### DFT Structure Calculations for 5

To gain insight into the possible isomeric structures based on the different positions of the two isocyanide ligands, the possible geometries of **5** were optimized by using DFT methods. Theoretically, there are four possible isomers for doubly substituted diiron complexes, that is ap/ap, ba/ap, ba/ba, and ap/ba configuration modes. Four optimized structures of the relevant isomers of **5** are shown in Figure 4. Selected geometrical parameters are summarized in the Supporting Information. A comparison of these structures reveals that the Fe–Fe distance is affected by the arrangement of the CO and 4-$IC_6H_4NC$ groups. This effect can be partly attributed to the competition between π-acceptors for the π electrons. The crystallographically characterized isomer **5** is analogous to the computed complex **5.4**. Notably, the bond lengths and angles are in good agreement with the X-ray data and the two phenylisocyanide groups in the basal positions are close to parallel.

From the relative energies of the four isomers shown in Table S1, it can be seen that in the monomer case the stabilization sequence of the four conformations for **5** in the gas phase is **5.2** > **5.3** > **5.4** > **5.1**. When considering the solvent effect, we found that the stabilization sequence changes and isomer **5.4** becomes the most stable one in $CCl_4$ solution at 298 K. The stabilization sequence in $CCl_4$ solution is **5.4** > **5.1** > **5.3** > **5.2**. Theoretical calculations show an important role for the solvent effect on structure selection

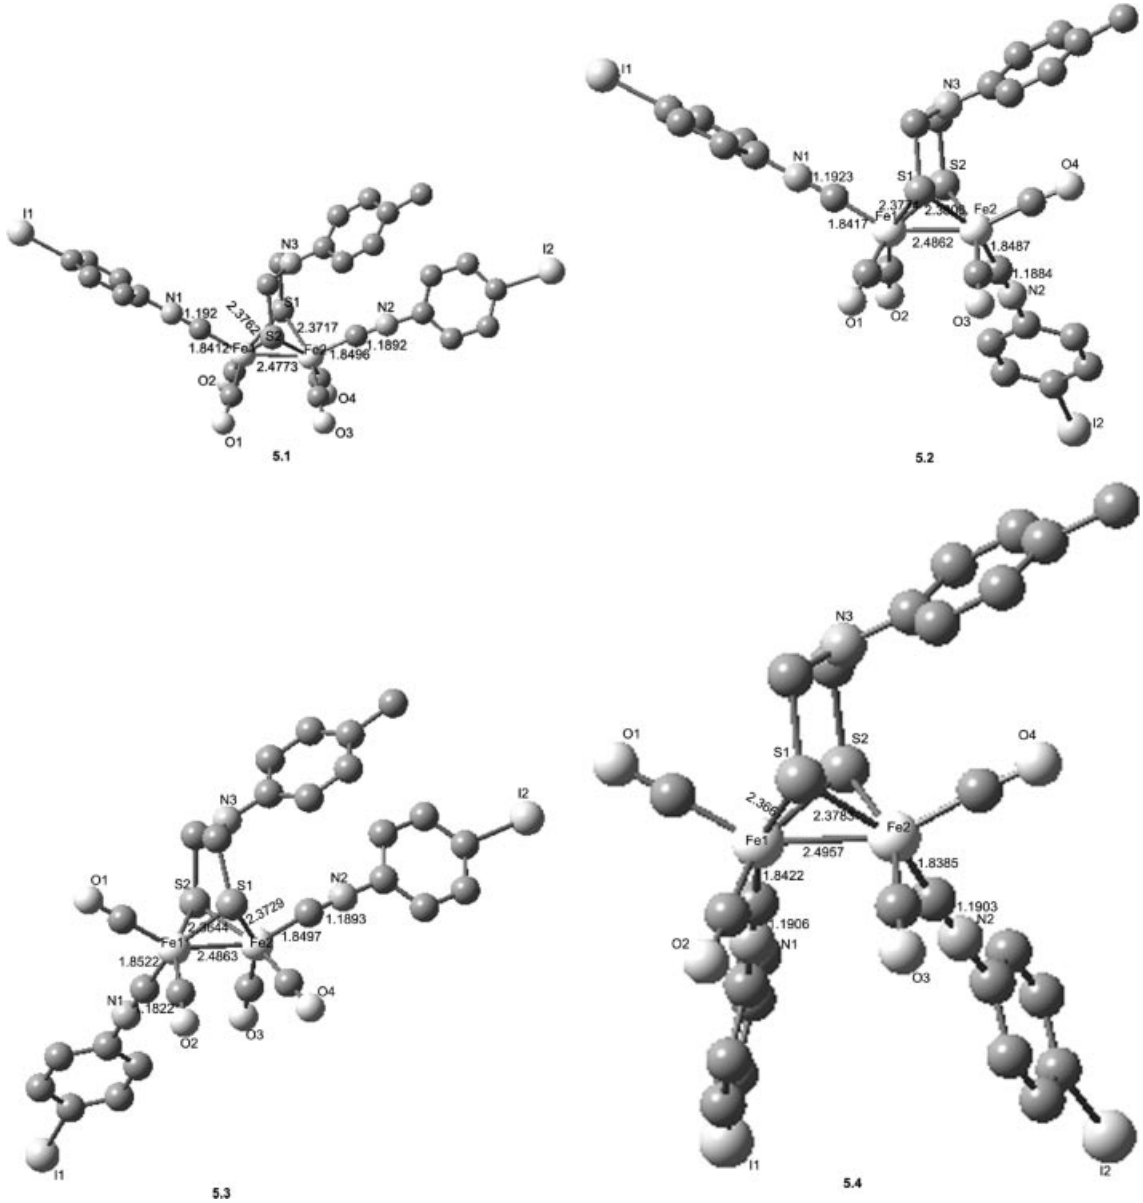

Figure 4. DFT-optimized structures of the four isomers of complex **5**. Selected bond lengths [Å] are given.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

during the crystallization of complex **5**. The energy difference between isomers is less than 15 kJ mol$^{-1}$, which means that isomers of complex **5** can interchange easily.

### Electrochemistry of Complexes 3 and 5

The ADT-bridged diiron hexacarbonyl compounds [(μ-ADT)$Fe_2(CO)_6$][33,35] and their phosphane-substituted derivatives[36] have been reported to undergo an electrochemically quasi-reversible/irreversible reduction at moderately negative potentials depending on the electron-donating abilities of the ligands on the diiron core. The cyclic voltammograms of complexes **3** and **5** shown in Figure 5 were recorded in $CH_3CN$ solution (with 0.1 M $n$Bu$_4$NPF$_6$ as electrolyte) and proceed, as indicated, in the cathodic direction. Complexes **3** and **5** display a quasi-reversible reduction peak and an irreversible oxidation wave, respectively. By comparison with electrochemical data for PDT-bridged diiron complexes[29,30] and ADT-bridged diiron analogues,[33,35,36] the reduction peaks at –1.55 V for **3** and –1.70 V for **5** vs. $Fc^+$/Fc can be assigned to the one-electron reduction process of $Fe^IFe^I$ to $Fe^IFe^0$. The oxidation peaks at 0.55 V for **3** and at 0.13 V for **5** can be attributed to a net one-electron process, but further work is needed to establish this aspect of the electrochemistry. In comparison to that of the parent complex **3**, the reduction potential of **5** shifts by about 0.15 V to a more negative value, and the oxidation peak shifts by about 0.42 V to a less positive value. These shifts of potential indicate that the introduction of 4-iodophenylisocyanide ligands in **5** makes the reduction of the iron core more difficult and the oxidation easier, which is consistent with the better donor capacity of 4-iodophenylisocyanide relative to CO. A similar trend in the diiron analogue [{(μ-$SCH_2)_2$N(4-$BrC_6H_4$)}$Fe_2(CO)_5$-$PPh_3$] has been reported by Sun and co-workers.[36]

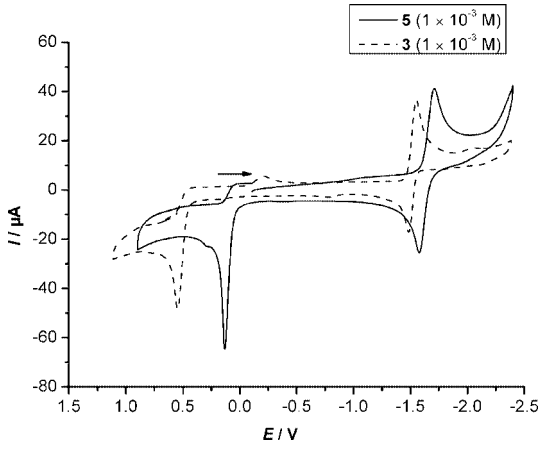

Figure 5. Cyclic voltammograms of **3** and **5** (1 mM) in 0.1 M $n$Bu$_4$NPF$_6$/$CH_3CN$ solution at a potential scan rate of 100 mV s$^{-1}$.

### Electrocatalytic Proton Reduction in $CH_3CN$ Solution

The electrocatalytic proton reduction by **5** was investigated by cyclic voltammetry in the presence of the moderately strong acid HOTs. The cyclic voltammogram recorded in $CH_3CN$ solution at different acid concentrations (0–4 mM) is shown in Figure 6. Upon addition of 1 mM of HOTs, two new reduction peaks were observed at around –1.20 and –1.43 V. As can be seen in Figure 6, the current height of the reduction peak around –1.20 V displays a slight increase with an increase of acid concentration, while the reduction wave at around –1.43 V shows a significant electrocatalytic response. The current intensity of this reduction peak gradually increases and the potential is shifted to a relatively more negative value with increasing acid concentration. The current intensity ($I_{pc}$) of this reduction displays a linear increase with an increase of the concentration of HOTs, as shown in Figure 7. The steeper slope is indicative of the sensitivity of the reduction to acid concentration. These features are typical of a catalytic proton reduction process.[41] At [$H^+$]/[**5**] ≥ 5, the reduction peak at around –1.70 V disappears and the height of the reduction event around –1.43 V also increases and its potential shifts to a more negative value (Figure S1). We conclude that the reduction peak around –1.43 V displays an electrocatalytic response to proton reduction. The reduction peak around –1.20 V may be the reduction process of a protonated product, and further work is needed to define it properly. To further confirm the catalytic activity of **5** around –1.43 V, bulk electrolysis of solutions of 2 mM **5** with 50 mM HOTs was performed at –1.50 V. After passage of 20 C of charge through the cell, a sample of gas was collected and analyzed. Analysis by gas chromatography showed the gas evolved during electrolysis to be $H_2$.

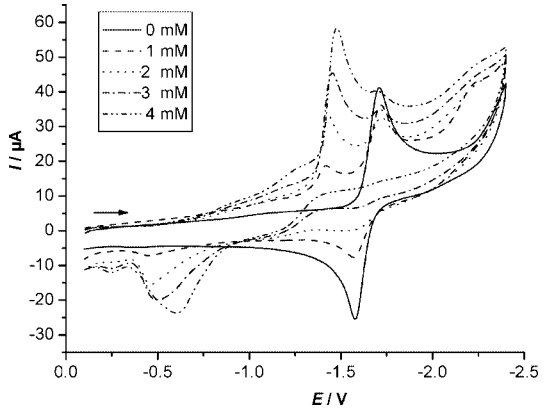

Figure 6. Cyclic voltammograms of **5** (1 mM) with 0–4 mM HOTs in 0.1 M $n$Bu$_4$NPF$_6$/$CH_3CN$ solution at a potential scan rate of 100 mV s$^{-1}$.

Electrocatalytic $H_2$ production by the cyano/phosphane-substituted diiron derivative [(μ-PDT){$Fe(CO)_2PMe_3$}-{$Fe(CO)_2CN$}]$^-$ has been reported by Rauchfuss and coworkers under similar acid conditions (HOTs).[31,32] The potential for the reduction of protons was found to be $E_p^{red}$ = –1.2 V vs. Ag/AgCl (corresponding to –1.69 V vs. $Fc^+$/Fc),[42] which means that the potential of complex **5** is shifted by about 260 mV to a more positive value. Compared with all other functionalized PDT-bridged substituted diiron compounds,[29,30] complex **5** also has a con-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

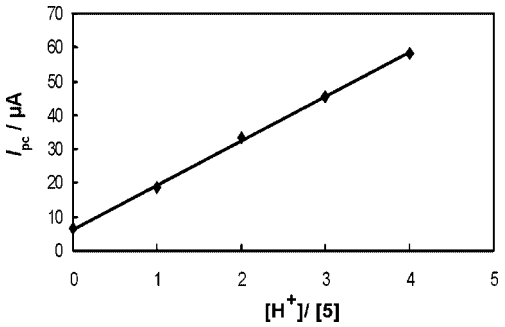

Figure 7. Dependence of current intensity of the reduction events of **5** (1 mM) around –1.43 V on concentration of HOTs.

siderably more positive potential of proton reduction. A reasonable interpretation for this is that the utilization of the basicity of the ADT heteronitrogen atom[43] and the introduction of isocyanide ligands shift the potential to a more positive value and therefore makes the reduction of protons remarkably easier.

Upon addition of acid, an irreversible event is observed at around –0.6 V on the reverse scan. This presumably results from a reduction-derived decomposition product.[29,44]

## Conclusions

The binuclear aromatic isocyanide substitute [{(μ-$SCH_2$)$_2$-N(4-$CH_3C_6H_4$)}$Fe_2(CO)_4$(4-$IC_6H_4NC$)$_2$] (**5**) has been prepared as an active site model of iron-only hydrogenases. Both **5** and its parent complex **3** have been fully characterized by X-ray diffraction. The structure of **5** is highly unusual in that the two phenylisocyanide ligands are in basal positions and are nearly parallel to each other. This suggests that steric or crystal packing forces control the stereochemistry of CO and the aromatic isocyanide ligands. The introduction of the isocyanide ligands in **5** makes the CO stretching frequencies shift to lower values. These lower values of $\nu_{(CO)}$ indicate that the diiron core is more electron-rich, which is also consistent with the shift of the reduction potential of **5** to a more negative value.

The results of DFT calculations show that the binuclear active site of **5** has four possible isomers. One of these was isolated and characterized crystallographically because of the potential for isomeric complexity. It is likely that the π–π stacking interaction between molecules of complex **5** makes the isomer **5.4** stable enough to crystallize from solution.

On the basis of electrochemical analyses of **5**, the reduction peak around –1.43 V is electrocatalytically active in the presence of HOTs. The iodo functionality in **5** could be used for further elaboration by incorporating a redox species. This offers a possibility of linking a ruthenium photosensitizer to the azadithiolatodiiron system **5** in an attempt to produce $H_2$ by action of light.[15] Further experimental efforts in these directions are underway.

## Experimental Section

**Reagents and Instrumentation:** All reactions and operations were carried out under $N_2$ using standard Schlenk techniques. All solvents were dried and distilled prior to use according to standard methods. Tetrahydrofuran was purified by distillation under $N_2$ from sodium/benzophenone. Acetonitrile was distilled once from $CaH_2$ and once from $P_2O_5$ and freshly distilled from $CaH_2$ prior to use. Dichloromethane was distilled from $P_2O_5$ under $N_2$. The following materials were commercially available reagents and used without further purification: paraformaldehyde, 4-methylaniline, and 4-iodoaniline. $LiEt_3BH$ was purchased from Aldrich and used as received. *N*,*N*-Bis(chloromethyl)-4-methylaniline (**2**), [(μ-S)$_2$-$Fe_2(CO)_6$], [(μ-LiS)$_2Fe_2(CO)_6$] (**1**), and 4-iodophenylisocyanide (**4**) were synthesized according to the literature procedures.[34,40,45,46]

Infrared spectra were recorded with a FT-IR spectrophotometer. $^1H$ and $^{13}C$ NMR spectra were recorded on a Varian INOVA 400 NMR spectrometer. Mass spectra were recorded with a HP 100 MSD. HR mass spectra were recorded on a Q-TOF mass spectrometer or a GC-TOF instrument (Micromass).

**Synthesis of [{(μ-$SCH_2$)$_2$N(4-$CH_3C_6H_4$)}$Fe_2(CO)_6$] (3):** $LiEt_3BH$ solution (1 M solution in thf, 2.9 mL, 2.9 mmol) was added to a solution of [(μ-S)$_2Fe_2(CO)_6$] (500 mg, 1.45 mmol) in thf (30 mL) by syringe at –78 °C over 30 min. A solution of *N*,*N*-bis(chloromethyl)-4-methylaniline (**2**) in thf (20 mL) was added to the resulting green solution, causing an immediate change of color to dark red. After stirring for 2 h at –78 °C and for 1 h at room temperature, the solvent was removed in vacuo and the resulting dark-red solid was purified by column chromatography on silica gel using $CH_2Cl_2$/hexane (1:10) as eluent to afford a dark-red solid. Yield: 57% (recrystallized from $CH_2Cl_2$/hexane). $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 7.12 (s, 2 H), 6.66 (s, 2 H), 4.31 (s, 4 H), 2.28 (s, 3 H) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$): $\delta$ = 209.0, 207.2, 142.8, 130.6, 130.2, 116.3, 53.6, 50.2, 19.5 ppm. IR ($CH_2Cl_2$): $\nu_{(CO)}$ = 2071, 2030, 1999 $cm^{-1}$. MS (API-ES): (*m*/*z*): 478 $[M + H]^+$. HR-MS (ESI) calcd. for $[M + H]^+$: 477.8805; found 477.8793.

**Synthesis of [{(μ-$SCH_2$)$_2$N(4-$CH_3C_6H_4$)}$Fe_2(CO)_4$(4-$IC_6H_4NC$)$_2$] (5). Method A:** A solution of complex **3** (1 g, 2.09 mmol) in $CH_3CN$ (30 mL) was treated with a solution of 4-$IC_6H_4NC$ (0.96 g, 4.19 mmol) in $CH_2Cl_2$ (30 mL) at room temperature, followed by the addition of $Me_3NO{\cdot}H_2O$ (0.465 g, 4.19 mmol) in $CH_3CN$ (20 mL). The solution immediately turned dark purple, and after 5 h the color had changed again to dark red. The mixture was stirred at room temperature for 48 h and TLC showed the reaction was complete. The solvent was removed in vacuo and the dark-red residue was purified by column chromatography on silica gel eluting with hexane/dichloromethane (5:1). Two main bands were observed: the first red band, containing [{(μ-$SCH_2$)$_2$N(4-$CH_3C_6H_4$)}-$Fe_2(CO)_5$(4-$IC_6H_4NC$)] [IR ($CH_2Cl_2$): $\nu_{CN}$ = 2124 $cm^{-1}$, $\nu_{CO}$ = 2040, 2000, 1975 $cm^{-1}$], was collected with around 600 mL of eluent, and the second red band (**5**), with a further 1000 mL of eluent, was collected to give the red product **5**. Yield: 640 mg (34%) (recrystallized from $CH_2Cl_2$/hexane). $^1H$ NMR (400 MHz, [$D_6$]acetone): $\delta$ = 7.77 (d, *J* = 8.4 Hz, 2 H), 7.11 (d, *J* = 8.4 Hz, 2 H), 7.03 (d, *J* = 8.0 Hz, 2 H), 6.77 (d, *J* = 8.0 Hz, 2 H), 4.38 (s, 4 H), 2.14 (s, 3 H) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$): $\delta$ = 211.5 (CN), 205.5, 202.5 (CO), 147.0, 143.5, 138.6, 130.2, 128.7, 127.5, 115.8, 93.3, 49.8, 20.5 ppm. IR ($CH_2Cl_2$): $\nu_{(CN)}$ = 2122, 2094 $cm^{-1}$; $\nu_{(CO)}$ = 1996, 1980, 1950 $cm^{-1}$. HR-MS (EI) calcd. for $[M^+]$: 878.7605; found 878.7601.

**Methods B:** A 100-mL Schlenk flask was charged with [{(μ-$SCH_2$)$_2$-N(4-$CH_3C_6H_4$)}$Fe_2(CO)_6$] (**3**; 500 mg, 1.04 mmol) and 4-$IC_6H_4NC$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(479 mg, 2.09 mmol), 50 mL of $CH_2Cl_2$ was added to this flask, and the solution was stirred 48 h at room temperature. The solvent was removed in vacuo and the residue was purified by column chromatography on silica gel, eluting with hexane/dichloromethane (5:1). The first band, containing a large quantity of the monoisocyanide-substituted product, was collected with about 800 mL of eluent, and the second red band containing **5** with a further 200 mL. Yield of **5**: 92 mg (10%; recrystallized from $CH_2Cl_2$/hexane).

**X-ray Structure Determinations:** The single-crystal X-ray data were collected with a Siemens SMART CCD diffractometer for **3**, while the measurement for **5** was performed on a Siemens P4 four-circle diffractometer. In all cases, the data were collected at 293 K using graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) in the $\omega$–2$\theta$ scan mode. Data processing was accomplished with the SAINT processing program.[47] Intensity data were corrected for absorption with empirical methods. The structures of complexes **3** and **5** were solved by direct methods and refined on $F_o^2$ against full-matrix least-squares with the SHELXTL 97 program package.[48] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located by geometrical calculation, but their positions and thermal parameters were fixed during the structure refinement. A summary of the crystallographic data and structural determinations for **3** and **5** is provided in Table 3.

Table 3. X-ray crystallographic data for **3** and **5**.

| | **3** | **5** |
|---|---|---|
| Formula | $C_{15}H_{11}Fe_2NO_6S_2$ | $C_{27}H_{23}Fe_2I_2N_3O_6S_2$ |

[a] $R1 = (\Sigma||F_o| - |F_c||)/(\Sigma|F_o|)$. [b] $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

CCDC-293055 (for **3**) and -289306 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Methods:** The density functional theory (DFT) method was used to optimize the isomeric geometries of complex **5**. Calculations were performed with the B3LYP functional[49] included in the Gaussian 03 program package.[50] The D95 basis set[51] was used for all atoms except Fe and I, for which the LANL2DZ basis set[52] was used with the effective core potential (ECP) of LANL2DZ. The effect of solvent on the stability of the isomers was considered by optimizing all the geometries in $CCl_4$ solution using the PCM method[53] included in Gaussian 03.

**Electrochemistry:** Acetonitrile used for electrochemical measurements was distilled once from $CaH_2$ and once from $P_2O_5$ and freshly distilled from $CaH_2$ under $N_2$. Measurements were made with a BAS 100B electrochemical workstation. All cyclic voltammograms were obtained in a conventional three-electrode cell under argon and at ambient temperature. The working electrode was a glassy carbon electrode (diameter 3 mm) that was successively polished with 3-μm and 1-μm alumina pastes and sonicated in ion-free water for 15 min prior to use. The supporting electrolyte was 0.1 M $n$Bu$_4$NPF$_6$ (Fluka, electrochemical grade). The experimental reference electrode was a nonaqueous Ag/Ag$^+$ electrode (0.01 M $AgNO_3$/0.1 M $n$Bu$_4$NPF$_6$ in $CH_3CN$). Ferrocene was used as an internal standard. All potentials reported in this paper are relative to the Fc$^+$/Fc couple. The counter electrode was platinum wire. During the electrocatalytic experiments under argon, increments of acid were added by microsyringe. Bulk electrolysis experiments were performed under argon with a BAS 100 B/W electrochemical analyzer, which was carried out on a glassy carbon rod ($A$ = 3.14 cm$^2$) in a gas-tight H-type electrolysis cell containing about 14 mL of $CH_3CN$ solution. Gas chromatography was performed with a GC 920 instrument equipped with a thermal conductivity detector (TCD) under isothermal conditions with argon as carrier gas.

**Supporting Information** (see also the footnote on the first page of this article): Energetic properties of isomers of complex **5** calculated both in the gas phase and $CCl_4$ solution using PCM method. Geometrical bond lengths and angles calculated for the isomers **5.1**–**5.4**.

# New Copper(II) Complexes as Efficient Catalysts for Olefin Aziridination: The Effect of Ligand Steric Hindrance on Reactivity

**Thirumanasekaran Dhanalakshmi,[a] Eringathodi Suresh,[b] Helen Stoeckli-Evans,[c] and Mallayan Palaniandavar*[a]**

**Keywords:** Aziridination / Copper / N ligands / Tridentate ligands / Steric hindrance

Three new copper(II) complexes derived from the tridentate $N_3$ ligands 4-methyl-1-(pyrid-2-ylmethyl)-1,4-diazacycloheptane (L1), 1-(quinol-2-ylmethyl)-1,4-diazacycloheptane (L2), and 4-methyl-1-(quinol-2-ylmethyl)-1,4-diazacycloheptane (L3) have been prepared and examined as copper catalysts for olefin aziridination. In the X-ray crystal structures of the complexes $[Cu(L2)Cl_2]$ (**2**) and $[Cu(L3)Cl_2]$ (**3**) copper(II) adopts a trigonal-bipyramidal distorted square-based pyramidal geometry (TBDSBP) as seen from the values of the trigonality index $\tau$ (0.08 for **2** and 0.48 for **3**). The enhanced trigonal distortion in **3** is due to the presence of an N-Me group, the lone pair orbital of which is not oriented exactly along the $d_{x^2-y^2}$ orbital of copper(II). While $[Cu(L1)(H_2O)](ClO_4)_2$ (**1**) assumes a tetragonal geometry in solution, complexes **2** and **3** adopt a distorted tetragonal geometry, as revealed by UV/Vis and EPR spectral studies. The complexes undergo quasi-reversible $Cu^{II}/Cu^{I}$ redox behavior in methanol solution. The ability of the complexes to mediate nitrene transfer from PhINTs to olefins to form *N*-tosylaziridines has been studied. The complexes are found to be efficient catalysts (in 5 mol-% amounts) for the aziridination of the reactive olefin styrene, with yields varying from 80 to 90% (with respect to PhINTs). They exhibit significant catalytic nitrene transfer reactivity (yields of 30 to 60%) also towards the less reactive olefins cyclohexene and cyclooctene. A remarkable observation is the significantly accelerated rate of aziridination by **3**, which is ascribed to the steric crowding around copper(II) imposed by the bulky quinolyl and N-Me groups of the tridentate ligand L3.

## Introduction

Similar to epoxides, aziridine rings enjoy special attention in organic synthesis, particularly as intermediates[1,2] in the synthesis of amines and amino alcohols. Furthermore, naturally occurring azinomycin and mitomycin, which contain aziridines in their core, exhibit cytotoxic properties.[3] The development of new catalysts for the preparation of aziridines has therefore been an active area of investigation. Of the two different catalytic processes that lead to the formation of aziridines,[4–6] that involving addition of an "NR" nitrene unit to a C=C double bond (alkene; Scheme 1) has been more extensively studied than the other, which involves the addition of a "CR" carbene unit to a C=N (imine) bond. This reaction is often catalyzed by transition metals through coordination of the nitrene[4] or by Lewis acids through substrate activation.[5] In transition-metal-catalyzed olefin aziridination reactions, the most widely employed reaction (Scheme 1) has been nitrene transfer from (tosylimino)phenyliodinane (PhINTs).[7–9]

Scheme 1.

Many copper-based catalysts have been reported for nitrene-transfer reactions from PhINTs to alkenes, although they have rarely been structurally characterized.[4,10–14] Halfen et al. have systematically investigated[10] the structural and electronic factors that regulate the catalytic activity of copper complexes in such nitrene-transfer reactions. They used the complex $[Cu(i\text{Pr}_3\text{TACN})(O_2CCF_3)_2]$ to effect the near-quantitative aziridination of styrene derivatives. They also reported aziridination of olefins catalyzed by a series of square-based copper(II) complexes in which tetradentate pyridyl-appended diazacycloalkane ligands are meridionally coordinated.[13] In these complexes the axial coordination site(s) are either vacant or occupied by a readily displaced solvent or counterion, which facilitates the aziridination with the nitrene source PhINTs. The reactivity of the copper(II) complexes is significantly enhanced for aziridination of styrene when the ligand denticity is lowered from tetradentate to tridentate.[15] Very recently Vadernikov

et al. have reported that coordinative unsaturation at copper is responsible for the very high catalytic activity of certain four-coordinate copper(II) chloride complexes of pyridine-based ligands.[16]

We decided to prepare copper(II) complexes of tridentate $N_3$ ligands and study them systematically to identify the key ligand structural and electronic properties for optimum copper catalyst performance. As the highly oxidized copper-nitrene species are suggested[10] to be stabilized by electron-rich and sterically hindered ligands, sterically hindering N–Me and quinolyl moieties were incorporated into the tridentate $N_3$ ligands (Scheme 2) chosen for the present study. The ring system of the ligand would provide resistance[13] towards oxidative degradation of the catalyst by the strongly oxidizing nitrene transfer agent PhINTs. The coordinative unsaturation as well as steric crowding around copper(II) in the present complexes is expected to lead to improved selectivity, reaction rates, and broad substrate tolerance. The X-ray crystal structures of two of the complexes were determined to establish the degree of coordinative unsaturation and distortion in the complexes. The solution structures of the complexes have been probed by employing spectroscopic and electrochemical methods to understand the effect of the ligand architecture on the copper(II) coordination geometry. All the complexes examined were found to be fast and efficient catalysts for the aziridination of styrene, cyclohexene, and cyclooctene when a high amount (5–10 equiv.) of olefin was treated with PhINTs (1 equiv.).

## Results and Discussion

### Synthesis of Ligands and Complexes

The tridentate ligands L1–L3 were prepared as oils in good yields (50–70%) by stirring the appropriate diazacycloheptane (homopiperazine or *N*-methylhomopiperazine) with one equivalent of 2-picolyl chloride or 2-quinolyl chloride and two equivalents of triethylamine in ethanol at room temperature for three days. The copper(II) complexes of the ligands were prepared by the addition of either $CuCl_2{\cdot}H_2O$ or $Cu(ClO_4)_2{\cdot}6H_2O$ in methanol to a methanolic solution of the ligands; they were characterized by analytical and spectroscopic methods and studied as catalysts for aziridination reactions. The ligands occupy three coordination positions in the X-ray crystal structures of both **2** and **3**, with a chloride ion in the equatorial position. Conductivity studies revealed that complex **1** behaves as a 2:1 electrolyte (190 $\Omega^{-1}cm^2M^{-1}$) while **2** and **3** behave as 1:1 electrolytes (**2**, 98 and **3**, 86 $\Omega^{-1}cm^2M^{-1}$) in methanol solution, corresponding to dissociation of the axial chloride to give $[Cu(L)Cl]^+$ ions. The longer equatorial chloride can dissociate in solution in the presence of the substrates and facilitate aziridination reaction.

### Description of the Crystal Structures

An ORTEP view of the structures of complexes **2**·$CH_3CN$ and **3**, along with the atom numbering schemes, are shown in Figures 1 and 2 respectively. Selected bond lengths and bond angles relevant to the copper coordination spheres are given in Table 1. In the complex **2**·$CH_3CN$ copper(II) is bound to two chloride ions and two nitrogen atoms (N2 and N3) of the homopiperazine moiety and the nitrogen atom (N1) of the quinoline moiety of the tridentate ligand L2. The value of the structural index[17] $\tau$ (0.08) suggests that the pentacoordinate complex is very slightly distorted square pyramidal and the coordination geometry around copper(II) may be best described as trigonal-bipyramidal distorted square-based pyramidal (TBDSBP)[18] in which the square plane is constituted by the three nitrogen atoms (N1, N2, N3) of L2 and one chloride ion (Cl1) and the apical position occupied by the other chloride ion (Cl2). Two crystallographically independent complex molecules with the same chemical formula are present in the asymmetric unit cell of complex **3**. In both these molecules copper(II) is coordinated by three nitrogen atoms, two (N2 and N3) from the homopiperazine moiety and one (N1) from the quinoline moiety of ligand L3, and two chloride ions (Cl1 and Cl2), as in **2**·$CH_3CN$. The value of the structural index[17] $\tau$ (0.48) reveals that the coordination geometry around copper(II) in **3** is best described as TBDSBP in which the corners of the square plane are occupied by the three nitrogen atoms of L3 and one chloride ion (Cl1), and the apical position by the other chloride ion (Cl2). In fact, the coordination geometry lies exactly midway between trigonal-bipyramidal and square-pyramidal geometries. The value of the trigonality index $\tau$ for **3** is much higher than

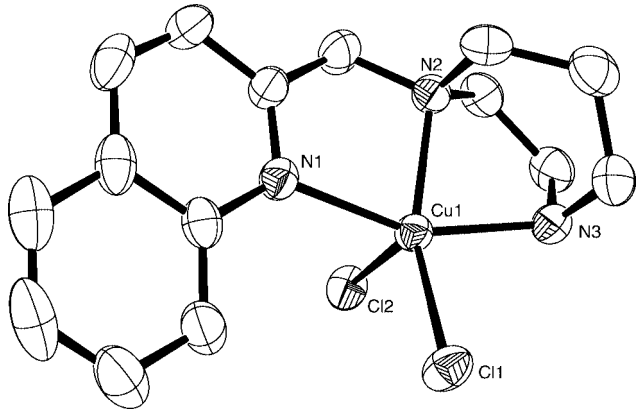

Figure 1. ORTEP drawing of $[Cu(L2)Cl_2]$ (**2**) showing the atom numbering scheme and the thermal motion ellipsoids (50% probability level).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

that for **2**·$CH_3CN$, thus revealing that incorporation of the sterically hindering N–Me group in **3** leads to a greater geometrical constraint at copper(II). The Cu–$N_{amine}$ distances in both **2**·$CH_3CN$ and **3** are in the range expected[15] and, interestingly, they are longer in **3** (2.052, 2.068 Å) than those (2.036, 2.0392 Å) in **2**·$CH_3CN$, thus revealing that the lone pair orbitals of the N-Me group in **3** are not oriented exactly along the $d_{x^2-y^2}$ orbital of copper(II).[19] Further, the axial chloride ions in both **2**·$CH_3CN$ and **3** are located further away from the metal (2.456 Å in **2** and 2.462 Å in **3**) than the equatorial chloride ions (2.272 Å in **2** and 2.304 Å in **3**). This is obviously because of the presence of two electrons in the $d_{z^2}$ orbital of copper(II) in the square-based environments of both complexes. It is interesting to note that both **2**·$CH_3CN$ and **3** are monomeric, which is in contrast to the dimeric structure of the complex [(L4)Cu(μ-Cl)$_2$-Cu(L4)], where L4 is 5-methyl-1-(2-pyridylmethyl)-1,5-diazacyclooctane, the pyridine analogue of ligands L2 and L3. The incorporation of the sterically hindering quinolyl moiety in place of the pyridyl moiety in L4 and that of the ethylene linker instead of propylene one in the homopiperazine backbone of L4 prevent the dimerization of both **2** and **3**. We have previously shown[20] that incorporation of a sterically hindering $NMe_2$ group in the place of a pyridine donor enhances the Fe–O–C bond angle in iron(III) complexes of certain tetradentate monophenolate ligands from 128.5° to 136.1°. The equatorial chloride ion in **2**·$CH_3CN$ and **3** can be replaced by PhINTs, which leads to catalysis of aziridination reactions, as observed for copper(II) complexes of didentate ligands.[16]

## Spectral Properties

The solid-state reflectance spectra of all the complexes show a broad ligand-field feature (540–850 nm) in the visible region, which appears to contain more than one band; this is typical of $Cu^{II}$ located in a square-based environment, as evidenced from the X-ray crystal structures of complexes **2** and **3** (Table 2). On dissolution in methanol, only one ligand-field feature is observed (640–760 nm, Figure 3) for all the complexes, which suggests changes in their coordination geometries such as dissociation of the axial chloride ion in solution. The ligand-field energies of complexes **2** and **3** are much lower, with higher molar absorptivities, than those of **1**, thereby indicating that the replacement of the pyridyl moiety in **1** by the bulky quinolyl moiety in **2** and **3** leads to an enhancement of the distortion in the square-pyramidal geometry towards trigonal bipyramidal. Further, the ligand-field energy of **3** is lower, and the molar absorptivity higher, than those of **2**, as expected from the weaker σ-coordination of N(3), as explained above, and due to the steric hindrance imposed by the N-Me group leading to a more distorted coordination geometry, as evident from the X-ray structures of the complexes. A similar decrease in ligand-field energy has been observed upon replacing an NHMe group by an $NMe_2$ group in the coordination sphere of copper(II) complexes of tridentate pyridine-based ligands.[19]

The polycrystalline EPR spectra of complexes **1** and **2** are axial while that of **3** is rhombic, which is consistent with the distorted square-based geometry found in the X-ray crystal structure of **3**. The frozen solution spectra (Figure 4) of all the complexes are axial [$g_{\|} > g_{\perp} > 2.0$, $G = (g_{\|} - 2)/(g_{\perp} - 2) = 3.0–4.3$],[21] which is usual for mononuclear tetragonal copper(II) complexes with a $d_{x^2-y^2}$ ground state.[22] Copper(II) complexes with a square-based $CuN_4$ coordination sphere exhibit $g_{\|}$ and $A_{\|}$ values of around

[a] Concentration: $2\times10^{-3}$ M for ligand-field and $2\times10^{-5}$ M for ligand-based transitions. [b] $A_\parallel$ in $10^{-4}$ $cm^{-1}$. [c] Methanol/acetone (4:1, v/v) glass at 77 K. [d] π–π* transitions within the ligand.

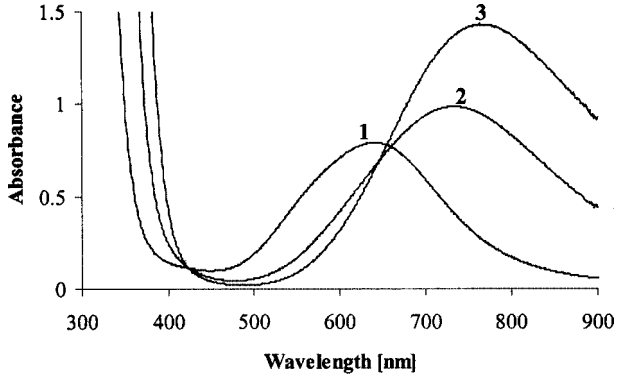

Figure 3. Electronic absorption spectra of complexes **1**–**3** in methanol solution. Concentration of the complexes: $5\times10^{-3}$ M.

2.200 and $200\times10^{-4}$ $cm^{-1}$, respectively. Replacement of a coordinated nitrogen in this chromophore by oxygen (solvent methanol) is expected to enhance the $g_\parallel$ value and decrease the $A_\parallel$ value. Thus, the $g_\parallel$ (2.225–2.231) and $A_\parallel$ (180–$130\times10^{-4}$ $cm^{-1}$) values of **1**–**3** are suggestive of the presence of a square-based $[Cu(N_3)Cl]^+$ chromophore.[19] Interestingly, the $A_\parallel$ values of **2** and **3** are much lower than that of **1**, which suggests that the coordination geometries in them are strongly distorted from planarity. In fact, the values of their $g_\parallel/A_\parallel$ quotient (152 cm for **2** and 171 cm for **3**) is higher than that for **1** (117 cm). This suggests a large deviation from a perfectly square-planar geometry ($g_\parallel/A_\parallel$ = 105–135 cm)[23] because of the incorporation of sterically demanding quinolyl moiety in **2** and **3** in place of the pyridyl moiety in **1**. Further, the $g_\parallel$ and $A_\parallel$ values of **2** are lower and higher, respectively, than those for **3**, and the $g_\parallel/A_\parallel$ value for **2** is lower than that for **3**. This reveals that the distortion from a square-based geometry in **3** is higher than that in **2** because of the sterically hindering N-Me substitution, which is consistent with the above X-ray structures and electronic spectral results.

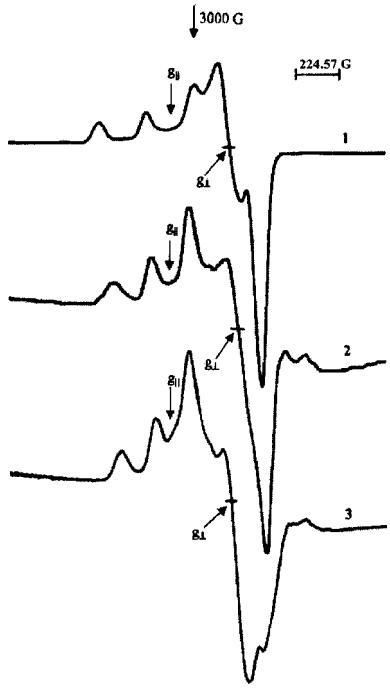

Figure 4. X-band EPR spectra of complexes **1**–**3** at 77 K in methanol/acetone (4:1 v/v) glass.

## Electrochemical Properties

The electrochemical data obtained for the present complexes in methanol solution using TBAP as supporting electrolyte are collected in Table 3. The cyclic (CV) and differential pulse voltammograms (DPV) were recorded using Pt as working electrode and Ag/AgCl as reference electrode. For all the complexes the $Cu^{II}$ to $Cu^{I}$ reduction ($E_{pc}$, –0.325 to –0.475 V) is associated with a reoxidation peak ($E_{pa}$, –0.244 to –0.318 V) in the reverse scan. The value of the limiting peak-to-peak separation ($\Delta E_p$ = 158–

[a] Potential measured vs. non-aqueous $Ag/AgNO_3$ reference electrode; add 0.544 V to convert to standard hydrogen electrode (SHE); $Fc/Fc^+$ couple: $E_{1/2}$ = 0.038 V (CV), $\Delta E_p$ = 88 mV; scan rate: 50 mV s$^{-1}$; supporting electrolyte: tetrabutylammonium perchlorate (0.1 M); complex concentration: $1 \times 10^{-3}$ M. [b] Differential pulse voltammetry (DPV); scan rate: 1 mV s$^{-1}$; pulse height: 50 mV. [c] Potential at half-height $E_{p1/2}$.

210 mV) is higher than that for the $Fc/Fc^+$ couple ($\Delta E_p$ = 88 mV) under identical conditions. This suggests that the heterogeneous electron-transfer process in the present complexes is far from reversible and that considerable stereochemical reorganization of the coordination sphere occurs on electron transfer. The $Cu^{II}/Cu^{I}$ redox potentials follow the trend **3** > **2** > **1** (Figure 5). This reveals the importance of the sterically hindering quinolyl moiety in destabilizing the $Cu^{II}$ form of **2**, thereby facilitating the electron transfer. Similarly, the incorporation of the sterically hindering and weakly σ-bonding N-Me group in **2** to obtain **3** further destabilizes the $Cu^{II}$ oxidation state, which is consistent with the X-ray structures of the complexes. Similar results have been observed by incorporating an $NMe_2$ group in the copper(II) complexes of certain pyridine-based linear $N_3$ ligands.[19]

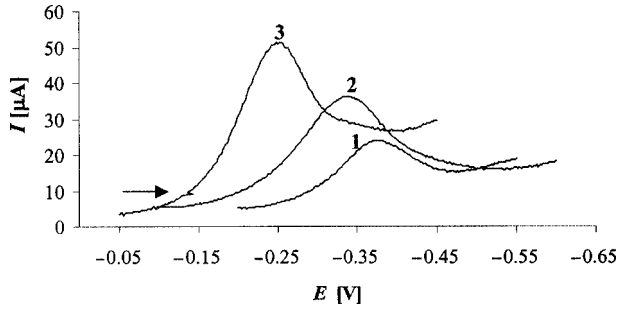

Figure 5. Differential pulse voltammograms of complexes **1**–**3** in methanol solution at 25 °C at a scan rate of 0.05 V s$^{-1}$. Complex concentration: 0.001 M.

### Application to Catalytic Olefin Aziridination Reactions

The newly synthesized copper(II) complexes **1**–**3** were examined for their ability to catalyze the aziridination of olefins, especially styrene, cyclohexene, and cyclooctene, using PhINTs as the nitrene source; the results are collected in Table 4. When a 10:1 olefin:PhINTs ratio was employed with a catalyst loading of 5 mol-%, all the complexes gave high yields (85–90%) for the aziridination of the most reactive olefin styrene. However, when the olefin:PhINTs ratio was decreased to 5:1, slightly lower yields (75–80%) were obtained. When this ratio was decreased from 5:1 to 1:1 as for **3**, the yield decreased further. A remarkable observation is the significantly accelerated rate of aziridination of styrene (within an hour) for complex **3**. The presence of labile ligands and the coordinative unsaturation around copper(II) promotes faster coordination of PhINTs to copper(II) (otherwise slow) and is responsible for the high yield and reduced reaction times. In fact, on treatment of **3** with excess PhINTs in acetonitrile solution, the ligand-field band is shifted from 799 to 794 nm with enhanced absorptivity, thus suggesting the coordination of PhINTs to copper(II). Further, the persistence of the blue or green color of the reaction mixtures after dissolution of PhINTs reveals that the resting state of the catalyst is always $Cu^{II}$. According to the very recently proposed mechanism for copper-catalyzed aziridination,[16] the coordination of =NTs to copper(II) is required for intramolecular electron transfer. This leads to the formation of PhI and a highly reactive copper-nitrene radical-like intermediate [$(L3)Cu^{II}$=NTs], which is then involved in consecutive nitrene transfer to olefin. Obviously, the steric crowding around copper(II) imposed by the bulky quinolyl moiety and the N-Me group (see above) of the tridentate ligand would stabilize this intermediate and facilitate the aziridination. Also, it would prevent any side reactions like recoordination of chloride. In fact, when aziridination was performed for complex **3** after the removal of two chloride ions by treatment with $AgNO_3$, the reaction time decreased further, as expected, but with no change in yield. It is interesting to note that the incorporation of a sterically hindering $NMe_2$ group in the place of a pyridine donor enhances the dioxygenase activity of iron(III) complexes of certain tetradentate monophenolate ligands.[20] No change in yield was observed with a decrease in the olefin:PhINTs ratio; however, the reaction becomes faster (completed within 30 min).

Aziridination of the less reactive cyclohexene was performed with 5 mol-% catalyst loading. When the olefin:PhINTs ratio was 5:1, all the complexes showed a good yield of more than 60%. It is remarkable that the yield of aziridine observed for cyclohexene is higher than those for other complexes available in the literature (except $[Cu(MeCN)_4]ClO_4$, 77%).[4] Also, and interestingly, no allylic sulfonamide insertion product was obtained. The complexes also catalyze the aziridination of the other less reactive olefin *cis*-cyclooctene, although the yield is very low (30–45%). When the olefin:PhINTs ratio was decreased from 10:1 to 5:1, the yield was also reduced. Again, complex **3** catalyzes the aziridination (within an hour) faster than the other two complexes.

## Conclusions

Copper(II) complexes of three new tridentate $N_3$ ligands have been isolated. Two of them have been structurally characterized to contain the meridionally coordinated ligand, and the incorporation of a sterically hindering quinolyl moiety and N-Me donor group in the ligand leads to a strong trigonal distortion of the copper(II) coordination geometries. All the complexes exhibit significant catalytic nitrene transfer reactivity with PhINTs towards three olefins. While good yields (above 80%) were obtained for the reactive olefin styrene, yields exceeding 60% were obtained for less reactive cyclohexene; however, lower yields (30–45%) were obtained for cyclooctene. The present findings confirm that both the degree of coordinative unsaturation and the steric congestion in copper-based systems are important factors that determine their catalytic activity. It is fascinating to note that the use of low-coordinate copper(II) species with distorted geometries as catalysts dramatically accelerates the aziridination (reaction times 0.5–1 h) for reactive as well as less reactive olefinic substrates. This finding could be expected to pave the way for the rational design of new and more active catalysts for aziridination and related group-transfer reactions.

