A brief analysis of the protonation constants summarized in Table 1 indicates that the $\log K_1$ (9.6, 10.2) values of ligands $H_2L^n$ ($n$ = 2, 4) should be attributed to the protonation of the sulfonamide group. The lower value of $\log K_1$ found for $H_2L^2$, as compared to $H_2L^1$, is probably due to an electron donation effect that maybe slightly higher for the hydroxamate than the carboxylate group. The values calculated for the hydroxamate protonation constants of ligands $H_2L^1$ ($\log K_2$ = 8.75) and $H_2L^3$ ($\log K_1$ = 8.47) are also slightly lower than the previously calculated value for $H_2L^5$ ($\log K_1$ = 9.11[12]) due to a possible cumulative effect of the carboxylate group on the stabilisation of the $H_2L^5$ protonated form through a bifurcated hydrogen bond network with the *N*-amine. For $H_2L^1$, the protonation processes of the hydroxamate and the sulfonamidate groups seem to overlap and so the corresponding values of $\log K_1$ and $\log K_2$ presented in Table 1 cannot be accurately assigned to each individual group.

Regarding the acid-base properties of the hydroxypyrimidinone derivatives, the protonation constants calculated for $H_2L^4$ and $HL^6$ present very similar values, namely for the hydroxy ($\log K_2$ 7.09 and 7.11) and the *N*-imine groups ($\log K_3$ 2.90 and 2.99). The fact that the amine group of $H_2L^1$ ($\log K_3$ = 3.21) presents a lower basicity than those of $H_2L^2$ ($\log K_2$ = 5.86) and $H_2L^5$ ($\log K_2$ = 5.75) must be due to the presence of the adjacent negatively charged carboxylate groups in $H_2L^2$ and $H_2L^5$, which stabilise the formation of the positively charged ammonium group. Finally, analysis of the protonation constants obtained for the carboxylate groups shows that lower values were obtained for $H_2L^2$ ($\log K_3$ = 1.76) and $H_2L^5$ ($\log K_3$ = 1.6), than for $H_2L^3$ ($\log K_2$ = 2.99); that difference can be rationalized in terms of an extra stabilization of the conjugate base due to the electrostatic interaction between the positively charged amine and the negatively charged carboxylate groups, as well as to hydrogen bonding interaction between the ammonium proton and the carboxylate, involving 5-member ring intermediates.

### 2.2. Zinc Complexation Studies

In this study, the chelating ability of four sulfonamide derivatives towards $Zn^{II}$ in aqueous solution was evaluated. Although the sulfonamides, in their neutral form, are expected to be poor ligands due to the withdrawal of electron density from the nitrogen atom onto the electronegative oxygen atoms, if this *N*-atom has a dissociable proton, the electron-withdrawing effect increases its acidity making the sulfonamide anions effective sigma-donor ligands.

The global formation constants of the $H_iL^n$ ($n$ = 1–4) zinc complexes were determined by potentiometry at conditions of 1:1, 1:2 and 2:1 metal-to-ligand molar ratios and they are collected in Table 1, together with the reported values for two analogues ($H_2L^5$ and $HL^6$).

Figure 3 shows representative potentiometric titration curves for one of the ligands ($H_2L^1$), alone and in the presence of $Zn^{II}$. Analysis of the titration curve profiles (Figure 3) indicates the noninvolvement of the *N*-amine group in the zinc coordination and that the hydroxamic acid deprotonation feels the presence of the metal ion. For pH values above 6.5–7.0, precipitation occurred and the potentiometric titrations were stopped.

Regarding the other ligands under study, the potentiometric titration curves also showed the noninvolvement of specific groups in the coordination to the $Zn^{II}$ ion, namely: the carboxylate group for $H_2L^3$ and the *N*-imine group for $H_2L^4$. In the case of $H_2L^2$, the potentiometric curves cannot give information about the involvement of the carboxylate group in the zinc coordination since the determined value of $\log K_3$ is extremely low ($<2$).

Aimed at getting some further information about coordination modes, $^1$H NMR titrations of solutions containing the systems $Zn^{II}/H_2L^n$ ($n$ = 1, 2, 4) were performed and the corresponding titration curves compared to those of the respective ligand alone. However, for some of those solution zinc systems, precipitation occurred due to the eventual formation of neutral zinc complexes, namely: for $H_2L^1$ (at pH above 7), for $H_2L^2$ (at pH ca. 4.5–9) and for $H_2L^4$ (at pH 6–10). Therefore, conclusions can be only drawn for pH ranges outside the precipitation zone. $^1$H NMR studies of the $Zn^{II}$ complexes ($C_L/C_M$ = 1) with $H_2L^n$ ($n$ = 2, 4) suggested the noninterference of the sulfonamide group in the coordination mode of these complexes, which is in accordance with the formation of more soluble zinc-hydroxo species for high pH values. In fact, the NMR titration curves of the ligands and respective zinc complexes are superimposed at pD > 11. In the case of $H_2L^1$, it is possible to confirm the noninvolvement of the amine group in the zinc coordination (Figure S1 in the Supporting Information). Moreover, the binding of compounds $H_2L^1$ and $H_2L^4$ to $Zn^{II}$, via the two oxygen atoms of the hydroxamic moiety, was also somehow supported by the absence of significant modifications of the $^1$H NMR spectrum of these ligands due to the presence of the metal ion.[13]

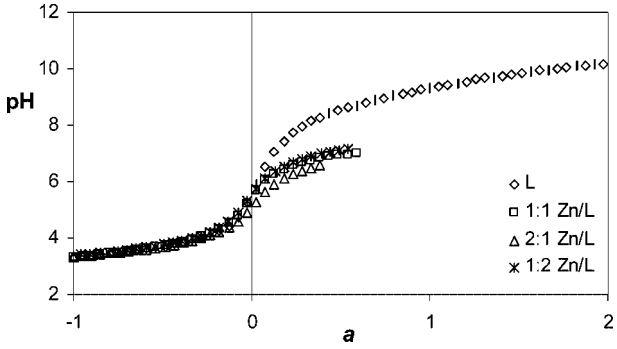

Figure 3. Potentiometric titration curves of $H_2L^1$ and 1:1, 2:1 and 1:2 $Zn^{II}/H_2L^1$ systems ($C_L$ = 0.67 mM).

Analysis of Table 1, containing the results of the solution complexation studies of the diverse compounds ($H_2L^n$, $n$ = 1–4) with $Zn^{II}$, indicates the existence of 1:1 (ZnHL and ZnL) and 1:2 ($ZnH_2L_2$ and $ZnL_2$) complex species in the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

adopted equilibrium model. As expected, the $Zn^{II}$ complexes with typical (*O*,*O*) hydroxamate coordination, as those formed with $H_2L^1$, $H_2L^4$ and HL[6], have analogous $\log\beta_{MHL}$ and $\log\beta_{MH_2L_2}$ values. For the complexes with $H_2L^1$ or $H_2L^4$, the sulfonamide groups are protonated and the net charges are +1 and 0 for the MHL and the $MH_2L_2$ species, respectively. The speciation at different pH conditions for the zinc binary systems under study ($H_2L^n$, $n$ = 1–4) is illustrated in Figure S2 of the Supporting Information.

Concerning $H_2L^2$, the NMR spectral changes with pD showed the noninvolvement of the sulfonamide group in the metal coordination, in agreement with the potentiometric results that indicated a coordination via amine group. The carboxylate group may also be coordinated to zinc, although the estimated value of $\log\beta_{ZnL}$ (ca. 3.6, $\log\beta_{ZnHL} - \log K_1$) is lower than the reported one for glycine (4.96 with α-aminocarboxylate coordination mode[14]) probably due to the electron-withdrawing effect of the amide group in its vicinity. With regard to $H_2L^3$, a comparative analysis of the potentiometric curve profiles of the ligand, alone and in the presence of $Zn^{II}$, showed a superimposition of the two curves in the buffer region corresponding to the deprotonation of the carboxylic group, thus indicating that the carboxylate group is not in the coordination sphere of the metal ion, according to our expectations. Furthermore, the global formation constants calculated for the zinc complexes with this ligand ($\log\beta_{ZnL}$ = 4.96 and $\log\beta_{ZnL_2}$ = 8.68) are quite similar to the reported values for the corresponding complexes with glycinehydroxamic acid (5.38, 10.07[15]), thus suggesting that for $H_2L^3$ the complexation with zinc should also involve a (*O*,*O*) hydroxamate coordination mode (the small differences found for the stability constants of those two ligands are ascribed to the electron-withdrawing effect of the sulfonamide group). So, the coordination mode for the 1:1 zinc complex with $H_2L^3$ is different from that previously presented for $H_2L^5$ (see Figure 4), in which the species ZnL evidenced an (*N*,*N*,*O*) coordination type with the involvement of the hydroxamate-*N* atom, but also the amine-*N* atom and the carboxylate group.[12]

To make a comparative analysis of the affinity of the studied compounds towards $Zn^{II}$, the corresponding pM values at the physiological pH (pM = –log[M], $C_L/C_M$ = 10 and $C_L = 10^{-5}$ M, pH = 7.4) were calculated, in order to account for the distinct proton concentration dependence of the compounds. Table 1 shows that, in spite of the possible different coordination modes, all the compounds present quite similar affinity for zinc (pZn ≈ 6).

The infrared (IR) spectra of the solid-state samples for the ligands $H_2L^n$ ($n$ = 1–4) and their corresponding zinc species were also performed to aid the identification of the metal coordination modes, namely the eventual involvement of the sulfonamide group. IR data for the ligands and respective zinc species are listed in Table 2 with provisional assignments of the selected vibrational modes.

The IR spectra of ligands $H_2L^n$ ($n$ = 1, 2, 4) present two bands (near 1330 and 1160 $cm^{-1}$), attributable to the asymmetric (as) and symmetric (sy) S=O stretching (st) frequencies; the spectra of the corresponding zinc complexes

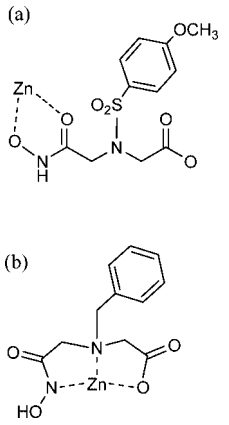

Figure 4. Proposed structures for 1:1 $Zn^{II}$ complexes with the following ligands: (a) $H_2L^3$ and (b) $H_2L^5$[12] (charges and coordinated water molecules are omitted).

show these bands with lower intensity and two new bands appear at lower wave numbers (1260 and 1130 $cm^{-1}$), the intensity of which increases with $Zn^{II}$ excess, namely from 1:1 to 2:1 (M:L) stoichiometric conditions (see Figure 5). The blue shifts of these IR bands, upon complexation,[16] suggest the involvement of the sulfonamide group on the zinc complexation, at least in the solid phase, for the compounds $H_2L^n$ ($n$ = 1, 2, 4).

On the contrary, the IR spectra obtained for $H_2L^3$ and the corresponding zinc complex reveal that the sulfonamide group is not coordinated to the metal ion, even in conditions of metal ion excess, since there is no shift of the S=O stretching frequencies (see Table 2).

The spectra of $H_2L^n$ ($n$ = 1, 3) also present a strong band near 1650 $cm^{-1}$, which should be attributed to the C=O st of the amide groups; upon zinc complexation, this band is shifted to lower wave numbers, thus suggesting that the coordination of these ligands to $Zn^{II}$ occurs via the hydroxamate group. The corresponding C=O st band for the hydroxypyrimidinone derivative ($H_2L^4$) appears at a higher wave number (1722 $cm^{-1}$) than the primary hydroxamic acids, caused by the higher double character of this carbonyl group, and it is considerably shifted to lower energy upon complexation with zinc, thus giving support to the expected hydroxypyrimidinone (*O*,*O*) coordination mode.

Moreover, in the IR spectra of compounds containing carboxylate groups, besides the strong C=O st band corresponding to the amide groups, it is also possible to identify two bands near 1630 $cm^{-1}$ ($COO^-$ st, very strong) and 920 $cm^{-1}$ ($COO^-$ bending $\delta$). For the systems containing $H_2L^2$, upon complexation, these two bands shifted to lower wave numbers, which is consistent with the participation of the carboxylate group in the zinc coordination. Nevertheless, for the $H_2L^3$ spectra, there is a broad band at 1628 $cm^{-1}$, probably arising from overlapping of C=O st (amide) and $COO^-$ st (carboxylate), which upon complexation presents only a slight shift to lower wave numbers. Although this feature cannot give much help to the elucidation of the group involved in the coordination (hydroxamate or carboxylate), the fact that no shift was observed

Table 2. Infrared spectroscopic data of compounds $H_iL^n$ ($n$ = 1–4) and respective zinc(II) species ($C_M/C_L$ = 2).

| Systems | Vibrational spectra $\nu$ [cm$^{-1}$] S=O as st | S=O sy st | C=O st amide | $COO^-$ as st | $COO^-$ δ |
|---|---|---|---|---|---|
| $H_2L^1$ | 1334 | 1162 | 1653 | – | – |
| (2:1) $Zn^{2+}/H_2L^1$ | 1259 | 1138 | 1641 | | |
| $H_2L^2$ | 1334 | 1160 | 1660 | 1633 | 912 |
| (2:1) $Zn^{2+}/H_2L^2$ | 1265 | 1136 | 1639 | 1605 | 858 |
| $H_2L^3$ | 1346 | 1151 | 1628 | 1628 | 943 |
| (2:1) $Zn^{2+}/H_2L^3$ | 1342 | 1151 | 1616 | 1616 | 945 |
| $H_2L^4$ | 1306 | 1167 | 1722 | – | – |
| (2:1) $Zn^{2+}/H_2L^4$ | 1261 | 1136 | 1634 | | |

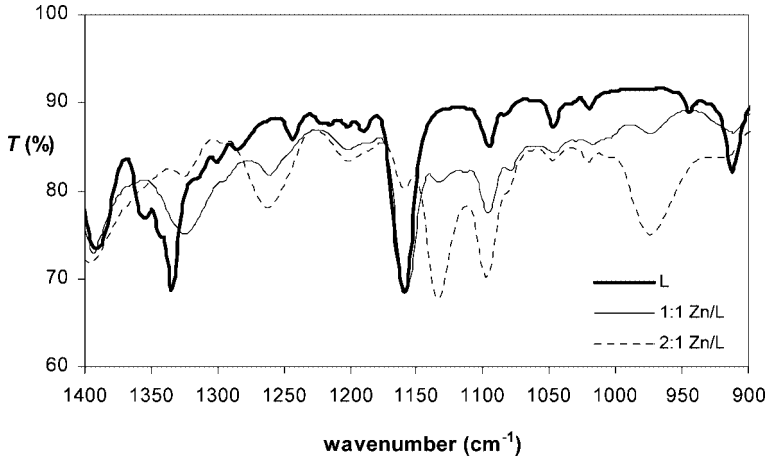

Figure 5. IR spectra of $H_2L^2$ and corresponding 1:1 and 2:1 $Zn^{II}/H_2L^2$ systems in KBr pellets.

for the $COO^-$ bending band, supports the noninvolvement of the carboxylate group in the coordination to the metal ion.

Therefore, the solid-state IR data corroborate the coordination modes found in the solution studies for all the ligands and indicate that for the zinc $H_2L^2$ complex the carboxylate group may be also involved in the metal coordination. Furthermore, it also illustrated the existence of coordination via the sulfonamide group in conditions of metal ion excess.

Previous studies of the compounds $H_2L^n$ ($n$ = 1–6) as MMP and CA inhibitors showed that the sulfonamide derivatives present, in general, a much higher activity against these metalloenzymes than the corresponding non-sulfonamide analogues. In fact, from all the compounds under study, enzyme inhibition ($IC_{50}$) of nanomolar order was only detected for the primary sulfonamide derivatives ($H_2L^1$, $H_2L^2$, $H_2L^4$), against CA I and CA II, and the secondary sulfonamide derivative ($H_2L^3$) against MMP-2, MMP-7 and MMP-9.[8,9] However, the present complexation studies reveal that, in aqueous solution, the sulfonamide group does not seem to be involved in the zinc-coordination. Therefore, since the primary sulfonamides are believed to bind the zinc active site of CAs,[4] the difference between the in vivo and the aqueous solution behaviour should be due to the inaccessibility of the active site to the stronger binding moieties. Concerning the secondary sulfonamide derivative ($H_2L^3$), its high inhibitory activity can be rationalized in terms of extra-functional interactions between the sulfonyl groups and specific amino-acid residues, namely through hydrogen bonds and lipophilic interactions at the active site of the metalloenzymes, as suggested by molecular simulation.[8]

## 3. Conclusions

The complexation equilibrium studies of four sulfonamide derivatives ($H_2L^n$, $n$ = 1–4), already known for their inhibitory activity towards zinc-containing enzymes, show that they have similar affinity for zinc (pZn ≈ 6). The solution and solid infrared studies proved that the 1:1 complexes with ligands $H_2L^n$ ($n$ = 1, 3, 4) present ($O,O$) hydroxamate coordination mode, while the zinc complex with $H_2L^2$ seems to involve both the $N$-amine and the carboxylate groups. Moreover, the infrared studies of the solid complexes indicate that the metal coordination via the sulfonamide groups can mainly occur under conditions of zinc excess. Therefore, the considerable improvements observed in the enzyme inhibitory activity of these sulfonamide-containing compounds, as compared to the non-sulfonamide derivatives, does not seem to be determined by their zinc coordination mode but by extra-binding or specific stereochemical requirements for the accommodation of the inhibitor into the enzyme active site.

## 4. Experimental Section

### 4.1. Materials and General Information

The synthesis of the compounds has already been reported or is in the process of being published, namely the hydroxamic/acetic acid derivatives[8,9,12]: 2-(*N*-{[2-(4-sulfamoylphenyl)ethyl-carbamoyl]methyl}-*N*-benzyl-amino)acetohydroxamic acid ($H_2L^1$), 2-(*N*-{[2-(4-sulfamoylphenyl)ethylcarbamoyl]methyl}-*N*-benzylamino)acetic acid ($H_2L^2$), *N*-[(hydroxycarbamoyl)methyl]-*N*-(4-methoxyphenylsulfonyl)aminoacetic acid ($H_2L^3$), *N*-{(hydroxycarbamoyl)methyl}-*N*-benzylaminoacetic acid ($H_2L^5$), and the hydroxy-pyrimidinone derivatives:[10,11] 4-(2-(4-sulfamoylphenyl)-ethylamino)-1-hydroxy-2(1*H*)-pyrimidinone ($H_2L^4$) and 4-(5-aminopentylamino)-1-hydroxy-2(1*H*)-pyrimidinone ($HL^6$).

All $^1$H NMR spectra were recorded with a Varian Unity 300 MHz spectrometer at probe temperature. Chemical shifts are reported in ppm ($\delta$) from internal reference DSS (sodium 3-trimethylsilyl-[$D_4$]-propionate). The pD values were adjusted with DCl or $CO_2$-free KOD, by using a ThermoORION model 420 instrument fitted with a combined Mettler Toledo U402-M3 S7/200 microelectrode. The IR spectra were performed with a FTS3000MX Bio-Rad spectrophotometer.

### 4.2. Potentiometric Titrations

**Solutions:** The $ZnCl_2$ (0.0156 M) solution from Merck was standardized by titration with $K_2H_2EDTA$ (EDTA = ethylenediaminetetraacetic acid). The titrant (KOH) was prepared from a carbonate-free commercial concentrate (Titrisol) and standardized by titration with a solution of potassium hydrogen phthalate, being discarded whenever the percentage of carbonate (Gran's method[17]) was higher than 0.5% of the total amount of base.

**Measurements:** The equipment used was as previously described.[18] All the potentiometric titrations were performed at 25.0 ± 0.1 °C and ionic strength ($I$) 0.10 M KCl, the atmospheric $CO_2$ being excluded from the cell by passing purified $N_2$ across the top of the experimental solution. Because of the low water-solubility of $H_2L^4$, this compound and $HL^6$ were studied in a 5% DMSO aqueous medium. For these studies, the calibration procedure was analogous to that in an aqueous medium, but in a 5% DMSO/95% water solvent mixture, and the same procedure was adopted for the parent ligand $HL^6$.

The cell ligand concentrations, in the absence and in the presence of the metal ion, at different stoichiometric conditions (1:1, 1:2 and 2:1 molar ratios), were ca. $(6.0–7.0)\times10^{-4}$ M, except for $H_2L^3$ ($C_L = 1\cdot10^{-3}$ M). The measurement of the electromotive force of the cell allowed the calculation of $[H^+]$[19] and the determined value of $K_w$ used in the computations was $10^{-13.76}$ and $10^{-13.74}$ for the water and 5% DMSO studies, respectively.

**Calculation of Equilibrium Constants:** The stepwise protonation constants, $K_i = [H_iL]/[H_{i-1}L][H]$, and the overall zinc complex stability constants, $\beta_{Zn_mH_hL_l} = [Zn_mH_hL_l]/[Zn]^m[H]^h[L]^l$, were calculated by fitting analysis of the potentiometric titration curves of the ligand in the absence and in the presence of the zinc ion, respectively, with the HYPERQUAD 2003 program.[20] The stability constants determined in aqueous medium for the $Zn^{2+}$ hydrolytic species[21] were included in all the equilibrium models proposed for the metal complex systems and the species distribution curves were plotted with the HYSS program.[20] The quoted errors are the standard deviations of the overall stability constants given by the program for the input data. The $K_i$ standard deviations were determined by the normal propagation rules and do not represent the total experimental errors.

### 4.3. $^1$H NMR Titrations

**Measurements:** $^1$H NMR titrations of solutions containing $H_2L^n$ ($n$ = 1, 2, 4, $C_L \approx 10$ mM) or of the corresponding $Zn^{II}/H_2L^n$, 1:1 systems were performed in NMR tubes. The adopted medium was $D_2O$ and 1:4 DMSO/$D_2O$ solutions for ligands $H_2L^n$, with $n$ = 1, 2 and $n$ = 4, respectively. The pH* value corresponds to the reading of the pH meter calibrated with the aqueous buffers (pH 4 and 7) and it was adjusted with DCl or $CO_2$-free KOD. The final pD values are determined from the equation pD = pH* + 0.40.[22]

**Calculation of Equilibrium Constants:** The $\log K_3^D$ value for $H_2L^2$ was calculated by fitting analysis of the experimental data, using the PSEQUAD program[23] and then that value determined in $D_2O$ was converted into the corresponding value in $H_2O$ by the equation $pK^D = 0.32 + 1.044\ pK^H$.[24]

### 4.4. IR Measurements

The solid-state IR spectra of the compounds $H_2L^n$ ($n$ = 1–4) and related zinc species were performed as KBr pellets. The complexes were prepared by adding to the ligand solution the corresponding amount of 0.0156 M $ZnCl_2$ standard solution, in order to obtain a 1:1 or 2:1 metal-to-ligand molar ratio. In the cases of $H_2L^1$, $H_2L^2$ and $H_2L^4$, 1 M HCl solution was added to enhance the solubility. Afterwards, the pH was raised (6–8) with 0.5 M KOH solution until precipitation occurred; the solid was filtered and dried before recording the IR spectra.

**Supporting Information** (see also the footnote on the first page of this article): Figure S1 containing the $^1$H NMR titration curves of $H_2L^1$ and 1:1 $Zn^{II}/H_2L^1$ systems and Figure S2 containing species distribution diagrams for the 1:2 $Zn^{2+}$-to-ligand systems with ligands $H_2L^n$ ($n$ = 1–4).

# Click Chemistry with an Active Site Variant of Azurin

**Thyra E. de Jongh,[a] Anne-Marie M. van Roon,[a][‡] Miguel Prudêncio,[a][‡‡] Marcellus Ubbink,[a] and Gerard W. Canters*[a]**

**Keywords:** Metalloproteins / Protein structures / Zinc / Copper / Metal replacement

The active site of the blue copper protein azurin (Azu) from *Pseudomonas aeruginosa* consists of a Cu ion immobilized by bonds to four amino acid side chains. The protein assists in electron transfer *in vivo*. Replacement of Cu-ligand His117 by a Gly makes the Cu site accessible for exogenous ligands. Incubation of the H117G Azu with *n*-alkane linkers carrying imidazole groups at opposite ends leads to the formation of noncovalently linked Azu dimers. The active site of H117G Azu is vulnerable to Cu-catalyzed oxidative attack. Replacement of $Cu^{II}$ by $Zn^{II}$ leads to stable dimers, whose structures have been determined by X-ray diffraction. These structures are reported here. The similarity in the structure of the active site between the wild type (*wt*) Zn-Azu and the dimer is remarkable in light of the different relation of the coordinating imidazole to the protein framework (covalently attached vs. exogenous origin, respectively). The part of the "ligand loop" running from amino acid 116 to 121 has acquired increased flexibility in the mutant. The connected subunits have adopted an unexpected orientation relative to each other.

## Introduction

When applied to proteins, "click" chemistry can provide decisively new insight in structure and function. Click chemistry refers to the technique by which a side chain or a prosthetic group is removed from a protein framework, either chemically or by site-directed mutagenesis, and the resulting gap is filled by exogenous compounds. In this way, modified flavins or heme groups have been inserted into the apo forms of flavoproteins and heme proteins.[1–3] It allows the modification of active sites of enzymes in a simple and straightforward manner. When the prosthetic group is extended with a linker ("hot wire"), click chemistry can also allow for the connection of the active site of an enzyme to a partner molecule or to an electrode.

In copper-containing proteins, the active site consists of one or more Cu ions that are immobilized in the protein through coordinate bonds to side chains. By replacing one of these side chains by a small amino acid (Gly or Ala), the Cu centre becomes directly accessible for exogenous ligands. The technique has been successfully applied to the active site of blue copper proteins and to the type-1 site of the Cu-containing nitrite reductase.[4,5]

In the case of the small blue copper protein azurin (Azu) from *Pseudomonas aeruginosa*, His117 has been subjected to such modification. In Azu the Cu is bound by the Sγ and Sδ atoms of Cys112 and Met121, respectively, and the Nδ atoms of the residues His46 and His117. There is also a weak interaction with the backbone carbonyl of Gly45.[6] Azu is an electron-transfer protein, possibly involved in oxidative stress response.[7] With many electron-transfer proteins, a small part of the prosthetic group (flavin in the case of flavodoxins or heme in the case of cytochromes, for instance) or the active centre (the Fe-S cluster in ferredoxins or the Cu site in cupredoxins, for instance) is directly accessible from the outside. In Azu this part of the structure is formed by the Cu-ligand His117. It protrudes through the protein surface at a shallow depression in the so-called hydrophobic patch. His117 provides for electronic coupling with the Cu and, presumably, represents the site where physiological partners dock.[8,9]

Replacement of His117 by a Gly results in a slightly destabilized form of the protein with a Cu site that has been classified as Type-2 with spectral characteristics (EPR, UV/Vis) that clearly differ from the native protein but revert to those of the native protein upon incubation with imidazole.[4,10,11] So far, attempts to determine the structure of this Azu variant by crystallography failed because the destabilized Cu site appears vulnerable to $Cu^{2+}$ catalyzed oxidative attack by oxygen, which converts the Cys112 sulfur into a sulfonate.[12] NMR studies showed an increased mobility of the ligand loop (running from Cys112 to Met121) on which His117 is located.[13] Click chemistry can enable the formation of protein multimers by using multifunc-

tional linkers. It has, for instance, been shown that the incubation of H117G Azu with 1,ω-di(imidazol-1-yl)-*n*-alkane linkers leads to formation of dimers when butane, pentane and hexane are employed as the alkane moiety.[14]

In principle, the Cu-catalyzed oxidative modification of the Cu site in H117G Azu should be avoidable by substituting the Cu by the redox-inactive Zn. It is known that in the small blue copper proteins this substitution leads to minimal distortion of the native structure and of the active site in particular, the changes in the latter being limited to a shortening of the $M^{2+}$–Gly45 carbonyl bond and an elongation of the $M^{2+}$–Sδ(Met121) bond.[15]

Here we report on the preparation and characterization of the 1,5-di(imidazol-1-yl)pentane (1,5-dip) and 1,6-di(imidazol-1-yl)hexane (1,6-dih) linked dimers of Zn-H117G Azu. The results provide insight into the structural and dynamic properties of the H117G Azu variant. In particular, they give an unexpected perspective on the mobility of the ligand loop in native and H117G Azu.

## Results

### Dimerization of Zn-H117G Azurin

As Zn-H117G Azu is colourless, coordination of the imidazole-based linkers can not be followed by the green-to-blue optical transition that occurs upon coordination of

imidazole to $Cu^{II}$-H117G Azurin.[4,10] Instead, ligand binding was monitored by $^1H$ NMR spectroscopy. Addition of 0.7 molar equiv. of 1,5-dip or 1,6-dih to apo-H117G Azu had no discernible effect on the $^1H$ NMR spectrum (not shown), whereas subsequent addition of a slight molar excess of $Zn(SO_4)_2$ to the sample led to the occurrence of several new protein resonances in the downfield region of the spectrum (Figure 1C, D). This demonstrates the formation of a new species for which Zn is required. The new species exhibits a 3–4 Hz increase in line width corresponding to a 40–60% increase in $T_2^{-1}$. As the latter varies proportionally with the rotational correlation time, $\tau_c$, the increase in line width reflects an increase in $\tau_c$. While doubling of the molecular weight should be accompanied with a doubling of $\tau_c$ for a spherical molecule, the smaller increase may reflect the nonspherical shape of the dimer. The line broadening and the appearance of new resonances confirm the formation of $Zn^{II}$-His117Gly Azu dimers noncovalently linked by di(imidazolyl)alkanes.

To check the stoichiometry, samples of Zn-H117G Azu were titrated with 1,5-dip and 1,6-dih. The NMR spectra are shown in Figure 1C and Figure 1D. In the course of the 1,5-dip titration, the signals at 12.56, 11.91 and 10.26 ppm (Figure 1C: signals a, b and c) grew, while the peaks around 10.1 ppm, consisting of a number of partially overlapping signals, changed shape. Similar observations were made for signals at 12.59, 11.90 and 10.11 ppm (Figure 1D: signals a′, b′ and c′) in the case of the 1,6-dih titration. In the latter case, signal c′ almost completely overlaps with the signals clustered around 10.1 ppm. The average intensities of signals a and a′ as a function of the added amount of linker are shown in Figure 1B. The signal intensities depend on the equilibria L + A ⇄ LA and LA + A ⇄ ALA, with dissociation constants $K_1$ and $K_2$, respectively. Reliable determinations of $K_1$ and $K_2$ require concentrations of the reactants at which there is substantial dissociation. Since $K_1$ and $K_2$ are expected to be in the micromolar range,[14] and NMR measurements require millimolar quantities for the titrations, no accurate $K$ values could be extracted from Figure 1B. What the data do demonstrate is that the equivalence point in the titration is reached at an [L]/[A] ratio of about 1:2, confirming that one linker molecule associates with two Azu molecules. (The accuracy of the data points in Figure 1B is limited by an uncertainty in the linker concentration and the inherent inaccuracy of the peak intensities caused by line-width variations in the NMR spectra. This explains why the equivalence points are not reached at exactly [L]/[A] = 1:2.)

### Crystal Structure of (Zn-H117G)$_2$-1,6-dih Azurin

From diffraction data collected at 100 K, the crystal structure of (Zn-H117G)$_2$-1,6-dih Azu was solved to 2.85 Å resolution (Table 3). Data collected at room temperature showed that the resolution is directly limited by the quality of the crystals and is not affected by the freezing process. The asymmetric unit contains a total of four protein molecules arranged as a pair of dimers (Figure 2), reminiscent of the molecular arrangement observed in crystals of *wt* Azurin.[16] Each of the molecules within the dimer is aligned with its long axis roughly parallel to the 1,6-dih linker. The intramolecular Zn-to-Zn distance amounts to 16.1 Å. The four molecules within the asymmetric unit are superimposable with an RMSD of 0.4 Å for the Cα trace of the entire protein backbone, which diminishes to 0.2 Å when the loop region between residues 116 and 120 is excluded, indicating a well conserved core structure. The Cα trace of Zn-H117G Azu, averaged over all four molecules in the asymmetric unit, is superimposable with *wt* Zn-Azu within 1.1 Å which diminishes to 0.5 Å when residues 116–120 are ignored. The structural details of the metal site are reported in Table 1.

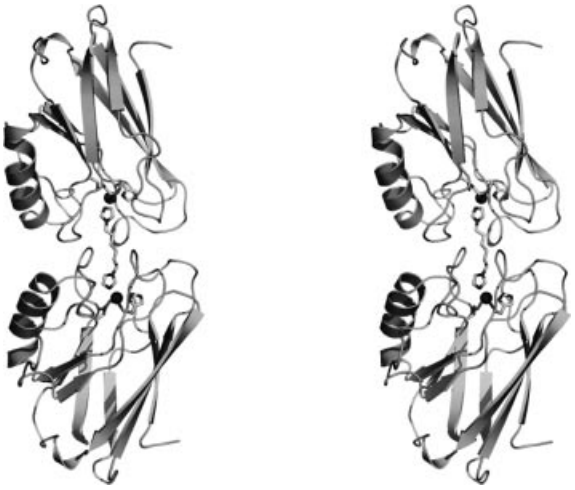

Figure 2. Stereo view of the $(Zn\text{-}H117G)_2$-1,6-dih Azu dimer. The side chains of residues G45, H46, C112, and M121 as well as the 1,6-dih linker are shown as sticks while both zinc atoms are depicted as spheres.

## Discussion

### Metal Site Structure

Although the limited resolution of the structure of the H117G dimer reported here requires caution with the interpretation of the data, averaging over all of the molecules within the asymmetric unit permits us to compare the structural characteristics of the metal site with those in *wt* $Cu^{II}$- and $Zn^{II}$-Azu (Table 1). The main structural difference between the $Cu^{II}$ and $Zn^{II}$ sites in *wt* Azu relates to the decrease in the distance between the metal and the carbonyl of Gly45 and the concomitant increase in the metal–Sδ(Met121) distance when Cu is substituted by Zn. Clearly, the "hard" Zn ion is pulled over from the "soft" sulfur ligand to the "harder" oxygen ligand so that the Zn ion ends up at the other side of the $N_2S$ plane as compared with the Cu ion. A similar observation applies for *wt* Zn-H117G Azurin.[15] The extent to which the structural details of the Zn site in the dimer seem to reproduce those of the *wt* Zn-Azu is remarkable, despite the fact that the imidazole ring is not covalently attached to the protein framework in the dimer. In particular, the positions of the three hard ligands His46, Ser112, and His117/Linker which together form a near-equatorial plane are well conserved. The two axial ligands Met121 and Gly45 show slightly larger deviations relative to *wt* Zn-Azu. They form weak coordinate bonds to the Zn ion and have more positional freedom.

### NMR Titration

The NMR titration data (Figure 1) clearly demonstrate that the $Zn^{II}$-H117G Azu does bind the bifunctional linkers used for this study. The signals used to follow the titration have not been assigned. In native *wt* $Cu^{I}$ Azu there are seven distinct high-field signals in the range of from 9.60 to 11.30 ppm.[27] They derive from the backbone amide protons of Asn38, Asn47, Thr52, Ile87, Thr113, Phe114 and Ser118. Three of these stand out because they occur at very high chemical shift positions: 11.30 (N38), 10.58 (N47) and 10.48 (F114) ppm. Those of N47 and F114, in the *wt* structure, form a H-bridge with the Sγ of the Cys112 metal ligand; their chemical shifts to some extent reflect the charge distribution over the metal site. The amide proton of Asn38 forms a H-bridge with the carboxyl group of Asp11 which is located in the interface of the $Zn^{II}$-H117G Azu-dimer. One expects these three signals to stand out in the spectrum of the dimer as well, but a definitive identification of the high-field signals a–c and a′–c′ must await a detailed assignment of the spectrum. The low-intensity resonances at 10.14 and 9.96 ppm derive from an apo-Azu impurity.

### Ligand Loop Dynamics

Although the overall protein structure of each of the subunits is very similar to *wt* Zn-Azu, the loop on which residues 116 to 119 are located has adopted different conformations in each of the four subunits in the asymmetric unit (Figure 3A). They all have relatively high B factors indicative of increased flexibility (Figure 3B) This flexibility is understandable, given that in H117G Azu the loop is comprised of a series of small, flexible amino acids (Gly-Gly-Ser-Ala) and is consistent with the finding by Jeuken et al. that for $Cu^{I}$-H117G Azu the residues 116–120 display increased backbone dynamics in solution relative to *wt* Azu.[13]

It is interesting to note that the complete ligand loop runs from Cys112 to Met121 but that only the part running from residues 116–119 shows enhanced disorder. Apparently residues 112–115 are sufficiently strongly anchored to the protein framework to keep them fixed in the structure even when His117 is replaced by a Gly. Of the residues 116–119 in the *wt* structure, only the side chain of His117 is anchored to the protein structure, namely through a bond of the imidazole ring to the Cu. Yet, this is not what keeps His117 in place because in apo-Azu this loop retains its native conformation.[17] It is found that some of the ligand loop residues of $Zn^{II}$-H117G Azu occur in the disallowed regions of the Ramachandran plot (Figure 4). These dihedral angles have become accessible to the protein only because the His117 has been replaced by a Gly. It is therefore impossible for the ligand loop in *wt* Azu to adopt a configuration as seen here. To what extent the flexibility of the ligand loop in Azu differs from those in other blue copper proteins like plastocyanin, pseudoazurin and amicyanin remains to be seen.

### Interface Packing and Solvation

It is of interest to compare the relative orientation of the Azu monomers in the $(Zn\text{-}H117G)_2$-1,6-dih Azu structure with what has been observed for *wt* Azu. For *wt* Azu, the α-helices of the two monomers are situated on opposite sides of the dimer (Figure 5). Covalent dimers of Azu, in

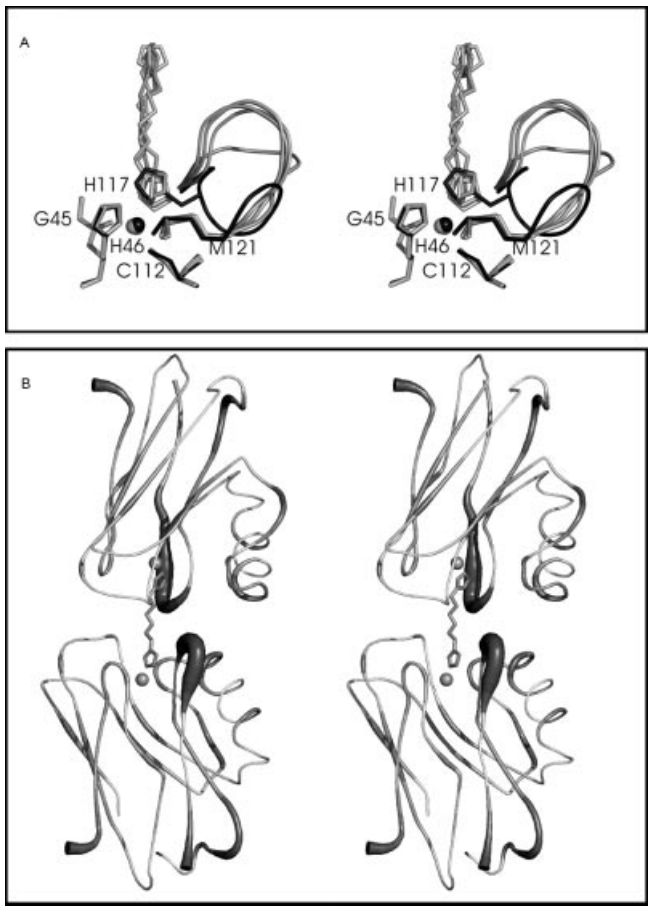

Figure 3. Representation of structural data. (A) Stereo view of residues G45, H46, C112, H/G117 and M121 of each of the monomeric subunits of (Zn-H117G)$_2$-1,6-dih Azu (grey) in the asymmetric unit, superimposed on the structure of Zn-*wt* Azu (black). The ligand loops between residues 115–121 are shown in cartoon representation; the zinc atoms are shown as spheres. Labels correspond to the ligands of *wt* Azu. (B) Stereo image of one of the dimers of (Zn-H117G)$_2$-1,6-dih Azu observed in the asymmetric unit. Darker shading and larger tube diameter indicate increased B factors. The 1,6-dih linker is shown in stick representation; the zinc atoms are shown as spheres. The dimer shown has the most flexible ligand loops of the two dimers found within the asymmetric unit.

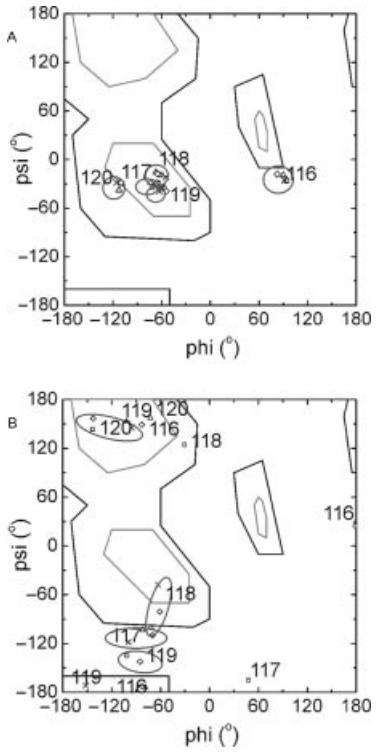

Figure 4. Ramachandran plots of the loop residues 116-120 of (A) Zn-*wt* Azu and (B) (Zn-H117G)$_2$-1,6-dih Azu. Different symbols are used to represent the individual amino acid chains within the asymmetric unit.

Figure 5. Cartoon representations of (Zn-H117G)$_2$-1,6-dih Azu (left) and the crystal packing of Zn-*wt* Azu (right); the α-helical regions are shown in dark grey. The zinc atoms are shown as large spheres (black). Hydrogen-bonded water molecules in the protein interface of *wt* Azu are shown as small spheres (light grey).

which the Azu moieties are connected through a bis(maleimidomethyl) ether (BMME) linker also have a tendency to adopt this orientation.[18] In contrast, the structure of the noncovalent dimer of (Zn-H117G)$_2$-1,6-dih Azu, in which the metal ions are connected with the linker through coordinate Zn-imidazole bonds, has both α-helices on the same side (Figure 5). Somewhat similar orientations have been observed for the C112D and F114A mutants of Azu (1AG0 and 1AZN, respectively).[19,20]

Although the interface area in the dimer is largely retained, its solvent accessibility is slightly larger than that in the structures of *wt* Azu or the BMME-linked N42C Azu-dimer, both of which display the classical hydrophobic interaction packing (Table 2).[16,18,21] A disulfide-linked N42C Azu dimer does not fit in this comparison and is a separate case: its *intra*-dimer interface is very small (ca. 360 Å$^2$) since two monomers are rotated around the C42–C42 disulfide bond as compared with the *wt* packing. The *inter*-dimer interface is sizeable but smaller than in the *wt* case. The decrease in interface for the (Zn-H117G)$_2$-1,6-dih Azu, however, although not large, is significant and is related to

[a] The coordinate file used for the calculation contained a single monomer; additional monomers were removed from the asymmetric unit. [b] The coordinate files used for the calculation were edited to contain only the molecules that share the contact surface under consideration. [c] Numbers correspond to the intermolecular interface between two different dimers in the asymmetric unit.

the packing of the monomers. From previous experiments on H117G Azu it was concluded that 1,5-dip gives optimal packing of the Azu monomers and that 1,6-dih Azu is slightly too long to let monomers approach as close as in the *wt* case.[14] The increase in metal-to-metal distance in the Zn-H117G Azu dimer (16.1 Å *vs.* 14.9 Å in *wt* Azu[16]) is in line with this conclusion. A slightly larger distance between the two Azu halves in the dimer would also mean a smaller contact area, in agreement with the data in Table 2.

The findings reported here and in the preceding discussion show that the packing of two Azu molecules with their hydrophobic patches together is thermodynamically favourable. Previous experiments have shown that the gain in free energy when two Azu molecules associate is 2.1 kcal/mol.[14] The present data show that Azu molecules prefer to pack with their hydrophobic patches opposite to each other, but that the precise mutual orientation of the monomers may vary and probably depends on small variations in the free energy of association caused by small adjustments in the van der Waals energy, remote charge effects and the precise configuration of hydrogen bridges across the interface.

## Conclusions

Site-directed mutagenesis of the copper ligand H117 of the blue copper protein Azu (*P. aeruginosa*) creates a solvent-exposed aperture in the protein, which can accommodate a variety of ligands, thereby permitting "hotwiring" of the protein. Incubation of the H117G variant with bifunctional linkers like the 1,ω-di(imidazol-1-yl)-*n*-alkanes allows the formation of Azu dimers noncovalently linked by the functionalized alkanes. The (Zn-H117G)$_2$-1,6-dih Azu dimer was crystallized and its structure was solved to 2.85 Å resolution. Relative to *wt* Azu, H117G Azu shows increased flexibility in the loop region between residues 116–120, surrounding the site of mutation. The displacement of this loop from the protein interior may facilitate the coordination of larger exogenous ligands. The structure represents a type of dimer in which the proteins have adopted a relative orientation distinct from those previously reported for dimers of Azu.

## Experimental Section

**Protein Expression and Isolation:** Apo-H117G Azu was produced and purified as described previously. The concentration of apoprotein was determined from the absorbance at 280 nm ($\varepsilon_{280}$ = 9.1 ± 0.1 mM$^{-1}$ cm$^{-1}$) recorded at room temperature (r.t.) on a Perkin–Elmer lambda 18 spectrophotometer.

**Linkers:** The bifunctional ligands (Figure 1A) 1,5-di(imidazol-1-yl)pentane and 1,6-di(imidazol-1-yl)hexane were synthesized as previously reported.[14] Purity and integrity of the samples after prolonged storage was confirmed by $^1$H NMR and working solutions of 6 mM were prepared in MilliQ grade water.

**NMR Spectroscopy:** All $^1$H NMR spectra were recorded with a Bruker Avance DMX 600 MHz spectrometer at 304 K with a spectral width of 12.98 ppm in 4 K memory by using a Watergate-filtered pulse sequence. Free induction decays were Fourier transformed by using a squared sine window function. All samples were prepared in potassium phosphate ($KP_i$), pH 6.5 buffer (20 mM) supplemented with 6% $D_2O$ for locking of the signal. The binding of 1,6-dih to Zn-H117G Azu was assessed by addition of linker (0.7 equiv.) to a solution of apo-H117G Azu (0.5 mM). After recording of the $^1$H NMR spectrum, $Zn(SO_4)_2$ (2 equiv.) was added, and the sample was incubated at r.t. for ca. 10 min allowing coordination of the linker to the reconstituted protein. The effects of coordination of 1,6-dih or 1,5-dip on the $^1$H NMR spectra of Zn-H117G Azu were compared by titration of protein (1 mM) in $KP_i$, (20 mM, pH 6.5) with either of the linkers. Zn-H117G Azu was prepared by incubating a solution of the apoprotein at the desired concentration with $ZnSO_4$ (1.2 equiv.) for 10 min at r.t. This solution was used as prepared.

**Crystallization and X-ray Data Collection:** A solution of apo-H117G Azu (10 mg/mL) in Tris-HCl (10 mM, pH 7.5) was incubated with $ZnCl_2$ (1.3 equiv.) for 2 h at r.t. Excess $ZnCl_2$ was removed by ultracentrifugation (Centricon, MWCO 10,000). The sample was then incubated with either 1,5-dip (0.6 equiv.) or 1,6-dih (0.6 equiv.). Prior to crystallization the samples were filtered through a low-protein-binding, 0.22-μm filter (Millipore). Crystals of (Zn-H117G)$_2$-1,6-dih were obtained by sitting drop vapour diffusion at 295 K by using equal volumes of protein and reservoir solution. Crystals suitable for X-ray crystallography appeared within 3 d, from protein solution (1 μL) mixed with reservoir solution (1 μL) containing Tris-HCl (100 mM, pH 8.56) and 20% (w/v) polyethylene glycol (PEG) 8000. No crystals were obtained for (Zn-H117G)$_2$-1,5-dip. X-ray diffraction data of (Zn-H117G)$_2$-1,6-dih were collected on an in-house beam by using a MAR345 Image Plate detector. A crystal was mounted in a cryo-loop (Hampton Research) and passed quickly through a cryo-protectant solution

containing 20% glycerol, followed by flash-freezing in a nitrogen gas stream at 100 K. A data set was collected to 2.85 Å resolution. All collected data were indexed, integrated and scaled with HKL2000.[22] Data collection and refinement statistics can be found in Table 3.

[a] Values of reflections recorded in the highest resolution shell are shown in parentheses. [b] $R_{merge} = \Sigma_o(|I-<I>|)/\Sigma(I)$ (scalepack output). The coordinates have been deposited in the Protein Data Bank under accession code 2IWE.

**Structure Determination and Refinement:** The structure of (Zn-H117G)$_2$-1,6-dih was solved by molecular replacement by using the program Molrep[23] from the CCP4 program suite[24] by employing the structure of Zn-*wt* Azu (PDB entry 1E67)[15] as a search model. A solution was obtained with an *R* factor of 39.7% and a correlation coefficient of 58.8. After several rounds of rigid-body and restrained refinement with Refmac5,[25] the mutated amino acids were built in manually with Xtalview,[26] followed by automatic solvent building with ARP/wARP.[27] Upon inspection of an $F_o - F_c$ difference density map, a double conformation of the main chain running from residue G116 to M121 of molecule A could be modelled and refined, leading to an improvement of $R_{free}$. Extra density was also observed for this flexible loop in the three other molecules present in the asymmetric unit but was considered too weak to build any amino acids. Final refinement by using tight NCS restraints between residues 1 to 114 of each protein chain and refinement of translation, liberation and screw (TLS) parameters[28] resulted in a model with an *R* factor of 19.2% ($R_{free}$ 23.3%). The quality of the model was checked by PROCHECK[29] and WHATIF[30] (see Table 3). The coordinates and structure factors have been deposited in the Protein Data Bank under accession code 2IWE. Figure 2, Figure 3 and Figure 5 were made in PyMOL 0.98.[31] Figure 3 was generated with the help of the color_b.py script for colouring according to B factor (http://adelie.biochem.queensu.ca/~rlc/).

**Solvent Accessibility and Interface Areas:** The solvent-accessible surface area (ASA) was calculated by using the program NACCESS 2.1.1 with a probe radius of 1.4 Å. The interface area was defined as the sum of the ASAs of the individual proteins minus the ASA of the complex.

# New Polar Pyrazolylborate Ligands and Their Basic Zinc Complex Chemistry

**Cristina Pérez Olmo,[a] Karin Böhmerle,[a] Gunther Steinfeld,[a] and Heinrich Vahrenkamp*[a]**

**Keywords:** Tripod ligands / Pyrazolylborate ligands / Zinc complexes / Structure elucidation / Coordination modes

By refinement of Trofimenko's procedures, four new tris(pyrazolyl)borate (Tp) ligands bearing pyridyl and carboxamide substituents at the 3-positions of the pyrazole rings, were obtained. Two of them were identified by structure determinations of their potassium salts. Their coordinative properties were explored by preparing Tp*Zn-X complexes, with X = Cl, Br, I, $NO_3$, OAc, phenolate, thiophenolate and diorganophosphate, including the cationic complexes $[Tp^*Zn{\cdot}L]^+$ with L = methanol and pyrazole. From the spectra and structure determinations of these complexes it has become evident that the polar Tp* ligands favor coordination numbers higher than four for zinc, either by inducing bidentate coordination of the coligands X and L, using the carboxamide oxygen atoms for coordination, or by linking two Tp*Zn-X units through the pyridyl nitrogen atoms. As a result, the structural chemistry of these complexes is quite varied, and includes coordination dimers and polymers.

## Introduction

Trofimenko's tris(pyrazolyl)borate (Tp) ligands[1] have been the key to success in biomimetic zinc complex chemistry, in our own hands[2] as well as in those of our competitors,[3] as evidenced by Parkin's recent review.[4] One reason for this is the ease by which their structures can be varied, for example, by attaching various substituents at the 3- and 5-positions of their pyrazole rings. The substituents at the 3-positions create and control the protective pocket around the zinc ion, which is the "active center" of the enzyme model. Substituents as small as methyl groups at the 5-positions protect the B–N bonds, preventing hydrolytic self-destruction of the ligands due to the presence of zinc ions.

Until now most of the 3-substituted Tp ligands bear nonpolar, i.e. mostly hydrocarbon, substituents. This is due to the fact that most functional organic groups do not survive the reaction conditions during the Tp ligand synthesis that occurs in the presence of $KBH_4$ at 150–200 °C. The advantage of the nonpolar $Tp^{R,Me}$ ligands (with Me at the 5-positions and the variable R at the 3-positions) is that they can be relied upon to form tetrahedral zinc complexes including $Tp^{R,Me}$Zn-OH the essential enzyme model, and that the resultant ligand pocket around the zinc ion stabilizes many kinds of reaction products that model the intermediates of the zinc enzyme catalyzed processes.[2–4] Their disadvantage is that these "intermediates" form such stable zinc complexes that so far the $Tp^{R,Me}$Zn-OH species could not be used for catalytic processes, and that both the potassium salts and the zinc complexes of the Tp ligands are not soluble in water, thereby severely hampering their suitability as enzyme models.

Until now only a few attempts have been made to overcome these limitations. We have attached 3-pyridyl substituents to Tp ligands and studied their zinc complex chemistry,[5–7] and Ward did the same with 2-pyridyl groups.[8,9] Carrano reported Tp ligands with carboxylic ester and carboxamide substituents and a number of zinc complexes thereof;[10,11] unfortunately this work could not be reproduced by us.[12] In our eyes the most promising approach has been reported recently by Trofimenko and involved pyrrolidinocarbonyl substituents,[13] which have not yet been exploited in zinc complex chemistry. Insofar as zinc complexes of these Tp ligands with polar substituents have been studied, it was found that the benefit of their enhanced polarity comes along with a liability: the coordination number of zinc goes up to five or six, either by using the substituents' donor groups for coordination, or by the attachment of additional donor ligands.

In this paper we describe some attempts by our group to improve this situation. Our plan was to develop pyrazolylborate ligands whose polar substituents have a reduced tendency to coordinate to the zinc ion in the complex, but support the solubility of their zinc complexes in protic media by having the potential to form hydrogen-bonding interactions. The latter condition led to the choice of pyridyl and amide functionalities, and the former required these donor groups to point away from the metal ion, or to be sterically hindered. We succeeded in preparing four new ligands, **L$^1$**–**L$^4$** (Scheme 1). This paper demonstrates their suitability for

basic zinc complex chemistry. Their use for enzyme modeling will be the subject of a subsequent publication. It should be mentioned that the ligand hydridotris[3-(4′-pyridyl)pyrazolyl]borate, which is a relative of **L¹**, has recently been obtained and used in some complexes by Ward.[14]

## Results and Discussion

### Ligands L¹–L⁴

All four ligands were prepared according to Trofimenko's method, i.e. by heating the appropriate pyrazole with $KBH_4$. In case of **L¹** and **L²** the most cumbersome part of this synthesis was the preparation of the substituted pyrazoles, via the corresponding β-diketones, by previously reported procedures.[15–18] The best yields for the potassium salts of **L¹** and **L²** were obtained by heating $KBH_4$ with 4 equiv. of the pyrazole to 200 °C without solvent. In this way K**L¹** and K**L²** were obtained as colorless crystalline materials in yields of 40–50%. These compounds are insoluble in hydrocarbons, diethyl ether and chloroform, but soluble in DMSO, acetonitrile, methanol and water/methanol mixtures. The ligand K**L¹** possesses a rare property for pyrazolylborates in that it is, as expected, soluble in water.

The crystallinity of K**L¹** allowed its structure to be determined by X-ray diffraction. Figure 1 shows that the ligand **L¹** acts as a tripodal donor towards the potassium ion; however, the sideways coordination of the pyrazole nitrogen atoms N3 and N6 is weak. In addition, all the pyridyl nitrogen atoms are attached to different potassium ions. If one counts N3 and N6 as being coordinated at a single position, the potassium ions have a reasonably perfect octahedral coordination.

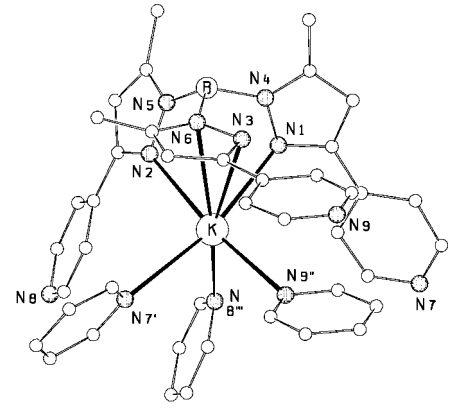

Figure 1. Coordination of the potassium ions in K**L¹**. Bond lengths [Å]: K–N1 2.897(3), K–N2 2.810(3), K–N3 3.022(3), K–N6 2.954(3), K–N7′ 3.152(4), K–N8′′′ 2.869(3), K–N9′′ 2.802(4).

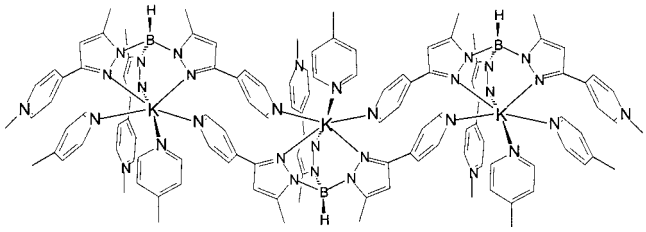
Crystalline K**L¹** is a 3D coordination polymer. A substructure of this polymer is displayed in Scheme 2, showing that the pairwise coordination of the pyridyl nitrogen atoms to neighboring potassium ions creates a chain-like array. The third remaining pyridyl nitrogen atom of each **L¹** ligand is used to build the 3D network. In general, the structure of K**L¹** resembles the structures of our K**L** compounds, with **L** being 3-pyridyl-substituted pyrazolylborates.[5]

The preparation of the carboxamide-substituted ligands **L³** and **L⁴** was even more time-consuming than for **L¹** and **L²**. One reason for this was the multistep syntheses required for the preparation of the corresponding pyrazoles via diketopiperazines,[19–22] as outlined by Trofimenko.[13] Secondly, the unavoidable non-stoichiometric compositions of the $KBH_4$/pyrazole reaction mixtures resulted in purification problems for the K**L** products. As for **L¹** and **L²**, the pyrazoles had to be provided in excess during the reactions with $KBH_4$ in order to obtain reaction mixtures from which

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

the desired ligands could be isolated. Again, these reactions were performed without solvent, this time at temperatures around 150–160 °C. After the purification procedures, only K**L**$^4$ could be obtained free from byproducts. One reason for the problems experienced in purifying K**L**$^3$ is its high solubility,·K**L**$^3$ is soluble in chloroform and more polar organic solvents,·K**L**$^4$ is insoluble in chloroform and acetonitrile, but soluble in alcohols. Both compounds are soluble in alcohol/water mixtures, but not in water.

While K**L**$^3$ could be identified, in the presence of its pyrazole, by its spectra, it had to be converted into the zinc halide complexes **2a** and **2b** (see below) to enable crystallographic proof of the **L**$^3$ structure to be obtained, and to generate a starting material so its zinc complex chemistry could be investigated. In contrast, K**L**$^4$ could be crystallized and subjected to structure determination by X-ray diffraction. The solvated crystals contain one K**L**$^4$ unit, one water molecule, and 2.5 methanol molecules per asymmetric unit. The solvent molecules are severely disordered, so their positions in the coordination sphere of the potassium ion are ill-defined. In Figure 2 the water molecule, and the methanol molecule with the highest occupancy factor located near the potassium ion, are included in the drawing. While it is meaningless to discuss the coordination geometry of the metal ion, the binding of the pyrazolylborate ligand to the potassium ion is neatly defined. Unlike in K**L**$^1$, it coordinates in the established tripodal fashion. In addition, two of its three carboxamide substituents use their oxygen atoms for coordination to two different neighboring potassium ions, thereby making **L**$^4$ a pentadentate ligand.

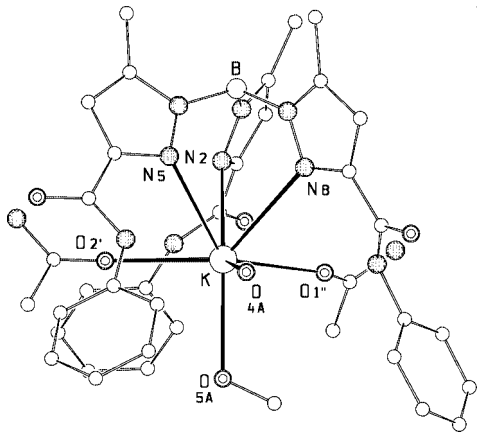


Figure 2. Coordination of the potassium ions in K**L**$^4$. Bond lengths [Å]: K–N2 2.802(2), K–N5 3.122(2), K–N8 3.040(2), K–O1′′ 2.860(2), K–O2′ 2.822(2), K–O4a 2.707(3), K–O5a 2.762(4).

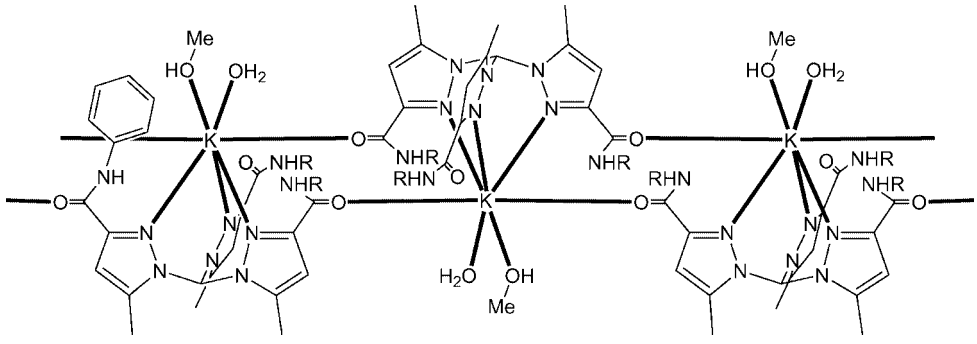
Like in K**L**$^1$, the linking of neighboring complex units in K**L**$^4$ occurs in a pairwise manner, resulting in a chain-like array, as shown in Scheme 3. Unlike in K**L**$^1$, there are no further links to create a 3D network, as the third carbonyl oxygen atom of each **L**$^1$ unit remains uncoordinated.

### Zinc Complexes of L$^1$

The coordinative properties of the new pyridyl-substituted Tp ligands were explored by preparing some zinc complexes of **L**$^1$. Thus, the halide complexes **1a**–**1c** resulted from the reaction of K**L**$^1$ and the corresponding zinc halides. Their $^1$H-NMR spectra in DMSO solution show split resonances for the pyrazolyl as well as the pyridyl protons, with intensity ratios between 2:1 and 5:1, and their ν(BH) IR bands in KBr are also split. This indicates different coordination modes for the "arms" of the **L**$^1$ tripod, and possibly different coordination modes for different tripods, the simplest explanation for which is oligomerization, which was found in almost all the crystal structures reported in this paper. **1a**–**1c** did not yield suitable crystals for analysis, and therefore could not be used to verify this hypothesis.



Scheme 3.

$\mathbf{L^1}$Zn-Cl **1a** $\mathbf{L^1}$Zn-Br **1b** $\mathbf{L^1}$Zn-I **1c**

The reactions between K$\mathbf{L^1}$ and zinc acetate or zinc nitrate led to complexes **1d** and **1e**. While the $^1$H-NMR spectrum of **1d** is simple, indicating the monomeric nature of the complex, the spectrum of **1e** shows split resonances, just like those seen in the spectra of complexes **1b** and **1c**, with intensity ratios of 5:1, pointing to an as yet unidentified oligomeric state being present in solution.

$\mathbf{L^1}$Zn-OCOCH$_3$ **1d** $\mathbf{L^1}$Zn-ONO$_2$ **1e**

The solid-state nature of both **1d** and **1e** could be determined by X-ray methods. Complex **1d** is a monomer containing a semi-bidentate acetate ligand, see Figure 3. Its zinc coordination sphere offers no unusual features compared to the many (pyrazolylborate)zinc carboxylate structures in the Cambridge Structural Database. However, this makes **1d** an exception among the zinc complexes of $\mathbf{L^1}$.

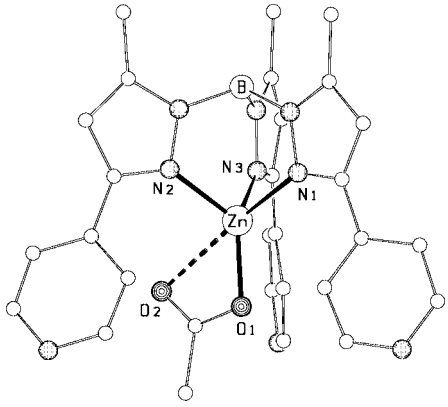

Figure 3. Molecular structure of **1d**. Bond lengths [Å]: Zn–N1 2.108(3), Zn(N2) 2.018(3), Zn–N3 2.018(3), Zn–O1 1.919(3), Zn–O2 2.534(3).

The nitrate complex **1e** is a 1D coordination polymer. Figure 4 shows the coordination sphere for one of the zinc ions in this polymer. Ligand $\mathbf{L^1}$ is nicely tripodal and the nitrate is symmetrically bound in a bidentate manner. One of the pyridyl nitrogen atoms coordinates to a neighboring zinc ion. This results in an octahedral coordination environment for the zinc ion, albeit a quite distorted one. The polymer chains comprise a zig-zag array of $\mathbf{L^1}$ZnONO$_2$ units linked by the pyridyl substituents.

The *p*-nitrophenolate complex **1f** and the bis(*p*-nitrophenyl)phosphate complex **1g** were prepared. It was thought that they would result from the hydrolytic cleavages of *p*-nitrophenyl acetate and tris(*p*-nitrophenyl)phosphate, reactions which were to be performed in subsequent studies with suitable $\mathbf{L^1}$ZnX compounds. For their unambiguous identification they were prepared from K$\mathbf{L^1}$, zinc perchlorate, and *p*-nitrophenolate and bis(*p*-nitrophenyl)phosphate, respectively.

The syntheses of **1f** and **1g** did not yield crystals suitable for structure determinations, and **1g** could not be obtained in an analytically pure form. Their $^1$H-NMR spectra show

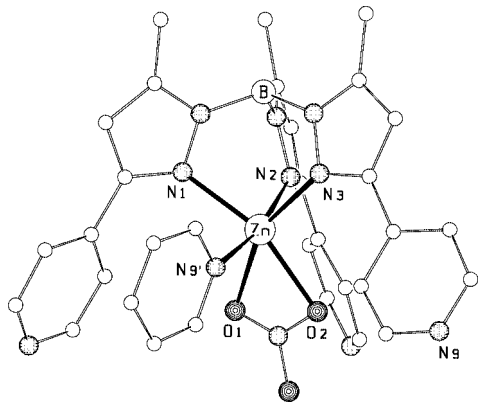

Figure 4. Monomeric fragment of polymeric **1e**. Bond lengths [Å]: Zn–N1 2.126(3), Zn–N2 2.263(3), Zn–N3 2.102(3), Zn–O1 2.189(3), Zn–O2 2.200(3), Zn-N9′ 2.250(3).

$\mathbf{L^1}$Zn-ONit **1f** $\mathbf{L^1}$Zn-OPO(ONit)$_2$ **1g**

no splitting of the pyrazolyl or pyridyl resonances, thereby indicating a monomeric structure. This was also the case for the corresponding zinc complexes with the 3-pyridyl-substituted Tp ligands. Of these, the nitrophenolate is a pyridyl-bridged dimer,[23] while the phosphate is a hydrated monomer with five-coordinate zinc ions.[24] The structures of **1f** and **1g** may be similar to either of these. Complex **1f** is precipitated with one water molecule per formula unit.

Finally, an attempt was made to obtain a zinc perchlorate complex of $\mathbf{L^1}$. To achieve this purpose, K$\mathbf{L^1}$ was treated with $Zn(ClO_4)_2$ in a dichloromethane/methanol solution. However, it became apparent that methanol is a better ligand for zinc than perchlorate, and the methanol complex **1h** was obtained. In the case of the related sulfur-containing tripod ligands, there is precedence for the preferred coordination of alcohol and perchlorate ligands.[25,26]

[$\mathbf{L^1}$Zn(CH$_3$OH)] ClO$_4$ **1h**

The $^1$H-NMR spectrum of **1h**, just like the spectra for several other complexes of **1**, displays a splitting of the pyrazolyl and pyridyl resonances with intensity ratios of 1:5,

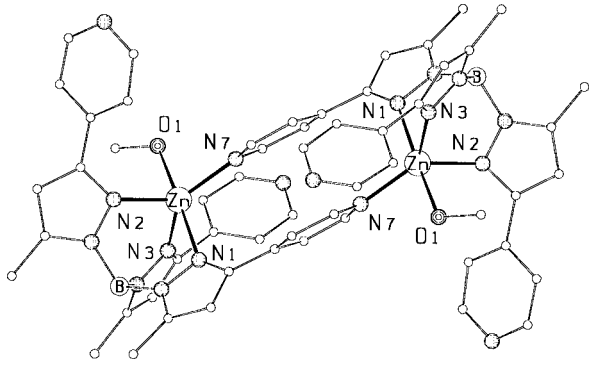

Figure 5. Structure of the dimeric cations of **1h**. Bond lengths [Å]: Zn–N1 2.210(2), Zn–N2 2.047(2), Zn–N3 2.047(2), Zn–O1 2.185(2), Zn–N7′ 2.034(2).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

indicating the presence in solution of a complex with an unknown mode of oligomerization. In the solid state **1h** is dimeric, with the two complex units being held together by a pair of bridging pyridine rings that lie across a center of symmetry, see Figure 5. This type of coordination with trigonal-bipyramidal zinc ions has precedence in the zinc complexes of the 3-pyridyl-substituted Tp ligands.[6] The methanol ligand in **1h** is positioned on the axis of the trigonal bipyramid. It is linked by a hydrogen bond to a pyridyl nitrogen atom of a neighboring complex unit, such that a pairwise linkage across a center of symmetry exists. In this way a zig-zag array of complex units is seen in the solid state, that are bridged by pairs of pyridine donors and hydrogen bonds in an alternating fashion.

### Zinc Complexes of $L^3$ and $L^4$

As mentioned above, ligand $\mathbf{L^3}$ had to be converted into a zinc halide complex in order to have a clean starting material for the synthesis of the $\mathbf{L^3}$Zn complexes. This was done by treating the crude reaction product, K$\mathbf{L^3}$, with zinc chloride and bromide, leading to **2a** and **2b**. Likewise, K$\mathbf{L^4}$ was easily converted with zinc chloride to yield **3a**. All three halide complexes show a rather low solubility, even in dichloromethane and methanol. This points to an oligomeric nature, but their $^1$H-NMR spectra are simple, and thus yield no further information.

$\mathbf{L^3}$Zn-Cl **2a** $\mathbf{L^3}$Zn-Br **2b** $\mathbf{L^4}$Zn-Cl **3a**

The zinc nitrate complex of $\mathbf{L^3}$, **2c**, was prepared from **2b** and silver nitrate. The treatment of **2c** with potassium acetate yielded **2d**. The two corresponding complexes of $\mathbf{L^4}$, **3b** and **3c**, were synthesized in a more direct fashion from K$\mathbf{L^4}$ and the zinc salts. All four of these complexes are noticeably more soluble than the halide complexes, indicating a monomeric or dimeric nature, as observed for **1d** and **1h**. Only in case of **3c** did the $^1$H-NMR spectrum yield structural information, as it showed split signals for the methyl groups of the pyrazole with a 2:1 intensity ratio. The simplest explanation for this is that dimerization has occurred with a pair of bridging carboxamide substituents. However, this must remain a speculative structural assignment until the structural chemistry of the zinc complexes of $\mathbf{L^3}$ and $\mathbf{L^4}$ can be based on a sufficient number of X-ray structure determinations.

$\mathbf{L^3}$Zn-$ONO_2$ **2c** $\mathbf{L^3}$Zn-$OCOCH_3$ **2d**
$\mathbf{L^4}$Zn-$ONO_2$ **3b** $\mathbf{L^4}$Zn-$OCOCH_3$ **3c**

As noted above, the *p*-nitrophenolate complex **2e** and the *p*-nitrothiophenolate complex **2f** were prepared in order to have reference materials for their identification in product mixtures during subsequent studies of zinc-catalyzed hydrolytic ester cleavage reactions. Compounds **2e** and **2f** resulted from the reaction between **2b**, KOH, and the corresponding phenols (as yellow powders). Complex **2e** was not obtained analytically pure. Again, little information could be gathered concerning their structures. They are more soluble in solvents of low polarity than the other complexes of $\mathbf{L^3}$ and $\mathbf{L^4}$, and hence may be monomeric.

$\mathbf{L^3}$Zn-ONit **2e** $\mathbf{L^3}$Zn-SNit **2f**

As for $\mathbf{L^1}$, a simple reaction of $\mathbf{L^3}$ aimed at preparing a perchlorate complex did not yield the desired product, but instead a solvated cationic zinc complex of $\mathbf{L^3}$ was produced. Treating the raw product K$\mathbf{L^3}$, which contains considerable amounts of 3-*tert*-butylcarboxamido-5-methylpyrazole (Pz*), with zinc perchlorate in dichloromethane/methanol produced a small amount of the pyrazole complex **2g**, which could be identified by its spectra.

[$\mathbf{L^3}$Zn(Pz*)] $ClO_4$ **2g**

Unlike the other complexes of $\mathbf{L^3}$ and $\mathbf{L^4}$, **2g** was produced as crystals suitable for X-ray structure determination. The result is displayed in Figure 6. Complex **2g** is mononuclear. Ligand $\mathbf{L^3}$ is coordinated to the zinc ion in the normal tripodal fashion, with the notable detail that all three carboxamide oxygen atoms are pointing towards the zinc ion. The pyrazole coligand is bidentate and produces a five-membered O,N chelate ring. Thereby **2g** resembles the large number of TpZn chelate complexes which are frequently discussed as models for enzyme-inhibitor complexes.[27,28] The coordination of the zinc ion can be described as reasonably close to trigonal-bipyramidal, with N8 and O4 on the axis forming the long Zn–X bonds. Additional rigidity in the structure comes from a hydrogen bond between the NH group of the pyrazole coligand and one carboxamide oxygen atom. Thus, the structure of **2g** has yielded two valuable pieces of information with respect to the subsequent use of ligands like $\mathbf{L^3}$ and $\mathbf{L^4}$ for modeling zinc enzymes: firstly, these ligands can form mononuclear zinc complexes and secondly, the carboxamide functional groups can show polar interactions and hydrogen bonding at, or near, the zinc center.

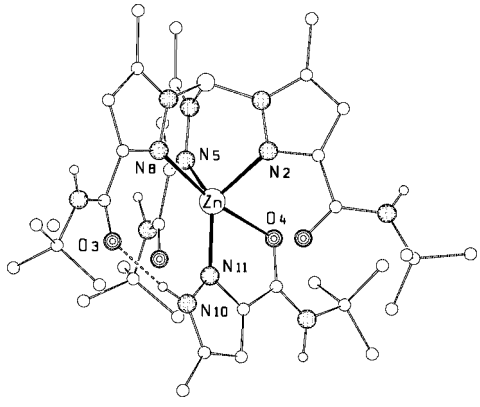

Figure 6. Molecular structure of complex **2g**. Bond lengths [Å]: Zn–N2 2.036(5), Zn–N5 2.036(5), Zn–N8 2.269(5), Zn–N11 1.979(5), Zn–O4 2.312(4), N10···O3 2.602(6).

## Conclusions

The four new pyrazolylborate ligands described in this paper have been found to have conventional properties (i.e. they coordinate to the zinc ion in the tripodal fashion) as well as novel features that qualify them for a biomimetic zinc complex chemistry (i.e. they contain further donor functional groups, they allow for variable metal coordination numbers, they engage in various kinds of hydrogen bonds, and they form complexes which are soluble in water-containing solvents or even in pure water). Just like the previously described Tp ligands with 3-pyridyl substituents they allow, or more accurately they enforce, coordination numbers higher than four for zinc. The well-established term "tetrahedral enforcer", which qualifies many Tp ligands, does not hold for **L**$^{1}$–**L**$^{4}$.

Variability in coordination numbers and geometries, as seen for the zinc complexes described herein, is a prerequisite for catalytic activity. This, together with the increased solubility in water-containing solvents, indicates that zinc complexes of **L**$^{1}$–**L**$^{4}$ with coordinated water or hydroxide, or with labile coligands X, should qualify as new, or better, models for, hydrolytic zinc enzymes. In this context, the carboxamide-substituted ligands **L**$^{3}$ and **L**$^{4}$ deserve special attention. Their CO–NH functionality mimics the peptide environment of the zinc ion in an enzyme in terms of its hydrogen-bonding ability, as well as in its polarity and donor quality. We therefore believe that the carboxamide-substituted pyrazolylborates should lead to significant advancements in enzyme modeling with zinc complexes, and once again Swiatoslaw Trofimenko has to be praised for being the first person to prepare such ligands.

## Experimental Section

**General:** For general working and measuring procedures see ref.[29] Zinc salts and organic starting materials were obtained commercially.

**Pyrazoles:** The synthesis of the two pyrazoles needed for the synthesis of **L**$^{1}$ and **L**$^{2}$ started with the Claisen condensation of acetone with ethyl isonicotinate (commercially available) and ethyl 2-methylisonicotinate[15] to yield the corresponding diketones.[16] Their reaction with hydrazine hydrate, as previously described,[17,18] resulted in 5-methyl-3-(4′-pyridyl)pyrazole and 5-methyl-3-[4′-(6′-methyl)pyridyl]pyrazole in good yields. The two pyrazoles needed for the synthesis of **L**$^{3}$ and **L**$^{4}$ were obtained from the same intermediate, 2,7-dimethyldipyrazolo[1,5-*a*;1′,5′-*a*′]pyrazine-4,9-dione, which was synthesized according to literature procedures.[13,19–22] Treatment of this with *tert*-butylamine or aniline in refluxing toluene, as previously described,[13,22] resulted in 3-(*tert*-butylcarboxamido)-5-methylpyrazole and 3-(phenylcarboxamido)-5-methylpyrazole, respectively, in very good yields.

### Tripod Ligands

**KL**$^{1}$**:** A mixture of 6.28 g (39.44 mmol) of 5-methyl-3-(4′-pyridyl)-pyrazole and 532 mg (9.86 mmol) of $KBH_4$ was stirred in a three-necked 100-mL flask equipped with an immersing thermometer. The temperature was slowly increased to 200 °C over a period of 30 min. At 140–160 °C, the mixture melted and the gas evolution became brisk. The melt was stirred continuously at 200 °C until it started to turn brown (ca. 3 h) and then slowly cooled to room temperature. The resulting glassy residue was carefully powdered and refluxed in 100 mL of toluene for 30 min, in order to remove unreacted pyrazole impurities. The mixture was filtered while hot, and the light brown residue was washed 3 times with 5 mL of boiling toluene and once with 5 mL of petroleum ether (30–50 °C). Recrystallization from 50 mL of acetonitrile at –20 °C yielded 2.59 g (50%) of K**L**$^{1}$ as colorless crystals, m.p. 328 °C. $C_{27}H_{25}BKN_9$ (525.46): calcd. C 61.72, H 4.80, N 23.99; found C 61.23, H 4.85, N 23.87. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 2.02 [s, 9 H, Me(pz)], 6.44 [s, 3 H, H(pz)], 7.58 (dd, $J$ = 4.5 and 1.5 Hz, 6 H, Py), 8.42 (dd, $J$ = 4.5 and 1.5 Hz, 6 H, Py) ppm. IR (KBr): $\tilde{\nu}$ = 2446 m (BH), 1605 vs (Py) cm$^{-1}$.

**KL**$^{2}$**:** 5-Methyl-3-[4′-(6′-methyl)pyridyl]pyrazole (2.66 g, 15.35 mmol), and 207 mg (3.84 mmol) of $KBH_4$ were mixed by stirring in a three-necked 50-mL flask equipped with an immersing thermometer. The temperature was slowly increased to 200 °C over a period of 30 min. The melt was continuously stirred at 200 °C until it started to turn brown (ca. 3 h) and then slowly cooled to room temperature. The resulting glassy residue was carefully powdered and refluxed in 50 mL of toluene for 30 min, in order to remove unreacted pyrazole impurities. The mixture was filtered while hot, and the light brown residue was washed 3 times with 5 mL of boiling toluene and once with 5 mL of petroleum ether (30–50 °C). Recrystallization from 50 mL of undried acetonitrile at –20 °C yielded 871 mg (40%) of K**L**$^{2}$ as colorless crystals, m.p. 319 °C (dec.). $C_{30}H_{31}BKN_9{\cdot}H_2O$ (567.54 + 18.02): calcd. C 61.54, H 5.68, N 21.53; found C 61.05, H 5.76, N 21.33. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 1.99 [s, 9 H, Me(pz)], 2.41 [s, 9 H, Me(py)], 6.41 [s, 3 H, H(pz)], 7.38 (d, $J$ = 5.1 Hz, 3 H, Py), 7.45 (s, 3 H, Py), 8.28 (d, $J$ = 5.1 Hz, 3 H, Py) ppm. IR (KBr): $\tilde{\nu}$ = 2486 m (BH), 1612 vs (Py) cm$^{-1}$.

**KL**$^{3}$**:** 3-(*tert*-butylcarboxamido)-5-methylpyrazole (3.03 g, 16.65 mmol), and 0.28 g (5.08 mmol) of $KBH_4$ were mixed by stirring in a 100-mL three-necked flask equipped with an immersing thermometer, and slowly heated until melting, which occurred at 130 °C. The temperature was raised to 160 °C over a period of 2 h, after which time the gas evolution ceased. After cooling, the solid residue was carefully powdered and stirred in chloroform overnight. Then the suspension was filtered and the filtrate concentrated to dryness, leaving behind 2.34 g of a colorless mixture of K**L**$^{3}$ and the unreacted pyrazole. According to NMR analysis, the mixture contained 1.78 g (59%) of K**L**$^{3}$. Attempts at further purification resulted in increasing the amount of impurities present. $^1$H NMR of K**L**$^{3}$ ($CD_3OD$): $\delta$ = 1.38 (s, 27 H, *t*Bu), 2.05 [s, 9 H, Me(pz)], 6.39 [s, 3 H, H(pz)] ppm. IR of K**L**$^{3}$ (KBr): $\tilde{\nu}$ = 3396 m (NH), 2444 m (BH), 1652 vs (CO) cm$^{-1}$.

**KL**$^{4}$**:** A mixture of 3.29 g (16.35 mmol) of 3-methyl-5-(phenylcarboxyamido)pyrazole and 221 mg (4.09 mmol) of $KBH_4$ was stirred in a three-necked 50-mL flask equipped with an immersing thermometer. The temperature was slowly increased to 150 °C over a period of 30 min, at which point the mixture melted. The melt was continuously stirred at 150 °C until no more hydrogen was evolved (ca. 2 h), and then heated to 160 °C over a period of 30 min. It was then cooled to room temperature. The resulting glassy residue was carefully powdered and refluxed in 30 mL of acetonitrile for 30 min in order to remove unreacted pyrazole impurities. The mixture was filtered while hot, and the residue was washed 3 times with 5 mL of boiling acetonitrile and once with 2 mL of water. Recrystallization from 40 mL of methanol/dichloromethane (1:2) at –20 °C yielded 300 mg (11%) of K**L**$^{4}$ as large crystals, m.p. 250 °C. $C_{33}H_{31}BKN_9O_3{\cdot}H_2O$ (651.58 + 18.02): calcd. C 59.19, H 4.97, N 18.83; found C 59.43, H 5.14, N 18.44. $^1$H NMR ([D$_6$]DMSO): $\delta$

= 2.01 [s, 9 H, Me(pz)], 6.46 [s, 3 H, H(pz)], 7.01 (m, 3 H, Ph), 7.27 (m, 6 H, Ph), 7.64 (d, $J$ = 7.6 Hz, 6 H, Ph), 9.25 (s, 3 H, NH) ppm. IR (KBr): $\tilde{\nu}$ = 3365 s (NH), 2470 m (BH), 1653 vs. (CO) $cm^{-1}$.

**Zinc Complexes of $L^1$**

**1a:** A solution of 46 mg (0.33 mmol) of $ZnCl_2$ in 5 mL of methanol was added dropwise to a solution of 160 mg (0.30 mmol) of $KL^1$ in 20 mL of methanol/dichloromethane (1:1) over a period of 5 min. After 6 h of stirring, a small amount of a cloudy precipitate was removed by filtration, and the clear filtrate was slowly concentrated at room temperature to yield, after 2 d, 116 mg (65%) of **1a** as colorless needles, m.p. 238 °C. $C_{27}H_{25}BClN_9Zn{\cdot}1.5H_2O$ (587.21 + 27.02): calcd. C 52.80, H 4.59, N 20.52; found C 52.63, H 4.48, N 20.66. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 2.02 [s, 6 H, Me(pz)], 2.54 [s, 3 H, Me(pz)], 6.44 [s, 2 H, H(pz)], 6.65 [s, 1 H, H(pz)], 7.58 (d, $J$ = 6.0 Hz, 4 H, Py), 7.70 (d, $J$ = 5.5 Hz, 2 H, Py), 8.41 (d, $J$ = 6.0 Hz, 4 H, Py), 8.59 (d, $J$ = 6.0 Hz, 2 H, Py) ppm. IR (KBr): $\tilde{\nu}$ = 2553 and 2496 w (BH), 1619 s (Py) $cm^{-1}$.

**1b:** A solution of 150 mg (0.67 mmol) of $ZnBr_2$ in 10 mL of methanol/dichloromethane (1:1) was added dropwise to a stirred solution of 318 mg (0.61 mmol) of $KL^1$ in 20 mL of methanol/dichloromethane (1:1) over a period of 30 min. A white solid precipitated immediately, but the mixture was allowed to react for 6 h. Then the solvent was removed in vacuo and the residue was dissolved in chloroform/methanol (90:10) under reflux. After storage at 5 °C for 2 d, a precipitate of **1b**, 298 mg (78%), as colorless needles formed, m.p. 252 °C. $C_{27}H_{25}BBrN_9Zn$ (631.66): calcd. C 51.34, H 3.99, N 19.96; found C 50.77, H 4.11, N 19.53. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 2.07 [s, 1.5 H, Me(pz)], 2.53 [s, 7.5 H, Me(pz)], 6.46 [s, 0.5 H, H(pz)], 6.63 [s, 2.5 H, H(pz)], 7.61 (m, 6 H, Py), 8.42 (d, $J$ = 5.3 Hz, 1 H, Py), 8.62 (d, $J$ = 4.9 Hz, 5 H, Py) ppm. IR (KBr): $\tilde{\nu}$ = 2557 and 2499 w (BH), 1621 vs (Py) $cm^{-1}$.

**1c:** The preparation of **1c** was analogous to that of **1b**, but with $ZnI_2$ (127 mg, 0.40 mmol) in place of $ZnBr_2$. Recrystallization from chloroform/methanol (90:10) at 5 °C yielded 184 mg (75%) of **1c** as colorless needles, m.p. 226 °C. $C_{27}H_{25}BIN_9Zn$ (678.66): calcd. C 47.78, H 3.71, N 18.57; found C 47.09, H 3.83, N 19.00. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 2.00 [s, 1.5 H, Me(pz)], 2.54 [s, 7.5 H, Me(pz)], 6.46 [s, 0.5 H, H(pz)], 6.63 [s, 2.5 H, H(pz)], 7.56 (m, 6 H, Py), 8.41 (d, $J$ = 6.0 Hz, 1 H, Py), 8.72 (dd, J = 4.6 Hz and 1.4 Hz, 5 H, Py) ppm. IR (KBr): $\tilde{\nu}$ = 2557 and 2491 w (BH), 1617 s (Py) $cm^{-1}$.

**1d:** A solution of 174 mg (0.79 mmol) of $Zn(OAc)_2{\cdot}2H_2O$ in 5 mL of methanol was added dropwise to a solution of 379 mg (0.72 mmol) of $KL^1$ in 20 mL of methanol/dichloromethane (1:1) over a period of 5 min. After 6 h of stirring, a small amount of a cloudy precipitate was removed by filtration, and the clear filtrate was concentrated to dryness in vacuo. Recrystallization from 15 mL of methanol at 5 °C yielded 401 mg (91%) of **1d** as large colorless crystals, m.p. 242 °C. $C_{29}H_{28}BN_9O_2Zn$ (610.80): calcd. C 57.03, H 4.62, N 20.64; found C 56.49, H 4.82, N 20.42. $^1$H NMR ([D$_6$]-DMSO): $\delta$ = 1.51 (s, 3 H, Ac), 2.56 [s, 9 H, Me(pz)], 6.64 [s, 3 H, H(pz)], 7.60 (dd, J = 4.6 and 1.4 Hz, 6 H, Py), 8.60 (d, $J$ = 6.0 Hz, 6 H, Py) ppm. IR(KBr): $\tilde{\nu}$ = 2558 m (BH), 1608 vs (Py) $cm^{-1}$.

**1e:** A solution of 146 mg (0.49 mmol) of $Zn(NO_3)_2{\cdot}6H_2O$ in 5 mL of methanol was added dropwise to a solution of 234 mg (0.45 mmol) of $KL^1$ in 20 mL of methanol over a period of 5 min. A white solid precipitated immediately, but the mixture was stirred for 6 h. Then the solvent was removed in vacuo and the residue was dissolved in chloroform/methanol (90:10) under reflux. After storage at 5 °C for 5 d, a precipitate of **1e**, 188 mg (69%), as colorless crystals formed, m.p. 210 °C (dec.). $C_{27}H_{25}BN_{10}O_3Zn{\cdot}H_2O$ (613.76 + 18.02): calcd. C 51.33, H 4.31, N 22.17; found C 51.47, H 4.01, N 22.05. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 2.01 [s, 1.5 H, Me(pz)], 2.55 [s, 7.5 H, Me(pz)], 6.45 [s, 0.5 H, H(pz)], 6.62 [s, 2.5 H, H(pz)], 7.56 (m, 6 H, Py), 8.41 (d, $J$ = 5.7 Hz, 1 H, Py), 8.72 (d, $J$ = 5.9 Hz, 5 H, Py). IR(KBr): $\tilde{\nu}$ = 2550 m (BH), 1613 s (Py) cm.

**1f:** To a stirred mixture of 266 mg (0.50 mmol) of $KL^1$ and 207 mg (0.55 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$ in 30 mL of methanol/dichloromethane/water (1:1:0.5) at 0 °C was added a solution of 42 mg (0.75 mmol) of KOH in methanol/dichloromethane (1:1). After 1 h of stirring at 0 °C, a solution of 68 mg (0.49 mmol) of *p*-nitrophenol in 5 mL of methanol was added. After 6 h of stirring and subsequent filtration, all volatiles were removed in vacuo, and the residue was recrystallized from 15 mL of methanol/dichloromethane (1:2) at –20 °C, yielding 314 mg (93%) of **1f** as a light yellow powder, m.p. 254 °C (dec.). $C_{33}H_{29}BN_{10}O_3Zn{\cdot}H_2O$ (689.86 + 18.02): calcd. C 55.99, H 4.41, N 19.79; found C 56.15, H 4.42, N 19.74. $^1$H NMR ($CDCl_3$): $\delta$ = 1.66 (br. s, 2 H, $H_2O$), 2.62 [s, 9 H, Me(pz)], 5.88 (d, $J$ = 9.1 Hz, 2 H, Ph), 6.43 [s, 3 H, H(pz)], 7.51 (m, 8 H, Py, Ph), 8.41 (dd, J = 4.5 and 1.4 Hz, 6 H, Py) ppm. IR (KBr): $\tilde{\nu}$ = 2559 w (BH), 1607 s (Py), 1584 s and 1304 vs (NO) $cm^{-1}$.

**1g:** The method for the preparation of **1g** is like the synthetic procedure for **1f**. The reaction mixture contained 266 mg (0.50 mmol) of $KL^1$, 207 mg (0.55 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$, 42 mg (0.75 mmol) of KOH, and 183 mg (0.54 mmol) of bis(*p*-nitrophenyl)phosphoric acid in 35 mL of methanol/dichloromethane (2:1) at 0 °C. After 2 h of stirring and subsequent filtration, all volatiles were removed in vacuo and the raw product was suspended in 5 mL of chloroform. The suspension was filtered again and the filtrate concentrated to dryness, leaving behind 134 mg (31%) of impure **1g** as a light yellow powder, m.p. 231 °C. Attempts at purification by recrystallization were unsuccessful. $^1$H NMR ($CDCl_3$): $\delta$ = 2.60 [s, 9 H, Me(pz)], 6.40 [s, 3 H, H(pz)], 6.85 (d, $J$ = 8.9 Hz, 4 H, Ph), 7.52 (d, $J$ = 5.9 Hz, 6 H, Py), 7.98 (d, $J$ = 9.1 Hz, 4 H, Ph), 8.61 (d, $J$ = 5.7 Hz, 6 H, Py) ppm. IR (KBr): $\tilde{\nu}$ = 2566 w (BH), 1621 s (Py), 1591 s and 1346 vs (NO) $cm^{-1}$.

**1h:** Compound $KL^1$, 210 mg (0.40 mmol), was dissolved in 30 mL of methanol/dichloromethane (1:1), and a solution of 163 mg (0.44 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$ in 5 mL methanol was added dropwise over a period of 10 min. A slurry of $KClO_4$ precipitated immediately. This was filtered off and the clear filtrate was stirred for 6 h. After this time, a large amount of colorless solid had precipitated. This precipitate was filtered off and dried in vacuo to yield 180 mg (66%) of **1h** as a colorless powder, m.p. 284 °C. The mother liquor was concentrated in vacuo to ca. 20 mL and kept at 5 °C overnight to yield 10 mg (4%) of **1h** as X-ray quality crystals. $C_{28}H_{29}BClN_9O_5Zn{\cdot}H_2O$ (683.25 + 18.02): calcd. C 47.96, H 4.46, N 17.98; found C 47.75, H 4.36, N 17.60. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 2.01 [s, 1.5 H, Me(pz)], 2.55 [s, 7.5 H, Me(pz)], 3.34 (s, 3 H, MeOH), 6.45 [s, 0.5 H, H(pz)], 6.62 [s, 2.5 H, H(pz)], 7.56 (m, 6 H, Py), 8.41 (d, $J$ = 5.9 Hz, 1 H, Py), 8.73 (d, $J$ = 5.9 Hz, 5 H, Py) ppm. IR (KBr): $\tilde{\nu}$ = 3572 m (OH), 3428 bs ($H_2O$), 2574 m (BH), 1623 s (Py), 1094 vs (ClO) $cm^{-1}$.

**Zinc Complexes of $L^3$ and $L^4$**

**2a:** To a stirred solution of 1.59 g of impure $KL^3$ (ca. 2.0 mmol of $KL^3$) in 10 mL of methanol was added dropwise a solution of 0.44 g (3.2 mmol) of $ZnCl_2$ in 3 mL of methanol. After 4 h of stirring, the volume was reduced to 3 mL in vacuo. The precipitate was filtered off and washed with 5 mL of water. After drying in vacuo, it was suspended in 4 mL of THF and 1 mL of methanol. The remaining precipitate was filtered off and dried in vacuo, yielding 430 mg (27%) of **2a** as a colorless powder, m.p. 278 °C. $C_{27}H_{48}BClN_9O_3Zn{\cdot}0.5H_2O$ (653.35 + 9.01): calcd. C 48.96, H 6.70, N 19.03; found C 48.80, H

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

6.74, N 18.86. $^1$H NMR ($CD_3OD$): $\delta$ = 1.48 (s, 27 H, *t*Bu), 2.46 [s, 9 H, Me(pz)], 6.54 [s, 3 H, H(pz)] ppm. IR (KBr): $\tilde{\nu}$ = 3398 m (NH), 2505 w (BH), 1648 vs and 1605 vs (CO) cm$^{-1}$.

**2b:** The method of synthesis for **2b** is like the procedure for the preparation of **2a**. From 1.97 g (ca. 2.5 mmol) of **KL$^3$** and 0.90 g (4.03 mmol) of $ZnBr_2$, 650 mg (38%) of **2b** was obtained as a colorless powder, m.p. 260 °C. $C_{27}H_{48}BBrN_{10}O_6Zn{\cdot}1.5H_2O$ (679.80 + 27.03): calcd. C 44.74, H 6.40, N 17.39; found C 44.94, H 6.22, N 17.39. $^1$H NMR ($CD_3OD$): $\delta$ = 1.48 (s, 27 H, *t*Bu), 2.46 [s, 9 H, Me(pz)], 6.55 [s, 3 H, H(pz)] ppm. IR(KBr): $\tilde{\nu}$ = 3397 w (NH), 2500 w (BH), 1650 vs and 1605 vs (CO) cm$^{-1}$.

**3a:** A solution of 22 mg (0.16 mmol) of $ZnCl_2$ in 2 mL of methanol was added dropwise to a solution of 96 mg (0.15 mmol) of **KL$^4$** in 10 mL of methanol/dichloromethane (1:1). After 3 h of stirring, a small amount of cloudy precipitate was removed by filtration, and the clear filtrate was slowly concentrated at room temperature to yield after 1 d 91 mg (87%) of **3a** as colorless needles, m.p. 216 °C. $C_{33}H_{31}BClN_9O_3Zn{\cdot}H_2O$ (713.32 + 18.02): calcd. C 54.20, H 4.55, N 17.05; found C 53.74, H 4.66, N 17.05. $^1$H NMR ($CDCl_3$): $\delta$ = 1.57 (br. s, 2 H, $H_2O$), 2.53 [s, 9 H, Me(pz)], 6.80 [s, 3 H, H(pz)], 7.14 [m, 3 H, Ph], 7.33 (m, 6 H, Ph), 7.74 (d, *J* = 7.8 Hz, 6 H, Ph), 8.89 (s, 3 H, NH) ppm. IR (KBr): $\tilde{\nu}$ = 3315 s (NH), 2511 w (BH), 1648 vs and 1598 vs (CO) cm$^{-1}$.

**2c:** A solution of 30 mg (0.19 mmol) of $AgNO_3$ in 2 mL of methanol was slowly added dropwise to a stirred solution of 0.13 g (0.19 mmol) of **2b** in 15 mL of methanol at 0 °C. After 30 min, the precipitate was filtered off and the filtrate concentrated to dryness, leaving behind 100 mg (77%) of **2c** as a colorless hygroscopic powder, m.p. 190 °C (dec.). $C_{27}H_{48}BN_9O_3Zn{\cdot}2H_2O$ (679.90 + 36.04): calcd. C 45.30, H 6.62, N 19.56; found C 45.34, H 6.68, N 19.08. $^1$H NMR ($CD_3OD$): $\delta$ = 1.48 (s, 27 H, *t*Bu), 2.46 [s, 9 H, Me(pz)], 6.55 [s, 3 H, H(pz)] ppm. IR (KBr): $\tilde{\nu}$ = 3294 m (NH), 2557 w (BH), 1642 s and 1608 s (CO) cm$^{-1}$.

**2d:** A solution of 8 mg (0.08 mmol) of KOAc in 1 mL of methanol was added dropwise to a stirred solution of 50 mg (0.07 mmol) of **2c** in 4 mL of dichloromethane. After 2 h of stirring, the precipitate was filtered off and the filtrate concentrated to dryness. The residue was washed with 1 mL of water and dried in vacuo, leaving behind 35 mg (74%) of **2d** as a colorless powder, m.p. 188 °C. $C_{29}H_{46}BN_9O_5Zn{\cdot}2H_2O$ (676.94 + 36.04): calcd. C 48.85, H 7.07, N 17.68; found C 48.96, H 7.12, N 17.40. $^1$H NMR ($CD_3OD$): $\delta$ = 1.47 (s, 27 H, *t*Bu), 1.90 (s, 3 H, OAc), 2.46 [s, 9 H, Me(pz)], 6.54 [s, 3 H, H(pz)] ppm. IR (KBr): $\tilde{\nu}$ = 3293 w (NH), 2559 w (BH), 1648 vs and 1605 s (CO) cm$^{-1}$.

**3b:** A solution of 50 mg (0.17 mmol) of $Zn(NO_3)_2{\cdot}6H_2O$ in 5 mL of methanol was added dropwise to a solution of 100 mg (0.15 mmol) of **KL$^4$** in 10 mL of methanol. After 3 h of stirring, a small amount of cloudy precipitate was removed by filtration, and the clear filtrate was concentrated to dryness in vacuo. Recrystallization from 10 mL of methanol/dichloromethane (1:1) at 5 °C yielded 87 mg (77%) of **3b** as a white powder, m.p. 190 °C. $C_{33}H_{31}BN_{10}O_6Zn$ (739.87): calcd. C 53.57, H 4.22, N 18.93; found C 52.93, H 4.31, N 19.01. $^1$H NMR($CDCl_3$): $\delta$ = 2.39 [s, 9 H, Me(pz)], 6.54 [s, 3 H, H(pz)], 6.76 (m, 9 H, Ph), 7.03 (d, *J* = 8.2 Hz, 6 H, Ph), 9.80 (s, 3 H, NH) ppm. IR (KBr): $\tilde{\nu}$ = 3282 m (NH), 2566 w (BH), 1648 s and 1601 s (CO) cm$^{-1}$.

**3c:** A solution of 35 mg (0.16 mmol) of $Zn(OAc)_2{\cdot}2H_2O$ in 2 mL of methanol was added dropwise to a solution of 94 mg (0.14 mmol) of **KL$^4$** in 10 mL of methanol/dichloromethane (2:1). After 3 h of stirring, a small amount of cloudy precipitate was removed by filtration, and the clear filtrate was slowly concentrated at room temperature to yield after 1 d 93 mg (88%) of **3c** as colorless crystals, m.p. 216 °C. $C_{35}H_{34}BN_9O_5Zn$ (736.91): calcd. C 57.05, H 4.65, N 17.11; found C 56.29, H 4.75, N 16.84. $^1$H NMR ($CDCl_3$): $\delta$ = 1.75 (s, 3 H, OAc), 2.39 [s, 3 H, Me(pz)], 2.52 [s, 6 H, Me(pz)], 6.69 [m, 5 H, H(pz) + Ph], 7.08 (m, 6 H, Ph), 7.28 (m, 4 H, Ph), 7.67 (d, *J* = 7.6 Hz, 4 H, Ph), 8.95 (br. s, 1 H, NH) ppm. IR (KBr): $\tilde{\nu}$ = 3307 m (NH), 2573 w (BH), 1650 s and 1600 s (CO) cm$^{-1}$.

**2e:** A solution of 11 mg (0.15 mmol) of *p*-nitrophenol in 2 mL of methanol was deprotonated by the addition of a solution of 9 mg (0.16 mmol) of KOH in 1 mL of methanol. This intensive yellow solution was added to a solution of 0.11 g (0.15 mmol) of **2b** in 12 mL of methanol. After 3 h, the clear solution was concentrated under vacuum until the first turbidity appeared, at this time the solution had been reduced to 3 mL. Addition of 3 mL of dichloromethane caused a pale yellow precipitate to form. After filtration, the filtrate was concentrated to dryness. A yellow-brown powder (68 mg) remained, which consisted mainly of **2e**, but could not be purified by recrystallization. $^1$H NMR ($CDCl_3$): $\delta$ = 1.37 (s, 27 H, *t*Bu), 2.44 [s, 9 H, Me(pz)], 6.36 [s, 3 H, H(pz)], 6.55 (s, 1 H, NH), 6.65 (d, *J* = 9.0 Hz, 2 H, Ph), 7.96 (d, *J* = 9.0 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 3332 w (NH), 2559 w (BH), 1647 s and 1606 s (CO) cm$^{-1}$.

**2f:** The procedure for the preparation of **2f** is like the method for the synthesis of **2e**. From 20 mg (0.13 mmol) of *p*-nitrothiophenol, 8 mg (0.14 mmol) of KOH, and 0.09 g (0.13 mmol) of **2b**, 67 mg (67%) of **2f** resulted. Recrystallization from benzene/dichloromethane reduced this amount to 18 mg (18%) of pure **2f**, m.p. 234 °C. $C_{33}H_{47}BN_{10}O_5SZn$ (772.05): calcd. C 51.34, H 6.13, N 18.14; found C 51.08, H 6.20, N 17.90. $^1$H NMR ($CD_3OD$): $\delta$ = 1.35 (s, 27 H, *t*Bu), 2.44 [s, 9 H, Me(pz)], 6.50 [s, 3 H, H(pz)], 7.29 (d, *J* = 8.9 Hz, 2 H, Ph), 7.68 (d, *J* = 8.9 Hz, 2 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 3305 m (NH), 2482 w (BH), 1645 s and 1604 vs (CO) cm$^{-1}$.

**2g:** A solution of 1.89 g (5.08 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$ in 3 mL of methanol was added to a stirred solution of 2.57 g of raw **KL$^3$** contaminated with 3-(*tert*-butylcarboxamido)-5-methylpyrazole (ca. 2.7 mmol of **KL$^3$**) in 10 mL of dichloromethane. After 2 h of stirring, the precipitate was filtered off and the filtrate was concentrated to dryness. The residue was dissolved in 5 mL of dichloromethane/methanol (20:1) and the mixture subjected to slow concentration. After one week, 140 mg (6%) of **2g** had precipitated as colorless crystals, m.p. 250 °C. $C_{36}H_{58}BClN_{12}O_8Zn{\cdot}CH_3OH$ (898.57 + 32.04): calcd. C 47.75, H 6.71, N 18.06; found C 47.37, H 6.67, N 18.04. $^1$H NMR ($CD_3OD$): $\delta$ = 1.40 [s, 9 H, *t*Bu(Pz*)], 1.45 (s, 27 H, *t*Bu), 2.34 [s, 3 H, Me(Pz*)], 2.48 [s, 9 H, Me(pz)], 6.55 [s, 4 H, H(Pz*) and H(pz)] ppm. IR (KBr): $\tilde{\nu}$ = 3397 (m, NH), 3356 m (NH), 2561 w (BH), 1676 s and 1647 vs and 1557 vs (CO), 1076 vs (ClO) cm$^{-1}$.

**Structure Determinations:**[30] Crystals were obtained by the slow evaporation of solvents: acetonitrile for **KL$^1$**, dichloromethane/methanol for **KL$^2$** and **1h**, methanol for **1d**, chloroform/methanol for **1e** and anhydrous dichloromethane for **2g**. In those cases where the crystals contained solvent, care had to be taken to avoid solvent loss. Diffraction data were recorded at room temperature for **KL$^2$** and **2g**, and at –50 °C for **KL$^1$**, **1d**, **1e** and **1h** with a Bruker Smart CCD diffractometer. The datasets for **KL$^1$**, **KL$^2$**, **1h** and **2g** were subjected to an empirical absorption correction (SADABS).[31] The structures were solved with direct methods and refined anisotropically using the SHELX program suite.[31] Serious disorder problems concerning the cocrystallized solvent molecules hampered the refinements of **KL$^2$** and **1h**. In the case of **1h** we had to resort to using Spek's SQUEEZE program, which includes the total electron

# Multicomponent Supramolecular Devices: Synthesis, Optical, and Electronic Properties of Bridged Bis-dirhodium and -diruthenium Complexes

**Anne Petitjean,[a][‡] Fausto Puntoriero,[b] Sebastiano Campagna,*[b] Alberto Juris,[c] and Jean-Marie Lehn*[a]**

*Dedicated to Professor Vincenzo Balzani*

**Keywords:** N ligands / Electronic coupling / Electrochemistry / Metal–metal interactions / Optical properties

Four ruthenium- and rhodium-based metal–metal-bonded multicomponent systems have been synthesized, and their absorption, redox, spectroelectrochemical and structural properties have been studied. The absorption spectra of the four bis-dimetallic compounds $M_2LM_2$, where L is a bridging ligand and M is rhodium or ruthenium, exhibit very strong bands in the UV, visible and, for the diruthenium species, near-IR region. The low-energy absorption bands are assigned to charge-transfer transitions involving a metal–metal bonding orbital as the donor and an orbital centered on the bis-tetradentate aromatic ligands as the acceptor (metal–metal to ligand charge transfer, $M_2LCT$). Each compound exhibits reversible bridging-ligand-centered reductions at mild potentials and several reversible oxidation processes. The oxidation signals of the two equivalent dimetallic centers of each bis-dimetallic compound are split, with the splitting – a measure of the electronic coupling – depending on both the metal and bridging ligand. The mixed-valence species of the dirhodium species was investigated, and the electronic coupling matrix element calculated from the experimental intervalence band parameters for one of them (86 $cm^{-1}$) indicates a significant inter-component electronic interaction which compares well with good electron conducting anionic bridges such as cyanides. Although none of these compounds is luminescent, the $M_2LCT$ excited state of one of the bis-dirhodium complexes is relatively long-lived (about 6 μs) in degassed acetonitrile at room temperature. The results presented here are promising for the development of linear poly-dimetallic complexes built on longer naphthyridine-based strands, with significant long-range electronic coupling and molecular-wire-like behavior.

## Introduction

Since the discovery of mixed-valence complexes by Creutz and Taube[1] over 30 years ago, architectures including several redox centers of the same[2] or different[3] nature and capable of exhibiting inter-component electronic interaction have been the center of much attention. Due to their rich redox properties, transition metal ions connected by a bridging spacer have been the focus of much work in this field, although recent examples have also proved the tremendous potential of organic redox-active species connected through bridging transition metal complexes.[4] A variety of systems connecting mononuclear metal ions have been explored, where the spacer is itself a ligand[1,5] or where spacer and ligands are decoupled and involve single bonds[6] and multiple bonds (alkynyl for 1D,[7] 2D,[7b,7c] and 3D[7c] architectures; alkenyl,[5b] cumulenes,[7a,8] aryl[5b,7b,7d,9a,9b]). These systems may incorporate other inert[10a] or labile[7b,10b] complexes and have the electronic communication between the two sites modulated by pH,[11] light,[12a,12b] or auxiliary ligands.[13] The field has more recently been extended to metal–metal-bonded redox units because they themselves can include multiple bonds,[14] similar to carbon-based units but energetically more accessible, and may therefore play the role of a conductor. The dissymmetry around the metal sites allows for testing of the communication along the metal–metal bond through axial ligands and spacers similar to their mononuclear counter-

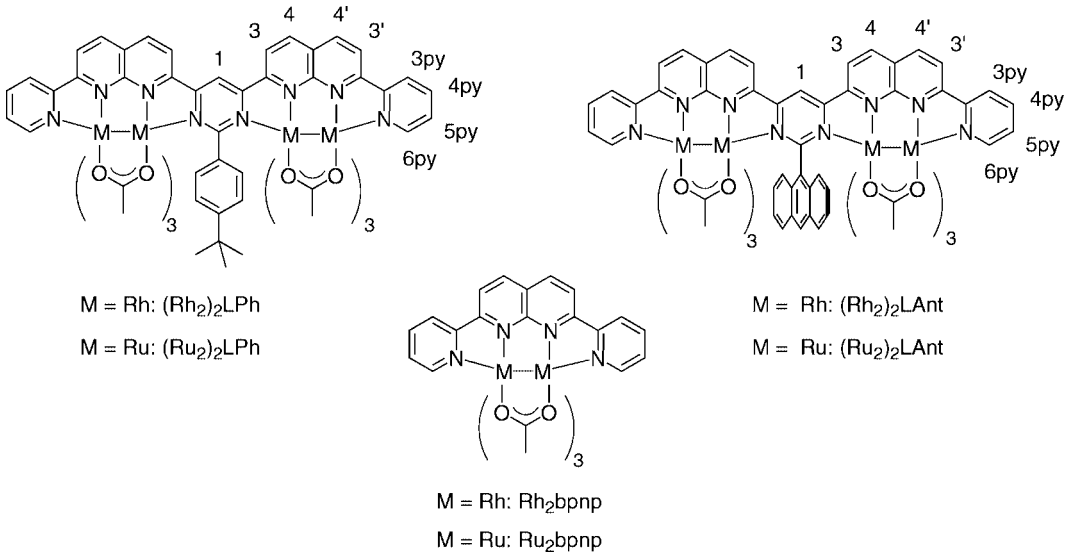

Figure 1. Formulae and abbreviation of the complexes. Numbering is related to the discussion of the $^1$H NMR spectroscopic data.

parts (e.g., triple bonds[15] and double bonds[16]), but also successfully along the equatorial direction.[17]

We report here the synthesis and characterization, absorption spectra, redox behavior, and spectroelectrochemistry of four bi-component systems in which each "component" or subunit is made of a metal–metal-bonded dimetallic site (Figure 1). The excited-state properties of one such species are also investigated. As we will see later, each dimetallic site can indeed be viewed as a single component of a "dinuclear" system from a redox viewpoint.

## Results and Discussion

### Synthesis

#### *Ligands*

The naphthyridine-based ligands 2-(4-*tert*-butylphenyl)-4,6-bis(7-pyridin-2-yl[1,8]naphthyridin-2-yl)pyrimidine (LPh) and 2-anthracen-9-yl-4,6-bis(7-pyridin-2-yl[1,8]naphthyridin-2-yl)pyrimidine (LAnt) were obtained by a Friedländer condensation methodology applied to a pyrimidine scaffold, in a very similar fashion as previously reported[18] (Schemes 1 and 2). Two synthetic routes were used to access the central pyrimidine unit. In the case of the 4-*tert*-butylphenyl substituent leading to LPh (Scheme 1), the pyrimidine ring was built by condensation of the corresponding amidine **2**, resulting from ammonia addition to the corresponding nitrile **1**, with diethyl malonate. The obtained dihydroxypyrimidine **3** was then chlorinated with a combination of phosphoryl chloride and *N*,*N*-dimethylaniline to yield the dichloropyrimidine **4**Ph. The 9-anthracenyl-substituted dichloropyrimidine **4**Ant, on the other hand, was prepared directly from unsubstituted 4,6-dichloropyrimidine by deprotonation at the 2-position, reaction with 9-bromoanthracene, and oxidation with DDQ, as published earlier (Scheme 2).[19] The dichloropyrimidines **4**Ph and **4**Ant were then coupled with 1-(tri-*n*-butylstannyl)-1-vinyl ethyl ether[20] and submitted to acidic hydrolysis to yield the corresponding diketones **5**Ph and **5**Ant, ready for Friedländer condensation. Once again, different routes were used for the butyl- and anthracenyl-substituted ligands. The butyl-substituted ligand was obtained by two consecutive Friedländer condensations: a base-catalyzed condensation with 4-aminopyrimidine-5-carboxaldehyde[21] yielded pyrimidine-ended intermediate **6**Ph, which was then converted into the bis(aminocarbaldehyde) **7**Ph under acidic conditions. The latter was then condensed with commercially available 2-acetylpyridine to yield the final ligand LPh. Bis(ketone) **5**Ant, on the other hand, was directly condensed with 6-amino-2,2′-bipyridinyl-5-carbaldehyde (**9**) to yield ligand LAnt. Compound **9** was also synthesized by Friedländer condensation of 2-acetylpyridine and 4-aminopyrimidine-5-carboxaldehyde (**8**) followed by acidic hydrolysis. LAnt displays the fluorescence emission typical of anthracene derivatives.

#### *Metal Complexes*

Both dirhodium complexes were obtained by treatment of a suspension of the ligand with commercially available dirhodium tetraacetate in methanol in the presence of two equivalents of protons (1 equiv. per acetate bridge to be substituted).[22a] Heating a suspension of the ligand with the mixed-valence complex $[Ru_2(OAc)_4Cl]$[23] in methanol yielded the desired diruthenium(II) complexes without additional reductant.[22b] All complexes were isolated as their hexafluorophosphate salts.

### Characterization

#### *$^1$H NMR Spectroscopy*

The diamagnetic dirhodium(II) complexes show a simple set of signals, thus revealing that the $C_2$ symmetry of the ligands is maintained in the complexes and therefore that

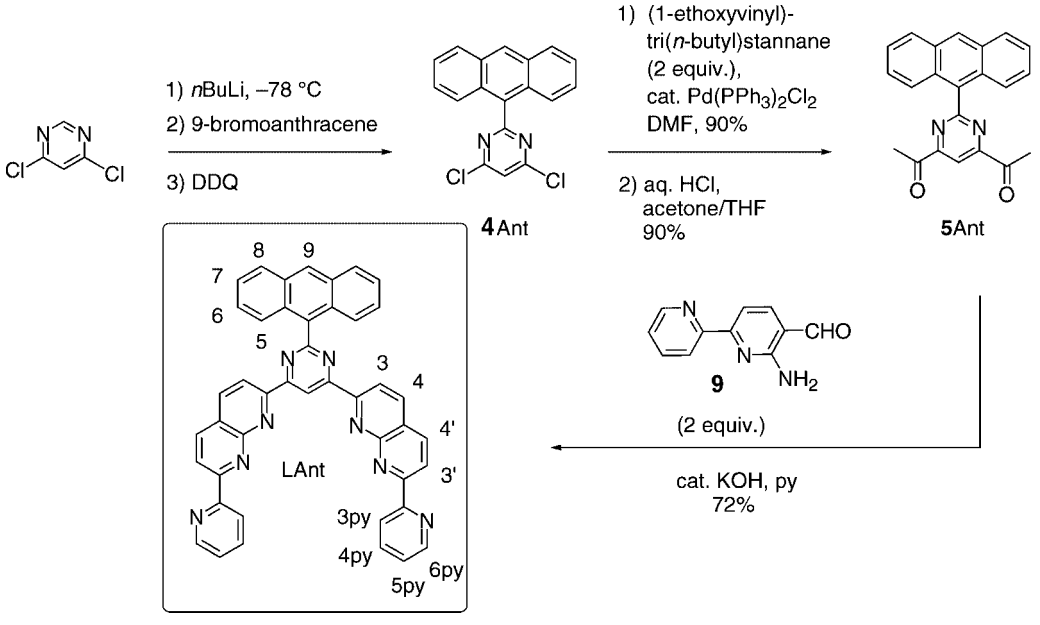

Scheme 2. Synthesis of LAnt (numbering relates to the discussion of the $^1$H NMR spectroscopic data).

both dinuclear binding sites are occupied (in agreement with elemental analysis and mass spectrometry measurements). The two sets of signals from the acetate ligands confirm the dissymmetry introduced by a single L ligand (two different signals for the 12 equatorial and the six axial $CH_3$ acetate protons). The six axial acetate protons are shielded due to the ring effect provided by the anthracene moiety, thua confirming the involvement of the pyrimidine nitrogen atoms in the coordination of the $Rh_2$ units and the rotation of the C–C bonds between the heteroaryl units compared to the initial ligands. Although the spectra of free ligands and metal complexes were recorded in different solvents

Table 1. Chemical shifts [ppm] of the protons in ligands LPh and LAnt (in $CDCl_3$) and their dirhodium complexes (in $CD_3CN$).

| Compound | H1 | H3 | H3′ | H3py | H4 | H4′ | H4py | H5py | H6py | Ha | Hb | *t*Bu |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| LPh | 10.06 | 8.81–9.0 | | | 8.42 | 8.47 | 7.97 | 7.43 | 8.8 | 8.73 | 7.64 | 1.44 |
| $[(Rh_2)_2LPh]$ | 9.71 | 8.8–9.0 | | | | | 8.58 | 8.29 | 9.67 | 9.24 | 7.75 | 1.49 |

| Compound | H1 | H3 | H3′ | H3py | H4 | H4′ | H4py | H5py | H6py | H5 | H6 | H7 | H8 | H9 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| LAnt | 10.3 | 8.7–8.85 | | 9.03 | 8.3–8.4 | | 7.99 | 7.4–7.6 | 8.7–8.9 | 7.88 | 7.4–7.6 | | 8.14 | 8.67 |
| $[(Rh_2)_2LAnt]$ | 10.1 | 9.47 | | 8.8–9.1 | 8.8–9.1 | | 8.52 | 8.2–8.3 | 9.50 | 7.92 | 7.31, 7.47 | | 8.2–8.3 | 8.8–9.1 |

and therefore the chemical shifts cannot be accurately compared (cf. *t*Bu signal as a probe of solvent effect), the introduction of the $Rh_2$ units has a significant deshielding effect on the protons *para* to the nitrogen atoms of the bound heterocycles (ca. +0.5 ppm for H4, H4′and H4py; Table 1) and on the pyridine protons. The substituents on the pyrimidine ring also undergo a downfield shift due to the proximity of the acetate ligands (ca. +0.5 ppm for Ha in LPh and ca. +0.2 ppm for H9 in LAnt).

The diruthenium(II) complexes are paramagnetic, as expected for the distribution of the 12 d-electrons of the two ruthenium(II) centers in a $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*2}$ configuration. The $^1H$ NMR spectra nevertheless show well-defined peaks ranging from $\delta$ = –50 to 80 ppm (Figure 2) whose number is in accordance with the expected symmetry.

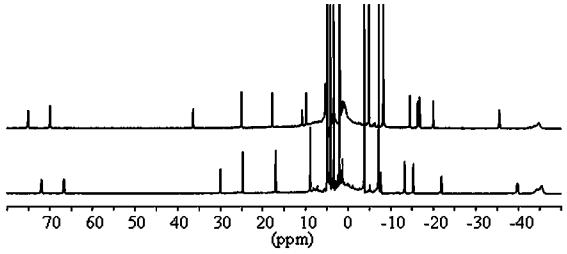

Figure 2. $^1H$ NMR spectra of the paramagnetic complexes $[(Ru_2)_2LAnt]^{2+}$ (top) and $[(Ru_2)_2LPh]^{2+}$ (bottom) ($CD_3CN$, 200 MHz, 25 °C).

### *X-ray Structure Determination*

Single-crystal X-ray analysis of $[(Rh_2)_2LPh]$[24] confirmed the anticipated structure of the bis-dirhodium complex (Figure 3). All nitrogen sites are bound to the rhodium centers. The distance between the two rhodium centers (2.40 Å) is the same as that found in the parent $[Rh_2bpnp]^+$ complex [$Rh_2$ is $Rh_2(OAc)_3$ and bpnp is bis(pyridyl)naphthyridine],[22a] as are the distances involving the coordinated

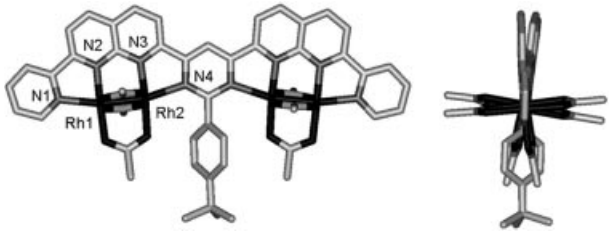

Figure 3. Solid-state structure of $[(Rh_2)_2LPh]$[24] showing the alignment of the two bis-dirhodium units bridged by the central pyridimine (hydrogen atoms, solvent, and counter anions have been omitted for clarity).

naphthyridines [Rh(1)–N(2) 2.00 and Rh(2)–N(3) 1.98 Å]. As anticipated by the difference in basicity, the strong coordinative contribution of the pyridine [Rh(1)–N(1) 2.16 Å] stands in contrast to the weaker binding of the pyrimidine ring [Rh(2)–N(4) 2.31 Å]. Overall, the quasi-planar, crescent-shaped ligand[25] holds the two bis-dirhodium metallic units in a linear alignment that is bridged by the central pyrimidine and slightly bent by the coordination-induced pinching of the subunits.

### *IR Spectra*

The IR spectra of all complexes show many common features (number and location of bands), which is further evidence for their similar functional and structural environments as well as identical symmetry.

### *Absorption Spectra*

All complexes are deeply colored. The optical properties are represented in Figure 4 and reported in Table 2, together with those of the simple $[M_2bpnp]^+$ dimetallic complexes reported earlier by other groups[22a,22b] (M = $Ru^{II}$ or $Rh^{II}$; these complexes were synthesized again for comparison purposes). The absorption spectra are very rich, as expected because of the presence of several chromophoric units. The spectra of all the complexes exhibit an intense absorption feature between 320 and 400 nm. This feature should therefore receive contribution from spin-allowed π–π* transitions involving the common L bridging ligand. In $[(Rh_2)_2LAnt]$ and $[(Ru_2)_2LAnt]$, the spin-allowed, anthracene-centered $^1L_a$ transitions are expected within the same wavelength range,[26c,27,28] and their contribution is clear when looking at the vibrational progression appearing in the spectra of both species. For these latter species, the very intense absorption band around 254 nm can be straightforwardly assigned to the $^1B_a$ transition of the anthryl subunits.[26c,27,28]

As far as the visible absorption is concerned, the lowest-energy band of the rhodium species is attributed to a charge-transfer transition from each dirhodium subunit (most likely from a π* orbital extending over the two metal centers) to the bridging ligand. Such a transition is a form of metal–metal to ligand charge transfer ($M_2LCT$) transition because of the strong interaction between the metal–metal-bonded units of each component. The red shift of the lowest-energy absorption band in the present compounds {$\lambda_{max}$ = 622 and 634 nm for $[(Rh_2)_2LPh]$ and $[(Rh_2)_2LAnt]$, respectively} compared to that of the parent species $[Rh_2bpnp]$ ($\lambda_{max}$ = 578 nm) supports the CT assignment, since in the dicomponent species the LUMO of the polypyr-

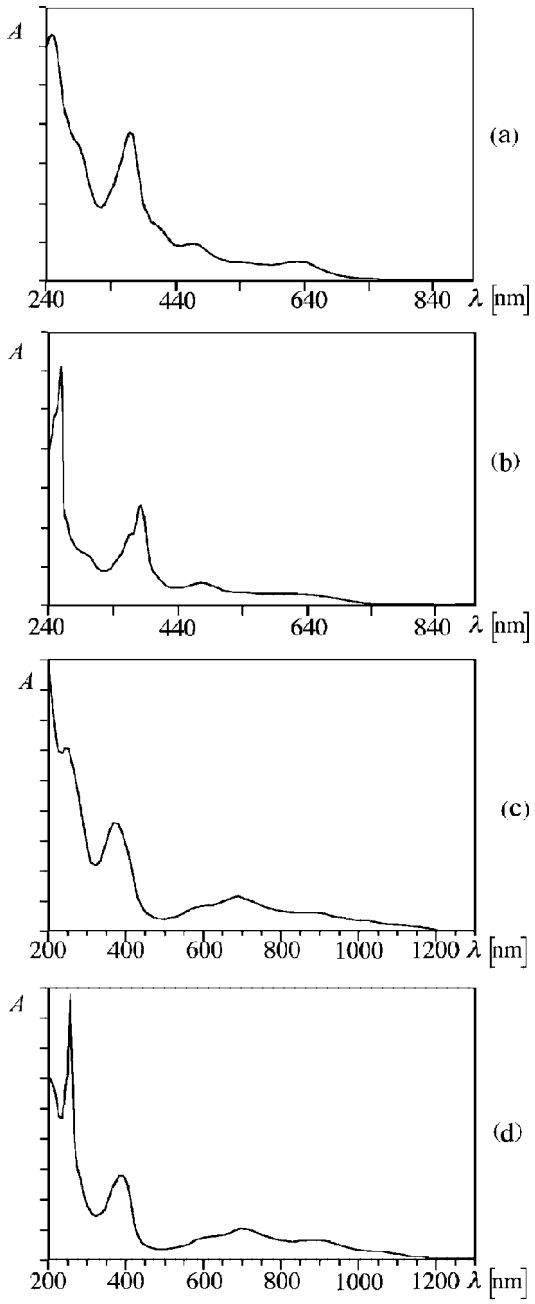

Figure 4. Absorption spectra of $[(Rh_2)LPh(Rh_2)]$ (a), $[(Rh_2)$-$LAnt(Rh_2)]$ (b), $[(Ru_2)LPh(Ru_2)]$ (c), and $[(Ru_2)LAnt(Ru_2)]$ (d) in acetonitrile solution.

idine-type bridging ligand (i.e., the acceptor orbital of the CT transition) is lower in energy than the LUMO of bpnp (see below).

For the ruthenium compounds, the absorption bands, which have a similar origin to those of the rhodium analogues, are displaced to lower energies than the rhodium species, with the lowest-energy band in the near-IR region (Figure 4). This is also in agreement with a $M_2LCT$ assignment, since the metal-based HOMOs of the ruthenium compounds are higher in energy than those of the corresponding rhodium species (see redox behavior).

## Redox Behavior

The four bis-dimetallic species investigated here exhibit a rich redox behavior. Figure 5 shows the cyclic voltammograms of the compounds and Table 3 reports the main redox data, together with data relative to the free ligands (bpnp and LPh) and parent $[Rh_2bpnp]^+$ complex for comparison. To better evidence the bi-component nature of the studied compounds, these latter are labeled $(M_2)L(M_2)$ instead of $(M_2)_2L$ (M = Rh or Ru; L = LPh or LAnt) in this paragraph.

As already discussed,[24] the easier reduction of the LPh ligand compared to the bpnp ligand ($\Delta E_{1/2}^{\text{first-red}} = -0.28$ V) is mirrored by the reduction properties of the complexes, with $[(Rh_2)LPh(Rh_2)]$ being easier to reduce than $[Rh_2bpnp]^+$ ($\Delta E_{1/2}^{\text{first-red}} = -0.43$ V). This observation is in accordance with earlier work describing the LUMO of $[Rh_2(acetate)_3L]^+$ complexes (L = chelating pyridine/naphthyridine-type ligand) as being mainly ligand-based.[29] Substituting a pyridine for a more easily reduced pyrimidine yields a new ligand and its derived complexes with less negative reduction potentials. The lowering of the LUMO of polypyridyl-type ligands upon complexation has also already been observed.[26b] Such considerations allow us to assign the reduction potential of all the bis-dimetallic complexes studied here to bridging-ligand-based processes.

Table 3 also indicates that both bis-dirhodium complexes are easier to reduce than their bis-diruthenium counterparts (ca. 0.1 V difference). This may be due to an enhanced π back-donation in the bis-diruthenium complexes, which have metal-centered HOMOs of higher energy (see below).

| $[(Rh_2)LAnt(Rh_2)]$ | +1.32 [1], +1.53 [2][c] | –0.18 [1][b] |
| $[(Ru_2)LPh(Ru_2)]$ | +0.76 [1], +0.85 [1] | –0.31 [1][b] |
| $[(Ru_2)LAnt(Ru_2)]$ | +0.73 [1], +0.86 [1], +1.51 [1][c] | –0.30 [1][b] |

[a] Data taken from ref.[24] For the free ligands, the solvent is dichloromethane and the reported values were obtained at 0 °C. [b] Further reduction processes take place for all the complexes but they are ill-behaved and will not be discussed here. [c] Irreversible process.

The contribution of the diruthenium unit to the LUMO destabilization thus results in a more negative reduction potential.

Several oxidation waves are observed for all complexes, as evidenced by the cyclovoltammograms reported in Figure 5. $[(Rh_2)LPh(Rh_2)]$ shows two very close oxidation waves (resolved by differential voltammetry), each of which corresponds to a one-electron oxidation and is related to the sequential removal of one electron from each $Rh_2$ unit. Therefore, the first oxidation process leads to the mixed-valence, bi-component system $[(Rh_2^{5+})LPh(Rh_2^{4+})]$, whereas $[(Rh_2^{5+})LPh(Rh_2^{5+})]$ is obtained upon further oxidation. The first one-electron oxidation of $[(Rh_2)LAnt(Rh_2)]$ is followed by a two-electron irreversible oxidation at 1.53 V. To assign the various processes occurring in this latter compound to specific subunits, it is useful to consider that an irreversible oxidation at +1.51 V is observed for $[(Ru_2)LAnt(Ru_2)]$ (attributed to oxidation of the anthryl center, see below) and the second oxidation of the dimetallic subunit of $[(Rh_2)LPh(Rh_2)]$ occurs at +1.50 V (see above). It is therefore likely that the first oxidation process of $[(Rh_2)LAnt(Rh_2)]$ corresponds to the oxidation of one bimetallic subunit and the subsequent irreversible bi-electronic oxidation involves both the one-electron oxidation of the second $Rh_2$ unit and the irreversible oxidation of the anthracene unit.

Both the bis-diruthenium complexes are much easier to oxidize than their bis-dirhodium counterparts. This indicates that the HOMOs are higher in energy for the diruthenium centers than for the dirhodium ones. Once again, two consecutive one-electron oxidations occur for the bis-ruthenium species (Table 3, Figure 5), which are assigned to the consecutive oxidation of the interacting dimetallic subunits. The additional irreversible oxidation at 1.51 V in $[(Ru_2)LAnt(Ru_2)]$, mentioned above, is attributed to the anthracene oxidation.

### Intercomponent Interactions

The observation of two distinct oxidation potentials for the two $M_2$ units in $[(M_2)LPh(M_2)]$ and $[(M_2)LAnt(M_2)]$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

suggests that a non-negligible electronic interaction exists between the two metal–metal-bonded dimetallic subunits of the four complexes. Actually, the difference between the two oxidation potentials is a function of the degree of interaction between the two redox centers.[30] The splittings between the first two oxidation waves reported in Table 4 show that [(Ru$_2$)LPh(Ru$_2$)] displays a slightly greater degree of electronic interaction than its bis-dirhodium counterpart (for the LAnt series, overlap between the second metal-based oxidation and the anthracene-based irreversible oxidation in [(Rh$_2$)LAnt(Rh$_2$)] makes the comparison meaningless). To rationalize such a difference, it is useful to recall that, beside Coulombic factors, which are expected to be identical for both the dirhodium and diruthenium compounds studied here, contribution to the electronic interaction can be related to the separation between the energetic levels of the HOMOs, which are centered on the metallic unit, and the LUMO, which is centered on the bridging ligand, assuming that an effective mechanism for inter-component electronic interaction is superexchange via an electron-transfer pathway involving the bridging ligands.[30] Hence, on the basis of the Koopman theorem, which approximates the energy of the orbitals to the redox potential values, a smaller difference between first oxidation and reduction potentials corresponds to a larger inter-component interaction. From the redox data in Table 3, the HOMOs of the bis-diruthenium compounds are located at higher energy than those of the bis-dirhodium species, and this justifies why the interaction is larger in the former compounds (the effect on the HOMO is only partially compensated by a reversed effect on the LUMO).

As highlighted in Table 4, it also appears that the anthracene-derived ligand promotes a larger electronic coupling than the 4-*tert*-butylphenyl-substituted ligand: the half-potential difference for [(Ru$_2$)LAnt(Ru$_2$)] is 0.13 V, compared with 0.09 V for [(Ru$_2$)LPh(Ru$_2$)], and, although the potential of the metal-based oxidation of [(Rh$_2$)LAnt(Rh$_2$)] is not known exactly, the same appears also to be valid for the dirhodium couple of complexes. Comparison between the redox properties of the bis-dimetallic compounds studied here with those of closely related dinuclear complexes in which each component is made by a Ru$^{II}$ polypyridine subunit[26b–26d] reveals striking similarities. The structure of the naphthyridine-based ligands LPh and LAnt is indeed derived from that of the pyridine-based parents L′Ph and L′Ant, which accommodate mononuclear ruthenium(II) complexes (see Table 4, right, for the structure of the Ru$^{II}$ complexes). Interestingly, the enhancement of the electronic interaction provided by the anthracene pyrimidine substituent in the bis-dimetallic complexes and the "classic" dinuclear Ru$^{II}$ polypyridine complexes[26b–26d] is the same (0.04 V), thus suggesting that similar processes could be occurring.

Two main contributions can explain the anthracene effect. On the one hand, the anthracene moiety moves the electronic levels of the bridging ligand to lower energies, as also suggested by the reduction potentials {[(Rh$_2$)-LAnt(Rh$_2$)] is easier to reduce than [(Rh$_2$)LPh(Rh$_2$)], see Table 3, with the reduction mainly based on the bridging ligand}, probably because the anthryl substituent can contribute to a better delocalization of the added electron. As a consequence, the LUMO–HOMO gap becomes smaller and the interaction is enhanced. However, according to this mechanism, the effect on the HOMO(s) should be negligible, but this is not the case, since the data in Table 3 indicate that on passing from the LPh to the LAnt series the HOMOs are even more affected than the LUMO by the presence of the anthracene group. On the other hand, the anthracene moiety may contribute to the electronic coupling between the redox sites by opening a new pathway for superexchange, for example by mediating a through-space interaction involving anthracene-based orbitals. The redox data indeed indicate that the anthracene-based HOMO is close in energy to the metal-centered orbitals, so that a hole-transfer pathway involving the anthracene HOMO is quite possible. It is likely that both contributions come into play. This situation is schematized in Figure 6.

Table 4. Differences in half-wave potentials between the first two one-electron oxidations of the four bis-dimetallic complexes and the two related ruthenium-based bis-mononuclear analogues (the structure of the latter is presented on the right).

| Complex | $E_{1/2}^{ox2} - E_{1/2}^{ox1}$ | |
|---|---|---|
| (Rh$_2$)LPh(Rh$_2$) | 0.07 V[a] |  |
| (Rh$_2$)LAnt(Rh$_2$) | n.d.[b] | |
| (Ru$_2$)LPh(Ru$_2$) | 0.09 V[a] | |

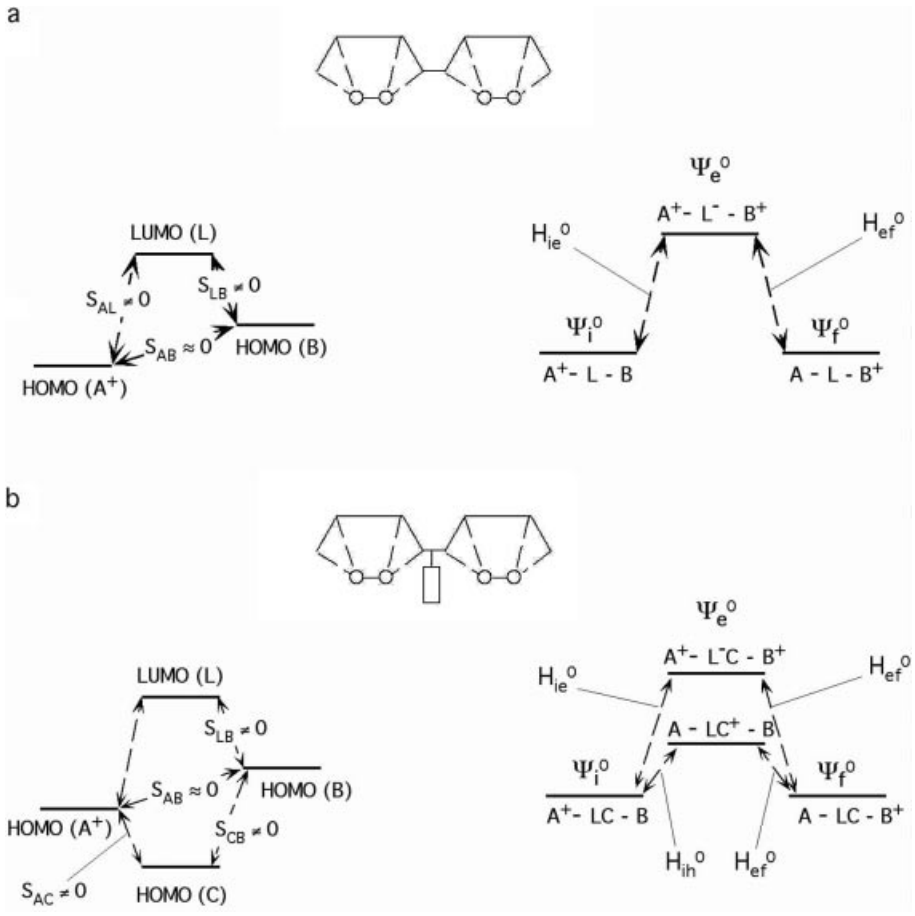

Figure 6. Schematic representation of the interaction between the subunits. In the scheme, A and B represent the dimetallic subunits, with one of them oxidized (so the mixed-valence species is considered, for clarity). (a) refers to species with LPh as the bridge and (b) to LAnt as the bridging ligand. Orbital interactions are shown on the left and interactions between states are represented on the right. In (b), the anthracene (identified as "C") HOMO contributes to the overall coupling; the bridge is here labeled LC on the "state" diagram to highlight the contribution of anthracene. S indicates overlap integrals, Ψ the wavefunctions of the various states, and H the electron coupling matrix elements. The superscript 0 indicates zero-order quantities (i.e. quantities that derive from pure, localized electronic configurations). The subscripts i, f, e, and h indicate the initial, final, electron- and hole-transfer states, respectively (these latter two are "virtual" states).[30]

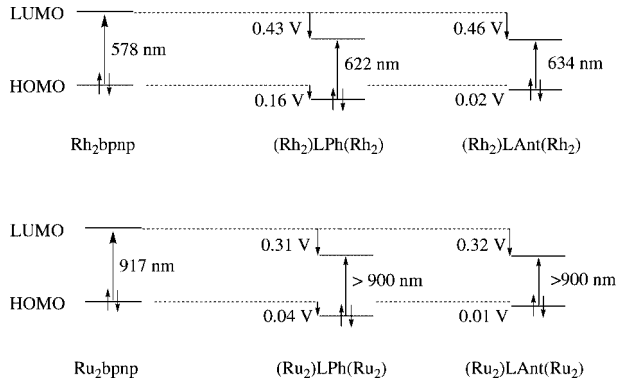
The electronic information gathered through the electrochemical (and electronic absorption) studies reported above is summarized in Scheme 3. In both the metal–metal-bonded dirhodium and diruthenium complexes, the LUMO–HOMO gap is reduced on going from the bpnp-based "mononuclear" to the LPh- and LAnt-based "dinuclear" complexes, mainly due to a significant LUMO lowering (LUMO centered on the ligand where a pyridine is substituted by a pyrimidine, plus bimetallic coordination of the second chelating site). An additional gap reduction is caused by changing the substitution of the pyrimidine substituent from a phenyl to an anthryl moiety, which results in a small further decrease of the LUMO energy and an increase of the HOMO level.



Scheme 3. Compared electronic levels of the one and two dimetallic site complexes of rhodium and ruthenium.

### Spectroelectrochemistry

The splitting of the oxidation processes of the four bis-dimetallic compounds, which indicates a relatively high stability of the mixed-valence species with respect to the isovalent forms,[31] prompted us to investigate the properties of their mixed-valence compounds in more detail by performing spectroelectrochemistry experiments. However, results were poor for the ruthenium complexes: featureless absorption spectra were obtained, probably due to the very

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

broad and unresolved absorption spectra of the starting compounds (see Figure 4), particularly in the otherwise diagnostic visible and near-IR region. For this reason, our discussion will be limited to [($Rh_2$)LPh($Rh_2$)] and [($Rh_2$)-LAnt($Rh_2$)].

Figure 7 shows the changes in the absorption spectrum of [($Rh_2$)LPh($Rh_2$)] on applying increasingly positive potentials. At the beginning (potential: +1.45 V), a slight increase of absorption in the range 680–900 nm occurs, with simultaneous decrease of the absorption of the $M_2$LCT band at about 640 nm. A slight absorption decrease of the 350-nm band also takes place, with formation of a new absorption in the range 380–450 nm. The absorption feature in the red is attributed to an intervalence transfer (IT) transition from the $Rh_2^{4+}$ subunit to the $Rh_2^{5+}$ component of the mixed-valence "dinuclear" [($Rh_2^{5+}$)LPh($Rh_2^{4+}$)] species obtained upon first oxidation, whereas the decrease of the $M_2$LCT band is a consequence of the disappearance of one of the donor orbitals of the corresponding CT transition. The changes in the 340–440-nm region are probably the consequence of an asymmetry of the coordination sites of the otherwise symmetric bridge induced by the mixed-valence nature of the species. On increasing the applied potential, a new process starts, as indicated by the isosbestic points at about 440 and 345 nm (not visible in Figure 7, where only a limited numbers of spectra are shown for clarity): the IT band disappears, as does the $M_2$LCT band, and the ligand-centered bands continue to change. The final spectrum is constant upon successive increase of applied potential, and the initial spectrum is recovered when the potential is eliminated, in agreement with the reversibility of the oxidation processes.

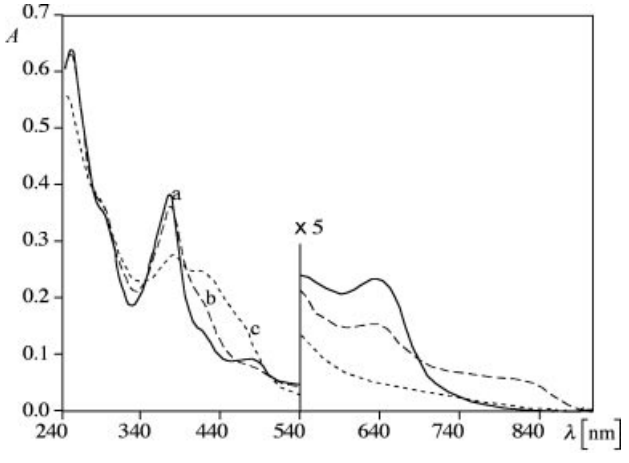


Figure 7. Changes in the absorption spectrum of [($Rh_2$)LPh($Rh_2$)] in acetonitrile on applying positive potentials: (a) starting spectrum; (b) applied voltage of +1.45 V; (c) applied voltage of +1.60 V.

Figure 8 shows the changes of the absorption spectrum of [($Rh_2$)LAnt($Rh_2$)] upon oxidation at relatively mild potentials. In this case, probably due to the increased separation between the two oxidation potentials (Table 4), it is possible to follow the first oxidation process in more detail, as evidenced by the several isosbestic (or quasi-isosbestic) points. Indeed, Figure 8 only shows changes related to the first oxidation process: as for the former compound, a new absorption (assigned to the IT transition) appears in the 680–900-nm region even for [($Rh_2$)LAnt($Rh_2$)], with concomitant decrease of the $M_2$LCT band and changes in the 330–450-nm ligand-centered region. Removing the applied potential leads back to the starting spectrum quantitatively, whereas the increase of the positive applied potential leads to the disappearance of both IT and $M_2$LCT bands and further changes in the ligand-centered region (not shown) also in this case.

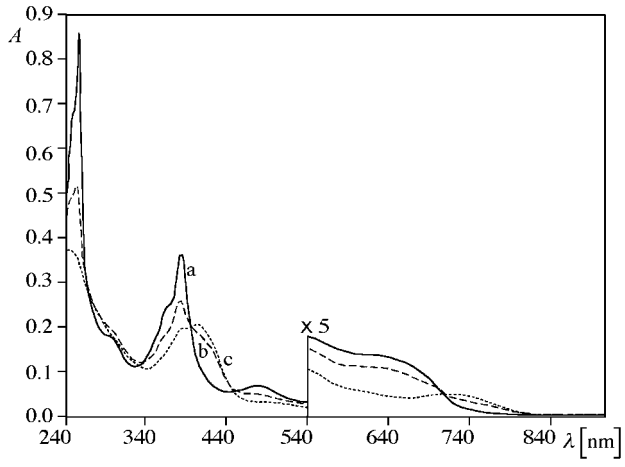

Figure 8. Changes in the absorption spectrum of [($Rh_2$)LAnt($Rh_2$)] in acetonitrile on applying positive potentials: (a) starting spectrum; (b) applied voltage of +1.40 V; (c) applied voltage of +1.55 V.

The possibility of following the formation and disappearance of the IT band in [($Rh_2$)LAnt($Rh_2$)] allowed us to calculate the electronic interaction parameters from Equation (1).[32]

$$\varepsilon_{max} = (2380\ r^2/E_{op}\ \Delta\nu^{1/2})\ H_{AB}^2 \quad (1)$$

According to Hush,[32] Equation (1) correlates the optical inter-valence transfer band with the magnitude of the electronic coupling matrix element between the two subunits A and B (in the present case, the $Ru_2^{4+}$ subunits), $H_{AB}$, $\varepsilon_{max}$ is the maximum molar absorption coefficient of the IT band, $E_{op}$ and $\Delta\nu$ are the band maximum energy and half-width (in $cm^{-1}$), respectively, and $r$ is the inter-component distance (in Å). For [($Rh_2$)LAnt($Rh_2$)], $\varepsilon_{max}$ is 1900 $M^{-1}cm^{-1}$, $E_{op}$ is 13700 $cm^{-1}$, $\Delta\nu$ is 3000 $cm^{-1}$, and $r$ is 9.0 Å ($r$ is taken as the center-to-center distance). By using the above experimental parameters, a value of 86 $cm^{-1}$ is calculated for $H_{AB}$. This value compares well with the electronic coupling matrix elements of dinuclear $Ru^{II}$ polypyridine complexes bridged by good electron coupling mediator spacers such as cyanide ligands,[33] thus confirming the significant inter-component interaction mediated by the LAnt bridge.

## Excited-State Properties

None of the four bis-dimetallic compounds studied here (including the two species containing the LAnt ligand,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

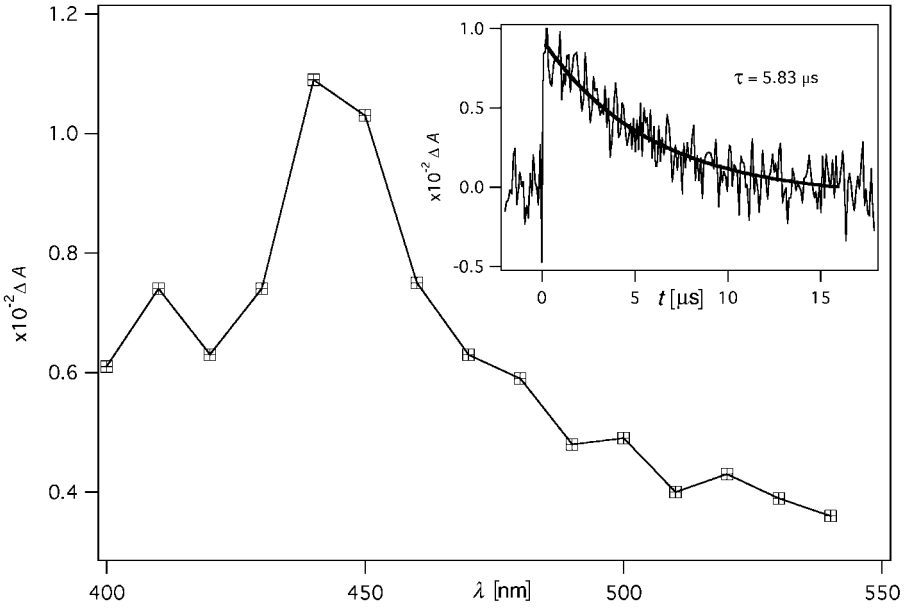

Figure 9. Transient absorption spectrum and (inset) decay of [($Rh_2$)LPh($Rh_2$)] in acetonitrile. Excitation wavelength: 532 nm.

which shows the typical anthracene fluorescence when not coordinated to metals) exhibits any luminescence, either at room temperature or at 77 K. This agrees with the excited-state properties of metal–metal-bonded acetate species, which are known to deactivate by nonradiative transitions.[34] However, it has recently been reported[35] that dirhodium compounds of this class, although nonluminescent, can exhibit lifetimes on the microsecond timescale and can therefore be easily involved in bimolecular photoinduced electron- and energy-transfer processes. This is the case, for example, for the complexes [$Rh_2(O_2CCH_3)_4(L)_2$] (L = $CH_3OH$, tetrahydrofuran, triphenylphosphane, pyridine).[35] However, the nature of the long-lived excited state was not clarified.

The similarity between the dirhodium complexes reported to exhibit the long-lived excited state[35] and the bis-dimetallic species studied here prompted us to perform nanosecond transient absorption spectroscopy (in degassed acetonitrile at room temperature) on the present systems. With our nanosecond-limited equipment, no transient spectrum could be recorded for [($Rh_2$)LAnt($Rh_2$)], [($Ru_2$)-LAnt($Ru_2$)], or [($Ru_2$)LPh($Ru_2$)]. This suggests that the excited states of these latter species decay faster than the laser flash (10 ns). On the contrary, a clear absorption feature appeared in the transient absorption spectrum of [($Rh_2$)-LPh($Rh_2$)]. This transient absorption exhibits a broad maximum around 440 nm that extends over a large part of the visible region (Figure 9). It resembles the absorption spectrum of the *reduced* [($Rh_2$)LPh($Rh_2$)], so it can be assigned to the absorption of the radical anion of the bridging ligand, in agreement with the $M_2$LCT assignment of the lowest-energy excited state for the complex.

The transient spectrum of [($Rh_2$)LPh($Rh_2$)] disappears with a monoexponential decay, yielding a lifetime of 5.8 μs, the same timescale reported for the excited state of other metal–metal-bonded dirhodium complexes.[35] The reason for the absence of such long excited-state lifetimes in the other compounds studied here could be the nature of the metal (for the diruthenium species, for which the $M_2$LCT state is probably so low in energy that nonradiative transitions are very fast) and the presence of the anthracene moiety {for [($Rh_2$)LAnt($Rh_2$)]; the anthracene moiety could introduce other low-lying excited states, such as an anthracene-to-bridging ligand CT level, which can accelerate the decay to the ground state}. Nevertheless, the relatively long-lived excited state of [($Rh_2$)LPh($Rh_2$)] indicates that this class of compounds also has a good potential to be involved in processes based on light as the energy input.

## Conclusion

The naphthyridine-based ligands reported here are able to accommodate two sets of dimetallic redox active units that show electronic communication with one another. Bis-dirhodium and bis-diruthenium complexes of similar structure have been synthesized and characterized. Among the two families of species, electronic communication is stronger in the diruthenium complexes than in their dirhodium counterparts and is further enhanced by the replacement of the phenyl group born by the bridging pyrimidine with an anthryl moiety. The positive effect of the anthracene substituent on the electronic communication between dimetallic units is similar to that observed earlier with analogous mononuclear ruthenium complexes and is proposed to be mainly due to the involvement of an anthracene-based HOMO in the interaction mechanism. Moreover, one of the compounds exhibits a long-lived (microsecond timescale) excited state. The results presented here are promising for the development of poly-dimetallic complexes built on

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

longer naphthyridine-based strands. Furthermore, the replacement of the bridging pyrimidine by a pyrazine group should lead to a linear (not curved) structure with stronger electronic coupling between subunits, as is the case in mononuclear bi-component complexes.[26e] The introduction of dimetallic units characterized by single metal–metal (such as the those described here) but also by multiple metal–metal bonds (e.g., $Mo_2$, $Re_2$) in larger ligands is currently in progress to extend the work on mononuclear ruthenium racks[26] towards nanoscale molecular wires.[36]

## Experimental Section

**Materials and Methods:** All reagents were used as received. Dry solvents (dichloromethane, toluene, THF) were distilled over drying agents (calcium hydride, Na, Na/benzophenone, respectively) under argon. 4-Amino-5-cyanopyrimidine,[37] 4-aminopyrimidine-5-carboxaldehyde,[21] (1-ethoxyvinyl)tri(*n*-butyl)stannane,[20] 2-(anthracen-9-yl)-4,6-dichloropyrimidine,[26b] and tetra-μ-acetodiruthenium(II,III) chloride $[Ru_2(OAc)_4Cl]$[23] were prepared according to published protocols. $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker AC 200 (200 and 50 MHz respectively) at 25 °C. Electronic and luminescence spectra were recorded with a Varian CARY 13e and an AMINCO Bowman Series 2 spectrometer, respectively, in the reported spectroscopic grade solvents. Mass spectrometry was performed at the Laboratoire de Spectrométrie de masse Bio-organique (LSMBO, Strasbourg, France) and elemental analyses at the elemental analysis service, Louis Pasteur University (Strasbourg, France). IR spectra: (f) = weak, (F) = strong, (m) = medium.

The electrochemical equipment and methods have been described previously.[26e] Absorption spectroscopy in the near-IR region were recorded with a JASCO V570 spectrophotometer. For spectroelectrochemical measurements, the latter spectrophotometer was used in connection with an EG&G 273A potentiostat. Nanosecond transient absorption experiments were performed in argon-purged acetonitrile solutions. A Continuum Surelite SLI-10 Nd:YAG laser was used to excite the sample with 10-ns pulses at 355 nm. The monitoring beam was supplied by a Xe arc lamp, and the signal was detected by a red-sensitive photodiode after passing through a high radiance monochromator. Differential absorption spectra were recorded point-by-point, while kinetic measurements were made at a fixed wavelength. Sixty four individual laser shots were averaged to improve the reliability of each acquisition. The signals were stored and analyzed on a dedicated PC.

**7-(Pyridin-2-yl)pyrido[2,3-*d*]pyrimidine (8):** Two drops of 10% methanolic sodium hydroxide were added to a hot solution of 4-aminopyrimidine-5-carboxaldehyde[21] (198 mg, 1.61 mmol) and 2-acetylpyridine (220 mg, 1.82 mmol, 1.13 equiv.) in 23 mL of absolute ethanol. The solution was then refluxed for 4 h under argon and concentrated in vacuo. The residue was recrystallized from ethanol to yield 229 mg of an off-white solid (68%, m.p. 205 °C). $^1H$ NMR ($CDCl_3$): $\delta$ = 9.57 (s, 1 H), 9.50 (s, 1 H), 8.92 (d, $^3J$ = 8.5 Hz, 1 H), 8.88 (d, $^3J$ = 7.9 Hz, 1 H), 8.8 (br. d, 1 H), 8.44 (d, $^3J$ = 8.5 Hz, 1 H), 7.93 (td, $^3J$ = 7.9, $^4J$ = 1.7 Hz, 1 H), 7.45 (m, 1 H) ppm. FAB+: *m*/*z* 209.1 [$MH^+$]. $C_{12}H_8N_4$ (208.22) + 0.025 $CHCl_3$: calcd. C 68.38, H 3.83, N 26.53; found C 68.42, H 3.85, N 26.53.

**6-Amino-2,2′-bipyridinyl-5-carbaldehyde (9):** A solution of 7-(pyridin-2-yl)pyrido[2,3-*d*]pyrimidine (229 mg, 1.1 mmol) in 2 N aqueous hydrochloric acid (80 mL) was refluxed for 2.5 h and then cooled in ice. The solution was neutralized with concentrated aqueous ammonia (pH ca. 8–9), extracted with ethyl acetate (3 × 50 mL), and the combined organic layers were dried ($Na_2SO_4$), concentrated, and the brown residue purified by column chromatography (basic alumina, $CH_2Cl_2$/EtOAc) to give 180 mg (82%) of the desired amino aldehyde as a yellow powder (m.p. 143 °C). $^1H$ NMR ($CDCl_3$): $\delta$ = 9.90 (s, 1 H), 8.70 (br. d, $^3J$ = 4.3 Hz, 1 H), 8.36 (d, $^3J$ = 8.0 Hz, 1 H), 7.94 (d, $^3J$ = 7.9 Hz, 1 H), 7.85 (d, $^3J$ = 7.7 Hz, 1 H), 7.81 (br. t, $^3J$ = 8.0 Hz, 1 H), 7.33 (ddd, $^3J_{5',4'}$ = 7.5, $^3J_{5',6'}$ = 4.8, $^4J_{5',3'}$ = 1.4 Hz, 1 H) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 192.3, 160.2, 158.0, 155.1, 149.3, 145.0, 136.8, 124.5, 122.1, 113.8, 110.6 ppm. FAB+: *m*/*z* 200.1 [$MH^+$]. $C_{11}H_9N_3O$ (199.21) + 0.064 EtOAc: calcd. C 66.00, H 4.68, N 20.51, O 8.81; found C 66.00, H 4.62, N 20.50.

**2,7-Dipyridin-2-yl[1,8]naphthyridine (bpnp):** Two drops of a 10% methanolic potassium hydroxide solution were added to a hot solution of 6-amino-2,2′-bipyridinyl-5-carbaldehyde (**3**; 75 mg, $3.76 \times 10^{-4}$ mol) and 2-acetylpyridine (51 mg, $4.21 \times 10^{-4}$ mol, 1.1 equiv.) in absolute ethanol (15 mL). The solution was further refluxed for 6 h under dinitrogen. The solvent was evaporated and the solid taken up in dichloromethane (35 mL) and washed with water (10 mL). The aqueous layer was extracted with dichloromethane (5 mL) and the combined organic layers washed with brine (15 mL), dried ($Na_2SO_4$), filtered, concentrated, purified by column chromatography (basic $Al_2O_3$, $CH_2Cl_2$), and washed with acetone and diethyl ether to yield an off-white solid (88 mg, 82%). $^1H$ NMR ($CDCl_3$): $\delta$ = 8.89 (d, $^3J$ = 8.0 Hz, 2 H), 8.75 (d, $^3J$ = 8.5 Hz, 2 H), 8.8 (m, 2 H), 8.36 (d, $^3J$ = 8.5 Hz, 2 H), 7.92 (td, $^3J$ = 7.7, $^4J$ = 1.7 Hz, 2 H), 7.41 (ddd, $^3J$ = 7.5, $^3J$ = 4.8, $^4J$ = 1.0 Hz, 2 H) ppm.

**4-*tert*-Butylbenzamidine Hydrochloride (2):**[38] Gaseous hydrogen chloride was bubbled into a solution of 4-*tert*-butylbenzonitrile (**1**; 15.94 g, 0.10 mol) in a mixture of dry benzene (25 mL) and absolute ethanol (20 mL) until saturation was attained. The solution was stirred for an hour and left to stand at room temperature for three days. The solution was then concentrated to half its volume in vacuo until white crystals appeared. The flask was cooled in ice and diethyl ether was added. The white solid was then filtered and washed with diethyl ether (3 × 15 mL) and dried in vacuo. It was then suspended in absolute ethanol (40 mL) and 60 mL of ammonia-saturated ethanol was added. A white precipitate formed immediately and the reaction mixture was stirred for a day and left to stand for four days. The white suspension was filtered and the filtrate concentrated in vacuo. The solid residue was then collected and washed with diethyl ether and dried in vacuo to yield 16.71 g [78%; m.p. 155 °C (dec.)] of the desired amidine hydrochloride as a white solid. $^1H$ NMR ([D$_6$]DMSO): $\delta$ = 9.5 (br. s, 2 H), 9.3 (br. s, 2 H), 7.85 (d, $^3J$ = 8.6 Hz, 2 H), 7.62 (d, $^3J$ = 8.6 Hz, 2 H), 1.30 (s, 9 H) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 165.4, 156.9, 127.9, 125.7, 124.9, 34.8, 30.6 ppm. IR (KBr): $\tilde{\nu}$ = 3061 (F), 1674 (m), 1486 (m), 852 (f), 734 (f), 674 (f), 557 (f), 210 (m) $cm^{-1}$. FAB+: *m*/*z* 177.2 $[C_{11}H_{17}N_2]^+$. $C_{11}H_{17}ClN_2$ (212.72): calcd. C 62.11, H 8.06, N 13.17; found C 62.20, H 7.92, N 13.14.

**2-(4-*tert*-Butylphenyl)-4,6-dihydroxypyrimidine (3):**[39] A freshly prepared solution of sodium methoxide (6.6 g sodium in 75 mL absolute methanol) was added dropwise, at room temperature, to a suspension of 4-*tert*-butylbenzamidine hydrochloride (16.71 g, 79 mmol) and diethyl malonate (12.8 mL, 84 mmol, 1.07 equiv.) in absolute ethanol (150 mL). The mixture was refluxed under dinitrogen for 7 h. The volatile solvents were removed and the pinkish residue taken up in water (120 mL) and acidified to pH 3–4 with concentrated hydrochloric acid (ca. 20 mL). The pale-yellow precipitate was filtered and washed with water (2 × 20 mL), dried in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

air and in vacuo to yield 18.4 g of 2-(4-*tert*-butylphenyl)-4,6-dihydroxypyrimidine [92%, m.p. > 260 °C (dec.)]. $^1$H NMR ([D$_6$]-DMSO): $\delta$ = 8.8 (br. s, 1 H), 8.05 (d, $^3J$ = 8.5 Hz, 2 H), 7.54 (d, $^3J$ = 8.6 Hz, 2 H), 5.32 (s, 1 H), 1.31 (s, 9 H) ppm. $^{13}$C NMR ([D$_6$]-DMSO): $\delta$ = 167.3, 157.2, 154.6, 129.3, 127.5, 125.3, 88.1, 34.6, 30.8 ppm. IR (KBr): $\tilde{\nu}$ = 2962 (m), 1637 (F), 1325 (m), 1268 (m), 1197 (f), 844 (f), 520 (f) cm$^{-1}$. FAB+: *m*/*z* 245.2 [MH$^+$]. $C_{14}H_{16}N_2O_2$ (244.29): calcd. C 68.83, H 6.60, N 11.47, O 13.10; found C 68.79, H 6.60, N 11.33.

**2-(4-*tert*-Butylphenyl)-4,6-dichloropyrimidine (4Ph):**[39] Phosphoryl chloride (21 mL, 0.23 mol, 5.3 equiv.) was added dropwise followed by 2-(4-*tert*-butylphenyl)-4,6-dihydroxypyrimidine (10.34 g, 42.3 mmol) portionwise to *N*,*N*-dimethylaniline (9.2 mL, 73 mmol, 1.7 equiv.) at room temperature under argon. The brown mixture was allowed to warm up whereupon it turned reddish. The mixture was refluxed for 1.25 h, then allowed to cool and cautiously poured onto ice (ca. 80 g). The pinkish solid was filtered, washed with water until the filtrate was colorless, dried in air and in vacuo, and purified by flash chromatography ($SiO_2$; hexane/$CH_2Cl_2$, 80:6 to 40:7) to yield 21.6 g of a crystalline white solid (92%, m.p. 93 °C). $^1$H NMR ($CDCl_3$): $\delta$ = 8.35 (d, $^3J$ = 8.6 Hz, 2 H), 7.51 (d, $^3J$ = 8.7 Hz, 2 H), 7.22 (s, 1 H), 1.37 (s, 9 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 165.9, 162.0, 156.0, 132.3, 128.8, 125.8, 118.4, 35.1, 31.3 ppm. $R_f$ ($SiO_2$; hexane/$CH_2Cl_2$, 2.0:0.3) = 0.47. IR (KBr): $\tilde{\nu}$ = 2964 (f), 1551 (F), 1519 (F), 1387 (m), 1248 (f), 1097 (f), 830 (m), 642 (f), 218 (F) cm$^{-1}$. FAB+: *m*/*z* 281.1 [MH$^+$]. $C_{14}H_{14}Cl_2N_2$ (280.05): calcd. **1-[6-Acetyl-2-(4-*tert*-butylphenyl)pyrimidin-4-yl]ethyl Ketone (5Ph):**[20] Dichlorobis(triphenylphosphane)palladium(II) (450 mg) was added to a solution of 2-(4-*tert*-butylphenyl)-4,6-dichloropyrimidine (**4Ph**; 6.0 g, 21,3 mmol) and (1-ethoxyvinyl)tri(*n*-butyl)-stannane[20] (17.68 g, 49 mmol, 2.3 equiv.) in dry DMF (90 mL). The solution was heated at 80 °C under argon for 12 h. At room temperature, the black solution was poured into an aqueous solution of potassium fluoride (20 g KF in 200 mL of water). The brown precipitate was filtered and washed with diethyl ether (300 mL and 4 × 80 mL). The organic layer was washed with brine (6 × 40 mL), dried ($Na_2SO_4$), filtered, and concentrated. The resulting beige solid was purified by flash chromatography ($SiO_2$; hexane/diethyl ether, 95:5) to yield 7.22 g of the bis(vinyl) ether as a pale-yellow solid (97%). The latter (5.11 g, 14.5 mmol) was dissolved in acetone (80 mL), 2 N aqueous HCl (15 mL) was added, and the solution stirred at room temperature for 6 h. The volatile solvent was removed and the white residual solid taken up in dichloromethane (200 mL) and washed with an aqueous saturated solution of sodium hydrogen carbonate (60 mL). The aqueous layer was extracted with dichloromethane (3 × 20 mL) and the combined organic layers dried ($Na_2SO_4$), filtered, concentrated, and purified by flash chromatography ($SiO_2$; hexane/$CH_2Cl_2$, 1.0:2.0) to yield the desired bis-acetylated arylchloropyrimidine (4.1 g, 95%, m.p. 136 °C). $^1$H NMR ($CDCl_3$): $\delta$ = 8.50 (d, $^3J$ = 8.6 Hz, 2 H), 8.25 (s, 1 H), 7.58 (d, $^3J$ = 8.6 Hz, 2 H), 2.83 (s, 6 H), 1.40 (s, 9 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 199.2, 165.4, 161.4, 155.4, 133.6, 128.4, 125.9, 110.5, 35.1, 31.3, 25.8 ppm. $R_f$ ($SiO_2$; hexane/$CH_2Cl_2$, 1.0:2.0) = 0.30. IR (KBr): $\tilde{\nu}$ = 2963 (m), 1712 (F), 1551 (F), 1419 (F), 1355 (F), 1239 (F), 1182 (F), 854 (m), 790 (m), 565 (m), 210 (F) cm$^{-1}$. FAB+: *m*/*z* 297.4 [MH$^+$]. $C_{18}H_{20}N_2O_2$ (296.36): calcd. C 72.94, H 6.81, N 9.46, O 10.8; found C 72.84, H 6.79, N 9.61.

**4,6-Bis(2-amino-3-formylpyridyl)-2-(4-*tert*-butylphenyl)pyrimidine (7Ph):**[40] Five drops of a 10% methanolic potassium hydroxide solution were added to a solution of 1-[6-acetyl-2-(4-*tert*-butylphenyl)pyrimidin-4-yl] ethyl ketone (**5Ph**; 1.00 g, 3.41 mmol) and 4-aminopyrimidine-5-carboxaldehyde (890 mg, 7.23 mmol, 2.1 equiv.) in absolute ethanol (100 mL) at reflux under argon. The solution rapidly turned brown and a beige precipitate appeared. The mixture was refluxed for 8 h, cooled to room temperature, and the precipitate was centrifuged and dried in vacuo. It was then suspended in 2 N aqueous HCl (340 mL) and vigorously stirred at reflux for 5 h. At room temperature, the mixture was neutralized with concentrated ammonia. The orange suspension was filtered, washed with water (2 × 15 mL), dried in vacuo, and purified by flash chromatography ($SiO_2$; $CH_2Cl_2$/EtOAc, 400:15 to 400:40) to yield the desired bis(aminoaldehyde) [1.1 g, 70%, m.p. > 260 °C (dec.)] as a yellow solid. A sample was recrystallized from dichloromethane/hexane for analysis. $^1$H NMR ($CDCl_3$): $\delta$ = 9.99 (s, 2 H), 9.11 (s, 1 H), 8.60 (d, $^3J$ = 8.5 Hz, 2 H), 8.16 (d, $^3J$ = 7.4 Hz, 2 H), 8.01 (d, $^3J$ = 7.6 Hz, 2 H), 7.59 (br. s), 7.59 (d, $^3J$ = 8.5 Hz, 2 H), 6.86 (br. s, 4 H), 1.43 (s, 9 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 193.4, 163.3, 163.0, 157.8, 157.0, 153.9, 146.2, 134.1, 127.9, 125.5, 114.6, 111.8, 110.0, 34.6, 30.9 ppm. $R_f$ ($SiO_2$; $CH_2Cl_2$/EtOAc, 2.0:0.3) = 0.46. IR (KBr): $\tilde{\nu}$ = 3349 (m), 2961 (m), 1671 (m), 1619 (m), 1581 (m), 1534 (F), 1379 (m), 1211 (m), 795 (m), 210 (F) cm$^{-1}$. FAB+: *m*/*z* 453.0 [MH$^+$]. $C_{26}H_{24}N_6O_2$ (452.51) + 0.37hexane: calcd. C 69.97, H 6.07, N 17.35, O 6.61; found C 69.97, H 6.07, N 16.53.

**2-(4-*tert*-Butylphenyl)-4,6-bis(7-pyridin-2-yl[1,8]naphthyridin-2-yl)-pyrimidine (LPh):** Two drops of a 10% methanolic potassium hydroxide solution were added to a hot solution of bis(aminoaldehyde) **7**Ph (150 mg, $3.31 \times 10^{-4}$ mol) and 2-acetylpyridine (103 mg, $8.5 \times 10^{-4}$ mol, 2.6 equiv.) in pyridine (26 mL) and the solution stirred at 75 °C for 22 h. The solvent was removed in vacuo and the solid taken up in chloroform (60 mL), which was successively washed with water (20 mL), brine (15 mL), dried ($Na_2SO_4$), filtered, and concentrated. The residue was washed with acetone to yield an off-white solid (184 mg, 90%; m.p. > 260 °C), which was recrystallized from chloroform and acetone and then purified by flash chromatography ($SiO_2$; $CH_2Cl_2$/$CH_3OH$, 1.0:0.1). $^1$H NMR ($CDCl_3$): $\delta$ = 10.06 (s, 1 H), 9.0 (br. d, $^3J$ = 8.4 Hz, 4 H), 8.81 (d, $^3J$ = 8.4 Hz, 2 H), 8.8 (m, 2 H), 8.73 (d, $^3J$ = 8.5 Hz, 2 H), 8.47 (d, $^3J$ = 8.5 Hz, 2 H), 8.42 (d, $^3J$ = 8.6 Hz, 2 H), 7.97 (td, $^3J$ = 7.7, $^4J$ = 1.8 Hz, 2 H), 7.64 (d, $^3J$ = 8.5 Hz, 2 H), 7.43 (ddd, $^3J$ = 7.5, $^3J$ = 4.8, $^3J$ = 1.1 Hz, 2 H), 1.44 (s, 9 H) ppm. IR (KBr): $\tilde{\nu}$ = 1604 (F), 1525 (F), 1469 (f), 1427 (m), 1371 (f), 862 (f), 792 (m), 409 (f) cm$^{-1}$. FAB+: *m*/*z* 623.1 [MH$^+$], 645.3 [MNa$^+$]. $C_{40}H_{30}N_8$ (622.72) + 0.32 $CHCl_3$: calcd. C 74.55, H 4.70, N 17.30; found C 74.49, H 4.83, N 17.09. # Synthesis and Reactivity of New Mono- and Dinuclear Hydridoirida-β-diketones – The Formation and Characterization of a Dinuclear Tris-μ-acyliridium(III) Complex

**Francisco Acha,[a] María A. Garralda,*[a] Ricardo Hernández,[a] Lourdes Ibarlucea,[a] Elena Pinilla,[b] M. Rosario Torres,[b] and Malkoa Zarandona[a]**

*Dedicated to Professor Victor Riera on the occasion of his retirement*

**Keywords:** Iridium / Hydride ligands / Bridging ligands / P ligands

The hydridoirida-β-diketone [IrH{[$PPh_2$(*o*-$C_6H_4CO$)]$_2$H}Cl] (**1**) reacts with silver salts of potentially coordinating anions such as tosylate ($^-$OTs) or triflate ($^-$OTf) to afford the mononuclear neutral derivatives [IrH{[$PPh_2$(*o*-$C_6H_4CO$)]$_2$H}(X)] [X = OTs (**2**), OTf (**3**)]. In acetone solution the triflate anion in **3** is displaced by the solvent to afford the cationic complex [IrH{[$PPh_2$(*o*-$C_6H_4CO$)]$_2$H}(acetone)]OTf (**4**), which is stable only in acetone solution. The reaction of **1** with halide scavengers containing less coordinating anions such as $PF_6^-$ or $BF_4^-$ results in the formation of cationic compounds [{IrH[{$PPh_2$(*o*-$C_6H_4CO$)}$_2$H]}$_2$(μ-Cl)]A [A = $BF_4$ (**5**), $PF_6$ (**6**)] containing a dinuclear species with a single chlorine atom bridging two hydridoirida-β-diketone fragments. Both fragments are magnetically non-equivalent and the acylphosphane groups in each hydridoirida-β-diketone fragment are chemically equivalent. This species undergoes a fluxional process in solution, with $\Delta H^{\ddagger}$ = 7.8 ± 0.4 kcal mol$^{-1}$ and $\Delta S^{\ddagger}$ = –10.9 ± 0.5 eu. A combination of rotation around the Ir–Cl bonds and variation of the Ir–Cl–Ir angle is suggested to be responsible for the fluxionality. Complex **5** reacts further with $AgBF_4$ to undergo chloride abstraction along with hydrogen loss and deprotonation to give the cationic dinuclear complex [$Ir_2$H{$PPh_2$(*o*-$C_6H_4CO$)}{μ-$PPh_2$(*o*-$C_6H_4CO$)}$_3$]$BF_4$ (**7**), which contains an acylphosphane chelate along with three acylphosphane bridging ligands and a single hydrido ligand. Bubbling of HCl through an MeOH solution of **7** gives **1**, thus making the loss of hydride, enolic protons and chloride from complex **1** a reversible process. All the complexes were fully characterized spectroscopically. Single-crystal X-ray diffraction analysis was performed on complexes **5** and **7**.

## Introduction

Metalla-β-diketones can be considered as enol tautomers of neutral β-diketones in which the methine group has been substituted by a transition metal organometallic moiety. Therefore, they may also be understood as acyl(hydroxycarbene) complexes that are stabilized by an intramolecular hydrogen bond between the acyl and the hydroxycarbene moiety (see Scheme 1). Hydroxycarbene complexes, for which a tautomeric equilibrium with the acyl hydrides has been reported,[1] have been proposed as important intermediates in CO reduction reactions[2] or in alkene hydrocarbonylation reactions to produce alcohols.[3] Metalla-β-diketones were synthesized for the first time by Lukehart et al. by the protonation of diacylmetalate anions [$L_x$M(COR)(COR′)]$^-$ (M = Mo, W, Mn, Re, Fe, Os).[4] Rhena-β-diketones can be deprotonated by transition metal complexes containing basic ligands to give rhena-β-diketonate derivatives of $Cu^{II}$, $Fe^{II}$, $Cr^{III}$ and $Zn^{II}$.[5] More recently, Steinborn et al. have reported mono- and dinuclear platina-β-diketones obtained by the reaction of hexachloroplatinic acid with alkynes or by the reaction of diacylhydridoplatinum(IV) complexes with $TlPF_6$.[6] Partial deprotonation of the dinuclear derivatives with amines affords platina-β-diketonates of platina-β-diketones.[7] The reaction of [Ir(Cl)(H)-{$PPh_2$(*o*-$C_6H_4CO$)}(cod)] (cod = 1,5-cyclooctadiene) with $PPh_2$(*o*-$C_6H_4CHO$) in protic solvents has allowed the preparation of the first hydridoirida-β-diketone [IrH{[$PPh_2$(*o*-$C_6H_4CO$)]$_2$H}Cl].[8] Cationic mononuclear hydridoirida-β-

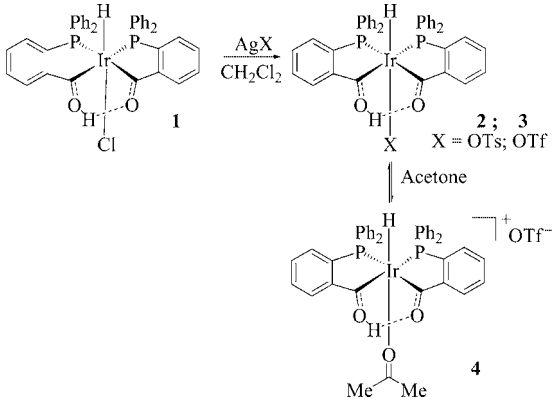
diketones $[IrH\{[PPh_2(o\text{-}C_6H_4CO)]_2H\}(L)]^+$ may undergo reversible deprotonation/protonation reactions, and their reaction with amines affords neutral diacylhydridoiridium(III) derivatives.[9]

We report now on the preparation of new hydridoirida-β-diketones, including novel dinuclear species, and on the deprotonation of the latter to afford a dinuclear tris-μ-acyliridium(III) complex.

## Results and Discussion

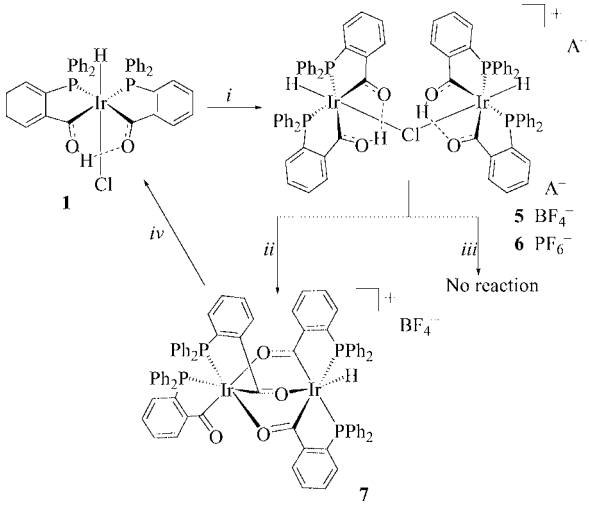
The hydridoirida-β-diketone $[IrH\{[PPh_2(o\text{-}C_6H_4CO)]_2H\}Cl]$ (**1**) reacts with silver salts of potentially coordinating anions such as tosylate ($^-$OTs) or triflate ($^-$OTf) to afford the neutral complexes $[IrH\{[PPh_2(o\text{-}C_6H_4CO)]_2H\}(X)]$ [X = OTs (**2**), OTf (**3**)] with loss of AgCl, as shown in Scheme 2. The IR spectrum of **3** indicates the presence of the coordinated triflate anion, as shown by the presence of a ν(SO) absorption at 1317 cm$^{-1}$, which is shifted to higher wavenumbers with respect to the free anion (1270 cm$^{-1}$) upon coordination, as expected.[10] The IR spectrum of **2** contains a ν(SO) absorption at 1259 cm$^{-1}$, which is also shifted towards higher wavenumbers with respect to the silver tosylate (1205 cm$^{-1}$).[11] The FAB mass spectra show the corresponding $[M - X]^+$ peak, as expected for mononuclear complexes. Both the ν(Ir–H) absorptions (2224 cm$^{-1}$ for **2** and 2264 cm$^{-1}$ for **3**) at rather high wavenumber and the hydride resonances ($\delta$ = –24.24 ppm for **2** and –25.89 ppm for **3**) at rather high field are in accordance with a hydrido ligand being *trans* to the bonded oxygen atom of the anion.[8] The σ-donor strength of O-coordinated anions is among the smallest and this is reflected in the *trans* effect.[12] The NMR spectroscopic data for both **2** and **3** indicate the presence of two equivalent acylphosphane fragments. The $^{31}P\{^1H\}$ NMR spectra show singlets at $\delta \approx 30$ ppm and the $^{13}C\{^1H\}$ NMR spectrum of **2** shows a doublet at $\delta$ = 256.9 ppm, in the range expected for irida-β-diketones with acyl(hydroxycarbene) character, with a large $J_{P,C}$ coupling constant of 102 Hz due to the acyl groups being *trans* to the phosphorus atoms. The $^1H$ NMR spectra show the hydride resonances as triplets due to a $J_{P,H}$ coupling of about 12 Hz, which agrees with the hydride being *cis* to both phosphane ligands, and sharp, low-field singlets at $\delta$ = 22.72 ppm for **2** and 22.69 ppm for **3**, which support the presence of fairly strong O···H···O hydrogen bonds and the existence of irida-β-diketones containing a formally tetradentate PCCP ligand.[8,9]

Complex **2** behaves as nonelectrolyte in acetone solution, whereas acetone solutions of **3** show conductivity values expected for 1:1 electrolytes.[13] This indicates that in acetone solution the tosylate group remains bonded to the iridium ion while the triflate anion is easily displaced by the solvent to afford the cationic complex $[IrH\{[PPh_2(o\text{-}C_6H_4CO)]_2H\}(acetone)]OTf$ (**4**), as shown in Scheme 2. To confirm this assumption, we recorded the NMR spectra of both complexes in [D$_6$]acetone solution. The $^1H$ NMR spectrum of **2** in [D$_6$]acetone is almost the same as that in $CDCl_3$, with the hydride resonance at $\delta$ = –24.03 (t, $J_{P,H}$ = 13.25 Hz) ppm, while the $^1H$ NMR spectrum of **3** shows two hydride resonances in a 6:1 ratio according to the integrals. The most abundant signal – that of the hydride at $\delta$ = –24.59 (t, $J_{P,H}$ = 12.80 Hz) ppm – is due to **4** and appears at lower field (ca. 1 ppm) than that of **3**, which appears at $\delta$ = –25.74 (t, $J_{P,H}$ = 13.25 Hz) ppm in $CDCl_3$. Attempts to obtain the acetone complex **4** proved unsuccessful and only resulted in the isolation of complex **3**.



Scheme 2.

The reaction of $[IrH\{[PPh_2(o\text{-}C_6H_4CO)]_2H\}Cl]$ (**1**) with halide scavengers containing noncoordinating anions such as $Et_3OPF_6$, $Et_3OBF_4$ or $AgBF_4$ and using Ir/scavenger ratios of 2:1 results in the abstraction of only one half of the chlorine atoms in the starting material and the formation of the compounds $[\{IrH[\{PPh_2(o\text{-}C_6H_4CO)\}_2H]\}_2(\mu\text{-}Cl)]A$ [A = $BF_4$ (**5**), $PF_6$ (**6**)], which contain a cationic dinuclear species with a single chlorine atom bridging two hydridoirida-β-diketone fragments (see *i* in Scheme 3). The spectroscopic data for the cation in compounds **5** and **6** are the same. Compounds **5** and **6** show a ν(Ir–H) absorption and a hydride resonance that agree with a hydride ligand being *trans* to a chlorine atom, and a sharp, low-field singlet at $\delta$ = 22.66 ppm that supports the presence of an O···H···O



Scheme 3. *i*: $AgBF_4$, $Et_3OBF_4$ or $Et_3OPF_6$ in $CH_2Cl_2$; *ii*: $AgBF_4$ in $CH_2Cl_2$; *iii*: $Et_3OBF_4$ or $Et_3OPF_6$ in $CH_2Cl_2$; *iv*: HCl in MeOH.

fragment. They behave as 1:1 electrolytes in acetone solution and the FAB spectrum of **6** shows the $[M]^+$ peak at $m/z$ = 1581, as expected for such a dinuclear species.

In order to ascertain the structure shown in Scheme 3, a single-crystal X-ray diffraction study of compound **5** was undertaken. Selected bond lengths and angles, including the enolic hydrogen bond, are listed in Table 1. The crystal structure consists of discrete, cationic dinuclear units formed by pseudo-octahedral Ir moieties sharing the position occupied by the chloro ligand and $BF_4^-$ anions. An ORTEP view of the cation is given in Figure 1. Both bridging Ir–Cl distances in **5** are equal within experimental error and are, as expected, significantly longer [2.539(3) Å] than the terminal Ir–Cl distance in **1** [2.485(3) Å].[8] As far as we are aware, there is only one precedent of a dinuclear iridium complex containing a single chlorine bridge, which is *trans* to an $SiR_2R'$ group.[14] The Ir–Cl distances in **5** are shorter than those found in this previously reported complex and this difference may reflect the expected stronger structural *trans* influence of $SiR_3$ groups than of hydrido ligands.[15] The coordination around both Ir atoms is pseudo-octahedral with distortions of the type usually observed in hydrido complexes (maximal deviation from ideal angles of 19° and 16° for Ir1 and Ir2, respectively). The Ir1–Ir2 distance (4.609 Å) and the Ir1–Cl1–Ir2 angle [130.3(1)°] exclude any Ir–Ir interaction. This angle is similar to those reported for related octahedral rhodium [138.15(7)°] or molybdenum [134.0(1)°] complexes containing a single chlorine bridge between two metal atoms.[16] The best least-squares equatorial planes (P1, P2, C20, C1) and (P3, P4, C39, C58) of the Ir atoms form a dihedral angle of 54.1(2)°, in accordance with the Ir1–Cl1–Ir2 angle. There are some differences between both moieties. For example, the average Ir–P distances are slightly longer [by 0.023(3) Å] in the Ir1 moiety and the relative disposition of the pseudo-octahedra is eclipsed with a slight torsion angle of 26.71°. These facts mean a breaking of the $C_2$ symmetry around the chlorine atom for the whole structure and the twofold axis is only

kept for the Ir cores. The C=O distances, which are in the range 1.27–1.31 Å, are similar to those found in monomeric irida-β-diketones. The O···O distances and O–H–O angles are in accordance with a strong enolic character for the hydrogen bond and agree with those reported for other irida-β-diketones.[8,9]

In keeping with the crystal structure, the $^{31}P\{^1H\}$ NMR spectra of **5** and **6** show two singlets at $\delta$ = 30.7 and 18.3 ppm, respectively, at 203 K, and in the $^{13}C\{^1H\}$ NMR spectra two doublets at $\delta$ = 257.6 ($J_{P,C}$ = 101 Hz) and 255.6 ppm ($J_{P,C}$ = 103 Hz) are observed. The $^1H$ NMR spectra contain a triplet at $\delta$ = –23.17 ($J_{P,H}$ = 14.6) ppm and a singlet at $\delta$ = 22.66 ppm. Such a pattern is consistent with the nonequivalence of the hydridoirida-β-diketone fragments connected through the chlorine bridge, the equivalence of the acylphosphane groups in each hydridoirida-β-diketone fragment, and the NMR parameters of the hydride ions and of the enolic protons of both fragments being equal. Inspection of the $^{31}P\{^1H\}$ NMR spectra at various temperatures shows that on raising the temperature the singlets broaden and coalesce at 253 K, giving rise to a broad resonance centered at $\delta$ = 25 ppm at room temperature (see Figure 2). On the other hand, at room temperature the $^{13}C\{^1H\}$ NMR spectra show only a doublet at $\delta$ = 256.5 ($J_{P,C}$ = 101 Hz) ppm due to the bonded acyl groups. The $^1H$ NMR spectra remain unaltered in the whole temperature range. From line-shape analysis[17] of the variable-temperature $^{31}P\{^1H\}$ NMR spectra of complex **5**, the activation parameters $\Delta H^{\ddagger}$ = 7.8 ± 0.4 kcal mol$^{-1}$ and $\Delta S^{\ddagger}$ = –10.9 ± 0.5 cal K$^{-1}$ mol$^{-1}$ have been determined. The entropy of activation is indicative of an intramolecular rearrangement process.[18] A combination of rotation around the Ir–Cl bonds, which is restricted at low temperatures due to the presence of the phenyl groups, and variation of the Ir–Cl–Ir angle may account for the observed fluxional behavior.

Complex **5** reacts further with $AgBF_4$ to give complex **7**, which contains three acylphosphane bridging groups (see *ii* in Scheme 3). Compound **7** shows an IR stretch at 1628 cm$^{-1}$ due to the terminal acyl group and a strong stretch at 1525 cm$^{-1}$ assigned to the bridging acyl groups. It behaves as 1:1 electrolyte in acetone solution and the FAB spectrum shows the $[M]^+$ peak at $m/z$ = 1543, as expected for such a dinuclear species. At 223 K, the NMR spectra of **7** are consistent with the structure shown in Scheme 3. The $^1H$ NMR spectrum shows only one resonance at high field ($\delta$ = –23.24 ppm) as a doublet of doublets, with a $J_{P,H}$ coupling of about 18 Hz, due to the presence of one hydrido ligand *cis* to two nonequivalent phosphorus atoms. The formation of three bridging acyl groups breaks the equivalence of the acylphosphane fragments present in the starting material **5**. The $^{31}P\{^1H\}$ NMR spectrum consists of two sets of doublets due to the presence of four nonequivalent acylphosphane fragments, two per iridium atom, and the $J_{P,P}$ coupling constants agree with both phosphorus atoms bonded to the same iridium atom being mutually *cis*. The $^{13}C\{^1H\}$ NMR spectrum contains a singlet at $\delta$ = 209.1 ppm due to the terminal acyl group and three resonances at $\delta$ = 266.5 (d), 264.8 (d), and 257.5 (d) ppm,

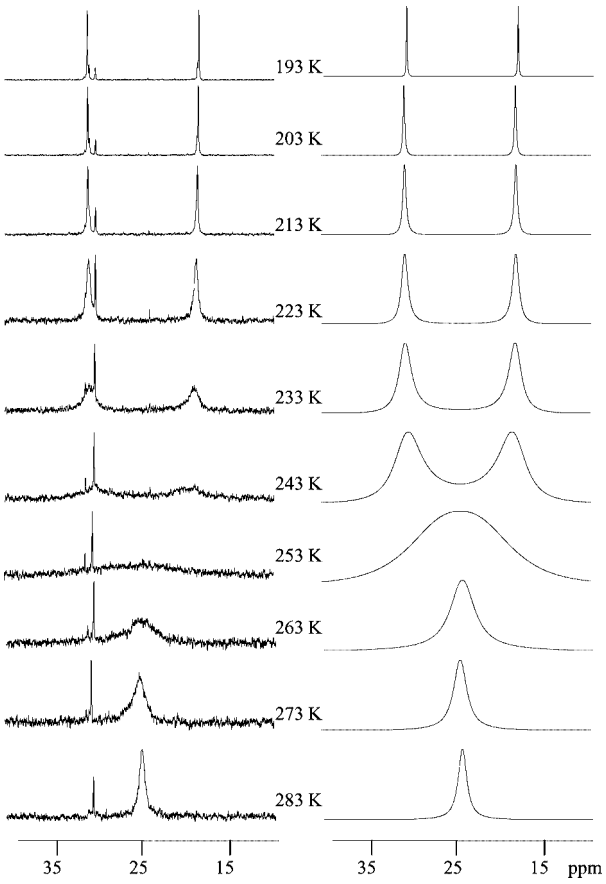

Figure 2. Variable-temperature $^{31}P\{^1H\}$ NMR spectra of **5**; experimental in $CD_2Cl_2$ (left) and calculated (right).

respectively, with high $J_{P,C}$ coupling constants of about 95 Hz, due to three acyl groups *trans* to phosphorus atoms. The rather low field of the latter suggests the bridging nature and significant carbene-like character for all three acyl groups.[19–21] Inspection of the NMR spectra at variable temperature shows that on raising the temperature the doublet of doublets due to the hydrido ligand collapses into a triplet at $\delta$ = –23.23 ($J_{P,H}$ = 18.3 Hz) ppm. The $^{31}P\{^1H\}$ resonances at lower field ($\delta$ = 23 and 21 ppm) show a marked chemical shift temperature dependence such that $\Delta\delta$ decreases as the temperature increases and the AX system observed at low temperature becomes an AB system centered at $\delta$ = 22.3 ppm. The two chemical shifts coincide at room temperature, and above this temperature they exchange position. This behavior has also been reported for monomeric $Ir^{III}$ complexes.[22] Over the whole temperature range, the corresponding $J_{P,P}$ value, the $^{31}P\{^1H\}$ resonances at higher field, and the $^{13}C\{^1H\}$ resonances remain unchanged. A $\{^1H,^{31}P\}$ HSQC experiment at room temperature shows that the hydrido ligand is coupled to the $^{31}P$ AB system at $\delta$ = 22 ppm.

Acyl groups are well known as bridging ligands towards transition metals, although their behavior as such in iridium homodinuclear complexes is scarce,[21] and the acylphosphane chelating ligand *o*-$PPh_2(C_6H_4CO)$ has been reported to behave as a bridging acyl group only in ruthenium or

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

osmium clusters.[23] We have succeeded in isolating complex **7** as single crystals suitable for X-ray diffraction. To the best of our knowledge no structural report on dinuclear transition metal complexes with three bridging acyl groups has been published, although a crystallographic study of a triacetylrhenate complex of boron has been reported.[24] The crystal structure of **7** shows the presence of dinuclear cations and $BF_4^-$ anions packed within normal van der Waals interaction distances. Two crystallographically independent cations and anions were identified in the structural determination, namely A and B. No significant differences are observed in the molecular geometries of both. Selected bond lengths and angles are listed in Table 2, and Figure 3 shows a molecular drawing of the cation A. The dinuclear cation consists of two pseudo-octahedral iridium(III) moieties, assuming that the hydrido ligand occupies the sixth coordination site on Ir1A, with three bridging acyl groups. Two of the corresponding carbon atoms are bonded to the iridium atom coordinated to the hydrido ligand such that the coordination around Ir1 is similar to that of the parent hydridoirida-β-diketone **5**. The hydrido ligand is *trans* to the oxygen atom in **7** instead of to the chlorine atom in **5** and the two oxygen atoms are bonded to the iridium atom in **7** instead of to a proton in **5**. Ir2 is bonded to two oxygen atoms and one carbon atom of the bridging acyl groups and six-coordination is attained with two phosphane groups and one terminal acyl group. The Ir–P distances in the Ir1A moiety and the Ir2A–P3A distance are equivalent [average of 2.354(4) Å] and longer than the Ir2A–P4A distance of 2.242(4) Å as a consequence of the weaker structural *trans* influence of the oxygen atom *trans* to P4 than that of an acyl carbon atom *trans* to P1, P2, and P3. The Ir–O distances [2.23(1), 2.19(1), and 2.12(1) Å for Ir1A–O4A, Ir2A–O1A, and Ir2A–O2A, respectively] reflect the *trans* influence being strongest for the hydrido ligand, similar or slightly weaker for the acyl carbon atom, and weaker for the phosphorus atom. Bridging acyl groups can be described by acyl↔oxycarbene resonance structures and this is reflected by shorter M–C and longer C–O bond lengths than in terminal acyl ligands.[19–21] In spite of the oxycarbene character of the bridging acyl groups suggested by $^{13}C$ NMR spectroscopy, the Ir–C and C–O distances for the bridging groups in complex **7** [average of 2.03(2) and 1.23(2) Å, respectively] are similar to the Ir2A–C39A [1.97(2) Å] and the C39A–O3A [1.26(2) Å] distances of the terminal acyl ligand. These fea-

tures may be related to the fact that the terminal acyl ligand is *trans* to the oxygen atom, which has a weak *trans* influence, while the carbon atoms of the bridging ligands are *trans* to the phosphorus atoms, and/or to the acyl resonance structure being a stronger contributor than the oxycarbene resonance structure to the ground-state structure, as suggested for related iridium(III) complexes.[22]

The reaction of **5** with $AgBF_4$ to give **7** is a complex transformation and its mechanism is not yet totally clear. Complex **5** contains two hydrido ligands and also two enolic protons along with a chlorine atom, while complex **7** contains only one hydrido ligand; this means release of one Cl and three H atoms. Attempts to abstract the chloride ion from complexes **5** or **6** by using $Et_3OBF_4$ or $Et_3OPF_6$ proved unsuccessful (see *iii* in Scheme 3) and this indicates that the silver salt promotes a reaction path that is not available for other halide scavengers. It is known that metathesis reactions of silver salts may lead to the formation of different adducts that can involve silver coordination to the iridium atom,[25] or formation of a halide bridge between both metal atoms.[26] In our case, replacement of the enolic protons by silver ions, similar to that observed in pyrazolyliridium complexes,[27] can also be considered. Cationic acyl(hydroxycarbene)platinum(II) complexes can be obtained by the reaction of diacylhalohydridoplatinum(IV) complexes with $TlPF_6$ and may involve an intermolecular deprotonation/protonation reaction.[28] We believe that the silver salt is responsible for the abstraction of the chloride ion and one proton, while evolution of $H_2$, formed by combination of one hydride ion and one proton, occurs.

Bubbling of HCl through an MeOH solution of **7** gives **1** (see *iv* in Scheme 3). This result shows that the loss of hydrido ligands, enolic protons, and chloride ions in complex **1** can be reversed; this observation has potential interest in studies directed toward catalytic ionic hydrogenation.[29]

## Conclusions

Neutral, mononuclear hydridoirida-β-diketones containing labile anions have been prepared that can be used to afford mononuclear, cationic hydridoirida-β-diketones. Fluxional, dinuclear, cationic hydridoirida-β-diketones containing a single chloride bridge can be obtained upon treatment with a halide abstractor. Silver salts may afford an asymmetric, dinuclear iridium complex with three acylphosphane bridging ligands. The starting material can be recovered by addition of HCl. The loss and recovery of hydride ions and protons could be relevant to studies of catalytic processes such as ionic hydrogenation.

## Experimental Section

**General Procedures:** The preparation of the metal complexes was carried out at room temperature under nitrogen by using standard Schlenk techniques. [IrH{[$PPh_2$(*o*-$C_6H_4CO$)]$_2$H}Cl] (**1**) was prepared as reported previously.[8] Microanalysis were carried out with a Leco CHNS-932 microanalyser. Conductivities were measured in acetone solution with a Metrohm 712 conductimeter. IR spectra were recorded with a Nicolet FTIR 510 spectrophotometer in the range 4000–400 $cm^{-1}$ using KBr pellets. NMR spectra were recorded with Bruker Avance DPX 300 or Bruker Avance 500 spectrometers. $^1H$ and $^{13}C\{^1H\}$ (TMS internal standard), $^{31}P\{^1H\}$ ($H_3PO_4$ external standard) and 2D spectra were measured for $CDCl_3$, $CD_2Cl_2$, or [$D_6$]acetone solutions. Mass spectra were recorded with a VG Autospec, by the liquid secondary ion (LSI) technique using nitrobenzyl alcohol as matrix and a cesium gun (Universidad de Zaragoza).

**Preparation of [IrH{[$PPh_2$(*o*-$C_6H_4CO$)]$_2$H}(OTs)] (2):** AgOTs (42 mg, 0.150 mmol) was added to a dichloromethane solution of **1** (60 mg, 0.075 mmol). After stirring for 24 h, the silver salts were filtered off. Addition of diethyl ether to the solution gave a yellow precipitate, which was filtered off, washed with diethyl ether, and vacuum-dried (yield: 50 mg, 70%). IR (KBr): $\tilde{\nu}$ = 2224 (w) [ν(IrH)], 1632(s) [ν(C=O)], 1259(s) [ν(SO)] $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = –24.24 (t, $J_{P,H}$ = 12.24 Hz, 1 H, HIr), 2.19 (s, 3 H, $CH_3$), 22.72 (s, 1 H, OHO) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 256.9 (d, $J_{P,C}$ = 102 Hz, CO), 21.2 (s, $CH_3$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 29.9 (s) ppm. FAB MS: calcd. for $C_{45}H_{37}IrO_5P_2S$ 944, found 773 [M – OTs]$^+$. $C_{45}H_{37}IrO_5P_2S{\cdot}0.25CH_2Cl_2$ (965.25): calcd. C 56.31, H 3.92, S 3.32; found C 56.18, H 3.89, S 3.44.

**Preparation of [IrH{[$PPh_2$(*o*-$C_6H_4CO$)]$_2$H}(OTf)] (3):** AgOTf (38 mg, 0.150 mmol) was added to a dichloromethane solution of **1** (60 mg, 0.075 mmol). After stirring for 30 min, the silver salts were filtered off. Addition of diethyl ether to the solution gave a yellow precipitate, which was filtered off, washed with diethyl ether, and vacuum-dried (yield: 47 mg, 68%). IR (KBr): $\tilde{\nu}$ = 2264 (w) [ν(IrH)], 1628 (s) [ν(C=O)], 1317 (s) [ν(SO)] $cm^{-1}$. $\Lambda_M$ = 116 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = –25.89 (t, $J_{P,H}$ = 12.86 Hz, 1 H, HIr), 22.69 (s, 1 H, OHO) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 31.21 (s) ppm. FAB MS: calcd. for $C_{39}H_{30}F_3IrO_5P_2S$ 922; found 773 [M – OTf]$^+$. $C_{39}H_{30}F_3IrO_5P_2S$ (921.89): calcd. C 50.81, H 3.28, S 3.48; found C 50.74, H 3.57, S 3.45.

**Preparation of [{IrH[{$PPh_2$(*o*-$C_6H_4CO$)}$_2$H]}$_2$(μ-Cl)]A [A = $BF_4$ (5), $PF_6$ (6)]:** $Et_3OPF_6$ (9.42 mg, 0.038 mmol) or $Et_3OBF_4$ (7.22 mg, 0.038 mmol) was added to a dichloromethane solution of **1** (60 mg, 0.075 mmol). After stirring for 60 min, addition of diethyl ether to the solution gave a yellow precipitate, which was filtered off, washed with diethyl ether, and vacuum-dried. IR (KBr): $\tilde{\nu}$ = 2221 (m) [ν(IrH)], 1629 (s) [ν(C=O)] $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 203 K): $\delta$ = –23.17 (t, $J_{P,H}$ = 14.2 Hz, 1 H, HIr), 22.66 (s, 1 H, OHO) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 203 K): $\delta$ = 257.6 (d, $J_{P,C}$ = 101 Hz, CO), 255.6 (d, $J_{P,C}$ = 103 Hz, CO) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$, 203 K): $\delta$ = 30.7 (s), 18.3 (s) ppm. FAB MS: calcd. for $C_{76}H_{60}ClO_4P_4Ir_2$ 1581; found 1581 [M]$^+$. **Data for 5:** Yield: 42 mg (68%). $\Lambda_M$ = 147 $\Omega^{-1}cm^2mol^{-1}$. $C_{76}H_{60}BClF_4Ir_2O_4P_4$ (1667.9): calcd. C 54.73, H 3.63; found C 54.61, H 3.57. **Data for 6:** Yield: 48 mg (73%). $\Lambda_M$ = 179 $\Omega^{-1}cm^2mol^{-1}$. $C_{76}H_{60}ClF_6Ir_2O_4P_5{\cdot}0.5CH_2Cl_2$ (1768.5): calcd. C 51.96, H 3.48; found C 52.03, H 3.23.

**Preparation of [$Ir_2$H{$PPh_2$(*o*-$C_6H_4CO$)}{μ-$PPh_2$(*o*-$C_6H_4CO$)}$_3$]$BF_4$ (7):** To a dichloromethane solution of **5** (125 mg, 0.075 mmol) was added $AgBF_4$ (29.1 mg, 0.15 mmol). After stirring for 30 min, the silver salts were filtered. Addition of diethyl ether to the solution gave a yellow precipitate that was filtered off, washed with diethyl ether and vacuum-dried (yield: 68 mg, 53%). IR (KBr): $\tilde{\nu}$ = 2189 (w), [ν(IrH)], 1628 (s), 1525 (s) [ν(C=O)] $cm^{-1}$. $\Lambda_M$ = 152 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR ($CDCl_3$, 223 K): $\delta$ = –23.24 (dd, $J_{P,H}$ = 19.2 and 18.3 Hz, 1 H, HIr) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 223 K): $\delta$ = 23.6 and 21.2 (d, $J_{P,P}$ = 12 Hz), 20.1 and 14.2 (d, $J_{P,P}$

**Reaction of $[Ir_2H\{PPh_2(o\text{-}C_6H_4CO)\}\{\mu\text{-}PPh_2(o\text{-}C_6H_4CO)\}_3]BF_4$ (7) with HCl:** HCl gas was bubbled at room temperature through a methanol solution of **7** (30 mg, 0.018 mmol) for 30 min, upon which a small amount of precipitate was formed. The solvent was evaporated and the residue analyzed by NMR spectroscopy. According to the spectra, the solid contained mainly complex **1**.

**X-ray Structure Determination of 5 and 7:** Yellow prismatic single crystals of **5** and needles of **7** suitable for X-ray diffraction were successfully grown by slow diffusion of diethyl ether into dichloromethane or methanol solutions, respectively. Data collection was carried out at room temperature on a Bruker Smart CCD diffractometer, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), operating at 50 kV and 20 mA. In both cases, data were collected over a hemisphere of the reciprocal space by combination of three exposure sets. Each exposure of 10 s covered 0.3° in $\omega$. The first 100 frames were recollected at the end of the data collection to monitor crystal decay after X-ray exposition; no appreciable drop in the intensities was observed. A summary of the fundamental crystal data for the crystals is given in Table 3. The structures were solved by direct methods and conventional Fourier techniques. The refinement was done by full-matrix least squares on $F^2$ for **5** and by blocked full-matrix least squares on $F^2$ for **7**.[30] Anisotropic parameters were used in the last cycles of refinement for all non-H atoms, with some exceptions. The $BF_4^-$ anions in both compounds were refined by three isotropic cycles and in subsequent cycles their thermal parameters were kept constant while their coordinates were refined with geometric restraints and a variable common B–F distance. For **7**, the carbon atoms of some phenyl rings were refined isotropically. After the last cycles of refinement, the Fourier difference of **5** showed some residual electronic density. This was assigned to one half solvent $CH_2Cl_2$. The carbon and chlorine atoms were treated like the $BF_4^-$ anions, i.e. three isotropic cycles and geometrical restraints. All hydrogen atoms were calculated at geometrical positions and refined as riding on their respective carbon atoms, except the hydride atoms (H1A, H1B) and the enolic hydrogen atoms (H2A, H2B) for **5**, which were found in a difference Fourier synthesis and their coordinates and thermal parameters fixed. For **7**, it was impossible to locate the hydride ions. These features led to $R1$ factors of 0.0585 (6212 reflections observed) and 0.0553 (8848 reflections observed) for **5** and **7**, respectively. The largest residual peaks in the final difference map (1.54 and 1.62 e Å$^{-3}$, respectively) were found in the vicinity of the fluorine atoms of the $BF_4^-$ groups in both compounds. CCDC-606708 (**5**) and -606709 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/datarequest/cif.

# Tetra- and Triphosphane Pyridine Podands and Their Cobalt(II) and Nickel(II) Complexes

**Stephan W. Kohl,[a] Frank W. Heinemann,[b] Markus Hummert,[a] Hardy Weißhoff,[c] and Andreas Grohmann*[a]**

*Dedicated to Professor Robert Weiß on the occasion of his 65th birthday*

**Keywords:** Cobalt / Nickel / N,P ligands

The reaction of the 2,6-diethylpyridine-derived tetraphosphane ligand $C_5H_3N[CMe(CH_2PMe_2)_2]_2$ (**1**$_{Me}$) with nickel(II) or cobalt(II) perchlorate or tetrafluoroborate in methanol produces complexes of approximate square-pyramidal geometry ($NP_4$ coordination). The nickel complexes are diamagnetic, with NMR spectral features ($^{31}P$) that reflect a tetrahedral distortion of diametrically opposite phosphorus donors; this is also found in the solid state. In terms of bond lengths and angles, all complexes differ significantly from their analogues containing the phenyl-substituted ligand $C_5H_3N[CMe(CH_2PPh_2)_2]_2$. The ligand **1**$_{Me}$ is readily and completely oxidised to the corresponding tetrakis(phosphane oxide) upon reaction with NO. Slow oxidation of the cobalt(II) tetrafluoroborate complex of **1**$_{Me}$ with aerobic oxygen in acetonitrile produces a trinuclear cobalt complex containing two equivalents of partially oxidised ligand ($C_2$-symmetrical; donor set: $[PMe_2]_2[P(O)Me_2]_2$). Four phosphane oxide oxygen atoms coordinate the central cobalt(II) ion in tetrahedral fashion, whereas the lateral cobalt(II) ions are in a square-pyramidal environment provided by two $PMe_2$ donors and three acetonitrile ligands in each case. The reaction of the cobalt(II) perchlorate complex of **1**$_{Me}$ with carbon monoxide gives an octahedral, 19-valence-electron dicarbonyl complex in which one of the dimethylphosphanyl groups is uncoordinated. A structural relative of **1**$_{Me}$, $C_5H_3N[CMe(CH_2PMe_2)_2][CMe_2(CH_2PMe_2)]$ (**2**), which contains one fewer dimethylphosphanyl donor, can be prepared in a straightforward manner from 2-ethyl-6-isopropylpyridine in a four-stage process. In a series of mononuclear nickel(II) complexes, **2** employs only its three phosphane donors which, together with a monodentate ligand (acetonitrile, acetamide, or bromide), provide a tetragonal coordination environment for the metal ion which is intermediate between square planar and tetrahedral. The acetamide complex is generated from the acetonitrile complex by slow hydrolysis of the coordinated ligand. Full spectroscopic details for the complexes, as well as X-ray structure analyses, are reported.

## Introduction

Phosphanes are the workhorse ligands of transition metal chemistry due to their variability in terms of steric demand and electronic properties. Both factors, which are mutually dependent, may be controlled within wide limits, depending on the bulk of substituents and the σ-donor/π-acceptor balance they impart to the donor atom. The major application of phosphane complexes is in catalysis, where the phosphane-coordinated metal ion is the mediator of the desired reaction.[1] It is mainly for the mechanistic implications in catalysis that the reactivity, or lack thereof, of coordinated tertiary phosphanes themselves (e.g., metallation of C–H or C–P bonds) has become a focus of investigation.[2]

Within this context, we have extended our study of tetrapodal pentadentate ligands[3] to include tetraphosphane pyridine ligands (general formula: **1**). We are especially interested in *mono*nuclear complexes of these ligands in which the "coordination cap" focuses the properties of several $PR_2$ donors on a single metal ion M. Such coordination modules can bind an additional monodentate ligand, L, to form complexes of pseudo-octahedral geometry. Previous reports have described the diphenylphosphanyl derivative **1**$_{Ph}$, whose steric bulk causes the metal centres to be largely inert with respect to further coordination (e.g., $M = Co^{II}$, $L = O_2$),[4] and iron(II) complexes of the dimethylphosphanyl derivative (**1**$_{Me}$), which undergo unusual P–C bond breaking and re-forming reactions, depending on the nature of

the solvent (nucleophilic/non-nucleophilic), the anion, and other conditions.[5] The present contribution summarises coordination chemistry aspects of this ligand with respect to nickel(II) and cobalt(II), and introduces a structural relative having only three $PMe_2$-substituted "tentacles" (**2**).

## Results and Discussion

The tetraphosphane $\mathbf{1}_{Me}$ {systematic name: 2,6-bis[1,3-bis(dimethylphosphanyl)-2-methylpropan-2-yl]pyridine; "py($PMe_2$)$_4$"} may be prepared in good yield (>80%) from the reaction of the corresponding tetrabromide $C_5H_3N[CMe(CH_2Br)_2]_2$ (**3**)[4] with four equivalents of $LiPMe_2$[6] in diethyl ether.[5] The yield of this reaction increases considerably with the purity of the halogenated precursor. Whereas **3** had previously been obtained as an oil or waxy solid, which reflected the presence of minor impurities introduced during the multi-stage synthesis, we have recently been able to obtain **3** in its crystalline form. The compound crystallises solvent-free in the space group *Pbca*, with no crystallographically imposed molecular symmetry ($C_1$; Figure 1). One of the 1,3-dibromo-2-methylprop-2-yl chains (involving Br3, Br4) adopts a "*syn*-pentane arrangement", whereas the other has a more random orientation, also with respect to the pyridine ring. The bond distances and angles are unexceptional.[7]

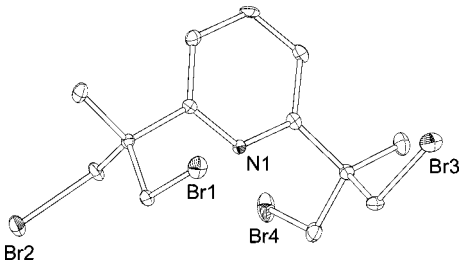

Figure 1. Structure of the tetrabromide **3**.

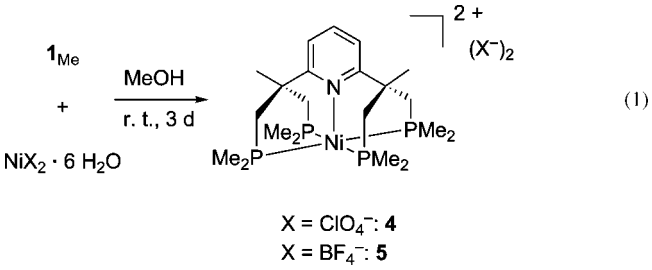
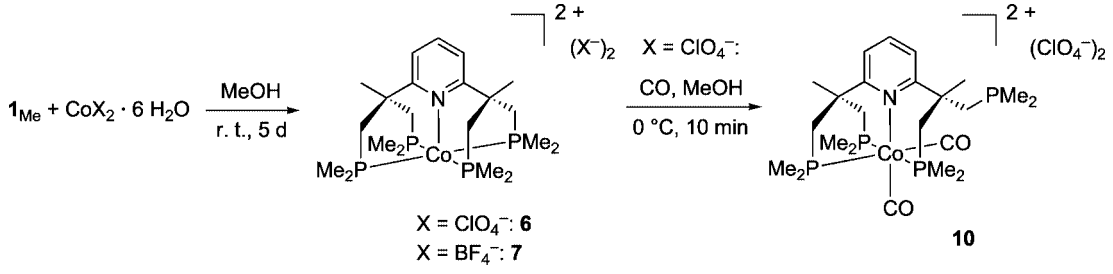
Compound $\mathbf{1}_{Me}$, which is obtained as a colourless oil, has the expected spectroscopic signature ($^1H$, $^{13}C$, $^{31}P$), suggesting $C_{2v}$ symmetry in solution. Upon mixing methanol solutions of equimolar amounts of $\mathbf{1}_{Me}$ and the hexahydrate salts of nickel(II) or cobalt(II) perchlorate or tetrafluoroborate at room temperature, complex formation is spontaneous, as judged by the immediate appearance of a deep red or brown colour. The reaction mixtures soon begin to deposit microcrystalline precipitates which, upon filtration and drying, analyse for the respective $LMX_2$ complexes [L = $\mathbf{1}_{Me}$, M = $Ni^{II}$, X = $ClO_4$ (**4**) or $BF_4$ (**5**); M = $Co^{II}$, X = $ClO_4$ (**6**) or $BF_4$ (**7**); see Equation (1), Scheme 1, and Exp. Sect.].



(1)

In the IR spectra of **4**–**7**, there is no indication for the coordination (if weak) of the perchlorate or tetrafluoroborate counterions, which would lead to a splitting of the respective anion bands owing to the reduction of local symmetry from $T_d$ to $C_{3v}$.[8] The nickel complexes **4** and **5** are diamagnetic, with well-resolved and very similar NMR spectra. In the $^1H$ NMR spectra, the pyridine protons appear as an $AB_2$ spin system (triplet/doublet), and in the $^{13}C$ spectra there are three signals for the pyridine carbon atoms. These features and others, taken together, suggest



Scheme 1. Preparation of the cobalt complexes **6** and **7**, and reaction of **6** with CO to form **10**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

largely symmetrical (i.e., to a first approximation, square pyramidal) coordination of the ligand. The proton-decoupled $^{31}P$ NMR spectra ([$D_3$]acetonitrile) contain two signals for the four ligand P atoms, at $\delta$ = –13 ppm and –15 ppm, thus indicating a tetragonal distortion of the basal ligands (two diametrically opposite P donor atoms above and two below the $NiP_4$ best plane) in solution. This structural feature persists in the solid state in both the nickel(II) and the cobalt(II) complex. Figures 2 and 3 show the crystal structures of the cations in **4**·$CHCl_3$ and **7**·MeOH, respectively (the cation structure of **5**·MeOH is very similar; see deposited crystallographic data).

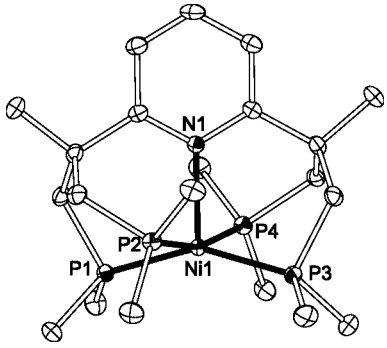


Figure 2. Structure of the dication in the nickel(II) complex **4**·$CHCl_3$ (perchlorate salt).

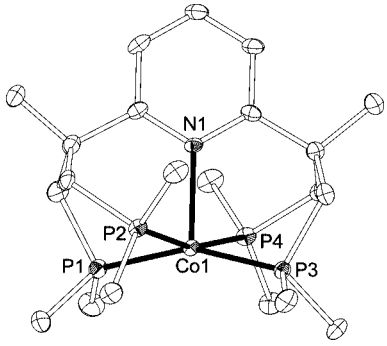

Figure 3. Structure of the dication in the cobalt(II) complex **7**·MeOH (tetrafluoroborate salt).

The bond lengths (see Table 1) involving the central ions in **4** and **7** are markedly shorter than in the structures of the phenyl-substituted ligand $\mathbf{1}_{Ph}$.[4] Whereas the metal–nitrogen distance is approximately 2.13 Å in both **4** and **7**, it is 2.28 and 2.19 Å in the nickel(II) and cobalt(II) complexes of $\mathbf{1}_{Ph}$, respectively, and whereas the metal–phosphorus distances in **4** and **7** vary around 2.20 Å within a relatively narrow range, the range is much wider (2.23–2.33 Å) in the corresponding complexes of $\mathbf{1}_{Ph}$. The N–M–P and P–M–P angles of the two sets of complexes vary accordingly. These differences reflect the considerable decrease in steric bulk of the ligand periphery upon going from $\mathbf{1}_{Ph}$ to $\mathbf{1}_{Me}$.

Table 1. Selected bond distances [Å] and angles [°] in **4**·$CHCl_3$ and **7**·MeOH (standard deviations in parentheses). The structural parameters of **5**·MeOH are very similar (see CCDC data).

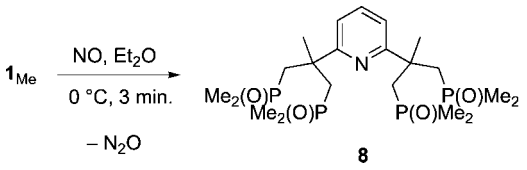
| P2–M1–P3 | 94.58(5) | 93.31(6) |
| P3–M1–P4 | 89.26(5) | 89.72(6) |
| P4–M1–P1 | 94.30(5) | 94.84(6) |
| P1–M1–P3 | 150.94(5) | 156.62(6) |
| P2–M1–P4 | 164.57(6) | 163.31(6) |

Steric factors, in addition to electronic ones, can also be expected to play a major role in determining the readiness with which the polyphosphane is oxidised. Whereas $\mathbf{1}_{Ph}$ does not react with nitrogen monoxide at 0 °C,[4] the reaction of $\mathbf{1}_{Me}$ under the same conditions is quantitative after a few minutes, giving the tetrakis(phosphane oxide) **8** as a white microcrystalline material [Equation (2)]. Similar to the reaction of $\mathbf{1}_{Ph}$ under more forcing conditions, the reaction proceeds with concomitant formation of $N_2O$. The P=O stretching vibration appears as a strong band in the IR spectrum (KBr disc) at 1161 $cm^{-1}$, and the $^{31}P$ chemical shift of the $RP(O)Me_2$ functions is $\delta$ = 44.95 ppm (s), similar to the values reported for $P(O)Me_3$ ($\delta$ =36.2 or 41.0 ppm).[9] The ligand properties of **8** are as yet unstudied. No oxidation of the ligand is observed when the nickel(II) complexes **4** or **5** are treated with NO under identical conditions.



(2)

Whereas the cobalt(II) complexes $[\mathbf{1}_{Ph}Co]X_2$ (X = $ClO_4$, $BF_4$) were found to be unreactive towards aerobic oxygen,[4] preliminary results indicate that the methyl derivative $[\mathbf{1}_{Me}Co](BF_4)_2$ (**7**) does react to a minor extent, albeit with partial oxidation of the ligand and not with spontaneous formation of cobalt(III), as might initially be expected. While the processes involved require further study, we have been able to isolate (in very small amount) and characterise one oxidation product (**9**) structurally: it is the acetonitrile solvate of a trinuclear complex in which two symmetry-related molecular halves, each made up of a cobalt(II) ion and a partially oxidised ligand, hinge upon a central cobalt ion which is also in the +II oxidation state (space group *C*2/*c*; the central cobalt ion lies on a crystallographic twofold rotation axis). The overall charge of the trinuclear complex

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

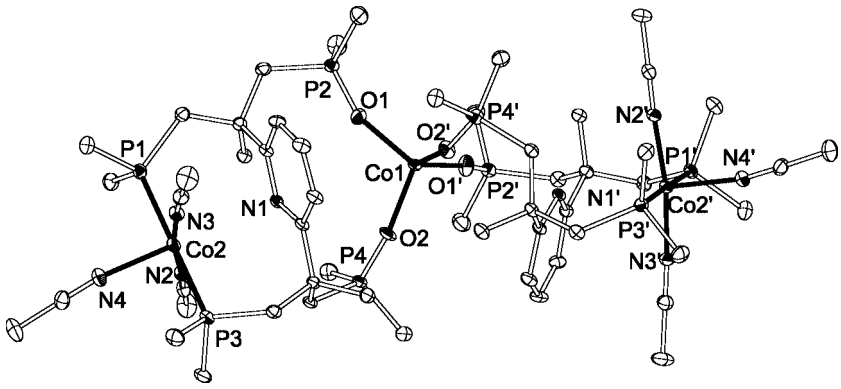


Figure 4. Structure of the hexacation in **9**·2$CH_3CN$ (tetrafluoroborate salt).

is balanced by six tetrafluoroborate anions [Figure 4, composition: $C_{54}H_{100}Co_3N_8O_4P_8(BF_4)_6$·2$CH_3CN$]. The donor set of the chelate ligand is $(PMe_2)_2(P[O]Me_2)_2$, with the pyridine nitrogen atom remaining uncoordinated. The pairs of $P[O]Me_2$ donors in either ligand coordinate the central cobalt ion in a tetrahedral fashion, while the remaining pair of $PMe_2$ donors in each ligand coordinates an additional cobalt ion in a *trans* arrangement. These lateral cobalt(II) ions have three additional acetonitrile ligands, and thus approximate a square-pyramidal coordination geometry, with Co–P bond lengths slightly longer (at 2.27 Å; Table 2) than in **7**. The 1,3-didentate ligand side-arms each contain one $PMe_2$ and one $P[O]Me_2$ donor and are homochiral, thereby reducing the symmetry from $C_{2v}$ in **1** to $C_2$ in the partially oxidised tetrapodal ligand (Figure 5). The formation of **9** parallels, to a certain extent, the partial oxidation of the triphos ligand, $MeC(CH_2PPh_2)_3$, upon reaction of its cobalt(II) complex with aerobic oxygen, as described by Huttner et al.[10]

The pentacoordinate cobalt(II) complexes are 17-valence-electron species, and the coordination of an additional ligand is therefore possible in principle. We studied the behaviour of methanol solutions of the perchlorate salt **6** towards carbon monoxide (see Exp. Sect.), and obtained a well-defined product which, by elemental analysis and based on its IR spectroscopic and MS data, is a dicarbonylcobalt(II) complex in which one phosphane donor has become decoordinated, as shown in Scheme 1. In addition to two very strong bands for CO stretching vibrations (at 1988 and 1937 $cm^{-1}$), there is a prominent band at 875 $cm^{-1}$ due to the P–C rocking deformation vibration of an uncoordinated dimethylphosphanyl group.[11] Further, the mass spectrum (MALDI-TOF) has three prominent peaks associated with the parent ion {546 (28) $[M - H]^+$, 430 (100) $[M - H - Co - 2CO]^+$, 273.5 (18) $[M]^{2+}$}, thus supporting the assignment of **10** as a 19-valence-electron, dicarbonylcobalt(II) complex of the pyridine-based tetraphosphane ligand. However, a 17-valence-electron species with an uncoordinated pyridine nitrogen atom is also possible.

