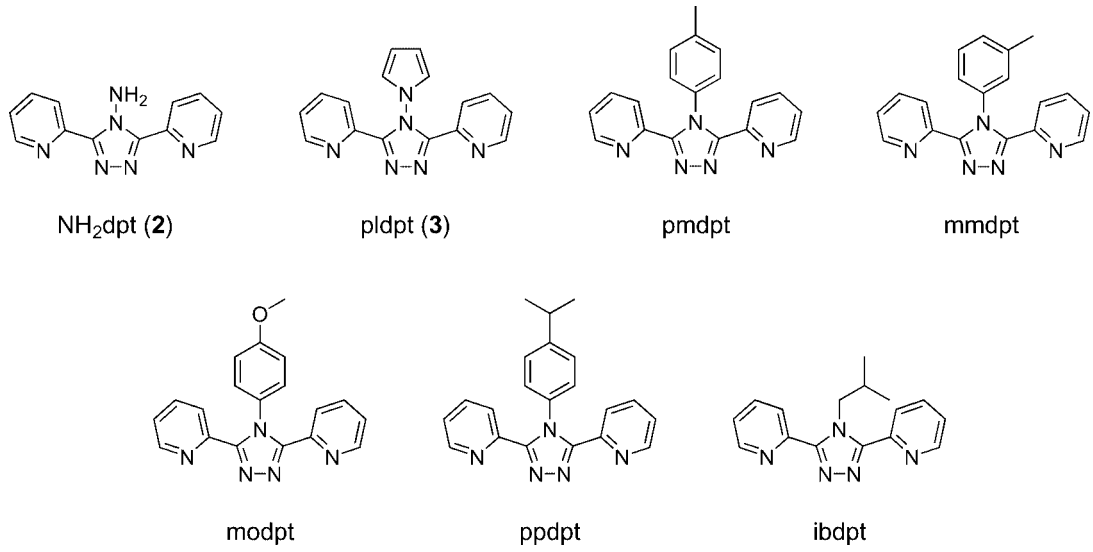

Figure 1. Structural drawings of the 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles that have been employed to date as ligands in coordination compounds.

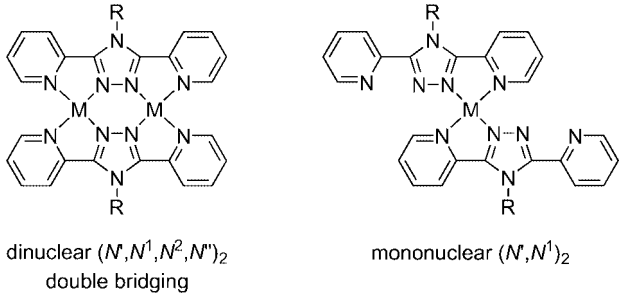

Figure 2. Schematic representation of the two most common coordination modes of 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles. In the actual complexes the metal centres can bind additional co-ligands according to the respective coordination geometries.

to date. 4-Isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ibdpt)[30] (Figure 1), with its electron-donating alkyl substituent on $N^4$, has also been found to afford both di- and mononuclear complexes.[31–33] In contrast, the 4-aryl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles have almost exclusively produced mononuclear complexes to date, in some cases despite the reaction being carried out with a metal-to-ligand molar ratio of 1:1.[4,34–42] The first, and so far the only, dinuclear complex of a 4-aryl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole, namely a dinuclear silver(I) complex of 4-(4-isopropylphenyl)-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ppdpt) (Figure 1) obtained from MeCN employing a 1:1 metal-to-ligand molar ratio, was reported very recently.[43] Given that in these complexes the aryl substituents on $N^4$ form angles of about 68–84° with the triazole ring, no significant π-interactions are expected between them. Therefore, any electronic effect that the aryl substituent on $N^4$ might exert on the triazole ring must occur through the σ-bond framework so is likely to be small. There is only one report in the literature dealing with 3,5-di(2-pyridyl)-4-(1*H*-pyrrol-1-yl)-4*H*-1,2,4-triazole (pldpt, **3**) (Figure 1) and it describes the structural characterisation of the dinuclear complex $[Co^{II}_2(pldpt)_2(H_2O)_4]Cl_4{\cdot}2MeOH{\cdot}2H_2O$, which was formed from the 1:1 reaction of $CoCl_2{\cdot}6H_2O$ and pldpt (**3**) in MeOH/$H_2O$, 4:1.[44]

Overall it appears that the factors which combine to determine the nature of the products of such a complexation reaction, in particular whether a di- or mononuclear complex is formed as the main product, include the reaction stoichiometry, the choice of the counterions and the solvent used, as well as the influence of the $N^4$ substituent on the electronic structure and conformation of the respective ligand and on the relative solubility of the various possible product complexes. Systematic studies aimed at investigating the relative importance of these factors are currently lacking but clearly desirable so we are beginning to address this as part of our ongoing studies which are directed towards the synthesis and characterisation of dinuclear 1,2,4-triazole-bridged complexes of such ligands,[2,3,30,32,33,45–51] with a particular interest in iron(II) complexes.[52] Given that to date dinuclear 1,2,4-triazole-bridged complexes are far less common than the corresponding mononuclear complexes, here we target the controlled formation of further examples of dinuclear complexes of pldpt (**3**) by employing a metal-to-ligand molar ratio of 1:1 in the complexation reactions and varying the solvents and counterions.

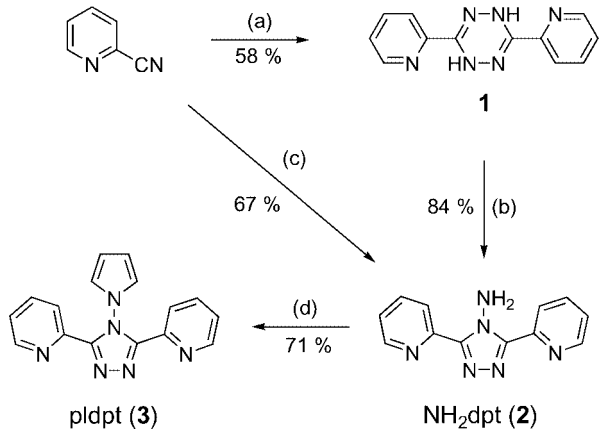
## Results and Discussion

### Ligand Synthesis

Following the classic two-step procedure of Geldard and Lions,[53] the condensation of 2-pyridinecarbonitrile with $N_2H_4{\cdot}H_2O$ gave 3,6-di(2-pyridyl)-1,4-dihydro-1,2,4,5-tetrazine (**1**) in 58% yield (Scheme 1). The subsequent rearrangement of the dihydrotetrazine **1** in 2 M HCl afforded $NH_2$dpt (**2**) in 84% yield.[53] Alternatively, $NH_2$dpt (**2**) could be obtained directly from the two reactants by em-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ploying the one-pot procedure described by Lagrenée and co-workers (Scheme 1).[54] However, it was found that the reaction was much slower than reported and difficult to drive to completion. The initial product thus obtained had to be recrystallised at least twice in order to obtain pure material. This caused the final yield of $NH_2$dpt (**2**) to drop significantly and the two-step procedure of Geldard and Lions[53] was therefore preferred. The reaction of $NH_2$dpt (**2**) with 2,5-dimethoxytetrahydrofuran[55,56] in AcOH/1,4-dioxane (1:1) readily gave pldpt (**3**) in 77% yield.[44] Compounds **1**–**3** were fully characterised by spectroscopic methods. In addition, pldpt (**3**) was characterised by single-crystal X-ray diffraction (Figures S1 and S2).



Scheme 1. Synthesis of 3,5-di(2-pyridyl)-4-(1*H*-pyrrol-1-yl)-4*H*-1,2,4-triazole (pldpt, **3**). Reagents and conditions: (a) $N_2H_4{\cdot}H_2O$, reflux; (b) 2 M HCl, reflux; (c) $N_2H_4{\cdot}H_2O$, $N_2H_4{\cdot}H_2SO_4$, 1,2-ethandiol, 130 °C; (d) 2,5-dimethoxytetrahydrofuran, AcOH, 1,4-dioxane, reflux.

There has been some confusion about the exact nature of the dihydrotetrazine intermediates arising from the condensation of nitriles with hydrazine. Especially in the older literature, including leading reviews on tetrazines and their dihydro derivatives[57–59] as well as one on a related topic,[60] these compounds are mostly considered to be the 1,2-tautomers. However, at least in the case of the condensation of 2-pyridinecarbonitrile with $N_2H_4{\cdot}H_2O$, it has now been proven unequivocally by two independent research groups on the basis of single-crystal X-ray diffraction that the product of this reaction is in fact the 1,4-tautomer.[61,62]

### Synthesis of the Cobalt(II) Complexes

According to the literature, the reaction of pldpt (**3**) with $CoCl_2{\cdot}6H_2O$ in a 1:1 molar ratio in MeOH/$H_2O$ (4:1) gives, on slow evaporation of the reaction mixture, orange crystals of $[Co^{II}_2(pldpt)_2(H_2O)_4]Cl_4{\cdot}2MeOH{\cdot}2H_2O$ in 60–70% yield.[44] Following this procedure as closely as possible, the synthesis of this material was attempted. However, instead of orange crystals, irregular beige crystals started to separate from the orange-brown solution after a few days. Over the course of four weeks the solution was allowed to evaporate almost completely forming even more of the beige material. On filtration and drying, the beige crystalline material became dull which indicated the loss of some solvent. Visual examination of the resulting solid under a microscope showed that it contained a few tiny orange prisms, presumably of $[Co^{II}_2(pldpt)_2(H_2O)_4]Cl_4{\cdot}2MeOH{\cdot}2H_2O$. The small amount of orange product was separated physically from the bulk beige material but since it could not be obtained in sufficient amounts for an elemental analysis its presumed identity could not be verified. The elemental analysis of the beige solid was in good agreement with a mononuclear 1:2 complex with a composition of $Co^{II}(pldpt)_2Cl_2$(solvent). These findings are in marked contrast to the results reported by Mandal and co-workers.[44]

In the hope of getting a well-defined and less soluble solid product directly from the reaction mixture the reaction was subsequently carried out in neat EtOH instead of MeOH/$H_2O$ (4:1). Thus, the reaction of pldpt (**3**) with $CoCl_2{\cdot}6H_2O$ in a 1:1 molar ratio at reflux resulted in the initial formation of a blue solid. After 15 minutes the reaction mixture was cooled and stirring the resulting suspension at room temperature for 24 hours caused the solid to turn pink, presumably due to slow co-ligand exchange of a kinetic product to form a thermodynamically more stable product. The elemental analysis of this pink solid was in good agreement with a dinuclear 2:2 complex with a composition of $Co^{II}_2(pldpt)_2Cl_4$(solvent). This material proved to be insoluble in all organic solvents, including DMF, $MeNO_2$ and DMSO, and could only be dissolved in $H_2O$. However, since all attempts to obtain a crystalline material from $H_2O$ were unsuccessful, further purification and characterisation was not possible.

As a result of these disappointing findings using $CoCl_2{\cdot}6H_2O$ the coordination behaviour of pldpt (**3**) towards $Co(ClO_4)_2{\cdot}6H_2O$ was investigated next, in the hope of obtaining a solid product straight from the reaction mixture that would exhibit better solubility in organic solvents, thus allowing purification and proper characterisation. In order to achieve the formation of a dinuclear 2:2 complex, $Co(ClO_4)_2{\cdot}6H_2O$ was treated with pldpt (**3**) in a 1:1 molar ratio in MeCN. The resulting orange solid, which separated from the reaction mixture in ca. 90% yield, gave an elemental analysis in good agreement with a dinuclear 2:2 complex with a composition of $Co^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**4**). The solvent content of this material varied widely from batch to batch and the drying of samples at 60 °C in vacuo (CAUTION!) for several days similarly resulted in the formation of materials of variable solvent content. While complex **4** was only very sparingly soluble in MeCN, the addition of a little DMF led to dissolution. Vapour diffusion of $Et_2O$ into a solution of complex **4** in MeCN/DMF (10:1) resulted in the formation of two different kinds of crystalline materials, namely orange prisms and yellow blocks, in variable relative amounts. Both species were studied by single-crystal X-ray diffraction. Thus, the orange crystals were identified as the dinuclear complex $[Co^{II}_2(pldpt)_2(DMF)_2(H_2O)_2](ClO_4)_4{\cdot}0.5Et_2O$ (**5**) (Figure 3) whereas the yellow crystals were found to be of the mononuclear complex $[Co^{II}(pldpt)_2(DMF)_2](ClO_4)_2$ (**6**) (Figure 4). These findings suggest that in the presence of DMF

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the initial dinuclear complex **4** is unstable, resulting in the formation of a mixture of di- and mononuclear species, complexes **5** and **6**, respectively.

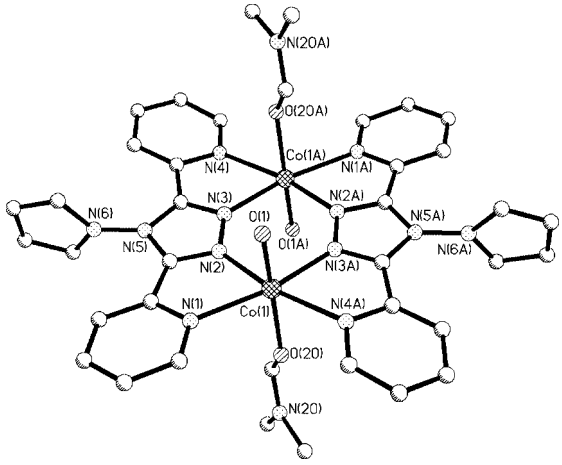


Figure 3. View of the molecular structure of the cation of $[Co^{II}_2(pldpt)_2(H_2O)_2(DMF)_2](ClO_4)_4{\cdot}0.5Et_2O$ (**5**). Hydrogen atoms have been omitted for clarity. Symmetry operation used to generate equivalent atoms: (A) $-x + 1, -y + 1, -z + 2$.

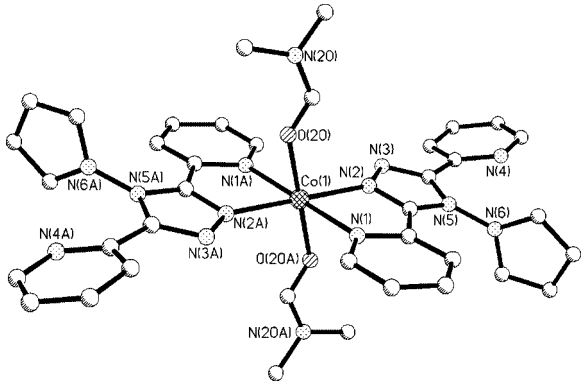

Figure 4. View of the molecular structure of the cation of $[Co^{II}(pldpt)_2(DMF)_2](ClO_4)_2$ (**6**). Hydrogen atoms have been omitted for clarity. Symmetry operation used to generate equivalent atoms: (A) $-x + 1, -y, -z$.

Faced with the need to use DMF as a co-solvent in order to dissolve the $ClO_4^-$ complex **4** and the resulting formation of a mixture of species of different nuclearities, the synthesis of the $BF_4^-$ analogue was carried out as this material was expected to exhibit better solubility in MeCN and therefore might not require the use of DMF. Thus, reacting $Co(BF_4)_2{\cdot}6H_2O$ with pldpt (**3**) in a 1:1 molar ratio in MeCN afforded a pale orange powder, in ca. 80% yield, which had a composition of $Co^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**7**). As found earlier for the $ClO_4^-$ analogue **4**, the solvent content of the material was variable and prolonged heating in vacuo afforded only partially desolvated materials of variable compositions. As anticipated, this complex could be readily redissolved in MeCN. Vapour diffusion of $Et_2O$ into the MeCN mother liquor, or into a solution of complex **7** in MeCN, gave only one crystalline species which was identified as $[Co^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**8**) (Figure S3) by single-crystal X-ray diffraction. Thus, in MeCN alone the initial dinuclear complex **7** is stable and is not broken down into a mixture of di- and mononuclear species.

### Synthesis of the Nickel(II) Complexes

In parallel with the attempted synthesis of $[Co^{II}_2(pldpt)_2(H_2O)_4]Cl_4{\cdot}2MeOH{\cdot}2H_2O$[44] the reaction of pldpt (**3**) with $NiCl_2{\cdot}6H_2O$ in a 1:1 molar ratio under analogous conditions was examined. The slow evaporation of the olive-green MeOH/$H_2O$ (4:1) reaction mixture over the course of six weeks produced a mixture of a greenish crystalline solid and blue prisms in an estimated 3:1 ratio. As the physical separation of the two materials was practically impossible no analytical data for either of the compounds could be obtained. However, it is quite likely that, by analogy to the experiment employing $CoCl_2{\cdot}6H_2O$ described above, a mixture of di- and mononuclear compounds was formed. Carrying out the reaction of pldpt (**3**) with $NiCl_2{\cdot}6H_2O$ in a 1:1 molar ratio in EtOH instead of MeOH/$H_2O$ (4:1) gave a pale green solid which was subsequently identified, on the basis of its elemental analysis, as a dinuclear 2:2 complex with a composition of $Ni^{II}_2(pldpt)_2Cl_4$(solvent). This material showed the same low solubility in organic solvents as the cobalt(II) analogue and this prevented its purification and further characterisation.

The reaction of pldpt (**3**) with $Ni(ClO_4)_2{\cdot}6H_2O$ in a 1:1 molar ratio in MeCN afforded $Ni^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**9**) as a pale violet powder in ca. 80% yield. The solvent content of the initial powder was very variable. Once again prolonged heating in vacuo (CAUTION!) afforded materials of variable solvent content. As with the cobalt(II) analogue **4** the addition of a little DMF was necessary to dissolve the powder in MeCN. Vapour diffusion of $Et_2O$ into a solution of complex **9** in MeCN/DMF (10:1) afforded an inseparable mixture of blue fern-like crystals and pink buttons, none of which were suitable for single-crystal X-ray diffraction studies. Here too, the use of DMF as a co-solvent has resulted in the formation of two different, presumably di- and mononuclear, species.

Employing $Ni(BF_4)_2{\cdot}6H_2O$ instead of the $ClO_4^-$ salt in the 1:1 reaction with pldpt (**3**) in MeCN gave $Ni^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**10**) as a pale violet powder in ca. 40% yield and variable degrees of solvation. It could not be obtained in solvent-free form. As for the cobalt(II) analogues, this $BF_4^-$ complex exhibited good solubility in neat MeCN, unlike its $ClO_4^-$ analogue **9**. Vapour diffusion of $Et_2O$ into a solution of complex **10** in MeCN or into the MeCN mother liquor of the initial powder afforded purple-blue prisms of $[Ni^{II}_2(pldpt)_2(MeCN)_4](BF_4)_4{\cdot}2MeCN$ (**11**) (Figure S4). Only one crystal type was observed so once again the initial dinuclear complex **10** is stable in MeCN.

### Synthesis of the Copper(II) Complexes

The reaction of $Cu(ClO_4)_2{\cdot}6H_2O$ with pldpt (**3**) in a 1:1 molar ratio in MeCN gave a sea-green solution from which

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a blue powder separated after a few hours. This solid was identified as the mononuclear 1:2 complex $[Cu^{II}(pldpt)_2(ClO_4)_2]$ (**12**) on the basis of its elemental analysis. Thus, the yield was subsequently calculated as 59%. Complex **12** could be readily dissolved in MeCN to give a blue solution. Vapour diffusion of $Et_2O$ into this solution afforded blue single crystals of $[Cu^{II}(pldpt)_2(ClO_4)_2]\cdot 2DMF$ (**13**) (Figure 5). While the origin of the DMF solvates in complex **13** could not be determined with absolute certainty it is likely that the glassware used was contaminated with DMF.

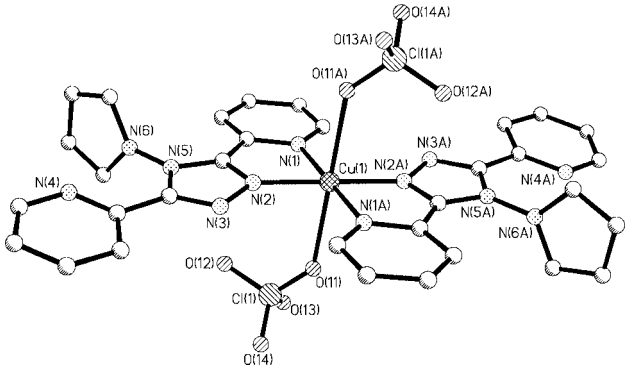

Figure 5. View of the molecular structure of $[Cu^{II}(pldpt)_2(ClO_4)_2]\cdot 2DMF$ (**13**). Hydrogen atoms have been omitted for clarity. The DMF solvates are not shown. Symmetry operation used to generate equivalent atoms: (A) $-x, -y, -z + 1$.

Interestingly, the mother liquor remaining after filtering off the blue mononuclear complex **12**, now significantly enriched in $Cu^{2+}$ ions relative to pldpt (**3**), retained its sea-green colour, suggesting the presence of a different species in solution. Subjecting this sea-green solution to vapour diffusion of $Et_2O$ produced a small quantity of large green blocks. Single-crystal X-ray diffraction studies of these crystals revealed their dinuclear nature and led to the formulation of $[Cu^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ (**14**) (Figure 6).

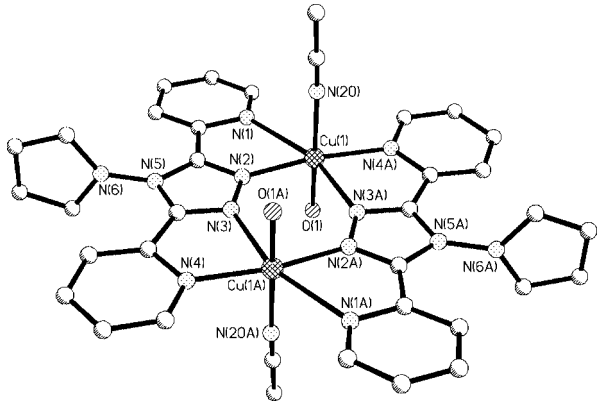

Figure 6. View of the molecular structure of the cation of $[Cu^{II}_2(pldpt)_2(H_2O)_2(MeCN)_2](ClO_4)_4$ (**14**). Hydrogen atoms have been omitted for clarity. Symmetry operation used to generate equivalent atoms: (A) $-x + 2, -y + 1, -z + 1$.

It is noteworthy that of all the $ClO_4^-$ complexes of pldpt (**3**) only the copper(II) complexes were readily soluble in neat MeCN. In addition, while in all other cases the initial precipitates consisted of dinuclear species, in the case of $Cu(ClO_4)_2\cdot 6H_2O$ the mononuclear complex $[Cu^{II}(pldpt)_2(ClO_4)_2]$ (**12**) was the initial solid product despite the 1:1 metal-to-ligand molar ratio employed in the reaction.

### Synthesis of the Zinc(II) Complexes

The reaction of pldpt (**3**) with $Zn(ClO_4)_2\cdot 6H_2O$ in a 1:1 molar ratio in MeCN afforded $Zn^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**15**) as a colourless powder in ca. 80% yield. The solvent content of this material was variable and it could not be obtained in a solvent-free form even by heating it in vacuo (CAUTION!) for several days. Recrystallisation by vapour diffusion of $Et_2O$ into a MeCN/DMF (10:1) solution of complex **15** gave colourless blocks and visually only one crystal type could be detected. Numerous attempts to grow single crystals by this method were made but only once could a poor X-ray data set be collected and this indicated that the crystals were of a dinuclear product. However, due to the very poor quality of the data, a complete analysis of the structure was not possible. Consistent with these findings, the elemental analysis of complex **15** clearly confirmed the 2:2 stoichiometry of this complex and the symmetrical NMR spectra obtained in $[D_7]$DMF were also in agreement with the presence of only one species, specifically one with a symmetrical dinuclear architecture (see below). It is interesting to note that this dinuclear zinc(II) $ClO_4^-$ complex does not form an equilibrium with a mononuclear species when it is dissolved in DMF as, if it did, this should be observed in the NMR spectra. This contrasts with the behaviour of the dinuclear cobalt(II) and nickel(II) $ClO_4^-$ analogues, complexes **4** and **9**, respectively, which on recrystallisation from solutions containing DMF form mixtures of di- and mononuclear solid products. The relative amounts of these products present in solution are unknown.

In order to access better single crystals, our attention shifted from using the $ClO_4^-$ salt to using the $BF_4^-$ salt. Under the same conditions as employed for the preparation of the analogous $BF_4^-$ complexes of cobalt(II) and nickel(II), complexes **7** and **10**, respectively, $Zn^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**16**) was obtained from pldpt (**3**) and $Zn(BF_4)_2\cdot 6H_2O$, in ca. 60% yield, as a colourless powder. As with all complexes of pldpt (**3**) synthesised in this work, the solvent content of complex **16** varied considerably from batch to batch and the drying of samples at 60 °C in vacuo for several days again resulted in materials of variable solvent content. Vapour diffusion of $Et_2O$ into a solution of complex **16** in MeCN, or into its MeCN mother liquor, gave colourless blocks which were identified by single-crystal X-ray diffraction as the dinuclear complex $[Zn^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**17**) (Figure S5).

### Description of the Structures

Single crystals of pldpt (**3**), in the form of colourless blocks, were obtained by slow evaporation of a solution of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the compound in EtOH. There are two crystallographically independent molecules in the asymmetric unit (Figures S1 and S2). The most noteworthy feature of this structure is the dissimilar orientation of the pairs of pyridine rings in the two molecules. While in the first molecule the pyridine nitrogen atoms point in opposite directions, both pyridine nitrogen atoms in the second molecule point away from the $N_2$ unit of the central five-membered heterocyclic ring. For the related ligand 2,5-di(2-pyridyl)-1,3,4-thiadiazole the latter conformation was recently calculated to be energetically favoured over the other two local minima forms with one or both pyridine nitrogen atoms pointing towards the $N_2$ unit.[63] Indeed, an orientation of the pyridine rings with the nitrogen atoms pointing away from the $N_2$ unit of the central triazole ring is the only one previously observed in 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles[30,37,64–73] and it is also the one usually adopted by non-coordinating pyridine rings in mononuclear 2:1 complexes incorporating such ligands.[2] There are, in fact, only very few examples of complexes in the literature where the non-coordinated pyridine ring is reported to point away from the $N^4$ substituent.[13,40,42] The reason for the adoption of this unusual conformation for one of the two crystallographically independent molecules of pldpt (**3**) is difficult to pinpoint but presumably arises from a complex combination of weak π–π and other packing effects. The conformation of the N(1)- and N(4)-pyridine rings was established by the differences in electron density for the two possible sites of the nitrogen atoms within the rings. This assignment was further supported by the fact that a hydrogen atom could only be located from the difference map at one of the two possible sites within the respective rings. Refinement of the structure with the alternative orientations was tried but was found to fit less well with the data.

In the dinuclear orange complex $[Co^{II}_2(pldpt)_2(DMF)_2(H_2O)_2](ClO_4)_4\cdot 0.5Et_2O$ (**5**) (Figure 3) the $(N',N^1,N^2,N'')_2$ double-bridging coordination mode (Figure 2) is realised. The two cobalt centres are 4.273(2) Å apart (Table 1) and in a distorted octahedral environment with a DMF and a $H_2O$ molecule as axial co-ligands completing the coordination sphere (Table 2 and Table 3). While in this complex the normal situation of longer Co–$N_{pyr}$ distances [2.235(5) and 2.244(5) Å] than Co–$N_{trz}$ distances [2.085(5) and 2.098(4) Å] is again observed, the former are slightly longer than the corresponding distances observed in dinuclear cobalt(II) complexes of the related ligand 4-isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ibdpt)[32] and also slightly longer than those in the mononuclear complex $[Co^{II}(pldpt)_2(DMF)_2](ClO_4)_2$ (**6**) and the dinuclear complex $[Co^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**8**) described below. Within

the pyridine–triazole–pyridine moiety of complex **5** the N(4)-pyridine ring shows the largest twist, being inclined by 10.4(3)° relative to the triazole mean plane. The pyrrole ring intersects with the triazole mean plane at an angle of 82.4(3)° (Table 4). There are hydrogen bonds between the $H_2O$ co-ligand and the two $ClO_4^-$ counterions [O(1)···O(11) 2.78 and O(1)···O(21) 2.84 Å].

The mononuclear yellow complex $[Co^{II}(pldpt)_2(DMF)_2](ClO_4)_2$ (**6**) (Figure 4) features the common *trans*-($N'$,$N^1$)$_2$ coordination mode (Figure 2). The coordination sphere about the cobalt centre is a strongly distorted octahedron with two DMF molecules in the axial positions (Table 2 and Table 3). In this complex the Co–$N_{pyr}$ distances are actually shorter than the Co–$N_{trz}$ distances [2.189(3) and 2.209(3) Å, respectively], albeit only slightly, which is a geometrical feature that has not been observed previously in complexes of any 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole. In complexes of this ligand type the M–$N_{pyr}$ distances are usually longer, often significantly, than the M–$N_{trz}$ distances.[2] In addition, both the Co–$N_{pyr}$ and the Co–$N_{trz}$ distances are unusually long compared to those observed in related systems [2.102(4)–2.147(3) and 2.052(4)–2.124(2) Å, respectively].[36,37,42] As is normal, the nitrogen atom of the non-coordinated pyridine ring points towards

| $[Zn^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**17**) | 5.2(3) | 5.5(3) | 88.4(2) |

[a] Values in square brackets refer to the N(7)-pyridine, N(10)-pyridine and N(12)-pyrrole rings of the second ligand molecule within the asymmetric unit.

the pyrrole ring which intersects with the triazole mean plane at an angle of 87.4(1)°. The N(1)- and N(4)-pyridine rings are tilted by 6.1(2)° and 24.7(2)°, respectively, relative to the triazole mean plane (Table 4).

The overall architecture of the dinuclear orange complex $[Co^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**8**) (Figure S3) is very similar to that of the corresponding $ClO_4^-$ complex **5** described above. Here, the $(N',N^1,N^2,N'')_2$ double-bridging coordination mode (Figure 2) is realised with a MeCN molecule being the second axial co-ligand, instead of DMF, in addition to the $H_2O$ molecule which forms hydrogen bonds to the two $BF_4^-$ counterions [O(1)···F(11) 2.72 and O(1)···F(21) 2.73 Å]. The usual situation of longer Co–$N_{pyr}$ distances [2.1876(12) and 2.2188(12) Å] than Co–$N_{trz}$ distances [2.0769(12) and 2.0976(12) Å] is again observed (Table 2 and Table 3). The distance between the two cobalt centres of 4.2660(4) Å is almost identical to the value observed for the $ClO_4^-$ complex **5** (Table 1). The pyridine–triazole–pyridine moiety is almost perfectly planar [4.7(1) and 5.6(1)°] while the pyrrole ring is practically perpendicular [88.2(1)°] to the triazole mean plane (Table 4).

The dinuclear $(N',N^1,N^2,N'')_2$ double-bridging coordination mode (Figure 2) is also featured in the purple-blue complex $[Ni^{II}_2(pldpt)_2(MeCN)_4](BF_4)_4 \cdot 2MeCN$ (**11**) (Figure S4). Here, each of the two nickel centres binds two MeCN co-ligands in the axial positions resulting in distorted octahedral $N_6$ coordination environments (Table 2 and Table 3). The distance of 4.170(1) Å between the two nickel centres is somewhat larger than the distances observed in other nickel(II) complexes of related ligands (Table 1).[5,32] The Ni–$N_{pyr}$ and Ni–$N_{trz}$ distances of 2.149(2)–2.184(2) and 2.023(2)–2.042(2) Å, respectively, in complex **11** are in the same range as those observed in related complexes.[5,32] The four Ni–$N_{MeCN}$ distances are all very similar and within the range of 2.025(2)–2.038(2) Å. In both ligand molecules the pyridine–triazole–pyridine moiety is almost flat [7.7(2) and 4.1(2)°] while the respective pyrrole rings are virtually perpendicular [88.0(1)°] to the triazole mean plane (Table 4).

The copper centre in $[Cu^{II}(pldpt)_2(ClO_4)_2] \cdot 2DMF$ (**13**) (Figure 5) is octahedrally $N_4O_2$ coordinated with two molecules of pldpt (**3**) occupying the equatorial positions and two $ClO_4^-$ ions being bound axially, giving rise to the *trans*-$(N',N^1)_2$ coordination mode (Figure 2). Thus, the overall architecture of complex **13** is the same as in $[Cu^{II}(pyppt)_2(ClO_4)_2] \cdot MeCN$,[49] $[Cu^{II}(ibdpt)_2(ClO_4)_2]$[32] and $[Cu^{II}(pmdpt)_2(ClO_4)_2]$[41] with the Cu–$N_{pyr}$, Cu–$N_{trz}$ and Cu–O distances [2.034(2), 1.979(2) and 2.470(2) Å, respectively] (Table 2 and Table 3) having very similar values as the corresponding distances observed in these related complexes [2.038(3)–2.045(2), 1.962(3)–1.989(2) and 2.466(3)–2.471(3) Å, respectively]. Both the coordinated and the non-coordinated pyridine rings show only slight deviations from planarity [3.8(2) and 8.2(1)°, respectively] with respect to the triazole mean plane. The pyrrole ring is almost perpendicular [85.3(1)°] to the triazole mean plane (Table 4).

In all of the previous structures of dinuclear complexes of 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles featuring the dinuclear $(N',N^1,N^2,N'')_2$ double-bridging coordination mode (Figure 2), described in this paper and elsewhere,[5,32,43,44] the two ligand molecules have been found to be in practically perfect alignment with each other, i.e. with the four nitrogen atoms of the bridging $N_2$ units of the two triazole moieties forming a rectangle. In contrast, in $[Cu^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ (**14**) (Figure 6) the two ligand molecules are offset sideways from one another, i.e. with the four nitrogen atoms of the bridging $N_2$ units of the two triazole moieties forming a parallelogram with acute angles of about 78°, resulting in a pronounced tetragonal distortion of the copper(II) centres. The consequences with regard to the distances between the two equivalent copper centres and their donor atoms are quite dramatic. The Cu–$N_{pyr}$ and Cu–$N_{trz}$ distances in complex **14** are the longest observed for any complex of a ligand featuring the bidentate pyridine–triazole moiety. The two Cu–$N_{pyr}$ distances are markedly different from each other [2.5170(18) and 2.0264(17) Å] as are the two Cu–$N_{trz}$ distances [1.9908(17) and 2.2564(17) Å] (Table 2 and Table 3). These geometrical features are a manifestation of an unsymmetrical Jahn–Teller elongation of the distorted $CuN_5O$ coordination octahedron along the N(1)–Cu(1)–N(3A) axis [Cu(1)–N(1) 2.5170(18) and Cu(1)–N(3A) 2.2564(17) Å]. The Cu(1)–N(20) and the Cu(1)–O(1) distances between the metal centre and the axial MeCN and $H_2O$ co-ligands, respectively, are practically identical [2.0024(19) and 2.0029(16) Å]. In contrast, in $[Cu^{II}(pldpt)_2(ClO_4)_2] \cdot 2DMF$ (**13**) (see above) as well as in analogous copper(II) complexes of related ligands the Jahn–Teller elongation of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coordination octahedron occurs along the $X_{axial}$–Cu–$X_{axial}$ axis and is symmetrical. The distance of 4.3140(5) Å between the two copper centres in complex **14** is in between the corresponding distances observed in $[Cu^{II}_2(NH_2dpt)(H_2O)_4(SO_4)_2]\cdot H_2O$[12] and $[Cu^{II}_2(ibdpt)_2(MeCN)_2(ClO_4)_2](ClO_4)_2\cdot 2MeCN$[32] (Table 1). The axial $H_2O$ co-ligand is involved in hydrogen bonding to the two $ClO_4^-$ counterions [O(1)···O(11) 2.78 and O(1)···O(21) 2.81 Å]. Here too, the pyridine–triazole–pyridine moiety is nearly planar [4.4(1) and 4.7(1)°], with the pyrrole ring intersecting the triazole mean plane almost at 88.8(1)° (Table 4).

The molecular structure of $[Zn^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**17**) (Figure S5) is basically the same as that of the cobalt(II) analogue $[Co^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**8**) (Figure S3). Complex **17** is the first dinuclear zinc(II) complex of any 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole to be synthesised and structurally characterised. The two zinc centres are separated by 4.455(2) Å (Table 1) and the pyridine–triazole–pyridine moiety shows only a slight deviation from planarity [5.2(3) and 5.5(3)°], while the pyrrole ring is almost perpendicular [88.4(2)°] to the triazole mean plane (Table 4). The complex adopts the dinuclear $(N',N^1,N^2,N'')_2$ double-bridging coordination mode (Figure 2). Here too, the two ligand molecules are somewhat shifted sideways relative to each other resulting in a slight tetragonal distortion of the system which is manifested in the relatively large variation of the Zn–$N_{pyr}$ and Zn–$N_{trz}$ distances [2.173(4)–2.227(4) and 2.119(4)–2.164(4) Å, respectively] (Table 2 and Table 3). The $H_2O$ co-ligand forms hydrogen bonds to the two $BF_4^-$ counterions [O(1)···F(11) 2.75 and O(1)···F(21) 2.77 Å].

In all of the complexes of pldpt (**3**) synthesised and structurally characterised in the course of this work the mean planes of the central triazole ring and the π-electron-rich pyrrole ring of the ligand are not co-planar but rather intersect at almost right angles [82.4(3)–88.8(1)°] (Table 4). This precludes an electronic interaction occurring between them by a π-pathway. Therefore, if there is any transmission of electron density between these two heterocyclic rings it must occur across the σ-bond between them. Consequently, it is likely to be small.

## Mass Spectrometry

ESI mass spectra were recorded in MeCN for all of the initial powdery complexes. In all of the spectra the parent peak was assigned to the species $[(pldpt) + H]^+$. The spectra of the dinuclear $ClO_4^-$ complexes **4**, **9** and **15** showed, almost exclusively, peaks that were assigned to mononuclear species, including the fragments $[M(pldpt)_3]^{2+}$ at $m/z$ = 461.7 (M = $Co^{II}$), 461.1 (M = $Ni^{II}$) and 464.3 (M = $Zn^{II}$), respectively, with a metal-to-ligand molar ratio of 1:3 which has not been observed for complexes of any 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole in the solid state so far. As the only peaks assignable to dinuclear species, the three spectra also had in common peaks for the fragments $[M_2(pldpt)_2(ClO_4)_3]^+$ at $m/z$ = 993.3 (M = $Co^{II}$), 991.2 (M = $Ni^{II}$) and 1003.1 (M = $Zn^{II}$), respectively.

Despite their good solubility in MeCN, and the fact that only one dinuclear solid state species was formed in each case on crystallisation, the ESI mass spectra of the $BF_4^-$ complexes **7**, **10** and **16** were not particularly informative and showed only about half the number of assignable peaks that the analogous $ClO_4^-$ complexes had. As was the case with the $ClO_4^-$ analogues, the spectra of complexes **7**, **10** and **16** all had peaks for the fragments $[M(pldpt)_3]^{2+}$ in common, while no peaks corresponding to dinuclear species were observed for these compounds.

The ESI mass spectrum of $[Cu^{II}(pldpt)_2(ClO_4)_2]$ (**12**) was in full agreement with the other analytical data of this complex, albeit that most of the peaks were assigned to copper(I) rather than copper(II) species, the former arising from reduction of the metal centre under the conditions of the experiment.

## NMR Spectroscopy

The $^1H$ NMR spectrum of the dinuclear zinc(II) $ClO_4^-$ complex **15** in [$D_7$]DMF showed only six signals in the aromatic region, which was in agreement with only one species being present (Figure S6). This confirmed that this complex does not exist in an equilibrium with mononuclear species in DMF solution but retains its symmetrical dinuclear architecture in this solvent, in contrast to the recrystallisation behaviour of the analogous cobalt(II) and nickel(II) complexes **4** and **9**, respectively, in the presence of this solvent. Five of the signals were well resolved and only the signal at $\delta$ = 7.55 ppm, which was assigned to 3-Py*H*, was broad. While the other five signals were shifted downfield, as could be expected upon coordination, by 0.12–0.23 ppm relative to the signals of free pldpt (**3**) in [$D_7$]DMF, the signal for 3-Py*H* was shifted upfield by 0.40 ppm, thus swapping places with the signal for 5-Py*H*. The single-crystal X-ray structure analysis of the analogous $BF_4^-$ complex **17** shows that the pyrrole ring is, as expected on steric grounds, almost perpendicular to the two pyridine rings and the triazole ring in the solid state. The significant upfield shift of the signal for 3-Py*H* observed in the $^1H$ NMR spectra of both the $ClO_4^-$ complex **15** and the $BF_4^-$ complex **16** (see below) in [$D_7$]DMF indicates that the same relative orientation is adopted in solution, as this proton appears to be interacting with the π-electron system of the adjacent pyrrole ring. As outlined above, the normal conformation of the pyridine rings in non-coordinated 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles is the one where the nitrogen atoms of the pyridine rings point towards the face of the pyrrole ring, i.e. the pyrrole ring is almost at a right angle to the triazole ring in all of the structurally characterised compounds, whereas on coordination in a dinuclear complex the pyridine rings are held the other way round due to the binding of the metal ions, so the 3-Py*H* protons now point towards the face of the pyrrole ring. For complex **17** the two independent distances between the 3-Py*H* and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the centroid of the pyrrole ring are 3.02 and 3.66 Å in the solid state. Finally, given that in the dinuclear complex the coordinated pyridine and triazole rings are expected to be approximately co-planar, these NMR spectroscopic data in [$D_7$]DMF are consistent with the triazole and pyrrole rings being almost perpendicular to one another, precluding an electronic interaction occurring between them by a π-pathway and indicating that any electronic interactions occur via the N–N σ-bond.

The $^{13}C$ NMR spectrum of the dinuclear zinc(II) $ClO_4^-$ complex **15** in [$D_7$]DMF, which was very similar to the corresponding spectrum of pldpt (**3**) with all of the signals being shifted only slightly (Figure S7), was also consistent with the formulation of a dinuclear solution species and with only one species being present in DMF solution.

As expected, the NMR spectra, recorded in [$D_7$]DMF, of the dinuclear zinc(II) $BF_4^-$ complex **16**, which upon recrystallisation from MeCN/$Et_2O$ afforded the structurally characterised dinuclear complex **17** (see above), were practically identical to those observed for the analogous $ClO_4^-$ complex **15**. Attempts were also made to record NMR spectra of complex **16** in [$D_3$]MeCN for comparison but for unknown reasons this failed and useful spectral information could not be obtained using this solvent.

### Conductivity Measurements

The molar conductivities of the $ClO_4^-$ complexes **4**, **9** and **15** were determined in DMF. The values obtained (260, 300 and 255 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$, respectively) are in agreement with the expected value of about 240–300 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ for a 4:1 electrolyte in this solvent.[74] For the $BF_4^-$ complexes **7**, **10** and **16** the corresponding values, determined in DMF, were found to be 280, 250 and 270 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$, respectively, which are also within the expected range. Likewise, the molar conductivities of complexes **7**, **10** and **16** in MeCN (480, 470 and 475 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$, respectively) were found to be in good agreement with the expected value of about 420–500 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ for 4:1 electrolytes in this solvent.[74] The molar conductivity of the mononuclear copper(II) complex **12** was determined as 245 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ in MeCN. This value agrees well with that expected for a 2:1 electrolyte in MeCN (220–300 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ ).[74]

### Magnetic Studies

Magnetic measurements were carried out on powder samples of the two dinuclear cobalt complexes $Co^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**4**) and $Co^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**7**) as well as of the two dinuclear nickel complexes $Ni^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**9**) and $Ni^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**10**), revealing in each case weak antiferromagnetic coupling between the metal centres (Table 6).

The dinuclear cobalt(II) complexes **4** and **7** exhibited almost identical magnetic behaviour despite the different counterions, thus indicating that the nature of the latter has practically no influence on the magnetism of these compounds. Similarly, the magnetic behaviour of different samples of the same compound was found to be independent within experimental error from the actual solvent content. The magnetic moments for complexes **4** (Figure 5) and **7** (Figure S7) at room temperature were 4.50 and 4.29 $\mu_B$ per cobalt(II) centre, respectively, and thus somewhat higher than for spin-only $d^7$ high-spin systems as a result of spin-orbit coupling and ligand field splitting effects acting on the $^4T_{1g}$ single ion states. For both complexes the fitted curves for the temperature dependence of the molar magnetic susceptibility showed a maximum, at $T$ = 13 K with $\chi_m$ = 0.06806 $cm^3\cdot mol^{-1}$ for complex **4** (Figure 7) and with

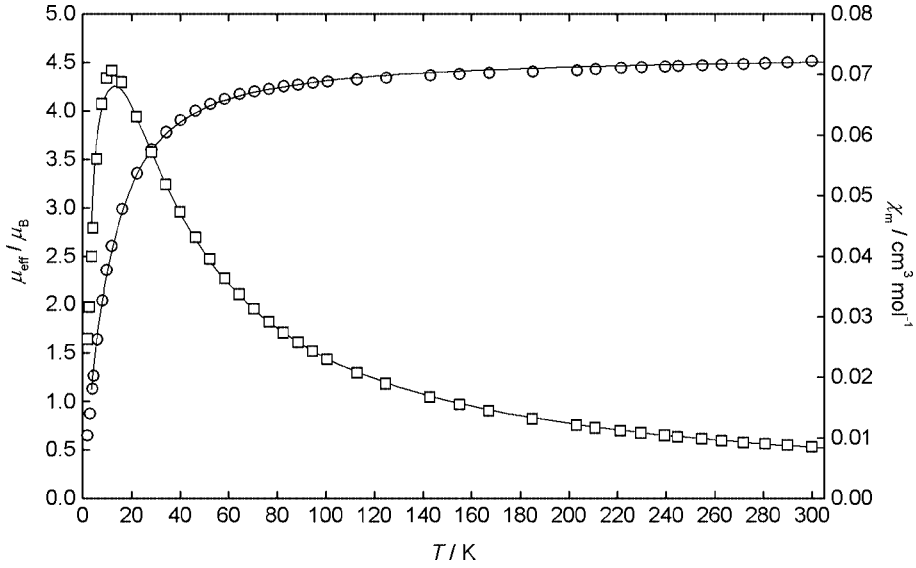

Figure 7. Temperature dependence of the effective magnetic moment $\mu_{eff}$ (○) and the molar magnetic susceptibility $\chi_m$ (□) per cobalt(II) centre for $Co^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**4**) ($m$ = 1, $n$ = 0). The solid lines represent the best fit using the parameters given in Table 5.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$\chi_m$ = 0.06166 cm$^3$·mol$^{-1}$ for complex **7** (Figure S8), a feature typical for antiferromagnetic exchange coupling. The magnetic data were fitted well by an $S$ = 3/2 dimer model of the spin-only Heisenberg–Van Vleck type ($-2J\mathbf{S_1}\cdot\mathbf{S_2}$)[75] indicating that orbital degeneracy had largely been removed. The best fit parameters are given in Table 5. The magnitude of the coupling between the two cobalt(II) centres in the $ClO_4^-$ complex **4** ($J$ = –3.1 cm$^{-1}$) and the $BF_4^-$ complex **7** ($J$ = –3.1 cm$^{-1}$) was similar to the corresponding value observed for $[Co^{II}_2(TsPMAT)_2](BF_4)_4\cdot 4H_2O$ ($J$ = –3.3 cm$^{-1}$)[51] and was only slightly less than that reported for related complexes of other 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles.[5,32]

Table 5. Magnetic data for $Co^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**4**), $Co^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**7**), $Ni^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**9**) and $Ni^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**10**).

| Complex | $m$ | $n$ | $J$ [cm$^{-1}$] | $g$ | *TIP* [cm$^3$·mol$^{-1}$] | Monomer [%] |
|---|---|---|---|---|---|---|
| **4** | 1 | 0 | –3.1 | 2.36 | 60·10$^{-6}$ | 0.1 |
| **7** | 1 | 2 | –3.1 | 2.25 | 65·10$^{-6}$ | 0.4 |
| **9** | 0 | 0 | –8.8 | 2.05 | 0 | 0.5 |
| **10** | 0 | 4 | –7.8 | 2.15 | 65·10$^{-6}$ | 0.5 |

The room temperature effective magnetic moment of 2.82 $\mu_B$ per nickel(II) centre for the $ClO_4^-$ complex **9** (Figure 8) was reduced from the typical uncoupled value of ca. 3.1 $\mu_B$ thus indicating that antiferromagnetic coupling was occurring. For the $BF_4^-$ complex **10** the corresponding value was 3.00 $\mu_B$ (Figure S9) and hence the nickel(II) centres are less strongly coupled than in complex **9**. The fitted curves for the temperature dependence of the molar magnetic susceptibility of complexes **9** (Figure 8) and **10** (Figure S9) had maxima at $T$ = 26 K with $\chi_m$ = 0.01639 cm$^3$·mol$^{-1}$ and $T$ = 22 K with $\chi_m$ = 0.02058 cm$^3$·mol$^{-1}$, respectively. The antiferromagnetic coupling between the two nickel(II) centres in the $ClO_4^-$ complex **9** was somewhat larger than in the $BF_4^-$ complex **10**, the coupling constants being –8.8 and –7.8 cm$^{-1}$, respectively. Here too, the magnetic behaviour of different samples of the same compound was found to be independent within experimental error from the actual solvent content. As with the cobalt(II) complexes of this ligand described above, the antiferromagnetic coupling in complexes **9** and **10** was less than that observed in related nickel(II) complexes of other 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles.[5,32]

## Conclusion

The coordination behaviour of the known ligand pldpt (**3**)[44] towards the first-row transition-metal ions $Co^{2+}$, $Ni^{2+}$, $Cu^{2+}$ and $Zn^{2+}$ in reactions with a metal-to-ligand molar ratio of 1:1 has been investigated in detail for the first time. From these studies it is clear that this ligand can act as a bis-bidentate chelator and thus form dinuclear complexes but it has also been revealed that its dinuclear complexes can be labile in solution depending on the solvent used. Although in most cases the initial precipitates are dinuclear, equilibria between di- and mononuclear species can occur in solution, depending on the metal salt and the solvent employed. Thus, for example, the strongly polar aprotic solvent DMF causes the dinuclear cobalt(II) and nickel(II) $ClO_4^-$ complexes **4** and **9**, respectively, to break up to some extent giving rise to mixtures of di- and mononuclear species, while the corresponding dinuclear zinc(II) $ClO_4^-$ complex **15** appears to be perfectly stable in this solvent. In contrast, from solutions of the analogous $BF_4^-$ complexes **7**, **10** and **16** in the less polar solvent MeCN only dinuclear species are isolated.

Given that our primary interest in pldpt (**3**) was to use it to prepare and study further examples of, prior to our re-

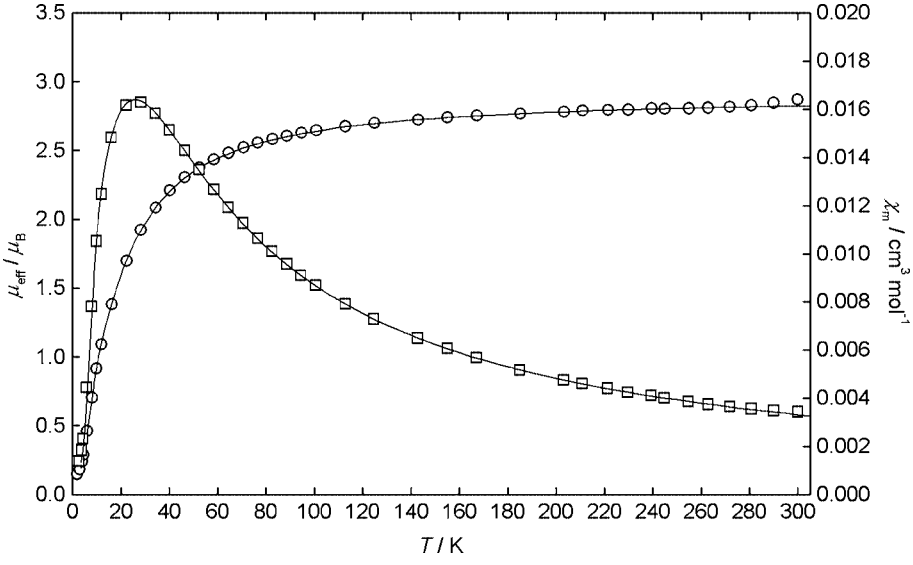

Figure 8. Temperature dependence of the effective magnetic moment $\mu_{eff}$ (○) and the molar magnetic susceptibility $\chi_m$ (□) per nickel(II) centre for $Ni^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**9**) ($m$ = 0, $n$ = 0). The solid lines represent the best fit using the parameters given in Table 5.

search, rarely observed, discrete dinuclear complexes of 4-substituted-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles, the deliberate preparation of mononuclear complexes employing metal-to-ligand molar ratios of 1:2 or 1:3 was not attempted in the course of this particular study. However, such studies are currently being carried out as an integral component of our ongoing investigation into the iron(II) coordination chemistry of pldpt (**3**) and related ligands.[52]

The enhanced dinucleating ability of pldpt (**3**), as compared to the 4-aryl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles, is attributed largely to the effect of the 4-(1*H*-pyrrol-1-yl) group on the relative solubility of the various possible products in the solvents employed. The X-ray crystallographic data, and the NMR spectroscopic data for the zinc(II) complex **15**, indicate that the electronic effect of this particular substituent is probably quite small because the potentially strong π-donation from the pyrrole ring is switched off due to the near-perpendicular orientation of the pyrrole ring relative to the triazole ring, leaving only the effects transmitted by the σ-pathway, which are likely to be weak. These findings are consistent with the suggestion that the substituent on $N^4$ in 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles influences the ability of such a ligand to form only mononuclear or both di- and mononuclear complexes by a complex mixture of factors, the most important of which, in the case of pldpt (**3**), appears to be its effect on the relative solubility of the various possible products in the solvents employed during the preparation and/or the recrystallisation of the complexes, although in other cases subtle electronic effects may also be at work.[2,31,32,52]

Magnetic studies carried out on the dinuclear cobalt(II) complexes **4** and **7** and the dinuclear nickel(II) complexes **9** and **10** have shown that the two central triazole bridges provided by pldpt (**3**) mediate weak antiferromagnetic exchange coupling between the two metal centres of these complexes. With a view to systematically accessing families of spin crossover systems, the exploration of the coordination behaviour of pldpt (**3**), and related ligands, towards iron(II) salts in 1:1, 1:2 and 1:3 metal-to-ligand molar ratios, in a variety of solvents, is well underway and the results of this study will be reported in due course.[52]

## Experimental Section

**General Remarks:** All solvents used for reactions were laboratory reagent grade while UV/Vis/NIR and conductivity measurements were carried out in HPLC-grade solvents. All chemicals were purchased from Aldrich and used as received. Elemental analyses were carried out by the Campbell Microanalytical Laboratory at the University of Otago. Melting points were determined with a Gallenkamp melting point apparatus in open-glass capillaries and are uncorrected. $^1$H and $^{13}$C NMR spectra were recorded with a Varian INOVA-500 spectrometer at 25 °C. Chemical shifts are given relative to TMS using the residual solvent signals as secondary reference ($CDCl_3$: $\delta_H$ = 7.26 ppm, $\delta_C$ = 77.16 ppm; [$D_7$]DMF: $\delta_H$ = 8.02 ppm, $\delta_C$ = 163.15 ppm). Peak assignments were made on the basis of chemical shifts, integration patterns and coupling constants as well as two-dimensional correlation experiments where necessary. IR spectra were recorded in the range 4000–400 cm$^{-1}$ with a Perkin–Elmer Spectrum BX FT-IR spectrophotometer. UV/Vis/NIR spectra were recorded with a Varian CARY 500 Scan UV/Vis/NIR spectrophotometer in the range 200–1400 nm. Conductivity measurements were carried out at 25 °C using a Suntex SC-170 conductivity meter. ESI mass spectra of organic compounds were run on a Shimadzu LCMS-QP8000α spectrometer while spectra of complexes were run on a MicroMass LCT spectrometer. For all compounds MeCN was used as the solvent. Magnetic data were recorded in the range 300–4.2 K using a Quantum Design MPMS5 SQUID magnetometer with an applied field of 1 T.

***Caution:*** *While no problems were encountered in the course of this work, reactions involving $N_2H_4{\cdot}H_2O$ may form potentially explosive mixtures so must be carried out with extreme caution. Similarly, $ClO_4^-$ salts are potentially explosive so should be handled with appropriate care.*

**3,6-Di(2-pyridyl)-1,4-dihydro-1,2,4,5-tetrazine (1):** A heterogeneous mixture of 2-pyridinecarbonitrile (20.8 g, 0.20 mol) and $N_2H_4{\cdot}H_2O$ (50 mL) was refluxed for 2 hours during which time the mixture became homogeneous, turned orange and a solid separated from the solution with heavy foaming. After cooling, all volatiles were evaporated under reduced pressure and the orange solid thus obtained was dried in vacuo. Recrystallisation from pyridine gave 13.8 g (58%) of analytically pure 3,6-di(2-pyridyl)-1,4-dihydro-1,2,4,5-tetrazine (**1**) as bright orange needles. M.p. 191–193 °C. $C_{12}H_{10}N_6$ (238.25): calcd. C 60.50, H 4.23, N 35.27; found C 60.50, H 4.14, N 35.33. $^1$H NMR (500 MHz, $CDCl_3$, ppm): $\delta$ = 7.34 [ddd, $^3J_{4,5}$ = 7.7 Hz, $^3J_{5,6}$ = 4.8 Hz, $^4J_{3,5}$ = 1.2 Hz, 2 H, 2×5-Py*H*], 7.74 [dt, $^3J_{3,4}$ = $^3J_{4,5}$ = 7.7 Hz, $^4J_{4,6}$ = 1.8 Hz, 2 H, 2×4-Py*H*], 8.05 [ddd, $^3J_{3,4}$ = 7.7 Hz, $^4J_{3,5}$ = 1.2 Hz, $^5J_{3,6}$ = 0.9 Hz, 2 H, 2×3-Py*H*], 8.54–8.59 [m, 4 H, 2×6-Py*H* and 2×PyCN*H*]. $^{13}$C{$^1$H} NMR (125 MHz, $CDCl_3$, ppm): $\delta$ = 121.41 [2×3-Py*C*], 124.97 [2×5-Py*C*], 136.83 [2×4-Py*C*], 146.75 [2×N*C*NH], 147.65 [2×2-Py*C*], 148.51 [2×6-Py*C*]. IR (KBr): $\tilde{\nu}$ = 3343, 3296, 3058, 1588, 1564, 1470, 1446, 1387, 1288, 1251, 1155, 1117, 1089, 1077, 1041, 995, 981, 903, 885, 795, 787, 771, 745, 720, 677, 667, 655, 622, 490 cm$^{-1}$. ESI-MS (pos., MeCN): *m*/*z* = 239 [M + H]$^+$, 261 [M + Na]$^+$, 277 [M + K]$^+$.

**4-Amino-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole ($NH_2$dpt, 2):** 3,6-Di(2-pyridyl)-1,4-dihydro-1,2,4,5-tetrazine (**1**) (11.9 g, 50.0 mmol) was dissolved in 2 M HCl (100 mL) and the dark brown solution was refluxed for 30 minutes. After cooling, the resulting golden solution was basified to pH ≈ 9 by dropwise addition of concd. $NH_3$ resulting in the formation of a voluminous colourless precipitate. The solid was filtered off, washed with $H_2O$ and dried in vacuo. Recrystallisation from $H_2O$/EtOH (1:1) gave 10.1 g (84%) of analytically pure $NH_2$dpt (**2**) as colourless needles. Alternatively, a mixture of 2-pyridinecarbonitrile (10.4 g, 0.10 mol), $N_2H_4{\cdot}H_2SO_4$ (13.0 g, 0.10 mol) and $N_2H_4{\cdot}H_2O$ (15.0 g, 0.30 mol) in 1,2-ethanediol (50 mL) was heated at 130 °C for 24 hours. An orange solid that soon separated from the solution with heavy foaming redissolved almost completely over time. On cooling to room temperature, the reaction mixture solidified to give an almost colourless solid contaminated with some orange material. $H_2O$ (100 mL) was added, the resulting slurry was filtered and the crude product was washed with water and dried in vacuo. Recrystallisation from $H_2O$/EtOH (1:1) gave 8.06 g (67%) of crude $NH_2$dpt (**2**) as a yellowish solid. This material could be used in the next step without further purification. Analytically pure material was obtained as colourless needles only after at least one more recrystallisation from $H_2O$/EtOH (1:1). M.p. 185–187 °C. $C_{12}H_{10}N_6$ (238.25): calcd. C 60.50, H 4.23, N 35.27; found C 60.35, H 4.10, N 35.00. $^1$H NMR (500 MHz, $CDCl_3$, ppm): $\delta$ = 7.36 [ddd, $^3J_{4,5}$ = 7.7 Hz, $^3J_{5,6}$ =

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

4.8 Hz, $^4J_{3,5}$ = 1.2 Hz, 2 H, 2×5-Py*H*], 7.86 [dt, $^3J_{3,4}$ = $^3J_{4,5}$ = 7.7 Hz, $^4J_{4,6}$ = 1.8 Hz, 2 H, 2×4-Py*H*], 8.38 [ddd, $^3J_{3,4}$ = 7.7 Hz, $^4J_{3,5}$ = 1.2 Hz, $^5J_{3,6}$ = 0.9 Hz, 2 H, 2×3-Py*H*], 8.49 [br. s, 2 H, TzN$H_2$], 8.65 [ddd, $^3J_{5,6}$ = 4.8 Hz, $^4J_{4,6}$ = 1.8 Hz, $^5J_{3,6}$ = 0.9 Hz, 2 H, 2×6-Py*H*]. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, ppm): $\delta$ = 122.97 [2×3-Py*C*], 124.11 [2×5-Py*C*], 137.41 [2×4-Py*C*], 147.82 [3- and 5-Tz*C*], 148.10 [2×2-Py*C*], 148.43 [2×6-Py*C*]. IR (KBr): $\tilde{\nu}$ = 3421, 3293, 1588, 1566, 1545, 1465, 1432, 1412, 1390, 1318, 1273, 1249, 1148, 1093, 1074, 1041, 998, 968, 912, 795, 787, 737, 693, 677, 623, 586, 489 $cm^{-1}$. **3,5-Di(2-pyridyl)-4-(1*H*-pyrrol-1-yl)-4*H*-1,2,4-triazole (pldpt, 3):** A mixture of $NH_2$dpt (**2**) (4.77 g, 20 mmol) and 2,5-dimethoxytetrahydrofuran (3.30 g, 25.0 mmol) in 1,4-dioxane (20 mL) and acetic acid (20 mL) was refluxed for 24 hours. After cooling, all volatiles were removed in vacuo to give a dark crystalline solid. This was taken up in $CH_2Cl_2$ (50 mL) and the mixture was filtered through a short column of silica gel. The filtrate was evaporated under reduced pressure and the yellowish solid thus obtained was dried in vacuo. Recrystallisation from EtOH gave 4.46 g (77%) of analytically pure pldpt (**3**) as colourless needles. M.p. 199–201 °C. $C_{16}H_{12}N_6$ (288.31): calcd. C 66.66, H 4.20, N 29.15; found C 66.90, H 3.96, N 29.22. $^1H$ NMR (500 MHz, $CDCl_3$, ppm): $\delta$ = 6.22 [t, $^3J$ = 2.4 Hz, 2 H, 3- and 4-Pl*H*], 6.86 [t, $^3J$ = 2.4 Hz, 2 H, 2- and 5-Pl*H*], 7.30 [ddd, $^3J_{4,5}$ = 7.7 Hz, $^3J_{5,6}$ = 4.8 Hz, $^4J_{3,5}$ = 1.2 Hz, 2 H, 2×5-Py*H*], 7.75 [dt, $^3J_{3,4}$ = $^3J_{4,5}$ = 7.7 Hz, $^4J_{4,6}$ = 1.8 Hz, 2 H, 2×4-Py*H*], 7.84 [ddd, $^3J_{3,4}$ = 7.7 Hz, $^4J_{3,5}$ = 1.2 Hz, $^5J_{3,6}$ = 0.9 Hz, 2 H, 2×3-Py*H*], 8.52 [ddd, $^3J_{5,6}$ = 4.8 Hz, $^4J_{4,6}$ = 1.8 Hz, $^5J_{3,6}$ = 0.9 Hz, 2 H, 2×6-Py*H*]. $^1H$ NMR (500 MHz, [$D_7$]DMF, ppm): $\delta$ = 6.12 [t, $^3J$ = 2.4 Hz, 2 H, 3- and 4-Pl*H*], 7.20 [t, $^3J$ = 2.4 Hz, 2 H, 2- and 5-Pl*H*], 7.51 [ddd, $^3J_{4,5}$ = 7.7 Hz, $^3J_{5,6}$ = 4.8 Hz, $^4J_{3,5}$ = 1.2 Hz, 2 H, 2×5-Py*H*], 7.95 [ddd, $^3J_{3,4}$ = 7.7 Hz, $^4J_{3,5}$ = 1.2 Hz, $^5J_{3,6}$ = 0.9 Hz, 2 H, 2×3-Py*H*], 8.00 [dt, $^3J_{3,4}$ = $^3J_{4,5}$ = 7.7 Hz, $^4J_{4,6}$ = 1.8 Hz, 2 H, 2×4-Py*H*], 8.54 [ddd, $^3J_{5,6}$ = 4.8 Hz, $^4J_{4,6}$ = 1.8 Hz, $^5J_{3,6}$ = 0.9 Hz, 2 H, 2×6-Py*H*]. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, ppm): $\delta$ = 108.44 [3- and 4-Pl*C*], 122.34 [2- and 5-Pl*C*], 123.54 [2×3-Py*C*], 124.90 [2×5-Py*C*], 136.84 [2×4-Py*C*], 145.33 [2×2-Py*C*], 149.93 [2×6-Py*C*], 153.16 [3- and 5-Tz*C*]. $^{13}C\{^1H\}$ NMR (125 MHz, [$D_7$]DMF, ppm): $\delta$ = 108.51 [3- and 4-Pl*C*], 124.02 [2- and 5-Pl*C*], 124.74 [2×3-Py*C*], 126.16 [2×5-Py*C*], 138.21 [2×4-Py*C*], 146.69 [2×2-Py*C*], 150.79 [2×6-Py*C*], 154.15 [3- and 5-Tz*C*]. IR (KBr): $\tilde{\nu}$ = 3118, 1587, 1569, 1533, 1465, 1443, 1435, 1423, 1332, 1281, 1246, 1181, 1150, 1088, 1069, 1044, 1010, 992, 963, 912, 790, 736, 729, 710, 703, 633, 619, 608, 524, 489 $cm^{-1}$. ESI-MS (pos., MeCN): *m*/*z* = 289 $[M + H]^+$, 311 $[M + Na]^+$, 327 $[M + K]^+$. UV/Vis/NIR (MeCN): $\lambda_{max}$ ($\varepsilon$/L·mol$^{-1}$·cm$^{-1}$) = 251 (14600), 281 nm (18500).

**Reaction of pldpt (3) with $CoCl_2·6H_2O$ (Method A):** A pinkish-red solution of $CoCl_2·6H_2O$ (238 mg, 1.00 mmol) in $H_2O$ (5 mL) was added to a colourless solution of pldpt (**3**) (288 mg, 1.00 mmol) in MeOH (20 mL) dropwise at room temperature and the resulting orange-brown solution was stirred for 30 minutes. Slow evaporation over the course of 4 weeks led to the formation of a large quantity of a beige solid and a few tiny orange prisms. The solid products were filtered off and washed with MeOH. Drying in vacuo gave $Co^{II}(pldpt)_2Cl_2(H_2O)_{1.5}$. $C_{32}H_{27}Cl_2CoN_{12}O_{1.5}$ (733.49): calcd. C 52.40, H 3.71, N 22.92, Cl 9.67; found C 52.36, H 3.49, N 23.17, Cl 9.66.

**Reaction of pldpt (3) with $CoCl_2·6H_2O$ (Method B):** A deep blue solution of $CoCl_2·6H_2O$ (238 mg, 1.00 mmol) in EtOH (5 mL) was added to a colourless refluxing solution of pldpt (**3**) (288 mg, 1.00 mmol) in EtOH (20 mL). A blue solid formed almost immediately. The resulting suspension was refluxed for another 15 minutes and was then stirred at room temperature for 24 hours. The solid was filtered off and washed with EtOH. Drying in vacuo gave 388 mg (ca. 90%) of $Co^{II}_2(pldpt)_2Cl_4(H_2O)$ as a pink powder. $C_{32}H_{26}Cl_4Co_2N_{12}O$ (854.32): calcd. C 44.99, H 3.07, N 19.67; found C 45.38, H 3.05, N 19.51.

**Reaction of pldpt (3) with $Co(ClO_4)_2·6H_2O$:** An orange solution of $Co(ClO_4)_2·6H_2O$ (366 mg, 1.00 mmol) in MeCN (5 mL) was added to a colourless refluxing solution of pldpt (**3**) (288 mg, 1.00 mmol) in MeCN (20 mL). An orange solid formed almost immediately. The resulting suspension was cooled to room temperature and the solid was filtered off and washed with MeCN. Drying in vacuo gave 555 mg (ca. 90%) of $Co^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**4**) as a pale orange powder. The solvent content of the initial products varied considerably from batch to batch. Heating of the powders at 60 °C in vacuo for several days similarly afforded materials of variable solvent content. A sample analysing as $Co^{II}_2(pldpt)_2(ClO_4)_4(MeCN)$ was used for characterisation purposes. $C_{34}H_{27}Cl_4Co_2N_{13}O_{16}$ (1133.34): calcd. C 36.03, H 2.40, N 16.07; found C 36.08, H 2.54, N 16.26. IR (KBr): $\tilde{\nu}$ = 1611, 1544, 1517, 1473, 1439, 1405, 1354, 1302, 1263, 1188, 1113, 1074, 1012, 931, 911, 794, 746, 725, 701, 654, 635, 625 $cm^{-1}$. ESI-MS (pos., MeCN): *m*/*z* = 235.1 $[Co(pldpt)(MeCN)_3]^{2+}$, 289.1 $[(pldpt)H]^+$, 338.1 $[Co(pldpt)_2(MeCN)]^{2+}$, 446.0 $[Co(pldpt)(ClO_4)]^+$, 461.7 $[Co(pldpt)_3]^{2+}$, 487.0 $[Co(pldpt)(MeCN)(ClO_4)]^+$, 577.4 $[(pldpt)_2H]^+$, 734.3 $[Co(pldpt)_2(ClO_4)]^+$, 993.3 $[Co_2(pldpt)_2(ClO_4)_3]^+$. Molar conductivity (DMF): $\Lambda_m$ = 260 $\Omega^{-1}$·cm$^2$·mol$^{-1}$. Vapour diffusion of $Et_2O$ into an orange solution of complex **4** in MeCN/DMF (10:1) afforded orange crystals of $[Co^{II}_2(pldpt)_2(H_2O)_2(DMF)_2](ClO_4)_4·0.5Et_2O$ (**5**) and yellow crystals of $[Co^{II}(pldpt)_2(DMF)_2](ClO_4)_2$ (**6**).

**Reaction of pldpt (3) with $Co(BF_4)_2·6H_2O$:** An orange solution of $Co(BF_4)_2·6H_2O$ (341 mg, 1.00 mmol) in MeCN (5 mL) was added to a colourless refluxing solution of pldpt (**3**) (288 mg, 1.00 mmol) in MeCN (20 mL). The resulting orange solution was refluxed for 10 minutes and was then stirred at room temperature for another 4 hours during which time an orange precipitate formed. The solid was filtered off and washed with MeCN. Drying in vacuo gave 465 mg (ca. 80%) of $Co^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**7**) as a pale orange powder. The solvent content of the initial products varied considerably from batch to batch. Heating of the powders at 60 °C in vacuo for several days similarly afforded materials of variable solvent content. A sample analysing as $Co^{II}_2(pldpt)_2(BF_4)_4(MeCN)(H_2O)_2$ was used for characterisation purposes. $C_{34}H_{31}B_4Co_2F_{16}N_{13}O_2$ (1118.79): calcd. C 36.50, H 2.79, N 16.28; found C 36.37, H 2.75, N 16.17. IR (KBr): $\tilde{\nu}$ = 1610, 1577, 1545, 1518, 1474, 1440, 1402, 1356, 1297, 1263, 1189, 1073, 911, 862, 796, 765, 749, 727, 705, 655, 636, 563, 533, 521, 436, 414 $cm^{-1}$. ESI-MS (pos., MeCN): *m*/*z* = 289.1 $[(pldpt)H]^+$, 317.6 $[Co(pldpt)_2]^{2+}$, 338.1 $[Co(pldpt)_2(MeCN)]^{2+}$, 461.7 $[Co(pldpt)_3]^{2+}$, 722.3 $[Co(pldpt)_2(BF_4)]^+$. UV/Vis/NIR (MeCN): $\lambda_{max}$ ($\varepsilon$/L·mol$^{-1}$·cm$^{-1}$) = 252 (25200), 291 (37000), 481 (46), 1022 nm (12). Molar conductivity (MeCN): $\Lambda_m$ = 480 $\Omega^{-1}$·cm$^2$·mol$^{-1}$. Molar conductivity (DMF): $\Lambda_m$ = 280 $\Omega^{-1}$·cm$^2$·mol$^{-1}$. Vapour diffusion of $Et_2O$ into the orange MeCN mother liquor or an orange solution of complex **7** in MeCN afforded orange crystals of $[Co^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**8**).

**Reaction of pldpt (3) with $NiCl_2·6H_2O$ (Method A):** A grass green solution of $NiCl_2·6H_2O$ (238 mg, 1.00 mmol) in $H_2O$ (5 mL) was added to a colourless solution of pldpt (**3**) (288 mg, 1.00 mmol) in MeOH (20 mL) dropwise at room temperature and the resulting olive-green solution was stirred for 30 minutes. Slow evaporation over the course of 6 weeks led to the formation of an inseparable

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mixture of a greenish crystalline solid and blue prisms in an estimated 3:1 ratio. These were not easily separable so no analytical data were obtained for either of the products.

**Reaction of pldpt (3) with $NiCl_2{\cdot}6H_2O$ (Method B):** A grass green solution of $NiCl_2{\cdot}6H_2O$ (238 mg, 1.00 mmol) in EtOH (5 mL) was added to a colourless solution of pldpt (**3**) (288 mg, 1.00 mmol) in EtOH (20 mL) dropwise at room temperature. The resulting green solution was stirred at room temperature for 4 hours during which time a green precipitate formed. The solid was filtered off and washed with EtOH. Drying in vacuo gave 275 mg (ca. 60%) of $Ni^{II}_2(pldpt)_2Cl_4(H_2O)_3$ as a very pale green powder. $C_{32}H_{30}Cl_4Ni_2N_{12}O_3$ (889.86): calcd. C 43.19, H 3.40, N 18.89; found C 43.62, H 3.28, N 18.74.

**Reaction of pldpt (3) with $Ni(ClO_4)_2{\cdot}6H_2O$:** A blue solution of $Ni(ClO_4)_2{\cdot}6H_2O$ (366 mg, 1.00 mmol) in MeCN (5 mL) was added to a colourless refluxing solution of pldpt (**3**) (288 mg, 1.00 mmol) in MeCN (20 mL). A purple solid formed almost immediately. The resulting suspension was cooled to room temperature and the solid was filtered off and washed with MeCN. Drying in vacuo gave 475 mg (ca. 80%) of $Ni^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**9**) as a pale violet powder. The solvent content of the initial products varied considerably from batch to batch. Heating of the powders at 60 °C in vacuo for several days similarly afforded materials of variable solvent content. A sample analysing as $Ni^{II}_2(pldpt)_2(ClO_4)_4$ was used for characterisation purposes. $C_{32}H_{24}Cl_4Ni_2N_{12}O_{16}$ (1091.81): calcd. C 35.20, H 2.22, N 15.39; found C 35.18, H 2.53, N 15.59. IR (KBr): $\tilde{\nu}$ = 1612, 1548, 1526, 1517, 1474, 1440, 1410, 1355, 1304, 1265, 1195, 1114, 1074, 1025, 1012, 931, 911, 793, 747, 725, 700, 659, 636, 625 $cm^{-1}$. ESI-MS (pos., MeCN): *m/z* = 214.1 $[Ni(pldpt)(MeCN)_2]^{2+}$, 234.6 $[Ni(pldpt)(MeCN)_3]^{2+}$, 255.1 $[Ni(pldpt)(MeCN)_4]^{2+}$, 289.1 $[(pldpt)H]^+$, 317.1 $[Ni(pldpt)_2]^{2+}$, 337.7 $[Ni(pldpt)_2(MeCN)]^{2+}$, 358.2 $[Ni(pldpt)_2(MeCN)_2]^{2+}$, 445.0 $[Ni(pldpt)(ClO_4)]^+$, 461.1 $[Ni(pldpt)_3]^{2+}$, 486.0 $[Ni(pldpt)(MeCN)(ClO_4)]^+$, 527.1 $[Ni(pldpt)(MeCN)_2(ClO_4)]^+$, 568.2 $[Ni(pldpt)(MeCN)_3(ClO_4)]^+$, 577.4 $[(pldpt)_2H]^+$, 733.2 $[Ni(pldpt)_2(ClO_4)]^+$, 991.2 $[Ni_2(pldpt)_2(ClO_4)_3]^+$. Molar conductivity (DMF): $\Lambda_m$ = 300 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$.

**Reaction of pldpt (3) with $Ni(BF_4)_2{\cdot}6H_2O$:** A blue solution of $Ni(BF_4)_2{\cdot}6H_2O$ (340 mg, 1.00 mmol) in MeCN (5 mL) was added to a colourless refluxing solution of pldpt (**3**) (288 mg, 1.00 mmol) in MeCN (20 mL). The resulting purple solution was refluxed for 10 minutes and was then stirred at room temperature for another 4 hours during which time a purple precipitate formed. The solid was filtered off and washed with MeCN. Drying in vacuo gave 215 mg (ca. 40%) of $Ni^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**10**) as a pale violet powder. The solvent content of the initial products varied considerably from batch to batch. Heating of the powders at 60 °C in vacuo for several days similarly afforded materials of variable solvent content. A sample analysing as $Ni^{II}_2(pldpt)_2(BF_4)_4(H_2O)_4$ was used for characterisation purposes. $C_{32}H_{32}B_4F_{16}N_{12}Ni_2O_4$ (1113.28): calcd. C 34.52, H 2.90, N 15.10; found C 34.55, H 2.70, N 15.09. IR (KBr): $\tilde{\nu}$ = 1612, 1578, 1549, 1521, 1475, 1441, 1410, 1356, 1300, 1265, 1190, 1073, 911, 796, 750, 727, 705, 694, 659, 637, 564, 533, 522, 439, 415 $cm^{-1}$. ESI-MS (pos., MeCN): *m/z* = 289.1 $[(pldpt)H]^+$, 317.1 $[Ni(pldpt)_2]^{2+}$, 337.6 $[Ni(pldpt)_2(MeCN)]^{2+}$, 358.1 $[Ni(pldpt)_2(MeCN)_2]^{2+}$, 461.1 $[Ni(pldpt)_3]^{2+}$, 721.3 $[Ni(pldpt)_2(BF_4)]^+$. UV/Vis/NIR (MeCN): $\lambda_{max}$ ($\varepsilon$/L·mol$^{-1}$·cm$^{-1}$) = 238 (24400), 295 (36400), ca. 530 sh (ca. 70), 866 nm (40). Molar conductivity (MeCN): $\Lambda_m$ = 470 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. Molar conductivity (DMF): $\Lambda_m$ = 250 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. Vapour diffusion of $Et_2O$ into the purple MeCN mother liquor or a purple solution of complex **10** in MeCN afforded purple crystals of $[Ni^{II}_2(pldpt)_2(MeCN)_4](BF_4)_4{\cdot}2MeCN$ (**11**).

**Reaction of pldpt (3) with $Cu(ClO_4)_2{\cdot}6H_2O$:** A blue solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (371 mg, 1.00 mmol) in MeCN (5 mL) was added to a colourless refluxing solution of pldpt (**3**) (288 mg, 1.00 mmol) in MeCN (20 mL). The resulting green solution was refluxed for 10 minutes and was then stirred at room temperature for another 4 hours during which time a blue precipitate formed. The solid was filtered off and washed with a minimum amount of MeCN. Drying in vacuo gave 249 mg (59%) of $[Cu^{II}(pldpt)_2(ClO_4)_2]$ (**12**) as a blue powder. $C_{32}H_{24}Cl_2CuN_{12}O_8$ (839.07): calcd. C 45.81, H 2.88, N 20.03; found C 45.52, H 2.78, N 20.05. IR (KBr): $\tilde{\nu}$ = 1614, 1588, 1571, 1554, 1533, 1513, 1485, 1456, 1434, 1340, 1311, 1272, 1193, 1105, 1023, 991, 929, 913, 793, 750, 742, 722, 698, 645, 622, 568, 495 $cm^{-1}$. ESI-MS (pos., MeCN): *m/z* = 289.1 $[(pldpt)H]^+$, 319.6 $[Cu(pldpt)_2]^{2+}$, 340.1 $[Cu(pldpt)_2(MeCN)]^{2+}$, 351.0 $[Cu(pldpt)]^+$, 369.1 $[Cu(pldpt)(H_2O)]^+$, 392.1 $[Cu(pldpt)(MeCN)]^+$, 639.2 $[Cu(pldpt)_2]^+$, 738.2 $[Cu(pldpt)_2(ClO_4)]^+$. UV/Vis/NIR (MeCN): $\lambda_{max}$ ($\varepsilon$/L·mol$^{-1}$·cm$^{-1}$) = 242 (35000), 295 (33500), 659 nm (90). Molar conductivity (MeCN): $\Lambda_m$ = 245 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. Vapour diffusion of $Et_2O$ into a blue solution of complex **12** in MeCN gave blue crystals of $[Cu^{II}(pldpt)_2(ClO_4)_2]{\cdot}2DMF$ (**13**) while vapour diffusion of $Et_2O$ into the green MeCN mother liquor afforded green crystals of $[Cu^{II}_2(pldpt)_2(H_2O)_2(MeCN)_2](ClO_4)_4$ (**14**). The occurrence of the DMF solvates in complex **13** was probably due to the use of contaminated glassware.

**Reaction of pldpt (3) with $Zn(ClO_4)_2{\cdot}6H_2O$:** A colourless solution of $Zn(ClO_4)_2{\cdot}6H_2O$ (372 mg, 1.00 mmol) in MeCN (5 mL) was added to a colourless refluxing solution of pldpt (**3**) (288 mg, 1.00 mmol) in MeCN (20 mL). A colourless solid formed almost immediately. The resulting suspension was cooled to room temperature and the solid was filtered off and washed with MeCN. Drying in vacuo gave 470 mg (ca. 80%) of $Zn^{II}_2(pldpt)_2(ClO_4)_4(MeCN)_m(H_2O)_n$ (**15**) as a colourless powder. The solvent content of the initial products varied considerably from batch to batch. Heating of the powders at 60 °C in vacuo for several days similarly afforded materials of variable solvent content. A sample analysing as $Zn^{II}_2(pldpt)_2(ClO_4)_4(H_2O)_4$ was used for characterisation purposes. $C_{32}H_{32}Cl_4N_{12}O_{20}Zn_2$ (1177.25): calcd. C 32.65, H 2.74, N 14.28; found C 32.28, H 2.59, N 14.30. $^1H$ NMR (500 MHz, [D$_7$]-DMF, ppm): $\delta$ = 6.35 [t, $^3J$ = 2.4 Hz, 4 H, 2×3- and 4-Pl*H*], 7.37 [t, $^3J$ = 2.4 Hz, 4 H, 2×2- and 5-Pl*H*], 7.55 [br. s, 4 H, 4×3-Py*H*], 7.69 [ddd, $^3J_{4,5}$ = 7.7 Hz, $^3J_{5,6}$ = 4.8 Hz, $^4J_{3,5}$ = 1.2 Hz, 4 H, 4×5-Py*H*], 8.12 [dt, $^3J_{3,4}$ = $^3J_{4,5}$ = 7.7 Hz, $^4J_{4,6}$ = 1.8 Hz, 4 H, 4×4-Py*H*], 8.68 [ddd, $^3J_{5,6}$ = 4.8 Hz, $^4J_{4,6}$ = 1.8 Hz, $^5J_{3,6}$ = 0.9 Hz, 4 H, 4×6-Py*H*]. $^{13}C\{^1H\}$ NMR (125 MHz, [D$_7$]DMF, ppm): $\delta$ = 109.91 [2×3- and 4-Pl*C*], 123.38 [2×2- and 5-Pl*C*], 124.08 [4×3-Py*C*], 127.49 [4×5-Py*C*], 139.61 [4×4-Py*C*], 144.25 [4×2-Py*C*], 150.95 [4×6-Py*C*], 154.01 [2×3- and 5-Tz*C*]. IR (KBr): $\tilde{\nu}$ = 1611, 1546, 1525, 1517, 1476, 1441, 1354, 1306, 1297, 1264, 1192, 1117, 1089, 1014, 930, 911, 795, 748, 724, 703, 653, 636, 625 $cm^{-1}$. other 4 hours during which time a colourless precipitate formed. The solid was filtered off and washed with MeCN. Drying in vacuo gave 345 mg (ca. 60%) of $Zn^{II}_2(pldpt)_2(BF_4)_4(MeCN)_m(H_2O)_n$ (**16**) as a colourless powder. The solvent content of the initial products varied considerably from batch to batch. Heating of the powders at 60 °C in vacuo for several days similarly afforded materials of variable solvent content. A sample analysing as $Zn^{II}_2(pldpt)_2(BF_4)_4(H_2O)_2$ was used for characterisation purposes. $C_{32}H_{28}B_4F_{16}N_{12}O_2Zn_2$ (1090.63): calcd. C 35.24, H 2.59, N 15.41; found C 35.13, H 2.58, N 15.33. IR (KBr): $\tilde{\nu}$ = 1609, 1576, 1546, 1526, 1518, 1477, 1442, 1400, 1355, 1298, 1264, 1192, 1073, 911, 862, 797, 766, 750, 727, 706, 653, 640, 563, 533, 522, 436, 412 $cm^{-1}$). ESI-MS (pos., MeCN): *m/z* = 289.1 $[(pldpt)H]^+$, 320.1 $[Zn(pldpt)_2]^{2+}$, 340.6 $[Zn(pldpt)_2(MeCN)]^{2+}$, 464.2 $[Zn(pldpt)_3]^{2+}$, 727.2 $[Zn(pldpt)_2(BF_4)]^+$. Molar conductivity (MeCN): $\Lambda_m$ = 475 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Molar conductivity (DMF): $\Lambda_m$ = 270 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Vapour diffusion of $Et_2O$ into the colourless MeCN mother liquor or a colourless solution of complex **16** in MeCN afforded colourless crystals of $[Zn^{II}_2(pldpt)_2(MeCN)_2(H_2O)_2](BF_4)_4$ (**17**).

**X-ray Crystallography:** X-ray data (Table 6) were collected with a Bruker SMART CCD area detector using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods with SIR-92[76] or SHELXS-97[77,78] and refined against $F^2$ using all data by full-matrix least-squares techniques with SHELXL-97.[79] All non-hydrogen atoms were refined anistropically. All hydrogen atoms, except H(101) and H(102) of the axial $H_2O$ co-ligands in complexes **5**, **8**, **14** and **17**, were placed at calculated positions using a riding model with thermal parameters 1.2 times the equivalent isotropic thermal parameter of the atom to which they were bonded. The hydrogen atoms of the $H_2O$ co-ligands in complexes **8**, **14** and **17** were located from the difference maps and allowed to refine freely. For complex **5** they were placed in calculated positions and subsequently fixed in their respective positions with thermal parameters 1.2 times the equivalent isotropic thermal parameter of the atom to which they were bonded. Further details of the refinement of the structures and the modelling of the disordered $ClO_4^-$ counterions and $Et_2O$ solvate in complex **5** can be found in the respective CIF files. CCDC-277057 (for **3**), -277058 (for **5**), -277059 (for **6**), -277060 (for **8**), -277061 (for **11**), -277062 (for **13**), -277063 (for **14**) and -277064 (for **17**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): A PDF file (six pages) with supporting information for this article is available on the WWW under http://www.eurjic.org or from the authors. It contains a view of the asymmetric unit of ligand **3** (Figure S1), an overlay of the two crystallographically independent molecules within the asymmetric unit of ligand **3** (Figure S2), views of the molecular structures of the cations of complexes **8**, **11** and **17** (Figure S3, S4 and S5, respectively), comparisons of the $^1H$ and $^{13}C$ NMR spectra, respectively, of ligand **3** and complex **15** (Figures S6 and S7, respectively) and the curves for the molar magnetic susceptibilities and effective magnetic moments of complexes **7** and **10** over the range 300–4.2 K (Figures S8 and S9, respectively).

## Acknowledgments

This work was supported by grants from the University of Otago (including a University of Otago Postgraduate Scholarship to MHK and a Bridging Grant) and the Australian Research Council (Discovery Grant). The authors are grateful to Ms. T. Groutso and Prof. G. R. Clark (University of Auckland) for collecting some of the X-ray data, to Mr. B. M. Clark (University of Canterbury) for recording the ESI mass spectra of the complexes reported in this paper and to Mr. R. M. Hellyer (University of Otago) for his help. Prof. G. B. Jameson (Massey University), Prof. W. T. Robinson (University of Canterbury) as well as Dr. D. S. Larsen, Dr. J. Klingele (née Hausmann) and Dr. C. D. Brandt (University of Otago) are thanked for helpful discussions.

# An Investigation of the Reactivity of [(diimine)(dithiolato)M] Complexes Using the Fukui Functions Concept

**Christodoulos Makedonas[a] and Christiana A. Mitsopoulou*[a]**

**Keywords:** Density functional calculations / Fukui indices / Oxidation / S ligands / Schiff bases / Stacking interactions

Fukui functions are widely used when investigating the reactivity of organic molecules, but rarely with metal complexes. Here, we investigate the reactivity of [(diimine)(dithiolato)M] complexes with different types of reagents and upon oxidation employing this concept. Mixed-ligand complexes of this type have a peculiar electronic description due to the mixed-metal-ligand-to-ligand charge-transfer band, which is why they are considered as very promising candidates for non-linear optical (NLO) materials and molecular photochemical devices (MPD). As a result, their reactivity is of crucial importance for their potential applications. The obtained results of $f^+$ and $f^-$ for the neutral [(diimine)(dithiolato)M] complexes (M = Pd, Ni and Pt) not only predict that the sulfur atom is the preferable active site for electrophilic attack but also reveal the different tunability of these complexes when they are subjected to an oxidation process, in agreement with experimental results. Under the framework of the Fukui indices we also provide an alternative explanation for crystal packing that could find widespread application.

## 1. Introduction

The concept of reactivity is a milestone in the investigation of chemical phenomena. Electron density plays a fundamental role in understanding chemical reactivity as it explains the attack of reagent on the basis of electrostatic interactions. However, it seems that things are not as simple as that as electron density by itself does not provide an answer to every question that arises. The reason for this is the influence of the approaching reagent. Small changes in the electron-density distribution and how susceptible this is to these changes are also of importance. In recent years, much attention has been paid to the insights that density functional theory (DFT) can give into chemical reactivity. Global reactivity parameters such as electronegativity ($\chi$), hardness ($\eta$) and the electrophilicity index ($\omega$), accompanied by local indices like the local softness and the Fukui function [$f(\mathbf{r})$], have been introduced in the chemical literature[1–3] and have eventually obtained legitimacy within DFT.[4] The latter was proposed by Parr and Yang[5–8] and represents one of the most effective tools of conceptual DFT for the investigation of molecular reaction sites. This model is frequently employed for the interpretation of factors and trends that influence the tunability of organic molecules, but is more rarely used in the case of transition-metal complexes.[9] Here it is the main tool in our effort to gain insight into the reactivity of [(diimine)(dithiolato)M]-type complexes.

Over the last three decades [(diimine)(dithiolato)M] complexes of group VIII metals have attracted the attention of numerous researchers because of their unique properties, which include solution luminescence, solvatochromism, large molecular hyperpolarizabilities, and large excited-state oxidation potentials.[10–29] Due to these properties, they are considered as very promising candidates for non-linear optical (NLO) materials and molecular photochemical devices (MPD), especially in view of their peculiar electronic structure. This specific structure is dominated by the presence of two different unsaturated chelating ligands in the same molecule, one of which is a good π*-donor (the dithiolato ligand) and the other a good π*-acceptor (the diimine). Moreover, the intense solvatochromic band in the low-energy region of their electronic spectra is considered to involve the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO), the former of which is a mixture of metal and dithiolato orbitals and the latter is a π*-orbital of the diimine. This transition has been assigned as a "mixed-metal-ligand-to-ligand charge-transfer" (MMLL′CT) transition on the basis of both experimental[15] and theoretical[28,29] work. The square-planar geometry of these complexes permits one to tailor their properties for potential applications as photosensitizers or photocatalysts by designing both the diimine and dithiolato ligands appropriately.

On the other hand, [(diimine)(dithiolato)M] complexes are known to be susceptible to oxidation, either photochemically or chemically induced. The first contributions to this field were provided by Vogler,[19] Srivastava,[20–22] and Schanze.[23] In 1997, Connick and Gray reported the com-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plete structural and spectroscopic characterization of the photooxidation products of [Pt(bpy)(bdt)] (bpy = 2,2′-bipyridine, bdt = 1,2-benzenedithiolate); they identified both a monosulfinate and a disulfinate complex depending on the oxidation conditions.[24] Later, Cocker and Bachman reported that the related Pd complex has a similar tunability, while the reactivity of the nickel analogue is substantially different. In the latter case they managed to isolate an octahedral disulfonate complex and a dimetallic one, suggesting that the mechanistic pathway for their production is not simply the result of differences in the electronic structure of Ni compounds. They attributed it to the ability of nickel to adopt an octahedral coordination and to the relative stability of metal–oxygen bonds for first-row transition metals.[25,26] Matsubashi and co-workers,[27] in order to increase the electrical conductivity of these compounds, have performed halogen doping experiments and proposed that partial oxidation occurred on the sulfur ligand, a suggestion that is also supported by Tang.[17] Other compounds of the same class with ligands such as bme-daco [*N*,*N*′-bis(2-sulfanylethyl)-1,5-diazacyclooctane] are known to be easily thermally or photochemically oxidized.[30] Furthermore, these complexes also undergo electrophilic substitution reactions, as recently demonstrated by Chen.[18]

Here we have employed density functional techniques[4] in order to obtain insight into the oxidation of [(diimine)(dithiolato)M] complexes and to address the reactivity factors of these compounds through the local hard–soft acid–base principle (HSAB) and the Fukui functions.[1–8] For this purpose, the complexes [Pd(phen)(bdt)] (**1**), [Pd(bpy)(bdt)] (**2**), [Ni(bpy)(bdt)] (**3**), [Pt(bpy)(bdt)] (**4**), [Pt(bpy)(edt)] (**5**), and [Pt(bpy)(mnt)] (**6**) have been taken under consideration.

The main part of this report is organized as follows: a brief description of the background theory is given in Section 2. The theoretical results are critically analyzed and compared with experimental ones in Section 3. This section is subdivided into three subsections. In Section 3.1 both theoretical and experimental structural data are compared in order to test the correctness of our calculations. The local softness parameters $f^+$ and $f^-$ are compared to locate the preferable electrophilic and nucleophilic sites, respectively, in these complexes in Section 3.2. Moreover, differences in the local softness descriptors induced by changing both the central metal and the ligands are discussed and compared to experimental results. They are also used to evaluate intermolecular reactivity sequences. The importance of local softness parameters for explaining the molecular stacking in the crystal lattice is shown for the first time in Section 3.3.

## 2. Theoretical Background

By definition, the Fukui function is given by the functional derivative of the chemical potential with respect to a change in the external potential. Alternatively, because of the Maxwell relations, it is identical to the change in electron density upon a change in the number of electrons and can be written as

$$f(\vec{r}) = \left(\frac{\delta \mu}{\delta v(\vec{r})}\right)_N = \left(\frac{\partial \rho(\vec{r})}{\partial N}\right)_{v(\vec{r})} \quad (1)$$

where $\mu$ is the chemical potential, $v(\mathbf{r})$ is the external potential, and the derivative must be taken at a constant number of electrons. An important feature of the Fukui function is that it integrates to unity.

The physical meaning of $f(\mathbf{r})$ is implied directly by its definition as $[\delta\mu/\delta v(\mathbf{r})]_N$: it measures how sensitive a system's chemical potential is to an external perturbation at a particular point. Moreover, local softness is given by[31]

$$S(\vec{r}) = \left(\frac{\partial \rho(\vec{r})}{\partial \mu}\right)_{v(\vec{r})} = \left(\frac{\partial \rho(\vec{r})}{\partial N}\right)_{v(\vec{r})}\left(\frac{\partial N}{\partial \mu}\right)_{v(\vec{r})} = f(\vec{r})S \quad (2)$$

From the above equation it is obvious that the Fukui function provides the same information for the system under study as the local softness, and can be used instead of it in deriving the relative site reactivity in a molecule. This implies that the regions of a molecule where the Fukui function is large are chemically softer than those with a small value of the function, and by invoking the HSAB principle in a local sense one may establish the tunability of different sites with respect to different reagents.[32]

Application of a *finite difference* approximation to Equation (1) leads to the following working equations, known as condensed Fukui functions according to Yang and Mortier[8]

$$f_i^+ = -[q_i(N+1) - q_i(N)], \text{ for nucleophilic attack} \quad (3a)$$

$$f_i^- = -[q_i(N) - q_i(N-1)], \text{ for electrophilic attack} \quad (3b)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$f_i^0 = -\{\frac{1}{2}[q_i(N+1) - q_i(N-1)]\}$, for radical attack (3c)

where $q_i$ is the partial charge of atom $i$, extracted from a Mulliken gross population analysis,[33] in a compound with $N-1$, $N$, and $N+1$ electrons, calculated in the ground-state geometry of the $N$-electron system, while the negative sign obeys the convention of negative electron charge.

Alternatively, employing a Mulliken population based approach to the *frozen core* approximation[2,5] we derive

$$f_i^- \approx \sum_{a\in i}^{AO} |c_{aHOMO}|^2 + \sum_{b\neq a}^{AO} |c_{bHOMO} \times c_{aHOMO}| S_{ab} \quad \text{for electrophilic attack} \quad (4a)$$

$$f_i^+ \approx \sum_{a\in i}^{AO} |c_{aLUMO}|^2 + \sum_{b\neq a}^{AO} |c_{bLUMO} \times c_{aLUMO}| S_{ab} \quad \text{for nucleophilic attack} \quad (4b)$$

$f_i^0 \approx \frac{1}{2}[f_i^+ + f_i^-]$, for radical attack (4c)

where HOMO and LUMO are the frontier orbitals. Apart from Mulliken population analysis (MPA), there are also other partitioning schemes for the electronic density, such as natural bond orbital analysis and Hirshfield analysis. In fact, Roy et al.[34–38] have shown that the latter is more reliable than MPA for calculating local reactivity descriptors and also produces nonnegative condensed Fukui function values. A lot of other work on nonnegative Fukui functions has been reported,[39–41] and it can be concluded that the Fukui function itself can be negative, although condensed Fukui functions cannot be negative, except in certain cases.

Equations (4a–4c) indicate the relationship between Fukui indicators and molecular orbitals.[7] In a sense, a nucleophilic reaction could be considered as involving the HOMO of the nucleophile and the LUMO of the electrophile. One of the major benefits of using the Fukui functions instead of the frontier orbitals − Equations (3a–3c) instead of Equations (4a–4c) − is that Fukui functions include the effects of orbital relaxation, which is very important.[42–44]

## 3. Results and Discussion

### 3.1. Molecular Structure

The six complexes under study have a square-planar geometry with almost $C_{2v}$ molecular symmetry. They were selected as suitable candidates for investigation of the influence induced by the different contributing fragments to the molecule's reactivity. Compounds **1** and **2** were selected, because 1,10-phenanthroline and 2,2′-bipyridine, along with their substituted derivatives, are the most widely used diimines in synthesis. Complexes **4**, **5**, and **6** were used to study the role of the dithiolate by choosing substituents with different π*-accepting ability. More precisely, CN is a better π*-accepting group than H, while benzenedithiolate is a widely used aromatic ligand. Finally, the series **2**–**4** was employed in order to incorporate the role of the metal in our analysis. For this purpose two ligands with medium π*-accepting and π*-donating ability, namely bpy and $bdt^{2-}$, respectively, were selected.

Their structures were fully optimized at the B3LYP/SDD/6-311+G* level of theory. A comparison between the theoretically derived bond lengths and angles and the crystallographically extracted ones is presented in Table 1, where it can be seen that, apart from the calculated M–X bonds, which are systematically overestimated by 0.04 Å, something that is anticipated,[46] all the other structural parameters are in good agreement with the crystallographic data. Based on these facts the overall agreement between theory and experiment is judged as satisfactory. It is noteworthy that the M–N bonds are longer than those observed in bis(diimine) compounds, while the M–S distances are shorter than those of the related bis(dithiolenes). This trend is a direct consequence of a significant *trans* influence, with $d_{C-S}$ and $d_{C-N}$ being in the area of C–S($sp^2$) and N–C($sp^2$), respectively. An extensive analysis of the compounds' electronic structure has been presented elsewhere[28,47] and will not be discussed further here.

### 3.2. Searching Reactivity Sites

We begin our analysis with the palladium complexes **1** and **2** by investigating the diimine's role. Employing the condensed Fukui functions formalism under the *finite difference* approximation we derived the values for $f_i^+$, $f_i^-$, and $f_i^0$. These values are presented in Figures 1 and 2 along with the numbering of the corresponding atoms. Inspection of the two figures shows that the most reactive sites of the molecules upon electrophilic attack are the sulfur atoms in both cases.

Table 1. Comparison of selected calculated bond lengths [Å] and angles [°] for **1**–**6** with experimental values from X-ray analysis.

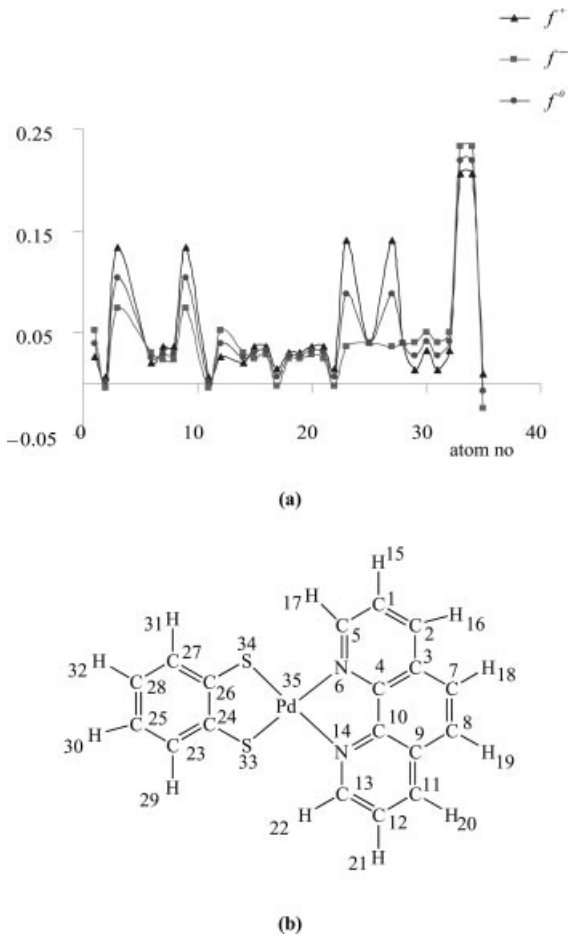

Figure 1. Condensed Fukui indices for **1** as derived from the *finite difference* approximation (a) and the atom numbering system (b).

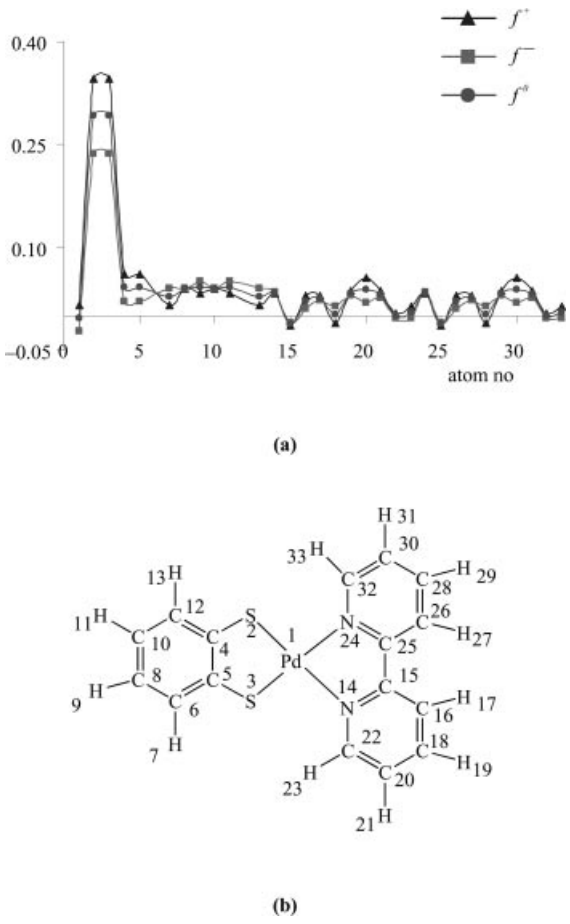

Figure 2. Condensed Fukui indices for **2** as derived from the *finite difference* approximation (a) and the atom numbering system (b).

Moreover, the sulfur atoms tend to react similarly during a radical attack, according to the $f^0$ values. In the phenanthroline compound **1** the reactive sites could also be the diimine's C1/C12 and C3/C9 atoms, although to a considerably lower degree. On the other hand, things change when discussion comes to $f^+$. The most reactive atoms are bdt's C23/C27 and phenanthroline's C3/C9 atoms in **1**. Of course, based on the relative nucleophilicity ($s_k^-/s_k^+$) and electrophilicity ($s_k^+/s_k^-$) introduced by Roy et al.,[48] we could accurately locate the preferable site for electrophilic and nucleophilic attack, respectively, and distinguish these carbon atoms. The reactive sites in **2** would also be dithiolate's C4/C5 and bpy's C20/C30. In other words, selection of the diimine as a bipyridine or phenanthroline derivative would not affect the complexes' reactivity towards an electrophile, but would certainly do so in the case of nucleophiles. The reason for this different reactivity is due to the nature of these attacks. In the case of the $f_i^+$ index, for example, one more electron is added to the system and the latter has to partition the excess of charge. Complex **1** can easily accommodate an extra electron through extended resonance of the phen's three condensed aromatic rings. Complex **2** can also accommodate an extra electron because of the presence of the two aromatic rings (bpy), but this is less effective than with phen rings. On the contrary, an electron subtraction from an almost identical HOMO (if the situation warranted, for example when an electrophile approaches S atoms), is expected to have a similar effect in both cases. In other words, although the HOMO has the same nature in both complexes, the LUMO is different since it is mainly present on diimine rings (phen vs. bpy).

Complex **2** would also be more reactive than **1** in the case of radical attack. Taking all these results into account, we conclude that, despite the similarity of the frontier orbitals of **1** and **2**, as was shown previously by us,[28] the two complexes are not expected to show an identical reactivity. Since most experimental results in this field have their origin in an electrophilic attack type of reaction or oxidation, in the next section we will try to shed light on their thermodynamics. Proceeding in a similar manner, we examine the dithiolate's role during electrophilic attack (Figure 3). In Figure 3(b) the numbering scheme concerns **4** but is also the same for **5** and **6** along with the following additions. Contributions from the dithiolate protons in **5** are represented by positions 31 and 32, while the nitrile carbon and nitrogen atoms in **6** are labeled as sites 10 and 11, and 31 and 32, respectively.

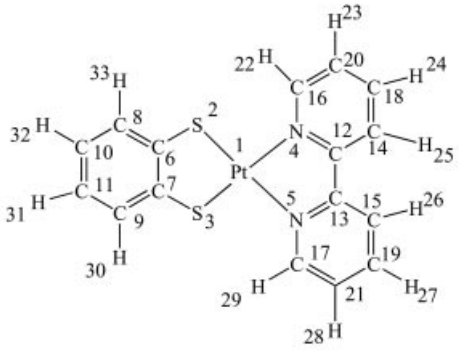
(a)



(b)

Figure 3. Condensed Fukui indices $f_i^-$ for **4**, **5**, and **6** as derived from the *finite difference* approximation (a), along with the atom numbering system (b).

Figure 3 shows that electron-accepting groups on the dithiolate moiety increase the sulfur atom's softness towards electrophilic reagents in keeping with the observed softness of the sulfur atoms in the series **6** > **5** > **4** (or mnt > edt > bdt). Moreover, in the case of **6**, the nitrogen atoms of the CN groups seem to be an additional reactive site on the molecule. As a result, 1,2-dithiolates with strong electron-accepting groups as substituents are considered to be more reactive towards soft electrophiles or photochemically/chemically induced oxidation than those having donor groups, while the presence of a π*-delocalized system on the S ligand reduces its reactivity.

Complexes **2**–**4** provide a great opportunity for demonstrating the role of the metal from the Fukui functions (Figure 4). We prefer to elaborate the Fukui function in this series in terms of the *frozen core* instead of the *finite difference* approximation due to the fact that metal atoms in the case of the latter give a value slightly below zero as a result of the following partitioning scheme (MPA). Thus, $q_i(N-1)$ is found to have a higher value than $q_i(N)$ and when these are replaced in Equation (3b) a negative $f_i^-$ value is obtained.

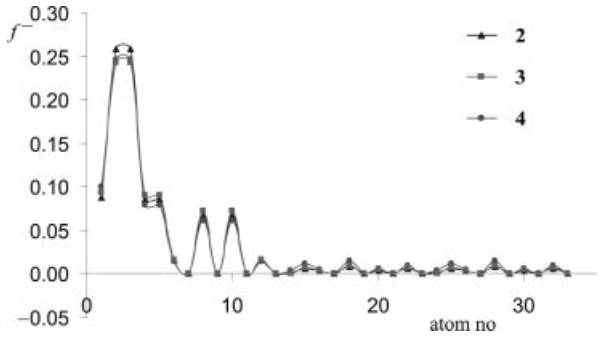


Figure 4. Condensed Fukui indices for **2**–**4** as derived from the *frozen core* approximation. The numbering system is the same as in Figure 2(b).

In a previous paper,[28] based on spectroscopic and mainly on DFT and TDDFT results, we clarified that the main, highly solvatochromic band in these complexes' visible spectra arises from a mixed-metal-ligand-to-ligand charge transfer despite the relatively low metal contribution in the frontier orbitals. Moreover, we have suggested that the metal atom is not just the right connector between the two conductors but its role is essential for the reactivity of this class of compounds. In order to test the validity of this suggestion, we examined the reactivity of **2**–**4** towards a common reagent ($O_2$) in combination with Fukui indices. Before we proceed to the analysis of experimental results, however, the bonding picture of these compounds should be given. First of all, recalling results from Table 5 in ref.[28] we can see that the HOMO is mainly localized on the dithiolato ligand (85.4% for **2**, 84.2% for **3**, and 81.1% for **4**), whereas the metal contribution is 8.8%, 9.3%, and 10.0% for **2**, **3**, and **4**, respectively.

The HOMO is the orbital where any oxidation process or electrophilic attack should take place. A closer inspection reveals that it originates from the antibonding combination of the metal's $d_{xz}$ orbital with the dithiolate's $4b_1$ out-of-plane HOMO localized mainly on sulfur's $3p_z$ (51.7% for **2**, 48.6% for **3**, and 49.1% for **4**), whereas the diimine's contribution arises from the $4b_1$ LUMO of bipyridine. Hence, the dithiolate, which is a strong π-donor, interacts in an antibonding way with the metal's $t_{2g}$ (under a pure $O_h$ geometry) orbital. This interaction is valid since both orbitals lie relatively close in energy, and the stronger the interaction the higher the HOMO lies. On the other hand, the metal back-donates electron density to the diimine, which is a good π-acceptor. As the metal–dithiolate interaction increases, back-donation becomes more effective. Taking the whole picture into consideration, it is clear that the metal's involvement in the HOMO increases as a direct consequence of a more effective interaction with the $bdt^{2-}$ moiety, the nucleophilicity of whose sulfur atoms also rises (the HOMO in all cases is largely a sulfur-based orbital). Grapperhaus et al. have referred to a relative bonding situation using the term π-repulsion.[47] Moreover, since the above description of the HOMO is, by definition, consistent with the characteristics of the Fukui function $f^-$, according to the *frozen core* approximation, it is clear that the driving

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

force of the reaction with an electrophilic reagent is maximized in **4** (thermodynamic criterion), according to the series **4** > **3** > **2** (Pt > Ni > Pd). On the other hand, as the sulfur contribution to the HOMO is lower for Ni compounds (48.6% vs. 51.7% for Pd), an electrophilic attack on it could elongate the Ni–S bond and break it. Thus, the sulfur atom is not favorable for electrophilic attack (Figure 4).

On the basis of the points mentioned above, and in order to test our results, we elaborated Bachman and Gray's excellent oxidation experiments.[24–26] Our analysis showed that the sulfur atoms in platinum complex **4** are more nucleophilic and thus more reactive, while the metal's larger contribution to the HOMO raises its energy and makes it more easily oxidized with more stable oxidation products (vide supra). Comparing the reported oxidation potentials for **2** (25 mV)[24] and **4** (165 mV),[25] we conclude that the first two results are correct. Moreover, the similarity of the $f^-$ index (Figure 4) for both **2** and **4** indicates that both complexes yield the same product upon oxidation. Indeed, oxidation takes place for both Pd and Pt complexes (Scheme 1).[25]

The reactivity of the nickel analogue **3** is substantially different, according to the $f^-$ function (based on finite difference approximation). Indeed, the sulfur atoms do not appear to be the unique active sites in this complex as the Ni atom and the C atoms of the bdt and bpy moieties also take part in the oxidation. In addition to these results, we must take into consideration that $Ni^{II}$ can also form complexes with octahedral or trigonal-bipyramidal structures, whereas $Pd^{II}$ and $Pt^{II}$ cannot. The observed photochemical oxidation of **3** to give a mixture of octahedral disulfonate complex **8** and a dimetallic complex **9** is in agreement with this (Scheme 2).[25]

We have shown that the most reactive sites in [(diimine)-(dithiolato)M] complexes from an electronic point of view are the sulfur atoms, although the site preferences for each type of attack differ. Thus, an electrophilic attack should occur from the upper (or lower) side of the molecule while a nucleophilic substitution should occur from the side (Figures 5 and 6). Based on these diagrams we can select the appropriate ligands in order to proceed stereochemically or

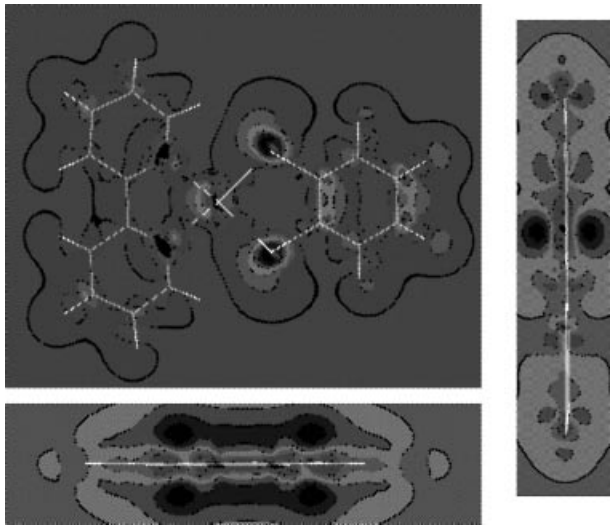

Figure 5. Projections of the difference in electron density between the neutral and the cationic form of **2**.

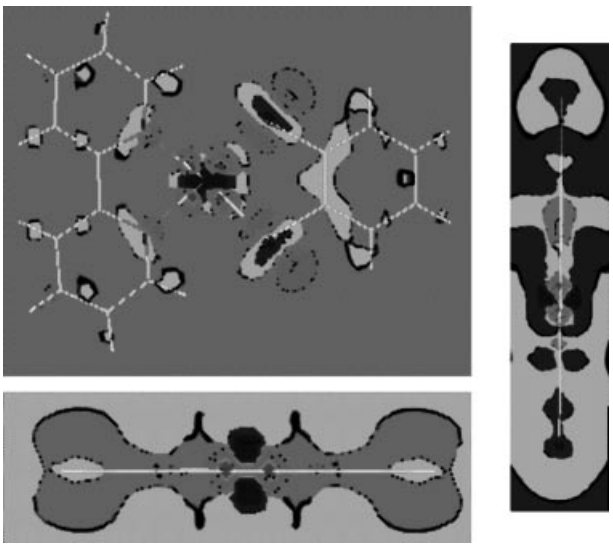

Figure 6. Projections of the difference in electron density between the anionic and the neutral form of **2**.

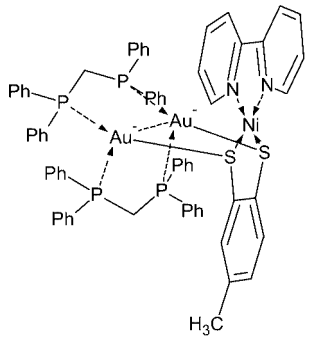
stop a certain type of substitution reaction. An experimental proof of the above discussion would be the complexes' interaction with electrophiles. Chen et al. in their fine paper[18] have shown that a series of platinum complexes analogous to **4** can act as ligands to unsaturated [bis(diphenylphosphanyl)methane]$Ag^{I}$ and -$Au^{I}$ compounds, yielding heterotrinuclear complexes of the type $Pt^{II}Au^{I}_2$ or $Pt^{II}Ag^{I}_2$. The formation of this class of compounds, and especially their structure, can be understood from the Fukui functions in Figures 3 and 5. Both $Au^{I}$ and $Ag^{I}$ are soft, and their soft–soft interaction with mixed (diimine)(dithiolato) complexes will take place from the upper side of the molecule at the sulfur atom to yield compound **10**.



**10**

### 3.3. Crystal Packing Under the Prism of Soft–Soft Interactions

Until now crystal packing has been explained mainly in terms of π–π interactions, hydrogen bonding, and intermolecular metal–ligand interactions. We report here an alternative explanation of stacking in terms of the Fukui functions (vide supra). Our working hypothesis starts from the assumption that in a molecule with distinct electrophilic and nucleophilic atoms or areas it is very likely that these atoms/areas interact and play a major role in the formation of the complexes' lattice. Complex **1** crystallizes in the $P2_1/c$ space group,[28] and slight intermolecular interactions seem to be present in the crystal (Figure 7).

If packing is examined in terms of Fukui function indices for **1**, as computed under the *finite difference* approximation (vide supra), S33/S34–C3/C9 and C3/C9–C23/C29 interactions of the electrophile–nucleophile type are expected. The latter provides a reasonable explanation for the relative position of each molecule in the crystal lattice and simultaneously implies that soft–soft interactions define the molecules' stacking. In a forthcoming paper the validity of this working hypothesis will be tested both experimentally and theoretically for a series of analogous Ni, Pd, and Pt complexes.[49]

## 4. Conclusions

In this study we have tested the usefulness of condensed Fukui functions in locating the preferred sites (atoms) for nucleophilic and electrophilic attack in a metal complex and predicting/explaining the products (even the minor ones) obtained during a reaction. The studied cases are referred especially to the addition of oxygen and other electrophiles such as unsaturated complexes of $Ag^{I}$ or $Au^{I}$ to mixed (diimine)(dithiolato) complexes.

For this purpose, the condensed Fukui indices were determined to characterize the nucleophile (and electrophile) sites in [(diimine)(dithiolato)M] complexes (M = Ni, Pd, and Pt). The former were calculated by two approximations well established in the literature, namely *frozen core* and *finite difference*. In general, we have found a good agreement between the results obtained for the condensed Fukui indices of [(diimine)(dithiolato)M] complexes and the experimental results of electrophilic attack and oxidation. In every case, except Ni complexes, the electrophilic attack occurs at a unique atomic site – the sulfur atom. Different reactive sites upon changing the central metal are reflected

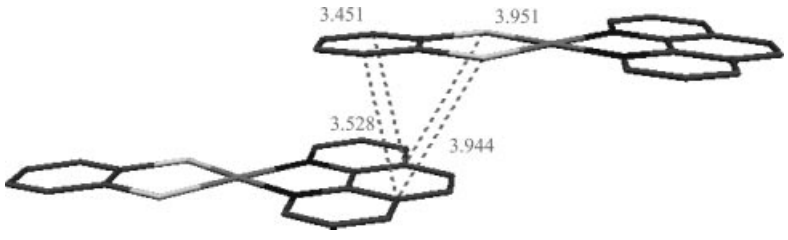


Figure 7. Packing of two molecules in molecular crystals of **1**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in the differences products obtained, in accordance with experimental results. Moreover, the nucleophilicity of the sulfur atoms has been shown to increase in the series phen ≈ bpy, mnt > edt > bdt and Pt > Ni > Pd. There is total agreement between the condensed Fukui function indices and the existence of different products obtained upon oxidative addition to mixed (diimine)(dithiolato) complexes. Moreover, the Fukui indicators provide the correct intermolecular reactivity sequence of these complexes, which is not always attainable when comparing only the frontier orbitals. Last but not least, a different approach from π-stacking theory for crystal packing of these complexes is proposed based on Fukui indices and soft–soft interactions. This idea could be applied generally and could be the main reason for the different ways of molecular stacking in a crystal lattice, even within the same class of compounds, although the validity of this hypothesis has yet to be verified.

## 5. Experimental Section

### 5.1. Computational Details

Ground-state electronic structure calculations of all compounds under study were performed using density functional theory (DFT) [4] methods employing the GAUSSIAN 98/03 software package.[50] The functional used throughout this study is the B3LYP, which consists of a nonlocal hybrid exchange functional as defined by Becke's three-parameter equation[51] and the nonlocal Lee–Yang–Parr correlation functional.[52] The ground-state geometries were obtained in the gas phase by full geometry optimization, starting from structural data, regularized in order to satisfy the $C_{2v}$ symmetry. The VeryTight option was used in all cases, which demands tighter convergence criteria than the default ones, while numerical integration was performed using the UltraFine option, which requests a pruned (99,590) grid. The optimum structures located as stationary points on the potential-energy surfaces were verified by the absence of imaginary frequencies. The derived wavefunctions were found to be free of internal instabilities.

The basis set used for all nonmetal atoms was the well-known valence triple-ζ 6-311+G*.[53,54] The quasi-relativistic Stuttgardt–Dresden effective core potential of the type ECP10MDF, ECP28MWB, and ECP60MWB was used for Ni, Pd, and Pt, respectively.[55] The core potentials were complemented by the relative valence basis sets.[55] For all other calculations related to the properties' investigation an additional diffuse and polarization function was added to the hydrogen atoms. Percentage compositions of molecular orbitals from the three contributing fragments (metal, dithiolate, diimine) and condensed Fukui functions according to the *frozen core* approximation were calculated using the AOMix program.[56,57] The graphics presented here were drawn with the aid of GaussView[58] and Molekel.[59]

# Novel Carbonyliridium and -rhodium Complexes Containing 2,6-Bis[(4′*S*)-4′-isopropyloxazolin-2′-yl]pyridine (*i*Pr-pybox) and 2,6-Bis[(4′*R*)-4′-phenyloxazolin-2′-yl]pyridine (Ph-pybox) Ligands

**Darío Cuervo,[a] Josefina Díez,[a] M. Pilar Gamasa,*[a] José Gimeno,[a] and Paloma Paredes[a]**

**Keywords:** Carbonyl complexes / Homogeneous catalysis / Iridium / N ligands / Rhodium

The iridium(I) complexes [Ir(CO)(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] [R-pybox = (*S*,*S*)-*i*Pr-pybox (**1**), (*R*,*R*)-Ph-pybox (**2**)] have been prepared by reaction of their precursor complexes [Ir(η$^2$-$C_2H_4$)$_2$(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] (R = *i*Pr or Ph) with carbon monoxide. The analogous carbonylrhodium(I) complexes [Rh(CO)(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] [R-pybox = (*S*,*S*)-*i*Pr-pybox (**3**), (*R*,*R*)-Ph-pybox (**4**)] have been synthesised by reaction of [Rh(μ-Cl)(η$^2$-$C_2H_4$)$_2$]$_2$, carbon monoxide, R-pybox and $NaPF_6$. Complexes **1**–**4** undergo oxidative addition reactions with iodine and $CH_3I$ leading, with high stereoselectivity, to the complexes [MI(X)(CO)(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] [M = Ir, R = *i*Pr, X = I (**5**); M = Rh, R = *i*Pr, X = I (**6**); M = Rh, R = Ph, X = I (**7**); M = Ir, R = *i*Pr, X = $CH_3$ (**8**); M = Ir, R = Ph, X = $CH_3$ (**9**); M = Rh, R = *i*Pr, X = $CH_3$ (**10**); M = Rh, R = Ph, X = $CH_3$ (**11**)]. The treatment of complexes **1** and **2** with HCl, allyl chloride or acyl chloride results, in most cases, in the stereoselective formation of the iridium(III) complexes [IrHCl(CO)(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] [R = *i*Pr (**12**), Ph (**13**)], [IrCl(η$^1$-$CH_2CH{=}CH_2$)(CO)(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] [R = *i*Pr (**14**), Ph (**15**)] or [IrCl{η$^1$-C(O)$CH_3$}(CO)(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] [R = *i*Pr (**16**), Ph (**17**)], respectively. The structures of derivatives **10** and **15** have been determined by single-crystal X-ray diffraction analysis. The catalytic activity of monocarbonylrhodium(I) and -iridium(I) complexes **1** and **3** in the hydrosilylation and dehydrosilylation of acetophenone with diphenylsilane has also been examined.

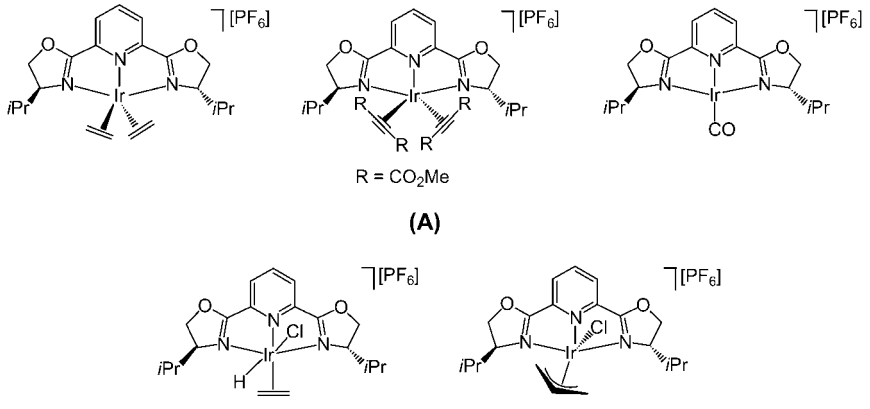
## Introduction

In the last few years the enantiopure, tridentate nitrogen ligands R-pybox [R-pybox = 2,6-bis(4′-R-oxazolin-2′-yl)-pyridine; R = *i*Pr, Ph, *t*Bu, etc.] have been shown to be efficient chiral ancillary ligands in transition-metal-catalysed asymmetric synthesis. A recent and specific survey discusses the state-of-the-art of this field.[1]



Despite the importance of iridium complexes in catalytic processes, as far as we know only a few examples of asymmetric catalysis using [IrCl(cod)]$_2$/pybox mixtures as the catalyst have been described. Thus, a reductive aldol reaction catalysed by [IrCl(cod)]$_2$/indane-pybox[2] and a regio- and enantioselective allylic substitution catalysed by mix-

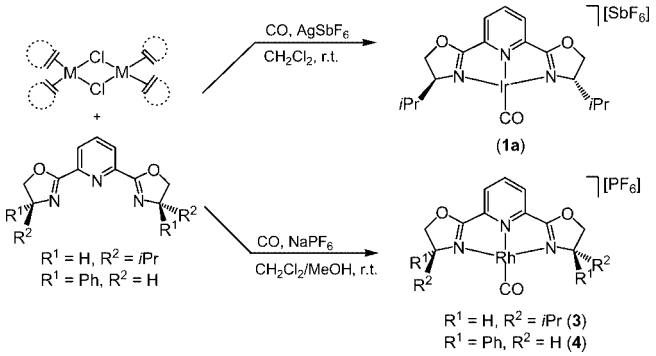
tures of $[IrCl(cod)]_2$/phenyl-pybox and nitrogen nucleophiles such as oximes, amines and hydroxylamines, have been reported recently.[3,4] Moreover, we have just described the preparation of the first (pybox)iridium complexes,[5] namely diolefin-, dialkyne- and monocarbonyliridium(I) complexes (**A**) as well as hydrido(olefin)- and $\eta^3$-allyliridium(III) derivatives (**B**). In light of these recent results, we decided it would be interesting to explore the synthesis of (pybox)-iridium complexes in order to understand their properties and eventually apply them in asymmetric catalysis. Therefore, we report here the synthesis of novel carbonyliridium(I) and -iridium(III) complexes containing the enantiopure (*S*,*S*)-*i*Pr-pybox and (*R*,*R*)-Ph-pybox ligands. This paper also deals with the synthesis of the analogous carbonylrhodium complexes, a type of systems that are scarcely found in the literature.[6] Moreover, the monocarbonyl(*i*Pr-pybox)rhodium(I) and -iridium(I) complexes have been tested as catalysts in the asymmetric hydrosilylation of acetophenone with diphenylsilane.

stirring a mixture of $[Rh(\mu\text{-}Cl)(\eta^2\text{-}C_2H_4)_2]_2$ (1 equiv.), R-pybox (2 equiv.) and $NaPF_6$ (3 equiv.) in dichloromethane/methanol (4:1) under CO at room temperature for 1 h. The monocarbonyl complexes $[Rh(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ were isolated as air-stable solids in high yields [R = *i*Pr (**3**), 91%; R = Ph (**4**), 84%; Scheme 2]. The preparation of complexes **1** and **3** has been reported previously.[5,6]



Scheme 2.

## Results and Discussion

### Synthesis of the Complexes $[M(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ [M = Ir, R = *i*Pr (1), Ph (2); M = Rh, R = *i*Pr (3), Ph (4)]

The reaction of complexes $[Ir(\eta^2\text{-}C_2H_4)_2(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ (R = *i*Pr[5] or Ph) with carbon monoxide (1 atm) in dichloromethane at room temperature results in the replacement of two ethylene molecules and the formation of the complexes $[Ir(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ [R = *i*Pr (**1**), Ph (**2**)], which were isolated as air-stable solids in excellent yields (96% and 94%, respectively; Scheme 1). Complexes **1** and **2** can be obtained in higher purity if a flow of nitrogen is slowly bubbled through the dichloromethane solution during the reaction over 50 min and before work-up. The IR spectra in the ν(CO) region show, along the reaction course, the initial formation of a non-isolated dicarbonyl complex intermediate [ν(CO) = 2088, 2021 $cm^{-1}$], which leads to the 16-electron monocarbonyl complexes when the reaction mixture is worked up [ν(CO) = 1989 (**1**), 1996 (**2**) $cm^{-1}$].

Complex **1** was also isolated as the hexafluoroantimonate derivative $[Ir(CO)\{\kappa^3\text{-}N,N,N\text{-}(S,S)\text{-}i\text{Pr-pybox}\}][SbF_6]$ (**1a**) after treatment of $[Ir(\mu\text{-}Cl)(\eta^2\text{-}C_8H_{14})_2]_2$ ($C_8H_{14}$ = cyclooctene) with *i*Pr-pybox (2 equiv.), CO (1 atm) and $AgSbF_6$ (4 equiv.) in $CH_2Cl_2$ at room temperature. Similarly, the analogous rhodium complexes were prepared by

The analytical and spectroscopic data [IR and $^1H$, $^{13}C\{^1H\}$ NMR] for complexes **1**–**4** support the proposed formulations (see Experimental Section for details). In particular: (a) the NMR spectroscopic data are consistent with the $C_2$-symmetric structure of the compounds, (b) a low-field singlet or doublet signal in the $^{13}C\{^1H\}$ NMR spectra [$\delta$ = 182.3 (**1**), 173.8 (**2**), 191.7 (d, $J_{C,Rh}$ = 76.3 Hz; **3**), 189.9 (d, $J_{C,Rh}$ = 76.3 Hz; **4**) ppm] confirms the presence of the carbonyl group, (c) the IR spectra of $CH_2Cl_2$ solutions show a strong ν(CO) absorption band in the ranges of 1996–1989 $cm^{-1}$ (for **1** and **2**) and 2014–2001 $cm^{-1}$ (for **3** and **4**).

Since oxidative addition is one of the most typical reactions of square-planar iridium(I) and rhodium(I) complexes, a comparative study of such a process for the cationic monocarbonyliridium(I) and -rhodium(I) complexes **1**–**4** was performed.

### Synthesis of the Complexes $[MI_2(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ [M = Ir, R = *i*Pr (5); M = Rh, R = *i*Pr (6), Ph (7)]

The reaction of equimolar amounts of $[M(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ (M = Ir, R = *i*Pr; M = Rh, R = *i*Pr, Ph) and iodine in dichloromethane at room temperature

Scheme 3.

gives stereoselectively the complexes $[IrI_2(CO)\{\kappa^3\text{-}N,N,N\text{-}(S,S)\text{-}i\text{Pr-pybox}\}][PF_6]$ (**5**) and $[RhI_2(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ [R = *i*Pr (**6**),[6] Ph (**7**)] by oxidative addition (Scheme 3). Complexes **5**–**7** were isolated as air-stable, garnet (**5**) or orange-brown (**6**, **7**) solids in high yields (83–89%) and were characterised by elemental analyses and NMR spectroscopy (see Experimental Section for details). In particular, it must be noted that: (a) $CH_2Cl_2$ solutions of complexes **5**–**7** show the ν(CO) absorption as a strong band in the range of 2125–2092 $cm^{-1}$, which is at higher energy than that found for the rhodium(I) and iridium(I) precursors **1**–**4** (2014–1989 $cm^{-1}$), in accordance with the higher effective oxidation state of the metal atom in complexes **5**–**7**; (b) the NMR spectroscopic data for **5**–**7** are consistent with the presence of the $C_2$ symmetry axis shown by the precursor complexes, thus indicating that the iodine atoms are in a *trans* arrangement;[7] (c) a low-field signal in the $^{13}C\{^1H\}$ NMR spectra due to the carbonyl group is observed as a singlet at $\delta$ = 157.8 ppm for **5** or as a doublet at $\delta$ = 177.9–177.2 ppm ($J_{C,Rh}$ = 55.1–53.4 Hz) for **6** and **7**.

### Synthesis of the Complexes $[MI(CH_3)(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ [M = Ir, R = *i*Pr (8), Ph (9); M = Rh, R = *i*Pr (10), Ph (11)]

The room-temperature reaction of complexes **1** and **2** with methyl iodide (1:10 molar ratio) in dichloromethane leads to the formation of the complexes $[IrI(CH_3)(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ [R = *i*Pr (**8**), Ph (**9**); Scheme 3]. However, the synthesis of analogous rhodium complexes $[RhI(CH_3)(CO)(\kappa^3\text{-}N,N,N\text{-R-pybox})][PF_6]$ [R = *i*Pr (**10**),[6] Ph (**11**)] requires the rhodium complexes **3** and **4** to be heated at 30 °C in neat $CH_3I$. Complexes **8**–**11** were isolated from the reaction mixture as yellow solids in high yields [up to 90% (**8**, **9**) and 70–80% (**10**, **11**)] and were characterised by elemental analyses and NMR spectroscopy (see Experimental Section for details). In particular: (a) the presence of the methyl group is confirmed in the $^1H$ NMR spectra by a singlet or doublet ($^2J_{H,Rh}$ = 1.5–1.7 Hz) in the range of $\delta$ = 1.40–0.73 ppm; (b) this methyl carbon atom resonates in the $^{13}C\{^1H\}$ NMR spectra at high field as a singlet or doublet [$\delta$ = –9.5 (**8**), –10.9 (**9**), 10.3 ($J_{C,Rh}$ = 18.3 Hz; **10**), 9.3 ($J_{C,Rh}$ = 17.2 Hz; **11**) ppm], while the carbonyl carbon atom appears at low field as either a singlet or a doublet at $\delta$ = 166.8–165.1 and 185.5–184.0 ppm ($J_{C,Rh}$ = 60.4–59.8 Hz) for the iridium and rhodium complexes, respectively.

Even though the synthesis of complexes **9**–**11** is completely stereoselective, the reaction of complex **1** with $CH_3I$ gives rise to the complex **8** along with a minor amount of another diastereoisomer (*de* = 80%) according to the $^1H$ NMR spectrum of the crude reaction mixture. Since the NMR and IR spectroscopic data of complexes **9**–**11** did not allow us to unambiguously determine their stereochemistry, an X-ray crystal structure analysis was performed for complex **10**, which shows the expected octahedral coordination of the rhodium atom as well as a *trans* orientation for the methyl and iodo ligands. Selected bond lengths and angles are collected in Figure 1 (see also ref.[6] for further structural data). We assume that complexes **8** (major isomer), **9** and **11** have the same stereochemistry.

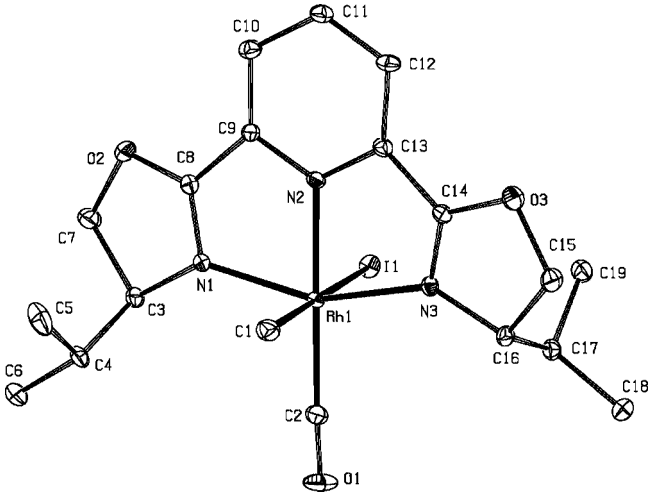

Figure 1. ORTEP-type view of the molecular structure of the cation of $[RhI(CH_3)(CO)\{\kappa^3\text{-}N,N,N\text{-}(S,S)\text{-}i\text{Pr-pybox}\}][PF_6]$ (**10**) drawn at the 10% probability level. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Rh–N(1) 2.059(5), Rh–N(2) 1.994(5), Rh–N(3) 2.056(5), Rh–C(1) 2.120(8), Rh–C(2) 1.900(7), Rh–I 2.7759(14), C(2)–O(1) 1.113(10); N(3)–Rh–N(1) 156.5(2).

As we have described above, monocarbonylrhodium(I) and -iridium(I) complexes **1**–**4** undergo oxidative addition reaction with iodine and $CH_3I$. However, monocarbonyliridium(I) complexes **1** and **2** also react under mild reaction conditions with HCl and allyl and acyl chloride to give the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

iridium(III) complexes **12**–**17**, whereas the rhodium complexes **3** and **4** remain unchanged under similar or stronger conditions ($CH_2Cl_2$ or refluxing MeOH). This behaviour is in accordance with the well-known higher stability of iridium(III) complexes in comparison with that of rhodium(III) complexes.[8]

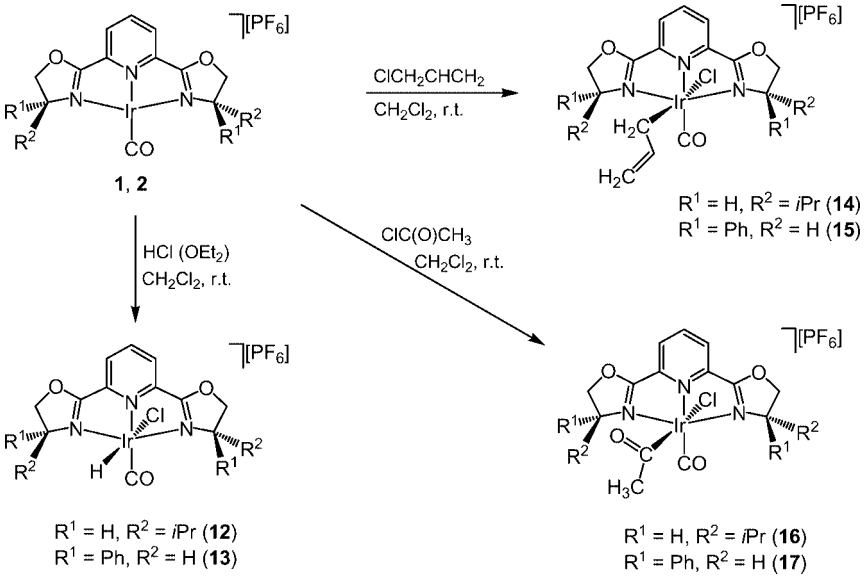
### Synthesis of the Complexes [IrHCl(CO)(κ³-*N*,*N*,*N*-R-pybox)][$PF_6$] [R = *i*Pr (12), Ph (13)]

We are particularly interested in the synthesis of hydrido complexes as they are extensively found as intermediates in both stoichiometric and catalytic processes. The treatment of a solution of complexes **1** and **2** in dichloromethane with a solution of HCl in diethyl ether at room temperature gives stereoselectively the complexes [IrClH(CO){κ³-*N*,*N*,*N*-(*S*,*S*)-R-pybox}][$PF_6$] [R = *i*Pr (**12**), Ph (**13**)], which were isolated as air-stable, yellow solids (92–94% yield; Scheme 4). Complexes **12** and **13** were characterised by elemental analysis and NMR spectroscopy (see Experimental Section for details). The most significant features of the spectroscopic data are: (a) the characteristic ν(Ir–H) and ν(CO) IR absorptions at 2180–2164 and 2083–2075 $cm^{-1}$, respectively, (b) the high-field singlet for the hydrido ligand in the $^1H$ NMR spectra at $\delta$ = –19.25 (**12**) and –19.73 (**13**) ppm, and (c) the low-field singlet for the carbonyl carbon atom in the $^{13}C\{^1H\}$ NMR spectra at $\delta$ = 165.6 (**12**) and 163.0 (**13**) ppm. The NMR and IR spectroscopic data are consistent with three possible stereoisomers. Unfortunately, all attempts to crystallise complexes **12** or **13** from a number of solvents were unsuccessful, therefore an X-ray analysis could not be performed. We assume that the hydrido and chloro ligands are *trans* to each other, in a similar stereochemical environment to that found for complexes **10** and **15** (see below), whose structures were determined by X-ray diffraction analysis.