## Experimental Section

**Materials and Methods:** $CuCl_2·2H_2O$, cyclohexene, triethylamine, (Merck, India), *p*-toluenesulfonamide, iodosobenzene diacetate (Merck, Germany), *tetra*-butylammonium bromide (G. F. Smith), *N*-methylhomopiperazine, homopiperazine, 2-picolylchloride hydrochloride, 2-quinolylchloride hydrochloride, $Cu(ClO_4)_2·6H_2O$, and *cis*-cyclooctene (Aldrich) were used as received. Styrene was distilled from KOH pellets at 25 °C under vacuum (0.3 Torr) and was stored at –20 °C. Anhydrous acetonitrile was used in catalytic aziridinations and was handled and stored under $N_2$. The iodinane PhINTs was prepared by a modified literature procedure and was stored in the dark.[7] *tetra*-Butylammonium perchlorate (TBAP) was prepared by the addition of sodium perchlorate to a hot ethanol solution of *tetra*-butylammonium bromide. The product was recrystallized from aqueous ethanol and was tested for the absence of bromide. $^1$H NMR spectra were obtained using a Bruker 200 MHz spectrometer at room temperature. $^1$H NMR chemical shifts are reported relative to TMS and are referenced to residual solvent peaks. Electronic absorption spectra were acquired using a Varian 300 spectrophotometer (200–900 nm). FTIR spectra (4000–400 $cm^{-1}$ range, KBr pellets) were recorded with a Jasco FT-IR spectrometer. EPR spectra were recorded with a JEOL JES-TE 100 X-band spectrometer, the field being calibrated with diphenylpicrylhydrazyl (dpph). The $g_0$ and $A_0$ values were estimated at ambient temperature and $g_\parallel$ and $A_\parallel$ at 77 K. The values of $g_\perp$ and $A_\perp$ were computed as $1/2(3g_0 - g_\parallel)$ and $1/2(3A_0 - A_\parallel)$ respectively. Electrochemical experiments were conducted using a EG & G PAR 273 potentiostat/galvanostat with EG & G M270 software, using a platinum sphere working electrode, an $Ag/AgNO_3$ reference electrode, and a platinum plate auxiliary electrode. Cyclic voltammograms were obtained in methanol using 0.1 M TBAP as supporting electrolyte. Elemental analyses were performed at Bharathiar University, Coimbatore. Conductivity measurements on methanolic solution of the complexes were made using an Elico conductivity bridge.

***Caution!*** Perchlorate salts of transition metal complexes containing organic ligands are potentially explosive and should be prepared in small quantities and handled with appropriate precautions. While no difficulties were encountered with the complexes reported herein, due caution should be exercised.

**4-Methyl-1-(pyrid-2-ylmethyl)-1,4-diazacycloheptane (L1):** An aqueous solution (5 mL) of NaOH (0.40 g, 10 mmol) was added dropwise to an aqueous solution (10 mL) of 2-picolyl chloride hydrochloride (0.82 g, 5 mmol) at 0 °C. An aqueous solution (10 mL) of *N*-methylhomopiperazine (0.57 g, 5 mmol) was then added to this mixture over 15 min. The mixture was stirred in a loosely sealed flask at room temperature for three days. The reaction mixture was then extracted with $CHCl_3$ (3 × 50 mL). The organic layer was washed with saturated sodium hydrogen carbonate solution, evaporated, and then dried ($Na_2SO_4$). The organic solvent was removed on a rotary evaporator to yield the crude product as a pale-yellow oil. The pure product was obtained by extracting the oil once again with ethyl acetate. The product obtained was used as such for the complex preparation. Yield: 0.58 g (56%). $C_{12}H_{19}N_3$ (205.16): calcd. C 70.20, H 9.33, N 20.47; found C 70.15, H 9.48, N 20.37. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 8.64–7.29 (m, 4 H), 3.95 (s, 2 H), 2.48 (m, 4 H), 2.36 (m, 4 H), 1.49 (quint, 2 H), 2.27 (br. s, 3 H) ppm. IR: $\tilde{\nu}$ = 3023 (m), 2983 (s), 2888 (w), 1467 (m), 1407 (s), 1240 (m), 941 (s), 779 (s) $cm^{-1}$.

**1-(Quinol-2-ylmethyl)-1,4-diazacycloheptane (L2):** The ligand L2 was synthesized by a slightly modified procedure that was reported for the preparation of the monosubstituted diazocyclooctane li-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gands.[24] Triethylamine (1.01 g, 10 mmol) was added to 2-quinolyl chloride hydrochloride (1.07 g, 5 mmol) in ethanol (25 mL) at 0 °C, and a solution of homopiperazine (2.00 g, 20 mmol) in ethanol (10 mL) was added slowly to this mixture with stirring. The whole mixture was refluxed for 2 h. The solution was stirred for 2 d at room temperature and the ethanolic solution was removed on a rotary evaporator to dryness. Water was added to the residue and the pH of the solution was adjusted to 10 with sodium carbonate. The solution was extracted with chloroform and the extracts were dried with sodium sulfate. The ligand was isolated as a yellow oil after rotary evaporation of the chloroform extracts. Yield: 0.75 g (61%). $C_{15}H_{19}N_3$ (241.16): calcd. C 74.65, H 7.94, N 17.41; found C 74.55, H 8.13, N, 17.32. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 8.02–7.36 (br. m, 6 H), 3.93 (s, 2 H), 2.65 (m, 2 H), 2.55 (m, 2 H), 2.45 (m, 2 H), 2.33 (m, 2 H), 1.51 (quint, 2 H), 2.91 (br. s, NH) ppm. IR: $\tilde{\nu}$ = 3432 (br), 3010 (s), 2884 (s), 1432 (s), 1230 (w), 760 (s), 629 (s) cm$^{-1}$.

**4-Methyl-1-(quinol-2-ylmethyl)-1,4-diazacycloheptane (L3):** A slightly different procedure was followed for the synthesis of L3. Triethylamine (1.01 g, 10 mmol) was added to 2-quinolyl chloride hydrochloride (1.07 g, 5 mmol) in ethanol (25 mL) at 0 °C. A solution of *N*-methylhomopiperazine (0.57 g, 5 mmol) in ethanol (10 mL) was added to this mixture slowly with stirring. The whole mixture was refluxed for 2 h and then stirred for 2 d at room temperature. The ethanolic solution was removed on a rotary evaporator to dryness, water was added to the residue, and the pH of the solution was adjusted to 10 with sodium carbonate. The solution was extracted with chloroform and the extracts were dried with sodium sulfate. The ligand was isolated as dark yellow oil after rotary evaporation of the chloroform extracts. Yield: 0.98 g (77%). $C_{16}H_{21}N_3$ (255.17): calcd. C 75.26, H 8.29, N 16.46; found C 75.33, H 8.15, N 16. 52. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 8.27–7.32 (br. m, 6 H), 3.98 (s, 2 H), 2.46 (m, 4 H), 2.36 (m, 4 H), 1.49 (quint, 2 H), 2.27 (br. s, 3 H) ppm. IR: $\tilde{\nu}$ = 3054 (s), 2981 (s), 2865 (s), 1459 (s), 1215 (w), 766 (s), 628 (s) cm$^{-1}$.

**[Cu(L1)(H$_2$O)](ClO$_4$)$_2$ (1):** A solution of L1 (0.21 g, 1 mmol) in methanol (15 mL) was treated with $Cu(ClO_4)_2 \cdot 6H_2O$ (0.37 g, 1 mmol) to obtain a deep-blue color. After 15 min of stirring, diethyl ether was allowed to diffuse into the solution. After a period of several days blue crystals of the product were deposited. Yield: 0.32 g (56%). $C_{12}H_{21}Cl_2CuN_3O_9$ (484.01): calcd. C 28.07, H 3.85, N 8.93; found C 28.11, H 3.78, N 8.98. IR: $\tilde{\nu}$ = 3451 (br), 2923 (w), 2869 (w), 1610 (s), 1089 (br, $ClO_4^-$), 890 (s), 626 (s, $ClO_4^-$) cm$^{-1}$.

**[Cu(L2)Cl$_2$] (2):** A procedure analogous to that used to prepare **1** was followed, using $CuCl_2 \cdot 2H_2O$ (0.17 g, 1 mmol) and L2 (0.24 g, 1 mmol) instead of L1. The pure product was isolated as blue crystals. Yield: 0.19 g (47%). $C_{15}H_{19}Cl_2CuN_3$ (374.04): calcd. C 47.94, H 5.10, N 11.18; found C 47.78, H 5.23, N 11.21. IR: $\tilde{\nu}$ = 3442 (br), 3235 (s), 2927 (s), 2884 (s), 1481 (w), 786 (s), 634 (s) cm$^{-1}$. X-ray diffraction quality crystals of **2**·$CH_3CN$ were obtained by the vapor diffusion of diethyl ether into a solution of the complex in acetonitrile.

**[Cu(L3)Cl$_2$] (3):** This complex was prepared by the addition of L3 (0.26 g, 1 mmol) in methanol (15 mL) to a methanolic solution of $CuCl_2 \cdot 2H_2O$ (0.17 g, 1 mmol) with stirring. After 15 min of stirring, the solution was layered with diethyl ether. Green crystals were deposited after two days. Yield: 0.26 g (65%). $C_{16}H_{21}Cl_2CuN_3$ (388.05): calcd. C 49.30, H 5.43, N 10.78; found C 49.42, H 5.38, N 10.71. IR: $\tilde{\nu}$ = 3442 (br), 3079 (w), 2981 (m), 2869 (m), 1610 (s), 782 (s), 634 (s) cm$^{-1}$. Suitable single crystals of **3** for X-ray diffraction were obtained by slow evaporation of the methanolic solution of the complex.

**Catalytic Aziridinations. Styrene:** Aziridinations were performed by stirring mixtures of PhINTs (0.3–0.4 mmol), styrene (10 to 1 equiv. vs. PhINTs), and the copper catalyst (5 mol% vs. PhINTs) in 2 mL of anhydrous $CH_3CN$ under a dry $N_2$ atmosphere as reported previously.[10] At the completion of the reactions, the clear, pale-green solutions were passed through a short column of neutral alumina to remove copper species, eluted with ethyl acetate, and the eluates were evaporated to yield oily residues. These crude product mixtures (of iodobenzene, 2-phenyl-1-tosylaziridine, and *p*-toluenesulfonamide) were treated with hexane to produce the crude aziridine products, which were recrystallized from hexane/diethyl ether mixtures at –20 °C. The 2-phenyl-1-tosylaziridine obtained was characterized by $^1$H NMR spectroscopy and the data were identical with those reported in the literature.[13]

**Cyclooctene:** Aziridinations were performed as described above by stirring mixtures of PhINTs (0.3–0.4 mmol), the olefin (10 to 5 equiv. vs. PhINTs), and the copper catalyst (5 mol-% vs. PhINTs) in 2 mL of anhydrous $CH_3CN$. At the completion of the reactions, the clear, pale-green solutions were passed through a short column of neutral alumina to remove copper species, eluted with ethyl acetate, and the eluates were evaporated to yield semi-solid residues. These crude product mixtures were treated with hexane, and the resultant mixtures were filtered to remove *p*-toluenesulfonamide. The filtrates were evaporated and dried overnight under vacuum to yield the pure aziridine products. $^1$H NMR spectroscopic data confirmed the formation of the aziridine.

**Cyclohexene:** Aziridinations were performed as described above by stirring mixtures of PhINTs (0.3–0.4 mmol), the olefin (5 equiv. vs. PhINTs), and the copper catalyst (5 mol-% vs. PhINTs) in 2 mL of anhydrous $CH_3CN$. At the end of the reaction, flash column chromatography (3 × 18 cm silica, 4:1 hexane/ethyl acetate) yielded the aziridine as a white crystalline solid. The *N*-(*p*-tolylsulfonyl)-7-azabicyclo-[4.1.0]heptane obtained was characterized by $^1$H NMR spectroscopy and the data were identical with those reported in the literature.[4e]

**X-ray Crystallography**: The single-crystal diffraction experiments for **2**·$CH_3CN$ were carried out on a Bruker SMART APEX CCD diffractometer at room temperature. The SMART[25] program was used for collecting frames of data, indexing reflections, and determining the lattice parameters; SAINT[25] was used for integration of the intensity of reflections and scaling; SADABS[25] was used for absorption correction, and the SHELXTL[25] program for space group and structure determination and least-squares refinements on $F^2$. The structure was solved by the heavy-atom method. Other non-hydrogen atoms were located in successive difference Fourier syntheses. The final refinement was performed by full-matrix least-squares. Most of the hydrogen atoms were located from the difference Fourier map and refined isotropically, except for the hydrogen atoms of the lattice acetonitrile molecule, which was placed at a geometrical position. For **3**, the intensity data were collected at 173 K on a Stoe Image Plate Diffraction System.[26] Image plate distance: 70 mm; φ oscillation scans: 0–200°; step: Δφ = 1.0°; exposure time: 3 min; 2$\theta$ range: 3.27–52.1°; $d_{min.}$–$d_{max.}$ = 12.45–0.81 Å. The structure was solved by direct methods using the programme SHELXS-97.[27] The refinement and all further calculations were carried out using SHELXL-97.[28] The H atoms were included in calculated positions and treated as riding atoms using the SHELXL default parameters. The non-H atoms were refined anisotropically, using weighted full-matrix least-squares on $F^2$. There are two independent molecules per asymmetric unit ($Z$ = 8, $Z'$ = 2). A multi-scan absorption correction was applied using the MULscanABS routine in PLATON;[29] transmission factors:

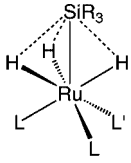
# σ-Silane Ruthenium Complexes: The Crucial Role of Secondary Interactions

**Sébastien Lachaize[a] and Sylviane Sabo-Etienne*[a]**

**Keywords:** σ-Complexes / Ruthenium / Silanes / Hydrides / Coordination modes / Intramolecular interactions / Oxidative addition / Hypervalent compounds

*On pages 2118–2120 of the original article,[1] the references in Tables 1 and 2 are incorrect as a result of an inadvertent error during the revision of the article, and in Figure 6 on page 2121 of the same article,[1] the ligand L′ was omitted; the correct version of Tables 1 and 2 and Figure 6 are given.*



L, L' = phosphane, CO, σ-$H_2$
R = alkyl, aryl, alkoxy, amino or halogen

Figure 6. Schematic representation of a series of complexes of general formula $RuH_3(SiR_3)L_2L'$.

## COVER PICTURE

**The cover picture shows** the three-dimensional supramolecular arrangement of 1,10-phenanthroline (phen) residues in compound $(Hphen)_6[Ge_6(OH)_6(hedp)_6]\cdot 2(phen)\cdot 20H_2O$ (where $H_4$hedp stands for etidronic acid). Protonated organic residues, $Hphen^+$, π-π-stack along the [101] direction of the unit cell, which leads to the formation of columns that are interconnected through a series of weak C−H···π interactions with neighbouring 1,10-phenanthrolines. The resulting organic framework is highly porous and contains charge-balancing centrosymmetric hexameric anionic $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moieties within the channels and a large number of highly disordered water molecules (total available volume of ca. 2462 Å$^3$ per unit cell). Details are discussed in the article by J. Rocha et al. on p. 4741 ff.

# Azide as a Bridging Ligand and Magnetic Coupler in Transition Metal Clusters

**Albert Escuer[a] and Guillem Aromí*[a]**

**Keywords:** Cluster compounds / Azides / Magnetic properties / Single-molecule magnets

The synthesis of transition metal spin-clusters has become an important sub-discipline of coordination chemistry, especially since the discovery of single-molecule magnets (SMMs) in the early nineties. In this context, complexes with high spin-numbers and large anisotropy are particularly desired. The use of the azide ligand to act as a bridge and magnetic coupler within cages of paramagnetic ions has become increasingly common in this field, especially during the last five years, mainly because of the coordination versatility of this ligand, which is capable of bridging several metals in a variety of coordination modes, and its ability to induce ferromagnetic interactions. Several high-spin 3d metal aggregates have been prepared in this manner, a significant number of which behave as SMMs. This review covers the rapid progress made with this relatively recent synthetic approach by describing the structures and summarising the magnetic properties of the systems prepared in this manner. Some of the trends identified could serve as a privileged starting point for the further development of this promising area.

## Introduction

The synthesis of coordination polynuclear complexes has been stimulated to a large extent by the field of molecular magnetism.[1,2] Most of these species contain paramagnetic 3d ions and are thus susceptible to exhibiting large spin-numbers as a result of intramolecular magnetic exchange. Such high-spin molecules have been perceived as potential building blocks in the construction of molecule-based magnets. In this context, magnetic studies on the cluster $[Mn_{12}O_{12}(OAc)_{16}(H_2O)_4]$, hereafter referred to as $[Mn_{12}OAc]$ (**1**),[3] led to the discovery of single-molecule magnet (SMM) behaviour.[4,5] SMMs are molecular species capable of maintaining the orientation of their magnetisation fixed below a certain *blocking temperature*, $T_b$. This molecular property is caused by an energy barrier to the equilibration of the various spin angular momentum orientations, which is calculated as $S_T^2|D|$ (integer spin) or $(S_T^2 - 1/4)|D|$ (half-integer spin),[6] where $S_T$ is the total spin of the molecule at the ground state and $D$ is the zero-field splitting parameter gauging the axial anisotropy, which has

*Albert Escuer was born in Lleida, Spain, in 1956. He completed both his BSc (1978) and PhD (1984) degrees at the Universitat de Barcelona, the latter under the supervision of Prof. J. Ribas. In 1986 he was a postdoc with Prof. Dante Gatteschi at the Universita degli Studi di Firenze (Italy). He became full professor of Inorganic Chemistry in 2003 and he is the current director of the Inorganic Chemistry Department of the Universitat de Barcelona. His research interests concern the study of coordination compounds with small bridging ligands, mainly pseudohalides, with particular interest in magnetochemistry. He is the author of more than 150 papers in international chemistry journals.*

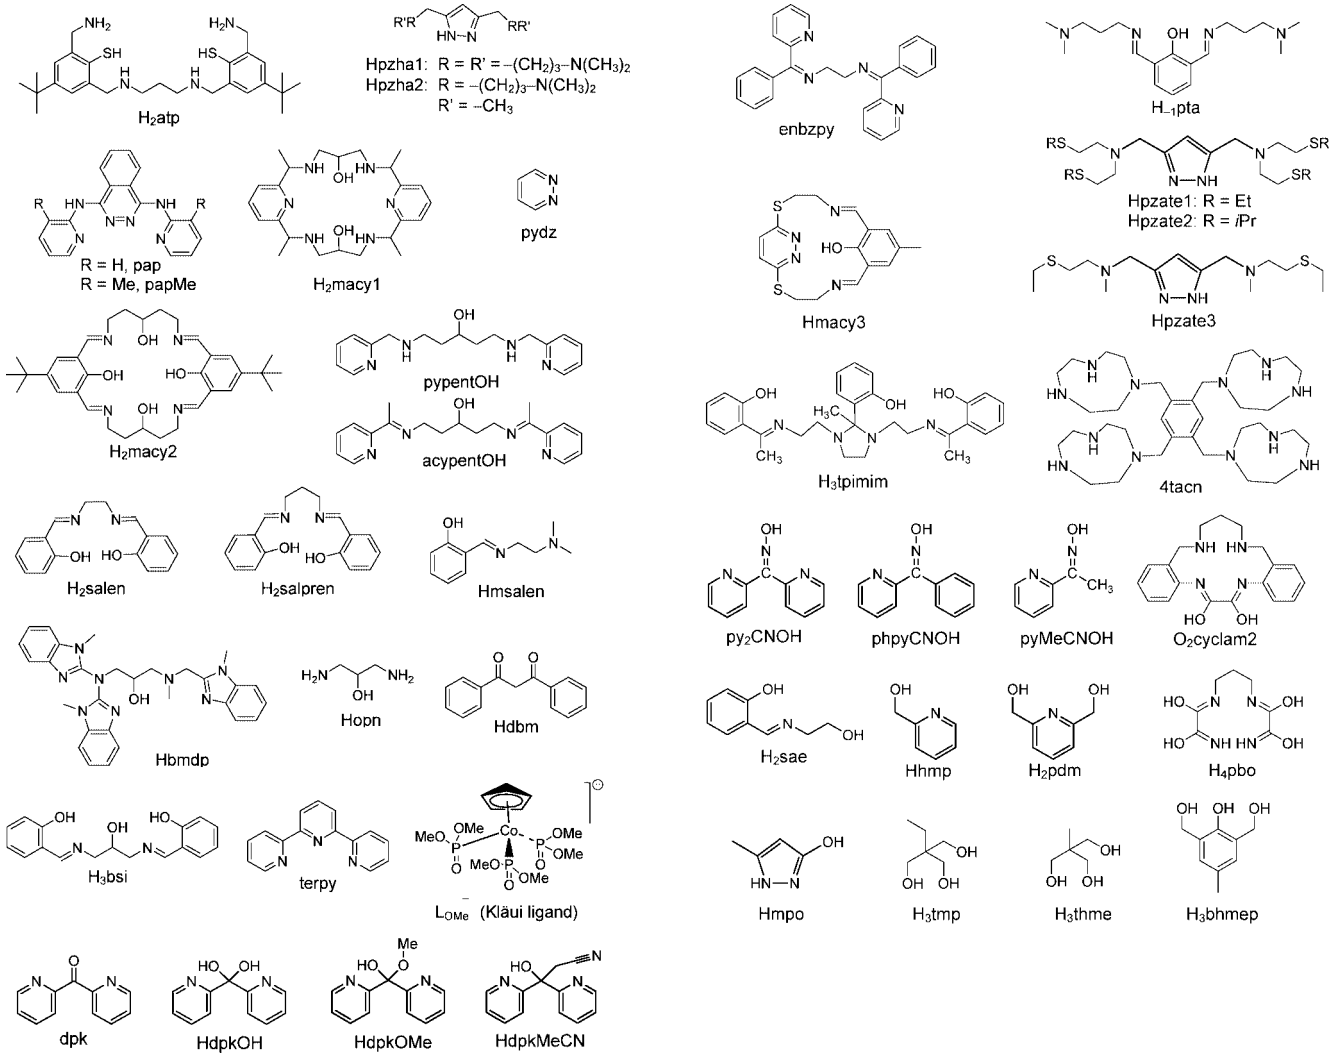
*Dr. Guillem Aromí graduated in Chemistry from the Universitat de Barcelona and obtained his degree of Chemical Engineer at the European Higher Institute of Chemistry in Strasbourg. He received his PhD in 1999 from Indiana University, under the supervision of Prof. George Christou, and worked as a Postdoctoral fellow in the group of Prof. Jan Reedijk (Leiden University) and later in the group of Prof. Richard Winpenny (Manchester University). In 2003, he was awarded a Spanish Fellowship "Ramón y Cajal" to develop his research at the Universitat de Barcelona, where he currently works. His research interests are the development of synthetic strategies for the preparation of novel polynuclear coordination complexes, and the study of their magnetic properties. Dr. Aromí is a member of the International Advisory Board of the European Journal of Inorganic Chemistry.*

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to be of the Ising type ($D < 0$). The search for new examples of SMMs has undoubtedly intensified efforts aimed at the preparation of more and different cluster coordination complexes,[7] possibly with high spin numbers and enhanced magnetoanisotropy.

The vast majority of these compounds have been prepared by the so-called method of "serendipitous self-assembly".[2] In this methodology, transition metal ions react with small bridging ligands (e.g. $O^{2-}$, $OH^-$, $OMe^-$, $Cl^-$, $N_3^-$) to form stable polynuclear arrays. Growth into infinite networks is blocked by terminal ligands that can either be monodentate (e.g. pyridine, alcohols, MeCN, carboxylic acids) or polydentate (e.g. bipyridine, 1,3-diketonates, picolinic acid). Additional bridging ligands are commonly included in the reaction system, and these, because of their versatility and varied coordination modes, have led to the formation of very diverse and large families of clusters. Among these categories of compounds are those containing carboxylates,[1] pyridones,[8] polyalcohols,[9] amino alcohols,[10] dipyridyl ketones,[11] etc. Of this important number of compounds, a relatively low percentage display spin ground-states larger than 5/2 (the maximum spin that can be achieved with a mononuclear d metal complex). This is, in part, true because antiferromagnetic interactions are more common than ferromagnetic ones.

Azide ligands have been widely employed in coordination chemistry, most of the time as part of 1-, 2- or 3D extended arrays or dinuclear complexes.[12] This research has allowed the discovery of magnetostructural correlations,[13,14] which have established, for example, that end-on $N_3^-$ ligands usually mediate ferromagnetic interactions, except in some recognized situations.[15] Moreover, this ligand has been shown to exhibit a wide variety of coordination modes (see below). For these reasons, the azide ligand constitutes a suitable entry into novel high-spin clusters, although this has been recognized only recently. Indeed, many members of the growing family of azide-bridged discrete polynuclear complexes display ferromagnetic interactions and large spin-numbers, of which an exceptionally large portion behave as SMMs. Interestingly, more than 80% of examples (containing four or more metal centres) have been reported during the last five years. It is thus clear that this category of com-



Scheme 1. Ligands discussed in this review.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pounds constitutes a large and promising field of open investigation in the search for magnetic clusters and SMMs. The area, however, is developing quite rapidly, and thus constitutes an excellent topic for a microreview, where the achievements made up to now are summarised while possible trends for future developments may be suggested. All the azide-bridged clusters containing four or more metal centres reported to date are gathered together in this account and organized, where possible, by structural types. The structures of the co-ligands of all the compounds reviewed are shown in Scheme 1. Structural descriptions are presented along with summaries and short discussions of their magnetic properties, where possible. A few compounds that are yet to be published have also been included in this compendium with the permission of the authors of their discovery.

## Structural Overview

A survey of the literature reveals that the metals most frequently observed as part of azide-bridged clusters are Ni and Cu, followed at a distance by Mn, Co and Fe. All nuclearities from four to ten have been observed, and there is then a large gap until the next observed metal count of nineteen. This number is then followed by twenty five and the highest nuclearity of thirty two. Of these topologies, the tetranuclear arrangement clearly dominates, making up about 70% of examples. Thus, most examples in the latter category can be analysed according to certain structural patterns, namely cyclic types (metallacrowns), linear arrays, cubanes and defective cubanes. Among all the complexes structurally characterised, about 10% behave as SMMs. Of the compounds reviewed, Cu derivatives are the most numerous, although most of their azide bridges are of the axial–equatorial type and consequently the intramolecular magnetic exchange is severely diminished. These compounds have, nevertheless, been included in this review for completeness. The clusters discussed in this review are listed in Table 1.

### Cyclic $M_4$ Clusters

The seven documented tetranuclear compounds with a cyclic topology (Figures 1 and 2) are $[Ni_4(atp)_2(pydz)_2(N_3)_2](BPh_4)_2$ (**1**),[16] $[Ni_4(pzha1)_2(N_3)_4](BPh_4)_2$ (**2**),[17,18] $[Ni_4(pzha2)_2(N_3)_4](X)_2$ (**3**; X = $ClO_4^-$, $BF_4^-$),[18] $[Cu_4(pap)_2(N_3)_8(MeOH)_2]$ (**4**),[19,20] $[Cu_4(papMe)_2(N_3)_4(H_2O)_2(NO_3)_2](NO_3)_2$ (**5**),[19] $[Mn_2(Hmacy1)(N_3)_2]_2(ClO_4)_2$ (**6**),[21] $[Cu_4(macy2)(N_3)_4]$ (**7**)[22] and $[Ni_4(N_3)_4(opn)_2(Hopn)_2](ClO_4)_2$ (**8**).[23] Of these, complexes **1**–**6** can be described as dimers of dinuclear units linked to each other by azide ligands where the co-ligand is playing the role of a dinucleating scaffold. The $N_3^-$ bridges linking the dimers are all of the end-to-end (EE) type (see Scheme 2), with the exception of **6**, where the end-on (EO) mode is observed. Presumably, EE coordination only occurs when the steric encumbrance prevents the EO mode from occurring, and this can be argued for complexes **1**–**6**. Complexes **7** and **8** are closer to true cycles rather than dimers-of-dimers.

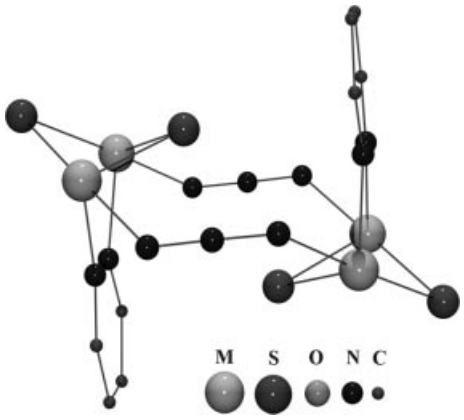


Figure 1. The core of $[Ni_4(atp)_2(pydz)_2(N_3)_2](BPh_4)_2$ (**1**) and the grey scale and size code of atoms used throughout the whole paper.

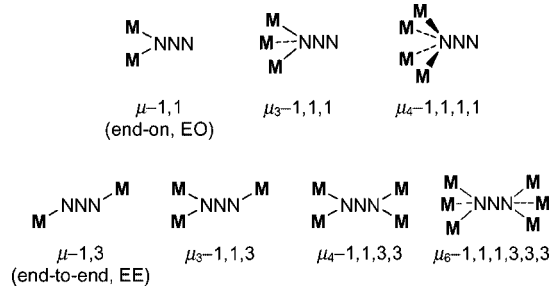

Scheme 2. Coordination modes observed for the azide ligand.

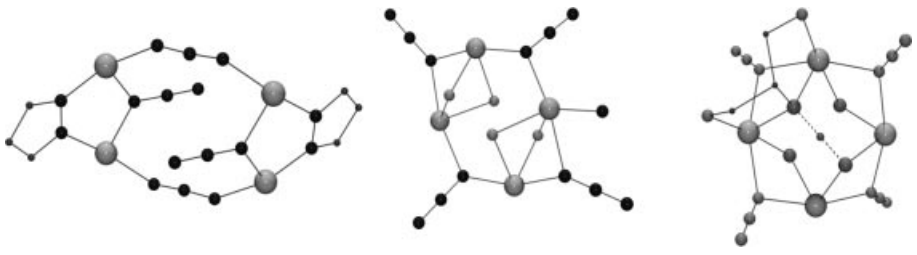

Figure 2. Several representative cores for cyclic $M_4$ azido clusters. Left: the $\mu_{1,3}$-azido-bridged dimer-of-dimers core of $[Ni_4(pzha1)_2(N_3)_4](BPh_4)_2$ (**2**), which is very similar to **3**, **4** and **5**. Centre: $\mu_{1,1}$-azido-bridged dimer-of-dimers core of $[Mn_2(Hmacy1)(N_3)_2]_2(ClO_4)_2$ (**6**). Right: true cyclic core of $[Ni_4(N_3)_4(opn)_2(Hopn)_2](ClO_4)_2$ (**8**) showing one of the H-bonds that helps to stabilize the structure (dashed bonds).

### *[Ni$_4$(atp)$_2$(pydz)$_2$(N$_3$)$_2$](BPh$_4$)$_2$ (1)*

The core of complex **1** is shown in Figure 1.[16] It is a rectangular array resulting from the bridging by two $\mu_{1,3}$-$N_3^-$ ligands of two dinuclear [Ni$^{II}_2$] units, held together by a hexadentate aminothiophenolate ligand (atp), with the additional support of a pyridazine (pydz) group. This molecule forms from independent $[Ni_2(atp)_2]^+$ dinuclear complexes as a precursor of the higher nuclearity species upon reaction with $N_3^-$. It displays an $S = 4$ spin ground-state, which can be modelled as the result of ferromagnetic interactions through both type of bridges — the thiophenolato-pyridazine and the EE-azido. In the first case, it can be argued that the ferromagnetic coupling occurs because the Ni–S–Ni angle is close to 90°, whereas for the $N_3^-$ bridge, the observed Ni–N–N–N–Ni torsion angle of 76.4° (i.e. larger than 55°) is the cause of the ferromagnetism.[24–26]

### *[Ni$_4$(pzha1)$_2$(N$_3$)$_4$](BPh$_4$)$_2$ (2) and [Ni$_4$(pzha2)$_2$(N$_3$)$_4$](X)$_2$ (X = ClO$_4^-$, 3a; BF$_4^-$, 3b)*

Complexes **2** and **3** are similar to **1**, with each [Ni$^{II}_2$] moiety now supported by one polyaminopyrazolyl group (pzha, Scheme 1) and one $\mu_{1,1}$-$N_3^-$ ligand. Both dinuclear entities are connected by EE azide groups to complete the cyclic structure (Figure 2, left).[17,18] The spin ground-state, however, was found to be either $S = 0$ or $S = 4$. Fits of bulk magnetisation data were conducted by considering constants for the intra- and interdimer couplings. The first one was always found to be ferromagnetic, as expected from the influence of the EO azide bridge. The interactions through the EE azides, however, were found to be of either sign, depending on the value of the Ni–$N_3$–Ni torsion angle. Thus, torsion angles sufficiently close to 180° (as commonly encountered) facilitate antiferromagnetic coupling (as observed for **2** and **3b**, $S = 0$), whereas values close to 90° lead to ferromagnetic interactions (as seen for **3a**, $S = 4$).[24–26]

### *[Cu$_4$(pap)$_2$(N$_3$)$_8$(MeOH)$_2$] (4) and [Cu$_4$(papMe)$_2$(N$_3$)$_4$(H$_2$O)$_2$(NO$_3$)$_2$](NO$_3$)$_2$ (5)*

Complexes **4** and **5** are related[19,20] and their structure is analogous to those of **1**, **2** and **3**. The dinucleating ligand of both is a phthalazine aminopyridyl ligand (pap or papMe) with the Cu pairs also linked by EO $N_3^-$ ligands. The [Cu$^{II}_2$] dimers in **4** and **5** are linked to each other by EE $N_3^-$ groups and the difference between both complexes lies in the terminal ligands, which affect the charge of the complex, and the fact that **4** possesses two additional μ-MeOH molecules. The coupling in both complexes is antiferromagnetic, presumably because of the dominant influence of the phthalazine ligand. However, the magnetic data do not fit the Bleaney–Bowers equation satisfactorily and give unrealistic Weiss terms $\theta$. This was ascribed to the presence of a temperature-dependent $J$ value as a result of the possible variation of the Cu–N–Cu angle with temperature within the [Cu$^{II}_2$] groups. Possible exchange through the EE $N_3^-$ groups was not considered.

### *[Mn$_2$(Hmacy1)(N$_3$)$_2$]$_2$(ClO$_4$)$_2$ (6)*

Complex **6** is an [Mn$^{II}_2$]$_2$ species with each pair of metals assembled by one octadentate macrocycle (Scheme 1) containing amino, pyridyl and alcohol groups.[21] An EO $N_3^-$ bridge serves as an additional support of the intradimer connection (Figure 2, centre). Interestingly, both dimers are bridged here by $N_3^-$ ligands in the end-on form, instead of end-to-end. All Mn$^{II}$ ions in **6** are seven-coordinate, with a pentagonal bipyramidal geometry. Magnetic measurements show the overall coupling within **6** to be antiferromagnetic, thus indicating an $S = 0$ ground state. Although these results were not discussed in terms of the bridging ligands, it is conceivable that the alkoxide bridges cause a strong antiferromagnetic interaction within the dimers, which masks any possible (weaker) ferromagnetic pathway mediated by the $\mu_{1,1}$-$N_3^-$ links.

### *[Cu$_4$(macy2)(N$_3$)$_4$] (7)*

The large macrocyclic ligand in complex **7** (Scheme 1) keeps the tetranuclear cycle together by means of four alkoxide bridges, whereas two EE $N_3^-$ bridges support the link between two pairs of Cu$^{II}$ ions.[22] The coupling is antiferromagnetic due to the alkoxide bridges of the macrocycle.

### *[Ni$_4$(N$_3$)$_4$(opn)$_2$(Hopn)$_2$](ClO$_4$)$_2$ (8)*

Of the series of tetranuclear compounds with a cyclic arrangement, complex **8** is the only one that is square rather than rectangular (Figure 2, right).[23] All Ni$^{II}$ ions in this complex are equivalent and bridged by one EO azide group and the O atom of 1,3-diaminopropan-2-ol (Hopn). In fact, four diamino alcohol molecules share two of the hydroxy protons, which connect the four oxygen atoms pairwise through hydrogen bonds above and below the plane of the molecule. The $\chi_M T$ vs. $T$ curve of **8** ($\chi_M$ is the molar paramagnetic susceptibility) clearly indicates that the Ni···Ni interactions here are ferromagnetic and suggests an $S = 4$ ground state. When first published, complex **8** was the first azide-bridged, ferromagnetically coupled tetranuclear Ni$^{II}$ cluster ever synthesised. More than ten years after its discovery, ultra-low-temperature studies are underway to determine whether this complex behaves as an SMM.

## Linear M$_4$ Clusters

Of the nine reported clusters of this type, all but one can be described as two [M$^{II}_2$] dimers linked together by $N_3^-$ ligands in either an EO or an EE fashion. In all these cases, the dimers are kept together by polydentate ligands and the azide ligands complete the coordination and/or act as bridges between them.

### *[Fe$_4$(N$_3$)$_6$(pypentO)$_2$] (9) and [Fe$_4$(N$_3$)$_4$(acpypentO)$_2$] (10)*

Complexes **9**[27] and **10**[28] are analogous. Both consist of two [Fe$^{II}_2$] units mutually linked by two $\mu_{1,1}$-$N_3^-$ ligands. Each dimeric unit is held together by one pentadentate hydroxy/amine (**9**) or imine (**10**)/pyridyl ligand, supplemented

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

by another EO azide (Figure 3). Their magnetic behaviour is also very similar; in both cases the intradimer coupling is antiferromagnetic and the interdimer interaction ferromagnetic.

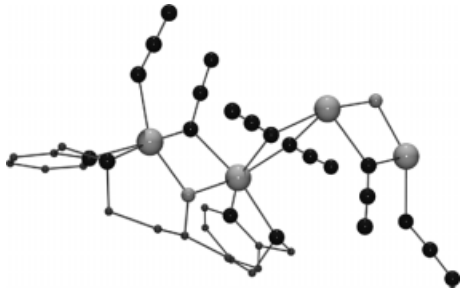

Figure 3. Plot of $[Fe_4(N_3)_6(pypentO)_2]$ (**9**). For clarity, only one of the pypentO ligands is represented.

### *[Ni$_4$(pzha2)$_2$(N$_3$)$_6$] (11)*

Compound **11** is very similar to complexes **2** and **3**, where the pyrazolyl $[Ni^{II}_2]$ units are now shifted so that the azide groups linking the dimers are in the very rare $\mu_{1,1,3}$ coordination mode.[17] As for **2** and **3**, the intradimer interactions are ferromagnetic due to the presence of EO azide ligands, whereas in this case the EE $N_3^-$ groups mediate antiferromagnetic coupling.

### *[Cu$_4$(msalen)$_2$(N$_3$)$_2$(H$_2$O)(MeOH)] (12), [Cu$_4$(salen)$_2$-(N$_3$)$_4$] (13) and [Cu$_4$(salpren)$_2$(N$_3$)$_4$(DMSO)$_2$] (14)*

These three complexes are related. They all consist of two dimers of $Cu^{II}$ formed by polydentate Schiff-base ligands (see Scheme 1) that are connected linearly through a pair of $\mu_{1,1}$-$N_3^-$ groups. Fitting of the magnetic susceptibility data from **13** yielded antiferromagnetic coupling constants for both Cu···Cu bridges.[29] This compound was claimed to be the first to exhibit antiferromagnetic coupling for the Cu–($\mu_{1,1}$-$N_3$)$_2$–Cu bridging mode. It needs to be pointed out, however, that such an interaction has been found several times before for this moiety, where some of the Cu–N bonds do not lie in equatorial positions.[30,31] In such cases the interaction is always very weak since the asymmetric bridge causes very little overlap between the magnetic orbitals of $Cu^{II}$ ($d_{x^2-y^2}$), contrary to the case where the bridge takes place through all basal positions.[32] The antiferromagnetic coupling in this complex was modelled theoretically on an experimental structure by means of density functional calculations,[15] although no explanation for this behaviour was offered. The magnetic analysis of complexes **12**[33] and **14**[34] was not provided.

### *[Cu$_4$(bmdp)$_2$(OAc)$_2$(N$_3$)](ClO$_4$)$_3$ (15) and [Cu$_4$(O$_2$cyclam1)$_2$(tmen)$_2$(N$_3$)](ClO$_4$)$_3$ (16)*

Complexes **15** and **16** are formed by two dimers of asymmetric dinucleating ligands, each featuring a coordinatively unsaturated $Cu^{II}$ that reacts selectively with one azido ligand to form $\mu_{1,3}$-$N_3^-$-linked tetranuclear complexes. In **15**,[35] the large ligand is based on 1,3-diaminopropan-2-ol and three *N*-methylbenzimidazole groups and this system shows weak ferromagnetic coupling, which could not be unambiguously assigned as either intra- or interdimeric coupling. In complex **16** (tmen = *N*,*N*,*N*′*N*′-tetramethylethylenediamine), the dinucleating ligand is a cyclic oxamide ligand. No magnetic properties were reported.[36]

### *[Cu$_4$(acac)$_2$(phen)$_4$(N$_3$)$_4$(ClO$_4$)$_2$] (17)*

This complex is a genuine linear tetranuclear array exclusively bridged by (single or double) $\mu$-$N_3^-$ ligands, with the remaining coordination sites saturated by chelating ligands [acetylacetonate (acac) and phenanthroline (phen)] or perchlorate.[37] Despite occurring through bridges of the axial–equatorial type, the coupling within this molecule is ferromagnetic and the ground state $S = 2$.

## $M_4$ Cubanes

The cubic arrangement is one of the most common structural motifs of tetranuclear coordination clusters {236 hits in the CCDC (version 5.27, August 2006) for the cubic $[M_4O_4]$ feature; M = first row transition metal}. Some of these have been found to act as SMMs (M = Ni, Mn, Fe, Co).[7] In most cases the cube is formed by four symmetrically equivalent metals and four monoatomic donors in a $\mu_3$-bridging mode, which are usually alkoxides, hydroxides or oxides. Because of its coordination versatility (Scheme 2), the $N_3^-$ group has also been found to act as a core ligand within cubane structures on a few occasions.

### *[Ni$_4$(N$_3$)$_4$(dbm)$_4$(EtOH)$_4$] (18)*

Complex **18** features four metals that are equivalent by idealised symmetry (Figure 4, top).[38,39] This compound was the first reported paramagnetic cluster containing $N_3^-$ ligands in the triply bridging mode, although many more examples have been reported since then (see below). These ligands are responsible for the weak ferromagnetic coupling that yields a spin ground state of $S = 4$. The peripheral ligation around the cubic core is completed by one chelating dibenzoylmethine ($dbm^-$) and one monodentate ethanol ligand on each $Ni^{II}$ ion.

### *[Mn$_4$O$_3$(N$_3$)(OAc)$_3$(dbm)$_3$] (19)*

Complex **19**[40] belongs to a group of cubane clusters with general formula $[Mn_4O_3X(OAc)_3(dbm)_3]$ that contain a distorted $[Mn^{III}_3Mn^{IV}XO_3]$ cubane core with a variable ligand X (X = $OH^-$, $OMe^-$, $F^-$, $Cl^-$, $Br^-$, $N_3^-$, $NCO^-$, $AcO^-$, $NO_3^-$, etc.)[40–42] along with a bridging $AcO^-$ that links each $Mn^{III}$ to a $Mn^{IV}$ ion and chelating ligands ($dbm^-$, on each $Mn^{III}$; Figure 4, bottom). Several features of these compounds make them good models of the $[Mn_4]$ complex of Photosystem II. Ferromagnetic coupling between the $Mn^{III}$ centres, together with the antiferromagnetic interaction within the $Mn^{IV}$···$Mn^{III}$ pairs, invariably confer the $S = 9/2$ spin ground state to all these clusters, which make up the second most important family of structurally related SMMs (after the $[Mn_{12}]$ complexes); complex **19** is the member of this family in which X = $N_3^-$. In this series of compounds, the X ligand consistently mediates ferromag-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

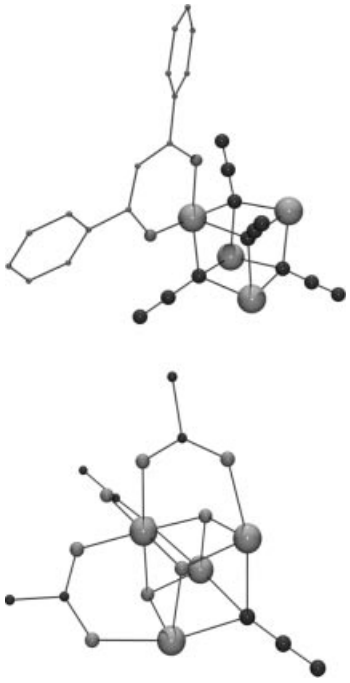

Figure 4. Top: core of $[Ni_4(N_3)_4(dbm)_4(EtOH)_4]$ (**18**), representative of the cubane systems with exclusively end-on azido bridges in the corners. One of the four dbm ligands is also shown. Bottom: core of $[Mn_4O_3(N_3)(OAc)_3(dbm)_3]$ (**19**), an unusual asymmetric cubane with only one azido bridge in one of the corners.

netic coupling between the metals it bridges, therefore replacement of any $\mu_3$-X ligand by azide does not imply the change to ferromagnetism observed for other families of complexes (see below).

### *$[Ni_4(L_{OMe})_4(N_3)_4]$ (20) and $[Co_4(L_{OMe})_4(N_3)_4]$ (21)*

Complexes **20** and **21** were obtained while studying the reactivity of the Kläui tripodal ligand $L_{OMe}$ (Scheme 1) with 3d transition metals[43] in an attempt to isolate adducts different from full-sandwich compounds $[M(L_{OMe})_2]$. Both clusters were obtained in the same manner, namely from the reaction of the labile mononuclear precursor $[M(L_{OMe})(NO_3)(acetone)]$ with $NaN_3$. The molecular structure of both complexes consists of a cubane with four $M^{II}$ metals and four $\mu_3$-$N_3^-$ ligands in the core, the hexacoordination around each metal being completed by a tripodal $L_{OMe}$ ligand. The magnetic properties of these compounds were not studied.

### *$[Cu_4(bsi)_2(N_3)_2]$ (22)*

This complex displays a very unconventional cubane structure with a $[Cu_4N_2O_2]$ core[44] where the N atoms belong to azide groups and the O donors are from alkoxides provided by a pentadentate Schiff-base ligand, which also serves to complete the peripheral ligation around $Cu^{II}$. The particularity of **22** within the category of cubanes is that it has two missing edges since these would be too long to consider them as bonds, which means that the cubane is open and the bridging N and O core atoms are $\mu$ and $\mu_3$, respectively. Magnetic measurements revealed that the coupling within the cubane core is dominated by antiferromagnetic interactions, which leads to a spin ground state of $S = 0$. This was modelled by considering three coupling constants describing single alkoxido, bis-alkoxido, and alkoxido/azide-bridged Cu···Cu pairs. The first two were found to be negative, as expected, whereas the mixed bridge was described as mediating ferromagnetic exchange, consistent with most instances involving EO azide.