There is a certain degree of similarity between the coordination mode adopted by the tetrapodal ligand in compound **10**, where it coordinates through an $NP_3$ donor subset, and the coordination mode adopted by a P–C bond

activated form of the same ligand in an iron(II) complex, where the donor set is likewise $NP_3$, augmented by a carbanionic methylene group which results from methanol-induced nucleophilic cleavage of one of the dimethylphosphanyl moieties.[5] For this reason, we decided to synthesise a structural relative (**2**) of the tetraphosphane ligand $\mathbf{1}_{Me}$, which can formally be derived from it by replacing one of the dimethylphosphanyl substituents by a hydrogen atom. The synthetic protocol is summarised in Scheme 2. It starts from 2-ethyl-6-isopropylpyridine, which is exhaustively hydroxymethylated in the reactive α-carbon positions by reaction with aqueous formaldehyde in an autoclave at elevated

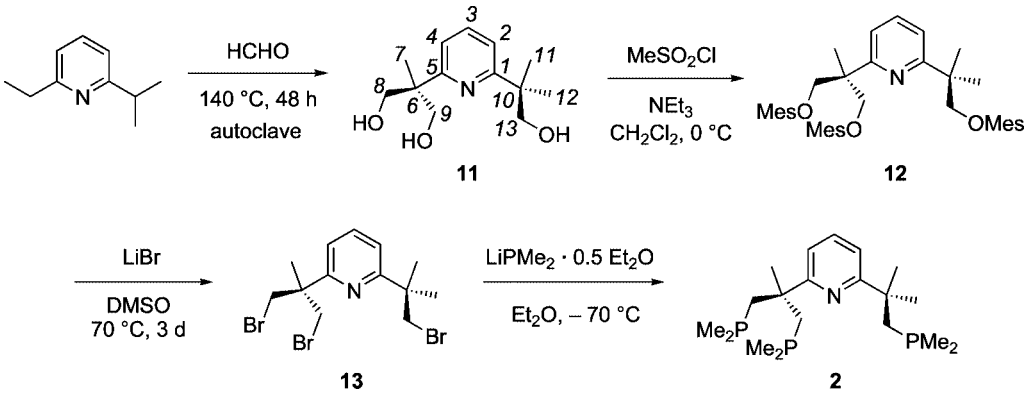

Scheme 2. Preparation of the tripodal tetradentate ligand **2**.

temperature. The trialcohol **11** is then successively transformed into the mesylate **12**, the bromide **13** and, upon treatment with lithium dimethylphosphide according to a procedure described by Karsch et al.,[6] into the triphosphane **2**. The intermediacy of the tribromide **13** is mandatory, as we found the mesylate, in a manner similar to the tosylated derivative, does not react cleanly with dimethylphosphide.

The reaction of **2** with $Ni(BF_4)_2{\cdot}6H_2O$ in anhydrous acetonitrile initially gives the $CH_3CN$-coordinated complex **14** (Scheme 3); when reaction mixtures are allowed to stand for several days, solvate water initiates hydrolysis of the coordinated, and hence activated, nitrile,[12] to give the acetamide complex **15**. Freshly prepared nitrile complex **14** is transformed into the bromo complex **16** upon treatment with lithium bromide in methanol (Scheme 3). In every one of the complexes **14**–**16**, the chelate ligand **2** is tridentate, with an uncoordinated pyridine nitrogen atom, and there is one additional monodentate ligand (acetonitrile, acetamide or bromide). The solid-state structures (Figures 6, 7 and 8, respectively) show the nickel ion in a coordination geometry intermediate between square planar and tetrahedral, with varying degrees of distortion. The following discussion applies to all three complexes, with complex **14** singled out for reference.

The exocyclic methyl substituents (**14**: C13, C14) are in different stereochemical environments, which makes the complex topologically chiral. It is diamagnetic in acetonitrile solution, as may be inferred from its fully assigned NMR spectra (see Exp. Sect. and Figure 6 for the numbering scheme used). Significantly, in solution at ambient temperature and on the NMR timescale, the cation has $C_s$ symmetry, as indicated by the equivalence of the phosphanyl substituents P1 and P2, the methyl groups C13/14 (radiating from the quaternary carbon atom C2) and the methyl substituents C11/12 on P3. We are currently investigating whether or not the implied stereochemical flexibility of the P3-substituted ligand arm can be "frozen" in solution by

forcing the pyridine nitrogen atom to coordinate to the central metal: this would cause the newly formed –N1–C3–C2–C1–P3–M– chelate ring to adopt a boat conformation, which would force either the methyl group C13 or the methyl group C14 into closer proximity to the metal and thus make C2 a stereogenic centre, as in structurally related iron(II) complexes.[5] The nickel–phosphorus bond lengths are within the normal range (Table 3), with the bond *trans* to the monodentate ligand being the shortest in each complex. This resembles the situation in a structurally related chloro complex of the phenyl-substituted tetrapodal ligand $\mathbf{1}_{Ph}$,[4] in which one phosphane arm, in addition to the pyridine nitrogen atom, is uncoordinated. The non-bonded distances between nickel(II) and the pyridine nitrogen atom are similar in complexes **14**–**16**, ranging from 2.9 to 3.1 Å (Table 3).

## Conclusions

Approximately square-pyramidal nickel(II) and cobalt(II) complexes are obtained with the pyridine-derived tetraphosphane ligand $C_5H_3N[CMe(CH_2PMe_2)_2]_2$ ($\mathbf{1}_{Me}$), its $NP_4$ donor set being fully employed in coordination. The formal replacement of one dimethylphosphanyl group in $\mathbf{1}_{Me}$ by a hydrogen atom gives the new ligand $C_5H_3N[CMe(CH_2PMe_2)_2][CMe_2(CH_2PMe_2)]$ (**2**) which, in a series of nickel(II) complexes, acts as a chelating triphosphane, with no involvement of the pyridine nitrogen atom in coordination. Instead, two ten-membered chelate rings are formed. This contrasts sharply with the situation in a series of iron(II) complexes,[5] where **2**, formed in situ by cleavage of one of the $PMe_2$ substituents in $\mathbf{1}_{Me}$, coordinates through its complete $NP_3$ donor set. This forces one of the $CMe_2$ methyl substituents into close proximity to the metal and allows it to act as an agostic two-electron donor.

## Experimental Section

***CAUTION!*** The perchlorate complexes **4** and **6** (and possibly also **10**) are explosive in the solid state. They explode when put under mechanical stress (e.g., upon tapping with a metal spatula). They are to be prepared in quantities not exceeding 150 mg, and the utmost care is to be exercised in their handling.

**Materials and Instrumentation:** Unless noted otherwise, all reactions were carried out at room temperature in dried solvents under dry dinitrogen, using standard Schlenk techniques. $\mathbf{1}_{Me}$ and **3** were

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

prepared as described in the literature.[5] $Co(BF_4)_2{\cdot}6H_2O$, $Co(ClO_4)_2{\cdot}6H_2O$, $Ni(BF_4)_2{\cdot}6H_2O$, and $Ni(ClO_4)_2{\cdot}6H_2O$ were purchased from Aldrich and used without further purification. Carbon monoxide (99.997%) and nitrogen monoxide (99.99%) were purchased from Air Liquide, and 2-ethyl-6-isopropylpyridine was purchased from Alfa Aesar. The IR spectra of solids were measured using KBr disks. IR spectra were assigned on the basis of literature data.[11] Spectroscopic data were obtained using the following instruments: IR spectroscopy: Nicolet Magna System 750; mass spectrometry: Varian 311A, Bruker Daltonics Esquire 3000+ and Voyager-DE Biospectrometry Workstation, PerSeptive Biosystems; NMR spectroscopy: Bruker ARX 200 and Bruker ARX 400. Signs of coupling constants in the $^1H$, $^{13}C$, $^{19}F$, and $^{31}P$ spectra were not determined. The atom numbering (superscripts) used for NMR assignments of compounds **2** and **11**–**13** follows the numbering scheme adopted for compound **11** (Scheme 2). The atom numbering (superscripts) used for NMR assignments of compounds **14** and **16** follows the labelling of the X-ray crystal structure of the compounds (Figures 6 and 8, respectively). Elemental analyses were carried out using a Thermo Finnigan, Flash EA, 1112 Series analyser.

**Preparation of 2:** A solution of **13** (1.2 g, 2.7 mmol) in diethyl ether (25 mL) was added from a dropping funnel over a period of 1 h at –70 °C to a suspension of $LiPMe_2{\cdot}0.5Et_2O$ (1.0 g, 9.5 mmol) in diethyl ether (20 mL). The mixture was warmed to room temperature overnight. The colour changed from brown to red, and all solid dissolved. After distilling off the solvent, the yellow residue was treated with pentane (25 mL) and filtered. The light-yellow solution was dried to yield a colourless oil (0.8 g, 83%). EI-MS (70 eV): *m/z* (%) 356 (100) $[M - CH_3]^+$. $^1H$ NMR (200 MHz, [D$_8$]-THF, 25 °C, TMS): $\delta$ = 7.53 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, *H*$^3$), 7.15 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, *H*$^2$), 7.13 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, *H*$^4$), 2.14–1.86 (ddd, AB, $^2J_{H,H}$ = 10.7, $^2J_{P,H}$ = 3.5 Hz, 4 H, *H*$^{8,9}$), 1.87 (d, $^2J_{P,H}$ = 3.4 Hz, 2 H, *H*$^{13}$), 1.57 (s, 3 H, *H*$^7$), 1.44 (s, 6 H, *H*$^{11,12}$), 0.85–0.63 (3 × d, $^2J_{P,H}$ = 3.2 Hz 18 H, PC*H*$_3$) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, [D$_8$]THF, 25 °C, TMS): $\delta$ = 167.47 (s, 1 C, *C*$^1$), 165.83 (s, 1 C, *C*$^5$), 136.81 (s, 1 C, *C*$^3$), 118.17 (s, 1 C, *C*$^2$), 117.48 (s, 1 C, *C*$^4$), 49.50 (m, 3 C, *C*$^{8,9,13}$), 44.73 (t, 1 C, *C*$^6$), 41.59 (d, 1 C, *C*$^{10}$), 29.63 (m, 2 C, *C*$^{11,12}$), 26.48 (m, 1 C, *C*$^7$), 16.18 (m, 6 C, P*C*H$_3$) ppm. $^{31}P\{^1H\}$ NMR (80.95 MHz, [D$_8$]THF, 25 °C, 85% $H_3PO_4$): $\delta$ = –61.84 [s, 1 × *P*(Me$_2$)], –62.06 [s, 2 × *P*(Me$_2$)] ppm.

**Preparation of 4:** A solution of $Ni(ClO_4)_2{\cdot}6H_2O$ (87 mg, 0.239 mmol) in methanol (2.0 mL) was added over a period of 10 min at room temperature with stirring to a solution of **1** (103 mg, 0.239 mmol) in methanol (1.5 mL). The colour of the solution changed immediately from green to red, and a red microcrystalline precipitate began to form. After three days of continued stirring, the product was filtered off, washed with methanol (3 × 1.0 mL) and dried in vacuo to yield a red solid (148 mg, 90%). $C_{21}H_{41}Cl_2NNiO_8P_4$ (689.05): calcd. C 36.60, H 6.00, N 2.03; found C 36.92, H 5.81, N 1.97. IR (KBr): $\tilde{\nu}$ = 2977 m, 2922 m, 1572 m, 1454 s, 1424 m, 1300 m, 1091 vs ($ClO_4^-$), 944 s, 918 s, 622 s cm$^{-1}$. MALDI-TOF MS: *m/z* (%) 490 (100) $[(py\{PMe_2\}_4)Ni]^+$. $^1H$ NMR (200 MHz, [D$_3$]acetonitrile, 25 °C, TMS): $\delta$ = 8.11 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H, *para-H*), 7.88 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, *meta-H*), 2.37–2.29 (m, 8 H, C*H*$_2$), 1.83 (s, 6 H, C*H*$_3$), 1.74 (m, 24 H, PC*H*$_3$) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, [D$_3$]acetonitrile, 25 °C, TMS): $\delta$ = 165.68 (s, 2 C, *ortho-C*), 141.89 (s, 1 C, *para-C*), 125.26 (s, 2 C, *meta-C*), 44.79 (s, 2 C, *C*CH$_2$), 36.72 (m, 4 C, *C*H$_2$), 33.07 (m, 2 C, *C*H$_3$), 16.72 (m, 8 C, P*C*H$_3$) ppm. $^{31}P\{^1H\}$ NMR (80.95 MHz, [D$_3$]acetonitrile, 25 °C, 85% $H_3PO_4$): $\delta$ = –13.16 [m, 2 × *P*(Me$_2$)], –14.97 [m, 2 × *P*(Me$_2$)] ppm.

**Compound 5:** The procedure is similar to the preparation of compound **4** but with $Ni(BF_4)_2{\cdot}6H_2O$ (114 mg, 0.336 mmol) and **1** (145 mg, 0.336 mmol). Complex **5** was isolated as a red microcrystalline solid; yield: 203 mg (91%). $C_{21}H_{41}B_2F_8NNiP_4$ (663.75): calcd. C 38.00, H 6.23, N 2.11; found C 37.71, H 5.85, N 2.11. IR (KBr): $\tilde{\nu}$ = 2978 m, 2929 m, 1575 m, 1453 s, 1425 m, 1306 m, 1055 vs ($BF_4^-$), 946 s, 916 s, 520 m cm$^{-1}$. MALDI-TOF MS: *m/z* (%) 490 (100) $[(py\{PMe_2\}_4)Ni]^+$. $^1H$ NMR (200 MHz, [D$_3$]acetonitrile, 25 °C, TMS): $\delta$ = 8.12 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H, *para-H*), 7.88 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, *meta-H*), 2.38–2.30 (m, 8 H, C*H*$_2$), 1.81 (s, 6 H, C*H*$_3$), 1.71 (m, 24 H, PC*H*$_3$) ppm. $^{13}C\{^1H\}$ NMR (50.32 MHz, [D$_3$]acetonitrile, 25 °C, TMS): $\delta$ = 165.65 (s, 2 C, *ortho-C*), 141.91 (s, 1 C, *para-C*), 125.27 (s, 2 C, *meta-C*), 44.80 (s, 2 C, *C*CH$_2$), 36.71 (m, 4 C, *C*H$_2$), 33.11 (m, 2 C, *C*H$_3$), 16.73 (m, 8 C, P*C*H$_3$) ppm. $^{19}F\{^1H\}$ NMR (188.31 MHz, [D$_3$]acetonitrile, 25 °C, $CFCl_3$): $\delta$ = –147.88 (s, 4 F, $BF_4^-$) ppm. $^{31}P\{^1H\}$ NMR (80.95 MHz, [D$_3$]acetonitrile, 25 °C, 85% $H_3PO_4$): $\delta$ = –13.15 [m, 2 × *P*(Me$_2$)], –14.99 [m, 2 × *P*(Me$_2$)] ppm.

**Compound 6:** The procedure is similar to the preparation of compound **4** but with $Co(ClO_4)_2{\cdot}6H_2O$ (55 mg, 0.15 mmol) and **1** (65 mg, 0.15 mmol). The reaction mixture changed colour from pink to brown and gave an olive-green microcrystalline precipitate; reaction time: five days. The product is an olive-green microcrystalline solid. Yield: 90 mg (87%). $C_{21}H_{41}Cl_2CoNO_8P_4$ (689.29): calcd. C 36.59, H 6.00, N 2.03; found C 36.82, H 6.02, N 2.02. IR (KBr): $\tilde{\nu}$ = 2978 m, 2923 m, 1573 m, 1453 s, 1424 m, 1299 m, 1089 vs ($ClO_4^-$), 944 s, 918 s, 622 s cm$^{-1}$. MALDI-TOF MS: *m/z* (%) 490 (80) $[(py\{PMe_2\}_4)Co]^+$, 430 (100) $[M - H - Co]^+$.

**Compound 7:** The procedure is similar to the preparation of compound **4** but with $Co(BF_4)_2{\cdot}6H_2O$ (328 mg, 0.962 mmol) in methanol (4.0 mL) and **1** (415 mg, 0.962 mmol) in methanol (5.0 mL); addition time: 20 min at room temperature; observed colours as for compound **6**; reaction time: five days. The product is an olive-green microcrystalline solid. Yield: 543 mg (85%). $C_{21}H_{41}B_2CoF_8NP_4$ (663.99): calcd. C 37.99, H 6.22, N 2.11; found C 37.84, H 6.03, N 2.00. IR (KBr): $\tilde{\nu}$ = 2975 m, 2924 m, 1574 m, 1454 s, 1426 m, 1300 m, 1054 vs ($BF_4^-$), 945 s, 919 s, 520 s cm$^{-1}$. MALDI-TOF MS: *m/z* (%) 490 (81) $[(py\{PMe_2\}_4)Co]^+$, 430 (100) $[M - H - Co]^+$. $^{31}P\{^1H\}$ NMR (80.95 MHz, [D$_4$]methanol, 25 °C, 85% $H_3PO_4$): $\delta$ = 48.12 [br., 4 × *P*(Me$_2$)] ppm.

**Preparation of 8:** Nitrogen monoxide was bubbled through a solution of **1** (110 mg, 0.255 mmol) in diethyl ether (8.0 mL) at approximately 0 °C for three minutes. A white microcrystalline powder precipitated, which was filtered off and washed with diethyl ether (3 × 2.5 mL) to yield a white solid (124 mg, 98%). $C_{21}H_{41}NO_4P_4$ (495.45): calcd. C 50.91, H 8.34, N 2.83; found C 50.71, H 8.25, N 2.78. IR (KBr): $\tilde{\nu}$ = 2978 m, 2911 m, 1653 m, 1574 m, 1457 s, 1420 m, 1384 s, 1295 s, 1161 vs (P=O), 941 s, 875 s, 745 m cm$^{-1}$. EI-MS (70 eV): *m/z* (%) 494 (100) $[M - H]^+$. $^1H$ NMR (200 MHz, [D$_3$]-acetonitrile, 25 °C, TMS): $\delta$ = 7.78 (t, $^3J_{H,H}$ = 7.5 Hz, 1 H, *para-H*), 7.44 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, *meta-H*), 2.69–2.61 (dd, AB, $^2J_{H,H}$ = 6.0 Hz, 8 H, C*H*$_2$), 1.86 (s, 6 H, CC*H*$_3$), 1.35–1.28 (2 d, $^2J_{P,H}$ = 2.4 Hz, 24 H, PC*H*$_3$) ppm. $^{31}P\{^1H\}$ NMR (80.95 MHz, [D$_3$] acetonitrile, 25 °C, 85% $H_3PO_4$): $\delta$ = 44.95 [s, 4 × *P*(O)Me$_2$] ppm.

**Preparation of 9:** A solution of **7** (160 mg, 0.241 mmol) in acetonitrile (3.0 mL) was refluxed in air for five minutes, then placed in a Dewar vessel filled with hot water (80 °C), and the complete setup cooled to 2 °C in a refrigerator. This produced a few single crystals of **9**·2CH$_3$CN within 7 d. Due to lack of material, the crystals were characterised solely by X-ray crystallography.

**Preparation of 10:** A brownish solution of 6 (105 mg, 0.152 mmol) in methanol (6.0 mL) was cooled in an ice bath, and a stream of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

carbon monoxide was passed through the solution for five seconds. The colour of the solution darkened, and stirring was continued for a further ten minutes. The solvent was then evaporated, and the residue washed with a 1:2 mixture of methanol and diethyl ether (3 × 1.5 mL) to yield a brown solid (61 mg, 54%). $C_{23}H_{41}Cl_2CoNO_{10}P_4$ (745.31): calcd. C 37.06, H 5.54, N 1.88; found C 36.82, H 5.66, N 1.98. IR (KBr): $\tilde{\nu}$ = 2983 m, 2921 m, 1988 vs (CO), 1937 vs (CO), 1575 s, 1453 s, 1422 s, 1300 s, 1093 vs ($ClO_4^-$), 944 s (P–C, coordinated), 917 s (P–C, coordinated), 875 s (P–C, uncoordinated), 623 vs $cm^{-1}$. MALDI-TOF MS: *m/z* (%) 546 (28) $[M - H]^+$, 430 (100) $[M - H - Co - 2CO]^+$, 273.5 (18) $[M]^{2+}$.

**Preparation of 11:** An autoclave (volume: 2.1 L) was charged with 2-ethyl-6-isopropylpyridine (50 g, 0.33 mol) and an aqueous formaldehyde solution (37%, stabilised with 10% methanol; 250 mL, 3.30 mol) and the mixture heated to 140 °C for 48 h. After cooling to room temperature, the pressure was released and the solvent evaporated. The yellow oily residue was then heated to 100 °C for 24 h to remove excess formaldehyde. The residue was dissolved in trichloromethane (250 mL) and extracted with water (20 × 70 mL). The aqueous phase was separated, water removed on a rotary evaporator, and the remaining syrupy material dried for a further two days in vacuo at a temperature of 95 °C to yield a white solid, which was purified by washing with diethyl ether (27.7 g, 35%). $C_{13}H_{21}NO_3$ (239.31): calcd. C 65.25, H 8.84, N 5.75; found C 64.97, H 8.80, N 5.67. IR (KBr): $\tilde{\nu}$ = 3299 vs (OH), 2961 vs, 2873 vs, 1577 vs, 1461 vs, 1409 m,1042 vs, 1027 vs, 756 s $cm^{-1}$. EI-MS (70 eV): *m/z* (%) 239 (100) $[M]^+$. $^1$H NMR (400 MHz, [D$_1$]trichloromethane, 25 °C, TMS): $\delta$ = 7.66 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H, $H^3$), 7.20 (d, $^3J_{H,H}$ = 8.0 Hz, 1 H, $H^2$), 7.17 (d, $^3J_{H,H}$ = 8.0 Hz, 1 H, $H^4$), 4.14 (br., 3 H, O$H$), 3.92–3.75 (dd, AB, $^2J_{H,H}$ = 11.2 Hz, 4 H, $H^{8,9}$), 3.66 (s, 2 H, $H^{13}$), 1.29 (s, 6 H, $H^{11,12}$), 1.17 (s, 3 H, $H^7$) ppm. $^{13}$C{$^1$H} NMR (100.64 MHz, [D$_1$]trichloromethane, 25 °C, TMS): $\delta$ = 165.23 (s, 1 C, $C^1$), 163.27 (s, 1 C, $C^5$), 137.56 (s, 1 C, $C^3$), 118.95 (s, 1 C, $C^2$), 118.66 (s, 1 C, $C^4$), 71.83 (s, 1 C, $C^{13}$), 69.38 (s, 2 C, $C^{8,9}$), 45.97 (s, 1 C, $C^6$), 42.01 (s, 1 C, $C^{10}$), 24.95 (s, 2 C, $C^{11,12}$), 19.89 (s, 1 C, $C^7$) ppm.

**Preparation of 12:** A solution of **11** (11.0 g, 0.046 mol) and triethylamine (29.2 mL, 0.207 mol) in dichloromethane (200 mL) was cooled to –2 °C, and a solution of methanesulfonyl chloride (12.8 mL, 0.166 mol) in dichloromethane (50 mL) added dropwise, taking care that the temperature did not exceed +2 °C. The resulting suspension was warmed to room temperature and stirred for one hour. The reaction product was washed successively with hydrochloric acid (1 N, 1 × 50 mL), water (1 × 50 mL), sodium carbonate solution (1 × 50 mL), brine (1 × 50 mL) and finally again with water (1 × 50 mL). After drying over $Na_2SO_4$ and evaporating the solvent, the residue was dried in vacuo to yield the product as a colourless oil (20.3 g, 93%). IR (KBr): $\tilde{\nu}$ = 3029 vs, 2976 vs, 2941 vs, 1578 vs, 1352 vs, 1172 vs, 958 vs, 528 vs $cm^{-1}$. EI-MS (70 eV): *m/z* (%) 394 (100) $[M - CH_3SO_2]^+$. $^1$H NMR (200 MHz, [D$_1$]trichloromethane, 25 °C, TMS): $\delta$ = 7.70 (t, $^3J_{H,H}$ = 8.0 Hz, 1 H, $H^3$), 7.27 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, $H^2$), 7.21 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, $H^4$), 4.63–4.52 (dd, AB, $^2J_{H,H}$ = 8.8 Hz, 4 H, $H^{8,9}$), 4.47 (s, 2 H, $H^{13}$), 2.96 (s, 6 H, $SO_2$-C$H_3$), 2.86 (s, 3 H, $SO_2$-C$H_3$), 1.50 (s, 3 H, $H^7$), 1.41 (s, 6 H, $H^{11,12}$) ppm. $^{13}$C{$^1$H} NMR (50.32 MHz, [D$_1$]trichloromethane, 25 °C, TMS): $\delta$ = 163.36 (s, 1 C, $C^1$), 158.42 (s, 1 C, $C^5$), 137.56 (s, 1 C, $C^3$), 119.13 (s, 1 C, $C^2$), 118.86 (s, 1 C, $C^4$), 77.64 (s, 1 C, $C^{13}$), 72.74 (s, 2 C, $C^{8,9}$), 45.14 (s, 1 C, $C^6$), 41.35 (s, 1 C, $C^{10}$), 36.84 (s, 2 C, $SO_2CH_3$), 36.74 (s, 1 C, $SO_2CH_3$), 24.57 (s, 2 C, $C^{11,12}$), 19.16 (s, 1 C, $C^7$) ppm.

**Preparation of 13:** Compound **12** (6.27 g, 0.013 mol) was dissolved in anhydrous dimethyl sulfoxide (150 mL) and heated to 70 °C. Vigorously dried (vacuo, 100 °C, 3 d) lithium bromide (5.17 g, 0.059 mol) was then added in one portion, and the solution stirred for two days at 70 °C. After cooling to room temperature, water (200 mL) was added, and the mixture stirred for 30 min. The milky solution was extracted with diethyl ether (7 × 70 mL), and the combined ether extracts washed with water (3 × 50 mL) to remove residual dimethyl sulfoxide. The organic phase was separated, dried with $Na_2SO_4$, and the solvent evaporated to give an oily, crude product. Column chromatography ($SiO_2$, 0.060–0.200 mm, pore diameter ca. 6 nm) using a combination of ethyl acetate and hexane (3:1) as eluent yielded the product as a colourless oil (3.1 g, 56%). IR (KBr): $\tilde{\nu}$ = 2969 vs, 2870 m, 1576 vs, 1458 vs, 1423 m, 1247 vs, 750 s $cm^{-1}$. EI-MS (70 eV): *m/z* (%) 416 (32) $[M - CH_3]^+$, 414 (98) $[M - CH_3]^+$, 412 (100) $[M - CH_3]^+$, 410 (34) $[M - CH_3]^+$. $^1$H NMR (200 MHz, [D$_1$]trichloromethane, 25 °C, TMS): $\delta$ = 7.66 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H, $H^3$), 7.23 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, $H^2$), 7.18 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, $H^4$), 4.00–3.86 (dd, AB, $^2J_{H,H}$ = 10.0 Hz, 4 H, $H^{8,9}$), 3.80 (s, 2 H, $H^{13}$), 1.63 (s, 3 H, $H^7$), 1.49 (s, 6 H, $H^{11,12}$) ppm. $^{13}$C{$^1$H} NMR (50.32 MHz, [D$_1$]trichloromethane, 25 °C, TMS): $\delta$ = 164.07 (s, 1 C, $C^1$), 160.04 (s, 1 C, $C^5$), 137.07 (s, 1 C, $C^3$), 118.48 (s, 1 C, $C^2$), 118.36 (s, 1 C, $C^4$), 46.01 (s, 2 C, $C^{10,13}$), 42.10 (s, 3 C, $C^{6,8,9}$), 26.63 (s, 2 C, $C^{11,12}$), 23.09 (s, 1 C, $C^7$) ppm.

**Preparation of 14:** A solution of $Ni(BF_4)_2{\cdot}6H_2O$ (311 mg, 0.915 mmol) in acetonitrile (3.5 mL) was added over a period of 10 min at room temperature to a solution of **2** (340 mg, 0.915 mmol) in acetonitrile (2.5 mL). The solution changed colour immediately from green to red, and was stirred overnight. Diffusion of diethyl ether into this solution produced a red crystalline solid within 3 d. The product was filtered off and washed with diethyl ether (3 × 1.5 mL) to yield red crystals (442 mg, 75%). $C_{21}H_{39}B_2F_8N_2NiP_3$ (644.78): calcd. C 39.12, H 6.10, N 4.34; found C 39.09, H 6.19, N 4.30. IR (KBr): $\tilde{\nu}$ = 2970 s, 2932 s, 2292 m (CN), 1574 vs, 1426 vs, 1296 s, 1056 vs ($BF_4^-$), 948 vs, 920 vs, 520 s $cm^{-1}$. ESI-MS: *m/z* (%) 236 (100) $[M]^{2+}$. $^1$H NMR (400 MHz, [D$_3$]acetonitrile, 25 °C, TMS): $\delta$ = 7.88 (t, $^3J_{H,H}$ = 7.3 Hz, 1 H, $H^5$), 7.53 (d, $^3J_{H,H}$ = 7.2 Hz, 1 H, $H^6$), 7.52 (d, $^3J_{H,H}$ = 7.2 Hz, 1 H, $H^4$), 2.50–2.00 (2 × m, 4 H, C$H_2^{9,10}$), 2.46 (s, 2 H, C$H_2^1$), 1.96 (s, 3 H, C$H_3^{21}$), 1.53–1.50 (m, 6 H, PC$H_3^{16,18}$), 1.51 (s, 3 H, C$H_3^{15}$), 1.46–1.43 (m, 6 H, PC$H_3^{17,19}$), 1.45 (2 × s, 6 H, C$H_3^{13,14}$), 1.26–1.22 (m, 6 H, PC$H_3^{11,12}$) ppm. $^{13}$C{$^1$H} NMR (100.64 MHz, [D$_3$]acetonitrile, 25 °C, TMS): $\delta$ = 166.78 (s, 1 C, $C^3$), 162.87 (s, 1 C, $C^7$), 139.79 (s, 1 C, $C^5$), 122.26 (s, 1 C, $C^4$), 121.22 (s, 1 C, $C^6$), 43.80 (s, 1 C, $C^8$), 42.25 (s, 1 C, $C^2$), 41.38 (d, $^1J_{P,C}$ = 23.3 Hz, 1 C, $C^1$), 37.69 (m, 2 C, $C^{9,10}$), 32.86 (s, 2 C, $C^{13,14}$), 32.13 (s, 1 C, $C^{15}$), 16.66 (m, 2 C, P$CH_3^{11,12}$), 15.62 (m, 4 C, P$CH_3^{16-19}$), 1.75 (s, 1 C, $C^{21}$) ppm. $^{19}$F{$^1$H} NMR (188.31 MHz, [D$_3$]acetonitrile, 25 °C, $CFCl_3$): $\delta$ = –147.90 (s, 4 F, $BF_4^-$) ppm. $^{31}$P{$^1$H} NMR (80.95 MHz, [D$_3$]acetonitrile, 25 °C, 85% $H_3PO_4$): $\delta$ = –3.53 (d, $^2J_{P,P}$ = 70.5 Hz, 2 P, $P^{2,1}$), –8.64 (t, $^2J_{P,P}$ = 70.5 Hz, 1 P, $P^3$) ppm.

**Preparation of 15:** Prepared similar to **14**, from $Ni(BF_4)_2{\cdot}6H_2O$ (150 mg, 0.441 mmol); solvent: acetonitrile (3.0 mL); addition time: 10 min at room temperature; **2**: 190 mg, 0.512 mmol; solvent: acetonitrile (2.0 mL); observed colours as for compound **14**; reaction time: seven days; appearance of product: orange blocks. $C_{21}H_{41}B_2F_8N_2NiOP_3$ (662.79): calcd. C 38.06, H 6.24, N 4.23; found C 38.29, H 6.39, N 4.34. ESI-MS: *m/z* (%) 245 (100) $[M]^{2+}$.

**Preparation of 16:** A solution of **14** (115 mg, 0.178 mmol) and LiBr (16 mg, 0.18 mol) in methanol (4.5 mL) was stirred at room temperature for 1 h. The solvent was evaporated, the residual red solid dried in vacuo, stirred in diethyl ether (10 mL) for 10 min, the mixture filtered, and the remaining solid dried again in vacuo. Dif-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fusion of diethyl ether into a saturated solution of **16** in methanol produced a red microcrystalline solid, as well as single crystals, within 4 d. The single crystals were separated, and the polycrystalline material filtered off and washed with diethyl ether (3 × 1.0 mL) to yield a red solid (85 mg, 80%). $C_{19}H_{36}BBrF_4NNiP_3$ (596.83): calcd. C 38.24, H 6.08, N 2.35; found C 38.20, H 6.06, N 2.30. $^1H$

NMR (400 MHz, [D$_4$]methanol, 25 °C, TMS): $\delta$ = 8.16 (t, $^3J_{H,H}$ = 7.3 Hz, 1 H, $H^3$), 7.83 (d, $^3J_{H,H}$ = 7.3 Hz, 1 H, $H^4$), 7.81 (d, $^3J_{H,H}$ = 7.3 Hz, 1 H, $H^2$), 2.39–1.90 (2×m, 4 H, C$H_2^{7,10}$), 2.28 (s, 2 H, C$H_2^{15}$), 1.87 (s, 3 H, C$H_3^{13}$), 1.81 (s, 6 H, C$H_3^{18,19}$), 1.72–1.65 (m, 6 H, PC$H_3^{8,11}$), 1.59–1.53 (m, 6 H, PC$H_3^{9,12}$), 0.74–0.69 (m, 6 H, PC$H_3^{16,17}$) ppm. $^{13}$C{$^1$H} NMR (100.64 MHz, [D$_4$]methanol, 25 °C, TMS): $\delta$ = 168.52 (s, 1 C, $C^1$), 167.97 (s, 1 C, $C^5$), 143.09 (s, 1 C, $C^3$), 124.86 (s, 1 C, $C^2$), 123.79 (s, 1 C, $C^4$), 43.58 (s, 1 C, $C^6$), 42.75 (s, 1 C, C$^{14}$), 38.68 (m, 1 C, $C^{15}$), 38.24 (m, 2 C, $C^{7,10}$), 32.52 (s, 2 C, $C^{18,19}$), 31.16 (s, 1 C, $C^{13}$), 15.44 (m, 2 C, P$C$H$_3^{16,17}$), 14.38 (m, 4 C, P$C$H$_3^{8,9,11,12}$) ppm. $^{19}$F{$^1$H} NMR (188.31 MHz, [D$_4$]-methanol, 25 °C, CFCl$_3$): $\delta$ = –147.92 (s, 4 F, B$F_4^-$) ppm. $^{31}$P{$^1$H} NMR (80.95 MHz, [D$_4$]methanol, 25 °C, 85% H$_3$PO$_4$): $\delta$ = 3.00 (d, $^2J_{P,P}$ = 83.6 Hz, 2 P, $P^{2,1}$), –0.90 (t, $^2J_{P,P}$ = 83.6 Hz, 1 P, $P^3$) ppm.

**X-ray Crystallography for Compounds 3, 4, 5, 7, 9, 14, 15 and 16:** Colourless single crystals of "pyBr$_4$" (**3**) formed upon keeping the oily product under oil pump vacuum for three weeks. Red single crystals of [(py{PMe$_2$}$_4$)Ni](ClO$_4$)$_2$·CHCl$_3$ (**4**·CHCl$_3$) were obtained within 10 d by isothermal diffusion of diethyl ether into a saturated solution of the reaction product in chloroform. Red crystals of [(py{PMe$_2$}$_4$)Ni](BF$_4$)$_2$·MeOH (**5**·MeOH) and green crystals of [(py{PMe$_2$}$_4$)Co](BF$_4$)$_2$·MeOH (**7**·MeOH) were similarly obtained by isothermal diffusion of diethyl ether into a saturated solution of the reaction product in methanol within a few days. Violet blocks of [{(py{PMe$_2$}$_2${OPMe$_2$}$_2${CH$_3$CN}$_3$)Co}$_2$Co](BF$_4$)$_6$·2CH$_3$CN (**9**·2 CH$_3$CN) formed after a solution of the reaction product in acetonitrile had been saturated hot and subsequently cooled to 2 °C. Single crystals of [(py{PMe$_2$}$_3$CH$_3$CN)Ni](BF$_4$)$_2$ (yellow, **14**), [(py{PMe$_2$}$_3$CH$_3$CONH$_2$)Ni](BF$_4$)$_2$ (orange, **15**) and [(py{PMe$_2$}$_3$Br)Ni](BF$_4$) (red, **16**) were obtained by isothermal diffusion of diethyl ether into an acetonitrile (**14** and **15**) or a methanol (**16**) solution. Crystal data for compounds **3**, **4**·CHCl$_3$, **5**·MeOH, **9**·2 CH$_3$CN, **14**, **15** and **16** are given in Table 4, and selected distances and angles are listed in Tables 1–3. Structures are presented in Figures 1–8. Compounds **4**, **5** and **7** are isostructural. Intensity data for **4**·CHCl$_3$ and **14** were collected on a Stoe Stadi 4 diffractometer; data for **5**·MeOH, **7**·MeOH and **9**·2 CH$_3$CN were collected on a SMART CCD diffractometer; data for **15** were collected on a Bruker-Nonius KappaCCD diffractometer and data for **3** and **16** on a Oxford Diffraction Xcalibur S Sapphire diffractometer using Mo-$K_a$ radiation ($\lambda$ = 0.71073 Å, graphite monochromator) in all cases. The structures were solved by direct methods using SHELXS-97[13] or SIR 97[14] and were refined on $F^2$ using SHELXL-97.[15] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions using a riding model. SADABS[16] was used to perform area detector scaling absorption corrections, as applicable (Table 4). The absolute structure in non-centrosymmetric space groups was determined with SHELXL-97 according to Flack.[13] The geometrical features of the structures were analysed using the DIAMOND programme.[17]

CCDC-608569 (for **3**), -608571 (for **4**·CHCl$_3$), -608566 (for **5**·MeOH), -608567 (for **7**·MeOH), -608568 (for **9**·2 CH$_3$CN), -608564 (for **14**), -608565 (for **15**) and -608570 (for **16**) contain the supplementary crystallographic data. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Testing Phosphanes in the Palladium-Catalysed Allylation of Secondary and Primary Amines

Claire Thoumazet,[a] Hansjörg Grützmacher,[b] Bernard Deschamps,[a] Louis Ricard,[a] and Pascal le Floch*[a]

**Keywords:** Allylation / Amines / Catalysis / Palladium / Phosphorus

The electronic nature of the ligand plays a crucial role in the palladium-catalysed allylation of amines with allylic alcohols. The better the ligand is as a π acceptor, the more active the catalyst. Experiments with a series with mono- and bidentate ligands featuring phosphanes and phospholes applied in the catalytic allylation of aniline clearly demonstrate this. Bolstered by DFT calculations, we have devised a new efficient catalyst for this process which carries the strong π acceptor 1,2,5-triphenylphosphole as a ligand.

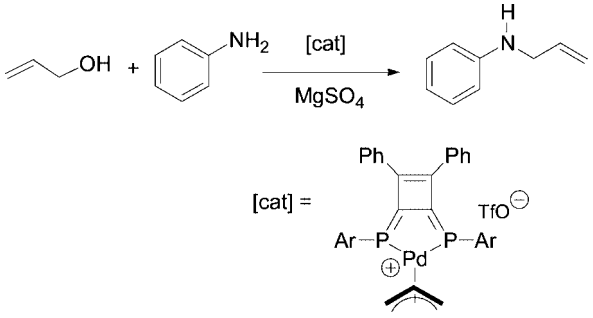
## Introduction

Carbon–nitrogen bond formation is a major challenge in organic synthesis for the preparation of nitrogen containing molecules of biological and physiological interest.[1] Among various metal promoted catalytic processes, the Tsuji–Trost[1a,2] coupling reaction involving the reaction of a nucleophile with a transient allyl palladium complex proves to be one of the most straightforward routes towards allylamines. Various nucleophiles and protected allylic alcohols can be employed and this reaction usually proceeds with good conversion under mild conditions.[3] However, as in other allylic alkylation processes, the presence of a good leaving group such as carboxylate, carbonate, phosphate or other related derivatives on the allylic moiety is a prerequisite in most cases in order to obtain sufficient activity. From a practical, economical and environmental point of view an interesting goal consists of directly using allylic alcohols as alkylating agents.[4] This approach has been explored by Tamaru as well as Ozawa and Yoshifuji in 2002. Tamaru et al. showed that classical palladium(0) complexes, such as $Pd(PPh_3)_4$ and $Pd(OAc)_2/PnBu_3$, could be employed as catalysts for the allylation of primary and secondary amines using a variable amount of $BEt_3$ (between 0.3 and 2.4 equiv.) as a cocatalyst. The group of Ozawa demonstrated that DPCB Pd(allyl) complexes (DPCB stands for diphosphanylidenecyclobutene ligands) efficiently catalyse the coupling between aniline derivatives and allylic alcohols in the presence of $MgSO_4$ as a water scavenger to afford the corresponding allylamines in good yields (Scheme 1).[4a–4d] Recently, we showed that allyl palladium complexes of mixed bidentate P-S ligands featuring a phosphabarrelene moiety and a diphosphanyl sulfide pendant arm are efficient catalysts for the bis(allylation) of primary amines under mild conditions.[5]



Scheme 1. Allylation of primary amines by DPCB based complexes.

Though the mechanism of this new catalytic process has not been explored in detail, the experimental results suggest that the π accepting capacity of the ligand likely plays a decisive role in the outcome of the reaction. That is, the stronger the π accepting capacity, the faster the process. In this article we report on the use of mono- and bidentate ligands in this allylation process and show through DFT calculations that the electronic nature of the phosphane indeed plays a crucial role. As will be seen, these studies led

us to devise a new efficient catalyst featuring the easily available 1,2,5-triphenylphosphole[6] as a ligand.

## Results and Discussion

### Synthesis of Complexes

All experiments were carried out using cationic palladium(allyl) complexes as precursors. As neutral donor ligands, various acyclic and cyclic phosphanes and one 1,4-diazabutadiene ligand **1** (Ar = 2,6-diisopropylbenzene) were tested as models for N–N chelating ligands (see Scheme 2 for a representation of all ligands employed in this study). The classical triphenylphosphane ligand **2** was used as a reference and its activity was compared with that of chelating ligands such as dppe **3** [dppe = 1,2-bis(diphenylphosphanyl)ethane] and dppp **4** [dppp = 1,3-bis(diphenylphosphanyl)propane] to assess the importance of the chelate effect. Furthermore, a series of phosphole based ligands was investigated including the readily available 1,2,5-triphenylphosphole **5** and the phenyldibenzophosphole **6**[7] as well as the chelate ligands **7** and **8**[8] which are the phospholyl counterparts of dppe and dppp, respectively. To complete this series, we extended our study to the 1-dibenzotropylidene-*P*-dibenzophosphole **9**, a ligand which has already proved to be very efficient in the Suzuki–Miyaura cross coupling process allowing the synthesis of arylboronic esters.[9] Note that it was shown previously that this highly rigid phosphane alkene (PAL) acts as a firmly binding bis(chelate) because of its well preorganised concave shaped binding site.

All cationic palladium complexes were conventionally prepared by treating equimolar amounts of the ligand with the $[PdCl(allyl)]_2$ dimer in dichloromethane at room temperature. After stirring for 5 min, the formation of the complexes $[Pd(allyl)(L_2)]Cl$ ($L_2$ = two monodentate ligands or one bidentate ligand) was verified by $^{31}P$ NMR spectroscopy (see the experimental section for $^{31}P$ NMR spectroscopic data of the intermediary complexes). Subsequently, a silver salt AgX (X = OTf or $NTf_2$; Tf = $-SO_3CF_3$) was added to exchange the chloride thereby affording the expected cationic complexes **10a**–**17a** (X = OTf) or **10b**–**17b** (X = $NTf_2$) (see Scheme 3). Complexes **10a**,**b** were isolated as orange powders in excellent yields and their structures are in accord with by NMR spectroscopy and elemental analysis. Complex **10a** was also structurally characterised (X-ray crystal structure given in the available supplementary material). Complexes **11a**,**b** were characterised by NMR spectroscopy and elemental analyses and their NMR spectroscopic data were compared with those reported in the literature for the $[Pd(PPh_3)_2(allyl)][X]$ complexes.[10] The dppe and dppp complexes **12a**,**b**, and **13a**,**b** as well as the phosphole derivatives **14a**,**b** and **15a**,**b** were synthesised by following the same experimental procedure and isolated as colourless or pale-yellow powders (fully characterised by NMR spectroscopy and elemental analyses). X-ray analyses of single-crystals of complexes **11a** (not reported in this paper), **12b** and **13a** (given in the available supplementary material) and of the phosphole complexes **14a** and **15a** were performed to elucidate their structures. The structures of the latter are presented in Figure 1 and Figure 2, respectively. Information concerning the data col-

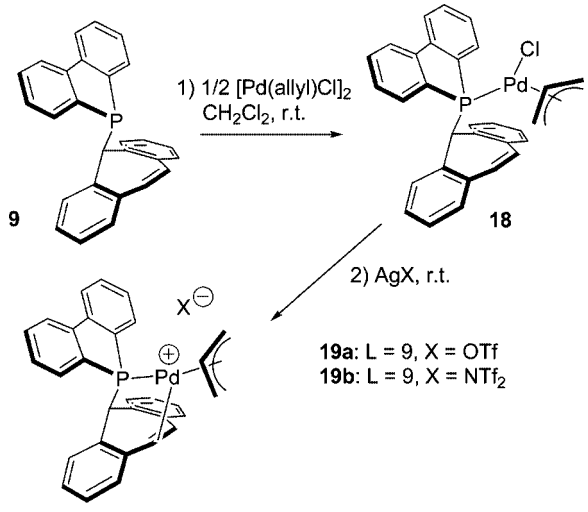
Table 2. Selected bond lengths [Å] and bond angles [°] for complex **15a**.

| | | | |
|---|---|---|---|
| P1–Pd1 | 2.3096(7) | C9–C10 | 1.465(4) |
| P2–Pd1 | 2.2882(7) | C10–C15 | 1.398(4) |
| Pd1–C1 | 2.190(3) | C15–P1 | 1.824(3) |
| Pd1–C2 | 2.176(3) | P1–Pd1–P2 | 99.13(2) |
| Pd1–C3 | 2.164(3) | C1–C2–C3 | 121.0(3) |
| P2–C4 | 1.804(3) | C15–P1–C4 | 91.2(1) |
| C4–C9 | 1.405(4) | P1–Pd1–C3 | 67.5(1) |

As displayed in Figure 1, complex **14a** adopts the expected square-planar geometry. The two phenyl rings of the phosphole ligands point in opposite directions in order to minimise the steric congestion with the second phosphole ligand. No stacking interactions between the two phosphole rings or their phenyl substituents can be observed. The P1–Pd1 and P2–Pd1 bond lengths at 2.307(1) Å and 2.325(1) Å are comparable with the corresponding Pd–P bonds in the $PPh_3$ complex (**11a**) [2.311(1) Å and 2.339(1) Å]. Similarly, the Pd–$C_{allyl}$ bonds (see Table 1) fall in the same range as those of the $PPh_3$ complex [2.153(2), 2.174(4) and 2.236(8) Å]. Note that in the 1,4-diazabutadiene complex **10a**, the Pd–$C_{allyl}$ bonds [2.107(3), 2.122(2) and 2.114(3) Å] are significantly shorter than in the two phosphole complexes indicating a stronger bond between the Pd atom and the allyl group.

The structure of **15a** is different and π stacking between the planar dibenzophosphole ligands can be observed (distance between the two planes: 3.66 Å). Other metric parameters are close to those recorded for the structures of complexes **11a** and **14a**. The bidentate ligands **7** and **8** have already been synthesised by Neibecker et al. following the classical procedure which consists of treating the 2,5-diphenylphospholide anion with 1,2-dibromoethane and 1,3-dibromopropane.[8] Complexes **17a**,**b** were straightforwardly formed and isolated as dark-red powders and their identities were ascertained by NMR spectroscopic studies and elemental analyses (see Scheme 3). On the contrary, the synthesis of complexes **16a**,**b** failed. Whatever the experimental conditions used, each attempt led to the formation of dark solids that could not be dissolved in common organic solvents and despite many efforts, the insoluble materials could not be characterised.

The synthesis of complexes **19a**,**b** took a slightly different reaction pathway. Specifically, the reaction of ligand **9** with $[Pd(allyl)Cl]_2$ did not yield a cationic complex with chloride as the counter-anion but the neutral species **18** which results from the breaking of the dimer, the chloride ligand remaining coordinated to the palladium centre (see Scheme 4). Complex **18** was characterised by $^{31}P$ NMR spectroscopy and its structure determined by an X-ray diffraction study.



Scheme 4. Synthesis of cationic complexes **18** and **19a**,**b**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Figure 3 shows the result and selected bond lengths and angles are listed in Table 3. The structure of complex **18** shows that the 1-dibenzotropylidene-*P*-dibenzophosphole is coordinated to the metal centre by means of the phosphorus atom only, the C=$C_{trop}$ unit remaining uncoordinated. In order to minimise repulsive steric interactions, the tropylidene and the allyl fragment point in opposite directions with respect to the central plane through the Pd atom.

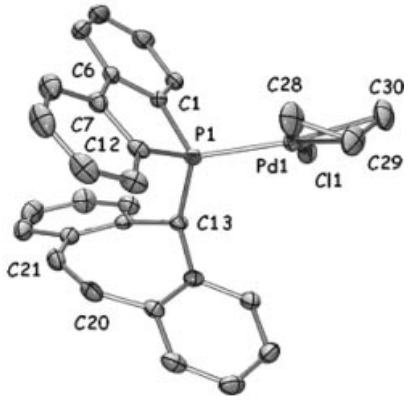


Figure 3. A view of one molecule of complex **18**.

Table 3. Selected bond lengths [Å] and bond angles [°] for complex **18**.

| | | | |
|---|---|---|---|
| P1–Pd1 | 2.2822(6) | Pd1–C29 | 2.170(4) |
| P1–C1 | 1.813(2) | Pd1–C30 | 2.215(4) |
| C1–C6 | 1.407(3) | Pd1–Cl1 | 2.3767(7) |
| C6–C7 | 1.466(3) | C20–C21 | 1.337(4) |
| C7–C12 | 1.403(3) | C28–C29–C30 | 120.5(7) |
| C12–P1 | 1.811(2) | C1–P1–C12 | 91.6(1) |
| P1–C13 | 1.875(2) | P1–Pd1–C28 | 96.7(2) |
| Pd1–C28 | 2.104(5) | P1–Pd1–C30 | 164.0(2) |

Treatment with one equivalent of AgX (X = OTf, $NTf_2$) yielded the expected cationic species **19a**,**b** which were isolated as very stable colourless powders (see Scheme 4). The coordination of the double bond to the metal was ascertained by NMR studies and is also seen in the solid-state structure of complex **19b** (Figure 4). Selected bonding parameters are listed in Table 4. Details concerning the crystal data collection and refinement are given in Table 9.

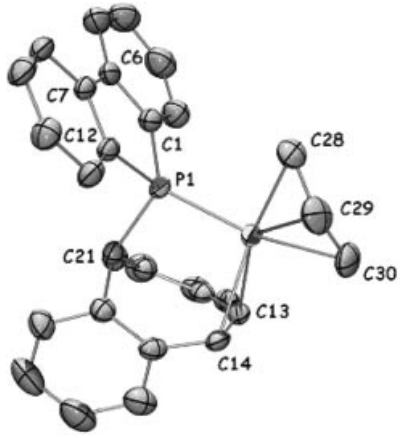

Figure 4. A view of one molecule of complex **19b**.

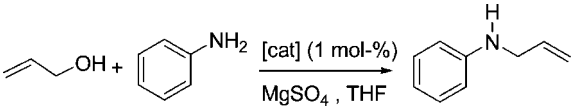
Table 4. Selected bond lengths [Å] and bond angles [°] for complex **19b**.

| | | | |
|---|---|---|---|
| P1–Pd1 | 2.272(1) | Pd1–C30 | 2.214(4) |
| P1–C1 | 1.815(4) | Pd1–C13 | 2.306(3) |
| C1–C6 | 1.406(5) | Pd1–C14 | 2.293(3) |
| C6–C7 | 1.468(6) | C13–C14 | 1.380(6) |
| C7–C12 | 1.415(5) | C28–C29–C30 | 120.2(5) |
| C12–P1 | 1.788(4) | C1–P1–C12 | 92.1(2) |
| P1–C21 | 1.866(4) | C13–Pd1–C14 | 34.9(1) |
| Pd1–C28 | 2.135(4) | P1–Pd1–C28 | 99.0(1) |
| Pd1–C29 | 2.166(4) | P1–Pd1–C30 | 165.9(1) |

The metric parameters of complex **19b** are comparable with those found in complex **15a**. The C=$C_{trop}$ bond length of the tropylidene unit [1.380(6) Å] is slightly lengthened when compared with the uncoordinated C=$C_{trop}$ bond in **18** indicating π back donation from the metal fragment to the ligand.

## Catalytic Experiments

Having all these complexes at hand, we investigated their performance in catalytic allylic aminations. The allylation of aniline was chosen as a model reaction (Scheme 5). All experiments were carried under the same experimental conditions, that is, in THF or toluene at room temperature with $MgSO_4$ as a water scavenger using 1 mol-% of catalyst, two equiv. of aniline and one equiv. of allylic alcohol. These conditions are similar to those used by Ozawa et al. during their studies with the above mentioned DPCB complexes. The use of two equiv. of aniline disfavours the formation of the bis(allylation) derivatives.



Scheme 5. Catalytic coupling of allyl alcohol with aniline using palladium allyl complexes **10a**,**b**–**19a**,**b** as catalyst precursors.

A first series of experiments showed that the use of toluene or THF as solvent had no influence and gave similar results. Therefore, all subsequent experiments were performed in THF. As shown in Table 5, only catalysts **11a**,**b**, **14a**,**b**, **15a**,**b** and **19b** gave a complete or nearly complete conversion (80 to 100%) after a reaction time of 24 h. In the experiments with **11a**,**b**–**17a**,**b**, the nature of counteranion did not have a significant influence on the catalytic performance. However, under the reaction conditions used in these experiments, a strong influence was seen with complexes **19a**,**b**, where the triflate derivative **19a** gave only a 20% conversion (vide supra).

Table 5. Conversion in the catalytic coupling of allyl alcohol with aniline using palladium allyl complexes **10a**,**b**–**19a**,**b** as catalyst precursors. (n.t. = not tested).

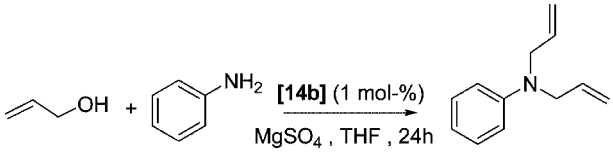
| Catalyst | 24 h | 1 h | Catalyst | 24 h | 1 h |
|---|---|---|---|---|---|
| **10a** | 0% | n.t. | 14a | 100% | 72% |
| **10b** | 0% | n.t. | 14b | 100% | 100% |
| **11a** | 100% | 47% | 15a | 100% | 52% |
| **11b** | 80% | 27% | 15b | 85% | 34% |
| **12a** | 20% | n.t. | 17a | 73% | 18% |
| **12b** | 5% | n.t. | 17b | 69% | 13% |
| **13a** | 5% | n.t. | 19a | 20% | n.t. |
| **13b** | 2% | n.t. | 19b | 98% | 30% |

Hard σ donor ligands such as the diazadiene ligand in complexes **10a**,**b** are not suited to the Pd-catalysed allylation of aniline and no conversion was achieved. Complexes such as **12a**,**b** and **13a**,**b** with bidentate ligands also showed very low activities with conversions not exceeding 20%. The chelate complexes **17a**,**b** carrying the bis(phosphole) ligand **8** gave better results but no complete conversion was observed after 24 h.

In a second series of experiments, the most active catalysts were selected and the reaction was stopped after 1 h. As the results in Table 5 show, catalyst **14b** proved to be the most active (complete conversion) and, as previously observed with **19a**,**b**, this complex with the $NTf_2$ counteranion was more active than its triflate counterpart **14a** (72%). However, complete conversion with **14a** was achieved after 2 h. The second best catalyst in terms of efficiency is the dibenzophosphole based complex **15a** which afforded a conversion of 52%. In this case, the $NTf_2$ derivative **15b** was less active (34%). The triphenylphosphane complex **11a** (47% of conversion) ranks in third place. Among the complexes which showed substantial conversion after 1 h reaction time, complex **19b** was the least efficient catalyst (30%). Note that in all these experiments the addition of $MgSO_4$ is not necessary and the absence of this water scavenger resulted only in a small decrease in the conversion yields (about 10%).

Having identified **14b** as an efficient catalyst, some additional experiments were also conducted with a lower loading of catalyst (0.5 and 0.1 mol-%) and by varying the substitution scheme of the allyl alcohol. These results are presented in Scheme 6. Longer reaction times or heating were needed to achieve a nearly complete conversion when a low loading of the catalyst was used (7 h at room temp. with 0.5 mol-% of catalyst and 5 h at 70 °C with 0.1 mol-% of catalyst). Methylallyl alcohol and *trans*-crotyl alcohol were also used as substrates. Introduction of a methyl group at the alpha position of the alcohol resulted in a significant decrease in the catalytic activity and, after 24 h at room temp., only 40% of the substrate was converted. As previously observed by Ozawa and Yoshifuji, introduction of a methyl group at the β position (*trans*-crotyl alcohol) leads to a mixture of $SN_2$ and $SN_2'$ products in a 71:12 ratio.

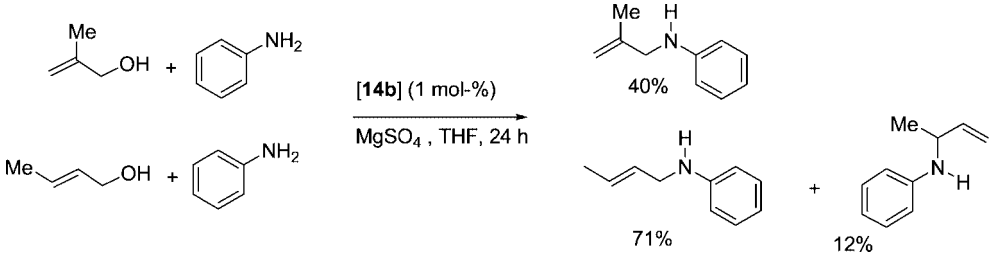
To complete this study, we then focused our efforts on the bis(allylation) of primary amines as well as on the monoallylation of secondary amines. This latter transformation is known, in particular, to be much more difficult to achieve.[4c–4d,5] For the bis(allylation) process, catalyst **14b** (1 mol-%) was treated with one equiv. of amine and two or three equiv. of the allylic alcohol in THF at room temperature with $MgSO_4$. With two equiv. of alcohol a nearly complete conversion was obtained after 39 h of stirring [92% of bis(allylation), 8% of monoallylation]. With three equiv. a complete conversion could be obtained after 14 h of reaction (see Scheme 7).



Scheme 7. Bis(allylation) of primary amines with catalyst **14b**.

Experiments to test the activity of **14b** in the allylation of secondary amines were conducted with 1 mol-% of catalyst, one equiv. of amine and two equiv. of allyl alcohol in THF (at room temperature and 50 °C) in the presence of $MgSO_4$. Three amines were tested: morpholine, dibenzylamine and *N*-methylaniline. A complete conversion was obtained after 24 h of heating at 50 °C with morpholine and *N*-methylaniline as substrates. Note that **14b** is therewith the most efficient catalyst reported to date for this transformation.[5] All the results are summarised in Table 6.

The results from the catalyses clearly demonstrate that the electronic nature of the phosphane plays a crucial role for the activity. As previously observed, strong π acceptor ligands lead to higher TON (TON = turn over numbers). Because diarylalkyl-substituted phosphanes such as dppe, dppp and ligand **8** show weaker π accepting capacities than triaryl phosphanes, the better performance of $[Pd(C_3H_5)(PPh_3)_2][X]$ **11a**,**b** can be explained. However, the



Scheme 6. Reaction of aniline with methyl alcohol and *trans*-crotyl alcohol catalysed by complex **14b**.

Table 6. Conversion in the catalytic coupling of allyl alcohol with secondary amines with **14b** as a catalyst precursor.

| Secondary amines | Temperature | Conversion |
|---|---|---|
| *N*-Methylaniline | room temp. | 100% |
| Morpholine | room temp. | 28% |
| Morpholine | 50 °C | 100% |
| Dibenzylamine | room temp. | 11% |
| Dibenzylamine | 50 °C | 44% |

explanation of the especially high activity of catalyst precursor **14** with the 2,5-diphenylphosphanylphosphole **5** as ligand as compared with **15** with the dibenzophosphole derivative **6** is less straightforward and requires a better understanding of the electronic nature of the ligands. Consequently, a DFT study was carried out.

### DFT Calculations

Calculations were carried out at the B3PW91/6-31G* level of theory using the Gaussian 03 set of programs. Views of the two calculated structures are shown in Figure 5 and selected bond lengths and angles are listed in Table 7. The agreement between the calculated and experimentally found bonding parameters[11] is satisfactory. Because of the nonplanarity of the phosphorus atom, phospholes are weakly aromatic.[12] The aromaticity of phospholes has been the subject of many debates and several factors determine the degree of aromaticity, such as the substitution pattern at the carbon atoms, the pyramidalisation of the coordination sphere at phosphorus and, most importantly, the nature of the substituent at phosphorus which determines the amplitude of the overlap between the π system of the $C_4$-butadienyl fragment and the P–R bond. This has been recently demonstrated with a series of 1-R–P substituted phospholes.[13] Both **5** and **6** carry a phenyl group as the substituent, hence the degree of deviation $\varphi$ of the P–C bond from the ring plane can be used in first approximation as an indicator. Thus **5** ($\varphi$ = 68°) would show a higher degree of aromaticity than **6** ($\varphi$ = 72°). The significantly lower inversion barrier at the phosphorus atom for **5** (16.9 kcal mol$^{-1}$) than in **6** (26.2 kcal mol$^{-1}$) supports this conclusion (see the supporting information for a presentation and structure parameters of the transition states of the inversions calculated at the same level of theory). Two explanations can be proposed to rationalise the weaker inversion barrier in phosphole **5**. First one may propose that the higher barrier for **6** is the result of significant overlap between the σ-P–R bond and the π system of the butadienyl fragment (negative hyperconjugation) which stabilises the ground state of this less aromatic ring system. Note that the inversion barrier for triphenylphosphane **2** was found to be equivalent to that of **6**, that is 26.2 kcal mol$^{-1}$. A second possibility is to consider that in the transition state the phosphole **5** is more aromatic than **6** since in this fused system the π electrons are delocalised into the two neighbouring six-membered aromatic rings.[14] To confirm our findings further, the nucleus independent chemical shifts (NICS) were calculated for both phospholes and their transition states (noted **TS5** and **TS6**, respectively). There is a good relationship between the NICS and other aromaticity criteria in phospholes and the more negative the NICS the higher the aromatic character.[15] NICS calculations were performed with the optimised structures at the RHF/6-311+G** level of theory (measured at 1 Å above the plane defined by the ring, opposite to the substituent at phosphorus). Table 8 shows that phosphole **5** is more aromatic than **6**. Not surprisingly, the presence of two fused benzene rings in **6** decreases the aromatic character of the central phosphole nucleus. A similar phenomenon has already been reported by Schleyer in the case of other fused structures such as phenanthrene.[15b] In **6**, the NICS value of the peripheral benzene rings (–10.3) is higher than that calculated for benzene (–8.4) using the same method and basis set. NICS calculations were also performed on the two transitions states **TS5**

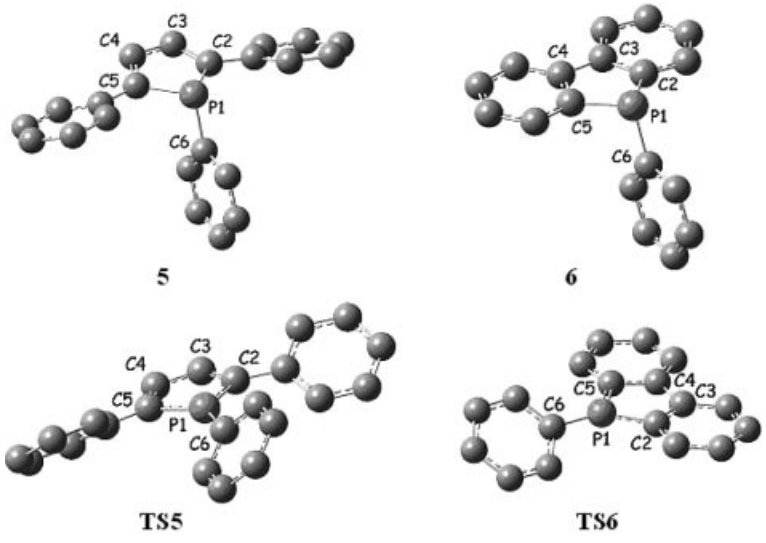

Figure 5. Views of the optimised geometries of the two ligands **5** and **6** and **TS5** and **TS6** (hydrogens have been excluded).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and **TS6**, the structures of which are also presented in Figure 5. Both transition states are, as expected, more aromatic than their respective precursors but the differences between the NICS values are insignificant (NICS for **TS5**: –9.0; NICS for **TS6** = –8.9), that is, the degree of aromaticity of the transition states is not the determining factor (see Scheme 8).

Table 7. A comparison between calculated and experimental bond lengths [Å] and angles [°] for ligands **5** and **6**.

| | **5** theoretical | **5**[11a] experimental | **6** theoretical | **6**[11b] experimental |

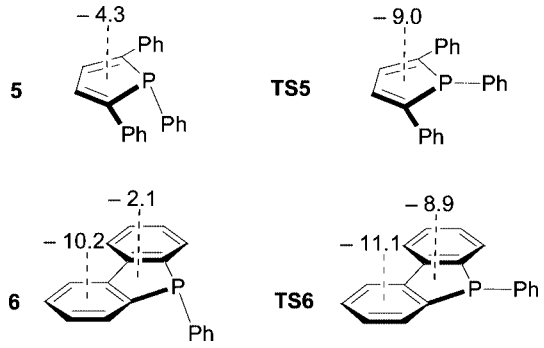
| C3–C2 | 114.8 | 116.1 | 110.0 | 110.2 |
| P1–C5 | 1.821 | 1.822 | 1.832 | 1.818 |

Table 8. Sum of the bond angles around the P atoms, Σ° (P), deviation $\varphi$ of the P–C bond out the $PC_4$ plane in the calculated structures of ligands **5** and **6**. NICS values and data from CDA calculations for complexes **I**, **II** and **III**. *b* and *d* values are expressed in electrons and *d*/*b* and *b*/*d*+*b* ratios are given in percent.

| Ligands and complexes | **5** | **6** | **I** | **II** | **III** |
|---|---|---|---|---|---|
| Σ° (P) | 302 | 296 | | | |
| $\varphi$° | 68 | 72 | | | |
| NICS (1 Å) | – 4.3 | – 2.1 | | | |
| donation (d) | | | 0.437 | 0.406 | 0.420 |
| back-donation (b) | | | 0.065 | 0.086 | 0.067 |
| *d*/*b* | | | 6.7 | 4.7 | 6.3 |
| *d*/*d*+*b* | | | 13 | 17.5 | 13.7 |
| *r* | | | – 0.341 | – 0.331 | – 0.331 |
| $\Delta$ | | | – 0.010 | – 0.009 | – 0.009 |

The binding properties of **5** and **6** towards transition metal fragments were estimated by means of a charge decomposition analysis (CDA) as developed by Frenking et al.[16] For simplicity, and in order to allow comparison with previous work, we chose, as models, the $Ni(CO)_3$ complexes **I**, **II** and **III** with triphenylphosphane **2**, triphenylphosphole **5** and dibenzophosphole **6** as ligands, respectively (Figure 6).



Scheme 8. NICS values calculated at the RHF/6-311+G** level of theory (measured at 1 Å above the plane defined by the ring, opposite to the substituent at phosphorus) for **5**, **6**, **TS5** and **TS6**.

Results of this CDA analysis are presented in Table 8, further details are given in the experimental section. The small residual term ($\Delta$) in all complexes shows that the electron density has been adequately partitioned into the repulsive term, *r*, and L→M donor, *d*, as well as the M→L back-donating terms, *b*. Hence, the discussion of the data from the CDA is meaningful.

The data given in Table 8 show that the ligands $PPh_3$ and dibenzophosphole **6** have similar electronic properties, that is, they have similar donation/back-donation ratios, *d*/*b*, of about 6.5. The triphenylphosphole **5** is a better acceptor, its *d*/*b* ratio is significantly smaller (4.7).

Inspection of the MO's involved in the bonding in complexes **II** (HOMO-12 and HOMO-2, see Figure 7) and **III** (HOMO-11 and HOMO-2) revealed that, as expected, the most significant contribution to the bonding comes from the orbital which describes the lone pair at phosphorus, i.e. the HOMO-1 in **5** and the HOMO in **6**. On the other hand, the π back donation mainly results from the combination of a filled orbital of the $Ni(CO)_3$ fragment with the LUMO+7 of **5** and **6** (σ* orbitals).

In summary, the results from the DFT calculations fully support the idea that the π accepting capacity of the ligand governs the catalytic activity of the palladium complexes prepared from them: while $[Pd(C_3H_6)(PPh_3)_2]X$ **10a**,**b** and $[Pd(C_3H_6)(\mathbf{6})]X$ **15a**,**b** perform similarly, $[Pd(C_3H_3)(\mathbf{5})]$ **14a**,**b** stands out with its exceptional activity.

## Conclusions

The performance of a series of catalysts with different phosphane ligands and one complex with a diazabutadiene ligand was evaluated in the palladium catalysed allylation of primary and secondary amines. In this way, a new efficient catalyst carrying the 1,2,5-triphenylphosphole **5** as a ligand (complexes **14a**,**b**) was found which enables these coupling reactions under mild conditions. DFT calculations enabled a comparison of the electronic structures of the ligands which gave the most active catalysts and, in combination with calculations on simple model complexes, strongly support the proposition that the best catalysts are obtained with π accepting ligands. Further studies will now focus on a systematic investigation of other strong π acceptor ligands, especially suitably substituted phospholes and phosphanes. Though significant progress has been achieved through this study, the influence of the ligands and their related complexes on the mechanistic pathway has yet to be precisely assessed as well as details on the stereochemical course of the reaction. DFT calculations aimed at determining the whole catalytic cycle of this important transformation are currently underway and will be presented in due course.

## Experimental Section

**General Remarks:** All reactions were routinely performed under an inert atmosphere of argon or nitrogen by using Schlenk and glovebox techniques and dry deoxygenated solvents. Dry THF and hexanes were obtained by distillation from Na/benzophenone. Dry dichloromethane was distilled from $P_2O_5$, dry toluene from Na and dry acetonitrile from $CaH_2$. NMR spectra were recorded on a Bruker Avance 300 spectrometer operating at 300 MHz for $^1H$, 75.5 MHz for $^{13}C$ and 121.5 MHz for $^{31}P$. Solvent peaks were used as internal references relative to $Me_4Si$ for $^1H$ and $^{13}C$ chemical shifts (ppm). $^{31}P$ chemical shifts are relative to an 85% $H_3PO_4$ external reference and coupling constants are expressed in Hertz. Abbreviations used: b broad, s singlet, d doublet, t triplet, m multiplet, p pentuplet, sext sextuplet, sept septuplet, v virtual. Elemental analyses were performed by the Service d'analyse du CNRS at Gif sur Yvette, France. $[Pd(COD)Cl_2]$,[17] *P*-phenyldibenzophosphole (**6**),[7] (dibenzo[*a*,*d*]cyclohepten-5-yl)dibenzophosphole (**9**),[9] triphenylphosphole (**5**),[6] diazadiene (**1**)[18] and (2,5-diphenylphosphol-1-yl)alkanes **7** and **8**[8] were prepared according to literature procedures. All other reagents and chemicals were obtained commercially and used as received. The GC yields were determined on a Varian Star 3400 gas chromatograph equipped with a CHROMPACK column (column type: WCOT FUSED SILICA, stationary phase: CP-SIL 5 CB).

**Theoretical Methods:** The calculations were performed with the GAUSSIAN 03 series of programs.[19] The geometries of compounds **2** and **5** and **6** were optimised by using the B3PW91 functional.[20] The standard 6-31G* basis set was used for all atoms (H, C and P). NICS calculations were performed at the RHF/6-311+G** level of theory using geometries calculated at the RB3PW91/6-31G* level of theory. The $Ni(CO)_3$ complexes **I**, **II** and **III** were calculated with the B3PW91 functional using the 6-31+G** basis set for P atoms, the 6-31G** basis set for the carbonyl groups and the 6-31G basis set for the H and C atoms. The basis set for the metal was that associated with the pseudo potential, with a standard double-ζ LANL2DZ contraction. In each case, harmonic frequencies were calculated at the same level of theory to characterise the stationary points and to determine the zero-point energies (ZPE). Intrinsic reaction coordinate calculations (IRC) were performed to ensure that transition states were found for the inversion at the phosphorus atoms in the structures of **5** and **6**. All optimised structures reported here have only positive eigenvalues of the Hessian matrix, i.e they are minima on the potential energy surface. Inspection of ligand to metal donor-acceptor interactions were performed using the charge-decomposition analysis (CDA). In the CDA method the (canonical, natural or Kohn–Sham) molecular orbitals of the complex are expressed in terms of MO's of appropriately chosen fragments. In the cases studied, the Kohn–Sham orbitals of the calculations are formed in the CDA procedure as a linear combination of the MO's of the phosphorus ligands **2**, **5** and **6** and those of the remaining $[Ni(CO)_3]$ fragment. In all cases, the ligands and the metal fragments were computed in the geometry of the complex. The orbital contributions are divided into four parts: (i) the mixing of the occupied MO's of the ligand and the unoccupied MO's of the metal fragment. This value (noted *d*) represents the L→M donation; (ii) the mixing of the unoccupied MO's of the ligand and the occupied MO's of the metal fragment. This value (noted *b*) accounts for the M→L back donation; (iii) the mixing of the occupied MO's of the ligand and the occupied MOs of the metal fragment. This term (noted *r*), which describes the repulsive polarisation between the ligand and metal fragment, is negative because electronic charge is removed from the overlapping area of the occupied orbitals; (iv) the residual term ($\Delta$) which results from the mixing of the unoccupied MO's of the two respective fragments. Usually this term is very close to zero for closed-shell interactions. This value constitutes an important probe for determining whether the bonding studied can be really classified as a donor-acceptor interaction following the Dewar–Chatt–Duncansson model. Important deviations from $\Delta = 0$ imply that the bond studied is more conventionally described as a normal covalent bond between two open shell fragments. A more detailed presentation of the CDA method and the interpretation of the results can be found in the literature. Compositions of molecular orbitals, overlap populations between molecular fragments, bond orders and density-of-states spectra were calculated by using the AOMix program developed by I. Gorelski (version 6.23).[21]

**X-ray Structure Data:** Nonius KappaCCD diffractometer, $\varphi$ and $\omega$ scans, Mo-$K_\alpha$ radiation ($\lambda = 0.71073$ Å), graphite monochromator, $T = 150$ K, structure solution with SIR97,[22] refinement against $F^2$ in SHELXL97[23] with anisotropic thermal parameters for all non-hydrogen atoms, calculated hydrogen positions with riding isotropic thermal parameters (Table 9).

CCDC-294689 to -294695 contain the crystallographic data for the structures reported in this paper and have been deposited with the Cambridge Crystallographic Data Centre. Copies of these data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Complexes 10a,b [Pd(1)($\eta_3$-$C_3H_5$)][X]:** To a solution of glyoxal-bis(2,6-diisopropylphenyl)imine (100 mg, 0.26 mmol) in dichloromethane (2 mL) was added $[Pd(allyl)Cl]_2$ (48.6 mg, 0.13 mmol). After 5 min stirring, the silver salt AgX (0.26 mmol, **10a**: 68.2 mg, **10b**: 99.3 mg) was added and the pale-yellow solution became orange. Filtration of AgCl on celite followed by evaporation of the dichloromethane yielded the complexes as orange powders in very good yields (**10a**: 97%, 170 mg; **10b**: 98%, 201 mg). Single-crystals of **10a** were obtained by slow diffusion of hexanes into a solution of the complex in chloroform at room temperature. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 1.32 (m, 24 H, CHC$H_3$), 3.03 (m, 2 H, C$H$CH$_3$), 3.17 (vd, AA′BB′C, Σ $J$ = 12.8 Hz, 2 H, $CH_{allyl}$), 3.25 (m, 2 H, C$H$CH$_3$), 3.59 (vd, AA′BB′C, Σ $J$ = 7.0 Hz, 2 H, $CH_{allyl}$), 5.56 (tt, $J$ = 7.0 and 12.8 Hz Hz, 1 H, $CH_{allyl}$), 7.26–7.40 (m, 6 H, $m$-Ph), 8.61 (s, 2 H, C$H$=N) ppm. $^{13}$C NMR ($CDCl_3$, 25 °C): $\delta$ = 23.0 (CH$C$H$_3$), 23.7 ($C$H=N), 28.9 ($C$HCH$_3$), 65.1 ($CH_{2allyl}$), 120.1 ($CH_{allyl}$), 124.1–128.8 ($m$-Ph), 138.1 ($o$-Ph), 146.1 ($ipso$-Ph), 170.0 ($p$-Ph) ppm. $C_{30}H_{41}F_3N_2O_3PdS$ (673.14): calcd. C 53.53, H 6.14; found C 53.28, H 6.12.

**Synthesis of Complexes 12a,b [Pd(3)($\eta_3$-$C_3H_5$)][X]:** To a solution of 1,2-bis(diphenylphosphanyl)ethane (100 mg, 0.25 mmol) in dichloromethane (2 mL) was added $[Pd(allyl)Cl]_2$ (0.13 mmol, 45.9 mg). After stirring for 5 min, the formation of a bidentate complex was confirmed by $^{31}$P NMR ($\delta$ = 51.2 ppm). The silver salt AgX was then added (0.25 mmol, **12a**: 64.5 mg, **12b**: 93.9 mg). Filtration of AgCl on celite followed by evaporation of the dichloromethane yielded the complexes as white powders in very good yields (**12a**: 98%, 170 mg; **12b**: 98%, 200 mg). Single-crystals of **12b** were obtained by slow diffusion of hexanes into a solution of the complex in dichloromethane at room temperature. $^{31}$P NMR ($CDCl_3$, 25 °C): $\delta$ = 51.4 ppm. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 2.70 (m, $A_2A'_2XX'$, Σ $J$ = 99.5 Hz, 4 H, C$H_2$PPh$_2$), 3.39 (vddd, AA′BB′CXX′, Σ$J$ = 24.8 Hz, 2 H, $CH_{allyl}$), 4.86 (m, AA′BB′CXX′, Σ $J$ = 12.4 Hz, 2 H, $CH_{allyl}$), 5.81 (vtt, $AB_2C_2X_2$, Σ $J$ = 42.5 Hz, 1 H, $CH_{allyl}$), 7.43–7.60 (m, 20 H, Ph) ppm. $^{13}$C NMR ($CDCl_3$, 25 °C): $\delta$ = 27.5 (vt, AXX′, Σ $J$ = 46.0 Hz, $CH_2$PPh), 71.4 (vt, AXX′, Σ $J$ = 33.2 Hz, $CH_{2allyl}$), 123.6 (vt, AXX′, Σ $J$ = 12.2 Hz, $CH_{allyl}$), 129.9–132.8 (Ph) ppm. $C_{31}H_{29}F_6NO_4P_2PdS_2$ (826.1): calcd. C 45.07, H 3.54; found C 44.85, H 3.53.

**Synthesis of Complexes 13a,b [Pd(4)($\eta_3$-$C_3H_5$)][X]:** To a solution of 1,2-bis(diphenylphosphanyl)propane (100 mg, 0.24 mmol) in dichloromethane (2 mL) was added $[Pd(allyl)Cl]_2$ (0.12 mmol, 44.5 mg). After 5 min stirring, the formation of a bidentate complex was confirmed by $^{31}$P NMR ($\delta$ = 6.3 ppm). The silver salt AgX was then added (0.24 mmol, **13a**: 61.7 mg, **13b**: 89.8 mg). Filtration of AgCl on celite followed by evaporation of the dichloromethane yielded the complexes as white powders in very good yields (**13a**: 96%, 165 mg; **13b**: 95%, 190 mg). Single-crystals of **13a** were obtained by slow diffusion of hexanes into a solution of the complex in dichloromethane at room temperature. $^{31}$P NMR ($CDCl_3$, 25 °C): $\delta$ = 6.8 ppm. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 2.00 (m, $A_2M_4X_2$, Σ $J$ = 147.7 Hz, 2 H, C$H_2$CH$_2$PPh$_2$), 2.76 (m, $A_2A'_2M_2XX'$, Σ $J$ = 87.4 Hz, 4 H, CH$_2$C$H_2$PPH$_2$), 3.28 (vddd, AA′BB′CXX′, Σ $J$ = 25.6 Hz, 2 H, $CH_{allyl}$), 3.95 (vddd, AA′BB′CXX′, Σ $J$ = 13.5 Hz, 2 H, $CH_{allyl}$), 5.7 (vtt, $AB_2C_2X_2$, Σ $J$ = 42.2 Hz, 1 H, $CH_{allyl}$), 7.31–7.48 (m, 20 H, Ph) ppm. $^{13}$C NMR ($CDCl_3$, 25 °C): $\delta$ = 18.7 (s, $C$H$_2$CH$_2$PPh$_2$), 25.3 (vt, AXX′, Σ $J$ = 30.7 Hz, CH$_2$C$H_2$PPh$_2$), 73.7 (vt, AXX′, Σ $J$ = 32.5 Hz, $CH_{2allyl}$), 123.0 (vt, AXX′, Σ $J$ = 12.4 Hz, $CH_{allyl}$), 128.9–132.8 (Ph) ppm. $C_{31}H_{31}F_3O_3P_2PdS$ (709.0): calcd. C 52.51, H 4.41; found C 52.35, H 4.40.

**Synthesis of Complexes 14a,b [Pd(5)($\eta_3$-$C_3H_5$)][X]:** To a solution of $[Pd(allyl)Cl]_2$ (0.16 mmol, 58.6 mg) in dichloromethane (2 mL) was added triphenylphosphole (0.32 mmol, 100 mg). The formation of the monophosphole complex was confirmed by $^{31}$P NMR ($\delta$ = 20.9 ppm). A second equiv. of triphenylphosphole (0.32 mmol, 100 mg) was added and after 5 min stirring, the formation of the

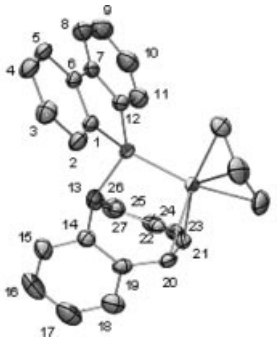
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bis(phosphole) complex was confirmed by $^{31}P$ NMR ($\delta$ = 11.0 ppm). The chloride was then abstracted with a silver salt AgX (0.32 mmol, **14a**: 83 mg, **14b**: 120 mg). Filtration of AgCl on celite followed by evaporation of the dichloromethane yielded the complexes as yellow powders in very good yields (**14a**: 98%, 280 mg; **14b**: 95%, 325 mg). Single-crystals of **14a** were obtained by slow diffusion of hexanes into a solution of the complex in dichloromethane at room temperature. $^{31}P$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 22.7 ppm. $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 3.61 (vdd, AA′BB′CXX′, $\Sigma J$ = 22.5 Hz, 2 H, $CH_{allyl}$), 4.61 (vdd, AA′BB′CXX′, $\Sigma J$ = 9.5 Hz, 2 H, $CH_{allyl}$), 5.75 (vsept, $AB_2C_2X_2$, $\Sigma J$ = 41.9 Hz, 1 H, $CH_{allyl}$), 6.88 (m, $A_2A'_2XX'$, $\Sigma J$ = 68.9 Hz, 4 H, $H_\beta$), 7.03–7.32 (m, 30 H, $H_{Ph}$) ppm. $^{13}C$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 80.1 (vt, AXX′, $\Sigma J$ = 25.8 Hz, $CH_{2allyl}$), 122.8 (vt, AXX′, $\Sigma J$ = 9.9 Hz, $CH_{allyl}$), 126.7 (vt, AXX′, $\Sigma J$ = 7.5 Hz, $CH_{Ph}$), 127.0 (vt, AXX′, $\Sigma J$ = 7.4 Hz, $CH_{Ph}$), 129.0 (s, $CH_{Ph}$), 129.1 (s, $CH_{Ph}$), 129.2 (s, $CH_{Ph}$), 129.6 (vt, AXX′, $\Sigma J$ = 10.9 Hz, $CH_{Ph}$), 131.9 (s, $CH_{Ph}$), 132.4 (vt, AXX′, $\Sigma J$ = 11.6 Hz, $C_{Ph}$), 133.1 (vt, AXX′, $\Sigma J$ = 14.4 Hz, $C_{Ph}$), 133.2 (vt, AXX′, $\Sigma J$ = 14.4 Hz, $C_{Ph}$), 135.0 (vt, AXX′, $\Sigma J$ = 13.5 Hz, $CH_\beta$), 135.4 (vt, AXX′, $\Sigma J$ = 13.4 Hz, $CH_\beta$), 142.6 (m, $\Sigma J$ = 121.7 Hz, Cα) ppm. $C_{48}H_{39}F_3O_3P_2PdS$ (921.3): calcd. C 62.58, H 4.27; found C 62.18, H 4.25.

**Synthesis of Complexes 15a,b [Pd(6)($\eta_3$-$C_3H_5$)][X]:** To a solution of $[Pd(allyl)Cl]_2$ (0.14 mmol, 50 mg) in dichloromethane (2 mL) was added the 1-phenyl dibenzophosphole (0.27 mmol, 71 mg). The formation the monophosphole complex was confirmed by $^{31}P$ NMR ($\delta$ = 15.8 ppm). A second equiv. of 1-phenyl dibenzophosphole (0.27 mmol, 71 mg) was added and after 5 min stirring, the formation of the bis(phosphole) complex was confirmed by $^{31}P$ NMR ($\delta$ = 11.9 ppm). The chloride was then abstracted with a silver salt AgX (0.27 mmol, **15a**: 70 mg, **15b**: 102 mg). Filtration of AgCl on celite followed by evaporation of the dichloromethane yielded the complexes as pale yellow powders in very good yields (**15a**: 98%, 217 mg; **15b**: 97%, 245 mg). Single-crystals of **15a** were obtained by slow diffusion of hexanes into a solution of the complex in dichloromethane at room temperature. $^{31}P$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 13.9 ppm. $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 3.84 (br. s, 4 H, $CH_{allyl}$), 5.71 (vq, $AB_2C_2X_2$, $\Sigma J$ = 41.9 Hz, 1 H, $CH_{allyl}$), 7.68–7.21 (m, 26 H, Ph) ppm. $^{13}C$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 74.23 (br. s, $CH_{2allyl}$), 121.0 (br. s, $CH_{allyl}$), 122.2 (d, $J_{PH}$ = 5.0 Hz, $CH_{Ph}$), 129.1 (d, $J_{PH}$ = 11.2 Hz, $CH_{Ph}$), 129.3 (d, $J_{PH}$ = 12.3 Hz, $CH_{Ph}$), 131.1 (br. s, $CH_{Ph}$), 131.3 (s, $CH_{Ph}$), 131.6 (vt, AXX′, $\Sigma J$ = 11.9 Hz, $CH_{Ph}$), 142.7 (d, $J_{PH}$ = 8.7 Hz, $C_{Ph}$) ppm. $C_{40}H_{31}F_3O_3P_2PdS$ (817.1): calcd. C 58.80, H 3.82; found C 58.57, H 3.82.

**Synthesis of Complexes 17a,b [Pd(8)($\eta_3$-$C_3H_5$)][X]:** To a solution of bis(2,5-diphenylphosphol-1-yl)propane (100 mg, 0.20 mmol) in dichloromethane (2 mL) was added $[Pd(allyl)Cl]_2$ (0.10 mmol, 35.7 mg). After 15 min stirring, the silver salt AgX was added (0.10 mmol, **17a**: 50.2 mg, **17b**: 73 mg) and the formation of the complexes were confirmed by $^{31}P$ NMR ($\delta$ = 9.0 ppm). Filtration of AgCl on celite followed by evaporation of the dichloromethane yielded the complexes as dark-red powders in very good yields (**17a**: 95%, 150 mg; **17b**: 96%, 174 mg). $^{31}P$ NMR ($CDCl_3$, 25 °C): $\delta$ = 9.0 ppm. $^1H$ NMR ($CDCl_3$, 25 °C): $\delta$ = 2.24 [m, 6 H, $P(CH_2)_3P$], 3.19 (vdt, AA′BB′CXX′, $\Sigma J$ = 23.5 Hz, 2 H, $CH_{allyl}$), 4.17 (vd AA′BB′CXX′, $\Sigma J$ = 7.0 Hz, 2 H, $CH_{allyl}$), 5.58 (vsept, $AB_2C_2X_2$, $\Sigma J$ = 41.1 Hz, 1 H, $CH_{allyl}$), 7.15–7.45 (m, 24 H, Ph and $H_\beta$) ppm. $^{13}C$ NMR ($CDCl_3$, 25 °C): $\delta$ = 19.1 (vt, AXX′, $\Sigma J$ = 29.4 Hz, $CH_2CH_2P$), 20.3 (s, $CH_2CH_2P$), 75.3 (vt, AXX′, $\Sigma J$ = 25.6 Hz, $CH_{2allyl}$), 121.9 (vt, AXX′, $\Sigma J$ = 9.1 Hz, $CH_{allyl}$), 126.3 (m, $CH_{Ph}$), 128.0 (s, $CH_{Ph}$), 128.7 (vd, $\Sigma J$ = 10.1 Hz, $CH_{Ph}$), 132.5 (vt, AXX′, $\Sigma J$ = 14.6, $C_{Ph}$), 132.9 (vt, AXX′, $\Sigma J$ = 14.6, $C_{Ph}$), 134.9 (vt, AXX′, $\Sigma J$ = 14.6 Hz, $CH_\beta$), 135.6 (vt, AXX′, $\Sigma J$ = 14.8 Hz, $CH_\beta$), 144.9 (m, $\Sigma J$ = 86.7 Hz, Cα) ppm. $C_{41}H_{35}F_3O_3P_2PdS$ (833.2): calcd. C 59.11, H 4.23; found C 58.88, H 4.22.

**Synthesis of Complexes 19a,b [Pd(9)($\eta_3$-$C_3H_5$)][X]:** To a solution of ligand (100 mg, 0.27 mmol) in dichloromethane (2 mL) was added $[Pd(allyl)Cl]_2$ (0.13 mmol, 48.8 mg). After stirring for 5 min, the formation of the intermediate complex **18** was confirmed by $^{31}P$ NMR ($\delta$ = 49.5 ppm) and single-crystals of **18** were grown by slow diffusion of hexanes into a solution in dichloromethane at room temperature. The chloride was then abstracted with a silver salt AgX (0.27 mmol, **19a**: 68.6 mg, **19b** 100 mg). Filtration of AgCl on celite followed by evaporation of the dichloromethane yielded the complexes as white powders in very good yields (**19a**: 97%, 175 mg; **19b**: 96%, 205 mg). Single-crystals of **19b** were obtained by slow diffusion of hexanes into a solution of the complex in dichloromethane at room temperature.



$^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 55.8 ppm. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 3.25 (m, 2 H, $CH_{allyl}$), 4.10 (vdd, ABCDEX, $\Sigma J$ = 23.4 Hz, 1 H, $CH_{allyl}$), 4.62 (d, $J_{PH}$ = 15.8 Hz, 1 H, $H^{13}$), 5.43 (vt, ABCDEX, $\Sigma J$ = 13.6 Hz, 1 H, $CH_{allyl}$), 5.77 (vsept, ABCDEX, $\Sigma J$ = 41.9 Hz, 1 H, $CH_{allyl}$), 6.08 (dd, $J_{H,H}$ = 7.5, $J_{P,H}$ = 7.5 Hz, 2 H, $H^5$–$H^8$), 7.01 (m, $\Sigma J$ = 10.5 Hz, 2 H, $H^{15}$–$H^{26}$), 7.15 (m, $\Sigma J$ = 21.3 Hz, 2 H, $H^3$–$H^{10}$), 7.53 (m, 6 H, $H^{17}$–$H^{24}$, $H^{16}$–$H^{25}$ and $H^4$–$H^9$), 7.66 (s, 2 H, $H^{20}$–$H^{21}$), 7.72 (m, $\Sigma J$ = 8.9 Hz, 2 H, $H^{18}$–$H^{23}$), 7.95 (m, $\Sigma J$ = 9.6 Hz, 2 H, $H^2$–$H^{11}$) ppm. $^{13}C$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 54.8 (d, $J_{P,C}$ = 14.2 Hz, $C^{13}$), 66.0 (s, $CH_{2allyl}$), 85.9 (d, $J_{PC}$ = 24.7 Hz, $CH_{2allyl}$), 104.3 (s, $C^{20}$–$C^{21}$), 122.3 (d, $J_{P,C}$ = 6.1 Hz, $C^2$–$C^{11}$), 124.9 (d, $J_{P,C}$ = 5.3 Hz, $C^3$–$C^{10}$), 129.0 (d, $J_{P,C}$ = 10.5 Hz $C^{15}$–$C^{26}$), 129.5 (d, $J_{P,C}$ = 2.4 Hz, $C^4$–$C^9$), 130.8 (d, $J_{P,C}$ = 22.2 Hz, $C^5$–$C^8$), 130.9 (d, $J_{P,C}$ = 2.7 Hz, $C^{16}$–$C^{25}$), 131.8 (d, $J_{P,C}$ = 45.9 Hz, $C^1$–$C^{12}$), 131.9 (d, $J_{P,C}$ = 4.5 Hz, $C^{18}$–$C^{23}$), 132.9 (d, $J_{P,C}$ = 2.1 Hz, $C^{17}$–$C^{24}$), 133.5 (d, $J_{P,C}$ = 9.2 Hz, $C^{14}$–$C^{27}$), 135.3 (d, $J_{P,C}$ = 2.8 Hz, $C^{19}$–$C^{22}$), 142.8 (d, $J_{P,C}$ = 9.6 Hz, $C^6$–$C^7$) ppm, missing $CH_{allyl}$. $C_{32}H_{24}F_6NO_4PPdS_2$ (802.1): calcd. C 47.92, H 3.02; found C 47.57, H 3.01.

**General Procedure for Catalytic Reactions:** The catalyst (1 mol-%) was placed in a Schlenck tube with $MgSO_4$ (0.25 g) and THF (1 mL). The Schlenck tube was then filled with aniline (182 μL, 2 mmol) and allyl alcohol (68 μL, 1 mmol). The mixture was stirred at room temperature and the progress of the reaction was monitored by GC. The mixture was filtered to remove the $MgSO_4$ and the solvent evaporated in vacuo. The product was then isolated by column chromatography on alumina (hexanes).

# Synthesis, Characterization, and Luminescence Properties of $Eu^{3+}$ 3-Phenyl-4-(4-toluoyl)-5-isoxazolonate Based Organic-Inorganic Hybrids

**Patricia P. Lima,[a,b] Severino A. Junior,[a] Oscar L. Malta,[a] Luis D. Carlos,[b] Rute A. Sá Ferreira,[b] Rani Pavithran,[c] and M. L. P. Reddy*[c]**

**Keywords:** Organic-inorganic hybrids / $Eu^{3+}$ / Heterocyclic β-diketonates / Synthesis / Characterization / Luminescence

Organic-inorganic hybrids incorporating $Eu(TPI)_3{\cdot}3H_2O$ or $Eu(TPI)_3{\cdot}2TOPO$ [where TPI and TOPO stand for 3-phenyl-4-(4-toluoyl)-5-isoxazolone and tri-*n*-octylphosphane oxide, respectively] were synthesized either by acetic acid solvolysis or a conventional hydrolysis sol-gel route. The host framework of these materials, named as di-ureasil, consists of a siliceous skeleton grafted, through urea cross-linkages, to both ends of poly(ethylene oxide) chains. The resulting $Eu^{3+}$-based di-ureasils were characterized by X-ray diffraction and Fourier transform mid-IR, $^{29}Si$ and $^{13}C$ NMR, and photoluminescence spectroscopy. The room-temperature photoluminescence (PL) spectra of the $Eu^{3+}$-based di-ureasils display the typical $Eu^{3+}$ red emission, assigned to transitions between the first excited state ($^5D_0$) and the ground multiplet ($^7F_{0-4}$). Enhanced $^5D_0$ quantum efficiency ($\eta$ = 13 % vs. 32 %) and a longer lifetime ($\tau$ = 0.30 vs. 0.42 ms) was noticed for the hybrid incorporating the $Eu(TPI)_3{\cdot}3H_2O$ complex, compared with the undoped complex. The enhancement is explained by the coordination ability of the organic counter part of the host structure, which is strong enough to displace the water molecules of the $Eu(TPI)_3{\cdot}3H_2O$ complex from the $Eu^{3+}$ neighborhood in the hybrids. On the other hand, a decrease in the $^5D_0$ quantum efficiency ($\eta$ = 76 % vs. 61 %) and lifetime ($\tau$ = 0.98 vs. 0.75 ms) was noticed for the hybrid incorporating the $Eu(TPI)_3{\cdot}2TOPO$ complex, relative to the undoped complex, probably because of an increase in the nonradiative transition probability.

## Introduction

Lanthanide complexes with organic ligands are of great interest for a wide range of photonic applications, such as tuneable lasers, optical fibres for telecommunications, components of emitting layers in multilayer organic light-emitting diodes (OLEDs), and light conversion molecular devices (LCMDs).[1–5] The β-diketone ligand is one of the most important "antenna" from which the energy can be effectively transferred to lanthanide ions for high harvest emissions.[4] Despite lanthanide β-diketonate complexes being characterized by a highly efficient light emission under UV excitation they have not been employed so far as tuneable solid-state lasers or phosphor devices essentially because of their low thermal and photochemical stability and poor mechanical properties.[6] Furthermore, lanthanide β-diketonate chelates are usually isolated as hydrates in which two or three water molecules are included in the first coordination sphere of the central metal ion, quenching the emission from the activation of nonradiative decay paths.[4,7–8]

One of the strategies adopted in recent years to simultaneously improve the thermal stability, mechanical properties, and light-emission properties of lanthanide β-diketonate complexes is to incorporate these complexes into sol-gel-derived organic-inorganic hybrids.[9–13] The main interest of the organic-inorganic hybrid concept basically derives from the possibility of tailoring the properties of novel multifunctional advanced materials through the combination, at the nanosize level, of the organic and inorganic components in one single material.[14,15] Among the sol-gel-derived structures proposed so far, a family of interesting lanthanide-based hybrid compounds have been reported.[16] The host matrix, termed as di-ureasil, comprises poly(ethylene oxide) (PEO) chains of variable length grafted to both ends to a siliceous backbone through urea cross linkages. These xerogels, which are easily produced as thin, elastomeric and highly transparent monoliths, may withstand a large amount of guest dopants. When doped with trivalent lanthanide ions like $Nd^{3+}$, $Eu^{3+}$, and $Tb^{3+}$ the di-ureasils display remarkable emission properties. Besides a broad long-lived emission covering the whole visible range of the electromagnetic spectrum, the di-ureasils exhibit the typical intra-4f narrow line emission in the green ($Tb^{3+}$),[17] red ($Eu^{3+}$),[18–20] and even in the near infrared ($Nd^{3+}$) region,[21] thus opening new prospects for their applications.

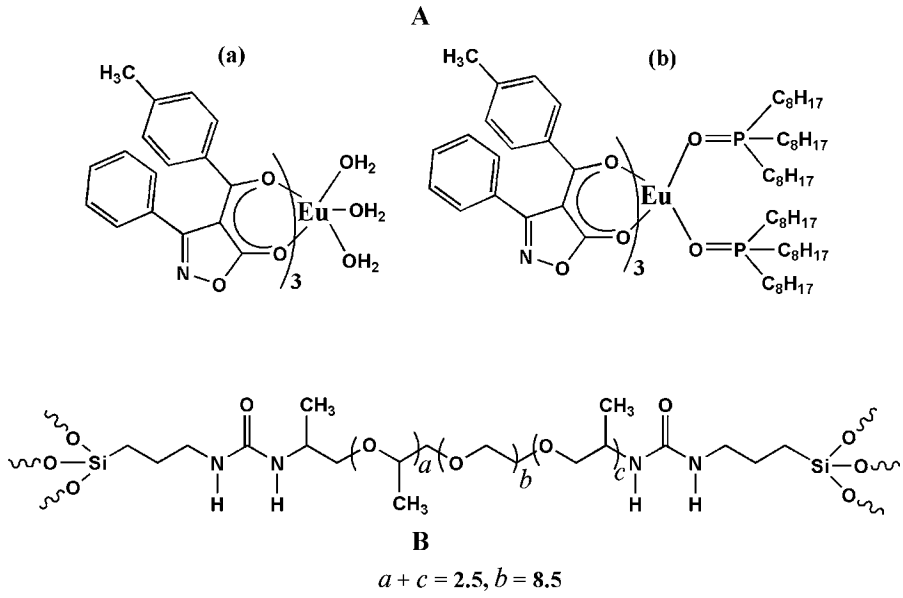

Figure 1. A: Chemical structure of (a) $Eu(TPI)_3{\cdot}3H_2O$ (**1**) and (b) $Eu(TPI)_3{\cdot}2TOPO$ (**2**); B: d-U(600) di-ureasil hybrid.

A significant part of the research strategy in the field involves the encapsulation of lanthanide organic complexes with β-diketonates, aromatic carboxylic acids and heterocyclic ligands in sol-gel-derived matrices. These complexes can be embedded in the matrix by using the ligands covalently grafted to the framework or by anchoring the lanthanide ion to specific functional groups of the hybrid matrix. Recently, $Eu^{3+}$ β-diketonate complexes have been successfully incorporated into organic-inorganic hybrids and their photophysical properties have been investigated.[9–11] Nevertheless, the incorporation of heterocyclic β-diketonate complexes, namely $Eu^{3+}$ 4-acyl-3-phenyl-5-isoxazolonate complexes, into organic-inorganic hybrids has not been attempted to date.

In this paper, heterocyclic β-diketone $Eu^{3+}$ complexes with the molecular formulae $Eu(TPI)_3{\cdot}3H_2O$ and $Eu(TPI)_3{\cdot}2TOPO$ [where TPI = 3-phenyl-4-(4-toluoyl)-5-isoxazolone and TOPO = tri-*n*-octylphosphane oxide], recently introduced as light conversion molecular devices by Reddy et al.,[22] were incorporated into di-ureasil organic-inorganic hybrids (Figure 1) by conventional hydrolysis and acetic acid solvolysis. The photoluminescence (in excitation and emission modes), the $^5D_0$ quantum efficiency, and lifetime of the di-ureasil hybrids were investigated and compared with those of the precursor complexes.

## Results and Discussion

The synthesis procedures and characterization of the complexes $Eu(TPI)_3{\cdot}3H_2O$ (**1**) and $Eu(TPI)_3{\cdot}2TOPO$ (**2**) (Figure 1A) are detailed in our earlier publication.[22] The complexes **1** and **2** were incorporated into the di-ureasil host by acetic acid solvolysis according to the procedure described elsewhere.[10] Complex **2** was also incorporated into di-ureasil by a conventional hydrolysis sol-gel route.[10] Figure 1B illustrates the structure of the undoped hybrid matrix.

### Powder X-ray Diffraction (XRD)

The X-ray diffraction patterns of d-U(600)-**1**-AA [$Eu(TPI)_3{\cdot}3H_2O$ (**1**) incorporated into the d-U(600) di-ureasil by acetic acid (AA) solvolysis], d-U(600)-**2**-AA [$Eu(TPI)_3{\cdot}2TOPO$ (**2**) incorporated into the d-U(600) di-ureasil by acetic acid (AA) solvolysis], and d-U(600)-**2** [$Eu(TPI)_3{\cdot}2TOPO$ (**2**) incorporated into the d-U(600) di-ureasil by conventional hydrolysis] are shown in Figure 2. The patterns display a main peak centered at ca. 21.0–21.7° associated with ordering within the siloxane domains. The second-order peak appears as a broad weak hump around 38–46°. The structural unit distance, calculated using the Bragg law, is approximately 4.07–4.21 Å. These results are similar to those reported for carboxylic acid solvolysis derived undoped hybrids.[14] These data reveal that the $Eu^{3+}$-based hy-

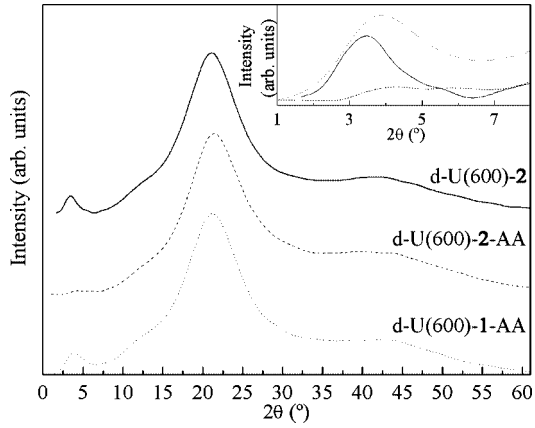

Figure 2. XRD patterns of the $Eu^{3+}$-based di-ureasil hybrids.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

brids are highly amorphous. The peak appearing at lower angles in the XRD patterns, at ca. 3.5 and 5.2° (inset of Figure 1), has been assigned to interparticle scattering interference between siliceous domains[23] located at the ends of the polymer chain and spatially correlated at a mean distance of 25 ± 1 Å, for d-U(600)-**1**-AA, 28 ± 1 Å, for d-U(600)-**2**, and 19 ± 1 Å, for d-U(600)-**2**-AA. The different values calculated for the hybrids incorporating complex **2** indicate that the synthesis methods induce significant differences in the hybrid structure.

### Fourier-Transform Infrared Spectroscopy (FT-IR)

The FT-IR spectra of d-U(600)-**1**-AA, d-U(600)-**2**-AA, and d-U(600)-**2** are shown in Figure 3. The shoulder at ca. 920 $cm^{-1}$ provides evidence that in the di-ureasils the PEO chains attain complete disorder. Compared with the undoped di-ureasil,[24] the intensity of the shoulder shows a very slight decrease, indicating a very weak interaction between the polymer and the complex.[10] The bands at 1324 $cm^{-1}$ are characteristic of the amorphous state.[10] The 1354 $cm^{-1}$ bands, ascribed to the $CH_2$ wagging vibrations, are clearly seen in the spectra. It is known that the νCO mode of PEO is an excellent tool to probe the changes that the polymer chains of the hybrids undergo upon incorporation of the guest compounds. The fact that peaks at about 1110 $cm^{-1}$, characteristic of noncoordinated oxyethylene moieties,[24] are almost unchanged in the spectra of the $Eu^{3+}$-based di-ureasils suggests that the PEO chains of the host materials persist in an uncomplexed state.

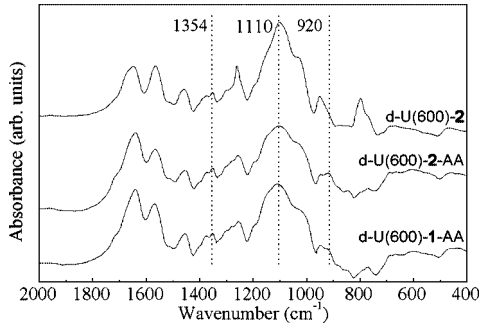

Figure 3. FTIR spectra of the $Eu^{3+}$-based di-ureasil hybrids.

In order to study in detail the vibrations of the urea groups, spectral deconvolutions to the so-called "amide I" (1800–1600 $cm^{-1}$) and "amide II" (1600–1500 $cm^{-1}$) regions were carried out using Gaussian band shapes, as reported elsewhere.[14,24] Three components were isolated for the "amide I" band at 1700, 1672, and 1647 $cm^{-1}$. According to the literature,[19,24] the former two components are ascribed to the vibrations of urea–polyether hydrogen-bonded structures, whereas the last one is ascribed to the strong self-associated hydrogen-bonded urea–urea associations. For the $Eu^{3+}$-doped di-ureasils, besides the three mentioned peaks, a new peak appears at 1619–1625 $cm^{-1}$, indicating an effective interaction between the $Eu^{3+}$ ions and the carbonyl oxygen atoms of the urea cross-links. While for the hybrids incorporating complex **1** this result suggests the probable substitution of the water molecules in the $Eu^{3+}$ coordination sphere, for those with complex **2** an interaction between the $Eu^{3+}$ ions and the urea cross-links through the carbonyl groups should occur. In addition, the absence of an individual band at ca. 1750 $cm^{-1}$ in all the spectra indicates that neither C=O nor N–H groups from urea cross-linkages are left free in the hybrid materials.[10] The "amide II" mode is a mixed contribution of the N–H in-plane bending, C–N stretching, and C–C stretching vibrations, peaking, for all the samples, at ca. 1565 $cm^{-1}$.

### NMR Spectra

The $^{29}Si$ MAS NMR spectra of d-U(600)-**1**-AA and d-U(600)-**2**-AA exhibit broad signals characteristic of $T_1$, $T_2$, and $T_3$ units (Figure 4). These sites are labeled using the conventional $T_n$ notation, where $n$ ($n$ = 1, 2, 3) is the number of Si-bridging oxygen atoms. The absence of $T_0$ indicates that, although the polycondensations are not, in most cases, complete, no precursor is left unreacted. The $T_2$ and $T_3$ environments (at $\delta \approx -58$ and –66 ppm, respectively) are clearly dominant, showing the presence of two main types of local structures: $(SiO)_2Si(CH_2)_3OH$ and $(SiO)_3Si(CH_2)_3$. The very weak shoulder displayed in these hybrids at $\delta \approx 51.5$ and 53.1 ppm, for d-U(600)-**1**-AA and d-U(600)-**2**-AA, respectively, is ascribed to $T_1$ sites. The condensation degree $c$ (Table 1), was calculated using the expression $c = 1/3(\%T_1 + 2\%T_2 + 3\%T_3)$. Compared with the undoped sample[14] the condensation degree decreases, suggesting that there are some interactions between the complex and the matrix (urea cross-links) and that the relatively larger molecular size for the complex sterically prevents the polycondensation process and results in the lower condensation degree.

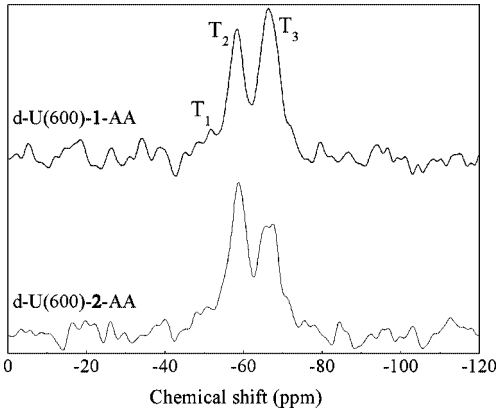

Figure 4. $^{29}$ Si MAS NMR spectra of the $Eu^{3+}$-based di-ureasil hybrids prepared by solvolysis.

The $^{13}C$ CP MAS NMR spectra of d-U(600)-**1**-AA and d-U(600)-**2**-AA display a peak at $\delta$ = 70.6 ppm, attributed to $-(OCH_2CH_2)-$, whereas the shoulder at about 75.0 ppm originates from the main-chain carbons of propylene oxide.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 1. $^{29}Si$ NMR chemical shifts (ppm), population of different $T_n$ ($n$ = 1, 2, 3) species (%), and degree of condensation (%), $c$, of d-U(600)-AA, d-U(600)-**1**-AA, and d-U(600)-**2**-AA.

| Hybrids | $T_1$ | $T_2$ | $T_3$ | $c$ |
|---|---|---|---|---|
| d-U(600)-AA | –55.5(11) | –58.9(28) | –66.9(61) | 83[10] |
| d-U(600)-**1**-AA | –51.5(19.3) | –58.2(25.4) | –66.5(55.3) | 75.3 |
| d-U(600)-**2**-AA | –53.1(26.8) | –58.6(27.9) | –66.6(45.3) | 72.8 |

The peaks at ca. 46 and 24 ppm are characteristic of the $(CH_2)_3$ aliphatic chains. The signal at $\delta$ = 18.5 ppm is assigned to different $CH_3$ groups of the polymer chains, while the shoulder at $\delta$ = 17.4 ppm is ascribed to the ethoxy groups of the carbon atoms. The weak peak at $\delta \approx 159$ ppm is associated with the C=O groups of the urea linkages,[25,26] supporting the interaction between the complex and the hybrid matrix, in agreement with the results obtained from FT-IR spectroscopy. These results are similar to those reported elsewhere.[10]

## Photoluminescence

Figures 5A and B compare the room-temperature excitation spectra (monitored around the peak of the intense $^5D_0 \rightarrow {}^7F_2$ transition) of complexes **1** and **2** with those of d-U(600)-**1**-AA, d-U(600)-**2**-AA, and d-U(600)-**2**. While the spectrum of complex **1** is dominated by the intra-4f$^6$ lines corresponding to the $^7F_{0-1} \rightarrow {}^5D_{1-2}$ transitions, the spectrum of complex **2** displays an intense broad band, with three main components at ca. 298, 330, and 400 nm, ascribed to the ligand levels. For the latter complex the relative intensity of the intra-4f$^6$ lines is weaker than the absorption of the organic ligands, indicating that luminescence sensitization from the ligand excitation is more efficient than the direct intra-4f$^6$ absorption. Moreover, in that complex the $Eu^{3+}$ ions are excited over a much larger wavelength range (240–440 nm) than that observed for complex **1** (310–440 nm). The spectra of the $Eu^{3+}$-based di-ureasils are blueshifted with respect to that of the two complexes presenting mainly a broad band (260–450 nm) peaking around 375 nm and related to the ligand levels and to the hybrid host emitting centers. This reinforces that the complex incorporation of the d-U(600) host changes the $Eu^{3+}$ surroundings. As illustrated for complex **2** in Figure 5B, the synthesis route used to incorporate the complexes leads to slight differences in the $Eu^{3+}$ excitation paths, as reported for analogous $Eu^{3+}$-based di-ureasil hybrids.[10] It is worth noting that the efficiency of the sensitized process in the hybrids is almost constant over a very broad UV/Vis spectral region (250–450 nm). Moreover, the absence of $Eu^{3+}$ intra-4f$^6$ lines in the excitation spectra of the hybrids strongly suggests that the metal ions are essentially excited by an efficient sensitized process rather than by direct population of the intra-4f$^6$ levels (the di-ureasil host contributes to enhancing the $Eu^{3+}$ sensitization process).

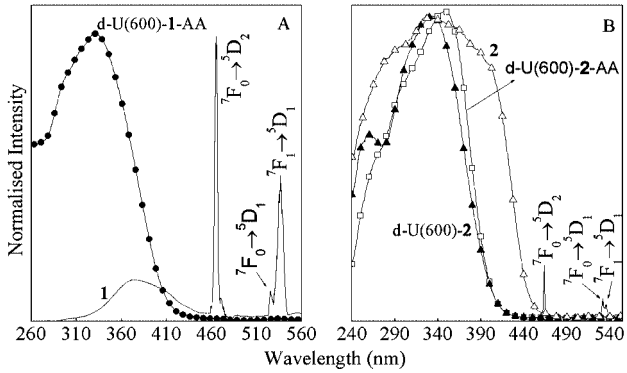

Figure 5. Room-temperature excitation spectra (monitored around 610–614 nm) of (A) complex **1** (solid line), d-U(600)-**1**-AA (solid circles) and of (B) complex **2** (open triangles), d-U(600)-**2**-AA (solid triangles), d-U(600)-**2** (open squares).

Figures 6 and 7 show the room-temperature emission spectra of the two complexes and the corresponding $Eu^{3+}$-based di-ureasils. The spectra display the characteristic sharp peaks of the $Eu^{3+}$ $^5D_0 \rightarrow {}^7F_{0-4}$ transitions (575–725 nm) being dominated by the hypersensitive $^5D_0 \rightarrow {}^7F_2$ lines, which point to a highly polarizable chemical environment around the $Eu^{3+}$ ion.[11,13] The detection of a single $^5D_0 \rightarrow {}^7F_0$ transition for all the samples investigated (Figure 6 and Figure 7B), with a typical full-width at half-maximum (fwhm) value of ca. 20 cm$^{-1}$, suggests the presence of a single $Eu^{3+}$ chemical environment. The detection of that line, the local-field splitting of the $^7F_{1,2}$ levels in the 3 and 4 Stark components (Figure 6, Figure 7C and D) and the higher intensity of the $^5D_0 \rightarrow {}^7F_2$ transition indicate that the $Eu^{3+}$ local coordination site has a low symmetry without an inversion center. For the two complexes, no emission arising from the ligand triplet levels is detected, pointing to an efficient ligand-to-$Eu^{3+}$ energy transfer. On the other hand, the emission spectra of the hybrids display a very-low-intensity band in the blue-green region, as illustrated in the inset of Figure 6 for d-U(600)-**1**-AA. This band has been as-

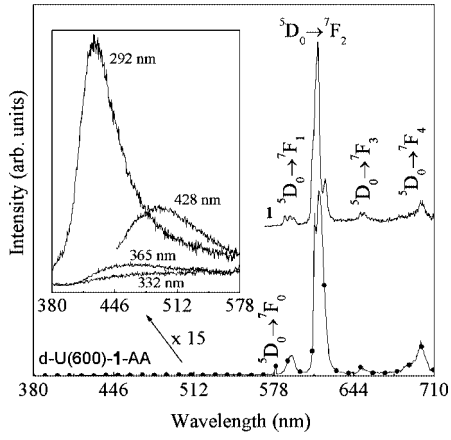

Figure 6. Room-temperature emission spectra of complex **1** (solid line) and d-U(600)-**1**-AA (solid circles), excited at 341 and 332 nm, respectively. The inset shows the magnification of the low-wavelength side of the emission spectra of d-U(600)-**1**-AA for different excitation wavelengths between 292 and 428 nm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cribed to the hybrid host emission originated from donor–acceptor pair recombination occurring in the NH groups of the urea linkages and in the siliceous nanodomains.[27–30] The negligible intensity of this emission clearly suggests the presence of active energy transfer channels between the emitting centers of the hybrid and the $Eu^{3+}$ ions, a claim that is in agreement with the suggested interaction between the $Eu^{3+}$ ions and the urea cross-links through the carbonyl groups. Comparing the emission spectra of d-U(600)-**2**-AA and d-U(600)-**2** (Figure 7), changes were observed in the energy peak values, fwhm of each line, and number of Stark components, suggesting that the two different synthesis methods affect the $Eu^{3+}$ first coordination sphere, as already noticed in the excitation spectra.

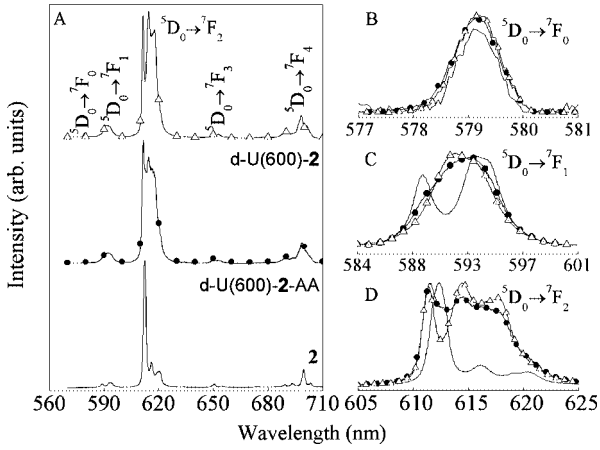

Figure 7. A: Room-temperature emission spectra of (a) complex **2**, d-U(600)-**2**-AA (solid circles) and d-U(600)-**2** (open triangles); the excitation wavelengths are 339 nm for d-U(600)-**2**, 348 nm for d-U(600)-**2**-AA and 327 nm for complex **2**. B, C, D: Details of the $^5D_0\rightarrow{}^7F_{0-2}$ transitions.

The Judd–Ofelt theory is a useful tool for analyzing f–f electronic transitions.[31] Interaction parameters of ligand fields are given by the Judd–Ofelt parameters, $\Omega\lambda$ (where $\lambda$ = 2, 4, and 6). In particular, $\Omega_2$ is more sensitive to the symmetry and sequence of ligand fields. To produce faster $Eu^{3+}$ radiation rates, antisymmetrical $Eu^{3+}$ complexes with larger $\Omega_2$ parameters need to be designed. The experimental $\Omega_2$ and $\Omega_4$ intensity parameters were determined from the emission spectra given in Figures 6 and 7 by using the $^5D_0\rightarrow{}^7F_2$ and $^5D_0\rightarrow{}^7F_4$ electronic transitions, respectively, and by expressing the emission intensity $I_J = \hbar\omega_{J0}A_{RAD}(J)$-$N(^5D_0)$ in terms of the area under the emission curve. Here, $\hbar\omega_{J0}$ is the transition energy and $N$ is the population of the $^5D_0$ level. The radiative emission rates, $A_{RAD}(J)$, are given by [Equation (1)],[32] where $e$ is the electronic charge, $\omega$ the angular frequency of the transition, $\hbar$ the Planck's constant over $2\pi$, $c$ the velocity of light, $\chi$ the Lorentz local field correction term given by $n(n^2+2)^2/9$, where $n$ is the refraction index, and $\langle {}^7F_J\|U^{(\lambda)}\|{}^5D_0\rangle^2$ is a squared reduced matrix element whose values are 0.0032 and 0.0023, for $J$ = 2 and 4, respectively.[33]

$$A_{RAD} = \frac{4e^2\omega^3}{3\hbar c^3}\chi\sum_{\lambda}\Omega_\lambda\left\langle {}^7F_J\left\|U^{(\lambda)}\right\|{}^5D_0\right\rangle^2\frac{1}{2J+1} \quad (1)$$

The magnetic dipole allowed $^5D_0\rightarrow{}^7F_1$ transition was taken as the reference,[13,32] in vacuo $A_{RAD}(^5D_0\rightarrow{}^7F_1)$ = 14.65 $s^{-1}$.[31] An average index of refraction equal to 1.5[34] was considered leading to $A_{RAD}(^5D_0\rightarrow{}^7F_1) \approx 50\ s^{-1}$.[13] The $\Omega_6$ parameter was not determined since the $^5D_0\rightarrow{}^7F_{5,6}$ transitions could not be experimentally detected. Table 2 lists the $\Omega_2$ and $\Omega_4$ intensity parameters estimated for complexes **1** and **2** and corresponding hybrids. A point to be noted is the relatively high values of the $\Omega_2$ parameter. This might be interpreted as being a consequence of the hypersensitive behavior of the $^5D_0\rightarrow{}^7F_2$ transition.[35] The dynamic coupling mechanism is, therefore, dominant, indicating that the $Eu^{3+}$ ion is in a highly polarizable chemical environment.

Table 2. Experimental intensity parameters ($\Omega_2$ and $\Omega_4$), radiative decay rates, $A_{RAD}$, nonradiative decay rates, $A_{NRAD}$, $^5D_0$ lifetimes, $\tau$, and quantum efficiency, $\eta$, for the complex and hybrids. The parameters' errors are estimated within 5–10%.

| Compounds | $\Omega_2$ $\times10^{-20}$ [$cm^2$] | $\Omega_4$ $\times10^{-20}$ [$cm^2$] | $A_{RAD}$ [$s^{-1}$] | $A_{NRAD}$ [$s^{-1}$] | $\tau$ [ms] | $\eta$ [%] |
|---|---|---|---|---|---|---|
| Complex **1**[22] | 8.1 | 5.8 | 381 | 2952 | 0.30 | 13 |
| d-U(600)-**1**-AA | 19.3 | 8.2 | 751 | 1630 | 0.42 | 32 |
| Complex **2**[22] | 20.7 | 6.4 | 773 | 242 | 0.98 | 76 |
| d-U(600)-**2** | 19.8 | 8.0 | 765 | 822 | 0.63 | 48 |
| d-U(600)-**2**-AA | 21.1 | 8.6 | 813 | 520 | 0.75 | 61 |

The $^5D_0$ lifetime values ($\tau$) were determined by fitting the emission decay profiles to a mono-exponential function, Table 2. The shorter $^5D_0$ lifetime of complex **1**, relative to that of complex **2**, is associated with the nonradiative decay channel from the vibronic coupling with water molecules.[22] While the lifetime of the d-U(600)-**1**-AA hybrid increases around 40%, relative to that of complex **1**, the incorporation of complex **2** into the hybrid host induces a decrease of the $^5D_0$ lifetime between 24 and 36%, depending on the synthesis route. On the basis of the emission spectra and the lifetime measurements, and considering that only nonradiative and radiative processes are essentially involved in the depopulation of the $^5D_0$ state, we can estimate the emission quantum efficiency of the $^5D_0$ excited state ($\eta$) as [Equation (2)], where $A_{RAD}$ is obtained by summing the radiative rates $A_{0J}$ for each $^5D_0\rightarrow{}^7F_{0-4}$ transition[31] and the nonradiative rates, $A_{NRAD}$, are calculated from the experimental decay rates [Equation (3)].

$$\eta = \frac{A_{RAD}}{A_{RAD} + A_{NRAD}} \quad (2)$$

$$\frac{1}{\tau} = A_{RAD} + A_{NRAD} \quad (3)$$

Table 2 lists the $A_{RAD}$, $A_{NRAD}$, and $\eta$ for the complexes and hybrids. The nonradiative rate of d-U(600)-**1**-AA decreases by ca. 55%, relative to that of complex **1**, causing

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

an enhancement in the emission quantum efficiency ($\eta$ = 32%) in comparison with complex **1** ($\eta$ = 13%[22]). This result is in agreement with the suggested interaction between the hybrid host and the $Eu^{3+}$ ions through the oxygen atom of the carbonyl group, replacing water molecules present in the precursor complex. The lower $^5D_0$ quantum efficiency found for the hybrid prepared by the conventional sol-gel route, relative to that prepared by solvolysis, is mainly because of an increase in $A_{NRAD}$, meaning that a more efficient nonradiative channel involving the first excited triplet state exists in the former di-ureasil. These results indicate that the substitution of the water molecules in the $Eu^{3+}$ coordination sphere of complex **1** by two TOPO molecules induces a higher $^5D_0$ emission quantum efficiency relative to the interaction with the oxygen atoms of the carbonyl groups from the d-U(600) host.

## Conclusions

Di-ureasil organic-inorganic hybrids incorporating $Eu(TPI)_3{\cdot}3H_2O$ or $Eu(TPI)_3{\cdot}2TOPO$ complexes were prepared either by acetic acid solvolysis or by conventional hydrolysis. XRD and FT-IR, $^{29}Si$ and $^{13}C$ MAS NMR spectroscopic results demonstrate an effective interaction between the $Eu^{3+}$ 3-phenyl-4-(4-toluoyl)-5-isoxazolonate complex and carbonyl groups of the urea linkages. The PL spectra of these di-ureasil organic-inorganic hybrids display the characteristic $Eu^{3+}$ $^5D_0 \rightarrow {}^7F_{0-4}$ transitions. The broad emission typical of amine-functionalized hybrids has negligible intensity pointing to the activation of energy channels between the emitting centers of the hybrid host and the $Eu^{3+}$ ions. The high values obtained for the experimental 4f–4f $\Omega_2$ intensity parameters suggest that the dynamic coupling mechanism is quite operative in these compounds. The incorporation of complex **1** into the d-U(600) host enhanced the $^5D_0$ quantum efficiency and lifetime because of the coordination ability of the organic counterpart of the host structure to displace water molecules from the complex coordination sphere. A suitable choice of ligands that better sensitize the $Eu^{3+}$ emission together with a fine control of the synthesis process definitely endorse the design of nanohybrids with better emission performance.

## Experimental Section

**Materials and Synthesis:** The synthesis procedures of the complexes $Eu(TPI)_3{\cdot}3H_2O$ and $Eu(TPI)_3{\cdot}2TOPO$ and their characterizations are described in a recent publication.[22] The diamine α,ω-diamine-poly(oxyethylene-co-oxypropylene) with a molecular weight of about 600 a.m.u., corresponding to approximately 8.5 ($OCH_2CH_2$) repeat units and commercially designated as Jeffamine ED-600® (Fluka), was dried with molecular sieves (4 Å, 1.6 mm pellets, Aldrich) before use. ICPTES (3-isocyanatopropyltriethoxysilane, 95%, Fluka) and acetic acid (AA, 99.7%, Aldrich) were used without further purification. Tetrahydrofuran (THF) and absolute ethanol were dried with molecular sieves at room temperature before use. The synthesis of the di-ureasils has already been described in detail elsewhere.[14] The first stage of the synthesis involved the reaction in THF of the isocyanate group of the alkoxysilane precursor ICPTES with the terminal amine groups of the doubly functional diamine to form a urea cross-linked organic-inorganic hybrid precursor, so-called ureapropyltriethoxysilane [d-UPTES(600)]. In the second step, complexes were incorporated into the hybrid host by dissolving an appropriate amount of these complexes in ethanol and chloroform. A typical synthetic procedure was as follows.

**Step 1. Synthesis of the Di-ureasil Precursor d-UPTES(600):** Jeffamine ED-600® (1.0 mL, 1.75 mmol) was dissolved in dried THF (5.0 mL) in a flask in a fume hood. ICPTES (0.91 mL, 3.5 mmol) was then added to this solution whilst stirring. The molar ratio of Jeffamine ED-600/ICPTES was 1:2. The flask was sealed and the solution was stirred at room temperature under $N_2$ for 24 h.

**Step 2. Synthesis of the Di-ureasils Incorporating $Eu(TPI)_3{\cdot}3H_2O$ and $Eu(TPI)_3{\cdot}2TOPO$ Complexes by the Conventional Sol-Gel Method or the Carboxylic Acid Solvolysis Process:** The THF in the precursor solution was evaporated under vacuum, and a transparent precursor d-UPTES(600) oil was thus obtained. For the synthesis of the hybrids by the conventional sol–gel method, the $Eu(TPI)_3{\cdot}2TOPO$ complex (0.0116 mmol) was dissolved in $CH_3CH_2OH$ (0.82 mL, 14.04 mmol), and then chloroform (0.5 mL) and HCl at pH = 2 (0.096 mL, 5.34 mmol) were added to this solution. The molar ratio of ICPTES/$CH_3CH_2OH$/$H_2O$ is 1:4:3. Finally, this mixed solution was added to the precursor whilst stirring in air at room temperature. The solution was further stirred for 24 h. For the synthesis of hybrids by acetic acid solvolysis, the $Eu(TPI)_3{\cdot}3H_2O$ and $Eu(TPI)_3{\cdot}2TOPO$ complexes (0.0116 mmol) were dissolved in $CH_3CH_2OH$ (0.82 mL, 14.04 mmol) and chloroform (0.5 mL) was added to this solution. The mixture was added to the precursor. Finally, AA (0.60 mL) was added whilst stirring under $N_2$ at room temperature, and the mixture was stirred for 24 h.

**Experimental Techniques:** Mid-IR spectra were recorded at room temperature using a MATTSON 7000 FTIR Spectrometer. The spectra were collected over the range 4000–400 $cm^{-1}$ by averaging 64 scans at a maximum resolution of 4 $cm^{-1}$. The compounds were finely ground (about 2 mg), mixed with approximately 175 mg of dried potassium bromide (Merck, spectroscopic grade) and pressed into pellets. Consecutive spectra were recorded until reproducible results were obtained. X-ray diffraction patterns were recorded using a Philips X'Pert MPD Powder X-ray diffractometer system. The powders were exposed to Cu-$K_\alpha$ radiation ($\lambda$ = 1.54 A°) at room temperature in a $2\theta$ range (scattering angle) between 1 and 70°. The xerogel samples, analyzed as films, were not submitted to any thermal pre-treatment. $^{29}Si$ magic-angle spinning (MAS) and $^{13}C$ cross-polarization (CP) MAS NMR spectra were recorded with a Bruker Avance 400 (9.4 T) spectrometer at 79.49 and 100.62 MHz, respectively. $^{29}Si$ MAS NMR spectra were recorded with 2 μs (equivalent to 30°) rf pulses, a recycle delay of 60 s and at a 5.0 kHz spinning rate. $^{13}C$ CP/MAS NMR spectra were recorded with a 4 μs $^1H$ 90° pulse, 2 ms contact time, a recycle delay of 4 s, and at a spinning rate of 8 kHz. Chemical shifts are quoted in ppm from tetramethylsilane (TMS). The emission, PL, excitation, and PLE spectra and the lifetimes were measured at room temperature with a modular double grating excitation spectrofluorimeter with a TRIAX 320 emission monochromator (Fluorolog-3, Jobin Yvon-Spex), coupled to an R928 Hamamatsu photomultiplier, using the front face acquisition mode. All the photoluminescence spectra were corrected for optical and detection spectral responses.

# Metal-Dependent Formation of Mononuclear Complexes and $M_2L_2$ Mesocates with Schiff-Base Ligands

John Fielden,[a] De-Liang Long,[a] Cameron Evans,[a] and Leroy Cronin*[a]

**Keywords:** Supramolecular chemistry / Schiff-base ligands / Coordination modes / Silver / Cadmium

The coordination chemistry of the tetradentate pyridyl N-donor ligands *r*-1-hydroxy-*t*-3,*t*-5-bis{[(2-pyridinyl)methylene]amino}cyclohexane (DDOP) and *r*-1-hydroxy-*t*-3,*t*-5-bis{[(*E*)-(6-methyl-2-pyridinyl)methylene]amino}cyclohexane (DDMOP) has been investigated with the $d^{10}$ metal centres silver(I) and cadmium(II). These conformationally flexible ligands offer two coordination modes; either a mononucleating tetradentate coordination pocket or a bridging bis(bidentate) chelate. Hence, reaction with $Cd^{II}$ produced six-coordinate mononuclear complexes whose compositions were determined by X-ray crystallography as $[Cd(DDOP)(NO_3)_2]$ (**1**) and $[Cd(DDMOP)(Cl)_2]$·MeOH (**2**), while $Ag^I$ led to the four-coordinate dinuclear mesocate structures $[\{Ag(DDOP)\}_2](CF_3SO_3)_2$ (**3**) and $[\{Ag(DDMOP)\}_2](CF_3SO_3)_2$·0.5MeOH (**4**). It is thought that the mononuclear, octahedral complexes in the case of zinc(II) and cadmium(II) result from the energetic stabilisation gained through two extra coordinate bonds, while in the case of silver(I) the lower propensity of the metal centre for six-coordination causes the ligand to retain its energetically preferred dinucleating conformation and to form the mesocates.

## Introduction

Control over the nuclearity and shape of coordination complexes has been a vital topic in inorganic chemistry for decades, most particularly since the emergence of supramolecular chemistry in the late 1970s, and provides the key to future development of designed functional materials.[1–3] Through careful choice of ligand topology, numerous research groups have been able to control formation of oligomeric and polymeric structures; for example the formation of double- and triple-stranded helicates/mesocates,[4–6] molecular squares and boxes,[7,8] and infinite inorganic grids.[9,10] Such chemistry often relies on the use of large, rigid aromatic N-donor sets, for example the various bi- and terpyridines, linked by spacers whose shape and rigidity (or relative flexibility) determines the type of complex. Schiff-base derivatisation of aliphatic amines or anilines with pyridinecarbaldehydes provides an attractive route to aromatic N-donor ligands, due to the relative synthetic ease of this transformation and the availability of many different parent amines.[11]

Recent work in our laboratory has focused on the synthesis and coordination behaviour of the small, cyclohexane-based aliphatic amino ligands *r*-1,*t*-3,*t*-5-triaminocyclohexane (TACH)[12–14] and *t*-3,*t*-5-diamino-*r*-1-hydroxycyclohexane (DAHC).[15–17] While becoming rigid upon coordination due to conformational locking of the cyclohexane backbone, these ligands offer two coordination modes; either bridging with the *cis*-diamino donor set in the equatorial plane, or bidentate chelating upon "ring-flip" to the bis(axial) conformation. Derivatisation of the amine groups of these ligands with Schiff bases allows the synthesis of pyridyl N-donor ligands which, like their parent amines, possess two distinct coordination modes. Such ligands may form complexes with different nuclearity according to the coordination preferences of the metal centre.[18,19] Herein, we describe mono- and dinuclear coordination complexes of the DAHC Schiff-base derivatives *r*-1-hydroxy-*t*-3,*t*-5-bis{[(2-pyridinyl)methylene]amino}cyclohexane (DDOP) and *r*-1-hydroxy-*t*-3,*t*-5-bis{[(*E*)-(6-methyl-2-pyridinyl)methylene]amino}cyclohexane (DDMOP) with the $d^{10}$ transition-metal ions $Cd^{II}$ and $Ag^I$.

## Results and Discussion

### Overview

DDOP and DDMOP were synthesised from DAHC by a simple Schiff-base derivatisation using the appropriate pyridinecarbaldeyhyde, yielding a more highly pre-organised ligand with a tetradentate [or bis(bidentate)] donor set. The aromatic rings increase the system's rigidity, strengthening the hand of the ligand and reducing the influence of anions, solvent and metal centres on the outcome of the complexation. Furthermore, they provide a hydrophobic surface capable of participating in π-stacking or other van der Waals interactions.

Despite the rigidity of the donor set, the conformational flexibility of the cyclohexane backbone gives these ligands two possible coordination modes (Scheme 1); either as a dinucleating, bis(bidentate) chelator, or a bis(axial) tetradentate mononucleating conformation. Both coordination modes are observed in this study, the dinuclear compounds being formed with silver(I) and mononuclear, ring-flipped compounds occurring with cadmium(II). The ligands direct the formation of $M_2L_2$ mesocate structures when in their bis(equatorial) conformation, since the two $N_2$ donor sets are suitably oriented to bind to one side of the metal–metal axis, and the angle of approximately 105° between the planes of the aromatic rings provides an effective corner piece. Consequently, formation of dinuclear complexes is favoured by four-coordinate, tetrahedral metal centres whose ca. 90° twist angle provides a good geometric match for the bis(equatorial) ligand. Mononuclear species are favoured by coordination to octahedral metal centres, whose equatorial sites can accept the planar $N_4$ donor set of the bis(axial) ligand, with their axial sites being occupied by solvent molecules or counterions. Formation of the two types of complexes is described by the balanced equations below, which summarise the reaction of two metal centres with two ligands:

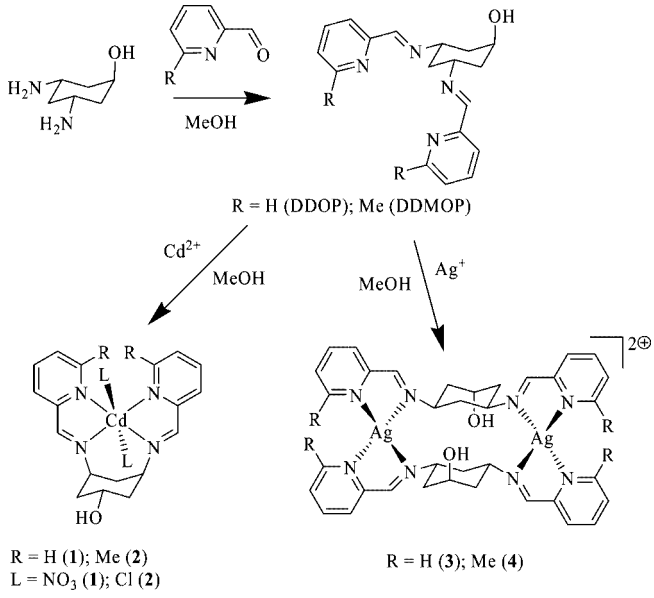
Dinuclear complex:

$2\ MX_2{\cdot}nH_2O + 2\ L \rightarrow M_2L_2^{4+} + 4\ X^- + 2n\ H_2O$; $(2n + 5)$ species, 8 coordinate bonds.

Mononuclear complex:

$2\ MX_2{\cdot}nH_2O + 2\ L \rightarrow 2\ MLX_2 + 2n\ H_2O$; $(2n + 2)$ species, 12 coordinate bonds.

For silver(I) and cadmium(II), which can access both tetrahedral and octahedral coordination geometries, the two reactions are in competition with each other. It can be seen from the larger number of species formed that four-coordinate $M_2L_2$ structures are favoured due to entropic factors; furthermore, the bis(equatorial) ligand conformation observed in such complexes is more energetically favourable due to reduced steric clash between the imine arms and the cyclohexane ring. However, the extra coordination bonds formed in the mononuclear case means that these complexes are favoured by enthalpy.



Scheme 1. Parent amine DAHC, and mono- and dinuclear species formed by complexation of its Schiff-base derivatives DDOP and DDMOP.

## Cadmium(II) Complexes

Cadmium(II) complexes of DDOP and DDMOP were prepared in moderately low yields by reaction with cadmium(II) salts (nitrate or chloride) in methanol, followed by crystallisation by diffusion of diethyl ether. This yielded the (DDOP)bis(nitrato)cadmium complex [Cd(DDOP)-$(NO_3)_2$] (**1**), and the (DDMOP)bis(chlorido)cadmium complex [Cd(DDMOP)$Cl_2$]·MeOH (**2**) (the DDMOP complex would not crystallise with the nitrato ligand). In both, the $N_4$ ligand acts as a tetradentate chelator in the equatorial plane, while the chlorido or nitrato ligands occupy the axial coordination sites (Figure 1). However, interestingly, the asymmetric unit of **1** contains two crystallographically independent complexes, which appear to be associated with each other through a slipped π-stacking interaction with a centroid-to-centroid distance of around 3.80 Å.

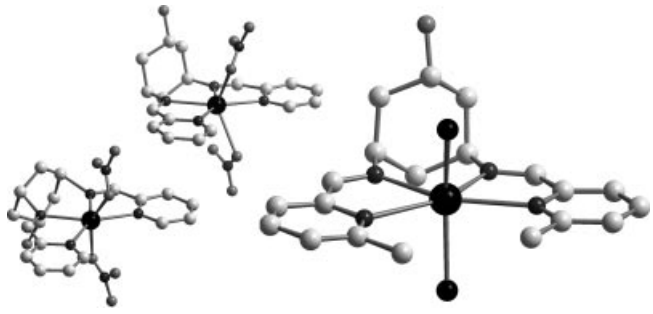


Figure 1. The two [Cd(DDOP)$(NO_3)_2$] complexes in the asymmetric unit of **1** (left) and the complex in [Cd(DDMOP)$(Cl)_2$]·MeOH (**2**). C: light grey; N: dark grey; O: medium grey; Cl: small black spheres; Cd: large black spheres; H: omitted.

Curiously, the pair of complexes in **1** differs quite noticeably in its Cd–O bond lengths; Cd2 has longer bonds to the oxygen atoms, and shorter bonds to the equatorial nitrogen atoms (Table 1). The size of the cadmium cation causes the pyridyl arms of the ligand to open from their idealised parallel alignment, as indicated by longer coordination bonds to the pyridyl nitrogen atoms, and also by an N–Cd–N angle that is much larger between the pyridyl nitrogen atoms than the imino nitrogen atoms. This effect is more dramatic in **2**, where replacement of hydrogen with a methyl group at the 6-position of the pyridyl ring forces the imine arms to open wider to accommodate the increased steric demand (Figure 1). Bond lengths to the axial chlorido ligands are comparable to the axial Cd2–O bond lengths in compound **1**. In solution, $^1$H NMR spectroscopy ($CD_3OD$) reveals the ring-flipped structure of these complexes, as shown by the

multiplicities of the cyclohexane protons which provide an excellent conformational probe. Identical NMR spectra were obtained by directly dissolving the ligand and a small excess of the cadmium salt in $CD_3OD$, indicating that the low yields are due to inefficient crystallisation, rather than formation of other architectures. Furthermore, coordination to Cd is indicated by satellites resulting from coupling of the imine protons to the $I$ = 1/2 isotopes $^{111}Cd$ and $^{113}Cd$ (combined abundance = 25%).

The differing shapes and hydrogen-bonding properties of the chlorido and nitrato ligands result in contrasting extended structures for the two compounds. In **1** there are alternating layers of the two crystallographically independent complexes (Figure 2), in which they associate in chains parallel to the crystallographic *c*-axis through hydrogen-bonding interactions between the nitrato ligands and the DDOP alcohol groups (2.976 Å in the Cd1 layer). However, in the Cd2 layers the nitrato–hydroxy distance (3.126 Å) is longer than the sum of the van der Waals radii. Association of the layers appears to occur by the π-stacking interactions observed in the asymmetric unit. In **2**, the [Cd(DDMOP)-$Cl_2$] units are arranged in hydrogen-bonded chains parallel to the crystallographic *b*-axis (Figure 2). To generate the chains, one chlorido ligand accepts a hydrogen bond from the DDMOP alcohol group (3.195 Å) of the next complex, and the other chlorido ligand accepts a hydrogen bond from an included methanol molecule (3.140 Å). The pyridyl–pyridyl separations observed are too large to suggest any significant contributions from π-stacking.

To investigate the influence of temperature on these complexations, reactions were also performed at –94 °C, –78 °C, and in refluxing *n*-propanol (97 °C). It was anticipated that low temperatures might reduce the conformational flexibility of the ligand, encouraging formation of dinuclear aggregates on kinetic grounds, while higher temperatures would increase the influence of entropy, again favouring dinuclear species. However, $^1H$ NMR revealed that mononuclear species still result under these conditions.

### Silver(I) Complexes

In contrast to cadmium(II), complexation of DDOP and DDMOP with silver(I) results in the formation of $M_2L_2$ mesocates, synthesised in analogous fashion to the cadmium complexes by reaction with silver(I) triflate. The $M_2L_2^{2+}$ complex cations are formed by two ligands in the bis(equatorial) conformation, linked by two Ag(1) centres with distorted pseudo-tetrahedral geometries (Figure 3). These dinuclear structures occur because the octahedral coordination mode is less accessible for silver(I) than cadmium(II), and because nonplanar geometries are favoured by four-coordinate silver atoms.[18] Furthermore, the bis-(equatorial) coordination mode is more favourable for the ligand as it minimises steric clashes between the pyridyl and cyclohexane rings. $^1H$ NMR ($CD_3OD$) reveals the $M_2L_2$ form of the complexes upon dissolution, and while coupling of the imine protons to the silver ion ($I$ = 1/2) is only observed in **4**, the change in chemical shift relative to uncomplexed ligand suggests that **3** does not dissociate. Identical spectra obtained simply by mixing the silver salt and ligand in $CD_3OD$ suggest that the low yield obtained for **3** is due

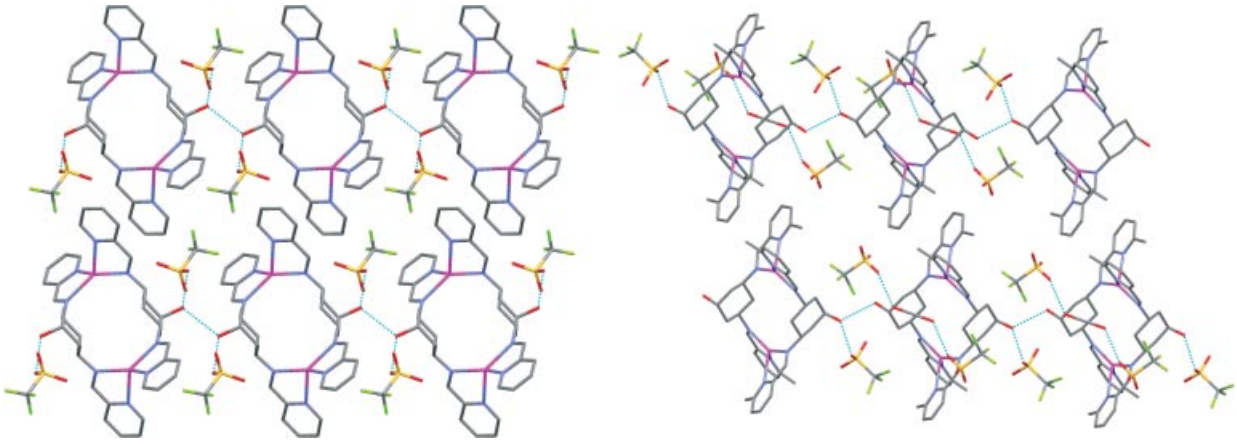

Figure 4. Crystal packing in $[\{Ag(DDOP)\}_2](CF_3SO_3)_2$ (**3**, left) and $[\{Ag(DDMOP)\}_2](CF_3SO_3)_2$ (**4**, right). S yellow; F light yellow; Ag purple; C grey; N blue; O red; H omitted. Disordered atoms are omitted for clarity. Hydrogen-bonded interactions shown by blue dotted line.

to inefficient crystallisation rather than formation of other architectures.

In both complexes, the coordination geometry around the silver atoms is substantially distorted from the tetrahedral ideal, as shown by the wide range of bond lengths and angles in Table 2. Most importantly, the twist angle between the two donor sets of each tetrahedron, ideally 90°, is around 79.5° in **3**, and 68° and 71.5° at the two crystallographically independent silver centres in **4**, compensating for the >100° corner piece provided by the ligands.

Both complexes pack in one-dimensional chains of hydrogen-bonded complex cations and counterions (Figure 4). In **3**, these chains propagate parallel to a line bisecting the crystallographic *bc* plane through the origin, with each DDOP alcohol group donating a bifurcated hydrogen bond to one triflate counterion (3.011 Å) and the alcohol group of the next cation (2.886 Å) in the chain. Edge–face contacts of around 3.73 Å suggest a contribution from C–H–π interactions,[20] although there do not appear to be any face–face π–π interactions. In the DDMOP complex **4** the chains run parallel to the crystallographic *a*-axis, with the cations connected by hydrogen bonds between their alcohol groups (2.818 Å), while one of the two triflate anions per formula unit also accepts a hydrogen bond from a DDMOP alcohol group (2.775 Å). The second triflate counterion is disordered and interacts with disordered methanol molecules (2.696 Å), but not the cations. It appears that slipped face-to-face π-stacking interactions may control the association of the hydrogen-bonded chains, with a number of C–C contacts in the range of 3.45–3.92 Å.

## Conclusions

A series of closed-shell transition-metal complexes of two novel Schiff-base ligands have been synthesised and charac-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

terised in the solid and solution states. These ligands offer two possible coordination modes, and while mononuclear complexes are preferred with cadmium(II), $M_2L_2$ mesocates form with silver(I). This preference for mononuclear complexes with cadmium(II) prevails over a wide temperature range and is due to the greater ability of $Cd^{II}$ to accept six-coordinate environments, and the consequent gain in stability through formation of two extra coordinate bonds to solvent molecules or counterions. Further investigation will be carried out into the possibility of using the conformational "switch" as a sensor.

## Experimental Section

**Materials, Methods and Instrumentation:** The ligands DDOP and DDMOP were synthesised by reaction of *t*-3,*t*-5-diamino-*r*-1-hydroxycylcohexane with 2-pyridinecarbaldehyde or 6-methyl-2-pyridinecarbaldehyde.[16] All other reagents and solvents were purchased (Fisher/Lancaster/Riedel-de Haën/Aldrich) as AR grade and used without further purification. Deuterated solvents were obtained from Aldrich. All complexations were performed under ambient conditions. IR spectra were measured with a Jasco FTIR-410 spectrometer and $^1$H NMR measurements were performed at room temperature with Bruker DPX-400 and Avance-400 spectrometers. X-ray diffraction data were collected with a Nonius Kappa-CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.7107 Å) and a graphite monochromator.

**Preparation of [Cd(DDOP)(NO$_3$)$_2$] (1):** DDOP (0.070 g, 0.226 mmol) was dissolved in methanol (20 mL). $Cd(NO_3)_2{\cdot}4H_2O$ (0.105 g, 0.340 mmol) was added in methanol (5 mL) and the solution stirred for 5 h, before the volume was reduced to ca. 3 mL in vacuo. A white solid was removed by filtration and the solution was set for crystallisation by $Et_2O$ diffusion. After 24 h, clear and colourless crystals of **1** were observed (0.030 g, 0.0551 mmol, 23.8% yield). $^1$H NMR (400 MHz, $CD_3OD$): $\delta$ = 9.01 (d, 2 H, 2Ar*H*), 8.81 [m (s with satellites from coupling to $I$ = 1/2 Cd isotopes $^{111}$Cd and $^{113}$Cd, combined abundance 25%), 2 H, 2 *H*C=N], 8.33 (pseudo-td, 2 H, 2 Ar*H*), 8.03 (d, 2 H, 2 Ar*H*), 7.94 (m, 2 H, 2 Ar*H*), 4.51 (m, 2 H, 2 *H*C–N), 4.39 (tt, 1 H, *H*COH), 2.34–2.14 (m, 4 H, 3 $H_{eq}$CH, $H_{ax}$CH), 2.01 (pseudo-td, 2 H, 2 $H_{ax}$CH) ppm. IR (KBr disc): $\tilde{\nu}$ = 3431 s, 3062 w, 2933 m, 1651 m, 1595 s, 1423 s, 1296 vs cm$^{-1}$. $C_{18}H_{20}CdN_6O_7$ (544.80): calcd. C 39.68, H 3.70, N 15.43; found C 39.39, H 3.72, N 15.18.

**Preparation of [Cd(DDMOP)(Cl)$_2$]·MeOH (2):** DDMOP (0.070 g, 0.208 mmol) was dissolved in methanol (20 mL). $CdCl_2{\cdot}2.5H_2O$ (0.047 g, 0.210 mmol) was added in methanol (5 mL), and the solution stirred overnight, before the volume was reduced to ca 4.5 mL in vacuo. A white solid was removed by filtration and after 24 h, clear, colourless crystals of **2** were produced by diffusion of diethyl ether into the methanolic solution (0.027 g, 0.0489 mmol, 23.5% yield). $^1$H NMR (400 MHz, $CD_3OD$): $\delta$ = 8.73 [m (s with satellites from coupling to 25% abundace $I$ = 1/2 Cd isotopes), 2 H, 2 *H*C=N], 8.08 (pseudo-t, 2 H, 2 Ar*H*), 7.74 (d, 2 H, 2 Ar*H*), 7.67 (d, 2 H, 2 Ar*H*), 4.68 (tt, 1 H, *H*COH), 4.44 (m, 2 H, 2 *H*CN), 3.03 (s, 6 H, 2 $H_3$CAr), 2.36–2.13 (m, 4 H, 3 $H_{eq}$CH, $H_{ax}$CH), 1.98 (pseudo-td, 2 H, 2 $H_{ax}$CH) ppm. IR (KBr disc): $\tilde{\nu}$ = 3404 s, 2923 m, 1647 s, 1591 s, 1458 s, 1256 m, 1163 m, 1129 m 1002 m, 808 s cm$^{-1}$. $C_{21}H_{28}CdCl_2N_4O_2$ (551.79): calcd. C 45.71, H 5.11, N 10.15; found C 45.40, H 4.74, N 10.09.

**Preparation of [{Ag(DDOP)}$_2$](CF$_3$SO$_3$)$_2$ (3):** DDOP (0.070 g, 0.226 mmol) was dissolved in methanol (20 mL). AgOTf (0.0875 g, 0.339 mmol) was added in methanol (5 mL) and the solution stirred in the dark for 48 h, before the volume was reduced to ca 4 mL in vacuo. After a few minutes, the formation of very small crystals was observed. The solution was filtered and set to crystallise by $Et_2O$ diffusion. Within 24 h, small, colourless cubic or rectangular crystals of **3** were observed (0.0411 g, 0.0364 mmol, 16.1% yield). $^1$H NMR (400 MHz, $CD_3OD$): $\delta$ = 8.91 (s, 4 H, 4 *H*C=N), 8.39 (d, 4 H, 4 Ar*H*), 8.16 (pseudo-td, 4 H, 4 Ar*H*), 7.92 (d, 4 H, 4 Ar*H*), 7.17 (m, 4 H, 4 Ar*H*), 4.45 (m, 4 H, 4 *H*CN), 4.29 (m, 2 H, 2 *H*COH), 2.13 (m, 8 H, 6 $H_{eq}$CH, 2 $H_{ax}$CH), 1.84 (m, 4 H, 4 $H_{ax}$CH) ppm. IR (KBr disc): $\tilde{\nu}$ = 3429 s, 2924 m, 1645 m, 1593 s, 1441 m, 1281 vs, 1255 vs, 1555 s, 1030 s cm$^{-1}$. $C_{38}H_{40}Ag_2F_6N_8O_8S_2$ (1130.63): calcd. C 40.37, H 3.57, N 9.91; found C 40.29, H 3.40, N 9.79.

**[{Ag(DDMOP)}$_2$](CF$_3$SO$_3$)$_2$·0.5MeOH (4):** DDMOP (0.070 g, 0.208 mmol) was dissolved in methanol (20 mL). AgOTf (0.0802 g, 0.310 mmol) was added in methanol (5 mL) and the solution stirred in the dark for 48 h, before the volume was reduced to ca 3 mL in vacuo. After a few minutes, the formation of very small crystals was observed. The solution was filtered and set to crystal-

lise by $Et_2O$ diffusion. Within 24 h, small, colourless cubic or rectangular crystals of **4** were observed (0.0744 g, 0.0620 mmol, 59.5% yield). $^1$H NMR (400 MHz, $CD_3OD$): $\delta$ = 8.90 (d, 4 H, 4 *H*C=N, d due to coupling with $I$ = 1/2 Ag), 8.03 (pseudo-t, 4 H, 4 Ar*H*), 7.74 (d, 4 H, 4 Ar*H*), 7.58 (d, 4 H, 4 Ar*H*), 4.48 (m, 4 H, 4 *H*CN), 4.32 (m, 2 H, 2 *H*COH), 2.26–2.01 (m, 8 H, 6 $H_{eq}$CH, 2 $H_{ax}$CH), 2.20 (s, 12 H, 4 $H_3$CAr), 1.90 (m, 4 H, 4 $H_{ax}$CH) ppm. IR (KBr disc): $\tilde{\nu}$ = 3423 s, 2920 m, 1642 m, 1592 s, 1458 m, 1278 vs, 1261 vs, 1030 s cm$^{-1}$. $C_{42}H_{48}Ag_2F_6N_8O_8S_2$ (1186.74, losing solvent): calcd. C 42.58, H 3.91, N 9.46; found C 42.51, H 4.01, N 9.27.

**Single-Crystal Structure Determination:** Suitable single crystals of **1**–**4** were mounted on the end of a thin glass fibre using Fomblin oil. X-ray diffraction intensity data were measured at 150 or 293 K with a Nonius Kappa-CCD diffractometer [$\lambda$(Mo-$K_\alpha$) = 0.7107 Å]. Structure solution and refinement for **1**–**4** were carried out with SHELXS-97[21] and SHELXL-97[22] using WinGX.[23] Corrections for incident and diffracted beam absorption effects were applied using empirical[24] or numerical methods.[25] Compound **1** crystallised in the space group *Pc* and compounds **2**, **3** and **4** in $P\bar{1}$, as determined by systematic absences in the intensity data, intensity statistics and the successful solution and refinement of the structures. All structures were solved by a combination of direct methods and difference Fourier syntheses and refined against $F^2$ by the full-matrix least-squares technique. Crystal data, data collection parameters and refinement statistics for **1**–**4** are listed in Table 3. CCDC-605439 to -605442 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Zinc Hydrazide and Zinc Alkoxide Hydrazide Cages with $Zn_4N_8$ and $Zn_4N_6O$ Cores – Cluster Isomerism as a Result of Subtle Changes in Ligand Size

**Surajit Jana,[a] Roland Fröhlich,[b] and Norbert W. Mitzel*[a]**

**Keywords:** Zinc / Hydrazines / Cage compounds / Cocrystalline compounds / N ligands

The hydrazide cluster $[(i\text{PrZn})_4(NHNMe_2)_4]$ (**1**) was synthesised by the reaction of diisopropylzinc with *N*,*N*-dimethylhydrazine and was characterised by $^1H$- and $^{13}C$ NMR and IR spectroscopy, mass spectrometry, elemental analysis and X-ray crystallography. This compound forms asymmetric aggregates containing $Zn_4N_8$ cores. The Zn atoms in these aggregates are arranged in topological tetrahedra in which the triangular faces are bridged by $NHNMe_2$ substituents. Each NH group is connected to two Zn atoms and each $NMe_2$ group to one Zn atom. Alkoxide clusters were prepared in one-pot syntheses by treating diisopropylzinc solutions with mixtures of *N*,*N*-dimethylhydrazine and ROH (R = Et, *i*Pr). The resulting compounds have the formula $[(i\text{PrZn})_4(NHNMe_2)_3(OR)]$ [R = Et (**3**), *i*Pr(**4**)] and contain $Zn_4N_6O$ cages, such that one $NHNMe_2$ in **1** is replaced by one alkoxide group. Two different aggregation modes were found for these $Zn_4N_6O$ cages. In compound **3**, one Zn atom is bound to two $NMe_2$ groups and one NH group. The other three Zn atoms each have three bonds to NH groups and one dative bond to an $NMe_2$ group. The cage consists of one four-membered and one six-membered ring as well as four five-membered rings. In compound **4**, the fourth zinc atom is exclusively bonded to three anionic NH functions in such a way that the rings in the cage are all five-membered. Compounds **3** and **4** were characterised by NMR spectroscopy and single-crystal X-ray diffraction. Hydrazide hydroxide clusters were also obtained through the reaction of a diisopropylzinc solution with *N*,*N*-dimethylhydrazine and a small amount of water. The structure of the resulting cocrystalline material, $[(i\text{PrZn})_4(NHNMe_2)_4]\cdot[(i\text{PrZn})_4(NHNMe_2)_3(OH)]$ (**2**), was also confirmed by X-ray diffraction. The hydroxide cluster in **2** contains a $Zn_4N_6O$ cage, with a similar aggregation mode to that of **4**.

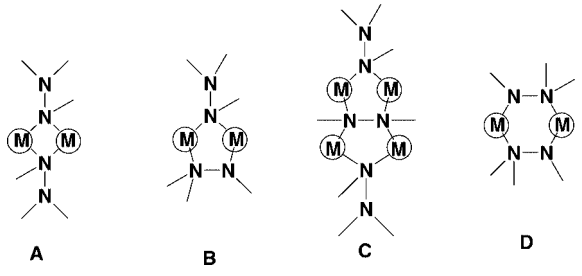
## Introduction

The great variety of the chemistry of group 13 metal hydrazides has recently been reviewed by Uhl.[1] Such metal hydrazides can be employed as single-source precursors for the generation of metal nitrides[2] by CVD methods, although they have been applied in this context less frequently than metal amides.[3] The compounds reported include simple dimers like $[(Me_2Al\text{-}\mu\text{-}NHNMe_2)_2]$,[4] trimers like $[(Me_2Ga\text{-}\mu\text{-}NHNMe_2)_3]$[5] or more complex ladder-type aggregates such as $[Al_4(NHNMe_2)_8(NNMe_2)_2]$.[6] The different aggregation modes in such metal hydrazides originate from the presence of two directly connected inequivalent donor sites. Scheme 1 shows some examples of typical bridging modes realised in various metal hydrazides.



Scheme 1.

A few of these hydrazides also show β-donor bonding leading to three-membered AlNN units.[7a–7e] The reaction between hydrazine, $N_2H_4$, and $GaMe_3$ affords a singular bicyclic compound, $[(Me_2Ga)_4(N_2H_2)(NHNH_2)_2]$,[8] in which two five-membered heterocycles are connected by a common N–N bond and also have N–$NH_2$ groups in exocyclic positions as in type C. A high degree of coordinative flexibility has also recently been documented for the related hydroxylamides in organoaluminium and -gallium chemistry; examples of the corresponding four-, five- and six-membered ring isomers have been reported.[9]

On the basis of these results, it seems surprising that a corresponding organometallic chemistry with group 12 elements, in particular with zinc, which neighbours gallium, has not been extensively established so far. Zinc alkoxides are a well-established class of compounds.[10] They include homoleptic compounds,[10b] alkylzinc alkoxide clusters,[10c] and the zinc siloxide clusters, which have been described as early as 1960 by Schmidbaur and co-workers[10d,10e] and have recently been investigated by Driess and co-workers, who uncovered new varieties of aggregation and interesting thermolysis behaviour.[10f–10h] The only known hydrazide of zinc was $[Zn(N_2H_3)_2]$,[11] but this compound is quite cumbersome to synthesise and furthermore has the disadvantage of containing the $N_2H_3$ group, which exhibits a considerable explosion hazard. In our recent work, we have synthesised the first organometallic zinc hydrazide clusters of the type $[(RZn)_4(NHNMe_2)_4]$ (R = Me, Et) and their alkoxide and hydrazide hydroxide derivatives.[12] Hydrazides of other divalent metal ions have been described, examples include the magnesium hydrazides $\{Mg[NPhN(SiMe_3)_2]_2\}$ and $\{Mg[N(SiMe_3)NMe_2]_2\}$[13] and the beryllium hydrazide $[Be(NMeNMe_2)_2]$.[14] The results of these investigations can be compared with the better established chemistry of the alkali metal hydrazides, in particular that of lithium, which has a large variety of structural motifs.[15–21]

The driving force for preparing these zinc hydrazides and their oxygen derivatives is to explore their aggregation chemistry and behaviour in pyrolysis. Zinc oxide is a widely used semiconductor as it has a wide bandgap. The substitution of oxide by nitride in zinc-based materials such as ZnO would result in a *p*-type semiconductor, which was so far only realised with Ga codoping or by treatment with active nitrogen or with nitrogen oxides such as $N_2O$.[22a–22c] However, these substitution processes show poor reproducibility. The synthesis of such materials by using a molecular precursor route has not been tried to date, probably because of the restricted number of readily accessible thermolabile Zn/N precursor compounds.

In this contribution, we report the synthesis of new organozinc hydrazides and derivatives thereof in which hydrazide units are replaced by hydroxide or alkoxide units. This will be the starting point for the exploration of a new class of compounds, which could possibly be used as molecular precursors for new materials.

## Results and Discussion

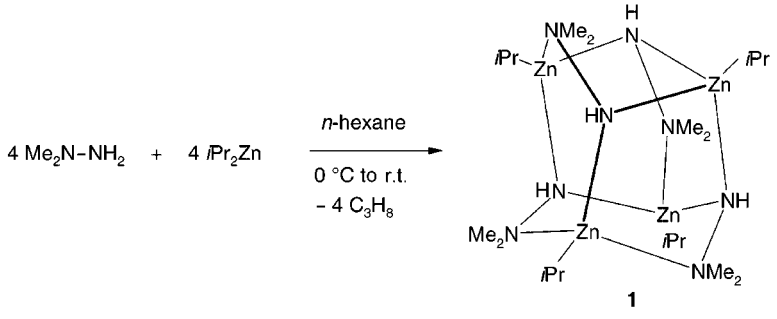
### Isopropylzinc Hydrazide

The reaction of diisopropylzinc with *N*,*N*-dimethylhydrazine gives the hydrazide $[(i\text{PrZn})_4(NHNMe_2)_4]$ (**1**) in moderate yield (Scheme 2). It is soluble in all hydrocarbons and ethers and is easily purified by crystallisation. Compound **1** melts at 228–229 °C.

Hydrazide **1** was formed by combining $i\text{Pr}_2\text{Zn}$ and $H_2NNMe_2$ in a 1:1 ratio and was characterised by NMR spectroscopy and elemental analysis. The presence of tetrameric aggregates was proven by mass spectroscopy; the highest mass found was that of the tetramer minus one isopropyl group. Two bands at 3150 and 3174 $cm^{-1}$ in the IR spectrum proved the presence of NH functions. The $^1H$- and $^{13}C$ NMR spectra in $CDCl_3$ solution indicated the absence of molecular symmetry in the tetramer, as all four hydrazide methyl groups and all four isopropyl groups at zinc gave individual sets of signals. However, it is impossible to prove the formation of a single aggregation type solely from these data. Therefore, analysis by X-ray diffraction was performed on colourless single crystals of **1**, grown by storing an *n*-hexane solution of the compound at –26 °C for several days.

Compound **1** exhibits an unusual $M_4N_8$ cage structure which is $C_1$ symmetric (Figure 1). The topology is related to that of $[(MeGa)_4(NHNPh)_4]$, which contains a $Ga_4N_8$ cage and a dianionic ligand compensating for the formal double charge of the cationic unit $MeGa^{2+}$.[23] There is also a structural resemblance to the zinc oximate $[(MeZn)_4(ONCMe_2)_4]$, which also has a $Zn_4N_4O_4$ core,[24] but has oxygen as the primary binding atom. Furthermore, the structure is similar to the dimethyl- and diethylhydrazides $[(RZn)_4(NHNMe_2)_4]$ (R = Me, Et) recently reported by us.[12]

In compound **1**, all the zinc and nitrogen atoms have coordination number four. There are altogether six rings, two of which are six-membered ($Zn_2N_4$) and four are five-membered ($Zn_2N_3$). The zinc atoms in **1** span a topological tetrahedron, each one of whose four triangular faces are capped by a hydrazide ligand. Each hydrazide unit forms two bonds to zinc atoms from its NH group and one dative bond from its $NMe_2$ group. The distribution of these types of bonds is uneven: Zn1 has three bonds to NH units, Zn2



Scheme 2.

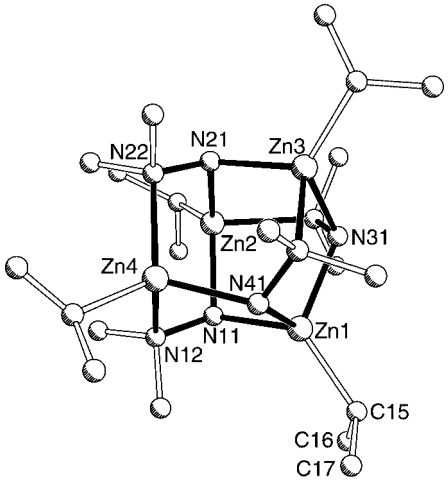

Figure 1. Molecular structure of $[(i\text{PrZn})_4(\text{NHNMe}_2)_4]$ (**1**) as determined by X-ray crystallography. Hydrogen atoms are omitted for clarity.

and Zn3 have two to NH units and one to an $NMe_2$ group, and finally Zn4 has one bond to an NH unit and two to $NMe_2$ groups. The bonds from the Zn atoms to the formally anionic NH groups are shorter by more than 0.1 Å than those to the $NMe_2$ groups. Table 1 lists selected geometric parameters for **1**.

### Isopropylzinc Hydrazide Hydroxide

We have previously reported the formation of the mixed hydrazide hydroxide clusters $[(\text{MeZn})_4(\text{NHNMe}_2)_3(\text{OH})]$ and $[(\text{EtZn})_4(\text{NHNMe}_2)_3(\text{OH})]$[12] from the one-pot reaction between dimethyl- or diethylzinc, *N*,*N*-dimethylhydrazine and water. By carrying out the reaction under similar conditions, but with diisopropylzinc as the organometallic component, we expected to obtain $[(i\text{PrZn})_4(\text{NHNMe}_2)_3(\text{OH})]$. Unexpectedly, the cocrystalline compound $[(i\text{PrZn})_4(\text{NHNMe}_2)_4]\cdot[(i\text{PrZn})_4(\text{NHNMe}_2)_3(\text{OH})]$ (**2**) (Scheme 3) formed and was characterised by single-crystal X-ray diffraction. The presence of the OH group was also confirmed by IR spectroscopy. In the $^1$H NMR spectrum, we could find three sets of signals for the hydrogen atoms at the isopropyl groups. Adding larger amounts of water to the mixture of diisopropylzinc and *N*,*N*-dimethylhydrazine leads to the formation of complicated mixtures of compounds and insoluble precipitates, which could not be separated or identified.

Compound **2** is very soluble in *n*-hexane and in ethereal solvents. Single crystals were obtained by cooling an *n*-hexane solution of **2** for several days at –26 °C.

The crystals of **2** adopt the monoclinic space group $P2_1/c$ and comprise $M_4N_8$ and $M_4N_6O$ cores (Figure 2). Selected geometric parameters for **2** are listed in Table 2.

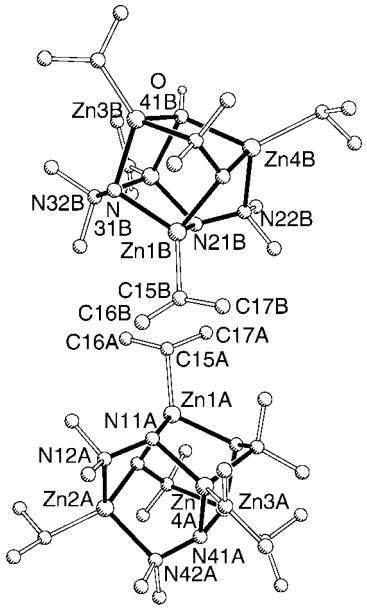

Figure 2. Molecular structure of the cocrystalline compound $[(i\text{PrZn})_4(\text{NHNMe}_2)_4]\cdot[(i\text{PrZn})_4(\text{NHNMe}_2)_3(\text{OH})]$ (**2**) as determined by X-ray crystallography. Hydrogen atoms except the one bound to oxygen are omitted for clarity.

### Isopropylzinc Monoalkoxide Trihydrazide

In order to obtain zinc alkoxide hydrazide compounds, we combined dialkylzinc solutions, alcohol and hydrazine in one-pot syntheses. To achieve the formation of monoalkoxide clusters, a diisopropylzinc/hydrazine/alcohol ratio of 4:2.4:2 was employed (Scheme 4). From this mixture we obtained the compounds $[(i\text{PrZn})_4(\text{NHNMe}_2)_3(\text{OR})]$ [R = Et (**3**), *i*Pr(**4**)]. In an earlier publication, we mentioned the formation of similar products by alcoholysis of the pure hydrazides with dimethyl- and diethylzinc units.[12]

The $^1$H and $^{13}$C NMR spectra of **3** and **4** show one set of alcoholate signals and three sets of signals for the hydrogen atoms at isopropyl groups. The integration ratio gives a zinc alkyl/hydrazide/alkoxide stoichiometry of 4:3:1. The IR spectra show bands corresponding to NH stretching modes. The highest peak in the mass spectrum corresponds to the mass of the molecular cations minus the mass of the alkyl group attached to the O atom. Compounds **3** and **4** melt at 195 °C and 223 °C, respectively. They are soluble in hydrocarbons and ethereal solvents.

The structures of **3** and **4** were obtained by single-crystal X-ray diffraction (Figure 3 and Figure 4). The compounds crystallise in the monoclinic space groups $P2_1/n$ and $P2_1/c$, respectively, from *n*-hexane solutions upon cooling to –26 °C for several days.

The quality of the diffraction data for compound **3** was poor, mainly because of the conformational flexibility of the isopropyl groups, as we frequently observe in this area of chemistry. Therefore, the structural data, which we provide here for the purpose of comparison, should not be overinterpreted.

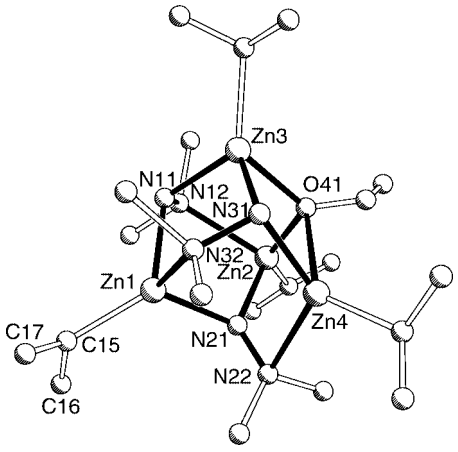

Figure 3. Molecular structure of $[(i\text{PrZn})_4(\text{NHNMe}_2)_3(\text{OEt})]$ (**3**) as determined by X-ray crystallography. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Zn1–N21 2.040(12), Zn1–N11 2.057(11), Zn1–N32 2.17(2), Zn2–N21 2.001(12), Zn2–N12 2.199(12), O41–Zn2 2.018(15), O41–Zn3 1.989(18), O41–Zn4 2.34(3); C15–Zn1–N21 122.3(9), C15–Zn1–N11 123.7(10), C15–Zn1–N32 119.1(8), N21–Zn1–N11 94.3(5), N11–Zn1–N32 88.7(8), Zn1–N21–N22 123.1(11), O41–Zn3–N11 91.0(5), Zn2–O41–Zn3 111.9(7).

Both **3** and **4** contain $Zn_4N_6O$ cores in their molecular structures. We found two different types of aggregation mode in the crystal cores of **3** and **4**. In **3**, the three zinc atoms that are connected to oxygen form one bond to an anionic NH unit and one dative bond to an $NMe_2$ group. The fourth zinc atom is bound to one NH unit and forms two dative bonds to $NMe_2$ groups. Therefore, compound **3**

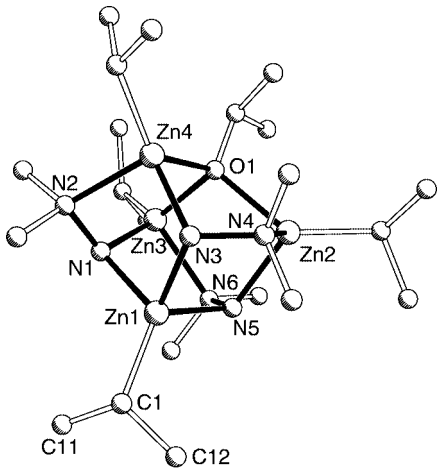

Figure 4. Molecular structure of one of the two independent molecules of $[(i\text{PrZn})_4(\text{NHNMe}_2)_3(\text{O}i\text{Pr})]$ (**4**) as determined by X-ray crystallography. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Zn1–C1 2.016(7), Zn1–N1 2.067(6), Zn2–N5 2.041(5), Zn2–N4 2.150(6), O1–Zn2 2.117(5), O1–Zn4 2.142(6); C1–Zn1–N1 121.3(3), N1–Zn1–N5 94.8(2), N1–Zn1–N3 92.9(3), Zn1–N1–Zn3 107.6(3), O1–Zn3–N1 92.2(3), Zn2–O1–Zn3 108.0(2).

forms one four-membered $Zn_2NO$ and one six-membered $Zn_2N_4$ ring as well as two five-membered $Zn_2N_3$ and two five-membered $Zn_2N_2O$ rings. By contrast, in compound **4**, the fourth zinc atom, which is not connected to the oxygen atom, bonds to three anionic NH units, allowing all six rings to be five-membered (Figure 5). This shows that subtle changes in the sizes of the oxygen substituents can lead to substantial variations in the cage structure of such aggregates. On the other hand, these results indicate that such different cage constitutions vary only slightly in energy.

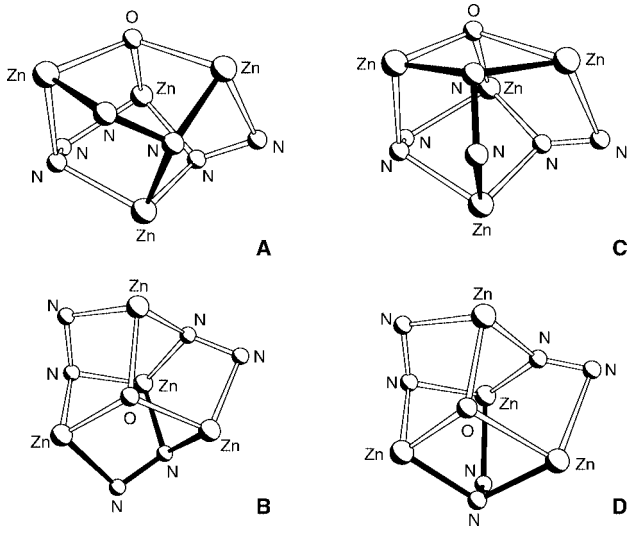

Figure 5. Illustration of the possible aggregation isomers of one of the hydrazide units at the common core structure $Zn_4(\text{NHNMe}_2)_2(\text{OR})$ in $[(i\text{PrZn})_4(\text{NHNMe}_2)_3(\text{OEt})]$ (**3**, **C** and **D**) and $[(i\text{Pr}_2\text{Zn})_4(\text{NHNMe}_2)_3(\text{O}i\text{Pr})]$ (**4**, **A** and **B**). Only the two different $Zn_4N_6O$ cores are shown in two views rotated by about 90°. The structures of the common $Zn(N_2)_2(O)$ cores of the $Zn_4(\text{NHNMe}_2)_2(\text{OR})$ units are shown in hollow lines, the orientation of the $N_2$ unit of the $\text{NHNMe}_2$ group and its connection to the rest of the structure are shown in filled lines.

## Experimental Section

**General Considerations:** All manipulations of air-sensitive compounds were carried out under a dry nitrogen atmosphere with standard Schlenk and high-vacuum techniques by using double manifolds or in a glovebox operated under argon. Solvents were purified and dried by standard methods immediately prior to use. *N*,*N*-Dimethylhydrazine was purchased from Aldrich Chemical Company and dried by distillation from $CaH_2$ under dry nitrogen. Diisopropylzinc was synthesised according to a literature procedure.[25] $^1$H and $^{13}$C NMR spectra were recorded with a Varian Inova-300, 400, 500 or a Varian Unity Plus 600 spectrometer in $CDCl_3$ which was dried with activated molecular sieves. $^1$H- and $^{13}$C assignments were confirmed when necessary by use of two-dimensional $^1$H–$^1$H and $^{13}$C–$^1$H correlation NMR experiments. All spectra were recorded at 25 °C and referenced internally to residual protiosolvent ($^1$H) or solvent ($^{13}$C) resonances. Chemical shifts are quoted in ppm and coupling constants in Hz. A Nonius Kappa-CCD ($\lambda$ = 0.71073 Å) (for compounds **1**, **2** and **3**) or a Bruker Smart CCD X-ray diffractometer ($\lambda$ = 1.54184 Å) (for compound **4**) was used to collect the scattering intensities for single-crystal X-ray diffraction experiments. IR spectra were measured with a Bruker IFS (103 V) by using KBr pellets prepared in the glovebox.

**$[(i\text{PrZn})_4(\text{NHNMe}_2)_4]$ (1):** $i\text{Pr}_2\text{Zn}$ (8.00 mL of a 2.5 M solution in *n*-hexane/diethyl ether; 20.0 mmol) was added dropwise with a syringe to a stirred solution of $H_2\text{NNMe}_2$ (2.30 mL, 30.0 mmol) in *n*-hexane (20 mL) at 0 °C. The reaction mixture was gradually warmed to room temp. and stirred for 6 h. Solvents were removed under reduced pressure The residue was then dissolved in *n*-hexane and filtered. The clear, colourless filtrate was stored at –26 °C to afford colourless, plate-like crystals.

Yield: 63% (2.11 g, 3.14 mmol). M.p. 228–229 °C. $^1$H NMR (400 MHz): $\delta$ = 0.07 [sept, $^3J_{\text{H,H}}$ = 7.7 Hz, 1 H, ZnC*H*], 0.14–0.30 [m, 2 H, ZnC*H*], 0.37 [sept, $^3J_{\text{H,H}}$ = 7.7 Hz, 1 H, ZnC*H*], 1.13–1.25 [m, 24 H, $\text{ZnCH}(\text{C}H_3)_2$], 2.06, 2.09, 2.12 [s, 4 H, N-*H*], 2.23–2.77 [m, 24 H, $\text{N}(\text{C}H_3)_2$] ppm. $^{13}$C{$^1$H} NMR (125.7 MHz): $\delta$ = 10.22, 11.07, 11.32, 11.69 [Zn*C*H], 24.73, 24.89, 25.15, 25.31, 25.33, 25.50, 25.59, 25.73 [$\text{ZnCH}(C\text{H}_3)_2$], 53.87, 54.76, 55.14, 55.64, 56.51, 56.83, 57.14, 57.89 [$\text{N}(C\text{H}_3)_2$] ppm. $C_{20}H_{56}N_8Zn_4$ (670.24): calcd. C 35.83, H 8.42, N 16.72; found C 35.75, H 8.21, N 16.38. EI-MS [*m*/*z* (%)]: 627 (100), $[\text{M}^+-\text{C}_3\text{H}_7]$, 567 (53), $[\text{M}^+-\text{C}_3\text{H}_7-(\text{NHNMe}_2)]$, 459 (78), $[\text{M}^+-2\ \text{C}_3\text{H}_7-(\text{NHNMe}_2)]$. IR (KBr): $\tilde{\nu}$ = 3150, 3174 (w, N–H), 2867 (vs), 2821 (vs), 2693 (w), 1465(vs) 1161 (s), 994 (s) 951 (s), 820 (vs), 571 (s) cm$^{-1}$.

**$[(i\text{PrZn})_4(\text{NHNMe}_2)_4]\cdot[(i\text{PrZn})_4(\text{NHNMe}_2)_3(\text{OH})]$ (2):** $i\text{Pr}_2\text{Zn}$ (4.00 mL, 2.5 M in *n*-hexane/diethyl ether, 10.0 mmol) was added dropwise with a syringe to a stirred solution of $H_2\text{NNMe}_2$ (0.60 mL, 7.83 mmol) in *n*-hexane (10 mL) at 0 °C. Water (0.07 mL, 3.88 mmol) was added dropwise with a syringe. The reaction mixture was gradually warmed to room temp. and stirred for 6 h. After removal of the solvent under reduced pressure, the residue was dissolved in *n*-hexane and filtered. Colourless crystals of **2** were obtained by storing an *n*-hexane solution of **2** at –26 °C.

Yield: 62% (1.00 g, 1.54 mmol). M.p. 263–264 °C (decomp.). $^1$H NMR (300 MHz): $\delta$ = 0.21 [sept, $^3J_{\text{H,H}}$ = 7.6 Hz, 1 H, ZnC*H*-$(\text{CH}_3)_2$], 0.44 [sept, $^3J_{\text{H,H}}$ = 7.6 Hz, 1 H, $\text{ZnC}H(\text{CH}_3)_2$], 0.83 [sept, $^3J_{\text{H,H}}$ = 7.5 Hz, 2 H, $\text{ZnC}H(\text{CH}_3)_2$], 1.09–1.29 [m, 24 H, $\text{ZnCH}(\text{C}H_3)_2$], 2.06–2.78 [m, 21 H, N-*H*, $\text{N}(\text{C}H_3)_2$] ppm. $^{13}$C{$^1$H}

**Crystal Structures:** Crystals of compounds **1**, **2** and **3** were selected and prepared under perfluoropolyether and mounted in a drop of this solution onto the glass fibre tip of the goniometer head. The crystallographic data sets for compounds **1**, **2** and **3** were collected with a Nonius Kappa CCD diffractometer; the data set for **4** was collected with a Bruker Smart CCD diffractometer. The structures were solved by direct methods and refined with the full-matrix least-squares procedure (SHELXTL[26]) against $F^2$. Details of the crystal data and refinements are provided in Table 3. The generation of good quality crystals of this class of substance has proven very difficult previously,[12] probably because of the ball-shaped structure of the tetrameric or pseudotetrameric aggregates. Despite the limited accuracy of the geometry parameters which could be achieved with the crystalline materials, the crystal structure determination results give valuable information regarding the constitution of the cluster-like aggregates.

One of the two independent molecules in the crystal of **4** is less well defined than the other. In this molecule, two isopropyl groups were refined as a split model to give abundances for the major disorder components of 0.54 and 0.87. Furthermore, two N–N bonds [N(1)–N(2) and N(9)–N(10)] in this molecule were restrained

to a length of 1.46 (1) Å and the bonds Zn(4)–N(2) and Zn(7)–N(10) to a length of 2.13(1) Å as they tended to refine to inappropriate values. All the distances (bonding and non-bonding) in the disordered isopropyl groups containing C(7) and C(8) were restrained to the average geometry values for the isopropyl groups in the other, better defined molecule. Crystallographic data (excluding structure factors) for the structures reported in this paper have been forwarded to the Cambridge Crystallographic Data Centre as supplementary publications. The deposition numbers are listed in the last line of Table 3. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We are grateful to the NRW Graduate School of Chemistry at Münster (GSC-MS) for a PhD stipend for S.J. The authors would like to thank Dr. F. Rogel for collecting the X-ray data set of **4**, Dr. K. Bergander for recording the NMR spectroscopic data and M. Ullrich for providing diisopropylzinc solutions and for helpful discussions.

# Drug Self-Templated Synthesis of Ibuprofen/Mesoporous Silica for Sustained Release

Fengyu Qu,[a,b] Guangshan Zhu,*[a] Huiming Lin,[a] Jinyu Sun,[a] Daliang Zhang,[a] Shougui Li,[a] and Shilun Qiu*[a]

**Keywords:** Template synthesis / Ibuprofen / Mesoporous materials / Silica

The synthesis of Ibuprofen/mesoporous silica has been achieved by a drug self-templated one-step co-condensation process. The drug template of Ibuprofen, a co-template of 3-aminopropyltriethoxysilane (APTES), and tetraethoxysiliane (TEOS) were self-assembled into Ibuprofen/mesoporous silica in a neutral aqueous reaction system. This drug/mesoporous silica was characterized by powder XRD diffraction, FTIR spectroscopy, $N_2$ adsorption/desorption, TEM, and $^{29}Si$/MAS and $^{13}C$/MAS NMR spectroscopy. The Ibuprofen/mesoporous silica system gives a well-sustained release profile.

## Introduction

Over the past three decades there has been rapid growth in sustained/controlled drug delivery in the field of modern medication and pharmaceuticals since sustained/controlled release can bring both therapeutic and commercial value to health-care products.[1] Among a wide number of materials, micelles, liposomes, and polymeric and co-polymeric nanoparticles are widely employed as drug carriers for sustained/controlled delivery. Recently, a new application of mesoporous silica as a drug-delivery system has been explored,[2] and there is now growing interest in the use of mesoporous silica as a sustained/controlled drug delivery system due to its several attractive features, such as stable uniform mesoporous structure, high surface area, tunable pore sizes with narrow distributions, well-defined surface properties,[1,3] nontoxic nature,[4] and good biocompatibility.[5–7] Several research groups have reported on the design of mesoporous silica-based carriers for sustained/controlled drug-delivery systems.[1–3,6,8–12]

Up to now, the loading of drugs into the channel of mesoporous silica was mainly post-synthesis, that is, the mesoporous silica carrier was synthesized first followed by storage of the drug molecules. The post-synthesis introduction of drug molecules has been achieved by two general strategies: (i) by physical adsorption of drug molecules in the pure mesoporous silica[2,5,8,10,12] or by an acid-base interaction of the drug molecules with amine-supported mesoporous silica,[1,3] or (ii) by anchoring the drug molecules with modified mesoporous silica by covalent attachment to form a pro-drug with release potential.[11]

Ibuprofen is frequently employed as a model drug for sustained/controlled delivery owing to its suitable molecule size of about $1.0 \times 0.5$ nm,[2] good pharmacological activity, and short biological half-life (2 h).[13]

Here, we propose a novel approach to encapsulating Ibuprofen in the channels of mesoporous silica by a one-step, drug self-templating technique. The Ibuprofen/mesoporous silica sample was characterized by powder XRD diffraction, FTIR spectroscopy, $N_2$ adsorption/desorption, TEM, and $^{29}Si$/MAS and $^{13}C$/MAS NMR spectroscopy. Drug-release profiles have also been determined.

## Results and Discussion

Figure 1 schematically illustrates the one-step, drug self-templated synthesis of our mesoporous silica drug-carrier system. The synthesis is based on $S^-N^+–I^-$ template pathways,[14–16] where $S^-$ denotes the anionic drug template and $N^+$ and $I^-$ represent the protonated amine group and negatively charged silane group, respectively. The formation mechanism is thought to be controlled by the electrostatic interaction between the negatively charged carboxylic headgroup of the drug template (Ibuprofen) and the protonated amine group of the organoalkoxysilane (APTES). Condensation occurs preferentially at the alkoxysilane sites in APTES to onset the formation of the silicate framework. Meanwhile, drug molecules are encapsulated in the channels of the mesoporous silicate to finally give the drug-encapsulated Ibu/MS system.

The XRD pattern of Ibu/MS shows only one reflection (see Supporting Information Figure S1), with a *d*-spacing of

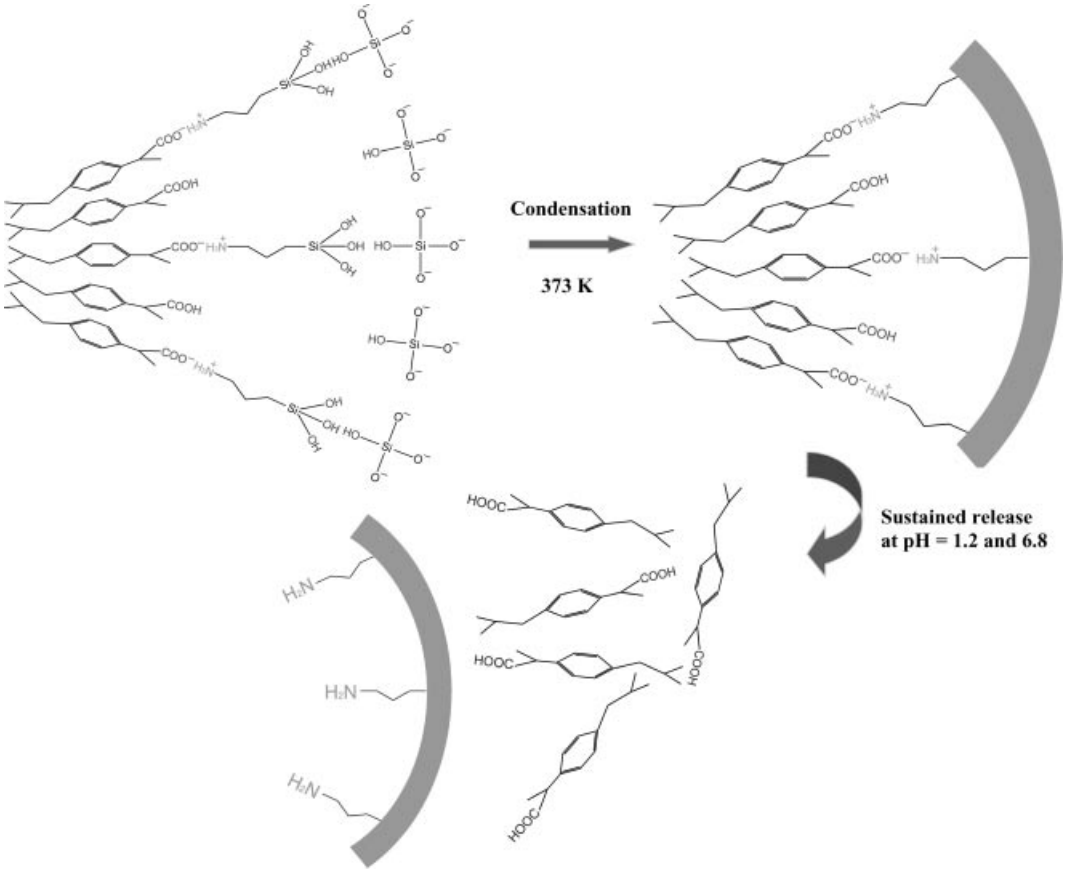

Figure 1. The one-step, drug self-templated synthesis of Ibu/MS system and sustained release.

4.28 nm. The TEM image confirms that the Ibu/MS sample possesses an ordered mesoporous structure (Figure 2). Furthermore, the characteristic mesoporous system was also confirmed by nitrogen adsorption/desorption measurements (shown in Figure 3), which revealed that the samples possess a high specific surface area of 1262 $m^2 g^{-1}$, a large pore volume of 0.66 $cm^3 g^{-1}$, and an average pore size of 2.08 nm. It can be seen that a well-defined step occurs in the adsorption curve at a relative pressure, $P/P_o$, of 0.2–0.3, which indicates the filling of framework-confined mesopores.[17] This isotherm can be classified as type IV.[18]

The FT IR spectra of Ibuprofen show that the band corresponding to a free carboxylic acid (1723 $cm^{-1}$) has changed to a carboxylate one (1463 and 1637 $cm^{-1}$) in the Ibu/MS sample (see Supporting Information, Figure S2), which suggests $COO^{-}\cdots N^{+}$ bonding between Ibuprofen and the co-template (APTES).[1,3,8,19] In addition, bands for the quaternary carbon atom of Ibuprofen at 1463 and 1519 $cm^{-1}$ and bands for C–$H_x$ of APTES at 2919 and 2962 $cm^{-1}$ can be clearly seen in the Ibu/MS system.[20] These observations show that Ibuprofen and APTES are involved in the formation of the mesoporous phase.

Figure 4 (part A) shows a typical $^{29}Si$/MAS NMR spectrum for the Ibu/MS sample. In addition to the free hydroxy group ($Q_3$) at $\delta$ = –110 ppm and cross-linked silicon atoms ($Q_4$), a new peak group appears between $\delta$ = –50 and –80 ppm in Ibu/MS, which is assigned to the Si atoms covalently bound to organic groups {$T_2$ [$(SiO)_2Si(OH)CSi$] and $T_3$ [$(SiO)_3SiCSi$], respectively}.[21–23]

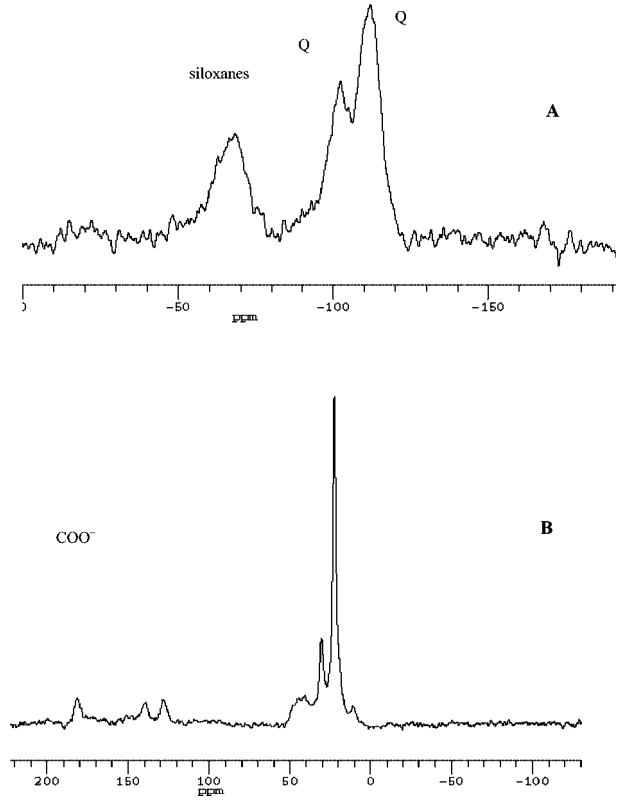

Figure 4. NMR spectra of Ibu/MS: (A) $^{29}Si$/MAS NMR spectrum; (B) solid-state $^{13}C$/MAS NMR spectrum.

The $^{13}C$/MAS NMR spectrum of Ibu/MS is shown in part B of Figure 4. The peaks of $-CH_2CH_3$ at $\delta$ = 58 and 14 ppm of pure APTES have disappeared in the Ibu/MS system due to the condensation of APTES with TEOS, which is consistent with $^{29}Si$ MAS/NMR observations. Furthermore, the peak of the carboxylic acid group of pure Ibuprofen at $\delta$ = 183.22 ppm is shifted slightly to a higher shielding of $\delta$ = 181.16 ppm in the Ibu/MS system due to the shift of a proton from the carboxylic acid to the amine. These NMR spectra are in agreement with the results of the FT IR spectra, which further confirms the $COO^{-}$-$N^{+}$ interaction between Ibuprofen and the co-template, as well as the encapsulation of Ibuprofen in the channels of the mesoporous silica.

The loading of ibuprofen in the Ibu/MS sample is about 24%, as determined from the drug released ($M_\infty$) at infinite time. Since Ibuprofen is mainly adsorbed in the stomach and proximal intestine, the release profiles of Ibu/MS in simulated gastric and proximal intestine were determined; the cumulative release rates are shown in Figure 5. This diagram clearly proves that both systems exhibit sustained-release profiles. Only 8.61 wt.-% of Ibuprofen is released within 2 h, and it takes nearly 12 and 45 h to reach 45.06 and 95.2 wt.-% of drug released in simulated gastric fluid, respectively. The release rate in simulated proximal intestine fluid is higher than that in the simulated gastric fluid. Thus, 13.95 wt.-% of Ibuprofen is released within 2 h, 52.22 wt.-% of the drug is released in 12 h, and drug release is finished in 45 h. The difference of release profiles should be mainly due to the different solubility of Ibuprofen at different pH values. Additionally, the integrity of the drug molecules is maintained upon their release from the mesoporous silica (see Supporting Information, Figure S5).

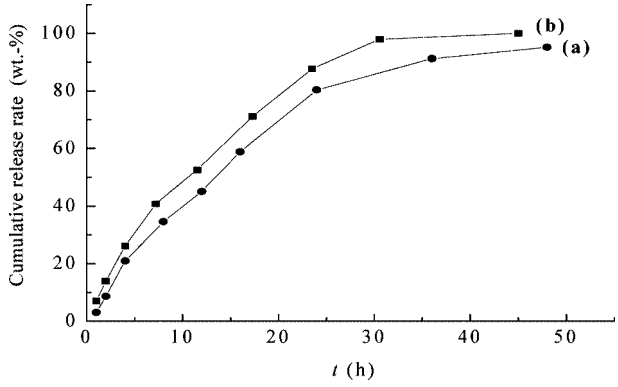

Figure 5. Cumulative release rates of Ibuprofen in simulated (a) stomach and (b) proximal intestinal fluid.

For comparison, MCM-41 was functionalized with APTES and the release kinetics were studied (see Supporting Information, Figure S6). It can be seen that this system shows a faster initial release rate than the Ibu/MS system, with 17.5 wt.-% of Ibuprofen released within 2 h and 55.56 wt.-% of the drug released in 12 h.

In order to investigate the release behavior of Ibuprofen, the drug-release kinetics were analyzed with the Korsmeyer–Peppas model.[24,25] This model often deviates from Fick's law and follows an anomalous behavior that follows the exponential model $M_t/M_\infty = kt^n$, where $M_t$ is the drug released at time $t$, $M_\infty$ is the quantity of drug released at infinite time, $k$ is the kinetic constant, and $n$ is the release exponent, which characterizes the drug-transport mechanism. When $n$ = 0.5, the drug diffusion and release from the matrix follow Fick's law and drug initial release is slower, while for $1 > n > 0.5$ it follows an anomalous non-Fick-type transport and drug initial release is faster than that of $n$ = 0.5. A relatively larger initial drug release is essential for sustained/controlled drug release. The ln(frac-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tional release of Ibuprofen) is plotted as a function of ln(time) with the data up to 45 h. The exponent for the Ibu/MS system is 0.763 and 0.876 at pH 1.2 and 6.8, respectively (Table 1), which suggests that Ibuprofen release from this system follows an anomalous non-Fick-type transport behavior.

Table 1. The Korsmeyer–Peppas model fit of Ibuprofen release.

| Samples | Release medium | $\ln(M_t/M_\infty)$ vs. $\ln t$ | $n$ | R |
|---|---|---|---|---|
| Ibu/MS | pH 1.2 | $y = 0.763x - 2.519$ | 0.763 | 0.9949 |
| Ibu/MS | pH 6.8 | $y = 0.876x - 3.094$ | 0.876 | 0.9775 |

## Conclusions

In summary, we have achieved a novel and effective method that uses a drug in a one-step template synthesis that leads to an Ibu/mesoporous silica system. The reported Ibu/MS system possesses an ordered mesoporous structure and gives a well-sustained release profile. The release mechanism follows an anomalous non-Fick-type behavior. This new drug/mesoporous silica synthesis technique is likely find applications in the encapsulation of drugs, fragrances, nanoparticles, and (bio)macromolecules inside mesoporous silica systems.

## Experimental Section

**Materials:** (3-Aminopropyl)triethoxysilane (APTES, Aldrich), tetraethoxysilane (TEOS, Tiantai Co., Tianjin), and Ibuprofen (Ibu, Tianzunzezhong, Chemical Co., Nanjing) were used as received.

**Synthesis of Ibuprofen/Mesoporous Silica System:** In a typical procedure, 0.11 g of Ibu was first dissolved in a mixture of 0.1 g of APTES and 0.5 mL of distilled water by stirring until a clear solution had formed. Then, 1.01 g of TEOS was added with continuous stirring for 24 h at room temperature. The pH value of the final gel was about 7. This white gel was sealed in a Teflon-lined stainless-steel autoclave and heated at 323 K for 8 h, followed by further heating at 373 K overnight under static conditions. The white precipitate obtained was filtered and washed extensively. The as-synthesized sample was air-dried at room temperature for 48 h.

**Characterization:** Powder XRD diffraction data were collected on a SIEMENS D5005 diffractometer with Cu-$K_\alpha$ radiation at 40 kV and 30 mA. Nitrogen adsorption/desorption was measured with a Micromeritics ASAP 2010 M sorptometer. Before measurement, the samples was calcined at 723 K for 5 h, degassed at 373 K for 12 h, and the measurements were carried out at 77 K. Specific surface areas and pore-size distributions were calculated using the Brunauer–Emmett–Teller (BET) and Barrett–Joyner–Halenda (BJH) models from the adsorption branches, respectively. Solid-state/MAS NMR spectra were recorded on a Varian infinity plus 400 spectrometer. $^{29}$Si/MAS NMR: resonance frequency: 79.41 MHz; spinning frequency: 4.00 kHz; pulse delay: 10.00 s; pulse width: 30°; $^{13}$C/MAS NMR: resonance frequency: 100.52 MHz; contact time: 1.00 min; spin rate: 3.33 kHz. UV/Vis spectra were recorded with a UV-2450 visible spectrophotometer from Shimadzu. An FT-IR spectrometer (JASCOFT/IR-420) was used to record infrared spectra of the samples by the KBr method. Powder materials were pressed into a tungsten mesh grid and installed in an in situ FTIR transmission cell; the samples were outgassed in a vacuum system with a residual pressure of less than $3 \times 10^{-4}$ Torr at ambient temperature. TEM images were recorded with a JEOL 3010 at an acceleration voltage of 300 kV.

**Drug Release:** After the Ibu/MS sample has been compressed into tablet with a diameter of 10 mm and a thickness of 0.5 mm, the release rate was obtained by soaking the sample tablets (150 mg) in 500 mL of simulated gastric and proximal intestinal fluid (pH 1.2 HCl and pH 6.8 buffer solution), respectively, at a temperature of 310 K. At predetermined time intervals, 3-mL samples were withdrawn and immediately replaced with an equal volume of dissolution medium to keep the volume constant. These samples were filtered (0.45 μm), diluted, then the Ibuprofen contents were analyzed at 222 nm using a UV/Vis spectrophotometer.

**Supporting Information** (see footnote on the first page of this article): Figure S1 shows the powder X-ray diffraction spectra of Ibu/MS, which confirms the mesoporous structure. Figure S2 shows the FTIR spectra of (a) pure Ibuprofen and (b) Ibu/MS. Figure S3 shows the $^{13}$C/MAS NMR spectrum of neat APTES. Figure S4 shows the $^{13}$C/MAS NMR spectrum of neat Ibuprofen, which may give information that ibuprofen and APTES may be involved in the formation of the mesoporous structure. Figure S5 shows the UV/Vis spectra of (a) neat Ibuprofen and (b) Ibuprofen released from the Ibu/MS system. Figure S6 shows the cumulative release rates of Ibuprofen from functionalized MCM-41 in simulated fluid. Figure S7 shows SEM images of the Ibu/MS sample.

# Organoethynylxenon(II) Tetrafluoroborates, [RC≡CXe][$BF_4$] – The First Examples of Isolated Alkynylxenonium Salts: Preparation and Multi-NMR Characterisation

**Hermann-Josef Frohn*[a] and Vadim V. Bardin[b]**

**Keywords:** Alkynes / Boranes / Xenon / NMR spectroscopy

The perfluorinated organoethynylxenon(II) salts, [RC≡CXe][$BF_4$] [R = $CF_3$, $C_3F_7$, $(CF_3)_2CF$, *cis*-, *trans*-$CF_3CF$=CF, $C_6F_5$], were prepared by the reaction of $XeF_2$ with the corresponding perfluoroorganoethynyldifluoroboranes, RC≡$CBF_2$, in 1,1,1,3,3-pentafluoropropane (PFP) or $CH_2Cl_2$ at –60 to –40 °C and isolated in 30–98 % yield. Similarly, the non-fluorinated organoethynylxenon(II) salts [$C_4H_9$C≡CXe][$BF_4$] and [$(CH_3)_3$CC≡CXe][$BF_4$] were obtained in 20 to 40 % yield. All [RC≡CXe][$BF_4$] salts are soluble in anhydrous HF (aHF) and the salts with R = $C_4H_9$ or R = $(CH_3)_3$C display sufficient solubility in the weakly coordinating solvents $CH_2Cl_2$ and PFP. The xenonium salts [RC≡CXe][$BF_4$] were unambiguously characterised by their $^1$H-, $^{11}$B-, $^{13}$C-, $^{19}$F-, and $^{129}$Xe NMR spectra in solution.

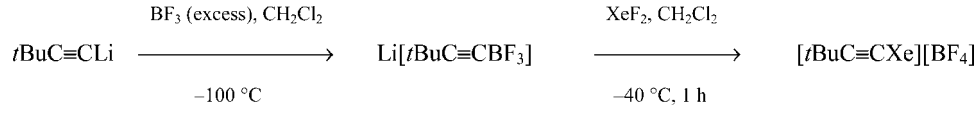
## Introduction

The preparative chemistry of organoxenon compounds was established in 1989 with the synthesis of pentafluorophenylxenon(II) salts, [$C_6F_5$Xe][Y], obtained by the reaction of $XeF_2$ with $(C_6F_5)_3$B.[1,2] In the subsequent years xenonium salts, [RXe][Y], with different types of organo groups in the cation (R = substituted phenyl, polyfluorocycloalk-1-enyl) as well as arylxenon(II) molecules ArXeX (X = F, Cl, $O_2CC_6F_5$, CN, $C_6F_5$) and the first example of a Xe(IV)–C compound, [$C_6F_5XeF_2$][$BF_4$], were investigated. The achievements made in the first decade of xenon–carbon chemistry are compiled in some reviews published in 1999–2002.[3] In the following years reactivities of arylxenon(II) salts,[4,5] of diarylxenon ArXeAr′,[6] and the preparation and reactivity of a series of acyclic polyfluoroalk-1-enylxenon(II) salts [RCF=CR′Xe][$BF_4$][7–9] were reported. In 2004 Naumann et al. observed RC≡CXeF molecules (R = Me, Bu, Ph) in the fluoride-catalysed reaction of $XeF_2$ and $Me_3$SiC≡CR. The authors reported a significant decomposition of RC≡CXeF in solution above –60 °C.[10]

In 1992, Zhdankin et al. published a short communication on the salt [*t*BuC≡CXe][$BF_4$] obtained by the reaction of Li[*t*BuC≡$CBF_3$] with $BF_3$ and $XeF_2$ in $CH_2Cl_2$ (Scheme 1).[11] This salt, which could not be isolated because of its decomposition at –30 °C, was characterised by $^1$H-, $^{11}$B-, $^{13}$C-, and $^{129}$Xe NMR spectroscopy at –40 °C, by IR spectroscopy at 0 °C, and by the alkynylation of $PPh_3$ to [*t*BuC≡C$PPh_3$][$BF_4$] at –78 °C.

In the analogous reactions of $XeF_2$ with alkynylsilanes, RC≡$CSiMe_3$ (R = Et, Pr, *t*Bu, and $Me_3$Si), and $BF_3$·$OEt_2$ in $CD_2Cl_2$ at –45 °C, the authors reported no multi-NMR spectroscopic data of the desired products, the xenonium salts. Each reaction solution was only characterised by a singlet in the $^{129}$Xe NMR spectrum. No $^{129}$Xe resonances were found in the spectra of the reaction solutions for R = H, Me, Ph, $CF_3$, 4-$CH_3C_6H_4SO_2$, $(i$Pr$)_3$Si, $PhMe_2$Si.[11]



Scheme 1.

We published a preliminarily report of the first isolation of an alkynylxenon(II) salt in 2003 when we succeeded in preparing trifluoropropynylxenon(II) tetrafluoroborate [$CF_3$C≡CXe][$BF_4$].[12] We employed the previously developed approach to polyfluorinated arylxenon(II) and alk-1-enylxenon(II) salts: the reaction of xenon difluoride with

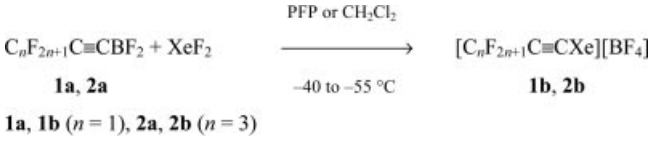
polyfluoroorganoboron difluoride in the appropriate solvent.[3b] This preparative method allowed for the isolation of the new salt as a pure product and opened the possibility of extensive and unambiguous characterisation. Subsequently, we extended this preparative method to a representative series of alkynylxenon(II) salts, $[RC{\equiv}CXe][BF_4]$, where R represents any alkyl chain, a perfluoroalkyl group, a perfluoroalk-1-enyl group or a perfluoroaryl group.

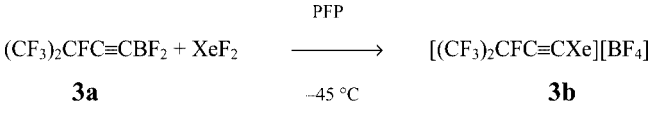
## Results and Discussion

The addition of $XeF_2$ to the solution of either trifluoropropynyldifluoroborane (**1a**) or heptafluoropent-1-ynyldifluoroborane (**2a**) in PFP[13] at –40 to –55 °C was accompanied by the precipitation of trifluoropropynylxenon(II) tetrafluoroborate (**1b**) or heptafluoropent-1-ynylxenon(II) tetrafluoroborate (**2b**), respectively. Both salts are insoluble in PFP and form white solids. After decantation of the mother liquors and removal of the residual volatiles in vacuo, alkynylxenon salts **1b** and **2b** were isolated in 60–90% yield (Scheme 2).



Scheme 2.

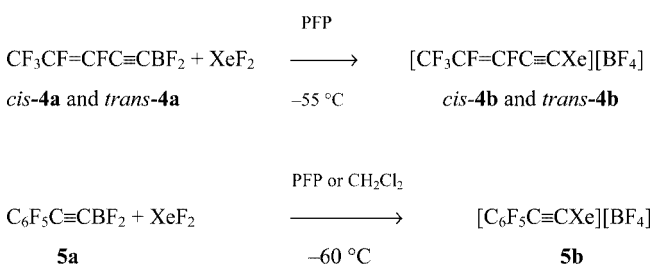
In a similar way, the reaction of heptafluoro-3-methylbut-1-ynyldifluoroborane (**3a**) with $XeF_2$ gave heptafluoro-3-methylbut-1-ynylxenon(II) tetrafluoroborate (**3b**) in 82% yield (Scheme 3).



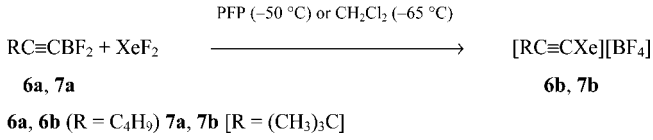
Scheme 3.

The replacement of the perfluorinated alkyl group at C-2 of boranes **1a**, **2a**, and **3a** by the pentafluoropropenyl or pentafluorophenyl group did not affect the course of the reaction. Both pentafluoropent-3-en-1-ynyldifluoroboranes (*cis*-**4a**) and (*trans*-**4a**) and pentafluorophenylethynyldifluoroborane (**5a**) were successfully converted into pentafluoropent-3-en-1-ynylxenon(II) tetrafluoroborates (*cis*-**4b**) and (*trans*-**4b**) and pentafluorophenylethynylxenon(II) tetrafluoroborate (**5b**), respectively. No addition of fluorine to the double bond in the perfluorinated propenyl or phenyl moiety of **4a** or **5a** occurred. The ratio *cis*-**4b**/*trans*-**4b** = 1:2 was equal to that in the parent boranes **4a** (Scheme 4).

To complete the investigations of xenon difluoride with alkynyldifluoroboranes, we studied the reaction of $XeF_2$ with boranes that contained a hydrocarbon alkynyl chain. $XeF_2$ was treated with hex-1-ynyldifluoroborane (**6a**) and 3,3-dimethylbut-1-ynyldifluoroborane (**7a**) under the conditions mentioned above and formed hex-1-ynylxenon(II) tetrafluoroborate (**6b**) and 3,3-dimethylbut-1-ynylxenon(II) tetrafluoroborate (**7b**), respectively (Scheme 5). Surprisingly, these salts are significantly soluble in PFP even below –40 °C. Salt **6b** is more soluble than salt **7b**. Thus, under comparable reaction conditions in PFP at –50 °C, **6b** remained in solution whereas half of isomer **7b** precipitated. When borane **6a** reacted with $XeF_2$ in $CH_2Cl_2$ at –65 °C solely a solution of **6b** was obtained.



Scheme 4.



Scheme 5.

In contrast to the reaction of alk-1-enyldifluoroboranes, $RCF{=}CFBF_2$, with $XeF_2$,[7] neither the alk-1-enyltrifluoroborate anions, $[RCF{=}CFBF_3]^-$, nor their fluorination products, $[XBF_3]^-$ (X = RCF=CF, $RCF_2CF_2$), were observed.

The results demonstrate the easy xenodeborylation (replacement of the three-coordinate boron atom by xenon) of both non-fluorinated organoethynyldifluoroboranes and perfluoroorganoethynyldifluoroboranes, $RC{\equiv}CBF_2$, in reactions with xenon difluoride. Significant differences between the present reactions and the previously studied reactions of $XeF_2$ with alk-1-enyldifluoroboranes are their insensitivity to the type of R group attached to C-2 of the multiple C–C bond. It is worth mentioning that in the reactions of hydrocarbon alk-1-enyldifluoroboranes with $XeF_2$ no xenonium salts were obtained. Thus under the same reaction conditions as those of alkynyldifluoroboranes, *cis*- and *trans*-hex-1-enyldifluoroboranes, $C_4H_9CH{=}CHBF_2$, only gave complex mixtures but no hexenylxenon compounds.[7]

The novel alkynylxenon(II) compounds **1b**–**5b** were isolated as white solids at low temperatures (<–40 °C). When warmed from –40 °C the solutions took on a brown colouration, and at 20 °C the conversion into dark liquids took place within a few minutes (**4b**, **5b**) or a few hours (**1b**–**3b**). Salts **1b**–**5b** are very soluble in aHF and insoluble in PFP and $CH_2Cl_2$. A characteristic property of solutions of **1b**–**5b** in aHF is their longer lifetime at room temperature than that of the salts themselves in the solid state. In detail, no decomposition of perfluoroalkynylxenon tetrafluoroborates **1b**–**3b** was detected in aHF solutions within 20–24 h. The salts **4b** and **5b**, which contain the unsaturated perfluoro groups R = $CF_3CF{=}CF$ and R = $C_6F_5$, respectively, at C–

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2, decomposed much faster than **1b**–**3b**. Salt **5b** totally decomposed in aHF at –40 °C within 1 h, whereas the total decomposition of **4b** in aHF at 22–24 °C took ca. 4 h. The complete decomposition of pure solids **4b** and **5b** at 20 °C led to the formation of brown materials, insoluble in aHF, which consisted of non-volatile complex mixtures ($^{19}$F NMR).

Hex-1-ynylxenon(II) tetrafluoroborate **6b** and its isomer **7b** were isolated as brownish powders (probably contaminated with impurities) which were easily liquefied above –40 °C (cf.[11]). Solutions or suspensions of these salts in either PFP or $CH_2Cl_2$ decomposed in a manner similar to that of the salts in the solid state. Surprisingly, solutions of **6b** and **7b** in aHF are stable at 22–25 °C for more than 12 h. After 22 h, 38% of **6b** and 80% of **7b** still remained unchanged. Finally the complete decomposition led to tar.

Salts **1b**–**7b** were unambiguously characterised by multi-NMR spectroscopy. The $^{19}$F NMR spectra of fluoroorganoethynylxenon(II) tetrafluoroborates **1b**–**5b** in aHF displayed signals for the fluoroorgano groups and for the $[BF_4]^-$ anion (at approximately $\delta$ = –148 ppm) with the expected integrations. Long-range couplings $J_{^{19}F,^{129}Xe}$ were observed in the spectra of both isomers of $[CF_3CF{=}CFC{\equiv}CXe][BF_4]$. The signal for F-4 at $\delta$ = –128.2 ppm (*cis*-**4b**) and F-3 at $\delta$ = –149.3 ppm (*trans*-**4b**) displayed $^{129}$Xe satellites ($^5J_{F\text{-}4,Xe}$ = 17 Hz and $^4J_{F\text{-}3,Xe}$ = 6 Hz, respectively) in accordance with the natural abundance of the $^{129}$Xe isotope of 26%. The assignment of the coupling $^4J_{F\text{-}3,Xe}$ = 8 Hz in the $^{19}$F NMR spectrum of $[(CF_3)_2CFC{\equiv}CXe][BF_4]$ was confirmed in a $^{19}F\{^{19}F(CF_3)\}$ homodecoupling NMR experiment. In the $^{19}$F NMR spectrum of salts with unbranched perfluoroalkyl R groups, as in **1b** (signal for the $CF_3$ group at $\delta$ = –52.5 ppm, $\tau_{1/2}$ = 1.5 Hz) or **2b** [$^{19}F\{^{19}F(CF_3)\}$ spectrum of the $CF_3CF_2CF_2$ group] such couplings were not observed. For comparison, in the case of *cis*-perfluoroalk-1-enylxenonium salts, larger $^4J_{F\text{-}3,Xe}$ couplings are known. In the spectra of [*cis*-$YCF_2CF{=}CFXe][BF_4]$, $^4J_{F\text{-}3,Xe}$ = 40 Hz (Y = F) and $^4J_{F\text{-}3,Xe}$ = 56 Hz (Y = $CF_3$) were measured.[7]

The $^{129}$Xe NMR signals of salts $[RC{\equiv}CXe][BF_4]$ **1b**–**5b** in aHF at –60 °C are singlets located between $\delta$ = –3600 and –3662 ppm (Table 1). The influence of the type of the perfluorinated R group in $[RC{\equiv}CXe]^+$ on the $^{129}$Xe NMR chemical shifts is demonstrated by the remarkably high-frequency shift (deshielding) of the xenon atom parallel to the replacement of fluorine atoms in $[CF_3C{\equiv}CXe]^+$ by perfluoroalkyl groups: $\delta(^{129}Xe)$ = –3636 ppm ($R_F{=}CF_3$) < –3609 ppm ($R_F{=}CF_3CF_2CF_2$) < –3600 ppm [$R_F$ = $(CF_3)_2CF$]. Furthermore, there is yet a very small but still experimentally detectable distinction in the $^{129}$Xe NMR chemical shifts caused by configurational distinctions at C-4 as shown in the case of the isomeric cations [*cis*-$CF_3CF{=}CFC{\equiv}CXe]^+$ ($\delta$ = –3613.2 ppm) and [*trans*-$CF_3CF{=}CFC{\equiv}CXe]^+$ ($\delta$ = –3613.4 ppm).

Solutions of the salts $[C_4H_9C{\equiv}CXe][BF_4]$ and $[(CH_3)_3CC{\equiv}CXe][BF_4]$ in aHF (–60 °C) displayed the most shielded xenon nuclei in the series of alkynylxenonium salts with $^{129}$Xe resonances at $\delta$ = –3775 ppm and $\delta$ = –3781 ppm, respectively (Table 1).

The $^{13}$C NMR spectra of $[RC{\equiv}CXe][BF_4]$ are of particular interest because they should allow a direct and unambiguous proof of the C–Xe bond in alkynylxenon(II) salts. To our surprise, the resonances C-1 are located at unusually low frequencies between 8 and –24 ppm. The shielding of C-1 in aHF solutions of alkynylxenon(II) salts bearing either hydrocarbon or perfluoroalkyl groups increases in the same order as the shielding of the xenon atom, e.g. from R = $(CF_3)_2CF$ to R = $(CH_3)_3C$ (Table 1). Salts **4b** and **5b** with unsaturated perfluoro R groups attached to C-2 possess the most deshielded C-1, which is probably the result of a π-electron interaction of the $CF_3CF{=}CF$ group or the $C_6F_5$ group with the C≡C triple bond. The $^{13}$C NMR spectra for C-1 of the cations $[RC{\equiv}CXe]^+$ contains satellites from the $^{13}$C–$^{129}$Xe coupling, which increases from ca. $^1J_{C\text{-}1,Xe}$ = 265 Hz [R = $C_4H_9$, $(CH_3)_3C$] to $^1J_{C\text{-}1,Xe}$ = 308 Hz (R = $C_6F_5$) to approximately $^1J_{C\text{-}1,Xe}$ = 345 Hz (R = perfluoroalkyl). An opposite course of couplings is found for $^2J_{C\text{-}2,Xe}$. In addition, it is worth mentioning that the chemi-

[a] The coupling $^{13}$C–$^{129}$Xe was not observed because of the low intensity of the parent signal. [b] Extrapolated to –60 °C from the equation: $\Delta\delta(^{129}Xe)/\Delta T$ = –0.22 ppm $K^{-1}$.[20]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cal shift values for C-2 in the above series show an opposite trend to that of C-1 and diminish from $\delta$ = 107 ppm to approximately $\delta$ = 80 ppm.

In contrast to **1b**–**5b**, the salts $[C_4H_9C{\equiv}CXe][BF_4]$ and $[(CH_3)_3CC{\equiv}CXe][BF_4]$ are soluble in weakly coordinating solvents such as $CH_2Cl_2$ and PFP and do not decompose in these solutions below –60 °C over the course of several weeks. The $^{129}$Xe resonances of **6b** and **7b** in PFP are similar to those in aHF but are slightly shifted by (9–13 ppm) to higher frequencies. In contrast, the NMR spectra of **6b** and **7b** in $CH_2Cl_2$ display significant distinctions relative to those in aHF. Thus, in $CH_2Cl_2$ the $^{129}$Xe NMR spectra show signals that are shifted by 67 ppm (**7b**) and 77 ppm (**6b**) to higher frequencies. In the $^{13}$C NMR spectra of both salts, the resonance for C-1 is even shifted by 8 ppm into the same direction, whereas the resonance for C-2 moves by 2 ppm in the opposite direction. The position of the resonance for the $[BF_4]^-$ anion in the $^{19}$F NMR spectra of **6b** and **7b** is shifted to $\delta = -144 \pm 1$ ppm in $CH_2Cl_2$ and to $\delta = -140 \pm 1$ ppm in PFP. For comparison, solutions of $[Bu_4N][BF_4]$ in aHF (–20 °C), $CH_2Cl_2$ (24 °C) and PFP (–10 °C) display the $^{19}$F NMR signal at $\delta$ = –148.3, –151.8 and –148.4 ppm, respectively. The deshielding of the signal for the anion in the $^{19}$F NMR spectra of the solutions of salts **6b** and **7b** in $CH_2Cl_2$ and PFP is attributed to a significant cation–anion interaction (borderline description as contact or tight ion pair). This is in contrast to their behaviour in aHF solutions where the salts exist as solvent-shared ion pairs. The solvation of $[BF_4]^-$ in aHF can be described as the protonation of the fluorine terminus by the superacid aHF or by the formation of a hydrogen bridge between $[BF_4]^-$ and the fluorine atom of the HF molecule. Recently the related phenomena have been reported for solutions of (aryl)(pentafluorophenyl)iodonium tetrafluoroborates[14] and (pentafluorophenyl)(perfluoroalkenyl)iodonium tetrafluoroborates[15] in $CH_2Cl_2$ and aHF.