### Synthesis of the Complexes [IrCl(η¹-$CH_2CH{=}CH_2$)(CO)(κ³-*N*,*N*,*N*-R-pybox)][$PF_6$] [R = *i*Pr (14), Ph (15)] and [IrCl{η¹-$C(O)CH_3$}(CO)(κ³-*N*,*N*,*N*-R-pybox)][$PF_6$] [R = *i*Pr (16), Ph (17)]

The oxidative addition of allyl chloride and acyl chloride to complexes **1** and **2** was also performed. Thus, the reaction of **1** and **2** with allyl chloride (3 equiv.) and acyl chloride (1 equiv.) in dichloromethane at room temperature produces the allyl- and acyliridium(III) complexes **14**/**15** and **16**/**17**, respectively (Scheme 4). These complexes were isolated as air-stable, yellow solids in 85–91% yield. Their analytic and spectroscopic data (IR and $^1H$, $^{13}C\{^1H\}$ NMR) support the proposed formulations (see Experimental Section for details). In particular, the following can be pointed out: (a) the IR spectra of **16** and **17** show the expected ν(COMe) absorptions of the acyl group at 1677–1669 $cm^{-1}$, (b) the $^1H$ and $^{13}C$ NMR resonances of the allyl group in complexes **14** and **15** are in accordance with the σ-coordination mode [$^{13}C\{^1H\}$ NMR spectra show the expected resonances in the ranges $\delta$ = 5.9–5.7 (s) and 112.9–112.1 (s) ppm for the $C_\alpha$ and $C_\gamma$ nuclei, respectively, of the η¹-allyl group], (c) the low-field singlet signals for the carbonyl carbon nuclei of the acyl and carbonyl ligands in the $^{13}C\{^1H\}$ NMR spectra appear in the range $\delta$ = 196.9–196.0 and 165.9–164.1 ppm, respectively.

The stereochemistry of complex **15** was confirmed by a single-crystal X-ray analysis. An ORTEP view of the molecular structure is shown in Figure 2. Selected bond lengths and angles are collected in Table 1.The structure exhibits a distorted octahedral geometry around the iridium atom which is bonded to the three nitrogen atoms of the Ph-pybox ligand, a chlorine atom, a carbon monoxide molecule and an η¹-allyl group (Figure 2). The chlorine atom and the allyl group are located in a *trans* disposition. The Ir–N(1) [2.032(8) Å], Ir–N(2) [2.014(8) Å] and Ir–N(3) [2.024(10) Å] distances as well as the N–Ir–N [77.0(3)°, 78.6(4)° and



Scheme 4.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

155.6(4)°] bond angles fall in the range observed for the related complexes [Ir($\eta^2$-$C_2H_4$)$_2$\{$\kappa^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox\}][$PF_6$][5] and [IrCl($\eta^3$-$C_3H_5$)\{$\kappa^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox\}][$PF_6$].[5] The Ir–allyl distances [Ir–C(1) = 2.118(11), C(1)–C(2) = 1.427(13) and C(2)–C(3) = 1.223(17) Å] are slightly shorter than those found for other σ-allyliridium(III) complexes such as [Ir($\eta^1$-$CH_2CH{=}CH_2$)$_3$($PP_2$)] [$PP_2$ = $PhP(CH_2CH_2PPh_2)_2$; Ir–C(1) = 2.208(4)–2.186(4), C(1)–C(2) = 1.488(6)–1.463(6) and C(2)–C(3) = 1.319(6)–1.253(9) Å].[9] Finally, the C–O bond length of the CO ligand in complex **15** [1.117(13) Å] is comparable to that found in the case of the carbonylrhodium complex **10** [C(2)–O(1) = 1.113(10) Å]. In conclusion, both complexes **10** and **15** present the same stereochemistry, with the CO ligand *trans* to the pyridine nitrogen atom of the pybox ligand (see Figures 1 and 2).

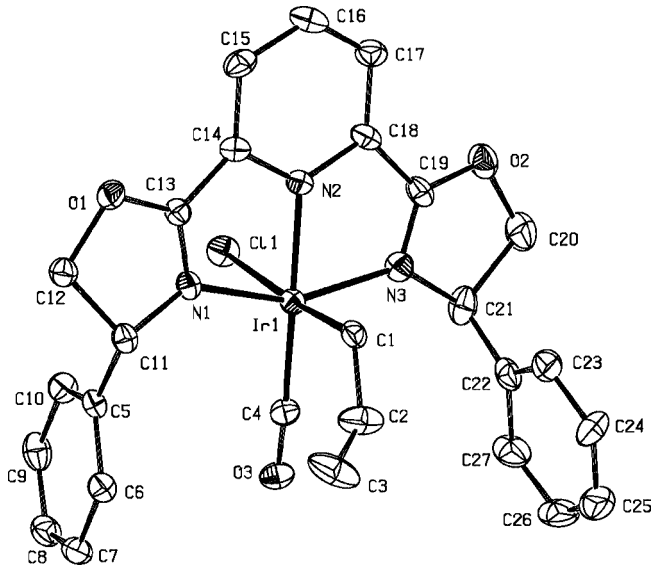


Figure 2. ORTEP-type view of the molecular structure of the cation of [IrCl($\eta^1$-$CH_2CH{=}CH_2$)(CO)\{$\kappa^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox\}][$PF_6$] (**15**) drawn at the 10% probability level. Hydrogen atoms have been omitted for clarity.

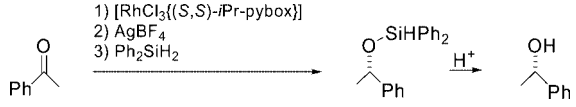
We have recently reported the synthesis of the complex [IrCl($\eta^3$-$C_3H_5$)\{$\kappa^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox\}][$PF_6$][5] by treatment of the complex [Ir($\eta^2$-$C_2H_4$)$_2$\{$\kappa^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox\}][$PF_6$] with allyl chloride in acetone at room temperature. The reaction presumably involves the formation of an intermediate monoolefiniridium(III) complex with the allyl group having a monodentate coordination. However, complexes **14** and **15** are stable in the sense that they do not evolve into the corresponding $\eta^3$-allyl complexes [IrCl($\eta^3$-$C_3H_5$)($\kappa^3$-*N*,*N*,*N*-*R*-pybox)][$PF_6$] (R = *i*Pr, Ph) by loss of carbon monoxide.

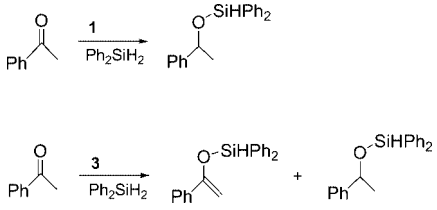
### Hydrosilylation of Acetophenone

The rhodium(III) complexes [$RhCl_3$(R-pybox)] (R = *i*Pr, *s*Bu, *t*Bu, etc.) were first used as catalyst precursors by Nishiyama and co-workers in the enantioselective synthesis of secondary alcohols by the asymmetric reduction of ketones with diphenylsilane.[10] (Scheme 5). They assumed the formation of a rhodium(I) complex as the active species in situ by reduction of the precatalyst in the presence of $AgBF_4$ and diphenylsilane.



Scheme 5.

We became interested to know the behaviour of the cationic carbonyliridium(I) and -rhodium(I) complexes reported here since neither the previous reduction of the precatalyst nor the use of $AgBF_4$ as additive would be necessary. Therefore, the catalytic activity of the complexes [M(CO)\{$\kappa^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox\}][$PF_6$] [M = Ir (**1**), Rh (**3**)] in the hydrosilylation/reduction of acetophenone was investigated (Scheme 6 and Table 2).



Scheme 6.

[Ir(CO)\{$\kappa^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox\}][$PF_6$] (**1**) was found to be catalytically active, with complete conversion of the ketone into the corresponding silyl ether at room temperature after 72 h of reaction (Table 2, entry 1). However, the desilylation of the product led to racemic 1-phenylethanol, which means that the reduction takes place without asym-

[a] The reactions were carried out under conditions similar to those reported in the literature.[11] Details of the procedure are given in the Experimental Section. [b] The values in the last three columns were calculated by integration of signals in the $^1$H NMR spectra.

metric induction. At first sight, this fact can be understood if the *i*Pr-pybox ligand decoordinates before the active species is formed, otherwise some degree of induction should have been observed. This result contrasts with those obtained with the rhodium(I) complex [Rh(CO){κ$^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox}][$PF_6$] (**3**; Table 2, entries 2–5), since variable mixtures of the expected diphenylsilyl ether (as racemate) and diphenylsilylenol ether are obtained when the reaction is run either at 0 °C or at room temperature (Scheme 6). The latter product results from the reductive O–Si coupling between diphenylsilane and the enol tautomer of the ketone. In all cases the conversion is quantitative and the diphenylsilyl enol ether is the major reaction product. We also found that the best selectivity in favour of the silyl enol ether is achieved at room temperature (Table 2, Entries 4 and 5 vs. 2 and 3) and that no excess of ligand is required at that temperature (Entries 4 and 5). A dehydrogenative silylation of ketones with a bifunctional organosilane catalysed by a mixture of the chiral or achiral complexes derived from [$RhCl_3$(pybox)] and AgOTf was reported in 1993 by Nishiyama.[11] Representative examples of the transition-metal-catalysed dehydrogenative silylation of ketones with hydrosilanes have been reported.[12]

In conclusion, acetophenone is easily and quantitatively transformed into its corresponding diphenylsilyl enol ether, at room temperature, with very high selectivity (9:1) in the presence of 1.0 mol% of [Rh(CO){κ$^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox}][$PF_6$]. Silyl enol ethers are reagents of enormous interest in organic synthesis that take part in numerous organic transformations.[13]

## Conclusions

In summary, the synthesis of monocarbonyl derivatives [M(CO)(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] (M = Rh, Ir) containing the enantiopure (*S*,*S*)-*i*Pr-pybox and (*R*,*R*)-Ph-pybox ligands has been reported. This paper also deals with the synthesis of new organometallic iridium(III) and rhodium(III) complexes by stereoselective oxidative addition reactions. The catalytic activity of the complexes [M(CO){κ$^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox}][$PF_6$] (M = Rh, Ir) in the hydrosilylation of acetophenone has been examined. In particular, the complex [Rh(CO){κ$^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox}][$PF_6$] has been demonstrated to be a very efficient catalyst for the dehydro-*O*-silylation of acetophenone to give the silyl enol ether PhC(OSiH$Ph_2$)=$CH_2$ as the major product.

## Experimental Section

**General:** All reactions were performed under dry nitrogen using vacuum-line and standard Schlenk techniques. All reagents were obtained from commercial suppliers and used without further purification. Solvents were dried by standard methods and distilled under nitrogen before use. The complexes [Ir(η$^2$-$C_2H_4$)$_2${κ$^3$-*N*,*N*,*N*-(*S*,*S*)-*i*Pr-pybox}][$PF_6$], [Ir(μ-Cl)(η$^2$-$C_8H_{14}$)$_2$]$_2$ ($C_8H_{14}$ = cyclooctene) and [Rh(μ-Cl)(η$^2$-$C_2H_4$)$_2$]$_2$ were prepared according to previously reported methods.[5,14] Infrared spectra were recorded with a Perkin–Elmer FT 1720-X or Paragon 1000 spectrometer. The conductivities were measured at room temperature, for approx. $5\times10^{-4}$ M acetone solutions, with a Jenway PCM3 conductimeter. The C, H and N analyses were carried out with a Perkin–Elmer 240-B microanalyzer. Mass spectra (FAB) were determined with a VG-Autospec mass spectrometer, operating in the positive mode; 3-nitrobenzyl alcohol (NBA) was used as the matrix. NMR spectra were recorded with a Bruker AC300 (DPX-300 or AV-300) instrument at 300 MHz ($^1$H) or 75.4 MHz ($^{13}$C) or a Bruker AMX-400 instrument at 400 MHz ($^1$H) or 100.6 MHz ($^{13}$C), using $SiMe_4$ as standard. DEPT experiments were carried out for most of the complexes.

**Synthesis of [Ir(η$^2$-$C_2H_4$)$_2${κ$^3$-*N*,*N*,*N*-(*R*,*R*)-Ph-pybox}][$PF_6$]:** A flow of ethylene was slowly bubbled at room temperature into a suspension of [Ir(μ-Cl)(coe)$_2$]$_2$ (0.448 g, 0.5 mmol) in 5 mL of methanol. After the solution colour became yellow, Ph-pybox (0.369 g, 1 mmol) was added and the mixture stirred at –40 °C for 40 min. $NaPF_6$ (0.248 g, 1.45 mmol) was added to the resulting red solution and the mixture stirred at –40 °C for 45 min. Diethyl ether was then added (ca. 100 mL) and the resulting red solid was washed with cold diethyl ether (3 × 5 mL) and then vacuum-dried (89% yield). Yield: 89% (0.064 g). Colour: red. $C_{27}H_{27}F_6IrN_3O_2P$ (762.70): calcd. C 42.52, H 3.57, N 5.51; found C 41.32, H 3.40, N 5.34. FAB-MS: *m*/*z* = 590 [$M^+ - C_2H_4$], 562 [$M^+ - 2\ C_2H_4$]. IR (KBr): $\tilde{\nu}$ = 840 ($PF_6^-$) cm$^{-1}$. Conductivity (acetone, 20 °C): 129 Ω$^{-1}$ cm$^2$ mol$^{-1}$. $^1$H NMR (300 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 8.17 (s, 3 H, $C_5H_3N$), 7.40, 7.09 (2 × m, 10 H, CH*Ph*), 5.23 (m, 2 H, $OCH_2$ or C*H*Ph), 4.81 (m, 2 H, $OCH_2$ or C*H*Ph), 4.47 (m, 2 H, $OCH_2$ or C*H*Ph), 2.33 (br., 4 H, $C_2H_4$), 1.97 (br., 4 H, $C_2H_4$) ppm. $^{13}$C{$^1$H} NMR (75.48 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 170.09 (s, OCN), 145.66 (s, $C^{2,6}$ $C_5H_3N$), 136.60 (s, $C^4$H $C_5H_3N$), 130.31, 129.66, 128.30, 126.52 (s, $C^{3,5}$H $C_5H_3N$ and Ph), 79.27 (s, $OCH_2$), 66.99 (s, *C*HPh), 32.97 (s, $C_2H_4$) ppm.

**Synthesis of Complexes [Ir(CO)(κ$^3$-*N*,*N*,*N*-R-pybox)][X] [X = $PF_6$, R = *i*Pr (1), Ph (2); X = $SbF_6$, R = *i*Pr (1a)]. Method A:** A solution of [Ir(η$^2$-$C_2H_4$)$_2$(κ$^3$-*N*,*N*,*N*-R-pybox)][$PF_6$] (R = *i*Pr or Ph) (0.1 mmol) in dichloromethane (10 mL) was stirred at room temperature under CO for 5 min. The resulting solution was then concentrated to about 3 mL and the residue diluted with 30 mL of diethyl ether to yield a dark solid, which was washed with diethyl ether (3 × 5 mL) and vacuum-dried. Complexes **1** and **2** were obtained in higher purity if a flow of nitrogen was slowly bubbled into the dichloromethane solution over 50 min and the mixture worked up as above. **Method B:** A solution of [Ir(μ-Cl)(η$^2$-$C_8H_{14}$)$_2$]$_2$ (0.036 g, 0.04 mmol) in dichloromethane (10 mL) was stirred at room temperature under CO for 5 min. *i*Pr-pybox (0.024 g, 0.08 mmol) and $AgSbF_6$ (0.052 g, 0.15 mmol) were then added and the mixture was stirred in the dark for 4 h. The suspen-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sion was filtered through kieselguhr and the resulting solution was then concentrated to about 3 mL. Addition of hexane (30 mL) yielded a dark solid, which was washed with hexane (3 × 5 mL) and vacuum-dried. **1:** Yield: 96% (0.064 g). Colour: dark green. $C_{18}H_{23}F_6IrN_3O_3P$ (666.58): calcd. **General Procedure for Catalytic Reactions:** A 10-mL flask was charged with the complex catalyst (0.04 mmol, 1.0 mol%), *i*Pr-pybox (when applicable; 0.16 mmol, 4.0 mol%) and acetophenone (4.00 mmol) under dry nitrogen. After cooling to –10 °C, $Ph_2SiH_2$ (6.4 mmol) was added dropwise. The reaction mixture was warmed to the reaction temperature and stirred until completion of the reaction. The disappearance of acetophenone was monitored by TLC. Before the aqueous workup, an aliquot was taken and examined by $^1$H NMR spectroscopy. The workup of the reaction mixture was carried out as described by Nishiyama.[10] The enantiomeric excess was determined, after hydrolysis, by GC analysis with a Supelco β-DEX 120 chiral capillary column.

**X-ray Structure Determination of 15:** Single crystals suitable for an X-ray study were obtained by slow diffusion of diethyl ether into a solution of complex **15** in dichloromethane. An orange, prismatic single crystal (0.50 × 0.25 × 0.17 mm), orthorhombic, space group $P2_12_12_1$ (determined from systematic absences) was used. Diffraction data were recorded at 293(2) K with a Nonius Kappa CCD single-crystal diffractometer, using Cu-$K_\alpha$ radiation (λ = 1.5418 Å). The crystal–detector distance was fixed at 29 mm, and a total of 2432 frames were collected using the oscillation method, with 2° oscillation and a 60 s exposure time per frame. The data-collection strategy was calculated with the program Collect.[15] Data reduction and cell refinement were performed using the programs HKL Denzo and Scalepack.[16] Unit-cell dimensions were determined from 7669 reflections. Unit-cell parameters: $a$ = 13.0003(8), $b$ = 13.4939(9), $c$ = 17.8850(8) Å, $V$ = 3137.5(3) Å$^3$, $Z$ = 4, $D_{calcd.}$ = 1.717 g cm$^{-3}$. Absorption coefficient: $\mu$ = 10.121 mm$^{-1}$. A total of 50428 reflections were collected, with 5662 independent reflections ($R_{int}$ = 0.087). Data completeness was 98.7%. The software package WINGX was used for space-group determination, structure solution and refinement.[17] The structure was solved by Patterson interpretation and phase expansion using DIRDIF.[18] An empirical absorption correction was applied using XABS2.[19] (Ratio of minimum to maximum apparent transmission: 0.164460.) Isotropic least-squares refinement on $F^2$ was carried out using SHELXL-97.[20] During the final stages of the refinements, all positional parameters and the anisotropic temperature factors of all the non-H atoms were refined. The H atoms were placed geometrically and their coordinates were refined riding on their parent atoms. The final cycle of full-matrix least-squares refinement based on 5662 reflections and 379 parameters converged to a final value of $R_1$ [$F^2 > 2\sigma(F^2)$] = 0.0607, $wR_2$ [$F^2 > 2\sigma(F^2)$] = 0.1580, $R_1$ ($F^2$) = 0.0656, $wR_2$ ($F^2$) = 0.1631. The absolute structure parameter was found to be 0.053(19). The function minimised was $[(\Sigma wF_o^2 - F_c^2)/\Sigma w(F_o^2)]^{1/2}$, where $w = 1/[\sigma^2(F_o^2) + (0.1216P)^2]$ with $\sigma(F_o^2)$ from counting statistics and $P = [\mathrm{Max}(F_o^2,0) + 2F_c^2]/3$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[21] Final difference electron density maps showed no features outside the range +1.135 to –0.764 e Å$^{-3}$. Geometrical calculations were made with PARST.[22] The crystallographic plots were made with PLATON.[23] CCDC-278506 (**15**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Properties of Cryptands with a Thioether Bridge and π-Donors – Silver(I) and Copper(I)-Complexes

René Koschabek,[a] Rolf Gleiter,*[a] and Frank Rominger[a]

**Keywords:** Cage compounds / Alkynes / Silver / Copper

The syntheses of seven bridgehead diazabicycloalkanes are reported. The bridges are represented by either a thioether chain and two 3-hexyne units (**4** and **6**–**8**), one selenoether chain and two 3-hexyne units (**5**), or one dithioether chain and two 4,4′-diethylbiphenyl units (**9**, **10**). X-ray investigations reveal for **4**–**10** the *in*/*in* conformation at the bridgehead nitrogen atoms. Reactions with $Cu^{I}$ triflate yield the endohedral $Cu^{I}$ complexes of **4**–**6**. Endohedral complexes of **6**, **7**, and **10** were isolated with silver triflate. X-ray investigations and spectroscopic studies on the metal complexes reveal interactions between the metal ion and the nitrogen-, chalcogen-, and π-units. In addition to the bicyclic systems **4**–**10** we synthesized the tripodal systems **28**–**33** in a one-pot reaction. In the cases of **28** and **33** we were able to isolate the corresponding $Ag^{I}$ complexes. X-ray studies show an interaction between the metal ion and the nitrogen atom and one double bond of each of the three adjacent phenyl rings.

## Introduction

After the seminal papers of Pedersen[1] on crown ethers and Lehn et al.[2] on cryptands these types of compounds were in the focus of chemists. Quite some time had to pass until crown thioethers participated in this development[3] because safe and high-yield routes to these species were lacking. Advances in synthetic methodology[4] and safe and general, high-yield routes[5] resulted in strong activity in this field.[5] Reports on the corresponding podands[6] and cryptands[7] with thioether bridges such as **1** are sparse, probably because a method that provides them in high yields is still missing.

The starting point of the research reported in this manuscript was a simple one-pot synthesis of the bridgehead diazabicycloalkanes **2** and **3**[8,9] with alkyne and phenyl units in the bridges (Figure 1). The two species were able to form isolable complexes with $Cu^{+}$ and $Ag^{+}$ (**2**) and $Ag^{+}$ (**3**), respectively. In both cases the metal ion does not only interact with the nitrogen atoms but also with the π-units. In order to extend the variety of ligands for transition metals it was of interest to have easy access to bicyclic ligands with at least one thioether bridge and further alkyne or phenyl ligands. In this paper we report a one-pot synthesis of the bicyclic cryptands **4**–**10** and their complexing properties with silver and/or copper(I) ions.

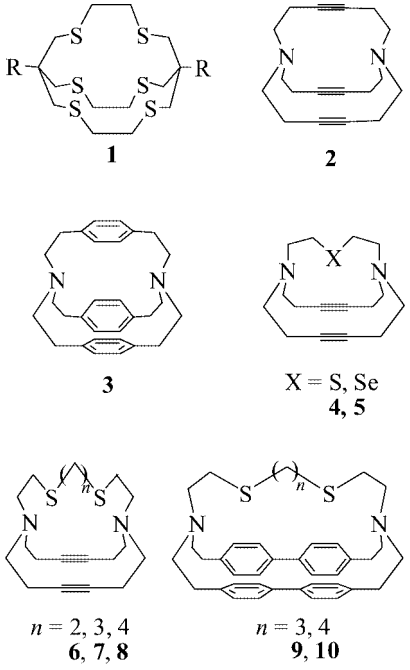

Figure 1. Bicyclic cryptands **1**–**10**.

## Results

### (a) Synthesis and Structures of 4–8

To synthesize our target molecules we adopted a one-pot synthesis developed for bridgehead diazabicycloalkanes.[10] The preparation of **4**–**8** was achieved in a three-component cyclization from an α,ω-diamine (**11**) and an α,ω-dibromide

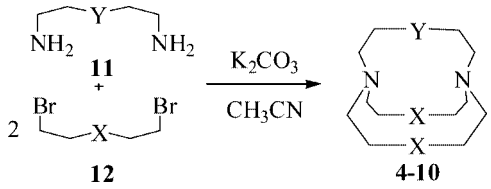
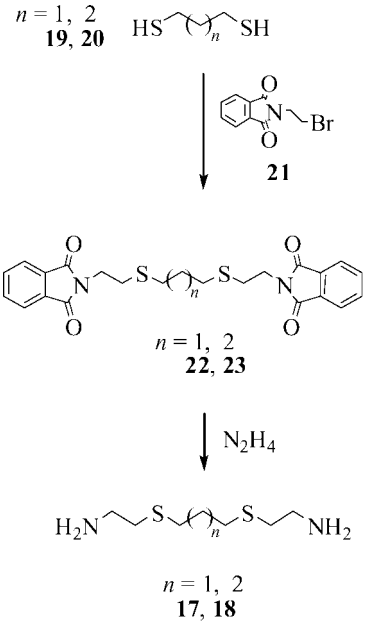
(**12**) as shown in Scheme 1. The components were heated in acetonitrile under reflux. The yields varied between 33% (**5**) and 53% (**7**). From the starting materials 1,5-diamino-3-thiapentane (**13**),[11] 1,5-diamino-3-selenapentane (**14**),[12] 1,8-diamino-3,6-dithiaoctane (**15**),[13] as well as 1,6-dibromohex-3-yne (**16**)[14] were prepared according to literature procedures.



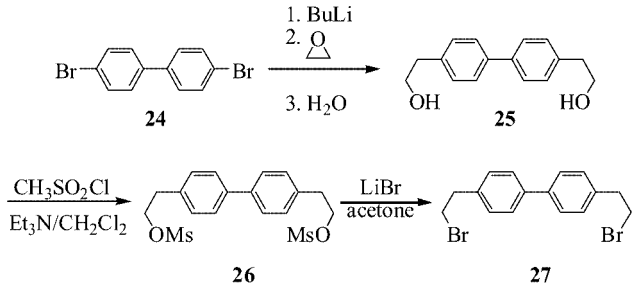
Scheme 1.

The synthesis of 1,9-diamino-3,7-dithianonane (**17**) and 1,10-diamino-3,8-dithiadecane (**18**) followed those procedures[13] used for **13**–**15** and is summarized in Scheme 2. The dianions of the α,ω-dithiols **19** and **20** were reacted with *N*-(2-bromoethyl)phthalimide (**21**) to the α,ω-diphthalimidodithianes **22** and **23**. The protecting groups were removed by heating of **22** and **23**, respectively, with hydrazine in ethanol to afford **17** and **18** in good yields.



Scheme 2.

The preparation of 4,4′-bis(2-hydroxyethyl)biphenyl (**25**) (Scheme 3) was described in the literature from biphenyl and ethylene oxide under Lewis acid catalysis.[15] This procedure gave us a mixture of the 4-(2-hydroxyethyl)biphenyl and **25** which was difficult to separate. Therefore, a different path as shown in Scheme 3 was used. The starting point was the commercially available 4,4′-dibromobiphenyl (**24**), which was treated with an excess of *n*-butyllithium and ethylene oxide to afford **25** in 92% yield. The diol **25** was converted via the dimesylate **26** into the dibromide **27** in a straight forward way (Scheme 3).



Scheme 3.

With regard to the silver(I) complexes of **3**, **9**, and **10** we also prepared the tripodal systems **28**–**33** listed in Figure 2. The synthesis follows that given in Scheme 1 by applying a one-pot reaction of (2-bromoethyl)benzene[15] or 4-(2-bromoethyl)biphenyl[16] with the corresponding amines such as (2-aminoethyl)benzene which was commercially available, 4-(2-aminoethyl)biphenyl,[17] or 1-aminobut-3-yne.[18,19] The components were heated in acetonitrile under reflux with an excess of potassium carbonate.

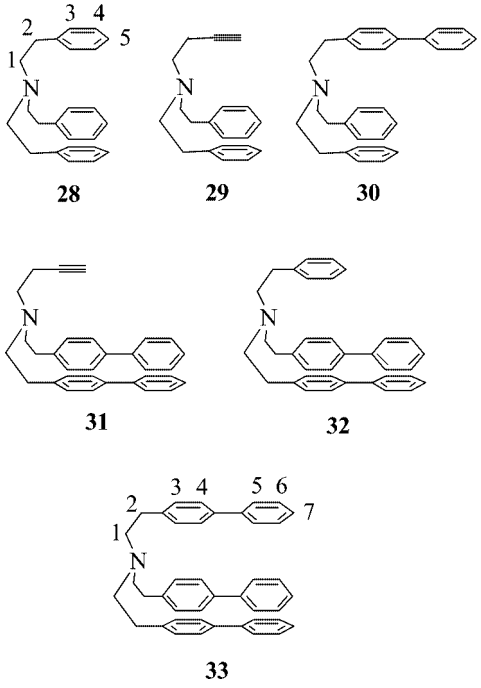


Figure 2. Tripodal systems **28**–**33**.

### (b) Spectroscopic and Structural Properties

In Table 1 we list the $^{13}C$ chemical shift of the sp centers of **4**–**8** as well as the wave numbers for the C,C stretching mode of the triple bonds derived by Raman spectroscopy. It is seen that the $\delta$ values for the sp centers vary only slightly between 79.5 and 81 ppm indicating hardly any strain in these systems. This view is supported by the wave numbers for the stretching vibration of the triple bonds. For **7** and **8** we encountered dynamic processes in the $^1H$ NMR spectra which led to a line broadening at room temperature.

Table 1. Comparison of the chemical shift of the sp carbon atoms ($\delta$) and the alkyne wave numbers of **4**–**8**.

| Compound | **4** | **5** | **6** | **7** | **8** |
|---|---|---|---|---|---|
| $\delta$(sp) [ppm] | 80.6[b] | 80.6[b] | 79.5[a] | 79.9[a] | 80.2[a] |
| $\tilde{\nu}$ [cm$^{-1}$][c] | 2228 | 2227 | 2236 | 2231 | 2237 |
| | 2291 | 2289 | 2300 | 2293 | 2297 |

[a] $CDCl_3$. [b] $CD_2Cl_2$. [c] Raman spectroscopic data.

For **4**–**10** we grew single crystals which allowed a comparison of the geometrical parameters. In Figure 3 we show the structures of **4**, **6**, **7**, and **10**. In all cases we find the *in*/*in* conformation at the bridgehead positions. A single nearly planar nitrogen atom is only seen in **4**. The heteroatoms of the bridges point outwards and do not seem very well suited for the complexation of a cation in the inside of the cages. In Table 2 we list the distances between the bridgeheads (N···N), the sum of the bonding angles ($\Sigma_{\omega N}$), and the distance between the centers of the π-systems, either triple bonds (**4**–**8**) or aromatic rings (**9**, **10**). In the latter case each biphenyl ring provides two centers. It is interesting to note that the N···N distance of **4** is larger than that of **5**. We ascribe this difference to the larger C–S–C angle (99°) of **4** as compared to the C–Se–C angle (97°) of **5**. In all cases the triple bonds are not oriented parallel to each other. In the biphenyl-bridged cages the N···N distances amount to nearly 10 Å.

### (c) Formation of Metal Complexes

The reactions of **28** and **33** with silver triflate afforded the 1:1 complexes. For **29**, **30**, and **32** the corresponding 1:1 silver complexed ions were only detected in the mass spectrum (FAB+). In Figure 4 we show the molecular structures of **28**·$Ag^+$ and **33**·$Ag^+$ in a front and side view. In **28**·$Ag^+$ the distance between the nitrogen center and silver atom amounts to 2.41 Å. This distance is closer than that found in the silver complex of **3** (2.47 Å).[10] The interaction between the silver ion and the aromatic rings is evident from the change of the NMR shifts. In the uncomplexed species (**28**) the protons at the $sp^3$ centers (positions 1 and 2 in **28**) show two close lying multiplets at 2.75–2.81 and 2.84–2.90 ppm. Similarly, the aromatic protons resonate at 7.21–7.24 and 7.32 ppm. In the silver complex the $CH_2$ protons give rise to two pronounced triplets at $\delta$ = 2.70 and 2.94 ppm. In the aromatic region two protons of each $C_6H_5$ ring give rise to a doublet at $\delta$ = 6.84 ppm. These spectroscopic data are in line with the observation that the silver ion shows a much closer contact with the *ortho* carbon atoms (position 3 in **28**) of the benzene rings as compared to the other $sp^2$ centers. For the three phenyl rings in **28**·$Ag^+$ we observe a tilting of the aromatic rings in a conrotatory fashion parallel to the $C_3$ axis. This brings one carbon atom per ring close to the metal center. The distance between these carbon atoms of the phenyl rings and the metal ion (average 2.47 Å, see Table 3) are similar to that found for various silver complexes of [2.2.2]- and [2.2.1]cyclophanes.[20–25] For **33**·$Ag^+$ we observe in the $^1$H NMR spectrum two triplets at $\delta$ = 2.83 and 2.99 ppm for the hydrogen atoms at centers 1 and 2 (see Figure 2). Six of the aromatic hydrogen atoms are shifted towards higher field due to the complexation and give rise to a doublet at $\delta$ = 6.96 ppm. The other 21 aromatic hydrogen atoms show up at 7.35–7.44 ppm. These results suggest a similar situation for the silver atom as in **28**·$Ag^+$. Indeed, the molecular structure of **33**·$Ag^+$ reveals that the metal ion is situated close to the nitrogen atom. The N–$Ag^+$ distance amounts to 2.37 Å (Table 3). The view along the N···Ag axis of **33**·$Ag^+$ shows that the aromatic rings are twisted in a conrotatory way similar to that found in **28**·$Ag^+$. This orientation allows a closer interaction between the metal atom and C3 than to the other $sp^2$ centers (average 2.43 Å, Table 3).

For **4**–**10** we infer from the downfield shift of the signals for the aliphatic hydrogen atoms in the $^1$H NMR spectra and from the mass spectrometric data the inclusion of silver and/or copper(I) ions into the cavities of these species. In all cases except for **9** this result was confirmed by the isolation of single crystals which allowed a detailed study of the molecular structure. For **4** and **5** we were able to isolate only complexes with copper(I) triflate. The reaction of **6** with silver or copper triflate gave complexes with one metal ion in the cavity. For all the other cryptates, only silver complexes could be characterized. In the case of **10** even two silver ions were incorporated in the cavity. In Figure 5 we show the molecular structures of **4**·$Cu(CF_3SO_3)$, **8**·$Ag(CF_3SO_3)$, and **10**·$2[Ag(CF_3SO_3)_2]$.

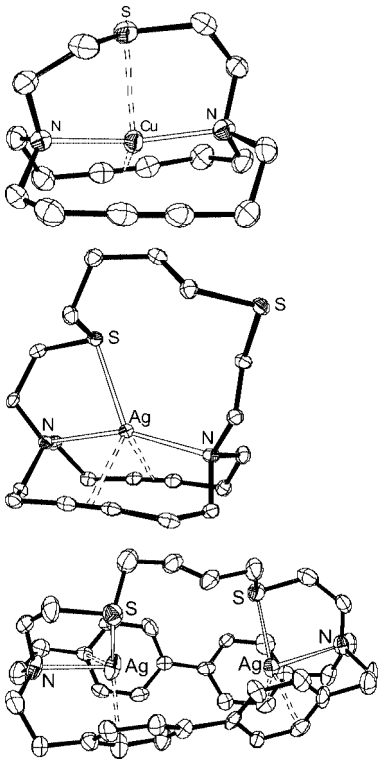

Figure 5. Molecular structures of **4**·$Cu^+$ (top), **8**·$Ag^+$ and **10**·2($Ag^+$) (bottom).

In Table 4 we collected the most relevant distances and angles of the metal complexes of **4**–**8** and **10**. The copper complex of **4** shows a considerable change in the conformation of the ligand. The N···N distance is substantially shortened from 4.72 Å (free ligand) to 4.20 Å (complex) (see Figure 3 and Figure 5). As a result of this change the triple bonds are oriented almost parallel and the chalcogen center of the bridge is turned towards the metal. This change allows almost equal distances to both nitrogen centers (2.10 and 2.16 Å) but close contact to only one triple bond (2.13 Å), whereas the distance to the other (2.71 Å) is considerably longer. The copper–nitrogen distances are expanded with regard to copper(I) amine complexes (average value 2.18 Å)[26] but comparable to those reported for **2**·$Cu^+$ (2.11 Å).[9] The distance Cu–S (2.52 Å) is longer than those reported in other thioether-$Cu^I$ complexes (2.25–2.30 Å).[27]

The molecular structure of **5**·$Cu^+$ is isomorphous to that of **4**·$Cu^+$. The N···N distance in the complex (4.21 Å) is about as long as that in **4**·$Cu^+$ (4.20 Å). The same holds for the N–Cu distances and the N–M–N angle, 160.5° in **4**·$Cu^+$ and 161.6° for **5**·$Cu^+$. Also both triple bonds are almost oriented parallel to each other in contrast to the free ligand. The selenium atom is bent sideways to interact with the copper ion (Cu–Se = 2.62 Å). The complex shows one close contact to one triple bond (2.16 Å) only.

Table 4. Selected distances [Å] and angles (degrees) of $Ag^I$ or $Cu^I$ triflates of **4**–**8** and **10**.

| Compound | **4**·$Cu^+$ | **5**·$Cu^+$ | **6**·$Ag^+$ | **6**·$Cu^+$ | **7**·$Ag^+$ | **8**·$Ag^+$ | **10**·2($Ag^+$) |

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The molecular structures of **6**·$Ag^+$ and **6**·$Cu^+$ are shown in Figure 6. In the case of **6**·$Ag^+$ we are not dealing with a purely endohedral complex between ligand and metal. The unit cell does not only show the endohedral metal ion but also exohedral metal ions between the thioether groups (see Figure 6) that lead to a coordination polymer. In the endohedral complex the metal ion deviates from the N···N axis in the direction of the thioether bridge N···Ag···N (197.3°). This deviation is due to a interaction between the silver ion and the sulfur centers. The Ag···S distances found (Table 4; 2.76 Å and 2.88 Å) compare well with other thioether–silver distances.[28,29] The distances between the exohedral silver centers and the thioether groups amount to 2.49 Å and 2.50 Å. The average Ag···N distance (2.45 Å) is longer than the one reported for **2**·Ag (2.31 Å).[8] The distances between the endohedral silver ions and the triple bonds (2.61, 2.66 Å) are still within the reach of a weak metal–π-bond. Raman studies on **6**·$Ag^+$ failed due to a fast decomposition of the complex during the Raman experiment. Our studies show that the large silver ion prefers a coordination number of 6.

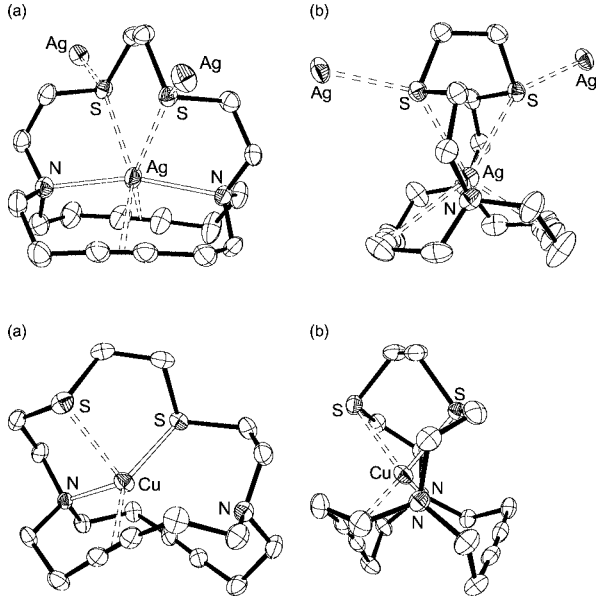

Figure 6. Molecular structure of **6**·$Ag^+$ (top) and **6**·$Cu^+$ (bottom) in a front view (a) and a view along the N–N axis (b). The hydrogen atoms are omitted for the sake of clarity.

The structure of **6**·$Cu^+$ (Figure 6) is remarkably different from that of **6**·$Ag^+$. The position of the metal is shifted towards one nitrogen center and one triple bond. The distance to the nitrogen center amounts to 2.15 Å and to the triple bond to 2.09 Å. The distances to the second nitrogen center and to the second triple bond in **6**·$Cu^+$ exceed 3 Å (Table 4). As a consequence both triple bonds in **6**·$Cu^+$ are not oriented parallel (Figure 6). Furthermore, the metal ion coordinates to both thioether groups (2.28, 2.56 Å). This establishes a coordination number of 4 for the metal in **6**·$Cu^+$.

The inclusion of $Ag^I$ in the cavity of **7** does not change the tilting of the triple bonds, but changes the conformation of the 3,7-dithiononane bridge in so far as the sulfur centers are turned inward to interact with the metal ion. The N···N distance is even increased as compared to the free ligand. The silver ion is shifted considerably out of the N···N axis towards the sulfur atoms (N–Ag–N angle 211.6°). In line with this, the distances between the triple bonds and the silver ion amount to 2.64 and 2.72 Å. These values are about 0.2 Å larger than those reported for **2**·$Ag^+$.[9] In the case of **7**·$Ag^+$ it was possible to measure the wave number for the stretching vibration of the triple bond ($\tilde{\nu}$ = 2281 and 2206 $cm^{-1}$). These values are shifted towards lower energy as compared to the free ligand ($\tilde{\nu}$ = 2293 and 2231 $cm^{-1}$) which is evidence for an interaction between the metal and the triple bonds. The distances between the sulfur centers and the metal atom amount to 2.75 and 2.77 Å. These values are close to those reported for thioether-silver distances (2.6–2.8 Å).[28,29]

The molecular structure of **8**·$Ag^+$ (Figure 5) is quite different from that of **7**·$Ag^+$ in so far as only one sulfur atom of the flexible dithia bridge interacts with the silver center. The other sulfur atom points outwards. The Ag–S distance (2.57 Å) is rather close compared to the other values. The N···N distance is shortened by about 0.5 Å compared to the uncomplexed system. The N–Ag distances (2.37 and 2.47 Å) are much shorter than for **7**·$Ag^+$ (see Table 4) and the two triple bonds are oriented parallel to each other. The interaction between the silver ion and the triple bonds is evident not only from the distances (2.66 and 2.75 Å) but also in the lowering of the wave numbers for the stretching vibration ($\tilde{\nu}$ = 2266 and 2204 $cm^{-1}$) as compared to **8** ($\tilde{\nu}$ = 2297 and 2237 $cm^{-1}$). The reaction of **9** with silver(I) triflate afforded a 1:1 complex as evidenced by HR-FAB$^+$ data. The comparison between the $^1$H NMR spectroscopic data of **9**·$Ag^+$ with those of **9** shows a downfield shift of the signals for the protons.

The reaction of **10** with silver(I) triflate afforded single crystals which could be investigated by means of the X-ray technique. It turned out that the cavity of **10** is large enough to house two silver ions (Figure 5). The incorporation of the two metal ions causes only a small change in the length of the cavity but a large one in the conformation of the thioether chain. The sulfur atoms are now turned inwards (see also Figure 3). The distance between the two silver ions in **10**·2($Ag^+$) was found to be 5.18 Å. This value is clearly larger than the sum of the van der Waals radii of $Ag^+$ (3.1–3.2 Å).[30,31] The average distance to the nitrogen atoms was found to be 2.44 Å which compares well with those recorded for **6**·$Ag^+$ and **8**·$Ag^+$ (Table 4). A closer look at the Ag···phenyl interaction reveals a situation very similar to that encountered for **28**·$Ag^+$and **33**·$Ag^+$ as well as for various [2.2.2] and [2.2.1]cyclophanes.[20–25] One carbon atom per ring is much closer to the silver ion than the other $sp^2$ centers. For three phenyl rings this is a *ortho* carbon (average distance 2.48 Å), only in one case is the silver ion closest to the *ipso*-carbon (2.50 Å). This coordination does not affect the planarity of the aromatic rings. The Ag–S distance of 2.50 Å is similar to that found in **8**·$Ag^+$ and shorter than in **6**·$Ag^+$ and **7**·$Ag^+$ (see Figure 6).

## Concluding Remarks

Our main goal to find a simple procedure for the preparation of N-bridgehead diazabicyclo-cages with one thioether bridge and π units in the other two was achieved. Like in crown thioethers the sulfur atoms adopt the exodentate orientation. However, when a metal ion was in the cavity this unfavorable position was changed to a more favorable one, mostly to the endodentate one. The prepared cage systems afforded endohedral complexes with silver or copper ions. It could be shown that the metal ions try to interact with a maximum of *n*-donors (N, S, Se) and π-donors (triple bonds or phenyl rings).

## Experimental Section

**General Methods:** All melting points are uncorrected. Elemental analyses were carried out by the Mikroanalytisches Laboratorium der Universität Heidelberg. UV/Vis absorption data were recorded with a Hewlett-Packard HP 8452A Diode Array-spectrometer, IR spectra were recorded with a Bruker Vector 22 FT-IR instrument. The NMR spectra were measured with a Bruker WH 300 or Avance 500 spectrometer ($^1$H NMR at 300 or 500 MHz and $^{13}$C NMR at 75 or 125 MHz), using the solvent as an internal standard ($\delta$). FAB mass spectra refer to data from a JEOL JMS-700 instrument. As matrix for the FAB experiments, *m*-nitrobenzyl alcohol was used. All reactions were carried out in dried glassware under argon using dried and oxygen-free solvents. Starting materials were prepared according to literature procedures. From the starting materials 1,5-diamino-3-thiapentane,[11] 1,5-diamino-3-selenapentane,[12] 1,8-diamino-3,6-dithiaoctane,[13] 1,6-dibromohex-3-yne,[14] (2-bromoethyl)benzene,[15] 4-(2-bromoethyl)biphenyl,[16] 4-(2-aminoethyl)biphenyl[17], and 1-aminobut-3-yne[18,19] were prepared according to literature procedures. 2-Aminoethylbenzene and 4,4′dibromobiphenyl were commercially available.

**X-ray Crystallographic Study:** Data were collected with a Bruker Smart CCD diffractometer at 200 K for **4**, **6**, **7**, **4**·$Cu^+$, **5**·$Cu^+$, **6**·$Cu^+$, **6**·$Ag^+$, **7**·$Ag^+$, **10**·2($Ag^+$), **28**·$Ag^+$, **33**·$Ag^+$, and with a Bruker APEX diffractometer at 100 K for **5**, **8**, **9**, **10**, and **8**·$Ag^+$. Mo-$K_\alpha$ radiation was used in all cases and the intensities were corrected for Lorentz, polarization, and absorption effects. Relevant crystal and data collection parameters are given in Tables 5, 6, 7, 8 and 9. The structures were solved by direct methods and refined against $F^2$ with a full-matrix least square algorithm by using the SHELXTL software package.[32] Hydrogen atoms were refined isotropically for **8**, in all other cases they were considered at calculated positions and refined using appropriate riding models. In **10**, **10**·2($Ag^+$), and **6**·$Ag^+$ some solvent molecules or anions had to be treated as disordered, in **4**·$Cu^+$ and **5**·$Cu^+$ on one side of the cage the three methylene groups next to the nitrogen atom occur in two alternative positions, in **9** an ethylene unit of the thioether bridge is affected by disorder. In **4**·$Cu^+$ and **5**·$Cu^+$ the copper position is not fully occupied. The charge balance is maintained by partial replacement of the metal ion by a proton, which could be refined isotropically with an occupation of about 30% in both cases. CCDC-279304 (for **4**), -279305 (for **5**), -279306 (for **6**), -279307 (for **7**), -279308 (for **8**), -279309 (for **9**), -279310 (for **10**), -279311 (for **4**·$Cu^+$), -279312 (for **5**·$Cu^+$), -279313 (for **6**·$Cu^+$), -279314 (for **6**·$Ag^+$), -279315 (for **7**·$Ag^+$), -279316 (for **8**·$Ag^+$), -279317 [for **10**·2($Ag^+$)], -279318 (for **28**·$Ag^+$), and -279319 (for **33**·$Ag^+$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**1,10-Diphthalimido-3,8-dithiodecane (23):** To a solution of 1,3-propanedithiol (4.8 g, 39 mmol) in dry toluene (250 mL), cooled to –30 °C was added dropwise *n*BuLi in hexane (51 mL). After 30 min of mechanical stirring at –30 °C a solution of *N*-2-bromoethylphthalimide (20 g, 78.7 mmol) in dry toluene (250 mL) was added dropwise over a period of 1 h so that the temperature was maintained below 0 °C. After mechanical stirring overnight at room temperature the suspension was finally refluxed for 1 h. To workup water (100 mL) was added and the organic layer was washed further 2× with water. After drying with magnesium sulfate and removal of the solvent, pure **23** (12.1 g, 66%) was obtained by crystallization from acetone as a white solid, m.p. 100 °C. $^1$H NMR (500 MHz, $C_6D_6$): $\delta$ = 1.39 (s, 4 H, C$H_2$), 2.27 (s, 4 H, C$H_2$), 2.57 (t, $^3J$ = 7.1 Hz, 4 H, C$H_2$), 3.62 (t, $^3J$ = 7.0 Hz, 4 H, C$H_2$), 6.82–6.86 (m, 4 H, $C_{ar}H$), 7.38–7.42 (m, 4 H, $C_{ar}H$) ppm. $^{13}$C NMR (125 MHz, $C_6D_6$): $\delta$ = 28.6 (s, *C*H$_2$), 30.1 (s, *C*H$_2$), 31.2 (s, *C*H$_2$), 37.2 (s, *C*H$_2$), 123.1 (t, $C_{ar}$), 132.6 (q, $C_{ar}$), 133.6 (t, $C_{ar}$), 167.9 (q, *C*O) ppm. IR (KBr): $\tilde{\nu}$ = 3460, 3102, 3048, 3018, 2945, 2923, 2865, 1774, 1699, 1613, 1578, 1464, 1433, 1417 cm$^{-1}$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (lg $\varepsilon$) = 294 (3.5) nm. HRMS (FAB) calcd. for $C_{24}H_{24}N_2O_4S_2$ 469.1256; found 469.1263. $C_{24}H_{24}N_2O_4S_2$ (469.13): calcd. C 61.52, H 5.16, N 5.98, S 13.68; found C 61.26, H 5.15, N 6.01, S 13.56.

**1,9-Diamino-3,7-dithiononane·Dihydrochloride (17·2HCl):** To a solution of **22** (13.2 g, 29.1 mmol) in dry ethanol (50 mL) was added dropwise a solution of hydrazine (3.1 g, 61.1 mmol) in water (5 mL). After temporary clearance of the solution a solid precipitate commenced to separate. The whole mixture was heated at reflux for 2 h then concentrated hydrochloric acid (12 mL) was added slowly and the obtained clear solution was stirred for a further 30 min. The alcohol was removed by evaporation and the suspension was dissolved in water. The solid was filtered off and washed with water. The water was removed by evaporation and the raw material was crystallized from methanol to obtain **17·2HCl** (7.5 g, 96%) as a white solid, m.p. 192 °C. $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 1.86–1.96 (m, 2 H, C$H_2$), 2.72 (t, $^3J$ = 7.1 Hz, 4 H, C$H_2$), 2.86 (t, $^3J$ = 6.9 Hz, 4 H, C$H_2$), 3.16 (t, $^3J$ = 6.7 Hz, 4 H, C$H_2$), 4.84 (s, 6 H, N$H_3$Cl) ppm. $^{13}$C NMR (75 MHz, $CD_3OD$): $\delta$ = 29.7 (s, *C*H$_2$), 30.3 (s, *C*H$_2$), 31.1 (s, *C*H$_2$), 40.2 (s, *C*H$_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3440, 3023, 2040, 1718, 1628, 1459, 1412 cm$^{-1}$. $C_7H_{20}Cl_2N_2S_2$ (267.29): calcd. C 31.46, H 7.54, N 10.48, S 23.99, Cl 26.53; found C 31.61, H 7.52, Cl 26.42, N 10.34, S 23.71.

**1,10-Diamino-3,8-dithiodecane·Dihydrochloride (18·2HCl):** To a solution of **23** (5.5 g, 11.7 mmol) in dry ethanol (25 mL) was added dropwise a solution of hydrazine (1.23 g, 24.6 mmol) in water (2 mL). After temporary clearance of the solution a solid precipitate commenced to separate. The whole mixture was heated at reflux for 2 h then concentrated hydrochloric acid (12 mL) was added slowly and the obtained clear solution was stirred for further 30 min. The alcohol was removed by evaporation and the suspension was dissolved in water. The solid was filtered off and washed with water. The water was removed by evaporation and the raw material was crystallized from methanol to obtain **18·2HCl** (2.7 g, 83%) as a white solid, m.p. 203 °C. $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 1.71–1.76 (m, 4 H, C$H_2$), 2.63 (t, $^3J$ = 7.1 Hz, 4 H, C$H_2$), 2.83 (t, $^3J$ = 6.9 Hz, 4 H, C$H_2$), 3.15 (t, $^3J$ = 6.8 Hz, 4 H, C$H_2$), 4.83 (s, 6 H, N$H_3$Cl) ppm. $^{13}$C NMR (75 MHz, $CD_3OD$): $\delta$ = 29.4 (s, *C*H$_2$), 29.7 (s, *C*H$_2$), 31.9 (s, *C*H$_2$), 40.0 (s, *C*H$_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3440, 2999, 2045, 2059, 1582, 1508, 1463 cm$^{-1}$. $C_8H_{22}Cl_2N_2S_2$ (281.31): calcd. C 34.16, H 7.88, N 9.96, S 22.79, Cl 25.21; found C 34.31, H 7.85, Cl 25.27, N 9.90, S 22.83.

**4,4′-Bis(2-hydroxyethyl)biphenyl (25):** To a suspension of 4,4′-dibromobiphenyl (30.00 g, 96 mmol) in dry hexane (1200 mL) was added a solution of 10 M *n*BuLi in hexane (42 mL, 420 mmol). The mixture was heated at reflux for 12 h. To this suspension dry THF (500 mL) was added and cooled to –40 °C. Subsequently ethylene oxide (31 mL, 617 mmol) was added. After 36 h of mechanical stirring at –35 °C water (500 mL) was added. Subsequently the mixture was stirred for a further 30 min. The white precipitate was then filtered off and dried with silica gel and finally crystallized from hexane to yield **25** (21 g, 92%), m.p. 183 °C. $^1$H NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 1.45 (t, $^3J$ = 5.8 Hz, 2 H, OH), 2.87 (t, $^3J$ = 6.6 Hz, 4 H, C$H_2$), 3.85 (t, $^3J$ = 6.6 Hz, 4 H, C$H_2$), 7.29 (d, $^3J$ = 8.1 Hz, 4 H, $C_{ar}H$), 7.53 (d, $^3J$ = 8.1 Hz, 4 H, $C_{ar}H$) ppm. $^{13}$C NMR (125 MHz, $CD_2Cl_2$): $\delta$ = 38.8 (s, *C*H$_2$), 63.44 (s, *C*H$_2$), 126.9 (t, $C_{ar}$), 129.4 (t, $C_{ar}$), 137.9 (q, $C_{ar}$), 138.9 (q, $C_{ar}$) ppm. IR (KBr): $\tilde{\nu}$ = 3420, 3030, 2942, 2878, 2049, 1911, 1633, 1500, 1476 cm$^{-1}$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (lg $\varepsilon$) = 258 (4.3) nm. HRMS (FAB) calcd. for $C_{16}H_{18}O_2$ 242.1307; found 242.1323. $C_{16}H_{18}O_2$ (242.13): calcd. C 79.31, H 7.49; found C 79.17, H 7.31.

**4,4′-Bis(2-methylsulfonylethyl)biphenyl (26):** To a solution of **25** (21.4 g, 88.3 mmol) in dichloromethane (350 mL) was added by cooling to –20 °C triethylamine (28.8 g, 285 mmol). Subsequently methanesulfonyl chloride (24.5 g, 213.8 mmol) was added to the mixture at such a rate that the temperature was maintained below –10 °C. After the addition was completed the suspension was stirred for 2 h. For workup water (100 mL) was added and the organic layer was washed with 10% hydrogen chloride solution, followed by saturated sodium hydrogen carbonate solution and again by saturated sodium chloride solution and water. The organic layer was dried with magnesium sulfate and the solvent evaporated. Purification by column chromatography (alumina; cyclohexane/ethyl acetate, 4:1) afforded **26** (29.0 g, 82%) as a white solid, m.p. 82 °C. $^1$H NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 2.87 (s, 6 H, C$H_3$), 3.09 (t, $^3J$ = 6.8 Hz, 4 H, C$H_2$), 4.43 (t, $^3J$ = 6.8 Hz, 4 H, C$H_2$), 7.32 (d, $^3J$ = 8.2 Hz, 4 H, $C_{ar}H$), 7.56 (d, $^3J$ = 8.2 Hz, 4 H, $C_{ar}H$) ppm. $^{13}$C NMR (75 MHz, $CD_2Cl_2$): $\delta$ = 35.6 (s, *C*H$_2$), 37.6 (*C*H$_3$), 70.9 (s, *C*H$_2$), 127.5 (t, $C_{ar}$), 129.9 (t, $C_{ar}$), 136.2 (q, $C_{ar}$), 139.7 (q, $C_{ar}$) ppm. IR (KBr):$\tilde{\nu}$ = 3434, 3027, 2942, 1913, 1500, 1428, 1401 cm$^{-1}$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (lg $\varepsilon$) = 258 (4.4) nm. HRMS (FAB) calcd. for $C_{18}H_{22}O_6S_2$ 398.0858; found 398.0850. $C_{18}H_{22}O_6S_2$ (398.09): calcd. C 54.25, H 5.56, S 16.09; found C 54.61, H 5.54, S 15.85.

**4,4′-Bis(2-bromoethyl)biphenyl (27):** A solution of **26** (20 g, 50.2 mmol) in acetone (800 mL) was refluxed with LiBr (26 g, 301.1 mmol) overnight. Water was added to dissolve the precipitated salt and the acetone was removed by evaporation. The aqueous layer was extracted 5× with dichloromethane, and the combined organic layers were dried with magnesium sulfate. After evaporation of the solvent pure **27** (14.3 g, 81%) was obtained by column chromatography (alumina; hexane/diethyl ether, 5:1) as a white solid, m.p. 107 °C. $^1$H NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 3.20 (t, $^3J$ = 7.5 Hz, 4 H, C$H_2$), 3.63 (t, $^3J$ = 7.4 Hz, 4 H, C$H_2$), 7.30 (d, $^3J$ = 8.1 Hz, 4 H, $C_{ar}H$), 7.56 (d, $^3J$ = 8.2 Hz, 4 H, $C_{ar}H$) ppm. $^{13}$C NMR (125 MHz, $CD_2Cl_2$): $\delta$ = 33.5 (s, *C*H$_2$), 39.2 (s, *C*H$_2$), 127.3 (t, $C_{ar}$), 129.5 (t, $C_{ar}$), 138.4 (q, $C_{ar}$), 139.6 (q, $C_{ar}$) ppm. IR (KBr): $\tilde{\nu}$ = 3444, 3052, 3026, 2959, 2930, 2051, 1633, 1493, 1447 cm$^{-1}$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (lg $\varepsilon$) = 260 (4.4) nm. HRMS (FAB) calcd. for $C_{16}H_{16}Br_2$ 367.9599; found 367.9607. $C_{16}H_{16}Br_2$ (367.96): calcd. C 52.21, H 4.38, Br 43.41; found C 52.35, H 4.44, Br 43.19.

**General Procedure for the Condensation of Primary Amines with Terminal Bromo Compounds to the Tertiary Amines 28–33:** A primary amine (5 mmol) and a terminal bromo-compound (10 mmol) were added together to a suspension of finely powdered potassium

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

carbonate (4.9 g, 35 mmol) in acetonitrile (200 mL). The mixture was stirred intensively and refluxed for 2 d until the starting material was consumed. The mixture was filtered and the solvent evaporated. The residue was purified by column chromatography on alumina.

**Tris(2-phenylethyl)amine (28):** 945 mg (58%); m.p. 31 °C; cyclohexane/ethyl acetate, 50:1. $^1$H NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 2.75–2.81 (m, 6 H, C$H_2$), 2.84–2.90 (m, 6 H, C$H_2$), 7.21–7.24 (m, 9 H, $C_{ar}H$), 7.32 (t, $^3J$ = 7.2 Hz, 6 H, $C_{ar}H$) ppm. $^{13}$C NMR (75 MHz, $CD_2Cl_2$): $\delta$ = 34.2 (s, $CH_2$), 56.4 (s, $CH_2$), 126.2 (t, $C_{ar}$), 128.7 (t, $C_{ar}$), 129.2 (t, $C_{ar}$), 141.4 (q, $C_{ar}$) ppm. IR (KBr): $\tilde{\nu}$ = 3480, 3086, 3028, 2957, 2933, 2864, 2798, 1946, 1873, 1809, 1751, 1600, 1491, 1452 cm$^{-1}$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ (lg $\varepsilon$) = 258 (3.0) nm. IR (KBr): $\tilde{\nu}$ = 3441, 2922, 2868, 1630, 1460, 1427 cm$^{-1}$. HRMS (FAB) calcd. for $C_{16}H_{24}CuN_2Se$ 387.0400; found 387.0406.

**General Procedure for the Synthesis of Silver Complexes [6·Ag$^+$][$CF_3SO_3^-$], [10·2(Ag$^+$)][$CF_3SO_3^-$]$_2$, [28·Ag$^+$][$CF_3SO_3^-$], and [33·Ag$^+$][$CF_3SO_3^-$]:** To a solution of silver triflate (53 mg, 0.2 mmol) in anhydrous dichloromethane (5 mL) was added in the absence of light a solution of the corresponding cryptand (0.1 mmol) in anhydrous dichloromethane (5 mL). After stirring for 1 h the mixture was filtered and evaporation of the solvent gave the corresponding silver complex in quantitative yield.

**Complex [6·Ag$^+$][$CF_3SO_3^-$]:** $^1$H NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 2.46–2.61 (m, 16 H, C$H_2$), 2.69–2.73 (m, 4 H, C$H_2$), 2.77–2.81 (m, 4 H, C$H_2$), 2.93 (s, 4 H, SC$H_2$C$H_2$S) ppm. $^{13}$C NMR (75 MHz, $CD_2Cl_2$): $\delta$ = 18.6 (s, *C*H$_2$), 29.3 (s, *C*H$_2$), 30.7 (s, *C*H$_2$), 53.0 (s, *C*H$_2$), 53.1 (s, *C*H$_2$), 79.3 (q, $C_{alkyne}$) ppm. IR (KBr): $\tilde{\nu}$ = 3444, 2963, 2920, 2849, 1461, 1434 cm$^{-1}$. HRMS (FAB) calcd. For $C_{18}H_{28}AgN_2S_2$ 445.0741; found 445.0701.

**Complex [7·Ag$^+$][$CF_3SO_3^-$]:** $^1$H NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 1.79 (t, $^3J$ = 6.6 Hz, 4 H, C$H_2$), 2.13–2.22 (m, 2 H, C$H_2$), 2.47–2.54 (m, 8 H, C$H_2$), 2.61 (m, 4 H, C$H_2$), 2.74 (t, $^3J$ = 5.5 Hz, 4 H, C$H_2$), 2.86–2.93 (m, 8 H, C$H_2$), 2.63–3.68 (m, 4 H, C$H_2$) ppm. $^{13}$C NMR (75 MHz, $CD_2Cl_2$): $\delta$ = 19.4 (s, *C*H$_2$), 25.9 (s, *C*H$_2$), 31.6 (s, *C*H$_2$), 32.3 (s, *C*H$_2$), 53.3 (s, *C*H$_2$), 53.7 (s, *C*H$_2$), 68.0 (q, OTf$^-$), 79.7 (q, $C_{alkyne}$) ppm. IR (KBr): $\tilde{\nu}$ = 3441, 2963, 2916, 2840, 2823, 1629, 1459, 1446, 1433, 1418 cm$^{-1}$. Raman: $\tilde{\nu}$ = 2206, 2281 cm$^{-1}$. HRMS (FAB) calcd. for $C_{19}H_{30}AgN_2S_2$ 459.0898; found 459.0888.

**Complex [8·Ag$^+$][$CF_3SO_3^-$]:** $^1$H NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 1.92 (s, 4 H, C$H_2$), 2.53–2.66 (m, 16 H, C$H_2$), 2.76 (t, $^3J$ = 6.5 Hz, 4 H, C$H_2$), 2.91 (s, 4 H, C$H_2$), 2.98 (t, $^3J$ = 6.5 Hz, 4 H, C$H_2$) ppm. $^{13}$C NMR (125 MHz, $CD_2Cl_2$): $\delta$ = 18.5 (s, *C*H$_2$), 26.4 (s, *C*H$_2$), 31.4 (s, *C*H$_2$), 32.2 (s, *C*H$_2$), 53.4 (s, *C*H$_2$), 60.9 (q, OTf$^-$), 78.9 (q, $C_{alkyne}$) ppm. IR (KBr):$\tilde{\nu}$ = 3443, 2924, 2846, 1629, 1457, 1439 cm$^{-1}$. HRMS (FAB) calcd. for $C_{20}H_{32}AgN_2S_2$ 471.1058; found 471.1075.

**Complex [9·Ag$^+$][$CF_3SO_3^-$]:** $^1$H NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 0.77 (s, 2 H, C$H_2$), 1.63 (s, 4 H, C$H_2$), 2.27 (t, $^3J$ = 6.8 Hz, 4 H, C$H_2$),

# A Prime Example of Hard-Hard and Soft-Soft Interactions: Complexes between 4,7-Dioxa-1,10-diazabicyclo[8.6.6]docosa-13,19-diyne and $Li^+$, $Na^+$, $Cu^+$, $Ag^+$, $Cd^{2+}$, $Hg^{2+}$

**Andreas Kunze,[a,b] Rolf Gleiter,*[a] and Frank Rominger[a]**

**Keywords:** Cage compounds / Alkynes / Metal complexes

The crystal structures of 4,7-dioxa-1,10-diazabicyclo[8.6.6]-docosa-13,19-diyne (**7**), its *N*,*N*′-dioxide derivative **10** and the complexes of **7** with $LiClO_4$, $NaNO_3$, $Cu^I$ and $Ag^I$ triflate, $Cd(NO_3)_2$, and $HgCl_2$ were investigated. The $Li^+$ and $Na^+$ ions reveal a strong interaction between the ether bridge and the nitrogen atoms of **7**. The $Cu^I$ ion prefers an interaction between the nitrogen centers and the alkyne units whereas the $Ag^I$ ion interacts with the hard oxygen and nitrogen centers as well as with the alkyne units. The reaction of $HgCl_2$ with **7** in the presence of water afforded a molecule which could be looked at as the intermediate of a mercury-catalyzed addition of water to the triple bonds.

## Introduction

Some time ago we found that 1,8-diazabicyclo[6.6.6]-eicosa-4,11,17-triyne (**1**) provided a flexible cage structure with the *in*/*in* conformation of the bridgehead lone-pairs.[1] This and the triple bonds in the bridges were responsible for including copper(I) and silver(I) ions inside the cage.[1b] In the preceding paper we reported the synthesis and properties of diazacryptands which can be derived from **1** by replacing one 3-hexyne unit of the bridge by a tether with thioether functions (see Figure 1), the cage systems **2**–**6**.[2]

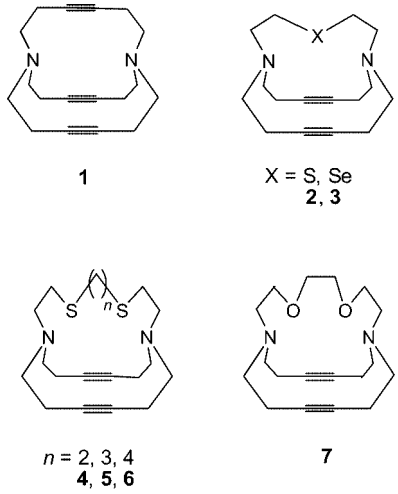

Figure 1. Bicyclic cryptands **1**–**7**.

The investigations of **2**–**6** afforded a series of endohedral copper(I) and silver(I) complexes when the reaction was carried out with copper(I) and silver(I) triflates. In the resulting complexes the soft metal ion interacted with the soft alkyne and chalcogen units as well as with the nitrogen centers. A comparison among the cryptands **2**–**6** revealed that the geometrical requirements for a metal heteroatom and metal–alkyne interaction were optimal in **4**. These results led us to synthesize the title compound **7** as a cryptand, because the compound should be able to host soft as well as hard ions according to the HSAB concept.[3,4]

## Results

The synthesis of **7** was achieved by a one-pot reaction with two equivalents of 1,6-dibromohex-3-yne (**8**)[5] and one equivalent of 1,8-diamino-3,6-dioxaoctane (**9**). Both components were heated in acetonitrile with a surplus of ground potassium carbonate to afford **7** in 40% yield (Scheme 1). The rather high yield of this three-component reaction we ascribe to a fixation of **9** by a potassium ion in a conformation where an intramolecular ring closure is favored over an intermolecular one.[6,7] The yields with lithium carbonate and cesium carbonate turned out to be much less than with potassium carbonate.

The structure of **7** was confirmed by X-ray investigations on single crystals. The results revealed the *in*/*in* conformation for both nitrogen atoms.[8,9] The molecule adopts noncrystallographic $C_2$ symmetry. The two triple bonds are inclined towards each other by 55°. The intramolecular distance of the nitrogen atoms amounts to 5.49 Å which is longer than in **4** (4.87 Å). The molecular structure of **7** is shown in Figure 2. The oxygen atoms of the ether bridge

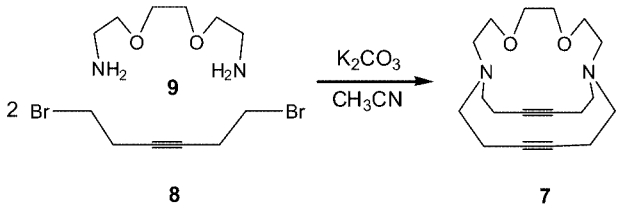

Scheme 1.

point outwards. The longer ether bridge as compared to the 3-hexyne bridge in **1** gives **7** more flexibility. This shows up when **7** is oxidized with hydroperoxide. The resulting *N*,*N*′-oxide **10** now adopts the *out*/*out* conformation at the bridgeheads (Scheme 2, Figure 2). The N–O groups are tilted by 46° relative to the N···N axis and the ether oxygen atoms point inside the cavity.

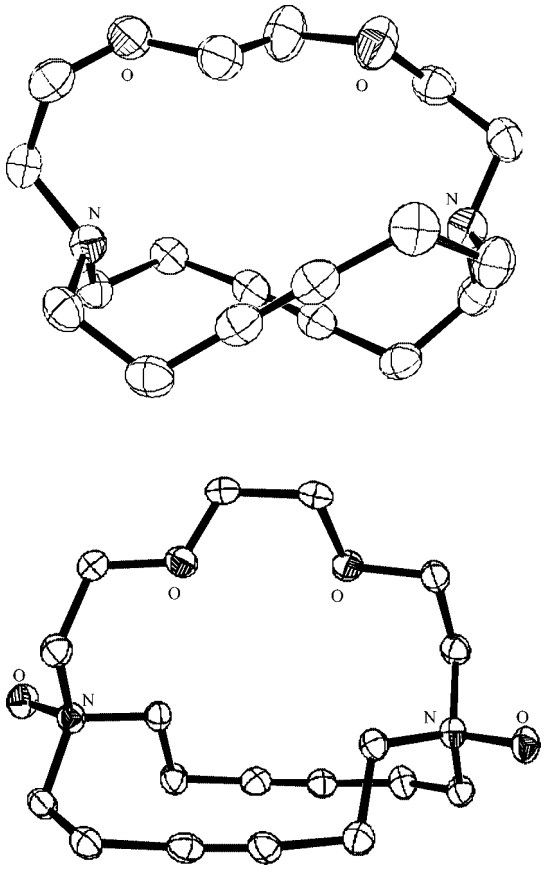

Figure 2. Molecular structures of **7** (top) and **10**.

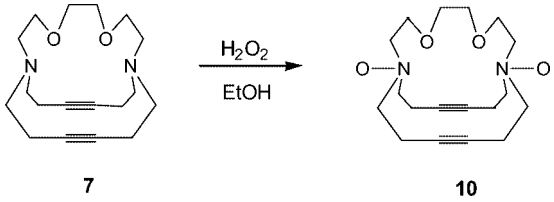

Scheme 2.

To probe the complexation properties of **7** we reacted this ligand with silver(I) and copper(I) triflates in dichloromethane and with lithium perchlorate, sodium nitrate, and cadmium nitrate in methanol. In all five experiments we obtained a colorless crystalline powder which allowed us to grow single crystals for X-ray investigations.

In Table 1 we list the most relevant distances and angles of the metal complexes of **7**. In Figure 3 we show a side view of the molecular structures. It is seen that the small copper ion prefers a close contact with the nitrogen centers and the triple bonds. No contact with the oxygen atom can be observed. As a consequence the N···N distance is shortened to 4.12 Å as compared to the 5.49 Å of the free ligand. The distances between the copper ion and the center of the triple bonds amount to 2.34 and 2.55 Å. These values are larger than the copper alkyne distances reported for copper–alkyne complexes[10,11] (1.87–2.00 Å) but similar to those found in the copper complex of **1** (2.46–2.57 Å).[1b] We also notice a lowering of the stretching frequencies found for the triple bonds in the Raman spectrum for [**7**·Cu]$^+$ as compared to **7**. A criterion for the preference of the alkyne units over the oxygen centers is the N–Cu–N angle of 170.6°.[12]

Table 1. Most relevant distances, angles, and wave numbers in the $Ag^+$, $Cu^+$, $Li^+$, $Na^+$, and $Cd^{2+}$ cryptates with **7**. The distances are given in Å and the angles in degrees.[12]

| Compound | [**7**•Cu]$^+$ | [**7**•Ag]$^+$ | [**7**•Li]$^+$ | [**7**•Na]$^+$ | [**7**•Cd]$^{2+}$ | **7** |

[a] $cm^{-1}$.

The larger silver ion prefers a coordination with N, O, and the triple bonds. The flexible ether chain in **7** has now changed its conformation in such a way that the oxygen centers point inside the cavity. The N···N distance is longer than in the copper complex (Table 1) and the N–Ag–N angle amounts to 198.5°.[12] The distance between the silver ion and the center of the triple bonds amounts to 2.64–2.65 Å. This value is longer than that reported for cyclic alkynes (2.33 Å)[10,13] and also longer than that reported for [**1**·Ag]$^+$ (2.44–2.51 Å). The N–Ag distances (2.42, 2.47 Å) are somewhat longer with regard to the value found for **1** (2.31 Å) but rather expanded compared to values reported for homoleptic two coordinated silver(I) amine complexes

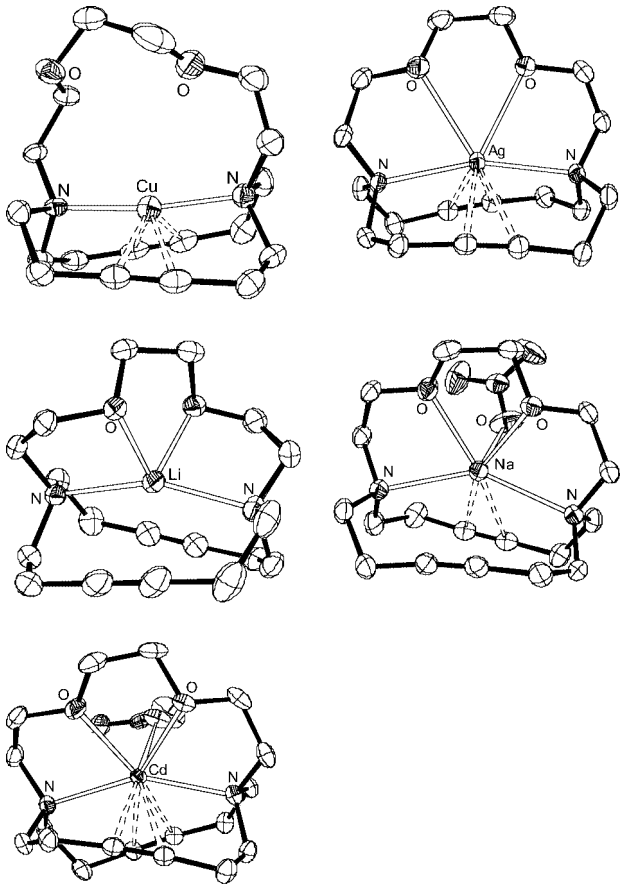

Figure 3. Molecular structures of the $Cu^+$, $Ag^+$, $Li^+$, $Na^+$, and $Cd^{2+}$ complexes of **7**. In the cases of the $Na^+$ and $Cd^{2+}$ complexes the coordinated nitrate anion is shown.

e.g. $Ag(NH_3)_2NO_3$ (2.12 Å).[14] The silver-alkyne interaction in [**7**·Ag]$^+$ also shows up in a lowering of the wave number of the stretching vibration of the triple bond (Table 1). The Ag–O–distance (2.64–2.72 Å) is close to that reported for other silver-ether complexes (average value 2.59 Å).[15] The complex [**7**·Ag]$^+$ is rather stable. We could not detect any precipitate of silver iodide when we reacted [**7**·Ag]$^+$ with iodide ions. Such an absence of precipitation was also reported for [**1**·Ag]$^+$ and silver salts of aza-bridged macrocycles.[16]

The lithium ion prefers to coordinate with the nitrogen and oxygen centers. This shows up in the short Li–O (2.09 Å) and Li–N (2.21 Å) distances and a N–Li–N angle of 202.6°. The measured Li–O and Li–N distances are close to those reported for lithium crown ether complexes (average value Li–O = 2.02 Å, Li–N = 2.07 Å).[15] We also do not find any significant change for the stretching vibration of the triple bond in [**7**·Li]$^+$. The sodium ion prefers a coordination sphere with six donor groups: The two ether oxygen atoms (Na–O = 2.39, 2.41 Å), the two nitrogen atoms (Na–N = 2.59 Å), one oxygen atom from the nitrate anion (Na–O = 2.43 Å) and one alkyne unit ($Na^+$ to the center of triple bond = 2.73 Å). This latter interaction hardly has any influence on the stretching vibration of the triple bond. The recorded Na–O and Na–N distances are close to those found in sodium crown ether complexes (average value Na–O = 2.47 Å, Na–N = 2.59 Å).[15] The even larger $Cd^{2+}$ ion adopts a coordination number of seven by interacting with all donor units. The N–Cd–N angle of 208.4° shows that the N,O coordination is preferred over the interaction with the triple bonds. The latter at most weakly influences the stretching vibration of the triple bonds (Table 1). The complex [**7**·Cd]$^{2+}$ shows a significant low field shift of the resonances for the $CH_2$ protons as compared to **7** by 0.2–0.4 ppm. Like in the sodium complex the metal in [**7**·Cd]$^{2+}$ coordinates with one oxygen center of the nitrate anion (Cd–O = 2.23 Å).

The reaction of a solution of **7** in methanol with $HgCl_2$ yielded first a colorless precipitate which was insoluble in all common solvents. In analogy to a protocol described by Pickardt and Kühn[17] we carefully added to an aqueous solution of $HgCl_2$ a solution of the ligand **7** in methanol in such a way that the two solutions formed two layers. After one month crystals appeared between the two phases. Unfortunately, the crystals were insoluble in common solvents. The mass spectrum revealed that we are dealing with an adduct of **7** with two equivalents of water, three mercury cations, and two chloride anions. The IR spectrum revealed two intensive peaks in the CO region. Fortunately, the isolated material, **11**, contained single crystals which allowed a diffraction experiment. In Figure 4 we show a side view and a view along the N···N axis of **11**. The molecule contains one central mercury atom bound to the two nitrogen centers, to two carbon atoms adjacent to the CO groups and to the two oxygen atoms of the ether bridge (Scheme 3). To the former sp centers, adjacent to the CO groups two further HgCl units are attached which point outwards. The distances between the central mercury atom and the ether oxygen atoms amount to 2.87 and 2.97 Å. These values are somewhat longer than that reported for the mean distance between $Hg^{2+}$ and ether (2.83 Å).[15] The Hg–N distances (2.61 and 2.62 Å) are also longer than the mean value reported in the literature (2.35 Å).[15] Of interest are the short bonds between both Hg centers and the carbon atoms in the α position to the CO groups. For the central mercury we find Hg–C distances of 2.22 and 2.17 Å. For the HgCl groups the C–Hg distances are even shorter (2.08 and 2.11 Å). We ascribe the longer C–Hg bond for the central metal to the donor effects of the oxygen and nitrogen atoms. The low stretching frequencies recorded for the CO groups (1601, 1551 $cm^{-1}$) point to a delocalization of the formal negative charge at the carbon atoms in the α positions to the CO groups. We find a distance between the central and the peripheral mercury atoms of 3.29 and 3.39 Å. This points to a $d^{10}$–$d^{10}$ interaction between the metals due to relativistic effects.[18]

Of special interest is the regioselectivity of the twofold oxymercuration of **7** to **11** which occurred under preservation of the $C_2$ axis of the molecule. We ascribe this observation to the twisted arrangement of the alkyne units in **7**. To rationalize the regioselectivity we assume that the inclusion of a $Hg^{2+}$ ion into the cavity slows down the interchange between the enantiomeric twist conformations of **7**

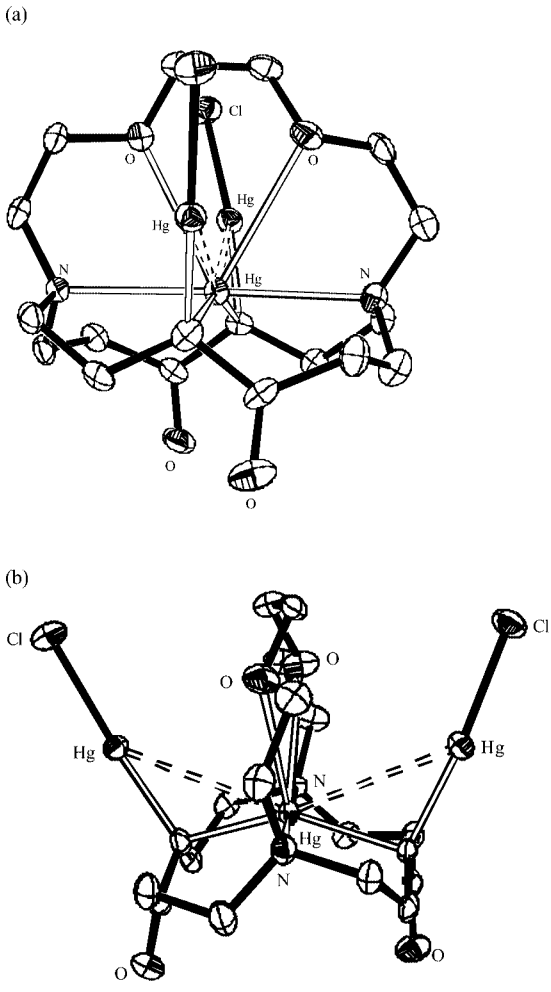

Figure 4. Molecular structure of the product **11** obtained by the reaction of **7** with $HgCl_2$ in the presence of water.

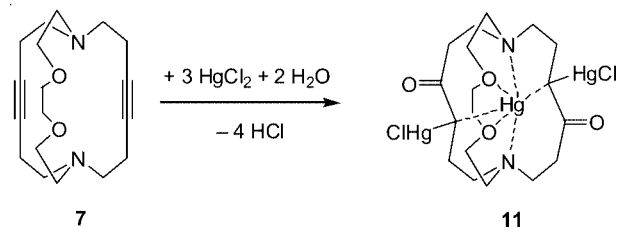
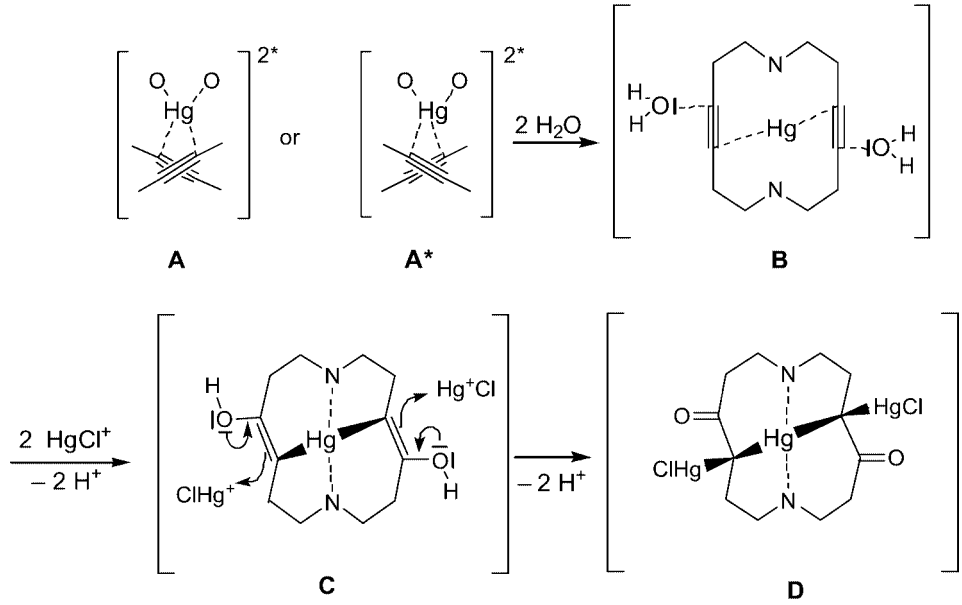


Scheme 3.

(Scheme 4). The coordination of the $Hg^{2+}$ with the ether bridge forces the metal closer to one sp center of one triple bond than to the other (**A**, **A***). Supported by water molecules an *endo*-mercuration starts (**B**) followed by the addition of water (**C**) and *exo*-mercuration of the vinyl alcohol to **D**. In connection with the proposed mechanism in Scheme 4 it is interesting to note that we found single crystals with both enantiomers of the product.

## Concluding Remarks

The replacement of one 3-hexyne unit in **1** by the 3,6-dioxaoctane unit gives the resulting cryptand **7** more flexibility and more coordination possibilities. The higher flexibility is also demonstrated by the oxidation of **7** to **10**. A look at the five structures in Figure 2 shows that the hard ions ($Li^+$, $Na^+$, and to some extent $Cd^{2+}$) prefer the complexation with the hard centers (O, N). The soft ion $Cu^+$ prefers the nitrogen centers and the triple bonds. The larger silver ion adopts a coordination number of six. Only in the cases of the $Cu^+$ and the $Ag^+$ complexes is the stretching vibration of the triple bonds altered significantly. In the cryptates shown in Figure 3 the ions are less shielded than in the cryptates of **1**, this is shown in the $Na^+$ and $Cd^{2+}$ salts where the corresponding anion is coordinated.



Scheme 4.

## Experimental Section

**General Methods:** All melting points are uncorrected. Elemental analyses were carried out by the Mikroanalytisches Laboratorium der Universität Heidelberg. UV/Vis absorption spectra were recorded with a Hewlett–Packard HP 8452A Diode-Array spectrometer, IR spectra were recorded with a Bruker Vector 22 FT-IR instrument. The NMR spectra were measured with a Bruker WH 300 or Avance 500 spectrometer ($^1$H NMR at 300 MHz or 500 MHz and $^{13}$C NMR at 75 or 125 MHz) using the solvent as an internal standard ($\delta$). FAB mass spectra refer to data from a JEOL JMS-700 instrument. As matrix for the FAB experiments *m*-nitrobenzyl alcohol was used. All reactions were carried out in dried glassware under argon using dried and oxygen-free solvents. Compound **8** was prepared according to literature procedure[5] and **9** as well as the inorganic salts were commercially available.

**X-ray Crystallographic Study:** Data were collected with a Bruker Smart CCD diffractometer at 200 K for **7**, **10**, **11**, [**7**·Cu]$^+$, [**7**·Ag]$^+$, [**7**·Na]$^+$ and with a Nonius CAD 4 diffractometer at 293 K for [**7**·Li]$^+$ and 223 K for [**7**·Cd]$^{2+}$. Mo-$K_\alpha$ radiation was used in all cases and the intensities were corrected for Lorentz, polarization, and absorption effects. The structures were solved by direct methods and refined against $F^2$ with a full-matrix least square algorithm by using the SHELXTL software package.[19] Relevant crystal and data collection parameters are given in Tables 2 and 3. Hydrogen atoms were refined isotropically for **7** and [**7**·Li]$^+$ and in all other cases they were considered at calculated positions and refined using appropriate riding models. In the case of **10**, **11**, [**7**·Li]$^+$, and [**7**·Cd]$^{2+}$ some solvent molecules or anions had to be treated as disordered, in [**7**·Cu]$^+$ disorder was observed in parts of the complex cation itself. On one side of the cage the three methylene groups next to the nitrogen atom occur in two alternative positions, also the ether bridge is partially affected by disorder. CCDC-277362 (for **7**), -277363 (for **10**), -277364 (for **11**), -277365 {for [**7**·Cu]($CF_3SO_3$)}, -277366 {for [**7**·Ag]($CF_3SO_3$)}, -277367 {for [**7**·Li]($CLO_4$)}, -277368 {for [**7**·Na]($NO_3$)}, and -277369 {for [**7**·Cd]($NO_3$)$_2$} contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**4,7-Dioxa-1,10-diazabicyclo[8.6.6]docosa-13,19-diyne (7):** To a suspension of finely ground dry potassium carbonate (16 g) in dry acetonitrile (500 mL) was added 1,6-dibromo-3-hexyne (**8**) (6.3 g, 26.2 mmol) and 1,8-diamino-3,6-dioxaoctane (**9**) (1.3 g, 8,3 mmol) and it was refluxed for 4 d. After cooling of the mixture the residual potassium carbonate was filtered off and the solvent was removed in vacuo. The raw material of the reaction was chromatographed on ALOX III using cyclohexane/ethyl acetate (1:1) as the solvent. The product was recrystallized from ethyl acetate to yield colorless crystals (1.1 g, 43%) with a m.p. of 68 °C. $^1$H NMR (500 MHz, $CD_3OD$): $\delta$ = 2.26 (m, 8 H, C$H_2$–C≡), 2.43–2.52 (m, 12 H, C$H_2$–N), 3.63 (m, 4 H, C$H_2$–O), 3.78 (s, 4 H, O–C$H_2$–C$H_2$–O) ppm. $^{13}$C NMR (125 MHz, $CD_3OD$): $\delta$ = 20.0 (*C*H$_2$–C≡), 55.7 (4, *C*H$_2$–N), 58.0 (2, *C*H$_2$–N), 71.5 (*C*H$_2$–O), 72.1 (O–*C*H$_2$–*C*H$_2$–O), 80.5 (*C*≡C) ppm. IR (KBr): $\tilde{\nu}$ = 2937, 2903, 2803, 2740, 1459, 1334, 1291 cm$^{-1}$. Raman (neat): $\tilde{\nu}$ = 2957, 2903, 2821, 2292, 2227, 1457, 1419 cm$^{-1}$. $C_{18}H_{28}N_2O_2$ (304.43): calcd. C 71.02, H 9.27, N 9.20; found C 71.23, H 9.21, N 9.27.

**4,7-Dioxa-1,10-diazabicyclo[8.6.6]docosa-13,19-diyne *N*,*N*′-Dioxide (10):** To a solution of **7** (37 mg, 0.1 mmol) in ethanol (5 mL) was added hydrogen peroxide (1 mL, 30%) solution in water at room temperature. After stirring for 6 d a colorless precipitate was found. After separation and recrystallization from methanol/water colorless crystals were obtained (23 mg, 60%), m.p. 145 °C (decomp). $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 2.79 (m, 8 H, C$H_2$–C≡), 3.61–3.93 (m, 16 H, C$H_2$), 3.65 (s, 4 H, O–C$H_2$–C$H_2$–O) ppm. $^{13}$C NMR (75 MHz, $CD_3OD$): $\delta$ = 15.8 (*C*H$_2$–C≡), 65.9 (N–*C*H$_2$–*C*H$_2$–C≡), 66.1 (N–*C*H$_2$–*C*H$_2$–O), 71.5 (*C*H$_2$–O), 81.2 (*C*≡*C*) ppm. IR (KBr): $\tilde{\nu}$ = 2924, 1435, 1351, 1246 cm$^{-1}$. HRMS (FAB$^+$) $C_{18}H_{29}N_2O_4$ calcd. 337.2127; found 337.2132.

**4,7-Dioxa-1,10-diazabicyclo[8.6.6]docosa-13,19-diyne (7) Complex with Silver Triflate:** In a Schlenk tube a solution of **7** (50 mg, 0.16 mmol) and silver(I) triflate (43 mg, 0.17 mmol) in dry dichloromethane (6 mL) was stirred for 3 h at room temperature under argon. The silver triflate complex (90 mg, 100%) of **7** was isolated in quantitative yield as a colorless powder, m.p. 165 °C (decomp.). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 2.46–2.59 (m, 16 H, N–C$H_2$–C$H_2$–C≡), 2.69 (t, $^3J$ = 4.8 Hz, 4 H, C$H_2$–N), 3.56 (t, $^3J$ = 4.8 Hz, 4 H, N–C$H_2$–C$H_2$–O), 3.66 (s, 4 H, O–C$H_2$–C$H_2$–O) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 17.9 (*C*H$_2$–C≡), 53.7 (N–*C*H$_2$–CH$_2$–C≡), 55.2 (*C*H$_2$–N), 66.5 (N–CH$_2$–*C*H$_2$–O), 69.8 (O–*C*H$_2$–*C*H$_2$–O), 78.2 (C≡C) ppm. IR (KBr): $\tilde{\nu}$ = 2963, 2904, 1453, 1363 cm$^{-1}$. Raman (neat): $\tilde{\nu}$ = 2910, 2859, 2273, 2207, 1452, 1335 cm$^{-1}$. HRMS (FAB$^+$) $C_{18}H_{28}{}^{109}AgN_2O_2$: calcd. 413.1198, found: 413.1221. $C_{18}H_{28}{}^{107}AgN_2O_2$: calcd. 411.1201, found: 411.1212. $C_{19}H_{28}AgF_3N_2O_5S$ (561.37): calcd. C 40.65, H 5.03; found C 40.65, H 5.33.

**4,7-Dioxa-1,10-diazabicyclo[8.6.6]docosa-13,19-diyne (7) Complex with Cu$^I$ Triflate:** A solution of **7** (30 mg, 0.1 mmol) and the benzene complex of Cu$^I$ triflate (27 mg, 0.1 mmol) in dry dichloromethane (10 mL) was stirred under argon for 3 h at room temperature. Filtration of the precipitate yielded a colorless powder (43 mg, 85%), m.p. 127 °C (decomp.). $^1$H NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 2.66 (t, $^3J$ = 5.4 Hz, 8 H, C$H_2$–C≡), 2.73–2.84 (m, 12 H, C$H_2$–N), 3.71 (s, 4 H, O–C$H_2$–C$H_2$–O), 3.83 (t, $^3J$ = 5.0 Hz, 4 H, C$H_2$–O) ppm. $^{13}$C NMR (125 MHz, $CD_2Cl_2$): $\delta$ = 18.3 (*C*H$_2$–C≡), 55.6 (N–*C*H$_2$–CH$_2$–C≡), 55.7 (*C*H$_2$–N), 68.2 (*C*H$_2$–O), 69.7 (O–*C*H$_2$–*C*H$_2$–O), 80.7 (C≡C) ppm. IR (KBr): $\tilde{\nu}$ = 3108, 2962, 2870, 1453 cm$^{-1}$. Raman (neat): $\tilde{\nu}$ = 2922, 2874, 2268, 2229, 2202, 1454 cm$^{-1}$. HRMS (FAB$^+$) $C_{18}H_{28}{}^{65}CuN_2O_2$: calcd. 369.1429; found 369.1419. $C_{18}H_{28}{}^{63}CuN_2O_2$: calcd. 367.1446; found 367.1430.

**4,7-Dioxa-1,10-diazabicyclo[8.6.6]docosa-13,19-diyne (7) Complex with Lithium Perchlorate:** A solution of **7** (50 mg, 0.16 mmol) and lithium perchlorate (15 mg) in dry methanol (5 mL) was stirred for 3 h at room temperature. After removal of the solvent the residue was washed with toluene to yield **7**·$LiClO_4$ (42 mg, 63%) as colorless crystals, m.p. 160 °C (decomp.). $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 2.33 (m, 8 H, C$H_2$–C≡), 2.51 (m, 8 H, N–C$H_2$–CH$_2$–C≡), 2.56 (t, $^3J$ = 5.2 Hz, 4 H, N–C$H_2$–CH$_2$–O), 3.66 (t, $^3J$ = 5.2 Hz, 4 H, N–CH$_2$–C$H_2$–O), 3.78 (s, 4 H, O–C$H_2$–C$H_2$–O) ppm. $^{13}$C NMR (75 MHz, $CD_3OD$): $\delta$ = 19.8 (*C*H$_2$–C≡), 55.5 (N–*C*H$_2$–CH$_2$–C≡), 57.4 (N–*C*H$_2$–CH$_2$–O), 70.6 (N–CH$_2$–*C*H$_2$–O), 71.2 (O–*C*H$_2$–*C*H$_2$–O), 80.7 (C≡C) ppm. IR (KBr): $\tilde{\nu}$ = 2930, 2848, 2020, 1464, 1350 cm$^{-1}$. Raman (neat): $\tilde{\nu}$ = 2931, 2861, 2285, 2228, 1445, 1342 cm$^{-1}$. HRMS (FAB$^+$) $C_{18}H_{26}LiN_2O_2$: calcd. 311.2311; found 311.2305. $C_{18}H_{28}ClLiN_2O_6$ (410.82): calcd. C 52.61, H 6.87, N 6.82; found C 52.44, H 7.19, N 6.70.

**4,7-Dioxa-1,10-diazabicyclo[8.6.6]docosa-13,19-diyne (7) Complex with Sodium Nitrate:** A solution of **7** (50 mg, 0.16 mmol) and $NaNO_3$ (14 mg, 0.17 mmol) in dry methanol (5 mL) was stirred at room temperature for 12 h. After removal of the solvent in vacuo the residue was washed with toluene to yield **7**·$NaNO_3$ (42 mg, 66%) as colorless crystals, m.p. 165 °C (decomp.). $^1$H NMR

# Structural, Electrochemical, and Theoretical Investigations of New Thio- and Selenoether Complexes of Molybdenum and Tungsten

Xiaoli Ma,[a] Kerstin Starke,[a] Carola Schulzke,*[a] Hans-Georg Schmidt,[a] and Mathias Noltemeyer[a]

**Keywords:** Bioinorganic chemistry / Molybdenum / Tungsten / Ligand effects / Redox chemistry

Molybdenum and tungsten complexes with tridentate bis-anionic ligands ($^{-}OC_2H_4XC_2H_4O^{-}$, X = S, Se) were synthesized and analyzed electrochemically. Crystal structures of $[\{MoO_2[O(CH_2)_2S(CH_2)_2O]\}_2]$ and $[\{WO_2[O(CH_2)_2S(CH_2)_2O]\}_3]$ were obtained. For these two complexes as well as for the virtual molybdenum trimer and the tungsten dimer, DFT calculations were performed in order to better understand the formation of two significantly different complexes for molybdenum and tungsten with the same ligand and by the same preparation method. The compound $WO_2Cl_2[MeS(CH_2)_2SMe]$ was synthesized and characterized by crystal structure analysis. A structural and electrochemical comparison of this compound with the recently published analogous molybdenum compound and the dme analogs of molybdenum and tungsten were undertaken. All these data were used to evaluate the structural and electronic influences of replacing molybdenum by tungsten and of varying the ligand atoms (O/S/Se) from the point of view of the different coordination spheres of the molybdopterin-dependent oxygen-atom-transfer enzymes.

## Introduction

Molybdenum as well as tungsten can be found at the active sites of the molybdopterin-containing oxygen-atom-transfer enzymes (OATs),[1] which catalyze oxygen transfer by two-electron redox reactions. This is not surprising because of the chemical similarity of the two metals. The distribution of the metals is quite interesting; molybdenum is found mainly in mesophilic organisms while tungsten is found mainly in thermophilic and hyperthermophilic microorganisms, and it is not known until today whether this distribution was developed for reasons of supply,[2,3] stability,[2,4] or reactivity[5] (i.e. redox potential). Therefore, the comparison of the characteristics of corresponding molybdenum and tungsten compounds remains a vital field of research.

Another interesting diversity of these enzymes is that, in the DMSO reductase family[6] (molybdenum enzymes with two molybdopterin ligands), the metal is bound to the peptide moiety through either serine (O),[7] cysteine (S),[8] selenocysteine (Se),[9] or aspartate (O, mono- or bidentate).[10] The amino acid ligands are supposed to play a role in stabilizing the enzyme–substrate complexes. It is still not known whether the different types of amino acid ligands are used purposefully or merely accidentally. The coordination of selenocysteine as well as the coordination of sulfur atoms to tungsten were also established, although far fewer structures of tungsten-containing OATs are available.[11,12]

High-valent metal complexes with thioether or selenoether ligands that represent hard–soft metal–ligand combinations are relatively rare mainly because these compounds are rather unstable.[13]

Even though molybdenum(VI) and tungsten(VI) can be considered as moderately hard, only a handful of thioether or selenoether complexes of these metals are known.[14–17]

In spite of the assumption that these kinds of complexes with $Mo^{VI}$ and $W^{VI}$ may not be easy to prepare and handle, we tried to synthesize and characterize a small variety of these compounds with additional alkoxy functions at the ligands for enhanced stability. In the synthesis we focused on the simple replacement of acetylacetonate ligands in $MO_2(acac)_2$ (M = Mo, W) by alkali salts of alkoxylates containing a thio- or selenoether function. We had two reasons for this: (i) In this way we would obtain complexes that mimic the active sites of the OATs where the coordination sphere of the metal consists only of oxygen and sulfur or selenium, respectively, and where one oxo ligand is present with an oxidation state of +6 for the metal. (ii) We would also obtain complexes that enable us to compare the influences of molybdenum versus tungsten and sulfur versus selenium with regard to their redox properties. Although in the enzymes the sulfur atom is bound as the thiolate or sulfido ligand and the selenium as the selenate ligand, the investigation of the ether variants of these ligand atoms could give some insight into their influence. The focus here

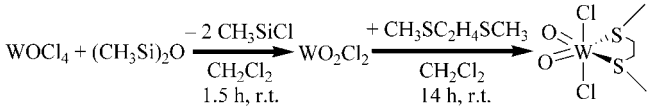
was to evaluate atom-dependent structural and redox potential changes that might offer a clue as to whether the different types of OATs having different coordinated amino acids, were developed for fine tuning of the redox potential, for their structural influence, or just by chance.

We also synthesized the compound $WO_2Cl_2[MeS(CH_2)_2SMe]$, which is analogous to a recently published molybdenum compound.[14] The compounds $MO_2Cl_2(dme)$ are well-established for both metals.[18,19] Therefore, with this new compound a thorough structural and electrochemical investigation of these compounds and a comparison between oxygen and sulfur coordination as well as a comparison between molybdenum and tungsten compounds could be undertaken. The results are presented here.

## Results and Discussion

### Synthesis and Structural Analysis

$WO_2Cl_2[MeS(CH_2)_2SMe]$ (**1**) was synthesized by an analogous method to the published preparation of $MoO_2Cl_2[MeS(CH_2)_2SMe]$[14] (Scheme 1). The starting material ($WO_2Cl_2$) was prepared in situ from $WOCl_4$.



Scheme 1. Preparation of $WO_2Cl_2(CH_3SC_2H_4SCH_3)$ (**1**).

The structures of $MoO_2Cl_2[MeS(CH_2)_2SMe]$[14] and $WO_2Cl_2[MeS(CH_2)_2SMe]$ (**1**) (see Figure 1) are almost identical, and the largest differences occur for the metal–chlorine bond length (0.05 Å) and the O=M=O angle (1°) (see Table 1). Both compounds crystallize in the same crystal system (hexagonal) and space group ($P6_1$).

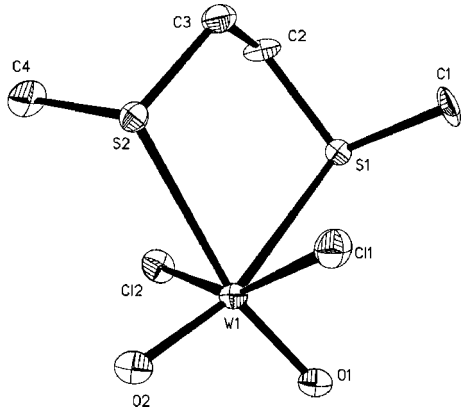


Figure 1. View of the structure of $WO_2Cl_2[MeS(CH_2)_2SMe]$ (**1**) (with numbering Scheme). Hydrogen atoms are not shown. Ellipsoids are drawn at 50% probability.

This is also true for the compounds $MoO_2Cl_2(dme)$[18] and $WO_2Cl_2(dme)$,[19] where the largest difference for a bond length is that for the M–O(ether) bond of 0.04 Å, and the difference for the O(ether)–M–O(ether) angle is 0.4°, which is the largest difference for an angle. Nevertheless, it has to be noted that the value for the Cl–Mo–Cl angle is not mentioned in the respective publication.[18] Again, both compounds crystallize in the same crystal system (monoclinic) and space group ($P2_1/n$).

The differences observed as a result of a comparison of ether and thioether ligands are of course larger, but only for those values that are derived directly from the different radii of the oxygen and sulfur atoms. The difference in the metal–ether/thioether bond is 0.49 Å for the molybdenum complexes and 0.50 Å for the tungsten complexes. The values for the O/S–M–O/S angles differ by 6.5° for the molybdenum and by 6.9° for the tungsten compound, where the angles for the thioether ligands are wider. All other distances and angles involving the metal center are only slightly influenced; the largest difference for a bond length was 0.05 Å for the Mo–Cl bond and the largest difference for an angle was 2.5° for the Cl–W–Cl angle.

This is an indication that the electronic influence of replacing oxygen ligand atoms by sulfur ligand atoms is only very small. Otherwise we would have observed larger differences, especially in the parameters for the ligand atoms that are in a *trans* position to the ether/thioether functions (oxo ligands in all four cases).

The compounds $[\{MoO_2[O(CH_2)_2S(CH_2)_2O]\}_2]$ (**2**), $[\{WO_2[O(CH_2)_2S(CH_2)_2O]\}_3]$ (**3**), and $[\{WO_2[O(CH_2)_2Se(CH_2)_2O]\}_n]$ (**4**) were all prepared by the same method (Scheme 2). The ligand and the $MO_2(acac)_2$ precursor were combined in a $CH_2Cl_2$ solution, stirred at room temperature for one to two days, and filtered. The compounds were isolated from the filtrate by crystallization or drying in vacuo. The yields range from a rather good 60% for the tungsten selenoether (**4**) compound (obtained by drying) to only 32% for the tungsten thioether compound (**3**). Because we were unable to obtain crystals of the tungsten selenium compound, $^{77}Se$ NMR spectroscopy was performed on the complex ($\delta$ = 100.22 ppm) as well as on the ligand ($\delta$ = 68.23 ppm), in addition to the usual characterization methods. In both spectra, we observed only one signal that was shifted to higher frequencies/lower field in the complex, which indicates that a metal–selenium bond was indeed formed.[20]

Suitable crystals of the molybdenum and tungsten thioether compounds were analyzed by X-ray crystallography with quite interesting results (see Figure 2 and Figure 3).

The molybdenum complex with the thioether ligand has a dimeric structure in which the two molybdenum atoms are bridged by one alkoxylate function of each of the two thioether ligands. The tungsten, on the other hand, forms a trimeric structure in which one of the former oxo ligands of each metal bridges two tungsten atoms, forming a six-membered ring. In both structures, the metal achieves a slightly distorted octahedral coordination geometry through the two different kinds of aggregation, although the molybdenum is explicitly only bound to five ligand atoms with rather long metal–sulfur distances. Instead of the usual distance between the metal (molybdenum or tungsten) and sulfur atoms of a thioether ligand, which is in the range of 2.45 to 2.77 Å,[14,21] we found distances of 2.93

and 3.00 Å, indicating only weak bonds, if bonds at all. The tungsten–sulfur distances are shorter (2.79, 2.81, and 2.83 Å), even though the central metal is slightly larger, and these interactions can be considered bonds.

In spite of the fact that five-ring complexes with thio- or selenoether functions are supposed to be stable,[14] the expected molybdenum–sulfur bond with this ligand is not explicitly formed. The reaction of the OSO ligand with $MoO_2(acac)_2$ results in a compound that instead of forming two stable five-ring units, somehow rather resembles an eight-ring complex. In contrast, a certain monomeric molybdenum complex with the analogous ligand that contains an ether function instead of the thioether function is known to exhibit an oxygen(ether)–metal bond even though the distance is longer than usual.[22] This is not completely surprising for these kinds of ligands although the analogous cobalt complexes, with ligands where the alkoxylate and the ether/thioether functions are bridged by phenyl rings, show the reverse behavior. With the ether function, no bond is formed between the metal and oxygen atoms, whereas with the thioether function, there is a bond between the cobalt and sulfur atoms.[23]

Unfortunately, the crystals of **3** were racemic twins, and the structure could only be solved in an acentric space group. The crystallographic problem encountered was one reason for performing DFT calculations on this compound. The results of the DFT calculations confirmed those of the structural analysis with some differences especially in the bond lengths between the metal and sulfur atoms (see Table 2). In general, the distances obtained from X-ray analysis are shorter than the calculated ones, with the only exception of the metal–oxo distances, which are slightly longer. With these two data sets (X-ray data and DFT data) for **3**, we are now able to discuss the structural parameters of compound **3** as well as of compound **2** with some certainty, despite the crystallographic problems concerning the structure of **3**.

In compound **2** the metal is pseudo-octahedrally coordinated. The thioethers form only very weak bonds, if at all, to the molybdenum atoms (interatomic distances: 2.931, 3.002 Å). The molybdenum atoms are positioned above (0.3647 and 0.3664 Å) the plane that consists of three alkox-

[a] OSO = $^{-}OC_2H_4SC_2H_4O^{-}$.

ylate groups and one oxo function in the direction of the second oxo ligand at each molybdenum atom, which is coordinated *trans* to the thioether sulfur. Within the $Mo_2O_2$ ring, the angles at the metal atom are smaller than 90°, whereas the angles at the oxygen atom are larger. The tridentate ligands and the oxo ligands that are coordinated *trans* to the sulfur atoms are positioned on different sides of the $Mo_2O_2$ ring. The two oxo functions, as well as the two tridentate ligands, are on the same side of this ring, although one could assume that the *trans* form would be sterically less demanding.

Compound **3** is analogous to the published tungsten trimer, but phenyl rings bridge the alkoxylate and thioether functions instead of ethyl groups.[24] In the published complex, two of the tridentate ligands and one oxo function are positioned on one side of the W1–W2–W3 plane, whereas the remaining two oxo functions and one tridentate ligand are on the opposite side. For compound **3**, all oxo functions are positioned on the same side of the W1–W2–W3 plane and all tridentate ligands on the opposite side. From the structural analysis, we obtained metal–oxo distances that were longer, and metal–sulfur and metal–oxygen distances that were shorter than the parameters obtained from DFT calculations. The significantly longer metal–sulfur distances in the theoretical investigations were also observed for compound **2** (compare Table 2 and Table 3). Therefore, we think that the structural analysis gives a more accurate value for this parameter than the DFT calculations. In compound **3**, the metal is again coordinated in a pseudo-octahedral geometry that is slightly less distorted than that of compound **2**. The tungsten–sulfur distances (2.79, 2.81, and 2.83 Å) are shorter than the molybdenum–sulfur distances in compound **2**. The oxo ligand is bound *trans* to the sulfur atom with a short distance of 1.71 to 1.73 Å. In this way, the ligand that is most tightly bound to tungsten is in a *trans* position to the ligand that is most weakly bound to the metal, which is the most stable geometry. All other metal–oxygen distances to the alkoxylate functions as well as to the bridging oxygen atoms are within the usual range of 1.86 to 1.95 Å for oxygen–tungsten single bonds. The tungsten atoms are positioned slightly above the equatorial plane (two bridging oxygen atoms, two alkoxylate functions) in the direction of the oxo ligands by 0.04 to 0.36 Å.

## DFT Calculations

DFT calculations were not only performed to confirm the results of the X-ray crystal structure analysis for compound **3**, but also to understand the formation of surprisingly different complexes for molybdenum and tungsten with the same ligand and by the same preparation method. The most important differences between the two structures can be summarized shortly as follows: (i) a trimeric structure for the tungsten compound versus a dimeric structure for the molybdenum compound; (ii) former oxo ligands as bridging atoms for the tungsten compound versus alkoxylate functions of the thioether ligand for the molybdenum compound.

We performed calculations on both of the observed structures for the two metals in order to better understand the different behavior of molybdenum and tungsten regarding the formation of the two significantly different complexes. The important parameters obtained from DFT calculations are summarized in Table 3.

The most significant differences between the molybdenum and the tungsten compounds are as follows: The metal-to-bridging-oxygen distances for the trimer are much more unsymmetrical for the molybdenum than for the tungsten compound. It seems that the molybdenum center is somehow reluctant to share one of its oxo ligands with another molybdenum atom and to form a single bond instead of a double bond to the respective oxygen atom. The double-bond character of the metal–oxygen interaction is certainly more conserved in the molybdenum than in the tungsten trimer. In the dimer as well as in the trimer the molybdenum–oxo bonds are shorter than the tungsten–oxo bonds. All this is an indication that the molybdenum–oxo

[a] OSO = $^-OC_2H_4SC_2H_4O^-$.

bond is stronger than the tungsten–oxo bond, as would be expected when taking the hard–soft interactions into account.

The metal–sulfur distances provide a further clue to the differing behavior of the two metals in reaction with the same ligand. It has to be noted that, although these calculated parameters are the ones that differ most from the X-ray structural parameters, at least the trend seems to be represented correctly. The metal–sulfur distances for the dimer as well as for the trimer are shorter for the tungsten than for the molybdenum compound, and the metal–sulfur distances for the trimers are shorter than the distances for the dimers. The octahedral geometry is less distorted for the tungsten trimer than for the tungsten dimer, providing more space for the sixth ligand, the sulfur atom. Even though the metal–sulfur distances in all four cases are significantly longer than for a regular metal–thioether bond, the observed parameters show that the trimer provides a coordination geometry that enhances the formation of a metal–sulfur bond much more than the dimer does. We also have to keep in mind that the actual metal–sulfur distances, at least for the two compounds that were analyzed by X-ray diffraction, are much shorter than those provided by the DFT calculations. We conclude from all of this that molybdenum forms the dimeric structure, because it is able to keep both of the doubly bonded oxo ligands, and that tungsten forms the trimeric structure because it is able to form a stronger metal–sulfur interaction. This behavior is confirmed by the fact that with similar ligand sets, only a tungsten trimer,[24] where terminal oxo ligands are converted into bridging oxo ligands, and molybdenum monomers[22] and dimers,[25] where the oxo ligands are retained as doubly bonded, are obtained and structurally characterized.

Again, this shows that molybdenum forms stronger interactions with oxygen than tungsten but weaker interactions with sulfur.

## Electrochemical Results

In order to evaluate the influence of the metal and of the ligand atoms (S versus Se) on the redox properties, compounds **2**, **3**, and **4** were investigated by differential pulse voltammetry (DPV). This method was chosen over cyclic voltammetry because all compounds, but especially compound **4**, were only slightly soluble in acetonitrile, and the signals of the redox processes in the cyclic voltammograms were rather weak (see Figure 4), whereas in the oxidative as well as in the reductive DPVs all transitions were sharp and sufficiently intense and therefore easily detected (Figure 5). The peak positions given in Table 4 were determined from both the reductive and the oxidative DPVs as an average. For each of the compounds [**2** (MoS), **3** (WS), **4** (WSe)], two reversible transitions were observed in the differential pulse voltammograms for the redox processes $M^{IV} \leftrightarrow M^{V}$ and $M^{V} \leftrightarrow M^{VI}$ (see Figure 4). As expected, the redox processes $M^{VI} \leftrightarrow M^{V}$ and $M^{V} \leftrightarrow M^{IV}$ for the molybdenum compound are at a higher voltage than those for the respective tungsten compound, and those for the tungsten–selenium compound are at a higher voltage than those for the tungsten–sulfur compound. A third redox process was found at a rather high voltage for all three compounds. It showed irreversible behavior in the cyclic voltammograms, but a slightly shifted transition was also observed in the reductive DPV (see Figure 5). This leads to the conclusion that the third redox process is due to a structural reorganization of the molecule, where the oxidation occurs much more readily than the reduction. Because the oxidation probably takes place at the sulfur/selenium atom, the metal–sulfur/metal–selenium bond must dissolve, and therefore a reorganization of the molecule is necessary. We assume that the reduction at the sulfur/selenium atom involves a more demanding structural reorganization than the oxidation process. Therefore, reduction occurs much more slowly, and it could not

be observed in the CV but in the much slower DPV recording. Interestingly, the third transition for compound **4** (WSe) is at a significantly lower voltage than the transition for compound **3** (WS), reversing the observed behavior for the two transitions taking place at the metal atom with more positive potentials for **4** (WSe) than for **3** (WS). This is another indication that this redox process does indeed take place at the ligand atom. Here, the oxidation of selenium is easier to achieve than that of sulfur, as would be expected by taking the sizes of the two atoms and the metallic character of the selenium atom into account.

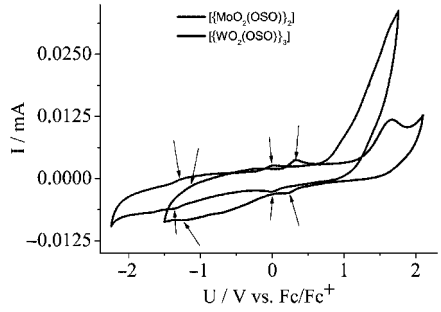

Figure 4. Cyclic voltammograms of compounds $[\{MoO_2[O(CH_2)_2S(CH_2)_2O]\}_2]$ (**2**) and $[\{WO_2[O(CH_2)_2S(CH_2)_2O]\}_3]$ (**3**) referenced vs. ferrocene/ferrocenium showing two reversible redox processes (indicated by arrows) and an irreversible oxidation (of very poor intensity for **3**). The current values of **3** were multiplied by a factor of 4 in order to fit all the data into one graph.

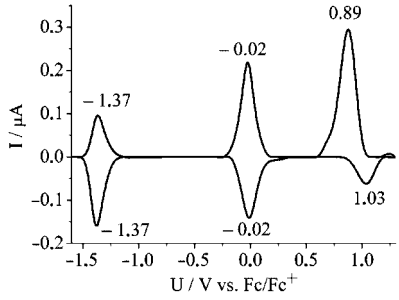

Figure 5. Reductive and oxidative differential pulse voltammograms of compound **4** referenced vs. ferrocene/ferrocenium. The plots were generated using the automatic baseline correction function of the Gepris software.

The redox potentials of compounds $MoO_2Cl_2$(dme),[18] $WO_2Cl_2$(dme),[19] $MoO_2Cl_2[MeS(CH_2)_2SMe]$,[14] and $WO_2Cl_2[MeS(CH_2)_2SMe]$ (**1**) were also compared (see Table 5). Here, we used cyclic voltammetry and observed quasi-reversible behavior for all compounds for the $M^{V}\leftrightarrow M^{VI}$ transition. In the range –1.0 to –1.5 V, an irreversible reduction occurs in all cases probably because of the loss of one oxo ligand accompanying the reduction to $M^{IV}$. The formation of this new species led to the emergence of new signals in the voltammograms. We therefore only compared the potentials of the quasi-reversible process assigned to the $M^{V}\leftrightarrow M^{VI}$ transition. Figures showing a long-range cyclic voltammogram (including the irreversible reduction and ligand-centered quasi-reversible oxidation) of $MoO_2Cl_2$(dme), a short-range cyclic voltammogram of $MoO_2Cl_2(MeSC_2H_4SMe)$, and a long-range cyclic voltammogram of $WO_2Cl_2$(dme) with the internal reference ferrocene can be found in the Supporting Information.

Table 5. Redox potentials for the molybdenum and tungsten compounds with the bidentate ether/thioether ligands for the $M^{V}\leftrightarrow M^{VI}$ redox processes referenced internally vs. ferrocene/ferrocenium.

| Compound | $E_{1/2}$ $M^{V}\leftrightarrow M^{VI}$ vs. $Fc/Fc^{+}$ [V] |
|---|---|
| $MoO_2Cl_2$(dme) | –0.17 |
| $MoO_2Cl_2(MeSC_2H_4SMe)$ | –0.15 |
| $WO_2Cl_2$(dme) | –0.34 |
| $WO_2Cl_2(MeSC_2H_4SMe)$ (**1**) | –0.28 |

Again, the molybdenum compounds have potentials that are higher than their tungsten analogs, and the complexes with sulfur ligand atoms have potentials that are higher than their counterparts with oxygen ligand atoms. The latter differences are again smaller (between 20 and 60 mV) than the differences between molybdenum and tungsten compounds, which are about three times larger (between 130 and 170 mV). Since the bonds between metal and sulfur atoms exhibit π–π-interactions, it can be noted that the differences between the redox potentials of the molybdenum and tungsten thioether complexes are smaller than those between the complexes with the oxygen ligand atoms.

Again, changing the metal atoms has a much more significant influence on the redox potentials than changing the ligand atoms.

## Concluding Remarks

We have seen that molybdenum and tungsten form almost identical complexes with the bidentate ether and thioether ligands. The metal atom does not affect the structure of the complexes, though it has an influence on the stability of the complexes because of a difference in the strength of orbital overlap. For the oxygen-atom-transfer enzymes, where only mono- or bidentate ligands are present, a geo-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metrical or steric influence as a result of changing the metal atom can be excluded.

Changing the ligand atoms does not result in any significant structural alterations, with the only exception of the metal-to-ether/thioether-ligand-atom bond length and angle, but these differences are merely a result of the different radii of the ligand atoms. There was no indication of a significant electronic influence of changing the ligand atoms (oxygen versus sulfur) on the metal, except that the potentials of the molybdenum and tungsten complexes were closer together with sulfur ligation than with oxygen ligation.

With the tridentate bisanionic ligands, molybdenum and tungsten form rather different complexes, the former giving a dimeric and the latter a trimeric complex. Interestingly, the thioether function forms no explicit bond with the molydenum, whereas the analogous ether ligand does form a bond with this metal atom (no analogous compound was published for tungsten).[22]

We conclude from this that the structural influence of the ligand atom plays a vital role in structurally demanding ligands (tridentate) but not in those with a simpler geometry (bidentate or monodentate).

This may be because the hard–soft interactions between the ether/thioether function of the ligands and the metal center favor the oxygen–molybdenum combination over the sulfur–molybdenum combination. Molybdenum prefers O-functional ligands although it has been said that the bond strength of ether functions to metals increases within the group of the chalcogens.[21] Interestingly, in nature the ligand–metal combinations that are less favorable than others from this point of view occur at the active sites of the OATs: for instance the coordination of thiolate (cysteine) to molybdenum at the active site of the DMSO reductase of *Desulfovibrio desulfuricans*[8] or the coordination of serine to tungsten in the aldehyde oxidoreductase of *Pyrococcus furiosus*.[11]

The influence of the metal on the redox potential is, as expected, such that the molybdenum complexes have more positive redox potentials than the analogous tungsten complexes in all cases. With regard to the enzymes, this means that in all cases one metal is better suited for the catalyzed reaction with the substrate, while with the other metal the active site is more easily regenerated. For a given enzyme, there is always an advantage as well as a disadvantage in using either of the two metals, molybdenum or tungsten. If the redox potential is important for the choice of the metal, the basis of this choice would be a difference in the redox behavior of the two metals at different temperatures[26] rather than their relative redox potentials at room temperature.

The influence of the ligand atoms on the redox potentials is small but of consequence; the sulfur ligands cause more positive redox potentials than the oxygen ligands, and the selenium ligands cause more positive potentials than the sulfur ligands. However, the observed differences are smaller than those that result from changing the metal atoms.

The fact that there are two molybdenum cofactors that both catalyze the reduction of DMSO but contain molybdenum coordinated to cysteine in one case (*Desulfovibrio desulfuricans*)[8] and to serine in the other case (*Rhodobacter spharoides*)[7a,7b] is another indication that the use of different amino acids as ligands to the active sites is probably not an answer to the substrate demands on the redox potentials of the enzymes.

In addition, there does not seem to be any correspondence between the atom that is oxidized or reduced and the coordinated amino acid. Carbon can be oxidized by active sites that have selenocysteine (formate dehydrogenase from *E. coli*) or serine (aldehyde oxidoreductase from *P. furiosus*)[11] coordination. As mentioned above, sulfur can be oxidized by active sites that have serine or cysteine coordination, and nitrogen can be reduced by active sites that have cysteine (nitrate reductase from *E. coli*)[27] or aspartate (nitrate reductase from *Paracoccus pantotrophus*)[10] coordination, to name only a few examples.

The only parameters that are significantly influenced by changing the ligand atoms and which are not compromised by being part of a multidentate ligand system within the enzymes are the length and the strength of the metal–amino acid bond. If there is a reason for using different amino acid ligands, it is probably the ability to stabilize the active-site–substrate complex during turnover of the enzymatic reaction in cooperation with the peptide side chain residues close to the active site. A substantial effect of the coordinated amino acid on the enzymatic reaction by itself seems to be unlikely.

To finally answer the question about the reason for using different amino acid ligands at the active sites of the OATs, two strategies are to be followed. One is to synthesize model compounds for the enzyme–substrate complexes and to evaluate the ability of different amino acid ligands to stabilize these complexes with different substrates. The other is to undertake theoretical investigations of the intermediate states of the active sites, taking into account the influence of the peptide side chain on the stabilizing effect of the coordinated amino acid. These are challenging tasks for the future.

## Experimental Section

**Materials:** $MoO_2Cl_2(dme)$,[18] $WO_2Cl_2(dme)$,[19] $MoO_2Cl_2[MeS(CH_2)_2SMe]$,[14] $WOCl_4$,[28] $Me(SCH_2CH_2S)Me$,[29] $WO_2(acac)_2$[30] and bis(2-hydroxyethyl)selenide[31] were prepared as described in the literature. $MoO_2(acac)_2$ and bis(2-hydroxyethyl) sulfide are commercially available and were used as received. Reagent-grade solvents were dried and distilled prior to use. All manipulations were performed under dry and oxygen-free conditions in nitrogen using Schlenk line techniques.

### Syntheses

**$WO_2Cl_2(MeSCH_2CH_2SMe)$ (1):** Liquid $(Me_3Si)_2O$ (0.341 g, 2.10 mmol) was added to a suspension of freshly sublimed $WOCl_4$ (0.68 g, 2.00 mmol) in $CH_2Cl_2$ (20 mL). The orange crystals were

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

slowly consumed to give a yellow solution. After stirring for approximately 1.5 h at room temp., a light yellow solid precipitate was obtained. A solution of $MeSCH_2CH_2SMe$ (0.366 g, 3.00 mmol) in $CH_2Cl_2$ (10 mL) was added, and the reaction mixture was stirred overnight and filtered to remove the brownish precipitate. The clear yellow filtrate was concentrated at room temp. in vacuo until the solid began to precipitate. After keeping this solution at 4 °C overnight colorless crystals were obtained. The crystals were collected on a filter, washed once with diethyl ether (5 mL), and dried in vacuo. Yield: 0.53 g, 65%. M.p. 128–130 °C. $C_4H_{10}Cl_2S_2O_2W$ (407.90): calcd. C 11.75, H 2.46; found C 11.95, H 2.54. **$[\{MoO_2[O(CH_2)_2S(CH_2)_2O]\}_2]$ (2):** Bis(2-hydroxyethyl) sulfide (0.25 g, 2.05 mmol) was added to a stirred solution of $MoO_2(acac)_2$ (0.65 g, 2.00 mmol) in $CH_2Cl_2$ (20 mL) at room temp. The reaction mixture was stirred for 24 h. A small amount of white precipitate was filtered off, and the solvent was removed in vacuo. The residue was extracted with *n*-hexane (20 mL) and stored at room temp. for several days to yield colorless crystals. Yield: 0.10 g, 41%. M.p. 190 °C. $C_8H_{16}O_8S_2Mo_2$ (499.84): calcd. C 19.36, H 3.25; found C 19.61, H 3.26. IR (KBr): $\tilde{\nu}$ = 1460 (m) 1415 (m), 1403 (m), 1368 (s), 1305 (w), 1277 (m), 1263 (m), 1218 (w), 1181 (w), 1069 (s, $\nu_{Mo=O}$), 1041 (s), 1025 (s), 997 (m), 936 (m), 910 (m), 802 (s), 723 (m), 694 (w), 651 (w), 571 (m), 530 (m), 475 (m), 396 (m), 360 (s) $cm^{-1}$. $^1$HNMR ($CDCl_3$, 200 MHz): $\delta$ = 2.31 (t), 3.36 (t) ppm. EI-MS (70 eV): *m/z* (%) = 248 (11) $[\{MoO_2[O(CH_2)_2S(CH_2)_2O]\}^+]$, 216 (40) $[\{Mo[O(CH_2)_2S(CH_2)_2O]\}^+]$.

**$[\{WO_2[O(CH_2)_2S(CH_2)_2O]\}_3]$ (3):** Bis(2-hydroxyethyl) sulfide (0.12 g, 1.00 mmol) was added to a stirred solution of $WO_2(acac)_2$ (0.41 g, 1.00 mmol) in $CH_2Cl_2$ (20 mL) at room temp. The reaction mixture was stirred for 24 h. The white precipitate was filtered off, and the clear filtrate was concentrated under reduced pressure until the solution was saturated. The solution was stored overnight at room temp. to yield colorless crystals. Yield: 0.11 g, 32%. M.p. 240 °C (dec.). $C_{12}H_{24}O_{12}S_3W_3$ (1007.90): calcd. C 14.30, H 2.40; found C 14.51, H 2.50. IR (KBr): $\tilde{\nu}$ = 1464 (vs), 1378 (vs), 1306 (w), 1262 (w),1261 (w), 1170 (w),1153 (w),1091 (m), 1066 (m, $\nu_{W=O}$), 1033 (m), 962 (w), 935 (w), 858 (w), 838 (w), 801 (m), 722 (m), 657 (w) $cm^{-1}$. EI-MS (70 eV): *m/z* (%) = 352 (33) $[\{WO_3[O(CH_2)_2S(CH_2)_2O]\}^+]$, 337 (100) $[\{WO_2[O(CH_2)_2S(CH_2)_2O]\}^+]$.

**$[\{WO_2[O(CH_2)_2Se(CH_2)_2O]\}_n]$ (4):** A solution of bis(2-hydroxyethyl)selenide (0.17 g, 1.00 mmol) in $CH_2Cl_2$ (5 mL) was added to a stirred solution of $WO_2(acac)_2$ (0.41 g, 1.00 mmol) in $CH_2Cl_2$ (20 mL) at room temp. The reaction mixture was stirred for 2 d. The green solution turned yellow, and a small amount of yellow precipitate formed. The precipitate was filtered off, and ether was added to the filtrate to precipitate the product. The yellow product was collected by filtration and washed with diethyl ether twice. The compound was dried in vacuo. Yield: 0.23 g, 60%. M.p. 210 °C. $C_4H_8O_4SeW$ (383.91): calcd. C 12.55, H 2.11; found C 12.63, H 2.18. IR (KBr): $\tilde{\nu}$ = 1527 (w), 1459 (m), 1400 (m), 1377 (m), 1261 (vs), 1094 (vs, $\nu_{W=O}$), 1020 (vs), 962 (w), 939 (w), 863 (w), 800 (vs), 722 (w), 703 (w), 668 (w), 583 (w), 533 (w), 472 (w) $cm^{-1}$. $^1$HNMR ([D$_6$]DMSO, 300 MHz): $\delta$ = 2.60 (t), 3.56 (t) ppm. $^{13}$CNMR ([D$_6$]-DMSO, 300 MHz): $\delta$ = 26.14 (s), 61.62 (s) ppm. $^{77}$Se NMR ([D$_6$]-DMSO, 500 MHz): $\delta$ = 100.22 (s) ppm. EI-MS (70 eV): *m/z* (%) = 355 (50) $[M^+ - CH_2CH_2]$.

### Electrochemistry

Electrochemical measurements were performed with an AUTOLAB PGSTAT12 potentiostat/galvanostat with a glassy carbon working electrode, a platinum wire reference electrode, and a platinum wire auxiliary electrode, in acetonitrile solutions within a glove box under argon. The supporting electrolyte was $Bu_4NPF_6$ (0.1 M) used as received from Fluka. Acetonitrile used for the electrochemistry was predried with $CaCl_2$, dried by reflux over $CaH_2$ for 2 d, and distilled onto freshly regenerated molecular sieves A3. Referencing was done internally using the ferrocene/ferrocenium couple. The temperature during the measurements was controlled with a Julabo refrigerated/heating circulator FP50-MV at 25 °C. The solutions were prepared within a glove box by dissolving the $Bu_4NPF_6$ electrolyte ($10^{-3}$ mol) and the compounds ($10^{-6}$ mol) in acetonitrile (10 mL) to give $10^{-4}$ M solutions. For reasons of poor solubility, compound **4** could only be prepared as an approximately $0.5 \times 10^{-5}$ M solution.

### Other Physical Measurements

Melting points were obtained in sealed capillaries with a Büchi B 540 instrument and were not corrected. Elemental analyses were performed with a Heraeus CHN-O-Rapid elemental analyzer. Infrared spectra were recorded as KBr pellets with a Bio-Rad Digilab FTS-7 spectrometer from 4000 to 300 $cm^{-1}$. NMR spectra were recorded with Bruker Avance 200, AM 300 and Bruker Avance 500 NMR spectrometers and referenced to the chemical shifts of the deuterated solvent. All NMR-grade solvents were dried prior to use. The chemical shifts are reported in ppm; external reference $SiMe_4$ for $^1$H and $^{13}$C nuclei, and $SeMe_2$ for $^{77}$Se nuclei. Mass spectra were obtained with a Finnigan MAT system 8230 or Varian MAT CH5 instrument by EI-MS methods.

### X-ray Crystallography

Data for crystal structures of compounds **1**, **2**, and **3** were collected with a Stoe–Siemens–Huber four-circle diffractometer coupled to a Siemens CCD area detector with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). All structures were solved by direct methods (SHELXS-97)[32] and refined with all data by full-matrix least-squares methods on $F^2$.[33] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included at geometrically calculated positions and refined using a riding model. Parameters of the X-ray crystallography are summarized in Table 6. CCDC-280029 (**1**), CCDC-280030 (**2**), and CCDC-280028 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

### DFT Calculations

All calculations have been carried out with the Gaussian G03[34] program package using the implemented DFT variant B3LYP[35,36] (Becke three-parameter exchange functional B3 and the Lee–Yang–Parr correlation functional LYP). A basis consisting of the well-established small core ECP[37] (for Mo and W), 3-21g[38] (for carbon and hydrogen) and following a proposal by K. Peterson,[39,40] a modified 6-31G basis including double diffuse functions [6-31G(d′, p′)] to give a suitable description of the lone pairs on oxygen and sulfur were used.

All structures were fully optimized without employing any symmetry constraints. The starting geometries were taken from experimental data. Analytical frequency calculations were performed to verify these structures as local minima.

# Electrochemical Detection of High Oxidation States of Chromium(IV and V) in Chromium-Doped Cassiterite and Tin-Sphene Ceramic Pigmenting Systems

**Antonio Doménech,*[a] Francisco Jose Torres,[b] Esther Ruiz de Sola,[b] and Javier Alarcón[b]**

**Keywords:** Chromium / High oxidation states / Voltammetry / Cassiterite / Tin-sphene

Solid-state electrochemistry is applied to detect the presence of chromium centres with high oxidation states in chromium-doped cassiterite and tin-sphene ceramic pigmenting systems. Voltammetric data indicate that $Cr^{V}$ and $Cr^{IV}$ centres with different coordinative arrangements exist in the studied materials, and yield proton-assisted reduction processes at +0.95, +0.42 AgCl/Ag in contact with 0.50 M $H_2SO_4$. Electrochemical measurements are correlated with spectroscopic data. The $Cr^{IV}$ and $Cr^{V}$ metal ions display a significant light-driven electrocatalytic effect on the oxidation of 1,4-dihydrobenzoquinone and $Fe(CN)_6^{4-}$ ions that involves the formation of surface-confined adducts.

## Introduction

Ceramic pigments are formed by crystalline phases containing cromophore cations. These materials are dispersed in particulate form in the bulk ceramic body or in the outer glassy layer on the ceramic support. During the thermal processing of ceramic materials, these particulate components must be stable at the high temperatures reached and must be inert to the chemical action of other components of the ceramic body, i.e. other crystalline phases and/or glassy phases.

Purple and pink chromium-containing, tin-based ceramic pigments have been widely used in the industry for years. Two of the main crystalline structures included in this group of ceramic pigments are cassiterite ($SnO_2$) and sphene or malayaite ($CaSnSiO_5$), which produce the purple and pink colours, respectively. As is well known, cassiterite has a rutile-type structure, while sphene possesses a titanite-type structure.

The preparation and characterisation of these two types of chromium-containing pigments have been widely studied by different authors for the past decades.[1,2] Different preparation procedures have been used in order to facilitate the kinetics of the reaction, which lead to the Cr-doped cassiterite or sphene particulate materials.[3–5] Microstructural features such as morphology, shape and size of the crystals, as well as important characteristics of particulate materials, have also been investigated extensively.[6,7]

The crystallochemistry of cassiterite and sphene structures indicates that the chromium cations in both structures are in octahedral sites, replacing the $Sn^{IV}$ centres. There is agreement amongst various authors on this point. However, the controversy on the chemical states of the doped chromium cation exists for some time now.[6–11] Thus, Ren et al.,[8] on the basis of electron spin resonance spectroscopy, reflectance spectroscopy and magnetic susceptibility measurements, claimed that the violet colour of the Cr-$SnO_2$ pigment is caused by the simultaneous presence of $Cr^{IV}$ and $Cr^{III}$ ions, the former as a $Cr^{IV}$-$SnO_2$ solid solution and the latter as $Cr_2O_3$. López-Navarrete et al.[6–8] reached the same conclusion from X-ray photoelectron, diffuse reflectance and magnetic susceptibility data. More recently, these authors concluded that in Cr-doped sphene structures most of the tetravalent chromium cations form a solid solution with the sphene lattice by mostly substituting the $Sn^{IV}$ cations in the isolated octahedral positions, while a very small amount of $Cr^{IV}$ also substitutes the tetrahedral $Si^{IV}$ ions. In contrast, Pavlov et al.,[10] from electronic absorption spectroscopy studies, concluded that the chromium cation is in the oxidation state +3 in Cr-$SnO_2$, while in the Cr-doped sphene there is an additional band in the near-IR part of the spectrum (around 1200 nm), which can be attributed to $Cr^{IV}$.

Recently, Julián et al.,[11] using a wet synthetic route, indicated that the violet colour in the Cr-$SnO_2$ pigmenting system is mainly produced by $Cr^{III}$ and/or $Cr^{IV}$ ions incorporated in the cassiterite structure. On the basis of electron spin resonance spectroscopy data, these authors concluded that different amounts of $Cr^{V}$, $Cr^{IV}$ and $Cr^{III}$ ions are present in chromium-doped cassiterite.

From the above reports it seems possible that in both ceramic-pigmenting systems, the chromium cation can be present in several oxidation states. However, it can also be

concluded that it is quite difficult to establish unambiguously the presence of these oxidation states of chromium in both host lattices from spectroscopic and magnetic techniques. Furthermore, the small amount of chromium in such materials makes it even more difficult to check the presence of $Cr^{IV}$ or even $Cr^{V}$ cations. Therefore, it would be interesting to use an experimental technique with enough sensitivity to distinguish between the different oxidation states of chromium in the Cr-doped cassiterite and Cr-doped sphene ceramic pigments. The coexistence of metal ions in different oxidation states is of interest in a wide variety of contexts. In particular, the simultaneous presence of $Cr^{III}$ and $Cr^{IV}$ in porous chromium-containing α-tin phosphate[12] and silica optical fibres[13] has been reported recently.

Over the last years the voltammetry of microparticles has emerged as a powerful technique to obtain chemical information on doped materials. Therefore, in this paper the possible presence of high oxidation states of chromium in the studied materials will be investigated by square wave voltammetry upon attachment of solid samples to paraffin-impregnated graphite electrodes (PIGEs). This follows the methodology of the voltammetry of microparticles approach, an increasingly growing research field for which extensive reviews are available.[14,15] The voltammetry of tin oxide microparticles and related compounds has not been described in detail in spite of the wide range of applications of tin oxide electrodes.[16] Recently, Scholz et al. described the electrochemistry of natural and synthetic tin sulfosalts using the voltammetry of microparticles methodology.[17] This scheme has previously been applied for studying the electrochemistry of $SnO_2$ and Sn-rich glazed ceramics.[18] Studies on nanosized $SnO_2$ particles dispersed on graphite electrodes,[19] nanocrystalline tin oxide electrodes[20] and modification of the film of $SnO_2$ nanocrystallites with organic reagents,[21] all devoted to the detection of selected analytes, have also been reported. The electrochemical dissolution of chromium oxides, spinels, and chromites has been studied by Blesa et al.[22–24] and Grygar et al.[25–27] Other reports on the solid-state electrochemistry of chromium concern chromium(II), hexacyanochromate(III),[28] some organic Cr complexes[29] and chromium oxide films deposited on stainless steel.[30] However, no detailed studies on the presence of high oxidation states of chromium have been reported.

The electrochemical reduction of chromate and dichromate in solution is complicated by adsorption processes.[31] Three reduction waves appear at acidic pH values for the electrochemical pathway involving any $Cr^{IV}$ intermediate species.[32] However, intermediate $Cr^{V}$ species have been electrochemically characterised in the oxidation of oxalic acid by chromic acid at pH 1.[33]

We report here on a solid-state electrochemical study devoted to the determination of the possible presence of high oxidation states of chromium in chromium-doped cassiterite and chromium-doped tin-sphene. For this purpose, solid samples were attached to paraffin-impregnated graphite electrodes in contact with electrolytic solutions of aqueous $H_2SO_4$ or $HClO_4$, and $NaClO_4$. Cyclic and square wave voltammetry were used as detection modes. The latter technique is of particular interest because of its high sensitivity and immunity to capacitive effects.[34] In an attempt to correlate voltammetric and spectroscopic data, the electrocatalytic effect of chromium-doped materials on the oxidation of hexacyanoferrate(II) ions and 1,4-dihydrobenzoquinone in aqueous solution has been studied. Apart from its applications in chemical sensing and electrosynthesis, such catalytic processes can be used as amplifiers of the electrochemical properties of the catalytic centres, as illustrated by prior data on vanadium-doped zirconias and cobalt-containing cordierite materials.[35–37]

## Results and Discussion

### Characterisation of Chromium-containing Cassiterite and Sphene

X-ray diffraction patterns of the ceramic pigmenting systems, based on cassiterite and sphene structures, are supplied in the Supporting Information. The formation of a crystalline phase with a sphene structure is displayed in samples M-1 to M-4, after thermal treatment at 1300 °C and a 2-h holding time. In accordance with the JCPD card number 70-0437, all peaks can be associated with the main crystalline phase. It is worth noting that a small amount of $SnO_2$ is still present in the sample of M-2. For samples M-5 and M-6, the only crystalline phase detected is that of the cassiterite structure (JCPD card number 41-1445).