### Defective Dicubane $M_4$ Arrangements

This topology has been described for ten complexes; three of $Ni^{II}$, four of $Co^{II}$, one of $Mn^{II}$ and two of $Cu^{II}$. Their formulae are $[Ni_4(dpkOH)_2(dpkOCH_3)_2(N_3)_2(H_2O)_2](ClO_4)_4$ (**23**),[45] $[Ni_4(dpkOH)_4(N_3)_4]$ (**24**),[46] $[Ni_4(N_3)_8(enbzpy)_2]$ (**25**),[47] $[Co_4(dpkOH)_4(N_3)_2(OBz)_2]$ (**26**),[48] $[Co_4(dpkOH)_4(N_3)_2(AcO)_2]$ (**27**),[49] $[Co_4(dpkOH)_2(dpkOCH_3)_2(N_3)_2(H_2O)_2](BF_4)_2$ (**28**),[50] $[Co_4(dpkOH)_2(dpkOMe)_2(N_3)_4]$ (**29**),[51] $[Mn_4(dpkOH)_2(dpkOMe)_2(N_3)_4]$ (**30**),[51] $[Cu_4(macy3)_2(OEt)_2(N_3)_4]$ (**31**)[52] and $[Cu_4(pta)_2(N_3)_6](ClO_4)_4$ (**32**).[53] The two latter complexes are best described as two dimers linked through very long axial bonds. In these, the magnetic behaviour is dominated by the coupling within the dimers, as imposed by the phenolate-based dinucleating ligands (very strongly antiferromagnetic). Seven of the remaining clusters (**23**, **24** and **26**–**30**) have been prepared using dipyridyl ketone (dpk) as reagent and exhibit a common skeleton in which the four metallic atoms are bridged by two end-on $\mu$-azide groups, two $\mu$-oxido and two $\mu_3$-oxido centres (Figure 5, top). The remaining coordination sites are occupied by four dpkOH or dpkOMe ligands and two monodentate terminal groups such as aquo, azido, acetato or benzoato. In contrast, although with the same metal topology, the skeleton of **25** contains only $N_3^-$ bridges (Figure 5, bottom) and is one of the rare examples of clusters with a mainly azide based core. Of the non-copper clusters, only **30** ($Mn^{II}$) shows an overall antiferromag-

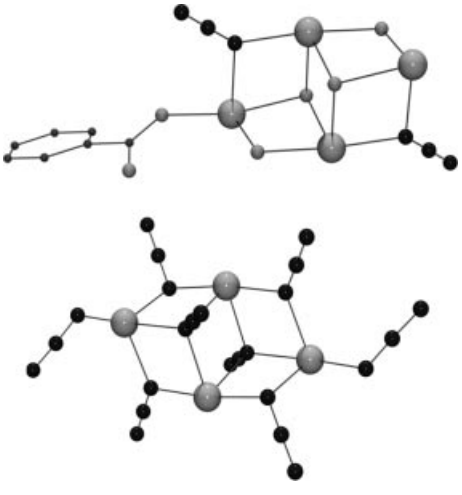

Figure 5. Top: core of compound $[Co_4(dpkOH)_4(N_3)_2(OBz)_2]$ (**26**). This core is common to compounds **23**, **24** and **26**–**30**, which differ in the counteranion or in the monodentate ligand. Bottom: end-on azido core of compound $[Ni_4(N_3)_8(enbzpy)_2]$ (**25**).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

netic coupling with $S = 0$. The $Ni^{II}$ clusters all display ferromagnetic interactions due the EO-$N_3^-$ bridges and/or Ni–O–Ni angles close to 90°, which leads to an $S = 4$ ground state. This situation is analogous to the case of the $Co^{II}$ compounds. In these clusters, however, the analysis of the magnetic behaviour is complicated by the effect of spin-orbit coupling within the metals. Since at low temperature the $Co^{II}$ ions are better described as local $S_i = 1/2$ centres, the ground state of the $[Co_4]$ clusters can be considered as displaying a total $S = 2$ spin ground state with fairly large $g_{eff}$.

### Genuine $\mu_{1,1,3}$-$N_3^-$ Coordination in an $M_4$ Cluster

The group of complexes with general formula $[Ni_4(pzate\textit{n})_2(N_3)_3(O_2CR)](ClO_4)_2$ (R = Me, pzate1 **33**; R = Ph, pzate1 **34**; R = Ph, pzate2; **35**) were the first examples with azide in the $\mu_{1,1,3}$-bridging mode (Scheme 2).[54,55] They are described as two $[Ni_2]$ dimers of a pyrazole/amine-based ligand that are bridged asymmetrically by azide (seen in three different coordination modes) and carboxylate (Figure 6). Dominant antiferromagnetic interactions were observed for the three complexes, resulting in a diamagnetic ground state. Modelling of the bulk magnetisation data unveiled the presence of a combination of antiferromagnetic and ferromagnetic coupling (two $J$ constants of each type). The Ni···Ni pair bridged by two $\mu_{1,1}$-$N_3^-$ groups was assigned a moderate ferromagnetic constant in the three complexes, whereas weak ferromagnetic coupling was attributed to the pathway formed by a single $\mu_{1,3}$-$N_3^-$ ligand. The strongest antiferromagnetic coupling was ascribed to the link built by one $\mu_{1,1,3}$-azide and one pyrazolate, whereas the remaining single $\mu_{1,1,3}$-azide bridge was associated with the weakly antiferromagnetic constant. The last three assignments were made on the basis of the Ni–NNN–Ni torsion angles and the Ni–N–N angles. Indeed, observation of ferromagnetism within $Ni^{II}$ pairs as mediated by only one EE azide is very uncommon and requires these two angles to be close to 90° and larger than 155°, respectively.[16,56]

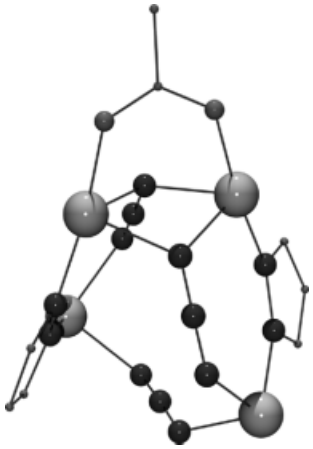

Figure 6. Core of compound $[Ni_4(pzate1)_2(N_3)_3(AcO)](ClO_4)_2$ (**33**), common to compounds **33**–**35**.

### Rare $\mu_{1,1,3,3}$-$N_3^-$ Coordination in an $M_4$ Cluster

The $\mu_{1,1,3,3}$ coordination mode (Scheme 2) was first observed in a group of compounds with formulae $[Ni_4(pzate\textit{n})_2(N_3)_3(O_2CR)_2](ClO_4)$ (pzate1: R = Me **36**, R = Ph **37**; pzate2: R = adamantyl **38**) and $[Ni_4(pzate3)_2(N_3)(O_2CR)_4](ClO_4)$ (R = adamantyl **39**). These complexes are $[Ni^{II}_4]$ rectangles with a central $\mu_4$-$N_3^-$ ligand, a pair of opposite sides occupied by bridging "pzate" ligands (Scheme 1) and the other pair of edges formed by either one $\mu$-$N_3^-$ and one $\mu$-$O_2CR^-$ (**36**, **37** and **38**; Figure 7), or by two bridging carboxylates (**39**).[54,57] Interestingly, the structural differences imposed by the bridging of these edges determine the disposition of the central azide ligand. Thus, in complexes of the former type the central azide caps the $Ni_4$ plane on one of its faces to form a sort of roof with $C_{2v}$ symmetry, whereas in complex **39** the metals form a flattened tetrahedron with the $\mu_4$-$N_3^-$ azide ligand inserted inside; this fragment displays $D_2$ symmetry. The magnetic properties of both types of complexes are marked by the coupling through the central azide, which is strongly antiferromagnetic along the edge spanned by the pyrazolate bridge (because of the EE azide) and ferromagnetic along the other edge (because of the EO mode of the $\mu_4$-$N_3^-$ ligand and reinforced by an additional EO azide in complexes **36**, **37** and **38**). The diagonal exchange is weakly ferromagnetic because of the large Ni–NNN–Ni torsion angle involved. The overall result is an $S = 0$ ground state for all complexes.

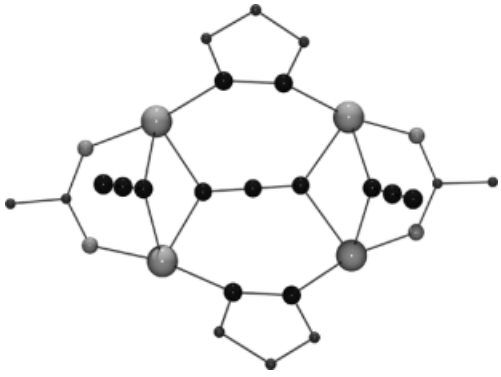

Figure 7. Core of compound $[Ni_4(pzate3)_2(N_3)_3(AcO)_2](ClO_4)$ (**36**), common to compounds **36**–**38**. Compound **39** shows a very similar core with coordination of a second carboxylate instead of the end-on azido ligands.

### *[Cu₄(tpimim)₂(N₃)]Cl (40)*

Complex **40** is the only $Cu^{II}$ species that contains azide in the $\mu_{1,1,3,3}$ mode.[58] As in complexes **36**–**39**, the central $\mu_4$-$N_3^-$ in **40** bridges a rectangle of four metals that now exhibits $C_{2h}$ symmetry. The metals spanned by two of the opposite edges are not supported by any additional ligand, while the other two sides are also spanned by two heptadentate tpimim ligands. Contrary to the Ni compounds with a central $\mu_4$-$N_3^-$ ligand, complex **40** exhibits very weak magnetic coupling. The likely reason for this is that the ligand is bound to $Cu^{II}$ at the apical positions and is thus

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

far from the magnetic orbitals. The interaction between the ions bridged by the tpimim ligand is weakly ferromagnetic, most probably because of the imidazolidine bridge, rather than the azide. The coupling mediated by EE azide pathways is, as usual, antiferromagnetic.

### A Tetrahedral and a Rectangular $M_4$ Cluster

The cluster $[Mn_4O(N_3)(O_2Bz)_3(phpyCNO)_4]$ (**41**)[59] shows a tetrahedral $[Mn^{IV}Mn^{II}_3O]^{8+}$ core (Figure 8) and is a rare example of a mixed-valent tetranuclear manganese complex exhibiting a $2e^-$ difference between oxidation states. There are four types of bridging ligands, including one $N_3^-$ group, which contributes to the ferromagnetic interaction between $Mn^{II}$ centres. The $Mn^{IV}$ ion is, in turn, coupled antiferromagnetically to the other three metals and this leads to a total spin ground state of $S = 6$, as shown by bulk magnetic measurements as well as EPR spectroscopy. The cluster $[Ni_4(SO_4)_2(N_3)_2(SH)_2(pyMeCNOH)_4]$ (**42**)[60] is a rectangle with two edges spanned by EO $\mu$-$N_3^-$ and the other two by $\mu$-$SH^-$ groups. The latter presumably originate from reduction of sulfate ligands. Two such ligands cap each face of the rectangle in an $\eta^2$:$\mu_4$-$SO_4^{2-}$ coordination mode and four pyridyl oxime ligands chelate the four metals to complete their octahedral coordination environment. No magnetic data are yet available for this compound.

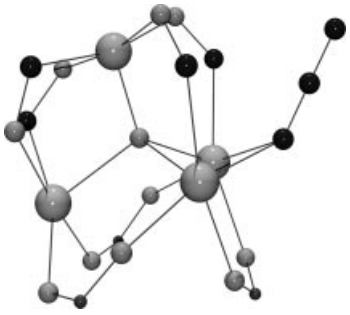

Figure 8. Core of compound $[Mn_4O(N_3)(O_2Bz)_3(phpyCNO)_4]$ (**41**).

### An $Mn_4$ Dimer of Separate Dimers

The compound $[Cu_4(4tacn)(N_3)_4](PF_6)$ (**43**)[61] is formed by a large ligand containing four tacn macrocycles (Scheme 1) that bind four $Cu^{II}$ ions, which are linked as two separate pairs through double $\mu$-$N_3^-$ bridges. As expected, ferromagnetic coupling operates within these pairs, whereas the presence of zero-field splitting and/or inter-pair interactions was modelled with a Curie–Weiss constant.

### Three Azido Bowties in $M_5$ Clusters

Azido-bridged clusters of five metals are much less common than tetranuclear complexes. Three Ni derivatives exhibit this nuclearity, namely $[Ni_5(N_3)_4(phpyCNO)_4(O_2CR)_2(MeOH)_4]$ (R = H **44a**, Me **44b**)[62] and $[Ni_5(N_3)_4(phpyCNO)_4(phpyCNOH)_4](ClO_4)_2$ (**45**).[63] These three compounds can be described as two $Ni^{II}$ triangles with a common vertex (a bowtie) linked by means of oximato and azido bridges in two different arrangements (Figure 9): **44a** and **44b** contain oximato bridges between the central and the peripheral $Ni^{II}$ atoms with $\mu_{1,1}$-azido and carboxylate bridges between the external cations and $\mu_{1,1,1}$ bridges at the centre of each triangle, whereas **45** has four $\mu_{1,1}$ bridges between the central and external $Ni^{II}$ atoms and the centres of the triangles are occupied by oximate $\mu_3$-(NO) bridges. The main difference in the preparation of these compounds is the presence in the reaction mixture of either a coordinating anion (carboxylate) or a non-coordinating one (perchlorate). Preliminary magnetic measurements indicate an $S = 5$ ground state for **44b** and **44b**. Moreover, the frequency dependence of the magnetisation has been observed for **44a**, which constitutes initial evidence that this compound behaves as an SMM. No magnetic data have been collected yet for complex **45**.

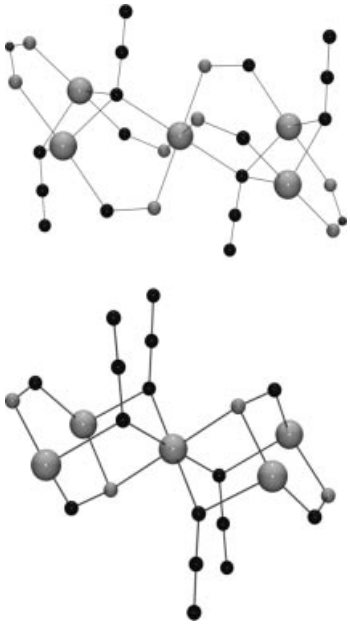

Figure 9. Core of compounds $[Ni_5(N_3)_4(phpyCNO)_4(O_2CH)_2(MeOH)_4]$ (**44**) (top) and $[Ni_5(N_3)_4(phpyCNO)_4(phpyCNO)_4](ClO_4)_2$ (**45**; bottom). It is noticeable that $N_3^-$ and oximate exchange their roles from one compound to the other.

### A Linear $Cu^{II}_5$ Arrangement

The compound $[Cu_5(terpy)_2(N_3)_{10}]$ (**46**; terpy = terpyridine) comprises a linear central trinuclear unit held together by two double $\mu$-$N_3^-$ bridges, with each external copper ion of this unit linked by a single EO azido ligand to a $[Cu(terpy)(N_3)]^+$ moiety.[64] Bulk magnetisation studies reveal that the peripheral $Cu^{II}$ centres essentially do not interact with the central unit, and the latter exhibits weak ferromagnetic coupling.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### $M_6$: The Largest Cycle

The only example of an azide-bridged cyclic cluster with six metals (Figure 10) is the complex $[KNi_6(CO_3)(N_3)_6(OAc)_3(dpkMeCN)_3]_2[K_2(H_2O)_2]$ (**47**).[65] It crystallises in the form of dimers of hexanuclear wheels that are connected through weak interactions to $K^+$ ions. Complex **47** is the only known metallacycle that is symmetrically bridged by $N_3^-$, besides complex **8** (see above). In addition to azide, the bridges within the cycle are completed by three *syn*,*syn*-OAc groups, which alternate with the μ-O atoms from three dpkMeCN$^-$ ligands, and by a central $\mu_6$-$CO_3^{2-}$ group. This compound exhibits intramolecular ferromagnetic coupling, as expected, which confers it the spin ground state $S = 6$. Fitting of the experimental data yielded the values $J_1 = 2.9$ and $J_2 = 25.4$ cm$^{-1}$, respectively, for the two types of bridge present (using the convention $H = \Sigma -J_{ij}S_iS_j$ for the exchange coupling). In both cases, the μ-$N_3^-$ bridge determines the ferromagnetic nature of the coupling. The strongest coupling is ascribed to the counter-complementarity effect[66] caused by the simultaneous presence of a μ-OAc$^-$ ligand. The other path involves an alkoxide bridge, which does not have the symmetry to cause this effect. $D$ was found to be positive (10.3 cm$^{-1}$) in this complex, which explains the lack of SMM behaviour.

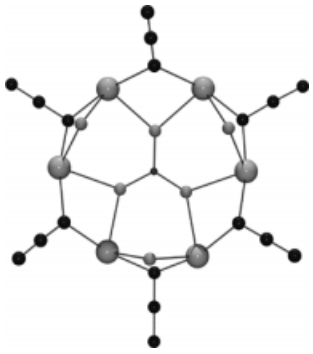

Figure 10. Core of one of the hexanuclear subunits of $[KNi_6(CO_3)(N_3)_6(OAc)_3(dpkMeCN)_3]_2[K_2(H_2O)_2]$ (**47**) showing the unusual $\mu_6$-carbonato anion in the centre of the complex.

### $M_6$: A Dimer of Trinuclear Units and a Trimer of Dinuclear Motifs

The complex $Na_2[Ni_4Cu_2(dpa)_4(pbo)_2(H_2O)_2](ClO_4)_4$ (**48**; dpa = 3,3′-diaminodipropylamine) consists of a hexanuclear cyclic structure in which the azido ligands bind two [NiCuNi] subunits (Figure 11, top). In spite of the heterometallic nature of the cycle, the azido bridges only link nickel atoms. Inside each trinuclear unit there is strong antiferromagnetic coupling via the oxamato ligands ($J_1$ = –101 cm$^{-1}$). The large Ni–$N_3$–Ni torsion angle justifies the low value for the interaction provided by the azido bridge ($J_2$ = –3.2 cm$^{-1}$ in the $H = \Sigma -J_{ij}S_iS_j$ convention), which results in an $S = 0$ ground state.[67]

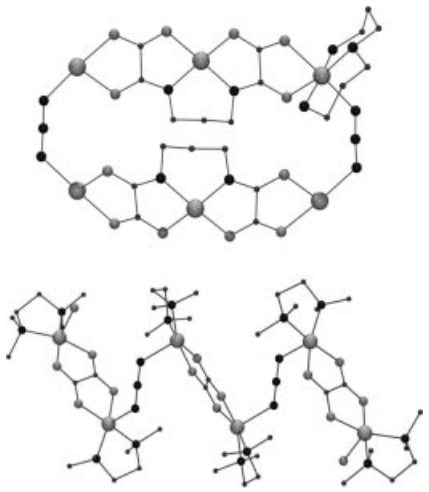

Figure 11. Top: plot of the dimer of trimers $Na_2[Ni_4Cu_2(dpa)_4(pbo)_2(H_2O)_2](ClO_4)_4$ (**48**). The copper atoms show a square-planar coordination whereas the Ni atoms in the corners exhibit an octahedral environment. For clarity, only one complete coordination sphere of the Ni atoms is shown. Bottom: plot of the trimer of dimers $[Cu_6(tmen)_6(N_3)_2(C_2O_4)_3(H_2O)_2](ClO_4)_4$ (**49**).

The hexanuclear complex $[Cu_6(tmen)_6(N_3)_2(C_2O_4)_3(H_2O)_2](ClO_4)_4$ (**49**; tmen = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine)[68] is a rare combination of $[Cu_2(tmen)_2(C_2O_4)]^{2-}$ units connected by two EE $N_3^-$ groups, with both external metallic ions capped by $H_2O$ molecules (Figure 11, bottom). The magnetic behaviour of this linear cluster is governed by the strong antiferromagnetic coupling within the oxalate-bridged pairs, with the coupling through azide remaining negligible. Another hexanuclear cluster results from dimerisation of $[Cu_3]$ units bound to a trinucleating ligand, each of which features one pair of $Cu^{II}$ ions supported by μ-$N_3^-$.[69]

### $M_7$: An Unusual Nuclearity

There is only one compound with a nuclearity of seven containing azido bridges and it has the formula $[Ni_7(AcO)_6(py_2CNO)_6(N_3)_2(H_2O)_2]$ (**50**).[70] The compound consists of two pairs of $Ni^{II}$ triangular arrays fused through one edge and sharing the central cation (Figure 12). The four triangles are supported by four $\mu_3$-(NO) oximate bridges, and additional bridging is provided by two deprotonated oximate groups, six *syn*,*syn* acetate ligands and two EO azides, whereas peripheral coordination is completed by

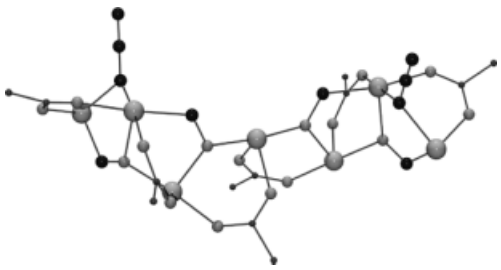

Figure 12. Core of $[Ni_7(AcO)_6(py_2CNO)_6(N_3)_2(H_2O)_2]$ (**50**).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

two water molecules. Preliminary susceptibility measurements indicate an $S = 3$ ground state, which is greater than the expected value ($S = 1$) for a purely antiferromagnetic cluster and suggests the presence of ferromagnetic interactions between the nickel atoms bridged by the azido bridge; the remaining interactions remain antiferromagnetic.

### $M_8$: A Nickel-Based SMM

The SMM $[Ni_8Na_2(N_3)_{12}(OBz)_2(mpo)_4(Hmpo)_6(EtOAc)_6]$ (**51**; Figure 13)[71] was prepared in light of the benefits of using $N_3^-$ to dramatically increase the spin of metal clusters in a family of $[M_9]$ complexes (see below). Complex **51** features an $[Ni_8(N_3)_{12}]^{4+}$ core in the form of four "defective cubanes" bound to two additional peripheral $Ni^{II}$ ions. In addition, the complex contains two $Na^+$ ions. The bridging within this cluster is completed by two μ-$OBz^-$ groups and four pyrazolinolate ligands ($mpo^-$); terminal ligands saturate the remaining positions of the metals (six Hmpo and six EtOAc molecules). The presence of EO $N_3^-$ groups connecting all $Ni^{II}$ centres confers ferromagnetic character on this cluster and leads to an $S = 8$ spin ground state. Many high-spin clusters do not behave as SMMs because they do not possess magnetic anisotropy ($D \approx 0$) or because they are not of the Ising type ($D > 0$). In this case, however, $D = -0.07$ cm$^{-1}$, and the cluster exhibits slow relaxation of the magnetisation, as manifested by the presence of hysteresis loops at very low temperatures.

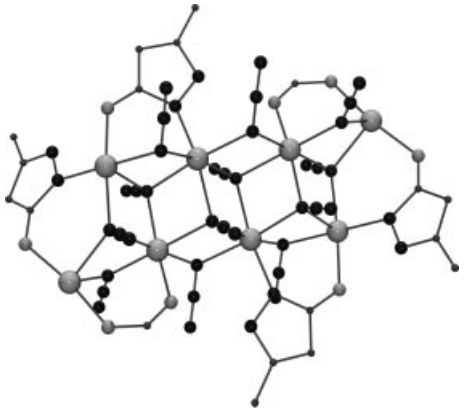

Figure 13. Plot of $[Ni_8Na_2(N_3)_{12}(OBz)_2(mpo)_4(Hmpo)_6(EtOAc)_6]$ (**51**). For clarity, only the bridging ligands are shown. Compound **51** is one of the few complexes in which the inner core contains exclusively end-on azido bridges.

### *[{Mn$_4$O(sae)$_4$(N$_3$)(MeOH)}$_2$(N$_3$)](N$_3$) (52)*

Complex **52** is the other only example of an azide-bridged cluster with a nuclearity of eight. The structure consists of two tetranuclear units linked to one other by a single $\mu_{1,3}$-$N_3^-$ ligand and held together by Schiff-base ligands (sae) and one EO azide.[72] The overall coupling within the cluster was found to be antiferromagnetic and no further discussion was offered.

### $M_9$: Activation of High Spin Numbers by Azide

The nuclearity of nine has been found for three analogous azide-containing complexes obtained with three different metals. These are $[Ni_9(N_3)_2(AcO)_8(dpkO)_4]$ (**53**),[73] $[Co_9(N_3)_2(AcO)_8(dpkO)_4]$ (**54**)[74] and $[Fe_9(N_3)_2(AcO)_8(dpkO)_4]$ (**55**).[75] The core of these compounds can be described as two square pyramids of metals with a common apex, the latter exhibiting (Figure 14) an unusual eight coordination environment ($MO_8$). Each doubly deprotonated $dpkO^{2-}$ ligand links up to five cations. The basal edges of each pyramid are spanned by a crown of four *syn*,*syn* acetate ligands and its square face is capped by one $\mu_4$-$N_3^-$ ligand. Azido ligands acting as a bridge between four cations are very unusual and these three compounds are currently the only examples of the monoatomic $\mu_{1,1,1,1}$ coordination mode for this ligand. The nickel and cobalt compounds are highly symmetric due to the presence of a crystallographic $C_4$ axis, whereas for the iron compound (**55**) the structure is the same but the symmetry is only idealised. In the three compounds, introduction of EO $N_3^-$ signifies the establishment of ferromagnetic interactions within both groups of four basal metals, thereby dramatically increasing

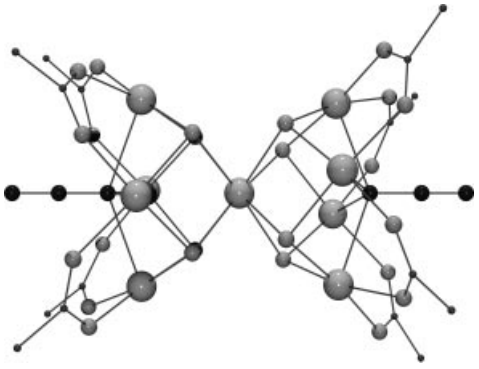

Figure 14. Core of compound $[Ni_9(N_3)_2(AcO)_8(dpkO)_4]$ (**53**). With minor differences besides the metals, this core is the same for **54** and **55**.

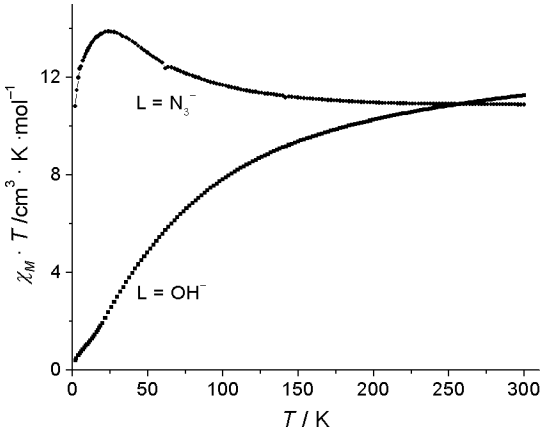

Figure 15. Plots of $\chi_M T$ vs. $T$ for complexes $[Ni_9(L)_2(AcO)_8(dpkO)_4]$ [L = $N_3^-$ (**53**) and the related compound with L = $OH^-$]. These compounds provide a good example of how end-on azido coordination can drastically modify the magnetic properties of clusters with the same skeleton.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the spin ground states ($S$ = 9 for **53**, $S$ = 14 for **55** and undetermined for **54** because of the spin-orbit coupling). These values are in sharp contrast to those observed for analogous clusters containing $OH^-$ bridges instead of $N_3^-$, where the coupling is systematically antiferromagnetic and the ground state is the equivalent to that of only the central metal (Figure 15). When studied under an ac magnetic field, complex **55** showed an SMM response, with frequency-dependent $\chi_M''$ signals (out-of-phase magnetic susceptibility) peaking between 2.34 and 2.00 K for frequencies varying between 1000 and 50 Hz. The energy barrier, $\Delta E$, calculated from these signals is 29 $cm^{-1}$.

### High-Spin Decanuclear Clusters

#### *[$Ni_{10}(tmp)_2(N_3)_8(acac)_6(MeOH)_6$] (56)*

This complex is an elegant example of one of the main messages of this review, which is that incorporation of azide within reaction schemes leading to coordination clusters is not only beneficial from a structural point of view but is potentially very convenient for changing the magnetic properties. Compound **56** originates from the reaction between $Ni(acac)_2$, the tripodal ligand $H_3$tmp and $NaN_3$ in methanol.[76] The structure (Figure 16, top) comprises a planar $[Ni_{10}O_{10}(N_3)_8]$ core where the oxygens originate from two $\mu_6$-$tmp^{3-}$ ligands and $acac^-$ groups. The latter appear in two coordination modes (terminal and bridging), whereas the $N_3^-$ ligands are all bridging ($\mu$ or $\mu_3$). Magnetic measurements show this compound to possess an $S$ = 10 spin ground state and large, Ising-type magnetoanisotropy, which converts it into the slowest relaxing Ni SMM known to date. This property is corroborated by the presence of temperature-dependent hysteresis loops of the magnetisation (Figure 17).

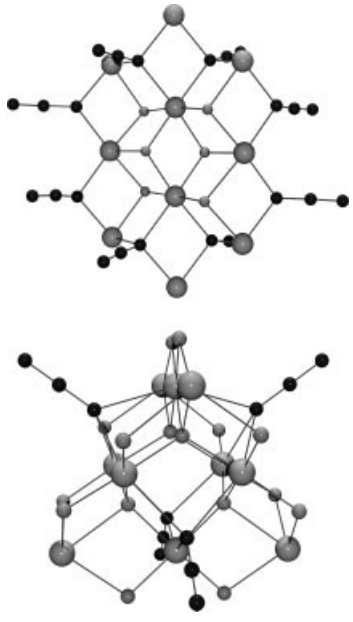

Figure 16. Top: core of $[Ni_{10}(tmp)_2(N_3)_8(acac)_6(MeOH)_6]$ (**56**). In a similar way to **51**, the core is formed by defective cubanes linked by end-on azido bridges. Bottom: core of $[Mn_{10}O_4(N_3)_4(hmp)_{12}](X)_2$ (**57**, **58**) in which the peripheral end-on azido bridges link the sub-sheets of Mn atoms.

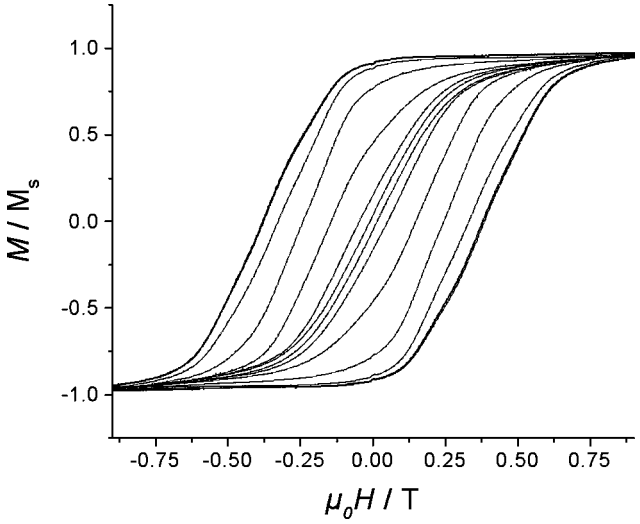

Figure 17. Single crystal magnetisation ($M$) vs. field ($H$) hysteresis loops for complex **56** at a field sweep rate of 0.002 $T s^{-1}$ and temperatures of 0.7, 0.6, 0.5, 0.4, 0.3, 0.2 and 0.04 K (the loops become wider with increasing temperature); the magnetisation is normalised to its saturation value.

#### *[$Mn_{10}O_4(N_3)_4(hmp)_{12}](X)_2$ ($X = N_3^-$ 57, $ClO_4^-$ 58)*

The very recently reported complexes **57** and **58**[77] display high symmetry (crystallographically imposed $T$) and each is formed by a central $[Mn^{III}]$ octahedron bridged by four $\mu_3$-$N_3^-$ ligands and four $\mu_4$-$O^{2-}$ atoms that also bind to four external $Mn^{II}$ ions (Figure 16, bottom). There are twelve $hmp^-$ ligands that ensure the bridging between the $Mn^{III}$ and $Mn^{II}$ centres as well as the peripheral ligation. The spin ground state in both clusters is $S$ = 22, the maximum possible, thanks to the ferromagnetic interaction induced by the azide ligands and by the $Mn^{III}$–O–$Mn^{II}$ connections with very acute angles. Given the high symmetry of the cluster, the total $D$ value is practically zero and therefore these compounds do not show SMM behaviour despite displaying one of the highest spin values ever observed for a molecular system.

### $M_{19}$: The Highest Ground Spin State ($S$ = 83/2)

The use of azide in combination with an oxide source and the polyalcohol $H_3$bhmep (Scheme 1) in a reaction with $MnCl_2$ led to the formation of the nonadecanuclear cluster $[Mn_{19}O_8(N_3)_8(Hbhmep)_{12}(MeCN)_6]Cl_2$ (**59**, Figure 18).[78] The presence of azide leads again to the maximum possible spin multiplicity for the cluster, leading to the highest molecular spin ground state ever observed ($S$ = 83/2). The small overall magnetic anisotropy, however, is the reason why hysteresis of the magnetisation is only observed below 0.5 K. Whether this behaviour at low temperature is ascribed to the SMM nature of **59** or is due to other reasons remains an open question.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

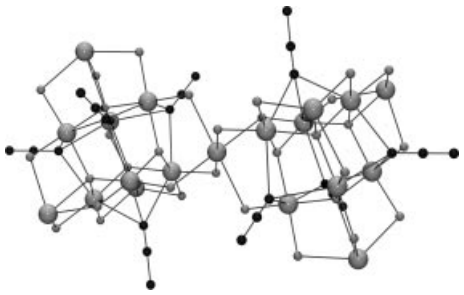

Figure 18. Core of $[Mn_{19}O_8(N_3)_8(Hbhmep)_{12}(MeCN)_6]Cl_2$ (**59**).

### The $M_{25}$ Cluster $[Mn_{25}O_{18}(OH)_2(N_3)_{12}(pdm)_6(pdmH)_6](Cl)_2$ (60)

Complex **60** is the second highest nuclearity cluster constructed to date with the help of azide ligands (Figure 19).[79] The composition of the metal ions is $6\,Mn^{II}$, $18\,Mn^{III}$ and $Mn^{IV}$. Of the twelve $N_3^-$ ligands, six are terminal and six bridge two metals each. The structure is held together by $\mu_4$-$O^{2-}$, $\mu_3$-$O^{2-}$ and $\mu_3$-$OH^-$ ions, with the help of Hpdm or $pdm^-$ ligands. The total spin of the cluster is postulated to be $51/2 \pm 1$, presumably as a result of a combination of ferro- and antiferromagnetic interactions. The SMM behaviour of **60** was proven through micro-squid measurements, which revealed the presence of low-temperature hysteresis loops of the magnetisation.

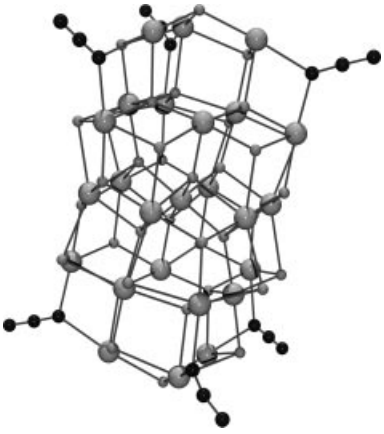

Figure 19. Core of $[Mn_{25}O_{18}(OH)_2(N_3)_{12}(pdm)_6(pdmH)_6](Cl)_2$ (**60**).

### $Mn_{32}$: A Truncated Cube

The largest manganese cluster containing bridging azides is $[Mn(bpy)_3]_{1.5}[Mn_{32}(thme)_{16}(bpy)_{24}(N_3)_{12}(OAc)_{12}](ClO_4)_{11}$ (**61**).[80] This spectacular cluster is made up of eight tetranuclear moieties, each cemented by the oxygen atoms of six tripodal $thme^{3-}$ ligands (Figure 20). These $[Mn_4]$ "stars" are located at the vertices of a cube and connected to each other through acetate and EO azide bridges. Chelating bpy helps to complete the coordination. A combination of weak ferro- and antiferromagnetic interactions leads to a spin ground state of close to 9 (or 10) with many low lying excited states, which precludes an accurate determination and characterisation of the spin ground state.

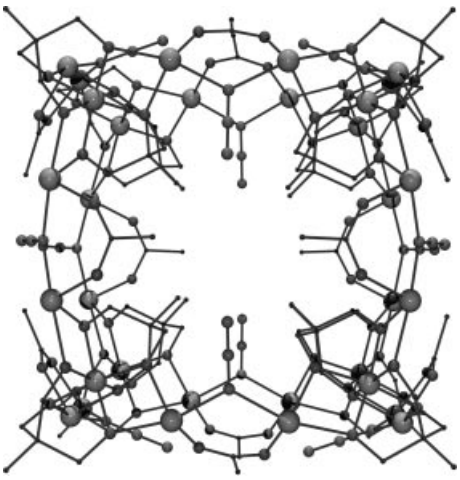

Figure 20. Core of $[Mn(bpy)_3]_{1.5}[Mn_{32}(thme)_{16}(bpy)_{24}(N_3)_{12}(OAc)_{12}](ClO_4)_{11}$ (**61**).

### Clusters with Heterometallic Azide Bridges

Compared with the plethora of homometallic azido systems reported to date, compounds in which the azido ligand acts as a bridge between two different paramagnetic centres (excluding different oxidation states of the same metallic atom) are extremely rare. The first such compound reported was an $[Ni_2Mn]$ triangular system containing $\mu_{1,1}$-azido bridges.[81] A few more examples of low nuclearity systems of this type have been reported recently, such as one [CuNi] dinuclear complex with $\mu_{1,1}$-azido bridges,[82] two trinuclear clusters, [FeCuFe] and [FeNiFe], linked by means of $\mu_{1,3}$-azido bridges[83,84] and two $\mu_{1,3}$ chain-like [NiMn] or [CoMn] alternating compounds.[85]

To the best of our knowledge, there is only one system with a nuclearity higher than four that contains heterometallic azido bridges, namely $[Cu_4(O_2cyclam2)_4Mn_2(N_3)_4]$ (**62**).[86] The asymmetric unit of this compound consists of a [CuMnCu] trinuclear unit in which the manganese atom is bridged to both copper atoms by means of oxamide bridges (Figure 21). Each $Cu^{II}$ ion is embedded within a macrocycle that is part of the oxamide moiety. The remaining coordination sites of the octahedral coordination sphere around manganese are occupied by two azido ligands. One of them acts as a terminal ligand whereas the second azido binds to the axial position of the square-pyramidal copper atom of

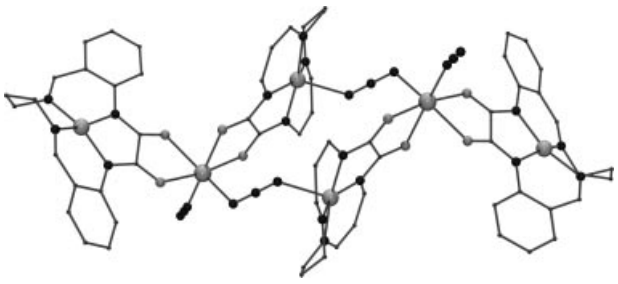

Figure 21. Plot of the structure of compound $[Cu_4(O_2cyclam2)_4Mn_2(N_3)_4]$ (**62**). Mn atoms exhibit hexacoordination whereas Cu atoms are coordinated only to the macrocyclic ligand.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a second trinuclear unit. The role of the azido bridges in the magnetism of **62** is marginal since these are coordinated to the axial sites of the copper atoms.

### Azido Clusters of Transition Metals and Polyoxometallates

A relatively new class of molecular magnetic materials is that whose members are prepared by using lacunary polyoxometallates (POMs) in combination with paramagnetic transition metal ions.[87] Recently, very interesting examples have been reported where the azide ligand has been employed as both bridge and magnetic coupler. Thus, the new cluster anions $[(\gamma\text{-}SiW_{10}O_{36})_2Mn_4(OH)_4(N_3)_2(H_2O)]^{10-}$ (**63**), $[(\gamma\text{-}SiW_{10}O_{36})_2Cu_4(N_3)_4]^{12-}$ (**64**), $[(\gamma\text{-}SiW_{10}O_{36})_2Cu_4(H_2O)_2(N_3)_4]^{12-}$ (**65**) and $[(SiW_8O_{31})_3Cu_9(OH)_3(H_2O)_6(N_3)_4]^{10-}$ (**66**) have been prepared,[88,89] and their magnetic properties analysed. The latter is especially remarkable because it features an unprecedented coordination mode for azide, namely $\mu_{1,1,1,3,3,3}$ (Scheme 2).[88]

### General Remarks about the Coordination by Azide

The above sections of this review have shown that the azido ligand is able to act as a bridge within high nuclearity clusters and can do so in a large variety of coordination modes. These are summarised in Scheme 2, and can be divided into two main groups: (i) modes in which the two ends of the ligand act as donors ($\mu_{1,3}$, $\mu_{1,1,3}$, $\mu_{1,1,3,3}$ or $\mu_{1,1,1,3,3,3}$), which need at least two metallic ions placed at more than 5 Å, and (ii) modes where the azido ligand acts as a monoatomic bridge ($\mu_{1,1}$, $\mu_{1,1,1}$ or $\mu_{1,1,1,1}$ modes) linking two or more metallic centres separated by about 3 Å.

EE $N_3^-$ bridges typically lie within the core of the cluster and are usually surrounded by other organic ligands, as can be seen in Figure 22, left. In contrast, EO azido bridges are attached to the metallic centres and point outwards approximately perpendicular to the surface of the cluster (Figure 22, right). In the latter case, the space requirement is minimal.

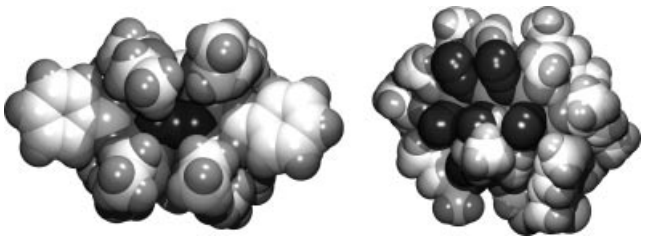

Figure 22. Left: space-filling diagram of complex **37**, emphasising the insertion of the EE $N_3^-$ ligand within the cluster. Right: space-filling diagram of complex **56**, showing the efficiency of EO $N_3^-$ in bridging metals with minimal space requirements.

EE is the most common coordination mode in extended systems such as chains, planes or 3D azido derivatives, whereas alternating $\mu_{1,3}/\mu_{1,1}$ compounds are not rare. However, coordination polymers with exclusively EO azido bridges are very scarce. In contrast, cluster azido chemistry is clearly dominated by EO coordination modes. Because of the similar stability of both coordination modes, the steric hindrance becomes one of the most determining factors favouring monoatomic coordination over EE modes.

Analysis of the structures reviewed above allows other trends regarding coordination by azide to be identified. It has been observed that single EO azido bridges are extremely rare, something that was known already from extended azido-based systems. Therefore, additional bridges always support the presence of $\mu\text{-}N_3^-$ groups. These are often the usual bridges found in cluster coordination chemistry, such as oxido, hydroxido, alkoxido, oximato or carboxylate groups (in addition to $N_3^-$ itself), which accommodate pairs of metals at M···M distances in the neighbourhood of 3 Å (Figure 23). Therefore, the core of most azido clusters reported to date is made up of such combinations of ligands. It must be pointed out, however, that a few prominent examples exist where the metallic core is held together almost exclusively by $N_3^-$ ligands, such as complexes **18** (cubane), **25** (double defective cubane), **46** (linear pentanuclear) and **51** ($Ni_8$).

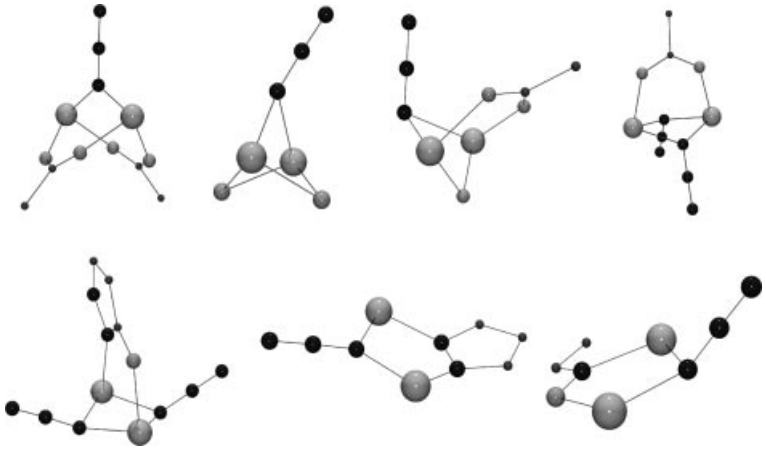

Figure 23. Several of the bridges encountered within the clusters of this review, involving the end-on azido ligand and at least a second bridge. Among the latter, the most common are oxido, hydroxido or carboxylato, but other bridges such as pyrazolato, pyrazolinolato or oximato are also not rare.

## Conclusions and Perspectives

The azide ligand has characteristics that render it very attractive for the synthesis of magnetic clusters. From a structural point of view it can participate in multiple bridges, very often in combination with other conventional ligands of cluster coordination chemistry (such as oxides or carboxylates). Magnetically, it usually induces ferromagnetic interactions that have yielded clusters with ground states ranging between $S = 4$ and 83/2. The unusually high number of compounds in this family that show SMM responses is also notable.

If we consider that the vast majority of these compounds have been synthesised in the last five years, we can suppose that the exploitation of this ligand for the synthesis of novel clusters with new and interesting properties relevant to SMM research is only in its infancy and that a very eventful and promising future lies ahead. We hope that this review will constitute an adequate reference for scientists eager to know about the state of this sub-discipline of magnetic cluster synthesis in its early stages. Given the speed at which this sub-area is developing, we are acutely aware that this account will soon become outdated.

# Dimerization of Diruthenium Coordination Compounds via Olefin Metathesis

**Wei-Zhong Chen,[a] John D. Protasiewicz,[b] Amanda J. Shirar,[a] and Tong Ren*[a]**

**Keywords:** Olefin metathesis / Dimerization / Diruthenium compounds / ω-Alkene-α-carboxylate

Diruthenium compounds containing an ω-alkene-α-carboxylate ligand, $Ru_2Cl[D(3,5\text{-}Cl_2Ph)F]_3[O_2C(CH_2)_nCH{=}CH_2]$ [$n$ = 1 (**1a**) and 2 (**1b**)], were prepared from the reactions between $Ru_2Cl[D(3,5\text{-}Cl_2Ph)F]_3(O_2CCH_3)$ [D(3,5-$Cl_2$Ph)F = *N*,*N*′-bis-(3,5-dicholorophenyl)formamidinate] and ω-alkene-α-carboxylic acids. Both compounds **1a** and **1b** undergo olefin cross-metathesis reactions catalyzed by $(Cy_3P)_2Cl_2Ru(=CHPh)$ to afford the dimerized compounds $[Ru_2Cl\{D(3,5\text{-}Cl_2Ph)F\}_3]_2[\mu\text{-}O_2C(CH_2)_nCH{=}CH(CH_2)_nCO_2]$ [$n$ = 1 (**2a**) and 2 (**2b**)]. Molecular structures of compounds **1a**/**1b** and **2a**/**2b** were established by X-ray diffraction studies, which revealed the formation of *trans* product only in the case of shorter tether (**2a**) and a mixture of *cis*-/*trans* isomers in the case of longer tether (**2b**).

## Introduction

Catalytic olefin metathesis, arguably one of the most important organic reactions discovered in the 20th century,[1] has found broad applications in organic and materials syntheses.[2,3] In comparison, there are only a limited number of applications of catalytic olefin metathesis in the synthesis of coordination and organometallic compounds.[4] Earlier studies by Rudler demonstrated that the W compounds of carbene ligands bearing alkene tails underwent ring-closing metathesis (RCM) with $WOCl_4/Ph_2SiH_2$ as the catalyst.[5] The RCM method was subsequently applied to the high-yield synthesis of Cu-templated [2]catenanes.[6] More recently, both the cross metathesis (CM) and RCM reactions have been utilized to prepare bridged metallocenes and pincer compounds.[7] The most noteworthy are the creative efforts from the laboratory of Gladysz in applying RCM to a variety of metal compounds with phosphane ligands bearing terminal alkene, which resulted in novel compounds including sterically shielded linear Pt–polyyne molecules and gyroscope-like molecules.[4,8]

Our laboratory has been developing methodologies to covalently modify diruthenium compounds at the ligand periphery, and Sonogashira and Suzuki cross couplings were successfully executed on N,N′-bridging ligands containing aryl iodo substituents.[9,10] Reported in this contribution is the synthesis of diruthenium compounds containing ω-alkenyl-α-carboxylate ligand, which subsequently undergoes cross metathesis reactions to afford a unique set of dimeric diruthenium compounds.