Finally, we have to mention that some of the NMR spectroscopic data of salt **7b** presented here differ (see Table 1) from those reported for the product solution obtained in accordance with Scheme 1.[11]

## Experimental Section

The NMR spectra were recorded with an AVANCE 300 Bruker spectrometer. The chemical shifts are referenced to TMS ($^1$H, $^{13}$C), $BF_3{\cdot}OEt_2/CDCl_3$ (15% v/v) ($^{11}$B), $CCl_3F$ ($^{19}$F) [with $C_6F_6$ as a secondary reference, $\delta$ = –162.9 ppm], and $XeOF_4$ ($^{129}$Xe) [with $XeF_2$ as a secondary reference, $XeF_2$/MeCN/24 °C (c→0), $\delta$ = –1813.28 ppm].[16] The multiplicities of the $^{13}$C- and $^{19}$F NMR signals caused by couplings with the $^{129}$Xe nucleus (satellites) are denoted by (*). The composition of the reaction mixtures and the yields of the products were determined by NMR spectroscopy by using the internal quantitative standard 1,1,2-trichlorotrifluoroethane.

1,1,1,3,3-Pentafluoropropane (Honeywell), 1,1,2-trichlorotrifluoroethane (Merck) were used as supplied. Dichloromethane (Fluka) was purified and dried by standard procedures.[17] Anhydrous hydrogen fluoride was stored over $CoF_3$. Solutions of organoethynyldifluoroboranes **1a**–**7a** were prepared from the corresponding potassium organoethynyltrifluoroborate salts.[18] All manipulations with organoethynyldifluoroboranes, organoethynylxenon(II) salts and anhydrous HF were performed in FEP (block copolymer of tetrafluoroethylene and hexafluoropropylene) equipment under an atmosphere of dry argon.

**Trifluoropropynylxenon(II) Tetrafluoroborate, $[CF_3C{\equiv}CXe][BF_4]$, (1b):** A solution of $CF_3C{\equiv}CBF_2$ (0.45 mmol) in PFP (1.5 mL) was cooled to –47 °C, and xenon difluoride (83 mg, 0.49 mmol) was added in one portion. Within a few minutes, a white suspension was formed which was stirred at –45 °C for an additional 1.5 h before all volatiles were removed in vacuo at –45 °C to give **1b** (82 mg, 59%). Similarly, salt **1b** (123 mg, 57%) was prepared in $CH_2Cl_2$ (4.8 mL) at –55 °C from $CF_3C{\equiv}CBF_2$ (0.80 mmol) and xenon difluoride (120 mg, 0.71 mmol).

**1b:** $^{11}$B NMR (96.29 MHz, aHF, –20 °C): $\delta$ = –2.4 (s, $[BF_4]^-$) ppm. $^{13}$C{$^{19}$F} NMR (75.46 MHz, aHF, –20 °C): $\delta$ = 112.2 (C-3), 80.5 (d*, $^2J_{C,Xe}$ = 69 Hz, C-2), –5.2 (d*, $^1J_{C,Xe}$ = 345 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, aHF, –20 °C): $\delta$ = –52.5 (s, 3 F, $CF_3$), –148.0 (s, 4 F, $[BF_4]^-$) ppm.

**Heptafluoropent-1-ynylxenon(II) Tetrafluoroborate, $[C_3F_7C{\equiv}CXe][BF_4]$, (2b):** A solution of $C_3F_7C{\equiv}CBF_2$ (0.66 mmol) in PFP (1.5 mL) was cooled to –40 °C, and xenon difluoride (99 mg, 0.58 mmol) was added in one portion. The resulting white suspension was stirred at –40 °C for 2 h before the volatiles were removed in vacuo (0.13 hPa) at –40 °C to give **2b** (237 mg, 98%).

**2b:** $^{11}$B NMR (96.29 MHz, aHF, –20 °C): $\delta$ = –1.3 (s, $[BF_4]^-$) ppm. $^{13}$C{$^{19}$F} NMR (75.46 MHz, aHF, –20 °C): $\delta$ = 117.5 (C-5), 107.9 and 106.9 (C-3 and C-4), 80.9 (d*, $^2J_{C,Xe}$ = 70 Hz, C-2), –0.7 (d*, $^1J_{C,Xe}$ = 349 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, aHF, –20 °C): $\delta$ = –78.6 (t, $^4J_{F,F}$ = 9 Hz, 3 F, F-5), –101.1 (t, $^3J_{F,F}$ = 3 Hz, q, $^4J_{F,F}$ = 9 Hz, 2 F, F-3), –124.2 (t, $^3J_{F,F}$ = 3 Hz, 2 F, F-4), –147.2 (s, 4 F, $[BF_4]^-$) ppm.

**Heptafluoro-3-methylbut-1-ynylxenon(II) Tetrafluoroborate, $[(CF_3)_2CFC{\equiv}CXe][BF_4]$, (3b):** A solution of $(CF_3)_2CFC{\equiv}CBF_2$ (0.73 mmol) in PFP (2 mL) was cooled to –45 °C before solid xenon difluoride (128 mg, 0.75 mmol) was added in one portion. Within a few minutes, a white suspension was formed which was stirred at –40 °C for an additional 1.5 h. The mother liquor was decanted, and the residue was washed with cold (–40 °C) PFP (1 mL). After drying in vacuo (0.13 hPa) at –40 °C, salt **3b** (207 mg, 69%) was obtained. The mother liquor contained borane **3a** (0.16 mmol) along with traces of $(CF_3)_2CFC{\equiv}CH$ and unknown products ($^{19}$F NMR).

**3b:** $^{11}$B NMR (96.29 MHz, aHF, –20 °C): $\delta$ = –1.3 (s, $[BF_4]^-$) ppm. $^{13}$C{$^{19}$F} NMR (75.46 MHz, aHF, –20 °C): $\delta$ = 118.8 ($CF_3$), 85.9 (C-3), 80.4 (d*, $^2J_{C,Xe}$ = 68 Hz, C-2), –0.5 (d*, $^1J_{C,Xe}$ = 343 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, aHF, –20 °C): $\delta$ = –74.0 (d, $^3J_{F,F}$ = 10 Hz, 6 F, $CF_3$), –170.9 ($^3J_{F,F}$ = 10 Hz, d*, $^4J_{F,Xe}$ = 8 Hz, septet, 1 F, F-3), –147.6 (s, 4 F, $[BF_4]^-$) ppm.

**Pentafluoropent-3-en-1-ynylxenon(II) Tetrafluoroborate, $[CF_3CF{=}CFC{\equiv}CXe][BF_4]$, (4b):** A solution of $CF_3CF{=}CFC{\equiv}CBF_2$ (0.50 mmol) (*cis*/*trans* = 1:2) in PFP (2 mL) was cooled to –55 °C, and solid xenon difluoride (84 mg, 0.50 mmol) was added in one portion. Within a few minutes, a white suspension was formed which was stirred at –55 °C for an additional 1 h. After centrifugation at –78 °C, the mother liquor was decanted at –60 °C, the residue was washed with cold (–60 °C) PFP (2 mL) and dried in vacuo at –55 °C to give **4b** (130 mg, 70%).

***cis*-4b:** $^{11}$B NMR (96.29 MHz, aHF, –20 °C): $\delta$ = –1.3 (s, $[BF_4]^-$) ppm. $^{13}$C{$^{19}$F} NMR (75.46 MHz, aHF, –60 °C): $\delta$ = 150.3 and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

135.1 (C-3 and C-4), 119.5 (C-5), 79.8 (d*, $^2J_{C,Xe}$ = 64 Hz, C-2), 6.9 (C-1) (the signal was too low in intensity to detect $^1J_{C,Xe}$) ppm. $^{19}$F NMR (282.40 MHz, aHF, –60 °C): $\delta$ = –68.1 (d, $^3J_{F,F}$ = 12 Hz, d, $^4J_{F,F}$ = 6 Hz, 3 F, F-5), –128.2 (d, q, $^3J_{F,F}$ = 12 Hz, $^3J_{F,F}$ = 3 Hz, d*, $^5J_{F,Xe}$ = 17 Hz, 1 F, F-4), –134.4 (d, $^3J_{F,F}$ = 3 Hz, q, $^4J_{F,F}$ = 6 Hz, 1 F, F-3), –147.5 (s, 4 F, [B$F_4$]$^-$) ppm.

***trans*-4b:** $^{11}$B NMR (96.29 MHz, aHF, –20 °C): $\delta$ = –1.3 (s, [*B*$F_4$]$^-$) ppm. $^{13}$C{$^{19}$F} NMR (75.46 MHz, aHF, –60 °C): $\delta$ = 148.0 and 133.2 (C-3 and C-4), 116.3 (C-5), 79.8 (d*, $^2J_{C,Xe}$ = 64 Hz, C-2), 7.9 (d*, $^1J_{C,Xe}$ = 332 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, aHF, –60 °C): $\delta$ = –67.9 (d, $^3J_{F,F}$ = 7 Hz, d, $^4J_{F,F}$ = 18 Hz, 3 F, F-5), –150.0 (d, $^3J_{F,F}$ = 139 Hz, q, $^3J_{F,F}$ = 7 Hz, 1 F, F-4), –149.3 (d, $^3J_{F,F}$ = 139 Hz, q, $^4J_{F,F}$ = 18 Hz, d*, $^4J_{F,Xe}$ = 6 Hz, 1 F, F-3), –147.5 (s, 4 F, [B$F_4$]$^-$) ppm.

**Pentafluorophenylethynylxenon(II) Tetrafluoroborate, [$C_6F_5C{\equiv}CXe$][$BF_4$], (5b)**

**A:** A solution of $C_6F_5C{\equiv}CBF_2$ (0.34 mmol) in PFP (0.9 mL) was cooled to –55 °C, and xenon difluoride (50 mg, 0.29 mmol) was added in one portion. The resulting suspension was stirred at –50 to –55 °C for 1 h. After centrifugation at –78 °C the brown mother liquor was decanted at –45 °C. The residue was dried in vacuo (0.13 hPa) at –45 °C, and pale brownish **5b** was obtained (37 mg, 31%). The dissolution in aHF at –40 °C was accompanied by decomposition of **5b**. Total decomposition occurred within 30–50 min ($^{19}$F and $^{129}$Xe NMR).

**B:** A solution of $C_6F_5C{\equiv}CBF_2$ (0.26 mmol) in $CH_2Cl_2$ (1.5 mL) was cooled to –60 °C and xenon difluoride (38 mg, 0.22 mmol) was added in one portion. The white suspension was stirred at –60 °C for 1 h, and subsequently **5b** (0.15 mmol, 68%) ($^{19}$F NMR) was extracted with cold (–65 °C) aHF (0.5 mL).

**5b:** $^{11}$B NMR (96.29 MHz, aHF, –60 °C): $\delta$ = –1.7 (q, $^1J_{B,F}$ = 11 Hz, [*B*$F_4$]$^-$) ppm. $^{13}$C{$^{19}$F} NMR (75.46 MHz, aHF, –60 °C): $\delta$ = 149.5, 145.7, 137.9, 95.2 (C-2,6, C-4, C-3,5, and C-*ipso*, $C_6F_5$), 81.0 (d*, $^2J_{C,Xe}$ = 62 Hz, C-2), 0.6 (d*, $^1J_{C,Xe}$ = 308 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, aHF, –60 °C): $\delta$ = –131.7 (m, 2 F, F-*ortho*), –142.4 (t, $^3J_{F,F}$ = 19 Hz, t, $^4J_{F,F}$ = 6 Hz, 1 F, F-*para*), –159.0 (m, 2 F, F-*meta*), –148.1 (s, 4 F, [B$F_4$]$^-$) ppm.

The solution of **5b** in aHF obtained as described under *B* showed no significant decomposition at –60 °C over 13 h ($^{19}$F-, $^{129}$Xe NMR), but when the temperature was raised above –30 °C, **5b** quickly decomposed to give mainly *cis*-$C_6F_5CF{=}CHF$.[19]

***cis*-$C_6F_5CF^2{=}CHF^1$:** $^1$H NMR (300.13 MHz, $CDCl_3$, 24 °C): $\delta$ = 6.80 (d, $^2J_{H,F\text{-}1}$ = 71 Hz, d, $^3J_{H,F\text{-}2}$ = 16 Hz) ppm. $^{19}$F NMR (282.40 MHz, $CDCl_3$, 24 °C): $\delta$ = –135.9 (d, $^3J_{F,H}$ = 16 Hz, d, $^3J_{F,F}$ = 15 Hz, t, $^4J_{F,F\text{-}ortho}$ = 15 Hz, 1 F, F-2), –138.0 (m, 2 F, F-*ortho*), –149.1 (d, $^2J_{F,H}$ = 71 Hz, d, $^3J_{F,F}$ = 15 Hz, t, $^5J_{F,F\text{-}ortho}$ = 5, d, $^7J_{F,F\text{-}para}$ = 3 Hz, 1 F, F-1), –149.8 (t, $^3J_{F,F}$ = 21 Hz, 1 F, F-*para*), –160.4 (m, 2 F, F-*meta*) ppm.

**Hex-1-ynylxenon(II) Tetrafluoroborate, [$C_4H_9C{\equiv}CXe$][$BF_4$], (6b)**

**A:** A solution of $C_4H_9C{\equiv}CBF_2$ (0.25 mmol) in $CH_2Cl_2$ (0.6 mL) was cooled to –70 °C and added in one portion to the cold (–70 °C) suspension of xenon difluoride (60 mg, 0.35 mmol) in $CH_2Cl_2$ (0.2 mL). The dark reaction mixture was stirred at –65 to –70 °C for 1 h. The $^1$H- and $^{19}$F NMR spectra showed the quantitative conversion of **6a** into **6b**.

**6b:** $^1$H NMR (300.13 MHz, $CH_2Cl_2$, –60 °C): $\delta$ = 2.59 (t, $^3J_{H,H}$ = 7 Hz, 2 H, 3-H), 1.55 (t, $^3J_{H,H}$ = 7 Hz, t, $^3J_{H,H}$ = 7 Hz, 2 H, 4-H), 1.35 (t, $^3J_{H,H}$ = 7 Hz, q, $^3J_{H,H}$ = 7 Hz, 2 H, 5-H), 0.87 (t, $^3J_{H,H}$ = 7 Hz, 3 H, 6-H) ppm. $^{11}$B NMR (96.29 MHz, $CH_2Cl_2$, –60 °C): $\delta$ = –1.4 (s, [*B*$F_4$]$^-$) ppm. $^{13}$C{$^1$H} NMR (75.46 MHz, $CH_2Cl_2$, –60 °C): $\delta$ = 98.7 (d*, $^2J_{C,Xe}$ = 75 Hz, C-2), 28.7, 21.8, 20.5 (C-3, C-4, C-5), 13.4 (C-6), –16.7 (d*, $^1J_{C,Xe}$ = 288 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, $CH_2Cl_2$, –60 °C): $\delta$ = –143.0 (s, [B$F_4$]$^-$) ppm.

aHF (0.4 mL) was added to a solution of **6b** in $CH_2Cl_2$ and stirred at –45 °C for 10 min before the acidic phase was decanted.

**6b:** $^1$H NMR (300.13 MHz, aHF, –30 °C): $\delta$ = 2.68 (t, $^3J_{H,H}$ = 7 Hz, 2 H, 3-H), 1.66 (t, $^3J_{H,H}$ = 7 Hz, t, $^3J_{H,H}$ = 7 Hz, 2 H, 4-H), 1.46 (t, $^3J_{H,H}$ = 7 Hz, q, $^3J_{H,H}$ = 7 Hz, 2 H, H-5), 0.95 (t, $^3J_{H,H}$ = 7 Hz, 3 H, 6-H) ppm. $^{11}$B NMR (96.29 MHz, aHF, –30 °C): $\delta$ = –1.2 (s, [*B*$F_4$]$^-$) ppm. $^{13}$C{$^1$H} NMR (75.46 MHz, aHF, –30 °C): $\delta$ = 101.6 (d*, $^2J_{C,Xe}$ = 69 Hz, C-2), 29.0, 21.9, 20.1 (C-3, C-4, C-5), 12.0 (C-6), –24.0 (d*, $^1J_{C,Xe}$ = 264 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, aHF, –30 °C): $\delta$ = –147.8 (s, [B$F_4$]$^-$) ppm.

**B:** A solution of $C_4H_9C{\equiv}CBF_2$ (0.25 mmol) in PFP (0.7 mL) was cooled to –70 °C and added in one portion to the cold (–70 °C) suspension of xenon difluoride (54 mg, 0.32 mmol) in PFP (0.2 mL). The brown reaction mixture was stirred at –65 °C for 1 h. The NMR spectra of the suspension showed the total conversion of **6a** and the formation of **6b** in >25% yield.

**6b:** $^1$H NMR (300.13 MHz, PFP, –60 °C): $\delta$ = 1.58 (m, 2 H, 4-H), 1.42 (m, 2 H, 5-H), 0.91 (t, $^3J_{H,H}$ = 7 Hz, 3 H, 6-H) ppm (the signal for 3-H overlapped with the resonance of PFP at 2.6 ppm). $^{11}$B NMR (96.29 MHz, PFP, –60 °C): $\delta$ = –0.1 (s, [*B*$F_4$]$^-$) ppm. $^{13}$C{$^1$H} NMR (75.46 MHz, PFP, –60 °C): $\delta$ = 99.3 (d*, $^2J_{C,Xe}$ = 73 Hz, C-2), 28.5, 21.4, 19.6 (C-3, C-4, C-5), 12.1 (C-6), –21.2 (d*, $^1J_{C,Xe}$ = 279 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, PFP, –60 °C): $\delta$ = –140.7 (s, [B$F_4$]$^-$) ppm. No changes were found in a solution of **6b** in $CH_2Cl_2$ after storage at –70 °C over 5 months. When **6b** was stored as aHF solution at 22 °C the content of **6b** was reduced from 95–100% (after 2 h) to 38% (after 22 h) to 10% (after 46 h).

**3,3-Dimethylbut-1-ynylxenon(II) Tetrafluoroborate, [$(CH_3)_3$-$CC{\equiv}CXe$][$BF_4$], (7b)**

**A:** A cold (–60 °C) solution of $(CH_3)_3CC{\equiv}CBF_2$ (0.44 mmol) in PFP (1.7 mL) was added in one portion to the cold (–60 °C) stirred suspension of xenon difluoride (69 mg, 0.40 mmol) in PFP (0.1 mL). After 2 h, the reaction mixture was centrifuged at –78 °C and subsequently the brown mother liquor was decanted at –65 °C. The precipitate was dried at –60 °C in vacuo to give **7b** (37 mg, 0.12 mmol). The mother liquor still contained borane **7a** (0.05 mmol) along with product **7b** (0.15 mmol) ($^1$H-, $^{11}$B-, $^{19}$F NMR).

**7b:** $^1$H NMR (300.13 MHz, PFP, –50 °C): $\delta$ = 1.30 (s, C$H_3$) ppm. $^{11}$B NMR (96.29 MHz, PFP, –50 °C): $\delta$ = –1.4 (s, [*B*$F_4$]$^-$) ppm. $^{19}$F NMR (282.40 MHz, PFP, –50 °C): $\delta$ = –138.9 (s, [*B*$F_4$]$^-$) ppm.

**7b:** $^1$H NMR (300.13 MHz, aHF, –60 °C): $\delta$ = 1.26 (s, C$H_3$) ppm. $^{11}$B NMR (96.29 MHz, aHF, –50 °C): $\delta$ = –1.2 (quintet, $^1J_{B,F}$ = 10 Hz, [B$F_4$]$^-$) ppm. $^{13}$C{$^1$H} NMR (75.46 MHz, aHF, –60 °C): $\delta$ = 107.0 (d*, $^2J_{C,Xe}$ = 76 Hz, C-2), 30.9 (C-3), 27.6 (*C*$H_3$), –23.7 (d*, $^1J_{C,Xe}$ = 267 Hz, C-1) ppm. $^{19}$F NMR (282.40 MHz, aHF, –50 °C): $\delta$ = –148.0 (s, [B$F_4$]$^-$) ppm.

**B:** When a solution of **7b** in PFP was warmed to 20 °C, it became dark, and a black precipitate was formed within 5–10 min. The decomposition of the colourless solution of **7b** in aHF proceeded slowly at 20 °C and led to a dark colouration. The intensity of the $^{129}$Xe NMR signal was also reduced to 80% (after 24 h) and then to 11% (after 44 h).

**7b:** $^1$H NMR (300.13 MHz, $CH_2Cl_2$, –60 °C): $\delta$ = 1.28 (s, C$H_3$) ppm. $^{11}$B NMR (96.29 MHz, $CH_2Cl_2$, –60 °C): $\delta$ = –1.4 (s, [*B*$F_4$]$^-$) ppm. $^{13}$C{$^1$H} NMR (75.46 MHz, $CH_2Cl_2$, –40 °C): $\delta$ = 105.7 (C-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2), 30.4 (C-3), 28.9 ($CH_3$), –15.7 (C-1) ppm. $^{19}F$ NMR (282.40 MHz, $CH_2Cl_2$, –60 °C): $\delta$ = –144.7 (s, $[BF_4]^-$) ppm.

**Supporting Information** (see also the footnote on the first page of this article): Multi-NMR spectra of the [RC≡CXe][$BF_4$] salts.

# Tuned Helical Array of $Rh^{III}/Ir^{III}$ Cp* Complexes with Polypyridyl Ligands

Sanjay K. Singh,[a] Manish Chandra,[a] Santosh K. Dubey,[a] and Daya S. Pandey*[a]

**Keywords:** Rhodium-Cp* / Iridium-Cp* / Polypyridyl ligands / Tuned helical / Weak interactions

Reactions of the chloro-bridged dimeric complexes $[\{(\eta^5\text{-}C_5Me_5)M(\mu\text{-}Cl)Cl\}_2]$ (M = Rh, Ir) with the polypyridyl ligands 2,3-di(2-pyridyl)pyrazine (dpp) and 2,4,6-tri(2-pyridyl)-1,3,5-triazine (tptz) in the presence of ammonium tetrafluoroborate gave the mononuclear complexes $[(\eta^5\text{-}C_5Me_5)MCl(\kappa^2\text{-}dpp)]BF_4$ [M = Rh (**1**), Ir (**2**)] and $[(\eta^5\text{-}C_5Me_5)MCl(\kappa^2\text{-}tptz)]BF_4$ [M = Rh (**3**), Ir (**4**)]. The complexes have been characterised by elemental analysis, FAB-MS, ESMS, IR, NMR, electronic and emission spectroscopic studies and the molecular structures of **1**, **2** and **3** have been crystallographically determined. Structural studies on the complexes revealed the presence of helical superstructures resulting from C–H···X (X = N, F, Cl and π) interactions.

## Introduction

The chemistry and photophysical properties of the $Rh^{III}$ and $Ir^{III}$ complexes of polypyridyl ligands and substituted cyclopentadienyl group are well documented.[1] Since their discovery in 1968 the pentamethylcyclopentadienyl complexes $[\{(\eta^5\text{-}C_5Me_5)M(\mu\text{-}Cl)Cl\}_2]$ (M = Rh, Ir) have attracted the attention of many research groups because of their potential as precursors and uses as hydride transfer catalysts.[2] The complexes undergo a rich variety of chemical transformations via the intermediacy of chloro bridge cleavage reactions leading to the formation of a series of interesting neutral and cationic mononuclear complexes.[3] Despite extensive studies on the complexes $[\{(\eta^5\text{-}C_5Me_5)M(\mu\text{-}Cl)Cl\}_2]$ (M = Rh, Ir), their reactivity with potential bridging ligands, viz. 2,3-di(2-pyridyl)pyrazine (dpp) and 2,4,6-tri(2-pyridyl)-1,3,5-triazine, has yet to be explored. Furthermore, the construction of self-assembled structures has attracted increasing scientific attention.[4,5] A properly designed building block with a metal ion defines the morphology of coordination networks and huge supramolecular architectures.[4] The use of forces such as hydrogen bonding and weak interactions as a powerful tool for self-assembling is widely accepted. The introduction of helices into artificial systems (as in supramolecular chemistry) has increased the number of intensive investigations by chemists for many years.[4,5]

During past few years we have become interested in this area and, in continuation of our studies in this direction, we have examined the reactivity of the polypyridyl ligands 2,3-di(2-pyridyl)pyrazine and 2,4,6-tri(2-pyridyl)-1,3,5-triazine with the chloro-bridged complexes $[\{(\eta^5\text{-}C_5Me_5)M(\mu\text{-}Cl)Cl\}_2]$ (M = Rh, Ir) under varying reaction conditions.[6–7] We present herein, reproducible syntheses and spectroscopic properties of the complexes $[(\eta^5\text{-}C_5Me_5)MCl(\kappa^2\text{-}dpp)]BF_4$ [M = Rh (**1**), Ir (**2**)] and $[(\eta^5\text{-}C_5Me_5)MCl(\kappa^2\text{-}tptz)]BF_4$ [M = Rh (**3**), Ir (**4**)]. We also describe the crystal and molecular structures of the representative dpp and tptz complexes $[(\eta^5\text{-}C_5Me_5)Rh(\kappa^2\text{-}dpp)]BF_4$ **1**, $[(\eta^5\text{-}C_5Me_5)Ir(\kappa^2\text{-}dpp)]BF_4$ **2** and $[(\eta^5\text{-}C_5Me_5)RhCl(\kappa^2\text{-}tptz)]BF_4$ **3** as well as our results from studies of weak interaction in these complexes.

## Results and Discussion

### Synthesis and Characterisation

The reactions of the chloro-bridged dimeric complexes $[\{(\eta^5\text{-}C_5Me_5)M(\mu\text{-}Cl)Cl\}_2]$ (M = Rh, Ir) with an excess of the polypyridyl ligands 2,3-di(2-pyridyl)pyrazine and 2,4,6-tri(2-pyridyl)-1,3,5-triazine in methanol afforded cationic mononuclear complexes in reasonably good yields (Scheme 1). The complexes were isolated as their tetrafluoroborate salts $[(\eta^5\text{-}C_5Me_5)RhCl(\kappa^2\text{-}dpp)]BF_4$ (**1**), $[(\eta^5\text{-}C_5Me_5)RhCl(\kappa^2\text{-}tptz)]BF_4$ (**2**), $[(\eta^5\text{-}C_5Me_5)IrCl(\kappa^2\text{-}dpp)]BF_4$ (**3**) and $[(\eta^5\text{-}C_5Me_5)IrCl(\kappa^2\text{-}tptz)]BF_4$ (**4**).

The cationic orange-red crystalline compounds with high melting temperatures were isolated as air-stable, nonhygroscopic solids. The complexes are soluble in methanol, acetone, dichloromethane, chloroform, acetonitrile, dimethylformamide and dimethylsuphoxide but insoluble in petroleum ether and diethyl ether. They form air sensitive solutions in acetonitrile, dimethyl sulfoxide and dimethylformamide and turn brownish-black after a couple of hours. The structural identities and homogeneity of **1**–**4** were estab-

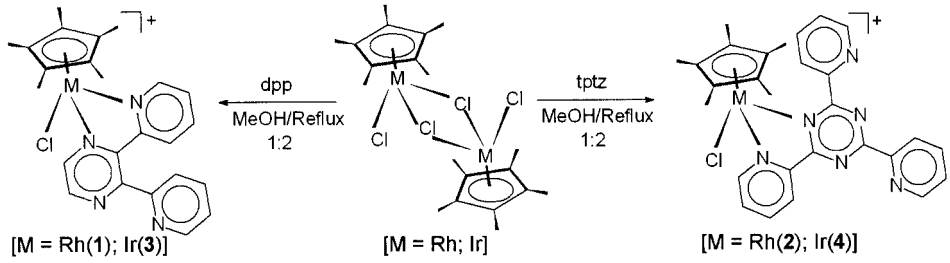

Scheme 1.

lished by analytical techniques, the results of which are consistent with their proposed formulations. Further information regarding compositions was obtained from FAB-mass spectrometry. FAB-mass spectrometric data (reported in the Exp. Sect.) of **1**–**4** are consistent with their respective formulations. $^1$H NMR spectroscopic data in $CDCl_3$ for **1**–**4** are reported in the experimental section and representative spectra for $[(\eta^5\text{-}C_5Me_5)RhCl(\kappa^2\text{-dpp})]BF_4$ (**1**) in $CDCl_3$ are shown in Figure 1. The $^1$H NMR spectrum of **1** exhibits distinct resonances at $\delta$ = 7.14 (d, $J$ = 6.0 Hz, 1 H), 7.60 (dd, $J$ = 4.5 Hz, 1 H), 7.78 (t, $J$ = 2.9 Hz, 2 H), 8.08 (d, $J$ = 3.9 Hz, 2 H), 8.64 (d, $J$ = 4.5 Hz, 1 H), 8.89 (t, $J$ = 3.3 Hz, 1 H), 9.00 (d, $J$ = 2.7 Hz, 1 H) and 9.07 (d, $J$ = 2.7 Hz, 1 H) ppm corresponding to the pyrazyl and pyridyl protons of 2,3-di(2-pyridyl)pyrazine (dpp). The $\eta^5$-Cp* protons resonate as a singlet at $\delta$ = 1.80 ppm. The positions and integrated intensities of the various resonances corroborate well with the formulation of **1**. The $^1$H NMR spectrum of the complex $[(\eta^5\text{-}C_5Me_5)RhCl(\kappa^2\text{-tptz})]BF_4$ **2** exhibits signals at $\delta$ = 7.61 (t, $J$ = 7.2 Hz, 2 H), 7.95 (t, $J$ = 5.4 Hz, 2 H), 8.03 (m, 2 H), 8.22 (t, $J$ = 7.8 Hz, 1 H), 8.95 (m, 4 H) and 9.19 (d, $J$ = 7.8 Hz, 1 H) ppm assignable to the pyridyl protons of the coordinated tptz ligand and a singlet at $\delta$ = 1.79 ppm corresponding to $\eta^5$-Cp* protons. A similar trend was observed in the resonances of the analogous iridium complexes **3** and **4**.

Comparative absorption spectra of **1**–**4** recorded in dichloromethane are shown in Figure 2a. Transitions in the 327–455 nm region can be assigned to $M_{d\pi}\rightarrow L_{\pi}^*$ metal to ligand charge-transfer bands (MLCT) and higher energy transitions at ca. 280 nm to the intra-ligand $\pi$–$\pi$* transition. The absorption bands for the rhodium complexes **1** and **2** are blue shifted relative to those of the iridium(III) counterpart. The complexes were found to be luminescent at room temperature in dichloromethane. Emission spectra of **1** and **2** are shown in Figure 2b. Upon excitation at their respective excitation bands (in parentheses) the complexes exhibit moderate green-yellow to yellow-orange luminescence [449 nm (396 nm) for **1**; 427 nm (351 nm) for **2**; 475 nm (415 nm) for **3** and 469 nm (347 nm) for **4**]. The resultant emissions correspond to $[M_{d\pi}\rightarrow L_{\pi}^*]$ $^3$MLCT transitions for the polypyridyl ligand since the MCp*Cl moiety does not emit. The Rh–dpp, **1** and Ir–dpp, **3** complexes exhibit analogous emission spectra suggesting $M_{d\pi}\rightarrow dpp_{\pi}^*$ as a common transition origin. This view is further strengthened by a significantly red shifted emission band for the iridium complexes compared with the analogous rhodium complex. This is in keeping with the fact that the $d_{\pi}$ orbitals of $Rh^{III}$ are more stable than those of $Ir^{III}$. Rigidity and the delocalisation factor of the acceptor ligand play an appreciable role in the overall photophysical properties of the complexes because they decrease the extent of structural changes in the excited state which in turn decreases the nonradiative decay and stabilises the $^3$MLCT based excited state. The analogous Rh–tppz, **2** and Ir–tppz, **4** complexes exhibit equally intense emissions as the respective dpp complexes. These emissions, however, are blue shifted, much broader and less distinct. These results may be better viewed as a consequence of more delocalisation and rigidity of the framework in the coordinated dpp than in tptz.

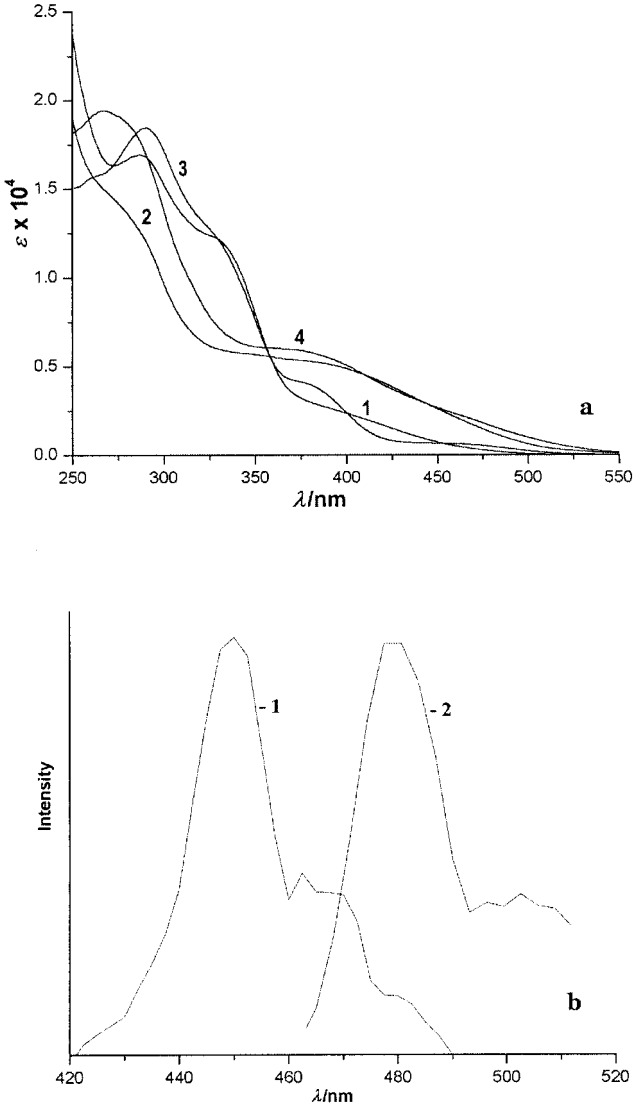

Figure 2. (a) Electronic spectra of **1**, **2**, **3** and **4**; (b) emission spectra of **1** ($\lambda_{ex}$ = 396 nm) and **2** ($\lambda_{ex}$ = 351 nm) in dichloromethane.

### *Solid-State Characterisation of 1, 2 and 3*

Suitable crystals with distinct morphologies of **1**, **2**·$CH_2Cl_2$, and **3**·0.5$H_2O$ were grown from dichloromethane and petroleum ether (40–60°) by diffusion. ORTEP[8] depictions, including atom-numbering schemes of the cations of **1**, **2** and **3** are shown in Figure 3 with selected bond lengths and bond angles listed in Table 1. Complexes **1** and **3** crystallise in the monoclinic space groups $P2_1$ and $P2_1/n$, respectively, while **2** crystallises in the orthorhombic $P2_12_12_1$ space group. Two crystallographically independent molecules can be observed in the unit cell of **1**, the only major difference between them being the orientation and a lengthening of the Rh–Cl and Ru–N bonds in one molecule. The solid-state structures of **1** and **3** are analogous, each metal centre is coordinated to a pyridyl nitrogen, a pyrazyl nitrogen, a chlorine ligand and an $\eta^5$-coordinated Cp* group. In **2**, the Rh metal centre is coordinated to N(1) and N(2) from the tptz ligand, the chlorine ligand Cl(1) and the $\eta^5$ Cp* group. Considering the Cp* as a single coordination site, the overall coordination geometry about the metal centres in the complexes **1**, **2** and **3** is pseudo-octahedral or typical piano stool geometry. Average $M–C_{Cp^*}$ distances in **1** (two asymmetric units), **2** and **3** are 2.141 Å [range 2.114(18)–2.19(2) Å; Rh–$C_{ct}$ 1.759 Å], 2.179 Å [range 2.135(19)–2.231(19) Å; Rh–$C_{ct}$ 1.817 Å], 2.154 Å [range 2.127(10)–2.184(12) Å; Rh–$C_{ct}$ 1.776 Å] and 2.169 Å [range 2.154(10)–2.190(10) Å; Ir–$C_{ct}$ 1.795 Å], respectively.[9,10a] The C–C bond lengths within the Cp* ring and the C–$CH_3$ bond lengths are normal. The M–Cl distances in **1**, **2** and **3** are normal [Rh–Cl 2.378(5), 2.403(6) Å **1**; 2.408(3) Å **2** and Ir–Cl 2.395(3) Å **3**].[9a,10] The Rh–N bond lengths in **1** and **2** are all within reported values.[9a,10,13] The Ir–N distances are comparable with those in related Cp*Ir complexes.[3c,3d,9a] The angles N–M–N and N–M–Cl (M = Rh, Ir) are as expected for all the complexes. The molecular structures of **1** and **3** show that the coordinated pyridyl ring and pyrazine ring deviate slightly from planarity [9(2)°, 10(2)° **1** and 9(2)° **3**] while the uncoordinated pyridyl ring is inclined at an angle of ca. 44° with respect to the coordinated pyrazine ring plane [44(2)°, 42(3)° **1** and 44.6(15)° **3**]. However, in the free dpp ligand, the dihedral angles between the pyrazine and pyridyl rings are 42.2°.[11] The pyrazyl rings in both the **1** and **3** are planer with a deviation of ca. 8°. In **2**, upon coordination with the metal centre rhodium in the $\kappa^2$-mode, the tptz ligand loses its planarity. The coordinated pyridyl ring subtends an angle of 11.9(13)° with respect to central triazine ring whereas the uncoordinated pyridyl rings are inclined from the central triazine ring by 9.6(14)° for the N(1)–C(5) ring and 34.6(14)° for the N(6)–C(14) ring. The average C–C($C_5Me_5$) bond lengths in the Cp* group are 1.415 Å and 1.438 Å in **1**, 1.432 Å in **2** and 1.443 Å in **3** and the exterior C($C_5Me_5$)–C($C_5Me_5$) average bond lengths are 1.482 Å and 1.500 Å in **1**, 1.479 Å in **2** and 1.493 Å in **3**.[12]

Weak interaction studies on the isostructural complexes **1**, **2** and **3** revealed the presence of supramolecular helical self-assembled architectures with their individual peculiarities (Figure 4). Various intra- and intermolecular C–H···X (X = F, Cl, N, and π) weak interactions are involved in stabilising the helical superstructures of the complexes **1**–**3**.[4,5,13] Determinant intermolecular interactions D–H···A–X ($d$ = H···A, $D$ = D–H···A, $\theta$ = D–H···A, $\varphi$ H···A–X and $\omega$ = D–H···A–X) which stabilise the helical superstructures are listed in Table 2. A distorted circular void space can be visualised for the complexes when viewed parallel to the $a$ axis as depicted in Figure 5. A correlation between the pitch length and void size has been established. The helical superstructures for all the complexes involve two molecular residues in each coil though a steady contraction of the void space may be observed upon moving from **1** to **3**. The observed pitches are 7.639, 11.354 and 15.186 Å for **1**, **2** and **3**, respectively. Furthermore, it was observed that as the pitches of the helical superstructures show an increase of almost 50% (ca. 7.5 Å) and the diameter of the void spaces decrease by ca. 8.0 Å (80%) (diameters of the void space are ca. 10.0 Å in **1**, ca. 5.0 Å in **2** and ca. 2.0 Å in **3** as

shown in Figure 5).[14] Thus it is noteworthy to mention here that *the pitch size is inversely proportional to the diameter of the void space in the helical superstructure.* Though no guest molecules are included in the void spaces of the helical frameworks in any of the complexes they are, however, prospective hosts for guest inclusion.

## Conclusions

In this work we have presented four new cationic mononuclear rhodium(III) and iridium(III) complexes $[(\eta^5\text{-}C_5Me_5)MCl(\kappa^2\text{-}L)]BF_4$ (M = Rh, L = dpp **1**, tptz **2** and M = Ir, L = dpp **3**, tptz **4**) and have described spectroscopic properties and molecular structures of three representative complexes. Due to the presence of uncoordinated pendant donor sites, these have the potential to behave as *synthons* or *metallo-ligands* and could find applications in the synthesis of $[(\eta^5\text{-}C_5Me_5)MCl]$ (M = Rh, Ir) containing homo- or heterobimetallic complexes. We have also illustrated here an approach towards the organisation of 3D helices, which are stabilised by weak interactions in the crystalline state. Furthermore, a noteworthy relationship between the pitches and the diameters of the void space in the helical superstructures has been observed.

## Experimental Section

**General:** Analytical grade chemicals were used throughout. Solvents were dried and distilled prior to use following standard literature procedures. 2,3-di(2-pyridyl)pyrazine, 2,4,6-tri(2-pyridyl)-1,3,5-triazine, pentamethylcyclopentadiene, ammonium tetrafluoroborate, hydrated rhodium(III) chloride and iridium(III) chloride (all from Aldrich) were used as received. The precursor complexes $[\{(\eta^5\text{-}C_5Me_5)M(\mu\text{-}Cl)Cl\}_2]$ (M = Rh, Ir) were prepared by literature procedures.[15] Elemental analyses on the complexes were performed by the Microanalytical Laboratory, Sophisticated Analytical Instrument Facility, Central Drug Research Institute, Lucknow. Electronic and emission spectra in dichloromethane were obtained on a Shimadzu UV-1601 and a Perkin–Elmer-LS 55 luminescence spectrometer, respectively. Infrared spectra were recorded on a Perkin–Elmer-577 spectrophotometer. $^1H$ NMR spectra in $CDCl_3$, using tetramethylsilane as an internal reference, were recorded at room temperature on a Bruker-DRX 300 NMR machine. FAB mass spectra were obtained on a JEOL SX 102/DA-6000 mass spectrometer system using xenon as the FAB gas (6 kV, 10 mA). The accelerating voltage was 10 kV and spectra were recorded at room temperature using *m*-nitrobenzyl alcohol as the matrix.

**Synthesis of $[(\eta^5\text{-}C_5Me_5)RhCl(\kappa^2\text{-}dpp)]BF_4$ (1):** A suspension of $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}Cl)Cl\}_2]$ (0.618 g, 1.0 mmol) in methanol (30 mL) was treated with 2,3-di(2-pyridyl)pyrazine (0.468 g, 2.0 mmol) and stirred at room temperature. The precursor complex slowly dissolved resulting in an orange-red solution. The resultant solution was further stirred at room temperature for about 4 h and then filtered through celite to remove any solid residue. To the filtrate was added a saturated methanolic solution of $NH_4BF_4$ (10 mL) and the resultant solution was left for slow crystallization in the refrigerator at ca. 4 °C. After a couple of days, a shiny crystalline product appeared which was separated by filtration, washed with methanol (2×10 mL), diethyl ether (2×10 mL) and dried in vacuo. Red-brown solid, yield 0.363 g (61%). $C_{24}H_{25}BClF_4N_4Rh$ (594.65): calcd. C 48.47, H 4.23, N 9.42; found C 48.21, H 4.35, N 9.24. IR (nujol): $\tilde{\nu}$ = 1079 $cm^{-1}$ (B–F). $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 1.80 (s, 15 H, $C_5Me_5$), 7.14 (d, $J$ = 6.0 Hz, 1 H), 7.60 (dd, $J$ = 4.5 Hz, 1 H), 7.78 (t, $J$ = 2.9 Hz, 2 H), 8.08 (d, $J$ = 3.9 Hz, 2 H), 8.64 (d, $J$ = 4.5 Hz, 1 H), 8.89 (t, $J$ = 3.3 Hz, 1 H), 9.00 (d, $J$ = 2.7 Hz, 1 H), 9.07 (d, $J$ = 2.7 Hz, 1 H). FAB-MS: $m/z$ = 507 $[M]^+$, 472 $[M - Cl]^{2+}$, 237 $[M - Cl - dpp]^{2+}$. UV/Vis: $\lambda_{max}$ ($\varepsilon$, $dm^3\,mol^{-1}\,cm^{-1}$) = 396 ($2.4\times10^3$), 328 ($1.2\times10^4$), 286 ($1.7\times10^4$), 237 ($3.3\times10^4$) nm.

**Synthesis of $[(\eta^5\text{-}C_5Me_5)RhCl(\kappa^2\text{-}tptz)]BF_4$ (2):** This was prepared from $[\{(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}Cl)Cl\}_2]$ (0.618 g, 1.0 mmol) in methanol following the above procedure for **1** but using tptz (0.624 g, 2.0 mmol) in place of dpp. Bright yellow solid, yield 0.417 g (62%). $C_{28}H_{27}BClF_4N_6Rh$ (673.72): calcd. C 49.92, H 4.04, N 12.47; found C 49.97, H 3.98, N 12.31. IR (nujol): $\tilde{\nu}$ = 1083 $cm^{-1}$ (B–F). $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 1.79 (s, 15 H, $C_5Me_5$), 7.61 (t, $J$ = 7.2 Hz, 2 H), 7.95 (t, $J$ = 5.4 Hz, 2 H), 8.03 (m, 2 H), 8.22 (t, $J$ = 7.8 Hz, 1 H), 8.95 (m, 4 H), 9.19 (d, $J$ = 7.8 Hz, 1 H). FAB-MS: $m/z$ = 585 $[M]^+$, 550 $[M - Cl]^{2+}$, 238 $[M - Cl - tptz]^{2+}$. UV/Vis: $\lambda_{max}$ ($\varepsilon$, $dm^3\,mol^{-1}\,cm^{-1}$) = 370 ($5.4\times10^3$), 273 ($1.5\times10^4$), 235 ($2.7\times10^4$) nm.

**Synthesis of $[(\eta^5\text{-}C_5Me_5)IrCl(\kappa^2\text{-}dpp)]BF_4$ (3):** This was prepared by following the same procedure as for **1** but using $[\{(\eta^5\text{-}C_5Me_5)Ir(\mu\text{-}Cl)Cl\}_2]$ (0.796 g, 1.0 mmol) in methanol (30 mL) and 2,3-di(2-pyridyl)pyrazine (0.468 g, 2.0 mmol). Yellow-orange solid, yield 0.451 g (66%). $C_{24}H_{25}BClF_4N_4Ir$ (683.94): calcd. C 42.11, H 3.65, N 8.19; found C 42.20, H 3.50, N 8.26. IR (nujol): $\tilde{\nu}$ = 1081 $cm^{-1}$ (B–F). $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 1.75 (s, 15 H, $C_5Me_5$), 7.20 (d, $J$ = 3.2 Hz, 1 H), 7.58 (t, $J$ = 5.9 Hz, 1 H), 7.76 (t, $J$ = 4.1 Hz, 2 H), 8.11 (m, 2 H), 8.66 (d, $J$ = 4.3 Hz, 1 H), 8.79 (t, $J$ = 3.3 Hz, 1 H), 8.93 (d, $J$ = 3.2 Hz, 1 H), 9.08 (d, $J$ = 3.1 Hz, 1 H). FAB-MS: $m/z$ = 596 $[M]^+$, 560 $[M - Cl]^{2+}$, 326 $[M - Cl - dpp]^{2+}$.

UV/Vis: $\lambda_{max}$ ($\varepsilon$, $dm^3 mol^{-1} cm^{-1}$) = 452 ($6.3 \times 10^2$), 380 ($4.0 \times 10^3$), 326 ($1.2 \times 10^4$), 290 ($1.8 \times 10^4$), 233 ($1.9 \times 10^4$) nm.

**Synthesis of [($\eta^5$-$C_5Me_5$)IrCl($\kappa^2$-tptz)]$BF_4$ (4):** This was prepared following the above procedure for **3** but using tptz (0.624 g, 2.0 mmol) in place of dpp. Red-brown solid, yield 0.480 g (63%). $C_{28}H_{27}BClF_4N_6Ir$ (763.02): calcd. C 44.09, H 3.54, N 11.02; found C 44.15, H 3.68, N 11.10. IR (nujol): $\tilde{\nu}$ = 1084 $cm^{-1}$ (B–F). $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 1.69 (s, 15 H, $C_5Me_5$), 7.68 (t, $J$ = 7.1 Hz, 2 H), 7.91 (t, $J$ = 5.5 Hz, 2 H), 8.10 (m, 2 H), 8.27 (t, $J$ = 7.5 Hz, 1 H), 9.01 (m, 4 H), 9.23 (d, $J$ = 7.6 Hz, 1 H). FAB-MS: $m/z$ = 675 $[M]^+$, 639 $\{M - Cl\}^{2+}$, 327 $[M - Cl - tptz]^{2+}$. UV/Vis: $\lambda_{max}$ ($\varepsilon$, $dm^3 mol^{-1} cm^{-1}$) = 455 ($2.5 \times 10^3$), 366 ($6.0 \times 10^3$), 265 ($1.9 \times 10^4$), 233 ($2.2 \times 10^4$) nm.

**X-ray Crystallography:** Suitable crystals of **1**, **2** and **3** for X-ray crystallographic studies were obtained from $CH_2Cl_2$/petroleum ether by diffusion. X-ray data for **1** and **3** were collected on an automatic Enraf–Nonius MACH 3 diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation at 293(2) K. For **2**, X-ray data were collected at 293(2) K on an Enraf–Nonius CAD-4 diffractometer using monochromated Cu-$K_\alpha$ radiation, $\lambda$ = 1.54180 Å. The structures were solved by direct methods and refined by using MAXUS-99 and SHELX-97.[16] The non-hydrogen atoms had anisotropically refined thermal parameters. All hydrogen atoms were geometrically fixed and were refined using a riding model. The computer program PLATON was used for analysing the interactions and stacking distances.[16] All the pertinent crystallographic data are listed in Table 3.

CCDC-604770 to -604772 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

Financial support from Department of Science and Technology, New Delhi, is gratefully acknowledged. We also thank The Head, RSIC, Central Drug Research Institute, Lucknow, for providing analytical and spectroscopic facilities. Special thanks are due to the Head, A. P. S. University, Rewa (M.P.), the Head of the Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi, for extending laboratory facilities and Prof. T. P. Singh, Head, Department of Biophysics, AIIMS, New Delhi, for providing single-crystal X-ray facilities.

# Syntheses, Structures and Near-IR Luminescent Studies on Ternary Lanthanide ($Er^{III}$, $Ho^{III}$, $Yb^{III}$, $Nd^{III}$) Complexes Containing 4,4,5,5,6,6,6-Heptafluoro-1-(2-thienyl)hexane-1,3-dionate

**Li-Ning Sun,[a,b,c] Jiang-Bo Yu,[a] Guo-Li Zheng,[a,c] Hong-Jie Zhang,*[a] Qing-Guo Meng,[a] Chun-Yun Peng,[a] Lian-She Fu,[a] Feng-Yi Liu,[a] and Ying-Ning Yu[a]**

**Keywords:** Lanthanides / Luminescence / Optical amplification

The ligand Hhfth [4,4,5,5,6,6,6-heptafluoro-1-(2-thienyl)hexane-1,3-dione], which contains a heptafluoropropyl group, has been used to synthesize several new ternary lanthanide complexes (Ln = Er, Ho, Yb, Nd) in which the synergistic ligand is 1,10-phenanthroline (phen) or 2,2′-bipyridine (bipy). The two series of complexes are [Ln(hfth)$_3$phen] [abbreviated as (Ln)**1**, where Ln = Er, Ho, Yb] and [Ln(hfth)$_3$bipy] [abbreviated as (Ln)**2**, where Ln = Er, Ho, Yb, Nd]. Members of the two series have been structurally characterized. The growth morphology, diffuse reflectance (DR) spectra, thermogravimetric analyses, and photophysical studies of these complexes are described in detail. After ligand-mediated excitation of the complexes, they all show the characteristic near-infrared (NIR) luminescence of the corresponding $Ln^{3+}$ ions (Ln = Er, Ho, Yb, Nd). This is attributed to efficient energy transfer from the ligands to the central $Ln^{3+}$ ions, i.e. an antenna effect. The heptafluorinated substituent in the main hfth sensitizer serves to reduce the degree of vibrational quenching. With these NIR-luminescent lanthanide complexes, the luminescent spectral region from 1300 to 1600 nm, which is of particular interest for telecommunication applications, can be covered completely.

## Introduction

There has been increasing interest in the use of near-infrared (NIR) light, which is one of the best strategies to obtain high-resolution pictures of deep tissues as NIR light diffracts much less than visible light [diffraction is proportional to $1/(\lambda)^{SP}$, SP = scattering power].[1] Recently, the lanthanide ions that are emissive in the NIR region of the spectrum (800–1700 nm), such as $Yb^{III}$, $Nd^{III}$, $Ho^{III}$, and $Er^{III}$, have received much attention. Interest in the photophysical properties of these lanthanide ions mainly stems from the following three points. First, the $Yb^{3+}$ ion emission occurs in the NIR region (approximately 1000 nm) where biological tissues and fluids (e.g. blood) are relatively transparent, thus the development of $Yb^{3+}$ ion luminescence for various analytical and chemosensor applications is promising. Second, Nd-containing systems have been regarded as the most popular infrared luminescent materials for application in laser systems (the basis of the common 1064-nm laser). Third, two telecommunication windows for amplification are commonly used for long-distance communication, one at 1.3 μm using Nd emission and the other at 1.5 μm using Er or Ho emission.[2]

However, the low optical cross-section due to the forbidden nature of the 4f→4f transitions of these NIR-luminescence lanthanide ions results in inefficient direct excitation.[3] Since the discovery that energy transfer from the triplet state of an organic ligand can efficiently sensitize the emissive states of lanthanide ions,[4] there has been considerable effort devoted to designing ligands that optimize this energy transfer and thus give efficient lanthanide luminescence. β-Diketones are most commonly used for the complexation of lanthanide ions. Because of their potential applications, tris- and tetrakis(β-diketonato)lanthanides(III) are the most widely studied complexes of the 4f-element series.[5] In addition, noncharged ligands like 1,10-phenanthroline (phen) or 2,2′-bipyridine (bipy) can serve as the synergistic agent, since an important issue in the design of NIR-emitting lanthanide complexes is to prevent water molecules from binding to the lanthanide ions. Sensitizer-functionalized $Eu^{3+}$ and $Tb^{3+}$ complexes have already been applied as long-lasting luminescent probes in time-resolved fluoroimmunoassays,[6] whereas sensitizer-functionalized complexes of the NIR-emitting lanthanide ions $Er^{3+}$, $Yb^{3+}$, $Nd^{3+}$, and especially $Ho^{3+}$, are less well studied. These com-

plexes are very promising not only for application in fluoroimmunoassays, but also for use in laser systems and for amplification of light.[2]

It is well established that the NIR-emitting $Ln^{3+}$ ions are particularly prone to vibrational deactivation. Species containing high-energy oscillators, such as C–H and O–H bonds (typically found in the ligand), are able to quench the metal excited states nonradiatively, thereby leading to lower luminescence intensities and shorter excited-state lifetimes. The replacement of C–H bonds with C–F bonds is important in the syntheses of lanthanide complexes with efficient photoemission properties.[5,7] According to the literature reported previously, the replacement of C–H bonds in a β-diketone ligand with lower-energy C–F oscillators is able to lower the vibration energy of the ligand, which decreases the energy loss caused by ligand vibration and enhances the emission intensity of the lanthanide ion.[8] Due to the heavy-atom effect,[7e] which facilitates intersystem crossing, the lanthanide-centered luminescent properties are enhanced.[9] It has been reported that the fluorescence quantum yield of a europium(III) complex increases with more fluorinated alkyl groups on the β-diketonate ligand.[5,8c] More fluorinated β-diketones form more stable ternary complexes with Lewis bases in organic solvents.[7f] In this work, the β-diketone ligand Hhfth [4,4,5,5,6,6,6-heptafluoro-1-(2-thienyl)hexane-1,3-dione], which contains a long perfluoroalkyl chain, is used as the main sensitizer for synthesizing new NIR-emitting lanthanide complexes.

In this context, and in connection with our interest in photoluminescence and electroluminescence,[2a,8a,9,10] we are interested in studying the crystal structures and luminescence properties of lanthanide complexes. Herein, we report the syntheses and structures of new sensitizer-functionalized NIR-luminescence complexes [$Ln(hfth)_3phen$] [abbreviated as (Ln)**1**, where Ln = Er, Ho, Yb] and [$Ln(hfth)_3bipy$] [abbreviated as (Ln)**2**, where Ln = Er, Ho, Yb, Nd], which contain the hfth ligand with a heptafluoropropyl group (see Figure S1, Supporting Information). The properties of these complexes were investigated using diffuse reflectance (DR) spectra and thermogravimetric analyses, and the photophysical properties were studied in detail and compared with those of the [$Ln(hfth)_3(H_2O)_2$] complexes.

## Results and Discussion

### Design and Preparation of Complexes (Ln)1 and (Ln)2

The molar ratio of the lanthanide ion and the β-diketonate investigated was determined to be 1:3 or 1:4. Three possible types of lanthanide complexes can be designed depending on the ratio:[11,12] (1) When the ratio is 1:3, a simple tris(complex) can be obtained with three hfth ligands coordinated to one lanthanide ion. However, the six oxygen atoms from three hfth ligands are not sufficient to complete the coordination number requirement of a lanthanide ion (typically 8 or 9). Thus, the tris(complex) usually contains water or other solvent molecules in the first coordination sphere, which is disadvantageous for obtaining high luminescence intensity. (2) When a metal/ligand ratio of 1:4 is used, the tetrakis(complex) can be obtained. Although the tetrakis(complexes) usually show much higher luminescence intensity, the disadvantage is that a single positively charged counterion is needed to assure the electrical neutrality of the complex. This is problematic in the design of electroluminescent devices for charged species. The above two types leave us with the third option. (3) In addition to a metal/ligand ratio of 1:3, a Lewis base such as phen or bipy is added to give a Lewis base adduct of the tris(complex). The function of phen or bipy is to saturate the coordination sphere of the lanthanide ion and also to absorb excitation energy that can be transferred to the excited states of the lanthanide ion.

It is well known that the positions of the luminescence bands in the spectrum are characteristic for a specific lanthanide ion. This means that the given organic ligands that are capable of coordinating with different lanthanide ions can serve various applications operating at different wavelengths simply by changing the central lanthanide ion (in our case Ln = Er, Ho, Yb, Nd).

### Crystal Structures

The structure of the lanthanide complex is essential to understand the energy transfer from the coordinated ligands to the central lanthanide ion. Therefore, a considerable number of these complexes with various β-diketonates have been structurally characterized by X-ray crystallography since the 1970s. In the present work, the single-crystal X-ray diffraction studies revealed isostructural crystals (orthorhombic, $Z = 8$) for complexes (Ln)**1** and (Ln)**2** whose crystals fall in the same *Pbca* space group. Thus, only the structures of (Er)**1** and (Yb)**2** will be described in detail as examples.

The crystal structure of (Er)**1**, with the numbering scheme, is displayed in Figure 1a. Analysis of the crystal structure indicates that the central $Er^{3+}$ ion is eight-coordinate, with six oxygen atoms from three hfth ligands and two nitrogen atoms from the phen ligand. From the coordination angles, the coordination geometry may be described as a square antiprism, one of the two most stable eight-coordinate polyhedra (shown in Figure 1b). The crystal structure of (Yb)**2** (Figure 2a) is similar. The coordination number of the central $Yb^{3+}$ ion is also eight, with six oxygen atoms from three hfth ligands and two nitrogen atoms from the bipy ligand. The coordination polyhedron can also be regarded as a square antiprism (see Figure 2b). For these two complexes, the Ln–O bonds adjacent to the thienyl ring are slightly longer than the others, which is probably due to the inductive effect of the fluorine atoms on the alkyl chain. In the β-diketone rings of the lanthanide complexes, all of the average distances for the C–C and C–O bonds are shorter than a single bond but longer than a double bond. This can be explained by the fact that there is conjugation between the thienyl ring and the coordinated β-diketonate, which

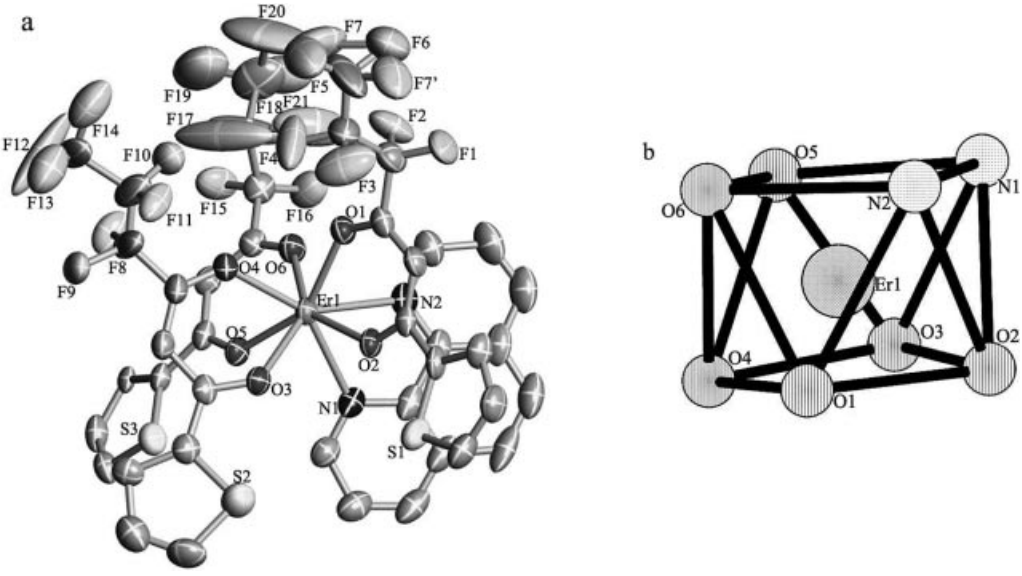

Figure 1. (a) ORTEP plot for (Er)**1** with ellipsoids drawn at the 30% probability level. Hydrogen atoms have been omitted for clarity. (b) Coordination polyhedron of the $Er^{III}$ ion.

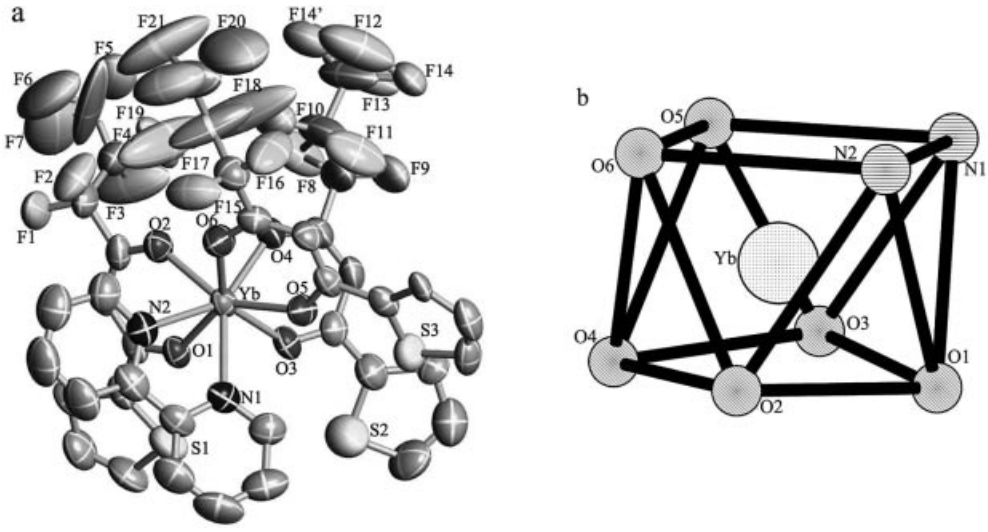

Figure 2. ORTEP plot for (Yb)**2** with ellipsoids drawn at the 30% probability level. Hydrogen atoms have been omitted for clarity.

leads to the delocalization of electron density of the coordinated β-diketonate chelate ring. However, the C–C bond lengths near the fluorine atoms are close to that of a C=C bond, which is due to the inductive effect of the fluorine atoms.[13] The central $Ln^{3+}$ ion is completely surrounded by the bulky anionic ligand hfth and the synergistic ligands phen [for (Ln)**1**] or bipy [for (Ln)**2**], and this encapsulated structure therefore meets the structural requirements of a lanthanide luminescent sensor[14] by protecting the metal ion from vibrational coupling and increasing the light absorption cross-section by the "antenna effect".

The average Ln–O and Ln–N bond lengths in the crystals are shown in Table 1, where it can be seen that the average Ln–O and Ln–N bond lengths decrease from Ho to Yb [for (Ln)**1**] and from Nd to Yb [for (Ln)**2**] due to the so-called "lanthanide contraction". It can also be seen that the cell volume contracts by about 3.81% for (Ln)**1** when the lanthanide ion changes from Ho to Yb and about 1.58% for (Ln)**2** when the lanthanide ion changes from Nd to Yb.

Table 1. Average Ln–O and Ln–N bond lengths [Å] for (Ln)**1** and (Ln)**2**.

| | (Ho)**1** | (Er)**1** | (Yb)**1** | (Nd)**2** | (Ho)**2** | (Yb)**2** |
|---|---|---|---|---|---|---|
| Ln–O | 2.310 | 2.296 | 2.276 | 2.393 | 2.311 | 2.279 |
| Ln–N | 2.551 | 2.520 | 2.501 | 2.633 | 2.532 | 2.492 |

## Observed Growth Morphology

Of the single crystals obtained, all the (Ln)**1** crystals show a regular, diamond-like shape whereas the shape of the (Ln)**2** crystals is irregular. We are not sure about the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

reason for this phenomenon, although we think that it may be due to the different molecular structures of phen and bipy. All atoms of the phen molecule are in the same conjugate area, yet those of the bipy molecule are not. Microscope pictures of a single crystal of (Er)**1** with a diamond shape are shown in Figure 3 to illustrate the growth morphology that is representative for crystals of (Ln)**1** but not for those of (Ln)**2**. A schematic sketch of each crystal selected is shown in Figure 3 (right), which reveals the growth habit of the crystals.

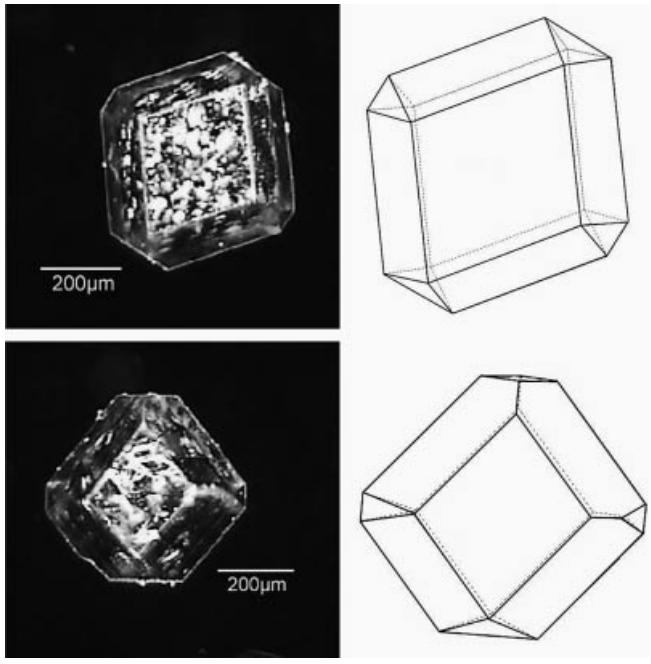

Figure 3. Microscope images and corresponding sketches of the (Er)**1** crystals grown from the ethanol/acetone mother liquor.

## DR Spectra

The DR Spectra of (Ln)**1** and (Ln)**2** (Ln = Er, Ho, Yb, Nd) are shown in Figure 4. In the UV region of the DR curves (200–400 nm), all broad absorption bands are observed and can be assigned to electronic transitions from the ground-state level $S_0$ to the excited level $S_1$ of the organic ligands. In the region above 400 nm in these figures, each absorption band corresponds to a characteristic transition between two spin-orbit coupling levels of the lanthanide ion (see the insets of Figure 4). Based on the energy level scheme of each ion, these bands can be assigned to the transitions from the ground levels $^4I_{15/2}$, $^5I_8$, $^2F_{7/2}$, and $^4I_{9/2}$ to the higher energy levels for the erbium, holmium, ytterbium, and neodymium complexes, respectively.[15–17]

## Photophysical Properties

In 1942, Weissman reported that lanthanide luminescence can be improved by using an intramolecular energy transfer, the so-called "antenna effect".[4a] Because the intraconfigurational f↔f transitions are forbidden, absorption of the lanthanide(III) is very weak. In most cases, one can use the excitation of strongly absorbing ligands followed by energy transfer to promote the lanthanide ion to the emitting state.[18] Each of the lanthanide ions used in the course of this work is known to exhibit one or more spectral emission bands in the 800–1700 nm region. Thus, to provide a clear understanding of the photophysics and luminescence properties of these new series of lanthanide complexes, the excitation and emission spectra of each complex as well as the absorption spectra of the ligands were characterized and discussed in detail.

The excitation spectra of (Ln)**1** and (Ln)**2** (Ln = Er, Ho, Yb, Nd) and the absorption spectra of the ligands (phen,[2a] Hhfth, and bipy) were obtained (Figure S2, Supporting Information). As is clearly visible in this figure, there are overlaps between the excitation band of each lanthanide complex and the absorption bands of Hhfth and phen (or Hhfth and bipy), which indicates the typical sensitization of the $Ln^{3+}$ ions by the two organic ligands[19] and thus confirms that the $Ln^{3+}$ ions are surrounded by hfth and phen (or hfth and bipy) in the complexes.[3a,20] It is also worth noting that the overlap between the absorption band of Hhfth and the lanthanide excitation band is larger than that between the absorption band of phen (or bipy) and the excitation band, which suggests that the antenna effect of the hfth ligand is more efficient than that of the synergistic ligand (phen or bipy). Thus, it is reasonable to deduce that the intramolecular energy transfer in the lanthanide complexes mainly occurs between the hfth ligand and the $Ln^{3+}$ ions.[13]

The emission studies were carried out in the NIR region on all of these complexes upon excitation of the ligand absorption bands, followed by NIR emission for the $Er^{3+}$, $Ho^{3+}$, $Yb^{3+}$, and $Nd^{3+}$ complexes where the synergistic ligand is phen or bipy. Using identical experimental settings (slit width, integration time, excitation wavelength, sampling interval), the direct comparison of the emission intensity of the NIR luminescence for the same lanthanide ion with different synergistic ligands was investigated.

### *Erbium*

As is shown in Figure S2, the excitation spectra of the (Er)**1** and (Er)**2** complexes were obtained by monitoring the characteristic emission of the $Er^{3+}$ ion at 1541 nm. In the excitation spectra, a broad band ranging from 260 to 435 nm for (Er)**1** and a broad band from 235 to 430 nm for the (Er)**2** complex are observed. The two broad bands can be assigned to the absorption of the organic ligands, which is in agreement with the DR spectra mentioned above (Figure 4a). Some small bands, originating from f–f absorption transitions of the $Er^{3+}$ ion, are also observed in the excitation spectra of the two complexes. They correspond to the energy transitions $^4I_{15/2}\rightarrow{}^4F_{7/2}$ [492 nm for (Er)**1** and 486 nm for (Er)**2**] and $^4I_{15/2}\rightarrow{}^2H_{11/2}$ [528 nm for (Er)**1** and 524 nm for (Er)**2**], which is also in agreement with the DR spectra (Figure 4a).

Excitation of the ligand absorption bands at 397 nm resulted in the emission spectra (Figure 5) of the two Er complexes. For (Er)**1** and (Er)**2**, the emission bands cover large

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

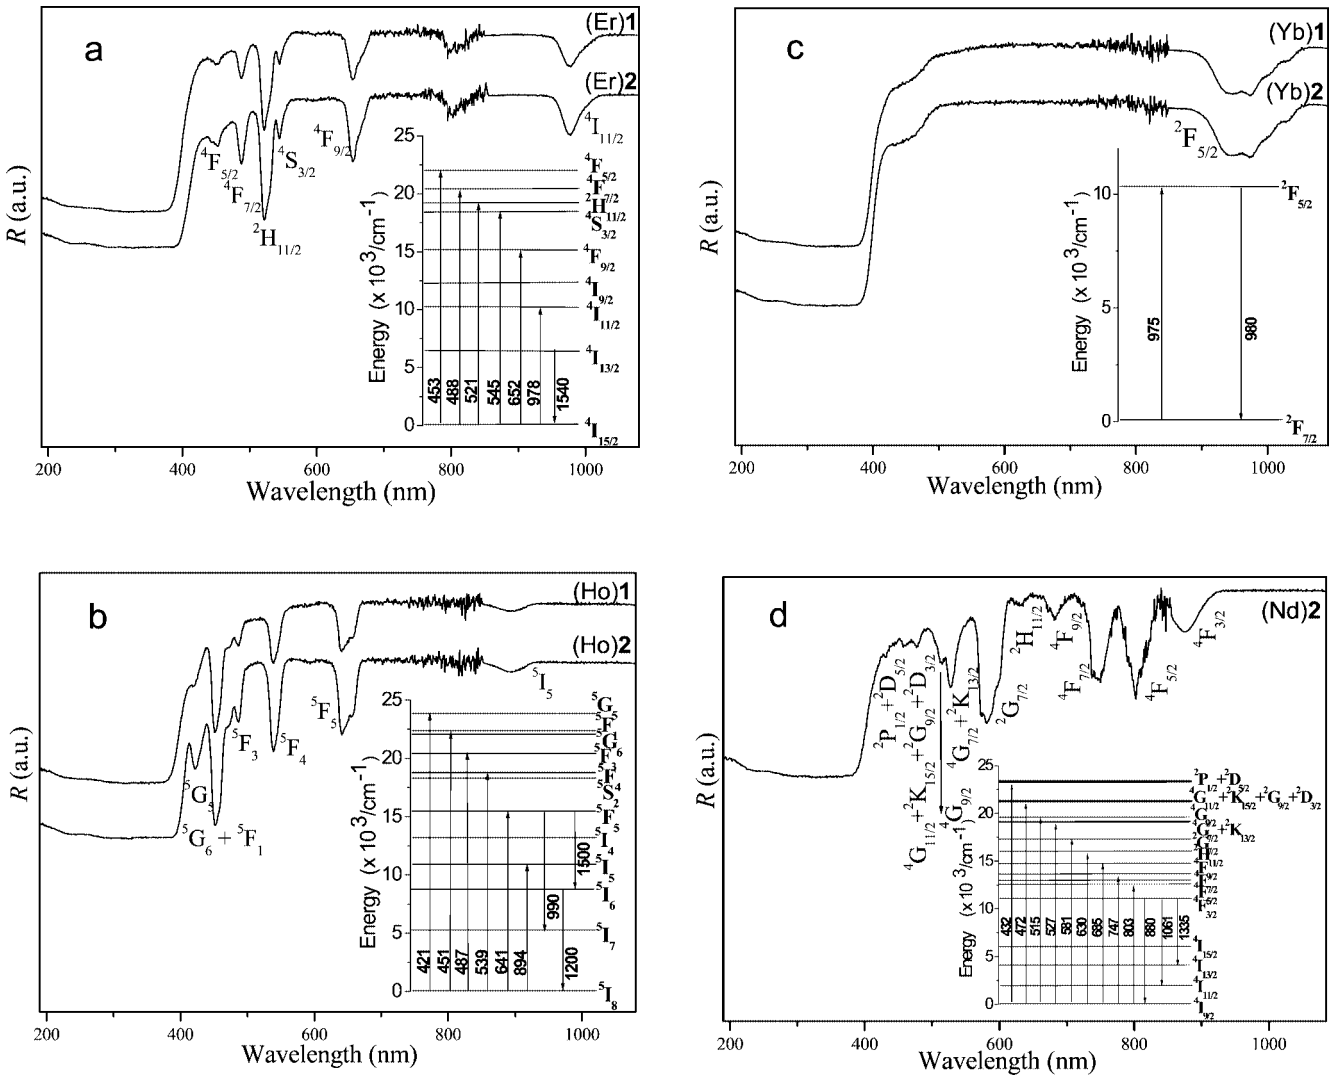

Figure 4. DR spectra of (Er)**1** and (Er)**2** (a), (Ho)**1** and (Ho)**2** (b), (Yb)**1** and (Yb)**2** (c), and (Nd)**2** (d). The insets show the energy level diagrams of $Er^{3+}$, $Ho^{3+}$, $Yb^{3+}$, and $Nd^{3+}$. The transitions of the bands [nm] are indicated by arrows.

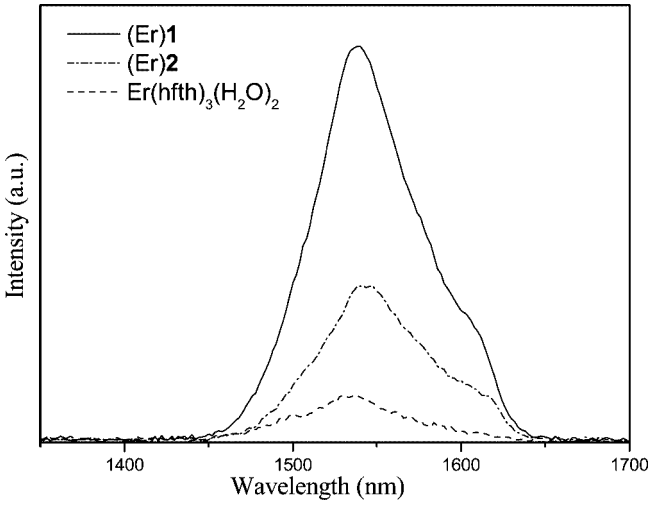

Figure 5. Emission spectra ($\lambda_{ex}$ = 397 nm) of (Er)**1**, (Er)**2**, and $[Er(hfth)_3(H_2O)_2]$ (in the solid state as powder) at room temperature.

spectrum ranges extending from 1414 to 1664 nm and from 1448 to 1656 nm, respectively, with the emission maxima both located at 1540 nm. The emission obtained is attributed to the transition from the first excited state ($^4I_{13/2}$) to the ground state ($^4I_{15/2}$) of the partially filled 4f shell of the $Er^{3+}$ ion (see the inset of Figure 4a). The erbium complexes are especially interesting for application in optical amplification because the transition around 1540 nm is in the right position for the third telecommunication window. To enable a wide-gain bandwidth for optical amplification, a broad emission band is desirable.[2d,21] The full widths at half maximum (FWHM) of the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition for the (Er)**1** and (Er)**2** complexes are 76 and 74 nm, respectively, which enable a wide-gain bandwidth for optical amplification.[22]

### *Holmium*

In the excitation spectra of (Ho)**1** and (Ho)**2** (Figure S2), the broad excitation bands in the UV region are both observed, which can be attributed to the absorption of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ligands. The excitation edge of the ligands overlaps some absorption bands corresponding to the characteristic transitions of the $Ho^{3+}$ ion. These f–f transitions correspond to $^5I_8 \rightarrow {}^5G_4 + {}^3F_7$ (389 nm), $^5I_8 \rightarrow {}^5G_5$ (421 nm), $^5I_8 \rightarrow {}^5G_6 + {}^5F_1$ (453 nm), and $^5I_8 \rightarrow {}^5F_3$ (488 nm), which are in agreement with those of the DR spectra discussed above (Figure 4b).

Of importance is the observation of less frequently investigated NIR luminescence in holmium complexes.[1b,2e,23] The emission spectra of (Ho)**1** and (Ho)**2**, after ligand-mediated excitation at 397 nm, are shown in Figure 6. Both luminescence spectra consist of three bands at 990, 1200, and 1500 nm, which are attributed to the $^5F_5 \rightarrow {}^5I_7$, $^5I_6 \rightarrow {}^5I_8$, and $^5F_5 \rightarrow {}^5I_6$ transitions, respectively. For (Ho)**1** and (Ho)**2**, the intensity sequence of the bands is $I(^5F_5 \rightarrow {}^5I_7) > I(^5F_5 \rightarrow {}^5I_6) > I(^5I_6 \rightarrow {}^5I_8)$. As is shown in the energy diagram of the $Ho^{3+}$ ion (inset of Figure 4b), the $^5I_7 \rightarrow {}^5I_8$ transition (>1900 nm) exceeds the measurement range of our detector. Since the optimum energy difference favors efficient ligand-to-ion energy transfer, it is supposed that the $^5F_4$, $^5S_2$, and $^5F_5$ levels are the main acceptor levels, and the excited electrons on the $^5F_5$ and $^5I_6$ levels could partially come from the relaxation of the upper levels followed by the transitions to the lower levels to give the NIR emission of the $Ho^{3+}$ ion.[2e] Among these obtained NIR emissions, the 1500-nm emission is particularly attractive for its good agreement with the efficient working window of a quartz fiber. For the (Ho)**1** complex, the 1500-nm emission, which covers from 1420 to 1550 nm, may be due to the Stark splitting of the $^5F_5$ and $^5I_6$ levels, providing a satisfying waveband for the wavelength division multiplexing technology in optical communications.[2e] The FWHM of this emission is 62 nm, which is a broad bandwidth for the potential application of the optical communication systems.

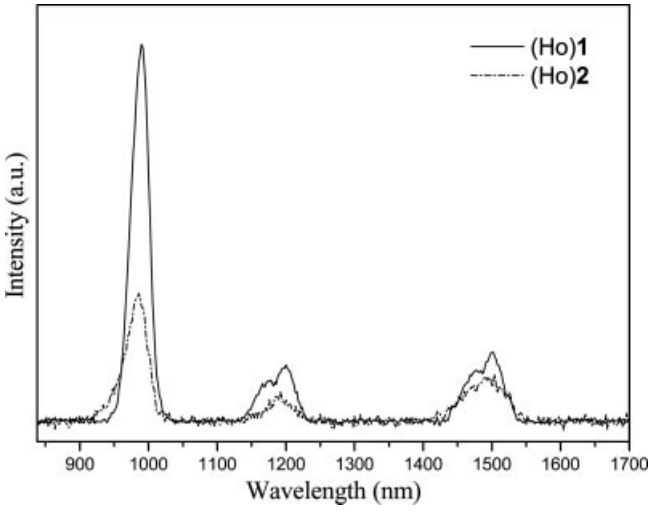

Figure 6. Emission spectra ($\lambda_{ex}$ = 397 nm) of (Ho)**1** and (Ho)**2** (in the solid state as powder) at room temperature.

### *Ytterbium*

The excitation spectra of (Yb)**1** and (Yb)**2** were obtained by monitoring the characteristic emission of the $Yb^{3+}$ ion at 980 nm (Figure S2). The excitation spectra are dominated by a broad band ranging from 200 to 500 nm for both complexes. These two broad bands can be assigned to the absorption of the organic ligands and are in agreement with those in the DR spectra (Figure 4c). The emission spectra of the two complexes (Figure 7), after ligand-mediated excitation at 397 nm, clearly show the characteristic emission bands of the $Yb^{3+}$ ion at 980 nm, which are assigned to the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition. It should be noted that the $Yb^{3+}$ ion emission in the two complexes is not a single sharp band but an envelope of bands arising at the lower energy side (1009 and 1038 nm) of the primary 980-nm emission band. A similar splitting has been reported previously.[24–26] According to the literature, these bands arise from the $M_J$ splitting of the emitting and/or fundamental state as a consequence of ligand-field effects.[26]

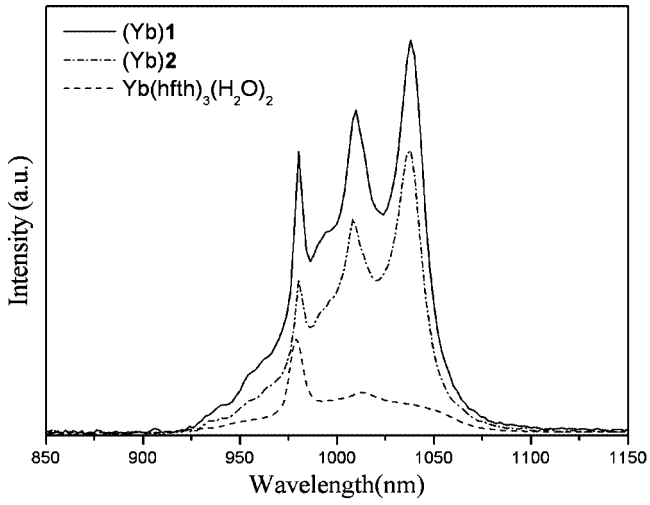

Figure 7. Emission spectra ($\lambda_{ex}$ = 397 nm) of (Yb)**1**, (Yb)**2**, and $[Yb(hfth)_3(H_2O)_2]$ (in the solid state as powder) at room temperature.

The $Yb^{3+}$ ion plays an important role in laser emission because of its very simple f–f energy level structure: besides the $^2F_{7/2}$ ground multiplet, there is only the $^2F_{5/2}$ excited multiplet at around 10000 $cm^{-1}$. There is no excited-state absorption on reducing the effective laser cross-section, no up-conversion, no concentration quenching, and no absorption in the visible range. The intense $Yb^{3+}$ ion absorption lines are well suited for laser diode pumping in this range and the smaller Stokes shift (about 650 $cm^{-1}$) between absorption and emission reduces the thermal loading of the material during laser operation.[27] These properties of the $Yb^{3+}$ ion and the obtained high intensity emission make these Yb complexes very important for various photonic applications in ionic crystals and glasses.[28] In addition, the relative transparency of human tissue at approximately 1000 nm suggests that in vivo luminescent probes operating at this wavelength (Yb-based emission) could have diagnostic value.[29]

### *Neodymium*

In the excitation spectrum of (Nd)**2** ($\lambda_{em}$ = 1061 nm), a broad band ranging from 260 to 498 nm due to the absorp-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion of the organic ligands superimposed with some excitation bands originating from the characteristic absorption transition of the $Nd^{3+}$ ion is observed (Figure S2). These f–f transitions correspond to $^4I_{9/2}\rightarrow{}^2P_{1/2} + {}^2D_{5/2}$ (432 nm), $^4I_{9/2}\rightarrow{}^4G_{11/2} + {}^2K_{15/2} + {}^2G_{9/2} + {}^2D_{3/2}$ (474 nm), $^4I_{9/2}\rightarrow{}^4G_{9/2}$ (515 nm), and $^4I_{9/2}\rightarrow{}^2K_{13/2} + {}^4G_{7/2}$ (529 nm) of the $Nd^{3+}$ ion, which are well in agreement with those of the DR spectrum (Figure 4d). It should be noted that these absorption transitions are much weaker than that of the ligands, which proves that luminescence sensitization by excitation of the ligands is much more efficient than direct excitation of the absorption levels of the $Nd^{3+}$ ion.

The excitation of the Nd complex by strongly absorbing ligands ($\lambda_{ex}$ = 397 nm) is quite feasible, as expected based on the energy level of the triplet state, which is higher than the Nd luminescent excited state $^4F_{3/2}$ (11527 $cm^{-1}$). The emission spectrum of the Nd complex (Figure 8) consists of three bands at $\lambda$ = 880, 1061, and 1335 nm, which are attributed to the f–f transitions $^4F_{3/2}\rightarrow{}^4I_{9/2}$, $^4F_{3/2}\rightarrow{}^4I_{11/2}$, and $^4F_{3/2}\rightarrow{}^4I_{13/2}$, respectively. Some crystal-field fine structure can be observed, which is an indication that the $Nd^{3+}$ ion occupies well-defined crystallographic sites in the complex.[23] Among the three emission bands of the Nd complex, the intensity of the transition at 1061 nm is the strongest and is potentially applicable for laser emission. The fine structure of the 1335-nm band of the complex offers the opportunity to develop new materials suitable for optical amplifiers operating at 1.3 μm.[30]

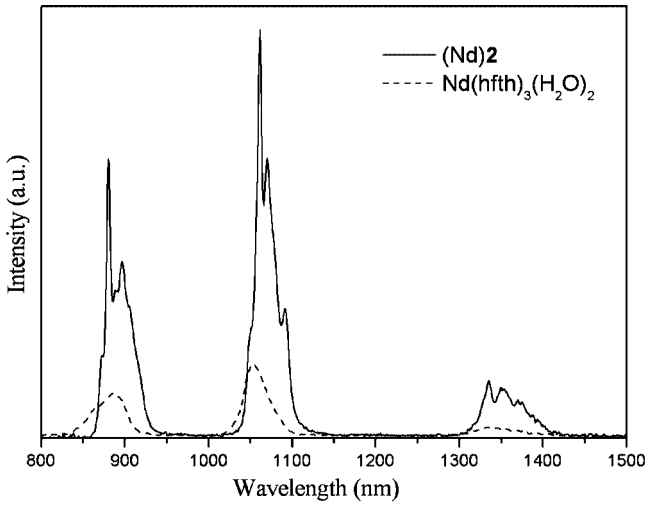

Figure 8. Emission spectra ($\lambda_{ex}$ = 397 nm) of (Nd)**2** and [Nd(hfth)$_3$(H$_2$O)$_2$] (in solid state as powder) at room temperature.

Upon excitation of the ligand absorption band (397 nm), these lanthanide complexes all show the characteristic NIR luminescence of $Ln^{3+}$ ions. The NIR luminescence obtained in this study shows that the ligands shield the lanthanide ions well from their surroundings and transfer energy from their triplet states to the $Ln^{3+}$ ions efficiently.[31–34] Because no direct excitation of the lanthanide moiety occurs at the excitation wavelength (397 nm), the observed NIR emission signals only arise by sensitization of the lanthanide ions by the ligands.

Many authors have reported the influence of water on the intensity of $Eu^{III}$ luminescence.[35] In fact, the NIR luminescence is even more sensitive to water than the visible luminescence. As shown in Figures 5, 7, and 8, respectively, an obvious decrease of the NIR-emission intensity for [Ln(hfth)$_3$(H$_2$O)$_2$] (Ln = Er, Yb, Nd) is detected when compared to the intensity of the corresponding (Ln)**1** or (Ln)**2** complex. This is probably related to the replacement of solvent molecules (ethanol or water) by phen or bipy in the $Ln^{III}$ coordination sphere, which could depress nonradiative deactivation pathways through vibrational quenching.[36] These results suggest that the introduction of a second ligand instead of water molecules is able to increase the efficiency of energy transfer from the ligands to the central metal ions, thus resulting in an improvement in the emission intensity. In the meantime, it is worth noting that the relative emission intensity of (Ln)**1** is stronger than that of (Ln)**2** (Ln = Er, Ho, Yb). Basically, in the lanthanide complexes the ligands may sensitize the $Ln^{3+}$ ion by energy transfer, and the probability of energy transfer is strongly influenced by the energy difference between the energy donor and acceptor.[37] The triplet-state energy level of bipy was measured and calculated to be 23095 $cm^{-1}$ from the shortest-wavelength phosphorescence band of the phosphorescence spectrum for [Gd(bipy)$_3$Cl$_2$] (Figure S3, Supporting Information), in which the fine-structure is observed. We have measured the triplet energy states of the phen[38] and Hhfth[10c] ligands to be 22173 and 20400 $cm^{-1}$, respectively. So, the energy difference between the phen ligand and the Hhfth ligand is smaller than that between the bipy ligand and the Hhfth ligand. The phen ligand may transfer energy to hfth more efficiently and accordingly afford a stronger sensitization of the $Ln^{3+}$ ion emission.[35a,39] In addition, all the C and N atoms of the phen molecule are located in the same conjugate area, yet those of the bipy molecule are not. It is therefore concluded that the presence of a rigid planar structure in the complex causes a higher intensity of the sensitized luminescence because such a structure allows a better energy transfer.[5] Therefore, the combination of phen and hfth ligands may sensitize the $Ln^{3+}$ ion more efficiently, followed by the stronger NIR luminescence of the $Ln^{3+}$ ion.

The luminescence decay curves obtained from time-resolved luminescence experiments could be fitted monoexponentially, thus confirming that the chemical environment of the $Ln^{3+}$ ion is uniform in the materials.[20,40] The corresponding lifetimes of the lanthanide excited states are shown in Table 2. Due to the weakness of the signal and the limitations of our equipment, no reliable decay time could be measured for the Ho complexes. The quantum yields of the lanthanide-centered luminescence in these complexes were determined by taking [Yb(tta)$_3$phen] (tta = thenoyltrifluoroacetonate) as standard. The quantum yields ($Q$) of these complex samples (S) were calculated by using the following equation,[24c,41] where $n$ is the refractive index

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the solvent, $I$ is the wavelength-integrated area of the corrected emission spectrum, and $A$ is the absorbance value at the excitation wavelength.

$$Q_S = \frac{n_S^2 I_S A_R}{n_R^2 A_S I_R} Q_R$$

Table 2. Emission properties for the different NIR-emitting lanthanide complexes.

| Complex | Transition | $\lambda_{em}$ [nm] | $\tau$ [μs][a] | $Q_S$ [%][b] |
|---|---|---|---|---|
| (Er)**1** | $^4I_{13/2}\rightarrow{}^4I_{15/2}$ | 1541 | 2.73 | 0.019 |
| (Er)**2** | $^4I_{13/2}\rightarrow{}^4I_{15/2}$ | 1541 | 2.27 | 0.014 |

[a] Luminescence lifetimes in the solid state. [b] Quantum yields of the solution of these complexes in toluene. The excitation wavelength is 355 nm.

The quantum yield of the reference (R), [Yb(tta)$_3$phen] in toluene solution ($n$ = 1.4964), was taken as $Q_R$ = 1.1%.[42] Then, the quantum yields of the solution of these complexes in toluene were obtained (Table 2). It can be seen that the quantum yields of these complexes in toluene increase in the order (Ln)**1** > (Ln)**2**, which agrees well with the corresponding lengthening of the emission lifetime. This correlation further shows that the combination of hfth and phen ligands may sensitize the $Ln^{3+}$ ion more efficiently than the combination of hfth and bipy ligands. It should also be noted that the emission lifetimes and quantum yields for the Yb and Nd complexes investigated are considerably longer than those of the corresponding [Ln(hfth)$_3$(H$_2$O)$_2$] complexes, probably because the two water ligands (containing four potentially quenching O–H oscillators) have been replaced by phen or bipy, in which most of the C–H oscillators are remote from the metal center.

The luminescence lifetimes and quantum yield values obtained are in line with, or a little higher than, other recently published results on NIR-luminescent lanthanide complexes.[36,42,43] High-frequency oscillators, such as C–H vibrations in the ligand, can provide a very efficient nonradiative pathway for relaxation of the luminescent state of the NIR-emitting lanthanide ions by vibronic coupling, since it can be effectively mediated by the ubiquitous molecular vibrations. It would appear that the heptafluorinated substituent in the main sensitizer hfth serves to reduce the degree of vibrational quenching, which, in turn, probably leads to a slightly longer lived $Ln^{3+}$ ion excited state. There still exists one C–H bond in the β-diketonate chelate ring of the complex, however, and this results in the main nonradiative factor. Suppression of such vibrational excitation in the system requires deuteration of the C–H bonds or replacement of C–H bonds with C–F bonds in the ligand.[7g] In addition, improvement of the spectral overlap of the NIR-emitting $Ln^{3+}$ ion and the antenna and optimization of the luminescence quantum yield could be achieved by incorporating antenna chromophores with lower lying triplet states. This ligand feature is particularly important in the design of NIR-emitting lanthanide complexes.

### Thermogravimetric Analyses

The TGA-DTA analyses of all the (Ln)**1** and (Ln)**2** complexes were carried out. The TGA diagrams of (Ln)**1** and (Ln)**2** are similar, and all reveal two main weight losses. (Yb)**1** and (Nd)**2** are given as examples in Figure 9. For (Yb)**1**, the analysis show that the melting point is 207.04 °C. The first weight loss of 74.02% is close to the calculated value (73.23%) corresponding to the loss of the hfth ligands and the second weight loss of 12.57% corresponds to the loss of the phen ligand (calculated: 13.65%). For (Nd)**2**, the analysis displays a first weight loss of 74.22% corresponding to the loss of hfth ligands (calculated: 76.23%) and a second weight loss of 12.23% corresponding to the loss of the bipy ligand (calculated: 12.33%). The final residues for (Yb)**1** and (Nd)**2** are composed of $Yb_2O_3$ and $Nd_2O_3$, respectively. The analyses show that the melting points of the (Ln)**1** and (Ln)**2** complexes are between 200 and 215 °C, and the decomposition temperatures are higher than 350 °C. These results suggest that these complexes have good thermal stability. This may be due to the heptafluorinated substituent in the ligand, as we and other authors have reported that a fluorinated substituent in a ligand leads to an improved thermal and oxidative stability and increases

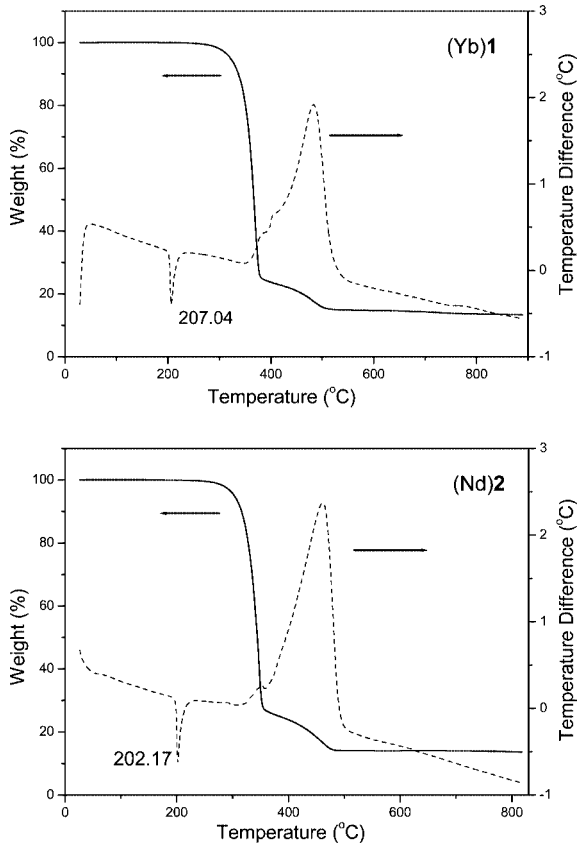

Figure 9. TGA (−) and DTA (---) curves of (Yb)**1** and (Nd)**2**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the volatility of the complex.[9,10c,44] The improved thermal stability and volatility result in good film-forming ability, which facilitates the fabrication of electroluminescent devices.

## Conclusions

Based on the ligand hfth, seven new ternary lanthanide complexes (Ln)**1** (Ln = Er, Ho, Yb) and (Ln)**2** (Ln = Er, Ho, Yb, Nd) have been synthesized. Their single-crystal X-ray diffraction analyses [except (Er)**2**], growth morphology, DR spectra, optical properties, and TGA-DTA analyses have been reported. We have demonstrated the characteristic NIR luminescence of the corresponding lanthanide complexes upon excitation of the ligand absorption bands, mediated by the sensitizing effect of the ligands in the complexes, known as the antenna effect. The broadband emission at 1540 nm for the Er complexes, 1500 nm for the Ho complexes, and the fine structure at 1335 nm for the Nd complex offer the opportunities to develop new materials suitable for optical amplifiers operating at 1.5 and 1.3 μm, the two telecommunications windows. The heptafluorinated substituent in the main sensitizer hfth serves to reduce the degree of vibrational quenching. In addition, improvement of the spectral overlap of the NIR-emitting $Ln^{3+}$ ion and the antenna and optimization of the luminescence quantum yield could be achieved by incorporating antenna chromophores with lower lying triplet states. This ligand feature is particularly important in the design of NIR-emitting lanthanide complexes and further work is in process. Furthermore, the above results are pertinent to the application of these complexes in NIR electroluminescent devices. In ongoing work, we are exploring the properties of electroluminescent devices fabricated using these lanthanide complexes as the active materials.

## Experimental Section

**Materials:** Ytterbium oxide ($Yb_2O_3$, 99.99%), neodymium oxide ($Nd_2O_3$, 99.99%), holmium oxide ($Ho_2O_3$, 99.99%), erbium oxide ($Er_2O_3$, 99.99%), and gadolinium oxide ($Gd_2O_3$, 99.99%) were purchased from Yue Long Chemical Plant (Shanghai, China). Sodium metal (≥98%, A. R.), 1,10-phenanthroline monohydrate (phen·$H_2O$, 99%, A. R.), and 2,2′-bipyridine (≥99.5%, A. R.) were bought from Beijing Fine Chemical Co. (Beijing, China). Hhfth was purchased from Acros Organics Co. (Geel, Belgium) and Htta (2-thenoyltrifluoroacetone) from Aldrich. All these reagents were used directly without further purification. The toluene solvent was dried by a standard procedure (with Na/benzophenone), distilled under nitrogen, and kept over molecular sieves. The $LnCl_3$ (Ln = Er, Ho, Yb, Nd, Gd) ethanol solution was prepared as follows: the rare earth oxide ($Ln_2O_3$) was dissolved in concentrated hydrochloric acid (HCl) and the surplus HCl was removed by evaporation. The residue was diluted with anhydrous ethanol. The concentration of the rare earth ion was measured by titration with a standard EDTA (ethylenediaminetetraacetic acid) aqueous solution.

**Instrumentation:** The CHN elemental analyses were carried out with a VarioEL analyzer. The DR measurements were performed with a Hitachi U-4100 spectrophotometer. The UV/Vis absorption spectra (solutions of Hhfth and bipy in ethanol; solutions of the investigated complexes in toluene) were recorded with a TU-1901 spectrophotometer. The excitation and emission spectra were measured with an Edinburgh Analytical Instruments FLS920 equipped with a laser diode (LD) from the PicoQuant Company as the light source. The time-resolved measurements for the Yb and Nd complexes were performed with an Edinburgh Analytical Instruments FLS920 equipped with a 397-nm picosecond laser diode (LD) from the PicoQuant Company and for Er complexes with an Edinburgh Combined Fluorescence Lifetime and Steady State Spectrometer FLS920 equipped with a μF900 lamp ($\lambda_{ex}$ = 397 nm). Freshly collected (Er)**1** crystals were mounted on the glass and were observed and recorded with an infrared microscope (HYPERION 3000) from German Bruker Company. All measurements were performed at room temp. The low-temperature phosphorescence spectrum of the $Gd^{3+}$ complex was measured with a Hitachi F-4500 spectrophotometer at liquid nitrogen temperature (77 K). The TGA-DTA analyses were measured with an SDT 2960 Simultaneous DSC-TGA of American TA Instruments, with a heating rate of 10 °C min$^{-1}$.

**Synthesis of the (Ln)1 Complexes (Ln = Er, Ho, Yb):** Hhfth (190 μL, 0.9 mmol) and phen·$H_2O$ (0.0595 g, 0.3 mmol) were dissolved in a suitable volume of anhydrous ethanol. Then, an appropriate amount of 1.0 M sodium hydroxide solution was added dropwise to the solution to adjust the pH value to approximately 7. $LnCl_3$ ethanol solution (0.3 mmol), prepared separately, was then added dropwise to this mixture with stirring. The mixture was heated to reflux and kept at 78 °C for 6 h, and then cooled to the room temperature. The precipitates were collected by filtration, washed with water and ethanol, and dried at 70 °C under vacuum overnight. The lanthanide complex was recrystallized from an ethanol/acetone mixture. Pink (for erbium), pale-yellow (for ytterbium), or yellow crystals (for holmium) suitable for X-ray single-crystal structural determination were grown from the mother liquor at room temp.

**Synthesis of the (Ln)2 Complexes (Ln = Er, Ho, Yb, Nd):** The procedure used to prepare the (Ln)**2** was the same as that used for the (Ln)**1** complex expect that bipy (0.0469 g, 0.3 mmol) was dissolved in anhydrous ethanol instead of phen·$H_2O$ (0.0595 g, 0.3 mmol). The (Ln)**2** complex obtained was also recrystallized from an ethanol/acetone mixture. Lilac (for neodymium), pale-yellow (for ytterbium), or yellow crystals (for holmium) suitable for X-ray single-crystal structural determination were grown from the mother liquor at room temp. The purity of the compounds was verified by CHN elemental analysis (Table S1, Supporting Information).

**Synthesis of the [Ln(hfth)$_3$(H$_2$O)$_2$] Complexes (Ln = Er, Ho, Yb, Nd):** An appropriate amount of 1.0 M sodium hydroxide solution was added dropwise to an Hhfth (190 μL, 0.9 mmol) ethanol solution whilst stirring to adjust the pH value to approximately 7. The $LnCl_3$ ethanol solution (0.3 mmol) was added dropwise to this mixture with stirring. Then, an appropriate amount of water was added and the mixture was heated to reflux and kept at 60 °C for 6 h. The rest of the procedure was similar to that used for the (Ln)**1** complex. All complexes were found to be dihydrates.

**Synthesis of [Gd(bipy)$_3$Cl$_2$]:** At room temperature, 1.5 mmol of bipy was dissolved in a suitable volume of anhydrous ethanol. Then, 0.5 mmol of a $GdCl_3$ ethanol solution was added whilst stirring and the solution was heated under reflux for 2 h. The white powder was filtered and washed with ethanol. The resulting complex was dried at 60 °C under vacuum overnight.

**Synthesis of [Yb(tta)$_3$phen]:** This complex was synthesized according to a published method.[45]

**Single-Crystal X-ray Diffraction Study:** X-ray data for the selected crystal mounted on a glass fiber were collected with a CCD area detector with graphite-monochromated Mo-$K_\alpha$ radiation. Reflections were collected with a Bruker SMART APEX detector and processed with SAINT from Bruker. Data were corrected for Lorentz and polarization effects. The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms [for (Yb)**1** except F3–F7, F17–F21; for (Nd)**2** except F atoms] were refined anisotropically. The hydrogen atoms were included using a riding model. All calculations were performed using the SHELXL-97 crystallographic software package.[46] For the crystallographic data some $R$ values are high, and for the ORTEP plots some of the ellipsoids of some fluorine atoms have a very irregular shape. These problems could be due to the poor X-ray data and disorder of the fluorine atoms. Crystallographic data and structural refinements for compounds (Ln)**1** and (Ln)**2** are summarized in Table 3. CCDC-266576 [for (Ho)**2**], -266577 [for (Ho)**1**], -266578 [for (Er)**1**], -266579 [for (Yb)**2**], -266816 [for (Yb)**1**], and -266983 [for (Nd)**2**] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Molecular structures of the complexes (Ln)**1** and (Ln)**2** (Figure S1), excitation spectra of (Ln)**1** and (Ln)**2** complexes (Ln = Er, Ho, Yb, Nd) and absorption spectra of the ligands (phen, Hhfth and bipy) (Figure S2), phosphorescence spectrum of $[Gd(bipy)_3Cl_2]$ (Figure S3), results of elemental analyses of complexes (Ln)**1** and (Ln)**2** (Table S1).

## Acknowledgments

This work was supported by the National Natural Science Foundation of China (grant nos. 20372060, 20131010, 20490210, 20340420326) and financial aid from MOST of China ("973" Program, no. 2006CB601103). We are grateful to Dr. E. Ma and Prof. J. G. Mao of the Fujian Institute of Research on the Structure of Matter, Chinese Academy of Sciences, and Prof. Q. Su and Dr. L. Feng of Sun Yat-sen University for assistance with the fluorescence measurements. We also thank Dr. D. M. Wang and Dr. Y. J. Zhang (Changchun Institute of Applied Chemistry) for their help with the microscope pictures of the crystals.

# Chiral Platinum(II) Compounds Containing Ferrocenyl Schiff Bases Acting as (N), $(N,O)^-$, $[C(sp^2,ferrocene),N]^-$ or $[C(sp^2,ferrocene),N,O]^{2-}$ Ligands

**Concepción López,*[a] Amparo Caubet,[a] Sonia Pérez,[a] Xavier Solans,[b] Mercè Font-Bardía,[b] and Elies Molins[c]**

**Keywords:** Platinum / Ferrocene / Platinacycles / N ligands / N,O ligands

A study of the reactions of the following ferrocenyl Schiff bases: ($S_C$)-(+)-[FcCH=NCH($R^1$)$CH_2$OH] {Fc = ($\eta^5$-$C_5H_5$)-Fe($\eta^5$-$C_5H_4$), $R^1$ = Me (**1a**) or $CHMe_2$ (**1b**)} with *cis*-[$PtCl_2$(dmso)$_2$] under different experimental conditions is reported. This study enabled the isolation and characterisation of the enantiomerically pure platinum(II) complexes *trans*-($S_C$)-[Pt{FcCH=NCH($R^1$)$CH_2$OH}$Cl_2$(dmso)] {$R^1$ = Me (**2a**) or $CHMe_2$ (**2b**)} and *cis*-($S_C$)-[Pt{FcCH=NCH($R^1$)-$CH_2$OH}$Cl_2$(dmso)] {$R^1$ = Me (**3a**) or $CHMe_2$ (**3b**)} as well as four isomeric forms of ($S_C$)-[Pt{FcCH=N–CH($R^1$)-$CH_2$O}Cl(dmso)] {$R^1$ = Me or $CHMe_2$} (**4**–**7a**,**b**). These isomers differ in the conformation of the imine {*anti*-(*E*) (in **4** and **6**) or *syn*-(*Z*) (in **5** and **7**)} or in the relative arrangement of the nitrogen and the dmso group {*trans* (in **4** and **5**) or *cis* (in **6** and **7**)}. Imines **1** behave as a N-donor ligand in **2** and **3** and as a $(N,O)^-$ group in **4**–**7**. We also prepared the diastereomers {($S_p$,$S_C$) and ($R_p$,$S_C$)} of the platinacycles [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)$CH_2$OH]Fe($\eta^5$-$C_5H_5$)}Cl(dmso)] {**8** and **9**; $R^1$ = Me ($S_p$,$S_C$) (**8a**) and ($R_p$,$S_C$) (**9a**) or $R^1$ = $CHMe_2$ ($S_p$,$S_C$) (**8b**) and ($R_p$,$S_C$) (**9b**)}, [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)$CH_2$O]-Fe($\eta^5$-$C_5H_5$)}(dmso)] {**10** and **11**; $R^1$ = Me ($S_p$,$S_C$) (**10a**) and ($R_p$,$S_C$) (**11a**) or $R^1$ = $CHMe_2$ ($S_p$,$S_C$) (**10b**) and ($R_p$,$S_C$) (**11b**)} and [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)$CH_2$OH]Fe($\eta^5$-$C_5H_5$)}Cl-($PPh_3$)] {**12** and **13**; $R^1$ = Me ($S_p$,$S_C$) (**12a**) and ($R_p$,$S_C$) (**13a**) or $R^1$ = $CHMe_2$ ($S_p$,$S_C$) (**12b**) and ($R_p$,$S_C$) (**13b**)}, containing a $[C(sp^2,ferrocene),N]^-$ (in **8**, **9**, **12** and **13**) or a $[C(sp^2,ferrocene),N,O]^{2-}$ (in **10** and **11**) group. The X-ray crystal structures of **1b**·$H_2O$, **3b**, **7b**·$CH_2Cl_2$·1/2$H_2O$ and **9a** are also reported. Our study allows the elucidation of the factors affecting the preferential formation of a given platinum(II) complex.

## Introduction

Palladium(II) and platinum(II) complexes containing chiral ligands attract great interest because of their potential applications in different fields.[1–11] It is well known that compounds of this kind are useful in homogeneous catalysis[3–4] and as chiral derivatising agents,[5] as reagents to determine enantio- or diastereomeric excesses of organic substrates,[6] or even due to their antitumoral activity.[1c,7] Of the examples reported, those having a bidentate $[C(sp^2,aryl),N]^-$ group are particularly relevant.[1,3,6,8–11] The utility of chiral pallada- and platinacycles in asymmetric catalytic processes[8] including asymmetric Claisen rearrangements[10] is well documented. Notably, Leung et al.[11] have recently described the first example of a platinacycle that promotes the asymmetric [4+2] Diels–Alder reaction between diphenylvinylphosphane and *N*-(diphenylphosphanyl)pyrrole.

On the other hand, palladium(II) complexes containing (N), (N,E), $(C,N)^-$ or $(C,N,E)^-$ (E = N′, S or P) ferrocenyl ligands have attracted great interest in recent years,[12–17] mainly because of their applications in homogeneous catalysis[16] or in organometallic synthesis.[17] Platinum(II) analogues are less common[18,19] but some of these also exhibit antitumoral activity against cisplatin-resistant cells.[19] Despite *a*) the wide variety of chiral ferrocene derivatives reported so far, *b*) the prochiral nature of the ferrocenyl unit in the metallation process[20] and *c*) the interest in chiral palladium(II) and platinum(II) complexes containing ferrocenyl units, only a few enantio- or diastereomerically pure palladacycles with a σ[Pd–$C(sp^2$,ferrocene)] bond are described,[21,22] and the platinum(II) derivatives are less common.[23] Cycloplatination of [$FcCH_2NMe_2$] (**I**) or [Fc-$C(R^1)$=$NR^2$] (**II**) {Fc = ($\eta^5$-$C_5H_5$)Fe($\eta^5$-$C_5H_4$), $R^1$ = H, Me or Ph, and $R^2$ = OH, $(CH_2)_3NMe_2$ or phenyl groups} led to the enantiomers $R_p$ and $S_p$.[24] Ryabov et al.[23] have re-

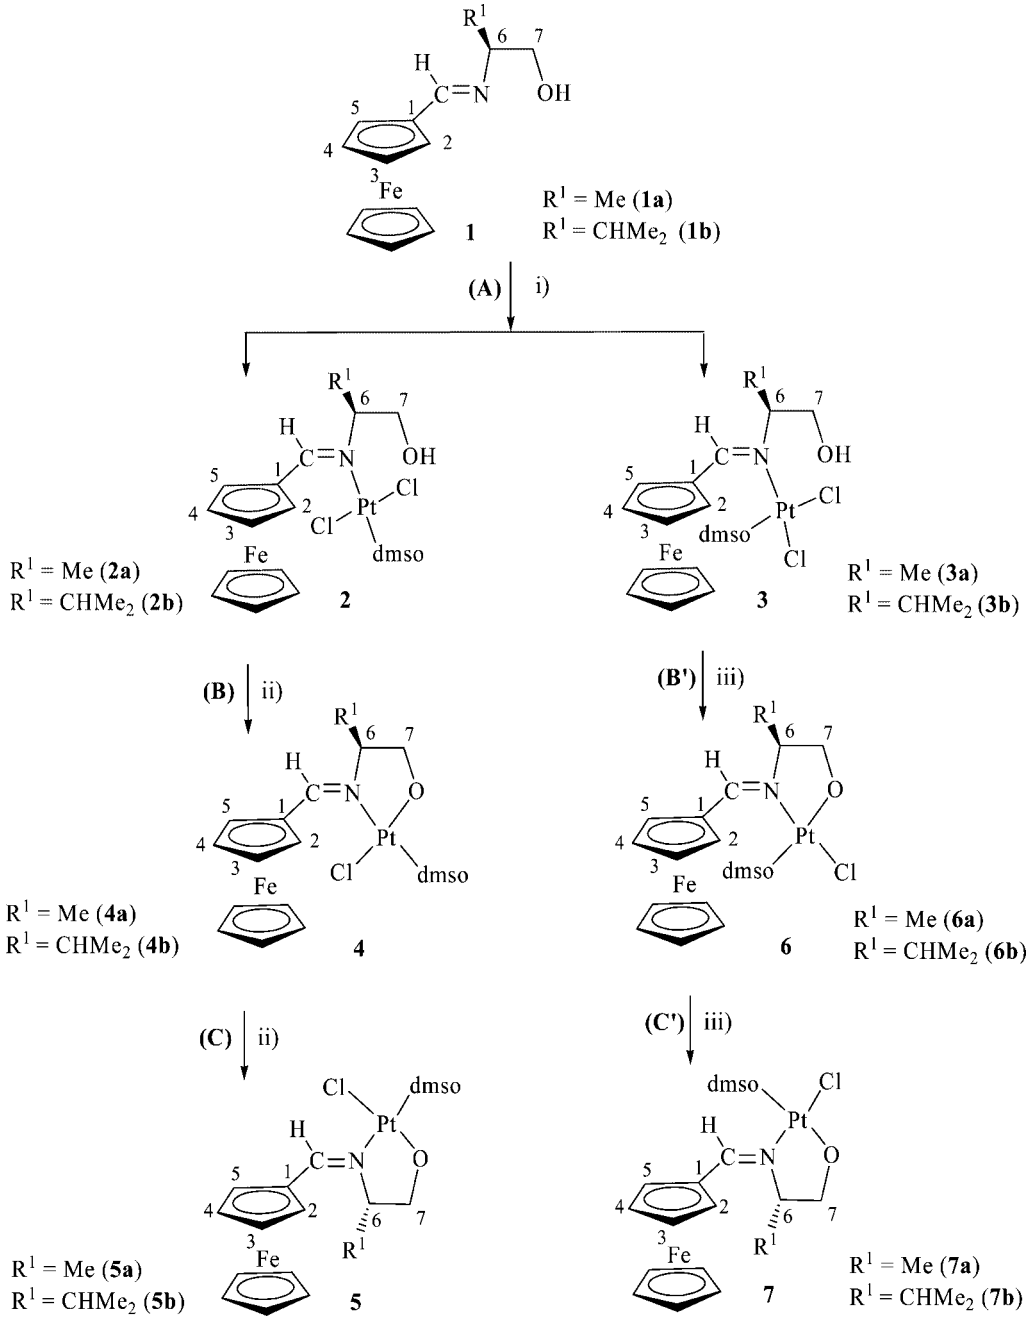
ported the synthesis of the diastereomers ($R_p$,$S_S$) and ($S_p$,$S_S$) of [Pt{[($\eta^5$-$C_5H_3$)$CH_2NMe_2$]Fe($\eta^5$-$C_5H_5$)}Cl-{S(O)Me($C_6H_4$-4Me)}].

In view of these facts and as a part of a project directed towards the preparation of chiral platinum(II) compounds with potentially bi- or tridentate ligands, we prepared the enantiomerically pure ferrocenyl Schiff bases: ($S_C$)-(+)-[FcCH=NCH($R^1$)$CH_2$OH] (**1**) {$R^1$ = Me (**1a**) or $CHMe_2$ (**1b**)} (Scheme 1) and studied their reactivity with *cis*-[$PtCl_2$(dmso)$_2$]. We then *a*) evaluated the potential coordination abilities of these ligands to platinum(II), *b*) achieved a variety of enantio- and diastereomerically pure platinum(II) complexes and *c*) established the best experimental conditions required to achieve the desired chiral platinum(II) compounds. A preliminary account in this field has recently been reported.[25]



Scheme 1. *i*) Equimolar amount of *cis*-[$PtCl_2$(dmso)$_2$] in refluxing methanol for 4 h followed by $SiO_2$ column chromatography (see text). *ii*) Addition of NaOD (in [$D_4$]methanol) to a solution of **2** or **4** in chloroform. For molar ratios NaOD/**2** = 1 compounds **4** were the major components. The complete conversion of **2** (or **4**) into **5** requires molar ratios NaOD/**2** = 1.8. The formation of **5a** was achieved at room temperature, but that of **5b** required the reaction mixture to be warmed up at 333 K for 1.5 h (see text). *iii*) The method used was identical to that of (*ii*), but because of the small amount of compounds **3** available the intermediate species **6** were detected by NMR but they were not isolated using this procedure. A more effective method to achieve compounds **7** is presented in the text.

## Results and Discussion

### The Ligands

The ferrocenyl Schiff bases ($S_C$)-(+)-[FcCH=NCH($R^1$)-$CH_2OH$] {$R^1$ = Me (**1a**) or $CHMe_2$ (**1b**)} were prepared following the procedure described for [FcCH=$NR^2$] with $R^2$ = phenyl, benzyl groups.[26] This method consists in the reaction of equimolar amounts of ferrocenecarboxaldehyde (FcCHO) and the amine under reflux using a Dean–Stark apparatus. When ($S_C$)-(+)-$H_2$NCH($R^1$)$CH_2OH$ ($R^1$ = Me or $CHMe_2$) was used, the process yielded **1a** and **1b**, respectively. Elemental analyses of **1a** and **1b**[27] agreed with those expected for [FcCH=N–CH(Me)$CH_2OH$] and [FcCH=NCH($CHMe_2$)$CH_2OH$]·$H_2O$, respectively and NMR spectra suggested, according to the literature,[26] that they adopted the *anti*-(*E*) conformation in solution. The crystal structure of **1b**·$H_2O$ (Figure 1) consists of equimolar amounts of [FcCH=NCH($CHMe_2$)-$CH_2OH$] and $H_2O$ molecules. The >C=N- bond length [1.172(11) Å] is slightly shorter than the values reported for [FcC($R^3$)=$NR^2$] ($R^3$ = H, Me or Ph and $R^2$ = phenyl, benzyl or naphthyl substituents),[26,28] the imine moiety forms an angle of 4.80(9)° with the $C_5H_4$ ring and the value of the torsion angle C(10)–C(11)–N–C(12) [176.6(11)°] is consistent with the *anti*-(*E*) conformation.

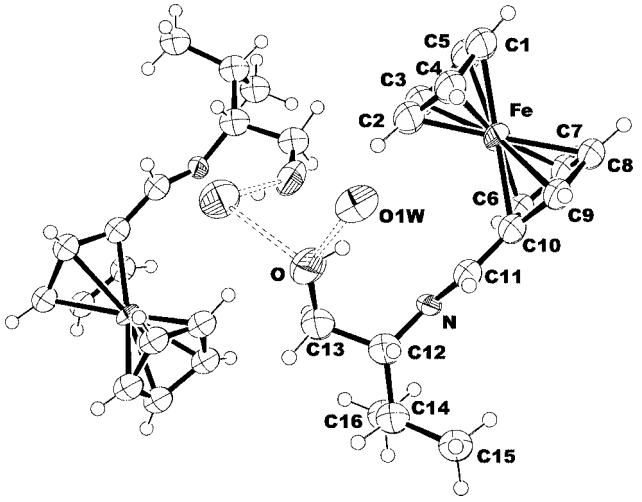

Figure 1. Molecular structure and atom labelling scheme for ($S_C$)-(+)-[FcCH=NCH($CHMe_2$)$CH_2OH$] (**1b**)·$H_2O$ showing the H–O···H interactions. Selected bond lengths (Å) and angles (°): O–C(13) 1.523(13), N–C(11) 1.172(11), N–C(12) 1.396(9), C(10)–C(11) 1.365(9), C(12)–C(13) 1.520(9), C(12)–C(14) 1.523(12), C(14)–C(15) 1.544(10), C(14)–C(16) 1.373(13), C(6)–C(10)–C(11) 117.3(4), C(9)–C(10)–C(11) 132.7(4), C(11)–N–C(12) 134.5(12), N–C(11)–C(10) 144.4(17), N–C(12)–C(13) 113.3(6), N–C(12)–C(14) 121.2(10), C(13)–C(12)–C(14) 115.9(7), C(12)–C(13)–O 112.7(8), C(16)–C(14)–C(12) 102.3(10), C(16)–C(14)–C(15) 119.1(10), C(12)–C(14)–C(15) 110.4(8).

Bond lengths and angles of the Fc moiety agree with those reported for most ferrocene derivatives,[29] and the two pentagonal rings are planar and nearly parallel {tilt angle = 3.6(5)°}, deviating by about 7.35° from the ideal eclipsed conformation. In the crystal, the distance between the hydrogen of the O–H group of the ligand and the oxygen of the water molecule, O(1W), is 2.696(13) Å and the O–H···O bond angle is 113.98°, thus suggesting a weak O–H(10)···O(1W) intermolecular interaction.

### Platinum(II) Compounds

In a first attempt to evaluate the potential coordination abilities of the ferrocenyl Schiff bases **1** to platinum(II), their reactivity with *cis*-[$PtCl_2$(dmso)$_2$] under different experimental conditions was studied. Because of the variety of products isolated, the most representative results obtained are in Table 1 and Scheme 1.

When **1a** (or **1b**) was treated with *cis*-[$PtCl_2$(dmso)$_2$] in refluxing methanol for 4 h, two compounds were isolated {Table 1, entries ***Ia*** and ***Ib*** and Scheme 1, step (A)}. One of these was identified as FcCHO. The $^1$H NMR spectrum of the crude materials showed the typical resonances of this product. This suggests that it hydrolyses during the reaction with residual water in the solvent. Examples of a partial hydrolysis of related Schiff bases induced by the presence of palladium(II) or platinum(II) salts have been reported in the literature.[24c,30] The first portions of the second band gave [Pt{FcCH=NCH($R^1$)$CH_2OH$}$Cl_2$(dmso)] {$R^1$ = Me (**2a**) or $CHMe_2$ (**2b**)} and the remaining ones produced orange solids containing **2a** (or **2b**) and traces of an additional isomer (**3a** and **3b**, respectively). Longer refluxing periods (6 h) did not substantially improve the molar ratios **2a/3a** and **2b/3b** (1.00:0.10 and 1.00:0.11, respectively).

Previous $^1$H NMR spectroscopic studies of platinum(II) and palladium(II) complexes derived from imines have shown that the chemical shift of the methinic proton is indicative of the conformation of the ligand.[24b,26,30–35] If the imine is in the *syn*-(*Z*) form in the complexes, the signal of the imine proton is shifted downfield relative to the free ligand because of the paramagnetic anisotropy of the metal,[34] which is close to this proton. In contrast, for compounds where the imine is in the *anti*-(*E*) form the resonance of the methinic proton is high-field shifted. The comparison of $^1$H NMR spectra of **2** and **3** with those of their parent ligands **1** indicated that in **2a**, **3a**, **2b** and **3b** the ligands had the *anti*-(*E*) conformation and {$^1$H-$^1$H}-NOESY spectra confirmed this result. Fractional crystallisation of the solids containing the isomeric forms enabled the isolation of small amounts of **3a** and **3b** and highly enriched (about 98%) **2a** and **2b**. Characterisation data of **2**–**3a**,**b**[27] agreed with the formulas presented in Scheme 1.

The crystal structure of **3b** consists of discrete molecules of [Pt{FcCH=NCH($CHMe_2$)$CH_2OH$}$Cl_2$(dmso)] separated by van der Waals contacts (Figure 2). The platinum(II) is in a slightly distorted square-planar environment bound to the imine nitrogen, the sulfur of the S(O)$Me_2$ ligand and two chlorines {Cl(1) and Cl(2)}. The Pt–S bond length [2.194(4) Å] agrees with the values reported for other platinum(II) complexes with dimethyl sulfoxide.[12,24,29,35] The chloro ligands are in a *cis* arrangement and the value of the torsion angle C(1)–C(11)–N(12)–C(13) [179.6(14)°] is consistent with an *anti*-(*E*) conformation. Because of the

Table 1. Summary of the experimental conditions [reagents, solvents, temperature ($T$) and reaction periods ($t$)] used in the studies of the reactivity of **1** with *cis*-[$PtCl_2(dmso)_2$], which is abbreviated as [Pt], or of some of the platinum(II) complexes together with the products isolated in these reactions.

| Entry | Reagent (molar ratio) | Solvent | $T$ [K] | $t$ | Final products[a] (molar ratios) |
|---|---|---|---|---|---|
| ***Ia*** | **1a** and [Pt] (1:1) | MeOH | reflux | 4 h | **2a** and **3a** [b] |
| ***Ib*** | **1b** and [Pt] (1:1) | MeOH | reflux | 4 h | **2b** and **3b** (1.00:0.05) |
| ***IIa*** | **2a** and NaOD (1:1) | $CDCl_3$/MeOD | 298 | 5 min | **4a** |
| ***IIb*** | **2b** and NaOD (1:1) | $CDCl_3$/MeOD | 298 | 5 min | **4b** |
| ***IIIa*** | **2a** and NaOD (1:1.8) | $CDCl_3$/MeOD | 298 | 5 min | **5a** |
| ***IIIb*** | **2b** and NaOD (1:1.8) | $CDCl_3$/MeOD | 333 | 1.5 h | **5b** |
| ***IVa*** | **2a** and NaOAc (1:2) | MeOH/toluene[c] | reflux | 72 h | **8a** and **9a** (1:1) |
| ***IVb*** | **2b** and NaOAc (1:2) | MeOH/toluene[c] | reflux | 72 h | **8b** and **9b** (1:1) |
| ***Va*** | **1a**, [Pt] and NaOAc (1:1:2) | MeOH/toluene[c] | reflux | 72 h | **8a** and **9a** (1:1) |
| ***Vb*** | **1b**, [Pt] and NaOAc (1:1:2) | MeOH/toluene[c] | reflux | 72 h | **8b** and **9b** (1:1) |
| ***VIa*** | **8a** (or **8b**) and NaOD[d] (1:1) | $CHCl_3$/MeOH[d] | 298 | | **10a** (or **10b**) |
| ***VIb*** | **9a** (or **9b**) and NaOD[d] (1:1) | $CHCl_3$/MeOH[d] | 298 | | **11a** (or **11b**) |

[a] In entries ***Ia,b*** and ***IV–Va,b*** small amounts of FcCHO were also isolated as a byproduct. $^1$H NMR spectra of the crude materials obtained also showed the presence of this aldehyde, thus suggesting that the formation of FcCHO takes place during the reaction because of residual water in the solvent and that it is not a byproduct generated in the course of the work-up of the column. [b] The presence of a small amount of **3a** (about 5 mg) was detected. [c] A (1:4) mixture. [d] Saturated solution of NaOD in [$D_4$]methanol.

similarity between the NMR spectroscopic data[27] of **3a** and **3b** we assumed that the environment of the platinum(II) in **3a** is the same as in **3b** and consequently, in **2a** and **2b** the two $Cl^-$ ligands would be in a *trans* arrangement.

On the other hand, the presence of the OH group in the dangling arm of **2** and **3** prompted us to study whether the addition of a base could induce the deprotonation of the OH group and the formation of enantiomerically pure platinum(II) complexes containing imines **1** acting as bidentate $(N,O)^-$ ligands. In a first attempt to achieve this aim, the reactions of **2a** (in $CDCl_3$) with NaOD dissolved in methanol (in molar ratios NaOD/**2a** varying from 0.2 to 1.8) were studied on an NMR scale {Scheme 1, steps (B) and (C)}. The results showed that, for molar ratios smaller than 0.4, **2a** and a new platinum(II) complex (**4a**) coexisted in solution. As can be easily seen in Figure 3, the proportion **2a**/**4a** decreased as the molar ratio NaOD/**2a** increased and for a NaOD/**2a** ratio of 1 (Table 1, entry ***IIa***) the major product was **4a** and only traces of **2a** and of a new byproduct (hereafter referred to as **5a**) were detected. NMR studies revealed that in **4a** the ligand adopted the *anti*-(*E*) conformation and behaved as a $(N,O)^-$ bidentate ligand. In view of the characterisation data available,[27] for **4a** we postulate the chemical formula depicted in Scheme 1. An increase of the NaOD/**2a** molar ratio (up to 1.8) reduced the relative abundance of **2a** and **4a** compared with that of **5a** and the complete conversion of **2a** into **5a** was achieved

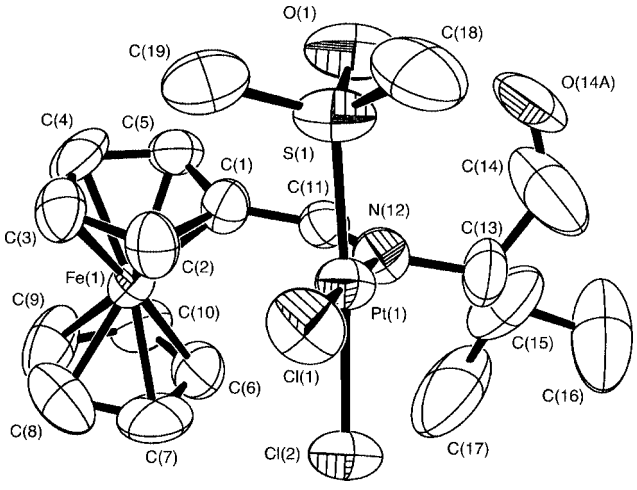

Figure 2. ORTEP plot of *cis*-($S_C$)-[Pt{FcCH=NCH(CHMe$_2$)-CH$_2$OH}Cl$_2$(dmso)] (**3b**). Thermal ellipsoids at 50% probability; hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Pt(1)–Cl(1) 2.294(4), Pt(1)–Cl(2) 2.306(4), Pt(1)–N(12) 2.041(11), Pt(1)–S(1) 2.194(4), C(1)–C(11) 1.431(18), C(11)–N(12) 1.322(16), N(12)–C(13) 1.496(19), C(13)–C(14) 1.45(3), C(14)–O(14A) 1.26(4), C(13)–C(15) 1.46(3), C(15)–C(16) 1.58(4), C(15)–C(17) 1.583(5), Cl(1)–Pt(1)–Cl(2) 89.75(16), Cl(1)–Pt(1)–S(1) 90.71(18), S(1)–Pt(1)–N(12) 91.1(4), N(12)–Pt(1)–Cl(2) 88.6(4), C(1)–C(11)–N(12) 128.9(12), C(11)–N(12)–C(13) 118.1(16), N(12)–C(13)–C(14) 114.2(19), N(12)–C(13)–C(15) 118.1(16).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

using NaOD/**2a** = 1.8 {Table 1, entry ***IIIa*** and Scheme 1, step (C)}. Similar results were obtained when these experiments were performed using **2b** (Table 1, entries ***IIb***–***IIIb***),[36] showing the formation of an intermediate complex **4b**, which could be partially transformed into **5b** upon the addition of NaOD {Scheme 1, steps (B) and (C)}. The reaction **4b** → **5b** at 298 K was slower than the process **4a** → **5a**, but it could be accelerated by warming at 333 K. Characterisation data of **5**[27] were consistent with those expected for the isomeric form of [Pt{FcCH=NCH($R^1$)$CH_2$O}-Cl(dmso)] {$R^1$ = Me (**5a**) or $CHMe_2$ (**5b**)} that contains a $(N,O)^-$ bidentate imine [in a *syn*-(*Z*) conformation] and a *trans* arrangement between the oxygen and the $Cl^-$ ligand.

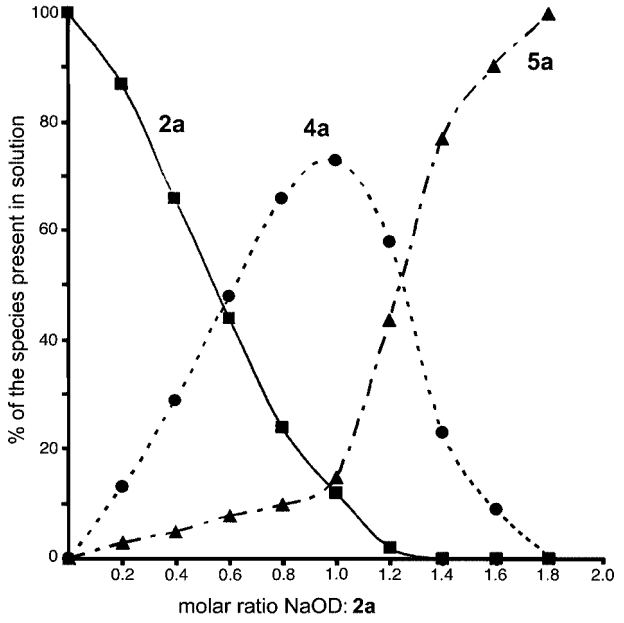

Figure 3. Graphic plot showing the dependence of the relative abundance (in %) of compounds **2a** (squares), **4a** (circles) and **5a** (triangles) on the molar ratios NaOD/**2a**.

The different ease with which **4a** and **4b** undergo the *anti*-(*E*) → *syn*-(*Z*) isomerisation of the ligand could be attributed to the different bulk of the substituents (Me or $CHMe_2$) on the stereogenic carbon.

All these findings suggest that: *a*) NaOD promotes the conversions of **2a** into **4a** and **5a** (or of **2b** into **4b** and **5b**) and *b*) these reactions proceed in two consecutive steps: the formation of the five-membered chelate ring, followed by the *anti*-(*E*) → *syn*-(*Z*) isomerisation of the imine.

In order to evaluate the potential reversibility of these reactions, the action of DCl on **5a** (or **5b**) was also studied. In all cases FcCHO was isolated as the major product and only traces of **2a** (or **2b**) could be detected by $^1$H NMR spectroscopy. This suggests that: *a*) the hydrolysis of the coordinating ligand was promoted in acidic media and *b*) the transformations **5a** → **2a** and **5b** → **2b** were not feasible under these experimental conditions.

Similarly, the reaction of **3a** (or **3b**) with NaOD gave **7a** (or **7b**) {Scheme 1, steps (B′) and (C′)}. However, the effectiveness of this procedure is limited because of the small amounts of **3a** or **3b** available from experiments ***Ia***,***b***. In these reactions, evidence of the formation of intermediate species (**6a** and **6b**, in Scheme 1) was also detected by NMR spectroscopy.

Compounds **7** could be isolated in a higher yield using an alternative path that consists in the treatment of equimolar amounts of the corresponding ligand, *cis*-[$PtCl_2$(dmso)$_2$] and NaOAc in refluxing methanol for 72 h.[37] These reactions lead to mixtures of FcCHO and the platinum(II) complexes **2**, **3**, **5** and **7** (in molar ratios **2a/3a/5a/7a** = 0.51:0.40:0.02:1.00 and **2b/3b/5b/7b** = 0.41:0.20:0.26:1.00). Characterisation data of **7**[27] agreed with the proposed formulae and complex **7b**·$CH_2Cl_2$·1/2$H_2O$ was also characterised by X-ray diffraction.

The crystal structure is formed by molecules of [Pt{FcCH=NCH($CHMe_2$)$CH_2$O}Cl(dmso)] (Figure 4), $CH_2Cl_2$ and $H_2O$ in a 1:1:0.5 molar ratio. In the heterodimetallic molecules, the platinum(II) is bound to a chloride, the sulfur of the dmso ligand, the nitrogen and the oxygen of ligand **1b** in a slightly distorted square-planar environment. Bond lengths and angles around the platinum(II) agreed with those of related compounds containing similar cores.[29] The values of the Cl(1)–Pt–O(14) bond angle [85.5(6)°] indicate a *cis* arrangement between the Cl(1) and the oxygen of the ligand and consequently the $S_{(dmso)}$ and N atoms occupy adjacent positions of the coordination plane. The metallacycle has an envelope-like conformation in which the C(13) atom deviates by about 0.667 Å (towards the $Fe^{II}$ atom) from the mean plane. The ligand adopts the *syn*-(*Z*) form, the >C=N– group is not included in the five-membered chelate ring and the C(11)–N(12) bond length is similar to those of other platinum(II) compounds containing ferrocenyl or organic imines.[24b,24c,29,30,35]

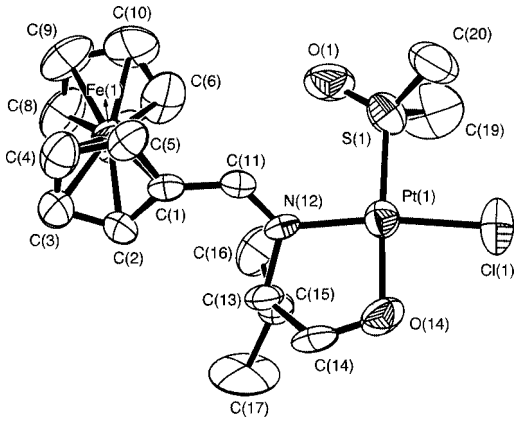

Figure 4. ORTEP plot of ($S_C$)-[Pt{FcCH=NCH($CHMe_2$)-$CH_2$O}Cl(dmso)] (**7b**). Thermal ellipsoids at 50% probability; hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Pt(1)–Cl(1) 2.310(7), Pt(1)–S(1) 2.194(8), Pt(1)–N(12) 2.013(18), Pt(1)–O(14) 1.956(19), C(1)–C(11) 1.44(3), C(11)–N(12) 1.28(3), C(14)–O(14) 1.42(4), C(13)–C(15) 1.45(4), C(15)–C(16) 1.56(4), C(15)–C(17) 1.60(4), N(12)–Pt(1)–O(14) 96.5(5), O(14)–Pt(1)–Cl(1) 85.5(6), Cl(1)–Pt(1)–S(1) 92.4(3), S(1)–Pt(1)–N(12) 96.8(5), Pt(1)–O(14)–C(14) 109.4(15).

More interesting were the results obtained when compounds **2** were treated with sodium acetate (in a molar ratio $AcO^-$:**2** = 2) in a toluene/methanol (4:1) mixture under re-

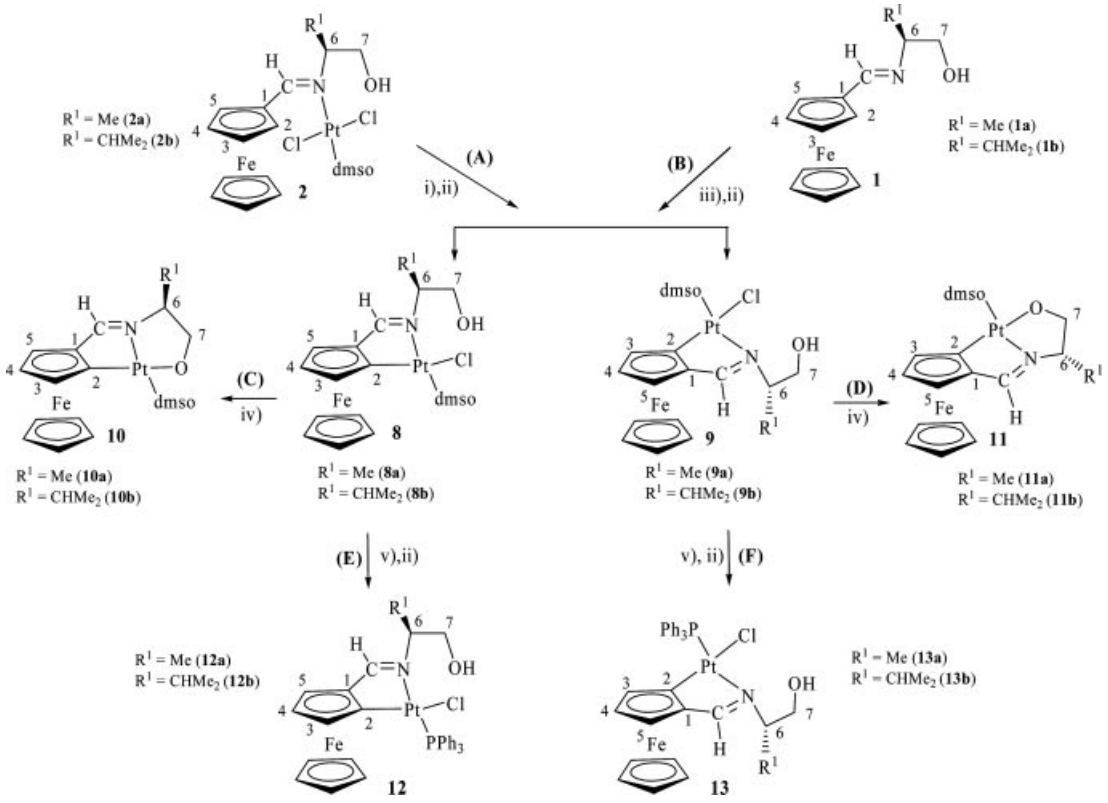
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

flux for 72 h {Scheme 2, step (A) and Table 1, entries ***IVa*** and ***IVb***}. These reactions gave FcCHO and purple solids whose elemental analyses[27] were consistent with those expected for the platinacycles [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)-$CH_2OH$]Fe($\eta^5$-$C_5H_5$)}Cl(dmso)] and their $^1$H NMR spectra showed two sets of superimposed signals of identical intensity. These platinum(II) complexes arise from the activation of the σ[C($sp^2$,ferrocene)–H] bond and because of the prochiral nature of the ferrocenyl moiety in process,[1a,20,21,22b,23,24] the duplicity of the signals detected in their NMR spectra could be attributed to the presence of diastereomers of [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)$CH_2OH$] Fe($\eta^5$-$C_5H_5$)}Cl(dmso)] {**8** and **9**; $R^1$ = Me ($S_p$,$S_C$) (**8a**) and ($R_p$,$S_C$) (**9a**) or $R^1$ = $CHMe_2$ ($S_p$,$S_C$) (**8b**) and ($R_p$,$S_C$) (**9b**)}. Their characterisation data[27] and the crystal structures of two of these compounds (**8b** and **9a**) (see below) confirmed this result.

Compounds **8** and **9** could also be isolated when a mixture of the corresponding ligand **1**, *cis*-[$PtCl_2(dmso)_2$] and NaOAc (in a 1:1:2 molar ratio) was dissolved in a toluene/methanol (4:1) mixture and refluxed for 72 h {Scheme 2, step (B) and Table 1, entries ***Va*** and ***Vb***}. This is an alternative and more effective path to achieve compounds **8**–**9a**,**b** (with slightly higher yields and in shorter times) than that shown in entries ***IVa*** and ***IVb*** and Scheme 2, step (A).

The two diastereomers of [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)-$CH_2OH$]Fe($\eta^5$-$C_5H_5$)}Cl(dmso)] {**8** and **9**; $R^1$ = Me ($S_p$,$S_C$) (**8a**) and ($R_p$,$S_C$) (**9a**) or $R^1$ = $CHMe_2$ ($S_p$,$S_C$) (**8b**) and ($R_p$,$S_C$) (**9b**)} were separated and characterised.[27] The crystal structure of **8b** was reported in a preliminary communication[25] and that of **9a** consists of two nonequivalent molecules (**I** and **II**) of [Pt{[($\eta^5$-$C_5H_3$)CH=NCH(Me)$CH_2OH$]-Fe($\eta^5$-$C_5H_5$)}Cl(dmso)] (Figure 5) separated by van der Waals contacts. In molecules **I** and **II**, the platinum(II) atom is bound to a chlorine {Cl(1) or Cl(1A)}, the sulfur {S(1) or S(1A)} of the dmso ligand, the nitrogen {N(1) or N(1A)} and the carbon atoms {C(6) (in **I**) or C(6A) (in **II**)}. This results in a slightly distorted square-planar environment. Bond lengths around the platinum(II) atom are similar to those of other platinacycles with "Pt(C,N)-$ClS_{(dmso)}$" cores.[12,18,29] The values of the bond angles Cl(1)–Pt(1)–N(1) and Cl(1A)–Pt(1A)–N(1A) {91.7(8)° and 95.2(9)°, respectively} indicate that the $Cl^-$ and the N are in a *cis* arrangement. The platinacycles are nearly planar and the large separation between the $Fe^{II}$ and the $Pt^{II}$ atoms precludes the existence of any direct interaction between them.

The main difference between molecules **I** and **II** arises from the relative orientation of the pendant OH arm. The values of the torsion angles O(2)–C(14)–C(12)–C(13) and



Scheme 2. *i*) In toluene, addition of NaOAc (in a NaOAc:**2** molar ratio of 2) dissolved in methanol followed by a reflux of the reaction mixture for 72 h (see text). *ii*) $SiO_2$ column chromatography. *iii*) *cis*-[$PtCl_2(dmso)_2$] and NaOAc in a molar ratio **1**/$Pt^{II}$/NaOAc = 1:1:2 in a toluene/methanol (4:1) mixture under reflux for 72 h (see text). *iv*) Addition of the stoichiometric amount of NaOD dissolved in methanol. *v*) In benzene followed by the addition of the equimolar amount of $PPh_3$ and stirring at 343 K for 1 h.

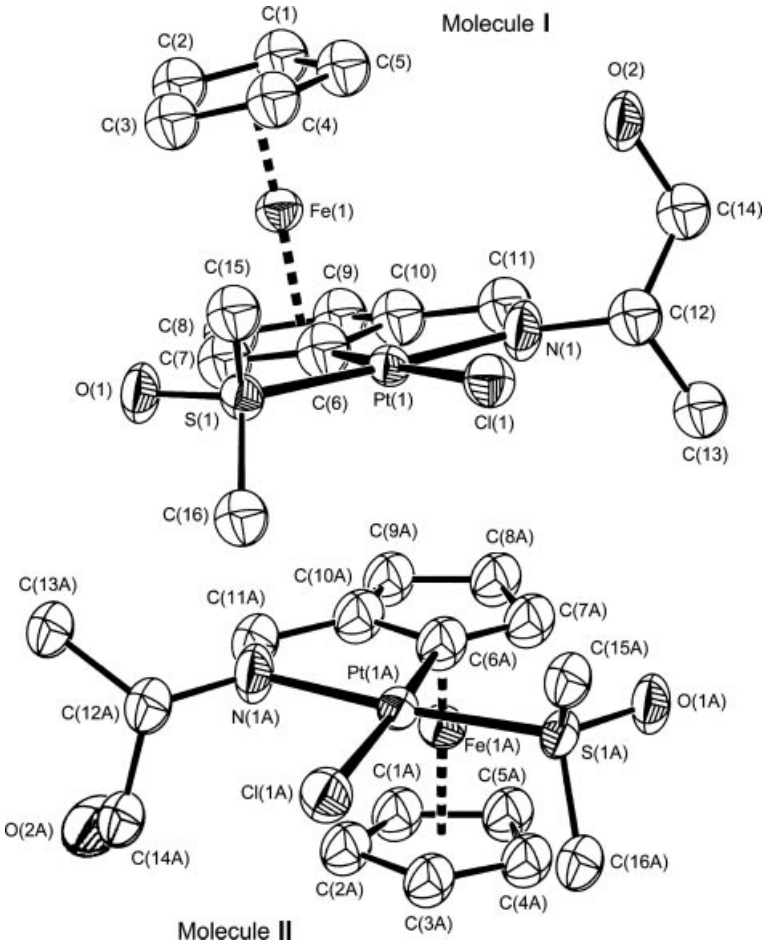

Figure 5. ORTEP plot of ($R_p$,$S_C$)-(+)-[Pt{[($\eta^5$-$C_5H_3$)CH=NCH(Me)$CH_2$OH]Fe($\eta^5$-$C_5H_5$)}Cl(dmso)] (**9a**). Thermal ellipsoids at 50% probability; hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Pt(1)–C(6) 2.01(3), Pt(1)–N(1) 2.05(2), Pt(1)–S(1) 2.214(2), Pt(1)–Cl(1) 2.427(8), C(10)–C(11) 1.40(4), N(1)–C(11) 1.26(3), N(1)–C(12) 1.50(2), O(2)–C(14) 1.40(3), Pt(1A)–C(6A) 2.03(3), Pt(1A)–N(1A) 2.01(3), Pt(1A)–S(1A) 2.197(8), C(10A)–C(11A) 1.46(4), N(1A)–C(11A) 1.24(4), N(1A)–C(12A) 1.51(4), O(2A)–C(14A) 1.42(3), C(6)–Pt(1)–N(1) 81.5(12), C(6)–Pt(1)–S(1) 97.8(10), N(1)–Pt(1)–Cl(1) 91.7(8), S(1)–Pt(1)–Cl(1) 89.0(3), C(6A)–Pt(1A)–N(1A) 78.6(12), C(6A)–Pt(1A)–S(1A) 95.9(9), N(1A)–Pt(1A)–Cl(1A) 95.2(9), S(1A)–Pt(1A)–Cl(1A) 90.4(3).

O(2A)–C(14A)–C(12A)–C(13A) are 174(2)° and 61(3)°; as a consequence of this arrangement the separation between the $Fe^{II}$ and the oxygen of the OH group in **I** is greater than in **II**.

The formation of platinacycles of general formula [Pt(C,N)Cl(dmso)] {$(C,N)^-$ = cyclometallated imine (L)} from [Pt(L)$Cl_2$(dmso)] requires a proper orientation between the σ(C–H) bond to be activated and the platinum(II)[1a,38] and the release of one of the $Cl^-$ ligands. The formation of a nearly equimolar ratio of **8** and **9** can be explained assuming a free rotation around the $C_{ipso}$–$C_{imine}$ bond of **2a** or **2b**. A similar argument has been used for the cyclopallada- or cycloplatination of several 1,1′-ferrocenyldiimines or diamines.[39]

In order to explore the coordinating ability of the oxygen to the platinum(II) and the potential hemilability[40] of the σ(Pt–O) bond, solutions of **8a**, **8b**, **9a** or **9b** were treated separately with the equimolar amount of NaOD. In all cases, the corresponding diastereomer of [Pt{[($\eta^5$-$C_5H_3$)-CH=NCH($R^1$)$CH_2$O]Fe($\eta^5$-$C_5H_5$)}(dmso)][27] {**10** and **11**; $R^1$ = Me ($S_p$,$S_C$) (**10a**) and ($R_p$,$S_C$) (**11a**) or $R^1$ = $CHMe_2$ ($S_p$,$S_C$) (**10b**) and ($R_p$,$S_C$) (**11b**)} {Scheme 2, steps (C) and (D)} was isolated. These compounds arise from the activation of the σ(O–H) bond. In their $^1$H NMR spectra the signal due to the imine proton exhibited the typical satellites due to the coupling with the $^{195}$Pt nucleus and appeared at higher fields than for the parent complex. Besides, the resonance of the $^{13}$C nuclei of the "$>CHCH_2$–" moiety shifted downfield. These findings suggested, in keeping with the bibliography,[41] a $(C,N,O)^{2-}$ mode of binding of the ligand.

Solutions of **10** and **11** (in $CDCl_3$) changed with time and after 3 days the spectra revealed the coexistence of the pairs (**8** and **10**) or (**9** and **11**) (molar ratios **8a/10a** = 1.1, **9a/11a** = 1.0, **8b/10b** = 1.5 and **9b/11b** = 0.9). The addition of DCl to solutions of **10** (or **11**) gave **8** (or **9**) and subsequent cycles exposing **8** or **9** to acidic and basic conditions showed that the transformations **8** ↔ **10** and **9** ↔ **11** were reproducible and robust, enabling these systems to function as a simple molecular switch.[42] Therefore, the deproton-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ation of the OH group by the action of a base and the subsequent intramolecular replacement of the adjacent chloride moiety can be easily tuned by manipulating the acidity/basicity of the media. Examples of diastereomerically pure metallacycles exhibiting this behaviour are still unknown.

Finally, and in order to elucidate the potential utility of the platinacycles [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)$CH_2$OH]-Fe($\eta^5$-$C_5H_5$)}Cl(dmso)] (**8** and **9**) as precursors for the synthesis of other diastereomerically pure platinum(II) derivatives, we studied the reactions of **8**–**9a**,**b** with $PPh_3$. In all cases, the platinacycles [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)-$CH_2$OH]Fe($\eta^5$-$C_5H_5$)}Cl($PPh_3$)] {**12**–**13**; $R^1$ = Me ($S_p$,$S_C$) (**12a**) and ($R_p$,$S_C$) (**13a**) or $CHMe_2$ ($S_p$,$S_C$) (**12b**) and ($R_p$,$S_C$) (**13b**)} {Scheme 2, steps (E) and (F)} were isolated. $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectroscopic data[27] for **12**–**13** were consistent with those reported for other platinacycles containing a cyclometallated Schiff base,[24b,24c,43] in which the phosphane and the metallated carbon are in a *cis* arrangement, in good agreement with the *transphobia effect*.[44]

In summary, the results presented have allowed us to establish the best experimental conditions to selectively control the mode of binding {(N), $(N,O)^-$, [C($sp^2$,ferrocene),N]$^-$ or [C($sp^2$,ferrocene),N,O]$^{2-}$} of ligands **1** to platinum(II). For each one of the ligands, three different pairs of enantiomerically pure complexes (**2**–**7a**,**b**) are isolated. These compounds differ in the mode of binding of the ferrocenyl ligand {N-donor group (in **2** and **3**) or a monoanionic $(N,O)^-$ group (in **4**–**7**)}, or in the relative arrangement between: *a*) the monodentate ligands bound to platinum(II) (in **2** and **3**), *b*) these groups and the two heteroatoms of the ferrocenyl Schiff base (in **4**–**7**) or *c*) the conformation of the ligand *anti*-(*E*) (in **4** and **6**) or *syn*-(*Z*) (in **5** and **7**). Moreover, these studies also enable the isolation of the diastereomerically pure platinacycles: [Pt{[($\eta^5$-$C_5H_3$)-CH=NCH($R^1$)$CH_2$OH]Fe($\eta^5$-$C_5H_5$)}Cl(L)] {L = dmso (**8** and **9**) or $PPh_3$ (**12** and **13**)} and [Pt{[($\eta^5$-$C_5H_3$)-CH=NCH($R^1$)$CH_2$O]Fe($\eta^5$-$C_5H_5$)}(dmso)] (in **10** and **11**) {with a [C($sp^2$,ferrocene),N]$^-$ or [C($sp^2$,ferrocene),N,O]$^{2-}$ ligand, respectively}. As far as we know, chiral ligands exhibiting such interesting and versatile modes of binding to transition metals and, in particular, to platinum(II) have not been described so far.

The studies undertaken also showed the outstanding reactivity of compounds **2** and their utility for the preparation of a wide variety of chiral platinum(II) complexes by: *a*) activation of the σ(O–H) to give **4** {which may be transformed into **5** by the subsequent isomerisation *anti*-(*E*) → *syn*-(*Z*) of the coordinated Schiff base, Scheme 1, steps (B) and (C)} or *b*) the cycloplatination of the ferrocenyl unit {Scheme 2, step (A)} to give the diastereomers **8** and **9**. In the presence of NaOH, **8** (or **9**) evolve to the chiral derivatives **10** (or **11**) with a [C($sp^2$,ferrocene),N,O]$^{2-}$ ligand {Scheme 2, steps (C) and (D)}. Moreover, the reactivity of **2** through pathways (B) and (A) in Scheme 1 and Scheme 2, respectively, can be easily controlled by the appropriate selection of the reagent (NaOH or NaOAc) and the solvent. The use of equimolar amounts of NaOH and MeOH as solvent promotes the formation of the coordination compounds with $(N,O)^-$ bidentate ligands (**4**), while larger excesses induce the *anti*-(*E*) → *syn*-(*Z*) isomerisation of the ligands giving **5**. The replacement of NaOH by NaOAc and the decrease of the polarity of the reaction media promotes the activation of the σ[C($sp^2$,ferrocene)–H] bond, giving the platinacycles **8** and **9**, which can be easily transformed into [Pt{[($\eta^5$-$C_5H_3$)CH=NCH($R^1$)$CH_2$O]Fe($\eta^5$-$C_5H_5$)}(dmso)] (**10** and **11**) {with a [C($sp^2$,ferrocene),N,O]$^{2-}$ ligand}. Platinacycles **8**–**13** are especially attractive as they may be used as starting materials for the synthesis of a wide variety of diastereomerically pure platinum(II) compounds, or even platinum(IV) derivatives (through oxidative addition reactions). Furthermore, the results presented have demonstrated that the interconversion between the pairs of the corresponding diastereomerically pure platinacycles (**8** and **10** or **9** and **11**) can be viewed as an acid–base controlled molecular switch.[42] These transformations modify the hapticity of the ligand and are particularly relevant in view of the potential utility of **8**–**11** in homogeneous catalysis. Moreover, the environments around the platinum(II) in **2**, **3**, **8** and **9** are similar to those of [Pt{[($\eta^5$-$C_5H_3$)$CH_2$N$Me_2$]-Fe($\eta^5$-$C_5H_5$)}Cl(dmso)] or [Pt{Fc$CH_2$N$Me_2$}$Cl_2$(dmso)],[19] which exhibit antitumoral activity, and consequently they are also interesting from this point of view.

Finally, preliminary results reveal that the procedures described here can also be extended to other imino-alcohols derived from **1** by the replacement of the ferrocenyl group by a phenyl {i.e. ($S_C$)-$C_6H_5$CH=NCH($R^1$)$CH_2$OH with $R^1$ = Me or $CHMe_2$}. Thus, these studies constitute an initial step toward further research focused on the synthesis and the study of the properties and potential applications of a wide variety of novel enantio- or diastereomerically pure platinum complexes.

## Experimental Section

**Materials:** *cis*-[$PtCl_2$(dmso)$_2$] was prepared as described.[45] Ferrocenecarboxaldehyde, ($S_C$)-(+)-$H_2$NCH($R^1$)$CH_2$OH {$R^1$ = Me or $CHMe_2$} and the remaining reagents were obtained from Aldrich and used as received. The methanol was HPLC grade,[46] and the remaining solvents used, except benzene, were dried and distilled before use.[47]

**Instrumentation:** Elemental analyses were carried out at the Serveis Cientifico-Tècnics (University of Barcelona) and Servei de Recursos Cientifics i Tècnics (University Rovira i Virgili, Tarragona). Infrared spectra were obtained with a Nicolet Impact 400 instrument using KBr discs. Proton and the two-dimensional NMR [{$^1$H-$^1$H}-(COSY) and (NOESY) and the {$^1$H-$^{13}$C}-(HSQC) and (HMBC)] experiments were run at 500 MHz with either Varian 500 or Bruker Avance 500DMX instruments. Except where quoted, the solvent used for the $^1$H NMR experiments was $CDCl_3$ (99.9%) and $SiMe_4$ was the internal reference. $^{195}Pt\{^1H\}$ NMR spectra as well as $^{31}P\{^1H\}$ NMR spectra were recorded with a Bruker-250DXR instrument using $CDCl_3$ (99.9%) as solvent and referenced to $H_2[PtCl_6]$ [$\delta^{195}Pt\{H_2[PtCl_6]\}$ = 0.0 ppm] and $P(OMe)_3$ [$\delta^{31}P\{P(OMe)_3\}$ = 140.17 ppm], respectively. In all cases the chemical shifts ($\delta$) are given in ppm and the coupling constants ($J$) in Hz.

[a] Data from ref.[51]

The optical rotations were determined in $CH_2Cl_2$ at 293 K using a Perkin–Elmer 241 MC polarimeter and the concentration used is specified in the characterisation section of each compound. Mass spectra ($FAB^+$) were obtained with a VG-Quattro Fisions instrument using 3-nitrobenzylalcohol (NBA) as matrix.

**Crystallography:** A prismatic crystal of **1b**·$H_2O$ (orange, 0.2×0.1×0.1 mm), **3b** (orange, 0.59×0.16×0.14 mm), **7b**·$CH_2Cl_2$·1/2$H_2O$ (red, 0.53×0.12×0.12 mm) or **9a** (purple, 0.2×0.1×0.1 mm) was selected and mounted on an Enraf–Nonius CAD4 diffractometer. Unit-cell parameters (Table 2) were determined from automatic centring of 25 reflections {in the ranges: 12° < $\Theta$ < 21° (for **1b**·$H_2O$ and **9a**), 8.3° < $\Theta$ < 15.4°(for **3b**) and 8.73° < $\Theta$ < 17.9° (for **7b**·$CH_2Cl_2$·1/2$H_2O$)} and refined by the full-matrix least-squares method. For **3b**, **7b**·$CH_2Cl_2$·1/2$H_2O$ and **9a** Lorentz polarisation corrections and absorption corrections were made.

The structures were solved by direct methods using the SHELXS computer program[48] and refined by the full-matrix least-squares method with the SHELX97 or SHELX93 computer programs.[49] The function minimised was $\Sigma w||F_o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.0434P)^2]^{-1}$ (for **1b**·$H_2O$), $[\sigma^2(I) + (0.1070P)^2 + 9.0330P]^{-1}$ (for **3b**), $[\sigma^2(I) + (0.1467P)^2]^{-1}$ (for **7b**·$CH_2Cl_2$·1/2$H_2O$) and $[\sigma^2(I) + (0.0132P)^2]^{-1}$ (for **9a**) and $P = (|F_o|^2 + 2|F_c|^2)/3$; scattering factors were taken from the literature.[50] The chirality of the structures was determined by the Flack coefficient.[51]

CCDC-299520 to -2999523 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Experimental procedures for the preparation of all the compounds and their characterisation data; graphical plot of the relative abundance of the species present on solution when **2b** was treated with NaOD (Figure S1).

[46] The success of the preparations of compounds **2**–**11a,b** is strongly dependent on the quality of the methanol used. The presence of small amounts of water induces the formation of large amounts of FcCHO and reduces the yields. Thus, the use of MeOH (HPLC grade) is strongly required.

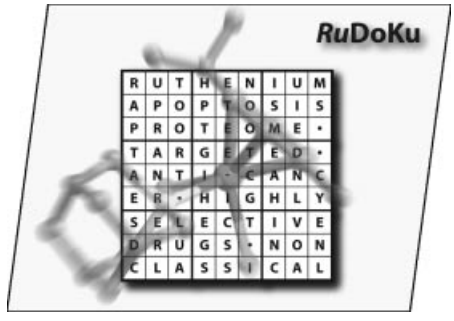
## COVER PICTURE

**The cover picture shows** an organoruthenium antimetastasis compound, superimposed over a Sudoku puzzle, representing the challenge of discovering new anticancer drugs and elucidating their mechanisms of action. One needs to uncover pieces of information which are interrelated, and eventually, the complete "picture" is revealed. In this review, we describe the extent to which the picture has been revealed for ruthenium-based drugs, which are currently growing in interest as a result of recent successes in clinical trials. The emphasis is directed towards classifying the vast array of ruthenium compounds already evaluated in vitro and in vivo against primary and secondary cancers within the context of their probable target. It is hoped that on the basis of the picture presented here more of this intriguing puzzle will be revealed soon. Details are presented in the Microreview by W. H. Ang and P. J. Dyson on p. 4003 ff.



## MICROREVIEW

**Contents**

# Classical and Non-Classical Ruthenium-Based Anticancer Drugs: Towards Targeted Chemotherapy

**Wee Han Ang[a] and Paul J. Dyson*[a]**

**Keywords:** Ruthenium / Anticancer drugs / Targeted chemotherapy / DNA binding / Antimetastasis drugs

Ruthenium-based anticancer chemotherapies are making significant advances in clinical trials. Until recently, the focus has been on coordination complexes, and mechanisms such as "activation by reduction" and "transferrin-targeted delivery" have been proposed to account for the excellent cytotoxicity and low general toxicity of these complexes. More recently organoruthenium compounds, which to some extent appear not to follow the established rules, have started to be investigated. Despite such differences, similar activities between certain coordination and organometallic compounds suggest similar modes of action are present. DNA, the classic target, is believed to be the dominant mechanism for cytotoxicity with certain ruthenium drugs, while with others, non-classical targets are thought to be more important. In this article we describe these features and show how both ruthenium coordination complexes and organoruthenium compounds represent an ideal scaffold for further drug design and optimisation.

## Introduction

The landmark discovery of the antitumoural properties of *cis*-diamminedichloroplatinum(II) (*cisplatin*), by Rosenberg in 1965, heralded a new era of anticancer research based on metallopharmaceuticals.[1] To date, cisplatin and its analogues are some of the most effective chemotherapeutic agents in clinical use (see Figure 1), often as the first line of treatment in testicular and ovarian cancers.[2,3] However, they are not without their problems. In particular, their high toxicity and incidence of drug resistance, acquired or intrinsic, remain the main challenges in their clinical application.[4] These limitations have provided the motivation for alternative chemotherapeutic strategies. For example, *satraplatin* is a platinum(IV) prodrug, that could be orally administered, and is reduced by intracellular biomolecules to yield cytotoxic platinum(II) moieties once inside the cell.[5] Platinum(IV) compounds with functionalised ligands have also been harnessed to defeat glutathione-S-transferase-mediated drug resistance, to target estrogen receptor-positive breast cancer and as a pro-drug for photo-chemotherapy (see Figure 1).[6] There are also a number of platinum(II) compounds that target aspects of cancer cells to enhance uptake and improve selectivity.[7] At the same time, the search for effective anticancer compounds based on other metal centres has intensified. In particular, anticancer drugs based on ruthenium have gained significant prominence.

Ruthenium is an attractive alternative to platinum: besides the rich synthetic chemistry, ruthenium has a range of oxidation states ($Ru^{II}$, $Ru^{III}$ and $Ru^{IV}$) accessible under physiological conditions, which is unique among the platinum-group metals.[8] This feature is significant since the activities of most metal-based anticancer drugs are dependent on their oxidation states. In addition, ruthenium compounds are known to be less toxic than their platinum counterparts.[8–10] This is believed to be due to the ability of ruthenium to mimic iron in the binding to biological molecules, such as albumin and transferrin, although plati-

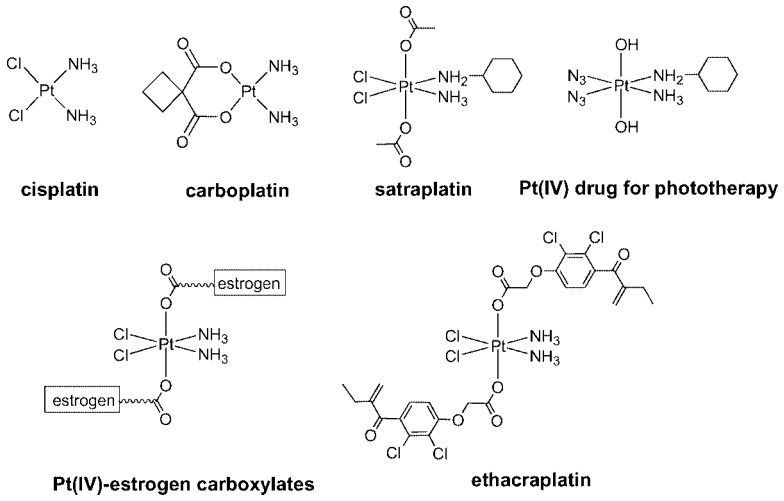

Figure 1. Clinical and preclinical platinum-based anticancer drugs.

num drugs can also bind to these proteins. Since rapidly dividing cells, such as cancer cells, have a greater demand for iron, transferrin receptors are over-expressed, thereby allowing ruthenium-based drugs to be more effectively delivered to cancer cells.[9,10] In addition, the "activation by reduction" mechanism could also account for the lower general toxicity of some ruthenium compounds.[9] Two ruthenium-based anticancer drugs, namely NAMI-A and KP1019 (see Figure 2), have successfully completed phase 1 clinical trials and are scheduled to enter phase 2 trials in the near future.[11–13]

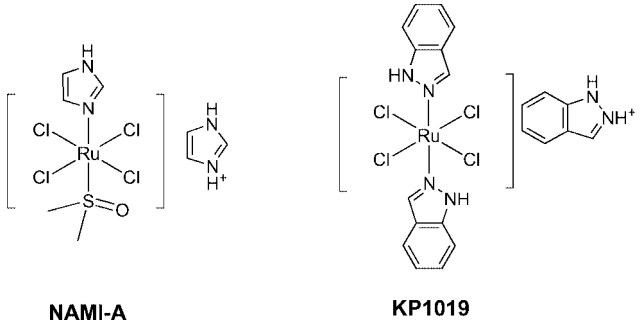

Figure 2. Ruthenium-based anticancer drugs under clinical evaluation.

In the past two decades, a new approach to treating cancer, known as targeted therapy, has started to take root.[14] The new strategy involves targeting cellular signalling pathways of cancer cells, yielding highly effective cancer treatments with much reduced severe side effects.[14,15] A few of them, e.g. Imatinib mesylate and Erlotinib hydrochloride (see Figure 3), have demonstrated such potential that their approval processes were fast-tracked by the US Food and Drug Administration. Eventually, targeted therapies could become mainstream as the first line therapeutic options, replacing existing classical anticancer drugs such as 5-fluorouracil and cisplatin. It is therefore worthwhile to consider if the existing approaches being used to develop ruthenium-based anticancer drugs are adequate.

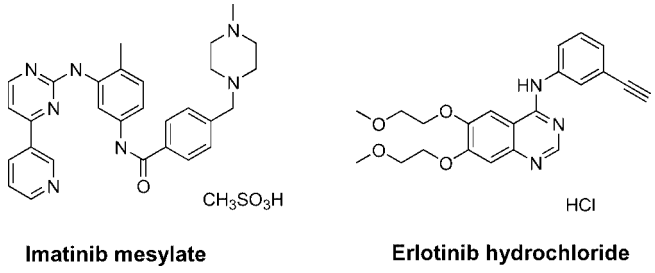

Figure 3. Drugs for targeted therapy in clinical use.

## Classical versus Targeted Chemotherapy

Classical (or conventional) chemotherapy, which originated in the 1950s, refers to drugs interfering with replication and mitotic processes of tumour cells.[14] Historically, these were the main "target" of chemotherapy, since cancer biology was not well established at that time and little was known about the causes of cancer and its mechanism, so the general therapeutic strategy was largely premised on the fact that cancer cells replicate their DNA more frequently than normal cells and hence are more susceptible to DNA damage. Examples of cytotoxic substances include alkylating agents, mitosis inhibitors and topoisomerase inhibitors. In recent years, with the advent of molecular oncology, the study of cancer at the molecular level has been made possible.[14] The discovery of receptors and growth factors, such as epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF), cyclin-dependent kinases (CDK) that are upregulated in cancer cells, provides new "targets" for cancer therapy.[15,16] Whereas the strategy of classical chemotherapy relies on damaging cancerous cells more than normal cells, targeted therapies are far more specific and their toxicity profile more manageable. Important classes of target therapeutic agents include monoclonal antibodies that interfere with the activities of EGFR, VEGF or proteasome, small molecule inhibitors of the tyrosine ki-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nase receptor (which includes EGFR), as well as immunotherapeutic agents that trigger an immune response against CD20 antigens.[15,17]

The main drawback of classical chemotherapy strategies is that by blocking the metabolism of rapidly dividing malignant cells, it inadvertently inflicts damage on healthy cells that divide frequently, such as hair follicles, bone marrow and cells lining of the gastrointestinal tract. Consequently, there are associated side effects, such as hair loss, anaemia and neutropenia, that are often severe and limit the treatment options.[18] In contrast, targeted therapies focus on specific cellular signalling pathways on which the cancer cells depend for growth, proliferation, metastasis and angiogenesis, and are therefore much more selective.[15] It is of no doubt that the centre of efforts in anticancer research has shifted towards the latter approach, and while targeted therapies are still in their infancy, they offer considerable potential.[14,16]

Despite the potential of targeted therapies, classical chemotherapeutic drugs, like cisplatin, remain the most effective and widely available drugs in use. This is because classical chemotherapeutic approaches target the most fundamental aspect of cancer cells, their rapidly dividing nature, whereas targeted approaches are contingent on discovering unique and specific features of particular cancer cells. As it stands, most targeted therapeutic drugs are only effective in fairly specific types of cancer, e.g. Imatinib mesylate for chronic myelogenous leukaemia, Erlotinib for advanced non-small cell lung cancer, etc. This limits their applicability and most common cancers cannot be treated with "targeted" chemotherapeutic agents, although this is expected to change in the future.

In recent years, ruthenium-based drug research appears to be moving away from classical approaches into the realm of "non-classical" ruthenium-based drugs. It is useful to take stock of the developments so far, drawing on the lessons learnt with respect to drug design and development. In this review, we explore the major classes of classical and non-classical ruthenium-based drugs and highlight the principal and emerging development strategies.

## Classical Ruthenium Anticancer Drugs

### *Polypyridyl-Ru-Complexes*

Polypyridyl-Ru systems have been exploited extensively as molecular DNA probes, given their photoluminescence properties and the ability of polypyridyl ligands to intercalate DNA. The large, rigid, multidentate polypyridyl ligands confer shape and chirality to the ruthenium complexes that could be exploited to achieve customised DNA-binding properties. This has provided the motivation to develop polypyridyl-Ru complexes as DNA-targeting anticancer agents, and a large number of these complexes have been screened for anticancer activity. Typical polypyridyl ring ligands include 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen) and 2,2′:6′2′′-terpyridine (terpy) as they are commercially available and readily form stable complexes with ruthenium (see Figure 4). Some of the earliest polypyridyl-Ru complexes studied for potential anticancer properties include *cis*-[Ru(bpy)$_2$Cl$_2$] (both Δ and Λ enantiomers) and *mer*-[Ru(terpy)Cl$_3$]. In vitro, *mer*-[Ru(terpy)Cl$_3$] was significantly more cytotoxic (L1210, HeLa) than both enantiomers of *cis*-[Ru(bpy)$_2$Cl$_2$], which matches the in vivo data (BALB/c × C$_{57}$BL/6 female mice).[19] This trend correlates to the ability of *mer*-[Ru(terpy)Cl$_3$] to form DNA-interstrand crosslinks, whereas the inactive *cis*-[Ru(bpy)$_2$Cl$_2$] appears to exhibit no such interactions.[19,20] There have also been numerous examples of polypyridyl-Ru complexes comprising one or more [Ru(bpy)$_2$L]$^{2+}$ or [Ru(phen)$_2$L]$^{2+}$ units [where L = derivatised quinolines, 2,6-(2′-benzyimidazolyl)pyridine/chalcone, aryldiazo-β-diketonate, 4-substituted thiosemicarbazides, 4-substituted thiopicolinanalides, 2-phenylazoimidazole, etc.] in an attempt to improve the DNA-intercalating ability of the complex.[21] However, it is not clear if there has been any serious attempt to advance these compounds into clinical trials. A series of DNA-binding ruthenium(II) complexes with tetradentate cyclam rings and varying DNA-intercalating quinonediimide ligands were studied in vitro (KB-3–1, KB-V1). It was noted that cytotoxicity was linked to the ability of the quinonediimide ligands to intercalate, although the IC$_{50}$ values were considered too high to be of interest.[22] Reedijk et al. reported an example of a NO-containing polypyridyl-Ru complex that readily liberates NO upon irradiation under a mercury lamp and that could potentially be applied in phototherapy.[23] The complex *cis*-(Cl,Cl)-[Ru$^{II}$(terpy)(NO)Cl$_2$]Cl exhibited good cytotoxicity towards A2780 human ovarian carcinoma cell lines, significantly higher than that of *mer*-[Ru(terpy)Cl$_3$], cisplatin or carboplatin, although their activity under irradiation was not reported. Harding et al. reported the synthesis of ruthenium analogues of streptonigrin, a DNA-targeting antitumour antibiotic.[24] On the basis of structural activity studies, the investigators identified the key structures responsible for their activity and synthesised quinolinide and bipyridine ligands to mimic the active sites. Subsequent dicarbonyl(dichloro)ruthenium(II) complexes [Ru(CO)$_2$Cl$_2$L] (where L = quinolinide and bipyridine mimics of streptonigrin) were prepared, although it appears that no further in vitro studies were undertaken. More recently,

a heteronuclear (Pt, Ru) complex, comprising a Ru(terpy) moiety, with a highly flexible bridging chain was developed (see Figure 5).[25] The Pt end was designed to bind directly to DNA, leaving the Ru(terpy) end to intercalate, thereby providing additional anchor support. Ultimately, this type of hybrid complex could provide the basis for customised DNA-targeting agents that could form long-range DNA adducts.

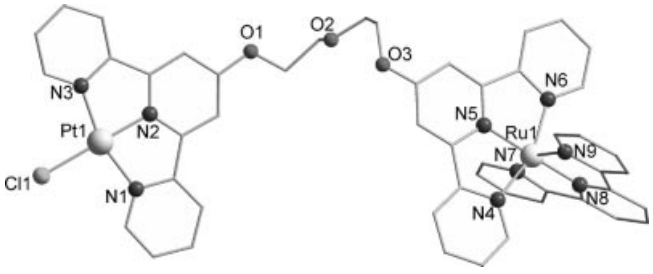

Figure 5. Ball and stick representation of a heteronuclear (Pt, Ru) complex that potentially coordinates *and* intercalates DNA.

### *Ru-Polyaminocarboxylate Complexes*

The use of polyaminocarboxylate (pac) ligands in metallopharmaceutical applications is of growing interest not only because of their ability to bind strongly with metal centres but also because their amino and carboxylate binding entities are akin to those in biological systems.[26] One of the earlier pac-Ru complexes evaluated for anticancer activity is the highly water-soluble dichloro(1,2-propylenediaminetetraacetate)ruthenium(III), Ru(pdta)$Cl_2$ (see Figure 6), which demonstrated antitumoural activity in vivo (EAT, L1210, P388, MX-1, M5076) with low systemic toxicity.[27] The presence of the two chloride ligands in the *cis*-conformation was found to be an important feature of its biological activity; under physiological conditions, the chlorides rapidly hydrolyse.[28] Ru(pdta)$Cl_2$ was found to alter the DNA conformation in pHV14 DNA and inhibit DNA lysis by restriction enzymes.[29] The structurally similar K[$Ru^{III}$(eddp)$Cl_2$] complex (where eddp = ethylenediamine-*N*,*N*-di-3-propionate) also displayed cytotoxicity in vitro (HeLa, BT-20, HT-29) and was found to induce DNA cleavage.[30] A related compound, $K_2$[$Ru^{III}$(dmgly)$Cl_4$] (where dmgly = *N*,*N*′-dimethylglycine), was reported to be cytotoxic towards the murine C6 astrocytoma cell line but not towards primary rat astrocytes, further demonstrating the selective toxicity of ruthenium complexes towards cancer cells.[31] Another class of pac-Ru complexes that has been extensively studied, K[$Ru^{III}$(pac)Cl], contains ethylenediaminetetraacetatic acid and its derivatives as the pac ligands (see Figure 6).[26,32] Like Ru(pdta)$Cl_2$, these complexes also rapidly hydrolyse to yield Ru(pac)($H_2O$) species at low pH. In vitro cytotoxicity against tumour cell lines (MCF-7, NCI-H460, SF-268) showed K[$Ru^{III}$(pdta)Cl] and K[$Ru^{III}$(edta)Cl] to be more efficacious inhibitors of cell growth, presumably because of their higher reactivity towards nucleotides.[26,32,33] In addition, several of these complexes were found to be effective NO scavengers and protease inhibitors, thus they could be used to treat various diseases or serve as antiviral agents.[34]

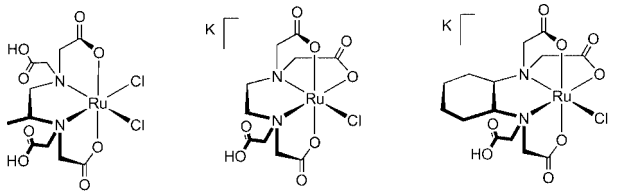

Figure 6. Examples of Ru-pac complexes investigated for anticancer activity (cdta = cyclohexane-1,2-*trans*-diamine-*N*,*N*,*N*′,*N*′-tetraacetate).

### *Dimethyl Sulfoxide-Ru Complexes*

As early as 1988, *cis*- and *trans*-Ru(DMSO)$_4X_2$ (where X = Br, Cl) were screened for antitumour activity (C75B1/BD2F1 female mice with lung carcinoma) and *trans*-Ru(DMSO)$_4Cl_2$ was 20-fold more active against metastasis than its *cis* counterpart (see Figure 7).[35,36] In leukaemic mice, the complexes were able to prolong the lifespan of the host without affecting the number of tumour cells.[35,37] No further development of *cis*- and *trans*-Ru(DMSO)$_4Cl_2$ was reported, presumably in favour of NAMI-A which was found to be a strong antimetastatic agent by the same investigators. However, analogues of *cis*- and *trans*-Ru(DMSO)$_4Cl_2$ containing chelating DMSO ligands such as bis(methylsulfinyl)ethane, bis(ethylsulfinyl)ethane (BESE), bis(propylsulfinyl)ethane and bis(methylsulfinyl)propane have since been reported and studied in vitro (CHO).[38] The compounds were found to be non-cytotoxic under aerobic and hypoxic conditions, despite accumulating significantly within the cellular DNA. *cis*-Ru(DMSO)$_4Cl_2$, in particular, has been used as a synthon for numerous compounds such as *cis*,*cis*,*trans*-Ru$L_2$(DMSO)$_2Cl_2$ (where L corresponds to cytotoxic nitrofurylsemicarbazone ligands), although the conjugated products did not offer improved cytotoxicity (MCF-7, TK-10, HT-29).[39] Similarly, complexes with derivatised DMSO, *cis*,*cis*,*trans*-Ru$L_2$("DMSO")$_2Cl_2$ and *cis*-Ru("DMSO")$_2$(mal)$_2$ type compounds (where L = metroidazole and mal = maltol or ethylmaltol), show no advantageous improvement in cytotoxicity (MDA-MB-435S).[40] *cis*-Ru(DMSO)$_4Cl_2$ has been used to prepare heterodinuclear Pt–Ru compounds crosslinked by 1,4-diaminobutane, i.e. [{*cis*,*fac*-Ru$Cl_2$-(DMSO)$_3$}($NH_2(CH_2)_4NH_2$){*cis*-Pt($NH_3$)$Cl_2$}], with a view to develop a compound that could crosslink DNA–DNA or DNA–protein structures (see Figure 7).[41] On the basis of DNA-binding studies, it was demonstrated that the heterodinuclear compound could form specific DNA lesions that could cross-link proteins to DNA, but its sensitivity to light and rapid hydrolysis prevented further evaluation.[25,42] More recently, both *cis*- and *trans*-Ru(DMSO)$_4Cl_2$ were investigated for their phototoxicity under UVA illumination.[43] Both complexes exhibited photodependent cytotoxicity against human and murine mela-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

noma cell lines (SK-MEL 188, S91) – the *trans* isomer was more photocytotoxic. In addition, their reactivity towards oligonucleotides was found to be greatly accelerated through a photochemical pathway when irradiated by UVA.

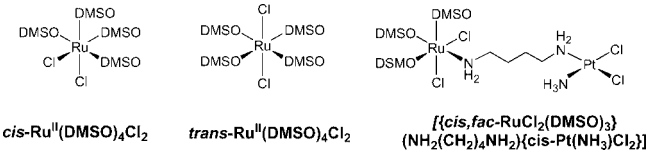

Figure 7. Examples of DMSO–ruthenium compounds evaluated for antitumour activity.

### *Ruthenium Arylazopyridine Complexes*

Arylazopyridine ruthenium(II) complexes, $Ru(azpy)_2Cl_2$ (where azpy = 2-phenylazopyridine), represent a class of well-characterised anticancer compounds with a strong structural dependency. Although these complexes can exist in up to five different isomeric forms, arising from the lack of a twofold symmetry axis, only three have been reported, namely the α, β and γ isomers, and their structures unequivocally established by X-ray crystallography (see Figure 8).[44,45] The structural characteristics have a significant impact on the efficacy of the compounds as cytotoxic agents. Reedijk et al. reported that the high cytotoxicities of the α and γ isomers in vitro (A498, EVSA-T, H226, IGROV, MCF-7, WIDR, M19) were comparable to those of cisplatin and 5-fluorouracil and is about 10-fold higher than that of the corresponding β isomer. This result is surprising since the α and β isomers are structurally similar and differ only in the orientation of the azpy ligand.[45,46] The addition of methyl groups to either the pyridine or phenyl moiety, as in $Ru(tazpy)_2Cl_2$ and $Ru(mazpy)_2Cl_2$ (tazpy = *o*-tolylazopyridine and mazpy = 4-methyl-2-phenylazopyridine), did not alter the trend, validating the structure–activity relationship of the isomers on cytotoxicity.[46] DFT calculations suggest that the ability of the $Ru(mazpy)_2Cl_2$ isomers to intercalate to DNA decreases from γ > α > β isoforms on the basis of the geometric and electronic factors, which correlates with the observed cytotoxicity.[47] The γ isomer has the most preferential geometric arrangement of the mazpy ligand for DNA intercalation, as well as the lowest LUMO energy level and smallest HOMO–LUMO energy gap. Accordingly, it is the most reactive towards DNA. A mixed ligand analogue, *cis*-Ru(bpy)(azpy)$Cl_2$, which is structurally similar to α-$Ru(azpy)_2Cl_2$, was found to be 2–10 fold more cytotoxic in vitro (A498, EVSA-T, H226, IGROV, MCF-7, WIDR, M19) than *cis*-$Ru(bpy)_2Cl_2$ but much less cytotoxic (>50-fold) than either α- or β-$Ru(azpy)_2Cl_2$.[48] The replacement of the chloride ligands with a 2,2′-bipyridine group, as in $[Ru(bpy)_n(azpy)_{3-n}](PF_6)_2$, also did not offer any significant advantage over the parent α-$Ru(azpy)_2Cl_2$.[49] Some water-soluble derivatives of the α isoform, where the chloride ligands are replaced by bridging carboxylate ligands, e.g. oxalate, malonate or 1,1-cyclobutanedicarboxylate, overcome one of the main limitation of these complexes.[50] Although the compounds are 5–10 fold less cytotoxic than α-$Ru(azpy)_2Cl_2$ (A2780, A2780cisR) and slightly less cytotoxic than cisplatin, its cytotoxicity is comparable to that of carboplatin (see Figure 9). Another water-soluble derivative $[NEt_4]_2[Ru(sazpy)_2Cl_2]$ (where sazpy = 2-phenylazopyridine-5-sulfonate), which contains a sulfonate functionality on the azpy group,[51] was >100-fold less cytotoxic (A2780, A2780cisR) than α-$Ru(azpy)_2Cl_2$. More recently, dinuclear analogues with bridging azpy ligands, comprising two azpy units joined at the *para* position of the phenyl rings by a bridging methylene group, have been reported.[52] The supramolecular complexes each contain two $Ru(azpy)_2Cl_2$ moieties arranged in either the α or γ isoforms. Three isomers have been isolated that contain either α/α-, α/γ- or γ/γ- "$Ru(azpy)_2Cl_2$" units and their structures have been confirmed by X-ray crystallography (see Figure 9). The α/γ and γ/γ isomers were tested in vitro on cancer and non-tumourgenic cell lines (T47D, HBL-100) with the γ/γ isoform exhibiting the highest cytotoxicity – >30-fold higher than that of cisplatin.

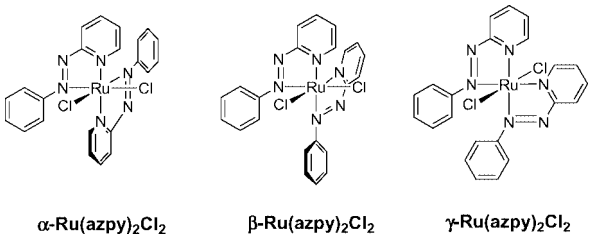

Figure 8. Different isomeric forms of $Ru(azpy)_2Cl_2$ complexes.

### *Organometallic Arene–Ruthenium-Complexes*

Organometallic ruthenium complexes bearing $\eta^6$-arene ligands have been investigated extensively as potential anticancer drug candidates. One of the earlier examples is ($\eta^6$-benzene)Ru(DMSO)$Cl_2$ (see Figure 10), which has been shown to strongly inhibit topoisomerase II activity by cleavage complex formation.[53] The authors suggested that the ruthenium complex interacts with DNA and forms cross-links with topoisomerase II. The complex exhibited antiproliferative activity in vitro (Crit-2), but it is inconclusive if there is a direct link to its ability to inhibit topoisomerase II activity. Arene–ruthenium complexes containing BESE, which is essentially a bidentate "DMSO" ligand, have been tested in vitro (MDA-MB-435s), but their cytotoxicities were more than 5-fold higher than that of cisplatin, and no further investigation was reported.[54] In contrast, monofunctional $Ru^{II}$ complexes of the type $[(\eta^6\text{-arene})Ru(en)X]^+$ (where en = ethylenediammine or its derivatives and X = halide) exhibit high cytotoxicity in vitro (A2780, A2780cisR, A2780adr, HT29, Panc-1, NX02), comparable to that of cisplatin, that is dependent on the arene ligand (see Figure 10).[55] Large arene ligands, such as biphenyl and tetrahydroanthracene, improved the cytotoxicity of the drug. Replacement of the en ligand with bpy or tmeda (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine) resulted in complexes with poor cytotoxicity.[56] Extensive oligonucleotide studies have been carried out and $[(\eta^6\text{-cymene})Ru(en)X]^+$ have been found to preferentially bind to guanine bases to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

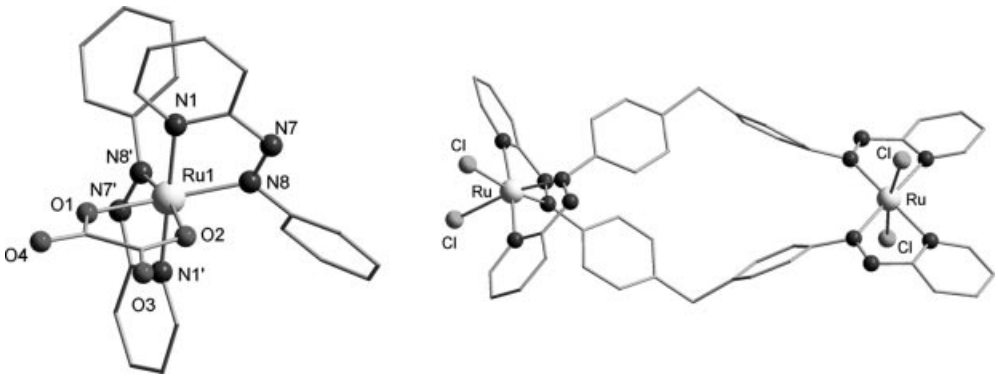

Figure 9. Ball and stick representation of derivatives of α-Ru(azpy)$_2$Cl$_2$. Unlabelled spheres represent N atoms.

form monofunctional DNA adducts.[57] This was supported by NMR spectroscopic studies that suggest that the binding of the [(η$^6$-arene)Ru(en)X]$^+$ moiety to guanine is enhanced through H-bonding interactions between the en ligand and the exocylic oxygen atom (i.e. C$^6$–O) on the guanine nucleotide.[58] In contrast, binding to adenine is weakened because of steric interactions between the en ligand and the exocyclic amino groups (i.e. C$^6$–NH$_2$),[58] whereas (η$^6$-cymene)-Ru(acac)Cl (where acac = acetylacetonate) [see Figure 10] binds to both adenine and guanine bases – the authors noted that these results could lead to compounds designed to target specific DNA nucleotides.[59] With large arene rings systems, e.g. dihydroanthracene and tetrahydroanthracene, binding of [(η$^6$-arene)Ru(en)X]$^+$ complexes to nucleotide bases was promoted by hydrophobic arene–purine base π–π stacking interactions, which could explain the enhanced cytotoxicity of those derivatives.[60] There was also evidence of dynamic chiral recognition of ethylguanine by the diastereomers of [(η$^6$-biphenyl)Ru(Et-en)Cl]$^+$, realizing the concept of induced-fit recognition of DNA by chiral derivatives of ruthenium complexes.[61]

## Non-Classical Ruthenium Anticancer Drugs

### *Antimetastatic NAMI-A Type Complexes*

Imidazolium *trans*-[tetrachloro(DMSO)(imidazole)ruthenate(III)] H$_2$im[*trans*-RuCl$_4$-(DMSO)Him], more commonly known as NAMI-A (see Figure 11), was the first ruthenium-based anticancer drug to enter clinical trials – as

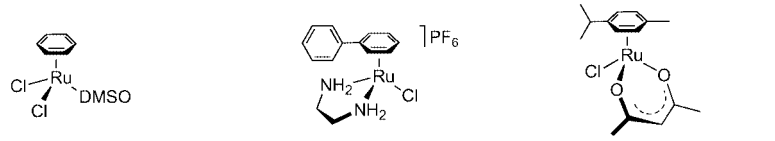

Figure 10. Examples of organometallic (η$^6$-arene) ruthenium anticancer drugs.

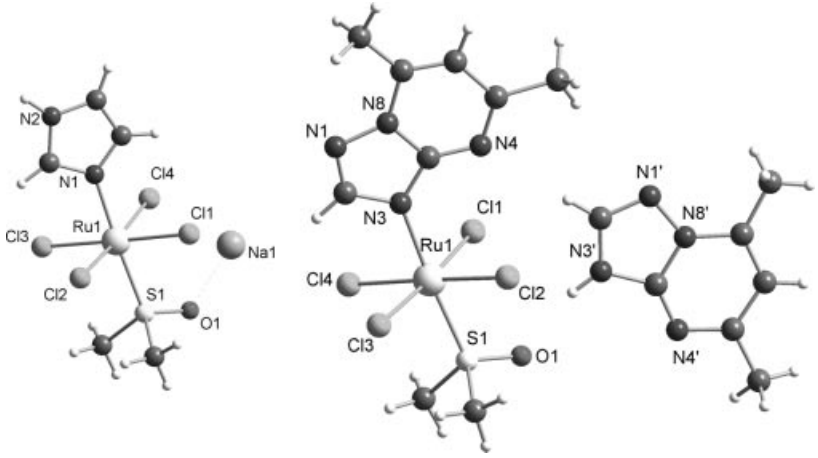

Figure 11. Ball and stick representation of NAMI-A precursor, Na[*trans*-RuCl$_4$–(DMSO)Him] (left) and Hdmtp[*trans*-RuCl$_4$-(DMSO)dmtp] (right).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a drug candidate against non-small cell lung cancer (NSCLC).[62] Compared to other transition-metal-based drugs such as cisplatin, NAMI-A is unique. In vitro, it is virtually devoid of cytotoxicity, while in vivo, it inhibits lung metastases formation and reduces metastases weight without affecting the primary tumour,[63] in contrast to platinum-based drugs which typically exhibit strong growth inhibition on primary tumours. Indeed, both in vitro and in vivo data appear to exclude DNA as the primary target, in line with the observation that the binding of NAMI-A to DNA is much weaker than that of platinum complexes.[63–65] Instead, strong binding to serum proteins is observed and the drug could potentially exploit receptor-mediated delivery by transferrin for selective delivery to cancer cells.[66] There is strong evidence linking the antimetastatic behaviour to the lack of cytotoxicity in vitro, cell-cycle changes corresponding to cell arrest in the premitotic $G_2$-M phase and inhibition of Matrigel invasion, which could constitute an in vitro screening strategy for ruthenium complexes with similar properties.[67] Phase 1 clinical trials showed that the drug was well-tolerated in patients, reversible blister formation is the dose-limiting toxicity.[12] Several NAMI-A analogues have been studied for potential antimetastatic activity as a means to ascertain the structure–activity relationships in this class of compounds. NAMI-A derivatives [*mer*-$RuCl_3$(DMSO)(acv)($H_2O$)] and [*mer*-$RuCl_3$(DMSO)(acv)-(MeOH)] and [*trans*-$RuCl_4$(DMSO) guaH] (where acv = acyclovir and gua = guanine) exhibited low cytotoxicity in vitro (TS/A), similar to NAMI-A.[68] Analogues with the dmtp ligand (where dmtp = 5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyridmidine) were also investigated and found to be slightly cytotoxic in vitro (TS/A, KB, B16-F10).[69] In particular, Hdmtp[*trans*-$RuCl_4$(DMSO) dmtp] exhibited a similar in vivo profile to NAMI-A (CBA mice with MCa carcinoma), strongly inhibiting lung metastases formation without significantly affecting the primary tumours (see Figure 11).[69] This trend has also been replicated in NAMI-A analogues with pyrazine, pyrazole and bidentate *N*-heterocyclic ligands, e.g. 4,4′-bipyridine, 1,2-bis(4,4′-pyridyl)ethane, suggesting that the imidazole fragment is not an essential feature for the antimetastatic property of NAMI-A.[70]

### *Exploiting the Transferrin Delivery Mechanism*

Indazolium *trans*-[tetrachlorobis(1*H*-indazole)ruthenate-(III)] $H_2$in[*trans*-$RuCl_4(Hin)_2$], KP1019 (see Figure 12), the only other ruthenium drug presently undergoing clinical evaluation, contains two indazole ligands in the *trans* conformation (whereas in NAMI-A the imidazole ligand is *trans* to a DMSO moiety). Unlike NAMI-A, KP1019 is significantly cytotoxic in vitro against colorectal cell lines (SW480, HT29) by induction of apoptosis.[71] There is also evidence of P-glycoprotein (Pgp) mediated drug resistance to KP1019, although other multidrug resistance (MDR) associated proteins (MRP1, BCRP and LRP) did not affect its activity significantly.[72] The drug was evaluated in vivo against autochthonous colorectal tumours in rats and was found to be highly effective in reducing tumour growth (superior to 5-fluorouracil, the most effective drug in clinical use against colorectal cancer).[11] In contrast, cisplatin was inactive in the in vivo model. The activity of KP1019 is attributed, at least in part, to transferrin-mediated drug transport, with KP1019 binding strongly to transferrin in the iron-binding pockets.[73] Indeed, its imidazolium analogue, which binds more weakly to transferrin, is taken up less effectively by transferrin and is also less cytotoxic in vitro.[71] Another possible mechanism in play is that the drug is activated by reduction, from $Ru^{III}$ to $Ru^{II}$, selectively in hypoxic tumour tissue by endogenous bioreductants such as glutathione. It appears that KP1019 induces apoptosis in colorectal cell lines predominantly by the intrinsic mitochondria pathway and that DNA could be a target, although studies have shown that the DNA lesions formed by KP1019 is different to that by cisplatin.[11,74] In phase 1 clinical trials, the drug was well-tolerated, and five out of six patients treated achieved disease stabilisation.[11,13] A large number of KP1019 analogues, comprising different types and numbers of *N*-heterocyclic rings, have been reported.[75,76] Notably, it was found that increasing the number of indazole ligands, as in *trans*-$Ru^{II}Cl_2(Hin)_4$ and [*trans*-$Ru^{II}Cl_2(Hin)_4$]Cl, improved the in vitro cytotoxicity significantly (CH1, SW480).[76] This was correlated with the increased cellular uptake and a higher reduction potential of the homologues, in line with the "activation by reduction" hypothesis.

### *Ruthenium-Based Selective Estrogen Receptor Modulators*

Selective estrogen receptor modulators (SERMs), such as tamoxifen (see Figure 13), are a class of drug that have been successfully used to treat hormone-dependent (ER-positive) breast cancer, i.e. which express the estrogen receptor ERα. At the same time, there is no satisfactory therapeutic treatment for hormone-independent (ER-negative) breast tumours that contain another estrogen receptor ERβ, which accounts for about one-third of breast cancer cases. Jaouen et al. have developed a series of hydroxytamoxifen derivatives comprising ferrocene (hydroxyferrocifen) (see Figure 13), and other potentially cytotoxic organometallic fragments of rhodium, manganese, titanium and rhenium have been reported, representing a strategy to defeat breast tumours which contain both ERα and ERβ receptors.[77] Hydroxytamoxifen analogues containing organometallic ruthenocenes and their biological evaluation in vitro (MCF7, MDA-MB231) have also been reported.[78] Although the hydroxytamoxifen-Ru complexes (see Figure 13) were found to bind strongly to both ERα and ERβ, unlike hydroxyferrocifen, hydroxytamoxifen-Ru exhibits no cytotoxic effect towards ER-negative breast cancer cell lines, possibly because of the increased stability of the ruthenium fragment compared to the iron analogue with respect to oxidation, and thus would not offer any therapeutic advantage over existing treatment options. Nonetheless, the authors noted that the hydroxytamoxifen-Ru complexes could be suitable for radioimaging of tumour cells using either of two γ-emitting Ru isotopes, $^{97}$Ru and $^{103}$Ru.[78]

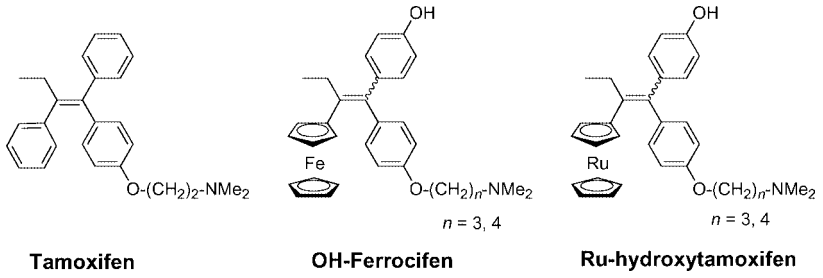

Figure 13. Derivatives of tamoxifen.

### *Ruthenium Ketoconazole Complexes*

Ketoconazole (KTZ) and clotrimazole (CTZ) are azole compounds that were originally developed as antifungal agents. They also exhibit anticancer properties and ketoconazole in particular is being used in the clinic as a second-line agent for hormone-refractory prostate cancer. Ketoconazole-ruthenium $Ru(KTZ)_2Cl_2$ and clotrimazole-ruthenium $Ru(CTZ)_2Cl_2$ complexes were originally developed to treat tropical diseases,[79] but more recently, they have been evaluated for anticancer activity. In vitro, $Ru(KTZ)_2Cl_2$ and $Ru(CTZ)_2Cl_2$ were found to be more effective inhibitors of cell growth proliferation (C8161) than the parent ligands KTZ and CTZ.[80] The effects of $Ru(KTZ)_2Cl_2$ on various cell signalling pathways were investigated. In particular, it was observed that A431 spheroids, known to overexpress EGF-R and to be resistant to either $Ru(KTZ)_2Cl_2$ or C225 *anti*-hEGF-R monoclonal antibody (MAb), were susceptible towards a combination treatment of $Ru(KTZ)_2Cl_2$ and the C225 antibody. C225 is an experimental monoclonal antibody presently under clinical evaluation as a targeted therapeutic agent against EGFR-expressing metastatic colorectal cancer. The authors suggested that $Ru(KTZ)_2Cl_2$ could potentially be used to enhance other targeted therapeutic treatment methods.[80]

### *Ruthenium-Based Protein Kinase Inhibitors*

The three-dimensional structure of many biomolecules is complicated and their syntheses are often difficult given the need to maintain specific conformity and spatial orientation. With a view to develop synthetic compounds with superior biological activity, Meggers et al. reported an organometallic ruthenium complex that mimics the shape of a known protein kinase inhibitor, staurosporine (see Figure 14).[81,82] The strategy exploits the relative ease of synthesising ruthenium moieties of a specific spatial conformation to mimic aspects of an inhibitor not easily accessible using purely organic scaffolds.[81,83,84] The authors further demonstrated the superior binding of the ruthenium mimic to Pim-1, a protein kinase, and reported co-crystallisation of the protein with the ruthenium complex.[81] This provides a basis for the development of further transition-metal-based enzyme inhibitors and could lead to new types of organometallic-targeted therapeutic agents.

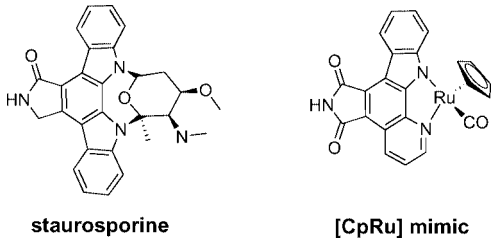

Figure 14. Staurosporine and an organometallic ruthenium mimic.

### Arene PTA Ruthenium(II) (RAPTA) Complexes

The RAPTA compounds comprise a class of organometallic ruthenium(II) complexes with a monodentate 1,3,5-triaza-7-phosphatricyclo[3.3.1.1]decane (pta) ligand and a $\eta^6$-arene ligand. The compounds are readily synthesised in two steps: the first step involves the reaction of $C_6$-dienes,

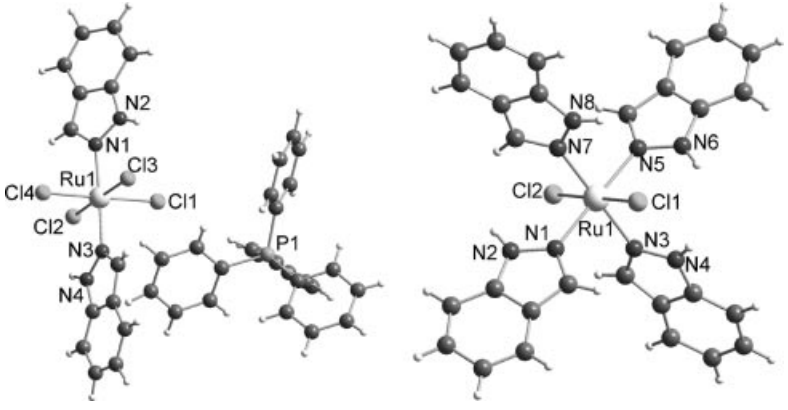

Figure 12. Ball and stick representation of $PPh_4[trans\text{-}RuCl_4(Hin)_2]$ (left) and $trans\text{-}Ru^{II}Cl_2(Hin)_4$ (right).

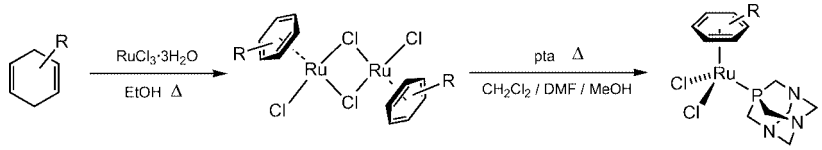

Scheme 1. General synthesis of RAPTA complexes.

typically derived using Birch reduction of the desired arene, with hydrated $Ru^{III}Cl_3$ to yield dimeric $[(\eta^6\text{-arene})Ru^{II}Cl_2]_2$.[85] In the second step, 2 equiv. pta are added to $[(\eta^6\text{-arene})RuCl_2]_2$ in organic solvents to yield the desired RAPTA complex (see Scheme 1). The reaction is thermodynamically favoured and proceeds in high yield. Alternatively, ligand exchange using the arene-labile complex $[(\eta^6\text{-}PhCO_2Et)RuCl_2]_2$ can be carried out for arene ligands that cannot be readily reduced by Birch reduction, such as benzocrown ethers, but yields are lower.[86] In comparison to typical phosphane ligands, pta is relatively compact and sterically undemanding, with a cone angle of 103° (c.f. $PPh_3$ 143° and $PMe_3$ 134°).[87] As such, RAPTA compounds are generally air-stable complexes with good thermodynamic stability. The pta ligand can also be readily derivatised to form acetylated species, e.g. 3,7-diacetyl-1,3,7-triaza-5-phosphabicyclo[3.3.1]nonane (pta-Ac) or methylated species (pta-$Me^+$), further expanding the scope of possible RAPTA compounds.[87] Importantly, the presence of the phosphorus atom makes the characterisation of RAPTA compounds by $^{31}P$ NMR spectroscopy fairly straightforward. RAPTA is also unusual in comparison with other phosphane ruthenium complexes in that it is not only soluble in polar organic solvents, but also in water. The prototype $[(\eta^6\text{-cymene})Ru^{II}(pta)Cl_2]$, RAPTA-C, has been central to biological evaluation and is the reference compound from which other RAPTA compounds are developed (see Figure 15). Two key approaches have thus been adopted. The first is centred on evolving RAPTA into an effective drug that is highly selective towards tumour cells with a low systemic toxicity. In vitro evaluation and oligonucleotide-binding studies supplemented by computational studies were undertaken, with a view that DNA is a possible target, as with most transition-metal-based anticancer drugs. The second approach is aimed at discovering "non-classical" chemotherapeutic applications for RAPTA complexes and to study drug interactions at the proteome level. Early on, specific protein binding interactions were detected with RAPTA, which could be the basis for new therapeutic targets beyond DNA. Furthermore, the remarkably similar in vivo activity of RAPTA-T and NAMI-A suggests that they could respond to similar targets.[10] The development of complementary proteomic techniques as well as rational drug design for RAPTA complexes has been carried out. On the basis of these two approaches, more than 20 RAPTA complexes of the general formula (arene)$Ru^{II}$(pta)$X_2$, where X = Cl, Br, I, SCN or bridging carboxylate ligands, have so far been synthesised and studied (see Scheme 2). In addition, RAPTA analogues containing other organometallic fragments, namely [CpRu], [Cp*Ru], [Cp*Rh] and [CyOs] have also been studied.[88]

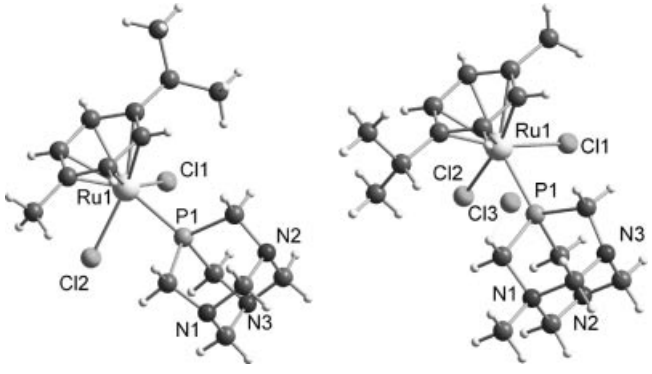

Figure 15. Ball and stick representation of RAPTA-C **1** (left), RAPTA($Me^+$)-C **14** (right).

### *Evolution of RAPTA Complexes: Hybrid Classical / Non-Classical Compounds*

The motivation to study RAPTA complexes as potential anticancer drugs came from the observation that RAPTA-C **1** induces pH-dependent DNA damage against *E Coli* pBR322 DNA plasmids, with a significant retardation of the migration of the supercoiled DNA at pH <7.0 because of unwinding of the DNA as a result of drug interactions.[89] This provided a means to target cancer cells, since they generally exhibit lower pH as a result of metabolic changes, partly because of accelerated cell division. Binding studies using calf thymus DNA further suggested that RAPTA-C stabilises the DNA upon binding (see Figure 16), with a significant increase in the melting temperature of the DNA-RAPTA-C adduct.[90] This suggests that the reaction between DNA and RAPTA-C could be thermodynamically driven and thus highly favourable. However, the RAPTA complexes do not show selective binding to DNA in vitro, proteins and RNA appear to be the main intracellular targets.[91]

The reactivity of RAPTA complexes towards single-strand oligonucleotides, studied by ESI-MS, shows that RAPTA-C **1** and its methylated analogue RAPTA($Me^+$)-C **14** bind to the 14-mer oligomer (5′-ATACATGGTACATA-3′) across a range of pH values and concentrations, irrevocably with the loss of the chloride and arene ligands, while the pta ligand remains intact.[92] Although the purine bases could, in principle, offer heterocyclic aromatic rings for an arene-type π-bonding mode with the ruthenium centre, DFT calculations revealed that such binding would be unlikely, and it is more probable that the interaction is based on multiple coordinative N-donor bonds, such binding only possible with RNAs.[92]

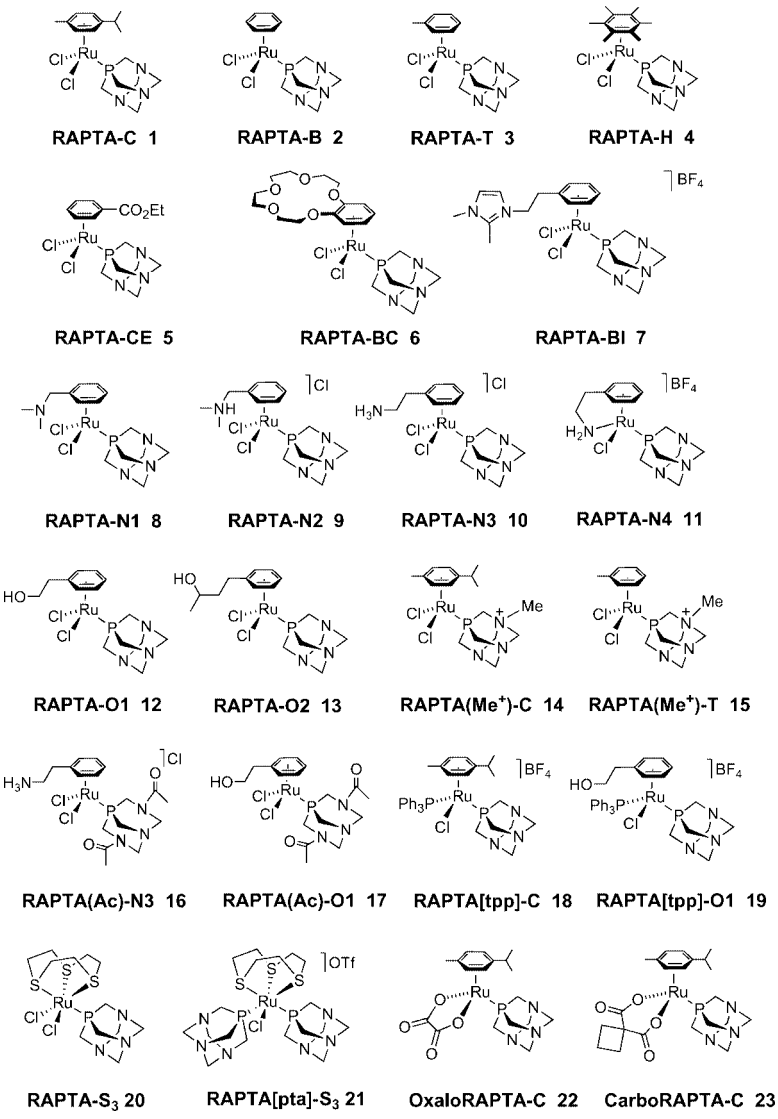

Scheme 2. Family of RAPTA complexes.

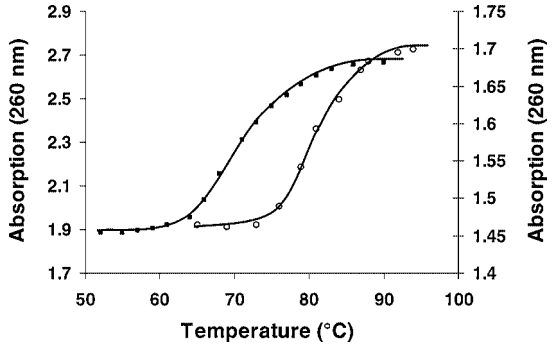

Figure 16. DNA melting curves of calf thymus DNA alone (■) and calf thymus DNA with RAPTA-C (1:1 ratio) (○), buffer: 10 mM phosphate buffer and 50 mM $NaClO_4$.

The cytotoxicity of the RAPTA complexes is generally very low, at least in both TS/A murine adenocarinoma and non-tumourgenic HBL-100 human mammary cell lines in comparison to cisplatin (see Table 1).[90] However, the lead RAPTA complexes **1**–**3** exhibit selective cytotoxicity towards the TS/A cancer cell lines relative to HBL-100, which provided early indication that the complexes are benign towards healthy cells. This is important since high systemic toxicity is associated with the drastic side-effects of cisplatin and related drugs and limits the amount of drug that can be administered. Similarly, NAMI-A is non-cytotoxic to both TS/A and HBL-100 cell lines up to 1 mM concentration. The pta fragment appears to play a significant part in determining this selectivity. When pta was replaced with pta-$Me^+$, as in **14** and **15** (see Figure 15), selectivity was lost and the compounds were equally toxic in both the cancerous and non-tumourgenic cell lines.[90] This coincides with the hypothesis that RAPTA compounds derived their cytotoxic activity through the protonation of its pta ligand under hypoxic pH conditions,[89] although such a process is deemed unlikely given the low p$K_a$ of the coordinated pta moiety.

The aromatic fragment is significant, to a certain degree, in influencing the drug uptake and in vitro activity. The presence of the ester group significantly improved the drug uptake in RAPTA-CE **5**, with a corresponding improvement in cytotoxicity against TS/A cells. Upon entering the cells, endogenous esterases could cleave the ester bond, thereby retaining the charged species within the cell walls.[90] Addition of functional groups such as benzocrown and an imidazolium moiety appeared to improve cytotoxicity towards TS/A, but not to a significant degree to warrant further studies.[90] RAPTA complexes with H-bonding groups attached to the arene ring (complexes **8**–**13**, **16**, **17** in Scheme 2) were developed and found to be generally more reactive than lead compounds **1**–**3** with respect to oligonucleotide binding.[93] However, in vitro, they are not only less cytotoxic towards TS/A cells but also less selective between the cell lines. This correlated with drug uptake studies on TS/A cells which showed that the uptake of these complexes decreased, presumably because of the incorporation of the hydrophilic H-bonding substituents. The addition of the hydrophobic triphenylphosphane (tpp) ligand in RAPTA complexes **18** and **19** reversed the trend. The complexes were found to be cytotoxic towards both cell lines, hence poorly selective, presumably because of increased drug uptake (see Figure 17).[94] The replacement of the aromatic fragment with a [9]ane$S_3$ ligand, RAPTA-$S_3$ **20**, results in only a slight decrease in selectivity and cytotoxicity, alluding to the fact that the aromatic fragment may not be an essential feature for in vitro activity and could be effectively replaced by another face-capping ligand with low steric demand (see Figure 17).[95] Interestingly, RAPTA[pta]-$S_3$ **21**, with [9]ane$S_3$ and two pta ligands, shows good selectivity and cytotoxicity towards TS/A cells, comparable to that of **1** and **2**. RAPTA analogues are presently being evaluated.

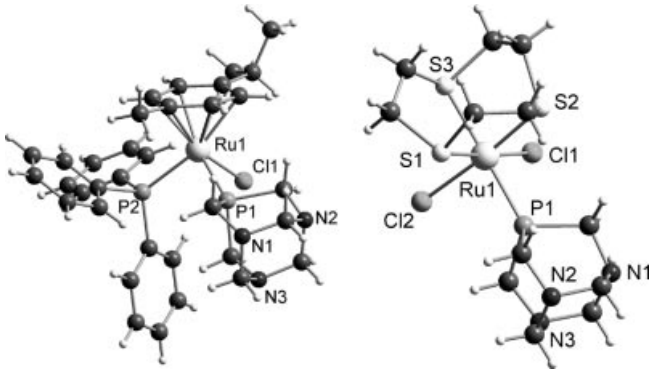

Figure 17. Ball and stick representation of RAPTA[tpp]-C **18** (left) and RAPTA-$S_3$ **20** (right); the $BF_4$ anion on **18** was omitted for clarity.

One of the potential issues with regard to eventual clinical application is the behaviour of drugs in water. Second-generation cisplatin drugs with oxalate and 1,1-cyclobutane-dicarboxylate ligands have been developed to improve the stability and solubility of the platinum complexes in water.[2] RAPTA complexes are prone to hydrolysis and would have to be administered in saline to suppress the cleavage of the chloride ligands. With a view to develop drugs that could resist hydrolysis in aqueous media, RAPTA complexes **22** and **23**, bearing chelating carboxylate ligands instead of the two chloride ligands, have been

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

developed (see Figure 18).[96] They were found to be kinetically more stable than **1**, and essentially, retained the carboxylate ligand in aqueous solution. Preliminary investigations show that these derivatives exhibit the same order of cytotoxicity in vitro (A549, T47D, MCF7, HT29) as **1** and exhibit similar oligonucleotide binding characteristics, hence proving to be a possible replacement for RAPTA-C in clinical studies.[96]

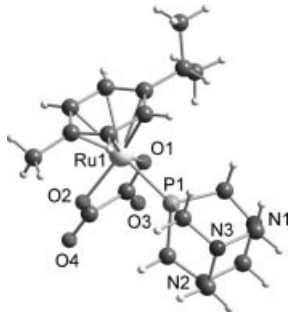

Figure 18. Ball and stick representation of OxaloRAPTA-C **22**.

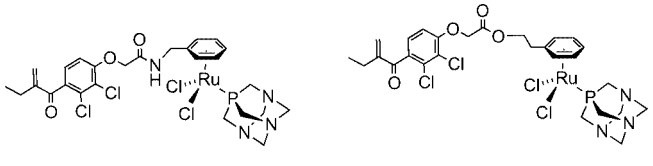
As a strategy to enhance drug efficacy, the next generation of RAPTA complexes should be more "targeted". Such complexes could have multiple modes of activity, functionalised to achieve specific, desirable outcomes. As proof of concept, RAPTA complexes designed to inhibit Glutathione-S-Transferases (GST), a cytosolic detoxification enzyme associated with drug resistance, have been developed (see Figure 19.).[97] GST catalyses the conjugation of intracellular xenobiotics with glutathione, which is then expelled from cells by the GS-export pump. RAPTA complexes conjugated through the arene ring to ethacrynic acid, a known inhibitor of GST enzymes, were found to be effective GST inhibitors with significantly increased cytotoxic activity, i.e. showing comparable cytotoxicity to that of cisplatin in cell lines known to contain elevated levels of GST (A549, HT29, T47D). Other potential enzyme targets are presently being investigated.



**24** **25**

Figure 19. RAPTA complexes designed to defeat GST-mediated drug resistance.

### *Beyond the Classical Approach: RAPTA as Antimetastatic Agents*

Despite the differences in oxidation state and ligand sphere, the striking semblance of RAPTA complexes to NAMI-A in vitro, primarily their low toxicity towards non-tumourgenic HBL-100, prompted the investigation of the lead RAPTA complexes **1**, **2** and **3** for potential antimetastatic activity.[90] In vivo experiments on MCa mammary carcinoma in CBA mice were used to evaluate the effects of the drugs i.p. on primary tumour growth and lung metastases formation. Firstly, it was found the lead RAPTA complexes were well tolerated by the mice at very high doses, consistent with in vitro data. Secondly, a low sustained treatment regime of RAPTA-C at 4× 100 mg/kg/day resulted in significant reduction in both lung metastases weight and number in treated mice whilst leaving the primarily tumour unaffected. In fact, under this regime 40% of the mice were completely free from metastases at the end of the treatment. This phenomenon was replicated in RAPTA-B and RAPTA-T under various treatment regime conditions and at 3× 80 mg/kg/day, RAPTA-T was able to reduce lung metastases in treated mice by 75%.[91] This result is comparable to that of NAMI-A which typically at 6× 35 mg/kg/day, reduces lung metastases by 71–90% and metastases number by 40–60%. Accordingly, there is no corresponding activity on the primary tumour. While the RAPTA complexes displayed marginally less antimetastatic activity than NAMI-A, it is much less toxic to mice and can potentially be administered at much higher dosage.

It is therefore apparent that the antimetastatic behaviour is not unique to NAMI-A, but applicable to other classes of ruthenium complexes. In the case of the well-studied NAMI-A, it is apparent that DNA is not the target, and more likely, activity is a consequence of drug–protein interactions. Therefore, a proteomic-based analytical approach based on 2-D PAGE and laser-ablation inductively-coupled mass spectrometry (ICP-MS) is being developed to identify the specific proteins interacting with ruthenium-based drugs.[98,99] The analytical technique utilises well-established methods in protein separation and exploits the high sensitivity of ICP-MS instruments in detecting non-endogenous transition-metal isotopes (in the order of parts per billion). While the technique is still under development, it has been used effectively to identify drug–protein interactions in human blood plasma, and was used to identify the main protein target of cisplatin in bacteria using 1D PAGE.[99,100]

At the same time, with a view to rationally develop other ruthenium-based antimetastatic agents, a new class of imidazole ($\eta^6$-arene)ruthenium complexes of the general formula [($\eta^6$-arene)$Ru^{II}Cl_2$(imid)], [($\eta^6$-arene)$Ru^{II}$Cl$(imid)_2$]X or [($\eta^6$-arene)$Ru^{II}(imid)_3]X_2$ (where imid = imidazolium ligand, X = Cl, $BF_4$, $BPh_4$, 15 examples) have been prepared, combining the unique structural aspects of NAMI-A and the "piano-stool" arene ruthenium(II) complexes.[101] The derived complexes exhibit similar cytotoxicity with RAPTA complexes in vitro (TS/A, HBL-100) and several of the complexes exhibit selectivity towards cancer cells. Specifically, [($\eta^6$-cymene)$Ru^{II}$Cl(vinylimid)$_2$]Cl **26** and [($\eta^6$-benzene)$Ru^{II}(mimid)_3](BF_4)_2$ **27** have been identified for further in vivo experiments (see Figure 20).[101] Further derivatisation of the imidazolium moiety, to yield antimetastatic ruthenium complexes conjugated to ethacrynic acid and other inhibitors of multidrug resistance-associated enzymes, is also being carried out.[97]

Figure 20. New class of RAPTA-NAMI antimetastatic drug candidates.