The diffuse reflectance spectra of both types of samples, i.e. cassiterite- and sphene-based structures, are shown in Figure 1. For the Cr-sphene specimens, two bands around 540 nm and 1200 nm are detected. The first one is attributed to the $^4A_{2g}$–$^4T_{2g}$ spin-allowed transition of the $Cr^{III}$ ion with octahedral coordination,[10] as well as to the $Cr^{IV}$ centres.[9,38] The band in the near-infrared part of the spectrum, centred at 1200 nm, is assigned to $^3A_2$–$^3T_1$ transitions of $Cr^{IV}$ in tetrahedral surroundings.[9,39] The sphene structure can be described as composed of chains of corner-sharing $SnO_6$ octahedra running parallel to the cell edges that are cross-linked by silicate tetrahedra to form a $SnOSiO_4$ framework that accommodates $Ca^{2+}$ in irregular hepta-coordinated polyhedra. Here, López-Navarrete et al.[9] recently suggested that $Cr^{IV}$ replaced the partially octahedral $Sn^{IV}$ and tetrahedral $Si^{IV}$ sites.

The spectra of the chromium-containing cassiterite consist of a strong band at 560 nm and a weak band at 740 nm, which are attributed to $Cr^{III}$ with octahedral coordination. However, the first band has also been ascribed to $Cr^{IV}$ ions with octahedral symmetry.[9] In contrast to the Cr-sphene-based materials, in the cassiterite-derived materials there is no band around 1200 nm. The reason for the absence of the band associated with the $Cr^{IV}$ ions with tetrahedral coordination is that there are no available tetrahedral sites in this structure.

The investigation by FESEM of the final ceramic pigments indicates that the particles that have formed have a

well-defined morphology. Micrographs of samples of M-4 and M-6 are shown in the Supporting Information. The discrete particles are prismatic and their sizes are smaller than 2 μm long and 0.5 μm wide.

### Electrochemical Study of Prepared Materials

The electrochemistry of the studied materials is, in principle, dominated by tin-centred processes. This can be seen in Figure 2, in which the cyclic voltammograms (CVs) of: (a) M-2 and (b) M-5 in 0.50 M $H_2SO_4$ are shown. Such voltammograms are essentially identical to those recorded for sphene and cassiterite, respectively. For M-2 a reduction peak at –0.55 V vs. AgCl/Ag appears, followed by a prominent reduction current increasing from –0.70 V. In the reverse scan, a weak anodic peak near –0.50 V appears. The response of M-5 was similar, but here a prominent cathodic current appears at –0.55 V, while in the subsequent anodic scan a well-defined tall peak at –0.50 V is recorded. This corresponds, as described in detail elsewhere,[18] to the stripping oxidation of Sn to $Sn^{2+}$ in solution, thus denoting that the prior cathodic step results in the formation of a deposit of Sn metal. In the positive region of potentials, a weak anodic peak near +0.5 V is also recorded.

Sn-centred electrochemical processes can be described in terms of the reduction of $Sn^{IV}$ via the stepwise formation of solid $Sn^{II}$ to Sn metal. These electrochemical processes can be represented for cassiterite as:

$$SnO_2(s) + 2\ H^+ + 2e^- \rightarrow x\ SnO(s) + (1 - x)\ Sn^{2+}(aq) + H_2O \quad (1)$$

$$SnO(s) + 2\ H^+ + 2e^- \rightarrow Sn(s) + H_2O \quad (2)$$

$$Sn^{2+}(aq) + 2\ e^- \rightarrow Sn(s) \quad (3)$$

(s) denotes the solid phases.

On scanning the potential in the positive direction, after a reductive step, the metal deposits generated electrochemically are oxidized to $Sn^{2+}$ ions and $SnO^{2+}$ in the solution phase:

$$Sn(s) \rightarrow Sn^{2+}(aq) + 2\ e^- \quad (4)$$

$$Sn^{2+}(aq) + H_2O \rightarrow SnO^{2+}(aq) + 2\ H^+ + 2\ e^- \quad (5)$$

this last step is responsible for the oxidation signal at +0.5 V.

Chromium-centred processes were studied for sample-modified PIGEs upon immersion into an electrolytic solution of $H_2SO_4$ or $HClO_4$, and $NaClO_4$. To prevent the appearance of tin-centred electrochemical processes, potentials between 0.0 and +1450 mV were routinely used. The response of $Cr_2O_3$, taken as a reference in this potential

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

range, is illustrated by the square wave voltammograms (SQWVs) in Figure 3. On scanning the potential in the positive direction, a prominent oxidation wave (I) is recorded at +1340 mV (Figure 3, a). This peak shows well-defined anodic and cathodic components of the square wave current, thus suggesting a quasi-reversible behaviour.[34] Following Grygar et al.,[25–27] this wave corresponds to the oxidative dissolution process:

$$Cr_2O_3(s) + 4\ H_2O \rightarrow Cr_2O_7^{2-} + 8\ H^+ + 6\ e^- \quad (6)$$

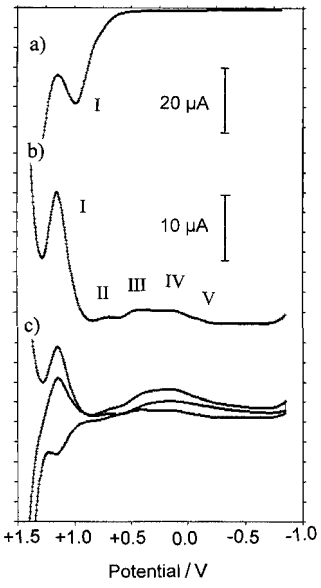

Figure 3. SQWV of $Cr_2O_3$ in contact with 0.10 M $HClO_4$ and 0.15 M $NaClO_4$. (a) potential scan initiated at –0.25 V in the positive direction; (b) potential scan initiated at +1.45 V in the negative direction; (c) id. with separate plots for the forward, backward and current increment vs. potential. Potential step increment 4 mV; square wave amplitude 25 mV; frequency 15 Hz.

On scanning the potential from +1450 mV in the negative direction, a peak near +1240 mV appears (I), followed by overlapping peaks at +700, +430, +250 and 0 mV (labelled as II, III, IV and V, respectively), as depicted in Figure 3 (b). The peak at +1240 mV corresponds to the oxidation of $Cr_2O_3$, as represented by Equation (6), and also appears when the potential is scanned in the positive direction because square wave voltammetry provides simultaneous inspection of both oxidation and reduction processes. Peaks II–V decrease rapidly until they disappear altogether when the potential scan is initiated at potentials below +950 mV, a potential for which no significant oxidative dissolution of $Cr_2O_3$ takes place; thus this denotes that such electrochemical processes are due to chromium species in solution generated during the electrochemical oxidation of chromium oxide.

The peak potential of I shifts positively on increasing the square wave frequency, *f*, while peaks II, III and IV remain essentially independent of *f* in the frequency range between 5 and 200 Hz [$E_p$(I) = +1140 ± 20 + (68 ± 2)log *f* (*N* = 9, *r* = 0.994)]. In this frequency range, peak V shifts to negative potentials on increasing the square wave frequency [$E_p$(V) = +145 ± 5 – (65 ± 5)log *f* (*N* = 9, *r* = 0.991)]. Interestingly, separate plots of the anodic and cathodic contributions to the square wave current, measured at the start and end of potential pulses, provided well-defined anodic and cathodic components for the peak at +1215 mV. However, peaks II–V exhibit only cathodic contributions as can be seen in Figure 3 (c): this denotes that these are essentially irreversible reduction processes.[34] These processes can be attributed to the stepwise reduction of $Cr_2O_7^{2-}$ ions in solution generated in the oxidative dissolution of $Cr_2O_3$. Electrochemical reduction of dichromate to $Cr^{III}$ and $Cr^{II}$ involves the formation of $Cr^{V}$ and $Cr^{IV}$ intermediates by processes II and III, but $Cr^{IV}$ is thermodynamically unstable in solution and disproportionates into $Cr^{III}$ and $Cr^{VI}$:[22]

$$6\ Cr^{IV} \rightarrow 4\ Cr^{3+} + Cr_2O_7^{2-} \quad (7)$$

Peak II is therefore enhanced with respect to peak III.

SQWVs of the studied materials exhibited some significant differences compared with those of $Cr_2O_3$. To clearly discriminate from the chromium-centred processes, in all cases, the SQWV of cassiterite and sphene was subtracted from that of the corresponding chromium-doped material. Thus, as shown in Figure 4 for: (a) M-2, and (b) M-5, the peak I appears at potentials that are more positive than that for $Cr_2O_3$ (+1290 mV) and is lowered. For samples M-2, M-3 and M-4 (Figure 4, a), an additional well-defined peak at +970 mV (VI) appears that precedes the separated peaks at +420 (VII), –30 (VIII) and –420 mV (IX). The peak VII exhibits a tall profile, suggesting that it corresponds to different electrochemical processes from those recorded for $Cr_2O_3$ at similar potentials. For samples M-5 and M-6 (see Figure 4, b), the peak VI is well developed and enhanced with respect to peaks VII, VIII and IX. Remarkably, peaks VI, VII, VIII and IX are enhanced on decreasing the frequency, a property typical of electrochemical processes involving solid phases.

Peaks VIII and IX shift to negative potentials on increasing the frequency [$E_p$(VIII) = 40 ± 5 – (60 ± 3)log *f* (*N* = 7, *r* = 0.997); $E_p$(IX) = –275 ± 5 – (99 ± 6)log *f* (*N* = 9, *r* = 0.992)], while peaks VI and VII remain essentially independent of frequency. On initiating the potential scan at +1050 mV, i.e. at a potential at which no significant oxidative dissolution of chromium centres occurs, peaks VI–IX appear with no significant decrease when compared with voltammograms initiated at +1450 mV. The above features are in contrast with those of the SQWV of $Cr_2O_3$ – peaks III–V decrease significantly on lowering the starting potential below +1250 mV.

The differences between $Cr_2O_3$ and the studied materials can be seen in Figure 5 in which the charge passed through processes III and VII ($q_{III}$, $q_{VII}$), calculated as the area under the voltammetric peak, is plotted as a function of the starting potential of the SQWVs, $E_i$. For chromium oxide, a fast decrease of $q_{III}$ with decreasing $E_i$ is obtained, whereas for the studied materials $q_{III}$ becomes insensitive to changes in $E_i$ at starting potentials below +950 mV.

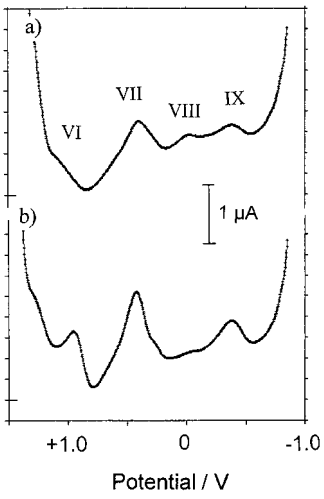

Figure 4. Semi-derivative convolution of SQWVs of : (a) M-2, and (b) M-5 immersed into 0.10 M $HClO_4$ and 0.15 M $NaClO_4$ after subtracting the SQWV of sphene and cassiterite, respectively. Potential scan initiated at +1.45 V in the negative direction. Potential step increment 4 mV; square wave amplitude 25 mV; frequency 5 Hz.

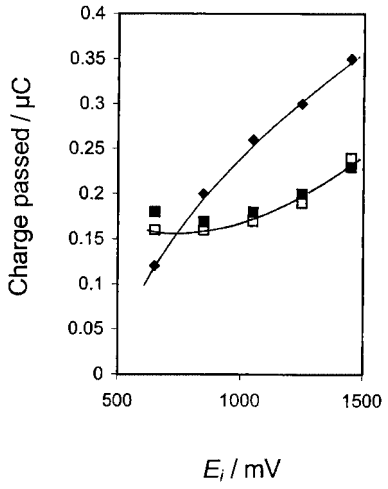

Figure 5. Variation of the charge passed during the electrochemical process III/VII with the starting potential of the SQWVs for diamonds: $Cr_2O_3$; squares: M-3; solid squares: M-6. Electrolyte: 0.10 M $HClO_4$ and 0.15 M $NaClO_4$. Potential step increment 4 mV; square wave amplitude 25 mV; frequency 5 Hz.

In the pH range between 1.5 and 4.0, peaks VII and IX shift to negative potentials on increasing the pH. For M-5, SQWVs with a potential step increment of 4 mV, a square wave amplitude of 25 mV and a frequency of 15 Hz produced: $E_p$(VII) = 585 ± 5 – (97 ± 6)pH ($N$ = 7; $r$ = 0.993); $E_p$(IX) = –255 ± 5 – (78 ± 6)pH ($N$ = 7, $r$ = 0.992). Peaks VI and VIII are essentially pH independent.

The voltammetric profile of peaks VI and VII is significantly different from that of peaks II–V recorded for $Cr_2O_3$. Remarkably, the peaks VI and VII exhibit well-developed anodic and cathodic components of the square wave current, as can be seen in Figure 6 for M-5. Here, peaks VIII and IX behave irreversibly.

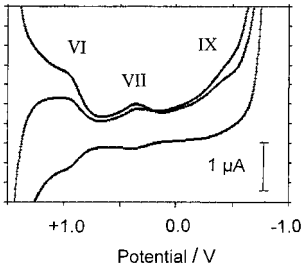

Figure 6. Separate forward, backward and current increment vs. potential graphs for the SQWVs of M-3 immersed in 0.10 M $HClO_4$ and 0.15 M $NaClO_4$. Potential scan initiated at +1.45 V in the negative direction. Potential step increment 4 mV; square wave amplitude 25 mV; frequency 15 Hz.

On comparing the SQWVs in Figure 6 with those depicted in Figure 3 (c), corresponding to $Cr_2O_3$, one can appreciate a notable increase in the reversibility of the electrochemical processes of VI and VII of the studied materials in contrast with the processes II–IV recorded for chromium oxide.

Additionally, peak VII is significantly enhanced in chromium-doped materials relative to peak I, while peaks II and IV disappear. Since it is not possible to control the exact amount of material transferred to the electrode, the quotients between the peak currents were used for comparing the voltammetric response of the studied materials with that of $Cr_2O_3$. Thus, the quotient between the peak currents of VII and I for chromium-doped materials, $i_p$(VII)/$i_p$(I), is larger than the $i_p$(III)/$i_p$(I) ratio determined for chromium(III) oxide. Interestingly, the $i_p$(VII)/$i_p$(I) ratio for M-3 increases abruptly at low frequencies, as can be seen in Figure 5. This behaviour is in contrast with that observed for $Cr_2O_3$. Here, as shown in Figure 7, the $i_p$(III)/$i_p$(I) ratio increases slowly on decreasing the frequency. For all chromium-doped cassiterites and chromium-doped sphenes, the $i_p$(VII)/$i_p$(I) ratio increases on increasing the chromium content. Pertinent peak potential data are summarised in Table 1.

All these data suggest that an amount of high oxidation states of chromium exists in the studied materials. Accordingly, the response of such materials results from the superimposition of solution processes initiated in the oxidative dissolution of $Cr^{III}$, which is similar to those described for $Cr_2O_3$, and a solid-state pathway starting from the reduction of chromium centres that exist in high oxidation states of the solids. Then, peak VI can be attributed to the reduction of $Cr^{V}$ centres mainly existing in chromium-doped cassiterite, while the peak VII, which prevails in chromium-doped sphenes, is attributable to the reduction of pristine $Cr^{IV}$ centres. In view of the possible presence of $Cr^{IV}$ centres in two different coordinations, peaks VII and VIII can be associated with the reduction of differently coordinated $Cr^{IV}$ units. This assignment is consistent with prior data showing the existence of site-characteristic voltammetric responses in vanadium-doped zircon,[35] zirconia[36] and cobalt cordierites[37] and appears to be in agreement with spectral data (vide infra). In this scheme, pro-

cesses VI–VIII can be described in terms of solid-state redox reactions yielding $Cr^{IV}$ and $Cr^{III}$ centres. Under the experimental conditions employed here, both processes behave reversibly in such a way that proton transfer does not affect the overall reaction rate.

### Electrochemical Pathway

This reaction scheme can, in principle, be related to the model of Lovric, Scholz, Oldham and co-workers for describing the electrochemistry of insulating solids.[40–43] Redox conductivity occurs by electron hopping between adjacent redox centres and by the exchange of ions or protons with the electrolyte, as a consequence of the gradient of the electrochemical potential in the particle.

In the studied cases, the propagation of the redox reaction through the solid microparticle requires the presence of appropriate redox-active centres on the surface of the particles and free access of protons or electrolyte ions from the supporting electrolyte. The foregoing considerations also apply for the fast charge transfer observed for organic complexes of Cr,[44] metallocenes[45] and organic compounds.[46]

Subsequent reduction of the $Cr^{IV}$ centres to $Cr^{III}$ centres involves two irreversible proton-assisted reduction processes that probably result in the formation of $Cr^{III}$ centres in the solid phase (peak VII) and in solution through the processes VIII–IX.

It should be noted that in this solid-state pathway the $Cr^{IV}$ oxidation state is stabilised with respect to disproportionation, as denoted by the appearance of the well-resolved, separated peak III′.

Following a scheme similar to that previously postulated for vanadium-doped zirconias,[37] formation of $Cr^{V}$ centres may be described in terms of a process involving the insertion of OH groups and lattice distortion. Formally this can be represented as:

$$Sn_{1-x}Cr^{III}{}_xO_{2-x/2} + 2y\ OH^- \rightarrow Sn_{1-x}Cr^{III}{}_{x-y}Cr^{V}{}_yO_{2-x/2}(OH)_{2y} + 2y\ e^- \quad (8)$$

This picture is, in principle, consistent with the reaction schemes proposed for the oxidative dissolution of chromium oxides by oxometallates. According to Blesa et al., the reaction with oxometallates proceeds by oxygen transfer from the oxidant to surface $Cr^{III}$ sites and is mediated by the oxo bridge Cr–O–M.[21–23] Then, peak VI at +970 mV can be attributed to the reduction of $Cr^{V}$ surface centres to $Cr^{IV}$ centres. To describe this kind of electrode process, it is assumed that a fraction of the total $Cr^{V}$ centres is reduced to $Cr^{IV}$ ones with concomitant loss of $OH^-$ groups to ensure charge conservation and provide minor lattice distortion. Tentatively, this process can be represented by the redox reaction:

$$Sn_{1-x}Cr^{III}{}_{x-y}Cr^{V}{}_yO_{2-x/2}(OH)_{2y} + y\ e^- \rightarrow Sn_{1-x}Cr^{III}{}_{x-y}Cr^{IV}{}_yO_{2-x/2}(OH)_y + y\ OH^- \quad (9)$$

$Cr^{IV}$ centres are subsequently reduced to $Cr^{III}$ centres. Following the above criteria, this reduction process (peak VII at +420 mV) can be formulated for cassiterite as:

$$Sn_{1-x}Cr^{III}{}_{x-y}Cr^{IV}{}_yO_{2-x/2}(OH)_y + y\ e^- \rightarrow Sn_{1-x}Cr^{III}{}_{x-y}Cr^{IV}{}_yO_{2-x/2} + y\ OH^- \quad (10)$$

Reduction of the $Cr^{IV}$ centres in sphene probably involves two different processes that correspond to the octahedral $Cr^{IV}$ centres substituting for $Sn^{IV}$ and tetrahedral $Cr^{IV}$ centres substituting for $Si^{IV}$. Such electrode processes

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

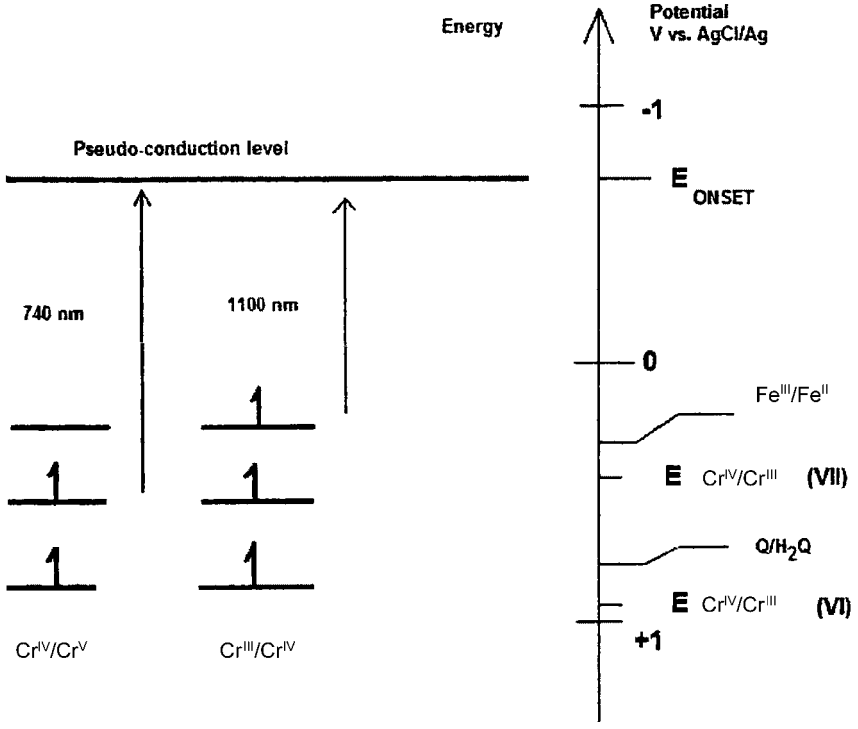

Figure 8. Energy/redox potential diagram for correlating spectrophotometric and electrochemical data in Cr-doped cassiterite and Cr-doped sphene.

can correspond to peak VIII and eventually can form $Cr^{3+}$ ions in solution:

$$CaSn_{1-x}Cr^{III}_{x-y}Cr^{V}_{y}SiO_{5-x/2}(OH)_y + y\ H^+ + y\ e^- \rightarrow CaSn_{1-x}Cr^{III}_{x}SiO_{5-x/2} + y\ H_2O \quad (11)$$

Finally, the peak IX can be attributed to the reduction of $Cr^{3+}$ to $Cr^{2+}$ in the solution phase.

## Correlation Between Spectral and Electrochemical Data

Correlation between electrochemical and spectroscopic data in solids usually focuses on the determination of the bandgap energy and the electrochemical HOMO and LUMO energies ($E^{HOMO}$, $E^{LUMO}$), corresponding to the estimated position of the upper edge of the valence band (HOMO) and the lower edge of the conduction band (LUMO).[47] In our case, spectral properties of chromium centres can be correlated with formal electrode potentials on the basis of energy diagrams of the 3d energy states of $Cr^{III}$, $Cr^{IV}$, and $Cr^{V}$ proposed by Sakai et al.,[48] and Moretti and Michel-Calendini[49] with respect to the cluster valence edge of chromium-doped $BaTiO_3$ and to those recently calculated by Long et al.[50] for describing the spectra of $Cr^{III}$-doped $LaSc_3(BO_3)_4$, by Torchia et al.[51] for $Cr^{III}$ ions in $LiNbO_3$, by Kammoun[52] for $Cr^{IV}$ ions in $LiAlO_2$ and by Herren et al.[53] for $Cr^{V}$ in chromium-doped $SiO_2$ glass.

From this one can attribute energies of 2.06, 0.98 and 0.36 eV to the $Cr^{III}$ ($^4A_2$ state), $Cr^{IV}$ ($^3T_1$) and $Cr^{V}$ ($^2T_2$) centres in octahedral coordination, respectively, relative to the valence band edge corresponding to the O 2p $t_{1g}$ level relevant to the $MO_6$ cluster. Term energies for crystal field transitions are: $Cr^{III}$ ($^4A_2 \rightarrow {}^4T_1$, $^4T_2$) 2.10 eV; $Cr^{IV}$ ($^3T_1 \rightarrow {}^1T_2$) 1.26 eV; $Cr^{V}$ ($^2T_2 \rightarrow {}^2E_2$) 2.60 eV.[50–53] Formal electrode potentials are correlated with the vacuum level by assuming that the normal hydrogen electrode is 4.4 eV below the vacuum level.[54,55] Accordingly, the AgCl/Ag electrode will be 4.6 eV below the vacuum level. The corresponding energy diagram is shown in Figure 8. The upper edge of the valence band can in principle be approached by the voltammetric onset potential obtained from the intersection of the two tangents drawn at the rising current and the baseline charging current of the curves for the oxidation process.[56,57] The onset potential taken from the rising background current in Figure 4 was +1.43 V. Examination of the energy diagram in Figure 8 reveals that formal electrode potentials for the $Cr^{V}/Cr^{IV}$ and $Cr^{IV}/Cr^{III}$ couples are close to the vacuum energy levels for $Cr^{V}$ and $Cr^{IV}$ ions, respectively.

## Electrocatalytic Processes

As already reported,[36,37] inorganic materials doped with electroactive species can exert a significant catalytic effect on selected electrochemical processes. Thus, Figure 9 shows a comparison of the CVs recorded in a 0.50 mM $K_4Fe(CN)_6$ and a 0.50 M $H_2SO_4$ solution at: (a) bare PIGE, (b) M-3 under dark conditions and (c) M-3 under Vis-IR illumination. As can be seen in Figure 9 (a), at the unmodified PIGE, the CVs of $Fe(CN)_6^{4-}$ solutions exhibit a well-defined reversible couple at peak potentials of +445 (anodic) and +335 mV (cathodic). For electrodes modified with chromium-doped materials under "dark" conditions, the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

anodic portion of the CV becomes significantly modified. As can be seen in Figure 9 (b), an additional peak at +620 mV appears coupled with a weak cathodic signal near +580 mV and the overall peak current is enhanced. For samples M-2, M-3 and M-4, this response changes upon illumination. As can be seen in Figure 9 (c) for M-3, the current is depleted, while the peak at +620 mV vanishes. However, for samples M-5 and M-6 the catalytic effect remains insensitive to illumination with visible light.

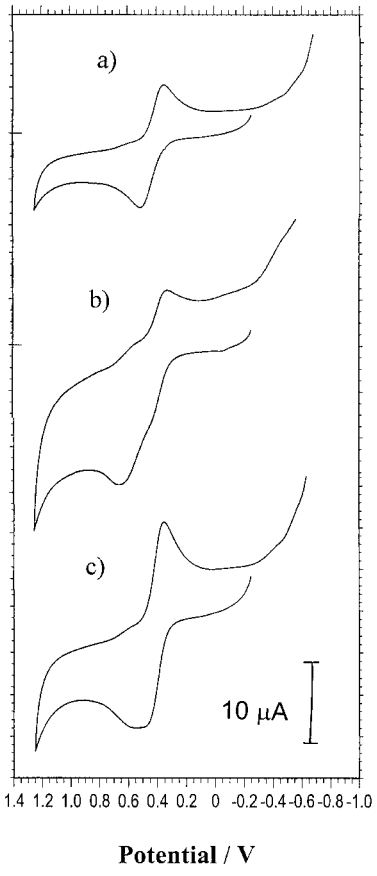

Figure 9. CVs recorded in a 0.50 mM $K_4Fe(CN)_6$ and 0.50 M $H_2SO_4$ solution at: a) bare PIGE; b) M-3-modified electrode under dark conditions, and c) M-3-modified electrode under illumination. Potential scan rate 50 mV $s^{-1}$.

The anodic peak at +620 mV can be attributed to the modifier-mediated oxidation of $Fe(CN)_6^{4-}$. In view of the close proximity of the potentials for the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$, $Cr^V/Cr^{IV}$ and $Cr^{IV}/Cr^{III}$ couples, the catalytic effect can, in principle, be attributed to both $Cr^V$ and $Cr^{IV}$ centres, in agreement with the theory for mediated electrocatalysis.[58] The observed voltammetric profile can be interpreted in terms of the formation of a surface (chromium centre)–$Fe(CN)_6^{4-}$ adduct and the superimposition of the currents for the nonmediated (peak at +440 mV) and mediated (peak at +620 mV) oxidation of $Fe(CN)_6^{4-}$.

This is consistent with the variation with the frequency of the SQWVs illustrated in Figure 10 for M-4 in contact with 0.50 mM $K_4Fe(CN)_6$ and 0.50 M $H_2SO_4$. The peak at +620 mV is enhanced as the frequency decreases, in agreement with the assignment of this peak to the oxidation of a surface-confined species.

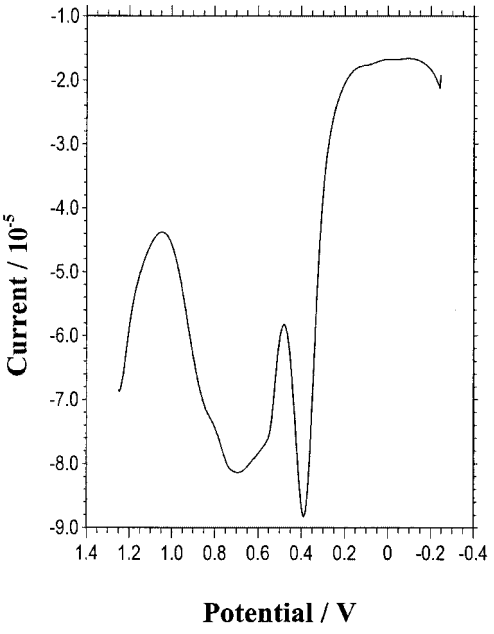

Figure 10. SQWV of a 0.50 mM $K_4Fe(CN)_6$ and 0.50 M $H_2SO_4$ solution at an M-4-modified electrode under dark conditions. Potential step increment 4 mV; square wave amplitude 25 mV; frequency 25 Hz.

The decrease in the catalytic ability of samples M-2, M-3 and M-4 under illumination can be rationalised on the basis of previously discussed spectroscopic data assuming that $Cr^{IV}$ centres act as catalytic sites, as suggested by the close vicinity of its redox potential (+420 mV) and that of the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple (+390 mV). Upon illumination, there is excitation of $Cr^{IV}$ centres that is equivalent, in agreement with literature data,[50,53] to a negative potential shift of 1.03 V of the $Cr^{IV}/Cr^{III}$ couple, as schematised in Figure 8. These features result in a significant decrease in the catalytic ability of chromium centres, which is reflected in the lowering of the peak current.

Comparable features were obtained for the electrocatalyis of 1,4-dihydrobenzoquinone ($H_2Q$) oxidation, illustrated in Figure 11 for a 0.40 mM solution of $H_2Q$ in 0.50 M $H_2SO_4$. As depicted in Figure 11 (a), at a bare graphite electrode, two overlapping anodic peaks appear at +700 and +850 mV, corresponding, in agreement with extensive literature on the electrochemistry of $H_2Q$, to the stepwise oxidation of hydroquinone to quinone:[59,60]

$$H_2Q \rightarrow Q + 2\,H^+ + 2\,e^- \quad (12)$$

As shown in Figure 11 (b) for M-6, the current for $H_2Q$ oxidation is enhanced at electrodes modified with Cr-doped cassiterite under dark conditions. Again, the catalytic effect decreases upon illumination with visible light, as can be seen in Figure 11 (c). Remarkably, the catalytic effect is almost entirely absent for Cr-doped sphene samples. Such electrochemical data can again be interpreted with the help of the energy/redox potential diagram in Figure 8. Here, the

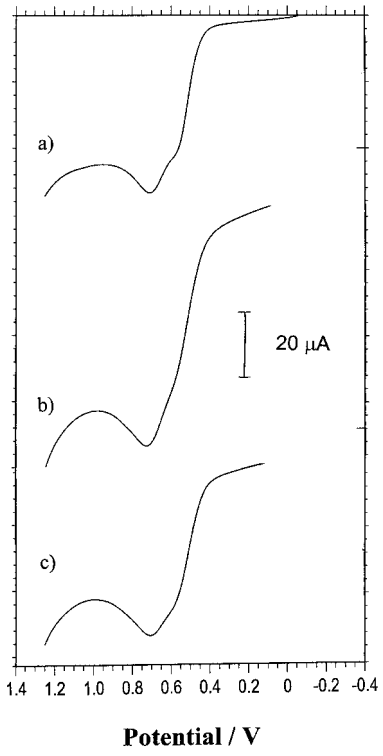

Figure 11. LSVs of a 0.40 mM solution of 1,4-dihydrobenzoquinone in 0.50 M $H_2SO_4$ at: a) bare PIGE; b) M-6 under dark conditions; and c) M-6 under illumination. Potential scan rate 20 mV $s^{-1}$.

formal potential of the $Cr^V/Cr^{IV}$ couple (+970 mV) is close to the redox potential for $H_2Q$ oxidation (+850 mV), thus suggesting that the $Cr^V$ species in Cr-doped cassiterite are now catalytically active. Excitation of $Cr^V$ centres upon illumination involves a gain in energy of 2.60 eV,[48,53] equivalent to a significant negative shift of the potential of the $Cr^V/Cr^{IV}$. Accordingly, illumination produces a significant decrease in the catalytic ability of $Cr^V$ centres in chromium-doped cassiterite.

## Final Considerations

Solid-state electrochemical data suggest that $Cr^V$ and $Cr^{IV}$ centres exist in chromium-doped cassiterite and sphene materials. The well-defined reduction of $Cr^V$ centres to $Cr^{IV}$ ones occurs at +0.97 mV for Cr-doped $SnO_2$. The oxidation state $Cr^{IV}$ prevails in Cr-doped sphene, where the solid-state $Cr^{IV}$ to $Cr^{III}$ reduction takes place at +420 mV.

$Cr^{IV}$ centres produce a significant catalytic effect on the electrochemical oxidation of $Fe(CN)_6^{4-}$ ions in acidic aqueous media. For chromium-doped sphenes the electrocatalytic effect decreases upon visible light irradiation. Electrochemical and spectroscopic data are consistent with an electrocatalytic pathway involving the formation of a surface-confined $Cr^{IV}$–hexacyanoferrate(II) adduct. Similarly, the oxidation of 1,4-dihydrobenzoquinone is catalysed by Cr-doped sphene, but the catalytic effect decreases upon illumination. This electrocatalytic effect can be associated with the presence of $Cr^V$ in such materials.

All these results illustrate the capabilities of the voltammetry of microparticles for providing chemical information on doped materials.

## Experimental Section

### Preparation and Characterisation of Specimens

We have used two methods of synthesis in order to show the industrial preparation of these ceramic pigmenting systems. The undoped and Cr-doped sphene were prepared by a sol-gel technique used previously.[5] The prepared samples contain an amount of chromium that replace the Sn cations, and in order to preserve the electroneutrality the divalent calcium cation was replaced by neodymium or ytrium trivalent cations. The prepared samples of the undoped $CaSnSiO_5$, $Ca_{0.95}Nd_{0.05}Sn_{0.95}Cr_{0.05}SiO_5$ and $Ca_{0.95}Y_{0.05}Sn_{0.95}Cr_{0.05}SiO_5$, are referred to as M-1, M-2 and M-3, respectively. An additional sample was prepared by replacing some of the silicium cations by aluminium cations, $Ca_{0.90}Y_{0.10}Sn_{0.95}Cr_{0.05}Si_{0.95}Al_{0.05}O_5$, and is referred to as M-4. Tetraethylorthosilicate (TEOS), $CaCl_2{\cdot}2H_2O$, $CrCl_3{\cdot}6H_2O$, and $Y^{III}$ acetate (from Merck), $SnCl_2$ (from Aldrich) and $Nd(NO_3)_3{\cdot}6H_2O$ (from Rhône–Poulenc) were used as reagents. Gels were prepared by refluxing an ethanolic solution containing the required amounts of cation salts and TEOS at 70 °C. The TEOS/$H_2O$/ethanol molar ratio in the final solution was 1:12:20. The obtained gel was further dried at 120 °C.

The Cr-doped $SnO_2$ samples were prepared by a wet method that is similar to that described previously.[2] Samples with stoichiometry $Cr_xSn_{1-x}O_2$ ($x$ = 0.05 and 0.1, referred to as M-5 and M-6) were prepared from $Cr(NO_3)_3{\cdot}6H_2O$ and $SnO_2$ (from Merck). First, the required amount of chromium nitrate was dissolved in distilled water. $SnO_2$ was then added to the above, and the final concentration of the solution was 0.05 mol·$dm^{-3}$. The obtained dispersion was heated whilst stirring until the water was removed. Further drying of the powdered sample was performed at 120 °C. Dried gels were thermally treated at several temperatures from 800 to 1300 °C with 2 h holding time.

$H_2SO_4$, $HClO_4$ (Panreac) and $NaClO_4$ (Merck) were used for electrolyte preparation. $SnO_2$ (Fluka) and $Cr_2O_3$ (Fluka) were used as reference materials. Electrocatalytic experiments were performed in solutions of $K_4Fe(CN)_6$ (Carlo Erba) and 1,4-dihydrobenzoquinone (Fluka).

### Characterisation Techniques

The structural and microstructural features of the final pigmenting systems were examined using different techniques. X-ray diffraction analysis (Model D-500, Siemens, Karlsruhe, Germany) was performed using a graphite-monochromated Cu-$K_a$ radiation. The diffractometer had two 1° divergence slits, the scatter and receiving slits were 1° and 0.05°, respectively.

UV/Vis spectra of the specimens (Model Lambda 9, Perkin–Elmer, Norwalk, Connecticut, U.S.A.) were obtained using the diffuse reflectance technique in the range of 200 to 1000 nm using a $BaSO_4$ plate as the reflectance standard. The absorbance was represented by the emission function, $F(R) = (1 - R)^2/2R$, where $R$ is reflectance.

The microstructure of the final powdered samples was observed by field emission scanning electron microscopy at 30 kV (Model S-4100, Hitachi Ltd., Tokyo, Japan). To check the quality of the observation, some of the samples were etched with a diluted HF solution for 10 s and subsequently washed with distilled water.

**Modified Electrode Preparation and Electrochemical Techniques**

Paraffin-impregnated graphite electrodes (PIGEs) consist of cylindrical rods of graphite, with a diameter of 5 mm, which are impregnated under vacuum by paraffin. Preparation details are described in ref.[1]

To prepare sample-modified PIGEs, 0.1–1 mg of the material was powdered in an agate mortar and pestle, and placed on a glazed porcelain tile to form a spot of finely distributed material and then abrasively transferred to the surface of a PIGE by rubbing the electrode over that spot of sample.

Electrochemical experiments were performed at 298 K in a three-electrode cell under argon using a AgCl (3 M NaCl)/Ag reference electrode and a platinum-wire auxiliary electrode. Linear potential scan, cyclic and square wave voltammograms were obtained with BAS CV 50 W and CH I420 instruments. Unless stated, SQWVs were recorded by initiating the potential scan either at +0.85 and –0.85 V using a potential step increment of 4 mV and varying the square wave amplitude between 20 and 200 mV and the frequency between 2 and 200 Hz. Eventually semi-derivative convolution of data was performed in order to increase peak resolution.

Electrocatalytic experiments were performed in $K_4Fe(CN)_6$ solutions in two ways: (a) under dark conditions, confining the cell within the BAS CE-2 box, and (b) upon exposing the cell to direct illumination with conventional VIS and IR lamps located in azimuthal positions with respect to the electrochemical cell.

**Supporting Information:** (see footnote on the first page of this article). X-ray diffraction patterns of specimens thermally treated at final temperatures for 2 h: M1 at 1400 °C and M-5 and M-6 at 1300 °C; and field emission scanning electron microscopy micrographs of specimens thermally heated at 1300 °C.

# Reactions of Furylruthenium Complexes with Oxygen and Trimethylsilyl Azide

**Ku-Hsien Chang,[a] Hui-Ling Sung,[a] and Ying-Chih Lin*[a]**

**Keywords:** Ruthenium / Furyl ligand / Oxygen

The reaction of the (α-alkoxyfuryl)ruthenium complexes **4** with oxygen opens the five-membered furyl ring to give the addition product [Ru]$O_2$CCR=CHC$O_2$$CH_3$, (**5**, [Ru] = Cp($PPh_3$)$_2$Ru). Further reactions of **5** with $CH_3I$ and with organic acid gave $CH_3O_2$CCR=CHC$O_2$$CH_3$, (**6**), and $HO_2$CCR=CHC$O_2$$CH_3$, (**7**), respectively. The reaction of **4** with $TMSN_3$ [TMS = $(CH_3)_3$Si] gives the ruthenium azide [Ru]–$N_3$ and α-alkoxyfuran, which is readily hydrolyzed to lactone in acidic medium. Treatment of the cyclopropenylruthenium complex **11b** containing a methyl crotonate group with $TMSN_3$ affords the five-membered-ring triazole and [Ru]–CN. In this reaction cleavage of the C=C double bond of the three-membered ring could be caused by consecutive additions of $TMSN_3$ to olefinic carbon atoms of intermediates formed during the reaction.

## Introduction

Chemistry of organometallic ruthenium complexes plays important role in many catalytic reactions, such as asymmetric hydrogenation,[1] olefin metathesis[2] and polymerization.[3] Metal-mediated processes in many instances make possible certain reactions, which are not feasible without the involvement of metal ions. It is therefore important to better understand how an organic moiety attached on the metal undergoes chemical transformation. We previously reported the synthesis of cyclopropenyl complexes of ruthenium through a deprotonation reaction of vinylidene complexes.[4] The same approach could also be used for the synthesis of metal-coordinated azirinyl complexes from metal isocyanide complexes.[5] Highly strained organic cyclopropene and azirine compounds are synthetically useful.[6] Participation of *d* orbital of Ru metal may stabilize this highly strained organic moiety consisting of a three-membered ring thus making these complexes readily accessible for further exploitation for the preparation of organic molecules. For example, reactions of various cyclopropenylruthenium complexes with $TMSN_3$ gave a number of tetrazole and triazole compounds depending on the substituents on the three-membered ring.[7] And the reactions of azirinylruthenium complexes with aldehyde or acetone gave oxazolinyl complexes.[6] The previously reported regiochemistry of the carbon–carbon bond formation in the photoreaction of organic azirine with carbonyl group is reversed.[8]

Interestingly, upon deprotonation of vinylidene complexes containing an ester group at Cγ of the vinylidene ligand, we observed formation of furyl complexes as thermodynamic products. The corresponding cyclopropenyl complex was also observed as a kinetic product. It is known that organic cyclopropenyl ketones in the presence of metal halides could be converted to furans.[9] D′yakonov and his co-workers also reported that the reaction of ethyl diazoacetate with 1-phenylpropyne give cyclopropene ester and 2-ethoxyfuran.[10] The former compound underwent photolysis to give the latter one, which yielded diethyl ester upon air oxidation.[11] Synthesis and reactions of a few transition-metal furyl complexes have been reported. Iridium hydride complex containing σ-furyl ligand can be obtained by the reaction of metal cyclooctadienyl complex with furan.[12] The metal furyl complex reacted with *tert*-butylacetylene by insertion of the alkyne into the Ir–C bond to form an vinyl iridium hydride complex.[13] Furyl tungsten complexes are obtained by the reaction of propargyl tungsten complexes with aldehydes. This furyl ligand is easily dissociated from the metal fragment and further reacts with Grignard reagent.[14]

Trimethylsilyl azide and sodium azide were used widely in organic or organometallic reactions.[15] Organic azides react with alkenes or alkynes giving triazoline or triazole compounds through a [3+2] cycloaddition.[16] However, for efficient [3+2] cycloaddition to give triazoles, the presence of an electron-withdrawing group is needed either at the alkyne or at the azide part. Coupling reaction between azide, such as $TMSN_3$, with simple alkyne and allyl carbonates catalyzed by $Pd^0$/$Cu^I$ was reported by Yamamoto and his co-workers[17] as an efficient method for the synthesis of triazoles. The azide reagent is also commonly used in the synthesis of metal complexes with N-heterocyclic ligand. A number of N-coordinated Fe tetrazole derivatives were obtained by the reaction of sodium azide with the coordinated CN of the N-coordinated iron nitrile complex. The mechanism probably involves nucleophilic attack of the azide

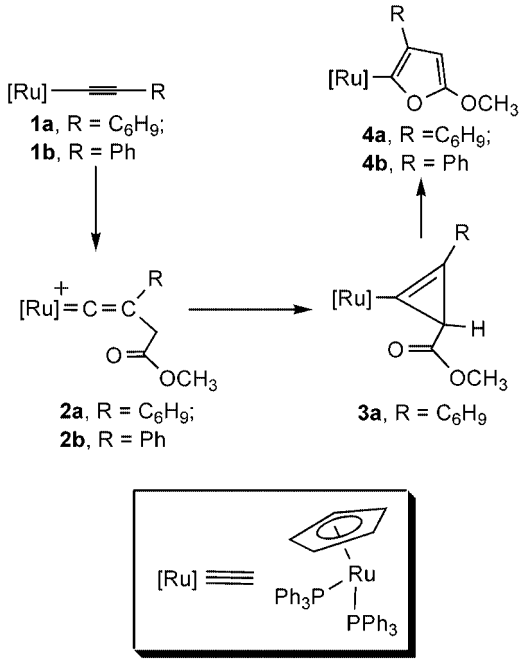
[a] Department of Chemistry, National Taiwan University, Taipei, Taiwan 106, Republic of China

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience 

anion to the carbon atom of the coordinated nitrile followed by cyclization.[18] The reaction of furyl metal complexes with $TMSN_3$ was not investigated before. Herein we report reactions of the furylruthenium complex with oxygen and $TMSN_3$ and the reaction of the cyclopropenylruthenium complex containing a crotonate group with $TMSN_3$ is also reported.

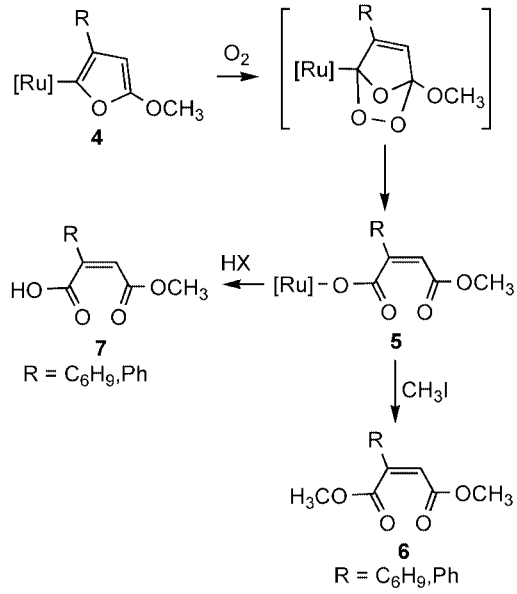
## Results and Discussion

**Preparation of Furyl Complexes:** The reaction of the vinylidene complex **2a** containing a 1-cyclohexenyl group at $C_\beta$ and an ester group at $C_\gamma$ with $n$Bu$_4$NOH in acetone yields the furyl complex **4a** as the thermodynamic product (Scheme 1). The reaction proceeds through protonation at $C_\gamma$ followed by an intramolecular cyclization first giving the three-membered cyclopropenyl complex **3a** as the kinetic product with a small amount of **4a** within 0.5 h. Conversion of **3a** to **4a** is completed within 3 h. The $^{31}$P NMR spectrum of **4a** displays a singlet resonance at $\delta$ = 50.6 ppm, however, the $^{31}$P NMR spectrum of the kinetic product **3a** displays a two-doublet pattern at $\delta$ = 52.5, 48.5 ppm with $J_{P-P}$ = 36.4 Hz indicating the presence of a stereogenic carbon center at the cyclopropenyl ligand. As shown in Scheme 1, the furylruthenium complex **4b** was also prepared by deprotonation of the vinylidene complex **2b** containing a phenyl substituent.[4b] Deprotonation reaction of dinuclear vinylideneruthenium complexes containing an ester substituent at C$\gamma$ gave the dinuclear bisfuryl complexes.[4e] Organic furan adds to [Ir(COD)(PMe$_3$)$_3$]Cl to yield a furyl iridium hydride complex.[12]



Scheme 1.

**Reaction of 4 with Oxygen:** Exposure of complex **4a** as a solid in air for two weeks generates the oxygen addition product [Ru]O$_2$CC(C$_6$H$_9$)=CHCO$_2$CH$_3$, (**5a**) in almost quantitative yield. The reaction is faster in solution but is accompanied with extensive decomposition. Under the same reaction condition, exposure of complex **4b** also yields the analogous oxygen addition product **5b** (Scheme 2).



Scheme 2.

In the $^1$H NMR spectrum of **5a** two singlet resonances at $\delta$ = 5.53 and 4.79 ppm are assigned to the olefinic proton and the Cp group, respectively. The $^{31}$P NMR spectrum of **5a** in $CDCl_3$ displays a singlet resonance at $\delta$ = 39.5 ppm. In the $^{13}$C NMR spectrum the resonance at $\delta$ = 174.2 ppm is assigned to the O-coordinated $CO_2$ group and the resonance at $\delta$ = 166.9 ppm is assigned to the $CO_2$ group of the terminal ester.

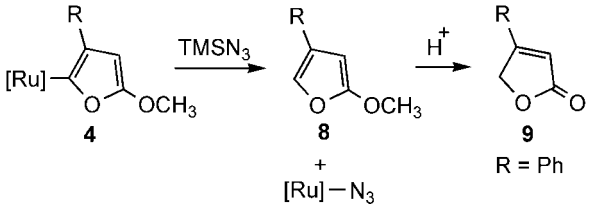
Furan is known to react with singlet oxygen.[19] It has been reported by Scarpati and her co-workers that photosensitized oxidation of various substituted furans under strictly anhydrous conditions at about –15 °C generated in quantitative yields the *endo*-peroxides, which decomposed at room temperature in the absence of solvent and moisture. However, at 4 °C the *endo*-peroxide in nitromethane was converted into the oxiranes.[20] These *endo*-peroxides could also react with diethyl sulfide at 0 °C yielding diones, which further react with *tert*-butyl hydroperoxide in the presence of triethylamine to give oxiranes. On the basis of these reports, we propose that the reaction of the furylruthenium complex with $O_2$ could proceed through the formation of the *endo*-peroxide intermediate with subsequent ruthenium migration to oxygen accompanied with cleavage of both C–O and O–O bonds affording complex **5a** (Scheme 2). The reaction could occur in both solid and liquid state without prior formation of singlet oxygen.[19] The *endo*-peroxide intermediate was not observed in our system. This facile reaction could possibly be assisted by the participation of the *d* orbital of the ruthenium metal and/or the presence of the neighboring methoxy group.[11]

Further reaction of **5a** with $CH_3I$ generates metal iodide [Ru]–I and the diester **6a** containing a 1-cyclohexenyl sub-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stituent[21] by cleavage of the Ru–O bond (Scheme 2). The reaction was carried out at 50 °C and the organic product **6a** was extracted with diethyl ether and was identified by NMR spectroscopy. In the $^1$H NMR spectrum of **6a**, two singlet resonances at $\delta$ = 3.88 and 3.71 ppm with the ratio 1:1 are assigned to two $OCH_3$ groups. Analogous, the diester compound **6b** can also be obtained from the reaction of **5b** with $CH_3I$. Compound **6b** was previously obtained from the reaction of phenylacetylene with alcohol at room temperature under atmospheric pressure of carbon monoxide in the presence of Pd catalyst.[22] The reaction of **5** with protic acid breaks the Ru–O bond and yields compound **7**, which was identified by NMR and high-resolution mass spectroscopy.

**Reactions of $TMSN_3$ with Furylruthenium Complexes:** Reactions of $TMSN_3$ with furylruthenium complexes **4a** and **4b** give the metal-free α-alkoxyfuran **8**, (**8a**, R = $C_6H_9$; **8b**, R = Ph), respectively, and the ruthenium azide complex [Ru]–$N_3$[7a] in high yield (Scheme 3). In the $^1$H NMR spectrum of **8a**, the doublet resonance at $\delta$ = 5.25 with $^4J_{H,H}$ = 1.2 Hz is assigned to the olefinic hydrogen. In the 2D-NMR COSY spectrum, this resonance is found to correlate with the resonance at $\delta$ = 6.78 ppm (overlapped with those of phenyl hydrogen) assignable to the other olefinic proton on the furyl ring. Hydrolysis of α-alkoxyfuran **8b** in acidic condition gave organic the lactone 4-phenyl-2(5*H*)-furanone (**9b**) in quantitative yield. The $^1$H NMR spectrum of **9b** displays a triplet resonance at $\delta$ = 6.36 ppm and a doublet resonance at $\delta$ = 5.22 ppm with a ratio of 1:2 with $^4J_{H,H}$ = 1.8 Hz. Hydrolysis of alkoxyfuran to lactone has been reported.[23] Comparison of spectroscopic data with those of the authentic sample[24] confirms the structure of **9b**.



Scheme 3.

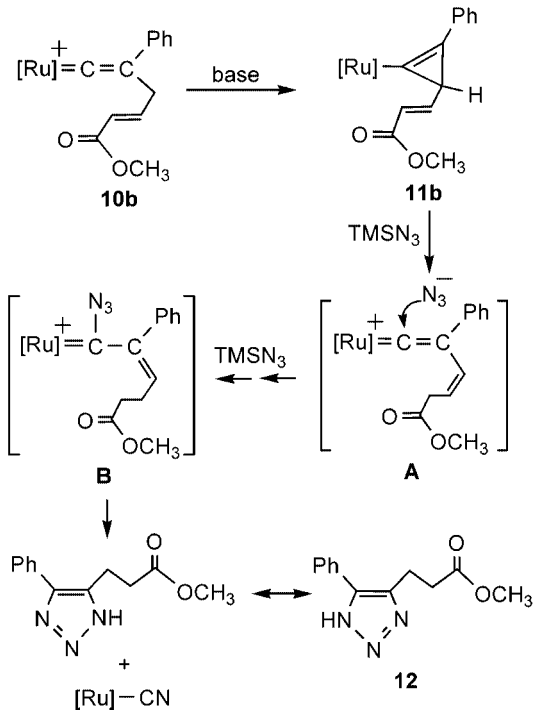
The reaction of $TMSN_3$ with the cyclopropenylruthenium complex[7] caused opening of the three-membered ring, but the reaction of **4** with $TMSN_3$ brought about cleavage of the M–C bond. This could be explained as follows: Organic cyclopropene is highly strained with the estimated strain energy well over 50 kcal/mol.[25] However, the cyclopropenyl ligand can be stabilized by coordination to a transition metal through back-bonding from the metal *d* orbital to $C_\alpha$. We previously reported solid-state structure of several cyclopropenylruthenium complexes.[4] From single-crystal X-ray diffraction studies, Ru–C bond lengths are in the range of 2.0345–2.0482 Å for these complexes, which are consistently shorter than that of a typical Ru–C($sp^2$) single bond [bond length 2.0637–2.09012 Å].[26] This might indicate that the Ru–C bond in cyclopropenyl-Ru complex could be slightly stronger than a regular Ru–C single bond indicating some degree of back-bonding from the metal moiety. In contrast, furan compounds have less ring strain. It thus requires less or even no back-bonding of the metal *d* electron for the coordination of the relatively more stable furyl group. Thus, unlike the M–C bond in cyclopropenyl complex, the M–C bond in furyl metal complexes is relatively weak and cleavage of the bond was observed in the reaction with $TMSN_3$.

**Synthesis and Reactions of Vinylidene Complex Containing Crotonate Group:** Because the five-membered ring furyl complex was readily prepared from the vinylidene complex containing a terminal ester group, it would be interesting to carry out deprotonation reaction of the vinylidene complex containing a crotonate group, which als possess a terminal ester group. A seven-membered ring ligand is expected to be obtained. We prepared the cationic vinylidene complex {[Ru]=C=C(R)$CH_2$CH=CH–$CO_2CH_3$][Br]} (R = $C_6H_9$, **10a**; R = Ph, **10b**) containing a terminal methyl crotonate group at $C_\beta$ in high yield by the treatment of [Ru]–C≡C–R ([Ru] = $Cp(PPh_3)_2Ru$, R = $C_6H_9$, **1a**; R = Ph, **1b**) with $BrCH_2CH$=$CHCO_2CH_3$. These cationic pink vinylideneruthenium complexes are stable in air and soluble in polar solvent but insoluble in ether and hexane. Spectroscopic data of **10a** displays of a deshielded $C_\alpha$ resonance as a triplet at $\delta$ = 351.8 ppm with $J_{P-C}$ = 15.4 Hz in the $^{13}$C NMR spectrum and a singlet $^{31}$P NMR resonance at $\delta$ = 42.3 ppm in $CDCl_3$ at room temperature. Complex **10b** was isolated in 88% yield. In the $^{13}$C NMR spectrum of **10b**, resonances at $\delta$ = 153.9 and 144.7 are assigned to the olefinic carbon atoms of the crotonate group and the corresponding $^1$H NMR resonances appear at $\delta$ = 6.71 and 5.62 ppm, assigned from the 2D HMQC spectrum.

However, in the deprotonation of the vinylidene complex containing a crotonate group only the cyclopropenyl complex was obtained. The reaction of **10b** with $n$Bu$_4$NOH gives the three-membered ring cyclopropenyl complex **11b**, (Scheme 4). The $^{31}$P NMR spectrum of **11b** displays two-doublet resonances at $\delta$ = 52.2 and 48.9 ppm with $J_{P-P}$ = 36.1 Hz due to the presence of a stereogenic carbon center at the three-membered ring. In the $^1$H NMR spectrum of **11b** the doublet resonance at $\delta$ = 2.62 with $J_{H,H}$ = 9.62 Hz is assigned to the CH group of the three-membered ring indicating the presence of a CH group of the adjacent double bond. However, deprotonation of the vinylidene complex **10a** containing a 1-cyclohexenyl group gave several unidentifiable decomposition products, no cyclopropenyl complex was observed. Conjugate double bond of the cyclopropenyl and 1-cyclohexenyl groups could possibly lower the degree of back donation from the metal, thus destabilizing the compound.

The reaction of the cyclopropenylruthenium complex **11b** containing a methyl crotonate substituent with excess of $TMSN_3$ resulted in formation of a five-membered triazolate ring organic product **12** (Scheme 4) and [Ru]–CN.[27] The organic product **12** was collected by extraction of the reaction mixture with hexane and was identified by $^1$H NMR spectrum and high-resolution mass spectrum. In the $^1$H NMR spectrum of compound **12**, the resonance at $\delta$ = 3.31

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4.

ppm is assigned to the $OCH_3$ group, and two triplet resonances at $\delta$ = 3.07 and 2.71 ppm with $^3J_{H,H}$ = 7.39 Hz are assigned to two neighboring $CH_2$ groups. Tautomerism of the triazole compound **12** might occur to yield two possible structures shown in Scheme 4.

The reaction of **11b** with $TMSN_3$ results in cleavage of the C=C double bond of the cyclopropenyl ring yielding [Ru]–CN and **12**. A possible reaction sequence is depicted in Scheme 4. The reaction may start with an addition of a TMS group to the double bond of the methyl crotonate group. This is accompanied with opening of the three-membered ring resulting in the formation of a cationic vinylidene intermediate followed by hydrolysis of TMS to afford **A** (Scheme 4). Then addition of the azide anion at $C_\alpha$ accompanied with addition of the second TMS group at $C_\delta$ followed by hydrolysis of the TMS group gave **B**. The single-bond character of the $C_\alpha$–$C_\beta$ in **B** may facilitate its cleavage. Loss of $N_2$ and a [3+2] cycloaddition of the $C_\beta$–$C_\gamma$ double bond with $N_3^-$ give the triazole **12** and [Ru]–CN. This result is the same as that observed for the reaction of $TMSN_3$ with cyclopropenyl complex containing a vinyl group.[7]

Recently, synthesis of organic tetrazolates complexes using transition-metal complexes as catalysts has received much attention.[28] The three-component coupling reaction using organic cyano compounds, allyl methyl carbonate, and trimethylsilyl azide catalyzed by a palladium complex gave various 2-allyltetrazoles in good yields. Tetrazolate complexes of palladium have also been prepared by nucleophilic attack of azide anion at the carbon atom of the coordinated nitrile followed by cycloaddition reaction.[17]

## Concluding Remarks

The reactions of furyl and cyclopropenylruthenium complexes with $O_2$ and $TMSN_3$ are investigated. While the cyclopropenyl complex with an ester substituent undergoes tautomerization to give the furyl complex, the methyl crotonate cyclopropenyl complex is inert toward such a transformation. The reaction of furyl metal complex with oxygen through *endo*-peroxide requires no assistance of photo-irradiation. Cleavage of the Ru–C bond was observed in the reaction of $TMSN_3$ with the furylruthenium complex. Reaction of $TMSN_3$ with the cyclopropenylruthenium complex containing a methyl crotonate substituent yielded ruthenium cyanide and organic triazole. The reaction causes cleavage of the C=C double bond of the three-membered ring.

## Experimental Section

**General Procedures:** All manipulations were performed under nitrogen using vacuum-line, dry box, and standard Schlenk techniques. $CH_3CN$ and $CH_2Cl_2$ were distilled from $CaH_2$ and diethyl ether and THF from Na/ketyl. All other solvents and reagents were of reagent grade and were used without further purification. NMR spectra were recorded with Bruker DMX-500, AM-300 and AC-200 (FT-NMR spectrometers at room temperature unless states otherwise) and were reported in units of $\delta$ with residual protons in the solvent as a standard ($CDCl_3$, δ = 7.24 ppm; $C_6D_6$, δ = 7.15 ppm; $C_2D_6CO$, δ = 2.04 ppm). FAB mass spectra were recorded with a JEOL SX-102A spectrometer. Vinylidene complexes ([Ru]=C=C(R)$CH_2CO_2CH$, R = $C_6H_9$, **2a**; R = Ph, **2b**) and furyl complexes **4** (R = $C_6H_9$, **4a**; R = Ph, **4b**) were prepared following the method reported in the literature.[4b] Elemental analyses were carried out at the Regional Center of Analytical Instrument located at the National Taiwan University.

**Synthesis of Vinylidene Complexes with Ester Group [Ru]=C=C($C_6H_9$)$CH_2CO_2CH_3$][Br] (2a):** To a $CH_2Cl_2$ (20.0 mL) solution of [Ru]C≡C$C_6H_9$[4b] (200 mg, 0.25 mmol) (**1b**), $BrCH_2CO_2CH_3$ (0.12 mL, 1.25 mmol) was added under nitrogen. The resulting solution was stirred at room temperature for 18 h, then, the solvent was concentrated to about 5 mL. This mixture was slowly added to 60 mL of vigorously stirred diethyl ether. The light-orange precipitate thus formed was filtered off and washed with diethyl ether and hexane and dried under vacuum to give the product **2a** (172 mg, 79% yield). Spectroscopic data for **2a** are as follows: $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.42–6.95 (m, 30 H, Ph), 5.77 (br., 1 H, CH of $C_6H_9$), 5.22 (s, 5 H, Cp), 3.69 (s, 3 H, $OCH_3$), 2.69 (s, 2 H, $CH_2$), 2.14, 1.88, 1.68, 1.49 (br., 8 H, 4 $CH_2$ of $C_6H_9$) ppm. $^{31}$P{$^1$H} NMR (121.6 MHz, $CDCl_3$, 25 °C): $\delta$ = 42.1 (s) ppm. $^{13}$C NMR (75.4 MHz, $CDCl_3$, 25 °C): $\delta$ = 351.5 ($C_\alpha$, $J_{C,P}$ = 15.0 Hz), 171.8 ($CO_2$), 134–128.4 (Ph), 125.6 ($C_\beta$), 94.5 (Cp), 52.2 ($OCH_3$), 28.8 ($CH_2$), 27.5, 26.0, 22.7, 21.6 ($CH_2$ of $C_6H_9$) ppm. MS FAB: *m*/*z* = 869.0 [$M^+$ – Br], 606.9 [$M^+$ – Br, $PPh_3$], 428.8 [$M^+$ – Br, $PPh_3$, $C_2(C_6H_9)CH_2CO_2CH_3$], 345.1 [$M^+$ – Br, 2$PPh_3$]. $C_{52}H_{49}BrO_2P_2Ru$ (948.88): calcd. C 65.82 H, 5.20; found C 66.17, H 5.36.

**Synthesis of 4a:** To a solution of **2a** (100 mg, 0.11 mmol) in 5 mL of acetone was added a solution of $n$Bu$_4$NOH (0.2 mL, 0.2 mmol) under nitrogen. The mixture was stirred at room temperature for 4 h yielding a light yellow microcrystalline precipitate. The product was filtered off and washed with 2×5 mL of acetone, 2×5 mL of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$CH_3CN$, then dried under vacuum and was identified as **4a** (74 mg, 74% yield). Spectroscopic data for **4a** are as follows: $^1H$ NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.43–6.96 (m, 30 H, Ph), 5.99 (br., 1 H, CH of $C_6H_9$), 5.12 (s, 1 H, CH), 4.50 (s, 5 H, Cp), 2.97 (s, 3 H, $OCH_3$), 2.46, 2.29, 1.86, 1.78 (br., 8 H, 4 $CH_2$ of $C_6H_9$) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $C_6D_6$, 25 °C): $\delta$ = 50.6 (s) ppm. $^{13}C$ NMR (75.4 MHz, $C_6D_6$, 25 °C): $\delta$ = 164.9 (CO), 141.4 (t, $J_{C,P}$ = 18.8 Hz, $C_\alpha$), 139.7–127.8 (Ph), 124.5 (=CH), 85.5 ($C_\gamma$), 84.9 (Cp), 57.9 ($OCH_3$), 32.2, 26.3, 24.5, 23.4 ($CH_2$ of $C_6H_9$) ppm. MS FAB: *m*/*z* = 869.4 [$M^+$ + 1]. $C_{52}H_{48}O_2P_2Ru$ (867.97): calcd. C 71.96, H 5.57; found C 71.83, H 5.48.

**Observation of 3a:** To a solution of **2a** (100 mg, 0.12 mmol) in 5 mL of acetone was added a solution of $n$Bu$_4$NOH (0.3 mL, 0.3 mmol, 1 M in $CH_3OH$) under nitrogen at room temperature. $H_2O$ was added to the mixture immediately and yielded the light yellow microcrystalline precipitate. The product was filtered off and washed with 2×5 mL of $CH_3CN$, then dried under vacuum and identified as **3a** (89 mg, 89% yield). Complex **3a** is not stable at room temperature. By monitoring the $^{31}P$ NMR spectrum, **3a** was found as a pure product at the initial stage, spectroscopic data of **3a** was obtained within 3 min. Then the product **4a** was observed. Spectroscopic data for **3a** are as follows: $^1H$ NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.44–6.94 (m, 30 H, Ph), 5.65 (br., 1 H, CH of $C_6H_9$), 4.65 (s, 5 H, Cp), 3.74 (s, 3 H, $OCH_3$), 2.47 (s, 1 H, CH), 2.50–1.24 (br., 8 H, 4 $CH_2$ of $C_6H_9$) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $C_6D_6$, 25 °C): $\delta$ = 52.5, 48.5 (AX, $J_{P-P}$ = 36.4 Hz) ppm.

**Synthesis of [Ru]$O_2CC(C_6H_9)$=$CHCO_2CH_3$ (5a):** Complex **4a** (0.20 g, 0.23 mmol) was exposed to air for 5 days at room temperature, and the light yellow powder became deep yellow. The product was identified as **5a** (0.20 g, 99% yield). Spectroscopic data for **5a** are as follows: $^1H$ NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.64–6.96 (m, 30 H, Ph), 5.79 (br., 1 H, CH of $C_6H_9$), 5.53 (s, 1 H, CH), 4.79 (s, 5 H, Cp), 3.51 (s, 3 H, $OCH_3$), 1.99, 1.45, 1.26, 1.01 (br., 8 H, 4 $CH_2$ of $C_6H_9$) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $C_6D_6$, 25 °C): $\delta$ = 39.5 (s) ppm. $^{13}C$ NMR (75.4 MHz, $C_6D_6$, 25 °C): $\delta$ = 174.2 ($RuO_2C$), 166.9 ($CO_2CH_3$), 160.3 ($CC_6H_9$), 139.6–127.4 (Ph), 107.2 (CH), 80.2 (Cp), 50.6 ($CH_3$), 26.7, 25.4, 23.1, 22.2 ($CH_2$ of $C_6H_9$) ppm. MS FAB: *m*/*z* = 901 [$M^+$ + 1], 869 [$M^+$ + 1 – $O_2$], 719.2 [$M^+$ + CO – $O_2CC(C_6H_9)$=$CHCO_2CH_3$], 691.1 [$M^+$ – $O_2CC(C_6H_9)$=$CHCO_2CH_3$], 638 [$M^+$ + 1 – $PPh_3$], 429.0 [$M^+$ – $PPh_3$, $O_2CC(C_6H_9)$=$CHCO_2CH_3$]. $C_{52}H_{48}O_4P_2Ru$ (899.97): calcd. C 69.40, H 5.38; found C 69.28, H 5.22.

**Synthesis of [Ru]$O_2CC(Ph)$=$CHCO_2CH_3$ (5b):** Complex **4b** (0.20 g, 0.23 mmol) was exposed to air for 10 days at room temperature, and the orange powder became yellow. The $^{31}P$ NMR was used to confirm complete transformation. The yellow product was identified as **5b**, and the yield is almost quantitative (0.21 g, 99% yield). Spectroscopic data of **5b** are as follows: $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.40–6.93 (m, 35 H, Ph), 5.76 (s, 1 H, CH), 4.44 (s, 5 H, Cp), 3.63 (s, 3 H, $OCH_3$) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $CDCl_3$, 25 °C): $\delta$ = 40.85 (s) ppm. $^{13}C$ NMR (75.4 MHz, $CDCl_3$, 25 °C): $\delta$ = 174.0 ($RuO_2C$), 166.0 ($CO_2CH_3$), 157.3 ($CPh$), 138.2–25.2 (Ph), 111.9 (CH), 78.6 (Cp), 51.1 ($CH_3$) ppm. MS FAB: *m*/*z* = 896.1 [$M^+$], 719.2 [$M^+$ + CO, $O_2CC(Ph)$=$CHCO_2CH_3$], 691.2 [$M^+$ – $O_2CC(Ph)$=$CHCO_2CH_3$], 634.1 [$M^+$ – $PPh_3$]. $C_{52}H_{44}O_4P_2Ru$ (895.93): calcd. C 69.70, H 4.95; found C 69.56, H 4.82.

**Reaction of 5 with $CH_3I$:** To a solution of complex **5a** (100 mg, 0.11 mmol) in $CDCl_3$ prepared under $N_2$ in a NMR tube, 36 μL (0.58 mmol) of $CH_3I$ was added. The reaction was carried out at 50 °C for 3–4 h. The solvent was removed under vacuum. The organic product along with excess $CH_3I$ was extracted with diethyl ether. The solvent and $CH_3I$ were removed under vacuum. The organic product is identified as **6a** (21 mg, 85% yield). The organometallic product was identified as [Ru]–I[29] (82 mg, 92% yield). **6a:** $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 5.08 (br., 1 H, CH of $C_6H_9$), 5.77 (s, 1 H, =CH), 3.88 (s, 3 H, $OCH_3$), 3.71 (s, 3 H, $OCH_3$), 2.21–1.59 (br., 8 H, 4 $CH_2$ of $C_6H_9$) ppm. MS (EI): *m*/*z* = 224 [$M^+$]. High-resolution MS for $C_{12}H_{16}O_4$: calcd. 224.2567; found 224.2563. The same procedure was used for the reaction of **5b** (100 mg, 0.11 mmol) with $CH_3I$ (36 μL, 0.58 mmol), and the product extracted with diethyl ether was identified as **6b** in 89% yield (21 mg). The organometallic product was identified as [Ru]–I (84 mg, 94% yield). **6b:** $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.25–7.18 (m, 5 H, Ph), 6.29 (s, 1 H, CH), 3.92 (s, 3 H, $CH_3$), 3.76 (s, 3 H, $CH_3$) ppm. $^{13}C$ NMR (75.4 MHz, $CDCl_3$, 25 °C): $\delta$ = 168.3, 165.4 (two $COCH_3$), 149.0 ($CPh$), 133.1–126.8 (Ph), 117.0 (CH), 52.7, 52.0 (two $CH_3$) ppm. High-resolution MS for $C_{12}H_{12}O_4$: calcd. 220.0736; found 220.0732.

**Reaction of 5 with Protic Acid:** To a solution of complex **5a** (100 mg, 0.10 mmol) in $CDCl_3$ prepared under $N_2$ in an NMR tube, hydrochloric acid (50 μL of aqueous 37% HCl, 0.6 mmol) was added. The reaction is complete within about 4 h at room temperature. The solvent was removed under vacuum. The organic product was extracted with diethyl ether and identified as **7a** (18 mg, 86% yield). The organometallic product was identified as [Ru]–Cl (73 mg, 92% yield). The solvent and HCl were removed under vacuum at 60 °C. **7a:** $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 6.82 (s, 1 H, CH), 6.30 (br., 1 H, CH of $C_6H_9$), 3.73 (s, 3 H, $OCH_3$), 2.22–1.58 (br., 8 H, 4 $CH_2$ of $C_6H_9$) ppm. MS (EI): 210 [$M^+$]. The same procedure was used for the reaction of **5b** (100 mg, 0.11 mmol) with acid, and the product extracted with diethyl ether was identified as **7b** (17 mg, 90% yield). The organometallic product was identified as [Ru]–Cl (65 mg, 90% yield). **7b:** $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.25–7.01 (m, 5 H, Ph), 6.28 (s, 1 H, CH), 3.76 (s, 3 H, $CH_3$) ppm. $^{13}C$ NMR (75.4 MHz, $CDCl_3$, 25 °C): $\delta$ = 170.6 ($CO_2H$), 165.5 ($CO_2CH_3$), 148.8 ($CPh$), 133.3–126.8 (Ph), 116.8 (CH), 52.0 ($CH_3$) ppm. MS (EI): *m*/*z* = 174 [$M^+$ – $CH_3OH$]. The HCl could be replaced with trifluoroacetic acid or acetic acid yielding **7** and [Ru]–$OCOCF_3$[30] or [Ru]–$OCOCH_3$,[30] respectively. Both reactions completed in 36 h. Trifluoroacetic acid and acetic acid could be removed under vacuum without heating.

**Reaction of 4a with $TMSN_3$:** A solution of **4a** (100 mg, 0.12 mmol) in THF (10 mL) was treated with $TMSN_3$ (0.07 mL, 0.54 mmol). The resulting solution was stirred at room temperature for 1 h then the solvent was removed under vacuum. The mixture was added to a stirred diethyl ether. Orange precipitates thus formed were filtered off and washed with diethyl ether. The organometallic product was identified as [Ru]–$N_3$ (79 mg, 90% yield). The organic product was collected by extraction with ether and purified by chromatography, then, the solvent was removed under vacuum to give **8a**, (19 mg, 90% yield). **8a:** $^1H$ NMR (300 MHz, $C_6D_6$ 25 °C): $\delta$ = 6.78 (d, $^4J_{H,H}$ = 1.2 Hz, 1 H, CH), 5.88 (br., 1 H, CH of $C_6H_9$), 5.25 (d, $^4J_{H,H}$ = 1.2 Hz, 1 H, CH), 3.79 (s, 3 H, $OCH_3$), 2.16–1.58 (br., 8 H, 4 $CH_2$ of $C_6H_9$) ppm. MS (EI): *m*/*z* = 178 [$M^+$].

**Reaction of 4b with $TMSN_3$:** To a flask containing compound **4b** (0.20 g, 0.23 mmol) in THF (10 mL), $TMSN_3$ (0.20 mL, 1.49 mmol) was added. The solution was stirred at room temperature for 2 h, then the solvent was removed under vacuum. The yellow solid was washed with hexane and identified as [Ru]–$N_3$ (0.16 g, 95% yield). The organic product was extracted with hexane and was found to contain some triphenylphosphane oxide. The pure organic product was obtained by eluting the mixture with diethyl ether on a silica gel column and solvent was removed on a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rotary evaporator. The organic product was identified as compound **8b** (34 mg, 91% yield). **[Ru]–$N_3$:** $^1$H NMR (300 MHz, $C_6D_6$ 25 °C): $\delta$ = 7.32–7.08 (m, 30 H, Ph), 4.18 (s, 5 H, Cp) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $CDCl_3$, 25 °C): $\delta$ = 41.8 (s) ppm. **8b:** $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.30–7.10 (m, 5 H, Ph), 6.96 (d, 1 H, CH, $^4J_{H,H}$ = 1.3 Hz), 5.24 (d, 1 H, CH, $^4J_{H,H}$ = 1.3 Hz), 3.23 (s, 3 H, $CH_3$) ppm. High-resolution MS for $C_{11}H_{10}O_2$: calcd. 174.0681; found 174.0691. **Isolation of 9b:** Transformation of **8b** to **9b** under acidic condition was monitored by NMR in $CDCl_3$. Addition of HCl (37%, 9.2 μL) to the solution of **8b** (19 mg, 0.11 mmol) caused the formation of **9b** (16 mg, 95% yield) in about 30 min. **9b:** $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.48 (s, 5 H, Ph), 6.36 (t, $J_{H,H}$ = 1.8 Hz, 1 H, CH), 5.22 (d, $J_{H,H}$ = 1.8 Hz, 2 H, $CH_2$) ppm. $^{13}$C NMR (75.4 MHz, $CDCl_3$, 25 °C): $\delta$ = 173.9 (OC), 163.9 (*C*Ph), 131.8–129.6 (Ph), 113.0 (CH), 71.0 ($CH_2$) ppm. High-resolution MS for $C_{10}H_8O_2$: calcd. 160.0524; found 160.0521.

**Synthesis of Vinylidene Complexes with Methyl Crotonate:** To a Schlenk flask charged with [Ru]C≡C$C_6H_9$ (**1a**) (200 mg, 0.25 mmol) in $CH_2Cl_2$ (20 mL), $BrCH_2CH{=}CHCO_2CH_3$ (0.15 mL, 1.25 mmol) was added under nitrogen. The mixture was stirred at room temperature for 6 h, then the solution was concentrated to about 5 mL and added dropwise to 60 mL of a vigorously stirred diethyl ether. The pink precipitate thus formed was filtered off, and washed with diethyl ether and hexane. The product was identified as [Ru]=C=C($C_6H_9$)$CH_2CH{=}CHCO_2CH_3$][Br] (**10a**) (179 mg, 85% yield). **10a:** $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.41–6.99 (m, 30 H, Ph), 6.71, 6.68 (dt, $J_{H,H}$ = 10.0, 6.4 Hz, 1 H, C*H*=C), 5.73 (br., 1 H, CH of $C_6H_9$), 5.70 (d, $J_{H,H}$ = 10.0 Hz, 1 H, =C*H*), 5.11 (s, 5 H, Cp), 3.76 (s, 3 H, $OCH_3$), 2.73 (d, $J_{H,H}$ = 6.4 Hz, 2 H, $CH_2$), 2.16, 1.71, 1.52, 1.49 (br., 8 H, 4 $CH_2$ of $C_6H_9$) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $CDCl_3$, 25 °C): $\delta$ = 42.3 (s) ppm. $^{13}$C NMR (75.4 MHz, $CDCl_3$, 25 °C): $\delta$ = 351.8 ($C_\alpha$, $J_{C,P}$ = 15.4 Hz), 166.4 ($CO_2$), 145.8, 122.3 (C=C), 134.3–128.0 (Ph), 130.1 (CH of $C_6H_9$), 125.1 ($C_\beta$), 94.2 (Cp), 51.5 ($OCH_3$), 27.3, 25.8, 22.6, 21.5 ($CH_2$ of $C_6H_9$), 25.4 ($CH_2$) ppm. MS FAB: *m*/*z* = 895.4 [$M^+$ – Br], 633.2 [$M^+$ – Br, $PPh_3$], 429.0 [$M^+$ – Br, $PPh_3$, $C_2(C_6H_9)$-$CH_2CH{=}CHCO_2CH_3$], 371.1 [$M^+$ – Br, 2$PPh_3$]. $C_{54}H_{51}BrO_2P_2Ru$ (974.92): calcd. C 66.53, H 5.27; found C 66.27, H 5.19. To a solution of [Ru]C≡CPh[4b] (**1b**) (200 mg, 0.25 mmol) in $CH_2Cl_2$ (20 mL), $BrCH_2CH{=}CHCO_2CH_3$ (0.15 mL, 1.25 mmol) was added under nitrogen. The mixture was stirred at room temperature for 6 h, then the volume was reduced to about 5 mL. Addition of the mixture dropwise into 60 mL of a vigorously stirred diethyl ether caused a pink-red solid to precipitate out. The precipitate thus formed was filtered off and washed with diethyl ether and hexane and dried under reduced pressure to yield the product [Ru]=C=C(Ph)$CH_2CH{=}CHCO_2CH_3$][Br] (**10b**) (197 mg, 88% yield). **10b:** $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.41–6.80 (m, 35 H, Ph), 6.71, 6.68 (dt, $J_{H,H}$ = 15.4, 6.58 Hz, 1 H, C*H*=C), 5.62 (d, $J_{H,H}$ = 15.4 Hz, 1 H, =C*H*), 5.11 (s, 5 H, Cp), 3.70 (s, 3 H, $CH_3$), 3.07 (d, $J_{H,H}$ = 6.58 Hz, 2 H, $CH_2$) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $CDCl_3$, 25 °C): $\delta$ = 41.9 (s) ppm. $^{13}$C NMR (75.4 MHz, $CDCl_3$, 25 °C): $\delta$ = 347.8 ($C_\alpha$, $J_{C,P}$ = 14.7 Hz), 166.4 ($CO_2$), 153.9, 144.7 (C=C), 134.7–126.7 (Ph), 123.0 ($C_\beta$), 94.4 (Cp), 51.6 ($OCH_3$), 29.2 ($CH_2$) ppm. MS FAB: *m*/*z* = 891.1 [$M^+$ – Br], 629.3 [$M^+$ – Br, $PPh_3$], 429.1 [$M^+$ – Br, $PPh_3$, $C_2$(Ph)$CH_2CH{=}CHCO_2CH_3$]. $C_{54}H_{47}BrO_2P_2Ru$ (1050.79): calcd. C 66.80, H 4.88; found C 66.72, H 4.82.

**Synthesis of 11b:** To a solution of **10b** (200 mg, 0.22 mmol) in 5 mL of acetone was added a 1 M solution of $n$$Bu_4NOH$ (0.3 mL, 0.3 mmol, in $CH_3OH$). The mixture was stirred for 1 h yielding the light yellow microcrystalline precipitate which was filtered off and washed with 2×5 mL of $CH_3CN$, dried under vacuum. The product was analytically pure and was identified as **11b** in 72% yield. (140 mg) Spectroscopic data for **11b** are as follows: $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.91 (q, $J_{H,H}$ = 15.1, 9.62 Hz, 1 H, C*H*=), 7.39–6.90 (m, 35 H, Ph), 6.67 (d, $J_{H,H}$ = 15.1 Hz, 1 H, =C*H*), 4.56 (s, 5 H, Cp), 3.62 (s, 3 H, $CH_3$), 2.62 (d, $J_{H,H}$ = 9.62 Hz, 1 H, CH) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $C_6D_6$, 25 °C): $\delta$ = 52.2, 48.9 (AX, $J_{P-P}$ = 36.1 Hz) ppm. $^{13}$C NMR (75.4 MHz, $C_6D_6$, 25 °C): $\delta$ = 169.1 (CH=), 168.3 (C=O), 140.2–125.8 (Ph), 112.6 (=CH), 86.4 (Cp), 50.2 ($OCH_3$), 36.7 (CH) ppm. MS FAB: *m*/*z* = 891.4 [$M^+$ + 1], 629.3 [$M^+$ + 1, $PPh_3$], 429.1 [$M^+$ + 1 – $PPh_3$, =C=C(Ph)$CH_2CH{=}CHCO_2CH_3$]. $C_{54}H_{46}O_2P_2Ru$ (899.97): calcd. C 72.88, H 5.21; found C 72.63, H 5.12.

**Reaction of 11b with $TMSN_3$:** To a Schlenk flask charged with complex **11b** (50 mg, 0.06 mmol) was added THF (10 mL) under nitrogen. The resulting yellow solution was stirred and $TMSN_3$ (0.1 mL, 0.75 mmol) was added. The mixture was stirred at room temperature for 4 h, then the solution was concentrated to about 3 mL, and slowly added to 20 mL of a stirred hexane solution. The orange precipitate thus formed was filtered off, and washed with diethyl ether. The product was identified as [Ru]–CN (39 mg, 90%). The organic product was extracted with hexane, then the extract was filtered through silical gel. Solvent of the filtrate was removed under vacuum and the product was identified as **12** (12 mg, 88% yield). **[Ru]–CN:** $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.81–6.96 (m, 30 H, Ph), 4.45 (s, 5 H, Cp) ppm. $^{31}P\{^1H\}$ NMR (121.6 MHz, $C_6D_6$, 25 °C): $\delta$ = 50.38 (s) ppm. **12:** $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.81–6.96 (m, 5 H, Ph), 3.31 (s, 3 H, $OCH_3$), 3.07 (t, 2 H, $CH_2$, $^3J_{H,H}$ = 7.39 Hz), 2.71 (t, 2 H, $CH_2$, $^3J_{H,H}$ = 7.39 Hz) ppm. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.67–7.06 (m, 5 H, Ph), 3.67 (s, 3 H, $OCH_3$), 3.19 (t, 2 H, $CH_2$, $^3J_{H,H}$ = 7.39 Hz), 2.80 (t, 2 H, $CH_2$, $^3J_{H,H}$ = 7.39 Hz) ppm. $^{13}$C NMR (75.4 MHz, $CDCl_3$, 25 °C): $\delta$ = 173.9 (CO), 134.1–128.0 (Ph), 52.4 ($OCH_3$), 33.1 ($CH_2O$), 21.1 ($CH_2$) ppm. MS (EI): *m*/*z* = 230 [$M^+$]

## Acknowledgments

# X-ray Crystal Structure and Characterization in Aqueous Solution of {*N*,*N*′-Ethylenebis(pyridoxylaminato)}zinc(II)

**Isabel Correia,[a] Agnes Dornyei,[b] Fernando Avecilla,[c] Tamás Kiss,*[b] and João Costa Pessoa*[a]**

**Keywords:** N,O ligands / Speciation / Structure elucidation / Zinc

The complexation of $Zn^{II}$ with $H_2Rpyr_2en$ [$H_2Rpyr_2en$ = *N*,*N*′-ethylenebis(pyridoxylaminato)] in aqueous solution has been studied by pH potentiometry and $^1H$ NMR spectroscopy. Complex formation constants are determined and binding modes proposed. Complex formation starts at around pH 4, and several species with a 1:1 ligand-to-metal ratio with different protonation states form up to pH 12. Only above pH 10 does a hydrolytic species $[ZnLH_{-1}]^-$ become important. The crystal and molecular structures of $[ZnCl(H_2Rpyr_2en)]^+Cl^-\cdot 1.5H_2O$ (**1**) have been determined by X-ray diffraction. The coordination of the $H_2Rpyr_2en$ ligand involves the two phenolate-O and two amine-N atoms in a distorted square-pyramidal geometry. The two pyridine-N atoms are protonated, and a $Cl^-$ atom completes the coordination sphere. Upon coordination, both N-amine atoms of $H_2Rpyr_2en$ become stereogenic centres, and in both molecules of the unit cell of **1** one of the N-amine donors has an (*R*)-configuration, and the other an (*S*)-configuration.

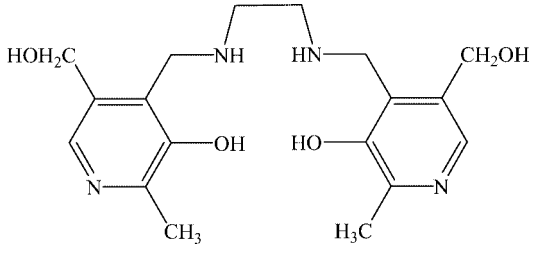
## Introduction

$Sal_2en$-type ligands are known to coordinate several metal ions in different oxidation states and are among the most studied/important ligand systems used in asymmetric catalysis.[1–3] Their reduced derivatives (frequently named tetrahydrosalen or salan ligands),[4] are much less studied and exhibit different structural and chemical properties: the presence of an amine backbone (instead of an imine) results in a more flexible structure that is also more resistant to hydrolysis of the C–N bond. Moreover, the N-amine atoms become stereogenic centres upon coordination, and this may lead to complexes that give a higher enantiomeric excess when used in catalysis.

Despite the interest of zinc $sal_2en$ complexes as models of the active site of carbonic anhydrase and other zinc-containing enzymes,[4–6] they are not easily obtained. Their low solubility in most common solvents is another drawback, and only a few complexes have been characterized by X-ray diffraction. The $Zn^{II}$ ion in these complexes is either five-coordinate with a square-pyramidal geometry[6,7] or has a dinuclear structure.[8] Singer et al.[6] have characterized two mononuclear zinc complexes with $sal_2en$-type SB's (SB = Schiff base) containing a solvent molecule in a fifth coordination position. When using a reduced derivative they obtained a dinuclear arrangement with a trigonal-bipyramidal geometry around the metal ion.

We recently[9] reported the synthesis and characterization of the SB *N*,*N*′-ethylenebis(pyridoxylideneiminato) ($pyr_2en$) and of its reduced derivative *N*,*N*′-ethylenebis(pyridoxylaminato) ($H_2Rpyr_2en$; structure depicted in Scheme 1). Both compounds are vitamin $B_6$ analogues and are water-soluble, and several vanadium-based $Rpyr_2en$ complexes have been prepared and characterized.[9,10] Two molecular structures were obtained for the dioxovanadium(v) complexes[9,10] with $H_2Rpyr_2en$, which emphasises the flexibility of the ligand when coordinated to the metal ion.



Scheme 1. Formula of $H_2Rpyr_2en$ ($H_2L$), which is a water-soluble compound. It may be considered as two pyridoxamine molecules linked by an ethylene bridge. In its fully protonated form the molecule corresponds to $H_6L^{4+}$, and in its totally deprotonated form to $L^{2-}$. As a ligand it may coordinate through the two amine-N and two phenolate-O atoms, either with both pyridine-N atoms protonated ($H_2L$), monoprotonated ($HL^-$), or deprotonated ($L^{2-}$).

Several vanadium complexes have been shown to be insulin mimetics,[11–13] namely vanadium–$Rpyr_2en$ com-

plexes.[9,10,14,15] Zinc–Rpyr$_2$en complexes may also be good candidates as insulin mimetics,[16] and in this work we report the preparation of $Zn^{II}$–$H_2$Rpyr$_2$en complexes and the characterisation of $[ZnCl(H_2Rpyr_2en)]^+Cl^-\cdot 1.5H_2O$ (**1**) by X-ray diffraction. The molecular structure of **1** shows that the $H_2$Rpyr$_2$en ligand is tetracoordinated in a distorted square-pyramidal geometry, with a chlorine atom completing the coordination sphere. The aqueous solution behaviour of the $Zn^{II}$ + $H_2$Rpyr$_2$en system has been studied by pH-potentiometry and $^1$H NMR spectroscopy.

## Results and Discussion

### Synthesis and Characterization

A white solid, which was characterized by elemental analysis and $^1$H NMR and IR spectroscopy, was obtained from an aqueous solution containing $H_2$Rpyr$_2$en and $ZnCl_2$ (1:1) at pH 9.5. The elemental analysis results are consistent with the formulation $Zn(Rpyr_2en)\cdot 5H_2O$. All $^1$H NMR peaks of the compound dissolved in $D_2O$ at pH 7.6 are broad, and only the peaks assigned to $CH_2N$ clearly show two resonances (see Exp. Sect.).

Colourless crystals of $[ZnCl(H_2Rpyr_2en)]^+Cl^-\cdot 1.5H_2O$ (**1**) were obtained from an alcoholic solution containing zinc acetate, $H_2$Rpyr$_2$en and $Cl^-$ (from HCl, which was used to set the pH) and characterized by single-crystal X-ray diffraction. Figure 1 shows an ORTEP diagram with the atom labelling scheme, and Table 1 contains selected bond lengths and angles. The molecule is cationic, with both pyridine N-atoms protonated, and the $H_2$Rpyr$_2$en ligand is tetracoordinated through the two $O_{phenolate}$ and the two $N_{amine}$ atoms. A chloride in the axial position completes the coordination sphere of the metal. The molecule is not planar, but presents a shape similar to an open umbrella. The geometry that best describes the metal centre is square-pyramidal, with the $H_2$Rpyr$_2$en donor atoms occupying the basal plane and the $Cl^-$ the apical position. The flexibility of the ligand can be analysed in terms of the deformation of the $N_2O_2$ plane and the displacement of the zinc ion from it. The rms deviation of the four donor atoms O(1)–N(1)–N(2)–O(2) from planarity is 0.0140(16) Å; the central Zn(1) ion lies 0.5105(17) Å above the plane. These values indicate that there is a significant deformation of the coordination plane, which is greater than in other Zn–sal$_2$en complexes.[5,17] The Zn–$O_{phenolate}$ bond lengths are within the normal range for this type of bonds,[6,18,19] as are the Zn–$N_{amine}$ and Zn–Cl bonds.[6,20,21] Overall, the complex has one positive charge and the counterion is a chloride, which is 7.76 Å away from the zinc centre. The C–O bond lengths are normal for phenolate-O atoms coordinated to zinc (1.318 and 1.296 Å),[18,19] and the C–N distances (1.480–1.483 Å) are typical of single bonds.[6,20] There are no important changes in the C–$N_{amine}$ bond lengths upon coordination to the zinc ion − they increase by less than 0.012 Å − but the C–$O_{phenolate}$ bonds decrease by more than 0.03 Å (0.061 Å for one of them).[9]

Both pyridoxal rings are approximately planar, with rms deviations from the plane of the six atoms of 0.0183(27) and 0.0114(28) Å. The ligand is quite flexible, this being evidenced, for example, by the torsion angles between N(1)–C(2)–C(1)–N(2), C(4)–C(3)–N(1)–C(2) and C(11)–C(10)–N(2)–C(1), which are 57.7(5)°, 168.9(3)° and 176.3(5)°, respectively. Some relevant H-bonds in the crystal packing (see Figure 2) are included in Table 1.

Comparing this structure with that reported for $[Zn^{II}(pyridoxamine)_2(H_2O)_2](NO_3)_2$,[22] several differences become clear, namely i) that the pyridoxamine complex corresponds to an octahedral geometry, and ii) the Zn–$N_{amine}$ bond lengths are shorter than the Zn–O bonds, which is probably due to the different coordination number and to the higher steric requirement in the Zn–$H_2$Rpyr$_2$en complex.

The IR spectra of the Zn–$H_2$Rpyr$_2$en complexes in the powder and crystalline forms are similar. They are quite complex in the 2600–3500 cm$^{-1}$ range, which contains several bands assigned to stretching (symmetrical and asym-

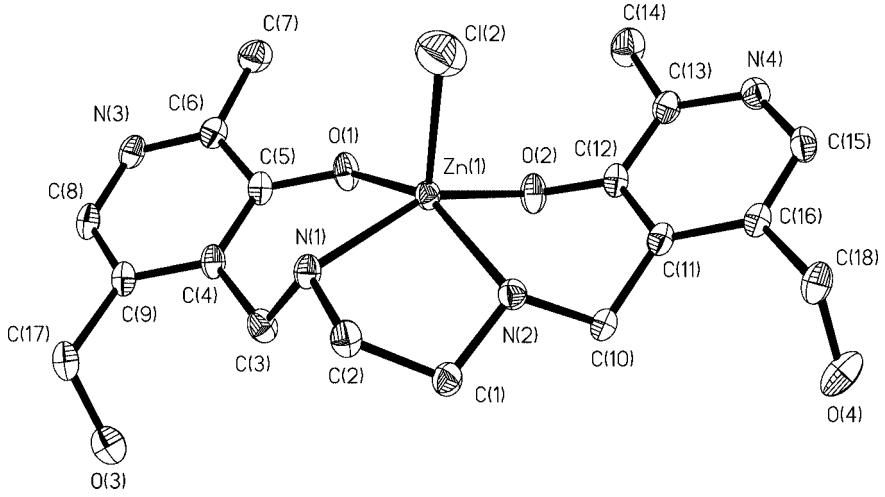

Figure 1. ORTEP diagram of $[ZnCl(H_2Rpyr_2en)]^+Cl^-\cdot 1.5H_2O$ (**1**) showing the atom labelling scheme. The ligand coordinates through the two amine-N and two phenolate-O atoms, with both pyridine-N atoms protonated. The thermal ellipsoids are drawn at 30% probability level. The hydrogen atoms and water molecules are not included, namely those bound to the pyridine N atoms N(3) and N(4).

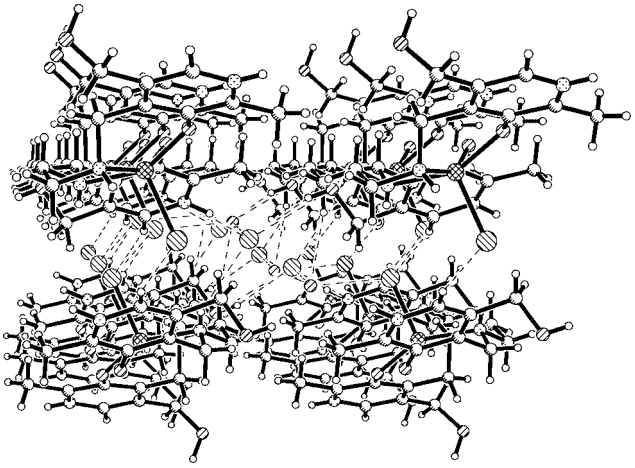

Figure 2. Crystal packing of the $[ZnCl(H_2Rpyr_2en)]^+Cl^-\cdot 1.5H_2O$ molecules, showing the hydrogen-bonding network.

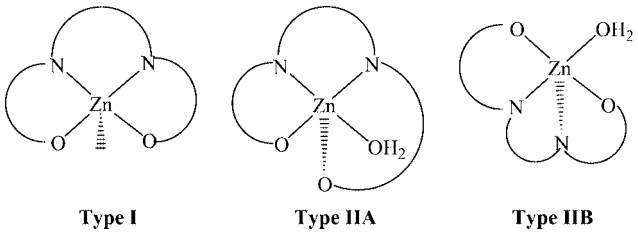
metrical) of the hydrogen-bonded $CH_2O$–H groups of the pyridoxal ring and water molecules.[23,24] The $\nu$(N–H) absorption, which is present in the ligand spectrum at 3286 $cm^{-1}$,[9] appears at 3210 and 3261 $cm^{-1}$ in the crystal and powder complexes, respectively, in agreement with the coordination through the amine-N atoms. The $\nu(C–O)_{phenolate}$ absorptions are in the expected range for this type of compounds at 1294 and 1296 $cm^{-1}$, respectively.[23,24] The two $\nu(N_{pyridine}–H)$ absorptions appear at 3317 and 3340 $cm^{-1}$ in the spectrum of the crystal.

We found[9] that two main types of isomers, which correspond to different energies, form in solution for the $V^{IV}O$– and $V^VO_2$–$H_2Rpyr_2en$ complexes. For the $V^{IV}O$ complexes, two types of binding modes can form, one with the two N-amines and two O-phenolates as equatorial donors, and the other with one of these donor atoms in an axial position, the fourth equatorial donor atom now being an O atom from a water ligand. The two types of isomers give distinct peaks in the EPR spectrum (for the $V^{IV}O$ complexes), and for the $V^VO_2$ complexes two broad $^{51}V$ NMR resonances and two distinct $^1H$ NMR peaks are observed for all H-atoms. If similar isomers were to form in solution for the $Zn^{II}$–$H_2Rpyr_2en$ system (see Scheme 2, type I and type II isomers), we would also expect the observation of distinct $^1H$ NMR resonances for the H-atoms of the isomers with either one O-phenolate (type IIA) or one N-amine (type IIB) in an axial position. However, this is not the case (see below), therefore only one type of isomer forms, namely the one with a binding mode similar to that found for **1**, but with no apical $Cl^-$ donor atom, i.e. type I in Scheme 2. For similar complexes with $[V^{IV}O\{R(SO_3\text{-sal})_2en\}]$ ($SO_3$-sal = salicylaldehyde-5-sulfonate), we have also observed that the isomers with one equatorial $H_2O$ ligand essentially do not form.[10]



Scheme 2. Schematic representation of the main types of isomeric complexes that may form in solution.

As the coordinated N-amine atoms of $H_2Rpyr_2en$ are stereogenic centres, two main types of stereoisomeric complexes may form for the type I binding mode, namely those with both N-amine donors either *R* or *S*, and those with one *S* and one *R*. As found for the $V^{IV}O$– and $V^VO_2$–$H_2Rpyr_2en$ complexes,[9] we could expect that for the $Zn^{II}$–$H_2Rpyr_2en$ system these isomeric complexes also correspond to approximately similar energy. In the $^1H$ NMR spectra of **1** the peaks are relatively broad, and only in the case of the $CH_2NH$ resonances are separate peaks observed.

## Speciation Studies

### *pH-Potentiometry*

The acid–base behaviour of $H_2Rpyr_2en$ and its complex formation with $V^{IV}O$ and $V^V$ have been reported previously.[9] The study of the $Zn^{II}$–$H_2Rpyr_2en$ system by pH-potentiometry and $^1H$ NMR spectroscopy is presented here. The pH-metric titration curves were measured between pH 2.2 and 11.7, and the evaluation was made by considering a model similar to that obtained for the $V^{IV}O$ system, which corresponds to the best model fitting the experimental data. The formation constants are listed in

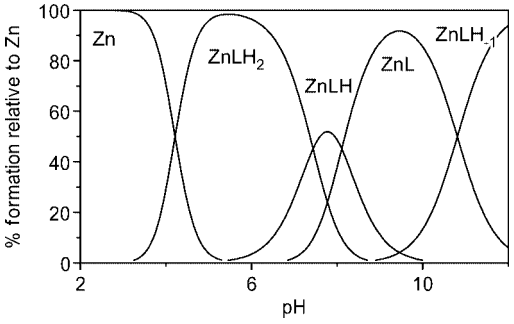

Figure 3. Species-distribution diagram for the complexes formed in the $Zn^{II}$–$H_2Rpyr_2en$ system; $C_{Zn}$ = 2.0 mM and L/M = 2.

Analysis of the potentiometric data with the PSEQUAD program[25] showed the presence of only 1:1 complexes of different protonation states ($[ZnLH_2]^{2+}$, $[ZnLH]^{+}$, [ZnL] and $[ZnLH_{-1}]^{-}$) in the pH range studied. Coordination starts at around pH 4 with the displacement of four protons from the ligand to form $[ZnLH_2]^{2+}$. Further deprotonation, now involving the pyridine-N atoms, results in the progressive formation of $[ZnLH]^{+}$ and [ZnL]. Above pH 10 a hydrolytic species, $[ZnLH_{-1}]^{-}$, becomes important. Upon comparison with the $V^{IV}O$–, $Ni^{II}$– and $Cu^{II}$–$H_2Rpyr_2en$ systems,[9,26] the proton displacement constants ($K$*), which refer to the process $H_6L + M^{2+} \rightleftharpoons MLH_2^{2+} + 4H^{+}$ [$K$*($CuLH_2^{2+}$) = –3.24; $K$*($V^{IV}OLH_2^{2+}$) = –5.63; $K$*($NiLH_2^{2+}$) = –10.08; $K$*($ZnLH_2^{2+}$) = –11.38], give the stability order $Cu^{II} > V^{IV}O > Ni^{II} > Zn^{II}$.

Complexation of $Zn^{II}$ with a hexadentate diacetic acid derivative of $H_2Rpyr_2en$, namely PLED (*N*,*N*′-dipyridoxyethylenediamine-*N*,*N*′-diacetic acid),[27–29] presents a similar speciation, although with a higher stability for the complex formed {$K$*($ZnLH_2$) = –5.33 [$T$ = 25 °C, $I$ = 0.1 M (NaCl)]} due to the hexadentate coordination of the ligand.[29]

### *$^1$H NMR Spectroscopic Studies*

The acid–base properties and the protonation scheme of $Rpyr_2en^{2-}$ have been studied by $^1$H NMR spectroscopy and pH-potentiometry previously.[9] The formation of H bonds between the phenolic and the amino groups is favourable as the phenolic protons are quite acidic and are even more acidic than those of pyridoxamine.[9] Figure 4 shows the ligand, the atom labelling scheme used in the $^1$H NMR spectra and the pH-dependence of the chemical shifts for solutions containing a total $Zn^{II}$ concentration ($C_{Zn}$) of 4 mM and a ligand-to-metal (L/M) ratio of 2.

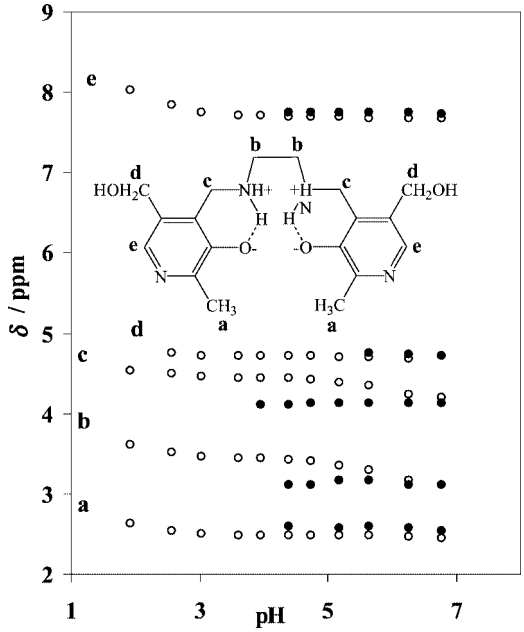

Figure 4. pH-dependence of the chemical shifts ($\delta$ in ppm) of the ligand protons in the absence (open circles) and the presence of $Zn^{II}$ ion (L/M = 2, full circles); $C_{ligand}$ = 8 mM. The $H_2Rpyr_2en$ molecule and the proton-labelling scheme are also depicted in the figure.

The complex formation of $H_2Rpyr_2en$ with $Zn^{II}$ was also studied by $^1$H NMR spectroscopy by measuring spectra at room temperature for L/M ratios of 1 and 2, with $C_{Zn}$ = 4 mM. Below pH 4 no complexes could be detected in solution, all peaks being directly assignable to the free ligand. At a pH of around 4, however, where complex formation starts (see Figure 3), the peaks broaden, then new, slightly shifted peaks appear for all protons (see Figure 5), i.e. separate peaks can be ascribed to protons in the free and the complexed ligand, suggesting an exchange that is somewhat slower than the NMR timescale. The peaks of protons **a**, **e** and **d** in the complexes are slightly deshielded relative to the ligand, while protons **b** and **c** are shielded. Precipitation occurs above pH 7. This is probably due to the higher concentrations used in the $^1$H NMR titrations. Moreover, while in the pH-metric titrations the equilibrium was reached very rapidly, in the $^1$H NMR titrations a few minutes were required to stabilize the pH readings.

Due to the presence of the amine bonds (instead of imine as in $sal_2en$-type ligands) $H_2Rpyr_2en$ is a more flexible molecule and its coordination does not yield similarly symmetrical complexes. As mentioned above, the coordinated amine-N atoms of $H_2Rpyr_2en$ are stereogenic centres, and for binding mode I (Scheme 2) several stereoisomers may

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

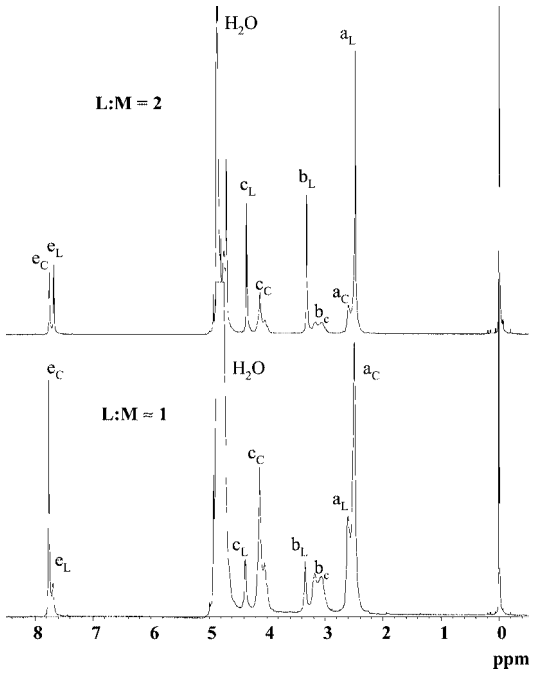

Figure 5. $^1$H NMR spectra for solutions containing $Zn^{II}$ ($C_{Zn}$ = 4 mM) and $H_2Rpyr_2en$ at pH 5.47. The approximate L/M ratios and the peak assignments are indicated. See Figure 4 for the proton-labelling scheme. The subscripts L and C mean free and coordinated ligand, respectively. For the spectrum shown at L/M ≈ 1, a small excess of ligand is present.

form as both amine donors may be either *R* or *S*, or both *S*, or both *R* (three isomers for $ZnLH_2$ and ZnL stoichiometries and four for the ZnLH stoichiometry).

This is probably the reason why two peaks are observed for the protons of the $CH_2CH_2$ and $CH_2N$ groups in the coordinated ligand. The intensity ratios of these peaks are not clear as some are broader than others, and they strongly overlap, but from the NMR spectra the intramolecular non-equivalence of these protons is clear.

Overall, and despite some different experimental conditions (e.g. ionic strength, equilibrium time and concentrations), the spectroscopic results confirm the pH-metric data obtained for the $Zn^{II}$–$H_2Rpyr_2en$ system.

## Conclusions

The coordination of $Zn^{II}$ to $H_2Rpyr_2en$ has been investigated. The complexes have moderate solubility in aqueous solution. The compound $[ZnCl(H_2Rpyr_2en)]^+Cl^-\cdot 1.5H_2O$ (**1**) has been characterized by single-crystal X-ray diffraction, thereby confirming the flexibility of the reduced Schiff base as compared with the Schiff base $pyr_2en$. In the molecular structure of **1**, one of the coordinated amine-N atoms has an (*S*)-configuration and the other an (*R*)-configuration. All combinations of these configurations presumably occur in solution, and in the $^1$H NMR spectra either broader peaks and/or two distinct resonances are observed for the hydrogen atoms of the coordinated ligand, namely for the H atoms of the $CH_2NCH_2CH_2NCH_2$ moiety. The $H_2Rpyr_2en$ ligand in **1** is coordinated through the two phenolate-O and amine-N atoms in a distorted square-pyramidal geometry. To the best of our knowledge this is the first example of a monomeric $Zn^{II}$–reduced salen-type SB that does not dimerize. The solution studies have revealed the high stability of the $Zn^{II}$ complexes formed, although they are less stable than those formed by $H_2Rpyr_2en$ with $Cu^{II}$, $Ni^{II}$ or $V^{IV}O$. Vanadium and copper complexes with chiral $sal_2an$ type ligands are presently being tested for catalytic asymmetric synthesis. The additional stereogenic centres formed upon coordination of the N-amine donors may favour higher enantiomeric excesses in some of these catalytic systems.

## Experimental Section

**$H_2Rpyr_2en$:** The synthesis of this ligand has been reported previously.[9]

**$[Zn(Rpyr_2en)]\cdot 5H_2O$:** $H_2Rpyr_2en$ (66mg, 0.18 mmol) was dissolved in 10 mL of $H_2O$ containing a few drops of 1 M HCl. $ZnCl_2$ (10.2 mL of a 0.0156 M solution) was added and the pH adjusted to 9.5 with 1 M KOH. The solution was stirred for one hour, and a white precipitate was removed by filtration, washed with ethanol and diethyl ether and dried under vacuum. $C_{18}H_{24}N_4O_4Zn\cdot 5H_2O$ (515.9): calcd. C 41.91, H, 6.64, N 10.86; found C 42.2, H 7.0, N 10.7. $^1$H NMR (300 MHz, $D_2O$, 25 °C, pH 7.63): $\delta$ = 7.67 (s, 2 H, $CH_{arom}$), 4.66 (s, 4 H, $CH_2OH$), 4.02 (d, $J$ = 0.1 Hz, 4 H, $CH_2N$), 3.09 (s, 4 H, $CH_2CH_2$), 2.38 (s, 6 H, $CH_3$) ppm.

**Crystals of $[ZnCl(H_2Rpyr_2en)]^+Cl^-\cdot 1.5H_2O$ (1):** $H_2Rpyr_2en$ (0.20 g, 0.55 mmol) was dissolved in a mixture of ethanol and water (1:1, 5 mL) containing a few drops of 1 M NaOH, and $Zn(CH_3COO)_2\cdot 2H_2O$ (0.12 g) dissolved in 5 mL of water was slowly added. The pH was adjusted to 7 by addition of a 1 M HCl solution. The mixture was then refluxed at 70 °C for 2 h. No precipitation was observed and the solution was cooled and kept at about 5 °C. After about one month colourless crystals were collected for single-crystal X-ray analysis.

**X-ray Crystal Structure Determinations:** X-ray data were collected on a Bruker SMART 1000 CCD diffractometer by the $\varphi$–$\omega$ scan method at room temperature. Reflections were measured for a hemisphere of data with frames covering 0.3° in $\omega$. Of the 7285 reflections measured, all of which were corrected for Lorentz and polarization effects and for absorption by semi-empirical methods based on symmetry-equivalent and repeated reflections, 3949 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. Complex scattering factors were taken from the program package SHELXTL.[30] The structure was solved by direct methods and refined by full-matrix least-squares methods on $F^2$. The hydrogen atoms were left to refine freely, except the hydrogen atoms H3, H7A, H7B, H7C, H14A, H14B and H14C, which were included in calculated positions and refined in a riding mode. Refinement converged with allowance for thermal anisotropy of all non-hydrogen atoms. Crystal data and details on data collection and refinement are summarized in Table 3.

CCDC-276399 (for **1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Physical and Spectroscopic Studies:** IR spectra were recorded with a BioRad FTS 3000 MX FTIR spectrometer. $^1$H NMR spectra were recorded with a Varian Unity 300 spectrometer at a probe temperature of about 25 °C.

**pH-metric Titration:** Protonation and formation constants were determined by pH-metric titration of 25-mL samples. The ionic strength was adjusted to 0.2 M with KCl and the temperature was 25.0 ± 0.1 °C. The ligand concentrations were 0.002 or 0.004 M and the L/M ratios varied from 1 to 4. Titrations were normally carried out from pH 2.2 up to 11.7, with carbonate-free KOH solution of known concentration (ca. 0.2 M) under purified argon. The $Zn^{II}$ stock solution was prepared by dissolving ZnO of *puriss.* quality in excess HCl solution. The $Zn^{II}$ content was determined gravimetrically from the oxinate. The free-acid content was measured by pH-potentiometry. An automatic titration set including a Dosimat 665 autoburette, an Orion 710A precision digital pH-meter and an IBM-compatible computer was used. A Metrohm 6.0234.100 semi-micro combined glass electrode was calibrated for hydrogen-ion concentration as described earlier.[31] The p$K_w$ calculated from strong acid–strong base titration was 13.755 ± 0.010. The concentration stability constants, $\beta_{pqr} = [M_pL_qH_r]/[M]_p[L]_q[H]_r$, were calculated with the aid of the computer program PSEQUAD.[25] When referring to stoichiometries of species present in solution, the normal $M_pL_qH_r$ notation is used, where L = $Rpyr_2en^{2-}$.

**$^1$H NMR Spectroscopy:** All NMR samples were prepared at room temperature immediately before recording the spectra. A quantity of $ZnCl_2$ aqueous solution of known concentration (ca. 0.02 M) was evaporated to dryness and $D_2O$ added and evaporated at least three times to replace the H by D. The samples were prepared in $D_2O$ (99.995% D) by weighing the appropriate amount of ligand and $Zn^{II}$ to give the desired concentration and L/M ratio. The pD values of these solutions were adjusted with DCl and $CO_2$-free NaOD solutions and measured with a Thermo Orion 420A+ pH-meter with a Mettler Toledo U402-M3-S7/200 combined electrode. The microelectrode was previously calibrated with standard buffered aqueous solutions, and the pH was measured directly in the NMR tubes. The pH-meter readings were converted into pD by using the equation pD = pH + 0.40.[32] Two sets of experiments were performed as a function of pH, with metal-ion concentrations of 4 mM and L/M ratios of 1 and 2. The $^1$H NMR chemical shifts were referenced relative to DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) at $\delta$ = 0 ppm. The signal intensities of the NMR resonances were obtained using the program NUTS.[33]

# Heterobimetallic Ruthenium-Cobalt Complexes Containing the Pentamethylcyclopentadienyl or Indenyl Ligand

**Sin Yee Ng,[a] Lai Yoong Goh,*[a] Lip Lin Koh,[a] Weng Kee Leong*[a] Geok Kheng Tan,[a] Suming Ye,[b] and Yinghuai Zhu[b]**

**Keywords:** Heterometallic complexes / Ruthenium / Cobalt / Phosphanes / Indenyl

The salt elimination reaction between $NaCo(CO)_4$ and the ruthenium complexes LRu(diphos)Cl and [(Ind)$Ru(CO)_2Cl$] afforded the Ru–Co bimetallic complexes [$LRu(\mu\text{-}CO)_2(\mu\text{-}diphos)Co(CO)_2$] [L = $C_5Me_5$ ($Cp^*$), diphos = $Ph_2P(CH_2)_nPPh_2$, **3a**: $n$ = 1 , or **3b**: $n$ = 2; **3**: L = $C_9H_7$ (Ind), diphos = $Ph_2PCH_2PPh_2$ ] and [(Ind)$Ru(CO)_2Co(CO)_4$] (**3d**), respectively, in high yields. However, the same reaction with the monophosphane analogue, [(Ind)$Ru(PPh_3)_2Cl$], gave the heterobimetallic complex [(Ind)$Ru(PPh_3)(CO)(\mu\text{-}CO)Co(CO)_3$] (**3e**) in fair yield, together with redox-initiated derivatives $Ru(PPh_3)_2(CO)_3$ (**4e**) and [(Ind)$Co(CO)(PPh_3)$] (**6e**). A similar redox process in the reaction of the dppf analogue, [(Ind)Ru(dppf)Cl] (dppf = 1,1′-diphenylphosphanylferrocene) gave [Ru(dppf)$(CO)_3$] (**4f**) and [(Ind)$Co(CO)_2$] (**6f**), together with a complex salt [(Ind)Ru(dppf)(CO)][$Co(CO_4)$] [**5f·Co(CO)$_4$**].

## Introduction

There has been much research activity on the employment of heterobimetallic complexes in catalysis.[1] The prime motivation for this has been the possibility of cooperative reactivity of adjacent heterometallic centres, which may impart new reactivity patterns significantly different from those of the homobimetallic complexes. Early reports of the superb catalytic efficacy of mixtures of cobalt and ruthenium compounds,[2] and later of ruthenium-cobalt heterobimetallic complexes,[2e] in methanol homologation, had spurred a surge in synthetic and reactivity studies of these complexes.[3,4] When supported on silica, they have also been found to be effective catalysts in hydroformylation.[5]

Synthetic routes to metal–metal bonded heterobimetallic complexes are very well documented;[6] one of the most commonly employed being the displacement of a halide ligand by an anionic metal fragment such as $[Co(CO)_4]^-$. Nevertheless, ruthenium-cobalt heterobimetallic complexes containing a half-sandwich ruthenium moiety have been relatively less studied. Ligands such as cyclopentadienyl (Cp) or Cp* often confer stability on the complexes, and when derivatised can effect changes in properties at the metal centre. The indenyl ligand is of much interest on account of its "indenyl effect", which is primarily a reflection of the ligand's ability to undergo $\eta^5 \leftrightarrow \eta^3$ ring slippage, thereby creating a vacant site on the metal centre without any ligand dissociation. Most of the reported compounds of this class were isolated in low yields, e.g., [(*p*-cymene)Ru$(CO)(\mu_2\text{-}PPh_2)Co(CO)_3$] (30% yield),[3d] [$CpRu(CO)_2$-$Co(CO)_4$] (10% yield),[3a] [$CpRu(PPh_3)_2Co(CO)_4$] (28% yield),[2e] and [$CpRuCo(CO)_3$(R-DAB)] (R = *i*Pr, *t*Bu, DAB = 1,4-diaza-1,3-butadiene) (10% yield).[3f] However, Matsuzaka et al. managed to isolate [$Cp^*Ru(CO)_2(\mu_2\text{-}CO)$-$Co(CO)_3$] in high yield (86%);[3h,7] subsequent substitution by dppm, *t*BuNC and alkynes (HC≡CTol, HC≡$CCO_2$Me) in the presence of $Me_3NO{\cdot}2H_2O$ gave very high yields of the substituted products.

In this paper, we present results from the reactions of various Cp* and Ind complexes of ruthenium with $NaCo(CO)_4$ (**1**), which gave in addition to the anticipated Ru–Co metal–metal bonded complexes, derivatives arising from redox pathways.

## Results and Discussion

Salt elimination reactions between $NaCo(CO)_4$ (**1**), and the ruthenium complexes LRu(diphos)Cl (**2**) [L = Cp*, diphos = $Ph_2P(CH_2)_nPPh_2$, **2a**: $n$ = 1 , or **2b**: $n$ = 2; **2c**: L = Ind, diphos = $Ph_2PCH_2PPh_2$], at room temperature afforded Ru–Co bimetallic complexes [$LRu(\mu\text{-}CO)_2(\mu\text{-}diphos)$-$Co(CO)_2$] (**3**), in 78–85% yields (Scheme 1). The displacement of the halide ligand by the anionic metal fragment $[Co(CO)_4]^-$ is accompanied by the bridging of the diphosphane and two carbonyl ligands across the Ru–Co bond. We note that while [(Ind)$Ru(CO)_2Cl$] (**2d**) reacted with **1** to give the metal–metal bonded complex **3d**, $Cp^*Ru(CO)_2Cl$

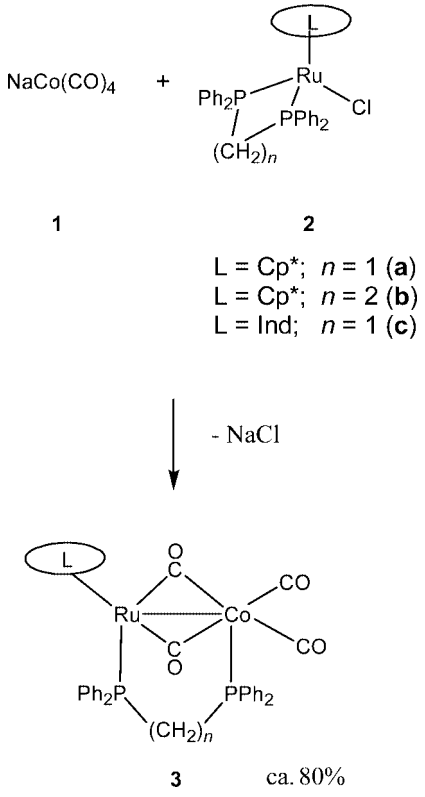
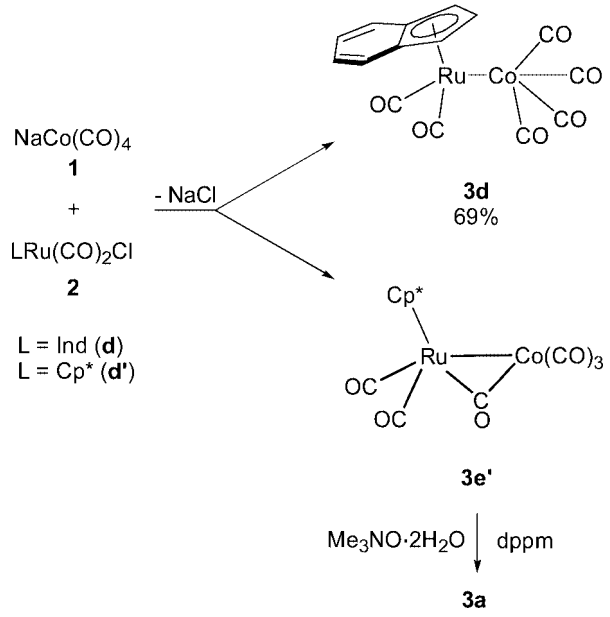
(**2d**′) gave a monocarbonyl-bridged complex **3e**′ (the prime refers to previously reported complexes), which could be decarbonylated to produce **3a** (Scheme 2).[3h]



Scheme 1.



Scheme 2.

The complexes **3a**–**c** exhibited the expected resonances for the diphosphanes and Cp* or indenyl ligands in their $^1$H NMR spectra. Their $^{31}$P{$^1$H} NMR spectra all showed a sharp doublet and a broad doublet at lower field; the latter due to quadrupolar coupling to the cobalt. The IR spectra indicated the presence of both terminal and bridging carbonyls. Complex **3c** has also been characterized by a single-crystal X-ray structural study (Figure 1); that for **3a** has already been reported.[3h] Their molecular structures are very similar in that both comprise a bimetallic complex in which the ruthenium and cobalt atoms are connected by a metal–metal bond, two bridging CO ligands and a bridging diphos ligand. The Ru–Co bond length in **3c** is shorter than that in **3a** [2.6474(4) and 2.677(2) Å, respectively] and probably reflects the weaker indenyl-ruthenium compared to the Cp*–ruthenium interaction; stronger interaction in the latter would be expected to lengthen the metal–metal bond via a *trans* influence. The metal–phosphane bond lengths in both **3a** and **3c** are shorter to cobalt than to ruthenium [Ru(1)–P(3) = 2.3048(6) Å and Co(2)–P(4) = 2.2199(7) Å for **3c**]; these are comparable to the Co–P bond length of 2.175(1) Å in $Co_2(CO)_6(PMe_3)_2$,[8] and the Ru–P bond length of 2.385 Å in $\{Ru_2(CO)_4(PMe_3)_2(\mu\text{-}O_2CCH_2CO_2)\}_2$,[9] and suggest that the difference is due to the different formal oxidation states [Co(0) vs. Ru$^{I}$] since ruthenium and cobalt have the same covalent radii (1.26 Å). However, the reverse situation seems to be the case with regard to the bridging carbonyls.

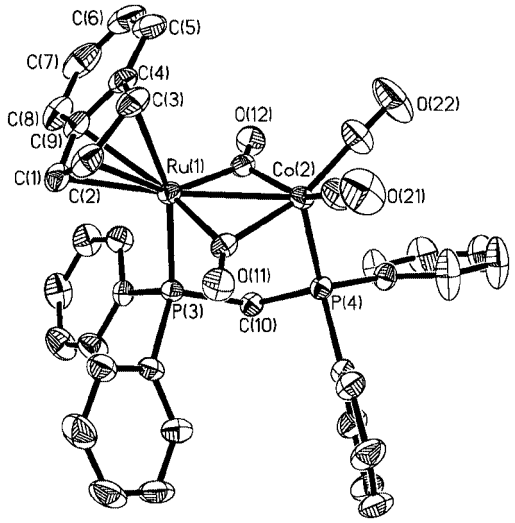


Figure 1. ORTEP diagram (50% probability thermal ellipsoids, hydrogen atoms omitted) and selected bond lengths [Å] and angles [°] of **3c**. Ru(1)–Co(2) = 2.6474(4); Ru(1)–P(3) = 2.3048(6); Co(2)–P(4) = 2.2199(7); Ru(1)–C(11) = 1.947(3); Ru(1)–C(12) = 1.962(3); Co(2)–C(22) = 1.772(3); Co(2)–C(21) = 1.776(3); Co(2)–C(12) = 2.002(3); Co(2)–C(11) = 2.021(3); O(11)–C(11) = 1.170(3); O(12)–C(12) = 1.182(3); O(21)–C(21) = 1.144(4); O(22)–C(22) = 1.130(4); P(3)–Ru(1)–Co(2) = 92.116(18); P(4)–Co(2)–Ru(1) = 99.16(2); Ru(1)–C(11)–Co(2) = 83.69(10); Ru(1)–C(12)–Co(2) = 83.80(10).

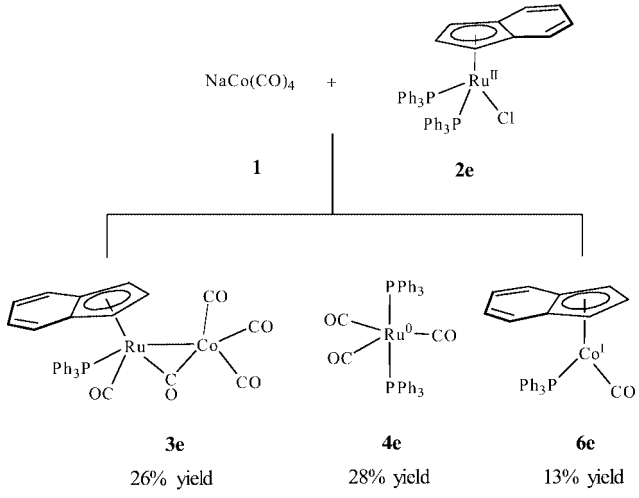
The IR spectrum of [(Ind)Ru(CO)$_2$Co(CO)$_4$] (**3d**) showed clearly the absence of any bridging carbonyl ligand, in contrast to that for the Cp* analogue **3e**′. This may be attributed to the greater electron donating ability of Cp* compared to Ind,[3h] and hence the tendency for the carbonyl ligands to bridge. This tendency is further enhanced by phosphane substitution at the metal centres, as observed in **3a**–**3c**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The analogous reaction of the monophosphane-substituted derivative [(Ind)Ru($PPh_3$)$_2$Cl] (**2e**), however, was more complex (Scheme 3). In addition to the expected heterobimetallic product [(Ind)Ru($PPh_3$)(CO)($\mu_2$-CO)Co(CO)$_3$] (**3e**), there were the mononuclear complexes Ru($PPh_3$)$_2$-(CO)$_3$ (**4e**), and [(Ind)Co(CO)($PPh_3$)] (**6e**). These three compounds have been characterized completely, including by single-crystal X-ray crystallographic studies which confirmed that exchange of CO and $PPh_3$ ligands had occurred between the metal centres. The structure of **4e** determined here in the form of its $CH_2Cl_2$ solvate is essentially similar to that of its THF solvate reported previously.[10] The molecular structures of **3e** and **6e** are shown in Figure 2 and Figure 3, respectively.



Scheme 3.

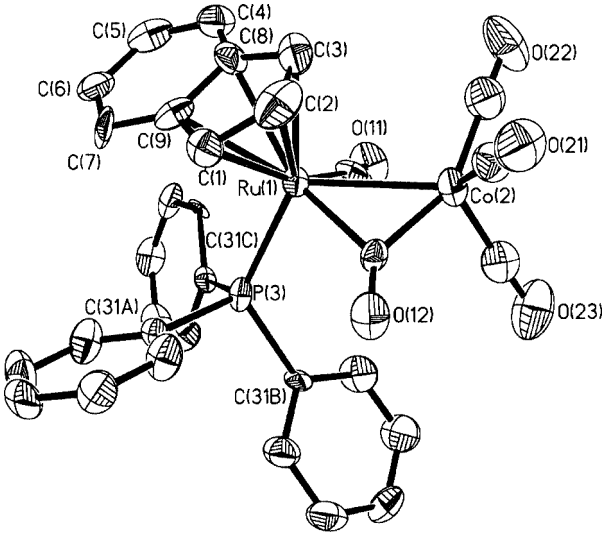


Figure 2. ORTEP diagram of **3e** (50% probability thermal ellipsoids, hydrogen atoms omitted).

There is no known Cp or Cp* analogue to **3e**. However, it is interesting to compare its structure with those of the previously reported Cp* parent carbonyl [Cp*Ru(CO)$_2$($\mu$-CO)Co(CO)$_3$] (**3e′**) and its isocyanide derivative [Cp*Ru(CNBu$^t$)(CO)($\mu$-CO)Co(CO)$_3$] (**3f′**);[3h] a common

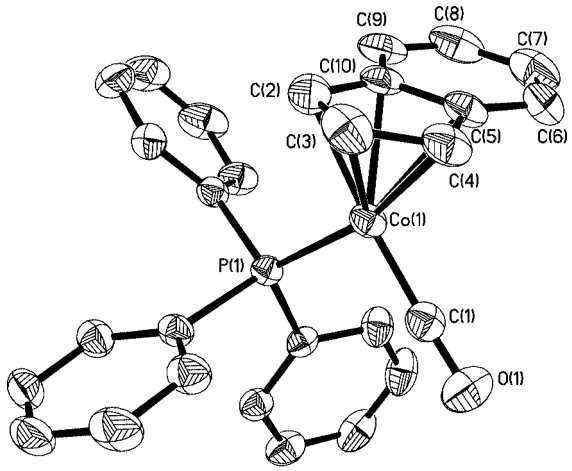

Figure 3. ORTEP diagram (50% probability thermal ellipsoids, hydrogen atoms omitted) and selected bond lengths [Å] and angles [°] of **6e**. Co(1)–C(1) = 1.711(3); Co(1)–P(1) = 2.1459(7); O(1)–C(1) = 1.156(3); C(1)–Co(1)–P(1) = 95.39(9); O(1)–C(1)–Co(1) = 176.3(3).

atomic numbering scheme and selected bond parameters are collected in Table 1. The overall structural features of the three compounds are the same, comprising of a single carbonyl bridging the Ru–Co bond, a terminal carbonyl on the ruthenium, and three on the cobalt. As in the case of **3c**, the Ru–Co bond length for **3e** is significantly shorter than in either of the Cp* analogues [2.677(2) vs. 2.7445(6) and 2.735(4) Å in **3e**, **3e′** and **3f′**, respectively]. The bridging carbonyl is obviously skewed towards the cobalt in all three compounds, as in the case of **3c**. Although there appears to be only one bridging carbonyl in these three compounds, in contrast to two for **3a** and **3c**, the carbonyl which should have made up the second bridging carbonyl [CO(11)] is actually semi-bridging [$\angle$Ru–C(11)–O(11) $\approx$ 167–169°, compared with $\angle$Co–C–O $\approx$ 173–179°].[11] This can be attributed to the presence of an electron-donating phosphorus on cobalt in the case of **3a** and **3c**, which increased electron density on the cobalt and hence the propensity towards bridging carbonyl.[12]

The molecular structure of **6e** is similar to those of known cyclopentadienyl analogues such as [CpCo(CO)$_2$],[13] and [Cp*Co(CO)$_2$],[14] and substituted indenyl analogues such as [($\eta^5$-C$_9$H$_3$Me$_4$)Rh(CO)$_2$],[15] and [($\eta^5$-C$_9$H$_6$CHPh$_2$)-Rh(CO)(P*i*Pr$_3$)].[16] The indenyl ligand is coordinated unsymmetrically to the Co centre, as indicated by the longer bond lengths (by $\approx$ 0.1 Å) from the metal to the bridgehead carbons than to the other three carbons of the five-membered ring. The values of the slip-fold parameters: slip distortion, $\Delta$ = 0.12(3) Å; hinge angle, HA = 5.6°; and fold angle, FA = 5.3°, are in agreement with $\eta^5$ coordination of the indenyl.[15,17]

The presence of the complexes **4e** and **6e** indicated that ligand exchange and redox reaction between the ruthenium and cobalt precursors had occurred. While the oxidation state of Ru has been reduced from +2 to 0 in **4e**, that for Co has been increased from –1 to +1 in **6e**; the ruthenium complex has also lost its indenyl and phosphane ligands in

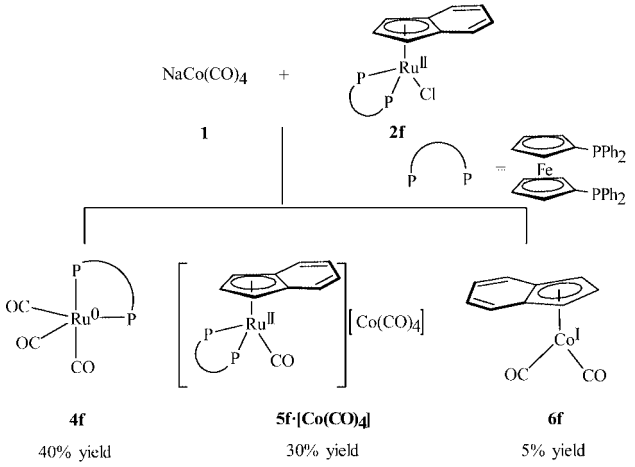
[a] Refers to centroid of the five-membered ring.

exchange for three carbonyls. This result was in sharp contrast with the reported chemistry of the Cp analogue, for which the heterobimetallic complex, viz., $[CpRu(PPh_3)_2Co(CO)_4]$ was isolated in low yield from the reaction of $[CpRu(PPh_3)_2Cl]$ with $TlCo(CO)_4$, but on switching from the $Tl^+$ to the $Na^+$ salt, the complex salt $[CpRu(PPh_3)_2(CO)][Co(CO)_4]$ was isolated instead.[3e] Neither the displacement of $PPh_3$ by CO, nor the redox products that we have observed, were reported in these reactions.

Similar redox chemistry was also observed in the case of [(Ind)Ru(dppf)Cl] (**2f**). However, the heterobimetallic complex was not isolated and instead the complex salt [(Ind)-Ru(dppf)(CO)][$Co(CO_4)$] (**5f·[Co(CO)$_4$]**) was obtained, together with the $Ru^0$ complex $[Ru(dppf)(CO)_3]$ (**4f**) and the known $Co^I$ complex $[(Ind)Co(CO)_2]$ (**6f**) (Scheme 4).[18] The IR spectrum of **4f** exhibited three CO stretching bands (2007, 1924 and 1896 $cm^{-1}$), as opposed to one (1896 $cm^{-1}$) for **4e**. This indicated that they have different symmetries, as was confirmed by an X-ray crystallographic study on **4f** (Figure 4). Complex **4f** adopts a distorted trigonal bipyramidal geometry at the ruthenium atom. The two phosphorus atoms of the diphos occupy an axial [P(1)] and an equatorial position [P(2)].

However, the $^{31}P$ NMR spectrum of **4f** showed only a singlet at $\delta$ = 40.8 ppm, implying fluxionality, as may be expected for a five-coordinate complex. Complex **5f·[Co(CO)$_4$]** was characterized spectroscopically and analytically. Its IR spectrum showed two carbonyl stretches at 1972 and 1889 $cm^{-1}$; very similar to the values for $[CpRu(PPh_3)_2(CO)][Co(CO)_4]$ ($\tilde{\nu}_{CO}$ = 1978 and 1872 $cm^{-1}$).[3e] The cation showed up as a molecular ion in the positive mode of the FAB-MS at *m*/*z* 799, together with fragments corresponding to subsequent loss of a CO and an indenyl ligand, while the anion appeared in the negative mode at *m*/*z* 171.



Scheme 4.

The failure to form the heterobimetallic complex at all in this case was intriguing. We have found that the halide ligand in **2f** could not be substituted by CO in a direct reaction to form [(Ind)Ru(dppf)(CO)]Cl (**5f·Cl**); a mixture of products which were not characterized was obtained instead. However, stirring **2f** under 1 atm of CO and in the presence of $NaPF_6$ afforded **5f·PF$_6$** in high yield; the same product could also be obtained from the reaction of the solvated complex $[(Ind)Ru(dppf)(NCCH_3)]PF_6$ (**7**) with 1 atm of CO (Scheme 5). We therefore believe that in the reaction between **2f** and **1**, the $Cl^-$ ligand was abstracted and this was replaced by the coordination of CO originating from the decomposition of $[Co(CO)_4]^-$. It is this coordination of CO to the Ru centre which inhibits formation of a Ru–Co bond, presumably because of the reduced electrophilicity.

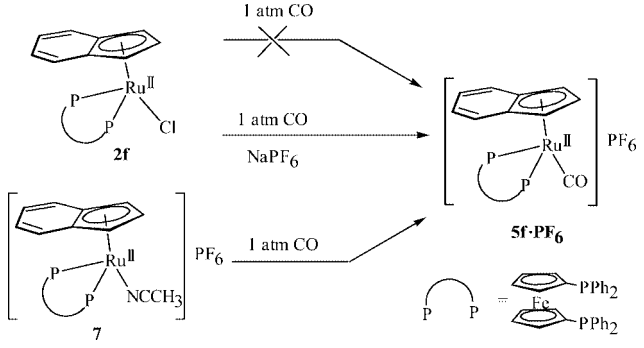

Scheme 5.

## Concluding Remarks

The results above clearly show that the salt elimination reaction between $NaCo(CO)_4$ and Cp* or indenyl ruthenium chloride complexes do not always lead simply to a heterobimetallic species. The nature of the products depends on the nature of the ligands on ruthenium; in some cases, there are redox processes involved. Unfortunately, no clear trend is discernible yet as to when redox processes can become important although it would appear that a suitable diphosphane that can bridge across the heterometallic metal–metal bond is important for stabilization of the heterobimetallic product.

## Experimental Section

**General Procedures:** All reactions were performed under dry nitrogen using Schlenk techniques or under argon in a Braun Labmaster 130 glovebox. Chromatographic separations were performed inside the glovebox. $^1H$, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker ACF300 NMR spectrometer, with chemical shifts referenced to residual non-deuterio solvent and external $H_3PO_4$, respectively. IR spectra were obtained as either KBr pellets or as a solution with a Shimadzu Prestige-21 FTIR-8400S spectrometer. Mass spectra were obtained with either a Finnigan MAT95XL-T (FAB) or a Finnigan MAT LCQ (ESI) spectrometer. All elemental analyses were performed by the Microanalytical Laboratory in NUS. The complexes **1**[19] and **2a**–**f**,[20] were prepared according to published methods. All other reagents are commercially available and used without further purification. All solvents were distilled from standard drying agents before use.

**Reaction of $NaCo(CO)_4$ with [Cp*Ru{$Ph_2P(CH_2)_nPPh_2$}Cl] ($n$ = 1, 2):** To a THF (10 mL) solution of [Cp*Ru($Ph_2PCH_2PPh_2$)Cl] (**2a**) (100 mg, 0.15 mmol) was added a solution of $NaCo(CO)_4$ (**1**) in THF (1 equiv. in 5 mL) by cannula transfer, and the solution was refluxed for 40 h. The solvent was then removed in vacuo and the resulting residue extracted with $CH_2Cl_2$. Removal of the solvent gave an orange-red solid which was recrystallized from THF/hexane to afford [Cp*Ru(μ-$CO)_2$(μ-$Ph_2PCH_2PPh_2$)$Co(CO)_2$] (**3a**) as red crystals. Yield 102 mg (85%). IR (KBr, $cm^{-1}$): $\tilde{\nu}_{CO}$ = 1973 s, 1913 s, 1784 w, 1721 s (lit. values:[3h] (THF) $\tilde{\nu}_{CO}$ = 1985 s, 1923 s, 1728 m). $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 1.60 (s, 15 H, Cp*), 2.14 (t, 2 H, $PCH_2P$), 7.20–7.37 (m, 20 H, Ph) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 55.8 (d, $^2J_{PP}$ = 103 Hz, Ru–P), 43.5 (br. s, Co–P) ppm. MS (ESI): $m/z$ (%) = 791 $[M]^+$, 677 $[M - Co(CO)_2]^+$. $C_{39}H_{37}CoO_4P_2Ru$: C 59.2, H 4.7; formula mass 791.67; found C 59.2, H 5.2. The residue from a similar reaction between **1** and [Cp*Ru{$Ph_2P(CH_2)_2PPh_2$}Cl] (**2b**) was dissolved in a minimum volume of THF for chromatographic separation on silica gel. The main fraction (eluent: hexane/THF, 5.5:1, v/v) gave [Cp*Ru(μ-$CO)_2${μ-$Ph_2P(CH_2)_2PPh_2$}$Co(CO)_2$] (**3b**) as an orange-red solid. Yield 94 mg (78%). IR (KBr, $cm^{-1}$): $\tilde{\nu}_{CO}$ = 1978 s, 1920 s, 1771 w, 1722 s. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 1.60 (s, 15 H, Cp*), 2.04, 1.84 (m, 4 H, $PCH_2CH_2P$), 7.19–7.68 (m, 20 H, Ph) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 45 (s, Ru–P), 34.6 (br. s, Co–P) ppm. MS (ESI): $m/z$ (%) = 806 $[M]^+$, 778 [M – CO], 691 $[M - Co(CO)_2]^+$. $C_{40}H_{39}CoO_4P_2Ru$: calcd. C 59.6, H 4.9; formula mass 805.70; found C 59.9, H 5.2.