## Results and Discussion

Our approach began with the preparation of diruthenium compounds containing ω-alkene-α-carboxylate. $Ru_2[D(3,5\text{-}Cl_2Ph)F]_3(OAc)Cl$ [D(3,5-$Cl_2$Ph)F = *N*,*N*′-bis(3,5-dicholorophenyl)formamidinate][9,10] readily reacted with excess $HO_2C(CH_2)_nCH{=}CH_2$ ($n$ = 1, vinylacetic acid; $n$ = 2, 4-pentenoic acid) under reflux in THF/MeOH to afford the new compounds $Ru_2[D(3,5\text{-}Cl_2Ph)F]_3[\mu\text{-}O_2C(CH_2)_nCH{=}CH_2]Cl$ ($n$ = 1, **1a**; 2, **1b**) as purple crystalline materials, which were purified on silica column to ensure the complete removal of the unidentified by-products that might poison the metathesis catalyst. Although the paramagnetic nature of the compounds **1a/b** ($S$ = 3/2) prevents the recording of NMR spectra, both **1a** and **1b** were analyzed satisfactorily and characterized by single-crystal X-ray diffraction. Structural plots of molecules **1a** and **1b** are shown in Figure 1 and Figure 2, respectively, and the similarity in $Ru_2$ coordination spheres among **1a**, **1b** and $Ru_2[D(3,5\text{-}Cl_2Ph)F]_3(OAc)Cl$[9,10] is clear from the comparison of both the structural plots and key geometric parameters including the averaged Ru–N and Ru–O bond lengths. Interestingly, the lengths of terminal olefin, 1.29(2) Å for C3–C4 in **1a** and 1.356(9) Å for C4–C5 in **1b**, differ significantly, which may be attributed to the positional disorder caused by structural flexibility of terminal olefins. Also noteworthy is the averaged Ru–O distance for **1a/b** (ca. 2.05 Å), which is significantly longer than those of $Ru_2(O_2CR)_4Cl$ (2.02–2.03 Å)[11] due to the *trans* influence of D(3,5-$Cl_2$Ph)F ligand. Obviously, it is a concern whether such structural destabilization may translate into the lability

of ω-alkene-α-carboxylate during the metathesis reaction (Scheme 1).

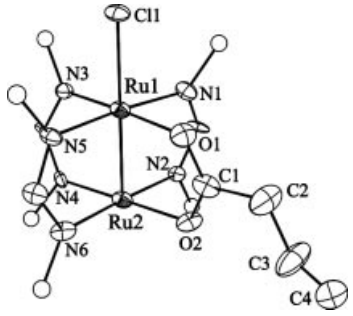

Figure 1. ORTEP plot of molecule **1a** at 40% probability level. All 3,5-$Cl_2$phenyl groups except for the *ipso*-carbon centers (shown as isotropic spheres) were removed for clarity. Selected bond lengths [Å] and angles [°]: Ru1–Ru2 2.321(2), Ru1–Cl1 2.382(3), Ru–N(av.) 2.060(11), Ru–O(av.) 2.051(9), C3–C4 1.29(2), C2–C3–C4 128(2).

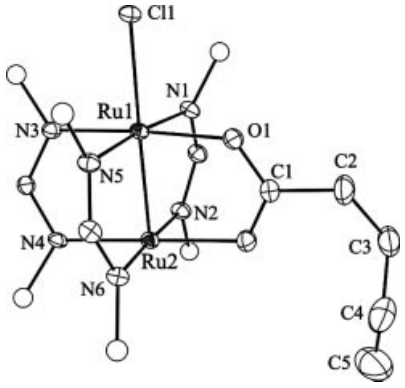

Figure 2. ORTEP plot of molecule **1b** at 40% probability level. All 3,5-$Cl_2$phenyl groups except for the *ipso*-carbon centers (shown as isotropic spheres) were removed for clarity. Selected bond lengths [Å] and angles [°]: Ru1–Ru2 2.3131(4), Ru1–Cl1 2.3828(8), Ru–N(av.) 2.064(4), Ru–O(av.) 2.056(4), C4–C5 1.356(9), C3–C4–C5 120.3(6).

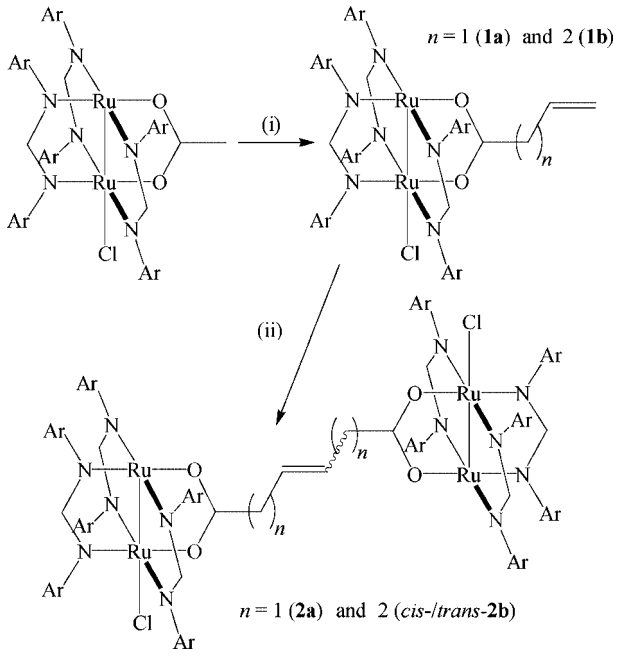
Having incorporated ω-alkene-α-carboxylate into the coordination sphere of $Ru_2$ core, we were in position to investigate the feasibility of metathesis reactions. Compound **1a** was refluxed in $CH_2Cl_2$ in the presence of $(Cy_3P)_2Cl_2Ru(=CHPh)$ and a gradual build-up of a new compound **2a** was noted over a period of 5 d. The dimeric nature of **2a** was confirmed by both the observation of $[\mathbf{2a}\text{-}Cl_2]^+$ in MALDI-TOF-MS (2544) and a preliminary X-ray study, the latter of which revealed the *trans* configuration of the olefin bridge.[12] However, the conversion of **1a** to **2a** was only about 40% despite several additions of fresh catalyst during the course of reaction. In contrast, refluxing of compound **1b** under the same conditions resulted in a complete conversion of **1b** in 2 d to two new compounds that were similar in polarity ($R_f$ = 0.55 and 0.45 in THF/hexanes, 1:5, v/v) and yielded the same $[\mathbf{2b}\text{-}Cl]^+$ peak in ESI-MS (2606). The new compounds are obviously the *cis*/*trans* isomers, and the structural determination of the compound of $R_f$ = 0.45 (Figure 3) revealed a *trans* configuration of the olefin bond derived from the CM reaction. It is interesting to note that the cross metathesis of the coordinated vinyl acetate in



Scheme 1. (i) 10 equiv. $HOOC(CH_2)_nCH=CH_2$, THF/MeOH (1:1), reflux; ii) 5 mol-% $(Cy_3P)_2Cl_2Ru(=CHPh)$, $CH_2Cl_2$, reflux 2–5 d. Ar = 3,5-$Cl_2C_6H_3$.

**1a** was slow and gave the *trans* product only, while the reaction of the coordinated 4-pentenoate proceeded much faster and yielded a mixture of *cis*/*trans* products. Apparently, extension of the tether by a single methylene unit significantly reduces the steric strain imposed by the bulky diruthenium units between the during the CM reaction. Also critical is the use of chromatographically purified starting materials, as compounds **1** purified by recrystallization showed little or no reactivity under the same CM conditions. In comparison, the homo-dimerization reaction of acrylic acid was also classified as "slow" (15 h at 40 °C) with $(Cy_3P)(NHC)Cl_2Ru(=CHPh)$ as the catalyst.[13]

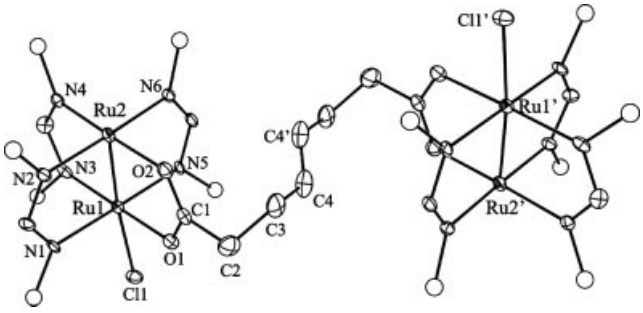


Figure 3. ORTEP plot of molecule *trans*-**2b** at 40% probability level. All 3,5-$Cl_2$phenyl groups except for the *ipso*-carbon centers (shown as isotropic spheres) were removed for clarity. Selected bond lengths [Å] and angles [°]: Ru1–Ru2 2.329(1), Ru1–Cl1 2.382(2), Ru–N(av.) 2.059(7), Ru–O(av.) 2.050(6), C4–C4′ 1.30(2), C3–C4–C4′ 111(1).

In the structure of *trans*-**2b**, there is a crystallographic inversion center that bisects the C4–C4′ bond and relates one half of the molecule to the other half. The structural features of the diruthenium unit in **2b** bear close resem-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

blance to those of **1a/b**. Also obvious from Figure 3 is the formation of 1,8-dicarboxy-4-octene from the cross metathesis of **1b**.

When two identical metallic centers are tethered covalently, an obvious question is whether two centers are corporative (electronically coupled) or modular (electronically independent). To investigate the effect of dicarboxylate bridges, the redox properties of compounds **1a/b** and **2a/b** were examined with cyclic voltammetric (CV) measurements, and the CVs. of **1a** and **2a** are shown in Figure 4. Similar to the parent compound $Ru_2[D(3,5\text{-}Cl_2Ph)F]_3(OAc)Cl$, compound **1a** underwent a reversible oxidation (**A**) and a quasireversible reduction (**B**) in the potential window shown. The dimeric derivative **2a** displayed a nearly identical CV, except that the peak currents were roughly doubled. Similar comparison can be made between compounds **1b** and **2b**. Clearly, two diruthenium units remain modular in compounds **2**. Further corroborating the modular feature, both compounds **1** and **2** absorb intensely at 520 nm, and the molar extinction coefficients of the latter are about twice of that of the former (see supporting information).

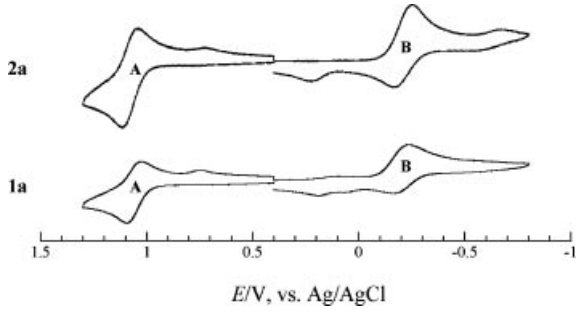

Figure 4. Cyclic voltammograms of **1a** and **2a** recorded in 0.20 M THF solution of $Bu_4NPF_6$ at a scan rate of 0.10 V/s.

## Conclusions

Formation of compounds **2a/b** from **1a/b** are the first examples of cross metathesis of coordinated ω-alkene-α-carboxylate to the best of our knowledge,[2] and represents a novel approach in applying olefin metathesis to inorganic chemistry. Supramolecules consisting of a pair of $Mo_2$ units linked by a dicarboxylate linker have been extensively studied by the laboratory of Cotton,[14] and supramolecules of $Ru_2$ units linked with both di-/tricarboxylates and other ditopic ligands have also been reported.[15] In most cases, the assemblies occur via the coordination to $M_2$ centers by pre-formed di-/tricarboxylate linkers. Clearly, the metathesis method developed here may be utilized as a novel alternative for the preparation of the $M_2$ supramolecules. In addition to the simple dimerization, we also envision the possibilities of macrocyclization through intra- and intermolecular metathesis and ring-opening polymerization based on $Ru_2$-containing scaffolds, which are being explored in our laboratory.

## Experimental Section

**General:** Vinylacetic acid and pentenoic acid were purchased from ACROS, silica gel was purchased from Merck, and $(Cy_3P)_2Cl_2Ru(=CHPh)$ was purchased from Aldrich. $Ru_2[D(3,5\text{-}Cl_2Ph)F]_3(OAc)Cl$ was prepared as reported earlier.[9] Magnetic susceptibility was measured at 294 K with a Johnson Matthey Mark-I Magnetic Susceptibility Balance. Elemental analysis was performed by Atlantic Microlab, Norcross, GA. Visible absorption spectra were recorded with a Cary300 UV/Vis spectrophotometer. Cyclic voltammograms were recorded in 0.2 M $(n\text{Bu})_4NPF_6$ solution (THF, $N_2$-degassed) with a CHI620A voltammetric analyzer with a glassy carbon working electrode (diameter 2 mm), a Pt-wire auxiliary electrode and a Ag/AgCl reference electrode. The concentration of diruthenium species was always 1.0 mM. The ferrocenium/ferrocene couple was observed at 0.582 V (vs. Ag/AgCl) under the experimental conditions.

**Preparation of $Ru_2[D(3,5\text{-}Cl_2Ph)F]_3(\mu\text{-}O_2CCH_2CH{=}CH_2)Cl$ (1a):** A mixture of $Ru_2[D(3,5\text{-}Cl_2Ph)F]_3(OAc)Cl$ (200 mg, 0.15 mmol), vinylacetic acid (10 equiv.), THF (20 mL) and methanol (20 mL) was refluxed in air overnight. The solvent was removed and the residue was washed repeatedly with $H_2O$ and hexanes. Further purification was carried out on a silica column (THF/hexanes, 1:5) to yield a purple crystalline material (170 mg, 81%). UV-Vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 520 (11,200) nm. $C_{43}H_{26}Cl_{13}N_6O_2Ru_2{\cdot}THF$ (1393.84): calcd. C 40.50, H 2.46, N 6.03; found C 40.36, H 2.48, N 6.13. $\chi_{mol}$ (corrected) = $6.40{\cdot}10^{-3}$ emu, $\mu_{eff}$ = 3.90 BM. Cyclic voltammogram ($E_{1/2}$ [V], $\Delta E_p$ [V], $i_{backward}/i_{forward}$): **A**, 1.092, 0.066, 0.676, **B**, –0.208, 0.044, 0.704.

**Preparation of $Ru_2[D(3,5\text{-}Cl_2Ph)F]_3(\mu\text{-}O_2CCH_2CH_2CH{=}CH_2)Cl$ (1b):** Synthesis of **1b** was similar to that of **1a** with vinylacetic acid being replaced by pentenoic acid. Yield 87%. UV-Vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 520 (10,400) nm. $C_{44}H_{28}Cl_{13}N_6O_2Ru_2$ (1335.76): calcd. C 39,56, H 2.11, N 6.29; found C 39.96; H 2.19, N 6.39. $\chi_{mol}$ (corrected) = $6.55{\cdot}10^{-3}$ emu, $\mu_{eff}$ = 3.95 BM. Cyclic voltammogram ($E_{1/2}$ [V], $\Delta E_p$ [V], $i_{backward}/i_{forward}$): **A**, 1.105, 0.065, 0.585; **B**, –0.215, 0.039, 0.742.

**Preparation of $[Ru_2[D(3,5\text{-}Cl_2Ph)F]_3]_2(\mu\text{-}O_2CCH_2CH{=}CH_2CH_2CO_2)Cl_2$ (2a):** $(Cy_3P)_2Cl_2Ru(=CHPh)$ (5 mol-%, 9 mg) was added to **1a** (300 mg) in 80 mL of dry $CH_2Cl_2$ . The resulting solution was refluxed under $N_2$ for 5 d. The reaction progress was monitored by TLC (THF/hexanes, 1:5, same below) and the product **2a** was detected; $R_f$ = 0.45 . The purification of **2a** was performed by a silica column chromatography (THF/hexanes, 1:7 to 1:5). Yield: 120 mg, 40%. MALDI-TOF-MS: $m/z$ = 2544, $[\mathbf{2a}\text{-}Cl_2]^+$. UV-Vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 520 (22,800) nm. $C_{84}H_{56}Cl_{26}N_{12}O_4Ru_4{\cdot}THF$ (2687.51): calcd. C 39.33, H 2.10, N 6.25; found C 39.25, H 1.95, N 6.51. Cyclic voltammogram ($E_{1/2}$ [V], $\Delta E_p$ [V], $i_{backward}/i_{forward}$): **A**, 1.075, 0.061, 0.699; **B**, –0.212, 0.043, 0.715.

**Preparation of $[Ru_2[D(3,5\text{-}Cl_2Ph)F]_3]_2(\mu\text{-}O_2CCH_2CH_2CH{=}CH_2CH_2CH_2CO_2)Cl_2$ (*cis*-2b and *trans*-2b):** $(Cy_3P)_2Cl_2Ru(=CHPh)$ (5 mol-%, 10 mg) was added to **1b** (320 mg) in 80 mL of dry $CH_2Cl_2$. The resultant solution was refluxed under $N_2$ for 2 d. The metathesis products *cis*-**2b**/*trans*-**2b** with $R_f$ of 0.55 and 0.45, respectively, were detected. The compounds *cis*-**2b**/*trans*-**2b** were partially separated by a chromatography (THF/hexanes, 1:7 to 1:5). Combined yield: 191 mg, 60%.

**Data for *cis*-2b:** ESI-MS: $m/z$ = 2606, $[\mathbf{2b}\text{-}Cl]^+$. UV-Vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 520 (23,100) nm. $C_{86}H_{52}Cl_{26}N_{12}O_4Ru_4{\cdot}THF$ (2715.57): calcd. C 39.81, H 2.23, N 6.19; found C 39.89, H 2.11, N 6.39.

# Crystal Structure, Solid-State NMR Spectroscopic and Photoluminescence Studies of Organic-Inorganic Hybrid Materials $(HL)_6[Ge_6(OH)_6(hedp)_6]\cdot 2(L)\cdot nH_2O$, L = hqn or phen[‡]

**Luís Mafra,[a] Filipe A. Almeida Paz,[a] Fa-Nian Shi,[a] Rute A. Sá Ferreira,[b] Luís D. Carlos,[b] Tito Trindade,[a] Christian Fernandez,[c] Jacek Klinowski,[d] and João Rocha*[a]**

**Keywords:** Germanium / Organic–inorganic hybrid materials / Crystal structure / NMR spectroscopy / Photoluminescence

Two germanium–$hedp^{4-}$ solids with heteroaromatic amines 8-hydroxyquinoline (hqn) and 1,10-phenanthroline (phen), $(HL)_6[Ge_6(OH)_6(hedp)_6]\cdot 2(L)\cdot nH_2O$ (L = hqn or phen), in **I** and **II** respectively, have been prepared and characterised by single-crystal XRD, thermogravimetry, FTIR and UV/Vis spectroscopy. The complex hydrogen-bond networks, particularly in compound **I**, have been studied by advanced high-resolution solid-state NMR spectroscopy that combines homonuclear recoupling techniques (two-dimensional $^1$H-$^1$H DQF and $^1$H-$^1$H RFDR MAS NMR) and combined rotation and multiple-pulse spectroscopy (two-dimensional $^1$H-$^1$H FS-LG, $^1$H-$^{31}$P FS-LG). The fine details of the crystal structure of **I** have been elucidated, mainly those involving the π–π stacking of 8-hydroxyquinoline and the relative orientation of adjacent such molecules. Compound **II** exhibits an emission from the lowest triplet-state energy (π–π* 0-phonon transition) of the aromatic rings at 320 nm (31250 $cm^{-1}$) from 14 K to room temperature. In contrast, the triplet emission of **I** at 530 nm (18868 $cm^{-1}$) is only detected at low temperature, because of thermally activated non-radiative mechanisms. The emission spectra of **I** and **II** display a lower-energy component with a larger life time, which results from the formation of an excimer state that originated from the π–π phenanthroline and hydroxyquinoline interactions, respectively.

## Introduction

Crystalline inorganic–organic hybrid materials have been the subject of much interest because of their structural diversity, interesting properties and potential applications in areas such as catalysis, magnetism, optics, medicine, electronics, photochemistry, gas storage, and coating films.[1–12] The organic components of these hybrid materials, until recently based mainly on carboxylic acid functional groups, are at present being replaced by phosphonic acid moieties because of their higher chelating versatility and ability to direct interesting structural topologies.[9,13,14] Examples of these organic chelating molecules include *N*-(phosphonomethyl)iminodiacetic acid ($H_4$pmida)[15] and 1-hydroxyethane-1,1-diphosphonic acid ($H_4$HEDP).[16–18]

In general, the $^1$H NMR spectra of solids suffer from homogeneous line broadening as a result of strong proton homonuclear dipolar couplings and the large concentration of protons in the materials. To circumvent this problem and to record high-resolution spectra, fast $^1$H MAS NMR techniques and Combined Rotation and Multiple-Pulse Sequences (CRAMPS) have been used. In organic materials,[19–22] hydrogen-bond networks have been much studied by solid-state $^1$H NMR spectroscopy, for example, by double-quantum filtered (DQF) NMR techniques.[21,23–26] However, advanced $^1$H NMR techniques have been much less applied to the study of complex inorganic-hybrid materials.[27–29]

Here, we wish to report the synthesis, single-crystal structure and photoluminescence properties of two germanium–$hedp^{4-}$ solids with heteroaromatic amines 8-hydroxyquinoline and 1,10-phenanthroline, $(HL)_6[Ge_6(OH)_6(hedp)_6]\cdot 2(L)\cdot nH_2O$ (L = hqn or phen), in **I** and **II**, respectively, which are involved in columnar π–π stacking interactions and exhibit complex hydrogen-bond networks. The materials have been further characterised by elemental analysis, thermogravimetry and FTIR, Raman and UV/Vis spectroscopy. High-resolution solid-state NMR spectroscopy has been used to study the complex hydrogen-bond networks, particularly in compound **I**. The combination of homonuclear recoupling techniques (2D $^1$H-$^1$H DQF,[30,31] 2D $^1$H-$^1$H

[‡] hedp, hqn and phen stand for 1-hydroxyethylidenediphosphonic acid, 8-hydroxyquinoline and 1,10-phenanthroline, respectively.

RFDR MAS NMR[32,33]) and CRAMPS[34] (2D $^1$H-$^1$H FS-LG, $^1$H-$^{31}$P FS-LG) provided a powerful means of characterising these organic–inorganic hybrid materials.

## Results and Discussion

### X-ray Crystallography

The hydrothermal reaction between germanium(IV) oxide, etidronic acid (or 1-hydroxyethylidenediphosphonic acid, $H_4$hedp, $C_2H_8O_7P_2$) and 8-hydroxyquinoline (hqn, $C_9H_7NO$) or 1,10-phenanthroline (phen, $C_{12}H_8N_2$), followed by slow evaporation at ambient temperature (Experimental Section), afforded highly crystalline materials, which were formulated as $(Hhqn)_6[Ge_6(OH)_6(hedp)_6]\cdot 2(hqn)\cdot 33H_2O$ (**I**) and $(Hphen)_6[Ge_6(OH)_6(hedp)_6]\cdot 2(phen)\cdot 20H_2O$ (**II**) on the basis of single-crystal X-ray diffraction (Table 1) in combination with thermogravimetry and solid-state NMR studies.

The main structural feature, common to both compounds, is the presence of the centrosymmetric hexameric anionic $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moiety (Figure 1), which bears some similarity with the fragment present in materials reported recently.[35] This anionic moiety is composed of three crystallographically unique $Ge^{4+}$ centres [Ge(1), Ge(2) and Ge(3), Figure S2 in Supporting Information], each coordinated to two $hedp^{4-}$ residues (through the phosphonate moieties) and to two $\mu_2$-bridging hydroxy groups, and exhibits $\{GeO_6\}$ in a slightly distorted octahedral coordination geometry: for both compounds, all the Ge–O bonds are in the range 1.79 to 1.91 Å (Table S3 in Supporting Information); however, the *cis* and *trans* octahedral angles range from 85.2° to 95.3° and 174.2° to 179.3°, respectively (Table S4 in Supporting Information). The centrosymmetric hexameric anionic unit described here is different in a fundamental way from that previously reported by Seifullina and collaborators.[35] Indeed, while in compounds **I** and **II**, the centre of gravity of this anionic unit is located at an inversion centre (Table 1), which necessarily requires the presence of three crystallographically unique $Ge^{4+}$ centres, for the compounds reported by Seifullina et al., inversion arises as a combination of other symmetry elements, namely a twofold axis and a mirror plane (space group *C*2/m), and therefore only requires two single $Ge^{4+}$ centres.[35] Consequently, the $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moiety present in compounds **I** and **II** is more distorted than its *C*2/*m* counterpart. A possible reason for this decrease in symmetry is the significant number of strong hydrogen bonds present in **I** and **II** that involve the phosphonate groups.

In both compounds, the $hedp^{4-}$ organic residues are chelating bridging ligands, linking neighbouring $Ge^{4+}$ centres through the two phosphonate groups, which coordinate the $Ge^{4+}$ centres in *cis* positions (Figure 1a). The Ge···Ge internuclear distances range from ca. 3.32 to 3.50 Å (Figure 1), which is in good accord with the values reported by Seifullina and collaborators[35] (ca. 3.39–3.50 Å). Because

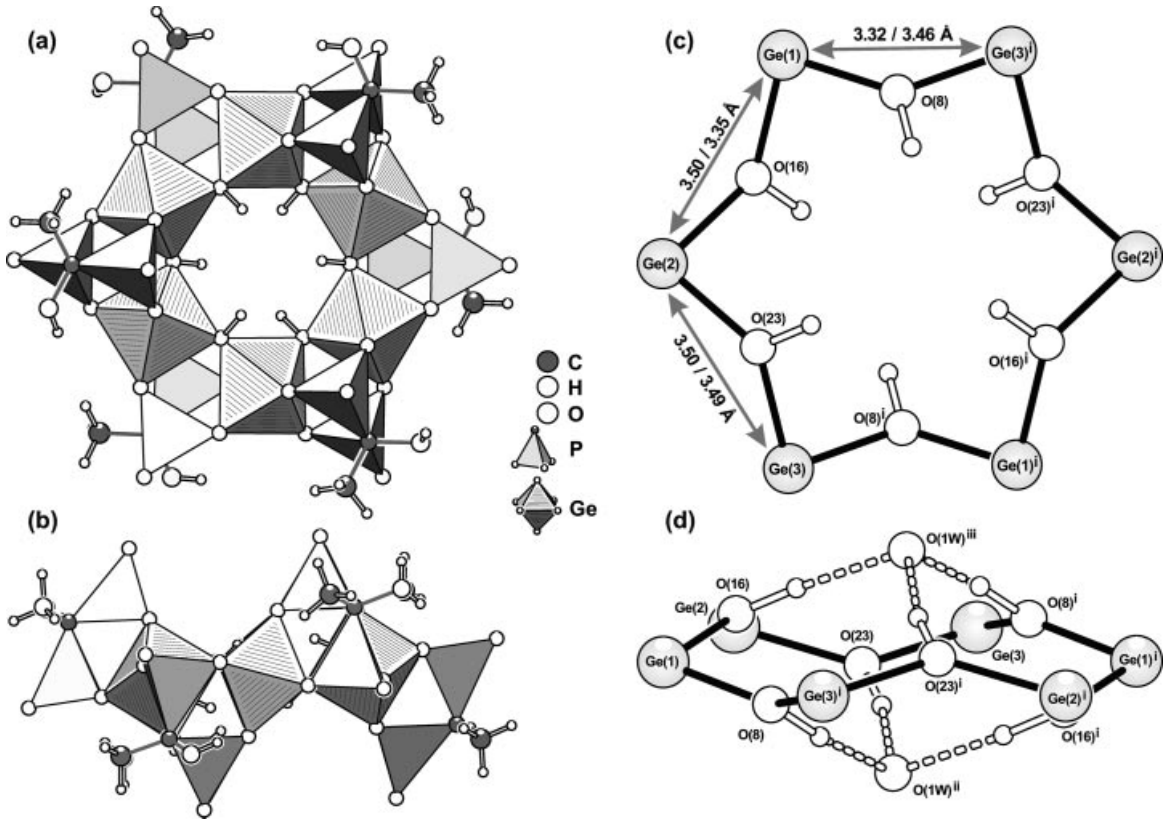

Figure 1. (a) and (b) Polyhedral representation of the hexameric anionic $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moiety viewed from the top and from a lateral perspective. (c) and (d) Ball-and-stick representation of the internal $\{Ge_6(OH)_6\}$ hexagonal ring of the anionic $[Ge_6(OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moieties. Hydrogen bonds with neighbouring O(1W) water molecules are represented as dashed lines. Selected bond lengths and angles are given in Tables S3 and S4 and the hydrogen bonding geometry in Tables S5 and S6 (Supporting Information). Symmetry codes used to generate equivalent atoms, **I**: (i) $1-x$, $2-y$, $2-z$; (ii) $x$, $y$, $1+z$; (iii) $1-x$, $2-y$, $1-z$.; **II**: (i) $1-x$, $1-y$, $2-z$; (ii) $x$, $-1+y$, $z$; (iii) $1-x$, $1-y$, $2-z$.

of steric hindrance, the six $hedp^{4-}$ ligands forming the anionic $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moiety are distributed above and below the plane formed by the six $Ge^{4+}$ centres (Figure 1a and Figure 1b). An identical distribution also occurs for the six $\mu_2$-bridging hydroxy groups located and pointing towards the inner space of the hexameric moiety (Figure 1c and Figure 1d). Each one of the three $\mu_2$-OH groups from one side of the $\{Ge_6(OH)_6\}$ hexagonal ring interacts with a neighbouring water molecule of crystallisation (Figure 1d) through strong and highly directional O–H···O hydrogen bonds [average O···O internuclear distance and <(O–H···O) angle of 2.70 Å and 163°, respectively, for both compounds, Tables S5 and S6 in Supporting Information]. Within the dihydrated anionic $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moiety, the O(1W)···O(1W) distances are ca. 3.18 and 3.31 Å for **I** and **II**, respectively. Interestingly, such an arrangement was reported by Seifullina et al. only for the material containing $[Mg(H_2O)_6]^{2+}$ cations, with a reported corresponding distance of ca. 3.17 Å.[35] The charge of the hexameric anionic $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moieties is compensated by the presence of protonated 8-hydroxyquinoline ($Hhqn^+$, for **I**) or 1,10-phenanthroline ($Hphen^+$, for **II**) organic residues, which appear to be π–π stacked, thus leading to the formation of cationic columnar arrangements (Figures S3 and S4 in Supporting Information): while for **I**, the organic residues alternate in a hqn/$Hhqn^+$/$Hhqn^+$ fashion, for **II**, the rod-like columns are only formed by protonated phen residues. The location of these charge-balancing $H^+$ could only be unequivocally confirmed in the crystal structures by solid-state NMR spectroscopy (see below). This π–π stacking arrangement of organic molecules in both compounds seems to arise mainly as a result of the presence of the relatively large hexameric anionic unit. For example, the crystal structure of pure 1,10-phenanthroline does not contain any π–π interactions, and the stacking of adjacent molecules is instead driven by numerous weak C–H···π interactions.[36] For **I**, this particular feature led to significant and interesting photoluminescence properties, as will be discussed later.

Connections between neighbouring cationic columnar arrangements are mainly assured by weak C–H···π interactions with pairs of π–π-stacked organic molecules. While for compound **I**, this distribution generates organic layers (Figure S3 in Supporting Information), for **II**, the packing is much more efficient, which leads to a three-dimensional supramolecular arrangement of phen/$Hphen^+$ residues (Figure S4 in Supporting Information). Therefore, even though compound **II** has a significantly more available volume per unit cell, the volume accessible to solvent molecules (calculated by using Cerius$^2$ routines[42]) is approxi-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mately half of that for **I** (Figure S5 and Table S2 in Supporting Information). These supramolecular arrangements of organic residues closely interact with the hexameric anionic $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moieties and water molecules of crystallisation through a series of strong hydrogen bonds (Tables S5 and S6 in Supporting Information), which will be discussed in more detail in the solid-state NMR section.

As suggested by thermogravimetry and previous studies on multi-dimensional coordination frameworks exhibiting

large channels,[37] it was clear that both compounds would contain a large number of highly disordered water molecules of crystallisation located within the voids, thus resulting in a significant spread-out electron density visible in the XRD data. Peak search routines of SHELXL are not designed to locate maxima in density ridges, which thus lead to additional difficulties during refinement and mask important structural features. SQUEEZE[38] subroutines included with the software package PLATON[39,40] were therefore employed to eliminate the contribution to the electron density of the water molecules of crystallisation present in the solvent-accessible area [except for the hydrogen-bonded O(1W) molecule, Figure 1c and Figure 1d]. Figure 2 and Figure 3 show the SQUEEZE contour maps for **I** and **II**, respectively, and emphasise the diffuse electron density present in some of the regions with solvent-accessible voids. For **I**, PLATON estimated that the unit cell has ca. 1363 Å$^3$ that is potentially accessible to the solvent (ca. 35.8% of the total volume) in a large cavity centred at (–0.032 0.082 0.439), with ca. 263 electrons per unit cell (Figure 4 and S5 in Supporting Information). For **II**, the unit cell only has ca. 1144 Å$^3$ that is potentially accessible to the solvent (ca. 16.3% of the total volume), which is distributed along two identical cavities centred at the special positions (0 0 0) and (1/2 1/2 1/2), with ca. 547 electrons per unit cell (Figure 5, S5 and S6 in Supporting Information). In all calculations, O(1W) was assumed to belong to the hybrid hydrogen-bonded frameworks.

Perspective views along the (a) [100] and (b) [010] directions of the 2×2 unit cell packing of **II**, enhancing the shape of the two identical cavities centred at (0 0 0) and (1/2 1/2 1/2). Images created by generating Connolly surfaces (1.4 Å probe radius and 12.0 dot density) with the software package Cerius$^2$.[42]

## Solid-State NMR Spectroscopy

### *$^{13}$C CP MAS NMR Spectra*

The spectra of **I** and **II** exhibit similar features (Figure S1). The hexameric $[Ge_6(\mu_2\text{-}OH)_6(C_2H_4O_7P_2)_6]^{6-}$ moiety gives the following resonances for **I** and **II**, respectively: quaternary carbon atoms (C1, C3, C5) 70.9 and 71.3 ppm; methyl (C2, C4, C6) carbon atoms 18.6 and 19.9 ppm. This moiety has three crystallographically inequivalent quaternary and methyl carbon atoms, but three resonances are only clearly observed (as shoulders) in the quaternary carbon region of **I**. Above 100 ppm, resonances are assigned to the aromatic carbon atoms involved in the extensive columnar π–π stacking.

### *$^1$H Spectra: Hydrogen-Bonding Assignment*

The F1 projection of the $^1$H-$^1$H FS-LG and the $^1$H fast (30 kHz) MAS spectra (Figure 6) have similar resolution, and show up to 8 resolved peaks. However, a judicious choice of 2D F2 slices proves the presence of some 10 resonances (consider Figure 6c). The resonances ($H^a$-$H^c$) in the range 16.6–13.1 ppm are assigned to strong hydrogen bonds, because of their relatively high-frequency shifts (Table 2). Hydrogen-bonded systems involving carboxylic (C=O) and phosphonic (P=O) acids as electron donors (i.e. proton acceptors) were reported to resonate in the ranges 12–20 ppm and 11–17 ppm, respectively.[43] In **I**, the P=O groups are within the hydrogen-bonding distance of the OH groups of the 8-hydroxyquinoline (ArO–H) moieties ($r_{O\cdots O}$ = 2.61 Å). P=O groups involved in hydrogen bonds with OH residues have been reported to resonate at 11–12 ppm.[20,43] Resonance $H^c$ is tentatively attributed to ArO–H···O=P environments. Such hydrogen bonds (ArO–H···O=P) are likely to be stronger than other CO–H···O=P bonds[20] because the conjugated base ($ArO^-$) of the hydrogen donor (ArO–H) is weak, owing to aromatic ring stabilisation. When the acidity of a hydrogen-bonded OH group increases, its chemical shift also increases, and the resonance $H^c$ therefore appears at a chemical shift larger than 12 ppm.

The crystallographic N···O distance range (2.72–2.78 Å) suggests that the protonated nitrogen atom of 8-hydroxyquinoline is hydrogen-bonded to water molecules ($N^+$–H···$OH_2$). The presence of $N^+$–H groups involved in this type of interaction is likely because the charge of the anionic hexameric unit must be compensated by $H^+$. Protonation and hydrogen bonding result in a significant increase in the $^1$H chemical shift. Thus, the $H^a$ and $H^b$ resonances

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

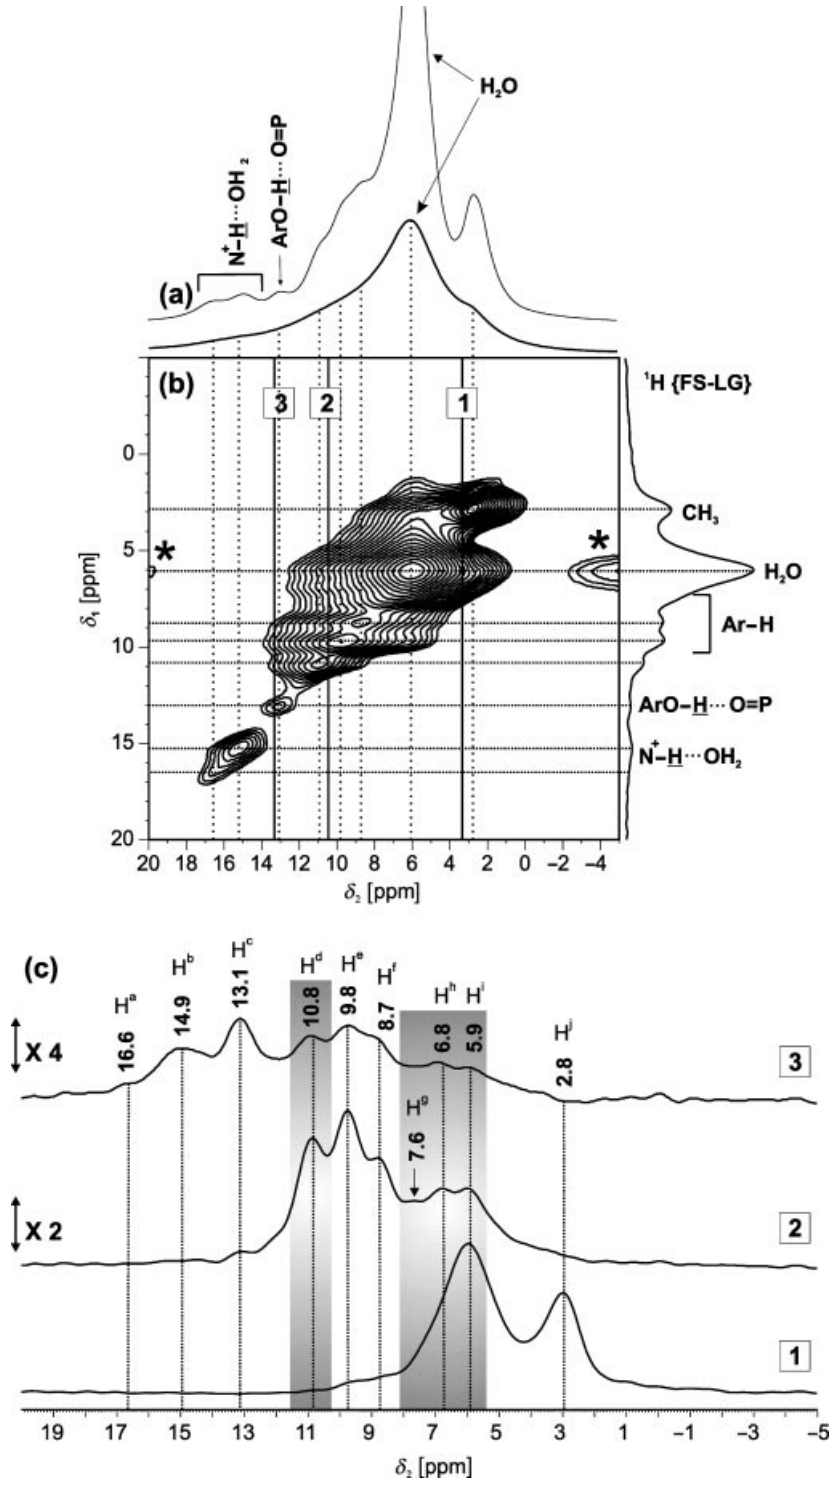

Figure 6. (a) $^1$H MAS and (b) 2D $^1$H-$^1$H FS-LG spectra of **I**. (c) F2 cross-sections of the $^1$H-$^1$H FS-LG spectrum of **I** taken at 3.4, 10.5 and 13.3 ppm. Asterisks depict spinning sidebands.

at $\delta$ = 16.6 and 14.9 ppm are tentatively assigned to $N^+$–H···$OH_2$ environments (and confirmed below by $^1$H-$^1$H DQF spectroscopy).

The $^1$H resonances $H^i$ and $H^j$ at ca. 5.9 and 2.8 ppm, respectively, are assigned to lattice water and $CH_3$ groups. The remaining $^1$H peaks between ca. 6 and 11 ppm cannot be assigned without information from other 2D techniques (see below).

The $^1$H-$^1$H FS-LG spectrum of **II** (Figure S8) displays fewer resonances than that of **I**. In particular, a peak is observed at ca. 15.1 ppm, which shows the presence of strong hydrogen bonds between the protonated nitrogen

| | | 11.5 | $H^j\cdots H^f$ |

[a] Resonances observed in the $^1H$-$^1H$ FS-LG and $^1H$-$^1H$ DQF spectra are considered. [b] DQ coherences are not considered for the self-correlation peaks (diagonal peaks). [c] There is evidence of $H^e\cdots H^j$ and $H^g\cdots H^j$ correlations, but their observation is difficult (Figure 7b). [d] These $^1H$ resonances refer to the two resolved peaks ($H^h$ and $H^i$) observed in Figure 6, which are tentatively assigned to $H_2O$ protons.

[N(21)] of 1,10-phenanthroline and the P=O(6) groups of the anionic unit ($r_{N(21)\cdots O(14)}$ = 2.68 Å, Table S6). This supports the assignment of resonances $H^a$ and $H^b$ proposed above for compound **I**.

The presence of signals in the $^1H$-$^1H$ DQF spectrum (Figure 7b) reveals dipolar couplings between nuclei and allows the identification of mobile water molecules by comparison with the 30 kHz MAS $^1H$ NMR spectrum (Figure 7a). The latter is dominated by mobile water molecules located in the channels, which resonate at ca. 5.9 and 6.8 ppm for **I** and **II**, respectively (Figure 7a and S9a). This peak is suppressed in DQF experiments, simplifying the spectra (Figure 7b and S9b). In the following discussion, SQ coherences (Table 2) identified from $^1H$-$^1H$ FS-LG are taken into consideration in the study of the SQ-DQ correlations.

The Ar-H protons ($H^e$, $H^f$ and $H^g$, Scheme 1) are classed into three main groups on the basis of the chemical shifts of their resonances, which are expected in the order $\delta(H^e) > \delta(H^f) > \delta(H^g)$. In solution, pure 8-hydroxyquinoline resonates in the range 7.3–9.0 ppm, while for **I**, the chemical shifts range from 7.6 and 9.8 ppm. The identification of the Ar-H resonances was made possible by analysing the DQ frequency of the off-diagonal peaks (Figure 7b) that involve the hydrogen-bonded $^1H$ resonances ($H^a$, $H^b$ and $H^c$), which are well resolved.

In the 2D $^1H$-$^1H$ DQF spectrum, $H^e$ resonances exhibit strong off-diagonal correlations with those of $H^a$ and $H^b$ as these protons are in *ortho* positions (adjacent) and are thus relatively close (2.16–2.28 Å). DQ chemical shifts of ca. 26.4 (16.6 + 9.8) and 24.7 (14.9 + 9.8) ppm for $H^a$ and $H^b$, respectively, are observed. This evidence allows the assignment of

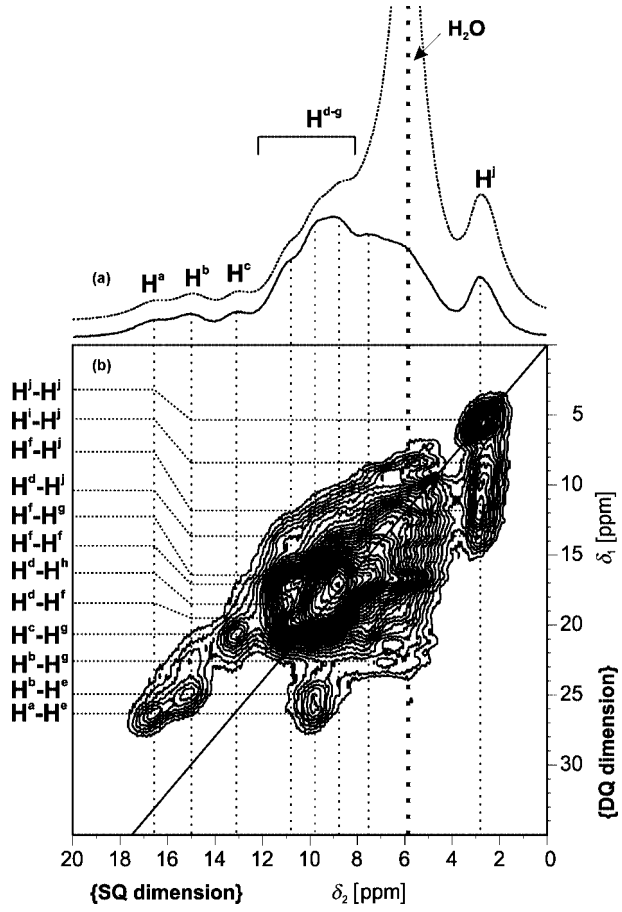

Figure 7. (a) $^1H$ MAS and (b) $^1H$-$^1H$ DQF MAS NMR spectra of **I**.

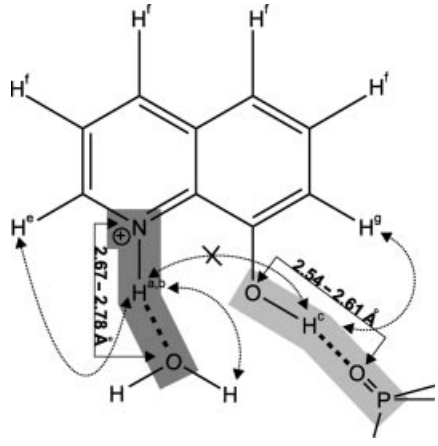

Scheme 1. Hydrogen bonds formed by 8-hydroxyquinoline in compound **I**. Dashed arrows show the interactions revealed by XRD (Table S5).

$H^a$ and $H^b$ to $N^+$–H···$OH_2$ bonds determined by XRD. In a similar way, the resonance at ca. 13.1 ppm ($H^c$) has a DQ frequency of ca. 20.7 ppm, which allows for the assignment of the peak at ca. 7.6 ppm to $H^g$, as this proton is also in an *ortho* position to $H^c$. Besides, $H^c$ is not correlated with $H^e$ because no DQ frequency appears at ca. 22.9 (13.1 + 9.8) ppm. Therefore, $H^c$ is not assigned to $N^+$–H protons in-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

volved in hydrogen bonds with water; these latter protons ($H^a$ and $H^b$) have always shown to be correlated with $H^e$ (Scheme 1).

Because the peaks are hidden by neighbouring resonances, the correlations involving $H^f$ are harder to ascertain. The remaining peak in the aromatic region at 8.7 ppm is assigned to $H^f$. This is supported by the DQ self-correlation $H^f\cdots H^f$ peak at ca. 17.4 ppm in the DQ dimension. The assignment of DQ coherences involving $H^f\cdots H^g$ and $H^f\cdots H^e$ was not possible because of the lack of resolution.