## Outlook - Towards Targeted Chemotherapy

Drug discovery and evaluation strategies for ruthenium-based anticancer complexes rely largely on the classical approach of screening for biological activity using specific in vitro or in vivo models, identifying potential drug candidates, deriving structure–activity relationships and thereafter cycles of structural modifications and testing for improved drug efficacy. These tests are "result-oriented", especially those based on the effect of the drug on cell viability, and reveal immediately the inhibitory effect of the drug on cell growth proliferation. However, even if potential drugs are identified, to establish directly the drug mechanism is not trivial, especially where there is no target definition in the drug design, and investigators often rely on peripheral experiments in order to rationalise drug behaviour. It is therefore fortunate that ruthenium, and indeed other transition metals not endogenous to biological systems, can be detected using ICP-MS to high levels of sensitivity. Analytical methods based on ICP-MS could therefore directly establish the fate of ruthenium drugs once administered. Keppler et al. employed capillary electrophoresis and size exclusion chromatography techniques, coupled to ICP-MS, to determine drug–protein binding of ruthenium drugs in human blood plasma, and much is now known about metal-drug plasma-protein interactions.[102] We have demonstrated the efficacy of proteomic methods in protein separation on polyacrylamide gels, in conjunction with laser-ablation ICP-MS, to establish drug–protein interactions in the human plasma and from cell samples.[98,100] The ultimate goal is to create a map of drug–protein interactions in the proteome of a cancer cell line after treatment with ruthenium drugs. This is important not only in establishing the mechanism of drug activity, but also as a way of identifying areas in the proteome on which ruthenium drugs could target, and hence towards a more systematic way of developing non-classical ruthenium drugs.

It is debatable whether the inhibition of cell growth proliferation or cytotoxicity should continue to be the predominant "measure of success" for ruthenium-based anticancer drugs. Many ruthenium drugs are known for their low systemic toxicity as compared to established platinum-based drugs. If cytotoxicity is the sole determinant, it is unlikely that ruthenium drugs would offer significant therapeutic advantages. Instead, attributes like cancer-cell selectivity or low systemic toxicity need to be incorporated into drug evaluation, which would focus preclinical drug development towards highly selective ruthenium drugs of low toxicity. Furthermore, existing cytotoxicity assays ignore other aspects of ruthenium drugs that would have greater therapeutic scope. Indeed, NAMI-A failed the in vitro evaluation using the NCI's protocol against a 60-panel cell lines and would have been omitted for further evaluation if the conventional method of drug screening were strictly followed.[98] Sava et al. demonstrated the antimetastatic potential of ruthenium-based drugs, and we have subsequently shown that this attribute is not confined to NAMI-A, while Keppler et al. has exploited known ruthenium–transferrin interactions for drug delivery.[11,63,64] Clearly, more suitable models for testing ruthenium drugs are needed but it is imperative that these testing methods exploit the unique biological profile of ruthenium.[10]

A relatively uncharted area that holds much potential for the application of ruthenium-based drugs is combination therapy. An example is the ketoconazole ruthenium complex which is found to potentiate A431 cells overexpressing EGF-R to C225 MAb treatment, although the mechanism is not fully understood.[80] More recently, in vivo experiments (CBA mice with MCa carcinoma) showed that the combination treatment of NAMI-A and cisplatin led to a synergistic enhancement in the inhibition of metastases formation and growth of primary tumour in mice, as compared to the treatment of NAMI-A or cisplatin alone. At the same time, the increase in toxicity was additive, which was anticipated since both drugs are based on transition-metal centres and discharged mainly by renal excretion.[98] Such a strategy would be extremely attractive but would be dependent on finding other unique applications of ruthenium drugs, such as the antimetastatic behaviour of NAMI-A, which is beyond the scope of existing therapies.

Beyond developing better ways to augment existing drug discovery strategies, Meggers et al. have demonstrated the viability of organometallic ruthenium-based protein-kinase inhibitors, in a strategy that employs chiral ruthenium moieties surrounded by stable inert ligands as a spatial replacement for the carbohydrate moiety which is difficult to synthesise. In this way, the ruthenium centre plays a relatively minor role in determining biological activity and serves more as a connector for other ligands which provides the shape and conformation.[81,83] The sheer range of possible ligands of different shapes and sizes gives a high degree of synthetic flexibility, but it would not be unreasonable to replace the ruthenium by other transition metals and those which occur in living systems may prove preferable. The possibility of ruthenium clusters extending the scope of this approach could also be worth considering, especially since clusters have already been shown to have pharmacological potential.[103] Another approach would be to modify existing receptor and inhibitor molecules, e.g. in the approaches taken by Jaouen et al. in the design of SERMs and by our group in the development of multifunctional RAPTA complexes.[78,97] Nonetheless, developing ruthenium complexes for target therapies would invariably involve structural biology in the design phase of the receptor/inhibitor molecule. Designing the receptor/inhibitor molecule around the ruthenium scaffold in the beginning, rather

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

than in retrospect, could lead to viable ruthenium drugs with well-defined and predictable modes of activity.

It is clear that with two ruthenium compounds proceeding through clinical trials, combined with the limited number of platinum drugs that have entered the clinic since the discovery of cisplatin and putative drugs based on other transition metals being withdrawn from clinical trials, ruthenium systems hold great potential. With the new strategies outlined in this review, it is likely that we will witness increased research efforts in this domain.

# Incorporation of the Unnatural Organometallic Amino Acid 1′-Aminoferrocene-1-carboxylic Acid (Fca) into Oligopeptides by a Combination of Fmoc and Boc Solid-Phase Synthetic Methods

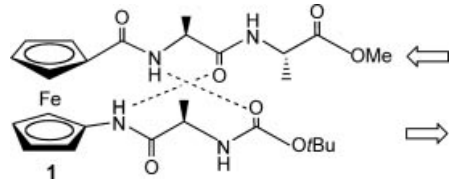
**Lidija Barišić,[a] Vladimir Rapić,[a] and Nils Metzler-Nolte*[b][‡]**

**Keywords:** Bioorganometallic chemistry / Ferrocene / Peptides / Solid-phase peptide synthesis / Unnatural amino acids

The organometallic amino acid 1′-aminoferrocene-1-carboxylic acid (Fca) was incorporated internally into a peptide sequence by solid-phase methods combining natural Fmoc-protected amino acids and Boc-Fca-OH to give the pentapeptide Boc-Fca-Ala-Gly-Val-Leu-$NH_2$ (**2**) and the octapeptide Ac-Val-Gly-Ala-Fca-Ala-Gly-Val-Leu-$NH_2$ (**3**). Compound **3** was found to have a helically ordered structure by NMR and CD spectroscopy, which is stabilized by intramolecular hydrogen bonding in an antiparallel β-sheet-like arrangement.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

Turn structures are ubiquitous secondary structural elements in proteins that have become important targets in medicinal chemistry.[1–4] Metal complexes, in particular ferrocene, may serve as turn mimetics in peptides.[5] The use of ferrocene-1,1′-dicarboxylic acid as a turn inducer was described by several groups, particularly those of Herrick, Hirao and Kraatz.[6–14] Ferrocene derivatives bearing *parallel* podand peptide strands were shown to induce helically ordered structures which are controlled by strong intramolecular hydrogen bonds as shown in the solid state by X-ray crystallography studies as well as in solution by IR, $^1$H NMR and CD spectroscopy.[7–10,15,16]

In previous work we investigated the role of 1′-aminoferrocene-1-carboxylic acid (Fca) as a turn mimetic in the tetrapeptide Boc-Ala-Fca-Ala-Ala-OMe (**1**) which contains *antiparallel* peptide strands stabilized by two intramolecular hydrogen bonds in both, solution and solid phases (Scheme 1).[17] All derivatives of ferrocene-1,1′-dicarboxylic acid and Fca so far were prepared by stepwise synthesis in solution. Solid-phase peptide synthesis (SPPS) using orthogonal protecting groups and linkers is the standard method for the synthesis of small to medium-sized peptides. Twenty years ago, a few papers were published dealing with the application of SPPS to metallocenes. Ferrocenylalanine (Fer) and cymantrenylalanine (Cym) were incorporated into biologically active peptides (enkephalin, bradykinin and substance P). Most work was carrid out on enkephalin which was transformed into [Fer$^4$,Leu$^5$] or [Cym$^4$,Leu$^5$] analogues by replacement of the phenylalanine side chain (Phe$^4$) with Fer or Cym, thus preserving the aromatic character of this residue.[18–21] It is worth to mention SPPS of a "ferrocenophanic" conformationally constrained analogue of substance P.[22] Very recently, SPPS of *N*-terminated cobaltocenium-NLS peptides[23] and metallocenoyl (M = Fe, Co) tripeptides[24] with antibacterial activity were described by one of us. In all peptides described up to the present day, the organometallic group is part of the side chain or linked to the *N*-terminus. We therefore set out to incorporate a metallocene such as Fca into the peptide backbone by SPPS. In this paper we describe for the first time an SPPS procedure for constitutive insertion of a ferrocene derivative into the peptide chain back bone.



Scheme 1. The antiparallel orientation of peptide strands in tetrapeptide **1** is induced by the unnatural amino acid 1′-aminoferrocene-1-carboxylic acid (Fca) and stabilized by intramolecular hydrogen bonds.

In recent years, the fluorenylmethoxycarbonyl (Fmoc) group has largely replaced the original Merrifield *tert*-butoxycarbonyl (Boc) group as the temporary *N*-terminal protecting group because it may be easily removed under mild basic conditions. Boc removal, on the other hand, requires strong acid which is incompatible with sensitive com-

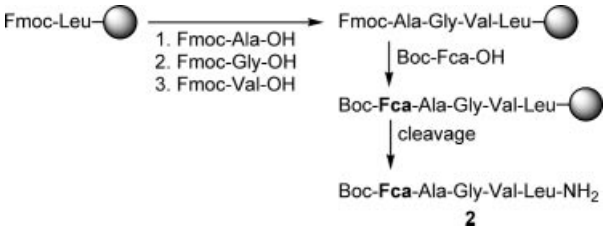
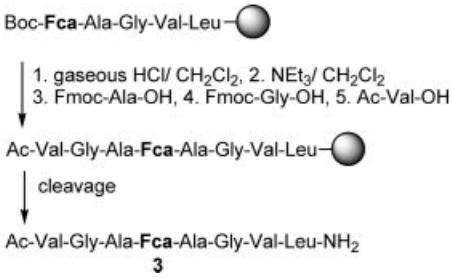
pounds, for instance some organometallic complexes.[25,26] For this reason, we originally planned to synthesize Fca-containing oligopeptides according to the standard Fmoc approach.[27] However, *N*-Fmoc-Fca-terminated oligopeptides turned out to be very unstable. Therefore, a combination of Boc-Fca-OH and Fmoc-Aaa-OH had to be chosen, thereby reintroducing the classical Merrifield method to the synthesis of Fca-containing peptides by solid-phase synthesis.

Pentapeptide **2** was obtained by standard Fmoc SPPS, starting from Fmoc-Leu loaded TentaGel S resin with the base-labile HMB linker, Fmoc-Val-OH, Fmoc-Gly-OH and Fmoc-Ala-OH.[27] Subsequent coupling to Boc-Fca-OH, cleavage from the resin by concentrated ammonia in methanol and thin layer chromatography (TLC) purification gave Boc-Fca-Ala-Gly-Val-Leu-$NH_2$ (**2**) (Scheme 2).



Scheme 2. Solid-phase synthesis of the Fca-containing pentapeptide **2**.

Octapeptide **3** was prepared starting from pentapeptide **2** attached to the solid support. The temporary Boc-protecting group masking the α-amino group of Fca was removed by gaseous HCl in $CH_2Cl_2$ during 1 h. The resulting ammonium salt was converted by the action of 10% $NEt_3/CH_2Cl_2$ into the corresponding amino species which was coupled with Fmoc-Ala-OH, Fmoc-Gly-OH and Ac-Val-OH to give octapeptide Ac-Val-Gly-Ala-Fca-Ala-Gly-Val-Leu-$NH_2$ (**3**) (Scheme 3). The product was cleaved from the resin by concd. $NH_3$ in MeOH and purified by TLC. The yields of both compounds after TLC purification (14% for **2** and 23% for **3**, respectively) were in the expected range for SPPS procedures, given that no effort was made for optimization in these initial experiments. The purity of both peptides **2** and **3** was confirmed by analytical HPLC (see Supporting Information).



Scheme 3. Solid-phase synthesis of octapeptide **3** with the organometallic amino acid Fca incorporated internally.

Evidence for the proposed composition of **2** and **3** was obtained from ESI-MS where peaks at $m/z$ = 1391.7 $[2 \times M + Na]^+$ (**2**) and $m/z$ = 876.5 $[M + Na]^+$ (**3**) were observed. The $^1H$ NMR spectra confirmed the proposed structures, too. Due to the limited solubility of the metallocene peptides, all spectra were measured in $[D_6]$DMSO (approx. 10 mM), which competes as a hydrogen-bond acceptor. First of all, the correct number of amide proton signals confirms the number of amino acids, i.e. six for **2** and nine for **3**, both including the *C*-terminal amide with the intensity of 2 H. Upon closer inspection, the $^1H$ NMR spectrum of **2** shows two signals at $\delta > 8$ ppm, whereas **3** has five amide signals at $\delta > 8$ ppm. Intermolecular hydrogen bonding is unlikely to occur in DMSO at mM concentrations. Thus, these signals are indicative of relatively strong intramolecular hydrogen bonds between the peptide strands.[14] From this analysis it follows for **2** that a structure similar to the one in Scheme 1, but with a Boc group on the ferrocene amide moiety, is stabilized by only two hydrogen bonds, one being between Gly-NH and the Boc group carbonyl oxygen atom. Much stronger stabilization prevails in **3**, with about five intramolecular hydrogen bonds. This situation is indeed similar to an antiparallel β-sheet-like protein structure.

CD spectra (in DMSO) were recorded in order to further elucidate the hydrogen bonding situation (Figure 1). The strong Cotton effect in the CD spectrum of octapeptide **3** at about 480 nm is evidence for a chiral conformation at the ferrocene core, similar to our results on the tetrapeptide **1**. The strong intramolecular hydrogen bonding is retained even in DMSO, which confirms our NMR analysis above. A positive signal, as observed for **3**, correlates with a (*P*)-helical arrangement as shown by Hirao[9,10] and by us.[14,17] Compound **2** lacks one pendant peptide strand and, as explained above, the secondary structure is far less stabilized. Consequently, the absence of a Cotton effect in the CD spectrum of **2** may be readily explained by the lack of strong intramolecular hydrogen bonding.

In conclusion, we have prepared and characterized two peptides containing the organometallic amino acid Fca as part of the backbone by SPPS, namely pentapeptide **2** and octapeptide **3**. Our method is unique because it combines Fmoc and Boc procedures. The total decomposition of Fmoc-Fca-Ala-Gly-Val-Leu-resin upon removal of the protecting group led us to terminate this peptide with Boc-Fca which is a convenient intermediate either for further elongation of the peptide chain by Fmoc-protected amino acids to yield **3** or for its successfully cleavage from the resin (for **2**). The target molecules of previously reported SPPS with metallocenes were: (*i*) bioconjugates obtained by replacement of one or two Phe "internal" subunits by metallocenylalanine or (metallocene-1,1′-diyl)bis(alanine),[18–22] (*ii*) *N*-metallocenoyl terminated peptide sequences.[23,24] In this paper, we show that it is possible to incorporate the unnatural ferrocene amino acid Fca into the peptide backbone by SPPS. To this end, a suitable combination of Fmoc and Boc SPPS strategies, which are usually seen as orthogonal, had to be adopted. The two cyclopentadienyl rings in ferrocene may rotate almost freely against each other. This gives ferrocene-based turn mimetics a unique degree of structural flexibility compared to all known organic systems. Indeed, we obtained evidence for an antiparallel β-

sheet-like arrangement for the first time with an organometallic turn inducer. Further work in our groups will explore the possibilities inherent in such biomimetic organometallic systems.[28–31]

# Straightforward Light-Driven Synthesis of Ultrasmall, Water-Soluble Monolayer-Protected Platinum Nanoparticles

**Salvatore Giuffrida,[a] Giorgio Ventimiglia,[b] Fiorella L. Callari,[a] and Salvatore Sortino*[a]**

**Keywords:** Platinum / Nanoparticles / Monolayers / Carboxylates / Light

A facile synthetic methodology to obtain, in one-step, ultrasmall (ca. 1 nm) and water-soluble carboxylate-terminated platinum nanoparticles is reported. It involves visible light as a reaction trigger and platinum acetylacetonate and thioglycolic acid as the only chemical reactants. These nanoparticles are stable for weeks and can be easily transferred into organic solvents such as toluene, chloroform or dichloromethane by using the cationic surfactant tetraoctylammonium bromide as the phase-transfer agent. To the best of our knowledge, they are among *the smallest* water-soluble platinum nanoparticles prepared to date and represent the *first example* of preparation of thiol-protected platinum nanoparticles exclusively driven by light.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

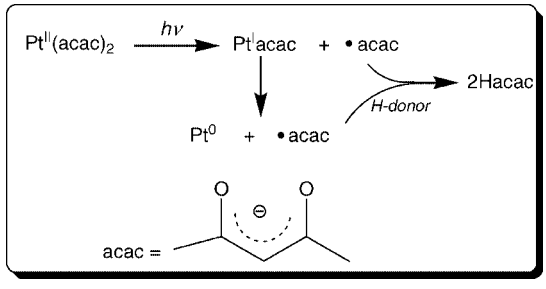
## Introduction

Metal nanoparticles are continuing to draw a great deal of attention by interdisciplinary areas of the scientific community due to their exciting optical, electronic, magnetic and catalytic properties.[1] Potential applications of metal nanoparticles span indeed from molecular electronics and optoelectronics to medicine and biology.[2] The modification of metal nanoparticles with monolayers of thiol derivatives, has been proven to be an appropriate strategy to achieve monolayer-protected clusters which are air-stable, isolable and dispersible in organic solvents.[3] In contrast to the large number of reports focused on the preparation of thiol-capped gold nanoparticles, only limited examples have addressed the synthesis of thiol-protected platinum nanoparticles.[4–7] The interest on these hybrid nanostructures is strongly motivated not only by their well-established catalytic activity, but also by their biomedical relevance. Furthermore, as these nanoparticles are characterized by negligible plasmon absorption into the visible region,[8] they represent ideal platforms for the fabrication of hybrid optical nanodevices by self-assembling of functional chromogenic units.[9] Many practical applications necessitate platinum nanoparticles to be dispersible in water with preservation of their physicochemical properties over long time.[10] In this regard, Chen and Kimura have shown simple synthetic protocols to prepare water-soluble platinum nanoparticles, with diameters ranging from 2.5 to 4.7 nm, capped with mercaptosuccinic acid and involving the chemical reduction of water-soluble platinum salts.[7]

Herein we report a facile synthetic methodology to obtain ultrasmall (ca. 1 nm), water-soluble and stable platinum nanoparticles, implying visible light as a reaction trigger and platinum acetylacetonate, $Pt(acac)_2$, and thioglycolic acid (TA) as the only chemical reactants.

## Results and Discussion

Differently to β-diketonate complexes with metals such as Cu, Ni, and Pd, $Pt(acac)_2$ undergoes photodecomposition with comparable efficiency upon irradiation with both UV and Vis light due to the absence of low-lying d,d states which deactivate the reactive π,π* state.[11] In hydrogen-donating solvents $Pt(acac)_2$ undergoes efficient photodegradation to yield colloidal platinum and β-diketones.[11a] The main steps for this photoprocess are recalled in Scheme 1 for the sake of clarity. They involve the homolytic cleavage of the metal–ligand bond followed by hydrogen abstraction by the ligand-centered radical.



Scheme 1. General photodecomposition mechaism of $Pt(acac)_2$ in the presence of hydrogen donors.

We have recently demonstrated that colloidal platinum can also be obtained in water medium by irradiation of $Pt(acac)_2$ caged in a β-cyclodextrin cavity acting as suitable host and excellent hydrogen donor.[12] Accordingly, when $Pt(acac)_2$ is irradiated in acetonitrile, which is not a hydrogen donor, the photodecomposition is negligible and does not lead to the formation of platinum colloids. On these grounds, we irradiated with visible light an acetonitrile solution of $Pt(acac)_2$ in the presence of TA. The role of TA is expected to be twofold. In fact, it is a good hydrogen donor (the hydrogen atom bound to the sulfur atom is highly reactive towards free radicals) and represents a suited capping agent to obtain platinum nanoparticles with negatively charged surface due to the presence of carboxylate groups. The almost colorless solution turned yellow upon irradiation. As shown in Figure 1, the disappearance of the $Pt(acac)_2$ absorption was accompanied by the appearance of the typical absorption band of Hacac (see dotted spectrum, for comparison) and a structureless absorption extending up to the visible region, attributed to colloidal platinum. The quantum yield for the photochemical reaction (see Experimental Section) was $\Phi = 0.02 \pm 0.005$.

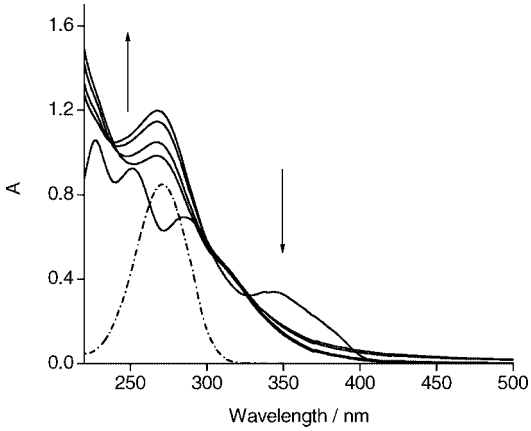

Figure 1. Absorption spectral changes observed upon 0, 8, 16, 40, 50 min of light irradiation of a 0.5 mM acetonitrile solution of $Pt(acac)_2$ in the presence of 1 mM TA. The dotted line shows the absorption spectrum of Hacac in acetonitrile. The arrows indicate the direction of the spectral evolution with time. Cell pathlength 1 mm.

A control experiment carried out with an acetonitrile solution of Hacac provided unambiguous evidence for the quantitative release of the ligand from $Pt(acac)_2$ upon irradiation. As Hacac does not absorb the exciting light, it is not photodecomposed during the course of the photoreaction and thus, can be easily removed from the reaction mixture by drying the irradiated solution under vacuum at 70 °C for 1 h. The dried sample was very soluble in water at pH = 8 but not at pH = 2, according to the presence of the ionizable carboxylic groups bound to the metal surface. This pH dependence allowed the removal of the unbound TA through few cycles of redispersion/centrifugation at pH = 2. The absence of free TA in the supernatant was verified by ESI-MS. At last, the precipitate was solubilized in water at pH = 8 and the absorption spectrum was recorded. As shown in Figure 2A, the spectrum obtained does not show any detectable absorption associated to Hacac but is exclusively characterized by a structureless absorption extending into the visible region which is in full agreement with the spectra reported in the literature for other platinum nanoparticles.[4a,7,8a,8b] High-resolution transmission electron microscopy (HRTEM) on this sample (Figure 2B) shows that the platinum nanoparticles are quite well dispersed and are characterized by an average diameter of $(1.0 \pm 0.3)$ nm. The FFT analysis (inset Figure 2B) reveals that the nanoparticles are single crystals with fcc structure.

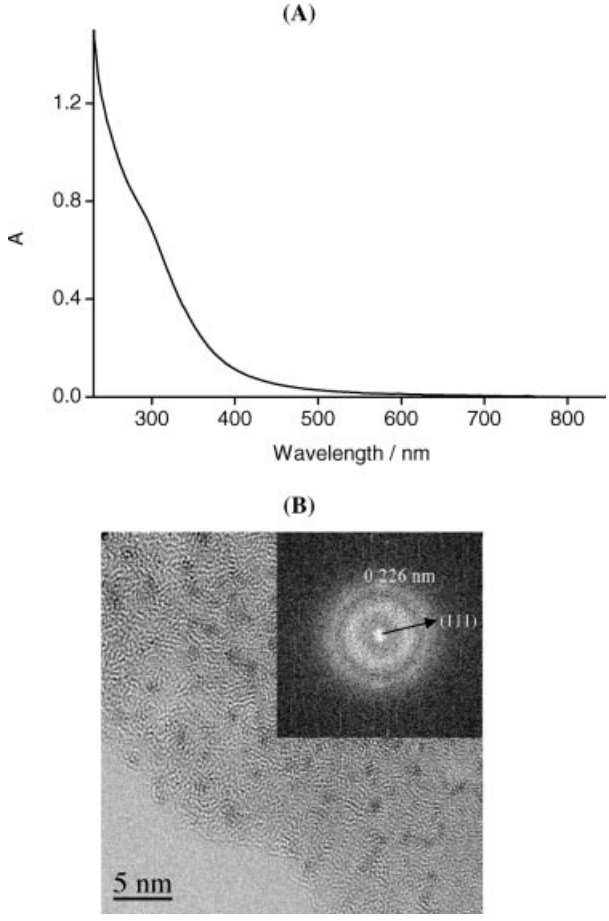

Figure 2. (A) Absorption spectrum in water solution at pH = 8, cell pathlength 1 mm and (B) HRTEM micrograph of the TA-modified platinum nanoparticles. The inset shows the FFT analysis showing an fcc packing arrangement.

Elemental analysis conducted on the sample gave the following results: C 4.65, H 0.42, Na 4.48, O 6.40, Pt 74.49, S 6.33. The atomic ratio of C/H/O/S/Na is 1.94:2.15:2.05:1.01:1. This result provides evidence for the chemisorption of TA through the mercapto termination as well as for the existence of the carboxylate form ($C_2H_2O_2SNa$).

These colloidal nanoparticles exhibited good air stability. Indeed, they remained dispersed in water for several weeks with no relevant aggregation, as evidenced by the negligible variation of the absorption spectrum and the particle size noted after this period of aging.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Interestingly, the monolayer-protected nanoparticles can be easily transferred into organic solvents such as toluene, chloroform or dichloromethane by using the cationic surfactant tetraoctylammonium bromide (TOAB) as the phase-transfer agent. Figure 3A shows representative images of the aqueous solution of the TA-modified platinum nanoparticles before (left) and after (right) shaking with dichloromethane containing 0.1 M TOAB. The color change between the aqueous and organic phase clearly indicates that a complete phase transfer is achieved. It is also noteworthy that the phase transfer occurs without any aggregation as suggested by the negligible variation of the surface plasmon absorption after the nanoparticles transfer into the organic phase (Figure 3B).[13] In fact, particle aggregation would have led to significant broadening of the plasmon absorption.[15] These transference experiments provide a further confirmation that the platinum nanoparticles are negatively charged due to the presence of the carboxylate moieties. Pure electrostatic interaction between these functional groups and the positively charged TOAB has indeed pointed out by Chen and Kimura in the case of modified platinum and gold nanoparticles.[7,16]

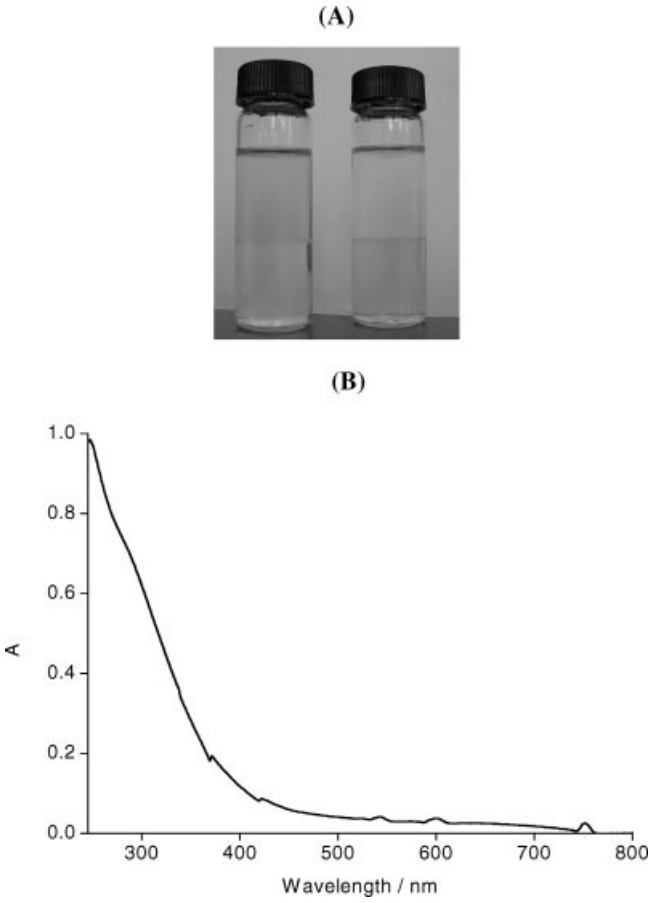

Figure 3. (A) Photograph of the TA-modified platinum nanoparticles in water at pH = 8 before (left) and after (right) shaking with a dichloromethane solution containing 0.1 M TOAB. (B) Absorption spectrum of the TA-modified platinum nanoparticles after transferring in dichloromethane. Cell pathlength 1 mm.

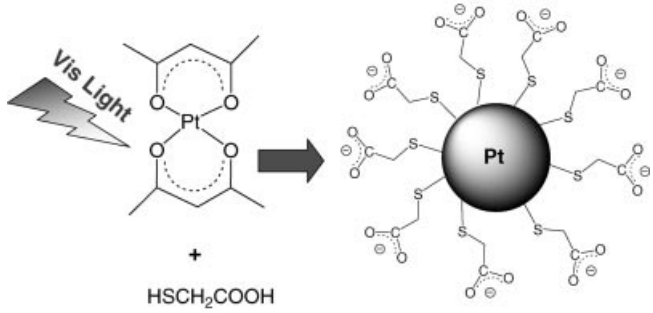
As shown in Scheme 1, the release of the free ligand involves hydrogen abstraction reaction by the ligand-centered radical. Since the occurrence of such a process from acetonitrile is, of course, out of question because thermodynamically not favored, it is reasonable to conceive that the acac˙ radical leads to the formation of Hacac by abstraction of the –SH hydrogen atom, according to the high reactivity of thiols towards free radicals.[17]

## Conclusions

The photochemical methodology pictorially sketched in Scheme 2 is very simple, and effective to produce ultrasmall, water-soluble and stable platinum nanoparticles in a single step. To the best of our knowledge, they are among *the smallest* water-soluble platinum nanoparticles prepared to date and represent the *first example* of preparation of thiol-protected platinum nanoparticles exclusively driven by light. The advantage offered by the light radiation as a reaction trigger is twofold. Firstly, the use of visible excitation produced by conventional lamps with moderate light intensity is environmentally friendly and cheap in contrast to the use of toxic chemicals and sophisticated laser sources. Secondly, the light radiation allows to produce a large number of atoms homogeneously and instantaneously, exerting a key function in the nucleation, growth and dispersion of the nanoparticles. In view of their small sizes and the well-known role of the carboxylic moiety in the formation of self-assembled supramolecular architectures,[18] these carboxylate-terminated platinum nanoparticles might be intriguing candidates for potential biological applications and building-up of two- and three-dimensional self-assembled nanocomposite devices.



Scheme 2. Pictorial view illustrating the single-step formation of the monolayer-protected platinum nanoparticles.

## Experimental Section

All reagents were obtained from Sigma–Aldrich and used as received. The solvents used were of analytical and spectrophotometric grade. All glassware used was immersed in piraña solution (70:30 $H_2SO_4/H_2O_2$) at 70 °C for 1 h. ***Warning:*** *piraña solution should be handled with caution!* Next, the glassware was rinsed with large amounts of high-purity water and dried. Water was purified through a Millipore Milli-Q system. Irradiation was carried out under a continuous argon flux in a 10 mm quartz cuvette with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

3 mL capacity using a Rayonet photochemical reactor equipped with 16 RPR lamps with an emission in the 380–480 nm range with a maximum at 420 nm. The incident photon flux on the sample was ca. $10^{16}$ quanta $s^{-1}$. The total irradiation time was 50 min, the concentrations of $Pt(acac)_2$ and TA were 0.5 mM and 1 mM, respectively. The photodecomposition quantum yield for the $Pt(acac)_2$ complex was determined spectrophotometrically by using the following equation: $\Phi = \Delta[C]V/\Delta t I_0 F$, where $\Delta[C]/\Delta t$ is the rate of disappearance of the platinum complex, $V$ is the volume of the irradiated solution, $I_0$ is the intensity of the incident photons and $F$ is the fraction of the photons absorbed by the platinum complex. Absorption spectra were recorded with a Jasco V-560 spectrophotometer. ESI mass spectra were recorded with an Agilent 1100 series ESI/MSD spectrometer. Experimental conditions were as follows: capillary voltage, 3.5 kV; fragmentor, 100 V; source temperature, 350 °C; drying gas, $N_2$ (10 L/min); carrier solvent, methanol (0.4 mL/min). HRTEM images were obtained by means of an FEG JEM 2010F instrument with a field emission gun operating at 200 kV. The electro-optical configuration guarantees ultrahigh spatial resolution (0.19 nm). This microscope is equipped with the GIF (Gatan Image Filter) apparatus which allows to realize images filtered to narrow windows of the electron energy loss spectrum. Elemental analyses were conducted by means of standard techniques.

## Acknowledgments

We thank Mr. C. Bongiorno of the IMM-IMETEM-CNR (Catania) for his precious technical assistance in the TEM measurements.

# An Eight-Coordinate Mononuclear Double Helical Complex

**Michael G. B. Drew,[a] Debarati Parui,[b] Senjuti De,[b] Jnan P. Naskar,[b] and Dipankar Datta*[b]**

**Keywords:** Cadmium / Single helicate / Double helicate / N ligands / Seven-coordinate complexes / Eight-coordinate complexes

From the reaction of $Cd(CH_3COO)_2{\cdot}2H_2O$ with the 1:2 condensate (L) of benzil dihydrazone and 2-acetylpyridine, $[CdL(CH_3COO)(H_2O)]PF_6{\cdot}3H_2O$ (**1**) is isolated by adding $NH_4PF_6$. L reacts with $Cd(ClO_4)_2{\cdot}xH_2O$ to yield $[CdL_2](ClO_4)_2{\cdot}0.5H_2O$ (**2**). The yellowish complexes **1** and **2** are characterized by NMR and single-crystal X-ray diffraction. **1** is found to be a seven-coordinate single helical complex having a $Cd^{II}N_4O_3$ core and homoleptic **2** an eight-coordinate double helical complex with a $Cd^{II}N_8$ core.

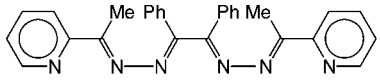
## Introduction

Many naturally occurring molecules are helical.[1] But synthetic helical organic molecules like [*n*]helicenes[2] are rare. These are achieved only through designed synthesis.[3,4] Non-helical organic molecules containing suitable hetero donor atoms can give rise to helical topology when they bind to many metal ions because of the coordination properties of the metal ions.[1,5,6] This has been an important area of research in metallo-organic chemistry in recent times. Metallo-organic helices, commonly, can be single, double, or triple. A single helical complex may contain a single metal ion or multiple metal ions. But for multiple helical complexes, it seems that at least two metal ions in combination with an at least tetradentate ligand are necessary. So far, only one example of a mononuclear triple helical complex is known where the metal ion is nine-coordinate $La^{III}$ and the helicand is tridentate.[7] To date there is no example of a mononuclear double helical inorganic complex. Herein we report such a complex. The metal ion in our case is $Cd^{II}$ and the ligand is a tetradentate N donor.

## Results and Discussion

The ligand L we used is helical. It is a 1:2 condensate of benzil dihydrazone and 2-acetylpyridine.[8] In the area of inorganic helices, others have been using non-helical ligands. But for quite some time, we have been engaged in generating helical topologies by using ligands which are themselves helical.[9,10] The helical twist in L is brought about by the N=C(Ph)–C(Ph)=N torsion angle which is 85.9(5)° in the solid state.[11]



ligand L

Reaction of $Cd(CH_3COO)_2{\cdot}2H_2O$ with L in an equimolar ratio in methanol at room temperature and subsequent addition of a stoichiometric amount of $NH_4PF_6$ gives $[CdL(CH_3COO)(H_2O)]PF_6{\cdot}3H_2O$ (**1**) in 65% yield. From the reaction of $Cd(ClO_4)_2{\cdot}xH_2O$ and L in an equimolar ratio in methanol at room temperature, $[CdL_2](ClO_4)_2{\cdot}0.5H_2O$ (**2**) is isolated in 20% yield. The yield of **2** increased to 60% when the Cd/L ratio was 1:2. Both complexes **1** and **2** have a faint yellow colour.

The X-ray crystal structures of **1** and **2** have been determined. The structure of the cation of **1** is shown in Figure 1 together with the atomic numbering scheme. The metal atom is bonded to four nitrogen atoms of the tetradentate ligand L, two oxygen atoms of an acetate group at 2.354(9), 2.396(10) Å and a water molecule at 2.342(7) Å. The bond lengths to the four nitrogen atoms of L are 2.390(7) Å to N(11), 2.411(7) Å to N(18), 2.428(6) Å to N(23), and 2.405(7) Å to N(30), thus the distances to the pyridine nitrogen atoms are slightly shorter. The conformation of the ligand is described by the N=C(Ph)–C(Ph)=N torsion angle which is 75.4(1)°. The geometry of the coordination sphere can be described as a capped trigonal prism with the water molecule O(100) capping the face of N(11), N(23), N(30), and O(52) but this is severely distorted by the small bite of the acetate group. The Cd atom in **1** is seven-coordinate; but in the homoleptic complex **2**, its coordination sphere expands to

eight to accommodate two ligands. The structure of the cation of **2** is shown in Figure 2 together with the atomic numbering scheme. The geometry is a distorted dodecahedron in which the pyridine nitrogen atoms N(11), N(30), N(41), N(60) form one plane (r.m.s. deviation 0.01 Å) and the acyclic nitrogen atoms N(18), N(23), N(48), N(53) (r.m.s. deviation 0.30 Å) the other plane, the two planes intersecting at 85.8°. In this structure there is a much greater variation in Cd–N bond lengths, no doubt because of steric crowding in the metal coordination sphere. For one of the ligands, distances are Cd(1)–N(11) 2.422(4), Cd(1)–N(18) 2.504(4), Cd(1)–N(223) 2.495(4), and Cd(1)–N(30) 2.414(4) Å showing a regular pattern in which the bonds to the acyclic nitrogen atoms are longer than the bonds to the pyridine nitrogen atoms. However, the distances to the other ligand are more irregular with Cd(1)–N(41) 2.506(4), Cd(1)–N(48) 2.596(4), Cd(1)–N(53) 2.513(4), and Cd(1)–N(60) 2.460(4) Å. The conformations of the ligands are the same as that found in **1**; the N=C(Ph)–C(Ph)=N torsion angle in the two independent ligand moieties are 73.6 and 77.7 °, respectively. Complexes **1** and **2** contain seven-membered chelate ring(s).

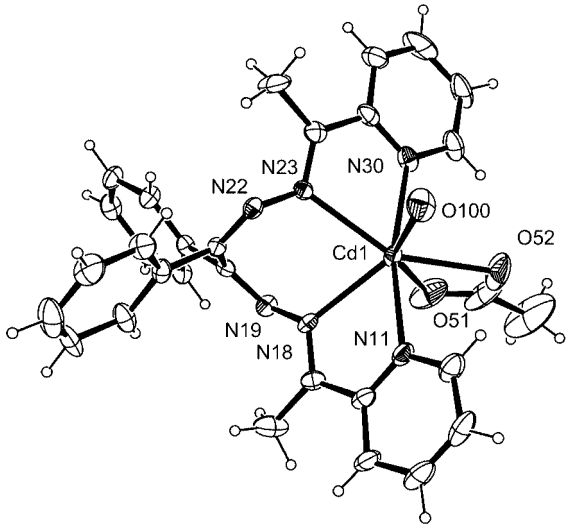

Figure 1. The structure of the cation in **1** with ellipsoids at 25% probability. The hydrogen atoms on the water molecule were not located. Selected bond lengths [Å] and angles [°]: Cd1–O100 2.342(7), Cd1–O51 2.354(9), Cd1–N11 2.390(7), Cd1–O52 2.396(10), Cd1–N30 2.405(7), Cd1–N18 2.411(7), Cd1–N23 2.428(6); O100–Cd1–O51 144.9(4), O100–Cd1–N11 88.4(3), O51–Cd1–N11 93.2(3), O100–Cd1–O52 90.7(5), O51–Cd1–O52 54.9(5), N11–Cd1–O52 83.6(3), O100–Cd1–N30 85.2(3), O51–Cd1–N30 85.3(3), N11–Cd1–N30 166.5(3), O52–Cd1–N30 84.6(3), O100–Cd1–N18 126.9(3), O51–Cd1–N18 85.0(4), N11–Cd1–N18 66.5(2), O52–Cd1–N18 128.7(4), N30–Cd1–N18 126.6(2), O100–Cd1–N23 81.6(3), O51–Cd1–N23 125.0(4), N11–Cd1–N23 123.0(2), O52–Cd1–N23 151.7(3), N30–Cd1–N23 67.8(3), N18–Cd1–N23 75.8(2).

The topologies of the complexes **1** and **2** are helical which can be discerned better from their space-filling models shown in Figure 3. Complex **1** is a mononuclear single helix. Many examples of such mononuclear single helices are known,[5,6] but very few with Cd.[12,13] Complex **2** is a mononuclear double helical complex which is unprecedented in its coordination chemistry. Though similar experimental conditions were used for obtaining complexes **1** and **2**, their compositions are different. We believe this difference is due to the difference in the coordinating ability of the anions. Since acetate is much more coordinating in nature than perchlorate, the presence of acetate gives rise to a heteroleptic complex such as **1**. At present we are engaged in studying the effect of the anion on the nature of the product of our synthetic method. Starting with $Cd(NO_3)_2{\cdot}4H_2O$, it seems that we obtain a single helical complex of composition $CdL(NO_3)_2{\cdot}H_2O$.

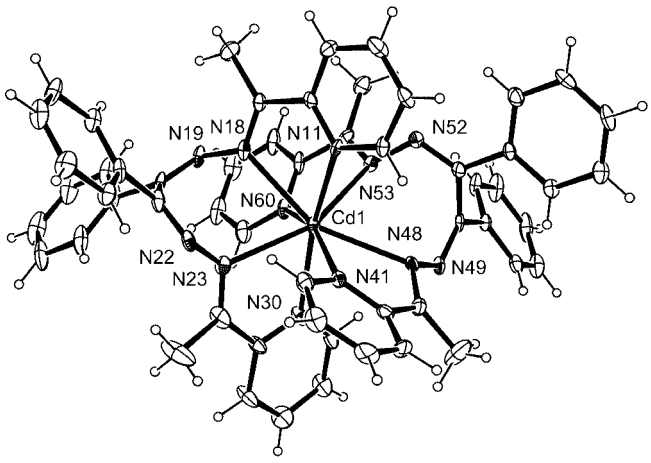

Figure 2. The structure of the cation in **2** with ellipsoids at 25% probability. Selected bond lengths [Å] and angles [°]: Cd1–N11 2.422(4), Cd1–N18 2.504(4), Cd1–N23 2.495(4), Cd1–N30 2.414(4), Cd1–N41 2.506(4), Cd1–N48 2.596(4), Cd1–N53 2.513(4), Cd1–N60 2.460(4); N30–Cd1–N11 160.2(1), N30–Cd1–N60 79.1(1), N11–Cd1–N60 120.7(1), N30–Cd1–N23 66.9(1), N11–Cd1–N23 108.8(1), N60–Cd1–N23 93.7(1), N30–Cd1–N18 127.2(1), N11–Cd1–N18 64.7(1), N60–Cd1–N18 73.1(1), N23–Cd1–N18 71.1(1), N30–Cd1–N41 80.3(1), N11–Cd1–N41 79.9(1), N60–Cd1–N41 159.4(1), N23–Cd1–N41 77.0(1), N18–Cd1–N41 119.6(1), N30–Cd1–N53 118.9(1), N11–Cd1–N53 73.9(1), N60–Cd1–N53 64.7(1), N23–Cd1–N53 153.9(1), N18–Cd1–N53 88.0(1), N41–Cd1–N53 128.1(1), N30–Cd1–N48 78.5(1), N11–Cd1–N48 92.4(1), N60–Cd1–N48 112.5(1), N23–Cd1–N48 131.5(1), N18–Cd1–N48 153.9(1), N41–Cd1–N48 64.1(1), N53–Cd1–N48 73.0(1).

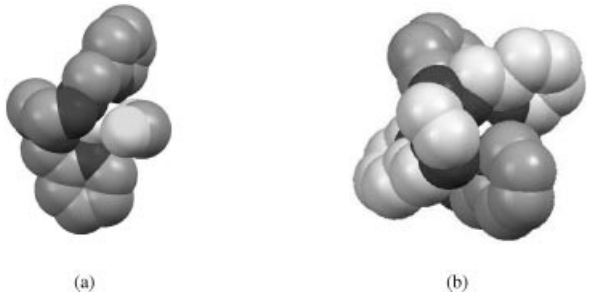

Figure 3. Space-filling models of the cations in **1** (a) and **2** (b) showing the helical nature of the complexes. The methyl and phenyl groups, and H atoms are removed for clarity. Code: (a) C, dark grey; N, black; O, light grey; Cd, white; (b) in one of the ligand strands C is dark grey and in the other light grey, the others are the same as in (a).

Since compounds **1** and **2** are helical, enantiomers are expected. Complex **1** crystallises in the non-centrosymmetric space group *Cc* and twinned refinement gave no evi-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dence for a twin being present, so the structure can be considered as non-racemic in the individual single crystals. On the other hand, complex **2** crystallises in the centrosymmetric space group *Pbca* and therefore represents a racemic mixture in the solid state.

Bidentate ligands cannot afford a mononuclear helix. However, they can form at least dinuclear helicates by bridging two metal ions.[14] From the example of the $La^{III}$ compound of Renaud et al.,[7] it is clear that, to generate a mononuclear helical metal complex, the minimum denticity of the helicand (ligand) has to be three. Now, with some imagination it can be realized that with a six-coordinate metal ion, which can give rise to an octahedral geometry, a tridentate ligand will never yield a mononuclear double helix. This is the reason why so far a mononuclear double helical complex has never been found with a six-coordinate metal ion. So the next choice is a tetradentate ligand with an eight-coordinate metal ion. Both the conditions are fulfilled in complex **2**.

## Experimental Section

**General:** L was synthesised as reported earlier.[8] Microanalyses were performed with a Perkin–Elmer 2400II elemental analyser. FT-IR spectra (KBr) were recorded with a Shimadzu FTIR-8400S spectrometer, UV/Vis spectra in $CH_2Cl_2$ with a Shimadzu UV-160A spectrophotometer and 300 MHz NMR spectra in $CD_2Cl_2$ (reference: TMS) with a Bruker DPX300 spectrometer.

**Synthesis of $[CdL(CH_3COO)(H_2O)]PF_6\cdot 3H_2O$ (1):** $Cd(CH_3COO)_2\cdot 2H_2O$ (0.13 g, 0.5 mmol), dissolved in methanol (5 mL), was added to a methanolic (20 mL) solution of the ligand L (0.22 g, 0.5 mmol), synthesised by a procedure previously published.[8] After stirring the resulting light-yellow solution for 30 min, a methanolic solution (5 mL) of $NH_4PF_6$ (0.84 g, 0.5 mmol) was added and the mixture left for the solvent to evaporate. When the volume was ca. 5 mL, the deposited yellow crystals were filtered off and found to be suitable for X-ray diffraction. Yield: 0.27 g (65%). $C_{30}H_{35}CdF_6N_6O_6P$ (833.01): calcd. C 43.23, H 4.24, N 10.09; found C 43.33, H 4.12, N 10.19. FTIR (KBr): $\tilde{\nu}$ = 839 (vs) [$\nu(PF_6)$] $cm^{-1}$. UV/Vis: $\lambda_{max}$ ($\varepsilon_{max}$) = 219 ($6.2\cdot10^4$), 265 ($2.5\cdot10^4$), 310 ($2.8\cdot10^4$ $M^{-1}cm^{-1}$) nm. $^1H$ NMR: $\delta$ = 2.03 (s, methyl of acetate), 2.51 (s, methyl of L), 7.11–8.01 (aromatic protons) ppm.

**Synthesis of $[CdL_2](ClO_4)_2\cdot 0.5H_2O$ (2):** $Cd(ClO_4)_2\cdot xH_2O$ (0.15 g, 0.5 mmol), dissolved in methanol (5 mL), was added to a methanolic (35 mL) solution of L (0.44 g, 1 mmol) and the mixture stirred for 2 h (a white crystalline compound started appearing within 15 min). Then the precipitate was filtered, washed with petroleum ether (5 mL) and dried in air. Yield: 0.36 g (60%). Single crystals were grown by direct diffusion of *n*-hexane into a moderately concentrated solution of the complex in dichloromethane. $C_{56}H_{49}CdCl_2N_{12}O_{8.5}$ (1208.36): calcd. C 55.29, H 4.08, N 13.52; found C 55.41, H 4.12, N 13.78. FTIR (KBr): $\tilde{\nu}$ = 1089 (vs), 623 (s) [$\nu(ClO_4)$] $cm^{-1}$. UV/Vis: $\lambda_{max}$ ($\varepsilon_{max}$) = 265 ($8.6\cdot10^4$), 305 ($8.8\cdot10^4$ $M^{-1}cm^{-1}$) nm. $^1H$ NMR: $\delta$ = 2.52 (s, methyl protons), 7.12–8.03 (aromatic protons) ppm.

**X-ray Crystallography:** Crystal Data for **1**: $C_{30}H_{35}CdF_6N_6O_6P$, $M$ = 833.01, monoclinic, space group *Cc*, $Z$ = 4, $a$ = 19.74(2), $b$ = 11.304(14), $c$ = 17.277(19) Å, $\beta$ = 100.59(1)°, $V$ = 3790(8) $Å^3$, $d_{calcd.}$ = 1.460 $gcm^{-3}$. Crystal data for **2**: $C_{56}H_{48}$ Cd $Cl_2$ $N_{12}$ $O_{8.50}$, $M$ = 1208.36, orthorhombic, space group *Pbca*, $Z$ = 8, $a$ = 16.2318(7), $b$ = 21.0442(10), $c$ = 32.2236(14) Å, $V$ = 11007(1) $Å^3$, $d_{calcd.}$ = 1.458 $gcm^{-3}$. Data for **1** were collected with a Marresearch Image Plate system at 293 K using Mo-$K_\alpha$ radiation. The crystal was positioned at 70 mm from the Image Plate. 95 frames were measured at 2° intervals with a counting time of 2 min. Data reduction was carried out using the XDS program[15] to give 5256 independent reflections. Data for **2** were collected with an Oxford Instruments X-Calibur CCD system at 150 K using Mo-$K_\alpha$ radiation. The crystal was positioned at 50 mm from the CCD. 321 frames were measured with a counting time of 10 s. Data reduction was carried out using the Crysalis program[16] to give 16192 independent reflections. Both structures were solved using Shelxs97.[17] The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they are attached. Absorption corrections were carried out using the DIFABS program[18] for **1** and the ABSPACK program[19] for **2**. The structures were refined on $F^2$ using Shelxl97 to give $R1$ = 0.0525, $wR2$ = 0.1382 (for **1**) and $R1$ = 0.0964, $wR2$ = 0.1239 (for **2**) using 4786 (for **1**) and 9503 (for **2**) reflections with $I > 2\sigma(I)$. CCDC-611911 (for **1**) and -611912 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Adducts of $Cp_3Ln$ with LGa(Me)OH, Syntheses and X-ray Crystal Structures of $LGa(Me)HO{\rightarrow}LnCp_3$ {Ln = Sm, Nd, Yb; L = $HC[C(Me)N(2,6\text{-}iPr_2C_6H_3)]_2$}

**Sanjay Singh,[a] Aritra Pal,[a] Herbert W. Roesky,*[a] and Regine Herbst-Irmer[a]**

**Keywords:** Adducts / Hydroxides / Gallium / Heterodimetallic compounds / Lanthanides

Various heterodimetallic (gallium-lanthanide) compounds have been prepared by the reaction of LGa(Me)OH (**2**) with $Cp_3Ln$. Thus, the adducts $LGa(Me)HO{\rightarrow}LnCp_3$ (Ln = Sm, **3**; Nd, **4**; Yb, **5**) were obtained and characterized by IR spectroscopy and elemental analyses. The single-crystal X-ray structures of **3** and **4** are also reported.

## Introduction

Due to our long-standing interest in the syntheses of molecular main group hydroxides, we have successfully assembled several novel hydroxido complexes.[1–4] Among these, soluble group 13 hydroxides of aluminum[5] are of special interest in view of their utilization in the syntheses of alumoxanes[6] and other heterodimetallic compounds of potential applications.[7–10] The toluene/liquid ammonia two-phase hydrolysis[5] or the hydrolysis in the presence of N-heterocyclic carbenes, as an HCl scavenger,[8] are genuine routes to prepare these molecules. According to the latter method, we have assembled the methylgallium hydroxide (Scheme 1) and have also utilized it as a synthon to prepare new heterodimetallic compounds. Thus, the reaction of the gallium hydroxide LGa(Me)OH (**2**) with $Cp_2ZrMe_2$ gave the Ga–Zr mixed oxide LGa(Me)–O–Zr(Me)$Cp_2$.[11] Also, the reaction of LAl(Me)OH (**1**) with $Cp_3Ln$ (Ln = Yb, Er, Dy) led to the formation of various aluminum–lanthanide mixed oxides (Scheme 2).[9]

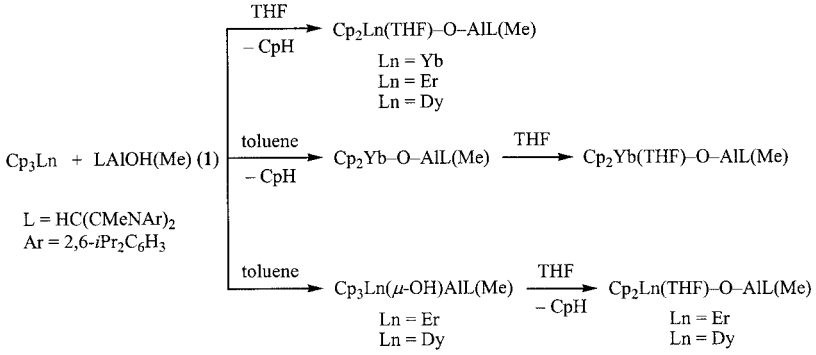
This new area of research that combines both main group and lanthanide elements to constitute a novel class



Scheme 2.

of heterodimetallic species started with the work of Mehrotra and co-workers who reported in the late 1970s the isopropoxides of gallium and lanthanides (La, Pr, Nd, Sm, Gd, Ho and Er), $[Ln\{Ga(OiPr)_4\}_3]$, by the reaction of either

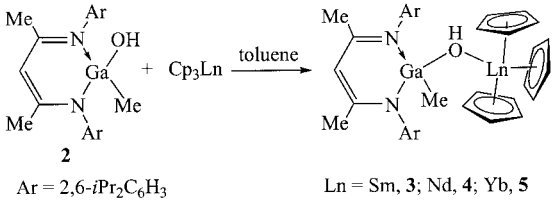
lanthanide chlorides with potassium gallium isopropoxides or by the reaction of lanthanide isopropoxides with gallium isopropoxides.[12,13] However, none of these compounds were structurally characterized and to the best of our knowledge there has been no other attempt to prepare mixed metal oxides or hydroxides of gallium with lanthanide atoms. It is to be noted that heterodimetallic compounds containing aluminum and lanthanides are well known but the corresponding gallium compounds are very rare. Our main aim in this area is to prepare mixed metal gallium–lanthanide compounds connected by an oxygen atom. Therefore, we report herein the synthesis and structural characterization of various Ga–Ln metal hydroxides by the reaction of LGa(Me)OH with $Cp_3Ln$ (Ln = Sm, Nd, Yb). Moreover, the reactivity of LGa(Me)OH is also compared with its aluminum analogue LAl(Me)OH.

## Results and Discussion

Reaction of LGa(Me)OH (**2**) with 1 equiv. of $Cp_3Ln$ was carried out in toluene at room temperature to afford the adducts LGa(Me)(μ-OH)Ln$Cp_3$ (Ln = Sm, **3**; Nd, **4**; Yb, **5**) (Scheme 3) in good yields. Compounds **3** and **5** are stable yellow solids and **3** melts at 275 °C whereas **5** melts with decomposition at 275 °C. Compound **4** is a blue-green solid that melts with decomposition at 254 °C. As observed in the IR spectrum of the adducts **3**, **4** and **5**, elimination of CpH did not occur and the (μ-OH) stretching frequency was observed at 3592, 3591, and 3609 $cm^{-1}$ respectively. These frequencies are redshifted when compared to that of LGa(Me)OH (**2**) observed at 3676 $cm^{-1}$, which also confirms that the hydroxide group bridges between the Ga and Ln atom. This is in contrast to the reaction of the corresponding aluminum hydroxide LAl(Me)OH (**1**) with $Cp_3Ln$ where the elimination of CpH occurred (Scheme 2). This indicates that the proton of LGa(Me)OH (**2**) is less acidic than that of LAl(Me)OH (**1**).[9]



Scheme 3.

Single crystals of **3** and **4** were obtained from a toluene solution. Figures 1 and 2 show the structures of **3** and **4**, respectively. Both **3** and **4** are isomorphous and crystallize in the monoclinic space group $P2_1/m$ with half of a molecule in the asymmetric unit. The lanthanide ions possess a pseudotetrahedral geometry surrounded by three cyclopentadienyl rings and an oxygen atom. The Ga atom forms a distorted tetrahedron with two nitrogen atoms of the β-diketiminato ligand, one carbon atom of the methyl group and an oxygen atom of the hydroxy bridge. The hydrogen atom of the bridging hydroxido group [O(1)] in compound **3** cannot be located in the electron density map, probably due to the refinement against non-merohedrally twinned data. However, its presence was confirmed by the infrared spectrum and also due to the presence of three cyclopentadienyl rings connected to the samarium atom.

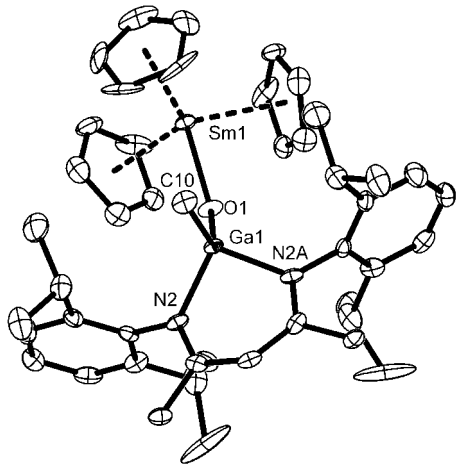


Figure 1. Molecular structure of LGa(Me)(μ-OH)Sm$Cp_3$ (**3**). Thermal ellipsoids are shown at 50% probabilities. Hydrogen atoms are omitted for clarity.

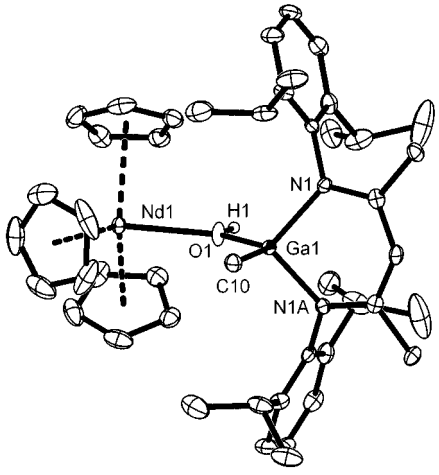

Figure 2. Molecular structure of LGa(Me)(μ-OH)Nd$Cp_3$ (**4**). Thermal ellipsoids are shown at 50% probabilities. Hydrogen atoms (except that at the oxygen atom) are omitted for clarity.

The Ga(1)–O(1) bond in compounds **3** [1.862(7) Å] and **4** [1.851(3) Å] is longer than that found in LGa(Me)OH [1.831(1) Å]. This elongation is expected due to coordination of the hydroxy group to the other metal atoms in **3** and **4**. The Sm(1)–O(1) bond of 2.465(7) Å is significantly shorter than that of the corresponding aluminum compound LAl(Me)(μ-OH)Sm$Cp_3$ [2.500(4) Å][9] but longer than that of $[Cp^*_2Sm(\mu\text{-}O_2CSPh)]_2$ [2.328(2) Å].[14] The Nd(1)–O(1) bond of 2.479(3) Å is longer than the bridging Nd–O bond in $Nd_5O(OiPr)_{13}$ [2.304(12)–2.345(11) Å] and significantly longer than the terminal Nd–O bonds [2.082(11)–2.123(11) Å].[15] The Ga(1)–O(1)–Sm(1)/Nd(1) core is bent with an angle of 149.3(4)° (**3**)/149.7(2)° (**4**)

## Conclusion

We have attempted to synthesize heterodimetallic compounds containing gallium and lanthanide elements. The adducts thus obtained represent rare examples for such a system. We anticipate that further reaction of LGa(Me)OH with other suitable lanthanide precursors may allow the formation of heterodimetallic gallium–lanthanide oxides. Such studies are underway in our laboratory.

## Experimental Section

**General:** All manipulations were performed under dry and oxygen-free $N_2$ or Ar using Schlenk-line and glove-box techniques. Solvents were purified according to conventional procedures and were freshly distilled prior to use. LGa(Me)OH,[11] Cp$_3$Yb,[16] and Cp$_3$Nd[16] were synthesized according to literature procedures. Cp$_3$Sm was purchased from Aldrich and used without further purification.

**Synthesis of LGa(Me)(μ-OH)SmCp$_3$ (3):** Toluene (40 mL) was added to a mixture of LGa(Me)OH (0.52 g, 1.00 mmol) and Cp$_3$Sm (0.35 g, 1.00 mmol) at room temperature. The mixture was stirred overnight when the color of the mixture slowly turned to yellow from orange. After removal of all volatiles in vacuo, toluene (60 mL) was added and the mixture was heated to 80 °C and filtered while hot. The clear yellow filtrate was kept at room temperature to afford yellow crystals of **3** (0.58 g), another crop of yellow crystals was obtained from the mother liquor (0.17 g). Total crystal yield (0.75 g, 87%). M.p. 275 °C. $C_{45}H_{60}GaN_2OSm$ (865.05): calcd. C 62.48, H 6.99, N 3.24; found C 62.17, H 6.80, N 3.22. EI-MS: *m*/*z* (%) = 504 (72) [M$^+$ – Me – Cp$_3$Sm]. IR (Nujol): $\tilde{\nu}$ = 3592, 1521, 1442, 1384, 1311, 1255, 1204, 1176, 1105, 1013, 967, 941, 867, 801, 772, 755, 725, 587, 557, 442 cm$^{-1}$.

**Synthesis of LGa(Me)(μ-OH)NdCp$_3$ (4):** Toluene (45 mL) was added to a mixture of LGa(Me)OH (0.26 g, 0.50 mmol) and Cp$_3$Nd (0.17 g, 0.50 mmol) at room temperature. The mixture was stirred overnight when the color of the mixture slowly turned to light blue-green. After removal of all volatiles in vacuo, toluene (40 mL) was added to the residue. The mixture was heated to 90 °C and filtered while hot. The clear light blue-green filtrate was kept at room temperature to afford greenish crystals of **4**. Crystal yield (0.38 g, 88%). M.p. 254 °C (decomp.). $C_{45}H_{60}GaN_2NdO$ (858.93): calcd. C 62.92, H 7.04, N 3.26; found C 62.69, H 7.13, N 3.22. EI-MS: *m*/*z* (%) = 792 (2) [M$^+$ – CpH], 503 (24) [M$^+$ – Me – Cp$_3$Nd]. IR (Nujol): $\tilde{\nu}$ = 3591, 1553, 1521, 1463, 1440, 1378, 1311, 1258, 1204, 1177, 1106, 963, 942, 868, 801, 784, 770, 953, 725, 587, 557, 442 cm$^{-1}$.

**Synthesis of LGa(Me)(μ-OH)YbCp$_3$ (5):** Toluene (40 mL) was added to a mixture of LGa(Me)OH (0.26 g, 0.50 mmol) and Cp$_3$Yb (0.18 g, 0.50 mmol) at room temperature. The mixture was stirred overnight when the color of the mixture slowly turned to orange-

yellow from green. After removal of all volatiles in vacuo, toluene (45 mL) was added and the mixture was heated to 90 °C and filtered while hot. The clear orange-yellow filtrate was kept at room temperature to afford yellow crystals of **5**. Crystal yield (0.37 g, 91%). M.p. 275 °C (decomp.). $C_{45}H_{60}GaN_2OYb$ (887.73): calcd. C 60.88, H 6.81, N 3.16; found C 60.79, H 6.86, N 3.20. EI-MS: *m*/*z* (%) = 726 (50) [$M^+$ – 2 Cp – 2 Me], 711 (60) [$M^+$ – 2 Cp – 3 Me]. IR (Nujol): $\tilde{\nu}$ = 3609, 1552, 1524, 1440, 1398, 1315, 1261, 1177, 1106, 1015, 940, 832, 817, 797, 760, 643, 555, 444 $cm^{-1}$.

**X-ray Structure Determination of 3 and 4:** A suitable crystal of **3** and **4** was mounted on a glass fibre and coated with paraffin oil. Data for **3** and **4** were obtained with a Bruker three-circle diffractometer equipped with a SMART 6000 CCD detector using mirror-monochromated Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å). Data of both structures were non-merohedrally twinned. The twin operation in both cases is a twofold axis along the reciprocal axis 001. The fractional contribution of the minor domain refined to 0.475(2) (**3**) and 0.495(1) (**4**). The structures were solved by direct methods using SHELXS-97[17] and refined against $F^2$ on all data by full-matrix least squares with SHELXL-97.[18] All non-hydrogen atoms were refined anisotropically. Atom scattering factors (including anomalous scattering) were taken from the "International Tables for X-ray Crystallography".[19] Hydrogen atoms connected to carbon atoms were included at geometrically calculated positions and refined using a riding model. The hydrogen atom of the OH group could be located in **4** in the electron density map and was refined with distance restraints (Table 2). CCDC-614180 (**3**) and -614181 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Cyclodimethylsiloxane $(Me_2SiO)_m$ ($m$ = 3–6) Ring Transformations on Reactions with $AgSbF_6$; Crystal Structure of $Ag(Me_2SiO)_7SbF_6$

**Andreas Decken,[a] Francis Arthur LeBlanc,[a] Jack Passmore,*[a] and Xinping Wang[a]**

**Keywords:** Cyclodimethylsiloxane / Host–guest systems / Silver / Silicon ethers / Ring transformation / Hexafluoroantimonate / Pseudo crown ethers / Lewis bases

The reaction of $D_m$ (D = $Me_2SiO$, $m$ = 3–6) with silver hexafluoroantimonate in liquid $SO_2$ affords a mixture of $AgD_nSbF_6$ ($n$ = 6–8) complexes. Upon the addition of $CH_3CN$, $Ag^+$-directed ring transformations are effected, which allows for the isolation of neat $D_n$ ($n$ = 6–8). The $AgD_n^+$ cations are rare examples of Lewis acid donor complexes of silicon ethers and $Ag^+$ oxygen donor complexes, and their isolation implies that numerous metal cation cyclosiloxanes can be prepared from readily available starting materials.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

We recently reported the preparation of $Li^+$-cyclodimethylsiloxane host–guest cations directly from their components[1] and provided rare examples of silicon ethers behaving as Lewis bases as shown in Equation (1). Their structures imply that cyclodimethylsiloxanes ($D_5$ and $D_6$, D = $Me_2SiO$) act as pseudo crown ethers. Apart from alkali metal cations ($Li^+$ and $K^+$[2]) with large anions, no other examples of a metal-cation–siloxane adduct have been reported. Metal-cation–siloxane salt formation is favored by large anions, which minimizes the unfavorable lattice-energy changes. Therefore, the question as to whether the formation of the complexes could be extended to the use of commercially available salts with smaller anions as the starting materials remains. The $Ag^+$ cation is regarded as a soft Lewis acid[3] and has a low affinity to oxygen donor ligands.[4] Nevertheless, we report below the first examples of the transition-metal-cation–siloxane $SbF_6^-$ salts of $AgD_n^+$ ($n$ = 6–8) formed by the reactions of $D_m$ ($m$ = 3–6) with $AgSbF_6$ in liquid $SO_2$. Unlike the Li[Al] case, transformation of the siloxane rings occur with $Ag^+$ acting as a template for the formation of the most thermodynamically stable metal-cation–cyclodimethylsiloxane complex. The formation of macrocyclic ethers by the reaction of $AgAsF_6$ with $(CH_2O)_3$ or ethylene oxide was described by Roesky and his coworkers.[5] However, no similar ring transformation reactions of cyclodimethylsiloxanes under mild conditions have been previously reported.[6] Ring-opening polymerization of $D_m$ ($m$ = 3–6) has been widely investigated, and these results are also of interest in this context.

$$\mathrm{Li[Al]} + \mathrm{D}_m \xrightarrow[\text{r.t.}]{\mathrm{CH_2Cl_2}} \mathrm{LiD}_m\mathrm{[Al]} \quad (1)$$

$$\mathrm{[Al]} = \mathrm{Al(OC(CF_3)_3)_4},\ m = 5 \text{ or } 6;\quad = \mathrm{Al(OC(CF_3)_2Ph)_4},\ m = 6$$

The reaction of excess $AgSbF_6$ with $D_5$ (1.4:1) in liquid $SO_2$ affords a colorless, highly hygroscopic solubilized product. When a saturated $SO_2$ solution of the product is cooled, a colorless crystalline material is afforded. Several single-crystals were identified by X-ray diffraction analysis as $AgD_7SbF_6$. However, the mass spectrum of the material showed fragments which can be attributed to $(D_6 - Me)^+$ and $(D_7 - Me)^+$. This implies that the crystalline material was a mixture of $AgD_7SbF_6$ and $AgD_6SbF_6$. Addition of a large excess of $CH_3CN$ to the solubilized product led to a two-phase liquid. GC–MS analysis of the upper oily phase showed three main components: $D_6$, $D_7$ (3.4:1), and $D_8$ (Figure 1). The amount of $D_8$ present in the sample was very small in comparison with that of $D_6$ and $D_7$ (Figure 1c),[7] but its presence implies that a small amount of $AgD_8SbF_6$ was part of the mixture. The composition of the product was further confirmed by in situ $^{29}Si\{^1H\}$ NMR (Figure 1a) of the reaction of $AgSbF_6$ with $D_5$ (1.5:1). Three peaks (–13.585 [$AgD_7^+$], –14.187 [$AgD_6^+$], –12.83 ppm [$AgD_8^+$]) in a molar ratio of $AgD_7^+/AgD_6^+/AgD_8^+$ = 3.7:1:0.2 were found in the spectrum, which is consistent with the GC results ($D_7/D_6$ = 3.4:1). The change in the intensity of the peaks in the $^{29}Si\{^1H\}$ NMR spectrum with temperature implies that an equilibrium in liquid $SO_2$ exists: $2AgD_7^+ \rightleftarrows AgD_6^+ + AgD_8^+$ (Supporting Information, Figure S2.3). The $^{29}Si\{^1H\}$ NMR spectrum (in $SO_2$, Figure 1b) of the solution obtained after the addition of an excess amount of $CH_3CN$ showed $D_7$ (–23.09 ppm) and $D_6$

(–22.42 ppm) with traces of $D_4$ (–20.67 ppm) and $D_5$ (–21.89 ppm).[8] The reaction of $AgSbF_6$ with $D_5$ leads to the ring transformation of $D_5$ to $D_6$, and $D_7$ can be expressed as shown in Scheme 1. The separate reactions of excess $AgSbF_6$ with $D_3$, $D_4$, and $D_6$ gave similar results (Supporting Information, Figure S2.4). Thus, these $AgD_n^+$ ($n$ = 6–8) cations are intermediates in cyclosiloxane ring transformations. The $AgD_nSbF_6$ complexes slowly decompose in $SO_2$ solutions to afford $Me_2SiF_2$, $(MeFSi)_2O$, $Me_2SiFOMe_2SiOSiFMe_2$, and $(Me_2SiFOMe_2SiF)_2O$ (Supporting Information, Figure S2.5).[9]

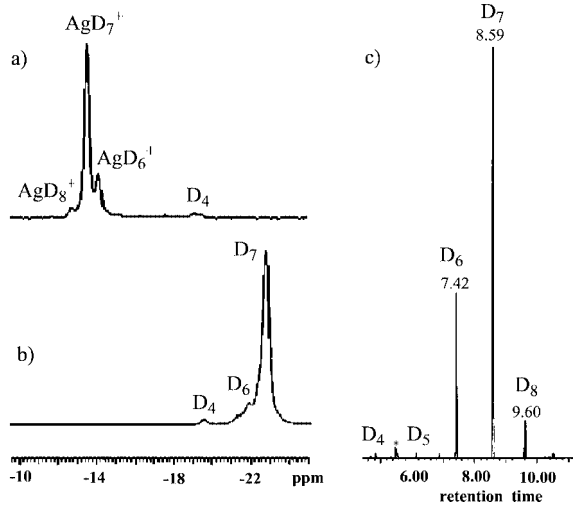

Figure 1. a) In situ $^{29}Si\{^1H\}$ NMR spectrum of the reaction of $AgSbF_6$ + $D_5$ (1.5:1) in liquid $SO_2$; b) in situ $^{29}Si\{^1H\}$ NMR spectrum after the addition of excess $CH_3CN$ into the $AgSbF_6$ + $D_5$ (1.5:1) mixture in liquid $SO_2$; c) GC of the oily phase upon the addition of $CH_3CN$ onto the solid product of the $AgSbF_6$ + $D_5$ (1.4:1) mixture in liquid $SO_2$ (The peak marked with * is due to an unidentified siloxane chain or rearranged siloxane ring).

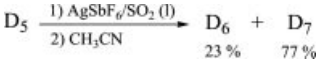

Scheme 1.

The solid-state structure[10] of $AgD_7SbF_6$ (Figure 2) shows discrete $AgD_7^+$ cations and $SbF_6^-$ anions connected by four weak Ag–F contacts {4×[2.785(2) Å, 0.070 v.u.]}[11] which forms a chain along the *c*-axis (Figure 2c). The Ag atom coordinates with five oxygen atoms from $D_7$; three of these interactions are strong {Ag–O1 2.489(2) Å, 0.174 v.u.; 2×[Ag–O4 2.553(1) Å, 0.146 v.u.]} in comparison with the Ag–O distances in $[(CH_2O)_6Ag_2]^{2+}$ and $Ag(12\text{-crown-}4)_2^+$ {6× [2.458(5) Å, 0.188 v.u.] and 8×[2.57(1) Å, 0.137 v.u.]}. Two of the Ag–O2 contacts are weak {2×[2.811(1) Å, 0.073 v.u.]}. There are no significant contacts between the Ag and the O3 atoms {2×[3.601(1) Å, 0.0086 v. u.]}. The sum of the bond valences (0.909 v.u.) of all the Ag–O contacts [0.174 + (0.146×2) + (0.073×2) + (0.0086×2) = 0.629 v.u.] and the Ag–F contacts (0.070×4 = 0.280 v.u.) correspond to one positive charge on Ag. The $Si_7O_7$ framework and the Ag atom are approximately planar, and the $AgD_7^+$ has an overall crystallographic $C_{2v}$ symmetry.[12] This is different from the approximate $D_{7h}$ symmetry found for $KD_7^+$ where $K^+$ is coplanar with the ring and interacts with all seven oxygen atoms of the cyclosiloxane ring. Near-planar pentadentate silver(I) complexes have been reported,[13] but this coordination mode is not common for silver(I) complexes. These complexes usually adopt a linear or octahedral coordination geometry.[4] The oxygen atoms that are not bonded to silver have Si–O bond lengths of 1.608 (2) Å (average), which is significantly shorter than the Si–O bond lengths for the oxygen atoms [1.636(1) Å, average] that are bonded to silver. This is similar to the situation for $LiD_6^+$. The average Si–O–Si angle at the coordinated O atoms, 144.1(1)°, is much smaller than that at the noncoordinated O atoms, 166.9(1)°. To the best of our knowledge, this Si–O–Si angle [166.9(1)°] is the largest reported among the Si–O–Si angles in cyclodimethylsiloxane. The nature of the bonding in $AgD_7^+$ is likely similar to that previously described in $LiD_6^+$, the differences are currently under investigation.

Some of the steps in a tentative $Ag^+$-directed ring transformation process are shown in Scheme 2. Coordination of $Ag^+$ to $D_m$ lengthens and weakens the Si–O bond and induces a higher positive charge on silicon. Abstraction of $F^-$ from $SbF_6^-$ [fluoride ion affinity of $SbF_5$ (g) = 514 or 503 kJ·mol$^{-1}$][14] is therefore promoted and is driven by the formation of the Si–F bond (bond enthalpy of Si–F = 582 kJ·mol$^{-1}$),[15] which leads to the formation of the $FSiMe_2(OSiMe_2)_{m-2}OSiMe_2O^-$ anion. This anion can react further with $D_m$ or $AgD_n^+$, which can lead to larger chain anions. These chain anions can then attack the silicon atoms to afford the most thermodynamically favored $AgD_n^+$ species (e.g. $AgD_7^+$ is more stable than $AgD_6^+$ [$Ag^+$ (g) + 1.4 $D_5$ (g) → $AgD_7^+$ (g), $\Delta H$ = –439 kJ·mol$^{-1}$; $Ag^+$ (g) + 1.2 $D_5$ (g) → $AgD_6^+$ (g), $\Delta H$ = –414 kJ·mol$^{-1}$].[16] The changes in the intensities of the $AgD_n^+$ ($n$ = 6–8) signals with temperature in the $^{29}Si\{^1H\}$ NMR spectra (Supporting Information, Figure S2.3) imply that the system is in thermodynamic equilibrium. A cation-induced ring-opening mechanism has been established for base-initiated cyclodimethylsiloxane ring-opening polymerization. Alkali metal cyclodimethylsiloxane adducts are proposed as the intermediates; the mechanism is supported by the structure of $AgD_7^+$ and the detection of $AgD_n^+$ ($n$ = 6–8) in this study.

This work implies that numerous salts of metal cyclodimethylsiloxane complexes can be prepared from commercially available starting materials. Cyclosiloxanes are believed to act as pseudo crown ethers. The work also suggests that other polycyclosiloxanes may be prepared if the metal cation is tailored in size. The size and nature of the anion, along with related ring transformations (e.g. cyclophosphazenes), may also be affected by $AgSbF_6$ or related salts.

## Experimental Section

**Reaction of $AgSbF_6$ with $D_5$ (mole ratio $AgSbF_6/D_5$ = 1.4:1) To Afford Single-Crystals of $AgD_7SbF_6$:** $AgSbF_6$ (1.237 g, 3.6 mmol) in one tube (OD 1.5 cm) of a two-tube (Pyrex), two-valve (Teflon in glass) vessel with an incorporated medium frit was treated with $(Me_2SiO)_5$ (1 mL, 2.58 mmol). The vessel was cooled in liquid $N_2$ and degassed. $SO_2$ (7 mL) was distilled onto the mixture, and the reaction was warmed to room temperature. A small amount of colorless precipitate was then observed over a clear solution. This mixture was stirred overnight at 5 °C and then filtered. Removal of the volatiles afforded a colorless solubilized product (1.863 g) and a very small amount of colorless insoluble product. Insoluble product: IR (KBr, Nujol Mull, room temp.): $\tilde{\nu}$ = 3488 (wb), 2921 (s), 1613 (w), 1458 (s), 1377 (s), 1264 (s), 1061 (sb), 897 (s), 809 (s), 667 (s), 632 (m), 476 (m) $cm^{-1}$. Scanning electron microscopy-energy dispersive angle X-ray (SEM-EDAX) analysis showed that the insoluble product probably contained $SiO_2$, $Sb_2O_3$, $SbF_3 \cdot SbF_5$, and AgF. The solubilized product that was obtained in similar reactions was used in the following workups: i) *Crystallization*: $SO_2$ (about 8 g) was added to the solubilized products (1.65 g) in a two-tube vessel. The resulting solution was concentrated until saturation and then cooled to 5 °C overnight, to afford a colorless crystalline product. The vessel was cooled to –78 °C and one valve opened. Crystals were quickly picked out of the solution with a miniature nickel spoon.[18] Single-crystals suitable for X-ray diffraction were coated with paratone-N oil, mounted with a glass fiber, and frozen in liquid nitrogen while mounted on the goniometer. The crystalline product was collected in dry box (0.375 g, 23%). M.p: 150 °C (decomp.). IR (KBr, neat, room temp.): $\tilde{\nu}$ = 2959 (m), 2903 (w), 1605

(wb), 1446 (wb), 1412 (w), 1377 (w), 1262 (s), 1056 (vs), 859 (m), 799 (vs), 701 (m), 658 (s, $SbF_6^-$), 536 (w), 506 (w), 382 (s, $SbF_6^-$) $cm^{-1}$. EI-MS (60 ev): *m/z* (%) = 503 (25) $[D_7 – 15]^+$, 429 (12) $[D_6 – 15]^+$. ii) *Displacement*: $CH_3CN$ (3 mL) was condensed onto the solubilized product (2 g) in a 10 mm-NMR tube glass-blown onto a valve (Teflon in glass) to afford a two-layer solution. The upper layer of oily liquid was removed by syringe (0.6 mL). GC–MS: *m/z* (%) = 429 (21) $[D_6 – 15]^+$, 503 (100) $[D_7 – 15]^+$, 429 (21) $[D_6 – 15]^+$, 577 (9) $[D_8 – 15]^+$. GC-FID: % = 23 ($D_6$), 77 ($D_7$).

**In situ NMR Reaction of $AgSbF_6$ with $D_5$ (1.5:1):** $SO_2$ (4 mL) was condensed onto $AgSbF_6$ (2.018 g, 5.87 mmol) and $D_5$ (1.5 mL, 3.87 mmol) in a 10 mm NMR tube described above and sonicated in ice water for 0.5 h to afford a colorless solution over a small amount of colorless precipitate. $^{29}Si\{^1H\}$ NMR (79.4 MHz, $SO_2$, 25 °C): $\delta$ = –14.187 (s, $AgD_6^+$), –13.585 (s, $AgD_7^+$), –12.83 (s, $AgD_8^+$) ppm. $^{29}Si\{^1H\}$ NMR (79.4 MHz, $SO_2$, 5 °C):$\delta$ = –14.106 (s, $AgD_6^+$), –13.502 (s, $AgD_7^+$), –12.01 (s, $AgD_8^+$) ppm. $^{29}Si\{^1H\}$ NMR (79.4 MHz, $SO_2$, –5 °C): $\delta$ = –14.03 (s, shoulder, $AgD_6^+$), –13.456 (s, $AgD_7^+$), –12.02 (s, $AgD_8^+$) ppm. $^{29}Si\{^1H\}$ NMR (79.4 MHz, $SO_2$, –15 °C): $\delta$ = –13.403 (br. s, $AgD_7^+$) ppm. $^{29}Si\{^1H\}$ NMR (79.4 MHz, $SO_2$, –40 °C): $\delta$ = –13.547 (s, $AgD_7^+$), –12.379 (s, $AgD_8^+$) ppm. $^{29}Si\{^1H\}$ NMR (79.4 MHz, $SO_2$, –70 °C): $\delta$ = –13.315 (s, $AgD_7^+$), –12.196 (s, $AgD_8^+$) ppm. $^1H$ NMR (400 MHz, $SO_2$, 25 °C): $\delta$ = 0.225 (s, $SiMe_2$) ppm; $^{13}C\{^1H\}$ (100 MHz, $SO_2$, 25 °C): $\delta$ = 0.414 (s, $SiMe_2$) ppm. $CH_3CN$ (ca. 1.5 mL) was then condensed into this solution and sonicated in ice water for 1 h. $^{29}Si\{^1H\}$ NMR (79.4 MHz, $SO_2$/$CH_3CN$, 25 °C): $\delta$ = –23.093 (s, $D_7$), –22.415 (s, $D_6$), –21.90 (s, $D_5$), –20.668 (s, $D_4$) ppm. $^1H$ NMR (400 MHz, $SO_2$, 25 °C): $\delta$ = 1.350 (s, $CH_3CN$), –0.693 (s, $SiMe_2$) ppm; $^{13}C\{^1H\}$ (100 MHz, $SO_2$, 25 °C): $\delta$ = 119.027 (s, $CH_3{}^{13}CN$), 1.586 (m, $^{13}CH_3CN$ and $SiMe_2$) ppm.

**Supporting Information** (see footnote on the first page of this article): General experimental techniques, in situ $^{29}Si$ NMR reactions of $AgSbF_6$ with $D_m$ (*m* = 3, 4, and 6) in liquid $SO_2$, FT-IR, MS, and $^{29}Si\{^1H\}$ NMR spectra, and full details of the crystal structure of $AgD_7SbF_6$ as well as a comparison with $KD_7^+$.

# The Remarkable Solvent-Dependent Crystallization of the Mono- and Bis(4-pyrrol-1-ylbenzonitrile) Adducts of Bis(pentafluorophenyl)zinc

**Eddy Martin,[a] David L. Hughes,[a] and Simon J. Lancaster*[a]**

**Keywords:** Crystal structure / Zinc / Pentafluorophenyl group / Nitrile adduct / Intermolecular interaction / Arene coordination

Treatment of a toluene solution of $Zn(C_6F_5)_2$ with *p*-$C_4H_4N$–$C_6H_4CN$ yields (*p*-$C_4H_4N$–$C_6H_4CN)_2Zn(C_6F_5)_2$, which has been structurally characterised following recrystallization from 1,2-difluorobenzene by single-crystal X-ray diffraction and possesses the expected distorted tetrahedral molecular geometry. However, crystallization from dichloromethane yields a trigonal planar complex with only one *p*-$C_4H_4N$–$C_6H_4CN$ ligand. The three-coordinate complex forms an intermolecular dimer in the solid state through a cooperative combination of zinc–arene, offset homoaromatic and dipole–dipole interactions.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

The coordination chemistry of zinc continues to enjoy healthy academic interest spurred by diverse applications in biology,[1] materials[2–4] and catalysis.[5–6] The characteristic properties of zinc are the predominance of the redox-resistant zinc(II) oxidation state, flexible coordination number and geometry, and Lewis acidity of its complexes. Four- to six-coordinate complexes of zinc are most common but there are many examples of two-coordinate zinc centres, particularly with amide, silyl and alkyl donors.[1] In contrast, mononuclear trigonal-planar complexes of zinc are relatively rare, but can be favoured through steric factors[7,8] or the combination of sterics and electrostatics as is the case for the $[Zn(C_6F_5)_3]^-$ anion.[9]

To date, all structurally characterised neutral adducts of the form $ZnX_2L_n$, where X is Cl, Br, I or the pseudohalide $C_6F_5$, and L is a monodentate Lewis base, have been shown to adopt essentially tetrahedral geometries where *n* is 2.[1,10] As part of our continuing investigations into the supramolecular architectures of bis(pentafluorophenyl)zinc complexes, we have structurally characterised a series of $(nitrile)_2Zn(C_6F_5)_2$ adducts.[11] We report here the unexpected isolation of the mono(nitrile) adduct (*p*-$C_4H_4N$–$C_6H_4CN)Zn(C_6F_5)_2$ and compare its solid-state structure to that of the bis(nitrile) (*p*-$C_4H_4N$–$C_6H_4CN)_2Zn(C_6F_5)_2$.

In the solid-state structure of the donor-free form of $Zn(C_6F_5)_2$ (**1**), the essentially linear geometry is perturbed only by a weak intermolecular C–F···Zn interaction.[12] Compound **1** is most conveniently prepared by the exchange between $ZnEt_2$ and $B(C_6F_5)_3$ in an aromatic solvent, from which it crystallizes with 1 equiv. of the arene.[13] The solid-state structure of the $\eta^2$-bonded toluene adduct $(MeC_6H_5)Zn(C_6F_5)_2$ (**2**) has very recently been determined.[14] This weakly bound toluene ligand can be readily displaced by Lewis bases. For example, we find that treatment of a toluene solution of **1** with 2 equiv. of the nitrogen donor ligands $tBuNH_2$, $Me_2NH$, $(PhCH_2)_2NH$, *cyclo*-$C_4H_8NH$, pyridine or benzonitrile followed by removal of toluene under reduced pressure and recrystallisation from a dichloromethane and light petroleum solvent mixture gives X-ray quality single crystals. In all but the instance discussed herein, complexes of the form $L_2Zn(C_6F_5)_2$ with distorted tetrahedral zinc environments are obtained.[11,15]

Treatment of a toluene solution of **1** with 2 equiv. of 4-(pyrrol-1-yl)benzonitrile followed by solvent removal yields a crude white solid. Subsequent crystallization from a dichloromethane and light petroleum solvent mixture at –28 °C yielded crystals (Scheme 1), which were determined by X-ray crystallography to be the mono(nitrile) complex (*p*-$C_4H_4N$–$C_6H_4CN)Zn(C_6F_5)_2$ (**3**) (Figure 1). This result was unexpected and initially assumed to be a consequence of a mistake in the reaction stoichiometry. However, despite taking great care over the reagent ratios, crystallization from dichloromethane consistently gave compound **3**. Employing identical preparative conditions but attempting crystallisation from toluene instead of dichloromethane yielded small colourless crystals that gave a different unit cell from those of **3** but did not diffract strongly enough for a full structure determination. Larger crystals, with an identical cell to those from toluene, were grown from a 1,2-difluorobenzene and light petroleum solvent mixture at +2 °C. Crystallographic analysis of this sample revealed it

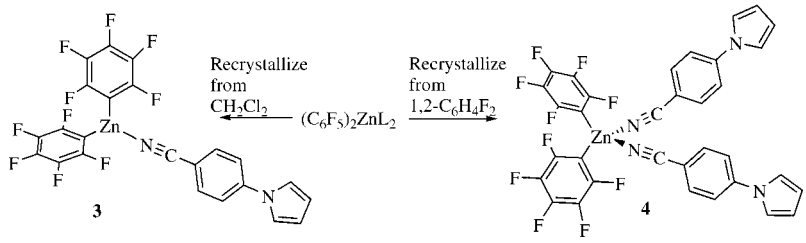

Scheme 1.

to be the bis(nitrile) adduct ($p$-$C_4H_4N$–$C_6H_4CN)_2Zn(C_6F_5)_2$ (**4**) (Figure 2). It therefore seems likely that the expected bis(nitrile) adduct is initially formed in the reaction but that recrystallization from dichloromethane yields the mono(nitrile) adduct.

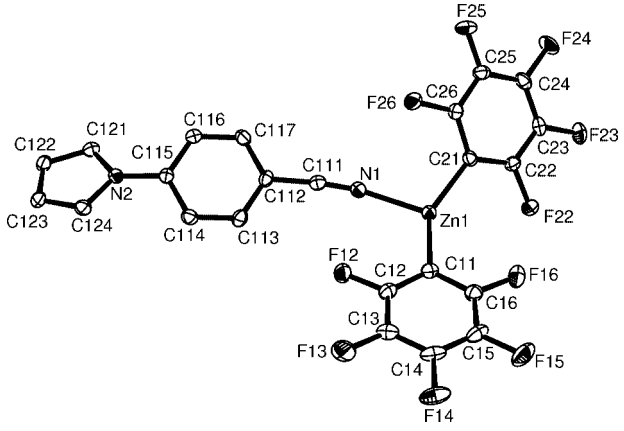

Figure 1. ORTEP representation of the molecular structure of **3** with 30% displacement ellipsoids. The hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]; e.s.d.s are in parentheses: Zn(1)–N(1) 2.094(4), Zn(1)–C(11) 1.983(4), Zn(1)–C(21) 1.981(4), C(111)–N(1) 1.147(6), C(111)–C(112) 1.436(6), C(115)–N(2) 1.411(5); C(21)–Zn(1)–C(11) 140.1(2), C(21)–Zn(1)–N(1) 106.4(2), C(11)–Zn(1)–N(1) 108.2(2), C(111)–N(1)–Zn(1) 165.9(4), C(112)–C(111)–N(1) 174.7(5).

Complex **3** is best described as trigonal-planar, the sum of the angles about the Zn atom is 354.6° and the Zn atom is only 0.258(3) Å removed from the plane defined by C(11), C(21), and N(1). The greater steric requirement of the Zn–$C_6F_5$ groups explains the somewhat larger C–Zn–C vs. C–Zn–N angles. Scheme 2 shows the only other structurally characterised neutral nitrogen-ligated trigonal-planar zinc complexes we are aware of and in each case the neutral nitrogen donor is part of a bidentate ligand. The Zn–N distances for the neutral $sp^2$ benzimidazole and imine donors were 2.067(4), 2.089(2) 1.9805(23), and 1.962(2) Å for **I**, **II**, **III**, and **IV**, respectively. Some of these are somewhat shorter than the 2.094(4) Å found for **3**.[7,8] The average Zn–C bond length [1.982(1) Å, for **3**] is 0.03 Å less than that in $[Zn(C_6F_5)_3]^-$, which presumably reflects the combination of reduced steric congestion and electrostatic repulsion.[9] The dihedral angle between the aromatic planes in the coordinated nitrile ligand in **3** is 23.2(2)°.

The zinc center of the bis(nitrile) adduct **4** has an asymmetrically distorted tetrahedral coordination sphere. The 123.55(6)° C(11)–Zn–C(21) angle and the Zn–C(21) and Zn–C(11) bond lengths at 2.021(2) and 2.029(2) Å, respectively, lie well within the range observed for four-coordinate amine adducts of $Zn(C_6F_5)_2$. The average dative Zn–N bonding distance of 2.09 Å is similar to those observed for $(RR'R''N)_2Zn(C_6F_5)_2$ (2.09–2.16 Å),[11] and only slightly longer than those found in $(MeCN)_2ZnCl_2$ (2.05 Å) and $(MeCN)_2ZnI_2$ (2.04 Å).[16,17] We ascribe the differences between the Zn–N distances and the dihedral angles between the aromatic rings in the ligand bonded through N(11) [2.0660(14) Å and 6.22(7)°] compared to that containing N(21) [2.1206(15) Å and 26.71(7)°] to subtle crystal packing effects. There are no other significant structural differences between the two ligands. The N(11)–Zn–N(21) angle [95.75(6)°] is somewhat smaller than those observed in the $(RR'R''N)_2Zn(C_6F_5)_2$ series, doubtless as a consequence of the modest cone angle of the nitrile ligand, and is comparable to the N–Zn–N angles in $(MeCN)_2ZnCl_2$ and $(MeCN)_2ZnI_2$.[18] There is no evidence for the sort of steric congestion that would favour a three-coordinate complex.

Multinuclear NMR investigations of amine adducts of bis(pentafluorophenyl)zinc have previously indicated solution-phase equilibria involving rapid exchange of free and coordinated amine [Equation (1)]. Addition of further equivalents of amine produced a movement in the observed $^1H$ chemical shifts towards the values for the free amine, but very little change to the $^{19}F$ resonances of the Zn–$C_6F_5$ groups, which we interpreted as the equilibrium strongly favouring the four-coordinate complex.[11] This is consistent with simple thermodynamic considerations favouring the four-coordinate adduct in which two dative bonds have been formed. Regardless of the position of the solution equilibrium, the four-coordinate complexes had invariably been observed to crystallize preferentially until the isolation of **3**.

For comparison we conducted a variable-temperature $^1H$ and $^{19}F$ NMR study of complex **4** (an analogous study with complex **3** was not possible because of its poor solubility in toluene). The $^{19}F$ MMR spectrum of a [$D_8$]toluene solution barely changed on cooling from 20 to –60 °C. In contrast,

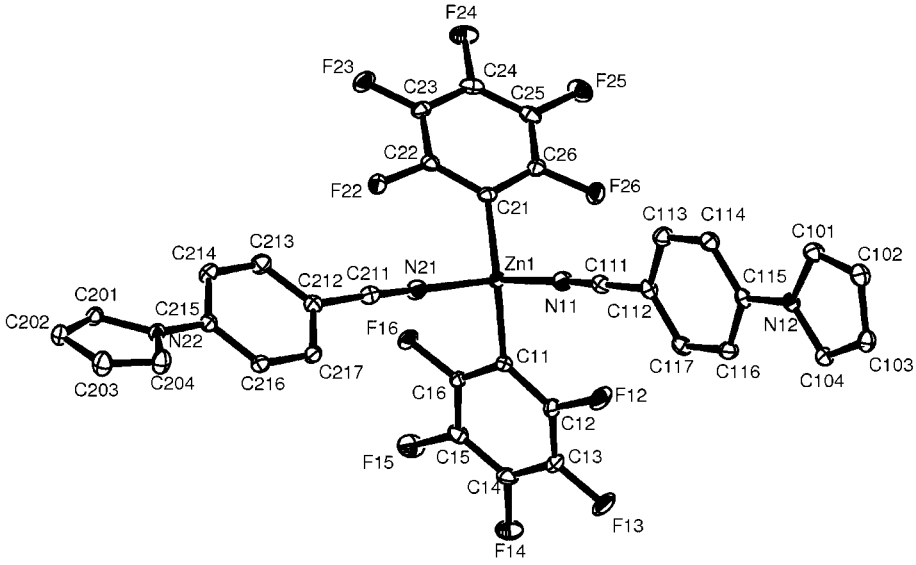

Figure 2. ORTEP representation of the molecular structure of **4** with 30% displacement ellipsoids. The hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]; e.s.d.s are in parentheses: Zn(1)–N(11) 2.0660(14), Zn(1)–N(21) 2.1206(15), Zn(1)–C(21) 2.0209(15), Zn(1)–C(11) 2.0292(16), C(111)–N(11) 1.139(2), C(111)–C(112) 1.437(2), C(115)–N(12) 1.409(2), C(211)–N(21) 1.143(2), C(211)–C(212) 1.437(2), C(215)–N(22) 1.412(2); C(21)–Zn(1)–C(11) 123.55(6), C(21)–Zn(1)–N(11) 114.80(6), C(11)–Zn(1)–N(11) 107.92(6), C(21)–Zn(1)–N(21) 105.58(6), C(11)–Zn(1)–N(21) 104.96(6), N(11)–Zn(1)–N(21) 95.75(6), Zn(1)–N(11)–C(111) 175.60(14), N(11)–C(111)–C(112) 179.4(2), Zn(1)–N(21)–C(211) 174.76(14), N(21)–C(211)–C(212) 176.54(17).

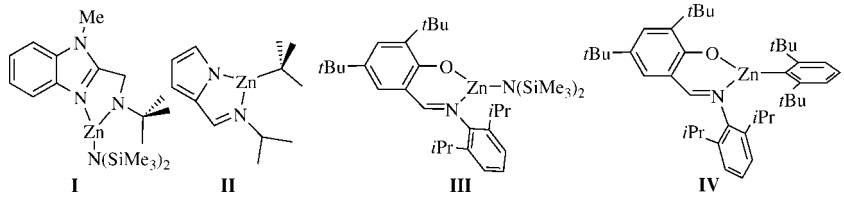

Scheme 2.

the chemical shifts of the $^1$H resonances exhibited significant temperature dependence (Supporting Information). However, there was no sign of decoalescence down to –60 °C and therefore no indication for the position of this equilibrium (1).

$$(C_6F_5)_2ZnL + L \rightleftharpoons (C_6F_5)_2ZnL_2 \quad (1)$$

Analysis of the crystal packing for complex **3** suggests a possible explanation for its preferential crystallisation. In the solid state, molecules of **3** are closely paired about centres of symmetry (Figure 3), in such a fashion that the *p*-$C_4H_4N$–$C_6H_4CN$ ligand of one molecule runs parallel and in the opposite direction to that of the associated molecule. As well as counter-aligning the two ligand dipoles, this arrangement also leads to an offset homoaryl interaction between the phenyl rings. The centroid···centroid distance is 3.71 Å and the centroid–plane separation is 3.37 Å. The supramolecular motif in which hydroaromatics form offset pairs or stacks has been well documented.[19,20] Nevertheless, we believe that two short zinc–pyrrole ring contacts are most significant in directing this intermolecular pairing. The Zn–C(122′) distance is 2.73 Å, which is well within the sum of the van der Waals radii (ca. 3.1 Å), while the distances to C(121′) and C(123′) are in excess of 3 Å. The Zn···π interaction in **3** is evidently weaker than those reported for $(C_6F_4\text{-}2\text{-}C_6F_5)_2Zn$·(toluene) in which there is a close [2.524(3) Å] contact to one arene carbon atom, and for **2** in which two contacts of 2.784(2) and 2.685(2) Å were found.[14] It is, however, strikingly similar to the Zn···π interaction observed in the solid-state structure of **II**, which also forms an intermolecular dimer with a 2.715(3) Å contact between the zinc atom and the carbon atom in the 3-position of the pyrrolyl ring.[7c]

We propose that this intermolecular association yields a species which is significantly less soluble in dichloromethane than complex **4**, and crystallizes out, thereby driving the equilibrium to the "three-coordinate" complex. In 1,2-difluorobenzene solution presumably either the formation of the intermolecular dimer is inhibited or perhaps more likely it is no longer significantly less soluble than the four-coordinate adduct **4**.

In summary, during the course of a structural survey of bis(nitrile) adducts of bis(pentafluorophenyl)zinc, an unusual and surprising example of a three-coordinate complex, (*p*-$C_4H_4N$–$C_6H_4CN$)$Zn(C_6F_5)_2$, was isolated from dichloromethane solution and structurally characterised.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

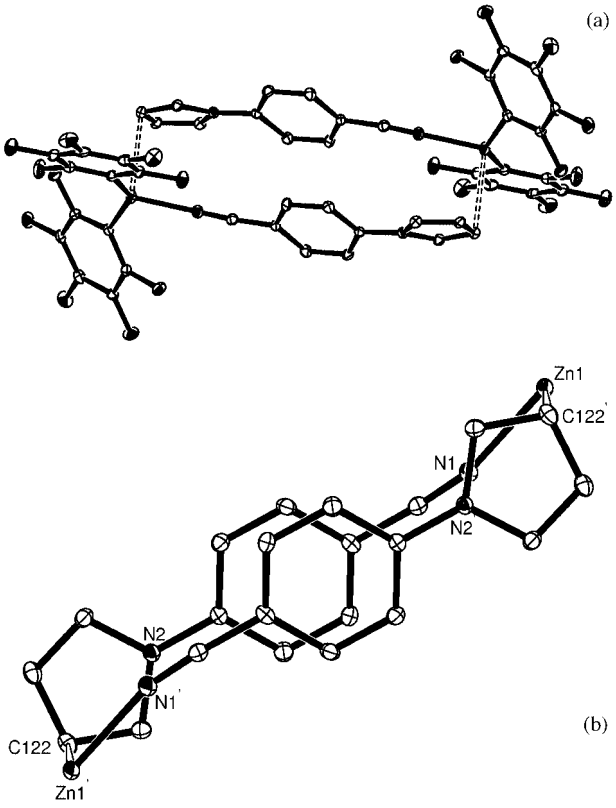

Figure 3. ORTEP representations of (a) the intermolecular dimer of **3** and (b) the alignment of the two interacting fragments projected on to the plane of the $C_6$ ring (the displacement ellipsoids are at 30% probability and the hydrogen atoms have been omitted for clarity).

The driving force for its crystallization is thought to be intermolecular dimerisation predominantly through Zn···π interactions.

## Experimental Section

**General:** All experimental procedures were conducted using standard Schlenk techniques under anhydrous and anaerobic conditions. [21] The toluene adduct of bis(pentafluorophenyl)zinc was prepared according to a literature procedure.[13] 4-(Pyrrol-1-yl)benzonitrile was prepared from 4-aminobenzonitrile and 2,5-dimethoxytetrahydrofuran in refluxing acetic acid according to a modified literature procedure.[22] $^1$H and $^{19}$F NMR chemical shifts are referenced to the residual solvents and $CFCl_3$ respectively.

**(*p*-$C_4H_4N$–$C_6H_4CN$)Zn($C_6F_5$)$_2$ (3):** A solution of ($MeC_6H_5$)-Zn($C_6F_5$)$_2$ (0.44 g, 0.9 mmol) in toluene (10 mL) was treated with *p*-$C_4H_4N$–$C_6H_4CN$ (0.3 g, 1.8 mmol). The reaction mixture was stirred for 30 min before being filtered to separate a small amount of solid material. The volatiles were removed under reduced pressure and the residue was purified by crystallisation from a mixture of dichloromethane and light petroleum at –28 °C to afford colourless crystals of **3** (0.30 g, 0.52 mmol, 58%). Crystals suitable for single-crystal X-ray diffraction required a further recrystallization step. $C_{23}H_8F_{10}N_2Zn$ (567.69): calcd. C 48.66, H 1.42, N 4.93; found C 47.92, H 1.24, N 5.30. $^1$H NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 7.76 (d, $^3J_{H\text{-}H}$ = 8.1 Hz, 2 H, Ar), 7.54 (d, $^3J_{H\text{-}H}$ = 8.7 Hz, 2 H, Ar), 7.19 (t, $^3J_{H\text{-}H}$ = 2.1 Hz, 2 H, Pyr), 6.41 (t, $^3J_{H\text{-}H}$ = 2.1 Hz, 2 H, Pyr) ppm. $^{19}$F NMR (282 MHz, $CD_2Cl_2$): $\delta$ = –162.79 to –162.81 (m, 4 F, *o*-*F*), –157.06 (t, $^3J_{F\text{-}F}$ = 19.8 Hz, 2 F, *p*-*F*), –118.99 to –118.78 (m, 4 F, *m*-*F*) ppm.

**(*p*-$C_4H_4N$–$C_6H_4CN$)$_2$Zn($C_6F_5$)$_2$ (4):** Compound **4** was prepared according to precisely the same experimental method prior to crystallization as compound **3**. The crude solid was crystallised from a mixture of 1,2-difluorobenzene and light petroleum at +2 °C affording colourless crystals of **4** (0.65 g, 0.88 mmol, 98%) suitable for X-ray analysis. $C_{34}H_{16}F_{10}N_4Zn$ (735.89): calcd. C 55.49, H 2.19 N 7.61; found C 54.94, H 2.14, N 7.91. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 6.41 (t, $^3J_{H\text{-}H}$ = 2.1 Hz, 2 H) 7.19 (t, $^3J_{H\text{-}H}$ = 2.1 Hz, 2 H), 7.56 (d, $^3J_{H\text{-}H}$ = 8.7 Hz, 2 H), 7.82 (d, $^3J_{H\text{-}H}$ = 8.7 Hz, 2 H) ppm. $^{19}$F NMR (282 MHz, $CDCl_3$): $\delta$ = –163.6 to –163.4 (m, 4 F, *o*-*F*), –158.7 (t, $^3J_{F\text{-}F}$ = 17 Hz, 2 F, *p*-*F*), –119.0 (d, $^3J_{F\text{-}F}$ = 18 Hz, 4 F, *m*-*F*) ppm.

**X-ray Analyses:** Intensity data for crystals of **3** and **4** were collected with an Oxford Diffraction Xcalibur-3 CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and graphite monochromator. Data were processed using the CrysAlis-CCD and -RED programs.[23] The structures were determined by direct methods in SHELXS and refined using full-matrix least squares with SHELXL.[24] The non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in idealised positions and their $U_{iso}$ values were set to ride on the $U_{eq}$ values of the parent carbon atoms. Scattering factors for neutral atoms were taken from ref.[25] The analysis process was run through WinGX.[26] CCDC-615024 (**3**) and -615025 (**4**) contain the supplementary crystallographic data. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystal Structure and Refinement Data for 3:** $C_{23}H_8F_{10}N_2Zn$, $F_W$ = 567.7 g·mol$^{-1}$; monoclinic, $P2_1/c$, $a$ = 6.8993(3), $b$ = 20.4167(8), $c$ = 14.2444(16) Å, $\beta$ = 93.691(6)°, $V$ = 2002.3(3) Å$^3$, $Z$ = 4, $T$ = 140(1) K, $\rho_{calcd.}$ = 1.883 Mg/m$^3$, $\mu$(Mo-$K_\alpha$) = 1.335 mm$^{-1}$, $F$(000) = 1120; colourless prism 0.35 × 0.30 × 0.15 mm. The total number of reflections, recorded to $\theta_{max}$ = 27.5°, was 25382, of which 4550 were unique ($R_{int}$ = 0.041); 3803 were "observed" with $I > 2\sigma_I$. Final $R$ factors: $wR_2$ = 0.132 and $R_1$ = 0.066 for all 4550 reflections weighted, $w = [\sigma^2(F_o^2) + 11.38\ P]^{-1}$ where $P = (F_o^2 + 2F_c^2)/3$; for the "observed" data only, $R_1$ = 0.055. Largest residual electron density 1.69 e·Å$^{-3}$, located close to C(123).

**Crystal Structure and Refinement Data for 4:** $C_{34}H_{16}F_{10}N_4Zn$, $F_W$ = 735.9 g·mol$^{-1}$; triclinic, $P\bar{1}$, $a$ = 8.0378(5), $b$ = 14.0455(7), $c$ = 14.5510(9) Å, $\alpha$ = 114.357(6), $\beta$ = 91.807(5), $\gamma$ = 97.603(5)°, $V$ = 1476.60(15) Å$^3$, $Z$ = 2, $T$ = 140(1) K, $\rho_{calcd.}$ = 1.655 Mg/m$^3$, $\mu$(Mo-$K_\alpha$) = 0.928 mm$^{-1}$, $F$(000) = 736; colourless prism 0.59 × 0.33 × 0.30 mm. The total number of reflections, recorded to $\theta_{max}$ = 25°, was 16139, of which 5174 were unique ($R_{int}$ = 0.022); 4726 were "observed" with $I > 2\sigma_I$. Final $R$ factors: $wR_2$ = 0.063 and $R_1$ = 0.026 for all 5174 reflections weighted, $w = [\sigma^2(F_o^2) + (0.0338P)^2 + 0.589P]^{-1}$ where $P = (F_o^2 + 2F_c^2)/3$; for the "observed" data only, $R_1$ = 0.023. Largest residual electron density 0.36 e·Å$^{-3}$, located close to Zn(1).

**Supporting Information** (see footnote on the first page of this article): Figure showing the temperature dependence of the $^1$H NMR chemical shifts of a [$D_8$]toluene solution of complex **4**.

[5,10,15,20-Tetrakis(*p*-sulfonatophenyl)porphyrinato]-manganese(III) in its diaqua form $[(H_2O)_2Mn^{III}(tpps)]$ forms a complex with heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin (TMe-β-CD) to afford a stable 2:1 host–guest inclusion complex whose binding constants, $K_1$ and $K_2$, in phosphate buffer at pH 7.0 and 25 °C are $8.1 \times 10^5$ and $2.8 \times 10^4$ $M^{-1}$, respectively. $[(H_2O)_2Mn^{III}(tpps)]$ dissociates into the monohydroxo complex $[(H_2O)(OH^-)Mn^{III}(tpps)]$ above pH 11 ($pK_a$ = 11.9) when incorporated into the TMe-β-CD cavities. The $pK_a$ value of $[(H_2O)_2Mn^{III}(tpps)]$ in the absence of TMe-β-CD is 12.4, which suggests that the monohydroxo form without a net charge on the central porphyrin is stabilized by complexation with TMe-β-CD. In an aqueous alkaline solution of TMe-β-CD, $[(H_2O)(OH^-)Mn^{III}(tpps)]$ is autoreduced to $[(H_2O)Mn^{II}(tpps)]$ by an electron transfer from bound $OH^-$ to $Mn^{III}$. TMe-β-CD stabilizes the low-valent $[(H_2O)Mn^{II}(tpps)]$. For example, the rate of autoxidation of $[(H_2O)Mn^{II}(tpps)]$ in the presence of TMe-β-CD at pH 7.0 was reduced by a factor of $2.8 \times 10^4$ as compared with the rate without TMe-β-CD. The redox potentials ($E_{1/2}$) of [Mn(tpps)] were measured by spectroelectrochemical methods. The $E_{1/2}$ values in phosphate buffer at pH 7.0 in the absence and the presence of TMe-β-CD are –211 and –108 mV (vs. NHE), respectively. TMe-β-CD causes a positive shift of $E_{1/2}$, which indicates the stabilization of low-valent $[(H_2O)Mn^{II}(tpps)]$ by TMe-β-CD against autoxidation. These electrochemical data, as well as the thermodynamic ones, give the $K_1K_2$ values for complexation of $[(H_2O)Mn^{II}(tpps)]$ with TMe-β-CD to be $1.2 \times 10^{12}$ $M^{-2}$, while that for $[(H_2O)_2Mn^{III}(tpps)]$ is $2.3 \times 10^{10}$ $M^{-2}$.

## Introduction

Although manganese porphyrins (MnPor) are not known to be prosthetic groups of metalloproteins, they have widely been utilized as functional models of metalloproteins such as the manganese-stabilizing protein in photosynthesis II,[1] cytochrome P450,[2] superoxide dismutases,[3] catalases,[4] and peroxidases.[5] MnPors have many advantages when it comes to mimicking the functions of metalloproteins. For example, they have poor ability to form μ-oxo dimers[6] and to bind inorganic anions[7] and have a high ability to resist degradation of their ligands and to take various high-valent metal states.[8] The modeling of cytochrome P450 function using MnPor is a typical example. The formation of an $Fe^{IV}$=O cation radical, the so-called "compound I", has not been proved in artificial systems, although such a high-valent iron-oxo complex has been assumed as a dominant intermediate in oxygenation catalyzed by cytochrome P450.[9] Meanwhile, a high-valent $Mn^{V}$=O porphyrin complex has been verified spectroscopically when a porphyrin ligand has positively charged pyridinium substituents at the *meso* positions of the porphyrin.[10] The $Mn^{V}$=O complex is a reactive intermediate in the epoxidation of alkenes by *m*-CPBA. $Mn^{V}$=O corrole with a Mn out-of-plane orientation is more stable than the corresponding porphyrin complex with a Mn in-plane orientation.[8d,11] MnPors have mainly been utilized as substitutes of heme and/or hemin.

Since the prominent function of a metalloprotein is apparently dominated by its prosthetic group, the main interest of chemists tends to be focused on the chemical behavior of this group. In general, however, a protein surrounding the prosthetic group plays an essential role in its biological activity. Therefore, construction of a model system involving functions of both the protein and prosthetic group is a very important subject in biomimetic chemistry.[12] There are various kinds of hemoproteins in nature. In spite of a common prosthetic group (heme), each hemoprotein shows different functions. A typical example of the inherent characteristics is the oxidation-reduction potentials of hemoproteins (see Supporting Information).[13] Although myoglobin (Mb), hemoglobin (Hb), and peroxidases have a common

core structure composed of an iron center and an imidazole moiety as an axial monoligand, their redox potentials differ. The redox potentials of Mb (+50 mV vs. NHE) and Hb (+170 mV) are positive, meaning low reactivity in autoxidation of heme to hemin, with these proteins having particular affinity for dioxygen binding. On the other hand, cytochrome c peroxidase has a redox potential of –194 mV. The redox potential of cytochrome P450cam with cysteine as an axial ligand is –300 mV. Hemoproteins with negative redox potentials tend to form high-valent iron complexes as active intermediates in their enzymatic reactions. The protein surrounding an iron center regulates the redox potential and hence the functions of the hemoprotein.

In the present study, we focused on the effects of incorporation of [5,10,15,20-tetrakis(*p*-sulfonatophenyl)porphyrinato]manganese [Mn(tpps)] by heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin (TMe-β-CD) on the redox behavior of [Mn(tpps)] in aqueous solution. We,[14] as well as Tonellato et al.,[15] have reported the extremely strong ability of TMe-β-CD to include water-soluble porphyrins to afford *trans*-type 2:1 host–guest complexes. Previously, we interpreted the novel ability of TMe-β-CD to include the water-soluble porphyrins in terms of induced-fit-type inclusion by TMe-β-CD, whose cavity is transformable because of the absence of intramolecular hydrogen bonding.[14d] Recently, we also found metMb-mimetic functions of a 2:1 complex of TMe-β-CD and [$Fe^{III}$(tpps)], which shows selective binding of inorganic anions in aqueous solution.[16] In advance of our study, Lawrence and co-workers reported their pioneering work on a hemoprotein mimic composed of a cationic ferric porphyrin and heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (2,6-DMe-β-CD).[17] These results led us to prepare a Mb model that works in aqueous solution.[18] Since the 1970s, many Mb models have been proposed.[19] Typically, these models have bulky substituents at the *meso* positions of tetraphenylporphyrin to prevent μ-oxo dimer formation. Although those model compounds whose ferrous center is coordinated by a base such as imidazole or pyridine bind dioxygen in absolute organic solvents, no dioxygen adducts are formed if the system contains a trace amount of water. Recently, we succeeded in preparing a Mb model (hemoCD) in aqueous solution that is composed of an *O*-methylated β-cyclodextrin dimer containing a pyridine linker and [$Fe^{II}$(tpps)].[18] HemoCD binds dioxygen in aqueous solution ($P_{1/2}^{O_2}$ = 16.9 Torr and $t_{1/2}$ = 30 h in pH 7.0 phosphate buffer at 25 °C). In this model system, tight encapsulation of [$Fe^{II}$(tpps)] by two *O*-methylated β-cyclodextrin moieties is essential to stabilize [$Fe^{II}$(tpps)] and to bind dioxygen. As an extension of this work, we decided to study the redox behavior of a manganese porphyrin complexed with TMe-β-CD. In the present study, we tried to obtain information about the effects of TMe-β-CD on the stabilization of the low-valent manganese complex [$(H_2O)Mn^{II}$(tpps)]. In order to prepare a good functional model of Mb and/or Hb, the system should be designed to stabilize $Fe^{II}$Por, which is labile in a homogeneous aerobic solution, by using an artificial protein such as cyclodextrin. Control of the redox potential of a metalloporphyrin by an artificial protein is essential to develop a new artificial and functional metalloprotein. The present study might contribute to these subjects.

## Results and Discussion

### Complexation of [$Mn^{II}$(tpps)], [$Mn^{III}$(tpps)], and [$Mn^{IV}$(tpps)] with TMe-β-CD

At first, complexation of [$Mn^{III}$(tpps)] with TMe-β-CD was studied by means of UV/Vis spectroscopy and isothermal titration calorimetry (ITC). Figure 1 shows the UV/Vis spectral changes of [$(H_2O)_2Mn^{III}$(tpps)] in 0.05 M phosphate buffer at pH 7.0 upon addition of TMe-β-CD. The Soret band at 466 nm is shifted to shorter wavelength and increases in intensity with increasing concentration of TMe-β-CD. Three titration curves obtained by monitoring the absorbances at three different wavelengths were fitted simultaneously by a set of binding constants ($K_1$ and $K_2$) using a nonlinear least-squares method (Figure 1, b).[14b]

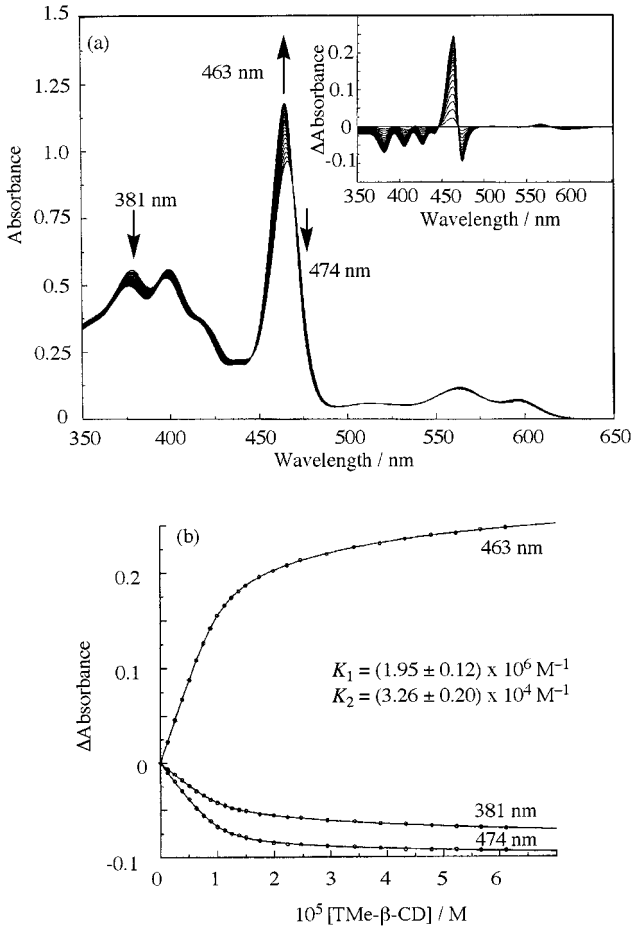

Figure 1. UV/Vis spectral changes of [$(H_2O)_2Mn^{III}$(tpps)] ($1.0 \times 10^{-5}$ M) in 0.05 M phosphate buffer at pH 7.0 upon addition of TMe-β-CD at 25 °C (a) and the plots of the changes in absorbances of [$(H_2O)_2Mn^{III}$(tpps)] vs. [TMe-β-CD] (b). The solid lines are the best fit of the data to an equation for the simultaneous 1:1 and 1:2 complexation.

[a] In 0.05 M phosphate buffer at pH 7.0. [b] In 0.1 M succinic acid buffer at pH 4.0. [c] In 0.05 M phosphate buffer at pH 7.0. The measurement was carried out in the presence of excess $Na_2S_2O_4$. [d] In 1.0 M aqueous NaOH solution. [($OH^-$)$Mn^{IV}$(tpps)] was prepared by oxidation of [$(H_2O)_2Mn^{III}$(tpps)] with three equivalents of $K_3[Fe(CN)_6]$.

The titration curves were well-fitted by a theoretical equation for 2:1 host–guest complexation. The $K_1$ and $K_2$ values (Figure 2) were determined to be $(2.0 \pm 0.1) \times 10^6$ and $(3.3 \pm 0.2) \times 10^4$ $M^{-1}$, respectively (Table 1).

We decided to check the accuracy of the binding constants by a different method (ITC). ITC simultaneously provides the thermodynamic parameters for complexation of [$(H_2O)_2Mn^{III}$(tpps)] with TMe-β-CD. The isothermal calorimetric titration curve obtained by the addition of TMe-β-CD to the [$(H_2O)_2Mn^{III}$(tpps)] solution at pH 7.0 is shown in Figure 3. The titration curve was analyzed by an equation for 2:1 host–guest complex formation; the results are summarized in Table 1. The $K_1$ and $K_2$ values from ITC are somewhat smaller than those from UV/Vis spectroscopy; the reasons for this are not clear. However, both methods clearly indicate that $K_1$ is larger than $K_2$. Since tpps is a dianionic ligand, a positive charge remains at the center of [$(H_2O)_2Mn^{III}$(tpps)]. Capping of such a polar metal center by two hydrophobic cyclodextrin cavities seems to be inadequate compared with the 1:1 complexation where half of the metalloporphyrin is exposed to the bulk aqueous phase. This might be the reason why $K_1$ is larger than $K_2$. Such an assumption is supported by the thermodynamic parameters for complexation. Both enthalpy ($\Delta H_1{}^0$) and entropy changes ($\Delta S_1{}^0$) for the 1:1 complexation are negative and large, thereby suggesting the contribution of a van der Waals interaction to the 1:1 complex formation as a main binding force. The negative and large value of $\Delta S_1{}^0$ is ascribed to the restriction of free rotation of the sulfonatophenyl groups at the 10- and 20-positions of the porphyrin due to inclusion of a sulfonatophenyl group at the 5-position. The complexation of the 1:1 complex with TMe-β-CD to form a 2:1 complex is accompanied by a positive $\Delta S_2{}^0$. From this observation we assume that dehydration which is needed for further complexation supports the formation of the 2:1 complex.

As mentioned below, [$Mn^{III}$(tpps)] exists in a diaqua form [$(H_2O)_2Mn^{III}$(tpps)] in aqueous solution at pH 7.0. Under the same conditions, the ferric porphyrin [$Fe^{III}$(tpps)] forms a μ-oxo dimer in the absence of TMe-β-CD. Since the apparent p$K_a$ value for the equilibrium between [$(H_2O)_2Fe^{III}$(tpps)] and the μ-oxo dimer is 6.4,[20] the $K_1$ and $K_2$ values for [$(H_2O)_2Fe^{III}$(tpps)] in aqueous solution below pH 5 seem to be meaningful to compare with those for [$(H_2O)_2Mn^{III}$(tpps)]. The binding constants and the thermodynamic parameters for [$(H_2O)_2Fe^{III}$(tpps)] at pH 4.0 are shown in Table 1.[16] A similar behavior has been observed in the complexation of [$(H_2O)_2Fe^{III}$(tpps)] with

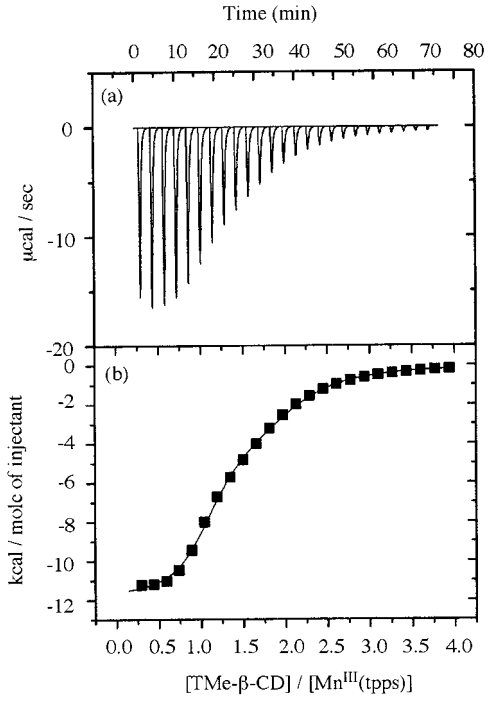

Figure 3. Calorimetric titration of $[(H_2O)_2Mn^{III}(tpps)]$ ($2.28 \times 10^{-4}$) with 25 aliquots (10 μL each) of TMe-β-CD ($4.79 \times 10^{-3}$ M) in 0.05 M phosphate buffer at pH 7.0 and 25 °C. The solid line represents the best fit of the experimental data to the 1:2 Sequential Binding Sites Model in the ORIGIN software.

TMe-β-CD, although the $\Delta S^0$ value for $[(H_2O)_2Fe^{III}(tpps)]$ is much larger than that for $[(H_2O)_2Mn^{III}(tpps)]$.

$[(H_2O)_2Mn^{III}(tpps)]$ is easily reduced to $[(H_2O)Mn^{II}(tpps)]$ by sodium dithionite ($Na_2S_2O_4$). The UV/Vis spectral changes of $[(H_2O)Mn^{II}(tpps)]$ in pH 7.0 phosphate buffer containing an excess amount of $Na_2S_2O_4$ were monitored as a function of the concentration of TMe-β-CD (see Supporting Information). The spectral change was clearly saturated upon addition of two equivalents of TMe-β-CD, thus indicating the formation of an extremely stable 2:1 host–guest complex. Binding constants and thermodynamic parameters for $[(H_2O)Mn^{II}(tpps)]$ could not be determined by either UV/Vis spectroscopy or ITC because of the too-large $K$ values, although the $K_1K_2$ value was estimated (vide infra). Since the net charge at the center of $[(H_2O)Mn^{II}(tpps)]$ is zero, the encapsulation of $[(H_2O)Mn^{II}(tpps)]$ by two TMe-β-CD molecules seems to proceed satisfactorily from the viewpoint of polarity matching between the host and the guest.

$[Mn^{III}(tpps)]$ was oxidized to $[Mn^{IV}(tpps)]$ in 1.0 M aqueous NaOH solution upon addition of $K_3[Fe(CN)_6]$.[21] A strongly basic solution is needed to stabilize the high-valent $Mn^{IV}$ state by coordination of $OH^-$ to $Mn^{IV}$. In the presence of an excess amount of TMe-β-CD, the second-order rate constant ($k_{ox}$) for oxidation of $[(H_2O)(OH^-)Mn^{III}(tpps)]$ to $[(OH^-)_nMn^{IV}(tpps)]$ ($n$ = 1 or 2) was determined to be 50.1 $M^{-1}s^{-1}$ at 25 °C (Figure 4). Harriman et al. have determined the $k_{ox}$ value for the same oxidation in the absence of TMe-β-CD to be $1.08 \times 10^5$ $M^{-1}s^{-1}$.[21] It is clear that encapsulation of $[(H_2O)(OH^-)Mn^{III}(tpps)]$ by two TMe-β-CD molecules markedly depresses the oxidation by the polar ferricyanide ion. In other words, the TMe-β-CD molecules provide a very hydrophobic environment around the center of $[(H_2O)(OH^-)Mn^{III}(tpps)]$ that isolates it from the aqueous bulk phase.

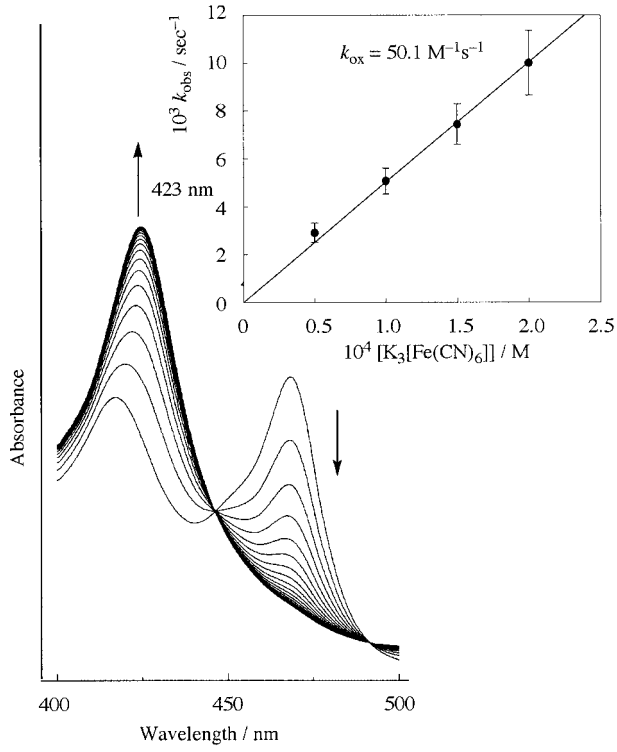

Figure 4. UV/Vis spectral changes of $(H_2O)(OH^-)Mn^{III}(tpps)$ ($1.0 \times 10^{-5}$ M) to $[(OH^-)Mn^{IV}(tpps)]$ in 1.0 M aqueous NaOH solution containing TMe-β-CD ($2.0 \times 10^{-4}$ M) upon addition of $K_3[Fe(CN)_6]$ ($1.0 \times 10^{-4}$ M) at 25 °C and the dependence of the pseudo first-order rate constant ($k_{obs}$) for the oxidation of $(H_2O)(OH^-)Mn^{III}(tpps)$ to $[(OH^-)Mn^{IV}(tpps)]$ on the concentration of $K_3[Fe(CN)_6]$ to determine the second-order rate constant ($k_{ox}$).

The $K_1$ and $K_2$ values for complexation of $[(OH^-)_nMn^{IV}(tpps)]$ with TMe-β-CD were determined in 1.0 M aqueous NaOH solution by ITC (see Supporting Information). The results are shown in Table 1. To the best of our knowledge, the axial ligation of $[Mn^{IV}(tpps)]$ in aqueous NaOH solution has not been clarified. If $[Mn^{IV}(tpps)]$ exists as $[(OH^-)Mn^{IV}(tpps)]$, the net charge at the center of the porphyrin is +1, the same as that of $[(H_2O)_2Mn^{III}(tpps)]$. The $K_1$ and $K_2$ values for $[(OH^-)_nMn^{IV}(tpps)]$ in aqueous NaOH solution are not much different from those of $[(H_2O)_2Mn^{III}(tpps)]$ at pH 7.0. However, the thermodynamic parameters for $[(OH^-)Mn^{IV}(tpps)]$ differ markedly from those for $[(H_2O)_2Mn^{III}(tpps)]$. The entropy change for the 1:1 complexation of $[(OH^-)_nMn^{IV}(tpps)]$ is positive while that of $[(H_2O)_2Mn^{III}(tpps)]$ is negative and large. The entropy change for the second complexation of $[(OH^-)_nMn^{IV}(tpps)]$ is also larger than that of $[(H_2O)_2Mn^{III}(tpps)]$. It is assumed that the high-valent $Mn^{IV}$ porphyrin gathers a larger amount of water molecules to its metal center than

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the $Mn^{III}$ porphyrin. It is interesting that complexation of high-valent $[(OH^-)_nMn^{IV}(tpps)]$ is entropically favorable due to extended dehydration while it is enthalpically unfavorable due to weak hydrophobic effect. Complexation promoted by extended dehydration is commonly observed in cyclodextrin chemistry.[22] The difference between the thermodynamic parameters of $[(OH^-)_nMn^{IV}(tpps)]$ and $[(H_2O)_2Mn^{III}(tpps)]$ might be ascribed to the difference in the net charges of the manganese porphyrins. In other words, there is a possibility of $[(OH^-)_2Mn^{IV}(tpps)]$ rather than $[(OH^-)Mn^{IV}(tpps)]$. The axial ligation of $[Mn^{IV}(tpps)]$ in aqueous alkaline solution could not be clarified from the present study.

### pH Titration

$[Mn^{III}(tpps)]$ exists as a diaqua form in aqueous solution at neutral pH.[6a] An increase in pH up to 11 did not cause any UV/Vis spectral change for $[(H_2O)_2Mn^{III}(tpps)]$ ($\lambda_{max}$ = 465 nm) in aqueous solution containing TMe-β-CD. However, the absorption spectrum changes markedly above pH 11 (Figure 5) and the pH-titration curve gave a p$K_a$ of 11.9. Since the isosbestic points are observed clearly, there should only be an equilibrium in the pH range between 2.5 and 13.5. The most reasonable process is the acid dissociation of $[(H_2O)_2Mn^{III}(tpps)]$ to $[(H_2O)(OH^-)Mn^{III}(tpps)]$. In the absence of TMe-β-CD, the p$K_a$ value was determined to be 12.4, somewhat lower than that of the $[(H_2O)_2Mn^{III}$-(tpps)]/TMe-β-CD complex. Such a result means that $[(H_2O)(OH^-)Mn^{III}(tpps)]$ is stabilized by complexation with TMe-β-CD. Harriman et al. have reported two p$K_a$ values (8.6 and 11.6) for $[Mn^{III}(tpps)]$ in aqueous solution without cyclodextrin.[6a] However, we could not observe the equilibrium corresponding to p$K_a$ 8.6. It should be noted that a weak absorption band was observed at 433 nm in the higher pH region. The absorption maximum of this band is in good agreement with that of $[(H_2O)Mn^{II}(tpps)]$. This band did not affect the isosbestic points, which suggests only an equilibrium in this system. Such a contradiction might be ascribed to the formation of only a small amount of $[(H_2O)Mn^{II}(tpps)]$.

### Autoreduction of $[Mn^{III}(tpps)]$ in Aqueous Alkaline Solution

Figure 6 shows the absorption spectral changes of $[(H_2O)(OH^-)Mn^{III}(tpps)]$ in 1.0 M aqueous NaOH solution containing TMe-β-CD at 50 °C under a nitrogen atmosphere. The absorbance at 463 nm due to $[(H_2O)(OH^-)$-$Mn^{III}(tpps)]$ gradually decreases and a band with a peak at 434 nm, which is ascribed to $[(H_2O)Mn^{II}(tpps)]$, appears. $[(H_2O)(OH^-)Mn^{III}(tpps)]$ is autoreduced to $[(H_2O)Mn^{II}$-(tpps)] in aqueous alkaline solution under anaerobic conditions. Since such an autoreduction occurs only in aqueous alkaline solution, the $OH^-$ ion must participate in this reduction. Clear isosbestic points indicate the quantitative nature of this reaction. Arasasingham and Bruice have reported that [5,10,15,20-tetrakis(2,4,6-trimethylphenyl)porphyrinato]manganese(III) $[Mn^{III}(tmp)]$ is reduced to $[Mn^{II}$-(tmp)] in $CH_3CN$ containing methanolic tetrabutylammonium hydroxide.[23] Jeon et al. have also studied the autoreduction of [5,10,15,20-tetrakis(2,6-dichlorophenyl)porphyrinato]manganese(III) $[Mn^{III}(tcp)]$ in $CH_3CN$ containing aqueous tetraethyl hydroxide.[24] Both groups reported the formation of five-coordinate $[(L)Mn^{II}Por]$ complexess (L: solvent; $\lambda_{max}$ = 436–437 nm) via $[(L)(OH^-)Mn^{III}Por]$ and/or $[(L)(CH_3O^-)Mn^{III}Por]$. As a next step, ligand exchange of $[(L)Mn^{II}Por]$ to $[(OH^-)Mn^{II}Por]$ ($\lambda_{max}$ = 444–445 nm) proceeds. The former group assumed further conversion of

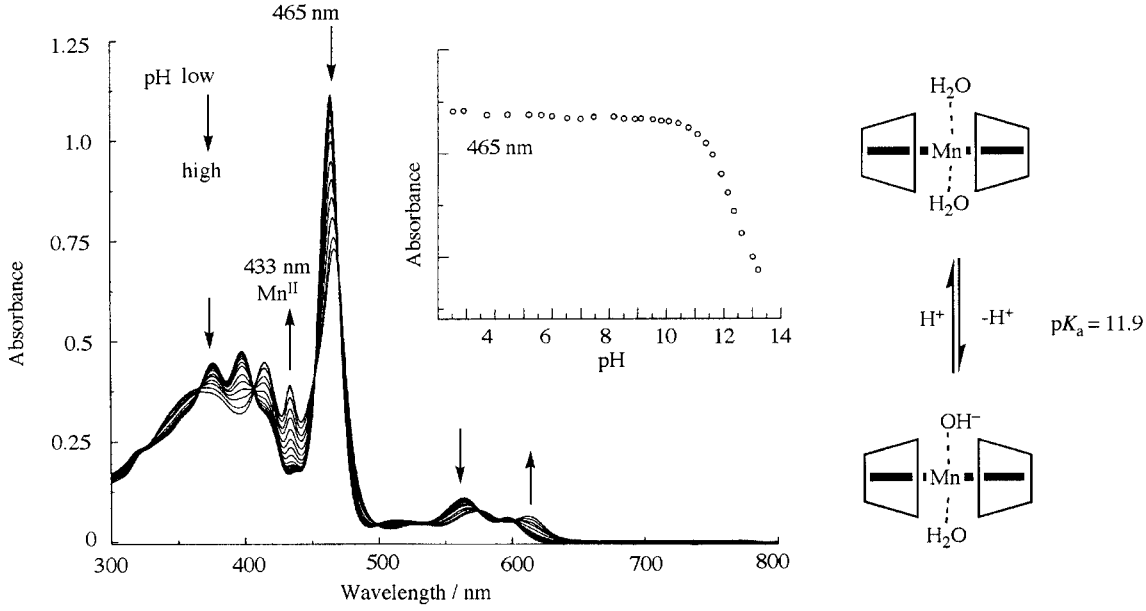

Figure 5. UV/Vis spectral changes of $Mn^{III}(tpps)$ ($1.0\times10^{-5}$ M) in aqueous TMe-β-CD ($1.0\times10^{-3}$ M) solution in the presence of 0.1 M $NaClO_4$ as a function of pH.

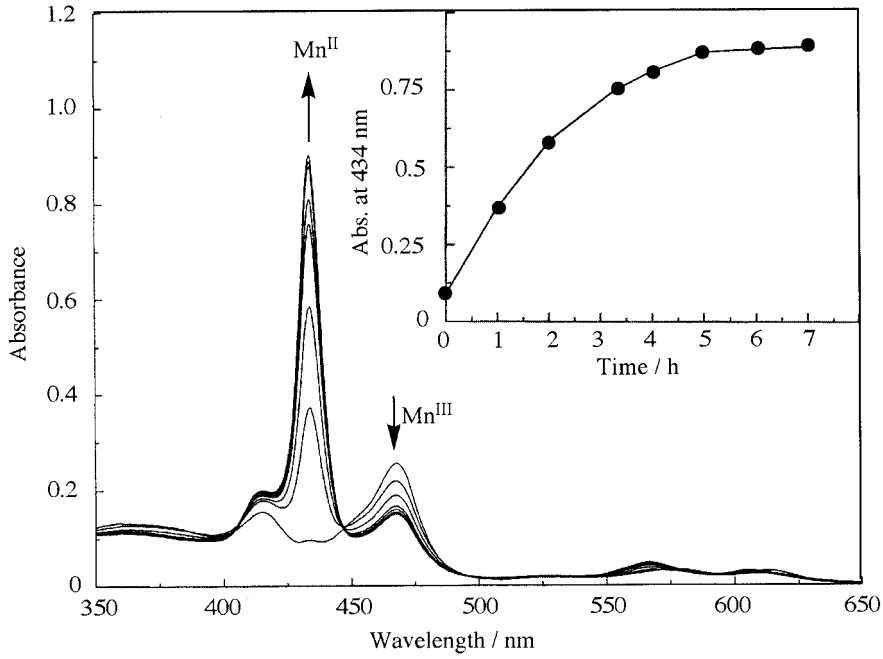

Figure 6. Progressive UV/Vis spectral changes of $[(H_2O)(OH^-)Mn^{III}(tpps)]$ ($5.0\times10^{-6}$ M) to $[(H_2O)Mn^{II}(tpps)]$ in 1.0 M aqueous NaOH solution containing TMe-β-CD ($1.0\times10^{-4}$ M) at 50 °C under $N_2$. Inset: time course in absorbance at 434 nm due to $[(H_2O)Mn^{II}(tpps)]$.

$[(OH^-)Mn^{II}(tmp)]$ to a mixture of $[(OH^-)_2Mn^{III}(tmp)]$, $[(OH^-)(CH_3O^-)Mn^{III}(tmp)]$, and $[(CH_3O^-)_2Mn^{III}(tmp)]$ with absorption maxima at 412 and 448 nm, although the mechanism was not clarified.[23] The present system is simpler than the systems in $CH_3CN$. Only autoreduction of $[(H_2O)(OH^-)Mn^{III}(tpps)]$ to $[(H_2O)Mn^{II}(tpps)]$ occurs in 1.0 M aqueous NaOH solution containing TMe-β-CD at 50 °C. We measured the pH-dependent absorption spectral change of $[(H_2O)Mn^{II}(tpps)]$ complexed with TMe-β-CD and could not find any spectral change in the pH range between 3.0 and 13.5, therefore no equilibrium exists between $[(H_2O)Mn^{II}(tpps)]$ and $[(OH^-)Mn^{II}(tpps)]$ under the present conditions. In the absence of TMe-β-CD, no autoreduction occurred in 1.0 M aqueous NaOH solution. Although we did not study the mechanism of the autoreduction in detail, one-electron transfer from bound $OH^-$ to the $Mn^{III}$ center might occur, as demonstrated by Sawyer and co-workers, who found that the oxidation potentials of $OH^-$ and a phenoxide ion in $CH_3CN$ shift to less positive potentials upon coordination to $[Mn^{III}Por]$.[25] As a preliminary experiment, we measured the ESI mass spectrum (positive mode) of the $CHCl_3$ extract of a reaction mixture obtained by heating a mixture of TMe-β-CD ($1\times10^{-3}$ M) in 1.0 M aqueous NaOH solution containing $[(H_2O)(OH^-)Mn^{III}(tpps)]$ ($5\times10^{-4}$ M) at 70 °C for 16 h. The molecular ion peaks were observed at *m/z* 1438.6, 1452.6, 1468.6, and 1550.6, which correspond to $[(TMe\text{-}β\text{-}CD - OCH_3 + OH + Na)^+$; calcd. 1438.2], $[(TMe\text{-}β\text{-}CD + Na)^+$; calcd. 1452.5], $[(TMe\text{-}β\text{-}CD + K)^+$; calcd. 1468.6], and $[(TMe\text{-}β\text{-}CD + CHCl_3 + H)^+$; calcd. 1550.9], respectively (see Supporting Information). These results strongly suggest that generated $^{\cdot}OH$ radical reacts with TMe-β-CD leading to replacement of an $OCH_3$ group of TMe-β-CD with an OH group.

### Stabilization of Low-Valent $[(H_2O)Mn^{II}(tpps)]$ by TMe-β-CD

As shown in Figure 5, the autoreduction occurs even under aerobic conditions if TMe-β-CD is present in the system. We therefore studied the effects of TMe-β-CD on stabilization of $[(H_2O)Mn^{II}(tpps)]$. Oxidation of $[(H_2O)Mn^{II}(tpps)]$ was carried out by bubbling oxygen through asolution of $[(H_2O)Mn^{II}(tpps)]$, which was prepared by the reaction of $[(H_2O)_2Mn^{III}(tpps)]$ with $Na_2S_2O_4$ in phosphate buffer at pH 7.0. In the absence of TMe-β-CD, $[(H_2O)Mn^{II}(tpps)]$ ($\lambda_{max}$ = 432 nm) was oxidized at once to $[(H_2O)_2Mn^{III}(tpps)]$ ($\lambda_{max}$ = 466 nm) immediately after $S_2O_4^{2-}$ disappeared upon oxidation with $O_2$ (Supporting Information). In the presence of TMe-β-CD, however, the autoxidation of $[(H_2O)Mn^{II}(tpps)]$ to $[(H_2O)_2Mn^{III}(tpps)]$ occurs gradually (Figure 7), thus indicating that low-valent $[(H_2O)Mn^{II}(tpps)]$ is stabilized against autoxidation by complexation with TMe-β-CD.

The pseudo-first-order rate constants for autoxidation of $[(H_2O)Mn^{II}(tpps)]$ ($1.7\times10^{-6}$ M) in 0.05 M phosphate buffer containing TMe-β-CD ($3.4\times10^{-5}$ M) at pH 7.0 and 25 °C were determined as a function of partial dioxygen pressure (see Supporting Information). The second-order rate constant ($k$) for the autoxidation was determined to be 5.4 $M^{-1}s^{-1}$. In the absence of TMe-β-CD, the second-order rate constant has been reported to be $1.5\times10^5$ $M^{-1}s^{-1}$.[26] Encapsulation of $[(H_2O)Mn^{II}(tpps)]$ by two TMe-β-CD molecules drastically depresses the autoxidation. Such a phenomenon is quite similar to the effect of globin on the stabilization of a ferrous porphyrin (heme) against autoxidation.

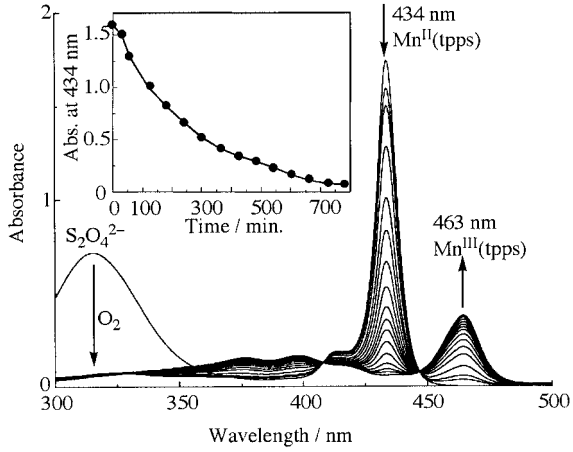

Figure 7. UV/Vis spectral changes of $[(H_2O)Mn^{II}(tpps)]$ ($5.0\times10^{-6}$ M) in 0.05 M phosphate buffer at pH 7.0 and 25 °C in the presence of TMe-β-CD ($1.0\times10^{-4}$ M) after bubbling $O_2$ gas through the solution. $[(H_2O)Mn^{II}(tpps)]$ was prepared by the reduction of $[(H_2O)_2Mn^{III}(tpps)]$ with an excess amount of $Na_2S_2O_4$. Inset: The time course in absorbance at 434 nm due to $[(H_2O)Mn^{II}(tpps)]$ after $O_2$ bubbling.

There are two plausible mechanisms for autoxidation of $[(H_2O)Mn^{II}Por]$ (Figure 8). Mechanism 1 is an outer-sphere electron-transfer mechanism where the electron transfer occurs intermolecularly. Mechanism 2 is similar to the mechanism proposed for autoxidation of oxy-myoglobin[27] and its model oxy-hemoCD.[18b] Dioxygen complexes of $Mn^{II}$ porphyrin complexes are known to be formed in organic solvents at low temperature.[28] To the best of our knowledge, the dioxygen adduct of $Mn^{II}$Por has not been detected at ambient temperature, meaning that the dioxygen adduct of $Mn^{II}$ porphyrin is very unstable. In Mechanism 2, the rate-determining step of the autoxidation must be the ligand-exchange step of $[(H_2O)Mn^{II}Por]$ to $[(O_2)Mn^{II}Por]$ because the autoxidation obeys second-order kinetics. In our previous work, we determined the rate constant for dioxygen association to the iron(II) center of hemoCD to be $4.7\times10^7$ $M^{-1}s^{-1}$.[18b] The penetration of dioxygen into the cleft formed by the *O*-methylated β-cyclodextrin dimer is extremely fast. The cleft of hemoCD should be much less labile than the present case, where the cleft is formed intermolecularly by two TMe-β-CD molecules. The less labile nature of hemoCD is ascribed to the lower mobility of the cyclodextrin moieties linked to each other by a covalent bond and to ligation of the pyridine moiety involved in the linker to the $Fe^{II}$ center. On the basis of these considerations, mechanism 2 can be excluded. In other words, $[(H_2O)Mn^{II}(tpps)]$ seems to be oxidized by an outer-sphere electron-transfer mechanism (mechanism 1). Since the penetration of dioxygen into the cleft formed by two TMe-β-CD molecules is expected to be a fast process, the marked stabilization of $[(H_2O)Mn^{II}(tpps)]$ by the TMe-β-CD molecules is not ascribed to the encapsulation effect due to tight blocking of the $Mn^{II}$ center. One possibility that explains the stabilization of low-valent $[(H_2O)Mn^{II}(tpps)]$ is alteration of the redox potential of [Mn(tpps)] upon inclusion into the TMe-β-CD cavities. We therefore measured the redox potentials of [Mn(tpps)] in the absence and presence of TMe-β-CD.

## Redox Potential of $[(H_2O)_2Mn^{III}(tpps)]$

At first, cyclic voltammetry (CV) was applied to determine the $Mn^{III}$-$Mn^{II}$ redox potential of $[(H_2O)_2Mn^{III}$-(tpps)]. In the absence of TMe-β-CD, CV provided a redox potential, $E_{1/2}$, of –410 mV (vs. Ag/AgCl) in 0.05 M phosphate buffer at pH 7.0 containing 0.1 M $Na_2SO_4$ as supporting electrolyte (see Supporting Information). In the presence of TMe-β-CD, however, no redox peak appeared because the metal center of $[(H_2O)_2Mn^{III}(tpps)]$ is blocked by two TMe-β-CD molecules. It has been shown that an electrode reaction is strictly inhibited by inclusion of a sample in cyclodextrin.[29] Ribo et al. measured the cyclic voltammograms of $Mn^{III}$(tpps) complexed with cyclodextrins such as α-cyclodextrin and 2-hydroxypropyl-β-cyclodextrin.[6b] They assumed the electrode reactions of the Mn(tpps)-cyclodextrin complexes adsorbed on the electrode. We were unable to observe any redox peak when TMe-β-CD, a stronger host for water-soluble porphyrins, was added to the system, therefore we decided to use a spectroelectrochemical method, which is the established method to determine the redox potential of metalloenzymes as well as metal complexes,[30] to study the electrochemistry of the Mn(tpps)/TMe-β-CD complex.

The Nernst equation [Equation (1)] applied to an electrode reaction is

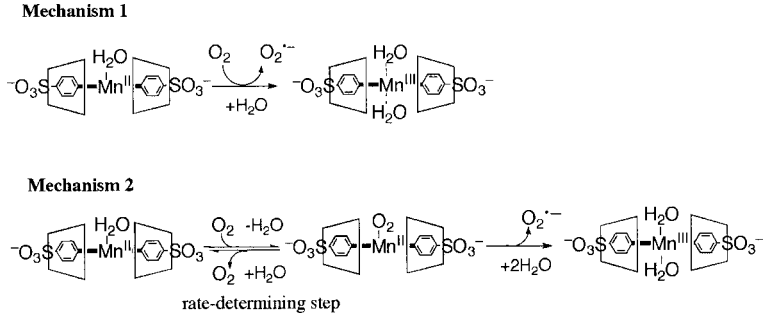

Figure 8. Plausible mechanisms for autoxidation of $[(H_2O)Mn^{II}(tpps)]$ complexed with TMe-β-CD.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$E = E_{1/2} + [(RT)/(nF)]\ln(a_{Ox}/a_{Red}) \quad (1)$$

where $E$ and $E_{1/2}$ are the actual potential and the standard redox potential, respectively, and $a_{Ox}$ and $a_{Red}$ are the chemical activities of the chemical species on the oxidized and reduced electrodes, respectively. $R$, $T$, and $F$ are the gas constant, the absolute temperature, and the Faraday constant, respectively. Equation (1) can be transformed into Equation (2), which is the equation for a one-electron redox reaction at 25 °C applicable to a spectroelectrochemical measurement.

$$E = E_{1/2} + 0.05914\log[(A_{Red} - A)/(A - A_{Ox})] \quad (2)$$

where $A$ is the experimentally observed absorbance of a sample at $E$ and a certain wavelength and $A_{Red}$ and $A_{Ox}$ are the absorbances of the reduced and oxidized species, respectively, at the same wavelength. In order to accelerate the electrode reaction, 9,10-anthraquinone-2-sulfonate ($E_{1/2}$ = –442 mV vs. Ag/AgCl)[31] was used as an electron mediator. The UV/Vis spectral changes of [Mn(tpps)] in phosphate buffer containing 0.1 M $Na_2SO_4$ as a function of applied potential ($E$ = –200 to –475 mV vs. Ag/AgCl) are shown in Figure 9. The spectral changes as a function of $E$ indicate the existence of only equilibrium between $[(H_2O)_2Mn^{III}(tpps)]$ and $(H_2O)Mn^{II}(tpps)$. From the Nernst plot, the $E_{1/2}$ value for the $Mn^{III}$-$Mn^{II}$ redox of the Mn(tpps)/TMe-β-CD complex was determined to be –320 ± 3 mV at pH 7.0 and 25 °C. A similar spectroelectrochemical titration provided an $E_{1/2}$ value of –423 ± 8 mV for [Mn(tpps)] in phosphate buffer (pH 7.0) without TMe-β-CD (see Supporting Information). Interestingly, complexation of [Mn(tpps)] with TMe-β-CD causes a positive shift of $E_{1/2}$ by about 100 mV, which suggests stabilization of low-valent $[(H_2O)Mn^{II}(tpps)]$ against autoxidation by TMe-β-CD. The free-energy change ($\Delta G^0$) during a redox reaction can be evaluated from Equation (3).

$$\Delta G^0 = -nFE_{1/2} \quad (3)$$

The free-energy changes for the equilibria shown in Figure 10 were calculated from the $E_{1/2}$ values and the binding constants for complexation of $[(H_2O)_2Mn^{III}(tpps)]$ and TMe-β-CD. The $\Delta G^0$ value for the redox reaction of [Mn(tpps)] in the presence of TMe-β-CD is 10 kJ mol$^{-1}$, while that for the system in the absence of TMe-β-CD is 20 kJ mol$^{-1}$. From the thermodynamic and electrochemical data, the $K_1K_2$ value for the complexation of $[(H_2O)Mn^{II}$-(tpps)] with TMe-β-CD to form a 2:1 host–guest complex can be calculated to be $1.2\times10^{12}$ M$^{-2}$. In the case of $[(H_2O)_2Mn^{III}(tpps)]$, the $K_1K_2$ value is $2.3\times10^{10}$ M$^{-2}$. It is clear that a positive net charge remaining on the center of $[(H_2O)_2Mn^{III}(tpps)]$ greatly destabilizes the 2:1 host–guest complex.

Although we also measured the $Mn^{III}$-$Mn^{IV}$ redox potentials in aqueous alkaline solutions with and without TMe-β-CD, we could not obtain reliable data to compare the redox potential of the Mn(tpps)/TMe-β-CD complex with that of free [Mn(tpps)] (see Supporting Information).

## Conclusions

The present study leads to the following conclusions:
(1) The 1:2 inclusion complex of $[(H_2O)Mn^{II}(tpps)]$ and TMe-β-CD is much more stable than that of $[(H_2O)_2Mn^{III}$-(tpps)] and TMe-β-CD. Destabilization of $[(H_2O)_2Mn^{III}$-(tpps)]/TMe-β-CD is ascribed to a positive net charge remaining on the center of the metalloporphyrin;
(2) $[(H_2O)(OH^-)Mn^{III}(tpps)]$ in aqueous alkaline solution containing TMe-β-CD gradually changes to $[(H_2O)Mn^{II}$-

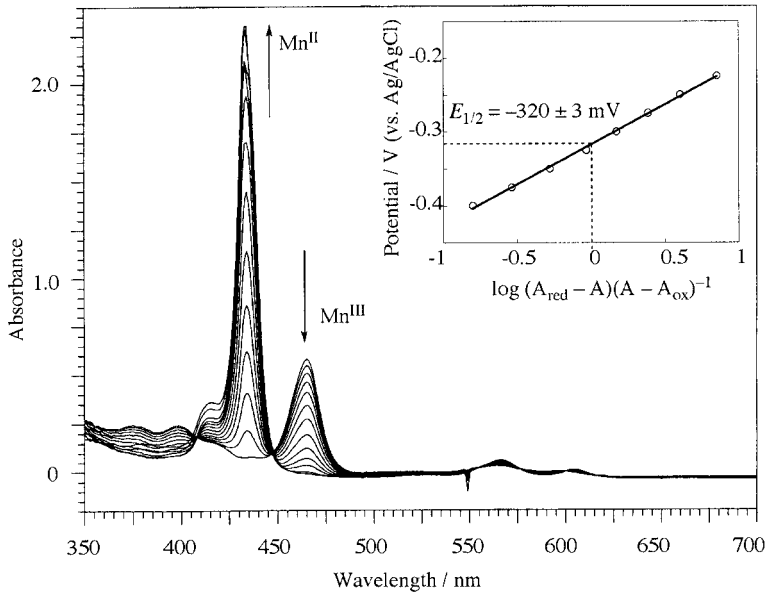

Figure 9. UV/Vis spectral changes of [Mn(tpps)] ($5.0\times10^{-5}$ M) in 0.05 M phosphate buffer containing $5.0\times10^{-4}$ M TMe-β-CD and 0.1 M $Na_2SO_4$ at various applied potentials ($E$ = –200 to –475 mV vs. Ag/AgCl) during the spectroelectrochemical titration at pH 7.0 and 25 °C. Inset: the Nernst plot obtained from the spectral changes at 463 nm.

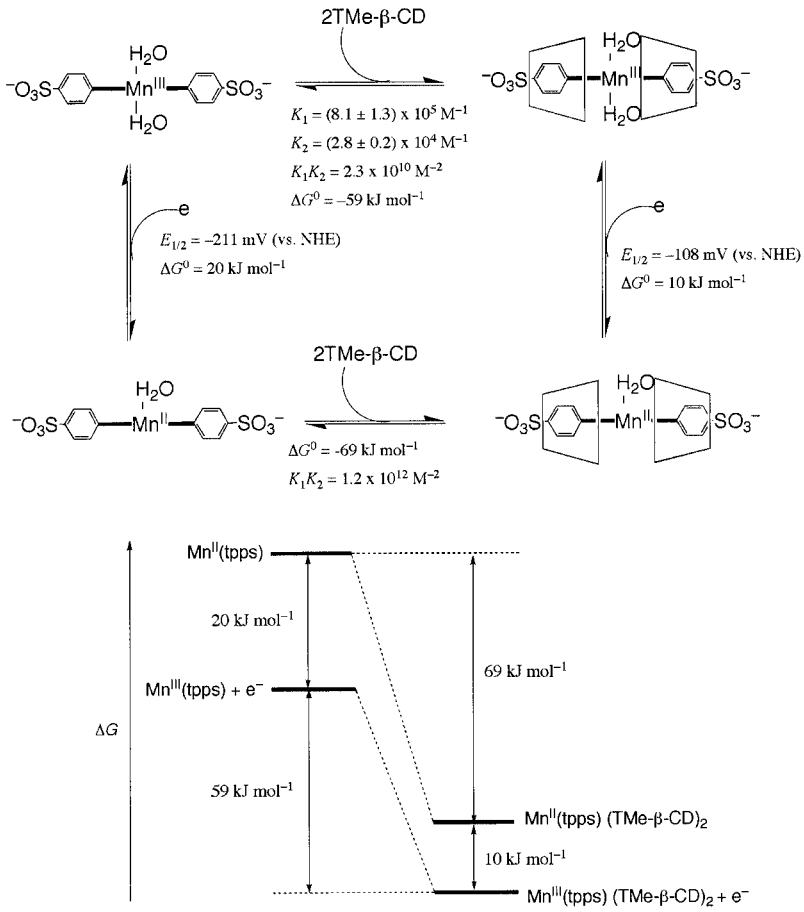

Figure 10. Free-energy changes for the equilibria of the Mn(tpps)/TMe-β-CD system in aqueous solution at pH 7.0 and 25 °C.

(tpps)] through a one-electron transfer from bound $OH^-$ to $Mn^{III}$. Formation of low-valent [$(H_2O)Mn^{II}$(tpps)] is detectable even under aerobic conditions because of marked stabilization due to incorporation of [$(H_2O)Mn^{II}$(tpps)] into the TMe-β-CD cavities;

(3) The redox potentials of [Mn(tpps)] in pH 7.0 phosphate buffer are –211 and –108 mV (vs. NHE) in the absence and the presence of TMe-β-CD, respectively. [$(H_2O)Mn^{II}$(tpps)] is stabilized against autoxidation by complexation with TMe-β-CD, which mimics the function of proteins in biological systems.

## Experimental Section

**Materials:** [5,10,15,20-Tetrakis(*p*-sulfonatophenyl)porphyrinato]-manganese(III) chloride in an acidic form (Frontier Scientific), TMe-β-CD (Nacalai), and anthraquinone-2-sulfonate sodium salt (Nacalai) were purchased and used as received. On the basis of the extinction coefficient of [$(H_2O)_2Mn^{III}$(tpps)] ($\varepsilon_{466} = 9.5 \times 10^4$), the purchased manganese porphyrin was determined to be the hexahydrate. Water was purified with a Millipore Simpak 1 apparatus. Pure $O_2$ (99.999%) and pure $N_2$ (99.999%) gases were purchased from Sumitomo Seika Chemicals.

**Measurements:** UV/Vis spectra were recorded with a Shimadzu UV-2450 spectrophotometer with a thermostatted cell holder. The pH values were measured with a Horiba pH meter M-12. Determination of the binding constants for the complexation of [Mn(tpps)] with TMe-β-CD was performed from the UV/Vis spectral titrations according to a published method.[14b,16] Microcalorimetric measurements were carried out using a Microcal Isothermal Titration Calorimeter VP-ITC. The titration curve obtained was analyzed using the Sequential Binding Sites Model for 2:1 host–guest complexation in the ORIGIN software program.[32]

Mixed $O_2$ gases with various partial pressures in $N_2$ were prepared with a KOFLOC GM-4B gas-mixing apparatus.

Cyclic voltammetry was carried out with a BAS CV-50W electrochemical analyzer. A gold working electrode, a platinum counter electrode, and a Ag/AgCl (3 M NaCl) reference electrode were utilized in a single-component cell. The working electrode was polished with 0.05-μm alumina and washed with pure water prior to use. The measurements were carried out under a $N_2$ atmosphere.

The spectroelectrochemical measurements were carried out using an optically transparent thin-layer electrode cell (BAS, optical length: 0.5 mm). A working platinum mesh electrode ($7 \times 8 \times 0.2\ mm^3$, 80 mesh) was immersed in the cell. A platinum wire and Ag/AgCl (3 M NaCl) were used as the counter and reference electrodes, respectively. The potential was controlled by a potentiostat system (ALS1100A electrochemical analyzer, BAS). The UV/Vis spectra during electronic reduction were recorded with a Shimadzu Multispec-1500 spectrometer with a thermostatted cell holder. Anthraquinone-2-sulfonate was used to mediate electron transfer between the Mn(tpps)/TMe-β-CD complex and the working electrode. The measurements were carried out at 25 °C under

# Luminescent Cyclometalated Iridium(III) Polypyridine Complexes Containing a Thiourea Moiety: Synthesis, Characterization, Photophysics, Electrochemistry and Anion-Binding Properties

**Kenneth Kam-Wing Lo,*[a] Jason Shing-Yip Lau,[a] David Ka-Kit Lo,[a] and Larry Tso-Lun Lo[a]**

**Keywords:** Fluorescence spectroscopy / Iridium / Luminescence / N ligands / Sensors

A series of new luminescent cyclometalated iridium(III) polypyridine thiourea complexes $[Ir(N\text{-}C)_2(N\text{-}N)](PF_6)$ [HN-C = 2-phenylpyridine (Hppy), N-N = *N*-ethyl-*N*′-1,10-phenanthrolin-5-yl thiourea (phen-TU-Et) (**1a**), *N*-phenyl-*N*′-1,10-phenanthrolin-5-yl thiourea (phen-TU-Ph) (**1b**), *N*-(1-adamantanemethyl)-*N*′-1,10-phenanthrolin-5-yl thiourea (phen-TU-MeA) (**1c**); HN-C = 7,8-benzoquinoline (Hbzq), N-N = phen-TU-Et (**2a**), phen-TU-Ph (**2b**), phen-TU-MeA (**2c**); HN-C = 2-phenylquinoline (Hpq), N-N = phen-TU-Et (**3a**), phen-TU-Ph (**3b**), phen-TU-MeA (**3c**)] have been synthesized and characterized. The photophysical and electrochemical properties of these complexes have been investigated. On the basis of the photophysical and electrochemical data, the nature of the emissive states has been assigned. The thiourea moieties of the complexes allow them to act as receptors for anions; the binding of $OAc^-$, $F^-$, and $H_2PO_4^-$ to the complexes has been investigated by emission titrations.

## Introduction

Recognition of anions is an interesting area of research because of the important roles of anions in industrial and biological processes and environmental science. Hydrogen-bonding interactions have been commonly used in the development of artificial anion receptors;[1–9] for example, traditional amide-based receptors have been employed as hydrogen-bond donors to bind various anions.[1–5] Recently, the thiourea moiety has attracted much attention because of its specific binding of $F^-$ and oxyanions such as $OAc^-$ and $H_2PO_4^-$.[6–9] It has been attached to various organic chromophores and fluorophores to produce effective anion sensors.[6–8]

The photophysics and photochemistry of luminescent iridium(III) polypyridine complexes have attracted much attention recently.[10–25] This interest originates from the successful use of these complexes as dopants in the fabrication of light-emitting diode devices.[16a,16e] Some luminescent iridium(III) polypyridine complexes have been developed as luminescent sensors for various analytes, including oxygen,[11c] proton,[17a] and alkali and alkaline-earth metal cations.[23d] However, the use of luminescent iridium(III) polypyridine complexes as anion sensors is very limited.[17b] With our recent interest in using luminescent iridium(III) polypyridine complexes as biological labeling reagents and probes,[25] we envisage that incorporation of a thiourea moiety into these complexes can afford a new anion-sensory system. Herein, we report the synthesis, characterization, photophysics, and electrochemistry of a series of new luminescent cyclometalated iridium(III) polypyridine thiourea complexes $[Ir(N\text{-}C)_2(N\text{-}N)](PF_6)$ [HN-C = 2-phenylpyridine (Hppy), N-N = *N*-ethyl-*N*′-1,10-phenanthrolin-5-yl thiourea (phen-TU-Et) (**1a**), *N*-phenyl-*N*′-1,10-phenanthrolin-5-yl thiourea (phen-TU-Ph) (**1b**), *N*-(1-adamantanemethyl)-*N*′-1,10-phenanthrolin-5-yl thiourea (phen-TU-MeA) (**1c**); HN-C = 7,8-benzoquinoline (Hbzq), N-N = phen-TU-Et (**2a**), phen-TU-Ph (**2b**), phen-TU-MeA (**2c**); HN-C = 2-phenylquinoline (Hpq), N-N = phen-TU-Et (**3a**), phen-TU-Ph (**3b**), phen-TU-MeA (**3c**)] (Scheme 1). The emission and electrochemical properties of these complexes have been compared to those of their amine and isothiocyanate counterparts $[Ir(N\text{-}C)_2(N\text{-}N)](PF_6)$ [HN-C = Hppy, N-N = 5-amino-1,10-phenanthroline (phen-$NH_2$) (**1d**), 5-isothiocyanato-1,10-phenanthroline (phen-ITC) (**1e**); HN-C = Hbzq, N-N = phen-$NH_2$ (**2d**), phen-ITC (**2e**); HN-C = Hpq, N-N = phen-$NH_2$ (**3d**), phen-ITC (**3e**)] (Scheme 1).[25a,25c] The binding of anions including $OAc^-$, $F^-$, and $H_2PO_4^-$ to the thiourea complexes has been investigated by emission titrations.

## Results and Discussion

### Synthesis

The isothiocyanate group of $[Ir(N\text{-}C)_2(phen\text{-}ITC)](PF_6)$ reacts readily with primary amines to form thiourea linkages. We have used these luminescent complexes as labeling reagents for amine-containing biological molecules.[25a,25c] All the cyclometalated iridium(III) thiourea complexes in the current work were prepared by the reaction of $[Ir(N\text{-}C)_2(phen\text{-}ITC)](PF_6)$ with the corresponding amines. To investigate the effects of the substituent of the thiourea moiety on the photophysical, electrochemical, and anion-binding properties of the target complexes, we have employed an electron-donating ethyl group and an electron-withdrawing phenyl ring as the substituents. Additionally, a relatively bulky 1-adamantanemethyl unit has also been employed. All the iridium(III) thiourea complexes were characterized by $^1H$ NMR spectroscopy, positive-ion ESI-MS, IR spectroscopy, and gave satisfactory microanalysis.

### Electronic Absorption and Emission

The electronic absorption spectroscopic data of the iridium(III) thiourea complexes are listed in Table 1. The electronic absorption spectra of complexes **1a**, **2a**, and **3a** in $CH_2Cl_2$ are shown in Figure 1. All the complexes showed intense spin-allowed intra-ligand ($^1$IL) ($\pi\rightarrow\pi^*$) (N-N and N-C⁻) absorption bands at around 252–348 nm ($\varepsilon$ of the order of $10^4\ M^{-1}cm^{-1}$) and spin-allowed metal-to-ligand charge-transfer ($^1$MLCT) [$d\pi(Ir)\rightarrow\pi^*$(N-N and N-C⁻)] absorption shoulders at around 370–521 nm. Similar to related cyclometalated iridium(III) polypyridine systems,[10–16,17a,17c–17e,18–24] spin-forbidden $^3$MLCT [$d\pi(Ir)\rightarrow\pi^*$(N-N and N-C⁻)] absorption tailing was also observed in a lower-energy region (ca. 518–550 nm) due to spin-orbital coupling associated with the iridium(III) center. It is noteworthy that the absorption data of the complexes with the same cyclometalating ligand but different substituents on the thiourea moiety (i.e. ethyl, phenyl or 1-adamantanemethyl) are very similar, thus indicating that these substituents do not substantially affect the energy levels of the $\pi^*$ orbitals of the diimine ligands.

Upon irradiation, all the iridium(III) thiourea complexes displayed intense and long-lived green to orange luminescence under ambient conditions and in low-temperature alcohol glass. The emission data of these complexes and their amine (**1d**–**3d**) and isothiocyanate (**1e**–**3e**) counterparts are summarized in Table 2. The emission spectra of

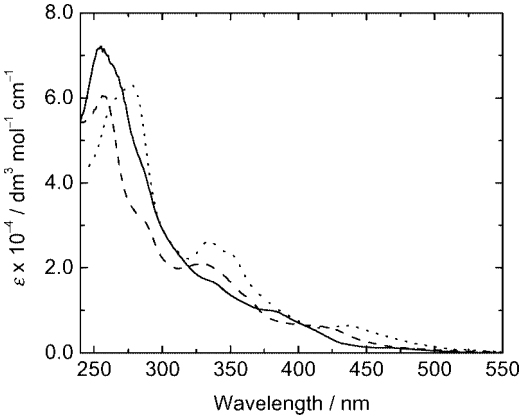

Figure 1. Electronic absorption spectra of complexes **1a** (—) **2a** (---), and **3a** (···) in $CH_2Cl_2$ at 298 K.

complexes **1a**, **2a**, and **3a** in degassed $CH_2Cl_2$ at 298 K and in alcohol glass at 77 K are shown in Figures 2, 3, and 4, respectively. The emission of the ppy⁻ (**1a**–**1c**) and bzq⁻ (**2a**–**2c**) thiourea complexes occurred at a lower energy with a shorter excited-state lifetime and lower emission quantum yield in more polar $CH_3CN$ than in less polar $CH_2Cl_2$ (Table 2). These findings suggest that the emissive states bear a high parentage of triplet MLCT [dπ(Ir)→π*(N-N)] character.[10,11b–11f,13a,14a,15,16,17c–17e,19a,20–24,25a,25c,25d,25f] This assignment is supported by the observations that the iridium(III) thiourea complexes emitted at lower energy than complexes **1d** and **2d**, which contain an electron-donating amine group on the diimine ligand, and at higher energy than complexes **1e** and **2e**, which contain an electron-withdrawing isothiocyanate group on the diimine ligand. Interestingly, in fluid solutions at 298 K the emission spectra of all the pq⁻ complexes **3a**–**3c** showed very similar structural features, with an emission maximum at around 558–563 nm and a shoulder at around 584–588 nm (Table 2 and Figure 4). The independence of the nature of the diimine ligands on the emission behavior is further reflected by the fact that the phen-$NH_2$ complex **3d** and the phen-ITC complex **3e** also exhibited very similar emission energies (Table 2). The excited-state lifetimes of the pq⁻ thiourea complexes varied from around 3.11 to 1.27 μs and are much longer than those of their ppy⁻ and bzq⁻ counterparts. On the basis of these observations, we propose that the emissive states of these pq⁻ complexes are essentially triplet IL (π→π*) (pq⁻) in nature, perhaps with mixing of some $^3$MLCT [dπ(Ir)→π*(pq⁻)] character. Similar $^3$IL emission has been observed for related iridium(III) pq⁻ systems.[25c,25d]

Upon cooling to 77 K, the emission bands of the ppy⁻ (**1a**–**1c**) and bzq⁻ (**2a**–**2c**) thiourea complexes showed large hypsochromic shifts (Table 2, Figure 2 and Figure 3), which is a typical feature of common iridium(III) $^3$MLCT emitters.[10a,10c,11b,11c,11e,11f,13a,14b,15,16b–16e,17c,19a,20a,21,22,25a,25c,25d,25f] Bi-exponential emission decays were observed; the longer- and shorter-lived counterparts are ascribed to $^3$MLCT excited states involving the cyclometalating and di-

imine ligands, respectively.[10,13a] On the contrary, the emission bands of the $pq^-$ thiourea complexes **3a**–**3c** only showed small blue shifts upon cooling to 77 K (Table 2 and Figure 4). The complexes displayed very similar and vibronically structured emission spectra with an excited-state lifetime of about 6 μs in alcohol glass at 77 K. It is conceivable that the nature of the emissive states is essentially $^3$IL ($\pi\rightarrow\pi^*$) ($pq^-$), probably mixed with some $^3$MLCT [$d\pi(Ir)\rightarrow\pi^*(pq^-)$] character.

It is important to note that the emission properties of these cyclometalated iridium(III) polypyridine complexes are sensitive to the substituents on the diimine ligands. In most cases, the emission energies of the complexes follow the order: phen-$NH_2$ > phen-thiourea > phen-ITC, which is indicative of the involvement of $^3$MLCT [$d\pi(Ir)\rightarrow\pi^*$(N-N)] character in the emissive states. On the contrary, variation of the substituent of the thiourea moiety does not result in any substantial difference of the emission properties of the thiourea complexes (Table 2). It appears that the thiourea bridge does not facilitate electronic communication and its substituent cannot profoundly perturb the electronic structures of the diimine ligand and the iridium(III) complex.

## Electrochemistry

The electrochemical properties of the iridium(III) thiourea complexes have been studied by cyclic voltammetry. The electrochemical data of these complexes and the phen-$NH_2$ and phen-ITC analogs are listed in Table 3. All the iridium(III) thiourea complexes showed an irreversible wave at about +1.08 to +1.19 V vs. SCE, which is assigned to the oxidation of the thiourea groups because similar waves are absent in the cyclic voltammograms of the phen-$NH_2$ and phen-ITC complexes (Table 3). An additional quasi-reversible oxidation couple appeared at about +1.21 to +1.31 V, attributable to the metal-centered $Ir^{IV/III}$ oxidation.[10a,10c,11–13,14a,15b,15c,19a,19b,23a,24b,24c,25] The lower reversibility of these couples compared to that of typical iridium(III) polypyridine complexes could be a result of the irreversible thiourea-based oxidation that occurred at lower potentials. The iridium(III) thiourea complexes exhibited the first reduction waves at about –1.32 to –1.37 V vs. SCE. These waves are assigned to the reduction of the diimine ligands. This assignment agrees with the find-

Table 3. Electrochemical data of the iridium(III) polypyridine complexes in $CH_3CN$ (0.1 M TBAP) at 298 K (glassy-carbon working electrode; sweep rate: 100 mV $s^{-1}$; all potentials vs. SCE).

ings that the potentials of these waves are less negative than those of the phen-$NH_2$ (ca. –1.42 to –1.45 V) and more negative than the phen-ITC analogs (ca. –1.20 to –1.21 V) due to the electron-donating and -withdrawing properties of the amine and isothiocyanate groups, respectively. Whilst most diimine-based reductions of cyclometalated iridium(III) polypyridine complexes are reversible in nature (see references cited above), the irreversibility of these waves suggests the possible involvement of thiourea in the reduction process. Again, variation of the substituent of the thiourea moiety does not cause much difference in the reduction potentials of these complexes (Table 3), thus confirming that the π* orbitals of the diimine ligand are not strongly affected by the substituents on the other side of the thiourea linkage. Other irreversible and distorted waves appeared at lower potentials; these are assigned to reduction of the cyclometalating ligands.

### Anion-Binding Properties

Since the $OAc^-$, $F^-$, and $H_2PO_4^-$ ions are well known to bind to thiourea,[6–9] we have studied their binding to the iridium(III) thiourea complexes. The absorption spectra of the complexes did not exhibit any changes in the presence of these three ions. It is therefore likely that the binding does not significantly alter the π* energy levels of the diimine ligands and hence the energies of the $^1$IL and $^1$MLCT transitions. Emission titrations have been performed to study the anion-binding properties of the complexes. As an example, the luminescence spectral traces for complex **3c** in $CH_3CN$ upon addition of $OAc^-$, $F^-$, and $H_2PO_4^-$ ions are illustrated in Figures 5(a), 6(a), and 7(a), respectively. The emission intensities of all the iridium(III) thiourea complexes in the current work were reduced in the presence of these three anions. These findings are attributed to binding of the anions to the thiourea moieties because no changes were observed for the control complexes $[Ir(N\text{-}C)_2(phen)](PF_6)$ ($N\text{-}C^-$ = $ppy^-$, $bzq^-$, $pq^-$).[26] It is worth mentioning that the emission energies of the thiourea complexes were not altered upon the binding events, thereby suggesting that the uptake of the anions by the thiourea moieties did not increase the π* levels of the diimine ligands. To a certain extent, this is in agreement with the independence of the emission properties of the complexes on the substituents of the thiourea moieties (see above). We tentatively ascribe the observed emission quenching to a more efficient nonradiative deactivation pathway. Similar anion-induced emission quenching has also been observed in the luminescent rhenium(I) polypyridine thiourea complexes that we reported previously.[9]

Treatment of the emission titration data of all the iridium(III) thiourea complexes and the three anions using a 1:1 binding model gave satisfactory fits.[27] Plots of $I_o/(I_o - I_x)$ vs. $[A^-]^{-1}$ ($A^-$ = $OAc^-$, $F^-$, $H_2PO_4^-$) for complex **3c** and the corresponding theoretical fits are shown in Figures 5(b), 6(b), and 7(b), respectively. The $\log K_s$ values for the binding of all the iridium(III) thiourea complexes and the three

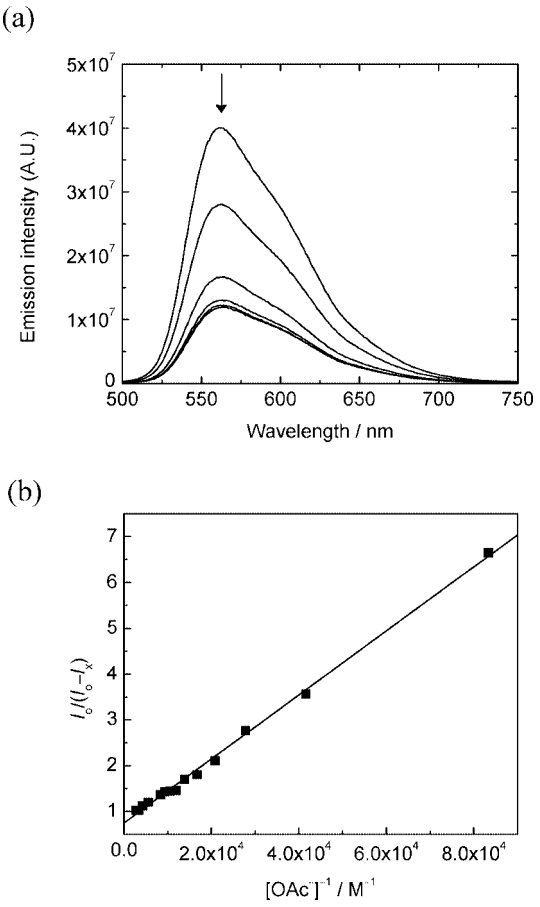

Figure 5. (a) Luminescence spectral traces of complex **3c** (120 μM) in $CH_3CN$ (0.1 M TBAP) upon addition of $OAc^-$ at 298 K. The concentrations of $OAc^-$ were 0, 24, 48, 72, 96, and 120 μM, respectively. (b) A plot of $I_o/(I_o - I_x)$ vs. $[OAc^-]^{-1}$ (■) and the theoretical fit on the basis of a 1:1 binding stoichiometry (—).

anions in $CH_3CN$ have been determined from the fitting (Table 4). The $\log K_s$ values for the binding of $OAc^-$ range from 4.03 to 4.35 and are larger than those for $F^-$ (from 3.13 to 3.73) and $H_2PO_4^-$ (from 3.12 to 3.68). Importantly, variation of the cyclometalating ligands and the substituents of the thiourea moieties did not lead to any noticeable difference in the anion-binding properties of the complexes. The minor role of the cyclometalating ligands on the anion-binding behavior is reasonable. However, the use of various thiourea substituents of different electronic and structural properties was expected to affect the anion-binding affinities of the complexes. Our experimental results indicate, however, that these effects are minimal. A possible reason is that these thiourea substituents can only control the electronic density of one of the two NH groups of the thiourea moiety, and that the bulky adamantane unit does not hamper the binding properties owing to the flexible methylene linkage. Overall, the iridium(III) thiourea complexes revealed a stronger affinity for $OAc^-$ than for the $F^-$ and $H_2PO_4^-$ ions (Table 4). A similar trend has been observed for a related naphthalimide-thiourea conjugate [$\log K_s$ = 4.47 ($OAc^-$), 3.80 ($F^-$), 3.48 ($H_2PO_4^-$) in DMSO][8f] and a

(b) A plot of $I_o/(I_o - I_x)$ vs. $[H_2PO_4^-]^{-1}$ (■) and the theoretical fit on the basis of a 1:1 binding stoichiometry (—).

rhenium(I) polypyridine anthraquinone thiourea complex [$\log K_s$ = 4.61 ($OAc^-$), 3.66 ($F^-$), 3.70 ($H_2PO_4^-$) in $CH_3CN$].[9] It is likely that this preferential binding of $OAc^-$ ion is associated with the basicity of the anions [$pK_a$ = 4.75 (HOAc), 3.45 (HF), 2.12 ($H_3PO_4$) in aqueous solution at 298 K].[28] The binding affinities of the iridium(III) thiourea complexes to $F^-$ and $H_2PO_4^-$ are very similar. The geometry of the anions appears to contribute strongly to the stabilities of the receptor–anion adducts,[29] with the trigonal $OAc^-$ and tetrahedral $H_2PO_4^-$ ions fitting the trigonal planar shape of the thiourea unit better than the spherical $F^-$ ion. Thus, it is likely that the binding affinities of the iridium(III) thiourea complexes to $OAc^-$, $F^-$, and $H_2PO_4^-$ are a combined effect of the basicity and molecular geometry of the guest ions.

Table 4. $\log K_s$ values for the binding of anions by the iridium(III) polypyridine thiourea complexes in $CH_3CN$ (0.1 M TBAP) at 298 K.

## Conclusions

This paper describes the synthesis, characterization, photophysics, electrochemistry, and anion-binding properties of a series of new luminescent cyclometalated iridium(III) polypyridine thiourea complexes. The emission intensities of all the complexes were reduced upon addition of anions $OAc^-$, $F^-$, and $H_2PO_4^-$. The binding stoichiometries were determined to be 1:1 in all cases, and the $\log K_s$ values ranged from 3.12 to 4.35. The binding affinity of the iridium(III) thiourea complexes for $OAc^-$ was higher than those for $F^-$ and $H_2PO_4^-$, which is a combined effect of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

basicity and molecular geometry of the anions. Interestingly, the substituents of the thiourea moieties did not affect the photophysical, electrochemical, and anion-binding properties of the complexes, probably due to insufficient communication between these substituents and the diimine ligand. Nevertheless, these thiourea complexes are the first systematic design of specific anion receptors derived from luminescent cyclometalated iridium(III) polypyridine complexes. The development of related luminescent transition metal complexes as anion receptors is in progress.

## Experimental Section

**Materials and Reagents:** All solvents were of analytical grade and were purified according to published procedures.[30] Ethylamine (2 M in THF) (International Laboratory), aniline (Aldrich), 1-adamantanemethylamine (International Laboratory), tetra-*n*-butylammonium acetate (TBAOAc; Aldrich), tetra-*n*-butylammonium fluoride (TBAF; Acros), and tetra-*n*-butylammonium dihydrogen phosphate ($TBAH_2PO_4$; Aldrich) were used without purification. Tetra-*n*-butylammonium hexafluorophosphate (TBAP; Aldrich) was recrystallized from hot ethanol twice and dried in vacuo at 110 °C before use.

**Synthesis:** A mixture of $[Ir(N\text{-}C)_2(phen\text{-}ITC)](PF_6)$ (HN-C = Hppy, Hbzq, Hpq; 0.12 mmol)[25c] and the corresponding amine (ethylamine, aniline, 1-adamantanemethylamine; 0.12 mmol) in acetone (30 mL) was stirred at room temperature under an inert atmosphere of nitrogen in the dark for 12 h. Recrystallization of the products from a mixture of acetone and diethyl ether gave air-stable orange-yellow crystals.

**[Ir(pq)$_2$(phen-TU-Et)](PF$_6$) (3a):** Yield: 86 mg (70%). $^1$H NMR (300 MHz, [D$_6$]acetone, 298 K, relative to TMS): $\delta$ = 9.24 (s, 1 H, phen-N*H*), 9.03 (d, *J* = 7.8 Hz, 1 H, 2-H of phen), 8.75–8.65 (m, 3 H, 3-H, 8-H and 9-H of phen), 8.58–8.46 (m, 5 H, 4-H, 6-H and 7-H of phen and 3-H of quinolinyl ring of pq$^-$), 8.31 (d, *J* = 7.6 Hz, 1 H, 5-H of quinolinyl ring of pq$^-$), 8.15–7.96 (m, 2 H, 4-H of quinolinyl ring of pq$^-$), 7.89 (s, 1 H, Et-N*H*), 7.81 (d, *J* = 6.7 Hz, 2 H, 8-H of quinolinyl ring of pq$^-$), 7.41–7.21 (m, 6 H, 6-H and 7-H of quinolinyl ring and 3-H of phenyl ring of pq$^-$), 6.95–6.86 (m, 4 H, 4-H and 5-H of phenyl ring of pq$^-$), 6.68 (d, *J* = 7.9 Hz, 2 H, 6-H of phenyl ring of pq$^-$), 3.62–3.58 (m, 2 H, C$H_2$CH$_3$), 1.32 ppm (t, *J* = 7.2 Hz, 3 H, CH$_2$C$H_3$). IR (KBr): $\tilde{\nu}$ = 3387 (m, N–H), 1288 (m, C=S), 846 (s, $PF_6^-$) $cm^{-1}$. Positive-ion ESI-MS: ion cluster at *m/z* 882 $[M]^+$. $C_{45}H_{34}F_6IrN_6PS{\cdot}H_2O$ (1046.1): calcd. C 51.67, H 3.47, N 8.03; found C 51.58, H 3.27, N 8.24.

**[Ir(pq)$_2$(phen-TU-Ph)](PF$_6$) (3b):** Yield: 96 mg (74%). $^1$H NMR (300 MHz, [D$_6$]acetone, 298 K, relative to TMS): $\delta$ = 10.35 (s, 1 H, phen-N*H*), 10.06 (s, 1 H, Ph-N*H*), 8.95 (d, *J* = 8.5 Hz, 1 H, 2-H of phen), 8.72–8.63 (m, 3 H, 3-H, 8-H and 9-H of phen), 8.58–8.46 (m, 4 H, 4-H and 7-H of phen and 3-H of quinolinyl ring of pq$^-$), 8.31 (dd, *J* = 7.8 and 3.2 Hz, 2 H, 5-H of quinolinyl ring of pq$^-$), 8.22 (s, 1 H, 6-H of phen), 8.06–7.99 (m, 2 H, 4-H of quinolinyl ring of pq$^-$), 7.80 (t, *J* = 6.9 Hz, 2 H, 2-H and 6-H of Ph), 7.65 (d, *J* = 8.8 Hz, 2 H, 8-H of quinolinyl ring of pq$^-$), 7.41–7.13 (m, 9 H, 3-H, 4-H and 5-H of Ph and 6-H and 7-H of quinolinyl ring and 3-H of phenyl ring of pq$^-$), 6.94–6.84 (m, 4 H, 4-H and 5-H of phenyl ring of pq$^-$), 6.69 ppm (d, *J* = 7.6 Hz, 2 H, 6-H of phenyl ring of pq$^-$). IR (KBr): $\tilde{\nu}$ = 3351 (m, N–H), 1288 (m, C=S), 845 (s, $PF_6^-$) $cm^{-1}$. Positive-ion ESI-MS: ion cluster at *m/z* 931 $[M]^+$. $C_{49}H_{34}F_6IrN_6PS{\cdot}1.5\,H_2O$ (1103.12): calcd. C 53.35, H 3.38, N 7.62; found C 53.25, H 3.44, N 7.78.

**[Ir(pq)$_2$(phen-TU-MeA)](PF$_6$) (3c):** Yield: 106 mg (77%). $^1$H NMR (300 MHz, [D$_6$]acetone, 298 K, relative to TMS): $\delta$ = 10.87 (s, 1 H, phen-N*H*), 9.20 (d, *J* = 8.2 Hz, 1 H, 2-H of phen), 9.00 (s, 1 H, CH$_2$-N*H*), 8.68 (d, *J* = 4.4 Hz, 1 H, 9-H of phen), 8.60–8.53 (m, 5 H, 3-H, 6-H and 8-H of phen and 3-H of quinolinyl ring of pq$^-$), 8.48–8.44 (m, 2 H, 4-H and 7-H of phen), 8.30 (d, *J* = 8.2 Hz, 2 H, 5-H of quinolinyl ring of pq$^-$), 7.98–7.93 (m, 2 H, 4-H of quinolinyl ring of pq$^-$), 7.78 (d, *J* = 8.2 Hz, 2 H, 8-H of quinolinyl ring of pq$^-$), 7.38–7.20 (m, 6 H, 6-H and 7-H of quinolinyl ring and 3-H of phenyl ring of pq$^-$), 6.92–6.85 (m, 4 H, 4-H and 5-H of phenyl ring of pq$^-$), 6.68 (dd, *J* = 7.6 and 2.3 Hz, 2 H, 6-H of phenyl ring of pq$^-$), 2.83 (s, 2 H, C$H_2$NH), 1.90 (s, 3 H, CH of adamantane), 1.70–1.62 ppm (m, 12 H, $CH_2$ of adamantane). IR (KBr): $\tilde{\nu}$ = 3410 (m, N–H), 1288 (m, C=S), 846 (s, $PF_6^-$) $cm^{-1}$. Positive-ion ESI-MS: ion cluster at *m/z* 1002 $[M]^+$. $C_{54}H_{46}F_6IrN_6PS{\cdot}0.5\,H_2O$ (1157.26): calcd. C 56.05, H 4.09, N 7.26; found C 56.26, H 4.38, N 7.38.

**Instrumentation and Methods:** Equipment for characterization and photophysical and electrochemical studies has been described previously.[25c] Luminescence quantum yields were measured by the optically dilute method[31] using an aerated aqueous solution of $[Ru(bpy)_3]Cl_2$ ($\Phi$ = 0.028)[32] as the standard solution.

**Anion-Binding Studies:** Steady-state emission spectral titrations were used to determine the binding constants. A supporting electrolyte (0.1 M TBAP) was present in the titration solutions to maintain a constant ionic strength. The binding constant, $K_s$, of the anion $A^-$ to the receptor Ir for the following equilibrium

$$\mathrm{Ir} + \mathrm{A}^- \overset{K_s}{\rightleftharpoons} \mathrm{Ir\text{-}A}^-$$

was obtained by fitting the experimental data to Equation (1)[27]

$$\frac{I_o}{I_o - I_x} = \left(\frac{I_o}{I_o - I_\infty}\right)\left(\frac{1}{K_s[A^-]} + 1\right) \quad (1)$$

where $I_o$ is the emission intensity of the receptor only, $I_x$ is the emission intensity of the receptor in the presence of the anion at a concentration [$A^-$], and $I_\infty$ is the limiting emission intensity.

## Acknowledgments

[26] a) The possibility that the change is due to deprotonation[26b] of the thiourea protons is excluded by $^1$H NMR studies using acetone or DMSO as solvents. For example, in the presence of $OAc^-$ or $F^-$, ([Ir] = 0.01 M, [anion$^-$] = 0.05 M), the resonance signals of the thiourea protons of complex **1a** disappeared[26b] and those of 6-H of the phen-TU-R ligands were shifted to lower field, from about $\delta$ = 8.47 to 8.80 ppm. These changes are typical of hydrogen-bonding interactions between the thiourea protons and the anions, see: b) V. Amendola, D. Esteban-Gómez, L. Fabbrizzi, M. Licchelli, *Acc. Chem. # Quantum Chemical Analysis of the Enantiomerisation Mechanism of Complexes of the Type $[M^{II}(XU)_4]F^+$ (M = Pt, Pd, Ni; X = S, Se, Te; U = urea)

**Ralph Puchta,[a,b] Roland Meier,[a] Nico J. R. van Eikema Hommes,[b] and Rudi van Eldik*[a]**

**Keywords:** Enantiomers / Density functional calculations / Metal complexes

The enantiomerisation pathway for $\{[Pt(thiourea)_4]\}F^+$ [a model for the $C_4$-symmetric $[Pt(SU)_4]SiF_6$ (SU = thiourea) complex] and derivatives is explored by density functional theory (B3LYP/LANL2DZp) und the activation barrier for the one-step process from $C_4$ to $C_4'$ via a $C_4$ transition state is computed. The substitution of $Pt^{2+}$ by $Pd^{2+}$ and $Ni^{2+}$ and the exchange of selenourea and tellurourea increase the barrier. ($\{[Pt(thiourea)_4]\}F^+$: 4.2 kcal/mol, $\{[Pd(thiourea)_4]\}F^+$: 4.5 kcal/mol, $\{[Ni(thiourea)_4]\}F^+$: 7.6 kcal/mol, $\{[Pt(selenourea)_4]\}F^+$: 5.3 kcal/mol, $\{[Pt(tellurourea)_4]\}F^+$: 8.8 kcal/mol).

## Introduction

Besides the common use of platinum complexes as catalysts in industrial processes,[1–4] $Pt^{II}$ complexes deliver the most common anti-tumour drugs for certain types of cancer.[5] Intracellular thiols are known to play an important role in the metabolism of Pt anti-tumour drugs because of their participation in trapping the drug.[6] Also, thiols can influence renal toxicity and can be involved in other side-effects.[7] Thiourea (SU) is one of the best-known nucleophiles for $Pt^{II}$ complexes[8,9] and is commonly used in the investigation of ligand-substitution reactions in coordination chemistry. Hence, thiourea can very easily displace other ligands from the metal centre in $Pt^{II}$ complexes, including S-bonded ligands such as L-cysteine in $[Pt(terpy)(S\text{-}cys)]^+$.[10] The strong binding ability of S-donor nucleophiles can also be applied to reverse unwanted side-effects in chemotherapy.[11,12] It has been demonstrated that thiourea could restore the biological activity of Pt-loaded DNA.[13] Thiourea and other sulfur-containing compounds have been applied as emergency or protective agents in order to reduce the toxicity of platinum anti-tumour complexes.[14–16] The protective effect of these compounds is either to prevent or to reverse the formation of Pt–S adducts of proteins.

As shown in Figure 1, thiourea is able to coordinate in different ways to the $Pt^{II}$ centre depending on the packing forces and H-bonding networks in different solid $[Pt(SU)_4]^{2+}$ salts,[17,18] which is controlled by the selected counter anions. There is current interest in the design of selective receptors for anions,[19,20] held together by either electrostatic or hydrogen-bonding-based forces.[21,22] Even though thiourea seems to show an inherently flexible coordination of the $S{=}C(NH_2)_2$ branches to the platinum centre, the IOIO conformation has until recently been known as the only isomer of $[Pt(SU)_4]^{2+}$, based on the structure of $[Pt(SU)_4]Cl_2$.[17,18,23] In contrast, $[Pd(SU)_4]Cl_2$ and $[Pd(SU)_4]I_2$ show the IIOO conformer.[23,24] While investigating the effects of solvent[25] and dicarboxylates[26] on the structure of $[Pt(SU)_4]^{2+}$, Gale et al. isolated IIOO as a new conformer. By serendipity they were able to build a molecular capsule from two $[Pt(SU)_4]^{2+}$ moieties in the OOOO conformer complexing endohedrally to a $Cl^-$ ion. This molecular capsule is stabilised by a hydrogen-bonded corset of croconates. In a recent study, we were able to show that all

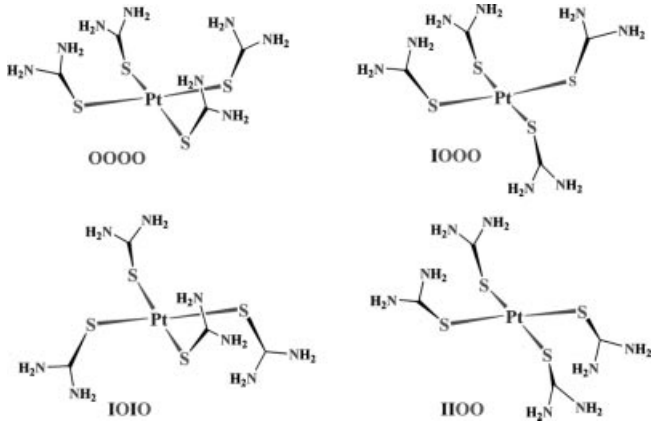

Figure 1. The four possible conformers of $[Pt(SU)_4]^{2+}$.

four possible conformers (see Figure 1) of the $[Pt(SU)_4]^{2+}$ unit can be realised in the solid state by nothing more than a systematic tuning of the molecular structure by the hydrogen-bonding ability of the counter anion.[27] The chiral $C_4$-symmetric (four SU moieties up) was realised in $[Pt(SU)_4]SiF_6$, where four $NH_2$ groups interact with the $SiF_6^{2-}$ ion (see Figure 2).

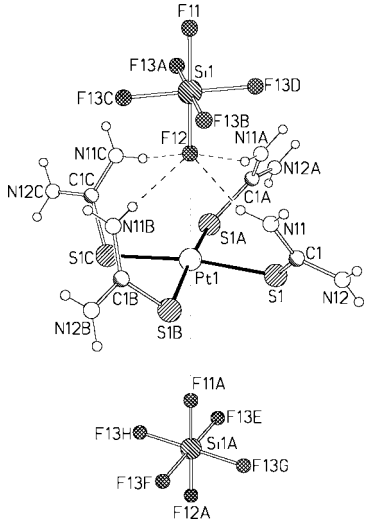

Figure 2. Conformation and H-bonding in $[Pt(SU)_4]SiF_6$ (OOOO).[27]

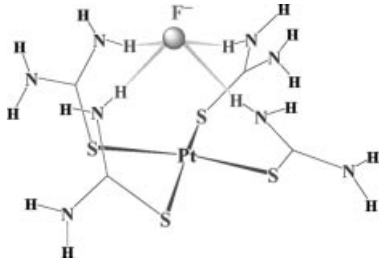
The H-bonds of the $NH_2$ protons formed with adjacent acceptors usually lead to the formation of clusters bearing interesting host–guest motifs.[28] The H-bonds formed by the $NH_2$ protons are especially important in terms of the motivation for the current study. We recently studied a larger number of $[Pt(SU)_4]X_2$ salts (X = $S_2O_6^{2-}$, $SiF_6^{2-}$, $ClO_4^-$, $CF_3SO_3^-$, $I^-$, $BPh_4^-$, etc.),[29] and found that the relatively strong N–H···X interactions in the case of X = one $F^-$ of the $SiF_6^{2-}$ anion in $[Pt(SU)_4]SiF_6 \cdot 0.25H_2O$ drives the $[Pt(SU)_4]^{2+}$ cation into the OOOO conformation (see Scheme 1). An analogous arrangement to that shown in Scheme 1 was recently also found by Gale et al. for the salt where X = $Cl^-$.[30,31]



Scheme 1. View of the N–H···$F^-$ interactions in the $\{[Pt(SU)_4]F\}^+$ unit of $[Pt(SU)_4]SiF_6 \cdot 0.25H_2O$.

In these $[Pt(SU)_4]X$ units, six-membered proton chelate rings of the type Pt–S–C–N–H···X are formed. As found so far,[30] these four rings give rise (in the solid state) to either λλλλ or δδδδ chiral patterns (cf. Scheme 2).

Scheme 2. Enantiomers of the $\{[Pt(SU)_4]F\}^+$ unit based on the difference in ring chirality.

The question that we want to answer in the present study concerns the mechanistic details of the interconversion between the enantiomers shown in Scheme 2. On the basis of the well-known flexibility of the Pt–S bond, one would expect a nondissociative enantiomerisation mechanism, but the nature of this pathway is so far completely unknown. In order to simplify our computational studies, the $SiF_6^{2-}$ counterion was replaced by a simple $F^-$ ion leading to the $C_4$ model units $\{[Pt(SU)_4]F\}^+$ (see Scheme 2). In order to learn more about the influence of the metal centre and the donor atoms coordinated to the metal ion, we extended our investigation of the enantiomerisation mechanism to $[Ni(SU)_4]F^+$ and $[Pd(SU)_4]F^+$, and also to the $Pt^{II}$ complexes of the heavier analogue, viz. selenourea (SeU) and tellurourea (TeU).

## Results and Discussion

Two alternative pathways seem to be possible for the enantiomerisation of the $\{[Pt(SU)_4]F\}^+$ entity shown in Scheme 2, viz. a dissociative or a nondissociative mechanism. Bond breakage would imply either cleavage of the Pt–S bond or rupture of the N–H···F H-bond. The nondissociative alternative is ruled out based on the strength of both the Pt–S bond and the N–H···F interactions.

The $\{[Pt(SU)_4]F\}^+$ unit can be considered to be a {3}-cryptand consisting of one metal bridgehead, one fluorine bridgehead and four *pseudo bidentate* SU ligands (one S-donor and one NH-hydrogen-bond donor, see Figure 3). Therefore, $\{[Pt(SU)_4]F\}^+$ can be regarded as a special cryptand, viz. a mixed {3}-metalla-halide-cryptand.

The nondissociative enantiomerisation can either proceed by a fully chiral pathway, in line with Mislow's paradoxon,[29,30] or via a nonchiral transition state of higher symmetry. In the present study, our DFT calculations clearly show that the twisted quadratic prismatic enantiomers with $C_4$ symmetry, containing four puckered semi-chelate rings of opposite chirality (λλλλ vs. δδδδ), are linked by a single-step, all-chiral enantiomerisation path (see Figure 4). In contrast to other enantiomerisation processes,[31] all ground and transition states have the same point group $C_4$.

The complexes in the present study contain ligands with puckered six-membered pseudo-chelate rings, where enantiomerisation involves flipping of these rings (cf. Figure 5).

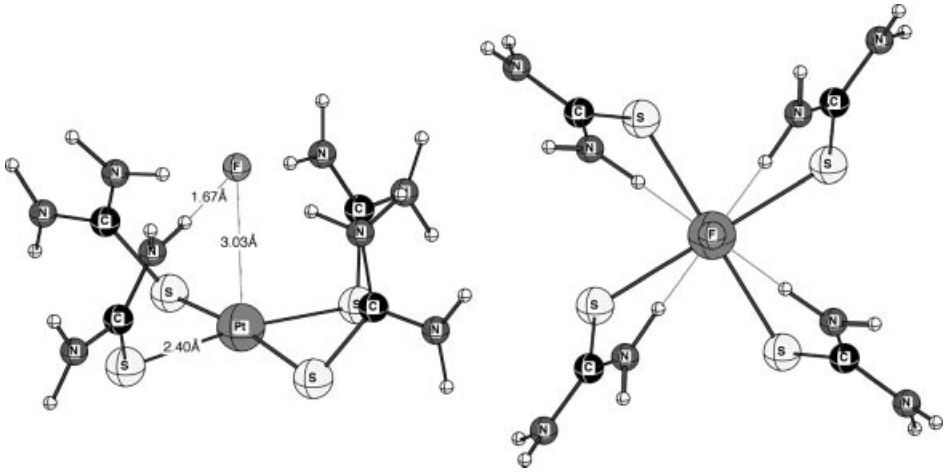

Figure 3. Calculated (RB3LYP/LANL2DZp) structure of $\{[Pt(SU)_4]F\}^+$.

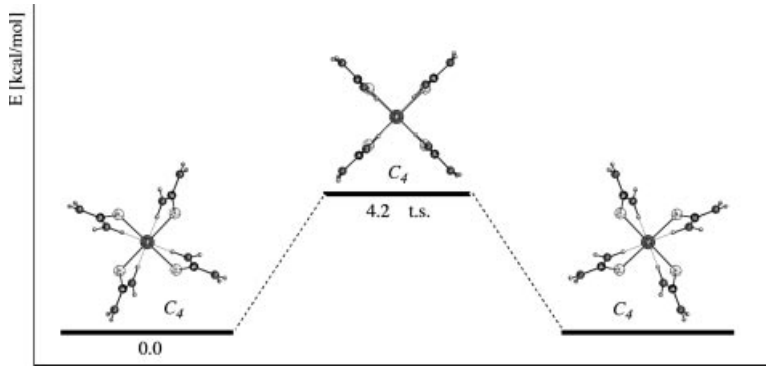

Figure 4. Calculated (RB3LYP/LANL2DZp) enantiomerisation pathway for $[Pt(SU)_4]F^+$.

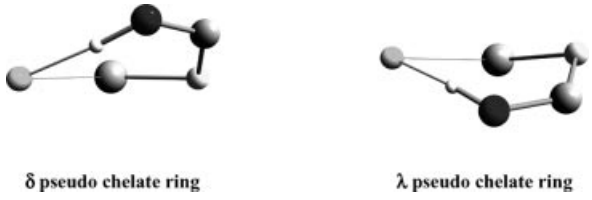

Figure 5. Comparison of the enantiomeric pseudo proton chelate rings belonging to the enantiomers shown in Scheme 2.

It is well known that the six-membered all-$sp^3$ carbon ring of cyclohexane can undergo ring inversion in a three-step process at room temperature. In contrast to $C_6H_{12}$, $\{[Pt(SU)_4]F\}^+$ and related complexes contain chelate rings with atoms linked by different types of bonding interactions and a type of hybridisation that differs from cyclohexane. These features seem to account for the unexpected single-step isomerisation pathway found in the present case. Despite extensive searches, no alternative isomerisation pathways could be found.

On the basis of planar six-membered rings in the transition state, one would expect an achiral $C_{4v}$ structure. This was computed to be a higher order saddle point (five imaginary frequencies), since the symmetry in the transition is diminished by the slightly pyramidal $NH_2$ groups of the XU ligands.

The activation barrier for enantiomerisation of the three $\{[M(SU)_4]F\}^+$ (M = $Ni^{2+}$, $Pd^{2+}$, $Pt^{2+}$) cations decreases from $Ni^{2+}$ to $Pd^{2+}$ and $Pt^{2+}$ to ca. 60% (see Table 1). Except for the obvious differences in the $M^{II}$–S bonds, the structural parameters of the three complexes, describing the ground and transition states, are essentially the same. On going from the ground state to the transition state, the $M^{II}$–S bonds are elongated somewhat, while the $M^{2+}\cdots F$ distances are slightly shortened and the twist angles [M–S···N–F] are reduced to a tenth of the value (see Table 2). The elongation of the $M^{II}$–S bond is most pronounced in the case of $Ni^{2+}$; we expect this to be the main reason for the higher activation barrier.

Table 1. Calculated (RB3LYP/LANL2DZp) energy barriers for the enantiomerisation of complexes of the type $[M(XU)_4]F^+$.[a]

| $[M(XU)_4]F^+$ | $[Ni(SU)_4]F^+$ | $[Pd(SU)_4]F^+$ | $[Pt(SU)_4]F^+$ | $[Pt(SeU)_4]F^+$ | $[Pt(TeU)_4]F^+$ |
|---|---|---|---|---|---|

Table 2. Calculated (RB3LYP/LANL2DZp) data for $[M(XU)_4]F^+$.[a]

| $[M(XU)_4]F^+$ | Ground state | | | | | Transition state | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | PG | M–donor [Å] | F–$H_{NH2}$ [Å] | F···M [Å] | [F–D···N–M] [°] | PG | M–donor [Å] | F–$H_{NH2}$ [Å] | F···M [Å] | [M–D···N–M] [°] |
| $[Ni(SU)_4]F^+$ | $C_4$ | 2.30 | 1.69 | 2.60 | 24.6 | $C_4$ | 2.33 | 1.67 | 2.55 | 2.3 |
| $[Pd(SU)_4]F^+$ | $C_4$ | 2.42 | 1.68 | 2.85 | 24.5 | $C_4$ | 2.43 | 1.67 | 2.79 | 2.3 |
| $[Pt(SU)_4]F^+$ | $C_4$ | 2.40 | 1.67 | 3.03 | 25.2 | $C_4$ | 2.41 | 1.66 | 3.01 | 2.5 |
| $[Pt(SeU)_4]F^+$ | $C_4$ | 2.51 | 1.67 | 3.05 | 26.3 | $C_4$ | 2.53 | 1.66 | 3.03 | 1.0 |
| $[Pt(TeU)_4]F^+$ | $C_4$ | 2.67 | 1.69 | 3.13 | 27.4 | $C_1$ | 2.70 | 1.68 | 3.07 | –5.3, 9.3, 7.4, –10.2 |

[a] SU = thiourea, SeU = selenourea, TeU = tellurourea.

companied by only a moderate increase in the barrier (4.2 and 5.3 kcal/mol, respectively), the barrier for TeU is almost twice as high (8.8 kcal/mol) compared to that for SU. This can obviously be attributed to the metalloid character of Te, as shown by the change in the Natural Population Analysis (NPA) charges for the platinum centre and the S, Se and Te atoms, respectively (see Table 3).[32]

Table 3. Calculated NPA charges (RB3LYP/LANL2DZp) for $Pt^{2+}$ and the coordinating donor atom of XU.[a]

| $[Pt(XU)_4]F^+$ | $[Pt(SU)_4]F^+$ | $[Pt(SeU)_4]F^+$ | $[Pt(TeU)_4]F^+$ |
|---|---|---|---|
| NPA charge of $Pt^{2+}$ | +0.2 | ±0.0 | –0.2 |
| NPA charge of donor (X) | –0.1 | ±0.0 | +0.2 |

[a] SU = thiourea, SeU = selenourea, TeU = tellurourea.

The $Pt^{2+}$–X bond lengths and the Pt···F distances increase in the expected range. The F···$H_{NH2}$ distances show no significant differences, neither in the ground state, nor in the transition state. The constant F···$H_{NH2}$ distances lead in the case of $\{[Pt(TeU)_4]F\}^+$ to a $C_1$ transition state, since the arms of the tellurourea cage have to be more twisted than in all other cases. Again, the $M^{2+}$–chalcogen bonds are slightly extended in the transition state, whereas the Pt···F distance is now somewhat reduced.

## Conclusions

We have shown that the enantiomerisation of $[M(TU)_4F]^+$ and related model complexes of this type do not require cleavage of the $M^{2+}$–chalcogen bonds nor the rupture of the N–H···X bond. Instead, a pathway with a chiral transition structure with four planar rings was found. The activation barrier is lowered by 60% along the series $[Ni(SU)_4]F^+$, $[Pd(SU)_4]F^+$ and $[Pt(SU)_4]F^+$. In the series $[Pt(SU)_4]F^+$, $[Pt(SeU)_4]F^+$ and $[Pt(TeU)_4]F^+$, the activation barrier increases slightly on going from the SU to the SeU derivatives, but doubles in the case of $[Pt(TeU)_4]F^+$.

## Quantum Chemical Methods

We performed hybrid density functional calculations using the B3LYP functional[33a–33c] and the LANL2DZ basis set with effective core potentials,[33d–33g] augmented with polarisation functions on non-hydrogen atoms.[33h] The performance of this level (denoted as B3LYP/LANL2DZp) has been documented by us and others.[34] Structures were characterised as minima, transition structures, or higher-order saddle points by computation of vibrational frequencies. Relative energies were corrected for zero point vibrational energy. The GAUSSIAN suite of programs was used.[35]

## Acknowledgments

The authors gratefully acknowledge financial support from the Deutsche Forschungsgemeinschaft within SFB 583 ("Redox-active Metal Complexes"). We thank Dr. W. Schiessl for stimulating discussions, Prof. Tim Clark for support and the Regionales Rechenzentrum Erlangen (RRZE) for a generous allotment of computer time.

# Chelating Phosphane–Boranes as Hemilabile Ligands – Synthesis of $[Mn(CO)_3(\eta^2\text{-}H_3B{\cdot}dppm)][BAr^F{}_4]$ and $[Mn(CO)_4(\eta^1\text{-}H_3B{\cdot}dppm)][BAr^F{}_4]$

**Nicolas Merle,[a] Christopher G. Frost,[a] Gabriele Kociok-Köhn,[a] Michael C. Willis,[a] and Andrew S. Weller*[a]**

**Keywords:** Boranes / Catalysis / Hemilabile ligands / Manganese / Phosphanes

Manganese complexes bearing the chelating phosphane–borane ligand $H_3B{\cdot}$dppm [dppm = bis(diphenylphosphanyl)-methane] have been prepared. Addition of $H_3B{\cdot}$dppm to $Mn(CO)_5Br$ using $Na[BAr^F{}_4]$ as a halide-abstracting reagent affords $[Mn(CO)_3(\eta^2\text{-}H_3B{\cdot}dppm)][BAr^F{}_4]$ (**1**). This reacts with CO to open the bidentate borane to afford $[Mn(CO)_4(\eta^1\text{-}H_3B{\cdot}dppm)][BAr^F{}_4]$ (**2**) in which the borane is now bound in a monodentate manner. The CO addition is reversible, and placing **2** under vacuum (hours) regenerates **1** quantitatively, demonstrating that the chelating phosphane–boranes can act as hemilabile ligands. The complexes **1** and **2** have been fully characterised by NMR spectroscopy and X-ray crystallography.

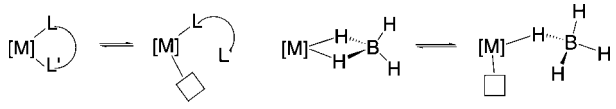
## Introduction

Reactions catalysed by Lewis acid transition metal fragments invariably rely on the generation of a vacant site on a cationic metal centre. Often this is generated by dissociation of a weakly bound ligand (e.g. solvent)[1] or anion.[2] An alternative mechanism – when a suitable ligand set is available – is one that involves a hemilabile ligand,[3–5] in which one donor atom in a chelate ligand has the ability to reversibly decoordinate in a catalytic cycle to reveal a coordinatively unsaturated metal centre. The design of hemilabile ligands is often based on ligands in which one end is a phosphane (which binds strongly) and the other a more weakly ligating group that can move away to generate a vacant site (Scheme 1). Examples of the weakly binding group include phosphane oxides,[6] sulfides,[7,8] and ether groups.[9] As pointed out nearly 30 years ago by Marks,[10] $[BH_4]^-$ can also potentially be a hemilabile ligand, by moving from $\eta^2$- to $\eta^1$-coordination modes (Scheme 1), thus generating the vacant site needed for substrate coordination. Examples of borohydride acting in this way are rare however, as on addition of ligand L loss of $H_3B{\cdot}$L often occurs with the concomitant generation of a metal hydride.[11,12] A recently reported observation of $\eta^2$- to $\eta^1$-borohydride hemilability comes from the addition of Lewis base (e.g. $PMe_2Ph$) to $Ru(PMe_2Ph)_2H(CO)(\eta^2\text{-}BH_4)$ to afford $Ru(PMe_2Ph)_3H(CO)(\eta^1\text{-}BH_4)$, although at temperatures above 300 K $H_3B{\cdot}PMe_2Ph$ is irreversibly lost to generate $Ru(PMe_2Ph)_3H_2(CO)$.[13]



Scheme 1.

One way of preventing borane loss would be to include the borohydride ligand in a chelate ring, allowing this potentially useful $\eta^2$- to $\eta^1$-transformation to occur without decomposition. Others[14,15] and we[16–18] have recently reported on the coordination chemistry of chelating phosphane–boranes $XH_2B{\cdot}$dppm (X = H, Cl, dppm = $PPh_2CH_2PPh_2$) in which one end of the ligand is valence-isoelectronic with borohydride while the other provides a firm phosphane anchor to the metal centre. These ligands show promise for hemilabile behaviour as the cationic complexes $[RuCp^*(\eta^2\text{-}XH_2B{\cdot}dppm)][Y]$ [X = H (**I**), Cl (**II**); Cp* = $\eta^5\text{-}C_5Me_5$; Y = $BAr^F{}_4$; $PF_6$] react with Lewis bases (CO, $PMe_3$) to open the borane from $\eta^2$ to $\eta^1$, thus forming $[RuCp^*(L)(\eta^1\text{-}XH_2B{\cdot}dppm)]^+$ (Scheme 2).[16,18] With these strong ligands the reaction is not reversible, and the ligand cannot be removed. The $\eta^2$-precursors **I** and **II** can thus be considered as being operationally unsaturated, effectively acting as a source of a reactive cationic 16-electron $\{RuCp^*(\eta^1\text{-}XH_2B{\cdot}dppm)\}^+$ fragment. The lack of borane loss on reaction with Lewis bases can be contrasted both with borohydride complexes, as discussed earlier, and also complexes of the monodentate phosphane–boranes developed by Shimoi, such as $MnCp^*(CO)_2(\eta^1\text{-}H_3B{\cdot}PMe_3)$, which react with weak Lewis bases to displace the borane.[19–21]

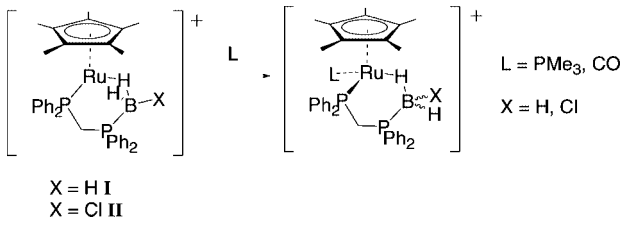
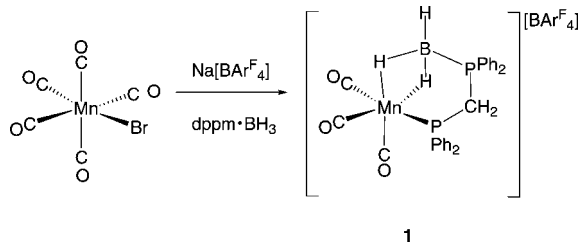


Scheme 2.



Scheme 3.

We report here the synthesis of some new cationic manganese complexes with the $H_3B$·dppm ligand. In these complexes the phosphane–borane opens and closes reversibly (i.e. shows true hemilabile behaviour) on the addition/removal of carbon monoxide.

## Results

Treatment of $Mn(CO)_5Br$ with $H_3B$·dppm using $Na[BAr^F_4]$ as a halide-abstracting reagent results in the isolation of analytically pure (46% yield) $[Mn(CO)_3(\eta^2\text{-}H_3B{\cdot}dppm)][BAr^F_4]$ (**1**) (Scheme 3). The equivalent reactions with $ClH_2B$·dppm or $BrH_2B$·dppm[18] only resulted in mixtures of intractable products. Complex **1** has been fully characterised by NMR spectroscopy and X-ray crystallography, which all show that the chelating phosphane–borane adopts a bidentate ($\eta^2$) bridging mode of the $BH_3$ group. Figure 1 shows the solid-state structure of **1**.

The $BH_3$ fragment binds to the manganese atom through two B–H–Mn 3-centre-2-electron interactions. The hydrogen atoms associated with the $BH_3$ group were located in the final difference map and freely refined. Within the limits of confidence associated with the location of hydrides by X-ray crystallography the two hydrogen atoms that bridge to the metal atom have B–H bonds that can be considered longer than that to the terminal hydride [B1–H1a 1.07(3) Å, B1–H1b 1.30(4) Å, B1–H1c 1.24(3) Å], consistent with the 3c–2e bond description. The Mn–B distance is short [2.146(4) Å] mirroring that observed in the ruthenium complexes **I** and **II**,[16,18] being slightly longer than that found in three-coordinate boryl complexes of Mn such as $(CO)_5MnB(O_2C_6H_4)$ [2.108(6) Å][22] and comparable with the σ-borane complex $Mn(\eta^5\text{-}C_5H_4Me)(CO)_2(HB\{O_2C_4Me_4\})$ [2.149(2) Å].[23] It is significantly shorter than in the four-coordinate boryl complex $Mn(CO)_4(PMe_2Ph)(BH_2{\cdot}PMe_3)$ [2.314(2) Å] for which an $[Mn(CO)_4(PMe_2Ph)]^-$-$[BH_2(PMe_3)]^+$ bonding description is suggested.[19] A similar short distance is observed in $[Cr(CO)_4(\eta^2\text{-}BH_4)][PPN]$

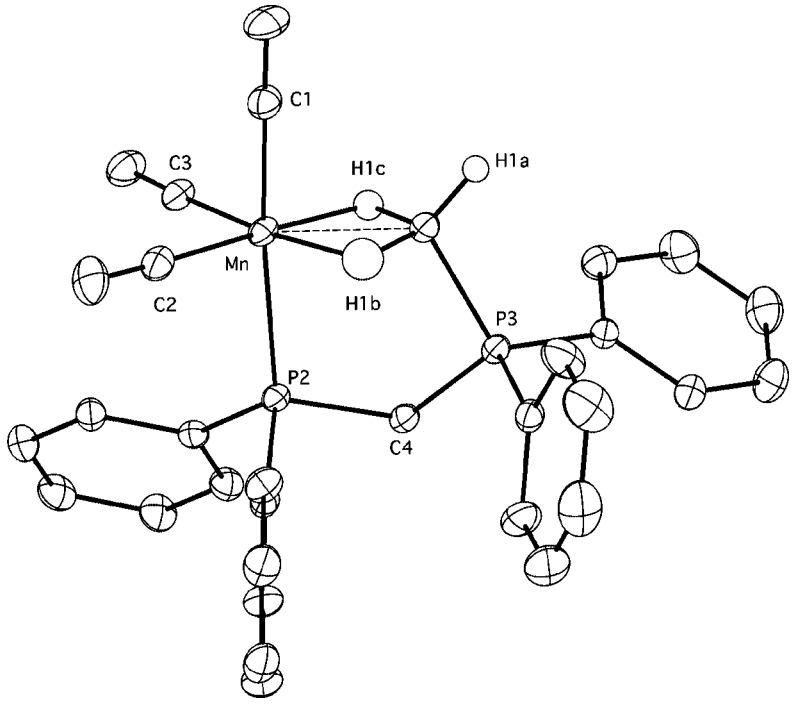


Figure 1. Solid-state structure of complex **1**. Thermal ellipsoids are shown at the 50% probability level; hydrogen atoms are omitted apart form those associated with the boron atom.

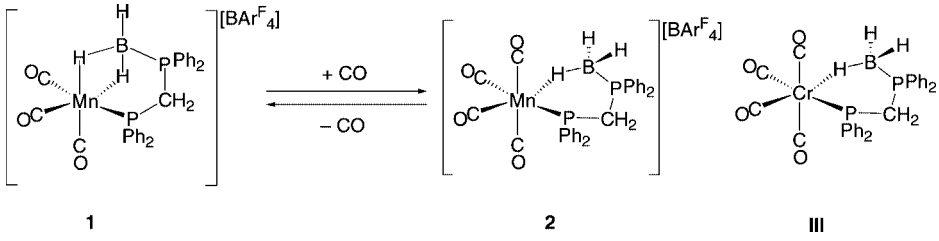
[2.29(1) Å] which is valence-isoelectronic with **1**.[24] As for **I** and **II**,[16,18] this interaction in **1** is best described as being like borohydride and not a dihydridoboryl complex, as the B–Mn–H and H–Mn–H angles are far more compressed than expected for a complex with two hydrides and a boryl ligand.[25] As expected for a relatively weakly bound $BH_3$ group, the M–C bond lengths associated with the carbonyl ligands *trans* to the bridging hydrides [Mn–C2 1.803(4) Å and Mn–C3 1.817(4) Å] are shorter than that *trans* to the phosphane group [Mn–C1 1.849(4) Å].

In solution, the $^{11}B$ NMR spectrum of **1** demonstrates the Mn···B interaction by a significant downfield shift of the signal of the $H_3B$·dppm ligand on coordination, from $\delta$ = –37.1 ppm in the free ligand to $\delta$ = 16.7 ppm ($\Delta\delta$ = +53.8 ppm) in **1**, consistent with $\eta^2$-coordination of the borane and a significant M···B interaction. In the $^1H\{^{11}B\}$ NMR spectrum two signals observed at $\delta$ = –9.08 (2 H) ppm and $\delta$ = 4.99 (1 H) ppm are assigned to the bridging and terminal BH groups, respectively, indicating that exchange between the terminal and bridging hydrides does not occur at room temperature. The methylene backbone in the dppm group is observed as an integral 2 H doublet of doublets, indicating time-averaged $C_s$ symmetry in solution. The $^{31}P\{^1H\}$ NMR spectrum displays two peaks, a sharp doublet at $\delta$ = 73.7 ppm and a broad signal as $\delta$ = 15.6 ppm, the latter assigned to the boron-bound phosphorus atom. Other spectroscopic data are also in full accord with the solid-state structure.