**Reaction of 1 with [(Ind)Ru($Ph_2PCH_2PPh_2$)Cl]:** To a THF (10 mL) solution of [(Ind)Ru($Ph_2PCH_2PPh_2$)Cl] (**2c**) (100 mg, 0.13 mmol) was added **1** (1 equiv.) and the solution was stirred at room temp. for 24 h. The solvent was removed under reduced pressure, and the residue was first washed with hexane, followed by extraction with toluene. The toluene extract was concentrated and loaded onto a silica gel column prepared in *n*-hexane. Elution with toluene gave a reddish brown band as the major eluate which afforded [(Ind)Ru(μ-$CO)_2$(μ-$Ph_2PCH_2PPh_2$)$Co(CO)_2$] (**3c**). Yield 97 mg (80%). IR ($CH_2Cl_2$, $cm^{-1}$): $\tilde{\nu}_{CO}$ = 1997 s, 1944 s, 1739 s. $^1H$ NMR (300 MHz, $C_6D_6$): $\delta$ = 2.03 [t, $J$ = 9.06 Hz, 2 H, $CH_2(PPh_2)_2$], 5.18–5.20 (m, 3 H, η$^5$-$C_9H_7$), 6.64–6.67, 6.89–7.01, 7.10–7.14, 7.30–7.36 [m, 24 H, $CH_2(PPh_2)_2$ and η$^5$-$C_9H_7$] ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 44.4 (br. d, $^2J_{PP}$ = 109 Hz, Co–P), 59.3 (d, $^2J_{PP}$ = 109 Hz, Ru–P) ppm. MS ($FAB^+$): $m/z$ (%) = 716 $[M - 2CO]^+$, 657 $[M - 2CO - Co]^+$, 629 $[M - 3CO - Co]^+$, 601 $[M - 4CO - Co]^+$. $C_{38}H_{29}CoO_4P_2Ru$: calcd. C 59.2, H 3.8; formula mass 771.60; found C 59.6, H 3.4.

For the reaction with [(Ind)$Ru(CO)_2$Cl] (**2d**) (30 mg, 0.098 mmol), the hexane extract was concentrated and cooled to –30 °C for 1 day

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to give [(Ind)Ru(CO)$_2$Co(CO)$_4$] (**3d**) (30 mg, 69%) as dark red crystals.

**For 3d:** IR (hexane, cm$^{-1}$): $\tilde{\nu}_{CO}$ = 2067 m, 2022 s, 1986 m, br., 1963 w, br., 1955 w, br. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 4.60 (t, $^3J_{HH}$ = 3.3 Hz, 1 H, $\eta^5$-$C_9H_7$), 4.81 (d, 2 H, $\eta^5$-$C_9H_7$), 6.79 (s, 4 H, $\eta^5$-$C_9H_7$) ppm. $^{13}$C NMR (75 MHz, $C_6D_6$): $\delta$ = 76.5 (s, C1,3), 91.5 (s, C2), 111.1 (s, C8,9), 124.2 and 129.8 (s, C4–7), 204.3 (CO) ppm. MS (FAB$^+$): *m/z* (%) = 444 [M]$^+$, 388 [M – 2CO]$^+$, 360 [M – 3CO]$^+$, 332 [M – 4CO]$^+$. $C_{15}H_7CoO_6Ru$: calcd. C 40.7, H 1.6; formula mass 443.22; found C 40.8, H 1.5.

For the reaction with [(Ind)Ru(PPh$_3$)$_2$Cl] (**2e**), the toluene extract was concentrated and chromatographed on a silica gel column. Elution gave four fractions: (i) A yellow eluate with hexane/toluene (4:1, v/v) yielded [(Ind)Co(CO)(PPh$_3$)] (**6e**) (8 mg, 13%) as air-sensitive dark red crystals after recrystallization from $CH_2Cl_2$/hexane; (ii) an orange-yellow eluate (severe tailing) with hexane/toluene (3:1, v/v) gave [Ru(PPh$_3$)$_2$(CO)$_3$] (**4e**) after several recrystallizations from toluene/hexane (1:4, v/v) (26 mg, 28%); (iii) a reddish brown eluate with hexane/toluene (1:1, v/v) yielded [(Ind)-Ru(PPh$_3$)(CO)($\mu_2$-CO)Co(CO)$_3$] (**3e**) (23 mg, 26%); and (iv) a red eluate with toluene/THF (1:1, v/v) afforded unreacted **2e** (20 mg, 20%).

**For 3e:** IR ($CH_2Cl_2$, cm$^{-1}$): $\tilde{\nu}_{CO}$ = 1975 s, 1920 s, 1744 m. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 4.98 (s, 3 H, $\eta^5$-$C_9H_7$), 6.57–6.93 (m, 4 H, $\eta^5$-$C_9H_7$), 7.03–7.72 (m, 15 H, PPh$_3$) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = 48.6 (s, PPh$_3$) ppm. MS (FAB$^+$): *m/z* (%) = 566 [M – 4CO]$^+$, 535 [M – Co – 3CO]$^+$, 479 [M – Co – 5CO]$^+$. $C_{32}H_{22}CoFeO_5P{\cdot}2C_6H_5CH_3$: calcd. C 64.4, H 4.0; formula mass 816.56; found C 64.1, H 4.2. The presence of toluene solvent has been confirmed by $^1$H NMR spectroscopy.

**For 4e:** IR ($CH_2Cl_2$, cm$^{-1}$): $\tilde{\nu}_{CO}$ = 1896 s (lit. values:[10b] (THF) $\tilde{\nu}_{CO}$ = 1900 s). $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 6.96–7.05 (m, 18 H, PPh$_3$), 7.87–7.93 (m, 12 H, PPh$_3$) ppm. $^{31}$P{$^1$H}NMR: $\delta$ = 55.9 (s, PPh$_3$) ppm.

**For 6e:** IR (KBr, cm$^{-1}$): $\tilde{\nu}_{CO}$ = 1922 s. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 4.61 (s, 2 H, $\eta^5$-$C_9H_7$), 5.67 (t, $^3J_{HH}$ = 3.3 Hz, 1 H, $\eta^5$-$C_9H_7$), 6.74–6.78 (4-lines m, 2 H, $\eta^5$-$C_9H_7$), 6.94–6.97, 6.98–7.01, 7.41–7.48 (each m, total 17 H, PPh$_3$ and $\eta^5$-$C_9H_7$) ppm. $^{31}$P NMR: $\delta$ = 65.6 (br. s, PPh$_3$) ppm. ESI$^+$-MS: 667 [2M – PPh$_3$]$^+$, 405 [2M – 2PPh$_3$]$^+$. $C_{28}H_{22}CoOP{\cdot}\frac{1}{8}CH_2Cl_2$: calcd. C 71.0, H 4.7; formula mass 475.00; found C 70.5, H 4.5. The presence of dichloromethane solvent has been confirmed by $^1$H NMR spectroscopy.

For the reaction with [(Ind)Ru(dppf)Cl] (**2f**), extraction with toluene was followed by extraction with $CH_3CN$. The toluene extract was concentrated and chromatographed on a silica gel column. Elution with hexane/toluene (2:1, v/v) gave a yellow eluate of [(Ind)-Co(CO)$_2$] (**6f**). Yield 4 mg (5%). IR ($CH_2Cl_2$): $\tilde{\nu}_{CO}$ = 2027 and 1970 cm$^{-1}$; lit. values ($CH_2Cl_2$):[18] 2030, 1970. Further elution with hexane/toluene (4:3, v/v) afforded an orange-yellow eluate which gave [Ru(dppf)(CO)$_3$] **4f** after several recrystallizations from toluene/hexane (1:4, v/v). Yield 37 mg (40%). The $CH_3CN$ extract gave [(Ind)Ru(dppf)(CO)][Co(CO$_4$)] (**5f·[Co(CO)$_4$]**) as a dark brown oil. Yield 36 mg (30%).

**For 4f:** IR ($CH_2Cl_2$, cm$^{-1}$): $\tilde{\nu}_{CO}$ = 2007 s, 1924 m, 1896 s. $^1$H NMR (300 MHz, $C_6D_6$): 4.27 (s, 4 H, $C_5H_4$), 4.28 (s, 4 H, $C_5H_4$), 7.02–7.88 (m, 20 H, Ph) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = 40.8 (s, dppf) ppm. MS (FAB$^+$): *m/z* (%) = 740 [M]$^+$, 712 [M – CO]$^+$, 684 [M – 2CO]$^+$, 655 [M – 3CO]$^+$. $C_{37}H_{28}FeO_3P_2Ru$: calcd. C 59.9, H 3.8; formula mass 739.49; found C 60.1, H 3.8.

**For 5f·[Co(CO)$_4$]:** IR ($CH_2Cl_2$): $\tilde{\nu}_{CO}$ = 1972 m, 1889 s cm$^{-1}$. $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 4.37 (s, 2 H, $C_5H_4$), 4.46 (s, 2 H, $C_5H_4$), 4.57 (s, 2 H, $C_5H_4$), 4.61 (s, 2 H, $C_5H_4$), 5.25 (s, 3 H, $\eta^5$-$C_9H_7$), 6.77–7.06 (m, 4 H, $\eta^5$-$C_9H_7$), 7.18–7.71 (m, 20 H, Ph) ppm. $^{31}$P{$^1$H}: $\delta$ = 54.8 (s, dppf) ppm. FAB$^+$-MS: *m/z* 799 [M]$^+$, 771 [M –

$CO]^+$, 655 $[M - CO - Ind]^+$. MS ($FAB^-$): *m/z* (%) = 171 $[Co(CO)_4]^-$. MS (HR-$FAB^+$): *m/z* (%) = 799.0562 (found), 799.0562 (calcd.).

**Synthesis of [(Ind)Ru(dppf)(CO)]$PF_6$**

**Method A:** $NaPF_6$ (5 mg, 0.03 mmol) was added to a solution of **2f** (20 mg, 0.02 mmol) in THF (10 mL). The mixture was subjected to three freeze-pump-thaw cycles, then CO (1 atm) was bubbled through the solution for about 10 min. The reaction mixture was stirred at room temp. for 24 h, during which the colour of the solution changed from red to yellow. The mixture was filtered and concentrated to ca. 2 mL. Addition of ether (5 mL) followed by cooling at –30 °C for 1 d gave [(Ind)Ru(dppf)(CO)]$PF_6$ (**5f·$PF_6$**). Yield 20 mg (85%).

**Method B:** A solution of **7** (20 mg, 0.02 mmol) in THF (10 mL) was degassed by three freeze-pump-thaw cycles, and then saturated with CO (1 atm; bubbling for ca. 10 min). The reaction mixture was stirred at room temp. for 24 h, filtered and then concentrated to ca. 2 mL. Addition of ether (5 mL) followed by cooling at –30 °C for 1 day gave **5f·$PF_6$**. Yield 17 mg (86%). IR (THF, $cm^{-1}$): $\tilde{\nu}_{CO}$ = 1973 s. $^1H$ NMR (300 MHz, $CD_3CN$): $\delta$ = 4.37 (s, 2 H, $C_5H_4$), 4.46 (s, 2 H, $C_5H_4$), 4.57 (s, 2 H, $C_5H_4$), 4.61 (s, 2 H, $C_5H_4$), 5.24 (s, 3 H, $\eta^5$-$C_9H_7$), 6.76–7.06 (m, 4 H, $\eta^5$-$C_9H_7$), 7.18–7.71 (m, 20 H, Ph) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 54.8 (s, dppf), –142.9 (sept, $PF_6$) ppm. MS ($FAB^+$): *m/z* (%) = 799 $[M]^+$, 771 $[M - CO]^+$, 655 $[M - CO - Ind]^+$. MS ($FAB^-$): *m/z* (%) = 145 $[PF_6]^-$. $C_{44}H_{35}F_6FeOP_3Ru$: calcd. C 56.0, H 3.7; formula mass 943.59; found C 56.0, H 3.7.

**Crystal Structure Determinations:** Crystals were grown from dichloromethane/hexane solutions and mounted on quartz fibres. X-ray data were collected with a Bruker AXS APEX system, using Mo-$K_a$ radiation, with the SMART suite of programs.[21] Data were processed and corrected for Lorentz and polarisation effects with SAINT,[22] and for absorption effects with SADABS.[23] Structural solution and refinement were carried out with the SHELXTL suite of programs.[24] Crystal and refinement data are summarised in Table 2. The structures were solved by direct methods or Patterson maps to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. All non-hydrogen atoms were generally given anisotropic displacement parameters in the final model (except for the carbon atoms of the disordered solvate in **4e**). Clusters **3c** and **4e** had one $CH_2Cl_2$ solvate molecule each, which exhibited disorder over two sites. For **3c**, the site occupancies were 0.75 and 0.25; for **4e**, these were 0.9 and 0.1. Appropriate restraints were placed on the atomic anisotropic parameters and bond and interatomic distances.

CCDC 283009–283013 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Dissociation of CP20 from Iron(II)(cp20)$_3$: A Pulse Radiolysis Study

**Martin Merkofer,[a] Anastasia Domazou,[a] Thomas Nauser,[a] and Willem H. Koppenol*[a]**

**Keywords:** Iron / Chelates / Reduction / Electron transfer / Kinetics

Deferiprone (CP20), a hydroxypyridine-4-one, is used in iron-chelation therapy. For the iron(III)-/(II)(cp20)$_3$ couple, a standard electrode potential of –620 mV was measured by cyclic voltammetry [Templeton et al., *Inorg. Chim. Acta* **1996**, *245*, 199; Merkofer et al., *Helv. Chim. Acta* **2004**, *87*, 3021]. On the basis of this value and the overall stability constant for the equilibrium of iron(III) and three CP20 molecules, ligand dissociation ought to take place after reduction of the iron(III)(cp20)$_3$ complex. By pulse radiolysis, we show that hydrated electrons reduce the iron(III)(cp20)$_3$ complex with a rate constant of $k = (6.4 \pm 0.3) \times 10^{10}$ M$^{-1}$ s$^{-1}$, and that the iron(II)(cp20)$_3$ complex aquates rapidly. The dissociation of the first two CP20 molecules takes place within a few μs after the pulse. The dissociation rate constant for the last CP20 ligand is $(8 \pm 1) \times 10^3$ s$^{-1}$. The observation of a dissociation illustrates that, under dilute conditions, iron(II) is not fully complexed by CP20 and could potentially participate in redox cycling to produce oxyradicals. The $CO_2^{\bullet-}$ radical does not reduce iron(III)(cp20)$_3$, which indicates that this complex reacts, as expected, very slowly with inner-sphere reductants.

## Introduction

Iron is essential to life. It is used, transported and stored by specific proteins such as haem proteins, transferrin and ferritin. When, for various reasons, iron is released from these proteins or excessively absorbed from food, it can participate in redox cycling that generates toxic oxyradicals.[1,2]

The bidentate chelating agent CP20 (1,2-dimethyl-3-hydroxypyrid-4(1*H*)-one, also known as deferiprone or L1, Scheme 1) is effective at facilitating iron removal from iron-overload patients when administered orally.[3] It forms five-membered chelate rings in which the metal is coordinated by two vicinal oxygen atoms. This chelating agent is an alternative to the well-established desferrioxamine, which requires intravenous administration. Another orally active drug, tridentate ICL670 (4-[3,5-bis(2-hydroxyphenyl)-1*H*-1,2,4-triazol-1-yl]benzoic acid), is under development.[4] It is generally assumed that these chelating agents are not toxic when the standard electrode potentials of the iron(III)/iron(II) couples are such that they cannot be reduced by ascorbate or oxidised by hydrogen peroxide, that is, below $E°'(Asc^{\bullet-},H^+/HAsc^-) = +282$ mV[5] or above $E°'(H_2O_2,H^+/HO^{\bullet},H_2O) = +370$ mV, respectively. The latter value is based on Gibbs energies of formation of the hydroxyl radical and hydrogen peroxide determined by Schwarz and Dodson[6] and Kern,[7] respectively. This is the case for the electrode potential of the iron(III)-/iron(II)(cp20)$_3$ couple, –620 mV at pH = 11. However, the in vivo conditions are far removed from those of the standard state: the concentration of iron–CP20 complexes is only in the micromolar range, and the pH is much lower than 11. By cyclic voltammetry, we could show that, under dilute conditions, the electrode potentials shift to more positive values, which may occur as a result of dissociation of ligands from iron(II).[8] Indeed, binding data derived from electrode potentials indicate that iron(II) complexes of CP20 are not fully formed at physiological pH and low iron concentration, even when CP20 is present in fivefold excess. We show here by pulse radiolysis that, indeed, the proposed ligand dissociation[8] occurs after rapid reduction of iron(III)(cp20)$_3$ by hydrated electrons.

## Results

### Distribution Diagram of the Iron(II)–(CP20) and Iron(III)–(CP20) Complexes

Speciation diagrams for the iron(II)–(CP20) and iron(III)–(CP20) complexes at 20 μM iron, 100 μM CP20 and pH = 7.2 are shown in Figure 1A and Figure 1B, respectively. As the binding constants $\beta_1$ and $\beta_2$ are not known for iron(II), we assumed that the ratios $\beta_3/\beta_2$ and $\beta_3/\beta_1$ for iron(II) are

similar to those of iron(III). The data for Figure 1A and Figure 1B were obtained from the literature.[8] While iron(III) tightly binds three CP20 ligands at pH = 7 and higher, iron(II) does not. In fact, not even the 1:1 complex of iron(II) and CP20 is fully formed at pH = 7.

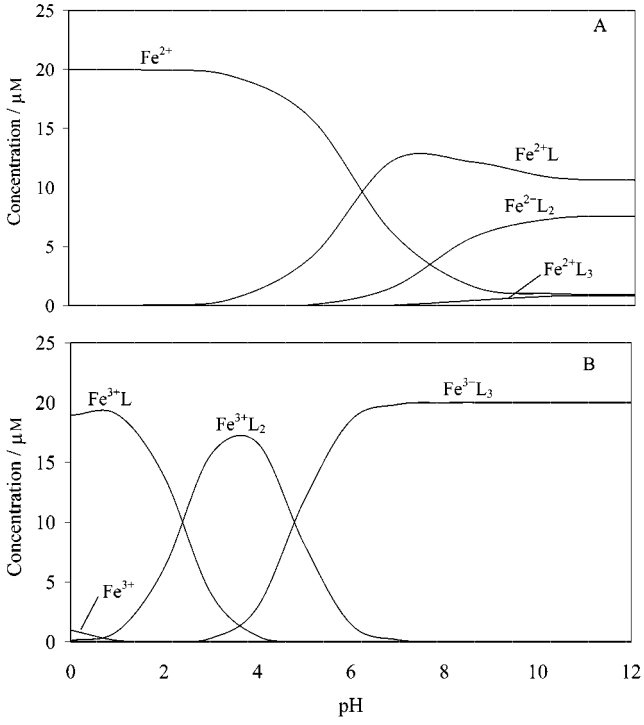

Figure 1. Iron(II) (**A**) and iron(III) (**B**) speciation in the presence of CP20. [CP20] = 100 μM, [$Fe^{2+}$] and [$Fe^{3+}$] = 20 μM. While iron(III) tightly binds three CP20 ligands at pH = 7 and higher, iron(II) does not. The p$K_a$ value used for CP20 is 9.76.[20]

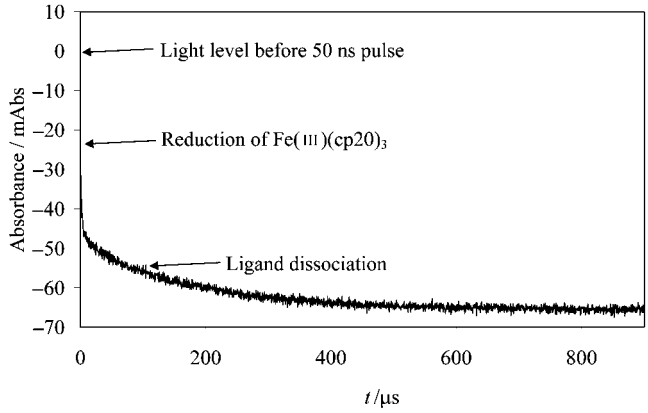

Figure 2. Reduction of $Fe^{III}(cp20)_3$ (100 μM) with hydrated electrons (14 μM) at 450 nm. Reaction conditions: phosphate buffer (5 mM) with *tert*-butyl alcohol (0.1 M) at pH = 7.2 and room temperature. Following rapid reduction, a slower process is observed that is ascribed to ligand dissociation. The reduction with hydrated electrons proceeds quantitatively.

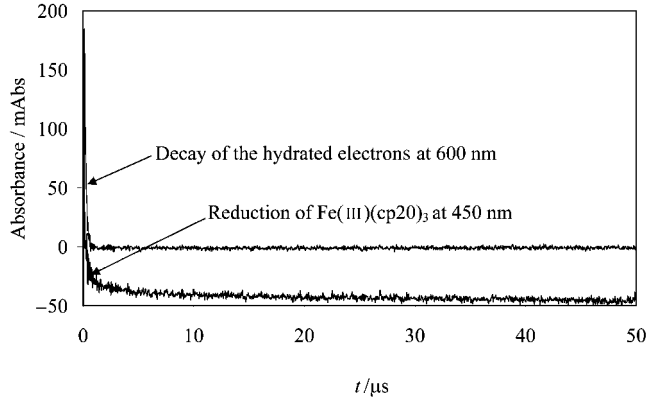

Figure 3. Reduction of $Fe^{III}(cp20)_3$ (100 μM) with hydrated electrons (12 μM) at 450 nm and decay of the hydrated electrons at 600 nm. Reaction conditions: phosphate buffer (5 mM) with *tert*-butyl alcohol (0.1 M) at pH = 7.2 and room temperature. The decay of the hydrated electrons at 600 nm shows the same time-dependence as the fast decay at 450 nm.

### Reduction of the Iron(III)(cp20)$_3$ Complex by $e^-_{aq}$ and $CO_2^{\cdot-}$

Rapid reduction of iron(III)(cp20)$_3$ (100 μM) by hydrated electrons (14 μM) leads to decreases in absorption at 450 nm. The fastest is finished within one μs and the slowest within one ms (Figure 2 and Figure 3). Reduction proceeds quantitatively (Figure 2), based on an extinction coefficient of 4600 $M^{-1}cm^{-1}$ for the iron(III)(cp20)$_3$ complex at 450 nm.[8] These processes are not caused by the presence of *tert*-butyl alcohol (data not shown). The rate of decay of hydrated electrons measured at 600 nm is identical to the rate of the fast process at 450 nm (Figure 3). This rate is first-order in iron(III)(cp20)$_3$ (Figure 4), from which a rate constant of $(6.4 \pm 0.3) \times 10^{10}$ $M^{-1}s^{-1}$ is calculated. The rate of decay of the hydrated electrons measured at 600 nm indicates that the reduction is over within one μs. The change in absorbance at 450 nm during 1 and 3 μs is interpreted as a result of the sequential dissociation of two CP20 ligands. The slow absorbance change after that process, which fits to a single exponential, is attributed to the dissociation of the last ligand, as described in Equation (1). The reaction is strictly first-order, with a reaction rate constant of $(8 \pm 1) \times 10^3$ $s^{-1}$.

$$[Fe^{II}(cp20)]^+ \rightarrow Fe^{2+} + CP20^- \quad (1)$$

Mechanistically, the observed first-order reaction might also be represented by Equation (2) at constant pH.

$$H^+ + [Fe^{II}(cp20)]^+ \rightarrow [Fe^{II}(Hcp20)]^{2+} \rightarrow Fe^{2+} + Hcp20 \quad (2)$$

However, control experiments at pH = 8.6 showed that the rate of reaction is independent of pH; therefore, reaction 2 is not relevant.

Identical results to those with *tert*-butyl alcohol were obtained when methanol was used as a hydroxyl-radical scavenger. Interestingly, dioxocarbonate(·1–), a strong reductant $E°$ ($CO_2/CO_2^{\cdot-}$) = –1.9 V,[9] did not reduce iron(III)(cp20)$_3$ to any detectable degree.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

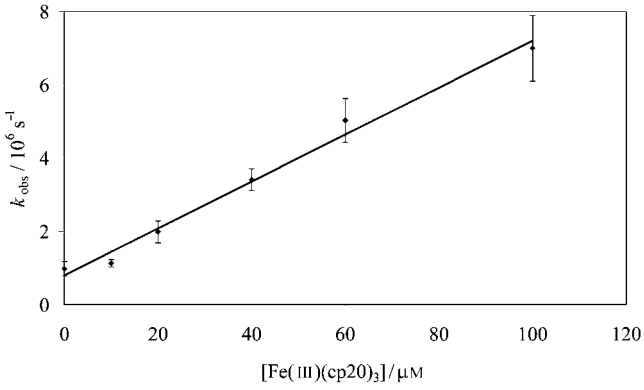

Figure 4. First-order rate constants at various concentrations of $Fe^{III}(cp20)_3$. The reactions with hydrated electrons (5 μM) were carried out at pH = 7.2 and room temperature. The reduction of iron(III)(cp20)$_3$ is linearly dependent on the complex concentration. The bimolecular rate constant is $k = (6.4 \pm 0.3) \times 10^{10}$ $M^{-1} s^{-1}$.

### Oxidation of Iron(II) by Hydrogen Peroxide in the Presence of CP20

The absorbance change of this oxidation, per reducing equivalent, should equal that for the reduction of iron(III)-(cp20)$_3$ by hydrated electrons. To calculate a difference spectrum for the iron(II)- and the iron(III)(cp20) complexes, we mixed a solution of iron(II) (20 μM) and CP20 (100 μM) with hydrogen peroxide (200 μM) at pH = 7.2 and 15 °C (Figure 5). At this temperature, the reaction becomes slower, and the signal-to-noise ratio of the time-dependent spectrum improves. Between 350 and 550 nm, the absorption increase per hydrogen peroxide matches the absorption decrease per hydrated electron in this range, as shown in Figure 6. The hydroxyl radical or oxoiron(IV) formed in the Fenton reaction is scavenged by the Tris buffer. The resulting Tris radical is not expected to re-reduce iron(III)-(cp20)$_3$. Because the iron(II)(cp20) complex can reduce water, it is impossible to prepare solutions of the pure complex: Under anaerobic conditions, in gas-tight syringes as well as in a flask purged with argon, the colour of the iron(II)(cp20) solution changes from light green to light orange within several minutes, indicating the formation of

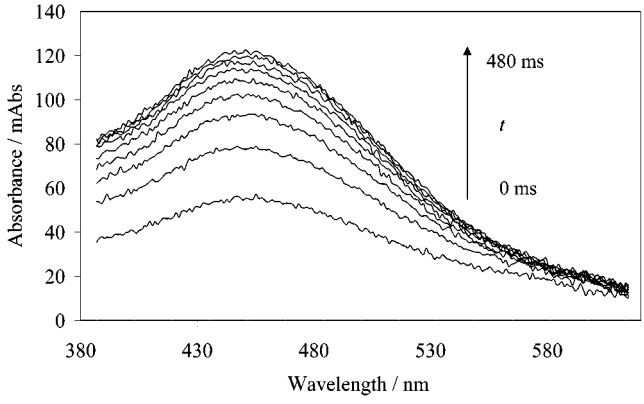

Figure 5. Time-dependent spectrum of the reaction of iron(II) (20 μM) and CP20 (100 μM) with hydrogen peroxide (200 μM) at pH = 7.2 and 15 °C. Formation of the iron(III)(cp20)$_3$ complex.

the iron(III) complex. At high pH values, this process is slower. Hegetschweiler and coworkers[10] reported that the iron(II)–ICL670 complex behaves similarly.

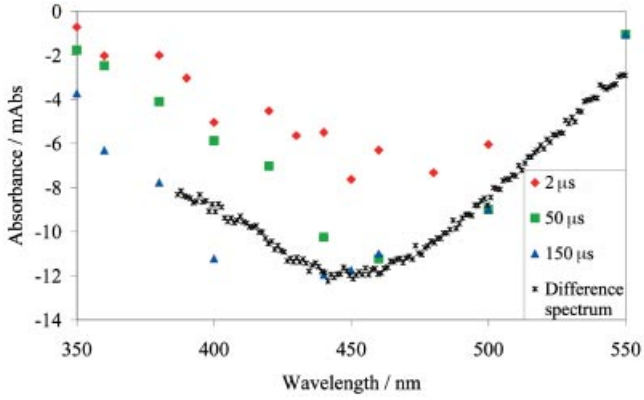

Figure 6. Time-dependent spectra measured by pulse radiolysis (diamonds, squares and triangles) of the reaction of iron(III) (33 μM) and CP20 (100 μM) with hydrated electrons (3.4 μM) at pH = 7.2 and room temperature. The small crosses indicate the difference spectrum of the iron(II)- and the iron(III)(cp20) complex measured by stopped-flow spectroscopy (see text). Per redox equivalent, the final difference spectrum from the pulse radiolysis is equal to that obtained by the stopped-flow technique.

## Discussion

As revealed by the speciation diagrams and as substantiated by kinetics experiments, CP20 stabilises iron(III), but not iron(II), very well. The first-order rate constant for the dissociation of the last CP20 molecule from iron(II) is of the same order of magnitude, $10^4$ $s^{-1}$, as that for the dissociation of a pyridine ligand from a ferriprotoporphyrin in chloroform.[11] CP20 is a bidentate ligand with two hard, oxygen coordination atoms, whereas pyridine is a monodentate ligand with a soft donor atom that stabilises iron(II), which leads to similar stability constants and similar dissociation rate constants. To the best of our knowledge, no other dissociation rates of ligands similar to hydroxypyridinones have been reported in the literature. The solvent-exchange rates for water ($k = 4.4 \times 10^6$ $s^{-1}$),[12] methanol ($k = 5 \times 10^4$ $s^{-1}$)[13] and acetonitrile ($k = 6.6 \times 10^5$ $s^{-1}$)[14] on iron(II) are higher. Given the speciation diagram (Figure 1A), the observed dissociation process involves all three ligands. After dissociation of CP20 from iron(II), monodentate ligands, such as water, bind to the metal ion and exchange much faster than CP20. Consequently, the probability that hydrogen peroxide coordinates to the metal centre and undergoes a Fenton reaction is increased.[15]

It is to be emphasised that the dissociation rate constant is independent of pH, and, therefore, does not result from protonation of the coordinated CP20 ligands. The spectral changes underline that the observed process is also not a dissociation of CP20 from iron(III), because this would result in a red shift, rather than the observed blue shift, of the spectrum.[8]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The reduction of the iron(III)(cp20)$_3$ complex by hydrated electrons is most likely a diffusion-controlled process. Reduction is possible with hydrated electrons, but not with dioxocarbonate(·1–) radicals, although from a comparison of the electrode potential of the iron(III)-/iron(II)(cp20)$_3$ couple (–0.62 V)[8] with that of the carbon dioxide/dioxocarbonate(·1–) couple (–1.90 V), it is clear that reduction is thermodynamically very favourable. This result shows that it is difficult to reduce the iron(III)(cp20)$_3$ complex with an inner-sphere reductant, because accessibility of the metal centre is sterically hindered by the large CP20 ligands. In a pulse radiolysis study of 2-pyridone, Moorthy et al.[16] could reduce the ligand with hydrated electrons, but not with dioxocarbonate(·1–) radicals. They concluded that an electrode potential smaller than –1.90 V is required to reduce 2-pyridone. On the basis of these and our observations, we conclude that the iron(III) is not directly accessible and is reduced via the ligand.

Reoxidation of iron(II) by hydrogen peroxide formed during the irradiation was not detected. This is understandable: if 10 μM iron(II) is produced, 2.5 μM hydrogen peroxide is also formed. Given a reaction rate constant of $10^4$ M$^{-1}$ s$^{-1}$ for the Fenton reaction, the pseudo-first-order rate constant would be ca. $10^{-2}$ s$^{-1}$.

We have shown that reduction by hydrated electrons is followed by ligand dissociation. One might now ask what would happen with more physiologically relevant reductants. El-Jammal and Templeton[17] proposed on the basis of their electrochemical measurements that reduction of iron(III) takes place after dissociation of the complex. We assess here the thermodynamics of two scenarios: first reduction followed by dissociation, and then the opposite. The standard electrode potential of the iron(III)-/iron(II)-(cp20)$_3$ couple is –0.62 V, and reduction by an electron donor with an electrode potential near 0 V "costs" ca. 58 kJ mol$^{-1}$. This process is then followed by favourable ligand dissociation. The dissociation of one CP20 ligand from the iron(III)(cp20)$_3$ complex requires less energy, about 53 kJ mol$^{-1}$, based on the difference between $\beta_3$ and $\beta_2$. In dilute solutions, this Gibbs energy decreases considerably, which makes the "ligand dissociation first" scenario more favourable. Therefore, for biologically relevant conditions, we agree with the proposal of El-Jammal and Templeton.[17]

Iron(II) complexes of other hydroxypyridinones and of ICL670 are also unlikely to be formed, given the similarly low electrode potentials.[8] Previously, a chelating agent with an electrode potential for its iron(III)/iron(II) complex of ca. –470 mV or lower, such as that of iron(III)-/iron(II) desferrioxamine,[18] was considered nontoxic. This hexadentate ligand binds iron(II) well at high dilution, in contrast to bi- and tridentate chelating agents. Iron complexes with bidentate chelating agents are more sensitive to dissociation upon dilution, which causes their electrode potentials to shift to more positive values.[8] Considering that the "free" iron concentration in vivo is about 10 times lower than that used here, one can conclude that CP20 does not bind iron(II) under physiological conditions. Recently, we showed that the electrode potentials of the iron(III)/iron(II) complexes with CP20 and ICL670 are near –150 mV under physiological conditions, and that superoxide is unable to reduce these complexes when they are fully formed. For complexes with less than three CP20 or two ICL670 molecules, reduction is thermodynamically feasible.[8] Electrode potentials of other reducing agents will be discussed in a future communication.

## Experimental Section

All chemicals used were of analytical reagent grade or higher. $Fe(NO_3)_3 \cdot 9H_2O$ was the source of $Fe^{III}$. Hydrogen peroxide stock solutions were prepared from Merck Analyzed Reagent 30% hydrogen peroxide. Water was purified with a Millipore Milli-Q unit fed with deionised water.

For pulse radiolysis, a Febetron 705 (Titan Systems Corp., San Leandro, CA, USA) 2.3-MeV accelerator with a pulse width (full width at half maximum) of <50 ns was used as the radiation source. The optical system consisted of a 75W Xe arc lamp (Hamamatsu, Schüpfen, Switzerland), a 1-cm quartz cell (Hellma GmbH & Co KG, Müllheim, Germany) and an Acton SP300 monochromator (Roper Scientific, Ottobrunn, Germany). For signal detection, there were two options: (1) a R928 photomultiplier (Hamamatsu, Japan) with a DHPCA-200 amplifier (Femto Messtechnik GmbH, Berlin, Germany) and a DL7100 digital storage oscilloscope (Yokogawa Electric Corporation, Tokyo, Japan) for kinetics traces or (2) a Princeton Instruments PI-MAX 512T gateable ICCD-camera (Roper Scientific) for time-resolved spectra. The dose per pulse used was 7–65 Gy, which corresponds to hydrated electron concentrations of 1.8–17 μM.[19] Dosimetry was carried out with thiocyanate.

The primary products from the radiolysis of water are $H^+_{aq}$, $e^-_{aq}$, $HO^\cdot$, $H^\cdot$, $H_2$ and $H_2O_2$. We used *tert*-butyl alcohol (0.1 M) or methanol (0.1 M) as scavengers for $HO^\cdot$ and $H^\cdot$ radicals to produce the fairly unreactive 2-hydroxy-2-methylpropyl- and hydroxymethyl radicals.[19] Solutions for experiments with hydrated electrons contained phosphate buffer (5 mM) and *tert*-butyl alcohol (0.1 M) or methanol (0.1 M), and were evacuated and saturated with argon at least five times.

The dioxocarbonate(·1–) radical was generated by reactions represented by Equation (3) and Equation (4). These solutions were saturated with dinitrogen monoxide (24 mM) and contained formate (50 mM, pH = 8.6).

$$e^-_{aq} + N_2O \rightarrow HO^\cdot + HO^- + N_2 \quad (3)$$

$$HCOO^- + HO^\cdot \rightarrow CO_2^{\cdot-} + H_2O \quad (4)$$

The kinetics of the reduction of the iron(III)(cp20)$_3$ complex and the ligand dissociation were recorded at 450 nm. The decay of the hydrated electrons was followed at 600 nm.

Stopped-flow experiments were obtained with an OLIS stopped-flow instrument (Bogart, GA, USA) equipped with an OLIS RSM 1000 rapid-scanning monochromator set to collect up to 1000 spectra per second. Solutions for the stopped-flow experiments were prepared in Tris buffer (0.1 M), and evacuated and saturated with argon at least five times before addition of iron(II). Hydrochloric acid was used to adjust the pH. The hydrogen peroxide solution was purged with argon for at least 30 min.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Species-distribution diagrams were calculated with the SPEC program (R. Kissner, ETHZ). In SPEC, which was designed to calculate the species distribution in solution equilibria from known formation constants and total concentrations, the Newton–Raphson algorithm is used to solve the system of nonlinear partition equations ("tangential method").

# Structural and Dynamic Studies of Zinc, Gallium, and Cadmium Complexes of a Dicarboxylate Pendant-Armed Cross-Bridged Cyclen

**Weijun Niu,[a] Edward H. Wong,*[a] Gary R. Weisman,*[a] Yijie Peng,[a] Carolyn J. Anderson,[b] Lev N. Zakharov,[c] James A. Golen,[c][‡] and Arnold L. Rheingold[c]**

**Keywords:** Zinc / Gallium / Cadmium / Cyclen / Cross-bridged ligand / Pendant arms

*Inadvertently, the wrong X-ray structure was reported[1] for the Zn-CB-DO2A complex. Instead, the structural data for a related zinc complex was actually presented. The first paragraph of the section X-ray Structural Data and Figure 5 on page 3312, Table 1 on page 3313, the last two sentences of the paragraph [Zn·**1**](NaClO$_4$)$_{1.5}$ and Table 3 on page 3314, and the paragraph X-ray Crystallography on page 3315 should be replaced as follows (in addition, a corrected X-ray CIF file was deposited with the CCDC):*

## X-ray Structural Data

The core structure of the zinc complex [Zn·**1**] is shown in Figure 5. The $Zn^{II}$ cation is fully enveloped within the *cis*-$N_4O_2$ donor set of the cross-bridged ligand in a distorted octahedral geometry. The axial N(3)–Zn(1)–N(4) angle of 156.97(11) [158.36(10)]° (structural data for a second independent molecule are given in brackets) is substantially away from linearity, showing that the $Zn^{II}$ is distended from the cross-bridged cyclen cavity. Previous structural data of zinc complexes of the cross-bridged cyclen and its derivatives have also shown this distention from the ligand cavity with axial N–Zn–N angles between 148 and 159°.[16–18] Another manifestation of these distortions can also be seen in their longer axial N–Zn bonds (2.17–2.26 Å), similar to the average of 2.19 Å found in [Zn·**1**]. All Zn–N and Zn–O bond lengths are within a relatively narrow range of 2.03–2.20 Å. Selected bond lengths and angles are shown in Table 1. An X-ray structure of a DOTA complex of zinc(II) featuring a related *cis*-$N_4O_2$ ligand coordination mode has been reported.[19] This has an axial N–Zn–N angle of 153.9°, an axial Zn–N distance of 2.232 Å, an equatorial Zn–N distance of 2.171 Å, and a shorter Zn–O distance of 2.037 Å. However, without the cross-bridging ethylene, the equatorial N–Zn–N angle is opened up to 107.8° [compared to the 83.6(1)° for N(1)–Zn(1)–N(2) here]. Also, the coordinated carboxylate pendant arms are on the equatorial macrocyclic nitrogen atoms rather than the axial ones and this DOTA structure is thus close to $C_{2v}$ symmetry.

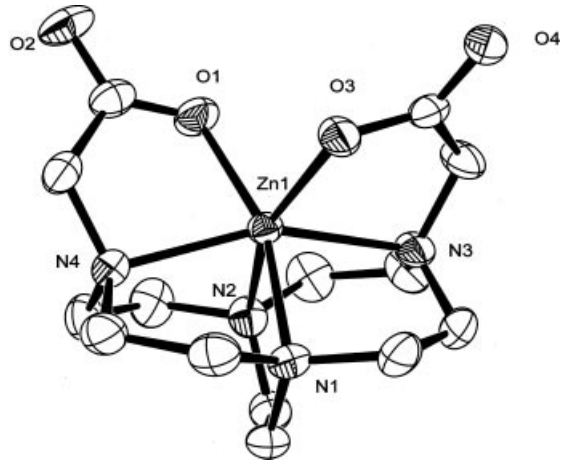

Figure 5. Molecular structure of Zn-CB-DO2A·NaClO$_4$; hydrogen atoms and sodium perchlorate have been omitted for clarity.

X-ray quality crystals were grown by ether diffusion into a sample dissolved in methanol solution. These have a composition of [Zn·**1**](NaClO$_4$)(CH$_3$OH)(H$_2$O).

**X-ray Crystallography:** Diffraction intensity data were collected with Bruker Smart Apex CCD ([Zn·**1**]) and Siemens P4 CCD ([Ga·**1**]NO$_3$) diffractometers. Crystal data collection and refinement parameters are given in Table 3. The structures were solved using direct methods, completed by subsequent difference Fourier syntheses, and refined by full-matrix least-squares procedures on $F^2$. SADABS absorption corrections were applied to [Ga·**1**]NO$_3$ data ($T_{min}/T_{max}$ = 0.724). In both structures all non-hydrogen

## COVER PICTURE

**The cover picture shows** the Mn12 single-molecule magnet (SMM), which has a 3-thiophenecarboxylate ligand and is formed by the ligand substitution reaction of Mn12-ac with 16 equiv. of 3-thiophenecarboxylic acid in toluene. The reaction of Mn12-ac with 17 equiv. of 3-thiophenecarboxylic acid affords a different Mn12 SMM that shows a more distorted structure and has a faster relaxation rate. The Mn12 SMM is strongly anchored on the gold surface through the sulfur atoms of the thiophenyl group. The Mn12 molecular film on Au(111) was characterized by XPS, STM, and AFM. Further details are discussed in the article by J. Kim et al. on p. 711 ff.

# Supported Ionic Liquid Phase (SILP) Catalysis: An Innovative Concept for Homogeneous Catalysis in Continuous Fixed-Bed Reactors

**Anders Riisager,*[a] Rasmus Fehrmann,[a] Marco Haumann,*[b] and Peter Wasserscheid[b]**

**Keywords:** Ionic liquids / Supported catalysts / Immobilisation / Homogeneous catalysis / Hydroformylation

Applications of ionic liquids to replace conventional solvents in homogeneous transition-metal catalysis have increased significantly during the last decade. Biphasic ionic liquid/organic liquid systems offer advantages with regard to product separation, catalyst stability, and recycling but utilise in the case of fast chemical reactions only a small amount of expensive ionic liquid and catalyst. The novel Supported Ionic Liquid Phase (SILP) catalysis concept overcomes these drawbacks and allows the use of fixed-bed reactors for continuous reactions. In this Microreview the SILP catalysis concept is surveyed by presenting results for the continuous gas-phase hydroformylation of propene, as a reaction example.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

In the last decade, ionic liquids have been studied extensively as alternative solvents for homogeneous catalysis.[1] Their ionic nature, nonvolatility, and thermal stability make them highly suitable for biphasic ionic liquid/organic liquid transition-metal catalysis.[2] The almost unlimited combinations of cation and anion allow the synthesis of tailor-made ionic liquids that can stabilise the catalytic species.[3] Moreover, appropriate ionic liquids can enhance substrate solubility while possessing low product solubility, and thus facilitate simple product separation and complete catalyst recovery.[4]

Biphasic ionic liquid/organic liquid systems generally require a large amount of ionic liquid. On the basis of economic considerations this is unattractive since ionic liquids remain relatively expensive even though they are now commercially available.[5] In addition, the high viscosity of ionic liquids can induce mass transfer limitations if the chemical reaction is fast, causing only a minor part of the ionic liquid and precious transition metal catalyst dissolved therein to take part in the catalysed reaction. This problem can, however, to some extent be circumvented by intense stirring to create smaller droplets with a larger reaction surface. This, on the other hand, necessitates a high energy input due to the viscosity of the ionic liquid and makes continuous processes economically unviable. Thus, in contrast to the conventional ionic liquid/organic liquid biphasic systems, an ideal catalyst system would consist of a bulk catalyst phase having the size of the diffusion layer, which allows all the available metal complexes and ionic liquid to be involved in the catalytic reaction. Additionally, solid catalyst systems would allow application of continuous-flow-operated fixed-bed processing.

A "heterogenised" type of homogeneous ionic liquid catalyst system, described as Supported Ionic Liquid Phase (SILP) catalysts, has recently been introduced and examined by us and other research groups for hydroformylation[6,7] (Rh-catalysed), carbonylation[8] (Rh-catalysed), hydrogenation[9] (Rh-catalysed), Heck reactions[10] (Pd-catalysed), hydroaminations[11] (Rh-, Pd-, and Zn-catalysed) and epoxidation[12] (W-catalysed). In these SILP systems, a thin film of ionic liquid containing the homogeneous catalyst is immobilised on the surface of a high-area, porous support material, as depicted in Figure 1.

In SILP catalysts the combination of high solvent polarity combined with nonvolatility [in contrast to water in Supported Aqueous Phase (SAP) catalysis], ensures that the catalytic species remain dissolved also in continuously operated reactions. Furthermore, the combination facilitates separation of the catalyst phase from the organic product

phase in contrast to many traditional organic liquid Supported Liquid Phase (SLP) catalysts. In addition, the high dispersion of the ionic liquid/catalyst solution on the support surface results in a very efficient use of ionic liquid, reducing the necessary amount of the precious catalyst and the ionic liquid required. Consequently, SILP catalyst systems offer significant advantages compared to biphasic catalysis in organic liquid/ionic liquid mixtures and to current SLP and SAP catalyst systems.

Despite the important advantages mentioned above it should be realised, however, that the use of SILP catalysts in most cases is limited to gas-phase applications. For liquid-phase reactions even a minor ionic liquid solubility in a liquid feedstock/product mixture can be sufficient to remove the catalyst from the carrier over time in both continuously operated or batch processes upon catalyst recycling (due to the very small amount of ionic liquid on the support). Even worse, the thin immobilised catalyst layer can physically be removed from the support by mechanical forces, for example, by a convective liquid flow.

One of the first examples of liquid SILP catalysis, where the problems of leaching became evident, was reported by Mehnert and co-workers on the hydroformylation of 1-hexene in batch autoclave mode.[6] They immobilised the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate ([BMIM][$PF_6$]) by covalent bonding (through pendant silyl groups) to the chemically modified surface of a silica gel. Two monodentate phosphane ligands, tris(*m*-sulfonylphenyl)phosphane trisodium salt (TPPTS) and tris(*m*-sulfonylphenyl)phosphane tris(1-butyl-3-methylimidazolium) salt (TPPTI) were used for ligand modification of the rhodium precursor Rh(acac)$(CO)_2$. The activity of the obtained Rh/SILP catalysts was almost three times higher than for comparable biphasic systems and was attributed to a higher rhodium concentration at the large reaction interface. However, at higher conversions significant rhodium leaching occurred accompanied by significant depletion of the supported ionic liquid layer. Recently, Rh–TPPTS/SILP catalysts have also been prepared by immobilising the complexes in the ionic liquids [BMIM][$PF_6$], [BMIM][$BF_4$], and

*Anders Riisager was born in Glostrup, Denmark in 1973. He finished his Master studies in chemistry at the University of Copenhagen in 1999 with a thesis on metal-templated amino acid synthesis. In the same year he started his Ph.D. on immobilisation of biphasic hydroformylation catalyst systems by use of SAP and SILP methodologies at the Interdisciplinary Research Center for Catalysis (ICAT) and Department of Chemistry at the Technical University of Denmark with Prof. Rasmus Fehrmann. In the period 2002–2005 he continued the work on SILP catalysis and examined other phase-separable ionic liquid systems in a postdoctoral research project with the group of Prof. Peter Wasserscheid at RWTH Aachen (later University of Erlangen-Nürnberg), Germany. Currently he is employed as Assistant Professor at the Department of Chemistry, Technical University of Denmark, where his main research interests are focused on further developments of the concept of supported ionic liquid phase catalysis.*

*Rasmus Fehrmann was born in Denmark in 1948. He studied Chemical Engineering at the Technical University of Denmark (DTU), where he received his master degree (M.Sc. Eng.) in 1973 and his Ph.D. degree in 1976 at the Department of Chemistry. In 1977 and 1979 he was awarded candidate and senior scholarships, respectively, from DTU and during the years 1981–1985 he held postdoctoral positions at the Institute of Catalysis, Novosibirsk (Russia), Université de Provence, Marseille (France), and University of Patras (Greece) in addition to periods at the Department of Chemistry, DTU, where he has been Associate Professor since 1986. In 1997 he was visiting professor at Georgia Institute of Technology (USA), and since 2000 he has been a member of the Danish National Committee for Chemistry. Administratively, he has been a member of the board and assistant head of the Department of Chemistry, DTU, since 1987. His main research interests have been in the field of inorganic molten salt chemistry, complex formation in ionic media and, with increasing importance, also within the areas of molten salt catalysis, environmental catalysis, and catalysis in ionic liquids with emphasis on performance and mechanistic understanding of industrial catalysts and model systems.*

*Marco Haumann was born 1969 in Dortmund, Germany. After preliminary studies in mechanical engineering in Dortmund he moved to TU Berlin where he studied chemistry until 1998. He finished his Ph.D. thesis in the group of Prof. Schomäcker on hydroformylation in microemulsions in 2001. In 2002 he started a postdoctoral research project funded by Sasol Technology, Pty, Ltd. at the University of Cape Town (Prof. John R. Moss) aiming at the synthesis of novel cobalt-based catalysts. At the end of 2002 he moved to Rand Afrikaans University in Johannesburg (Prof. Andre Roodt) to study the mechanism of cobalt phosphite catalysed hydroformylation. Since 12/2003 he has been employed as a research assistant in the group of Prof. Peter Wasserscheid. His main research interests are in the field of homogeneous catalyst immobilisation using the Supported Ionic Liquid Phase (SILP) concept and reaction engineering aspects of this innovative technology.*

*Peter Wasserscheid was born 1970 in Würzburg, Germany. He studied chemistry at the RWTH Aachen from 4/1991 till 3/1995. After his Ph.D. thesis with Prof. Willi Keim (10/1995–5/1998) he worked as an industrial post-doc for four months at BP/Sunbury, GB. Returning to RWTH Aachen, he carried out his Habilitation (08/1998–10/2002) at the Institute of Technical and Macromolecular Chemistry (ITMC) entitled "Ionic liquids – a new Solvent Concept for Catalysis". Since 10/2003 Peter Wasserscheid has been full professor for Chemical Reaction Engineering at the University of Erlangen-Nürnberg, Germany. He has been awarded several research prizes including the Carl-Zerbe award of DGMK (2000), the DECHEMA award of the Max-Buchner Forschungsstiftung (2001), and the "Innovation award of the German Industry" (with Solvent Innovation GmbH, Cologne) (2003). Together with Tom Welton he edited the monograph "Ionic Liquids in Synthesis" (Wiley-VCH, 2003). His main research interests are in the field of ionic liquid chemistry and in the application of advanced materials in continuous catalytic processes.*

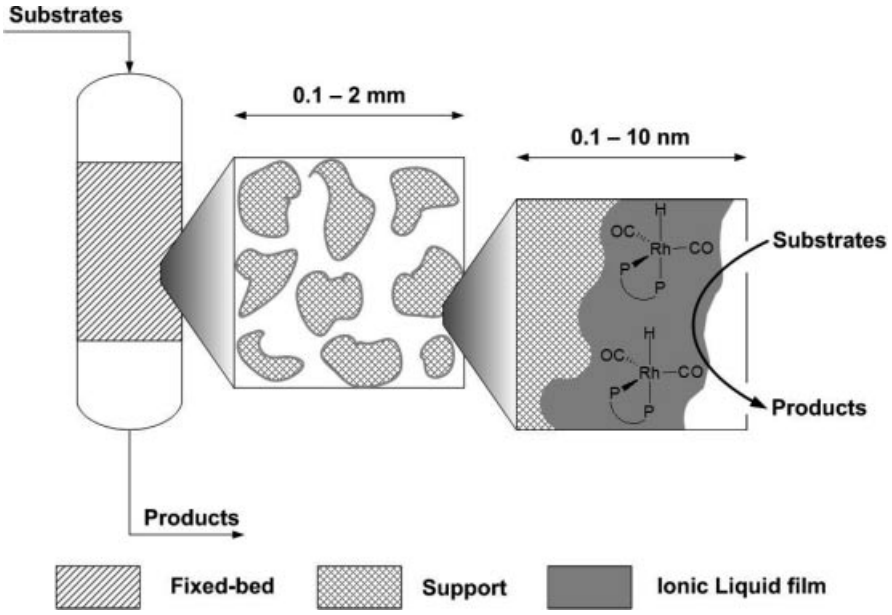

Figure 1. Schematic illustration of Supported Ionic Liquid Phase (SILP) catalysts for fixed-bed reactor technology.

tetramethylguanidinium lactate (TMGL) supported on mesoporous MCM-41.[13] The catalytic performance of these catalysts was investigated in hydroformylation of different alkenes ($C_6$ to $C_{12}$), and the SILP catalysts were further characterised by various methods. $^{31}P$ NMR spectroscopic data revealed that the Rh–TPPTS complex formation in the SILP system occurred in a similar way to that in an aqueous solution, clearly indicating the homogeneous nature of Rh/SILP catalyst systems. Using the specific combination of TMGL ionic liquid and MCM-41 support the leaching problem was here claimed to be negligible, most likely because of the slightly coordinating ability of the ionic liquid to the rhodium atom. Notable, however, in none of the above examples has a combination of good catalyst durability and high product selectivity towards linear aldehyde been demonstrated.

In this Microreview the advantages of SILP catalysis are exemplified for the Rh-phosphane catalysed, continuous gas-phase hydroformylation of propene. The Rh/SILP catalysts employed in the study contained 1-butyl-3-methylimidazolium-based ionic liquids and the phosphane ligands shown in Scheme 1. The involved ligands comprised both mono- and bisphosphanes modified with ionic groups. All the Rh(phosphane)/SILP systems, which can be stored under argon over several months, were prepared using impregnation by dissolving appropriate amounts of catalyst precursor, ligand, and ionic liquid in dried methanol, followed

by addition of dried support material and removal of methanol in vacuo (details about materials and methods are described in previous reports[7,14,15]). The catalysts are characterised by the nature of the support, the ionic liquid loading *α* (ratio ionic liquid volume/support pore volume), the rhodium content (mass ratio rhodium/support) and the molar ligand/rhodium ratio (L/Rh).

The $[Rh(\mu\text{-}CO)(\mathbf{3})(CO)]_2$ precursor **6** (see Scheme 2), dissolved in ionic liquid [BMIM][$PF_6$], has been investigated by van Leeuwen et al. in the hydroformylation of 1-octene.[16] In-situ high-pressure IR and NMR studies indicated that the formation of the active catalyst complex **7** occurred in a similar fashion to the formation in organic solvents.[17] Beside these studies, detailed mechanistic understanding of homogeneous catalysis in ionic liquids is still scarce.[18]

## Catalyst Composition Studies

### Variation of Support Material

As a first approach, different commercially available porous, high-area supports were used to prepare Rh(phosphane)/SILP catalyst systems containing the same type of ionic liquid and ligand content.[14] Table 1 compiles the support characteristics and Figure 2 shows the performance of the Rh(**3**)/SILP catalysts with regard to activity (turn-over frequency, TOF) and aldehyde selectivity (% *n*-butanal).

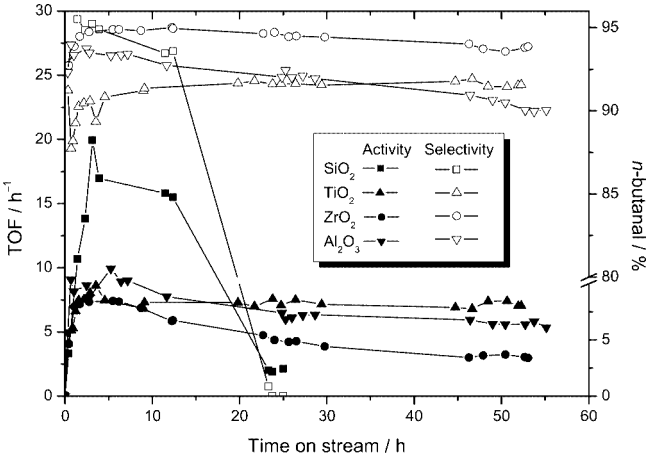

Figure 2. Propene hydroformylation activities and selectivities of Rh(**3**)/SILP catalyst systems.

Among the examined catalysts, the Rh(phosphane)/$SiO_2$/SILP catalysts revealed the highest initial activity (TOF = 21 $h^{-1}$) and selectivity (95% *n*-butanal), but deactivated almost completely within 24 h on stream ending up with very low activity and only half the initial selectivity. The Rh(phosphane)/$Al_2O_3$/SILP and Rh(phosphane)/$ZrO_2$/SILP catalysts had both a lower initial activity and selectivity than the $SiO_2$-based system but deactivated only slightly at prolonged reaction (55 h). The most stable system examined was the Rh(phosphane)/$TiO_2$/SILP catalyst which maintained the initial (but rather poor) performance over 55 h, showing no sign of deactivation. It should be noted that the ionic liquid loading differed for the various systems which made the comparison of the absolute catalyst activities difficult. Though, a trend appeared to be that higher pore volume of the support had a more pronounced effect on the initial activity of the resultant catalyst than the BET surface area. The use of supports with both low pore volume and BET area (i.e. $Al_2O_3$ and $ZrO_2$) apparently resulted in the least active SILP catalysts.

The different SILP catalysts were analysed by FT-IR prior to and after reaction. After short-term reactions, all SILP catalysts revealed CO stretching bands at ν(CO) ≈ 1998 and 1940 $cm^{-1}$, corresponding to the presence of catalytically active $[HRh(\mathbf{3})(CO)_2]$ complexes (examples are shown in Figure 3 for $TiO_2$ catalysts). However, only the FT-IR spectra of the used Rh(phosphane)/$TiO_2$/SILP cata-

lyst exhibited bands at ν(CO) = 1994 and 1936 $cm^{-1}$ after 55 h on-stream. In contrast, the analogous CO bands for the Rh(phosphane)/$SiO_2$/SILP catalyst gradually disappeared after only 4 h in use and were not present after 55 h of reaction.

For all SILP catalysts additional bands in the 1700–2100 $cm^{-1}$ region corresponding to bridging CO ligands, indicative of formation of inactive dimer or cluster compounds, were not observed. Hence, it was concluded that the deactivation was caused by a support effect. Because of the highest initial catalyst activity and selectivity, $SiO_2$ was used as the support material in all further experiments.

### Variation of Ligand and Ionic Liquid

In homogeneous hydroformylation with rhodium–phosphane catalysts the nature of the involved ligands are known to have a large influence on the catalytic performance of the resultant catalyst.[19] Generally, this is attributed to a combination of electronic and steric factors induced by the ligands to the metal atom thereby altering its coordination chemistry.

The effect of the phosphane ligand and of the ligand content (i.e. L/Rh ratio) contained in the SILP catalysts were evaluated by determining the catalytic performance of SILP catalysts containing the different ligands **1**–**3** (see Scheme 1).[7] These ligands are based on triphenylphosphane, bridged phosphinane (both monodentate), and diphenyl-xantphos (bidentate) backbones, respectively. The obtained results are summarised in Table 2.

Table 2. Catalytic performance of Rh(L)/$SiO_2$/SILP systems with different types of ligand and L/Rh ratios.

[a] Ionic liquid loading, $\alpha$ = ratio of ionic liquid volume to support pore volume. [b] Ionic liquid = [BMIM][*n*-$C_8H_{17}O$–$SO_3$]. All other catalysts were based on [BMIM][$PF_6$].

For the monophosphane catalysts the obtained selectivities were significantly lower than for analogous bis(phosphane) catalysts, as expected, with only 47–74% linear aldehyde being formed compared to typically 94–96% for the Rh(**3**) catalyst at identical catalyst composition. Furthermore, an increase in mono(phosphane) ligand content generally resulted in less active but more selective SILP catalysts (e.g. Entries 10 and 13). The effect on the selectivity was, however, less pronounced at very large excess of ligand, i.e. with L/Rh ratio of 21.4 (Entry 13), but remained significantly negative for the activity. Thus, the optimal L/Rh ratio for the mono(phosphane) **2** catalysts was found to be around 10.

The same ligand content trend observed for the catalysts based on ligands **1** or **2** was also observed for the catalysts containing the bidentate ligand **3** (Entries 15, 19, and 21). Additionally, for the Rh(**3**) catalysts with low L/Rh ratios of 2.5 the activity was found to be high only for the ionic-liquid-free system (Entry 14), while selectivities towards linear aldehyde were low in all reactions regardless of ionic liquid loading (Entries 14–16). This catalytic behaviour differed from the one observed with Rh(**3**) catalyst solutions in ionic liquid/organic and aqueous/organic biphasic systems, where catalysts having L/Rh ratios of 5 yielded product linearity > 97%.[20] Increasing the L/Rh ratio to 10 and 20 resulted in high linearities of 94.4–96.0%, similar to the ones for biphasic catalysis. Furthermore, for L/Rh ratios of 10 the activities were reasonably high with TOFs between 25 and 41 $h^{-1}$, depending on the liquid loading (Entries 17–20). Here the optimal L/Rh ratio was also found to be 10, indicating a support–ligand interaction which reduced the effective ligand excess for all three types of ligand-based catalysts. All consecutive experiments were carried out using ligand **3** with an L/Rh ratio of 10.

With respect to the ionic liquid in the catalysts, the ionic liquid [BMIM][$PF_6$] itself was not catalytically active in the hydroformylation (Entry 1), as expected. The degree of pore filling, indicated by the ionic liquid loading ($\alpha$), had, however, a significant effect on the activity of all three catalyst systems applied, revealing a decreasing activity with increasing liquid loading. Thus, for the mono(phosphane) ligand systems the highest initial activity was obtained in the absence of ionic liquid (Entries 2, 6, and 12), which might be attributed to the formation of surface-bound rhodium species exhibiting high activities and to the absence of any mass-transport-limiting factors in these purely heterogeneous catalysts. However, for catalysts with $\alpha$ values about 0.3 (Entries 3 and 7) exceptionally low activities were obtained for ligands **1** and **2**, the reason for this being at present not clear. For Rh(**3**) catalysts the highest initial activity was also obtained in the absence of ionic liquid (Entry 17). Moreover, a linear dependence between the decrease in activity and the ionic liquid loading could be correlated with results from nitrogen absorption studies, where the catalyst pore volume was found to decrease proportionally with the different ionic liquid loadings.[21]

In contrast to the ionic liquid content, the nature of the ionic liquid anion had essentially no influence on the SILP

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

catalyst performance. Thus, upon replacing [BMIM][$PF_6$] with the halogen-free ionic liquid [BMIM][$n$-$C_8H_{17}O$–$SO_3$] similar activities and selectivities were observed (Entries 16 and 23, and 20 and 24). Hence, in consecutive experiments catalysts containing [BMIM][$n$-$C_8H_{17}O$–$SO_3$] were applied, and the ionic liquid loading was maintained at $\alpha = 0.1$ in order to achieve high pore volume and large reaction surface area.

## Catalyst Stability Studies

### Support Pretreatment

From the results obtained in the catalyst composition studies (see above) it became obvious that ligand–support interactions probably were responsible for catalyst instability. In the case of titania catalysts, where the support contained practically no Brønsted acidic sites, long catalyst lifetimes beyond 50 h of reaction were achieved, whereas catalysts based on more Brønsted-acidic silica gel support deactivated relatively fast, indicated by loss of both activity and selectivity. In order to examine the effect of the support acidity, acidic sites on the silica gel support were reduced before use by thermal dehydroxylation of the support (500 °C, 15 h). Subsequently, using dehydroxylated silica catalysts with L/Rh ratio of 10 and ionic liquid loadings of $\alpha = 0.1$, the SILP catalyst systems proved stable over 60 h, as shown in Figure 4 for an Rh(**3**) catalyst.[15]

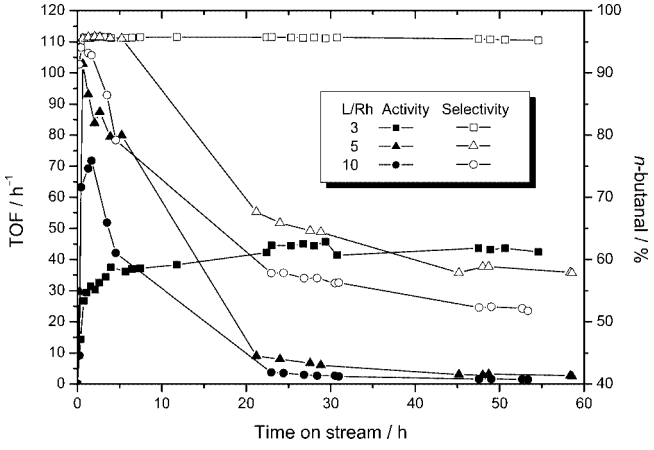

Figure 4. Propene hydroformylation activity and selectivity of Rh(**3**) silica-based SILP catalysts ($\alpha = 0.1$) as a function of **3**/Rh ratios.

The catalytic performance and catalyst stability, however, still proved to be significantly influenced by the ligand excess, as also shown in Figure 4. Rh(**3**) catalysts having low ligand contents (**3**/Rh ratios of 3 and 5) were initially very active compared to the catalyst with **3**/Rh ratio of 10 but less selective, and deactivated furthermore within the first 24 h of reaction resulting in very low catalytic performance (TOF = 4–5 $h^{-1}$, $n$/iso ratio = 1–1.3). In contrast, catalysts with a high ligand content (**3**/Rh ratios ≥ 10) retained the initial catalytic performance with significantly higher activity (TOF = 44 $h^{-1}$) and selectivity ($n$/iso ratio > 20) during prolonged (60 h) reactions. These results clearly indicated that a large excess of ligand was required to obtain a stable SILP catalytic system. Even after the thermal pretreatment, which induced a considerable removal of acidic surface sites, support–ligand reactions apparently still lowered the amount of effective ligand excess necessary for complex formation.

Beside the ligand content, the amount of ionic liquid also influenced the catalytic performance of catalysts based on the pretreated silica support, clearly signifying the importance of the ionic liquid solvent. Thus, varying the amount of ionic liquid loading ($\alpha = 0$–$0.5$), the catalyst systems containing no ionic liquid deactivated rapidly; only 30% of the initial activity and selectivity remained after 60 h of reaction time. The deactivation could be explained by surface diffusion of ligand **3** from the initially Rh-coordinated active state to the stronger surface-bonded state, in which the metal atom was less coordinated to the ligand but possibly more strongly coordinated to the support and thus less active and selective. Evidently, the Rh(**3**)/SILP catalysts required a certain amount of ionic liquid solvent; not only to provide a high selectivity but also to retain long-term stability during continuous processes.

Further, since the hydroformylation product selectivity with respect to aldehydes is known to depend on the available amount of ligand for coordination,[22] the simultaneous decrease in selectivity along with activity indicated that deactivation was closely related to a gradual degradation and removal of ligand from the catalyst complex system. The presence of surface–ligand interaction in the pretreated Rh(**3**) catalyst (**3**/Rh = 10) was confirmed by solid-state MAS $^{31}P$ NMR spectra recorded prior to reaction, as shown in Figure 5. Here, signals corresponding to free ligand ($\delta$ = –13 ppm, 27%), surface-bonded ligand ($\delta$ = –21 ppm, 54%), and complexed ligand ($\delta$ = 31 ppm, 19%) were found.[15]

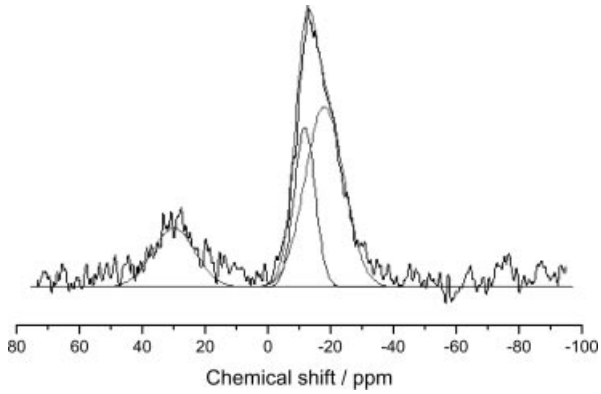

Figure 5. MAS $^{31}P$ NMR spectra and deconvoluted spectra of prepared Rh(**3**)/$SiO_2$/SILP catalyst (**3**/Rh ratio = 10). $\delta_1$ = –21 ppm, 54%, support-bonded **3**; $\delta_2$ = –13 ppm, 27%, **3**; $\delta_3$ = 31 ppm, 19%, complex-bonded **3**.

Additional explanation of the observed catalytic results was obtained from in-situ FT-IR measurements of complex formation at 100 °C and atmospheric pressure. In Figure 6 the FT-IR spectra of the catalyst with **3**/Rh = 10 under (a)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nitrogen, (b) after 15 min, and (c) 30 min exposure to syngas ($CO/H_2$ = 1:1) are shown. They indicate the relatively fast transformation (Scheme 2) from the pale-red dimeric complex [Rh(μ-CO)(**3**)(CO)]$_2$ (**6**) [$\nu$(CO) = 1990 (br.) cm$^{-1}$], which is a nonactive, stable state of the catalyst, to the light-yellow precatalytic monomeric HRh(CO)$_2$(**3**) ea- and ee-isomeric complexes **7-ea** [ν(CO) = 1994, 1948 cm$^{-1}$] and **7-ee** [ν(CO) = 2035 (w), 1964 cm$^{-1}$], which co-exist in dynamic equilibrium.[15]

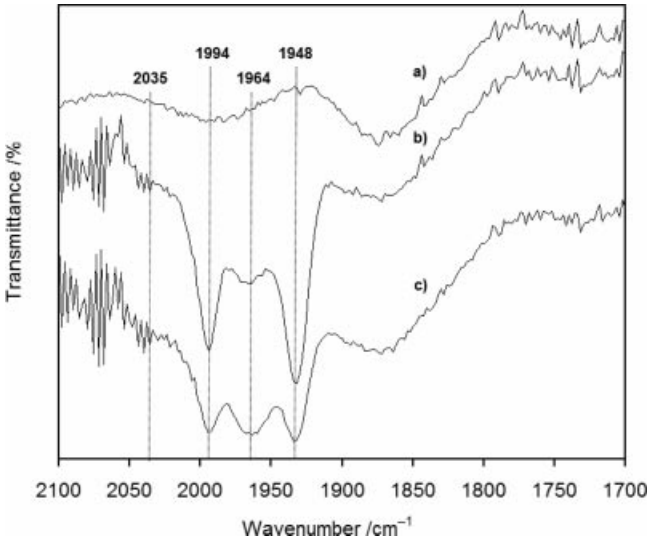

Figure 6. Part of FT-IR spectra of Rh(**3**)/$SiO_2$/SILP catalysts (**3**/Rh = 10, $\alpha$ = 0.5) at 100 °C after (a) 15 min nitrogen exposure, (b) 15 min syngas exposure, and (c) 30 min syngas exposure.

Re-exposure of the **7-ea/7-ee** isomeric mixture to inert gas slowly regenerated the dimer **6** reversibly, while air treatment presumably led to irreversible complex degradation and oxidation of excess ligand. The degradation product was dark yellow and had a broad CO band at ν(CO) = 1972 cm$^{-1}$. Importantly, the complex formation in the Rh(**3**)/$SiO_2$/SILP catalysts having **3**/Rh ratio of ≥ 10 were very similar to what previously has been reported for Rh(**3**) and analogous Rh(xanthene-based ligand) systems in ionic liquids[16] and organic solvents,[23] as shown in Table 3. Thus, it seemed reasonable to conclude that the Rh(**3**) complex was formed in the ionic liquid film and that the examined SILP hydroformylation reactions were indeed of purely homogeneous nature.[15]

In the FT-IR spectra recorded of the analogous catalysts with **3**/Rh ratios of 3 and 5, the degradation product was (in sharp contrast to the catalysts with high ligand content) irreversibly formed independent of the gas treatment, and was significantly more pronounced for catalysts with **3**/Rh = 3 than for catalysts having **3**/Rh = 5. This clearly suggested that an insufficient excess of ligand **3** was present in these systems with low ligand content to maintain the equilibrium between the modified hydrido complex **7** and the unmodified hydrido complex **8** in favour of complex **7**, as shown in Scheme 2. This was in excellent accordance with the relative catalyst selectivities and stabilities measured, since the unmodified hydrido complex provided low selectivity (*n*/iso ratio ≈ 2) and facilitated formation of inactive clusters at the modest CO partial pressure applied. Hence, it seemed unambiguously justified that the SILP catalyst stability was directly connected to the complex degradation reaction, which additionally seemed to be correlated to the amount of accessible ligand available for complex formation in the systems.

The content of acidic support OH groups (mostly Brønsted sites) contained in the partly dehydroxylated silica support was evaluated by ammonia temperature-programmed desorption (TPD) to be 69 μmol OH/g support, corresponding to 26% of the original content present in the untreated support. This was in relatively good agreement with the remaining fraction of 35% Si–OH groups (Q3, $\delta$ ≈ 100 ppm) relative to Si–O–Si groups (Q4, $\delta$ ≈ 111 ppm) measured by solid-state MAS $^{29}$Si NMR spectroscopy for analogous samples. Therefore, it seemed reasonable to assume that the applied pretreatment decreased the amount of acidic support OH groups only by dehydroxylation of surface silanol groups thereby causing no significant structural changes of the support. This was further affirmed by the identical $T_{max}$ values obtained for ammonia desorption (i.e. desorption sites are identical), and by the practically unchanged BET surface area and pore volume after dehydroxylation.

As a consequence, it should therefore be anticipated that highly stable SILP catalysts could only be obtained in those cases where the ligand content was sufficient to compensate the loss induced by the surface bonding as shown in Table 4. This was in excellent agreement with the experimental data from the catalytic reactions, thus clearly showing that the relative content of acidic support OH groups most probably was the key factor determining the long-term stability for silica-support-based Rh(phosphane)/SILP catalysts.[15]

### Deactivation/Reactivation Assessment

All the stability measurements of the Rh(**3**)/SILP catalyst discussed so far were initially studied at 100 °C and 10 bar syngas pressure ($H_2$/CO = 1:1) over a period of up to 36 h. This time on-stream was further extended to 180 h to test the long-term stability of the Rh(**3**) dehydroxylated catalyst system.[24]

In the extended reaction period the selectivity towards linear butanal remained constant around 95% (*n*/iso = 19), whereas the TOFs slightly decreased over time, corresponding to a total loss in activity of 17% or 0.1% per hour. Since the selectivity remained unchanged it was excluded that deactivation was caused by catalyst decomposition, as observed in the previous studies when using low L/Rh ratios.[7,14,15] ICP (inductively coupled plasma) analyses of the exit gas streams condensed by liquid nitrogen further established the rhodium contents to be below the detection limit of 3 ppm. Instead, the formation of high-boiling side-products, dissolving in the ionic liquid layer during reaction causing a lowering in the effective rhodium concentration, was suspected to be the reason of the slow activity decrease measured. Furthermore, the film thickness might be increased and smaller pores flooded, which would lead to a lower reaction surface. To confirm this hypothesis, the gas flow was temporary stopped after 180 h on-stream and the reaction setup evacuated for 10 min at 100 °C. When the experiment was continued after this procedure, the activity had indeed increased by 80% from initially 60 to 108 $h^{-1}$. Within the next 20 h of reaction the TOFs decreased again from 108 $h^{-1}$ to 76 $h^{-1}$ and the selectivity was re-established at 95% *n*-butanal. A second vacuum period of 10 min resulted in improved TOFs, as depicted in Figure 7. In both cases the observed "overshooting" of the activity directly after evacuation might be caused by either simultaneous removal of CO ligand of the Rh complex leading to higher activity or a rearrangement of the active surface due to sudden evaporation of dissolved heavies. In the first case a lower selectivity would be expected which was indeed observed directly after the evacuation. Thereafter, the catalyst solution was resaturated with CO gas and both the activity and the selectivity approached the initial levels.

The findings from the evacuation experiment confirmed the interpretation that the observed slight deactivation over time was not due to catalyst decomposition, as an accompanying decrease in activity and selectivity otherwise would have been observed. Instead, we expected the formation of 2-ethylhexanal and 2-ethylhexanol to be of relevance, as traces of these high-boiling side products were observed at particular high conversions.

To support this interpretation the deactivated catalyst was removed from the reactor and the pale yellow catalyst particles placed in two round-bottomed flasks containing cyclohexane and ethanol, respectively. Immediately, the ethanol solution became orange whereas the cyclohexane solution remained colourless, indicating that the ethanol wash led to removal of the ionic catalyst phase from the support while the cyclohexane wash did not. Both solutions were subsequently analysed by means of GC-MS (ethanol solution after distillation and separation of nonvolatile ionic liquid fragments), where content of small amounts of by-products 1-butanol, 2-ethylhexanal, and 2-ethylhexanol were confirmed, as expected. Additionally, IR analysis of both used and unused Rh/SILP catalysts was carried out. The used catalyst showed an absorbance band at 1730 $cm^{-1}$ (corresponding to the C=O stretching frequency) clearly indicating the presence of aldehydes in the catalyst.

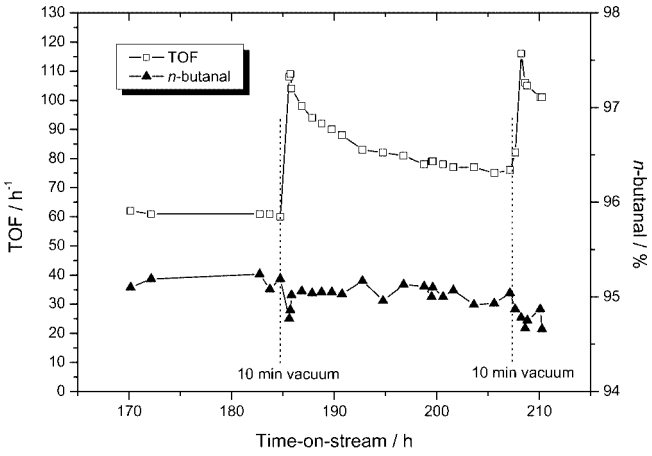

Figure 7. Reactivation of Rh(**3**)/$SiO_2$/SILP catalyst by consecutive application of vacuum. 100 °C, 10 bar syngas.

## Kinetic Studies

Long-term stability and kinetic experiments have been conducted in order to further prove the findings from the catalyst composition studies with Rh(**3**) catalysts. For these studies a continuous reactor setup equipped with online gas chromatography, described in detail previously, has been applied.[24] The general rate law for the hydroformylation of propene was assumed to be

$$r = k \cdot p^{n}_{\text{propene}} \cdot p^{x}_{\text{H}_2} \cdot p^{y}_{\text{CO}}$$

### Differential, Integral, and Arrhenius Analysis

In the first kinetic experiments the substrate concentration was varied by changing the propene partial pressure $p_{\text{propene}}$ in the feed gas (at constant total pressure) between 0.9 and 3.2 bar at temperatures in the range of 65–140 °C. In Figure 8 the obtained results are compiled.

As expected, the highest catalyst activities (corresponding to TOFs of about 500 $h^{-1}$) and the lowest selectivities (down to 88% linearity) were obtained at high propene partial pressure and high temperature. However, the activities at 140 °C were not as high as expected assuming a normal Arrhenius temperature dependence, which was attributed to the formation of high-boiling by-products dissolved in the ionic liquid layer, thus lowering the effective catalyst concentration (see "deactivation/reactivation assessment"). The rate constants *k* were derived from differential analyses of the data, and the reaction with respect to propene partial

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

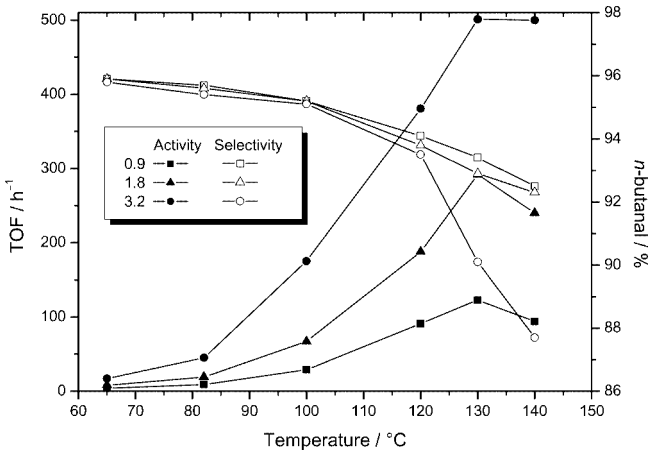

Figure 8. Activity and selectivity in Rh(**3**)/$SiO_2$/SILP-catalysed propene hydroformylation as a function of temperature and propene partial pressure.

pressure was determined to be of first order (i.e. $n = 1$). This dependency was similar to traditional organic and aqueous (phosphane)Rh-catalysed hydroformylation systems.[19]

At a constant propene partial pressure of 2.1 bar the residence time inside the catalyst bed was varied by altering the total reactant flow, as shown in Figure 9.

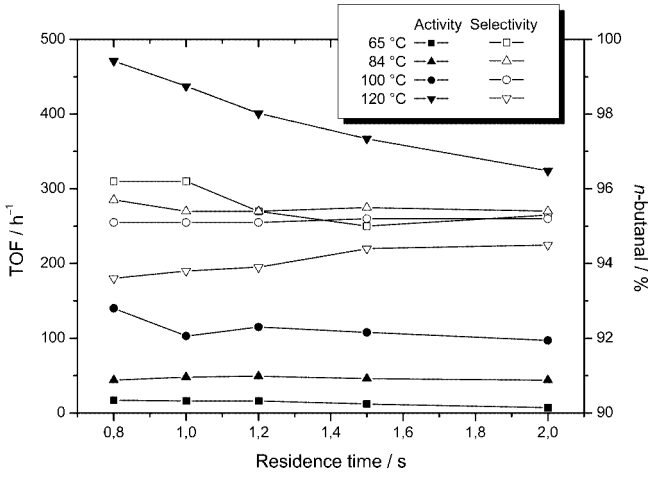

Figure 9. Activity and selectivity in Rh(**3**)/$SiO_2$/SILP-catalysed propene hydroformylation as a function of residence time.

The selectivity for the desired linear aldehyde was only influenced by temperature and not by residence time. Shorter residence times generally resulted in lower conversions, as expected. However, under nondifferential conditions at higher conversions the observed TOFs decreased slightly with longer residence times, due to lower mean levels of propene present in the reactor. An integral analysis of the data revealed the rate constants $k$ for the temperature range between 65 and 120 °C.

From the independent propene pressure and residence time experiments the activation energy was calculated from Arrhenius plots to be $63.3 \pm 2.1$ kJ·mol$^{-1}$. This value indicated that the Rh(**3**)/$SiO_2$/SILP catalyst was operating under kinetically controlled reaction conditions and added further proof to the homogeneous nature of the Rh/SILP catalyst as confirmed by spectroscopic studies (vide supra). In Table 5 the result obtained with the Rh(**3**)/SILP catalyst is compared with results for other rhodium-catalysed hydroformylations using sulfonated ligands in aqueous media and supported aqueous media.

Table 5. Comparison of results for Rh(**3**)/$SiO_2$/SILP hydroformylation with literature results.

| Substrate | Catalyst | $E_A$ [kJ·mol$^{-1}$] | Solvent | Support | Ref. |
|---|---|---|---|---|---|
| Propene | $HRh(CO)_2$(**3**) | 63.2 | IL[a] | $SiO_2$ | [20] |
| Propene | $HRh(CO)(L)_3$[b] | 77.0 | water | – | [21] |
| 1-Octene | $HRh(CO)(L)_3$[b] | 65.9 | water | – | [22] |
| 1-Octene | $HRh(CO)(L)_3$[b] | 71.0 | water | $SiO_2$ | [23] |
| Linalool | $HRh(CO)(L)_3$[b] | 60.7 | water | $SiO_2$ | [24] |
| 1-Dodecene | $HRh(CO)(L)_3$[b] | 72.8/70.9[c] | water[d] | – | [25] |

[a] Ionic liquid = [BMIM][$n$-$C_8H_{17}O$–$SO_3$]. [b] L = TPPTS. [c] Two different algorithms were used for data analysis. [d] CTAB (cetyltrimethylammonium bromide) surfactant used.

The activation energy of propene using Rh/SILP catalysts is slightly lower than the one determined by Mao et al. for $HRh(CO)(TPPTS)_3$ in water,[25] while the activation energy compared with $HRh(CO)(TPPTS)_3$ in supported aqueous phase (SAP) catalysis of higher alkenes[26–29] is in good agreement. This comparison provides additional evidence that the Rh/SILP catalyst truly acts as a homogeneous catalyst in the ionic liquid film immobilised on the silica.

### Variation in Syngas Composition and Total Pressure

In order to further assess the effect of parametrical changes to the Rh(**3**)/SILP hydroformylation system, the ratio between the partial pressures of hydrogen and carbon monoxide ($p_{H_2}/p_{CO}$ ratio) has been varied between 0.25 and 4 (at constant total pressure) in reactions performed at 65 and 100 °C.[24] Increasing the hydrogen partial pressure had a profound effect on the catalyst activity for both temperatures, as depicted in Figure 10.

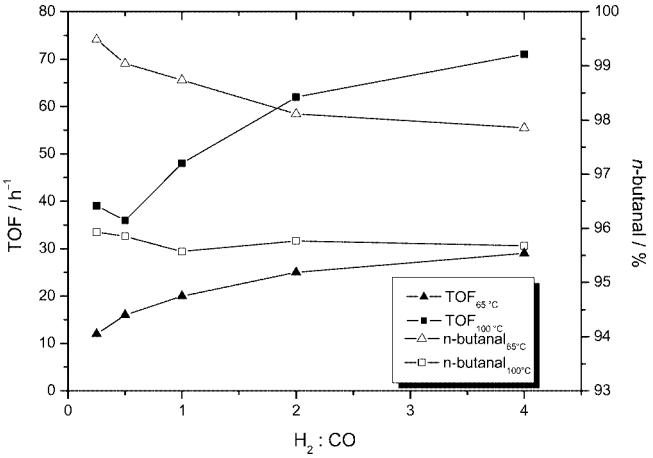

Figure 10. Activity of Rh(**3**)/$SiO_2$/SILP catalyst at different syngas compositions ($H_2$/CO ratios) and temperatures. 10 bar syngas pressure.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The positive effect of a high relative hydrogen pressure is well known in homogeneous hydroformylation[30] and can be derived from the generally accepted Wilkinson mechanism for ligand-modified rhodium catalysis,[31] in which the pre-equilibrium between dimer **6** and monomer **7** is shifted towards the active monomer **7** at higher partial pressures of hydrogen. Furthermore, the observed negative influence of high carbon monoxide partial pressures was also in accordance with this mechanism, in which the formation of catalytically active species requires the loss of CO during the cycle.[30,32] Thus, these findings provided further verification of the homogeneous nature of the Rh/SILP catalyst system.

At 100 °C the catalyst selectivity for *n*-butanal was practically independent of the $H_2$/CO ratio (< 0.5% variation), while the syngas ratio significantly influenced the selectivity at the lower temperature of 65 °C providing high selectivity of about 98% with an $H_2$/CO ratio of 4. Moreover, at 65 °C with a large excess of CO gas ($H_2$/CO = 0.25) *n*-butanal was formed exclusively with 99.5% selectivity (*n*/iso = 193). Such high selectivity has not previously been reported for Rh(**3**) catalyst systems in either homogeneous or biphasic reaction systems, normally performed in batch autoclaves. These results indicate the high potential of the SILP concept for obtaining a better mechanistic understanding in homogeneous catalysis, as exceptionally low steady-state conversions (impossible to realise in batch mode) can be adjusted in fixed-bed reactors. Additionally, the fixed-bed SILP catalytic concept allows a variety of reaction parameters to be altered over a broad range by using only small amounts of precious catalyst.

At a reaction temperature of 100 °C, the effect of the total syngas pressure $p_{total}$ on the catalyst performance was further examined by changing the pressure between 10 and 30 bar at fixed $p_{H_2}/p_{CO}$ pressure ratios.[24] From these pressure variations the reaction order with respect to hydrogen was determined to be $x = 0.4$ and the reaction order with respect to carbon monoxide to be $y = -0.4$. The selectivity remained nearly unchanged around 93% *n*-butanal for all experiments. By combining the obtained pressure dependencies for all of the three gases involved the general rate law for the propene hydroformylation using Rh(**3**)/$SiO_2$/SILP catalysts could therefore been established as

$$r = k \cdot p^{1}_{propene} \cdot p^{0.4}_{H_2} \cdot p^{-0.4}_{CO}$$

## Effect of Carbon Dioxide Cofeeding

Carbon dioxide gas is known to have high solubilities in most ionic liquids, lowering their viscosity and thus enhancing the diffusion of other gases.[33] In recent publications, the effect of super- and sub-critical $CO_2$ on hydrogen and oxygen solubilities has been reported.[34] In order to study the effect of $CO_2$ addition on the SILP-catalysed hydroformylation of propene, inert gas helium was replaced by a $CO_2$ cofeed corresponding to partial pressures between 1.8 and 36.4 bar.

From the results in Table 6 it became obvious that $CO_2$ indeed had a positive effect on the performance of the SILP catalyst. The initial activity obtained using helium could be increased by 2% at 1.8 bar $CO_2$ gas up to 35.1% at 36.4 bar $CO_2$ pressure. In contrast, the initial selectivity was not influenced by the $CO_2$ addition and remained constant around 94.5% throughout the experiments, and hydrogenation by-products could not be detected by GC analysis.

## Concluding Remarks

In this Microreview, we have described important progress in the very promising field of SILP catalysis, exemplified by the hydroformylation of propene. The long-term stability of Rh(**3**)/[BMIM][*n*-$C_8H_{17}O$–$SO_3$] catalysts supported on partly dehydroxylated silica was demonstrated, and clear spectroscopic evidence for the homogeneous nature of the catalysis in the supported ionic liquid layer was presented. Moreover, the prerequisite for obtaining active, highly selective, and Rh(**3**)/SILP hydroformylation catalysts with long-term stability was established to involve both the presence of an ionic liquid solvent and the content of a relatively large excess of phosphane ligand to compensate for some detrimental surface activity. The activation energy of 63.3 ± 2.1 kJ·mol$^{-1}$ added evidence that the catalyst was indeed homogeneous, i.e. a complex dissolved in an ionic liquid film on a support. Furthermore, the Rh/SILP catalyst performed similarly to a homogeneous catalyst with regard to variation in syngas composition. The presented work further confirms the high technical potential of the SILP catalysis concept as it allows the combination of homogeneous catalysis and its advantages with heterogeneous, fixed-bed technology. In this way, the SILP concept might provide a better mechanistic understanding of homogeneous catalysis (with only a small amount of precious catalyst) as reaction studies may be carried out at steady-state conversions unattainable by traditional batch reactions.

In perspective, we believe that the knowledge gained in this work could accelerate significantly the successful development of new SILP catalysts and future SILP catalysis

applications (e.g. other C–C couplings, hydrogenations etc.). Here, advent of task-specific ionic liquids (TSILs)[35] may also provide new opportunities for catalyst immobilisation and stabilisation in the ionic phase. From our work it becomes quite obvious that the combination of well-defined catalyst complexes, nonvolatile ionic liquids and solid, porous supports offers much more than traditional supported liquid-phase catalysis[36] using water or organic solvents which clearly suffers from evaporation of the supported solvent.[37] We therefore anticipate that the SILP catalysis concept may be able to contribute significantly to future developments aiming for highly selective, heterogenised homogeneous catalysts.

## Acknowledgments

This work was supported by the framework "Smart ligands – smart solvents" of ConNeCat financed by the German Federal Ministry for Education and Research (BMBF). Financial support by the Deutsche Forschungsgemeinschaft, DFG (M. H.), the Danish Research Council for Technology and Production, FTP, and the Villum Kann Rasmussen Foundation (A. R.) is gratefully acknowledged. The authors thank H. Gerhard, B. S. K. Gorle, B. Melcher, and C. Ernst, University of Erlangen-Nürnberg, and U. Maymann and A. Kustov, Technical University of Denmark, for their contributions in connection with analyses and SILP catalyst preparation. Furthermore, O. B. Lapina, Boreskov Institute of Catalysis (Novosibirsk, Russia) and G. Henze, University of Dortmund, are acknowledged for performing MAS NMR measurements and ICP analyses, respectively.

# A Simple and Efficient Synthetic Route to Enantiopure Scorpionate Ligands

**Antonio Otero,*[a] Juan Fernández-Baeza,*[a] Antonio Antiñolo,[a] Juan Tejeda,[a] Agustín Lara-Sánchez,[a] Luis Sánchez-Barba,[a] Margarita Sánchez-Molina,[a] Sonia Franco,[a] Isabel López-Solera,[a] and Ana M. Rodríguez[a]**

**Keywords:** Scorpionate ligands / Chiral ligands / Lithium / Titanium

A simple and efficient synthetic route for the preparation of enantiopure scorpionate ligands is described that allows the optimization and rapid access to ligands with diverse chiral environments.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The traditional approach to asymmetric catalysis with metal-based catalysts is an iterative operation that revolves around the synthesis of chiral ligands of high enantiopurity.[1] Once the chiral ligands have been bound to the metal centers, the new catalysts are examined to determine their enantioselectivities and activities. The results of these studies are evaluated, and the next generation of ligands is designed. In this process, the key to efficient reaction optimization is often rapid access to numerous catalysts with diverse chiral environments. Unfortunately, the synthesis of enantiopure ligands can be an arduous task, severely hampering the optimization of the asymmetric process.[2]

During the last decade, our research group has been interested in the synthesis of new "heteroscorpionate" ligands[3] with pyrazole rings. These new ligands are related to the tris(pyrazol-1-yl)methane system,[4] but in this case one of the pyrazole groups is replaced by a carboxylate, dithiocarboxylate, methoxy, or cyclopentadienyl[5] group. We recently reported a racemic example of a bis(pyrazol-1-yl)acetate tripod ligand in which the chirality originates from the two different pyrazolyl donor groups bound to the methoxyacetate moiety.[6] More recently, Burzlaff et al.[7] prepared two enantiopure NNO acetate–scorpionate ligands in which the chirality originates from pyrazolyl groups; the process involved three synthetic steps. We present here a simple, versatile, and efficient synthetic route for the preparation of enantiopure scorpionate ligands in one step by an insertion reaction of a commercial, enantiopure isocyanate or isothiocyanate into a conventional bis(pyrazol-1-yl)methane. This approach extends our method for the insertion of carbon dioxide into the bridging carbon atom to other types of heterocumulenes. We have prepared the first amidate and thioamidate lithium compounds as a new class of enantiopure scorpionate ligands. These ligand systems can be optimized by modifications in both the bis(pyrazol-1-yl)methane and the isocyanate or isothiocyanate moieties to give diverse chiral environments. Titanium complexes have been prepared with these types of chiral ligands.

## Results and Discussion

Deprotonation at the methylene group of bis(3,5-dimethylpyrazol-1-yl)methane (bdmpzm)[8] with *n*BuLi, followed by reaction with achiral and chiral isocyanates [e.g., *tert*-butyl isocyanate and (*S*)-(–)-α-methylbenzyl isocyanate] and isothiocyanates [e.g., *tert*-butyl isothiocyanate and (*S*)-(–)-1-phenylpropyl isothiocyanate] yielded the lithium compounds $[Li(tbpam)]_2$ (**1**) [tbpam = *N*-*tert*-butyl-2,2-bis(3,5-dimethylpyrazol-1-yl)acetamidate], $[Li(S\text{-}mbbpam)]_2$ (**2**) [S-mbbpam = (*S*)-(–)-*N*-α-methylbenzyl-2,2-bis(3,5-dimethylpyrazol-1-yl)acetamidate], $[Li(tbptam)]_2$ (**3**) [tbptam = *N*-*tert*-butyl-2,2-bis(3,5-dimethylpyrazol-1-yl)thioacetamidate], and $[Li(S\text{-}ppbptam)]_2$ (**4**) [S-ppbptam = (*S*)-(–)-*N*-1-phenylpropyl-2,2-bis(3,5-dimethylpyrazol-1-yl)thioacetamidate], which were isolated as white or yellow solids in good yield (85%) after the appropriate work-up (see Scheme 1).

The mass spectra (FAB) of **1**–**4** indicate a dinuclear formulation. The $^1H$ and $^{13}C\text{-}\{H\}$ NMR spectra of **1** and **3** (achiral compounds) show a single set of resonances for the pyrazole rings, indicating that the two pyrazole rings are equivalent. However, the $^1H$ and $^{13}C\text{-}\{H\}$ NMR spectra of complexes **2** and **4** (chiral compounds) exhibit two resonances for each of the $H^4$, $Me^3$, and $Me^5$ pyrazole protons, indicating that the two pyrazole rings are nonequivalent.

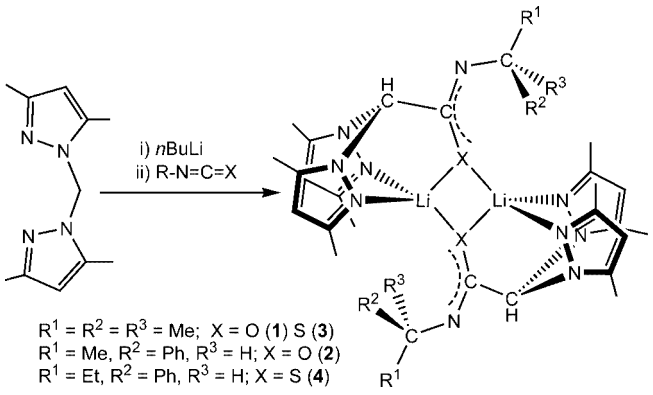

Scheme 1. Synthesis of lithium compounds **1**–**4**.

These results agree with a proposed tetrahedral arrangement for the lithium atoms with a $\kappa^3$-NNE-coordination (E = O or S) for the heteroscorpionate ligand, where the oxygen or the sulfur atom of the scorpionate ligands bridge the two lithium atoms (see Scheme 1). In this arrangement, when $R^1 = R^2 = R^3$ (achiral compounds), there is a symmetry plane that contains the lithium atoms, the bridging carbon atoms of the pyrazolyl rings, and the amidate or thioamidate fragments. However, when $R^1 \neq R^2 \neq R^3$, this symmetry plane does not exist, and the pyrazole rings are nonequivalent. This structural arrangement was corroborated by an X-ray crystal structure determination for **1** (see Figure 1).[9] The geometry around the Li atom can be described as a distorted tetrahedron with a "heteroscorpionate" ligand that acts in a tridentate fashion (two coordinated pyrazole rings and an oxygen atom from the amidate fragment bridge the lithium atoms). The dimeric aggregate is based on $Li_2O_2$ four-membered rings, which have previously been observed in other lithium compounds containing, for example, anionic tris(imidazol-2-yl)phosphanes,[10] boroxides,[11] aryloxides,[12] or ester enolate[13] ligands. However, it should be noted that compounds with this type of metallacycle containing a scorpionate ligand have not been reported in the literature. The corresponding Li–O bond lengths are essentially the same as in the lithium compounds mentioned above, although notable asymmetry is present within the amidate bridge [Li(1)–O(1) = 1.946(8) Å; Li(1)–O(2) = 1.825(8) Å; Li(2)–O(1) = 1.860(8) Å; Li(2)–O(2) = 1.978(7) Å]. Thus, the four-membered ring is approximately a square that is slightly folded about the Li···Li and O···O diagonal (21.0° and 24.4°, respectively), the Li···Li diagonal being much shorter than the O···O diagonal.

The C(12)–O(1) and C(12)–N(5) bond lengths [1.290(5) and 1.287(5) Å] or C(28)–O(2) and C(28)–N(10) bond lengths [1.291(5) and 1.271(5) Å] indicate the existence of a delocalized O–C–N bond in both amidate fragments of the heteroscorpionate ligands, which presents a Z-geometry for the C=N bonds. The absence of a response in the $^1$H NOESY-1D experiment from the *tert*-butyl group upon irradiating the methyne bringing group confirms this geometry in solution. In the chiral complexes **2** and **4**, we confirmed the presence of one enantiomer in solution by the addition of a chiral shift reagent, namely (*R*)-(–)-(9-anthryl)-2,2,2-trifluoroethanol. The addition of this compound did not modify the $^1$H NMR spectra of either compound. However, addition of the shift reagent to a racemic mixture of complex **2** gave rise to the appearance of two signals for each proton in the $^1$H NMR spectra, resulting from the two diastereoisomers of the corresponding two enantiomers. In addition, the specific rotations of **2** and **4** were examined by optical polarimetry. Preliminary studies also show that this type of isocyanate and isothiocyanate can be inserted into other types of bis(pyrazol-1-yl)methane.

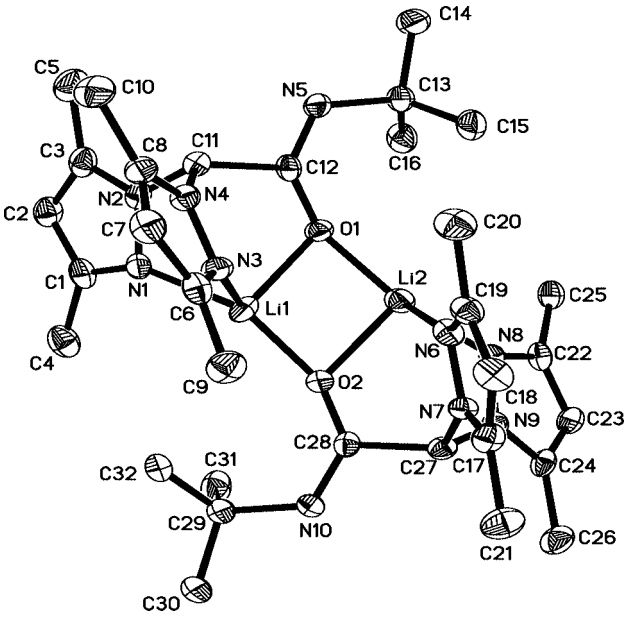

Figure 1. ORTEP diagram of **1** with 30% probability ellipsoids. Selected bond lengths [Å] and angles [°]: Li(1)–O(1), 1.946(8); Li(1)–O(2), 1.825(8); Li(2)–O(1), 1.860(8); Li(2)–O(2), 1.978(7); Li(1)–N(1), 2.063(8); Li(1)–N(3), 2.017(8); C(12)–O(1), 1.290(5); C(12)–N(5), 1.287(5); C(28)–O(2), 1.291(5); C(28)–N(10), 1.271(5); O(1)–Li(1)–O(2), 98.5(4); Li(1)–O(1)–Li(2), 80.4(3); O(1)–Li(2)–O(2), 96.1(3); Li(1)–O(2)–Li(2), 80.5(3).

These lithium compounds have been used for the synthesis of new titanium complexes. Thus, **2** and **3** reacted with $[TiCl_4(THF)_2]$ to give the complexes $[TiCl_3$(S-mbbpamH)]Cl (**5**) [S-mbbpamH = (*S*)-(–)-*N*-α-methylbenzyl-2,2-bis(3,5-dimethylpyrazol-1-yl)acetamide] and $[TiCl_3$(tbptamH)]Cl (**6**) [tbptamH = *N*-*tert*-butyl-2,2-bis(3,5-dimethylpyrazol-1-yl)thioacetamide] (see Scheme 2). Although the reactions were carried out under rigorously anhydrous experimental conditions, the presence of adventitious HCl proceeding from $TiCl_4$ in the reaction mixture during the work-up procedure was probably responsible for the protonation of the acetamidate or thioacetamide moieties and their transformation into carboxamide[14] or thiocarboxamide moieties, respectively. However, the character of the enantiopure scorpionate ligand in complex **5** is not modified. The $^1$H and $^{13}$C{H}-NMR spectra of **5** and **6** exhibit two singlets and one singlet, respectively for each of the $H^4$, $Me^3$ and $Me^5$ pyrazole protons. An X-ray crystal structure analysis was carried out for complex **6** (see Figure 2).[9] The titanium

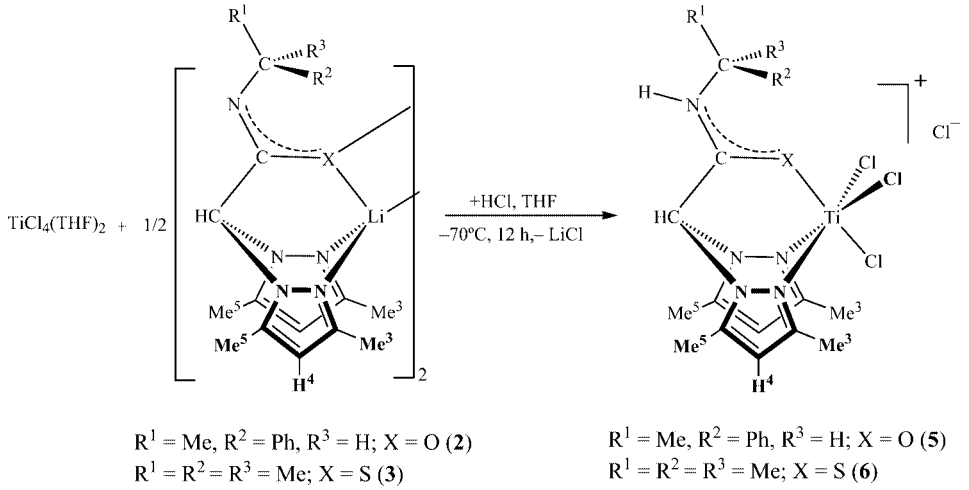

Scheme 2. Synthesis of titanium complexes **5** and **6**.

center has a distorted octahedral environment with a major distortion in the N(3)–Ti(1)–Cl(2) angle, which has a value of 166.1(2)°. In addition, the specific rotation of **5** was examined by optical polarimetry.

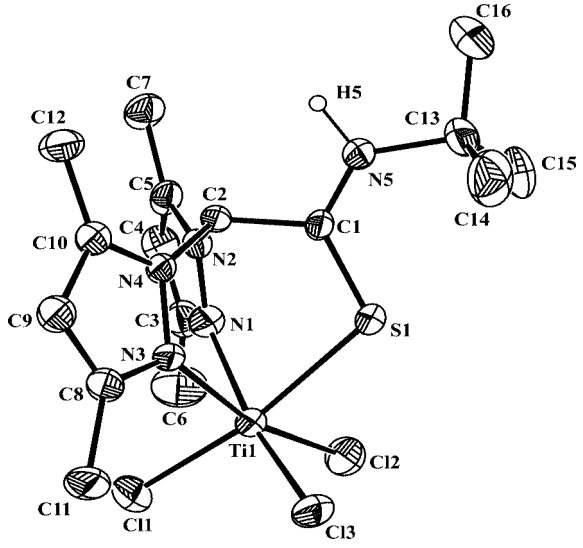

Figure 2. ORTEP diagram of **6** with 30% probability ellipsoids. Selected bond lengths (Å) and angles [°]: Ti(1)–N(3), 2.144(7); Ti(1)–N(1), 2.192(7); Ti(1)–Cl(3), 2.217(3); Ti(1)–Cl(1), 2.231(3); Ti(1)–Cl(2), 2.243(3); Ti(1)–S(1), 2.500(3); S(1)–C(1), 1.672(8); N(5)–C(1), 1.31(1); N(3)–Ti(1)–Cl(2), 166.1(2); N(1)–Ti(1)–Cl(3), 167.1(2); Cl(1)–Ti(1)–S(1), 170.5(1); N(5)–C(1)–S(1), 126.3(6).

In conclusion, we present here a simple and efficient synthetic route for the preparation of enantiopure scorpionate ligands. This approach will allow the optimization and rapid access to numerous ligands with diverse chiral environments by modification of the bis(pyrazol-1-yl)methane as well as the enantiopure isocyanate and isothiocyanate fragments. In addition, these lithium compounds are excellent reagents for the introduction of these ligands into transition-metal complexes.

## Experimental Section

All reactions were performed using standard Schlenk-tube techniques under dry nitrogen. Solvents were distilled from appropriate drying agents and degassed before use. Microanalyses were carried out with a Perkin–Elmer 2400 CHN analyzer. Mass spectra were recorded with a VG Autospec instrument using the FAB technique and nitrobenzyl alcohol as matrix. $^{1}$H- and $^{13}$C NMR spectra were recorded with a Varian Inova FT-500 spectrometer and referenced to the residual deuterated solvent. Optical rotations were determined with a Perkin–Elmer 241 MC polarimeter at the sodium D line, equipped with a quartz cell of 1.00-dm path length. Experimental procedures and characterization data for compounds **1**–**6** are given in the Supporting Information.

**Supporting Information** (see footnote on the first page of this article): Spectroscopic data and experimental procedures for compounds **1**–**6**.

# Molecular Structures and Magnetism of $Mn_{12}$ Nanomagnets Containing the 3-Thiophenecarboxylate Ligand

**Jin Mook Lim,[b] Youngkyu Do,[b] and Jinkwon Kim*[a]**

**Keywords:** Single-molecule magnet / $Mn_{12}$ complex / Molecular structure / Magnetic properties / Molecular films

The new $Mn_{12}$ single-molecule magnets containing thiophenyl ligands, $[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(HO_2CC_4H_3S)(H_2O)_2]\cdot 5CH_2Cl_2$(**1**) and $[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(H_2O)_4]\cdot 6CH_2Cl_2\cdot 2H_2O$ (**2**), have been synthesized by ligand-substitution reactions of 3-thiophenecarboxylic acid and $[Mn_{12}O_{12}(O_2CCH_3)_{16}(H_2O)_4]$ and investigated by magnetic measurements with a SQUID magnetometer. The X-ray analysis of **1** shows five-coordination geometry around the $Mn^{III}$ ion due to the unusual coordination of 3-thiophenecarboxylic acid to the $Mn^{III}$ ion. Compound **1** displays two different rates of magnetization relaxation, which are faster than that of compound **2** because of structural distortion in the $Mn_{12}$ complex of **1**. Magnetic susceptibility measurements on **1** and **2** give the following parameters: $U_{eff}$ (the faster relaxation form of **1**) = 51.81 K, $1/\tau_0 = 1.90\cdot 10^8\ s^{-1}$; $U_{eff}$ (the slower relaxation form of **1**) = 66.44 K, $1/\tau_0 = 1.50\cdot 10^8\ s^{-1}$; $U_{eff}$(**2**) = 67.09 K, $1/\tau_0 = 1.32\cdot 10^8\ s^{-1}$.

## Introduction

Single-molecule magnets (SMMs) have been the subject of intensive investigation in the last years.[1] SMM behavior was first observed in $[Mn_{12}O_{12}(OAc)_{16}(H_2O)_4]$ ($Mn_{12}Ac$) in 1993.[2,3] SMMs display stepwise magnetization hysteresis loops below the blocking temperature due to a very slow magnetization relaxation rate as well as a resonant quantum tunneling of magnetization. SMMs also exhibit quantum phase interference. Therefore, SMMs are regarded as the elementary units in ultimate high-density magnetic storage[4] and in the design of quantum computers.[5,6] One the other hand, recent research reports showed that molecular clusters possessing quantized magnetic properties may provide powerful new systems for single-molecule transistors.[7,8]

Investigating individual molecules is essential for realizing the proposed application of SMMs. An approach to accomplishing this goal is to deposit SMMs on a suitable substrate and use scanning probe microscopy (SPM) to sense individual molecules. Various types of SPM techniques, such as scanning tunneling microscopy (STM), atomic force microscopy (AFM), and magnetic force microscopy (MFM) can be employed to verify the electronic, mechanical, and magnetic characterization of the molecules. Recently, various attempts have been made in preparation and SPM characterization: Langmuir–Blodgett (LB) films of $Mn_{12}$ clusters,[9] MFM study on $Mn_{12}$ complexes embedded in a polycarbonate matrix,[10] STM study of $[Mn_{12}O_{12}\{16\text{-(hydrothio)hexanecanoate}\}_{16}(H_2O)_4]$ organized on a gold surface,[11] stamp assisted deposition and patterning,[12] the preparation of monolayer and multilayer films on functionalized surfaces,[13] and study of molecular ordering and magnetism of $[Mn_{12}O_{12}(t\text{BuCO}_2)_{16}(H_2O)_4]$ on a gold surface.[14] Very recently, grafting of $Mn_{12}$ complexes on a Si surface have been reported.[15,16] However, the methodology for depositing SMMs with monolayer or submonolayer coverage on a useful substrate such as silicon or gold is not yet well established, and the direct measurement of the characteristics of individual molecules of SMMs is still in the beginning stage. Therefore, we designed a new $Mn_{12}$ complex with surface-adhesive functional groups in peripheral ligands to give molecular monolayers on a gold surface. Here we report the synthesis, structure, and magnetic properties of $Mn_{12}$ complexes containing the thiophenyl group, $[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(HO_2CC_4H_3S)(H_2O)_2]\cdot 5CH_2Cl_2$ (**1**) and $[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(H_2O)_4]\cdot 6CH_2Cl_2\cdot 2H_2O$ (**2**).

## Results and Discussion

### Synthesis

The ligand-substitution reaction of $Mn_{12}Ac$ with 3-thiophenecarboxylic acid has been carried out by a modified azeotropic distillation method.[17] Most ligand-substitution reactions have been performed with a large excess of RCOOH. However, in our modified method, only a stoichiometric amount of 3-thiophenecarboxylic acid was al-

lowed to react with $Mn_{12}Ac$. The solubility of $Mn_{12}Ac$ is very poor in dichloromethane. Nevertheless, as $Mn_{12}Ac$ reacts with 3-thiophenecarboxylic acid, the color of the solution darkens, indicating that the ligand-substitution reaction proceeds. To complete the substitution reaction, toluene was added to the reaction mixture and evaporated to remove acetic acid as the toluene azeotrope. The reaction of $Mn_{12}Ac$ with 17 equiv. of 3-thiophenecarboxylic acid gives complex **1**, whereas complex **2** is obtained by a reaction with 16 equiv. 3-thiophenecarboxylic acid. Complex **1** has a 3-thiophenecarboxylic acid as terminal coordination ligand which can be substituted by a water molecule. Complex **1** is converted to complex **2** by recrystallization in wet $CH_2Cl_2$/hexane mixed solvent.

### Molecular Structures

An ORTEP diagram of $[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(HO_2CC_4H_3S)(H_2O)_2]$ is shown in Figure 1. Selected bond parameters are listed in Table 1 and Table 2. Complex **1** has unusual molecular structure compared with other normal $Mn_{12}$–carboxylate species. $Mn_{12}$–carboxylate complexes usually have sixteen carboxylates as peripheral bridging ligands which bridge the outer-ring $Mn^{III}$ atoms to both the inner $Mn^{IV}$ and the other outer-ring $Mn^{III}$ atoms. Four water molecules are coordinated to the outer-ring $Mn^{III}$ atoms. Complex **1** has sixteen 3-thiophenecarboxylates as peripheral bridging ligands, but it abnormally has one 3-thiophenecarboxylic acid and only two water molecules as terminal coordination ligands to $Mn^{III}$ ions. As a result of the coordination of 3-thiophenecarboxylic acid, the $Mn^{III}$ ion (Mn6) has highly distorted five-coordination geometry. The octahedral $Mn^{III}$–O bonds of $[Mn_{12}O_{12}]$ complexes are tetragonally elongated because of a Jahn–Teller distortion. An elongation axis is usually parallel to the molecular $C_2$ axis. However, there is no such elongation at Mn6 because of its five-coordination geometry. The longest $Mn^{III}$–O bond length around Mn6 is 2.067(7) Å, which is significantly shorter than the axially elongated $Mn^{III}$–O bond lengths (2.096–2.218 Å) of the six-coordinate $Mn^{III}$ atoms. Bond angles of O7–Mn6–O38 and O14–Mn6–O38 are 101.4(3)° and 92.8(3)°, respectively. Examples of five-coordinate $Mn^{III}$ atoms in $Mn_{12}$ complexes are quite rare and only observed previously in $[Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_3]$.[18] The two water molecules are located on the two Mn atoms (Mn8 and Mn12) to complete octahedral coordination.

The structure of complex **2** is quite similar in many respects to the previously characterized $Mn_{12}$ complexes. Complex **2** has normal $[Mn_{12}O_{12}]^{16+}$ core structure, as shown in Figure 2 and Figure 3, possessing four water ligands bound to three Mn centers (Mn8, Mn10, Mn12) with a 1:1:2 arrangement. All Jahn–Teller elongation axes of eight $Mn^{III}$ centers of both complexes are oriented approximately in the axial direction.

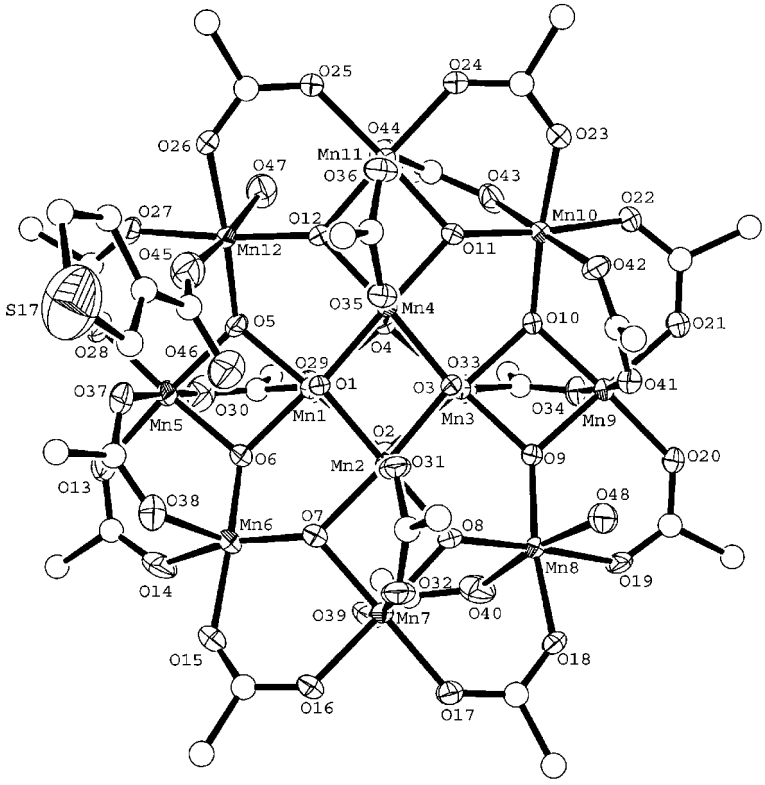

Figure 1. ORTEP representation of the $Mn_{12}$ complex of **1** showing 50% probability ellipsoids. For clarity, thiophenyl groups of the 3-thiophenecarboxylate bridging ligands are omitted.

### Magnetic Properties

Out-of-phase ac magnetic susceptibility ($\chi_M''$) measurements were carried out in the region of 2 to 10 K at zero dc field. As shown in Figure 4, frequency-dependent $\chi_M''$ peaks in the 4–7 K region of **1** are less symmetric compared with those of **2**, and the shoulders in the 3–6 K region indicate a chemical species having a faster relaxation rate of quantum tunneling of magnetization.

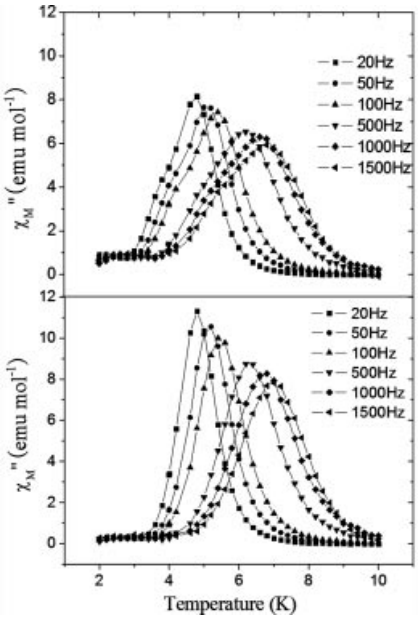

Figure 4. Comparison of out-of phase ac susceptibility signals of **1** (top) and **2** (bottom).

Magnetization relaxation rates ($1/\tau$) and effective anisotropy energy barriers were calculated from the theoretical Equation (1) given by

$$\ln(1/\tau) = -U_{eff}/kT + \ln(1/\tau_0) \quad (1)$$

where $U_{eff}$ is the effective anisotropy energy barrier, $k$ is the Boltzmann constant, and $T$ is the temperature. Magnetic relaxation times ($\tau$) are obtained from the relationship $\omega\tau = 1$ at the maxima of the $\chi_M''$ vs. $T$ plots. Peak maxima are accurately determined by fitting the peaks to a Lorentzian function. Figure 5 displays deconvolution of out-of-phase ac susceptibilities of **1** at 20 Hz. A least-squares fit (Figure 6) of ac susceptibility relaxation data to Equation (1) for faster-relaxation and slower-relaxation forms of **1** as well as **2** gives the following parameters: $U_{eff}$ (the faster-relaxation form of **1**) = 51.81 K; $1/\tau_0 = 1.90 \cdot 10^8$ s$^{-1}$, $U_{eff}$ (the slower-relaxation form of **1**) = 66.44 K; $1/\tau_0 = 1.50 \cdot 10^8$ s$^{-1}$, $U_{eff}$(**2**) = 67.09 K, $1/\tau_0 = 1.32 \cdot 10^8$ s$^{-1}$.

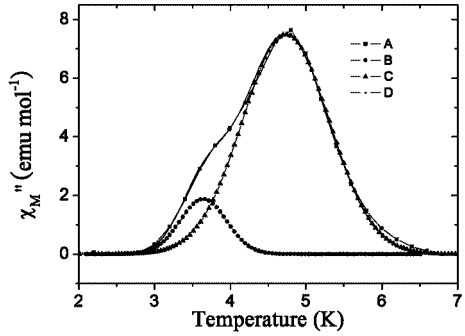

Figure 5. Deconvolution of ac susceptibilities of **1** at 20 Hz. A: original plot, B: deconvoluted low-temperature form, C: deconvoluted high-temperature form, D: sum of B and C.

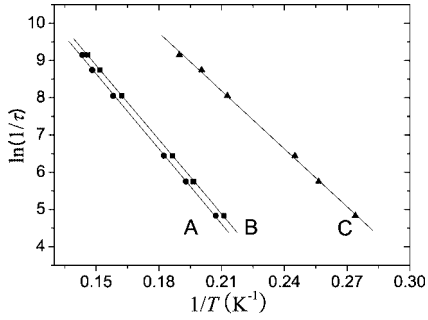

Figure 6. Arrhenius Plots of the natural logarithm of relaxation rate, $\ln(1/\tau)$ vs. inverse temperature for **1** and **2**. A: **2**, B: high temperature form of **1**, C: low temperature form of **1**.

The relaxation rate of the $Mn_{12}$ SMM is dependent on the structural distortion of the $Mn_{12}$ species because the rate of tunneling is determined by transverse magnetic fields (either outside or inside the molecule) or by transverse higher-order zero-field interaction terms.[19] Dislocations should be an external source of spin tunneling in $Mn_{12}$ crystals.[20] Jahn–Teller isomerism[21] is proposed as an internal source causing the tunneling rate of the $Mn_{12}$ species to increase. An example of Jahn–Teller isomerism can be given by mentioning the compounds $[Mn_{12}O_{12}(O_2CC_6H_4Me\text{-}4)_{16}(H_2O)_4]\cdot HO_2CC_6H_4Me\text{-}4$[19] and $[Mn_{12}O_{12}(O_2CPh\text{-}4\text{-}SMe)_{16}(H_2O)_4]\cdot 7CH_2Cl_2$,[17c] which have an equatorially elongated axis and predominantly a $\chi_M''$ peak in the region 2–4 K. Solvent molecules in the crystal lattice, which might be an external factor influencing the rate of tunneling, also affect the tunneling rate. For example, different tunneling rates were observed in the $Mn_{12}$–propionate complexes $[Mn_{12}O_{12}(O_2CCH_2CH_2Cl)_{16}(H_2O)_4]\cdot 0.5CH_2Cl_2\cdot 2H_2O$ and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[Mn_{12}O_{12}(O_2CCH_2CH_2Cl)_{16}(H_2O)_4]\cdot CH_2ClCH_2CO_2H$.[22] As shown in Figure 6, the rate of quantum tunneling in the magnetization of **1** is a little bit faster than that of **2** because of the unusual five-coordination around the Mn6 ion as well as the ligation of 3-thiophenecarboxylates in complex **1**. Such structural distortions can be regarded as an internal source that increases the rate of quantum tunneling.

Hysteresis loops for **1** (filled squares) and **2** (open circles) at 2 K are shown in Figure 7 (left). Small plateaus for both complexes are observed in the hysteresis loops because of quantum tunneling of magnetization (QTM). To clarify the positions of QTM, plots of $dM/dH$ vs. $H$ are drawn in Figure 7 (right). QTM occurs at the field of each peak. Plots of reduced magnetization ($M/N\mu_B$) as a function of $H/T$, where $N$ is Avogadro's number and $\mu_B$ is the Bohr magneton, were also obtained for compounds **1** and **2**. The data were fitted to the basic thermodynamic expression given in Equation (2), which takes the full power of the average of the magnetization into account:[23]

$$M = -\frac{N}{4\pi}\int_0^{2\pi}\int_0^{\pi}\frac{\sum_p (dE_p/dH)\exp(-E_p/k_BT)}{\sum_p \exp(-E_p/k_BT)} \times \sin\theta d\theta d\phi \quad (2)$$

In Equation (2), $k_B$ is the Boltzmann constant and $E_p$ is the eigenenergy obtained by diagonalization of the spin Hamiltonian matrix, including axial zero-field splitting and Zeeman interactions. The plots of reduced magnetization ($M/N\mu_B$) vs. $H/T$ fitted well with $S = 10$, $g = 1.84$, and $D = 0.61$ K for **1** and $S = 10$, $g = 1.86$, and $D = 0.65$ K for **2**.

The sulfur atoms of **2** are directed toward the outside and are able to form strong bonds to the gold surface. A molecular thin film of **2** was prepared by immersing atomically flat gold substrates in a 0.1 mM solution of **2** in toluene for more than 5 minutes. The atomically flat gold substrates were prepared by electron-beam evaporation of gold on mica at 300 °C and subsequent annealing at 500 °C for 30 minutes. XPS analysis was performed to determine the composition and the chemical state of the film of compound **2** on Au(111). A survey spectrum clearly displays the photoelectron peaks for manganese, sulfur, oxygen, carbon, and gold. Figure 8 shows the high-resolution spectrum of the Mn 2p region for the Mn12 film. The Mn $2p_{1/2}$ and $2p_{3/2}$ and peaks are observed at 654 eV and 642 eV, respectively, and are consistent with the values observed with the Mn12–ac crystal.[24] The surface morphology of the film has been investigated by STM and AFM.[25,26] These studies indicate that the thiophenyl group can be used to anchor the $Mn_{12}$ complex to the Au surface and demonstrate that individual molecules can be addressed and their physical properties can be investigated by using the SPM techniques. We plan to conduct an STM experiment at low temperatures of the SMM at the molecular level and eventually devise a strategy for the application of the SMM to quantum devices.

## Conclusions

The syntheses and X-ray structures of $[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(HO_2CC_4H_3S)(H_2O)_2]\cdot 5CH_2Cl_2$ (**1**) and $[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(H_2O)_4]\cdot 6CH_2Cl_2\cdot 2H_2O$ (**2**) are reported. There is a distorted five-coordination site due to the very unusual coordination of 3-thiophenecarboxylic acid as a terminal ligand in complex **1**. Complex **2** has normal coordination geometry. Such an internal structure distortion of **1** causes faster relaxation of magnetization in **1** relative to **2**. A molecular thin film of the Mn12 SMM has been successfully fabricated by using complex **2**. The molecules

of **2** are anchored on a gold surface strongly through sulfur atoms of 3-thiophenecarboxylate ligands.

## Experimental Section

**General Remarks:** $Mn_{12}Ac$ was prepared according to a published procedure.[27] All reagents and solvents were purchased from commercial sources and used as received.

**Physical Measurements:** Elemental analyses were carried out by the Analytical Laboratory of the Korea Basic Science Institute, Seoul. Infrared spectra were recorded with a Perkin–Elmer 16 PC spectrophotometer. Variable-temperature magnetic susceptibility measurements were carried out on powder samples of complex **1** and complex **2** using a Quantum Design MPMS*XL* susceptometer well equipped with a 50-kG magnet. The samples were introduced into the XPS chamber by means of a load lock system. The base pressure was $1 \cdot 10^{-10}$ Torr. All XPS spectra were recorded with a VG Scientific ESCALAB MK II spectrometer using an Al-$K_\alpha$ source run at 15 kV and 10 mA. The binding energy scale was calibrated to 284.6 eV for the main C 1s peak. Each sample was analyzed at a 90° angle relative to the electron analyzer. The ac field range was $1 \cdot 10^{-4}$ to 5 Oe, oscillating at a frequency in the range $5 \cdot 10^{-4}$ to 1512 Hz. The sets of ac susceptibility data were collected for the powdered, microcrystalline sample in an ac field of 3.0 Oe, oscillating in the 20–1500 Hz range. The samples were aligned in eicosane with an applied dc field of 5 T at a temperature above the melting point of eicosane for 15 min. Corrections for the diamagnetism of the complexes were estimated using Pascal's constants, and magnetic data were corrected for diamagnetic contributions of the sample holder.

**Synthesis of Complex 1:** A slurry of $Mn_{12}Ac$ (206 mg, 0.1 mmol) in dichloromethane (30 ml) was stirred with 3-thiophenecarboxylic acid (230 mg, 1.8 mmol) for 4 h at room temperature to give a dark blown solution. Azeotropic distillation with toluene (20 ml) was performed six times to completely remove the released acetic acid, and the resultant dark brown solid was dissolved in dichloromethane and filtered. The filtrate was allowed to diffuse with pentane vapor. After a week, black crystals of **1** were collected by filtration and washed with hexane. FTIR data: 1561(s), 1522(s), 1439(s), 1358(s), 1319(s), 1208(w), 1120(w), 1073(w), 940(w), 873(w), 833(W), 754(s), 702(m), 658(m), 628(m), 517(m) $cm^{-1}$. $C_{90}H_{66}Cl_{10}Mn_{12}O_{48}S_{17}$ (3474.23): calcd. C 33.48, H 1.85, S 17.87; found C 33.41, H 1.95, S 18.21.

**Synthesis of Complex 2:** Complex **2** was synthesized in the same manner as complex **1** except that 16 equiv. 3-thiophenecarboxylic acid (215 mg, 1.8 mmol) was treated with $Mn_{12}Ac$ (205 mg, 0.1 mmol) in dichloromethane (30 mL). After several azeotropic distillations, the dark brown product was recrystalized from dichloromethane/hexane to give complex **2**. $C_{86}H_{72}Cl_{12}Mn_{12}O_{50}S_{16}$ (3503.08): calcd. C 32.10, H 2.02, S 17.14; found C 31.78, H 2.11, S 17.26.

**Crystal Structure Determination:** Reflection data were collected with a Bruker SMART CCD diffractometer using monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation. The data were integrated and scaled using the SAINT software package.[28] Collected data were corrected for absorbance by using SADABS[28] based upon the Laue symmetry using equivalent reflections. Structures ware solved by the direct method and refined by least-squares calculations with the SHELXL-PLUS 5.05 software package.[29] The non-hydrogen atoms were refined anisotropically, and the geometrically restrained hydrogen atoms were treated using an appropriate riding model. A summary of the crystallographic parameters and data is given in Table 3. The proposed models include disorders of the thiophene rings and solvent molecules.

CCDC-280093 and CCDC-280094 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Characterization of Dinuclear Europium Complexes Showing Pure Red Electroluminescence

Hyosook Jang,[a] Chang-Hwan Shin,[a] Byung-Jun Jung,[b] Do-hyeon Kim,[a] Hong-Ku Shim,*[b] and Youngkyu Do*[a]

**Keywords:** Electroluminescence / Europium / Dinuclear complexes / 2,2′-Bipyrimidine

Two dinuclear $Eu^{III}$ complexes have been synthesized by employing β-diketones and 2,2′-bipyrimidine (bpm) as sensitizing ligands for the Eu ion and a bridging ligand, respectively, and characterized by various means including single-crystal X-ray crystallography. The use of dibenzoylmethane (dbm) and trifluorothenoylacetone (tta) as β-diketones gave $[Eu_2(dbm)_6(bpm)]$ (**1**) and $[Eu_2(tta)_6(bpm)]$ (**2**). Both show strong intermolecular π–π interactions that may be responsible for their high melting points. The analysis of the absorption, excitation, and emission spectra of the dinuclear complexes along with a comparison with analogous mononuclear complexes containing the same β-diketone ligands and 1,10-phenanthroline (phen) suggests that the dinuclear complexes follow the luminescence mechanism of general $Ln^{III}$ complexes. An EL device with the structure ITO/PEDOT/PVK + PBD + **1** 10 wt.-%/LiF/Al shows pure red emission with an efficiency similar to those of mononuclear complexes.

## Introduction

Luminescent metal complexes are attractive due to their potential applications in the development of organic light-emitting diodes (OLEDs),[1] sensors,[2] and molecular optoelectronic devices.[3] In particular, various metal complexes for OLEDs have been intensively studied and developed;[4,5] typical examples are lanthanide complexes.[5] Electroluminescent (EL) lanthanide complexes have the advantages of extremely narrow emission spectra and the possibility of high EL efficiency caused by the intramolecular energy transfer that consists of the absorption of energy by organic ligands, intersystem crossing into a triplet state of the organic ligands, and energy transfer to the central lanthanide cation.[5] Among lanthanide complexes, $Eu^{III}$ complexes are of particular interested because of their red emission. However, europium systems still require improvement in color purity, carrier-transporting, and thermal stability for practical use.

Although a number of mononuclear lanthanide complexes have been used in OLEDs,[5] examples of electroluminescent dinuclear lanthanide systems are very rare and to date $[Tb_2(acac\text{-}azain)_4(\mu\text{-}acac\text{-}azain)_2]$ [acac-azain = 1-(*N*-7-azaindolyl)-1,3-butanedionato], a green emitter in electroluminescent devices, is the only reported system.[6] Other dinuclear lanthanide complexes based on pyridylamine ligands ($Eu^{III}$, $Tb^{III}$, and $Dy^{III}$),[7] diketonate ligands ($Eu^{III}$, $Nd^{III}$, and $Sm^{III}$),[8] calix[8]arene ($Eu^{III}$),[9] and N,N,O donor ligands ($Sm^{III}$, $Eu^{III}$, $Tb^{III}$, and $Dy^{III}$;[10a] $La^{III}$–$Lu^{III}$[10b]) are known to display photoluminescence. It should also be noted that the lanthanide complexes $[Eu_xTb_{1-x}(acac)_3(phen)]$ ($x$ = 0–1)[11] employed in white-

light-emitting OLEDs have been claimed to be dinuclear systems, although in the absence of characterization data it is difficult to consider them as legitimate dinuclear systems. To lessen the scarcity of electroluminescent dinuclear lanthanide system, we have designed and synthesized a set of dinuclear $Eu^{III}$ complexes based on 2,2′-bipyrimidine (bpm) as a bridging ligand and β-diketones (L) as sensitizing ligands (Figure 1). We reported here the details of the synthesis, structures, and luminescence characteristics of $[Eu_2L_6(bpm)]$ [L = dibenzoylmethane (dbm) **1** and thenoyltrifluoroacetone (tta) **2**].

## Results and Discussion

### Syntheses and Structures

The dinuclear $Eu^{III}$ complexes $[Eu_2L_6(bpm)]$ (L = dbm, tta) were prepared in moderate yields by the reaction of $EuCl_3·6H_2O$, the corresponding β-diketone ligand, and bpm in a 2:6:1 molar ratio and fully characterized by various means. The use of $EuCl_3·6H_2O$, β-diketone ligand, and bpm in 1:3:1 molar ratio, a stoichiometric ratio for the as-yet-unknown mononuclear complex $[EuL_3(bpm)]$, also resulted in the formation of the corresponding dinuclear species. It is interesting to note that this reaction chemistry of $Eu^{III}$ was not similarly applied to diamagnetic $La^{III}$ since the analogous reaction systems with $LaCl_3·7H_2O$ gave mononuclear $[LaL_3(bpm)]$, as judged by $^1H$ NMR spectroscopy. The unavailability of mononuclear $[EuL_3(bpm)]$ led us to select the known complexes $[EuL_3(phen)]$[12] (L = dbm **3** and tta **4**) as closely corresponding mononuclear systems for comparison purposes. (Figure 1) The dinuclear $Eu^{III}$ complexes were initially isolated as solvates $[Eu_2L_6(bpm)]·2(solvent)$ (solvent = $Et_2O$ for **1** and THF for **2**) but the desolvated forms, confirmed by TGA and elemental analysis, were used for measurement purpose except the single-crystal X-ray diffraction studies. They are soluble in common organic solvents and **1** shows better solubility than **2**. Their solubility is similar to that of the corresponding mononuclear complexes **3** and **4**. They are air-stable both in the solid state and in solution. The thermal stability of the dinuclear systems, estimated by the temperature $T_{d5}$ causing 5% weight loss, is also similar to that of the corresponding mononuclear compounds, although the dinuclear species tend to have higher melting points than the mononuclear complexes.

The molecular structures of **1**·$2Et_2O$ and **2**·2THF are depicted in Figures 2 and 3, respectively. Selected bond lengths and angles are summarized in Tables 1 and 2. Compound **1** has two eight-coordinate $Eu^{III}$ sites that are separated by 7.011 Å and symmetrically related by an inversion center lying on the planar bpm moiety. The coordination sphere of each Eu center in **1** can be best described as a distorted square antiprism (Figure 4, a). The average Eu–O bond length is 2.343 Å and the average Eu–N bond length

is 2.677 Å. In the case of the analogous mononuclear complex **3**, the average Eu–O and Eu–N lengths are 2.355 and 2.642 Å, respectively.[13] The crystal of **1**·2$Et_2O$ contains moderate bimolecular π–π interactions between the phenyl rings of the dbm ligands, with an average π–π interaction distance of 3.765 Å, as shown in Figure 5. The stacking interactions are only present between the dimeric pairs.

For compound **2**, the Eu–Eu, average Eu–O, and average Eu–N distances are similar to those in **1** (6.993, 2.394, 2.687 Å, respectively), although the coordination sphere of a distorted hendecahedron (square bicapped trigonal prism; Figure 4, b)[14] for **2** is different from that for **1**. The two pyrimidine rings on the bpm ligand deviate slightly from planarity by 6.3°. The crystal of **2**·2THF exhibits two types of moderate π–π interactions, as shown in Figure 6: one is an intramolecular π–π interaction between the closer thiophene rings in a molecule and the other is a bimolecular π–π interaction between the thiophene rings of neighboring molecules. The average π–π interaction distances are 3.861 and 3.892 Å, respectively, and the stacking interactions are not extended into a one-dimensional array but are isolated between the dimeric pairs, as in **1**. We consider that these bimolecular π–π interactions, as well as the high molecular weight, might be responsible for the lack of sublimability of **1**·2$Et_2O$ and **2**·2THF.

The dinuclear entities of **1** and **2** are considered to remain unchanged in solution. Their electrospray mass spectra (see Exp. Sect. and Figure S1 in the Supporting Information) contain peaks centered at *m/z* = 1577 and 1568 assignable to $[(dbm)_3Eu(bpm)Eu(dbm)_2]^+$ and $[(tta)_3Eu(bpm)Eu(tta)_2]^+$, respectively, thereby demonstrating the formation of dinuclear species as well as the existence of the coordinated β-diketone sensitizing (dbm or tta) and bridging (bpm) ligands in solution. Additional efforts to probe the solution structures of paramagnetic lanthanide complexes **1** and **2** by recording the $^1H$ NMR spectra of the diamagnetic analogues to avoid the line-broadening effect associated with paramagnetism[8] were hampered by the dissimilar reactivity of $Eu^{III}$ and $La^{III}$ mentioned above.

### Absorption and Photoluminescence Properties

The UV/Vis absorption spectra and the normalized PL spectra of the dinuclear europium complexes **1** and **2** and their closely corresponding mononuclear complexes **3** and **4**, in chloroform, are illustrated in Figures 7 and 8, respectively. A close inspection of Figure 7 and the spectroscopic data summarized in Table 3 reveal that the electronic excitation spectra of all the europium complexes are similar and contain features similar to those of the uncoordinated β-diketone ligands (dbmH and ttaH) regardless of the nuclearity. The strong absorption around 350 nm is attributed to the $\pi \rightarrow \pi^*$ transition of the β-diketone ligands.[15] The excitation spectra also show features similar to the absorption spectra of the Eu complexes and are red-shifted by about 30 nm (see Table 3 and Table S2 in the Supporting Information), thus indicating the indirect excitation by energy transfer from the ligand to the $Eu^{III}$ ion.[8b,10a] Hence, we expect that the dinuclear complexes have the same luminescence mechanism mentioned in the Introduction. In fact, compounds **1**–**4** show very similar normalized PL spectra. All the complexes exhibit five peaks at 580, 591, 612, 651, and 692 nm corresponding to the $^5D_0 \rightarrow {}^7F_J$ ($J$ = 0–4) transitions of the $Eu^{3+}$ ion, respectively.[16] However, the full width at half maximum (FWHM) of the most intense $^5D_0 \rightarrow {}^7F_2$ transition at 612 nm in **1** and **2** is broader than that of **3** and **4**. We consider that the broadening of this hyper-

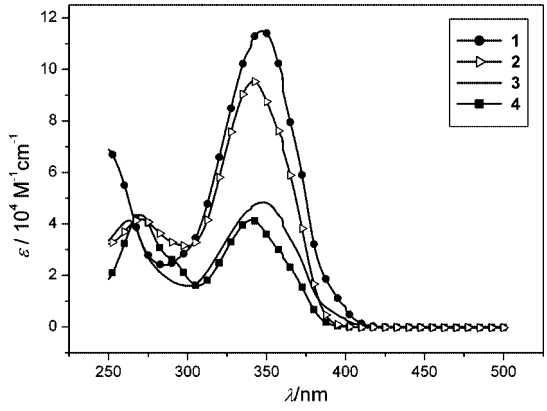

Figure 7. UV/Vis absorption spectra of **1**–**4** in chloroform solution.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sensitive transition arises from the fluxionality of the larger bimetallic complexes in solution compared to monometallic species.