We now consider the tentative assignment of the resonances of **I** at ca. 10.8 ($H^d$) and 6.8 ppm ($H^h$). The 2D $^1$H-$^1$H DQF spectrum suggests that these protons are close in space and lead to a DQ frequency of ca. 17.6 ppm ($H^d\cdots H^h$). In accord, XRD data reveals the presence of hydrogen bonds involving the $H^d$ protons of tertiary alcohol groups of $HEDP^{4-}$ and the $H^h$ protons of water molecules. Additionally, the $H^d$ protons ($\delta$ =10.8 ppm) exhibit another DQ frequency at 13.6 (10.8 + 2.8) ppm, showing the close proximity (<0.35 nm) between the CO–H and $CH_3$ groups. The spectrum also provides evidence for the proximity between the $CH_3$ protons ($H^j$) and 8-hydroxyquinoline because correlations with all the Ar-H ($H^e$, $H^f$ and $H^g$) resonances (Table 2 and Figure 3b) are observed.

As far as compound **II** is concerned, the main conclusion is that the high-frequency resonance (at $\delta$ = 15.1 ppm) may be assigned to $N^+$–H···O=P hydrogen bonds (Figure S9b). Indeed, **II** possesses only a single type of very short (1.86 Å) hydrogen bond.

The $^1$H-$^1$H exchange RFDR (Figure 8) and $^1$H-$^1$H DQF experiments provide complementary information — the former maps correlations involving both mobile and rigid species, while the latter maps only those involving the rigid species.

In **I**, the lattice water resonances ($H^i$) are correlated with all peaks even at low mixing times, revealing the presence of water molecules dispersed throughout the structure. On the other hand, at a mixing time of 0.53 ms (Figure 8a), the $CH_3$ ($H^j$) protons are not correlated with $H^a$, $H^b$ and $H^c$, thus supporting the DQF results and confirming that the $H^e$ protons are only near $H^a$ and $H^b$ (hydrogen bonds involving N–$H^+$–$OH_2$). Moreover, a clear correlation between $H^c$ and $H^g$ is observed. This pair of resonances ($H^c\cdots H^g$) is strongly correlated at low mixing times (Figure 8a), supporting the information given by $^1$H-$^1$H DQF spectroscopy (Figure 7b). The $^1$H-$^1$H RFDR spectrum of structure **II** is far less informative and will not be further discussed (Figure S10).

The $^1$H-$^1$H DQF spectrum of **I** also reveals important information on the spatial arrangement of the organic residues. Excellent reviews are available on the study of three-dimensional crystal packing based on ring-current effects arising from the aromatic π orbitals.[21,44,45] Moreover, the influence of ring currents on neighbouring molecules shifts the chemical shifts over a range of 2–5 ppm.[46] The Ar-H resonances ($H^e$, $H^f$ and $H^g$) of **I** are shifted to high frequency relative to the resonances of 8-hydroxyquinoline in solution, which may be due to either amine protonation or

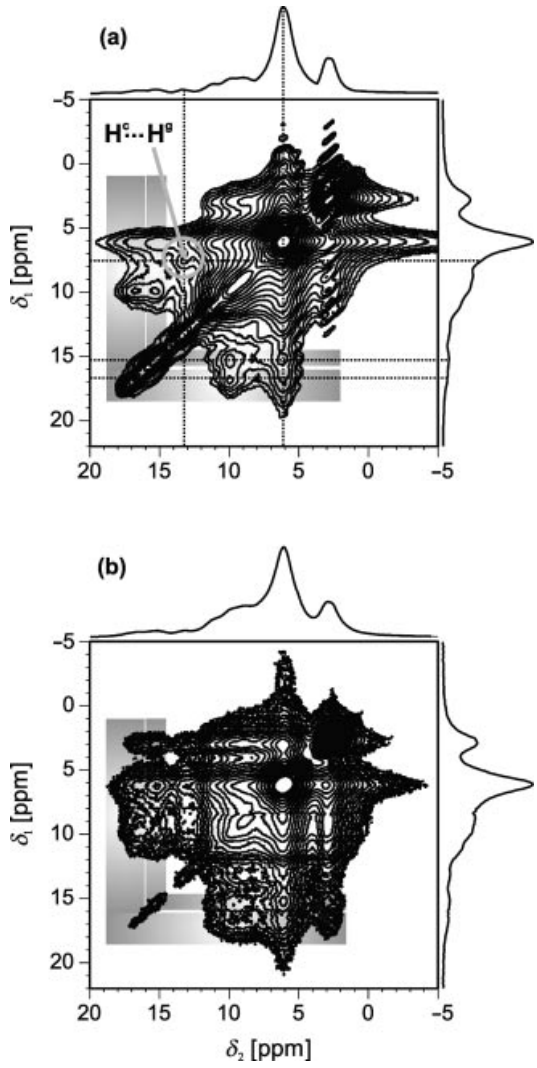

Figure 8. 2D $^1$H-$^1$H exchange RFDR spectra recorded with mixing times of (a) 0.53 ms and (b) 3.2 ms.

small ring-current effects caused by adjacent molecules. The relative orientation of adjacent 8-hydroxyquinoline molecules may be studied on the basis of the $^1$H-$^1$H DQF spectrum. The $H^b$ resonance shows an additional off-diagonal correlation at a DQ frequency of 22.5 ppm, clear evidence of spatial proximity between protons $H^b$ and $H^g$. Because the intra- and intermolecular distances between these protons are 5.3 and 3.2 Å, respectively, the SQ-DQ correlation is ascribed to the latter proton resonances. Moreover, the absence of diagonal peaks involving the resolved hydrogen bonds indicates that $H^a$, $H^b$ and $H^c$ are protons belonging to separate molecules (Figure 7b).

The $^1$H projection of the $^1$H-$^{31}$P FS-LG spectra of **I** (Figure S11) is better resolved than the F1 projection of the $^1$H-$^1$H FS-LG spectra (Figure 6b). Alternatively, the $^1$H-$^{31}$P FS-LG spectra are useful to probe the hydrogen bonds between the $HEDP^{4-}$ phosphonate group and the 8-hydroxyquinoline aromatic residues. At short contact times (0.2 ms), the $^1$H-$^{31}$P FS-LG $H^c$ resonances are slightly more

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

intense than those for $H^a$ and $H^b$, which indicates that the $H^c$ protons are hydrogen bonded to P=O groups, as mentioned above (Scheme 1).

### Photoluminescence Spectroscopy

Figure 9 shows the excitation spectrum of **I** recorded at 14 K. The spectrum consists of a broad band between 270 and 440 nm, assigned to aromatic ring π–π* transitions.[47] The excitation of **I** within such states leads to the observation of both a main band in the range 440 to 650 nm, peaking at 530 nm, and an emission component at higher wavelengths (Figure 9a). According to the crystal structures, the aromatic moieties have two distinct packing environments: columnar π···π stacking and adjacent molecules connected to the columns through weak C–H···π interactions. Hence, the former band may be assigned to the π–π* 0-phonon transition of the hydroquinoline adjacent rings,[47] which corresponds to a triplet-state energy of 18900 $cm^{-1}$, while the band at higher wavelengths is attributed to excimer formation through π···π hydroquinoline interactions. At room-temperature, no efficient emission could be detected, which indicates the presence of thermally activated non-radiative channels in **I**.

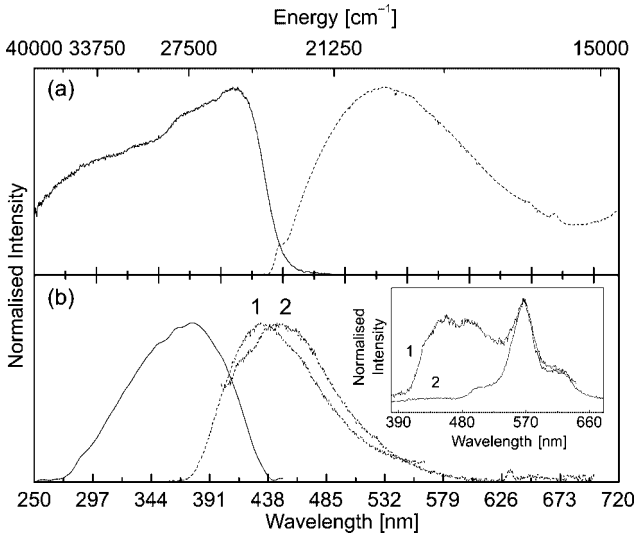

Figure 9. Excitation (solid line) and emission (dashed line) spectra of the complexes of (a) **I** and (b) **II** recorded at 14 K and room temperature, respectively. The excitation and emission spectra of **I** were monitored at 535 nm and excited at 408 nm, whereas for **II**, the monitoring wavelength was 490 nm and the excitation wavelengths were 330 nm (1) and 365 nm (2). The inset shows the time-resolved emission spectrum (14 K) of **II**, acquired with a starting delay of 0.05 ms and an acquisition window of 10.00 ms.

Figure 9b shows the room-temperature excitation spectra of **II** monitored at 490 nm. The spectrum displays a large broad band between 270 and 400 nm, peaking at 367 nm, ascribed to aromatic ring π–π* transitions.[48] The room-temperature reflectance spectrum (not shown) resembles the excitation spectra, displaying an absorption edge at 370 nm. This value is shifted to the red when compared with the singlet energy of the neutral 1,10-phenanthroline ligand (320 nm, 31250 $cm^{-1}$).[49] This energy difference is induced by the different local environment of 1,10-phenanthroline, in particular, the metal coordination and the packing of the complex in **II**.

Under UV excitation (Figure 9b), the emission of **II** consists of a large asymmetrical band between 380 and 550 nm. For excitation wavelengths in the range 270–370 nm, the emission energy peaks at 430 nm and does not depend on the excitation wavelength. For higher excitation wavelengths, a broadening and red-shift of the emission spectra are observed. The dependence on the excitation wavelength and the asymmetric shape of the emission suggest the appearance of a new emitting species, preferentially excited at higher wavelengths. As suggested for **I**, the presence of two distinct emission components may be due to the presence of two different packing environments for the 1,10-phenanthroline rings. The spectra acquired for excitation wavelengths between 270–370 nm may correspond to the preferential emission arising from the adjacent 1,10-phenanthroline rings. Like the excitation spectrum (Figure 9a), their emission energy is shifted with respect to that of the free 1,10-phenanthroline chromophore, whose lowest triplet-state energy (π–π* 0-phonon transition) peaks at 366 nm (27322 $cm^{-1}$);[50,51] however, the emission energy is very similar to that observed for $Gd(phen)_2Cl_3\cdot 2H_2O$[50], with a lowest triplet-state energy of 453 nm (22075 $cm^{-1}$).[52] The emission component at lower energy may be ascribed to the formation of an excimer through π···π phenanthroline interactions, as observed in 1,10-phenanthroline compounds with the same crystal packing of **II**.[50,51]

The presence of two distinct emissions in **II** was further established and investigated by time-resolved emission and lifetime measurements. These studies were performed at 14 K, since the room-temperature time-scale for the photoluminescence mechanisms is smaller than the detection limit of our equipment ($10^{-5}$ s). For lower excitation wavelengths, the spectrum consists of a structured broad band (inset in Figure 9b). Increasing the excitation wavelength results in a decrease in the relative intensity of the lower-wavelength-side of the spectra, which further indicates the presence of two distinct emitting species. Such an intensity decrease suggests that the time scale for the emission mechanisms of the emission component at lower wavelengths is smaller than that of the lower-wavelength emission. The short-lived emission is consistent with a monomer component, whereas the longer-lived and lower-energy emission is compatible with the formation of an excimer.[50,51,53] The excimer emission decay curve was monitored at 568 nm under 330 nm excitation wavelength (not shown). The decay curve is well reproduced by a single exponential function, which yields a lifetime of $4.33 \pm 0.11$ ms.

## Conclusions

Two germanium-$hedp^{4-}$ solids with heteroaromatic amines, 8-hydroxyquinoline (in **I**) and 1,10-phenanthroline (in **II**), have been prepared and characterised by single-crys-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tal XRD, thermogravimetry and FTIR and UV/Vis spectroscopy. High-resolution solid-state NMR spectroscopy has been used to study the complex hydrogen-bonded networks, particularly in compound **I**. Certain details of the crystal structure of **I** have been elucidated, mainly those involving the occurrence of π–π stacking of 8-hydroxyquinoline and the relative orientation of adjacent such molecules. It has been shown that the combination of homonuclear recoupling techniques (2D $^1$H-$^1$H DQF, 2D $^1$H-$^1$H RFDR MAS NMR) and CRAMPS techniques (2D $^1$H-$^1$H FS-LG, $^1$H-$^{31}$P FS-LG) provides a powerful toolbox for the characterisation of organic–inorganic hybrid materials.

Compound **II** displays an emission from the lowest triplet-state energy (π–π* 0-phonon transition) of the aromatic rings, which peaks at ca. 320 nm (31250 cm$^{-1}$) in the range 14 K to room temperature, whereas the triplet emission of complex **I** at ca. 530 nm (18868 cm$^{-1}$) is detected at low temperature. A long-lived and low-energy emission component, resulting from the formation of an excimer state and originating from π···π stacking of 1,10-phenanthroline and hydroxyquinoline residues, was observed for **I** and **II**, respectively.

## Experimental Section

**General:** Chemicals were readily available from commercial sources and were used as received without further purification. Elemental analyses for carbon, hydrogen and nitrogen were performed on a CHNS-932 Elemental Analyser instrument at the University of Aveiro. FTIR spectra were measured by using KBr disks (Aldrich, 99%, FTIR grade) on a Matson 7000 FTIR spectrometer. FT-Raman spectra were measured on a Bruker RFS 100 with a Nd:YAG coherent laser ($\lambda$ = 1064 nm). Thermogravimetric analyses (TGA) were carried out by using a Shimadzu TGA-50 instrument and Differential Scanning Calorimetry (DSC) analyses on a Shimadzu DSC-50 instrument with a heating rate of 5 °C/min under a nitrogen atmosphere with flow rate of 20 cm$^3$/min. PL and time-resolved spectra were recorded between 14 K and room temperature with a TRIAX 320 emission monochromator (Fluorolog-3, Jobin Yvon-Spex) coupled to an R928 Hamamatsu photomultiplier, using the front face acquisition mode.

**Synthesis of (Hhqn)$_6$[Ge$_6$(OH)$_6$(hedp)$_6$]·2(hqn)·33H$_2$O (I):** A suspension of 1-hydroxyethylidenediphosphonic acid (0.200 g, $H_4$hedp, $C_2H_8O_7P_2$, ≥97%, Fluka), germanium(IV) oxide amorphous (0.100 g, $GeO_2$, 99.99%, Aldrich), and 8-hydroxyquinoline (0.140 g, hqn, $C_9H_7NO$, 99%, Merck) in distilled water (ca. 12 g) was stirred thoroughly for 30 min at ambient temperature. The reactive mixture was transferred to a PTFE-lined stainless steel reaction vessel (ca. 40 cm$^3$), which was then placed inside an oven. The temperature was gradually increased to 120 °C and kept constant for 3 d, after which the vessel was cooled slowly to ambient temperature before opening. The resulting light-yellow phase was washed with distilled water, filtered and air dried at ambient temperature. The single-crystalline phase decomposes into a microcrystalline powder during this drying stage. Hence, (Hhqn)$_6$[Ge$_6$(OH)$_6$(hedp)$_6$]·2(hqn)·33H$_2$O samples suitable for single-crystal X-ray diffraction measurements were isolated while still wet directly from the autoclave mother liquor by slow evaporation at ambient temperature for 2 d. Elemental composition (based on single-crystal data for $C_{84}H_{158}Ge_6N_8O_{89}P_{12}$, $M_W$ 3511.36): calcd. C 28.73, N 3.20, H 4.54%; found C 28.87, N 3.08, H 4.51%. TGA data (mass losses): 20–86 °C: 14.2%; 86–155 °C: 3.3%; 155–210 °C: 2.3%; 210–400 °C: 5.5%. DSC peaks (endothermic processes): 76, 103, 184, 258 and 336 °C. Selected IR (KBr pellet) and Raman (in italics inside the parenthesis, cm$^{-1}$) data: $\nu$(HO–H/GeO–H/CO–H, with evidence of H-bonding) = 3430 vs/br., 3254 vs/br., 3093 vs/br. (*3116 w*); $\nu$(aromatic NH$^+$) = 2790 m/br.; $\nu$(C–H, aromatic) = 3093 br. (*3069 m*); $\nu_{as}$(C–H in –CH$_3$) = 2969 br. (*2979 w*, *2937 w*); $\nu_s$(C–H in –CH$_3$) = (*2875 w*); $\delta_s$(CO–H) and $\delta_{as}$(CH$_3$) = 1421 m, 1404 m; $\delta_s$(CH$_3$) = 1384 m (*1385 s*); $\nu$(N$^+$–H) = 2580 br.; $\delta$(–NH$^+$) = 1559 m; $\nu$(P=O) and $\nu$(C–O) = 1187 s and 1169 s (*1314*); $\nu$(C–C, skeletal vibrations) = 1603 m (*1606 m*); $\delta$(O–H, lattice water) = 1635 m (*1634 w*); $\nu$(C–N, heteroaromatic amines) and $\delta$(O–H, aromatic) = 1312 m (*1308 w*, *1279 w*); $\nu$(P–O) = 1010 vs (*1064 m*, *1038 w*); $\gamma$(C–C) = 488 w (*542 w*, *490 m*, *474 m*, *410 m*), various modes; $\gamma$(O–H, under H-bonding) = 976 br./vs; $\gamma$(C–H, aromatic) = 824 m (*716* vs); $\omega$(O–H, under H-bonding) = 583 br./m (*578*) cm$^{-1}$.

**Synthesis of (Hphen)$_6$[Ge$_6$(OH)$_6$(hedp)$_6$]·2(phen)·20H$_2$O (II):** A suspension of 1-hydroxyethylidenediphosphonic acid (0.200 g, $H_4$hedp, $C_2H_8O_7P_2$, ≥97%, Fluka), amorphous germanium(IV) oxide (0.240 g, $GeO_2$, 99.99%, Aldrich) and 1,10-phenanthroline monohydrate (0.190 g, phen, $C_{12}H_8N_2$·$H_2O$, ≥99.0%, Fluka) in distilled water (ca. 16 g) was stirred thoroughly for 30 min at ambient temperature. The reactive mixture was transferred to a PTFE-lined stainless steel reaction vessel (ca. 40 cm$^3$), which was then placed inside an oven. The temperature was gradually increased to 120 °C and kept constant for 3 d, after which the vessel was cooled slowly to ambient temperature before opening. The isolated microcrystalline light-brown phase was washed with distilled water, filtered and air-dried at ambient temperature. Single crystals of (Hphen)$_6$[Ge$_6$(OH)$_6$(hedp)$_6$]·2(phen)·20H$_2$O suitable for X-ray diffraction measurements were harvested from the autoclave mother liquor by slow evaporation at ambient temperature over 1 d. Elemental composition (based on single-crystal data for $C_{108}H_{140}Ge_6N_{16}O_{68}P_{12}$, $M_W$ 3557.54): calcd. C 36.46, N 6.33, H 3.97%; found C 35.47, N 5.46, H 4.20. TGA data (mass losses): 20–125 °C: 10.3%; 125–364 °C: 10.0%. Selected IR (KBr pellet) and Raman (in italics inside the parenthesis, cm$^{-1}$) data: $\nu$(HO–H/GeO–H/CO–H, with evidence of H-bonding) = 3389 vs/br., 3237 vs/br.; $\nu$(aromatic NH$^+$) = 2532 s/br.; $\nu$(C–H, aromatic) = 3062 m (*3066 m*); $\nu_{as}$(C–H in –CH$_3$) = 2932 m (*2990 w*, *2933 w*); $\nu_s$(C–H in –CH$_3$) = 2807 s, 2879 s (*2872 w*); $\delta_{as}$(CH$_3$) = 1452 m, 1469 m (*1452 s*, *1415* vs); $\delta_s$(CH$_3$) = 1373 w (*1373 m*); $\nu$(C–N, heteroaromatic amines) = 1316 m (*1316 w*); $\delta$(CO–H) = 1289 w (*1286 w*); $\nu$(N$^+$–H) = 2532 br.; $\delta$(–NH$^+$) = 1542 s; $\delta$(O–H, lattice water) = 1632 s/br. (*1629 w*); $\nu$(C–C, skeletal vibrations) = 1617 s, 1596 s (*1615 m*, *1596 m*); $\nu$(P=O) and $\nu$(C–O) = 1185 vs/br. (*1189 w*); $\nu$(P–O) = 1053 s (*1045 m*); $\gamma$(C–C) = 487 s, 461 s (*550 w*, *508 w*, *461 w*), various modes; $\gamma$(O–H, under H-bonding) = 971 vs/br., various modes; $\gamma$(C–H, aromatic) = 847 vs, 816 s (*848 w*); $\omega$(O–H, under H-bonding) = 620 vs, 592 vs, 568 vs, various modes (*598 w*) cm$^{-1}$.

CCDC-614629 and CCDC-614630 for **I** and **II** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Thermoanalytical and infrared results and detailed discussion are included. Technical and experimental details on the single-crystal X-ray diffraction, solid-state NMR spectroscopy and photoluminescence studies are also included. Additional structural drawings emphasizing the [Ge$_6$($\mu_2$-OH)$_6$($C_2H_4O_7P_2$)$_6$]$^{6-}$ moiety (and tables containing crystallographic bond lengths and angles), the or-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ganic frameworks and the solvent-accessible cavities are given. Results of a Cambridge Structural Database Survey for typical Ge–O–Ge bonds are presented. Tables summarising hydrogen-bonding geometries for the two compounds and additional NMR spectra [$^{13}C\{^1H\}$ RAMP-CP, $^1H$-$^1H$ FS-LG, $^1H$ MAS (for **II**), 2D $^1H$-$^1H$ RFDR (for **II**), $^1H$-$^{31}P$ FS-LG] are also included.

# Pentacoordination at Germanium by Transannular Bonding of Sulfur or Oxygen in an Eight-Membered Ring: An Experimental and Theoretical Study

**Simplicio González-Montiel,[a] Noemí Andrade-López,[a] Verónica García-Montalvo,[b] Juan Antonio Cogordan,[b] and José G. Alvarado-Rodríguez*[a]**

**Keywords:** Germanium / Hypercoordinate compounds / Structure elucidation / Density functional theory / NBO analysis

Treatment of $L_nGeCl_{4-n}$ with $D(C_6H_4SH)_2$ in the presence of *n*BuLi leads to the formation of the stable compounds $D(C_6H_4S)_2GeL_1L_2$ (for D = S, $L_1$ = Cl, $L_2$ = Ph, **1** and $L_1 = L_2$ = Ph, **3**; for D = O, $L_1$ = Cl, $L_2$ = Et, **4** and $L_1 = L_2$ = Ph, **5**). The $S(C_6H_4S)_2Ge(Ph)Br$ compound (**2**) has been synthesised by halogen exchange from **1** and potassium bromide. X-ray structure determinations of complexes **1**–**5** reveal that the germanium atom acts as an acceptor atom displaying an intramolecular transannular interaction with the chalcogen D atom. The geometry of the pentacoordinate Ge atom in the title compounds is described as distorted trigonal bipyramidal with a 64–31 % distortion displacement. The D→Ge (D = S, O) hypercoordinate interaction was studied by DFT methods using correlation consistent basis sets and relativistic ECP for Ge. NBO analysis showed that this interaction can be explained in terms of the interplay of covalent and Coulombic interactions.

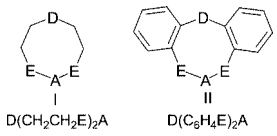
## Introduction

In order to gain a deeper insight into the nature of the secondary bonding[1] and its relation with the hypercoordination phenomena of group 14 and 15 elements, a large variety of metallocanes of type **I** $D(CH_2CH_2E)_2A$ (D = NR′, O, S; E = O, S, $CH_2$; A = Ge, Sn, Pb, As, Sb or Bi) have been prepared and structurally characterised (Scheme 1).[2–8] In the solid state metallocanes usually exhibit a strong 1,5-transannular interaction between a Lewis acidic acceptor A and a basic donor D atom (D→A), where the coordination mode of the ligand $D(CH_2CH_2E)_2^{2-}$ is formally tridentate, leading to an increase in the coordination number of A. In these compounds the richness of the conformational diversity in the solid state and solution is supported by a wide variety of molecular structural features, for example bond lengths, bond angles, torsion angles and the central eight-membered ring conformation, as well as intermolecular interactions in the crystal.[2]

Crystallographic X-ray studies of the more constrained tricyclic systems of type **II**, known as dibenzometallocines $D(C_6H_4E)_2A$ (Scheme 1), have also shown a 1,5-transannular interaction. These compounds have been long studied in particular where D = S, E = O and A is a d block or light p block element (mainly phosphorus and silicon), meanwhile, with a softer donor atom such as D = E = S the chemistry is fully dominated by the d block metals.[9] In these transition metal complexes the transannular distance between the acidic metal centre and the thioether-like sulfur is usually quite short, suggesting the large capabilities of the $S(C_6H_4S)_2^{2-}$ as a tridentate ligand.



Scheme 1.

We have studied some monohalogenated dibenzometallocines $D(C_6H_4S)_2AHal$ (for A = Sb[5], D = S, Hal = Cl, Br, I; D = O, Hal = Cl; for A = As[10], D = S, Hal = Cl, Br, I) and have shown by means of X-ray crystallographic studies (and also DFT studies in the case of antimony) the acidic behaviour of the central atom, where the A acceptor experiences a structural change from pyramidal tricoordinate to $\psi$-trigonal-bipyramidal tetracoordinate. These results prompted us to extend the chemistry of the ligand $S(C_6H_4S)_2^{2-}$ to other p block heavier elements such as germanium(IV), where structural studies with similar ligands are scarce[11–14] and have mainly focused on metallocanes.[2–4]

Here we report an experimental and theoretical study of type **II** complexes with germanium as the acceptor atom. These compounds are good models for further understand-

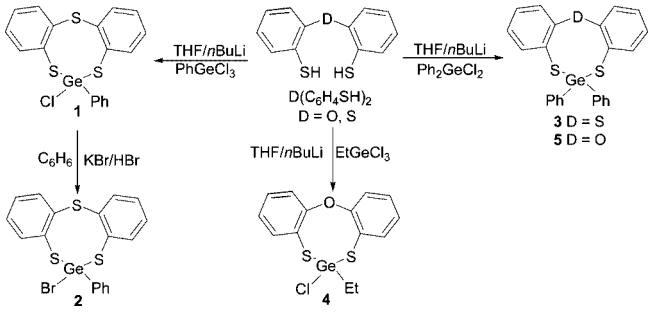
ing the nature of the D→Ge interaction. After the description of the synthesis of dibenzogermocines and the NMR spectroscopic and X-ray crystallographic data a theoretical study is presented and discussed.

## Results and Discussion

### Synthesis

The ligands $S(C_6H_4SH)_2$ and $O(C_6H_4SH)_2$ were prepared following the reported method.[9,15] The reaction of the corresponding organylgermanium(IV) in THF at 0 °C with the dilithium salt of the ligand, generated in situ from the dithiol and 2 equiv. of *n*BuLi, yielded the corresponding $Ge^{IV}$ complex (see Exp. Sect. for details). Treatment of $S(C_6H_4SLi)_2$ with $PhGeCl_3$ and $Ph_2GeCl_2$ yielded $S(C_6H_4S)_2GePhCl$ (**1**) and $S(C_6H_4S)_2GePh_2$ (**3**), respectively. $S(C_6H_4S)_2GePhBr$ (**2**) was synthesised from **1** by the treatment of excess KBr in a refluxing HBr/benzene mixture, giving **2** as colourless crystals. Treatment of $O(C_6H_4SLi)_2$ with $EtGeCl_3$ and $Ph_2GeCl_2$ yielded $O(C_6H_4S)_2GeEtCl$ (**4**) and $O(C_6H_4S)_2GePh_2$ (**5**), respectively (see Scheme 2).



Scheme 2.

All complexes are air-stable, soluble in benzene, toluene, dichloromethane and chloroform, and insoluble in pentane, hexane and 2-propanol.

### Mass Spectra

FAB mass spectra for **1**, **2**, **3** and **5** and electron impact mass spectra for **4** exhibit a low intensity ion with the appropriate isotopic ratio representing the molecular ion ($M^{\cdot+}$); in all cases a basis peak corresponding to the fragment M–L [L = Cl (**1**), Br (**2**), Ph (**3** and **5**), Et (**4**)] is observed and assigned to the $D(C_6H_4S)_2GeL$ [L = Ph (**1**, **2**, **3** and **5**), and Cl (**4**)] tricyclic moiety, confirming the binding of germanium to the sulfur thiolate-like atoms. There are peaks corresponding to the $D(C_6H_4)_2S$ moiety [D = S (**1**, **2**, **3**); O (**4**, **5**)] in all the spectra. In the case of the diphenyl germanium complexes **3** and **5** the cluster peak at 229 *m*/*z* is assigned to the protonated $GePh_2$ fragment. No more peaks could be assigned.

### NMR Spectroscopy

NMR spectra of complexes **1**–**5** were recorded in a $CDCl_3$ solution at room temperature. Chemical shifts are relative to TMS. The assignments of these complexes were carried out by heteronuclear and homonuclear correlation two-dimensional experiments (HETCOR, COLOC and COSY).

$^1$H NMR spectra for complexes **1**–**5** each show four signals for the $DC_6H_4SGe$ moiety in an ABCD pattern, Table 1. In solution the two $DC_6H_4SGe$ halves are equivalent (see Scheme 3). In all complexes, the *ortho* proton 1-H is shifted towards high frequencies with respect to the free

neutral ligands.[9,15] In **4** and **5** the *ortho* proton, 4-H, is also observed at higher frequencies.

Proton decoupled $^{13}C$ spectra of complexes **1**–**3** and **5** display ten signals in the aromatic region, Table 2. In **4** the ethyl group is observed at low frequencies (23.1 and 8.3 ppm). In complexes **1**–**5** the values obtained for the variation of the chemical shift ($\Delta\delta$) with respect to the starting materials (free ligands and organogermanium chlorides) show the ipso carbon C-4a and the carbon C-4 at high frequencies; in these compounds the **1**–**3** complexes present large values of $\Delta\delta$. The $\Delta\delta$ value for the C-4a and C-4 in **1** are 8.2 and 4.0 ppm; in **2** they are 8.2 and 4.1 ppm; in **3** they are 7.3 and 4.7 ppm; in **4** they are 0.6 and 1.6 and in **5** they are 2.7 and 2.0 ppm, respectively. In the double phenylated **3** and **5** complexes the $\Delta\delta$ for the ipso carbon C5a presented the smallest values when compared to the diphenylgermanium dichloride ($\delta$ =3.7 ppm in **3** and 1.9 ppm in **5**). The data obtained suggest that the D→Ge transannular interaction in the complexes **3** and **5** is either very weak or completely lacking in solution.

### X-ray Structures of Compounds 1–5

The molecular structures in the crystalline solid state of **1**–**5** were determined by single-crystal X-ray diffraction analyses. The ORTEP drawings are depicted in Figure 1 and selected bond lengths, angles and torsion angles are

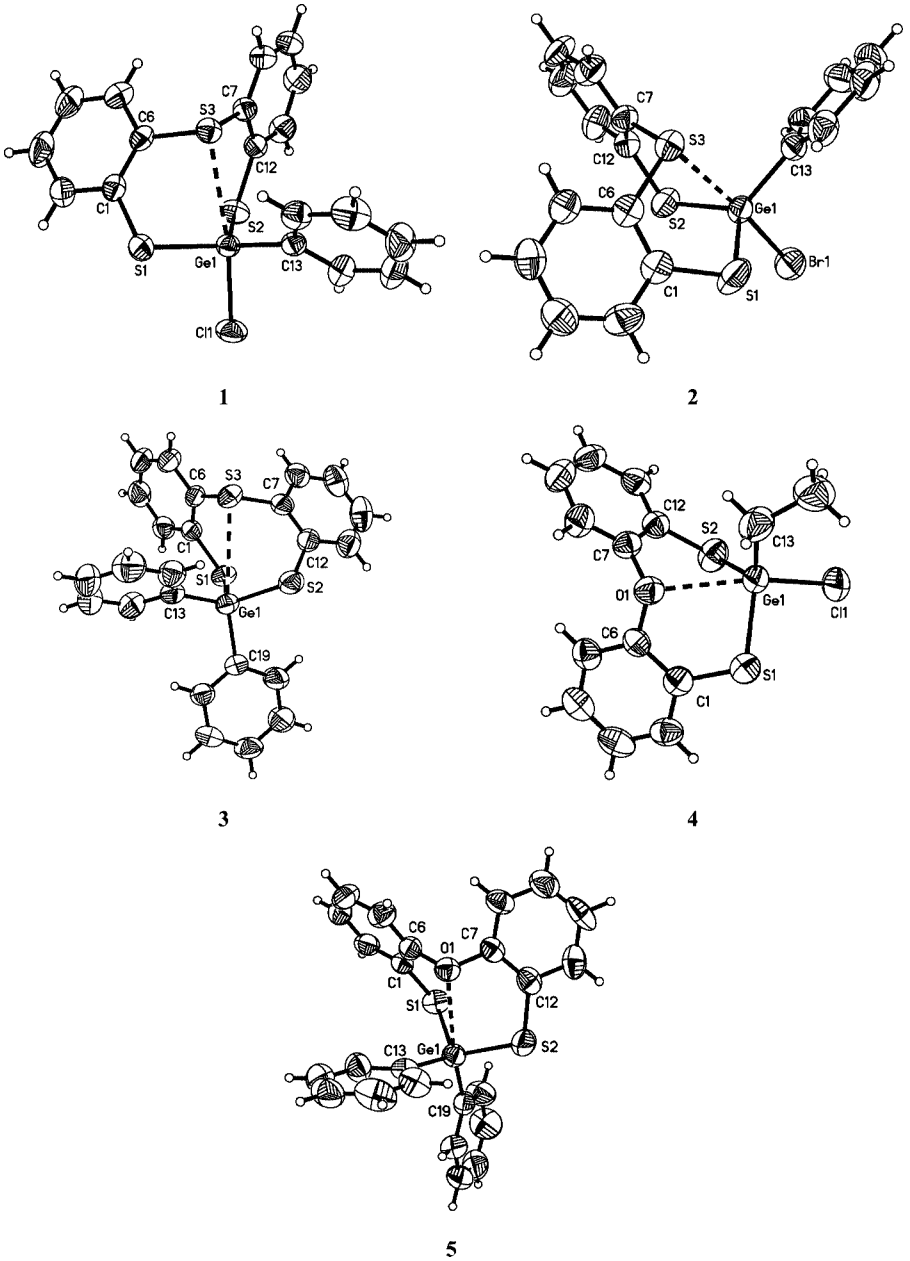

Figure 1. ORTEP diagrams of $S(C_6H_4S)_2GePhCl$ (**1**), $S(C_6H_4S)_2GePhBr$ (**2**), $S(C_6H_4S)_2GePh_2$ (**3**), $O(C_6H_4S)_2GeEtCl$ (**4**) and $O(C_6H_4S)_2GePh_2$ (**5**) (50% probability ellipsoids).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

given in Table 3. In all compounds, there were no intermolecular interactions between non-hydrogen atoms that were separated by a distance shorter than the sum of their van der Waals radii. This essentially resulted in monomeric molecules.

In all complexes, the Ge–S(thiolate) distances are in good agreement with those reported for eight-membered heterocycles and several other compounds containing germanium–sulfur bonds: 2.191(3) Å in $S(CH_2CH_2S)_2GeCl_2$,[16] 2.154(4)–2.217(4) Å in $O(CH_2CH_2S)_2GeCl_2$,[17] 2.216(1)–2.222(1) and 2.210(3)–2.236(3) Å in the spirocycles $\{O(CH_2CH_2S)_2\}_2Ge$ and $\{S(CH_2CH_2S)_2\}_2Ge$,[18] respectively, 2.111(1)–2.221(1) Å in the homoleptic Ge(S-4-$MeC_6H_4)_4$ compound,[19] but significantly shorter than the reported value in the spirocycle $\{PhP(C_6H_4S)_2\}_2Ge$ with a germanium atom in an octahedral local geometry [2.3429(12)–2.4000(10) Å].[11] The Ge–Cl distances in **1** and **4** are 6 and 4% longer, respectively, than that accepted as the common distance for Ge–Cl (2.10 Å in $GeCl_4$)[20] and similar to those found for $D(CH_2CH_2S)_2GeCl_2$ (D = O[17], S[16]); which are longer than that found in the 9,9-dichloro-9-germafluorene [2.1660(9) Å].[21] The Ge–Br distance is 4% longer than that observed for $GeBr_4$ (2.30 Å)[20] and intermediate between those found in $MeN(CH_2CH_2O)_2GeBr_2$ [2.4148(8) and 2.3215(9) Å].[4] The Ge–C distances are in good agreement with other compounds that contain germanium–carbon bonds.[12,22–24]

In addition to the expected bonding of the two sulfur atoms (thiolate-like) and the two exocyclic $L_1$ and $L_2$ ligands to germanium, a relatively short distance involving the transannular D and Ge atoms is observed (D = S in **1**, **2** and **3**; D = O in **4** and **5**). The S→Ge bond lengths in **1**, **2** and **3** are 2.834(1), 2.782(2) and 3.280(1) Å, respectively, which are 27, 24 and 46% longer than the covalent radii sum of Ge and S (2.24 Å)[25] but significantly shorter than the van der Waals radii sum (3.75 Å).[1,14] The magnitude of these distances is consistent with the existence of a secondary bonding.[1] These S→Ge distances in **1**, **2** and **3** are similar for the spirocycles $S(CH_2CH_2S)_2GeSO(C_2H_4)$ [2.842(1) Å],[2] $[S(CH_2CH_2S)_2]_2Ge$ [3.237(3) and 3.453(3) Å],[18] and $S(CH_2CH_2S)_2GeCl_2$ [3.01(3) Å],[16] and significantly longer than that reported for the spirocycle $[S(C_6H_4O)_2]_2Ge$ [2.447(1) Å].[14]

The O→Ge distances in **4** [2.656(3) Å] and **5** [2.872(3) Å] are significantly shorter than the van der Waals radii sum of Ge and O (3.47 Å)[1] and 41% and 53% longer than the covalent radii sum (1.88 Å),[2,25] respectively. The observed O→Ge bond lengths in **4** and **5** are significantly longer than those reported for $O(CH_2CH_2S)_2GeCl_2$ [2.36(1) and 2.39(1) Å],[17] for the spirocycles containing pentacoordinate germanium $O(CH_2CH_2S)_2GeSO(C_2H_4)$ [2.492(3) Å] and $O(CH_2CH_2S)_2GeS_2(C_2H_4)$ [2.616(1) Å], and shorter than those reported for the spiro compound containing hexacoordinate germanium $[O(CH_2CH_2S)_2]_2Ge$ displaying two crystallographic independent molecules in the solid state [2.914(3), 3.040(3), 2.955(3) and 2.946(3) Å][18]. If the transannular interaction (D→Ge) is taken into account, the geometry of the coordination sphere of the germanium atom can be described as trigonal bipyramidal (TBP), where the halogen (for **1**, **2** and **4**), carbon (for **3** and **5**) and D donor atoms (S for **1**, **2**, **3**, O for **4**, **5**) are in the axial positions, meanwhile the two thiolate-like sulfur and carbon atoms occupy equatorial positions.

Following the Holmes procedure based on the donor-acceptor atom bond length,[26–28] the degree of displacement at the Ge atom from tetrahedral to trigonal-bipyramidal geometry (TBP) was determined. Additionally and in order to evaluate the magnitude of the interaction based

Table 4. Comparison of D→Ge–$L_1$ geometrical bond parameters in complexes **1**–**5**; bond lengths [Å], bond angles [°], % TBP and Pauling bond order.

| Compound | D | $L_1$ | $L_2$ | D→Ge | D→Ge–L1 | % TBP | $\Delta d$[a] | BO[b] D→Ge |
|---|---|---|---|---|---|---|---|---|
| **1** | S | Cl | Ph | 2.834(1) | 169.57(4) | 60.7 | 0.594 | 0.1453 |
| **2** | S | Br | Ph | 2.782(2) | 175.99(4) | 64.1 | 0.542 | 0.1721 |

[a] Bond widening, $\Delta d = (d_{exp} - \Sigma r_{cov})$, according to standard bond lengths $d$(Ge S) 2.24, $d$(Ge O) 1.88.[1,2,14,25] [b] Mode of calculation $BO = 10^{-(1.41 \cdot \Delta d)}$.[29,30]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

on the distances, the Pauling-type bond order, BO, for the transannular interactions (D→Ge) in all compounds was also calculated.[29,30] These results are reported in Table 4.

The TBP% for halogen compounds are larger than those for other compounds in the series, indicating the importance of attaching an electronegative ligand to germanium in order to expand its coordination number.

In all compounds the eight-membered ring conformation can be described as a twist boat ($C_1$ symmetry) according to the torsion angle data, where the double phenylated **3** and **5** compounds are most distorted when the TBP and BO order are smaller.

## Theoretical Study

In order to study the intramolecular interactions (D→Ge) we carried out theoretical calculations. Hence, each one of the compounds **1**–**5** was modelled with a GaussView visualizer,[31] followed by a geometry optimisation with the PM3 semi-empirical method[32]. A further geometry optimisation was carried out with density functional theory (DFT) using the hybrid B3LYP functional[33]. For our DFT computations we employed the relativistic Stuttgart-Dresden Effective Core Potential for Ge[34] along with its Triple-Zeta correlation consistent basis set[35]. For all the other atoms in compounds **1** to **5**, Dunning's Double-Zeta correlation consistent all electron basis set[36] was used. The basis sets we employed include polarisation and diffusion functions. Hereafter these calculations will be referred to as B3LYP ccSDDTZ. The computed bond orders, interatomic overlaps and charges reported herein were computed within the NBO approach.[37] All our calculations were carried out with the suite of programmes in Gaussian 03.[38]

## Theoretical Results and Discussion

All optimised molecular conformations for **1**–**5** are in good agreement when compared with those observed by X-ray crystallographic data. A selected set of bond lengths and bond and torsion angles is listed in Table 5. It is relevant to mention that we explored the two possible geometrical isomers for complexes **1**, **2** and **4**, i.e. those with the halogen ligand in an axial or in an equatorial position, where isomers that resemble the conformation determined by X-ray diffraction experiments were the most stable. These correspond to the lowest energy conformation of those obtained with the procedure previously outlined. A comparison between the X-ray and the computed D–Ge bond lengths shows a remarkable difference for compounds **1**, **2** and **3**. The largest difference is for compound **2** (≈0.39 Å), followed by that of compounds **1** and **3**, ≈0.32 Å and ≈0.05 Å respectively, whereas for compounds **4** and **5** we noticed that the distances O→Ge are ca. 0.13 Å and 0.07 Å larger than those obtained by X-ray spectroscopy at 298 K. The DFT calculations at the level employed reproduce well the experimental overall geometries; the observed differences in the geometrical parameters are not unusual[3] and may be due to the temperature of the diffraction experiments as well as the packing forces in the crystal.

## NBO Analysis

In Table 6 the computed Wiberg bond index values for a selected number of atoms in compounds **1**–**5** are reported. It is worth noting that this index has approximately the same value for all germanium–sulfur thiolate bonds. However, in **1**–**3** this bond index is bigger for the S(thiolate-

Table 5. Selected bond lengths [Å] and angles [°] for compounds **1**–**5**. **a** columns are data from X-ray characterisation. **b** columns are data obtained from B3LYP ccSDDTZ computations.

To study the nature of this short Wiberg bond index, the computed overlap-weighted natural atomic orbital values are reported in Table 7. From this table it is possible to observe that compounds **1**–**3**, which contain the S→Ge interaction, have larger overlap values than compounds **4** and **5**, which contain the O→Ge interaction. It is important to observe that **3** and **5** exhibit the smallest overlap value in these two groups of molecules.

Table 7. NBO computed overlap-weighted natural atomic orbital values for compounds **1**–**5**. Data from computations with B3LYP cc-SDDTZ basis sets.

As a final element for our theoretical analysis we report, in Table 8, the charges obtained within the NBO procedure. It may be observed that the sulfur donor atoms in compounds **1**–**3** exhibit approximately the same positive charge, whereas the thiolate-like sulfur atoms roughly have the same negative charge. This may be a consequence of the different environments of the sulfur atoms in the dibenzotrithiagermocines: atoms S1 and S2 are dicoordinate and covalently bonded to a rather electropositive germanium atom while the S3 atom is bonded to a more electronegative carbon atom and also shares its electron density with the acidic germanium(IV) atom. The O1 atom in **4** and **5** has the same negative charge, according to the electronegativity of oxygen.

Table 8. Selected atom charges obtained within the NBO procedure for compounds **1**–**5**. Computations with B3LYP cc-SDDTZ basis sets.

## Discussion

The calculated Wiberg bond index values in Table 6 show the existence of a bond interaction between the D→Ge (where D = S or O) in compounds **1** to **5**. The reported numerical values in Table 7 for the NAO overlap-weighted analysis confirm this bond possibility and give it a covalent like character. However, the reported atomic charges in Table 8 suggest the possibility of interatomic interactions with a Coulombic character.

We may conclude that the interaction S3→Ge in **1** and **2** has two components: one covalent and a second one with a Coulombic character. In these two compounds the interaction is dominated by a covalent interaction, which screens the positive–positive S3–Ge Coulomb interaction. This behaviour is enhanced by the halogen atom coordinated to Ge and its role in the Coulomb field within the molecule. Similar arguments may be given to the O1→Ge interaction in **4**. However, in this case, the negative charge on the oxygen donor atom increases the intensity of the Coulomb field making this the dominant part of this interaction.

In compounds **3** and **5** we have the opportunity to appreciate how this covalent-Coulombic dual character works. In this case we do not have halogen atoms to enhance the interchange. Hence S3→Ge in **3** has a more covalent than Coulombic character, whereas O1→Ge is dominated by a strong Coulomb interaction, which makes their intramolecular distances shorter supporting the results of the structural analyses in terms of our TBP and BO analyses for these complexes.

## Conclusions

In order to study the phenomena of hypercoordination in germanium heterocyclic compounds we have synthesised and fully structurally characterised five new dibenzogermocines **1**–**5** by employing tridentate $[D(C_6H_4S)_2]^{2-}$ ligands. All compounds exhibit a bipyramidal-trigonal local geometry of the germanium(IV) atom with intramolecular interactions D→Ge. Geometry optimisations at the DFT level of theory, using the hybrid functional B3LYP renders molecular conformations in good agreement to those determined by X-ray diffraction studies. An NBO analysis was carried out on this electron structure. The TBP and BO analysis

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for the crystalline molecular structure and our NBO analysis show similar behaviour for the D→Ge interaction, which is enhanced by the presence of the halogen ligands.

## Experimental Section

**General Procedures:** All manipulations were performed under a dry, oxygen-free argon atmosphere using standard Schlenk techniques. Solvents were dried by standard methods and distilled prior to use. Melting points were determined with a Melt-Temp II instrument and are uncorrected. Spectra were recorded with the following instruments. Mass spectra: FAB-mass spectra were recorded with a JEOL JMS-AX505HA by using a Xe beam at 6 keV, with nitrobenzyl alcohol (NBA) as matrix. For EI, a Hewlett Packard 5989A mass spectrometer was used. Elemental analyses: Perkin–Elmer Series II CHNS/O Analyser. The IR spectra were record in the 4000-400 $cm^{-1}$ range with a Perkin–Elmer System 2000 FT-IR spectrometer, as KBr pellets. NMR: Jeol Eclipse 400 spectrometer; with the residual protio-solvent signal used as referenced for $^1H$ NMR spectra. $^{13}C\{^1H\}$ NMR spectra were referred through the solvent peaks. Chemical shifts are quoted on the $\delta$ scale (downfield shifts are positive) relative to tetramethylsilane ($^1H$, $^{13}C\{^1H\}$ NMR spectra). Spectra were recorded at 25 °C. $^1H$ NMR spectra; 399.78 MHz, $^{13}C\{^1H\}$ NMR spectra; 100.53 MHz. $S(C_6H_4SH)_2$[15] and $O(C_6H_4SH)_2$[9] were synthesised according to literature methods. $PhGeCl_3$, $Ph_2GeCl_2$, $EtGeCl_3$, *n*BuLi (1.6 M, in hexanes), KBr and HBr were purchased from Aldrich and Fluka and were used as supplied.