Addition of CO (1 atm) to **1** results in the rapid formation of the tetracarbonyl complex $[Mn(CO)_4(\eta^1\text{-}H_3B\cdot dppm)][BAr^F{}_4]$ (**2**) and the opening of the phosphane–borane ligand form $\eta^2$ to $\eta^1$ (Scheme 4). The NMR spectroscopic data for **2** are very similar to those for the isoelectronic complex $Cr(CO)_4(\eta^1\text{-}H_3B\cdot dppm)$ (**III**).[16] A diagnostic high-field chemical shift change for the $BH_3$ signal in the $^{11}B\{^1H\}$ NMR spectrum to $\delta$ = –37.5 ppm (similar to the free ligand[16,26]) indicates the $\eta^1$-binding mode and loss of a significant M···B interaction. In the $^1H$ NMR spectrum, the $BH_3$ group is observed as a quadrupolar, broadened integral 3 H signal at $\delta$ = –3.74 ppm, which sharpens on decoupling of $^{11}B$. The observation of one integral 3 H $BH_3$ signal at room temperature shows that the $BH_3$ group is rapidly spinning around the P–B bond at this temperature, exchanging terminal and bridging hydrides. Consistent with this fluxional process, the methylene group on the dppm ligand is observed as an integral 2 H doublet of doublets. In **III** this fluxional process also occurs but cannot be frozen out at low temperature. For **2**, cooling to 190 K ($CD_2Cl_2$) results in the observation of two broad signals in the ratio 2:1 at $\delta$ = 1.99 (fwhm = 160 Hz) ppm and $\delta$ = –15.52 (fwhm = 250 Hz) ppm in the $^1H\{^{11}B\}$ NMR spectrum, assigned to the terminal and bridging hydrides, respectively, showing that the exchange process has been halted. This difference between neutral **III** and cationic **2** can be attributed to the increased electrostatic attraction between the cationic manganese centre and the polarised $H^{\delta-}$–$B^{\delta+}$ group. At low temperature, the methylene protons for **2** are observed as a single integral 2 H broadened peak (fwhm = 50 Hz) centred at $\delta$ = 3.5 ppm in the $^1H\{^{11}B\}$ NMR spectrum, suggesting $C_s$ symmetry for the molecule at low temperature. In the solid-state structure (see below) the molecule adopts $C_1$ symmetry, resulting in the methylene protons and the B–H protons being all inequivalent, contrary to the observation of just two signals for the B–H protons and one for the methylene group. However, due to the broadness of these signals at 190 K and the inherent difficulty associated with reliably integrating such broad signals, it is not possible to say whether inequivalent environments are present for each group, or instead if a low-energy libration of the bridging hydride around the Mn–B vector is occurring to make both the dppm methylene and $BH_2$ protons each equivalent.

The solid-state structure of **2** shows an $\eta^1$-binding mode for the phosphane–borane ligand, which forms a δ-agostic Mn–H–B interaction (Figure 2). The structural metrics are similar to those already discussed for **III**,[16] as expected for this isoelectronic pair and are consistent with a relatively weak δ-agostic Mn–H–B interaction [Mn···H 1.71(3) Å, Mn···B 2.748(3) Å]. Notably the Mn···B bond is long – being similar to that calculated for $[Mn(CO)_4(PH_3)(\eta^1\text{-}H_3B\cdot PMe_3)]^+$ [2.780 Å][19] and slightly shorter than observed for neutral $Cr(CO)_5(\eta^1\text{-}H_3B\cdot PMe_3)$ [2.79(1) Å].[21] The Mn–H–B angle of 134(2)° means that the molecule does not have $C_s$ symmetry in the solid state, in contrast to the solution NMR spectroscopic data (vide supra). This angle is far more open than those observed in **1** [viz. 91(1), 93(1)°], consistent with move from didentate to monodentate coordination modes. The carbonyl ligand *trans* to the weakly bound $H_3B$ group has the shortest Mn–C distance, as expected. The Mn···H distance in **2** is significantly shorter than that found in γ-agostic complex $[Mn(CO)_3(PCy_3)_2][BAr^F{}_4]$ [2.01(9) Å],[27] in part a consequence of the polarised Bδ⁺···Hδ⁻ group interacting with the cationic metal centre.



Scheme 4.

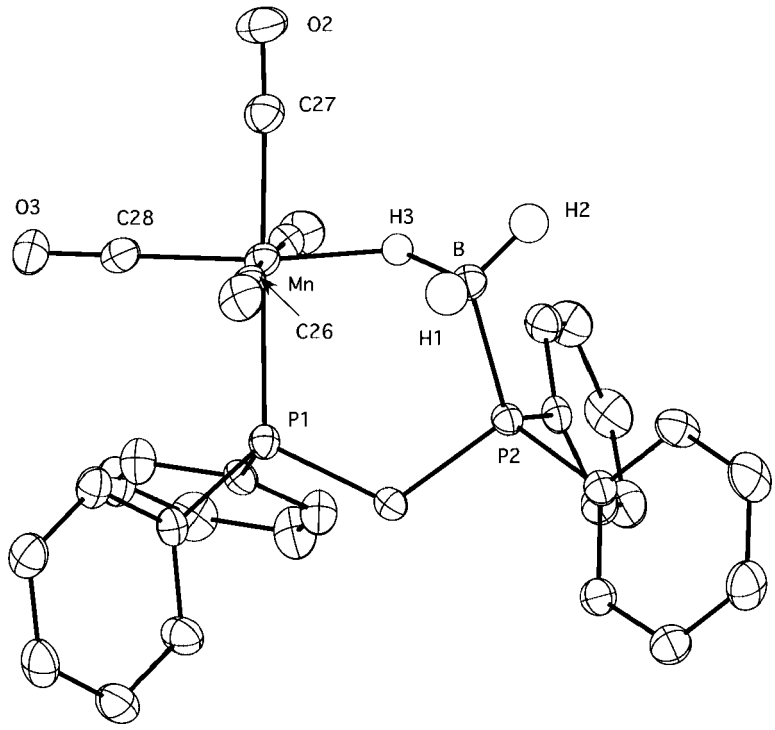

Figure 2. Solid-state structure of complex **2**. Thermal ellipsoids are shown at the 50% probability level; hydrogen atoms are omitted apart form those associated with the boron atom.

The addition of CO to **2** is reversible. Placing **2** under a dynamic vacuum (minutes) or under argon (days) regenerates **1** quantitatively in both the solid state and solution. For this reason, crystals of **2** are best obtained under CO and good microanalytical data could not be obtained. Addition of Lewis bases other than CO to **2** (MeCN, $PR_3$) resulted in decomposition. Addition of the weaker Lewis base $H_2$ did not displace the borane, and addition of $D_2$ did not result in H/D exchange. This is contrary to complexes **I** and **II** in which H/D exchange occurs, via a putative dihydride intermediate that results from the opening of the borane to $\eta^1$.[16,18] Presumably, the cationic $\{Mn(CO)_3\}^+$ fragment is reluctant to undergo oxidative addition of $H_2$ and thus no H/D exchange is observed in **1**.

Interestingly, the complex isoelectronic with **2**, $Mn(CO)_5(\eta^1\text{-}BH_4)$, has only been briefly reported as a possible intermediate in the formation of $Mn_3(CO)_{10}(BH_3)_3H$ from $Al[BH_4]$ and $Mn(CO)_5Br$,[28] while the borohydride complex equivalent to **1**, $Mn(CO)_4(\eta^2\text{-}BH_4)$, has not been reported apart from a calculated structure.[29] Related complexes with monodentate phosphanes such as $[Mn(CO)_4(PMe_2Ph)(\eta^1\text{-}H_3B{\cdot}PMe_3)][BAr^F{}_4]$[19] and $MnCp^*(CO)_2(\eta^2\text{-}H_3B{\cdot}PMe_3)$[20] are also unstable in solution. The stability of **2** is doubtlessly associated with the chelate ring, as we have commented on previously.[16]

## Conclusions

As with our earlier studies,[16,18] the results we report here show that the chelating phosphane–borane ligand $H_3B{\cdot}$dppm can open from $\eta^2$ to $\eta^1$ on addition of Lewis bases. For $[Mn(CO)_3(\eta^1\text{-}H_3B{\cdot}dppm)][BAr^F{}_4]$ this opening is reversible, and this observation of hemilabile behaviour suggests that, with suitable systems and substrates, they have the potential for application in catalysis.

## Experimental Section

**General:** All manipulations were carried out under argon, using standard Schlenk-line and glove-box techniques, unless otherwise stated. Glassware was pre-dried in an oven at 130 °C and flamed with a blowtorch under vacuum prior to use. Solvents were dried with activated alumina, copper or molecular sieves columns by using an MBraun solvent purification system and stored under slight vacuum in ampoules equipped with Young's taps. $CD_2Cl_2$ was distilled under vacuum from $CaH_2$. $Mn(CO)_5Br$,[30] $Na[BAr^F{}_4]$[31] and $H_3B{\cdot}$dppm[26] were prepared according to published routes. All other chemicals were used as received from Aldrich and Strem. Microanalyses were performed by Elemental Microanalysis Ltd, Devon, UK.

**NMR Spectroscopy:** $^1H$, $^1H\{^{11}B\}$, $^{11}B\{^1H\}$, $^{11}B$ and $^{31}P\{^1H\}$ NMR spectra were recorded with Bruker Avance 300 MHz or 400 MHz spectrometers. Resonances were referenced to residual hydrogen from the solvent for $^1H$ and $^1H\{^{11}B\}$ NMR spectra ($CD_2Cl_2$: $\delta$ = 5.30 ppm). $^{11}B$, $^{11}B\{^1H\}$ and $^{31}P\{^1H\}$ spectra were referenced against $BF_3{\cdot}OEt_2$ (external) and 85%% $H_3PO_4$ (external), respectively. Values are quoted in ppm. Coupling constants are quoted in Hz.

**X-ray Crystallography:** The crystal structure data for compounds **1** and **2** were collected with a Nonius KappaCCD diffractometer (Tables 1 and 2). Structure solution, followed by full-matrix least-squares refinement was performed using the SHELX suite of programs throughout.[32] Hydrogen atoms were included at calculated

positions throughout apart from those associated with the borane which were located in the final Fourier difference map and refined without constraints. For complex **2** two, partial occupancy, solvent molecules ($CH_2Cl_2$ and pentane) were included in the refinement. CCDC-284481 (**1**) and -284482 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**[(CO)$_3$Mn(η$^2$-BH$_3$·dppm)][BAr$^F_4$] (1):** $NaBAr^F_4$ (0.267 g, 0.301 mmol) was dissolved in 10 mL of diethyl ether and added to a mixture of $(CO)_5MnBr$ (0.083 g, 0.301 mmol) and dppm·$BH_3$ (0.120 g, 0.301 mmol) in 20 mL of $CH_2Cl_2$. The solution was stirred for 2 d with regular degassing of the solution to remove the released CO. The reaction mixture was filtered to remove the insoluble NaBr to give an orange solution. Solvent was removed in vacuo to leave an orange solid. Crystals suitable for an X-ray diffraction study were grown by dissolving the solid in a minimum of $CH_2Cl_2$ and layering with pentane to yield orange crystals (0.183 g, 46% yield). $^1H\{^{11}B\}$ NMR ($CD_2Cl_2$): *δ* = 7.79–7.24 (m, 32 H, Ph, $BAr_4^F$), 4.99 (s, 1 H, B*H*), 2.90 [dd, *J*(PH) = 10.5 Hz, *J*($P_{(BH3)}$H) = 12.5 Hz, 2 H, C*H*$_2$], –9.08 [br. d, *J*(PH) = 6 Hz, 2 H, B*H*$_2$] ppm. $^{31}P\{^1H\}$ ($CD_2Cl_2$): *δ* = 73.7 [d, *J*(PP) = 102.1 Hz, 1 P, *P*Ph$_2$], 15.6 (br., 1 P, *P*BH$_3$) ppm. $^{11}B\{^1H\}$ NMR ($CD_2Cl_2$): *δ* = 16.7 (br. s, 1 B, *B*H$_3$), –5.9 (s, 1 B, $BAr^F_4$). $C_{60}H_{37}B_2F_{24}MnP_2$ (1400): calcd. C 51.46, H 2.66; found C 51.60, H 2.74. IR (KBr): $\tilde{\nu}_{max}$ = 2519 (m, BH), 2070 (s, CO), 2010 (s, CO), 1975 (s, CO) cm$^{-1}$.

**[(CO)$_4$Mn(η$^1$-BH$_3$·dppm)][BAr$^F_4$] (2):** A $CH_2Cl_2$ solution of [(CO)$_3$Mn(η$^2$-BH$_3$·dppm)][$BAr^F_4$] (0.100 g, 0.074 mmol) was stirred under CO for 15 min to give a yellow solution. The compound loses a carbonyl group in vacuo to give **2**. Crystals suitable for an X-ray diffraction study were grown by layering the CO-saturated $CH_2Cl_2$ solution with CO-saturated pentane to yield yellow crystals. $^1H$ NMR ($CD_2Cl_2$): *δ* = 7.78–7.30 (m, 32 H, Ph, $BAr_4^F$), 3.54 [dd, *J*(PH) = 11.5 Hz, *J*($P_{(BH3)}$H) = 11.9 Hz, 2 H, C*H*$_2$], –3.74 [br., *J*(BH) 61.4 Hz, 3 H, B*H*$_3$]. Selected $^1H\{^{11}B\}$ NMR ($CD_2Cl_2$) data: *δ* = –3.74 [br. d, *J*(PH) = 8 Hz, 3 H, B*H*$_3$] ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): *δ* = 55.2 [d, 1 P, *J*(PP) = 54.7 Hz, *P*Ph$_2$], 16.0 (br., 1 P, *P*BH$_3$) ppm. $^{11}B\{^1H\}$ NMR ($CD_2Cl_2$): *δ* = –5.9 (s, 1 B, $BAr_4^F$), –37.5 (br. s, 1 B, *B*H$_3$) ppm. IR (KBr): $\tilde{\nu}_{max}$ = 2498 (m, BH), 2440 (m, BH) 2112 (s, CO), 2053 (s, CO), 2028 (s, CO), 2000 (s, CO) cm$^{-1}$. Selected low-temperature NMR spectroscopic data (190 K): $^1H\{^{11}B\}$ NMR ($CD_2Cl_2$): *δ* = 3.50 (br., 2 H, $CH_2$), 1.99 (v br., 2 H, B*H*), –15.52 (br., 1 H, B*H*) ppm.

# Bifunctional Materials Based on the Photochromic Cation $[RuNO(NH_3)_5]^{3+}$ with Paramagnetic Metal Complex Anions

**Lyudmila A. Kushch,*[a] Lyudmila S. Kurochkina,[a] Eduard B. Yagubskii,[a] Gennadii V. Shilov,[a] Sergei M. Aldoshin,[a] Vyacheslav A. Emel'yanov,[b] Yurii N. Shvachko,[c] Vladimir S. Mironov,[d] Dominik Schaniel,[e] Theo Woike,[e] Chiara Carbonera,[f] and Corine Mathonière[f]**

**Keywords:** Photochromism / Magnetic properties / Mononitrosyl ruthenium complexes / Paramagnetic metal complexes

The synthesis of a series of compounds containing the photochromic mononitrosyl cation, $[RuNO(NH_3)_5]^{3+}$ and metal complex paramagnetic anions $[M(CN)_6]^{3-}$ [M = Cr (**1**), Fe(**2**)], $[M(ox)_3]^{3-}$ [M = Cr(**3**), Fe(**4**)] and $[CrNO(CN)_5]^{3-}$ (**5**) is reported. The crystal structures of the salts **1** and **3** are discussed. In contrast to **1** and **3** which exhibit reversible photochromic properties, illumination of **2** and **4** results in an irreversible photochemical reaction and compound **5** is not photochromic at all. The magnetic properties of **1** and **3** have been investigated and complex **1** shows a weak reversible increase in the value of $\chi_M T$ under light irradiation at low temperature.

## Introduction

Over the last decade new types of molecular based magnets, namely functionalised magnets with combined magnetic and optical properties, have been studied extensively.[1–4] Current research in this field is focused not only on the improvement of magnetic properties but also on the search for unusual properties which have not been realised in magnets so far. In 1996, low-temperature photoinduced magnetisation was discovered in the prussian blue analogue $K_{0.2}Co_{1.4}[Fe(CN)_6]\cdot 6.9H_2O$.[1] The design of such bifunctionalised molecular materials with reversible modifications of their magnetic properties makes it possible to control magnetic properties by an external stimulus (light) and this opens up the possibility for technical applications in displays, information and energy storage devices and sensors.[5]

Up to now several strategies exist, using different types of light-sensitive building blocks, for producing the photomagnetic effect in molecular compounds combining magnetic and optical properties.[5] One of the approaches uses anionic photochromic mononitrosyl complexes of transition metals as light-sensitive units in the synthesis of bifunctionalised magnetic materials. This was successfully shown with $Ni[FeNO(CN)_5]$. The nitroprusside anion is diamagnetic but exhibits a photoinduced transition to two extremely long-lived metastable states, MSI and MSII, by irradiation with light in the blue-green spectroscopic range (350–580 nm) at temperatures below 180 K.[6,7] In $Ni[FeNO(CN)_5]$, randomly aligned neighbouring $Ni^{II}$ spins with $S = 1$ are ordered after excitation to MSI via two antiferromagnetically coupled spins formed by charge transfer from the Fe atom to the NO ligand. These spins induce magnetic coupling between the neighbouring Ni cations followed by the formation of a magnetic cluster with $S = 5$.[2a,2c]

Recently, it has been found that cationic mononitrosyl Ru complexes also exhibit photochromic properties. Like the anionic mononitrosyl complexes, the cationic Ru species exhibit two long-lived metastable states. MSI can be generated by light irradiation in the blue-green spectroscopic range (350–580 nm), while MSII can be obtained by subsequent illumination in the blue-green and infrared spectroscopic ranges (e.g. 1064 nm). In these Ru complexes, the metastable states have higher decay temperatures (up to +20 °C for MSI and up to –45 °C for MSII).[8–10]

It was of interest to use the photochromic mononitrosyl Ru cation as a light-sensitive building block for synthesising bimetallic compounds with paramagnetic anions.[11] Here we report the preparation, structures, photochromic and magnetic properties of bimetallic complexes containing the

photochromic cation $[RuNO(NH_3)_5]^{3+}$ and the paramagnetic metal complex anions $[M(CN)_6]^{3-}$, [M = Cr(**1**), Fe(**2**)], $[M(ox)_3]^{3-}$ [M = Cr(**3**), Fe(**4**)] and $[CrNO(CN)_5]^{3-}$(**5**). The influence of light on the magnetic properties of $[Ru(NH_3)_5NO][Cr(CN)_6]$ has been studied. A weak increase in the value of $\chi_M T$ under light irradiation at low temperature has been observed.

## Results and Discussion

### Synthesis and Structural Characterisation

The following series of salts, comprised of the mononitrosyl photochromic cation of $[RuNO(NH_3)_5]$ and paramagnetic anions, was synthesised by metathesis in water: $[RuNO(NH_3)_5][Cr(CN)_6]$ (**1**), $[RuNO(NH_3)_5][Fe(CN)_6]$ (**2**), $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$ (**3**), $[RuNO(NH_3)_5][Fe(ox)_3]\cdot xH_2O$ ($x \approx 3$) (**4**) and $[RuNO(NH_3)_5][CrNO(CN)_5]$ (**5**).

The crystal structures of **1**–**5** were investigated. Compound **2** is isostructural with **1** whereas **4** is not isostructural with **3**. The complete structural solutions of **2**, **4** and **5** are currently in progress. The main crystallographic data for **1** and **3** are presented in Table 1 and the crystal structure of **1** has been briefly published in ref.[11] The structure is formed from two independent structural units, i.e. $[RuNO(NH_3)_5]^{3+}$ and $[Cr(CN)_6]^{3-}$. The Ru and Cr atoms lie on a threefold axis and alternate along the *c* axis (Figure 1). There are numerous N···N contacts [2.93–3.23(2) Å] between the CN ligands of the anion and the $NH_3$ ligands of the cation. The occurrence of the N···N contacts is apparently due to the existence of C–N···H–N hydrogen bonds between complex components. The cations and anions located on the same threefold axis are coupled to each other by three hydrogen bonds. However, each cation and anion pair is linked by hydrogen bonds with three neighbouring cations and anions located on neighbouring threefold axes. It should be noted that the anion and cation from a pair are always linked with the cation and anion from different pairs, which results in the formation of a 3D network of hydrogen bonds in the crystal.

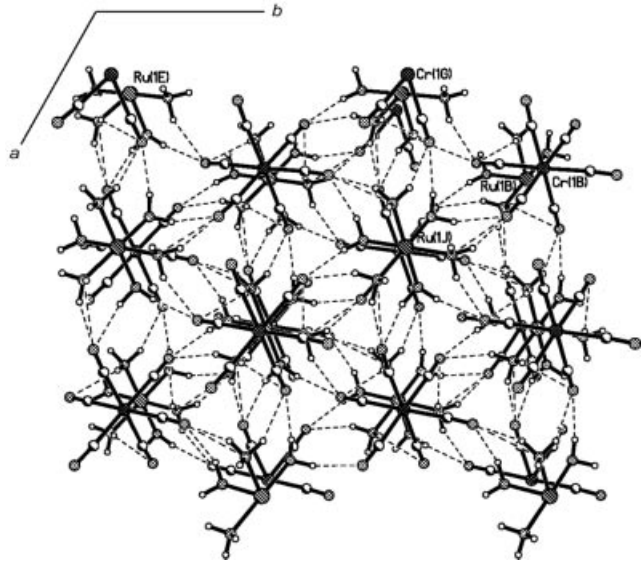

Figure 1. Projection of the crystal structure of **1** on the *ab* plane.

It should be especially emphasised that some anomalies can be observed in the structure of **1**: (a) the Ru–N–O linkage in the $[RuNO(NH_3)_5]^{3+}$ cations is bent (ca. 155°) and

(b) the Cr–C distances differ considerably (ca. 0.1 Å) in the $[Cr(CN)_6]^{3-}$ hexacyano anion. This deserves a special comment. In the ground state of mononitrosyl $Ru^{II}$ complexes such as $[RuNO(NH_3)_5]Cl_3 \cdot H_2O$,[13,24] $Na_2[RuNO(CN)_5]$,[14] $K_2[RuNOCl_5]$[21] and $K_2[RuNOBr_5]$[22] containing the positively charged $(NO)^+$ ligand, the M–N–O group is normally linear although a strongly bent M–N–O geometry (ca. 90°) may be observed in the photoexcited metastable MSII state in some of these complexes. Related six-coordinate iron(II), osmium(II) and some other mononitrosyl complexes such as $[Ni(NO)(\eta^5\text{-Cp})]$ show similar behaviour.[13] However, in complexes with a neutral NO ligand the M–N–O group is often strongly bent even in the ground state.[13,15,16] This is due to the role of the antibonding π*(NO) orbital of the NO ligand. According to the classification scheme of Feltham and Enemark,[17] the M–N–O bond angle in transition-metal nitrosyl complexes is defined by a total number of electrons, *n*, in the metal ion M and the π*(NO) orbital. For six-coordinate (pseudo-octahedral) mononitrosyl complexes, the M–N–O angle is 180 ± 10° for $n \leq 6$, 145 ± 10° for $n = 7$ and 125 ± 10° for $n = 8$. These data are consistent with quantum chemical calculations.[18,19]

The nonlinear ground-state geometry of the Ru–N–O group in $[RuNO(NH_3)_5]^{3+}$ is unusual since a study of the optical properties of **1** showed the NO group to be positively charged ($\tilde{\nu}_{NO}$ = 1947 and 1914 $cm^{-1}$). On closer inspection, however, this can naturally be rationalised in terms of attractive coulombic interactions between $NO^+$ and $CN^-$ groups (having opposite electrical charges) combined with the specific crystal structure of **1**, as illustrated in Figure 2. In the room-temperature crystal structure of **1**, the nitrosyl groups are statistically disordered in three equivalent positions. Therefore, the occupancy in the refined structure was assumed to be equal to ⅓ for the NO ligand and ⅔ for the corresponding $NH_3$ groups. However, regardless of the specific location of the $NO^+$ group in the "frozen rotation" configuration of the $[RuNO(NH_3)_5]^{3+}$ cations, the positively charged nitrosyl group (N1c and O1c atoms, Figure 2) is always in contact with five negatively charged cyano groups from three $[Cr(CN)_6]^{3-}$ anions, Figure 2. The environment of the O1c atom is symmetric enough: five contacts form a square bipyramid (contacts of the O1c atom with N4o, N3s, N4c, N4w, and N3g atoms, shown in solid grey lines). The resultant coulombic force is directed towards the N3g atom (black downward arrow). The environment of the nitrogen N1c atom of the nitrosyl group is less symmetric and consists of two short contacts [N1c–N3s 3.00(2) Å and N1c–N4o 3.09(2) Å] and two long contacts [N1c–N4w 3.58(2) Å and N1c–N4c 3.57(2) Å black lines]. The fifth contact (with the N3g atom) is absent. Since the positive electrical charge of the nitrosyl group is preferentially concentrated on the N1c atom (due to lower electronegativity), this atom is attracted to the two nitrogen atoms of two cyano groups with short contacts (N1c–N3s and N1c–N4o, two thin arrows, Figure 2). The resultant coulombic force should be directed approximately to the midpoint of the N3s–N4o line (this force is shown with a bold and long black arrow in Figure 2). As a consequence, two coulombic forces at O1c and N1c make a torsional moment which bends the Ru1c–N1c–O1c bond. Note that at such short distances (3.0–3.5 Å), attractive coulombic interactions are quite strong (ca. 2–4 eV, depending on effective charges on the actual atoms) resulting in such a pronounced distortion in the Ru–N–O bond angle (ca. 25°). Note that

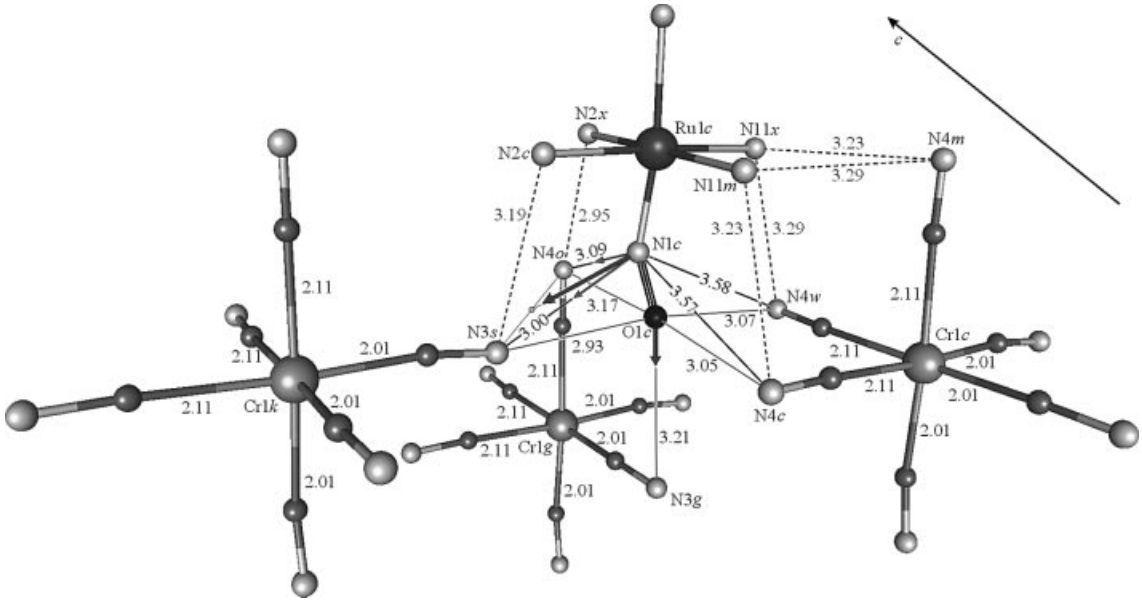

Figure 2. Immediate environment of the nitrosyl group (O1c and N1c atoms) in the 'frozen' orientation of the $[RuNO(NH_3)_5]^{3+}$ cation is drawn in perspective. The coulombic forces acting on the N1c and O1c atoms of the nitrosyl group are shown by arrows. Some of the H···N hydrogen bonds between H atoms of the $NH_3$ ligands of the $[RuNO(NH_3)_5]^{3+}$ cations and N atoms of the cyano groups of the $[Cr(CN)_6]^{3-}$ anions are shown with grey dashed lines as contacts between the N atoms of $NH_3$ ligand (N2c, N2x, N11m, and N11x, hydrogen atoms are not shown) with N atoms of the cyano groups (N4o, N3s, N4c, N4w, and N4m). Short (2.01 Å) and long (2.11 Å) Cr–C bonds of the $[Cr(CN)_6]^{3-}$ anions are indicated (the errors in length bonds do not exceed 0.02 Å).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the azimuthal orientation of the Ru1c–N1c–O1c plane is consistent with local geometry conditions for the coulombic forces shown in Figure 2. Therefore, despite rather limited accuracy in the refinement of the N–O position in the X-ray analysis of **1**, these arguments strongly support the existence of a bent Ru–N–O geometry. Furthermore a similar bent Ru–N–O ground-state structure (ca. 160°) was previously observed in the molecular compound $(BETS)_2[RuNOBr_5]$.[20] This anomaly was explained by the change in the effective charge on the nitrosyl ligand due to partial transfer of electron density from the organic BETS molecules. However, similar to the case of **1**, this can also be rationalised in terms of attractive coulombic attractions between the $NO^+$ group and the S centre of the BETS molecules and with $Br^-$ ligands of neighbouring $[RuNOBr_5]^{2-}$ anions. Interestingly, in the related complex $(BETS)_2[RuNOCl_5]$, the Ru–N–O group is almost linear (178°). This could be due to the differences in the specific geometry of $Ru–NO^+\cdots X^-$ contacts (distances, bond angles) in $(BETS)_2[RuNOX_5]$ (X = Cl, Br) which have different crystal structures. In the case of X = Br, the $NO^+–X^-$ attractive interactions seem to be stronger than in the case of X = Cl. Qualitatively, this is consistent with the fact that in the compound with X = Br the $NO^+$ group occupies only one crystallographic position, while in compound with X = Cl the $NO^+$ group is disordered between two positions. In contrast to $(BETS)_2[RuNOX_5]$ compounds, the Ru–N–O bond angles are almost linear in the precursor compounds $K_2[RuNOBr_5]$ and $K_2[RuNOCl_5]$, i.e. 174.4(1)° for X = Br and 176.7(5)° for X = Cl.[21,22] These observations indicate that in some molecular compounds with $[RuNOX_5]^{2-}$ building blocks, external interactions can strongly affect the Ru–N–O bond angle. This effect is sensitive to the specific crystal structure.

The second anomaly is associated with the distortion of the octahedral $Cr(CN)_6^{3-}$ anion. The Cr–CN bonds are essentially different, three of them are 2.01(1) Å and the other three are 2.11(1) Å (Figure 2). The C(2)–Cr(1)–C(2) angles are 87.3(2)° and the C(1)–Cr(1)–C(1) angles are 92.3(2)° (Figure 3). The origin of this structural anomaly in the $[Cr(CN)_6]^{3-}$ anions is less evident. In contrast to the case of the nitrosyl group, the immediate environment of the CN group can vary depending on the specific orientation of the $NO^+$ groups in the closest $[RuNO(NH_3)_5]^{3+}$ cations. These may rotate about the $C_3$ axis by 120° and many local configurations are therefore possible. An example of the local crystal structure around the $CN^-$ group is shown in Figure 3. The cyano group (N3 and C1 atoms in Figure 3) is involved in several $CN\cdots NH_3$ and $NO^+\cdots CN^-$ contacts with $[RuNO(NH_3)_5]^{3+}$ cations lying in the same Ru–Cr–Ru chain (running along the *c* axis, Figure 3) and in the neighbouring chains. Within each specific Ru–Cr–Ru chain, the cyano groups in contact with $NO^+$ groups (such as C2–N4 and C2b–N4b cyano groups in Figure 3) have considerably longer Cr–C bonds [2.11(1) Å] compared with those [2.01(1) Å] for cyano groups in contact only with $NH_3$ ligands (such as the C1–N3 and C1a–N3a cyano groups in Figure 3). This is unusual because in many molecular compounds containing $[Cr(CN)_6]^{3-}$, the octahedra are slightly distorted with the Cr–C distances fluctuating typically around 2.06 ± 0.03 Å.[23] Therefore, a pronounced difference in the Cr–C bond lengths indicates a strong perturbing effect of the $CN\cdots H(NH_3)$ hydrogen bonds and $NO^+\cdots CN^-$ coulombic attractions (they are comparable in magnitude). This implies that the actual "frozen" structure of the $[Cr(CN)_6]^{3-}$ anions can be considerably different from the statistically averaged crystallographic structure of $C_{3v}$ symmetry. In particular, some of the Cr–C bonds to the CN groups in contact with the $NO^+$ ligand of $[RuNO(NH_3)_5]^{3+}$ are even longer than 2.11 Å. Similarly, some of the Cr–C bonds of CN groups in contact with the $NH_3$ ligand may be shorter than 2.01 Å. This can cause a large zero-field splitting of the $^4A_{2g}$ ground spin state of the $[Cr(CN)_6]^{3-}$ anion (see below).

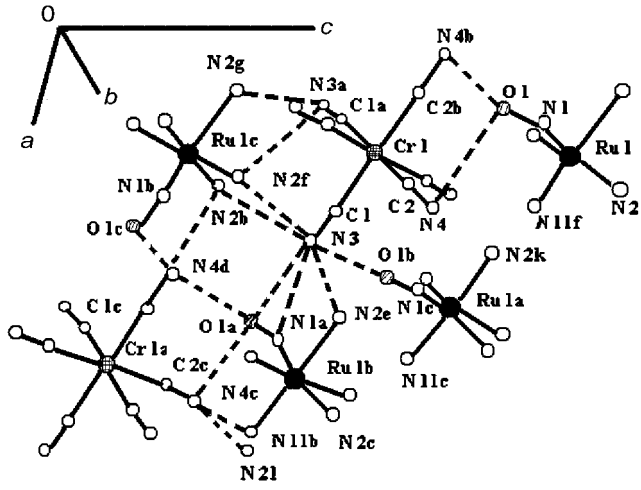

Figure 3. Fragment of the crystal structure of **1**. The threefold axes run through Ru(1), Cr(1), Ru(1c) and Cr(1a), Ru(1b), Ru(1a). The dotted lines show N···N and N···O contacts between CN ligands of the anions and $NH_3$ and NO ligands of the cations. The hydrogen atoms have been omitted for clarity.

An X-ray analysis of **3** showed that the crystal structure is formed from two types of $[RuNO(NH_3)_5]$ cations, $[Cr(ox)_3]$ anions and two types of water molecules. In two of the six $[Ru(1)NO(NH_3)_5]$ cations (Ru1) arranged in the unit cell, the NO group is disordered over six positions and in the other four $[Ru(2)NO(NH_3)]$ cations (Ru2) it is disordered over three positions (Figure 4, a). The Ru–N–O angle in Ru1 is 170(3)°, while in Ru2 it is equal to 178.5(2)°. Other valence angles and bond lengths in both types of cation are close to those found in **1** and $[RuNO(NH_3)_5]Cl_3\cdot H_2O$.[24] In two $[Cr(1)(C_2O_4)_3]$ (Cr1) anions all six Cr(1)–(O1) distances are 1.986(2) Å, while in four $[Cr(2)(C_2O_4)_3]$ (Cr2) groups the Cr–O distances are somewhat longer, namely, 2.017(2) and 2.013(2) Å. There are two different water molecules in the structure: one of them is in a general position (O7) and the other one is in a special position (O8). The water molecule (O8) is orientationally disordered. There are many shortened N···O and O···O contacts between cations, anions and water molecules. As in **1**, the occurrence of short N···O and O···O contacts is apparently due to the existence of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a net of N–H···O, N–O···O and O–H···O hydrogen bonds between the components of the complex (Figure 4, a and b). Ru1 cations are linked to Cr1 anions by five hydrogen bonds [intermolecular N(1)···O(1) contacts of 2.89(2) Å]. Instead of a sixth hydrogen bond, a shortened van der Waals O(11)···O(1) contact equal to 2.74(2) Å can be observed. A shorter contact O(11)···O(21) [2.47(2) Å] can be observed between the Ru1 and Ru2 cations (Figure 4, a). The Ru2 cations are linked by N(3)–H···O(2) hydrogen bonds with the Cr1 anion and intermolecular N(3)–H···O(2) contacts of 2.87(2) Å. The Cr1 and Cr2 anions are linked to each other by O(7) water molecules along the *c*

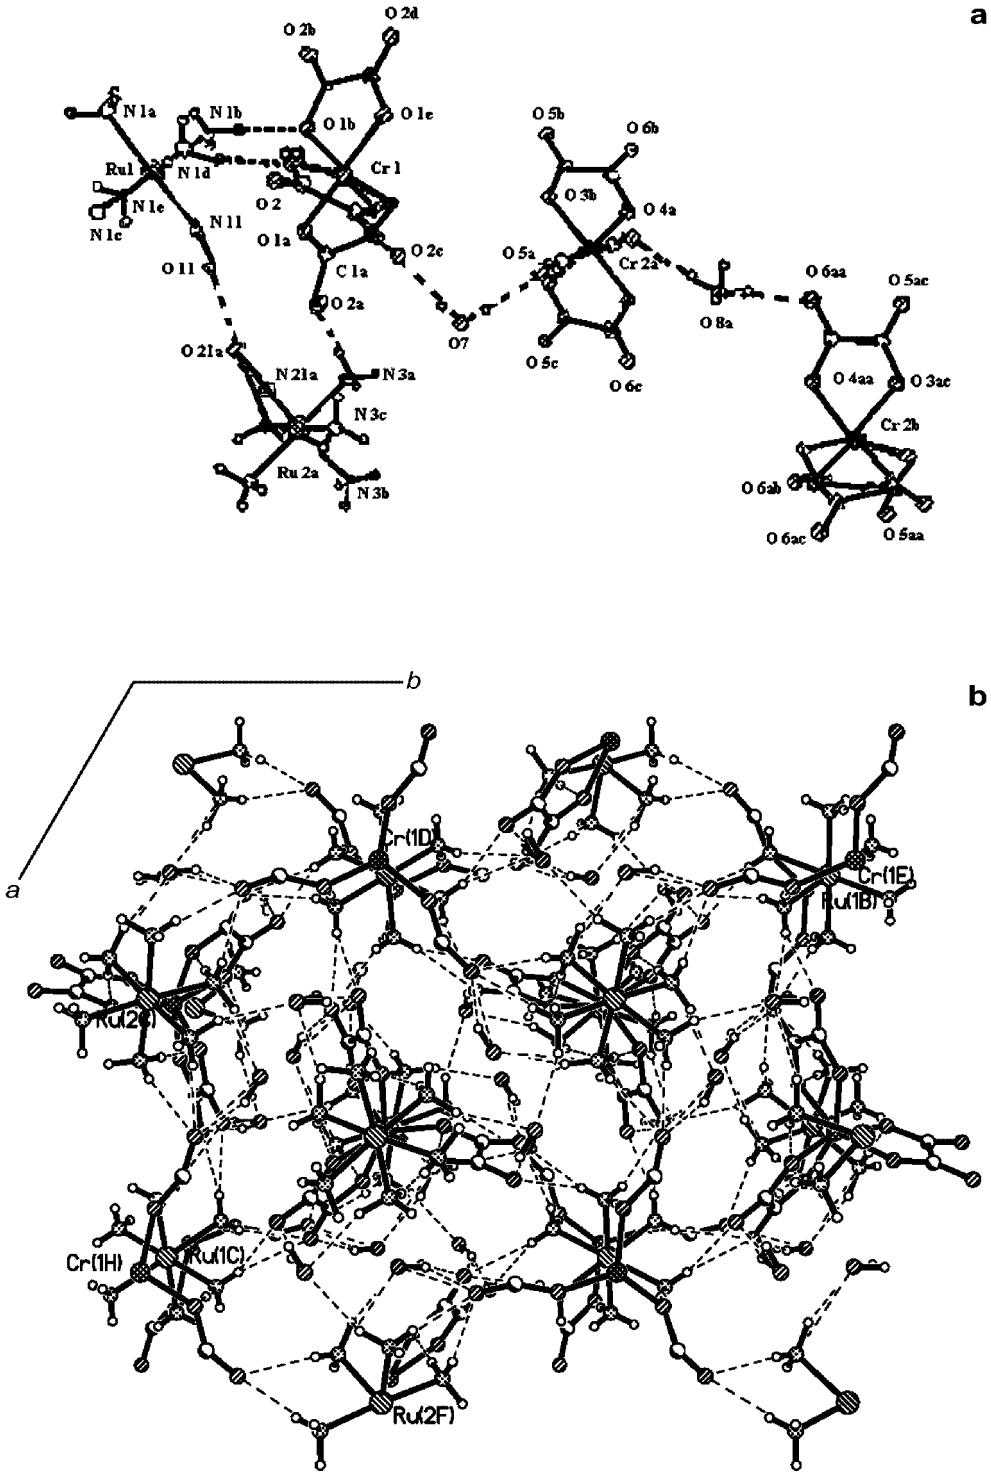

Figure 4. a) Fragment of the crystal structure of **3**. The dotted lines show O···N and O···O contacts between oxalate ligands of the anions and $NH_3$ and NO ligands of the cations and water molecules. The *c* axis runs parallel to the line connecting Ru(1) and Cr(1). b) Projection of crystal structure of **3** on the *ab* plane.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

axis [intermolecular O(2)···O(7) and O(7)···O(5) contacts of 2.86(2) Å and 2.95(2) Å, respectively]. The O(8) water molecule links Cr2 [O(8)···O(6)–2.88(2) Å] anions in the same direction (Figure 4, a). It should be noted that the carboxyl oxygen atoms of the Cr2 anions do not participate in the formation of the hydrogen bonds, which is distinct from Cr1. This is probably the reason for the distinction between the Cr–O bond lengths in the Cr1 and Cr2 anions.

### Differential Scanning Calorimetry

The photochromic properties of compounds **1**–**5** were investigated by differential scanning calorimetry (DSC). This technique has already been used to detect the existence of metastable states in complexes containing the nitroprusside anion[25,26] and some ruthenium mononitrosyl anionic[27,28] and cationic complexes.[29] With DSC we can determine the amount of energy, which heats the lattice during the thermal decay of metastable states. In contrast to mononitrosyl anionic complexes of transition metals, one exothermal peak was detected in **1** and **3** after their illumination with blue light (Figure 5).

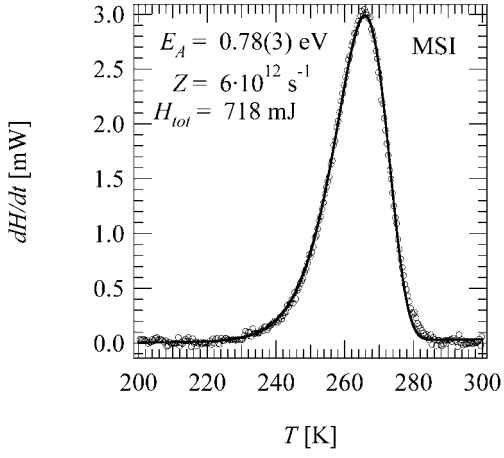

Figure 5. Thermal decay spectra ($q$ = 5 K min$^{-1}$) of $[RuNO(NH_3)_5][Cr(CN)_6]$ after irradiation at 120 K with $\lambda$ = 434 nm for MSI.

The appearance of the exothermal heatflow is associated with the transition of a photochromic cation from the metastable MSI state to the ground state (GS). The temperatures of the peak maxima observed in the spectra of these complexes are very close to that of $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ (ca. 260 K).[30] It should be noted that the intensity of the DSC signal in **3** was essentially lower than that in **1**. Since the area under the heatflow curve is proportional to the number density of cations in the metastable state, this is evidence of a low population in **3**. This is possibly due to a small penetration depth of light into the "oxalate" complex crystals, which are deep-brown in colour in contrast to the light-orange crystals of **1**.

It is known that the illumination of anionic photochromic complexes by NIR light (1064 nm) transforms MSI to MSII. Recently, it was shown that subsequent irradiation of $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ by light with wavelengths of 400–500 nm and 1000–1200 nm transfers MSI into MSII. The decay of MSII occurs at 220 K.[30] By irradiation of **1** in a manner completely analogous to $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ this second metastable state was also detected (Figure 6).

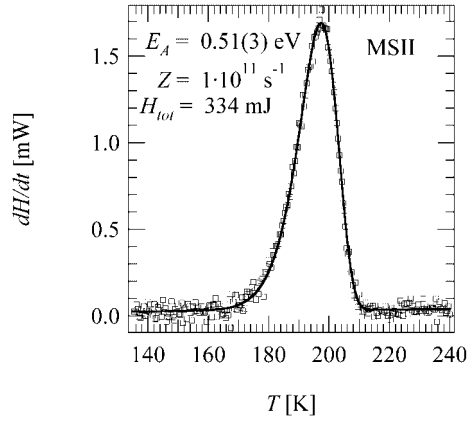

Figure 6. Thermal decay spectra ($q$ = 5 K min$^{-1}$) of $[RuNO(NH_3)_5][Cr(CN)_5]$ after irradiation at 120 K with $\lambda$ = 434 nm and $\lambda$ = 1064 nm for MSII.

It should be noted that the decay temperature of MSII in **1** ($T_d$ = 195 K) is 25 K lower than in the starting complex $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ ($T_d$ = 220 K). A possible explanation for this significant temperature reduction may be given by the structural peculiarities presented in Figure 2 and discussed above in terms of coulombic interactions. The generation of the metastable states implies that these attractive forces are overcome or at least neutralised. This may occur by means of the charge transfer from the ground state to the light-induced intermediate state π*(NO), in which the new charge distribution of the NO ligand reduces the attractive forces. During the lifetime of this intermediate state, the motion of the NO ligand is quasi-free and is finally stabilised in the new relaxed electron density distribution of the NO ligand. The same arguments apply to the generation of MSI. The key feature which allows the rotation of the NO ligand is the new charge configuration in the intermediate π*(NO) state in order to overcome the coulombic interactions. Otherwise no rotation could occur and the metastable states would not be occupied.

Since the decay of the metastable states is mono-exponential over time under isothermal conditions, the depopulation processes are first-order reactions and can be conveniently described by the Arrhenius law (see Exp. Sect.). In the present case, a fit of the experimental data allowed us to evaluate the activation energy ($E_a$) and the frequency factor ($Z$) for MSI and MSII in **1**. We obtained $E_a$ = 0.78(3) and 0.51(3) eV, and $Z = 6\times10^{12}$ and $5\times10^{11}$ s$^{-1}$ for MSI and MSII, respectively. The error in the frequency factor is one order of magnitude due to the small temperature range of the measurements. These high activation energies are within the range of those determined for $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ [$E_a$ = 0.73(3) eV, $E_a$ = 0.66(3) eV; $Z = 1\times10^{12}$ s$^{-1}$, $Z = 1\times10^{12}$ s$^{-1}$][31] and account for the stability of the induced metastable states at low temperature.

Complexes **2**, **4** and **5** have also been investigated by the DSC method. In contrast to **1** and **3**, which exhibit reversible photochromic properties, the illumination of **2** and 4, both of which are comprised of $[Fe(CN)_6]^{3-}$ and $[Fe(ox)_3]^{3-}$ anions, results in an irreversible photochemical reaction related to a partial reduction of $Fe^{3+}$ to $Fe^{2+}$. The IR spectrum of a photoproduct of **2** shows a new band near 2044 $cm^{-1}$ attributed to valence vibrations of the $CN^-$ group bound to $Fe^{2+}$.

The DSC signal was not observed in **5** with the $[CrNO(CN)_5]^{3-}$ anion. Possibly, the X-ray analysis of the crystal structure of **5** clarifies the reason for the absence of photochromic properties. Thus, the study of the photochromic properties of **1**–**5** shows that the nature of the paramagnetic metal complex anion strongly affects the photochromism of mononitrosyl Ru complexes.

### Magnetic Properties

Figure 7 shows the temperature dependence of the reciprocal paramagnetic susceptibility, $\chi_P^{-1}$, for $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$. The measurements were carried out at Field Cooling (FC) and $B = 10000$ G. A fit with the Curie–Weiss law, $\chi_P = C/(T - \Theta)$, with $C = 1.98$ emu K $mol^{-1}$ and $\Theta = 0.26$ K is in good agreement with experiment down to 1.8 K. The low-temperature part of the curve is depicted in the inset. Figure 8 shows the temperature evolution of $\chi_P^{-1}$ for $[RuNO(NH_3)_5][Cr(CN)_6]$ obtained under similar experimental conditions. The data are well described by the Curie–Weiss law with $C = 1.86$ emu K $mol^{-1}$ and $\Theta = 0.18$ K. Several experimental points at $T < 5$ K shown on the inset slightly deviate from the fitting curve. At 300 K $\chi_P$ values for **1** and **3** are equal to $6.07 \times 10^{-3}$ and $6.25 \times 10^{-3}$ emu $mol^{-1}$, respectively. A positive $\Theta$ value is usually indicative of ferromagnetic correlations, though for $S \geq 1$ such small values of $\Theta$ might also come from the zero-field splitting of the ground spin state, $D$. For a system of noninteracting spins with zero-field splitting, the average molar paramagnetic susceptibility $\chi_P$ shows an effective Weiss temperature $\Theta$ at $T > |D|/\kappa$ (due to interplay of perpendicular and parallel components). At $T < |D|/\kappa$, $\chi_P^{-1}$ deviates from the Curie–Weiss law. The Curie constants $C$ for both complexes are very close to 1.88 emu K $mol^{-1}$, which is characteristic of noninteracting $S = 3/2$ spins. Thus, the paramagnetism of both complexes can be attributed to the $Cr^{3+}$ spin system. No indications of the presence of a paramagnetic $Ru^{III}$ ($S = 1/2$) oxidation state were found. The temperature behaviour of $\mu_{eff}$ for both complexes [where $\mu_{eff} = (3\kappa\chi_P T/\mu_0 N_A)^{1/2} = 2.828(\chi_P T)^{1/2}$] is presented Figure 9. The magnetic moment $\mu_{eff}$ of both complexes is little affected in the temperature range from 300 K to 5 K. Below 5 K, $\mu_{eff}$ of $[RuNO(NH_3)_5][Cr(CN)_6]$ reveals a pronounced decrease from 3.83 to 2.91 $\mu_B$ (at 1.99 K) whereas $\mu_{eff}$ of $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$ remains nearly constant. In Figure 10 the magnetisation data in terms of magnetic moment $M$ in Bohr magnetons ($N_{A\mu B}$) are plotted against the reduced variable $B/T$ (in T/K). The diamagnetic response of the gel capsule has been subtracted. Samples of **1** and **3** were frozen in fields of 3 T and 5 T, respectively. Experimental points were obtained by decreasing the field to 0 at constant temperatures of 2.00 K and 1.83 K. Maximum values are 2.70 (5 T) and 2.20 (3 T), respectively. The field dependence for $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$ is consistent with the model of noninteracting spins. A solid line corresponds to the Brillouin function with $S = 3/2$ and $g = 2.080$. The enhanced $g$ value might be due to the ligand field splitting effect. The low-temperature behaviour of $[Cr(CN)_6]^{3-}$ anions in **1** is quite unusual and cannot be explained in terms of the Brillouin function. At higher fields ($B > 5000$ G) the effective spin value of the $Cr^{3+}$ ions in the ground state is considerably smaller than $S = 3/2$. On the other hand, at lower fields ($B < 5000$ G), the abrupt approach of $M$ to its maximum value is reminiscent of magnet behaviour. These peculiarities rapidly disappear at $T \geq 5$ K.

This anomalous magnetic behaviour of **1** below 5 K can be related to the zero-field splitting of the $^4A_{2g}$ ground spin state ($S = 3/2$) of $Cr^{3+}$ ions. In distorted $[Cr(CN)_6]^{3-}$ com-

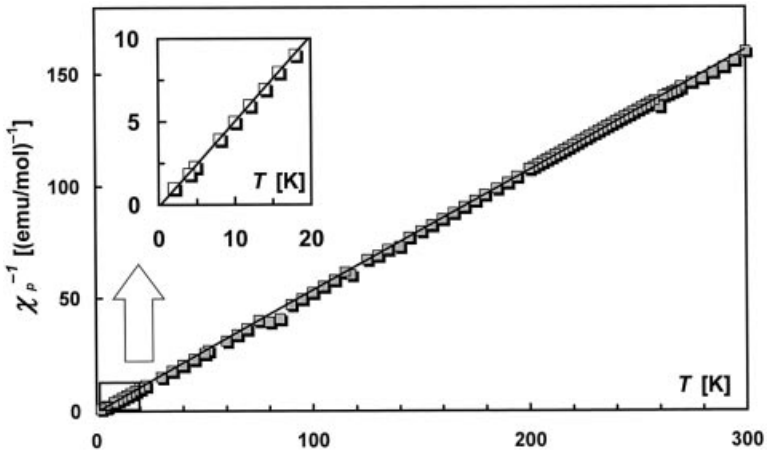

Figure 7. Temperature dependence of the reciprocal paramagnetic susceptibility, $\chi_p^{-1}$(T), at 10 kG for $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$. The inset shows the low temperature segment following the Curie–Weiss law with $C = 1.98$ emu K $mol^{-1}$ and $\Theta = 0.26$ K.

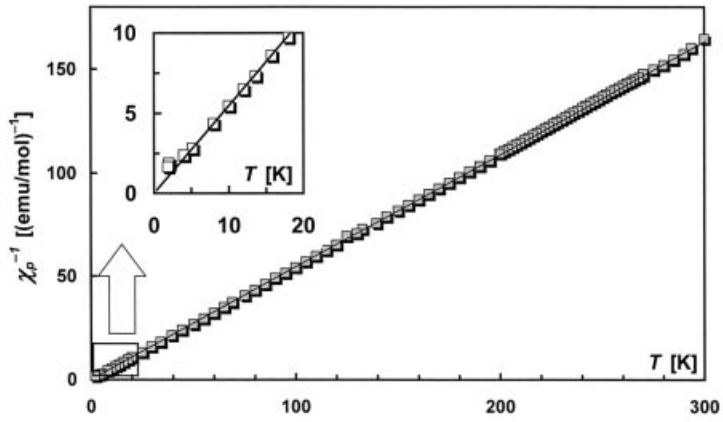

Figure 8. Temperature dependence of the reciprocal paramagnetic susceptibility, $\chi_p^{-1}(T)$, at 10 kG for $[RuNO(NH_3)_5][Cr(CN)_6]$. The inset shows the low temperature segment following the Curie–Weiss law with $C = 1.86$ emu K mol$^{-1}$ and $\Theta = 0.18$ K.

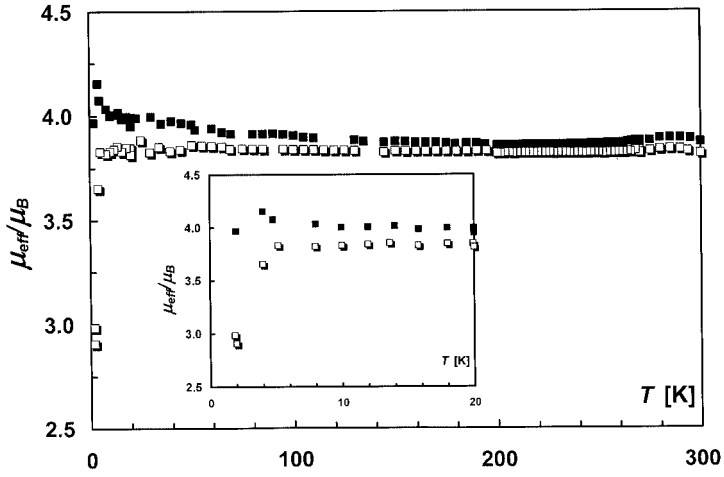

Figure 9. Temperature dependence of the effective magnetic moments of $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$ (filled squares) and $[RuNO(NH_3)_5][Cr(CN)_6]$ (open squares) microcrystals measured at cooling, $B = 10$ kG. The insert shows the low temperature segment.

plexes, the spin-orbit interaction combined with the low-symmetry crystal-field component splits the $^4A_{2g}$ ground spin state into two Kramers doublets separated by a gap of $2D$ zero-field splitting energy. As a result, at low temperatures ($kT < 2D$) the effective magnetic moment drops (from 3.83 to 2.91 $\mu_B$, Figure 9) due to preferential thermal population of the lower Kramers doublet. In this case, the low-temperature limit of the effective magnetic moment $\mu_{eff}$ of $[Cr(CN)_6]^{3-}$ can be calculated as $\mu_{eff}^2 = g_{av}^2\mu_B^2 S(S+1)$, where $S = 1/2$, $g_{av}^2 = (g_1^2 + g_2^2 + g_3^2)/3$ and $g_1$, $g_2$ and $g_3$ refer to the anisotropic $g$-tensor of the effective spin ($S = 1/2$) associated with the lower Kramers doublet of the split $^4A_{2g}$ ground state. Though the $g_1$, $g_2$, $g_3$ $g$-tensor components of the lower Kramers doublet can vary considerably for different distortions of $[Cr(CN)_6]^{3-}$ cyano complexes (typically, $g_1 = 1.97$, $g_2 = 3.78$, $g_3 = 4.08$ and $g_1 = 1.24$, $g_2 = 1.59$, $g_3 = 5.55$), the $g_{av}$ value is insensitive to the specific type of distortion ($g_{av} \approx 3.40$). Thus we obtained $\mu_{eff} = 2.95$ $\mu_B$ for the low-temperature magnetic moment of $[Cr(CN)_6]^{3-}$, which is remarkably close to the measured value of 2.91 $\mu_B$ (at 1.99 K, Figure 9). This is also consistent with the low-temperature field dependence of magnetisation in which the saturated magnetic moment of **1** is considerably smaller that that of **2**, Figure 10.

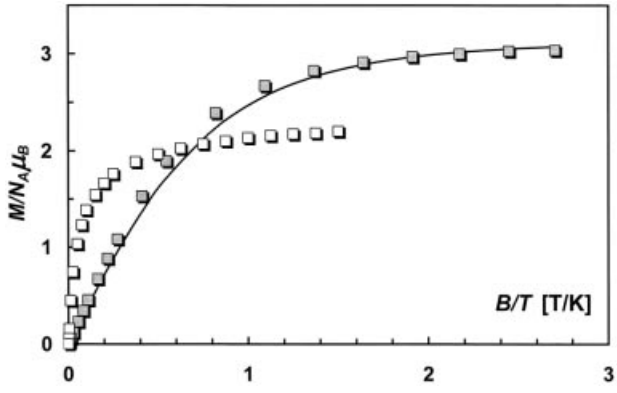

Figure 10. Field dependences of the magnetisation, $M/N_{A\mu B}$, of $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$ (filled squares) and $[RuNO(NH_3)_5][Cr(CN)_6]$ (open squares) microcrystals at 1.83 K and 2.00 K, respectively. Measurements were carried out by decreasing the field down to 0 after field cooling at 50 kG and 30 kG, respectively. The solid curve denotes fitting by the Brillouin function with $S = 3/2$ and $g = 2.0800$. The experimental points are depicted with a normalised OX scale of $B/T$, unit G K$^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The zero-field splitting of $[Cr(CN)_6]^{3-}$ in **1** is approximately of the order $2D/k \approx 5$ K ($2D \approx 3$ cm$^{-1}$), as can be estimated from the onset of the drop of the magnetic moment of **1** (ca. 5 K, Figure 9). In most of $Cr^{III}$ complexes (and $Cr^{3+}$ ions doped in host lattices), the zero-field splitting of the $^4A_{2g}$ state is within 1 cm$^{-1}$. However, in some cases $2D$ can be considerably larger. This is especially true for complexes with ligands producing strong crystal-field splittings, such as cyanide ligands in $[Cr(CN)_6]^{3-}$ (in which the crystal-field splitting energy is as large as 26600 cm$^{-1}$ [32]). It is important to note that the $2D$ splitting is sensitive to the strength of π-type metal–ligand interactions, which are especially strong for $CN^-$ ligands.[33] Qualitative estimates of the $2D$ value (in terms of angular-overlap model calculations taking into account spin-orbit interaction, see ref.[34] for detail) indicate that for some hypothetical distortions of $[Cr(CN)_6]^{3-}$ complexes corresponding to the "frozen" crystal structure of **1** (Figure 2), the zero field splitting can reach a value of 3 cm$^{-1}$ or even more.

On the other hand, an alternative explanation for the low-temperature magnetic behaviour of **1** in terms of through-space exchange interactions between paramagnetic $[Cr(CN)_6]^{3-}$ anions seems not to be reasonable since exchange interactions in **1** are expected to be very weak. This is evidenced from the fact that exchange interactions between $Cr^{3+}$ ions involved in bulk and well-isolated complexes are generally quite small.[35,36] Thus, exchange interactions between isolated $[Cr(CN)_6]^{3-}$ complexes in a closely related compound $[Co(NH_3)_5(H_2O)]$ $[Cr(CN)_6]$ were found to be as small as $J = -0.03$ cm$^{-1}$.[35] A similar strength to the exchange interactions between $[Cr(NH_3)_6]^{3+}$ complexes can be found in $[Cr(NH_3)_6](ClO_4)_2Br{\cdot}CsBr$.[36] More detailed information on the low-temperature magnetic properties of $[RuNO(NH_3)_5][Cr(CN)_6]$ could be obtained from direct EPR and magnetic measurements for single crystals. Unfortunately, in contrast to the case of $[Co(NH_3)_5(H_2O)][Cr(CN)_6]$,[35] the sizes of the crystals of **1** obtained in our experiments were still too small for such measurements. The absence of these anomalies in the oxalate complexes **2** is consistent with a smaller zero-field splitting in $Cr(ox)_3$, ($2D \approx 0.9$ cm$^{-1}$ ≈ 1.3 K.[37]).

Further information can be obtained from AC susceptibility measurements. The field dependences of the in-phase ($\chi'_M$) and out-of-phase ($\chi''_M$) AC susceptibility of $[RuNO(NH_3)_5][Cr(ox)_3]{\cdot}3H_2O$ and $[RuNO(NH_3)_5]$-$[Cr(CN)_6]$ are shown in Figure 11. We have not observed a maximum of $\chi'_M$ in the temperature dependences and this could be associated with the Curie constant. This indicates the absence of long-range order. However, the field dependences of $\chi''_M$ for $[RuNO(NH_3)_5][Cr(CN)_6]$ demonstrate a pronounced maximum of $3.46 \times 10^{-2}$ emu mol$^{-1}$ at 5200 G (note, that the $X$ scale in Figure 11 is nonlinear). Similarly, $\chi'_M$ demonstrates an abrupt decrease in the same field range, $1500 < B < 23000$ G. Such behaviour is not typical of usual paramagnetic insulators. $[RuNO(NH_3)_5][Cr(ox)_3]{\cdot}3H_2O$ exhibits similar behaviour but with a much smaller out-of-phase susceptibility of $5.08 \times 10^{-3}$ emu mol$^{-1}$ at 5200 G. Taking into account spin dynamics, the experimental data presented in Figure 9 and Figure 10 can be interpreted as indicative of short-range magnetic ordering in both hexacyanide and oxalate complexes. This could not be explained in terms of the single-ion zero-field splitting effects only. Such behaviour for **1** is most likely due to weak exchange interactions between $[Cr(CN)_6]^{3-}$anions (which are expected to be of order 0.03 cm$^{-1}$, as is the case in $[Co(NH_3)_5(H_2O)]$-$[Cr(CN)_6]$[35]) combined with a rather strong (> 1 cm$^{-1}$) zero-field splitting of the $^4A_{2g}$ ground state and a statistical disorder of strongly distorted $[Cr(CN)_6]^{3-}$ cyano complexes (caused by the $NO^+$–$CN^-$ coulombic interactions discussed above). In this case, magnetic interactions between strongly anisotropic ground Kramers doublets (effective spin $S = 1/2$) of $Cr^{3+}$ ions can differ considerably from the conventional

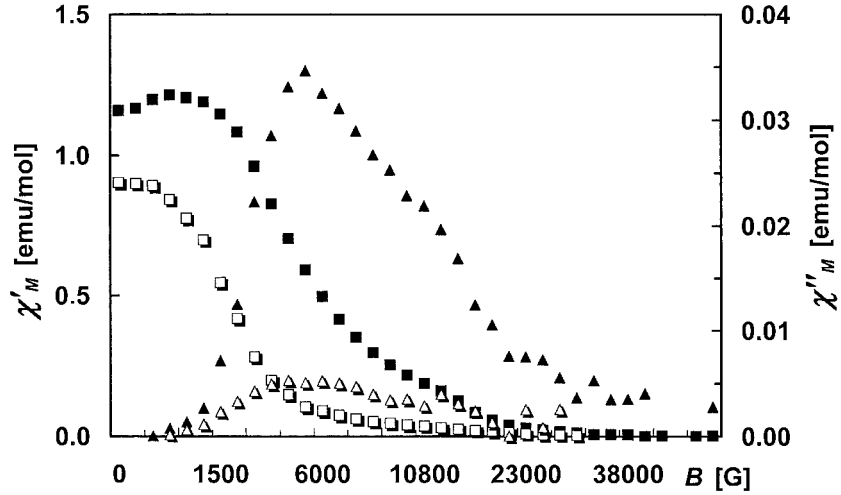

Figure 11. Field dependences of the AC magnetic susceptibilities of $[RuNO(NH_3)_5][Cr(ox)_3]{\cdot}3H_2O$ (open squares, open triangles) and $[RuNO(NH_3)_5][Cr(CN)_6]$ (filled squares, filled triangles) microcrystals measured at 1.81 K and 2.00 K, respectively. Solid squares denote the in-phase susceptibility, $\chi'_M$, (filled and open symbols respectively, left axis) and solid triangles denote the out-of-phase susceptibility, $\chi''_M$, (filled and open symbols respectively, right axis). The $x$ axis has a nonlinear scale.

isotropic (Heisenberg) spin-spin coupling model [which is typical of the spin-only ($S = {}^3/_2$) $^4A_{2g}$ state of $Cr^{3+}$ ions with a small zero-field splitting]. Interestingly, it has been found that the magnetic behaviour of a related compound $[Co(NH_3)_5(H_2O)][Cr(CN)_6]$ is compatible with the anisotropic Ising-type exchange interaction with $J = -0.18\ cm^{-1}$.[35] This value is consistent in magnitude with the paramagnetic Curie parameter $\Theta = 0.18$ K obtained for compound **1**. In principle, at low temperatures, this can lead to a spin-glass spin structure with strong local magnetic correlations caused by strongly anisotropic spin coupling. This might be responsible for the complicated low-temperature dynamic magnetic properties of **1** observed in our AC experiments. In contrast, AC magnetic characteristics of the oxalate compound are more compatible with the paramagnetic $S = {}^3/_2$ spin system with a small zero-field splitting. Further experiments on the AC susceptibility are in progress.

From the DSC experiments presented above one can conclude that the photochromic effect in $[RuNO(NH_3)_5][Cr(CN)_6]$ is stronger than that in $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$. This result correlates with low-temperature magnetic measurements, according to which $Cr^{3+}$ spins in hexacyanide complexes demonstrate a more pronounced dissipation to the lattice reservoir. This is generally consistent with a larger zero-field splitting of the $S = {}^3/_2$ ground spin state in $[Cr(CN)_6]^{3-}$ complexes, which provides a more efficient spin-lattice coupling.

### Photomagnetic Properties

We measured the magnetic properties of **1** at 10 K and 5000 Oe while irradiating with blue light. Figure 12 shows the result of this photomagnetic experiment. Before irradiation, the $\chi_M T$ value was 1.89 emu mol$^{-1}$ K. When the laser was switched on, thermal heating caused the sudden decrease of the magnetic signal, which then increased continuously until a plateau was reached after 8 h of light irradiation. When the laser was switched off, a sudden increase of the magnetic signal was observed due to the cessation of the thermal heating caused by the laser irradiation. The $\chi_M T$ value in the dark after the illumination was found to be 1.91 emu mol$^{-1}$ K. Hence the light induces an increase of only 1% in the magnetic signal of compound **1**. This small effect is real and fully reversible, as was demonstrated by anneling the material at 300 K and then cooling again to 5 K whereby the original $\chi_M T$ value of 1.89 emu mol$^{-1}$ K was measured again. The observation of such a weak photomagnetic effect is not really surprising, despite the fact that at 5 K the compound is in a photoexcited state. This may be interpreted as follows: the low-temperature metastable state is diamagnetic due to the $4d^6$ low-spin configuration of $RuNO(NH_3)_5$. In the irradiated compound, the NO ligand is rotated by about 180° from Ru–N–O (GS) to Ru–O–N (MSI). Hence, the coupling through hydrogen bonds to the paramagnetic $[Cr(CN)_6]$ anions changes with respect to the ground state as the attractive coulombic forces between the inverted NO (in MSI) and the $CN^-$ differ from those between $NO^+$ and $CN^-$ in GS. This indirect change of the electron density distribution in $[Cr(CN)_6]$ is the reason for the weak variation in the $\chi_M T$ value.

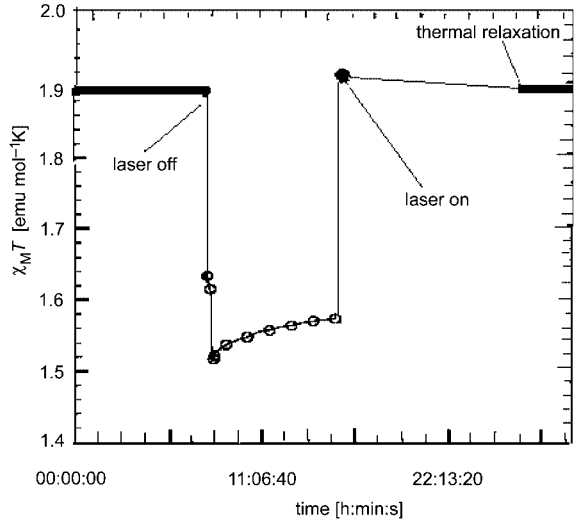

Figure 12. The time dependence of $\chi_M$T before, during and after irradiation at 406–415 nm ($P_{eff}$ = 10 mW cm$^{-2}$). The abrupt decreases are due to thermal effects when the laser is switched on.

## Conclusions

The use of the photochromic mononitrosyl $[RuNO(NH_3)_5]^{3+}$ cation complex as a light sensitive building block for the preparation of functionalised paramagnets led to five new compounds: $[RuNO(NH_3)_5][Cr(CN)_6]$(**1**), $[RuNO(NH_3)_5][Fe(CN)_6]$(**2**), $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$(**3**), $[RuNO(NH_3)_5][Fe(ox)_3]\cdot 3H_2O$(**4**) and $[RuNO(NH_3)_5][CrNO(CN)_5]$(**5**). The crystal structures of **1** and **3** are characterised by the presence of 3D networks of hydrogen bonds due to numerous N···N or N···O contacts between the CN (**1**) or ox (**3**) ligands of the anions and $NH_3$ ligands of the cations. The study of the photochromic properties of **1**–**5** showed that the anion's nature strongly affects the photochromism of the mononitrosyl Ru complex. In contrast to **1** and **3**, which exhibit reversible photochromic properties, the irradiation of **2** and **4** results in an irreversible photochemical reaction. Compound **5** composed of $[CrNO(CN)_5]^{3-}$ anions shows no photochromic behaviour. The study of the magnetic properties has shown that the paramagnetism of the complexes **1** and **3** is due to the $Cr^{3+}$ spin system. No indications of the presence of a paramagnetic $Ru^{III}$ oxidation state were found. The magnetic moment $\mu_{eff}$ of both complexes hardly changes in the temperature range from 300 K to 5 K. Below 5 K the $\mu_{eff}$ of $[RuNO(NH_3)_5][Cr(CN)_6]$ shows a pronounced decrease from 3.83 to 2.91 $\mu_B$ (at 1.99 K) whereas the $\mu_{eff}$ of $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$ remains nearly constant. The field dependence of magnetisation for $[RuNO(NH_3)_5][Cr(ox)_3]\cdot 3H_2O$ is consistent with the model of noninteracting spins while the low-temperature behaviour of the field dependence of **1** is unusual and can not be explained

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in terms of the Brillouin function. The anomalous magnetic behaviour of **1** below 5 K is due to both the zero-field splitting of the $S = {}^3/_2$ ground spin state of the $Cr^{3+}$ ions and a weak exchange interaction between $[Cr(CN)_6]^{3-}$ anions. A weak reversible increase in the $\chi_M T$ value of **1** under light irradiation at low temperature has been observed.

## Experimental Section

**Materials:** Chemicals: $H_2C_2O_4$, $FeCl_3$ (anhydrous), $K_3[M(CN)_6]$ (M = Cr, Fe), $K_3[Cr(ox)_3]$ and $(NH_4)_3[Fe(ox)_3]$ were used as purchased.

### Syntheses

**$[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$:** $[Ru(NH_3)_6]Cl_2$ (0.548 g, 2 mmol) synthesised as described in ref.[12] was dissolved in water (10 mL). 1 M HCl (10 mL) was added to the solution and then $NaNO_2$ (0.138 g, 2 mmol) was added in portions with continuous stirring. The resultant solution was heated in a water bath until intense gas evolution stopped. More $NaNO_2$ (0.069 g, 1 mmol) was then added to the cooled solution, which was then heated in a water bath until intense gas evolution stopped, concentrated to 10 mL, cooled and filtered from the $[RuNO(NH_3)_4Cl]Cl_2$ precipitate. The mother liquor was concentrated to ca. 2–3 mL, cooled and the $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ precipitate was separated. The product was dissolved in 0.1 M HCl (4–5 mL), filtered from the $[RuNO(NH_3)_4Cl]Cl_2$ impurity and re-precipitated by addition of 96% ethanol (15–20 mL) to the mother liquor. The yield of purified $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ was 516 mg (80%). $H_{17}N_6Cl_3O_2Ru$ (340.5): calcd. H 4.99, N 24.67, Cl 31.28; found H 4.98, N 24.09, Cl 31.21. IR: $\tilde{\nu}$ = 3432 ($NH_3$), 1928, 1913 (NO) $cm^{-1}$.

**$[RuNO(NH_3)_5][Cr(CN)_6]$ (1):** An aqueous solution (10 mL) of $K_3[Cr(CN)_6]$ (0.0487 g, 0.15 mmol) was added to an aqueous solution (5 mL) of $[RuNO(NH_3)_5]Cl_3H_2O$ (0.0511 g, 0.15 mmol). The yellow solution was allowed to stand for 2 d in the dark to form yellow-orange crystals. The crystals were collected by filter suction, washed with water and dried in vacuo over blue silica. The yield was 41.2 mg (65%). $C_6H_{15}N_{12}ORuCr$ (424): calcd. H 3.54, C 16.98, N 39.62; found H 3.50, C 17.03, N 39.98. IR: $\tilde{\nu}$ = 3432 ($NH_3$), 2199, 2127 (CN), 1947, 1914 (NO) $cm^{-1}$. Single crystals of quality suitable for X-ray diffraction analysis were selected from the synthetic sample.

**$[RuNO(NH_3)_5][Fe(CN)_6]$ (2):** The complex was prepared as a yellow powder in a similar way to the synthesis of **1** except that $K_3[Fe(CN)_6]$ was used instead of $K_3[Cr(CN)_6]$. The precipitate was formed immediately after mixing the solutions. The powder was collected by filter suction, washed with water and dried in vacuo over blue silica. The yield was 41.6 mg (65%). $C_6H_{15}N_{12}ORuFe$ (428.1): calcd. H 3.53, C 16.82, N 39.24; found H 3.80, C 17.03, N 39.17. IR: $\tilde{\nu}$ = 3449 ($NH_3$), 2112 (CN), 1944 (NO) $cm^{-1}$. Single crystals of quality suitable for X-ray diffraction were obtained by diffusion of the starting aqueous solutions into agar gel over 1.5 months.

**$[RuNO(NH_3)_5][Cr(ox)_3]{\cdot}3H_2O$ (3):** The compound was obtained as black hexagonal crystals in a synthesis similar to that of **1** except that $K_3[Cr(ox)_3]$ was used instead of $K_3[Cr(CN)_6]$. The yield was 86.8 mg (85%). $C_6H_{21}N_6O_{22}RuCr$ (682): calcd. H 3.58, C 12.29, N 14.33; found H 3.65, C 12.45, N 14.45. IR: $\tilde{\nu}$ = 3450 ($NH_3$), 1701 (C=O), 1918 and 1937 (NO) $cm^{-1}$. Single crystals of quality suitable for X-ray diffraction were selected from the synthetic sample.

**$[RuNO(NH_3)_5][Fe(ox)_3]{\cdot}xH_2O$($x \approx 3$) (4):** The complex was obtained as a yellow-orange powder in a synthesis similar to that used for **3** except that $(NH_4)_3[Fe(ox)_3]$ was used instead of $K_3[Cr(ox)_3]$. The precipitate was formed immediately after mixing the solutions. The yield was 80.1 mg (78%). $C_6H_{21}N_6O_{22}RuFe$ (686): calcd. H 3.56, C 12.20, N 14.24; found H 3.68, C 12.50, N 14.69. IR: $\tilde{\nu}$ = 3450 ($NH_3$), 1679 (C=O), 1914 (NO) $cm^{-1}$. Single crystals of quality suitable for X-ray diffraction analysis were prepared as follows: an aqueous solution (5 mL) of oxalic acid (0.27 g, 0.3 mmol) was added dropwise to a solution (5 mL) of $FeCl_3$ (anhydrous, 0.0163 g, 0.1 mmol) and an aqueous solution (5 mL) of $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ (0.0341 g, 0.1 mmol) was then added. The yellow-orange solution was allowed to stand for 3 weeks in the dark to allow the formation of yellow-orange hexagonal crystals.

**$[RuNO(NH_3)_5][CrNO(CN)_5]$ (5):** An aqueous solution (5 mL) of $[RuNO(NH_3)_5]Cl_3{\cdot}H_2O$ was mixed with a solution of $K_3[CrNO(CN)_5]$ (1:1 equal molar ratio) and a powder precipitated. The yield was 51.2 mg (80%). $C_5H_{15}N_{12}O_2RuCr$ (428): calcd. H 3.15, C 14.02, N 39.24; found H 3.25, C 14.65, N 38.94. IR: $\tilde{\nu}$ = 3449 and 3440 ($NH_3$), 2118 (CN), 1936 (NO) $cm^{-1}$. Single crystals of quality suitable for X-ray diffraction were obtained by diffusion of the starting aqueous solutions into agar gel over 1.5 months.

### Physical Measurements.

**Spectra:** Infrared spectra were recorded with a Perkin–Elmer spectrometer BX-2 in KBr pellets in the 4000-400 $cm^{-1}$ region.

**Crystallographic Data Collection and Structure Determination:** Single crystals of **1** and **3** were mounted on an automatic four-circle KUMA DIFFRACTION diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source [$\omega/2\theta$ scanning, 2($\theta$) max = 80°]. The crystal structures were solved by direct methods using the SHELX-97[38] program package.The positions of hydrogen atoms were found evenly from the difference Fourier syntheses. The structures were refined in an anisotropic approximation excluding hydrogen atoms. The positions of the latter were refined in an isotropic approximation. The positions of N and O (NO) were determined from the difference Fourier synthesis. Since the position of N is a weighted average value between those of N ($NH_3$) and N (NO), it was used as a basic value in the refinement. The structures were refined using the restrained bond lengths by considering the occupancies of the positions of $NH_3$ and NO: Ru1–N1 1.75(0.03) Å, Ru1–N11 2.13(0.01) Å, N1–O1 1.22(0.01) Å. Crystallographic data are summarized in Table 1.

CCDC-602209 and -602210 (for compounds **1** and **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Differential Scanning Calorimetry (DSC):** DSC measurements were performed using a modified differential scanning calorimeter (Mettler DSC 30, TA 3000) equipped with two quartz windows inside and outside the cryostat. The absolute calibration of enthalpy $H$ and temperature $T$ was controlled by measuring the phase-transition of In, Hg, pentane and $KH_2PO_4$. During illumination, the sample was kept at 120 K in a dry nitrogen atmosphere and subsequently heated at a constant heating rate $q = dT/dt = 5$ K/min. The exothermal heatflow is the time derivative of the enthalpy $H$. To obtain only the contribution of enthalpy of the metastable states, the enthalpy of the nonirradiated sample was subtracted from that of the irradiated one. The residual enthalpy was evaluated by fitting to the Arrhenius law modified for dynamic measurements.[10]

$$dH/dt = H_{tot}Z{\cdot}\exp[-\{(Z/q)\ {}_{T_0}\textstyle\int^{T}\exp(-E_A/k_BT) + (E_A/k_BT)\}]$$

($Z$ = frequency factor, $E_A$ = activation energy, $k_B$ = Boltzmann constant)

As a light source for generating MSI we used a metal-vapour lamp (HMI 575 Osram) filtered by dichroitic and interference filters to the spectroscopic range of 420–460 nm with the maximum at 434 nm. The intensity was 180 mW cm$^{-2}$. The irradiation time was 3 h which yielded an integrated flux of $Q$ = 1944 J cm$^{-2}$ on the sample. For the generation of MSII the samples were irradiated as described above and then irradiated with a Nd-YAG laser (1064 nm). The intensity was 138 mW cm$^{-2}$. The irradiation time was 0.5 h yielding an integrated flux of $Q$ = 250 J cm$^{-2}$.

**Magnetic and Photomagnetic Studies:** The temperature and magnetic field dependences of the molar paramagnetic susceptibility, $\chi_P$, magnetic moment in Bohr magnetons, $M/N_{A\mu B}$, effective magnetic moment, $\mu_{eff}/\mu_B$, and the in-phase ($\chi'_M$) and out-of-phase ($\chi''_M$) AC susceptibility of **1** and **3** were measured with a commercial SQUID magnetometer MPMS "Quantum Design". The temperature range was 1.8–300 K and the maximum magnetic field attained $B$ = 5.0 T. AC susceptibility measurements were carried out at 80 Hz with modulation field amplitude of 4 G. Randomly oriented microcrystals of a typical weight of ca. 10 mg were put into a gel capsule. Typical cooling rates were 2 K min$^{-1}$ for 300 K > $T$ >200 K, 4 K min$^{-1}$ for 200 K > $T$ > 15 K and 1 K min$^{-1}$ below 15 K. The background signal of a capsule was diamagnetic within the entire temperature range, not exceeding 16% (at 300 K) and 0.1% (at 1.98 K) of the sample signal. This was subtracted from the total signal. For field dependences, the signal from an empty capsule did not exceed 0.06%. The paramagnetic susceptibility was also corrected by taking into account the magnetic contributions of the ligands.

The photomagnetic experiments for **1** were performed with a $Kr^+$ laser coupled through an optical fibre directed into the SQUID cavity of the magnetometer working in the dc mode (MPMS-5S "Quantum Design"). Powdered samples of **1** were mounted on a sample holder as thin layers (weight 0.83 mg) to avoid surface effects during illumination. The mass was estimated based on the considering that at 5 K, the magnetisation after irradiation follows a Brillouin function for an $S$ = $^3/_2$ spin. With this method and calculating a molecular weight at 424.37 g, the estimated mass of the sample is 0.83 mg. The samples were irradiated continuously over 8 hours using the multiline 406–415 nm under a magnetic field of 5 kOe at 10 K. The effective power of the light on the sample was measured to ca. 10 mW cm$^{-2}$. Magnetic properties ($\chi_M T$) were recorded before and after irradiation, in each case the light being turned off to avoid thermal inhomogeneities.[10]

# Cobaloximes with Pyrazine and Their Dimetallic Complexes

**Debaprasad Mandal[a] and Bhagwan D. Gupta*[a]**

**Keywords:** Cobaloximes / Cyclic voltammetry / X-ray structure / Helical structures

Mono- and dinuclear cobaloximes with inorganic anions and pyrazine (Pz) as a base/bridging ligand were synthesized and characterized by $^1H$, $^{13}C$, UV/Vis and IR spectroscopy and X-ray structure analysis. Mononuclear complexes $XCo(dioxime)_2Pz$ were used as precursors for building homo- and heterodimetallic complexes. The X-ray crystal structures of $ClCo(dmgH)_2Pz$, $ClCo(dpgH)_2Pz$, $[Co(dpgH)_2(NO_2)_2]Na$, and $[Co(dmgH)_2(NO_2)_2]_2[Ag]_2{\cdot}H_2O$ are reported. $[Co(dmgH)_2(NO_2)_2]_2[Ag]_2{\cdot}H_2O$ shows two $Ag^I$ ions in different environments: one is in tetrahedral, whereas the other is in capped trigonal coordination and the metal-organic framework in this molecule shows helical structure. A cyclic voltammetry study in $[XCo(dioxime)_2]_2$-μ-Pz and $XCo(dioxime)_2Pz$ [dioxime = dmgH (dimethylglyoximato), dpgH (diphenylglyoximato)] is reported. The reduction, $Co^{III}$ to $Co^{II}$ and $Co^{II}$ to $Co^{I}$, is found to be more difficult in $[XCo(dpgH)_2]_2$-μ-Pz than in $XCo(dpgH)_2Pz$. The CV data have been interpreted in terms of cobalt anisotropy.

## Introduction

Organocobaloximes, initially proposed as models of the $B_{12}$ coenzyme, have now acquired an independent research field because of their rich coordination chemistry and potential application in organic synthesis.[1] The variation in the N–Co–C bond properties, including its strength, has been described not only in terms of the *trans* influence of the axial neutral base but also of the steric and electronic properties of the alkyl group.[2,3] The influence of the equatorial ligands on the axial ligands (*cis* influence) in dioximates, Costa's model, and iminates (cobalt complexes with tetradentate Schiff bases) has been previously reported.[2] Such studies are limited in cobaloximes.[4,5] In recent years the description of spectroscopic data and structure-property relationships and their correlation to Co–C bonds have been most emphasized.[6] We have shown that spectral correlations are much better understood in terms of field effect; the model takes into account the total effect of cobalt anisotropy of the $[Co(dioxime)_2]^+$ metallabicycle (electron-withdrawing power) and the ring current arising from the delocalization of electron density throughout the $[Co(dioxime)_2]^+$ metallabicycle.[5,7]

Ligand-bridged complexes are of interest in view of their role as reaction intermediates in inner-sphere electron-transfer processes[8] and pyrazine has been extensively used as a bridging ligand. Although a number of examples of the pyrazine-bridged mixed-valence homo- and heterodimetallic complexes of Ru, Fe, and Co are known,[9] there are few in cobaloxime chemistry.[10–12] A mixing of two cobalt centers with electron delocalization by pyrazine has been observed in the recently reported pyrazine-bridged organodicobaloximes, $[RCo(dioxime)_2]_2$-μ-Pz.[11,12]

Among the electrochemical studies on cobaloximes only few describe a correlation to related cobalt complexes to show the mutual *cis* and *trans* influence.[13] Recent work has shown that the reduction potential depends upon both the axial and equatorial ligands.[5,7,14] CV data have been rationalized in terms of cobalt anisotropy and this in turn is affected by the axial ligands; the effect is more distinct when the axial ligand is an inorganic group/atom.[5,7] A single peak with a very high reduction potential is observed in $[RCo(dioxime)_2]_2$-μ-Pz, which points to electron delocalization and also shows that the dicobaloximes are more difficult to reduce than the corresponding monocobaloximes.[12]

In general, the inorganic cobaloximes $XCo(dioxime)_2B$ (B = neutral base) give a better CV curve than organocobaloximes.[5,7] Also, the changes in NMR chemical shifts in the inorganic complexes are much more marked than in organocobaloximes and these are more effectively rationalized with the field effect.[4c,5,7,15]

It is therefore interesting and useful to study the pyrazine-bridged dinuclear inorganic cobaloximes, $[XCo(dioxime)_2]_2$-μ-Pz. The spectral and CV data in these dinuclear complexes should complement the reported data in $[RCo(dioxime)_2]_2$-μ-Pz. It would also be useful to compare the data with the corresponding mononuclear cobaloximes, $XCo(dioxime)_2Pz$.

The aim of the present study is (a) to synthesize $[XCo(dioxime)_2]_2$-μ-Pz, $XCo(dioxime)_2Pz$, and $XCo(dioxime)_2$-

## Results and Discussion

### Synthesis

The synthesis of complexes **1** and **4** was easy; an addition of pyrazine to the corresponding aqua complex ClCo(dioxime)$_2$H$_2$O in a 1:2 molar ratio afforded the corresponding dicobaloxime.

Two possibilities were considered for the preparation of complexes **2**, **3** and **5**, **6**:

(a) We have recently synthesized XCo(dioxime)$_2$Py (X = $NO_2$, $N_3$) complexes by the nucleophilic substitution of the chlorido ligand in ClCo(dioxime)$_2$Py.[5,7,15,16] An obvious choice was to follow the same route. However, the reaction of $NaN_3$ or $NaNO_2$ with [ClCo(dpgH)$_2$]$_2$-μ-Pz (**4**) did not give the desired compound, but instead a $Co^{III}$ complex was isolated that was sparingly soluble in chloroform and dichloromethane but soluble in methanol/water and acetone/water. The $^1$H NMR in [D$_6$]DMSO showed the absence of a pyrazine peak. It indicated the presence of a salt (discussed later).

(b) The same procedure as used in the preparation of **1** and **4** was followed. The dicobaloximes were formed in good yield. However, this procedure required the preparation of the corresponding aqua complexes, XCo(dioxime)$_2$-H$_2$O (**8**, **9**, **11**, **12**).[17] These were prepared from the corresponding aqua(chlorido)cobaloximes (**7** or **10**) by the nucleophilic substitution of the chlorido ligand. Any change in concentration or use of excess NaX led to the formation of a salt along with the desired product. The salt was identical to the product obtained earlier in the reaction of [ClCo(dpgH)$_2$]$_2$-μ-Pz (**4**) with $NaNO_2$ and was identified as [Co(dpgH)$_2$(NO$_2$)$_2$]$^-$ by X-ray crystallography (**19**). López et al. have reported a similar type of salt formation in the reaction of ClCo(dioxime)$_2$B with excess KCN.[18]

XCo(dioxime)$_2$Pz (**13**–**18**) were prepared by the reaction of the corresponding aqua complexes **7**–**12** with pyrazine in a 1:1 ratio by slow evaporation of the solvent. These were the only products formed in dilute solution, but in a concentrated solution the precipitation of the dinuclear product (**1** or **4**) occurred and no mononuclear product was formed. Also a rapid evaporation of the solvent resulted in the formation of a dinuclear complex.

### Spectroscopy: Characterization of the Complexes

The $^1$H NMR spectra of **1**–**6** and **13**–**18** are easily assigned based on the chemical shifts. The signals are assigned according to their relative intensities and are consistent with the related dioxime compounds previously described.[11] Complexes **1**–**3** are sparingly soluble in most organic solvents and it took more than 1000 scans to obtain a reasonable $^1$H NMR spectrum in $CDCl_3$. The $^1$H values are given in Table 1.

All four protons in the unligated pyrazine are equivalent and appear as a singlet at $\delta$ = 8.59 ppm. The ligated pyrazine in **4**–**6** appears as a singlet which is shifted downfield as compared to that of free pyrazine. On the other hand, pyrazine appears as two doublets in **13**–**18**; the one that is more upfield is assigned to the protons that are in close proximity to the cobaloxime moiety. The ring current of the metallabicycle affects these protons.[5,7] Hence, their signals are more downfield in **16**–**18** than in **13**–**15** because of the lower ring current in the dpgH complexes. $^1$H NMR spectroscopy in the region $\delta$ = 7.5–9.0 ppm can easily differentiate between the di- and mononuclear complexes; pyrazine appears as a singlet in the former and as two doublets in the latter.

### Spectral Studies

#### *NMR*

In the earlier NMR study on cobaloximes XCo(dioxime)$_2$Py (dioxime = dmgH, dpgH), $Py_\alpha$ and $Py_\gamma$ were

[a] $^{13}$C NMR: δ = 154.05, 147.31, 145.46, 129.92, 129.80, 129.31, 128.01 ppm. [b] Recorded in [$D_6$]DMSO. [c] $[Co(dpgH)_2(N_3)_2]^-$ ([$D_6$]-DMSO): $^1$H NMR: δ = 18.59, 7.41 (d, 4 H), 7.39 (d, 8 H), 7.27–7.24 (dd, 8 H) ppm; $^{13}$C NMR: δ = 151.5, 130.0, 128.7, 127.5 ppm.

found to be the most affected by a change in X.[5,15] The cobaloximes **13**–**18** are very similar to pyridine complexes except that pyridine is replaced by pyrazine (p$K_a$ of Pz 1.1,[19] Py 5.3[20]). Also, the spectral studies of pyrazine-bridged alkyl- (and benzyl-) dicobaloximes have already been reported from our laboratory.[11,12] Therefore, rather than going into the details about the spectroscopic data and *cis*/*trans* influence study in the present systems, we want to highlight only the salient points.

The coordination shift[21] $\Delta\delta^1$H of the $Pz_\alpha$ signal in **13**–**18** is very close to the coordination shift $\Delta\delta^1$H of the $Py_\alpha$ signal in the corresponding pyridine complexes, indicating further the similarity in the two systems (Table ST2). As $H_\alpha$ is affected by the dioxime ring current and cobalt anisotropy, its signal appears more upfield in the dmgH complexes than that of the dpgH complexes in both pyridine and pyrazine complexes.[4a,11,12] One of the major differences found in the pyridine and pyrazine complexes is the coordination shift of the β-hydrogen signal. It is almost unaltered in the pyrazine complexes, whereas it was shifted downfield (by 0.2–0.3 ppm) in the corresponding pyridine complexes. This is due to the presence of a nitrogen atom instead of a carbon atom at the sixth position in pyrazine. The cobalt anisotropy is less in the pyrazine complexes because of its lower p$K_a$ value and hence it compensates for the β-hydrogen signal downfield shift.

In the $[(R/X)Co(dioxime)_2]_2$-μ-Pz complexes, $Pz_\alpha$ is affected by the ring current and the cobalt anisotropy of the two metallabicycles (the factors ring current and cobalt anisotropy work in opposite directions: the $Pz_\alpha$ signal is shifted upfield by the ring current and downfield by the cobalt anisotropy) as compared to one in $(R/X)Co(dioxime)_2Pz$, therefore $\Delta\delta$ of the $Pz_\alpha$ signals should be much larger or even doubled in the former. It is found to be –0.2 to –0.3 ppm in **13**–**15** and –0.4 to –0.5 ppm in **1**–**3**; however, the difference is unexpectedly small in the corresponding dpgH complexes (compare **4**–**6** and **16**–**18** with $Pz_\alpha$ in free pyrazine). This is because of the higher cobalt anisotropy of dpgH, which completely compensates for the upfield shift due to the ring current. Similar compensation is also observed in the mono(pyrazine) complexes (compare **13**–**15** with **16**–**18**) as well as in the pyridine complexes $XCo(dioxime)_2Py$, viz. $\Delta\delta$ of the $Py_\alpha$ signals in the dmgH complexes is around –0.3 ppm, whereas it is close to zero in the dpgH complexes.

The pyrazine signals in $[RCo(dioxime)_2]_2$-μ-Pz were found to be shifted downfield in the dpgH complexes and upfield in the dmgH complexes as compared to the unligated pyrazine.[11,12] A similar trend is observed in the inorganic complexes **1**–**6** and $\Delta\delta$ of the $Pz_\alpha$ signals in $[RCo(dioxime)_2]_2$-μ-Pz complexes is larger than that in **1**–**6** because of the higher *trans* effect of the R group with respect to the X.

### *UV/Vis*

Three bands, a strong band at 263 nm corresponding to the Co→dioxime metal-to-ligand charge transfer (MLCT) and two shoulders around 313 and 330 nm (Co→Pz), are observed in **16**. A similar spectrum is obtained in **4** except that the intensity of the band corresponding to Co→Pz is significantly increased. This is expected because of the additive factor of the two identical chromophoric groups in the dinuclear complexes. A similar result is found in the dmgH complexes (see Table 2).

In general, organo-cobaloximes exist largely as pentacoordinate species in coordinating solvents like methanol and as hexacoordinate species in chloroform or dichloromethane.[4a,22] Pyrazine-bridged alkyldicobaloximes show similar behavior to the alkyl(pyridine)cobaloximes.[11] The base-on/base-off behavior of organocobaloximes has generally been studied by titration with the base, and the inference is made from the change in shape of the Co–C CT band with the

gradual addition of base to the cobaloxime. It has, however, not been possible to obtain a similar information in the present inorganic cobaloximes, because the phenomenon can be monitored by the Co→dioxime MLCT band only and this occurs at the same position as in the pyrazine case.

*Titration with $Cu^{I}BF_4$ Salt*

The titration of $Cu^+$ with a solution of **13** in dichloromethane was monitored by UV/Vis spectroscopy at 233 and 259 nm. The absorbance of the solution increased until 0.5 equiv. of $Cu^+$ was added (see Figure 1). No spectral change was observed after the addition of 0.5–1.0 equiv. of $Cu^+$. This suggests that there is a 2:1 complexation with $Cu^+$. Job's plot also suggests a 2:1 complexation (Figure S14).

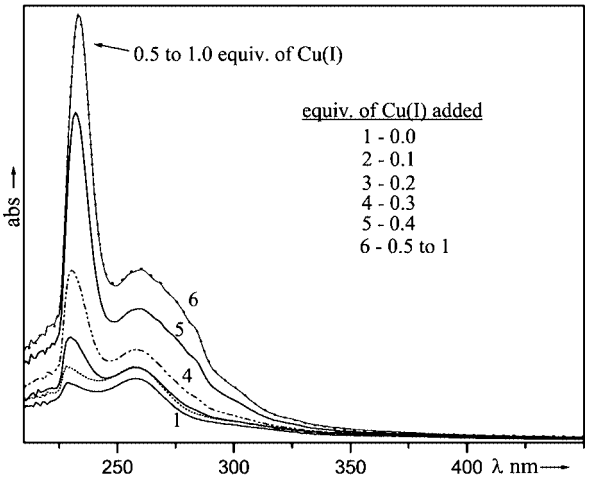

Figure 1. $Cu^+$ addition to a solution of $[ClCo(dmgH)_2Pz]$ (**13**). The $Cu^+$ saturation point is at 0.5 mol-equiv. $[ClCo(dmgH)_2Pz] = 1\times10^{-5}$ M (1 mL). $[Cu^+] = 1\times10^{-5}$ M (0.1–1.0 mL).

***IR***

All IR spectra were recorded as solid samples on KBr pellets and are tabulated in Table 3. The mononuclear and pyrazine-bridged dicobaloximes can be distinguished by IR spectroscopy; the O–H···O peak is a sharp doublet in monocobaloximes, whereas it is a broad singlet in the case of dicobaloximes. The O–H···O and C=N peaks appear at lower frequency in dpgH complexes as compared to dmgH complexes because of the higher cobalt anisotropy and lower electron density in the dpgH complexes. The $Cu^{I}PF_6$-bridged complex gives an IR spectrum identical to that of dicobaloxime **1** along with a distinct sharp peak at 845 cm$^{-1}$ for $PF_6^-$ (Figures S16 and S17).

**Cyclic Voltammetry**

The cyclic voltammogram (CV) of a cobaloxime shows three types of redox couples: $Co^{III}/Co^{II}$, $Co^{II}/Co^{I}$, and $Co^{IV}/Co^{III}$. Organo-cobaloximes, in general, give poor CVs and most of the time the $Co^{III}/Co^{II}$ redox couple is not visible. On the other hand, inorganic cobaloximes show relatively better CVs and all the redox couples are prominent. Two common solvents used for the study are dichloromethane and acetonitrile. We have preferred to use dichloromethane because of the higher solubility of the cobaloximes. The cyclic voltammogram of **13** (Figure 2A) shows an irreversible wave in the reductive half at –0.47 V corresponding to $Co^{III}/Co^{II}$ and a quasireversible wave at –1.08 V corresponding to $Co^{II}/Co^{I}$. [Interestingly, a CV of **13** recorded in acetonitrile gives a much better plot in which all the peaks are prominent and show the reversible nature (Figure 2B).] In comparison, **16** (Figure 2C) is much more easily reduced, with values at –0.32 and –0.73 V, respectively. In the oxidation half corresponding to $Co^{IV}/Co^{III}$, **13** and **16** show one reversible wave at +1.25 and 1.38 V, respectively. The CV data are very similar to those of the corresponding pyridine analogues except that the reduction potential values are low and the oxidation halves are high (see Table 3). This agrees well with the p$K_a$ of pyridine and pyrazine.

The CV data for both the oxidative and reductive halves can be rationalized on the basis of the cobalt anisotropy. The higher the cobalt anisotropy, the lower the reduction potential and the higher is the oxidation potential.[5,7] A comparison of the data in **13** with those in **16** shows that the reduction is easier and the oxidation is more difficult in **16** because of the higher cobalt anisotropy in dpgH complexes than in dmgH complexes. We have made a similar observation in the gH, dpgH, mestgH, and mixed dioxime complexes.[5,7,15] In view of this it is quite likely that the cobalt anisotropy may be the major factor responsible for the reduction/oxidation process.

We could not record the CV for **1** because of its insolubility in most organic solvents. The CV graph for **4** has three peaks; $Co^{IV}/Co^{III}$ is prominent but $Co^{III}/Co^{II}$ and $Co^{II}/Co^{I}$

[a] vs. Ag/AgCl. [b] vs. $Fc/Fc^+$. [c] Values refer to $E_{pc}$. [d] Value is in $CH_3CN$.

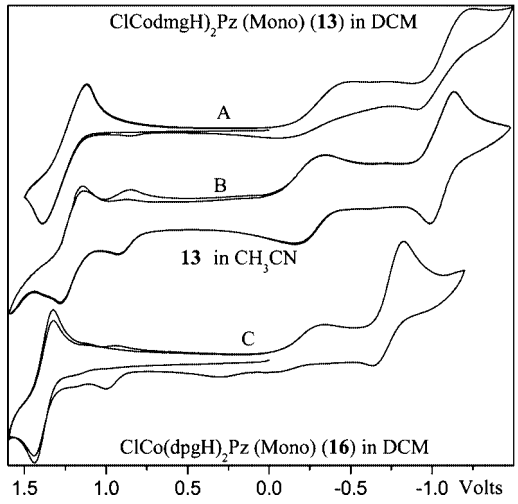

Figure 2. Cyclic voltammograms of **13** in dichloromethane (DCM) (A), in $CH_3CN$ (B), and **16** in DCM (C) with 0.1 M ($nBu_4N$)$PF_6$ as supporting electrolyte at 0.2 V $s^{-1}$ at 25 °C.

are not; however, the differential pulse voltammogram (DPV) clearly shows reduction. The pyrazine-bridged benzyl dpgH complex, $[PhCH_2Co(dpgH)_2]_2Pz$, also showed a poor CV in the reduction half.[12] The $Co^{III}/Co^{II}$ and $Co^{II}/Co^{I}$ values in **4** are –0.88 and –1.10 V, respectively. The $Co^{II}/Co^{I}$ reduction potential is much lower than the corresponding value in $[PhCH_2Co(dpgH)_2]_2Pz$ (–1.41 V). This is expected because of the higher cobalt anisotropy in **4**. Similarly, the oxidation potential $Co^{IV}/Co^{III}$ is higher (+1.33 V) in **4** than in $[PhCH_2Co(dpgH)_2]_2Pz$ (+1.12 V).

## X-ray Crystallographic Studies

### *Description of Structures 13 and 16*

The "diamond" diagrams of molecular structures **13** and **16** along with selected numbering schemes are shown in Figures 3 and 4, respectively. Selected bond lengths, bond angles, and structural parameters are given in Table 4. The crystal structure of **13** contains two molecules in its asymmetric unit. As there is a structural variation, they are numbered as **13-I** and **13-II** and the crystal data are given separately (Table 4).[23] Cobalt is in a distorted octahedral geometry with four nitrogen atoms of the dioxime in the equatorial plane and pyrazine and Cl axially coordinated. The cobalt atom deviates +0.013 and +0.028 Å from the mean equatorial $CoN_4$ plane toward the neutral pyrazine ligand in **13-I** and **13-II**, respectively, while the deviation is –0.016 Å in **16**. The positive sign means the deviation is towards the axial base group.[2]

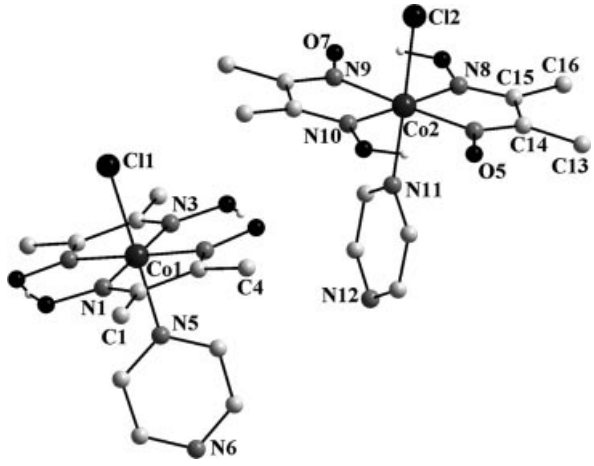

Figure 3. Molecular structure of $ClCo(dmgH)_2Pz$ (**13-I** and **13-II**) with two molecules in the asymmetric unit. The hydrogen atoms of the C–H bonds are omitted for clarity.

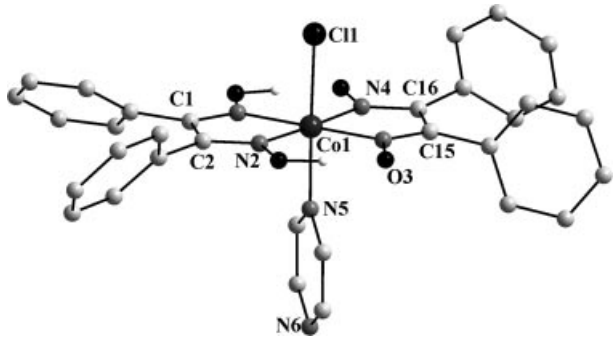

Figure 4. Molecular structure of $ClCo(dpgH)_2Pz$ (**16**). The hydrogen atoms of the C–H bonds are omitted for clarity.

The Co–Cl [2.2332(9), 2.2262(10), and 2.2185(10) Å] and Co–N5 [1.958(3), 1.967(3), and 1.961(3) Å] bond lengths in **13-I**, **13-II**, and **16** are very similar to their those of the corresponding $ClCo(dioxime)_2Py$ cobaloximes (dioxime = dmgH or dpgH). This indicates that the bond length does not change with a slight difference in the *cis* or *trans* influence.[2a,5] However, the Co–Cl [2.252(1) Å] and Co–N5 [1.981(3) Å] bonds are significantly longer in ClCbl.[24]

| *τ* [°] | 81.34 | 72.63 | 86.38 | 82.60 | 90, 0 | ca. 90 |

[a] Ag1–O8 2.426(6), Ag1–O10 2.428(6), Ag2–O3 2.548 (6), Ag2–O6 2.352(6), Ag2–O11 2.698(5), Ag2–O12 2.383(6), Ag2–O13 2.337(5) Å.

The pyrazine ring is almost parallel to the dioxime C–C bonds and the twist angles (*τ*)[25a] are 81.34, 72.63, and 86.38° in **13-I**, **13-II**, and **16**, respectively. The butterfly bending angle (*α*)[25b] in **13-I** and **13-II** is 4.14 and 1.04°, respectively, while it is 1.62° in **16**.

When **16** is crystallized with dichloromethane, the single-crystal analysis shows two dichloromethane molecules in the unit cell and its molecular structure differs from **16** (Figure S22). The Co–Cl and Co–N bond lengths are 2.2174(10) and 1.963(3) Å and comparable to the values in **16**; however, *α* (11.38°) and *d* (+0.054 Å) are larger and the twist angle is smaller (82.60°). These changes are the results of crystal packing forces due to the extensive H-bonding and π-interaction.

### *Description of Structure 19*

The characterization of **19** by X-ray analysis shows it to be $[Co(dpgH)_2(NO_2)_2]Na$ (Figure 5). An extensive hydrogen-bonding network results in large solvent-accessible voids of about 211 Å$^3$.

The crystal structure contains two cobaloxime molecules in its asymmetric unit and has two $Na^+$ as counter cations. The two cobaloxime molecules are structural isomers and differ only in their orientation of the $NO_2$ group; one is above the dioxime unit [with a Co–$N_{ax}$ distance of 1.943(3)] and the other is above the O–H···O unit [Co–$N_{ax}$ distance 1.948(4) Å]. Of the two units, one has a positional disorder of the $NO_2$ group attached to Co2. The Co–$NO_2$ distances are comparable to those of $NO_2$Cbl [1.942(6) Å][24] and $[Co(dmgH)_2(NO_2)_2]^-$ [1.945(3) Å][26] indicates no *cis* influence.

### *Description of the Structure of $[Co(dmgH)_2(NO_2)_2]_2$-$[Ag]_2$·$H_2O$*

The molecular structure shows the silver atoms in two distinct environments: a pseudo-four-coordinate and a pseudo-five-coordinate arrangement are displayed. A "diamond" picture of the unique portion of this structure is shown in Figure 6. Two cobaloxime units are repeated in three dimensions, linked by bridging Ag atoms, to form a 3D coordination polymer. The two silver atoms are in different coordination spheres: one is in a tetrahedral environment and the other is in a capped trigonal environment, as demonstrated in Figure 7.

We see two crystallographically inequivalent silver centers arranged linearly, whose differences arise from the binding mode of Ag. Ag1 is in a tetrahedral environment bridged by four oxygen atoms; two sets of symmetry-equivalent oxygen atoms are present. One set belongs to two nitro groups and the other set to two dioxime units. The Ag1–O bond lengths are 2.426(6) and 2.428(6) Å, respectively.

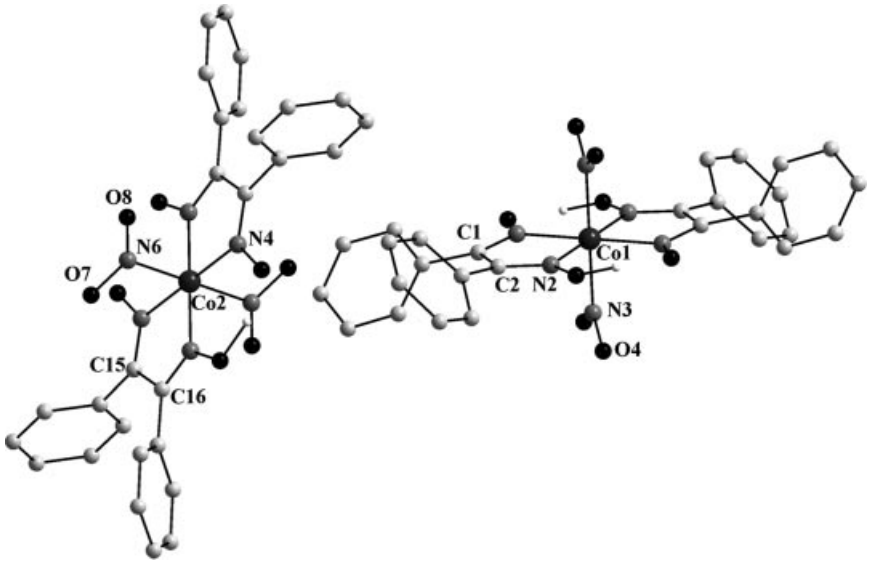

Figure 5. Molecular structure of $[Co(dpgH)_2(NO_2)_2]Na$ (**19**). Counter cations and hydrogen atoms of the C–H bonds are omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

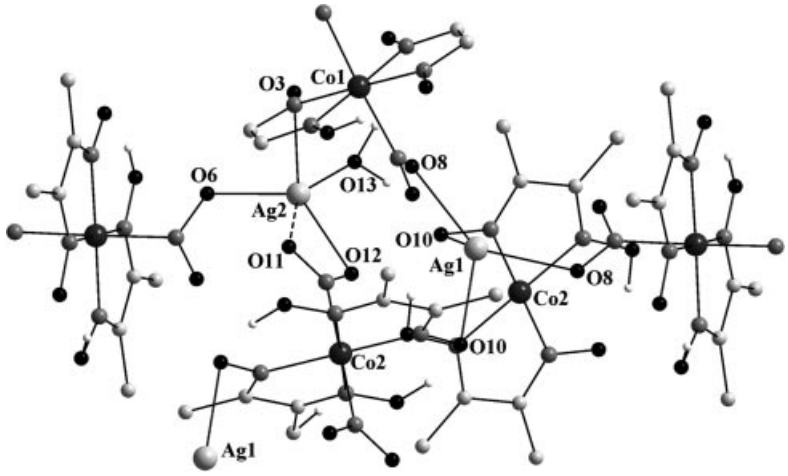

Figure 6. Molecular structure of $[Co(dmgH)_2(NO_2)_2]_2[Ag]_2{\cdot}H_2O$.

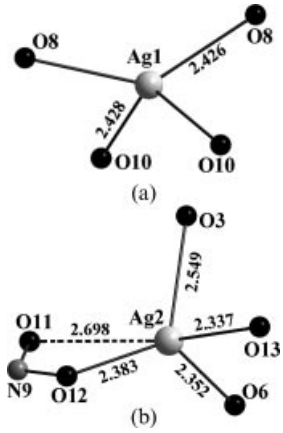

Figure 7. Ag1 and Ag2 coordination environment in $[Co(dmgH)_2(NO_2)_2]_2[Ag]_2{\cdot}H_2O$.

Ag2 has a (3+1) capped trigonal coordination sphere with four oxygen atoms. Three short bonds [Ag2–O6 2.352(6), Ag2–O12 2.383(6), Ag2–O13 2.337(5) Å] with bridging $NO_2$ groups and a water molecule form the trigonal geometry (slightly deviated from the planar geometry). The longer bond Ag2–O3 [2.548(6) Å] is with the dioxime oxygen atom; O11 acts like a chelating atom and has a weak interaction with Ag2 at a distance of 2.698(6) Å to generate a five-member silver-containing ring.[27]

In the solid state, these tetrahedral building blocks and cobaloxime units are linked together by the oxygen atom of the coordinated nitro group into a novel 2D helical structure along the *a*-axis. A right-handed helix present in the crystal structure is shown in Figure 8a. The helix is formed through four Ag–O bonding interactions (O8–Ag1–O8 and O6–Ag2–O12) along the $2_1$ screw axis (Figure 8b). Only one of the oxygen atoms of each nitro group takes part in the formation of the helix. Each coil of the helix contains six cobaloxime residues and six Ag atoms and the distance between the coils is 42.91(1) Å. Also it shows a 2D metal-organic framework (Figure S23) and an infinite zigzag coordination polymer (Figure S24).

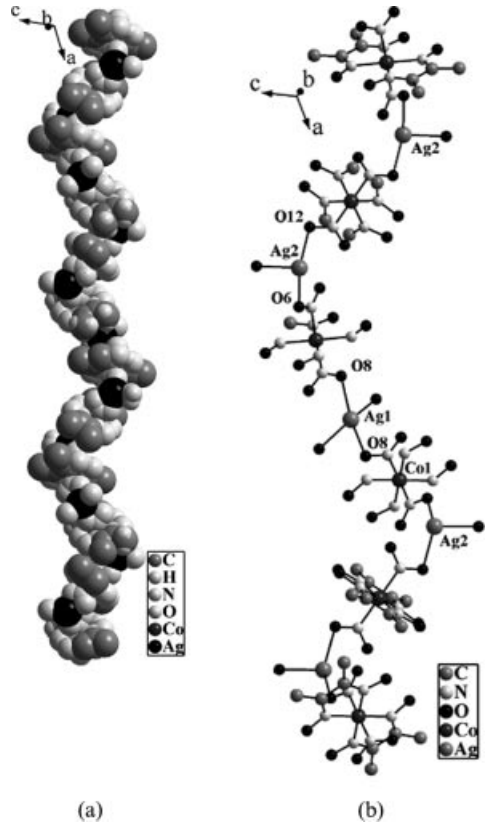

Figure 8. (a) Space-filling view of the right-handed helix of $[Co(dmgH)_2(NO_2)_2]_2[Ag]_2{\cdot}H_2O$. (b) 2D helical assembly along the *a*-axis. Some of the atoms have been omitted for clarity.

## Conclusions

Procedures were developed for the synthesis of mono- and dinuclear inorganic cobaloximes with pyrazine. The changes observed in NMR and CV are much more prominent than in organocobaloximes and these are more effectively rationalized with the field effect, a model proposed recently by us. Electron delocalization throughout the two metallabicycles through pyrazine is observed in the NMR

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and CV studies. $[XCo(dioxime)_2]_2$-μ-Pz complexes are more difficult to reduce than $XCo(dioxime)_2Pz$. Mononuclear pyrazine complexes behave similarly to the corresponding pyridine complexes. $[Co(dmgH)_2(NO_2)_2]_2[Ag]_2{\cdot}H_2O$ shows two $Ag^I$ ions in different environments: one is tetrahedral whereas the other is in a capped trigonal coordination, and the metal-organic framework in this molecule shows helical structure.

## Experimental Section

**General:** Cobalt chloride hexahydrate, dimethylglyoxime (SD Fine Chemicals, India), and pyrazine (Aldrich Chemical Company) were used as received. Diphenylglyoxime (Lancaster Chemicals) was washed with methanol before use. Silica gel (100–200 mesh) and distilled solvents were used in all chromatographic separations. $ClCo(dmgH)_2H_2O$,[28] $ClCo(dpgH)_2H_2O$,[29] $ClCo(dmgH)_2Pz$,[18] and $ClCo(dpgH)_2Pz$[18] were prepared according to the literature procedure. $^1H$ and $^{13}C$ NMR spectra were recorded with a JEOL JNM LA 400 FT NMR spectrometer (400 MHz for $^1H$ and 100 MHz for $^{13}C$) in $CDCl_3$ solution with TMS as internal standard. NMR spectroscopic data are reported in ppm. UV/Vis spectra were recorded with a JASCO V-570 spectrophotometer in dichloromethane (dry) and methanol (dry) at 298 K. IR spectra were recorded with KBr pellets in the range 4000–650 $cm^{-1}$ using a Vertex-70 Bruker Spectrophotometer. Elemental analysis was carried out at the Regional Sophisticated Instrumentation Center, Lucknow (see Table ST1). Cyclic voltammetry measurements were carried out using a BAS Epsilon Electrochemical workstation with platinum working electrode, Ag/AgCl reference electrode (3 M KCl), and a platinum wire counter electrode. All the measurements were performed in 0.1 M $nBu_4N(PF_6)$ in dichloromethane (dry) at a concentration of 1 mM of each complex. In addition, in a separate series of experiments, an internal reference system (ferrocene/ferrocenium ion) was used. Under the conditions used, the reversible $Fc/Fc^+$ potential occurred at 0.51 V versus the Ag/AgCl electrode.

**X-ray Structural Determination and Refinement:** Orange crystals were obtained by slow evaporation of the solvent {acetone/hexane for **13** and **16**; chloroform/methanol/hexane for **19**; dichloromethane/acetone for $[Co(dmgH)_2(NO_2)_2]_2[Ag]_2{\cdot}H_2O$}. Single-crystal X-ray data were collected at 100 K with a Bruker SMART APEX CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The linear absorption coefficients, scattering factors for the atoms, and the anomalous dispersion corrections were taken from the *International Tables for X-ray Crystallography*.[30a] The data integration and reduction were processed with SAINT[31] software. An empirical absorption correction was applied to the collected reflections with SADABS[32] using XPREP.[33] All the structures were solved by direct methods using SIR-97[34] and were refined on $F^2$ by the full-matrix least-squares technique using the SHELXL-97[30b] program package. All non-hydrogen atoms were refined anisotropically in all the structures. The hydrogen atoms of the OH group of oxime were located on difference Fourier maps and were constrained to those difference Fourier map positions. The hydrogen atom positions or thermal parameters were not refined but were included in the structure factor calculations. The pertinent crystal data and refinement parameters are compiled in Table 5. CCDC-299539, -299540, -299541, -299543, and -299544 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis**

**$[ClCo(dmgH)_2]_2$-μ-Pz (1):** Pyrazine (0.14 mmol, 0.01 g), dissolved in acetone (1 mL), was added to a clear brown solution of

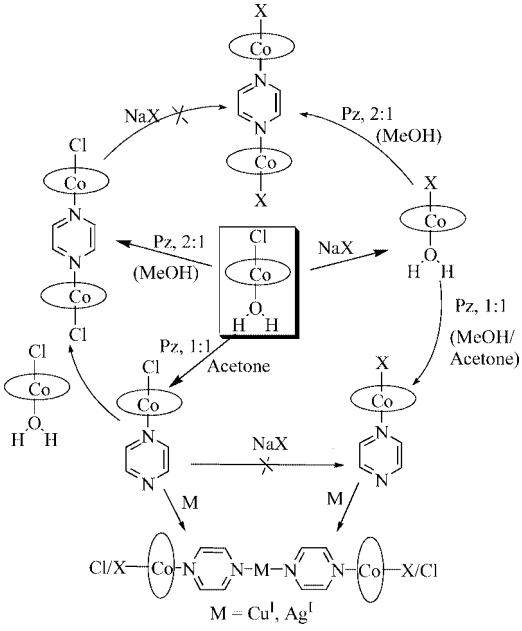
$ClCo(dmgH)_2H_2O$ (**7**) (0.29 mmol, 0.10 g in 10 mL of MeOH). An immediate precipitation occurred. The solution was stirred for several hours to ensure complete precipitation. The yellow precipitate was filtered, washed with acetone, and dried in vacuo over phosphorus pentoxide. Yield 0.091 g (89%) with respect to pyrazine.

**$[ClCo(dpgH)_2]_2$-μ-Pz (4):** The same procedure as in **1** was used except that $ClCo(dpgH)_2H_2O$ (**10**) (0.20 g, 0.34 mmol) was dissolved in acetone (2 mL) and methanol (1 mL). Yield 0.096 g (49%) with respect to pyrazine.

**$[XCo(dioxime)_2]_2$-μ-Pz (2, 3, 5, 6). (a):** A solution of $NaNO_2$ (0.03 g, 0.43 mmol) in water (2 mL) was added to a refluxing suspension of **4** (0.53 g, 0.43 mmol) in methanol (30 mL). The reaction mixture was further refluxed for 0.5 h. The solvent was evaporated to 2–5 mL. The product isolated was a salt and did not contain the pyrazine unit. **(b):** The complexes were prepared from the corresponding aqua complexes according to the method outlined for **1** and **4** (Scheme 2).



Scheme 2.

**$XCo(dmgH)_2H_2O$ (8, 9):**[35] These compounds were synthesized by the nucleophilic substitution of the chlorido ligand by $X^-$ in $ClCo(dmgH)_2H_2O$ (**7**). In a typical experiment, a solution of $NaNO_2$ (0.03 g, 0.43 mmol) in water (2 mL) was added to a refluxing suspension of $ClCo(dmgH)_2H_2O$ (**7**) (0.15 g, 0.43 mmol) in methanol (30 mL). The reaction mixture was further refluxed for 0.5 h. The solvent was evaporated to 2–5 mL and a sufficient amount of water was added to precipitate the compound; the precipitate was filtered and dried over phosphorus pentoxide. Yield (0.12 g, 77%).

**$XCo(dpgH)_2H_2O$ (11, 12):** The same procedure as outlined for $XCo(dmgH)_2H_2O$ was used. Two products, a salt and the desired compound **11**, were formed. The salt was identified as $[Co(dpgH)_2(NO_2)_2]^-$ by X-ray crystallography (**19**). However, when a dilute solution of $NaNO_2$ (0.03 g, in 10 mL) was treated with $ClCo(dpgH)_2H_2O$ (**10**) (0.25 g, 0.43 mmol) in methanol/acetone (1:1, 30 mL) (**11**), the desired product was formed exclusively. Yield (0.145 g, 71%).

**$XCo(dmgH)_2Pz$ (13–15):** Pyrazine (0.084 g, 1.05 mmol) dissolved in acetone (5 mL) was added to a clear brown solution of $N_3Co(dmgH)_2H_2O$ (0.34 g, 1.00 mmol) in acetone (70 mL). The solution was stirred for 1 h and kept aside for slow evaporation of the solvent. The needle-shaped brown crystals, formed after 2–3 d, were filtered and air-dried. Yield 60%. **(a):** When acetone was less than 70 mL, an immediate precipitation occurred and the compound identified was the dinuclear complex **3** (see above). **(b):** The use of methanol always led to the formation of a mixture of mono- and dinuclear complexes.

**$XCo(dpgH)_2Pz$ (16–18):** These were prepared from the corresponding aqua complexes according to the method outlined for **13**–**15**. Yield 80%.

**Heterodimetallic Complexes**

**Reaction of $Cu^IX$ (X = $BF_4$, $PF_6$, $ClO_4$) with $ClCo(dmgH)_2Pz$:** When $CuBF_4$ was added dropwise to $ClCo(dmgH)_2Pz$ (**13**) (both taken in dry dichloromethane), a dark red precipitate formed, which was completely insoluble in dichloromethane. (A similar kind of precipitation occurred with other $Cu^I$ salts also.) The precipitate dissolved instantaneously upon the addition of 2–3 drops of acetonitrile and the color changed to yellow. The precipitate was totally insoluble in most noncoordinating solvents and hence it could not be characterized by CV, NMR spectroscopy, or crystallographic studies.

**Reaction of $Ag^I(PF_6)$ with $XCo(dmgH)_2Pz$:** The addition of $Ag^I$ to **13** or **16** in dichloromethane/acetone immediately formed a white precipitate of AgCl, whereas the addition of an acetone solution of $AgPF_6$ to **14** gave an orange-yellow precipitate. In an effort to grow a single crystal by the layering process, most of the salt precipitated from the solution but a few orange crystals appeared on the inside wall of the tube. X-ray analysis of one of these crystals showed it to be $[Co(dmgH)_2(NO_2)_2][Ag]_2H_2O$. The complex may have formed during the crystallization process or because of a small impurity of $[Co(dmgH)_2(NO_2)_2]Na$ in **14**. However, this compound can be reproduced with addition of an $AgPF_6$ solution to $[Co(dmgH)_2(NO_2)_2]Na$ salt in acetone.

**Attempted Synthesis of Mixed Dicobaloximes $ClCo(dmgH)_2$-Pz-$Co(dpgH)_2Cl$ (20):** The synthesis of **20** turned out to be unexpectedly complicated. The procedure used in the synthesis of **1**–**6** did not afford the required product, for example the reaction of **10** with **13** (1:1) or the reaction of **7** with **16** (1:1) in chloroform formed **4** instead of the desired complex (**20**). The same reactions in acetone/methanol afforded **1** as the exclusive product. It is very difficult to offer any conclusive evidence for the formation of **4** or **1**. It is, however, possible that **4** is thermodynamically the more stable product and arises from the intermediate $ClCo(dpgH)_2$-Pz-$Co(dmgH)_2Cl$, a kinetically controlled product. [We have, however, not been able to isolate this compound, even at low temperatures (see Scheme S1).] Similarly, all efforts to synthesize other combinations like $ClCo(dmgH)_2$-Pz-$Co(dpgH)_2$*n*Pr and $MeCo(dmgH)_2$-Pz-$Co(dpgH)_2Cl$ also failed, although many procedures were tried (see Supporting Information).

**Supporting Information** (see footnote on the first page of this article): Representative figures of UV/Vis, IR, NMR spectra, and X-ray metal-organic framework for the subject compounds.

[17] It is worth noting that the procedure typically used for the preparation of $RCo(dioxime)_2H_2O$ from the corresponding pyridine complex by Dowex ($H^+$ form) has failed in the inorganic complexes.[11] This might be because pyridine is much less labile because of the poor *trans* effect of X as compared to R.

# New Polynuclear Mo–Fe Complexes with Ferrocenylamidobenzimidazole Ligands

**Paulo N. Martinho,[a,b] Susana Quintal,[a,b] Paulo J. Costa,[a,b] Serena Losi,[c] Vitor Félix,[d] M. Concepción Gimeno,[e] Antonio Laguna,[e] Michael G. B. Drew,[f] Piero Zanello,[c] and Maria José Calhorda*[a,b]**

**Keywords:** $Mo^{II}$ complexes / Ferrocenyl ligands / Polynuclear complexes / DFT calculations / Electrochemistry

The reaction between $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(NCMe)_2Br]$ (**1**) and the ferrocenylamidobenzimidazole ligands $FcCO(NH_2benzim)$ (**L1**) and $(FcCO)_2(NHbenzim)$ (**L2**) led to a binuclear (**2**) and a trinuclear (**3**) Mo–Fe complex, respectively. The single-crystal X-ray structure of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L2)Br]$ [L2 = $\{[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4CO)]_2$(2-NH-benzimidazolyl)$\}$] shows that **L2** is coordinated to the *endo* $Mo(\eta^3\text{-}C_3H_5)(CO)_2$ group in a $\kappa^2$-N,O-bidentate chelating fashion whereas the $Mo^{II}$ centre displays a pseudooctahedral environment with Br occupying an equatorial position. Complex **2** was formulated as $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L1)Br]$ on the basis of a combination of spectroscopic data, elemental analysis, conductivity and DFT calculations. **L1** acts as a $\kappa^2$-*N*,*N*-bidentate ligand. In both **L1** and **L2**, the HOMOs are mainly localised on iron while the C=O bond(s) contribute to the LUMO(s) and the next highest energy orbitals are Fe–allyl antibonding orbitals. When the ligands bind to $Mo(\eta^3\text{-}C_3H_5)(CO)_2Br$, the greatest difference is that Mo becomes the strongest contributor to the HOMO. Electrochemical studies show that, in complex **2**, no electronic interaction exists between the two ferrocenyl ligands and that the first electron has been removed from the $Mo^{II}$-centred HOMO.

## Introduction

Polynuclear complexes containing molybdenum and iron have received much attention as possible models for the site active metal centre(s) in nitrogenases.[1] In particular, organometallic ligands derived from ferrocene, with one or both the cyclopentadienyl rings properly functionalised with suitable substituents, represent an easy and successful way of designing polynuclear species able to mimic molecules featuring different biological functions or material science properties.[2] Common routes start either from ferrocene carbonyl chloride and an amine, elimination of HCl affording the desired product, or from lithiated ferrocene.[3] Interestingly, both ferrocenium and some ferrocenylalkyl benzimidazoles have been shown to exhibit antitumor properties.[4] A large amount of chemistry has been developed around the ferrocenyl amides, arising from the special biological properties characteristic of amino acids and peptides.[5] Ferrocene labelled amino acids have thus been synthesised,[6] their complexation behaviour towards other metal centres studied[7] and other properties[8] and applications, namely as sensors, investigated.[9] We recently described the synthesis of two new ferrocenylamidobenzimidazole ligands, $FcCO(NH_2benzim)$ (**L1**) and $(FcCO)_2$-(NHbenzim) (**L2**).[10] In this work, we studied their activity as ligands towards the $Mo^{II}$ complex $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(NCMe)_2X]$ (X = halide), **1**,[11] following our interest in the reactivity and properties of $Mo^{II}$ systems.[12,13] Complex **1** has been used as a synthetic precursor for obtaining several types of derivatives, some of which have proved to be suitable catalysts for, among other things, polymerisation of dienes or in organic synthesis for allylic alkylations.[14,15] The complex of **L2** was structurally characterised by single-crystal X-ray diffraction and the other complex by spectroscopic studies. Their redox properties were studied by electrochemical techniques and DFT calculations[16] were carried out to interpret the behaviour upon oxidation and to assign the molecular structure of the complex with **L1**.

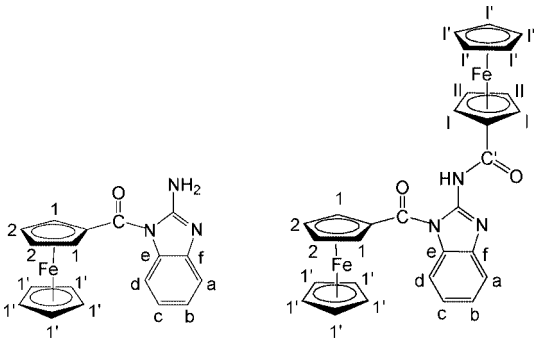
## Results and Discussion

### Chemical Studies

The coupling reaction between FcCOCl [Fc = $(\eta^5\text{-}C_5H_5)$-$Fe(\eta^5\text{-}C_5H_4)$] and 2-aminobenzimidazole, $[NH_2(benzimH)]$,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in 1:1 and 2:1 ratios led to the ligands FcCO(NH$_2$benzim) (**L1**) and (FcCO)$_2$(NHbenzim) (**L2**)[10] shown in Scheme 1.



**L1** **L2**

Scheme 1.

[Mo($\eta^3$-C$_3$H$_5$)(CO)$_2$(NCMe)$_2$Br], **1**, reacted with the ferrocenyl ligand **L1** in a 1:1 ratio affording, by means of substitution of the acetonitrile ligands, a new complex assigned as [Mo($\eta^3$-C$_3$H$_5$)(CO)$_2$(L1)Br] (**2**) from elemental analysis and spectroscopic data.

The infrared spectrum of **2** shows two very strong bands at 1933 and 1839 cm$^{-1}$, assigned to the two C≡O stretching modes typical of the carbonyl groups and shifted by 16 and 12 cm$^{-1}$ relative to those in the precursor complex **1**. The $\nu_{C=O}$ stretching frequency can be observed at 1675 cm$^{-1}$ which is essentially the same value as observed in the free ligand (1678 cm$^{-1}$) suggesting that the carbonyl group does not coordinate to the metal centre. In contrast, both the N–H asymmetric stretches of the NH$_2$ group and the C–NH$_2$ stretch are shifted to lower frequencies, from 3415 cm$^{-1}$ to 3392 cm$^{-1}$ and from 1304 cm$^{-1}$ to 1296 cm$^{-1}$, respectively. These changes indicate that the NH$_2$ amino group may be coordinated to the molybdenum. The bands assigned to the ferrocenyl subunits appear at 3101 ($\nu_{C-H}$), 1419 ($\nu_{C-C}$), 1107 (asymmetric ring breathing), 1002 $(\delta_{C-H})_{\|}$, 822 $(\pi_{C-H})_{\perp}$, 490 $(\delta_{Fe-Cp})_a$ and 438 cm$^{-1}$ ($\nu_{Fe-Cp}$), i.e. almost in the same positions as in the free ligand which are 3087 ($\nu_{C-H}$), 1450 ($\nu_{C-C}$), 1105 (asymmetric ring breathing), 1000 $(\delta_{C-H})_{\|}$, 823 $(\pi_{C-H})_{\perp}$, 494 $(\delta_{Fe-Cp})_a$ and 440 cm$^{-1}$ ($\nu_{Fe-Cp}$).[17]

The signals in the room temperature $^1$H NMR spectra of **2** and **3** in [D$_7$]DMF are too broad to be resolved. At room temperature, free rotation across the amide bonds leads to the interconversion between different rotamers of **2** and **3**, with proton resonances occurring on the same time scale. The temperature dependence of the variable hydrogen bonding networks present in the complexes, as seen in the crystal structure of **3** (below), has been reported for several related complexes and explains this behaviour.[6d–f,8] Upon decreasing the temperature to 253 K, the broad signals merge to very well defined signals.

At 253 K, one broad signal at $\delta$ = 7.95 ppm can be clearly assigned to the two NH$_2$ protons. This signal is downfield relative to that in the free ligand ($\delta$ =6.45 ppm), in agreement with the proposed coordination of the NH$_2$ group to molybdenum.

The Ha, Hb, Hd and Hc protons of the benzimidazole fragment in complex **2** can be seen in the aromatic region at 7.32 (doublet), 7.17 (triplet), 7.08 (doublet) and 6.98 ppm (triplet), respectively. In the free ligand **L1**, they appear at 7.29 (doublet, Ha), 7.06 (Hb), 6.93 (doublet, Hd) and 6.81 ppm (triplet, Hc). The deviations are quite small since these protons are not close to any atom likely to bind to the metal.

The signals of the ferrocenyl unit appear as multiplets (H1, H2 at 5.00, 4.79 ppm) and as a singlet (H1′ at $\delta$ = 4.38 ppm), close to the values for the free ligand (two multiplets at 4.89 and 4.53 ppm, and one at $\delta$ = 4.22 ppm). The upfield signals at 3.51 (multiplet), 3.30 and 1.18 ppm (doublets) can be assigned, respectively, to the H$_{meso}$, H$_{syn}$ and H$_{anti}$ protons of the allyl fragment. Despite the low global symmetry of the complexes, the signals reflect the local *C*s symmetry of the ferrocenyl ligands. There is no evidence in the NMR spectra for coordinated acetonitrile, suggesting that the two nitrile ligands in the precursor **1** are replaced by **L1**. The methyl signals at $\delta$ = 2.19 ppm in the $^1$H NMR and 1.34 ppm in the $^{13}$C NMR spectrum may be assigned to uncoordinated acetonitrile. The low molar conductivity ($\Lambda$M = 4.8 $\Omega^{-1}$ cm$^2$ mol$^{-1}$ in dmf) is characteristic of a neutral complex which is expected when two nitriles are lost but not when the bromide and one nitrile are lost. Both the IR and the NMR spectroscopic results thus suggest the coordination of the **L1** ligand in a $\kappa^2$-*N*,*N*-bidentate mode in [Mo($\eta^3$-C$_3$H$_5$)(CO)$_2$(L1)Br] (**2**). DFT calculations provided more information on the preferred geometry (see below).

The precursor complex [Mo($\eta^3$-C$_3$H$_5$)(CO)$_2$(NCMe)$_2$Br], **1**, also reacted with the ligand **L2** to give [Mo($\eta^3$-C$_3$H$_5$)(CO)$_2$(L2)Br], **3**, by substitution of the two acetonitrile ligands, as confirmed by single-crystal X-ray diffraction (see below). The infrared spectrum of **3** shows two very strong bands at 1927 and 1830 cm$^{-1}$, characteristic of the $\nu_{C\equiv O}$ stretching frequencies of the carbonyl groups. Two other very strong bands, at 1704 and 1655 cm$^{-1}$, can be assigned to C=O stretches. In the free ligand, only one very intense band was observed at 1678 cm$^{-1}$. The large shift of one band to lower frequency (1655 cm$^{-1}$) in the complex suggests coordination of one C=O group to molybdenum whereas the other frequency (1704 cm$^{-1}$) can be assigned to the uncoordinated C=O. The bands assigned to the ferrocenyl subunits appear at 3073 ($\nu_{C-H}$), 1434 ($\nu_{C-C}$), 1107 (asymmetric ring breathing), 1002 $(\delta_{C-H})_{\|}$, 827 $(\pi_{C-H})_{\perp}$ and 495 $(\delta_{Fe-Cp})_a$, approximately in the same positions as in the free ligand.

The $^1$H NMR spectrum of **3** at 253 K shows one broad signal at $\delta$ = 9.10 ppm assigned to one NH proton as well as four signals in the aromatic region at 8.54, 7.75, 7.53 and 7.39 ppm assigned to the Ha, Hb, Hd and Hc protons of the benzimidazole fragment of **L2**. The H1, H2, and H1′ signals of one ferrocenyl unit appear at $\delta$ = 4.73, 4.46 and 4.23 ppm with those of the other at $\delta$ = 5.13, 4.91 and 4.44 ppm, respectively. The H$_{meso}$, H$_{syn}$ and H$_{anti}$ protons of the allyl fragment can be observed at $\delta$ = 3.76, 3.30 and 1.18 ppm, respectively. Unfortunately, the $^{13}$C{$^1$H} NMR

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectrum was not of sufficient quality for making assignments.

### Crystallography

The X-ray diffraction study of the $Mo^{II}$ complex **3** showed that its crystal structure consists of discrete molecules of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L2)Br]$ and disordered $CH_2Cl_2$ solvent molecules. The chlorine atoms occupy two alternative tetrahedral positions with identical statistical occupancies. Selected bond lengths and angles are given in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] in the molybdenum coordination sphere.

| | | | |
|---|---|---|---|
| Mo–C(100) | 1.934(7) | Mo–C(200) | 1.964(8) |
| Mo–N(11) | 2.223(5) | Mo–O(34) | 2.225(4) |
| Mo–Br | 2.7169(9) | | |
| C(100)–Mo–C(200) | 81.9(3) | C(100)–Mo–N(11) | 97.4(2) |
| C(200)–Mo–N(11) | 88.4(2) | C(100)–Mo–O(34) | 174.1(2) |
| C(200)–Mo–O(34) | 100.5(2) | N(11)–Mo–O(34) | 77.4(2) |
| C(100)–Mo–Br | 93.8(2) | C(200)–Mo–Br | 168.1(2) |
| N(11)–Mo–Br | 81.2(1) | O(34)–Mo–Br | 82.84(1) |

The molecular structure of **3** presented in Figure 1 shows the molybdenum centre to have a pseudo octahedral coordination environment with the centroid of the $\eta^3$-allyl ligand and two carbonyl ligands assuming a *fac* arrangement. The **L2** ligand is coordinated in a $\kappa^2$-N,O-bidentate chelating fashion with the oxygen atom [O(34)] from a carbonyl group and the N donor atom from the benzimidazole ring occupying equatorial and axial coordination positions, respectively. The Mo–N and Mo–O distances are 2.223(5) and 2.225(4) Å, respectively, leading to a N–Mo–O bite angle of 77.4(2)° for the six-membered chelating ring. The metal coordination sphere is completed by a bromine atom in the equatorial position with a Mo–Br distance of 2.7169(9) Å. This gives rise to the axial isomer depicted in Scheme 2. In addition, in the solid-state, the $\eta^3$-allyl ligand adopts an *endo* conformation while the Cp rings of both ferrocenyl subunits display almost eclipsed conformations.

Comparable geometric arrangements with the donor atoms adopting the same spatial disposition around the molybdenum centre have been found for related $Mo^{II}(\eta^3\text{-}C_3H_5)$ complexes.[12,13] To the best of our knowledge, the X-ray structure determination reported here represents the first evidence for the formation of a molybdenum derivative of $(FcCO)_2(NHbenzim)$. The two carbonyl groups from the ligand **L2** adopt a *trans* configuration with the free carbonyl slightly twisted by 79.7(2)° relative to plane of the benzimidazole ring. This arrangement is stabilised by an intramolecular hydrogen bond between the oxygen atom O(20) of the free carbonyl group and the nitrogen atom N(32) from the chelating ring (N–H···O 2.08 Å, 127.0°). The distance between the two iron centres is 7.372(1) Å while the Mo is separated from the iron centres at distances of 5.666(1) and 7.051(1) Å, respectively. These long distances indicate that there is no through-space electronic communication between the three metal centres.

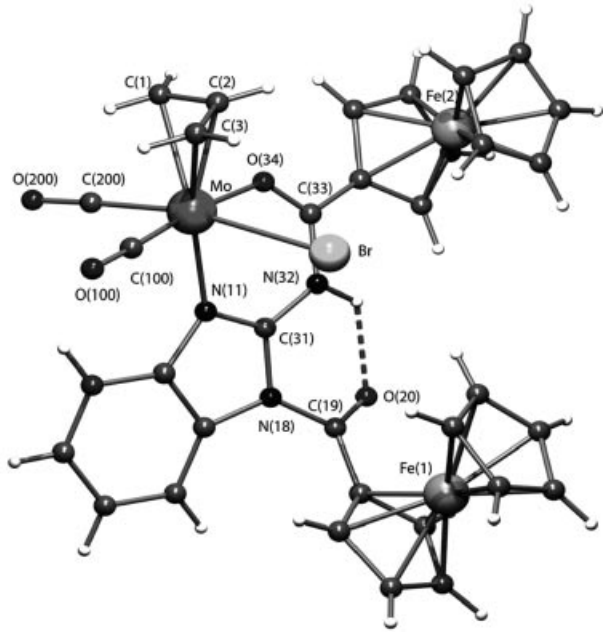


Figure 1. Molecular diagram showing the overall structure of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L2)Br]$ (**3**) with the atomic notation scheme used. The labels for the aromatic atoms have been omitted for clarity.

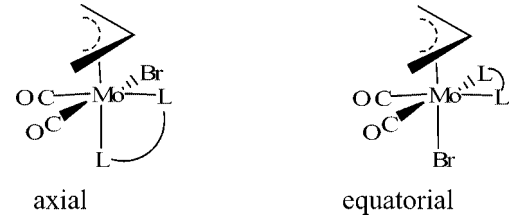

Scheme 2.

### DFT Calculations

$[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L1)Br]$ (**2**) can exist as one of two isomers, axial or equatorial (Scheme 2).

DFT[16] calculations (ADF program;[18] see section Computational Details) were performed in order to find the most stable isomer of **2**. The axial isomer (Figure 2) was found to be more stable by 3.2 kcal mol$^{-1}$. The four-membered ring motif has been found in many related Mo complexes.[19]

The second feature addressed by the DFT calculations was the nature of the frontier orbitals of the ligands **L1** and **L2** and of complexes **2** and **3** in order to further support the electrochemical results described below. The HOMO, LUMO and LUMO+1 of **L1** are shown in Figure 3.

The HOMO and the next levels with lower energy are strongly localised on Fe, as is characteristic of ferrocenes and they represent the orbitals derived from the $t_{2g}$ set of this pseudo octahedral structure of a $d^6$ species. The LUMO is mainly the $\pi^*$ orbital of the C=O group while the L+1 orbital is the antibonding Fe–Cp combination involving $x^2–y^2$ and Cp $\pi^*$.

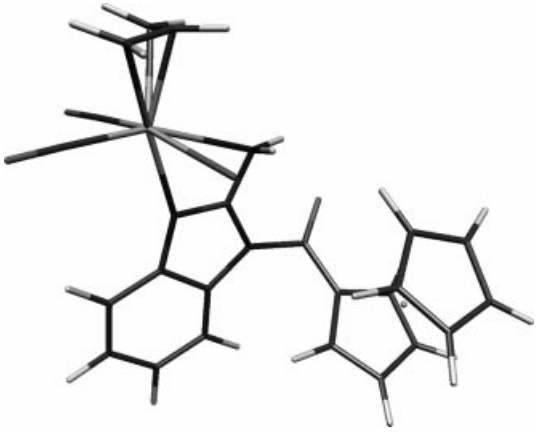

Figure 2. Molekel[20] 3D representation of the structure of the axial isomer of complex **2**, [Mo($\eta^3$-$C_3H_5$)$(CO)_2$(L1)Br].

$(FcCO)_2$(NHbenzim) (**L2**) has two ferrocenyl groups hanging from the benzimidazole unit. The frontier orbitals are comparable with those of **L1** but their number is double. The HOMO is the analogue of the HOMO of **L1**, localised on one Fc unit, while the H-1 is the same but localised on the second ferrocenyl. The LUMO also has a large contribution of the C=O π* orbital. The Fe–Cp antibonding levels appear at higher energies.

When the ligands bind to the $Mo^{II}$ centre a question about the nature of the HOMO arises, namely, is it localised on Mo or does it remain on Fe? In most known compounds, the higher occupied MOs are Fe orbitals, therefore enabling multiple applications of ferrocenyl derivatives as probes, although there are examples of the opposite behaviour.[21] The most relevant frontier orbitals of complex **2** are depicted in Figure 4.

The HOMO is strongly localised on the $Mo(CO)_2$ fragment, being Mo–C bonding, while the iron based orbitals start at H-1 and continue below. The LUMO is mostly the C=O π* orbital with some Fe contribution.

The same electronic structure can be observed for complex **3** with the HOMO located on $Mo(CO)_2$ and having some contribution from Br. The H-1 is more delocalised with participation of Mo, CO, Br and Fe. H-2 to H-6 are iron d orbitals as in Figure 3 (left). H-7 and H-8, despite a small Fe contribution, are essentially localised on the bromine atom. The LUMO and L+1 are again based on the two C=O π* orbitals, with different proportions of each. Both in the ligands and in their molybdenum complexes, the frontier orbitals are mostly localised on one of the metal atoms.

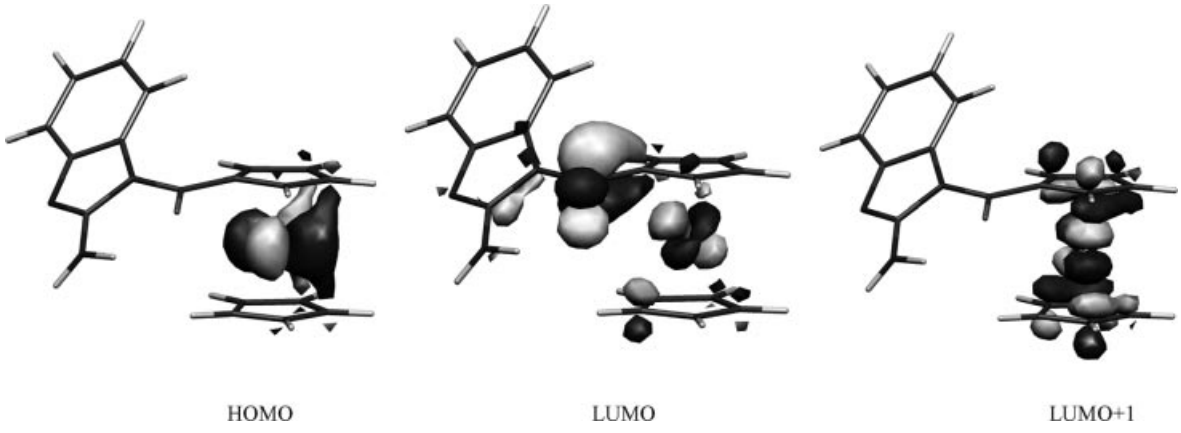

Figure 3. Molekel[20] 3D representation of the HOMO (left), LUMO (centre) and LUMO+1 (right) of FcCO($NH_2$benzim) (**L1**).

**Electrochemistry**

As deducible from Figure 5, the ferrocene/ferrocenium oxidation exhibited by ligand **L1** is accompanied by chemical complications.

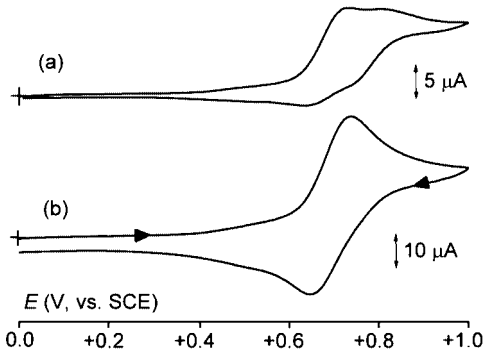

Figure 5. Cyclic voltammetric responses recorded at a platinum electrode in a $CH_2Cl_2$ solution of **L1** ($0.8\times10^{-3}$ mol dm$^{-3}$). $[NBu_4][PF_6]$ (0.2 mol dm$^{-3}$) supporting electrolyte. Scan rates: (a) 0.02 V s$^{-1}$; (b) 0.2 V s$^{-1}$.

In fact, at very low scan rates two almost overlapping anodic processes appear, which merge in a single process at higher scan rates. In confirmation of the chemical complications following the expected one-electron oxidation, controlled potential coulometric measurements ($E_w$ = +0.9 V) indicated that two electrons *per* molecule are consumed. Even if the closeness of the two processes makes difficult a detailed analysis of the overall process at low scan rates, it is conceivable that the original one-electron oxidation leads to a primary species which converts slowly to a new oxidisable species (ECE mechanism).[22]

It is hence not unexpected that the Mo complex **2**, which further contains the redox-active centres $Mo^{II}$ and $Br^-$, might afford a more complicated voltammetric pattern, Figure 6. As a matter of fact, three anodic steps can be detected, namely A, B and C. Unfortunately, any attempt to determine the precise number of electrons involved in each step by controlled potential coulometry failed, probably because of both their closeness and the underlying complex electron-transfer mechanisms.

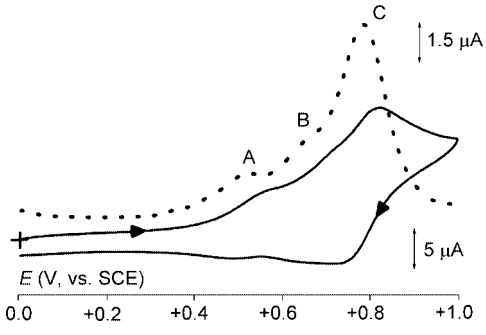

Figure 6. Cyclic (—) and Osteryoung square wave (···) voltammetric responses recorded at a platinum electrode in a $CH_2Cl_2$ solution of **2** ($0.7\times10^{-3}$ mol dm$^{-3}$). $[NBu_4][PF_6]$ (0.2 mol dm$^{-3}$) supporting electrolyte. Scan rates: (—) 0.2 V s$^{-1}$; (···) 0.1 V s$^{-1}$.

Based on the good extent of chemical reversibility, the most anodic process C can therefore be somewhat naïvely assigned to the ferrocene/ferrocenium oxidation, whereas the process B can be tentatively assigned to the oxidation of the bromide coligand. However, since under the same experimental conditions the free $Br^-$ ion affords two substantially irreversible oxidations[23] ($E_p$ = +0.71 V and +0.94 V, respectively), a contribution to peak C from the second bromide oxidation cannot be ruled out. Finally, in agreement with either the previous findings[24] or the above theoretical calculations, the anodic process A, which also looks likely to exhibit partial chemical reversibility, can be assigned to the $Mo^{II}/Mo^{III}$ couple.

As illustrated in Figure 7, a qualitatively similar situation is exhibited by the diferrocenyl couple **L2/3**.

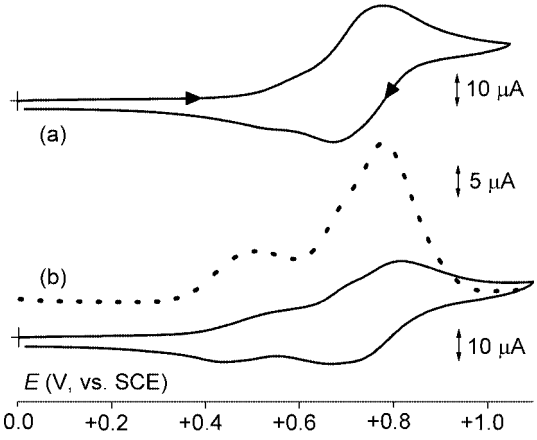

Figure 7. Cyclic (—) and Osteryoung square wave (···) voltammetric responses recorded at a platinum electrode in $CH_2Cl_2$ solutions of: (a) **L2** ($0.7\times10^{-3}$ mol dm$^{-3}$); (b) **3** ($0.6\times10^{-3}$ mol dm$^{-3}$). $[NBu_4][PF_6]$ (0.2 mol dm$^{-3}$) supporting electrolyte. Scan rates: (—) 0.2 V s$^{-1}$; (···) 0.1 V s$^{-1}$.

Controlled potential coulometric measurements corresponding to the anodic process of **L2** indicate that more than the expected two electrons *per* molecule are consumed (a low level of the electrolytic current still persists even after the consumption of 3.2 electrons per molecule). In this case, however, the final cyclic voltammetric control simply shows partial re-reduction of the oxidised product, which means that the chemical complication could be only due to slow regeneration of the original product likely triggered by traces of water present in the nominally anhydrous solvent. Such a drawback is not unusual in exhaustive electrolysis carried out at relatively high potential values.

It can be noted that the rather rounded peaks exhibited by **L2** give evidence for the postulation that the two ferrocenyl subunits are substantially electronically independent from each other. In turn, as deduced by crystal data, the insertion of the Mo fragment does not modify such electronic interactions.

Table 2 lists the formal electrode potentials for the oxidation of the ferrocenyl fragment in the two series of compounds.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2. Formal electrode potentials (V, vs. the SCE), peak-to-peak separations (mV) and current ratios for the ferrocene/ferrocenium ion oxidation processes in the couples **L1/2** and **L2/3** in $CH_2Cl_2$ solution.

| Complex | $E°'$ | $\Delta E_p$ [a] | $i_{pc}/i_{pa}$ [a] |
|---|---|---|---|
| **L1** | +0.69 | 70 | 0.86 |
| **2** | +0.78 | 70 | [b] |
| **L2** | +0.72 [c] | 93 | 0.80 |
| **3** | +0.76 [c] | 96 | [b] |
| $Fe(C_5H_5)_2/[Fe(C_5H_5)_2]^+$ | +0.39 | 76 | 1.0 |

[a] Measured at 0.1 $V s^{-1}$. [b] Difficult to determine because of close-spaced preceding processes (see text). [c] Nominal two-electron process; from OSWV.

It should be noted that the electron-withdrawing effect exerted by the Mo fragment with respect to the sandwich ligands is, as expected, almost halved on passing from the diferrocenyl to the monoferrocenyl complexes.

## Conclusions

The two new ferrocenylamidobenzimidazole ligands $FcCO(NH_2benzim)$ (**L1**) and $(FcCO)_2(NHbenzim)$ (**L2**) react with $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(NCMe)_2Br]$ to afford two polynuclear Mo–Fe complexes. Complex **3**, with the **L2** ligand was structurally characterised by single-crystal X-ray diffraction. The axial isomer was formed and **L2** was coordinated in a $\kappa^2$-N,O-bidentate mode using the benzimidazole nitrogen and the closest carbonyl oxygen as donor atoms. The N–H···O hydrogen bond to the second carbonyl of **L2**, already present in the free ligand, was preserved. A combination of spectroscopic data, elemental analysis, conductivity and DFT calculations led us to formulate complex **2** as $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L1)Br]$ with **L1** coordinating in the neutral form using both the benzimidazole and the $NH_2$ nitrogen atoms thereby resulting in the most stable axial isomer. The occupied frontier orbitals of the ligands were based on iron, with a LUMO located on the C=O bond(s) and the LUMO+1 being Fe–allyl antibonding. Coordination of the ferrocenyl ligands to Mo leads to Mo based HOMOs, the Fe orbitals coming next and the unoccupied levels being similar to those in the free ligands. In agreement with crystal data and theoretical calculations, electrochemistry shows that in complex **2** no electronic interaction exists between the two ferrocenyl ligands and the first electron is removed from the $Mo^{II}$-centred HOMO.

## Experimental Section

### Chemical Studies

Commercially available reagents and all solvents were purchased from standard chemical suppliers. Solvents were dried using common procedures. The syntheses of the molybdenum complexes were carried out under nitrogen using Schlenk tube techniques. The complex $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(NCCH_3)_2Br]$ was synthesised according to literature procedures.[5] The ligands **L1** and **L2** were prepared as described in the literature.[10] Infrared spectra were measured on a Mattson 7000 FT spectrometer. Samples were run as KBr pellets. NMR spectra were recorded on a Bruker Avance-400 spectrometer in $[D_7]$DMF. Electronic spectra were recorded with a UNICAM model UV-4 spectrophotometer. Materials and apparatus for electrochemistry have been described elsewhere.[25] Elemental analyses were carried out at ITQB.

**Preparation of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L1)Br]$ (2):** To a yellow solution of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(NCCH_3)_2Br]$ (0.177 g, 0.5 mmol) in dichloromethane (10 mL) was added **L1** (0.173 g, 0.5 mmol). The dark-red solution obtained was stirred at room temperature for 3 h. Addition of *n*-hexane resulted in the formation of red solid which was filtered, washed with *n*-hexane and dried under vacuum. Unsuccessful attempts to grow crystals suitable for X-ray diffraction were carried out by vapour diffusion of diethyl ether into a solution of the complex in $CH_2Cl_2$. Yield 0.274 g (78%). Elemental analysis for $\mathbf{2}\cdot CH_3CN\cdot 0.5CH_2Cl_2$ ($C_{25.5}H_{24}BrClFeMoN_4O_3$) (701.64): calcd. C 43.65, H 3.45, N 7.98; found C 44.12, H 3.51, N 7.73. $^1$H NMR (400 MHz, $[D_7]$DMF, 253 K): $\delta$ = 7.95 (br., $NH_2$), 7.32 (d, 1 H, Ha), 7.17 (t, 1 H, Hb), 7.08 (d, 1 H, Hd), 6.98 (t, 1 H, Hc), 5.23 ($CH_2Cl_2$, 1 H), 5.00 (br., 2 H, H1), 4.79 (br., 2 H, H2), 4.38 (br., 5 H, H1′), 3.51 (m, 1 H, $H_{meso}$), 3.30 (d, 2 H, $H_{syn}$), 2.19 (s, $CH_3CN$), 1.18 (d, 2 H, $H_{anti}$) ppm. $^{13}$C NMR (100.6 MHz, $[D_7]$DMF, 253 K): $\delta$ = 123.7 (Cb), 120.3 (Cc), 114.7 (Ca), 112.5 (Cd), 75.2 ($H_{meso}$), 73.1 (C2), 72.3 (C1), 70.9 (C1′), 57.6 ($C_{anti/syn}$), 1.34 ($CH_3CN$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ = 482 nm, $\varepsilon$ = 1377 $cm^{-1} mol^{-1} dm^3$.

**Preparation of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L2)Br]$ (3):** To a yellow solution of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(NCCH_3)_2Br]$ (0.177 g, 0.5 mmol) in dichloromethane was added **L2** (0.278 g, 0.5 mmol). The dark-red solution formed was stirred at room temperature for 30 min. Addition of *n*-hexane resulted in the formation of a red solid which was filtered, washed with *n*-hexane and dried under vacuum. Yield 0.382 g (66%). Elemental analysis for $\mathbf{3}\cdot 3CH_2Cl_2\cdot 2CH_3CN$ ($C_{41}H_{40}N_5O_4Cl_6Fe_2BrMo$) (1167.05): calcd. C 42.20, H 3.45, N 6.00; found C 41.73, H 3.26, N 6.00. $^1$H NMR (400 MHz, $[D_7]$DMF, 253 K): $\delta$ = 9.10 (br., NH), 8.54 (d, 1 H, Ha), 7.75 (m, 1 H, Hb), 7.53 (d, 1 H, Hd), 7.39 (t, 1 H, Hc), 5.91 ($CH_2Cl_2$, 6 H), 5.13 (br., 2 H, HI), 4.91 (br., 2 H, HII), 4.73 (m, 2 H, H1), 4.46 (m, 2 H, H2), 4.44 (s, 5 H, HI′), 4.23 (s, 5 H, H1′), 3.76 (m, 1 H, $H_{meso}$), 3.30 (d, 2 H, $H_{syn}$), 2.12 ($CH_3CN$, 6 H), 1.18 (d, 2 H, $H_{anti}$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ = 482 nm, $\varepsilon$ = 3750 $cm^{-1} mol^{-1} dm^3$.

### Crystallography

Red single-crystals of $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(L2)Br]$ (**3**) of suitable quality for X-ray diffraction were obtained by vapour diffusion of *n*-hexane into a solution of the complex in $CH_2Cl_2$.

**Crystal Data:** $C_{35}H_{30}BrCl_2Fe_2MoN_3$, $M_r$ = 915.07; monoclinic, space group $P2_1/n$, $Z$ = 4, $a$ = 15.784(17), $b$ = 12.632(14), $c$ = 18.170(21) Å, $\beta$ = 105.33(1)°, $V$ = 3494(7), $Z$ = 4, $\rho$(calc) = 1.740 $Mg m^{-3}$, $\mu$(Mo-$K_\alpha$) = 2.512 $mm^{-1}$. X-ray data were collected at room temperature on a MAR research plate system using graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at Reading University. The crystals were positioned at 70 mm from the image plate. 95 frames were taken at 2° intervals using an appropriate counting time. Data analysis was performed with the XDS program.[26] Intensities were corrected for absorption effects using the DIFABS program.[27] 21894 reflections were collected and merged to 6467 unique reflections giving an $R_{int}$ of 0.0449. The structure was solved by direct methods and by subsequent difference Fourier syntheses and refined by full-matrix least-squares on $F^2$ using the SHELX-97 system programs.[28] The $CH_2Cl_2$ solvent molecule was found to be disordered over two positions and the two chlorine atoms were refined in two alternative tetrahedral positions with occupancy factors of 1 – $x$ and $x$, $x$ being equal to 0.657(9). In addition, the C–Cl distances were constrained at 1.778 Å. Aniso-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tropic thermal parameters were used for the remaining non-hydrogen atoms. The hydrogen atoms bonded to the carbon and nitrogen atoms were included in the refinement in calculated positions with isotropic parameters equivalent to 1.2 times those of the atom to which they are attached. The protons and the hydrogen atoms were not located from the Fourier difference maps and their positions were not included in the refinement. The residual electronic density ranging from –1.157 to 1.480 e Å$^{-3}$ was within expected values. The final refinement of 433 parameters converged to final $R$ and $R_w$ indices $R_1 = 0.0664$ and $wR_2 = 0.1217$ for 5705 reflections with $I > 2\sigma(I)$ and $R_1 = 0.0767$ and $wR_2 = 0.1257$ for all 6467 *hkl* data. Molecular diagrams presented were drawn with the PLATON graphical package software.[29]

CCDC-603243 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details**

Density functional calculations[16] were carried out with the Amsterdam Density Functional program (ADF2005).[18] Gradient corrected geometry optimisations,[30] without any symmetry constraints, were performed using the Local Density Approximation of the correlation energy (Vosko, Wilk and Nusair's)[31] and the Generalised Gradient Approximation (Becke Perdew[32,33] exchange and correlation corrections).

A triple-ζ Slater-type orbital (STO) basis set augmented by one polarisation function was used for Mo, Fe, N, O, C and H. A frozen core approximation was used to treat the core electrons: (1s) for N, C and O; ([1–2]s, 2p) for Fe and ([1–3]s, [2–3]p, 3d) for Mo. The calculations were carried out on the crystal structure described above for complex **3** and the structure of L1[10] without any modifications. Geometries for **L2** and complex **2** were based on these structures.

# Substituted Ring-Fused Yttrium Derivatives – X-ray Crystal Structures of $[(L'YCl_2{\cdot}THF)_2LiCl{\cdot}2THF]$ and $[\{L'YCl(OH)\}_6{\cdot}2THF]$ (L′ = 2-Phenyl-4,5,6,7,8-hexahydroazulenyl)

**Gino Paolucci,*[a] Manuela Vignola,[a] Alessandra Zanella,[a] Valerio Bertolasi,[b] Eleonora Polo,*[c] and Silvana Sostero[c]**

**Keywords:** Yttrium / Fused-ring systems / Olefin polymerization

The reaction of lithium salts of ring-fused ligands (L), where the ring fused to the cyclopentadienyl moiety is a saturated one (six, seven, or eight carbon atoms), with $YCl_3$ in THF in 2:1 and 1:1 molar ratios affords complexes of formula $[L_2YCl]_2$ and $[(LYCl_2{\cdot}THF)_2LiCl{\cdot}2THF]$, respectively. Here we report the synthesis, spectroscopic characterization, and X-ray crystal structure of $[(L'YCl_2{\cdot}THF)_2LiCl{\cdot}2THF]$ (L′ = 2-phenyl-4,5,6,7,8-hexahydroazulenyl), together with the crystal structure of the hexameric species $[\{L'YCl(OH)\}_6{\cdot}2THF]$, which was quite unexpectedly isolated during the attempted crystallization of the latter complex and is probably formed by partial hydrolysis of that complex. The activity of the new complexes towards ethylene and 1-hexene polymerization reactions was also tested.

## Introduction

The chemistry of group 3 organometallics has undergone a spectacular growth in the past two decades.[1] Besides their activity as catalysts and reagents for a number of reactions,[2] they are also reckoned to be excellent models[3] and very active catalysts for Ziegler–Natta polymerizations of olefins, often without the aid of activators or co-catalysts.

Lanthanide chemistry has been dominated mainly by cyclopentadienyl complexes[4] because this family of ligands allows a wide range of modifications of the environment at the metal center through simple variation of the substitution pattern. Despite the interesting results thus far obtained, their high sensitivity to air and moisture, polar solvents,[5] and reagents[5,6] makes their application on an industrial scale still quite difficult. Furthermore, lanthanides with unsubstituted cyclopentadienyl ligands are almost insoluble in hydrocarbon solvents and usually show low activity.[7] Due to the delicate balance required in the ligand substitution pattern, it is advisable to find a family of cyclopentadienyl ligands provided with a more versatile structure and also capable of imparting higher stability and better solubility in most common organic solvents. In the framework of our research for metallocenes suitable for application in homogeneous catalysis, we have recently[8] synthesized several froup 4 ring-fused metallocenes where the ring (six, seven, or eight carbon atoms) fused to the cyclopentadienyl moiety is a saturated one. Besides their higher solubility, stability, and resistance to hydrolysis in comparison with the corresponding unsaturated counterparts, these complexes proved to be interesting polymerization catalysts,[9] since their particular structure introduces a conformational flexibility that can be finely tuned by varying the size of the cycloalkyl-ring and by introducing different substituents on the cyclopentadienyl ring. Here, we report the reactions of some ligands of this family with yttrium trichloride in 1:1 and 2:1 molar ratios as a test for lanthanides to check if they can produce more stable and soluble complexes for catalytic applications.

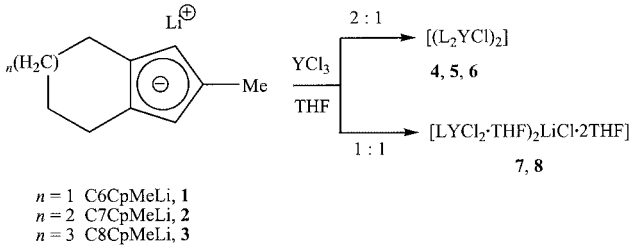
## Results and Discussion

### Synthesis and Characterization of Yttrium Complexes

The lithium salts (C6CpMe)Li (**1**; HL = 2-methyl-4,5,6,7-tetrahydro-1*H*-indene), (C7CpMe)Li (**2**; HL = 2-methyl-1,4,5,6,7,8-hexahydroazulene, and (C8CpMe)Li (**3**; HL = 2-methyl-4,5,6,7,8,9-hexahydro-1*H*-cyclopenta[8]annulene, prepared according to the literature procedures,[9a] were treated with $YCl_3$ in a 2:1 molar ratio to afford the corresponding complexes $[L_2YCl]_2$ with L = C6CpMe (**4**),

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

C7CpMe (**5**), and C8CpMe (**6**), and in a 1:1 ratio to give the complexes $[(LYCl_2{\cdot}THF)_2LiCl{\cdot}2THF]$ with L = C7CpMe (**7**) and C8CpMe (**8**); see Scheme 1.



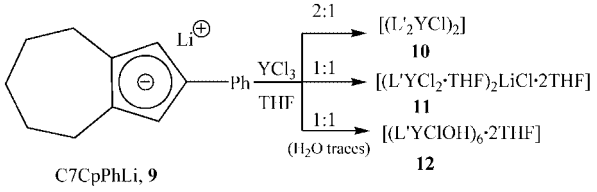
Scheme 1. Synthesis of the 2-methyl-substituted complexes.

The resulting complexes, which were isolated as dusty solids by precipitation with *n*-hexane from toluene or $CH_2Cl_2$ solutions, are also completely soluble in diethyl ether and THF. Analytical (elemental analyses and MS data) and NMR ($^1H$ and $^{13}C$; assignments by HMQC and HMBC experiments) data were consistent with the given formulations.

## Crystal Structures

Crystals of complexes **4**, **6**, **7**, and **8** were obtained by slow evaporation of concentrated $CH_2Cl_2$ solutions, but, despite repeated attempts, they were not suitable for X-ray analysis. This difficulty in obtaining ordered structures is probably due both to the flexibility of the saturated ring and to the small size of the methyl group. Only complex **5** gave crystals suitable for X-ray diffraction, but they did not withstand the treatment (Fomblin F06206R or dehydrated Nujol) necessary to protect them from air and moisture during X-ray data acquisition.

Since the reactivity, stability, and solubility of lanthanide compounds are highly dependent on the steric hindrance of the ligand preventing oligomer formation, we decided to substitute the methyl group in the 2-position of the ligands for a phenyl group in order to obtain more ordered crystals. We chose the ligand with a saturated ring of seven carbon atoms since it was the only one that gave acceptable crystals for **5** and **7**. Treatment of lithium 2-phenyl-1,4,5,6,7,8-hexahydroazulenyl (L′, **9**)[9b] with $YCl_3$ in a 2:1 or 1:1 molar ratio, afforded complexes $[(L'_2YCl)_2]$ (**10**) and $[(L'YCl_2{\cdot}THF)_2LiCl{\cdot}2THF]$ (**11**), respectively (Scheme 2).



Scheme 2. Synthesis of the 2-phenyl-substituted complexes.

Crystals suitable for X-ray diffractometry studies were obtained only in the case of complex **11**. While attempts to protect the crystals with Fomblin failed, the use of anhydrous Nujol allowed X-ray data collection at 150 K; this confirmed the analytical and NMR spectroscopic data, which correspond to a complex of formula $[(L'YCl_2{\cdot}THF)_2LiCl{\cdot}2THF]$ (L′ = C7CpPh; Figure 1).

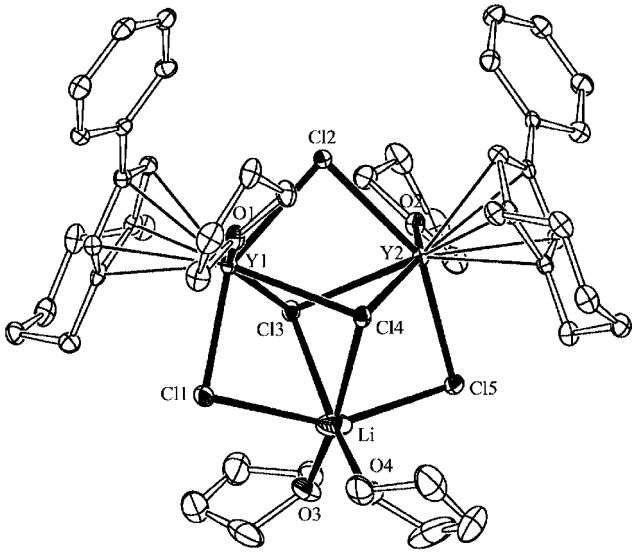


Figure 1. ORTEP[10] view of complex **11** displaying the thermal ellipsoids at 30% probability. The hydrogen atoms have been omitted for sake of clarity.

The structure (Figure 1, and Tables S1 and S2 in the Supporting Information) consists of a trimetallic complex where two atoms of yttrium and one atom of lithium, in a distorted octahedral coordination, are bridged by three μ-Cl (Cl1, Cl2, and Cl5) and two $\mu_3$-Cl (Cl3 and Cl4) anions. Each Y atom is coordinated to four chloride ions, an $\eta^5$-cyclopentadienyl ring of the 2-phenyl-1,4,5,6,7,8-hexahydroazulenyl ligand, and a molecule of THF, while the lithium cation is coordinated to four Cl ions (Cl1, Cl3, Cl4, and Cl5) and two molecules of THF. The six Y–C1 bonds involved in the formation of Y–Cl–Y bridges display distances in the range 2.677(1)–2.860(1) Å (2.77 Å on average), and are slightly longer than those observed in dimeric bis[(μ-Cl)$Y^{III}$(cyclopentadienyl)] complexes (2.66–2.70 Å).[11–13] This Y–Cl lengthening can be justified by the presence of a μ-Cl bridge between yttrium atoms and two $\mu_3$-Cl bridges which involve all three metal centers. The remaining μ-Cl1 and μ-Cl5 chlorides connecting yttrium atoms with lithium display shorter Y–Cl distances of 2.607(2) and 2.627(1) Å, in agreement with those found in the range 2.62–2.65 Å in similar Y–Cl–Li fragments.[14,15]

During our attempts to finding the appropriate crystallization solvents for complex **11**, in one crop we isolated several crystals stable to Fomblin treatment which allowed crystal data collection. Quite unexpectedly, they turned out to be the partial hydrolysis product of **11**, most probably caused by slight traces of water in the crystallization solvent. The results of the fast X-ray data collection at 120 K revealed the structure of an organometallic yttrium cluster, namely $[\{L'YCl(OH)\}_6{\cdot}2THF]$ (**12**; Figure 2 and Tables S3 and S4 in the Supporting Information). It is well known

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

that hydrolysis and oxidation reactions are a common mode of decomposition for organometallic complexes of yttrium and the f elements, giving in most cases organometallic species containing M–OH or M–O–O–M bonds.[16–18]

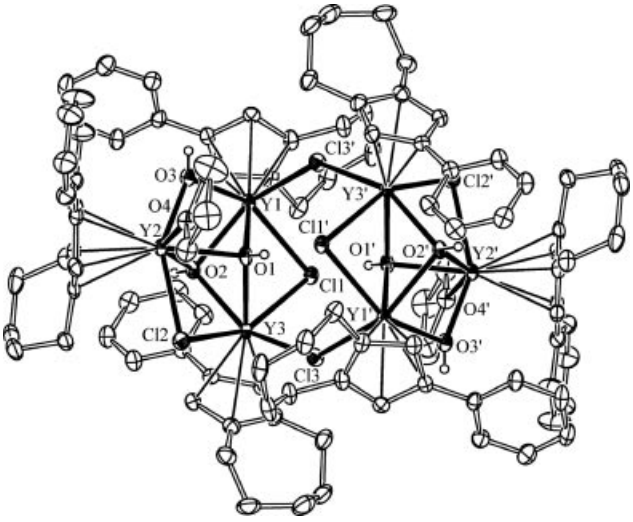

Figure 2. ORTEP view of complex **12** displaying the thermal ellipsoids at 30% probability. The hydrogen atoms have been omitted for sake of clarity.

The $^1$H NMR spectrum of crystals of complex **12** is quite similar to that of **11** except for the presence of a very broad singlet at $\delta$ = 2.73 ppm that can be attributed to the OH group. The IR spectrum in $CH_2Cl_2$ solution shows an OH stretch at 3540 cm$^1$.

Complex **12** is a hexamer where two trimetallic clusters of yttrium atoms are held together, around a center of symmetry, by two μ-Cl3 chlorides between Y1 and Y3 (Figure 3). In each trimer the yttrium atoms are surrounded by an $\eta^5$-bonded cyclopentadienyl ring belonging to a 2-phenyl-1,4,5,6,7,8-hexahydroazulenyl ligand and bridged by chloride and hydroxy groups. In particular, the three Cl1, Cl2, and O3H anions span the three edges of the triangles formed with the Y atoms, while the $\mu_3$-O1H and $\mu_3$-O2H hydroxy groups triply bridge above and below the triangle formed by the yttrium atoms. The sixfold coordination around Y2 is completed by the oxygen atom of a THF molecule.

Accordingly, the overall geometry about each yttrium atom can be described as a distorted octahedral coordination. The Y–(μ-Cl) distances (2.66–2.74 Å) are in agreement with those observed in dimeric bis[(μ-Cl)Y$^{III}$(cyclopentadienyl)] complexes. Furthermore, as observed in other compounds,[16–19] the Y–(μ-OH) distances of 2.230(6) and 2.216(4) Å for Y1–O3 and Y2–O3, respectively, are shorter than those of Y–($\mu_3$-OH), which are in the range 2.34–2.43 Å. In both complexes the Y–Cp(cyclopentadienyl centroid) bond length (2.37–2.40 Å) and the Y–O(THF) distance of 2.338(6) Å are in accordance with the respective values observed in other cyclopentadienylyttrium derivatives.[20–23]

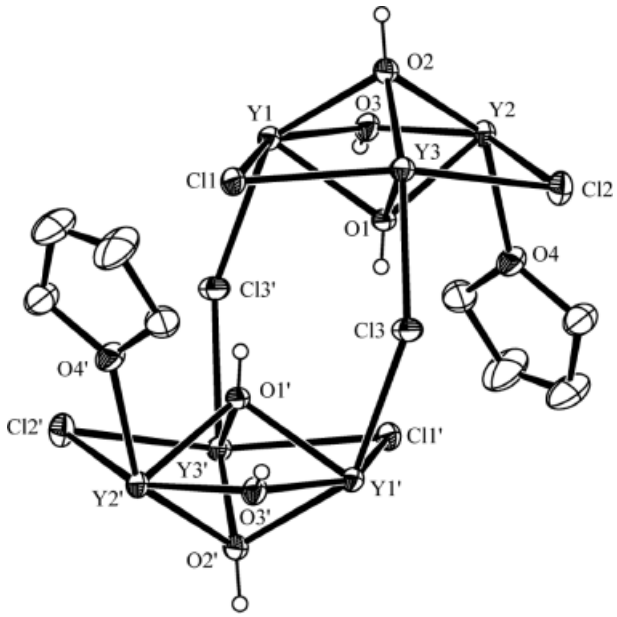

Figure 3. Diagram of the metal, halogen, and hydroxy framework of complex **12**, including the coordinated THF molecules.

## Polymerization Studies

We have examined the activity of the new yttrium complexes, with MAO as co-catalyst, as a preliminary test for their polymerization activity. It is known[2] that organolanthanide complexes often do not require a co-catalyst or an activator to show high activity, but they must be previously converted into the corresponding sterically demanding alkyl derivatives [(trimethylsilyl)methyl or bis(trimethylsilyl)-methyl], to prevent β-alkyl elimination, and as intermediates to the more unstable, but much more active, hydrides.

The bis(cyclopentadienyl) complexes **4**, **5**, **6**, and **10** did not show any activity towards ethene polymerization, while the mono(cyclopentadienyl) complexes **7** and **11**, which have a more open coordination sphere around the metal center, show a moderate activity (Table 1). This result can be interpreted by taking into account the fact that only a limited number of mono(cyclopentadienyl) half-sandwich rare-earth complexes of the type [($\eta^5$-$C_5R_5$)Ln$X_2$(L)$_n$] have been synthesized, and their catalytic performance is often hampered by "ate complex" formation with concomitant alkali metal salt incorporation.[24] We also noticed some differences between the polymers obtained with the methyl-substituted (**7**) and phenyl-substituted (**11**) derivatives. While with the methyl-substituted complex **7**, after the usual work-up, a single fraction of highly linear polyethylene was produced (single peak at $\delta$ = 27.7 ppm in the $^{13}$C NMR spectrum), with the phenyl-substituted complex **11** the yield was almost twice as high but the solid consisted of two fractions, the first (43%) of which is similar to the polymer isolated with the catalyst **7** and the second (57%) of which contains a mixture of oligomers. Apparently this different behavior can be attributed to the influence of the substituent in the ancillary ligand. It is likely that the methyl group, which exerts a symmetrical steric hindrance around the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metal center, produces a more homogeneous material than the phenyl with its different space occupancy. We also tried the polymerization of a more sterically demanding monomer, 1-hexene, but we could not get any polymer. In structurally similar achiral lanthanocenes,[2e,25] which are also inactive towards 1-alkene polymerization, this negative result has been attributed to the formation of stable $\eta^3$-allyl type complexes.[26]

Table 1. Results of ethane and 1-hexene polymerizations.

| Complex | Monomer | Activity[a] | Oligomers [%] |
|---|---|---|---|
| **4**, **5**, **6**, **10** | ethene[b] | – | – |
| **7** | ethene[b] | 820 | 7 |
| **11** | ethene[b] | 1650 | 57 |
| **7** | 1-hexene[c] | – | – |
| **11** | 1-hexene[c] | – | – |

[a] $g_{Pol}(mmol_Y\,h\,atm)^{-1}$. [b] Reaction conditions: toluene: 100 mL, [Y] = $8\times10^{-6}$ M, [MAO]/[Y] = 1100, $t_{rxn}$ = 24 h, room temp. [c] Reaction conditions: toluene: 100 mL, [Y] = $8\times10^{-6}$ M, [MAO]/[Y] = 1875, $t_{rxn}$ = 24 h, room temp.

## Conclusions

Novel unbridged bicyclic yttrium complexes containing six-, seven-, and eight-membered saturated rings fused to a cyclopentadienyl moiety substituted in position 2 ($CH_3$, Ph) have been synthesized with 2:1 and 1:1 ligand/metal ratios, and fully characterized. Unlike their analogous cyclopentadienyl derivatives, these complexes are very soluble in most common organic solvents but are highly sensitive to air and moisture. The crystal structure of complex **11** shows its dimeric nature, thus confirming that the high coordinative unsaturation of the monomer in the absence of high steric hindrance favors the formation of dimeric yttrium species. Quite unexpectedly, we have been able to isolate and fully characterize the hexameric yttrium organometallic cluster **12**, which is probably formed by the reaction of **11** with traces of water in the crystallization solvent. The yttriocenes **4**, **5**, **6**, and **10**, in combination with MAO as cocatalyst, are inactive in the polymerization of ethylene and 1-hexene, while complexes **7** and **11** show a low reactivity towards ethene polymerization and are also inactive towards 1-hexene. These unsatisfactory results can be attributed to the probably dimeric nature of the complexes, which is maintained after MAO activation, thus preventing access of the olefin to the reactive center due to steric hindrance. Further studies are necessary to modify the chloro complexes (i.e., by substitution with bulky alkyl groups) in order to produce monomeric yttrium species, which should be more efficient polymerization catalysts.

## Experimental Section

**General procedures:** All manipulations were carried out under an oxygen- and moisture-free atmosphere in a Braun MB 200 GII glove box. All solvents were thoroughly deoxygenated and dehydrated under argon by refluxing and distillation over a suitable drying agent (*n*-hexane, toluene, and THF over Na or K/benzophenone ketyl; $CH_2Cl_2$, $CD_2Cl_2$, and $CDCl_3$ over $CaH_2$; $C_6D_5N$ over KOH). $YCl_3$ (Aldrich) was used as received. Nujol (Aldrich) was degassed and dehydrated by reflux over potassium. Fomblin (ABCR) F06206R, viscosity 1600cSt, was degassed prior to use. The ligands C6CpMeH,[8] C6CpMeLi (**1**),[8] C7CpMeH,[8] C8CpMeH,[8] and C7CpPhH[9a] were prepared according to literature methods. Microanalyses were performed at the Istituto di Chimica Inorganica e delle Superfici, CNR, Padova. The Li contents of the complexes were determined by ICP using an ICP-MS Agilent 7500 apparatus. Mass spectra were recorded with a Finnigan Trace MS equipped with a probe for the direct introduction of the sample (EI = 70 eV, $T_{probe}$ = 120–150 °C). $^1H$ and $^{13}C$ NMR spectra were obtained for $CDCl_3$ or $CD_2Cl_2$ solutions with a Bruker AMX 300 spectrometer operating at 300 and 100.61 MHz, respectively. 2D-Heterocorrelated COSY experiments (HMQC and HMBC) allowed the identification of all $^1H$ and $^{13}C$ resonances.

**Lithium Salts of the Ligands. General Synthetic Procedure:** The starting diene (14 mmol) was suspended in *n*-hexane at –80 °C. *n*-Butyllithium (14 mmol) was then added dropwise, whilst stirring, and the solution was slowly allowed to reach room temperature (about 4 h) and stirred overnight. The lithium salt that separated from the solution was isolated by centrifugation, washed several times with *n*-hexane, and dried under vacuum to give a dusty solid.

**2-Methyl-1,4,5,6,7,8-hexahydroazulenyllithium (2):** White solid. Yield: 1.94 g (90%). $^1H$ NMR ([D$_5$]pyridine): $\delta$ = 1.73–1.94 (m, 6 H, C-CH$_2$-C$H_2$-), 2.43 (s, 3 H, C$H_3$), 2.85 (br. s, 4 H, -C-C$H_2$-CH$_2$-), 5.86 (s, 2 H, -C*H*-,Cp) ppm.

**2-Methyl-4,5,6,7,8,9-hexahydro-1*H*-cyclopenta[8]annulenyllithium (3):** White solid. Yield: 2.22 g (88%). $^1H$ NMR ([D$_5$]pyridine): $\delta$ = 1.57–1.74 (m, 8 H, C-CH-C$H_2$-), 2.41 (s, 3 H, C$H_3$), 2.68–2.74 (m, 4 H, -C-C$H_2$-CH$_2$-), 5.86 (s, 2 H, -C*H*-, Cp) ppm.

**2-Phenyl-1,4,5,6,7,8-hexahydroazulenyllithium (9):** Pink-white solid. Yield 1.82 g (60%). $^1H$ NMR ([D$_5$]pyridine): $\delta$ = 1.47–1.65 (m, 6 H, C-CH-C$H_2$-), 2.48 (m, 4 H, -C-C$H_2$-CH$_2$-), 6.11 (s, 2 H, -C*H*-, Cp), 6.50 (t, $^3J_{H,H}$ = 7.7 Hz, 1 H, *meta*-C$_5$H$_6$), 6.90 (t, $^3J_{H,H}$ = 7.7 Hz, 2 H, *para*-C$_5$H$_6$), 7.42 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, *ortho*-C$_5$H$_6$) ppm.

**Yttrium Complexes. General Synthetic Procedure:** $YCl_3$ (1.0 mmol) was dissolved in warm THF (30 mL) and cooled to room temperature. A solution of the lithium salt (2.0 or 1.0 mmol) dissolved in THF (20 mL) was then added with vigorous stirring at room temperature, and the reaction mixture stirred overnight. The solvent was then removed under reduced pressure, the residue washed with dichloromethane (3 × 10 mL), and separated from LiCl, when necessary, by centrifugation. The yellow solution was concentrated (to about 10 mL) and left at –25 °C for several days to give microcrystals.

**Bis[(μ-chloro){bis[η$^5$-(2-methyl-4,5,6,7-tetrahydro-1*H*-indenyl)]-yttrium}] (4):** Yellow solid. Yield: 0.508 g (65%). $C_{40}H_{52}Cl_2Y_2$ (781.57): calcd. C 61.47, H 6.71, Cl 9.07; found C 61.05, H 6.95, Cl 8.90. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.65–1.80 (m, 8 H, C-CH$_2$-C$H_2$-), 2.05 (s, 6 H, C$H_3$), 2.50–2.90 (m, 8 H, -C-C$H_2$-CH$_2$-), 5.90 (s, 4 H, -C*H*-, Cp) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 14.9 (*C*H$_3$), 29.9 (-C-CH$_2$-*C*H$_2$-), 33.1(-C-*C*H$_2$-CH$_2$-), 114.6 (-*C*H, Cp), 125.7 (-*C*-CH$_3$), 132.8 (-CH$_2$-*C*=CH-, Cp) ppm. MS ($T_{probe}$ = 120 °C): *m*/*z* (%) 766 (18) [M$^{+\cdot}$ – CH$_3$]$^+$, 751 (22) [M$^{+\cdot}$ – 2CH$_3$]$^+$, 746 (12) [M$^{+\cdot}$ – Cl]$^+$, 731 (10) [M$^{+\cdot}$ – CH$_3$ – Cl]$^+$.

**Bis[(μ-chloro){bis[η$^5$-(2-methyl-1,4,5,6,7,8-hexahydroazulenyl)]-yttrium}] (5):** Yellow solid. Yield: 0.611 g (73%). $C_{44}H_{60}Cl_2Y_2$ (837.68): calcd. C 63.09, H 7.22, Cl 8.46; found C 62.75, H 6.95, Cl 8.65. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.35–1.70 (m, 8 H, C-CH$_2$-C$H_2$-

**Complex 7:** Yellowish solid. Yield: 0.803 g (85%). $C_{38}H_{62}Cl_5LiO_4Y_2$ (944.92): calcd. C 48.30, H 6.61, Cl 18.76, Li 0.73; found C 47.95, H 6.55, Cl 18.45, Li 0.80. $^1$H NMR ($CDCl_3$): $\delta$ = 1.25–1.95 (m, 12 H, -C$H_2$-), 1.90 (br. s, 16 H, THF), 2.00 (s, 6 H, C$H_3$), 2.45–2.80 (m, 8 H, -C-C$H_2$-$CH_2$-), 3.80 (br. s, 16 H, THF), 5.95 (s, 4 H, -C*H*-, Cp) ppm.

**Complex 8:** Yellow solid. Yield: 0.807 g (83%). $C_{40}H_{66}Cl_5O_4LiY_2$ (972.96): calcd. C 49.38, H 6.84, Cl 18.22, Li 0.71; found C 49.15, H 6.75, Cl 18.45, Li 0.80. $^1$H NMR ($CDCl_3$): $\delta$ = 1.10–1.85 (m, 16 H, -C$H_2$-), 1.98 (br. s, 16 H, THF), 2.05 (s, 6 H, C$H_3$), 2.10–2.65 (m, 8 H, -C-C$H_2$-$CH_2$-), 4.04 (br. s, 16 H, THF), 5.72 (s, 4 H, -C*H*-, Cp) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 16.28 (*C*$H_3$), 25.81 (THF), 26.47 (-C-$CH_2$-C$H_2$-$CH_2$-), 27.71 (-C-*C*$H_2$-$CH_2$-$CH_2$-), 33.33 (C-$CH_2$-$CH_2$-*C*$H_2$-), 71.02 (THF), 114.16 (-*C*H, Cp), 123.0 (-*C*–$CH_3$), 129.91 (-$CH_2$-*C*=CH-, Cp) ppm.

**Bis[(μ-chloro){bis[η$^5$-(2-phenyl-1,4,5,6,7,8-hexahydroazulenyl)]-yttrium}] (10):** Deep-yellow solid. Yield: 0.847 g (78%). $C_{64}H_{68}Cl_2Y_2$ (1085.9): calcd. C 70.78, H 6.31, Cl 6.53; found C 70.45, H 6.15, Cl 6.75. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.12–2.10 (m, 12 H, -C$H_2$-), 2.25–2.85 (m, 8 H, -C-C$H_2$-$CH_2$-$CH_2$-), 6.14 (s, 4 H, -C*H*-, Cp), 7.12 (t, $^3J_{H,H}$ = 7.23 Hz, 2 H, *para*-$C_5H_6$), 7.33 (t, $^3J_{H,H}$ = 7.62 Hz, 4 H, 4 H, *meta*-$C_5H_6$), 7.46 (d, $^3J_{H,H}$ = 7.23, 4 H, *ortho*-$C_5H_6$) ppm. MS ($T_{probe}$ = 120 °C): *m/z* (%) 1085 (1) $[M]^{+\cdot}$, 877 (44) $[C_{48}H_{51}Cl_2Y_2]^+$, 667 (2) $[C_{32}H_{34}Cl_2Y_2]^+$, 543 (1) $[C_{32}H_{34}ClY]^+$, 528 (100) $[C_{31}H_{31}ClY]^+$, 493 (28) $[C_{31}H_{31}Y]^+$, 298 (1) $[C_{16}H_{16}Y]^+$, 210 (20) $[C_{16}H_{18}]^+$.

**Complex 11:** Deep-yellow solid. Yield: 0.823 g (77%). $C_{48}H_{66}Cl_5LiO_4Y_2$ (1069.05): calcd. C 53.93, H 6.22, Cl 16.58, Li 0.65; found C 54.10, H 6.05, Cl 16.80, Li 0.70. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.65 (m, 8 H, C-$CH_2$-C$H_2$-$CH_2$-), 1.78 (m, 4 H, C-$CH_2$-$CH_2$-C$H_2$-), 1.89 (br. s, 16 H, THF), 2.40–2.53 (m, 8 H, -C-C$H_2$-$CH_2$-$CH_2$-), 3.99 (br. s, 16 H, THF), 6.65 (s, 4 H, -C*H*-, Cp), 7.11 (t, $^3J_{H,H}$ = 7.3 Hz, 2 H, *para*-$C_5H_6$), 7.27 (t, $^3J_{H,H}$ = 7.3 Hz, 4 H, *meta*-$C_5H_6$), 7.43 (d, $^3J_{H,H}$ = 7.3 Hz, 4 H, *ortho*-$C_5H_6$) ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 25.7 (THF), 28.3 (-C-$CH_2$-*C*$H_2$-$CH_2$-), 28.4 (-C-$CH_2$-*C*$H_2$-$CH_2$-), 30.1 (-C-*C*$H_2$-$CH_2$-$CH_2$-), 30.7 (-C-*C*$H_2$-$CH_2$-$CH_2$-), 31.9 (-C-$CH_2$-$CH_2$-*C*$H_2$-), 70.4 (THF), 124.7 (*ortho*-$C_5H_6$), 126.1 (*para*-$C_5H_6$), 128.7 (*meta*-$C_5H_6$), 133.0 (-*C*H, Cp), 142.0 (*ipso*-$C_5H_6$), 142.8 (-*C*–$C_5H_6$), 143.6 (-$CH_2$-*C*=CH-, Cp) ppm. Crystals suitable for X-ray analysis were obtained from a very concentrated $CH_2Cl_2$ solution after four days at –26 °C.

**Complex 12:** Yellow solid, $C_{104}H_{108}Cl_6O_8Y_6$ (2232.12): calcd. C 55.96, H 5.73, Cl 9.53; found C 55.80, H 5.60, Cl 9.40. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 3540 cm$^{-1}$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.55–1.71 (m, 8 H, C-$CH_2$-C$H_2$-$CH_2$-), 1.71–1.83 (m, 4 H, C-$CH_2$-$CH_2$-C$H_2$-), 1.89 (br. s, 2.7 H, THF), 2.37–2.55 (m, 8 H, -C-C$H_2$-$CH_2$-$CH_2$-), 2.73 (br. s, 1 H, OH), 3.97 (br. s, 2.7 H, THF), 6.66 (s, 4 H, -C*H*-, Cp), 7.12 (t, $^3J_{H,H}$ = 7.0 Hz, 2 H, *para*-$C_5H_6$), 7.27 (t, $^3J_{H,H}$ = 7.0 Hz, 4 H, *meta*-$C_5H_6$), 7.44 (d, $^3J_{H,H}$ = 7.0 Hz, 4 H, *ortho*-$C_5H_6$) ppm.

**X-ray Crystallographic Structure Determinations for 11 and 12:** The crystal data for compounds **11** and **12** (Table 2) were collected at 120 and 150 K, respectively, using a Nonius Kappa CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation. The data sets were integrated with the Denzo-SMN package[27] and corrected for Lorentz, polarization, and absorption (SORTAV[28]) effects. The structures were solved by direct methods (SIR97[29]) and refined using full-matrix least-squares with all non-hydrogen atoms anisotropic and hydrogens included at calculated positions as riding on their carrier atoms. All calculations were performed using SHELXL97[30] and PARST[31] implemented in WINGX[32] system of programs.

Table 2. Crystal data for complexes **11** and **12**.

| Compound | **11** | **12** |
|---|---|---|
| Formula | $C_{48}H_{66}Cl_5LiO_4Y_2$ | $C_{104}H_{108}Cl_6O_8Y_6$ |

CCDC-297382 (for **11**) and -297383 (for **12**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Selected interatomic distances and angles are given in Tables S1–S4.

**General Polymerization Conditions:** All manipulations of air- and/or moisture-sensitive materials were carried out under inert atmosphere using either a dual vacuum/nitrogen line and standard Schlenk techniques or in a dry-box under nitrogen atmosphere

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(<10 ppm oxygen, <20 ppm water). MAO (Witco, 10 wt.-% solution in toluene) was used after drying in vacuo (5 h, 50 °C, 0.1 mbar) to remove the solvent and unreacted $AlMe_3$, and was stored under nitrogen. Nitrogen and ethylene were purified by passage through columns of BASF RS-11 (Fluka) and Linde 4-Å molecular sieves. 1-Hexene was deoxygenated and dehydrated under nitrogen by refluxing and distillation over $LiAlH_4$, and stored under nitrogen.

**Ethylene Polymerizations:** A 250-mL glass reactor equipped with a magnetic stirrer was charged with anhydrous toluene (100 mL) and MAO (8.8 mmol) from a syringe. Ethylene was then added until saturation. The polymerization was started by adding a solution of the catalyst (**7** or **11**) (8 μmol; [Al]/[Y] ratio: 1100) in toluene (5 mL) with a syringe under ethylene pressure. After 24 h the reaction was terminated by addition of a small amount of ethanol, and the polymer was precipitated by pouring the whole reaction mixture into ethanol (600 mL) to which concentrated hydrochloric acid (5 mL) had been added. The organic phase was separated, washed with $NaHCO_3$ saturated solution, deionized water, and dried with $MgSO_4$. After filtration, the solvent was evaporated under reduced pressure and the last traces of toluene were eliminated by azeotropic distillation with absolute ethanol (three times). Absolute ethanol was added again and the polymer was collected by filtration, washed with absolute ethanol, and dried overnight under vacuum at 70 °C. If oligomers were produced (as with catalyst **7**), they were retrieved as an oily residue after evaporation of the ethanol from the filtered solution, extraction with pentane, and evaporation of the solvent.

**1-Hexene Polymerizations:** A 250-mL glass reactor equipped with a magnetic stirrer was charged with anhydrous toluene (100 mL), 1-hexene (1 mol/L), and MAO (15 mmol). The polymerization was started by adding a solution of the catalyst (**7** or **11**) (8 μmol; [Al]/[Y] ratio: 1875) in toluene (5 mL) with a syringe under nitrogen pressure. After 24 h the polymerization was quenched by adding a small amount of ethanol. The contents of the reactor were poured into a conical flask, and a solution of concentrated HCl in ethanol (200 mL; 15% by volume) was added. After 30 min stirring, the mixture was transferred into a separating funnel, the organic phase was separated, washed once with $NaHCO_3$ saturated solution, twice with deionized water, and dried with $MgSO_4$. After filtration, the solvent was removed under reduced pressure. No polymer was obtained.

## Acknowledgments

The authors warmly thank Dr. F. Forlini of ISMAC-C.N.R. (Milano, Italy) for performing the polymerization tests. This work was funded by the MURST PRIN-2004 (prot. 2004030307_3).

# Controlled Synthesis of 3d–4d Heterobimetallic Complexes of a Symmetrical Tetraiminodiphenolate Macrocycle – Structural, Spectroscopic, and Redox Properties

**Bula Dutta,[a] Bibhutosh Adhikary,[b] Ulrich Flörke,[c] and Kamalaksha Nag*[a]**

**Keywords:** Heterobimetallic complexes / Macrocyclic complexes / Palladium / Rhodium / 3d metals(II)

The mononuclear complexes $[Rh(LH_2)Cl_2](ClO_4)\cdot 3H_2O$ (**1**) and $[Pd(LH_2)](ClO_4)_2$ (**2**) of the tetraiminodiphenolate macrocycle $L^{2-}$ have been synthesized by the transmetallation reaction between $[Pb(LH_2)](ClO_4)_2$, and $RhCl_3\cdot xH_2O$ and $Na_2[PdCl_4]$, respectively. In these compounds, the uncoordinated imino nitrogen atoms are protonated and are hydrogen bonded to the phenolate oxygen atoms to stabilize them against hydrolytic cleavage. Using these mononuclear complexes, the following heterodinuclear complexes: $[Rh^{III}Cl_2(L)Pd^{II}](X)$ [X = $ClO_4$ (**3**), $PF_6$ (**4**)], $[Pd^{II}(L)M^{II}(H_2O)_2](ClO_4)_2$ [M = Mn (**5**), Fe (**6**), Co (**7**), Ni (**8**)], $[Pd^{II}(L)M^{II}](ClO_4)_2$ [M = Cu (**9**), Zn (**10**)]; and the dipalladium(II) complex $[Pd_2L](ClO_4)_2$ (**11**) have been synthesized. The crystal structure determined for $[RhCl_2(L)Pd](PF_6)$ (**4**) shows an axially elongated octahedral geometry for $Rh^{III}$ and a square-planar geometry for $Pd^{II}$. In $[Pd^{II}(L)Cu^{II}](ClO_4)_2$ (**9**), both the metal ions lie in the flat plane of the macrocyclic ligand and they are positionally disordered with equal occupancies. The $Cu^{II}$ center has an apically elongated square-pyramidal geometry due to the weak perturbation by an oxygen atom of a perchlorate anion. Complexes **2**, **10**, and **11** on excitation at 400 nm exhibit luminescence at room temperature at 505, 437, and 443 nm, respectively. Spectrofluorimetric titrations of $[Pd^{II}(LH_2)]^{2+}$ with the acetate salts of zinc(II) and palladium(II) have shown that the formation of $[Pd(L)Zn]^{2+}$ and $[Pd_2L]^{2+}$ complex species are accompanied by blue shift of luminescence with increased and reduced emission intensities, respectively. The hyperfine-shifted $^1H$ NMR spectral features of the paramagnetic compounds **7**–**9** have been analyzed by determining their longitudinal ($T_1$) and transverse ($T_2$) relaxation times. Cyclic and square-wave voltammetric measurements have been carried out for complexes **7**–**9** in acetonitrile. For complexes **8** and **9**, reversible one-electron reduction occurs with $E_{1/2}$ = –0.10 V for $Pd^{II}Cu^{II}/Pd^{II}Cu^{I}$ and –0.80 V for $Pd^{II}Ni^{II}/Pd^{II}Ni^{I}$ versus Ag/AgCl. Complex **7** undergoes irreversible reduction for cobalt(II) at –0.78 V.

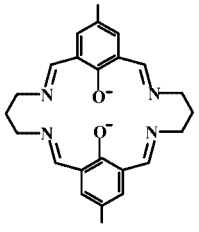
## Introduction

Over the past three decades extensive studies have been made on the chemistry of the phenolate-bridged tetraiminodiphenol macrocyclic complexes[1–17] derived from the symmetrical ligand $L^{2-}$ (**I**). The focus of interest in complexes of this sort has been to study the implications of cooperative metal–metal interactions that are manifested in spin-exchange couplings,[6–15] redox activities,[4,8,9a,11] and bimetallic reactivities.[9b,16]



**I** ($L^{2-}$)

There is considerable interest in involving heterobimetallic complexes in catalytic reactions by way of dual activation of substrates.[18–20] Heterobimetallic complexes also have distinct potentiality to act as precursors for producing bimetallic nanoparticles, especially those containing platinum metals and first-row transition metals.[21] The synthesis of heterobimetallic complexes where the two metal ions are held in close proximity by a bridging ligand is a nontrivial problem, particularly when the ligand is symmetrical in nature. The most common problem in such cases is either the preferential formation of a particular homodinuclear complex species or the statistical formation of a mixture of two products. Clearly, the development of a controlled synthetic route for the generation of heterobimetallic complexes is an important task. We have introduced a controlled systematic route to synthesize bimetallic systems of the symmetric

macrocyclic ligand $L^{2-}$ incorporating 4d–3d metal ions. Herein we report the synthesis, structures, and spectroscopic properties of the mononuclear complexes $[M(LH_2)]^{n+}$ ($M = Rh^{III}$, $Pd^{II}$; $n = 3$, 2) and the heterodinuclear complexes $[RhCl_2(L)Pd]^+$ and $[Pd(L)M]^{2+}$ ($M = Mn^{II}$, $Fe^{II}$, $Co^{II}$, $Ni^{II}$, $Cu^{II}$, $Zn^{II}$). The X-ray crystal structures of two heterodinuclear complexes $[RhCl_2(L)Pd](PF_6)$ and $[Pd(L)Cu](ClO_4)_2$ have been determined. Paramagnetic proton NMR studies have provided information about the influence of electron spins on the hyperfine-shifted spectral patterns of $[Pd(L)M^{II}]^{2+}$ (M = Fe, Co, Ni, Cu) complexes.

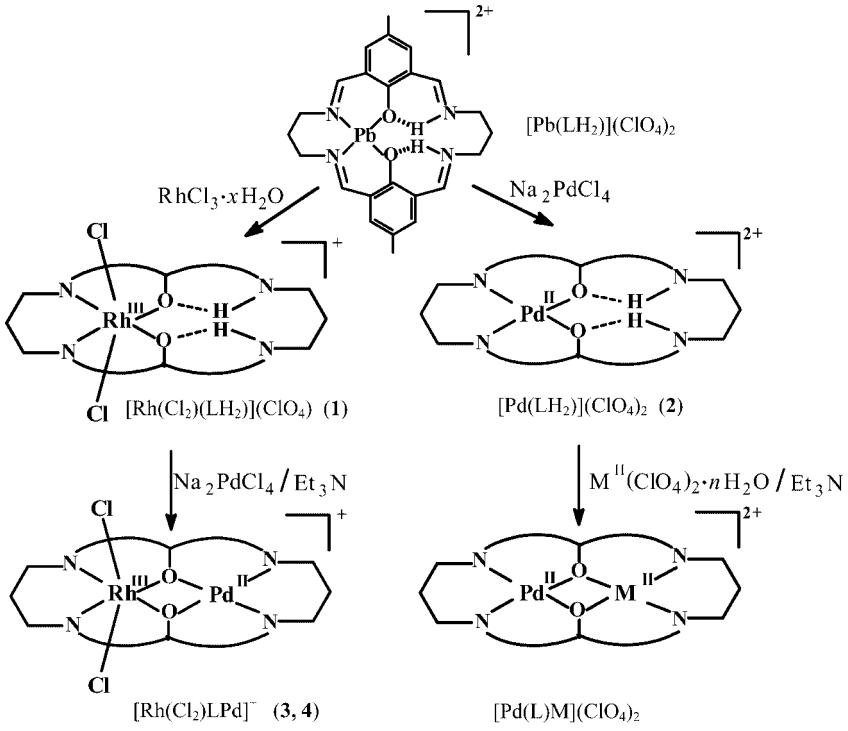
## Results and Discussion

### Syntheses

The synthesis of heterobimetallic complexes involving 3d–4d metal ions and the symmetrical compartmental macrocyclic ligand $L^{2-}$ would ideally require mononuclear precursor complexes in which one compartment of the ligand is metal-free. However, for the ligand $L^{2-}$ such mononuclear complexes are generally not obtainable.[1,2,5,16b] It has been reported[22] that metal-directed macrocyclization usually does not take place with nonlabile platinum metals. Indeed, we have failed to produce mononuclear or dinuclear complexes of palladium(II) and rhodium(III) of $L^{2-}$ through a [2+2] condensation reaction between 2,6-diformyl-4-methylphenol and 1,3-diaminopropane in the presence of $Na_2[PdCl_4]$ or $RhCl_3{\cdot}xH_2O$. In both cases, a mixture of reaction products was obtained which consisted of, inter alia, amine aldehyde condensed oligomers, metal diamine complexes, and $[Pd_2L']$ or $[RhL'(H_2O)Cl]$ where $H_2L'$ is the [2+1] Schiff base of 2,6-diformyl-4-methylphenol and 1,3-diaminopropane.

To obviate this problem, sometime back we reported the synthesis of a mononuclear lead(II) complex, $[Pb(LH_2)](ClO_4)_2$,[23] by reacting 1 equiv. of lead perchlorate with 2 equiv. each of 2,6-diformyl-4-methylphenol and 1,3-diaminopropane in the presence of acetic acid. In this complex, $LH_2$ represents the macrocycle in the zwitterionic form in which the two uncoordinated imine nitrogens are protonated and are hydrogen-bonded to the metal-bound phenolate oxygens. The utility of $[Pb(LH_2)](ClO_4)_2$ as a precursor to obtain other mononuclear complexes has been demonstrated by us[24] by isolating complexes $[M^{III}(LH_2)(H_2O)Cl](ClO_4)_2{\cdot}nH_2O$ of trivalent labile metal ions such as aluminum, gallium, and indium.

As shown in Scheme 1, the metathetical reaction involving stoichiometric amounts of $[Pb(LH_2)](ClO_4)_2$ and $RhCl_3{\cdot}xH_2O$ or $Na_2[PdCl_4]$ and excess $NaClO_4$ leads to the formation of $[Rh(LH_2)Cl_2](ClO_4){\cdot}3H_2O$ (**1**) and $[Pd(LH_2)](ClO_4)_2$ (**2**). The driving force for the reaction is precipitation of $PbCl_2$ and occupation of its vacant site by rhodium(III) or palladium(II). The palladium(II) complex (**2**), on reaction with a stoichiometric amount of a 3d metal perchlorate $M(ClO_4)_2{\cdot}6H_2O$ (M = Mn, Fe, Co, Ni, Cu, Zn)



Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and triethylamine, affords the heterodinuclear complexes $[Pd(L)M(H_2O)_2](ClO_4)_2$ (**5**–**8**, Mn–Ni), $[Pd(L)Cu](ClO_4)_2$ (**9**), and $[Pd(L)Zn(H_2O)](ClO_4)_2{\cdot}H_2O$ (**10**). If the above reaction is carried out with $Na_2[PdCl_4]$ and $NaClO_4$, the homodinuclear complex $[Pd_2L](ClO_4)_2$ (**11**) is obtained. In contrast to **2**, the reaction of $[RhCl_2(LH_2)](ClO_4){\cdot}3H_2O$ (**1**) with the above-mentioned metal perchlorates, however, failed to produce the desired $[RhCl_2(L)M(H_2O)_n]^+$-type complexes. On the other hand, when **1** is reacted with $Na_2[PdCl_4]$ and triethylamine in the presence of $NaClO_4$ or $NH_4[PF_6]$ the mixed-metal $[RhCl_2(L)Pd](ClO_4)/(PF_6)$ complexes **3**, **4** are readily obtained. This indicates that the *trans* axial chloride ions of **1** sterically inhibit the entry of a second metal ion into the ligand compartment if the coordination number of the incoming metal ion exceeds four. In the case of palladium(II), no difficulty is encountered in obtaining $[RhCl_2(L)Pd]^+$ because of the square-planar geometry of the palladium center.

It needs to be mentioned at this stage that the dipalladium(II) complex $[Pd_2L](BF_4)_2$ has been prepared earlier[16a] by reacting the macrocyclic ligand salt $[H_4L](BF_4)_2$ with palladium(II) chloride or acetate in acetonitrile in the presence of a 10-fold excess of triethylamine. The X-ray crystal structure of this compound has been reported.[16a] Further, the heterodinuclear complex $[PdLNi(CH_3CN)_2](ClO_4)_2$ has been previously synthesized[25] by reacting the much earlier reported mononuclear nickel(II) complex $[Ni(H_2L)](ClO_4)_2{\cdot}H_2O$[1] with palladium(II) acetate in acetonitrile. This compound has also been structurally characterized.[25] We note that the proton NMR spectra reported for $[PdLNi(CH_3CN)_2]^{2+}$ in $CD_3OD$ are similar to those of $[PdLNi(H_2O)_2]^{2+}$ in $CD_3CN$ obtained in this study.

## Crystal Structures

### *[Rh(Cl$_2$)(L)Pd]PF$_6$ (4)*

The structural analysis of complex **4** revealed the presence of the core cation $[Pd(L)RhCl_2]^+$ and one hexafluorophosphate anion. An ORTEP representation of the cation $[Pd(L)RhCl_2]^+$ is shown in Figure 1 and selected interatomic distances and angles are listed in Table 1.

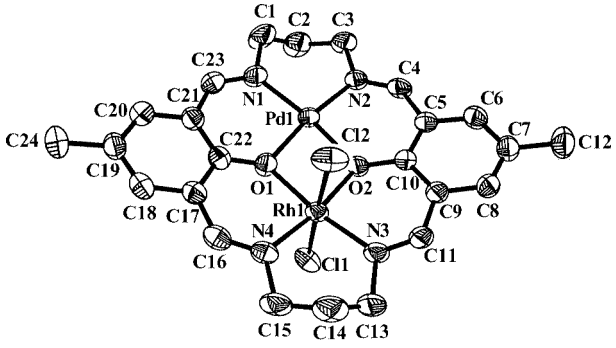


Figure 1. ORTEP representation of the $[Pd(L)Rh(Cl_2)]^+$ cation of complex **4** at the 50% probability level. H atoms omitted.

The structure of the cation of **4** consists of one palladium(II) and one rhodium(III) center bridged by the two phenolate oxygens O(1) and O(2) and they are separated by a distance of 3.150(1) Å. The dihedral angle between the two phenyl rings is 22.76(1)°, indicating significant deviation of the macrocycle from the planarity. For the Pd(1) center the basal plane is provided by the atoms O(1), O(2), N(1), and N(2) [Pd(1)–O(1) 2.022(2) Å, Pd(1)–O(2) 2.024(2) Å, Pd(1)–N(1) 1.980(3) Å, and Pd(1)–N(2) 1.990(3) Å]. These donor atoms are deviated from the mean plane by not more than ±0.010(1) Å and the Pd(1) center lies below the plane by 0.009(1) Å. The Rh(1) center is bonded to the phenolate oxygen atoms O(1) [Rh(1)–O(1) 2.056(2) Å] and O(2) [Rh(1)–O(2) 2.062(2) Å], and the imine nitrogen atoms N(3) [Rh(1)–N(3) 1.984(3) Å] and N(4) [Rh(1)–N(4) 2.001(3) Å]. The mean plane is formed by O(1), O(2), N(3), and N(4) atoms in which the deviations of the donor atoms do not exceed ±0.004(1) Å. The *trans* axial Cl(1) and Cl(2) atoms are placed above and below the metal plane to complete

Table 1. Selected bond lengths [Å] and angles [°] for $[RhCl_2(L)Pd](PF_6)$ (**4**).

the octahedron. The two Rh–Cl distances [Rh(1)–Cl(1) 2.339(1) Å and Rh(1)–Cl(2) 2.306(1) Å] are almost the same, albeit rather long. The Cl(2)–Rh(1)–Cl(1) angle [178.07(4)°] is practically linear. The displacement of Rh(1) from the least-square plane is only 0.003(1) Å.

### *[Pd(L)Cu](ClO$_4$)$_2$ (9)*

Compound **9** is comprised of the cation $[Pd(L)Cu]^{2+}$ and two perchlorate anions. The ORTEP view of the cation is shown in Figure 2. The relevant bond lengths and angles are given in Table 2. The $[Pd(L)Cu]^{2+}$ cation lies on a crystallographic inversion center and thus the $M_2O_2$ ring is planar with M = Pd and Cu centers disordered over both sites (site occupation factor 0.5). The two metal centers are bridged by the two phenolate oxygens O(1) and O(1A) and they are separated by a distance of 3.083(1) Å. The basal plane for either of the metal atoms is formed by the $N_2O_2$ donor atoms and the average metal–donor atom distances are M(1)–O(1) 1.965(4) Å, M(1)–O(1)#1 1.998(4) Å, M(1)–N(1) 1.997(5) Å, and M(1)–N(2) 1.971(6) Å. The deviation of the constituent $N_2O_2$ atoms from the mean plane is 0.024(1) Å and both the metal centers are equally displaced in opposite directions from the mean plane by 0.031(1) Å. The $[Pd(L)Cu]^{2+}$ cation is not perfectly flat, as the atoms C(2) and C(2A) are significantly off [0.62(1) Å] the mean cation plane. Moreover, the perchlorate anions are heavily disordered. The distance between the Cu center and a perchlorate oxygen O(14) is 2.54 Å. This Cu···O distance is not unusual for an apical perchlorate donor on otherwise square-planar copper(II).

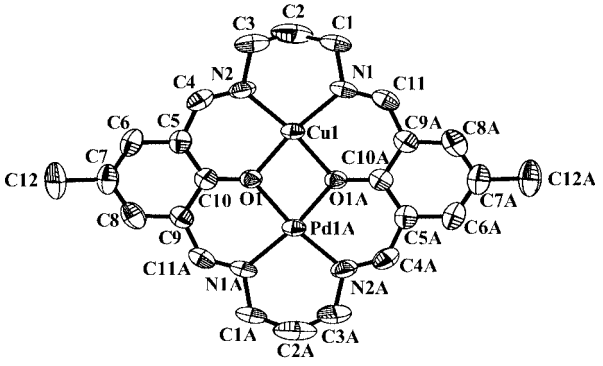

Figure 2. ORTEP representation of the $[Pd(L)Cu]^{2+}$ of complex **9** at the 50% probability level. H atoms omitted. "A" labels indicate symmetry-related atoms (–*x*, –*y* + 1, –*z* + 1).

It should be noted that 0.5:0.5 disorder of the palladium(II) and copper(II) centers over two sites might as well indicate that **9** is a 1:1 mixture of $[Pd_2L](ClO_4)_2$ and $[Cu_2L](ClO_4)_2$ rather than the mixed-metal complex $[Pd(L)Cu](ClO_4)_2$. However, it will be seen in the next section that the mass spectrum of **9** provides clear evidence that it is a truly heterodinuclear complex.

In this context it would be relevant to consider the crystal structures reported for the homodinuclear complexes of palladium(II) and copper(II). In $[Pd_2L](BF_4)_2 \cdot 2CH_3NO_2$,[16a] the average Pd–O, Pd–N, and Pd···Pd distances are 2.015(1), 1.987(6), and 3.1511(6) Å, respectively. The structure determined for the dicopper(II) complex $\{[Cu_2L(H_2O)_2(ClO_4)_2][Cu_2L(H_2O)_2](ClO_4)_2\}$[12b] showed the presence of two different complex units in the unit cell. In one of these units, the dicopper(II) centers are pseudo-octahedral because of *trans* axial coordination by the oxygen atoms of perchlorate and water and the relevant bond lengths are Cu–O 1.985(6) Å, Cu–N 1.956(8) Å, Cu–O(perchlorate) 2.589(10) Å, Cu–O(water) 2.451(9) Å, and Cu···Cu 3.091(3) Å. In the second unit, the copper(II) centers have square-pyramidal geometry with the following bond lengths: Cu–O 1.970(6) Å, Cu–N 1.965(9) Å, Cu–O(water) 2.451(6) Å, and Cu···Cu 3.096(3) Å. Further, in the first unit the copper center is displaced from the equatorial mean plane by only 0.019(4) Å, while in the second unit this displacement, 0.083(6) Å, is greater. A comparison of the structural geometries of the metal centers and the metrical parameters of **9** with the dipalladium(II) and dicopper(II) systems clearly reveals that **9** is a discrete compound.

### Mass Spectra

The electrospray ionization mass spectra (ESI positive) of complexes **1**–**11**, except for **5**, have been measured using their acetonitrile solutions (about $10^{-4}$ mol·dm$^{-3}$). The mononuclear complex **1** shows two peaks due to the cations $[Rh^{III}(Cl_2)(LH_2)]^+$ and $[Rh^{III}(Cl)(ClO_4)(LH_2)]^+$, whereas compound **2** shows peaks due to the cations $[Pd^{II}(LH_2)(ClO_4)]^+$ and $[Pd^{II}(LH_2)]^{2+}$. The heterodinuclear $Rh^{III}Pd^{II}$ compounds **3** and **4** show only a single peak due to the $[Rh^{III}(Cl_2)(L)Pd^{II}]^+$ cation.

For the heterodinuclear $Pd^{II}M^{II}$ complexes (M = Fe, Co, Ni, Cu, Zn) and the homodinuclear $Pd^{II}Pd^{II}$ complex similar spectral features have been observed. These are characterized by the occurrence of two types of positively charged species: $[Pd^{II}(L)M^{II}(ClO_4)]^+$ and $[Pd^{II}(L)M^{II}]^{2+}$, of which the doubly positive-charged ion forms the base peak. Figure 3 shows the cluster of peaks observed for the two types of molecular cations of **7** along with their corresponding simulated spectral patterns. It may be noted that the

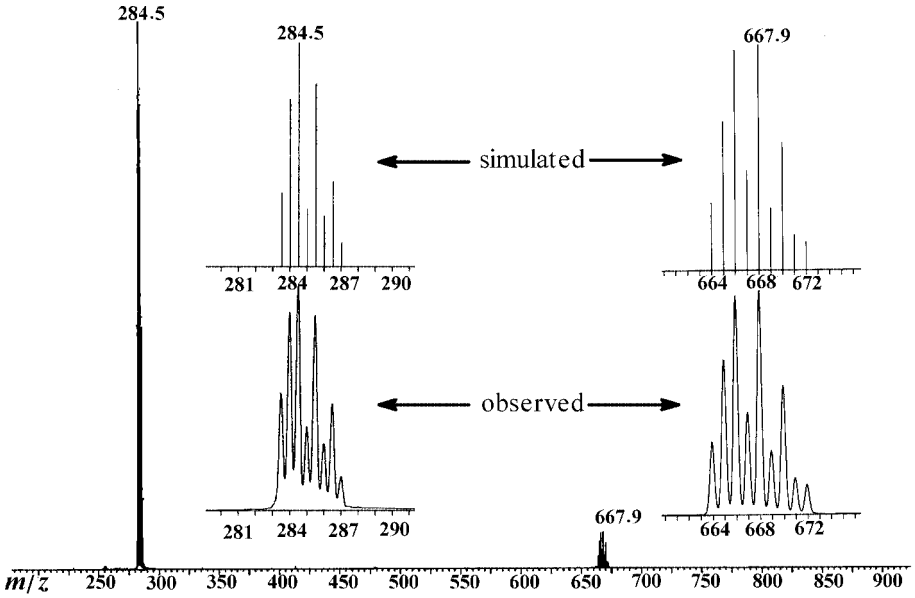

Figure 3. Electrospray ionization mass spectra (ESI-MS+) of $[Pd^{II}(L)Co^{II}](ClO_4)_2$ (**7**) in acetonitrile. Simulated isotropic spectral patterns are compared with the observed major positively charged cationic species.

number of peaks, *m*/*z* values, and the relative peak heights observed for the cations $[Pd^{II}(L)Co^{II}(ClO_4)]^+$ and $[Pd(L)Co]^{2+}$ are in excellent agreement with the calculated spectral patterns obtained by taking into consideration the relative abundances of the isotopes of the constituent elements.

The mass spectrum of the complex $[Pd(L)Cu](ClO_4)_2$ (**9**) has been of particular interest in this context because, as already noted, the X-ray structure of this compound raised the possibility of considering it as a mixture of $[Pd_2L](ClO_4)_2$ and $[Cu_2L](ClO_4)_2$. The spectrum of **9** (shown in Figure S1) depicts the presence of peaks only due to $[Pd(L)Cu(ClO_4)]^+$ with *m*/*z* = 671.9 (10%) and $[Pd(L)Cu]^{2+}$ with *m*/*z* = 287.5 (100%). The observed and calculated isotopic abundance ratio patterns of the positively charged species (see Figure S1, supporting information) are in excellent agreement with each other. Further, the total absence of peaks due to $[Pd_2(L)(ClO_4)]^+$ (715), $[Cu_2(L)(ClO_4)]^+$ (629), $[Pd_2(L)]^{2+}$ (309), and $[Cu_2(L)]^{2+}$ (265) rules out the possibility of **9** as a mixture of the two homodinuclear complexes.

## Infrared Spectra

The IR spectroscopic data of complexes **1**–**11** are given in the Exp. Sect. The $\nu_{C=N}$ stretching vibrations of all the complexes lie between 1650 and 1630 $cm^{-1}$. For the mononuclear complexes **1**, **2** the $\nu_{C=N}$ vibration is observed at 1650 $cm^{-1}$, while for the dinuclear complexes **3**–**11** this band is shifted to lower energy, 1635–1630 $cm^{-1}$. In the mononuclear complexes, a weak band is observed at about 3150 $cm^{-1}$ due to the protonated imine ($\nu_{NH}$), which is hydrogen-bonded to the phenolate oxygen. As expected, this band is not observed in the dinuclear complexes.