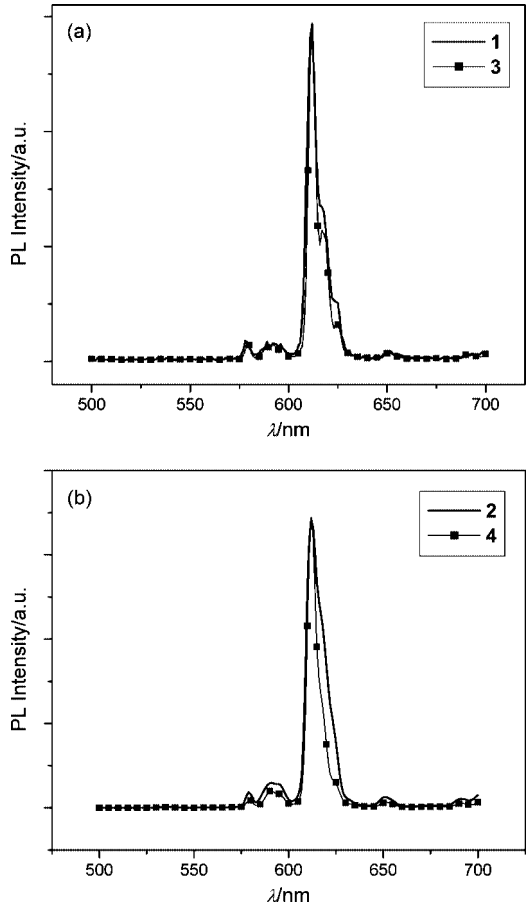

Figure 8. Normalized PL spectra of (a) dbm-containing complexes (**1**, **3**) and (b) tta-containing complexes (**2**, **4**) in chloroform solution.

The PL quantum efficiency of **1**–**4** measured in very dilute solutions of nearly the same optical density[17] decreases in the order **4** > **2** >> **1** ≈ **3** (Table 3). In addition, the europium complexes **1**, **3** containing the tta ligand show a higher efficiency than those (**2**, **4**) containing a dbm ligand due to the inductive effect of the thiophene and the fluorine substituent.[18]

The absorption and emission characteristics of **1**–**4** doped (4, 5, and 10 wt.-%) in PVK/PBD (7:3) films were also investigated. PVK, which has a good hole-transporting ability, was employed since its emission partially overlaps with the absorption spectra of the four Eu complexes. PBD is known to be a good electron-transporting and hole-blocking material and is widely used in polymer LEDs.[19] The 7:3 ratio of PVK/PBD was employed since the same mixed system has been used to fabricate white-light-emitting organic electroluminescent devices[19b] and the use of a large amount of discrete PBD would result in poor film quality. The UV/Vis spectra of the films are almost equal to that of a blank PVK/PBD host film. The minimum doping concentration at which red luminescence of $Eu^{3+}$ appears without the occurrence of PVK/PBD host emission is 10 wt.-% for **1**–**3** and 5 wt.-% for **4**. In addition, the shape of the film PL spectrum of each compound is similar to that of the solution PL spectrum. Therefore, a 7:3 PVK/PBD mixture is a good host for these dinuclear systems.

## Electroluminescent Properties

The EL devices were fabricated with a structure ITO/PEDOT (30 nm)/PVK + PBD + Eu complex (≈80 nm)/LiF (1 nm)/Al (100 nm). Chloroform and 1,2-dichloroethane (DCE) solutions were tested for spin-coating, and the DCE solution was chosen because of the better quality of its films. However, the films of tta-based complexes **2** and **4** were still of poor quality and many pin-holes and dark spots were formed immediately when the devices were operated, thus hampering the fabrication of stable EL devices with these complexes. On the other hand, dbm-containing complexes **1** and **3** show good film quality and stable red light emission. The EL spectra of **1**- and **3**-based devices (in Figure 9) resemble their PL spectra, thus the emission originates from $Eu^{3+}$ and differs only in the intensity at 593 and 625 nm. Nonetheless, **1** emits pure red light with the CIE color coordinate (0.66, 0.34) while **3** emits red-orange light with the CIE color coordinate (0.65, 0.33). The CIE color coordinate of NTSC pure red is (0.67, 0.33). Generally, in the blended system the CIE color coordinate is known to vary as the current density increases[6,20] but the extent of such a change in **1** is much smaller than in **3**, as shown in Figure 10. The EL device with **1** has a turn-on voltage ($V_T$) of 12 V, a maximum brightness ($L_{max}$) of 25.4 cd m$^{-2}$ at 16 V (Figure 11), and a quantum efficiency ($\eta_{EL}$) of 0.021% at 11 V. The EL characteristics of the **3**-

## Conclusions

Two new dinuclear $Eu^{III}$ complexes with formula $[Eu_2L_6(bpm)]$ have been synthesized and fully characterized. Single-crystal X-ray diffraction analyses reveal their dimeric structures formed due to intermolecular π–π interactions, which seem to contribute to the lack of sublimability to some degree. It seems that the solution PL efficiency depends more on the β-diketone sensitizing ligand than the nuclearity or the bridging ligand. The dinuclear compounds are also considered to follow the luminescence mechanism adopted in mononuclear lanthanide complexes. $[Eu_2(dbm)_6(bpm)]$ (**1**) readily forms a polymer EL device ITO/PEDOT (30 nm)/PVK + PBD + Eu complex (≈80 nm)/LiF (1 nm)/Al (100 nm) that produces pure red EL. Overall, the dinuclear system shows similar thermal stability, improved EL color purity, and comparable EL efficiency with respect to the corresponding mononuclear system. Nonetheless, in order to further confirm the concept of dinuclear europium systems in developing pure red EL materials, a synthetic route to sublimable dinuclear europium complexes needs to be developed. A search for ligand systems that can not only block the formation of intermolecular π–π interactions but also have good carrier-transporting ability is in progress.

## Experimental Section

**Materials:** The experiments were carried out using standard Schlenk techniques. THF and *n*-hexane were distilled from Na-K alloy, diethyl ether ($Et_2O$) from Na-benzophenone ketyl, and $CH_2Cl_2$ from $CaH_2$. Ethanol and other reagents were used without any further purification after purchase from Hayman (ethanol), Aldrich (dbmH, ttaH, phen, $EuCl_3·6H_2O$), and Lancaster (bpm). $[Eu(dbm)_3(phen)]$ (**3**) and $[Eu(tta)_3(phen)]$ (**4**) were prepared according to a literature procedure,[12b] purified from THF/*n*-hexane and dried at 110 °C at $10^{-5}$ Torr for 6 h. Chemicals for EL devices were purchased from Aldrich [poly(9-vinylcarbazole) (PVK), 2-(4-biphenylyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (PBD), LiF, Al, and anhydrous 1,2-dichloroethane (DCE)] and Bayer [poly(styrenesulfonate)-doped poly(3,4-ethylenedioxythiophene) (PEDOT)] and used without further purification.

**Synthesis of $[Eu_2(dbm)_6(bpm)]$ (1):** Aqueous NaOH solution (3.0 mL, 1.0 M) and then, rapidly, an aqueous solution of $EuCl_3·6H_2O$ (0.37 g, 1.0 mmol) were added to a 30-mL ethanol solution of dbmH (0.67 g, 3.0 mmol) and bpm (0.079 g, 0.50 mmol) in a two-necked flask. The reaction mixture was refluxed at 60 °C for 12 h and cooled to ambient temperature to give a yellow precipitate, which was filtered off and washed with water and ethanol. The resulting solid was air-dried and recrystallized from a $CH_2Cl_2$/$Et_2O$ solution as yellow crystals of **1**·2$Et_2O$. The solvate $Et_2O$ molecules in the crystals were removed at 110 °C under a vacuum of $10^{-5}$ Torr for 6 h after grinding. Yield: 1.1 g (59%). M.p. 240–242 °C. $T_{d5}$ = 300 °C. IR (KBr): $\tilde{\nu}$ = 444, 511, 609, 656, 670, 687, 719, 940, 1070, 1218, 1310, 1408, 1458, 1478, 1522, 1547, 1595 cm$^{-1}$. $C_{98}H_{72}Eu_2N_4O_{12}$ (1802.4): calcd. C 65.33, H 4.03, N 3.11; found C 64.88, H 4.02, N 3.12. MS (ESI): *m*/*z* = 159 [bpm + H]$^+$, 225 [dbmH + H]$^+$, 756 $[(dbm)_2Eu(bpm)]^+$, 822 $[(dbm)_3Eu + H]^+$, 914 $[(dbm)_2Eu(bpm)_2]^+$, 980 $[(dbm)_3Eu(bpm) + H]^+$, 1048 $[(dbm)_4Eu + 2H]^+$, 1577 $[(dbm)_3Eu(bpm)Eu(dbm)_2]^+$.

**Synthesis of $[Eu_2(tta)_6(bpm)]$ (2):** This complex was synthesized by an analogous method to **1** but with 3.0 mmol (0.67 g) of ttaH. Recrystallization from THF/*n*-hexane afforded light-yellow crystals of **2**·2THF. The solvate THF molecules in the crystals were removed at 110 °C under a vacuum of $10^{-5}$ Torr for 6 h after grinding. Yield: 1.1 g (59%). M.p. 268–270 °C. $T_{d5}$ = 305 °C. IR (KBr): $\tilde{\nu}$ = 499, 582, 641, 683, 759, 793, 935, 1061, 1143, 1187, 1231, 1251, 1308, 1354, 1413, 1459, 1509, 1540, 1580, 1600 cm$^{-1}$.

**X-ray Crystallography:** Suitable crystals of **1**·2$Et_2O$ and **2**·2THF were obtained by diffusion of $Et_2O$ into a $CH_2Cl_2$ solution and *n*-hexane into a THF solution, respectively. Reflection data were collected on a Bruker 1 K SMART CCD-based diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 293 K. A hemisphere of reflection data was collected as $\omega$ scan frames with a width of 0.3° per frame and an exposure time of 10 s per frame. Cell parameters were determined and refined with the SMART program.[21] Data reductions were performed with SAINT,[22] which corrects for Lorentz polarization effects; no corrections for crystal decay were required. Empirical absorption corrections were applied with SADABS.[23] The structures of the compounds were solved by direct methods and refined by full-matrix least-squares methods using the SHELXTL program package with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were placed at their geometrically calculated positions and refined riding on the corresponding carbon atoms with isotropic thermal parameters. Crystal data for both systems are summarized in Table 4.

CCDC-250346 (for **1**) and -250347 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Instrumentation:** Infrared spectra were obtained from KBr pellets with a Bruker EQUINOX-55 spectrometer. Elemental analyses were performed on an EA1110-FISONS (CE Instruments) by the Environmental Analysis Laboratory at KAIST. Electrospray mass spectra were measured on a Mariner instrument at the Korea Basic Science Institute. Melting points were determined on an Electrothermal IA 9100 apparatus. Thermogravimetric analyses (TGA) were carried out under a nitrogen atmosphere at a heating rate of 10 °C min$^{-1}$ with a Dupont 9900 Analyzer. UV/Vis spectra were obtained with a Jasco V-530 spectrophotometer. PL spectra and PL quantum efficiency were recorded with a Spex Fluorog-3 luminescence spectrometer. Excitation spectra were obtained with a Perkin–Elmer LS 50B luminescence spectrometer.

**Fabrication of EL Devices:** The configuration of the EL device was ITO/PEDOT/emitting layer (EML)/LiF/Al. PEDOT, used as a hole-injection layer, was spin-coated onto a pre-cleaned ITO/glass substrate at a spin speed of 1500 rpm for 60 s. Then, a layer of Eu complex-doped PVK/PBD (7:3) was fabricated by spin-coating from their 1,2-dichloroethane solutions (10–11 mg mL$^{-1}$) at 1250 rpm for 60 s. The film thickness of the EML was determined with a TENCOR alpha-step 500 profiler and was approximately 80 nm. LiF (1 nm) and Al (100 nm) were deposited on top of the EML using the vacuum-evaporation method at a pressure of $10^{-6}$ Torr. EL spectra were obtained with a Minolta CS-1000. The current–voltage and luminance–voltage characteristics were recorded with a current–voltage source (Keithley 238) and a luminescence detector (Minolta LS-100), respectively. All EL measurements were carried out at room temperature under an ambient atmosphere.

# Luminescent Polyoxotungstoeuropate Anion-Pillared Layered Double Hydroxides

**Filipa L. Sousa,[a] Martyn Pillinger,[a] Rute A. Sá Ferreira,[b] Carlos M. Granadeiro,[a] Ana M. V. Cavaleiro,[a] João Rocha,[a] Luís D. Carlos,[b] Tito Trindade,[a] and Helena I. S. Nogueira*[a]**

**Keywords:** Layered double hydroxides / Layered compounds / Polyoxometalates / Host–guest systems / Luminescence

Novel luminescent polyoxometalate anion-pillared layered double hydroxides (LDHs) were prepared by aqueous ion exchange of a Zn–Al LDH precursor in nitrate form with the europium-containing polyoxotungstate anions $[EuW_{10}O_{36}]^{9-}$, $[Eu(BW_{11}O_{39})(H_2O)_3]^{6-}$ and $[Eu(PW_{11}O_{39})_2]^{11-}$. The host–guest interaction has a strong influence on the nature of the final intercalated species, as evidenced by elemental analysis, powder X-ray diffraction (XRD), infra-red (IR) and Raman spectroscopy, solid state magic-angle spinning (MAS) $^{11}B$ and $^{31}P$ NMR spectroscopy, and photoluminescence spectroscopy.

## Introduction

Layered double hydroxides are an important class of ionic lamellar solids with the general formula $[M^{2+}_{1-x}M^{3+}_{x}(OH)_2](A^{m-})_{x/m}\cdot nH_2O$ ($M^{2+}$ = $Mg^{2+}$, $Zn^{2+}$, $Ni^{2+}$ etc., $M^{3+}$ = $Al^{3+}$, $Cr^{3+}$, $Ga^{3+}$ etc).[1] The positively charged layers, containing divalent and trivalent cations in octahedral positions, are separated by charge balancing anions and water molecules. The water molecules are connected to both the metal hydroxide layers and the interlayer anions through extensive hydrogen bonding. A range of organic or inorganic guests may be incorporated into LDHs by either ion exchange, direct synthesis or hydrothermal reconstruction of calcined precursors.[2,3] In particular, intercalation chemistry has been explored with the aim of introducing catalytically active sites and photo- and electroactive species. Many different types of metal coordination compounds and oxometalates have been immobilized in LDHs, including phthalocyanines, cyanocomplexes, oxalate complexes and polyoxometalates (POMs).[4]

The first report of LDHs containing polyoxometalates concerned their use as exhaust gas and hydrocarbon conversion catalysts.[5] Since then, a variety of iso- and heteropolyanions with different nuclearities and structures (Keggin, Dawson, Preyssler, Finke) have been incorporated into the interlayer space of these materials.[6–18] Two factors assume considerable importance for the successful intercalation of polyoxometalates into an LDH compound. First, the heteropoly species should carry sufficient charge in order to be spatially capable of compensating the host layer charge. Ideally, the charge should be higher than that necessary in order to increase the lateral separation of the anions in the interlayer and afford a material with microporosity. The second consideration is that the intercalated anion should be resistant to hydrolytic decomposition over the pH domain of stability of the LDH.

In recent years, heteropolyoxometalates incorporating lanthanide ions have excited interest because of their luminescence properties and potential use in lasers and luminescent materials.[19–23] As a result, the preparation of hybrid materials containing these species is now being investigated.[24–32] Francesconi and co-workers recently described Mg–Al LDHs intercalated by luminescent polyoxometalate anions with Dawson-like $[Eu(H_2O)_3(\alpha_2\text{-}P_2W_{17}O_{61})]^{7-}$ and Keggin-like $[Eu_2(H_2O)_2(PW_{11}O_{39})]^{4-}$ structures.[32] In the present work, new polyoxotungstoeuropate anion-pillared layered double hydroxides were prepared by anion exchange reactions of a Zn–Al LDH precursor in nitrate form. Reaction of the wet precursor with the species $[EuW_{10}O_{36}]^{9-}$, $[Eu(BW_{11}O_{39})(H_2O)_3]^{6-}$ and $[Eu(PW_{11}O_{39})_2]^{11-}$ gave the final materials, which were characterized by powder X-ray diffraction, solid state NMR ($^{11}B$, $^{27}Al$, $^{31}P$), infrared and Raman spectroscopy. The luminescence properties of the pillared LDHs were investigated in detail and are compared with those of the precursor polyoxotungstoeuropate anions.

## Results and Discussion

### Synthesis of Polyoxotungstate Anion-Pillared Layered Double Hydroxides

The layered double hydroxide starting material, denoted as $ZnAl[NO_3^-]$, was prepared using a standard coprecipi-

| ZnAl[$Eu(PW_{11}O_{39})_2^{11-}$] | 0.392 | 0.012 | 60 | 9.8 |

[a] Number of moles of polyoxometalate treated with precursor slurry containing 0.25 g clay material. [b] Polyoxometalate concentration. [c] Gallery height, calculated by subtracting the layer thickness (4.8 Å) from the $d_{(003)}$ spacing.

tation method with special attention paid to the avoidance of carbonate interference. Anion-exchange reactions were then carried out on an aqueous slurry of ZnAl[$NO_3^-$] with the polyoxotungstoeuropate anions [$EuW_{10}O_{36}$]$^{9-}$, [$Eu(BW_{11}O_{39})(H_2O)_3$]$^{6-}$ and [$Eu(PW_{11}O_{39})_2$]$^{11-}$ (Table 1). Analysis of the final polyoxotungstoeuropate anion-pillared layered double hydroxides was performed by ICP-AES and the metal atom ratios are presented in Table 2. The Zn/Al ratio was about 1.7 ($x$ = 0.37) for all of the materials and therefore unchanged compared with that for the ZnAl[$NO_3^-$] precursor. Polyoxometalate ($A^{m-}$) loadings were calculated for [$Zn_{1-x}Al_x(OH)_2$]($A^{m-}$)$_{x/m}$ as a percentage of the theoretical maximum calculated from the ICP-determined mol fractions of aluminium.

Table 2. Metal atom ratios determined by ICP-AES for the polyoxotungstoeuropate anion-pillared layered double hydroxides.

| Sample | Zn | Al | W | Eu | $L$[a] |
|---|---|---|---|---|---|
| ZnAl[$EuW_{10}O_{36}^{9-}$] | 1.73 | 1.00 | 1.02 | 0.09 | 92 |
| ZnAl[$Eu(BW_{11}O_{39})(H_2O)_n^{6-}$] | 1.68 | 1.00 | 1.44 | 0.13 | 79 |
| ZnAl[$Eu(PW_{11}O_{39})_2^{11-}$] | 1.77 | 1.00 | 1.26 | 0.05 | 63 |

[a] Polyoxometalate ($A^{m-}$) loadings as a percentage of the theoretical maximum calculated for [$Zn_{1-x}Al_x(OH)_2$]($A^{m-}$)$_{x/m}$ from the ICP-determined mol fractions of aluminium. The calculations assume that the only incorporated polyoxoanions are as indicated in the sample abbreviations.

### Powder X-ray Diffraction

Figure 1 shows the powder XRD patterns obtained for the ZnAl[$NO_3^-$] starting material and the pillared derivatives. Successful ion exchange of nitrate ions for POMs was revealed by the absence of reflections due to the starting material and the appearance of several new equally spaced (00$l$) harmonics with the (003) reflection having shifted to lower 2$\theta$ values. As is often observed for LDH-POM intercalates,[17] the first-order peaks for the pillared phases have very low intensity. This may be related to the high X-ray scattering power of the interlayer, out of phase with the brucite-like layer.[33] The positions of the (003) reflections are confirmed by the presence of the peaks at about 7.25 (006), 4.85 (009), 3.60 (0012) and 2.90 (0015) Å for the phases with $d_{(003)} \approx$ 14.5 Å [traces (c) and (d)], and 4.86 (006) and 3.26 (009) Å for the phase with $d_{(003)} \approx$ 9.6 Å [trace (b)]. The patterns also contain large and asymmetric (*hkl*) reflections in the 33–50° (2$\theta$) range. This is characteristic of some disorder in the periodicity of the layers, such as a turbostratic effect or an intergrowth of the rhombohedral and hexagonal polytypes.[34] Table 1 gives the gallery heights, calculated by subtracting the layer thickness (4.8 Å) from the $d_{(003)}$ spacing, for materials dried under reduced pressure in a vacuum desiccator. The anions [$Eu(BW_{11}O_{39})(H_2O)_3$]$^{6-}$ and [$Eu(PW_{11}O_{39})_2$]$^{11-}$ afforded pillared derivatives with a gallery height of about 10 Å. This layer separation is typical of LDHs pillared by Keggin-type or related structures and is consistent with a guest orientation in which the $C_2$ axis of the oxygen framework is perpendicular to the brucite-like layers.[8,11,12,18] The positions and relative intensities of the (00$l$) reflections in traces (c) and (d) are entirely in agreement with results reported in the literature for related compounds, for example a $Zn_2Al$-LDH pillared by [$\alpha$-$H_2W_{12}O_{40}$]$^{6-}$ anions.[8] A surprising result was obtained for the LDH-POM ZnAl[$EuW_{10}O_{36}^{9-}$]. The basal spacing of about 9.6 Å is only slightly larger than that measured for the precursor ZnAl[$NO_3^-$] (8.94 Å). In the sodium tetrastrontium salt $NaSr_4[EuW_{10}O_{36}]\cdot 34.5H_2O$ the structure of the decatungstoeuropate anion consists of two $W_5O_{18}^{6-}$ units (derived from the hexatungstate $W_6O_{19}^{2-}$

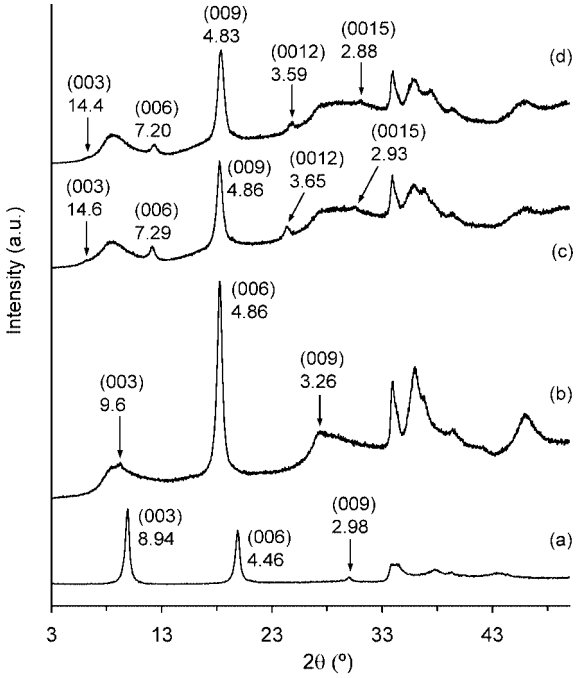

Figure 1. Powder XRD patterns for the LDH intercalates ZnAl[$NO_3^-$] (a), ZnAl[$EuW_{10}O_{36}^{9-}$] (b), ZnAl[$Eu(PW_{11}O_{39})_2^{11-}$] (c) and ZnAl[$Eu(BW_{11}O_{39})(H_2O)_n^{6-}$] (d). Values adjacent to the diffraction peaks are $d$ spacings in Å for several 00$l$ harmonics.

by removal of one W=O group) linked by the europium ion.[35] The four former bridging oxygen atoms from each $W_5O_{18}^{6-}$ unit form a square antiprism around Eu. The shortest dimension of the $[EuW_{10}O_{36}]^{9-}$ anion is about 10 Å (including van der Waals radii for the oxygen atoms). A basal spacing of at least 14.8 Å would therefore be expected for an LDH intercalate containing this anion. The observed basal spacing is much shorter and is in fact only compatible with the presence of two oxygen-atom layers in the interslab space. For example, a very similar powder XRD pattern was reported by Vaysse et al. for a NiCo LDH intercalated by $W_2O_7^{2-}$ anions.[36] All of the diffraction patterns for the exchanged products contain a broad and asymmetric peak at $2\theta$ = 5–11°. This is a common feature for LDH-POM composites and is often attributed to a quasi-crystalline $M^{2+}/M^{3+}$ salt of the POM formed in low quantities,[11] although alternative origins have also been claimed.[37]

### Infrared and Raman Spectroscopy

The infrared and Raman spectra of the polyoxotungstoeuropate anion-pillared layered double hydroxides showed that the exchange of nitrate anions for polyoxotungstate anions was almost complete (by the absence in the infrared spectra of the nitrate $\nu_3$ absorption band at 1384 $cm^{-1}$, or in one case just a very weak IR band present) and also that there was no carbonate present in these materials (by the absence in the infrared spectra of the carbonate $\nu_3$ absorption band at 1370 $cm^{-1}$). The intercalation of polyoxoanions into the layered double hydroxide was clearly shown by the presence in the infrared and Raman spectra of several bands in the range 700–1200 $cm^{-1}$, on top of the lattice vibrations of the host (Figure 2, Table 3), assigned to X–O stretch (X = B or P), the terminal W=O stretch (918–989 $cm^{-1}$), and the W–O–W corner or edge-shared stretching modes (700–900 $cm^{-1}$).[38,39] For ZnAl[$Eu(PW_{11}O_{39})_2^{11-}$] and ZnAl[$Eu(BW_{11}O_{39})(H_2O)_n^{6-}$] the similarity of the guest vibrations to those for the corresponding polyoxotungstoeuropate salts indicates that the structures of the core lacunary anions, i.e. $PW_{11}O_{39}^{7-}$ and $BW_{11}O_{39}^{9-}$, were unaffected by the ion-exchange reaction. In contrast, the bands

attributed to the guest species in ZnAl[$EuW_{10}O_{36}^{9-}$] are significantly different from those exhibited by solid $Na_9[EuW_{10}O_{36}]$, for example the W=O stretch for the guest species is shifted by 14 $cm^{-1}$ and the W–O–W stretching modes present a set of maxima at wavenumbers that are different from those for $Na_9[EuW_{10}O_{36}]$. These changes indicate that the intercalated species have a different structure, in agreement with the powder XRD data and the photoluminescence results discussed below.

### $^{11}B$, $^{27}Al$ and $^{31}P$ MAS NMR

Figure 3 shows the $^{11}B$ MAS NMR spectrum of the pillared LDH ZnAl[$Eu(BW_{11}O_{39})(H_2O)_n^{6-}$]. The spectrum consists of one main peak (with a broad low frequency shoulder) centred at $\delta$ = –6.8 ppm, with a full-width at half-maximum (fwhm) of about 580 Hz. For comparison, the potassium salt $K_5[\alpha\text{-}BW_{12}O_{40}]$ displays a single sharp (fwhm 15 Hz) and symmetric resonance at $\delta$ = –7.4 ppm, while the spectrum of lacunary $K_{6.5}Na_{1.5}[HBW_{11}O_{39}]$ (fwhm 130 Hz) consists of a second-order quadrupole powder pattern, showing that boron is in a distorted tetrahedral coordination.[31,40] The corresponding lanthanopolyoxotungstoborate salt, $K_5H[Eu(BW_{11}O_{39})(H_2O)_3]$, gives rise to a much broader peak (fwhm 440 Hz) at 0.1 ppm (Figure 3).[31] As described in ref.[31], the broadening of the resonance as compared with the monovacant Keggin polyoxotungstoborate is due to insertion of the europium ion into the polyoxoanion. Hence, the observation of the broad resonance at $\delta$ = –6.8 ppm in the $^{11}B$ MAS NMR spectrum of the pillared LDH ZnAl[$Eu(BW_{11}O_{39})(H_2O)_n^{6-}$] suggests that the coordination of the europium ions to the polyoxotungstoborate was maintained after intercalation into the LDH host. Taking into account the results from powder XRD, elemental analysis (which gave the W/Eu molar ratio as 11.1), vibrational spectroscopy and photoluminescence studies (see below), we propose that the resonance at $\delta$ = –6.8 ppm is due to intercalated monomeric 1:1 [$Eu(BW_{11}O_{39})(H_2O)_n]^{6-}$ anions. The crystal structure of the potassium salt, $K_5H[Eu(BW_{11}O_{39})(H_2O)_3]$, is unknown, but by comparison with the analogous $Ce^{3+}$ compound it is likely that a polymeric structure exists in the solid-state, comprising Keggin-type anions bridged by $Eu^{3+}$ cations.[41] The difference in the chemical shifts for the pillared LDH ($\delta$ = –6.8 ppm) and the potassium salt ($\delta$ = 0.1 ppm) may therefore be attributed to the dissociation of the polymer into the monomeric building blocks, and the intercalation of these species into the host LDH. In support of this, it has previously been shown that polymeric lanthanopolyoxotungstosilicates dissociate in aqueous solution.[42] As mentioned above, the peak at $\delta$ = –6.8 ppm in the $^{11}B$ MAS NMR spectrum of the pillared LDH has a weaker low frequency shoulder. This may be due to a small amount of an insoluble $K^+/Zn^{2+}/Al^{3+}$ salt of the POM $[Eu(BW_{11}O_{39})(H_2O)_3]^{6-}$ (related with the broad peak at $2\theta$ = 5–11° in the powder XRD pattern).

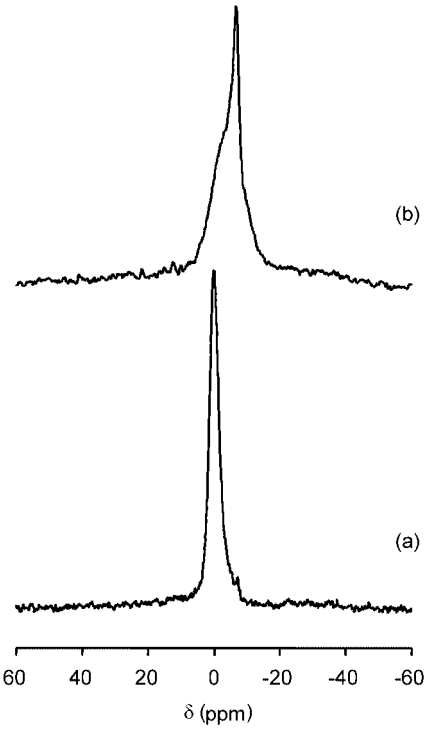

Figure 3. $^{11}B$ MAS NMR spectra of (a) $K_5H[Eu(BW_{11}O_{39})(H_2O)_3]$ and (b) ZnAl[$Eu(BW_{11}O_{39})(H_2O)_n^{6-}$].

The $^{31}P$ MAS NMR spectrum of solid $K_{11}[Eu(PW_{11}O_{39})_2]$ presents a peak centred at 0.3 ppm with a high frequency shoulder at $\delta$ = –1.5 ppm (not shown). The presence of two peaks is probably due to slight asymmetry in the structure with respect to the two $\{PW_{11}O_{39}\}$ moieties.[43] An aqueous solution of this potassium salt exhibits one resonance at $\delta$ = –0.3 ppm, suggesting that the 1:2 structure is stable in solution and that the two phosphorus atoms are equivalent.[43] A complicated $^{31}P$ MAS NMR spectrum was obtained for the pillared LDH ZnAl[$Eu(PW_{11}O_{39})_2^{11-}$], comprising several overlapping peaks between ca. 5 and –12 ppm (Figure 4). Spectral deconvolution gave four main components at –12.2, –10.1, –2.5 and 2.1 ppm in 1.0:1.0:5.3:1.9 intensity ratios. A much weaker peak was also found at $\delta$ = –7.7 ppm with a relative integration of 0.2. The major signal at $\delta$ = –2.5 ppm is assigned to intercalated $[Eu(PW_{11}O_{39})_2]^{11-}$ anions. The two overlapping peaks at –12.2 and –10.1 ppm are attributed to uncoordinated $[PW_{11}O_{39}]^{7-}$ anions in slightly different environments, and the peak at ca. 2.1 ppm is assigned to co-intercalated 1:1 $[Eu(PW_{11}O_{39})(H_2O)_n]^{4-}$ anions.[43] If we exclude the weak resonance at $\delta$ = –7.7 ppm (which, at present, we are unable to assign) and assume that there are no other tungsten or europium-containing species present, the peak area integrated intensities allow a value of 22.3 to be estimated for the overall W/Eu molar ratio. This is in reasonable agreement with the value of 25 found by elemental analysis.

All compounds were also characterized by $^{27}Al$ MAS NMR spectroscopy. The spectra for the precursor ZnAl[$NO_3^-$] and ZnAl[POM] samples present a sharp reso-

nance centred at 14.5–15.6 ppm that indicates the presence of octahedral aluminium only.[44]

### Photoluminescence

Figure 5 shows the room-temperature photoluminescence excitation (PLE) spectra of the europium-containing polyoxotungstate materials monitored within the $^5D_0 \rightarrow {}^7F_2$ lines. The spectra are mainly composed of a series of straight lines ascribed to intra-$4f^6$ transitions. Only the spectrum of $Na_9[EuW_{10}O_{36}]$ presents a large broad band in the UV spectral region with two main peaks around 270 and 320 nm. The origin of the PLE components may be related to ligand-to-europium charge-transfer (LMCT) transitions resulting from the interaction between the europium ion and the POM, in particular LMCT states associated with O → Eu and O →W transitions as already reported for other polyoxometalates containing $Eu^{3+}$ ions.[31,45,46] The higher intensity of the $Eu^{3+}$ straight lines indicate that the $Eu^{3+}$ ions are excited via direct excitation into the intra-$4f^6$ levels, and only for $Na_9[EuW_{10}O_{36}]$ is the sensitized process comparable with direct excitation into the $Eu^{3+}$ levels.

The incorporation of the europium-containing polyoxotungstate into the Zn–Al LDH (to give the material designated as $ZnAl[EuW_{10}O_{36}^{9-}]$) induces the appearance of a low-intensity band centred around 292 nm. For the other two LDH compounds the intensity of this band is negligible. The higher intensity of the $Eu^{3+}$ lines for all of the ion-exchanged LDH materials indicates that the excitation occurs essentially via direct lanthanide excitation, rather than by an efficient sensitized process involving the lanthanide ion ligands.

The changes induced in the $Eu^{3+}$ local structures due to intercalation of the polyoxotungstate anions in the LDH host were further investigated by comparison of the respective emission (PL) spectra. The spectra shown in Figure 6 were obtained for different excitation wavelengths, selected according to the excitation spectra in Figure 5, namely direct excitation into the $Eu^{3+}$ intra-$4f^6$ levels ($^5L_6$, 395 nm), and within the UV band, at 320 nm for $K_{11}[Eu(PW_{11}O_{39})_2]\cdot nH_2O$ and 292 nm for the LDH materials. We will first consider the emission features of the polyoxotungstate salts. All of the spectra display the well-known $Eu^{3+}$ orange-red emission ascribed to transitions between the first excited state $^5D_0$ and the $^7F_{0-4}$ levels of the ground multiplet. No emission from the ligands could be detected. The profile of the PL lines, namely the energy, fwhm and number of components, depends on the sample, confirming that the $Eu^{3+}$ local environments in the three compounds are different. For $K_5H[Eu(BW_{11}O_{39})(H_2O)_3]$ and $K_{11}[Eu(PW_{11}O_{39})_2]\cdot nH_2O$, the higher number of Stark components, in particular for the $^5D_0 \rightarrow {}^7F_{1,2}$ transitions (3 and 4 lines, respectively), suggests that the metal ion local structure is characterized by a low symmetry group without an inversion centre according to the higher intensity of the $^5D_0 \rightarrow {}^7F_2$ transition. The spectrum of $Na_9[EuW_{10}O_{36}]$ has already been reported.[45] The compound prepared by us revealed a different spectrum with singular features, in particular the absence of the $^5D_0 \rightarrow {}^7F_0$ transition and an abnormally high intensity for the $^5D_0 \rightarrow {}^7F_4$ transition. A deeper investigation of these singular emission features lies

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

beyond the scope of the present manuscript and will be discussed in a forthcoming study. For all of the polyoxotungstates, upon changing the excitation wavelength, no major variations are observed in the energy, fwhm and number of emission lines, suggesting that all of the metal ions occupy the same average local coordination site within each polyoxotungstate. This conclusion is further supported by the analyses of the decay curves monitored within the $^5D_0 \rightarrow {}^7F_2$ transition for an excitation wavelength around 395 nm. The decay curves are well reproduced by a single exponential function from which the $^5D_0$ lifetime was extracted (Table 4). For the $[EuW_{10}O_{36}]^{9-}$ anion the decay curve was also monitored for an excitation wavelength within the large broad band in the PLE spectrum, revealing a $^5D_0$ lifetime value similar to that obtained for direct excitation in the $^5L_6$ $Eu^{3+}$ level.

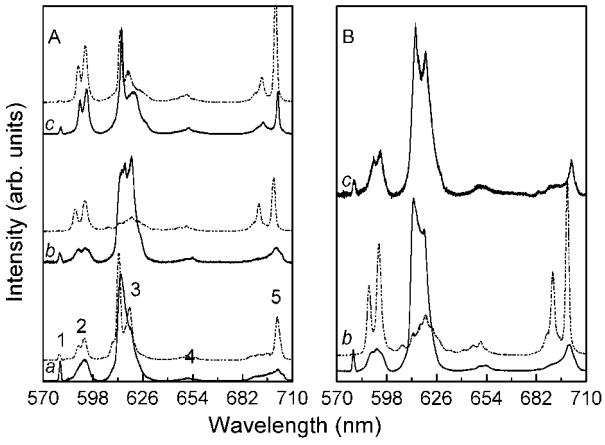

Figure 6. Room-temperature emission spectra of the polyoxotungstoeuropates (dotted lines) and the corresponding layered double hydroxide intercalates (solid lines): (a) $K_5H[Eu(BW_{11}O_{39})(H_2O)_3]$, $ZnAl[Eu(BW_{11}O_{39})(H_2O)_n^{6-}]$, (b) $Na_9[EuW_{10}O_{36}]$, $ZnAl[EuW_{10}O_{36}^{9-}]$, (c) $K_{11}[Eu(PW_{11}O_{39})_2]{\cdot}nH_2O$, $ZnAl[Eu(PW_{11}O_{39})_2^{11-}]$, excited around A: 395 nm and B: 292–320 nm.

Table 4. $^5D_0$ lifetimes, $\tau$, monitored around 611 nm at different excitation wavelengths (292 and 395 nm) for the polyoxotungstoeuropate anions and the respective anion-pillared layered double hydroxides.

The emission spectra of the LDH-POM intercalates obtained by direct excitation into the lanthanide ion levels resemble those of the precursor polyoxotungstoeuropate salts with the exception of $ZnAl[EuW_{10}O_{36}^{9-}]$, which presents an inversion of the relative intensities of the $^5D_0 \rightarrow {}^7F_{1,2}$ transitions, indicating that the $Eu^{3+}$ local coordination site in the ion-exchanged material is different from that in $Na_9[EuW_{10}O_{36}]$, in particular the local symmetry group around the metal ion lost the inversion centre after incorporation in the LDH. This is consistent with the results from powder XRD and vibrational spectroscopy. For the remaining polyoxotungstates, minor changes were measured in the PL spectra. For $ZnAl[Eu(PW_{11}O_{39})_2^{11-}]$, an increase was observed in the relative intensity of the $^5D_0 \rightarrow {}^7F_4$ transition, while for $ZnAl[Eu(BW_{11}O_{39})(H_2O)_n^{6-}]$ an enlargement of the emission lines was detected. These minor changes in the PL spectra are compatible with changes in the $Eu^{3+}$ second coordination shell, induced by the LDH incorporation. However, upon decreasing the excitation wavelength to 292 nm, major changes in the PL profile were recorded, in particular for $ZnAl[EuW_{10}O_{36}^{9-}]$ and $ZnAl[Eu(PW_{11}O_{39})_2^{11-}]$, which must be related with the presence of another $Eu^{3+}$ local site that was not observed in the precursor. This metal ion local coordination site must be related with the appearance of the large broad band in the PLE spectra. The spectrum of $ZnAl[Eu(BW_{11}O_{39})(H_2O)_n^{6-}]$ with an excitation wavelength of 292 nm was omitted from Figure 6 (see part B) because it resembles that obtained at 395 nm, thus strongly suggesting a single $Eu^{3+}$ environment. At this point it should be noted that the PL results for this material do not preclude the existence of a minor second phase comprising a quasi-crystalline $K^+/Zn^{2+}/Al^{3+}$ salt of the POM $[Eu(BW_{11}O_{39})(H_2O)_n]^{6-}$, the existence of which is indicated by the powder XRD and $^{11}B$ MAS NMR results.

In order to further investigate the number of distinct $Eu^{3+}$ local coordination sites in each material the PL and the lifetimes of the $^5D_0$ excited state were acquired at low-temperature for the same excitation wavelengths used to record the room-temperature emission. The number of $Eu^{3+}$ local coordination sites can be inferred through the analysis of the energy and fwhm of the $^5D_0 \rightarrow {}^7F_0$ transition, estimated by deconvoluting the spectrum assuming a Gaussian function. The analysis of the energy and fwhm of the $^5D_0 \rightarrow {}^7F_0$ transition is quite important, since this transition occurs between nondegenerated levels and its energy is usually correlated with the sum of the nephelauxetic effects arising from the $Eu^{3+}$ first neighbours.[47] The existence of more than one line or the variation of its energy and fwhm upon variation of the excitation wavelength suggest the presence of more than one $Eu^{3+}$ local coordination site. Figure 7 shows the low temperature PL spectra for the three LDH-POM samples.

For $ZnAl[Eu(BW_{11}O_{39})(H_2O)_n^{6-}]$ the data collected at low temperature support the conclusion drawn from the room temperature PL spectra, i.e. that the europium ions occupy the same average local coordination site, since the spectra obtained under different excitation wavelengths are essentially the same. Moreover, the energy and fwhm of the $^5D_0 \rightarrow {}^7F_0$ transition is independent of the selected excitation wavelength (Table 5). The nature of this local environment must involve a low site symmetry group without

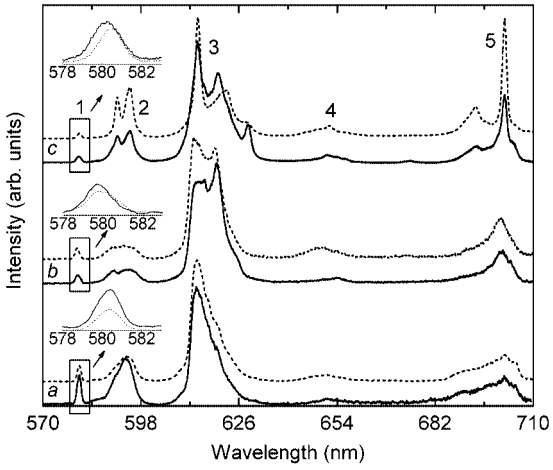

Figure 7. Emission spectra (10 K) for the LDH intercalates ZnAl-$[Eu(BW_{11}O_{39})(H_2O)_n^{6-}]$ (a), $ZnAl[EuW_{10}O_{36}^{9-}]$ (b) and ZnAl-$[Eu(PW_{11}O_{39})_2^{11-}]$ (c) excited at 292 (solid line) and 395 nm (dotted line). (1), (2), (3), (4) and (5) denote the $^5D_0 \rightarrow {}^7F_{0-2}$ transitions, respectively.

inversion centre according to the number of components for the $^5D_0 \rightarrow {}^7F_{0-2}$ transitions (1, 3 and 4, respectively) and the higher intensity of the $^5D_0 \rightarrow {}^7F_2$ lines, respectively.

For the other two LDH-POM samples, changes are observed in the number, energy, fwhm and relative intensity of the $^5D_0 \rightarrow {}^7F_{0-2}$ components as the excitation wavelength increases from 292 to 395 nm. Increasing the excitation wavelength for $ZnAl[EuW_{10}O_{36}^{9-}]$ induces a reduction of the fwhm and a blue-shift of the $^5D_0 \rightarrow {}^7F_0$ transition, suggesting the presence of more than one type of first coordination sphere for the europium ions. Moreover, changes are also observed in the energy and relative intensity of components for the remaining transitions. The presence of at least two distinct local coordination sites for the $Eu^{3+}$ cations is also apparent for $ZnAl[Eu(PW_{11}O_{39})_2^{11-}]$. Upon varying the excitation wavelength from 262 to 395 nm the fwhm and the energy of the $^5D_0 \rightarrow {}^7F_0$ transition decrease. An increase in the relative intensity of the $^5D_0 \rightarrow {}^7F_1$ transition and a decrease in the intensity of the $^5D_0 \rightarrow {}^7F_2$ transition are also detected. These results support the interpretation of the $^{31}P$ MAS NMR spectrum, that is, the co-intercalation of $[Eu(PW_{11}O_{39})_2]^{11-}$ and $[Eu(PW_{11}O_{39})(H_2O)_n]^{4-}$ anions.

The $^5D_0$ lifetime was measured at low temperature using two different excitation wavelengths (292 and 395 nm) and a monitoring wavelength around the more intense line of the $^5D_0 \rightarrow {}^7F_2$ transition (not shown). Regardless of the selected excitation wavelength, the experimental data for $ZnAl[Eu(BW_{11}O_{39})(H_2O)_n^{6-}]$ are well reproduced by a single exponential function, revealing a lifetime value of $0.255 \pm 0.002$ ms (Table 4), which further confirms the existence of a single $Eu^{3+}$ coordination site in this material. For $ZnAl[EuW_{10}O_{36}^{9-}]$, the decay curve is also well reproduced by a single exponential, but different lifetime values of $0.347 \pm 0.003$ and $0.289 \pm 0.001$ were obtained for excitation wavelengths around 292 and 395 nm, respectively (Table 5). The decay curves for $ZnAl[Eu(PW_{11}O_{39})_2^{11-}]$ revealed a two-exponential behaviour for the two selected excitation wavelengths, indicating lifetime values of $0.324 \pm 0.002$ and $2.950 \pm 0.118$ ms.

We can estimate the efficiency, $q$, of the $^5D_0$ $Eu^{3+}$ excited state. Assuming that only nonradiative and radiative processes are essentially involved in the depopulation of the $^5D_0$ state, $q$ can be defined as shown in Equation (1)

$$q = \frac{k_r}{k_r + k_{nr}} \quad (1)$$

where $k_r$ and $k_{nr}$ are the radiative and the nonradiative transition probabilities, respectively.

The emission intensity, $I$, taken as the integrated intensity $S$ of the emission curves, for the $^5D_0 \rightarrow {}^7F_{0-4}$ transitions, is expressed by Equation (2)

$$I_{i \rightarrow j} = \hbar w_{i \rightarrow j} A_{i \rightarrow j} N_i \equiv S_{i \rightarrow j} \quad (2)$$

where $i$ and $j$ represent the initial ($^5D_0$) and final ($^7F_{0-4}$) levels, respectively, $\hbar w_{i \rightarrow j}$ is the transition energy, $A_{i \rightarrow j}$ corresponds to Einstein's coefficient of spontaneous emission and $N_i$ is the population of the $^5D_0$ emitting level.[47b] The radiative contribution may be calculated from the relative intensities of the $^5D_0 \rightarrow {}^7F_{0-4}$. The branching ratio for the $^5D_0 \rightarrow {}^7F_{5,6}$ transitions must be neglected as they are not observed experimentally. Their influence on the depopulation of the $^5D_0$ excited state can therefore be ignored. Since the $^5D_0 \rightarrow {}^7F_1$ transition can be considered as a reference, due to its dipolar magnetic nature, $k_r$ can be calculated as shown in Equation (3)

$$k_r = A_{0 \rightarrow 1} \frac{\hbar\omega_{0 \rightarrow 1}}{S_{0 \rightarrow 1}} \sum_{J=0}^{4} \frac{S_{0-J}}{\hbar\omega_{0-J}} \quad (3)$$

where $A_{0-1}$ is Einstein's coefficient of spontaneous emission between the $^5D_0$ and the $^7F_1$ Stark levels. The $^5D_0 \rightarrow {}^7F_1$ transition does not depend on the local ligand field seen by $Eu^{3+}$ ions and, thus, may be used as a reference for the

Table 5. Energy, $E$, [$cm^{-1}$] and fwhm [$cm^{-1}$] of the $^5D_0 \rightarrow {}^7F_0$ transition at different excitation wavelengths (292 and 395 nm) for the anion-pillared layered double hydroxides.

whole spectrum; in vacuo $A_{0-1}$ = 14.65 s$^{-1}$.[48] An effective refractive index of 1.5 was used. It was not possible to evaluate the $q$ value for the LDH intercalates ZnAl-[EuW$_{10}$O$_{36}$$^{9-}$] and ZnAl[Eu(PW$_{11}$O$_{39}$)$_2$$^{11-}$], due to the presence of more than one local coordination site for the metal ions. Since it was not possible to selectively excite the emission ascribed to each $Eu^{3+}$ ion, the emission intensity, $I$, cannot be determined independently, thus preventing any $^5D_0$ quantum efficiency calculations.

The quantum efficiency value for the compound K$_5$H[Eu(BW$_{11}$O$_{39}$)(H$_2$O)$_3$] is lower than those for the other two polyoxotungstoeuropate salts, essentially due to a higher nonradiative transition probability, that may be due to a higher number of coordinated water molecules (Table 6). Although the radiative transition probability for the LDH intercalate ZnAl[Eu(BW$_{11}$O$_{39}$)(H$_2$O)$_3$$^{6-}$] is higher, there is also an increase in the nonradiative transition probability, contributing to a slight decrease of the overall $^5D_0$ quantum efficiency.

## Conclusions

A new family of luminescent materials has been prepared by treatment of a Zn–Al layered double hydroxide in nitrate form with different polyoxotungstoeuropate anions. The photoluminescence studies, in conjunction with elemental analysis, powder XRD, IR and Raman spectroscopy, and solid state MAS NMR, allow us to construct a detailed picture of the possible nature of the intercalated anions. After ion exchange with an aqueous solution of K$_5$H[Eu(BW$_{11}$O$_{39}$)(H$_2$O)$_3$], powder XRD, elemental analysis for W and Eu, vibrational and $^{11}$B MAS NMR spectroscopy strongly indicate that the guest species in the resultant material, ZnAl[Eu(BW$_{11}$O$_{39}$)(H$_2$O)$_n$$^{6-}$], are monomeric 1:1 [Eu(BW$_{11}$O$_{39}$)(H$_2$O)$_n$]$^{6-}$ anions, which give rise to a gallery height of about 10 Å. The photoluminescence data acquired at room temperature and also at low temperature confirm the existence of a single $Eu^{3+}$ coordination site in this material. Overall, the room-temperature excitation and emission spectra for the pillared LDH are not very different from those for the potassium salt, K$_5$H[Eu(BW$_{11}$O$_{39}$)(H$_2$O)$_3$]. Slight differences were, however, observed in the lifetimes and transition probabilities of the $^5D_0$ level. Ion exchange of the starting LDH compound with a solution of K$_{11}$-[Eu(PW$_{11}$O$_{39}$)$_2$] also gave a pillared derivative with a gallery height close to 10 Å. The photoluminescence data for this material show the presence of at least two distinct local coordination sites for the $Eu^{3+}$ cations, which supports the interpretation of the $^{31}$P MAS NMR spectrum, that is, the assignment of two of the peaks to co-intercalated 2:1 [Eu(PW$_{11}$O$_{39}$)$_2$]$^{11-}$ and 1:1 [Eu(PW$_{11}$O$_{39}$)(H$_2$O)$_n$]$^{4-}$ anions. The $^{31}$P MAS NMR spectrum also indicates the presence of uncoordinated [PW$_{11}$O$_{39}$]$^{7-}$ anions. All three of these species could conceivably give rise to pillared LDHs with gallery heights around 10 Å. Deconvolution of the $^{31}$P MAS NMR spectrum showed that the 2:1 Eu-containing anion was the major species present. These results show that, regardless of the initial polyoxometalate species in solution, the nature of the final intercalated species can be different, presumably due to the strong host–guest interaction(s). This was especially evident for the anion [EuW$_{10}$O$_{36}$]$^{9-}$, which gave rise to a material containing intercalated anions with a quite different and, as yet, unknown structure. The observed basal spacing was only compatible with the presence of anions smaller than the decatungstometalate species, and the photoluminescence studies reveal the presence of more than one first coordination sphere for the lanthanide ions.

## Experimental Section

**Reagents and Materials:** Commercial materials were of reagent grade or better and used without further purification. Literature methods were used to prepare sodium or potassium salts of the polyoxotungstoeuropate anions [EuW$_{10}$O$_{36}$]$^{9-}$,[49] [Eu(BW$_{11}$O$_{39}$)(H$_2$O)$_3$]$^{6-}$,[31] and [Eu(PW$_{11}$O$_{39}$)$_2$]$^{11-}$.[50] The Zn–Al LDH starting material, ZnAl[NO$_3^-$], was prepared as described previously.[12]

**Synthesis of Polyoxotungstoeuropate Anion-Pillared Layered Double Hydroxides:** Anion-exchange reactions with a series of europium-containing polyoxotungstate anions were carried out on an aqueous slurry of ZnAl[NO$_3^-$], using the method described by Evans et al. (Table 1).[12] A typical reaction scale was 12.5 cm$^3$ and involved dropwise addition of an aqueous solution of the polyoxometalate (up to 100% in excess over that theoretically required for complete exchange) to the ZnAl[NO$_3^-$] slurry. The mixtures were then stirred for 3 to 5 h in the temperature range of 60–70 °C (Table 1). Yields for approximately 0.25 g precursor clay: ZnAl[EuW$_{10}$O$_{36}$$^{9-}$], 0.36 g; ZnAl[Eu(BW$_{11}$O$_{39}$)(H$_2$O)$_3$$^{6-}$], 0.42 g; ZnAl[Eu(PW$_{11}$O$_{39}$)$_2$$^{11-}$], 0.30 g.

**Instrumentation:** The Zn, Al, Eu, W and P contents were measured by Inductively Coupled Plasma-Atomic Emission Spectrometry (ICP-AES, Analytical Laboratories, University of Aveiro). FT-IR spectra were collected from KBr pellets (Aldrich, 99%+, FT-IR grade) with a Mattson 7000 FT-IR spectrometer. FT-Raman spectra were recorded with a Bruker RFS100/S FT-Raman spectrometer (Nd:YAG laser, 1064 nm excitation). $^{11}$B, $^{27}$Al and $^{31}$P MAS NMR spectra were recorded with a Bruker Avance 400 spectrometer at, respectively, 128.37, 104.26 and 161.97 MHz, using spinning rates of 14 kHz. The $^{31}$P MAS NMR spectra were recorded with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

45° pulses and 50 s recycle delays. The $^{27}Al$ MAS NMR spectra were recorded with 9° pulses and 1 s recycle delays. The $^{11}B$ MAS NMR spectra were recorded with 15° pulses and 5 s recycle delays. Chemical shifts are quoted in ppm from $BF_3{\cdot}O(C_2H_5)_2$ ($^{11}B$), $Al(H_2O)_6^{3+}$ ($^{27}Al$) and 85% $H_3PO_4$ ($^{31}P$). Powder XRD data were collected at room temperature with a Philips X′pert diffractometer operating at 40 kV and 50 mA using Cu-$K_\alpha$ radiation. The diffractometer was equipped with a curved graphite monochromator, in a Bragg–Brentano *para*-focusing optics configuration. The ZnAl[$NO_3^-$] sample was step-scanned in 0.05° 2$\theta$ steps with a counting time of 1 s per step. For the other samples, a step size of 0.02° 2$\theta$ was used with a counting time of 16 s per step. The room-temperature emission and excitation spectra of the LDHs were recorded using a Jobin Yvon-Spex spectrometer (HR, 460) coupled to a R928 Hamamatsu photomultiplier. A Xe arc lamp (150 mW) coupled to a Jobin Yvon monochromator (TRIAX 180) was used as the excitation source. All of the spectra were corrected for the response of the detector. The room-temperature photoluminescence of the POMs and the spectra and lifetimes recorded at low-temperature (10 K) were detected with a modular double grating excitation spectrofluorimeter with a TRIAX 320 emission monochromator (Fluorolog-3, Jobin Yvon-Spex) coupled to a R928 Hamamatsu photomultiplier, in the front face acquisition mode. All of the photoluminescence spectra were corrected for optics and detection spectral response.

# The First Metal-Oxo Cluster Containing Lithium and Bismuth

**Michael Mehring,*[a] Dirk Mansfeld,[a] Burkhard Costisella,[a] and Markus Schürmann[a]**

**Keywords:** Bismuth / Lithium / Silanolate / Alkoxide / Metal-oxo cluster

The reaction of $[Bi(OtBu)_3]$ with $LiOSiMe_3$ gave the heterobimetallic bismuth-oxo cluster $[Bi_3Li_5(\mu_5\text{-}O)_2(\mu_3\text{-}OSiMe_3)_2(\mu_3\text{-}OtBu)_2(\mu_2\text{-}OtBu)_6]$ (**1**) after elimination of $Me_3SiOSiMe_3$. The cage compound **1** is the first example of a mixed-metal alkoxide/siloxide composed of lithium and bismuth. Crystals of **1**·2 $C_7H_8$ and **1**·1.5 THF suitable for X-ray single crystal structure analysis were obtained by crystallisation from toluene and THF, respectively. Both solvates crystallise in the orthorhombic space group *Pmmn* with $Z = 2$. The lattice constants are $a = 16.267(3)$ Å, $b = 17.126(3)$ Å and $c = 12.155(2)$ Å (**1**·2 $C_7H_8$) and $a = 16.353(2)$ Å, $b = 17.156(1)$ Å and $c = 12.256(1)$ Å (**1**·1.5 THF). In both compounds the solvent molecules occupy channels along the *c*-axis. The basic molecular unit is best described as a face-sharing double cubane $[Bi\text{-}Li_5(\mu_4\text{-}O)_2(\mu_3\text{-}OSiMe_3)_2(\mu_3\text{-}OtBu)_2]$ which is coordinated by two $[Bi(OtBu)_3]$ molecules. The compound is kinetically labile in solution and readily decomposes in 1,1,2,2-tetrachloroethane with elimination of 1,1,2-trichloroethylene.

## Introduction

Heterometallic bismuth-oxo compounds including element combinations such as Bi/Mo/O,[1,2] Bi/Ti/O,[3] Bi/Sr/Ta/O[4] as well as Bi/V/O[5] have found various applications as ferroelectric devices, oxide ion conductors, non-toxic pigments, catalysts and catalyst models. We are interested in novel precursors for bismuth-containing materials and therefore we have started to systematically explore the chemistry of bismuth silanolates[6] which has been scarcely reported before.[7,8] The synthesis of one of the most promising precursors, $[Bi(OSiMe_3)_3]$, was published in 1968 starting from $BiCl_3$ and $NaOSiMe_3$.[8] Our attempts to reproduce the synthetic procedure did not result in the pure bismuth tris(trimethylsilanolate). We always observed sodium contamination of the final material and isolated several heterobimetallic sodium bismuth-oxo clusters.[9] The formation of such heterobimetallic cage compounds composed of bismuth and sodium is not surprising given the similar ionic radii [$r(Bi^{3+}) = 117$ pm; $r(Na^+) = 116$ pm; coordination number CN = 6],[10] and the rich and variable coordination chemistry of both atom types. Indeed, several such heterobimetallic alkoxides composed of sodium and bismuth were synthesized previously.[11,12] In addition, heterobimetallic bismuth alkoxides including metals such as potassium,[12] barium,[13] vanadium,[14] titanium,[15] molybdenum,[2,16] and terbium[17] were reported. Mixed-metal carboxylates/alkoxides are also known for some transition metals.[18] However, to the best of our knowledge no heterobimetallic alkoxide containing lithium as the lightest metal atom [$r(Li^+) = 73$ pm; CN = 4][10] and bismuth, the heaviest stable element of the periodic table, was reported before. The only cage compound we are aware of is $[Li_2Bi_2(NtBu)_2(thf)_2]$.[19] Notably, the reaction of $[Bi(OtBu)_3]$ with $NaOtBu$ and $KOtBu$ was reported to give $[Bi_2Na_4O(OtBu)_8]$ and $[BiK(OtBu)_4]$, respectively, whereas no reaction was observed with $LiOtBu$.[12] This prompted us to look at the reaction of $[Bi(OtBu)_3]$ with $LiOSiMe_3$ as an alternative method for the synthesis of $[Bi(OSiMe_3)_3]$ by ligand exchange.

## Results and Discussion

The metathesis reaction of $[Bi(OtBu)_3]$ with $LiOSiMe_3$ was expected to provide the bismuth silanolate $[Bi(OSiMe_3)_3]$. However, the reaction according to Equation (1) gave the heterometallic bismuth-oxo cluster $[Bi_3Li_5(\mu_5\text{-}O)_2(\mu_3\text{-}OSiMe_3)_2(\mu_3\text{-}OtBu)_2(\mu_2\text{-}OtBu)_6]$ (**1**) (Figure 1) with high yield (> 90%). Both GC-MS and $^{29}Si$ NMR of the reaction solution from which compound **1** had been filtered off revealed the formation of $Me_3SiOSiMe_3$. Apparently, the trimethylsiloxy groups are the source for the $\mu_5$-oxygen atoms in compound **1**. Similarly, we did ob-

$$3\,[Bi(OtBu)_3] + 6\,LiOSiMe_3 \xrightarrow[-\,LiOtBu\;-\,2\,Me_3SiOSiMe_3]{THF} [Bi_3Li_5O_2(OSiMe_3)_2(OtBu)_8]$$

serve recently that $Me_3SiOSiMe_3$ is eliminated by the reaction of $BiCl_3$ with $NaOSiMe_3$ and also upon thermally induced decomposition of $[Bi(OSiMe_3)_3]$.[9,20] Notably, elimination of di-*tert*-butyl ether was reported to take place upon reaction of $[Bi(OtBu)_3]$ with $NaOtBu$ but not with $LiOtBu$.[12]

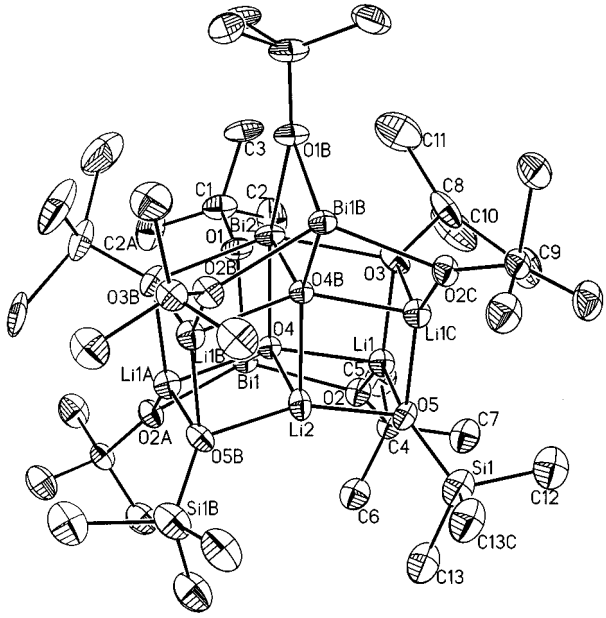

Figure 1. View of the molecular structure of $[Bi_3Li_5(\mu_5\text{-}O)_2(\mu_3\text{-}OSiMe_3)_2(\mu_3\text{-}OtBu)_2(\mu_2\text{-}OtBu)_6]$ (**1**) showing the atom numbering scheme (ORTEP drawing with 30% probability ellipsoids). Selected bond lenghts [Å] and angles [°] associated with Li (for Bi see also Figure 3): Li(1)–O(2) 1.865(13), Li(1)–O(3) 1.992(13), Li(1)–O(4) 2.087(12), Li(1)–O(5) 1.925(12), Li(2)–O(5) 1.897(8), Li(2)–O(4) 2.10(2); O(2)–Li(1)–O(3) 128.3(7), O(2)–Li(1)–O(4) 86.5(5), O(2)–Li(1)–O(5) 133.7(7), O(3)–Li(1)–O(4) 86.9(5), O(3)–Li(1)–O(5) 97.9(5), O(4)–Li(1)–O(5) 98.7(6), O(4)–Li(2)–O(4B) 84(1), O(4)–Li(2)–O(5) 99.1(5), O(5)–Li(2)–O(5B) 155(2), Li(1)–O(4)–Li(2) 76.6(4), Li(1)–O(5)–Li(2) 85.6(7), Li(1)–O(3)–Li(1C) 80.3(7), Li(1)–O(3)–Bi(2) 96.5(4), Li(2)–O(4)–Bi(2) 97.5(5), Li(2)–O(4)–Bi(1) 144.1(5), Bi(1)–O(1)–Bi(2) 96.9(2), Bi(1)–O(4)–Bi(2) 118.4(3). Symmetry operations used to generate equivalent atoms: A = $-x$ + 1/2, $y$, $z$; B = $-x$ + 1/2, $-y$ + 3/2, $z$; C = $x$, $-y$ + 3/2, $z$.

The molecular structure of compound **1** is best described to consist of the face-sharing double-cubane $[BiLi_5(\mu_4\text{-}O)_2(\mu_3\text{-}OSiMe_3)_2(\mu_3\text{-}OtBu)_2]$ and two $[Bi(OtBu)_3]$ molecules which are coordinated to the heterocubane through their oxygen atoms as well as the bismuth atoms (Figure 2). The incorporation of the large bismuth atom results in distortions from an ideal face-centred double cubane structure.

As a result of the high symmetry of compound **1** only two distinct lithium and bismuth atoms, respectively, are observed. Both lithium atoms are coordinated to four oxygen atoms and adopt a coordination geometry, which is best described as distorted trigonal bipyramid with one vertex being unoccupied. For Li(1) this vertex is in axial and for Li(2) it is in equatorial position. Slight differences in the Li–O bond lengths are observed depending on the bridging mode of the oxygen atoms. The shortest Li–O bond lengths are observed for $\mu_2$-$OtBu$ [Li(1)–O(2) 1.865(13) Å] followed

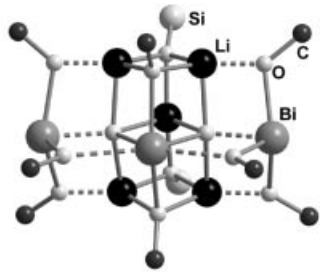

Figure 2. Ball and stick model of the face sharing double-cubane $[BiLi_5(\mu_4\text{-}O)_2(\mu_3\text{-}OSiMe_3)_2(\mu_3\text{-}OtBu)_2]$ coordinated by $[Bi(OtBu)_3]$. Methyl groups omitted for clarity. The dimensions of the spheres do not correlate with the effective ionic radii of the atoms.

by $\mu_3$-$OSiMe_3$/$\mu_3$-$OtBu$ [Li(1)–O(3) 1.992(13) Å, Li(1)–O(5) 1.925(12) Å, Li(2)–O(5) 1.897(8) Å] and $\mu_5$-O [Li(1)–O(4) 2.087(12) Å, Li(2)–O(4) 2.10(2) Å]. Irregular coordination polyhedra are observed for both bismuth atoms. The coordination geometry at Bi(1) might be described as a distorted *pseudo*-trigonal bipyramid $BiO_4X$ with the lone pair X occupying an axial position (Figure 3). The Bi–O bond lengths are in the range 2.087(6)–2.242(5) Å with the shortest bond lengths found in axial position. As a result of the stereochemical activity of the lone pair the torsion angle Bi(1)–O(1)–O(2A)–O(2) amounts to 22°. A [4+2]-coordination is observed for Bi(2) with a short Bi–O bond length of 2.087(6) Å for Bi(1)–O(4), a bond length of 2.331(7) Å for Bi(2)–O(3) and a longer bismuth–oxygen distance of 2.683(7) Å for Bi(2)···O(1). In first approximation the polyhedron might be described as strongly distorted *pseudo*-pentagonal bipyramid $BiO_6X$ with a stereochemically active lone pair occupying a position within the pentagonal plane. Consequently, the O(3)–Bi(2)–O(3B) angle decreases from 180° to 146.4(3)° and the O(1)–Bi(2)–O(1B) angle increases from 144° to 146.0(3)°.

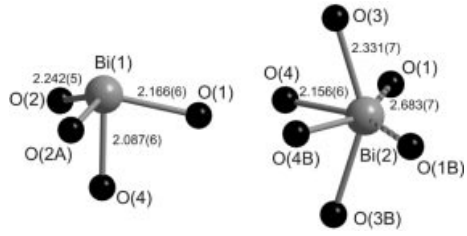

Figure 3. View of the bismuth–oxygen polyhedra observed for Bi(1) and Bi(2) including distances given in Å. Selected O–Bi–O angles [°]: O(1)–Bi(1)–O(2) 108.9(1), O(1)–Bi(1)–O(4) 78.3(2), O(2)–Bi(1)–O(2A) 128.6(2), O(2)–Bi(1)–O(4) 77.5(1); O(1)–Bi(2)–O(1B) 146.0(3), O(1)–Bi(2)–O(3) 94.9(1), O(1)–Bi(2)–O(4) 66.4(2), O(3)–Bi(2)–O(3B) 146.4(3), O(3)–Bi(2)–O(4) 77.3(1), O(4)–Bi(2)–O(1B) 147.6(2), O(4)–Bi(2)–O(4B) 81.3(3). Symmetry operations used to generate equivalent atoms: $A$ = $-x$ + 1/2, $y$, $z$; $B$ = $-x$ + 1/2, $-y$ + 3/2, $z$.

The heterometallic bismuth-oxo cluster crystallises from both toluene and THF in form of the solvates **1**·2 $C_7H_8$ and **1**·1.5 THF, respectively. In the solid state the metal-oxo clusters, which have a brick-like shape with approximate dimensions of $12 \times 11 \times 11$ Å$^3$ (atom to atom distance), arrange in such a way that channels along the *c-axis* are

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

formed. Solvent molecules occupy these channels. In Figure 4 a packing diagram of **1**·2 $C_7H_8$ leaving the voids unoccupied is shown. The diameter of the channels amounts to approximately 6 Å (atom to atom distance). The THF solvate **1**·1.5 THF shows similar crystallographic data.

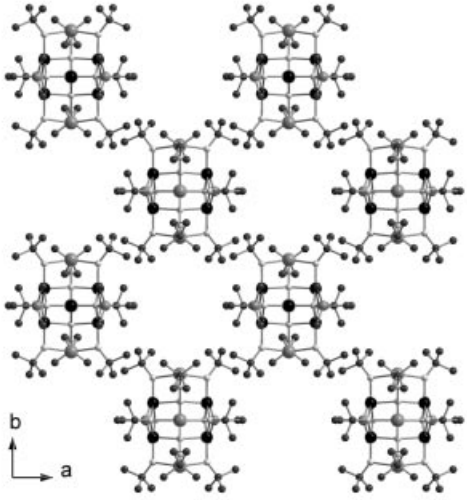

Figure 4. Packing diagram of **1**·2$C_7H_8$ in the solid state. The solvent molecules which occupy the channels along the *c*-axis are removed for clarity.

The moisture-sensitive compound dissolves in solvents such as $CD_2Cl_2$, $C_2D_2Cl_4$, $CCl_4$, toluene and THF at room temperature, but its solubility is significantly decreased at lower temperature. The $^1$H NMR spectrum of a [$D_6$]toluene solution of **1** is rather complex and shows a vast number of signals which are grouped in the regions (a): $\delta$ = 0.22–0.52 ppm and (b): $\delta$ = 1.05–1.67 ppm with an overall integral ratio of approximately 1:4 (see Figure S1 in the Supporting Information). Similarly, complex $^1$H NMR spectra are observed in other solvents such as 1,1,2,2-tetrachlorethane and $CCl_4$. These spectra are not compatible with the structure of compound **1** observed in the solid state. Thus we conclude that in solution the metal-oxo cluster is kinetically labile and gives a mixture of metal (oxo)alkoxides. This hypothesis is further supported by a comparison of the IR spectra of the solid material **1** and its saturated $CCl_4$ solution (Figure S2). Decomposition of compound **1** in 1,1,2,2-[$D_2$]tetrachloroethane under base-catalysed elimination of DCl to give [D]-1,1,2-trichloroethylene was observed at room temperature overnight. Heating of a 1,1,2,2-tetrachlorethane solution significantly enhances this process and a colourless solid containing chloride and bismuth was obtained.[21] In contrast compound **1** is stable in $CCl_4$ and heating a toluene solution of **1**·1.5 THF at reflux and subsequent crystallisation at –20 °C gave single crystals of the toluene solvate **1**·2 $C_7H_8$.

## Conclusion

In contrast to heterometallic sodium/bismuth oxoalkoxides and oxosilanolates those of lithium were not reported so far. We anticipated that formation of lithium derivatives is less likely as a result of the great difference of the ionic radii of lithium and bismuth. However, metathesis reaction of [Bi(O*t*Bu)$_3$] with $LiOSiMe_3$ gave the novel heterometallic metal-oxo cluster [$Bi_3Li_5(\mu_5\text{-}O)_2(\mu_3\text{-}OSiMe_3)_2(\mu_3\text{-}O$*t*$Bu)_2(\mu_2\text{-}O$*t*$Bu)_6$] (**1**) instead of [Bi(OSiMe$_3$)$_3$]. Formation of the metal-oxo cluster **1** proceeds through elimination of $Me_3SiOSiMe_3$. It should be noted that our attempts to prepare [Bi(OSiMe$_3$)$_3$] by salt elimination using $BiCl_3$ and $MOSiMe_3$ (M = Li, Na, K) also failed.[9] Apparently, the ready formation of $Me_3SiOSiMe_3$ makes the salt metathesis unfavourable for the synthesis of bismuth tris(trimethylsilanolate) even with the small lithium cation. However, heterometallic bismuth compounds might be suitable precursors for novel mixed metal oxide materials prepared through mild non-aqueous procedures.

## Experimental Section

**General Remarks:** Solvents were distilled from appropriate drying agents prior to use (THF, $Et_2O$ and toluene from sodium; $C_2D_2Cl_4$, $CD_2Cl_2$ and $CCl_4$ from $CaH_2$). All manipulations were carried out under argon using the Schlenk-type technique. [Bi(O*t*Bu)$_3$][22] and $LiOSiMe_3$[23] were prepared according to literature procedures. Elemental analyses were performed on a LECO-CHNS-932 analyser. The deviation from the calculated values results from the moisture sensitivity of the compound. NMR experiments were performed using a Bruker DPX 300, DRX 400 and DRX 500. Chemical shifts $\delta$ are given in ppm and were referenced against $Me_4Si$ ($^1$H, $^{29}$Si). The $^{29}$Si NMR of the reaction solution was recorded with a $D_2O$ capillary as external lock reference. NMR experiments were carried out in sealed NMR tubes. IR spectra were obtained from a Bruker FTIR IFS 28 spectrometer. The IR spectra were run as Nujol mulls and absorption bands assigned to the compound are listed in the range 400–1500 cm$^{-1}$. Decomposition of compound **1** in 1,1,2,2-tetrachloroethane to give 1,1,2-trichloroethylene and a colourless solid (**A**) was observed. GC-MS (Perkin–Elmer Turbomass Gold) of the supernatant solution revealed the formation of 1,1,2-trichloroethylene and *t*BuOH. The amount of 1,1,2-trichloroethylene was negligible in freshly distilled 1,1,2,2-tetrachlorethane. According to an EDX analysis (Hitachi FEG S 4500) the inhomogeneous solid material (**A**) contains Bi and Cl with a ratio in the range 1:2.8–4.8.

**[$Bi_3Li_5(\mu_5$-O)$_2(\mu_3$-OSiMe$_3)_2(\mu_3$-O*t*Bu)$_2(\mu_2$-O*t*Bu)$_6$] (1):** A solution of $LiOSiMe_3$ (15.36 g, 0.16 mmol) in 200 mL $Et_2O$ was added to a solution of [Bi(O*t*Bu)$_3$] (22.84 g, 0.05 mmol) in 250 mL THF at room temperature and the reaction mixture was stirred overnight to give a cloudy yellow solution. After filtration the amount of solvent was reduced to approximately 100 mL and fractional crystallisation at –20 °C gave colorless crystals of **1**·1.5 THF. The $^{29}$Si NMR of the supernatant solution showed a signal at 7.4 ppm assigned to $Me_3SiOSiMe_3$ and a second signal at 9.9 ppm assigned to $LiOSiMe_3$. The combined crystalline fractions (24.99 g, 92% based on Bi) were dried in vacuo to remove the THF and to leave a colourless amorphous solid. Comparison of the IR spectra of the single crystals **1**·1.5 THF and the amorphous material **1** indicates removal of the guest molecules THF without collapse of the molecular structure (see Supporting Information). Single crystals suitable for X-ray crystallography were obtained from both THF and toluene by dissolution of the amorphous material and subsequent crystallisation at –20 °C. Analytical data of **1**: $C_{38}H_{90}Bi_3Li_5O_{12}Si_2$ (1456.93): calcd. C 31.3, H 6.2; found C 30.7, H 6.7. $^1$H NMR

(500.13 MHz, $C_2D_2Cl_4$): $\delta$ = 0.02–0.06 ($OSiMe_3$), 1.22–1.28 (O*t*Bu), 1.36–1.40 ppm (O*t*Bu). $^1H$ NMR (400.13 MHz, [$D_8$]toluene): $\delta$ = 0.22–0.52 ($OSiMe_3$), 1.05–1.67 (O*t*Bu). $^{29}Si$ NMR (79.49 MHz, $CD_2Cl_2$): $\delta$ = –3.8, –3.9, –4.2 ppm (major signal), –4.3, –4.6. IR $\tilde{\nu}$ = 1357 (s), 1241 (m), 1229 (m), 1191 (s), 1020 (s), 984 (s), 941 (s), 918 (m), 828 (m), 752 (w), 742 (w), 639 (w), 576 (m), 546 (m), 528 (m), 480 (w), 463 (w), 445 $cm^{-1}$ (w).

**X-ray Crystallography:** Intensity data for the colorless crystal **1**·2$C_7H_8$ were collected with a Nonius KappaCCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation at 173 K. The data collection covered almost the whole sphere of reciprocal space with three sets at different $\kappa$-angles and 307 frames via $\omega$-rotation ($\Delta/\omega$ = 1°) at two times 75 s per frame. The crystal–detector distance was 3.4 cm. Crystal decay was monitored by repeating the initial frames at the end of data collection. Analyzing the duplicate reflections there was no indication for any decay. The structure was solved by direct methods SHELXS97[24] and successive difference Fourier syntheses. Refinement applied full-matrix least-squares methods SHELXL97.[25] The H atoms were placed in geometrically calculated positions using a riding model with $U_{iso}$ constrained at 1.2 times $U_{eq}$ of the carrier C atom for non-methyl and 1.5 times $U_{eq}$ of the carrier C atom for methyl groups. Atomic scattering factors for neutral atoms and real and imaginary dispersion terms were taken from the International Tables for X-ray Crystallography. An absorption correction was applied with a multi-scan method using SCALEPACK[26] ($T_{min}$ = 0.385, $T_{max}$ = 0.572). Disorder was found for two *tert*-butyl groups. The methyl group C3 (0.25, *y*, *z*) is disordered over two position and refined on a normal position with an occupancy of 0.5. Three methyl groups (C9–C11) on special position (*x*, 0.75, *z*) were refined with occupancies of 0.2 (C9), 0.9 (C10), and 0.4 (C11). All atoms of the solvent molecules toluene were isotropically refined with an occupancy of 0.25. Further details are listed in Table 1.

Table 1. Crystallographic data for $[Bi_3Li_5(\mu_5\text{-}O)_2(\mu_3\text{-}OSiMe_3)_2(\mu_3\text{-}OtBu)_2(\mu_2\text{-}OtBu)_6]$·2$C_7H_8$ (**1**·2$C_7H_8$).

# New Insights into the Redox Chemistry of Ruthenium Metallopharmaceuticals: The Electrochemical Behaviour of [LH][*trans*-$Ru^{III}Cl_4L_2$] (L = imidazole or indazole) Complexes

**Mauro Ravera,[a] Claudio Cassino,[a] Sara Baracco,[a] and Domenico Osella*[a]**

**Keywords:** Antitumor agents / Electrochemistry / Redox chemistry / Ruthenium

Here we report the findings from a study on the electrochemical behaviour of two $Ru^{III}$ complexes [LH][*trans*-$Ru^{III}Cl_4L_2$] (L = imidazole, ICR, or indazole, IndCR) in aqueous solution at different pH values. An electrochemically reversible and chemically quasi-reversible one-electron reduction is observed for both compounds. Despite the similarity of the structures, the fate of the electrogenerated $Ru^{II}$ species is different; in the case of ICR, imidazole, followed by a chloride ion, is released as the consequence of the reduction, while for IndCR two subsequent water for chloride substitutions take place. Our measurements suggests that the $Ru^{III}$ complexes under study may serve as pro-drugs, being activated by reduction in a suitable aqueous environment and, therefore, binding biomolecules more rapidly.

## Introduction

Three $Pt^{II}$ compounds, commercially known as cisplatin, carboplatin, and oxaliplatin, are currently the most widely used anticancer agents. Notwithstanding the widespread applications of platinum anticancer drugs, there is still a great need for the development of novel metal-based compounds with additional features.

The search for "nonclassical" metal antitumor drugs has long stimulated investigations into the field of non-platinum metal drugs. Non-platinum active compounds are likely to have different mechanisms of action, biodistribution and toxicity from those of platinum drugs, and might therefore be active against human malignancies that are resistant, or have acquired resistance, to the latter agents. They may also show reduced host toxicity. Ruthenium seems to be the most promising among the several metals investigated.[1,2]

Among the different metal complexes, [ImH][*trans*-$RuCl_4$(dmso-S)(Im)] (NAMI-A, where Im = imidazole) was selected because of its very good antimetastatic activity; from 1999 to 2002 it was introduced into clinical trials.[3] Two similar complexes, containing imidazole (Im) and indazole (Ind) as ligands, namely [ImH][*trans*-$RuCl_4Im_2$], ICR, and [IndH][*trans*-$RuCl_4Ind_2$], IndCR, showed excellent antitumour activity in various animal models.[4] In particular, IndCR entered phase I clinical trials in 2003 as an anticancer drug which is very active against colon carcinomas and in metastases (Figure 1).[2]

Despite the large number of works published, the mechanism of action of ruthenium complexes is still largely unknown. Given that $Ru^{III}$ complexes are kinetically more inert than the corresponding $Ru^{II}$ derivatives, an "activation by reduction" mechanism has been proposed to explain the biological activity of some ruthenium derivatives.[5,6] According to this hypothesis, NAMI-A is considered to be a *pro-drug*, a compound that is converted in the body through reductive metabolism to the $Ru^{II}$ pharmacologically active species. This reactive intermediate should link the biological target after rapid dissociation of some of its ligands. Solid tumours create hypoxic (reducing) regions because they grow faster than the tissue can generate new blood vessels to supply enough oxygen.[7] Nontoxic drugs which can only be "activated" in hypoxic regions (*hypoxia-activated prodrugs*) therefore offer the promise of a specific systemic treatment against solid tumours, including metastases. For this reason, the $Ru^{III}/Ru^{II}$ electron transfer reaction is particularly interesting.

Aquation of the imidazole (NAMI-A[8] and ICR[9]) and indazole (IndCR[10]) complexes leads mainly to mono- and diaqua complexes, at different time scales. The initial transformation into a monoaqua complex seems to play a crucial role for further biological activity, since reactions with biological substrates are much faster in "aged" solutions of ICR than in "fresh" solutions. Further hydrolysis products are unknown, but could be μ-oxo complexes. Formation of such di- or polynuclear Ru complexes is pH-dependent, as hydrolysis proceeds faster at higher pH, leading to precipitation. Recently, we reported a detailed electrochemical study on NAMI-A indicating the structural and chemical consequences stemming from the easy $Ru^{III}/Ru^{II}$ electron

## Results and Discussion

### Electrochemical Behaviour of ICR [ImH][*trans*-$Ru^{III}Cl_4Im_2$] (Im = imidazole)

As illustrated in Figure 2, the cyclic voltammetric (CV) response of an aqueous solution of $[Ru^{III}Cl_4Im_2]^-$ (1.0 mM Ru complex in 0.1 M $NaClO_4$, pH 4.0) at a glassy carbon (GC) electrode reveals a coulometrically checked (see below) one-electron reduction (peak A) coupled to chemical complications, as testified by the appearance of peak C in the back scan at $\Delta E_p$ = 260 mV.

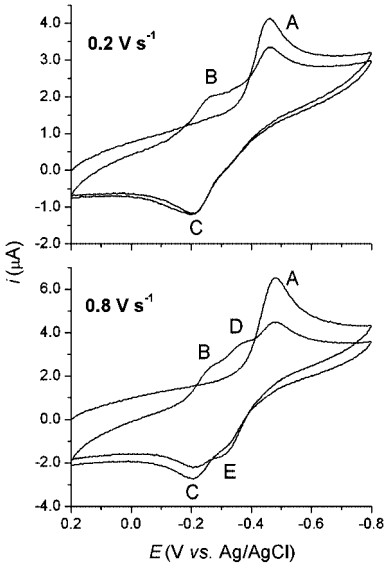

Figure 2. CV response of a 1.0 mM aqueous solution of $[Ru^{III}Cl_4Im_2]^-$ (0.1 M $NaClO_4$, pH 4.0), at a GC electrode, scan rate = 0.2 (top) and 0.8 (bottom) V $s^{-1}$.

transfer in aqueous solution.[11] Surprisingly, the reduction in acidic solutions (pH 6.0) generates the transient $Ru^{II}$ homologue, which quickly undergoes substitution of Im by a water molecule affording $[Ru^{II}(H_2O)Cl_4(DMSO)]^{2-}$, followed after a longer period by the substitution of one chloride ligand by a water molecule affording the ultimate product $[Ru^{II}(H_2O)_2Cl_3(DMSO)]^-$. At physiological pH (7.4), only the substitution of two chlorides by water is observed, just in the longer period of the electrolysis time scale. The hypoxic and acidic environment present in a tumoral tissue may favour the $Ru^{III}/Ru^{II}$ reduction and the subsequent Im hydrolysis, thereby promoting a unique means of activation of such a metallic drug in tumour tissue.

A thorough study of the electrochemical behaviour of the title compounds in aqueous solution has not yet been published. A few remarks were made by Sadler et al.[9] and, very recently, a seminal electrochemical study in organic solvents (DMF and DMSO) was published by Keppler et al.[12] In order to shed light on the redox properties of antitumour ruthenium complexes and their possible activation by reduction in experimental conditions nearer to the physiological ones, we show here a voltammetric, coulometric, and NMR study on ICR and IndCR in water at different pH values.

When a double cycle CV experiment is performed, the cathodic counterpart of the oxidation C (peak B) is observed, indicating that the peak system B/C is related to a stable species produced after the reduction occurring at peak A. In the scan rate ($v$) range 0.05–5.00 V $s^{-1}$, no return peak associated to peak A is observed. At a $v > 0.8$ V $s^{-1}$ a third peak system (D/E) appears between A and B/C. This new couple is chemically quasi-reversible and electrochemically reversible. For peak systems A and B/C, the current functions $i_p$ vs. $v^{1/2}$ and $i_p$ vs. concentration plots are linear through the origin, supporting the absence of adsorption phenomena. Table 1 summarizes the CV data.

All these observations are consistent with an ECE mechanism: the chemical reaction following reduction A produces further electroactive species.[13,14]

In order to substantiate the identity of such intermediates, the CV response of $[Ru^{III}Cl_4Im_2]^-$ was compared with that of two possible candidates, namely $[Ru^{III}(H_2O)Cl_3Im_2]$ and $[Ru^{III}(H_2O)Cl_4Im]^-$ (obtained on standing $[Ru^{III}Cl_5Im]^{2-}$ in water, see Experimental Section). Since $[Ru^{III}(H_2O)Cl_3Im_2]$ is stable only under acidic conditions (pH < 4.0),[15] an accurate comparison was feasible only with such pH values. Figure 3 shows the overlap of the three CVs. All three complexes display a similar ECE behaviour, with the final

Table 1. Relevant electrochemical data for $[Ru^{III}Cl_4Im_2]^-$ and its aquated compounds.

| | $E_p$(A) (V vs. Ag/AgCl at 0.2 V $s^{-1}$) | $E°'$(B/C) (V vs. Ag/AgCl) | $E°'$(D/E) (V vs. Ag/AgCl) |
|---|---|---|---|
| $[Ru^{III}Cl_4Im_2]^-$ | –0.46 | –0.24 | –0.34 (at $v$>0.8 V $s^{-1}$) |
| $[Ru^{III}(H_2O)Cl_3Im_2]$ | – | –0.24 | –0.34 |
| $[Ru^{III}(H_2O)Cl_4Im]^-$ | –0.44 | –0.23 | – |

redox couple (peaks B/C) located at the same potential, while the first reduction (A) is obviously located at different values.

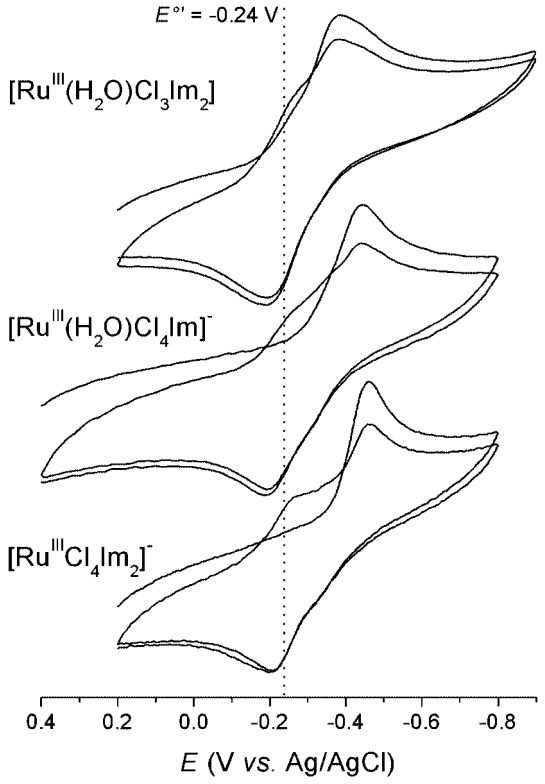

Figure 3. CV response of 1.0 mM aqueous solutions of $[Ru^{III}(H_2O)Cl_3Im_2]$ (top), $[Ru^{III}(H_2O)Cl_4Im]^-$ (middle), and $[Ru^{III}Cl_4Im_2]^-$ (bottom) (0.1 M $NaClO_4$, pH 4.0), at a GC electrode, scan rate = 0.2 V $s^{-1}$.

We propose the diaqua $[Ru^{III}(H_2O)_2Cl_3Im]$ as the final product of the ECE sequence, as it is the only intermediate that could reasonably be obtained from all three complexes. In the case of $[Ru^{III}Cl_4Im_2]^-$ the intermediate $[Ru^{III}(H_2O)Cl_3Im_2]$ is clearly present at $v > 0.8$ V $s^{-1}$ (Figure 2). The same behaviour and the same CVs are also observed in phosphate buffer (PB) at pH 6.0; for this reason, we can extend the mechanism of reaction (Figure 4) to this pH value as well.

Bulk electrolysis of an aqueous, acidic solution (pH 4.0 and 6.0) of $[Ru^{III}Cl_4Im_2]^-$ ($E_w$ = –0.60 V) consumes 1 mol of electrons per mol of complex, producing a change in colour from deep orange to lemon yellow, indicative of the formation of a $Ru^{II}$ species. In the longer electrolysis time scale, the Im/water and $Cl^-$/water exchanges occur completely so that the $E°'$ of the final species correspond to that of the B/C peak couple. The overall bulk electrolysis

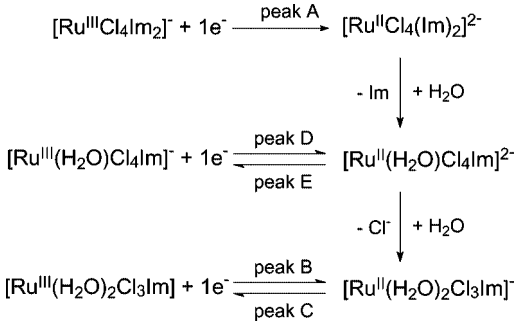

Figure 4. Proposed reaction scheme for the reduction of ICR.

behaviour is confirmed by the chemical reduction with reduced glutathione (GSH) followed by CV tests; the results show that the diaqua complex is obtained during the reaction (30 min), although some decomposition occurs (ca. 20%).

In neutral solution (0.1 M PB, pH 7.4) the general trend is maintained. However, there is a moderate shift in $E_p$(A) and a strong shift in $E°'$(B/C). Indeed, $E_p$(A) changes from –0.46 to –0.49 V by passing from pH 4.0 to 7.4, while $E°'$(B/C) shifts from –0.24 to –0.37 V in the same pH range. This may be due to the less efficient protonation of the leaving $ImH^+$ (peak A), and to the partial formation of hydroxylated aqua species (peaks B/C). Given that the A and B/C signals partially overlap, the peak couple D/E is also completely obscured at high $v$. The similarity of the behaviour at pH 7.4 of the two $Ru^{III}$ complexes with that at acidic pH values confirms the stepwise loss of Im and chloride with replacement by the water after the initial reduction step in the pH range 4.0–7.4.

## Chemical Reduction of ICR Followed by NMR Spectroscopy

In order to confirm the assignment of the species produced at different pH values, chemical reductions with GSH were followed by $^1H$ NMR spectroscopy. To avoid the interference of the imidazolium countercation, all experiments were performed with ICR sodium salt. The oxidation of glutathione to glutathione disulfide (GSSG) is a two-electron reaction (2 GSH → GSSG + $2e^-$ + 2 $H^+$). In order to increase the reaction speed, an ICR sodium salt/GSH ratio of 1:2 was used (37 °C, NMR measured after 15 min); the resulting mixture exhibited no broadening of the internal standard peak [referenced to the water-soluble silane 3-(trimethylsilyl)-1-propanesulfonic acid sodium salt, DSS] due to the presence of paramagnetic species as residual ICR ($Ru^{III}$ $d^5$) or glutathyil radical intermediate.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The reduction carried out on a 10 mM solution of ICR in 0.1 M acetate buffer (pH 4.0), and PB (pH 6.0 and 7.4), parallels that reported by Keppler et al.[16] (Figure 5). Two sets of signals are observed; the first corresponds to the free imidazole (A), while the second is typical of a coordinated imidazole (B). Pattern A increases with time, while pattern B decreases as the result of the reduction of the complex to the corresponding $Ru^{II}$ analogue and the following Im/$H_2O$ exchange. All these observations are consistent with the electrochemical data in which the substitution of Im by a water molecule in the reduced dianion $[Ru^{II}Cl_4Im_2]^{2-}$ (not observed in NMR) produces $[Ru^{II}(H_2O)Cl_4Im]^{2-}$ and/or $[Ru^{II}(H_2O)_2Cl_3Im]^-$ (pattern B). At longer reaction times, the reduced species is completely destroyed (only pattern A is observed).

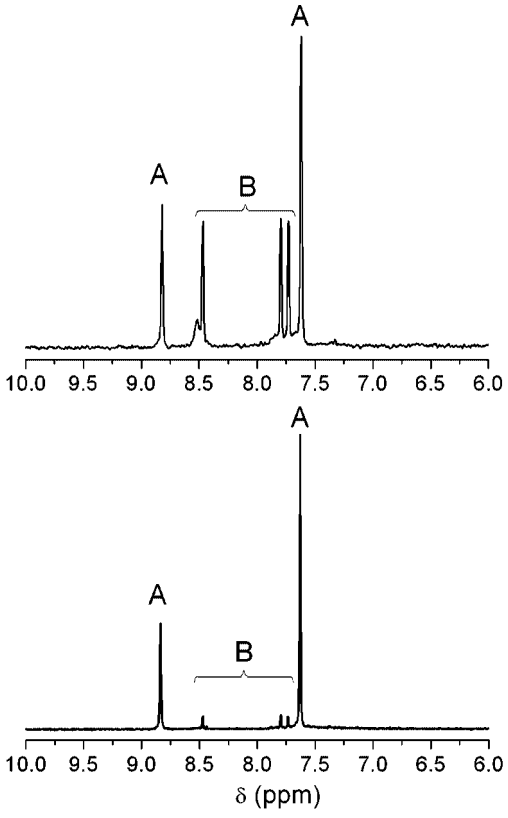

Figure 5. Expanded 6.0–10.0 ppm resonance region of the $^1H$ NMR spectrum of ICR (10 mM in 0.1 M phosphate buffer, pH 6.0) recorded 15 min (top) and 1 h (bottom) after the addition of glutathione (20 mM) at 37 °C.

### Electrochemical Behaviour of IndCR Sodium Salt [Na][*trans*-$Ru^{III}Cl_4Ind_2$] (Ind = indazole)

Since the indazolium salt of IndCR is barely soluble in water, all experiments were performed with the sodium salt.

Figure 6 shows the CV response of an aqueous solution of $[Ru^{III}Cl_4Ind_2]^-$ (1.0 mM Ru complex in 0.1 M $NaClO_4$, pH 4.0, water solution) at a GC electrode. The coulometrically checked one-electron reduction (peak-system F/G) is followed by chemical complications, as testified by the appearance of peak J in the back scan. In the scan rate range 0.05–5.00 V $s^{-1}$, the diagnostic electrochemical features are:

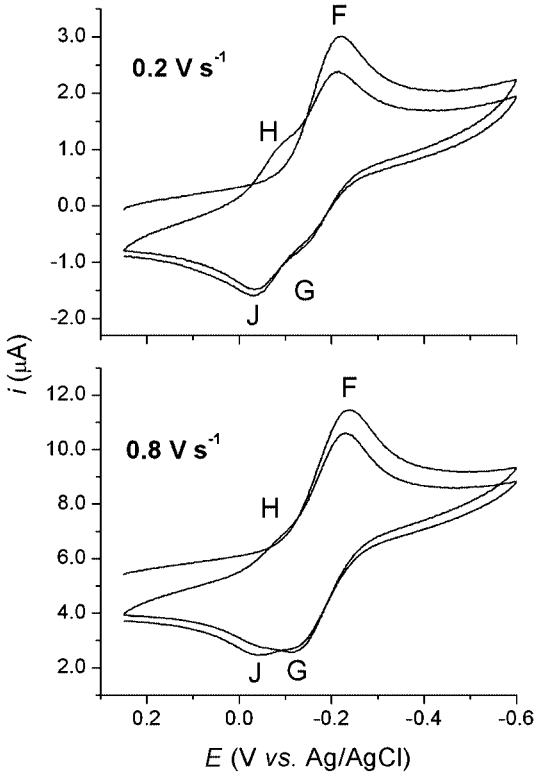

Figure 6. CV response of a 1.0 mM aqueous solution of $[Ru^{III}Cl_4Ind_2]^-$ (0.1 M $NaClO_4$, pH 4.0), at a GC electrode, scan rate: 0.2 (top) and 0.8 (bottom) V $s^{-1}$.

i. The current ratio $i_{p,a}(G)/i_{p,c}(F)$ is 0.3 at 0.05 V $s^{-1}$ and progressively increases with $v$ until it reaches unity at 1.5 V $s^{-1}$;
ii. The peak-to-peak separation $\Delta E_p = E_{p,a} - E_{p,c}$ remains practically constant (80 mV) by increasing $v$ in the range of $v$ where peak G is present ($v > 0.8$ V $s^{-1}$);
iii. The formal electrode potential $E°' = (E_{p,c} + E_{p,a})/2$ is equal to –0.160 V vs. Ag/AgCl ($v > 0.8$ V $s^{-1}$);
iv. The plots of $i_p$ vs. $v^{1/2}$ and $i_p$ vs. concentration are linear through the origin, indicating the absence of any adsorption process.

Also in this case, when a double cycle CV experiment is performed, the cathodic counterpart of the oxidation J (peak H) is observed. This couple is located at –0.072 V vs. Ag/AgCl, and shows electrochemical parameters similar to that of the F/G system.

After increasing the pH to 6.0 and 7.4, all the peaks remain at the same potential except peak H, which slightly shifts under peak F. The overall electrochemical behaviour is compatible with an ECE mechanism.

Bulk electrolysis of an aqueous, acidic solution (pH 4.0) of $[Ru^{III}Cl_4Ind_2]^-$ ($E_w$ = –0.35 V) consumes 1 mol of electrons per mol of complex, yielding the usual $Ru^{II}$ yellow lemon solution. Despite strong decomposition, after 0.5 Faradays, the two peak couples F/G and H/J are still present. After 1 Faraday, only a new species at $E°'$ = +0.065 V vs. Ag/AgCl is present (peaks K/L, Figure 7). At

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pH 6.0 only a species at $E°' = -0.065$ V, compatible with the H/J system, is present, while at pH 7.4 the decomposition is so high that after 45 min of electrolysis the complex is fully decomposed. The chemical reduction with GSH parallels the above-reported results.

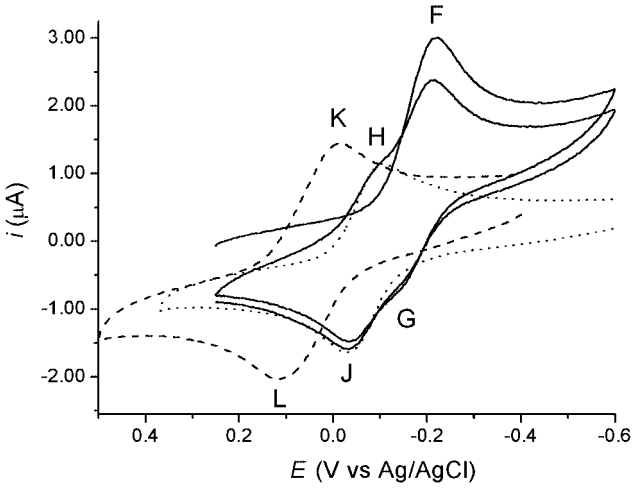

Figure 7. CVs performed before electrolysis (solid line), after 1 F in 0.1 M acetate buffer (pH 4.0, dashed line) and after 1 F in 0.1 M phosphate buffer (pH 6.0, dotted line).

### Chemical Reduction of IndCR Followed by NMR Spectroscopy

The reduction carried out with GSH ([IndCR] = 10 mM, IndCR/GSH ratio 1:2, 37 °C, NMR measured after 15 min) in 0.1 M acetate buffer (pH 4.0), and PB (pH 6.0, Figure 8) shows a similar pattern of peaks. Free indazole is not present throughout the experiment. If we consider only the set of signals at ca. 9 ppm (in particular, the singlet due to the proton in position 3; this signal is the most easily characterized), the fate of the chemically generated $Ru^{II}$ species is unambiguous: the singlet at $\delta = 9.06$ ppm (peak C) decreases until it disappears after 1 h, while another singlet at $\delta = 8.97$ ppm (peak D) increases as well. After 30 min, a new singlet at $\delta = 8.92$ ppm (peak E) starts to increase. At pH 6.0, peak C′ ($\delta = 8.96$ ppm) represents the only species present at the beginning of the experiment. After 30 min, peak D′ ($\delta = 8.92$ ppm) begins to increase. After 2 h a 1:1 ratio is reached, and after 4 h peak D′ is about twice as high.

By combining the experimental results obtained in CV and NMR, we can propose the reaction pattern reported in Figure 9. The reduction of IndCR produces the dianion $[Ru^{II}Cl_4Ind_2]^{2-}$. This species is more stable than the corresponding $[Ru^{II}Cl_4Im_2]^{2-}$, and slowly exchanges stepwise two $Cl^-$ for water. At pH 6.0 this exchange is inhibited, so that only the first step is observed both in NMR and bulk electrolysis. Surprisingly, in this case, the "traditional" $Cl^-$,$Cl^-$/$2H_2O$ substitution takes place, while in ICR the Im,$Cl^-$/$2H_2O$ substitution, as observed also for NAMI-A in acidic conditions, is the predominant reaction.

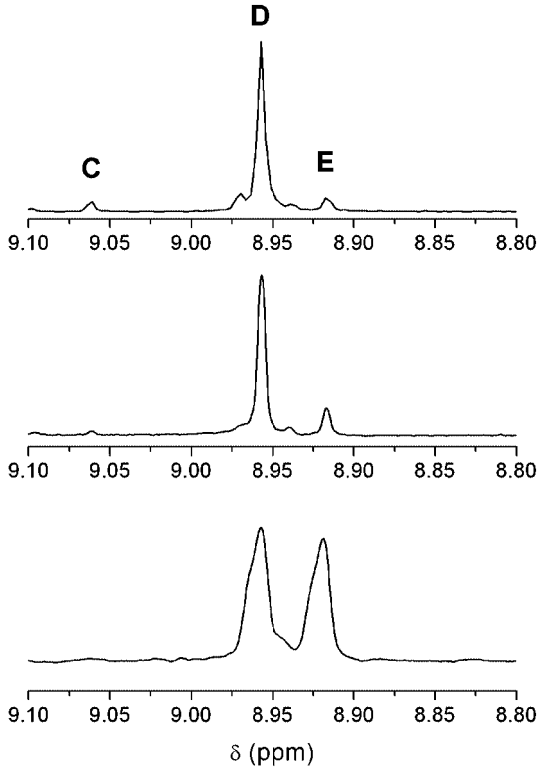

Figure 8. Expanded 8.80–9.10 ppm resonance region of the $^1H$ NMR spectrum of IndCR (10 mM in 0.1 M acetate buffer, pH 4.0) recorded 15 min (top), 1 h (middle), and 2 h (bottom) after the addition of glutathione (20 mM).

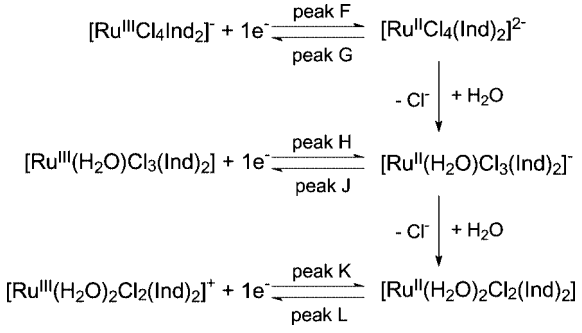

Figure 9. Proposed reaction scheme for the reduction of IndCR.

## Conclusions

We have reported on a study of the electrochemical behaviour of the two $Ru^{III}$ complexes [LH][*trans*-$RuCl_4L_2$] (L = imidazole, ICR, or indazole, IndCR) in aqueous solution at different pH values. An electrochemically reversible and partially chemically reversible one-electron reduction is observed for both compounds. Despite the similarity of the structure, the fate of the electrogenerated $Ru^{II}$ species is different; in the case of ICR, imidazole, followed by a chloride ion, is released as the consequence of the reduction, while in IndCR $Cl^-$,$Cl^-$/$2H_2O$ substitution takes place. The chemical complications following the electron transfer in IndCR are also independent of pH, and act only on the kinetic aspect of the substitutions. It is noteworthy that, while the acti-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vation of the $Ru^{III}$ homologues occurs in a time interval of hours,[9] that of the reduced species takes place in less than one hour. The differences in the chemical behaviour of the electrogenerated $Ru^{II}$ species may be imputable to the different basicity of Im ($pK_a$ = 7.11) and Ind ($pK_a$ = 1.25).[17] In fact, the propensity toward protonation of the axial ligand L (where L is Im or Ind) influences the formation of $[LH]^+$ and, hence, its detachment from the complex. As reported in the Introduction, we found precedents for this in a recent study on the electrochemical behaviour of NAMI-A:[11] Furthermore, as reduction of $Ru^{III}$ to $Ru^{II}$ fills the dπ orbitals, an axial ligand such as Ind, having a higher electronic delocalization than Im by virtue of annulation, could partially act as a π-acceptor and, thus, increase the Ru–L bond stability.

There are many redox couples in a cell that maintain the redox environment, with the glutathione disulfide/reduced glutathione (GSSG/2GSH) being the most abundant.[18] In proliferating cells, the reduction potential is about –0.24 V vs. NHE (i.e. –0.44 V vs. Ag/AgCl).[19] According to the $E°'(Ru^{III}/Ru^{II})$ measured, the biological reduction process of ICR and IndCR is thus possible. The $Ru^{II}$ species show a lower stability with respect to the $Ru^{III}$ counterpart and thus the chemical reactions following the electron transfer may produce more reactive intermediates. The combination of electrochemical and NMR measurements shed light on the overall mechanism, suggesting that $Ru^{III}$ complexes may serve as prodrugs, which may be activated by reduction in vivo to coordinate more rapidly to biomolecules. The low $O_2$ content in tumour cells (hypoxic environment) should favour the reduction to $Ru^{II}$, which is generally more active than $Ru^{III}$ enforcing the "activation by reduction" hypothesis.

## Experimental Section

Complexes $Na[RuCl_4Im_2]$[16] and $[ImH][RuCl_4Im_2]$,[20] (Im = imidazole), and $Na[RuCl_4Ind_2]$ (Ind = indazole)[21] were obtained following published procedures. Their aquated products ($[Ru(H_2O)Cl_4Im]^-$[22] and $[Ru(H_2O)Cl_3Im_2]$[15]) were obtained directly in solution according to data in the literature. The identity and the purity of all species were checked using the usual techniques. All salts were analytical grade and used as received. Deionized water was obtained through a Milli-Q (18 MΩ) deionizing system and was used for the preparation of all solutions. $^1H$ NMR spectra were measured in $D_2O$ with a JEOL Eclipse Plus spectrometer operating at 400 MHz. Proton chemical shifts were reported in parts per million (ppm) referenced to residual solvent proton resonance (i.e. HDO 4.8 ppm) or silane standard 3-(trimethylsilyl)-1-propanesulfonic acid sodium salt (DSS).

Electrochemical experiments were performed using an EG&G PAR 273 electrochemical analyser interfaced to a personal computer, employing PAR M270 electrochemical software. A standard three-electrode cell was designed to allow the tip of the reference electrode to closely approach the working electrode. The reference electrode was silver/silver chloride (Ag/AgCl), containing saturated, aqueous KCl. Its stability was checked using the $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ redox couple. The Ag/AgCl reference electrode was stable with a precision of ±5 mV. The working electrode was a glassy carbon disk (diameter 0.1 cm) sealed in epoxy resin. The solid electrodes were polished with alumina followed by diamond paste, then washed with distilled water and dried. This process yielded a reproducible surface for all experiments. Positive-feedback iR compensation was applied routinely. All electrochemical measurements were carried out under nitrogen in water; solutions were 1.0 mM with respect to the compounds under study and 0.1 M with respect to the supporting electrolyte. The temperature of the solution was kept constant (20 ± 1 °C), by circulation of a thermostatted water/ethanol mixture through a jacketed cell.

The reduced species were produced in quantitative yield by bulk electrolysis. This was carried out in a conventional two-compartment glass cell with porous glass separation. A Pt basket was used as the cathode at a potential ca. 100–150 mV more negative than the formal potential $E°'$, a Pt wire was used as the anode, and Ag/AgCl was the reference electrode. Nitrogen was continuously bubbled through the solution during electrolysis. In all cases, transformation of $Ru^{III}$ to $Ru^{II}$ was checked by current integration and by in situ CV.

## Acknowledgments

S.B. thanks the Consorzio CIRCMSB (Bari, Italy) for a grant. Johnson Matthey (Reading, UK) is gratefully acknowledged for a generous loan of $RuCl_3$. This research was carried out within the framework of the European Cooperation COST D20 action (Metal compounds in the treatment of cancer and viral diseases) and COST B16 action (Multidrug resistance reversal). The help of Dr. Silvia Gemme in the synthesis and electrochemical characterization of Ru complexes is also acknowledged. We are indebted to Dr. Laura McLean for her assistance in writing this manuscript.

# Chloro, Alkyl and Aryl Complexes of Rare Earth Metals Supported by Bulky Tetrasubstituted Guanidinate Ligands

**Alexander A. Trifonov,*[a] Dmitrii M. Lyubov,[a] Elena A. Fedorova,[a] Georgy K. Fukin,[a] Herbert Schumann,[b] Stefan Mühle,[b] Markus Hummert,[b] and Mikhail N. Bochkarev[a]**

**Keywords:** Alkyl complexes / Aryl complexes / Guanidinates / N ligands / Rare Earths

The reactions of anhydrous $LnCl_3$ (Ln = Y, Nd, Sm, Lu) with two equiv. of sodium *N*,*N*′-dicyclohexyl-*N*′′-bis(trimethylsilyl)guanidinate Na[$(Me_3Si)_2NC(NCy)_2$], obtained from Na[$N(SiMe_3)_2$] and the 1,3-dicyclohexyl-substituted carbodiimide CyN=C=NCy in THF, yield the monochloro bis(guanidinate) tetrahydrofuranate complexes [$(Me_3Si)_2NC(NCy)_2]_2$LnCl(THF) [Ln = Y (**1**), Nd (**2**), Sm (**3**) and Lu (**4**)]. The analogous reactions of $YCl_3$ and $LuCl_3$ with the lithium guanidinate [$Li(Et_2O)$][$(Me_3Si)_2NC(NCy)_2$] afford the bis(guanidinate) "ate" complexes [$(Me_3Si)_2NC(NCy)_2]_2$Ln(μ-Cl)$_2$Li(THF)$_2$ [Ln = Y (**5**) and Lu (**6**)]. Treatment of **5** with dimethoxyethane results in the formation of [$(Me_3Si)_2NC(NCy)_2]_2$Y(μ-Cl)$_2$Li(DME) (**7**). The carbyl complexes [$(Me_3Si)_2NC(NCy)_2]_2$Y-*t*Bu] (**8**), [$(Me_3Si)_2NC(NCy)_2]_2$Y(μ-Me)$_2$Li(TMEDA) (**10**) and [$(Me_3Si)_2NC(NCy)_2]_2$YPh(THF) (**13**) were obtained by interaction of complex **1** with RLi (R = *t*Bu, Me or Ph). The molecular structures of **1**, **6**, **7**, **8** and the side product [Li(TMEDA)]-[$(Me_3Si)_2NC(NCy)_2$] have been determined by single-crystal X-ray analyses. Agostic interactions between the yttrium atom and the *tert*-butyl group in complex **8** in the solid state as well as in solution have been substantiated by $^{13}C$ NMR spectroscopy and X-ray analysis.

## Introduction

The organometallic chemistry of the rare earth metals has made considerable progress in the course of the past two decades and has been generally dominated by the synthesis of cyclopentadienyl sandwich and half-sandwich complexes.[1] These complexes have been and remain of special interest because of their potential as catalysts in a wide range of transformations of unsaturated substrates.[2] Recently, research activity has been directed to the substitution of the cyclopentadienyl ligands by other coordinating systems in order to obtain complexes with modified structures and reactivities. To this end, many research groups have focused their work on "harder", mono-anionic polydentate N- and/or O- coordinating ligands providing enough steric bulk to prevent further coordination of Lewis bases, dimerisation or ligand redistribution reactions but still possessing high reactivity.[3] Ligand frameworks containing electronegative nitrogen atoms as donor atoms have turned out to be the most promising ligands since they show a high affinity for the hard Lewis acidic atoms of the rare earths metals[4] combined with structural diversity. Guanidinate anions $[R_2NC(NR'_2)]^-$ are isoelectronic with the cyclopentadienyl anion and have been widely used as supporting ligands for non-transition and d-block transition metals[5] and also, in recent years, for rare earth metals.[6] Based on their anionic character, the facile modification of their electronic and steric properties by variation of the substituents at the nitrogen atoms and their flexible coordination behavior, tetrasubstituted guanidinate anions are very attractive ligand systems for the synthesis of kinetically stable, low-coordinate rare earth metal complexes. We have already used the guanidinate anion $[(Me_3Si)_2NC(N\mathit{i}Pr)_2]^-$ for the successful synthesis of the hydrido complex {[$(Me_3Si)_2$-$NC(N\mathit{i}Pr)_2]_2$Lu(μ-H)}$_2$ which was found to be an active catalyst for the polymerisation of ethylene, propylene and styrene.[7] Here we report on the synthesis, properties and structures of some chloro, alkyl and aryl derivatives of bis(guanidinate)-coordinated complexes of some rare earth metals.

## Results and Discussion

In order to prepare low-coordinate organometallic complexes of rare earth metals which would be predicted to be resistant towards dimerisation, ligand redistribution and further coordination by Lewis bases, we used the bulky guanidinate ligand $[(Me_3Si)_2NC(NCy)_2]^-$ bearing cyclohexyl groups at the coordinating nitrogen atoms. The respective sodium and lithium guanidinates are available by treatment of Na[$N(SiMe_3)_2$] or [$Li(Et_2O)$][$N(SiMe_3)_2$] with 1,3-dicy-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

clohexylcarbodiimide, CyN=C=NCy, in THF and can be isolated in a pure state.[6a] Addition of anhydrous $LnCl_3$ (Ln = Y, Nd, Sm, Lu) to freshly prepared THF solutions of the sodium guanidinate (1:2 mol ratio) at room temperature allows the isolation of the monomeric crystalline lanthanide bis(guanidinate) chlorides $[(Me_3Si)_2NC(NCy)_2]_2$-LnCl(THF) [Ln = Y (**1**), Nd (**2**), Sm (**3**) and Lu (**4**)] from the respective solution in yields of 60 to 80% (Scheme 1).

The reactions of $YCl_3$ and $LuCl_3$ with the lithium salt $[Li(Et_2O)][(Me_3Si)_2NC(NCy)_2]$ instead of the sodium analogue afford the monomeric "ate" complexes $[(Me_3Si)_2$-$NC(NCy)_2]_2Ln(\mu\text{-}Cl)_2Li(THF)_2$ [Ln = Y (**5**), Lu (**6**)] in yields of 74 and 70%, respectively (Scheme 2). In contrast, the metathesis of $YCl_3$ with $[Li(Et_2O)][(Me_3Si)_2NC(N\textit{i}Pr)_2]$ containing less steric demanding isopropyl instead of cyclohexyl groups results in the formation of the dimeric complex $\{[(Me_3Si)_2NC(N\textit{i}Pr)_2]_2Y(\mu\text{-}Cl)\}_2$.[6b,6e] Furthermore, treatment of **5** with dimethoxyethane results in replacement of the two THF ligands coordinated to the lithium atom by a DME molecule producing $[(Me_3Si)_2NC(NCy)_2]_2Y(\mu\text{-}Cl)_2$-Li(DME) (**7**). Though $LaCl_3$ clearly reacts with sodium or lithium *N*,*N*′-dicyclohexyl-*N*′′-bis(trimethylsilyl)guanidinate under comparable reaction conditions, no THF-soluble lanthanum complex could be isolated.

The colourless (**1**, **4**, **5** to **7**), pale blue (**2**) or pale yellow (**3**) crystalline complexes are moisture- and air-sensitive. In an inert atmosphere they can be stored without decomposition at room temperature. They are soluble in ethers and aromatic hydrocarbons and moderately soluble in hexane and pentane but it should be added that the solubilities of the monochloro bis(guanidinate) complexes **1** to **4** are noticeably higher than those of the related "ate" complexes **5** and **6**.

The $^1H$ and $^{13}C$ NMR spectra of the diamagnetic complexes **1**, **4**, **5**, **6** and **7** in [D$_6$]benzene at 20 °C show the expected sets of resonances due to the guanidinate moiety and the coordinated THF and DME molecules. The $^1H$ NMR signals of the THF methylene protons in **1**, **4**, **5** and **6** appear as broad singlets reflecting the labile coordination. Crystals suitable for single-crystal X-ray diffraction studies of **1**, **6** and **7** were obtained from hexane solutions by slow evaporation of the solvent at room temperature (**1** and **7**) or by cooling the solution to –20 °C (**6**). The molecular structures of **1**, **6** and **7** are depicted in Figure 1, Figure 2 and Figure 3, respectively. The crystal and structural refinement data are listed in Table 1.

Complex **1** crystallises as the monomeric hexane solvate $[(Me_3Si)_2NC(NCy)_2]_2YCl(THF)(C_6H_{14})_{1/2}$ in the monoclinic space group $P2_1/c$ with four molecules in the unit cell. The molecular structure shows the yttrium atom hexacoordinated by two chelating guanidinate anions, one chlorine atom and one THF molecule (Figure 1).

The distances Y–N(1,2) [2.387(5), 2.327(5) Å] and Y–N(4,5) [2.377(4), 2.344(5) Å] as well as the distances

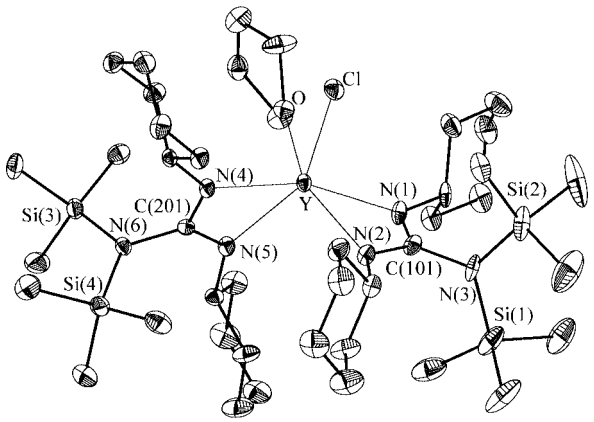

Figure 1. ORTEP diagram (30% probability thermal ellipsoids) of $[(Me_3Si)_2NC(NCy)_2]_2YCl(THF)$ (**1**) showing the non-hydrogen atom numbering scheme. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Y–N(1) 2.387(5), Y–N(2) 2.327(5), Y–N(4) 2.377(4), Y–N(5) 2.344(5), Y–C1 2.584(2), Y–O 2.406(4), C(101)–N(1) 1.335(8), C(101)–N(2) 1.332(7), C(101)–N(3) 1.442(7), C(201)–N(4) 1.314(8), C(201)–N(5) 1.348(7), C(201)–N(6) 1.451(7); N(1)–Y–N(2) 56.87(17), N(4)–Y–N(5) 56.84(17), N(1)–C(101)-N(2) 114.7(5), N(4)–C(201)–N(5) 115.2(5), O–Y–Cl 84.55(11).

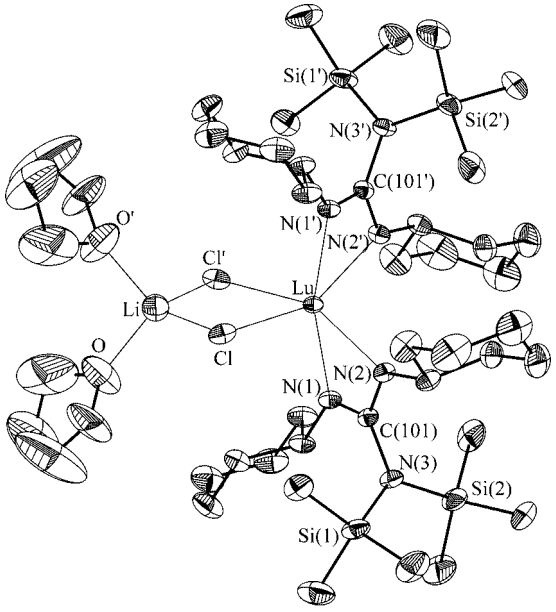

Figure 2. ORTEP diagram (30% probability thermal ellipsoids) of $[(Me_3Si)_2NC(NCy)_2]_2Lu(\mu\text{-}Cl)_2Li(THF)_2$ (**6**) showing the non-hydrogen atom numbering scheme. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Lu–N(1) 2.320(5), Lu–N(2) 2.291(5), Lu–Cl 2.7468(17), Li–Cl 2.304(14), Li–O 1.932(16), C(101)–N(1) 1.316(7), C(101)–N(2) 1.339(7), C(101)–N(3) 1.439(7); N(1)–Lu–N(2) 57.74(7), N(1)–Lu–N(2)′ 109.49(17), N(1)′–Lu–N(2)′ 57.74(17), N(1)–C(101)–N(2) 114.0(5), C(101)–Lu–C(101A) 130.3(2), Cl–Lu–Cl′ 83.90(6), Cl–Li–Cl′ 105.7(9). Symmetry operation: $-x$, $y$, to $-z + 0.5$.

C(101)–N(1,2) [1.335(8), 1.332(7) Å] and C(201)–N(4,5) [1.314(8), 1.348(7) Å] in the guanidinate ligands differ only slightly from each other, thus indicating electron delocalisation within the anionic NCN units. The considerably longer distances C(101)–N(3) [1.442(7) Å] and C(201)–N(6) [1.451(7) Å] indicate that the $N(SiMe_3)_2$ moiety does not take part in the conjugation. The opposite orientation of the $N(SiMe_3)_2$ and cyclohexyl groups relative to the NCN planes corresponds to the minimisation of their mutual steric repulsion. The dihedral angles between the planes formed by the SiNSi and the NCN fragments as well as between the mean plane of the cyclohexyl groups and the plane of the NCN fragment are close to 90° (89.7 and 82.9, and 73.8 and 96.6°, respectively).

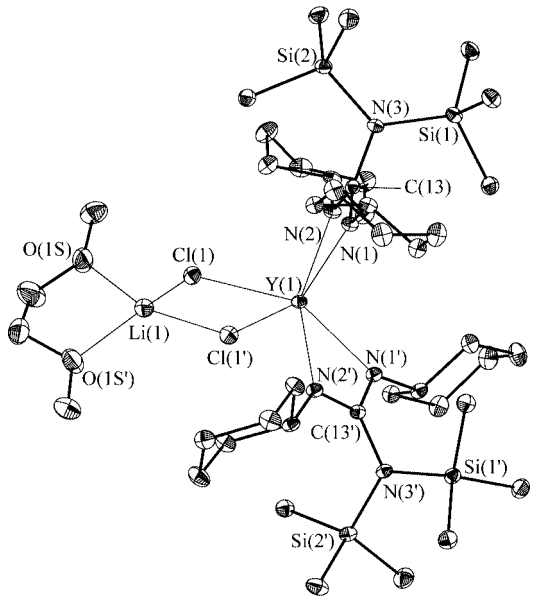

Figure 3. ORTEP diagram (30% probability thermal ellipsoids) of $[(Me_3Si)_2NC(NCy)_2]_2Y(\mu\text{-}Cl)_2Li(DME)$ (**7**) showing the non-hydrogen atom numbering scheme. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Y(1)–N(1) 2.3517(10), Y(1)–N(2) 2.3566(10), Y(1)–Cl(1) 2.6693(3), Li(1)–Cl(1) 1.2311(2), Li(1)–O(1S′) 1.980(3), N(1)–C(13) 1.3304(14), N(2)–C(13) 1.3325(15), N(3)–C(13) 1.4377(16); N(1)–Y(1)–N(2) 56.80(3), Cl(1)–Y(1)–Cl(1′) 82.106(14), N(1)–C(13)–N(2) 114.47(11), C(13)–Y(1)–C(13′) 125.77(5), O(1S′)–Li(1)–O(1S) 81.14(14), Cl(1′)–Li(1)–Cl(1) 98.70. Symmetry operation: $-x$, $y$, to $-z + 0.5$.

Complex **6** crystallises in the monoclinic space group *C*2/*c* with four molecules in the unit cell. The lutetium atom is hexacoordinated by the four nitrogen atoms of the two bidentate guanidinate ligands and by two chlorine atoms. The two chlorine atoms form bridges to the lithium atom which is in turn coordinated to two THF molecules (Figure 2).

As in the molecular structure of **1**, the small differences between the Lu–N(1,2) distances [2.320(5), 2.291(5) Å] and the C(101)–N(1,2) distances [1.316(7), 1.339(7) Å] indicate electron delocalisation within the anionic NCN fragments. The lengths of the lutetium-nitrogen bonds are very close to those in the related lutetium complex $[(Me_3Si)_2NC(N\textit{i}Pr)_2]_2Lu(\mu\text{-}Cl)_2Li(THF)_2$ [2.285(1)–2.346(1) Å] containing less sterically demanding isopropyl-substituted guanidinate ligands[7] and to the lengths of the Lu–N bonds in $[Li(THF)_4][(C_5H_5)_2Lu(NPh_2)_2]$ [2.290(7), 2.293(7) Å][8] but are much shorter than the coordinate N→Lu bonds in $(\eta^8\text{-}C_8H_8)Lu[o\text{-}C_6H_4CH_2N(CH_3)_2](THF)$ [2.479(6) Å][9] and

Lu[*o*-$C_6H_4CH_2N(CH_3)_2]_3$ [2.468(6), 2.478(5) and 2.588(5) Å].[10] Since the silylamine nitrogen is not involved in the conjugation, the (Si)N–C bond is substantially longer [1.439(7) Å] than the C–N(1,2) bonds. The bridging Lu–Cl distances in **6** [both 2.747(2) Å] are longer than the terminal Lu–Cl distances in $[(Me_3Si)_2NC(NiPr)_2]_2Lu(\mu\text{-}Cl)_2Li(THF)_2$ [2.600(1) and 2.622(1) Å][7] and $(tBu_2C_5H_3)_2Lu(\mu\text{-}Cl)_2Li$(TMEDA) [2.60(1) Å][11] which can be attributed to the stronger steric repulsions of the bulkier cyclohexyl groups and the THF molecules coordinated to the lithium atom. The angle C(101)–Lu–C(101A) [130.3(2)°], defined as a bite angle, is slightly smaller than the corresponding angle in $[(Me_3Si)_2NC(NiPr)_2]_2Lu(\mu\text{-}Cl)_2Li(THF)_2$ [132.30(6)°][7] but larger than the centroid-metal-centroid angle in $(tBu_2C_5H_3)_2Lu(\mu\text{-}Cl)_2Li$(TMEDA) [127.9(1)°].[11]

Complex **7** crystallises in the monoclinic space group *C*2/*c*. The unit cell contains four molecules and the coordination environment of the yttrium atom (Figure 3) is analogous to that of the lutetium atom in **6**. The Y–N(1,2) distances [2.352(1), 2.357(1) Å] differ only very slightly and are in the range of the corresponding distances for the related yttrium guanidinate and amidinate complexes $\{[(Me_3Si)_2NC(NiPr)_2]_2Y(\mu\text{-}Cl)\}_2$ [2.326(4)–2.388(4) Å],[6b] $\{[PhC(NSiMe_3)_2]_2Y(\mu\text{-}H)\}_2$ [2.327(3)–2.389(3) Å][12a] and $[PhC(NSiMe_3)_2]_2Y(\mu\text{-}Cl)_2Li$(TMEDA) [2.334(2)–2.373(2) Å].[13] The Y–Cl distances [2.669(1) Å] are slightly longer than those in the metallocene type "ate" complexes $Cp^*_2Y(\mu\text{-}Cl)_2Li(THF)_2$ [2.646(2), 2.655(2) Å][14] and $[(1,3\text{-}Me_3Si)_2C_5H_3]_2Y(\mu\text{-}Cl)_2Li(THF)_2$ [2.626(1), 2.631(1) Å][15] but shorter than the Y–Cl bonds in the dimeric complex $\{[(Me_3Si)_2NC(NiPr)_2]_2Y(\mu\text{-}Cl)\}_2$ [2.7128(15), 2.7166(15) Å].[12b] The bite angle C(13)–Y(1)–C(13′) [125.77(5)°] is substantially smaller than that in **6** [130.3(2)°]. As expected, the distance of the yttrium atom to the bridging Cl atoms [2.6693(3) Å] is significantly longer than to the terminal Cl atom in **1** [2.584(2) Å].

Complex **1** turned out to be suitable for alkylation and arylation reactions. The alkylation with *t*BuLi, carried out in hexane at 0 °C, affords the THF-free complex $[(Me_3Si)_2NC(NCy)_2]_2Y$–*t*Bu (**8**) (Scheme 3) which was isolated as colourless crystals in a yield of 52%. $^1$H NMR spectroscopic monitoring of the course of the reaction revealed that **8** is actually formed quantitatively. However, its isolation in a crystalline state is hampered by its very high solubility in hexane and pentane. The NMR spectra of **8**, recorded in [D$_6$]benzene at ambient temperature, conditions under which the complex is stable for at least the three days over which measurements were made, show three remarkable features: 1) The $^1$H NMR signal of the methyl protons of the *tert*-butyl group appears as a broadened singlet at $\delta$ = 1.48 ppm and the corresponding carbon atoms cause the appearance of two $^{13}C\{^1H\}$ NMR signals at $\delta$ = 30.6 and 30.7 ppm which can be interpreted as a doublet with a coupling constant $^2J_{Y,C}$ = 2.3 Hz. The tertiary carbon atom

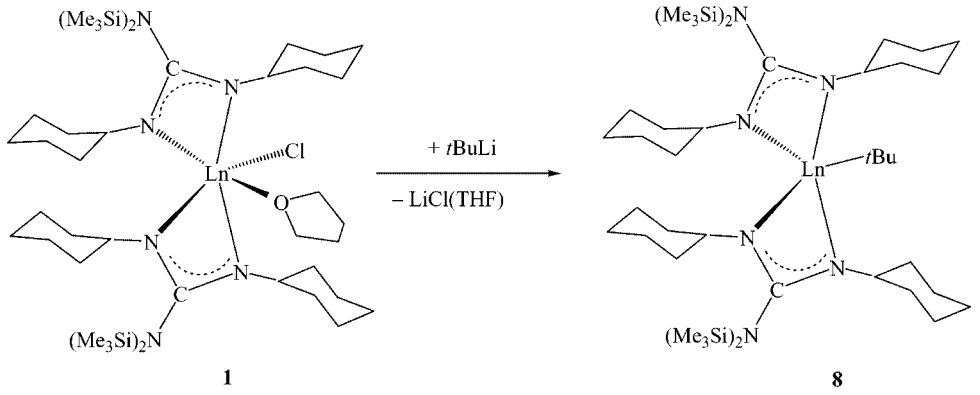

Scheme 3.

of the *tert*-butyl group bonded to the yttrium atom gives rise to a $^{13}C\{^1H\}$ NMR doublet at $\delta$ = 37.5 ppm with a coupling constant $^1J_{Y,C}$ = 56 Hz. 2) The methine protons of the four cyclohexyl groups appear as two broad multiplet signals at $\delta$ = 3.45 and 3.63 ppm with an intensity ratio of 1:3 which collapse to a very broad multiplet at $\delta$ = 3.54 ppm in the $^1H$ NMR spectrum in [D$_8$]toluene below –10 °C. The methine carbon atoms display a $^{13}C\{^1H\}$ NMR signal at $\delta$ = 55.2 ppm and their methylene carbon atoms show a single set of five signals at 24.9, 25.9, 26.1, 26.2 and 26.4 ppm. These observations indicate non-equivalence of the guanidinate ligands apparently resulting from the steric repulsion of the bulky *t*Bu and cyclohexyl groups. 3) The methylsilyl protons give rise to three singlet signals at $\delta$ = 0.28, 0.32 and 0.36 ppm in an intensity ratio of 1:3:2 at room temperature and in [D$_8$]toluene below –10 °C. They correspond to the three $^{13}C\{^1H\}$ NMR signals of the methylsilyl carbon atoms at 2.3, 2.4 and 2.8 ppm. The different shielding of the $CH_3$(Si) groups is not clear. It may be caused by restricted rotation of the N(SiMe$_3$)$_2$ units due to the neighbourhood of the bulky cyclohexyl moieties.

Crystals of **8** suitable for X-ray diffraction studies were obtained by prolonged cooling of concentrated hexane solutions to –30 °C. The molecular structure of **8** is shown in Figure 4 and the crystal and structure refinement data are listed in Table 1.

The coordination sphere of the yttrium atom is composed of the four nitrogen atoms of the two bidentate guanidinate ligands and the tertiary carbon atom of the *tert*-butyl group resulting in a formal coordination number of 5 for yttrium, a lower number than for other organo-yttrium compounds.[1] The most striking feature in the structure of **8** is the strongly distorted geometry of the *t*Bu ligand. The angles C(41)–C(39)–Y(1) [91.71(16)°] and C(42)–C(39)–Y(1) [98.99(16)°] are substantially smaller and the angle C(40)–C(39)–Y(1) [135.62(17)°] is much larger than the value expected for an sp$^3$ hybridised carbon atom, thus leading to rather close contacts between yttrium and the methyl carbon atoms C(41) [2.877(3) Å] and C(42) [3.038(3) Å] and the hydrogens belonging to them. The distance Y(1)–C(40) remains very long [3.639(3) Å] and indicates the absence of an interaction between the methyl group and yttrium. Despite the fact that the C–C distances

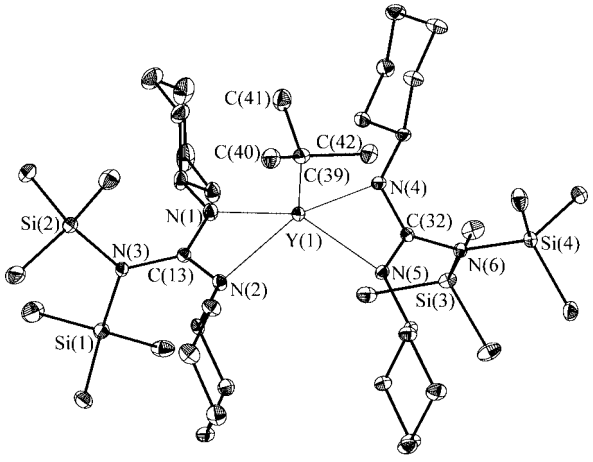

Figure 4. ORTEP diagram (30% probability thermal ellipsoids) of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$Y–*t*Bu (**8**) showing the non-hydrogen atom numbering scheme. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Y(1)–N(1) 2.3360(19), Y(1)–N(2) 2.3545(17), Y(1)–N(4) 2.3990(17), Y(1)–N(5) 2.3167(17), Y(1)–C(39) 2.399(2), N(1)–C(13) 1.338(3), N(2)–C(13) 1.333(3), N(3)–C(13) 1.432(3), N(4)–C(32) 1.334(3), N(5)–C(32) 1.341(3), N(6)–C(32) 1.429(3), C(39)–C(40) 1.515(4), C(39)–C(41) 1.518(4), C(39)–C(42) 1.527(3); N(1)–Y(1)–N(2) 57.05(6), N(4)–Y(1)–N(5) 57.14(6), N(1)–C(13)–N(2) 114.03(19), N(4)–C(32)–N(5) 115.03(18), C(39)–Y(1)–C(13) 112.08(7), C(39)–Y(1)–C(32) 116.23(7), C(40)–C(39)–Y(1) 135.62(17), C(41)–C(39)–Y(1) 91.71(16), C(42)–C(39)–Y(1) 98.99(16).

within the *tert*-butyl group do not change considerably [C(39–C(40) = 1.515(4), C(39)–C(41) = 1.518(4) and C(39)–C(42) = 1.527(2) Å] we suggest that agostic interactions are present in **8**. To evaluate qualitatively the hindrance of the *t*Bu group to rotation around the Y(1)–C(39) bond, the MOLDRAW program[17] was used to estimate the changes in the energies of non-bonding interactions as a function of the torsion angle N(5)–Y(1)–C(39)–C(42). As shown in Figure 5, the minimum energy corresponds exactly to a torsion angle of 22.5° estimated for **8** from its molecular structure. In this case, even the shortest intramolecular distances between the carbon atoms C(40) and C(42) and the carbon atoms of the cyclohexyl and the SiMe$_3$ groups are rather long ranging from 3.653 to 4.122 Å, thus excluding steric hindrance. According to the diagram the first and, at the same time, the highest maximum of energy corresponds to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a torsion angle of between 163.0 and 172.1°. Such an orientation of the *tert*-butyl group would cause a short contact of 2.700 Å between the C(41) methyl carbon atom and the C(8) methylene carbon atom of the cyclohexyl ring thus provoking steric repulsion. In the case of a torsion angle of 242.8–252.8° corresponding to the second maximum, the shortest intramolecular contact of 2.800 Å would be between the C(42) methyl carbon atom and the C(8) methylene carbon atom of the cyclohexyl moiety. In the last two cases, the distances to the methyl carbon atoms of the $SiMe_3$ groups are in the range of van der Waals contacts. These data clearly show that the hindrance to rotation of the *t*Bu group is caused by agostic interactions with the yttrium atom. At this point it should be noted that $[(Me_3Si)_2NC(NiPr)_2]_2Y$–*t*Bu, containing the less steric demanding *i*Pr groups, shows no signs of agostic interactions. In this compound the Y–C bond [2.332(9) Å][6b] is noticeably shorter than that in **8** [2.399(2) Å] and in other *N*,*N*- and *N*,*O*-coordinated alkyl yttrium complexes.[16] The bonding situation within the four-membered metallocycles in **8** is different from that in **7**. Whereas in complex **7** both guanidinate ligands are bonded to the metal atom in a symmetric fashion, the Y–N distances in **8** range from 2.3167(17) to 2.3990(17) Å. The very small differences in the bond lengths within the coordinating NCN fragments in **8** [C(13)–N(1) = 1.338(3), C(13)–N(2) = 1.333(3), C(32)–N(4) = 1.334(3) and C(32)–N(5) = 1.341(3) Å] are indicative of delocalised π systems.

Analogous to the synthesis of **8**, we treated equimolar amounts of **1** and MeLi in order to obtain the corresponding methyl yttrium complex. In fact, the NMR-scale reaction carried out in [$D_8$]toluene at 0 °C occurred with formation of $[(Me_3Si)_2NC(NCy)_2]_2YMe$ (**9**) as indicated by the appearance of a broad signal at –0.36 ppm in the $^1$H NMR spectrum which could be assigned to the protons of the yttrium bonded methyl group. However, the compound was no longer formed when the reaction was carried out on a preparative scale in hexane at 0 °C. On the other hand, the reaction of **1** with two equiv. of MeLi in hexane at 0 °C and in the presence of TMEDA afforded the corresponding "ate" complex $[(Me_3Si)_2NC(NCy)_2]_2Y(\mu\text{-}Me)_2Li(TMEDA)$ (**10**) as a colourless microcrystalline solid in 61% yield. As

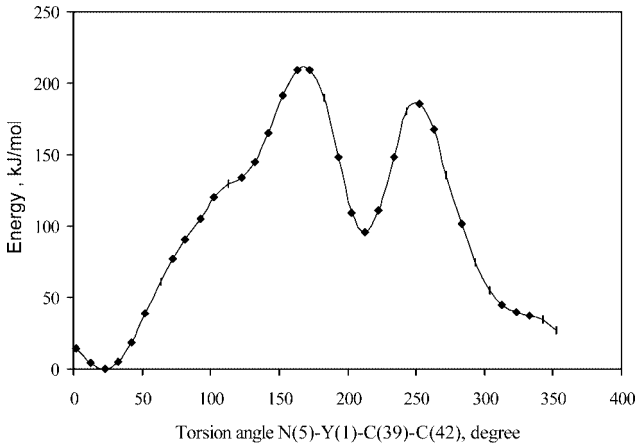

Figure 5. Energy diagram of the non-bonding interactions in complex **8** as function of the torsion angle N(5)–Y(1)–C(39)–C(42).

a side product, lithium guanidinate $[Li(TMEDA)][(Me_3Si)_2NC(NCy)_2]$ (**11**) was isolated in a yield of 7%.