**$S(C_6H_4S)_2GePhCl$ (1):** *n*BuLi in hexanes (1.6 M, 5.5 mL, 8.8 mmol) was added to a solution containing $S(C_6H_4SH)_2$ (1.0 g, 4.0 mmol) in THF (40 mL) at 0 °C. After the solution was stirred for 30 min, a red solution resulted, $PhGeCl_3$ (0.66 mL, 4.0 mmol) was added via a syringe. The solution was kept overnight at room temperature. The colourless solution was refluxed for 4 h, and then the resultant heterogeneous reaction mixture was cooled to room temperature. The precipitate of LiCl was removed by filtration. Volatiles were removed under an argon flow to provide colourless crystals of **1**, which were washed with hexanes (40 mL) and filtered by suction. Yield: 1.50 g (86%). Mass spectrum (FAB+) *m*/*z* (rel int) = 434 (5) [$M^+$], 399 (50) [$M^+$ – Cl], 216 (45) [$M^+$ – Cl–PhSGe]. M.p. 201–203 °C. $S(C_6H_5S)_2GePhCl$: calcd. C 49.56, H 3.22; found C 49.76, H 3.20. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.16 (ddd, $^3J_{3\text{-H},2\text{-H}} = {}^3J_{3\text{-H},4\text{-H}}$ = 7.74, $^4J_{3\text{-H},1\text{-H}}$ = 1.44 Hz, 2 H, 3-H), 7.27 (ddd, $^3J_{2\text{-H},1\text{-H}} = {}^3J_{2\text{-H},3\text{-H}}$ = 7.74, $^4J_{2\text{-H},4\text{-H}}$ = 1.44 Hz, 2 H, 2-H), 7.40 (m, 3 H, 6-H and 7-H), 7.44 (dd, $^3J_{4\text{-H},3\text{-H}}$ = 7.74, $^4J_{4\text{-H},2\text{-H}}$ = 1.44 Hz, 2 H, 4-H), 7.65 (dd, $^3J_{1\text{-H},2\text{-H}}$ = 7.74, $^4J_{1\text{-H},3\text{-H}}$ = 1.44 Hz, 2 H, 1-H), 7.81 (m, 2 H, 5-H) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 127.5, 128.9, 129.9, 130.9, 131.1, 131.2, 132.2, 134.2, 140.7, 141.5 ppm. IR (KBr pellet): $\tilde{\nu}$ = 3045, 1568, 1480, 1445, 1430, 1247, 1078, 1040, 1032, 851, 754, 733, 714, 689, 657 $cm^{-1}$.

**$S(C_6H_4S)_2GePhBr$ (2):** $S(C_6H_4S)_2GePhCl$ (**1**, 0.26 g, 0.60 mmol), KBr (0.18 g, 1.5 mmol) and HBr 48% (2 mL) were suspended in benzene (25 mL) and refluxed for 16 h. The water was removed from the resulting colourless solution by means of a Dean–Stark trap. The solution obtained was dried by means of a column of Celite and $Na_2SO_4$. The solution was left under an argon flow to provide colourless crystals of **2**, which were washed with hexanes (40 mL) and filtered by suction. Yield: 180 mg (63%). Mass spectrum (FAB+) *m*/*z* (rel int) = 478 (3) [$M^+$], 399 (50) [$M^+$ – Cl], 216 (20) [$M^+$ – Cl – PhSGe]. M.p. 197–199 °C. $S(C_6H_5S)_2GePhBr$: calcd. scaled, sorted and averaged using the SMART software package. The structures were solved by direct methods, using SHELXTL NT Version 5.10 and refined by full-matrix least-squares against $F^2$.[39] An empirical absorption correction based on the multiple measurement of equivalent reflections was applied by using the programme SADABS.[40] The displacement parameters of non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were kept fixed with a common isotropic displacement parameter. Selected crystallographic data are given in Table 9.[41]

# Synthesis, Solid-State Structures, and EPR Spectroscopic Studies on Polycrystalline and Single-Crystal Samples of α-Diimine Cobalt(II) Complexes

**Vítor Rosa,[a] Pablo J. Gonzalez,[a] Teresa Avilés,*[a] Pedro T. Gomes,[b] Richard Welter,*[c] Alberto C. Rizzi,[d] Mario C. G. Passeggi,[d,e] and Carlos D. Brondino*[d]**

**Keywords:** Cobalt(II) complexes / α-Diimine ligands / Single-crystal X-ray diffraction / EPR spectroscopy

Cobalt compounds of the general formula [$CoX_2$(α-diimine)], where X = Cl or I and the α-diimines are 1,4-diaryl-2,3-dimethyl-1,4-diaza-1,3-butadiene (Ar-DAB) and bis(aryl)-acenaphthenequinonediimine (Ar-BIAN) were synthesized by the direct reaction of the anhydrous cobalt salts $CoCl_2$ or $CoI_2$ and the corresponding α-diimine ligand in dried $CH_2Cl_2$. The synthesized compounds are [Co(Ph-DAB)$Cl_2$] (**1a**), [Co(*o*,*o*′,*p*-$Me_3C_6H_2$-DAB)$Cl_2$] (**1b**), and [Co(*o*,*o*′-$iPr_2C_6H_3$-DAB)$Cl_2$] (**1c**) with the ligands Ar-DAB, and also [Co(*o*,*o*′,*p*-$Me_3C_6H_2$-BIAN)$I_2$] (**2′b**) with the ligand Ar-BIAN. The crystal structures of all the compounds were solved by single-crystal X-ray diffraction. In all cases the cobalt atom is in a distorted tetrahedron, which is built up of two halide atoms and two nitrogen atoms of the α-diimine ligand. X-band EPR measurements of polycrystalline samples performed on compounds **1b**, **1c**, and **2′b** indicate a high-spin $Co^{II}$ ion ($S$ = 3/2) in an axially distorted environment. Single-crystal EPR experiments on compounds **1b** and **1c** allowed us to evaluate the orientation of the ***g*** tensor in the molecular frame.

## Introduction

Cobalt is a 3d transition metal element that has been extensively studied over the last decades. Interest in cobalt compounds arises from their participation in many different processes, from industrial and technological applications as catalysts to the essential role in several biological systems of central importance in nature.[1–5]

A large number of late transition metal complexes bearing α-diimine[6] ligands have been extensively studied in the commercial production of polyolefin from ethene and propene.[7,8] However, reports on cobalt complexes containing this type of ligands are still scarce.[9] Recently, some results from the insertion polymerization of ethylene have been reported using tetrahedral $Co^{II}$ complexes with related ligands.[10] α-Diimine ligands have also been the subject of different studies regarding the relative binding strengths,[11] as well as their reactivity with main group metals.[12]

Less information exists about the magnetic properties of these types of compounds. The $Co^{II}$ ions can be present in two different spin configurations (high, $S$ = 3/2 or low, $S$ = 1/2), but in general they adopt the high-spin configuration when they are in distorted coordination environments. A large amount of work has focused on the study of the magnetic properties of $Co^{II}$ compounds in different coordination environments, some of them analyzing $Co^{II}$ in metalloproteins and compounds of biological interest.[13–19] Most of them have involved EPR spectroscopic studies on powder or frozen solutions and the evaluation of thermodynamic properties such as magnetic susceptibility and magnetization. In contrast, only a small amount of work related to high-spin $Co^{II}$ compounds having a low symmetry has been devoted to the study of the correlation between the principal values and directions of the ***g*** tensor.[20–24] This type of information, which can be only obtained from oriented single-crystal EPR spectroscopic experiments, is essential to understand the electronic and magnetic properties of the systems containing $Co^{II}$ ion complexes.

We report herein the synthesis and characterization of a series of $Co^{II}$ complexes of general formula [$CoX_2$(α-diimine)], where X = Cl or I and the α-diimines are 1,4-diaryl-2,3-dimethyl-1,4-diaza-1,3-butadiene (Ar-DAB) or bis(aryl)acenaphthenequinonediimine (Ar-BIAN), namely, [Co(Ph-DAB)$Cl_2$] (**1a**), [Co(*o*,*o*′,*p*-$Me_3C_6H_2$-DAB)$Cl_2$] (**1b**), [Co(*o*,*o*′-*i*$Pr_2C_6H_3$-DAB)$Cl_2$] (**1c**), and [Co(*o*,*o*′,*p*-$Me_3C_6H_2$-BIAN)$I_2$] (**2′b**). Their crystal structures were solved by single-crystal X-ray diffraction. Powder samples

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of compounds **1b**, **1c**, and **2′b** were studied by EPR spectroscopy. Compounds **1b** and **1c** were also studied by single-crystal EPR spectroscopy. The EPR spectroscopic results obtained from both powder and single-crystal samples were correlated with the structures of the compounds.

## Results and Discussion

### General Characterization of the Compounds

The reaction of equimolar quantities of $CoX_2$, where X = Cl or I, and α-diimine ligands in dried $CH_2Cl_2$ at room temperature yields crystalline solids of compounds of the general formula [Co(α-diimine)$X_2$] in c.a. 75 to 85% yield (Scheme 1).

Elemental analyses, mass spectrometry, IR, X-ray, and EPR spectroscopy were used to characterize all of the synthesized compounds. The analytical data of the synthesized compounds are shown in Table 1.

The IR spectra of the cobalt complexes recorded as Nujol mulls display medium absorption bands in the region $\tilde{\nu}$ = 1643–1621 $cm^{-1}$, this is the absorption region for $\nu$(C=N). Bands assigned to C=N stretching vibrations of the free ligand were observed in the region $\tilde{\nu}$ = 1674–1633 $cm^{-1}$. The bands in the complexes are shifted to lower wavenumbers, which is a criterion for the coordination of both diimine nitrogen atoms of the α-diimine ligands to the cobalt(II) ion. Selected IR absorption bands are displayed in Table 2.

Table 2. Selected IR data in Nujol mulls (values of $\tilde{\nu}$ given in $cm^{-1}$).

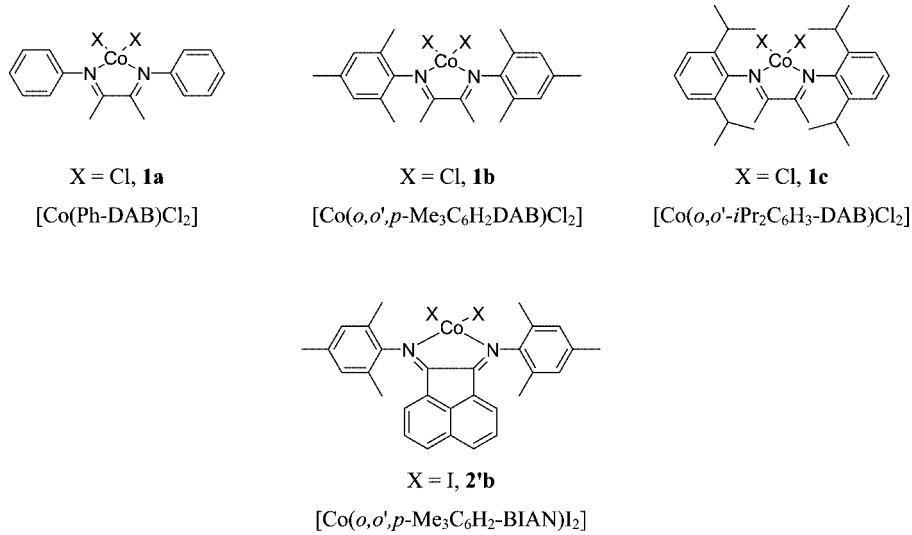
### Crystal Structure Descriptions

#### *Complex 1a*

The complex **1a** crystallizes in an orthorhombic space group $P2_12_12_1$. An ATOMS[25] view of the asymmetric unit of the crystal structure is shown in Figure 1. The cobalt atom is in a deformed tetrahedron, which is built up of two chloride atoms and two nitrogen atoms of the ligand [Co–Cl1: 2.214(1) Å; Co–Cl2: 2.210(1) Å; Co–N1: 2.043(4) Å;



Scheme 1. Synthesized complexes.

Table 1. Analytical data.

| | Molecular mass [g mol$^{-1}$]; Molecular formula | MS(FAB) $m/z$[a] | Microanalysis (calcd.) [%] C | H | N | Color |

Co–N2: 2.034(4) Å; Cl1–Co–Cl2: 119(1)°; N1–Co–N2: 80(1)°]. The [Co–N1–C1–C3–N2] plane is strictly planar [maximum deviation from least-squares plane is 0.007(5) Å] and makes an angle of 56(1)° with both phenyl groups ([C5–C10] and [C11–C16]). No hydrogen bonds have been found in this crystal structure.

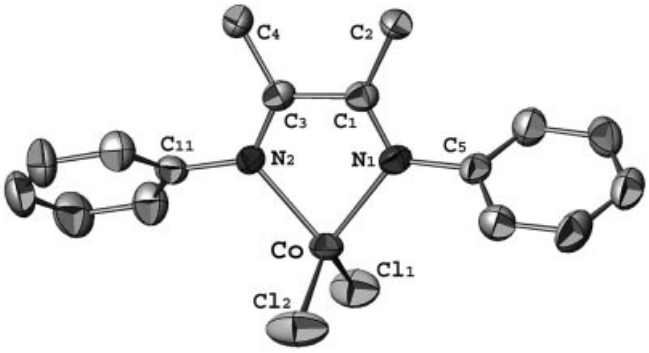

Figure 1. Molecular structure of complex **1a** (ATOMS view) with partial labeling scheme. The hydrogen atoms are omitted for clarity. The thermal ellipsoids enclose 50% of the electronic density.

### *Complex 1b*

The complex **1b** crystallizes in a monoclinic space group $P2_1/c$. An ATOMS view of the asymmetric unit of the crystal structure is shown in Figure 2. In this case again, the cobalt atom is in a deformed tetrahedron [Co–Cl1: 2.224(1) Å; Co–Cl2: 2.212(1) Å; Co–N1: 2.050(3) Å; Co–N2: 2.051(3) Å; Cl1–Co–Cl2: 113(1)°; N1–Co–N2: 80(1)°]. Two nonclassical intermolecular hydrogen bonds have been detected (PLATON software[26]) between C3 and Cl2 [H3B–CL2: 2.75(1) Å; C3–Cl2: 3.68(1) Å; C3–H3B–Cl2: 160(1)°] and C3 and Cl1 [H3C–CL1: 2.81(1) Å; C3–Cl1: 3.78(1) Å; C3–H3C–Cl1: 169(1)°]. The angle between both phenyl groups is 14(1)° and these groups are perpendicular to the central plane [Co–N1–C1–C2–N2] [maximum deviation from least-squares plane is 0.035(2) Å] with angles of 88(1)° and 90(1)°, respectively.

### *Complex 1c*

The complex **1c** crystallizes in an orthorhombic space group *Pnma*. An ATOMS view of the asymmetric unit of the crystal structure is shown in Figure 3. The deformed tetrahedral site around the Co atom is characterized by the following distances and angles: Co–Cl1: 2.197(2) Å; Co–Cl2: 2.201(1) Å; Co–N: 2.050(3) Å Cl1–Co–Cl2: 113(1)°; N1–Co–N2: 80(1)°. Compared to that observed in both the previous structures, the plane containing the Co atom is not well fitted by the least-squares planes calculation (SHELXL-97)[27] with a maximum deviation from the plane of 0.112(3) Å for both nitrogen atoms. This pseudo plane makes an angle of 87(1)° with both phenyl groups (identical by symmetry), the latter are tilted with an angle of 15(1)°, one compared to the other. At least two nonclassical intramolecular hydrogen bonds have been detected (PLATON software) between C9 and N [H9–N: 2.43(1) Å; C9–N: 2.94(1) Å; C9–H9–N: 111(1)°] and C12 and N [H12–N: 2.38(1) Å; C12–N: 2.88(1) Å; C12–H12–N: 110(1)°].

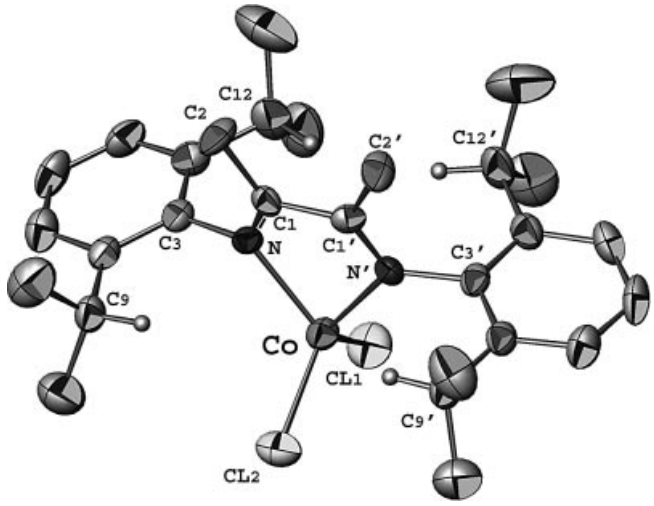

Figure 3. Molecular structure of complex **1c** (ATOMS view) with partial labeling scheme. The hydrogen atoms are omitted for clarity. The thermal ellipsoids enclose 50% of the electronic density. Operators for generating equivalent atoms: $x, y, -z+3/2$.

### *Complex 2′b*

The complex **2′b** crystallizes in an orthorhombic space group *Pcca*. An ATOMS view of the asymmetric unit of the crystal structure is shown in Figure 4. The deformed tetrahedral site around the Co atom is characterized by the

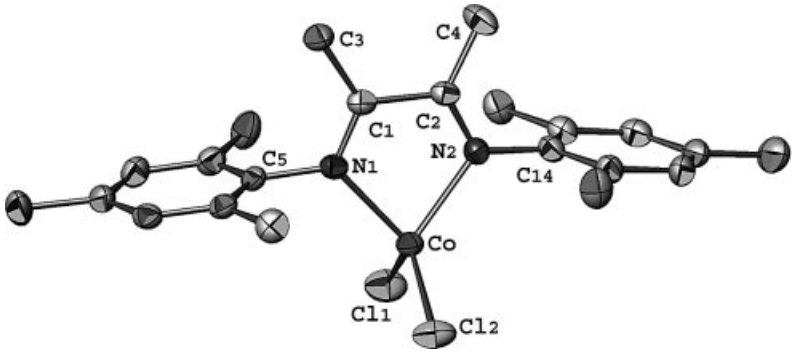

Figure 2. Molecular structure of complex **1b** (ATOMS view) with partial labeling scheme. The hydrogen atoms and the solvent molecules ($CH_2Cl_2$) are omitted for clarity. The thermal ellipsoids enclose 50% of the electronic density.

following distances and angles: Co–I: 2.509(1) Å; Co–N: 2.05(1) Å; I–Co–I′: 111(1)°; N–Co–N′: 82(1)°. The angle between both phenyl groups is 14(1)° and these groups make an angle of 85(1)° with the central plane [Co–N–C1–C1′-N′] [maximum deviation from least-squares plane is 0.001(4) Å]. It is important to note that the molecule of complex **2′b** is placed on a crystallographic mirror i.e. the following atoms are on the mirror (see Figure 4): Co, N, C8, C1, C2, C4, C5, C6, C7 and the corresponding equivalent atoms by the following symmetry operator: $-x$, $y$, $-z + 1/2$. No H bond has been detected in the case of this crystal structure. No H bond has been detected in the case of this molecular structure.

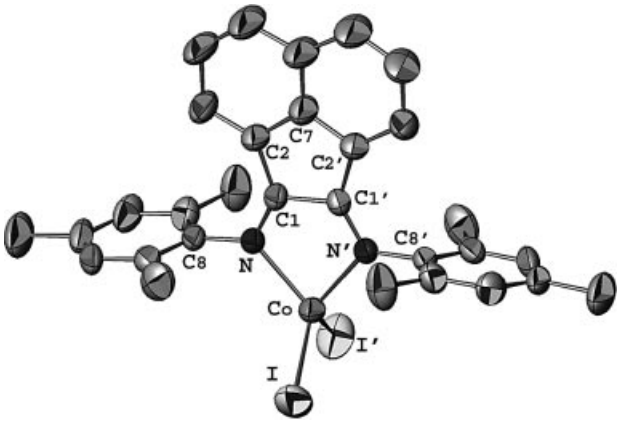

Figure 4. Molecular structure of complex **2′b** (ATOMS view) with partial labeling scheme. The hydrogen atoms and the solvent molecules ($CH_2Cl_2$) are omitted for clarity. The thermal ellipsoids enclose 50% of the electronic density. Operators for generating equivalent atoms: $-x$, $y$, $-z+1/2$.

## EPR Measurements

The X-band EPR spectra of polycrystalline samples of compounds **1b**, **1c**, and **2′b** and their simulations are shown in Figure 5. The peaks broaden at higher $T$ and disappear at ca. 50 K. The hyperfine structure expected for the 100% abundant $^{59}$Co isotope ($^{59}I = 7/2$) is not observed in any of the spectra of the powder samples. The values of the g factors $g_1$, $g_2$, and $g_3$ are given in Table 3 and are typical for $Co^{II}$ ions with a high spin $S = 3/2$ configuration.[17] The EPR spectrum obtained for compound **1a** (data not shown) is also compatible with a $Co^{II}$ ion in a high-spin configuration, however, a broad signal detected in the range 500–8000 Gauss and overlapping the $Co^{II}$ ion transitions precluded the interpretation.

In a purely tetrahedral environment, $Co^{II}$ has the orbital singlet $A_2$ at lowest energy,[13,14] and since $S = 3/2$, there is a fourfold spin degeneracy. As for compounds **1b**, **1c**, and **2′b** the sites are distorted, the fourfold spin degeneracy is lifted into two Kramers doublets. If the distortion is high enough ($>>kT$) to neatly separate both doublets and the experiments are performed at low temperatures, then the observed spectra can be assigned to transitions between the states of the lowest $S' = 1/2$ spin doublet, which is expected

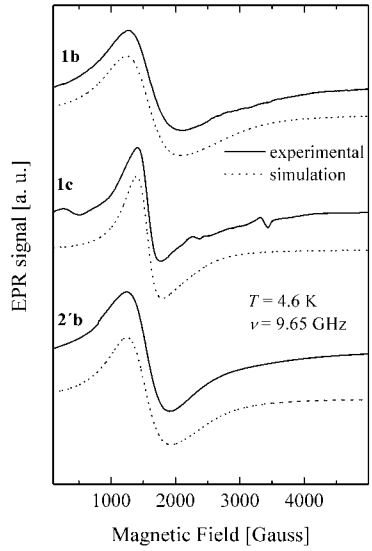

Figure 5. EPR spectra of powdered samples of compounds **1b**, **1c**, and **2′b** together with simulations. The EPR parameters obtained from simulation are given in Table 3. For compound **1c**, the peak at ≈3300 Gauss corresponds to $Cu^{II}$ impurities whereas the peak at ≈500 Gauss corresponds to a cavity background.

Table 3. EPR parameters obtained from powder and single-crystal samples for **1b**, **1c**, and **2′b**. Linewidths ($\Delta B$) are in Gauss. The components of the crystal $g$ tensors are expressed in the $abc^*$ ($c^* = a \times b$) and $abc$ coordinates system for compounds **1b** and **1c**, respectively. They were obtained by least-squares analyses of the single-crystal data.

| Compound | **1b** | **1c** | **2′b** |
|---|---|---|---|
| Powder sample | | | |
| $g_1$ | 4.83(5) | 4.85(5) | 4.87(5) |
| $g_2$ | 4.37(5) | 4.35(5) | 4.71(5) |
| $g_3$ | 2.58(9) | 3.12(9) | 3.08(9) |
| $\Delta B_1$ | 580(20) | 280(20) | 580(20) |
| $\Delta B_2$ | 680(20) | 280(20) | 480(20) |
| $\Delta B_3$ | 900(20) | 600(20) | 800(20) |
| Single crystal | | | |
| $g_{aa}$ | 2.66(2) | 4.47(1) | – |
| $g_{bb}$ | 4.83(1) | 3.12(2) | – |
| $g_{cc}$ | 4.32(1) | 4.71(1) | – |
| $g_{ac}$ | 1.51(4) | 0 | – |
| $g_{ab}$ | 0 | 0 | – |
| $g_{cb}$ | 0 | 0 | – |
| $g_{\parallel}$ | 2.58(2) | 3.12(2) | 3.08(9) |
| $g_{\perp}$ | 2.30(1) | 2.30(1) | 2.40(5) |
| E/D | 0.03 | 0.04 | 0.01 |

to be substantially populated.[28] The high anisotropy observed is also expected for $Co^{II}$ compounds with a distorted tetrahedral coordination.[29,30] Since the structural data do not show relevant chemical paths connecting the metal sites that could efficiently transmit exchange interactions, the principal $g$ values obtained from the powder spectra (Table 3) can be considered as corresponding to isolated $Co^{II}$ ions, in which the resonance lines may be broadened by dipolar interactions. The crystal lattice of all compounds consists of a 3D network of cobalt(II) ions, with closest

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metal center distances in the range 6.4–8.4 Å. This could be the cause of the unobserved hyperfine structure in the EPR powder spectra.

Single-crystal EPR spectroscopic measurements were only performed on compounds **1b** and **1c** as the size of the crystals of compounds **1a** and **2′b** was not appropriate for the EPR spectroscopic experiments. In order to understand the single-crystal EPR spectroscopic experiment, it is important to first analyze the orientation of the Co sites as well as the symmetry operations relating them within the unit cell. The unit cell of compound **1b** contains four identical Co molecules, which are related by the symmetry operations of the space group $P2_1/c$ (Figure 6a). Co1 at the general position ($x$,$y$,$z$) is related to Co2 by a $C_{2b}$ rotation, as well as Co3 to Co4. Co1 and Co2 are related to Co3 and Co4, respectively, by an inversion. From the magnetic point of view, this compound can be assumed as having two magnetically nonequivalent molecules per unit cell, because the Co sites related by an inversion are indistinguishable for EPR spectroscopy.

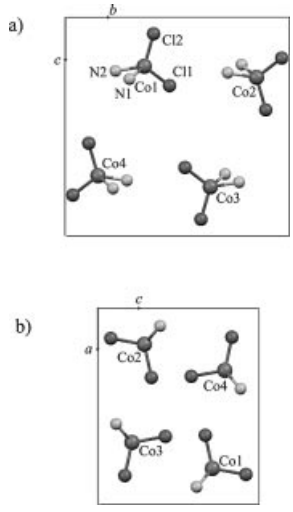

Figure 6. (a) Projection along $a$ of the four $Co^{II}$ ions and their ligands in the unit cell for compound **1b**. (b) Projection along $b$ of the four $Co^{II}$ ions and their ligands in the unit cell for compound **1c**.

Compound **1c** also has four identical Co molecules in the unit cell, related by the symmetry operations of the space group *Pnma* (Figure 6b). Co1 at the special position ($x$,1/4,$z$) is related to Co2, Co3, and Co4 by $C_{2b}$, $C_{2a}$, and $C_{2c}$ rotations, respectively. These operations determine that there are two $Co^{II}$ ion pairs magnetically equivalent per crystal plane, and also that the four Co sites are magnetically equivalent along the crystal $a$,$b$,$c$ axes. The Co molecule has a mirror plane defined by the $Co^{II}$ ion and the two Cl ligands, which is parallel to the *ca* plane. This particular local symmetry together with the space orientation of the Co molecules in the unit cell determines that the nonequivalent pairs of $Co^{II}$ ions are equivalent in the planes *ab* and *cb*.

Single-crystal EPR spectra were recorded with the magnetic field in three orthogonal crystal planes as explained in the experimental section. In all the planes and for the two compounds we observed one resonance line for all magnetic field orientations, except around the $b$ axis in the orthorhombic compound **1c**. In the planes *ab* and *cb* the signals become very broad around 90°, presumably because of a nonresolved hyperfine structure and therefore the position of the resonances in this zone could not be precisely evaluated. The position of the resonance line was obtained by least-squares fitting to a single Lorentzian line shape. Figure 7 shows the angular variation of the $g$ factor as a function of the magnetic field orientation for both compounds. The data in Figure 7 were least-squares fitted to a second rank tensor $g^2(\theta,\varphi) = \boldsymbol{h.g.g.h}$, in which $\boldsymbol{h} = \sin\theta\cos\varphi$, $\sin\theta\sin\varphi$, $\cos\theta$, is the magnetic field orientation, and $\boldsymbol{g}$ is the crystal $\boldsymbol{g}$ tensor defined as the average of the molecular $\boldsymbol{g}$ tensors of the nonequivalent $Co^{II}$ ions in the crystal lattice. The results are given in Table 3 and were used to obtain the solid lines in Figure 7. The overall symmetry of the evaluated $\boldsymbol{g}$ tensors follows the symmetry determined by the space group of each compound.

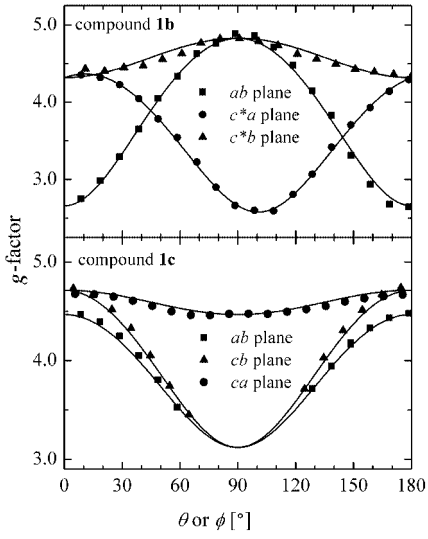

Figure 7. Angular variation of the $g$ factor obtained from oriented single-crystal EPR spectroscopic measurements of compounds **1b** and **1c** at 9.65 GHz and $T$ = 4.6 K. The solid lines in both plots were calculated with the components of the $\boldsymbol{g}^2$ tensor given in Table 3.

As discussed above, the angular variation of the $g$ factor in the orthorhombic compound **1c** can be associated with a single $Co^{II}$ ion in the planes *ab* and *cb*. By contrast, in the *ca* plane we would expect two resonance lines corresponding to the pairs Co1–Co2 and Co3–Co4. However, only one signal with a nearly isotropic angular variation was registered in this plane, which corresponds to the mirror Cl–Co–Cl plane. This fact can be due to either collapse by exchange interactions or resonance lines with similar $g$ factors. Taking into account that from the structural data we can discard the first possibility, the observed behavior can only be explained assuming two resonance lines with similar $g$ factors, which cannot be resolved by the EPR spectroscopic experiment at the X-band.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The orientation of the molecular ***g*** tensor for compound **1c** in the molecular frame can be evaluated from both the analysis of the geometry of coordination of the metal site and the EPR spectroscopic results. One eigenvector must correspond to the *b* crystal axis (0, 1, 0) because, as explained above, the planes *ab* and *cb* are associated with a single $Co^{II}$ ion and the angular variation of the *g* factor is symmetric around the *b* crystal axis ($g_3$ = 3.12). Thus, the two remaining eigenvectors must be in the Cl–Co–Cl plane. The Co molecule can be considered as having a local pseudo-$C_2$ symmetry axis (–0.760, 0, 0.650) determined by the intersection of the Cl–Co–Cl plane (parallel to the *ca* crystal plane) and the N–Co–N plane. This $C_2$ symmetry axis must correspond to another eigenvector. The direction of the third eigenvector is straightforward (0.650, 0, 0.760). The orientation of the ***g*** tensor is shown in Figure 8. This experiment allowed us to identify the eigenvalue along the *b* crystal axis, but not the remaining two eigenvalues because the single EPR line observed in the *ca* plane corresponds to two overlapping resonance lines associated with the pairs Co1–Co2 or Co3–Co4. However, they should correspond to the highest *g* values (4.35–4.85) of the ***g*** tensor obtained from the EPR powder spectra. Because of the above discussed nonequivalence of the cobalt ions in the *ca* plane both eigenvalues can be assigned to any of the $g_1$ and $g_2$ eigenvectors. The ***g***-tensor orientation of compound **1c** is similar to that determined in the pseudo-tetrahedral dichlorobis(triphenylphosphaneoxide)cobalt(II) compound.[21] This compound shows rhombic EPR spectra ($g_1$ = 5.67, $g_2$ = 3.69, $g_3$ = 2.16) with the two lowest *g* values approximately included in the Cl–Co–Cl plane. Compound **1c** presents a nearly axial signal, with the lowest *g* value ($g_3$) lying along the normal to the Cl–Co–Cl plane. The main structural difference between both compounds is that **1c** contains the stronger N ligands instead of O ligands. On the other hand, EPR spectroscopic studies performed on a square-pyramidal $Co^{II}$ complex showed that small deviations of the ideal $C_4$ site symmetry lead to important changes in the EPR spectroscopic properties of high-spin $Co^{II}$ ions.[22] Clearly, additional experimental work on a larger number of high spin $Co^{II}$ compounds with different structural characteristics is necessary to clarify how the different EPR spectroscopic properties can be correlated with differences in the coordination environment of the metal ion.

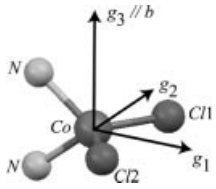

Figure 8. Orientation of the principal axes of the ***g*** tensor for the $Co^{II}$ site in compound **1c**. The direction cosines referring to the crystal axes are: (–0.760, 0, 0.650), (0.650, 0, 0.760), and (0, 1, 0) for $g_1$, $g_2$, and $g_3$ = 3.12, respectively. $g_1$ and $g_2$ can take either the values 4.35 and 4.85, respectively, or vice versa.

Structural data for compound **1b** show Co sites with coordination environments and space orientations similar to that of **1c**, but the local symmetry is lower (the local mirror plane cannot be defined in this case) and the Cl–Co–Cl plane is twisted by nearly 10° from the *cb* crystal plane (Figure 6a and b). The structural similarities are reflected in Figure 7: a nearly isotropic *g* factor was obtained in the plane *c***b*, and the lowest *g* value corresponds to a direction close to the normal of the Cl–Co–Cl plane. However, having nonresolved lines in the *ab* and *cb* planes precludes determining the ***g*** tensor associated with single $Co^{II}$ ions. Despite its lower symmetry, the coordination around $Co^{II}$ ions in both compounds shows no significant differences and we expect a ***g*** tensor orientation similar to that shown in Figure 8 for **1b**. Although we were not able to perform single-crystal EPR experiments on compounds **2′b**, the EPR spectroscopic data from powdered samples are similar for the three compounds. Consequently, we also expect similar ***g*** tensor orientation for the compounds in which I substitutes for Cl, but single-crystal experiments are necessary to confirm this hypothesis.

After this phenomenological assignment has been made, one wonders whether it might be possible to relate the highly anisotropic *g* factors corresponding to the effective $S' = 1/2$ of the lowest Kramers doublet with the distortions affecting the overall state of $S = 3/2$. The appropriate spin Hamiltonian within the $S = 3/2$ can be written as [Equation (1)]

$$H = \mu_B \mathbf{BgS} + \mathrm{D}\left(S_z^2 - \frac{1}{3}S(S+1)\right) + \mathrm{E}\left(S_x^2 - S_y^2\right) \quad (1)$$

where D and E are the axial and rhombic zero-field splitting parameters, respectively. The quantization axis *z* is assumed to be along the axial distortion. In principle, it is not required to assume that ***g*** will have its principal axes along any of these directions.

An effective Hamiltonian within the lowest $S' = 1/2$ (corresponding to either the originals $|3/2, \pm 3/2\rangle$ or the $|3/2, \pm 1/2\rangle$ states) Kramers doublet can be obtained under the form[31–34]

$\mathrm{H_{eff}} = \mu_B \mathbf{Bg'S'}$

If the ground state is that derived from to the original $|3/2, \pm 1/2\rangle$ doublet and if one assumes now that the principal axes of ***g*** coincide with that of the axial distortion such that $g_z = g_\parallel$ and $g_x = g_y = g_\perp$, one gets $g'_z = g_\parallel$ while $g'_x = 2g_\perp\left(1 - \frac{3}{2}\frac{\mathrm{E}}{\mathrm{D}}\right)$ and $g'_y = 2g_\perp\left(1 + \frac{3}{2}\frac{\mathrm{E}}{\mathrm{D}}\right)$. Note that $g'_x$, $g'_y$, and $g'_z$ correspond to $g_2$, $g_1$, and $g_3$, respectively, given in Table 3. The experimental data are not consistent with assigning the ground state to that derived from the original $|3/2, \pm 3/2\rangle$ doublet, in which $g'_z = 3g_\parallel$ while $g'_x \approx 0$ and $g'_y \approx 0$, which indicates a positive sign for the zero-field splitting parameter D. EPR data obtained from $Cs_3CoCl_5$ and $Cs_3CoBr_5$ complexes have been analyzed assuming a negative value for the D parameter,[35] and EPR spectroscopic results obtained from bis[dihydrobis(1-pyrazolyl)-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

borato]$Co^{II}$ have been interpreted assuming transitions |3/2, ±3/2>.[36] In contrast, our EPR spectroscopic data indicate a |3/2, ±1/2> ground state, in line with both theoretical and experimental results obtained from other pseudotetrahedral $Co^{II}$ compounds.[20,21]

According to the previous discussion, adopting a coordinate system in which the $z$ axis lies along the $g_3$ direction (in compound **1c** this coincides with the crystal $b$ axis), leads to $g'_z = g_{\|}$. One can also estimate $g_\perp$ by using the other two eigenvalues obtained from the powder spectra, e.g. $g_\perp \cong (g'_x + g'_y)/4$. On the other hand, under the same assumptions, one gets

$$\left|\frac{E}{D}\right| = \frac{2\left|g'_x - g'_y\right|}{3\left(g'_x + g'_y\right)}$$

Table 3 shows these parameters obtained for the three compounds using this model. The results indicate a weak rhombic distortion for all the compounds.

## Conclusions

A series of cobalt(II) complexes of general formula [Co(α-diimine)$X_2$], **1a**, **1b**, **1c**, and **2′b**, have been synthesized by the direct reaction of equimolar quantities of the corresponding cobalt dihalide and the α-diimine ligand in dried $CH_2Cl_2$ in c.a. 75 to 85% yield. Single-crystal X-ray structural data for all compounds show in all cases that the cobalt atom is in a distorted tetrahedral coordination, which is built by two halide atoms and two nitrogen atoms of the α-diimine ligand. X-band EPR measurements in polycrystalline samples performed on **1b**, **1c**, and **2′b** indicate high-spin $Co^{II}$ ($S = 3/2$) in an axially distorted environment. The single-crystal EPR spectroscopic experiment allowed us to determine the ***g***-tensor orientation for a low symmetry $Co^{II}$ compound. Structural and EPR spectroscopic results suggest similar ***g***-tensor orientations for all the compounds and the electronic properties of the $Co^{II}$ ions seem to be independent of the type of halide coordinated to the metal site.

## Experimental Section

### General Procedures and Materials

All reactions and manipulations of solutions were performed under an argon atmosphere using Schlenk techniques. Solvents were reagent grade and were dried according to literature methods. $CoCl_2$ and $CoI_2$ were purchased from Aldrich and the α-diimine ligands were synthesized as described elsewhere.[37]

### Physical Methods

Infrared spectra were recorded as Nujol mulls on NaCl plates using a Mattson Satellite FTIR spectrometer. Elemental analyses were performed at the Analytical Services of the Laboratory of REQUIMTE. Mass spectra were recorded using an HP298S GC/MS system by the Mass Spectra Service of the Universitat Autònoma de Barcelona, Spain.

X-band CW EPR spectra of polycrystalline samples and single-crystal samples were taken at 4.6 K with a Bruker EMX spectrometer using a rectangular cavity with 100 kHz field modulation, and equipped with an Oxford continuous flow cryostat. The EPR parameters of powdered samples were obtained from spectral simulations using the program Simfonia (v. 1.25, Bruker Instruments Inc.). Powder samples for EPR spectroscopy were obtained by grinding single crystals.

The samples for the single-crystal EPR spectroscopic measurements were oriented by gluing the *cb* and *ca* faces of **1b** and **1c**, respectively, to a cleaved KCl cubic holder, which defines a set of orthogonal laboratory axes. The habit of the crystals was determined by measuring the angles between crystal faces using a goniometric microscope. The sample holder was introduced into a 4 mm OD quartz tube, and positioned in the center of the microwave cavity (see ref.[38] for details). The tubes were attached to a goniometer and the sample was rotated in steps of 10° with the magnetic field in three crystal planes.

### Synthesis of Complexes

**Synthesis of [Co(*o*,*o*′,*p*-$Me_3C_6H_2$-DAB)$Cl_2$] (1b):** A suspension of $CoCl_2$ (0.26 g, 2 mmol) in $CH_2Cl_2$ (20 mL) was treated with a yellow solution of *o*,*o*′,*p*-$Me_3C_6H_2$-DAB, (0.64 g, 2 mmol) in $CH_2Cl_2$ (30 mL), a color change was observed almost immediately from the blue of the initial suspension to green. The mixture was left stirring at room temperature for about 2 h until everything was dissolved. The solution was filtered, and concentrated by vacuum removal of the solvent. A green crystalline solid precipitated, which was separated by filtration, washed with diethyl ether (2 × 10 mL) and petroleum ether (2 × 10 mL), and then recrystallized from hot $CH_2Cl_2$. **1b** (0.76 g) was obtained in 85% yield.

Compounds **1a** and **1c** were obtained by this method. Yields obtained were between 75 and 85%. Compounds **1a**, **1b**, and **1c** are moisture sensitive.

**Synthesis of [Co(*o*,*o*′,*p*-$Me_3C_6H_2$-BIAN)$I_2$] (2′b):** A green suspension of $CoI_2$ (0.16 g, 0.5 mmol) in $CH_2Cl_2$ (20 mL) was treated with a red solution of *o*,*o*′,*p*-$Me_3C_6H_2$-BIAN (0.21 g, 0.5 mmol) in $CH_2Cl_2$ (30 mL). The mixture quickly turned to a red-wine color, and it was stirred overnight until everything was dissolved. After filtration of the solution the solvent was partially removed leaving a dark-red solid, which was separated by filtration, washed with petroleum ether (2 × 10 mL), and then recrystallised from $CH_2Cl_2$/petroleum ether. **2′b** (0.29 g) was obtained in 78% yield.

**Crystallography:** Single crystals of complexes **1a**, **1b**, **1c**, and **2′b** were mounted on a Nonius Kappa-CCD area detector diffractometer (Mo-$K_\alpha$ $\lambda$ = 0.71073 Å). The complete conditions of data collection (DENZO software) and structure refinements are given below. The cell parameters were determined from reflections taken from one set of 10 frames (1.0° steps in phi angle), each at 20 s exposure. The structures were solved by direct methods (SHELXS97) and refined against $F^2$ using the SHELXL97 software.[27] The absorption was not corrected. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated according to stereochemistry and refined using a riding model in SHELXL97. Some disorders have been fixed for solvent molecules in the case of **1b** and **2′b** complexes (for details, see the corresponding cif files). The fully-labeled ORTEP views have been deposited as supplementary materials. CCDC-297433–297436 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Characterisation of Molecular Bismuth Phosphorus Compounds Containing $Bi_2$ Units with Bi–Bi Single and Double Bonds

**Carsten von Hänisch*[a] and Donna Nikolova[a]**

**Keywords:** Bismuth / Phosphorus / Double bonds

The compound $[BiP(SiPh_2tBu)_2]_2$ (**1**), featuring a Bi–Bi double bond and two Bi–P single bonds, has been obtained from the reaction of $BiCl_3$ with the lithium phosphanide $LiP(SitBuPh_2)_2$. As a byproduct of this transmetallation/redox reaction the diphosphane $P_2(SitBuPh_2)_4$ (**2**) has been isolated. This compound shows a remarkably short P–P bond due to π interactions of the phosphorus atoms. The reaction of the dilithium phosphandiide $Li_2PSitBuPh_2$ with $BiCl_3$ yielded the bicyclic compound $[Bi_2(PSiPh_2tBu)_4]$ (**3**), exhibiting a Bi–Bi single bond. NMR studies of **3** show the availability of four different P atoms, as observed in the crystal structure.

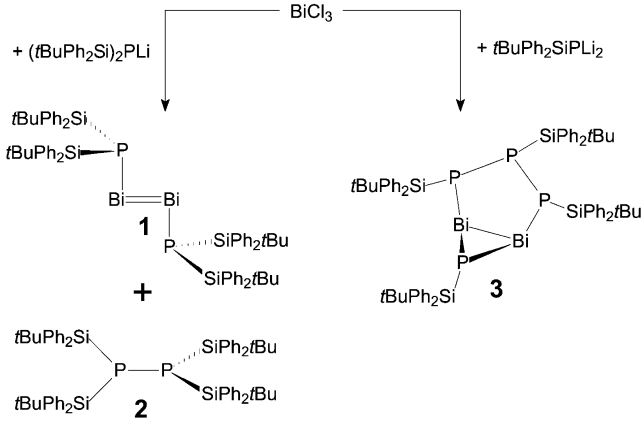
## Introduction

Organobismuth compounds containing Bi–Bi bonds are of considerable interest because of their chemical and physical properties.[1] In contrast to the extensive investigation of dibismuthanes,[2] very few dibismuthenes are known as yet. The first evidence for a Bi–Bi double bond was observed in the compound (Tbt)Bi=Bi(Tbt),[3] where Tbt = 2,4,6-$[(Me_3Si)_2CH]_3C_6H_2$. The compounds $[BiC_6H_3$-2,6-$Mes_2]_2$ and $[BiC_6H_3$-2,6-$Trip_2]_2$ (Mes = 2,4,6-$Me_3C_6H_2$, Trip = 2,4,6-$iPr_3C_6H_2$), also featuring Bi–Bi double bonds, were obtained by Power et al.'s group.[4] On the other hand, the use of less bulky substituents expands the knowledge in the field of the homonuclear cyclic and polycyclic compounds of bismuth. A remarkable development in the last years is the synthesis of the first cyclo-$R_4Bi_4$ [R = $(Me_3Si)_2CH$][5] compound in equilibrium with the cyclo-$R_3Bi_3$ species. Parallel work described the isolation of $[(Me_3Si)_3Si]_4Bi_4$ and the bicycle $[(Me_3Si)_3Sn]_6Bi_8$.[6] Molecular compounds containing Bi–P bonds are still rare, and for that reason we investigate whether sterically demanding phosphanyl groups can be used for the synthesis of new polynuclear bismuth compounds. We report here on the synthesis and crystal structures of the new binuclear bismuth compounds $[BiP(SiPh_2tBu)_2]_2$ (**1**) and $[Bi_2(PSiPh_2tBu)_4]$ (**3**) as well as the diphosphane $P_2(SitBuPh_2)_4$ (**2**) (Scheme 1).



Scheme 1. Synthesis of compounds **1**–**3**.

## Results and Discussion

By reaction of $(tBuPh_2Si)_2PLi$ with $BiCl_3$ in molar ratio 3:1 the dibismuthene $[BiP(SiPh_2tBu)_2]_2$ (**1**) and the diphosphane $P_2(SiPh_2tBu)_4$ (**2**) were obtained. Compound **1** forms red crystals and crystallises in the triclinic space group $P\bar{1}$ with the centre of inversion located in the middle of the molecule (Figure 1). The X-ray investigation revealed that **1** exists as a binuclear complex. There are no significant intermolecular Bi···Bi contacts between the Bi atoms of adjacent molecules because of the large steric requirement of the $(tBuPh_2Si)_2P$ substituents. The molecule shows a *trans* conformation, a structural feature represented by the majority of the previously known organobismuth compounds with a Bi–Bi double bond.[3,4,7] In particular, *cis* forms of dibismuthenes have been described in tungsten pentacarbonyl complexes.[8] The bismuth atoms and the phosphorus atoms show a planar alignment. The Bi–Bi bond length is 282.1 pm, which is in the usual range for double bonds between bismuth atoms. Similar Bi–Bi bond lengths of 282.1 and 283.3 pm, for example, can be observed in $(TbtBi)_2$[3] and $(2,6\text{-}Mes_2C_6H_3Bi)_2$,[4] whereas in [RBi=BiR{W-

$(CO)_5\}_2]$[8] (R = $Me_3CCH_2$, $Me_3SiCH_2$) these bonds are slightly longer (287.7–300.2 pm). The Bi–P bonds are 264.8 pm long. In the $Bi^{III}$ phosphide complex $[Bi(P_3tBu_3)_2]^-$, described by Wright and co-workers, the Bi–P bonds are between 263.0 and 291.1 pm long.[9] The Bi–Bi–P angle of 89.38° provides evidence for the very low tendency of bismuth to take part in hybridisation; the double bond is mostly composed from the orthogonally placed p orbitals.[10] Relatively wider Bi–Bi–C angles of 92.5° and 100.5° are observed in the structurally analogous dibismuthenes, mentioned above. One reason for the very low value of the Bi–Bi–P angle in **1** could be attractive interactions between Bi(1) and P(1′) [and Bi(1′) and P(1)]. The distances between these atoms are, at 386.5 pm, considerably shorter than the sum of the van der Waals radii (430 pm).