## Electronic Spectra

The electronic spectroscopic data for complexes **1**–**11** are listed in Table 3. The mononuclear complexes $[Rh(LH_2)Cl_2](ClO_4)\cdot 3H_2O$ (**1**) and $[Pd(LH_2)](ClO_4)_2$ (**2**) exhibit similar absorption spectral features with a relatively broad band around 406 nm and two intense bands around 260 nm and 220 nm. The latter two bands are due to intraligand charge transfer transitions, whereas the first one seems to be due to ligand (phenolate) to metal charge transfer (LMCT) transition. The spectral patterns observed for the heterodinuclear $Rh^{III}Pd^{II}$ complexes are again similar to those of **1** and **2**, although the LMCT band is shifted to 385 nm.

The heterodinuclear diamagnetic $Pd^{II}M$ (M = Zn, Pd) complexes **10**, **11** also exhibit spectral features as above (Table 3). Significant spectral changes occur when $M^{II}$ is a transition-metal ion. For example, the absorption spectrum of the $Pd^{II}Co^{II}$ complex (**7**) (Figure S2) shows three bands at 970 nm (16 $dm^3\cdot mol^{-1}\cdot cm^{-1}$), 375 nm (36400 $dm^3\cdot mol^{-1}\cdot cm^{-1}$) and 256 nm (177600 $dm^3\cdot mol^{-1}\cdot cm^{-1}$). While the band observed at 375 nm is due to the LMCT transition, the band at 970 nm is assignable to $^4T_{1g}$ (F) $\rightarrow$ $^4T_{2g}$ transition of high-spin $Co^{II}$ center in an octahedral environment. In the $Pd^{II}Ni^{II}$ complex **8**, in addition to the two bands in the UV region (378 and 260 nm), two more bands are observed in the visible (550 nm) and in the near-IR region (985 nm). Figure S3 shows the absorption spectrum of complex **8** in acetonitrile. The bands observed at 985 nm (8 $dm^3\cdot mol^{-1}\cdot cm^{-1}$) and 550 nm (17 $dm^3\cdot mol^{-1}\cdot cm^{-1}$) are due to $^3A_{2g} \rightarrow {}^3T_{2g}$ and $^3A_{2g} \rightarrow {}^3T_{1g}$ (P) transitions of the six-coordinate nickel(II) center. We note that a third band expected for $^3A_{2g} \rightarrow {}^3T_{1g}$ transition is not observed. The $Pd^{II}Cu^{II}$ complex **9** exhibits a single d–d band at 700 nm (39.9 $dm^3\cdot mol^{-1}\cdot cm^{-1}$) in addition to the bands at

375 and 258 nm (Figure S4). No d–d bands could be observed for the $Pd^{II}Mn^{II}$ and $Pd^{II}Fe^{II}$ complexes **5** and **6**, respectively.

### Luminescence Spectra

The luminescence spectra of the mononuclear palladium complex **2**, the heterodinuclear $Pd^{II}Zn^{II}$ complex **10**, and the dipalladium(II) complex **11** were measured in acetonitrile solution at room temperature. Table 3 summarizes the emission spectral characteristics of the complexes, including their quantum yields. The mononuclear $Pd^{II}$ complex on excitation at 400 nm exhibits a luminescence peak at 505 nm. In the $Pd^{II}Zn^{II}$ complex **10**, the luminescence peak is blue-shifted to 437 nm with increased intensity. On the other hand, for the dipalladium(II) complex **11**, considerable diminution of emission intensity occurs for the luminescence peak observed at 443 nm.

Spectrofluorimetric titrations carried out by adding incremental amounts of an acetonitrile solution of $Zn(OAc)_2·2H_2O$ to a solution of **2** containing 2 equiv. of sodium acetate in the same solvent, leading to the formation of **10**, is shown in Figure 4. The emission band of **2** at 505 nm ($\lambda_{ex}$ = 400 nm) progressively gets quenched with the addition of zinc(II), whereas a new band appearing at 437 nm due to the formation of **10** progressively increases. The growth of the emission band at 437 nm was monitored as a function of the concentration of zinc acetate added. The inset in Figure 4 shows that the luminescence intensity reached its maximum when 1 equiv. of $Zn(OAc)_2·2H_2O$ was added.

A similar observation has been made for the spectrofluorimetric titration of **2** with palladium acetate (Figure 5). With the incremental addition of palladium acetate the band at 505 nm decreases, giving rise to a new band at 443 nm corresponding to the formation of the dipalladium complex **11**. Again, the growth of the 443 nm band was complete when 1 equiv. of palladium acetate was added. It has been established from additional measurements that the presence of 2 equiv. of sodium acetate is essential for the completion of the reactions. For instance, when titrations were carried out without adding sodium acetate, 2 equiv. of

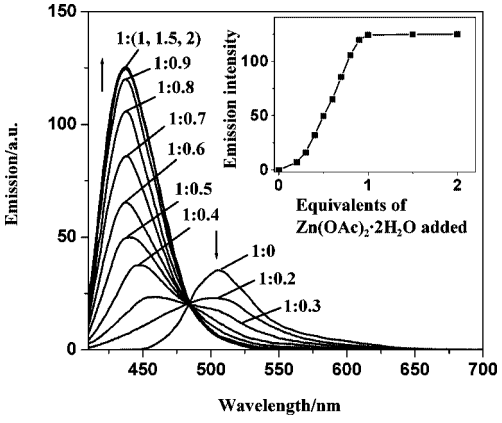

Figure 4. Spectrofluorimetric titration of a mixture of $[Pd(LH_2)][ClO_4]_2$ (**2**) ($1\times10^{-5}$ mol·dm$^{-3}$) and NaOAc ($2\times10^{-5}$ mol·dm$^{-3}$) with $Zn(OAc)_2·2H_2O$ in acetonitrile. The excitation wavelength used was 400 nm. The inset shows the variation of luminescence intensity with the number of equivalents of $Zn(OAc)_2·2H_2O$ added.

$M(OAc)_2$ were required for the completion of the reactions. Clearly, the role of the excess acetate is to provide a buffer effect to the liberated acetic acid in Reaction (1).

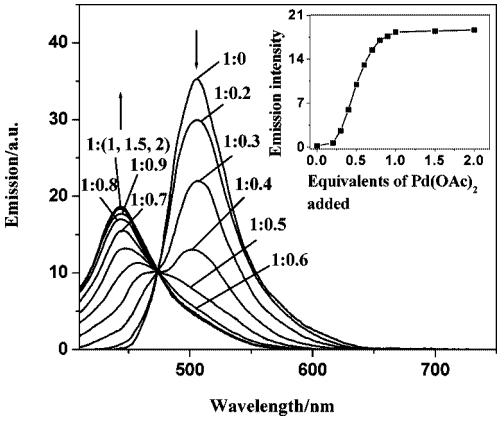

Figure 5. Spectrofluorimetric titration of a mixture of $[Pd(LH_2)][ClO_4]_2$ (**2**) ($1\times10^{-5}$ mol·dm$^{-3}$) and NaOAc ($2\times10^{-5}$ mol·dm$^{-3}$) with $Pd(OAc)_2$ in acetonitrile. The excitation wavelength used was 400 nm. The inset shows the variation of luminescence intensity with the number of equivalents of $Pd(OAc)_2$ added.

$$[Pd(LH_2)]^{2+} + M(OAc)_2 \rightleftharpoons [Pd(L)M]^{2+} + 2\ HOAc \quad (1)$$

In this context, it may be mentioned that relative to $[PdLZn]^{2+}$ the luminescence intensity of $[Zn_2L]^{2+}$ is seven times stronger.[26]

## Proton NMR Spectra

Proton NMR spectroscopic studies were carried out for the diamagnetic complexes **1**–**4**, **10**, **11** in $(CD_3)_2SO$ and for the paramagnetic complexes **6**–**9** in $CD_3CN$. The observed chemical shifts along with the spectral assignments are given in the Experimental Section.

The spectral features exhibited by the mononuclear $Rh^{III}$ complex **1** and $Pd^{II}$ complex **2** are quite similar. The hydrogen-bonded protonated imine N–H···O is observed as a broad singlet at $\delta$ = 12.44 ppm for **1** and 12.22 ppm for **2**. Complex **1** exhibits a doublet for the N=CH resonance in the metal-free compartment at $\delta$ = 8.75 ppm ($J$ = 14.8 Hz, 2 H), because of *trans* coupling between the NH and CH protons; however, for complex **2** this is observed as a singlet at $\delta$ = 8.80 ppm. The N=CH resonance in the metal-containing part appears as a singlet at $\delta$ = 8.06 ppm (for **1**) and 8.11 ppm (for **2**). The occurrence of the doublet at $\delta$ = 8.75 ppm in **1** can be alternatively argued as being due to the coupling of the CH=N proton with $^{103}Rh$ ($I$ = 1/2). However, we have recently reported[27] that in the $[Ln(LH_2)(NO_3)_3]$-type diamagnetic lanthanide (La, Lu, and Y) complexes the CH=N resonances are observed as a doublet between 8.73 and 8.80 ppm and a singlet between 8.20 and 8.30 ppm. Significantly, while $^{89}Y$ (100%) is a spin 1/2 nucleus, neither La nor Lu have a $I$ = 1/2 isotope, albeit for all three compounds the chemical shifts and splitting patterns are similar. It, therefore, appears more reasonable to us to conclude that the doublet arises because of *trans* coupling with the N–H proton. In the heterodinuclear $Rh^{III}Pd^{II}$ complexes **3**/**4**, the protons on the Rh-containing site are more shielded than the protons on the Pd-containing site, whereas in the $Pd^{II}Zn^{II}$ complex **10** the protons on the Pd site are more shielded than those on the Zn-containing site.

Studies on the paramagnetic $^1H$ NMR spectroscopic behavior of the heterodinuclear complexes **6**–**9** were carried out in $CD_3CN$ solution. The $Pd^{II}Mn^{II}$ complex **5** could not be investigated as it readily decomposes in solution. The spectroscopic data for complexes **6**–**9** are given in the Experimental Section. In paramagnetic compounds, hyperfine-shifted resonances are observed due to interactions between nuclear spin and unpaired electron spins, in addition to the normal diamagnetic nuclear spin interactions. Electron and nuclear spin interactions occurring through bonds give rise to contact shift, while those occurring through space interactions give rise to dipolar or pseudocontact shift. Dipolar shift depends on the magnetic anisotropy of the system and the position in space of a given proton. The contribution of contact shift decreases rapidly with the increase of the number of bonds connecting the proton with the paramagnetic center. However, when the unpaired electron spin is delocalized the interaction remains significant for protons many bonds away from the metal center. For assignment of signals in paramagnetic compounds, measurement of longitudinal relaxation times ($T_1$) and transverse relaxation times ($T_2$) are particularly important. $T_1$ correlates proximity of proton to paramagnetic center, while $T_2 = 1/\pi(\text{fwh})$, where fwh is full width of a signal at its half-height, correlates line width to proximity of a proton to the paramagnetic site. Closer proximity of a proton to the metal center gives rise to shorter $T_1$ and broader line width.[28]

Figure 6 and Figure 7 show the $^1H$ NMR spectra of $Pd^{II}Co^{II}$ (**7**) and $Pd^{II}Ni^{II}$ (**8**) compounds, while the spectrum of $Pd^{II}Cu^{II}$ (**9**) is available as supporting information (Figure S5). The assignments of signals given in Table 4 (numbering scheme for protons is shown in Scheme 2) have been made from $T_1$ values, line widths, and integration of protons. The M···H distances ($R_{M\cdots H}$) have been estimated by using the relation $R_{M\cdots H} = R_{ref}(T_1/T_{ref})^{1/6}$, where $R_{ref}$ and $T_{ref}$ are the reference values and in the present case the 4-methyl group is treated as the reference. As compared in Table 4, there is good agreement between the $R_{M\cdots H}$ values

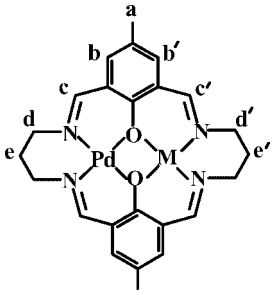
obtained by the NMR method and those obtained from the X-ray structure determinations of the compounds $Pd^{II}Ni^{II}$ (**8**)[25] and $Pd^{II}Cu^{II}$ (**9**). The $Pd^{II}Co^{II}$ compound **7** may be considered as isostructural with the $Pd^{II}Ni^{II}$ compound **8** and on that basis the Co···H distances obtained from $T_1$ measurements are in good agreement with the Ni···H distances obtained from the X-ray structure.



Scheme 2.

## Electrochemistry

The electrochemical properties of complexes **7**–**9** have been studied in acetonitrile using platinum and glassy carbon electrodes. Figure 8 (a) shows the cyclic voltammogram and square-wave voltammogram of $Pd^{II}Cu^{II}$ complex **9**, which undergoes one electron reduction of copper(II). The redox potential ($E_{1/2}$) of the $Pd^{II}Cu^{II}/Pd^{II}Cu^{I}$ couple, as obtained from CV, is –108 mV and the peak-to-peak separation is 60 mV versus Ag/AgCl. The $E_{1/2}$ obtained from square-wave voltammetry is –104 mV. In the potential range 0–1.5 V, an irreversible oxidation occurs for the $Pd^{II}Cu^{II}$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compound at 760 mV, which, however, is not observed for the $Pd^{II}Ni^{II}$ and $Pd^{II}Co^{II}$ complexes. It appears that this oxidation is not due to the formation of the ligand-based phenoxide radical because a similar observation has not been made for compounds **7** and **8**. As oxidation to the $Pd^{III}$ state seems unlikely, the formation of $Pd^{II}Cu^{III}$ species appears to be more plausible. As shown in Figure 8 (b), the $Pd^{II}Ni^{II}$ complex **8** also undergoes near-reversible reduction with $E_{1/2}$ = –803 mV for the couple $Pd^{II}Ni^{II}/Pd^{II}Ni^{I}$ and $\Delta E_p$ = 74 mV. In contrast, the $Pd^{II}Co^{II}$ complex **7** undergoes irreversible reduction for $Co^{II}$ at $E_{p,c}$ = –780 mV.

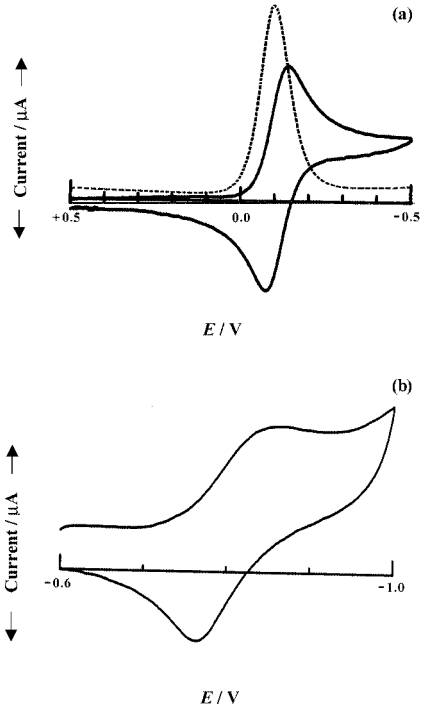


Figure 8. (a) Cyclic and square-wave voltammogram of $[Pd^{II}LCu^{II}](ClO_4)_2$ (**9**) and (b) cyclic voltammogram of $[Pd^{II}LNi^{II}(H_2O)_2](ClO_4)_2$ (**8**) in acetonitrile.

## Conclusions

Using $[Pb(LH_2)](ClO_4)_2$ as the precursor macrocyclic complex, mononuclear $[Pd(LH_2)_2](ClO_4)_2$ and $[Rh(LH_2)Cl_2](ClO_4)\cdot 3H_2O$ complexes have been prepared, which in turn have been used to produce 4d–3d heterobimetallic complexes, viz. $[Pd(L)M(H_2O)_2](ClO_4)_2$ (M = Mn, Fe, Co, Ni), $[Pd(L)Cu](ClO_4)_2$, and $[Pd(L)Zn(H_2O)](ClO_4)_2\cdot H_2O$ as well as $[RhCl_2(L)Pd](PF_6)$ and $[Pd_2L](ClO_4)_2$. The crystal structures of the $Rh^{III}Pd^{II}$ and $Pd^{II}Cu^{II}$ complexes have been determined. Proton NMR spectroscopic measurements have been carried out for the paramagnetic compounds and M···H (ligand proton) distances estimated from the relaxation time ($T_1$) values agreed fairly well with those obtained from X-ray studies. The mononuclear palladium(II) complex, which exhibits photoluminescence, during titration with $Pd(OAc)_2$ undergoes blue-shift of $\lambda_{em}$ and diminution of luminescence intensity because of the formation of the $[Pd_2L]^{2+}$ complex. On the other hand, the formation of $[Pd(L)Zn]^{2+}$ species, although it leads to a similar blue-shift of $\lambda_{em}$, is accompanied by augmentation of luminescence intensity. The $Pd^{II}Cu^{II}$ complex undergoes facile reversible electrochemical reduction to $Pd^{II}Cu^{I}$ with $E_{1/2}$ = –106 mV and irreversible oxidation to $Pd^{III}Cu^{II}$ at $E_{p,a}$ = 760 mV. The $Pd^{II}Ni^{II}$ complex also undergoes one-electron reversible reduction to $Pd^{II}Ni^{I}$ with $E_{1/2}$ = –803 mV, although no oxidation occurs up to +1.5 V. The redox behavior of the $Pd^{II}Co^{II}$ complex in the positive potential range (0 to +1.5 V) is again featureless, albeit reduction of the $Co^{II}$ center takes place irreversibly at $E_{p,c}$ = –780 mV.

## Experimental Section

**Materials:** Reagent grade chemicals obtained from commercial sources were used as received. Solvents were purified and dried according to standard methods.[29] 2,6-Diformyl-4-methylphenol was prepared according to the literature method.[30] The precursor complex $[Pb(LH_2)](ClO_4)_2$ was synthesized as reported earlier.[23]

**Preparation of the Complexes**

***CAUTION:*** All the perchlorate salts reported in this study are potentially explosive and therefore should be handled with care.

**Mononuclear Complexes $[Rh(LH_2)Cl_2](ClO_4)\cdot 3H_2O$ (1), $[Pd(LH_2)](ClO_4)_2$ (2):** A methanol solution (10 mL) of the metal chloride salts $RhCl_3\cdot xH_2O$ or $Na_2[PdCl_4]$ (1 mmol) and an acetonitrile solution (10 mL) of $NaClO_4\cdot xH_2O$ (550 mg, 4 mmol) were added to a boiling acetonitrile solution (50 mL) of $[Pb(LH_2)](ClO_4)_2$ (810 mg, 1 mmol). The color of the solution changed from yellow to wine red (for Rh) or orange (for Pd). The solution was refluxed for 12 h. After removal of the precipitated $PbCl_2$ by filtration, the filtrate was concentrated on a water bath to a volume of about 20 mL. The yellow or orange crystalline products that deposited on standing were collected by filtration and washed with methanol and diethyl ether.

**$[Rh(LH_2)Cl_2](ClO_4)\cdot 3H_2O$ (1):** Orange crystalline compound. Yield: 450 mg (62%). MS (ESI+ in $CH_3CN$): *m*/*z* = 577 $[Rh(Cl_2)(LH_2)]^+$ (100%), 641 $[Rh(Cl)(ClO_4)(LH_2)]^+$ (50%). $^1H$ NMR [300 MHz, $(CD_3)_2SO$, 25 °C]: $\delta$ = 12.44 (s, 2 H, N–H···O), 8.75 (d, $J$ = 14.8 Hz, 2 H, CH=N, metal-free site), 8.06 (s, 2 H, CH=N, metal-containing site), 7.57 (s, 2 H, Ar, metal-free site), 7.44 (s, 2 H, Ar, metal-containing site), 4.10 (s, 4 H, α-$CH_2$, metal-free site), 4.02 (s, 4 H, α-$CH_2$, metal-containing site), 2.21 (s, 6 H, $CH_3$), 2.09 (m, 4 H, β-$CH_2$) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 3459 br, 3147 w, 3080 w, 2919 w, 1650 s, 1550 s, 1469 m, 1445 m, 1357 m, 1279 m, 1237 m, 1122 s, 1084 s, 870 w, 823 w, 769 w, 628 m, 561 w, 487 w. $C_{24}H_{34}Cl_3N_4O_9Rh$ (731.82): calcd. C 39.39, H 4.68, N 7.66; found C 39.09, H 4.58, N 7.71.

**$[Pd(LH_2)](ClO_4)_2$ (2):** Yellow crystalline compound. Yield: 510 mg (72%). MS (ESI+ in $CH_3CN$): *m*/*z* = 611 $[Pd(LH_2)(ClO_4)]^+$ (10%), 256 $[Pd(LH_2)]^{2+}$ (100%). $^1H$ NMR [300 MHz, $(CD_3)_2SO$, 25 °C]: $\delta$ = 12.23 (s, 2 H, N–H···O), 8.80 (s, 2 H, CH=N, metal-free site), 8.11 (s, 2 H, CH=N, metal-containing site), 7.78 (s, 2 H, Ar, metal-free site), 7.63 (s, 2 H, Ar, metal-containing site), 3.98 (s, 4 H, α-$CH_2$, metal-free site), 3.85 (s, 4 H, α-$CH_2$, metal-containing site), 2.27 (s, 6 H, $CH_3$), 2.10 (s, 4 H, β-$CH_2$) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 3449 br, 3143 w, 3078 w, 2921 w, 1650 s, 1552 s, 1477 m, 1450 m, 1351 m, 1291 w, 1236 w, 1233 w, 1217 w, 1082 s, 1014 s, 861 w, 822 m, 624 m, 519 w. $C_{24}H_{28}Cl_2N_4O_{10}Pd$ (709.83): calcd. C 40.61, H 3.98, N 7.89; found C 40.52, H 4.05, N 7.87.

**$[RhCl_2(L)Pd](ClO_4)\cdot 0.5H_2O$ (3):** A methanol solution (15 mL) of $Na_2[PdCl_4]$ and an acetonitrile solution (15 mL) of triethylamine (40 mg, 0.4 mmol) were slowly added to an acetonitrile solution (15 mL) of compound **1** (150 mg, 0.2 mmol) with stirring. The resulting orange solution was refluxed for 4 h after which it was filtered. The filtrate was concentrated on a water bath to a volume of about 10 mL and then slowly cooled to room temperature. On standing for several hours a crystalline red-orange compound deposited, which was filtered and washed with methanol and diethyl ether. Yield: 110 mg (69%). MS (ESI+ in $CH_3CN$): *m*/*z* = 682.9 $[Rh(Cl_2)(L)Pd]^+$ (100%). $^1H$ NMR [300 MHz, $(CD_3)_2SO$, 25 °C]: $\delta$ = 8.19 (s, 2 H, CH=N, Pd site), 8.13 (s, 2 H, CH=N, Rh site), 7.65 (s, 2 H, Ar, Pd site), 7.62 (s, 2 H, Ar, Rh site), 3.94 (s, 4 H, α-$CH_2$, Pd site), 3.74 (s, 4 H, α-$CH_2$, Rh site), 2.27 (s, 6 H, $CH_3$), 2.07 (s, 4 H, β-$CH_2$) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 3422 br, 3065 w, 2924 w, 2866 w, 1630 s, 1569 s, 1468 m, 1435 m, 1367 w, 1330 s, 1279 m, 1248 m, 1089 s, 950 w, 833 m, 754 m, 624 m, 520 w, 439 w. $C_{24}H_{27}Cl_3N_4O_{6.5}PdRh$ (790.98): calcd. C 36.44, H 3.44, N 7.08; found C 36.52, H 3.69, N 6.86.

**$[RhCl_2(L)Pd](PF_6)$ (4):** Solid ammonium hexafluorophosphate (150 mg) was added to an acetonitrile solution (15 mL) of compound **3** (60 mg, 0.07 mmol), and the orange solution turned to red-orange. The solution was filtered and the filtrate was slowly concentrated on a hot plate. The product that deposited as red-orange crystals was collected by filtration. Crystals suitable for X-ray diffraction studies were obtained by diffusing diethyl ether into an acetonitrile solution of the compound. Yield: 40 mg (72%). MS (ESI+ in $CH_3CN$): *m*/*z* = 682.9 $[Rh(Cl_2)(L)Pd]^+$ (100%). IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 2942 w, 1629 s, 1571 s, 1469 m, 1433 m, 1330 m, 1277 w, 1247 m, 1198 w, 1117 m, 958 w, 839 s, 753 m, 646 w, 555 m, 518 m, 407 w. $C_{24}H_{26}Cl_2F_6N_4O_2PPdRh$ (827.69): calcd. C 34.82, H 3.17, N 6.77; found C 34.96, H 3.26, N 6.64. The $^1H$ NMR spectrum of **4** is identical to that of **3**.

**Heterodinuclear $[Pd^{II}(L)M^{II}(H_2O)_n](ClO_4)_2$ [M = Mn, Fe, Co, Ni, Cu, Zn] Complexes (5–10):** A generalized procedure for preparing these complexes is given. An acetonitrile solution (15 mL) of $M(ClO_4)_2\cdot 6H_2O$ ($M = Mn^{II}$, $Fe^{II}$, $Co^{II}$, $Ni^{II}$, $Zn^{II}$) was added to an acetonitrile solution (30 mL) of compound **2** (140 mg, 0.2 mmol). The resulting solution was then slowly treated with an acetonitrile solution (15 mL) of triethylamine (40 mg, 0.4 mmol). After refluxing the solution for 2 h, it was concentrated on a water bath to a volume of about 10 mL. Preparation of the $Pd^{II}Mn^{II}$, $Pd^{II}Fe^{II}$, and $Pd^{II}Co^{II}$ complexes was carried out under nitrogen. The product that deposited in crystalline form on keeping the solution at room temperature was collected by filtration and washed with methanol and diethyl ether.

**$[Pd(L)Mn(H_2O)_2](ClO_4)_2$ (5):** Light orange crystalline compound. Yield: 110 mg (73%). Satisfactory mass spectrum could not be obtained. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 3410 br, 2929 m, 2851 w, 1633 s, 1563 s, 1459 w, 1434 m, 1412 m, 1324 m, 1114 s, 1087 s, 966 w, 825 s, 759 w, 622 m, 561 w, 501 w. $C_{24}H_{30}Cl_2MnN_4O_{12}Pd$ (798.98): calcd. C 36.09, H 3.79, N 7.01; found C 36.17, H 3.79, N 7.09.

**$[Pd(L)Fe(H_2O)_2](ClO_4)_2$ (6):** Red-brown crystalline compound. Yield: 100 mg (67%). MS (ESI+ in $CH_3CN$): *m*/*z* = 662.9 $[Pd(L)Fe(ClO_4)]^+$ (9%) and 283 $[Pd(L)Fe]^{2+}$ (100%). $^1H$ NMR (300 MHz, $CD_3CN$, 25 °C): $\delta$ = 80.21 (4 H), 35.84 (2 H), 20.83 (2 H), 10.90 (2 H), 7.91 (2 H), 4.44 (2 H), 4.22 (2 H), 3.79 (6 H), 1.23 (2 H) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 3456 br, 3169 w, 2921 w, 2856 w, 1635 s, 1566 s, 1440 m, 1413 w, 1317 m, 1277 m, 1243 w, 1196 w, 1106 s, 959 w, 924 w, 821 m, 755 w, 622 m, 519 w. $C_{24}H_{30}Cl_2FeN_4O_{12}Pd$ (799.69): calcd. C 36.05, H 3.78, N 7.01; found C 36.29, H 3.78, N 7.10.

**$[Pd(L)Co(H_2O)_2](ClO_4)_2$ (7):** Red-orange crystalline compound. Yield: 120 mg (75%). MS (ESI+ in $CH_3CN$): *m*/*z* = 667.9 $[Pd(L)Co(ClO_4)]^+$ (11%) and 284.5 $[Pd(L)Co]^{2+}$ (100%). $^1H$ NMR (300 MHz, $CD_3CN$, 25 °C): $\delta$ = 168.31 (4 H), 34.46 (2 H), 26.73 (2 H), 22.07 (2 H), 17.6 (4 H), 11.09 (2 H), 6.58 (2 H), 6.09 (6 H) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 3433 br, 2923 w, 2852 w, 1634 s, 1563 s, 1555 m, 1461 w, 1438 m, 1412 m, 1326 s, 1279 w, 1242 w, 1195 w, 1114 s, 1087 s, 966 w, 922 w, 823 m, 759 w, 624 m, 519 w. $C_{24}H_{30}Cl_2CoN_4O_{12}Pd$ (802.78): calcd. C 35.91, H 3.77, N 6.98; found C 35.84, H 3.72, N 7.04.

**$[Pd(L)Ni(H_2O)_2](ClO_4)_2$ (8):** Light green crystalline compound. Yield: 120 mg (75%). MS (ESI+ in $CH_3CN$): *m*/*z* = 666.9 $[Pd(L)Ni(ClO_4)]^+$ (8%) and 285 $[Pd(L)Ni]^{2+}$ (100%). $^1H$ NMR (300 MHz, $CD_3CN$, 25 °C): $\delta$ = 128.10 (4 H), 25.53 (2 H), 11.15 (2 H), 9.42 (2 H), 6.14 (4 H), 2.96 (6 H), 2.60 (2 H), –5.00 (2 H) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 3428 br, 2909 w, 2851 w, 1643 s, 1618 s, 1565 s, 1461 m, 1438 m, 1413 m, 1326 s, 1283 m, 1243 w, 1195 w, 1121 s, 1092 sh, 1052 sh, 965 w, 922 w, 823 m, 760 w, 621 m, 520 w. $C_{24}H_{30}Cl_2N_4NiO_{12}Pd$ (800.54): calcd. C 36.01, H 3.78, N 6.99; found C 35.99, H 3.85, N 6.81.

**$[Pd(L)Cu](ClO_4)_2$ (9):** Deep green crystalline compound. Yield: 130 mg (86%). MS (ESI+ in $CH_3CN$): *m*/*z* = 671.9 $[Pd(L)Cu(ClO_4)]^+$ (10%) and 287.5 $[Pd(L)Cu]^{2+}$ (100%). $^1H$ NMR (300 MHz, $CD_3CN$, 25 °C): $\delta$ = 22.64 (2 H), 7.96 (2 H), 7.50 (2 H), 5.19 (4 H), 3.08 (6 H), 1.21 (2 H), –12.00 (2 H) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 2922 w, 2859 w, 1632 s, 1572 s, 1468 w, 1436 m, 1419 m, 1326 s, 1283 m, 1245 m, 1198 m, 1094 s, 961 w, 935 w, 826 m, 756 m, 620 m, 518 w. $C_{24}H_{26}Cl_2CuN_4O_{10}Pd$ (771.36): calcd. C 37.37, H 3.39, N 7.26; found C 37.37, H 3.27, N 7.42.

**$[Pd(L)Zn(H_2O)](ClO_4)_2\cdot H_2O$ (10):** Yellow crystalline compound. Yield: 110 mg (69%). MS (ESI+ in $CH_3CN$): *m*/*z* = 672.9 $[Pd(L)Zn(ClO_4)]^+$ (12%) and 288 $[Pd(L)Zn]^{2+}$ (100%). $^1H$ NMR [300 MHz, $(CD_3)_2SO$, 25 °C]: $\delta$ = 8.45 (s, 2 H, CH=N, Zn site), 8.10 (s, 2 H, CH=N, Pd site), 7.49 (s, 2 H, Ar, Zn site), 7.46 (s, 2 H, Ar, Pd site), 3.94 (s, 4 H, α-$CH_2$, Zn site), 3.82 (s, 4 H, α-$CH_2$, Pd site), 2.26 (s, 6 H, $CH_3$), 2.06 (s, 4 H, β-$CH_2$) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 3410 br, 2927 m, 2866 w, 1637 s, 1564 s, 1439 m, 1414 m, 1366 w, 1280 m, 1243 m, 1197 w, 1087 s, 969 w, 937 w, 890 w, 825 m, 761 m, 627 m, 572 w, 506 w. $C_{24}H_{30}Cl_2N_4O_{12}PdZn$ (809.23): calcd. C 35.62, H 3.74, N 6.92; found C 35.80, H 3.78, N 7.01.

**Homodinuclear $[Pd(L)Pd](ClO_4)_2$ Complex (11):** A methanol solution (15 mL) of $Na_2[PdCl_4]$ (60 mg, 0.2 mmol) and an acetonitrile solution (5 mL) of triethylamine (40 mg, 0.4 mmol) were added successively to an acetonitrile solution (30 $cm^3$) of $[Pd(LH_2)](ClO_4)_2$ (140 mg, 0.2 mmol). The mixture was refluxed for 2 h, during which time NaCl was precipitated and removed by filtration. $NaClO_4$ (50 mg) was added to the filtrate and the volume of the solution was reduced to about 15 mL on a rotary evaporator. After filtration, the filtrate was kept on a hot plate for slow evaporation and eventually orange crystals were deposited. The product was collected by filtration and washed with cold methanol and diethyl ether. Yield: 120 mg (75%). MS (ESI+ in $CH_3CN$): *m*/*z* = 714.9 $[Pd(L)Pd(ClO_4)]^+$ (8%) and 309 $[Pd(L)Pd]^{2+}$ (100%). $^1H$ NMR [300 MHz, $(CD_3)_2SO$, 25 °C]: $\delta$ = 8.16 (s, 4 H, CH=N), 7.77 (s, 4 H, Ar), 3.68 (s, 8 H, α-$CH_2$), 2.30 (s, 6 H, $CH_3$), 2.03 (s, 4 H, β-$CH_2$) ppm. IR (KBr [$cm^{-1}$]): $\tilde{\nu}$ = 2930 w, 2848 w, 1625 s, 1571 s, 1469 m, 1329 s, 1283 w, 1246 w, 1097 m, 1087 s, 955 m, 879 w, 838 m, 751 m, 620 m, 512 w. $C_{24}H_{26}Cl_2N_4O_{10}Pd_2$ (814.23): calcd. C 35.40, H 3.22, N 6.88; found C 35.59, H 3.18, N 6.91.

**Physical Measurements:** Elemental C, H, and N analyses were performed with a Perkin–Elmer 2400II elemental analyzer. The $^1H$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

NMR (300 MHz) spectra were performed in $CD_3CN$ (for **6**–**9**) and $(CD_3)_2SO$ solutions (for **1**–**4**, **10**, **11**) with a Bruker Avance DPX-300 spectrometer. Longitudinal relaxation times ($T_1$) were measured by the inversion recovery method. IR spectra were recorded using KBr disks with a FTIR Nexus Nicolet spectrometer using KBr disks. The electronic spectra of **1**–**11** in acetonitrile were measured in the range 250–1100 nm using Perkin–Elmer Lambda 950 spectrophotometer. Emission spectral measurements were carried out with a Perkin–Elmer LS55 luminescence spectrometer with $10^{-5}$ mol·dm$^{-3}$ acetonitrile solutions. Emission quantum yields ($\varphi$) were measured at room temperature in acetonitrile solution relative to perylene as the standard.[31] The quantum yields were calculated using the relation[32]

$$\varphi = \varphi_{std}(A_{std}/A)(I/I_{std})(\eta^2/\eta^2_{std})$$

where $A$, $I$, and $\eta$ refer to absorbance, integrated emission intensity, and solution refractive index, respectively. Electrospray ionization mass spectra (ESI-MS) of compounds **1**–**11** were measured in acetonitrile with a Micromass Qtof YA263 mass spectrometer. The electrochemical measurements were carried out with a BAS 100B electrochemistry system using a three-electrode assembly comprising a Pt or glassy carbon working electrode, Pt auxiliary electrode, and an aqueous Ag/AgCl reference electrode. The measurements (CV) were carried out at 25 °C under nitrogen in acetonitrile solution of complexes **7**–**9** (about 1 mmol·dm$^{-3}$) with tetraethylammonium perchlorate (TEAP) (0.1 mol·dm$^{-3}$) as the supporting electrolyte. The reference electrode was separated from the bulk electrolyte by a salt bridge containing 0.1 mmol·dm$^{-3}$ TEAP in acetonitrile/water (1:1). The potentials measured were automatically compensated for the iR drop and under this condition the ferrocene/ferrocenium couple occurred at 430 mV.

**X-ray Crystallography:** The crystal structure analyses were carried out for compounds **4** and **9**, whose intensity data were collected at 293 K and 203 K, respectively with a Bruker AXS P4 diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Crystal data and details of structure determinations are summarized in Table 5. The intensity data were corrected for Lorentz polarization effects and semiempirical absorption corrections were made from $\psi$-scans. The structures were solved by direct and Fourier methods and refined by full-matrix least-squares based on $F^2$ using SHELXTL.[33] The non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were placed at the geometrically calculated positions with fixed isotropic thermal parameters.

# Synthesis, Structure, and Magnetism of a Highly Thermally Stable Microporous Metal Organodiphosphonate with Reversible Dehydration/Rehydration Behavior

**Hua Li,[a] Guang-shan Zhu,*[a] Xiao-dan Guo,[a] Fu-xing Sun,[a] Hao Ren,[a] Yan Chen,[a] and Shi-lun Qiu*[a]**

**Keywords:** Organic–inorganic hybrid composites / Organophosphonates / Thermal stability / Dehydration/rehydration behavior / Microporous materials

The synthesis and crystal structure of a novel organic–inorganic hybrid material $Co_2(H_2O)_2[O_3PCH_2(C_6H_4)CH_2PO_3]$ is described. It crystallizes in the orthorhombic space group *Pca*2(1) [*a* = 9.6214(19), *b* = 5.6855(11), *c* = 21.725(4) Å, *V* = 1188.4(4) Å$^3$], which consists of two-dimensional cobalt–oxygen inorganic layers pillared by *p*-xylylenediphosphonate to form a three-dimensional framework, which has 10.850 × 5.687 Å channels running along the *b*-axis. The material is exceptionally stable, even when heated up to 500 °C in air. More interestingly, the framework components display a reversible dehydration/rehydration behavior. There is an antiferromagnetic interaction between the cobalt ions.

## Introduction

Organic–inorganic hybrid materials have received considerable interest because of their potential ability to incorporate an organic functionality within a robust framework and promising applications in adsorbents, optical materials, magnets, catalysts, and so forth.[1–4] One such group of hybrid materials that has attracted much attention is the metal phosphonate/diphosphonate family, which exhibits great possibilities for application in the areas of sensors, charge and energy storage, biotechnology, and so forth.[5–8] As one hydroxy group (OH) of the phosphonic acid can be replaced by other organic groups, the organic diphosphonic acid has a greater advantage in the synthesis of open-framework compounds than phosphonic acid. The structure and functionality of these materials can be rationally designed by controlling the organic portion of organodiphosphonate ligands ($[O_3P–R–PO_3]^{4–}$, R = organic unit). The combination of organodiphosphonate ligands with metal ions is expected to lead to new three-dimensional structures with open frameworks and unique properties.[9–11] Not only do these ligands form materials with progressively longer organic chains to expand the pore size or contain organic functional groups to present both metal and organic species to guest molecules within the pores,[12,13] but they are also desirable in their pillared framework with clearly different organic and inorganic parts. Investigations of di-, tri-, and tetravalent metal phosphonates in recent years have yielded exciting structural diversity with interesting properties.[14–16]

Because the metal polyhedra are bridged by phosphonic tetrahedra to form two-dimensional layers, many $M^{II}(RPO_3)\cdot H_2O$ compounds are two-dimensional structures, with the metal/$PO_3$ layer arrangement and the adsorption behavior of some dehydrated layered phosphates reported in the literature.[17–21] The hydrothermal method has proved to be a promising technique in the preparation of highly stable and infinite metal–ligand frameworks.[22,23] The organophosphorus compound *p*-xylylenediphosphonate, which possesses much longer chains and a more rigid framework, has been used successfully in the hydrothermal synthesis of diphosphonates. Ferey et al. solved the structure of the copper diphosphonate $Cu_2(H_2O)_2[O_3PCH_2(C_6H_4)CH_2PO_3]$ by powder X-ray diffraction to reveal that it was built up from inorganic layers covalently linked by the organic chains.[24] The inorganic layers are constructed by the dimers of edge-sharing $CuO_4(H_2O)$ square pyramids and the $PO_3C$ tetrahedron. Harvey et al. have reported $Ga_2[O_3PCH_2(C_6H_4)CH_2PO_3](H_2O)_2F_2$, containing linear chains of corner-sharing $GaO_4F_2$ octahedra connected by diphosphonate groups to form two-dimensional framework structures.[12] *meta*-Xylylenediphosphonic acid has been used instead of the *para* isomer, leading to a layered compound.[25]

However, frameworks of organic–inorganic hybrid materials showing simultaneously permanent porosity and high

thermal stability are extremely rare.[26,27] The inability of these materials to support a stable framework at higher temperatures or after removing guest molecules has hindered further application in many fields.[28] So the application of diphosphonates is still quite limited relative to that of zeolites or aluminophosphates, despite the extensive studies. Generally, they are thermally unstable when compared with inorganic phosphates and most of them are destroyed at high temperature (>300 °C).

Some diphosphonates containing coordinated water and showing dehydration behavior have been reported, but their dehydration behaviors are diverse. The copper ethylenediphosphonate loses water irreversibly from the metal center, resulting in the collapse of the structure.[29] The aluminum and gallium diphosphonates lose water in two stages: first the water residing within channels and subsequently the water from positions coordinated to metal cations, and the latter stage leads to loss of crystallinity.[30,31] The aluminum and vanadium ethylenediphosphonates show reversible dehydration/rehydration behavior without losing their crystallinity and may therefore have potential applications as adsorbents, sensors, and catalysts, but such diphosphonates are still not very common.[32,33]

We have successfully synthesized a novel three-dimensional cobalt diphosphonate $Co_2(H_2O)_2[O_3PCH_2(C_6H_4)$-$CH_2PO_3]$ with two-dimensional infinite cobalt–oxygen inorganic layers pillared by an organophosphorus *p*-xylylenediphosphonate. The compound is exceptionally stable even when heated up to 500 °C in air. More interestingly, the framework components display a reversible dehydration/rehydration behavior.

## Results and Discussion

### Description of Crystal Structure

Single-crystal X-ray analysis shows that the compound is a 3D structure that possesses 2D infinite cobalt–oxygen inorganic layers pillared by the P–$CH_2$–$C_6H_4$–$CH_2$–P group. As shown in Figure 1, the asymmetric unit contains two crystallographically independent cobalt atoms, one *p*-xylylenediphosphonate ligand, and two water molecules. Each of the cobalt atoms is located in an octahedral coordination environment with five oxygen atoms (O1, O2, O3, O4, O5 for Co1; O1, O2A, O3A, O4A, O8 for Co2) from the *p*-xylylenediphosphonate ligand, and one oxygen atom (O6 for Co1; O7 for Co2) from the water molecule.

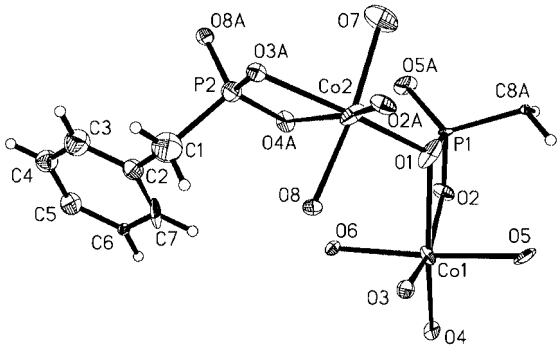

Figure 1. Thermal ellipsoid plot showing an asymmetric unit of $Co_2(H_2O)_2[O_3PCH_2(C_6H_4)CH_2PO_3]$.

The compound crystallizes in the orthorhombic space group *Pca*2(1). Interestingly, the structure consists of infinite inorganic layers of corner-sharing $CoO_6$ octahedra, which is totally different from other reported metal phosphonates using *p*-xylylenediphosphonate as the ligand.[24] The coordination between the cobalt atoms and the $PO_3$ groups in the compound is similar to that found in $Mn(C_6H_5PO_3)\cdot H_2O$[17] or $Zn(C_6H_5PO_3)\cdot H_2O$,[20] but these are 2D layered structures and the former is a 3D pillared

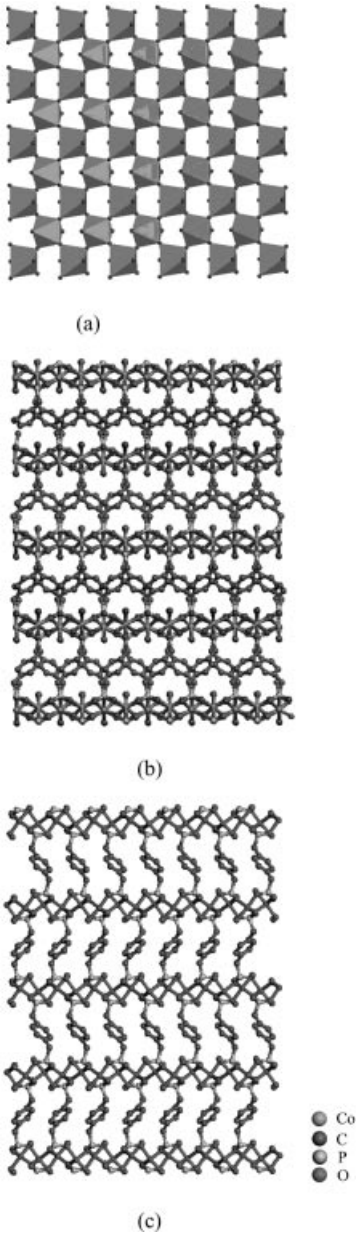

Figure 2. (a) The view of the Co–O layers of $Co_2(H_2O)_2$-$[O_3PCH_2(C_6H_4)CH_2PO_3]$ in the [001] plane. (b) A ball-and-stick representation of the structure viewed along the [100] and (c) [010] directions. Hydrogen atoms are omitted for clarity.

layered structure. As shown in Figure 2a, such a compound is a rare example of a hybrid metal oxide containing an infinite 2D –M–O–M–O– net framework.[34] The adjacent cobalt–oxygen layers are interconnected to each other through the organic part of *p*-xylylenediphosphonate, P–$CH_2$–$C_6H_4$–$CH_2$–P, to produce a 3D structure (Figure 2b). The pillars can connect the inner layers of the Co–O network and, thus, further stabilize the structure. As presented in Figure 2b, The *p*-xylylenediphosphonate groups link the inorganic octahedral layers in the fashion of an alternately left and right arrangement along the [100] direction. As indicated in Figure 2c, the framework along the [010] direction contains a 10.850 Å [Co1–Co1] × 5.687 Å [C3–C3] one-dimensional channel system. The overall structure may be described in terms of alternating inorganic infinite metal oxygen layers and organic pillars (P–$CH_2$–$C_6H_4$–$CH_2$–P). To the best of our knowledge, inorganic metal oxygen layers pillared by organophosphorus groups with the in situ hydrothermal method have not been reported so far.

## Thermal Stability

The thermal stability of the sample has been studied by using TGA and XRD at different temperatures. Thermogravimetric analysis (TGA) of the compound (Figure 3) showed that the first weight loss of 8.61% from 200 to 500 °C corresponds to the loss of two coordinated water molecules (calculated: 8.66%). The decomposition of the compound starts above 500 °C, which is in good agreement with the TGA of the calcined sample, except for the absence of the first weight loss, indicating that the coordinated water had already been removed during calcination (Figure S1). Considering the thermal stability of the compound, X-ray powder diffraction (PXRD) studies are performed for the as-synthesized sample and the samples heated at 350 °C, 400 °C, and 500 °C. Figure 4 presents X-ray diffraction (XRD) patterns simulated from single-crystal X-ray diffraction data as well as those of the as-synthesized sample, the calcined samples, and the rehydrated sample. The XRD pattern of the as-synthesized sample fits well with the simulated one, indicating that the sample is a pure phase. The XRD patterns for the calcined samples (Figure 4c, d, e) are similar to that of the as-synthesized sample (Figure 4b). The very intense peaks, (002) and (004), located at two Bragg angles $2\theta$ of 8.06° and 16.3°, are always maintained after calcination and rehydration, indicating that the structure of 2D cobalt–oxygen pillared by organophosphate does not collapse after the removal of the coordinated water molecules and that the calcined sample retains high crystallinity and pure phase. It is quite surprising that the compound could maintain its structure even when heated up to 500 °C, which is extremely rare in organophosphates and suggests that the compound can preserve its rigid and stable framework at high temperature. It is also clear that the dehydration of the water lattice is reversible (Figure 4f).

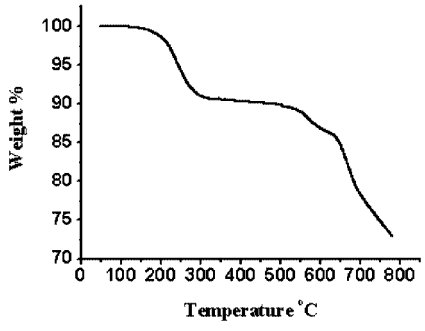

Figure 3. TGA curves of the sample.

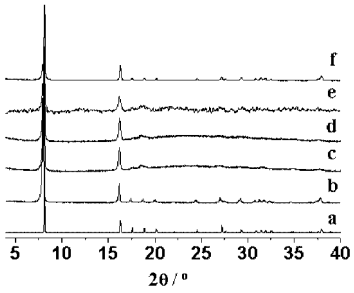

Figure 4. Simulated powder X-ray diffraction patterns of the single-crystal crystallography data (a), as-synthesized sample (b), dehydrated sample after calcination at 350 °C (c), 400 °C (d), 500 °C (e), and rehydrated sample after calcination at 350 °C (f).

## Dehydration/Rehydration Properties

Interestingly, it was found that the color of the crystals changed from pink to blue when they were heated at 350 °C for 2 h, while optical microscopy showed that they maintained their transparency and morphology (Figure 5a). Because of the difference in the crystal field splitting energy between the octahedral field and the square-pyramidal field,[35] the observed color of the compound containing octahedrally coordinated cobalt ions is pink, while that of the compound containing square-pyramidally coordinated cobalt is blue. Therefore, accompanying the change of color from pink to blue, the coordination environment of the cobalt ion is changed from octahedral to square-pyramidal.

For a deep understanding of how the structure of the compound changes with temperature and how it undergoes a reversible dehydration/rehydration process, it is instructive to simulate the distorted square-pyramidal coordination geometry of the cobalt atom in the dehydrated compound (Figure 5b). Notably, all the coordinated water can be removed from the structure at 350 °C within 2 h without loss of framework periodicity. The coordinated water is removed and diffuses out along the [100] direction, which is confirmed by the observation that some partly dehydrated crystals presented different colors after being calcined at 300 °C for 2 h: pink at the central part and blue at the two ends of the crystal (Figure 5c). Therefore, without sufficient time or higher temperature, the central part could not be fully dehydrated. More significantly, the crystals can be fully rehydrated when they are immersed in water for several hours. Thus, the rehydration process is accompanied by a return

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

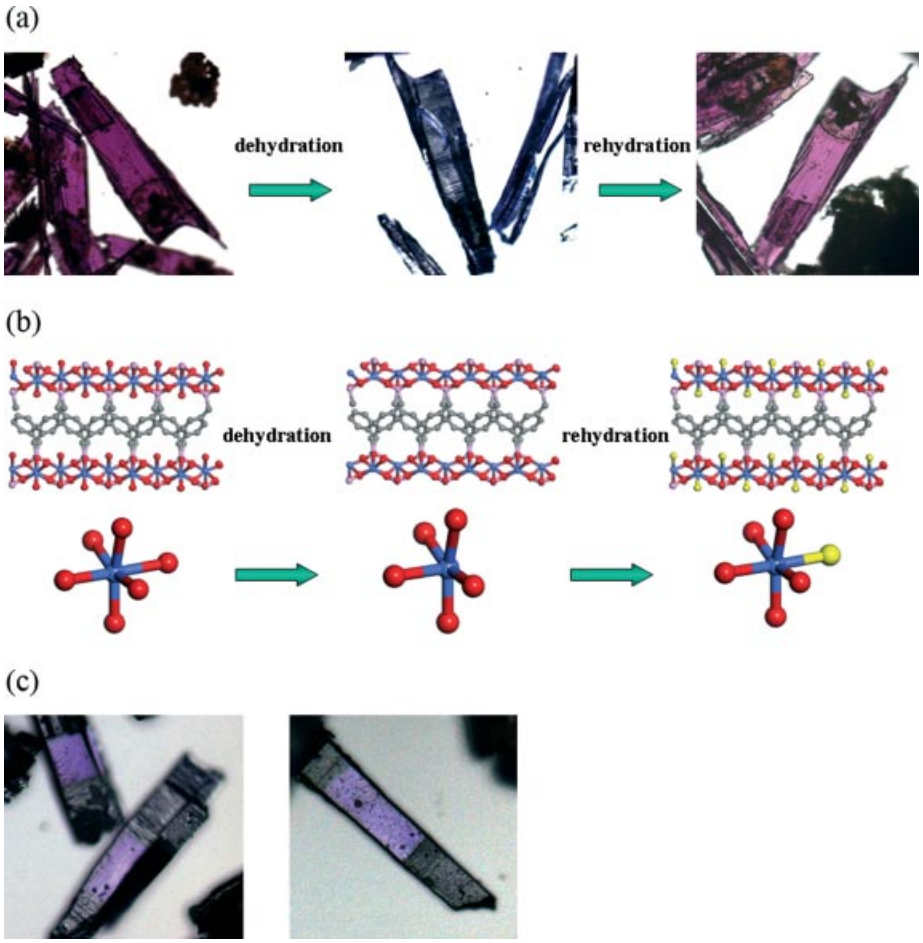

Figure 5. Pictorial representation of the dehydration/rehydration process and the partly dehydrated crystals. The pink crystals turned blue after dehydration, then changed back to pink after rehydration (a). Correspondingly, the cobalt coordination environment changed from octahedral to square pyramidal, and finally returned to octahedral (b). The partly dehydrated crystals are pink at the center and blue at the two ends (c).

of the original pink color (Figure 5a). The XRD pattern of the rehydrated sample (Figure 4f) indicates that a high degree of crystallinity is retained after water is resorbed.

### Water Sorption Properties

The phenomenon of dehydration/rehydration in the microporous frameworks and the thermal stability encouraged us to try to create the micropores after removing the coordinated and guest water molecules. The calcined compound was evacuated under reduced pressure ($1 \times 10^{-5}$ Torr) until no more weight loss occurred at 150 °C, and then it was exposed to water vapor. As shown in Figure S2, type I behavior is observed in the water adsorption isotherm of the sample in the range $P/P_0$ = 0–0.7. At saturation, the amount of water sorbed is 87.6 mg g$^{-1}$, which is equivalent to the adsorption of about eight water molecules per formula unit. Therefore, the pore volume is estimated to be approximately 0.09 mL g$^{-1}$ by the water adsorption isotherm.

### IR Spectrum

This dehydration process can be further confirmed by IR spectroscopy (Figure 6). The IR spectrum of the as-synthesized sample (Figure 6a) presents broad peaks at 3494 cm$^{-1}$

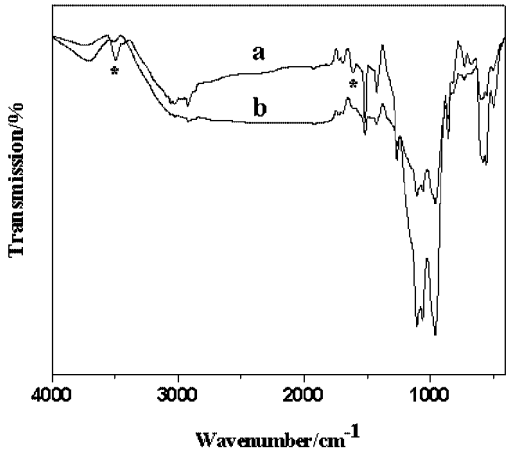

Figure 6. IR spectrum of the sample (a) and of the sample after calcination at 350 °C (b).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

corresponding to the stretching of water molecules and a sharp peak at 1618 $cm^{-1}$ corresponding to the bending vibration of coordinated water. After calcination at 350 °C for 2 h, the two types of peaks mentioned above decreased in size significantly (Figure 6b). The main structure peaks could correspondingly be observed in the spectrum of the calcined sample as compared to the as-synthesized sample, indicating that the main framework of the compound is retained after calcination.

### Magnetic Properties

The temperature-dependent (4–300 K) magnetic susceptibility of the compound is shown in Figure 7. Between 4 and 300 K, $\chi_m$ continuously increases with decreasing temperature and achieves a maximum of 0.115 $cm^3 mol^{-1}$ at 8.99 K. In the $1/\chi_m$ versus $T$ plot, the susceptibility can be fitted to the Curie–Weiss law with $C = 6.87\ cm^3 K mol^{-1}$. The Weiss temperature, $\theta = -50.97$ K, indicates that antiferromagnetic interactions exist between the metallic Co centers.

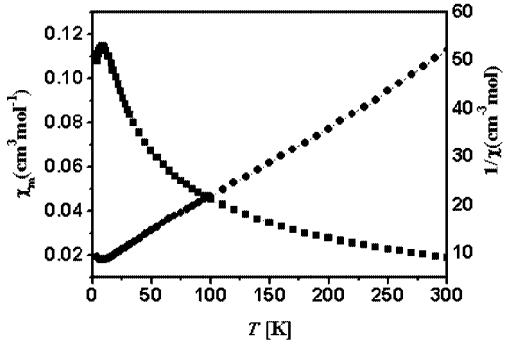

Figure 7. $\chi_m$ vs. $T$ and $1/\chi_m$ vs. $T$ plots of $Co_2(H_2O)_2[O_3PCH_2(C_6H_4)CH_2PO_3]$.

## Conclusions

A cobalt diphosphonate with micropores has been synthesized by a hydrothermal method. The structure was solved by single-crystal X-ray diffraction and found to be constructed of infinite cobalt oxygen layers pillared by *p*-xylylenediphosphonate groups. The compound is stable up to 500 °C, illustrating the exceptional stability of the framework. The more important feature is that it undergoes a reversible dehydration/rehydration process driven by temperature, which can be detected by changes in crystal color. This is a rare example of a metal diphosphonate framework that has a "defect" site with incomplete coordination, which can be created without loss of framework architecture. Such defect sites in compounds can result in changes in physical properties, such as color, and are expected to show shape-selective adsorption behavior for small molecules and could be potentially used as sensors, adsorbents, catalysts and so forth.

Currently, we are carrying out investigations into the ability of dehydrated compounds to absorb molecules other than water. Efforts toward the preparation of new hybrid materials containing other transition metals based on this type of ligand are underway.

## Experimental Section

**General Remarks:** All chemicals purchased were of reagent grade or better and were used without further purification. The elemental analyses were carried out with a Perkin–Elmer 240C elemental analyzer. TGA (thermal gravimetric analyses) were performed under nitrogen with a heating rate of 10 °C $min^{-1}$ by using a Perkin–Elmer TGA 7 thermogravimetric analyzer. XRD was performed with a Siemens D5005 diffractometer with Cu-$K_\alpha$ radiation, 40 kV, 35 mA at a scanning rate of 0.3°$min^{-1}$ ($2\theta$). The IR spectra were recorded (400–4000 $cm^{-1}$ region) with a Nicolet Impact 410 FTIR spectrometer by using KBr pellets.

**Synthesis of $Co_2(H_2O)_2[O_3PCH_2(C_6H_4)CH_2PO_3]$:** As a typical preparation procedure, a mixture of tetraethyl *p*-xylylenediphosphonate (0.03 mmol) and $Co(NO_3)_2{\cdot}4H_2O$ (0.03 mmol) was suspended in deionized water (8 mL) and cyclohexanol (2 mL), and then triethylamine (0.1 mL) was added while stirring to adjust the pH value of the mixture. The mixture (pH ≈ 6) was sealed in a 15-mL Teflon-lined autoclave after being stirred for 60 min. Upon being heated at 160 °C for 2 d, the autoclaved mixture was naturally cooled to room temperature. The pink crystals were collected, washed with deionized water, and dried at room temperature. The compound was stable in air and insoluble in water and common organic solvents. $C_8H_{12}Co_2O_8P_2$: calcd. C 23.10, H 2.90, Co 28.33, P 14.89; found C 23.40, H 3.34, Co 28.03, P 14.20.

**X-ray Crystallographic Study:** The intensity data were collected with a Smart CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ ($\lambda = 0.71073$ Å) radiation at 293 K in the $\omega$-scan mode. An empirical absorption correction was applied to the data by using the SADABS program.[36] The structures were solved by direct methods. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were fixed at calculated positions and refined by using a riding mode. All calculations were performed with the SHELXTL program.[37] The crystallographic data are summarized in Table 1, and the selected bond lengths and bond angles of the compound are listed in Table 2. CCDC-608190 for $Co_2(H_2O)_2[O_3PCH_2(C_6H_4)CH_2PO_3]$ contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Water Sorption Isotherm:** Water sorption isotherm studies were performed by measuring the increase in weight at equilibrium as a function of relative pressure. The weight of the sample was measured by a CAHN 2000 electrobalance and the adsorbate ($H_2O$) was added incrementally and manually.

**Supporting Information** (see footnote on the first page of this article): Figure S1, TGA curves of the compound after being calcined at 350 °C, and Figure S2, water sorption isotherm for the dehydrated compound, are available.

# Synthesis, Structure and Reactivity of Hydrated and Dehydrated Organotin Cations

**Vadapalli Chandrasekhar,*[a] Ramamoorthy Boomishankar,[a] Kandasamy Gopal,[a] Palani Sasikumar,[a] Puja Singh,[a] Alexander Steiner,[b] and Stefano Zacchini[b]**

**Keywords:** Organotin cations / Organooxotin / Organostannoxane / Acetylation / Transacetylation

Monomeric organotin dications $\{[n\mathrm{Bu_2Sn(H_2O)_4}]^{2+}\cdot 2\mathrm{C_6H_5SO_3^-}\}$ and $\{[n\mathrm{Bu_2Sn(H_2O)_4}]^{2+}\cdot 1,5\text{-}\mathrm{C_{10}H_6(SO_3^-)_2}\}$ have been synthesized by the reaction of $[n\mathrm{Bu_2SnO}]_n$ and the corresponding arylsulfonic acid. Dodecanuclear organooxotin macrocations $\{[(n\mathrm{BuSn})_{12}(\mu_3\text{-}\mathrm{O})_{14}(\mu_2\text{-}\mathrm{OH})_6]^{2+}\cdot 2\mathrm{RSO_3^-}\}$ (R = $\mathrm{C_6H_5}$; 2,5-$\mathrm{Me_2C_6H_3}$) have been synthesized by the reaction of *n*BuSn(O)(OH) and the corresponding arylsulfonic acid. The X-ray crystal structure of one of the dodecanuclear cages is reported. These organotin cations have been shown to be effective catalysts in acetylation and transacetylation reactions.

## Introduction

Organotin oxides $[(\mathrm{R_3Sn})_2\mathrm{O}; (\mathrm{R_2SnO})_n]$, hydroxides $[\mathrm{R_3SnOH}]$ and oxide hydroxides $[\{\mathrm{RSn(O)OH}\}_n]$ are important precursors for the synthesis of a large number of organotin compounds.[1] These precursors are the eventual hydrolysis products of the corresponding organotin halides. Initial hydrolysis of organotin halides leads to the formation of hydrated organotin cations.[2] Inspite of their apparent simplicity there have been very few reports on the isolation of such species in the solid state.[3] In most cases, dehydrated hydroxide-bridged compounds[4a] or oxo-bridged ladders[4b] are the products. In preliminary communications we have recently reported that arylsulfonic acids are effective in stabilizing $\{[n\mathrm{Bu_2Sn(H_2O)_4}]^{2+}\cdot 2\ 2,5\text{-}\mathrm{Me_2C_6H_3SO_3^-}\}$ (**1**)[5a] and $\{[n\mathrm{Bu_2Sn(H_2O)_3}]_2[\mu\text{-}1,5\text{-}\mathrm{C_{10}H_6(SO_3)_2}]\}^{2+}\cdot 1,5\text{-}\mathrm{C_{10}H_6(SO_3^-)_2}$ (**2**).[5b] Herein we report the general applicability of this synthetic procedure. Accordingly, the hydrated organotin cations, $\{[n\mathrm{Bu_2Sn(H_2O)_4}]^{2+}\cdot[x\mathrm{Y}]^{2-}\}$, where $x = 2$, $\mathrm{Y} = \mathrm{C_6H_5SO_3}$ (**3**); $x = 1$, $\mathrm{Y} = 1,5\text{-}\mathrm{C_{10}H_6(SO_3)_2}$ (**4**) have been prepared and characterized. Attempts to prepare hydrated monoorganotin cations resulted in the macromeric dodecanuclear organooxotin cages (*foot-ball cages*), $\{[(n\mathrm{BuSn})_{12}(\mu_3\text{-}\mathrm{O})_{14}(\mu_2\text{-}\mathrm{OH})_6]^{2+}\cdot 2\mathrm{RSO_3^-}\}$, where R = $\mathrm{C_6H_5}$ (**5**); 2,5-$\mathrm{Me_2C_6H_3}$ (**6**). The X-ray crystal structure of **6** is reported and compared with other members of this structural type. In view of the interest in neutral and cationic organotin compounds in esterification and transesterification reactions we have explored the catalytic activity of **1**–**6** towards acetylation of alcohols and phenols.

## Results and Discussion

### Synthesis of Organotin Cations

The synthesis of the organotin cations has been accomplished in high yields by the reaction of an organotin oxide with an arylsulfonic acid. The work-up of the reaction mixture and subsequent crystallization in open air allows the isolation of the compounds **1**–**4**. All of these organotin cations are air-stable solids. Compounds **3** and **4** are prepared by a reaction of the polymeric $[n\mathrm{Bu_2SnO}]_n$ with the corresponding sulfonic acids (Scheme 1). This procedure is similar to that reported by us recently for the synthesis of **1** (Scheme 1).[5a] Compound **2**, which contains two tin units bridged by a disulfonate, is synthesized by the dealkylation reaction involving a 1:1 reaction of $(n\mathrm{Bu_3Sn})_2\mathrm{O}$ with naphthalene-1,5-disulfonic acid.[5b] The dodecanuclear organooxotin cages **5** and **6** are assembled by the reaction of *n*-butylstannonic acid, *n*BuSn(O)(OH) with the corresponding sulfonic acids (Scheme 2).[6]

### Solution Studies

All of these compounds have been characterized by analytical and spectroscopic techniques (see experimental section). Consistent with the above formulation; conductivity studies on **3** and **4** revealed that these compounds are 1:2 electrolytes. While the specific and molar conductivities of **3** are 1811 $\mu\mathrm{S\,cm^{-1}}$ and 300 $\mathrm{S\,cm^2\,mol^{-1}}$ (3 mmol/L in

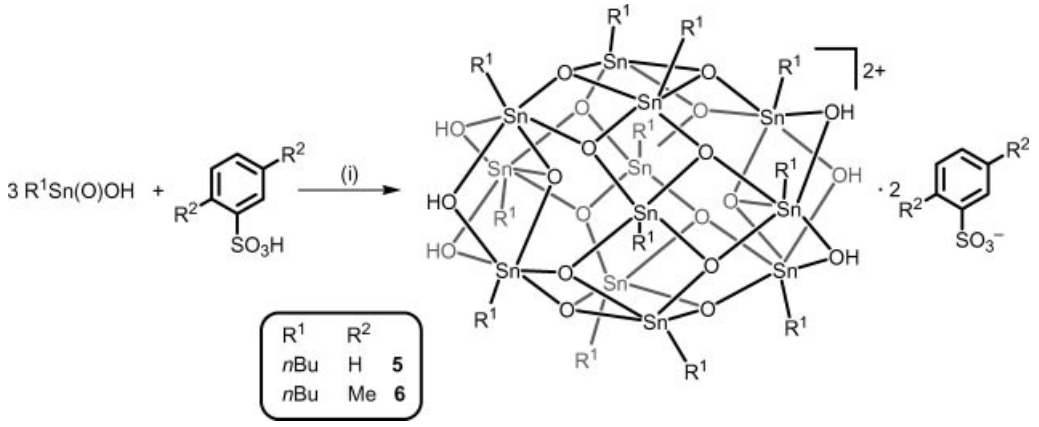

Scheme 2. Synthesis of monoorganotin macrocations **5** and **6**. (i) toluene, reflux, 72 h.

$CH_3OH$), **4** has a specific conductivity of 898 $\mu S\,cm^{-1}$ and a molar conductivity of 150 $S\,cm^2\,mol^{-1}$ (3 mmol/L in DMF) (Table 1). The increased ionic conductivity of **3** when compared to **1** [specific conductivity 946 $\mu S\,cm^{-1}$; molar conductivity 158 $S\,cm^2\,mol^{-1}$ (3 mmol/L in $CH_3OH$)][5a] and **4** is attributed to the increased acidic nature of **3** which arises due to the benzenesulfonate ligand. The $^{119}Sn$ NMR spectra of **3** and **4** show a single resonance at –360.6 and –384.9 ppm, respectively (Table 1), which are comparable to that observed for **1** (a single resonance at $\delta$ = –360.0 ppm)[5a] which is characteristic of a $C_2O_4$ environment around tin atoms.[1b]

The solution ionic conductivity measurement on **2** shows that the observed specific and molar conductivities are 2257 $\mu S\,cm^{-1}$ and 376 $S\,cm^2\,mol^{-1}$ (3 mmol/L in $CH_3OH$), respectively. These values suggest that in solution **2** does not exist as a 1:2 electrolyte but presumably undergoes an unsymmetrical disproportionation of the tin–sulfonate oxygen bond and thereby producing different kinds of cationic species. Support for such a hypothesis also comes from the $^{119}Sn$ NMR chemical shifts of the compound **2**. $^{119}Sn$ NMR spectrum of a [$D_6$]DMSO solution of **2** shows two resonances at –385.7 and 8.3 ppm (Table 1). Whereas, the signal at $\delta$ = –385.7 ppm corresponds to the six-coordinate

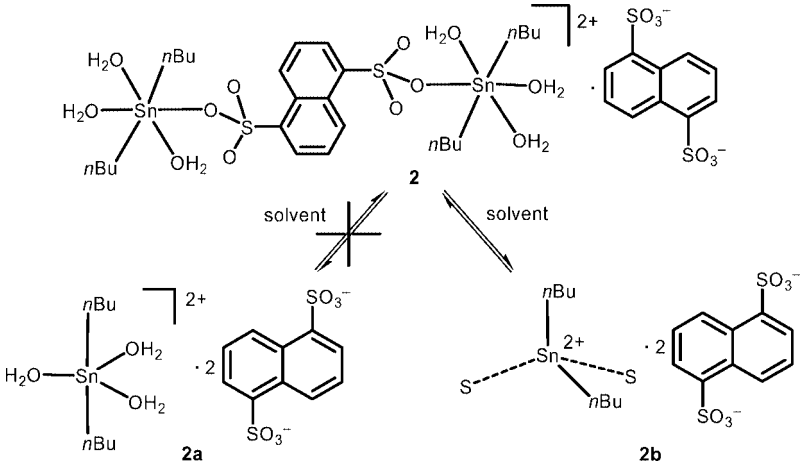

Scheme 3. Solution equilibrium exhibited by the cation **2**. S: more polar solvents ($CH_3OH$ or [$D_6$]DMSO).

$C_2O_4$ environment around tin, the value of +8.3 ppm is quite unusual for a diorganotin oxo species and could be attributed to a tetracoordinate tin containing two coordinated DMSO molecules.[7] If a very dilute solution is used only the signal at +8.3 ppm is seen. This could presumably due to the highly polar nature of the solvent DMSO which displaces all the ligated (water and sulfonate) groups of tin and thereby producing a $[n\mathrm{Bu_2Sn(DMSO)_2}]^{2+}$ species **2b** (Scheme 3).

The conductivity values of **5** and **6** suggest that these compounds are 1:2 electrolytes in solution. While the observed specific and molar conductivities of **5** are 1503 $\mu S\,cm^{-1}$ and 250 $S\,cm^2\,mol^{-1}$ (3 mmol/L in $CH_3OH$), the respective values observed for **6** are 971 $\mu S\,cm^{-1}$ and 162 $S\,cm^2\,mol^{-1}$ (3 mmol/L in $CH_3OH$), respectively (Table 1). The $^{119}Sn$ NMR spectra of **5** and **6** show two resonances around –280 and –460 ppm. The chemical shift value of $\delta$ = –280 ppm is characteristic of the five-coordinate tin situated at the equator of the molecule whereas the signal at $\delta$ = –460 ppm is due to the presence of six-coordinate tins at the poles.[6]

## Molecular Structure

Whereas the molecular structures of **1** and **2** have been determined previously,[5] that of **6** is reported here. The molecular structure of **6**·2(dioxane) is shown in Figure 1 (a). The macrocation is composed of a centrosymmetric $[(n\mathrm{BuSn})_{12}(\mu_3\text{-}O)_{14}(\mu_2\text{-}OH)_6]^{2+}$ moiety with the asymmetric unit possessing two symmetry-related "*half molecules*". The structure of this cationic tin cage was described previously by the use of anions such as chloride,[8a] hydroxide[8b] or phosphinate.[8c] There has been one report on the structure of this macrocation where *p*-toluenesulfonate is the counter anion.[6] The structure of the macrocation in **6** is like a *"football"* consisting of twelve tin atoms which are linked by $\mu_3$-oxo and $\mu_2$-hydroxo bridges. All the *n*-butyl chains situated on the tin atom are pointing outside the cage core. The bonding parameters found in this cage are given in Table 2 and are comparable with the literature values.[6,8] The structure of the molecule can be understood as follows. Among the twelve tin atoms present in the molecule, six are situated at the two poles of the cage and the remaining six

tin atoms occupy the equator of the cage. The poles consist of two trimeric *O-capped* subunits of $[(n\text{BuSn})_3(\mu_3\text{-O})(\mu_2\text{-OH})_3]$ (Figure 1, b).[9a] Within these subunits the tin atoms are hexa-coordinate and possess bridging oxo and hydroxo groups.

The shorter and longer Sn···Sn distances between the two poles are given in Figure 1 (b). The equator of the cage is spanned by a hexameric cycle $[(n\text{BuSn})_6(\mu_2\text{-O})_{12}]$ (Figure 1, c).[9a] In this sub-unit the tins are five-coordinate and are nearly square pyramidal. This hexameric cycle is stitched by means of six distannoxane motifs ($Sn_2O_2$) with the average diameter of the cycle being 6.366(5) Å. Thus, it is possible to envisage the construction of the cage by capping each side of the hexameric cycle by the two trimeric tin units.

## Supramolecular Assembly

In compound **6**, two molecules of the 2,5-dimethylbenzenesulfonate anion interact with three hydroxy groups at the poles through intermolecular O–H···O hydrogen bonding to generate a one-dimensional chain structure (Figure 2). The bonding parameters involved in these hydrogen bonds point to the fact that these are essentially strong hydrogen bonds. Hydrogen-bonding interactions among these cages have resulted in the formation of two different rings; a seven-membered $Sn_2O_4S$ ring and a 12-membered $Sn_2O_8S_2$ ring. The average O···O distance observed in this molecule is 2.72 Å and are comparable with the *p*-toluenesulfonate derivative.[6] The distance between two such polymeric sheets is 11.11 Å. Ribot et al. have utilized a similar type of cage as versatile nanobuilding blocks for the design of tin-based organic–inorganic hybrid materials.[10]

## Catalysis

In solution all the organotin cations behave as 1:2 electrolytes (Table 1). In view of their anticipated Lewis acidity, these compounds were tested as catalysts for acetylation of alcohols. All the organotin cations are very effective in the acetylation reactions of alcohols (Table 3 and Table 4). These reactions are completed much faster than those catalyzed by neutral tetraorganodistannoxanes.[11] Thus, acetylation of menthol (**7d**) and cholesterol (**7e**) are completed only in 15 min (Table 3; Entries 19–25 and 26–32). Interestingly, inspite of low positive charge, the macrocations **5** and **6** are also reasonably effective although the reaction times are slightly longer.[3d] The dications **1** and **3** are the most effective, in keeping with their increased Lewis acidity.

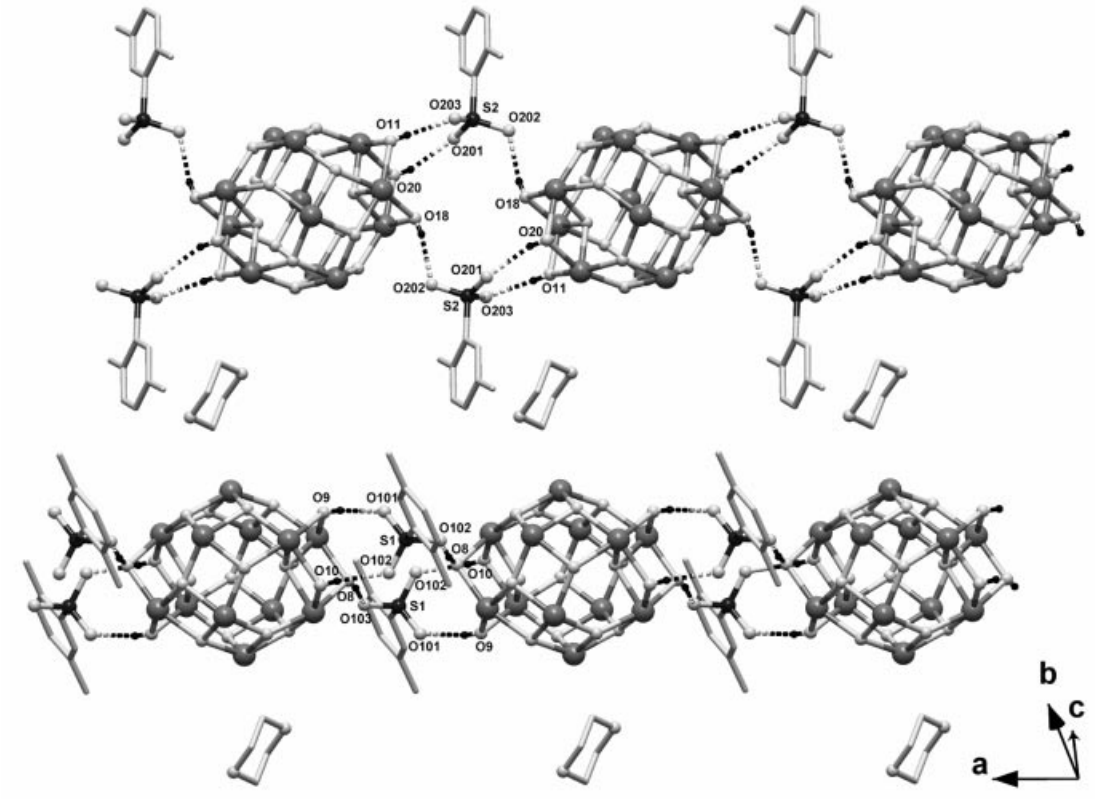

Figure 2. O–H···O hydrogen-bond-mediated one-dimensional supramolecular assembly in compound **6**. All the *n*-butyl groups on tin atoms along with their protons and protons in the sulfonate moieties are removed. Bonding parameters for hydrogen bonding are: O8–H8 0.701(1), H8···O103 2.027(2), O8···O103 2.701(1) Å, O8–H8···O103 161.45(3)°; O9–H9 0.680(4), H9···O101 2.104(3), O9···O101 2.757(3) Å, O9–H9···O101 161.21(4)°; O10–H10 0.688(2), H10···O102 2.043(4), O10···O102 2.725(5) Å, O10–H10···O102 171.22(1)°; O11–H11 0.696(6), H11···O203 1.985(4), O11···O203 2.681(8) Å, O11–H11···O203 178.18(5)°; O18–H18 0.696(1), H18···O202 2.053(3), O18···O202 2.736(8) Å, O18–H18···O202 167.44(1)°; O20–H20 0.690(1), H20···O201 2.058(3), O20···O202 2.721(5) Å, O20–H20···O201 161.45(2)°.

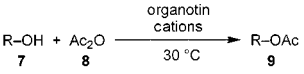
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Thus, even 0.05 mol-% of **1** is sufficient to drive the reaction to completion (Table 3; Entries 2 and 10). In all instances, just 0.2 mol-% of the organotin catalyst is sufficient for the completion of acetylation.

Table 3. Acetylation of alcohols catalyzed by organotin cations.[a]



| Entry | Substrate | Catalyst | Cat. conc. (mol-%) | Reaction time (min) | Yield (%)[b] |

[a] Reaction conditions: R–OH (1 mmol); $Ac_2O$ (1 mL); catalyst (mol-%); room temp. [b] Isolated yield. [c] See ref.[5a] [d] Product: diester.

Acetylation of phenols is also catalyzed quiet readily by the dications **1** and **3**. β-Naphthol (**7h**) is acetylated in the presence of **3** in nearly 55 min (Table 4; Entry 17). The reactions catalyzed by dinuclear and dodecanuclear organotin cations **2**, **5** and **6** require longer times (Table 4; Entries 5–7, 12–14 and 19–21). However, as before only 0.2 mol-% of the catalyst is required for completion of the reaction.

In order to assess if the organotin cations can be used for transacetylation reactions, two test cases were examined, using the reaction of the alcohols **7a** and **7b** with vinyl acetate (**10**) (Table 5). Transacetylation was completed in all cases quantitatively, although higher catalyst loadings were

## Conclusions

In summary, we report a series of organotin cations with varying nuclearity and charge and have shown their efficacy in acetylation and in transacetylation reactions. All of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

organotin cations are air-stable solids that can be prepared in excellent yields in a one-step synthesis, thus making them as potentially useful reagents.

## Experimental Section

**General Remarks:** Solvents were dried with sodium benzophenone ketyl and were collected from the still at the time of reaction. $(n\mathrm{Bu_3Sn})_2O$, $[n\mathrm{Bu_2SnO}]_n$, *n*BuSn(O)(OH), 1,5-$C_{10}H_6(SO_3H)_2{\cdot}4H_2O$ (Aldrich), L-menthol (Lancaster), cholesterol (Acro chemicals), cinnamyl alcohol (Fluka), $C_6H_5SO_3H$ (75% w/w water solution), phenol, *p*-cresol, acetic anhydride, vinyl acetate and β-naphthol (sd-fine, India) were purchased and used as such without any further purification. 2,5-$Me_2C_6H_3SO_3H$,[12] 1-phenylethanol,[12] 1,3-diphenyl-2-propen-1-ol[12] and organotin cations **1**[5a] and **2**[5b] were prepared by literature methods. Melting points were measured with a JSGW melting point apparatus and are uncorrected. Elemental analyses were carried out with a Thermoquest CE instruments model EA/110 CHNS-O elemental analyzer. Infrared spectra were recorded in dichloromethane solution as well as neat liquid or as KBr pellets with a FT-IR Bruker-Vector Model. $^1$H and $^{119}$Sn NMR spectra were obtained with a JEOL-JNM LAMBDA 400 model spectrometer using $CDCl_3$, $CD_3OD$ and $(CD_3)_2SO$ solutions with shifts referenced to tetramethylsilane (for $^1$H NMR) and tetramethyltin (for $^{119}$Sn NMR), respectively. $^{119}$Sn NMR spectra were recorded under broad-band decoupled conditions. Conductivity measurements were done with a Century Digital Conductivity Meter Model CC-601.

**Synthesis of $[n\mathrm{Bu_2Sn(H_2O)_4}]^{2+}{\cdot}2\mathrm{C_6H_5SO_3^-}$ (3):** A mixture of $[n\mathrm{Bu_2SnO}]_n$ (0.42 g, 1.68 mmol) and $C_6H_5SO_3H$ (75% w/w water solution) (0.70 g, 3.34 mmol) in toluene (60 mL) was heated under reflux for 8 h using a Dean–Stark apparatus to remove the water formed in the reaction by azeotropic distillation. A white puffy solid formed in the reaction was filtered by a sintered funnel (G-4), dried (in air) and identified as **3** (0.87 g, 87% yield). M.p. 270 °C (dec.). $C_{20}H_{36}O_{10}S_2Sn$ (619.33): calcd. C 38.78, H 5.85; found C 37.94, H 5.61. IR (KBr, cm$^{-1}$): $\tilde{\nu}$ = 3420 (br., $H_2O$), 1251 (s, $SO_3$ assym. str.), 1192 (s, $SO_3$ assym. str.), 1070 (s, $SO_3$ sym. str.), 1022 (s, $SO_3$ ionic) and 624 (m, C–S). $^1$H NMR (400 MHz, $CD_3OD$, ppm): $\delta$ = 0.83 (t, $J$ = 7.31 Hz, 6 H, butyl C$H_3$), 1.25 (q, $J$ = 7.31 Hz, 4 H, Sn–C$H_2$), 1.58–1.64 (m, 4 H, butyl C$H_2$), 1.75–1.80 (m, 4 H, butyl C$H_2$), 7.43–7.51 (m, 6 H, aromatic) and 7.82–7.85 (m, 4 H, aromatic). $^{119}$Sn NMR (150 MHz, $CD_3OD$, ppm): $\delta$ = –360.61 (s).

**Synthesis of $[n\mathrm{Bu_2Sn(H_2O)_4}]^{2+}{\cdot}1,5\text{-}\mathrm{C_{10}H_6(SO_3^-)_2}$ (4):** A mixture of $[n\mathrm{Bu_2SnO}]_n$ (0.30 g, 1.20 mmol) and 1,5-$C_{10}H_6(SO_3H)_2{\cdot}4H_2O$ (0.43 g, 1.20 mmol) was taken in toluene (60 mL) and heated under reflux for 8 h using a Dean–Stark apparatus to remove the water formed in the reaction by azeotropic distillation. A white solid formed in the reaction was filtered by a sintered funnel (G-4) and dried (in air) to obtain **4** in good yield (0.66 g, 93% yield). M.p. > 280 °C (dec.). $C_{18}H_{32}O_{10}S_2Sn$ (591.91): calcd. C 36.56, H 5.45; found C 36.29, H 5.19. IR (KBr, cm$^{-1}$): $\tilde{\nu}$ = 3454 (br., $H_2O$), 1206 (s, $SO_3$ assym. str.), 1161 (s, $SO_3$ assym. str.), 1044 (s, $SO_3$ ionic) and 613 (s, C–S). $^1$H NMR (400 MHz, [D$_6$]DMSO, ppm): $\delta$ = 0.86 (t, $J$ = 7.2 Hz, 6 H, butyl C$H_3$), 1.28 (q, $J$ = 7.2 Hz, 4 H, Sn–C$H_2$), 1.47–1.49 (m, 8 H, butyl C$H_2$C$H_2$), 7.44 (t, $J$ = 7.2 Hz, 2 H, aromatic), 7.95 (d, $J$ = 6.8 Hz, 2 H, aromatic) and 8.86 (d, $J$ = 8.4 Hz, 2 H, aromatic). $^{119}$Sn NMR (150 MHz, [D$_6$]DMSO, ppm): –384.91(s).

**Synthesis of $[(n\mathrm{BuSn})_{12}(\mu_3\text{-}O)_{14}(\mu_2\text{-}OH)_6]^{2+}{\cdot}2\mathrm{C_6H_5SO_3^-}$ (5):** A mixture of *n*BuSn(O)(OH) (1.80 g, 8.62 mmol) and $C_6H_5SO_3H$ (75% w/w water solution) (0.45 g, 2.87 mmol) in toluene (150 mL) was heated under reflux for 72 h using a Dean–Stark apparatus to remove the water formed in the reaction by azeotropic distillation. The reaction mixture was cooled and filtered through a sintered funnel (G-4) and the clear filtrate was evaporated in vacuo to yield **5** as a white amorphous solid (1.88 g, 95% yield). M.p. 196 °C. $C_{60}H_{124}O_{26}S_2Sn_{12}$ (2750.26): calcd. C 26.20, H 4.54; found C 26.09, H 4.24. IR (KBr, cm$^{-1}$): $\tilde{\nu}$ = 3214 (br., OH), 1258 (s, $SO_3$ assym. str.), 1194 (s, $SO_3$ assym. str.), 1126 (s, $SO_3$ sym. str.), 1035 (s, $SO_3$ ionic) and 618 (m, C–S). $^1$H NMR (400 MHz, $CDCl_3$, ppm): $\delta$ = 0.79–0.89 (m, 36 H, butyl C$H_3$), 1.05–1.69 (m, 72 H, Sn–C$H_2$C$H_2$C$H_2$) and 6.88–7.79 (m, 10 H, aromatic). $^{119}$Sn NMR (150 MHz, $CDCl_3$, ppm): $\delta$ = –284.28 [s, $^2J(^{117/119}\mathrm{Sn}{-}^{13}\mathrm{C})$ = 204, 208 Hz] and –463.8 [s, $^2J(^{117/119}\mathrm{Sn}{-}^{13}\mathrm{C})$ = 204 Hz].

**Synthesis of $[(n\mathrm{BuSn})_{12}(\mu_3\text{-}O)_{14}(\mu_2\text{-}OH)_6]^{2+}{\cdot}2$ 2,5-$\mathrm{Me_2C_6H_3SO_3^-}$ (6):** A mixture of *n*BuSn(O)(OH) (3.36 g, 16.10 mmol) and 2,5-$Me_2C_6H_3SO_3H$ (1.0 g, 5.37 mmol) in toluene (150 mL) was heated under reflux for 72 h using a Dean–Stark apparatus to remove the water formed in the reaction by azeotropic distillation. The reaction mixture was cooled and filtered through a sintered funnel (G-4) and the clear filtrate was evaporated in vacuo to yield **6** as a white amorphous solid (3.62 g, 96% yield). Crystals suitable for single-crystal X-ray diffraction were obtained by recrystallizing compound **6** in dioxane with 0.5% water. M.p. 158 °C. $C_{64}H_{132}O_{26}S_2Sn_{12}$ (2806.39): calcd. C 27.39, H 4.74; found C 26.97, H 4.85. IR (KBr, cm$^{-1}$): $\tilde{\nu}$ = 3198 (br., OH), 1193 (s, $SO_3$ assym. str.), 1195 (s, $SO_3$ assym. str.), 1088 (s, $SO_3$ sym. str.), 1021 (s, $SO_3$ ionic) and 616 (m, C–S). $^1$H NMR (400 MHz, $CDCl_3$, ppm): $\delta$ = 0.80 (t, $J$ = 7.32 Hz, 18 H, butyl C$H_3$), $\delta$ = 0.88 (t, $J$ = 7.36 Hz, 18 H, butyl C$H_3$), 1.19–1.32 (m, 24 H, Sn–C$H_2$), 1.38–1.70 (m, 48 H, butyl C$H_2$C$H_2$), 2.23 (s, 6 H, Ar–C$H_3$), 2.55 (s, 6 H, Ar–C$H_3$), 7.00 (s, 2 H, aromatic), 7.09 (s, 2 H, aromatic) and 7.69 (s, 2 H, aromatic). $^{119}$Sn NMR (150 MHz, $CDCl_3$, ppm): $\delta$ = –283.97 [s, $^2J(^{117/119}\mathrm{Sn}{-}^{13}\mathrm{C})$ = 204, 207 Hz] and –462.77 [s, $^2J(^{117/119}\mathrm{Sn}{-}^{13}\mathrm{C})$ = 205 Hz].

**General Procedure for Acetylation of Alcohols and Phenols:**[5a] A mixture of the alcohol or phenol (**7a**–**h**) (1 mmol), acetic anhydride (**8**) (1 mL) and catalytic amount (mol%) of the organotin catalyst **1**–**6** were stirred at room temperature. The progress of the reaction was monitored by TLC. At the end of the reaction excess acetic anhydride was removed in vacuo. The residual portion was dissolved in minimum amount of dichloromethane and filtered through a short column (in some cases the compound was eluted with ethyl acetate and hexane) to yield the corresponding acetate **9a**–**h**. All the acetates were characterized by $^1$H NMR spectra and compared with authentic samples.

**General Procedure for trans-Acetylation Reactions:** A mixture of alcohol (**7a**–**b**) (1 mmol), vinyl acetate (**10**) (10 mmol) and catalytic amount (1 mol%) of the tin catalyst **1**–**6** were refluxed at 75 °C. The progress of the reaction was monitored by TLC. After the reaction was complete, excess vinyl acetate was evaporated and the residue was subjected to column chromatography on silica gel to give acetates **9a**–**b** in good yields. All the acetates were characterized by $^1$H NMR spectra and compared with authentic samples.

**X-ray Crystallographic Study:** Colorless block-like crystal of **6** suitable for single-crystal X-ray diffraction was loaded on a Bruker AXS Smart Apex CCD diffractometer. The details pertaining to the data collection and refinement for **6** are as follows: size 0.4 × 0.4 × 0.3 mm$^3$; empirical formula $C_{66}H_{136}O_{27}S_2Sn_{12}$; $M_w$ = 2850.15; triclinic; space group $P\bar{1}$; $a$ = 12.6693(11) Å; $b$ = 16.4765(14) Å; $c$ = 24.8100(2) Å; $\alpha$ = 77.131(2)°; $\beta$ = 86.091(2)°; $\gamma$ = 69.637(2)°; $V$ = 4733.1(7) Å$^3$; $Z$ = 2; $T$ = 150(2) K; $D_{calcd.}$ = 2.000 Mg·m$^{-3}$; Mo-

$K_\alpha$ radiation; $\theta$ range 1.35 to 25.03°; 24859 reflections collected, 16441 independent reflections ($R_{int}$ = 0.0180); $R_1$ = 0.0271, $wR_2$ = 0.0688 [for $I > 2\sigma(I)$]; $R_1$ = 0.0314, $wR_2$ = 0.0715 (for all data); GOF = 1.015. The maximum and minimum electron densities are 0.964 and –0.727 e·Å$^{-3}$, respectively. The structure was solved by direct methods using SHELXS-97 and refined by full-matrix least-squares on $F^2$ using SHELXL-97.[13] The hydrogen atoms attached to oxygen atoms in the hydroxy groups were located from the difference map and their position were refined. All other hydrogen atoms were included in idealized positions, and a riding model was used. Non-hydrogen atoms were refined with anisotropic displacement parameters. A 1,4-dioxane molecule was also present in the asymmetric unit of **6** as a solvate.

CCDC-296001 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Figure 1 and 2 and its bonding parameters were obtained from DIAMOND 3.0 software package.[14]

# Synthesis and Reactivity of the $Ru^{III}$ Complexes $[RuTp(PR_3)Cl_2]$ − Precursors for RuTp Dihydrogen Complexes

**Sonja Pavlik,[a] Michael Puchberger,[b] Kurt Mereiter,[c] and Karl Kirchner*[a]**

**Keywords:** Ruthenium / N ligands / Dihydrogen complexes

The air-sensitive DMF-containing intermediate $[RuTp(PR_3)(Cl)(DMF)]$ is formed by refluxing a DMF solution of $[RuTp(COD)Cl]$ (**1**) in the presence of at least 1 equiv. of $PR_3$ ($PR_3$ = $PPh_3$, $PPh_2iPr$, $PiPr_3$, and $PCy_3$). On exposure to air in the presence of $CCl_4$, this complex is readily converted into the respective $Ru^{III}$ complexes $[RuTp(PR_3)Cl_2]$ (**2a–d**). These compounds are air-stable, readily accessible, permit easy variations as far as the electronic and steric properties of the $PR_3$ co-ligands are concerned, and are reducible to a variety of $Ru^{II}Tp$ complexes. Treatment of **2** with $NaBH_4$ affords dihydrogen compounds of the type $[RuTp(PR_3)(H)(\eta^2\text{-}H_2)]$. Reduction of **2** can also be accomplished with Zn in the presence of $CH_3CN$ and pyridine, which affords the diamagnetic $Ru^{II}$ compounds $[RuTp(PR_3)(CH_3CN)_2]^+$ (**4a–c**) and $[RuTp(PR_3)(py)Cl]$ (**5**). X-ray structures of representative complexes are presented.

## Introduction

In our continuing systematic studies of the chemistry of ruthenium trispyrazolylborate (Tp) complexes[1] we have shown that $[RuTp(PCy_3)(Cl)(DMF)]$ reacts with MeOH or EtOH in the presence of air to afford the $Ru^{III}$ alkoxide complexes $[RuTp(PCy_3)(Cl)(OR)]$ (R = Me, Et).[2] The formation of alkoxy compounds was restricted to very basic phosphanes, however, and failed, for instance, in the case of $PPh_3$. Nevertheless, these complexes turned out to be very useful precursors for a couple of new $Ru^{II}$ complexes of the types $[RuTp(PCy_3)(Cl)L]$ [L = $CH_3CN$, pyridine, CO, $P(OMe)_3$, $PMe_3$] and $[RuTp(PCy_3)(Cl)(=C=CHR)]$ (R = Ph, COOEt, $SiMe_3$, *n*Bu). In the present contribution, we sought a synthetic route to obtain alternative $Ru^{III}Tp$ precursors that are both air-stable, readily accessible, reducible to $Ru^{II}Tp$ complexes, and permit easy variations as far as the $PR_3$ co-ligands are concerned. We report here the synthesis, characterization, and reactivity of the dichloro $Ru^{III}$ complexes $[RuTp(PR_3)Cl_2]$ ($PR_3$ = $PPh_3$, $PPh_2iPr$, $PiPr_3$, $PCy_3$). These compounds turned out to be valuable precursors for dihydrogen complexes of the type $[RuTp(PR_3)(H)(\eta^2\text{-}H_2)]$ as well as other complexes containing the $[RuTp(PR_3)]^+$ fragment.

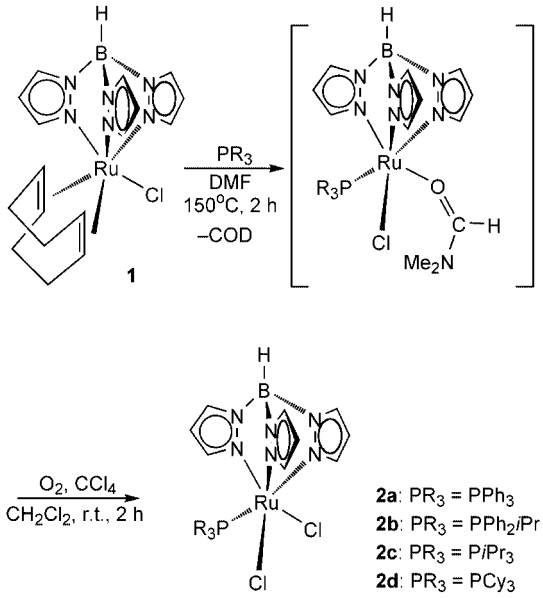
## Results and Discussion

The synthesis of $[RuTp(PR_3)Cl_2]$ ($PR_3$ = $PPh_3$, $PPh_2iPr$, $PiPr_3$, and $PCy_3$; **2a–d**) was performed as a one-pot reaction by refluxing a DMF solution of $[RuTp(COD)Cl]$ (**1**) in the presence of $PR_3$ (≥ 1 equiv.) to yield the air-sensitive DMF intermediate $[RuTp(PR_3)(Cl)(DMF)]$. On exposure to air in the presence of $CCl_4$, this complex is readily converted to afford, on workup, **2a–d** in 77–88% isolated yields (Scheme 1). No attempts were made to isolate the $[RuTp(PR_3)(Cl)(DMF)]$ intermediate in this reaction sequence. It should be noted, however, that the $PPh_3$ and $PPyr_3$ (Pyr = pyrrolyl) compounds $[RuTp(PPh_3)(Cl)(DMF)]$ and $[RuTp(PPyr_3)(Cl)(DMF)]$ have recently been isolated and even crystallographically characterized.[3] Complexes **2a–d** are thermally robust orange solids that are stable to air both in the solid state and in solution. They are very soluble in most common organic solvents such as $CH_2Cl_2$, THF, or toluene. All complexes were characterized by elemental analysis. The NMR spectra suffer from severe line broadening due to the paramagnetic nature of these complexes. The measured magnetic moments, $\mu_{eff}$, of **2a–2d** were determined at 295 K to be 1.89, 1.99, 1.90, and 1.40 $\mu_B$, respectively, consistent with a $d^5$ ($Ru^{III}$) low-spin configuration with one unpaired electron. To further probe the electronic structure of **2a–d**, we examined their redox behavior by cyclic voltammetry. All four complexes display only one oxidation-reduction wave with $E_{1/2}$ values vs. NHE of 0.31 ($PPh_3$), 0.24 ($PPh_2iPr$), 0.16 ($PiPr_3$), and 0.12 V ($PCy_3$). These values correlate roughly with the increasing electron σ-donating abilities and decreasing π-accepting properties of the tertiary phosphanes, i.e., the relative stability of the $Ru^{III}$ complexes follows the order $PPh_3$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$<$ $PPh_2iPr$ $<$ $PiPr_3$ $\approx$ $PCy_3$. Incidentally, the $E_{1/2}$ values decrease with increasing cone angles of the tertiary phosphane ligands.



Scheme 1.

The molecular structures of **2a**, **2b**, and **2d** are depicted in Figures 1, 2, and 3, respectively; selected bond lengths are reported in the captions. The coordination geometry of these complexes is approximately octahedral, and the bond lengths and angles in these three complexes are relatively uniform. Mean bond lengths for the three complexes are: Ru–Cl = 2.337(8) Å, Ru–N = 2.071(6) Å for N(2) and N(4), and Ru–N(6) = 2.112(4) Å; N(6) is *trans* to the phosphane, which exerts a *trans* effect, as shown by the Ru–N mean bond length elongation of 0.041 Å in comparison to the other Tp nitrogen atoms. The Ru–P bond lengths increase gradually from 2.364 Å in **2a** via 2.380 in **2b** to 2.417 Å in **2d**; this correlates with the electrochemical data. Another point of interest is the conformation of the $PPh_3$ ligand in **2a**, which instead of the frequent rotor (or propeller) has an irregular conformation, as can be shown by the Ru–P–

Selected bond lengths [Å] and angles [°]: Ru–N(2) 2.079(2), Ru–N(4) 2.069(2), Ru–N(6) 2.106(2), Ru–P 2.3642(6), Ru–Cl(1) 2.3236(6), Ru–Cl(2) 2.3368(6); P–Ru–Cl(1) 90.08(2), P–Ru–Cl(2) 90.28(2), Cl(1)–Ru–Cl(2) 95.80(2).

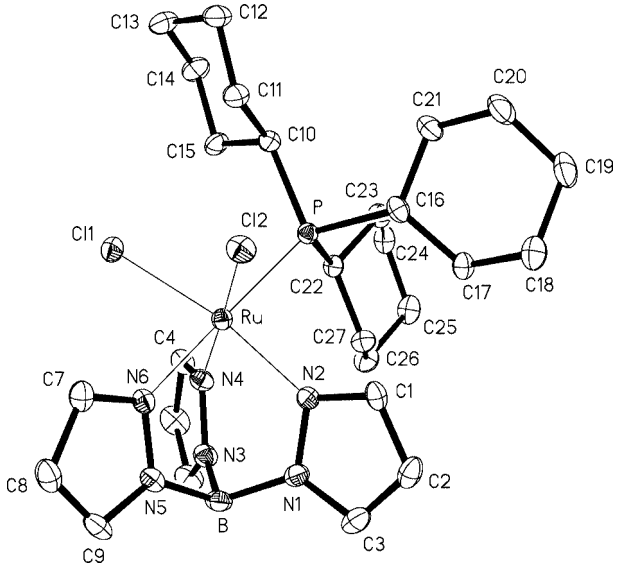

Figure 3. Structural view of $[RuTp(PCy_3)Cl_2]\cdot CH_2ClCH_2Cl$ (**2d**·$CH_2ClCH_2Cl$) showing 40% thermal ellipsoids (hydrogen and $CH_2ClCH_2Cl$ atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Ru–N(2) 2.065(2), Ru–N(4) 2.063(2), Ru–N(6) 2.114(2), Ru–P 2.4168(8), Ru–Cl(1) 2.3459(8), Ru–Cl(2) 2.3433(8), P–Ru–Cl(1) 95.36(3); P–Ru–Cl(2) 89.11(3), Cl(1)–Ru–Cl(2) 92.79(3).

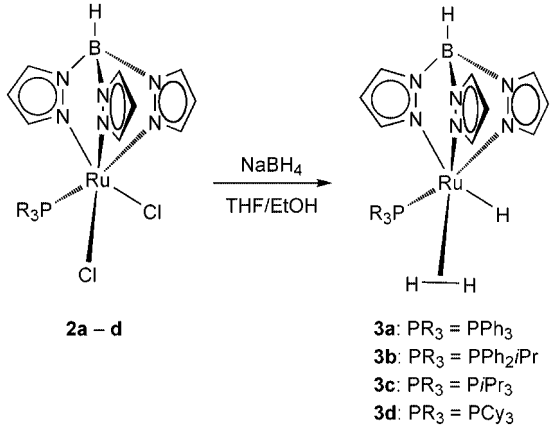
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$C_{ipso}$–C torsion angles of 63.6°, 66.8°, and –19.9° for phenyl rings C(10)–C(15), C(16)–C(21), and C(22)–C(27),[4] whereas the $PPh_3$ orientation relative to the $RuTpCl_2$ moiety is defined by an angle of 0.2° for N(2)–Ru–P–C(10). These data suggest that the phenyl ring C(22)–C(27) is in an approximately bisecting orientation and fits with C(23)–H(23) in between the two chlorine atoms (Figure 1). It is interesting to note that this appears to be a preferred configuration rather than merely a packing effect as the crystal structures of two solvates of **2a**, one with $ClCH_2CH_2Cl$ and one with $Et_2O$, have essentially the same complex conformation although they crystallize in entirely different lattices ($ClCH_2CH_2Cl$ solvate: orthorhombic, space group $P2_12_12_1$; $Et_2O$ solvate: triclinic, space group $P\bar{1}$).

Complexes **2** turned out to be useful reagents for the preparation of dihydrogen compounds of the types [RuTp(PR$_3$)(H)($\eta^2$-H$_2$)]. Thus, treatment of **2a**–**d** with $NaBH_4$ affords the diamagnetic $Ru^{II}$ compounds [RuTp(PR$_3$)(H)($\eta^2$-H$_2$)] (**3a**–**d**) in high yields (Scheme 2). All these compounds are thermally robust solids that slowly decompose in the presence of air both in the solid state and in solution. Characterization was accomplished by elemental analysis as well as $^1$H, $^{13}$C{$^1$H}, and $^{31}$P{$^1$H} NMR spectroscopy. Complexes **3a**–**d** show a doublet resonance for the hydride signal at all accessible temperatures in the range $\delta$ = –9.31 to –10.53 ppm (Table 1). The integration ratios toward the other ligands are in agreement with the presence of three metal-bound hydrogen atoms in all complexes. The presence of a dihydrogen ligand in **3b**–**d** is confirmed by the small $T_{1min}$ for the hydride signal, as shown in Table 1. Measurement of the relaxation time $T_{1min}$ has been reported previously for **3a**.[5] Irreversible isomerization to the ruthenium(IV) trihydride form [RuTp(PR$_3$)(H)$_3$] has not been observed, at variance with what commonly happens in related CpRu or Cp*Ru systems.[6]



Scheme 2.

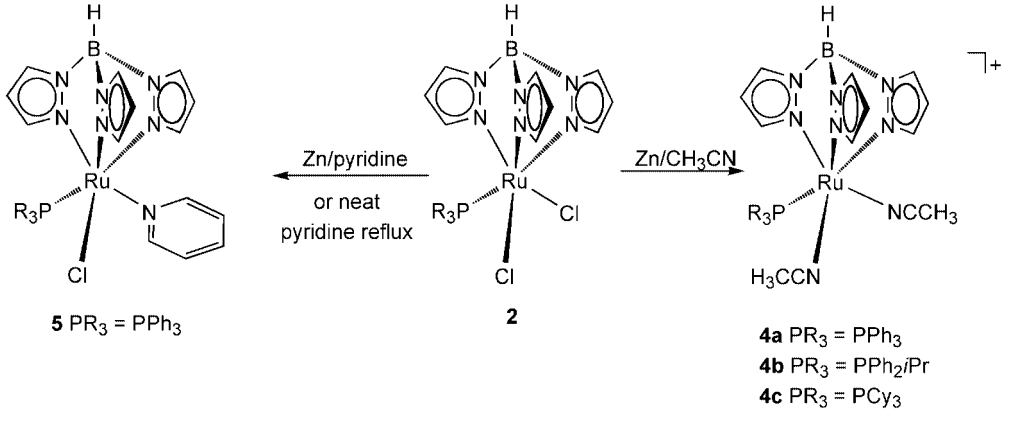
[a] Ref.[5]

It should be noted that this type of dihydrogen complex has also been prepared by different methods utilizing precursors such as [Ru(PCy$_3$)$_2$(H)$_2$HI],[7] [RuTp(PPh$_3$)(CH$_3$CN)H],[5] [RuTp(P*i*Pr$_2$Me)(CH$_3$CN)Cl],[8] and [RuTp*(COD)H].[9]

Reduction of complexes **2** can also be accomplished with Zn in the presence of suitable ligands. Thus, treatment of **2** with Zn in neat $CH_3CN$ affords the cationic diamagnetic $Ru^{II}$ compounds [RuTp(PR$_3$)(CH$_3$CN)$_2$]$^+$ (**4a**–**c**) with either $ZnCl_4^{2-}$ as counterion or, if the reaction is performed in the presence of $NaBPh_4$, with $BPh_4^-$ as counterion (Scheme 3). Similarly, reduction of **2** in the presence of pyridine (5 equiv.) yields the neutral complex [RuTp(PR$_3$)(py)Cl] (**5**). It is noteworthy that if **2** is refluxed in neat pyridine for 2 h, clean reduction to **5** also takes place in the absence of Zn powder. It was not possible to obtain the cationic bispyridine complex [RuTp(PR$_3$)(py)$_2$]$^+$ under these reaction conditions. Compounds **4** and **5** are thermally robust solids that are stable to air both in the solid state and in solution. Characterization was accomplished by elemental analysis and $^1$H, $^{13}$C{$^1$H}, and $^{31}$P{$^1$H} NMR spectroscopy; no unusual features were observed.



Scheme 3.

The structures of $[RuTp(PPh_2iPr)(CH_3CN)_2]_2(ZnCl_4)$ (**4b**) and $[RuTp(PPh_3)(py)Cl]$ (**5**) were determined by X-ray crystallography. The molecular structures are depicted in Figures 4 and 5, respectively; important bond lengths are reported in the caption. Complex **4b** is closely related in terms of stereochemistry and ligand disposition to complex **2b**, including the *trans* influence of the phosphane on the Ru–N(6) bond (Figure 4). Complex **5** is remarkable in having $PPh_3$ with a very regular propeller-like conformation, as can be seen by the three Ru–P–$C_{ipso}$–C torsion angles of –46.3°, –47.4°, and –54.1°. With this conformation and N(2)–Ru–P–C(10), the phenyl rings C(10)–C(15) and C(16)–C(21) exhibit stabilizing intramolecular π-π stacking interactions with one pyrazole and the pyridine ring.

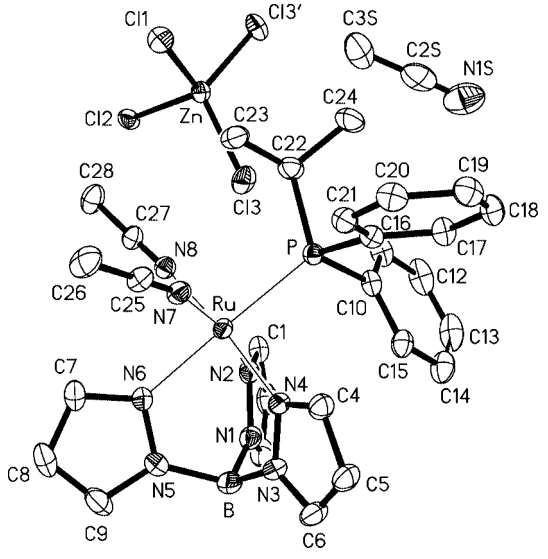

Figure 4. Structural view of $[RuTp(PPh_2iPr)(CH_3CN)_2]_2[ZnCl_4]\cdot CH_3CN$ (**4b**·$CH_3CN$) showing 30% thermal ellipsoids (hydrogen atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Ru–N(2) 2.064(2), Ru–N(4) 2.078(2), Ru–N(6) 2.113(2), Ru–P 2.3234(5), Ru–N(7) 2.028(8), Ru–N(8) 2.029(2), Zn–Cl(1) 2.258(1), Zn–Cl(2) 2.290(1), Zn–Cl(3) 2.307(1), Zn–Cl(3′) 2.238(2); P–Ru–N(7) 96.37(5), P–Ru–N(8) 92.90(4), N(7)–Ru–N(8) 90.54(6).

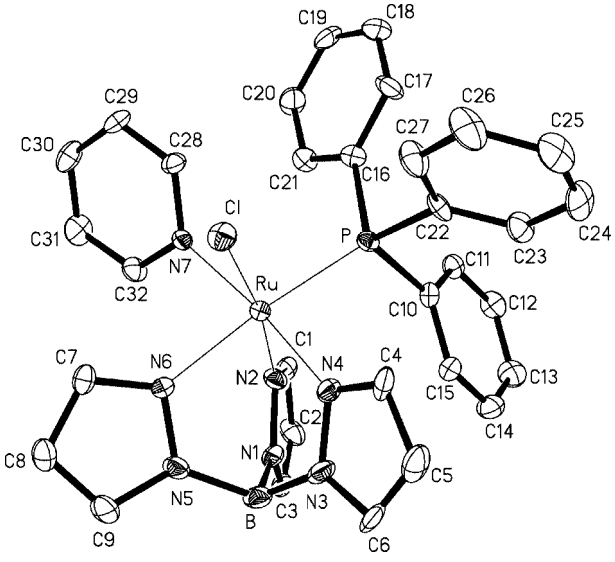

Figure 5. Structural view of $[RuTp(PPh_3)(py)(Cl)]\cdot$solv (**5**·solv) showing 30% thermal ellipsoids (hydrogen atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: Ru–N(2) 2.072(6), Ru–N(4) 2.063(7), Ru–N(6) 2.111(5), Ru–P 2.294(2), Ru–Cl 2.428(2), Ru–N(7) 2.080(7); P–Ru–Cl 98.44(6), P–Ru–N(7) 96.7(2), Cl–Ru–N(7) 86.2(2).

In summary, we have described a facile synthesis of a series air-stable dichloro $Ru^{III}$ complexes of the type $[RuTp(PR_3)Cl_2]$. These compounds are readily reduced to $Ru^{II}$ complexes containing the $[RuTp(PR_3)]^+$ fragment. The use of $NaBH_4$ as reducing agent gives the dihydrogen complexes $[RuTp(PR_3)(H)(\eta^2\text{-}H_2)]$, while with Zn in the presence of $CH_3CN$ and pyridine, respectively, complexes $[RuTp(PR_3)(CH_3CN)_2]^+$ and $[RuTp(PR_3)(py)Cl]$ are obtained.

## Experimental Section

**General:** All manipulations were performed under an inert atmosphere of purified argon by using Schlenk techniques. All chemicals were standard reagent grade and used without further purification. The solvents were purified according to standard procedures.[10] The deuterated solvents were purchased from Aldrich and dried with 4-Å molecular sieves. [RuTp(COD)Cl] (**1**) was prepared according to the literature method.[11] $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded with Bruker Avance-250, -300, and -400 spectrometers and are referenced to $SiMe_4$ and $H_3PO_4$ (85%), respectively.

**$[RuTp(PPh_3)Cl_2]$ (2a):** A suspension of **1** (150 mg, 0.33 mmol) and $PPh_3$ (89.1 mg, 0.34 mmol) in DMF (4 mL) was heated at reflux for 2 h. After removal of the solvent, the remaining residue was dissolved in $CH_2Cl_2$ and $CCl_4$ (2 mL) was added. After stirring of the solution for 2 h at room temperature, the volume of the solution was reduced to about 1 mL and the product was precipitated by addition of $Et_2O$ and petroleum ether. The residue was collected on a glass-frit, washed with $Et_2O$, and dried in vacuo. Yield: 183 mg (86%). $C_{27}H_{25}BCl_2N_6PRu$ (647.30): calcd. C 50.10, H 3.89, N 12.98; found C 50.21, H 3.91, N 12.41. $\mu_{eff}$ = 1.89 $\mu_B$.

**$[RuTp(PPh_2iPr)Cl_2]$ (2b):** This complex was prepared analogously to **2a** using **1** (150 mg, 0.33 mmol) and $PPh_2iPr$ (77.6 mg, 0.34 mmol) as starting materials. Yield: 174 mg (88%). $C_{24}H_{27}BCl_2N_6PRu$ (613.28): calcd. C 47.00, H 4.44, N 13.70; found C 47.11, H 4.35, N 13.88. $\mu_{eff}$ = 1.99 $\mu_B$.

**$[RuTp(PiPr_3)Cl_2]$ (2c):** This complex was prepared analogously to **2a** using **1** (150 mg, 0.33 mmol) and $PiPr_3$ (64.9 μL, 0.34 mmol) as starting materials. Yield: 156 mg (87%). $C_{18}H_{31}BCl_2N_6PRu$ (545.24): calcd. C 39.65, H 5.73, N 15.41; found C 39.55, H 5.40, N 15.53. $\mu_{eff}$ = 1.99 $\mu_B$.

**$[RuTp(PCy_3)Cl_2]$ (2d):** This complex was prepared analogously to **2a** using **1** (150 mg, 0.33 mmol) and $PCy_3$ (95.3 mg, 0.34 mmol) as starting materials. Yield: 169 mg (77%). $C_{27}H_{43}BCl_2N_6PRu$ (665.44): calcd. C 48.73, H 6.51, N 12.63; found C 48.60, H 6.91, N 12.70. $\mu_{eff}$ = 1.40 $\mu_B$.

**$[RuTpH(H_2)(PPh_3)]$ (3a):** $NaBH_4$ (28 mg, 0.75 mmol) was added to a solution of **2a** (100 mg, 0.15 mmol) in THF (5 mL) and EtOH (1 mL) and the reaction mixture was stirred at room temperature for 2 h. The solution was then evaporated to dryness and the residue was redissolved in THF. Insoluble materials were removed by filtration and the solution was again evaporated to dryness to yield

**[RuTp(PCy$_3$)(CH$_3$CN)$_2$]BPh$_4$ (4c):** $NaBPh_4$ (56.6 mg, 0.165 mmol) and Zn powder (98 mg, 1.5 mmol) were added to a solution of **2d** (100 mg, 0.15 mmol) in acetonitrile and the reaction mixture was stirred at room temperature for 2 h. Insoluble materials were removed by filtration. The volume of the solution was then reduced to about 1 mL and the product was precipitated by addition of $Et_2O$. The pale-yellow residue was collected on a glass frit, washed with $Et_2O$, and dried in vacuo. Yield: 126 mg (89%). $C_{51}H_{63}B_2N_8PRu$ (941.78): calcd. C 65.04, H 6.74, N 11.90; found C 64.97, H 6.78, N 11.89. $^1$H NMR ($CD_3CN$, 20 °C): $\delta$ = 7.91–7.79 (m, 3 H, Tp), 7.78–7.70 (m, 1 H, Tp), 7.67–7.55 (m, 2 H, Tp), 7.38–7.14 (m, 8 H, Ph), 7.09–6.92 (m, 8 H, Ph), 6.90–6.74 (m, 4 H, Ph), 6.37–6.22 (m, 3 H, Tp), 2.43 (6 H, C*H*$_3$CN), 2.26–2.05 (m, 3 H, Cy), 1.82–1.56 (m, 18 H, Cy), 1.54–1.32 (m, 4 H, Cy), 1.31–1.02 (m, 8 H, Cy) ppm. $^{13}$C{$^1$H} NMR ($CD_3CN$, 20 °C): $\delta$ = 146.1–121.7 (Ph, Tp, $CH_3CN$), 106.5 (Tp), 106.2 (d, $J_{C,P}$ = 2.1 Hz, Tp), 34.6 (d, $^1J_{C,P}$ = 18.6 Hz, CH), 29.1 ($CH_2$), 27.4 (d, $J_{C,P}$ = 9.7 Hz, $CH_2$), 26.3 ($CH_2$), 3.9 ($CH_3CN$) ppm. $^{31}$P{$^1$H} NMR ($CD_3CN$, 20 °C): $\delta$ = 38.8 ppm.

**[RuTp(PPh$_3$)(py)Cl] (5). Method (a):** Pyridine (63 μL, 0.75 mmol) and Zn powder (98 mg, 1.5 mmol) were added to a solution of **2a** (100 mg, 0.15 mmol) in toluene, and the reaction mixture was stirred at room temperature for 1 h. Insoluble materials were removed by filtration. The volume of the solution was then reduced to about 1 mL and the product was precipitated by addition of $Et_2O$ and petroleum ether. The yellow residue was collected on a glass frit, washed with $Et_2O$ and petroleum ether, and dried under vacuum. Yield: 102 mg (98%).

**Method (b):** A solution of **2a** (100 mg, 0.15 mmol) in pyridine (5 mL) was heated at reflux for 2 h. The volume of the solution was then reduced to about 1 mL and the product was precipitated by addition of $Et_2O$ and petroleum ether. The yellow residue was collected on a glass frit, washed with petroleum ether, and dried under vacuum. Yield: 98 mg (95%). $C_{32}H_{30}BClN_7PRu$ (691.11): calcd. C 55.63, H 4.38, N 14.19; found C 55.70, H 4.48, N 14.23. $^1$H NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 8.78 (d, $J_{H,H}$ = 8.8 Hz, 2 H, py), 7.99 (t, $J_{H,H}$ = 7.7 Hz, 1 H, py), 7.89–6.73 (m, 22 H, Ph, Tp, py), 6.63 (d, $J_{H,H}$ = 1.7 Hz, 1 H, Tp), 6.18–6.12 (m, 1 H, Tp), 5.92 (dd, $^1J_{H,H}$ = 2.2, $^2J_{H,H}$ = 2.3 Hz, 1 H, Tp), 5.80 (dd, $^1J_{H,H}$ = 2.3, $^2J_{H,H}$ = 2.3 Hz, 1 H, Tp) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 156.4 (py), 146.4 (Tp), 141.9 (Tp), 140.1 (Tp), 137.5–127.5 (Ph, Tp, py), 125.5 (py), 105.8 (Tp), 105.4 (Tp) ppm. $^{31}$P{$^1$H} NMR ($CD_2Cl_2$, 20 °C): $\delta$ = 54.7 ppm.

**X-ray Structure Determination:** Crystals of **2a**, **2b**, **4b**·$CH_3CN$, and **5**·solv were obtained by diffusion of $Et_2O$ or pentane into solutions in $CH_2Cl_2$ (**2a**, **2b**, **5**) or $CH_3CN$ (**4b**). Crystals of **2d**·$CH_2ClCH_2Cl$ were obtained by solvent evaporation. Crystal data and experimental details are given in Table 2. X-ray data were collected on a Bruker Smart CCD area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and 0.3° $\omega$-scan frames covering either hemispheres or complete spheres of the reciprocal space. Corrections for absorption, $\lambda$/2 effects, and crystal decay were applied.[12] The structures were solved by direct methods using the program SHELXS-97.[13] Structure refinement on $F^2$ was carried out with the program SHELXL-97.[4] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were inserted in idealized positions and were refined as riding on the atoms to which they are bonded. Solvent disorder (**2d**·$CH_2ClCH_2Cl$, **4b**·$CH_3CN$) and anion disorder (**4b**·$CH_3CN$) was taken into account. The disordered solvent in **5**·solv (a mixture of $CH_2Cl_2$ and $Et_2O$) was squeezed with the program PARST.[14]

**5**·solv) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electrochemical Studies:** Cyclic voltammograms were measured in a three-electrode cell using a 0.2-mm-diameter glassy carbon working electrode, a platinum auxiliary electrode, and a Ag|Ag$^+$ reference electrode containing 0.1 M $AgNO_3$, the potential of which was corrected using an internal standard redox couple of ferrocenium/ferrocene. Measurements were performed at room temperature using an EG & G PARC 273A potentiostat/galvanostat. Deaeration of solutions was accomplished by passing a stream of argon through the solution for 5 min prior to the measurement and then maintaining a blanket atmosphere of argon over the solution during the measurement. The potentials were measured in 0.15 M [*n*Bu$_4$N][BF$_4$]/CH$_3$CN, using FeCp$_2$ ($E_{1/2}$ = +0.69 V vs. NHE) as internal standard and are quoted relative to NHE.

**Magnetic Measurements:** For the determination of the magnetic susceptibility, the powdered complex was pressed into pellets. VT magnetic susceptibility measurements of the complex were performed with a superconductivity interferometer device (SQUID) in external fields of up to 3 T, within the temperature range 4.2–300 K.

## Acknowledgments

Financial support by the "Fonds zur Förderung der wissenschaftlichen Forschung" is gratefully acknowledged (project no. P16600-N11). We thank G. Hilscher for the measurements of the magnetic moments and C. Kowol for carrying out the electrochemical studies.

# New Coordination Modes of Substituted Benzohydroxamic Acid with Dialkyltin(IV): Structural Diversity through Ligand Isomerization

**Xian-mei Shang,[a,b] Ji-zhou Wu,*[b] and Qing-shan Li*[a,b]**

**Keywords:** Coordination modes / Organotin / Hydroxamic / Hydroximic / Isomerization

When $R_2SnCl_2$ (R = Me, *n*Bu) reacted with substituted benzohydroxamic acid (substituent = 4-F; 2,4-$Cl_2$; 2,5-$F_2$) and potassium hydroxide in aqueous methanol solution, two types of condensation products could be obtained, depending on the molar ratio $R_2SnCl_2$/RCONHOH/KOH. When a 1:1:2 molar ratio was used, 1:1 alkyltin hydroxamates $\{(n\text{-}C_4H_9)_2Sn[4\text{-}FC_6H_4C(O)NO]\}_n$ (**1**) and $\{(CH_3)_2Sn[2,5\text{-}F_2C_6H_3C(O)NO]\}_n$ (**2**) were formed. When a 1:2:2 ratio was used, another two unexpected 2:3 alkyltin hydroxamates, $\{(CH_3)_4Sn_2[(2,4\text{-}Cl_2C_6H_3C(O)NHO)_2][2,4\text{-}Cl_2C_6H_3C(O)NO]\}_n$ (**3**) and $\{(n\text{-}C_4H_9)_4Sn_2[(4\text{-}FC_6H_4C(O)NHO)_2][4\text{-}FC_6H_4C(O)NO]\}_n$ (**4**), were obtained. All these complexes were characterized by elemental analysis, IR, $^1H$, $^{13}C$, $^{119}Sn$ NMR spectra and X-ray diffraction analysis. The results indicated overall (*Z*)-iminol coordination mode in the hydroximic tautomeric form for **1** and **2**, and keto-iminol mixed-coordination mode including both in (*Z*)-hydroxamic and -hydroximic tautomeric forms for **3** and **4**.

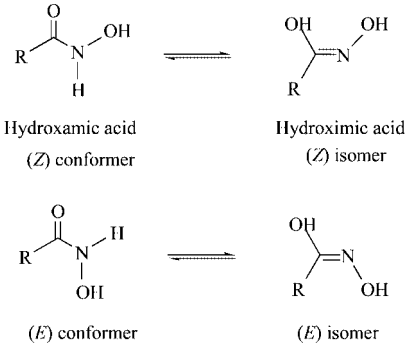
## Introduction

Hydroxamic acids (HAs) have attracted considerable attention recently as supporting ligands in organometallic chemistry and biology because of their tautomerization,[1] and potential as therapeutics agents.[2] The biological importance and different conformation of HAs may make their organometallic derivatives exert a subtle influence on their medicinal applications. In principle, each of the two oxygen atoms of the hydroxamato ligand is capable of acting as a coordination site, and the bonding modes are flexible. Moreover, tautomers of HAs assume different conformations or configurations, as indicated in Scheme 1. The HAs preferentially adopt the (*Z*) configurations when binding with metal ions to form a complex, either through the hydroxamic acid form or the hydroximic acid form. In addition, it is well documented by both theoretical[3] and experimental studies that the hydroxamic form is the dominant one in free acids[4] or metal hydroxamates.[5]

Despite these attractive features, studies on the coordination modes of the complexes possessing hydroxamic ligands are still relatively scarce. According to the literature,[6] the complexes of hydroxamic derivatives with metal formed O,O five-membered chelate rings in most cases, and the ligands were usually in the hydroxamic form rather than hydroximic form. To the best of our knowledge, the complexes in which ligands are only in the hydroximic form are rarely observed, and indeed, a case with the ligands coordinated to the metal center both in the hydroxamic and hydroximic forms in the same complex has not yet been reported.



Scheme 1. Isomers of hydroxamic acids.

On the other hand, in contrast to the extensive chemistry of transition-metal hydroxamato complexes,[7,8] little is known about the hydroxamato organotin(IV) complexes,[9] especially their coordination modes. The synthesis and structure of 1:2 diorganotin(IV)/hydroxamato complexes have been previously reported by our group,[10,11] which provides a novel coordination mode for hydroxamato diorganotin(IV) complexes. To obtain a deeper insight into the influence of the ligand and to further explore structural diversity, in this work, an extension of the work on the 1:2 diorganotin(IV)/hydroxamato complexes was carried out, and four unusual complexes containing the (*Z*) isomer hydroximic ligand were obtained, presenting novel 1:1 and 2:3 organotin(IV)/hydroxamato complexes with hydroximic ligands. Furthermore, the reaction of substituted benzohydroxamic acid with dialkyltin(IV) compounds, leading to

the formation of these special organotin(IV) complexes with hydroximato ligands, is also discussed.

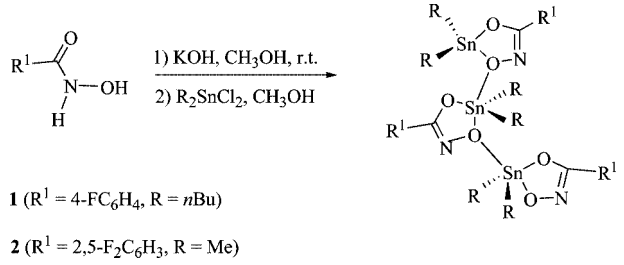
## Results and Discussion

### Reaction of Dialkyltin Dichloride with Substituted Benzohydroxamic Acid

To obtain a deeper insight into the coordination of hydroxamic acid to the tin center, the reaction of dialkyltin dichloride with substituted benzohydroxamic acid was studied. It was found that the reaction of dialkyltin dichloride ($Bu_2SnCl_2$ and $Me_2SnCl_2$) with substituted benzohydroxamic acid and potassium hydroxide at a 1:1:2 ratio in methanol/water gave 1:1 dialkyltin hydroxamates $\{(n\text{-}C_4H_9)_2Sn[4\text{-}FC_6H_4(O)C{=}NO]\}_n$ (**1**) and $\{(CH_3)_2Sn[2,5\text{-}2F\text{-}C_6H_3C(O)NO]\}_n$ (**2**). When a 1:2:2 ratio was used, another two unexpected 2:3 alkyltin hydroxamates, $\{(CH_3)_4Sn_2[(2,4\text{-}Cl_2C_6H_3C(O)NHO)_2][2,4\text{-}Cl_2C_6H_3C(O)NO]\}_n$ (**3**) and $\{(n\text{-}C_4H_9)_4Sn_2[(4\text{-}FC_6H_4C(O)NHO)_2][4\text{-}FC_6H_4C(O)NO]\}_n$ (**4**), were obtained. All of these complexes contain chelating hydroximic acid ligands [(*Z*) isomer], which is obviously different from well-known dialkyltin hydroxamates. Although the reactions of metal ions with hydroxamic acid have been studied extensively, most of them form 1:2 complexes containing hydroxamic acid ligands [(*Z*) conformer], and very little is reported on complexes containing hydroximic acid ligands [(*Z*) isomer]. Presumably, complexes **1**, **2**, **3**, and **4** could result from the tautomerism of the hydroxamic acid ligand, as shown in Scheme 1. The present observation might be attributed to three favorable factors: (1) the alkaline reaction conditions might make the equilibrium (as shown in Scheme 1) move from hydroxamic acid [(*Z*) conformer] toward hydroximic acid [(*Z*) isomer] easily, and thus, the hydrogen atom linked to the nitrogen atom could migrate to the oxygen atom of the carbonyl group; then the ratio of hydroximic acid in the keto-iminol tautomerism equilibrium would be raised in this way, resulting in these complexes with new coordinated modes; (2) the strong electron-withdrawing nature of F or Cl may enhance the 1,3-migratory aptitude of the hydrogen atom in the hydroxamic acid ligands; (3) it is also conceivable that a hydroxamic acid in the (*E*) conformation could also give the observed products, as any energy requirement for isomerism to the (*Z*) form would be compensated for by the favorable energetics associated with the formation of a stable five-membered chelate ring (i.e. chelate effect).

### Syntheses and Characterizations of 1 and 2

When dialkyltin dichloride ($Bu_2SnCl_2$; $Me_2SnCl_2$) reacts with substituted benzohydroxamic acid (substituent = 4-F; 2,5-$F_2$) and potassium hydroxide, 1:1 condensation products **1** and **2** can be obtained (Scheme 2). In the IR spectra for the two complexes, a remarkable difference is the complete disappearance of the stretching vibration bands of N–H in contrast to their free ligands. This unambiguously confirms that these ligands are coordinated to the tin atoms through the hydroximic form. The characteristic absorptions at both 1661–1610 $cm^{-1}$ in the spectra of **1** and **2** indicate the presence of a C=N group.[12–15] For **1**, the Bu–Sn–Bu angle of 129° calculated from the equation of Holeček and Lyčka[16] is very close to the value of 130.1(4)° found by X-ray analysis (Table 1). The Me–Sn–Me angle for **2** in solution calculated from the equation of Lockhart and Manders[17] is 128°, also close to the 131.45(19)° observed in the solid state (Table 2). The $^{119}Sn$ NMR spectroscopic data show only one signal at $\delta \approx -124.8$ ppm for **1** and $\delta \approx -129.9$ ppm for **2**, indicating a typical five-coordinate species,[16] which was further confirmed by single-crystal X-ray analysis.

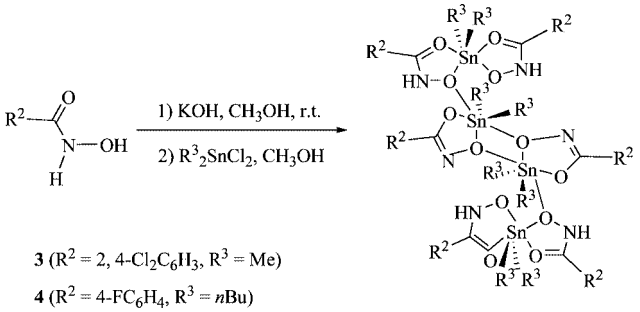


**1** ($R^1$ = 4-$FC_6H_4$, R = *n*Bu)

**2** ($R^1$ = 2,5-$F_2C_6H_3$, R = Me)

Scheme 2.

Reaction of dialkyltin dichloride ($Me_2SnCl_2$; $Bu_2SnCl_2$) with substituted benzohydroxamic acid (substituent = 2,4-$Cl_2$; 4-F) in 1:2 stoichiometry yields 2:3 condensation products **3** and **4** (Scheme 3). In their free ligands, a strong band near 3207 $cm^{-1}$ is observed, assigned to be the $\nu$(NH) absorption, which is shifted to higher frequency (near 3290 $cm^{-1}$) in the two complexes. This shows that the NH group is retained in the two complexes. In the $^1H$ NMR spectra of complex **3**, two single resonances for the proton in the –NH–O– group are observed at $\delta$ = 9.21 and 10.56 ppm, indicating that the proton of the –NH–O– group exists in complex **3**, and confirming the ligand coordinates to the tin atom in the keto (hydroxamato) form.



**3** ($R^2$ = 2, 4-$Cl_2C_6H_3$, $R^3$ = Me)

**4** ($R^2$ = 4-$FC_6H_4$, $R^3$ = *n*Bu)

Scheme 3.

The $^{119}Sn$ NMR spectroscopic data show two signals at $\delta \approx -222.6$ and –221.0 ppm for **3** ($\delta \approx -217.4$, –216.6 ppm for **4**), indicating the presence of two different tin sites in solution, which has been confirmed in the solid state for **3** and **4**. The $\delta(^{119}Sn)$ values of compounds **3** and **4** belong in the range of six-coordinate compounds.[16,18] In complexes

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**3** and **4**, the ligands are also coordinated to the tin atom in the iminol (hydroximato) form, which was verified by X-ray crystal diffraction technique and is discussed below.

### Crystal Structures of Complexes 1 and 2

Selected bond lengths and angles of complexes **1** and **2** are listed in Tables 1 and 2, respectively. The molecular structures of the two complexes are shown in Figures 1 and 2 for a single chain based on the one-dimensional oxygen-bridged dialkyltin(IV) complex. The substituted benzohydroximic ligands are found to be chelated to the Sn atom through the carbonyl O atom and the hydroxy O atom, and Sn–O bond lengths are 2.065(6) and 2.191(5) Å for **1**, and 2.064(2) and 2.155(2) Å for **2**. The $Sn^{IV}$ atoms are bonded to two alkyl groups, and the C(8)–Sn1–C(12) linkage for **1** [C(8)–Sn1–C(9) for **2**] is not linear, having an angle of 130.1(4)° for **1** [131.45(19)° for **2**]. All these Sn–C and Sn–O bond lengths and also all bond angles around the Sn center are typical values compared with other diorganotin(IV) complexes.[19,20]

However, the endocyclic C–N and C–O bond lengths are special in contrast with those of well-known 1:2 diorganotin hydroxamates. The bond length C(7)–N(1) in complex **1** is 1.237(9) Å, and is significantly shorter than the values in the known 1:2 complexes [the average C–N distance of 1.32 Å is comparable to the corresponding distance in diorganotin(IV) hydroxamates]. Moreover, no hydrogen atom is at the N1 position, suggesting that the C–N bond in complex **1** is a typical double bond.[21] Meanwhile, the bond length C(7)–O(1) in complex **1** is 1.378(9) Å, and is significantly longer than the typical value of C=O [the average C=O distance of 1.25 Å is comparable to the corresponding distance in diorganotin(IV) hydroxamates],[22] which shows the C–O bond in the complex should be a typical single bond. The bonding mode is in good agreement with hydroximic acid [(*Z*) isomer]. From the above analysis it could be concluded that the ligand is coordinated to the tin(IV) atom in the hydroximic acid form, and complex **1** is a hydroximate rather than a hydroxamate.

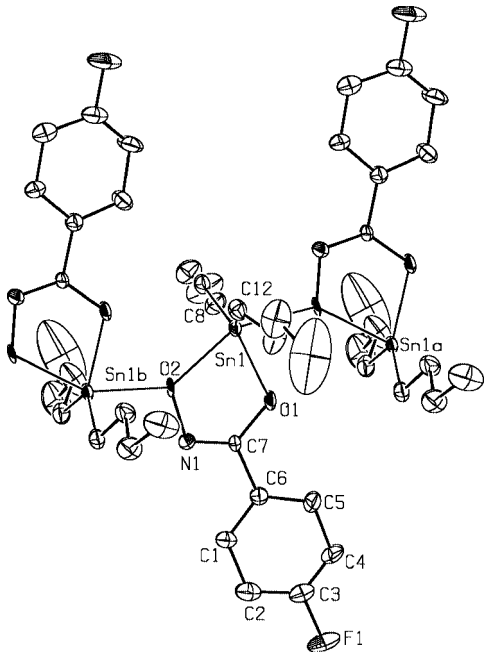


Figure 1. Diagram of a section of polymeric **1**. Hydrogen atoms are omitted for clarity.

For complex **2**, the overall structure (Figure 2, Table 2) is similar to that of complex **1**. The $Sn^{4+}$ ion is bonded with two $CH_3$ groups and one substituted benzohydroximic ligand. The coordination number of the Sn atom is 5. The complex has no unusual distances or angles in the $Me_2Sn$ unit.

Like complex **1**, the bond length C(7)–N(1) in complex **2** is 1.286(5) Å, and is significantly shorter than those values in the known 1:2 complexes.[11] Consistently, the average C(7)–O(2) distance [1.318(4) Å] of complex **2** is significantly

longer than the corresponding distance of C=O, indicating the C–O bond in complex **2** should be a typical single bond. These data show that the ligand is coordinated to the tin(IV) atom in the hydroximic acid form and the coordination mode of complex **2** is similar to that of complex **1**.

### Crystal Structures of Complexes 3 and 4

The molecular structures of **3** and **4** are shown in Figures 3 and 4, respectively. Selected bond lengths and angles for complexes **3** and **4** are listed in Tables 3 and 4, respec-

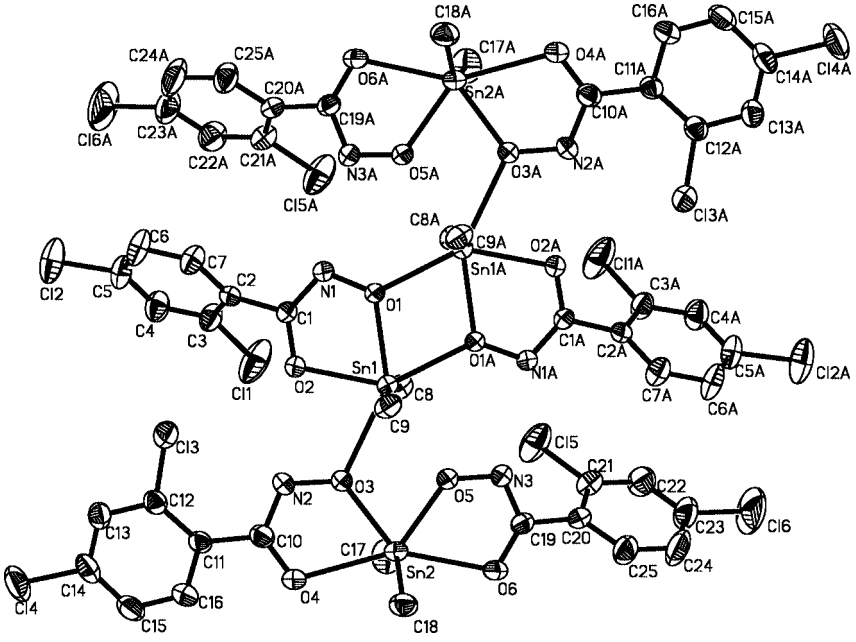

Figure 3. Diagram of the dimeric repeating units in polymeric **3**. Hydrogen atoms are omitted for clarity.

tively. The crystal structure of the two compounds consists of one-dimensional linear chains in which $Me_4Sn_2[(2,4\text{-}Cl_2C_6H_3C(O)NHO)_2][2,4\text{-}Cl_2C_6H_3C(O)NO]$ or $(n\text{-}C_4H_9)_4Sn_2\{[4\text{-}FC_6H_4C(O)NHO]_2\}[4\text{-}FC_6H_4C(O)NO]$ units are sequentially bridged by the oxygen atom of the N–O bond in the ligands and contain a central planar $Sn_2O_2$ four-membered ring. The ligands in the two complexes have been combined with dialkyltin(IV), forming many five-membered heterometallacycles. However, the number and configuration of the ligand bonded to a different Sn atom are obviously not consistent with each other. Only one ligand is coordinated to Sn1 through the hydroximic form, while the other two ligands are coordinated to Sn2 through the hydroxamic form. In contrast to the behavior observed for the 1:2 or 1:1 diorganotin hydroxamate complexes, both **3** and **4** are 2:3 condensation products with an unusual coordinating mode.

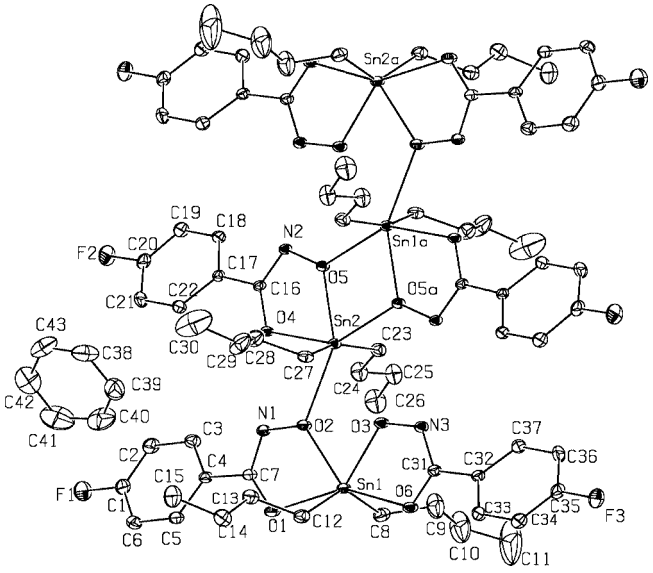

Figure 4. Diagram of the dimeric repeating units in polymeric **4**. Hydrogen atoms are omitted for clarity.

In complex **3**, the bond lengths N(2)–C(10) and N(3)–C(19) are 1.314(6) and 1.314(5) Å respectively. The distances are in the range of a typical single bond, and nearly equivalent N(2)–C(10) and N(3)–C(19) bond lengths suggest two similar hydroxamate ligands attached to the same Sn2 atom. Bond lengths C(10)–O(4) and C(19)–O(6) are 1.247(6) and 1.255(5) Å, respectively, which are in the expected range for C=O bond interaction with obvious double and donor-bond character. The bonding mode of the ligand is well in agreement with the (*Z*) conformer of hydroxamic acid, indicating that ligands are coordinated to Sn2 through the hydroxamic ligand [(*Z*) conformer] form.

Complex **4** is similar to complex **3** in molecular structure. The bond lengths N(1)–C(7) and N(3)–C(31) are 1.323(5) and 1.311(5) Å, respectively, indicating the distances are in the range of a typical single bond in diorganotin(IV) hydroxamates. The slight difference in the bond lengths N(1)–C(7) and N(3)–C(31) may be a result of the existence of solvent molecules (benzene). Bond lengths C(7)–O(1) and C(31)–O(6) are 1.241(5) and 1.255(5) Å, respectively, which are in the expected range for the C=O bond. The bonding mode of the ligand is in good agreement with the (*Z*) conformer of hydroxamic acid, indicating that the ligands are coordinated to Sn1 through the hydroxamic ligand [(*Z*) conformer] form.

Characteristically, the distance between the central carbon atom and the coordinated oxygen atom, C(1)–O(2), is 1.305(5) Å in complex **3** {the C(16)–O(4) distance [1.307(4) Å] in complex **4**}, significantly longer than that of the expected C=O double bond in typical diorganotin(IV) hydroxamates, indicating a typical single bond. Concurrently, the relatively short N(1)–C(1) [1.280(5) Å] bond in complex **3** and N(2)–C(16) [1.302(5) Å] bond in complex **4** exist in the same ligand and no hydrogen atom is at the nitrogen atom, indicating a C=N double bond. The ligand-bonding mode is consistent with hydroximic acid [(*Z*) isomer], indicating the ligand is coordinated to Sn1 in complex **3** (Sn2 in complex **4**) in the hydroximic ligand [(*Z*) isomer] form.

| O(2)–Sn(1)–O(6) | 138.10(10) | O(5)–Sn(2)–O(2) | 147.69(9) |

Based on the above studies, it could be concluded that a keto-iminol mixed-coordination mode including both hydroxamic and hydroximic tautomeric forms existed for complexes **3** and **4**.

## Conclusion

Under alkaline condition, dialkyltin dichloride ($Bu_2SnCl_2$; $Me_2SnCl_2$) and substituted benzohydroxamic acid (substituent = 4-F; 2,4-$Cl_2$; 2,5-$F_2$) in aqueous methanol solution form two types of condensation products: 1:1 dialkyltin hydroxamate complexes (**1** and **2**) and unexpected 2:3 alkyltin hydroxamate complexes (**3** and **4**). All of them have been verified by spectral methods and X-ray single-crystal diffraction analysis. The present results demonstrate that all of these alkyltin hydroxamates contain hydroximic ligands [(*Z*) isomer], presenting two kinds of new coordination modes. Concurrently, dialkyltin hydroxamate complexes exhibit structural diversity through the isomerism of hydroxamic ligand, which develops the coordination chemistry of diorganotin hydroxamic complexes. So far, the result proves that diorganotin complexes containing substituted hydroxamate ligands could take on three different coordination modes. Namely, ligands of the diorganotin complexes are only in hydroxamic form [(*Z*) conformer], or only in hydroximate form [(*Z*) isomer] or in both hydroxamate form and hydroximate form [(*Z*) conformer and (*Z*) isomer], forming diversiform hydroxamate complexes.

## Experimental Section

**Materials and Methods:** Dibutyltin(IV) dichloride, ethyl 4-fluorobenzoate, ethyl 2,5-difluorobenzoate, and 2,4-dichlorobenzoic acid were purchased from Aldrich and used as received. The other reagents were of analytical grade. 4-Fluorobenzohydroxamic acid, 2,5-difluorobenzohydroxamic acid, and 2,4-dichlorobenzohydroxamic acid were prepared according to reported methods.[23] Elemental analyses were performed with a PE-2400-II elemental analyzer. IR spectra in the range 4000–400 $cm^{-1}$ were recorded with a Perkin–Elmer FTIR spectrophotometer as KBr discs. $^1H$, $^{13}C$, and $^{119}Sn$ NMR spectra were recorded with a Varian INOVA 600 spectrometer (600.0 MHz for $^1H$, 150.8 MHz for $^{13}C$, 223.6 MHz for $^{119}Sn$) at ambient temperature [$\delta$ values in ppm relative to $Me_4Si$ ($^1H$, $^{13}C$) or $Me_4Sn$ ($^{119}Sn$)].

**Synthesis of $\{(n\text{-}C_4H_9)_2Sn[4\text{-}FC_6H_4(O)C{=}NO]\}_n$ (1):** Dibutyltin dichloride (0.304 g, 1.0 mmol) in methanol (10 mL) was added dropwise to an aqueous methanol solution (water/methanol, 1:3, v/v, 30 mL) of 4-fluorobenzohydroxamic acid (0.150 g, 1.0 mmol) and KOH (0.112 g, 2.0 mmol). The solution was stirred under $N_2$ at room temperature overnight. Water (30 mL) was added to form a white precipitate, which was separated by filtration. The white solid was then recrystallized from methanol/water. Colorless sheet-shaped crystals of **1** were slowly formed at room temperature. Yield: 0.12 g, 32%. M.p. 176–178 °C. $C_{15}H_{22}FNO_2Sn$ (385.69): calcd. C 46.67, H 5.74, N 3.63; found C 46.48, H 5.85, N 3.56. IR (KBr): $\tilde{\nu}$ = 1661 s, 1601 s (CO/NC), 913 s (N–O), 587 w (Sn–C), 531 s (Sn–O) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.12–7.70 (m, 4 H, $C_6H_4$), 1.64 [m, $^2J$(Sn,H) = 76 Hz, 4 H, 2 $CH^1_2$], 1.52 (m, 4 H, 2 $CH^2_2$), 1.37 (m, 4 H, 2 $C^3H_2$), 0.79 (t, $J$ = 7.2 Hz, 6 H, 2 $C^4H_3$) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 164.2 (CO), 161.4, 131.4, 127.6, 115.4 and 114.9 ($C_{arom}$), 27.3 [$^1J$($^{119}Sn$,$^{13}C$) = 537 Hz, $CH_2$–Sn], 23.7 [$^2J$($^{119}Sn$,$^{13}C$) = 40 Hz, $CH_2CH_2Sn$], 26.1 [$^3J$($^{119}Sn$,$^{13}C$) = 138 Hz, $CH_2CH_2CH_2Sn$], 14.0 (R–Sn) ppm. $^{119}Sn$ NMR ($CDCl_3$): $\delta$ = –124.8 ppm.

**Synthesis of $\{(CH_3)_2Sn[2,5\text{-}F_2C_6H_3(O)C{=}NO]\}_n$ (2):** Dimethyltin dichloride (0.220 g, 1.0 mmol) in methanol (10 mL) was added dropwise to an aqueous methanol solution (water/methanol, 1:3, v/v, 30 mL) of 2,5-difluorobenzohydroxamic acid (0.173 g, 1.0 mmol) and KOH (0.112 g, 2.0 mmol). The solution was stirred under $N_2$ at room temperature overnight. Water (30 mL) was added to form a white precipitate, which was separated by filtration. The white solid was then recrystallized from methanol/water. Colorless sheet-shaped crystals of **2** were slowly formed at room temperature. Yield: 0.10 g, 28.2%. M.p. 262 °C dec. $C_9H_9F_2NO_2Sn$ (319.86): calcd. C 33.79, H 2.84, N 4.38; found C 33.52, H 2.96, N 4.29. IR (KBr): $\tilde{\nu}$ = 1665 s, 1616 s (CO/NC), 926 s (N–O), 586 w (Sn–C), 528 s (Sn–O) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.70–7.16 (m, 3 H, $C_6H_3$), 0.89 [s, $^2J$(Sn,H) = 79 Hz, 6 H, 2 $CH_3$, R–Sn] ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 165.0 (CO), 163.4, 162.6, 132.3, 127.4 and 115.7 ($C_{arom}$), 6.6 [$^1J$($^{119}Sn$,$^{13}C$) = 584 Hz, $CH_3$, R–Sn] ppm. $^{119}Sn$ NMR ($CDCl_3$): $\delta$ = –129.9 ppm.

**Synthesis of $\{(CH_3)_4Sn_2[(2,4\text{-}Cl_2C_6H_3C(O)NHO)_2][2,4\text{-}Cl_2C_6H_3(O)C{=}NO]\}_n$ (3):** Dimethyltin dichloride (0.220 g, 1.0 mmol) was

added dropwise to an aqueous methanol solution (water/methanol, 1:4, v/v, 30 mL) of 2,4-dichlorobenzohydroxamic acid (0.412 g, 2.0 mmol) and KOH (0.112 g, 2.0 mmol). The solution was stirred under $N_2$ at room temperature overnight. Water (30 mL) was added to form a white precipitate, which was separated by filtration. The white solid was then recrystallized from methanol/benzene. Colorless block-shaped crystals of **3** were slowly formed at room temperature. Yield: 0.12 g, 26.3%. M.p. 188 °C (dec). $C_{50}H_{54}Cl_{12}N_6O_{12}Sn_4$ (1829.83): calcd. C 32.79, H 2.97, N 4.59; found C 32.62, H 3.01, N 4.55. IR (KBr): $\tilde{\nu}$ = 3290 s (N–H), 1591 s, 1569 s (CO/NC), 918 s (N–O), 575 s, 477 m (Sn–C), 541 s (Sn–O) cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 10.56 (s, H, N–H), 9.21 (s, H, N–H), 7.81–7.27 (m, 6 H, 2 $C_6H_3$), 1.25 [s, $^2J$(Sn,$^1$H) = 91 Hz, 2 $CH_3$, R–Sn], 0.94 [d, $^2J$(Sn,H) = 77 Hz, 4 $CH_3$, R–Sn] ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 164.2, 162.7 (CO), 158.4, 157.2, 131.1, 113.3, 111.1 and 103.3 ($C_{arom}$), 5.3 [$^1J$($^{119}$Sn,$^{13}$C) = 717 Hz, $CH_3$, R–Sn] and 6.9 [$^1J$($^{119}$Sn,$^{13}$C) = 845 Hz, $CH_3$, R–Sn] ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –222.6, –221.0 ppm.

**Synthesis of {$(C_4H_9)_4Sn_2$[(4-$FC_6H_4C(O)NHO)_2$][4-$FC_6H_4$(O)-C=NO]}$_n$ (4):** Dibutyltin dichloride (0.304 g, 1.0 mmol) in methanol (10 mL) was added dropwise to an aqueous methanol solution (30 mL) of 4-fluorobenzohydroxamic acid (0.310 g, 2.0 mmol) and KOH (0.112 g, 2.0 mmol). The solution was stirred under $N_2$ at room temperature overnight. Water (30 mL) was added to form a white precipitate, which was separated by filtration. The white solid was then recrystallized from methanol/benzene. Colorless block-shaped crystals of **4** were slowly formed at room temperature. Yield: 0.26 g, 56%. M.p. 160–161 °C. $C_{86}H_{112}F_6N_6O_{12}Sn_4$ (2010.58): calcd. C 51.33, H 5.57, N 4.18; found C 51.20, H 5.71, N 4.03. IR (KBr): $\tilde{\nu}$ = 3287 s (N–H), 2956 (Bu), 1617 s, 1559 s (CO/NC), 904 s (N–O), 579 s, 471 m (Sn–C), 579 s (Sn–O) cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 7.68–6.94 (m, 16 H, 4 $C_6H_4$), 1.67–1.62 (m, 8 H, 4 $CH^2{}_2CH^1{}_2$), 1.35–1.34 (m, 8 H, 4 $C^3H_2$), 0.92–0.84 (t, *J* = 7.2 Hz, 12 H, 4 $C^4H_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 165.5, 164.1 (CO), 163.9, 161.9, 133.9, 130.7, 128.8, 126.1, 120.4, 115.7 and 114.9 ($C_{arom}$), 28.5 [$^1J$($^{119}$Sn,$^{13}$C) = 701 Hz, $CH^1{}_2$, R–Sn] and 27.4 [$^1J$($^{119}$Sn,$^{13}$C) = 830 Hz, $CH^1{}_2$, R–Sn], 26.6, 23.2, 13.9–13.7 (R–Sn) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –217.4, –216.6 ppm.

**X-ray Data Collection, Structure Determination, and Refinement:** Suitable single crystals of the four complexes were mounted in glass capillaries for X-ray structural analysis. Diffraction data were collected with a Bruker SMART CCD diffractometer with Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation at room temperature. During the intensity data collection, no significant decay was observed. The intensities were collected for Lorentz-polarization effects and empirical absorption with the SADABS program. The structures were solved by direct methods using the SHELXL-97 program. All non-hydrogen atoms were found from difference Fourier syntheses. The H atoms were included in calculated positions with isotropic thermal parameters related to those of the supporting carbon atoms but were not included in the refinement. All calculations were performed using the Bruker Smart program.[24] A summary of the crystallographic data and selected experimental information are given in Table 5. CCDC-610570, -610571, -610572, and -610573 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Studies on the Interaction of Vanadia with Modified Silica Supports and Catalytic Activity for Oxidative Dehydrogenation of Propane: Effect of Support Modification by $Al^{3+}$, $Zr^{4+}$ or $Y^{3+}$

**Rajamma Sasikala,*[a] Vasanth Sudarsan,[a] and Shailendra K. Kulshreshtha[a]**

**Keywords:** Supported catalysts / Vanadia-support interaction / IR spectroscopy / Heterogeneous catalysis

Detailed structural studies of vanadia supported on $SiO_2$ and modified $SiO_2$ ($Si_{0.8}M_{0.2}O_{2\pm\delta}$ where M = $Al^{3+}$, $Zr^{4+}$ and $Y^{3+}$) were carried out using different techniques such as powder XRD, IR spectroscopy and $^{29}Si$, $^{27}Al$ and $^{51}V$ MAS NMR spectroscopy. All samples except vanadia impregnated on $Zr^{4+}$ or $Y^{3+}$ modified $SiO_2$ existed as amorphous phases. A crystalline phase of $ZrO_2$ was seen in $Zr^{4+}$ modified $SiO_2$ and $YVO_4$ was seen in $Y^{3+}$ modified $SiO_2$ after vanadia impregnation. Based on $^{29}Si$ MAS NMR and IR spectroscopic studies it was concluded that substitution of $Si^{4+}$ by M results in the breakage of the Si–O–Si network and formation of silicon structural units with Si–O–M type linkages. Unlike all other modified $SiO_2$, the silicon structural units remained unaffected in $Al^{3+}$ modified $SiO_2$ before and after vanadia impregnation. A profound change in the interaction of vanadia with the support was observed when the $SiO_2$ support was modified with different cations and in all cases the $V^{5+}$ preferentially interacted with the substituted cations. Two types of vanadia species, viz. the octahedral and tetrahedral $V^{5+}$, were present in vanadia impregnated silica and $Al^{3+}$ modified silica but the amount of tetrahedral $V^{5+}$ was more in the latter. In $Zr^{4+}$ modified silica, $V^{5+}$ was present in a crystalline environment which is the $V^{5+}$ dissolved in the $ZrO_2$ phase. Vanadia impregnated on $Y^{3+}$ modified silica exhibited very little chemical shift anisotropy indicating a symmetric environment around $V^{5+}$ in $YVO_4$. The catalytic activity for the selective oxidation of propane to propene was tested on these supported catalysts. Vanadia supported on $Zr^{4+}$ modified silica showed maximum selectivity whereas vanadia on silica and $Al^{3+}$ modified silica showed comparable selectivity for propene formation. Vanadia on $Y^{3+}$ modified silica did not show the formation of propene at all.

## Introduction

Supported vanadia catalysts are widely used for selective oxidation of hydrocarbons[1–4] and for the reduction of $NO_x$ by ammonia.[5,6] It is well known that the catalytic activity of vanadia catalysts varies with the supporting oxides. The reason for the observed change in the catalytic activity has been attributed to a vanadia-support interaction, which varies with the nature of the support. Different factors influencing the interaction are the acidity of the support, the concentration of vanadia as well as pretreatment conditions etc.[7–10] Thus, different types of vanadia species exist on different supports such as isolated tetrahedral vanadium ions, polymeric species, 2D layers of vanadium oxide or $V_2O_5$ crystallites.[11–15] It has been demonstrated that isolated vanadia species possessing $VO_4$ coordination predominate at low surface coverage of vanadia whereas at higher surface coverage both isolated and polymerised species may be observed on the surface of the support. A monolayer of vanadia is formed on the support when the surface coverage is 7–8 V atoms per $nm^2$.[2,16] However, in the case of $V_2O_5$ supported on $SiO_2$, only isolated vanadia species may be observed on the surface and the maximum attainable surface coverage is less than 3 V atoms per $nm^2$. Hence it is of interest to modify the $SiO_2$ support by partial substitution of $Si^{4+}$ by $Al^{3+}$, $Zr^{4+}$ or $Y^{3+}$ and to see whether the support modification improves the dispersion of vanadia on the surface and also to study the structure of the resultant vanadia species. Because the catalytic activity and turnover frequency of a reaction changes with the type of $VO_x$ species, which in turn depends on the nature of support, it is useful to study the interaction of vanadia with this modified support. To the best of our knowledge, the variation of the nature of the interaction of vanadia with the silica support when it is modified with different cations has not been reported so far.

In the present work $SiO_2$ was modified by partial substitution of the $Si^{4+}$ by $Al^{3+}$, $Zr^{4+}$ or $Y^{3+}$ and vanadia was loaded on these supports as well as on $SiO_2$. All supports and vanadia impregnated supports were investigated by various spectroscopic and diffraction techniques such as powder XRD, infrared and NMR spectroscopy to see whether there would be any change in the interaction of vanadia with the modified silica support compared with the

unmodified one. The activity of these supported vanadia materials as catalysts for the oxidative dehydrogenation of propane to propene has been examined in order to deduce the dependence of the product selectivity on the type of surface vanadia species.

## Results and Discussion

Figure 1 shows the powder XRD patterns of $SiO_2$, VS, SA, VSA, SZ, VSZ, SY and VSY ($Si_{0.8}M_{0.2}O_{2\pm\delta}$, M = $Al^{3+}$, $Zr^{4+}$ and $Y^{3+}$ represented as SA, SZ and SY, respectively). It can be seen from the figure that the XRD patterns of $SiO_2$, VS, SA, VSA, SZ and SY oxides show broad peaks centred around 22°, which is characteristic of amorphous silica. However, after vanadia impregnation, samples VSZ and VSY exhibited crystalline phases. The VSZ sample exhibits a pattern with three peaks centred around 30.3, 50.2 and 59.9°, which can be matched with the tetragonal phase of $ZrO_2$ (JCPDS card no. 17-0923). The presence of this phase was further confirmed from the XRD pattern of the sample heated at 650 °C for 18 h. This clearly showed peaks corresponding to the tetragonal phase of $ZrO_2$. It is known that $V_2O_5$ stabilises the tetragonal phase of $ZrO_2$.[2] The XRD pattern of VSY indicates a crystalline phase, the peak positions of which were found to be matching those of $YVO_4$. The three most intense peaks seen at 25.0, 33.6 and 49.8° are due to the $YVO_4$ phase (JCPDS card no. 17–0341). Table 1 gives the total surface area of $SiO_2$, all modified silica supports before and after vanadia impregnation and the amount of vanadia on these supports (% $V_2O_5$ on the support by weight, wt.-%). The surface area was found to decrease with vanadia impregnation and this is in agreement with the previous report.[12]

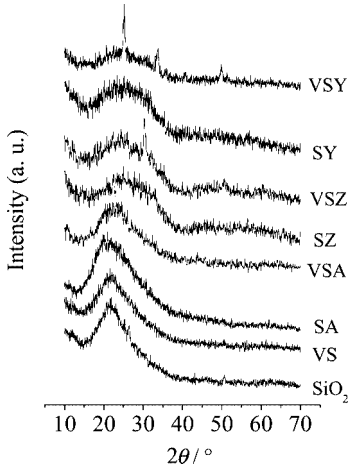

Figure 1. Powder X-ray diffraction patterns of $SiO_2$, modified silica samples and vanadia impregnated samples.

Since the XRD patterns of these samples indicate poor crystallinity, it was not possible to ascertain whether the $Al^{3+}$, $Zr^{4+}$ and $Y^{3+}$ cations had really substituted the $Si^{4+}$ sites. Since $^{29}Si$ NMR spectroscopy can give information regarding the local coordination of $Si^{4+}$ and Si–O–Si bonding in $SiO_2$, MAS NMR spectra of these samples were recorded. Figure 2 shows the $^{29}Si$ MAS NMR spectra of $SiO_2$, the modified silica support and modified supports impregnated with vanadia. For the $SiO_2$ and VS samples, a clear asymmetry was observed in their spectra indicating that more than one type of silicon structural unit ($Q^n$, where "$n$" represents the number of $SiO_4$ tetrahedra attached to $Si^{4+}$) is present in these samples. The peaks of all modified supports and vanadia containing supports are broad and showed varying amounts of asymmetry indicating the presence of different types of $Q^n$ structural units within them.

Table 1. Total surface area and wt.-% of $V_2O_5$ on different supports.

| Support | wt.-% $V_2O_5$ on the support | Surface area [$m^2 g^{-1}$] |
|---|---|---|
| $SiO_2$ | – | 73 |
| VS | 9.7 | 69 |
| SA | – | 72 |
| VSA | 9.7 | 47 |
| SZ | – | 173 |
| VSZ | 8.0 | 128 |
| SY | – | 125 |
| VSY | 8.0 | 75 |

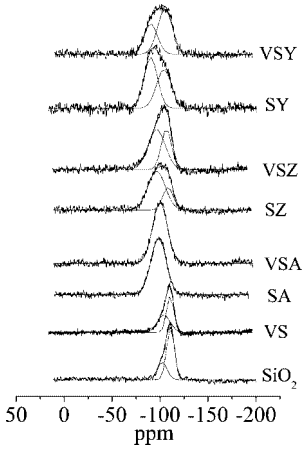

Figure 2. Deconvoluted $^{29}Si$ MAS NMR spectra of $SiO_2$, modified silica samples and vanadia impregnated samples.

However, the spectra of the SA and VSA samples are identical, with a peak maximum around –99 ppm indicating that no significant change occurs in the vicinity of the $SiO_4$ tetrahedra upon vanadia impregnation. A downfield shift seen in the spectra of SA and VSA with respect to $SiO_2$ indicates that $Al^{3+}$ units have substituted $Si^{4+}$ ion thereby forming an Si–Al mixed oxide.

In order to characterise the different structural units in detail, all spectra except those of SA and VSA were deconvoluted based on a Guassian fit and it was found that these patterns mainly consist of $Q^4$ and $Q^3$ structural units of silicon. The peak positions of the $Q^4$ and $Q^3$ units and their relative ratios are given in Table 2. It can be seen that the ratio of $Q^3$ to $Q^4$ is more for VS than that for $SiO_2$ indicating that $V^{5+}$ modifies the Si–O–Si network. Similarly, the ratio of $Q^3$ to $Q^4$ is more in all modified supports compared with in $SiO_2$ indicating that incorporation of $Al^{3+}$, $Zr^{4+}$ or

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Y^{3+}$ in silica results in the breakage of Si–O–Si linkages. The spectra of SA and VSA could be satisfactorily fitted only as a single Gaussian peak with a peak maximum around –99 ppm characteristic of $Q^3$ structural units. This establishes that $V^{5+}$ has no direct interaction with silicon structural units in the alumino-silicate network. Had there been any direct interaction between the silicon and vanadium structural units, this would have been reflected in the relative concentration of $Q^n$ structural units and their chemical shift values but this was not observed in the present study. It was observed, however, that a downfield shift occurs for the peaks corresponding to the $Q^4$ and $Q^3$ structural units in the spectra of modified silica supports compared with that of $SiO_2$ (see Table 2) and this has been attributed to the decreased Si–O–Si chain length brought about by the modification.

Table 2. Fitted peak positions of $Q^4$ and $Q^3$ units present in different samples and their relative ratios.

| Sample | Chemical shift [ppm] $Q^4$ | $Q^3$ | $Q^3/(Q^4+Q^3)$ |
|---|---|---|---|
| $SiO_2$ | –110·9 | –102.0 | 0.29 |
| VS | –110·6 | –103.9 | 0.46 |
| SA | – | –99.0 | ≈ 1.0 |
| VSA | – | –99.9 | ≈ 1.0 |
| SZ | –108.0 | –96.0 | 0.73 |
| VSZ | –106.7 | –96.5 | 0.65 |
| SY | –104.1 | –90.4 | 0.54 |
| VSY | –105.2 | –90.5 | 0.38 |

To obtain more information regarding the silicon structural units attached to OH groups in these samples, $^1H \rightarrow ^{29}Si$ cross polarisation (CP) MAS NMR spectra were recorded and these are shown in Figure 3. A comparison of a single pulse spectrum and a CPMAS NMR spectrum of pure $SiO_2$ reveals that even in unmodified $SiO_2$, $Q^3$ and $Q^2$ structural units exist in the form of Si–OH linkages.

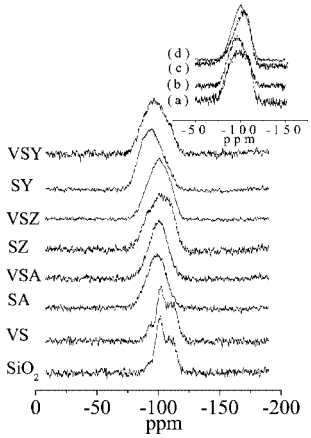

Figure 3. $^1H \rightarrow ^{29}Si$ CP MAS NMR spectra of $SiO_2$, modified silica samples and vanadia impregnated samples. Inset shows the $^{29}Si$ single pulse and CP MAS NMR spectra, respectively, for VSY (a and b) and VSZ (c and d).

A careful observation of the VS sample revealed a slight increase in the intensity of the peak corresponding to the $Q^2$ structural unit and this can be attributed to the breakage of Si–O–Si linkages brought about by the vanadia incorporation in silica. Unlike the single pulse spectra of these samples, the peak corresponding to the $Q^2$ unit can be clearly seen here due to the sensitivity of the technique to the OH groups attached to the silica structural units. The spectra of SA and VSA obtained from single pulse experiments and CP MAS experiments are exactly identical and can be superimposed over one another. This observation once again suggests that vanadia incorporation does not bring about any change in the vicinity of the $SiO_4$ tetrahedra and hence vanadia probably interacts with the $Al^{3+}$ of the support. For the SZ and SY samples, the spectra resulting from single pulse and CP MAS spectroscopy are identical, demonstrating that no Si–OH linkages are created by $Zr^{4+}$ or $Y^{3+}$ incorporation in silica. However for the VSZ and VSY samples, the CP MAS spectra showed a slightly different line shape with a downfield shift of the peak maxima over a range of 5–6 ppm compared with that obtained from single pulse experiments (see inset in Figure 3). This can be attributed to the formation of Si–OH ($Q^3$ type) linkages brought about by the removal of $Zr^{4+}/Y^{3+}$ from the VSZ/VSY samples to form $ZrO_2$ and $YVO_4$, respectively.

The $^{27}Al$ NMR spectra of SA and VSA are shown in Figure 4. A single peak with a chemical shift of 53 ppm with a comparable line shape can be seen indicating that $Al^{3+}$ is in a tetrahedral coordination environment before and after vanadia impregnation. Since there is no $Al^{3+}$ present in an octahedral coordination mode, it can be concluded that the $\gamma$-$Al_2O_3$ phase is not present in these samples. Due to the quadrupolar nature of the $Al^{3+}$ ion, it is less sensitive to the changes in the chemical environment brought about by vanadium incorporation and hence no change in the line shape is to be expected for the VSA sample and such is the case.

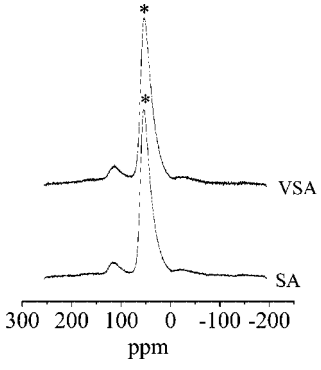

Figure 4. $^{27}Al$ MAS NMR spectra of SA and VSA samples (the peak marked with an asterisk is the isotropic peak).

The IR spectra of all modified silica samples with and without vanadia impregnation are shown in Figure 5. It can be seen that the spectra of all silica containing samples are somewhat similar to the spectrum of $SiO_2$. However, some subtle changes can be observed in the spectra of modified silica samples upon closer observation. The IR spectrum of $V_2O_5$ shows three prominent bands at 472, 810 and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1020 $cm^{-1}$. The band at 1020 $cm^{-1}$ corresponds to the unshared V=O stretching vibration and the bands located around 810, 472 and 364 $cm^{-1}$ can be assigned to the vibrations of the bound oxygen which are shared by two vanadium atoms.[17,18] The IR spectrum of silica mainly shows three broad bands centred at 1091, 808 and 470 $cm^{-1}$ which can be assigned to the Si–O stretching (antisymmetric stretching of the type ←Si O→ ←Si), Si stretching (symmetric stretching mode of type ←Si O Si→) and Si–O–Si bending of the characteristic groups, respectively.[19,20] Since the peak positions of both $V_2O_5$ and $SiO_2$ are close, they overlap and hence IR bands due to $V_2O_5$ cannot be seen in vanadia impregnated samples. In all substituted silica samples, it can be seen that the band around 1091 $cm^{-1}$ shifts to a slightly lower frequency compared with that in pure $SiO_2$. This is due to the substitution of some of the $Si^{4+}$ centres by bigger cations which form M–O bonds (M = $Al^{3+}$, $Zr^{4+}$ and $Y^{3+}$). This results in a softening of the Si–O bond. A similar effect has been observed for the Si stretching band located around 808 $cm^{-1}$. A downward frequency shift of the V–O stretch in $V_2O_5$–$MoO_3$ has been reported by Hirata et al.[21] due to the softening of this bond arising from the replacement of $V^{V}$ by $V^{IV}$ in this mixed oxide. The IR spectra of reduced $V_2O_5$ also show a similar effect in the V=O stretching vibration due to the $V^{IV}$ species, the ionic radius of which is larger than $V^{V}$.[17] In the case of the SZ and SY samples, it can be seen that the band around 1091 $cm^{-1}$ is very broad compared with that in $SiO_2$ and this is due to the distortion of the Si–O–Si bond brought about by the substitution. However, in the case of VSZ and VSY, a shift in this band to a slightly higher frequency can be observed. This high frequency shift can be attributed to the formation of $ZrO_2$ and $YVO_4$ compounds in SZ and SY, respectively, resulting from the removal of $Zr^{4+}$or $Y^{3+}$ from the silica structure. This observation is in accord with the $^{29}Si$ MAS NMR spectroscopic results. A weak narrow band around 1630 $cm^{-1}$ present in the IR patterns of all samples except $V_2O_5$ arises due to the bending vibrations of the OH groups attached to silicon.

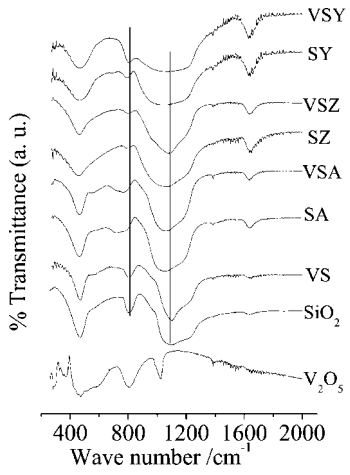

Figure 5. IR spectra of $V_2O_5$, $SiO_2$, modified silica samples and vanadia impregnated samples.

$^{51}V$ solid state NMR spectroscopy can give a clear understanding of the state of $V^{5+}$ species on different supports and many such studies have identified different vanadia species such as tetrahedrally or octahedrally coordinated $V^{5+}$ or vanadia crystallites on various supports.[22–28] Figure 6 shows the $^{51}V$ static and MAS NMR spectra of $V_2O_5$, VS and VSA. The static pattern of $V_2O_5$ is similar to that reported in the literature indicating a distorted octahedrally coordinated $V^{5+}$ ion with axial symmetry. The MAS NMR spectrum shows an isotropic peak at $\delta$ = –614 ppm with a side band pattern typical of this compound. The static spectrum of VS was found to be different from that of $V_2O_5$. It consists of two peaks with maxima around –380 and –597 ppm which are similar to those for the "a" (octahedral) and "b" (tetrahedral) type $V^{5+}$ species reported by Eckert and Wachs.[22] The MAS NMR spectrum of this sample consists of an extensive side band pattern superimposed over a weak broad peak. The extensive side band patterns have been attributed to the presence of bulk-like $V_2O_5$ or a precursor of $V_2O_5$[22,24] in which vanadium is in a distorted octahedral configuration. The weak broad background arises from the vanadium species existing in the tetrahedral configuration. Hence it can be concluded that both octahedral and tetrahedral $V^{5+}$ are present in this sample. The static spectrum of VSA also showed a similar pattern to that of VS with two peaks centred around –340 and –590 ppm showing the presence of both octahedral and tetrahedral $V^{5+}$. Unlike the MAS NMR spectrum of VS, the spectrum of the VSA sample clearly showed a side band pattern similar to that of bulk-like $V_2O_5$ superimposed over a broad peak characteristic of tetrahedral $V^{5+}$ species. From these results it can be inferred that the dispersion of vanadia is better on SA than on $SiO_2$. The static and MAS NMR spectra of VSZ, VSY and $YVO_4$ are shown in Figure 7. The static spectrum of VSZ shows two narrow peaks around –495 and –566 ppm having line widths significantly less than those of VS and VSA. The MAS NMR pattern for this sample is characterised by a sharp isotropic peak at $\delta$ = –566 ppm along with a number of side bands. Both static and MAS NMR spectroscopic results thus suggest that $V^{5+}$ structural units exist in a highly crystalline environment. However, the XRD pattern revealed that the only crystalline phase present in the sample is $ZrO_2$. Thus, based on the XRD and NMR results, it can be inferred that in the VSZ sample, the $V^{5+}$ species are dissolved in the $ZrO_2$ phase. The static spectrum of VSY showed a narrow peak (peak maximum at $\delta$ = –682 ppm), which suggests that $V^{5+}$ species exist in a symmetric environment and hence exhibit very little chemical shift anisotropy. Since the VSY sample showed a crystalline phase of $YVO_4$ in its XRD pattern, the NMR spectrum of $YVO_4$ was also recorded and is shown in Figure 7. Both the static and MAS NMR spectra of $YVO_4$ are similar to that of VSY. The MAS spectrum of $YVO_4$ showed an isotropic peak at –673ppm, which is very close to that of the VSY sample. Hence the peak seen at $\delta$ = –663 ppm for VSY can be assigned to the $YVO_4$ phase. Thus, $^{51}V$ NMR spectroscopy gives clear evidence for a different type of interaction between vanadia and modified

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

silica compared with unmodified silica. Based on the $^{29}Si$, $^{27}Al$ and $^{51}V$ NMR results it can be concluded that $V^{5+}$ selectively interacts with the substituted cations and not $Si^{4+}$. This conclusion is in agreement with the observation of Gao and Wachs[29] who reported a preferential interaction of V cations with Ti, Zr or Al on multilayered metal oxide catalysts such as $V_2O_5/MO/SiO_2$ where M = $Ti^{4+}$, $Zr^{4+}$ or $Al^{3+}$. Similarly, a preferential interaction of $Cr^{n+}$ with alumina compared with silica has been reported where the $Cr^{n+}$ is adsorbed as a chromate ion.[30]

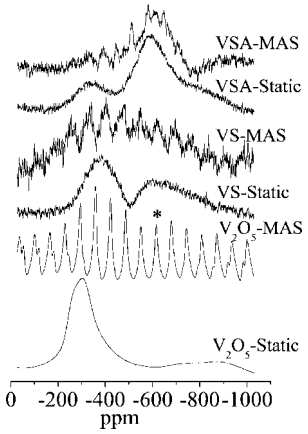

Figure 6. $^{51}V$ static and MAS NMR spectra of $V_2O_5$, VS and VSA (the peak marked with an asterisk is the isotropic peak).

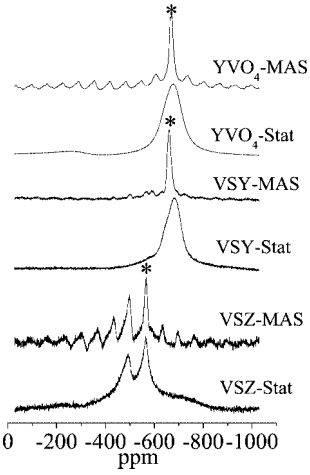

Figure 7. $^{51}V$ static and MAS NMR spectra of VSZ, VSY and $YVO_4$ samples (the peak marked with an asterisk is the isotropic peak).

The results of catalytic tests performed on these supported catalysts for the selective oxidation of propane to propene are summarised in Table 3. The products formed during the reactions were mainly propene and $CO_2$. Small quantities of $CH_4$ and $C_2H_4$ were detected and the selectivity for these products was around 1%. CO, if formed during the reaction, was not analysed. It can be seen from Table 3 that the catalytic activity and selectivity of vanadia varies as the silica support is modified with different cations. VSZ showed maximum selectivity for propene formation whereas VSY gave no propene formation at all. Though the $C_3H_8$ conversion was highest for VS, its selectivity for propene formation was less when compared with VSZ. The selectivity of VSA for catalytic propene formation was comparable with that of VS. These results clearly demonstrate that the product selectivity and catalytic activity depend significantly on the type of vanadia species, which in turn depends on the cations used for the modification of the silica support. The relatively low value of propene selectivity observed for these catalysts could be due to the low flow rate of the reactants. It has been reported that low flow rates result in an increased residence time of the reactants on the catalysts which can lead to the formation of $CO_x$ species from the secondary oxidation of $C_3H_6$ as observed in the present study.[2]

Table 3. Percentage conversion and selectivity data for oxidative dehydrogenation of propane for various $V_2O_5$ supported catalysts at 550 °C.

| No. | Catalyst | $C_3H_8$ conversion [%] | $C_3H_6$ selectivity [%] |
|---|---|---|---|
| 1 | VS | 51 | 14 |
| 2 | VSA | 34 | 12 |
| 3 | VSZ | 36 | 23 |
| 4 | VSY | 26 | – |

The salient feature of this study is that the interaction of vanadia with the support varies when the $SiO_2$ is modified by substitution of just 20% of the $Si^{4+}$ by different cations. This change in the interaction of vanadia with the modified support has a significant impact on its catalytic activity and selectivity for the oxidative dehydrogenation of propane to propene.

## Conclusions

The interaction of vanadia with silica supports varies as the silica is modified with cations such as $Al^{3+}$, $Zr^{4+}$or $Y^{3+}$. A preferential interaction of $V^{5+}$ with $Al^{3+}$, $Zr^{4+}$or $Y^{3+}$ cations present in $SiO_2$ occurs in these samples. Vanadia present on unmodified $SiO_2$ contains two types of $V^{5+}$ species which are tetrahedrally and octahedrally coordinated. Bulk-like $V_2O_5$ with a distorted octahedral configuration is the predominant species on unmodified $SiO_2$ whereas on $Al^{3+}$ modified $SiO_2$, both tetrahedral and octahedral $V^{5+}$ species can be clearly seen. On $Zr^{4+}$ modified silica, $V^{5+}$ becomes dissolved in the $ZrO_2$ phase. On $Y^{3+}$ modified silica, vanadia reacts with $Y^{3+}$ forming the $YVO_4$ phase. Catalytic tests conducted for the oxidative dehydrogenation of propane indicated that the catalytic activity and selectivity of vanadia varies with support modification. This is due to the presence of different types of surface vanadia species on these catalysts formed by the selective interaction of $V^{5+}$ with the cations present in modified silica.

## Experimental Section

Samples of $Si_{0\cdot8}M_{0\cdot2}O_{2\pm\delta}$ (M = $Al^{3+}$, $Zr^{4+}$ and $Y^{3+}$ represented as SA, SZ and SY, respectively, in the text) were prepared by the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coprecipitation technique. Aqueous solutions of aluminium nitrate, zirconium oxychloride and yttrium nitrate were used for the preparation of the SA, SZ and SY samples. Each of these solutions, with the required ratio of cations, was mixed thoroughly with sodium silicate solution and precipitated using ammonia solution (pH ≈ 8). The precipitates, after filtering, were washed thoroughly and dried in an oven for nearly 10 h. This was followed by calcination in air at 500 °C for 2 h. Unmodified $SiO_2$ was prepared by adding ammonia to an aqueous solution of sodium silicate, followed by a similar washing and heating procedure mentioned above. Vanadia was impregnated on these supports (6 atom-% of V) by an impregnation technique. $SiO_2$ and modified $SiO_2$ were kept in contact with an aqueous solution of ammonium vanadate and were then dried on a hot plate with constant stirring followed by heating in air at 500 °C for 2 h (vanadia impregnated on $SiO_2$, SA, SZ and SY are represented as VS, VSA, VSZ and VSY, respectively, in the text). The surface areas of these samples were measured using the BET technique with nitrogen as the adsorbing gas. Since a second phase of $YVO_4$ was seen in the VSY sample, $YVO_4$ was prepared for comparison purposes. $YVO_4$ was prepared by mixing ammonium vanadate and yttrium oxide thoroughly in the correct stiochiometric ratio and heating in air at 800 °C for 6 h. $V_2O_5$ obtained from Fluka was used for recording NMR and IR spectra.

Powder X-ray diffraction patterns of these samples were recorded using a Philips PW1820-X-ray diffractometer coupled with a PW 1729 generator, which was operated at 30 kV and 20 mA. A graphite crystal monochromator was used for generating monochromatic Cu-$K_\alpha$ radiation. IR spectra were recorded as KBr pellets using a Bomem MB102 FTIR machine having a range of 200–4000 $cm^{-1}$. NMR spectra were recorded with a Bruker Avance DPX 300 spectrometer at basic frequencies of 78.206, 59.6214 and 78.9005 MHz for $^{27}Al$, $^{29}Si$ and $^{51}V$, respectively. Spectra were recorded using 7 mm zirconia rotors packed with the sample. Different spinning speeds of 5 kHz, 4 kHz and 3 kHz were employed to identify the isotropic peaks. A typical 90° pulse duration for recording $^{27}Al$ NMR spectra was 3.5 μs and a delay time of 5 s was used. $^{51}V$ MAS spectra were recorded with a 90° pulse duration of 3.5 μs and a delay time of 4 s. Experiments were also carried out by varying the 90° pulse duration from 1 μs to 3 μs with a view to establishing any line distortion brought about by the satellite transitions of the quadrupolar $^{51}V$ nuclei. However, it was observed that the line shapes were unaffected by the different pulse durations. For recording $^{29}Si$ MAS NMR spectra, a 90° pulse duration of 4.0 μs and a delay time of 5 s were employed. Delay times were varied from 5 s to 20 s to see whether there would be any change in the line shape of the spectra since the $^{29}Si$ nucleus has a long relaxation time. For $^{1}H \rightarrow ^{29}Si$ cross polarisation (CP) MAS NMR experiments, a contact time of 5 μs and delay time of 6 s were employed. Around 4000 scans were recorded for each sample in order to obtain NMR patters with reasonable signal to noise ratios. All $^{29}Si$, $^{27}Al$ and $^{51}V$ NMR chemical shifts are expressed with respect to tetramethylsilane, aqueous $[Al(H_2O)_6]^{3+}$ and $VOCl_3$, respectively.

A preliminary test of the catalytic activity of these supported catalysts for the selective oxidation of propane to propene was carried out in a tubular quartz reactor of 25 cm length and 0.7 cm internal diameter using a fixed bed. A quantity of 200 mg of catalyst was used for each experiment and the reactant gas mixture had a composition of $C_3H_8$:$O_2$:He as 1.06:1.09:97.85 (by volume). The reaction was studied at 550 °C using a continuous flow method with a flow rate of 20 $cm^3\,min^{-1}$ of the reactant mixture. The effluent gas mixture was analysed online by an automatic gas sampling valve connected to a gas chromatograph (CIC, GC2011) equipped with a porapak Q column and a thermal conductivity detector. The hydrocarbons formed were also analysed in an FID mode using a porapak R column.

# Lithium Oligophosphanediides in the Li/$PhPCl_2$ System

**Daniel Stein,[a] Alk Dransfeld,[b] Michaela Flock,[b] Heinz Rüegger,[a] and Hansjörg Grützmacher*[a]**

**Keywords:** Alkali metals / Dianions / Ion pairs / NMR spectroscopy / Phosphorus / Reduction

Optimized conditions for the selective synthesis of $[Li_2(P_nPh_n)(tmeda)_x]$ ($n$ = 2, 3, 4) have been developed. X-ray diffraction with single crystals show $[Li_2(P_2Ph_2)(tmeda)_2]$ and $[Li_2(P_4Ph_4)(tmeda)_2]$ to be ion triples, while for $n$ = 3 the ion pair $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$ is observed. NMR experiments support the assumption that these structures are retained in solution. Structural differences between the lithium and the corresponding sodium compounds, $[Na_2(P_nPh_n)(tmeda)_x]$, can be partially rationalized using the electrostatic stabilization parameters, ESP = $\Sigma(1/r_{M^+,M^+}) + \Sigma(1/r_{P^-,P^-}) - \Sigma(1/r_{M^+,P^-})$; M = Li, Na.

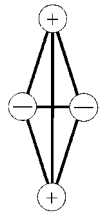
## Introduction

Dichlorophenylphosphane ($PhPCl_2$; also known as phenylphosphonous acid dichloride) is a versatile starting material in organophosphorus chemistry that is produced on a large scale from $PCl_3$ and benzene.[1] Its reductive dehalogenation reaction with alkali metals (M) to give cyclic oligo(phenyl)phosphanes, $(PhP)_n$ ($n$ = 3–6) has been investigated.[2a–2j] Further reaction of $(PhP)_n$ with strongly reducing metals (M = Li, Na, or K) leads to reductive bond cleavage (RBC) and formation of alkali metal *catena*-oligophosphane-α,ω-diides, $[M_2(P_nPh_n)(solv)_x]$.[2a,2b,3] In their pioneering work, Caulton[3a] and Baudler[3b,3c] were able to obtain some structural information about the dimetal 1,2,3-triphenyltriphosphane-1,3-diides $[M_2(P_3Ph_3)(solv)_x]$ and the 1,2,3,4-tetraphenyltetraphosphane-1,4-diides $[M_2(P_4Ph_4)(solv)_x]$ from $^{31}P$ NMR spectroscopy in solution. Recently, Hey-Hawkins et al.[4] and ourselves[5a–5c] have succeeded in the crystallization of various sodium *catena*-oligophosphane-α,ω-diides, namely 1,2-diphenyldiphosphane-1,2-diide $[Na_6(P_2Ph_2)_3(dme)_3]$ (**I**),[5a] 1,2,3-triphenyltriphosphane-1,3-diide $[Na_2(P_3Ph_3)(tmeda)_3]$ (**II**),[5a] and the 1,2,3,4-tetraphenyltetraphosphane-1,4-diides $[Na_2(P_4Ph_4)(tmeda)_2]$ (**IIIa**),[5a] $[Na_2(P_4Ph_4)(dme)_3]$ (**IIIb**),[5a] $[Na_2(P_4Ph_4)(thf)_4(tmu)]$ (**IIIc**),[5b] and $[Na_2(P_4Ph_4)(thf)_5]$ (**IIId**) (tmeda = tetramethylethylenediamine, tmu = tetramethylurea), which can be isolated from the $PhPCl_2$/Na system in organic solvents.[4] Figure 1 summarizes these results.

Compound **I** consists of a $[Na(dme)_3]^+$ cation and the cluster anion $[Na_5(P_2Ph_2)_3(dme)_3]^-$ (see Figure 1a for a schematic representation and Figure 1b for a space-filling model). The structure of **II** is shown in Figure 1 (c and d), parts e and f show the structure of **IIIa** as a representative of all $[M_2(P_4Ph_4)(solv)_n]$ compounds. A solvent molecule acts as bridging ligand L (L = dme, tmu, or thf) between the two $Na^+$ ions in **IIIb**–**d**. In the schematic pictures of the structures of **I**, **II**, and **III**, a plus sign is placed at the position of the sodium cations and a minus sign at the terminal phosphorus centers of the dianionic $(P_nPh_n)^{2-}$ chains. Compounds **II** and **III** are classical *ion triples* (two cations, one dianion). The cluster anion in **I** may be viewed as a cyclic trimer of a corner-sharing ion triple that is additionally capped by two sodium cations on the top and bottom of the central hexagonal $P_6$ prism. With the structural parameters of these ionic aggregates, the electrostatic stabilization parameter (ESP) given by Equation (1) was calculated. The resulting data are listed in Table 1.



$$\mathrm{ESP} = \sum \frac{1}{r_{+,-}} + \sum \frac{1}{r_{-,-}} - \sum \frac{1}{r_{+,}} \quad (1)$$

The ESP was introduced by Streitwieser Jr. to account for the amazingly high stability of ion triples in carbanion chemistry[6] and is simply the sum of the repulsive interactions between like charges, expressed by $(1/r_{+,+})$ and

$(1/r_{-,-})$, minus the sum of attractive interactions, expressed by $(1/r_{+,-})$. Despite the fact that the ESP treats the ions simply as point charges and completely neglects steric interactions and solvation energies, it can be used to interpret the stability of ion pairs qualitatively. For example, the high negative ESP value for **I** explains why the structure of this cluster is also maintained in solution.[5a] The ESP also indicates that ion pairs with the $(P_3Ph_3)^{2-}$ dianion like **II** may be labile because of the rather short P1···P3 distance (ca. 3.15 Å) and the significantly longer Na–P distances. These are caused by repulsive steric interactions between the phenyl groups, especially the one at the central phosphorus atom, and the solvent molecules coordinated to $Na^+$. In structures with the $(P_4Ph_4)^{2-}$ dianion, the steric encumbrance is less pronounced and the $Na^+$–$P^-$ distances are shorter, which leads to more negative ESPs.

Only in **IIIc**, which contains a bridging tmu molecule and a strongly folded $Na_2P_2$ ring, is the $Na^+$–$Na^+$ distance more than 1 Å shorter than in **IIIa** (no bridging L); as a result the electrostatic stabilization is slightly less than that of **II**.

The motivation for this work was i) to find reliable conditions for the synthesis and isolation of the dilithium(*catena*-oligophosphane-α,ω-diides) $[Li_2(P_nPh_n)(solv)_x]$ (here and further on $x$ stands for an unspecified number of solvent molecules), ii) to determine their solid-state structures, and iii) to make, whenever possible, proposals for their behavior in solution. We focused on the isolation of compounds with tmeda as co-ligand for $Li^+$ in order to obtain a set of comparable compounds.

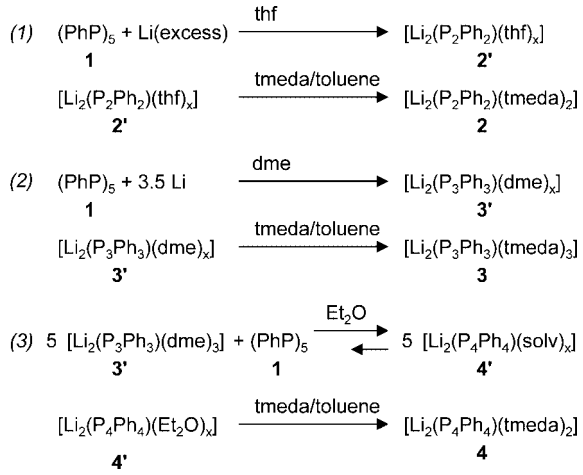
## Results and Discussion

### Syntheses

The syntheses that worked best in our hands and gave good yields of pure isolated and crystalline material are outlined in Scheme 1. In a reductive bond cleavage (RBC) reaction, pentaphenylcyclopentaphosphane (**1**)[2i] was treated with an excess of lithium powder in THF. The resulting orange-red solution showed only one signal at $\delta$ =

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

–102.9 ppm in the $^{31}$P NMR spectrum, thus indicating the formation of the $P_2^{2-}$ dianion. The primary product, $[Li_2(P_2Ph_2)(thf)_x]$ (**2′**) was obtained as red powder after evaporation of the solvent. Subsequent recrystallization of **2′** from hot toluene/tmeda (2:1 by vol.) gave red crystals of $[Li_2(P_2Ph_2)(tmeda)_2]$ (**2**).



Scheme 1. Syntheses of isolable dilithium(*catena*-oligophosphane-α,ω-diides), $[Li_2(P_nPh_n)(tmeda)_m]$ **2** ($n$ = 2, $m$ = 2), **3** ($n$ = 3, $m$ = 3), and **4** ($n$ = 4, $m$ = 2).

The best synthesis for dilithium 1,2,3-triphenyltriphosphane-1,3-diide (**3**) was found to be the reaction of $(PhP)_5$ with a stoichiometric amount of lithium in dme as reaction medium. In this solvent, the product $[Li_2(P_3Ph_3)(dme)_x]$ (**3′**) precipitates directly from the reaction mixture as a bright-orange powder in good yield (about 70%). The content of dme ($x$ = 2–3) was estimated by NMR spectroscopy. Subsequently, **3′** was dissolved in a 5:1 mixture of toluene and tmeda and this solution was concentrated to dryness under high vacuum to remove all volatiles, especially dme; the resulting yellow powder was recrystallized at 7 °C from toluene to give yellow crystals of the composition $[Li_2(P_3Ph_3)(tmeda)_3]$ (**3**).

The best method for the synthesis of pure dilithium 1,2,3,4-tetraphenyltetraphosphane-1,4-diide (**4**) turned out to be the stoichiometric reaction of **3′** with $(PhP)_5$ (**1**) in diethyl ether. After removal of all volatiles under vacuum, the resulting orange powder (**4′**) of composition $[Li_2(P_4Ph_4)(solv)_x]$ (solv = $Et_2O$, dme) was dissolved in a 10:3 mixture of toluene and tmeda, again concentrated to dryness under vacuum, and then recrystallized from methyl *tert*-butyl ether (mtbe) to give slightly yellow crystals of the composition $[Li_2(P_4Ph_4)(tmeda)_2]$ (**4**). Attempts to synthesize **4′** or **4** by a direct RBC reaction of **1** with the corresponding amount of lithium gave a lower yield (<50%).

## Structures

The structures of the dilithium *catena*-oligophosphane-α,ω-diides $[Li_2(P_nPh_n)]$ ($n$ = 2–4) were investigated by X-ray diffraction studies. All compounds contain tmeda molecules as co-ligands bonded to the lithium ions. The $Li^+Li^+$, $P^-P^-$, and $Li^+P^-$ distances in **2**, **3**, and **4** are listed in Table 2.

The centrosymmetric structure of **2** (Figure 2) can be viewed as the archetypical structure of an ion triple with two formal negative charges in the α-position of the dianion. The P–P distance [2.244(3) Å] is slightly longer than the comparable one in the sodium compound [2.20(1) Å]. The main structural difference resides in the orientation of the phenyl rings, which are in a *trans* arrangement in **2** while they take a gauche conformation in the cluster anion $[Na_5(P_2Ph_2)_3]^-$ of **I** (the C–P–P–C torsion angle is about –72°[5a]). The Ph–P–P–Ph moiety in **2** is planar. As a result of the short attractive $Li^+$–$P^-$ interactions, the ESP for **2** (–0.94 Å$^{-1}$) is considerably more negative than the ESP (–0.72 Å$^{-1}$) for a hypothetical $[Na_2(P_2Ph_2)]$ ion triple with a structure analogous to that of **2** (an Na–P distance of 2.98 Å, which is the average of the data listed in Table 1, is assumed).

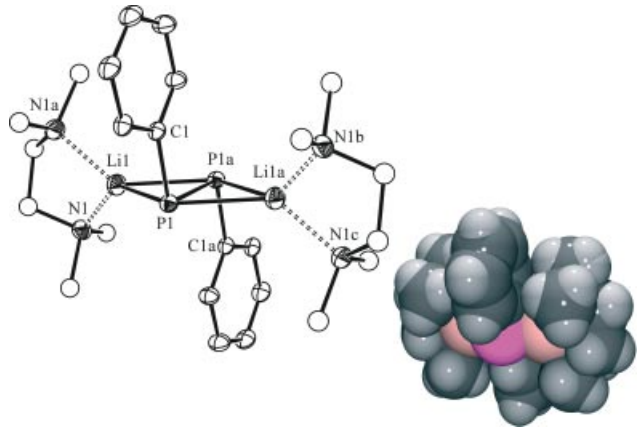


Figure 2. Structure of **2**. Selected distances [Å] and angles [°]: P1–P1 2.244(3), Li–P1 2.483(1), P1–C1 1.820(1), Li–N1 2.077(1); C1–P1–P1 98.66(2), C1–P1–Li 93.90(1), Li–P1–Li 126.28(3); torsion angles: Li–P1–LiA–P1A 0.0, P1A–P1–C1–C2 0.0, C1–P1–P1A–C1A 180.0.

In the solid state, **3** forms an *ion pair* composed of a $[Li(tmeda)_2]^+$ cation and an anionic *ion double*, namely $[Li(P_3Ph_3)(tmeda)]^-$. Only one lithium ion coordinates to the terminal phosphorus atoms P1 and P3 and, as expected for steric reasons, the coordination occurs from the opposite site to the central phenyl group at P2. The distance between the two terminal phosphorus atoms P1 and P3 in **2** is about 0.2 Å longer (the P–P–P angle is about 8° larger)

Table 2. Selected distances [Å] and the resulting ESPs for **2**–**4**.

| | $[Li_2(P_2Ph_2)(tmeda)_2]$ | $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$ | $[Li_2(P_4Ph_4)(tmeda)_2]$ |
|---|---|---|---|
| $r(Li^+Li^+)$ | 4.430(2) | – | 3.967(2) |
| $r(P^-P^-)$ | 2.244(3) | 3.347(1) | 3.229(2) |
| $r(Li^+P^-)$ | 2.483(1)×4 | 2.499(7), 2.525(7) | 2.618(4)×2, 2.653(4)×2 |
| ESP | –0.94 | –0.50 | –0.96 |

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

than in the neutral ion triple $[Na_2(P_3Ph_3)(tmeda)_3]$ (**II**), where two sodium ions coordinate to P1 and P3. The only other known triphosphanediide is found in the highly unstable ion pair $[Na(NH_3)_5]^+[Na(P_3H_3)(NH_3)_3]^-$, which contains the anionic ion double $[Na(P_3H_3)(NH_3)_3]^-$.[7] An even longer $P^-$–$P^-$ distance (3.67 Å) and larger P–P–P angle (113.4°) is observed in this compound. An increase of the $P^-$–$P^-$ distance will help to diminish the repulsive interactions in the ion doubles which, evidently, have less negative ESPs than the ion triples because of the long and hence less stabilizing Na–P distances {–0.79 $Å^{-1}$ for $[Na_2(P_3Ph_3)(tmeda)_3]$ **II**, –0.50 for $[Li(P_3Ph_3)(tmeda)]^-$, and only –0.37 for $[Na(P_3H_3)]^-$}. This loss of stabilizing electrostatic energy in the anionic ion doubles is compensated for by the solvation energy of the counter cations. Because these are much higher for lithium than for sodium,[8,9] the formation of an ion pair in the case of **3** and the formation of an ion triple for the sodium compound **II** is easily understood (Figure 3). Note that in the other ion pair, $[Na(NH_3)_5]^+[Na(P_3H_3)(NH_3)_3]^-$, the smaller size of the ammonia ligand compared to tmeda allows a higher coordination number at the sodium cations and a better solvation. Hence, the loss of ESP on going from the ion triple to the ion double can be compensated.

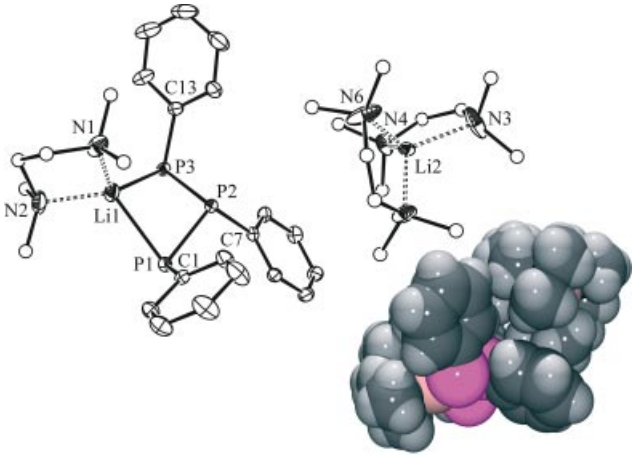

Figure 3. Structure of **3**. Selected distances [Å] and angles [°]: P1–P2 2.179(1), P2–P3 2.177(1), P1–C1 1.814(3), P2–C7 1.847(3), P3–C13 1.819(4), P1–Li1 2.493(7), P3–Li1 2.525(6), P1–P3 3.347(1), P1–P2–P3 100.02(5), P1–Li1–P3 83.37(2), C1–P1–P2 103.7(1), C7–P2–P3 105.8(1), C7–P2–P1 104.0(1), C13–P3–P2 102.8(1); torsion angles: C1–P1–P2–C7 106.7(2), C1–P1–P2–P3 40.9(2), C7–P2–P3–C13 112.9(2), C13–P3–P2–P1 139.3(1), Li1–P1–P2–C7 150.1(2), Li1–P3–P2–C7 148.2(2).

Finally, the structure of **4** was investigated. This compound has a composition very close to the corresponding sodium compound **IIIa** (both contain two tmeda molecules) and the solid-state structures are also very similar (Figure 4). Compounds **4** and **IIIa** are obtained as racemic mixtures and form ion triples in which the $P_4$ chain has either an (*R*,*R*)- or an (*S*,*S*)-configuration. Note the highly distorted coordination spheres around the lithium atoms and their contacts to the *ipso*-carbon atoms of the central phenyl rings. Both features are also observed in the sodium compound. However, due to the short $Li^+$–$P^-$ distances, the ESP for this ion triple is rather high (–0.96 $Å^{-1}$).

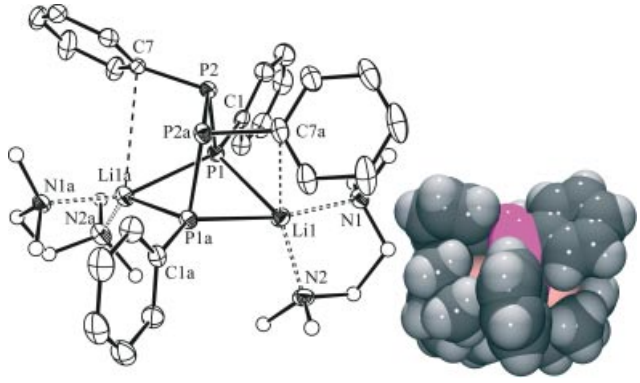

Figure 4. Structure of **4**. Selected distances [Å] and angles [°]: Li–P1 2.618(4), Li–P1A 2.652(4), Li–N1 2.144(4), Li–N2 2.095(5), P1–P2 2.167(1), P1–C1 1.832(2), P2–P2A 2.190(1), P2–C7 1.851(2); P1–Li–P1A 75.6(1), C1–P1–P2 102.26(9), P1–P2–P2A 103.37(2), P1–P2–C7 105.55(9), P2–P2A–C7A 99.70(8); torsion angles: P1–P2–P2A–P1A –13.3(1), C1–P1–P2–P2A –160.33(8), C1–P1–P2–C7 95.4(1), Li1–P1–P2–P2A –39.2(1), Li1A–P1A–P2A–P2 58.8(1).

The P–P distances for the $(P_2Ph_2)^{2-}$, $(P_3Ph_3)^{2-}$, and $(P_4Ph_4)^{2-}$ dianions are very similar in the lithium and sodium compounds. In the dianions of **2** and **I**, the P–P distance is greater than 2.2 Å, whereas in the dianions in **3** and **II** it is below 2.2 Å. The terminal P–P bonds in the $(P_4Ph_4)^{2-}$ dianions in **4** and **IIIa**–**d** are very slightly shorter (ca. 2.17 Å) than the central P–P bond (ca. 2.20 Å). The bonds between the formally negatively charged terminal phosphorus centers and the *ipso*-carbon atoms of the phenyl rings are a little shorter (by ca. 0.04 Å) in all compounds than the P–$C_{ipso}$ bonds at the central phosphorus atoms. This observation may be taken as an indication of some delocalization of the negative charges into the phenyl groups, although this effect is small compared to amides.[10]

## NMR Spectra

The compound $[Li_2(P_2Ph_2)(tmeda)_2]$ (**2**) is sparingly soluble in hydrocarbons but sufficiently soluble in $[D_8]$thf to obtain $^1H$, $^{13}C$, $^{31}P$, and $^7Li$ NMR spectra. All data correspond quite closely with those observed for the sodium cluster anion $[Na_5(P_2Ph_2)_3(dme)_3]^-$ in **I**. The *ipso*-$^{13}C$ carbon resonances of the phenyl groups are observed at $\delta$ = 162.2 ppm ($\delta$ = 160.7 ppm in **I**) and the $^{31}P$ NMR shifts also vary little ($\delta$ = –102.9 ppm in **2**, $\delta$ = –106.4 ppm in **I**). Unfortunately, the $^{31}P$-$^7Li$ couplings could not be resolved in the $^7Li$ NMR spectrum (broad signal at $\delta$ = 0.6 ppm). However, in view of the large loss of electrostatic stabilization energy upon dissociation of the ion triple into the ion pair $[Li(solv)_x][Li(P_2Ph_2)(solv)_y]$, we believe that the structure of **2** is retained in solution.

A $[D_8]$toluene solution of the salt $[Li(tmeda)_2]^+$-$[Li(P_3Ph_3)(tmeda)]^-$ (**3**) shows an $AM_2$ spin system with two multiplets centered at $\delta_A(^{31}P)$ = –52.3 ppm and $\delta_M(^{31}P)$ = –71.5 ppm. From a simulation of the spectrum, the coup-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ling constant $^1J_{A,M} \approx 224$ Hz was obtained. These data are very different from those for the sodium compound $[Na_2(P_3Ph_3)(tmeda)_3]$ (**II**), which shows an eight-line $AB_2$ spin system with $\delta_A = -54.0$ and $\delta_B = -56.7$ ppm ($^1J_{A,B}$ = 242 Hz). This finding indicates that different species containing the $P_3Ph_3$ unit are present in solution. The $^7$Li NMR spectrum in [D$_8$]toluene at low temperature confirms this assumption: two signals are observed, one broad singlet at $\delta = 10.5$ ppm for the $[Li(tmeda)_2]^+$ cation and one broad multiplet at $\delta = 11.4$ ppm for the $[Li(P_3Ph_3)(tmeda)]^-$ anion, that is, **3** exists as an ion pair in solution, as observed in the solid state. That we could not resolve the $^{31}$P-$^7$Li coupling is probably due to dynamic processes involving exchange of the Li-coordinated solvent molecules. On the contrary, the very different $^{31}$P NMR chemical shifts for the sodium compound indicate that this forms an intact ion triple in solution.

The tetraphosphanediide $[Li_2(P_4Ph_4)(tmeda)_2]$ (**4**) is sufficiently soluble in [D$_8$]toluene to allow NMR measurements. At room temperature, ill-resolved multiplets at $\delta$ = –35 to –39 ppm and very broad signals at about $\delta \approx -76$ and $\delta \approx -95$ ppm are observed. At low temperature (248 K), two species (**4** and **4′′**) are observed in a 100:80 ratio in the $^{31}$P NMR spectrum (see Figure 5, a). The major compound **4** shows two multiplets of an $AA'BB'X_2$ spin system in the $^{31}$P NMR spectrum with chemical shifts at

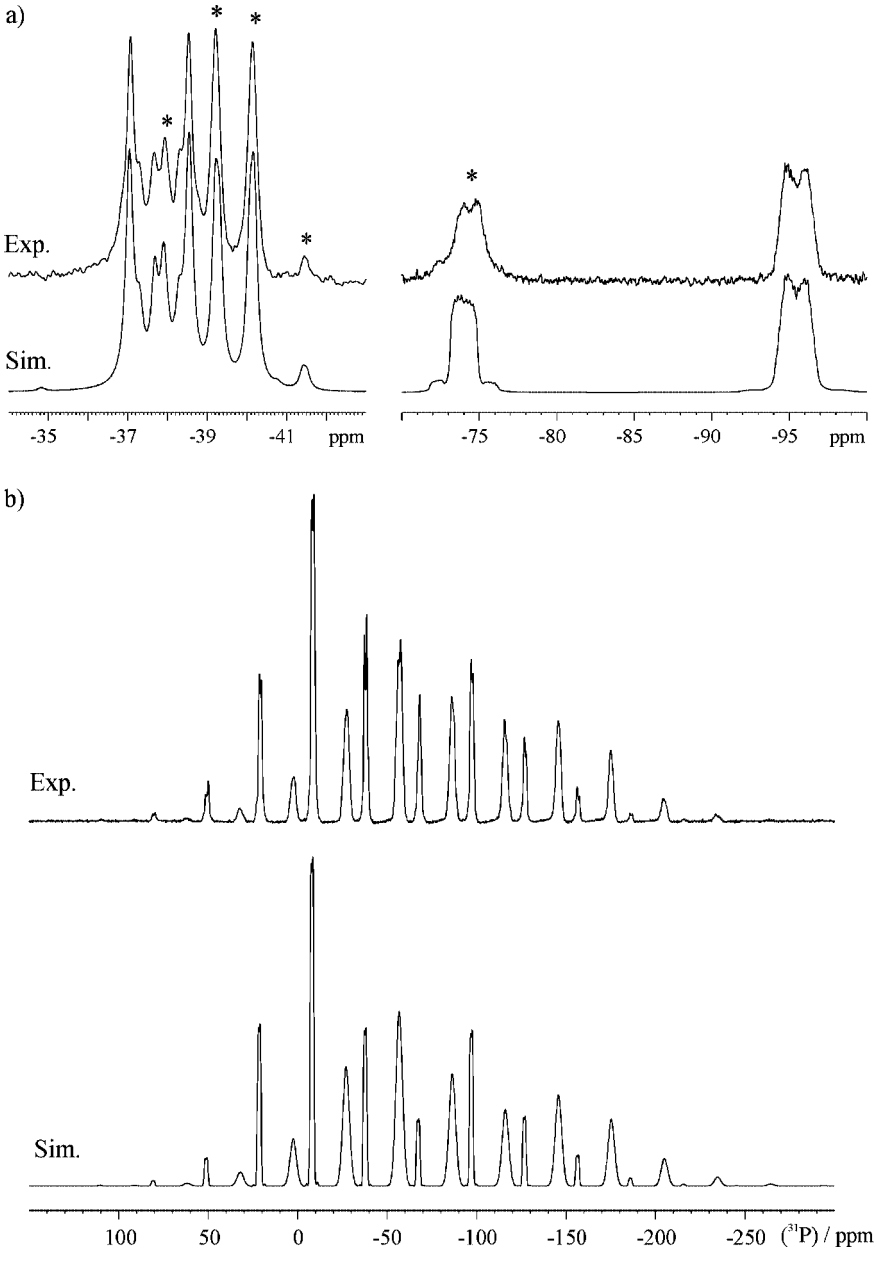

Figure 5. a) Experimental and simulated $^{31}$P NMR spectra of $[Li_2(P_4Ph_4)(tmeda)_2]$ (**4**) and **4′′** (marked with asterisks) in toluene solution at $T$ = 248 K. Chemical shifts and coupling constants are given in Table 3. b) $^{31}$P CMAS spectrum of $[Li_2(P_4Ph_4)(tmeda)_2]$ (**4**). Top: experimental spectrum at 6000 Hz rotation frequency. Bottom: simulated spectrum with: $P^{2,3}$: $\delta_{iso} = -38.0$, $\delta_{11} = 33$, $\delta_{22} = 13$, $\delta_{33} = -159$ ppm; $P^{1,4}$: $\delta_{iso} = -86.3$, $\delta_{11} = 20$, $\delta_{22} = -62$, $\delta_{33} = -217$ ppm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$\delta$ = –38.0 for $P^{2,3}$ and $\delta$ = –95.1 ppm for $P^{1,4}$. The X part is observed in the $^7$Li NMR spectrum, where a slightly broadened triplet at $\delta$ = 10.9 ppm is observed ($^1J_{Li,P}$ = 37 Hz).

The resonances of the protons in the *para*-position of the phenyl rings are sharp, whereas those of the *ortho*- and *meta*-protons are broadened at low temperature. This is probably due to hindered rotation of the phenyl groups in **4**. This species corresponds to the ion triple with a structure close to that observed in the solid state.

This is further bolstered by the solid-state $^{31}$P CPMAS spectrum of **4** (Figure 5, b). Only one species is present in the isolated crystalline material. The observation of only two isotropic chemical shifts ($\delta_{iso}$ = –38.0 and –86.3 ppm for the central and terminal P spins, respectively) is in agreement with the crystallographic $C_2$ symmetry of the ion triple **4** (see Figure 4). The principal elements of the chemical shift tensor, $\delta_{11}$ = 33, $\delta_{22}$ = 13, $\delta_{33}$ = –159 and $\delta_{11}$ = 20, $\delta_{22}$ = –62, $\delta_{33}$ = –217 ppm were obtained by a Herzfeld–Berger[11] analysis of the intensities of the spinning side-bands and refined by spectral simulation using the SIMPSON package.[12] It should be noted that the fine structure observed in the resonances shown in Figure 5 (b) is a consequence of orientation-dependent cross-terms involving the scalar and dipolar coupling and the chemical shift interactions and depends significantly on the frequency of magic angle spinning.[13] For the purpose of spectral simulation, phosphorus–phosphorus scalar coupling constants were taken into account as their isotropic solution values (Table 3) but were not refined, and coupling to the lithium isotopes was accounted for by processing with an appropriate Gaussian line-shape function.

It is interesting to note that while the isotropic chemical shifts of the central phosphorus atoms ($\delta_{iso}$ = –38.0 ppm) are equal, those of the terminal ones differ ($\delta_{iso}$ = –86.3 and –95.1 ppm in the solid state and solution, respectively). As there is no doubt about the constitution of **4** − in both cases the compound exists as the ion triple − we assume a slightly different conformation in solution, which might be due to loss of the Li–$C_{ipso}$ interaction present in the solid phase.

The other species (**4′′**) observed in [$D_8$]toluene solution at 248 K also shows an AA′BB′X spin system (marked with asterisks in Figure 5a) with chemical shifts at $\delta$ = –39.7 ppm for $P^{2,3}$ and a broad resonance at $\delta$ = –74.4 ppm for $P^{1,4}$ in the $^{31}$P NMR spectrum. For this species, no signal could be found in the $^7$Li NMR spectrum.

## Computations

Recently, Kaupp et al. have calculated the dependence of the $J_{P,P}$ coupling constants for the conformations **A** and **B** of the $P_4$ chain based on the experimentally known $M_2(P_4R_4)$ structures (Figure 6).[14] The coupling constants given in Table 3 depend on the alignment of nonbonding electron pairs at the phosphorus centers. In **A**, which has a small P–P–P–P torsion angle $\varphi$, the couplings follow the order $J_{1,4}$ (>300 Hz) >> $J_{1,3}/J_{2,4}$ (11–35 Hz), whereas in **B**,

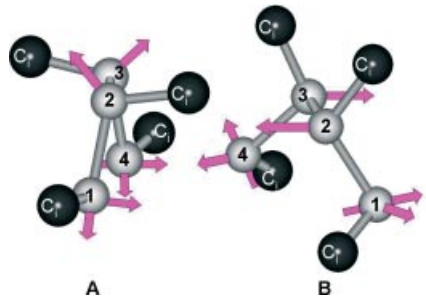

Figure 6. Conformations of the $P_4$ chains in tetraphosphanediides of type **A** {found in all $[M_2(P_4Ph_4)(solv)_x]$ with M = Li, Na, and $[Na_2(P_4tBu_4)(thf)_4]$} and **B** {observed in $[M_2(P_4Mes_4)(thf)_x]$ M = Na, $x$ = 4; M = K, $x$ = 6}. The *ipso* carbons of the aryl groups are indicated as $C_i$ and the nonbonding electron pairs at the phosphorus centers are shown as magenta-colored arrows.

Table 3. Experimentally derived $^{31}$P–$^{31}$P coupling constants [Hz] of the $P^1$–$P^2$–$P^3$–$P^4$ chain in **IIIa**,[5a] $[Na_2(P_4tBu_4)(thf)_4]$,[4] $[Na_2(P_4Mes_4)(thf)_4]$,[4] **4**, and **4′′**. The computed,[a] geometric, and magnetic properties for $Li_2(P_4H_4)_{opt}$,[b] $Na_2(P_4H_4)_{opt}$,[b] $Li_2(P_4Ph_4)(tmeda)_{2,cry,trunc}$,[c] and the $Li_2(tmeda)_1(P_4Ph_4)_{opt,trunc}$[c] isomers **A** and **B** are also given.

[a] Coupling constants in Hz calculated at GIAO/B3LYP/6-311+G**//B3LYP/6-31G*.[15] [b] opt = properties of B3LYP/6-31G*-optimized structure. [c] trunc = truncated geometry; the NMR properties are calculated for the molecule where phenyl groups have been replaced by H atoms at a standard P–H distance of 1.427 Å and solvent molecules (tmeda) are omitted. [d] $P^1$–$P^2$ = $P^3$–$P^4$ if only one distance and $^1J_{1,2}$ = $^1J_{3,4}$ and $J_{1,3}$ = $J_{2,4}$ if only one coupling is given.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

which has a large angle (>70°), a poor 1,4 alignment of the lone pairs causes the inverse ordering $J_{1,4}$ (<5 Hz) << $J_{1,3}$/$J_{2,4}$ (>100 Hz).

We performed the following computations:[15] i) $^{31}$P chemical shifts were calculated at the GIAO/B3LYP/6-31G* level for a number of structural isomers of molecules of the general formula [$Li_2(P_4Ph_4)(tmeda)_n$] ($n$ = 0, 1, 2). The values obtained for [$Li_2(P_4Ph_4)(tmeda)_2$] (**4**) with the structure observed in the crystal and with the optimized structure (B3LYP/6-31G*), denoted as $\mathbf{4}_{cry}$ and $\mathbf{4}_{opt}$, respectively, are $\delta$ = –108 ($\mathbf{4}_{cry}$, terminal), –52 ($\mathbf{4}_{cry}$, inner), –70 ($\mathbf{4}_{opt}$, terminal), and –17 ppm ($\mathbf{4}_{opt}$, inner), respectively. The chemical shift difference, $\Delta\delta$, between the terminal and the inner backbone $^{31}$P nuclei is rather constant (–53 ppm relaxed and –56 ppm crystal geometry). The calculated data reproduce the experimental ones satisfactorily, which means that the chosen theoretical level is sufficient; ii) for comparison, the structures of the simple molecules [$Li_2(P_4H_4)$] and [$Na(P_4H_4)$] were optimized at the B3LYP/6-31G* level; iii) the $^{31}$P–$^{31}$P coupling constants were calculated for model compounds in which the structure of the $M_2P_4$ core of the complete [$Li_2(P_4Ph_4)(tmeda)_n$] was maintained but the phenyl groups were replaced by hydrogen atoms and the tmeda molecules omitted. These truncated geometries are denoted as [$Li_2(P_4Ph_4)(tmeda)_n$]$_{trunc}$.

Table 3 lists the P–P coupling constants for the sodium tetraphosphanediides [$Na_2(P_4Ph_4)(tmeda)_2$] (**IIIa**),[5a] [$Na_2(P_4Ph_4)(thf)_5$] (**IIId**),[5] [$Na_2(P_4tBu_4)(thf)_4$],[4] and the lithium tetraphosphanediides **4** and **4′** as obtained by simulating the experimental spectra. The calculated data for $Li_2(P_4H_4)_{opt}$, $Na_2(P_4H_4)_{opt}$, [$Li_2(P_4Ph_4)(tmeda)_2$]$_{cry,trunc}$, and the isomers **A** and **B** of $Li_2(tmeda)(P_4Ph_4)_{opt,trunc}$ are given for comparison. We have also included the data of [$Na_2(P_4Ph_4)(thf)_{2.5}$]$_{cry,trunc}$ reported by Kaupp et al.[14]

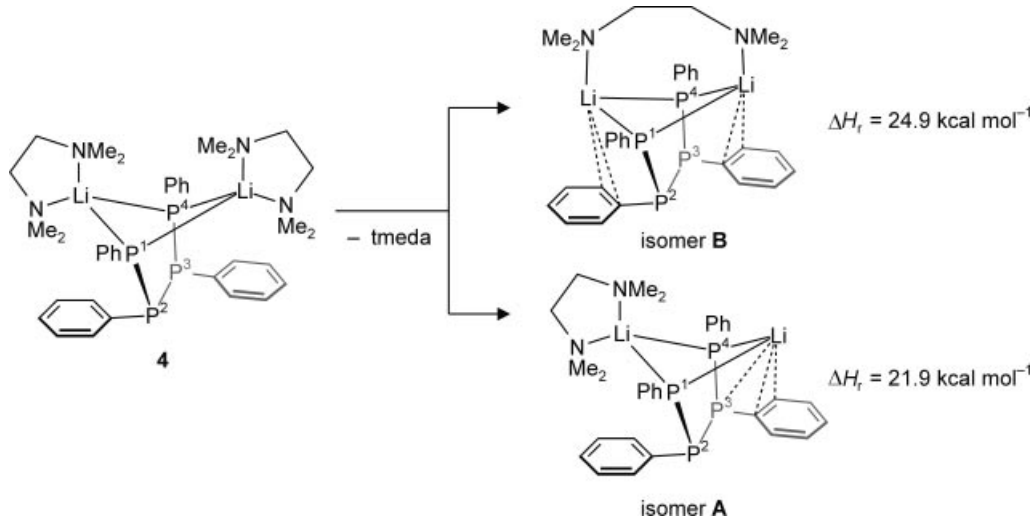
The experimental data listed for compounds of structure type **A** show that the one-bond P–P couplings $^1J_{1,2}$ = $^1J_{3,4}$ are somewhat smaller for M = Li (entries 4, 5) than for M = Na (entries 1–3) and this trend is reproduced with the calculated model structures (entries 6–9). The $P^{1,2}$–$P^{3,4}$ bonds in the optimized models [$M_2(P_4H_4)$]$_{opt}$ (M = Li, Na) are longer than in the truncated structures [$M_2(P_4H_4)$]$_{trunc}$ and consequently the $^1J$ couplings are smaller. The $^1J_{2,3}$ coupling is influenced by both the $P^2$–$P^3$ distance and also by the dihedral angle $\varphi$. In compounds with structure **B** (entry 3), where $\varphi$ is large, the $^1J_{2,3}$ coupling is rather small. As expected, the couplings $J_{1,3}$ = $J_{2,4}$ in the dilithium tetraphosphanediide [$Li_2(P_4Ph_4)(tmeda)_2$] (**4**) are in the range of the disodium compounds with the same structure type **A** and are smaller (entry 4) than for compounds with structure type **B** (entry 3). The $J_{1,4}$ coupling shows a dependency on the $P^1\cdots P^4$ distance and on the dihedral angle $\varphi$. At longer distances (>3.6 Å), $J_{1,4}$ decreases (compare entries 2 with entries 1 and 4). To some extent, this is also reflected by the calculations (compare entries 6 with 7 and 8 with 9). Especially small values for $J_{1,4}$ are observed for large torsion angles $\varphi$ (entry 3). In agreement with the experiment, the calculated coupling constants for [$Na_2(P_4H_4)$]$_{opt}$ and [$Li_2(P_4H_4)$]$_{opt}$ show only little differences. Nevertheless, the difference $\Delta\delta$ = $\delta(P^1,P^4)$ – $\delta(P^2,P^3)$ between the calculated chemical shifts of the terminal and internal $^{31}$P nuclei is strongly dependent on the alkali cation and significantly larger for Na [$Na_2(P_4H_4)$: $\Delta\delta$ = –176 ppm, with $\delta(P^1,P^4)$ = –232 and $\delta(P^2,P^3)$ = –56 ppm; $Li_2(P_4H_4)$: $\Delta\delta$ = –137 ppm, with $\delta(P^1,P^4)$ = –241 and $\delta(P^2,P^3)$ = –104 ppm]. It is noteworthy that the shifts of the atoms directly attached to the different cations are less affected than the remote phosphorus centers. Although much less pronounced, this is reflected by the experimental data {[$Na_2(P_4Ph_4)(tmeda)_2$] (**IIIa**): $\Delta\delta$ = –64.2 ppm with $\delta(P^1,P^4)$ = –89.1 and $\delta(P^2,P^3)$ = –24.9 ppm; [$Li_2(P_4Ph_4)(tmeda)_2$] (**4**): $\Delta\delta$ = –57.1 ppm, with $\delta(P^1,P^4)$ = –95.1 and $\delta(P^2,P^3)$ = –38.0 ppm}.