The moisture- and air-sensitive complex **10** is soluble in THF and toluene and moderately soluble in hexane. [$D_6$]benzene solutions of **10** are stable at room temperature for several days. The NMR spectra of **10** recorded in [$D_6$]benzene show a broad $^1$H singlet signal at –0.51 ppm and a broad $^{13}C\{^1H\}$ resonance at $\delta$ = 11.6 ppm with no resolved yttrium coupling for the yttrium bonded methyl groups. These chemical shift values are very close to those reported for the related methyl complexes $[(Me_3Si)_2NC(NiPr)_2]_2Y(\mu\text{-}Me)_2Li(TMEDA)$[6b] and $[PhC(NSiMe_3)_2]_2Y(\mu\text{-}Me)_2Li(TMEDA)$[12a,12b] but are noticeably lower-field compared with those of the metallocene type complexes such as $Cp^*_2Y(\mu\text{-}Me)_2Li(OEt_2)$.[12c] The guanidinate fragments give rise to a single set of signals indicating the equivalence of both ligands.

The lithium guanidinate $[Li(TMEDA)][(Me_3Si)_2NC(NCy)_2]$ (**11**), formed as a side product, was characterised by $^1$H and $^{13}$C NMR spectroscopy as well as by an X-ray structure analysis. An ORTEP drawing of its molecular structure is shown in Figure 6 and the crystal and structure refinement data are listed in Table 1. Unlike $[\{(Me_3Si)_2NC(NCy)_2\}Li]_2$[18] obtained from the reaction of ether-free

$Li[N(SiMe_3)_2]$ with CyN=C=NCy in toluene, complex **11** was found to be monomeric in the solid state.

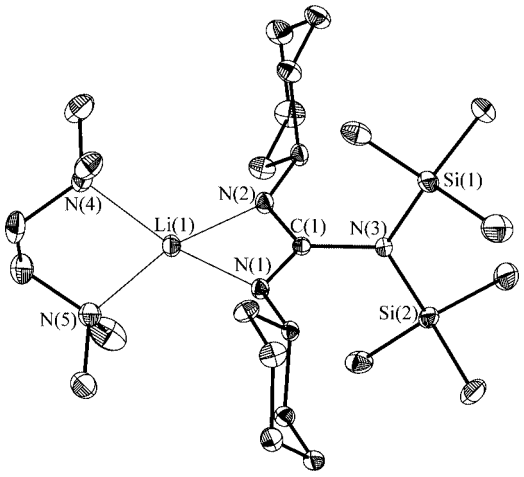

Figure 6. ORTEP diagram (30% probability thermal ellipsoids) of $[Li(TMEDA)][(Me_3Si)_2NC(NCy)_2]$ (**11**) showing the non-hydrogen atom numbering scheme. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Li(1)–N(1) 1.969(3), Li(1)–N(2) 1.971(3), Li(1)–N(4) 2.110(3), Li(1)–N(5) 2.089(3), N(1)–C(1) 1.3258(19), N(2)–C(1) 1.3217(19), N(3)–C(1) 1.4655(19); N(1)–Li(1)–N(2) 69.46(10), N(5)–Li(1)–N(4) 87.01(11).

At first, the reaction of **1** with $LiCH_2SiMe_3$ was carried out in an NMR tube in [D$_8$]toluene at 0 °C and the $^1$H NMR spectrum confirmed the formation of the alkylated product $[(Me_3Si)_2NC(NCy)_2]_2YCH_2SiMe_3$ (**12**) by the appearance of a characteristic doublet signal at –0.16 ppm with a coupling constant $^2J_{Y,H}$ = 3.0 Hz for the yttrium bonded methylene group. However, the reaction carried out on a preparative scale in hexane yielded an inseparable mixture of **12** and compounds which are most likely thermal decomposition products since the signal of TMS was detected in the $^1$H NMR spectrum of the reaction mixture.

The guanidinate supported phenyl yttrium derivative $[(Me_3Si)_2NC(NCy)_2]_2YPh(THF)$ (**13**) was synthesised by treatment of **1** with equimolar amounts of phenyllithium in THF (Scheme 4) and was isolated as a colourless microcrystalline solid in 61% yield. It is soluble in ethers, toluene and hexane. Under NMR conditions ([D$_6$]benzene solution, room temperature, inert atmosphere, sealed tube) it is stable for several days but decomposes immediately in the presence of air or moisture. The $^1$H NMR spectrum of **13** shows a complex multiplet in the region of 7.20–7.45 ppm for the five phenyl protons and two broad multiplets of equal intensity at $\delta$ = 3.24 and 3.55 ppm for the methine protons of the cyclohexyl groups. The methine carbon atoms give rise to two $^{13}C\{^1H\}$ singlet signals at $\delta$ = 54.8 and 56.9 ppm. The presence of the coordinated THF molecule is apparent from two broad $^1$H singlet signals at $\delta$ = 1.79 and 3.75 ppm and two $^{13}C\{^1H\}$ resonances at $\delta$ = 25.2 and 68.7 ppm.

## Conclusions

The *N*,*N*′-dicyclohexyl-*N*′′-bis(trimethylsilyl)-substituted guanidinate anion is a suitable ligand for the synthesis of stable monomeric monochloro and "ate" complexes of yttrium, neodymium, samarium and lutetium. Alkyl and phenyl complexes of yttrium with very low coordination numbers stabilised by this guanidinate ligand have been synthesised and characterised. Agostic interactions between yttrium and the methyl groups of the *tert*-butyl ligand in $[(Me_3Si)_2NC(NCy)_2]_2Y$–*t*Bu (**8**) in the solid state as well as in solution have been confirmed by X-ray structural analysis and NMR spectroscopy.

## Experimental Section

All experiments were performed in evacuated tubes using standard Schlenk techniques with rigorous exclusion of traces of moisture and air. After drying over KOH, THF was purified by distillation from sodium/benzophenone ketyl. Hexane and toluene were dried by distillation from sodium/triglyme and benzophenone ketyl prior to use. [D$_6$]benzene was dried with sodium and condensed in vacuo into the NMR tubes prior to use. *N*,*N*′-dicyclohexylcarbodiimide and *t*BuLi were purchased from Acros. Anhydrous $LuCl_3$,[19] $[Li(Et_2O)][N(SiMe_3)_2]$[20] and $Na[N(SiMe_3)_2]$[21] were prepared according to literature procedures. All other commercially available chemicals were used after appropriate purification. NMR spectra were recorded on a Bruker DPX 200 spectrometer ($^1$H, 200 MHz; $^{13}$C, 50 MHz). Chemical shifts for $^1$H and $^{13}$C spectra were referenced internally using the residual solvent resonances and are reported relative to TMS. IR spectra were recorded as Nujol mulls on a Specord M80 instrument. Lanthanide metal analyses were carried out by complexometric titration. The C,H elemental analyses were carried out by the microanalytical laboratory of the IOMC.

**Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$YCl(THF) (1):** To a solution of Na[N(SiMe$_3$)$_2$] (1.00 g, 5.45 mmol) in THF (30 mL) was added CyN=C=NCy (1.12 g, 5.45 mmol) slowly at 20 °C and after 45 min stirring $YCl_3$ (0.53 g, 2.72 mmol) was added. The reaction mixture was stirred for further 12 h and the NaCl formed was filtered off and from the clear solution and the solvent was evaporated in vacuo. The remaining solid was extracted twice with toluene (2 × 20 mL). After filtration of the toluene extracts, the toluene was evaporated in vacuo. The remaining off-white solid was dissolved in hexane (30 mL). The resultant solution was slowly concentrated at room temperature to a quarter of its volume and was then cooled to –30 °C. The crystalline precipitate formed overnight was washed with cold hexane and then dried in vacuo at room temperature for 40 min yielding **1** (1.67 g, 66%) as a colourless crystalline solid. $C_{42}H_{88}ClN_6OSi_4Y$ (929.2): calcd. C 54.28, H 9.47, Y 9.56; found C 53.83, H, 9.12, Y 9.83. $^1$H NMR (200 MHz, [D$_6$]benzene): $\delta$ = 0.43 [s, 36 H, Si(CH$_3$)$_3$], 1.12–1.88 (br. m, 44 H, CH$_2$/Cy, β-CH$_2$/THF), 3.29 (br. m, 4 H, CH/Cy), 3.94 (br. s, 4 H, α-CH$_2$/THF) ppm. $^{13}$C{$^1$H} NMR (50 MHz, [D$_6$]benzene): δ = 3.1 (N[Si(CH$_3$)$_3$]$_2$), 25.4 (β-CH$_2$/THF), 23.1, 26.3, 26.6, 31.9, 37.4 (CH$_2$/Cy), 55.1 (CH/Cy), 70.1 (α-CH$_2$/THF), 169.1 (CN$_3$) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 1620 (s), 1320 (m), 1240 (s), 1270 (m), 1200 (m), 1150 (m), 1100 (m), 1050(m), 950 (s), 930 (s), 860 (m), 830 (s) cm$^{-1}$.

**Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$NdCl(THF) (2):** Complex **2** was synthesised following the standard procedure described for **1** from Na[N(SiMe$_3$)$_2$] (1.80 g, 9.81 mmol), CyN=C=NCy (2.02 g, 9.81 mmol) and $NdCl_3$ (1.22 g, 4.90 mmol) in THF (30 mL). Complex **2** was isolated as a pale blue crystalline solid (1.67 g, 79%). $C_{42}H_{88}ClN_6NdOSi_4$ (984.6): calcd. C 51.23, H 8.93, Nd 14.64; found C 50.80, H 9.28, Nd 14.48. IR (Nujol, KBr): $\tilde{\nu}$ = 1620 (s), 1330 (m), 1290 (m), 1240 (s), 1160 (s), 1120 (s), 1050 (m), 990 (s), 950 (s), 930 (s), 850 (s), 830 (s) cm$^{-1}$.

**Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$SmCl(THF) (3):** Complex **3** was synthesised following the standard procedure described for **1** from Na[N(SiMe$_3$)$_2$] (1.00 g, 5.45 mmol), CyN=C=NCy (1.12 g, 5.45 mmol) and $SmCl_3$ (0.7 g, 2.72 mmol) in THF (30 mL). Complex **3** was isolated as a pale yellow crystalline solid (1.50 g, 56%). $C_{42}H_{88}ClN_6OSi_4Sm$ (990.6): calcd. C 50.92, H 8.88, Sm 17.17; found C 50.61, H, 8.49, Sm 17.51. IR (Nujol, KBr): $\tilde{\nu}$ = 1620 (s), 1335 (m), 1290 (s), 1240 (s), 1170 (m), 1120 (m), 1060 (m), 990 (s), 930 (s), 930 (s), 850 (s), 830 (s) cm$^{-1}$.

**Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$LuCl(THF) (4):** Complex **4** was synthesised following the standard procedure described for **1** from Na[N(SiMe$_3$)$_2$] (1.35 g, 7.36 mmol), CyN=C=NCy (1.51 g, 7.36 mmol) and $LuCl_3$ (1.03 g, 3.68 mmol) in THF (30 mL). Complex **4** was isolated as a colourless crystalline solid (1.67 g, 69%). $C_{42}H_{88}ClLuN_6OSi_4$ (1015.3): calcd. C 49.68, H 8.66, Lu 17.23; found C 49.30, H, 8.16, Lu 17.58. $^1$H NMR (200 MHz, [D$_6$]benzene): $\delta$ = 0.35 [s, 36 H, Si(CH$_3$)$_3$], 1.01–2.09 (br. m, 44 H, CH$_2$/Cy, β-CH$_2$/THF), 3.15 (br. m, 4 H, CH/Cy), 3.61 (br. s, 4 H, α-CH$_2$/THF) ppm. $^{13}$C{$^1$H} NMR (50 MHz, [D$_6$]benzene): $\delta$ = 2.8 (N[Si(CH$_3$)$_3$]$_2$), 25.7 (β-CH$_2$/THF), 22.8, 23.1, 25.1, 29.4, 31.2 (CH$_2$/Cy), 55.7 (CH/Cy), 68.1 (α-CH$_2$/THF), 169.6 (CN$_3$) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 1640 (m), 1305 (m), 1260 (s), 1250 (s), 1200 (m), 1150 (m), 1050 (s), 970 (m), 950 (s), 860 (s), 840 (s) cm$^{-1}$.

**Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$Y(μ-Cl)$_2$Li(THF)$_2$ (5):** Complex **5** was synthesised following the standard procedure described for **1** from [Li(Et$_2$O)][N(SiMe$_3$)$_2$] (1.28 g, 5.30 mmol), CyN=C=NCy (1.09 g, 5.30 mmol) and $YCl_3$ (0.52 g, 2.65 mmol) in THF (30 mL). Complex **5** was isolated as colourless crystalline solid (2.03 g, 74%). $C_{46}H_{96}Cl_2LiN_6O_2Si_4Y$ (1043.7): calcd. C 52.93, H 9.19, Y 8.51; found C 52.57, H, 8.81, Y 8.23. $^1$H NMR (200 MHz, [D$_6$]benzene): $\delta$ = 0.37 [s, 36 H, Si(CH$_3$)$_3$], 1.30–2.03 (br. m, 48 H, CH$_2$/Cy, β-CH$_2$/THF), 3.41 (br. m, 4 H, CH/Cy), 3.79 (br. s, 8 H, α-CH$_2$/THF) ppm. $^{13}$C{$^1$H} NMR (50 MHz, [D$_6$]benzene): $\delta$ = 2.8 (N[Si(CH$_3$)$_3$]$_2$), 25.2 (β-CH$_2$/THF), 26.1, 26.4, 37.1 (CH$_2$/Cy), 54.8 (CH/Cy), 71.0 (α-CH$_2$/THF), 169.0 (CN$_3$) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 1620 (m), 1340 (m), 1290 (m), 1240 (s), 1210 (m), 1100 (m), 1060 (m), 970 (m), 950 (s), 860 (m), 830 (s) cm$^{-1}$.

**Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$Lu(μ-Cl)$_2$Li(THF)$_2$ (6):** Complex **6** was synthesised following the standard procedure described for **1** from [Li(Et$_2$O)][N(SiMe$_3$)$_2$] (1.56 g, 6.49 mmol), CyN=C=NCy (1.34 g, 6.49 mmol) and $LuCl_3$ (0.91 g, 3.24 mmol) in THF (30 mL). Complex **6** was isolated as colourless crystalline solid (2.54 g, 70%). $C_{46}H_{96}Cl_2LiLuN_6O_2Si_4$ (1129.8): calcd. C 48.90, H 8.49, Lu 15.48; found C 48.48, H, 8.10, Lu 15.31. $^1$H NMR (200 MHz, [D$_6$]benzene): $\delta$ = 0.38 [s, 36 H, Si(CH$_3$)$_3$], 1.21–2.11 (br. m, 48 H, CH$_2$/Cy, β-CH$_2$/THF), 3.56 (br. m, 4 H, CH/Cy), 3.75 (br. s, 8 H, α-CH$_2$/THF) ppm. $^{13}$C{$^1$H} NMR (50 MHz, [D$_6$]-benzene): $\delta$ = 2.9 (N[Si(CH$_3$)$_3$]$_2$), 25.4 (β-CH$_2$/THF), 14.1, 22.8, 26.0, 26.3, 36.9, (CH$_2$/Cy), 54.9 (CH/Cy), 68.8 (α-CH$_2$/THF), 171.2 (CN$_3$) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 1630 (m), 1350 (m), 1300 (m), 1250 (s), 1210 (m), 1100 (m), 1050 (s), 950 (s), 920 (s), 870 (m), 830 (s) cm$^{-1}$.

**Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$Y(μ-Cl)$_2$Li(DME) (7):** Complex **5** (1.10 g, 1.05 mmol) was dissolved in DME (10 mL). Volatiles were evaporated in vacuo and the solid residue was recrystallised from hexane. Complex **7** was isolated as a colourless crystalline solid (0.77 g, 74%). $C_{42}H_{90}Cl_2LiN_6O_2Si_4Y$ (989.7): calcd. C 50.97, H 9.09, Y 8.98; found C 50.60, H, 8.71, Y 8.51. $^1$H NMR (200 MHz, [D$_6$]benzene): $\delta$ = 0.23 [s, 36 H, Si(CH$_3$)$_3$], 1.42–2.02 (br. m, 40 H, CH$_2$/Cy), 2.79 (s, 4 H, CH$_2$/DME), 3.15 (s, 6 H, CH$_3$/DME), 3.46 (br. m, 4 H, CH/Cy) ppm. $^{13}$C{$^1$H} NMR (50 MHz, [D$_6$]benzene): $\delta$ = 2.8 (N[Si(CH$_3$)$_3$]$_2$), 26.1, 26.2, 26.4, 33.4, 37.2 (CH$_2$/Cy), 54.8 (CH/Cy), 58.8 (OCH$_3$/DME), 70.2 (CH$_2$/DME), 168.6 (CN$_3$) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 1640 (s), 1320 (m), 1260 (s), 1240 (s), 1100 (w), 1060 (m), 950 (s), 880 (m), 830 (s) cm$^{-1}$.

**Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$Y–*t*Bu (8):** To a solution of **1** (0.82 g, 0.88 mmol) in hexane (20 mL) was added a solution of *t*BuLi in hexane (0.58 mL, 1.5 M solution, 0.88 mmol) slowly at 0 °C and the reaction mixture was stirred for 1 h. The mixture was then warmed to room temperature and was stirred again for 1 h. The pale-yellow solution was filtered and concentrated in vacuo to approximately a quarter of its initial volume. The concentrated solution was cooled to –30 °C and kept at that temperature overnight. The mother liquor was then decanted from the precipitate formed. The latter was washed with cold hexane and was dried in vacuo at room temperature for 30 min yielding **8** as colourless crystals (0.40 g, 52%). $C_{42}H_{89}N_6Si_4Y$ (879.4): calcd. C 57.36, H 10.12, Y 10.10; found C 56.99, H, 9.81, Y 9.79. $^1$H NMR (200 MHz, [D$_6$]-benzene): $\delta$ = 0.28, 0.32, 0.36 [3 s, 36 H, Si(CH$_3$)$_3$], 1.48 [s, 9 H, C(CH$_3$)$_3$], 1.27–2.04 (br. m, 40 H, CH$_2$/Cy), 3.45, 3.63 (2 br. m, 4 H, CH/Cy) ppm. $^{13}$C{$^1$H} NMR (50 MHz, [D$_6$]benzene): $\delta$ = 2.3, 2.4, 2.8 (N[Si(CH$_3$)$_3$]$_2$), 24.9, 25.9, 26.1, 26.2, 26.4 (CH$_2$/Cy), 30.65 [d, $^2J$ = 2.3 Hz, C(*C*H$_3$)$_3$], 37.5 [d, $^1J_{Y,C}$ = 56 Hz, *C*(CH$_3$)$_3$], 55.2 (CH/Cy), 168.7 (CN$_3$) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 1620 (s), 1330 (m), 1220 (s), 1260 (m), 1205 (m), 1150 (m), 950 (s), 930 (s), 830 (s) cm$^{-1}$.

**NMR Tube Synthesis of [(Me$_3$Si)$_2$NC(NCy)$_2$]$_2$YMe (9):** A solution of MeLi in diethyl ether (0.028 mL, 1.6 M, 0.0448 mmol) was added to a solution of **1** (41.62 mg, 0.0448 mmol) in [D$_8$]toluene (2 mL) in an NMR tube at 0 °C which was then sealed. The reaction mixture was warmed to room temperature, shaken for 30 min and then left for 45 min to allow the LiCl to settle. $^1$H NMR (200 MHz,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[$D_6$]benzene): $\delta$ = –0.36 (br. s, 3 H, $YCH_3$), 0.46, 0.47 [s, 36 H, $NSi(CH_3)_3$], 1.32–2.03 (br. m, 40 H, $CH_2$/Cy), 3.47, 3.95 (br. m, together 4 H, CH/Cy) ppm.

**Synthesis of [$(Me_3Si)_2NC(NCy)_2]_2Y(\mu$-Me)$_2$Li(TMEDA) (10):** To a solution of **1** (0.97 g, 1.04 mmol) in hexane (20 mL) were added TMEDA (0.24 g, 2.08 mmol) and a solution of MeLi in diethyl ether (1.3 mL, 1.6 M solution, 2.08 mmol) slowly at 0 °C. The reaction mixture was stirred for 45 min and was then warmed to room temperature and again stirred for 1.5 h. The pale-yellow solution was filtered and concentrated in vacuo to approximately half of its initial volume. When the precipitation of crystals started, the solution was cooled to –10 °C and kept at that temperature for 2 h. The mother liquor was decanted and the small amount of colourless crystals was washed with cold hexane, dried in vacuo at room temperature for 15 min and identified as the side product **11** (0.07 g, 7%). The decanted mother liquor was concentrated to the half of its initial volume, cooled to –30 °C and left at that temperature for one week. The crystalline solid formed was separated by decantation, washed with cold hexane and dried in vacuo leaving colourless crystals of **10** (0.40 g, 61%). $C_{46}H_{102}LiN_8Si_4Y$ (974.7): calcd. C 56.68, H 10.46, Y 9.12; found C 56.31, H, 10.02, Y 9.33. $^1$H NMR (200 MHz, [$D_6$]benzene): $\delta$ = –0.51 (br. s, 6 H, $\mu$-$CH_3$), 0.53 [s, 36 H, $Si(CH_3)_3$], 1.32–2.00 [br. m, 44 H, $CH_2$/Cy, $(NCH_2)_2$], 2.12 [s, 12 H, $N(CH_3)_2$], 3.58 (br. m, 4 H, CH/Cy). $^{13}$C{$^1$H} NMR (50 MHz, [$D_6$]benzene): $\delta$ = 3.1 ($N[Si(CH_3)_3]_2$), 11.6 (br., $\mu$-$CH_3$), 14.3, 23.0, 26.6, 26.7, 31.2 ($CH_2$/Cy), 46.2 ($[N(CH_3)_2]_2$), 55.2 (CH/Cy), 57.6 ($NCH_2$), 167.6 ($CN_3$) ppm. **11**: $C_{25}H_{56}LiN_5Si_2$ (489.8): calcd. C 61.29, H 11.43; found C 61.56, H, 11.81. $^1$H NMR (200 MHz, [$D_6$]benzene): $\delta$ = 0.31 [s, 18 H, $Si(CH_3)_3$], 1.15–2.00 [br. m, 24 H, $CH_2$/Cy, $(NCH_2)_2$], 2.15 [s, 12 H, $N(CH_3)_2$], 3.42 (m, 4 H, CH/Cy). $^{13}$C{$^1$H} NMR (50 MHz, [$D_6$]-benzene): $\delta$ = 3.0 ($N[Si(CH_3)_3]_2$), 26.6, 26.7, 31.2 ($CH_2$/Cy), 46.6 [$N(CH_3)$], 54.8 (CH/Cy), 57.4 ($NCH_2$), 165.3 ($CN_3$) ppm.

**NMR Tube Synthesis of [$(Me_3Si)_2NC(NCy)_2]_2YCH_2SiMe_3$ (12):** In an inert atmosphere, compound **1** (36.00 mg, 0.0387 mmol), $LiCH_2SiMe_3$ (3.64 mg, 0.0387 mmol) and [$D_8$]toluene (2 mL) were mixed in an NMR tube at 0 °C which was then sealed. The reaction mixture was warmed to room temperature, shaken for 30 min then left for 30 min for the LiCl to settle. The spectroscopic investigation of the solution product indicated the formation of **12**: $^1$H NMR (200 MHz, [$D_8$]toluene): $\delta$ = –0.16 (d, $^2J_{Y,H}$ = 3.0 Hz, 2 H, $YCH_2$), 0.37 [s, 36 H, $NSi(CH_3)_3$], 0.52 [s, 9 H, $CH_2Si(CH_3)_3$], 1.24–2.00 (br. m, 40 H, $CH_2$/Cy), 3.46 (br. m, 4 H, CH/Cy) ppm.

**Synthesis of [$(Me_3Si)_2NC(NCy)_2]_2YPh(THF)$ (13):** A solution of phenyllithium (0.10 g, 1.20 mmol) in THF (10 mL) was slowly added at 0 °C to a solution of **1** (1.12 g, 1.20 mmol) in THF (20 mL) and the reaction mixture was stirred for 2 h. After warming to room temperature the solvent was evaporated in vacuo. The remaining off-white solid was extracted with hexane (40 mL). The extract was filtered and concentrated to a quarter of its initial volume, cooled to –30 °C and left at that temperature for one week. The crystalline solid formed was separated from the mother liquor by decantation, washed with cold hexane and dried in vacuo at room temperature for 20 min leaving colourless crystals of **13** (0.66 g, 61%). $C_{48}H_{93}N_6OSi_4Y$ (970.8): calcd. C 59.38, H 9.57, Y 9.15; found C 59.00, H, 9.19, Y 9.41. $^1$H NMR (200 MHz, [$D_6$]-benzene): $\delta$ = 0.53 [s, 36 H, $Si(CH_3)_3$], 1.33–2.10 (br. m, 44 H, $CH_2$/Cy, $\beta$-$CH_2$/THF), 3.24, 3.55 (br. m, 4 H, CH/Cy), 3.75 (br. s, 4 H, $\alpha$-$CH_2$/THF), 7.20–7.45 (m, 5 H, Ar) ppm. $^{13}$C{$^1$H} NMR (50 MHz, [$D_6$]benzene): $\delta$ = 3.4 ($N[Si(CH_3)_3]_2$), 25.2 ($\beta$-$CH_2$/THF), 22.8, 25.8, 26.4, 26.9, 37.2 ($CH_2$/Cy), 54.8, 56.9 (CH/Cy), 68.7 ($\alpha$-$CH_2$/THF), 127.1, 127.6, 128.0, 137.2 (Ar), 169.4 ($CN_3$), 177.8 (d, $^1J_{Y,C}$ = 51 Hz, *ipso*-C, Ar) ppm.

**X-ray Crystallographic Study:** The crystal data and details of data collection are given in Table 1. X-ray data were collected on a Siemens SMART CCD diffractometer (graphite-monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, $\omega$-scan technique) with an area-detector at –100 °C. The intensity data were integrated with the SAINT program.[22] SADABS[23] was used to perform area-detector scaling and absorption corrections. The structures were solved by direct methods and were refined on $F^2$ using all reflections with SHELXTL.[24] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the THF ligands in **1** and **6** were placed in calculated positions and refined in the "riding-model". All other hydrogen atoms in **1** and **6** as well as in **7**, **8** and **11** were found from the Fourier syntheses and refined isotropically. CCDC-281699 (for **1**), -281698 (for **6**), -281697 (for **7**), -281695 (for **8**) and -281696 (for **11**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

This work was supported by the Russian Foundation for Basic Research (Grant No. 05–03–32390), the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft (Graduiertenkolleg "Synthetische, mechanistische und reaktionstechnische Aspekte von Metallkatalysatoren"). We gratefully acknowledge Dr. Yu. A. Kurskii for recording the NMR spectra.

# Reduction of $[Cp^*_2Mo_2O_5]$ in Aqueous Medium: Structure and Properties of a Triangular Mixed Oxo-Hydroxo-Bridged Product, $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4](X)_2$ (X = $CF_3CO_2$ or $CF_3SO_3$)

**Funda Demirhan,*[a] Bahar Çağatay,[a] Deniz Demir,[a] Miguel Baya,[b] Jean-Claude Daran,[b] and Rinaldo Poli*[b]**

**Keywords:** Bridging ligands / Hydrogen bonding / Metal–metal interactions / Molybdenum / Oxo ligands

The reduction of $[Cp^*_2Mo_2O_5]$ with Zn in a MeOH/$H_2O$ solution acidified with either $CF_3COOH$ or $CF_3SO_3H$ leads to the formation of the $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$ ion as its trifluoroacetate or trifluoromethanesulfonate salt. The structure of the compound was confirmed by X-ray analyses. The anions establish hydrogen-bonding interactions with all four bridging OH groups. Density functional calculations afford bonding parameters in close agreement with the observed structure and indicate that the cluster is best described as a valence-delocalized $Mo_3^{13+}$ species. The five metal electrons are distributed among an *a*-type ($z^2$) orbital, which accounts for most of the metal–metal attraction, and two essentially metal–metal nonbonding *e*-type (*xy*) orbitals with a slight Mo-(μ-O) π*-type contribution. Because of the $C_2$ symmetry, the latter orbitals are not degenerate. The calculations show that the unpaired electron is located in a molecular orbital with equal contribution from two Mo atoms, in agreement with the experimental observation of coupling of the unpaired electron to two Mo atoms in the isotropic EPR spectrum.

## Introduction

We have recently initiated a research program aimed at developing the chemistry of high-oxidation-state organometallic compounds in water, in the spirit of "green" chemistry[1–3] and with the long term goal of exploring the catalytic and electrocatalytic potential of organometallic compounds in water.[4,5] Unlike low-valent organometallic systems, which are generally supported by water-soluble modified phosphane or cyclopentadienyl ligands,[6–8] high-oxidation-state complexes are supported by oxo ligands, which makes them soluble in water by virtue of hydrogen bonding and protonation equilibria that yield charged hydroxo and aqua complexes. Although oxo-supported high-oxidation-state organometallic complexes are now well established and have interesting catalytic properties,[9,10] their systematic investigation in water has received little attention. We further argue that the greater metal electronegativity in these higher oxidation states confers a higher degree of covalency to the metal–carbon bonds with odd-electron carbon ligands (i.e. alkyls, allyls, cyclopentadienyls, etc.), which consequently may become quite resistant toward hydrolytic decomposition. For a redox-active metal, reduction of a high-oxidation-state oxo complex should favor the generation of aqua ligands and open the way to the generation of open coordination sites for substrate activation and catalytic and electrocatalytic applications.[11]

We have so far focused our attention on the speciation[12] and electrochemical behavior[13,14] of $[Cp^*_2Mo_2O_5]$. The Cp*–Mo bond in this complex is quite hydrolytically stable and is split only quite slowly at very low pH.[15] We have obtained novel oxo-supported complexes, the nature of which seems to depend intimately on the nature of the acid used, by chemical reduction with zinc in an acidic MeOH/$H_2O$ mixed solvent medium. For instance, with acetic acid we isolated the dinuclear $Mo^{IV}$ complex $[Cp^*_2Mo_2(\mu\text{-}O)_2(\mu\text{-}O_2CCH_3)_2]$ (**I**),[16] whereas with $CF_3COOH$ under the same conditions (mixed MeOH/$H_2O$ solvent, Zn as reducing agent) we obtained the $Mo^V$ trinuclear complex $[Cp^*_3Mo_3(\mu_3\text{-}O)(\mu\text{-}O)_3(\mu\text{-}O_2CCF_3)_3]^+$ (**II**) as a salt of the $Zn_2(O_2CCF_3)_6^{2-}$ dianion.[17] The formation of these compounds demonstrates that the removal of water ligands (from the expected protonation of oxo ligands, following the reduction process) generates vacant positions that are filled by the anions of the acids used. In previous contributions,[11,18] we have mentioned that another product may also be crystallized from the reaction mixture obtained by reduction in the presence of $CF_3COOH$, depending on the solvent and conditions used for the crystallization. This is another triangular cluster to which the formula $[Cp^*_3Mo_3(\mu\text{-}OH)_x(\mu\text{-}O)_{6-x}]^{2+}$ was assigned on the basis of an X-ray structural analysis. However, this product could

not be properly characterized because of severe disorder problems in the cation as well as in the $CF_3COO^-$ anion. This situation did not even allow the unambiguous identification of the *x* value (number of hydrogen atoms on the bridging oxygen atoms), and thus of the number of electrons in the cluster. We have now repeated the same reaction with a related strong acid, $CF_3SO_3H$, and crystallized the corresponding product. We report here the structure of these compounds and a description of their properties.

## Results

### Structure of the Trifluoroacetate Salt

The general procedure for the reduction of $[Cp^*_2Mo_2O_5]$, i.e. zinc reduction in a water-methanol solution acidified by $CF_3COOH$, has been described previously.[19] Numerous subsequent syntheses and crystallization of the resulting product consistently gave the same kind of crystals, which were always affected by the initially observed severe disorder problem (see above).[20] Interestingly, the same product (as revealed by the EPR study, vide infra) was also obtained in the presence of other weaker acids, in an attempt to obtain other kinds of carboxylate derivatives analogous to the previously reported $[Cp^*_2Mo_2(\mu\text{-}O)_2(\mu\text{-}O_2CCH_3)_2]$, when working at the same low pH.[16] This observation attests to the thermodynamic stability of this product.

Although badly disordered, the structure of the trifluoroacetate salt serves to identify the structural motif and to set the stage for the discussion of this compound. A view of the central $Mo_3O_6$ core, including the interaction with the two $CF_3CO_2$ anions, is shown in Figure 1 (a). The three Mo atoms form a nearly ideal equilateral triangle (vide infra), each edge of which is symmetrically bridged by two oxygen atoms, with one above and one below the $Mo_3$ plane. Thus, the three O atoms above the metal plane, and the three below, define two additional approximately equilateral triangles that are parallel to, and staggered with respect to, the $Mo_3$ triangle. The two anions are located above and below the $Mo_3$ plane and establish hydrogen-bonding interactions with the bridging O atoms, which desymmetrize the triangle. Both bridging O atoms of one particular $Mo_3$ edge (namely Mo1–Mo2 in Figure 1, a) are engaged in hydrogen bonding, each with an O atom of a different trifluoroacetate anion. The second O atom of each $CF_3COO^-$ anion interacts with a bridging O atom of a different edge (O4 bridges Mo1–Mo3 and O6 bridges Mo2–Mo3). The four O···O distances, in the range 2.59–2.64 Å, unambiguously show the presence of four OH groups. However, the quality of the structure is not sufficient to establish whether the two remaining bridging O atoms carry additional H atoms or not. Although of low quality, the structure of the trifluoroacetate salt indicates that the unique Mo1–Mo2 distance is slightly longer (2.797 Å) than the other two (Mo1–Mo3 2.786 Å; Mo2–Mo3 2.785 Å). It is important to stress that the spectroscopic and magnetic properties are insufficient to make an unambiguous choice because both an $(OH)_4(O)_2$ and a $(OH)_6$ structure correspond to an odd number of electrons (paramagnetic). Thus, they would not be easily distinguishable by EPR spectroscopy. They are likewise difficult to distinguish by infrared spectroscopy.

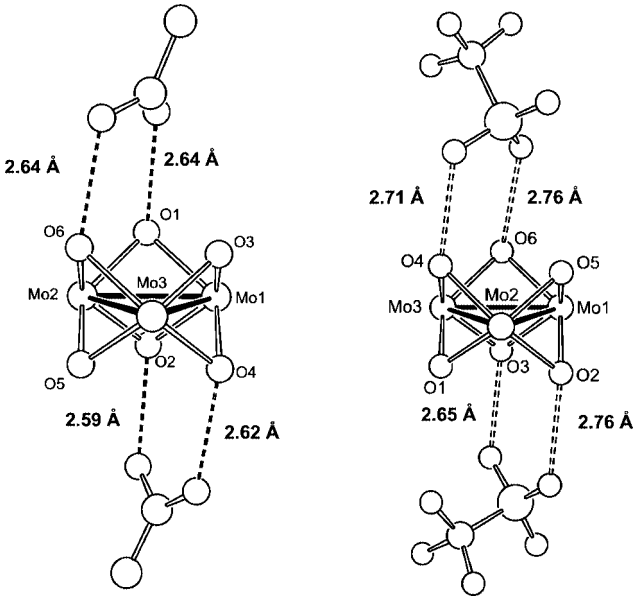

Figure 1. An ORTEP view of the central $Mo_3O_6$ core of $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$ in the acetate (left, the disordered F atoms are not shown) and trifluoromethanesulfonate salts (right), showing the hydrogen-bonding interactions with the two anions.

### Structure of the Trifluoromethanesulfonate Salt

The reduction process described in the previous section was repeated in the presence of triflic acid, with two objectives in mind. First, the different anion may allow a less problematic crystal-structure determination. Second, and most important, the triflate anion has three equivalent oxygen atoms available for hydrogen bonding. Therefore, should the two additional bridging functions that are not involved in hydrogen bonding with the trifluoroacetate anions (i.e. O3 and O5 in Figure 1, a) also bear hydrogen atoms, the triflate ions would be expected to establish an interaction with them. Conversely, the lack of such interactions may be taken as a strong indication against the presence of H atoms in these positions.

Complex $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4](CF_3SO_3)_2$ crystallizes under the same experimental conditions that lead to the crystallization of its trifluoroacetate congener. The compound dissolves readily in chlorinated solvents (dichloromethane, chloroform) and has identical EPR properties to those of the trifluoroacetate salt (vide infra). It is important to note that the crude product also gave NMR resonances that could be attributed to the Cp* protons of one or more diamagnetic products. However, a sample of carefully cleaned single crystals from the batch used for the X-ray structural analysis yielded NMR-silent $CDCl_3$ solutions.

The single-crystal X-ray analysis gave an orthorhombic unit cell and the structure was solved in the *Pbca* space

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

group. A peculiar twinning problem prevented refinement of the data to very low residuals (see Experimental Section). However, the structure was apparently not complicated by interstitial solvent, nor by disorder. The strongest residual peak and hole in the last difference Fourier map were reasonably low and without any chemical significance. A view of the $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$ cation is shown in Figure 2.

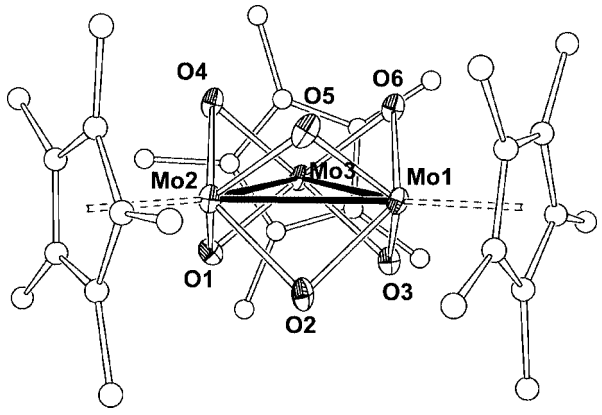

Figure 2. An ORTEP view of the $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$ ion from the structure of the trifluoromethanesulfonate salt. For clarity, the hydrogen atoms of the Cp* ligands are not shown and the ellipsoids of the Cp* C atoms are replaced by spheres of arbitrary radius. The ellipsoids of the Mo and O atoms are shown at the 30% probability level.

The relative arrangement of the ions in the structure is shown in Figure 1 (b). Like in the related trifluoroacetate salt, only two of the three bridging groups on each triangular face establish hydrogen bonds with the oxygen atoms of the $CF_3SO_3$ anions. The third O atom of each trifluoromethanesulfonate anion does not point toward the third bridging O atom. Specifically, the $CF_3SO_3$ anion located on the same side occupied by the bridging O1, O2, and O3 atoms places the third $SO_3$ oxygen atom away from (*exo*), and the $CF_3$ group on the same side as (*endo*), the triangle of the bridging O atoms. One $CF_3$ fluorine atom is in proximity of atom O1, but the F···O distance (3.22 Å) is too long to envisage a hydrogen bond (sum of van der Waals radii of F and O: 2.75 Å). The second $CF_3SO_3$ anion, which is located on the same side as O4, O5 and O6 from the $Mo_3$ triangle, places the third O atom *endo* and the $CF_3$ group *exo*, but the anion is tilted in such a way as to place the third O atom at 4.02 Å from O5, clearly indicating a repulsive interaction (sum of van der Waals radii of the two O atoms: 2.80 Å). This evidence allows us to propose the molecular formula of the dicationic trimetallic cluster as having four bridging hydroxo and two bridging oxo groups. Although the structure of the trifluoroacetate salt (vide supra) is much less precisely determined than that of the trifluoromethanesulfonate salt, a comparison of the hydrogen bonded O···O contacts shows that these are tighter with the former anion and looser with the latter one, in agreement with their relative basicity.

Although the structure has no crystallographically imposed symmetry, the trimetallic dication possesses an approximate $C_2$ local symmetry, with the pseudo-symmetry axis passing through the Mo2 atom and the middle of the Mo1–Mo3 bond. We shall refer to all averaged bonding parameters by using the symbol Mo for the unique atom Mo2 and the symbol Mo′ for the two pseudo-symmetry related Mo1 and Mo3 atoms. The unique Mo′–Mo′ bond is marginally, but significantly, longer than the two Mo–Mo′ bonds, possibly as a consequence of the different nature of the bridging groups. Indeed, the bridging Mo–(μ-O) and Mo′–(μ-O) bonds are significantly shorter than the corresponding Mo–(μ-OH) and Mo′–(μ-OH) bonds. The alternative interpretation of assigning a greater oxidation state (+5) to the Mo atom and a lower one (+4) to the Mo′ atoms seems excluded by the density functional calculations (vide infra). There is no significant difference, neither between the Mo–(μ-O) and Mo′–(μ-O) bonds [average 1.95(1) Å] nor between the Mo–(μ-OH) and Mo′–(μ-OH) bonds [average 2.05(1) Å], in agreement with an insignificant difference in metal ionic radius between Mo and Mo′. This analysis further serves to confirm the interpretation of atoms O1 and O5 as (μ-O) rather than (μ-OH) groups. The Mo–Mo distances are slightly longer than those found in related triangular $[Cp^*_3Mo_3(\mu\text{-}O)_6]$-type clusters, e.g. 2.730(13) Å in $[Cp^*_4Mo_5O_{11}]$ (where the central $[Cp^*_3Mo_3(\mu\text{-}O)_6]^-$ unit is capped by a $[Cp^*Mo^{VI}O_2(\mu\text{-}O)Mo^{VI}O_2]^+$ fragment),[21] and 2.744(9) Å in $[Cp^*_6Mo_8O_{16}]$ (where two equivalent $[Cp^*_3Mo_3(\mu\text{-}O)_6]^-$ units are bridged by a $[Mo^V_2O_2(\mu\text{-}O)_2]^{2+}$ fragment).[22] They are identical, on the other hand, to the average distance reported for $[Cp^*_3Mo_3(\mu\text{-}OH)_n(\mu\text{-}O)_{6-n}]Cl_2$ [2.78(3) Å]. The latter structure, however, was poorly defined because of solvent disorder.[21]

### Mass Spectrometric Characterization

Both salts (trifluoroacetate and triflate) were investigated by electrospray mass spectrometry (positive mode) in mixed $H_2O$/MeOH solvents. In both cases the spectrum shows the presence of trinuclear species and the absence of mono- and dinuclear species. For the trifluoroacetate salt, the major envelope is satisfactorily simulated on the basis of the formula $[Cp^*_3Mo_3(\mu\text{-}O)_5(\mu\text{-}OMe)]^+$ (see Figure 3). This shows that, under the conditions of the electrospray MS experiment, the dication readily loses one proton and exchanges the residual bridging OH group with the methanol solvent. The shape of the simulated envelope matches very closely the experimental one, but the major peak *m*/*z* value leaves a doubt as to the exact number of protons. This question was resolved by the additional experiments that will be presented in later sections. The minor envelope (Figure 3, c) corresponds to the formula ($[Cp^*_3Mo_3(\mu\text{–}O)_5(\mu\text{-}OMe)]^+$ + $CF_3COOH$ + MeOH) and therefore gives direct evidence for the presence of the trifluoroacetate anion. This envelope overlaps with a weaker peak distribution at higher *m*/*z* values, which could correspond to further addition of a water molecule. A parallel FAB (NBA matrix) spectrometric analysis shows the absence of solvent association phenom-

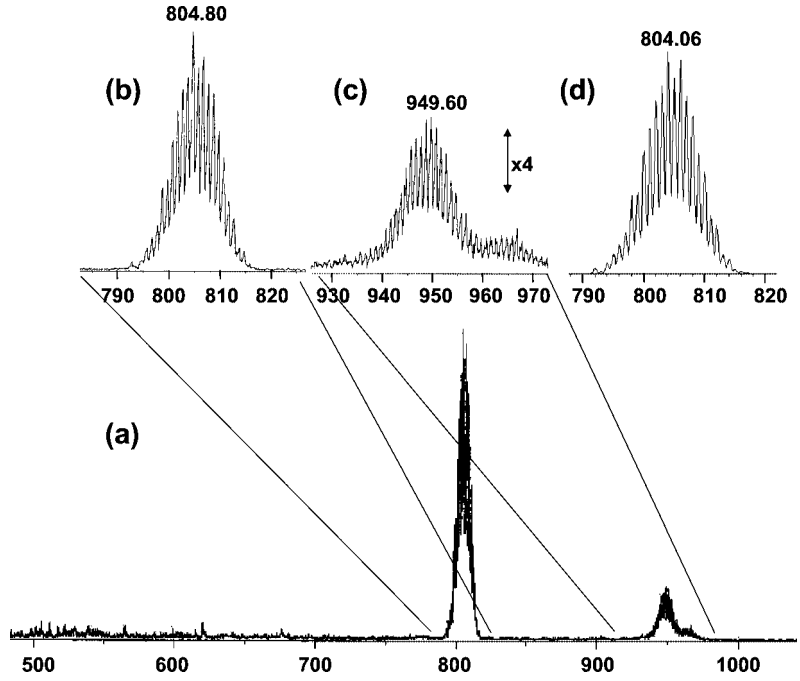

Figure 3. (a) Electrospray mass spectrum (positive mode) of $[Cp^*_3Mo_3(\mu\text{-}O)_4(\mu\text{-}OH)_2](O_2CF_3)_2$ in MeOH. Portions of this spectrum are shown in (b) and (c), and a simulation of the envelope corresponding to the $[Cp^*_3Mo_3(\mu\text{-}O)_5(\mu\text{-}OMe)]^+$ ion is given in (d).

ena. However, the spectrum is more complex because of reduction and fragmentation of the trinuclear unit. The highest peak distributions observed correspond to $[Cp^*_3Mo_3O_4(OH)_2]$ (massif centered around $m/z$ = 791) and $[Cp^*_3Mo_3O_4(OH)]$ (massif centered around $m/z$ = 774).

The spectrum of the triflate salt is closely related to that of the trifluoroacetate analogue. The major envelope, centered around $m/z$ = 804, is identical to that observed for the trifluoroacetate analogue (the major peak is found at $m/z$ = 804.25 in this case), whereas the smaller envelope at higher $m/z$ values is centered at 1036.35, corresponding to $([Cp^*_3Mo_3(\mu\text{-}O)_5(\mu\text{-}OMe)]^+ + CF_3SO_3H + 2\,MeOH + H_2O)$. Thus, this mass spectrum also gives direct evidence for the presence of the triflate counterion.

## EPR Spectroscopic Properties

Solutions of the complex $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$ (either salt) in dichloromethane exhibit a relatively sharp EPR spectrum at room temperature (see Figure 4), whereas the compounds are NMR-silent in $CDCl_3$. The absence of an NMR spectrum is consistent with the odd-electron nature of the cluster. The observation of an isotropic EPR spectrum at relatively high temperature, on the other hand, clearly indicates that the system must have a single unpaired electron ($S$ = ½) in a nondegenerate orbital. An accurate analysis of the Mo hyperfine coupling pattern helps us determine the localization of the unpaired electron. As Figure 4 shows, simulations were carried out using hyperfine coupling constant, shape, and line-broadening parameters from the experimental spectrum, but assuming coupling to either one, two, or all three cluster Mo atoms. The height and shape of the satellite peaks, relative to the central resonance and especially relative to each other, unambiguously identify the spectrum as involving coupling to two equivalent Mo nuclei. Unfortunately, the relative broadness of the spectrum conceals the outer peaks of the 1:2:3:4:5:6:5:4:3:2:1 envelope (6.25% overall intensity), which is generated by the isotopomers having two $I$ = 5/2 Mo nuclei. The spectrum was also recorded at temperatures down to 210 K in an attempt to improve the spectral resolution, but no significant change was noted.

## Magnetic Susceptibility

The compound exhibits a simple Curie behavior consistent with the presence of a single unpaired electron. Measurements carried out in the 6–60 K range show a linear $\chi^{-1}$ vs. $T$ plot, with a negligible value for the Curie temperature (–0.38 K; see Figure 5).

The corresponding effective magnetic moment, which is approximately temperature independent, averages 1.66 $\mu_B$ after correction for the ligands' diamagnetism. This is rather close to the expected spin-only value for one unpaired electron (1.73 $\mu_B$). This result is consistent with the EPR spectrum and confirms that the latter is representative of the bulk sample.

## Density Funtional Calculations

In order to further confirm the assignment of the chemical composition and electronic structure, we carried out a theoretical study. Before describing the computational results, it is useful to qualitatively analyze the electronic struc-

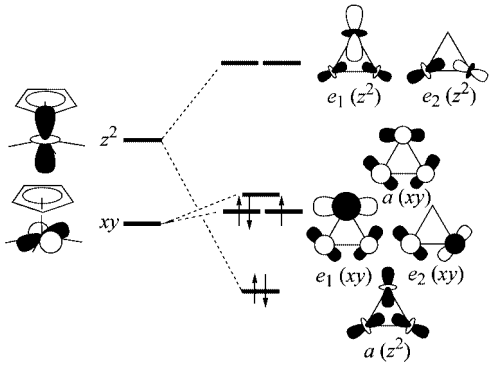

Scheme 1.

ture on the basis of first principles and relevant previous knowledge.[21,23,24] The cluster may be viewed as resulting from the assembly of three "four-legged piano stools" of the $Cp^*MoO_4$ type, whose electronic structure is well known,[25,26] as shown in Scheme 1. Taking a $D_{3h}$-symmetrical structure with six identical bridging ligands as a first approximation, it is possible to envisage that the interaction of the $z^2$-type orbitals will lead to one bonding (of type *a*) and two degenerate antibonding (of type *e*) combinations, and that the interaction of the *xy*-type orbitals will equally lead to one *a*-type bonding and two degenerate antibonding *e*-type combinations. As the overlap between the *xy* orbitals is much weaker, the energy of the MOs resulting from these orbitals will be less perturbed from that of the starting fragment orbitals. However, as well documented for other bridging systems, π* mixing with the bridging ligands' lone pairs should destabilize the *xy* orbital combinations.[27] It is easily predictable that this destabilization should be strongest for the symmetric (*a*-type) orbital, as shown in Scheme 1. The asymmetric nature of the bridging ligands (four OH and two O), however, is expected to alter this scheme, particularly by removing the degeneracy of the *e*-type combinations.

The DFT-optimized geometry agrees quite well with the experimental geometry (see Table 1). The minor variations could partly be attributed to the different environment (hydrogen-bonded, solid-state structure with the $CF_3SO_3$ anion for the experimental geometry, free, "gas-phase" dication for the DFT-optimized one); and partly to the well-known overestimation of bond lengths by DFT. In particular, it is comforting to see the same trend of Mo–O bond lengths [Mo-(μ-O) < Mo-(μ-OH)] in the optimized and experimental parameters, once again confirming the structural assignment.

The calculated electronic structure (Figure 6) confirms the qualitative expectations. The bonding $a(z^2)$ orbital is located just above the group of the six MOs describing the three double-sided Mo–Cp* π interactions. Above it, we find the pair of $e(xy)$ orbitals, which contains three electrons. The calculation converges with two electrons in the $e_1$-type orbital and one in the $e_2$-type orbital, whose degeneracy (in the ideal $C_3$ symmetry) is substantially split by the different nature of the bridging groups (O vs. OH). It is rewarding to see that the unpaired electron, according to the calculations, chooses to reside in the orbital from the *e* set that has the nodal plane parallel to the $C_2$ symmetry axis ($e_2$), rather than in the orbital with the nodal plane perpendicular to it ($e_1$). The half-occupied orbital has contributions only from the two Mo′ atoms and a symmetry-imposed zero contribution from the Mo atom, in perfect

[a] Mo indicates the unique atom with a $[Cp^*Mo(O)_2(OH)_2]$ coordination environment and Mo′ indicates the two symmetry-related atoms with a $[Cp^*Mo(O)(OH)_3]$ coordination environment. [b] CNT indicates the ring centroid of the pentamethylcyclopentadienyl ligand.

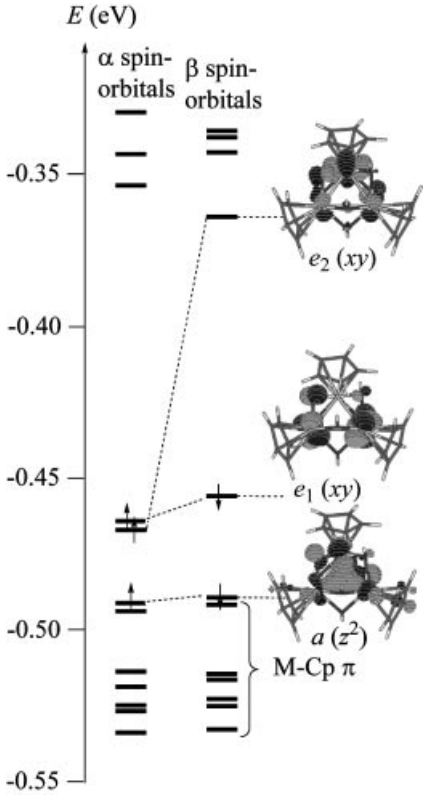

Figure 6. Electronic structure of the $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$ cluster as resulting from a gas-phase DFT calculation. The shape of the spin-orbitals connected by a dashed line is essentially identical (only one for each pair is shown).

agreement with the result of the EPR analysis above. Furthermore, the DFT calculation suggests that the cluster is completely valence-delocalized. Indeed, the computed natural charge[28] is very similar on atoms Mo (+1.075) and Mo′ (+1.100 and 1.101), and so is the computed Mulliken spin density (–0.820, 0.849, and 0.847, respectively). We note that the mean value of $S^2$ from the spin-unrestricted calculation is high (see Computational Details), suggesting the mixing of an excited $[a(z^2)]^2[e_1(xy)]^1[a_2(xy)]^1[a(xy)]^1$ configuration into the ground state. However, according to the result of the EPR experiment, this contribution must be negligible for the real system because the isotropic resonance is relatively sharp at room temperature and unaffected by cooling.

A somewhat related triangular $Mo_3$ cluster, $[Mo_3CuS_4(H_2O)_{10}]^{4+}$, which was described as having a $Cu^I$ ion and a $Mo_3^{11+}$ core,[29] has an electronic structure similar to that described here, although there are two additional electrons, thereby also involving occupation of the *a*(xy)-type orbitals. In that case, the experimental observation of electronic coupling to a single Mo nucleus in the EPR spectrum was interpreted as resulting from a valence-trapped $Mo^{IV}Mo^{IV}Mo^{III}$ structure, the unpaired electron being mostly localized on the $Mo^{III}$ center, although the calculations (at the EHMO level) indicated a delocalized shape for the MOs similar to that reported here.

## Discussion

It is useful to compare the salts reported here with a closely related one reported by Bottomley et al., namely $[Cp^*_3Mo_3(\mu\text{-}O)_{6-n}(\mu\text{-}OH)_n]^{2+}(Cl^-)_2$.[21] This compound was obtained by a synthetic strategy closely related to ours (zinc reduction of $[Cp^*MoO_2Cl]$ in $CHCl_3$ in the presence of concentrated HCl). The X-ray structure presented for this compound was affected by severe disorder, thus preventing the unambiguous determination of the number of bridging OH groups, as for the trifluoroacetate complex reported here. We have already pointed out above that the reported Mo–Mo distances for the dichloride salt are very similar to those reported here for the $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$-$(CF_3SO_3^-)_2$ salt. For $[Cp^*_3Mo_3(\mu\text{-}O)_{6-n}(\mu\text{-}OH)_n]^{2+}(Cl^-)_2$, the authors proposed 5 as the most likely *n* value, but also suggested the presence of a redox disproportionation equilibrium in solution that involves other species characterized by *n* = 4 and *n* = 6. This suggestion was based on magnetic, EPR, and NMR observations. In particular, the EPR spectrum was assigned to the *n* = 6 species, whereas two NMR resonances − a sharp one and a broad one − were assigned to the diamagnetic *n* = 5 species and to the paramagnetic *n* = 4 species, respectively. The room-temperature isotropic EPR spectrum reported for solutions of the dichloride salt seems very similar to that of the trifluoromethanesulfonate

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and trifluoroacetate salts reported here, but it was interpreted in that case as arising from coupling to three equivalent Mo nuclei. An argument given in favor of the above scheme is the fact that the $n = 4$ species could not yield an observable isotropic EPR spectrum, given the expected $(e)^3$ electronic configuration.[21] Our DFT calculation, however, shows that the asymmetry associated with the distribution of the two μ-O and four μ-OH groups splits this orbital degeneracy significantly. The trifluoromethanesulfonate and trifluoroacetate salts reported here (at least batches of clean single crystals) do not show any sharp or even broadened NMR signal that could be assigned to the Cp* ligand in a diamagnetic or paramagnetic compound. All evidence, therefore, points to the fact that the trifluoromethanesulfonate salt reported here maintains its identity as a single compound in solution.

Another useful comparison involves compounds $[Cp^*_4Mo_5O_{11}]$[21] and $[Cp^*_6Mo_8O_{16}]$,[22] both of which are described as containing a central $[Cp^*_3Mo_3(\mu\text{-}O)_6]^-$ unit (vide supra). In this unit, there are only four cluster electrons ($Mo_3^{IV,V,V}$) and the structures are stabilized by capping one triangular $O_3$ face with either $Mo^V$ or $Mo^{VI}$ ions. Therefore, it seems possible that the salts of $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$ exhibit interesting electrochemical properties, which may be dependent on pH and/or on the presence of other metal ions.

## Conclusion

We have shown in this paper that the zinc reduction of $[Cp^*_2Mo_2O_5]$ in an acidic aqueous environment leads to the triangular $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4]^{2+}$ cluster, containing a paramagnetic (five-electron) trimetallic core. The spectroscopic evidence points to a solution structure identical to the solid-state structure, with the unpaired electron located in a delocalized molecular orbital that has atomic orbital participation from only two Mo atoms. A study of the redox properties and acid/base properties of this system, followed by an investigation of its chemical reactivity, are now in progress and will be reported in due course.

## Experimental Section

**General Methods:** All preparations and manipulations were carried out with Schlenk techniques under an oxygen-free argon atmosphere. All glassware was oven-dried at 120 °C. Solvents were dried by standard procedures and distilled under dinitrogen prior to use. EPR spectra were measured with an Elexsys E500 Bruker spectrometer (X-band) equipped with both a frequency meter and a gaussmeter. Magnetic susceptibility measurements were carried out with a MPMS5 QUANTUM DESIGN magnetometer. Mass spectra were recorded with a NERMAG R10-10 instrument. The starting compound $[Cp^*_2Mo_2O_5]$ was prepared as described in the literature.[19]

**Synthesis and Crystallization of $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4](CF_3SO_3)_2$:** Metallic zinc (20 mesh, 0.48 g, 7.38 mmol) was added to a solution of $[Cp^*_2Mo_2O_5]$ (0.05 g, 0.092 mmol) in MeOH/$H_2O$ (1:1, 6 mL) after acidification with concentrated $CF_3SO_3H$ (10 drops). The mixture was stirred under argon at room temperature for two days, during which time it changed from a clear, yellow solution to a green suspension. The mixture was filtered and the solid was dried in vacuo. The solid was extracted with THF and, after filtration, addition of *n*-hexane yielded a green precipitate (0.021 g, 31.3%). A single crystal for the X-ray analysis was obtained by diffusion of *n*-hexane into a green $CH_2Cl_2$ solution at room temperature.

$C_{32}H_{49}F_6Mo_3O_{12}S_2{\cdot}2CH_2Cl_2$ (1261.53): calcd. C 32.37, H 4.23; found C 32.92, H 3.65. EPR ($CH_2Cl_2$): $g = 1.962$, $a_{Mo} = 26.2$ G. Average $\mu_{eff}$ in the 6–60 K range: 1.66 $\mu_B$ (diamagnetic correction: $-7.91 \times 10^{-4}$ cgs).

**X-ray Analyses:** Single crystals of $[Cp^*_3Mo_3(\mu\text{-}O)_2(\mu\text{-}OH)_4](X)_2$ (X = $CF_3CO_2$, $CF_3SO_3$) were mounted under inert perfluoropolyether at the tip of a glass fiber and cooled in the cryostream of an Oxford-Diffraction XCALIBUR CCD diffractometer. Data were collected using monochromatic Mo-$K_\alpha$ radiation ($\lambda = 0.71073$). The structures were solved by direct methods (SIR97[30]) and refined by least-squares procedures on $F^2$ using SHELXL-97.[31] Although the model could be easily defined by direct methods for both structures, its refinement appeared to be very poor, with large elongated ellipsoids for the Cp* and rather high $R$ and $wR_2$ values. The $CF_3CO_2$ salt did not lead to a successful refinement, so this structure is not further commented. For the $CF_3SO_3$ salt, the elongated ellipsoids suggest a free rotation of the Cp ring around the Mo–Cp* centroid axis. However, all attempts to refine a disordered Cp* model failed. The occurrence of a twinned structure by pseudo merohedry, considering a monoclinic cell, was also attempted but again without improvement of the refinement. Refinement in a noncentrosymmetric space group did not improve the result either. Careful examination of the reciprocal space revealed that the crystal used was certainly not single but an attempt to integrate using different domains failed. There is, however, no doubt about the reality of the model, as confirmed by different analytical methods. All H atoms attached to carbon were introduced in the calculation in idealized positions and treated as riding models. Owing to the poor quality of the refinement, the H atom attached to the hydroxy groups could not be located. The drawings were produced with the help of ORTEP32.[32] The structures were solved by direct methods (SIR97)[30] and refined by least-squares procedures on $F^2$ using SHELXL-97.[31] All H atoms attached to carbon were introduced in calculation in idealized positions and treated as riding models. The drawing of the molecules was realized with the help of ORTEP32.[32] The crystal data and refinement parameters are shown in Table 2 and selected geometric parameters are collected in Table 1.

**Computational Details:** The DFT calculation was carried out on a model system where the Cp* ligands were replaced by the simpler Cp rings. The starting geometry was based on the crystallographically determined structure of the triflate salt and no symmetry restrictions were imposed. The geometry was fully optimized and the resulting minimum of the potential energy surface (PES) was verified by the positive value of all second derivatives of the energy. The calculation, which used the spin-unrestricted formulation, was performed using the B3LYP three-parameter hybrid density functional method of Becke,[33] as implemented in the Gaussian03 suite of programs.[34] The basis sets used for the geometry optimizations are the standard 6-31G** for C, H, and P atoms, and the standard LANL2DZ basis set, which includes the Hay and Wadt effective core potentials (ECP),[35] for the metal atoms. The value of $<S^2>$ resulting from the calculation is 1.39 (0.81 after annihilation). This shows that there is significant spin contamination, indicating mixing with low-lying excited states. The correspondence between the resulting Kohn–Sham spin-orbitals was verified by producing contour plots with the aid of the program MOLDEN.[36]

# Ring Opening and Displacement by Chloride of the Bidentate Chelate Ligand from Dichloro[pyridine-2-(α-methoxymethanolato)]gold(III) – A Kinetic and Mechanistic Study

**Giampaolo Marangoni,*[a] Bruno Pitteri,[a] Giuliano Annibale,[a] and Marco Bortoluzzi[a]**

**Keywords:** Chelate displacement / Gold / Kinetics / Reaction mechanism

The kinetics of ring opening and displacement of the bidentate chelate ligand from dichloro[pyridine-2-(α-methoxymethanolato)]gold(III) [Au(N–O)$Cl_2$] (**1**) have been studied spectrophotometrically in methanol/water (95:5, v/v) at 25 °C and constant ionic strength ($I$ = 1 mol dm$^{-3}$, $LiClO_4$). In the presence of LiCl and perchloric acid the reaction consists of a pre-equilibrium protonation of the coordinated oxygen followed first by ring opening at oxygen accompanied by the entry of chloride or solvent and fast acetalisation of the hemiacetalic form of the ligand to give [$AuCl_3$(N–OMe)], and then by displacement of the *N*-bonded ligand to give [$AuCl_4$]$^-$. The ligand is not displaced in the absence of chloride and no reaction is observed in the presence of chloride alone.

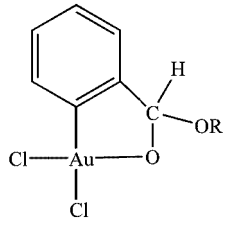
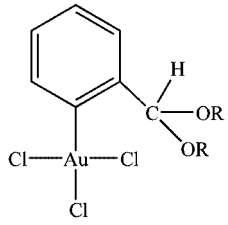
## Introduction

The lability of oxygen-donor ligands in the substitution reactions at square planar tetra-coordinate $Pt^{II}$, $Pd^{II}$ and $Au^{III}$ complexes depends very greatly upon their nature, ranging from the highly labile coordinated water to the very inert hydroxide.[1] Unfortunately, the lack of suitable substrates of $Au^{III}$, because of the synthetic difficulties involved in preparing appropriate complexes with monodentate oxygen ligands, has hampered any extensive study in this field. One way to overcome the problem is to incorporate the oxygen donor in a bi- or multidentate ligand so providing the required ease of preparation and stability. Very recently, gold(III) complexes of the type [Au(N–O)$Cl_2$] (N–O = pyridine-2-methanolato,[2] substituted pyridine-2-carboxylato[3]) have been reported to be excellent catalysts in organic synthesis. Some years ago we reported the preparation of dichloro(pyridine-2-carboxylato)gold(III) and dichloro(pyridine-2-methanolato)gold(III) neutral complexes and we studied the replacement of N–O bidentate ligands by chloride in acidic solutions.[4,5] In the first case it was shown that the chelate ring opened at nitrogen and the carboxylate group was displaced in a slower subsequent step. In the second case, because the change in the 2-substituent from $CO_2^-$ to $CH_2O^-$ increases the basicity of the nitrogen by more than three orders of magnitude and hence decreases the lability of the Au–N bond by about two orders of magnitude, and the bond to the alkoxide oxygen is considerably more labile to direct chloride substitution than the bond to carboxylate, the reaction sequence is reversed, ring opening at oxygen occurring in the first stage of the reaction.

In a recent study dealing with the interaction of pyridine-2-carbaldehyde (2CHO–py) with [$AuCl_4^-$] in water we found[6] that the initially formed *N*-coordinated [$AuCl_3$(2-CHO–py)] complex adds a molecule of $H_2O$ to the aldehydic group to form the corresponding diolic derivative which, by elimination of HCl, gives rise to *O*-chelation at the metal centre. Successive treatment with alcohols affords the corresponding N–O-chelated hemiacetalic complexes [(I), Scheme 1]. On the other hand, when the reaction be-



**I**: R = -H, -$CH_2CH_3$, -$CH_2CF_3$



**II**: R = -$CH_3$, -$CH_2CH_3$, -$CH_2CH_2CH_3$, -$CH_2CH_2CH_2CH_3$

Scheme 1.

[a] Department of Chemistry, Cà Foscari University of Venice, Calle Larga S. Marta 2137, 30123 Venice, Italy

tween pyridine-2-carbaldehyde and [$AuCl_4^-$] is carried out in alcohols at 60 °C, the *N*-coordinated acetal complexes trichloro(pyridine-2-carbaldehyde dialkyl acetal)gold(III) are directly formed [(II), Scheme 1]. Some of the complexes of both the series have been characterised by X-ray diffractometry.[6]

As an extension of that work, we have now prepared the analogous neutral dichloro[pyridine-2-(α-methoxymethanolato)]gold(III) (**1**), [Au(N–O)$Cl_2$], and have studied the displacement of the new type of N–O chelate ligand by chloride in acidic methanol containing 5% water.

## Results

The electronic spectrum in the wavelength range 250–370 nm of a $1 \times 10^{-4}$ mol dm$^{-3}$ solution of [Au(N–O)$Cl_2$] (**1**) in methanol/water (95:5 v/v) in the presence of a large excess of LiCl to suppress any solvolysis is shown in Figure 1 (curve *a*). This spectrum does not change over long periods of time.

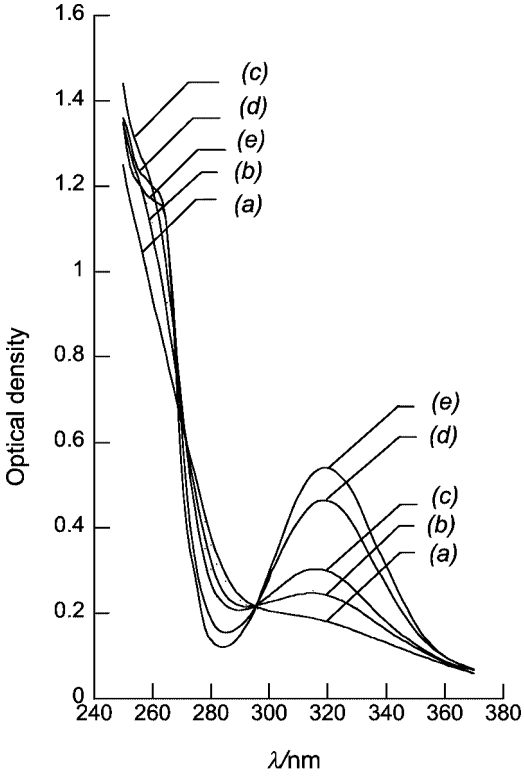

Figure 1. Electronic spectra of $1.0 \times 10^{-4}$ mol dm$^{-3}$ solutions of **1** in methanol/water (95:5 v/v) at 25 °C under the different experimental conditions reported in the text.

In the absence of lithium chloride, addition of perchloric acid to a solution of **1** of the same concentration causes a relatively fast change of the spectrum with time to finally give the spectrum represented by curve *b*. Successive addition of 1:1 LiCl gives rise to a rapid change of the spectrum *b* to that of curve *c*, which is identical to that of the trichloro(pyridine-2-carbaldehyde dimethyl acetal)gold(III) (**2**) measured under the same experimental conditions. Further addition of excess LiCl results in a slower reaction, which leads to the displacement of the 2-substituted pyridine ligand and formation of [$AuCl_4$]$^-$ with a well-maintained isosbestic point at 296 nm until the end of the reaction (curves *d*, *e*). When an excess of both LiCl and perchloric acid is added to a solution of **1**, the change of absorbance with time at 320 nm indicates a two-stage reaction, the second stage being identical to that described above.

### Kinetics

The kinetics were evaluated from the change in absorbance at a fixed wavelength (320 nm) where both stages lead to an increase of absorbance and as the two rate constants differed by at least ten, their separate evaluation presented no problem. Values of the rate constants for the first, $k_{obs}^{f}$, and second, $k_{obs}^{s}$, stages of the reaction in the presence of both LiCl and perchloric acid under pseudo-first-order conditions, as well as in the presence of perchloric acid alone, are collected in Table 1. Rate constants were accurate to within 5%.

At constant $[H^+]$, $k_{obs}^{f}$ varies with $[Cl^-]$ such that a plot of $k_{obs}^{f}$ versus $[Cl^-]$ is linear with a finite intercept (Figure 2), according to Equation (1).

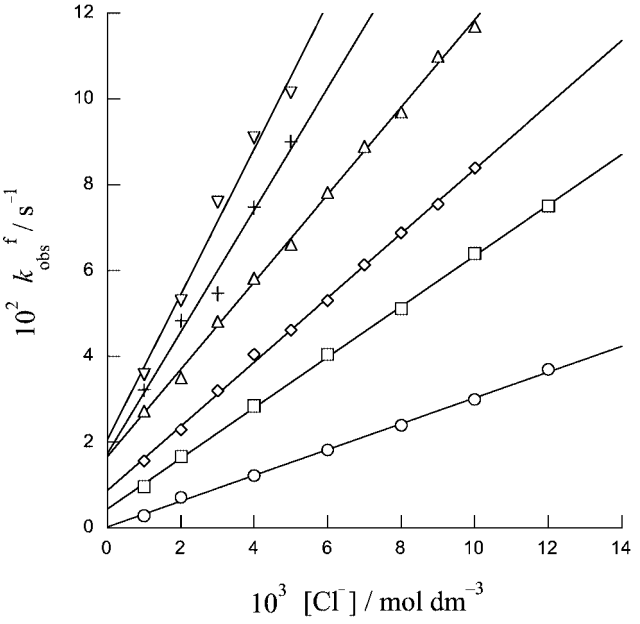

Figure 2. Plots of $k_{obs}^{f}$ vs $[Cl^-]$ for the reaction between [Au(N–O)$Cl_2$] (**1**) and chloride at $[H^+]$ = 0.05 (○), 0.1 (□), 0.15 (◊), 0.2 (△), 0.3 (+), 0.4 (▽) mol dm$^{-3}$.

$$k_{obs}^{f} = i + s[Cl^-] \quad (1)$$

Both $i$ and $s$ depend upon $[H^+]$ as shown in Figure 2 and Table 2.

Table 2. Values of parameters $i$ and $s$ at constant added acid.

| $[H^+]$ [mol dm$^{-3}$] | $i$ [s$^{-1}$] | $s$ [mol$^{-1}$ dm$^3$ s$^{-1}$] |
|---|---|---|
| 0.4 | $(1.9\pm0.3)\times10^{-2}$ | 17.4±0.1 |
| 0.3 | $(1.8\pm0.1)\times10^{-2}$ | 14.2±0.4 |
| 0.2 | $(1.3\pm0.1)\times10^{-2}$ | 10.9±0.2 |
| 0.15 | $(0.87\pm0.05)\times10^{-2}$ | 7.52±0.08 |
| 0.1 | $(0.43\pm0.04)\times10^{-2}$ | 5.95±0.06 |
| 0.05 | $(0.03\pm0.04)\times10^{-2}$ | 3.01±0.05 |

The dependence of $s$ upon $[H^+]$ shows a tendency to slow negative deviations as $[H^+]$ progressively increases, but a plot of $s^{-1}$ against $[H^+]^{-1}$ is linear (Figure 3) with intercept $c = (1.8\pm0.5)\times10^{-2}$ s$^{-1}$ and slope $d = (1.6\pm0.5)\times10^{-2}$ mol dm$^{-3}$ s$^{-1}$, from which the empirical Equation (2) can be derived.

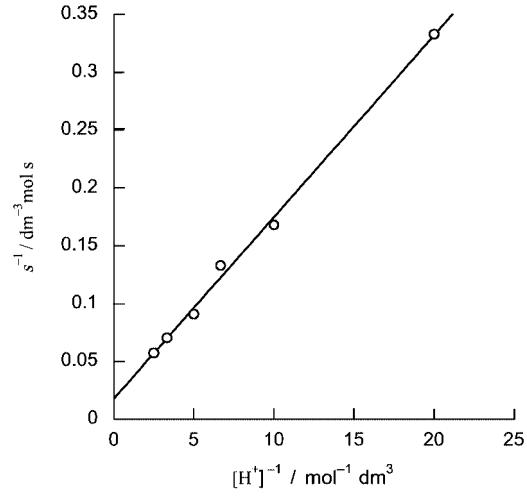

Figure 3. Linear dependence of $s^{-1}$ on $[H^+]^{-1}$. Data from Table 2.

$$s = \frac{[H^+]}{c[H^+] + d} \quad (2)$$

Owing to the large uncertainty in the values of $i$, its dependence on $[H^+]$ was better determined on studying the reaction in the absence of added LiCl. The values of the relative rate constants ($k'_{obs}{}^{f} \equiv i$) are collected in Table 1. $k'_{obs}{}^{f}$ increases as $[H^+]$ increases but appears to reach a limiting value at the higher $[H^+]$ concentrations. A plot of $(k'_{obs}{}^{f})^{-1}$ against $[H^+]^{-1}$ is linear in the range of examined $[H^+]$ (Figure 4) with intercept $e = (40\pm6)$ s and gradient $f = (35\pm1)$ mol dm$^{-3}$ s$^{-1}$.

These results are in agreement with Equation (3).

$$k'_{obs}{}^{f} = \frac{[H^+]}{e[H^+] + f} \quad (3)$$

On substituting Equations (3) and (2) into Equation (1), the experimental rate law for the first step of the reaction

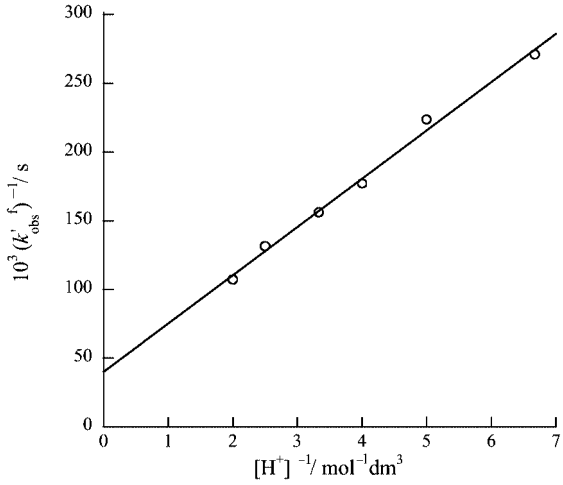

Figure 4. Plot of $(k'_{obs}{}^{f})^{-1}$ against $[H^+]^{-1}$ in the absence of added chloride.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

takes the form of Equation (4) which can be rearranged as Equation (5) with $e/f$ ($1.14 \pm 0.05$ mol$^{-1}$ dm$^3$) = $c/d$ ($1.1 \pm 0.4$ mol$^{-1}$ dm$^3$) within the limit of the experimental error and an average value of $1.12 \pm 0.03$.

$$k_{obs}^{f} = \frac{[H^+]}{e[H^+] + f} + \frac{[H^+][Cl^-]}{c[H^+] + d} \quad (4)$$

$$k_{obs}^{f} = \frac{\frac{1}{f}[H^+]}{1 + \frac{e}{f}[H^+]} + \frac{\frac{1}{d}[H^+][Cl^-]}{1 + \frac{c}{d}[H^+]} \quad (5)$$

The rate constants for the displacement of the *N*-coordinated pyridine ligand, $k_{obs}^{s}$ (Table 1), are independent from [H$^+$] and obey the usual relationship Equation (6) with $g = (2 \pm 1) \times 10^{-4}$ s$^{-1}$ and $h = (7.6 \pm 0.2) \times 10^{-2}$ mol$^{-1}$ dm$^3$ s$^{-1}$ (Figure 5).

$$k_{obs}^{s} = g + h[Cl^-] \quad (6)$$

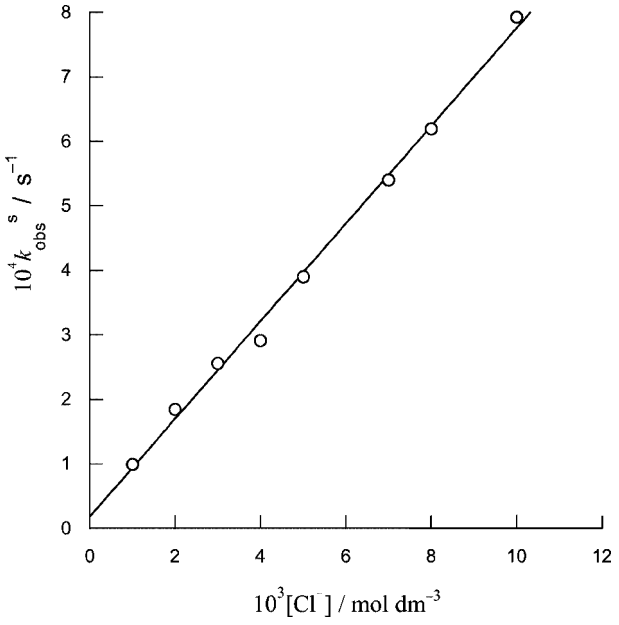

Figure 5. Plot of $k_{obs}^{s}$ against [Cl$^-$]. Data from Table 1.

## Discussion

The spectroscopic evidence together with the kinetic results are fully consistent with the reaction depicted in Scheme 2.

The reaction observed in the presence of $HClO_4$ alone is described as a fast protonation pre-equilibrium A⇌B followed by a slow reversible reaction to give the solvato species C (spectrum *b* in Figure 1). C is formulated as the acetalic species, assuming that acetylation of the hemiacetalic group is a fast process in acidic media (see below). Addition of an equimolar amount of LiCl rapidly affords the anation product P′ (spectrum *c* in Figure 1). The same species can also be formed directly from B by reaction with Cl$^-$. In the presence of higher [Cl$^-$], such as those used under pseudo-first-order conditions, displacement of the *N*-coordinated ligand through two parallel reactions, solvolysis and direct chloride substitution, occurs to give the final product P′′. This latter process corresponds to the second stage of the reaction observed in the kinetic runs, better followed in the presence of chloride ions in acidic solution. The derived rate law, $k_{obs}^{s} = k_1^{s} + k_2^{s}$[Cl$^-$] typical for the displacement of *N*-bonded pyridines is obeyed,[7] with a solvolytic rate constant $k_1^{s} = (2 \pm 1) \times 10^{-4}$ s$^{-1}$ and the second-order rate constant $k_2^{s} = (7.6 \pm 0.2) \times 10^{-2}$ mol$^{-1}$ dm$^3$ s$^{-1}$ nearly equal, within the limit of experimental error, to that relative to the displacement of the *N*-coordinated dimethyl acetal ligand from the trichloro(pyridine-2-carbaldehyde dimethyl acetal) gold(III) complex (**2**), [$k_2 = (7.875 \pm 0.003) \times 10^{-2}$ mol$^{-1}$ dm$^3$ s$^{-1}$], kinetically measured under the same experimental conditions, as well as to those found for the displacement of the strictly related pyridine-2-methanol ($k_2 = 7.58 \times 10^{-2}$ mol$^{-1}$ dm$^3$ s$^{-1}$) and 2-methoxymethylpyridine ($k_2 = 7.93 \times 10^{-2}$ mol$^{-1}$ dm$^3$ s$^{-1}$).[5] Values of $k_{obs}$ for the displacement of the ligand from the trichloro(pyridine-2-carbaldehyde dimethyl acetal)gold(III) complex (**2**) and the derived rate constants are reported in Table 3.

The close resemblance of the electronic spectra of the intermediate formed at the end of the first stage of the reaction and that of complex **2**, as well as the values of their second-order rate constants quoted above for the final displacement of the ligand, strongly support the conclusion that the hemiacetalic form of the chelated ligand, once protonated and then O-opened, undergoes a rapid process of acetalisation in the presence of the solvent MeOH under acidic conditions to give the derived *N*-coordinated dimethyl acetal as the true leaving 2-substituted pyridine in the second stage of the reaction. This behaviour is in agreement with the instability of the hemiacetals of the free organic carbaldehydes[8] that, under comparable experimental conditions, react with alcohols to rapidly give the corresponding acetals. This conclusion has been fully confirmed by the series of $^1$H NMR experiments reported in Figure 6.

When dichloro[pyridine-2-(α-methoxymethanolato)]gold(III) (**1**) in $CD_3NO_2$ [integrated proton ratio C–H ($\delta$ = 5.45 ppm)/O–$CH_3$ ($\delta$ = 3.56 ppm) of 1:3] (spectrum **A**) is added to methanol and DCl [molar ratio 5:1 and 1:1 with respect to the concentration of complex **1** ($2.56 \times 10^{-2}$ mol dm$^{-3}$)] its spectrum rapidly changes (spectrum **B**) to that of an authentic sample of the trichloro(pyridine-2-carbaldehyde dimethyl acetal)gold(III) (**2**) in $CD_3NO_2$ at a similar concentration ($2.34 \times 10^{-2}$ mol dm$^{-3}$ (spectrum **C**), both of them showing an integrated proton

ratio C–H ($\delta$ = 6.15 ppm)/O–CH$_3$ ($\delta$ = 3.66 ppm) of 1:6. Further addition of DCl [molar ratio 10:1 with respect to the concentration of complex **1**] allows the reaction to go to completion with release of the ligand in the form of the *N*-protonated pyridine-2-carbaldehyde dimethyl acetal [integrated proton ratio C–H ($\delta$ = 6.02 ppm)/O–CH$_3$ ($\delta$ = 3.64 ppm) of 1:6], as comes from a comparison of its spectrum (spectrum **D**) with the spectrum of the released ligand from **2** under the same experimental conditions (spectrum **E**). Spectrum **B** shows also the presence of some free *N*-protonated pyridine-2-carbaldehyde dimethyl acetal as a result of the incoming development of the second stage of the reaction.

From the reaction in Scheme 2, on assuming species C as a steady-state intermediate {d$C$/d$t$ = 0 which implies that ($k_{-1}^f$ + $k_2^f$[Cl$^-$]) >> $k_1^f$}, the following dependence of $k_{obs}^f$ on [H$^+$] and [Cl$^-$] is derived [Equation (7)].

Because under our experimental conditions in the presence of [H$^+$] ≥ 0.05 mol dm$^{-3}$ alone, the reaction is completely shifted towards the solvato species C, the condition $k_{-1}^f$ << $k_1^f$ must hold and hence, in the presence of Cl$^-$, the condition $k_2^f$[Cl$^-$] >> $k_{-1}^f$ must be satisfied. Under these conditions Equation (7) reduces to Equation (8).

Equation (8) is identical to the empirical Equation (5) if $k_1^f K$ = 1/f, $K$ = e/f, $k_3^f K$ = 1/d, from which the values of the equilibrium constant ($K$ = 1.12 ± 0.03 dm$^3$ mol$^{-1}$) and of the rate constants ($k_3^f$ = 56 ± 17 dm$^3$ mol$^{-1}$ s$^{-1}$, $k_1^f$ = 0.025 ± 0.001 s$^{-1}$) can be calculated. These values together with the rate constants for the second stage of the reaction ($k_1^s$ and $k_2^s$) are also reported in Scheme 2.

A point that deserves to be underlined is the different reactivity of complex **1** with respect to that of the previously studied dichloro(pyridine-2-methanolato)gold(III)[5] as regards the reaction with Cl$^-$ in the absence of acid. In the first case no reaction takes place, whereas in the second case the reaction goes to completion with ring opening at oxygen followed by substitution of the pyridine ligand. This different behaviour, which implies a stronger Au–O bond in complex **1**, would suggest a remarkable effect on the reactivity as a result of the replacement of a hydrogen atom with a methoxy group, possibly related to their different inductive effects. Accordingly, both the values of the protonation constant ($K$ = 1.12 mol$^{-1}$ dm$^3$) and the rate con-

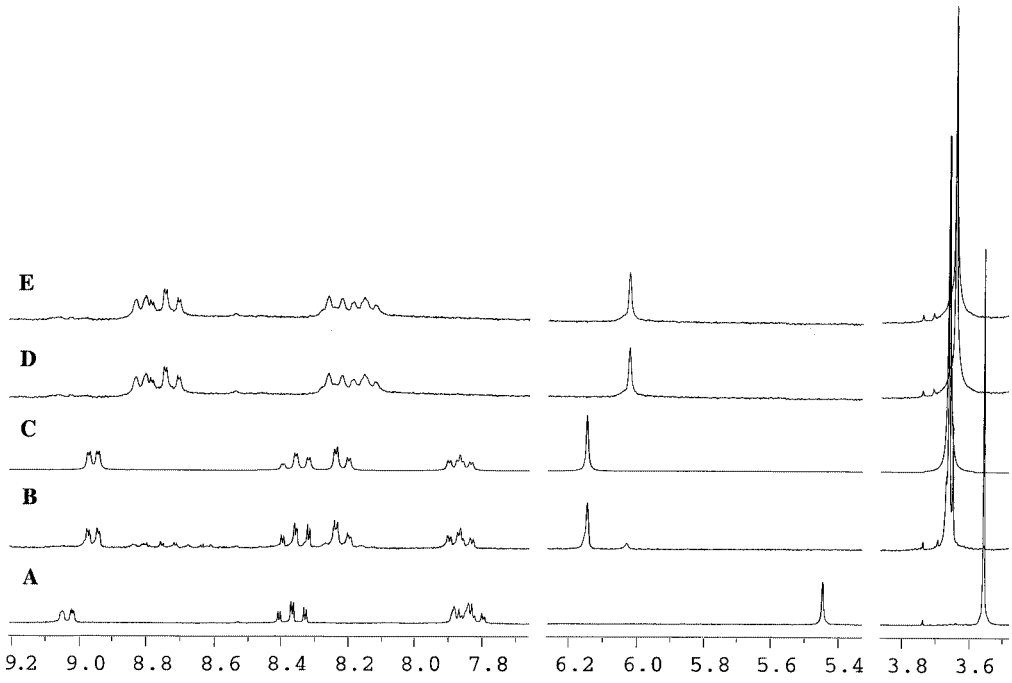

Figure 6. $^1$H NMR spectrum of **1** in $CD_3NO_2$ (spectrum **A**); spectrum of **1** in methanol and DCl [molar ratio 5:1 and 1:1 with respect to the concentration of the complex] (spectrum **B**); spectrum of an authentic sample of **2** in $CD_3NO_2$ (spectrum **C**); spectrum of the released ligand at the end of the reaction in the presence of methanol and an excess of DCl [molar ratio 5:1 and 10:1 with respect to the concentration of complex (**1**)] (spectrum **D**); spectrum of the released ligand from **2** under the same experimental conditions (spectrum **E**).

$$k_{obs}^{f} = \frac{K[H^+]}{1+K[H^+]}\left(\frac{k_1^{f}k_2^{f}[Cl^-]}{k_{-1}^{f}+k_2^{f}[Cl^-]}+k_3^{f}[Cl^-]\right) \quad (7)$$

$$k_{obs}^{f} = \frac{k_1^{f}K[H^+]}{1+K[H^+]}+\frac{k_3^{f}K[H^+][Cl^-]}{1+K[H^+]} \quad (8)$$

stant relative to the ring opening of the protonated species ($k_3^{f}$ = 56 mol$^{-1}$ dm$^3$ s$^{-1}$) for the hemiacetalic complex (**1**) are lower than the corresponding constants for the complex with pyridine-2-methanol ($K$ = 9.7 mol$^{-1}$ dm$^3$, $k$ = 126 mol$^{-1}$ dm$^3$ s$^{-1}$).[5]

The second stage of the reaction, that is the displacement of the 2-substituted pyridine by $Cl^-$ from the species P′, can be compared with other reactions of this sort as it is known that the second-order rate constant for the reaction with chloride depends upon the basicity of the leaving pyridine, according to the linear relationship $\log k_2 = a(pK_a) + C$ ($pK_a$ is that of the protonated base in water at 25 °C) and is independent from steric hindrance of the ring substituents.[7] In the mixture methanol/water (95:5, v/v) this relationship is also obeyed and the values of $a$ and $C$, already measured, are –0.67 and 2.81 respectively.[9] A $k_2^{s}$ value of $7.6\times10^{-2}$ mol$^{-1}$ dm$^3$ s$^{-1}$ leads therefore to a $pK_a$ of 5.86 for the leaving pyridine-2-carbaldehyde dimethyl acetal, which closely compares to those of pyridine-2-methanol and 2-(methoxymethyl)pyridine, as they both have a $pK_a$ value of 5.6.[5]

## Concluding Remarks

The kinetics of ring opening and displacement of the bidentate chelate ligand from dichloro[pyridine-2-(α-methoxymethanolato)]gold(III), [Au(N–O)$Cl_2$] (**1**) have been studied spectrophotometrically in methanol/water (95:5 v/v). Because of the relative inertness of the Au–alkoxide oxygen bond, complex **1** does not react with chloride alone. In the presence of LiCl and perchloric acid the reaction proceeds through a pre-equilibrium protonation of the coordinated oxygen followed first by ring opening at oxygen accompanied by the entry of chloride or solvent and then by displacement of the *N*-bonded ligand to give $[AuCl_4]^-$. However, once opened the hemiacetalic *N*-coordinated ligand is rapidly transformed in the corresponding 2-(pyridinecarbaldehyde dimethyl acetal), which is the true leaving ligand, to be displaced in the second stage of the reaction as a 2-substituted pyridine with a $pK_a$ value of 5.86.

## Experimental Section

**Materials:** Pyridine-2-carbaldehyde (Aldrich) was vacuum distilled and stored at 4 °C. Potassium tetrachloroaurate(III) dihydrate, the inorganic salts and the solvents were reagent grade products (Aldrich) used without further purification.

**Instruments:** UV/Vis spectra and kinetics were recorded with a Perkin–Elmer Lambda 5 spectrophotometer. IR spectra (4000–500 cm$^{-1}$, KBr disks; 600–50 cm$^{-1}$, polyethylene pellets) were collected with a Nicolet Magna FTIR 750 spectrometer. $^1$H NMR spectra in high purity $CD_3NO_2$ (Aldrich) were obtained with a Bruker AC 200 spectrometer. Chemical shifts (ppm) were internally

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

referenced to the residual undeuterated solvent resonances and related to tetramethylsilane ($\delta$ = 0 ppm). Conductivity measurements were carried out in dmf with a CDM 83 Radiometer Copenhagen conductivity meter and a CDC 334 immersion cell. Elemental analyses were performed by the Microanalytical Laboratory of the University of Padua.

**Synthesis of Complexes 1 and 2 and of the Ligand Released at the End of the Process (3)**

**Dichloro[pyridine-2-(α-methoxymethanolato)]gold(III) (1):** [Spectrum A in Figure 6] This complex was prepared following the same procedure as for the ethoxy species previously reported[4] using methanol instead of ethanol as a solvent. Yield (80%). $C_7H_8AuCl_2NO_2$ (406.02): calcd. C 20.71, H 1.99, Cl 17.46, N 3.45; found C 20.64, H 1.72, Cl 17.32, N 3.46. $^1$H NMR (200 MHz, $CD_3NO_2$, 25 °C): $\delta$ = 9.04 (d, $^3J_{HH}$ = 5.2 Hz, 1 H, py-$H_6$), 8.37 (td, $^3J_{HH}$ = 7.6, $^4J_{HH}$ = 1.4 Hz, 1 H, py-$H_4$), 7.92–7.77 (m, 2 H, py-$H_{3,5}$), 5.45 (s, 1 H, CH), 3.56 (s, 3 H, $OCH_3$) ppm. Selected IR bands: 1609 ($\nu_{C=N}$), 1079 ($\nu_{O-CH_3}$), 370, 349 ($\nu_{Au-Cl}$) cm$^{-1}$. $\Lambda_M$(dmf) = 2.7 Ω$^{-1}$ cm$^2$ mol$^{-1}$.

**Trichloro(pyridine-2-carbaldehyde dimethyl acetal)gold(III) (2):** [Spectra B, C in Figure 6] The complex was prepared as previously reported.[6] Yield (75%). $C_8H_{11}AuCl_3NO_2$ (456.51): calcd. C 21.05, H 2.43, Cl 23.30, N 3.07; found C 20.94, H 2.39, Cl 23.61, N 3.10. $^1$H NMR (200 MHz, $CD_3NO_2$, 25 °C): $\delta$ = 8.96 (d, $^3J_{HH}$ = 6.0 Hz, 1 H, py-$H_6$), 8.36 (td, $^3J_{HH}$ = 7.9, $^4J_{HH}$ = 1.4 Hz, 1 H, py-$H_4$), 8.22 (dd, $^3J_{HH}$ = 7.9, $^4J_{HH}$ = 1.8 Hz, 1 H, py-$H_3$); 7.87 (ddd, $^3J_{HH}$ = 6.0, $^3J_{HH}$ = 7.9, $^4J_{HH}$ = 1.8 Hz 1 H, py-$H_5$), 6.15 (s, 1 H, CH), 3.66 (s, 6 H, $OMe_2$) ppm. Selected IR bands: 1611 ($\nu_{C=N}$), 1098 ($\nu_{O-CH_3}$), 366, 349 ($\nu_{Au-Cl}$) cm$^{-1}$. $\Lambda_M$(dmf) = 2.3 Ω$^{-1}$ cm$^2$ mol$^{-1}$.

**2-CH(OMe)$_2$py·HCl (3):** [Spectra D, E in Figure 6] $^1$H NMR (200 MHz, $CD_3NO_2$, 25 °C): $\delta$ = 8.81 (d, $^3J_{HH}$ = 6.0 Hz, 1 H, py-$H_6$), 8.75 (td, $^3J_{HH}$ = 7.9, $^4J_{HH}$ = 1.6 Hz, 1 H, py-$H_4$), 8.30–8.08 (m, 2 H, py-$H_3$+$H_5$), 6.91 (br, 1 H, NH), 6.02 (s, 1 H, CH), 3.64 (s, 6 H, $OMe_2$) ppm.

**Kinetics:** The reactions were followed spectrophotometrically by measuring the changing absorbance at a suitable wavelength as a function of time. They were initiated by adding 10–20 μL of a 0.015 mol dm$^{-3}$ dimethylformamide (dmf) solution of **1** or **2** to a methanol/water (95:5 v/v) solution (3 cm$^3$) of the appropriate reagent, either $HClO_4$ or $HClO_4$, and LiCl, previously brought to the reaction temperature (25 °C) in the thermostatted cell in the spectrophotometer. All reactions were carried out at constant ionic strength ($I$ = 1.0 mol dm$^{-3}$, $LiClO_4$). Pseudo-first-order rate constants ($k_{obs}$/s$^{-1}$) were obtained either from the gradients of plots of $\log(D_t - D_\infty)$ versus time or from a nonlinear least-squares fit of experimental data to the equation $D_t = D_\infty + [D_0 - D_\infty \exp(-k_{obs}t)]$, where $D_0$, $D_\infty$ and $k_{obs}$ are the parameters to be optimised ($D_0$ is absorbance after mixing of reactants, $D_\infty$ is absorbance at completion of reaction). Rate constants were accurate within 5%.

# The Effective Electron-Transfer Distance in Dinuclear Ruthenium Complexes Containing the Unsymmetrical Bridging Ligand 3,5-Bis(2-pyridyl)-1,2,4-triazolate

**Deanna M. D'Alessandro,[a] Peter H. Dinolfo,[b] Joseph T. Hupp,[b] Peter C. Junk,[c][‡] and F. Richard Keene*[a]**

**Keywords:** Electron transfer / Mixed-valent compounds / Through-bond interactions / Dinuclear / Stereochemistry / Stark spectroscopy / Ruthenium

Electroabsorption (Stark effect) measurements on the intervalence charge-transfer (IVCT) transitions in the diastereoisomers of $[\{Ru(bpy)_2\}_2(\mu\text{-}bpt^-)]^{4+}$ [bpy = 2,2′-bipyridine, $bpt^-$ = 3,5-bis(2-pyridyl)-1,2,4-triazolate] in *n*-butyronitrile glass at 77 K reveal effective charge-transfer distances of 5.92 ± 0.03 Å for the ΔΛ/ΛΔ form and 5.44 ± 0.04 Å for the ΔΔ/ΛΛ form. These values correspond to approximately 95 and 88 %, respectively, of the geometrical metal–metal distance of 6.185(10) Å, obtained from the X-ray crystal structure of the cation in the related complex (ΔΛ)-$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-}bpt^-)](PF_6)_3$. The results are consistent with a localized Class II classification for the mixed-valence systems $[\{Ru(pp)_2\}_2(\mu\text{-}bpt^-)]^{4+}$, where pp = bpy, $Me_2bpy$ = 4,4′-dimethyl-2,2′-bipyridine.

## Introduction

Dinuclear polypyridyl complexes of ruthenium and osmium based on di-bidentate polypyridyl bridging ligands have been the subject of extensive research efforts over the past two decades, as part of rapid advances in metallosupramolecular chemistry. Bridging ligands provide the linkage between the metal centers in polymetallic assemblies and control the distances and relative orientations of the components, as well as the inter-component electron- and energy-transfer processes.[1–8]

The anion of 3,5-bis(2-pyridyl)-1,2,4-triazole (shown in Figure 1) is a particularly interesting bridging ligand, as it carries a negative charge and exhibits a high σ-donor and low π-acceptor ability.[9] As a consequence, $bpt^-$ constitutes a member of a relatively small class of bridging ligands, which mediate the electronic coupling between the metal centers (denoted by $M^1$ and $M^2$ in Figure 1) by a hole-transfer mechanism. Because these ligands possess electron-rich high-lying π* orbitals, the decisive factor in the metal–metal coupling is the energy gap between the highest-occupied molecular orbitals (HOMOs) of the bridge and the metal-based dπ orbitals, as shown in Figure 2.[6]

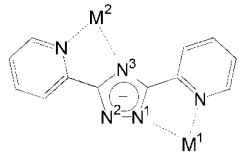

Figure 1. The 3,5-bis(2-pyridyl)-1,2,4-triazolate ($bpt^-$) bridging ligand. $M^1$ and $M^2$ denote the metal centers coordinated at the $N^1$ and $N^3$ sites, respectively.

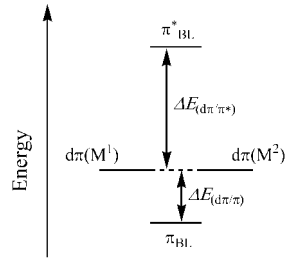

Figure 2. Schematic energy level diagrams for superexchange-assisted electronic coupling by a *hole-transfer* mechanism.[6] $M^1$ and $M^2$ denote the metal centers and BL denotes the bridging ligand.

The coupling between $M^1$ and $M^2$ can involve direct contributions from a "through-space" mechanism, and/or indirect contributions from a "through-bond" superexchange process where the bridging ligand mediates the donor-ac-

ceptor coupling. In the latter case, the superexchange theory[10] provides a conceptual framework for bridging ligand effects in intramolecular electron transfer.[5,6] The parameters, which are effective to describe the through-bond interaction are the overlap between the frontier orbitals of the metals, $d\pi(M^1)$ and $d\pi(M^2)$, and the bridging ligand ($\pi_{BL}$ and $\pi_{BL}^*$), and the electronic interactions between the atoms of the bridge connecting the frontier units to one another.

In dinuclear complexes incorporating bpt⁻, the coordination environments of the two metal centers are chemically distinct due to the enhanced σ-donor ability of the $N^1$ (≡ $N^2$) position of the triazolate ring relative to the $N^3$ position.[11] As a consequence, a "redox asymmetry" (denoted by $\Delta E_0$) exists between the inequivalent coordination sites.[12,13]

The classical theory developed by Hush[14,15] provides a conceptual framework for the contribution of redox asymmetry effects to the electron-transfer barrier through the analysis of the intervalence charge-transfer (IVCT) transitions generated in the mixed-valence forms of dinuclear complexes. In accordance with Equation (1), the energy ($\nu_{max}$) of an IVCT band, which is typically observed in the near-infrared (NIR) region of the absorption spectrum of the mixed-valence complex, is given in terms of the redox asymmetry and the Franck-Condon reorganizational energy contributions. The latter are composed of an inner-sphere component ($\lambda_i$) due to bond length and angle rearrangement, and also an outer-sphere component ($\lambda_o$) due to solvent and anion rearrangement in the secondary coordination sphere.[14,15]

$$\nu_{max} = = \lambda_i + \lambda_o + \Delta E_0 \quad (1)$$

In recent work from our laboratory, comparisons between the characteristics of the IVCT transitions, generated by the mixed-valence forms of the diastereoisomers, (ΔΛ/ΛΔ)- and (ΔΔ/ΛΛ)-[{Ru(bpy)$_2$}$_2$(μ-BL)]$^{n+}$ (BL = a range of bis-bidentate polypyridyl bridging ligands) have revealed a stereochemical dependence of the IVCT energies, intensities and bandwidths. The origins of such dependencies have been ascribed to redox asymmetry contributions to Equation 1) due to stereochemically-directed structural distortions[16] and ion-pairing interactions,[17] as well as the outer-sphere reorganizational contributions due to spatially-directed solvent interactions.[18] The present work broadens our investigation into the use of stereoisomers as probes for the factors that govern the electron-transfer barrier through the characterization of the IVCT transitions in the ΔΛ/ΛΔ and ΔΔ/ΛΛ diastereoisomers of [{Ru(pp)$_2$}$_2$(μ-bpt⁻)]$^{4+}$ (pp = bpy, Me$_2$bpy), shown in Figure 3. Electroabsorption (Stark effect) measurements on the IVCT bands of the diastereoisomers of [{Ru(bpy)$_2$}$_2$(μ-bpt⁻)]$^{4+}$ provide a measure of the *effective* charge-transfer distances, which may be shortened relative to the geometric metal–metal distances due to electronic delocalization, self-polarization and other effects.[19–23] Whereas Browne and co-workers[24] concluded that the stereoisomeric identity of the ΔΛ, ΛΔ, ΔΔ and ΛΛ forms of [{Ru(bpy)$_2$}$_2$(μ-bpt⁻)]$^{3+}$ had no influence on the photophysical properties of the complexes either at 77 K or room temperature, the influence of stereochemical effects on the IVCT properties of the systems were not addressed. Previous studies have, however, reported the redox and spectroscopic characteristics,[9,11,12,25–27] resonance Raman spectra[28] and photophysical behavior[9,29] of stereoisomeric mixtures of the homo- and hetero-dinuclear complexes of ruthenium, osmium, rhodium and iridium incorporating bpt⁻ and its protonated analog, Hbpt.

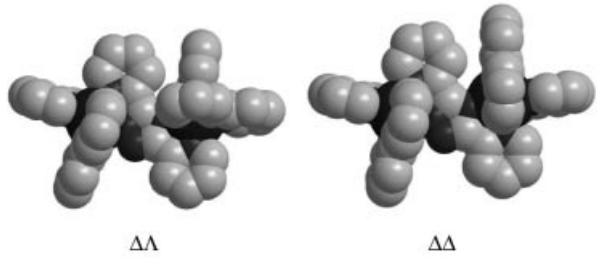

Figure 3. Schematic representations of (ΛΔ)- and (ΔΔ)-[{Ru(bpy)$_2$}$_2$(μ-bpt⁻)]$^{3+}$; hydrogen atoms are omitted for clarity.

It must be noted that due to the inequivalence of the metal coordination sites, the ΔΛ/ΛΔ form comprises a pair of geometric isomers. No attempt was made to separate the geometric forms in the present report.

The understanding of the fundamental stereochemical effects on the IVCT transitions in dinuclear complexes has important implications for the elucidation of spatial influences on electron migration in natural processes such as photosynthesis. Because the unsymmetrical component in bpt⁻ may be exploited to facilitate vectorial electron- and energy-transfer processes in polynuclear complexes, which form the basis of novel molecular-scale devices,[9,11,12,24,25,27–40] stereochemical effects may also offer a novel means of "fine-tuning" the metal–metal interactions.

## Results and Discussion

**Diastereoisomer Synthesis, Separation and Structural Characterization:** The complex [{Ru(bpy)$_2$}$_2$(μ-bpt⁻)]$^{3+}$ has been synthesized previously by the reaction of [Ru(bpy)$_2$Cl$_2$]·2H$_2$O with bpt in ethanol/water (2:1) under reflux.[11,33] In the present case, an alternative microwave-assisted methodology was employed[16,41–44] which produced equivalent or increased reaction yields of the dinuclear species compared with the thermal method; however, there was a significant reduction in the reaction times.

The chromatographic separation of the diastereoisomers of [{Ru(bpy)$_2$}$_2$(μ-bpt⁻)]$^{3+}$ by a semi-preparative HPLC technique has been reported previously;[24] in the present report, the separation was achieved using a cation-exchange chromatographic procedure with SP Sephadex C-25 as the support and aqueous solutions of sodium toluene-4-sulfonate as the eluent. The band 1 and 2 eluates were determined to be the ΔΛ/ΛΔ and ΔΔ/ΛΛ diastereoisomers, respectively. Interestingly, the two forms exhibited different colors on the column, with the ΔΛ/ΛΔ form displaying a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

red, and the ΔΔ/ΛΛ form displaying an orange coloration. During the procedure, a small amount of smearing was observed as the complex passed down the column. This was attributed to the presence of an uncoordinated nitrogen atom on the triazole ring of the bpt⁻ bridging ligand. Measurements on the pH dependence of the absorption spectrum of $[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)]^{3+}$ by Hage et al.[11] revealed a p$K_a$ of $-0.6 \pm 0.3$ for the complex in aqueous solution. This suggests that the protonation of the free nitrogen atom under the conditions employed in the chromatographic separation is unlikely.

Because poor microanalysis figures were obtained, the characterization and purity assessment of the diastereoisomers were based on the NMR spectra and electrochemical data. Incomplete combustion may in part account for these unsatisfactory figures;[45] however, the occlusion of variable numbers of solvent molecules and counter-anions may also be a factor. Such difficulties have previously been noted for dinuclear complexes of ruthenium(II).[46]

The $^1$H numbering schemes for the ligands in $[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)]^{4+}$ are shown in Figure S1 (Supporting Information; see footnote on the first page of this article) and the assignments of the spectra were performed with the assistance of $^1$H COSY spectra.[47] The coordinated bpy ligands exhibited the expected coupling constant values[48] ($J_{3,4}$ = 8, $J_{3,5}$ = 1.5, $J_{4,5}$ = 8, $J_{4,6}$ = 1.5 Hz and $J_{5,6}$ = 5 Hz) and coupling patterns based on the symmetry requirements of the complexes.

The assignment of the $^1$H resonances associated with individual terminal ligands was based on the differential anisotropic effects of the two ligands above (and below) the plane of the bridging ligand. Because an analysis of the $^1$H NMR spectra of the diastereoisomers of $[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)]^{3+}$ have been reported previously,[11] the assignments for the diastereoisomers of $[\{Ru(pp)_2\}_2(\mu\text{-bpt}^-)]^{3+}$ in the present investigation are listed in the Experimental Section only.

### Structural Considerations: X-Ray Crystallography

A limited number of crystal structures have been reported of dinuclear ruthenium complexes incorporating polypyridyl ligands. Of the three examples of dinuclear species containing unsymmetrical bridging ligands,[12,49] two have contained the bpt⁻ bridging ligand. In both cases, the crystals were obtained in the ΔΛ/ΛΔ form during an attempt to separate the diastereoisomers of the complexes through fractional crystallization. Accordingly, the single crystals of $(\Delta\Lambda/\Lambda\Delta)$-$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpt}^-)](PF_6)_3$ obtained in the present investigation represent the first example of the selective isolation of one of the components containing an unsymmetrical bridging ligand *prior* to crystal growth.

Figure 4 shows the X-ray crystal structure for the cation in $(\Delta\Lambda/\Lambda\Delta)$-$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpt}^-)](PF_6)_3$. The complex crystallises in the triclinic space group $P\bar{1}$ with two dinuclear cations in the unit cell. A summary of the crystal data and refinement are provided in Table S1 (Supporting Information). The ruthenium–nitrogen distances of 2.026(10)–2.109(10) Å correlate with those published for previous structures.[12,50–52] The Ru(2)–N(1) distance of 2.004(9) Å is significantly shorter than the Ru(1)–N(3) distance of 2.109(10) Å, which is consistent with the enhanced σ-donor ability of the N(1) site of the triazolate ring compared with the N(3) site.[9,11,12,27,33] The bond lengths and angles of the terminal $Me_2$bpy ligands are in the normal range for complexes incorporating $[Ru(Me_2bpy)_2]^{2+}$ and $[Ru(bpy)_2]^{2+}$ moieties.[12,50–52] The "bite-angles" of the terminal chelating ligands vary between 78.1(5)° and 79.4(5)°, which is typical for bipyridine-like ligands.[12,50–52]

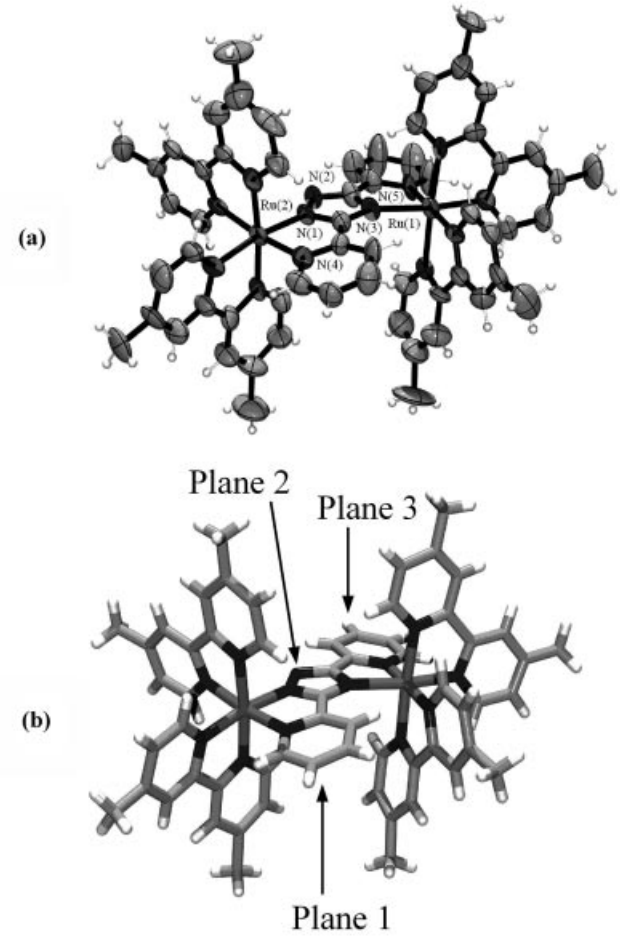

Figure 4. (a) Partial atom labelling, and (b) designation of the planes for the cation in $(\Delta\Lambda/\Lambda\Delta)$-$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpt}^-)](PF_6)_3$.

As shown in Figure 4 (b), the dihedral angles between the least-squares plane of the triazolate ring (plane 2) and the planes of the two pyridine rings (planes 1 and 3) are 10.8(5)° and 8.63(5)°, respectively, indicating a considerable deviation from planarity of the bpt⁻ ligand after the coordination of two $[Ru(Me_2bpy)_2]^{2+}$ moieties. This distortion appears to arise from steric crowding between the methyl groups oriented perpendicular to the "long axis" of the bridge. The methyl groups located "above" the plane of the bridging ligand induce a curvature in the bridge, which re-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sults in the pyridyl groups bending downwards away from the normal bridging plane. In the representation of the ΔΔ/ΛΛ diastereoisomer shown in Figure 3, one might anticipate less structural distortion relative to the ΔΛ/ΛΔ form, as the potentially unfavorable interactions between the methyl groups are avoided due to the parallel orientation of the terminal ligands above (and below) the bridging plane. The Ru(1)···Ru(2) separation is 6.185(10) Å.

### Electrochemical and UV/Vis/NIR Spectral Characterization

The redox potentials for the $E_{ox1}$ ([5+/4+]; i.e. $Ru^{III}$–$Ru^{II}$/$Ru^{II}$–$Ru^{II}$) and $E_{ox2}$ ([6+/5+]; i.e. $Ru^{III}$–$Ru^{III}$/$Ru^{III}$–$Ru^{II}$) couples for (ΔΛ/ΛΔ)- and (ΔΔ/ΛΛ)-$[\{Ru(pp)_2\}_2(\mu\text{-bpt}^-)]^{4+}$ (pp = bpy, $Me_2$bpy) were investigated by cyclic and differential pulse voltammetry in acetonitrile containing 0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$, and are reported in Table 1. $\Delta E_{ox}$ defines the potential difference between the [6+/5+] and [5+/4+] couples. The full electrochemical characteristics of the diastereoisomers $[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)]^{4+}$ in 0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$ and 0.02 M $[(n\text{-}C_4H_9)_4N]\{B(C_6F_5)_4\}$ electrolytes have been reported previously.[53]

Table 1. Electrochemical data (in mV relative to the $Fc^+/Fc^0$ couple) and comproportionation constants ($K_c$) for $[\{Ru(pp)_2\}_2(\mu\text{-bpt}^-)]^{3+}$ in 0.1 M $[(n\text{-}C_4H_9)_4N]PF_6/CH_3CN$.

| Complex | $K_c$[a] ($\times 10^{-5}$) | $\Delta E_{ox}$[b] | $E_{ox2}$ | $E_{ox1}$ |
|---|---|---|---|---|
| (ΔΛ/ΛΔ)-$[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)]^{3+}$ | 1.88 | 312 | 992 | 680 |
| (ΔΔ/ΛΛ)-$[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)]^{3+}$ | 1.61 | 308 | 992 | 684 |
| (ΔΛ/ΛΔ)-$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpt}^-)]^{3+}$ | 5.58 | 340 | 927 | 587 |
| (ΔΔ/ΛΛ)-$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpt}^-)]^{3+}$ | 3.78 | 330 | 902 | 572 |

[a] $K_c$ values are given by $K_c = \exp(\Delta E_{ox}F/RT)$ where $F/RT$ = 38.92 $V^{-1}$ at 298 K. [b] $\Delta E_{ox} = E_{ox2} - E_{ox1}$. Potentials are quoted ±3 mV.

The dinuclear systems are each characterized by two reversible one-electron redox processes corresponding to successive oxidation of the metal centers, in addition to multiple reversible ligand-based reductions in the cathodic region. The effect of terminal ligand variation on the redox couples is consistent with the trends observed for the mononuclear complexes $[Ru(pp)_3]^{2+}$ (pp = bpy, $Me_2$bpy);[54] the stronger σ-donor ability of $Me_2$bpy relative to bpy results in a less anodic potential for the first oxidation in the diastereoisomers of $[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpt}^-)]^{3+}$.

The separation between the two metal-centered oxidations is larger for the diastereoisomers incorporating the $Me_2$bpy terminal ligands relative to those incorporating bpy ligands, and small differences are observed between the diastereoisomeric forms of the same complex. As an increase in delocalization leads to a decrease in the magnitude of $\Delta E_{ox}$ for electron-rich bridging ligands such as $bpt^-$,[2] the results suggest that delocalization is enhanced for the bpy-based diastereoisomers. It should be noted, however, that these differences cannot be solely ascribed to variations in the extent of electronic delocalization, as the magnitude of $\Delta E_{ox}$ also reflects contributions from ion-pairing interactions,[53] solvation energies and statistical factors.[4,55]

### Electronic Spectroscopy and Spectroelectrochemistry

The UV/Vis/NIR spectroscopic data for the un-oxidized (+3), mixed-valence (+4) and fully-oxidized (+5) forms of (ΔΛ/ΛΔ)- and (ΔΔ/ΛΛ)-$[\{Ru(pp)_2\}_2(\mu\text{-bpt}^-)]^{n+}$ for the range 3050-30000 $cm^{-1}$ are characterized by a combination of overlapping $d\pi(Ru^{II}) \rightarrow \pi^*$(pp, $bpt^-$) singlet metal-to-ligand ($^1$MLCT) transitions. The lowest energy-absorption band is assigned as a $d\pi(Ru^{II}) \rightarrow \pi^*$(pp) transition.

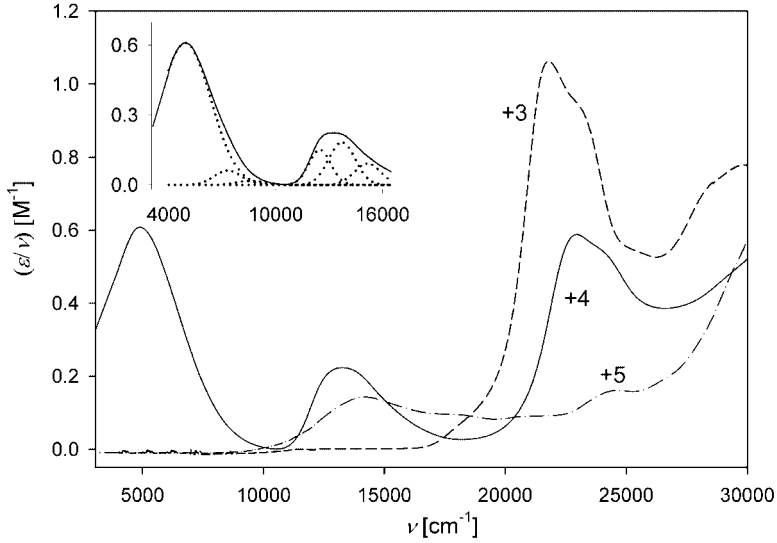

Figure 5. UV/Vis/NIR spectra of the reduced absorption spectra, ($\varepsilon/\nu$) vs. $\nu$, of (ΔΛ/ΛΔ)-$[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)]^{n+}$; $n$ = 3 (------), 4 (——), 5 (–·–·–·) in 0.1 M $[(n\text{-}C_4H_9)_4N]PF_6/CH_3CN$ at –35 °C. The inset shows the bands obtained by Gaussian deconvolution of the NIR spectra (·····).

[a] $\nu_{max}$ ±10/$cm^{-1}$ and $(\varepsilon/\nu)_{max}$ ±0.001/$M^{-1}$; sh = shoulder band.

The UV/Vis/NIR spectra for $(\Delta\Lambda/\Lambda\Delta)$-[{Ru(pp)$_2$}$_2$(μ-bpt$^-$)]$^{n+}$ ($n$ = 3, 4, 5) at –35 °C are shown in Figure 5, and the full details of the spectroscopic data for the series of complexes are reported in Table 2. Spectroelectrochemical generation of the +4 and +5 forms of the diastereoisomers revealed stable isosbestic points in the spectral progressions accompanying both oxidation processes. The $^1$MLCT absorption bands decreased in intensity on one-electron oxidation and collapsed on further oxidation to the +5 species. The formation of the mixed-valence complex was also characterized by the appearance of two new bands in the regions 5000–5500 $cm^{-1}$ and 13000–14500 $cm^{-1}$. The former was assigned as an IVCT band and disappeared on further oxidation to the +5 state. The band at 13000–14500 $cm^{-1}$ experienced a slight blue-shift on oxidation to the +5 state, and was assigned as a $\pi(bpy) \rightarrow d\pi(Ru^{III})$ ligand-to-metal charge-transfer (LMCT) transition, consistent with the LMCT transition at 12930 $cm^{-1}$ in [Ru(bpy)$_2$(bpt$^-$)]$^{2+}$ (see Table 2 and Figure S2 in the Supporting Information). As shown in the inset in Figure 5, the LMCT transition is composed of three underlying Gaussian-shaped transitions, which may arise due to the non-equivalence of the Ru centers bound to the $N^1$ and $N^3$ coordination sites in bpt$^-$ (Figure 1).

### Intervalence Charge Transfer

An overlay of the NIR spectra of the diastereoisomers of the mixed-valence systems [{Ru(pp)$_2$}$_2$(μ-bpt$^-$)]$^{4+}$ is shown in Figure 6, and the results of the IVCT band maxima $\nu_{max}$, molar absorption coefficients $(\varepsilon/\nu)_{max}$ and bandwidths $\Delta\nu_{1/2}$ derived from the deconvolution procedure are summarized in Table 3.

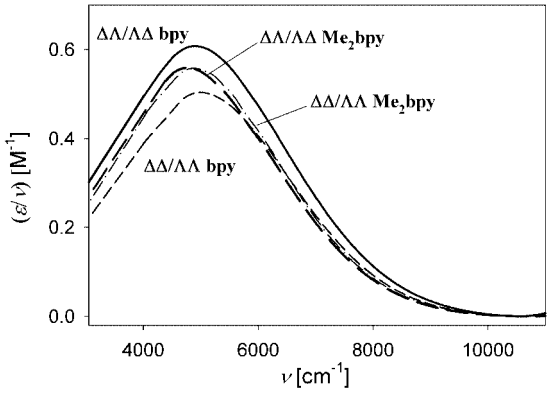

Figure 6. Overlay of the IVCT bands for the diastereoisomers of [{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{4+}$ ($\Delta\Lambda/\Lambda\Delta$ and $\Delta\Delta/\Lambda\Lambda$) and [{Ru(Me$_2$bpy)$_2$}$_2$-(μ-bpt$^-$)]$^{4+}$ ($\Delta\Lambda/\Lambda\Delta$ and $\Delta\Delta/\Lambda\Lambda$) in 0.1 M [($n$-$C_4H_9)_4N]PF_6/CH_3CN$ at –35 °C.

Whereas the IVCT properties for [{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{4+}$ (as a diastereoisomeric mixture) have been discussed previously,[11,12,38,56] the influence of the inherent stereochemical identity of the systems on their intramolecular electron-transfer properties had not been addressed. In the present investigation, the diastereoisomers of [{Ru(pp)$_2$}$_2$(μ-BL)]$^{4+}$ (pp = bpy, Me$_2$bpy) are seen to exhibit Gaussian-shaped IVCT bands. Because the lower energy side of the bands was obscured by the detector limit, the electronic coupling parameters ($H_{ab}$) were determined from Equation (2).[57,58] For simplicity (and due to a lack of detailed information) the issue of multiple overlapping intervalence bands was ignored in estimating $H_{ab}$. The zeroth-order moments ($M_0$) of the IVCT bands [see Equation (i) below and Exp. Sect.] were obtained by doubling the band area on the high-en-

[a] The errors in the observed parameters are ±10 $cm^{-1}$ for $\nu_{max}$, $M^1$ and $\Delta\nu_{1/2}$, ±0.001 $M^{-1}$ for $(\varepsilon/\nu)_{max}$, ±5 $M^{-1}$ for $M_0$ and ±0.001 e·Å for $|\mu_{12}|$.

ergy half of the bands, and the transition moments, $|\mu_{12}|$, were subsequently determined from Equation (ii) (see Exp. Sect.). For all complexes, $r_{ab}$ was initially equated with the through-space geometrical distance between the metal centers,[59] which was estimated as 6.185(10) Å from the X-ray crystal structure of (ΔΛ/ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$(μ-bpt$^-$)]$^{3+}$.

$$H_{ab} = \frac{|\mu_{12}|}{e r_{ab}} \nu_{max} \quad (2)$$

The IVCT manifolds were fitted by a Gaussian-shaped band, which reproduced the maximum energy and intensity, as shown by the deconvolution for (ΔΛ/ΛΔ)-[{Ru(bpy)$_2$}$_2$-(μ-bpt$^-$)]$^{4+}$ in the inset in Figure 5. Additional minor Gaussian-shaped bands were required to reproduce the bandwidth on the high-energy side. From a classical two-state analysis[60] of the IVCT transitions, the predicted bandwidth is given by Equation (3), where $16RT\ln 2$ = 1836 $cm^{-1}$ at 238 K. $\Delta E_0$ represents the energy difference induced by the unsymmetrical coordination environment, and has been estimated as 800 $cm^{-1}$ from electrochemical measurements on the two isomers of [Ru(bpy)$_2$(pyridyltriazole)]$^{2+}$.[12,13]

$$\Delta\nu_{1/2}° = [16\,RT\ln 2(\lambda - \Delta E_0)]^{1/2} \quad (3)$$

On the basis of the broad bandwidths compared with the theoretical bandwidths in Table 3, the complexes may be classified as localized Class II systems within the Robin and Day classification scheme.[61]

As electronic coupling decreases the *effective* electron-transfer distance relative to the geometrical metal–metal separation, the $H_{ab}$ values presented in Table 3 represent lower limits for the electronic coupling parameter. The *effective* electron transfer distance was determined from Stark effect spectroscopy on the IVCT transitions.[19]

## The *Effective* Electron-Transfer Distance: Stark Absorption Spectroscopy

Stark absorption spectra were obtained for the diastereoisomers of [{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{4+}$ in *n*-butyronitrile glass at 77 K and a field strength $F_{ext}$ of 4.0 MV·$cm^{-1}$. The quantitative Liptay analysis[62] of the Stark response[63–65] yielded the dipole moment change ($|\Delta\mu_{12}|$), the angle between the transition moment and the dipole moment change ($\xi$), the difference polarisability ($\Delta\alpha$), and the magnitude of the trace of the difference polarisability Tr($\Delta\alpha$). The results for the absorption $A(\nu)$ vs. $\nu$ and Stark absorption $\Delta A(\nu)$ vs. $\nu$ spectra for the diastereoisomers are pre-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sented in Table 4. The spectra for (ΔΛ/ΛΔ)-[{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{4+}$ are shown in Figure 7, where panel (a) shows the unperturbed absorption spectrum, and panels (b) and (c) show the first- and second-derivatives of the absorption spectrum, respectively. The Stark spectrum and the best fit to the spectrum are shown in panel (d). The corresponding spectra for (ΔΔ/ΛΛ)-[{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{4+}$ are shown in Figure S3 (Supporting Information).

The most notable features of the Stark signals in the range 3050–15000 cm$^{-1}$ are the presence of strong second-derivative components for the IVCT transition [Figure 7 (i)] and the two lowest-energy components of the LMCT manifold [Figure 7 (ii)]. As shown in Table 4, the energies of the absorption bands at 77 K are blue-shifted relative to those reported in Table 2 at 238 K (–35 °C). Whereas the IVCT band retains a Gaussian-shaped appearance at both temperatures, the bandwidth is relatively narrower in *n*-butyronitrile glass. On the basis of the classical analysis,[59] the IVCT band characteristics at 77 K are consistent with the localized (Class II) classification for the mixed-valence species, consistent with the findings from the UV/Vis/NIR spectroelectrochemical studies at 238 K.

The results for the parameters obtained from the Liptay analysis of the IVCT and LMCT bands [Equations (iii) and (iv), Exp. Sect.] are reported in Table 4. The IVCT bands in the ΔΛ/ΛΔ and ΔΔ/ΛΛ diastereoisomers exhibit dipole moment changes of 5.92 ± 0.03 e·Å and 5.44 ± 0.04 e·Å, respectively. From Equations (4) and (5), diabatic distances ($r_{ab}$) of 6.26 ± 0.03 Å and 5.74 ± 0.04 Å were obtained for the ΔΛ/ΛΔ and ΔΔ/ΛΛ forms, respectively, using the $|\mu_{12}|$ values reported in Table 3.[58]

$$r_{ab} = [(r_{12})^2 + (|\mu_{12}|)^2]^{1/2} \quad (4)$$

$$\text{where } r_{12} = |\Delta\mu_{12}|/e \quad (5)$$

Notably, the adiabatic charge-transfer distances for both diastereoisomers and the diabatic charge-transfer distance for the ΔΔ/ΛΛ form are shorter than the geometrical metal–metal separation ($r_{geo}$), which is estimated as 6.185(10) Å from the crystal structure of the (ΔΛ/ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$(μ-bpt$^-$)]$^{3+}$ cation. The diabatic distance for (ΔΛ/ΛΔ)-[{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{3+}$ is approximately identical to the geometrical separation. From Equation (6), $\Delta q$ represents the actual amount of charge transferred in the IVCT process, and is necessarily less than *e* (unit electronic charge). The quantity $(1 - \Delta q)/2$ can be identified with the amount of charge, which has been transferred prior to intervalence excitation. The adiabatic description reveals partial delocalization as a reduction in $r_{12}$ (the *effective* charge-transfer distance) relative to $r_{ab}$ (the true distance), whereas the diabatic description reveals delocalization as a reduction in the amount of charge ($\Delta q$) actually transferred. In the present case, $\Delta q$ is estimated as ca. 95% for both diastereoisomeric forms.

$$er_{12} = (\Delta q)r_{ab} \quad (6)$$

Accordingly, the $H_{ab}$ parameters for the ΔΛ/ΛΔ and ΔΔ/ΛΛ forms are re-evaluated as 773 and 707 cm$^{-1}$, respectively, from Equation (2) using the $r_{ab}$ values derived from the Stark analysis. These values are in close agreement to the estimates of 817 and 746 cm$^{-1}$ (respectively) obtained from the application of Hush theory to the IVCT absorption bands, when the geometric metal–metal separation was employed rather than $r_{ab}$.[60] The results confirm the localized assignment for the systems.

Interestingly, the two dominant underlying transitions of the LMCT manifold in the region 12000–15000 cm$^{-1}$ are well resolved at 77 K. As shown in Table 4, the LMCT transitions are characterized by dipole moment changes, which are significantly smaller than those for the IVCT transitions. It should be noted that the parameters obtained from spectral deconvolution of the LMCT manifold were somewhat arbitrary as the bands were assumed to be Gaussian-shaped. Accordingly, the apparent large differences in the Liptay parameters obtained for the first and second LMCT components should be interpreted cautiously.

As the uncertainties in the Stark-derived parameters reported in Table 4 reflect the errors obtained from the fitting procedure, the absolute error is likely to be considerably higher. The actual magnitudes will incorporate the uncertainties in the deconvolution and concentration, as well as the assumption of a value of 1.3 for the local field correction factor (*f*). The actual value of the latter depends on effects arising from the solvent, chromophore and counterion concentrations, which may also differ between the diastereoisomers. The shortcomings of the experimental and theoretical analysis of electroabsorption data have been discussed in detail previously by Boxer and co-workers.[66–69]

Table 4. Absorption and electroabsorption properties of the IVCT bands for the diastereoisomers of [{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{4+}$ in *n*-butyronitrile glass at 77 K and a field strength of 4.0 MVcm$^{-1}$.[a]

| Diastereoisomer | $\nu_{max}$ [cm$^{-1}$] | $\Delta\nu_{1/2}$ [cm$^{-1}$] | $\|\Delta\mu_{12}\|$ [e·Å] | $\|\Delta\mu_{12}\|$ [D] | $\Xi$ [b] [°] | Tr($\Delta\alpha$) [Å$^3$] | $\Delta\alpha$ [Å$^3$] |
|---|---|---|---|---|---|---|---|
| (ΔΛ/ΛΔ) | 5660 | 2980 | 5.92(3) | 28.2(2) | 0 | 8103(100) | 6787(70) |
| | 12546 | 1180 | 1.30(2) | 6.19(2) | 0 | –139(20) | –516(50) |
| | 13742 | 1354 | 2.44(1) | 11.6(1) | 0 | 632(30) | 1135(50) |
| (ΔΔ/ΛΛ) | 5530 | 2815 | 5.44(4) | 25.9(2) | 0 | 3755(50) | 3579(30) |
| | 12470 | 1210 | 1.20(2) | 5.72(3) | 0 | 740(10) | 761(150) |
| | 13760 | 1640 | 2.38(3) | 11.3(2) | 0 | 606(50) | 1755(200) |

[a] The errors in the observed and calculated parameters (not tabulated) are ±10 cm$^{-1}$ for $\nu_{max}$ and $\Delta\nu_{1/2}$, ±2° for $\xi$, and ±10 Å$^3$ for Tr($\Delta\alpha$) and $\Delta\alpha$. [b] The zero values for $\xi$ indicate that the direction of charge displacement in the excited state is aligned with the transition moment.

### The Mechanism of Electronic Coupling

The intra-metal coupling in complexes incorporating anionic bridging ligands such as bpt$^-$ is facilitated by a hole-transfer superexchange mechanism, utilising the high-lying π(bpt$^-$) HOMOs of the ligand.[11,12,38,56] The situation is depicted schematically in Figure 8, where the ground state of the mixed-valence system is depicted in part (a), and the hole-transfer virtual state in (b).

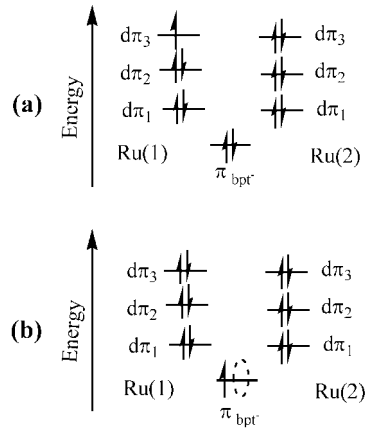

Figure 8. Schematic energy level diagram for the hole-transfer superexchange mechanism. Ground state (a) and (b) hole-transfer virtual state of the mixed-valence system [{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{3+}$ showing the composition of the three Ru(dπ) orbitals and the bpt$^-$ HOMO. The dotted oval represents the position of the hole on the bridging ligand.

While the σ-donor ability of N$^1$ site is greater than that of the N$^3$ site, the Ru center coordinated to N$^1$, denoted by Ru(1), is relatively more stabilized and undergoes oxidation prior to the Ru center coordinated to the N$^3$ site, denoted by Ru(2). As a consequence, the IVCT transition corresponds to the vectorial charge-transfer transition Ru(2) → Ru(1).

The similarity in the parameters of the IVCT transitions for the complexes incorporating the bpy and Me$_2$bpy terminal ligands demonstrates that terminal ligand variation has a minor influence on the extent of metal–metal interaction.

### Stereochemical Consequences on Electron Transfer

In addition to differences between the complexes incorporating the bpy and Me$_2$bpy terminal ligands, measurable differences are observed in the IVCT parameters between the diastereoisomeric forms of the same complex. Whereas the origins of the stereochemical dependence of the IVCT properties is uncertain, previous studies have revealed the presence of differential solvent and anion interactions with the diastereoisomers,[16,18] in addition to differential stereochemically-induced structural distortions in the bridging ligands.[16,17] In the present case, the crystal structure of the cation in (ΔΛ/ΛΔ)-[{Ru(Me$_2$bpy)$_2$}$_2$(μ-bpt$^-$)]$^{3+}$ reveals a slight curvature of the bridging ligand due to steric crowd-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing between the methyl groups on the terminal ligands. However, this minor distortion is expected to be similar for the corresponding ΔΔ/ΛΛ form, and should be negligible for both diastereoisomers of the complex incorporating the terminal bpy ligands, as described above. The stereochemical dependence of the IVCT parameters is therefore likely to arise from differential solvent and anion interactions with the two forms. Indeed, a recent report has demonstrated that differential anion interactions with the diastereoisomers of $[\{Ru(bpy)_2\}_2(\mu\text{-}bpt^-)]^{4+}$ lead to differences in the electrochemical potentials of the metal-based redox processes in the presence of the strongly ion-pairing electrolyte $[(n\text{-}C_4H_9)_4]PF_6$ (employed in the present study) and the weakly ion-pairing electrolyte $[(n\text{-}C_4H_9)_4]\{B(C_6F_5)_4\}$.[53,70]

## Conclusions

The synthesis and chromatographic separation of the diastereoisomeric forms of the complexes $[\{Ru(pp)_2\}_2(\mu\text{-}bpt^-)]^{3+}$ (pp = bpy, $Me_2$bpy) has permitted an investigation of the dependence of the IVCT properties of their mixed-valence forms on the stereochemical relationship of the metal centers. The *effective* metal–metal charge-transfer distances in the complexes incorporating the bpy terminal ligands were determined as 5.92 ± 0.03 Å for the ΔΛ/ΛΔ form, and 5.44 ± 0.04 Å for the ΔΔ/ΛΛ form, from Stark effect spectroscopy. These distances correspond to approximately 95 and 88%, respectively, of the geometrical metal–metal distance of 6.185(10) Å, obtained from the X-ray crystal structure of the cation in (ΔΛ/ΛΔ)-$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-}bpt^-)](PF_6)_3$. A classical analysis of the results from the IVCT absorption and electroabsorption spectra are consistent with a localized Class II classification for the mixed-valence systems.

## Experimental Section

**Materials:** Potassium hexafluorophosphate ($KPF_6$; Aldrich, 98%), ammonium hexafluorophosphate ($NH_4PF_6$; Aldrich, 99.99%), nitrosonium hexafluorophosphate ($NOPF_6$ stored under Ar; Alfa Aesar, 96%), ethylene glycol (Ajax, 95%), sodium toluene-4-sulfonate (Aldrich, 98%), DOWEX® 1×8, 50–100 mesh (Aldrich) anion-exchange resin and laboratory reagent solvents were used as received. Tetra-*n*-butylammonium hexafluorophosphate ($[(n\text{-}C_4H_9)_4N]PF_6$; Fluka, 99+%) was dried in vacuo at 60 °C prior to use and ferrocene (Fc; BDH) was purified by sublimation prior to use. SP Sephadex C-25 (Amersham Pharmacia Biotech), and silica gel (200–400 mesh, 60 Å, Aldrich) were employed for the chromatographic separation and purification of ruthenium complexes. Acetonitrile ($CH_3CN$; Aldrich, 99.9+%) was distilled from over $CaH_2$ prior to use and *n*-butyronitrile (Aldrich, 99+%) was used as received.

**General:** 1D and 2D $^1H$ NMR spectra were collected with a Varian Mercury 300 MHz spectrometer. $^1H$ NMR chemical shifts for all complexes are reported relative to 99.9% [$D_3$]acetonitrile [$CD_3CN$, Cambridge Isotope Laboratories (CIL)] at $\delta$ = 1.93 ppm. $^1H$ NMR assignments were performed with the assistance of COSY experiments to identify each pyridine ring system.

**Electrochemistry:** Electrochemical measurements were performed under argon using a Bioanalytical Systems (BAS) 100A Electrochemical Analyser. Cyclic (CV) and differential pulse (DPV) voltammograms were recorded in a standard three-electrode cell using a glassy carbon or platinum button working electrode, a platinum wire auxiliary electrode and an Ag/AgCl reference electrode (0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$ in $CH_3CN$). Ferrocene was added as an internal standard on completion of each experiment; the ferrocene/ferrocenium couple ($Fc^+/Fc^0$) occurred at +550 mV vs. Ag/AgCl. Solutions contained 0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$ as electrolyte. Cyclic voltammetry was performed with a sweep rate of 100 $mVs^{-1}$; differential pulse voltammetry was conducted with a sweep rate of 4 $mVs^{-1}$ and a pulse amplitude, width and period of 50 mV, 60 ms and 1 s, respectively. All potentials are reported ±3 mV.

**UV/Vis/NIR Spectroelectrochemistry:** UV/Vis/NIR spectroelectrochemistry was performed using a CARY 5E spectrophotometer interfaced to Varian WinUV software. The absorption spectra of the electrogenerated mixed-valence species were obtained in situ by the use of a cryostatted Optically Semi-Transparent Thin-Layer Electrosynthetic (OSTLE) cell.[71] An account of the procedure employed in the spectroelectrochemical measurements has been detailed previously.[72] Solutions for the spectroelectrochemial experiments contained 0.1 M $[(n\text{-}C_4H_9)_4N]PF_6$ supporting electrolyte in $CH_3CN$ and the complex (ca. $1\cdot10^{-3}$ M).

The analysis and spectral deconvolution of the data were performed as described in a previous report.[17] The IVCT spectra were scaled as $\int\varepsilon(\nu)/\nu\cdot d\nu$[14,73] and deconvolution of the NIR transitions was performed using the curve-fitting subroutine implemented within the GRAMS32 commercial software package.[72] On the basis of the reproducibility of the parameters obtained from the deconvolutions, the uncertainties in the energies $\nu_{max}$, intensities $(\varepsilon/\nu)_{max}$ and bandwidths $\Delta\nu_{1/2}$ were estimated as ±10 $cm^{-1}$, ±0.001 $M^{-1}$ and ±10 $cm^{-1}$, respectively. The transition moment $|\mu_{12}|$ in e·Å is defined by Equation (ii) where the zeroth-moment, $M_0$, represents the area under the band of the reduced absorption spectrum.

$$M_0 = \int_{\nu_1}^{\nu_2} f(\nu)d\nu \quad \text{(i)}$$

$$|\mu_{12}| = 0.0206\ \text{Å} \times M_0^{1/2} \quad \text{(ii)}$$

**Stark Absorption Spectroscopy:** Detailed accounts of the instrumentation, sample preparation and analysis have been reported previously.[63,64] In a typical experiment, the un-oxidized complex (ca. 5 mg) was dissolved in *n*-butyronitrile (1 mL) and the mixed-valence species was generated by chemical oxidation with $NOPF_6$ (saturated solution in *n*-butyronitrile, 1 mL).