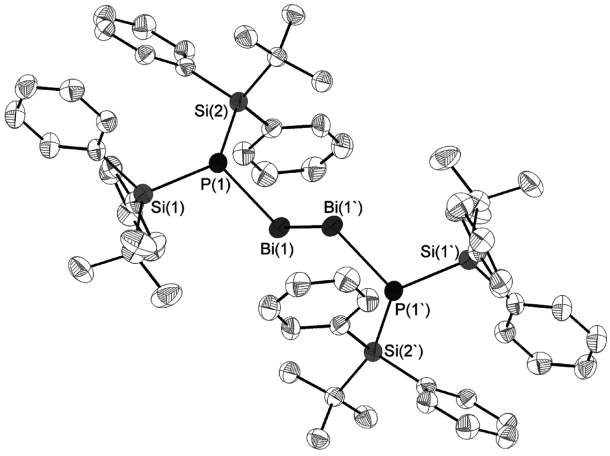

Figure 1. Molecular structure of **1** (ORTEP, thermal ellipsoids set at the 30% probability level). Hydrogen atoms are omitted for clarity. Selected bond lengths [pm] and angles [°]: Bi(1)–Bi(1′) 282.06(9), Bi(1)–P(1) 264.82(17), P(1)–Si(1) 227.3(3), P(1)–Si(2) 228.9(2); Bi(1′)–Bi(1)–P(1) 89.38(4), Bi(1)–P(1)–Si(1) 103.91(8), Bi(1)–P(1)–Si(2) 95.12(7), Si(1)–P(1)–Si(2) 110.78(9).

The $^{31}P\{^1H\}$ NMR spectrum of **1** in [$D_8$]THF displays one singlet at $\delta$ = –202.0 ppm. Compound **1** is stable in the solid but decomposes in THF solution within a few days, with formation of **2**, $(tBuPh_2Si)_2PH$, elemental bismuth as well as different oligophosphanes.

The second product of the transmetallation/redox reaction of $BiCl_3$ and $(tBuPh_2Si)_2PLi$ is the diphosphane **2**. It crystallises in the space group $P\bar{1}$ and is composed of two diorganophosphorus moieties, linked through a P–P single bond (Figure 2). Because of the steric effects of the bulky silyl groups, the geometry at each phosphorus atom is essentially planar (sum of bond angles: 353.8°) and the $P(SitBuPh_2)_2$ fragments show a twisted arrangement. An interesting aspect of the structure is the relatively short P–P bond length of 217.3 pm in comparison with the corresponding values in organophosphanes such as $P_2Ph_4$ (221.7 pm) and $tBu_4P_6$ (219.2–220.8 pm).[11,12] It seems that the twist structure and the almost planar environment of the phosphorus atoms is favourable for bond shortening due to some π bonding.[13] A similar explanation has recently been given for the short P–P bond in Hittorf's phosphorus.[14]

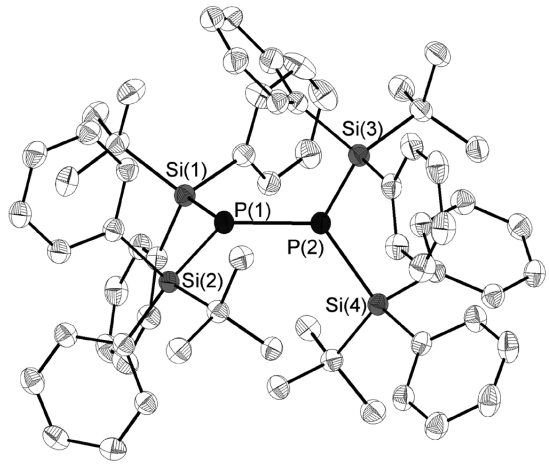

Figure 2. Molecular structure of **2** (ORTEP, thermal ellipsoids set at the 30% probability level). Hydrogen atoms are omitted for clarity. Selected bond lengths [pm] and angles [°]: P(1)–P(2) 217.31(13), P(1)–Si(1) 230.33(13), P(1)–Si(2) 231.16(15), P(2)–Si(3) 230.30(13), P(2)–Si(4) 231.12(14); P(1)–P(2)–Si(3) 108.62(5), P(1)–P(2)–Si(4) 125.36(5), P(2)–P(1)–Si(1) 108.55(6), P(2)–P(1)–Si(2) 124.81(6), Si(1)–P(1)–Si(2) 119.93(5), Si(3)–P(2)–Si(4) 119.36(5).

The reaction of $tBuPh_2SiPLi_2$ with $BiCl_3$ in molar ratio 3:2 affords the bicycle $[Bi_2(PSiPh_2tBu)_4]$ (**3**), which can be isolated in the form of red crystals. The compound crystallises in the triclinic space group $P\bar{1}$. It is constructed of five-membered $P_3Bi_2$ and three-membered $PBi_2$ rings sharing a common bridgehead (Figure 3). Of particular interest is the appearance of P–P and Bi–Bi single bonds in the molecule, obviously due to a reduction of the Bi atoms and corresponding oxidation of the P atoms. The central $Bi_2P_4$ unit features a nonplanar array; the plane through Bi(1), Bi(2), P(4) is virtually perpendicular to the $Bi_2P_3$ ring. Examination of the bond lengths and angles found in the bicyclic core of **3** indicates that there is a considerable amount of strain in this arrangement. The fold angles P(1)–Bi(1)–P(4) and P(3)–Bi(2)–P(4) are 82.65° and 103.36°, respectively. The comparatively large difference between these angles results from the manner of orientation of the sterically demanding silyl groups coordinated to P(1) and P(3). The $tBuPh_2Si$ substituent of P(1) is in *trans* position to the Bi(1)–P(4) bond, whereas the silyl group bonded to P(3) is in *cis* position to the Bi(2)–P(4) bond. The torsion angles Si(3)–P(3)–Bi(2)–P(4) and Si(1)–P(1)–Bi(1)–P(4) are 49.1° and 134.0° respectively. A similar structural pattern has been observed for the analogous antimony species $[Sb_2(PSiPh_2tBu)_4]$ in the course of our investigations.[15] The homonuclear bicyclic compound $tBu_4P_6$ reported by Baudler and co-workers however shows an all-*trans* arrangement of the *t*Bu groups.[12] The Bi–Bi bond is 294.1 pm and therefore shorter than the corresponding bond lengths in the structures of already known dibismuthanes, such as $Ph_4Bi_2$ (299.0 pm)[2a] and $(Me_3Si)_4Bi_2$ (303.5 pm).[2b] The bond shortening is possibly a conse-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

quence of the fact that the $Bi_2$ moiety is bridged by the P(4) atom. The P–P and Bi–P bonds in **3** are 221.5 pm and 268.6 pm on average.

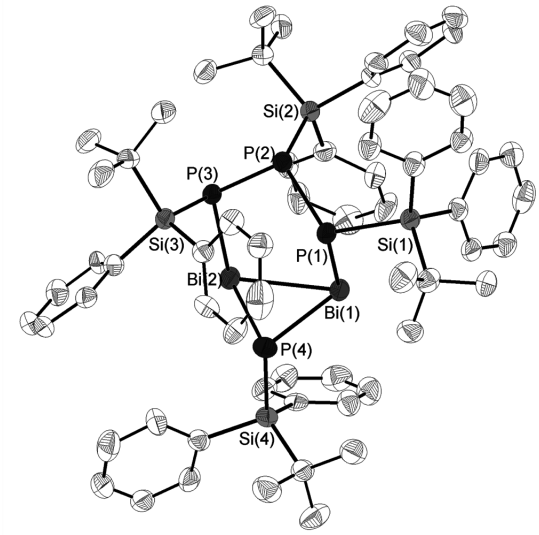

Figure 3. Molecular structure of **3** (ORTEP, thermal ellipsoids set at the 30% probability level). Hydrogen atoms are omitted for clarity. Selected bond lengths [pm] and angles [°]: Bi(1)–Bi(2) 294.2(2), Bi(1)–P(1) 266.3(6), Bi(1)–P(4) 269.2(6), Bi(2)–P(3) 269.3(6), Bi(2)–P(4) 269.5(6), P(1)–P(2) 221.9(8), P(2)–P(3) 221.2(7), P(1)–Si(1) 229.8(7), P(2)–Si(2) 232.0(8), P(3)–Si(3) 227.2(8), P(4)–Si(4) 227.7(9); Bi(1)–Bi(2)–P(4) 56.86(2), Bi(2)–Bi(1)–P(1) 90.26(2), Bi(2)–Bi(1)–P(4) 56.95(2), Bi(1)–P(4)–Bi(2) 66.19(4), Bi(1)–P(1)–P(2) 111.2(3), Bi(1)–P(3)–P(2) 113.1(2), P(1)–P(2)–P(3) 101.2(3), P(1)–Bi(1)–P(4) 82.65(8), P(3)–Bi(2)–P(4) 103.36(8).

The structure of **3** can be deduced from the $^{31}P\{^1H\}$ NMR spectrum, which shows, at room temperature, two triplet signals at $\delta$ = –77 ppm and $\delta$ = –265.5 ppm for the P(2) and P(4) atoms, respectively. An additional broad signal appears at $\delta$ = –115 ppm. At +70 °C two triplet signals and one doublet of doublets can be observed, which is consistent with chemically identical P(1) and P(3) atoms ($AM_2X$ spin system, $^1J_{P,P}$ = 400, $^2J_{P,P}$ = 87 Hz). At –50 °C the $^{31}P\{^1H\}$ NMR spectrum of **3** shows four multiplets, corresponding to four different P atoms, as observed in the crystal structure (Table 1).

As can be shown by the synthesis of compound **1**, sterically demanding disilylphosphanid ligands can be used for the kinetic stabilisation of unusual bonding situations. Hence they are an alternative to the frequently used bulky silyl or aryl groups such as $Si(SiMe_3)_3$ or 2,6-$Mes_2C_6H_3$. $R_3SiP$ fragments, however, can be used to build up binary polycycles, as can be seen from the synthesis of compound **3**.

## Experimental Section

All manipulations were carried out under rigorous exclusion of oxygen and moisture, using a Schlenk line and nitrogen atmosphere. Solvents were dried and freshly distilled before use. The starting material $t$BuPh$_2$SiPH$_2$ was prepared by LiCl-elimination reaction of $t$BuPh$_2$SiCl with [(dme)LiPH$_2$] in THF, in the manner described by us previously.[15] $BiCl_3$ was obtained from Aldrich and used as received. The $^{31}P$ NMR spectra were recorded with Bruker AC 250 and a Bruker Avance 300 spectrometers.

**($t$BuPh$_2$Si)$_2$PH:** This compound was isolated as a byproduct from the synthesis of $t$BuPh$_2$SiPH$_2$ and could be obtained as colourless crystals by recrystallisation of the distillation residue from *n*-pentane.[15] $C_{32}H_{39}PSi_2$ (510.81): calcd. C 75.24, H 7.70; found C 75.23, H 7.83. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.21 [s, C(C$H_3$)$_3$, 18 H], 1.82 (d, P$H$, $^1J_{P,H}$ = 200.1 Hz, 1 H), 7.04 (m, *o*-Ph, 8 H), 7.10 (m, *p*-Ph, 4 H), 7.60 (m, *m*-Ph, 8 H) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 20.8 [d, $C(CH_3)_3$, $^2J_{P,C}$ = 12.4 Hz], 28.3 [d, C($CH_3$)$_3$, $^3J_{P,C}$ = 2.6 Hz], 127.7 (s, Ph), 129.3 (s, Ph), 134.7 (d, $J_{P,C}$ = 5.7 Hz, Ph), 136.8 (d, $J_{P,C}$ = 3.3 Hz, Ph) ppm. $^{29}Si\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 4.9 (d, $^1J_{P,Si}$ = 36.6 Hz) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = –267 (d, $^1J_{P,H}$ = 200.1 Hz) ppm. 1588 (w), 1567 (w), 1486 (w), 1470 (m), 1426 (s), 1389 (m), 1359 (m), 1309 (w), 1262 (w), 1188 (m), 1157 (w), 1102 (vs), 1028 (w), 1007 (m), 934 (m), 846 (w), 816 (s), 740 (s), 698 (vs), 620 (w), 597 (s), 561 (w), 518 (vs), 483 (s), 454 (s), 402 (m) $cm^{-1}$.

**1 and 2:** Butyllithium solution (0.37 mL, 1.6 M) was added to a solution of $(t\text{BuPh}_2\text{Si})_2\text{PH}$ (0.3 g, 0.59 mmol) in $Et_2O$ (10 mL) at 0 °C. After warming to room temperature, the solution of $(t\text{BuPh}_2\text{Si})_2\text{PLi}$ was added to a suspension of 0.06 g (0.2 mmol) $BiCl_3$ in 10 mL $Et_2O$ at –60 °C. Subsequently the red mixture was slowly warmed to room temperature while stirring and then agitated overnight. The solution was reduced to 5 mL in vacuo. After filtration and cooling to 0 °C red crystals of **1** were obtained within a few hours. Subsequent reduction of the volume to 3 mL in vacuo and cooling of the solution for two days yielded a second crystal fraction consisting of **1** and colourless crystals of **2**.

**1:** Yield: 0.12 g (41.7%). $C_{64}H_{76}Bi_2P_2Si_4$ (1437.56): calcd. C 53.47, H 5.33; found C 53.84, H 5.32. $^1$H NMR ([D$_8$]THF): $\delta$ = 1.21 (s, CC$H_3$, 36 H), 7.28 (m), 7.50 (m), 7.54 (m): SiPh (40 H) ppm. $^{29}$Si{$^1$H} NMR ([D$_8$]THF): $\delta$ = 13.9 (m) ppm. $^{31}$P{$^1$H} NMR ([D$_8$]THF): $\delta$ = –202.0 (s) ppm. IR (KBr): $\tilde{\nu}$ =3132 (w), 3049 (m), 2961 (s), 2928 (s), 2889 (m), 2855 (s), 1958 (w), 1895 (w), 1822 (w), 1587 (w), 1567 (w), 1468 (m), 1426 (s), 1388 (w), 1360 (w) 1309 (w), 1262 (m), 1188 (w), 1155 (vw), 1099 (vs), 1006 (m), 935 (w), 884 (w) 814 (s), 737 (s), 701 (vs), 593 (s), 523 (vs), 485 (m), 408 (w) $cm^{-1}$. UV/Vis: $\lambda$ ($\varepsilon$ in $L\,mol^{-1}\,cm^{-1}$) = 820 (shoulder, 100), 564 (2944), 466 nm (shoulder, 1180).

**2:** Yield: about 0.02 g after sorting by hand. No satisfying elemental analysis can be obtained because of co-crystallisation of compound **1**. $^1$H NMR ([D$_8$]toluene): $\delta$ = 1.20 (s, CC$H_3$, 36 H), 7.06 (m), 7.19 (m), 7.57 (m): SiPh (40 H) ppm. $^{29}$Si{$^1$H} NMR ([D$_8$]-toluene): $\delta$ = 8.1 (pseudo-t, $J_{PSi}$ = 18.2 Hz) ppm. $^{31}$P{$^1$H} NMR ([D$_8$]toluene): $\delta$ = –199.8 (s) ppm. # Cu/Zn/Al Xerogels and Aerogels Prepared by a Sol–Gel Reaction as Catalysts for Methanol Synthesis

Yanzhi Guo,[a] Wolfgang Meyer-Zaika,[a] Martin Muhler,[b] Sascha Vukojević,[c] and Matthias Epple*[a]

**Keywords:** Heterogeneous catalysis / Copper / Zinc / Aluminum / Sol–gel processes / Mesoporous materials

$ZnO/Al_2O_3$, $CuO/Al_2O_3$, and $CuO/ZnO/Al_2O_3$ xerogels and aerogels have been prepared by a sol–gel route using propylene oxide as gelation initiator. For aerogel preparation, the solvent was extracted with supercritical $CO_2$. Calcination of these xerogels and aerogels was followed by thermogravimetry (TG), and the microstructure of these calcined xerogels and aerogels was investigated by TEM, powder XRD, EXAFS, and nitrogen physisorption (BET, BJH). The oxide mixtures $CuO/Al_2O_3$ and $CuO/ZnO/Al_2O_3$ were also studied by temperature-programmed reduction (TPR), and their catalytic activity in the formation of methanol from $CO/CO_2/H_2$ synthesis gas was measured. The aerogels have a higher specific surface area and a higher Cu surface area than the corresponding xerogels, which results in a higher catalytic activity for methanol synthesis. The presence of ZnO significantly increases the catalytic activities of both the xerogel and the aerogel.

## Introduction

$Cu/ZnO/Al_2O_3$ catalysts are widely used for the industrial synthesis of methanol, for methanol reforming, and for the water-gas shift reaction, and have therefore been intensively investigated in the last few decades.[1–3] Various methods have been developed for the preparation of $Cu/ZnO/Al_2O_3$ catalysts. The differences in preparation methods, synthesis conditions, and pre-treatment have a considerable influence on the structure of the catalysts, which finally leads to disparities in the catalytic performance. It is generally accepted that a large specific Cu surface area leads to an active methanol synthesis catalyst.[1,4] In addition, the metal–support interaction plays a key role in this catalytic reaction.[1,2,5,6]

Catalyst preparation usually involves complex processes and the performance of the final product is very sensitive to rather subtle changes in the synthetic procedures.[7–11] Copper/zinc oxide nanocomposites are usually prepared by co-precipitation from aqueous solutions. Typically, a mixed solution of copper and zinc salts (frequently nitrates or acetates) is prepared and the precipitation of both carbonates is induced by the addition of sodium or ammonium carbonate whilst stirring, followed by drying and calcination.[8,9,12] The particle size and crystallinity of the products can be adjusted by varying the pH, the reactant concentrations, the stirring rate, the duration of precipitation and aging, and the calcination conditions.[13] Günter et al. have investigated binary Cu/ZnO catalysts with varying Cu/Zn molar ratios (90:10 to 10:90) and found that the precursor phase composition directly influences the resulting Cu microstructure and, in turn, the performance of the Cu/ZnO catalyst.[8] The effect of pH on the composition of the precursors and the activity of the $Cu/ZnO/Al_2O_3$ catalysts for methanol synthesis has been studied by Fang et al.,[14] and Deng et al. have prepared ultra-fine $Cu/ZnO/Al_2O_3$ catalysts by an oxalate gel co-precipitation.[15] The obtained catalysts show a high activity in methanol synthesis. A non-aqueous organometallic route has been developed by Fischer et al. and uniform copper/zinc nanoparticles ("nanobrass") were obtained with $[Cu\{OCH(Me)CH_2NMe_2\}_2]$ and $Et_2Zn$ as precursors.[16] Schüth et al. have reported that colloidal copper nanoparticles prepared by reduction of copper acetylacetonate with trialkylaluminum are highly active for quasi-homogeneous methanol synthesis.[17] We have reported the preparation of copper/zinc nanocomposites by the thermolysis of dimetallic copper/zinc cyanide coordination compounds under mild conditions.[18–21] For instance, the copper/zinc cyanide compound $[Zn\{Cu(CN)_3\}]$ was precipitated by both a batch-wise and a continuous synthesis method. Depending on the ligands in the complex and the thermolysis conditions, the activity towards methanol synthesis could be controlled.[21]

The sol–gel route can be considered as a very interesting way of preparing catalysts because of the possibility to con-

trol many variables involved in the synthesis.[22] Traditionally, the sol–gel method has involved the use of metal alkoxide precursors that readily undergo catalyzed hydrolysis and condensation to form a sol of metal oxide particles with nanoscale dimensions (1–100 nm).[22] This route has proven to be an efficient, easy, and successful approach for the preparation of $SiO_2$-, $Al_2O_3$-, and $ZrO_2$-based porous materials.[23] A novel sol–gel technique was recently developed for the preparation of transition and main-group metal oxide aerogels, xerogels, and nanocomposites.[24] This method involves the use of epoxides as gelation initiators in the preparation of porous metal oxides such as $Fe_2O_3$, $Al_2O_3$, and $Cr_2O_3$.[25,26] Here we report the sol–gel preparation and catalytic performance of Cu-, Zn-, and Al-based di- and trimetallic nanocomposites by this method.

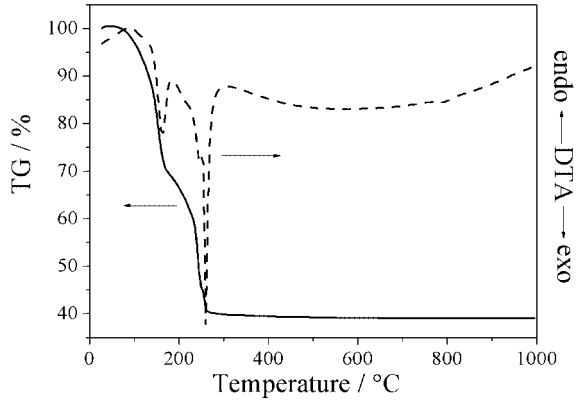

Figure 1. TG and DTA analysis of the Cu/Zn/Al dried xerogel (1:1:1) under dynamic oxygen atmosphere (5 $K\,min^{-1}$), leading to an intimate mixture of CuO, ZnO, and $Al_2O_3$.

## Results and Discussion

### Synthesis

Metal oxide aerogels and xerogels can be prepared directly from metal salts using epoxides as gelation initiators.[27,28] These initiators, which act as irreversible proton scavengers, induce the hydrolysis and condensation of hydrated metal cations. The initiators consume the protons from the hydrated metal species and enhance the sol–gel condensation reaction. The protonated epoxide is ultimately consumed during gelation by a ring-opening reaction with a suitable nucleophile. In this work, propylene oxide was used as gelation initiator and the gel formed within 30–60 min in ethanol solution. No shrinkage was observed either during the gelation process or in the drying process with supercritical carbon dioxide. However, shrinkage was observed after drying in air to a xerogel. As a result, the obtained oxide xerogels and aerogels exhibit very low densities, especially the latter. Different combinations of metals were realized.

### Thermolysis of the Zn/Al and Cu/Zn/Al Xerogels and Aerogels

The thermal decomposition of the air-dried xerogels and the aerogels to the corresponding oxides was studied by thermogravimetry (TG).[29] The decomposition behavior showed only a small dependence on the composition of the gel, i.e. the ratio of Cu/Zn/Al or the drying procedure (air-drying or extraction with supercritical $CO_2$). Figure 1 shows the TG and DTA curves of a Cu/Zn/Al air-dried xerogel (1:1:1) under dynamic oxygen atmosphere. The first peak is a broad endothermal one with a maximum at about 92 °C, which is probably due to the loss of residual volatile solvent (ethanol or water). The subsequent exothermal peaks at 160, 245, and 260 °C can be attributed to the oxidation of residual organic compounds, which is in good agreement with the literature.[28] The total weight loss is about 60%. A similar behavior has been observed for the other samples, although with slight temperature variations of the exothermal peaks.

### $ZnO/Al_2O_3$ Xerogels

TEM images of the calcined $ZnO/Al_2O_3$ xerogel with different Zn/Al ratios are shown in Figure 2. The particles in Figure 2a have a typical particle diameter of 10 nm. When the Zn/Al ratio was increased to 2:1, the homogeneity decreased, with particle sizes up to 30 nm (Figure 2b).

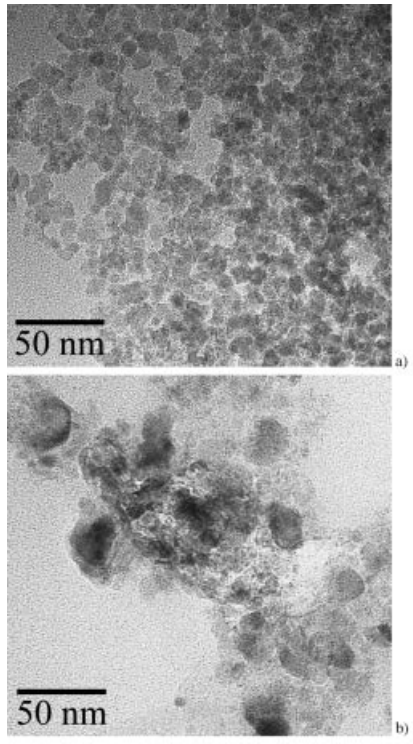

Figure 2. TEM images of $ZnO/Al_2O_3$ calcined xerogels (400 °C) with different Zn/Al molar ratios: a) Zn/Al = 1:2; b) Zn/Al = 2:1.

The structure of the sol–gel products depends on the type and concentration of the polyoxometalates present during the formation of the condensed gel.[26] The nature of these

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

transient species is determined by a number of synthesis parameters, such as the reaction pH, solvent, temperature, ionic strength of the solution, as well as the compositions in the case of mixed species. XRD studies showed that the crystallinity of the Zn/Al oxides is strongly affected by the Zn/Al ratio (Figure 3). $ZnO/Al_2O_3$ is X-ray amorphous for a Zn/Al ratio of 1:2, thus indicating the absence of long-range order. However, for a 2:1 ratio the crystallinity increases significantly, as indicated by peaks originating from ZnO nanocrystals corresponding to the presence of larger particles in the TEM image. The $Al_2O_3$ phase is always X-ray amorphous.

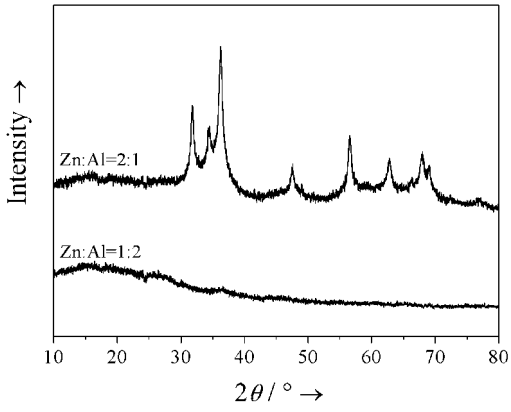

Figure 3. XRD patterns of $ZnO/Al_2O_3$ calcined xerogels (400 °C) with different Zn/Al molar ratio. All peaks in the upper diffractogram correspond to ZnO.

A closer look at the structure of the $ZnO/Al_2O_3$ calcined xerogel (400 °C) was obtained by EXAFS (Figure 4 and Table 1). In the Zn K-edge Fourier transform magnitudes, the first shell of Zn–O in ZnO is clearly present in both samples. The Zn–Zn shells at about 3 Å, however, are different for different Zn/Al ratios. For the sample with a Zn/Al ratio of 1:2 the Zn–Zn peak is almost invisible. The absence of Zn neighbors around Zn suggests a high structural disorder or a dispersion of ZnO in $Al_2O_3$ on the atomic scale. This dispersion can be beneficial when these $ZnO/Al_2O_3$ oxide mixtures are used as a support for metallic Cu catalysts in methanol synthesis. The Zn–Zn peak is much stronger for the 2:1 sample, thereby indicating the presence of ZnO nanocrystals; this is in good agreement with the XRD and the TEM results. In both cases, the coordination number of the Zn–Zn shell is much less than 12, which is the crystallographic coordination number of crystalline ZnO. We conclude that an appropriate concentration of $Al_2O_3$ can effectively disperse ZnO and inhibit the formation of crystalline ZnO.

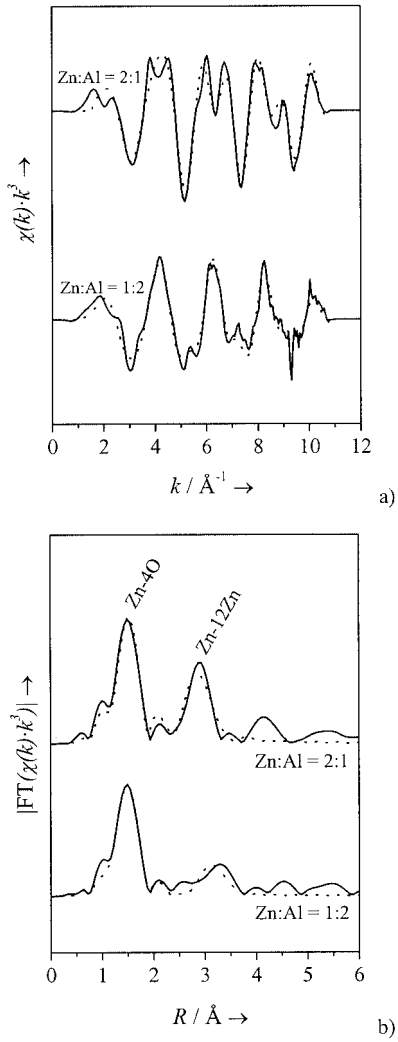

Figure 4. Zn K-edge EXAFS raw data (a) and Fourier transform magnitudes (b) of $ZnO/Al_2O_3$ calcined xerogels (400 °C) with different Zn/Al molar ratio. Solid line: experimental data; dotted line: fit data.

Nitrogen physisorption isotherms and the corresponding pore-size distributions of porous $ZnO/Al_2O_3$ samples are shown in Figure 5. The isotherms of both samples have significant hysteresis loops that are associated with the filling and emptying of mesopores by the condensate. $ZnO/Al_2O_3$ with a Zn/Al ratio of 1:2 has the smallest pore size and the narrowest distribution (Figure 5b). The pore sizes are in the range of 5–10 nm. With increasing Zn concentration, the pore size increases and the distribution is broadened considerably. When the Zn/Al ratio is 2:1 the pore sizes are in the range of 5–25 nm.

Table 1. Results of EXAFS fits of $ZnO/Al_2O_3$ calcined xerogels (Zn K-edge; 9659 eV).

| Zn/Al molar ratio | $R$(Zn–O) [Å] | $N$(Zn–O) | $\sigma^2$(Zn–O) [$Å^2 \times 10^3$] | $R$(Zn–Zn) [Å] | $N$(Zn–Zn) | $\sigma^2$(Zn–Zn) [$Å^2 \times 10^3$] |
|---|---|---|---|---|---|---|
| 1:2 | 1.95 | 3.5 | 7.7 | 3.52 | 0.6 | 1.97 |
| 2:1 | 1.96 | 3.7 | 6.1 | 3.21 | 7.3 | 13.2 |

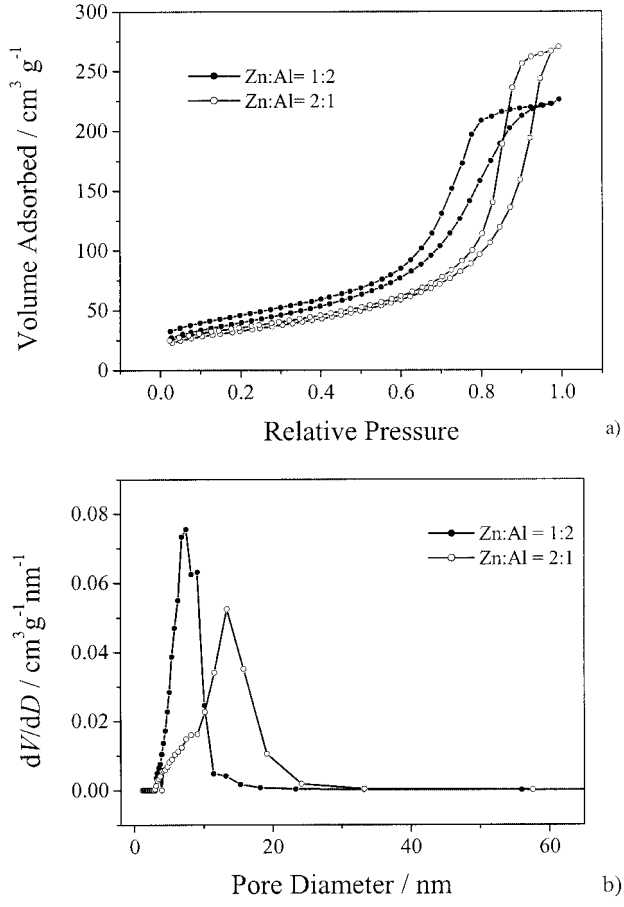

Figure 5. Nitrogen physisorption isotherms (a) and pore-size distribution (b) of $ZnO/Al_2O_3$ calcined xerogels (400 °C) with different Zn/Al ratios.

The BET surface area and the pore volume derived from nitrogen physisorption are listed in Table 2. An increase of the Zn concentration leads to a decrease of the BET surface area. A maximum surface area of 144 $m^2 g^{-1}$ was obtained for $ZnO/Al_2O_3$ with a Zn/Al ratio of 1:2, and this material also exhibits a smaller pore size and a narrower size distribution. The pore volume was found to be 0.42 $cm^3 g^{-1}$ for the sample with a Zn/Al ratio of 2:1. Baumann et al. have prepared $Al_2O_3$ aerogels by the same method and obtained a specific surface area of 289 $m^2 g^{-1}$, an average pore diameter of 32 nm, and pore volume of 2.6 $cm^3 g^{-1}$.[26] We conclude that the presence of Zn leads to smaller pores and a smaller specific surface area than with $Al_2O_3$ alone.

Table 2. BET surface area and pore volume of $ZnO/Al_2O_3$ calcined xerogels (400 °C).

| Zn/Al molar ratio | BET surface area [$m^2 g^{-1}$] | Pore volume [$cm^3 g^{-1}$] |
|---|---|---|
| 1:2 | 144 | 0.36 |
| 2:1 | 116 | 0.42 |

### Copper-Containing Xerogels and Aerogels (Cu/Al and Cu/Zn/Al Systems)

The industrial catalyst in methanol synthesis contains metallic copper, zinc oxide, and aluminum oxide, therefore the synthesis was extended to copper as the third component. Xerogels were obtained by simple drying in air. Aerogels were also prepared with these systems to obtain samples with a high specific surface area. Supercritical point drying of the wet gels with $CO_2$ gave highly porous, fluffy materials with an effective density of about 0.9 $g cm^{-3}$. The aerogels are blue and then turn black after calcination at 400 °C. The $Al_2O_3$ phase is X-ray amorphous in both the calcined xerogels and the aerogels. The XRD patterns of both the $CuO/Al_2O_3$ and the $CuO/ZnO/Al_2O_3$ calcined xerogels show strong CuO peaks, as shown in Figure 6a, with ZnO as a crystalline phase in the latter case. The ZnO peaks are weak, thereby indicating a good dispersion and a small crystallite size. The decrease of the CuO peak intensities can be attributed to an improved dispersion due to the presence of ZnO. Compared to the calcined xerogels, the calcined aerogels exhibit weaker CuO and ZnO contributions characterized by broad peaks (Figure 6b). We conclude that the dispersions of both Cu and Zn are improved by the drying process with supercritical $CO_2$.

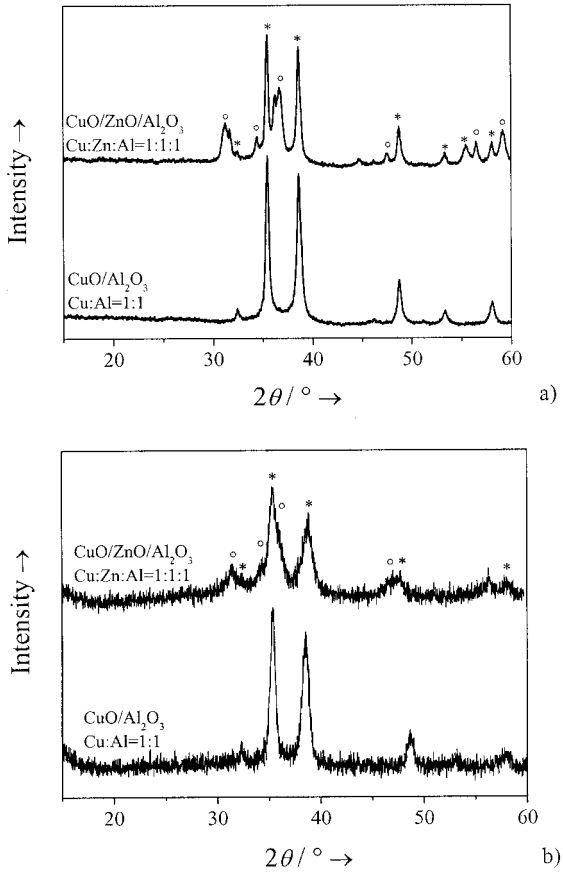

Figure 6. XRD patterns of $CuO/Al_2O_3$ and $CuO/ZnO/Al_2O_3$ calcined xerogels (a) and calcined aerogels (b). The marked peaks correspond to CuO (*) and ZnO (o), respectively.

Nitrogen physisorption of the $CuO/Al_2O_3$ and the $CuO/ZnO/Al_2O_3$ aerogels gave their pore-size distributions, which are broad in both cases (Figure 7). A narrow distribution in the range of 5–10 nm was obtained for the Zn/Al xerogel (see above). However, the Cu/Al aerogel gave a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

distribution from 2 nm up to more than 30 nm. The presence of Zn narrows the pore-size distribution slightly and reduces the average pore size, as indicated by the shift of the peak maximum to smaller pore diameters.

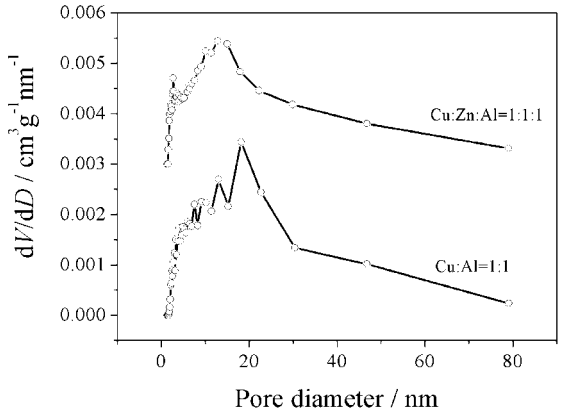

Figure 7. Pore-size distribution of $CuO/Al_2O_3$ and $CuO/ZnO/Al_2O_3$ calcined aerogels derived from nitrogen physisorption isotherms.

The CuO particle size and size distribution have a considerable influence on the reduction behavior.[30] For large CuO particles, the reduction of near-surface $Cu^{II}$ species can occur at lower temperature.[31] The reduction of the bulk then appears at higher temperature. For small particles, the reduction may be very fast so that separate peaks or shoulders cannot be observed. In addition, the reduction behavior becomes even more complex due to the presence of $CuZnO_x$[32] and $CuAl_2O_4$.[33]

The TPR spectra of the calcined $CuO/Al_2O_3$ xerogels and aerogels are shown in Figure 8. In both samples the reduction of CuO occurs in three steps, presumably due to intermediate phases like $Cu_2O$[34] and the broad particle-size distribution. The first reduction step of the xerogel is characterized by a broad shoulder. The reduction starts at about 140 °C for both aerogel and xerogel. The peak maximum of the aerogel appears at 176 °C, a lower temperature than that of the xerogel, for which it appears at 220 °C. The shift of the peak to higher temperature can be attributed to an increased particle size of CuO. The reduction of the $CuO/ZnO/Al_2O_3$ xerogel occurs in two steps, as indicated by a peak and a shoulder on the left-hand side (Figure 8c), although the aerogel gave only one peak (Figure 8d). The peak maxima appear at 166 °C and 197 °C for the aerogel and xerogel, respectively. The reduction temperature is lower than those of the corresponding $CuO/Al_2O_3$ aerogel (176 °C) and xerogel (220 °C), which can be attributed to an increased dispersion of CuO. Obviously, ZnO plays a key role in the dispersion of CuO by increasing the metal–support interaction. The intermediate phases during the reduction are clearly different with or without ZnO, as reflected by the different reduction behaviors. The CuO contents of the samples were derived from the TPR spectra. The results were found to be in good agreement with the results obtained by AAS elemental analysis (Table 3). This confirms that the reduction of CuO during TPR is com-

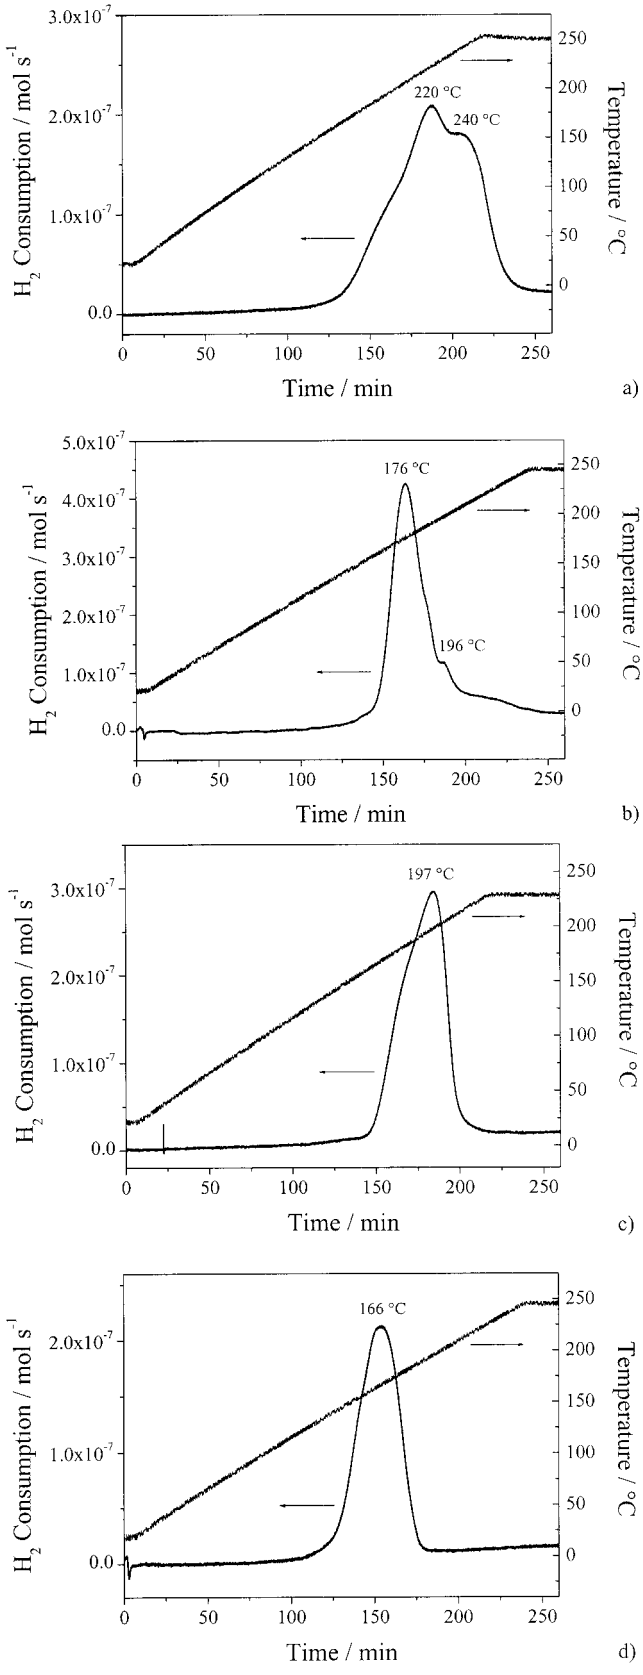

Figure 8. TPR patterns of $CuO/Al_2O_3$ (1:1) and $CuO/ZnO/Al_2O_3$ (1:1:1) calcined xerogels and aerogels at a heating rate of 1 K $min^{-1}$ in $H_2$/He: a) CuO/ZnO (1:1) xerogel; b) CuO/ZnO (1:1) aerogel; c) $CuO/ZnO/Al_2O_3$ (1:1:1) xerogel; d) $CuO/ZnO/Al_2O_3$ (1:1:1) aerogel.

plete, and that the consumption of $H_2$ by other phases can be excluded.

### Catalytic Activities of Cu-Containing Xerogels and Aerogels

The specific surface area of the samples was determined by nitrogen physisorption. Different drying methods (air or supercritical $CO_2$) have a significant influence on the surface area (Table 4). The porous microstructure of the wet gel is better preserved by supercritical drying, resulting in a higher specific surface area. High specific pore volumes (as much as 1 $cm^3 g^{-1}$) were found, compared to about 0.4 $cm^3 g^{-1}$ for the $ZnO/Al_2O_3$ calcined xerogel (Table 2). The specific Cu surface area,[4] as determined by $N_2O$ reactive frontal chromatography, is given in Table 4. The higher Cu surface area of the Cu/Al or Cu/Zn/Al calcined xerogels leads to a higher catalytic activity, and both aerogels show a much higher activity in methanol synthesis than the corresponding xerogels. The presence of ZnO also improves the catalytic activities. In the 1:1 Cu/Al xerogels, the catalytic activity increases from 2.0% to 4.9% despite a smaller specific Cu surface area. The higher activity of the ternary aerogel can be attributed to a strong metal–support interaction, as supported by the XRD and TPR investigations. We note that the presence of $Zn^{2+}$ or $Cu^{2+}$ leads to a smaller specific surface area and a lower pore volume, but also to a smaller average pore size.

## Conclusions

A sol–gel route has been employed to prepare Cu/Zn/Al xerogels and aerogels with propylene oxide as gelation initiator. ZnO can be atomically dispersed in $Al_2O_3$ in xerogels in a wide range of Zn concentrations. A higher Cu dispersion is found in the aerogels than in the xerogels, which leads to a higher specific surface area, a higher Cu surface area, and a higher catalytic activity in methanol synthesis. The presence of ZnO increases the catalytic activities in both the xerogel and aerogel, which we attribute to a strong metal–support interaction. The sol–gel method is easy to apply and well suited to the preparation of binary or ternary catalysts for methanol synthesis.

## Experimental Section

**Preparation of $ZnO/Al_2O_3$, $CuO/Al_2O_3$, and $CuO/ZnO/Al_2O_3$ Xerogels and Aerogels:** $Cu(NO_3)_2 \cdot 3H_2O$ (Merck, 98%), $Zn(NO_3)_2 \cdot 6H_2O$ (Merck, 98%), and $Al(NO_3)_3 \cdot 9H_2O$ (Merck, 98%) were used as metal precursors, and propylene oxide (Acros, 99%) was used as gelation initiator.[20–22] Metal nitrates of different compositions were dissolved in absolute ethanol (typically 10–20 mL) to give a clear solution with a total metal ion concentration of 1 M. Propylene oxide was then added to the solution. The molar ratio of propylene oxide to the molar sum of the metal ions was 10:1. After stirring at room temperature for 10 min, the reaction mixture was transferred into a closed vessel. A wet gel formed within 30–60 min. This wet gel was allowed to age at room temperature for 24 h in the closed vessel and then soaked in a bath of absolute ethanol for 24 h to exchange the water from the pores of the gel. Note that the water is the water of crystallization of the starting salts. The exchange of water with ethanol was performed twice. The air-dried xerogel was then obtained by drying of the gel under air at room temperature for 5–6 d. For the preparation of an aerogel, the obtained wet gel was soaked in a bath of acetone for 24 h to exchange the ethanol and water from the pores. The exchange was repeated twice. A $CO_2$ critical point dryer (BAL-TEC, CPD 030) was then used to dry the wet gel. The acetone in the pores was extracted with liquid $CO_2$ 6–8 times at 10 °C and 5.0 MPa. After that, the temperature was increased to 40 °C and the pressure to 7.5 MPa to give supercritical $CO_2$. The autoclave was then depressurized over about 1 h to give the aerogel. For calcination, the air-dried xerogel or aerogel was heated to 400 °C at a rate of 3 K $min^{-1}$ under a dynamic air atmosphere in a tubular reactor to give an intimate mixture of CuO, ZnO, and $Al_2O_3$. The reactor was held at that temperature for 3 h, and then cooled to room temperature. After calcination, all copper-containing samples were black due to CuO formation and the other ones were white. Table 5 lists all prepared samples.