With respect to a possible structure for the second species **4′′** in solutions of **4**, the data in Table 3 give some hints: the slightly smaller $J_{1,4}$ and the positive $J_{1,3}$ = $J_{2,4}$ indicate that the conformation of the $P_4$ chain in **4′′** has a P–P–P–P torsion angle $\varphi$ that is significantly larger than in **4** (>> 20°). The very small $^1J_{2,3}$ indicates that the $P^2$–$P^3$ bond may also be elongated. The fact that broadened $^{31}$P NMR signals for the terminal phosphorus nuclei $P^1$, $P^4$ are observed and no $^7$Li signal could be recorded even at low temperatures point to fast exchange processes. For the sodium compound, we have suggested previously the equilibrium [$Na_2(P_4Ph_4)(thf)_x$] ⇆ [$Na(thf)_y$]$^+$ + [$Na(P_4Ph_4)(thf)_z$]$^-$, (with $\delta_1$ = –73.3, $\delta_2$ = –30.8, $\delta_3$ = –16.8, and $\delta_4$ = –70.4 ppm and $^1J_{1,2}$ = 340, $^1J_{2,3}$ = 340, $^1J_{3,4}$ = 274, and $J_{2,4}$ = 148 Hz for the [$Na(P_4Ph_4)(thf)_z$]$^-$ anion).[5] A computational search of possible structures for a [$Li(P_4Ph_4)(thf)_z$]$^-$ anion only gave species with an almost co-planar $P_4$ chain and at least one significantly high-frequency-shifted resonance for an *internal* phosphorus nucleus (>39 ppm). This finding is not compatible with the experimental results, which show that the chemical shifts of the external $^{31}$P nuclei in **4** and **4′′** are quite different. In view of the rather high ESP, it seems likely that **4′′** also has the structure of an ion triple with a strongly distorted $P_4$ chain. We therefore inspected various possible structures for **4′′** that contain only one tmeda molecule as co-ligand to lithium (Scheme 2).

Two isomers were found: isomer **A**, with a chelating tmeda molecule binding to only one Li ion in a $\kappa^2$-fashion, and isomer **B**, where the tmeda molecule bridges the two lithium ions in a $\mu_2$-$\kappa^1$,$\kappa^1$-fashion. Isomer **A** is about 3 kcal mol$^{-1}$ more stable than isomer **B**. The calculated (gas-phase) energies, $\Delta H_r$, for the dissociation of one tmeda from **4** are in a reasonable range (21–24 kcal mol$^{-1}$; Scheme 2) to allow this process in solution. This idea is supported by measuring the diffusion coefficients of the $(P_4Ph_4)^{2-}$-containing species ($0.26746\times10^{-9}$ m$^2$ s$^{-1}$) and the tmeda molecules ($0.29214\times10^{-9}$ m$^2$ s$^{-1}$) by pulsed field gradient NMR techniques.[16] The significantly larger diffusion coefficient (ca. 10%) for the tmeda molecules is compatible with the dissociation process, [$Li_2(P_4Ph_4)(tmeda)_2$] ⇆ [$Li_2(P_4Ph_4)$-(tmeda)] + tmeda, where, on average, three tmeda molecule are coordinated and one tmeda molecule is free.

Indeed, the P–P–P–P torsion angle $\varphi$ in **A** (23.6°) and especially **B** (38.3°) is somewhat larger than that observed in crystals (13.3°) and calculated (12°) for **4**. For isomer **A**,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Computed reaction enthalpies for the dissociation $[Li_2(P_4Ph_4)(tmeda)_2] \rightarrow [Li_2(P_4Ph_4)(tmeda)] + tmeda$.

the predicted $^{31}P$ chemical shifts are: $P^1$: $\delta$ = –74.03 ppm; $P^2$: $\delta$ = 6.87 ppm; $P^3$: $\delta$ = –28.52 ppm; $P^4$: $\delta$ = –30.06 ppm; and for the more symmetric isomer **B**: $P^1$,$P^4$: $\delta$ = –55 ppm; $P^2$,$P^3$: $\delta$ = 7 ppm. Considering that the equilibrium shown in Scheme 2 is likely to be fast on the NMR timescale, the chemical shift difference ($\Delta\delta$ = –42 ppm) between the averages of the chemical shifts for the external and internal $^{31}P$ nuclei, ½($P^1$ + $P^4$) = –53 ppm and ½($P^2$ + $P^3$) = –11 ppm, in isomer **A** fits better the experimental data for **4**′′ ($\Delta\delta$ = –34.7 ppm) than isomer **B** ($\Delta\delta$ = –62 ppm). However, the agreement between the calculated and experimental $^{31}P$–$^{31}P$ couplings is very poor (see Table 3) and at this point we cannot draw any definitive conclusion about the exact nature of **4**′′.

## Conclusions

Optimized conditions for the selective syntheses of dilithium (*catena*-oligophosphane-α,ω-diides) $[Li_2(P_nPh_n)(solv)_x]$ have bee developed and the species with solv = tmeda and $n$ = 2, 3, and 4 have been isolated as crystalline materials and structurally characterized. The compounds $[Li_2(P_2Ph_2)(tmeda)_2]$ and $[Li_2(P_4Ph_4)(tmeda)_2]$ form centrosymmetric genuine ion triples in the solid state and very probably also in solution. The lithium salt of the triphosphanediide behaves differently and is an ion pair, $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$, in the solid and in solution. On average, the Li–P bonds (average of Li–P distances listed in Table 2: 2.55 Å) are 15% shorter than the Na–P distances (av. 2.98 Å) in comparable sodium oligophosphane-α,ω-diides (see Table 1). As a consequence, the electrostatic stabilization parameters, ESPs, of the lithium phosphanediides are significantly larger. Within its limits, this very simple model, which involves placing point charges at the positions of the cations and terminal phosphorus centers and neglecting all solvation energies and steric interactions, can be used to rationalize why $Li_2(P_2Ph_2)$ forms a simple ion triple while the sodium analogue forms a larger aggregate. Also, the fact that $[Na_2(P_3Ph_3)(solv)_x]$ forms an intact ion triple but the lithium analogue readily dissociates into an ion pair is expected. Specifically, the large drop of the ESP when going from the ion triple $[Na_2(P_3Ph_3)]$ (–0.79) to a hypothetical ion pair $[Na]^+$-$[Na(P_3Ph_3)]^-$ (ESP = –0.35; calculated with Na–P = 2.98 Å, P–P = 3.14 Å) cannot be overcompensated by the solvation of the dissociated $Na^+$ cation in an organic solvent. Further studies will concentrate on the question of whether these different aggregates also have different reactivity.

## Experimental Section

**General Techniques:** All manipulations were performed under argon. All solvents were dried and purified using standard procedures and were freshly distilled under argon from sodium/benzophenone (THF, toluene, tmeda, dme, mtbe) or from sodium/diglyme/benzophenone (*n*-hexane) prior to use. Air sensitive compounds were stored and weighed in a glove box (Braun MB 150 B-G system) and reactions on small scale were performed directly in the glove box.

NMR Spectra were measured on Bruker AVANCE 500, 400, 300, and 250 systems. The chemical shifts ($\delta$) are measured according to IUPAC[17] and expressed in ppm relative to TMS ($^1H$, $^{13}C$), LiCl ($^7Li$), and $H_3PO_4$ ($^{31}P$). No satisfactory elemental analysis could be obtained due to the high air and moisture sensitivity of the compounds.

**Solid State NMR:** $^{31}P$ CP-MAS solid-state NMR spectra were acquired at room temperature on a Bruker Avance instrument operating at a $^1H$ Larmor frequency of 500 MHz. Conventional cross-polarization and magic-angle-spinning techniques were implemented using 4-mm rotors, with which rotational frequencies of more than 11 kHz were achieved. The $^{13}C$ carboxylate resonance of α-glycine appeared at $\delta$ = 176.0 ppm. As a consequence, referencing of all isotopes could be achieved as for the solution NMR using the unified Ξ scale.[17] Chemical shifts are expressed relative to $H_3PO_4$.

**X-ray Crystallographic Investigations and Crystal Data:** Data collection for the X-ray structure determinations were performed on

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a Bruker SMART Apex diffractometer system with CCD area detector by using graphite-monochromated Mo-$K_\alpha$ (0.71073 Å) radiation and a low-temperature device. Crystals of $[Li_2(P_2Ph_2)(tmeda)_2]$ (**2**) suitable for X-ray diffraction were obtained by crystallization of a saturated toluene/tmeda solution at ambient temperature. Those of $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$ (**3**) were grown from a toluene solution at 7 °C and of $[Li_2(P_4Ph_4)(tmeda)_2]$ (**4**) from a saturated mtbe solution at ambient temperature. In order to avoid quality degradation the single crystals were mounted in paraffin oil on top of a glass fiber and then brought into the cold nitrogen stream of a low-temperature device so that the oil solidified. All calculations were performed with SHELXTL (ver. 6.12) and SHELXL-97 (G.M. Sheldrick, Göttingen, 1997). The structures were solved by direct methods and successive interpretation of the difference Fourier maps, followed by full-matrix least-squares refinement (against $F^2$). Moreover, an empirical absorption correction using SADABS (ver. 2.03) was applied to all structures. All non-hydrogen atoms were refined anisotropically in the X-ray structures of $[Li_2(P_2Ph_2)(tmeda)_2]$ (**2**) and $[Li_2(P_4Ph_4)(tmeda)_2]$ (**4**), whereas the tmeda ligand in $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$ (**3**) was refined isotropically. The ethylene bridge of the tmeda ligand is highly disordered on two positions and a large number (17) of restraints had to be used to achieve a satisfactory w$R$2 value. The contribution of the hydrogen atoms, in their calculated positions, was included in the refinement using a riding model for the X-ray structures of $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$ (**3**) and $[Li_2(P_4Ph_4)(tmeda)_2]$ (**4**). Some hydrogen atoms of $[Li_2(P_2Ph_2)(tmeda)_2]$ (**2**) could be located in the Fourier difference map and hence were refined freely. The disordering in this molecule, which is caused by a flip of the Li–P–P–Li plane by 48° with respect to the Li–Li vector, was fixed using the bond lengths of the main structure, resulting in a large number (12) of restraints. The contribution of the hydrogen atoms of the disordered part was included by using a riding model. Upon convergence, the final Fourier difference map of all structures showed no significant peaks. Relevant data concerning crystallographic data, data collection, and refinement details are summarized in Table 4.

CCDC-280997 to -280999 (for **2**–**4**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif

**Computational Methods:** Geometries were ab initio optimized[15] at the B3LYP/6-31G* level unless otherwise stated. Chemical shifts and nuclear spin-spin coupling constants were obtained for these geometries and truncated moieties by the GIAO/B3LYP/6-31G* method. The $^{31}$P chemical shift of $PH_3$ ($\delta$ = 586 ppm) was calculated using a B3LYP/6-31G* structure at the GIAO/B3LYP/6-31G* level and set to –240 ppm vs. $H_3PO_4$ as the reference shift for all computed structures.

**Synthesis of $[Li_2(P_2Ph_2)(tmeda)_2]$ (2):** Lithium sand (39 mg, 5.62 mmol, 6 equivalents) and ($P_5Ph_5$) (500 mg, 0.925 mmol, 1 equiv.) were stirred for 24 h in THF (10 mL). The remaining lithium sand was filtered off and the solvent of the deep red filtrate was removed under high vacuum. The orange red powder was suspended in hot toluene (10 mL) and filtered off. The red powder was recrystallized from a hot mixture of toluene (4 mL) and tmeda (2 mL) and, on cooling to ambient temperature, the product separated as red crystals (673 mg, 63%). Red, very air-sensitive single crystals of $[Li_2(P_2Ph_2)(tmeda)_2]$ were obtained by storing a saturated toluene/tmeda solution at ambient temperature. $[Li_2(P_2Ph_2)(tmeda)_2]$ ($C_{24}H_{42}Li_2N_4P_2$, M = 462.45 g mol$^{-1}$): M.p. 151–153 °C (single crystal, uncorrected). $^1$H NMR (500.23 MHz, [D$_8$]THF, 25 °C): $\delta$ = 2.18 [s, 8 H, $CH_{3(TMEDA)}$], 2.34 [s, 24 H, $CH_{2(TMEDA)}$], 6.33 (m, 2 H, *p*-H), 6.62 (m, 4 H, *m*-H), 7.26 ppm (m, 4 H, *o*-H). $^7$Li NMR (194.4 MHz, DME/[D$_8$]toluene, 25 °C): $\delta$ = 0.6 ppm [s (br.)]. $^{13}$C NMR (125.8 MHz, [D$_8$]THF, 25 °C): $\delta$ = 46.7 [s, $CH_{3(TMEDA)}$], 59.4 [s, $CH_{2(TMEDA)}$], 117.5 [s (br.), 4-C in Ph], 126.7 [t, ($^3J_{C,P}$ + $^4J_{C,P}$) = 2.4 Hz, 3,5-C in Ph], 131.0 [t, ($^2J_{C,P}$ + $^3J_{C,P}$) = 12.2 Hz, 2,6-C in Ph], 162.2 ppm [t, ($^1J_{C,P}$ + $^2J_{C,P}$) = 34.8 Hz, 1-C in Ph]. $^{31}$P NMR (202.5 MHz, [D$_8$]THF, 25 °C): $\delta$ = –102.9 ppm (s).

**Synthesis of $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$ (3):** Lithium sand (45 mg, 6.47 mmol; 3.5 equiv.) and ($P_5Ph_5$) (1.00 g, 1.85 mmol; 1 equiv) were stirred for 24 h in dme (10 mL). The orange precipitate was filtered off, washed with dme (2 mL), and dried in high vacuum. The light orange powder was dissolved in a mixture of toluene (5 mL) and tmeda (1 mL). The solvent was removed under

high vacuum to give a yellow powder (1.525 g, 72%). Yellow, very air-sensitive single crystals of $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$ were obtained by storing a saturated toluene solution for several days at 7 °C. $[Li(tmeda)_2]^+[Li(P_3Ph_3)(tmeda)]^-$ ($C_{36}H_{63}Li_2N_6P_3$, $M$ = 686.73 g mol$^{-1}$): M.p. 166 °C (single crystal, uncorrected). $^1$H NMR (300.1 MHz, [D$_8$]toluene, 25 °C): $\delta$ = 1.92 [s (br.), 12 H, $CH_{2(TMEDA)}$], 2.03 [s (br.), 36 H, $CH_{3(TMEDA)}$], 6.87 (m, 1 H, *p*-H in Ph at $P_A$), 6.89 (m, 2 H, *p*-H in Ph at $P_M$), 6.97 (m, 2 H, *m*-H in Ph at $P_A$), 7.20 (m, 4 H, *m*-H in Ph at $P_M$), 8.04 (m, 4 H, *o*-H in Ph at $P_M$), 8.18 ppm (m, 2 H, *o*-H in Ph at $P_A$). $^7$Li NMR (194.4 MHz, [D$_8$]toluene, –73 °C): $\delta$ = 11.4 [m (br.)], 10.5 ppm [s (br.)]. $^{13}$C NMR (75.5 MHz, [D$_8$]toluene, 25 °C): $\delta$ = 45.9 [s, $CH_{3(TMEDA)}$], 57.2 [s, $CH_{2(TMEDA)}$], 120.0 (s, 4-C in Ph at $P_M$), 124.8 (s, 4-C in Ph at $P_A$), 127.4 (m, 3,5-C in Ph at $P_A$), 128.1 (m, 3,5-C in Ph at $P_M$), 130.0 (m, 2,6-C in Ph at $P_M$), 131.0 (m, 2,6-C in Ph at $P_A$), 155.8 (m, 1-C in Ph at $P_M$), 159.1 ppm (m, 1-C in Ph at $P_A$). Multiplets in the $^{13}$C NMR spectra represent the X part of an AMM′X spin system. $^{31}$P NMR (101.3 MHz, [D$_8$]toluene, 25 °C): $\delta$ = –52.3 [m, $^1J_{P(M),P(A)}$ = 223.8 Hz, A part of an $AM_2$ spin system, $P_A$], –71.5 ppm [m, $^1J_{P(M),P(A)}$ = 223.8 Hz, M part of an AMM′ spin system, $P_{(M+M')}$].

**Synthesis of $[Li_2(P_4Ph_4)(tmeda)_2]$ (4):** $[Li_2(P_3Ph_3)(dme)_x]$ (**3′**; 892 mg, 1.466 mmol, 5 equiv., $x$ = 3) and ($P_5Ph_5$) (158 mg, 0.242 mmol, 1 equiv.) were suspended in $Et_2O$ (30 mL). The yellow suspension was stirred for 24 h. The almost clear yellow solution was filtered through a Teflon filter. The solvent was removed under high vacuum and the obtained orange powder was dissolved in a mixture of toluene (10 mL) and tmeda (3 mL). The solvent was removed under high vacuum to give a yellow powder (865 mg, 87%). Slightly yellow, very air-sensitive single crystals of $[Li_2(P_4Ph_4)(tmeda)_2]$ were obtained by storing a saturated mtbe solution for several days at ambient temperature. $[Li_2(P_4Ph_4)(tmeda)_2]$ ($C_{36}H_{52}Li_2N_4P_4$, M = 678.6 g mol$^{-1}$): M.p. 174 °C (single crystals, uncorrected). $^1$H NMR (500.2 MHz, [D$_8$]toluene, 25 °C): $\delta$ = 1.76 [s (br.), 8 H, $CH_{2(TMEDA)}$], 1.95 [s (br.), 24 H, $CH_{3(TMEDA)}$], 6.86 (m, 2 H, *p*-H in Ph at $P_A$), 7.02 (m, 2 H, *p*-H in Ph at $P_B$), 7.09 (m, 4 H, *m*-H in Ph at $P_A$), 7.14 (m, 4 H, *m*-H in Ph at $P_B$), 7.72 (m, 4 H, *o*-H in Ph at $P_A$), 8.22 ppm (m, 4 H, *o*-H in Ph at $P_B$). $^7$Li NMR (194.4 MHz, [D$_8$]toluene, –25 °C): $\delta$ = 10.9 ppm (t, $^1J_{Li,P}$ = 37.3 Hz, 2 Li) ppm. $^{13}$C NMR (125.8 MHz, [D$_8$]toluene, 25 °C): $\delta$ = 46.1 [s, $CH_{3(TMEDA)}$], 56.8 [s, $CH_{2(TMEDA)}$], 120.6 (s, 4-C in Ph at $P_A$), 125.7 (s, 4-C in Ph at $P_B$), 127.5 (s, 3,5-C in Ph at $P_A$), 127.6 (s, 3,5-C in Ph at $P_B$), 130.2 (m, 2,6-C in Ph at $P_A$), 133.9 (m, 2,6-C in Ph at $P_B$), 148.3 [m (br), 1-C in Ph at $P_B$], 154.3 ppm [m (br.), 1-C in Ph at $P_A$]. Multiplets in the $^{13}$C NMR spectra represent the X part of an AA′BB′X spin system. $^{31}$P NMR (202.5 MHz, [D$_8$]toluene, 25 °C): $\delta$ = –2.3 [m, $(PPh)_5$], –36.8 (br., $[Li_2(P_4Ph_4)(tmeda)_2]$), –53.3 (m, $[Li_2(P_3Ph_3)(tmeda)_3]$), –73.0 (m, $[Li_2(P_3Ph_3)(tmeda)_3]$), –76.0 (br., $[Li_2(P_4Ph_4)(tmeda)_2]$), –95.4 (br., $[Li_2(P_4Ph_4)(tmeda)_2]$) ppm. $^{31}$P NMR (202.5 MHz, [D$_8$]toluene, –25 °C): $\delta$ = –38.0 (m, B part of an AA′BB′$X_2$ spin system, $P_B$ [**4**]), –39.7 (m, B part of an AA′BB′X spin system, $P_B$ [**4′′**]), –74.4 (m, A part of an AA′BB′X spin system, $P_A$ [**4′′**]), –95.1 ppm (m, A part of an AA′BB′$X_2$ spin system, $P_A$ [**4**]); ratio **4**/**4′′** = 100:81. $^{31}$P{$^1$H} CPMAS (202.5 MHz, 25 °C): $\delta_{iso}$ = –38, $\delta_{11} \approx 50$, $\delta_{22} \approx -10$, $\delta_{33} \approx -155$ (B part); $\delta_{iso}$ = –87, $\delta_{11} \approx 0$, $\delta_{22} \approx -55$, $\delta_{33} \approx -205$ ppm (A part). $^7$Li NMR (194.4 MHz, [D$_8$]toluene, –25 °C): $\delta$ = 10.9 ppm (t, $^1J_{Li,P}$ = 37.3 Hz, 2 Li).

**Supporting Information** (see footnote on the first page of this article): Plots of the $^{13}$C NMR spectra of compounds **2**, **3**, and **4** and details of the simulation of the $^{31}$P CP-MAS spectrum with the SIMPSON package.

# A Cationic Order-Disorder Phase Transition in $KPb_2Cl_5$

Matias Velázquez,*[a] Alban Ferrier,[a] Olivier Pérez,[b] Stanislas Péchev,[c] Pierre Gravereau,[c] Jean-Pierre Chaminade,[c] and Richard Moncorgé[a]

**Keywords:** Halides / Solid-state structures / Structure elucidation / Phase transitions / Thermodynamics

The phase transition occurring at $T_t$ = 528 K in the natural mineral and synthetic laser host compound $KPb_2Cl_5$ has been characterized by means of both single-crystal X-ray diffraction (XRD) as a function of temperature and differential scanning calorimetry (DSC). The $K^+$ and $Pb^{2+}$(2) cations order on passing from the high-temperature orthorhombic phase (space group *Pmcn*; $a$ = 8.951, $b$ = 8.015, $c$ = 12.683 Å, $Z$ = 4 at 623 K) to the low-temperature monoclinic one (space group $P2_1/c$; $a$ = 8.849, $b$ = 7.918, $c$ = 12.472 Å, $\beta$ = 90.11°, $Z$ = 4, at room temperature), leading to a group-subgroup first-order phase transition displaying moderately fast kinetics and low entropy production upon thermal cycling around $T_t$. The positional entropy calculated from our crystal structure models corresponds to the transition entropy measured by DSC within the experimental error, and amounts to about 0.34 $R$. The driving force for the phase transition, $A \leq 22\ J\,mol^{-1}$, remains negligible with respect to both the thermal energy at $T_t$ ($RT_t \approx 4.4\ kJ\,mol^{-1}$) and the transition latent heat ($\Delta H \approx 790\ J\,mol^{-1}$), thereby suggesting that this phase transition is a close-to-equilibrium process.

## Introduction

$KPb_2Cl_5$ is a chloride[1] that has been known for a long time but has recently triggered a substantial body of literature because of its use as a host crystal for optical amplifiers in near- and middle-infrared solid-state lasers.[2] In this realm of applications, the growth of centimeter-sized high-quality single crystals is of paramount importance for several reasons. Firstly, it allows for the investigations of the intrinsic optical performances (grain boundaries and other microstructural defects can introduce passive losses within the laser cavity). Secondly, it permits the characterization of the anisotropy of these optical properties (absorption and emission cross-sections, for instance, can depend on the relative orientation of the electric field with respect to the optical axis of the crystal). Thirdly, it provides a means of concentrating a sufficiently large number of optically active ions with virtually no diffusion mobility within a cubic-centimeter-sized volume (with respect to gas lasers) to ensure optical amplification. In other respects, $KPb_2Cl_5$ occurs as a natural mineral named "challacolloite"[3] that readily forms in the flue dusts of steelmaking plants[4] and in the high-temperature fumarole gases of the Kudryavyi (Iturup Island, Kuril Islands), Vesuvius (Italy), and Satsuma–Iwojima (Japan) volcanoes.[3,5] Until now, the main crystal-growth method for elaborating pure and rare-earth-doped $KPb_2Cl_5$ single crystals has been the Bridgman–Stockbarger one: at least 20 different single crystals have been successfully elaborated by this method.[6–10] Powder X-ray diffraction (XRD) carried out at room temperature has established that $KPb_2Cl_5$ adopts the $NH_4Pb_2Cl_5$ structural type,[11] and a recent accurate refinement of single-crystal XRD data firmly confirmed this crystal structure.[12] Although several researchers have evoked the likelihood of a phase transition undergone by the crystals between the melting point and room temperature,[7,13] it is only recently that it was characterized by differential scanning calorimetry (DSC) and found to display a low entropy production per thermal cycle around $T_t$ = 528.15 K.[10] In this paper we present a combined crystallographic and thermodynamic analysis of the phase transition in $KPb_2Cl_5$ by means of single-crystal XRD as a function of temperature and DSC experiments which supplement the ones previously undertaken. We demonstrate that it corresponds to a close-to-equilibrium cationic order-disorder group-subgroup first-order transition that displays moderately fast kinetics.

## Results and Discussion

### Crystallographic Aspects

Both the room- and high-temperature structures consist of edge-sharing $Pb^{2+}$(1) monocapped octahedra that form

 InterScience © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

infinite chains along [100] (Figures 1 and 2). These are isolated from each other but surrounded by, and joined to, six $K^+/Pb^{2+}(2)$ face-sharing bicapped trigonal prism-based chains that also extend along the [100] direction (Figures 1 and 3). The $K^+$ and $Pb^{2+}(2)$ cations alternate in the room-temperature phase but are disordered in the high-temperature phase. The $K^+/Pb^{2+}(2)$ chains arrange in a pseudo-hexagonal network in the $(\bar{b}\bar{c})$ planes that contain the $Pb^{2+}(1)$ chains (Figure 4). Along [010], the $K^+/Pb^{2+}(2)$ polyhedra share one of their triangular faces, which gives rise to corrugated chains [with a 128.8° angle between three successive $K^+$ or $Pb^{2+}(2)$ cations] that are linked to each other by a Cl(5)–Cl(5) edge every three polyhedra (Figures 4 and 5). The $Pb^{2+}(1)$ monocapped octahedra share all their vertices but not more than one edge simultaneously with a neighboring $K^+$ and/or $Pb^{2+}(2)$ polyhedra. The two equatorial edges that are not linked to the $Pb^{2+}(1)$ polyhedra, along the [100] direction, are unshared. The three edges defining the triangular face at the opposite side from the capped face, as well as all the faces of the $Pb^{2+}(1)$ polyhedra, also remain unshared. In Figure 6 (a), the pseudo-quadrilateral face on the capped side has in common its four edges with the neighboring two $K^+$ and two $Pb^{2+}(2)$ polyhedra, which block the view of it. The rise in symmetry in the high-temperature phase stems from the fact that the $K^+$ and $Pb^{2+}(2)$ cations become equivalent, much like the (8d) $K^+$ cations do in $K_2PrCl_5$, which adopts the *Pnma* space group.[14] Hence, a mirror plane appears at 1/4,*y*,*z*, on which the $Pb^{2+}(1)$ cations are located (Figure 6). The 153.75° angle between the successive $Pb^{2+}(1)$ cations is virtually unaffected (155.6° at 623 K) by cationic ordering in the neighboring $K^+/Pb^{2+}(2)$ chains, whereas in the latter chains the angle between two consecutive $K^+$ and $Pb^{2+}(2)$ cations passes from 170.9° at room temperature to 180° at 623 K. Some of the structural parameters are quite sensitive to the phase transition. The analysis of the behavior of the unit-cell parameters (Figure 7) and of the diagonal coefficients of the anisotropic atomic displacement parameters (ADPs, presented in Figure 8) as a function of temperature is not devoid of interest for understanding the phase-transition mechanism. While the *a* and *b* parameters show a linear dependency on temperature from 293 to 573 K, the *c* parameter shows two breaks of slope at about 473 and 573 K, which provide clear evidence for the phase transition since they correspond to the initial and final peak temperatures in the $C_p$ vs. $T$[10] and $J_q$ vs. $T$ curves (Figure 9). The

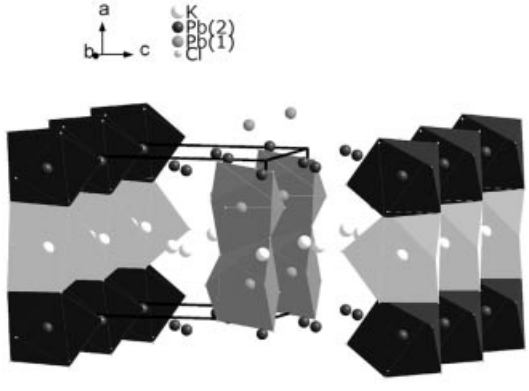

Figure 1. Simplified view of the $KPb_2Cl_5$ crystal structure at room temperature ($P2_1/c$) showing the two kinds of chains running along [100]: the ordered $K^+/Pb^{2+}(2)$ one and the $Pb^{2+}(1)$ one. In the high-temperature phase, the $K^+$ and $Pb^{2+}(2)$ cations become crystallographically equivalent and a cationic disorder appears in the $K^+/Pb^{2+}(2)$ chains over a length typically of 10–1000 Å (see text).

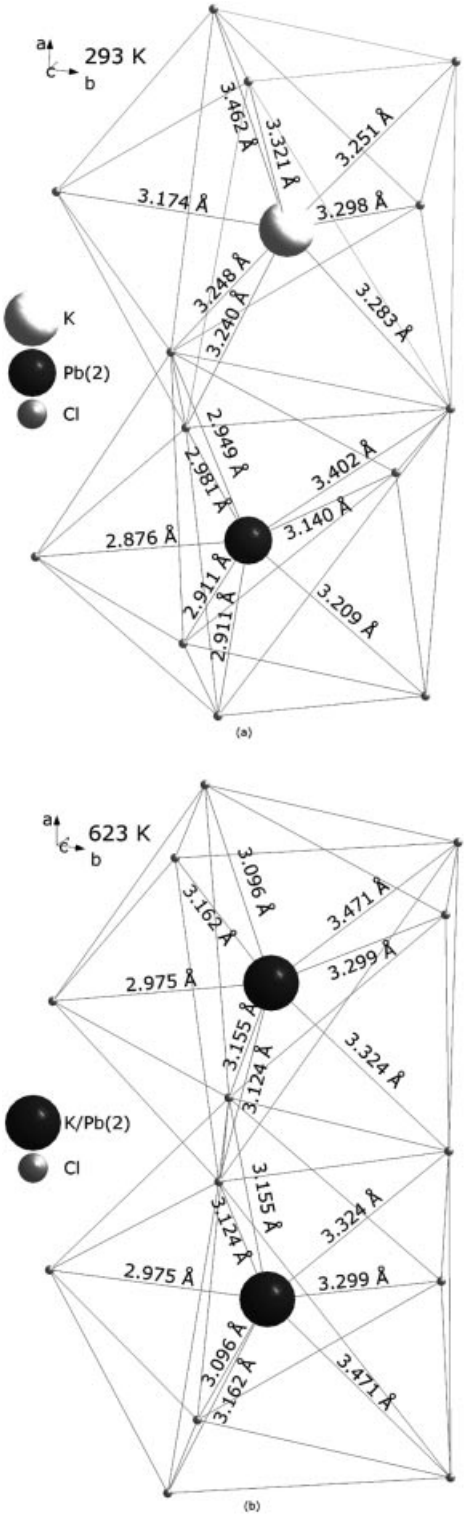

Figure 3. (a) Sketch of the ordered $K^+/Pb^{2+}(2)$ chains in the room-temperature phase along [100]; (b) sketch of the disordered $K^+/Pb^{2+}(2)$ chains at 623 K (*Pmcn* phase) along [100]. Both views show the triangular face-sharing of the bicapped trigonal prisms.

mean lattice-expansion coefficients are: $\frac{1}{a(293\text{ K})}\frac{da}{dT} \approx 38.6\times10^{-6}\text{ K}^{-1}$ (293–598 K), $\frac{1}{b(293\text{ K})}\frac{db}{dT} \approx 42.6\times10^{-6}\text{ K}^{-1}$ (293–598 K) and $\frac{1}{c(293\text{ K})}\frac{dc}{dT} \approx 39.3\times10^{-6}\text{ K}^{-1}$ (293–473 K). Although the lattice parameters' thermal expansion is not strictly equal to the thermal expansion tensor diagonal elements,[15] it provides a sufficiently accurate estimate of the latter quantities. Worthy of note is the patent decrease in the *c* parameter upon cooling, from 573 to 473 K $-\frac{1}{c(473\text{ K})}\frac{dc}{dT} \approx 97.9\times10^{-6}\text{ K}^{-1}$ − which suggests that in this temperature range the thermal stress may be substantial and also that a very slow cooling under an extremely flat temperature profile should be applied to the crystal to prevent the generation of dislocations in too large a concentration. The relative difference in unit cell volume between 293 K and the *Pmcn* phase at 623 K is about –3.9%. This anisotropic increase in lattice thermal expansion upon heating might be attributed to a larger density of weaker bonds along [001] than along the [100] and [010] directions. The $K^+$ and $Pb^{2+}$ chloride polyhedral framework along [001] does not imply any single face-sharing, unlike along the [100] and [010] directions; however, the highest rises in $U_{ii}$ values in the vicinity of the transition temperature occur along [100]. Analysis of the ADPs (Figure 8) supplies information about the possible diffusion paths for the $K^+$ and $Pb^{2+}(2)$ cations at high temperature. The doubling of the ADPs undergone by both $K^+$ and $Pb^{2+}(2)$ along the [100], [010] and [001] directions at the transition outlines the three-dimensional character of the diffusion of these two species. Moreover, the isotropy of the lattice thermal expansion up to 473 K, in conjunction with the interchain connections in the ($\vec{b}\vec{c}$) plane also indicate that the $KPb_2Cl_5$ structure possesses a good deal of three-dimensional character notwithstanding the existence of both ordered $K^+/Pb^{2+}(2)$ and $Pb^{2+}(1)$ chains in the room-temperature phase. The increase in the ADPs of the $Pb^{2+}(1)$ cations proves to be less marked than that of both $K^+$ and $Pb^{2+}(2)$. $Cl^-(1)$ shows a net rise in $U_{33}$ between 473 and 548 K whereas in the other directions the thermal evolution of its ADPs seems regular. $Cl^-(2)$, but above all $Cl^-(5)$ and $Cl^-(3)$, displays a sharp increase in the displacement parameter along [100]. From the knowledge of the structure, three possible K/Pb(2) microscopic jumps can be conjectured: one along the [100] direction through the $Cl^-(3)$–$Cl^-(5)$–$Cl^-(2)$ triangular face, another one along [010] through the $Cl^-(1)$–$Cl^-(2)$–$Cl^-(3)$ triangular face (Figure 5) and the last one along [001] through the $Cl^-(5)$–$Cl^-(5)$ edge mentioned previously. The anisotropy of the ADPs' elongation [Figure 8 (b)] observed for $Cl^-(1)$ and $Cl^-(5)$ suggests a possible diffusion path along [001]. Indeed, this elongation occurs along [100] for $Cl^-(5)$, i.e. perpendicularly to the jump direction, and along [001] for $Cl^-(1)$, as sketched in Figure 5. Although these features are consistent with $K^+/Pb^{2+}(2)$ cation diffusion along the [001] direction, they are still speculative and call for a detailed energy-landscape calculation. Figure 10 illustrates how an XRD experiment can evidence the temperature spreading over about 100 K[10] of the phase transition: the *hk0* ($h + k = 2n + 1$) reflections observed at

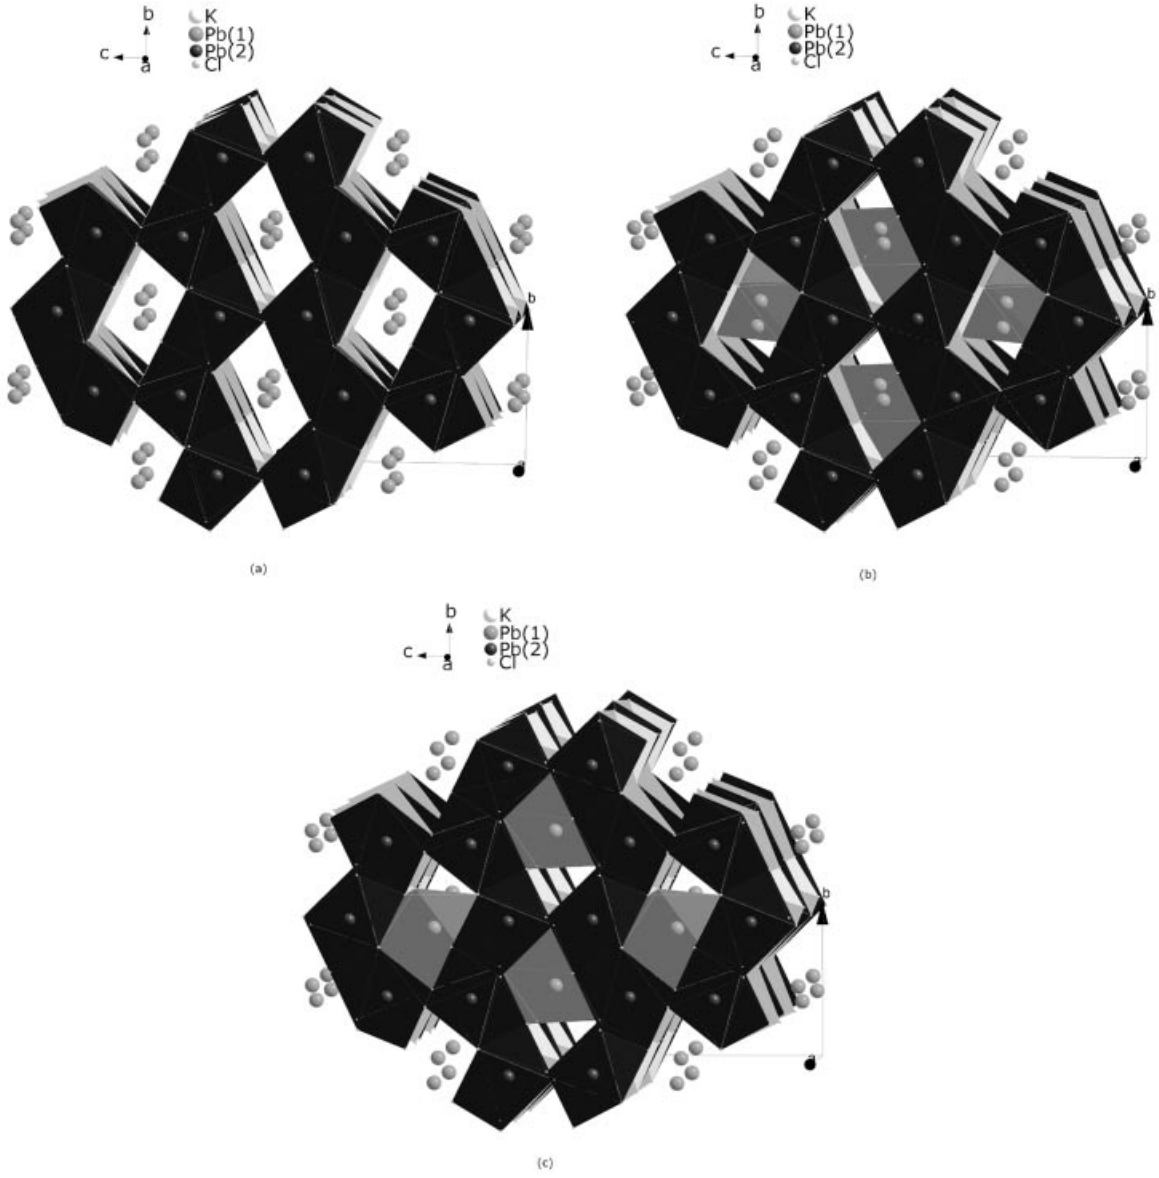

Figure 4. View of the $KPb_2Cl_5$ crystal structure at room temperature ($P2_1/c$) along [100] showing how the ordered $K^+/Pb^{2+}(2)$ chains share common edges in the ($\vec{b}\vec{c}$) planes to form a pseudo-hexagonal channel containing the $Pb^{2+}(1)$ chains: (a) without $Pb^{2+}(1)$ monocapped octahedra sketched; (b) with one $Pb^{2+}(1)$ monocapped octahedron drawn; (c) with the closest neighbor of the $Pb^{2+}(1)$ monocapped octahedron sketched in (b) drawn. These figures illustrate the zig-zag chains formed by the $Pb^{2+}(1)$ monocapped octahedra consistently with the 153.75° angle between three successive $Pb^{2+}(1)$ cations.

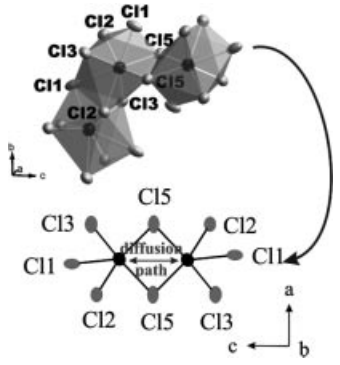

Figure 5. Speculative diffusion path for the $K^+$ and $Pb^{2+}(2)$ cations in $KPb_2Cl_5$ as deduced from the anisotropy of the $Cl^-$ anions' thermal vibrations.

293 and 473 K transform, at first, at 548 K, into diffuse scattering and then vanish at 623 K. The occurrence of diffuse scattering is likely to be due to the $K^+/Pb^{2+}(2)$ cationic diffusion.

### Structure of Rare-Earth Defects

Figures 6 (a) and (b) portray views of the $Pb^{2+}(1)$ polyhedron and chains that may prove useful when considering the local structure of the rare-earth defects that are liable to form when introduced within this compound to produce laser emission in the near- and middle-infrared wavelength range. In a recent work, we pointed out that the most expected rare-earth defects can be expressed in the Kröger–Vink notation as $RE^{\cdot}_{Pb} - V'_K$, $RE^{\cdot}_{Pb} - K'_{Pb}$, $RE^{\cdot\cdot}_K - V''_{Pb}$,

$RE^{\cdot}_{K} + 2V'_{K}$ and $2RE^{\cdot}_{Pb} + V''_{Pb}$. Let us now describe the situation more precisely by restricting our counting to nearest neighbors. There are six possible ways of forming each of the $RE^{\cdot}_{Pb(1)} - V'_{K}$, $RE^{\cdot}_{Pb(1)} - K'_{Pb(2)}$ and $RE^{\cdot}_{K} - V''_{Pb(1)}$ defects as the absence of symmetry elements makes all the nearest $K^+$ and $Pb^{2+}(2)$ neighbors symmetrically non-equivalent with respect to the $Pb^{2+}(1)$ sites. Along [100], there is only one possibility of finding the $RE^{\cdot}_{K} + V''_{Pb(2)}$ and $RE^{\cdot}_{Pb(2)} + V'_{K}$ defects. Owing to the inversion center located at 0,0,0 (right in the middle of the pseudo-hexagons drawn in Figure 4) three non-equivalent $RE^{\cdot}_{Pb(2)} + K'_{Pb(2)}$ defects can combine. The counting of three-center-type defects proves to be much more cumbersome, not only because of the lack of high-order symmetry elements [note, for example, thirty-six ways of forming $RE^{\cdot}_{Pb(2)} - V''_{Pb(2)} - RE^{\cdot}_{Pb(1)}$], but also because of the many possible combinations of $RE^{\cdot}_{Pb} - RE^{\cdot}_{Pb} - V''_{Pb}$. All in all, checking for the redundancies and with the proviso that the relaxation processes of atomic positions do not entail new symmetry element(s), this brings about more than 100 three-center defects in addition to the 23 two-center ones, all with a distinct formation free energy. Consequently, a distribution of

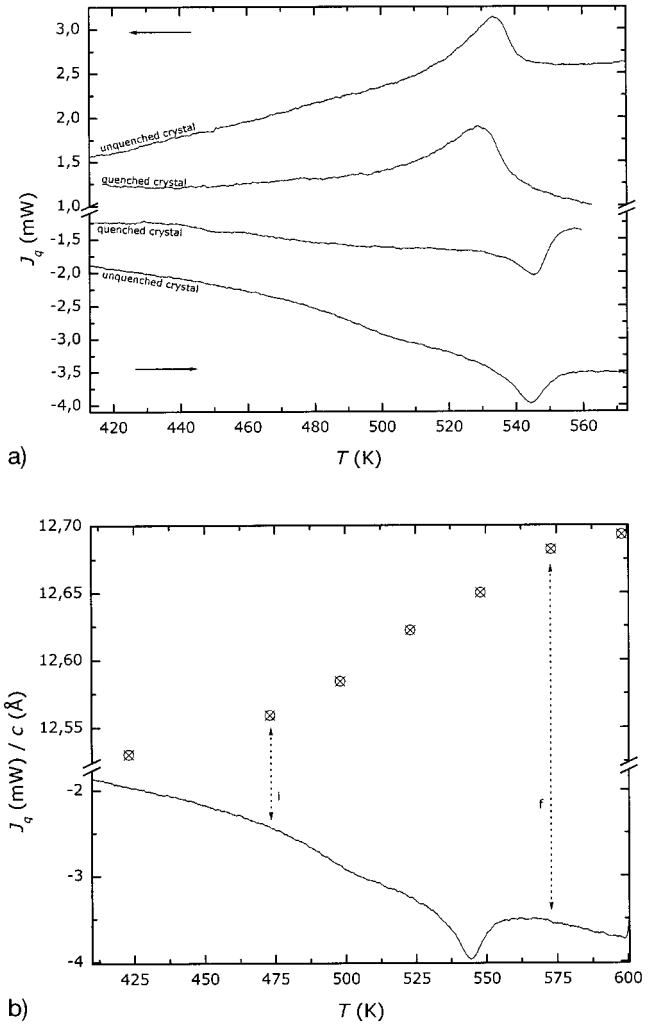

Figure 9. (a) Heat flux vs. temperature curves for raw $KPb_2Cl_5$ single crystals and $KPb_2Cl_5$ single crystals quenched from 633 K; (b) superposition of the unquenched $KPb_2Cl_5$ single crystal $J_q$ vs. $T$ and $c$ vs. $T$ curves. The double arrow labeled "i" indicates the initial peak temperature and that labeled "f" the final peak temperature.

them cannot be discarded a priori. It is even likely that the rare-earth defects' distribution depends on spatial coordinates because the formation free energy of a particular defect is affected by the concentration of its counterparts. These considerations put the recent attempts at characterizing the structure of rare-earth defects into perspective. A $Tb^{\cdot}_{Pb(1)} - V'_{K_4}$ defect, assumed to be the majority, has been supposed to account for the $^{159}Tb^{3+}$ high-frequency EPR spectra obtained in $Tb^{3+}$-doped $KPb_2Cl_5$ single crystals.[16] The labeling of the $K^+$ site is indicated in Figure 6 (a). By means of time-resolved fluorescence line-narrowing spectroscopy performed on $Eu^{3+}$-doped $KPb_2Cl_5$ single crystals, Cascales, Fernández and Balda concluded that three defects form, namely $Eu^{\cdot}_{Pb(2)} - V'_K$ (97%), $Eu^{\cdot}_{Pb(1)} - V'_{K_7}$ (1.9%) and $Eu^{\cdot\cdot}_K - V''_{Pb(?)}$ (1.1%), without unveiling which $K^+$ and $Pb^{2+}$ sites are involved in the latter two defects.[17]

## Thermodynamic and Kinetic Aspects

By making some assumptions, Defay and Prigogine established that the driving force of the transition should vary with time according to $A(t) = k\tau_r\cdot[1 - \exp(-t/\tau_r)]$.[18] Thus, during the phase transition, the value of the affinity $A$ changes from 0 to approximately $k\tau_r$. We suggest to determine $k$ according to $k \approx -\Delta H/\Delta t_t - \Delta V/V_m\cdot R\beta$, in which $\Delta t_t$, the time duration of the phase transition, can be obtained from the $T$ vs. $t$ DSC curve as the interval between the onset time of the baseline deviation and the time of the peak maximum; $\beta$, $\Delta V_m$, and $V_m$ stand for the temperature scanning rate, the molar volume contraction at fixed pressure and temperature, and some mean molar volume of the system in the vicinity of the transition, respectively. While the former is fixed by the experimenter, the latter can be estimated from the XRD data recorded around $T_t$. Our calorimetry and XRD data give $k \approx 11.6\,J\,mol^{-1}\,s^{-1}$. Furthermore, $\tau_r$ can be assigned an upper limit by a quenching experiment: this upper limit is $\tau_c$, the intrinsic cooling time of a crystal and its container quenched from a temperature higher than $T_t$, provided that the quenched sample exhibits the phase transition exactly like the slowly cooled crystals (see Experimental Section). As $\tau_r \leq \tau_c \approx 1.9$ s, we deduce that $A \leq 22\,J\,mol^{-1}$. This value is of the same order of magnitude as the Gibbs free energy change we previously estimated with Smith's formula ($\Delta G \approx 35\,J\,mol^{-1}$).[10] The fact that the affinity remains smaller than both the latent heat ($\Delta H \approx 790\,J\,mol^{-1}$) and the thermal energy at $T_t$ (ca. $4.4\,kJ\,mol^{-1}$), as well as the apparently fast energy relaxation kinetics and vanishingly small affinity threshold for the transition,[10] clearly indicate the close-to-equilibrium character of the transition, and are also consistent with its group-subgroup nature. The positional entropy can be approximated as $R\ln(x_{rt}/x_{ht})$, where $x_{ht}$ and $x_{rt}$ denote the number of atomic-position-independent parameters refined in the high-temperature phase (17) and in the room-temperature one (24), respectively. Hence, $\Delta S_{posn} = 0.345\,R \approx \Delta S_t$. In other words, this transition turns out to be an almost purely cationic order-disorder process, with virtually no phonon mode population redistribution or rotational disorder. Indeed, the extrapolation of the low-temperature part of the $C_p$ vs. $T$ curve falls into the high-temperature one.[10] This behavior of the specific heat baseline before and after the transition, and the fact that $\Delta S_t \approx \Delta S_{posn}$ lend support to the contention that $\Delta S_{vibr} \approx 0\,R$. Furthermore, as we were unable to detect any kind of collective tilt of the $K^+$ and $Pb^{2+}$ polyhedra, we think that $\Delta S_{orient} = 0\,R$. Thus, the increase in $U_{ii}$ values observed in Figure 8 certainly stems from the $K^+/Pb^{2+}(2)$ cations' positional disorder contribution to the Debye–Waller factor.[19] Assuming a $K^+/Pb^{2+}$ lattice interdiffusion coefficient of the order of magnitude of $10^{-11}$–$10^{-12}\,cm^2\,s^{-1}$ around $T_t$,[20] the fact that the same transition entropy is found in samples cooled from 633 K in about 1.9 s and in slowly cooled crystals leads us to presume that this cationic ordering takes place over a characteristic distance shorter than 1000 Å, that is, at the submesoscopic scale. On the other hand, owing to the ap-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

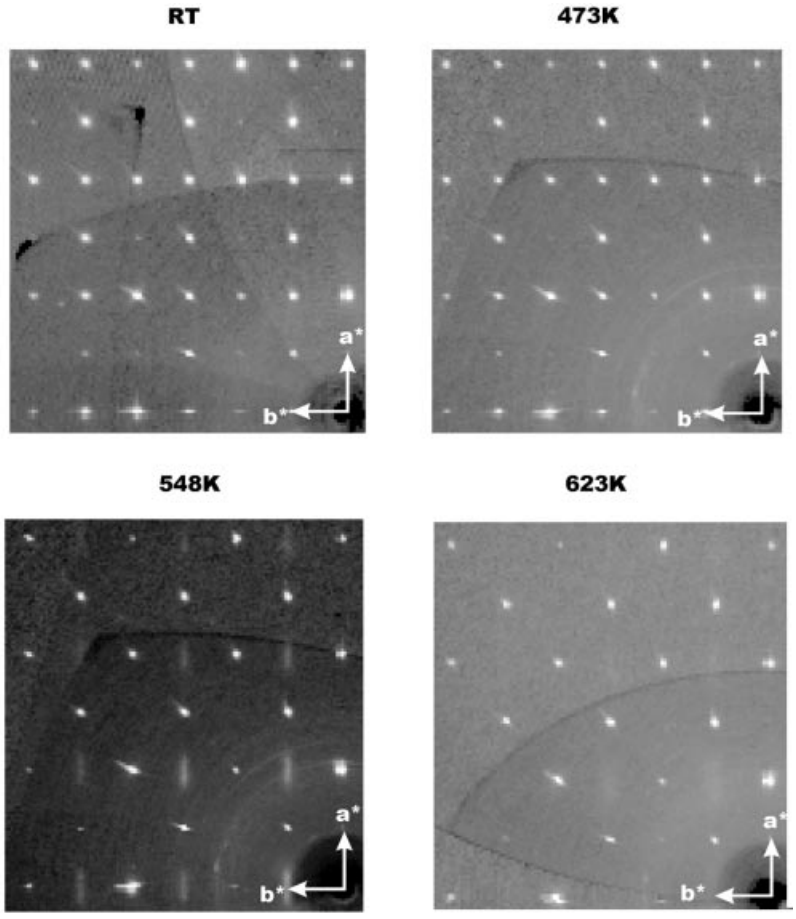

Figure 10. Plots of reciprocal lattice planes assembled from the series of experimental frames taken at various temperatures.

parently fast kinetics, low affinity, and group-subgroup nature of its phase transition, $KPb_2Cl_5$ is expected to belong to one of the two fully ferroelastic *mmmF*2/*m* species of Aizu's theory and display a 2×2 twinned domain microstructure.[21] The absence of splitting of the XRD spots (Figure 10) allows us to discard the possible coexistence of domains with different orientation states in the crystals of this study. This, in turn, suggests that the $K^+/Pb^{2+}$ diffusion upon ordering happens over a length larger than the interatomic distance. Finally, we would like to mention that although the form of the $KPb_2Cl_5$ $C_p$ vs. $T$ curve around the transition and that of $NaClO_4$ in the vicinity of the orthorhombic *Cmcm* to cubic *Fm*3*m* transition temperature are as alike as two peas in a pod,[10,22] the latter situation proves to be fundamentally different because it involves rotational degrees of freedom of the perchlorate anions in the transition mechanism.

## Conclusions

We have presented a consistent set of DSC and single-crystal XRD data that establishes the order-disorder group-subgroup phase transition occurring at 528 K in $KPb_2Cl_5$. This transition is of first order, displays moderately fast kinetics, and can be looked upon as a close-to-equilibrium process. In the high-temperature phase, a $K^+/Pb^{2+}(2)$ disorder takes place in the chains of bicapped trigonal prisms extending infinitely along the [100] direction. The lattice thermal expansion is almost isotropic from room temperature to about 473 K, but doubles its value along the [001] direction in the temperature range of the transition. We have also disentangled the connections between the $Pb^{2+}(1)$ chains embedded into the pseudo-hexagonal network of the $K^+/Pb^{2+}(2)$ chains.

## Experimental Section

**Synthesis and Crystal Growth:** KCl powder (63.4 mmol, Chempur 99.99% used as received) was mixed with $PbCl_2$ powder (126.8 mmol, Chempur 99.999% used as received) in an agate mortar in a ca. 2% wet-nitrogen-filled glovebox, dried in vacuo, and heated in successive stages from 425 to 565 K under electronic-grade HCl gas in a silica tube (mounted to a $10^{-8}$ atm vacuum assembly), in order to promote the solid-state reaction taking place according to $KCl + 2\ PbCl_2 \xrightarrow[425–565\ K]{HCl} KPb_2Cl_5$. Details of the subse-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

quent crystal growth by the Bridgman-Stockbarger method are given in ref.[10]

**Quenching Procedure:** Fresh $KPb_2Cl_5$ single crystals were taken from various locations of the bulk sample but neither from its beginning nor its end and sealed in a silica ampoule with a thickness of about 1 mm under 0.37 atm of HCl gas. The ampoule was placed in a vertical open furnace and heated at 633 K for 44 h. After this time, the ampoule was thrown into a mixture of ice and water. The intrinsic cooling time can be approximated to $\tau_{SiO_2} + \tau_{KPb_2Cl_5} \approx 1.9$ s, with $\tau_i = \frac{\rho_i C_p L_i^2}{M_i \kappa_i}$, $C_p(KPb_2Cl_5, 633\ K) \approx 40.3\,R$[10] and $\kappa(KPb_2Cl_5, 300\ K) \approx 4.62\ W\,m^{-1}\,K^{-1}$,[23] provided that the surface exchange contributions to heat dissipation can be neglected. The crystals did not seem to undergo mechanical breakdown upon quenching.

**Differential Scanning Calorimetry:** Calorimetric measurements were performed from room temperature to 600 K at a temperature variation rate of $\beta = \pm 10\ °C\,min^{-1} \approx \pm 167\ mK\,s^{-1}$, with a commercial continuous disk-type heat flux differential scanning calorimeter. A piece of fresh $KPb_2Cl_5$ crystal ($m = 34.3 \pm 0.2$ mg), and a quenched specimen ($m = 38.3 \pm 0.2$ mg) were placed without grinding into a stainless-steel crucible in a ca. 2% wet-nitrogen-filled glovebox. The crucibles were then sealed with a stainless-steel top and an Ni ring designed to resist pressures of around 100 atm at 873.15 K. The calorimetry cell was continuously purged with 4N5 $N_2$ gas. Temperature and caloric calibrations are explained in ref.[10] The results are shown in Figure 9 (a).

**Crystal Structure:** The XRD investigation was performed at different temperatures (293, 473, 548, and 623 K), with Mo-$K_\alpha$ radiation, with a Kappa CCD (Bruker Nonius) diffractometer equipped with a Cyberstar gas blower system. Large $\Omega$- and $\Phi$-scans were used to control both the crystalline quality of different samples and determine the unit-cell parameters. A single crystal of suitable size ($100 \times 150 \times 150$ μm) was then selected. The dependency of the cell parameters on the temperature was obtained from large $\Omega$- and $\Phi$-scans performed at different temperatures; the results are reported in Figures 7 (a–c). The evolution of the *c* parameter allowed us to probe the structural transition and fix the most adequate temperature for the data collection process. Suitable data-collection strategies were defined by considering the cell parameters, the spot size, and the obstruction of the diffractometer by the high-temperature conditioning apparatus. For the room-temperature measurement, a scanning angle of 0.8° and a *Dx* (detector–sample distance) of 55 mm were chosen; $\Phi$- and $\Omega$-scans were used. To collect a large number of weak reflections, but avoiding any detector saturation by reflections of strong intensity, two different exposure times (45 s/° and 5 s/°) were used to collect the data. The diffracted intensities were collected up to $\theta = 42°$. One independent monoclinic space was scanned. Plots of reciprocal lattice planes assembled from these series of experimental frames are sufficiently accurate to obtain an overall view of the reciprocal space. The diffraction pattern can be described within a monoclinic cell [cell parameters $a = 8.8492(3)$, $b = 7.9183(5)$, $c = 12.4716(7)$ Å, $\beta = 90.106(3)°$]. The observed conditions limiting the possible reflections, *h0l*: $l = 2n$ and *0k0*: $k = 2n$, are consistent with the $P2_1/c$ space group. The measurements at high temperatures are more tedious. The presence of both the conditioning apparatus and the high-temperature gas flow modifies the environment of the goniometer and generates new shadow zones. To decrease the obstruction near the sample and to avoid collisions or a direct contact of the gas flow with the detector, *Dx* was fixed at 60 mm and only $\Phi$-scans were used. All data collections at high temperatures were undertaken according

to the procedure reported in Table 1. The conditions limiting the possible reflections at 473 K are the one observed at room temperature, but at 548 and 623 K new conditions consistent with the *Pmcn* space group appear (*h0l*: $l = 2n$ and *hk0*: $h + k = 2n$; see Figure 10). At 623 K, the cell parameters are $a = 8.851(12)$, $b = 8.015(17)$, $c = 12.683(15)$ Å. It should be noted that *Pmcn* is a supergroup of $P2_1/c$. The existence of diffuse scattering centered on the nodes *hk0*: $h + k = 2n + 1$ in Figure 10 at 548 K should be noted. The EvalCCD software[24] was used to extract reflections from the collected frames and reflections were merged and rescaled as a function of the exposure time. Data were corrected from absorption using the SADABS program[25] developed for scaling and correction of area-detector data. At room temperature a structural model considering the $P2_1/c$ space group was built up with SIR2002[26] using direct methods. Then, the cations and the chloride anions were located. This model was subsequently introduced in the refinement program Jana2000,[27] all the atomic positions were refined, and finally anisotropic atomic displacement parameters were considered for all the atoms. The refinement led to an agreement factor of 2.8%.

It should be noted that the room-temperature data collection and refinement were performed using two different single crystals of the same batch, which gave the same results and that, in particular, none of the crystals investigated were twinned. The structure at 473 K, which exhibits a monoclinic symmetry, was refined using the final result of the room-temperature structure. Except for the ADPs, no significant modifications in the structure were observed (Table 2). The refinements of the structure at higher temperatures were carried out using a model generated in the *Pmcn* space group from the atomic positions determined at room temperature. One should bear in mind that, in the *Pmcn* symmetry, the $Cl^-(1)$ and $Cl^-(4)$ anions as well as the $K^+$ and $Pb^{2+}(2)$ cations become equivalent (Table 2). The behavior of the ADPs as a function of $T$ is displayed in Figure 8 (a) and (b). Further details of the crystal structure investigations may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany [Fax: +49-7247-808-666; E-mail: crysdata@fiz-karlsruhe.de] on quoting the depository numbers CSD-416430 (293 K), -416431 (473 K), -416432 (548 K), and -416433 (623 K).

# How Do the Different Defect Structures and Element Substitutions Affect the Nonlinear Optical Properties of Lacunary Keggin Polyoxometalates? A DFT Study

**Wei Guan,[a] Guo-Chun Yang,[a] Li-Kai Yan,[a] and Zhong-Min Su*[a]**

**Keywords:** Polyoxometalates / Nonlinear optics / Lacunary species / Tungsten / Density functional theory

Systematic DFT calculations have been carried out on the lacunary α-Keggin polyoxometalate derivatives $[PW_{11}O_{39}]^{7-}$, $[XW_9O_{34}]^{n-}$ (X = $Al^{III}$, $Si^{IV}$, $Ge^{IV}$, $P^V$, $As^V$, and $Sb^V$), $[XW_9M_2O_{39}]^{n-}$, and $[XW_9M_3O_{40}]^{n-}$ (X = $P^V$ and $Si^{IV}$, M = $Mo^{VI}$, $V^V$, $Nb^V$, and $Ta^V$) to investigate the geometric structure and element substitution effects on the molecular nonlinear optical response. Analysis of the computed static second-order polarizability ($\beta_0$) predicts that the molecular nonlinear optical activity of lacunary Keggin polyoxometalate derivatives can be modified by replacing the central heteroatom and the addenda metal atom. Substitution of the central Al atom or the addenda V atom causes significant enhancement in the molecular nonlinearity. Moreover, the $\beta_0$ values are substantially dependent on the defect structures. This class of inorganic complexes possesses remarkably large molecular optical nonlinearity, especially for the partial substitution complex $[SiW_9Nb_2O_{39}]^{10-}$ (**IIIc**), which has a computed $\beta_0$ value of 2071.0 a.u. Thus, lacunary Keggin polyoxometalates could become excellent candidates in the field of second-order NLO.

## Introduction

Nonlinear optical (NLO) materials based on molecular compounds have continued to be of considerable current interest because they hold promise for potential applications in optical signal processing, switching, and telecommunications. Among inorganic nonlinear materials, borates, phosphates, and niobates (β-$BaB_2O_4$, $LiB_3O_5$, $Li_2B_4O_7$, $CsLiB_6O_{10}$, $KH_2PO_4$, $LiNbO_3$, etc.) have already been widely studied. However, compared with the organic and organometallic compounds that have been extensively examined for their NLO responses recently, NLO studies of inorganic materials are relatively rare even though inorganic compounds are robust and are available as large single crystals. They also possess a large transparency range, suffer very low optical losses, and offer a large variety of structures and a great diversity of electronic properties shaped by the metal-characterized core and therefore may comprise a promising family of NLO materials.

Among the various inorganic compounds, polyoxometalates (POMs) have generated substantial interest in recent years because of their unique structural variety and exciting properties in fields such as catalysis, medicine, materials science, etc.[1] The most representative POM is the well-known α-Keggin heteropolyanion $[XM_{12}O_{40}]^{n-}$ (denoted as α-$XM_{12}$; X = $P^V$, $Si^{IV}$, $Ge^{IV}$, etc.; M = $Mo^{VI}$, $W^{VI}$, or $V^V$). The structure of α-$XM_{12}$ has overall $T_d$ symmetry and consists of a central $XO_4$ tetrahedron that shares its oxygen atoms ($O_a$) with four $M_3O_{13}$ groups. These $M_3O_{13}$ groups, made of three edge-sharing octahedra, are linked together by corners. Lacunary α-Keggin polyanions (species with defect structures) are derived from α-$XM_{12}$ by removing one $MO_6$ octahedron (α-$XM_{11}$, top series in Figure 1) or by removing three $MO_6$ octahedra from different $M_3O_{13}$ groups (A-α-$XM_9$, middle series in Figure 1) or the same $M_3O_{13}$ group (B-α-$XM_9$). In order to synthesize novel POMs with predicted structures, an approach widely used is to treat lacunary POM precursors with transition metal ions or organometallic fragments as lacunary structures possess a reactive nucleophilic polyoxygenated site. Different transition metal ions can partly or wholly fill these vacancies to give rise to compounds with magnetism or catalysts,[2] such as $PW_9Fe_2Ni$, $PW_9Fe_3$, or $PW_{11}Co$. The reactions of organometallic fragments with Keggin-type lacunary polyanions also give numerous novel compounds {e.g., open-type $[SiW_9O_{37}(SnR)_3]^{7-}$ and sandwich-type $[(SnR)_3(SiW_9O_{34})_2]^{7-}$}. Although the study of such lacunary polyanions is receiving considerable attention,[3] they need to be further investigated theoretically.

Murakami et al. have recently shown by the conventional powder second-harmonic generation (SHG) method that nanostructured materials made from lacunary POMs have larger NLO responses than $KH_2PO_4$. They also defined design criteria to obtain a large NLO response.[4] This experi-

mental result inspired us to further investigate the electronic and NLO properties of lacunary α-Keggin derivatives by a DFT method. In the past decade, DFT has been shown to be able to successfully predict the properties of molecules and materials, including the NLO properties.[5] The modeling of polyoxoanions has also made progress.[6] Recently, we have systematically investigated the bonding character, redox properties, protonation, stability, and NLO properties of $[X_2Mo_5O_{23}]^{6-}$, $[PTi_2W_{10}O_{40}]^{7-}$, $[Mo_6O_{17}R_2]^{2-}$, and $[H_{12}V_{13}O_{40}]^{3-}$ clusters by DFT.[7] Theoretical studies would be helpful in the rationalization of the observed properties and in the design of novel POM-based materials with functional properties by exploiting the unique electronic and structural characteristics of these complexes.

In this paper we present systematic DFT calculations on the static NLO responses of a series of lacunary α-Keggin polyanion derivatives, including $C_s$ systems: $[PW_{11}O_{39}]^{7-}$, $[PW_9Mo_2O_{39}]^{7-}$, $[SiW_9Mo_2O_{39}]^{8-}$, $[SiW_9Nb_2O_{39}]^{10-}$, and $[SiW_9Ta_2O_{39}]^{10-}$; and $C_{3v}$ systems: $[AlW_9O_{34}]^{11-}$, $[SiW_9O_{34}]^{10-}$, $[GeW_9O_{34}]^{10-}$, $[PW_9O_{34}]^{9-}$, $[AsW_9O_{34}]^{9-}$, $[SbW_9O_{34}]^{9-}$, $[PW_9V_3O_{40}]^{6-}$, $[SiW_9V_3O_{40}]^{7-}$, $[PW_9Nb_3O_{40}]^{6-}$, $[SiW_9Nb_3O_{40}]^{7-}$, $[PW_9Ta_3O_{40}]^{6-}$, $[SiW_9Ta_3O_{40}]^{7-}$, $[PW_9Mo_3O_{40}]^{3-}$, and $[SiW_9Mo_3O_{40}]^{4-}$. (Figure 1) The effects of geometric structure and element substitution on the molecular nonlinear response are analyzed and discussed in order to reveal the general rules governing the NLO properties of these polyanions.

## Results and Discussion

### Electronic Structures

The frontier molecular orbitals of all systems have a common character where the occupied orbitals formally delocalize over the p-oxygen orbitals, while the unoccupied d-

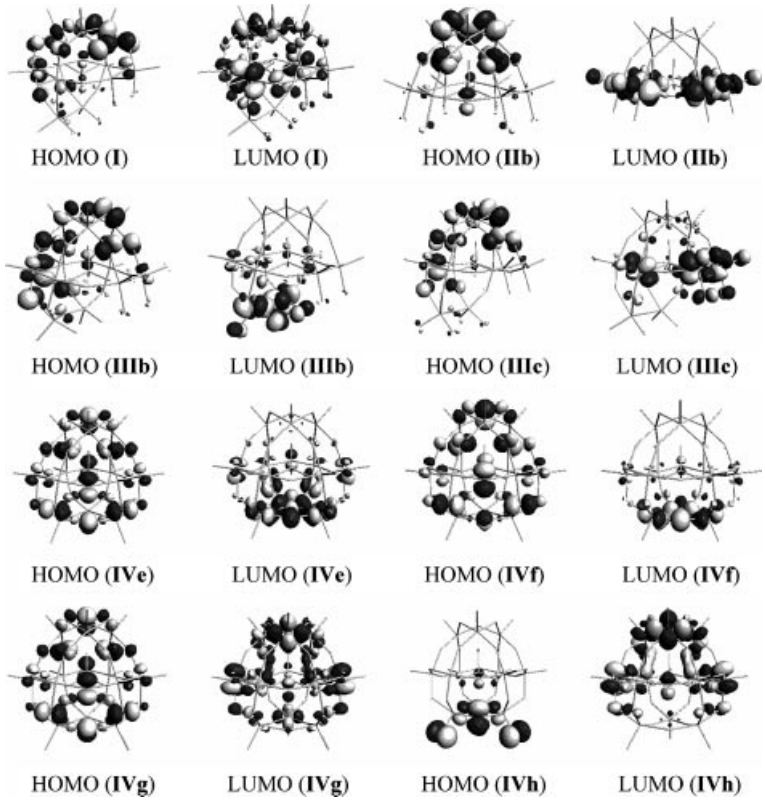

Figure 2. Frontier molecular orbitals of systems **I**, **IIb**, **IIIb**,**c**, and **IVe**–**h**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metal orbitals delocalize over the addenda atoms.[6,7] This kind of charge transfer, namely O→M, must be responsible for the NLO properties of lacunary α-Keggin POM derivatives. The diagrams for the frontier molecular orbitals of eight representative systems (**I**, **IIb**, **IIIb**,**c**, and **IVe**–**h**) are displayed in Figure 2, from which several conclusions can be drawn:

(1) The frontier molecular orbitals of series **II** have similar character (Figure 2, **IIb**) in that the HOMOs formally delocalize over the bridge oxygen atoms that are away from the lacunary sites, which is similar to system **I**. The LUMOs delocalize mostly over the six tungsten atoms that are close to the lacunary sites and partially over the terminal oxygen atoms. In addition, the unoccupied W(d)–O(p) bands have an antibonding interaction in series **II**.

(2) The distribution of HOMOs in series **III** has a similar character to that of series **II**. However, when compared with series **II** the LUMOs in series **III** change significantly as it is the d-orbitals of the Mo atoms that contribute mainly to the LUMO of **IIIa**,**b** (Figure 2). When Mo atoms are substituted by Nb or Ta atoms (**IIIc** and **IIId**), the LUMOs mostly delocalize over the two tungsten atoms that are close to the lacunary sites (Figure 2).

(3) For trisubstituted systems (series **IV**), the HOMOs extensively delocalize over the p-oxygen orbitals, except for the Ta-substituted systems **IVd** and **IVh**, where the HOMOs almost delocalize over the bridge oxygen atom that links two tantalum atoms [O(TaTa)] and the terminal oxygen atom that links to tantalum atoms [O(Ta); Figure 2] The LUMOs of systems **IVa**,**b** and **IVe**,**f** are mainly concentrated on the three substituted addenda atoms (Figure 2), which shows that the d-orbitals of molybdenum and vanadium play an important role in the redox reactions of trisubstituted systems.[6b] However, the delocalization of LUMOs is obviously enhanced by Nb and Ta substitution (Figure 2, **IVg**,**h**).

### Geometric Structure and Element Substitution Effects on $\beta$

In view of the molecular orbital character discussed above, we computed the static second-order polarizabilities ($\beta_0$) of the series of lacunary POM derivatives considered in this investigation by DFT. The static second-order polarizability is also termed the zero-frequency hyperpolarizability and is an estimate of the intrinsic molecular hyperpolarizability in the absence of any resonance effects. Geometric structure and element substitution effects were considered in a set of calculations by choosing mono- and trivacant Keggin derivatives and their mixed addenda species. The computed $\beta_0$ values of the studied complexes are given in Figure 1 (**I**, **IIa**–**c**, **IIIa**, and **IVa**). The results indicate some common trends, which are in agreement with the qualitative predictions of Murakami and co-workers on the NLO response of nanostructured materials made from lacunary POMs.[4] First, the trivacant Keggin complexes (**IIa**, **IIb**, and **IIc**) have larger $\beta_0$ values than the monovacant structure (**I**): all the $\beta_0$ values of **IIa**, **IIb**, and **IIc** are above 1100 a.u. whereas the present calculations predict the $\beta_0$ value of **I** to be just 794.0 a.u. Second, the replacement of the central heteroatom (X) slightly alters the $\beta_0$ values of **IIa**, **IIb**, and **IIc**, which increase as the heavy central atom changes in the order Ge ≥ Si > P; the difference between the $\beta_0$ values of **IIb** and **IIc** is relatively small. Third, partially substituting addenda metal atoms by molybdenum atoms (**IIIa**) causes significant enhancement in the molecular nonlinearity. As can be seen from Figure 1, the $\beta_0$ value of **IIIa** is much larger than that of **IVa**, the difference between the two systems exceeds 800 a.u., and this is confirmed by the frontier molecular orbital character (Figure 2 **IIIb** and **IVe**).

To shed further light on the second-order NLO properties of lacunary Keggin POM derivatives, more complexes (**IId**–**f**, **IIIb**–**d**, and **IVb**–**h**) were systematically calculated to understand the role of the central heteroatom (X) and addenda metal atom (M) in influencing the NLO response. The replacement of X in the trivacant complexes with five elements (Al, Si, P, As and Sb) results in different trends (Figure 3). The substitution by Al results in a larger effect than by Si, which, in turn, has a larger effect than P (**IId** > **IIb** > **IIa**); when X is one of the group 15 elements P, As, and Sb, the computed $\beta_0$ values indicate that the NLO response is **IIa** > **IIe** > **IIf**. As can be seen from two trends above, the magnitude of increase or decrease of $\beta_0$ with respect to the trivacant tungstates depends on both the atomic radius of the central heteroatom (Figure 3A) and its electronegativity (Figure 3B). When X is from the same row of the periodic table (e.g. the third row: Al, Si and P) the $\beta_0$ value is proportional to the atomic radius and is inversely proportional to the electronegativity; however, when X is from the same group (e.g. group 15: P, As, Sb) the opposite trend is observed: the $\beta_0$ value is proportional to the electronegativity and is inversely proportional to the atomic radius. From Figure 1, we also calculated the static second-order polarizabilities for series **II** employing the HF method ($\beta_0^{HF}$). According to the $\beta_0^{HF}$ values, it can be seen that DFT and HF methods give consistent trends for the static second-order polarizabilities. However, the HF method underestimates the second-order polarizabilities of series **II** as there is no correlation consideration in the HF method, while the DFT methods used in this paper overestimate the $\beta$ values. This is in accordance with the literature.[8] Therefore, it can also be concluded that DFT is a feasible method for the present POMs. Moreover, the central heteroatom substitution effects in series **III** and **IV** also obey the trends described above. Substitution by Si results in a larger effect than by P (**IIIb** > **IIIa**, **IVe** > **IVa**, **IVf** > **IVb**, **IVg** > **IVc**, and **IVh** > **IVd**). We believe that the sketch map in Figure 3 will be helpful in designing new NLO materials.

With regard to the role of the addenda metal atom, similar trends (Figure 3) can be seen from the calculated data (Figure 1: **IIIb**–**d** and **IVa**–**h**) obtained for series **III** and **IV**. Unfortunately, it is difficult to obtain a reasonable result for $[SiW_9V_2O_{39}]^{10-}$. The replacement of M with four elements (Mo, V, Nb, and Ta) significantly alters their $\beta_0$ values (Figure 1: **IIIc** > **IIId** > **IIIb**, **IVb** > **IVc** > **IVd** > **IVa**,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

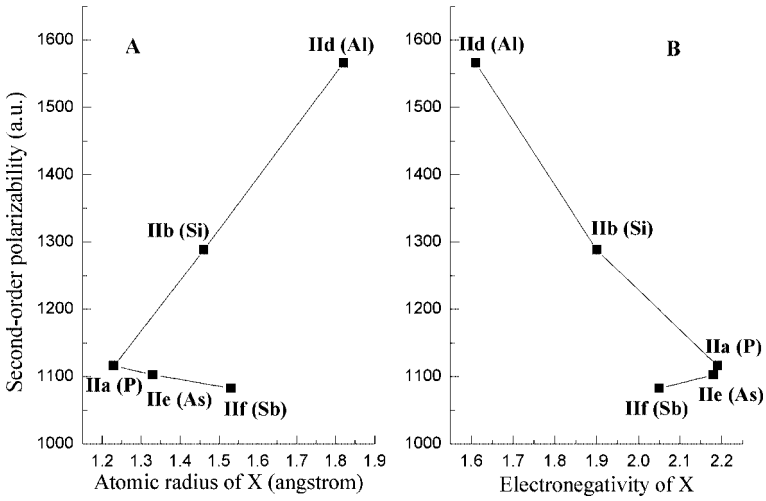

Figure 3. The second-order polarizabilities of trivacant complexes **IIa**–**f** as a function of the atomic radius (A) and electronegativity (B) of the central heteroatom (X).

and **IVf** > **IVg** > **IVh** > **IVe**), which increase as M changes in the order V > Nb > Ta > Mo. Thus, the computed $\beta_0$ values predict that the molecular nonlinear optical activity of lacunary Keggin POM derivatives can be fine-tuned by replacing the central heteroatom or the addenda metal atom. Substitution of the central Al atom or the addenda V atom causes a significant enhancement in the molecular nonlinearity. Furthermore, the defect structure plays a key role in increasing the $\beta_0$ value.

As can be seen from Figure 1, lacunary POMs have larger second-order polarizability coefficients, especially for the partially substituted complexes **IIIc**, whose computed $\beta_0$ value is even larger than that of the $Au_{20}$ cluster with an equivalent molecular size. The present DFT calculations predict the $\beta_0$ value of system **IIIc** to be 2071.0 a.u., whereas the predicted second-order polarizability of $Au_{20}$ is 1655.3 a.u.[9] All these complexes have high transparency in the visible area[4] therefore, in view of the merit of this class of inorganic complexes, they could be an excellent material for use in the second-order NLO field.

## Conclusions

A series of lacunary α-Keggin POM derivatives have been systematically investigated for their molecular nonlinear response, including $[PW_{11}O_{39}]^{7-}$, $[XW_9O_{34}]^{n-}$ (X = $Al^{III}$, $Si^{IV}$, $Ge^{IV}$, $P^{V}$, $As^{V}$, and $Sb^{V}$), $[XW_9M_2O_{39}]^{n-}$, and $[XW_9M_3O_{40}]^{n-}$ (X = $P^{V}$ and $Si^{IV}$; M = $Mo^{VI}$, $V^{V}$, $Nb^{V}$, and $Ta^{V}$). Geometric structure and element substitution effects on the molecular nonlinear response have been analyzed, and the computed $\beta_0$ values reveal the general rules to design a large nonlinearity: (i) the defect structured complex has a larger $\beta$ value than a defect-free complex (series **IV**), especially for trivacant Keggin complexes (series **II**) and partially substituted complexes (series **III**); (ii) the $\beta_0$ value depends on both the atomic radius of the central heteroatom (X) and the addenda metal atom (M) and their electronegativity. When X and M are from the same row of the periodic table (X = Al, Si, and P; M = Nb and Mo) the $\beta_0$ value is proportional to the atomic radius and inversely proportional to the electronegativity, whereas when X and M are from the same group (X = P, As and Sb; M = V, Nb and Ta) the opposite trend is observed. This class of inorganic complexes possesses remarkably large static second-order polarizability, especially for $[SiW_9Nb_2O_{39}]^{10-}$ (**IIIc**), which has a computed $\beta_0$ value of 2071.0 a.u. The frontier molecular orbital character reveals that the main origin of the NLO properties of lacunary α-Keggin POMs derivatives is O→M charge transfer. It is hoped that the results presented in this paper will stimulate experimental research in the field of NLO properties involving lacunary Keggin POM derivatives.

## Computational Details

The DFT calculations were carried out with the ADF2004.01 suite of programs.[10] The zero-order regular approximation (ZORA) was adopted in all the calculations to account for the scalar relativistic effects.[11] The generalized-gradient approximation (GGA) was employed in the geometry optimizations by using the Beck[12] and Perdew[13] (BP86) exchange-correlation (XC) functional. For the calculations, we made use of the standard ADF TZP basis set, which is a triple-ζ plus polarization STO basis set. The cores (O: 1s; Al, Si, P, V: 2p; Ge, As: 3p; Sb: 4p; Nb, Mo: 3d; Ta, W: 4d) were kept frozen. In calculations of the static second-order polarizability, the RESPONSE module[14] implemented in the ADF program was used based on the optimized geometries. The van Leeuwen–Baerends XC potential (LB94) was chosen for calculations of all the response properties.[15] The adiabatic local density approximation (ALDA) was applied for the evaluation of the first and second functional derivatives of the XC potential. Moreover, the value of the numerical integration parameter used to determine the precision of numerical integrals was 6.0. We also calculated the static second-order polarizabilities employing the Hartree–Fock (HF) method based on ab initio quantum chemistry with the GAUSSIAN03 program.[16] The basis set used for Al, Si, P, and O is the standard Gaussian basis set 6-31G(d) in which one set of d-polarization function is included. For 3d, 4d, and 5d transition

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metals, the LANL2DZ basis set[17] was used, in which the effective core potentials (ECPs) were adopted and mass-velocity, Darwin relativistic effects were incorporated.

**Supporting Information** (see footnote on the first page of this article): Cartesian coordinates of all systems (Tables S1–S19).

# Assembly and Upconversion Properties of Lanthanide Coordination Polymers Based on Hexanuclear Building Blocks with ($\mu_3$-OH) Bridges

**Danfeng Weng,[a] Xiangjun Zheng,*[a] and Linpei Jin*[a]**

**Keywords:** Hydroxido clusters / Lanthanide coordination polymers / Codoped complexes / Upconversion properties

Three novel hexanuclear core-based hydroxidolanthanide coordination polymers $[Ln_3(BDC)_{3.5}(OH)_2(H_2O)_2]\cdot H_2O$ [Ln = Y (**1**), Yb (**2**) and Er (**3**); BDC = 1,4-benzenedicarboxylate] were prepared by the hydrothermal method. The controlled hydrolysis of lanthanide ions led to an open hexanuclear cluster core. The hexanuclear core containing six ($\mu_3$-OH) bridged $Ln^{III}$ ions from two asymmetric units adopts a chair-like configuration. It behaves as a building block and is linked by the BDC ligands to form a 3D framework. The guest water molecules occupy the 1D channels in the structure. The upconversion spectra of the Y:Er-Yb codoped coordination polymers have been studied. The distinct upconversion emissions come from two-photon or three-photon excitation of Y:Er-Yb codoped coordination polymers and arise from $Er^{III}$ transitions of the type $^4F_{5/2}\rightarrow{}^4I_{15/2}$, $^2H_{11/2}\rightarrow{}^4I_{15/2}$, $^4S_{3/2}\rightarrow{}^4I_{15/2}$ and $^4F_{9/2}\rightarrow{}^4I_{15/2}$.

## Introduction

Polynuclear hydroxidolanthanide cluster compounds are enjoying increasing popularity due to their optical, electronic and catalytic properties, which may ultimately lead to potential technological applications such as optoelectronic devices, luminescent and biocatalyst materials.[1] Many polynuclear hydroxidolanthanide clusters have been reported in the past two decades. The reported structures show that the basic structural skeletons belong to two motifs, i.e. cubane-like clusters and square pyramids with the $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ cubane-like building block being regarded as a common structural motif in hydroxidolanthanide clusters.[1b,2] Many tetranuclear hydroxidolanthanide clusters have a cubane-like building block.[1a,b,c;2b;3] Two cubane-like units can be combined to a heptanuclear $[Ln_7(\mu_3\text{-}OH)_8]^{13+}$ cluster sharing one vertex.[4] Four or five vertex-sharing cubane-like cluster units centring around a halide anion template can be assembled to dodeca-[1a,1c] and pentadecanuclear clusters[1a,1c;5] with wheel structures. The pentanuclear square-pyramid unit appears to be another common structural motif in hydroxidolanthanide clusters.[1d,6] The $[Eu_5(\mu_4\text{-}OH)(\mu_3\text{-}OH)_4]^{10+}$ cluster has been reported[7] and the square-pyramidal $Ln_5$ unit can be considered as a building block for hexa-,[1a,1c;8] nona-[6a,9] and tetradecanuclear[1d,6b,10] clusters sharing their apexes or the square bases. To the best of our knowledge, the majority of hexanuclear $[Ln_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8]^{8+}$ skeletons are octahedral while the $[Ln_6(\mu_3\text{-}OH)_4]^{14+}$ chair-like core as building block has never been reported.

In the past decade, the upconversion of the infrared light into visible light has been extensively studied on various crystalline and amorphous materials for their potential applications in lasers,[11] optical devices, wave-guides, data storage devices, microfabrication,[12] biological labelling,[13] biosensors[14] and so on. The most frequently used upconversion ions are $Er^{III}$ or $Tm^{III}$ combined with $Yb^{III}$ as a sensitiser. Many different RE-doped (RE = rare earths) inorganic materials have been studied such as oxides,[15] silicates and phosphates,[16] oxyfluorides,[17] fluorides[18] and $NaYF_4$.[13b,14a,19] However, very few lanthanide-doped coordination compound materials have been achieved.[20] We report herein three new hexanuclear hydroxidolanthanide cluster coordination polymers $[Ln_3(BDC)_{3.5}(OH)_2(H_2O)_2]\cdot H_2O$ [Ln = Y (**1**), Yb (**2**), Er (**3**)] which are different from the reported motifs and the first examples with upconversion properties of the codoped lanthanide (Y, Er, Yb) coordination polymers.

## Results and Discussion

### Synthesis

The coordination polymers were obtained by hydrothermal synthesis. During the preparation, the pH of the reaction systems was adjusted by aqueous NaOH in the presence of NaAc to control the hydrolysis of the lanthanide ions. Then 1,4-benzenedicarboxylic acid was added to the resultant mixture.

### Structural Description

The single-crystal X-ray diffraction analysis revealed that compounds **1**, **2** and **3** are isomorphous and, consequently,

 InterScience © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

we will only describe the structure of **1** in detail. The asymmetric unit of **1** consists of a neutral trinuclear $[Y_3(BDC)_{3.5}(OH)_2(H_2O)_2]$ unit (Figure 1) and one lattice water molecule. The three $Y^{III}$ ions are all eight-coordinate but surrounded by different numbers of $\mu_3$-OH groups, coordinated $H_2O$ molecules and BDC anions. Around Y1, Y2 and Y3, there are five, five and four BDC ligands, respectively. For BDC, which adopts two coordination modes in the compound, the coordinated carboxyl units are divided into two types: bridging bidentate (I) and chelating/bridging tridentate (II) (Scheme 1). The hydroxy groups adopt a $\mu_3$-mode to bridge three $Y^{III}$ ions, while the water molecule only acts as a terminal ligand. Thus, the three $Y^{III}$ ions are coordinated in markedly different coordination environments (see Table 1). Selected bond lengths of **1** are listed in Table 2.

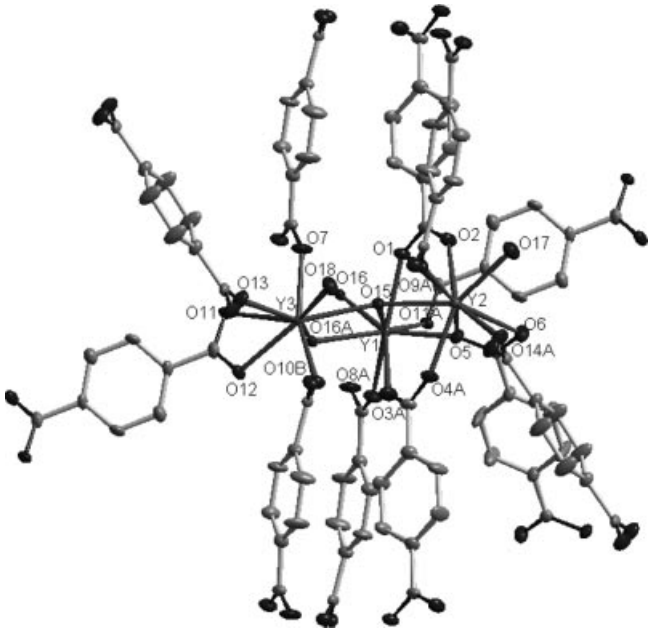

Figure 1. Coordination environment of $Y^{III}$ in complex **1** with ellipsoids drawn at the 30% probability level. All hydrogen atoms and lattice water molecule are omitted for clarity.

which is slightly above the basal face and the Y–O($\mu_3$-OH) distances range from 2.278 to 2.479 Å. These distances are comparable with Ln–O($\mu_3$-OH) distances in the reported octahedral hexanuclear compounds with an average of 2.433 Å.[8d,8e] Four $Y_3$($\mu_3$-OH) trigonal pyramids share their adjacent sides to form the hexanuclear cluster with a chair-like conformation (Figure 2b). This chair-like hexanuclear building block is different from the reported structural motifs based on square pyramids and cubane-like cores. The Ln···Ln distances ranging from 3.731 to 4.712 Å are longer than those found in the latter two kinds of clusters (the majority range from 3.5 to 3.8 Å).[1b,3c,4,6,8d,8e,9] This is due to the steric effect of the open construction of the $Ln_6$ entity whereas the reported hexanuclear clusters are all closed clusters.

Among the reported hexanuclear hydroxido clusters, most were almost zero-dimensional.[8a,8b,8d,8e] One 1D example was achieved by linking the hydroxidolanthanide cluster through Pd ions[8c] and a reported pseudo-3D network is based on hydrogen bonds[8f] whereas the hexanuclear cores in the title compounds are linked by the ligand BDC, resulting in 3D coordination polymers. The BDC ligands act as short bridges through one carboxylato end linking the hexanuclear nodes or longer bridges through the two carboxylate groups. The linkages consist of ten BDC ligands along the *a*-axis, four along the [2 0 $\bar{1}$] direction, two along the [0 $\bar{1}$ 1] direction with the remaining two following the [$\bar{1}$ 1 0] direction. The linear rigid BDC ligands take the main role in linking the hexanuclear building blocks into a complicated 3D structure. The lattice water molecules, fixed by hydrogen-bonding interactions to the frameworks, are located in 1D channels in the 3D networks (see Figure 3).

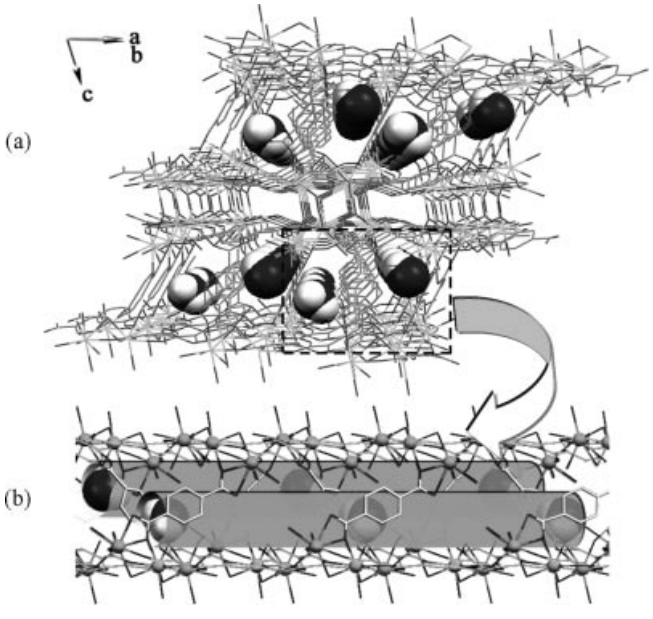

Figure 3. (a) Perspective view of the microporous framework of **1** along the [1 $\bar{1}$ 0] direction, showing 1D channels where guest water molecules reside and the guests are shown as space-filling models. (b) Lateral view of the 1D channels holding the water molecules.

## Upconversion Properties

The upconversion emission spectrum of the Y:Er-Yb codoped coordination polymer under 980 nm laser excitation is shown in Figure 4. The emission spectrum exhibits four bands. The red emission is centred at 654 nm and results from the $^4F_{9/2}(Er^{III})$ to $^4I_{15/2}(Er^{III})$ transition and the green band has centres at 545 and 524 nm and results from the transitions $^4S_{3/2}(Er^{III})/^2H_{11/2}(Er^{III})\rightarrow{}^4I_{15/2}(Er^{III})$. A seldom observed indigo emission centred at 455 nm can also be observed and corresponds to the transition $^4F_{5/2}(Er^{III})\rightarrow{}^4I_{15/2}(Er^{III})$.

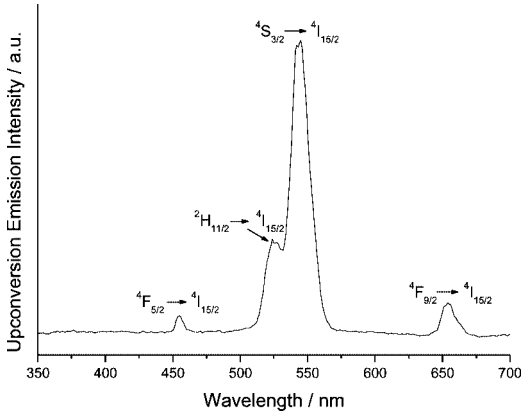

Figure 4. Upconversion emission for the $Er^{III}$ ion in the Y:Yb-Er codoped coordination polymer (laser power used is 640 mW, EM slit = 10.0 nm).

The 545 and 524 nm emissions can be described as a two-photon upconversion excitation mechanism.[15a,18a,18e,18f] First, the $Yb^{III}$ ions are easily excited to their $^2F_{5/2}(Yb^{III})$ level from ground $^2F_{7/2}(Yb^{III})$ level by absorbing a 980 nm photon. The energy is transferred to the $Er^{III}$ ions which become excited from the $^4I_{15/2}(Er^{III})$ level to the $^4I_{11/2}(Er^{III})$ level. A second photon transfer from the excited $Yb^{III}$ ions pumps the $Er^{III}(^4I_{11/2})$ ions to the $^4F_{7/2}(Er^{III})$ level. The $^4F_{7/2}(Er^{III})$ state can decay nonradiatively to the $^4S_{3/2}(Er^{III})$ and $^2H_{11/2}(Er^{III})$ levels.[15a,16c,18a] The green emissions observed result from the $^4S_{3/2}(Er^{III})\rightarrow{}^4I_{15/2}(Er^{III})$ and the $^2H_{11/2}(Er^{III})\rightarrow{}^4I_{15/2}(Er^{III})$ transitions. The decay processes were confirmed by a frequency of 2160 $cm^{-1}$ (1410 $cm^{-1}$ + 750 $cm^{-1}$, see Figure 5) and the peak at 1410 $cm^{-1}$ in the IR spectrum, for which the phonon energy corresponds to the energy gap between the $^4F_{7/2}(Er^{III})$ and $^4S_{3/2}(Er^{III})$ states, and the energy gap between $^4F_{7/2}(Er^{III})$ and $^2H_{11/2}(Er^{III})$ states. The possible channel for the green upconversion luminescence is given below:

$^2F_{5/2}(Yb^{III}) + {}^4I_{15/2}(Er^{III}) \rightarrow {}^2F_{7/2}(Yb^{III}) + {}^4I_{11/2}(Er^{III})$

$^2F_{5/2}(Yb^{III}) + {}^4I_{11/2}(Er^{III}) \rightarrow {}^2F_{7/2}(Yb^{III}) + {}^4F_{7/2}(Er^{III})$

$^4F_{7/2}(Er^{III}) \rightarrow {}^4S_{3/2}(Er^{III})/{}^2H_{11/2}(Er^{III})$ (nonradiative decay)

The 654 nm emission is caused by the transition to the $Er^{III}$ ground state $^4I_{15/2}(Er^{III})$ from the excited $^4F_{9/2}(Er^{III})$ state.[15a,18a,18e,18f] $Er^{III}$ ions in the $^4I_{11/2}(Er^{III})$ state lose their energy in the form of an OH vibration at 3500 $cm^{-1}$ [corresponding to the energy gap between $^4I_{11/2}(Er^{III})$ and $^4I_{13/2}(Er^{III})$], decay to the $^4I_{13/2}(Er^{III})$ state and then jump

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

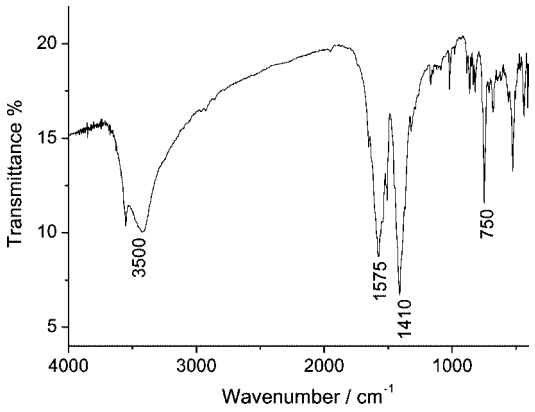

Figure 5. IR spectrum of the Y:Er-Yb codoped coordination polymer.

to the $^4F_{9/2}(Er^{III})$ level by a second pumping photon. This would account for the red emissions from the $^4F_{9/2}(Er^{III})$ level to the ground state. This mechanism can be described as:

$^2F_{5/2}\ (Yb^{III}) + {}^4I_{15/2}(Er^{III}) \rightarrow {}^2F_{7/2}(Yb^{III}) + {}^4I_{11/2}(Er^{III})$

$^4I_{11/2}(Er^{III}) \rightarrow {}^4I_{13/2}(Er^{III})$ (nonradiative decay)

$^2F_{5/2}\ (Yb^{III}) + {}^4I_{13/2}(Er^{III}) \rightarrow {}^2F_{7/2}(Yb^{III}) + {}^4F_{9/2}(Er^{III})$

The 455 nm indigo emission is unusual since upconversion emissions below 490 nm have seldom been observed for $Yb^{III}/Er^{III}$ materials.[15a] A probable three-photon mechanism for the population of the $^4F_{5/2}(Er^{III})$ level can be proposed to explain the indigo emission at 455 nm. There is a possibility that some excited $Er^{III}(^4I_{11/2})$ ions jump back to the lower $^4I_{13/2}(Er^{III})$ level giving the 3500 $cm^{-1}$ IR active decay. The two-photon energy from excited $Yb^{III}(^2F_{5/2})$ pumps the $Er^{III}(^4I_{13/2})$ to the $^2H_{9/2}(Er^{III})$ level via the $^2F_{9/2}(Er^{III})$ bridge and decays to the $^4F_{5/2}(Er^{III})$ level. The $^2H_{9/2}(Er^{III}) \rightarrow {}^4F_{5/2}(Er^{III})$ decay corresponds to 2325 $cm^{-1}$ (1575 $cm^{-1}$ + 750 $cm^{-1}$ in the IR spectrum). Therefore, the possible three-photon mechanism can be expressed as follows:

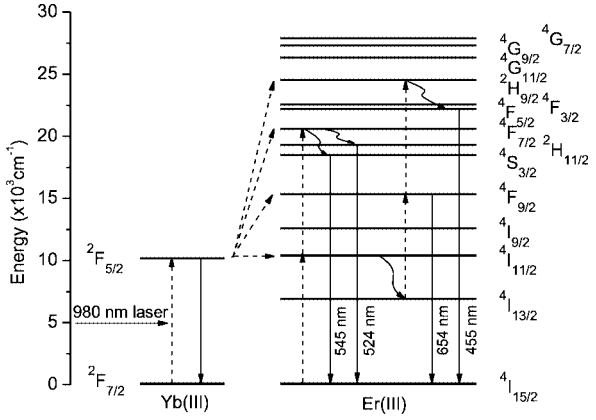

Figure 6. Energy-level diagram for the upconversion mechanism of the Y:Er-Yb codoped coordination polymer under 980 nm excitation.

$^2F_{5/2}\ (Yb^{III}) + {}^4I_{15/2}(Er^{III}) \rightarrow {}^2F_{7/2}(Yb^{III}) + {}^4I_{11/2}(Er^{III})$

$^4I_{11/2}(Er^{III}) \rightarrow {}^4I_{13/2}(Er^{III})$ (nonradiative decay)

$^2F_{5/2}\ (Yb^{III}) + {}^4I_{13/2}(Er^{III}) \rightarrow {}^2F_{7/2}(Yb^{III}) + {}^4F_{9/2}(Er^{III})$

$^2F_{5/2}\ (Yb^{III}) + {}^4F_{9/2}(Er^{III}) \rightarrow {}^2F_{7/2}(Yb^{III}) + {}^2H_{9/2}(Er^{III})$

$^2H_{9/2}(Er^{III}) \rightarrow {}^4F_{5/2}(Er^{III})$ (nonradiative decay)

The energy levels and overall upconversion Scheme of $Er^{III}$ are shown in Figure 6.

## Thermogravimetric Analysis and Powder X-ray Diffraction

We took complex **1** as a representative example for thermogravimetric analysis (see Figure 7). Under atmospheric conditions, thermogravimetric analysis performed on **1** showed the first weight loss of 5.5% in the range of 151–365 °C. This is related to the loss of the two coordinated water molecules and one lattice water molecule (calcd. weight loss 5.8%). The second mass loss began at 480 °C and is associated with the decomposition of the organic and hydroxy groups. The final residue, after the sample was heated to 836 °C, was $Y_2O_3$ (found weight loss 36.2%, calcd. 36.5%).

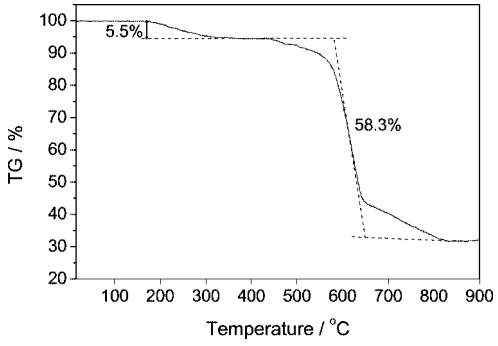

Figure 7. Thermogravimetric trace of **1**.

To confirm the thermogravimetric analysis, complex **1** was characterised by powder X-ray diffraction (PXRD) at 25, 100, 400, 635 and 880 °C (see Figure 8). The PXRD

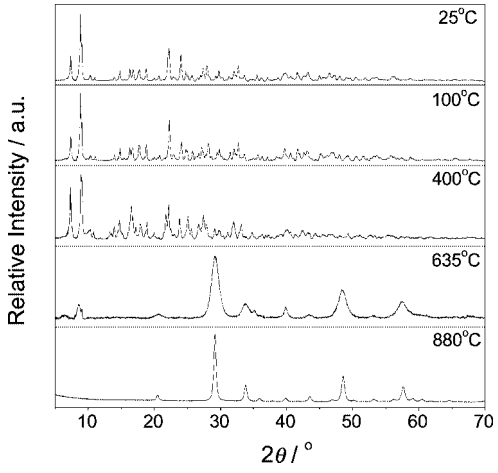

Figure 8. PXRD patterns for **1** taken at 25, 100, 400, 635 and 880 °C.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

patterns of the sample at 100 and 400 °C, although very similar, are not the same, which indicates the change of the frameworks after the removal of the lattice water and coordinated water molecules. Above 635 °C, the PXRD patterns change completely, suggesting the collapse of the framework. The remaining residue $Y_2O_3$ coincides quite well with the standard $Y_2O_3$ (No. 01-083-0927).

## Conclusions

Three coordination polymers based on hexanuclear building blocks with ($\mu_3$-OH) bridges have been achieved. The hexanuclear building block has an interesting chair-like configuration which is different from the reported motifs based on cubane-like clusters and square pyramids. The structure of the cluster core depends on the extent of the hydrolysis of the Ln ions which is closely related to the pH of the system. Hence, controlled hydrolysis could lead to polymeric materials based on polynuclear clusters exhibiting different configurations. Furthermore, the Y:Er-Yb co-doped coordination polymers have been synthesised successfully. We have demonstrated the feasibility of introducing red, green and indigo light emissions of $Er^{III}$ ions using IR spectroscopy as supporting evidence for the nonradiative decay. The upconversion emissions of the codoped polymers correspond to two-photon and three-photon upconversion excitation mechanisms.

## Experimental Section

**General:** All chemicals were obtained commercially and used without further purification. Elemental analyses of C, H and N were performed with an Elementar Vario EL analyser. The IR spectra were recorded with a Nicolet Avatar 360 FTIR spectrometer using the KBr pellet technique. The thermal stability was investigated using a ZRY-2P thermogravimetric analyser under atmospheric conditions at a heating rate of 10 °C min$^{-1}$, using α-$Al_2O_3$ as a reference. The inductively coupled plasma (ICP) analysis was performed with a JY ULTIMA spectrometer. The powder X-ray diffraction was carried with a PANalytical X'Pert PRO MPD diffractometer using Cu-$K_{\alpha1}$ radiation in the $2\theta$ range of 5°–70°.

**Synthesis of $[Y_3(BDC)_{3.5}(OH)_2(H_2O)_2]\cdot H_2O$(1):** A solution of NaAc·3$H_2O$ (0.020 g, 0.15 mmol), $YCl_3\cdot 6H_2O$ (0.030 g, 0.1 mmol), $H_2O$ (5 mL) and aqueous NaOH (0.3 mL, 0.65 mol L$^{-1}$) was stirred to bring about the hydrolysis of $YCl_3$ and 1,4-benzenedicarboxylic acid (0.017 g, 0.1 mmol) was then added. The pH of the solution was adjusted to 5.1 and the mixture was then sealed in a 25 mL stainless steel reactor with a Teflon liner and heated at 190 °C for 72 h. Colourless block-like crystals of **1** were obtained. Yield: 0.021 g (66.67% based on Y). $C_{28}H_{22}O_{19}Y_3$ (929.19): calcd. C 36.19, H 2.39; found C 36.25, H 2.36. IR (KBr): $\tilde{\nu}$ = 553 (s), 3421 (s), 1651 (m), 1571 (s), 1540 (s), 1510 (m), 1410 (s), 1318 (w), 1169 (w), 1016 (m), 745 (s), 525 (m) cm$^{-1}$.

**Synthesis of $[Yb_3(BDC)_{3.5}(OH)_2(H_2O)_2]\cdot H_2O$(2):** This compound was prepared according to the procedure for **1** but by using $Yb(NO_3)_3\cdot 6H_2O$ instead of $YCl_3\cdot 6H_2O$. Diamond-like crystals of **2** were obtained. Yield: 0.020 g (49.61% based on Yb). $C_{28}H_{22}O_{19}Yb_3$ (1177.54): calcd. C 28.45, H 1.86; found C 28.50, H 2.01. IR (KBr): $\tilde{\nu}$ = 3555 (s), 3435 (s), 1654 (m), 1583 (s), 1539 (s), 1502 (m), 1408 (s), 1320 (w), 1170 (w), 1017 (m), 751 (s), 526 (m) cm$^{-1}$.

**Synthesis of $[Er_3(BDC)_{3.5}(OH)_2(H_2O)_2]\cdot H_2O$(3):** This compound was prepared according to the procedure for **1** but by using $ErCl_3\cdot 6H_2O$ instead of $YCl_3\cdot 6H_2O$. Pink diamond-like crystals of **3** were obtained. Yield: 0.016 g (41.47% based on Er). $C_{28}H_{22}O_{19}Er_3$ (1164.25): calcd. C 28.89, H 1.91; found C 29.08, H 1.89. IR (KBr): $\tilde{\nu}$ = 3550 (s), 3424 (s), 1650 (m), 1578 (s), 1538 (s), 1509 (m), 1408 (s), 1323 (w), 1174 (w), 1019 (m), 749 (s), 520 (m) cm$^{-1}$.

**Synthesis of $[(Y:Er\text{-}Yb)_3(BDC)_{3.5}(OH)_2(H_2O)_2]\cdot H_2O$:** The codoped compounds were prepared according to the procedure for **1** but by using $YCl_3\cdot 6H_2O$, $ErCl_3\cdot 6H_2O$ and $Yb(NO_3)_3\cdot 6H_2O$ (for example, molar ratio: 94.00:2.00:4.00%) instead of 100% $YCl_3\cdot 6H_2O$. Colourless block-like crystals were obtained. Yield: 0.018 g (56.88% based on total Ln). $C_{28}H_{22}O_{19}(Y:Er\text{-}Yb)_3$ (943.83): calcd. C 35.63, H 2.35; found C 35.85, H 2.43. IR (KBr): $\tilde{\nu}$ = 3554 (s), 3423 (s), 1653 (m), 1574 (s), 1535 (s), 1508 (m), 1410 (s), 1319 (w), 1167 (w), 1020 (w), 749 (s), 527 (m) cm$^{-1}$. The ICP analysis showed that the molar ratio of Y/Yb/Er was 94.45:2.17:3.38 in the product.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The observed XRD patterns of the Y:Er-Yb codoped coordination polymer and **1** indicate that they are isomorphous.

**X-ray Structure Determination:** Intensity data for **1**, **2** and **3** were collected at 293 K with a Bruker SMART 1000 CCD area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) in $\varphi$ and $\omega$ scan modes with $\theta$ ranges of 1.78–27.88° for **1**, 2.09–25.01° for **2** and 1.70–25.01° for **3**. Semiempirical absorption corrections were applied using the SADABS program.[21] The structures were solved by direct methods[22] and refined by full-matrix least squares on $F^2$ using the SHELXS-97 and SHELXL-97 programs, respectively.[22,23] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were generated geometrically and treated with a mixture of independent and constrained refinements. Details of the crystallographic data of **1**, **2** and **3** are summarised in Table 3. CCDC-608985 to -608987 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/datarequest/cif.

**Luminescence Spectroscopy:** Upconversion spectra were obtained with an LS-50B fluorescence spectrophotometer (Perkin–Elmer Corp., Forster City, CA) with an external 0–800 mW adjustable laser (980 nm, Beijing Hi-Tech Optoelectronic Co., China) as the excitation source, instead of the xenon source in the spectrophotometer and with a fibre-optic accessory.

## COVER PICTURE

**The cover picture shows** the P=C=P backbones of stable, neutral diphosphaallenes along with the publication year of the first example reported for given coordination numbers of the phosphorus atoms. Since the synthesis of hexaphenylcarbodiphosphorane ($Ph_3P{=}C{=}PPh_3$), a $\sigma^4,\sigma^4$-diphosphaallene, in 1961, only two other classes of compounds with P=C=P sequences have been reported in the past decades. Details of the preparation of the phosphavinylidene(oxo)phosphorane Mes*P(O)=C=PMes* (Mes* = 2,4,6-tri-*tert*-butylphenyl), a diphosphaallene featuring $\lambda^5\sigma^3$- and $\lambda^3\sigma^2$-phosphorus atoms, NMR spectroscopic data and the first aspects of its reactivity are described in the article by H. Ranaivonjatovo, J. Escudié et al. on p. 4237 ff.

# Chiral Molecules Containing Metal–Metal Bonds

F. Albert Cotton*[a] and Carlos A. Murillo*[a]

**Keywords:** Metal–metal bonds / Chirality / Chromophores / Orthometalation / Helical molecules

Many chiral compounds having metal–metal bonds are now known in which the M–M unit is the chromophore. In this review they are classified as those where it is either (1) an inherently chiral chromophore owing to helical stacking of metal–ligand bonds, or (2) not inherently chiral but surrounded by a collection of ligands bearing chiral substituents. In only a few cases have the actual CD and/or ORD spectra been measured and analyzed. These include $M_2X_4(PP)_2$ molecules (PP = a bridging diphosphane) and $M_2(O_2CR)_4$ molcules where R is chiral. The more recently discovered helical extended metal atom chain (EMAC) molecules are also mentioned.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The way in which metal–metal (M–M) bonds are influenced by, and exert influence upon, a chiral environment is a topic that has not been comprehensively reviewed. There is now a large enough body of results to justify at least a small (surely at least *micro*) review. In general, metal–metal-bonded compounds are of interest in many areas such as catalysis,[1] medicine[2] and for synthesizing supramolecular arrays.[3]

We preface the main body of the review by reminding the reader that there are two fundamental classes of optically active molecules:[4]

[a] Department of Chemistry and Laboratory for Molecular Structure and Bonding, A&M University, College Station, P. O. Box 30012, Texas 77842-3012, USA
E-mail: cotton@tamu.edu
murillo@tamu.edu

(1) Those with inherently chiral chromophores

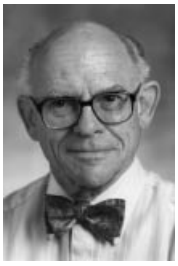
(2) Those with achiral chromophores embedded in chiral surroundings

We shall divide this review into two parts based on this difference.

### 1. Inherently Chiral Di- or Polymetal Chromophores

#### *1a. M–M Bond Twist Induced by Chiral Diphosphanes*

The first examples of molecules with the type of structure shown in Figure 1 were discovered by R. A. Walton and co-workers, in 1975 for rhenium compounds[5] and in 1978 for molybdenum compounds.[6] Tungsten analogs were reported in 1980.[7] The compounds with dppe ($Ph_2PCH_2CH_2PPh_2$) are generally regarded as prototypical, but many are known with other $R_2PCH_2CH_2PR_2$ and sim-



*F. Albert Cotton was born in Philadelphia in 1930. He is the Doherty-Welch Professor of Chemistry and director of the Laboratory for Molecular Structure and Bonding at Texas A&M University. He began his academic career at the Massachusetts Institute of Technology from 1955 to 1971. His successful Ph. D. students number 116. Among his honors are membership in the US National Academy of Sciences and the American Philosophical Society. He received the ACS George C. Pimental Award in Chemical Education in 2006. He is the coauthor of many books and almost 1600 research publications. His main research interest deals with the study of compounds with metal–metal bonds.*

*Carlos A. Murillo received a B. Sc in his native country from the University of Costa Rica in 1973 and a Ph. D. from Texas A&M University (TAMU) in 1976, working with F. A. Cotton. After one year at Princeton University working with M. H. Chisholm he took a position at the University of Costa Rica where he became Professor of Chemistry in 1986. He then moved to TAMU in 1991 where he is a senior lecturer and executive director of the Laboratory for Molecular Structure and Bonding. He is a charter member of the Costa Rican Academy of Sciences, a Fellow of the American Association for the Advancement of Science, a coauthor of Advanced Inorganic Chemistry, a coeditor of Multiple Bonds Between Metal Atoms and coauthor of nearly 250 research publications. His principal research interests are in the synthesis and characterization of compounds with metal-metal bonds.*

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ilar bridging diphosphanes.[8] The important feature of the $Re_2Cl_4(dppe)_2$ structure shown in Figure 1 is that the conformational requirements of the two six-membered rings that are fused along the metal–metal bond (triple in the rhenium compounds and quadruple for the molybdenum and tungsten ones) induce a partial twist away from an eclipsed conformation. This twist makes the M–M bond an inherently chiral chromophore. For the compounds with quadruple bonds, the δ→δ* transition is a particularly convenient electronic transition for studying the CD/ORD spectra.

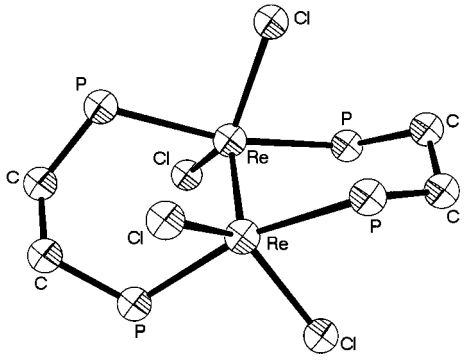


Figure 1. The core of the prototypical $Re_2Cl_4(dppe)_2$ molecule showing the twist away from an eclipsed conformation that produces a chiral chromophore.

No enantiomers of the $M_2X_4(R_2PCH_2CH_2PR_2)_2$ compounds have been resolved, but by introducing chirality into the backbone of the diphosphane, the chirality of the helix around the M–M core can be predetermined. For such work, the prototype compound is Λ-[$Mo_2Cl_4${(*S*,*S*)-dppb}$_2$], shown along with its CD spectrum in Figure 2, where (*S*,*S*)-dppb is (*S*,*S*)-2,3-(diphenylphosphanyl)butane. The structure, with its Λ sense of the twist, is both predicted by conformational analysis and confirmed by X-ray crystallography.[9,10]

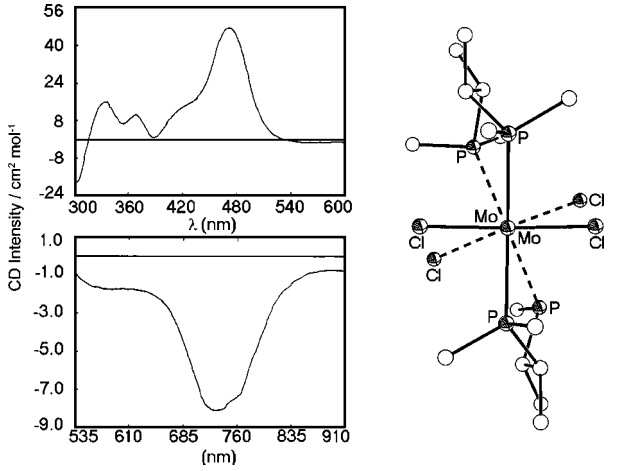

Figure 2. The β-$Mo_2Cl_4${(*S*,*S*)dppb}$_2$ molecule viewed down the Mo–Mo axis (right) and its CD spectrum (left).

The CD spectrum shows two principal features: a negative band at about 13500 $cm^{-1}$ that corresponds to the δ→δ* absorption band in the electronic spectrum and a positive band at about 21300 $cm^{-1}$. These same two principal features are seen in most similar molecules having $Mo_2^{4+}$ units.[11–14]

There is a very straightforward and unequivocal explanation of these CD results. For the δ→δ* transition, we refer to Figure 3, where it can be seen that there is a shift of charge both along and around the metal–metal bond. Therefore, the δ→δ* transition in such a helical molecule is both electric-dipole- and magnetic-dipole-allowed; it must, therefore, be CD allowed. As shown on the left side, when the Λ twist angle is less than 45°, the signs of the CD bands would be reversed for the Λ and Δ isomers. The entire analysis can be conveniently generalized into a sector diagram, as shown in Figure 4. This shows how the CD sign changes, alternating from one octant to the next, as a function of the L–M–M–L angle. Thus, even if it is known from conformational analysis whether to expect the Λ or Δ twist, the extent of the twist must also be known. The first actual test of this octant rule was made with $Mo_2Cl_4${(*R*,*R*)-DIOP}$_2$, where (*R*,*R*)-DIOP is shown in Scheme 1. The twist angle, $\chi$, in the dominant isomer of the dimolybdenum compound is $-45° < \chi < -90°$, and the sign of the CD for the δ→δ* transition is predicted from the sector diagram to be positive. As shown in Figure 5, this is found experimentally. The diamine molecule, $Mo_2Cl_4[(R)\text{-}H_2NCH(CH_3)\text{-}CH_2NH_2]_2$ was also shown to obey the sector diagram.[15]

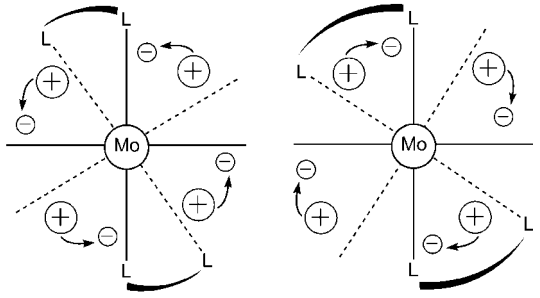

Figure 3. Diagrams of the transient charge distributions for the δ→δ* transition in twisted $Mo_2X_4(LL)_2$ molecules with torsion angle $\theta$ (a) in the range 0 to –45° and (b) in the range –45 to –90°. Note that the two ranges, though in the same direction geometrically, give transient charge distributions of opposite rotational sense.

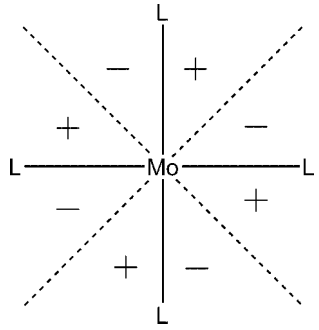

Figure 4. The sign rule for the CD of the δ→δ* transition. The sign of the CD refers to the vector in which the rear set of ligand atoms is found.

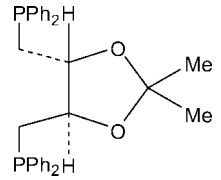
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. The (*R*,*R*)-DIOP molecule.

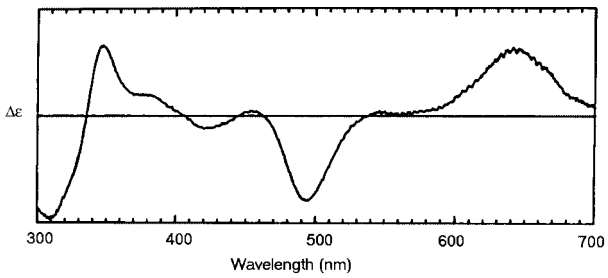


Figure 5. CD spectra of $Mo_2Cl_4\{(R,R)\text{-DIOP}\}_2$ in $CH_2Cl_2$ solution in the range from 300 to 700 nm.

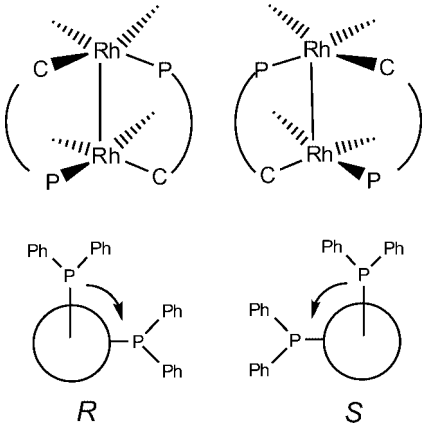
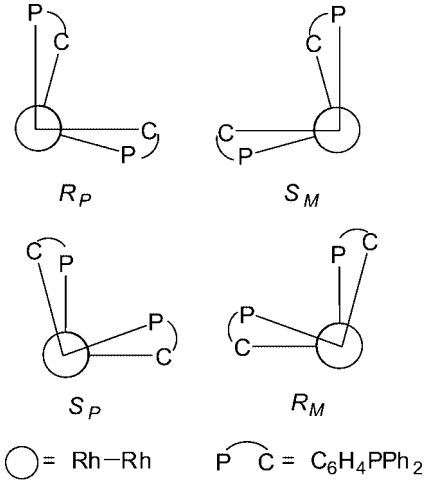
In all of the compounds just discussed, there is a band in the visible spectrum (ca. 22000 $cm^{-1}$) which has the opposite CD sign to that for the δ→δ* transition. This band is due to a $\delta_{xy}\rightarrow\delta_{x^2-y^2}$ transition, and it has been shown that it follows a sector diagram too, but with all of the signs reversed from those shown in Figure 3 for the δ→δ* transition.

### *1b. Molecules with Orthometalated Bridging Phenylphosphanes*

These are compounds with a dimetal unit bridged by two *cisoid* orthometalated phosphanes in a head-to-tail (H,T) arrangement. Two additional equatorial groups such as carboxylates usually complete the paddlewheel arrangement. The compounds *cis*-$Rh_2(C_6H_4PPh_2)_2(OAc)_2\cdot 2CH_3COOH$[16] and $Os_2(C_6H_4PPh_2)_2Cl_4$[17] were the first to be made. The dirhodium compound and its derivatives have been studied in great detail. Because of the H,T arrangement of the two orthometalated bridging ligands, the *cis*-$Rh_2(C_6H_4PPh_2)_2^{2+}$ unit has only $C_2$ symmetry and is therefore chiral. The (*R*) and (*S*) conformations are shown in Scheme 2. The interconversion of (*R*) and (*S*) isomers would require bond breaking and such isomers are not expected to interconvert at ordinary temperatures because of the large energy barriers associated with such processes. As shown in Scheme 3, there is also a secondary source of chirality induced by the twist pattern of each phosphane ligand designated as *P* (for positive torsion angle) and *M* (for negative torsion angle along the axis of the helix) following the nomenclature used for helical molecules.[18] While for the secondary chirality less energy is expected to be required for interconversion than for the primary source of chirality, this value may still be significant. Molecular mechanics calculations have been used to estimate the relative stability of the ($S_M$) and ($S_P$) conformers in *cis*-$Rh_2(C_6H_4PPh_2)_2(CH_3CN)_6^{2+}$,[19] which has a P–Rh–Rh–P torsion angle of –23°. The results indicate that the experimental ($S_M$) conformation is 88.1 kJ $mol^{-1}$ more stable than the ($S_P$) conformation having the same torsion angle, and that the energy barrier between the conformers is estimated to be much greater than $kT$ (153.3 kJ $mol^{-1}$)



Scheme 2. The (*R*) and (*S*) chirality imposed by the H,T arrangement of the *cisoid* orthometalated groups.



Scheme 3. The second chirality due to the magnitude and sign of the torsion angle along the P–Rh–Rh–P unit.

The stable (*R*) and (*S*) enantiomers have been resolved. The separation procedure makes use of the fact that in (*R*,*S*)-*cis*-$Rh_2(C_6H_4PPh_2)_2(OAc)_2\cdot 2CH_3COOH$, the orthometalated phosphane groups are not labile while the carboxylate groups are. Reaction with ProtosH (*N*-4-methylphenylsulfonyl-L-proline, see Scheme 4) yields (*R*,*S*)-*cis*-$Rh_2(C_6H_4PPh_2)_2(Protos)_2\cdot 2H_2O$ and the diastereoisomers are easily separated by column chromatography using silica gel and elution with a mixture of $CH_2Cl_2/Et_2O$.[20] Many analogs using a great variety of substituted phosphanes have also been synthesized. These compounds have applications in enantioselective C–H insertion of α-diazo ketones and other catalyzed reactions.[20,21]

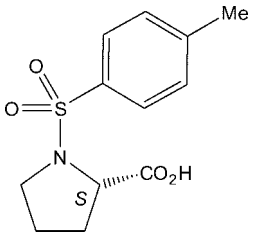

Scheme 4. The chiral ProtosH molecule.

Substitution reactions of the carboxylate groups from the diastereoisomers proceed without racemization, and the group Protos can be easily replaced by other groups such as carboxylates or acetonitrile. The orthometalated dirhodium unit in [(*R*)-*cis*-$Rh_2(C_6H_4PPh_2)_2(CH_3CN)_6](BF_4)_2$ has been useful as a corner piece for the synthesis of enantiopure supramolecular structures. Reaction with the dicarboxylate anions $O_2C(CF_2)_nCO_2$, $n$ = 2 and 3, give molecular loops in which each of the two $Rh_2(C_6H_4PPh_2)_2$ units is also coordinated by two carboxylate groups from each of the two linkers and two axial pyridine molecules, as shown in Figure 6 for $n$ = 2.[22] In this complex, the P–Rh–Rh–P torsion angles [75.7(1) and 74.56(9)°] are smaller than those of C–Rh–Rh–C [–116.9(4) and –119.2(4)°]. Therefore, the overall chirality of this dirhodium compound is ($R_MR_M$). This is uncommon for simple dirhodium compounds, in which the torsion angle of P–Rh–Rh–P is usually larger than that of C–Rh–Rh–C,[23] because of steric repulsions between the bulky phenyl groups in the phosphanes.

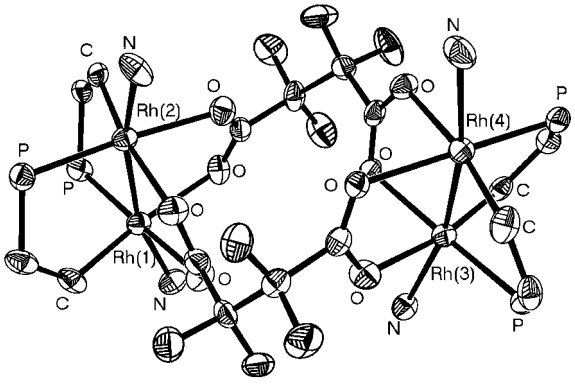

Figure 6. The core of the chiral molecular loop (*RR*)-[*cis*-$Rh_2(C_6H_4PPh_2)_2(py)_2O_2CF_2CF_2CO_2]_2$ for which the overall chirality is ($R_MR_M$).

A series of neutral molecular triangles having the formula [*cis*-$Rh_2(C_6H_4PPh_2)_2]_3$(dicarboxylate)$_3$·$(L_{ax})_6$ where $L_{ax}$ may be one of a variety of donor molecules such as DMF, MeOH or py, $CH_2Cl_2$ have also been made. These compounds, for which a representative core is shown in Figure 7, were first prepared by reaction of racemic [*cis*-$Rh_2(C_6H_4PPh_2)_2(CH_3CN)_6](BF_4)_2$ and tetraethylammonium salts of linear dicarboxylates such as, oxalate, terephthalate and 4,4′-biphenyldicarboxylate.[19] The relative chiralities of the dirhodium units in these triangles were established using a combination of data from X-ray crystallography and $^{31}$P NMR spectroscopy. It should be noted that the combination of the racemic mixture of *cis*-$Rh_2(C_6H_4PPh_2)_2^{2+}$ units with dicarboxylate anions to form triangles can produce four possible stereoisomers: (*RRR*), (*RRS*), (*SSR*), and (*SSS*), and each of these can be either ($R_P$) and ($R_S$), or ($S_P$) and ($S_M$) (see Scheme 3). For the oxalate compound, all the $Rh_2$ units in each triangle have the same chirality, and this compound exists as a mixture of ($R_PR_PR_P$) and ($S_MS_MS_M$) isomers having $D_3$ symmetry. It is notable that no ($R_M$) or ($S_P$) conformers were observed. For the terephthalate analog, the structure shows two dirhodium units with one chirality and the third one with another chirality [(*RRS*) or (*SSR*)] but again there are only ($R_P$) or ($S_M$) conformers.

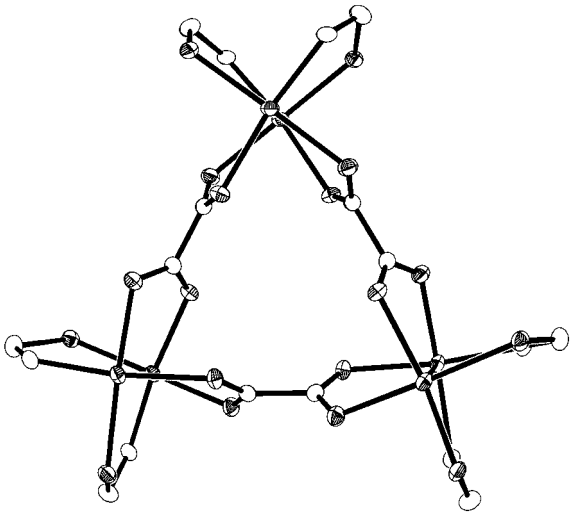

Figure 7. The core of the neutral molecular triangle [*cis*-$Rh_2(C_6H_4PPh_2)_2]_3$(oxalate)$_3$·$(L_{ax})_6$. Only the $Rh_2PCC$ portions of the orthometalated $Rh_2C_6H_4PPh_2$ units are shown. Axially coordinated ligands have also been removed for clarity. Carbon atoms are shown as open ellipsoids.

The $^{31}$P NMR spectra, shown in Figure 8, suggest that the structures observed in the solid state remain unchanged in solution, and that there are no interconversions in solution to other types of oligomers such as squares. For the compounds with oxalate and 4,4′-biphenyldicarboxylate linkers, the doublets are consistent with the high symmetry in the crystal, whereby all the orthometalated phosphane ligands are equivalent. Here, the doublets are due to coupling of the P atoms with the $I$ = 1/2 $^{103}$Rh nucleus. For the terephthalate analog, the three doublets with nearly identical coupling indicate that the (*RRS*) or (*SSR*) chirality of the solid state is again present in solution. The enantiopure analogs [(*RRR*) or (*SSS*)] have also been prepared from reaction of (*R*)- or (*S*)-[*cis*-$Rh_2(C_6H_4PPh_2)_2(CH_3CN)_6](BF_4)_2$ and the dicarboxylate salts.[24] The core structure of (*SSS*)-[*cis*-$Rh_2(C_6H_4PPh_2)_2]_3$(terephthalate)$_3$(py)$_6$ is shown in Figure 9 along with the packing diagram. Catalytic evaluation of these enantiopure triangles show that they are catalytically active and provide good results for the intermolecular cyclopropanation between styrene and ethyl diazoacetate.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

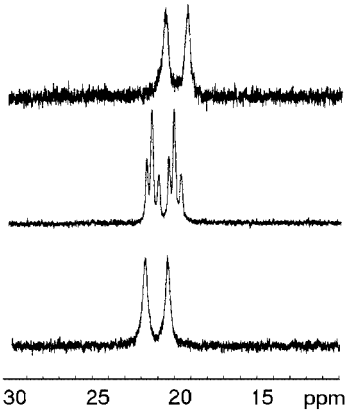

Figure 8. $^{31}P$ NMR in $CD_3Cl$ of the racemic triangular compounds with oxalate, terephthalate and 4,4′-biphenyldicarboxylate linkers shown in the same order from top to bottom.

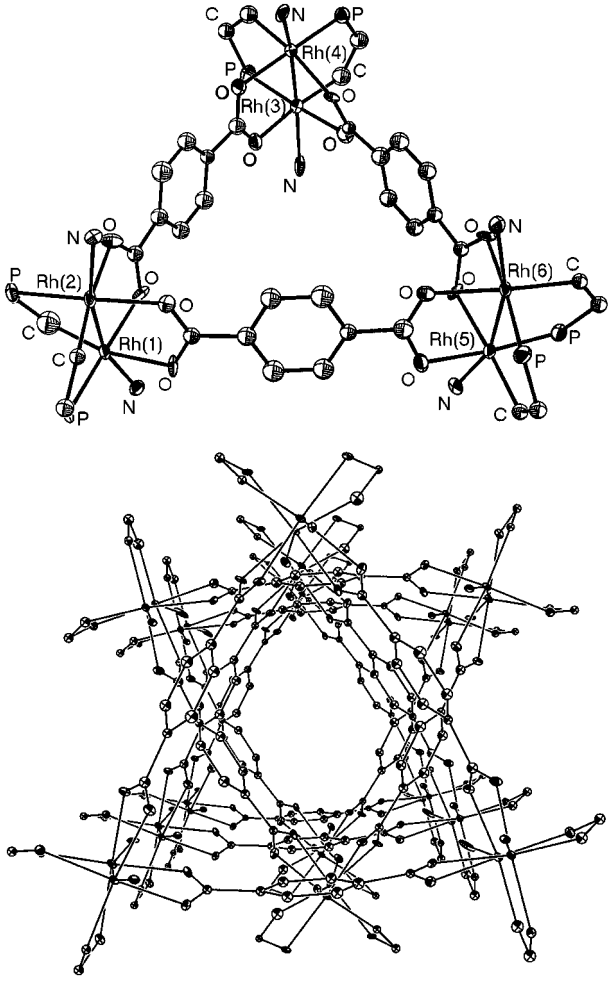

Figure 9. The core structure (top) and packing pattern (bottom) of (*SSS*)-[*cis*-$Rh_2(C_6H_4PPh_2)_2]_3$(terephthalate)$_3(py)_6$. Note that the molecules stack on top of each other, but alternately out of register, leaving a chiral channel. For the oxalate analog, the triangular molecules stack in register.

The same dirhodium corner piece has been used to build a molecule with pure rotational symmetry *T* by reaction of (*R*)-[*cis*-$Rh_2(C_6H_4PPh_2)_2(CH_3CN)_6](BF_4)_2$ and the trianion of benzene-1,3,5-tricarboxylic (trimesic) acid.[25] The compound $\{NEt_4\subset[(R)$-*cis*-$Rh_2(C_6H_4PPh_2)(py)_2]_6(1,3,5$-$C_6H_3(CO_2)_3)_4\}BF_4$, prepared by a designed synthesis and shown in Figure 10, has only eight $C_3$ and three $C_2$ rotations of the group *T*. It encapsulates a $NEt_4^+$ cation within the chiral spheroidal cavity of the cage. In this chiral carceplex there are six *cisoid* (*R*)-$Rh_2(C_6H_4PPh_2)_2^{2+}$ units (B) linked by four trimesate anions (A), each connecting to three different $Rh_2^{4+}$ units to give an $A_4B_6$ type molecule. All oxygen atoms of the trimesate anions are *trans* to either carbon or phosphorus atoms in the orthometalated ligands. The midpoints of the dirhodium units roughly describe an octahedron while the centers of the aryl groups of the anions describe a tetrahedron. Pyridine molecules are found at both axial positions of each dirhodium unit. This carceplex is an all (*R*) isomer.

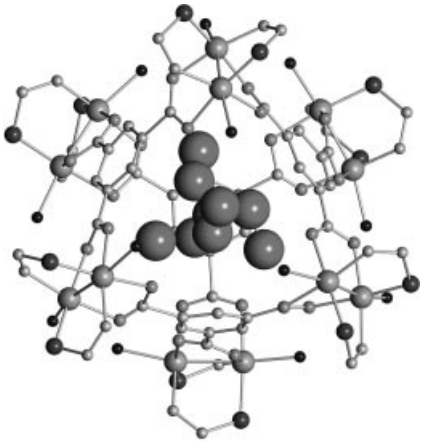

Figure 10. A view of the core structure of the carceplex Λ-$\{NEt_4\subset[(R)$-*cis*-$Rh_2(C_6H_4PPh_2)(py)_2]_6(1,3,5$-$C_6H_3(CO_2)_3)_4\}BF_4$ showing the encapsulated tetraethylammonium cation.

The $^1H$ NMR spectrum offers clear evidence that the tetraethylammonium cation remains encapsulated in solution, and shows two signals at high field (–0.035 and –0.278 ppm) in a ratio of 3:2. The large upfield displacement of these signals relative to those of a non-encapsulated $NEt_4^+$ cation is due to strong shielding by the cage. The $^{31}P$ NMR spectrum of the compound in $CD_2Cl_2$ in the presence of excess pyridine is consistent with the existence of only one highly symmetrical species in solution as it shows only one doublet because of coupling of each P atom to the adjacent $^{103}Rh$ nucleus.

### *1c. Helical Molecules with Three or More Metal Atoms*

The best known compounds are of the type $M_3(dpa)_4X_2$, where dpa = the anion of dipyridylamine, X is a monodentate group, typically a monoanion such as a halide, $PF_6$, acetylide, and others and M = Co, Cr, Rh, Ru, Ni.[26] One remarkable feature of compounds of this type is the tunable metal-to-metal interactions within the trinuclear unit and symmetrical and unsymmetrical arrangements may be obtained depending on the nature of the axial ligands. More importantly for this review is the typical helical arrangement of the four dpa anions about the $M_3$ unit as shown in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

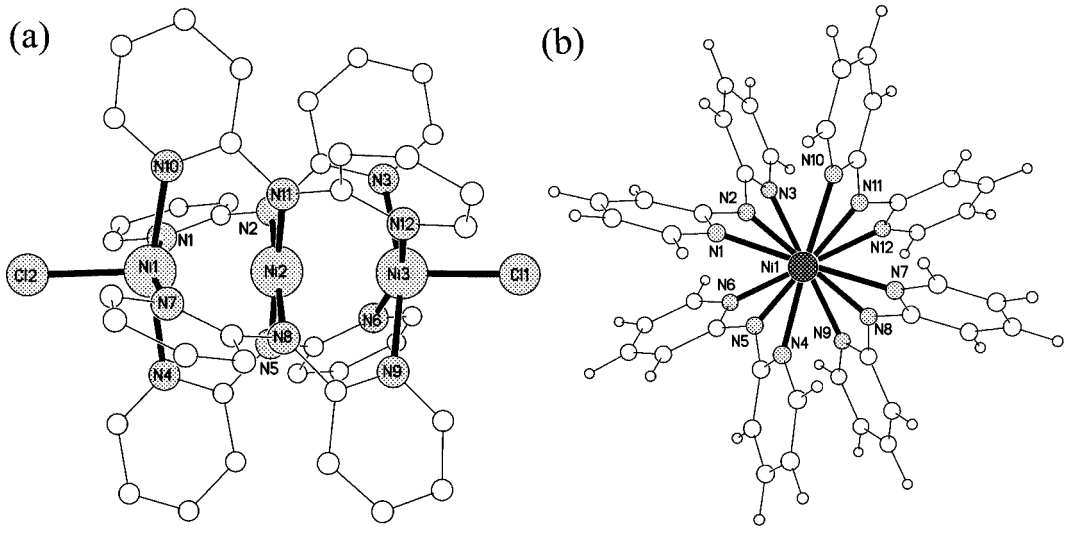

Figure 11. A typical structure of an $M_3(dpa)_4X_2$ as represented by $Ni_3(dpa)_4Cl_2$. The structure is shown (a) perpendicular to the $Ni_3$ axis, and (b) looking down the $Ni_3$ axis to emphasize the helical arrangement of the dpa ligands.

Figure 11 for a typical $M_3$ compound. While the set of four dpa ligands has the capacity to organize an extended metal atom chain (EMAC), it is also forced by internal nonbonded (H···H) contacts to form an overall molecular structure with a helical configuration having right- or left-handed helicity (referred to as Δ or Λ, respectively) as shown in Figure 12.

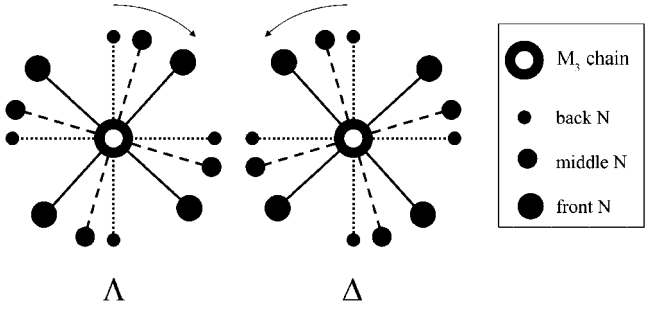

Figure 12. A schematic representation of the Δ and Λ isomers of an EMAC of the type $M_3(dpa)_4X_2$.

Most of the structures of these $M_3(dpa)_4X_2$ compounds are racemic but for $[Co_3(dpa)_4(CH_3CN)_2](PF_6)_2$ single crystals of the Δ and Λ isomers were isolated from solution and manually separated. Their absolute configurations were determined by X-ray crystallography and circular dichroism spectra (Figure 13) were measured on solutions made from crystals of known absolute configuration.[27] Both isomers exhibit significant Cotton effects. The bands were assigned from the electronic spectra with that at 312 nm corresponding to a spin-allowed π–π* transition. The transition at 369 nm was assigned to a charge-transfer band and the lower energy bands at 442 and 544 nm were assigned to metal-centered transitions in the $Co_3^{2+}$ core.[27] In general, the anisotropy or dissymmetry factor given by the $\Delta\varepsilon/\varepsilon$ ratio of circular dichroic to isotropic absorbance is associated with the nature of the transitions.[28] For electric-dipole-allowed and magnetic-dipole-forbidden transitions (CT and ligand π–π* transitions), the $\Delta\varepsilon/\varepsilon$ ratio $\leq 5{\cdot}10^{-3}$ and for magnetic-dipole-allowed and electric-dipole-forbidden transitions (ligand-field transitions, n–π* transitions), $\Delta\varepsilon/\varepsilon$ ratio $\geq 5{\cdot}10^{-3}$. The transition for the Λ isomer at 312 nm has a negative sign ($\Delta\varepsilon/\varepsilon = 8.2{\cdot}10^{-4}$) in the CD spectrum, while the bands at 369 nm ($\Delta\varepsilon/\varepsilon = 1.5{\cdot}10^{-3}$), 442 nm ($\Delta\varepsilon/\varepsilon = 8.25{\cdot}10^{-3}$), and 544 nm ($\Delta\varepsilon/\varepsilon = 5.0{\cdot}10^{-3}$) are positive. The CD spectra for the Δ and Λ isomers are mirror images, as expected for a pair of enantiomers. The CD bands at 312 and 369 nm have small $\Delta\varepsilon/\varepsilon$ values with the former corresponding to a ligand π–π* transition and the latter corresponding to a LMCT transition. Both are electric-dipole-allowed and magnetic-dipole-forbidden transitions. The greater dissymmetry factor $\Delta\varepsilon/\varepsilon$ for the bands at 442 and 544 nm is consistent with these bands being magnetic-dipole-allowed and electric-dipole-forbidden metal-centered transitions. Importantly, the equal intensity but opposite signs of the spectra from the two solutions of isomers having similar concentrations indicates that the two enantiomers do not interconvert in solution.

Spontaneous resolution upon crystallization as just described, is very rare. Normally only racemic crystals are obtainable. However, chromatographic resolution on columns of chiral adsorbants has recently been applied with success to several $M_3(dpa)_4X_2$ compounds.[29] There are two ways to determine the absolute helicity of each enantiomer. The most obvious is to crystallize one (or both) and employ X-ray crystallography. When this cannot be done, vibrational circular dichroism can be used. This has been done in the case of $Ni_3(dpa)_4(OH)_2$.[30] There are preliminary results showing that many other helical EMACs will be treatable by similar methods.

There are also structurally characterized EMACs with longer polypyridylamides having linear $M_5$, $M_7$ and $M_9$ cores. The structures resemble those with $M_3$ cores in that the molecules are helical. An example is that of $Ni_9$-

$(peptea)_4Cl_2$ (peptea = the anion of pentapyridyltetraamine),[31] which is shown in Figure 14. Recently examples of complexes with four anions derived from polypyridylnaphthyridine groups (Scheme 5) have been made containing $Co_6^{12+}$ and $Co_6^{11+}$ cores,[32] and $Ni_6^{12+}$ and $Ni_6^{11+}$ cores.[33] A schematic representation of the $Co_6^{n+}$ compounds is given in Figure 15. However, none of these racemic mixtures have been resolved.

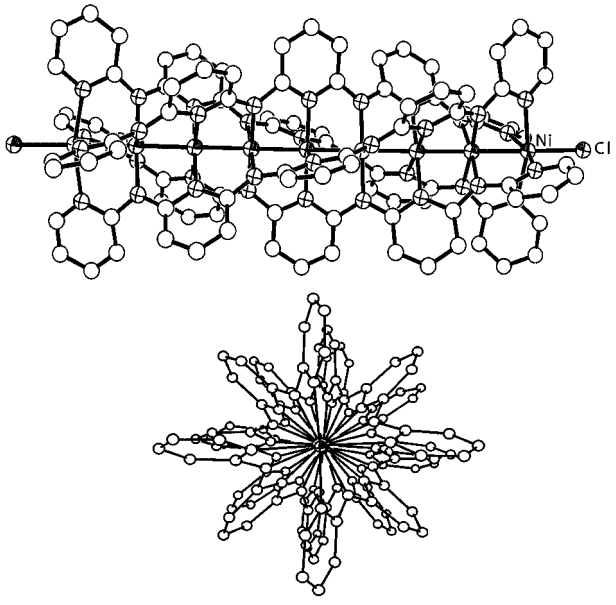

Figure 14. The structure of one of the enantiomers of $Ni_9(peptea)_4Cl_2$ (top). A view along the main axis of this molecule emphasizing the helical arrangement of the polypyridylamido ligands is at the bottom.

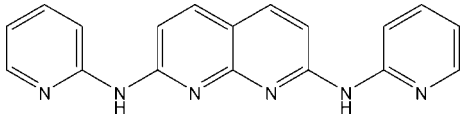

Scheme 5. A schematic drawing of 2,7-bis(α-pyridylamido)-1,8-naphthyridine used in the syntheses of compounds with $M_6^{12+}$ and $M_6^{11+}$ cores, M = Co and Ni.

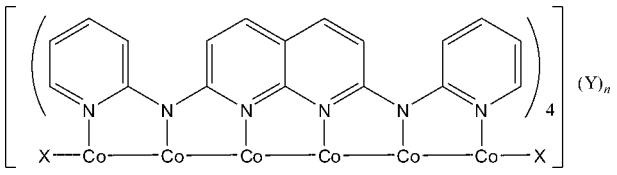

Figure 15. A 2-dimensional representation of the $Co_6^{n+}$ compounds synthesized with the ligand in Scheme 5, X = NCS or triflate anions, and Y = $PF_6$ or triflate anions. The way the EMACs twist is not shown.

## 2. Achiral Dimetal Chromophores in Chiral Environments

It appears that the first structurally characterized quadruply bonded $Mo_2^{4+}$ compound containing chiral ligands was $Mo_2(L\text{-isoleucine})_2(NCS)_4{\cdot}4.5H_2O$, but no spectroscopic data were collected.[34] Later, $Mo_2(\text{L-leucine})_4Cl_2(p\text{-toluenesulfonate})_2{\cdot}2H_2O$ was prepared, structurally characterized, and, because of very favorable alignment of the molecules in the crystal, used for detailed studies of the polarization and vibronic structure of the δ→δ* absorption band.[35] Again, however, no ORD or CD data were collected.

Chiral dicarboxylic acid anions, L-tartrate and D-aspartate, have been used to link $Mo_2(DAniF)_3^+$ units (DAniF = the *N*,*N*′-di-*p*-anisylformamidinate anion).[36] The structure of the tartrate is shown in Figure 16. An enantiomerically pure compound in the form of a loop has two *cis*-$Mo_2(DAniF)_2^{2+}$ units and two chiral dicarboxylates made from hydroquinone and ethyl (*S*)-lactate,[37] **L1**-*para*, shown in Scheme 6. The structure of the loop $[cis\text{-}Mo_2(DAniF)_2]_2(\mathbf{L1}\text{-}para)_2$ is shown in Figure 17. In the crystal, the molecules stack forming channels capable of hosting guest molecules such as $CH_2Cl_2$, as shown in Figure 18.

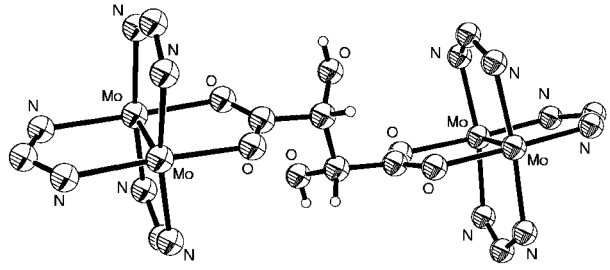

Figure 16. The structure of $[Mo_2(DAniF)_3]_2(L\text{-tartrate})$.

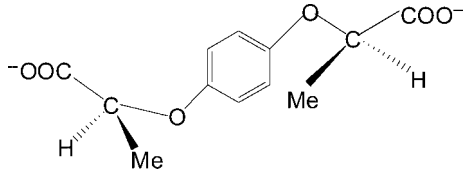

Scheme 6. The ligand **L1**-*para*, $p\text{-}^{-}O_2C(CH_3)(H)(O)\text{–}C_6H_4\text{–}(O)C(CH_3)(H)CO_2^{-}$, made from hydroquinone and ethyl (*S*)-lactate.

Other early work in this area was done by Snatzke,[38] whose goal was to employ the δ→δ* transition in the $Mo_2^{4+}$ chromophore, which is conveniently located at about

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

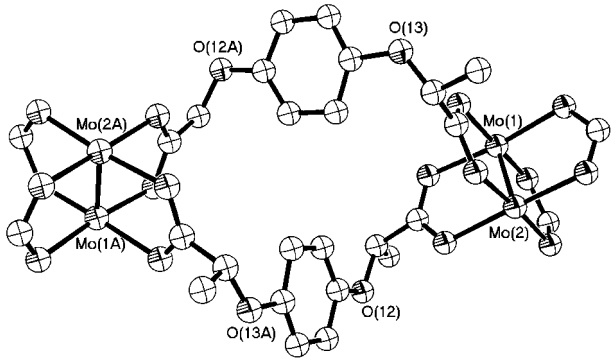

Figure 17. The structure of the molecular loop [*cis*-$Mo_2$(DAniF)$_2$]$_2$-(**L1**-*para*)$_2$.

20000 $cm^{-1}$, to determine the absolute configurations of functionalized organic molecules. Direct ORD or CD measurements of the organic molecules themselves was challenging because their lowest-energy transition was generally in the ultraviolet. Snatzke's approach was rather empirical; it consisted in simply adding $Mo_2(O_2CCH_3)_4$ to a solution of the organic compound of interest and measuring the CD spectrum in the visible region due to some generally undefined complex between the organic compound and some fragment of the $Mo_2(O_2CCH_3)_4$ molecule that had been introduced. Results varied with absolute and relative concentrations.

It was later proposed[39] that the ability of $Rh_2(O_2CCF_3)_4$ to bind almost every possible organic functionality including simple olefins, at its axial position might lead to a more reliable realization of Snatzke's concept, but there has been no follow up on this. It does not appear that the use of "spectator" dimetal units, either $Mo_2^{4+}$ or $Rh_2^{4+}$ is a very promising technique.

**Dirhodium Compounds**

In 1986 two $Rh_2(O_2CR)_4L_2$ compounds, one with R = CPh(OH)H and L = EtOH and the other with R = CPh(OMe)H and L = THF were structurally characterized and their CD spectra were measured and interpreted.[40] The structure of the (*S*)-mandelate is shown in Figure 19 and it resembles that of the $Mo_2^{4+}$ analog, except for the absence of axial ligands in the latter.[41] The electronic absorption and CD spectra of $Rh_2$[(*S*)-mandelate]$_4$(EtOH)$_2$ are shown in Figure 20. The interpretation, which is much too complex to recapitulate here, was carried out assuming that the central $Rh_2(O_2C–)_4$ core is inherently achiral, having $D_{4h}$ symmetry. A one-electron model of a type previously proposed by others[42] was employed and was found to be consistent with the fact that the CD signs associated with the two prominent absorption bands (at ca. 450 and 600 nm) have the same sign. The fact that both are negative (rather than both positive) was not predictable. However, because both have the same sign, a reversal of the absorption band assignments from those accepted at the time is not ruled out, and indeed MCD measurements reported se-

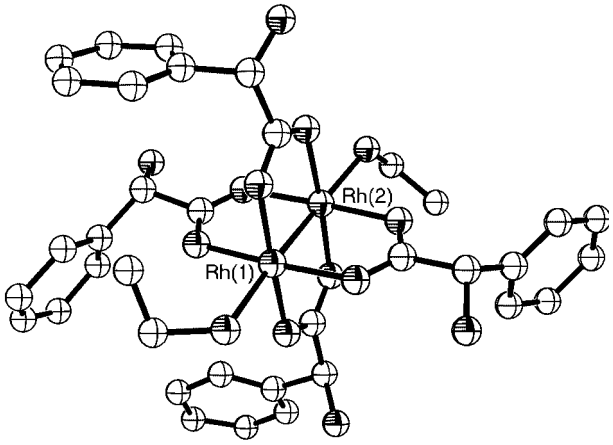

Figure 19. The structure of $Rh_2$[(*S*)-mandelate]$_4$(EtOH)$_2$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

veral years later[43] showed that such a reversal was required. Thus, while the CD results offer valuable evidence for assigning the electronic spectrum, they are not by themselves definitive.

Chiral dirhodium compounds are some of the most widely studied species with metal–metal bonds due to their applications in catalysis. Because this topic has been reviewed recently we will not elaborate any further here.[44]

## Conclusions

There is considerable diversity of chiral compounds that contain dimetal units. Those cited in this review suggest that there is great scope for further development, along both of the main avenues: (1) compounds in which the ligand arrangement renders the $M_2$ unit itself chiral, and (2) compounds in which the $M_2$ unit is not itself a seat for chirality but is the linchpin for a surrounding set of chiral ligands.

# "Isomerism" of Coordination Modes and Numbers in Pentanuclear Organozinc Hydroxylamides: An Exercise in Subtle Substituent Size Effects

**Matthias Ullrich,[a] Raphael J. F. Berger,[a] Christian Lustig,[a] Roland Fröhlich,[b] and Norbert W. Mitzel*[a]**

*Dedicated to Prof. Gerhard Erker on the occasion of his 60th birthday*

**Keywords:** Zinc / Hydroxylamines / Organometallic / Coordination modes / Crystal structure

The first organometallic zinc hydroxylamides $[Zn(RZn)_4(ONMe_2)_6]$ (**1**: R = Me; **2**: R = *i*Pr) and $[Zn(EtZn)_4(ONEt_2)_6]$ (**3**) have been prepared by alkane elimination from dialkylzinc solutions upon treatment with *N*,*N*-dialkylhydroxylamines. The molecular structures of **1** and **2** reveal that a subtle change in the constitution of the aggregates can make a striking difference. By the simple exchange of the $MeZn^+$ groups with *i*PrZn$^+$ groups, the coordination number of the central $Zn^{2+}$ nucleus increases from four (**1**) to six (**2**). The two cluster types are unprecedented in both hydroxylamine and organometallic chemistry. Compounds **1** and **3** adopt a doubly bridged fenestrane-like $Zn_5N_6O_6$ core with two dangling $NR_2$ moieties, whereas *i*PrZn species **2** comprises an octahedroid backbone with all donor atoms attached to the five Zn nuclei with the maintenance of the same heteroatom composition as **1** and **3**. Variable-temperature $^{13}C$ NMR experiments of all-ethyl cluster **3** reveal that the $R_2NO^-$ ligands rapidly exchange between the $RZn^+$ and $Zn^{2+}$ cations. This process is rationalised by a plausible model which also points out that the core structure of **3** could be an intermediate motif in the observed heteroatom connectivity exchange. In line with this, computational investigations reveal that both skeletons are very similar in energy. In sum, the coordination flexibility of the hydroxylamide ligand makes this group of organometallic zinc complexes a highly dynamic family of cluster compounds.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Compared to organometallics of the trivalent group 13 elements, zinc requires further contact to a donor atom to reach coordination number (CN) four because of its divalent nature. In metal alkoxide/aryloxide chemistry,[1] an increase in aggregate dimensionality is already well established [compare the $Al_2O_2$ ring $\{(Me_2Al)[O(2,6\text{-}iPr_2\text{-}C_6H_3)]\}_2$[2] with the "double cube" $[(MeZn)_3(OMe)_4]_2Zn$[3] (CN = 4, 6)].[4] The highly diverse chemistry of the O–N double-donor array (hydroxylamines or oximes) provides a plethora of aggregation motifs, for example in group 13 complexes,[5–9] and ought to be transferable to zinc for the exploration of similar extensions {compare the six-membered ring dimer $[(Me_2Al)(ON{=}CMe_2)]_2$[5a,5b] with the tetrahedroid oximate $[(MeZn)(ON{=}CMe_2)]_4$[10] (CN = 4)}. The high coordination flexibility of the hydroxylamide ligands that is demonstrated in Al and Ga organometallics (e.g. in the readily fluctuating tetracyclic $Al_3$ cluster $[\{(Me_2Al)[ON(Me)]_2CH_2\}_2(AlMe)]$[6]) can be expected by hypothesis to allow for the construction of highly dynamic Zn-based multinuclear cluster compounds. Zinc, on its own accord, has a very rich alkoxide chemistry.[1,3] However, hydroxylamide derivatives of divalent metals are rather poorly understood and encompass merely inorganic coordination compounds of zinc[11] {e.g. $[(H_2NOH)_2ZnCl_2]$, Crismer's salt[12]}, but organometallic examples are completely unknown.

We report herein the initial evidence to support the above hypothesis. The reaction of *N*,*N*-dialkylhydroxylamines $Me_2NOH$ or $Et_2NOH$ with binary zinc alkyls affords three pentanuclear organozinc cluster compounds: $[Zn(RZn)_4(ONMe_2)_6]$ (**1**: R = Me; **2**: R = *i*Pr) and $[Zn(EtZn)_4(ONEt_2)_6]$ (**3**, vide infra).

## Results and Discussion

With the focus on compounds **1** and **2** (Scheme 1), it is elegantly revealed that the highly flexible coordinating O–N ligands allow Zn atoms to adopt a CN > 4. This

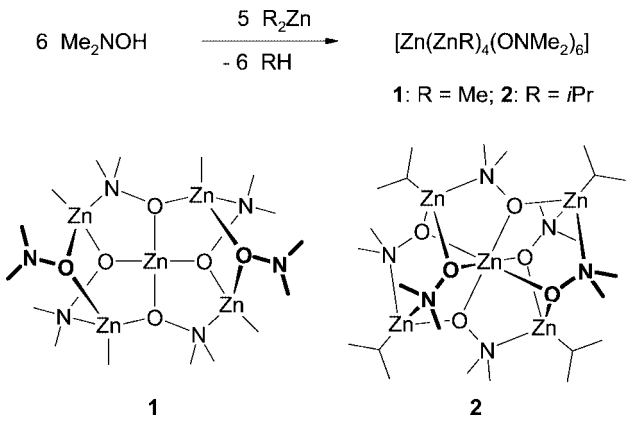
stands in contrast to the isoelectronically related organozinc hydrazides (N–N double-donor), where zinc is exclusively tetracoordinate.[13]



Scheme 1.

Though the formulae of **1** and **2** (apart from the alkyl groups on Zn) are identical, their three-dimensional coordination frameworks differ markedly. The all-methyl cluster $[Zn(MeZn)_4(ONMe_2)_6]$ (**1**) adopts a fenestrane-like motif, as determined by X-ray diffraction analysis (Figure 1).[14] Four O–N moieties coordinate around the central "inorganic" $Zn^{2+}$ ion by their oxygen atoms and are themselves interconnected by $RZn^+$ units via O–Zn–N linkages. The resulting dicationic heterofenestrane $\{[Zn(ONMe_2)_4(ZnMe)_4]^{2+}\}$ is then charge-compensated by two anionic $\mu^2$-O-bridging $Me_2NO^-$ ligands. If the latter are neglected, the core of **1** is reminiscent of a handful of known complexes (e.g. in bioinorganics),[15] but those complexes exhibit solely square-planar coordinated central metal ions and have no M–C bonds. The aggregation motif of **1** (all Zn atoms: CN = 4) is unprecedented in both hydroxylamine and organometallic chemistry.

With a subtle size change of the alkyl group at zinc (from Me to *i*Pr), the core structure of the aggregate completely shifts as revealed by the crystal structure of ether solvate **2**·$OEt_2$ (Figure 2).[14] In this cluster, the ether molecule fills a void but does not contact any of the Zn atoms. The hydroxylamide cluster $[Zn(ONMe_2)_6(Zn\textit{i}Pr)_4]$ (**2**) adopts an octahedral-based structure with all six O–N ligands O-bound to the central $Zn^{2+}$ (CN = 6). Charge compensation of this $[Zn(ONMe_2)_6]^{4-}$ fragment is achieved by four $\textit{i}PrZn^+$ groups, which bind to the six O–N units either in an N,O,O- or in an N,N,O mode. Because all of the O and N atoms are now coordinated to Zn, this contrasts the situation in **1** which has two dangling $NMe_2$ groups – one key feature of the observed coordination "isomerism". Consequently, cluster **2** is one of the limited examples of Zn species that exhibit mixed CNs, whether in organometallic[1,3] or in inorganic chemistry.[16]

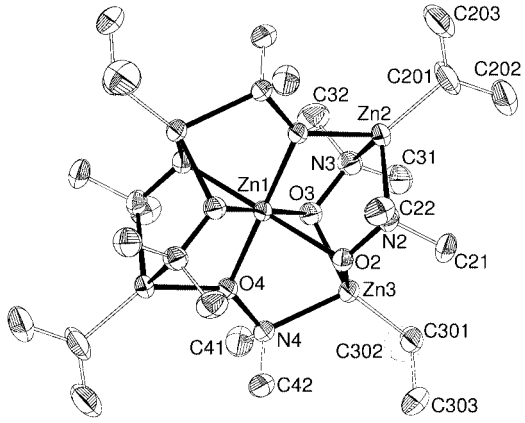


Figure 2. Solid-state structure of **2** in a crystal of the composition **2**·$OEt_2$ (thermal ellipsoids at 50% probability; hydrogen atoms and the $Et_2O$ solvate molecule are omitted; symmetry transformations used to generate equivalent atoms: $-x+1, -y+2, -z$). Selected distances and angles [Å/°]: Zn2–O4′ 1.974(2), Zn1–O2 2.205(2), Zn3–N4 2.135(2), O4–N4 1.433(2), Zn2–C201 1.987(3), N3–C32 1.467(3); O2–Zn1–O3 78.0(1), O2–Zn1–O3′ 102.0(1), O4′–Zn2–N12 85.2(1), O3–Zn3–N4 106.0(1), Zn1–O12–Zn3 102.1(1), Zn2–O3–Zn3 119.3(1), Zn3–O3–N3 108.5(1), Zn2–O3–N3 122.8(1), Zn3–N4–O4 112.2(2), Zn3–N4–C41 109.0(2), O3–N3–C33 106.9(2), C41–N4–C43 110.8(3).

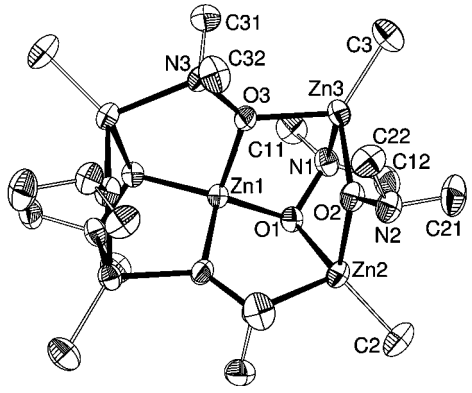

Figure 1. Crystal structure of **1** (thermal ellipsoids at 50% probability; hydrogen atoms are omitted; symmetry transformations used to generate equivalent atoms: $-x+1, y, -z+3/2$). Selected distances and angles [Å/°]: Zn1–O3 1.923(3), Zn2–O1 2.100(2), Zn3–N1 2.175(3), O3–N3 1.435(4), Zn2–C2 1.966(4), N3–C32 1.464(5); O1–Zn2–O2 86.8(1), O1–Zn1–O1′ 132.5(1), O3–Zn3–N1 85.8(1), O2–Zn2–N3′ 103.5(1), Zn1–O1–Zn2 100.0(1), Zn2–O2–Zn3 121.9(1), Zn1–O1–N1 107.9(2), Zn3–O2–N2 123.8(2), Zn3–N1–O1 107.3(2), Zn2–N3′–O3′ 111.6(2), Zn2–N3′–C32′ 110.2(3), O2–N2–C21 107.2(3), C21–N2–C22 109.8(4).

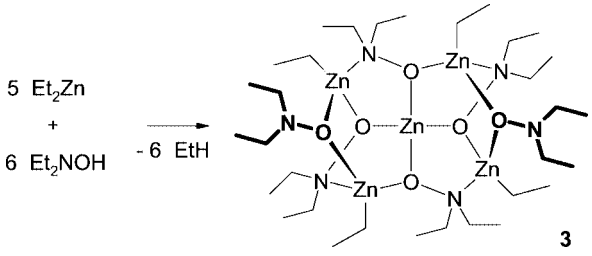
Although the structures of **1** and **2** are not the same, their core compositions are, and thus, the question arises whether a pathway for the interconversion between the two cluster types exists. VT-NMR spectroscopy sheds some light onto this and onto the molecular dynamics of the aggregates. Between 300 and 200 K, the $^1H$ NMR spectra of **1** show some signal broadening but no substantial change to indicate structural variations; the $^{13}C$ NMR spectra give a similar picture. A drawback to these measurements is the limited solubility of **1** especially at low temperatures, which is most probably due to its minimal alkyl periphery.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Fortunately, the all-ethyl analogue $[Zn(EtZn)_4(ONEt_2)_6]$ (**3**, Scheme 2) is much more soluble and represents an exquisite VT-NMR substitute for all-methyl cluster **1** because it adopts the same core motif (Figure 3). Furthermore, the fact that **1** and **3** exhibit the same coordination framework underlines that the structural differences between **1** and **2** cannot be accounted for merely by means of the steric congestion of the "organic sphere" about the $Zn_5N_6O_6$ heteroatom core. The number of carbon atoms in that sphere doubles from 16 (compound **1**) to 32 (compound **3**) without any effect on the aggregation motif. Exchange of the $MeZn^+$ groups (compound **1**) by $iPrZn^+$ groups (compound **2**) increases that number only by 8 (from 16 to 24). A simple focus on group sizes – though obvious when only differences between **1** and **2** are examined based on the literature findings of EtZn boryloxides[17] or Stephan's bulky $Me_2Al$ aryloxide[2] (compared to "normal" Al–O organyls with CN $> 4$[1]) – is not a definite reason for the varied CN of the present organozinc hydroxylamides. In fact, if bulkiness of the group had an influence on the CN of the central "inorganic" $Zn^{2+}$ nucleus, the opposite trend in the CN would be expected. The overall packing in the aggregation motif found for **2** is more compact than the one found for **1** and **3**.



Scheme 2.

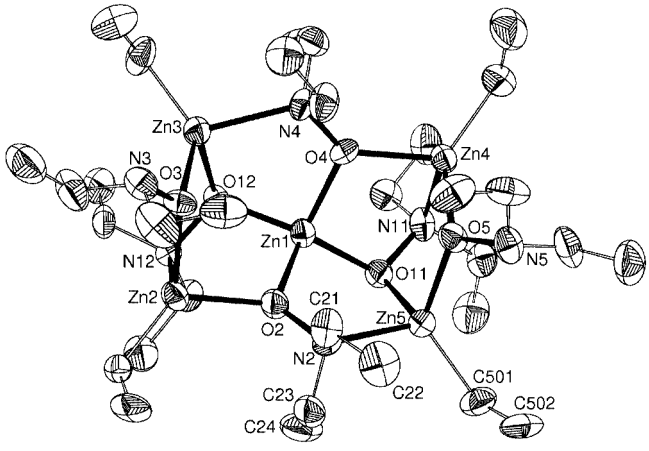


Figure 3. Crystal structure of **3** (thermal ellipsoids at 50% probability; hydrogen atoms and the disorder of the ethyl group at Zn2 are omitted). Selected distances and angles [Å/°]: Zn1–O11 1.944(7), Zn2–O3 2.041(7), Zn4–N11 2.186(9), O2–N2 1.444(11), Zn5–C501 1.972(12), N2–C23 1.461(15); O5–Zn5–O11 88.7(3), O11–Zn1–O12 139.7(3), O2–Zn2–N12 86.2(3), O3–Zn3–N4 107.8(3), Zn1–O11–Zn5 102.3(3), Zn4–O5–Zn5 117.7(3), Zn1–O12–N12 109.7(5), Zn4–O5–N5 121.9(6), Zn4–N11–O11 104.5(5), Zn5–N2–O2 112.9(6), Zn5–N2–C21 112.6(7), O2–N2–C23 106.0(8), C21–N2–C23 110.8(10).

The $^{13}C$ NMR spectrum of **3** at 298 K exhibits broad features for the nitrogen-bound ethyl substituents in the regions between ca. 50 and 60 ppm and between ca. 10 and 15 ppm (Figure 4). At 213 K however, all five resonances are well-resolved and observable. This is in accordance with a $C_2$ molecular symmetry with freely rotating O–N bonds to the dangling $NEt_2$ groups. The ethyl groups at zinc give two sets of sharp resonances at both low and ambient temperatures. Obviously, the $R_2NO^-$ units in compounds **1** and **3** exchange between the five Zn nuclei in a highly fluxional manner.

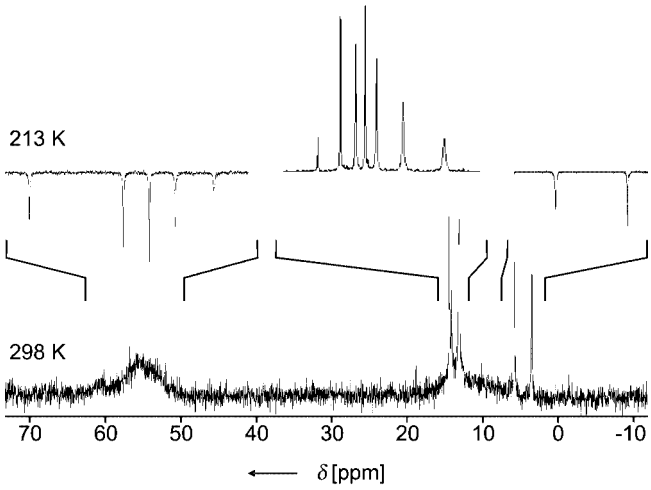

Figure 4. Details of the $^{13}C$ NMR spectra of $[Zn(ZnEt)_4(ONEt_2)_6]$ (**3**) at 298 K (in $[D_6]$benzene) and at 213 K (in $[D_8]$toluene, DEPT 135 mode).

The $^1H$ NMR spectrum of **2** (Figure 5) displays one prominent resonance for the $Me_2NO^-$ units at 300 K, which indicates an exchange on the NMR time scale comparable in magnitude to that found for the $R_2NO^-$ units of **1** and **3**. At temperatures below 270 K, this peak splits into a complex set of signals of rather low resolution. Thus, a drop in the symmetry of the molecule below that of the crystalline state ($C_2$) can be assumed since the latter would require six chemically different *N*–Me groups. From the complexity of the NMR spectrum, the presence of more than one isomeric species in solution is reasonable. The two motifs found in the solid state for **1** and **2** are two likely possibilities.

The observed highly dynamic behaviour is consistent with rapidly isomerising aggregates. A plausible model is illustrated in Scheme 3a with the heteroatom core of **1**. The process by which this core is transformed into itself can be reasoned by the division of the process into four single steps.[18,19] The first two steps involve the bond formation between the peripheral noncoordinated N atom and an $RZn^+$ group [colour code: green (1)]; in addition, there is a change in connectivity of the O atom of the hydroxylamide from a peripheral Zn atom to the central Zn atom [colour code: orange (2)]. The central Zn atom then becomes hexa-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

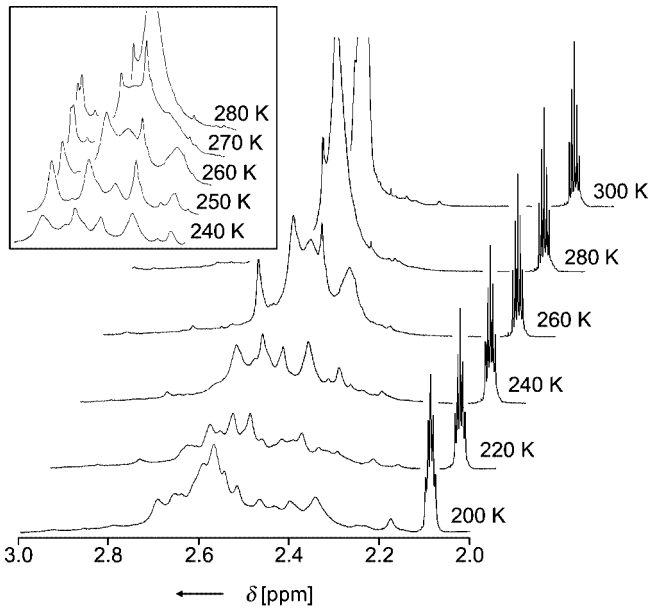

Figure 5. Variable-temperature $^1$H NMR spectra of **2** (in [$D_8$]toluene) in the chemical shift region of the $ONMe_2$ moieties. For clarity, the highlighted temperature range around the coalescence point is provided in steps of 10 K.

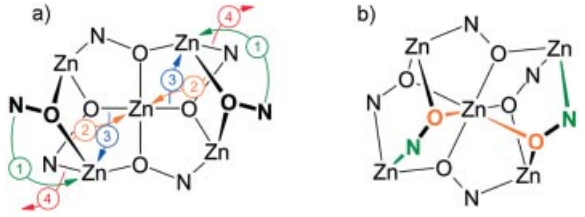
coordinate, and this finalises the transformation of the core structure from the type adopted by compound **1** to that of **2** in the crystalline state.



Scheme 3. a) Plausible model for the fluctuation of the O–N ligands. The overall $C_2$ symmetry compels each step to occur twice. b) The isomeric heteroatom cluster core as found for **2** in the solid state – an "intermediate" of the periodical fluctuation.

Two further steps that are reverse in nature to the preceding two allow the ligands to rearrange about the $RZn^+$ and $Zn^{2+}$ atoms to reconstruct the heteroatom connectivity pattern as found in the solid state of **1** {the O atom of one O–N unit moves from the central $Zn^{2+}$ nucleus to a peripheral $RZn^+$ group [colour code: blue (3)], and the N atom of the same O–N unit disconnects from the organozinc residue to become the dangling $NR_2$ group [colour code: red (4)]}.

In order to gain more detailed insight into the energetics of these systems, we calculated the energies of the two cluster types represented by **1** and **2** in the crystalline state for the most simple cases, all-methyl compound **1** and the $MeZn^+$ analogue of **2**, because both are unaffected by substituent conformations. The computations were carried out at the SCF/SV(P) and RI-BP/SV(P) levels of theory and reproduce the core structure parameters of the experimentally determined geometries well. At the SCF/SV(P) level, the aggregation adopted by compound **1** is slightly preferred by 5.4 kcal mol$^{-1}$. At the RI-BP/SV(P) level, the reverse was found; the structure of compound **2** was preferred with an energy difference of 1.2 kcal mol$^{-1}$.[20]

The small differences in the theoretical calculations along with the temperature-dependent NMR studies reveal both aggregation motifs to be very comparable in energy. This explains the sensitivity of the observed aggregation and coordination modes on small substituent effects and the highly dynamic behaviour of the species. Thus, pentanuclear organozinc hydroxylamides **1**–**3** disclose for the first time that a metal can be flexibly coordinated by O–N ligands not only in terms of coordination modes but also numbers. On the basis of the experimental findings and the unique ability of the hydroxylamide ligand to be flexibly coordinating, this group of organometallic zinc complexes forms a highly dynamic family of cluster compounds.

## Experimental Section

**CAUTION:** Pure zinc organyls may spontaneously ignite upon contact to air or moisture!

**Materials and Methods:** All manipulations were carried out under a dry nitrogen atmosphere with standard Schlenk and high-vacuum techniques with double manifolds or in a glove box (MBraun Lab Master 130) operated under an argon atmosphere. All solvents were purified by standard procedures immediately prior to use. $Me_2Zn$ was obtained in its pure form by the fractional distillation of a commercial solution (2.0 M in toluene, Aldrich). $Et_2Zn$ (Crompton GmbH, Bergkamen, Germany) was transferred into glassware in the glove box and used without further purification. $i Pr_2Zn$ was synthesised according to the literature[21] and further purified by fractional condensation (removal of trace $Et_2O$ from synthesis). It was stored in the dark at –78 °C because it decomposes quite quickly upon exposure to light or ambient temperature. $Me_2NOH$ was obtained from its hydrochloride salt (Aldrich) by treatment with excess $NH_3$ at –78 °C and separated from the $NH_4Cl$ residue by distillation.[22] $Et_2NOH$ (Aldrich) was purified by fractional distillation.

**General Synthetic Protocol:** $R_2Zn$ (R = Me, Et or *i*Pr) was condensed into a round-bottomed flask and then diluted with *n*-hexane to generate a ca. 1 M solution. With heavy stirring, a solution of $Me_2NOH$ or $Et_2NOH$ in THF (ca. 1 M) was slowly added at 0 °C. The ice bath was removed, and the reaction mixture was stirred until gas evolution had ceased. All volatiles were evaporated under reduced pressure, and the colourless to light yellow viscous solid was extracted with *n*-hexane/$Et_2O$ and filtered. The resulting solution was carefully concentrated under reduced pressure and stored at –26 °C (**1** and **3**) or –45 °C (**2**) for several days to yield colourless crystals.

**1:** From $Me_2Zn$ (15.8 mmol, 1.51 g) in *n*-hexane (15 mL), and $Me_2NOH$ (19.0 mmol, 1.16 g, 1.30 mL) in THF (20 mL). Colourless cubes. Yield 1.35 g (1.80 mmol, 57%). $^1$H NMR (200.1 MHz, $C_6D_5CD_3$): $\delta$ = –0.68 to –0.15 (m, 12 H, 4×ZnC$H_3$), 2.20–3.00 [m, very br., 36 H, 6×N(C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR (50.3 MHz, $C_6D_5CD_3$): $\delta$ = 3.4, 5.7 [2×(2 C, 2×ZnC$H_3$)], 51–61 [very br., 12 C, 6×N(C$H_3$)$_2$] ppm. $C_{16}H_{48}N_6O_6Zn_5$ (747.47): calcd. C 25.71, H 6.47, N 11.24; found C 25.34, H 6.32, N 11.12.

**2:** From $i Pr_2Zn$ (17.4 mmol, 2.64 g) in *n*-hexane (20 mL), and $Me_2NOH$ (21.0 mmol, 1.28 g, 1.44 mL) in THF (20 mL). Colourless blocks. Yield 2.70 g (2.89 mmol, 83%). $^1$H NMR (200.1 MHz,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$CDCl_3$): $\delta$ = 0.53 [sept, $^3J_{H,H}$ = 7.5 Hz, 4 H, 4×ZnC*H*($CH_3$)$_2$], 1.25 [d, $^3J_{H,H}$ = 7.5 Hz, 24 H, 4×ZnCH($CH_3$)$_2$], 2.70 [s, 36 H, 6×N($CH_3$)$_2$] ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz, $CDCl_3$): $\delta$ = 11.6 [4 C, 4×Zn*C*H($CH_3$)$_2$], 24.6 [8 C, 4×ZnCH(*C*H$_3$)$_2$], 52.9 [12 C, 6×N(*C*H$_3$)$_2$] ppm. MS (EI = 70 eV): *m*/*z* (%) = 648 (100) {M + H –(*i*Pr) –[(*i*Pr)ZnONMe$_2$]}$^+$. $C_{24}H_{64}N_6O_6Zn_5$ (859.66): calcd. C 33.53, H 7.50, N 9.78; found C 33.24, H 7.43, N 9.65.

**3:** From $Et_2Zn$ (19.0 mmol, 2.35 g) in *n*-hexane (20 mL), and $Et_2$-NOH (22.9 mmol, 2.04 g, 2.35 mL) in THF (20 mL). Colourless blocks. Yield 3.36 g (3.46 mmol, 91%). $^1H$ NMR (599.8 MHz, 298 K, $C_6D_5CD_3$): $\delta$ = 0.37, 0.37 [2×(q, $^3J_{H,H}$ = 8.1 Hz, 4 H, 2×ZnC*H*$_2$CH$_3$)], ca. 0.85–1.25 [m, very br., 24 H, 4×N$_{coord}$(CH$_2$C*H*$_3$)$_2$], 1.25 [t, $^3J_{H,H}$ = 7.2 Hz, 12 H, 2×N$_{uncoord}$(CH$_2$C*H*$_3$)$_2$], 1.51, 1.53 [2×(t, $^3J_{H,H}$ = 8.1 Hz, 6 H, 2×ZnCH$_2$C*H*$_3$)], ca. 2.70–3.20 [m, very br., 24 H, 6×N(C*H*$_2$-CH$_3$)$_2$] ppm. $^1H$ NMR (599.8 MHz, 213 K, $C_6D_5CD_3$): $\delta$ = 0.40–0.57 (m, 8 H, 4×ZnC*H*$_2$CH$_3$), 0.75, 0.86 (2×{t, br., 2×[3 H, 2×N$_{uncoord}$(CH$_2$C*H*$_3$)$_2$]}), 1.18, 1.21, 1.27, 1.28 (4×{t, br., 2×[3 H, 4×N$_{coord}$(CH$_2$C*H*$_3$)$_2$]}), 1.67, 1.69 [2×(t, br., $^3J_{H,H}$ = 8.3 Hz, 6 H, 2×ZnCH$_2$C*H*$_3$)], 2.27 (q, br., $^3J_{H,H}$ = 6.1 Hz), 2.64 (q, br.), 2.69 (q, br., $^3J_{H,H}$ = 6.3 Hz), 2.81 (q, br., $^3J_{H,H}$ = 6.9 Hz), 2.83 (q, br., $^3J_{H,H}$ = 6.9 Hz), 2.88 (q, br., $^3J_{H,H}$ = 6.4 Hz), 2.97 (q, br., $^3J_{H,H}$ = 6.2 Hz), 3.08 (q, br.), 3.80 (m, br.) {8×(2 H, N$_{coord}$C*H*$_2$CH$_3$); 1×[4×2 H, 2×N$_{uncoord}$(C*H*$_2$CH$_3$)$_2$]} ppm. $^{13}C\{^1H\}$ NMR (50.3 MHz, 298 K, $C_6D_6$): $\delta$ = 3.4, 5.7 [2×(2 C, 2×Zn*C*H$_2$CH$_3$)], ca. 11–17 [very br., 8 C, 4×N$_{coord}$(CH$_2$*C*H$_3$)$_2$], 13.1 [4 C, 2×N$_{uncoord}$(CH$_2$*C*H$_3$)$_2$], 14.1, 14.4 [2×(2 C, 2×ZnCH$_2$*C*H$_3$)], ca. 51–61 {very br., 12 C, 4×[2 C, 2×N$_{coord}$(*C*H$_2$CH$_3$)$_2$]; 1×[4 C, 2×N$_{uncoord}$(*C*H$_2$CH$_3$)$_2$]} ppm. $^{13}C\{^1H\}$ NMR (150.8 MHz, 213 K, $C_6D_5CD_3$): $\delta$ = 2.4, 5.4 [2×(2 C, 2×Zn*C*H$_2$CH$_3$)], 12.3, 13.0 [2×(2 C, 2×ZnCH$_2$*C*H$_3$)], 13.6, 13.8, 13.9, 14.2, 14.7 {4×[2 C, 2×N$_{coord}$(CH$_2$*C*H$_3$)$_2$]; 1×[4 C, 2×N$_{uncoord}$(CH$_2$*C*H$_3$)$_2$]}, 51.8, 53.8, 55.1, 56.4, 61.2 {4×[2 C, 2×N$_{coord}$(*C*H$_2$CH$_3$)$_2$]; 1×[4 C, 2×N$_{uncoord}$(*C*H$_2$CH$_3$)$_2$]} ppm. $C_{32}H_{80}N_6O_6Zn_5$ (971.87): calcd. [4] Note that within the metal alkoxides of group 13 (especially those of Al), a strong tendency of the metal/metal complex fragment to be bound by at least one additional donor unit is common and gives the metal a CN >4 (see ref.[1]). This is only suppressed if ligands of elevated steric demand are incorporated (see ref.[2]). Nevertheless, this tendency is mainly due to the Lewis-acidity and/or oxophilicity of the group 13 elements and cannot be accounted for by means of core shell saturation demands, as it is the case with Zn.

[18] For clarity, the single steps of isomerisation are discussed as if they occurred one after the other. By logic, a nearly simultaneous course of bond formation and disconnection is most likely to exist.
[19] In principle, the whole process of isomerisation of the heteroatom array into itself would consist of six such periods (if the single atoms of a same element were labelled distinguishable). After one period, a molecule equal by connectivity, but of inverted stereochemistry would be furnished. Thus, after three periods, the starting molecule would be reattained in its enantiomeric form. Conversion of this *ent*-molecule back to its original would then call for another three periods.

# Lead Halide Layers Linked by *trans*-Cu(Gly)$_2$ (Gly = $^{-}O_2C–CH_2–NH_2$) Pillars in Heterometallic Glycinate Based Organic–Inorganic Hybrids

**Wenhua Bi,[a] Nicolas Mercier,*[a] Nicolas Louvain,[a] and Michel Latroche[b]**

**Keywords:** Amino acids / Lead halides / Layered compounds / Glycinato / Copper

The novel hybrid compounds $Pb_2Cu(O_2C–CH_2–NH_2)_2X_4$ (X = Br, Cl) were prepared and characterized by single-crystal X-ray diffraction. TA analysis and DSC measurements show that the compounds are stable up to 200 °C. As in hybrid perovskites, their layered structures are based on metal(II) halide 2D frameworks, which are here covalently linked by *trans*-Cu(Gly)$_2$ flat SBUs. These rigid pillars are able to accommodate some of the void that exists in between the $PbX_2$ layers. However, the results from hydrogen absorption experiments that were conducted at 77 K indicate that the hybrids are not good candidates for absorption materials.

## Introduction

During the past decade, organic–inorganic compounds have received considerable attention because of the opportunity that exists to combine useful properties of both components. For example, in hybrid perovskites, whose typical formula is $(R\text{-}NH_3)_2M^{II}X_4$, the organic component allows the solution to be processed as thin films by room temperature techniques such as spin-coating, whereas the inorganic component may possess semiconducting properties.[1] Extensive work has been notably devoted to the study of materials that are based on iodostannate perovskite layers that can be used as semiconducting channels in thin-film field-effect transistors (TFTs)[2] with the potential of relatively high electrical mobility. For instance, a mobility of $0.6\ cm^2\ V^{-1}\ s^{-1}$ is attained in $(C_6H_5C_2H_5NH_3)_2SnI_4$.[2a] Nevertheless, this value remains two orders of magnitude smaller than that evidenced in $CH_3NH_3SnI_3$, which is a 3D perovskite with metallic conductivity.[3] Several strategies have been considered in order to improve the charge carrier mobility of such semiconducting thin film materials. This includes the search of new, possibly nonperovskite, halogenometallate-based salts.[4] Another way is to tune the bandgap that is associated to a given perovskite network. This is made possible because of the incorporation of selected cations that are able to impact the bonding features of the inorganic framework.[5] Hybrids with enhanced structural dimensionality have also been considered.[6,7] In particular, we recently showed that in $[Cu\{O_2C\text{-}(CH_2)_3\text{-}NH_3\}_2]PbBr_4$ the amino carboxylic acid zwitterionic molecules led both to the stabilization of a layered hybrid perovskite and to the formation of a Br–Cu–Cu–Br covalent bond pathway between adjacent perovskite layers.[7] In relation to amino acids, several coordination compounds have been prepared from molecules that adopt their zwitterionic form.[7–9] However, amino acids, which are ubiquitous in biology, are often used in material chemistry (e.g. coordination polymers, open-framework compounds) in their basic form, as they can coordinate to metal ions through both its carboxylate group and its amino group. With a focus on glycine, metal(II) glycinate salts that are based on robust $M^{II}(Gly)_2$ entities are often cluster-type[10] or pseudo 1D compounds;[11] only a few 2D coordination polymers of heterometallic glycinates have been reported.[12]

In this communication, we report the preparation and the X-ray structural characterization of two 3D heterometallic glycinate hybrids $Pb_2Cu(O_2C–CH_2–NH_2)_2X_4$ [X = Br (**1**), Cl (**2**)]. In the structure of both complexes, the adjacent lead halide layers are linked by *trans*-Cu(Gly)$_2$ (Gly = $^{-}O_2C–CH_2–NH_2$) to form 3D frameworks. These layered structures can be conceptually considered as a result of the intercalation of neutral *trans*-Cu(Gly)$_2$ entities in the $PbX_2$ layered network. The rigid pillars do not accommodate much of the void in between the $PbX_2$ layers and the structures are not porous[13] because of the small size of the glycinate ligand.

## Results and Discussion

Reactions of glycine, copper halide, and lead halide (halide = Br, Cl) give rise to two hybrid compounds:

$Pb_2Cu(O_2C–CH_2–NH_2)_2X_4$ [X = Br (**1**), Cl (**2**)]. A broad band in the 500–800 nm range with a maximum at about 620 nm, is observed in their UV/Vis absorption spectra, which is correlated to the blue color of the crystals and is assigned to a 3*d*–3*d* electronic transition of cupric ions (ESI). The form of the amino acids ($HO_2C$-R-$NH_2$) in the solution varies according to the pH value of the solution. The amino acids will be in the cationic, zwitterionic, or basic form in acidic, neutral, or basic solutions, respectively. In the field of hybrid perovskites, bifunctional molecules such as $HO_2C$-R-$NH_3^+$ have already been used by us and we demonstrated the role of 1D carboxylic acid supramolecular synthons in the formation of a noncentrosymmetrical hybrid perovskite structure.[14] Recently, we have also shown that $^-O_2C$-$(CH_2)_3$-$NH_3^+$ zwitterionic molecules form a paddle-wheel-type of cluster with copper, which connects the perovskite layers that are stabilized by ammonium counterions.[7] Here, we show that a mixture of glycine, copper, and lead halide, under neutral conditions, affords nice blue crystals of $Pb_2Cu(O_2C–CH_2–NH_2)_2X_4$ (X = Br, Cl) containing $^-O_2C–CH_2–NH_2$ anions. The compound crystallizes in the $P2_1/c$ space group, and the crystal structure can be described as layers of lead(II) halide that are linked together by *trans*-$Cu(Gly)_2$ pillars (Figure 1). Copper ions are at the center of a symmetrical unit that consists of two glycinato ligands, and all non-hydrogen atoms approximately lie in a plane that contains the *c* axis (Figures 1 and 2). Two more weakly bonded bromine atoms complete the [4+2] copper(II) coordination sphere as a result of the Jahn–Teller effect (Figure 1). All bond lengths [**1**: $d_{N–Cu}$ = 1.972(5) Å, $d_{O–Cu}$ = 1.967(4) Å, $d_{Br–Cu}$ = 3.167(4) Å; **2**: $d_{N–Cu}$ = 1.959(4) Å, $d_{O–Cu}$ = 1.976(3) Å, $d_{Cl–Cu}$ = 2.995(4) Å] are in good accordance with those reported in the literature for $Cu(Gly)_2$ entities[10,11] or Cu–Br in [4+2] copper polyhedra.[15]

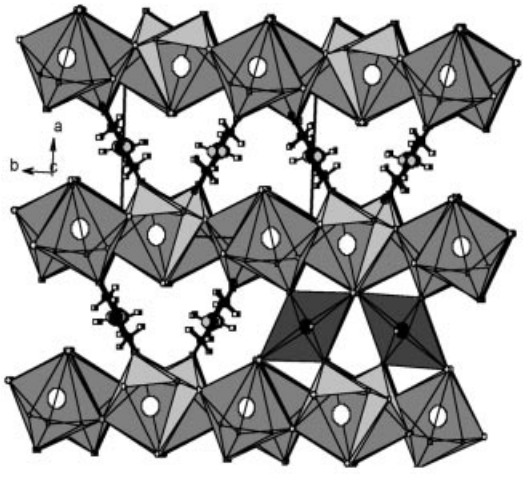

Figure 1. Structure of $Pb_2Cu(O_2C–CH_2–NH_2)_2Br_4$ viewed along the *c* axis that shows layers of lead polyhedra linked by pillars formed by *trans*-$Cu(Gly)_2$ entities. Two copper [4+2] coordination polyhedra, with the weakly bonded bromide atoms taken into account, are shown in deep grey.

Figure 2 shows *trans*-$Cu(Gly)_2$ entities and lead polyhedra that are connected to each other by the carboxylate groups of the organic ligands. The coordination mode of glycinato ligands is $[3.2_{12}\ 2_{23}\ 1_3]$ according to the Harris notation,[16] which means that the whole ligand is bound to three metals and that the donor atoms O1, O2 and N chelate to two $Pb^{2+}$ outer ions, one $Pb^{2+}$ and one inner $Cu^{2+}$ ion, and one inner $Cu^{2+}$ ion, respectively. Each lead atom is surrounded by three oxygen atoms and five bromine atoms to build a distorted polyhedron that can be described as an $O_2Br_4$ trigonal prism capped by two other Br1 and O1 atoms. The last rectangular face that is defined by O1–Br1–Br2–Br2 is open and certainly reveals the stereo effect of the $6s^2$ lone pair of electrons of lead(II) (Figure 2). Pb–O bond lengths are in the range 2.6–2.8 Å [1: O1 2.599(4) Å and 2.720(4) Å, O2 2.820(4) Å; 2: O1 2.585(3) Å and 2.682(3) Å, O2 2.777(7) Å], whereas the distance of the Pb–X bonds are in the range 2.928(1)–3.237(1) Å and 2.796(1) Å–3.120(1) Å for **1** and **2**, respectively. The ability of the soft $Pb^{2+}$ cation to be surrounded by more than six donor atoms together with the weak chelating effect of the bromine atoms allow for the formation of this layered compound which can be conceptually described to result from the intercalation of neutral *trans*-$Cu(Gly)_2$ entities into the $PbX_2$ layered structure. This intercalation would be associated with a concerted electronic effect between both components: copper(II) is stabilized by part of the electronic density that comes from the halide atoms in the lead halide layers, whereas all the lead atoms accept electronic density from the carboxylate moieties of the glycinato ligands (Figure 3).

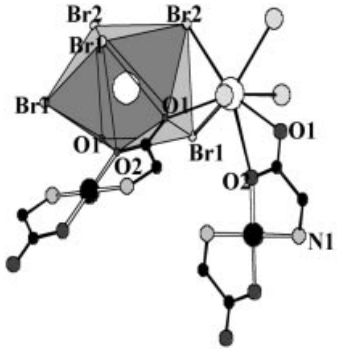

Figure 2. The coordination environment of $Pb^{II}$ and $Cu^{II}$ ions in **1** that shows the *trans*-$Cu(Gly)_2$ entities and the polyhedra of Pb linked together by the carboxylate groups of the organic ligands. The coordination mode of the glycinato ligands is $[2.2_{12}\ 2_{23}\ 1_3]$ according to the Harris notation[16] (All of the hydrogen atoms are omitted for clarity).

The representation of the structure by lead polyhedra and *trans*-$Cu(Gly)_2$ pillars (Figure 1) shows infinite channels that run along the *c* axis. However, the drawing of the [4+2] copper polyhedra in Figure 1, or a space filling representation (see Supporting Information) only show small windows, which reveals that both complexes are not porous structures with infinite channels. Nevertheless, consecutive *trans*-$Cu(Gly)_2$ pillars (or [4+2] copper polyhedra) along the *b* axis are shifted from each other by a distance of *c*/2; there are some discrete lattice voids between the lead halide layers and their spherical volume is defined by a radius of 1.6 Å.

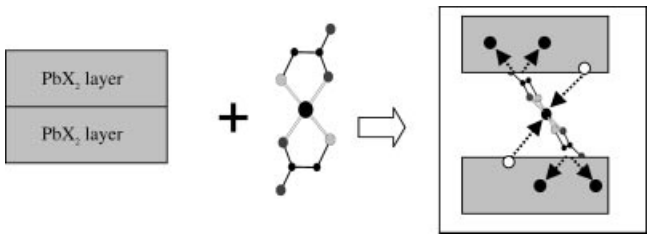

Figure 3. Schematic representation of an hypothetical intercalation of *trans*-Cu(Gly)$_2$ into the $PbX_2$ layered structure, which affords $Pb_2Cu(O_2C–CH_2–NH_2)_2X_4$. Arrows indicate the electron donor effect of the halide and the oxygen atom towards copper(II) and lead(II) ions, respectively.

$H_2$ absorption measurements were then carried out at 77 K under a pressure of up to 25 bars to give a maximum capacity at high pressure of 0.28% weight for the $Pb_2Cu(O_2C–CH_2–NH_2)_2Br_4$ sample (see Supporting Information), which is far from the values that were obtained in MOFs chemistry (1–8% range).[17]

In conclusion, we have described the synthesis and the structural characterization of 3D heterometallic glycinate salts $Pb_2Cu(O_2C–CH_2–NH_2)_2X_4$ (X = Br, Cl). As in hybrid perovskites, their layered structure is based on a metal(II) halide 2D framework, which is here covalently linked by *trans*-Cu(Gly)$_2$ units by the carboxylate groups of glycinato ligands. We now plan to use others such linkers with non-oxidative metals in order to achieve lead(II) or tin(II) iodide based materials that possess semiconducting properties. With regard to the field of coordination polymers, we have shown that the association of the glycinato ligands with both $Cu^{2+}$ and soft $Pb^{2+}$ cations and halide anions leads to an unprecedented 3D architecture. Suitable microporous coordination polymers, especially those that possess small pores or compounds that are based on ligands with incorporated open metal sites,[18] are increasingly sought, and *trans*-$M^{II}(Gly)_2$ could be considered as a building block for the design of such compounds.

## Experimental Section

**Synthesis and Thermal Analysis:** $CuBr_2$ (0.2241 g, 1 mmol, 99%) was dissolved in distilled water (60 mL). The solution was stirred and glycine (0.7539 g, 10 mmol, 99.7%) was then added. After 2 h, $PbBr_2$ (0.7345 g, 2 mmol, 98%) was added to the solution, and the solution was then heated at 60 °C and stirred for another 4 h before it was placed into an aerator. Diamond-like blue crystals were obtained several hours later in a yield of 68.3% (0.646 g, based on $CuBr_2$). The synthesis of **2** was almost the same as **1**, but blue crystals were obtained after one day in a yield of 53.6% (0.411 g, based on $CuCl_2·2H_2O$). For both compounds, X-ray powder diffraction indicated single-phase samples (ESI).

Thermogravimetric analysis measurements and differential scanning calorimetry were performed in the range of 20–900 °C and 20–450 °C, respectively. The first endothermic peak that was observed at about 200 °C was assigned to the melting of the compounds (DSC), and it occurs just before the first weight loss of 10.6% (for **1**) or 13.4% (for **2**) observed in TGA. The second weight loss of 81.3% (for **1**) or 69.8% (for **2**) can be assigned to the departure of $PbX_2$ (theoretical: **1** 77.6%, **2** 72.0%). The first weight loss probably corresponds to the departure of a part of the ligands [$H_2N–CH_2–COOH$: 150 g/mol, observed 99.3 g/mol (for **1**) or 102.9 g/mol (for **2**)], the remaining compound was CuO at higher temperature.

**Crystal Data for 1:** $C_4H_8Br_4CuN_2O_4Pb_2$, $M$ = 945.68, monoclinic, $a$ = 8.556(1) Å, $b$ = 10.971(2) Å, $c$ = 8.376(1) Å, $\beta$ = 108.68(3), $V$ = 744.8(3) Å$^3$, space group $P2_1/c$, $Z$ = 2, calculated density 4.217, crystal dimensions (mm$^3$): 0.12×0.10×0.08, $T$ = 293 K, Bruker Nonius Kappa CCD diffractometer, graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), $\mu$ = 34.69 mm$^{-1}$, $2\theta_{max}$ = 60.04°, 11337 measured reflections of which 2173 were unique ($R_{int}$ = 0.057) and 1744 had $I/\sigma(I) > 2$. The intensities were corrected for Lorentz-polarization effects, as well as for absorption effect (SADABS). The structure was solved by direct methods, and refined by full-matrix least-squares routines against $F^2$ with the use of the SHELXL97 package. Hydrogen atoms were placed in idealized positions in riding mode. The refinements of positions and anisotropic thermal motion parameters of the non-H atoms, converge to $R_{(F)}$ = 0.0274 (1744 reflections, 80 parameters), $wR_{2(F2)}$ = 0.0605 (all data), GOF on $F^2$ = 1.124, $\Delta\rho_{max}$ = 1.224 e Å$^{-3}$.

**Crystal Data for 2:** $C_4H_8Cl_4CuN_2O_4Pb_2$, $M$ = 767.84, monoclinic, $a$ = 8.424(1) Å, $b$ = 10.404(2) Å, $c$ = 8.237(1) Å, $\beta$ = 109.02(3), $V$ = 682.5(3) Å$^3$, space group $P2_1/c$, $Z$ = 2, calculated density 3.736, crystal dimensions (mm$^3$): 0.15×0.10×0.10, $T$ = 293 K, Bruker Nonius Kappa CCD diffractometer, graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), $\mu$ = 26.93 mm$^{-1}$, $2\theta_{max}$ = 60.04°, 8282 measured reflections of which 1987 were unique ($R_{int}$ = 0.039) and 1553 had $I/\sigma(I) > 2$. The intensities were corrected for Lorentz-polarization effects. The structure was solved by direct methods, and refined by full-matrix least-squares routines against $F^2$ with the use of the SHELXL97 package. Hydrogen atoms were placed in idealized positions in riding mode. The refinements of positions and anisotropic thermal motion parameters of the non-H atoms, converge to $R_F$ = 0.0276 (1553 reflections, 79 parameters), $wR_{2(F2)}$ = 0.0445 (all data), GOF on $F^2$ = 1.028, $\Delta\rho_{max}$ = 0.835 e Å$^{-3}$.

CCDC-613293 and -613294 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Hydrogen Storage Measurements:** Hydrogen storage measurements were made with a volumetric device (Sievert's method) equipped with calibrated and thermalized volumes and pressure gauges. In order to remove water and all species that can lie within the pores and channels, the samples were outgassed while heated at 150 °C over a 16 h period under primary vacuum. All weight capacities refer here to outgassed samples. For measurements at 77 K, the sample holder was immersed in liquid nitrogen and the pressure variations due to both gas cooling and hydrogen adsorption were measured with the use of high-purity hydrogen (Alphagaz H22). Under these thermodynamic conditions, the ideal gas law is no longer valid and different equations of state were used depending of the temperature ranges.[19]

**Supporting Information** (see footnote on the first page of this article): UV/Vis absorption and XRPD pattern of crystals **1** and **2**, TGA and DSC graphs of both compounds, absorption analysis and additional figures for structural illustration of **1**.

# Molecular Assembly with Axial Cyanato Ligands and Paddlewheel Tetracarboxylatodiruthenium(II,III) Fragments

**M. Carmen Barral,[a] Rodrigo González-Prieto,[a] Reyes Jiménez-Aparicio,*[a] J. Luis Priego[a] M. Rosario Torres[b] and Francisco A. Urbanos[a]**

**Keywords:** Diruthenium compounds / Metal–metal bonds / Molecular assembly / Ruthenium complexes / Cyanato ligands / Silver complexes

Homo and heteropolymetallic chains constructed with $[Ru_2(\mu\text{-}O_2CR)_4]^+$ building blocks and $OCN^-$ and $[Ag(OCN)_2]^-$ connectors are described. In the complexes $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4(OCN)]_n$ (**1**) and $\{[Ru_2(\mu\text{-}O_2CMe)_4][Ag(OCN)_2]\}_n$ (**2**) an infrequent $\mu_{1,1}$-*O* coordination mode of the $OCN^-$ ligand is observed. In addition, the formation of a Ag–OCN bond instead of the Ag–NCO coordination mode, which is more usual, is noteworthy in complex **2**.

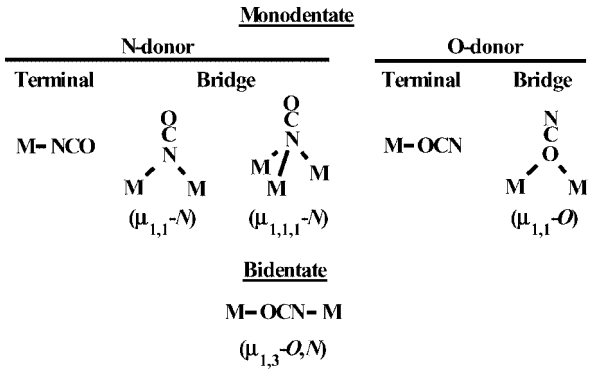
## Introduction

The use of $M_2$ paddlewheel species as building blocks to construct polynuclear assemblies has focused great interest in recent years due to the potential applications of these assemblies.[1–3] Especially, the preparation of supramolecular structures based on diruthenium cores has attracted much attention because of the singular electronic and magnetic properties of these structures.[4–7] Thus, numerous polymeric or molecular arrangements with tetracarboxylatodiruthenium(II,III) units that are linked by mononegative anions, neutral molecules or organic radicals have been described.[4,5] However, in spite of the fact that pseudohalide ligands represent an efficient way to generate interactions between metallic centres, these ligands have been little used to connect diruthenium units. Some thiocyanato complexes have been described,[8] but the cyanate group has not been used previously in this chemistry.

The cyanate group is a very versatile ligand that can be bonded in several ways. In Scheme 1 are collected the main coordination modes of this ligand. The N-bonded monodentate mode is the most usual, whereas $\mu_{1,1}$-*O* coordination has been scarcely observed.

On the other hand, the design of heteropolynuclear complexes combining the electronic and stereochemical peculiarities of two different metal ions is a very attractive strategy in obtaining complexes with interesting magnetic, electronic or electric properties.[9]



Scheme 1. Main coordination modes of the cyanato ligand.

In this communication we describe the formation of chains constructed by using $[Ru_2(\mu\text{-}O_2CR)_4]^+$ fragments and $OCN^-$ groups. The preparation of one heteropolynuclear species containing diruthenium and silver centres is also described.

## Results and Discussion

Treatment of $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4]BF_4$[10] with 5 equiv. sodium cyanate in methanol/water gives brown crystals of $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4(OCN)]_n$ (**1**). The X-ray crystal structure of **1** is shown in Figure 1.

This structure has two Ru atoms linked by four *trans*-2-methyl-2-pentenoato bridging ligands; the axial positions are occupied by cyanate groups, giving zigzag chains. These cyanato ligands are coordinated by an infrequent $\mu_{1,1}$-*O* coordination mode. The Ru–Ru and Ru–$O_{axial}$ distances are 2.2793(13) and 2.258(5) Å respectively, typical of those

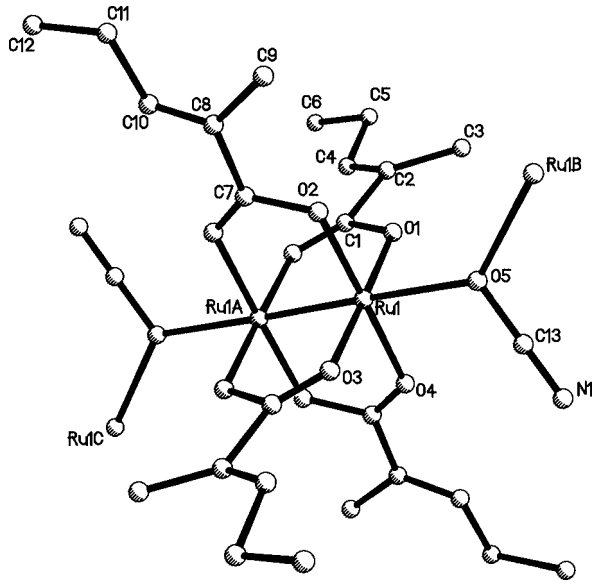

Figure 1. PLUTO view of $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4(OCN)]_n$ (**1**). Hydrogen atoms are omitted for clarity.

found in other polymeric complexes with O-donor bridging ligands.[4,5,11] The Ru–O–Ru angle [131.0(6)°] is larger than those found[4,5] in other nonlinear one-dimensional supramolecular structures formed with other bridging ligands. In contrast, the parent chlorido derivative $[Ru_2Cl\{\mu\text{-}O_2CC(Me)=CHEt\}_4]_n$ shows[10] an arrangement of linear chains in the solid state.

A methanol/water solution obtained from the reaction of $[Ru_2Cl(\mu\text{-}O_2CMe)_4]$ with $AgNO_3$ was treated again with 1 equiv. silver nitrate, and 2 equiv. sodium cyanate to give $\{[Ru_2(\mu\text{-}O_2CMe)_4][Ag(OCN)_2]\}_n$ (**2**). The crystal structure of **2** has been determined, and a PLUTO view is shown in Figure 2.

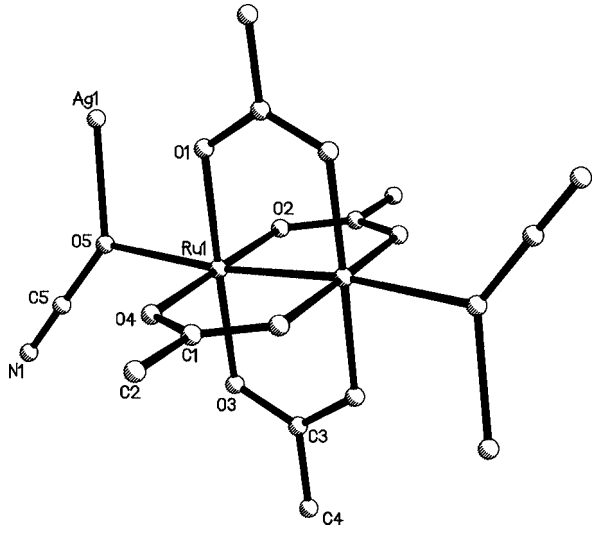

Figure 2. PLUTO view of $\{[Ru_2(\mu\text{-}O_2CMe)_4][Ag(OCN)_2]\}_n$ (**2**). Hydrogen atoms are omitted for clarity.

This compound is formed by zigzag chains that could be considered as $[Ru_2(\mu\text{-}O_2CMe)_4]^+$ units linked by $[Ag(OCN)_2]^-$ groups. The cyanato ligands display the same $\mu_{1,1}$-*O* coordination mode as those in complex **1**, but in this case they bridge the ruthenium and silver atoms (Figure 3).

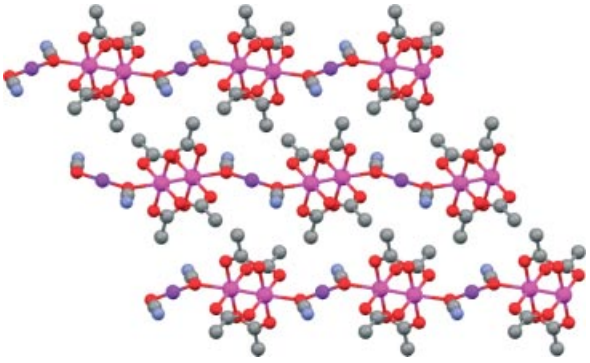

Figure 3. Packing of the zigzag chains of $\{[Ru_2(\mu\text{-}O_2CMe)_4][Ag(OCN)_2]\}_n$ (**2**). Hydrogen atoms are omitted for clarity.

The Ru–Ru bond length is 2.2740(9) Å, and the Ru–$O_{cyanate}$ bond length is 2.271(6) Å. The Ru–O–Ag angle [106.0(2)°] is smaller than the Ru–O–Ru angle in **1**.

An end-to-end (Ru–OCN–Ag) coordination mode for the cyanate group was expected in complex **2**, because the $OCN^-$ ligand is N-bonded in all the structures described[12] for silver complexes. The only exception is the compound $[Ag_2(NCO)_2(dpph)_2]$ [dpph = bis(diphenylphosphanyl)hexane], in which a $\mu_{1,3}$-*N*,*O* coordination mode has been found.[12b] Complex **2** is the first example where the cyanato ligand is coordinated to a silver centre by the oxygen atom, leaving the nitrogen atom uncoordinated. It is also noteworthy that the oxygen atom is shared with the neighbouring ruthenium atom to give $\mu_{1,1}$-*O* coordination. These results contrast with the existence of isocyanato ligands in the complex[13] $(NBu_4)[Ag(NCO)_2]$.

The magnetic measurements of both compounds show magnetic moments at room temperature corresponding to the presence of three unpaired electrons per diruthenium unit. These magnetic moments, 3.69 and 4.15 $\mu_B$ for **1** and **2** respectively, are in accordance with the ground-state configuration $\sigma^2\pi^4\delta^2(\pi^*\delta^*)^3$ proposed by Norman et al.[14] The representation of the magnetic moment vs. temperature shows a decrease in the magnetic moment, mainly at low temperatures (Figure 4).

The molar magnetic susceptibility increases continuously with decreasing temperature. This behaviour has been observed in other zigzag polymeric diruthenium(II,III) compounds and is due to a large zero-field splitting (ZFS) and a weak degree of antiferromagnetic coupling between the dimetallic units.[4–6,11] The magnetic moments for **1** are considerably lower than those for **2** in the whole temperature range. This behaviour indicates the existence of a stronger antiferromagnetic interaction in **1**. In order to estimate the *zJ* values, we have fitted the experimental magnetic data by using the model of Cukiernik et al.,[15] which incorporates

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

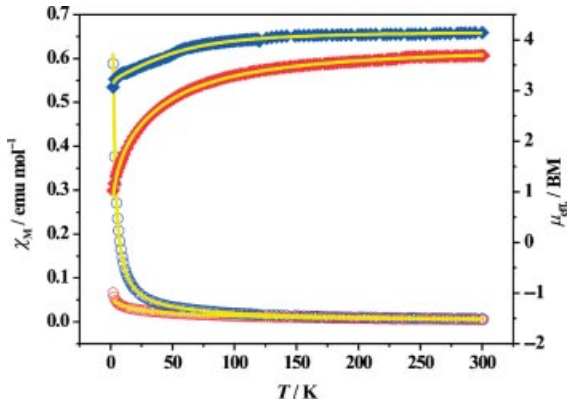

Figure 4. Temperature dependence of the molar magnetic susceptibility (●) and magnetic moment (♦) for **1** (red) and **2** (blue). The solid lines result from least-squares fits with $g = 2.0$, $D = 44.6$ cm$^{-1}$, $zJ = -5.0$ cm$^{-1}$ for **1** and $g = 2.2$, $D = 64.0$ cm$^{-1}$, $zJ = -0.1$ cm$^{-1}$ for **2**.

a strong ZFS as well as a weak intermolecular antiferromagnetism by the molecular field approximation. However, for complex **1** better parameters have been obtained with our model,[16] which introduces into the spin Hamiltonian the ZFS and a strong antiferromagnetic interaction. The fits of the experimental data (Figure 4) confirm the presence of a higher magnetic interaction for **1** (–5.0 cm$^{-1}$) than for **2** (–0.1 cm$^{-1}$). This behaviour could be explained on the basis of two factors: i) the different distances between the diruthenium units in **1** and **2** or ii) the nature of the linker $OCN^-$ or $[Ag(OCN)_2]^-$. However, a strong antiferromagnetic coupling between $Ru_2$(II,III) units with a long linker has been found by Ren et al.[17] Thus, although Ren's complex and **2** are different, we think that the difficulty of the electronic exchange through the diamagnetic $[Ag(OCN)_2]^-$ group is probably the main factor in the low magnetic coupling in complex **2**.

## Conclusions

The present work describes the first diruthenium units linked by $OCN^-$ or $[Ag(OCN)_2]^-$ groups that show an unusual $\mu_{1,1}$-*O* coordination mode. The design strategies reported in this communication lead to chains with a better magnetic interaction through the $OCN^-$ group than the $[Ag(OCN)_2]^-$ fragment. Our further work will explore the preparation of one-dimensional supramolecular structures formed by diruthenium units and anionic metallic cores.

## Experimental Section

**General Remarks:** All reactions were carried out in an inert atmosphere, by using standard Schlenk techniques. The complexes $[Ru_2Cl(\mu\text{-}O_2CMe)_4]$ and $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4]BF_4$ were prepared by literature procedures.[10,18] Other chemicals and solvents were obtained from commercial sources and used without further purification.

Elemental analyses were carried out by the Microanalytical Service of the Complutense University of Madrid. IR spectra were recorded with a Midac prospect FT-IR, or a Shimadzu FT-IR Prestige-21 spectrophotometer by using KBr discs. The variable-temperature magnetic susceptibility data were measured with a Quantum Design MPMS*XL* SQUID (Superconducting Quantum Interference Device) susceptometer over a temperature range of 2 to 300 K. All data were corrected for the diamagnetic contribution of both the sample holder and the compound to the susceptibility. The molar diamagnetic corrections for the complexes were calculated on the basis of Pascal's constants. Mass spectra were obtained with a Bruker Esquire-LC with Electrospray Ionization (ESI) by using methanol or dmso as solvent. Nominal molecular masses and isotopic distribution of all peaks were calculated with the MASAS[19] computer program by using a polynomial expansion based on natural abundances of the isotopes.

**Synthesis of $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4(OCN)]_n$ (1):** To a methanol solution (15 mL) of $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4]BF_4$ (0.22 g, 0.30 mmol) was added an aqueous solution of sodium cyanate (0.10 g, 1.50 mmol, 10 mL). The reaction mixture was stirred for 1 h. A brown precipitate was formed. The solid was filtered out, washed with water (4 × 20 mL) and dried under vacuum to give **1**. Yield: 161 mg (77%). $C_{25}H_{36}NO_9Ru_2$ (696.71): calcd. C 43.10, H 5.21, N 2.01; found C 42.98, H 5.11, N 2.13. Main IR data (KBr disk): 2968 (m), 2935 (m), 2876 (m), 2139 (vs), 2085 (w), 1647 (m), 1435 (v)s, 1415 (vs), 1384 (vs), 1349 (s), 1300 (w), 1258 (w), 1179 (m), 1105 (m), 1067 (w), 1036 (m), 989 (w), 906 (w), 841 (m), 786 w, 752 (m), 684 (s), 651 (w), 623 (w), 530 (s), 479 (w), 431 (w), 421 (w) cm$^{-1}$. $\mu_{eff.}$ (room temp.) = 3.69 $\mu_B$. Mass spectrometric data (ESI$^+$): *m*/*z* = 656 $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4]$.

Red-brown crystals of **1** suitable for X-ray diffraction were obtained when a methanol solution of $[Ru_2\{\mu\text{-}O_2CC(Me)=CHEt\}_4]BF_4$ was layered over a water solution of NaOCN.

**Synthesis of $\{[Ru_2(\mu\text{-}O_2CMe)_4][Ag(OCN)_2]\}_n$ (2):** To a suspension of $[Ru_2Cl(\mu\text{-}O_2CMe)_4]$ (0.14 g, 0.30 mmol) in methanol (10 mL) was added a solution of $AgNO_3$ (0.05 g, 0.30 mmol, 5 mL). The reaction mixture was stirred for 10 min to give a solid precipitate of AgCl and a brown solution containing the species $[Ru_2(\mu\text{-}O_2CMe)_4]^+$. The precipitate was removed by filtration, and the solution was treated again with an aqueous solution of $AgNO_3$ (0.05 g, 0.30 mmol, 10 mL) and an aqueous solution of NaOCN (0.04 g, 0.60 mmol, 10 mL). The reaction mixture was stirred for one hour, in the absence of light, and gave a brown precipitate. The solid was filtered out, washed with water (2 × 20 mL) and dried under vacuum to give **2**. Yield: 110 mg (58%). $C_{10}H_{12}AgN_2O_{10}Ru_2$ (630.22): calcd. C 19.06, H 1.92, N 4.44; found C 19.20, H 1.97, N 4.42. Main IR data (KBr disk): 2937 (w), 2155 vs, 2104 (w), 1444 vs, 1398 (m), 1349 (w), 1051 (w), 694 (s), 670 (w), 662 (w), 627 (w), 615 (w) cm$^{-1}$. $\mu_{eff.}$ (room temp.) = 4.15 $\mu_B$. Mass spectrometric data (ESI$^+$): *m*/*z* = 517 $[Ru_2(\mu\text{-}O_2CMe)_4(dmso)]$.

Crystals of **2** were obtained by slow diffusion of the solution containing the species $[Ru_2(\mu\text{-}O_2CMe)_4]^+$ and $Ag^+$ (molar ratio 1:1) over the aqueous solution of NaOCN.

**Crystal Structural Data for 1:** $C_{25}H_{36}NO_9Ru_2$, $M_r$ 696.69, crystal size 0.14 × 0.18 × 0.20 mm, monoclinic, space group *P*2/*c*, $a$ = 9.9698(8), $b$ = 12.0247(9), $c$ = 12.4202(9) Å, $\beta$ = 98.146(2)°, $V$ = 1473.96(19) Å$^3$, $Z$ = 2, $D_c$ = 1.570 g cm$^{-3}$, $F(000)$ = 706, $\mu$ = 1.072 mm$^{-1}$, 3559 independent reflections, $R_I$ [$I > 2\sigma(I)$] = 0.0865, $wR_2$ (all data) = 0.2914.

# A Novel Europium Carbodiimide that Contains Isolated Europium Tetrahedra and Parallel Chains of Edge-Sharing Open Handbag-Like $Eu_6$ Units

**Wuping Liao,[a] Ulli Englert,[b] and Richard Dronskowski*[b]**

**Keywords:** Europium / Carbodiimide / Lanthanides / Solid-state reactions / Crystal growth

$Eu_2I_2(NCN)$ is the first compound to contain discrete empty europium tetrahedra and infinite metal chains that are constructed from edge-sharing $Eu_6$ units with an open handbag-like motif. The europium tetrahedra and chains are bridged by coordinating carbodiimide ($NCN^{2-}$) anions in a three-dimensional network.