Stark absorption measurements were performed in a dual liquid-nitrogen immersion cryostat (Janis Research Corporation) at 77 K.[74] The electroabsorption cell consisted of two indium-tin oxide (ITO) coated quartz slides (Delta Technologies) separated by 100 μm Kapton spacers (DuPont). Electroabsorption measurements were performed at 77 K and a field strength of 4.0 MV·$cm^{-1}$ using a CARY-14 spectrophotometer featuring OLIS control software. Dry nitrogen gas was blown over the dewar windows to prevent fogging. Electroabsorption measurements over the range 3850–12500 $cm^{-1}$ were recorded with a photovoltaic HgCdTe detector that was thermoelectrically cooled to –40 °C (Judson Technologies), and a DE110 Silicon photodiode for measurements over the range 9090–20000 $cm^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The analysis of the data was performed according to the method of Liptay,[47] as described in detail elsewhere.[63–65] Each Stark spectrum, obtained from duplicate experiments at two angles (90° and 45°), was fitted to a linear combination of the zeroth-, first- and second-derivatives of the absorption spectrum (at 77 K) to yield values for the coefficients, $A_\chi$, $B_\chi$ and $C_\chi$ in Equation (iii).

$$\Delta A(\nu) = \left\{ A_\chi A(\nu) + \frac{B_\chi \nu}{15hc}\frac{d[A(\nu)/\nu]}{d\nu} + \frac{C_\chi \nu}{30h^2c^2}\frac{d^2[A(\nu)/\nu]}{d\nu^2} \right\} \mathbf{F}_{\text{int}}{}^2 \quad \text{(iii)}$$

Here, $\chi$ is the experimental angle between $\mathbf{F}_{ext}$ and the polarization of the incident light, $h$ is Planck's constant, and $c$ is the speed of light in a vacuum. $\mathbf{F}_{int}$ represents the internal electric field experienced by the chromophore, and is given by $f \times \mathbf{F}_{ext}$, where $f$ is the local-field correction factor (typically assumed to be 1.3 for organic solvents[19]). The coefficients $A_\chi$, $B_\chi$ and $C_\chi$ provide information on changes in the transition dipole moment, and the excited state/ground-state polarisability and dipole moment differences, respectively, according to Equation (iv).

$$A_\chi = \frac{\langle \alpha_m \rangle}{3} + \tfrac{1}{30}(3\cos^2\chi - 1)[3\langle \beta_m \rangle - 2\langle \alpha_m \rangle]$$

$$B_\chi = \tfrac{5}{2}\mathrm{Tr}(\Delta\alpha) + (3\cos^2\chi - 1)[\tfrac{3}{2}\hat{\mathbf{g}}\cdot\Delta\alpha\cdot\hat{\mathbf{g}} - \tfrac{1}{2}\mathrm{Tr}(\Delta\alpha)]$$

$$C_\chi = |\mu_v|^2\,[5 + (3\cos^2\xi - 1)(3\cos^2\chi - 1)] \quad \text{(iv)}$$

In these Equations, $\langle a_m \rangle$ and $\langle \beta_m \rangle$ are the scalar functions of the transition-moment polarisability and hyperpolarisability tensors, $\mathrm{Tr}(\Delta a)$ is the trace of the polarisability change between the ground and excited electronic states, $\hat{\mathbf{g}}\cdot\Delta\alpha\cdot\hat{\mathbf{g}}$ is the polarisability change along the transition moment ($\hat{\mathbf{g}}$ is the unit vector), $|\mu v|$ is the vector change in dipole moment (its sign is not determined), and $\xi$ is the angle between the transition dipole moment and change in dipole moment vectors.[21] Measurement of Stark spectra at two or more values of $\chi$ (incident angle of polarized light in relation to the electric field) are fitted to a sum of the zeroth-, first- and second-derivatives of the absorption spectrum to yield values for the molecular parameters according to Equation (iv).

While the Liptay treatment interprets first-derivative (*i.e.* $B_\chi$) contributions in Equations (iii) and (iv) in terms of polarisability changes, for the special case of symmetrical mixed-valence systems significant non-Liptay contributions due to field-induced changes in degenerate ground-state populations can be expected. For simplicity, we report $B_\chi$ only in terms of apparent polarisability changes.[75]

### Synthetic Procedures

3,5-Bis(2-pyridyl)-1,2,4-triazole (Hbpt)[11,76] and *cis*-$[Ru(pp)_2Cl_2]\cdot 2H_2O$ (pp = bpy, $Me_2bpy$)[77] were prepared according to the literature methods.

**$[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)](PF_6)_3$:** A suspension of Hbpt (21 mg, 0.094 mmol) in ethylene glycol (10 mL) was heated in a modified microwave oven (Model R-2V55; 600 W, 2450 MHz) on medium-high power[41] for 20 s to complete dissolution. *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (100 mg, 0.207 mmol) was added and the mixture heated at reflux for a further 8 min during which time the solution attained a red-orange coloration. The mixture was diluted with water (ca. 50 mL) and the dinuclear product was separated from the crude mixture by a gradient elution procedure on SP Sephadex C-25 support using aqueous 0.1–0.5 M NaCl. A band of mononuclear material eluted first (0.2 M NaCl), followed by the desired orange product (0.4 M NaCl), which was precipitated as the $PF_6^-$ salt by addition of a saturated aqueous solution of $KPF_6$. The solid was isolated by vacuum filtration and washed with diethyl ether (3·10 mL). Yield: 93 mg (66%). The separation of the diastereoisomers was achieved by cation-exchange chromatography on SP Sephadex C-25 support (dimensions 96 cm length, 1.6 cm diameter). The complex (ca. 100 mg) was loaded onto the column in aqueous solution (as the $Cl^-$ form, obtained by stirring an aqueous suspension of the complex with DOWEX® 1×8 anion exchange resin) and eluted with 0.15 M sodium toluene-4-sulfonate solution.[41] The diastereoisomers separated after passing through an effective column length of 1.5 m. The two bands were collected, and the products were precipitated by the addition of a saturated aqueous $KPF_6$ solution. The solids were isolated by vacuum filtration and washed with diethyl ether (3×10 mL).

Rigorous purification methods were employed prior to characterization because of the potentially strong associations between the complex cations and the anions present in the eluents employed for the chromatographic separations.[41,46] Each product was dissolved in a minimum volume of acetone and loaded onto a short column of silica gel (dimensions: 2 cm diameter, 4 cm length), washed with acetone, water and acetone and then eluted with acetone containing 5% $NH_4PF_6$. Addition of water and removal of the acetone under reduced pressure afforded a product of suitable purity for the physical measurements. Band 1 and band 2 exhibited different NMR spectra, with the former identified as the ΔΛ/ΛΔ and the latter as the ΔΔ/ΛΛ diastereoisomers. $^1$H NMR ($CD_3CN$): $\delta$ (**Band 1; ΔΛ/ΛΔ**) = 6.40 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpt$^-$), 6.82 (dd, $J$ = 8, 1.5 Hz, 1 H, H3′ bpt$^-$), 6.92 (t, $J$ = 8, 5 Hz, 1 H, H5 bpt$^-$), 7.00 (dd, $J$ = 8, 8 Hz, 1 H, H4 bpt$^-$), 7.04 (dd, $J$ = 8, 8 Hz, 1 H, H4′ bpt$^-$), 7.12 (t, $J$ = 8, 5 Hz, 1 H, H5 bpy), 7.23 (t, $J$ = 8, 5 Hz, 3 H, H5 bpy), 7.27 (t, $J$ = 8, 5 Hz, 1 H, H5 bpy), 7.33 (t, $J$ = 8, 5 Hz, 2 H, H5 bpy), 7.53 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpt$^-$), 7.56 (t, $J$ = 8, 5 Hz, 1 H, H5 bpy), 7.63 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 7.66 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 7.74 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 7.76 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 7.79 (t, $J$ = 8, 5 Hz, 1 H, H5′ bpt$^-$), 7.81 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 7.85 (dd, $J$ = 8, 8 Hz, 2 H, H4 bpy), 7.88 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 7.89 (dd, $J$ = 8, 8 Hz, 3 H, H4 bpy), 7.94 (dd, $J$ = 8, 8 Hz, 2 H, H4 bpy), 7.98 (dd, $J$ = 5, 1.5 Hz, 2 H, H6 bpy), 8.01 (dd, $J$ = 8, 8 Hz, 1 H, H4 bpy), 8.33 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpy), 8.36 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpy), 8.43 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpy), 8.44 (dd, $J$ = 5, 1.5 Hz, 1 H, H6′ bpt$^-$), 8.45 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpy), 8.48 (dd, $J$ = 8, 1.5 Hz, 2 H, H3 bpy), 8.52 (dd, $J$ = 8, 1.5 Hz, 2 H, H3 bpy); $\delta$ (**Band 2; ΔΔ/ΛΛ**) = 6.54 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpt$^-$), 6.98 (dd, $J$ = 8, 1.5 Hz, 1 H, H3′ bpt$^-$), 6.86 (t, $J$ = 8, 5 Hz, 1 H, H5 bpt$^-$), 7.06 (dd, $J$ = 8, 8 Hz, 1 H, H4 bpt$^-$), 7.42 (dd, $J$ = 8, 8 Hz, 1 H, H4′ bpt$^-$), 7.44 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpt$^-$), 7.89 (t, $J$ = 8, 5 Hz, 1 H, H5′ bpt$^-$), 8.38 (dd, $J$ = 5, 1.5 Hz, 1 H, H6′ bpt$^-$), 7.31 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 7.38 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 6.90-7.20 (5 H, H5 bpy), 7.89 (dd, $J$ = 8, 8 Hz, 1 H, H4 bpy), 7.92 (dd, $J$ = 8, 8 Hz, 1 H, H4 bpy), 7.70-8.00 (5 H, H4 bpy), 7.70-8.00 (5 H, H6 bpy), 7.98 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 8.13 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpy), 8.54 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpy), 8.60 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpy), 8.30-8.60 ($J$ = 8, 1.5 Hz, 5 H, H3 bpy) ppm.

**$[\{Ru(Me_2bpy)_2\}_2(\mu\text{-bpt}^-)](PF_6)_3$:** This compound was prepared from Hbpt (19 mg, 0.084 mmol) and $[Ru(Me_2bpy)_2Cl_2]\cdot 2H_2O$ (100 mg, 0.18 mmol) by a procedure analogous to that detailed above for $[\{Ru(bpy)_2\}_2(\mu\text{-bpt}^-)](PF_6)_3$. Yield: 107 mg (67%). The separation of the diastereoisomers was achieved by cation-exchange chromatography on SP Sephadex C-25 support using 0.15 M so-

dium toluene-4-sulfonate solution as the eluent. Band 1 and band 2 exhibited different NMR spectra, with the former identified as the ΔΛ/ΛΔ and the latter as the ΔΔ/ΛΛ diastereoisomers. $^1$H NMR ($CD_3CN$): $\delta$ (**Band 1; ΔΛ/ΛΔ**) = 2.45 (s, 6 H, $CH_3$), 2.48 (s, 6 H, $CH_3$), 2.51 (s, 6 H, $CH_3$), 2.57 (s, 6 H, $CH_3$), 6.38 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpt$^-$), 6.81 (dd, $J$ = 8, 1.5 Hz, 1 H, H3′ bpt$^-$), 6.90 (t, $J$ = 8, 5 Hz, 1 H, H5 bpt$^-$), 7.02 (dd, $J$ = 8, 8 Hz, 1 H, H4 bpt$^-$), 7.06 (dd, $J$ = 8, 8 Hz, 1 H, H4′ bpt$^-$), 7.05 (d, $J$ = 6 Hz, 1 H, H5 $Me_2$bpy), 7.23 (d, $J$ = 6 Hz, 3 H, H5 $Me_2$bpy), 7.23 (d, $J$ = 6 Hz, 1 H, H5 $Me_2$bpy), 7.29 (d, $J$ = 6 Hz, 2 H, H5 $Me_2$bpy), 7.51 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpt$^-$), 7.52 (d, $J$ = 6 Hz, 1 H, H5 $Me_2$bpy), 7.59 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 7.63 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 7.70 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 7.71 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 7.76 (t, $J$ = 8, 5 Hz, 1 H, H5′ bpt$^-$), 7.77 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 7.83 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 7.95 (d, $J$ = 6 Hz, 2 H, H6 $Me_2$bpy), 8.27 (s, 1 H, H3 $Me_2$bpy), 8.33 (s, 1 H, H3 $Me_2$bpy), 8.40 (s, 1 H, H3 $Me_2$bpy), 8.41 (dd, $J$ = 5, 1.5 Hz, 1 H, H6′ bpt$^-$), 8.37 (s, 1 H, H3 $Me_2$bpy), 8.46 (s, 2 H, H3 $Me_2$bpy), 8.49 (s, 2 H, H3 $Me_2$bpy); $\delta$ (**Band 2; ΔΔ/ΛΛ**) = 2.47 (s, 12 H, $CH_3$), 2.50 (s, 6 H, $CH_3$), 2.53 (s, 6 H, $CH_3$), 6.51 (dd, $J$ = 8, 1.5 Hz, 1 H, H3 bpt$^-$), 6.95 (dd, $J$ = 8, 1.5 Hz, 1 H, H3′ bpt$^-$), 6.81 (t, $J$ = 8, 5 Hz, 1 H, H5 bpt$^-$), 7.39 (dd, $J$ = 8, 8 Hz,1 H, H4′ bpt$^-$), 7.42 (dd, $J$ = 5, 1.5 Hz, 1 H, H6 bpt$^-$), 7.85 (t, $J$ = 8, 5 Hz, 1 H, H5′ bpt$^-$), 8.32 (dd, $J$ = 5, 1.5 Hz, 1 H, H6′ bpt$^-$), 7.26 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 7.35 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 6.80-7.15 (5 H, H5 $Me_2$bpy), 7.63-7.95 (5 H, H6 $Me_2$bpy), 7.94 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 8.07 (d, $J$ = 6 Hz, 1 H, H6 $Me_2$bpy), 8.51 (s, 1 H, H3 $Me_2$bpy), 8.57 (s, 1 H, H3 $Me_2$bpy), 8.22-8.55 (5 H, H3 $Me_2$bpy) ppm.

**X-ray Crystallography:** Single crystals of (ΔΛ/ΛΔ)-[{Ru($Me_2$bpy)$_2$}$_2$(μ-bpt$^-$)]($PF_6$)$_3$ were obtained by dissolution of ca. 1 mmol of the complex in acetone/water (1:1, 2 mL). Slow evaporation of the solution at room temperature yielded dark red rod-shaped crystals suitable for X-ray determination. The collection and refinement of X-ray data was performed in the Advanced Analytical Centre at James Cook University. Hemispheres of data were collected (capillary sealed specimens) at room temperature with a Bruker SMART CCD diffractometer using the omega scan mode. A summary of the data collection and refinement details is provided in Table S1 of the Supporting Information. Data sets were corrected for absorption using the program SADABS.[78] The solution and refinement for all structures was carried out using SHELXL-97[79] utilising the graphical interface X-Seed.[80] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-286553 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): Proton numbering schemes for NMR characterization (Figure S1), spectroelectrochemical progression for [Ru(bpy)$_2$(bpt$^-$)]$^{+/2+}$ (Figure S2) and Stark absorption spectra for (ΔΔ/ΛΛ)-[{Ru(bpy)$_2$}$_2$(μ-bpt$^-$)]$^{3+}$ (Figure S3).

## Acknowledgments

This work was supported by the Australian Research Council. Stark effect measurements were conducted at Northwestern University and DMD gratefully acknowledges the financial support of grants from Professor Joe Hupp and the JCU Doctoral Research Scheme for travel to Northwestern University. JTH gratefully acknowledges support from the Basic Energy Sciences Program, Office of Science, U.S. Dept. of Energy under grant No. DE-FG02-8713808.

# Self-Assembly, Structure and Solution Dynamics of Tetranuclear $Zn^{2+}$ Hydrazone [2×2] Grid-Type Complexes

**Mihail Barboiu,[a,b] Mario Ruben,[c] Georges Blasen,[a] Nathalie Kyritsakas,[d] Elizabeth Chacko,[e] Manisha Dutta,[e] Olga Radekovich,[e] Kimberly Lenton,[e] David J. R. Brook,*[e][‡] and Jean-Marie Lehn*[a]**

**Keywords:** Self-assembly / Grid-type complexes / Hydrazone ligands / Zinc / Supramolecular chemistry

We describe the self-assembly processes as well as the structural and physico-chemical properties of $[2\times2]Zn^{2+}_4$ grid complexes involving the bis-tridentate ligands **7**–**12**, based on bis(hydrazone)pyrimidine complexation subunits and octahedrally coordinated $Zn^{2+}$ ions. The NMR spectroscopic data and the X-ray crystal structure results indicate that in solution and in the solid state the complexes **13**–**18** adopt a very compact arrangement providing stable [2×2] hydrazone-grid arrays. The π–π stacking between the phenyl ring and the hydrazone units of the perpendicular ligands in the complexes induces a perfect orthogonal arrangement suitable for applications in self-organized metallosupramolecular systems. Zinc complexes provide an opportunity to study the acid–base chemistry without the added effects due to paramagnetism or redox chemistry. The intermediate protonated grids undergo relatively rapid proton exchange on the NMR timescale, the presence of a sharp pyrimidine proton resonance suggesting that there is significant delocalization of the negative charge along the backbone of the ligand. Rotation of the phenyl ring is observed. It involves probably a mechanism in which one of the ligands partially dissociates allowing the initially intercalated phenyl group to rotate, before recoordination of the terminal pyridine.

## Introduction

During the last decade, intense investigations have been carried out on the spontaneous generation of various types of supramolecular inorganic architectures, both as touchstone for the design of self-organization processes and as devices for nanotechnology.[1] The first complexes of [2×2] grid-type architecture employed bipyridine- and terpyridine-like binding subunits and respectively tetrahedrally ($Cu^+$ and $Ag^+$)[2a,2b,2f] and octahedrally ($Co^{2+}$, $Ni^{2+}$, $Zn^{2+}$)[2c–2f] coordinated metal ions. The latter in particular present remarkable electronic,[2d,3] magnetic,[4] and photophysical[7a] properties. The success in the formation of the [2×2] grid-type complexes as well as their interesting physical properties stimulated us to extend our investigations towards grids based on ligands for octahedrally coordinating metal ions, that would be synthetically more accessible than the earlier pyridine–pyrimidine sequences.[5]

The hydrazone unit is a suitable isomorphic analog of a pyridine group and is easily generated by hydrazine–carbonyl condensation. It has been implemented as a useful and simple method for the formation of molecular strands presenting extended helical architectures.[6] The *transoid*,*transoid* form of the free ligand is converted into the *cisoid,cisoid* form, corresponding to a terpyridine-type complexation site, on metal–ion binding (Scheme 1).

Thus, hydrazone-containing ligands were shown to yield [2×2] grid complexes presenting novel physical (optical,[7a] electrochemical,[7b,7c] magnetic[7d]) properties.

Based on these premises, we report here a study of the generation of several tetranuclear $[2\times2]Zn^{2+}_4$ grid-type complexes using such bis(hydrazone)pyrimidine ligands. It confirms their value as a synthetic alternative to the previously used pyridine–pyrimidine sequence and markedly simplifies the methodology for the synthesis of grid complexes based on octahedrally coordinated transition-metal ions.

We describe the self-assembly processes as well as the structural and physico-chemical properties of $[2\times2]Zn^{2+}_4$ grid complexes involving bis-tridentate ligands **7**–**12**, based on bis-hydrazone-pyrimidine complexation subunits and octahedrally coordinated $Zn^{2+}$ ions.

## Results and Discussions

### Synthesis and Characterization of Ligands 7–12 and of the $[2\times2]Zn^{2+}{}_4$ Grid-Type Complexes 13–18

The synthesis of the ligands **7**–**12** is outlined in Scheme 1.

The ligands **7**–**10** were obtained by the condensation of two equivalents of 2-pyridinecarboxaldehyde (**1**), or of 2-acetylpyridine (**2**), with one equivalent of dihydrazinopyrimidine (**3**) or of (dimethylhydrazino)pyrimidine (**4**) in ethanol. These ligands precipitate from the reaction mixture in ca. 90% yield as pure compounds. The NMR and ESI-MS spectra were in agreement with the proposed formula. Ligand **11** was obtained by the analogous condensation of the pyrimidinedicarbaldehyde **5** with 2-hydrazinopyridine (**6**). Ligand **12** was obtained through methylation of **11** in THF with $NaH/CH_3I$.

The grid-type complexes **13**–**18** resulted from spontaneous self-assembly of the ligands **7**–**12** with $Zn(CF_3SO_3)_2$ in acetonitrile (Scheme 1) at room temperature, followed by crystallization with diisopropyl ether or diethyl ether. The compounds **13**–**18** were characterized by NMR spectroscopy, positive ESI mass spectrometry, elemental analysis and in the case of **13**–**15** by single-crystal X-ray diffraction.

### Crystal Structure of the Complexes 13–15

Layering a 1:1 solution of the ligands **7**–**10** and $Zn(CF_3SO_3)_2$ in acetonitrile onto benzene resulted in the development of light-yellow prismatic crystals of grid-type Zn complexes **13**–**15**, which were investigated by X-ray crystallography.

In all these structures the complexes present a $[2\times2]Zn^{2+}{}_4$ grid-type architecture in which four metal ions form a square and lie close to an average common plane (Figure 1). In the case of complex **16** the overall quality of the crystal structure data is too low, and crystals of better quality are required for improving the structural data.

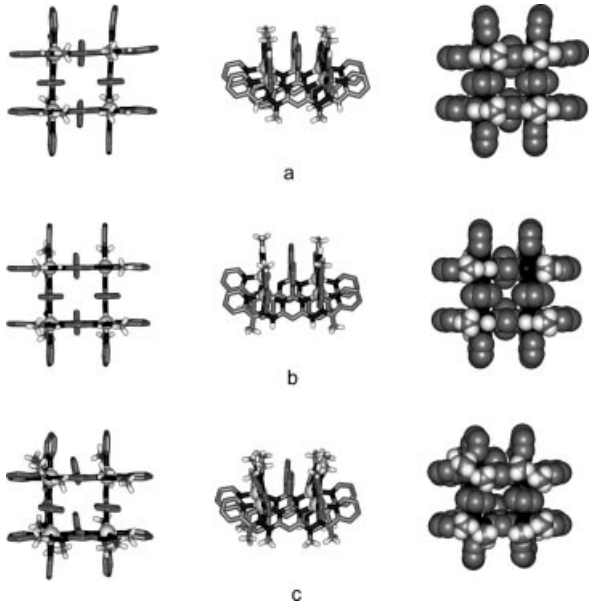

Figure 1. Crystal structure of the [2×2] $Zn_4^{2+}$ grid complexes: a) **13**, b) **14**, c) **15**: top view (left), side view in stick representation (center) and space-filling representation (right) The $Zn^{2+}$ ions are shown as spheres.

In the complexes **13**–**15** the $Zn^{2+}$ ions display a distorted octahedral coordination. The Zn–Zn distances lie in the range of 6.37–6.60 Å and the average inner angle between three Zn atoms of about 90°. The average Zn–N bonds are 2.17 Å for the pyridine nitrogen atoms, 2.20 Å for the pyrimidine nitrogen atoms and 2.14 Å for the hydrazone nitrogen atoms.

The average distance between two parallel ligands is 6.50 Å, and the average distance between the $–R^1C=N–NR^2–$ moiety of one ligand and the phenyl ring of the orthogonal one is 3.25 Å, indicating van der Waals contact and a strong π–π stacking. The almost parallel insertion of the phenyl substituent between two ligands, leads to an overall geometry of the $[2\times2]Zn^{2+}{}_4$ grid complexes **13** (Figure 1, a) and **14** (Figure 1, b) close to regular square. In the case of **15** (Figure 1, c) the steric interactions due to the close contacts (C–C distance of 2.95 Å) of the methyl substituents of the hydrazone moiety, are found to cause a distorted geometry, bending the planes of the ligands. The pinching angle provides information about the shape of complexes, smaller values being correlated with increased linearity of the ligand in the complex. It is smaller for **13**–**15** (16.5°) than for the analogous terpyridine grid-type[2e] (19.3°) and rack-type[8] (19.6°) $Zn^{2+}$ complexes.

### $^1$H NMR Spectra

The $^1$H NMR spectra of the ligands **7**–**12** are consistent with the presence of a *transoid*,*transoid* conformation along the connecting NC–CN bonds in both hydrazone pyridine functionalities. This conformation was further confirmed by intermolecular NOE interactions between the $H^4$ protons of external pyridines and the $H^5$ proton of internal pyrimidine, and between the protons of the $R^1$ (H or Me) and $R^2$ (H or Me) substituents of the hydrazone units.

The metal complexation leads to changes in $^1$H NMR spectra with large modifications in the chemical shifts of the protons of the ligands **7**–**12**. The metal–ion binding converts the wrapped *transoid*,*transoid* form of the free ligand to the linear *cisoid*,*cisoid* form, corresponding to a terpyridine-type complexation site (Scheme 1). This has been confirmed by a ROESY NMR experiment, where NOE interactions between $H^4$ and $R^1$ = H or Me as well as between $H^5$ and $R^2$ = H or Me are observed for the complexes **13**–**18**. The major changes observed in the NMR spectra on complexation reside in the strong shielding ($\Delta\delta$ = –1.66–3.34) of the phenyl protons when the zinc complexes **13**–**18** are formed (Table 1). Moreover, the *o*,*o′* and *m*,*m′* protons of the phenyl ring, which are equivalent in the ligands **7**–**12**, become non-equivalent in the complexes **13**–**17**, suggesting that in solution the grid-type-Zn complexes adopt a very compact structure where the phenyl rings of the two ligands on one face of the grid structure insert between the two ligands on the other face, blocking the rotation around the phenyl–pyrimidine C–C bonds, as seen in the parent grids.[2c] The phenyl insertion has been confirmed by a ROESY NMR experiment, where NOE interactions between $R^1$ and $H^{2'o}$, between $R^2$ and $H^{3'}$ and between $H^5$ and $H^{2'i}$ are observed for the complexes **9**–**12**.

The well-resolved NMR spectra of these species provide an opportunity to investigate the deprotonation of the hydrazone NH protons in these molecules. The hydrazones in the analogous complex $Zn(papy)_2$ are significantly more acidic as a result of metal complexation;[9] similar effects, with accompanying optical changes, have been reported for grids containing a hydrazone N–H group.[7a] Addition of eight equivalents of triethylamine to acetonitrile solutions of **18** results in the precipitation of the neutral complex **19** as gold-colored crystals. This deprotonation reaction can be monitored by titration with triethylamine and monitoring with $^1$H NMR spectroscopy (Figure 2).

The chemical shift of the ethyl $CH_2$ group is consistent with the nearly complete protonation of the triethylamine throughout the titration, confirming the high acidity of these complexes. Early in the titration, the exchange coupling to the ammonium NH proton is clearly resolved, indicating that proton-exchange processes are confined to the grid complex; however, as the titration proceeds, loss of this

[a] Chemical shifts for ligands **7**–**10** and complexes **13**–**16** were recorded at 500 MHz, chemical shifts for ligands **11**–**12** and complexes **17**–**18** were recorded at 300 MHz. [b] *i* and *o* designate the inner and outer *ortho* and *meta* protons, respectively, on the phenyl substituent. [c] 1H NMR spectrum of **11** was recorded in $[D_6]$DMSO.

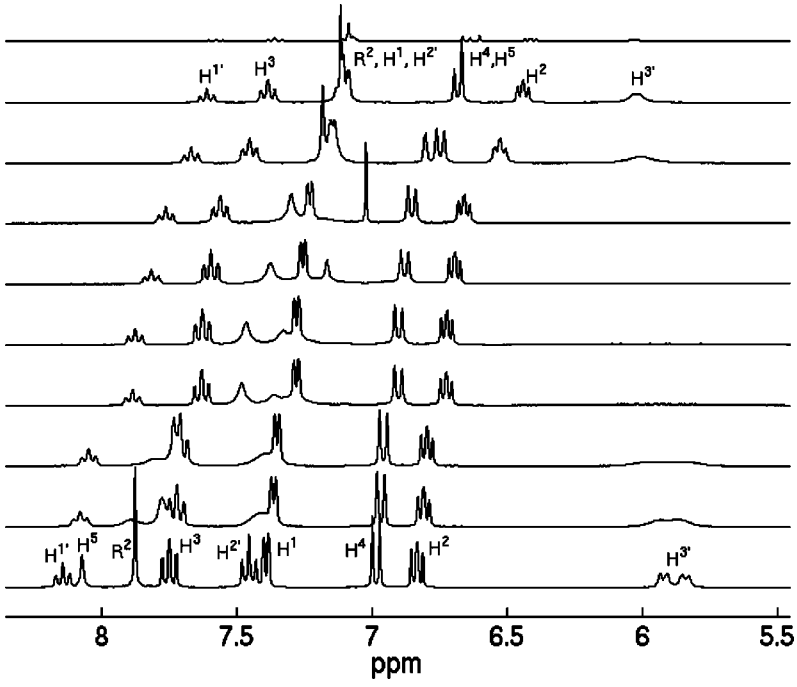

Figure 2. $^1H$ NMR of grid complex **17** with triethylamine in $[D_3]$acetonitrile. From bottom to top, the ratio $Et_3N$/**17** is 0.0, 0.7, 1.0, 2.5, 2.8, 3.5, 4.1, 5.0, 6.4, 7.9. The intensity of the last spectrum is reduced as a result of precipitation of the neutral complex.

resolution indicates rapid exchange of protons between the ammonium ion and the grid. During the titration, the $^1H$ NMR spectrum of the ligand undergoes a general upfield shift consistent with an increasing electron density on the ligand. The overall spectrum is remarkably simple indicating a rapid exchange of protons between sites on the grid, though significant broadening of some of the grid complex protons occurs. In particular, the imine and pyrimidine protons ($R^2$, $H^5$) show significant broadening consistent with deprotonation of the hydrazone N–H sites. Whereas the imine protons remain broadened until near the end of the titration, the pyrimidine proton appears as a sharp singlet around $Et_3N$/**18** ratios of 4:1 (i.e. deprotonation of half of the acidic NH sites). This is consistent with each ligand being deprotonated once before any are deprotonated a second time; with each ligand singly deprotonated, proton exchange does not significantly change the environment of the pyrimidine proton. More remarkable is the behavior of the phenyl *ortho* and *meta* protons, which rapidly broaden upon addition of traces of base. Halfway through the titration

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

these protons are barely visible as a broad rise in the baseline. The resonances only reappear toward the end of the titration but no longer show clear 'inner' and 'outer' peaks, which suggests a dynamic mechanism that allows rotation of the phenyl ring.

This is further supported by variable-temperature NMR studies of the neutral complex **19** in chloroform (Figure 3). While at room temperature the inner and outer phenyl protons are equivalent, lowering the temperature results in broadening of this resonance. Resolved inner and outer phenyl proton resonances were not observed for this complex above the freezing point of the solvent.

Repeating the titration in [$D_6$]DMSO results in significantly different observations (Figure 4). Initially, NMR indicates that the grid complex **18** is completely dissociated in [$D_6$]DMSO; the $^1$H NMR spectrum indicates only free ligand. Addition of $Et_3N$, however, results in loss of the free ligand and eventual formation of the neutral grid **19** upon

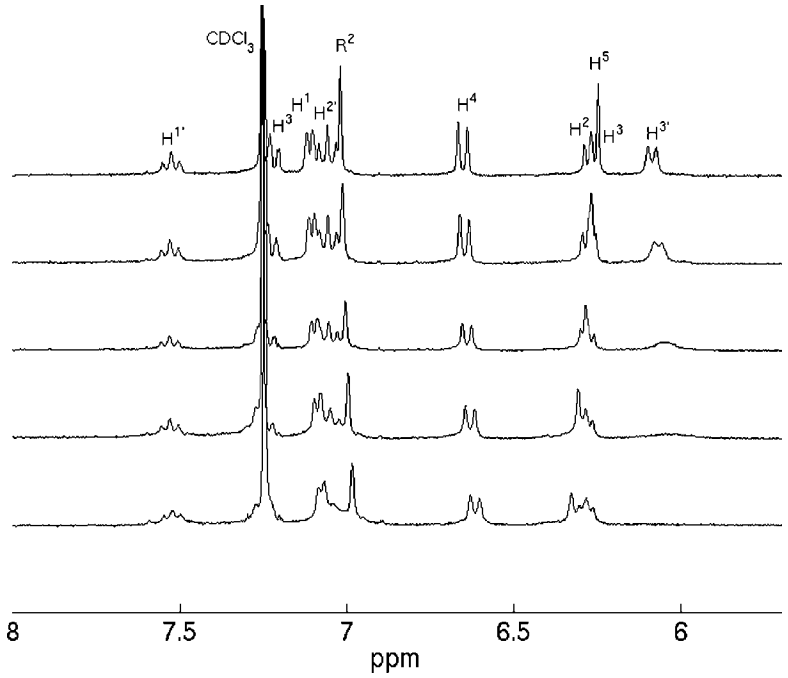

Figure 3. $^1$H NMR of neutral grid complex **19** in $CDCl_3$ at (top to bottom) 40 °C, 20 °C, 0 °C, –20 °C, –40 °C.

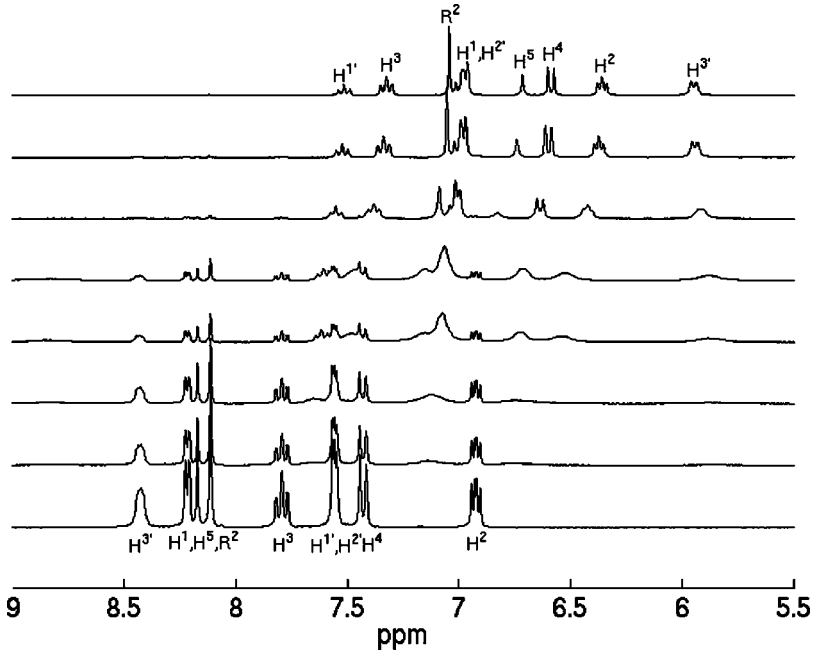

Figure 4. $^1$H NMR of grid complex **17** with triethylamine in [$D_6$]DMSO. From bottom to top, the ratio $Et_3N$/**17** is 0.0, 1.0, 2.0, 4.3, 5.0, 6.8, 9.3, 11.9.

addition of a full eight equivalents of base. That this is the only species in solution was confirmed by electrospray mass spectrometry. It is noteworthy that the coordinated ligand initially appears as very broad resonances in the $^1$H NMR spectrum, again indicative of dynamic processes, but upon completion of the titration a sharp spectrum is observed. Furthermore re-assembly of the grid is fast; the equilibration time allowed for collection of the data in Figure 4 was only that required to load and shim the sample and no further spectral changes were observed upon standing for 5–10 min.

## Discussion

The introduction of hydrazone links into the backbone of grid-forming ligands offers a means to modulate their properties and assembly through pH. The change in oxidation potential of protonated vs. unprotonated cobalt complexes has already been used to control the regioselective assembly of heterometallic cobalt grids.[7b] Zinc complexes provide an opportunity to study this acid–base chemistry without the added effects due to paramagnetism or redox chemistry. Any information on the pattern of deprotonation will give some information about the interactions within the grid complex. The quantitative protonation of triethylamine early in the titration clearly indicates the acidity of these complexes. Though the intermediate protonated grids undergo relatively rapid proton exchange on the NMR timescale, the presence of a sharp pyrimidine proton resonance at $Et_3N$/grid ratios of 4:1 indicates that not all of these are equally populated, and the ligands are all deprotonated once before they are further deprotonated. This suggests that there is significant delocalization of the negative charge along the backbone of the ligand. The intercalated phenyl ring could yield more information about the preferred tautomers; however, this is complicated by the presence of a dynamic process that allows interchange of inner and outer phenyl protons.

Rotation of the phenyl ring in a pyridine-type grid complex is a phenomenon that has not been previously observed. Examination of models suggests that simple phenyl rotation is unlikely because the cavity is too constrained; more likely is a mechanism in which one of the ligands partially dissociates allowing the initially intercalated phenyl group to rotate. In such a mechanism, the enhanced donor strength of the hydrazone anion ligand would increase the electron density on the metal ion and allow dissociation of one of the terminal pyridyl nitrogen atoms. The flexibility of the resulting five-coordinate metal-ion center would allow rotation of the phenyl ring before recoordination of the pyridine. The effect of the increased ligand donor strength accounts for the initially paradoxical observation of greater complex stability combined with greater flexibility observed in DMSO.

The NMR spectroscopic data and the X-ray crystal structure results suggest that in solution and in the solid state the complexes **13**–**18** adopt a very compact arrangement providing stable [2×2] hydrazone-grid arrays. The π–π stacking between the phenyl ring and the hydrazone units of the perpendicular ligands in the complexes induces a perfect orthogonal arrangement suitable for applications in self-organized metallosupramolecular systems.

## Experimental Section

**General:** Compounds **1** and **2** were obtained from commercial suppliers and used without purification. Compounds **3**, **4** and **5** were prepared according to the procedures described in the literature.[10] $^1$H NMR, COSY and ROESY correlation measurements were recorded with an ARX 500 MHz Bruker spectrometer or a JEOL Eclipse+ 300 MHz spectrometer in $CDCl_3$, [$D_6$]DMSO and $CD_3CN$, with the use of the residual solvent peak as reference. Mass spectrometric studies were performed in the positive ion mode with a quadrupole mass spectrometer (Micromass, Platform II) or an ion trap mass spectrometer (Agilent 1100 series). Samples were dissolved in acetonitrile and were continuously introduced into the mass spectrometer at a flow rate of 10 mL/min by using either a Waters 616HPLC pump or a syringe pump. The temperature (60 °C), and the extraction cone voltage ($V_c$ = 5–10 V) was usually set to avoid fragmentations. The microanalyses were carried out at Service de Microanalyses, Institut Charles Sadron, Strasbourg.

**General Procedure for the Synthesis of the Ligands 7–12:** Two equivalents of 2-pyridinecarboxaldehyde **1** or of 2-acetylpyridine **2** with one equivalent of dihydrazinopyrimidine **3** or of di-methylhydrazinopyrimidine **4** were refluxed in ethanol for 3 h. The resulting precipitates were filtered and washed with ethanol to give **7**–**12** as analytically pure compounds.

**Crystal Structure Determinations:** X-ray diffraction data for compounds **13**–**15** were collected with a Nonius Kappa charge-coupled device (CCD) diffractometer with a graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). $\varphi$ scans at 173 K, at the Laboratoire de Cristallochimie, Université Louis Pasteur, Strasbourg. The structures of the compounds **13**–**15** were determined using direct methods and refined (based on $F_2$ using all independent data) by full-matrix least-square methods (SHELXTL 97). Data were reduced by using the Bruker SAINT software. Hydrogen atoms were included at calculated positions by using a riding model. Single crystals of **13**–**15** were grown from acetonitrile/benzene. Crystals were placed in oil and a single crystal was selected, mounted on a glass fiber and placed in a low-temperature $N_2$ stream. The structure of **2-H** and **2-DH** were determined using direct methods and refined (based on $F_2$ using all independent data) by full-matrix least-square methods (SHELXTL 97). Hydrogen atoms were included at calculated positions by using a riding model.

**Complex [5$_4$Zn$_4$](CF$_3$SO$_3$)$_8$ (13):** Yellow single crystal of (**7**$_4$Zn$_4$)(CF$_3$SO$_3$)$_8$ (**13**), ($C_{120}H_{112}F_{24}N_{40}O_{24}S_8Zn_4$) of dimension 0.18×0.16×0.14 mm. The structure contains four grid complexes together with thirty two triflate anions and thirty two acetonitrile molecules. The unit cell was monoclinic with a space group of $C2/c$. Cell dimensions: $a$ = 27.5875(4) Å, $b$ = 26.9243(4) Å, $c$ = 20.1356(3) Å, $\alpha = \gamma$ = 90°, $\beta$ = 92.759(5)°, $V$ = 14938.9(4) Å$^3$ and $Z$ = 8 (FW is 7072, $\rho$ = 1.54 g cm$^{-3}$). Reflections were collected from 2.5° ≤ $\theta$ ≤ 27.48° for a total of 17483 of which 9423 were unique having $I > 3\sigma(I)$; number of parameters is 931. Final $R$ factors were $R_1$ = 0.103 (based on observed data), $wR_2$ = 0.121 (based on all data), GOF = 1.303, maximum residual electron density is 1.406 e·Å$^{-3}$.

**Complex [6$_4$Zn$_4$](CF$_3$SO$_3$)$_8$ (14):** Single yellow crystals of (**8**$_4$Zn$_4$)(CF$_3$SO$_3$)$_8$ (**14**), ($C_{120}H_{112}F_{24}N_{40}O_{24}S_8Zn_4$) of dimension 0.08×0.08×0.08 mm. The structure contains eight grid complexes together with sixty four triflate anions, thirty two acetonitrile molecules and thirty two water molecules. The unit cell was tetragonal with a space group of $P42/n$. Cell dimensions: $a$ = 17.9114(3) Å, $b$ = 17.9114(3) Å, $c$ = 22.7093(4) Å, $\alpha = \gamma = \beta$ = 90°, $V$ = 7285.6(2) Å$^3$ and $Z$ = 8 (FW is 3440, $\rho$ = 1.54 g cm$^{-3}$). Reflections were collected from 2.5° ≤ $\theta$ ≤ 27.48° for a total of 15477 of which 3415 were unique having $I > 3\sigma(I)$; number of parameters is 428. Final $R$ factors were $R_1$ = 0.087 (based on observed data), $wR_2$ = 0.107 (based on all data), GOF = 1.280, maximum residual electron density is 1.269 e·Å$^{-3}$.

**Complex [7$_4$Zn$_4$](CF$_3$SO$_3$)$_8$ (15):** Single yellow crystals of (**9**$_4$Zn$_4$)(CF$_3$SO$_3$)$_8$ (**15**), ($C_{136}H_{145}F_{24}N_{38}O_{28}S_8Zn_4$) of dimension 0.16×0.13×0.10 mm. The structure contains two grid complexes together with sixteen triflate anions, twelve acetonitrile molecules, three benzene molecules, two ethanol molecules and four water molecules. The unit cell was triclinic with a space group of $P\bar{1}$. Cell dimensions: $a$ = 18.212(2) Å, $b$ = 20.4537(2) Å, $c$ = 23.5718(4) Å, $\alpha$ = 99.242(5)°, $\beta$ = 1000.793(5)°, $\gamma$ = 103.058(5)°, $V$ = 82112(2) Å$^3$ and $Z$ = 2 (FW is 3830, $\rho$ = 1.51 g cm$^{-3}$). Reflections were collected from 2.5° ≤ $\theta$ ≤ 27.48° for a total of 64440 of which 14197 were unique having $I > 3\sigma(I)$; number of parameters is 1987. Final $R$ factors were $R_1$ = 0.072 (based on observed data), $wR_2$ = 0.097 (based on all data), GOF = 1.598, maximum residual electron density is 1.558 e·Å$^{-3}$.

# Mechanism of the MeOH/$H_2O$ Substitution in a Series of Biomimetic Bimetallo Zinc-Based $H_3O_2$ Complexes

**Elke Jaime[a] and Jennie Weston*[a]**

**Keywords:** Density functional calculations / Enzyme models / Metalloenzymes / $H_3O_2$ bridges / Zinc

Small bimetallo biomimetic zinc-based compounds containing a bridging μ-OH functionality can be easily hydrated to yield complexes containing an intramolecular Zn–$H_3O_2$–Zn bridge. Because such bridges are intrinsically more nucleophilic than the corresponding μ-OH functionality, this effectively activates the complex. The Zn–$H_3O_2$–Zn unit is labile, and one can successively substitute the "water" and the "hydroxide" in the bridge for methanol and methoxide to form metal-bound HO–H–OMe and MeO–H–OMe functionalities. We have performed an extensive density functional investigation of this substitution mechanism for a series of bimetallo zinc complexes which have been synthesised and investigated by F. Meyer et al. There are two mechanisms for water/methanol exchange – an addition–elimination and a direct exchange mechanism. If the metal ions are coordinatively unsaturated, and their ligand sphere does not sterically hinder the approach of the methanol, both pathways compete with each other. For coordinatively saturated bimetallo complexes with larger ligand spheres, only the direct exchange mechanism is possible. Regardless of the mechanism operating, the exchange is facile and is controlled by the relative thermodynamic stability of the intermediates.

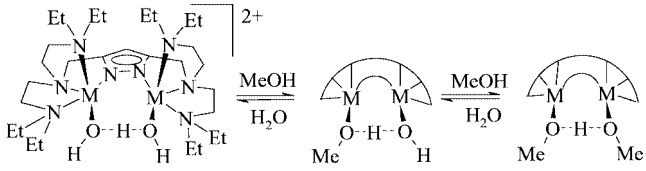
## Introduction

Binuclear metallo-hydrolases have been recognised as a wide class of enzymes which contain two divalent metal ions in close proximity to each other (3.5–4.5 Å apart) in the active site, that work together in a cocatalytic manner to activate various organic substrates for hydrolysis.[1] The resting state of these enzymes often contains a μ-hydroxide bridge where a deprotonated water molecule is shared between the ions.[1] This μ-OH linkage can be relatively easily hydrated to form an intramolecular M–$H_3O_2$–M functionality. This is not surprising because $H_3O_2^-$ anions are quite stable in the gas phase[2] and can even be crystallised as isolated $H_3O_2^-$ anions in the solid state.[3] In the meantime, small inorganic complexes containing such $H_3O_2$ linkages have been reported for most of the first-row transition-metal ions (V,[4] Cr,[5,6] Fe,[7] Co,[6,8] Ni,[9,10] Cu[10] and Zn[11]), as well as for Mo,[12] W[12] and Ru.[13] In several cases, F. Meyer et al. have shown that it is possible to *selectively* obtain the μ-OH or the M–$H_3O_2$–M form by fine-tuning the ligand environment.[9b,14] In addition, one can replace the μ-OH and/or the $H_3O_2$ functionality with other ligands; for example fluoride,[15] chloride,[16] nitriles,[9d] N=C=O,[9e] carboxylates,[9e,9f] urea,[9a,9b] or $N_3^-$.[17]

The pyrazolate dinucleating ligand **1a** developed by F. Meyer et al. leads to the urease biomimetic $\mathbf{1_{Ni}a}$ in the presence of nickel ions.[9a] The M–$H_3O_2$–M functionality in $\mathbf{1_{Ni}a}$ is rather labile, as extensive kinetic studies have shown (Scheme 1).[9a] If $\mathbf{1_{Ni}a}$ is dissolved in absolute methanol, a rapid ligand exchange occurs and a $CH_3O$–H–$OCH_3$ bridged species $\mathbf{1_{Ni}c}$ can be isolated.[9a] In methanol/water mixtures, an equilibrium between three different species ($\mathbf{1_{Ni}a}$, $\mathbf{1_{Ni}b}$ and $\mathbf{1_{Ni}c}$) occurs. At low water concentrations (0.1 M) the predominate species is $\mathbf{1_{Ni}b}$ which can be independently isolated.[18] Raising the $H_2O$ concentration to 2 M shifts the equilibrium to favour $\mathbf{1_{Ni}a}$.[9a]



Scheme 1. Methanol substitution in the $H_3O_2$ bridge of a binuclear urease biomimetic developed by F. Meyer et al.

Meyer's pyrazolate ligand **1a** can also be used to obtain the corresponding zinc ($\mathbf{1_{Zn}a}$)[18] and cobalt ($\mathbf{1_{Co}a}$)[19] "$H_3O_2$" complexes; both of which are possible functional models for binuclear phosphatases and/or peptidases. As for the nickel complex $\mathbf{1_{Ni}a}$, the M–$H_3O_2$–M functionality

in $\mathbf{1}_{Zn}\mathbf{a}$ and $\mathbf{1}_{Co}\mathbf{a}$ is relatively labile and can be successively exchanged with methanol in the same manner as illustrated in Scheme 1.[18,19]

Many mononuclear zinc complexes (biomimetics for carbonic anhydrase,[20] for example) contain a metal-bound hydroxide ligand. Although the p$K_a$ value of water (15.7) and methanol (15.1) are very similar, the Zn–OH form usually predominates in methanolic solutions, rather than the corresponding M–$OCH_3$ form.[21] In contrast to this, F. Meyer et al. have clearly demonstrated that, for the binuclear analogues, it is possible to select which form is present ($\mathbf{1}_{M}\mathbf{a}$, $\mathbf{1}_{M}\mathbf{b}$ or $\mathbf{1}_{M}\mathbf{c}$) by carefully controlling the reaction conditions.[18,19] This could possibly open new synthetic applications for functional binuclear biomimetica, and we have therefore, in co-operation with the research group of F. Meyer, recently become interested in the mechanism of this water/methanol exchange reaction.

There are fundamentally two possible mechanisms for the substitution of water bound in a bimetallo $H_3O_2$ linkage; both of which we considered in this study – an addition–elimination and a direct exchange mechanism. In the addition–elimination variant, the methanol first binds to one of the metal ions and, in a second step, displaces the water in the $H_3O_2$ bridge. Such an addition–elimination mechanism requires a free binding position at the metal ion, thus implicating a certain coordinative flexibility for the transition-metal ions involved. In the second variant, the methanol directly attacks the $H_3O_2$ bridge and replaces water through a direct exchange mechanism.

## Results and Discussion

### Model Systems

We selected three different model systems for study – a very simple carboxylate-bridged complex $\mathbf{2}_{Zn}\mathbf{a}$ (Scheme 2) which simulates the active site of many hydrolases containing two tetrahedrally coordinated metal ions held together by a bridging carboxylate ligand.[1] Compound $\mathbf{2}_{Zn}\mathbf{a}$ is small enough to investigate the hypersurface of these substitution reactions in detail. We then investigated the effect of the ligand sphere and the metal coordination geometry on the fundamental mechanism by means of Meyer's pyrazolate ligand-based complex $\mathbf{1}_{Zn}\mathbf{a}$,[18,19] and substituting the *N*-ethyl groups for *N*-methyl in order to reduce the calculational demand somewhat. This resulted in the model system $\mathbf{3}_{Zn}\mathbf{a}$. Increasing the complexity of the system, we then substituted the amino arms by pyridyl arms to yield the complex $\mathbf{4}_{Zn}\mathbf{a}$, which has also been reported by Meyer et al. to undergo reversible substitution by MeOH according to Scheme 1.[19] Both models $\mathbf{3}_{Zn}\mathbf{a}$ and $\mathbf{4}_{Zn}\mathbf{a}$ contain pentacoordinate metal ions. A comparison of all three of these models should allow us to determine how steric and electronic effects originating from the ligand sphere affects the intrinsic substitution mechanism(s). In all models, the ligand environments are symmetric for both metal cations. In the case of an asymmetric environment, the $H_3O_2$ functionality becomes polarised (as we have recently demonstrated for a computational model of the active site of bovine lens leucine aminopeptidase[22]) and one would need to investigate which "water" would be initially substituted. We selected zinc, because many of the natural systems are zinc-based hydrolases[1] and now report our findings in the present article. In continuance of our investigations, we are now calculating the cobalt analogues because many mechanistic investigations employ $Co^{2+}$-substituted enzymes due to the spectroscopic silence of $Zn^{2+}$.[23] It is quite often assumed that the mode of action of the $Co^{2+}$-substituted analogue parallels that of the natural $Zn^{2+}$-system – an assumption which we are now beginning to investigate in detail for these model compounds.

### Substitution Mechanism

Extensive calculations on the smallest model system $\mathbf{2}_{Zn}\mathbf{a}$ revealed that the hypersurface for the second methanol substitution is fundamentally the same as for the first. The following discussion therefore focuses on the mechanism of the first methanol/water exchange which is illustrated in Scheme 3 and Figure 1. The structures of the intermediates/transition structures involved in the second substitution can be found in the supporting information (Scheme S1 in the Supporting Information, for details see the footnote on the first page of this article).

As a methanol approaches the $H_3O_2$ bridge in compound $\mathbf{2}_{Zn}\mathbf{a}$, it interacts with the bridge to form a hydrogen-bonded initial encounter complex $\mathbf{2}_{Zn}\mathbf{E1}$. The methanolic oxygen is within electrostatic range (contact) of Zn1. In addition, the methanolic proton just barely "sees" the O2 in the $H_3O_2$ bridge. Each of these two rather weak electrostatic contacts is capable of opening up a different substitution pathway. If the MeOH swings up over transition structure $\mathbf{2}_{Zn}\mathbf{T1}$ and binds to Zn1 to generate the stable intermediate $\mathbf{2}_{Zn}\mathbf{1}$, a two-step addition–elimination mechanism is accessed. Addition of the MeOH triggers a conformational change from a tetrahedral to a trigonal bipyramidal binding situation at Zn1. This is a very low energy process with

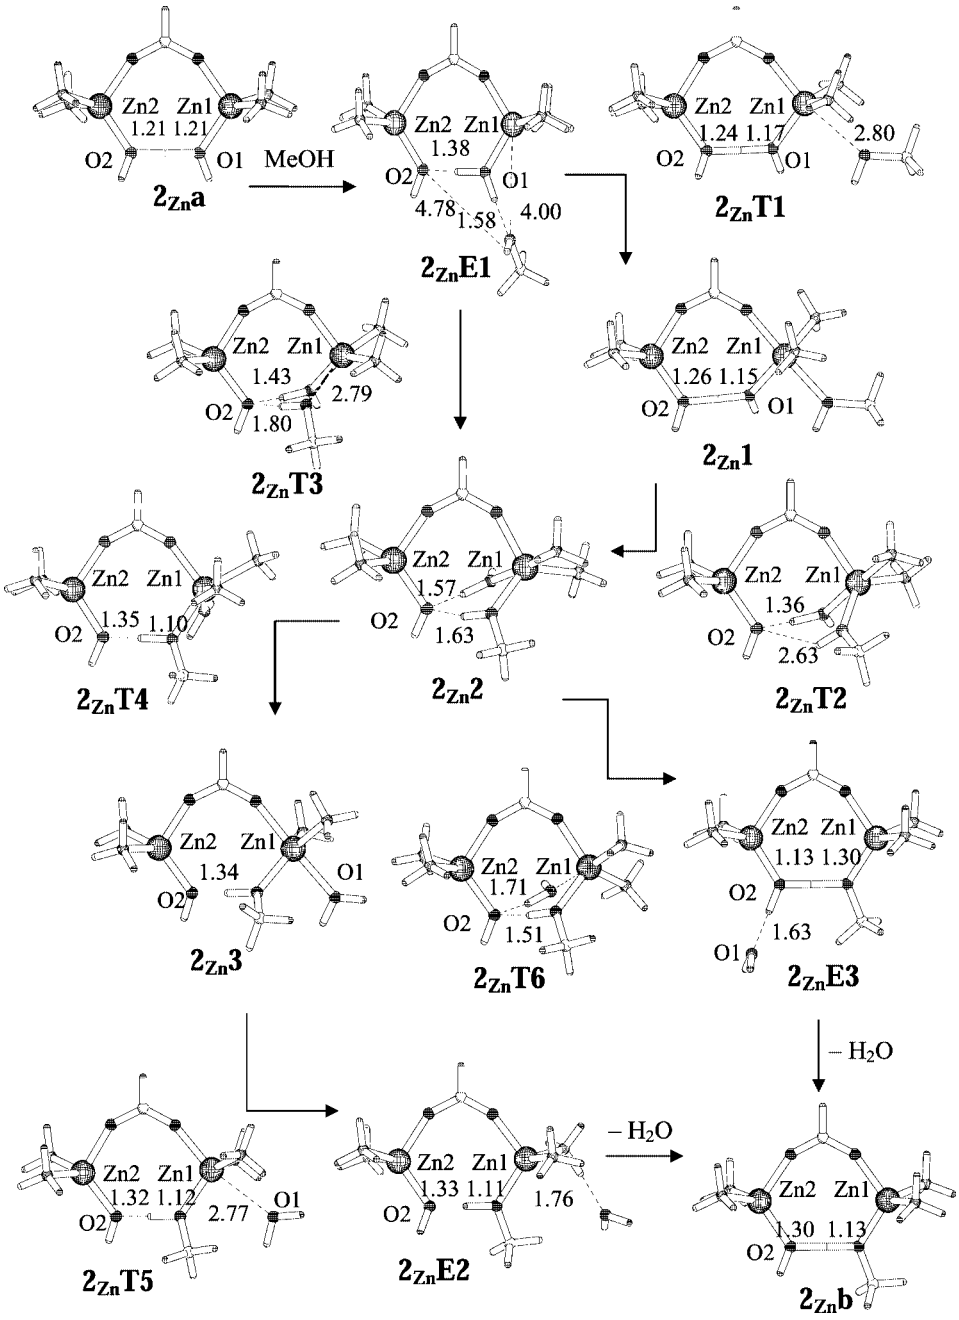

Scheme 3. Mechanism of the first $H_2O$/MeOH substitution in the model complex $\mathbf{2}_{Zn}$.

an activation barrier of only 3.3 kcal/mol respective to the encounter complex $\mathbf{2}_{Zn}$**E1** (Table 1). The differential coordination of the metal ions slightly polarises the $H_3O_2$ bridge in the direction of a Zn1-bound hydroxide and a Zn2-bound water in $\mathbf{2}_{Zn}$**1**. The barrier for hydrogen transfer is extremely low (less than 1 kcal/mol) and the hydrogen can easily move between both oxygen atoms in the bridge. In the second step of this addition–elimination pathway, a pseudorotation on Zn1 over the transition structure $\mathbf{2}_{Zn}$**T2** swings the MeOH into the plane of the bridge which begins to disrupt the $H_3O_2$ functionality. This coupled process exhibits a somewhat higher barrier (6.6 kcal/mol respective to $\mathbf{2}_{Zn}$**1**). The barrier is approximately additive, because 2–3 kcal/mol are needed for the pseudorotation and 3–4 kcal/mol for bridge distortion. In the course of this process, the methanolic proton builds a strong hydrogen bond to O2 which transfers the bridging hydrogen to O1. The stable intermediate $\mathbf{2}_{Zn}$**2** is generated, in which the MeOH and the (formerly bridging) water are now both bound in a lateral manner to Zn1 and a hydroxide (O2) is localised on Zn2.

In an alternative mechanism, intermediate $\mathbf{2}_{Zn}$**2** can be accessed in a one-step manner from the initial encounter complex $\mathbf{2}_{Zn}$**E1**. In this second pathway, the MeOH swings towards the $H_3O_2$ bridge over transition structure $\mathbf{2}_{Zn}$**T3** and inserts itself between the metal ions. In the absence of steric effects originating from the ligand sphere, the effective

| $\mathbf{2_{Zn}b}$ | –0.5 | $\mathbf{2_{Zn}c}$ | 1.2 |

barriers for both processes are very similar and an equilibrium between both pathways can be expected.

Complex $\mathbf{2_{Zn}2}$ now expels the Zn1-bound water. This can again occur through either a two-step or a one-step mechanism. In the first possibility, a pseudorotation at Zn1 over transition structure $\mathbf{2_{Zn}T4}$ pulls the water down and away from its bridging position. A stable HO–H–OMe bridged species $\mathbf{2_{Zn}3}$ results which contains a pentacoordinate zinc. The activation barrier (relative to intermediate $\mathbf{2_{Zn}2}$) for this pseudorotation is with 3.1 kcal/mol again quite low. The zinc ion in $\mathbf{2_{Zn}3}$ then regains its original tetrahedral geometry by kicking out the axial water over transition structure $\mathbf{2_{Zn}T5}$. As the water leaves, it first builds an encounter complex $\mathbf{2_{Zn}E2}$ in which the departing water forms a hydrogen bond to one of the ammonia ligands before it finally departs to yield $\mathbf{2_{Zn}b}$ in which one of the waters has been substituted by methanol.

Alternatively, $\mathbf{2_{Zn}2}$ can expel the water over a one-step mechanism. The water departs over $\mathbf{2_{Zn}T6}$ in a lateral manner and simply swings down to build an encounter complex $\mathbf{2_{Zn}E3}$ before finally departing. The monosubstituted complex $\mathbf{2_{Zn}b}$ is characterised by a slightly asymmetric O–H–O bridge in which the shared hydrogen is more tightly bound to the methanol than the hydroxide.

The mechanism for substitution by a second methanol is almost identical to that calculated for the first substitution and is therefore illustrated in the supporting information (Scheme S1). An incoming methanol interacts with the hydroxide in the HO–H–OMe bridge of $\mathbf{2_{Zn}b}$ to build an initial encounter complex identical to $\mathbf{2_{Zn}E3}$. A stable intermediate analogue to $\mathbf{2_{Zn}2}$ is then generated either over a two-step metal-based addition–elimination or a one-step direct insertion mechanism. A water is then eliminated through

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

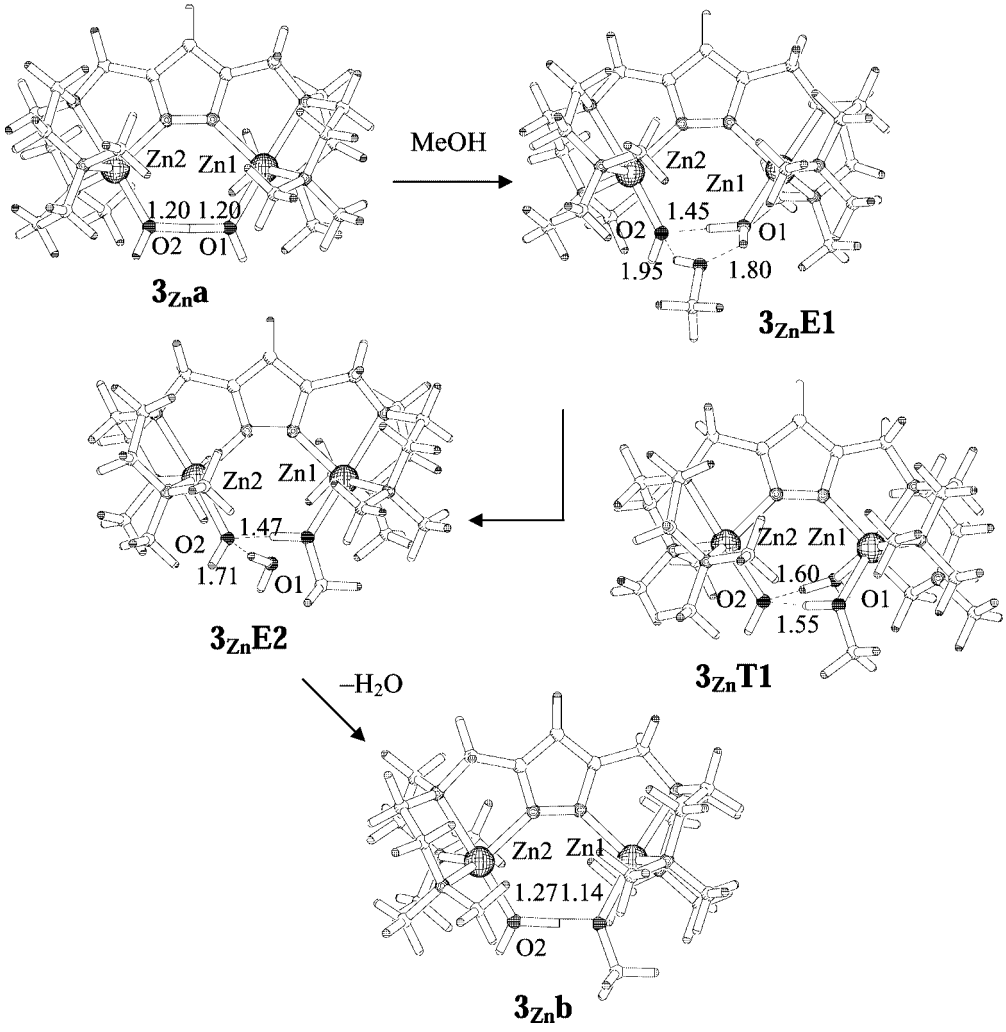
an analogous one- or two-step mechanism, which finally generates the bisubstituted product $\mathbf{2_{Zn}c}$ containing a symmetric MeO–H–OMe bridge.

As to be expected from the structural/mechanistic similarities calculated for both hypersurfaces (see Scheme 3 and Scheme S1 in the Supporting Information), the energetics of the first and the second substitution are very similar. All barriers are quite low (less than 10 kcal/mol), indicating that these processes are controlled by thermodynamic equilibrium processes. Throughout the course of these substitutions, the metal–metal distance remains with an average value of 4.57 Å quite constant.

The coordinational hypersurface is quite flat with pseudorotation barriers of only ca. 2–4 kcal/mol, thus facilitating an easy change in the coordination number. This is, in the case of zinc, not unusual[24] and is probably one of the reasons why nature often preferentially selects zinc over other transition-metal ions in the active site of multinuclear hydrolases.[1] Preliminary calculations (substitution of $Co^{2+}$ for $Zn^{2+}$ in model **2**) indicate that $Co^{2+}$ ions in binuclear systems also possess a flexible coordination sphere – and the mechanism for $H_2O$/methanol substitution is nearly independent of the identity of the metal ion.[25]

**Ligand-Sphere Effects**

We then turned our attention to the sterically more demanding system $\mathbf{3_{Zn}a}$ (Scheme 2) in which both metal ions are pentacoordinate. After extensive calculations, we conclude that the steric bulk of the ligands prevents an easy expansion to an octahedral coordination sphere. We did not succeed in finding a single stable intermediate with an axial Zn–OHMe coordination analogue to the species $\mathbf{2_{Zn}1}$ (Scheme 3). The hypersurface is thus considerably simplified because only a one-step, direct substitution mechanism is possible. Although bulky, the ligand environment allows the methanol to approach the $H_3O_2$ bridge in $\mathbf{3_{Zn}a}$ from beneath, and an initial hydrogen-bound encounter complex $\mathbf{3_{Zn}E1}$ is formed (Scheme 4). The methanol then swings in to interact with Zn1 (which undergoes a partial pseudorotation), thus disrupting the $H_3O_2$ bridge. In the transition structure $\mathbf{3_{Zn}T1}$, the MeOH and the (formerly bridging) water are now bound to Zn1, which is octahedrally coordinated, and a hydroxide is localised on Zn2. Steric constraints of the ligand environment stiffens the coordination sphere of Zn1 and destabilises $\mathbf{3_{Zn}T1}$, thus leading to a much larger barrier for the substitution (17.1 kcal/mol;



Scheme 4. Mechanism of the first $H_2O$/MeOH substitution in model complex $\mathbf{3_{Zn}}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2) than for the flexible model $\mathbf{2_{Zn}}$ (for which the corresponding structure $\mathbf{2_{Zn}2}$ is a stable intermediate). The complex $\mathbf{3_{Zn}T1}$ then eliminates the water which retains electrostatic contact with O2 and departs over a second encounter complex $\mathbf{3_{Zn}E2}$. The mechanism for introducing a second MeOH into the bridge to generate $\mathbf{3_{Zn}c}$ is completely analogue. The intermediates/transition structure for this second step can be found in Scheme S2 (Supporting Information).

Table 2. Relative energies (Gibb's free energies of reaction) for methanol/water exchange in the model complexes $\mathbf{3_{Zn}}$ and $\mathbf{4_{Zn}}$. Calculated at the B3LYP/lanl2dz level of theory and given in kcal/mol relative to $\mathbf{3_{Zn}a}$ or $\mathbf{4_{Zn}a}$ and a free methanol.

| | | $\mathbf{4_{Zn}c}$ | 6.9 |

The hypersurface is illustrated in Figure 2. Methanol exchange is an endothermic process and the intermediates $\mathbf{3_{Zn}b}$ (HO–H–OMe bridge) and $\mathbf{3_{Zn}c}$ (MeO–H–OMe) are 4.8 and 10.4 kcal/mol respectively less stable than the $H_3O_2$ form $\mathbf{3_{Zn}a}$. Although steric constraints have considerably increased the barriers ($\mathbf{3_{Zn}T1}$ = 17.1; $\mathbf{3_{Zn}T2}$ = 23.6 kcal/mol), they are still low enough to enable an equilibrium between the three species to take place under experimental conditions. It is therefore not surprising, that the bisubstituted form **c** can only be isolated from absolute methanol. The barrier for the second addition is higher than for the first, which corresponds well with the fact that the monosubstituted form **b** is preferred in water/methanol mixtures.[18,19]

The largest system we investigated is $\mathbf{4_{Zn}a}$ which contains *N*-pyridyl arms (Scheme 2). The methanol prefers to directly attack the $H_3O_2$ bridge in much the same manner as calculated for the system $\mathbf{3_{Zn}}$. An initial encounter complex $\mathbf{4_{Zn}E1}$ is formed, which then undergoes a metal-assisted insertion over $\mathbf{4_{Zn}T1}$ (Scheme 5). The *N*-pyridyl arms are not as rigid as the *N*-methyl arms in model $\mathbf{3_{Zn}}$ (the flat aromatic rings can swing out and away from the $H_3O_2$ functionality much better than the bulky *N*-methyl groups). The substitution barrier of $\mathbf{4_{Zn}T1}$ (10.5 kcal/mol) therefore lies considerably below that calculated for $\mathbf{3_{Zn}}$ (17.1 kcal/mol). Because of this increased flexibility, the hypersurface (Scheme 5 and Figure 2) is somewhat more complicated than for the model $\mathbf{3_{Zn}}$. There is enough room to comfortably bind both the MeOH and the water in a lateral manner to Zn1, and a stable intermediate $\mathbf{4_{Zn}1}$ results, which can be directly compared to $\mathbf{2_{Zn}2}$ calculated for the most flexible model system. The water molecule then leaves the coordination sphere of the zinc ions via the transition structure $\mathbf{4_{Zn}T2}$ to first generate the encounter complex $\mathbf{4_{Zn}E2}$ and finally the stable mixed bridged species $\mathbf{4_{Zn}b}$. As for all other models, the mechanism for the second substitution is identical to the first and is illustrated in the supporting information (Scheme S3).

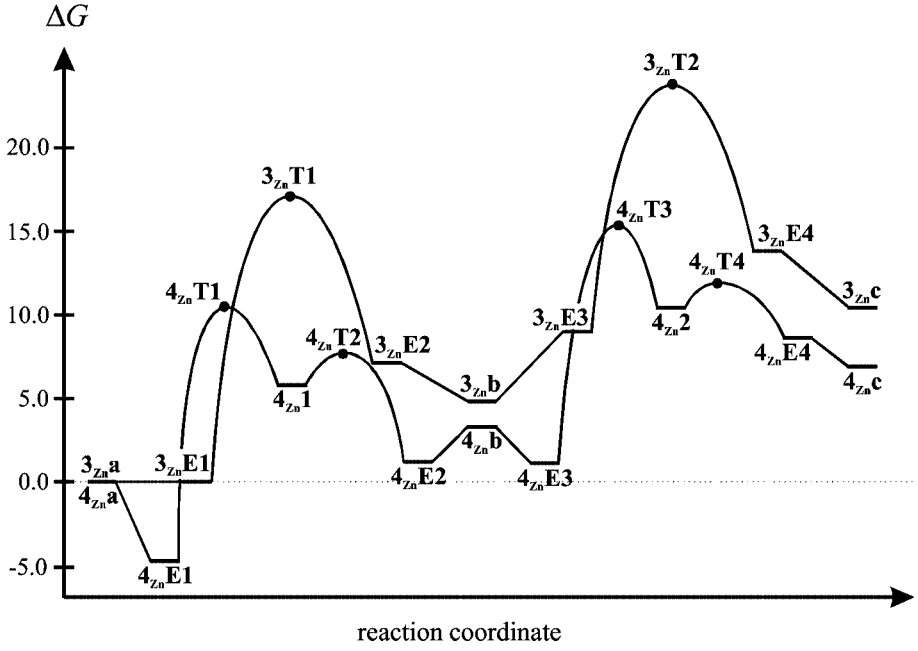

Figure 2. Energy diagram of water/methanol substitution in $\mathbf{3_{Zn}}$ and $\mathbf{4_{Zn}}$. Calculated at the B3LYP/lanl2dz level of theory and given relative to $\mathbf{3_{Zn}a}$ or $\mathbf{4_{Zn}a}$ and a free methanol.

**Relative Nucleophilicity**

Biomimetic complexes containing metallated A–O–H–O–B bridges (A, B = H and/or alkyl) are potentially quite interesting for synthetic applications because the refunctionalisation of simple esters, amides, phosphates, etc. under "biological" (mild) conditions is synthetically more valuable than their simple hydrolysis. We therefore addressed two final questions of interest – which functionality, the "hydroxide" or the "methoxide" in the bridge, will be the reacting nucleophile?

Due to the ionic nature of the Zn–O interactions, the oxygen atoms possess two lone electron pairs (the O–H–O three-centred bond and the OH/Me bonds are covalent in nature). One lone pair (sp-hybridised) is involved in the ionic bond and thus oriented towards the zinc cation. The orbital of the remaining lone pair is approximately p in character and is the only lone pair available (and properly oriented) for nucleophilic attack on an incoming substrate. The energy of this p-type orbital can be expected to be one of the major factors determining the nucleophilicity. The higher it lies, the easier will be an attack on the $\pi_{C=O}$* orbital of a substrate.

NBO (natural bond orbital) analyses (Table 3) show small but clear trends in the p-orbital energies as a function of increasing substitution by methanol. These trends are independent of the model (ligand sphere) selected. The "$H_3O_2$" species $\mathbf{X_{Zn}a}$ can clearly be expected to be the least and the "methoxide" species $\mathbf{X_{Zn}c}$ the most nucleophilic. It is quite interesting that, for mixed bridges ($\mathbf{X_{Zn}b}$), the calculations predict that the "hydroxide" will always be slightly (average difference of 0.2 eV in their orbital energies) more nucleophilic than the "methoxide". This means that practical applications (refunctionalisation instead of hydrolysis) will probably have to be carried out under non-aqueous conditions. The atomic charges (q) on oxygen in

| $\mathbf{2_{Zn}b}$ | $O_{wat}$ | –1.21 | –14.8 | $\mathbf{3_{Zn}b}$ | $O_{wat}$ | –1.23 | –13.0 | $\mathbf{4_{Zn}b}$ | $O_{wat}$ | –1.23 | –12.6 |
| | $O_{Me}$ | –0.95 | –14.5 | | $O_{Me}$ | –0.98 | –12.8 | | $O_{Me}$ | –0.99 | –12.4 |
| $\mathbf{2_{Zn}c}$ | $O_{Me}$ | –0.98 | –14.4 | $\mathbf{3_{Zn}c}$ | $O_{Me}$ | –1.01 | –12.6 | $\mathbf{4_{Zn}c}$ | $O_{Me}$ | –1.01 | –12.3 |

[a] Calculated using B3LYP/aug-cc-pVTZ wavefunctions. [b] Calculated using B3LYP/lanl2dz wavefunctions.

the bridges also show small but clear trends – opposing those calculated for the orbital energies. The oxygen atoms in the "$H_3O_2$" species $\mathbf{X_{Zn}a}$ are more negatively charged (average of 0.19 e) than those in the "methoxide" compounds $\mathbf{X_{Zn}c}$. This is due to the well known inductive effect of C–H bonds (partial delocalization of the negative charge on oxygen through hyperconjugation) and is a reason why charges should not be used to judge relative nucleophilicities.

## Conclusion

Extensive DFT calculations on a series of model complexes have provided mechanistic details for the experimentally observed replacement of water molecules by methanol (and other alcohols) in metallated M–$H_3O_2$–M functionalities. This replacement can occur through two fundamentally different substitution mechanisms – an addition–elimination, controlled by the metal ions, and a direct exchange mechanism in which the metal ions function as templates. If the ligand sphere in the bimetallo complex is flexible and there are free coordination holes on the metal ions, these mechanisms compete with each other. In the case of "stiff" ligands and a higher coordination number at the central ions, only the direct exchange mechanism is feasible. Stiffening the ligand sphere leads to an increase in the energy barrier for substitution. However, this effect is not enough to effectively hinder substitution under experimental conditions, and one can expect a thermodynamic equilibrium between all three possible intermediates ($H_3O_2$, HOHOMe and MeOHOMe bridges) to occur. A "methoxide" in such a bridge is fundamentally more nucleophilic than an "hydroxide". The "$H_3O_2$" form $\mathbf{X_{Zn}a}$ is clearly less nucleophilic than the "methoxide" form $\mathbf{X_{Zn}c}$. However, the "hydroxide" in a mixed species $\mathbf{X_{Zn}b}$ is more nucleophilic than the "methanol" component; a fact which will have experimental consequences.

## Computational Section

The calculations reported in this article were performed with the gradient-corrected, hybrid B3LYP[26] density functional using the Gaussian98[27] program package. In the case of the smallest model system $\mathbf{2_{Zn}}$, H, C, N and O were described with the very large correlation consistent aug-cc-pVTZ basis set.[28] The SDD basis[29] was employed for the central $Zn^{2+}$ ions. The size of the larger models $\mathbf{3_{Zn}}$ and $\mathbf{4_{Zn}}$ limited our computational investigations to the smaller lanl2dz basis set (D95[30] basis for the first row atoms and the Los Alamos effective core potential plus DZ was used for $Zn^{2+}$[31]). We found this smaller basis set to deliver qualitatively and quantitatively approximately the same results as the much larger aug-cc-pVTZ basis. All species found on the hypersurface were characterised as energetical minima or transition structures by vibrational analyses at the B3LYP/aug-cc-pVTZ or B3LYP/lanl2dz level of theory. Default convergence criteria were used and no symmetry was employed in any of the calculations. All relative stabilities reported are gas phase Gibb's free energies that contain standard thermochemical (298 K) and vibrational corrections. Natural bond orbital (NBO[32]) analyses were carried out using B3LYP/aug-cc-pVTZ (model $\mathbf{2_{Zn}}$) or B3LYP/lanl2dz wavefunctions (models $\mathbf{3_{Zn}}$ and $\mathbf{4_{Zn}}$) using NBO version 5.0[33] as patched into Gaussian98.

The mechanism for substitution by a second methanol is almost identical to that calculated for the first substitution for all model complexes ($\mathbf{2_{Zn}}$, $\mathbf{3_{Zn}}$ and $\mathbf{4_{Zn}}$) and is therefore illustrated in the supporting information, Schemes S1, S2 and S3 (see footnote on the first page of this article).

## Acknowledgments

Financial support by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 436, Jena, Germany) and by the Thüringer Ministerium für Wissenschaft, Forschung und Kultur (Erfurt, Germany) is gratefully acknowledged. Special thanks goes to Franc Meyer and his research group for providing us with unpublished solid-state structures and for stimulating discussions.

# Carboxylate-Containing Tin(IV) Isopropoxides: Synthesis and Characterization of $[Sn(OiPr)_2(O_2CR)_2]_2$ [R = $(CH_3)CCH_2$, $C_6H_5$, $CH_3$]

**Eugenia Martinez-Ferrero,[a] Kamal Boubekeur,[b] and François Ribot*[a]**

**Keywords:** Carboxylate ligands / Organic–inorganic hybrid composites / NMR spectroscopy / Sol–gel processes / Tin

Tin(IV) isopropoxide solvate has been modified by treatment with methacrylic, benzoic and acetic acid. For carboxylate to tin ratios ranging from 1.4 to 2, a dimer, namely $[Sn(\mu_2\text{-}OiPr)(OiPr)(O_2CR)_2]_2$ [R = $(CH_3)CCH_2$, $C_6H_5$, $CH_3$], is isolated. Its structure, as determined by X-ray diffraction on the methacrylate derivative, is based on two seven-coordinate tin atoms, terminal and bridging isopropoxy ligands, and purely chelating carboxylates. These compounds have also been characterized by $^{119}Sn$, $^{1}H$, and $^{13}C$ solution NMR and $^{119}Sn$ CP-MAS NMR spectroscopy. The possible use of this dimer as a precursor for carboxylate-modified tin–oxo clusters has been tested.

## Introduction

Hybrid organic–inorganic materials are excellent candidates for the design of new functional materials.[1] One approach to them relies on the chemical modification of metal alkoxides by suitable organic ligands,[2] which, in addition to providing a chemical link between the organic and inorganic components, control the reactivity of these precursors during the sol–gel process. The reaction of metal alkoxides with carboxylic acids, β-diketones, or related compounds is also often the first step in the synthesis of metal–oxo clusters of well-defined structure that can be used as versatile building blocks in the preparation of hybrid organic–inorganic materials.[3] Among the various modifying carboxylates used in the area of hybrid materials, the most extensively studied are probably methacrylate and acrylate, as they can be easily polymerized. A large number of modified transition metal–oxo clusters have been reported with these ligands[4–6] and polymerized with various co-monomers (e.g. methacrylic acid, methyl methacrylate) to yield materials with enhanced properties compared to those of the parent polymers.[7]

Methacrylic acid modified tin(IV) alkoxides have already been used to prepare tin dioxide thin films (with or without antimony doping).[8] The films were obtained by UV-induced free radical polymerization of the organic modifiers and the results showed that the direct photo-patterning process increases the conductivity of the films. The photo-patterned organo–metal polymer structures could, furthermore, be thermally decomposed into the corresponding metal oxides at elevated temperatures. However, these previous studies did not give any information about the structure of the methacrylate-modified tin(IV) alkoxides. Moreover, if compounds containing C–Sn bonds are excluded, there are only a few reports of tin(IV)–alkoxo clusters.[9] All this prompted us to look at the compounds formed by treating tin(IV) isopropoxide solvate with different carboxylic acids.

The work presented here reports the modification of tin(IV) isopropoxide solvate by methacrylic, benzoic, and acetic acids. The compounds $[Sn(OiPr)_2(O_2CR)_2]_2$ [R = $(CH_3)CCH_2$, $C_6H_5$, $CH_3$] were characterized by NMR spectroscopy ($^{119}Sn$, $^{1}H$, and $^{13}C$) and the X-ray structure of the methacrylate derivative was determined. The possibility of obtaining defined oxo clusters from this modified alkoxide was also tested.

## Results and Discussion

Crystals of $[Sn(OiPr)_2(OMc)_2]_2$ (**1**) were obtained with carboxylate to tin ratios ranging from 1.4 to 2 (see Experimental Section). According to previously reported data on the influence of the solvent in the preparation of mixed metal–oxo clusters,[9c,10] two different solvents, i.e. toluene and THF, were tested. No influence was found, and the same compounds were obtained with both solvents.

The structure of this complex was elucidated by single-crystal X-ray diffraction (Figure 1 and Table 1). The molecular unit corresponds to a centrosymmetric dimer containing two bridging isopropoxy groups. Each tin atom is also coordinated by two chelating carboxylate molecules. The remaining isopropoxy groups are terminal, resulting in an overall coordination number of seven for tin. The geometry around each tin atom is well described by a pentagonal

bipyramid, where O5 and O6 occupy the apical positions. The Sn–O bond lengths of the isopropoxy ligands are similar to those found in $[Sn(OiPr)_4{\cdot}HOiPr]_2$,[11a] and $[Sn(OiPr)_3(acac)]_2$,[11b] and are longer for the bridging groups [2.0601(5) and 2.0939(12) Å] than for the terminal ones [1.9549(16) Å]. The bridging isopropoxy ligands are planar, the sum of the angles about O6 being 360.0°. The angle at the oxygen atom of the in-plane terminal alkoxy is smaller in compound **1** [Sn1–O5–C9 = 119.21(12)°] than in $[Sn(OiPr)_4{\cdot}HOiPr]_2$ (139° and 160°)[11a] but similar to the ones observed in $[Sn(OiPr)_3(acac)]_2$ (122.0° and 124.4°)[11b] and $[Sn(OtBu)_4]$ (124.1° and 125.0°).[11a] These values of around 120° are expected for alkoxy ligands not involved in π-donation to the metal center. The carboxylate ligands are purely chelating and fairly symmetrical, with Sn–O bond lengths ranging from 2.1764(14) to 2.2465(15) Å. The charge of each carboxylate moiety is equally delocalized over the two oxygen atoms as the C–O bond lengths are almost identical [from 1.260(2) to 1.275(3) Å].

[a] Symmetry operation: $-x, -y, -z$.

To assess the purity of the crystalline precipitate the $^{119}$Sn solid-state NMR (CP-MAS) spectrum of compound **1** was recorded (Figure 2). It displays a single, sharp, isotropic resonance, at $\delta$ = –759 ppm, with an anisotropy ($\zeta$) and asymmetry ($\eta$) equal to 325 ppm and 0, respectively. The observation of a single resonance is in agreement with the presence of a unique tin environment in the crystal structure. Moreover, the axial (or nearly axial)[12] character of the chemical shielding tensor is in line with the pentagonal bipyramid coordination polyhedron.

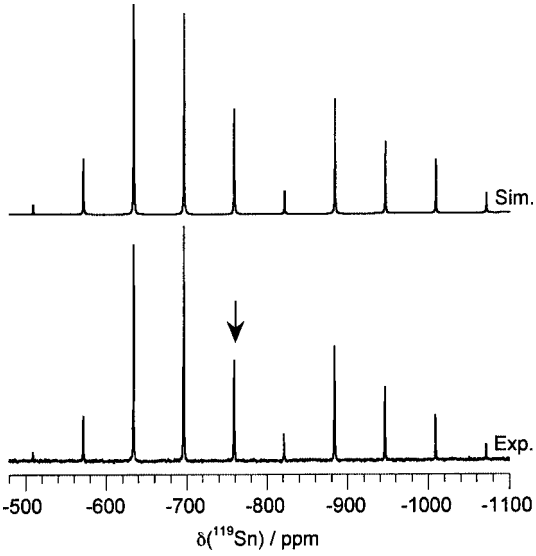

Figure 2. $^{119}$Sn CP-MAS NMR spectrum (111.9 MHz, $\nu_{MAS}$ = 7000 Hz) of $[Sn(OiPr)_2(OMc)_2]_2$ with its simulation (the arrow points to the isotropic chemical shift).

To the best of our knowledge there are very few reports of crystalline compounds in which a tin atom exhibits a sevenfold coordination based only on oxygen atoms ($SnO_7$ environment),[13] and no $^{119}$Sn NMR spectroscopic data have been reported for these compounds. For comparison, the $^{119}$Sn solid-state NMR (CP-MAS) spectrum of $[Sn(OiPr)_4{\cdot}HOiPr]_2$ was also recorded. It exhibits an isotropic chemical shift of $\delta$ = –654 ppm ($\zeta$ = 103 ppm and $\eta$ = 0.65) for its unique $SnO_6$ environment. The $^{119}$Sn NMR isotropic chemical shift of tin dioxide, in which tin is also six-coordinate, has been reported to be $\delta$ = –603 ppm.[14] For $SnO_8$ environments, there is a series of tin tetracarboxylates, the $^{119}$Sn NMR chemical shifts of which have been reported to lie in the range $\delta$ = –840 to –860 ppm,[15] and two tetrakis(*N*,*N*-dialkylcarbamato-*O*,*O'*)tin(IV) complexes, with $^{119}$Sn NMR chemical shifts of around $\delta$ = –925 ppm.[16] In conclusion, according to the general rules whereby an increase of one oxygen atom at tin causes a low-frequency shift of about 100 to 150 ppm,[17] the $^{119}$Sn NMR isotropic chemical shift observed for compound **1**, i.e. $\delta$ = –759 ppm, indeed falls in the expected range for a seven-coordinate tin atom surrounded only by oxygen atoms.

The $^{119}$Sn solution NMR spectrum of compound **1** shows a single narrow line at $\delta$ = –754.7 ppm, in very good agreement with the solid-state isotropic chemical shift and the heptacoordinate nature of tin. Moreover, this line exhibits a set of satellites the intensity and magnitude of which are consistent with a dimer and a two-bond $^{119}$Sn-$^{117}$Sn

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coupling constant. All these features indicate unambiguously that the molecular structure observed for compound **1** in the solid state is maintained in solution.

The $^{1}H$ and $^{13}C$ solution NMR spectra of compound **1**, at room temperature, indicate the presence of one type of methacrylate and two types of isopropoxy groups (2:1:1 ratio), in perfect agreement with the dimeric structure. The intensities of the $^{13}C$-$^{119/117}Sn$ coupling satellites for the methyne carbon of the isopropoxy groups account for about 19 and 35% of the resonances located at $\delta$ = 66.8 and 74.1 ppm, respectively. As a bridging alkoxy sees two tin atoms and a terminal alkoxy only one, the $^{13}C$ resonance at $\delta$ = 66.8 ppm can be assigned to the terminal isopropoxy groups while the one at $\delta$ = 74.1 ppm is assigned to the bridging ligands. This result shows that in compound **1**, the magnitudes of the $^{2}J_{^{13}C\text{-}^{119}Sn}$ coupling constants follow the rule observed for tin(IV) tetraalkoxide, i.e. they are larger for terminal alkoxides (ca. 40 Hz) than for doubly bridging alkoxides (ca. 20 Hz).[18] With these first assignments and with the help of 2D NMR experiments ($^{1}H$-$^{1}H$ COSY and $^{1}H$-$^{13}C$ HMQC), the $^{1}H$ and $^{13}C$ resonances of compound **1** have been fully attributed (Table 2). The $^{3}J_{^{1}H\text{-}^{119}Sn}$ coupling constants of the isopropoxy ligands appear to follow the same order as $^{2}J_{^{13}C\text{-}^{119}Sn}$ in that they are larger for a terminal than for a bridging alkoxy. These features likely arise from the longer Sn–O bond of a bridging alkoxy compared to a terminal one. The observation of several $^{n}J_{^{1}H\text{-}^{119}Sn}$ and $^{n}J_{^{13}C\text{-}^{119}Sn}$ scalar couplings, which, moreover, are different for the terminal and bridging isopropoxy groups, indicates that the exchange of ligands (isopropoxy or methacrylate) between different dimers and the exchange of terminal and bridging isopropoxy groups within the same dimer is either absent or very slow (slower than 1/*J*).

Syntheses were also performed with acetic or benzoic acid instead of methacrylic acid under the same conditions as for compound **1** (see Experimental Section). Transparent crystals were obtained with both acids and characterized by multinuclear NMR spectroscopy. Solution NMR ($^{119}Sn$, $^{1}H$, and $^{13}C$) clearly indicated that the same dimer is formed $[Sn(\mu_2\text{-}OiPr)(OiPr)(O_2CR)_2]_2$ (R = $CH_3$ or $C_6H_5$). Solid-state $^{119}Sn$ NMR (CP-MAS) spectra were also recorded for the benzoate (compound **2**) and acetate (compound **3**) derivatives. The spectra exhibit a single, sharp, isotropic resonance ($\delta$ = –757.3 and –759.5 ppm for **2** and **3**, respectively) very similar to the one reported for compound **1** and assigned to seven-coordinate tin atoms. Analysis of the spinning side-band manifolds for both compounds yields the same results, i.e. $\zeta$ = 280 ppm and $\eta$ = 0.0. As for compound **1**, the unique tin site of compounds **2** and **3** exhibits an axial environment. The tin shielding anisotropy is slightly smaller for compounds **2** and **3** than for **1**. This feature likely indicates that the tin environment in the acetate and benzoate derivatives is less distorted than in the methacrylate derivative.

Experiments with a carboxylate to tin ratio of 1 were also performed with acetic and benzoic acid. Clear solutions were obtained in toluene or THF and characterized by $^{119}Sn$ NMR spectroscopy (Figure 3). For benzoic acid (in THF), the $^{119}Sn$ NMR spectrum shows two main resonances of equal intensity (46% for each) at $\delta$ = –662.7 and –683.4 ppm, both with coupling satellites, the magnitude (180 Hz) and the intensity (17%)[19] of which are consistent with two nonequivalent tin atoms bridged by two alkoxy groups. The spectrum also shows minor resonances between $\delta$ = –632 and –654 ppm (8% for all). For acetic acid (in toluene), there are also two main resonances of equal intensity ($\delta$ = –664.9 and –687.5 ppm, 48% each), but their width prevented us from measuring the tin–tin scalar coupling which, however, could exist. The remaining 4% of tin atoms are located in a single minor resonance at $\delta$ = –645.3 ppm that could be assigned to tin isopropoxide solvate.[18] Bearing in mind that the tin starting material and the compound formed with two carboxylates per tin atoms are both dimers, it is reasonable to hypothesize that the major species formed with only one carboxylate per tin is also a dimer. Such a dimer has to be made of two nonequivalent six-coordinate tin atoms. Such a feature could arise from a molecular structure based on two edge-sharing octahedra {as in $[Sn(OiPr)\cdot HOiPr]_2$}[11a] with a chelating carboxylate on each tin (carboxylate/Sn = 1) but without any symmetry operation between the two carboxylates. Another possibility would be a dimer built by chelation, through two bridging isopropoxy ligands, of $[Sn(OiPr)_4]$ by $[Sn(OiPr)_2(O_2CR)_2]$. One tin atom would be coordinated by four terminal and two bridging isopropoxy groups, while the other would be coordinated by two chelating carboxylates and two bridging isopropoxy ligands. At this stage, there is no reason to prefer one possibility over the other.

Attempts were made to isolate the major compound by crystallization at low temperature or solvent evaporation and recrystallization. None of them were successful, but the $^{119}Sn$ NMR spectrum ($CDCl_3$) of the dried benzoate sample indicates a modification of the tin speciation. The peaks at $\delta$ = –662.8 and –683.2 ppm, assigned to a dimer, now account for only around 36% each, while two of the minor peaks, located at $\delta$ = –643.9 and –655.1 ppm increase to about 22 and 6%, respectively. The $^{1}H$ and $^{13}C$ spectra of the same sample reveal complex patterns made up of many different benzoates (at least six from the $^{13}C$ carbonyl signals at around $\delta$ = 172 ppm) and isopropoxy groups (at least ten from the $^{13}C$ methyne signals between $\delta$ = 77 and 65 ppm).

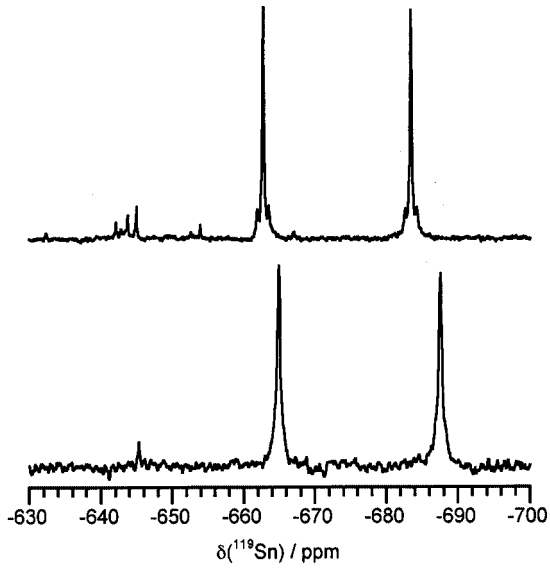

Figure 3. $^{119}$Sn NMR spectra (111.9 MHz) of $[Sn(OiPr)_4{\cdot}HOiPr]_2$ with 2 equiv. of benzoic acid in THF (top) and 2 equiv. of acetic acid in toluene (bottom).

Crystals of compounds **1**, **2**, and **3**, which exhibit a carboxylate to tin ratio of 2, can be precipitated for initial ratios smaller than 2. Therefore, some tin-containing species must remain in solution. Their nature was studied in the case of the benzoate derivative only. Compound **2** was prepared, in toluene, with a benzoic acid to tin ratio of 1.5 and the $^{119}$Sn NMR spectrum was recorded for the solution once the crystals of **2** had been removed. The spectrum exhibits the same resonances as those described for an experiment with a benzoic acid to tin ratio of 1.0. It also shows a small peak at around $\delta$ = –751 ppm that can be assigned to compound **2**. In conclusion, the tin-containing species that remain in solution correspond mainly to the dimer made of two nonequivalent tin atoms and discussed above.

The formation of carboxylate-modified metal–oxo clusters upon treatment of metal alkoxides with carboxylic acids generally results from esterification reactions[20,21] that can take place between free acid and released alcohol molecules, which results in the slow generation of water in situ for the controlled hydrolysis and condensation of the remaining alkoxy groups, or between a bonded carboxylate and a bonded alkoxy group, which yields an M–O–M link and an ester directly. Studies performed on titanium oxoacetate clusters have demonstrated that a very small increase of the AcOH/Ti ratio favors the formation of more condensed species. However, extreme conditions (e.g. solvothermal synthesis) might be needed in order to force the esterification process.[22] For instance, $[SnO(OtBu)(OAc)]_6$, a tin(IV) carboxylate oxo cluster, can only be obtained by refluxing $[Sn(OtBu)_4]$ and $[Sn(OAc)_4]$ in toluene, a noncoordinating solvent.[9c] We tried several approaches to the possible formation of well-defined methacrylate-modified tin–oxo clusters with compound **1** as precursor. Solvothermal treatment or refluxing compound **1** in different solvents (THF, DMF, toluene) gave gels or clear solutions. The $^{119}$Sn NMR spectra of the latter did not indicate any new resonance that could be associated with the formation of new, well-defined molecular species. Direct addition of various amounts of water to compound **1** always yielded transparent gels that are insoluble in organic solvents or turbid solutions that did not show any significant signals in the solution NMR spectra that could be linked back to a well-defined methacrylate-modified tin–oxo clusters.

In an alternative approach to prepare well-defined, methacrylate-modified tin–oxo clusters, syntheses were performed with higher McOH/Sn molar ratios, i.e. 5 and 10. In both cases a white precipitate was obtained. These precipitates are soluble in $CDCl_3$ but their $^{119}$Sn NMR spectra are silent and their $^1$H NMR spectra show only the presence of methacrylate ligands. The absence of any well-defined $^{119}$Sn NMR resonance might be attributed to the formation of ill-defined oxo polymers,[23] either by esterification or parasitic hydrolysis, but in any case indicates clearly that this alternative approach is not more successful for preparing well-defined, methacrylate-modified tin–oxo clusters.

## Conclusions

The behavior of tin(IV) isopropoxide towards the addition of different carboxylic acids (methacrylic, benzoic, and acetic) has been studied. The nature of the carboxylic acid does not affect the final result. Moreover, the solvent (i.e. toluene or tetrahydrofuran) does not seem to play any major role either. Thus, the main parameter is the carboxylate to metal molar ratio. For a ratio of 1, a dimer based on hexacoordinate tin atoms is likely formed but its exact structure remain unknown. For ratios between 1.4 and 2 the compound $[Sn(\mu_2\text{-}OiPr)(OiPr)(O_2CR)_2]_2$ [R = $(CH_3)CCH_2$, $C_6H_5$, and $CH_3$], based on heptacoordinate tin atoms, is isolated. Ratios higher than 2 do not seem to yield well-defined oxo species, as for titanium or zirconium,[21] but probably result in the formation of ill-defined polymeric species.

Studies with other tin(IV) alkoxides are in progress to check the influence of the nature of the alkoxide ligand on the carboxylate substitution reactions.

## Experimental Section

**Synthesis:** All the reactions were carried under inert atmosphere using Schlenk tubes and vacuum-line techniques. The compound $[Sn(OiPr)_4{\cdot}HOiPr]_2$ was prepared by isopropanolysis of $[Sn(OtBu)_4]$, which was obtained according to literature methods and purified by vacuum distillation.[24] The reactions between tin(IV) isopropoxide solvate and carboxylic acids were performed in toluene or tetrahydrofuran (THF) as tin(IV) isopropoxide solvate shows little solubility in its parent alcohol (2-propanol).

**$[Sn(OiPr)_2(OMc)_2]_2$ (OMc = methacrylate) (1):** A solution of methacrylic acid (1.22 g, 14.2 mmol) in THF (4.6 mL) was added to $[Sn(OiPr)_4{\cdot}HOiPr]_2$ (3.03 g, 3.7 mmol, McOH/Sn = 1.94). The resulting clear solution was kept at –18 °C after stirring. Crystals of **1** were obtained after one week. For $^1$H and $^{13}$C NMR ($C_6D_6$,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

25 °C) data see Table 2. $^{119}$Sn NMR ($C_6D_6$, 25 °C): $\delta$ = –754.7 ppm ($^2J_{^{119}Sn,^{117}Sn}$ = 190 Hz, with satellites corresponding to 7.3% of the total intensity). Yield: 76.7% (2.28 g). Compound **1** is highly soluble in chloroform, dichloromethane, and benzene. It is poorly soluble in acetonitrile, DMSO, and 2-propanol.

**[Sn(O*i*Pr)$_2$(O$_2$CC$_6$H$_5$)$_2$]$_2$ (2):** A similar compound was obtained by replacing methacrylic acid with benzoic acid. A solution of benzoic acid (0.91 g, 7.5 mmol) in THF (6 mL) was added to [Sn(O*i*Pr)$_4$·HO*i*Pr]$_2$ (2.00 g, 2.4 mmol, $C_6H_5CO_2H$/Sn = 1.55). $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 8.22 (d, 8 H, *o*-$C_6H_5CO_2$), 7.67 (m, 4 H, *p*-$C_6H_5CO_2$), 7.49 (m, 8 H, *m*-$C_6H_5CO_2$), 5.10 [sept, $^3J_{^1H\text{-}^{119/117}Sn}$ = 70 Hz, 2 H, OC*H*(CH$_3$)$_2$], 4.18 [sept, $^3J_{^1H\text{-}^{119/117}Sn}$ = 90 Hz, 2 H, OC*H*(CH$_3$)$_2$], 1.37 [d, 12 H, OCH(C*H*$_3$)$_2$], 1.08 [d, 12 H, OCH(C*H*$_3$)$_2$] ppm. $^{13}$C NMR ($CDCl_3$, 25 °C): $\delta$ = 178.0 [$^2J_{^{13}C\text{-}^{119/117}Sn}$ = 26 Hz, $C_6H_5CO_2$], 134.0 (*p*-$C_6H_5CO_2$), 131.5 (*o*-$C_6H_5CO_2$), 128.5 (*m*-$C_6H_5CO_2$), 127.9 ($^3J_{^{13}C\text{-}^{119/117}Sn}$ = 33 Hz, *i*-$C_6H_5CO_2$), 74.2 [$^2J_{^{13}C\text{-}^{119/117}Sn}$ = 17 Hz, $\mu_2$-OCH(CH$_3$)$_2$], 66.5 [$^2J_{^{13}C\text{-}^{119/117}Sn}$ = 54 Hz, OCH(CH$_3$)$_2$], 27.0 [$^3J_{^{13}C\text{-}^{119/117}Sn}$ = 48 Hz, OCH(*C*H$_3$)$_2$], 24.0 [$\mu_2$-OCH(*C*H$_3$)$_2$] ppm. $^{119}$Sn NMR ($CDCl_3$, 25 °C): $\delta$ = –751.3 ppm ($^2J_{^{119}Sn,^{117}Sn}$ = 180 Hz, with satellites corresponding to 8.7% of the total intensity). Yield: 58.9% (1.354 g).[25] Compound **2** is highly soluble in chloroform, dichloromethane, and benzene. It is poorly soluble in acetonitrile, DMSO, and 2-propanol.

**[Sn(O*i*Pr)$_2$(O$_2$CCH$_3$)$_2$]$_2$ (3):** A similar compound was obtained by replacing methacrylic acid by acetic acid. A solution of acetic acid (0.44 g, 7.4 mmol) in toluene (3 mL) was added to [Sn(O*i*Pr)$_4$·HO*i*Pr]$_2$ (2.00 g, 2.4 mmol, $CH_3CO_2H$/Sn = 1.53). $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 4.72 [sept, $^3J_{^1H\text{-}^{119/117}Sn}$ = 70 Hz, 2 H, OC*H*(CH$_3$)$_2$], 4.10 [sept, $^3J_{^1H\text{-}^{119/117}Sn}$ = 90 Hz, 2 H, OC*H*(CH$_3$)$_2$], 2.18 (s, 12 H, O$_2$CC*H*$_3$) 1.35 [d, 12 H, OCH(C*H*$_3$)$_2$], 1.14 [d, 12 H, OCH(C*H*$_3$)$_2$] ppm. $^{13}$C NMR ($CDCl_3$, 25 °C): $\delta$ = 183.6 ($^2J_{^{13}C\text{-}^{119/117}Sn}$ = 26 Hz, $CH_3CO_2$), 73.8 [$^2J_{^{13}C\text{-}^{119/117}Sn}$ = 16 Hz, $\mu_2$-OCH(CH$_3$)$_2$], 66.4 [$^2J_{^{13}C\text{-}^{119/117}Sn}$ = 52 Hz, OCH(CH$_3$)$_2$], 27.0 [$^3J_{^{13}C\text{-}^{119/117}Sn}$ = 47 Hz, OCH(*C*H$_3$)$_2$], 24.0 [$\mu_2$-OCH(*C*H$_3$)$_2$], 18.3 ($^3J_{^{13}C\text{-}^{119/117}Sn}$ = 32 Hz, *C*H$_3$CO$_2$) ppm. $^{119}$Sn NMR ($CDCl_3$, 25 °C): $\delta$ = –748.4 ppm ($^2J_{^{119}Sn,^{117}Sn}$ = 190 Hz, with satellites corresponding to about 8% of the total intensity). Yield: 24.4% (0.418 g).[25] Compound **3** is highly soluble in chloroform, dichloromethane, benzene and poorly soluble in acetonitrile, DMSO, and 2-propanol.

**Chemical Analyses:** Despite numerous attempts, including sampling under inert atmosphere, chemical analyses matching reasonably well the expected results could not be obtained due to a too high sensitivity of the sample to moisture. However, the $^{119}$Sn solid-state and solution NMR ($^{119}$Sn, $^1$H, and $^{13}$C) spectra indicate that the samples are pure.

**NMR Spectroscopy:** $^1$H, $^{13}$C, and $^{119}$Sn solution NMR experiments were performed on a Bruker AC300 spectrometer (300.13, 75.47, and 111.92 MHz for $^1$H, $^{13}$C, and $^{119}$Sn, respectively). $CDCl_3$ and $C_6D_6$ were used as solvent and internal lock. $^1$H and $^{13}$C chemical shifts are quoted relative to TMS, using the solvent or its protonated impurities as secondary internal reference ($^1$H: $\delta$ = 7.26 and 7.16 ppm for $CHCl_3$ and $C_6HD_5$, respectively; $^{13}$C: $\delta$ = 77.16 and 128.06 ppm for $CDCl_3$ and $C_6D_6$, respectively).[26] The $^{119}$Sn chemical shifts are quoted relative to external tetramethyltin ($\delta$ = 0 ppm). To avoid the loss of quantitativity that can arise from the Nuclear Overhauser effect, $^{119}$Sn-{$^1$H} spectra were obtained with an inverse gated decoupling sequence (pulse of about 30°, recycling delay set to 2 s for an acquisition/decoupling time of 0.18 s). $^1$H-$^1$H COSY and $^1$H-$^{13}$C HMQC experiments were performed on a Bruker Avance 400 spectrometer (400.13 and 100.61 MHz for $^1$H and $^{13}$C, respectively).

$^{119}$Sn solid-state NMR (CP-MAS) spectra were recorded at room temperature on a Bruker Avance 300 spectrometer (111.92 MHz for $^{119}$Sn) equipped with a 4-mm locked Bruker probe. The chemical shifts are quoted relative to tetramethyltin ($\delta$ = 0 ppm) using tetracyclohexyltin ($\delta$ = –97.35 ppm) as a secondary external reference. At least two different MAS speeds were used to locate the isotropic chemical shifts unambiguously. The contact time was 3 ms and the recycling delay 3 s. The chemical shielding tensor analyses were performed according to Herzfeld and Berger[27] using the software "dm2004".[28] The results are reported as the isotropic chemical shift ($\delta_{iso}$), the anisotropy ($\zeta = \sigma_{33} - \sigma_{iso}$), and the asymmetry ($\eta = |\sigma_{22} - \sigma_{11}|/|\zeta|$), with $\delta_{iso} = -(\sigma_{11} + \sigma_{22} + \sigma_{33})/3 = -\sigma_{iso}$ and the principal components of the tensor labeled according to $|\sigma_{33} - \sigma_{iso}| > |\sigma_{11} - \sigma_{iso}| > |\sigma_{22} - \sigma_{iso}|$.

**Crystal Structure Determination:** A single crystal of the moisture-sensitive compound **1** was selected, rapidly mounted on a glass fiber, and transferred into a cold nitrogen gas stream. Diffraction data were collected on a Nonius KappaCCD diffractometer at 123 K. Unit-cell parameters determination, data collection, and integration were carried out with the Nonius EVAL-14 suite of programs.[29] The data were corrected for absorption by a multi-scan method.[30] The structure was solved by direct methods with SHELXS-86,[31] refined by full-matrix least-squares on $F^2$ and completed with SHELXL-97.[32] Graphics were produced with DIAMOND.[33] All non-H atoms were refined with anisotropic displacement parameters and H atoms were simply introduced at calculated positions (riding model).

$C_{28}H_{48}O_{12}Sn_2$, $M$ = 814.04, monoclinic, $a$ = 11.1180(10), $b$ = 11.1316(10), $c$ = 14.3234(13) Å, $\beta$ = 101.36°, $V$ = 1737.9(3) Å$^3$, $T$ = 123(2) K, $P2_1/n$, $Z$ = 2, $d_{calcd.}$ = 1.556 g cm$^{-3}$, $\lambda$(Mo-$K_\alpha$) = 0.71073, $\mu$(Mo-$K_\alpha$) = 1.492 mm$^{-1}$, 28539 reflections measured, 6040 unique ($R_{int}$ = 0.0791) which were used in all calculations. The final $wR(F)^2$ was 0.0770 (all data).

CCDC-256335 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

This work was supported in part by the European Community's Human Potential Program under contract HPRN-CT-2002-00306 (NBB Hybrids). E.M.-F. thanks the European Community for financial support [HPRN-CT-2002-00306 (NBB Hybrids)]. Ms. Marie-Nöelle Rager is gratefully acknowledged for her kind and valuable help in recording and processing the 2D NMR spectra.

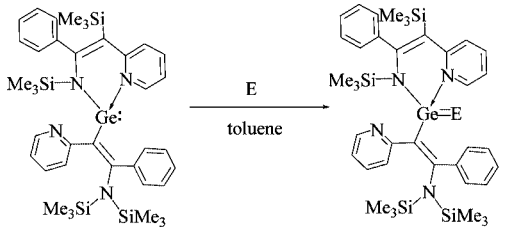
## Introduction

Compounds containing a double bond between group 14 and 16 elements are considered to be unstable due to the weak pπ–pπ bonding.[1] Nevertheless, stable chalcogenogermane and -stannane (>M=E) (M = Ge, Sn; E = S, Se, Te) complexes have been isolated in the past few years.[2] These compounds are either base-stabilized or stabilized by sterically bulky protecting group. For example, [{$\eta^4$-$Me_8$taa}M=E] (M = Ge, Sn; E = S, Se; $\eta^4$-$Me_8$taa = octamethyldibenzotetraaza[14]annulene),[3] [(Tbt)(Tip)Ge=E] {Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl; Tip = 2,4,6-triisopropylphenyl; E = S, Se, Te},[4] and [$R^N_2$M=E] [$R^N$ = CPh($SiMe_3$)$C_5H_4$N-2; M = Ge; E = S, Se, Te; $R^N$ = CH($SiMe_3$)$C_9H_6$N-8; M = Sn; E = S, Se, Te][5] have been reported. In contrast, chalcogeno group 14 metal halide complexes [RM(E)X] are rare, and to date only the complexes [{HC(CMeNAr)$_2$}Ge(E)X] (Ar = 2,6-*i*$Pr_2C_6H_3$, Ph; E = S, Se; X = F, Cl) have been prepared and structurally characterized.[6]

Recently, we have reported the synthesis of [Ge{C($C_5H_4$N-2)C(Ph)N($SiMe_3$)$_2$}{N($SiMe_3$)C(Ph)C($SiMe_3$)($C_5H_4$N-2)}] and [Ge{N($SiMe_3$)C(Ph)C($SiMe_3$)($C_5H_4$N-2)}Cl] from the reaction of $GeCl_2$·dioxane with the [3-(pyrid-2-yl)-1-azaallyl]lithium complex [Li{N($SiMe_3$)C(Ph)C(R)($C_5H_4$N-2)}]$_2$.[7] Herein, we report the synthesis of chalcogenogermanium complexes from the direct reaction of these complexes with elemental chalcogens.

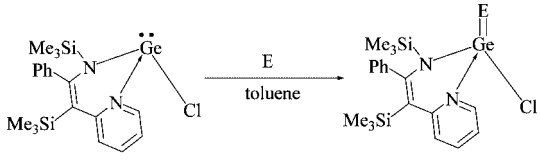
## Results and Discussion

The reaction of [Ge{C($C_5H_4$N-2)C(Ph)N($SiMe_3$)$_2$}{N($SiMe_3$)C(Ph)C($SiMe_3$)($C_5H_4$N-2)}] (**1**) with a stoichiometric amount of elemental chalcogen in toluene afforded the thermally stable germanethione **3** and -selone **4** (Scheme 1). Similarly, treatment of [Ge{N($SiMe_3$)C(Ph)C($SiMe_3$)($C_5H_4$N-2)}Cl] (**2**) with an equimolar amount of elemental chalcogen in toluene gave the thermally stable complexes [Ge(E){N($SiMe_3$)C(Ph)C($SiMe_3$)($C_5H_4$N-2)}Cl] [E = S (**5**), Se (**6**)] (Scheme 2).



**1** E = S (**3**), Se (**4**)

Scheme 1.



**2** E = S (**5**), Se (**6**)

Scheme 2.

Compounds **3**–**6** are yellow, crystalline solids that are soluble in $Et_2O$, toluene, and THF and sparingly soluble in hydrocarbon solvents. The $^{13}$C NMR spectra of **3** and **4** display three sharp singlets assignable to the three types of $SiMe_3$ groups, consistent with the solid-state structure. The $^1$H and $^{13}$C NMR spectra of **5** and **6** show a similar pattern and display one set of signals due to the 3-(pyrid-2-yl)-1-azaallyl ligand.

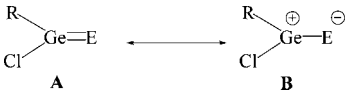
The $^{77}Se$ NMR spectrum of **4** displays a singlet at $\delta$ = –28.63 ppm, whereas the $^{77}Se$ NMR spectrum of **6** displays a singlet at $\delta$ = –266.21 ppm, which is similar to that found for [{HC(CMeNAr)$_2$}Ge(Se)Cl] (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$; $\delta$ = –228 ppm). The values for **4** and **6** lie between those of [Ge{(NSiMe$_3$)$_2$}$_2$(μ-Se)]$_2$ ($\delta$ = –476.0 ppm)[8] and [(Tbt)(Tip)Ge=Se] ($\delta$ = 940 ppm).[4b] We suggest that **4** and **6** exist as intermediates between the resonance forms **A** and **B** in solution (Scheme 3).



Scheme 3.

The molecular structures, with the atom-numbering schemes, of compounds **3** and **6** are shown in Figures 1 and 2, respectively. Selected bond lengths and angles of complexes **3/4** and **5/6** are listed in Tables 1 and 2, respectively.

Compounds **3** and **4** are isostructural. The germanium center is bonded to an [2-(pyrid-2-yl)ethenyl]amido-*N*,*N*′ chelate and an η$^1$-alkenyl ligand in a tetrahedral geometry, with the chalcogen atom occupying the axial position. Compounds **5** and **6** are also isostructural, and the geometry around the germanium center is also tetrahedral.

The Ge–S distance of 2.094(8) Å in **3** is similar to that of 2.11 Å in [{η$^4$-Me$_8$taa}Ge=S][3a] and 2.063(3) Å in [(Tbt)(Tip)Ge=S],[4a] and the Ge–S distance of 2.056(2) Å in **5** is comparable to that of 2.053(6) Å in [{HC(CMeNAr)$_2$}Ge(S)Cl] (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$).[6a] The Ge–S distances in **3** and **5** are close to the calculated value for a Ge=S bond (2.06 Å).[9] This suggests that the resonance structure **A** contributes more than the resonance **B** (Scheme 3) in compounds **3** and **5**.

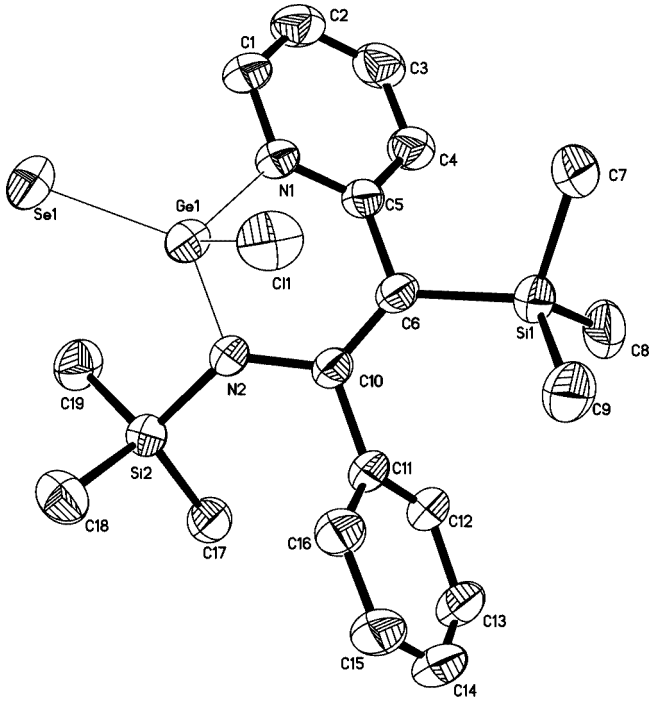


Figure 2. Molecular structure of **6**.

The Ge–Se distance of 2.223(9) Å in **4** is similar to that of 2.247(7) Å in [{C(SiMe$_3$)$_2$C$_5$H$_4$N-2}$_2$Ge=Se][10] and 2.247(1) Å in [{η$^4$-Me$_8$taa}Ge=Se],[3a] and the Ge–Se distance of 2.191(1) Å in **6** is comparable to that of 2.210(1) Å in [{HC(CMeNPh)$_2$}Ge(Se)Cl].[6b] The Ge–Se bond length in **4** lies between the calculated values for a Ge–Se single (2.39 Å) and double bond (2.19 Å), suggesting that the type of Ge–Se bonding in **4** lies somewhere between the reso-

| N(1)–Ge(1)–Cl(1) | 99.2(2) | 99.7(2) |
| N(1)–Ge(1)–E(1) | 114.9(2) | 112.9(1) |

nance structures **A** and **B**. The short Ge–Se distance in **6** indicates a double bond between germanium and selenium in the solid state.

The Ge–Cl distances of 2.180(2) Å in **5** and 2.179(2) Å in **6** are shorter than that of 2.283(9) Å in **2**. Similarly, the Ge–N$_{amide}$ distances [1.878(17) (**3**), 1.873(3) (**4**), 1.840(4) (**5**), 1.823(5) Å (**6**)] are shorter than those in the corresponding parent complexes [1.942(17) (**1**), 1.920(2) Å (**2**)].[7] This is because the germanium center in **3**–**6** has a higher oxidation state.

## Conclusions

A series of chalcogeno[2-(pyrid-2-yl)-1-azaallyl]germanium complexes has been synthesized, namely [Ge(E)-{C(C$_5$H$_4$N-2)C(Ph)N(SiMe$_3$)$_2$}{N(SiMe$_3$)C(Ph)C(SiMe$_3$)-(C$_5$H$_4$N-2)}] [E = S (**3**), Se (**4**)] and [Ge(E){N(SiMe$_3$)C(Ph)-C(SiMe$_3$)(C$_5$H$_4$N-2)}Cl] [E = S (**5**), Se (**6**)]. The Ge–E bond lengths in compounds **3**–**6** are indicative of a formal double bond or a Ge–E σ-bond with significant ionic character.[6a,6b]

## Experimental Section

**General Remarks:** All manipulations were carried out under dinitrogen by standard Schlenk techniques. Solvents were dried with, and distilled from, $CaH_2$ (hexane) and/or Na ($Et_2O$, toluene and THF). Anhydrous S and Se were purchased from Aldrich Chemicals and used without further purification. [Ge{C(C$_5$H$_4$N-2)C(Ph)-N(SiMe$_3$)$_2$}{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}] (**1**) and [Ge{N(SiMe$_3$)C(Ph)C(SiMe$_3$)-(C$_5$H$_4$N-2)}Cl] (**2**) were prepared according to literature procedures.[7] The $^1$H, $^{13}$C, and $^{77}$Se NMR spectra were recorded with Bruker WM-300 or Varian 400 instruments. All spectra were recorded in [D$_8$]THF, and the chemical shifts are given relative to SiMe$_4$ ($^1$H, $^{13}$C) or Se$_2$Me$_2$ ($^{77}$Se).

**[{N(SiMe$_3$)C(Ph)C(SiMe$_3$)(C$_5$H$_4$N-2)}{C(C$_5$H$_4$N-2)C(Ph)N(SiMe$_3$)$_2$}Ge=S] (3):** A solution of **1** (0.73 g, 0.97 mmol) in toluene (30 mL) was added slowly to a suspension of sulfur (0.03 g, 0.97 mmol) in toluene (25 mL) at 0 °C. The yellow mixture was warmed to room temperature and stirred at room temperature for 16 h. The precipitate was filtered and the filtrate was concentrated to yield yellow crystals of **3**. **X-ray Crystallographic Study:** Single crystals were sealed in Lindemann glass capillaries under nitrogen. X-ray data of **3**–**6** were collected with a Rigaku R-AXIS II imaging plate using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) from a rotating-anode generator operating at 50 kV and 90 mA. Crystal data for **3**–**6** are summarized in Table 3. The structures were solved by direct phase determination using the computer program SHELXTL-PC[11] with a PC 486 and refined by full-matrix least-squares with anisotropic thermal parameters for the non-hydrogen atoms. Hydrogen atoms were introduced in their idealized positions and included in structure factor calculations with assigned isotropic temperature factor calculations. CCDC-292827 (**3**), -292825 (**4**) -292826 (**5**), and -292824 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and X-ray Crystal Structures of the New, Three-Dimensional Ethylenediphosphonates [A{$HO_3P(CH_2)_2PO_3H_2$}] (A = Alkali Metal, Tl, or $NH_4$): Solid Brönsted Acids That Exhibit Topotactic Intercalation and Deintercalation of Ammonia

**Koya Prabhakara Rao[a] and Kanamaluru Vidyasagar*[a]**

**Keywords:** Intercalation / Organic–inorganic hybrid composites / Phosphonates / X-ray diffraction

Seven new ethylenediphosphonates with the formula [A{$HO_3P(CH_2)_2PO_3H_2$}] [A = Li (**1**), Na (**2**), K (**3**), Rb (**4**), Cs (**5**), Tl (**6**), and $NH_4$ (**7**)], have been synthesized and characterized by single-crystal X-ray diffraction, infrared spectroscopy, and thermal studies. They have four types of three-dimensional structures, with variations in the coordination of the $A^+$ ions. All of them are solid Brönsted acids that undergo room-temperature, acid–base intercalation reactions with ammonia.

## Introduction

Metal organophosphonates are a class of organic–inorganic hybrid materials in which the organophosphonate groups are covalently bonded to the metal inorganic backbone. In the recent past, there has been a renewed interest and activity in the research area of metal organophosphonates,[1–6] mainly due to their varied compositions, structural diversity, and potential applications,[7–11] for example, as sorbents, ion-exchangers, sensors, and catalysts. The expansion of metal organophosphonate chemistry includes phosphonates[12–15] and diphosphonates[16–18] of s-, p-, d- and f-block metals, and the structures reported for these compounds can be broadly classified into two categories, namely zero-dimensional types, such as mononuclear and complex molecular clusters, and extended framework types like one-, two-, and open three-dimensional networks. Low-dimensional structures such as chains and layers are mostly observed for compounds of the second type due to the segregation of hydrophobic regions of the organic moieties from the rest of the framework.

The solid-state chemistry of diphosphonates[16–18] is an emerging area of research, and several investigations concerning the synthesis, structures, and properties of di-, tri-, and tetravalent metal diphosphonates with extended frameworks,[16–18] such as $(VO)_2[CH_2(PO_3)_2]\cdot 4H_2O$, $[Ti_3O_2(H_2O)_2(O_3PCH_2PO_3)_2]\cdot(H_2O)_2$, $[Al_2\{(O_3PCH_2CH_2PO_3)\}(H_2O)_2F_2]\cdot H_2O$, $[Al_2\{(O_3PC_2H_4PO_3)_{1-x}(HPO_3)_{2x}\}(H_2O)_2F_2]\cdot H_2O$ ($0 \leq x \leq 0.32$), $[Al_2(OH)_2(H_2O)_2(O_3PCH_2CH_2PO_3)]$, $[Ga_2\{(O_3PCH_2CH_2PO_3)\}(H_2O)_2F_2]\cdot 2H_2O$, $[Sb_2\{O(O_3PCH_2PO_3H)\}]$, $[Ni_4(O_3PCH_2PO_3)_2]\cdot(H_2O)_n$ ($n$ = 3, 2, 0), $[Cr_2\{O_3P\text{-}(CH_2)_2\text{-}PO_3\}_2]\cdot 3H_2O$, $[Cu_2\{(O_3PCH_2CH_2PO_3)(H_2O)_2\}]$, $[Cu_2\{(O_3PC_3H_6PO_3)(H_2O)_2\}]\cdot H_2O$, $[Cu_2\{(O_3PC_4H_8PO_3)(H_2O)_2\}]\cdot 2H_2O$, $[Cu_2\{(O_3PC_5H_{10}PO_3)(H_2O)_2\}]\cdot 2.8H_2O$, $[Zn_2\{(O_3PCH_2CH_2PO_3)_2(H_2O)\}]$, $[Zn_2\{(O_3PC_3H_6PO_3)\}]$, $[Co_2(O_3PCH_2PO_3)]\cdot H_2O$, $[Fe_2\{(O_3PCH_2CH_2PO_3)\}]$, and $[Fe_2\{(O_3PCH_2CH_2PO_3)\}]\cdot 2H_2O$, have been reported. These examples illustrate the structural diversity and the compositional variations, with different ratios of metal to diphosphonates, inclusion of $F^-$, $O^{2-}$, and/or $H_2O$ in the coordination sphere of the metals, and di-, tri-, and tetraanionic forms of diphosphonic acids with different alkyl chain lengths. One noteworthy feature of all these alkyl diphosphonates is their insolubility in water, which enables their isolation as precipitates from aqueous solutions.

Among the many diphosphonates reported, there are only a few reports[18] of compounds with a metal to diphosphonic acid ratio of 1:1. These include $[Ti\{O_3P(CH_2)_nPO_3\}]$ ($n$ = 2, 3), $[LnH\{O_3P(CH_2)_nPO_3\}]$ ($n$ = 1–3), $[Sb\{O_3P(CH_2)_nPO_3H\}]$ ($n$ = 2, 3), and $[Sn(HO_3PCH_2PO_3H)]$. These tri- and divalent metal compounds contain $(HO_3PCH_2PO_3H)^{2-}$ and $(HO_3PCH_2PO_3)^{3-}$ anions and are, therefore, potential solid Brönsted acids. However, there are no reports of the intercalation properties of these diphosphonates. It is in this context that 1:1 diphosphonates of monovalent metals, [A{$HO_3P(CH_2)_nPO_3H_2$}], are envisaged to be strong, solid Brönsted acids that can undergo intercalation with bases. Only two monovalent metal diphosphonates, namely $[Ag_4\{O_3P(CH_2)_2PO_3\}]$ and [Na{$HO_3PCH_2PO_3H_2$}], have been reported[19] so far. We have recently synthe-

sized[20] seven new, low-dimensional 1:2 phenylphosphonates of monovalent metals, $[A(HO_3PPh)(H_2O_3PPh)]$ (A = Li, Na, K, Rb, Cs, $NH_4$, and Tl). These solid Brönsted acids undergo intercalation of amines and ammonia and, in a few cases, to the largest extent ever known. In view of these observations, we have undertaken a study of 1:1 metal alkyl diphosphonates of alkali and thallium metals and ammonium. We report here the successful synthesis, characterization, and ammonia-intercalation of the new, water-soluble ethylene diphosphonates $[A\{HO_3P(CH_2)_2PO_3H_2\}]$ [A = Li (**1**), Na (**2**), K (**3**), Rb (**4**), Cs (**5**), Tl (**6**), and $NH_4$ (**7**)].

## Results and Discussion

### X-ray Diffraction and Crystal Structures

The observed powder XRD patterns for all the seven structurally characterized $[A\{HO_3P(CH_2)_2PO_3H_2\}]$ compounds agree with those simulated with the LAZY-PULVERIX program[21] on the basis of single-crystal X-ray structures, thus indicating the single-phase nature of the samples. However, the observed relative intensities of some of the reflections are different from those calculated due to the preferential orientation of the crystallites. The crystal structures of ethylenediphosphonates **1**–**7** can be broadly classified into four structural types, namely those of compounds **1**, **2**, **3**, and **7**. From the point of view of A-P-O frameworks the sodium compound is two-dimensional, whereas the others are all one-dimensional compounds. However, these frameworks are connected three-dimensionally by the ethylene moiety.

$[Li\{HO_3P(CH_2)_2PO_3H_2\}]$ (**1**) contains half of one unit formula in the asymmetric unit. The lithium atom sits on a twofold axis and is tetrahedrally bonded to four O(1) atoms, which are near the inversion center 4b. Each $LiO(1)_4$ tetrahedron shares two edges with two such tetrahedra to form "$LiO_2$" chains parallel to the *c*-axis (Figure 1). O(1) is bonded to two Li atoms, and each diphosphonate, in turn, is bonded to four Li atoms, linking two such "$LiO_2$"chains. The ethylenediphosphonate groups connect these chains three-dimensionally. The four phosphonate moieties of different diphosphonates are positioned near the inversion center 4a such that O(3)–H(3) forms a hydrogen bond with O(2) and the other acidic hydrogen atom, H(2), at the inversion center is between two O(2) atoms, as shown in the encircled region of Figure 1. This unique region of space could be conceived as being porous. To the best of our knowledge this is the first lithium diphosphonate.

$[Na\{HO_3P(CH_2)_2PO_3H_2\}]$ (**2**) contains two formula units in the asymmetric unit. The two crystallographically distinct sodium atoms, Na1 and Na2, are confined approximately to the *xy* planes at $z \approx ¼$ and ¾ and octahedrally coordinated to ten of twelve crystallographically distinct oxygen atoms [O(1)–O(12)]. Only O(8) and O(11) are not bonded to sodium atoms. These two $NaO_6$ octahedra share the O(7)–O(10) edge to form a $Na_2O_{10}$ unit, which is linked to ten phosphonate moieties of five diphosphonates (Figure 2). Thus, the diphosphonates connect $Na_2O_{10}$ units in

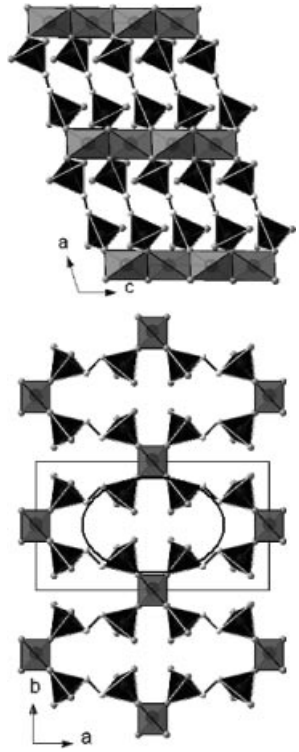

Figure 1. Polyhedral representation of the unit cell of $[Li\{HO_3P(CH_2)_2PO_3H_2\}]$ (**1**) viewed along the *b*-axis (top) and the *c*-axis (bottom).

the same plane as well as those in the adjacent planes, leading to a layered–pillared structure (Figure 2). The two diphosphonates are distinct in that one is bonded to six sodium atoms whereas the other is bonded to only four.

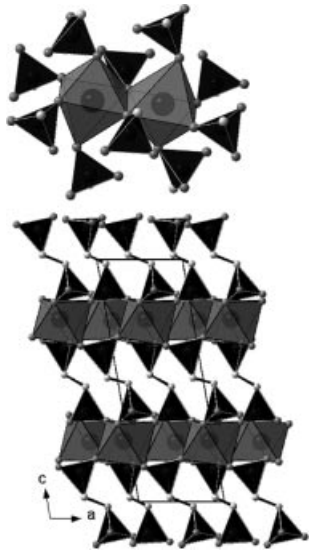

Figure 2. Polyhedral representation of the $Na_2O_{10}$ bi-octahedral unit with phosphonate moieties (top) and unit cell of $[Na\{HO_3P(CH_2)_2PO_3H_2\}]$ (**2**) viewed along the *b*-axis (bottom).

$[K\{HO_3P(CH_2)_2PO_3H_2\}]$ (**3**) has one formula unit in the asymmetric unit. The potassium atoms are confined approximately to the *xz* planes at $y \approx ¼$ and ¾ and coordinated dodecahedrally to oxygen atoms O(1)–O(6) of the di-

phosphonate, with the maximum value of the K–O bond length being 3.073(2) Å. Each $KO_8$ dodecahedron shares two O(1)–O(4) edges with two such polyhedra to form "$KO_6$" chains parallel to the *c*-axis (Figure 3). These chains are linked to one another three-dimensionally by diphosphonate moieties through the O(5) atoms. Thus, this compound is three-dimensional in nature. The diphosphonate is coordinated to five potassium atoms. Similarly, each potassium atom is bonded to five phosphonate moieties of different diphosphonates: three of them are bonded in a bidentate fashion and other two in a monodentate fashion. O(3)–H(3) and O(6)–H(6) form hydrogen bonds with O(1) and O(4), respectively. H(2) and H(5), at two inversion centers, represent two disordered positions of the other acidic hydrogen atom and are located, respectively, between the O(2) and O(5) atoms. These structural features are present in the similar three-dimensional rubidium (**4**), cesium (**5**), and thallium (**6**) compounds as well.

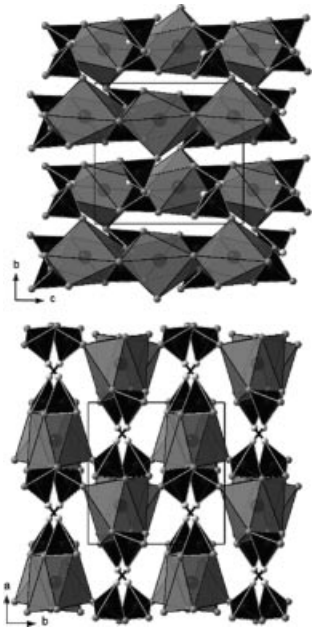

Figure 3. Polyhedral representation of the unit cell of $[K\{HO_3P(CH_2)_2PO_3H_2\}]$ (**3**) viewed along the *a*-axis (top) and the *c*-axis (bottom).

The rubidium (**4**) and cesium (**5**) compounds have the same positional parameters and contain half a formula unit in their asymmetric units. The metal atoms sit on twofold axes and are dodecahedrally coordinated to the O(1)–O(3) atoms of a diphosphonate moiety. The maximum values of the Rb–O and Cs–O bond lengths are 3.199(3) and 3.431(3) Å, respectively. Each $AO_8$ dodecahedron shares two O(1)–O(1′) edges with two such polyhedra to form "$AO_6$" chains parallel to [101]. These chains are linked to one another three-dimensionally, by diphosphonate moieties, through the O(1) atoms. Unlike cesium, which is bonded to eight diphosphonates in a monodentate fashion, rubidium is bonded to two diphosphonates in a bidentate fashion and another four in a monodentate mode. The hydrogen bonding is the same in both compounds: O(3)–H(3) forms a hydrogen bond with O(2) and the other acidic hydrogen atom, H(2), at the inversion center is between two O(2) atoms.

There are two distinct diphosphonates, which sit on inversion centers 2b and 2d, in the unit cell of $[Tl\{HO_3P(CH_2)_2PO_3H_2\}]$ (**6**). The thallium atoms are confined approximately to the *yz* planes at $x \approx 0.27$ and 0.77 and are coordinated dodecahedrally to oxygen atoms O(1)–O(6) of both diphosphonates, with the maximum value of the Tl–O bond length being as high as 3.47(3) Å. $TlO_8$ dodecahedra, similar to those in the potassium compound, share O(1)–O(1) and O(6)–O(6) edges to form "$TlO_6$" chains parallel to the *a*-axis; these chains are linked to one another through the O(4) atoms. The diphosphonate is bonded, in a monodentate fashion, to six thallium atoms. Similarly, the thallium atom is bonded to six phosphonate moieties of different diphosphonates. Both O(3)–H(3) and O(6)–H(6) form hydrogen bonds with O(5). H(2) and H(5), with half site-occupancies, represent two disordered positions of the other acidic hydrogen atom and are bonded, respectively, to the O(2) and O(5) atoms. O(2)–H(2) and O(5)–H(5) form hydrogen bonds with O(4) and O(3), respectively.

The nitrogen atoms in $[NH_4\{HO_3P(CH_2)_2PO_3H_2\}]$ (**7**) are confined approximately to the *ab* planes and are tetrahedrally hydrogen-bonded to oxygen atoms of the diphosphonates (Figure 4). The two crystallographically distinct ethylene diphosphonates sit on inversion centers 1h and 1b. All the six oxygen atoms, represented by O(4)–O(6), of one diphosphonate and only two oxygen atoms, O(1) and O(1′), of another diphosphonate are hydrogen-bonded to nitrogen. The connectivity pattern of $NO_4$ tetrahedra and "$PO_3C$" phosphonate moieties results in ladder-like chains parallel to the *a*-axis (Figure 4), with porous regions between them. Such a pattern is also observed[20] in $[NH_4(HO_3PC_6H_5)(H_2O_3PC_6H_5)]$. These chains in the adja-

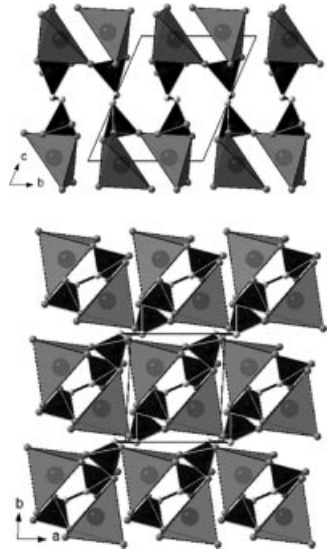

Figure 4. Polyhedral representation of the unit cell of $[NH_4\{HO_3P(CH_2)_2PO_3H_2\}]$ (**7**) viewed along the *a*-axis (top) and the *c*-axis (bottom).

cent layers are connected three-dimensionally through the C–C bonds of the $PO_3C$ phosphonate moieties. O(3)–H(3) and O(6)–H(6) form hydrogen bonds with O(4) and O(1), respectively, and O(2)–H(2) is strongly hydrogen bonded to O(5).

In the five compounds **1**, **3**, **4**, **5**, and **7**, the values of the P–O, P–C, and C–C bond lengths vary in the ranges 1.493(3)–1.575(2), 1.790(4)–1.795(3), and 1.522(5)–1.542(7) Å, respectively. These values compare with the 1.501(1)–1.553(2) Å range of P–O bond lengths, the 1.786(2) Å P–C bond length, and the 1.544(4) Å C–C bond length reported[22] for ethylenediphosphonic acid. The corresponding bond-length ranges of 1.48(2)–1.590(7), 1.74(3)–1.89(1), and 1.45(2)–1.55(2) Å in compounds **2** and **6** are a bit wider.

### Spectroscopic Studies

All seven compounds, as illustrated for **1** in Figure 5, have the following common infrared spectral features: (i) the C–H stretching vibrations[17c] of the ethylenediphosphonate group are observed around 2970 and 2924 $cm^{-1}$, whereas their bending vibrations are seen at 1380 $cm^{-1}$; (ii) the peaks in the region 1200–1000 $cm^{-1}$ are due to P–O stretching vibrations and the O–P–O bending vibrations[17c] are found in the region 540–410 $cm^{-1}$. The infrared spectrum of the ammonium compound shows two additional peaks at 3240 and 1401 $cm^{-1}$ corresponding to the stretching and bending vibrations of the ammonium ion.[23]

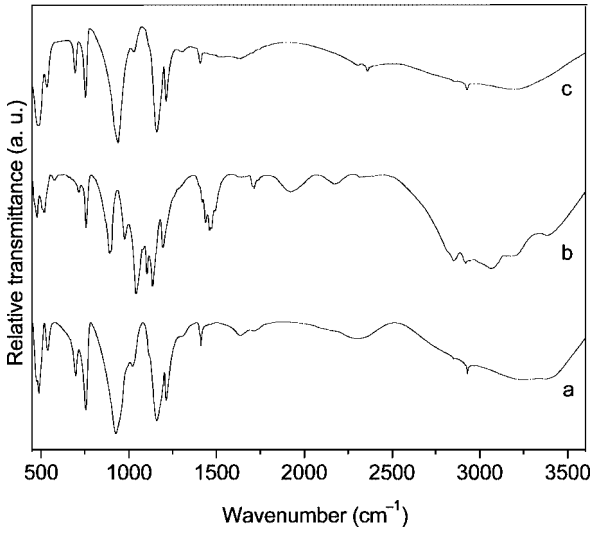

Figure 5. Infrared spectra of [Li{$HO_3P(CH_2)_2PO_3H_2$}] (**1**) (a), its intercalate **1**·$(NH_3)_{1.5}$ (b) and deintercalate (c).

### Thermal Analysis

Thermogravimetric analysis of all the seven compounds was carried out. The thermogravimetric curves of compounds **1**, **2**, and **7** are presented in Figure 6. No efforts have been made to identify the composition of the intermediate, residual solid products of decomposition and, therefore, only a factual description of these thermogravimetric curves is given. All these compounds are stable up to about 170–200 °C. Compounds **1**–**6** undergo total weight losses of 22.5–30% in the temperature range 200–800 °C, whereas the ammonium compound **7** has a maximum weight loss of 75%. These weight losses occur in two steps, with the second one at 460 °C being the major one.

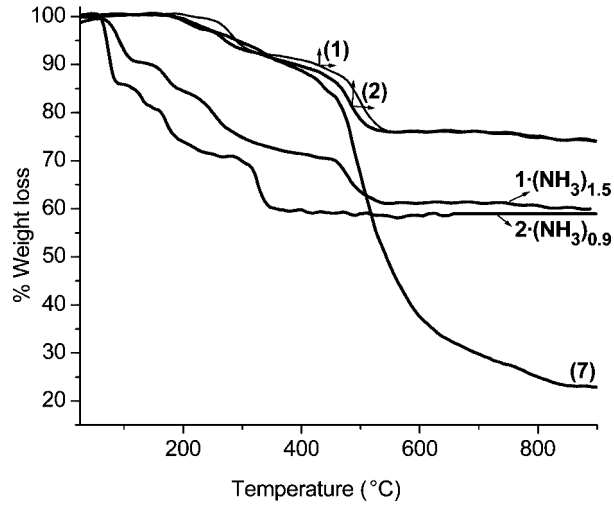

Figure 6. Thermogravimetric curves of compounds [A{$HO_3P(CH_2)_2PO_3H_2$}] [A = Li (**1**), Na (**2**), and $NH_4$ (**7**)] and ammonia intercalates **1**·$(NH_3)_{1.5}$ and **2**·$(NH_3)_{0.9}$.

### Intercalation and Deintercalation Reactions

All these ethylenediphosphonates are solid Brönsted acids. For example, the pH values of 1 M solutions of pure ligand and the sodium compound **2** are 2 and 3, respectively. Therefore, they were examined from the point of view of acid–base intercalation reactions with ammonia. These reactions, as determined from chemical analysis and spectroscopic and thermal studies, turned out to be successful. The success and extent of ammonia intercalation in the intercalates (**1**–**7**)·$(NH_3)_x$ were determined from the IR spectra and elemental analysis. The IR spectra (Figure 5) of compounds, (**1**–**6**)·$(NH_3)_x$ contain two additional peaks at 3240 and 1450 $cm^{-1}$ corresponding to the stretching and bending vibrations of the ammonium ion.[24] The $x$ values of (**1**–**7**)·$(NH_3)_x$ are 1.5, 0.9, 0.7, 0.5, 0.4, 1.0, and 1.6 respectively, and indicate partial intercalation and no systematic variation with the size and nature of A. The large value of $x$ for the lithium and ammonium compounds corroborates their large porosity and greater access to the porous regions. The differences in the powder XRD patterns of the parent diphosphonate and its ammonium intercalate are significant in the case of **1**, **3**, **6**, and **7**, which is indicative of intercalation of ammonia into the porous regions of the structure. However, the overall crystallinity decreases, as shown for **1**·$(NH_3)_{1.5}$ in Figure 7. Unlike the parent phases, the intercalates undergo a greater percentage of weight loss and begin to decompose at lower tempera-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tures. This is illustrated by the thermogravimetric curves of **1**·$(NH_3)_{1.5}$ and **2**·$(NH_3)_{0.9}$ in Figure 6. We also carried out ammonia deintercalation for a few selected intercalates, namely those of **1**, **2**, and **7**. They undergo deintercalation upon heating in the air-oven at about 170 °C for about 12 hours. The IR spectra (Figure 6), elemental analysis, and powder XRD patterns (Figure 7) of the deintercalated products, as illustrated in the case of **1**·$(NH_3)_{1.5}$, confirm that the deintercalation is complete and topotactic. To the best of our knowledge, this is the first time that such a reversible intercalation of ammonia in hybrid materials has been demonstrated.

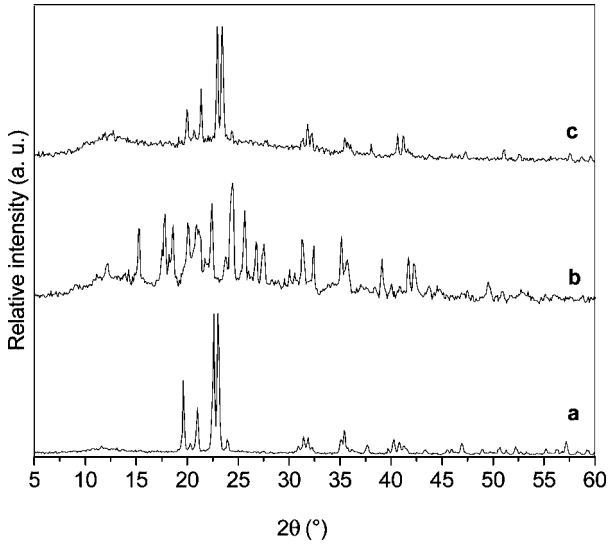

Figure 7. Powder X-ray diffraction patterns of [Li{$HO_3P(CH_2)_2PO_3H_2$}] (**1**) (a), its intercalate **1**·$(NH_3)_{1.5}$ (b) and deintercalate (c).

[$Zn(O_3PPh)$] and [$UO_2(HO_3PPh)_2(H_2O)]_2$·$8H_2O$ have been reported[9,25] to be sensors and proton conductors due to their intercalation and Brönsted-acidic properties, respectively. Compounds **1**–**7** exhibit both these properties and could be potentially useful as sensors and proton conductors.

## Concluding Remarks

A series of seven, new ethylenediphosphonates, [A{$HO_3P(CH_2)_2PO_3H_2$}] (A = alkali metal, Tl and $NH_4$), have four types of three-dimensional porous structures. They are solid Brönsted acids and undergo room-temperature intercalation reactions with ammonia. These intercalates can be deintercalated topotactically.

## Experimental Section

**Synthesis:** The high purity chemicals $A_2CO_3$ [A = Li, Na, K, $NH_4$ (SD Fine, India), Rb, Cs and Tl (Aldrich)] and 1,2-ethylenediphosphonic acid ($H_2O_3PCH_2CH_2PO_3H_2$, Lancaster) were used as purchased. The compounds [A{$HO_3P(CH_2)_2PO_3H_2$}] [A = Li (**1**), Na (**2**), K (**3**), Rb (**4**), Cs (**5**), Tl (**6**), and $NH_4$ (**7**)] were synthesized, on a 0.5–1.0-g scale, by evaporating aqueous solutions of stoichiometric reactant mixtures of ethylenediphosphonic acid and the appropriate carbonate. Slow evaporation, at room temperature, led to the formation of compounds as colorless, block-shaped or flaky crystals. However, evaporation in a steam bath yielded products in a polycrystalline form. In all the cases the yields were almost quantitative. These seven compounds were ascertained to be pure by elemental analysis with a Perkin–Elmer series 11 Model analyzer. $C_2H_7LiO_6P_2$ (195.96): calcd. C 12.25, H 3.60; found C 12.42, H 3.67. $C_2H_7NaO_6P_2$ (212.01): calcd. C 11.33, H 3.33; found C 11.80, H 3.38. $C_2H_7KO_6P_2$ (228.12): calcd. C 10.53, H 3.09; found C 10.61, H 3.00. $C_2H_7O_6P_2Rb$ (274.49): calcd. C 8.75, H 2.57; found C 8.62, H 2.67. $C_2H_7CsO_6P_2$ (321.93): calcd. C 7.46, H 2.19; found C 7.68, H, 2.23. $C_2H_7O_6P_2Tl$ (393.39): calcd. C 6.11, H 1.79; found C 6.15, H 1.79. $C_2H_{11}NO_6P_2$ (207.06): calcd. C 11.60, H 5.35, N 6.76; found C 11.62, H 5.22, N 6.50.

**Ammonia Intercalation and Deintercalation Reactions:** Intercalation of ammonia was achieved by passing ammonia gas over solid samples of ethylenediphosphonates **1**–**7** for 2 h. The amount ($x$) of intercalated ammonia was determined by analysis of the CHN content of the solid intercalates (**1**–**7**)·$(NH_3)_x$. Ammonia deintercalation was carried out by heating a sample of the intercalate in an oven at 170 °C for 12 h.

**X-ray Diffraction and Crystal Structure:** The powder X-ray diffraction (XRD) patterns of the seven ethylenediphosphontes **1**–**7** and their ammonia-intercalation products were recorded on a Shimadzu XD-D1 X-ray diffractometer using Cu-$K_\alpha$ ($\lambda$ = 1.5406 Å) radiation. Single crystals of compounds **1**–**7** suitable for X-ray diffraction were selected and mounted with glue on thin glass fibers. Crystals of compound **7** were found to be twinned. The X-ray data were gathered successfully at 25 °C, on an ENRAF-NONIUS CAD4 automated four-circle diffractometer, by standard procedures involving $\omega$–$2\theta$ techniques. These data sets were reduced by routine computational procedures. The program SHELXL-97[26] (Wingx) was employed for the structure solution and refinements and the graphic program DIAMOND[27] was used to draw the structures. The structure solutions were obtained by Patterson's method for compound **6** and by direct methods for the others. O(10) of **2** and O(1) of **6** were refined isotropically, whereas all other non-hydrogen atoms of these seven compounds were refined anisotropically. In each phosphonate moiety of compounds **1**–**7** the three oxygen atoms were labeled in increasing order of P–O bond lengths as they are different from one another. The oxygen atoms with short P–O bonds were considered to be formally double bonded to phosphorus atoms. The non-hydrogen-atom contents do not account for charge neutrality, thus indicating the presence of three acidic protons of diphosphonic acid moieties. These acidic hydrogen atoms, for all compounds except **2**, were located in the difference Fourier maps and refined with riding model restraints. Two of the three acidic hydrogen atoms of diphosphonate are bonded to the two oxygen atoms with long P–O bonds, whereas the third hydrogen atom is bonded to, or located between, those oxygen atoms with intermediate P–O bond lengths.[28] The ethylene hydrogen atoms were refined for all the seven compounds. For the ammonium compound **7**, the ammonium hydrogen atoms were located in the difference Fourier map and included in the final refinement. The structure refinement proceeded smoothly for all compounds but **2** and **6**. For compound **2**, the $R$ value was 10.5% and therefore an additional absorption correction, based on the isotropically refined model, was applied to the X-ray data using the program DIFABS.[29] The final difference Fourier map showed no residual peak with electron density of $>1$ e Å$^{-3}$ and the final $R$ value improved to around 7.8%. The C(2)–C(2)′ and C(4)–C(4)′ bond lengths in **2** were constrained to be 1.55 Å. For the thallium

[a] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $R_w = [\Sigma w(|F_o|^2 - |F_c|^2)^2/\Sigma w(|F_o|^2)^2]^{1/2}$.

compound **6**, refinement with correction for twin crystal-data was carried out. The final $R$ value was about 8% and the final difference Fourier map showed twenty ghost residual peaks with electron density greater than 1 e Å$^{-3}$. No additional absorption correction was applied to the X-ray data, as it could not improve the $R$ value. The $R_w$ values for **2** and **6** are a bit high and the desired improvisation of crystal structure refinement, for lower values, was not possible. However, the qualitative picture of these structures is totally correct and the quantitative details are, to a large extent, also correct. The pertinent crystallographic data of all these seven ethylenediphosphonates are presented in Table 1.

CCDC-281082, -281083, -281084, -281085, -281086, -281087 and -281088 (for **1**–**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Infrared Spectroscopic and Thermogravimetric Studies:** The infrared spectra in the range 400 to 4000 cm$^{-1}$, were measured on a Bruker IFS 66V FT-IR spectrometer. The samples were ground with dry KBr and pressed into transparent discs. Thermogravimetric analytical data were collected on a Netzsch STA 409C instrument. The samples were heated to 1000 °C at a rate of 10 °C per minute under flowing nitrogen gas.

# Hydrothermal Synthesis and Structural Characterization of Two pH-Controlled Cd–Squarate Coordination Frameworks, $[Cd_2(C_4O_4)_{2.5}(H_2O)_4]\cdot(dpaH)\cdot 1.5(H_2O)$ and $[Cd(C_4O_4)(dpa)(OH_2)]$ (dpa = 2,2′-dipyridylamine)

**Chih-Chieh Wang,*[a] Cheng-Han Yang,[a] and Gene-Hsiang Lee[b]**

**Keywords:** Hydrothermal synthesis / Self-assembly / Hydrogen bonds / Squarate / Cadmium

Two extended coordination frameworks of $Cd^{II}$–squarate complexes with the formulas $[Cd_2(C_4O_4)_{2.5}(H_2O)_4](dpaH)\cdot 1.5(H_2O)$ (**1**) and $[Cd(C_4O_4)(dpa)(H_2O)]$ (**2**) (dpa = 2,2′-dipyridylamine) have been synthesized under hydrothermal conditions and characterized by single-crystal X-ray diffraction studies. Structural determination reveals that compound **1** consists of a free monoprotonated 2,2′-dipyridylamine ion ($dpaH^+$) and a two-dimensional (2D) anionic, layered framework, $\{[Cd_2(C_4O_4)_{2.5}(H_2O)_4]^-\}$, which is formed with two antiprismatic square-boxes as the fundamental building unit through the connection between $Cd^{II}$ ions and hybrid $\mu_{1,2,3}$-, $\mu_{1,2,3,4}$-squarates. Each square-box acts as a host for the inclusion of one pyridine ring of $dpaH^+$. Adjacent $dpaH^+$ cations are then self-assembled by the parallel alignment of the other pyridine ring of $dpaH^+$ to complete a 3D network with one-dimensional (1D) channels intercalated by water molecules. Compound **2** contains a distorted octahedral $Cd^{II}$ center coordinated by two squarates, two waters and one dpa ligand to form a 1D 2-legged, ladder-like framework by the connection of a $[Cd(dpa)(\mu_2\text{-}H_2O)]_2^{4+}$ dimeric unit and a $\mu_{1,2}$-squarate. Weak π–π stacking interaction and hydrogen bonds of N–H···O, O–H···O and C–H···O among the squarate, water and dpa ligands provide additional intra- and intermolecular interactions on the stabilization of these two polymeric frameworks.

## Introduction

Metal-organic frameworks (MOFs)[1–5] have been attracting much attention owing to their potential applications as functional solid materials in gas storage, molecular sieves, size- or shape-selective catalysis, and ion exchange,[6–9] as well as because of their versatile structural topology. The design and synthesis of new open-framework coordination polymers have been the focus in current chemical and new material research. Of particular importance is the ability of the organic molecules to influence profoundly the structures of synthesized products, and to direct their formation with specific structures and potential applications, such as magnetism, host–guest chemistry, shape specificity and catalysis. In a relevant approach, the squarate (dianion of 3,4-dihydroxycyclobut-3-ene-1,2-dione, $H_2C_4O_4$) serves as a unique ligand, which possesses a four-membered cyclic aromatic structure, characterized by extensive π-electron delocalization over all carbon and oxygen atoms. Accordingly, squarate has been known as a polyfunctional ligand providing hydrogen bonding, π–π interactions, and the construction of extended frameworks. It is also widely used as a bridging ligand bonded with metal ions in various bridging modes to create numerous amazing metal–squarate frameworks, including one-dimensional (1D) chain, two-dimensional (2D) layer, three-dimensional (3D) cube- and cage-like frameworks.[10–17] Many squarate-bridged metal complexes with $\mu_{1,2}$- or $\mu_{1,3}$-bridging modes incorporating different nitrogen-based, flexible ligands have been structurally characterized[18–24] and showed interesting magnetic behavior.[25] In this contribution, we report the hydrothermal syntheses, structures and thermal stability of two novel Cd–squarate coordination frameworks, $[Cd_2(C_4O_4)_{2.5}(H_2O)_4](dpaH)\cdot 1.5(H_2O)$ (**1**) and $[Cd(C_4O_4)(dpa)(H_2O)]$ (**2**) by using flexible dpa and rigid squarate ligands as building blocks to form 3D microporous and 1D ladder-like extended networks.

## Results and Discussion

### Synthesis and IR Spectroscopy of Compounds 1 and 2

The reaction was carried out under hydrothermal conditions, by adjusting various molar ratios of $[Cd(NO_3)_2]\cdot 4H_2O$, dpa and $H_2C_4O_4$ (Table 1). The results showed that compounds **1** and **2** are not controlled by stoichiometry but rather by the pH-controlled products. Compound **1** was the favored product with relatively lower pH value (pH < 4), whereas compound **2** was the dominant product with rela-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tively higher pH value (pH > 4). Both compounds are air-stable at ambient temperature and insoluble in common solvents, such as water, alcohol and acetonitrile. The N–H stretching vibrations of both compounds appear in the 3000–3400 $cm^{-1}$ region, and their frequencies are consistent with the existence of hydrogen bonds between N–H and several H-acceptor groups. The most relevant IR features are those associated with the chelating squarate ligands. The coordinated CO groups are characterized by medium absorptions at 1664 and 1656 $cm^{-1}$ for **1** and **2**, respectively. A very strong band centered at around 1500 $cm^{-1}$ is attributed to the vibrational modes of a combination of C–O and C–C stretching motions; the assignment of which is in agreement with the characteristic of the $(CO)_n^{2-}$ salts.[26]

Table 1. Products for different reaction conditions by adjusting molar ratios of $[Cd(NO_3)_2]\cdot 4H_2O$, dpa and $H_2C_4O_4$.

| Molar ratios in 6 mL water | | | pH value | Product |
|---|---|---|---|---|
| $[Cd(NO_3)_2]\cdot 4H_2O$ | dpa | $H_2C_4O_4$ | | |
| 0.1 mmol | 0.1 mmol | 0.1 mmol | 2.45 | **1** |
| 0.1 mmol | 0.15 mmol | 0.1 mmol | 3.17 | **1** |
| 0.1 mmol | 0.2 mmol | 0.1 mmol | 4.31 | **2** |
| 0.1 mmol | 0.125 mmol | 0.06 mmol | 4.13 | **2** |

### Crystal Structure of $[Cd_2(C_4O_4)_{2.5}(H_2O)_4](dpaH)\cdot 1.5(H_2O)$ (1)

The X-ray structure determination reveals that compound **1** consists of a 2D anionic $[Cd_2(C_4O_4)_{2.5}(H_2O)_4]^-$ layered MOF [Figure 1 (top)], a monoprotonated $dpaH^+$ [Figure 1 (bottom)], and crystallization water molecules. The 2D anionic $[Cd_2(C_4O_4)_{2.5}(H_2O)_4]^-$ layer consists of three independent slightly distorted octahedral $Cd^{II}$ ions in the asymmetric unit, in which the Cd(1) atom is bonded to six oxygen atoms from four $\mu_{1,2,3}$-squarate and two water molecules with the following bond lengths: Cd(1)–O(1) 2.336(2), Cd(1)–O(3) 2.298(2), Cd(1)–O(5) 2.307(2), Cd(1)–O(7) 2.295(2), Cd(1)–O(11) 2.255(2), and Cd(1)–O(12) 2.234(2) Å (Figure 1). The Cd(2) and Cd(3) atoms are both located at the inversion center [(1.5 2.0 0.0) for Cd(2) and (1.0 1.5 0.0) for Cd(3)] and bonded to six oxygen atoms from two $\mu_{1,2,3}$-squarate, two $\mu_{1,2,3,4}$-squarate and two water molecules with the following bond lengths: Cd(2)–O(2) 2.265(2), Cd(2)–O(9) 2.322(2), Cd(2)–O(13) 2.231(2) and Cd(3)–O(6) 2.318(2), Cd(3)–O(10) 2.279(2), and Cd(3)–O(14) 2.236(2) Å (Figure 1). The corresponding bond lengths of the Cd–$O_{sq}$ and Cd–$O_w$ bonds (Table 2) all fall in the same range analogous to those in the $[Cd(C_4O_4)(H_2O)_2]$ complex.[10] It is important to note that the squarate ligand ($C_4O_4^{2-}$), acting as a bridging ligand with two different bridging modes, plays a key role in the construction of a novel 2D anionic framework. Three crystallographically distinct squarate ligands are found: the first one (C1–C4) adopts a $\mu_{1,2,3}$-bridging mode[12] (Figure 2) to link Cd(1) with Cd(2) (5.926 and 6.065 Å) and Cd(1) with Cd(1) (8.457 Å), respectively. The second one (C5–C8) also adopts a $\mu_{1,2,3}$-bridging mode[12] to link Cd(1) with Cd(3) (5.918

and 6.057 Å) and Cd(1) with Cd(1) (8.434 Å), respectively. The last one (C9–C10) adopts a $\mu_{1,2,3,4}$-bridging mode[10] (Figure 2) to link Cd(2) with Cd(3) ($2\times5.854$ and $2\times6.088$ Å), Cd(2) with Cd(2) (8.434 Å) and Cd(3)···Cd(3) (8.457 Å), respectively. To the best of our knowledge, compound **1** is the first coordination framework consisting of a Cd/squarate system with hybrid $\mu_{1,2,3}$- and $\mu_{1,2,3,4}$-bridging modes of squarates. It is also noted that, independent of $\mu_{1,2,3}$- or $\mu_{1,2,3,4}$-squarates, the differences among the four C–O distances are not obvious, with the averaged C–O distances of 1.254(4) and 1.255(4) Å for $\mu_{1,2,3}$-squarate and 1.252(4) Å for $\mu_{1,2,3,4}$-squarate, respectively. The result indicates a more π-delocalization bridging mode ($D_{4h}$) close to a free squarate ring. The free, monoprotonated $dpaH^+$ cation shown in Figure 1 (bottom) adopts an *anti-anti* conformation mode. The presence of the proton H(1) bound to N(1) [0.754 Å H(1)–N(1)] and its hydrogen bond with N(3) [2.672(5) Å N(1)···N(3)] accounts for the *anti-anti* conformation of $dpaH^+$ and the quasi co-planarity of the two pyridyl rings [the dihedral angles between the mean planes of two pyridine rings is only 5.22°]. All C–C and C–N bond lengths and bond angles in the $dpaH^+$ molecule are comparable to those reported previously.[27]

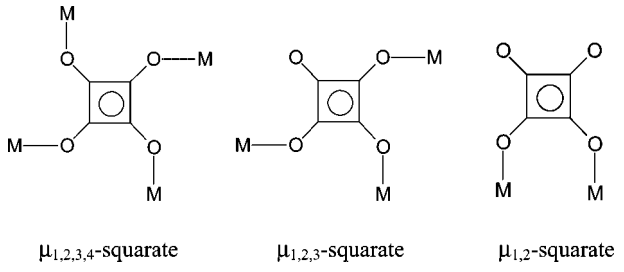

Figure 2. Binding modes of squarate in compound **1** and **2**.

The overall 3D architecture is depicted in Figure 3, and can be described as the self-assembly of 2D anionic Cd–squarate frameworks and free $dpaH^+$ cations. A face-sharing double-box shown in Figure 4 (top) is the fundamental building unit for the construction of the 2D anionic MOF. Each box consists of an antiprismatic square $Cd_8$ skeleton, bridged by four $\mu_{1,2,3}$-bridge squarates, acting as four sides of the box, and by one $\mu_{1,2,3,4}$-squarate ligand, acting as the base. Two boxes share a $\mu_{1,2,3,4}$-squarate to form a face-sharing double-box unit, whereas the neighboring double-box units share a $\mu_{1,2,3}$-squarate to complete a 2D-extended framework along the [100] and [010] directions. The dimensions of the box are approximately $5.0\times5.0\times4.9$ Å (shortest oxygen–oxygen contact distances not including the van der Waals radii), providing a vacant space for the inclusion of a pyridyl group of the $dpaH^+$ cation. It is worthy to note that the $dpaH^+$ cation plays the other important role in the construction of this 3D network. It acts not only as a counterion to balance the charge of the Cd–squarate anionic skeleton, but also as an inclusion molecule with one of the pyridyl groups in $dpaH^+$ cation inserting into each antiprismatic box. The pyridyl groups outside the boxes are then aligned parallel to one another (the separation distance of 4.2 Å between two centroid pyridyl groups) to complete the 3D-extended network, which allows a 1D microporous channel along the *c* axis (Figure 2). Two free, disordered water molecules, O15 with 0.5 occupancy and O16, O16′ with 0.67 and 0.33 occupancy, respectively, are intercalated into these channels. Hydrogen-bond formation serves as a important factor and is widely used in constructing coordination polymers.[28–32] In compound **1**, hydrogen-bonding

interactions, including the N–H···N, N–H···O and O–H···O hydrogen bonds among the $dpaH^+$, squarate ligands and water molecules, provide the additional stabilizing forces to enhance the 3D microporous network. Related bond lengths and angles of the N–H···N, N–H···O and O–H···O hydrogen bonds are summarized in Table 3.

### Crystal Structures of $[Cd(C_4O_4)(dpa)(H_2O)]$ (2)

The X-ray structural determination of compound **2** evidences a polymeric arrangement with a linear 2-legged, ladder-like MOF, which is isostructural with $[M(C_4O_4)(dpa)(H_2O)]$, M = Co, Ni, Zn.[33] The $Cd^{II}$ center is six-coordinate and adopts a slightly distorted octahedral coordination environment bonded to two nitrogen atoms from dpa ligands and two oxygen atoms from two squarate ligands and two water molecules. The related bond lengths and bond angles around the Cd center are listed in Table 4. Two Cd ions are linked together through two bridging water molecules to form a $[Cd(dpa)(H_2O)]_2^{4+}$ dimeric fragment (see Figure 5) in the equatorial plane [Figure 5 (top)] with bond lengths of Cd(1)–O(5) 2.330(2), Cd(1)–$O(5)_i$ 2.384(2), Cd(1)–N(1) 2.296(2) and Cd(3)–N(3) 2.276(2) Å. The squarate ligand adopts a $\mu_{1,2}$-binding mode[33] (Figure 2) to connect the neighboring $[Cd(dpa)(\mu_2\text{-}OH_2)]_2$ fragments at the axial sites with bond lengths of Cd(1)–O(1) 2.240(2), Cd(1)–O(2) 2.269(2) Å, constructing a 1D, linear, 2-legged, ladderlike MOF along the *a* axis [Figure 5 (bottom)]. The corresponding bond lengths of the Cd–$O_{sq}$ and Cd–$O_w$

bonds fall in the same range, analogous to those in the $[Cd(C_4O_4)(H_2O)_2]$ complex.[10] The Cd···Cd separations along the $\mu_2$-$O_{water}$ and $\mu_{1,2}$-$C_4O_4^{2-}$ bridges are 3.670(1) and 7.672(1) Å, respectively. It should be noted that adjacent ladders are displaced by half a repeating unit along the *a* and *c* axes. This arrangement effectively prevents steric hindrance between the inter-ladder dpa ligands. As a result, compound **2** favor a closer-packing building block as shown in Figure 6. The centroid pyridine rings in dpa ligands among the adjacent ladders are generally parallel and adopt a face-to-face alignment (Figure 5) with the separation distance of 3.9 Å, indicating a very weak but significant π–π stacking interaction[33–35] that may, in part, contribute to the stabilization of the extended framework. In compound **2**, two strong O–H···O hydrogen bonds [O(5)–H(5a)···O(4) and O(5)–H(5b)···O(3)] are found between uncoordinated oxygen atoms of squarate and the coordinated water molecules with the O···O distances in the range of 2.528–2.600 Å. In addition, the inter-ladder interactions are through one pair of the N–H···O [N(2)–H(2a)···O(4)] and C–H···O [C(11)–H(11a)···O(4)] hydrogen bonds from the same dpa molecule linked to the oxygen atom of squarate in the neighboring ladders to form a mixed N–H···O and C–H···O hydrogen bonds (dashed line in Figure 6). Similar hydrogen-bonding interactions have also been found in the

[Fe(oxa)(dpa)][28] (oxa = oxalate) and [$M_2$(dpa)$_2$($C_2O_4$)-($C_4O_4$)] (M = Cu, Zn) complexes.[34] Related bond lengths and angles of the O–H···O, N–H···O and C–H···O hydrogen bonds for **2** are summarized in Table 5.

### Thermogravimetric Analysis

To investigate the thermal stability of the 3D and 1D extended framework of **1** and **2**, the thermogravimetric analyses (TGA) were performed on samples consisting of numerous single crystals under nitrogen. The TGA data of **1** suggest that the first weight lost of 11.24% (calcd. 12.75%), corresponding to the lost of 1.5 solvated and four coordinated water molecules at the cadmium center, occurred over the range of 30–174 °C. In the temperature range of 180–312 °C, **1** underwent the weight lost of 24.64% corresponding to the lost of dpaH$^+$ cations (calcd. 22.16%). The resulting solid then slowly decomposed with loss of squarate ligands to yield cadmium oxide (CdO). Compound **2** underwent a continuous single-step weight-loss process (losing coordinated water first, and then dpa and squarate groups). The on-set temperature of the weight loss is approximately at 201 °C. The decomposition process was completed at approximately 391 °C and the final product of the pyrolysis is CdO.

## Conclusion

In conclusion, under hydrothermal conditions, we have successfully synthesized two pH-controlled Cadmium(II)–squarate compounds, [$Cd_2(C_4O_4)_{2.5}(H_2O)_4$](dpaH)·1.5($H_2O$) (**1**) and [Cd($C_4O_4$)(dpa)($H_2O$)] (**2**), with metal-organic frameworks; the structures of which are well characterized by X-ray diffraction method. In compound **1**, the overall 3D network with 1D microporous channels is constructed by the following intra- and inter-molecular interactions: (1) metal–squarate covalent bonds to form a anionic 2D framework through the connectivity between Cd ions and hybrid $\mu_{1,2,3}$- and $\mu_{1,2,3,4}$-squarates, (2) molecular inclusion of dpaH$^+$ pyridyl group into the antiprism square box, (3) π–π stacking interaction of pyridyl groups between neighboring dpaH$^+$ cations and (4) hydrogen bonds between water molecules, squarate and dpaH$^+$. For compound **2**, the squarate ligands afford a $\mu_{1,2}$-bridging coordination mode as well as hydrogen-bonding capability to build a 1D 2-legged, ladder-like MOF.

## Experimental Section

**Materials and Physical Techniques:** All chemicals were of reagent grade and were used as commercially obtained without further purification. Elementary analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer 2400 elemental analyzer. IR spectra were recorded with a Nicolet Fourier Transform IR, MAGNA-IR 500 spectrometer in the range of 500–4000 cm$^{-1}$ using the KBr disc technique. Thermogravimetric analyses (TGA) of compounds **1** and **2** were performed with a computer-controlled Perkin–Elmer 7 Series/UNIX TGA7 analyzer. Single-phased powder samples of **1** (4.014 mg) and **2** (1.228 mg) were loaded into alumina pans and heated with a ramp rate of 5 °C/min from room temperature to 900 °C under nitrogen.

**Synthesis of [$Cd_2(C_4O_4)_{2.5}(H_2O)_4$](dpaH)·1.5$H_2O$ (1):** The reaction of Cd($NO_3$)$_2$·4$H_2O$ (0.0325 g, 0.1 mmol), dpa (0.0175 g, 0.1 mmol), $H_2C_4O_4$ (0.0118 g, 0.1 mmol), and deionized water (6 mL, 0.3333 mol) in the molar ratio 1:1:1:3.333, in a Teflon-lined acid digestion bomb at 180 °C for three days, followed by slow cooling at 6 °C/h to room temperature, yielded colorless solutions. After evaporation for several days at room temperature, colorless crystals grew out of solution as needles and were collected after filtration and drying (yield: 0.0106 g, 34%). The final pH value was 2.45. $C_{20}H_{21}Cd_2N_3O_{15.5}$ (776.20): calcd. C 30.95, N 5.41, H 2.73; found C 30.99, N 5.39, H 2.58. IR (4000–400 cm$^{-1}$): $\tilde{\nu}$ = 3246 (m), 3083 (m), 1664 (m), 1610 (m), 1563 (m), 1506 (vs), 1457 (s), 1246 (w), 777 (m) cm$^{-1}$.

**Synthesis of [Cd($C_4O_4$)(dpa)($H_2O$)] (2):** The compounds Cd($NO_3$)$_2$·4$H_2O$ (0.0322 g, 0.1 mmol), dpa (0.0351 g, 0.2 mmol), $H_2C_4O_4$ (0.0116 g, 0.1 mmol), and deionized water (6 mL, 0.3333 mol) in the mol ratio 1:2:1:3.333 were sealed in a Teflon-lined acid digestion bomb at 180 °C for three days. They were then cooled at 6 °C/h to room temperature, yielding colorless plate crystals after filtration and drying (0.0162 g, 39%). The final pH value was 4.31. $C_{14}H_{11}CdN_3O_5$ (413.66): calcd. C 40.65, H 2.68, N 10.16; found C 40.31, H 2.81, N 10.34. IR (4000–400 cm$^{-1}$): $\tilde{\nu}$ = 3320 (w), 3206 (m), 3138 (m), 3082 (m), 3045 (m), 1656 (m), 1599 (m), 1538 (s), 1504 (vs), 1474 (vs), 1428 (s), 1373 (m), 1232 (m), 763 (m) cm$^{-1}$.

**X-ray Crystallographic Study:** Crystallographic data and experimental details of refinements for structural analyses are given in Table 6. Data collections of **1** and **2** were carried out with a Siemens SMART diffractometer with a CCD detector with Mo radiation ($\lambda$ = 0.71073 Å) at room temperature. A preliminary orientation matrix and unit cell parameters were determined from 3 runs of 15 frames each, each frame correspond to a 0.3°scan in 10 s, following by spot integration and least-squares refinement. For each structure, data were measured using $\omega$ scans of 0.3° per frame for 20 s until a complete hemisphere had been collected. Cell parameters were retrieved with SMART[36] software and refined with SAINT[37] on all observed reflections. Data reduction was performed with the SAINT[37] software and corrected for Lorentz and polarization effects. Absorption corrections were applied with the program SADABS.[38] Direct phase determination and subsequent difference Fourier map synthesis yielded the positions of all non-hydrogen atoms, which were subjected to anisotropic refinements. All hydrogen atoms were generated geometrically (C–H: 0.95) with the exception of the hydrogen atoms of the coordinated water mole-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cules, which were located in the difference Fourier map with the corresponding positions and isotropic displacement parameters being refined. The final full-matrix, least-squares refinement on $F^2$ was applied for all observed reflections [$I > 2\sigma(I)$]. All calculations were performed by using the SHELXTL software package.[39]

# Single-Electron-Transfer Reactions of α-Diimine dpp-BIAN and Its Magnesium Complex $(dpp\text{-}BIAN)^{2-}Mg^{2+}(THF)_3$

**Igor L. Fedushkin,*[a] Valentine M. Makarov,[b] Esther C. E. Rosenthal,[c] and Georgii K. Fukin[a]**

**Keywords:** Magnesium / N-ligands / Single-electron transfer

The reactions of (dpp-BIAN)$Mg(THF)_3$ (**1**) {dpp-BIAN = 1,2-bis[(2,6-diisopropylphenyl)imino]acenaphthene} with ethyl halides EtX (X = Cl, Br, I) in hexane proceed by single-electron transfer (SET) from the metal complex to the organic halide. Complexes $[(dpp\text{-}BIAN)(Et)]MgX(THF)_n$ [X = Cl, $n$ = 0 (**2**); X = Br, $n$ = 2 (**3**); X = I, $n$ = 1 (**4**)] are the products of ethyl transfer to an imine carbon atom of a coordinated diimine ligand. The compound [(dpp-BIAN)(Et)]MgBr (**3a**) was obtained from the reaction of free dpp-BIAN with ethylmagnesiumbromide in hexane. In this case SET from the Grignard reagent to the neutral diimine takes place. Compounds **2**–**4** and **3a** were isolated as crystals and characterized by $^1H$ NMR spectroscopy. The molecular structure of **3** was determined by single-crystal X-ray analysis.

## Introduction

Among the organometallic and coordination compounds of magnesium, only Grignard reagents are widely used in organic synthesis.[1] Despite the fact that magnesium amides, $R_2NMgX$ (X = halide), so-called Hauser bases, were found to be excellent deprotonating reagents for nitriles,[2] enolizable ketones,[3] and C–H acids,[4] they have not yet become regular reagents in organic synthesis. Reactions of Grignard reagents with organic substrates may proceed by two different mechanisms: concerted polar addition or single-electron transfer (SET) from RMgX to the organic compound.[5] The second mechanism implies oxidation of RMgX and reduction of the substrate by SET. During this process, an R–Mg bonding electron leaves the HOMO of RMgX. This leads to cleavage of this bond and formation of a radical R and an MgX cation, which then attack the respective centers of the substrate. Some time ago, we started our search for new electron transfer reagents based on main-group metals. Our original concept involved the preparation of metal complexes in which a complex HOMO is mainly ligand-localized and the ligand has further functionalities to bind the metal (e.g. heteroatom lone pairs). In these cases, the SET from the HOMO to the organic substrate should not cause cleavage of a metal–ligand bond. Long-known alkali metal naphthalenides or magnesium anthracenide are strong reducing agents, which are able to transfer electrons to different substrates. However, since the π-systems of these arenes are very weak bases, an electron transfer from these species causes not only oxidation of the ligand but also its release from the metal. α-Diimines have a low-lying LUMO (π*), which can be populated with electrons from the metal, and basic nitrogen atoms. The 1,2-bis[(2,6-diisopropylphenyl)imino]-acenaphthene (dpp-BIAN) ligand has an extended π system that is formed from diimine and naphthalene. Four-step reduction of this diimine with alkali metals produces its tetraanion.[6] Metallic magnesium easily reduces dpp-BIAN to a dianion and provides the monomeric solvated complex (dpp-BIAN)$Mg(THF)_3$ (**1**).[7] To some extent, this complex is related to Hauser bases because it readily deprotonates C–H acids,[8] ketones,[9] and nitriles.[10] Reaction of **1** with diphenylketone provides, by SET, the pinacolate complex $[(dpp\text{-}BIAN)^{-}\cdot Mg]_2(\mu\text{-}O_2C_2Ph_4)$.[11] Note that, during oxidation from dianion to radical-anion, the dpp-BIAN ligand still remains on magnesium. Iodine and some organic halides (e.g. $Ph_3SnCl$, $BrCH_2CH_2Br$) oxidize complex **1** to give radical-anionic species of the type $(dpp\text{-}BIAN)^{-}\cdot MgX$ (X = Cl, Br, I).[12] Recently we have reported the reverse process; the reduction of a magnesium-bound radical-anion to the corresponding dianion by reductive elimination of an alkyl radical from (dpp-BIAN)Mg(*i*Pr)($Et_2O$).[13] In this particular case, the SET occurred intramolecularly. Thus, the concept we wish to develop concerns the preparation of main-group metal complexes with ligands, which may vary their "oxidation state" while they are bound to the metal. This ap-

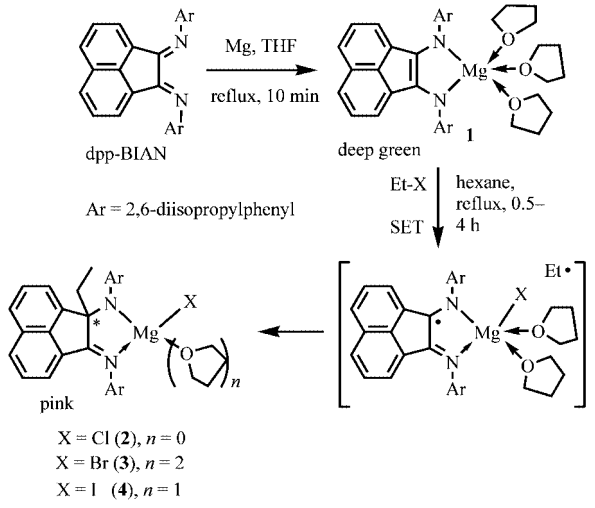
proach should provide redox-active complexes of redox-inactive metals (e.g. magnesium). In this paper, we report on the reactivity of **1** towards organic halides.

## Results and Discussion

Treatment of complex **1** with ethyl halides EtX (X = Cl, Br, I) in THF causes a color change from deep green to red within a few minutes at room temperature. Evaporation of the solvent affords a red oily residue, which solidifies only after repeated treatment with hexane and storage of the solution formed at ambient temperature for several days. Because **1** is insoluble in hexane, its reaction with EtX (X = Cl, Br, I) in this solvent proceeds only at reflux and takes up to 30 min in the case of EtI, one hour for EtBr, and several hours for EtCl. However, the use of hexane as solvent allows simple isolation of the products because the products crystallize from the reaction mixture during the reaction. Use of an excess of organic halide increases the reaction rates in hexane. Thus, when a fivefold excess of EtCl is used, the reaction in hexane is complete within 3 hours. Completion of the reaction may be seen by the disappearance of the green crystals of **1** and the precipitation of the red crystalline product.

According to the results of $^1$H NMR spectroscopy, the reaction of complex **1** with ethyl halides EtX (X = Cl, Br, I) yields the products of ethyl transfer to an imine carbon atom of the dpp-BIAN ligand coordinated to the magnesium atom (Scheme 1). The ethyl radical formed under SET from **1** to EtX attacks the radical-anion of dpp-BIAN, resulting in the formation of compounds **2**–**4** in good yields.



Scheme 1.

### Molecular Structure of 3

The molecular structure of **3** (Figure 1) was determined by single-crystal X-ray analysis. Free dpp-BIAN as well as the dpp-BIAN dianion in complex **1** possess two planes of symmetry, one is orthogonal to the acenaphthene plane and crosses the middle C–C bond of the naphthalene moiety, whereas the other coincides with the diimine plane. Attachment of the ethyl group to the imino carbon atom destroys this symmetry and causes the appearance of a chiral carbon atom [C(1)] in the molecule. In the unit cell *R* and *S* isomers are present. In **3** the magnesium atom is five-coordinate. The amido and imino Mg–N distances [Mg–N(1) 2.015(2) and Mg–N(2) 2.3320(19) Å, respectively] differ significantly. Asymmetric chelation of magnesium metal has already been observed in the products of addition of enolizable ketones to **1**.[9] Addition of ketones to **1** occurs with protonation of one of the nitrogen atoms of the dpp-BIAN ligand and results in an asymmetric amido/amino structure. For instance, in the addition product of 1,1-diphenylacetone, the amido and amino bond lengths are 2.051(2) and 2.410(2) Å, respectively. The N(2)–C(2) double bond in **3** [1.281(3) Å] is nearly the same as those in free dpp-BIAN (both N–C 1.28 Å).[12] The distance N(1)–C(2) [1.471(3) Å] corresponds well to a single N–C bond. The Mg–O distances [2.092(2) and 2.1286(17) Å] fall into the range of the respective distances in **1** (2.070, 2.084 and 2.224 Å).[7]

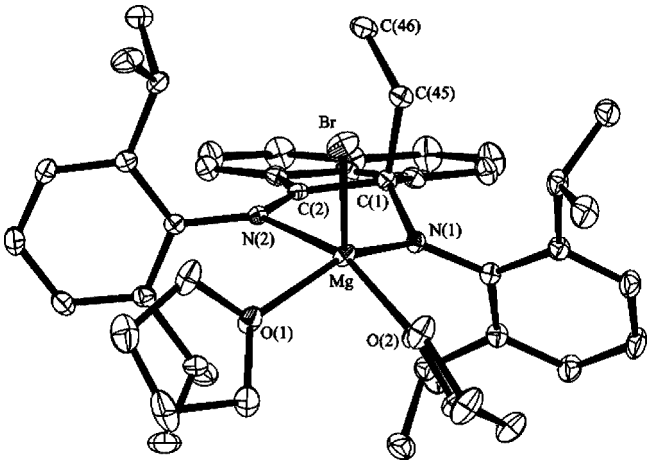


Figure 1. Molecular structure of **3** (*S* isomer). The hydrogen atoms are omitted. Thermal ellipsoids are drawn at 30% probability. Selected bond lengths [Å] and angles [°]: Mg–N(1) 2.015(2), Mg–N(2) 2.3320(19), Mg–O(1) 2.092(2), Mg–O(2) 2.1286(17), Mg–Br 2.5119(8), N(1)–C(1) 1.471(3), C(1)–C(2) 1.543(3), C(1)–C(45) 1.561(3), N(2)–C(2) 1.281(3); N(1)–Mg–O(1) 143.44(9), N(1)–Mg–O(2) 98.33(7), O(1)–Mg–O(2) 85.20(7), N(1)–Mg–N(2) 77.88(7), O(1)–Mg–N(2) 84.75(7), O(2)–Mg–N(2) 156.73(8), N(1)–Mg–Br 116.82(6), O(1)–Mg–Br 98.54(6), O(2)–Mg–Br 97.52(6), N(2)–Mg–Br 104.70(5).

### NMR Spectroscopy of 2–4

Selected $^1$H NMR spectroscopic data for **2**–**4** are given in Table 1. All three compounds reveal a similar spectral picture. The asymmetric amido/imino structure causes the twelve aromatic protons to be nonequivalent. The four methine protons of the isopropyl substituents give rise to four signals ranging from 4.85 to 2.97 ppm for **2** and **3** in [$D_8$]THF and from 5.25 to 3.06 ppm for **4** in $C_6D_6$. Because

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of restricted rotation around the N–C(*ipso*-Ph) bond, all eight methyl groups become unique and appear as eight doublets in the range from 1.40 to –0.15 ppm. The presence of the chiral carbon atom C(1) next to the methylene protons of the ethyl group causes them to be nonequivalent (**2**: 2.75, 2.54; **3**: 2.97, 2.51; **4**: 3.23, 2.88 ppm).

Table 1. Selected $^1$H NMR spectroscopic data for **2** and **3** in [$D_8$]-THF and **4** in $C_6D_6$ (200 MHz, 293 K).

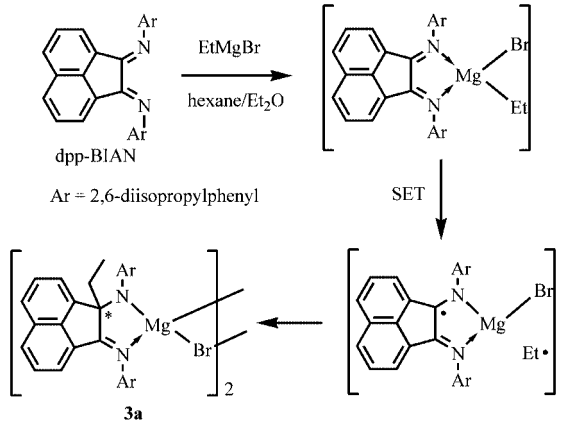
[a] Integral intensity corresponds to one proton. [b] Integral intensity corresponds to three protons.

Compound **3a** was prepared by the reaction of dpp-BIAN with EtMgBr (Scheme 2). Only its coordinating solvent differs from that of **3**.



Scheme 2.

Addition of an equimolar amount of EtMgBr (1.9 M in $Et_2O$) to a stirred suspension of dpp-BIAN in hexane at room temperature causes immediate dissolution of the diimine (and provides a clear red solution). Evaporation of the solvent in vacuo leads to rapid precipitation of a microcrystalline solid, which does not dissolve in hexane again, but readily dissolves in $Et_2O$ and toluene. Although the molecular structure of this product was not confirmed by X-ray crystallography, its identity was definitely established by $^1$H NMR spectroscopy. The $^1$H NMR spectroscopic data for the product obtained, together with those acquired for **2**–**4**, indicate that in the reaction of dpp-BIAN with EtMgBr a reverse process of SET – from Grignard reagent to neutral diimine ligand – takes place. Transfer of the alkyl radical formed to the imino carbon atom of dpp-BIAN follows this SET process. The $^1$H NMR spectrum of **3a** is shown in Figure 2. According to the $^1$H NMR data, the isolated compound **3a** does not contain coordinating solvent, e.g. diethyl ether. Therefore, we suggest that compound **3a** is dimeric in the solid state. This is supported by the recently reported dimeric structure of a closely related magnesium compound formed in the reaction of **1** with $Me_3SiCl$.[12] In this case, the SET from **1** to $Me_3SiCl$ causes the formation of $Me_3Si$ radicals, which attack THF molecules to form $Me_3SiO(CH_2)_3CH_2$ radicals. Transfer of these radicals to the imino carbon atom provided a compound that is an analog of **2**–**4**.

As in the case of compound **3**, the $^1$H NMR spectrum of **3a** (Figure 2) reveals the nonequivalence of all 12 aromatic protons, whose signals range from 7.84 to 6.10 ppm. Signals of four different methine protons are positioned at 4.85, 3.70, 3.05, and 2.96 ppm. Eight different methyl groups give rise to eight doublets centered at 1.39, 1.36, 1.26, 1.22, 1.12, 0.86, 0.44, and –0.15 ppm. The ethyl group provides three signals: two multiplets at 2.97 and 2.49 (1 H each) and a triplet at –0.07 (3 H) ppm.

The reduction of α-diimines to radical-anions with main-group organometallic compounds followed either by alkyl radical transfer to a radical-anionic ligand or by an alkyl radical release has been reported. Van Koten and coworkers have studied reactions of 1,4-diazabutadienes with different dialkylzinc compounds. Tertiary, benzylic, and some secondary organozinc compounds give C-alkylation products (sometimes accompanied with 1,3-prototropic shift), whereas primary dialkylzinc compounds give N-alkylation products.[14] Recently, Bailey and coworkers reported on the reactivity of $Me_2Mg$ towards dpp-BIAN and diacetal-bis(2,6-diisopropylphenylimine) (Ar′-DAD).[15] In both cases, the reactions occur with release of a methyl radical and afford complexes of radical-anionic ligands, e.g. (L$^{-\cdot}$)-MgMe (L = dpp-BIAN or Ar′-DAD). In the case of Ar′-DAD, the methyl transfer product was isolated in low yield when the reaction was carried out at low temperature. The formation of radical-anionic products in the above-mentioned reactions of organomagnesium compounds with diimines indicates clearly that these reactions occur by SET from the magnesium compound to the diimines. In order to find confirmation for the SET process in the course of the reaction of complex **1** with ethyl bromide, we have monitored this reaction by ESR spectroscopy. Addition of EtBr to a THF solution of complex **1** at –100 °C followed by slow warming of the reaction mixture to ambient temperature resulted in the appearance of the ESR signal of the dpp-BIAN radical-anion ($g$ = 2.0045, $A_N$ = 0.44, $A_{Br}$ = 0.2 mT).[12] In the course of several minutes this signal disappeared completely, indicating the recombination of the radical-anion and the ethyl radical.

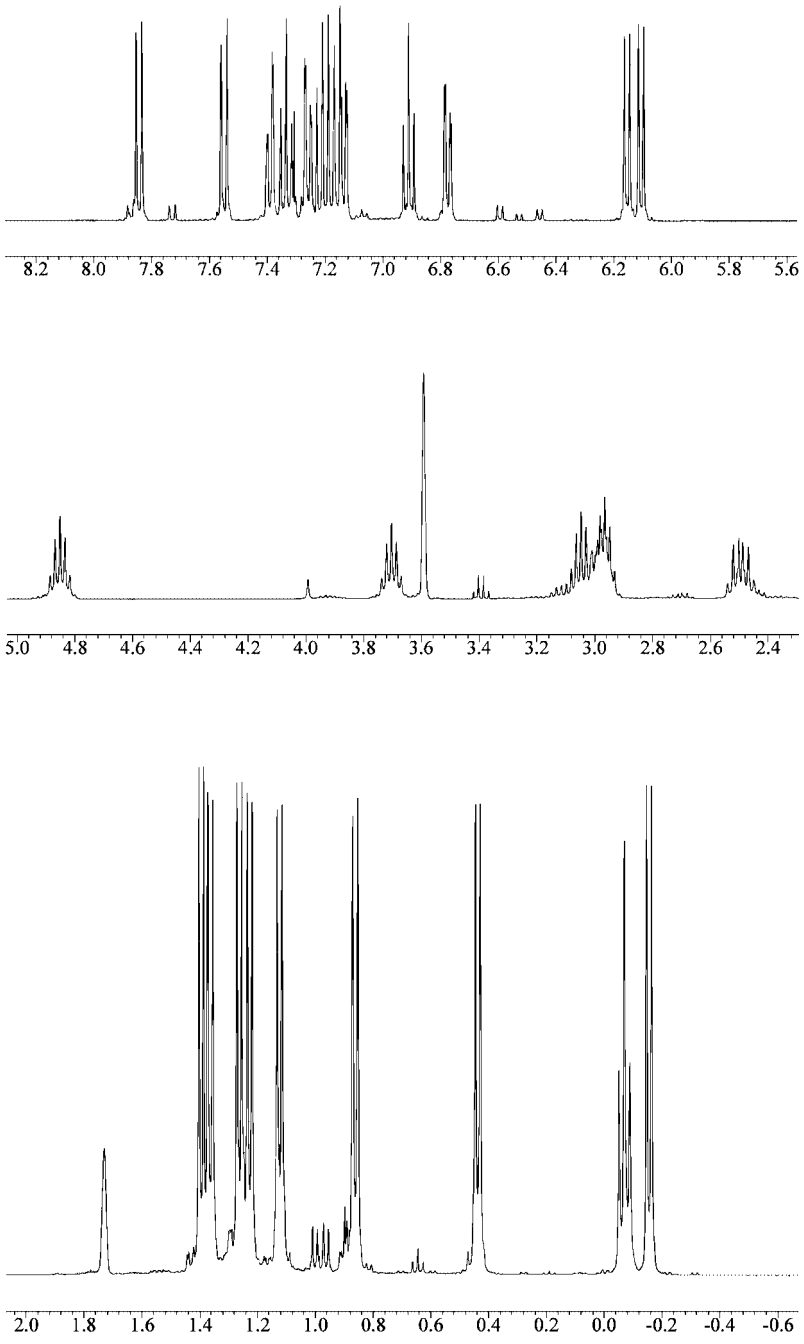

Figure 2. The $^1$H NMR spectrum of **3** divided in three sections ([$D_8$]THF, 400 MHz, 20 °C).

## Conclusions

In conclusion, we have demonstrated that diimine dpp-BIAN as well as its dianion may be involved in SET reactions. Thus, reagents having a low ionization potential, such as organometallic species, may reduce neutral dpp-BIAN. In contrast, the magnesium complex of the dpp-BIAN dianion acts as reducing agent towards organic halides. Taking into account the identity of the products isolated in both oxidation and reduction reactions one can suggest that both processes occur by the formation of the radical-anion of dpp-BIAN and an alkyl radical, which recombine to afford the final C–C coupling product.

## Experimental Section

**General Remarks:** All manipulations were carried out under vacuum using Schlenk ampoules. Tetrahydrofuran and diethyl ether were dried by distillation from sodium/benzophenone. [$D_8$]THF and $C_6D_6$ (both from Aldrich) used for NMR experiments were dried with sodium/benzophenone at ambient temperature and, just prior to use, condensed under vacuum into the NMR tubes already

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

containing the respective compound. Melting points were measured in sealed capillaries. IR spectra were recorded with an FTIR FSM-1201 spectrometer ("Monitoring Ltd."), $^1$H NMR spectra with Bruker DPX-200 and Bruker DRX-400 NMR spectrometers.

**(dpp-BIAN)Mg(THF)$_3$ (1):** Magnesium shavings (2.4 g, 100 mmol) and $I_2$ (0.5 g, 2.0 mmol) were placed in a Schlenk-like ampoule (ca. 100 mL volume) equipped with a Teflon stopcock. After evacuation of the ampoule (at $10^{-1}$ Torr for ca. 1 min), THF (40 mL) was added by condensation, and the mixture was stirred for 2 h. The $MgI_2(THF)_n$ formed was decanted together with the solvent, and the residual metal was washed three times with THF (40 mL). A suspension of dpp-BIAN (0.5 g, 1.0 mmol) in THF (20 mL) was then added to the activated magnesium metal, and the mixture was heated to reflux. Over the course of about 30 min, the reaction mixture turned deep green because of the formation of **1**. The solution was then cooled to ambient temperature and decanted from the excess magnesium. The solvent was evaporated in vacuo affording compound **1** as deep green, almost black crystals. The solid was washed three times with hexane (15 mL) and then used in the reactions with ethyl halides. The yields of the products **2**–**4** were calculated on the basis of the amount of dpp-BIAN used in the preparation of **1**.

**[(dpp-BIAN)(Et)]MgCl (2):** To a suspension of compound **1** (prepared from 0.5 g of dpp-BIAN) in hexane, was added ethyl chloride (0.32 g, 5 mmol). The reaction ampoule was sealed off under vacuum. In the course of 4 h at 80 °C, the precipitate of **1** dissolved completely. Slow cooling of the red solution to ambient temperature produced red crystals of **2** (0.39 g, 67%). M.p. 147 °C. $C_{38}H_{45}ClMgN_2$ (589.55): calcd. C 77.42, H 7.69; found C 77.11, H 7.91%. IR (Nujol): $\tilde{\nu}$ = 1626 (s), 1590 (m), 1307 (m), 1246 (m), 1188 (w), 1161 (w), 1103 (w), 1024 (m), 1015 (m), 934 (m), 857 (w), 854 (w), 800 (m), 780 (vs), 753 (s), 719 (s), 642 (w), 630 (w), 611 (w), 596 (w), 576 (w), 534 (w), 449 (s), 430 (s), 407 (vs) cm$^{-1}$. $^1$H NMR (200 MHz, [D$_8$]THF, 20 °C): $\delta$ = 7.84 (d, $J$ = 8.0 Hz, 1 H, CH arom.), 7.55 (d, $J$ = 8.3 Hz, 1 H, CH arom.), 7.39–7.15 (m, 5 H, CH arom.), 7.13 (dd, 1 H, $J$ = 7.5 and 1.7 Hz, CH arom.), 6.91 (t, $J$ = 7.5 Hz, 1 H, CH arom.), 6.77 (dd, 1 H, $J$ = 7.3 and 1.5 Hz, CH arom.), 6.17 (d, $J$ = 7.3 Hz, 1 H, CH arom.), 6.11 (d, $J$ = 7.0 Hz, 1 H, CH arom.), 4.82 [sept, 1 H, $J$ = 6.8 Hz, C$H$(CH$_3$)$_2$], 3.63 [sept, 1 H, $J$ = 6.8 Hz, C$H$(CH$_3$)$_2$], 3.09 [sept, 1 H, $J$ = 6.8 Hz, C$H$(CH$_3$)$_2$], 2.97 [sept, 1 H, $J$ = 6.8 Hz, C$H$(CH$_3$)$_2$], 2.75 (m, 1 H, C$H_2$CH$_3$), 2.54 (m,1 H, C$H_2$CH$_3$), 1.39 [d, $J$ = 6.8 Hz, 3 H, CH(C$H_3$)$_2$], 1.37 [d, $J$ = 6.8 Hz, 3 H, CH(C$H_3$)$_2$], 1.28 [d, $J$ = 6.8 Hz, 3 H, CH(C$H_3$)$_2$], 1.24 [d, $J$ = 6.8 Hz, 3 H, CH(C$H_3$)$_2$], 1.13 [d, $J$ = 6.8 Hz, 3 H, CH(C$H_3$)$_2$], 0.87 [d, $J$ = 6.8 Hz, 3 H, CH(C$H_3$)$_2$], 0.46 [d, $J$ = 6.8 Hz, 3 H, CH(C$H_3$)$_2$], –0.05 (t, $J$ = 7.3 Hz, 3 H, CH$_2$C$H_3$), –0.18 [d, $J$ = 6.8 Hz, 3 H, CH(C$H_3$)$_2$] ppm.

space group $P\bar{1}$, $Z = 2$, $\mu = 0.984\ mm^{-1}$, 12387 reflections measured, 7760 unique ($R_{int} = 0.0180$) which were used in all calculations. $R_1[I > 2\sigma(I)] = 0.526$, w$R_1$(all data) = 0.0635. The structures were solved by direct methods using SHELXS-97[16] and were refined on $F^2$ using SHELXL-97.[17] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were found from Fourier synthesis except those at C(38) and C(39) in the THF molecule. The hydrogen atoms at C(38) and C(39) as well as hydrogen atoms in the lattice $Et_2O$ molecule were placed in calculated positions and refined in the riding model. SADABS[18] was used to perform area-detector scaling and absorption corrections. CCDC-282656 (**3**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis, Structural Characterisation and Reactions of Some Vinylgold(I) Phosphane Complexes

**Fabian Mohr,[a] Larry R. Falvello,[a] and Mariano Laguna*[a]**

**Keywords:** Gold / Vinyl ligands / Phosphane ligands

A series of vinylgold(I) complexes [Au(CR=CHR)L] (R = H, Me; L = $PPh_3$, $PPh_2Me$, $PPhMe_2$) were prepared from the reaction of the Grignard reagents [MgBr(CR=CHR)] (R = H, Me) with the gold(I) phosphane complexes [AuCl(L)] (L = $PPh_3$, $PPh_2Me$, $PPhMe_2$) at low temperature. The complexes were characterised by various spectroscopic techniques and, in the case of [Au(CMe=CHMe)($PPh_3$)], by a single-crystal X-ray structure determination. The gold–carbon bonds of these vinylgold(I) complexes are easily cleaved by acids and, in the presence of potassium permanganate, by species containing acidic protons.

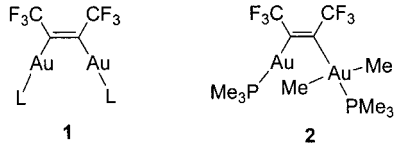
## Introduction

Organometallic gold(I) complexes of the type [AuR(L)], where R is an alkyl, aryl or alkynyl group and L is a neutral donor ligand such as a tertiary phosphane or isocyanide, have been studied in depth over the years and numerous derivatives have been synthesised, many of which have been structurally characterised.[1–4] In marked contrast, analogous vinylgold(I) complexes [Au(CR=$CR_2$)(L)] have received very little attention to date. In the 1970s a group of Russian workers reported the synthesis and some reactions of [Au(CH=$CH_2$)($PPh_3$)] but no X-ray structure was reported and the published experimental procedure seems dubious (see below).[5,6] Around the same time, other groups were studying reactions of [AuMe(L)] complexes with the fluorinated hydrocarbons $CF_3C{\equiv}CCF_3$ and $F_2C{=}CF_2$. Stone and Mitchell first observed that UV irradiation of a benzene solution of $CF_3C{\equiv}CCF_3$ and [AuMe($PPh_3$)] afforded a colourless product, which, based on $^{19}F$ NMR spectroscopic data and elemental analysis, they formulated as the binuclear complex [$Au_2$(μ-$CF_3C{=}CCF_3$)($PPh_3$)$_2$] (**1**).[7,8] The structure was later confirmed by an X-ray diffraction study, which showed that the complex consists of a $CF_3C{=}CCF_3$ molecule bridging two $AuPPh_3$ units.[9] Similar observations were made by Puddephatt and Johnson, who studied the reactions of [AuMe($PPhMe_2$)] and [AuMe($PMe_3$)] with $CF_3C{\equiv}CCF_3$. The initial reaction products, formulated as [$AuMe_2$($CF_3C{\equiv}CCF_3$)L] (L = $PPhMe_2$, $PMe_3$), undergo ethane elimination in acetone to give the binuclear complexes [$Au_2$(μ-$CF_3C{=}CCF_3$)$L_2$] (**1**), which is analogous to those observed earlier by Stone.[10] In the case of L = $PMe_3$, the crystal structure of the complex was obtained and shown to be the mixed-valence gold(I)/gold(III) complex [$Me_3PAu^{III}(Me)_2C(CF_3){=}C(CF_3)Au^{I}PMe_3$] (**2**), which contains a bridging $CF_3C{=}CCF_3$ unit.[11]



L = $PPh_3$, $PPhMe_2$, $PMe_3$

More recently, Brisdon and co-workers have prepared and structurally characterised the vinylgold(I) complexes [AuCR=$CF_2$($PPh_3$)] (R = Cl, F) by treating [AuCl($PPh_3$)] with the organolithium reagent $CF_2$=CRLi.[12] Puddephatt and Treurnicht reported the synthesis of the very thermally unstable vinylgold(I) complex [Au(CH=$CH_2$)(CNMe)], which could only be characterised by $^1H$ NMR spectroscopy at –20 °C.[13] Other approaches for adding vinyl groups to an $AuPPh_3$ unit have also been investigated. The vinyl(methyl)titanium complex [$Cp^*_2$TiMe(CH=$CH_2$)] reacts with [AuCl($PPh_3$)] to give [$Cp^*_2$TiCl(μ-C=$CH_2$)-$AuPPh_3$] (**3**), the structure of which contains a vinylidene unit bridging the titanium and gold atoms in an unsymmetrical fashion.[14] The vinylgold(I) complexes [Au{C(OR)=$CH_2$}($PPh_3$)M$(CO)_5$] (**4**) (M = Cr, Mo, W; R = Me, Et), in which the vinyl group is π-coordinated ($\eta^2$) to the M$(CO)_5$ fragment, are formed by treating the deprotonated carbene species Li[$(CO)_5$M=C(OR)$CH_2$] with [AuCl($PPh_3$)].[15] Addition of $PPh_3$ displaces the coordinated M$(CO)_5$ unit from **4** and produces the vinylgold(I) complex [Au{C(OR)=$CH_2$}($PPh_3$)].

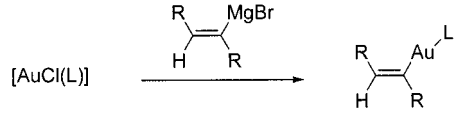
M = Cr, Mo, W; R = Me, Et

Our group has been studying the catalytic activity of various gold complexes in the addition of water or MeOH to terminal alkynes.[16] A vinylgold species has been suggested as a possible intermediate in this catalytic process. For this reason we were interested in preparing some vinylgold(I) complexes and studying their structures and reactivity. The results of this investigation are presented here.

## Results and Discussion

Initially, we attempted to reproduce the Russian work to prepare [Au(CH=CH$_2$)(PPh$_3$)] (**5a**). What seemed suspicious to us was the claim that the reaction between the vinyl Grignard reagent and [AuCl(PPh$_3$)] was carried out at +50 °C and that the complex was obtained in 90% yield![5] In our hands, these conditions led to complete decomposition of the reaction mixture to metallic gold. However, when vinylmagnesium bromide was added to an ethereal suspension of [AuCl(PPh$_3$)] at –78 °C the complex [Au(CH=CH$_2$)(PPh$_3$)] (**5a**) could be isolated in 73% yield after work-up. We found that when a large excess of Grignard reagent was used in the reaction and the subsequent hydrolysis was carried out with large volumes of water or aqueous NH$_4$Cl, significant decomposition to metallic gold occurred. This decomposition can be avoided by using only a small excess of Grignard reagent (ca. 10%), and simply exposing the reaction mixture to air was sufficient to hydrolyse the excess Grignard reagent. Following this procedure the vinylgold(I) complexes [Au(CR=CHR)(L)] (R = H, **5a**: L = PPh$_3$, **5b**: L = PPh$_2$Me, **5c**: L = PPhMe$_2$; R = Me, **6a**: L = PPh$_3$, **6b**: L = PPh$_2$Me, **6c**: L = PPhMe$_2$ ) were prepared in good to moderate yields (Scheme 1).



R = H
**5a**: L = PPh$_3$
**5b**: L = PPh$_2$Me
**5c**: L = PPhMe$_2$

R = Me
**6a**: L = PPh$_3$
**6b**: L = PPh$_2$Me
**6c**: L = PPhMe$_2$

Scheme 1.

All the complexes prepared are colourless, crystalline solids (except for **5c** and **6c**, which were isolated as pale-brown oils) that are air- and thermally stable in the solid state; in solution, however, decomposition occurs slowly (2–3 days) for the PPh$_3$ and PPh$_2$Me complexes, whilst the PPhMe$_2$ derivatives are stable in solution for less than 12 h. The $^1$H NMR spectra of the vinyl complexes **5a**–**5c** consists of three doublets of doublets displaying *trans,cis* and geminal coupling constants of 20, 14 and 5 Hz, respectively. The $^1$H NMR spectra of the dimethyl analogues **6a**–**6c** display a broad singlet at $\delta \approx 6.4$ ppm due to the vinylic proton. Furthermore, the two methyl groups attached to the vinyl group resonate as a broad singlet (coupling unresolved) and doublet of quartets for the α- and β-Me groups, respectively; the coupling constants confirm that the methyl groups are *trans* to each other. In the $^{13}$C NMR spectra of all six complexes we observed, in addition to the phenyl and Me signals, a singlet at $\delta \approx 129$ ppm due to the β-C of the vinyl group. The resonance of the α-C of the vinyl group attached to the gold atom could not be observed, presumably due to the large quadrupole moment of the proximal gold atom. As expected, the $^{31}$P{$^1$H} NMR spectra of all six complexes show singlet resonances whose chemical shift varies depending on the phosphane ligands. The FAB+ mass spectra of most of the complexes show weak molecular-ion peaks as well as peaks due to loss of the vinyl group and formation of higher mass ions [Au(phosphane)$_2$]$^+$; the latter are frequently observed in FAB mass spectra of gold(I) phosphane complexes.[17] The vinylgold(I) structure was confirmed by a partial X-ray diffraction study of **6a**. Due to the limited stability of the complex in solution, the crystals obtained were of poor quality and, more importantly, signs of twinning were apparent. However, the data were of sufficient quality to establish the connectivity and to derive geometric parameters of middling accuracy but wholly consistent with all other experimental data reported here and elsewhere for this and analogous compounds. A displacement ellipsoid plot of one molecule is shown in Figure 1.[18]

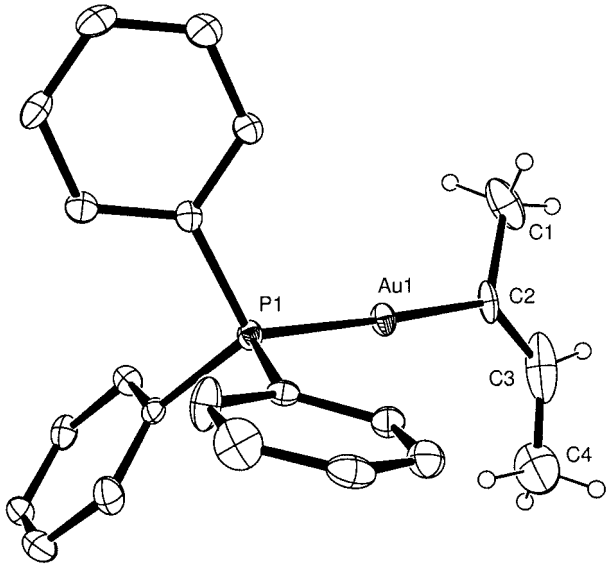


Figure 1. ORTEP view of one of the independent molecules of **6a**. Ellipsoids show 30% probability levels; phenyl hydrogen atoms have been omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

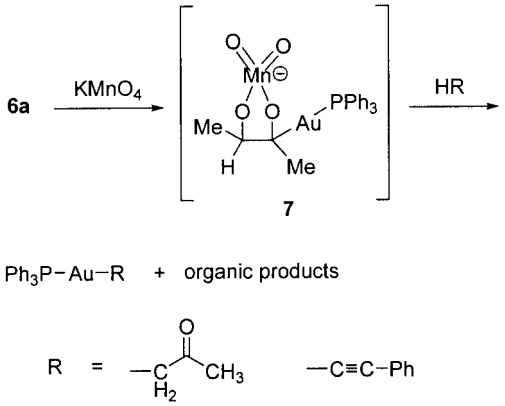
The structure was refined in the space group *C*2/*c* with two independent molecules in the asymmetric unit. Some bond lengths and angles differ slightly between the two molecules; but we do not wish to attribute chemical significance to this observation given that the differences are consistent with the inaccuracies evident in the diffraction data (vide infra) [$wR_2$ = 0.1482, $R_1$ = 0.0822, C–C bond precision 0.022 Å]. The structure of **6a** consists of a dimethylvinyl moiety (with the Me groups in a *trans* configuration) and a $PPh_3$ unit linearly [177.9(3)° and 175.4(4)°] coordinated to the gold(I) centre. The Au–P [2.3092(19) and 2.291(2) Å] and Au–C [2.004(7) and 2.053(10) Å] distances are similar to those in [Au(CF=$CF_2$)($PPh_3$)] [Au–P = 2.272(3) and Au–C = 2.028(9) Å] and [Au(CCl=$CF_2$)($PPh_3$)] [Au–P = 2.266(2) and Au–C = 2.026(10) Å].[12] The vinyl C=C distances [1.322(18) and 1.327(17) Å] are slightly longer than those in [Au(CF=$CF_2$)($PPh_3$)] [C=C = 1.297(14) Å][12] but shorter than that in [AuC(OMe)=$CH_2$($PPh_3$)Cr($CO)_5$] [C=C = 1.345(11) Å].[15]

### Reactions of Vinylgold(I) Complexes

The Russian workers studied the reactions of [Au(CH=$CH_2$)($PPh_3$)] (**5a**) with HCl, $HgCl_2$ $Br_2$, $(SCN)_2$, benzoic acid and $KMnO_4$.[6] In the first five cases the gold–carbon bond is cleaved to give [AuX($PPh_3$)] (X = Cl, Br, SCN, $O_2$CPh) as the gold-containing product. However, in the case of $KMnO_4$, neither metal–carbon bond cleavage nor oxidation of the carbon–carbon double bond occurs; instead, the acetonylgold(I) phosphane complex [Au{$CH_2C(O)CH_3$}($PPh_3$)] is formed in high yield.[6,19] The X-ray crystal structure of this complex was reported later, but neither the method of preparation nor source of the sample was mentioned.[20] In order to examine the generality of these reactions we studied the reaction of hydrochloric acid and $KMnO_4$ with the new vinylgold(I) complex **6a**. Treatment of an acetone solution of **6a** with a solution of HCl or DCl in $D_2O$ (the deuterated acid was more convenient to study by $^1$H NMR spectroscopy) results in electrophilic cleavage of the gold–carbon bond and formation of [AuCl($PPh_3$)] and *trans*-MeDC=CMeH, as was evident from the $^1$H and $^{31}$P NMR spectra; the chemical shift observed in the $^{31}$P NMR spectrum is identical to that of an authentic sample of [AuCl($PPh_3$)]. Treatment of an acetone solution of complex **6a** at 0 °C with $KMnO_4$ resulted in formation of a brown precipitate ($MnO_2$). After about 30 min reaction time a pale-yellow solid could be isolated from the mixture after filtration and removal of the solvent. On the basis of $^1$H and $^{31}$P{$^1$H} NMR spectroscopic data, this product was identified as the acetonylgold(I) complex [Au{$CH_2C(O)CH_3$}($PPh_3$)], identical to that reported by Nesmeyanov.[19] We were interested in investigating this reaction in more detail in order to gain some understanding of the mechanism and the exact role of the permanganate. To test whether species containing acidic protons, such as acetone or phenylacetylene, can react with **6a** in the absence of permanganate we treated $CDCl_3$ solutions of complex **6a** with an equivalent amount of acetone or phenylacetylene and examined the $^1$H and $^{31}$P NMR spectra over time. Even after a period of 48 h there was no evidence that any reaction had occurred − only signals from the starting complex were observed in the NMR spectra − thus confirming that permanganate is indeed required for this reaction. If a solution of $KMnO_4$ in $CD_3CN$ is then added to the NNR tubes containing complex **6a** and acetone or phenylacetylene a brown precipitate is observed after a few minutes and after about 30 min the main species in solution, determined by NMR spectroscopy, are [Au{$CH_2C(O)CH_3$}($PPh_3$)] and [Au(C≡CPh)($PPh_3$)], respectively. These results suggest that the permanganate reacts initially with the vinylgold(I) complex, probably oxidising the carbon–carbon double bond, via an intermediate gold(I)/manganese(V) cyclic ester **7** (Scheme 2). It is known that the oxidation of alkenes with permanganate proceeds via such cyclic $Mn^V$ ester intermediates, which undergo decomposition reactions to give organic products and $MnO_2$.[21] Recently, this [3+2] mechanism via cyclic $Mn^V$ esters has been confirmed by DFT calculations and kinetic isotope effect data.[22] In our case, the evidence presented above suggests that the presumed intermediate **7** causes deprotonation of acetone and phenylacetylene, thus producing the acetonyl- and alkynylgold(I) complexes as well as the diol, accompanied, perhaps even driven, by precipitation of insoluble $MnO_2$. We tried to identify the organic oxidation products by both $^1$H NMR and GC/MS spectroscopy, but no conclusive results were obtained. In an attempt to observe the intermediate species **7** we treated a $CDCl_3$ solution of **6a** with a $CD_3CN$ solution of $KMnO_4$ and observed immediate formation of a brown precipitate. The $^{31}$P NMR spectrum of the supernatant solution shows a singlet resonance at $\delta$ = 44.50 ppm, slightly shifted relative to that of the starting complex ($\delta$ = 44.77 ppm), which may be due to the intermediate. However, the presence of a multiplet at $\delta$ = 6.4 ppm in the $^1$H NMR spectrum, due to the vinylic proton, suggests that the C=C double bond in the vinyl ligand is still intact; in fact, the overall spectrum is almost identical to that of **6a**. When excess PhC≡CH is added to this solution the $^{31}$P NMR spectrum shows, in addition to the original peak at $\delta$ = 44.50 ppm, a new signal at $\delta$ = 42.15 ppm. The latter resonance is consistent with the presence of [Au(C≡CPh)($PPh_3$)], which was confirmed by comparison of chemical shifts of an authentic sample. Over a period of about 10 h the intensity of the signal due to [Au(C≡CPh)($PPh_3$)] increases, whilst that of the starting complex **6a** decreases. After about 24 h the major species in solution is [Au(C≡CPh)($PPh_3$)]. If the same experiment is carried out with acetone similar observations are made, namely the intensity of the $^{31}$P NMR signal due to the acetonylgold(I) complex [Au{$CH_2C(O)CH_3$}($PPh_3$)] increases over time, while that due to **6a** decreases. These results show that $KMnO_4$ is required for the vinylgold(I) complex to react with species containing acidic protons and, although we failed to detect any intermediate, the simple fact that addition of $KMnO_4$ to a solution of **6a** causes precipitation of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$MnO_2$ suggests that some reaction yielding an undetectable intermediate must be taking place. More detailed investigations are necessary to fully understand this process. Other oxidants including dichromate and $H_2O_2$ either do not react at all or, in the case of peroxide, oxidation of the phosphane occurs to give $Ph_3P{=}O$ and decomposition of the starting complex to gold metal.



Scheme 2.

In summary, we have shown that vinylgold(I) complexes can be prepared in good yields from the reaction of a vinyl Grignard reagent with $[AuCl(PPh_3)]$ at low temperatures. The gold–vinyl–C bond is easily cleaved by acids or, in the presence of $KMnO_4$, by species containing an acidic proton such as acetone and phenylacetylene. Further work is currently in progress to further elucidate the mechanism of this reaction and to study other reactions of vinylgold(I) compounds.

## Experimental Section

**General:** All reactions were performed under an atmosphere of dry argon using Schlenk techniques. Solvents were dried by standard methods and freshly distilled under argon before use. $^1H$, $^{13}C$ and $^{31}P\{^1H\}$ NMR spectra were recorded with a 400 MHz Bruker Avance spectrometer. Chemical shifts are quoted relative to external TMS ($^1H$ and $^{13}C$) or 85% $H_3PO_4$ ($^{31}P$). FAB mass spectra were measured on a VG Autospec spectrometer in positive ion mode using NBA as matrix. Elemental analyses were obtained in-house using a Perkin–Elmer 240B microanalyser. The chlorogold(I) precursor complexes were prepared by treating equivalent amounts of [AuCl(tht)] with the tertiary phosphanes in $CH_2Cl_2$. The vinyl Grignard reagents were obtained commercially (Aldrich).

**[Au(CH=CH$_2$)(PPh$_3$)] (5a):** A suspension of $[AuCl(PPh_3)]$ (0.402 g, 0.929 mmol) in dry $Et_2O$ (10 mL) was cooled to –78 °C and treated with a solution of vinylmagnesium bromide (1.0 mL 1 M solution in THF, 1.0 mmol). The mixture was warmed to room temperature over a period of 4 h. After this time the reaction vessel was exposed to air for about 10 min. to hydrolyze any unreacted Grignard reagent. The mixture was then filtered through anhydrous $MgSO_4$ and the filtrate evaporated to dryness in vacuo to afford 0.288 g (73%) of colourless product. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.42–7.61 (m, 15 H, Ph), 7.20 (dd, $J_{trans\text{-}H,H}$ = 20, $J_{cis\text{-}H,H}$ = 14 Hz, 1 H, AuC*H*), 6.04 (dd, $J_{trans\text{-}H,H}$ = 20, $J_{gem\text{-}H,H}$ = 5 Hz, 1 H, =C$H_2$), 5.53 (dd, $J_{cis\text{-}H,H}$ = 14, $J_{gem\text{-}H,H}$ = 5 Hz, 1 H, =C$H_2$) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 134.3 (d, $^3J_{P,C}$ = 13 Hz, *meta*-Ph), 131.4 (s, AuC=*C*), 131.2 (s, *para*-Ph), 129.0 (d, $^2J_{P,C}$ = 10 Hz, *ortho*-Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = 44.40 ppm ppm. FAB MS: *m*/*z* (%) = = 486 (5) $[M]^+$, 459 (95) $[Au(PPh_3)]^+$, 721 (100) $[Au(PPh_3)_2]^+$. $C_{20}H_{18}AuP$ (486.3): calcd. C 49.40, H 3.73; found C 49.30, H 3.50.

Compounds **5b** and **5c** were prepared in a similar manner.

**[Au(CH=CH$_2$)(PMePh$_2$)] (5b):** Colourless solid (0.252 g, 64% yield). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.60–7.70 (m, 4 H, Ph), 7.41–7.48 (m, 6 H, Ph), 7.14 (dd, $J_{trans\text{-}H,H}$ = 21, $J_{cis\text{-}H,H}$ = 14 Hz, 1 H, AuC*H*), 6.00 (dd, $J_{cis\text{-}H,H}$ = 14, $J_{gem\text{-}H,H}$ = 5 Hz, 1 H, =C$H_2$), 5.48 (dd, $J_{trans\text{-}H,H}$ = 21, $J_{gem\text{-}H,H}$ = 5 Hz, 1 H, =C$H_2$), 2.01 (d, $^2J_{P,H}$ = 8 Hz, 3 H, $PCH_3$) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 132.8 (d, $^3J_{P,C}$ = 13 Hz, *meta*-Ph), 132.7 (d, $^1J_{P,C}$ = 50 Hz, *ipso*-Ph), 131.5 (s, AuC=*C*), 131.0 (s, *para*-Ph), 129.0 (d, $^2J_{P,C}$ = 10 Hz, *ortho*-Ph), 13.9 (d, $^1J_{P,C}$ = 32 Hz, P*C*H$_3$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = 30.10 ppm ppm. FAB MS: *m*/*z* (%) = = 379 (60) $[Au(PMePh_2)]^+$, 597 (100) $[Au(PMePh_2)_2]^+$ 821 (35) [M + $Au(PPh_2Me)]^+$. $C_{15}H_{16}AuP$ (424.2): calcd. C 42.47, H 3.80; found C 42.84, H 3.71.

**[Au(CH=CH$_2$)(PPhMe$_2$)] (5c):** Pale-brown oil (0.108 g, 55% yield). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.70–7.78 (m, 2 H, Ph), 7.45–7.50 (m, 3 H, Ph), 7.10 (dd, $J_{trans\text{-}H,H}$ = 21, $J_{cis\text{-}H,H}$ = 14 Hz, 1 H, AuC*H*), 5.98 (dd, $J_{cis\text{-}H,H}$ = 12, $J_{gem\text{-}H,H}$ = 5 Hz, 1 H, =C$H_2$), 5.46 (dd, $J_{trans\text{-}H,H}$ = 21, $J_{gem\text{-}H,H}$ = 5 Hz, 1 H, =C$H_2$), 1.73 (br. s, 6 H, $PCH_3$) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 133.8 (d, $^1J_{P,C}$ = 49 Hz, *ipso*-Ph), 131.77 (d, $^3J_{P,C}$ = 13 Hz, *meta*-Ph), 131.5 (s, AuC=*C*), 131.1 (s, *para*-Ph), 128.9 (d, $^2J_{P,C}$ = 10 Hz, *ortho*-Ph), 15.34 (d, $^1J_{P,C}$ = 31 Hz, P*C*H$_3$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = 18.65 ppm. FAB MS: *m*/*z* (%) = 335 (62) $[Au(PPhMe_2)]^+$, 473 (100) $[Au(PPhMe_2)_2]^+$.

The following complexes were prepared as described above using 1-methyl-1-propenylmagnesium bromide.

**[Au(CMe=CHMe)(PPh$_3$)] (6a):** Colourless, crystalline solid (0.206 g, 63% yield). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.51–7.60 (m, 6 H, Ph), 7.40–7.51 (m, 9 H, Ph), 6.45 (m, 1 H, =C*H*Me), 2.06 (br. s, 3 H, AuC*Me*), 1.95 (dq, $^3J_{H,H}$ = 6, $^5J_{H,H}$ = 1 Hz, 3 H, =CH*Me*) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 134.3 (d, $^3J_{P,C}$ = 13 Hz, *meta*-Ph), 131.4 (d, $^1J_{P,C}$ = 48 Hz, *ipso*-Ph), 130.8 (s, *para*-Ph), 129.2 (AuC=*C*), 128.9 (d, $^2J_{P,C}$ = 10 Hz, *ortho*-Ph), 30.4 (s, AuC*Me*), 20.9 (s, CH*Me*) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = 44.77 ppm. FAB MS: *m*/*z* (%) = 514 (15) $[M]^+$, 459 (100) $[Au(PPh_3)]^+$, 721 (65) $[Au(PPh_3)_2]^+$. $C_{22}H_{22}AuP$ (514.4): calcd. C 51.37, H 4.31; found C 51.48, H 4.12. X-ray quality crystals were selected from the bulk sample.

**[Au(CMe=CHMe)(PPh$_2$Me)] (6b):** Colourless solid (0.118 g, 73% yield). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.61–7.71 (m, 4 H, Ph), 7.39–7.48 (m, 6 H, Ph), 6.47 (m, 1 H, =C*H*Me), 2.06 (br. s, 3 H, AuC*Me*), 2.01 (d, $^2J_{P,H}$ = 6 Hz, 3 H, P*Me*) 1.96 (dq, $^3J_{H,H}$ = 6, $^5J_{H,H}$ = 1 Hz, 3 H, =CH*Me*) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 133.2 (d, $^1J_{P,C}$ = 47 Hz, *ipso*-Ph), 132.7 (d, $^3J_{P,C}$ = 13 Hz, *meta*-Ph), 130.8 (s, *para*-Ph), 129.3 (s, AuC=*C*), 128.9 (d, $^2J_{P,C}$ = 10 Hz, *ortho*-Ph), 30.3 (s, AuC*Me*), 20.9 (s, CH*Me*), 13.7 (d, $^1J_{P,C}$ = 39 Hz, P*Me*) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = 30.96 ppm. FAB MS: *m*/*z* (%) = 452 (10) $[M]^+$, 397 (100) $[Au(PPh_2Me)]^+$, 597 (55) $[Au(PPh_2Me)_2]^+$. $C_{17}H_{20}AuP$ (452.3): calcd. C 45.14, H 4.46; found C 45.28, H 4.32.

**[Au(CMe=CHMe)(PPhMe$_2$)] (6c):** Pale-brown oil (0.170 g, 40% yield). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.68–7.80 (m, 2 H, Ph), 7.41–7.50 (m, 3 H, Ph), 6.45 (m, 1 H, =C*H*Me), 2.01 (br. s, 3 H, AuC*Me*), 1.92 (dq, $^3J_{H,H}$ = 6, $^5J_{H,H}$ = 1 Hz, 3 H, =CH*Me*),

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.70 (d, $^2J_{P,H}$ = 6 Hz, 6 H, P*Me*) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 131.8 (d, $^3J_{P,C}$ = 13 Hz, *meta*-Ph), 131.1 (s, *para*-Ph), 129.4 (s, AuC=*C*), 129.0 (d, $^2J_{P,C}$ = 11 Hz, *ortho*-Ph), 30.4 (s, AuC*Me*), 20.9 (s, CH*Me*), 15.3 (d, $^1J_{P,C}$ = 32 Hz, P*Me*) ppm. $^{31}$P{$^1$H} NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = 19.96 ppm. FAB MS: *m/z* (%) = 390 (11) $[M]^+$, 335 (100) $[Au(PPhMe_2)]^+$, 473 (90) $[Au(PPhMe_2)_2]^+$.

**Reaction of 6a with Acid:** A few drops of an approx. 1 M solution of DCl in $D_2O$ was added to a sample of **6a** dissolved in [$D_6$] acetone in an NMR tube. $^1$H and $^{31}$P NMR spectra were recorded after about 10 min. $^1$H NMR (400 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 7.53–7.66 (m, 15 H, Ph from $Ph_3PAuCl$), 5.35 (br. s, 1 H, C*H*Me), 1.54 (q, $^3J_{H,D}$ = 1 Hz, 3 H, CD*Me*), 1.53 (s, 3 H, CH*Me*) ppm. $^{31}$P{$^1$H} NMR (162 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 33.97 ppm. This $^{31}$P{$^1$H} NMR chemical shift is identical to that of an authentic sample of [$AuCl(PPh_3)$].

**Reaction of 6a with $KMnO_4$:** A sample of **6a** was dissolved in acetone and treated with an acetone solution of $KMnO_4$ at about 0 °C. After around 10 min a brown precipitate ($MnO_2$) was observed. The mixture was filtered and the filtrate was evaporated to dryness. $^1$H and $^{31}$P NMR spectra of the pale-yellow solid were recorded. $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.40–7.59 (m, 15 H, Ph), 2.71 (d, $^3J_{H,P}$ = 1 1 Hz, 2 H, AuC$H_2$), 2.22 (s, 3 H, C*Me*) ppm. $^{31}$P{$^1$H} NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = 42.20 ppm. In addition, there are trace amounts of starting complex **6a** and a further unidentified species present ($\delta_P$ = 44.7 and 29.2 ppm, respectively).

**NMR Reactions of 6a with $KMnO_4$ and Acetone or Phenylacetylene:** A solution of $KMnO_4$ in $CD_3CN$ was added to a $CDCl_3$ solution of **6a**. A brown solid ($MnO_2$) precipitated immediately. Acetone or phenylacetylene (4 μL) was then added to the NMR tube and $^{31}$P and $^1$H NMR spectra were recorded before and after the addition.

**Reaction of 6a with $H_2O_2$:** A sample of **6a** dissolved in acetone was treated with 30% $H_2O_2$. After stirring for about 30 min a gold mirror had formed on the inside of the flask. The solvents were removed in vacuo and the residue was analysed by $^{31}$P spectroscopy. $^{31}$P{$^1$H} NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = 29.69 ppm.

**X-ray Crystallography of Complex 6a:** Data were gathered twice, from two different crystals and using two different CCD-based diffractometers, with similar results in both cases. The results reported here were derived from data gathered using a four-circle diffractometer (Xcalibur2 with a Sapphire3 detector and sealed tube Mo Enhance source).[23] A crystal of dimensions 0.17 × 0.16 × 0.05 mm, and with a slight yellow tint as viewed under an optical microscope, was mounted with epoxy at the end of a quartz fibre and kept at 123 K for the measurements. A preliminary unit-cell determination yielded the same results that had been determined earlier using a Bruker Apex diffractometer, namely a monoclinic cell with one unusually long axis (ca. 45.8 Å). The cell dimensions were verified on the four-circle diffractometer using normal-beam axial photography. Because of the long axis, for the present data the crystal-to-detector distance was set to 90 mm and the data collection strategy was optimised accordingly. The faces of the crystal were indexed and absorption corrections were calculated numerically and applied to the integrated data. The structure was solved by direct methods and refined against $F_o^2$ using full-matrix least-squares.[24] Non-hydrogen atoms were refined anisotropically. Non-methyl hydrogen atoms were placed at calculated positions and refined as riders. Methyl hydrogen atoms were located successfully in local slant-Fourier calculations and refined as riding atoms but with a variable torsion angle about the local C–C bond. The refinement was stable and convergent, but the results showed effects that are normally considered characteristic of twinning, i.e. high residuals, some 20 difference peaks above 1 e Å$^{-3}$, and unusual analysis of variance with the worst-fit reflections largely having $F_o^2$ greater than $F_c^2$. Several twin models were tested, each of which produced some improvement in the crystallographic indicators but did not influence the chemical implications of the results. Concurrent twin models were also tested, with similar results. The results reported here are those obtained with no twin model; more information on other models can be obtained from the authors. Commonly employed structure validation tools (PLATON[25]) did not reveal the presence of missed crystallographic symmetry elements. Visual examination of the structural results suggests pseudo-translational symmetry, but at the same time reveals that the two independent molecules have very different environments and participate in quite distinct fashions in the crystal packing. One of the phenyl groups (C50–C55) shows prolate displacement ellipsoids and a short average C–C distance. While these are normally taken to be definitive symptoms of libration, we cannot rule out an association between these effects and the presence of a putative minor twin component.

# Synthesis, Characterisation and Biological Activity of Chiral Platinum(II) Complexes

David Jaramillo,[a] Damian P. Buck,[b] J. Grant Collins,[b] Ronald R. Fenton,[c] Frank H. Stootman,[a] Nial J. Wheate,[a] and Janice R. Aldrich-Wright*[a]

**Keywords:** Platinum / Chiral / Intercalator / Cancer / L1210 / Induced circular dichroism

Four platinum(II) complexes of 1,10-phenanthroline (phen) and 3,4,7,8-tetramethyl-1,10-phenanthroline (3,4,7,8-$Me_4$phen), with the chiral ancillary ligands (1*R*,3*S*) and (1*S*,3*R*)-1,3-diamino-1,2,2-trimethylcyclopentane (*R*,*S*-tmcp and *S*,*R*-tmcp, respectively) have been synthesised and their biological activity quantified using an in vitro cytotoxicity assay against the L1210 murine leukaemia cell line. [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$-phen)]$Cl_2$ showed an increase in biological activity over their non-methylated complexes, [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$. Some chiral discrimination was observed in the in vitro cytotoxicity experiments with the complexes having (*S*,*R*) configuration showing higher biological activity in L1210 cells. Titrations of the metal complexes into ct-DNA and observation of the changes induced in the CD spectra were used to determine the binding constants. The binding of these metal complexes to the hexamer d(GTCGAC)$_2$ was studied using two-dimensional $^1$H NMR spectroscopy. The addition of metal complexes to the hexamer produced upfield shifts of the metal complex of selected resonances, characteristic of intercalation for [Pt(tmcp)-(phen)]$Cl_2$, whereas the [Pt(tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ complexes only partially intercalate and in a "side-on" fashion. Through the observation of NOE cross-peaks, two-dimensional NMR experiments provided some insight into the site and groove preferences of these complexes when binding to DNA. Here, we report the biological activity of platinum(II) complexes containing an intercalator and a chiral diamine, which influences the degree to which the complexes can interact with DNA.

## Introduction

The interaction of positively charged metallointercalators with the base-pair stack of DNA has been an area of interest for some time.[1–7] Square-planar platinum(II) complexes derived from heterocyclic ligands have produced greater in vitro cytotoxicity against human ovarian cancer cell lines, than some current therapeutic agents.[8] These intercalating complexes introduce reversible binding, a mode that is different from that of cisplatin. Compounds like [Pt(en)(phen)]$Cl_2$, which bind reversibly and non-covalently, have also been widely studied using calorimetric studies and thermodynamic calculations,[9] circular dichroism (CD) polarimetry,[10] electronic absorption studies using nucleotides[11–12] and two-dimensional $^1$H nuclear magnetic resonance (NMR) spectroscopy[13] to further understand their interaction with DNA.

We recently published[14] our investigation of a series of platinum(II) complexes, of the type [Pt(en)(phen)]$Cl_2$ containing methylated derivatives of the ligand 1,10-phenanthroline [where en = 1,2-diaminoethane, phen = 1,10-phenanthroline and phen is substituted with 4-methyl-1,10-phenanthroline (4-Mephen), 5-methyl-1,10-phenanthroline (5-Mephen), 4,7-dimethyl-1,10-phenanthroline (4,7-$Me_2$phen), 5,6-dimethyl-1,10-phenanthroline (5,6-$Me_2$phen) or 3,4,7,8-tetramethyl-1,10-phenanthroline (3,4,7,8-$Me_4$phen)] and determined that the position and number of methyl groups on the 1,10-phenanthroline structure influences biological activity. Viscometry, CD and NMR studies indicated that all the platinum(II) complexes intercalate into the DNA base pair stack.[14]

A dependence of the mutagenic and anticancer activity in covalent platinum(II) complexes upon the configuration of the ancillary ligand has been previously reported.[14,15] Cytotoxic activity of a series of chiral *cis*-diaminodichloroplatinum(II) complexes, in various cell lines, has shown an enantioselective trend.[16]

[Pt(en)(phen)]$Cl_2$ proved to be the most efficient intercalator of the platinum(II) complexes investigated, whereas [Pt(en)(3,4,7,8-$Me_4$phen)]$Cl_2$ was one of the least efficient.

The wide range of biological activity seen for that series of platinum(II) complexes of 1,10-phenathrolines was encouraging and raised the question of whether other non-covalent binding platinum(II) complexes, with a wider range of substituting group-type, number and position/s on 1,10-phenanthroline and ancillary ligands have the potential to yield more active complexes.

Accordingly, we have prepared chiral platinum(II) complexes based on [Pt(en)(phen)]$Cl_2$ and [Pt(en)(3,4,7,8-$Me_4$phen)]$Cl_2$, where en is replaced by the 1*R*,3*S*- or the 1*S*,3*R*-form of 1,3-diamino-1,2,2-trimethylcyclopentane (*R*,*S*-tmcp and *S*,*R*-tmcp, respectively) (Figure 1). Each complex was examined for its growth inhibition against L1210 murine leukaemia cells, their effect on the viscometry of linear DNA, their induced circular dichroism upon addition to ct-DNA and $^1$H NMR binding with the hexanucleotide d(GTCGAC)$_2$. The results are compared with those for the parent complexes [Pt(en)(phen)]$Cl_2$ and [Pt(en)(3,4,7,8-$Me_4$phen)]$Cl_2$.

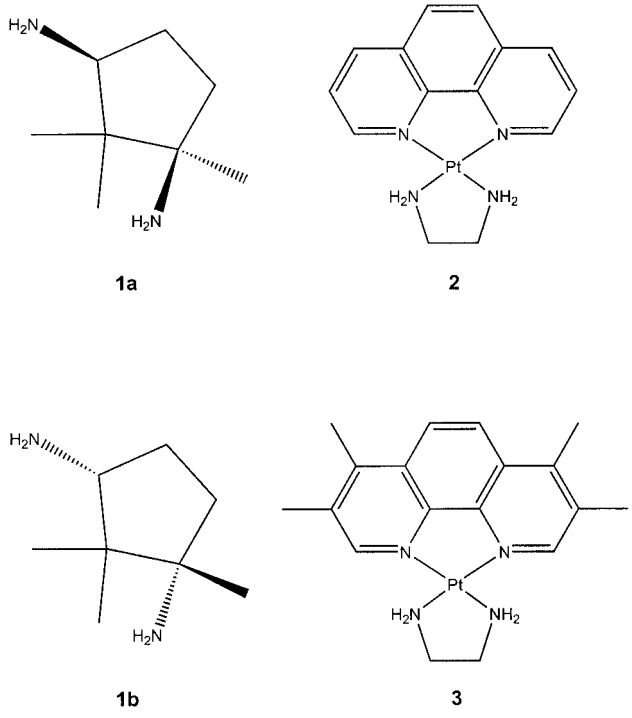

Figure 1. The structure of (1*R*,3*S*) (**1a**) and (1*S*,3*R*)-1,3-diamino-1,2,2-trimethylcyclopentane (**1b**) along with the metal complexes: [Pt(en)(phen)]$Cl_2$ (**2**) and [Pt(en)(3,4,7,8-$Me_4$phen)]$Cl_2$ (**3**).

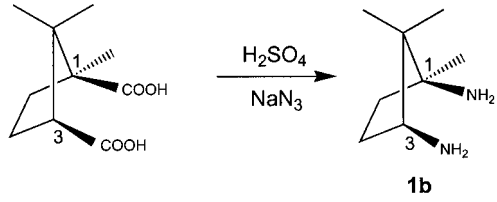
## Results and Discussion

### Metal Complex Syntheses

The ligands **1a** and **1b** were prepared by an adapted Schmidt reaction from (*R*,*S*) and (*S*,*R*)-camphoric acid, respectively (Scheme 1). The yields and $^1$H/$^{13}$C NMR of both compounds are consistent with published data.[14] The platinum(II) complexes were prepared by refluxing aqueous solutions of [Pt(phen)$Cl_2$], or [Pt(3,4,7,8-$Me_4$phen)$Cl_2$], with the appropriate chiral ligand, until the complex had completely dissolved. Despite their structural similarities, the methylated complexes [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$·4$H_2O$ (**3a**) and [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$·4$H_2O$ (**3b**) took longer to react (24 hours) in comparison to [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$·2$H_2O$ (**2a**) and [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$·2.5$H_2O$ (**2b**) (16 hours). The variation in reaction time can be ascribed to the difference in p$K_a$, where the reactivity observed in each complex increases with a decrease in base character {[Pt(phen)$Cl_2$] p$K_a$ = 4.96; [Pt(3,4,7,8-$Me_4$phen)$Cl_2$] p$K_a$ = 6.31}.[17] All complexes were isolated as chloride salts to facilitate aqueous solubility for biological testing.



Scheme 1.

The complexes were characterised by NMR and CD spectroscopy. All $^1$H NMR spectra were recorded in [$D_6$]-DMSO in the range of 0 to 10 ppm. The C2 methyl protons of [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$·2$H_2O$ (**2a**) and [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$·2.5$H_2O$ (**2b**), appeared at $\delta$ = 0.80 and 1.26 ppm. The C1 methyl proton occurred downfield at $\delta$ = 1.45 ppm as a consequence of shielding due to its proximity to the nitrogen and platinum(II) atoms. The C3 methine proton occurred as a multiplet at $\delta$ = 2.91 ppm, with the C5 protons further upfield at $\delta$ = 1.78 and 1.92 ppm. Assignment of the amine protons was based on 2D DQFCOSY experiments, with the two AB spin systems occurring at $\delta$ = 6.51 ppm for C(1)$NH_2$, and 6.78 ppm for C(3)$NH_2$. The C4 protons were observed at $\delta$ = 2.15 ppm through scalar coupling to the methine proton on C3. The coordination of the diamine species rendered the aromatic ligands asymmetric, producing further splitting of the characteristic proton signals. The signals of the phenanthroline ring resonated as two doublet of doublets at $\delta$ = 8.31 and 8.29 ppm for H7/14, and a singlet at $\delta$ = 8.35 ppm for H10/11. H6/15 and H8/13 appeared as a multiplet at $\delta$ = 9.15 ppm.

The aromatic protons of [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$·4$H_2O$ (**3a**) and [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$·4$H_2O$ (**3b**), H6′/15′ appeared as a singlet at $\delta$ = 8.38 ppm, and for H10′/11′ two singlets in the $^1$H NMR and were observed at $\delta$ = 9.06 and 8.99 ppm. The aromatic methyl groups were upfield at $\delta$ = 2.64 and 2.80 ppm. The signals for the chiral ancillary ligand occurred at similar chemical shifts to the non-methylated complex. $^{13}$C and DEPT NMR spectra accounted for all carbon atoms present for the four complexes.

[a] $IC_{50}$ values were determined for murine leukaemia L1210 cells and are reported for two experiments at 48 h continuous exposure to the metal complexes. [b] Replication = 2. [c] Replication = 4. [d] The intrinsic approach[18] was used to determine the values of α whereas the Scatchard model[18] was used to determine $K_b$ and $n$ for the CD ct-DNA titration data. [e] Data from ref.[14]. [f] Direct least-squares curve fitting, using a Levenberg–Marquardt method, to the same experimental points.[17] [g] Relative viscosity measurements were made for [metal]/[DNA] molar ratios equal to 0.125 or 0.250.

## Cytotoxicity

[Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ (**2a**) and [Pt(*S*,*R*-tmcp)(phen)]-$Cl_2$ (**2b**) produced an average $IC_{50}$ values of 11.3 and 11.2 μM, respectively, a decrease in potency when compared to [Pt(en)(phen)]$Cl_2$ ($IC_{50}$ = 9.7 μM) (Table 1). [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ (**3a**) and [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$, (**3b**) produced average $IC_{50}$ values of 11.5 and 8.5 μM, respectively. This is a marked increase in the potency when compared to the achiral parent complex, [Pt(en)(3,4,7,8-$Me_4$phen)]$Cl_2$, with an $IC_{50}$ value greater than 50 μM (Table 1).

## Viscosity

Platinum(II) complexes are able to bind DNA by reversible non-covalent intercalation, partial intercalation, electrostatic association or groove binding. To investigate the mode of binding the viscosity of a linearized DNA (≈ 200 bp) solution was measured in the presence of complexes (such as, ethidium bromide, cisplatin and Hoechst 33258, which each have different, known DNA binding modes) as well as the platinum(II) complexes. This provided a common reference and verified the sensitivity of the measurements towards the different binding modes.

Ethidium bromide, a classical organic DNA intercalator, increased the relative viscosity (1.13 at a binding ratio of 0.250) due to an increase in the axial length and rigidity of DNA.[19,20] Cisplatin, in contrast, produced a decrease in the relative viscosity (0.89 at a binding ratio of 0.250) as a consequence of kinking and bending that results from geometry of the Pt-DNA covalent adduct.[21] Partial intercalators also kink the DNA reducing its axial length, which is observed as a reduction in relative viscosity.[22] Hoechst 33258, a groove binder, did not alter the relative viscosity (1.00 at a binding ratio of 0.250) as it does not change the axial length of DNA.[20,23] The above results confirm the sensitivity of viscosity as a method to differentiate the modes of binding.

The viscosity of the ct-DNA solution (200 bp), decreased for [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$ when compared to [Pt(en)(phen)]$Cl_2$ at binding ratios of 0.250 to 0.97, 1.15 and 1.23, respectively, as shown in Table 1. These results suggest that regardless of chirality, the bulk of the ancillary ligand impedes intercalation for both [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$. The *S*,*R*-form of the diamine in [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$ may reduce the extent as to how far the aromatic rings can insert into the DNA helix and because [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ accentuates this trend, this would indicate that the orientation of the *R*,*S*-isomer further obstructs the phen from full intercalation.[14,22] The viscosity results therefore indicate that [Pt(*R*,*S*-tmcp)(phen)]$^{2+}$ undergoes partial intercalation.

[Pt(en)(3,4,7,8-$Me_4$phen)]$^{2+}$ intercalates with a relative viscosity of 1.08, but its ability to increase the axial length of linearized DNA is less than [Pt(en)(phen)]$Cl_2$. It is likely that the methyl groups on the 3,4,7,8-$Me_4$phen protrude into the binding site of the DNA duplex, obstructing intercalation. This interaction is further affected with the introduction of the bulky chiral ancillary ligands. The complexes [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ showed substantial decreases in viscosity 0.90 and 0.87, respectively (Table 1). Although the viscosity is similar to that of cisplatin it can be explained by kinking of the DNA[14] as the 3,4,7,8-$Me_4$phen

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

can only partially intercalate into the DNA helix. Here the change in structure, where the DNA bends (or kinks) to accommodate the ligand, is accompanied by an increase in the biological activity of the complex.

### Circular and Induced Circular Dichroism (ICD)

CD spectra were recorded for each of the platinum(II) complexes upon titration into DNA, and the changes in ct-DNA structural conformation were observed upon binding. The titration curves for each of the complexes are presented in Figure 2 and Figure 3 as CD and ICD spectra. The initial CD is consistent with B-type DNA, with a positive peak at 275 nm, a negative peak at 245 nm, zero between the peaks at ca. 258 nm and a negative peak at 210 nm. Changes in the CD spectra for the complexes were observed, but these are more obvious when they are represented as ICD spectra (as shown in Figure 2 and Figure 3). The ICD titration spectra of each complex were used to determine the average affinity and stoichiometry of binding.

The CD spectrum of DNA from 200–300 nm, is because of the skewed orientation of the bases.[18] Changes to the secondary structure, such as unwinding of the helix, or inclination of the bases, due to interaction with a metal complex, led to an alteration in the shape of the spectrum. If the spectrum intensity changes, but the shape of the peak remains uniform, a single binding mode by the ligand can be expected.[24] If the spectrum, however, changes both in shape and intensity, a modification to the DNA-drug interaction may be taking place. Such effect may be attributed to a number of factors which include: 1) occupancy of more than one binding site as the drug concentration increases; 2) ligand–ligand interactions, 3) changes in the DNA conformation.

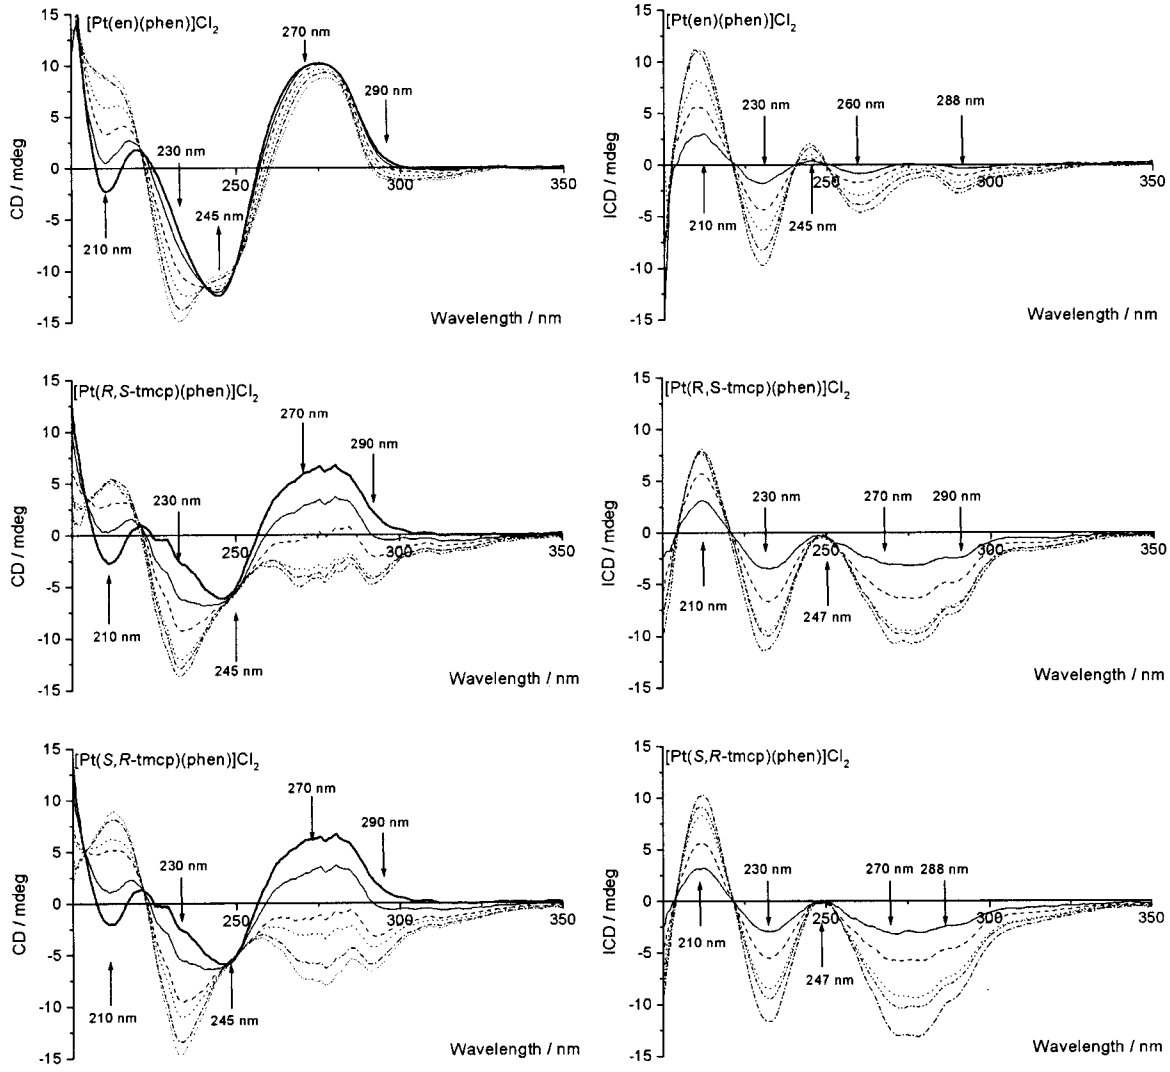

Figure 2. CD (left) and ICD (right) spectra of varying concentrations of the platinum(II) complexes, [Pt(en)(phen)]$Cl_2$ (**2**), [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ (**2a**) and [Pt(phen)(*S*,*R*-tmcp)]$Cl_2$ (**2b**) upon titration with ct-DNA solution in buffer (5 mM, Trizma, 50 mM NaCl, pH 7.5). The ratios of [Pt]/[DNA] are 0, 0.1, 0.2, 0.4. 0.5 and 1.0 and are indicated on the graph as –, –, ---, ···, ·-·, -··-, respectively.

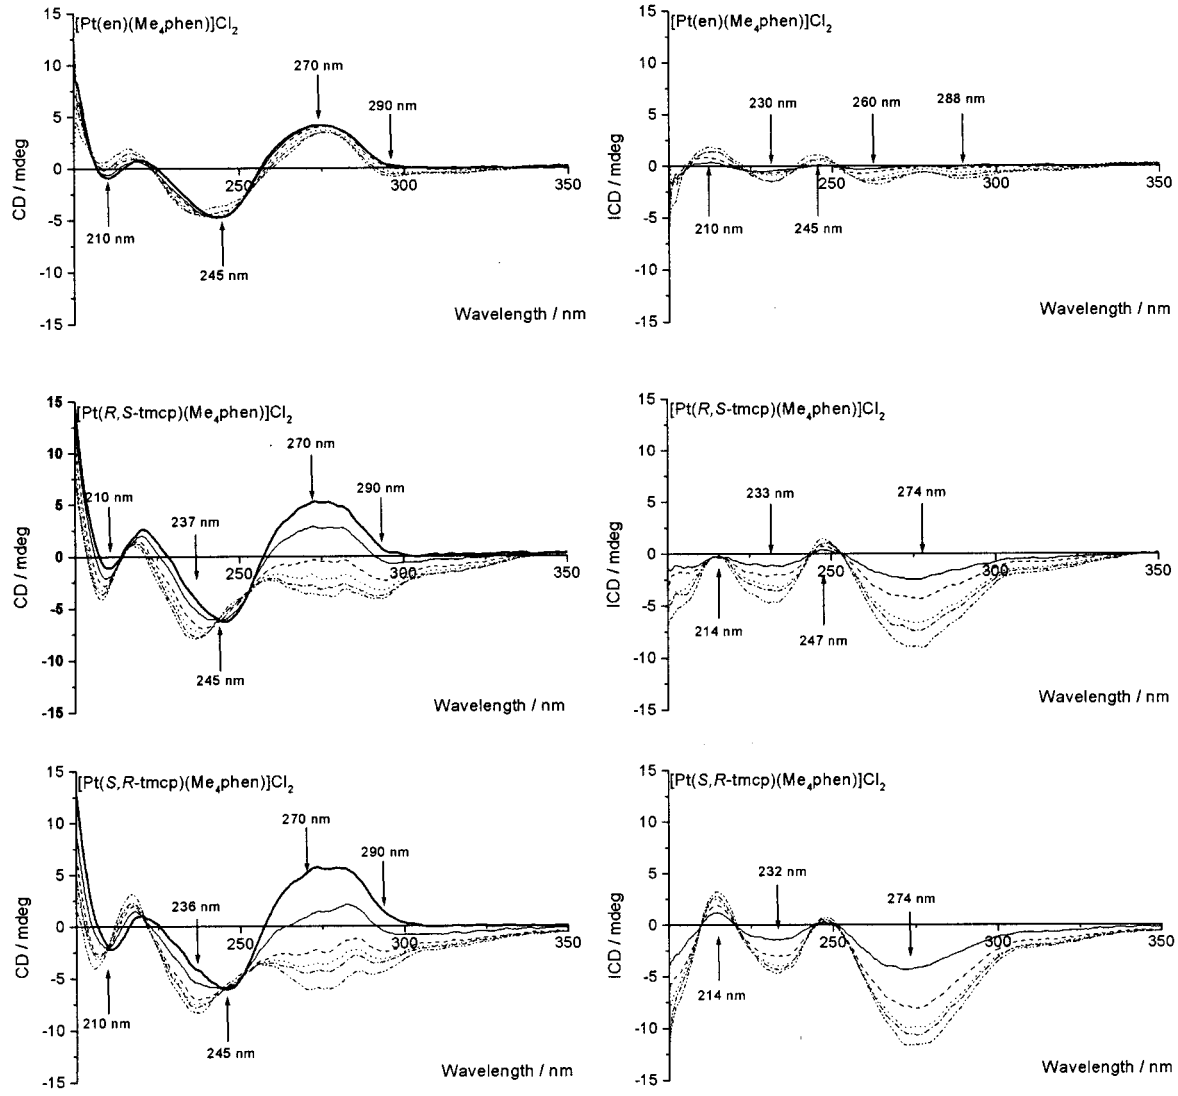

Figure 3. CD (left) and ICD (right) spectra of varying concentrations of the complexes, [Pt(en)(3,4,7,8-$Me_4$phen)]$Cl_2$ (**3**), [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ (**3a**) and [Pt(*S*,*R*-tmcp) (3,4,7,8-$Me_4$phen)]$Cl_2$ (**3b**) upon titration with ct-DNA solution in buffer (5 mM, Trizma, 50 mM NaCl, pH 7.5). The ratios of [Pt]/[DNA] are 0, 0.1, 0.2, 0.4. 0.5 and 1.0 and are indicated on the graph as –, – –, ---, ···, ·-·, -··-, respectively.

The ICD of [Pt(en)(phen)]$Cl_2$ (**2**), [Pt(*R*,*S*-tmcp)(phen)]-$Cl_2$ (**2a**) and [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$ (**2b**) change in comparable ways below 245 nm suggesting that the interaction in DNA is of a similar nature. Above 245 nm the two discrete peaks observed for [Pt(en)(phen)]$Cl_2$, develop into one broad peak for both [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$ (Figure 2). This peak is also observed for [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)-(3,4,7,8-$Me_4$phen)]$Cl_2$ (Figure 3). The intensity of this broad peak is consistent with a deformation of the DNA helix by the complex as shown in viscosity, perhaps by partial intercalation, where $S,R > R,S$.

[Pt(en)(3,4,7,8-$Me_4$phen)]$Cl_2$ makes little impact on the structure of DNA as the ICD spectra show only very small peaks upon the addition of metal complex. Both [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ have a profound effect on the CD, which is made more obvious in the ICD. The spectra below 245 nm are significantly different from that of the phen analogues.

Binding constants were determined using the data obtained from the titrations. Previously we have used the method of Roger and Nordén[24] to determine the binding constants; however, here a different data analysis technique, which utilises direct least-squares curve fitting and a Levenberg-Marquardt method, was also employed.[18] Some inconsistencies were observed, but on the whole, the new method proved to be effective, reducing the time required to process the data from days to one hour. The inconsistencies were observed when attempts to apply a Scatchard plot to all of the data were unachievable. The calculated values for $K_b$ and $n$ using both methods are included in Table 1. This new method allowed us to review the results and investigate alternative wavelengths when calculations for $K_b$ or $n$ where not reasonable.

### Binding of the Pt(tmcp) Complexes to the Hexamer d(GTCGAC)$_2$

Each platinum(II) complex was titrated into a solution containing the hexamer d(GTCGAC)$_2$, with one-dimensional $^1$H NMR spectra recorded at a metal complex to hexamer ratio (R) of 0.2, 0.4, 0.6, 0.8 and 1.0 and two-dimensional spectra, DQFCOSY and NOESY, recorded at $R = 1$.

The addition of each platinum(II) complex to d(GTCGAC)$_2$ induced significant broadening of the hexamer and metal-complex resonances (for example see Figure 4), indicating that each of the [Pt(tmcp)(Me$_n$phen)]Cl$_2$ complexes bind with intermediate exchange kinetics (on the NMR timescale). The observed intermediate exchange kinetics is consistent with an intercalative binding mode and that observed in the previous study with the [Pt(en)(3,4,7,8-Me$_4$phen)]Cl$_2$ complexes.[14] For each platinum(II) complex, significant upfield shifts of all 3,4,7,8-Me$_4$phen resonances were observed upon hexamer binding (see Table 2), again consistent with intercalation. The upfield shifts of the resonances for the [Pt(*R*,*S*-tmcp)(phen)]Cl$_2$ and [Pt(*S*,*R*-tmcp)(phen)]Cl$_2$ complexes were similar, as were the shifts for the [Pt(*R*,*S*-tmcp)(3,4,7,8-Me$_4$phen)]Cl$_2$ and [Pt(*S*,*R*-tmcp)(3,4,7,8-Me$_4$phen)]Cl$_2$ complexes; however, the upfield shifts for the phen ligand resonances were considerably larger for the phen complexes than the 3,4,7,8-Me$_4$phen complexes. This may indicate that the phen complexes intercalate more fully into the hexamer base-stack than do the 3,4,7,8-Me$_4$phen complexes. The binding of the *S*,*R* complexes to d(GTCGAC)$_2$ induced larger shifts for the hexamer resonances than the corresponding *R*,*S* complexes (see Table 3), with the phen complexes generally inducing larger shifts than the 3,4,7,8-Me$_4$phen complexes (see Table 4). As most nucleotide residues exhibited significant shifts, it was not possible to deduce the metal complex binding site from the changes in chemical shift.

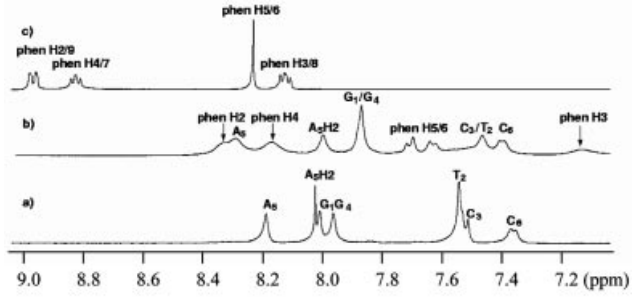

Figure 4. An expansion of the 1D NMR spectra of a) the free hexamer, b) [Pt(*S*,*R*-tmcp)(phen)]Cl$_2$ bound to d(GTCGAC)$_2$ at R = 1 and c) [Pt(*S*,*R*-tmcp)(phen)]Cl$_2$ in 10 mM phosphate buffer containing 1 mM EDTA and 20 mM NaCl at pH 7.0 and 25 °C.

NOESY spectra were recorded, at a range of temperatures and mixing times, in order to gain further information on the hexamer binding by the [Pt(tmcp)(3,4,7,8-Me$_4$phen)]-Cl$_2$ series of complexes. Figure 5 shows an expansion of the NOESY spectrum of the [Pt(*S*,*R*-tmcp)(phen)]Cl$_2$ complex bound to d(GTCGAC)$_2$ at $R = 1$. In addition to the expected intra-duplex NOEs, a range of NOE cross-peaks are also observed between the metal complex and hexamer resonances, indicating that the platinum(II) complex fully intercalates from the minor groove. A range of relatively strong NOEs are observed from the tmcp methyl protons to the hexamer minor groove protons, ie. to the A$_5$H2 and the H1′ and H4′/H5′/H5′′ protons of all nucleotide residues. In addition, NOEs are clearly observed from the phen H3 and H4 resonances to the both major and minor groove protons, whereas NOEs are only observed from the phen H5/H6 protons to the T$_2$Me protons that are located in the major groove. As all the observed intermolecular NOEs from the phen protons are to T$_2$, C$_3$, G$_4$ and A$_5$ protons, it is concluded that [Pt(*S*,*R*-tmcp)(phen)]Cl$_2$ mostly intercalates between the T$_2$·A$_5$ and C$_3$·G$_4$ base-pairs. The NOE data from the [Pt(*R*,*S*-tmcp)(phen)]Cl$_2$ complex bound to d(GTCGAC)$_2$ is similar, although the individual cross-peaks are weaker because of the greater degree of broadening of the metal complex resonances.

Due to the extreme broadening of all the resonances, it was difficult to resolve many of the intermolecular NOEs observed in NOESY spectra of the hexamer with either stereoisomer of [Pt(tmcp)(3,4,7,8-Me$_4$phen)]Cl$_2$; however, strong NOEs were observed from the tmcp-methyl protons to the hexamer A$_5$H2, H1′ and H4′/H5′/H5′′ protons. At temperatures between 40 and 50 °C a considerable number of metal complex-hexamer NOEs were clearly resolved. For

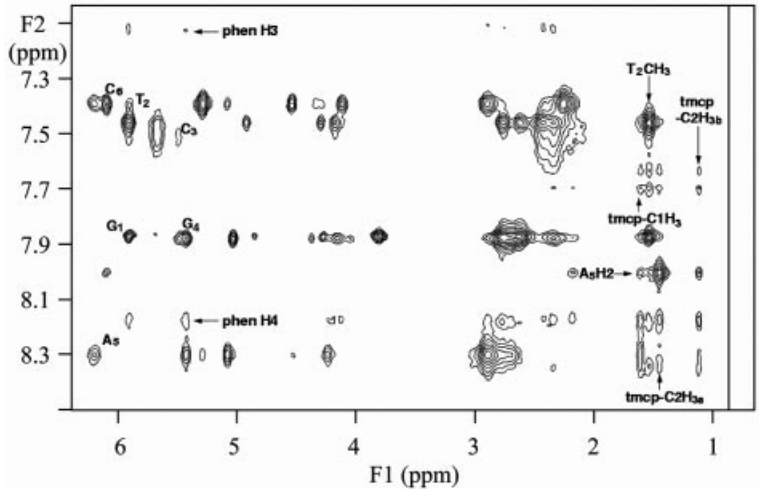

Figure 5. An expansion of the NOESY spectrum of the $[Pt(S,R\text{-tmcp})(phen)]Cl_2$ complex bound to $d(GTCGAC)_2$ at $R = 1$, in 10 mM phosphate buffer (pH, 7) containing 1 mM EDTA and 20 mM NaCl at 25 °C. The expansion shows the intermolecular connectivities between the metal complex phen and tmcp-methyl protons and the hexamer H1′ and $A_5H2$ protons, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ complex, NOEs were observed from the H2/H9 protons to the $G_1$, $T_2$, $C_3$, $G_4$ and $C_6$ H1′ protons, with the strongest NOEs to the $C_3$ and $G_4$. In addition, NOEs were detected between the hexamer $A_5$H8 and the metal complex C3/C8 phenanthroline methyl protons. This data indicates that the [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ complex intercalates from the minor groove at all possible intercalation sites; however, based on the relative strengths of the intermolecular NOEs, with some preference for intercalation between the $T_2$·$A_5$ and $C_3$·$G_4$ base-pairs. For hexamer binding by [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$, a similar pattern of intermolecular NOEs, but of lower intensity, to the corresponding *S*,*R* complex was observed.

As the NOESY spectra only represent exchange-averaged NOEs for the hexamer binding by the [Pt(tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ complexes, it is not possible to draw unambiguous conclusions on the intercalation geometry; however, the NMR spectroscopic data, coupled with the viscosity data, suggest that the [Pt(tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ complexes only partially intercalate and in a "side-on" fashion. Simple molecular modelling indicates that if the metal complex fully intercalated in a "head-on" fashion, NOEs would not be observed from the tmcp-methyl protons to the $A_5$H2 and the H1′ and H4′/H5′/H5′′ protons. Alternatively, for partial and side-on intercalation (as illustrated in Figure 6), the observed NOEs from the $A_5$H2 to the $C_2$-methyls and the strong NOEs between the tmcp-methyl protons and the H1′ and H4′/H5′/H5′′ protons would be expected, as these distances are less than 5 Å.

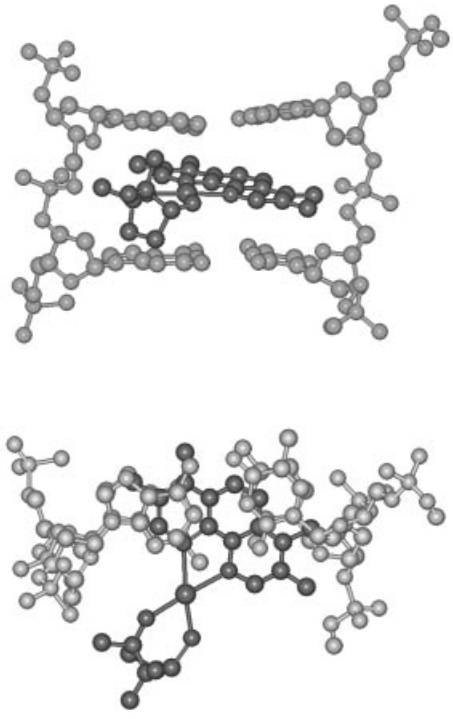

Figure 6. A HyperChem® molecular model of [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ (dark grey) intercalated from the minor groove of d(GTCGAC)$_2$ (light grey). For simplicity, only the $T_2$ and $C_3$ base pairs have been shown.

## Conclusions

An investigation into the biological activity of four platinum(II) complexes of 1,10-phenanthroline (phen) and 3,4,7,8-tetramethyl-1,10-phenanthroline (3,4,7,8-$Me_4$phen), with the ancillary ligands (1*R*,3*S*) and (1*S*,3*R*)-1,3-diamino-1,2,2-trimethylcyclopentane (*R*,*S*-tmcp and *S*,*R*-tmcp, respectively) has determined that the ancillary ligand can significantly influence biological activity.

In vitro cytotoxicity assays against the L1210 cell line, showed that [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ (**2a**) and [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$ (**2b**) produced an average $IC_{50}$ value of 11.3 and 11.2 μM, respectively, a decrease in potency when compared to [Pt(en)(phen)]$Cl_2$ with an average $IC_{50}$ value of 9.7 μM; whereas [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ (**3a**) and [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$, (**3b**) produced an average $IC_{50}$ value of 11.5 and 8.5 μM, respectively, an increase in potency when compared to [Pt(en)(3,4,7,8-$Me_4$phen)]$Cl_2$ with an average $IC_{50}$ value of $>50$ μM. This result suggests that the interaction between an intercalator, containing 3,4,7,8-$Me_4$phen, and DNA can be modulated in such a way as to increase activity.

Viscosity studies verified that the extent of intercalation had in fact been modulated, where the relative viscosities were reduced when compared to the parent complexes. Such that the viscosity of [Pt(*S*,*R*-tmcp)(phen)]$Cl_2$ and [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$ were reduced to 1.15 and 0.97 respectively when compared to [Pt(en)(phen)]$Cl_2$ at 1.23 and [Pt(*R*,*S*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ and [Pt(*S*,*R*-tmcp)(3,4,7,8-$Me_4$phen)]$Cl_2$ were reduced to 0.90 and 0.87 respectively when compared to [Pt(en)(3,4,7,8-$Me_4$phen)]-$Cl_2$ at 1.12. The increase in activity of the 3,4,7,8-$Me_4$phen analogues may come about because the bending of DNA is of an appropriate proportion to halt DNA replication.

Titrations of the metal complexes into ct-DNA and the observation of the changes in ICD spectra was used to determine the binding constants. The observed changes in the ICD are consistent with an intimate interaction and indicate that some small, but different, structural/conformational changes result when these complexes interact with DNA.

For each of the metal complexes studied with d(GTCGAC)$_2$, intermolecular NOE data and observed changes in chemical shift suggests that the [Pt(tcmp)(3,4,7,8-$Me_4$phen)]$Cl_2$ complexes bind the hexamer by intercalation from the minor groove, and predominantly, between the $T_2$·$A_5$ and $C_3$·$G_4$ base-pairs.

Significant differences in biological activity that are achieved by four platinum(II) complexes of 1,10-phenathrolines and 3,4,7,8-tetramethyl-1,10-phenathrolines, suggest that the use of chiral ancillary ligands can affect biological activity. Of the two stereoisomers, the *S*,*R* ligand is more active than the *R*,*S* ligand and may be related to the degree that each isomer can prevent intercalation. From both the viscosity and NMR experiments it was shown that the *R*,*S* isomer prevented intercalation in the DNA to a greater extent than the *S*,*R* isomer. As both ligands are located in the DNA minor groove when the metal complex is intercalated,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

it is possible the *R*,*S* ligand projects one of its methyl groups more deeply into the groove, thereby creating a steric clash. The results indicate that more active complexes might be developed by changing the chiral diamine ancillary ligands. Chiral ancillary ligands that have more steric bulk may result in a reduction in cytotoxicity, or the addition of stereospecific functional groups capable of forming hydrogen bonds with the DNA backbone may result in an increase in cytotoxicity.

## Experimental Section

**Instrumentation:** The melting points were determined (uncorrected) with a Gallenkamp Melting Point apparatus. UV spectra were recorded with a Varian Cary 1E Spectrophotometer, and CD spectra were obtained with a Jasco J-810 Spectropolarimeter, both at room temperature. Viscosity measurements were carried out using a Cannon-Manning semi-micro viscometer maintained at a constant temperature of 25 °C in a water bath. ct-DNA was prepared and purified according to the method of Chaires et al.,[25] and DNA concentration was determined with a molar extinction coefficient ($\varepsilon_{260}$) of 12,824 $M^{-1}cm^{-1}$ per base pair.[25] 1D and 2D NMR spectra were recorded with a 300 or 400 MHz Varian Mercury NMR spectrometer at 25 °C, using commercially available solvents referenced to TMS or internal standards. DNA-NMR $^1$H NMR spectra were recorded with a 400-MHz Varian Unityplus-400. Two-dimensional phase-sensitive NOESY spectra were acquired by the method of States et al.,[26] using 2048 data points in $t_2$ and 256–400 $t_1$ values with a pulse-repetition delay of 1.7 s. DQFCOSY experiments were accumulated using 2048 data points in $t_2$ for 256 $t_1$ values using a pulse-repetition delay of 1.7 s. Two-dimensional NMR spectroscopic data sets were zero-filled to 1024 points in the $t_1$ dimension and apodized with either a Gaussian or a shifted sinebell function. Microchemical analyses were performed at Australian National University, Canberra.

**Materials:** (*R*,*S*)- and (*S*,*R*)-camphoric acid, 1,10-phenanthroline (phen), 3,4,7,8-tetramethyl-1,10-phenanthroline (3,4,7,8-$Me_4$phen), calf thymus DNA (ct-DNA), IRA-400 (Cl) Amberlite ion exchange resin, Trizma [tris(hydroxymethyl)aminomethane hydrochloride] and all deuterated solvents were purchased from Aldrich Chemical Company. Potassium tetrachloroplatinate(II) was bought from Precious Metals Online Pty Ltd. CM-25 Sephadex and Waters C-18 Sep-Pak columns were obtained from Pharmacia. Oligonucleotides were purchased from Geneworks Inc. All other reagents were of analytical reagent or high purity grade.

### Syntheses

**(1*R*,3*S*)-1,3-Diamino-1,2,2-trimethylcyclopentane (*R*,*S*-tmcp) (1a):** The compound was prepared by a procedure based on the method of Gillard et al.[27] To a vigorously stirred mixture of (1*R*,3*S*)-camphoric acid (20.00 g, 0.10 mol), in concentrated $H_2SO_4$ (50 mL) and ethanol-free chloroform (300 mL), at 50 °C, was added sodium azide (19.50 g, 0.30 mol) in small amounts over a period of 2 h. The mixture was then stirred for a further 18 h at 50 °C. The mixture was cooled, poured into $H_2O$ (500 mL), and the aqueous phase made strongly basic with 12 M NaOH. The amine was extracted into $CHCl_3$ (2 × 500 mL), the organic extracts dried with anhydrous $Na_2SO_4$ and the chloroform removed in vacuo to give a clear oil. The oil was dissolved in diethyl ether (100 mL), the solution filtered, and the solvent removed in vacuo to give the product as a white solid (8.09 g, 57%). M.p. 128.1 °C. CD spectrum $\lambda_{max}$ ($\Delta\varepsilon$/$mol^{-1}dm^3cm^{-1}$, water) = 217 nm (–0.12). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 2.98 (dd, $^3J$ = 6.9, 8.5 Hz, 1 H), 2.01 (m, 2 H), 1.62 (m, 4 H), 1.29 (m, 2 H), 1.01 (s, 3 H), 0.80 (d, $^3J$ = 3.6 Hz, 6 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 61.0 (C), 60.8 (CH), 46.2 (C), 38.3 ($CH_2$), 30.2 ($CH_2$), 25.8 ($CH_3$), 22.2 ($CH_3$), 16.3 ($CH_3$) ppm.

**(1*S*,3*R*)-1,3-Diamino-1,2,2-trimethylcyclopentane (*S*,*R*-tmcp) (1b):** The ligand was prepared as described for **1a**, using (1*S*,3*R*)-camphoric acid, to yield the product as a white solid (7.21 g, 51%). M.p. 132.4 °C. CD spectrum $\lambda_{max}$ nm ($\Delta\varepsilon$/$mol^{-1}dm^3cm^{-1}$, water) = 218 (+0.13). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 3.00 (dd, $^3J$ = 7.0, 8.7 Hz, 1 H), 2.02 (m, 2 H), 1.60 (m, 4 H), 1.31 (m, 2 H), 1.03 (s, 3 H), 0.81 (d, 6 H, $^3J$ = 3.5 Hz) ppm.

**(1*R*,3*S*)-1,3-Diamino-1,2,2-trimethylcyclopentane(1,10-phenanthroline)platinum(II) Dichloride Dihydrate, [Pt(*R*,*S*-tmcp)(phen)]$Cl_2$·2$H_2O$ (2a):** The complex was prepared by a similar method as described previously.[14,28] [Pt(phen)$Cl_2$] (0.09 g, 0.20 mmol) and **1a** (0.23 g, 1.60 mmol) were refluxed in $H_2O$ (20 mL) until all of the complex had dissolved to yield a pale yellow solution. This was concentrated to a small volume (5 mL) and chilled (4 °C) 1 M HCl (6 mL) was added, which caused the product to precipitate. The reaction mixture was cooled and left overnight at 4 °C before the yellow product was collected, washed with cold 1 M HCl and acetone, then dried in vacuo at room temperature (0.11 g, 88%). $C_{20}H_{26}Cl_2N_4Pt$·2$H_2O$ (624.54): calcd. C 38.46, H 4.84, N 8.97; found C 38.39, H 5.02, N 8.83. Electronic spectrum: $\lambda_{max}$ ($\varepsilon$/$mol^{-1}dm^3cm^{-1}$, water) = 227 (35769), 277 nm (30857). **Cytotoxicity:** In vitro cytotoxicity studies were carried out at the Peter MacCullum Cancer Institute, Melbourne by a standard method.[29] The chiral platinum(II) complexes were dissolved in warm distilled water and then diluted to the required concentrations. Results of the growth inhibition for murine leukaemia L1210 cells are reported for two experiments at 48 h continuous exposure to the metal complex. Cells were counted by Coulter Counting. The results of the growth inhibition assays of the platinum(II) complexes against the L1210 mouse leukaemia cell line are presented in Table 1. Values represent $IC_{50}$ in μM. $IC_{50}$ is the concentration of platinum(II) complex required to induce 50% inhibition of cell growth. All complexes were administered in water. Cytotoxicity of the new platinum(II) complexes are compared with cisplatin, and their individual parent compounds [Pt(en)(phen)]Cl$_2$ and [Pt(en)(3,4,7,8-Me$_4$phen)]Cl$_2$,[14] to assess the contribution of the chiral ancillary ligands.

**Viscosity Studies:** Samples were made to a volume of 300 μL and the flow time for the BPES buffer (6 mM, $Na_2HPO_4$, 2 mM $NaH_2PO_4$, 1 mM $Na_2EDTA$, pH 7.0) used was 479 (±1) s. The ct-DNA solution (100 μM per base pair, molar absorptivity of 12824 M$^{-1}$cm$^{-1}$bp$^{-1}$ at 258 nm)[25] gave a flow time of 518 (±1) and samples were prepared to give total platinum(II) complex/base pair ratios of 0.125 and 0.25. Flow times were measured after a thermal equilibration period of 20 min and ranged from 500 (±1) to 552 (±1) depending on the concentration and the complex added. Each sample flow time was measured three times and an average calculated. Relative viscosity is presented as $(\eta/\eta_o)^{1/3}$ in accordance with the theory of Cohen and Eisenberg.[30] The value $\eta$ is the viscosity of the solution in the presence of a complex, and $\eta_o$ is the viscosity of the ct-DNA solution alone. This viscosity $\eta$ is calculated from the time for the sample ($t$) to flow through the viscometer subtracted by the time measured for the buffer ($t_o$) only.

**DNA Binding and Induced Circular Dichroism:** Titrations were performed to determine the affinity constants for the chiral platinum(II) complexes with ct-DNA (Figure 2 and Figure 3) using published methods.[24] The CD was recorded over the range 200 to 350 nm, for the ct-DNA solution (3000 μL, 28 or 35 μM) in buffer (5 mM, Trizma, 50 mM NaCl, pH 7.5), and after each titration with a small volume of metal-complex solution (10 or 5 mM). The small increase in the final volume was no more than 3%. Titrations were continued until no further change was observed in the CD spectrum, indicating that saturation of the DNA had been reached.

Using the information gained from the spectra and utilising the methods of Roger and Nordén,[24] binding constants for each of the complexes were determined as described previously.[14] CD data and the methodology for calculating the binding constant are included in the supporting information (for details see the footnote on the first page of this article). The calculated values for $K_b$ and $n$ [where $K_b$ is the equilibrium binding constant and $n$ is the number of binding sites (in base pairs)] are reported in Table 1. We have also developed a different data analysis technique, which utilises direct least-squares curve fitting, using a Levenberg–Marquardt method,[18] to our experimental points. Essentially we fit the equation below to the data, where the independent variable $L_T$ is the ligand concentration, $B_T$ the total DNA concentration, and the dependent variable $\varepsilon$ the CD response. The calculated values for $K_b$ and $n$ (the number of bases per binding site) using this method are also included in Table 1.

$$\frac{\varepsilon}{\alpha} = 0.5\left[\frac{1}{K_b} + L_T + \frac{B_T}{n_s} - \sqrt{\left(\left\{\frac{1}{K_b} + L_T + \frac{B_T}{n_s}\right\}^2 - \frac{4B_TL_T}{n_s}\right)}\right]$$

**Titration of d(GTCGAC)$_2$ by the Platinum(II) Complexes:** The hexamer was converted into the sodium salt using a CM-25 Sephadex column after residual impurities were removed by elution through a C-18 Sep-Pak as described previously.[14] The hexamer was dissolved in 700 μL of phosphate buffer (10 mM, pH 7) containing 20 mM NaCl and 0.1 mM EDTA. For experiments carried out in $D_2O$ the sample was repeatedly freeze-dried from $D_2O$ and finally made up in 99.96% $D_2O$. The hexamer concentration was determined from the $A_{260}$ absorbance using an extinction coefficient of 6600 M$^{-1}$cm$^{-1}$ per nucleotide.[13,14]

**Supporting Information** (see footnote on the first page of this article): Supporting information is available in electronic format only giving a description of how the DNA binding constants were determined, including mathematical forumlae; DNA binding data; and figures of the DNA binding curves.

## Acknowledgments

The University of Western Sydney Research Grant Scheme supported this work. We thank Dr. Carleen Cullinane from the Peter MacCullum Cancer Institute for cell line testing and Grace Hey for undertaking some of the CD titrations.

# Steric and Catalytic Effects in Tetraruthenated Manganese Porphyrins

Ildemar Mayer,[a] Genebaldo S. Nunes,[a] Henrique E. Toma,[a] and Koiti Araki*[a]

**Keywords:** Electrochemistry / Manganese / Porphyrinoids / Sensors / Supramolecular chemistry

A new tetraruthenated manganese(III) porphyrin has been obtained and characterized by spectroscopy, electrochemistry, and spectroelectrochemistry. It exhibits a saddle-shaped, nonplanar structure that conveys interesting catalytic, electrocatalytic, and spectroelectrochemical properties to the molecule. Selective steric influence induced by the peripheral ruthenium complexes has been detected in the catalytic oxidation of cyclohexane and cyclohexene with iodosylbenzene. Films formed by layer-by-layer electrostatic assembly with tetraanionic sulfonated copper phthalocyanine exhibit electrocatalytic activity for the oxidation of nitrite and sulfite, thus providing interesting applications in amperometric sensors.