## Introduction

Within the past three decades, solid-state (metal) cluster phases have drawn significant attention due to their interesting structural features and physical properties. There are many examples of both empty metal clusters and those filled by interstitial atoms; the differing cluster connectivities result in a large variety of structural motifs.[1] For instance, $Ln_6Z$ *octahedra* (Z = main-group elements such as H, B–O, Si, Ga, and $C_2$ units but also transition metals such as Mn–Cu, Ru–Pd, and Re–Au) serve as characteristic building blocks in the metal-rich rare-earth halides.[2] On the other side, $Ln_4Z$ (Z = N, O) *tetrahedra* are found for a couple of rare-earth halides and sulfides. The different linkages of these $Ln_4Z$ tetrahedra, by corners and/or by edges, lead to a large structural richness that involves oligomeric units, chains, or layers.[3] The polymorph number V of $PrI_2$ was recently reported to contain empty tetrahedral $Pr_4$ units.[4]

Our own research has resulted in novel europium carbodiimide compounds that contain discrete, but also oligomeric, $Eu_4$ tetrahedra and 1D chains that are constructed from the tetrahedra by vertex- and face-sharing $Eu_4$.[5] Nonetheless, there are few reports that outline the coexistence of empty metal clusters and 1D metal chains except for $Ln_{13}Br_{18}B_3$ (Ln = Gd, Tb)[6] which contains both discrete $Ln_{10}B_2$ bioctahedra and 1D metal chains that are constructed from edge-sharing $Ln_6B$ octahedra. In this communication, we present the novel phase $Eu_2I_2(NCN)$, which is another example of a compound that contains discrete metal clusters and chains; the latter are constructed from edge-sharing handbag-like $Eu_6$ units.

## Results and Discussion

The crystal structure of $Eu_2I_2(NCN)$ reveals isolated empty $Eu_4$ tetrahedra and parallel 1D metal chains that are bridged by $NCN^{2-}$ anions in a 3D network in which the iodide anions are located in the interstices (Figure 1, top). To the best of our knowledge, this is the first example of a crystal structure that contains both isolated *empty* metal tetrahedra and infinite metal chains. Another characteristic feature of $Eu_2I_2(NCN)$ is given by the uncommon open handbag-like $Eu_6$ entity (Figure 1, bottom) which *embraces* one $NCN^{2-}$ anion (either located centrally or shifted to the left or right side with partial occupancies) and is capped by another two $NCN^{2-}$ anions. As mentioned above, an octahedral $Ln_6$ entity would be a more typical structure for this type of compound, and the open handbag-like configuration is quite rare and has only been observed in molecular chemistry, namely to describe one of the lowest-energy structures of the water hexamer.[7]

There are four different crystallographic positions found for the Eu units: two fully occupied sites (Eu1 and Eu2) and two other disordered sites (Eu3 and Eu4); all four of the Eu sites differ in their coordination environments with coordination numbers between 6 and 8. While the first two Eu atoms generate the empty $(Eu1)_2(Eu2)_2$ tetrahedron, the other two are responsible for the open handbag-like $(Eu3)_4(Eu4)_2$ entity. The isolated $Eu_4$ tetrahedra are capped over all triangular faces by two kinds of $NCN^{2-}$ anions (Figure 2, top), which is a typical structure. The open handbag-like $Eu_6$ entity, however, is capped by two other $NCN^{2-}$ units as described above (Figure 1, bottom).The $Eu_6$ entities are interconnected to each other by edge-sharing to result in an infinite 1D chain (Figure 1, middle). Note that the encapsulated $NCN^{2-}$ anion excludes the interpretation of the 1D chain as a row of neighboring $Eu_4$ tetrahedra (Figure 2, top) because the filled monomer is nonexistent. The capping $NCN^{2-}$ anions interconnect the $Eu_4$ tetrahedra and the 1D chains into a 3D network that contains quasihexag-

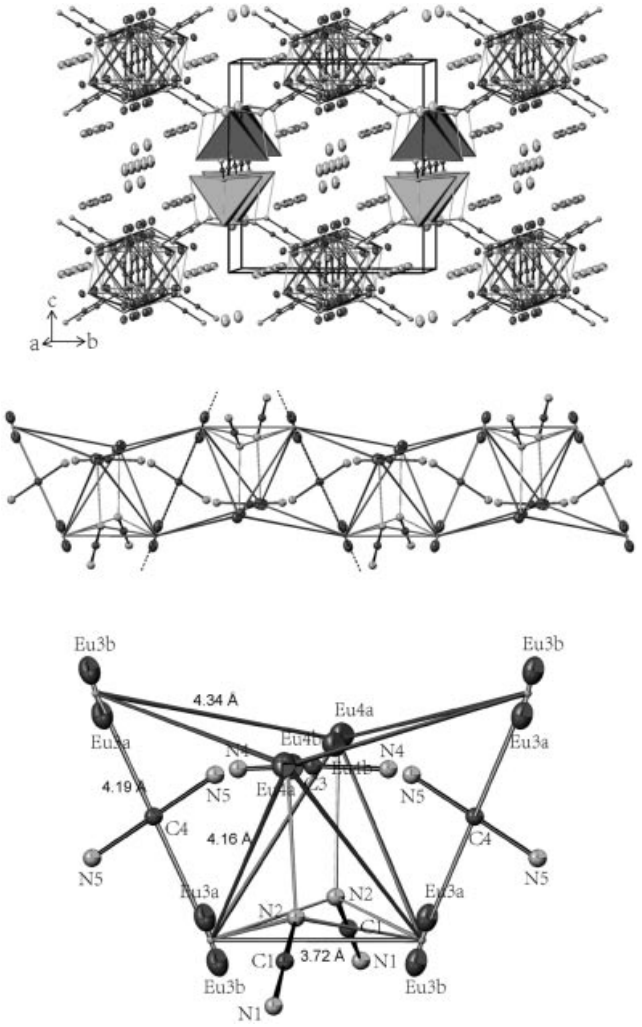

Figure 1. View of the structure of $Eu_2I_2(NCN)$ along the *a* axis which shows isolated $Eu_4$ tetrahedra and 1D metal chains (top), a single 1D metal chain with encapsulated and capping $NCN^{2-}$ anions (middle), and the open handbag-like $Eu_6$ unit coordinated by $NCN^{2-}$ anions (bottom). The I atoms are given as isolated grey spheres, Eu atoms as dark-grey spheres whereas N atoms are shown as small grey and C atoms as small dark-grey spheres.

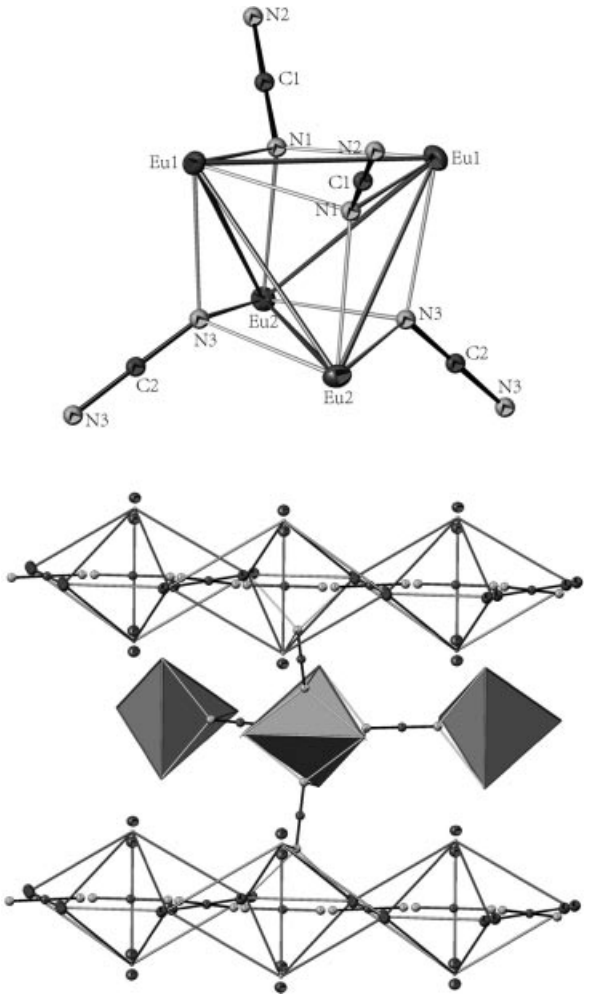

Figure 2. An isolated $Eu_4$ tetrahedron capped by $NCN^{2-}$ anions (top) and its coordination (bottom).

onal and orthorhombic channels for the iodide anions (Figure 1, top). Alternatively, the structure can be viewed as the alternate stacking of one layer of metal chains and two layers of isolated $Eu_4$ tetrahedra along the *c* axis. As a result, one $Eu_4$ tetrahedron is simultaneously interconnected to two metal chains and two other $Eu_4$ tetrahedra (Figure 2, bottom).

The Eu–Eu distances in the isolated $(Eu1)_2(Eu2)_2$ tetrahedron cover a range of 3.97–4.10 Å, which is comparable to 3.98 Å in $LiEu_2(NCN)I_3$ and 3.99–4.12 Å in $LiEu_4(NCN)_3I_3$.[5] The Eu–N bond for isolated $(Eu1)_2$-$(Eu2)_2$ is 2.60–2.62 Å, which is also comparable to 2.62 Å in $LiEu_2(NCN)I_3$ and 2.61–2.66 Å in $LiEu_4(NCN)_3I_3$. In the $(Eu3)_4(Eu4)_2$ entities, the distance between the barycenters of the electron densities of the europium sites cover a range of 3.72–4.45 Å (Figure 1, bottom, the Eu4–Eu4 distance is neglected). The bottom Eu3–Eu3 distance is much shorter (3.72 Å), which might be due to an ionic matrix effect of the nonmetal atoms[8] because there are two N atoms from the $NCN^{2-}$ anions bonded to this edge. The longer distance of the Eu4–Eu4 (4.45 Å) bond and also the Eu3–Eu4 (4.34 Å) bond might be due to the steric effect of the incorporated carbodiimide anion. The Eu–N distances (between the barycenters of Eu and N sites) lie in the range of 2.51–2.72 Å. The wide range goes back, in part, to the distortion of the Eu3 and Eu4 sites. The split positions of the Eu3 and Eu4 sites mirror the two possible sites of the encapsulated carbodiimide anion, either central or shifted to the left or right side of the $Eu_6$ unit. Nonetheless, there is no indication of any Eu valence instability (see Figure 3) and all europium atoms are clearly divalent in nature.

There are four different crystallographic sites for the C atoms which indicate that there are four different $NCN^{2-}$ anions (Table 1). Two of the anions are spatially separated and two are spatially correlated; the latter two correspond to alternatively occupied split positions. All four $NCN^{2-}$ anions have two double C=N bonds with (almost) equiva-

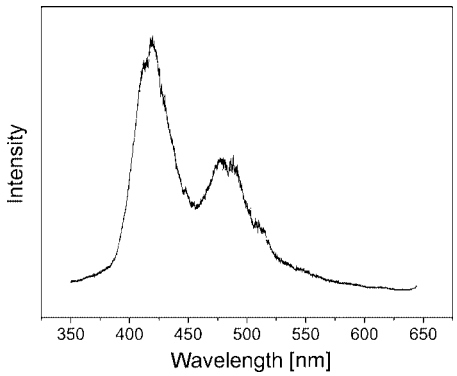

Figure 3. Photoluminescence of $Eu_2I_2(NCN)$ excited at 330 nm which indicates that europium is divalent.

lent distances such that they adopt the classic carbodiimide shape. The shape can be confirmed by analysis of the IR spectra in which characteristic carbodiimide frequencies (around 1958 $cm^{-1}$ for the asymmetric stretch and 665, 656, and 621 $cm^{-1}$ for the deformation vibration) are clearly detected. Different from the alternatively occupied N4–C3–N4 and N5–C4–N5 units, which are located in the interstices of the metal chain, the N2–C1–N1 and N3–C2–N3 units bridge all isolated $Eu_4$ tetrahedra and the metal chains in a 3D network. In particular, the N2–C1–N1 unit bridges the chain (by the N2 atom) and the $Eu_4$ tetrahedron (by the N1 atom), whereas the N3–C2–N3 unit connects two isolated $Eu_4$ tetrahedra. The N4–C3–N4 unit is slightly bent [176(3)°] whereas the other three $NCN^{2-}$ anions are linear (with N–C–N angles of 180°). Note again that an $NCN^{2-}$ unit (with 68% site probability, named N4–C3–N4) is located in the center of the spatially restricted $Eu_6$ entity, but it may also appear (with 32% occupancy, named N5–C4–N5) slightly shifted to the left or right. The very presence of these dislocated $NCN^{2-}$ units indicates the source for the distortion of the Eu3/Eu4 sites.

Table 1. C=N bond lengths [Å] and N=C=N angles [°].

In conclusion, a novel europium carbodiimide iodide serves as the first example of a structure that contains both isolated empty $M_4$ tetrahedra and infinite 1D metal chains. In $Eu_2I_2(NCN)$, the metal chains are constructed from uncommon $Eu_6$ entities that adopt an open handbag-like motif. All metal chains and isolated tetrahedra are bridged by carbodiimide anions in a 3D network with the iodide anions held in the interstices – a structural richness never seen before within europium cluster chemistry.

## Experimental Section

**Synthesis of $Eu_2I_2(NCN)$:** As recently reported, different thermal treatment of identical reactants may lead to the formation of up to three different compounds.[5d] The synthesis of $Eu_2I_2(NCN)$ is another example of a largely temperature-controlled synthesis. Typically, yellow single-crystals of $Eu_2I_2(NCN)$ are synthesized from the reaction of $EuI_2$, NaCN, $NaN_3$, and InI in a 2:1:1:1 ratio at elevated temperatures. $EuI_2$ (99.9%) and InI (99.999%) were used as purchased from Aldrich, and NaCN (95%, Merck) and $NaN_3$ (99%, Alfa) were thoroughly dried in vacuo heated at 160 °C for 3 d. It is important to follow this procedure because even traces of moisture or oxygen will lead to the immediate formation of $Eu_4OI_6$. The mixtures were transported in tantalum ampoules which were sealed with an arc welder and jacketed with quartz; both tasks were performed under an argon atmosphere. The sample was heated to 750 °C at a rate of 6 °C/min. The sample was heated at 750 °C for a week and then slowly cooled to 600 °C at a rate of 2 °C/min. After the sample was annealed at 600 °C for 2 weeks, the mixture was cooled to room temperature at a rate of 2 °C/min. The crystals of the target phase were easily separated from the surplus fluxes because the crystals were of different colors and shapes, and the yield was more than 50%. A single-crystal with a fresh surface was used for X-ray fluorescence (XRF) analysis. It revealed that the Eu and I molar percentiles – Eu/(Eu+I) and I/(Eu+I) – are 51.67% and 48.33%, respectively, which is comparable to the calculated values of 50% and 50%. The elements Na and In were not detected.

Photoluminescence emission spectra excited at 330 nm were recorded at room temperature with a spectrofluorometer (SPEX, DM3000F) equipped with two 0.22 m double monochromators (SPEX, 1680) and a 450 W xenon lamp. Two broad bands were detected with maxima at 417 and 483 nm, which can be assigned to the $4f^6 5d^1 \rightarrow 4f^7$ transition of $Eu^{2+}$. These two independent broad bands indicate two different coordinations of the Eu atoms (either from the isolated $Eu_4$ tetrahedra or from the metal chain). The small splitting of the broad bands may be attributable to the non-identity of chemically similar atoms such as Eu3 and Eu4.

**Crystal data:** $Eu_2I_2(NCN)$, $M$ = 597.75 g/mol, orthorhombic, $a$ = 11.0056(10) Å, $b$ = 10.8921(11) Å, $c$ = 11.5947(11) Å, $V$ = 1389.9(2) $Å^3$, $T$ = 120(2) K, Space group *Pmma* (no. 51), $Z$ = 8, $\mu$(Mo-$K_\alpha$) = 26.655 $mm^{-1}$; diffraction data collected with a Bruker SMART APEX CCD diffractometer with graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), empirical absorption correction, 38036 reflections measured, 1920 unique ($R_{int}$ = 0.0771) which were all used in the refinements. The final values for $wR_2$ (all data) and $R_1$ [$I > 2\sigma(I)$] were 0.0733 and 0.0312, respectively. Crystal structure solution/refinement was processed by means of SHELX programs.[9] The disordered sites of Eu3, Eu4, and I4 were refined to site occupation factors of 0.757(2) for Eu3a, 1–0.757(2) = 0.243(2) for Eu3b, 0.483(2) for Eu4a, 1–0.483(2) = 0.517(2) for Eu4b, 0.911(3) for I4a, and 1–0.911(3) = 0.089(3) for I4b, respectively. There is no indication whatsoever for a higher symmetry or a superstructure despite the presence of split positions for the Eu3/Eu4 sites. The partially occupied anions N4–C3–N4 and N5–C4–N5 were also refined with a charge constraint (all europium atoms are divalent indicated by the PL spectra), and their site occupation factors arrive at 0.68(3) and 1–0.68(3) = 0.32(3). We believe that the two possible carbodiimide locations induce the aforementioned europium split positions because of the spatial confinement of the $Eu_6$ unit. Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, 76344

# Phosphavinylidene(oxo)phosphorane Mes*P(O)=C=PMes*: A Diphosphaallene Featuring $\lambda^5\sigma^3$- and $\lambda^3\sigma^2$-Phosphorus Atoms

**Raluca Septelean,[a] Henri Ranaivonjatovo,*[b] Gabriela Nemes,[a] Jean Escudié,*[b] Ioan Silaghi-Dumitrescu,[a] Heinz Gornitzka,[b] Luminita Silaghi-Dumitrescu,[a] and Stéphane Massou[c]**

**Keywords:** Heterocumulenes / Phosphorus / Phosphaalkenes / Methylenephosphoranes

Bis(2,4,6-tri-*tert*-butylphenyl)phosphavinylidene(oxo)phosphorane (**1**) (Mes* = 2,4,6-tri-*tert*-butylphenyl), the first $1\lambda^5\sigma^3,3\lambda^3\sigma^2$-diphosphaallene, has been synthesised by addition of the phosphaalkenyllithium Mes*P=C(Li)Cl to dichlorophosphane oxide Mes*P(O)$Cl_2$. Compound **1** is stable in the solid-state but undergoes a slow intramolecular cyclisation in solution by addition of a C–H bond of an *ortho*-*tert*-butyl group to the $\sigma^3$-P=C double bond. Water adds chemoselectively and regioselectively to the $\lambda^5\sigma^3$-P=C bond, which appears to be more reactive than the $\lambda^3\sigma^2$-P=C bond. This leads to the hydrolysis compound **8** which has been structurally characterised. The new bis(phosphane oxide)-methylene **9** formed from the successive cyclisation of an *ortho*-*tert*-butyl group to the $\lambda^5\sigma^3$-P=C bond and addition of water to the $\lambda^3\sigma^2$-P=C bond has also been structurally characterised.

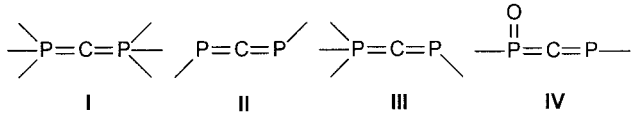
## Introduction

The high utility of ketenes, allenes and cumulenes has been well established in organic synthesis.[1] Phosphaallene derivatives, namely compounds with P=C=C or P=C=P skeletons, are phosphorus congeners of allenes and can thus be expected to be useful starting materials for new organophosphorus compounds.

Among the possible neutral heterocumulenes featuring the P=C=P sequence, $1\sigma^4,3\sigma^4$-diphosphaallenes **I**[2] and $1\sigma^2,3\sigma^2$-diphosphaallenes **II**[3,4] have been known for many years. More recently $1\sigma^4,3\sigma^2$-diphosphaallenes **III** have been isolated.[5]



Here we report the synthesis and the first aspects of the chemical behaviour of a hitherto unknown $1\sigma^3,3\sigma^2$-diphosphaallene **IV**. Despite continuing efforts over the past two decades to synthesise low-coordinate multiply bonded phosphorus compounds, such a functionalised molecule has never been described even as an intermediate. Moreover, such a structure is comprised of a methylene(oxo)phosphorane unit of which only two stable –P(O)=C< representatives have been reported to date.[6]

## Results and Discussion

Mes*P(O)=C=PMes*, bis(2,4,6-tri-*tert*-butylphenyl)phosphavinylidene(oxo)phosphorane **1** (Mes* = 2,4,6-tri-*tert*-butylphenyl), was obtained by addition, at –80 °C, of one equiv. of phosphaalkenyllithium **2**[7] to a solution of dichlorophosphane oxide **4**.[8] $^{31}$P NMR spectroscopic analysis of the crude mixture showed the presence of **3**, **4** and **1** in a ratio of 1:1:1. The one-pot preparation of **1** probably involves the preliminary formation of phosphaalkenylphosphane oxide **5** followed by a rapid CCl/CLi exchange with phosphaalkenyllithium **2** leading to the starting dichlorophosphaalkene **3** and intermediate **6**. The latter loses LiCl to afford the title compound **1** (Scheme 1), which could be easily obtained as a yellow powder from the reaction mixture by precipitation with pentane. The structure of **1** was unambiguously determined by sophisticated $^1$H, $^{13}$C and $^{31}$P NMR spectroscopic studies (1D selective $^{31}$P decoupling experiments and 2D HSQC, HMBC) (see supporting information). The $^{31}$P NMR spectrum of **1** displays an AX system at $\delta$ = 261.4 ($\sigma^2$-P) and 117.3 ppm ($\sigma^3$-P) with a coupling constant $^2J_{P,P}$ of 30.5 Hz. A large high-frequency shift of 120 ppm can be observed for the $\lambda^3\sigma^2$-P in comparison with the value reported for the diphosphaallene Mes*P=C=PMes* ($\delta^{31}$P = 140 ppm[4b]). The signal of the

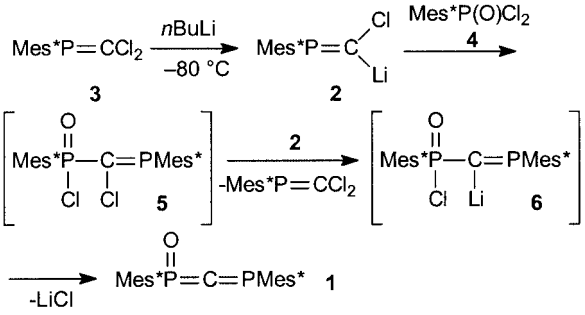
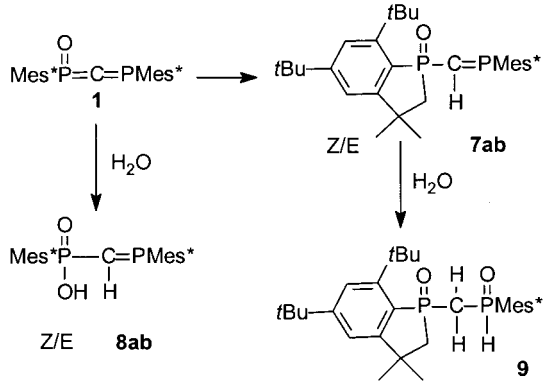
$\lambda^5\sigma^3$-phosphorus atom is slightly lower in frequency in relation to those observed for Mes*P(O)=C(R)SiMe$_3$ [$\delta^{31}$P = 153.7 ppm (R = Ph),[6a] 161.1 ppm (R = Me$_3$Si)[6b]]. The sp hybridised carbon atom gives rise to a doublet of doublets at $\delta$ = 229.1 ppm ($^1J_{C,P(O)}$ = 177.4, $^1J_{C,P}$ = 46.8 Hz). The $^1$H NMR spectrum at room temperature shows slow rotation of the Mes* group bonded to the $\lambda^3\sigma^2$-phosphorus atom. Dynamic $^1$H NMR spectroscopy was performed between 213 and 328 K and the coalescence temperatures for the *o*-*t*Bu groups and for the aromatic protons on the Mes* group bonded to the $\lambda^3\sigma^2$-P are 268 and 253 K, respectively, giving a rotation barrier of 12.2 kcal mol$^{-1}$. Similar values have been reported for the rotation barriers of Mes* groups in the phosphaarsaallene Mes*P=C=AsMes* (13.6 kcal mol$^{-1}$)[9] and in the diphosphaallene Mes*P=C=PMes* (14.0 kcal mol$^{-1}$).[10] Hindered rotation can be observed for the Mes* group bonded to the P(O) moiety even at 328 K (two singlets for the *o*-*t*Bu groups and two doublets of doublets for the aromatic protons). A molecular ion peak can be observed in the mass spectrum of **1** with the expected fragments at *m*/*z* = 565 [M – Me]$^+$ and 523 [M – *t*Bu]$^+$.



Scheme 1. Synthesis of Mes*P(O)=C=PMes* (**1**).

Compound **1** is stable for months at room temperature in the solid-state but attempts to crystallise it in various solvents at low temperatures did not afford satisfactory single crystals for X-ray diffraction studies. Compound **1** slowly rearranges within one day at room temperature in solution. The rearrangement affords the phosphaalkenylphosphane oxides **7a** and **7b** in near quantitative yield in the form of two geometric isomers in the ratio of 85:15 (Scheme 2). B3LYP/6-31G(d)//ONIOM B3LYP/6-31G(d):PM3 calculations support this easy isomerisation and **7** was found to be lower in energy than **1** by about 54 kcal mol$^{-1}$.

The $^{31}$P NMR spectra of **7a** and **7b** exhibit signals in the typical range for phosphalkenes[11a–11d] [$\delta^{31}$P for P=C in **7a** at $\delta$ = 339.1 ppm (dd, $^2J_{P,P}$ = 70.2 Hz, $^2J_{P,H}$ = 24.4 Hz) and in **7b** at $\delta$ = 353.0 ppm (dd, $^2J_{P,P}$ = 73.3 Hz, $^2J_{P,H}$ = 21.4 Hz, P=C)] and phosphane oxides[11e] [$\delta^{31}$P for P(O) in **7a** at $\delta$ = 49.3 ppm (d, $^2J_{P,P}$ = 70.2 Hz) and in **7b** at $\delta$ = 38.7 ppm (d, $^2J_{P,P}$ = 73.3 Hz)]. Similar chemical shifts at 327 and 10 ppm have been reported for Mes*P=CH–P(O)HMes*.[12] The *E* structure has been tentatively assigned to the major isomer **7a** on the basis of the $^2J_{P,H}$ coupling constant. For example, in the Mes*P=CHR system, the larger



Scheme 2. Rearrangement reaction and hydrolysis of **1**.

coupling constant always corresponds to the *E* isomer [18 Hz (*Z*) and 24.7 Hz (*E*) in Mes*P=C(H)SiMe$_3$].[7a] Moreover ONIOM B3LYP/6-31G(d):PM3 geometry optimisations of **7** place the *Z* isomer higher in energy by 3.63 kcal mol$^{-1}$.

This intramolecular cyclisation results from the addition of a C–H bond of an *ortho*-*tert*-butyl substituent of a supermesityl group to the $\sigma^3$-P=C double bond.[13] This rearrangement shows that the methylene(oxo)phosphorane moiety is much less stable than the phosphane oxide one. In contrast to bis(methylene)phosphoranes RP(=CR′$_2$)$_2$ which isomerise into phosphiranes,[14] the O=P=C unit in **1** does not undergo a similar cyclisation (which would lead to the three-membered ring oxaphosphirane).

The structure of **1** was also established unambiguously from its hydrolysis products. The $\lambda^5\sigma^3$-P=C double bond is much more reactive than the $\lambda^3\sigma^2$-P=C bond since one equiv. of water adds only to this double bond to afford the two geometric isomers **8a** and **8b** (Scheme 2). Again, ONIOM B3LYP/6-31G(d):PM3 optimisations show that **8b** (*E* isomer) is lower in energy by 5.27 kcal mol$^{-1}$.

The $^{31}$P NMR spectra of **8a** and **8b** exhibit characteristic signals of phosphaalkenes [$\delta^{31}$P **8a** = 305.5 ppm (dd, $^2J_{P,P}$ = 47.3 Hz, $^2J_{P,H}$ = 24.4 Hz, P=C), **8b** = 335.4 ppm (dd, $^2J_{P,P}$ = 68.5 Hz, $^2J_{P,H}$ = 24.4 Hz, P=C] and phosphinic acids [$\delta^{31}$P **8a** = 24.6 ppm {d, $^2J_{P,P}$ = 47.3 Hz, P(O)}; **8b** = 34.9 ppm {d, $^2J_{P,P}$ = 68.5 Hz, P(O)}].

This addition is regioselective and gives, as expected, the derivative with the hydrogen atom bonded to the central sp$^2$ carbon atom. However, since the reaction of water with **1** is slow in solution (about one day in pentane at room temperature), the competitive cyclisation products **7a**,**b** are also formed. Compounds **7** and **8** are obtained in the ratio **7a** (25%), **7b** (5%), **8a** (20%) and **8b** (50%). The X-ray structure of the *Z* isomer **8b** has been determined (Figure 1) and displays standard bond lengths and angles.

Addition of water to the *Z*/*E* mixture of **7** afforded, after one week, the new bis(phosphane oxide)methylene **9** in the form of only one diastereoisomer, which was isolated as pale yellow crystals in 85% yield. The $^{31}$P NMR spectrum of **9** displays two doublets at $\delta$ = 52.1 and 4.8 ppm (small coupling constant $^2J_{P,P}$ of 2.7 Hz). In the nondecoupled $^{31}$P NMR spectrum, derivative **9** exhibits a doublet of doublets

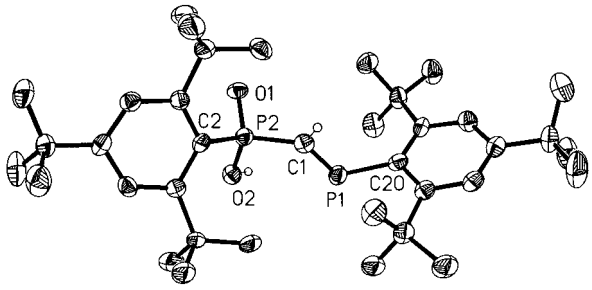

Figure 1. Structure of **8** (*E*) (50% probability level). Selected bond lengths [Å] and angles [°]: P1–C1 1.650(4), P2–C1 1.822(3), P2–C2 1.828(4), P1–C20 1.847(5), P2–O1 1.510(3), P2–O2 1.550(3), P1–C1–P2 122.3(3), O1–P2–C1 108.72(17), O2–P2–C1 107.32(18), O1–P2–C2 108.39(17), O2–P2–C2 105.60(18), C1–P2–C2 116.26(19), C20–P1–C1–P2 168.0.

of triplets for the signal at 4.8 ppm ($^1J_{P,H}$ = 517.4 Hz, $^2J_{P,H}$ = 2.8 Hz, $^2J_{P,P}$ = 2.7 Hz), the very large $^1J_{P,H}$ coupling constant being characteristic of a hydrogen bonded to a $\lambda^5\sigma^4$-phosphorus atom. The $^1$H and $^{13}$C NMR spectra display hindered rotation of the Mes* group. Dynamic $^1$H NMR spectroscopy was performed between 253 and 323 K. The coalescence temperatures for the *o*-*t*Bu groups and for the aromatic protons on the Mes* group bonded to the P(H) atom are 288 K in both cases, corresponding to a rotation barrier of 14.2 kcal mol$^{-1}$ which is 2 kcal mol$^{-1}$ higher than that of the Mes* group bonded to the $\lambda^3\sigma^2$-phosphorus atom in **1**.

The X-ray structure of **9** (Figure 2) displays standard bond lengths and angles.

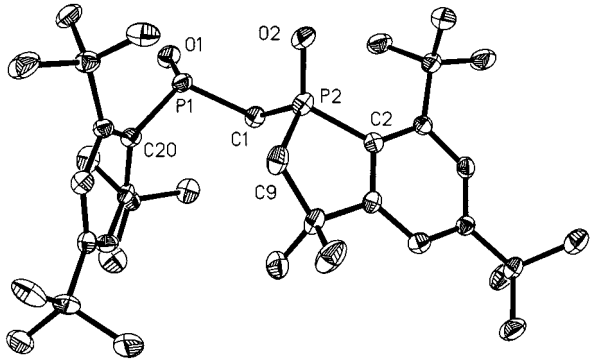

Figure 2. Structure of **9** (50% probability level). Selected bond lengths [Å] and angles [°]: P1–C1 1.827(3), P2–C1 1.822(3), P2–C2 1.819(3), P2–C9 1.794(4), P1–C20 1.818(4), P1–O1 1.482(2), P2–O2 1.481(2), P1–C1–P2 115.14(18), O1–P1–C1 112.78(15), O2–P2–C1 111.13(14), O2–P2–C2 119.96(16), O1–P1–C20 120.11(14).

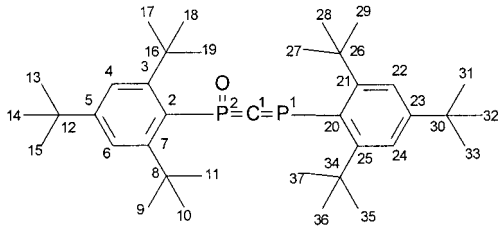
In conclusion, the first phosphavinylidene(oxo)phosphorane **1**, a derivative with three "cumulated formal double bonds", was obtained as a stable compound in the solid-state in a one-pot procedure. The ability of **1** to form transition metal complexes is now under investigation.

## Experimental Section

**General:** All experiments were carried out in flame-dried glassware under an argon atmosphere using high-vacuum-line techniques. Solvents were dried and freshly distilled from sodium benzophenone ketyl and carefully deoxygenated on a vacuum line by several "freeze-pump-thaw" cycles. NMR spectra were recorded in $CDCl_3$ on the following spectrometers: $^1$H, Bruker Avance 300 (300.13 MHz) and Avance 400 (400.13 MHz); $^{13}$C{$^1$H}, Bruker Avance 300 (75.47 MHz) and Avance 400 (100.62 MHz) (reference TMS); $^{31}$P, Bruker AC200 (81.02 MHz) and Avance 400 (162.04 MHz) (reference $H_3PO_4$). Melting points were determined on a Wild Leitz-Biomed apparatus. Mass spectra were obtained on a Hewlett–Packard 5989A spectrometer by EI at 70 eV.

**Synthesis of Mes*P(O)=C=PMes* (1):** To a solution of Mes*P=CCl$_2$ **3** (3.15 g, 8.67 mmol) in THF (20 mL) cooled to –80 °C was added a solution of *n*-butyllithium (5.7 mL, 1.6 M in hexane, 9.1 mmol). After stirring for 1 h, the solution of Mes*P=C(Cl)Li was transferred by cannula to a solution of Mes*P(O)Cl$_2$ **4** (3.00 g, 8.67 mmol) in THF (30 mL) at –80 °C. The reaction mixture became dark brown and after 15 min stirring and subsequent warming to –20 °C, the solvent was removed under vacuum. Pentane (30 mL) was added to the residue and **3** and **4** dissolved. However **1** and LiCl precipitated due to both being very poorly soluble in pentane. After filtration, **1** was extracted with $CH_2Cl_2$. Removal of the solvent gave a pale yellow powder of **1** (2.01 g, 40%, m.p. 125 °C, dec.).

The carbon and phosphorus atoms are numbered as follows:



**1**

In order to assign all the signals observed in the $^1$H and $^{13}$C NMR spectra, HSQC, HMBC and selective $^{31}$P decoupling experiments were performed. $^1$H NMR ($CDCl_3$, 400.13 MHz, 213 K): $\delta$ = 1.10 (s, 9 H, H on C27–29), 1.23 (s, 9 H, H on C17–19), 1.34 (s, 9 H, H on C13–15), 1.36 (s, 9 H, H on C31–33), 1.65 (s, 9 H, H on C35–37), 1.79 (s, 9 H, H on C9–11), 7.27 (broad s, 1 H, H on C22), 7.37 (broad d, $^4J_{H,P}$ = 5.2 Hz, 1 H, H on C6), 7.46 (broad s, 1 H, H on C24), 7.48 (broad d, $^4J_{H,P}$ = 6.1 Hz, 1 H, H on C4) ppm. $^{13}$C NMR ($CDCl_3$, 100.62 MHz): $\delta$ = 31.3 (C13–15), 31.5 (C31–33), 32.8 (C17–19), 33.1 (d, $^4J_{C,P1}$ = 6.5 Hz, C27–29), 33.3 (C9–11), 33.9 (C35–37), 35.2 (C30), 35.5 (C12), 37.4 (C26), 38.1 (d, $^3J_{C,P2}$ = 3.1 Hz, C16), 38.5 (C34), 38.7 (d, $^3J_{C,P2}$ = 3.6 Hz, C8), 119.7 (d, $^1J_{C,P2}$ = 127.5 Hz, C2), 121.7 (C22), 122.6 (d, $^3J_{C,P2}$ = 13.8 Hz, C6), 122.7 (C24), 122.9 (d, $^3J_{C,P2}$ = 15.6 Hz, C4), 138.3 (dd, $^1J_{C,P1}$ = 74.6 Hz, $^3J_{C,P2}$ = 28.5 Hz, C20), 150.3 (C23), 152.0 (C21), 153.6 (d, $^2J_{C,P2}$ = 6.7 Hz, C7), 153.9 (C25), 154.2 (d, $^2J_{C,P2}$ = 11.0 Hz, C3), 154.6 (d, $^4J_{C,P2}$ = 2.9 Hz, C5), 227.3 (dd, $^1J_{C,P1}$ = 47.1 Hz, $^1J_{C,P2}$ = 184.7 Hz, C1) ppm.

$^{31}$P NMR ($CDCl_3$, 81.02 MHz, 298 K): $\delta$ = 117.3 (d, $^2J_{P,P}$ = 30.5 Hz, P2), 261.4 (d, $^2J_{P,P}$ = 30.5 Hz, P1) ppm. MS (EI = 70 eV): *m*/*z* (%) = 580 (1) [M]$^+$, 565 (3) [M – Me]$^+$, 523 (20) [M – *t*Bu]$^+$, 467 (5) [M – 2 *t*Bu + 1]$^+$, 335 (30) [M – Mes*]$^+$, 57 (100) [*t*Bu]$^+$. $C_{37}H_{58}OP_2$ (580.81): calcd. C 76.51, H 10.07; found C 76.76, H 9.75. At 253 K, the signals of C21, 22, 24–26, 27–29, 34, and 35–37 ($^{13}$C NMR) and the signals of H on C22, 24, 27–29, 35–37 ($^1$H NMR) are too broad to be observed. At 328 K, the free rotation of Mes* bonded to P1 occurs and the following signals may be

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

observed: 33.8 (C27–29 and C35–37), 37.8 (C26 and C34), 121.9 (C22 and C24) and 153.2 ppm (C21 and C25) in the $^{13}C$ NMR spectrum; 1.39 (s, C27–29 and C35–37) and 7.32 ppm (s, C22 and C24) in the $^{1}H$ NMR spectrum.

**Synthesis of Cyclisation Products 7a and 7b:** A solution of Mes*-P(O)=C=PMes* **1** (1.20 g, 2.01 mmol) in toluene (10 mL) was heated at 80 °C for 1 h. NMR analysis showed the conversion of **1** into **7a** and **7b** in the ratio 85:15. Removal of solvent in vacuo led to a powder of **7a**,**b**. Attempts at fractional crystallisation in various solvents (pentane, $Et_2O$, $CHCl_3$) did not allow the complete separation of the two isomers **7a** and **7b**. Selective $^{31}P$ decoupled $^{1}H$ and $^{13}C$ NMR experiments were performed. At 283 K, signals of some *t*Bu groups were too broad to be observed by $^{1}H$ NMR spectroscopy.

**7a [(*E*) isomer]:** $^{1}H$ NMR ($CDCl_3$, 400.13 MHz, 283 K): $\delta$ = 1.31, 1.48 and 1.56 (3s, 27 H, H from *t*Bu groups), 2.36 [ddd, $^{2}J_{H,H}$ = 15.0 Hz, $^{2}J_{H,P2}$ = 19.3 Hz, $^{4}J_{H,P1}$ = 3.9 Hz, 1 H, H on C9 (carbon atom bonded to P2)], 2.50 (dd, $^{2}J_{H,H}$ = 15.0 Hz, $^{2}J_{H,P2}$ = 7.1 Hz, 1 H, H on C9), 7.16, 7.28, 7.36 and 7.40 (4 broad s, 4 × 1 H, arom H), 7.58 (dd, $^{2}J_{H,P1}$ = 22.3 Hz, $^{2}J_{H,P2}$ = 13.8 Hz, 1 H, H on C1) ppm. $^{13}C$ NMR ($CDCl_3$, 100.62 MHz, 283 K): $\delta$ = 31.2, 31.3 and 32.5 (C13–15, C17–19, C31–33), 34.2 (d, $^{4}J_{C,P1}$ = 7.0 Hz, C27–29, C35–37), 37.5 (C30), 38.3 (C26, C34), 39.0 (d, $^{2}J_{C,P2}$ = 5.8 Hz, C8), 40.0 (d, $J_{C,P2}$ = 2.8 Hz) and 40.8 (d, $J_{C,P2}$ = 3.6 Hz) (C12, C16), 43.7 (dd, $^{1}J_{C,P2}$ = 75.9 Hz, $^{3}J_{C,P1}$ = 6.0 Hz, C9), 118.7 (d, $^{3}J_{C,P2}$ = 13.8 Hz) and 122.8 (d, $^{3}J_{C,P2}$ = 10.0 Hz, C4, C6), 122.2 (C22, C24), 127.1 (d, $^{1}J_{C,P2}$ = 95.6 Hz, C2), 138.8 (dd, $^{1}J_{C,P1}$ = 67.5 Hz, $^{3}J_{C,P2}$ = 17.7 Hz, C20), 150.1 (C23), 153.4 (C21, C25), 154.2 (d, $^{2}J_{C,P2}$ = 7.2 Hz) and 157.0 (d, $^{2}J_{C,P2}$ = 20.2 Hz, C3, C7), 155.7 (d, $^{4}J_{C,P2}$ = 2.5 Hz, C5), 165.3 (dd, $^{1}J_{C,P2}$ = 74.8 Hz, $^{1}J_{C,P1}$ = 63.2 Hz, C1) ppm. $^{31}P$ NMR ($CDCl_3$, 81.02 MHz, 298 K): $\delta$ = 49.3 (d, $^{2}J_{P,P}$ = 70.2 Hz, P2), 339.1 (dd, $^{2}J_{P,P}$ = 70.2 Hz, $^{2}J_{P,H}$ = 24.4 Hz P1) ppm. MS (EI = 70 eV): *m*/*z* (%) = 565 (8) $[M - 15]^+$, 523 (15) $[M - t\text{Bu}]^+$, 335 (100) $[M - \text{Mes*}]^+$, 57 (90) $[t\text{Bu}]^+$.

**7b [(*Z*) isomer]:** $^{1}H$ NMR ($CDCl_3$, 400.13 MHz, 283 K): $\delta$ = 7.82 (dd, $^{2}J_{H,P2}$ = 212.0 Hz, $^{2}J_{H,P1}$ = 17.6 Hz, 1 H, CH=P) ppm (other $^{1}H$ signals and $^{13}C$ signals of the minor isomer could not be assigned unambiguously). $^{31}P$ NMR ($CDCl_3$, 81.02 MHz, 298 K): $\delta$ = 38.7 (d, $^{2}J_{P,P}$ = 73.3 Hz, PO), 353.0 (dd, $^{2}J_{P,P}$ = 73.3 Hz, $^{2}J_{P,H}$ = 21.4 Hz P=C) ppm.

**Hydrolysis of 7a and 7b. Synthesis of 9:** An excess of degassed water was added to the mixture of **7a**,**b** (0.60 g, 1.04 mmol) in $Et_2O$. After stirring for a week at room temperature, NMR analysis showed the formation of **9**. $Et_2O$ was removed under vacuum and recrystallisation from pentane afforded pure **9** as pale yellow crystals (0.48 g, 78%, m.p. 203 °C). HSQC, HMBC, NOESY and selective $^{31}P$ decoupled $^{1}H$ and $^{13}C$ NMR experiments were performed. $^{1}H$ NMR ($CDCl_3$, 400.13 MHz, 253 K): $\delta$ = 0.46 (dd, $^{2}J_{H,P2}$ = 6.2 Hz, $^{2}J_{H,H}$ = 15.3 Hz, 1 H, H on C9, carbon atom bonded to P2), 0.90 and 1.21 (2s, 2 × 3 H, H on C10,11), 1.30 (s, 9 H, H on C13–15), 1.38 (s, 9 H, H on C31–33), 1.52 and 1.65 (2s, 2 × 9 H, H on C27–29 and C35–37), 1.53 (s, 9 H, H on C17–19), 1.54 (dd, $^{2}J_{H,P2}$ = 20.4 Hz, $^{2}J_{H,H}$ = 15.3 Hz, 1 H, H on C9), 2.43 (dddd, $^{2}J_{H,P1}$ = 15.0 Hz, $^{2}J_{H,P2}$ = 7.2 Hz, $^{2}J_{H,H}$ = 15.3 Hz, $^{3}J_{H,H}$ = 7.1 Hz, 1 H, H on C1), 3.30 (dt, $^{2}J_{H,P1}$ and $^{2}J_{H,P2}$ = 16.6 Hz, $^{2}J_{H,H}$ = 15.3 Hz, 1 H, H on C1), 7.07 (dd, $^{4}J_{H,P2}$ = 2.0 Hz, $^{4}J_{H,H}$ = 1.0 Hz, 1 H, H on C4), 7.41 (dd, $^{4}J_{H,P2}$ = 5.2 Hz, $^{4}J_{H,H}$ = 1.0 Hz, 1 H, H on C6), 7.45 (dd, $^{4}J_{H,P1}$ = 2.0 Hz, $^{4}J_{H,H}$ = 1.0 Hz, 1 H, H on C22), 7.54 (dd, $^{4}J_{H,P1}$ = 4.1 Hz, $^{4}J_{H,H}$ = 1.0 Hz, 1 H, H on C24), 8.52 (ddd, $^{1}J_{H,P1}$ = 517.4 Hz, $^{3}J_{H,P2}$ = 2.8 Hz, $^{3}J_{H,H}$ = 7.1 Hz, 1 H, H on P1) ppm. $^{13}C$ NMR ($CDCl_3$, 100.62 MHz, 253 K): $\delta$ = 31.2 (C13–15), 31.4 (C31–33), 31.9 and 33.5 (C10–11), 32.2 (C17–19), 33.6 and 34.3 (C27–29 and C35–37), 35.3 (C30), 35.4 (C12), 37.7 (C16), 38.7 (d, $^{2}J_{C,P2}$ = 6.2 Hz, C8), 39.2 (C26 and C34), 39.6 (d, $^{1}J_{C,P2}$ = 72.1 Hz, C9), 40.6 (dd, $^{1}J_{C,P1}$ = 55.1 Hz, $^{1}J_{C,P2}$ = 50.5 Hz, C1), 118.9 (d, $^{3}J_{C,P2}$ = 14.4 Hz, C4), 123.3 (d, $^{3}J_{C,P2}$ = 10.2 Hz, C6), 123.6 (d, $^{3}J_{C,P1}$ = 11.9 Hz) and 124.1 (d, $^{3}J_{C,P1}$ = 13.4 Hz) (C22 and C24), 125.2 (dd, $^{1}J_{C,P2}$ = 96.5 Hz, $^{3}J_{C,P1}$ = 3.9 Hz, C2), 128.2 (d, $^{1}J_{C,P1}$ = 99.0 Hz, C20), 153.6 (d, $^{4}J_{C,P1}$ = 3.1 Hz, C23), 154.2 (d, $^{2}J_{C,P2}$ = 8.1 Hz, C7), 156.0 (d, $^{2}J_{C,P1}$ = 5.7 Hz, C21), 156.3 (d, $^{2}J_{C,P2}$ = 33.0 Hz, C3), 156.6 (d, $^{4}J_{C,P2}$ = 2.4 Hz, C5), 157.4 (d, $^{2}J_{C,P1}$ = 11.9 Hz, C25) ppm. $^{31}P$ NMR ($CDCl_3$, 81.02 MHz, 298 K): $\delta$ = 4.8 (ddt, $^{2}J_{P,P}$ = 2.7 Hz, $^{1}J_{P,H}$ = 517.4 Hz, $^{2}J_{P,H}$ = 2.8 Hz, P1), 52.1 (d, $^{2}J_{P,P}$ = 2.7 Hz, P2) ppm. MS (EI = 70 eV): *m*/*z* (%) = 599 (2) $[M + 1]^+$, 581 (1) $[M - O - 1]^+$, 541 (100) $[M - t\text{Bu}]^+$, 353 (85) $[M - \text{Mes*}]^+$, 57 (70) $[t\text{Bu}]^+$ $C_{37}H_{60}O_2P_2$ (598.82): calcd.C 74.21, H 10.10; found C 74.56, H 9.85.

**Synthesis of 8a and 8b by Hydrolysis of the P(O)=C Double Bond of 1:** An excess of degassed water was added to a solution of **1** (1.15 g, 1.98 mmol) in pentane (20 mL). After stirring for 2 d at room temperature, NMR analysis showed the formation of a mixture of **7a**,**b** and **8a**,**b**. Attempts at crystallisation from various solvents did not allow complete separation of the two derivatives and only some single crystals of **8**, suitable for an X-ray structure determination, could be obtained by crystallisation from $CHCl_3$ and cyclohexane. $^{31}P$ NMR ($CDCl_3$, 81.02 MHz, 298 K) **8a** (30%), $\delta$ = 24.6 (d, $^{2}J_{P,P}$ = 47.3 Hz, PO), 305.5 ppm (dd, $^{2}J_{P,P}$ = 47.3 Hz, $^{2}J_{P,H}$ = 24.4 Hz, P=C) **8b** (70%), $\delta$ = 34.9 ($^{2}J_{P,P}$ = 68.5 Hz, PO), 335.4 ppm (dd, $^{2}J_{P,P}$ = 68.5 Hz, $^{2}J_{P,H}$ = 24.4 Hz, P=C).

**X-ray Structure Determinations**

**Crystal Data for 8 and 9. Compound 8:** $C_{43}H_{73}Cl_3O_2P_2$, $M$ = 790.30 ($CHCl_3$ and cyclohexane in the lattice), triclinic, $P\bar{1}$, $a$ = 13.998(2), $b$ = 14.106(2), $c$ = 14.348(2) Å, $\alpha$ = 91.531(4), $\beta$ = 119.170(3), $\gamma$ = 108.678(3)°, $V$ = 2285.6(6) Å$^3$, $Z$ = 2, $T$ = 173(2) K. 9004 reflections (5491 independent, $R_{int}$ = 0.0740) were collected. Largest electron density residue: 0.341 e Å$^{-3}$, $R_1$ [for $I > 2\sigma(I)$] = 0.0565 and $wR_2$ = 0.1433 (all data) with $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR_2 = [\Sigma w (F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$. **Compound 9:** $C_{37}H_{60}O_2P_2$, $M$ = 598.79, monoclinic, $P2_1/c$, $a$ = 10.275(1), $b$ = 25.939(2), $c$ = 14.342(1) Å, $\beta$ = 110.884(2)°, $V$ = 3571.4(6) Å$^3$, $Z$ = 4, $T$ = 173(2) K. 15676 reflections (5066 independent, $R_{int}$ = 0.1213) were collected. Largest electron density residue: 0.250 e Å$^{-3}$, $R_1$ [for $I > 2\sigma(I)$] = 0.0558 and $wR_2$ = 0.0943 (all data).

All data for structures reported in this paper were collected at low temperature using an oil-coated shock-cooled crystal on a Bruker-AXS CCD 1000 diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods (SHELXS-97)[15] and all non-hydrogen atoms were refined anisotropically using the least-squares method on $F^2$ (SHELXL-97).[16]

CCDC-605519 (for **8**) and -605520 (for **9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information:** (for details see the footnote on the first page of this article): variable temperature $^{1}H$ NMR, 2D HSQC and 2D HMBC, $^{13}C\{^{1}H,^{31}P\}$ and $^{13}C\{^{1}H\}$ Jmod spectra of diphosphaallene Mes*P(O)=C=PMes* (**1**), variable-temperature $^{1}H$ NMR spectra of bis(phosphane oxide)methylene **9**.

# (Alkyl)- and (Alkyl)(alkylidene)(pentamethylcyclopentadienyl)tantalum Complexes

**Mikhail V. Galakhov,[a] Manuel Gómez,*[b] Pilar Gómez-Sal,[b] and Patricia Velasco[b]**

*Dedicated to Prof. Victor Riera on the occasion of his 70th birthday*

**Keywords:** Tantalum / Alkyl / Alkylidene / Cyclopentadienyl ligands

Alkylation of [TaCp*$Cl_4$] (Cp* = $\eta^5$-$C_5Me_5$) with 3 equiv. of $MgCl(CH_2SiMe_3)$ gives the chloridotris(trimethylsilylmethyl) complex [TaCp*$Cl(CH_2SiMe_3)_3$] (**1**). TaCp*$Cl_2Me_2$ reacts with 2 equiv. of LiR (R = $CH_2Ph$, $CH_2SiMe_3$) to give the mixed alkyl derivatives [TaCp*$Me_2R_2$] (R = $CH_2Ph$, **2**; $CH_2SiMe_3$, **3**). The dimethyldineopentyl complex [TaCp*$Me_2(CH_2CMe_3)_2$] (**4**) was obtained by reaction of TaCp*$Cl_2(CH_2CMe_3)_2$ with 2 equiv. of LiMe. The treatment of a toluene solution of TaCp*$Cl_2Me_2$ with 2 equiv. of neophyllithium in a standard vacuum line gave a mixture of three compounds, [{TaCp*$Me_2(CH_2CMe_2Ph)$}$_2$(**μ**-O)] (**5**), [TaCp*$Me_2(CH_2CMe_2$–*o*-$C_6H_4$-κ$^2$*C*,*C*)] (**6**) and [TaCp*$Me(CH_2CMe_2Ph)(CH_2)$] (**7**), which were identified by NMR spectroscopy. However, when the reaction was carried out under rigorously anhydrous conditions, only complexes **6** and **7** were isolated. A chlorido(trimethylsilylmethyl)(trimethylsilylmethylidene) complex [TaCp*$Cl(CH_2SiMe_3)(CHSiMe_3)$] (**8**) was prepared by heating **1** at 60 °C, or by leaving it at room temperature for a long time. A 3:2 (**9**/**10**) mixture of [TaCp*$MeR(CHSiMe_3)$] (R = $CH_2SiMe_3$, **9**; Me, **10**) was obtained by thermal treatment of **3**, which was accompanied by the evolution of $CH_4$ and $SiMe_4$. However, irradiation of a [$D_6$]benzene solution of **3** with a sun lamp gave a mixture of **9** and [TaCp*$(CH_2SiMe_3)R(CH_2)$] (R = Me, **11**; $CH_2SiMe_3$, **12**) in a 2:1:1 (**9**/**11**/**12**) ratio. When a [$D_6$]benzene solution of **4** was heated at 60 °C, a mixture of the (alkyl)(neopentylidene) derivatives [TaCp*$MeR(CHCMe_3)$] (R = Me, **13**; $CH_2CMe_3$, **14**) in a 4:1 (**13**/**14**) ratio was detected by NMR spectroscopy, while irradiation with a sun lamp produced a mixture of alkylidene complexes [TaCp*$(CH_2CMe_3)R(CH_2)$] (R = Me, **15**; $CH_2CMe_3$, **16**) in a 3:1 (**15**/**16**) ratio. On the other hand, the alkylation of TaCp*$Cl_2(CH_2CMe_3)_2$ with 2 equiv. of $LiCH_2SiMe_3$ gave the (alkyl)(alkylidene) complex [TaCp*$(CH_2CMe_3)(CH_2SiMe_3)(CHCMe_3)$] (**17**) with the elimination of $SiMe_4$, whereas the treatment of TaCp*$Cl_2(CH_2SiMe_3)_2$ with the appropriate reagent gave [TaCp*$(CH_2R)(CH_2SiMe_3)(CHR')$] (R = R′ = Ph, **18**; R = $CMe_2Ph$, R′ = $SiMe_3$, **19**) with the elimination of $SiMe_4$ and $CMe_3Ph$, respectively. All compounds were studied by IR and NMR spectroscopy, and the molecular structures of complexes **1**, **4** and **5** were determined by X-ray diffraction methods.

## Introduction

The study of early-transition-metal compounds in high oxidation states has been a topic of intense research because of their applications in organic synthesis and in catalysis.[1] In particular, metal alkyls and alkylidenes are among the most studied derivatives. Alkyl derivatives have been extensively used as catalysts for the polymerization of olefins,[1,2] while the importance of alkylidenes is demonstrated by a comprehensive study of the olefin metathesis reactions that they are able to catalyse.[3] Further, in combination with stronger Lewis acids they form highly reactive species that are important as catalysts in other processes involving olefins.[3b,3c,4–6] Additionally, μ-alkylidene complexes have been postulated as intermediates in Fischer–Tropsch, olefin metathesis and Ziegler–Natta catalytic processes.[7]

Preliminary reports from our group have focused on the ability of tetrachlorido(cyclopentadienyl)niobium and -tantalum compounds to coordinate with bulky alkyl substituents. Thus, the crowding of the coordination sphere of the metal by the trimethylsilylmethyl group is the basis for the formation of an alkylidene complex by a spontaneous α-hydrogen-elimination process.[8] On the other hand, we reported[9] that the use of the 2-[(dimethylamino)methyl]-phenyl ligand leads to the synthesis of tantalum(V) complexes that can be transformed into new cyclometalated (alkylidene)tantalum derivatives by the activation of carbon–hydrogen bonds in one of the methylamino groups of

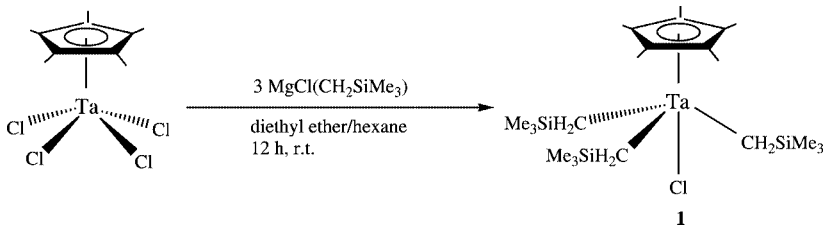

Scheme 1.

the ligand. More recently, the μ-alkylidene complexes $[(TaCp^*Cp')_2(\mu\text{-}CHR)_2]$ ($Cp^*$ = $\eta^5$-$C_5Me_5$, Cp′ = $\eta^5$-$C_5H_4SiMe_3$, R = $C_6H_5$, $SiMe_3$, $CMe_3$) have been prepared by treatment of the (mixed dicyclopentadienyl)tantalum compound $TaCp^*Cp'Cl_2$ with an appropriate amount of the corresponding alkyllithium.[10]

In this article, we report the preparation of new (alkyl)- and (alkyl)(alkylidene)mono(pentamethylcyclopentadienyl)-tantalum(V) complexes. All compounds were studied by spectroscopic methods. In addition, the molecular structures of complexes **1**, **4** and **5** were determined by X-ray diffraction.

## Results and Discussion

$[TaCp^*Cl(CH_2SiMe_3)_3]$ (**1**) was synthesized in good yield by the reaction of $[TaCp^*Cl_4]$ ($Cp^*$ = $\eta^5$-$C_5Me_5$) with 3 equiv. of $MgCl(CH_2SiMe_3)$ (Scheme 1). In contrast, we previously reported[8] the preparation of a dialkyl(alkylidene) derivative $[TaCp^*(CH_2SiMe_3)_2(CHSiMe_3)]$ by the reaction of the tetrachlorido complex with 4 equiv. of an alkylating reagent. Two absorptions bands were observed in the IR spectrum of **1** at $\tilde{\nu}$ = 1026 and 1243 $cm^{-1}$, which can be assigned to $\nu_{C-C}(Cp^*)$[11] and $\delta_{as}(CH_3)(SiMe_3)$,[11c] respectively. The NMR spectra of this complex are in agreement with a $C_{3v}$ local symmetry around the tantalum atom.

The crystal structure of complex **1** (Figure 1) shows a tantalum atom in a distorted trigonal bipyramidal environment with the three alkyl groups occupying the equatorial positions, and the centroid of the pentamethylcyclopentadienyl ring and the chlorine atom at the apical sites. The tantalum atom is displaced towards the Cp* ring by 0.46 Å from the equatorial plane containing the three carbon (alkyl) atoms.[12] The bond lengths for Ta–Cp*(centroid), Ta–C (average), and Ta–Cl are 2.180, 2.160 and 2.481(1) Å, respectively (Table 1). The Ta–C(alkyl) distance is in the range corresponding to normal values for a Ta–C[11d,13,14] single bond, whereas the Ta–Cl distance is shorter than that for a bridging chlorine[15] and longer than that for a terminal chlorine.[11d,14b,16] The angle Cp*–Ta–Cl is 176.84° and confirms the apical position of the chlorine atom. This pentacoordination is unusual, and to the best of our knowledge, no other group 5 metal (alkyl)chlorido(cyclopentadienyl) derivative has this trigonal bipyramidal configuration; all other examples have a four-legged piano-stool arrangement.[11b–d,17,18] In this case, such an arrangement is very unfavourable because of the important steric requirement of the trimethylsilylmethyl substituent.

[a] Cp1 is the centroid of the C1–C5 ring.

The mixed alkyl complexes $[TaCp^*Me_2R_2]$ (R = $CH_2Ph$, **2**; $CH_2SiMe_3$, **3**) were obtained (Scheme 2) at room temperature by treatment of toluene solutions of $TaCp^*Cl_2Me_2$ with stoichiometric amounts of the alkyllithium, LiR, under rigorously anhydrous conditions, while the dimethyldineopentyl complex $[TaCp^*Me_2(CH_2CMe_3)_2]$ (**4**) was synthesized by alkylation, at –78 °C, of the dichloridodineopentyl derivative with 2 equiv. of LiMe in a diethyl ether/hexane mixture.

The mixed alkyl complexes **2**–**4** are extremely air- and moisture-sensitive, are soluble in most organic solvents and were characterised by analytical and spectroscopic methods.

[a] Cp1 is the centroid of the C1A–C5A ring and Cp2 is the centroid of the C1–C5 ring.

Complex **4** is a monomer, and if Cp* is considered as occupying the apical coordination site, it has distorted square pyramid geometry. Two independent molecules were found in the asymmetric unit, and their geometrical parameters were essentially coincident. The tantalum atom deviates towards the Cp* ring by 0.75 Å from a plane passing through the atoms C11, C12, C13 and C14, and the two methyl groups and the two neopentyl groups are mutually *trans* in order to separate the sterically demanding groups. This arrangement is usual in five-coordinate cyclopentadienyl complexes.[11b,11c,11d,17,18] All the bond lengths and angles are in the normal ranges.

The $^1$H NMR spectrum of **4** in [D$_2$]dichloromethane at 298 K shows two sets of signals in a ratio of 14:1. For the major compound, a quintuplet ($\delta$ = 0.59 ppm) and a septuplet ($\delta$ = 0.20 ppm, $^4J_{H,H}$ = 1.29 Hz) were observed for the Ta–(C$H_3$)$_2$ and the Ta–(C$H_2$CMe$_3$)$_2$ moieties, respectively. On the other hand, the minor component, detected in a NOESY1D spectra (Figure 3), shows an AB spin system ($^2J_{H,H}$ = 12.8 Hz) for the Ta–(C$H_2$CMe$_3$)$_2$ diastereotopic protons.

In contrast to **4**, the Ta–(C$H_2$SiMe$_3$)$_2$ resonance appears as a broad signal ($\Delta\nu_{1/2}$ = 37 Hz) at $\delta$ = –0.25 ppm in the $^1$H NMR spectrum of **3** at 298 K, while the signal corresponding to Ta–(C$H_3$)$_2$ was observed as a quintuplet ($^4J_{H,H}$ = 1.31 Hz) at $\delta$ = 0.44 ppm.

Further, the variable low temperature spectra of **3** indicate the occurrence of a typical spin exchange process between two very differently populated positions. The minor position (10%) was detected by EXSY1D at 213 K and showed an AB spin system ($^2J_{H,H}$ = 11.6 Hz) at $\delta_{av}$ = –0.01 for the Ta–(C$H_2$SiMe$_3$)$_2$ resonance.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

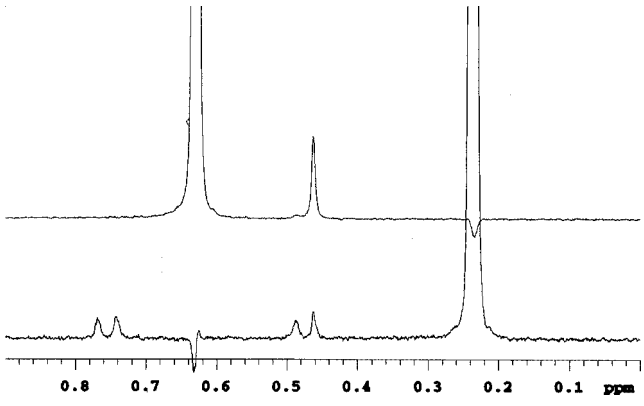

Figure 3. The PFG WFG noesy 1d (mix = 500 ms) proton spectra (spectrum phase = 180°) of complex **4** at 298 K [bottom: Ta–($CH_2CMe_3$)$_2$; top: Ta–($CH_3$)$_2$ resonances].

This spectral behaviour is in agreement with a *trans* arrangement of the methyl and the alkyl groups ($C_{2v}$ local symmetry) in the major component and a *cis* arrangement of the groups in the minor ($C_s$ symmetry) isomers, which undergo the mutual spin-exchange process known as Berry pseudorotation.[14c,14d,16b,18] We hypothesise that in solution both isomers of the **2**–**4** mixed alkyl complexes exhibit pseudo-square-pyramidal geometry in the ground state and a distorted trigonal bipyramidal environment, similar to that of **1**, in the transition state. Moreover, the isomerization process in complex **3** is faster than that in **4**, this is probably caused by the size of the alkyl group. The $^{13}C$ NMR spectra of complexes **2**–**4** show all the expected resonances (see Experimental Section).

The addition of 2 equiv. of $LiCH_2CMe_2Ph$ to a toluene solution of $TaCp^*Cl_2Me_2$ by using a standard vacuum line (Scheme 3) gives a mixture of the dimethyl(neophyl)(μ-oxido) complex [{$TaCp^*Me_2(CH_2CMe_2Ph)$}$_2$(μ-O)] (**5**), the dimethyltantalabenzocyclopentene complex [$TaCp^*Me_2$-($CH_2CMe_2$-*o*-$C_6H_4$-κ$^2$*C*,*C*)] (**6**) and the (methyl)(methylidene)(neophyl) complex [$TaCp^*Me(CH_2CMe_2Ph)(CH_2)$] (**7**), which were observed by NMR spectroscopy. Complexes **5**–**7** can be isolated as pure samples by successive recrystallisations from hexane (see Experimental Section). However, when the same reaction is carried out under rigorously anhydrous conditions (glove box) complex **5** is not formed. We suggest, as a plausible pathway for this alkylation reaction, the initial formation of a mixed alkyl complex "[$TaCp^*Me_2(CH_2CMe_2Ph)_2$]", that, when followed by orthometalation[10,19] of the phenyl ring and by α-hydrogen activation[7e,20] of a methyl group with the elimination of $CMe_3Ph$, produces complexes **6** and **7**, respectively, while the hydrolysis of this mixed alkyl complex produces the μ-oxido complex **5**.

In the IR spectrum of complex **5** the absorption band observed at 740 cm$^{-1}$ could be assigned to $\nu_{Ta-O-Ta}$,[15,21] while all the NMR spectroscopic data (see Experimental Section) are in agreement with a structural formulation that shows a *trans* arrangement of the methyl groups.

The molecular structure of complex **5** (Figure 4) shows two $TaCp^*Me_2(CH_2CMe_2Ph)$ fragments bonded through a bridging oxygen atom, which acts as an inversion centre. The angle Ta1–O1–Ta2 is 180,° and the bond length Ta–O is 1.9227(6) Å (Table 3). This distance is very short and in agreement with the existence of a π-bonding interaction between the oxygen and tantalum atoms.[14c] Each tantalum atom exhibits the normal four-legged piano-stool geometry[11,17,18] in which the pentamethylcyclopentadienyl ring occupies the apical position and the metal centre is displaced towards the Cp* ring by 0.78 Å from a plane formed by the atoms C21, C6, C8 and O1. The bridging oxygen atom is located in a *trans* position with respect to the bulky ligand. This fact, together with the inversion centre, eliminates steric problems. The distance Ta–C21 [2.294(12) Å] is significantly longer than the bonds between the metal and the methyl groups[18] [Ta–C6 2.208(11) Å and Ta–C8 2.194(12) Å], which is probably a result of the *trans* influence.

[a] Cp1 is the centroid of the C1–C5 ring. Symmetry transformations used to generate equivalent atoms: #1 $-x+1$, $-y+2$, $-z$.

The NMR spectrum of **6**, which is a monomer species [$D = (11.7 \pm 0.2) \times 10^{-11}$ m$^2$s$^{-1}$][22] in [D$_2$]dichloromethane [$D = (29.2 \pm 0.5) \times 10^{-11}$ m$^2$s$^{-1}$] at 298 K, exhibits an ABCD spin system at $\delta$ = 8.1, 7.3, 7.2 and 7.12 ppm corresponding to the $C_6H_4$ moiety, and four singlets for the $\eta^5$-$C_5Me_5$ ($\delta$ = 1.94 ppm, 15 H), Ta–CH$_2$C*Me*$_2$Ph ($\delta$ = 1.15 ppm, 6 H), Ta–C*H*$_2$CMe$_2$Ph ($\delta$ = 0.88 ppm, 2 H, $\Delta\nu_{1/2}$ = 8.7 Hz) and Ta–*Me*$_2$ ($\delta$ = 0.27 ppm, 6 H) proton resonances, which justifies the assignment of $C_s$ symmetry to this complex. Unfortunately, the variable temperature spectra did not show any significant changes ($\Delta\nu_{1/2max}$ = 12.7 Hz) to enable the study of any possible fluxional behaviour. NOE data at 203 K indicate short distances between the pentamethylcyclopentadienyl ring and the –CMe$_2$–, Ta–Me$_2$ and Ta–CH$_2$– moieties, and between Ta–Me$_2$ and the phenyl (H2 proton) ring, suggesting an axial position for the phenyl group in the distorted trigonal bipyramidal structure of **6**, as shown in Scheme 3.

The $^1$H NMR spectrum of complex **7** in [D$_2$]dichloromethane at 298 K shows a singlet for the Cp* ring ($\delta$ = 1.95 ppm), three multiplets for the $C_6H_5$ group ($\delta$ = 7.4, 7.3, 7.13 ppm), two diastereotopic –C*Me*$_2$– ($\delta$ = 1.46, 1.40 ppm) groups and an ABC$_3$ spin system at $\delta$ = 1.26, 0.04 (AB) and –0.52 (d, $^2J_{H,H}$ = 14.8 Hz, $^4J_{H,H}$ = 1.1 Hz) ppm for the Ta–C*H*$_2$CMe$_2$Ph and Ta–*Me* moieties, respectively. Although **7** contains an asymmetric tantalum(V) central atom, the Ta=CH$_2$ resonance is observed as one singlet ($^1$H NMR, $\delta$ = 5.27 ppm; $^{13}$C NMR, $\delta$ = 205.9 ppm, $^1J_{C,H}$ = 126.1 Hz), which is not like an AB spin system. In the variable temperature $^1$H NMR study, the maximum broad line ($\Delta\nu_{1/2}$ = 110 Hz) of the methylidene resonance was observed at 173 K, although the multiplicity could not be resolved. We believe that this experimental result could be due to the fast rotation ($\Delta G^{\neq 173\ K} < 32$ kJ mol$^{-1}$) about the Ta–C vector that accompanies the heterolytic rupture of the double bond, which is in accordance with the reactivity of these complexes. This is known to occur in other methylidene complexes,[18c,23] organic imines[24] and organometallic complexes.[14c,18d]

(Alkyl)(alkylidene)tantalum compounds were obtained by the thermal or photochemical treatment of mixed alkyl derivatives. So, when a toluene or [D$_6$]benzene solution of **1** was heated at 60 °C for 48 h, the (alkyl)(alkylidene)chlorido complex [TaCp*Cl(CH$_2$SiMe$_3$)(CHSiMe$_3$)] (**8**) was formed with the elimination of SiMe$_4$ (Scheme 4). However, complex **1** in [D$_2$]dichloromethane slowly transforms into complex **8** at room temperature.

The $^1$H NMR spectrum of **8** ($D = 13.0 \times 10^{-10}$ m$^2$s$^{-1}$)[22] shows signals at $\delta$ = 5.54 (1 H) and 0.065 ppm (9 H) for Ta=C*H*Si*Me*$_3$ ($^{29}$Si NMR, $\delta$ = –8.2 ppm), an AB spin system at $\delta$ = 0.053 and 0.23 ppm ($^2J_{H,H}$ = 12.65 Hz, 2 H) and one singlet at $\delta$ = 0.12 ppm (9 H) for the Ta–C*H*$_2$Si*Me*$_3$ moiety, and also a resonance for the Cp* ring at $\delta$ = 2.15 ppm. Further, free SiMe$_4$ ($D = 24.5 \times 10^{-10}$ m$^2$s$^{-1}$) that was eliminated from **1** during the reaction was also observed in the solution. The assignment of the trimethylsilyl resonances and the determination of the $^{29}$Si NMR chemical shifts were based on CIGAR data (Figure 5).

When a [D$_6$]benzene solution of **3** was heated at 60 °C for 20 h, a mixture of the dialkyl(alkylidene) compounds [TaCp*MeR(CHSiMe$_3$)] (R = CH$_2$SiMe$_3$, **9**; Me, **10**) was generated in a 3:2 ratio; this mixture was identified by NMR spectroscopy. The reaction occurred with the elimination of CH$_4$ and SiMe$_4$ (Scheme 5). On the other hand, the irradiation of a [D$_6$]benzene solution of **3** with a sun lamp gave a mixture of **9** and [TaCp*(CH$_2$SiMe$_3$)R(CH$_2$)] (R = Me, **11**; CH$_2$SiMe$_3$, **12**) in a 2:1:1 ratio. Both processes, thermal and photochemical, take place by C–Hα activation of the CH$_2$SiMe$_3$ or Me groups. Complex **9** is the major product that results from the preferential elimination of CH$_4$.

In addition, [D$_6$]benzene solutions of the mixed tetraalkyl complex **4** slowly decomposed at room temperature when exposed to a sun lamp, yielding a mixture of the alkylidenes **13**–**16**. When solutions of **4** were heated at 60 °C, the decomposition was faster, and a mixture of (alkyl)(neo-

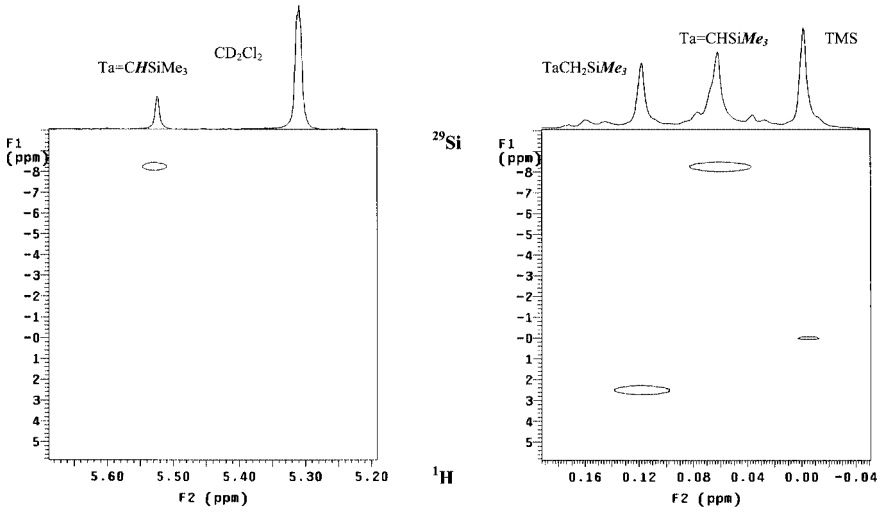

Figure 5. PFG Accord HMBC (CIGAR) $^{1}H$-{$^{29}Si$} spectra of **8** acquired over a period of 20 minutes in a Mercury VX spectrometer with PFG-Z VT 5 mm ATB NMR probe. All parameters were optimized for the $^{1}H$–$^{29}Si$ geminal spin coupling.

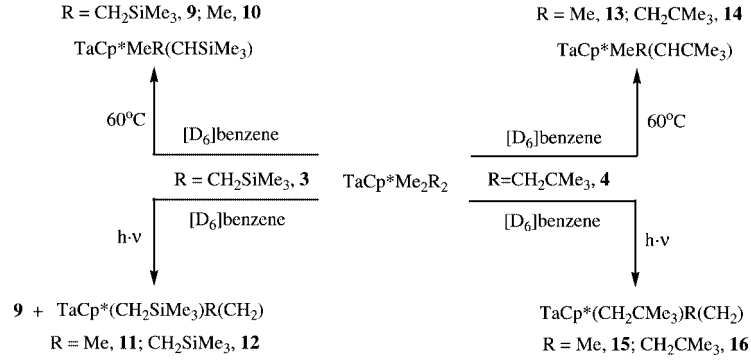

Scheme 5.

pentylidene) derivatives [TaCp*MeR(CHCMe$_3$)] (R = Me, **13**; $CH_2CMe_3$, **14**) in a 4:1 ratio was produced and identified by NMR spectroscopy. Further, a mixture of the (alkyl)(methylidene) complexes [TaCp*($CH_2CMe_3$)R($CH_2$)] (R = Me, **15**; $CH_2CMe_3$, **16**) in a 3:1 ratio was obtained from the irradiation of a [$D_6$]benzene solution of **4** with a sun lamp. These results indicate that a C–Hα bond is activated by thermal (–$CH_2CMe_3$) and photochemical (–$CH_3$) processes, but in both cases the elimination of neopentane is preferential.

A spontaneous α-hydrogen-abstraction process takes place in unstable mixed tetraalkyl intermediates formed by the reaction of complexes [TaCp*$Cl_2$($CH_2R$)$_2$] (R = $CMe_3$, $SiMe_3$) with an alkylating reagent. So, the reaction of [TaCp*$Cl_2$($CH_2CMe_3$)$_2$] with 2 equiv. of $LiCH_2SiMe_3$ gave the (alkyl)(alkylidene) complex [TaCp*($CH_2CMe_3$)($CH_2SiMe_3$)(CHCMe$_3$)] (**17**) with the selective elimination of $SiMe_4$ (Scheme 6). The use of neophyllithium or benzylmagnesium chloride leads to an unidentified mixture of alkylidene derivatives. However, new (alkyl)(alkylidene) derivatives [TaCp*($CH_2R$)($CH_2SiMe_3$)(CHR′)] (R = R′ = Ph, **18**; R = $CMe_2Ph$, R′ = $SiMe_3$, **19**) were prepared by treatment of [TaCp*$Cl_2$($CH_2SiMe_3$)$_2$] with 2 equiv. of the appropriate alkylating reagent; these reactions occur with the elimination of $SiMe_4$ and $CMe_3Ph$, respectively.

For some reported coordinatively unsaturated alkylidene complexes,[8,25] the stretching frequency corresponding to the C–H bond in the IR spectrum was assigned to absorp-

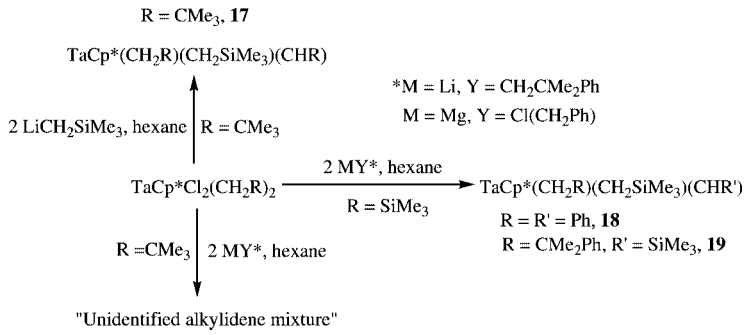

Scheme 6.

tion bands localized in the 2700–2350 $cm^{-1}$ region, which are at a lower wavenumber than those for normal C–H stretches probably as a result of the observed increase in the length of the C–H bond. In the case of (alkyl)(alkylidene) compounds **7** and **17**–**19**, the absorption band localized at $\tilde{\nu}_{average}$ = 2553 $cm^{-1}$ can be assigned to $\nu_{C-H}$.

In accordance with all the NMR spectroscopic data (see Experimental Section) the alkylidene complexes **7**–**19** are monomeric species with the expected three-legged piano-stool geometry.[8,26,27] A large degree of deshielding is observed for the alkylidene carbon resonances ($\delta > 200$ ppm). The direct proton–carbon coupling constants for the Ta=*CH*R signals for complexes **7**, **11**, **12**, **15** and **16** are smaller than the $^1J_{C,H}$ values resulting from coupling involving an $sp^3$ carbon (Ta–*CH*$_2$R groups) and are comparable to other $d^0$ terminal (alkylidene)niobium and -tantalum complexes.[26,27] For the rest of the complexes, we found similar values for the isostructural alkylmethylidene moiety.

## Conclusions

New trialkylchlorido and dialkyldimethyl(pentamethylcyclopentadienyl)tantalum complexes [TaCp*$Cl_xMe_yR_z$] ($x$ = 1, $y$ = 0, $z$ = 3, R = $CH_2SiMe_3$, **1**; $x$ = 0, $y$ = $z$ = 2, R = $CH_2Ph$, **2**; $CH_2SiMe_3$, **3**; $CH_2CMe_3$, **4**) have been prepared by the direct reaction of tetrachlorido or dialkyldichlorido derivatives [TaCp*$Cl_{4-x}R_x$] ($x$ = 0; $x$ = 2, R = Me, $CH_2CMe_3$) with the appropriate alkylating reagent. However, when lithium neophyl is used as the reagent under standard conditions, a different sequence of reactions takes place, which leads to a mixture from which [{TaCp*$Me_2(CH_2CMe_2Ph)$}$_2$(μ-O)] (**5**), [TaCp*$Me_2$-($CH_2CMe_2$–o-$C_6H_4$-κ$^2$*C*,*C*)] (**6**) and [TaCp*Me-($CH_2CMe_2Ph$)($CH_2$)] (**7**) were isolated and identified by NMR spectroscopy. Thermal treatment of toluene or [$D_6$]-benzene solutions of **1** leads to an intramolecular C–Hα bond activation in an alkyl group, giving the (alkyl)(alkylidene)chlorido complex [TaCp*Cl($CH_2SiMe_3$)($CHSiMe_3$)] (**8**) with the evolution of $SiMe_4$. A mixture of dialkyl(alkylidene) derivatives [TaCp*MeR($CHSiMe_3$)] (R = $CH_2SiMe_3$, **9**; Me, **10**) was produced when **3** was heated at 60 °C in [$D_6$]benzene; the mixture was identified by NMR measurements. Further, the direct irradiation of a [$D_6$]benzene solution of **3** gave a mixture of **9** and [TaCp*($CH_2SiMe_3$)-R($CH_2$)] (R = Me, **11**; $CH_2SiMe_3$, **12**). On the other hand, [$D_6$]benzene solutions of **4** slowly decompose at room temperature, giving a mixture of alkylidenes [TaCp*MeR($CHCMe_3$)] (R = Me, **13**; $CH_2CMe_3$, **14**) and [TaCp*($CH_2CMe_3$)R($CH_2$)] (R = Me, **15**; $CH_2CMe_3$, **16**), but the decomposition is faster when activated thermally or photochemically, leading to a mixture of **13**–**14** and **15**–**16**, respectively. Finally, a spontaneous α-hydrogen-abstraction process occurs during the alkylation reaction of TaCp*$Cl_2(CH_2CMe_3)_2$ with $LiCH_2SiMe_3$, which gives [TaCp*($CH_2CMe_3$)($CH_2SiMe_3$)($CHCMe_3$)] (**17**) with selective elimination of $SiMe_4$. However, new (alkyl)(alkylidene) complexes [TaCp*($CH_2$R)($CH_2SiMe_3$)(CHR′)] (R = R′ = Ph, **18**; R = $CMe_2Ph$, R′ = $SiMe_3$, **19**) were obtained by treatment of TaCp*$Cl_2(CH_2SiMe_3)_2$ with 2 equiv. of the appropriate alkylating reagent; these reactions occurred with the elimination of $SiMe_4$ and $CMe_3Ph$, respectively.

## Experimental Section

All operations were carried out under a dry argon atmosphere, by using standard Schlenk tube and cannula techniques, or in a conventional argon-filled glove-box. Solvents were refluxed over an appropriate drying agent, distilled and degassed prior to use: [$D_6$]-benzene and hexane (Na/K alloy), and toluene (Na). Starting materials Ta(η$^5$-$C_5Me_5$)$Cl_4$,[28] Ta(η$^5$-$C_5Me_5$)$Cl_2Me_2$,[13] Ta(η$^5$-$C_5Me_5$)-$Cl_2(CH_2CMe_3)_2$[26a,29] and the alkylating reagents LiR (R = $CH_2SiMe_3$, $CH_2CMe_2Ph$)[30] and Li($CH_2C_6H_5$)(tmeda)[31] were prepared as previously described. Reagent grade LiMe (1.5 M in diethyl ether, Aldrich) and MgCl($CH_2SiMe_3$) (1 M in diethyl ether, Aldrich) were purchased from commercial sources and were used without further purification.

Samples for infrared spectroscopy were prepared as KBr pellets or as Nujol mulls between CsI plates, and the spectra were recorded with a Perkin–Elmer Spectrum 2000 spectrophotometer (4000–400 $cm^{-1}$). The NMR spectra were recorded with Unity 300, Mercury VX 300 and Unity $^{Plus}$ 500 (Varian NMR Systems) spectrometers; chemical shifts were referenced to the $^{13}$C- and residual $^1$H resonances of the deuterated solvents. Microanalyses (C, H) were performed with a LECO CHNS 932 microanalyser.

**[TaCp*Cl($CH_2SiMe_3$)$_3$] (1):** A solution of MgCl($CH_2SiMe_3$) [6.90 mL, 1 M, 6.60 mmol] in diethyl ether was added, at room temperature, to a suspension of TaCp*$Cl_4$ (1.00 g, 2.20 mmol) in hexane (25 mL), and the mixture was stirred for 12 h. The resulting

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

suspension was filtered through Celite and then concentrated to ca. 10 mL, the solution was cooled to –20 °C to give **1** as a yellow microcrystalline solid. Yield 0.90 g (68%). IR (KBr): $\tilde{\nu}$ = 2917 (vs), 1494 (m), 1441 (m), 1380 (s), 1243 (vs), 1105 (s), 1026 (s), 845 (vs), 749 (s), 678 (s), 470 (m), 407 (m) $cm^{-1}$. $^1H$ NMR (300 MHz, [$D_6$]-benzene, 25 °C): $\delta$ = 1.78 (s, 15 H, $C_5Me_5$), 0.65 (s, 6 H, $CH_2SiMe_3$), 0.35 (s, 27 H, $CH_2SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [$D_6$]benzene, 25 °C): $\delta$ = 121.5 ($C_5Me_5$), 88.0 ($CH_2SiMe_3$), 12.8 ($C_5Me_5$), 4.2 ($CH_2SiMe_3$) ppm. $C_{22}H_{48}ClSi_3Ta$ (613.28): calcd. C 43.08, H 7.89; found C 43.31, H 7.78.

**[TaCp*Me$_2$(CH$_2$C$_6$H$_5$)$_2$] (2):** This reaction was carried out in a dry box by using darkened glassware designed for photosensitive materials. A solution of Li($CH_2$Ph)(tmeda) (0.31 g, 1.44 mmol) in toluene (20 mL) was added to a solution of TaCp*$Cl_2Me_2$ (0.30 g, 0.72 mmol) in toluene (30 mL) at room temperature, and the mixture was stirred for 10 h. The suspension was concentrated to dryness and the residue extracted with hexane (3 × 20 mL). The solution was filtered, concentrated to ca. 10 mL, and cooled to give **2** as a red microcrystalline solid. Yield 0.29 g (80%). IR (KBr): $\tilde{\nu}$ = 2916 (s), 1591 (m), 1484 (vs), 1450 (m), 1379 (s), 1203 (s), 1150 (m), 1062 (s), 1025 (s), 807 (m), 750 (vs), 698 (vs), 601 (m), 529 (m), 443 (w) $cm^{-1}$. $^1H$ NMR (300 MHz, [$D_6$]benzene, 25 °C): $\delta$ = 7.21 (m, 2 H), 7.11 (m, 2 H), 6.85 (m, 1 H, $H_5C_6CH_2$–Ta), 1.67 (br., 4 H, Ta–$CH_2$Ph), 1.60 (s, 15 H, $C_5Me_5$), 0.86 (br., 6 H, Ta–$Me_2$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [$D_6$]benzene, 25 °C): $\delta$ = not detected ($C_i$), 127.9 ($C_m$), 127.3 ($C_o$), 123.2 ($C_p$, $C_6H_5CH_2$–Ta), 119.5 ($C_5Me_5$), 94.8 (Ta–$CH_2C_6H_5$), 81.3 (Ta–$Me_2$), 11.4 ($C_5Me_5$) ppm. $C_{26}H_{35}Ta$ (528.51): calcd. C 59.08, H 6.67; found C 58.98, H 6.70.

**[TaCp*Me$_2$(CH$_2$SiMe$_3$)$_2$] (3):** A stirred suspension of TaCp*$Cl_2Me_2$ (0.50 g, 1.20 mmol) in toluene (30 mL) was treated with a solution of $LiCH_2SiMe_3$ (0.23 g, 2.40 mmol) in toluene (20 mL). The reaction mixture was stirred for 10 h at room temperature, and the resulting suspension was decanted and filtered. The solution was concentrated to dryness and the residue extracted with hexane (3 × 15 mL). The solution was filtered, concentrated to ca. 10 mL, and cooled to –40 °C to give **3** as a yellow microcrystalline solid. Yield 0.35 g (74%). IR (KBr): $\tilde{\nu}$ = 2947 (vs), 1490 (m), 1432 (s), 1380 (m), 1295 (w), 1241 (s), 1160 (m), 1026 (m), 947 (s), 856 (vs), 823 (vs), 744 (m), 718 (s), 676 (m), 612 (m), 521 (w), 442 (m) $cm^{-1}$. $^1H$ NMR (500 MHz, [$D_2$]dichloromethane, 25 °C): $\delta$ = 2.00 (s, 15 H, $C_5Me_5$), 0.40 (quint, $^4J_{H,H}$ = 1.1 Hz, 6 H, Ta–$Me_2$), 0.06 (s, 18 H, Ta–$CH_2SiMe_3$), –0.30 (m, 4 H, Ta–$CH_2SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [$D_6$]benzene, 25 °C): $\delta$ = 118.9 ($C_5Me_5$), 83.6 (Ta–$CH_2SiMe_3$), 71.7 (Ta–$Me_2$), 11.7 ($C_5Me_5$), 3.8 ($CH_2SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, [$D_2$]dichloromethane, 25 °C): $\delta$ = 118.9 ($C_5Me_5$), 83.2 (Ta–$CH_2SiMe_3$), 70.7 (Ta–$Me_2$), 11.1 ($C_5Me_5$), 3.5 ($CH_2SiMe_3$) ppm. $C_{20}H_{43}Si_2Ta$ (520.68): calcd. C 46.12, H 8.32; found C 45.90, H 8.02.

**[TaCp*Me$_2$(CH$_2$CMe$_3$)$_2$] (4):** A solution of LiMe in diethyl ether (1.30 mL, 1.5 M, 1.95 mmol) was added to a solution of TaCp*$Cl_2(CH_2CMe_3)_2$ (0.40 g, 0.75 mmol) in hexane (40 mL) at –78 °C, and the mixture was stirred for 5 h. The suspension was then warmed to room temperature and LiCl filtered off. The solution was concentrated to ca. 10 mL and cooled to –40 °C to give a yellow microcrystalline solid identified as **4**. Yield 0.30 g (81%). IR (KBr): $\tilde{\nu}$ = 2940 (vs), 1431 (m), 1379 (s), 1205 (s), 1157 (m), 1023 (m), 804 (w), 746 (m), 601 (m), 522 (m), 455 (m) $cm^{-1}$. $^1H$ NMR (300 MHz, [$D_6$]benzene, 25 °C): $\delta$ = 1.66 (s, 15 H, $C_5Me_5$), 1.40 (s, 18 H, Ta–$CH_2CMe_3$), 0.92 (6 H, Ta–$Me_2$), 0.34 (4 H, Ta–$CH_2CMe_3$) ppm. $^1H$ NMR (500 MHz, [$D_2$]dichloromethane, 25 °C): $\delta$ = 1.96 (s, 15 H, $C_5Me_5$), 1.07 (s, 18 H, Ta–$CH_2CMe_3$), 0.59 (quint, $^4J_{H,H}$ = 1.3 Hz, 6 H, Ta–$Me_2$), 0.20 (sept, $^4J_{H,H}$ = 1.3 Hz, 4 H, Ta–$CH_2CMe_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [$D_6$]-benzene, 25 °C): $\delta$ = 118.6 ($C_5Me_5$), 111.2 (Ta–$CH_2CMe_3$), 76.6 (Ta–$Me_2$), not detected (Ta–$CH_2CMe_3$), 36.3 (Ta–$CH_2CMe_3$), 11.7 ($C_5Me_5$) ppm. $C_{22}H_{43}Ta$ (488.53): calcd. C 54.09, H 8.87; found C 53.95, H 8.72.

**[{TaCp*Me$_2$(CH$_2$CMe$_2$Ph)}$_2$(μ-O)] (5):** Complex **5** was isolated together with complexes **6** and **7** by using a standard vacuum line and Schlenk techniques. A mixture of TaCp*$Cl_2Me_2$ (0.50 g, 1.20 mmol) and $LiCH_2CMe_2Ph$ (0.34 g, 2.40 mmol) was stirred in toluene (30 mL) at room temperature for 15 h. LiCl was filtered off, and the resulting solution was concentrated to dryness. The brown residue was extracted with hexane (3 × 10 mL), concentrated to ca. 10 mL, and then cooled to –40 °C to give **5**. The filtrate was cooled to –78 °C to give **6** as a yellow microcrystalline solid, and the final solution was concentrated to dryness to give **7** as a brown oil. IR (KBr): $\tilde{\nu}$ = 2912 (s), 1599 (w), 1491 (m), 1436 (s), 1378 (s), 1203 (w), 1157 (m), 1027 (m), 740 (vs), 709 (s), 650 (m), 555 (w), 466 (m) $cm^{-1}$. $^1H$ NMR (300 MHz, [$D_6$]benzene, 25 °C): $\delta$ = 7.62 (m, 4 H), 7.33 (m, 4 H), 7.12 (m, 2 H, $H_5C_6Me_2C$–$CH_2$–Ta), 1.79 (s, 12 H, Ta–$CH_2CMe_2Ph$), 1.68 (s, 30 H, $C_5Me_5$), 1.04 (s, 4 H, Ta–$CH_2CMe_2Ph$), 0.68 (s, 12 H, Ta–$Me_2$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [$D_6$]benzene, 25 °C): $\delta$ = 157.3 ($C_i$), 127.9, 126.3, 124.8 ($H_5C_6Me_2C$–$CH_2$), 117.8 ($C_5Me_5$), 88.3 (Ta–$CH_2CMe_2Ph$), 61.4 (Ta–$Me_2$), 43.7 (Ta–$CH_2CMe_2Ph$), 35.2 (Ta–$CH_2CMe_2Ph$), 11.4 ($C_5Me_5$) ppm.

**[TaCp*Me$_2$(CH$_2$CMe$_2$-*o*-C$_6$H$_4$-κ$^2$*C*,*C*)] (6) and [TaCp*Me(CH$_2$CMe$_2$Ph)(CH$_2$)] (7):** Under rigorously anhydrous conditions (glove box), a solution of TaCp*$Cl_2Me_2$ (0.50 g, 1.20 mmol) in toluene (30 mL) was treated with a solution of $LiCH_2CMe_2Ph$ (0.34 g, 2.40 mmol) in toluene (10 mL), and the mixture was stirred at room temperature for 15 h. The resulting suspension was concentrated to dryness, and the residue extracted with hexane (2 × 15 mL). The solution was filtered, concentrated to ca. 10 mL and cooled to –78 °C over a period of several minutes to give a pale brown microcrystalline solid identified as **6**. Compound **6** was then filtered off, and the solution was concentrated to dryness to give **7** as a sticky brown solid.

Data for **6**: Yield 0.18 g (32%). IR (KBr): $\tilde{\nu}$ = 2909 (vs), 1654 (w), 1574 (w), 1492 (m), 1438 (s), 1377 (s), 1238 (m), 1102 (m), 1024 (m), 762 (s), 731 (vs), 560 (m), 460 (m), 411 (m) $cm^{-1}$. $^1H$ NMR (500 MHz, [$D_2$]dichloromethane, –40 °C): $\delta$ = 8.05 (m, 1 H, $H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 7.27 (m, 1 H, $H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 7.20 (m, 1 H, $H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 7.10 (m, 1 H, $H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 1.89 (s, 15 H, $C_5Me_5$), 1.07 (s, 6 H, $H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 0.77 (s, 2 H, $H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 0.18 (s, 6 H, Ta–$Me_2$) ppm. $^{13}C$ NMR[32] (125 MHz, [$D_2$]dichloromethane, 25 °C): $\delta$ = 219.1 ($C_i$–Ta), 137.1, 124.0, 123.8, 123.2, 160.3 ppm ($H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 115.9 ($C_5Me_5$), 112.4 ($H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 67.4 (Ta–$Me_2$), 49.5 ($H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 34.0 ($H_4C_6$–*o*-$CMe_2$–$CH_2$–Ta), 10.2 ($C_5Me_5$) ppm. $C_{22}H_{33}Ta$ (478.45): calcd. **[TaCp*(CH$_2$Ph)(CH$_2$SiMe$_3$)(CHPh)] (18):** This reaction was carried out in a glove box in darkened glassware designed for photosensitive materials. A 1 M solution of MgCl(CH$_2$Ph) in diethyl ether (1.50 mL, 1.45 mmol) was added to a solution of TaCp*Cl$_2$-(CH$_2$SiMe$_3$)$_2$ (0.40 g, 1.71 mmol) in hexane (30 mL), and the mixture was stirred for 14 h. The resulting suspension was decanted and filtered through Celite. The red solution was concentrated to ca. 5 mL and cooled to –40 °C overnight to give **18** as a red microcrystalline solid. Yield 0.27 g (65%). IR (CsI): $\tilde{\nu}$ = 2914 (vs), 2494 (w), 1856 (w), 1592 (m), 1485 (vs), 1449 (s), 1378 (m), 1242 (s), 1199 (m), 1054 (m), 1027 (s), 950 (m), 850 (vs), 750 (vs), 695 (s), 536 (m), 438 (w) cm$^{-1}$. $^1$H NMR (300 MHz, [D$_6$]benzene, 25 °C): $\delta$ = 7.29–6.86 (several phenyl, $H_5C_6CH_2$–Ta, $H_5C_6CH$=Ta), 5.45 (s, 1 H, Ta=C*H*Ph), 1.79 (s, 15 H, C$_5$*Me*$_5$), 1.68 (AB, $^2J_{H,H}$ = 12.3 Hz, 1 H, Ta–CH*H*Ph), 1.61 (AB, $^2J_{H,H}$ = 12.3 Hz, 1 H, Ta–CH*H*Ph), 0.88 (AB, $^2J_{H,H}$ = 12.1 Hz, 2 H, Ta–CH*H*Ph , Ta–CH*H*SiMe$_3$), 0.09 (s, 9 H, Ta–CH$_2$Si*Me*$_3$), –1.29 (AB, $^2J_{H,H}$ = 12.1 Hz, 2 H, Ta–CH*H*Ph, Ta–CH*H*SiMe$_3$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, [D$_6$]benzene, 25 °C): $\delta$ = 216.7 (d, $^1J_{C,H}$ = 82.6 Hz, Ta=*C*HPh), 151.1–122.9 (several phenyl, $H_5C_6CH_2$–Ta, $H_5C_6CH$=Ta), 114.5 (*C*$_5$Me$_5$), 69.1 (t, $^1J_{C,H}$ = 119.4 Hz, Ta–*C*H$_2$Ph), 64.1 (t, $^1J_{C,H}$ = 104.2 Hz, Ta–*C*H$_2$SiMe$_3$), 11.3 (C$_5$*Me*$_5$), 2.7 (Ta–CH$_2$Si*Me*$_3$) ppm. $C_{28}H_{39}SiTa$ (584.65): calcd. C 57.52, H 6.72; found C 57.48, H 6.75.

**[TaCp*(CH$_2$CMe$_2$Ph)(CH$_2$SiMe$_3$)(CHSiMe$_3$)] (19):** TaCp*Cl$_2$-(CH$_2$SiMe$_3$)$_2$ (0.30 g, 0.53 mmol) and Li(CH$_2$CMe$_2$Ph) (0.16 g, 1.20 mmol) were stirred in toluene (40 mL) at room temperature for 15 h. The volatiles were removed under reduced pressure, and the residual solid was extracted with hexane (2 × 15 mL). The solution was filtered and concentrated to dryness to give **19** as a pale brown oil. Yield 0.26 g (81%). IR (CsI): $\tilde{\nu}$ = 2910 (vs), 2564 (w), 1599 (w), 1492 (m), 1442 (s), 1379 (s), 1242 (vs), 1169 (m), 1028 (m), 945 (vs), 847 (vs), 762 (s), 702 (s), 626 (w), 552 (m), 434 (m) cm$^{-1}$. $^1$H NMR (300 MHz, [D$_6$]benzene, 25 °C): $\delta$ = 7.44 (m, 2 H, $H_5C_6Me_2CCH_2$–Ta), 7.26 (m, 2 H, $H_5C_6Me_2CCH_2$–Ta), 7.09 (m, 1 H, $H_5C_6Me_2CCH_2$–Ta), 4.17(s, 1 H, Ta=C*H*SiMe$_3$), 1.79 (s, 15 H, C$_5$*Me*$_5$), 1.70 (s, 3 H), 1.57 (s, 3 H, Ta–CH$_2$C*Me*$_2$Ph), 1.01 (AB, $^2J_{H,H}$ = 14.4 Hz, 1 H), not detected (AB, $^2J_{H,H}$ = 14.4 Hz, 1 H), 0.40 (AB, $^2J_{H,H}$ = 11.7 Hz, 2 H, Ta–CH*H*CMe$_2$Ph, Ta–CH*H*SiMe$_3$), 0.28 (s, 9 H), 0.14 (s, 9 H, Ta–CH$_2$Si*Me*$_3$, Ta=CHSi-*Me*$_3$), –2.05 (AB, $^2J_{H,H}$ = 11.7 Hz, 2 H, Ta–CH*H*CMe$_2$Ph, Ta–CH*H*SiMe$_3$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, [D$_6$]benzene, 25 °C): $\delta$ = 226.8 (d, $^1J_{C,H}$ = 76.6 Hz, Ta=*C*HSiMe$_3$), 153.6 (C$_i$), 128.5 (C$_o$), 126.4 (C$_m$), 125.5 (C$_p$, $H_5C_6Me_2CCH_2$–Ta), 114.4 (*C*$_5$Me$_5$), 86.7 (t, $^1J_{C,H}$ = 109.5 Hz, Ta–*C*H$_2$CMe$_2$Ph), 64.0 (t, $^1J_{C,H}$ = 103.4 Hz Ta–*C*H$_2$SiMe$_3$), 40.1 (Ta–CH$_2$*C*Me$_2$Ph), 36.9, 31.9 (Ta–CH$_2$C*Me*$_2$Ph), 11.9 (C$_5$*Me*$_5$), 3.6, 2.8 (Ta–CH$_2$Si*Me*$_3$, TaCHSi-*Me*$_3$).

**Crystal Structure Determination for Compounds 1, 4 and 5:** Crystallographic and experimental details of the crystal structure determinations are given in Table 4. Suitably sized crystals were sealed under argon in a Lindemann capillary tube and mounted on an Enraf Nonius CAD 4 automatic four circle diffractometer with graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Intensities were collected at room temperature and corrected for Lorenz and polarization effects in the usual manner. No extinction corrections were made. Empirical absorption corrections (DIFABS)[33] were made to the data for **1** and **4**, and the data for **5** were corrected with $\psi$

scan methods. Structures were initially solved by direct methods, completed by the subsequent difference Fourier techniques and refined by full-matrix least-squares on $F^2$ (SHELXL-97).[34] Anisotropic thermal parameters were included in the last cycles of refinement for the non-hydrogen atoms, except for five carbon atoms in compound **5** that remained isotropic. The hydrogen atoms were included from geometrical calculations and refined by using a riding model. All the calculations were performed with the WINGX system.[35]

CCDC-299683(**1**), 299684(**4**) and 299685(**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Site-Specific Recognition of Dipeptides Through Non-Covalent Inter-Ligand Interactions for the Hydrolysis of Dipeptide to Amino Acid Ligands Mediated by Ternary Cobalt(III) Complexes

**Koichiro Jitsukawa,*[a] Tomohiro Mabuchi,[a] Hisahiko Einaga,[a] and Hideki Masuda[a]**

**Keywords:** Ligand design / Hydrolysis / Coordination modes / Cobalt / Host–guest systems

Molecular recognition of dipeptide (DP) compounds is performed with a ternary cobalt(III) complex containing the tripodal tetradentate ligand bis-*N*,*N*-carboxymethyl-L-phenylalanine ($H_3$bcmpa). The coordination structure of the complex [Co(bcmpa)(dp)]$^-$ (**1**–**14**) was spectroscopically assigned by UV/Vis, CD, and $^1$H NMR spectroscopic methods. Site-specific recognition of the dipeptide on the ternary complex is achieved by various weak, non-covalent, inter-ligand interactions, such as hydrogen bonding, steric repulsion, and electrostatic interaction, etc. Some dipeptides having C-terminal aromatic side-chains also demonstrate inter-ligand CH–π interactions between the aromatic ring and the α-hydrogen of bcmpa. Coordination of the N-terminal nitrogen atom of the dipeptide to cobalt at the *trans*(N)-position to the tertiary nitrogen of bcmpa in the octahedral geometry provides an aminopeptidase model. Under slightly alkaline conditions, the dipeptide ligand of some of these complexes is cleaved to give the ternary complex, [Co(bcmpa)(aa)]$^-$ (aa = amino acidato). The rate for the hydrolysis of dipeptide decreases upon increasing the steric bulkiness of the C-terminal side-chain. In the cases of the ternary complexes [Co(bcmpa)(gly-phe)]$^-$ (**6** and **11**), which have C-terminal L- or D-phenylalanine, the hydrolysis of gly-phe to gly was completely prevented. On the other hand, the ternary cobalt(III) complexes [Co(bcmga)(gly-phe)]$^-$ (**18** and **19**), where $H_3$bcmga (bis-*N*,*N*-carboxymethyl-L-glutamic acid) is the more hydrophilic tripodal ligand, give a small amount of the corresponding cleavage product [Co(bcmga)(gly)]$^-$. The hydrophobic sphere generated around the metal complex in **6** and **11** regulates approach of $OH^-$ ion to the amide carbonyl group. Multi-site interactions mediated on the ternary complexes are available for the design of an artificial hydrolysis enzyme. This is the first report describing the substrate-specific cleavage of peptides using a simple enzyme model complex.

## Introduction

Various models for the enzyme reaction have been investigated in the course of studying biomimetic catalysis.[1,2] Hydrolysis of the peptide bond is usually carried out in strongly acidic or alkaline conditions as the reaction in neutral aqueous media is very slow. Although hydrolysis of a gly-val compound under non-catalytic conditions requires more than 200 years,[3] the presence of an enzyme accelerates the process remarkably.[4] Kimura has reported the sequential hydrolysis of peptides in the presence of a [Co(trine)(OH)($H_2O$)]$^{2+}$ complex, in which various oligopeptides were cleaved to give amino acids.[5] At around the same time, Bentley et al. also reported cleavage of peptide ligands mediated by the [Co(trine)(OH)($H_2O$)]$^{2+}$ complex.[6] Using this cobalt(III) complex, moreover, Boreham, et al. have reported a mechanistic investigation of the intermediate of the amide cleavage reaction.[7] In these previous studies using cobalt(III) complexes, the selectivity of the cleavage reaction was not discussed. Using cobalt(III) complexes combined with peptide-hapten, Iverson and Lerner reported the sequence-specific hydrolysis of the gly-phe bond.[8] Unlike these previous reports, exopeptidase activity was demonstrated by the regioselective cleavage of lysozyme using [Co($NH_3$)$_4$X($H_2O$)] (X = OH or $H_2O$) complexes as artificial metallopeptidases.[9] Recently, Chae et al. have reported that a cobalt(III) cyclen complex containing a diamide moiety shows an *endo*-selective cleavage activity for peptides.[10] However, there have been few reports demonstrating selectivity for the cleavage of peptides mediated by cobalt(III) complexes. Since Kostic et al. first reported that platinum(II) or palladium(II) ions show catalytic activity for the hydrolysis of peptides,[11] there have been some examples reported of the selective cleavage of peptide compounds. These systems are considered to be an artificial enzyme because the peptide itself becomes a ligand due to coordination of the sulfur or nitrogen atom, for example with peptides including cysteine (cys), methionine (met), or histidine (his).[12] Although a detailed mechanism for the

hydrolysis reaction is not yet clear, the carbonyl group of the amide bond to a neighboring cys, met, or his residue was found to be selectively hydrolyzed under mild conditions when platinum(II) complexes containing two substitutionally labile sites were used.[13]

With a view to investigating metalloenzymes, transition metal complexes provide an attractive tool for constructing an artificial enzyme model of peptidase through various weak, non-covalent interactions.[14–18] A combination of non-covalent interactions observed at or near the active site of the enzyme causes high efficiency and specificity for an enzymatic reaction, which is essential for biological reactions involving substrate recognition.[19] For example, various non-covalent interactions, such as hydrogen bonding, hydrophobic interactions, steric repulsions, and electrostatic interactions, have been clearly demonstrated at the active site of the enzyme–substrate complex formed from aminopeptidase and bestatin.[20] Moreover, an interesting approach to delineate the non-covalent bonds between chromium(III) complexes containing a nitrilotriacetate framework and a protein surface has been described that uses NMR and CD spectroscopy.[21] We have hitherto been interested in the construction of molecular recognition models for enzyme–substrate complexes,[22–25] in which the cobalt(III) complex $[Co(bcmpa)(aa)]^-$, which contains the tripodal tetradentate ligand bis-*N*,*N*-carboxymethyl-L-phenylalanine ($H_3$bcmpa), is considered as an enzyme model, with a didentate amino acid (AA) as substrate. Various amino acids were found to coordinate to $Co^{III}$-bcmpa in a *trans*(N) configuration rather than a *cis*(N) one.[22,24] It is very interesting that such a simple metal complex demonstrates the coordination-selective recognition of amino acids through various non-covalent interactions between bcmpa and the amino acid moiety.[17] In addition, this $Co^{III}$-bcmpa complex self-assembled on a Au electrode also becomes a new promoter electrode that recognizes the electron-transfer site in enzymes.[26]

In this study, we report the synthesis of ternary cobalt(III) complexes $[Co(bcmpa)(dp)]^-$ with a dipeptide (DP) ligand and characterize the inter-ligand interactions for the site-selective recognition of dipeptides on the complexes spectroscopically in solution. We also investigate the cleavage reaction of the dipeptide ligand in slightly alkaline solution. Selective hydrolysis of the dipeptide ligand mediated by the ternary cobalt(III) complexes is caused by the various non-covalent inter-ligand interactions, which allow this complex to be considered as an aminopeptidase model.

## Results and Discussion

### Coordination Structure of the Ternary Cobalt(III) Complexes with Dipeptide Ligands

The complexation of $K_2[Co(bcmpa)(CO_3)]$ with various dipeptide compounds in neutral aqueous solution in the presence of active charcoal gave two negatively charged complexes after QAE Sephadex exchange column separation with aqueous KCl solution. One of the separated bands was found to contain the orange-colored complex K[Co(bcmpa)(dp)] (**1**–**14**), whereas the other contained the pink-colored complex K[Co(bcmpa)(aa)]; the ratio of the former to the latter was about 10:1. The UV/Vis spectra of the main band containing cobalt(III) complexes with a dipeptide ligand are very similar to those of the previously reported complexes *trans*(N)-$[Co(bcmpa)(gly)]^-$ and *trans*(N)-$[Co(bcmpa)(leu)]^-$.[22] The first absorption band at $19.6–19.8 \times 10^3$ $cm^{-1}$ ($\log\varepsilon$ = 2.15–2.18) with a shoulder at about $16 \times 10^3$ $cm^{-1}$ ($\log\varepsilon$ = about 1.3) of complexes **1**–**14** indicates that two nitrogen atoms occupy the *trans* position in an octahedral geometry.[24,27,28] Their second absorption bands are found at about $26.2–26.4 \times 10^3$ $cm^{-1}$ ($\log\varepsilon$ = 2.17–2.19). On the basis of the spectral analogy to *trans*(N)-$[Co(N)_2(O)_4]^-$, which is supported by the X-ray single crystal analysis of *trans*(N)-$[Co(bcmpa)(gly)]^-$, *trans*(N)-$[Co(bcmpa)(leu)]^-$, and *trans*(N)-$[Co(bcmle)(phe)]^-$,[22,23] we consider that the *trans* position to the bcmpa nitrogen in the $[Co(bcmpa)(dp)]^-$ complex is occupied by the N-terminal amine nitrogen and the *cis* position by the amide carbonyl oxygen atom.[17,22] The compounds included in the pink-colored minor band were identified as *trans*(N)-$[Co(bcmpa)(aa)]^-$ complexes on the basis of the spectral analogy of their previously reported analogs.[22,24] When the complexation with $K_2[Co(bcmpa)(CO_3)]$ and dipeptide was carried out at higher pH, the yield of the pink-colored band increased and that of the orange-colored one decreased. These findings indicate that complex formation between the dipeptide and $[Co(bcmpa)(CO_3)]^{2-}$ is accompanied by hydrolysis of the amide bond. Moreover, the –1 charge of the reaction product, as determined by the column separation behavior, reveals that the amide carbonyl group of the dipeptide coordinates to the metal center without deprotonation. The hydrogen atom attached to the amide nitrogen of *trans*(N)-$[Co(bcmpa)(dp)]^-$ is not removed in neutral or weakly alkaline media under complex formation conditions.

The character of the ternary cobalt(III) complexes consisting of the optically active bcmpa and dipeptide was also investigated by recording their CD spectra.[27,29] The three positive CD peaks of the *trans*(N)-$[Co(bcmpa)(gly\text{-}gly)]^-$ complex **1** observed at 16.2, 19.6, and $26.0 \times 10^3$ $cm^{-1}$ are very similar to those of *trans*(N)-$[Co(bcmpa)(gly)]^-$.[24] Two dipeptide complexes, namely $[Co(bcmpa)(leu\text{-}gly)]^-$ (**5**) and $[Co(bcmpa)(phe\text{-}gly)]^-$ (**7**), show positive CD peaks at 16.7, 18.7, and $26.4 \times 10^3$ $cm^{-1}$ and a negative one at $20.9 \times 10^3$ $cm^{-1}$, respectively, very similar to complexes of $[Co(bcmpa)(leu)]^-$ with coordinated didentate optically active amino acids.[22,24] Moreover, the intensity of the posi-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tive CD peaks of **5** and **7** is relatively strong in comparison with those of [Co(bcmpa)(gly-ala)]$^-$ (**2**), [Co(bcmpa)(gly-leu)]$^-$ (**4**), and [Co(bcmpa)(gly-phe)]$^-$ (**6**). Enhancement of the CD intensity indicates the coordination of the asymmetric amino acid moiety of the dipeptide to the cobalt(III) ion. As shown in Figure 1, the differential CD spectrum between [Co(bcmpa)(gly-D-ala)]$^-$ (**10**) and [Co(bcmpa)(gly-gly)]$^-$ (**1**) has a perfectly antipodal form, as does that between **2** and **1**.[29] Similar differential CD spectra were observed in the complexes coordinated by gly-L-phe (**6**) and gly-D-phe (**11**). The characteristic CD spectra of complexes **1**–**14** reveal that the N-terminal nitrogen atom of the dipeptide coordinates to the cobalt ion in a *trans*(N) manner.

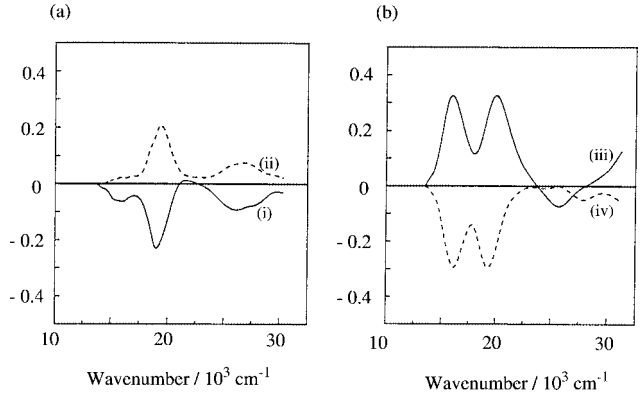

Figure 1. Differential CD spectra of the cobalt(III) complexes with dipeptide ligands. (a) Effect of C-terminal alanine: (i) [Co(bcmpa)(gly-ala)]$^-$ (**2**) – [Co(bcmpa)(gly-gly)]$^-$ (**1**); (ii) [Co(bcmpa)(gly-D-ala)]$^-$ (**10**) – [Co(bcmpa)(gly-gly)]$^-$ (**1**). (b) Effect of C-terminal phenylalanine: (iii) [Co(bcmpa)(gly-phe)]$^-$ (**6**) – [Co(bcmpa)(gly-gly)]$^-$ (**1**); (iv) [Co(bcmpa)(gly-D-phe)]$^-$ (**11**) – [Co(bcmpa)(gly-gly)]$^-$ (**1**).

The coordination structure of the diamagnetic cobalt(III) complex in solution was investigated by $^1$H NMR spectroscopy. The characteristic $^1$H NMR spectra of dipeptide complexes **1**–**14** are summarized in Table 1, where they are compared with those of [Co(bcmpa)(aa)]$^-$ previously identified.[24] In [Co(bcmpa)(gly-gly)]$^-$ (**1**), three pairs of AB patterns are observed in the methylene region. One of these ($\delta$ = 3.98 and 4.63 ppm, $J$ = 18.0 Hz) was assigned to the R-ring hydrogens of bcmpa.[30] The G-ring hydrogens of bcmpa at $\delta$ = 3.20 and 4.13 ppm show a slightly smaller coupling constant of 16.8 Hz.[31] The others at $\delta$ = 4.24 and 4.25 ppm ($J$ = 17.3 Hz) were identified as the N-terminal methylene hydrogens of the coordinating glycine moiety. The ABX pattern demonstrated by two benzyl hydrogens at $\delta$ = 3.51 ($J$ = 15.1 and 10.6 Hz) and 3.64 ppm ($J$ = 15.1 and 4.8 Hz) and the adjacent α-hydrogen at $\delta$ = 4.90 ppm ($J$ = 10.6 and 4.8 Hz) is derived from the Gs-ring of bcmpa.[30] The singlet observed at $\delta$ = 3.82 ppm was identified as the C-terminal methylene hydrogens of the glycine moiety. The aromatic hydrogens of the bcmpa side-chain appear at $\delta$ = 7.4–7.6 ppm. As shown in Table 1, the chemical-shift values of the α-hydrogens of the N-terminal amino acid residue appear slightly downfield in comparison with those of the C-terminal one except for complexes **9** and **12**, which contain a C-terminal phenylglycine moiety. The above complex formation shifts of the N-terminal amino acid moiety indicate N-terminal coordination of the dipeptide to cobalt with formation of an N–O chelate. Taking account of the UV/Vis, CD, and $^1$H NMR spectral investigations, the coordination structure of the dipeptide complex was determined to be that shown in Figure 2 (a), although other structures (b–f) are also possible.

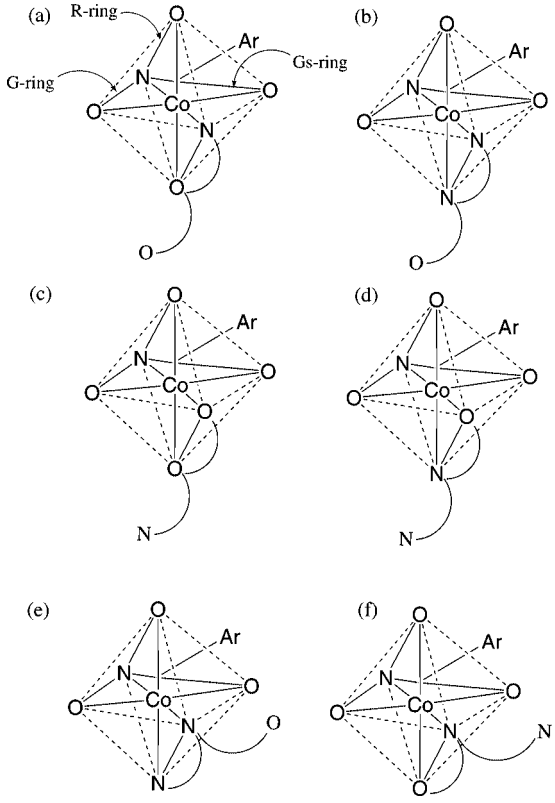

Figure 2. Six possible coordination modes of a dipeptide to a cobalt(III) complex with a tripodal $NO_3$-type ligand: (a) *trans*(N)-NO (coordination of N-terminal amine nitrogen *trans* to the tertiary amine of the tripodal $NO_3$-type ligand and the amide carbonyl oxygen); (b) *trans*(N)-NN (coordination of N-terminal amine nitrogen *trans* to the tertiary amine of the tripodal $NO_3$-type ligand and the amide nitrogen); (c) *trans*(O)-OO (coordination of C-terminal carboxylic oxygen *trans* to the tertiary amine of the tripodal $NO_3$-type ligand and the amide carbonyl oxygen); (d) *trans*(O)-ON (coordination of C-terminal carboxylic oxygen *trans* to the tertiary amine of the tripodal $NO_3$-type ligand and the amide nitrogen); (e) *cis*(N)-NN (coordination of the N-terminal amine nitrogen *cis* to the tertiary amine of the tripodal $NO_3$-type ligand and the amide nitrogen); (f) *cis*(O)-ON (coordination of C-terminal carboxylic oxygen *cis* to the tertiary amine of the tripodal $NO_3$-type ligand and the amide nitrogen).

## Inter-Ligand Interactions Observed for the [Co(bcmpa)(dp)] Complexes

In the $^1$H NMR spectra of the dipeptide complexes, the α-hydrogens of the Gs ring of complexes **1**–**5**, **7**, **8**, **10**, **13**, and **14**, appear at about $\delta$ = 4.8–4.9 ppm, whereas those of complexes **6** and **9** appear at about $\delta$ = 3.8–4.7 ppm. The downfield shift observed in the former complexes indicates

a hydrogen-bonding interaction between the α-hydrogen of bcmpa and the coordinating carbonyl oxygen of the dipeptide. This interaction, which is mediated by the cobalt(III) complex with a bcmpa ligand, has also been observed in the crystal structure of amino acid complexes, in which the atomic distances between the α-carbon of bcmpa and the carboxyl oxygen of amino acid in *trans*(N)-[Co(bcmpa)-(leu)]$^-$ are 2.83 and 2.84 Å.[22] These data are within the range for a hydrogen bond.[32] In complex **6**, however, the corresponding signal appears at $\delta$ = 4.32 ppm, which signifies an upfield shift relative to that for **1** ($\delta$ = 4.90 ppm) with no aromatic side-chain. Some α-hydrogens of the Gs-ring in the [Co(bcmpa)(dp)]$^-$ complexes with a C-terminal aromatic amino acid are detected in the high-field region despite the downfield shift caused by the hydrogen bond described above. This is due to the ring current effect of the benzene ring. The larger upfield shift in complex **9** indicates that the benzene ring of the C-terminal phenylglycine residue approaches the α-position more closely in solution. In addition, the G-ring methylene hydrogens in **11** and **12**, which have a C-terminal aromatic D-amino acid residue, appear at $\delta$ = 2.7–3.4 ppm. The highest values of all [Co(bcmpa)(dp)]$^-$ complexes employed here indicate that the aromatic ring of the D-amino acid at the C-terminus of the dipeptide in **11** and **12** approaches the α-position of the bcmpa Gs-ring, which is interpreted in terms of an attractive inter-ligand CH–π interaction.[33] We consider that the CH–π interaction between the aromatic side-chain and the chelate ring methylene group assembles the aromatic rings around the outer coordination sphere of the ternary complex.[33,34]

To confirm the inter-ligand interactions, solvent effects on the $^1$H NMR spectra of some complexes were examined. The α-hydrogen of **6** appears at $\delta$ = 4.40 ppm in less polar solvent (75% [$D_8$]dioxane and 25% $D_2O$) and at $\delta$ = 4.32 ppm in more polar solution ($D_2O$). Notably, all the other hydrogens of **6** appear in the up-field region under less polar conditions. In the cases of **1** and **4**, which have no C-terminal aromatic ring, all hydrogens appear in the upper field region under less polar conditions than those provided by $D_2O$. Hydrophobic interaction such as the CH–π interaction that is present in the aqueous phase does not form under less polar conditions.[33,34] The results are listed in Table 2.

Solvent effects were also investigated by CD spectroscopy. In complexes **1**, **13**, and **14**, whose only asymmetric ligand is bcmpa, no CD spectral variations were observed between polar (water) and less polar (water/dioxane = 1:3) solvents. In the case of **4**, which contains bcmpa and an asymmetric C-terminal bulky aliphatic group, the CD intensity at about $16 \times 10^3$ cm$^{-1}$ in water increases and that at $20 \times 10^3$ cm$^{-1}$ decreases upon addition of dioxane, as shown in Figure 3 (a). Such a spectral change is caused by a conformational change of the asymmetric ligand bound to the cobalt(III) center. On the other hand, in the case of **6**, which contains bcmpa and an asymmetric C-terminal aromatic group, the CD intensities at about 16 and $20 \times 10^3$ cm$^{-1}$ gradually decrease upon addition of dioxane to the aqueous solution, as shown in Figure 3 (b). These findings are interpreted in terms of a hydrophobic inter-ligand interaction between the C-terminal aromatic side-chain of the dipeptide and the benzene ring of bcmpa in the ternary complexes.

We have previously reported that three inter-ligand interactions, such as hydrogen bonds, steric repulsion, and electrostatic interactions, regulate the coordination structure of the ternary cobalt(III) complexes [Co(bcmpa)(aa)]$^-$.[22,24] Two kinds of hydrogen bond in the ternary complexes employed here act between N-terminal amino hydrogens of the dipeptide and carboxyl oxygen atoms of bcmpa and between the α-hydrogen of bcmpa and the amide carbonyl group of the dipeptide. The hydrogen bond plays an important role in the recognition of the dipeptide N-terminus because it supplies a large fraction of energy required for stabilization of the transition state of an enzyme reaction.[35] Steric repulsion of the hydrogen atoms between the methylene groups on the G- or Gs-chelate rings of bcmpa and the N-terminal amino group is expected to promote the formation of the *trans*(N) geometry. An electrostatic interaction is expected to inhibit the formation of the *cis*(N) one because it acts repulsively between the negative charge of the two carboxylate moieties. From the above discussion, which is summarized in Figure 4(a), a ternary cobalt(III) complex coordinated by the N-terminal nitrogen of the dipeptide and bcmpa with a *trans*(N) geometry is formed preferentially. This is an interesting model for mimicking aminopeptidase, even though it is a low-molecular compound. In the case of complexation of a dipeptide having a C-terminal aromatic side-chain, the inter-ligand CH–π interaction assembles the benzene rings of the dipeptide and bcmpa to form a hydrophobic sphere, as shown in Figure 4(b). Although we were not able to obtain a crystal of [Co(bcmpa)(dp)]$^-$, the coordination structures in Figure 4 are proposed based on the above spectral considerations.

### Hydrolysis of Dipeptide Ligands Mediated by the Ternary Cobalt(III) Complexes

*cis*-Diaquacobalt(III) complexes are known to hydrolyze carbonyl esters, amides, nitriles, and phosphate esters by the coordination of these substrates to the metal center.[36] Buckingham et al. have shown that the hydrolysis of amino acid esters and peptides is accelerated 106 times in the presence of a cobalt(III) complex of a linear tetraamine ligand in neutral media.[17,37] These reactions are promoted by the nucleophilic attack of hydroxide at the amide carbonyl group activated by coordination to the metal center. Under these reaction conditions, however, selectivity for the cleavage reaction was not reported.[38] Since the tetraamine ligand has no functional groups for recognition of the peptide, it could not show any selectivity. Exceptionally, a β-$[Co(trien)(OH)(H_2O)]^{2+}$ complex has been reported to show selective hydrolysis of peptides[5] even though no inter-ligand interactions were observed in this complex. Here, we have designed ternary cobalt(III) complexes containing a bcmpa ligand, which is expected to regulate the selective hydrolysis of dipeptides due to its having a recognition site for the aromatic group. From the viewpoint of the selective cleavage of peptide bonds, a ternary cobalt(III) complex having inter-ligand interaction sites becomes a molecular recognition model for aminopeptidases. In order to determine the active species for the hydrolysis of the amide bond, we carried out the reaction with $[Co(bcmpa)(leu\text{-}gly)]^-$ (**5**) under different pH conditions at 40 °C. The yield of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[Co(bcmpa)(leu)]^-$ complex generated upon hydrolysis of the leu-gly moiety of **5** was higher at higher pH, as shown in Figure 5. This finding indicates that the reaction is promoted by $OH^-$ ion. Since the amount of unidentified cobalt(III) complexes increased in the higher pH region, all reactions were carried out at pH 9.

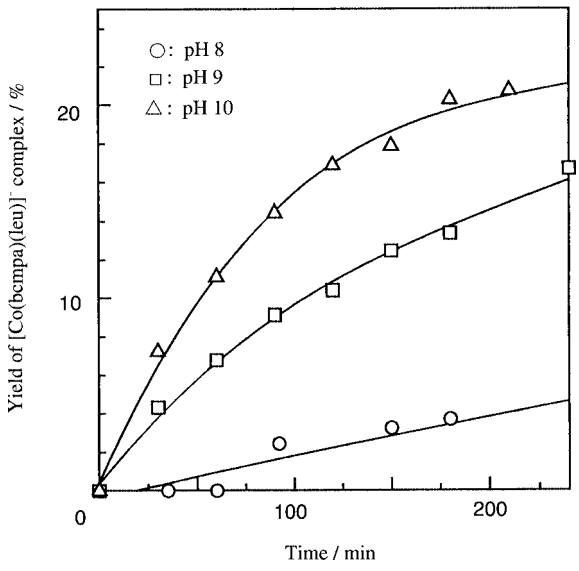

Figure 5. Rate of formation of $[Co(bcmpa)(leu)]^-$ during the hydrolysis of $[Co(bcmpa)(leu\text{-}gly)]^-$ (**5**) and its dependence on pH.

The yields of the cleavage product, $[Co(bcmpa)(aa)]^-$, at the initial stage of the reaction are listed in Table 3. The most striking observation in these reactions is the complete inhibition of hydrolysis of complexes **6** and **11**. The $[Co(bcmpa)(gly)]^-$ complex was not detected even after reaction of **6** and **11** at pH 9.0 and 40 °C for 3 h. This finding is in contrast to a previous report that Co-trien-dp complexes can be used for cleavage reactions of peptides including C-terminal aromatic amino acid residues.[17] The hydrolysis of complexes **1** and **2**, which have a C-terminal glycine or alanine residue, proceeded easily, as shown in Figure 6. On the other hand, the yield of $[Co(bcmpa)(gly)]^-$ from the reaction of **4** and **8**, which have C-terminal bulky dipeptides such as gly-val and gly-leu, was poor. The hydrolysis rate for complex **1** was fivefold higher than those for **4** and **8**. Upon increasing the steric bulkiness of the side chain of the dipeptide at the C-terminus, the yield of the hydrolysis product decreased according to the order glycine (C-0), alanine (C-1), valine (C-3), and leucine (C-4). The reaction of the dipeptide complexes having C-terminal aromatic side-chain (**9** and **12**) did not give the corresponding amino acid complexes, and neither did the complex with C-terminal phenylalanine. In contrast to the above findings, the reaction of **5**, which has an N-terminal bulky substituent, gave $[Co(bcmpa)(leu)]^-$ in moderate yield. In the case of complex **14**, which has an α,α-disubstituted amino acid at the C-terminus, the yield of the $[Co(bcmpa)(gly)]^-$ complex was only 1.7% after 3 h; this was also interpreted in terms of a steric effect.

Table 3. Reactivity for the cleavage reaction of various dipeptides at the ternary cobalt(III) complexes.[a]

| Cobalt(III) complexes | | Yield of gly complex[b] (%) |
|---|---|---|
| bcmpa | gly-gly (**1**) | 24.9 |
| | gly-ala (**2**) | 16.0 |
| | gly-leu (**4**) | 3.9 |
| | leu-gly (**5**) | 13.4[c] |
| | gly-phe (**6**) | 0.0 |
| | gly-val (**8**) | 5.1 |
| | gly-phg (**9**) | 3.7 |
| | gly-D-ala (**10**) | 17.3 |
| | gly-D-phe (**11**) | 0.0 |
| | gly-D-phg (**12**) | 2.0 |
| | gly-Mala (**14**) | 1.7 |
| bcmga | gly-gly (**15**) | 26.3 |
| | gly-ala (**16**) | 8.9 |
| | gly-leu (**17**) | 2.2 |
| | gly-phe (**18**) | 2.9 |
| | gly-D-phe (**19**) | 4.6 |

[a] The reaction was performed on a $1.25 \times 10^{-5}$ mol scale in an aqueous solution of boric buffer (pH 9) at 40 °C for 3 h. [b] Yield of $[Co(bcmpa)(gly)]^-$ or $[Co(bcmga)(gly)]^{2-}$ determined by HPLC analysis based on the starting complexes $[Co(bcmpa)(dp)]^-$ or $[Co(bcmga)(dp)]^{2-}$. [c] $[Co(bcmpa)(leu)]^-$.

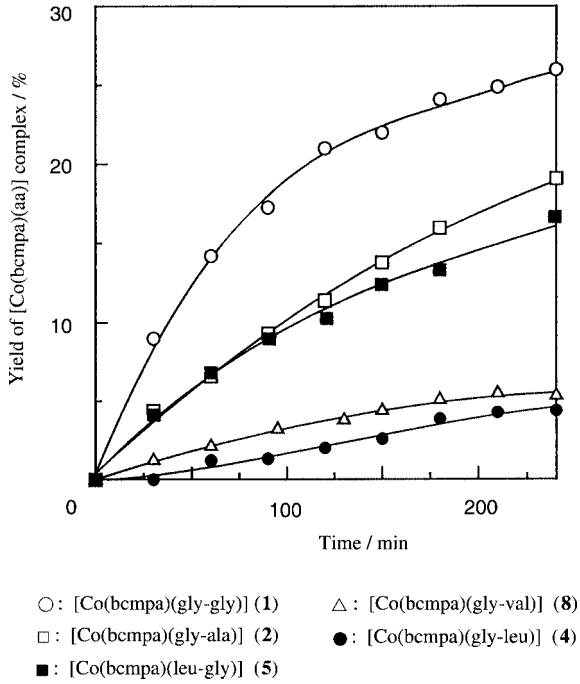

Figure 6. Cleavage reactions of various Co-bcmpa-dp complexes.

Two plausible mechanisms for the hydrolysis of amide compounds mediated by the mononuclear cobalt(III) complex have been proposed.[17,39] One involves external attack of $OH^-$ species on the amide carbonyl group, which is activated by coordination to the metal center,[40] and the other involves internal attack of the $OH^-$ species, which is activated by coordination to the metal center where the amide carbonyl group is coordinated.[41] In the cases of metalloen-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

zymes containing a mononuclear active site, the internal attack mechanism has been proposed on the basis of the X-ray crystal structural analysis of carboxypeptidase A.[20] However, the ternary cobalt(III) complexes employed here have no coordination site available for the $OH^-$ species, as illustrated in Figure 4, therefore hydrolysis of the dipeptide must occur externally. With bcmpa as ligand hydrolysis of **6** and **11** did not give the corresponding amino acid, in contrast to the reaction with bcmga as ligand. As bcmga has a carboxylate moiety instead of the phenyl moiety of bcmpa, this makes for a more hydrophilic coordination sphere. In the hydrolysis reactivity of dipeptide complexes containing a C-terminal aliphatic side-chain, no difference was found between the bcmpa and bcmga ligands (Table 3). In Figure 7, however, the reactivity of complexes **6**, **11**, **18**, and **19**, which have C-terminal aromatic side-chains is clearly not equal; the dipeptide complexes with bcmga give small amounts of the corresponding cleavage products whereas those with bcmpa give no cleavage products. In the case of the bcmpa system, the hydrophobic interaction around the outer coordination sphere [Figure 4 (b)], which is generated by the assembly of the benzene ring of bcmpa and the C-terminal side-chain of the dipeptide, inhibits the approach of $OH^-$ to the amide carbonyl group. In the case of bcmga, however, such a hydrophobic sphere is not formed around the complex. Although the overall charges of the complexes Co-bcmpa (–1) and Co-bcmga (–2) are different, the effect of the charge on acceleration of the cleavage reaction is not yet clear. The more negatively charged $[Co(bcmga)(dp)]^{2-}$ complex and the carboxylate moiety attached to bcmga seems to attract hydrophilic $OH^-$ species externally. It is interesting that such a simple complex is able to perform the sequence-specific cleavage of peptides by a combination of inter-ligand interactions. We have also reported the selective cleavage of various peptides using simple enzyme model complexes in which the bulkiness of the aliphatic side-chain in the ternary cobalt(III) complex with a terpy ligand controls the specificity of the oxidative degradation of peptides.[42]

In summary, some ternary cobalt(III) complexes ($[Co(bcmpa)(dp)]^-$) containing an asymmetric tripodal ligand and dipeptides have been prepared. Their coordination geometry has been determined by UV/Vis, CD, and $^1H$ NMR spectroscopic methods. Site-specific recognition of dipeptides occurs by various kinds of weak non-covalent inter-ligand interactions. Such interactions are also observed in the ternary complexes with an amino acid ligand, $[Co(bcmpa)(aa)]^-$, some of whose structures have been determined by X-ray crystallography. Under slightly alkaline conditions, the dipeptide ligand of the ternary complexes is cleaved to give $[Co(bcmpa)(aa)]^-$. Selectivity for hydrolysis of the dipeptide ligand is regulated by the above interactions. This is the first report describing selectivity for the cleavage of various peptides using simple enzyme model complexes. The hydrophobic interaction between bcmpa and the C-terminal side-chain of the dipeptide regulates the approach of $OH^-$ to the amide carbonyl group coordinated to the cobalt center. In particular, the CH–π interaction caused by assembly of the benzene ring of bcmpa and the C-terminal aromatic amino acid moiety inhibits the approach of $OH^-$ and prevents hydrolysis of the dipeptide. The present ternary (Co-bcmpa-dp) system provides a method for the selective cleavage of peptide compounds due to multi-site interactions that is superior to the previous ternary (Co-trien-dp) system without the recognition site. We conclude that the multi-site interactions mediated by the metal complexes could be used to design an artificial hydrolysis enzyme.

## Experimental Section

**Material:** The $NO_3$-type tripodal tetradentate ligand $H_3$bcmpa, was prepared from L-phenylalanine by a literature procedure.[22,24] $H_3$bcmga [bis-*N*,*N*-carboxymethyl-L-glutamic acid], which is a coordination analogue of bcmpa, was prepared in a similar manner from L-glutamic acid. QAE Sephadex A-25 ($Cl^-$ type) was supplied by Pharmacia. All amino acid derivatives (L- and D-isomers) and gly-gly (grade AA) were obtained from Peptide Institute Inc. and used without further purification. Other dipeptide compounds, namely gly-ala, ala-gly, gly-leu, leu-gly, gly-phe, phe-gly, gly-val, gly-phg, gly-D-ala, gly-D-phe, gly-D-phg, gly-β-ala, and gly-Mala, were synthesized by a DCC coupling method from the corresponding protected amino acid derivatives.

**Measurements:** The UV/Vis spectra were recorded with a JASCO UVDEC-660 spectrophotometer. The circular dichroism (CD) spectra were recorded with a JASCO J-500C spectropolarimeter. All measurements for the ternary cobalt(III) complexes were carried out in water and/or water–dioxane solution at room temperature. $^1H$ NMR spectra were recorded with a JEOL JNM-FX-400 spectrometer in $D_2O$ and/or $D_2O$/[$D_8$]dioxane solvent, with DSS as an internal standard. The HPLC analytical system was constituted by a JASCO Gulliver Series with a finepak SIL $NH_2$-5 column. The analytical conditions of HPLC were as follows: the mobile

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phase (flow rate: 1 mL min$^{-1}$) was a 2:8 mixture of methanol and $NaHPO_4$ buffer (0.05 M) and the product complexes were monitored with a UV/Vis detector (wavelength: 510 nm).

**Preparation of Ternary Cobalt(III) Complexes with a Dipeptide Ligand:** K[Co(bcmpa)(gly-gly)] was prepared in a manner analogous to K[Co(bcmpa)(aa)].[22,24] An equimolar amount of gly-gly and 0.05 g of active charcoal were added to 10 mL of an aqueous solution of $K_2$[Co(bcmpa)($CO_3$)] (0.2 M). The resulting mixture was stirred for 24 h at 40 °C with addition of dilute HCl to maintain the pH at 6–7. After filtration of active charcoal and desalting with methanol, the resulting mixture was poured onto a QAE Sephadex A-25 column ($Cl^-$ form, 2.5 × 35 cm). The cobalt(III) complexes adsorbed on the anion exchange column were washed with distilled water to remove neutral and cationic complexes, and then two negatively charged bands were separated with KCl solution (0.1 M). The orange-colored first eluting band was the main fraction, which gave 0.49 g of product complex (49% yield) after usual isolation, and the pink-colored second one was the minor product (0.05 g, 5% yield). On the basis of the spectroscopic analysis, the former was identified as the dipeptide complex K[Co(bcmpa)(gly-gly)] (**1**) and the latter as the amino acid complex K[Co(bcmpa)(gly)]. Other negatively charged bands were also eluted in this separation, but they were unable to be identified because of lack of product.

**K[Co(bcmpa)(gly-gly)] (1):** $^1$H NMR ($D_2O$): $\delta$ = 3.20 (d, $J$ = 16.8 Hz, 1 H, G-ring-H),[30] 3.51 (dd, $J$ = 15.1 and 10.6 Hz, 1 H, benzyl-H of bcmpa), 3.64 (dd, $J$ = 15.1 and 4.8 Hz, 1 H, benzyl-H of bcmpa), 3.82 (s, 2 H, C-terminal glycine α-H), 3.98 (d, $J$ = 18.0 Hz, 1 H, R-ring-H), 4.13 (d, $J$ = 16.8 Hz, 1 H, G-ring-H), 4.24 (d, $J$ = 17.3 Hz, 1 H, N-terminal glycine α-H), 4.25 (d, $J$ = 17.3 Hz, 1 H, N-terminal glycine α-H), 4.63 (d, $J$ = 18.0 Hz, 1 H, R-ring-H), 4.90 (dd, 10.6 and 4.8 Hz, 1 H, Gs-ring-H), 7.4–7.6 (m, 5 H, aromatic-H).

The other K[Co(bcmpa)(dp)] complexes **2**–**14** were prepared by the same procedure using the appropriate dipeptide instead of gly-gly. The $K_2$[Co(bcmga)(dp)] complexes **15**–**18** were prepared from $K_3$[Co(bcmga)($CO_3$)]. Their $^1$H NMR spectroscopic data are listed in Table 1.

**Hydrolysis of Dipeptide Ligands:** Hydrolysis of dipeptide ligand mediated by the cobalt complexes was carried out as follows. K[Co(bcmpa)(dp)] or $K_2$[Co(bcmga)(dp)] (about 0.07 g, $1.25 \times 10^{-5}$ mol) was dissolved in 50 mL of an aqueous solution of 0.1 M $H_3BO_3/Na_2HBO_3$ buffer, which was maintained at pH 9.0 and 40 °C. The ionic strength during the reaction was 1.0 M of KCl. An aliquot of the reaction mixture passed through a 0.45-μm filter was analyzed by HPLC at 30 min intervals. After 3 h, the reaction solution was treated with the same isolation method as described above. Mono-negative charged complexes generated by the reaction after QAE Sephadex column separation with 0.1 M KCl solution were characterized by $^1$H NMR, UV/Vis, and CD spectroscopy.

# Synthesis, Structure and Magnetism of Metal-Organic Framework Materials with Doubly Pillared Layers

Hong-Peng Jia,[a] Wei Li,[a] Zhan-Feng Ju,[a] and Jie Zhang*[a]

**Keywords:** Metal-organic frameworks / Pillared-layer structure / Iron(II) / Cobalt(II) / Hydrothermal synthesis / Magnetic properties / Carboxylates

Two novel coordination polymers with a 3D pillared-layer framework, $[M^{II}(Tdc)(4,4'\text{-Bpy})]_n$ [M = Fe (**1**), Co (**2**); Tdc = thiophene-2,5-dicarboxylate; 4,4′-Bpy = 4,4′-bipyridine), have been hydrothermally synthesised and structurally characterised. A simultaneous reduction of iron(III) to iron(II) occurs under hydrothermal conditions in the self-assembly process of complex **1**. The complexes are isostructural and, in each complex, the metal ions are linked by double $\mu_2$-carboxylate bridges in a *syn-syn* mode, giving rise to dinuclear units that are connected to each other by chelating carboxylate groups from the Tdc ligands in an approximately perpendicular orientation to form 2D rectangle-grid layers. The adjacent layers are held together through 4,4′-Bpy molecules in a double-pillar support fashion to give a 3D network with three intersecting perpendicular channels. Variable-temperature magnetic susceptibility measurements revealed weak antiferromagnetic coupling interactions in both complexes and a field-induced magnetic transition can be observed in **2**.

## Introduction

There has been continuous interest in the design and synthesis of metal-organic coordination polymers and supramolecular architectures due to their potential applications in the fields of magnetism, porous materials, catalysis and nonlinear optical activities or molecular recognition.[1–6] In the rational development of new strategies for the crystal engineering of coordination networks and supramolecular architectures, the pillared-layer assemblies have been shown to be precursors in an efficient route for the construction of porous frameworks with controllable channel sizes and chemical functionalities.[7–9] In particular, the pillared-layer networks based on coordination bonds are more attractive than those based on the hydrogen-bonded assemblies owing to their high structural and thermal stabilities.[10–13] Although the advantages of the pillared-layer assemblies are generally due to their suitability for manipulation of the pore structures by means of simple modifications to the pillar module, the search for new layer-building units is also quite necessary for systematic fine-tuning of structural and functional features. In this paper, we report two novel coordination polymers with a 3D porous pillared-layer framework, namely $[Fe^{II}(Tdc)(4,4'\text{-Bpy})]_n$ (**1**) and $[Co^{II}(Tdc)(4,4'\text{-Bpy})]_n$ (**2**). Thiophene-2,5-dicarboxylate (Tdc) ligands link the metal ions by bridging and chelating carboxylate groups to form a rare type of 2D rectangle-grid layer containing the dimetallic carboxylate subunits in a mutually perpendicular orientation. Each 4,4′-Bpy ligand as a rigid spacer is coordinated to the axial positions of the metal ions, connecting the $[M^{II}(Tdc)]_n$ layers into a 3D coordination framework with twofold interpenetration. An interesting aspect of the structure is that the 4,4′-Bpy ligands bind to the layers in a double-pillar support fashion (Scheme 1), which results in a molecular architecture with a higher thermal stability. In addition, the Tdc ligand displays both chelating and $\mu_2$-bridging carboxylate coordination modes in the assemblies (Scheme 2) and this is the first

observation of such behaviour for the Tdc ligand.[14] Variable-temperature magnetic susceptibility measurements revealed weak antiferromagnetic coupling interactions in both complexes and a field-induced magnetic transition can be observed in **2**.

## Results and Discussion

### Synthesis and Structural Description

Single-crystal X-ray diffraction analyses revealed that complexes **1** and **2** are isostructural and crystallise in the orthorhombic space group *Pccn*. As a representative example, the crystal structure of complex **1** is described here in detail. It is interesting to note that a simultaneous reduction of iron (III) to iron (II) occurs in the self-assembly process of complex **1** under hydrothermal conditions. There have been some reports that several metal ions can be reduced in the presence of 4,4′-Bpy under hydrothermal conditions. Although the mechanisms of redox reactions are still unknown, hydrothermal conditions are essential for achieving the reduced product.[15] The fundamental building unit of **1** is composed of a six-coordinate $Fe^{II}$ centre, a Tdc ligand and a 4,4′-Bpy ligand. Each $Fe^{II}$ centre exhibits a distorted octahedral geometry with two pyridyl nitrogen atoms (N1, N2D) from different 4,4′-Bpy ligands at the axial positions and four oxygen atoms in the equatorial plane of which two (O3A, O4B) are from two $\mu_2$-bridging bidentate carboxylate groups from two different Tdc ligands and the other two (O1, O2) are from a chelating carboxylate group of a Tdc ligand, as shown in Figure 1. The Fe–O bond lengths are in the range of 1.999(3)–2.387(3) Å and the Fe–N bond lengths are 2.195(3) and 2.168(3) Å, respectively. The O1–Fe–O2 bite angle of 58.07(10)° is much smaller than the O3A–Fe–O4B bond angle of 117.90(12)°.

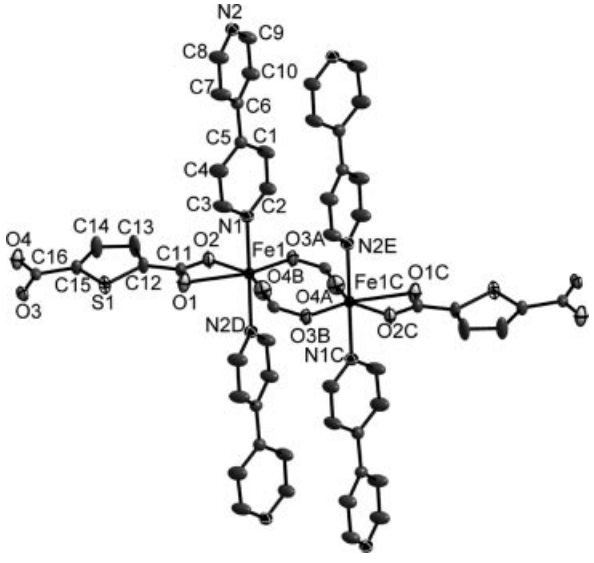

Figure 1. Coordination environment of the $Fe^{II}$ ion with atom labelling in **1**. Hydrogen atoms are omitted for clarity.

Two equivalent $Fe^{II}$ ions related by a twofold axis with a separation of 4.149 Å are bridged by two carboxylate groups from two different Tdc ligands in a *syn-syn* mode to form a dinuclear subunit. These dinuclear units are aligned approximately perpendicular to each other in the *ac* plane and linked further by additional Tdc ligands in a chelating mode to give rise to a neutral 2D sheet with a rectangular window of 8.8 × 11.0 Å (Figure 2). It is worthy of note that the orthogonal arrangement of dimetallic subunits within a 2D layer is still rare in metal carboxylate complexes in which dinuclear units are generally parallel to each other.[16] Each Tdc ligand coordinates to three $Fe^{II}$ ions through the two terminal carboxylate groups in chelating and bridging modes, respectively, illustrating an unreported coordination mode for the Tdc molecule. An interesting aspect of the structure is that the 2D porous sheets are connected by 4,4′-Bpy ligands through the axial positions of both $Fe^{II}$ centres in subunits to form a 3D doubly pillared-layer structure with three intersecting perpendicular channels (Figure 3). The whole structure can also be described as a 3D frame-

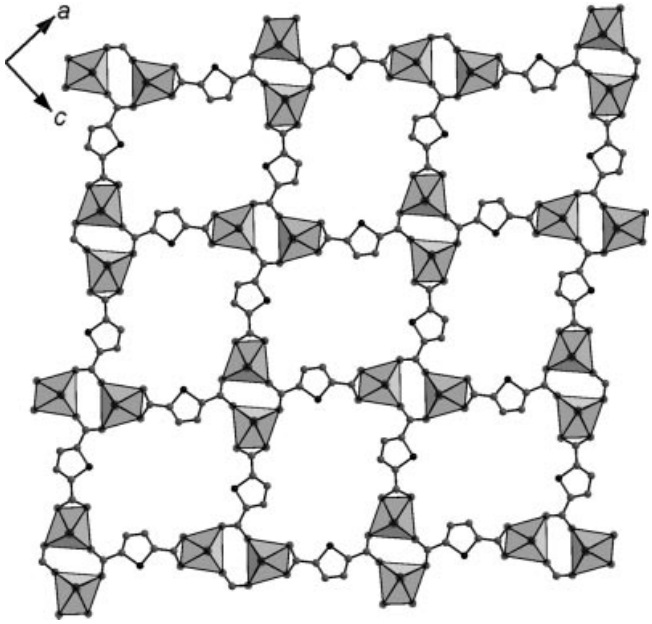

Figure 2. Perspective view of the $[Fe(Tdc)]_n$ sheet subunit with rectangular windows of about 8.8 Å × 11.0 Å. Hydrogen atoms are omitted for clarity.

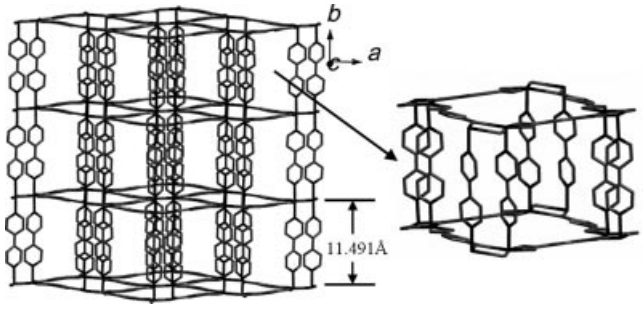

Figure 3. (a) Perspective view of the pillared-layer 3D network of **1**; (b) cuboid-like unit in **1**.

work composed of cuboid-like cavities with dimensions of 12.16 × 12.16 × 11.49 Å (based on the centre of the dinuclear subunit). The large cavities in the structure lead to a tendency to form an interpenetrating network. As shown in Figure 4, a twofold interpenetrating topological structure can be observed. The volume of the effective void is about 9.9% of the unit-cell volume in the self-inclusion structure.

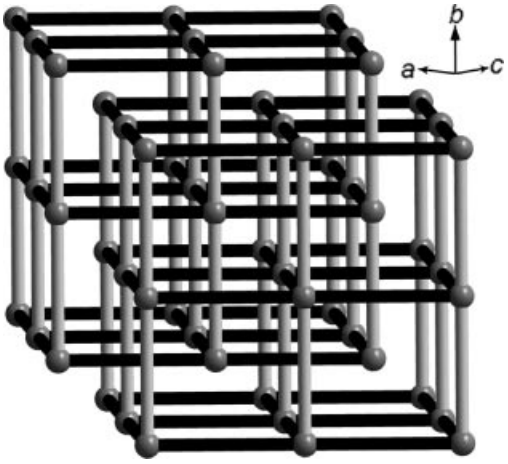

Figure 4. Structure topology of **1** displaying twofold interpenetration (darker and grey rods representing the Tdc and 4,4′-Bpy ligands, respectively).

### Thermogravimetric Analysis

The thermal stabilities of the two complexes were determined by thermogravimetric analysis (TGA) in air with a heating rate of 20 °C min$^{-1}$. Complexes **1** and **2** exhibit high thermal stabilities (Figure S2, Supporting Information). A sharp weight loss occurs in the temperature range 360–470 °C for **1** (74.8%) and 380–480 °C for **2** (72.7%), corresponding to the removal of ligands and decomposition of the framework. The final residues of complexes **1** and **2** were found to be amorphous and could not be identified.

### Magnetic Properties

The temperature dependences of the magnetic susceptibilities of **1** and **2** under an applied field of 5000 Oe are shown in Figure 5 in the form of an $\chi_m T$ vs. $T$ plot, where $\chi_m$ is the molar magnetic susceptibility per formula unit. At room temperature, the $\chi_m T$ value of **1** is 3.35 emu mol$^{-1}$ K per Fe$^{II}$ ion, corresponding to an average $g$ value of 2.11. This is in agreement with the typical value for a high-spin Fe$^{II}$ ion with some orbital contributions.[17] As the temperature is lowered, the $\chi_m T$ value remains almost constant in the range 300–50 K and then rapidly decreases to 1.44 emu mol$^{-1}$ K at 2 K. The magnetic susceptibility above 2.5 K follows the Curie–Weiss equation $\chi_m = C/(T - \theta)$ with $C$ = 3.37 emu mol$^{-1}$ K and $\theta$ = –2.01 K. Such behaviour is consistent with a weak antiferromagnetic coupling interaction between the magnetic centres.

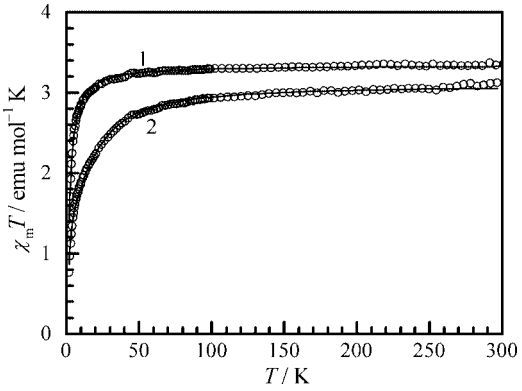

Figure 5. Temperature dependence of $\chi_m T$ for complexes **1** and **2**, the solid lines represent the best fits obtained from the models described in the text.

In the structure of **1**, the carboxylate-bridged dinuclear units are connected by 4,4′-Bpy and Tdc units to form the 3D framework. The Fe–Fe distance of 4.149 Å over the $\mu_2$-carboxylate bridge is much shorter than those over the 4,4′-Bpy (11.49 Å) and the Tdc (10.38 Å) bridges and, consequently, the exchange coupling through the double $\mu_2$-carboxylate bridge in the dinuclear subunits should be dominant. In order to obtain reliable simulation results, the magnetic behaviour of **1** was analysed using an analytical expression[18] based on the Hamiltonian taking into account the anisotropy $g$ and the zero-field-splitting term in Equation (1).

$$H = g_{\perp}\beta H_{\perp}[{}^1/_2(S_1^+ + S_1^- + S_2^+ + S_2^-)] + g_{\parallel}\beta H_{\parallel}(S_{z1} + S_{z2}) - 2J[S_{z1}S_{z2} + {}^1/_2(S_1^+S_2^-) + {}^1/_2(S_1^-S_2^+)] + D(S_{z1}^2 + S_{z2}^2) \quad (1)$$

In addition, a molecular field approximation[19] was applied to Equation (1) to account for the interdimer exchange interaction ($zJ'$) in the 3D system [Equation (2)].

$$\chi_m = \chi_{di}/(1 - 2zJ'\chi_{di}/Ng^2\beta^2) \quad (2)$$

Calculations were performed with the MAGPACK package.[20] The best fit was obtained with the following sets of parameters: $J$ = –0.242 cm$^{-1}$, $g_{\parallel}$ = 2.015, $g_{\perp}$ = 2.289, $D$ = 0.09 cm$^{-1}$, $zJ'$ = 0 and an agreement factor $R$ {defined as $R = \Sigma[(\chi_m T)_{calcd} - (\chi_m T)_{obs}]^2/\Sigma(\chi_m T)_{obs}^2$} of 4.18 × 10$^{-5}$. The value obtained for $D$ is smaller and the ratio of $|J|/D$ is equal to 2.69. When $J$ is much larger or smaller than $D$, exchange coupling or ZFS will be dominant and the smaller term can be treated as a perturbation. Thus, the decreases in $\chi_m T$ at lower temperatures are mainly due to antiferromagnetic coupling for complex **1**.

For **2**, the $\chi_m T$ value at room temperature is equal to 3.15 emu mol$^{-1}$ K, which is much higher than the spin-only value of 1.875 emu mol$^{-1}$ K expected for an isolated high spin Co$^{II}$ ion with $S = {}^3/_2$ and $g$ = 2.00 owing to the orbital contribution of the Co$^{II}$ ion.[21] Upon cooling, the $\chi_m T$ value slightly decreases until around 50 K, then rapidly decreases to 0.76 emu mol$^{-1}$ K at 2 K. Above 32 K, the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

magnetic data follow the Curie–Weiss law with $C = 3.20\ \text{emu mol}^{-1}\,\text{K}$ and $\theta = -8.8$ K. The negative Weiss constant suggests an antiferromagnetic interaction between the $Co^{II}$ ions. The presence of a small maximum in $\chi_m$ at 2.5 K is indicative of long-range antiferromagnetic ordering (Figure 6a). Complex **2** has the same structure as **1** and in order to fit the magnetic data of **2** quantitatively, we used the MAGPACK package[20] with a similar Hamiltonian model and taking into account the anisotropy $g$, the zero-field splitting parameter $D$ ($S_1 = S_2 = {}^3/_2$) and the molecular field approximation[19] for the interdimer exchange interaction ($zJ'$). The results of the best fit of the experimental data in the whole temperature range are shown in Figure 5 with $J = -0.37\ \text{cm}^{-1}$, $g_{\parallel} = 2.42$, $g_{\perp} = 2.85$, $D = 21.00\ \text{cm}^{-1}$, $zJ' = -0.001\ \text{cm}^{-1}$ and $R = 1.25 \times 10^{-4}$. The $D$ value is larger than the $|J|$ value and so the decreases in $\chi_m T$ at lower temperatures are mainly due to the zero-field splitting of complex **2**. Until now, only a few $Co^{II}$ complexes bridged by carboxylate groups in a *syn-syn* mode have been rigorously studied from a magnetic point of view due to inherent difficulties resulting from strong spin-orbit coupling and magnetic anisotropy orbital degeneracy. Antiferromagnetic interactions are generally observed in these complexes.[22] The complex magnetic behaviour of $Co^{II}$ ions did not allow us to accurately simulate the magnitude of the magnetic interaction taking into account all factors, thus the value of $D$ obtained for **2** is larger than that for **1**.

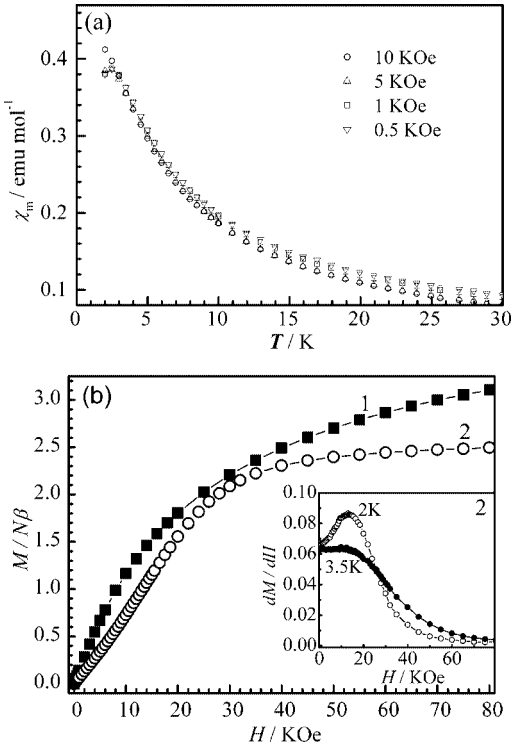

Figure 6. (a) Temperature-dependent molar magnetic susceptibilities of **2** measured at different external fields; (b) field-dependent magnetisations of **1** and **2** at 2 K. The inset shows the d$M$/d$H$ derivative curves of **2** at 2 K and 3.5 K.

In fact, the Fe1–O1 (2.387 Å) and Co1–O1 (2.333 Å) bonds are much longer than the others in the equatorial planes in the structures of **1** and **2**. Ignoring these bonds, we can think of the $Fe^{II}$ and $Co^{II}$ centres as being in distorted trigonal-bipyramidal rather than distorted octahedral environments. The idealised trigonal-bipyramidal geometry belongs to the $D_{3h}$ point group and the orbital momentum is quenched except for the E′ and E″ terms. However, when the structure is distorted and the symmetry deviates from pure $D_{3h}$, the quenching of the ground $^4A_2'$ term may not be sufficient and an admixture of the upper $^4E''$ term may bring the orbital momentum into the ground term, resulting in an obviously high $\mu_{eff}$ value and a deviation of $g$ from 2.0.[23] In **2**, the $\mu_{eff}$ value (5.02 $\mu_B$) is much higher than the spin-only value (3.87 $\mu_B$) but lies in the range of 4.26–5.03 $\mu_B$ for trigonal-bipyramidal cobalt(II) complexes.[24]

In comparison with **1**, the magnetic behaviour of **2** is more complex in the low-temperature range. The small maximum of $\chi_m$ at around 2.5 K only appears at low field. When the external field is increased, this maximum vanishes above 10 kOe (Figure 6a). Furthermore, the field-dependent magnetisation of **1** exhibits a smooth increase at 2 K, reaching 3.1 $N\beta$ at 80 kOe which is less than the expected saturation value of 4 $N\beta$ for a magnetically isolated $Fe^{II}$ centre with $g = 2.0$, while the magnetisation of **2** shows a sigmoid-like curve and gives a saturation value of 2.5 $N\beta$ at 80 kOe (Figure 6b). For the $Co^{II}$ ion, an $S = {}^1/_2$ ground state is usually observed at low temperatures due to the overall effect of the crystal field and spin-orbit coupling. The saturation magnetisation value of **2** is within the range expected for a free cobalt ion with an effective $S = {}^1/_2$ and large anisotropic $g$ values ranging from 4.1 to 5.0.[25]

The disappearance of the $\chi_m$ maximum at higher fields and the sigmoid-like magnetisation curve of **2** suggest the occurrence of a field-induced magnetic transition. The transition field, determined by the d$M$/d$H$ derivative curve is ca. 12 kOe at 2 K (inset in Figure 6b). The AC isothermal magnetisation measurements at 2 K with the DC field from 0 to 50 kOe display a peak value of the in-phase component of the susceptibility ($\chi'$) at 11 kOe, consistent with the transition observed in the d$M$/d$H$ curve. It is worthy of note that a nonzero out-of-phase component of the AC susceptibility ($\chi''$) appears at 17 kOe with a further increase in the applied field, indicating the occurrence of the second magnetic transition. Additional measurements at 3.5 and 5 K show the temperature dependence of the second magnetic transition, the $H$ value increases slightly as the temperature increases (Figure 7).

The magnetic behaviour of **2** is analogous to some observations in the complexes with field-induced spin-flop phase transitions (SF), which is characteristic for antiferromagnetic (AF) systems with weak anisotropy.[26] Although this transition does not generally appear in a system with large anisotropy such as the Ising mode, similar transition behaviour has been discussed for several $Co^{II}$ complexes.[27] In **2**, the spin-flop field ($H_{SF}$) appears at 11 kOe, corresponding to a transition from an antiferromagnetic to a spin-flop state. The AF-SF transition is a first-order transition and there is a discontinuity in the magnetisation on crossing the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

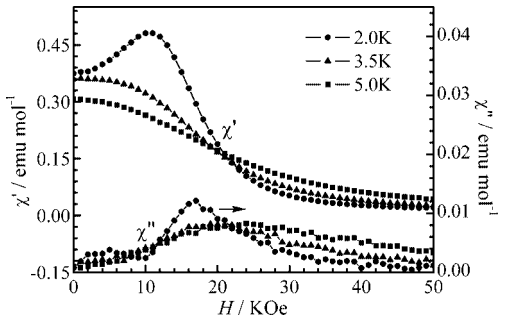

Figure 7. Field-dependent AC magnetic susceptibilities of **2** measured at different temperatures.

AF-SF phase boundary. Thus, an inflexion can be observed in the $M(H)$ curve and a peak also appears in the $\chi'(H)$ plot.[26] Another critical field ($H_C$) is not evident in $\chi'(H)$ although an obvious peak around 17 kOe can be observed in the $\chi''(H)$ curve, which can be identified as the second-order transition field ($H_C$) from a spin-flop to a ferromagnetic-like state.[28,29] The lack of a sharp conversion in $\chi'(H)$ suggests that this second phase-transition process is rather gradual.[29] To further substantiate the spin-flop transition in **2**, additional temperature-dependent AC magnetic susceptibility measurements at different DC fields were carried out (Figure 8). The zero-field AC magnetic susceptibility measurements exhibit a maximum value of $\chi'$ at 2.5 K and a negligible $\chi''$ value, in agreement with the existence of antiferromagnetic ordering. The data measured at 12 kOe clearly show the disappearance of the $\chi'$ maximum, indicating that an antiferromagnetic coupling has been overcome. At an applied field of 17 kOe, $\chi'$ exhibits a new broad peak around 6.9 K, accompanied by a maximum peak of $\chi''$ at somewhat lower temperatures. This feature is quite consistent with a ferromagnetic-like state. It is also notable that the similar small peaks around 6.9 K already appear in $\chi'(T)$ and $\chi''(T)$ plots at 12 kOe, which is in accordance with the continuity and gradualness of this second-order phase transition. With the above results, the anisotropy field $H_A \approx 0.71$ kOe and the exchange field $H_E \approx 1.21$ kOe were estimated based on the mean-field relation $H_{SF} = (2H_EH_A - H_A^2)^{1/2}$ and $H_C = 2H_E - H_A$.[30] The anisotropy constant $a = H_A/H_E$ is 0.59. Although no related parameter can be found in $Co^{II}$ complexes for comparison, a lower anisotropy field in **2** suggests that its magnetisation process can possibly proceed through the spin-flop-like transition.[31]

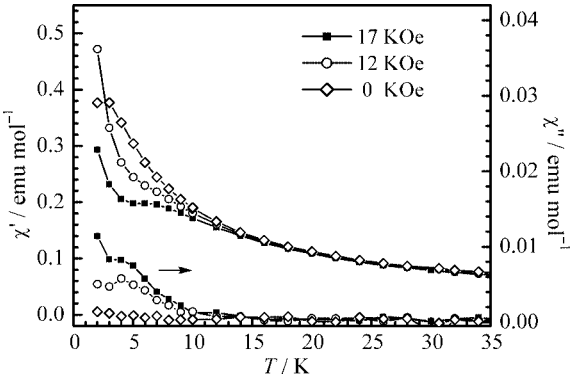

Figure 8. Temperature dependence of the AC magnetic susceptibilities of **2** measured in a field amplitude of 3 Oe (711 Hz) and a DC bias field of 0, 12 and 17 kOe.

## Conclusions

In summary, two novel 3D porous frameworks were hydrothermally synthesised and structurally characterised. Metal ions are connected by chelating and bridging carboxylate groups of Tdc groups to form 2D rectangle-grid layers containing dinuclear subunits in an approximately perpendicular orientation. The interconnection of the 2D layers by the secondary metal linker (4,4′-Bpy) leads to the doubly pillared-layered 3D architecture with twofold interpenetration. Variable-temperature magnetic susceptibility measurements reveal weak antiferromagnetic coupling interactions in both complexes and a field-induced magnetic transition can be observed in **2**.

## Experimental Section

**General:** All the syntheses were performed in Parr Teflon-lined stainless steel autoclaves under autogenous pressure. All chemicals were analytical reagent grade and were used as received. IR spectra were recorded with a Spectrum One FT-IR spectrophotometer in KBr pellets in the range 4000–400 $cm^{-1}$. Elemental analyses were determined with an Elementar Vario EL III elemental analyser. The thermal analysis was performed under air with a Netzsch STA449C thermal analyser at a heating rate of 20 °C $min^{-1}$. Magnetic susceptibilities were measured using a Quantum Design PPMS-9T system. Diamagnetic corrections were estimated from Pascal's constants. The pore-volume analysis was performed with the PLATON software package.

**Synthesis of $[Fe^{II}(tdc)(bpy)]_n$ (1):** This compound was synthesised by the hydrothermal method. A mixture of $FeCl_3·6H_2O$ (65 mg, 0.24 mmol), $H_2Tdc$ (70 mg, 0.41 mmol), NaOH (33 mg, 0.83 mmol) and 4,4′-Bpy (74 mg, 0.47 mmol) in $H_2O$ (5 mL) was homogenised at room temperature for 20 min. The resultant mixture was transferred and sealed in a Teflon-lined steel autoclave (23 mL) at 120 °C for 3 d and was then cooled to room temperature at a rate of 1.7 K $h^{-1}$. The dark-red crystals were isolated in 35.9% yield based on Fe. $C_{16}H_{10}FeN_2O_4S$ (382.17): calcd. C 50.28, H 2.64, N 7.33; found C 49.82, H 2.98, N 7.36. IR (KBr): $\tilde{\nu}$ = 3434 (m), 1604 (s), 1570 (s), 1524 (m), 1490 (w), 1414 (s), 1384 (vs), 1221 (w), 1072 (w), 1046 (w), 1033 (w), 1008 (w), 818 (m), 769 (m), 731 (w), 684 (w), 631 (m), 475 (m) $cm^{-1}$.

**Synthesis of $[Co^{II}(tdc)(bpy)]_n$ (2):** This compound was obtained using a procedure similar to that of **1**, except that $CoCl_2·6H_2O$ was used instead of $FeCl_3·6H_2O$. The pink crystals were isolated in 27.6% yield based on Co. $C_{16}H_{10}CoN_2O_4S$ (385.25): calcd. C 49.88, H 2.62, N 7.27; found C 49.56, H 3.04, N 7.54. IR (KBr): $\tilde{\nu}$ = 3435 (m), 1607 (s),1564 (s),1524 (m),1491 (w),1416 (s),1385 (vs),1221 (w), 1075 (w), 1045 (w), 1029 (w), 1011 (w), 821 (m), 767 (m), 732 (w), 682 (w), 634 (m), 477 (m) $cm^{-1}$.

**X-ray Crystallographic Study:** The intensity data of **1** were collected with a Rigaku CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature. An empiri-

cal absorption correction for **1** was performed using the CrystalClear program.[32] The crystal structure determination of **2** was performed with a Siemens SMART CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature. An empirical absorption correction for **2** was applied using the SADABS program.[33] The structure was solved by direct methods and refined by full-matrix least-squares fitting on $F^2$ using the SHELXS-97[34] and SHELXL-97[35] programs. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were located by geometric calculations. Crystallographic data and structural refinements for **1** and **2** are summarised in Table 1. Selected bond lengths and angles for **1** and **2** are listed in Table 2. CCDC-298904 (**1**) and -298903 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# An Unusual Reaction of (β-Dimethylaminoethoxy)triethyltin with Phenyltin Trichloride. The First X-ray Structural Evidence of the Existence of Complexes $R_2SnXY{\cdot}R_2SnXY$ (R = Alkyl, Aryl; X, Y = Hal, OR, X ≠ Y) Both as Unsymmetrical Adducts $[R_2SnX_2{\cdot}R_2SnY_2]$ and Symmetrical Dimers $[R_2SnXY]_2$

**Keywords:** Complexation / Tin / Dimerization / Stannanes / X-ray diffraction

The substituent exchange reaction of $PhSnCl_3$ with $[Et_3Sn(OCH_2CH_2NMe_2)]$ gives rise unexpectedly to the unsymmetrical adduct $[Ph_2SnCl_2{\cdot}Ph_2Sn(OCH_2CH_2NMe_2)_2]$ (**2**). It has been unambiguously proved for the first time that compounds of the $RSnX_3$ type are able to undergo the hydrocarbon substituent redistribution reaction. The analogous tin complexes $[Et_2SnCl_2{\cdot}Et_2Sn(OMe)_2]$ (**5**) and $[Bu_2Sn(OAc)_2{\cdot}Bu_2Sn(OMe)_2]$ (**6**), which have ligands other than β-dimethylaminoethoxy and could be considered as "organotin analogs of Grignard reagents" have symmetrical dimeric structures, i.e., can be formulated as $[Bu_2Sn(OMe)(OAc)]_2$ and $[Et_2Sn(OMe)Cl]_2$, respectively. Both types of structures, viz., unsymmetrical adduct (**2**) and symmetrical dimer (**5**, **6**), have been characterized by X-ray diffraction analysis.

## Introduction

Redistribution reactions are a convenient and widely used method for the synthesis of organometallic compounds.[1] It has been shown previously that penta- and hexacoordinate organotin compounds such as $[Me_nSnAr_{4-n}]$ and $[Bu_2SnArCl]$, which contain electron-donating groups in the aryl ligands, are more active towards redistribution, and related (transmetallation), reactions than tetracoordinate tin(IV) derivatives.[2] Therefore, the redistribution reactions of hypercoordinate organotin compounds $[R_nSnX_{4-n}]$ containing electron-donating groups in the functional substituents X but not in the hydrocarbon substituents R, have been of significant interest. As a continuation of our investigations into the chemistry of (β-dimethylaminoethoxy)germanium and -tin derivatives,[3] we report here on the surprising results of the interaction between (β-dimethylaminoethoxy)triethyltin and -phenyltin trichloride.

Very recently, we have found that the reaction of $PhGeCl_3$ with $[Et_3Ge(OCH_2CH_2NMe_2)]$ affords $[PhGe(OCH_2CH_2NMe_2)_2Cl]$ in high yield.[3f] However, the analogous reaction in the case of tin unexpectedly results in the unsymmetrical adduct $[Ph_2SnCl_2{\cdot}Ph_2Sn(OCH_2CH_2NMe_2)_2]$ as the main reaction product.

## Results and Discussion

The reaction was carried out by the gradual addition of $[Et_3Sn(OCH_2CH_2NMe_2)]$ to a $PhSnCl_3$ solution in diethyl ether or tetrahydrofuran. In our opinion, it proceeds in three stages. In the first stage, diphenyldichloro- and dichlorodialkoxystannanes are formed. The formation of these products apparently proceeds by the initial formation of a $[PhSn(OCH_2CH_2NMe_2)Cl_2]$ intermediate, which can further disproportionate by two paths: either by the exchange of Ph and $OCH_2CH_2NMe_2$ substituents (path a) or by the exchange of Cl and $OCH_2CH_2NMe_2$ substituents (path b). Path a gives rise immediately to $[Ph_2SnCl_2]$ and $[Cl_2Sn(OCH_2CH_2NMe_2)_2]$, whereas path b first gives rise to $[PhSn(OCH_2CH_2NMe_2)_2Cl]$ (**1**) and $PhSnCl_3$, and a subsequent interchange of the Ph and Cl substituents affords $[Ph_2SnCl_2]$ and $[Cl_2Sn(OCH_2CH_2NMe_2)_2]$ (Scheme 1).

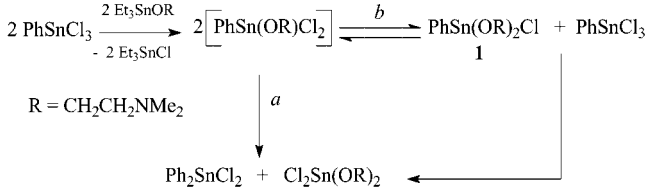

Scheme 1.The first stage of the reaction of $[PhSnCl_3]$ with $[Et_3Sn(OCH_2CH_2NMe_2)]$.

Scheme 1 was confirmed by an NMR spectroscopic study of the products of the reaction between the monochloroorganostannane **1**, which was prepared by an independent method involving reverse order of the reagent mixing (see below), and trichlorophenylstannane. In accordance with the multinuclear NMR spectroscopy data, the reaction mixture contains $[Ph_2SnCl_2]$ and $[Cl_2Sn(OCH_2CH_2NMe_2)_2]$. The latter was identified by comparison of its NMR spectral characteristics with those of the compound prepared by treatment of $HgCl_2$ with $[Sn(OCH_2CH_2NMe_2)_2]$.

A single-crystal X-ray diffraction analysis of **1** (Figure 1, Table 1) provided proof for the proposed structure and revealed that the tin atom is hexacoordinate with one carbon, one chlorine, two oxygen, and two nitrogen atoms, with an overall slightly distorted octahedral *cis-cis-trans* configuration, respectively.

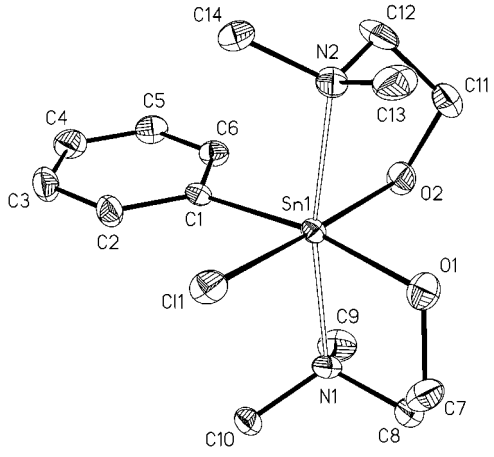

Figure 1.View of compound **1**. The hydrogen atoms have been omitted for clarity. Displacement ellipsoids are scaled to the 50% probability level. The coordination bonds are shown by open lines.

It is important to note that, in contrast to $[PhGe(OCH_2CH_2NMe_2)_2Cl]$, which tends to ionize in hydrogen-bond-donor solvents such as $CHCl_3$ to form the ionic pentacoordinate form $[PhGe(OCH_2CH_2NMe_2)_2][Cl]$ rather than the neutral hexacoordinate form,[3f] compound **1** exists only in the neutral hexacoordinate form.

The second stage is obviously the alkoxylation reaction of $[Ph_2SnCl_2]$, which yields $[Ph_2Sn(OCH_2CH_2NMe_2)_2]$, and the third stage is the complexation reaction between $[Ph_2SnCl_2]$ and $[Ph_2Sn(OCH_2CH_2NMe_2)_2]$, which yields the final poorly soluble complex **2**.

| O(2)–Sn(1)–N(1) | 89.82(12) | | |

Proof of the structure of **2** came from a single-crystal X-ray diffraction analysis (Figure 2, Table 2), which revealed that **2** is the adduct $[Ph_2SnCl_2{\cdot}Ph_2Sn(OCH_2CH_2NMe_2)_2]$ formed by the bridging oxygen atoms of the β-dimethylaminoethoxy ligands, with an unsymmetrical arrangement of the substituents at the tin atoms. It is located on a crystallographic $C_2$ axis that passes through the tin atoms. The tin atoms are hexacoordinate, with the phenyl groups in the *trans* configuration. The C–Sn–C angle at Sn1 [132.6(3)°] deviates substantially from the value of 180° (the phenyl rings are shifted towards the longer Sn←N coordination bonds), whereas that at Sn2 is essentially linear [177.3(3)°]. The basal plane of Sn1 is defined by an $N_2O_2$ donor set defined by two chelating β-dimethylaminoethoxy ligands with very long Sn←N bond lengths [2.766(4) Å]. Two chlorine and two oxygen atoms in the *cis* configuration make up the basal plane of Sn2. The bond angles in the equatorial planes vary from 70.8(1)° to 147.8(2)° for Sn1 and from 66.2(2)° to 105.44(7)° for Sn2. Thus, the geometry of Sn1 is best described as skew-trapezoidal bipyramidal, while that of Sn2 is best described as distorted octahedral.

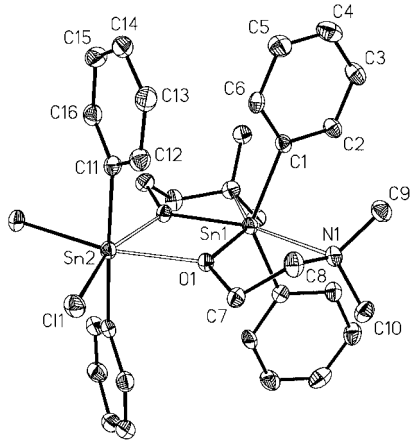

Figure 2.View of complex **2**. The hydrogen atoms have been omitted for clarity. Thermal ellipsoids are scaled to the 40% probability level. The coordination bonds are shown by open lines.

The covalent Sn–O [2.091(3) Å] and coordination Sn←O [2.242(3) Å] bond lengths in the four-membered $Sn_2O_2$ ring are significantly different and close to the corresponding

[a] Symmetry transformations used to generate equivalent atoms: i: $-x$, $y$, $-z + 1/2$.

bond lengths in previously investigated mononuclear hexacoordinate diphenyltin complexes.[4] The Sn–C and Sn–Cl bond lengths are also similar to those found in other related dichloro- and diphenyltin compounds.[4,5]

It is of interest that the result of the reaction of $[PhSnCl_3]$ with $[Et_3Sn(OCH_2CH_2NMe_2)]$ depends to a great extent on the order of reagent mixing. Upon the reverse order of mixing, i.e., when $[PhSnCl_3]$ is added to $[Et_3Sn(OCH_2CH_2NMe_2)]$ solution, di(alkoxy)chlorophenylstannane (**1**) is produced in high yield instead of **2**. Moreover, the use of an excess of $[Et_3Sn(OCH_2CH_2NMe_2)]$ does not allow the complete substitution of all three chlorine atoms in $[PhSnCl_3]$ with β-dimethylaminoethoxy groups. For the sake of comparison, we also carried out the same reaction for the alkyltin derivatives $[MeSnCl_3]$ and $[EtSnI_3]$. However, despite the utilization of similar reactions, in the case of the alkyltin derivatives, the reactions stopped after the first step, affording $[MeSn(OCH_2CH_2NMe_2)_2Cl]$ (**3**) and $[EtSn(OCH_2CH_2NMe_2)_2I]$ (**4**), respectively, in high yields. As for **1**, compounds **3** and **4** exist only in the neutral hexacoordinate form.

It is very important to point out that unique phenyl group migration from $[PhSnCl_3]$ takes place in the reaction described here. Phenyl group migration has previously been observed only for the ionic complexes $[PhSnHal_4]^-$ or $[PhSnHal_5]^{2-}$, in which such migration is promoted by fluoride ion or tributylphosphane.[6,7] Moreover, in these reports the final reaction products were not isolated from the reaction mixture and their structures were not determined unambiguously. In our case, however, only stannanes take part in the reaction and the structures of all key products have been determined by elemental analysis, multinuclear NMR spectroscopy, and X-ray diffraction. Thus, we have unambiguously proved for the first time that compounds of the type $RSnX_3$ are able to undergo a redistribution reaction of the hydrocarbon substituent. A more detailed verification of the supposed reaction scheme will be the subject of further investigations.

Complex **2** is the first compound of the type $R_2SnX_2 \cdot R_2SnY_2$ whose structure has been determined by X-ray diffraction. Previously, Kocheshkov and co-workers have reported the existence of unsymmetrical adducts in solution by studying the interaction of $[R_2Sn(OMe)_2]$ with $[R_2SnCl_2]$ or $[R_2Sn(OAc)_2]$ (R = alkyl) by calorimetric, dielcometric, dielectrometric, and cryoscopic methods.[8] However, as was shown later by Davies and co-workers, the structure of these complexes in solution is additionally complicated by the occurrence of the equilibria presented in Scheme 2. These authors suggested that complexes of the type $R_2SnXY \cdot R_2SnXY$ could be considered to be "organotin analogs of Grignard reagents".[9] However, no unambiguous evidence of the structure of the complexes $R_2SnXY \cdot R_2SnXY$ was available until now. It should be noted that in the paper cited above, the authors gave preference to the symmetrical structure of type **II** for these complexes.

Taking into account the possible application of these reactions to the solution of different synthetic and applied problems,[10] we have decided to fill this gap. To this end, we carried out the reactions of diethyltin dichloride with dimethoxydiethyltin and dibutyltin diacetate with dimethoxydibutyltin. The products obtained were studied by X-ray diffraction analysis. It turned out that they consist of symmetrical dimers $[Et_2Sn(Cl)(OMe)]_2$ (**5**) and $[Bu_2Sn(OAc)(OMe)]_2$ (**6**) (Figures 3 and 4 and Tables 3 and 4), respectively, with Sn atoms linked by bridging methoxy groups in the crystal. The coordination geometry around the metal atoms is a strongly distorted trigonal bipyramid with the two C atoms and the covalently bonded O atom of the bridging methoxy group in the equatorial plane. The coordinated O atom of the bridging methoxy group and Cl or OAc substituents for **5** and **6**, respectively, occupy the axial positions. The distortion from the ideal trigonal-bipyramidal geometry is especially apparent in the C–Sn–C and O–Sn←O angles. The tin atoms in these compounds can also be regarded as [4+1]-coordinate, i.e. they represent model compounds along the transformation path tetrahedron ↔ trigonal bipyramid.

Note that the disposition of the substituents implies the presence of an intrinsic inversion center in both **5** and **6**. However, in the crystal, the crystallographically imposed inversion center is retained only in the case of **5**. In the crystal structure of **6**, two out of the four butyl groups adopt different conformations and are slightly disordered (Figure 4); the inversion center is lost because of this.

Similar to **2**, the covalent Sn–O and coordination Sn←O bond lengths in the four-membered $Sn_2O_2$ rings of **5** and **6** are substantially different [2.054(2) and 2.246(2) Å for **5** and 2.054(2) and 2.277(2) and 2.058(2) and 2.271(2) Å for **6**, respectively]. However, in contrast to **2**, these bonds occupy mutually opposite rather than neighboring positions in the $Sn_2O_2$ rings.

According to the DFT calculations (see Supporting Information), there are no complexes of type **I** on the potential energy surfaces corresponding to the interactions of $[Et_2SnCl_2]$ with $[Et_2Sn(OMe)_2]$ and $[Bu_2Sn(OAc)_2]$ with $[Bu_2Sn(OMe)_2]$. The rearrangement of X and OMe substituents to yield monomeric $[R_2Sn(OMe)X]$ is exothermic ($\Delta H^0 = -1.5$ kcal mol$^{-1}$ for R = Et, X = Cl and

## Conclusions

The isolation of complexes **2**, **5**, and **6** provides evidence for the existence of complexes $R_2SnXY{\cdot}R_2SnXY$ (R = Alk, Ar; X, Y = Hal, OR, X ≠ Y) both as unsymmetrical adducts $[R_2SnX_2{\cdot}R_2SnY_2]$ and symmetrical dimers $[R_2SnXY]_2$. Moreover, it has been unambiguously proved for the first time that compounds of the type $[RSnX_3]$ are able to undergo a hydrocarbon substituent redistribution reaction. The similarity of the redistribution reactions of hypercoordinate organotin compounds containing electron-donating groups both in the hydrocarbon R and in the functional X substituents indicates that the chemical properties of these compounds are determined primarily by the coordination mode of the tin atom rather than by the types of ligands. We believe that our findings open-up alluring prospects for the investigation of different transmetallation processes.

## Experimental Section

**General Procedures:** All manipulations were carried out under purified argon using standard Schlenk and high-vacuum-line techniques. The commercially available solvents were purified by conventional methods and distilled immediately prior to use. $[PhSnCl_3]$,[11] $[MeSnCl_3]$,[11] $[EtSnI_3]$,[11] $[Et_3Sn(OCH_2CH_2NMe_2)]$,[3a] $[Et_2Sn(Cl)(OMe)]_2$ (**5**),[8] and $[Bu_2Sn(OAc)(OMe)]_2$ (**6**)[8] were synthesized as described earlier. NMR spectra were recorded with a Bruker AM-360 NMR spectrometer at 360.134 MHz ($^1$H) and 90.555 MHz ($^{13}$C) for samples in $CDCl_3$ or $CD_2Cl_2$. Chemical shifts are relative to $SiMe_4$ for H, C or indirectly refer-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

enced to TMS via the solvent signals. The accuracy of the coupling constants is ±0.1 Hz, and the accuracy of chemical shift measurements is ±0.01 ppm for $^1H$ and ±0.05 ppm for $^{13}C$. Melting points were measured in sealed capillaries with a SANYO Gallenkamp PLC melting point apparatus without any additional corrections. Elemental analyses were performed on a Carlo Erba EA1108 CHNS-O elemental analyzer.

**$[PhSn(OCH_2CH_2NMe_2)_2Cl]$ (1):** A solution of $[PhSnCl_3]$ (3.78 g, 12.50 mmol) in thf (20 mL) was added to an intensely stirred solution of $[Et_3Sn(OCH_2CH_2NMe_2)]$ (11.85 g, 40.35 mmol) in 70 mL of thf. The solution was stirred for 2 h. The solvent was then removed under vacuum to about one sixth of the initial volume and 70 mL of hexane was added. A white crystalline precipitate was obtained, filtered, and washed three times with hexane (in 30 mL portions) and dried in vacuo. The yield was 3.05 g (60%). M.p. 129–131 °C. $C_{14}H_{25}ClN_2O_2Sn$ (407.50): calcd. C 41.26, H 6.18, N 6.87; found C 40.98, H 6.55, N 6.40. $^1H$ NMR ([D$_8$]thf): $\delta$ = 2.29 (br. s, 12 H, $Me_2N$), 2.62–2.68, 2.76–2.86 (two br. m, 4 H, $NCH_2$), 3.81–3.86, 3.93–3.99 (two br. m, 4 H, $OCH_2$), 7.10–7.40 (m, 3 H, Ph), 8.12–8.40 (br. s, $^3J_{Sn,H}$ = 99.0 Hz, 2 H, Ph) ppm. $^{13}C$ NMR ([D$_8$]thf): $\delta$ = 46.12 (br., $Me_2N$), 58.59 ($NCH_2$), 63.47 ($OCH_2$), 128.60 ($^3J_{Sn,C}$ = 112/108 Hz, $C_m$), 129.52 ($^4J_{Sn,C}$ = 21.6 Hz, $C_p$), 138.04 (br., $^2J_{Sn,C}$ = 61.7 Hz, $C_o$), 148.99 ($C_i$) ppm.

**$[Ph_2SnCl_2{\cdot}Ph_2Sn(OCH_2CH_2NMe_2)_2]$ (2):** A solution of $[Et_3Sn(OCH_2CH_2NMe_2)]$ (7.82 g, 26.63 mmol) in thf (30 mL) was added slowly to a stirred solution of $[PhSnCl_3]$ (4.08 g, 13.50 mmol) in $Et_2O$ (50 mL) or thf (50 mL) at room temperature. A large amount of white precipitate appeared immediately. After stirring the mixture for 2 h and storing it overnight the white precipitate was filtered, washed with benzene, and dried in vacuo. The yield of white solid was 1.33 g (49.7% scaled to the amount of $[PhSnCl_3]$). M.p. 168.7–169 °C. $C_{32}H_{40}Cl_2N_2O_2Sn_2$ (792.94): calcd. C 48.47, H 5.08, N 3.53; found C 48.30, H 5.30, N 3.55. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 2.36 (br. s, 12 H, $NMe_2$), 2.73–2.78 (br. m, 4 H, $NCH_2$), 3.91–3.96 (br. m, 4 H, $OCH_2$), 7.87–7.91, 7.10–7.50 (two m, 20 H, Ph) ppm. $^{13}C$ NMR ($CD_2Cl_2$): $\delta$ = 45.45 (br., $NMe_2$), 45.60, 45.92 ($NMe_2$), 60.43, 61.06 ($NCH_2$), 62.48 (br., $OCH_2$), 128.87, 129.10 ($C_m$), 129.03, 129.40 ($C_p$), 130.11, 130.51 ($C_o$), 136.03, 136.20 ($C_i$) ppm.

**Reaction of $[PhSn(OCH_2CH_2NMe_2)_2Cl]$ (1) With $[PhSnCl_3]$ (NMR Experiment):** A solution of **1** (0.52 g, 1.3 mmol) and $[PhSnCl_3]$ (0.39 g, 1.3 mmol) in thf (10 mL) was mixed in a vacuum of $10^{-3}$ Torr. The mixture was stored for 1 h at about 20 °C, then thf was removed by evacuation and $CD_2Cl_2$ (1 mL) was introduced. The solution was transferred to a 5-mm NMR tube and sealed. According to the $^1H$ and $^{13}C$ NMR spectra, the solution contained $[Cl_2Sn(OCH_2CH_2NMe_2)_2]$ and $[Ph_2SnCl_2]$ as the main products. $Ph_2SnCl_2$: $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 7.60–7.67 (m, 3 H, Ph), 7.81–7.84 (m, $^3J_{Sn,H}$ = 81.2 Hz, 2 H, Ph) ppm. $^{13}C$ NMR ($CD_2Cl_2$): $\delta$ = 130.32 ($^3J$ = 85.1 Hz, $C_m$), 132.48 ($^4J$ = 18.4 Hz, $C_p$), 135.57 ($^2J$ = 63.6 Hz, $C_o$), 137.50 ($C_i$) ppm.

**$[Cl_2Sn(OCH_2CH_2NMe_2)_2]$:** A solution of $[Sn(OCH_2CH_2NMe_2)_2]$ (1.76 g, 5.96 mmol) in thf (15 mL) was quickly added to an intensely stirred solution of $HgCl_2$ (1.62 g, 5.96 mmol) in thf (20 mL). A large amount of heavy dark-grey precipitate appeared immediately. The mixture was stirred for 30 min and stored overnight. After filtration, the solvent was removed under vacuum to about one sixth of the initial volume. After addition of hexane (50 mL) a white crystalline precipitate was obtained. This was filtered under argon, washed with hexane, and dried in vacuo. The yield was 2.12 g (97%). M.p. 205 °C (with decomp.). $C_8H_{20}Cl_2N_2O_2Sn$

(365.87): calcd. C 26.26, H 5.51, N 7.66; found C 26.05, H 5.41, N 7.40. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 2.73, 2.74 (two s, 12 H, Me); 2.83–2.86 (m, 4 H, $CH_2N$), 3.80–3.85 (m, 4 H, $CH_2O$) ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 46.78, 46.87 (two s, $Me_2N$), 58.03 ($^3J_{Sn,C}$ = 24.5 Hz, $CH_2N$), 63.02 ($^2J_{Sn,C}$ = 57.5 Hz, $CH_2O$) ppm.

**[MeSn(OCH$_2$CH$_2$NMe$_2$)$_2$Cl] (3):** A solution of [Et$_3$Sn(OCH$_2$CH$_2$NMe$_2$)] (6.65 g, 23.33 mmol) in $Et_2O$ (20 mL) was added dropwise to a stirred solution of [$MeSnCl_3$] (2.80 g, 11.66 mmol) in $Et_2O$ (30 mL). After two hours of stirring an abundant white precipitate had formed. This was filtered, washed with hexane, and dried in vacuo. The yield was 2.49 g (61.8%). M.p. 139–140 °C. $C_9H_{23}ClN_2O_2Sn$ (345.45): calcd. C 31.29, H 6.71, N 8.11; found C 31.05, H 6.80, N 7.97. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 0.71 (br. s, $^2J_{Sn,H}$ = 99.0/103.6 Hz, 3 H, MeSn), 2.57 (br. s, 12 H, $Me_2N$), 2.70 (br., 4 H, $CH_2N$), 3. 78 (br. m, 4 H, $CH_2O$) ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 10.80 (MeSn), 46.27 ($Me_2N$), 58.74 (br., $CH_2N$), 63.61 (br., $CH_2O$) ppm.

**[EtSn(OCH$_2$CH$_2$NMe$_2$)$_2$I] (4):** A solution of [Et$_3$Sn(OCH$_2$CH$_2$NMe$_2$)] (4.47 g, 15.21 mmol) in thf (25 mL) was added dropwise to a stirred solution of $EtSnI_3$ (4.04 g, 7.64 mmol) in $Et_2O$ (30 mL). The mixture was stirred for 2 h and stored overnight. The solvent was removed in vacuo to about one sixth of the initial volume, then 50 mL of hexane was added to give a white crystalline precipitate. This was filtered under argon, washed with hexane, and dried in vacuo. The yield was 1.90 g (56%). M.p. 108–109 °C. $C_{10}H_{25}IN_2O_2Sn$ (450.93): calcd. C 26.64, H 5.59, N 6.21; found C 26.35, H 5.78, N 6.15. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.20 (m, 3 H, C*H$_3$*CH$_2$Sn), 1.73 (m, 2 H, CH$_3$C*H$_2$*Sn), 2.63 (br. s, 12 H, $Me_2N$), 2.72 (br., 4 H, $CH_2N$), 3.80 (br. m, 4 H, $CH_2O$) ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 10.49 (br., CH$_3$*C*H$_2$Sn), 13.39 ($^2J_{Sn,C}$ = 64.4 Hz, *C*H$_3$CH$_2$Sn), 46.82 (br., $Me_2N$), 58.66 ($CH_2N$), 63.32 ($CH_2O$) ppm.

**X-ray Crystal Structure Determination:** Data were collected on a Bruker three-circle diffractometer equipped with a SMART 1000 CCD detector and corrected for absorption using the SADABS program.[12] Data reduction was performed with the SMART[13] and SAINTPlus[14] programs (see Table 5 for details). The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ with anisotropic thermal parameters for non-hydrogen atoms. The value of the Flack parameter for complex **6**, 0.363(18), indicates that the absolute structure in this case cannot be determined unambiguously due to the specific centrosymmetric arrangement of the heavy tin atoms as well as most of the substituents (see above). All calculations were carried out using the SHELXTL program (PC Version 5.10).[15]

CCDC-607745 through -607748 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Details of the quantum-chemical calculations.

## Acknowledgments

This work was supported financially by the Russian Foundation for Basic Research (projects nos. 04-03-32662 and 04-03-32549) and the Russian Academy of Sciences within the frame of the subprogram "Theoretical and experimental study of chemical bonding and mechanisms of chemical reactions and processes". We thank Dr. M. G. Kuznetsova for performing the multinuclear NMR measurements.

# Structural Studies of $[CpMoL_2(CO)_2]^+$ (L = NCMe, $L_2$ = 2,2′-biimidazole) Complexes and Their Inclusion Compounds with Cyclodextrins

**Cláudia C. L. Pereira,[a] Susana S. Braga,[a] Filipe A. Almeida Paz,[a] Martyn Pillinger,[a] Jacek Klinowski,[b] and Isabel S. Gonçalves*[a]**

**Keywords:** Cyclodextrins / Inclusion compounds / Half-sandwich complexes / Molybdenum / Cyclopentadienyl metal carbonyls

Protonation of $[CpMo(\eta^3\text{-}C_3H_5)(CO)_2]$ followed by addition of acetonitrile or 2,2′-biimidazole ($H_2$biim) gave the complexes $[CpMo(NCMe)_2(CO)_2](BF_4)$ (**1**) and $[CpMo(H_2biim)(CO)_2](BF_4)$ (**2**) in good yields. The structures of **1** and **2** were determined by single-crystal X-ray diffraction in the orthorhombic *Pbca* and triclinic $P\bar{1}$ space groups, respectively. Both complexes have similar metal ion coordination environments, which can be envisaged as slightly distorted pseudo-square pyramids, a coordination geometry commonly compared with a four-legged piano stool. The two complexes were immobilised in native and permethylated β-cyclodextrins (β CD and TRIMEB) by methods tailored according to the stabilities and solubilities of the individual components and this gave four adducts with a 1:1 host/guest stoichiometry. The formation of true inclusion compounds was supported by powder X-ray diffraction (XRD), thermogravimetric analysis (TGA), $^{13}C\{^1H\}$ CP/MAS NMR and FTIR spectroscopy. In the case of the TRIMEB adduct containing complex **1**, the crystal packing arrangement is markedly similar to that previously reported for the corresponding 1:1 TRIMEB adducts of the neutral guests $[CpMoX(CO)_3]$ (X = Cl, $CH_2CONH_2$), featuring columns in which the macrocycles are arranged along the *b* axis in a tilted fashion.

## Introduction

Half-sandwich metal carbonyl compounds bearing cyclopentadienyl (Cp = $\eta^5\text{-}C_5H_5$) and $\eta^6$-arene groups have been, and continue to be, investigated for applications in various fields such as catalysis,[1] nonlinear optics[2] and medicine.[3] The bioorganometallic chemistry of these compounds is of particular interest, especially in relation to their use as pharmaceuticals. For example, technetium and rhenium tricarbonyl complexes with derivatised cyclopentadienyl ligands have been investigated for radiopharmaceutical applications in the diagnosis ($^{99m}$Tc) and treatment ($^{188}$Re and $^{186}$Re) of cancer.[4] In these compounds it is the radioactive metal centre that provides the activity, although the ligands attached to the metal centre will ultimately determine the selectivity and efficiency of these compounds towards target diseased cells. Considering the known antitumour action of metallocenes such as $Cp_2TiCl_2$ and $Cp_2MoCl_2$,[5] it is also possible that half-sandwich metal carbonyl compounds containing nonradioactive elements may exhibit anticancer properties. These studies are, however, in their infancy. Researchers have also examined metal carbonyls for applications that directly involve the CO ligands. One of these is their potential use as biological tracer agents.[6] The carbonylmetalloimmunoassay procedure is based on the IR stretching vibrations of organometallic carbonyl groups and has a sensitivity comparable with that of radioactive tracers.[6a] A second example is the use of metal carbonyls as carbon monoxide-releasing molecules.[7]

As indicated above, the primary way to control the properties of half-sandwich metal carbonyl compounds is to modify the steric, electronic and other properties of the first sphere ligands, for example the substituents on the Cp ring. A second approach involves introduction of a second-sphere ligand noncovalently attached to the first-sphere ligands. One of the most promising applications of this idea is the formation of inclusion compounds with cyclodextrins (CDs).[8] CDs and their derivatives are known to bind half-sandwich complexes such as $[CpFeX(CO)_2]$ (X = Cl, Me, CN),[9] $[CpFe(NH_3)(CO)_2](PF_6)$,[10] $[CpMn(CO)_3]$,[11] $[(\eta^6\text{-}C_6H_6)Cr(CO)_3]$,[12] $[CpMoX(CO)_3]$ (X = Cl, $CH_2CONH_2$),[9e,13] $[Cp'Mo(\eta^3\text{-}C_3H_5)(CO)_2]$,[14] $[Cp'Mo(\eta^3\text{-}C_6H_7)(CO)_2]$ and $[Cp'Mo(\eta^4\text{-}C_6H_8)(CO)_2](BF_4)$ (Cp′ = Cp, Ind).[15] Some of these encapsulated metallo-organic complexes exhibit markedly different physical and chemical characteristics in comparison with the bulk material. CD inclusion compounds are interesting for pharmaceutical use because of the enhanced solubility, stability and bioavailability of the drug molecules, as well as the reduced toxic

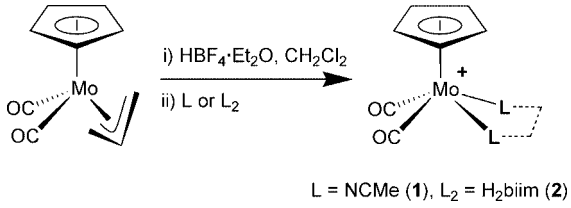
side-effects.[16] As part of an ongoing study aimed at improving the properties of potential organometallic pharmaceuticals by encapsulation in CDs, we now report on the encapsulation of the complexes $[CpMo(NCMe)_2(CO)_2](BF_4)$ and $[CpMo(H_2biim)(CO)_2](BF_4)$ ($H_2biim$ = 2,2′-biimidazole) in β-CD and 2,3,6-tris-*O*-methyl-β-CD (TRIMEB). The molecular structures of the "free" dicarbonyl complexes have been determined by single-crystal X-ray diffraction and the inclusion compounds were characterised in the solid state by various techniques.

## Results and Discussion

### Preparation and Crystal Structures of the Molybdenum(II) Dicarbonyl Complexes

Treatment of $[CpMo(\eta^3\text{-}C_3H_5)(CO)_2]$ with $HBF_4{\cdot}Et_2O$ in dichloromethane affords the labile complex $[CpMo(\eta^2\text{-}C_3H_6)(CO)_2(FBF_3)]$,[17] which readily reacts with acetonitrile to give $[CpMo(NCMe)_2(CO)_2](BF_4)$ (**1**) and with 2,2′-biimidazole to give $[CpMo(H_2biim)(CO)_2](BF_4)$ (**2**) (Scheme 1). As expected, complexes **1** and **2** exhibit two ṽ(CO) stretching vibrations in their FTIR spectra, which can be attributed to the *cis*-$(CO)_2$ fragment. The bands for **2** (1976 and 1878 $cm^{-1}$) appear at lower frequencies than those for **1** (1988 and 1893 $cm^{-1}$) because $H_2biim$ is a better electron donor (and acceptor) than acetonitrile and this results in higher Mo→CO back-donation and a weaker C≡O bond.



Scheme 1.

The crystal structures of compounds **1** and **2** were elucidated from single-crystal X-ray diffraction studies at low temperature (see Exp. Sect.) and show a number of striking similarities with respect to the geometries of the 18-electron half-sandwich molybdenum(II) cationic complexes and the crystal packing of each material.

Complex **1** crystallises in the orthorhombic *Pbca* space group with the asymmetric unit comprised of four individual residues (two metal complex cations plus two highly disordered tetrafluoroborate anions) and corresponding to the empirical formula $[CpMo(NCMe)_2(CO)_2](BF_4)$. Even though a great number of molybdenum complexes with $\eta^5$-cyclopentadienyl and carbonyl[18] or acetonitrile[19–26] ligands have been reported, only one structure containing the latter two ligands is known.[27] To the best of our knowledge, compound **1** represents the first complex containing all three of these ligands.

As often occurs for transition metal organometallic complexes, the structure of **1** contains two crystallographically independent $[CpMo(NCMe)_2(CO)_2]^+$ cations showing the same structural arrangement and rather similar coordination environments (Figure 1, Table 1). These coordination geometries can be envisaged as slightly distorted pseudo-square pyramids with the basal plane formed by two *cis*-coordinated carbonyl groups and two acetonitrile ligands and the apical position occupied by an $\eta^5$-coordinated cyclopentadienyl which, for clarity, is hereafter regarded as unidentate, with the coordination site being the centroid of the aromatic ring, $C_g$ (Figure 1). This coordination geometry is commonly compared with a four-legged piano-stool[21] in which the metal centre emerges above the basal plane (ca. 0.92 and 0.93 Å for the two crystallographically independent complexes) leading to bond angles which deviate significantly from the ideal 90°. The Mo–C (carbonyl) and Mo–N bond lengths for the two complexes [1.967(4)–1.988(4) and 2.160(3)–2.179(3) Å, respectively] are in good agreement with those typically found in similar Mo/Cp complexes as revealed by a search of the Cambridge Structural Database (CSD) (Version 5.26, updated in August 2005).[28] Thus, while the typical Mo–C (carbonyl) bond lengths were found in the 1.64–2.37 Å range (from 1415 entries with a median of 1.97 Å), the Mo–N (acetonitrile) bond lengths are instead in the 2.12–2.20 Å range (from 16 entries with a median of 2.14 Å). Individual $Mo–C_{aromatic}$ bond lengths (Table 1) are also consistent with the values found in related compounds [2.12–2.74 Å for 2468 entries with a median of 2.34 Å]. However, as commonly encountered for complexes with the four-legged piano-stool resemblance,[29] the observed $Mo–C_{aromatic}$ bond lengths also indicate a slight "slip" from the expected $\eta^5$-coordination mode towards an $\eta^3$-type with the torsion angles between the planes defined by the Cp rings and the N···N···C···C bases of the pyramids being ca. 3.0 and 5.4° [for Mo(1) and Mo(2), respectively]. Indeed, the Mo–C(4,5) and Mo–C(13,14) bond lengths are statistically longer than the remaining distances within each Cp aromatic ring (Table 1). This structural feature is depicted in Figure 1 for one $[CpMo(NCMe)_2(CO)_2]^+$ complex cation. C(4) and C(5) are the closest atoms to the slightly bulkier acetonitrile ligands and the increase in the $Mo–C_{aromatic}$ bond length [$\Delta_{average}$(Mo–C) of ca. 0.09 Å with the largest being ca. 0.12 Å] presumably arises as the result of a tendency to reduce the steric pressure imposed upon the complex. The same occurs for the second complex cation but for atoms C(13) and C(14) instead [not represented – $\Delta_{average}$(Mo–C) and the largest bond length difference are identical to the values for the other complex].

Even though the coordination environments of the two crystallographically independent $[CpMo(NCMe)_2(CO)_2]^+$ cations show several similarities, a few geometric aspects of the square-pyramids are fundamentally different. As summarised in Table 1, the (N,C)–Mo–(N,C) bond angle ranges for the basal planes of the molybdenum square-pyramids are slightly distinct for the two complexes [76.60(10)–79.69(12)° and 74.57(15)–81.47(14)°], these differences arising from the way in which each crystallographically independent complex close-packs in the solid-state. Indeed, one

| Mo(2)–$C_g$ | 1.980(1) | $C_g$–Mo(2)–N(4) | 117.20(2) |

[a] $C_g$ corresponds to the centroid of the coordinated $\eta^5$-Cp aromatic rings [C(1)–C(5) and C(12)–C(16)].

complex packs along the [100] direction of the unit cell in a typical interlocked head-to-head fashion, stabilised by π-π interactions between neighbouring $\eta^5$-Cp aromatic rings (distance of ca. 3.5 Å, Figure 2, a). Along this cationic chain the Mo(1)···Mo(1) distances alternate between 5.529(1) and 7.372(1) Å for head-to-head and tail-to-tail packing, respectively. However, the other crystallographically independent complex is instead distributed along the same direction in a head-to-tail fashion [see part c in Figure 2, Mo(2)···Mo(2) distance of 6.441(1) Å] which, in the absence of stabilising interactions between the aromatic ring and the carbonyl and/or acetonitrile moieties, leads to a slightly higher steric pressure on the basal plane, thus resulting in the increase of the (N,C)–Mo–(N,C) bond angles mentioned above.

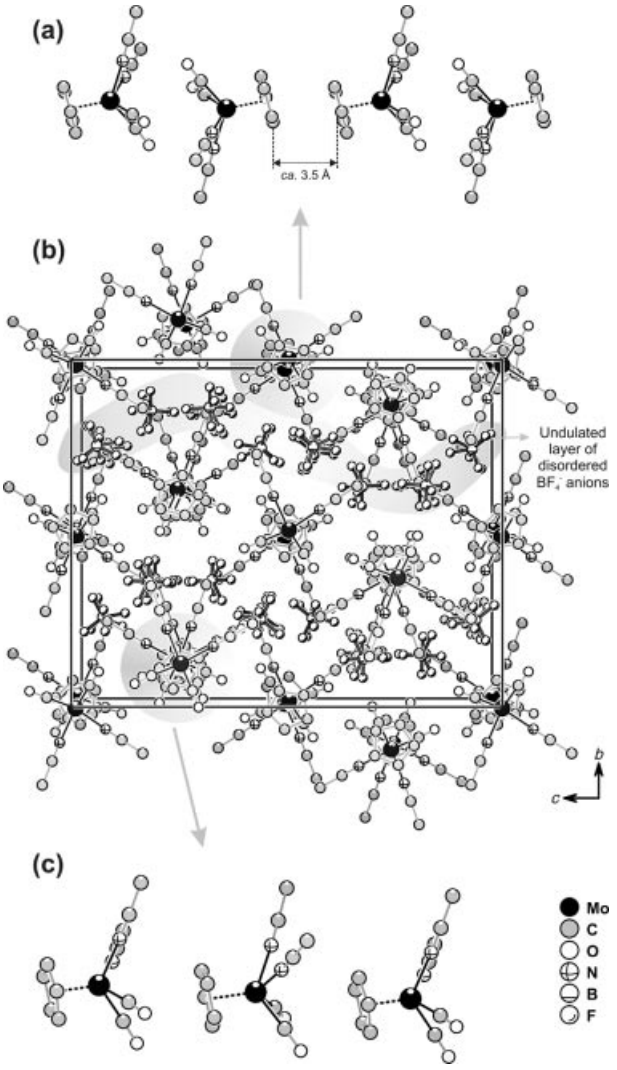

Figure 2. (a) Head-to-head-faced $[CpMo(NCMe)_2(CO)_2]^+$ complex cations in **1** distributed along the [100] direction, showing the π-π interactions between neighbouring $\eta^5$-Cp aromatic rings; (b) Crystal packing of **1** viewed in perspective along the [100] direction of the unit cell, emphasising the alternation in the [010] direction of undulated layers of $[CpMo(NCMe)_2(CO)_2]^+$ complex cations and $BF_4^-$ anions; (c) Head-to-tail-faced $[CpMo(NCMe)_2(CO)_2]^+$ complex cations distributed along the [100] direction. Hydrogen atoms and Mo–C bonds to the coordinated $\eta^5$-Cp have been omitted for clarity.

The crystal packing of **1** is best described as the alternation along the [010] direction of the unit cell of undulated layers formed by the two crystallographically independent $[CpMo(NCMe)_2(CO)_2]^+$ cations with layers of disordered $BF_4^-$ anions (Figure 2). Interactions between these moieties

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

are assured by a large number of weak C–H···F interactions (not shown).

The basic building unit of the complex [CpMo($H_2$biim)(CO)$_2$]($BF_4$) (**2**) is the 18-electron half-sandwich [CpMo($H_2$biim)(CO)$_2$]$^+$ cation, the molecular structure of which was first reported a few years ago by Romão and coworkers for [CpMo($H_2$biim)(CO)$_2$]$ReO_4$ (**2R**).[30] Notably, that report still constitutes, to date, the only crystallographic study of a molybdenum complex with the chelating $H_2$biim ligand. Here we describe the second compound containing this complex cation, in which the tetraoxorhenium(VII) [$ReO_4^-$] moiety has been substituted by tetrafluoroborate anions and the crystal structure determined with increased precision and at low temperature (see Exp. Sect. for crystallographic details for the present study; **2R** was determined at ambient temperature with a very large $R_1$ reliability factor of 9.07%).

For compounds **2** and **2R**, the cation [CpMo($H_2$biim)(CO)$_2$]$^+$ contains the molybdenum centre bound to a chelating $H_2$biim residue, two *cis*-coordinated carbonyl groups and an $\eta^5$-Cp moiety. The coordination geometry is, once again, best described as distorted square-pyramidal and very much resembles a four-legged piano-stool in which the base is formed by the chelating $H_2$biim and the carbonyl residues (Figure 3). The Mo–N and Mo–C (carbonyl) bond lengths are in agreement with those reported for **2R** and related compounds (Table 2). A search in the CSD for typical Mo–N distances of chelating ethanediimines shows values spanning from ca. 2.04 to 2.39 Å with a median of 2.24 Å (from 20 entries in the database). The bite angle of $H_2$biim to the Mo centres is comparable for the two complexes, being ca. 72.8° for **2R** and 72.6° for **2**.

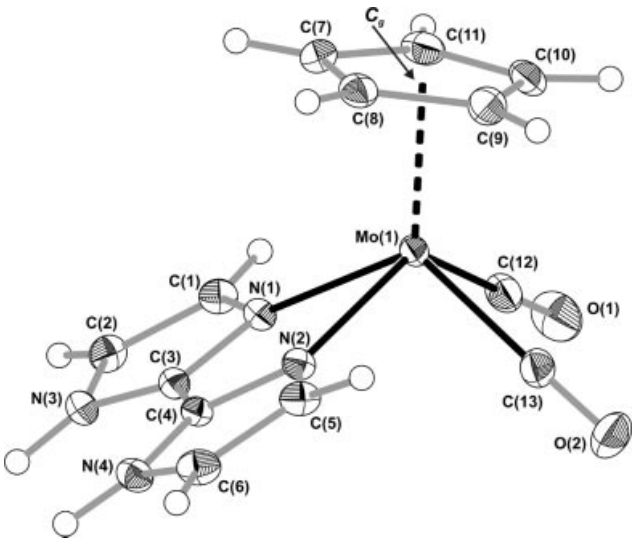

Figure 3. Schematic representation of the [CpMo($H_2$biim)(CO)$_2$]$^+$ complex cation present in the crystal structure of **2**, emphasising the distorted square-pyramidal coordination environment for the $Mo^{2+}$ metal centre and showing the labelling scheme for all non-hydrogen atoms. Displacement ellipsoids are drawn at the 30% probability level and hydrogen atoms are represented as small spheres. All Mo–C bonds to the coordinated $\eta^5$-Cp have been omitted for clarity and replaced by a black-filled dashed bond line to the centroid, $C_g$. For selected bond lengths and angles see Table 2.

Table 2. Selected bond lengths [Å] and angles [°] for the molybdenum coordination environment of the [CpMo($H_2$biim)(CO)$_2$]$^+$ complex cation present in **2**.

| | | | |
|---|---|---|---|
| Mo(1)–N(1) | 2.189(2) | N(2)–Mo(1)–N(1) | 72.55(8) |
| Mo(1)–N(2) | 2.182(2) | C(12)–Mo(1)–N(1) | 80.81(10) |
| Mo(1)–C(12) | 1.981(3) | C(12)–Mo(1)–N(2) | 130.11(9) |
| Mo(1)–C(13) | 1.955(3) | C(13)–Mo(1)–N(1) | 119.59(9) |
| Mo(1)–C(7) | 2.381(3) | C(13)–Mo(1)–N(2) | 80.89(9) |
| Mo(1)–C(8) | 2.396(3) | C(13)–Mo(1)–C(12) | 76.76(12) |
| Mo(1)–C(9) | 2.313(3) | $C_g$–Mo(1)–C(12) | 115.86(2) |
| Mo(1)–C(10) | 2.265(3) | $C_g$–Mo(1)–C(13) | 120.45(2) |
| Mo(1)–C(11) | 2.296(3) | $C_g$–Mo(1)–N(1) | 119.86(2) |
| Mo(1)–$C_g$[a] | 1.996(1) | $C_g$–Mo(1)–N(2) | 113.95(2) |

[a] $C_g$ corresponds to the centroid of the coordinated $\eta^5$-Cp aromatic ring [C(7)–C(11)].

By employing a much smaller anion ($BF_4^-$) to balance the charge of the Mo complex, the crystal packing driving forces mediated by hydrogen bonding interactions (see below) lead to a significant distortion of the geometry of the N···N···C···C base of the pyramid with observed *trans* angles of 130.11(9)° and 119.59(9)°. The corresponding values for **2R** are 124.9(10)° and 126.3(9)°. However, if we consider an average plane for the atoms forming this base, the displacement of the Mo centre towards the $\eta^5$-Cp moiety is ca. 0.96 Å, a value statistically identical to that observed for **2R** [0.94(1) Å]. The latter coordinated moiety is, once again, located at the apex of the distorted square-pyramid and also exhibits a deviation from the ideal $\eta^5$-coordination mode so as to release the steric repulsion with the $H_2$biim molecule. Indeed, compared with the acetonitrile molecules in compound **1**, the $H_2$biim molecule is bulkier and imposes statistically longer Mo–C(7,8) bonds [Table 2; $\Delta_{average}$(Mo–C) of ca. 0.07 Å with the largest being ca. 0.13 Å].

Individual [CpMo($H_2$biim)(CO)$_2$]$^+$ cations close-pack in **2** along the [100] direction in a head-to-tail fashion (Figure 4, a) leading to a chain in which the minimum Mo···Mo separation is 6.531(2) Å. The crystal structure of **2** is formed by the alternation, in the [001] direction of the unit cell, of double layers of [CpMo($H_2$biim)(CO)$_2$]$^+$ complex ions with $BF_4^-$ anions. Interactions between these moieties are assured by strong N–H···F hydrogen bonds (see part b of Figure 4 and Table 3) and, as also reported for compound **1**, by a series of weak C–H···F interactions (not shown).

Table 3. Hydrogen bonding geometry (distances in Å and angles in °) for [CpMo($H_2$biim)(CO)$_2$]($BF_4$) (**2**).[a]

| D–H···A | *d*(D···A) | <(DHA) |
|---|---|---|
| N(3)–H(3)···F(4)$^i$ | 2.868(3) | 144(3) |
| N(4)–H(4)···F(4)$^i$ | 3.116(3) | 139(2) |

**Cyclodextrin Inclusion Compounds**

The relative solubilities of β-CD, TRIMEB and the complexes $[CpMo(NCMe)_2(CO)_2](BF_4)$ (**1**) and $[CpMo(H_2biim)(CO)_2](BF_4)$ (**2**) determined the method used for the preparation of the respective inclusion compounds. An initial CD/organometallic molar ratio of 1:1 was always used. For the preparation of β-CD·$[CpMo(NCMe)_2(CO)_2](BF_4)$ (**3**), an acetonitrile solution of **1** was added to an aqueous solution of β-CD, whereas for the preparation of β-CD·$[CpMo(H_2biim)(CO)_2](BF_4)$ (**5**) both components were dissolved in water. Compounds **3** and **5** were obtained as light brown and light brick coloured solids, respectively, after removal of the solvents by freeze-drying. The TRIMEB inclusion compounds TRIMEB·$[CpMo(NCMe)_2(CO)_2](BF_4)$ (**4**) and TRIMEB·$[CpMo(H_2biim)(CO)_2](BF_4)$ (**6**) were obtained by dissolving the components in either dichloromethane (**4**) or a mixture of dichloromethane and ethanol (**6**), followed by evaporation of the solvent(s) under reduced pressure.

X-ray diffraction studies enable the identification of true inclusion complexes of cyclodextrins, mainly based on the empirical evidence that the powder XRD patterns of these complexes should be clearly distinct from those obtained by the superimposition of the diffractograms of the individual components.[9e,31] Figure 5 shows the patterns for complexes **1** and **2**, plain β-CD hydrate, TRIMEB and the adducts **4** and **5**. The diffractograms of the adducts are clearly different from the sum of the individual patterns for complex **1** and TRIMEB, or complex **2** and β-CD. The TRIMEB adduct **4** is quite crystalline and the diffractogram shares similarities with the patterns exhibited by the corresponding 1:1 TRIMEB adducts of $[CpMoX(CO)_3]$ (X = Cl, $CH_2CONH_2$).[9e,13] A hypothetical structural model of the inclusion compound TRIMEB·$[CpMoCl(CO)_3]$ was obtained by global optimisation using simulated annealing.[9e] The compound crystallises in the space group $P2_12_12_1$ and the crystal packing features columns in which the macrocycles are arranged along the *b* axis in a tilted position. The TRIMEB inclusion compound **6** was found to be much less crystalline than **4**, exhibiting very broad and weak features at about 9.1, 11.5, 18.5 and 23.2° for $2\theta$ in the powder XRD pattern (not shown). The β-CD adducts **3** and **5** had moderate crystallinity, with diffraction patterns very similar to that exhibited by the compound β-CD·$[CpMo(CH_2CONH_2)(CO)_3]$.[13]

Thermogravimetric analysis of compounds **3**–**6** was also useful for the recognition of inclusion complex formation. Figure 6 shows the TGA curves for $[CpMo(NCMe)_2(CO)_2](BF_4)$ (**1**), compounds **3** and **4**, and 1:1 physical mixtures of the pure hosts and complex **1**. Complex **1** features a weight loss of about 38% from 100 to 210 °C, which is in good agreement with the expected loss of 36% calculated for the removal of 2 NCMe and 2 CO ligands. A further gradual weight loss of 21% takes place up to 500 °C, leaving a residual mass of 38.2%. The first of these decomposition steps can be clearly seen in the TG profiles for the physical mixtures and is followed by the onset of cyclodextrin decomposition at about 270 °C for β-CD hydrate and