Table 5. Prepared samples of different compositions and molar ratios.

| Xerogel | $ZnO/Al_2O_3$ Zn/Al = 2:1 | $ZnO/Al_2O_3$ Zn/Al = 1:2 | $CuO/Al_2O_3$ Cu/Al = 1:1 | $CuO/ZnO/Al_2O_3$ Cu/Zn/Al = 1:1:1 |
|---|---|---|---|---|
| Aerogel | | | $CuO/Al_2O_3$ Cu/Al = 1:1 | $CuO/ZnO/Al_2O_3$ Cu/Zn/Al = 1:1:1 |

**Characterization:** Thermogravimetry was carried out with a Netzsch STA 409 TG-DTA/DSC instrument. Samples were heated from room temperature to 1000 °C at a rate of 5 K min$^{-1}$ under dynamic $O_2$ atmosphere at a flow rate of 50 mL min$^{-1}$. The structure of the resulting products was studied by TEM with a Philips CM 200 FEG instrument. Powder XRD was carried out at room temperature in transmission mode at the B2 beamline at HASYLAB with monochromatic radiation or with a Siemens D5000 instrument with Cu-$K_\alpha$ radiation. EXAFS was carried out at the E4 beamline at HASYLAB/DESY in transmission mode at 77 K. The programs SPLINE and XFIT[35] were used for quantitative data evaluation. Theoretical standards were computed with the program FEFF 6.01a.[36] The amplitude reduction factor, $S_o^2$, was fixed to 1. Variation parameters were the bond lengths, the coordination numbers, the Debye–Waller factors ($\sigma^2$), and the zero-energy correction ($E_o$). The specific surface area was determined by nitrogen physisorption at 77 K (BET method). The pore-size distribution was obtained using the BJH method from the desorption branch of the isotherms. Temperature-programmed reduction (TPR) was carried out for the calcined xerogels and aerogels. About 0.1 g of the sample was placed in a quartz reactor. The reduction was performed under flowing diluted $H_2$ (4.2 vol-% $H_2$ in He) by increasing the temperature to 240 °C at 1 K min$^{-1}$ and maintaining that temperature for 1 h. The active surface area of Cu was determined by $N_2O$ reactive frontal chromatography at 300 K.[37] Atomic absorption spectroscopy (AAS) was performed with a Thermo Electron Corporation instrument (M series) to determine the copper content of the samples.

**Catalytic Activity Measurements:** Catalytic measurements were performed in a high-throughput 49-parallel channel reactor.[38] The catalyst (100 mg diluted with 200 mg of quartz per well) was placed in a sample holder consisting of a stainless-steel cartridge closed at the bottom by a stainless-steel sinter metal frit. Prior to the catalytic measurements, the catalysts were reduced with $H_2$ at 245 °C according to the procedure for the commercial benchmark catalyst ICI Katalco 51-8. Before measuring the catalytic activity, all samples were equilibrated for 3 h (reaction pressure: 4.5 MPa; reaction temperature: 245 °C; analytic flow: 20 mL min$^{-1}$). The reaction gas consisted of 70 vol-% $H_2$, 24 vol-% CO, and 6 vol-% $CO_2$. A double GC system (HP GC 6890) equipped with a methanizer FID was used for online gas analysis. Oxo product separation ($H_3COH$, $HCOOCH_3$, $H_3CCOOCH_3$, $H_3CCH_2OH$) was carried out on a SuppelcoWAX 0.53 mm column and CO, $CO_2$, and $CH_4$ were separated on a Carboxen 1006 column. Methanol productivities for all measured samples were compared to the productivity of the industrial benchmark catalyst ICI Katalco 51-8.

## Acknowledgments

# Copper/Zinc L-Tartrates: Mixed Crystals and Thermolysis to a Mixture of Copper Oxide and Zinc Oxide That Is Catalytically Active in Methanol Synthesis

**Rainer Weiss,[a] Sascha Vukojević,[b] Christian Baltes,[b] Raoul Naumann d'Alnoncourt,[c] Martin Muhler,[c] and Matthias Epple*[a]**

**Keywords:** Heterogeneous catalysis / Copper / Zinc / Thermochemistry

The system consisting of copper/zinc L-tartrate mixed crystals has been systematically explored in the whole range from pure copper tartrate to pure zinc tartrate. Mixed crystal L-tartrates were prepared and their thermochemical behaviour under oxygen was investigated. Oxidic precatalysts (CuO/ZnO) for catalytic tests in methanol synthesis were prepared by mild thermolysis of the mixed tartrates in air at 300 °C. Catalytic tests were performed with a multi-channel parallel reactor. The catalytic activity shows a maximum at about equal amounts of copper and zinc whereas the specific surface area (BET surface) increases strongly when going from CuO to ZnO. This system offers a convenient, inexpensive route to CuO/ZnO precatalysts with adjustable compositions that avoids all other metals during preparation.

## Introduction

Methanol is the most important chemical base material due to its use as a solvent or as a parent compound for the industrial synthesis of higher organic compounds.[1] The industrial synthesis of methanol is typically carried out with synthesis gas containing $H_2$, CO and $CO_2$ with Cu/ZnO/$Al_2O_3$ as catalyst, which is prepared by reduction of a CuO/ZnO/$Al_2O_3$ precatalyst.[2–8] These oxide composites are usually prepared by thermolysis of co-precipitated hydroxycarbonate precatalysts in which all three metals are present.[9] Despite numerous experimental and theoretical studies, the catalytic processes on the surface of the bulk catalysts are not yet fully understood.[9–15] The activities of the obtained catalysts depend on many factors. To reduce the number of factors that influence the performance of the catalyst, the catalytic system is often limited to the system Cu/ZnO. Even then, the thermolysis temperature and pressure, the reduction temperature and the composition remain important external factors.[3–5,7,9,11,12,16] In the case of dinuclear complexes that contain both copper and zinc, the thermolysis is always complex due to the decomposition of the corresponding anions.[17,18] It was our goal to find a precursor that contains both metals in one solid phase (to achieve a good interaction in the final catalyst) and which can be decomposed at moderate temperature (to avoid sintering to larger crystals). Mixed copper/zinc L-tartrates turned out to be well suited for this purpose because their synthesis is straightforward and also because inorganic counterions like alkali metals or carbonate can be avoided.

## Results and Discussion

### Preparation

Metal L-tartrates (MTTs) with different ratios of Cu/Zn were prepared in aqueous solution by precipitation from copper acetate and zinc acetate with L-tartaric acid ($H_2TT$) [Equation (1)].

$$x\,Cu(OAc)_2 + y\,Zn(OAc)_2 + H_2TT \rightarrow Cu_xZn_yTT{\cdot}n\,H_2O + 2\,HOAc;\ x + y = 1 \text{ and } n \leq 3 \quad (1)$$

Note that the only counterion is acetate, which remains quantitatively in solution. At a final tartrate concentration of 0.05 M large single crystals were obtained after slow crystallisation. Unfortunately, these were always twinned and not suitable for single-crystal X-ray structure analysis. At a higher final tartrate concentration of 0.2 M a fast precipitation occurred and the product was obtained as a microcrystalline powder. These microcrystalline samples were used for all experiments described below. In all cases we obtained hydrates of the mixed tartrates in which the water

loss starts at room temperature. In order to obtain anhydrous samples with a defined stoichiometry the products were fully dehydrated at 130 °C in air. Elemental analysis (Table 1) showed that the compositions of the samples were in good accordance with the intended composition, i.e. that all metal ions present in solution were also present in the same ratio in the precipitate. The Cu/Zn ratio was thereby easily controlled by variation of the ratio of copper/zinc in solution. Unfortunately, it was not possible to synthesise a ternary precursor that also contains aluminium by precipitation or crystallisation due to the high solubility of $Al_2TT_3$.

## Crystal Structures, Powder Diffraction Patterns and Precursor Morphology

The structures of the hydrates $ZnTT{\cdot}2.5\,H_2O$[19] and $CuTT{\cdot}3\,H_2O$[20] are both known. These compounds are not isostructural. No structural data are available in the literature for Cu/Zn tartrate mixed crystals. The crystal structures of anhydrous copper L-tartrate and zinc L-tartrate are also unknown. However, after the removal of water of crystallisation all precursor samples were still crystalline according to X-ray diffractometry. The diffraction patterns of copper and zinc L-tartrate are similar, but still distinguishable (Figure 1). The change between the two structures occurs around an equimolar ratio of copper/zinc. Because the single-crystal structures are not known, it is not possible to draw safe conclusions about the phases that are present. However, the powder diffractograms clearly indicate that two structurally different phases of dimetallic tartrate precursors are present, both of which contain copper and zinc in the same phase.

The morphology of the Cu/Zn dimetallic tartrates was studied by SEM (Figure 2). The particle shape depended on the ratio of the two metals, but all samples were microcrystalline, as also supported by the narrow X-ray diffraction peaks in Figure 1.

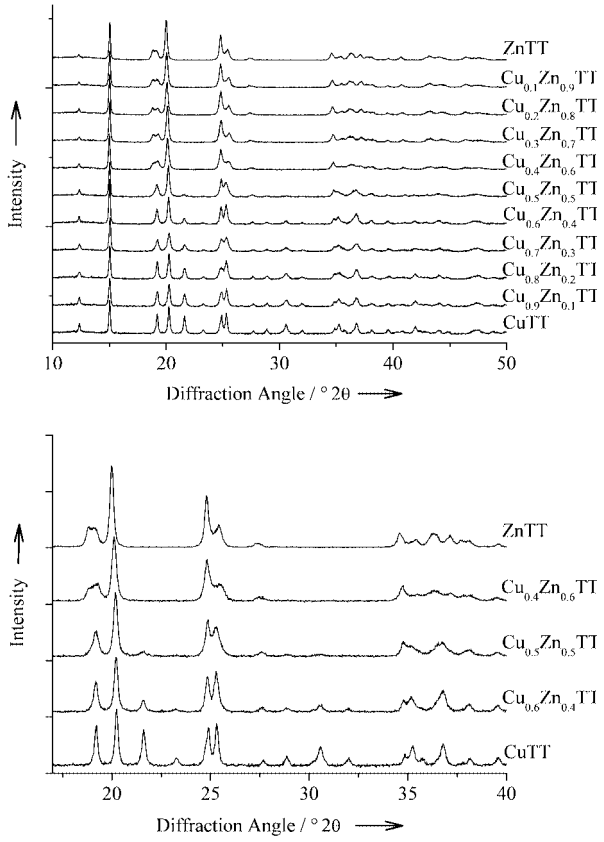

Figure 1. Powder diffraction patterns of the mixed Cu/Zn tartrates. Top: overview; bottom: magnification of selected samples.

## Thermogravimetric Analysis

Three MTT samples were heated to 500 °C under pure oxygen (50 mL min$^{-1}$) at 5 K min$^{-1}$. The thermolysis occurs in one step and is accompanied by sharp exothermic DTA peaks (Figure 3). Incidentally, the exothermic nature of the thermolysis (combustion) was clear from the observation that the sample glowed red in the furnace, even at 300 °C (autocatalytic oxidation by oxygen). The onset temperature

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

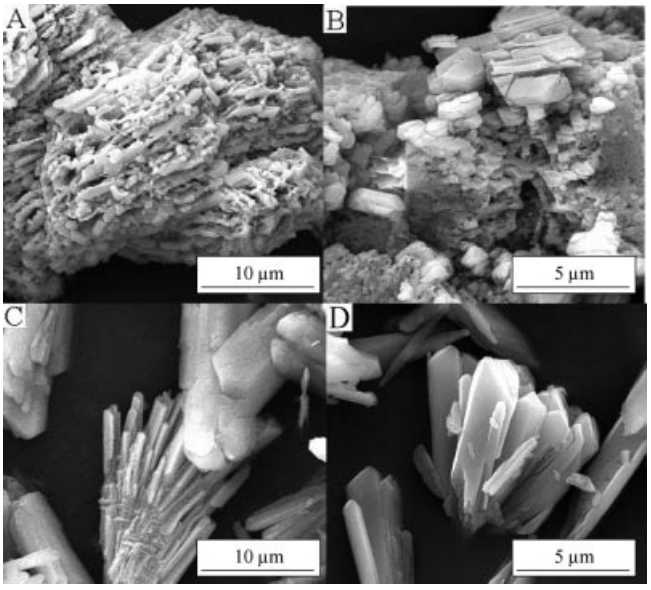

Figure 2. Scanning electron micrographs of the tartrates CuTT (A), $Cu_{0.7}Zn_{0.3}TT$ (B), $Cu_{0.3}Zn_{0.7}TT$ (C) and ZnTT (D).

of thermolysis increases with increasing zinc content. The mass increase above 250 °C for CuTT can be ascribed to an oxidation of the initially formed $Cu_2O$ to CuO. Interestingly, such a mass increase was not observed for $Cu_{0.5}Zn_{0.5}TT$, which means that this sample is directly converted into CuO/ZnO during the combustion step. The obtained final masses at 500 °C (CuTT: 36.7 wt.-%; $Cu_{0.5}Zn_{0.5}TT$: 38.4 wt.-%; ZnTT: 37.3 wt.-%) correspond well to the calculated masses (CuO from CuTT: 37.5 wt.-%; CuO/ZnO from $Cu_{0.5}Zn_{0.5}TT$: 37.8 wt.-%: ZnO from ZnTT: 38.1 wt.-%). The final products contained neither carbon nor hydrogen (by elemental analysis). The external morphology of the tartrate crystals is preserved in the assembly of the product crystals (Figure 4). Note that Schmid and Felsche have reported that the thermolysis of copper tartrate under inert gas (argon) leads to copper metal.[21]

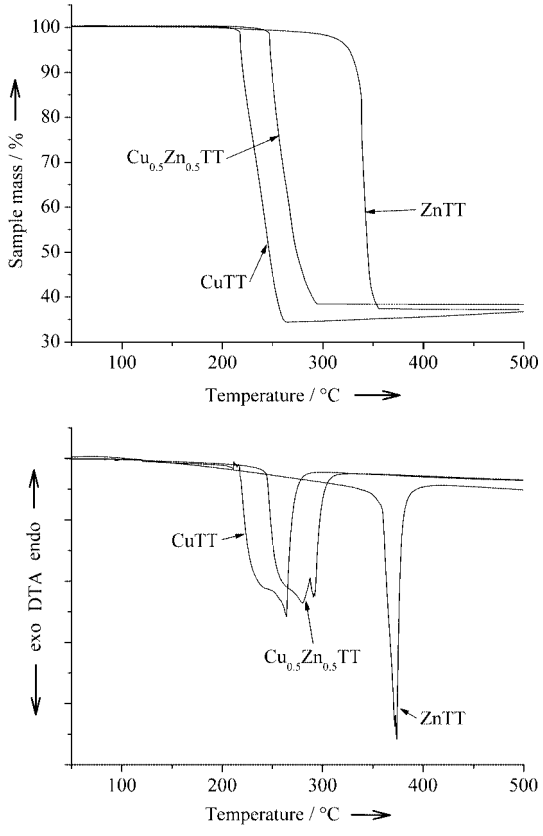

Figure 3. Top: Thermogravimetric measurements of CuTT, $Cu_{0.5}Zn_{0.5}TT$ and ZnTT under a dynamic oxygen atmosphere. Bottom: The mass loss is accompanied by sharp exothermic DTA peaks in all three cases, indicating local combustion processes.

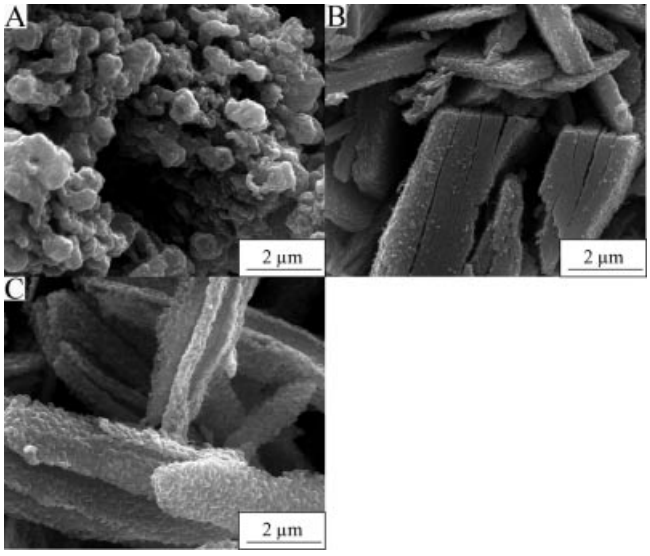

Figure 4. Scanning electron micrographs of the oxide samples obtained after thermogravimetry of CuTT (A), $Cu_{0.5}Zn_{0.5}TT$ (B) and ZnTT (C) under oxygen (500 °C). Note the preservation of the morphology of the original large crystals.

## Thermolysis in Air and Morphologic Studies

Larger amounts of the oxide samples for catalytic studies were prepared by thermolysis in air at 300 °C for 24 h, followed by slight mechanical grinding. Note that a thermolysis at 250 °C for 48 h gave very similar results. The lowermost temperature necessary for complete thermolysis was chosen in order to avoid sintering of the reaction products to larger crystals. Note that a small crystallite size is important for the catalytic performance.[22] A high specific copper surface area is also important for a good catalytic performance.[2,23] The diffraction pattern of the product from CuTT shows the presence of $Cu_2O$ and CuO. In contrast, all mixed oxide samples that contain copper contain only CuO and ZnO. ZnTT leads to ZnO after thermolysis (Figure 5). Under these conditions, the precursor morphology is better conserved and the surface of the former tartrate crystals is smoother (Figure 6).

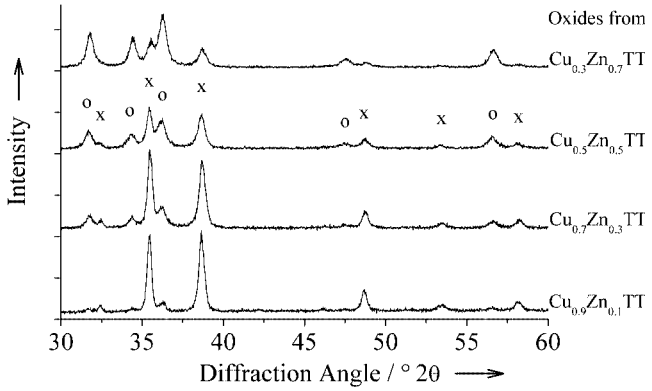

Figure 5. Powder diffraction patterns of oxide mixtures obtained by thermolysis in air at 300 °C (24 h) and containing CuO (x; tenorite; JCPDS no. 481548) and ZnO (o; wurtzite; JCDPS no. 361451).

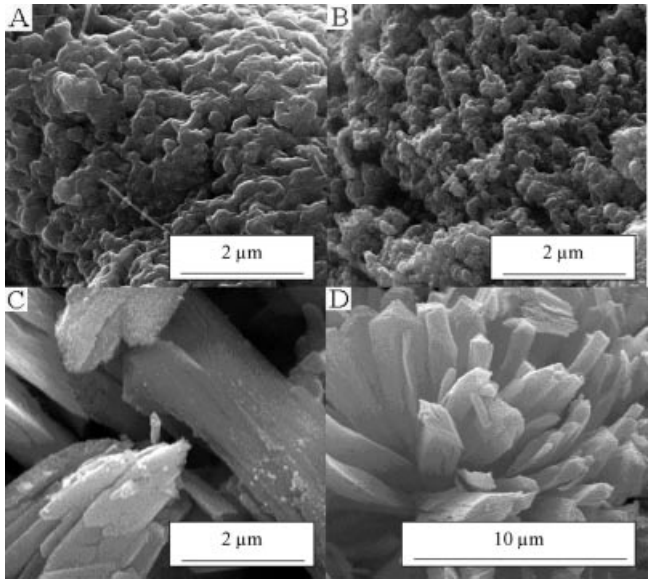

Figure 6. Scanning electron micrographs of the oxide samples obtained by thermolysis of CuTT (A), $Cu_{0.7}Zn_{0.3}TT$ (B), $Cu_{0.3}Zn_{0.7}TT$ (C) and ZnTT (D) in air at 300 °C (24 h).

### Catalytic Activity

The oxide samples were tested regarding their ability to catalyze the formation of methanol from synthesis gas (CO, $CO_2$ and $H_2$). The CuO/ZnO mixture was reduced directly in the catalytic reactor to Cu/ZnO with $H_2$. The Cu/Zn ratio had a remarkable influence on the catalytic activity, showing a clear maximum for an approximately equimolar ratio of Cu and Zn (Figure 7). Although the thermolysis was performed at moderate temperatures, the catalytic activities are low in comparison to an industrial benchmark catalyst (set to 100%). However, the maximum activity (17%) was of the order of a Cu/ZnO catalyst prepared from co-precipitated hydroxycarbonate (about 25%).[18] The specific surface area of the oxide precatalysts shows an almost linear increase, starting from almost zero (0.46 $m^2 g^{-1}$) for pure CuO up to 30–40 $m^2 g^{-1}$ for samples with high zinc content. The sample $Cu_{0.5}Zn_{0.5}TT$ was also subjected to temperature-programmed reduction (TPR) and to reactive frontal chromatography (RFC). The content of 50 mol-% Cu was confirmed by TPR. However, the specific copper surface area (by RFC) was only 0.34 $m^2 g^{-1}$ (note that the accuracy of values below 1 $m^2 g^{-1}$ is limited), which is surprisingly small given the considerable catalytic activity of this sample. For comparison, the specific copper surface area is 17.0 $m^2 g^{-1}$ for the aforementioned hydroxycarbonate-based catalyst and 23.4 $m^2 g^{-1}$ for the industrial reference catalyst.[18]

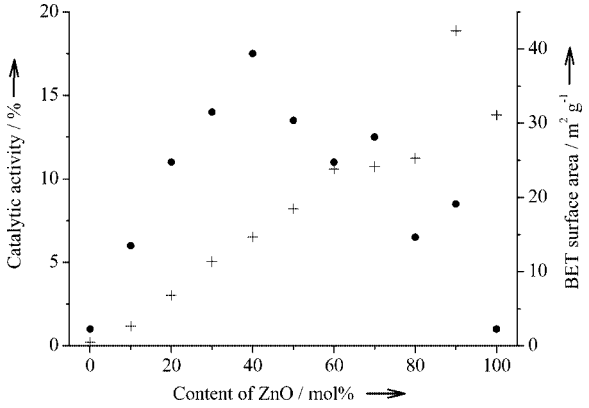

Figure 7. Catalytic activity of CuO/ZnO samples after thermolysis of mixed tartrates (300 °C; air; 24 h) after reduction to Cu/ZnO in situ in a multireactor with $H_2$, measured at 245 °C and 4.5 MPa (●; left scale). The activity of a technical methanol catalyst was set to 100%. The BET surface area of the oxide precatalysts (i.e. before reduction) is shown on the right (+).

A possible explanation for the lower activity compared to hydroxycarbonate-derived catalysts could be the fact that the thermolysis of the tartrates is associated with an exothermic effect, in contrast to the endothermic decomposition of hydroxycarbonates. This exothermic effect may lead to microscopic self-heating and thereby to a growth of oxide crystals. This is supported by the X-ray diffraction data (Figure 5), which show narrow peaks for the oxides, i.e. no nanocrystalline particles that would give rise to diffraction peak broadening. These CuO particles form the active centres of the final reduced catalyst (Cu on ZnO), and it is known that larger copper crystals are catalytically less active than smaller copper crystals.[2,22,23] This is corroborated by the small observed specific copper surface area for the 50:50 sample.

## Conclusions

Metal L-tartrates that contain both copper and zinc as a mixed crystal are well-suited precursors to prepare CuO/ZnO precatalysts that can then be reduced to Cu/ZnO, i.e. an active methanol catalyst. The maximum activity is found at about equimolar amounts of copper and zinc, although the specific surface area increases strongly with increasing zinc content. The presence of this activity maximum reflects the interplay between metal (Cu) and support (ZnO) and the necessity for a sufficiently high specific surface area. The preparation by precipitation easily allows control of the ratio of Cu/Zn in the precursor, and thereby of the catalytic

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

activity. Except for carbonate, other ions are avoided during the synthesis. This synthetic method presents an alternative to classical hydroxycarbonate precursors.

## Experimental Section

**General:** Deionised water was used for all preparations.

**Preparation of the Precursor Samples:** A solution of 50 mmol of copper acetate and/or zinc acetate in the appropriate ratio in 200 mL of water (55 °C) and a solution of 50 mmol of L-tartaric acid in 50 mL of water (room temperature) were prepared. The solution of the acid was rapidly poured into the solution of the metal acetates with vigorous stirring. Approximately 30 s after the addition, the precursor began to precipitate. The mixture was stirred at about 50 °C for another 15 min. After sedimentation of the precipitate, the precipitate was filtered and washed three times with water and then once with ethanol. The tartrates were first dried at 70 °C for 2 h and then at 130 °C for 12 h. With the exception of ZnTT, all products were obtained as fine powders. CuTT was slightly blue, ZnTT was white, and the mixed crystals showed a continuous row of intermediate colours.

**Catalytic Measurements:** Measurements were performed in a high-throughput 49-parallel channel reactor.[5] The samples (100 mg diluted with 200 mg of quartz per well) were placed in a sample holder consisting of a stainless-steel cartridge closed at the bottom by a stainless-steel sinter metal frit. Prior to the catalytic measurements, the catalysts were reduced with $H_2$ at 245 °C according to the procedure for the commercial benchmark catalyst ICI Katalco 51-8. Before measuring the catalytic activity, all samples were equilibrated for 3 h (reaction pressure: 4.5 MPa; reaction temperature: 245 °C; analytic flow: 20 mL min$^{-1}$). The reaction gas consisted of 70 vol% $H_2$, 24 vol% CO and 6 vol% $CO_2$. A double GC system (HP GC 6890) equipped with a methanizer FID was used for online gas analysis. Oxo product separation ($H_3COH$, $HCOOCH_3$, $H_3CCOOCH_3$, $H_3CCH_2OH$) was carried out on a SuppelcoWAX 0.53 mm column and CO, $CO_2$ and $CH_4$ were separated on a Carboxen 1006 column. Methanol productivities for all measured samples were compared to the productivity of the industrial benchmark catalyst ICI Katalco 51-8 [$P_{ICI}$ = 40 mol MeOH(kg$_{cat}$ h)$^{-1}$ at 245 °C and 4.5 MPa].

**Analytical Techniques:** Combined thermogravimetry-IR spectroscopy (TG-IR) was carried out with a Netzsch STA 209 TG-DTA/DSC instrument. Samples were heated from 30 to 500 °C at a rate of 5 K min$^{-1}$ under dynamic $O_2$ atmosphere (50 mL min$^{-1}$). Scanning electron microscopy images were recorded with an ESEM Quanta 400 instrument (FEI) on Au/Pd-sputtered samples. X-ray powder diffractometry was carried out in Bragg–Brentano mode with a Bruker AXS D8 Advance instrument with Cu-$K_\alpha$ radiation. Atomic absorption spectroscopy (AAS) was performed with a Thermo Electron Corporation instrument (M series) to determine the contents of copper and zinc in the samples. The contents of carbon and hydrogen were determined by standard combustion analysis with an EA 1110 (CE Instruments) instrument. The specific surface area was determined by nitrogen physisorption at 77 K (BET method) on the oxide precatalysts (i.e. CuO/ZnO). Temperature-programmed reduction (TPR) was carried out on the oxide product from the sample $Cu_{0.5}Zn_{0.5}$TT. About 0.1 g of this sample was placed in a quartz reactor. The reduction was performed under flowing diluted $H_2$ (4.2 vol% $H_2$ in He) by increasing the temperature to 240 °C at a rate of 1 K min$^{-1}$ and maintaining that temperature for 1 h. The active surface area of Cu was determined by $N_2O$ reactive frontal chromatography at 300 K on the same sample of $Cu_{0.5}Zn_{0.5}$TT.[24]

# A Facile Hydrothermal Route to Flower-Like Cobalt Hydroxide and Oxide

Li-Xia Yang,[a,b] Ying-Jie Zhu,*[a] Liang Li,[a,b] Ling Zhang,[a,b] Hua Tong,[a,b] Wei-Wei Wang,[a,b] Guo-Feng Cheng,[a] and Jie-Fang Zhu[a]

**Keywords:** Cobalt hydroxide / Cobalt oxide / Materials science / Nanostructures / Solvothermal synthesis

Flower-like cobalt hydroxide [β-$Co(OH)_2$] consisting of nanosheet networks has been synthesized by a hydrothermal method from $Co(CH_3COO)_2{\cdot}4H_2O$ in mixtures of water and glycerol/ethylene glycol at 200 °C. The morphology and phase of the cobalt hydroxide can be controlled by adjusting the experimental parameters that include cobalt acetate concentration and the volume ratio of water to glycerol/ethylene glycol. The possible formation mechanism of flower-like cobalt hydroxide is discussed on the basis of experimental results. Cobalt oxide ($Co_3O_4$) flowers have also been obtained by thermal decomposition of cobalt hydroxide flowers in air at 400 °C. The products were characterized by powder XRD, TEM, selected-area electron diffraction (SAED), high resolution TEM (HRTEM), and field-emission SEM (FESEM).

## Introduction

Research into nanomaterials has increased recently due to their unique electrical, optical, magnetic, and catalytic characteristics in comparison with the bulk materials. Currently, inorganic architectures with a hierarchical structure based on nano units and their specific properties for applications are attracting much interest in materials chemistry.[1–5] For example, the mediator-template assembly of gold nanoparticles into size-controllable nanostructures has been reported.[1] The interesting morphological and optical properties of these nanoparticle assemblies could potentially be exploited for optical sensing applications.[1] CoPt nanopolypods derived from the assembly of nanorods have been synthesized by a simple and large-scale-applicable thermolytic reaction,[2] and high-order superstructures of zeolite doughnuts with nanoscale building blocks (sheet-like discs) have been synthesized by a synergic dual-template method in a one-pot reaction.[3] The controlled construction of primary building blocks into curved structures provides another challenge for materials synthesis because of their potential use in new technological applications.

Cobalt hydroxide [$Co(OH)_2$] has recently received increasing attention due to its important technological applications. For example, cobalt hydroxide is usually added to nickel hydroxide electrodes to enhance the electrode conductivity and chargeability,[6,7] and composite materials of cobalt hydroxide and ultra-stable Y zeolite molecular sieves have shown potential applications in electrochemical capacitors.[8] Cobalt hydroxide films show catalytic and reversible electrochromic properties.[9,10] In particular, Kurmoo has reported the incorporation of different anions into the interlayers of cobalt hydroxide to form organic magnetic materials.[11] The preparation of single-crystalline β-$Co(OH)_2$ nanosheets is easily achieved because of their intrinsic lamellar structures.[12–14] However, there are few reports on the formation of 3D β-$Co(OH)_2$ architectures assembled from nanostructures, except the butterfly-like nanocrystals of β-$Co(OH)_2$ prepared by an ethylenediamine-mediated route.[15] At present, the synthesis of β-$Co(OH)_2$ hierarchical nanostructures is still a big challenge for researchers.

Spinel cobalt oxide ($Co_3O_4$), which is an important p-type semiconductor, has potential applications in sensors, lithium-ion batteries, and catalysis.[16–19] Furthermore, $Co_3O_4$ nanoparticles show interesting magnetic and field-emission properties.[20,21] There have been some reports on the synthesis of cobalt oxide nanocubes, nanorods, nanotubes, hollow spheres, and nanoboxes.[22–27] However, to the best of our knowledge, there has been no report on the synthesis of $Co_3O_4$ flowers consisting of nanosheet building blocks.

Here we report a simple hydrothermal approach to the synthesis of two kinds of β-$Co(OH)_2$ flowers consisting of nanosheet building blocks by the hydrolysis of cobalt acetate in solvent mixtures containing a polyalcohol and deionized water. $Co_3O_4$ flowers are readily obtained by thermal decomposition of $Co(OH)_2$ flowers in air. These β-$Co(OH)_2$ and $Co_3O_4$ flowers are expected to have potential applications in sensors, batteries, and catalysis.

## Results and Discussion

The phase of the as-prepared sample was examined by XRD. Figure 1(a) shows the XRD pattern of sample 1 prepared in a mixture of water and glycerol. All diffraction peaks in this pattern can be indexed as a single phase of the hexagonal brucite-like β-$Co(OH)_2$, which is consistent with the values in the literature (JCPDS no. 74-1057). The typical FESEM micrographs shown in Figure 1b–d reveal that sample 1 consists of relatively uniform flower-like structures. Each flower-like structure is composed of a network of nanosheet building blocks. The sizes of these flowers are in the range 6–9 μm, and the thickness of the nanosheets is less than 100 nm. The above results demonstrate that β-$Co(OH)_2$ with a flower-like morphology can be produced using the present synthetic scheme.

It is believed that the physical and chemical properties of the solvent can influence the solubility, reactivity, and diffusion behavior of the reagents and the intermediate.[28] In our reaction system, the properties of the mixed solvents can be easily adjusted by varying the volume ratio of glycerol to water. The volume ratio of glycerol to water ($V_g/V_w$) has a great influence on the formation of the product. As discussed above, a single phase of hexagonal β-$Co(OH)_2$ was obtained when $V_g/V_w$ was 1:3 (sample 1). When $V_g/V_w$ was adjusted to 1:6.5, however, a mixture of $Co_3O_4$ and β-$Co(OH)_2$ was obtained at 200 °C after 10.5 h [sample 2, Figure 2(a)]. When the reaction time was prolonged to 24.5 h (sample 3), a single phase of β-$Co(OH)_2$ was obtained (Figure 2b), thus indicating that glycerol can act as a reducing agent to reduce $Co^{3+}$ to $Co^{2+}$, which results in the transformation of $Co_3O_4$ to $Co(OH)_2$. Compared with the reaction with $V_g/V_w$ = 1:3, it takes a relatively longer time to form a single phase of β-$Co(OH)_2$ when using less glycerol. We also studied the effect of cobalt acetate concentration on the product, with a constant $V_g/V_w$ ratio of 1:3. When the amount of cobalt acetate was decreased to 0.100 g, a single phase of β-$Co(OH)_2$ with a pink color was still obtained (sample 4). However, if more cobalt acetate was used (1.000 g, sample 5), the product was blue, similar to that of α-$Co(OH)_2$, although the XRD pattern (Figure 2c) cannot be indexed to that of α-$Co(OH)_2$.

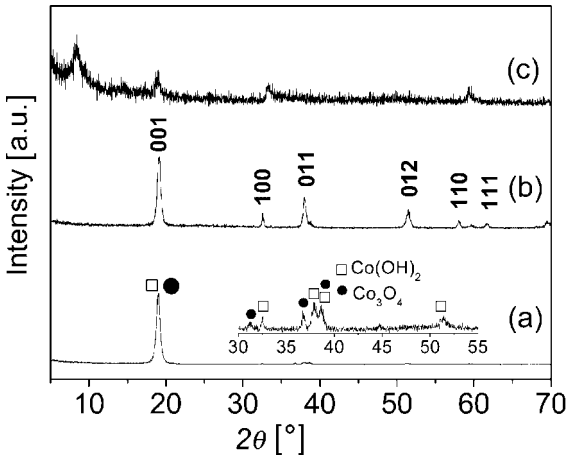

Figure 2. XRD patterns of different samples prepared by hydrothermal treatment at 200 °C: (a) sample 2; (b) sample 3; (c) sample 5.

In order to understand the formation process of β-$Co(OH)_2$ flowers, the morphologies of samples 3 and 4 were also examined by FESEM. When using less cobalt acetate (sample 4, Figure 3a), imperfect flowers assembled from

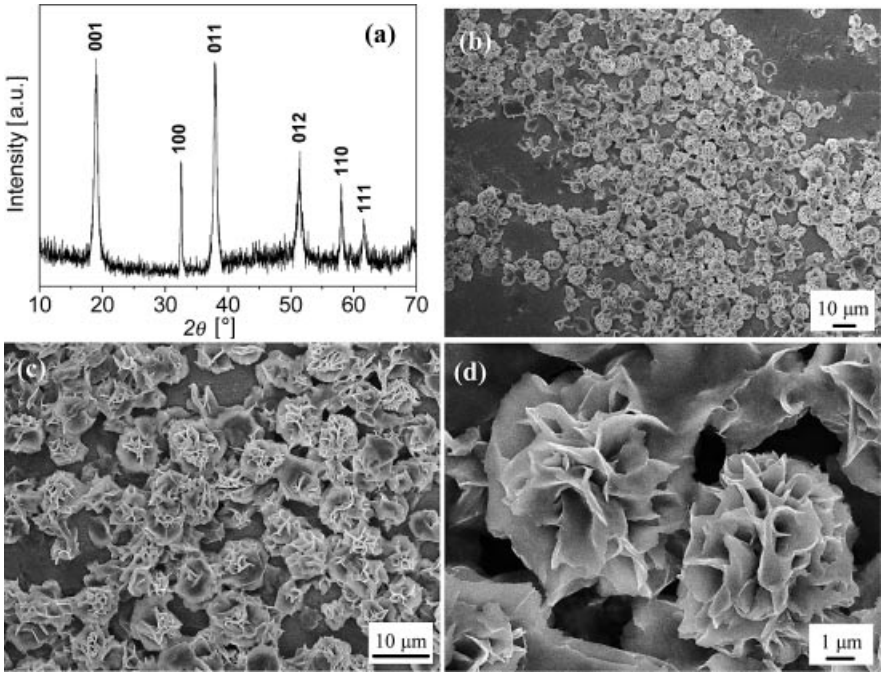

Figure 1. (a) XRD pattern of the obtained β-$Co(OH)_2$ (sample 1); (b–d) FESEM micrographs of β-$Co(OH)_2$ flowers (sample 1) at different magnifications.

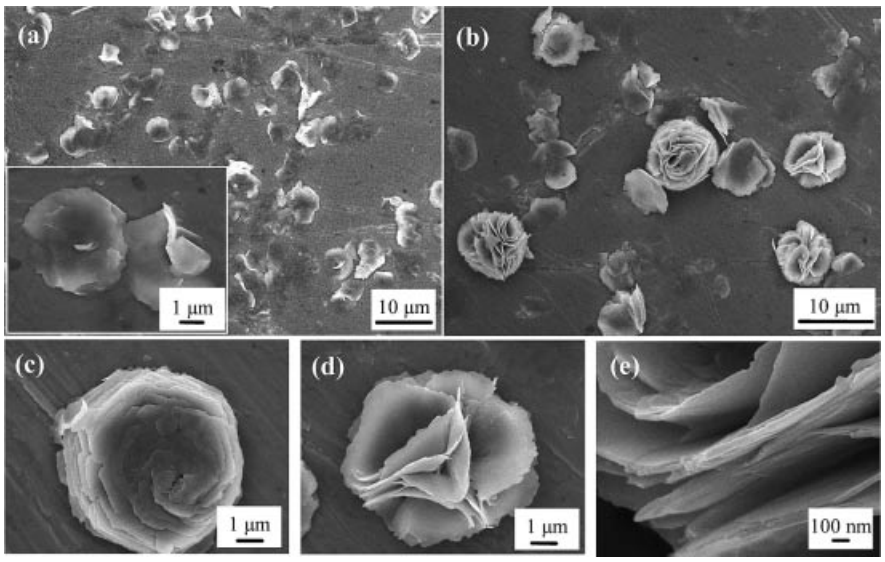

Figure 3. (a) FESEM micrograph of sample 4; (b) FESEM micrograph of sample 3; (c) and (d) FESEM micrographs of single flowers in sample 3; (e) a magnified FESEM micrograph of a flower in sample 3.

nanosheets were observed with dimensions below 7.5 μm, along with a few single nanosheets. The number of petals in these flowers is less than those in sample 1, as shown in Figure 3a. Upon decreasing the volume of glycerol, sample 3 shows a mixed morphology of nanosheets and flowers. Two kinds of flowers are observed, as shown in Figures 3c and 3d, which show that one kind of flower consists of flat nanosheets and the other of curved nanosheets. The morphology in Figure 3c was not observed in sample 1, so we suggest that it is due to the lower volume of glycerol used. The thickness of the nanosheets in the flowers was estimated to be below 50 nm (Figure 3e).

Ethylene glycol (EG) was also used as a co-solvent to substitute glycerol in order to understand the formation mechanism of the β-$Co(OH)_2$ flowers. The same experimental conditions as for the formation of sample 1 were adopted except for the use of EG instead of glycerol, and a mixture of β-$Co(OH)_2$ and $Co_3O_4$ was obtained, thereby illustrating that EG cannot completely reduce $Co^{3+}$ to $Co^{2+}$ at 200 °C after 10.5 h. A single phase of β-$Co(OH)_2$ was obtained upon increasing the volume ratio of EG to water and prolonging the reaction time to 20.5 h (sample 6, Figure 4a). Surprisingly, a different kind of flower was observed, as shown in the FESEM micrographs of sample 6 (Figure 4). The β-$Co(OH)_2$ flowers look like carnations consisting of curved nanosheet building blocks. These carnations have sizes in the range 5–15 μm.

On the basis of the above results, we can propose a formation mechanism for the β-$Co(OH)_2$ flowers. First, the hydrolysis of cobalt acetate results in the formation of $OH^-$ ions ($CH_3COO^- + H_2O \rightarrow CH_3COOH + OH^-$), which provide a basic environment for the formation of cobalt hydroxide. Sheet-like $Co(OH)_2$ forms as a general morphology due to its layered structure. In addition, glycerol/EG can act as a reducing agent. In the absence of glycerol or EG, only $Co_3O_4$ nanocubes are obtained. $Co_3O_4$ is formed by the oxidation of β-$Co(OH)_2$ by oxygen in the autoclave and is then reduced by glycerol/EG to form a single phase of β-$Co(OH)_2$. Besides acting as a reducing agent, glycerol/EG could coordinate to the cobalt ions to form complexes in solution,[29,30] which decreases the free $Co^{2+}$ concentration in solution and results in the slow generation of β-$Co(OH)_2$. This coordination between cobalt ions and glycerol/EG may be favorable for the formation of the flower nuclei,

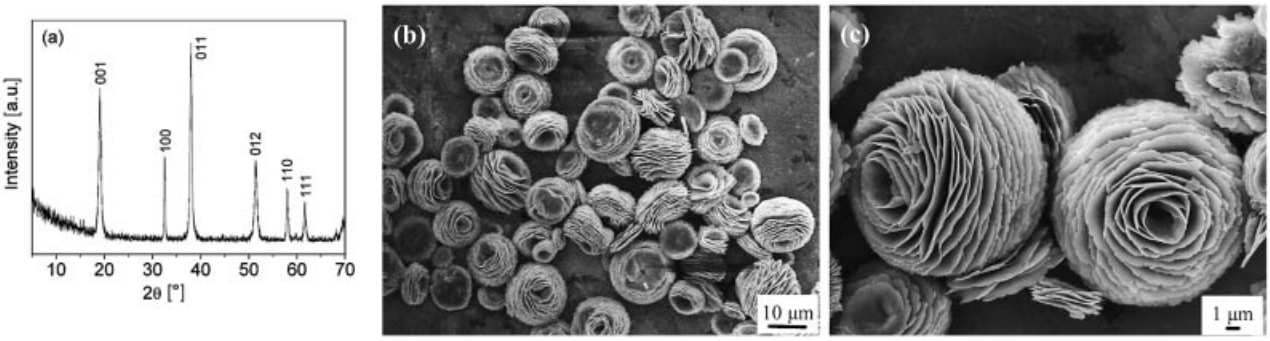

Figure 4. (a) XRD pattern of sample 6; (b) and (c) FESEM micrographs of sample 6 at different magnifications.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

resulting in the formation of flower-like β-$Co(OH)_2$. Furthermore, glycerol helps to generate a highly viscous and stable mixture solution, which favors the stable growth of nanosheets and the formation of β-$Co(OH)_2$ flowers with nanosheets as building blocks. As discussed above, a higher $V_g/V_w$ ratio favors the formation of flowers consisting of curved nanosheets instead of those with flat nanosheets (samples 1 and 3), thus indicating that the higher viscosity caused by glycerol can prohibit the aggregation of nanosheets and promotes the formation of flowers with curved nanosheets. Qian et al.[31] have reported the synthesis of copper nanowires by a complex-surfactant-assisted hydrothermal reduction process in a mixture of water and glycerol. The high viscosity shows a good effect on prohibiting the aggregation of copper particles and results in a relatively stable suspension. One of the keys to the formation of these flower structures is the use of cobalt acetate as the cobalt source without the addition of any base. The slower hydrolysis of acetate and the complexation of cobalt ions with glycerol/EG are favorable for the formation of these superstructures. In the presence of glycerol, when NaOH is added to the solution (sample 7), only irregular nanosheets are formed (Figure 5). Although glycerol provides a viscous environment, the introduction of a strong base (NaOH) could accelerate the reaction and prevent the formation of flowers. However, in the presence of EG, the viscosity is not as high as with glycerol, therefore the nanosheets tend to self-assemble to reduce the surface energy in the mixture of EG and water, and follows a layer-by-layer growth style so that hierarchical carnation structures are formed.

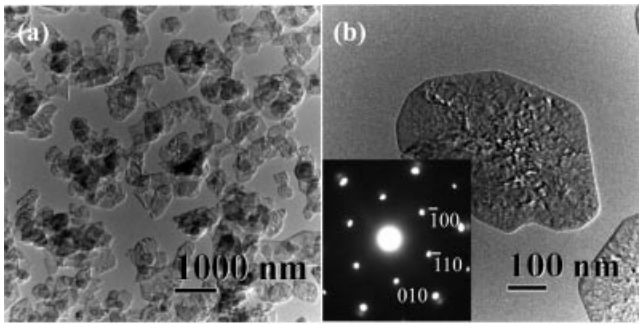

Figure 5. (a, b) TEM micrographs of the obtained β-$Co(OH)_2$ nanosheets of sample 7; the inset of (b) is the corresponding SAED pattern.

TEM was used to study the crystal structure of β-$Co(OH)_2$. Figure 6a shows a single nanosheet of sample 4. The SAED pattern (Figure 6b) of this nanosheet exhibits a hexagonal symmetry, thus indicating that the surface of the nanosheet is the $(00\bar{1})$ plane of β-$Co(OH)_2$, and the direction along the thickness of the obtained β-$Co(OH)_2$ is $[00\bar{1}$; the *c* axis of hexagonal β-$Co(OH)_2$]. The SAED pattern changes rapidly under electron irradiation to give another set of diffraction patterns that are close to the original one that show elongated diffraction spots rather than bright dots, thereby indicating the coexistence of two different species (Figure 6c). The inner set of hexagonal diffraction spots is still due to β-$Co(OH)_2$, and the outer set of diffraction spots corresponds to CoOOH. The electron beam is also along the $[00\bar{1}]$ direction of hexagonal CoOOH (JCPDS no. 26-1107). A similar SAED pattern has been reported for a mixture of β-$Co(OH)_2$ and CoOOH.[32] The diffraction pattern of β-$Co(OH)_2$ vanishes after prolonged irradiation by the electron beam and another set of SAED patterns (Figure 6d) is obtained, which shows the coexistence of CoOOH and $Co_3O_4$. The diffraction dots indicated by the white arrows show a hexagonal symmetry and can be indexed to the SAED pattern of a cubic $Co_3O_4$ phase (JCPDS no. 80-1541) with the incident electron beam along the [111] direction. This phenomenon implies that the thin β-$Co(OH)_2$ nanosheets synthesized using the current method are not stable under electron beam irradiation and that prolonged exposure of the sample to the electron beam during the TEM observation will destroy the structure of β-$Co(OH)_2$, resulting in the formation of $Co_3O_4$ nanoparticles with sizes of 1–4 nm, as shown in the high-resolution TEM (HRTEM) image of Figure 6e. The interplanar dis-

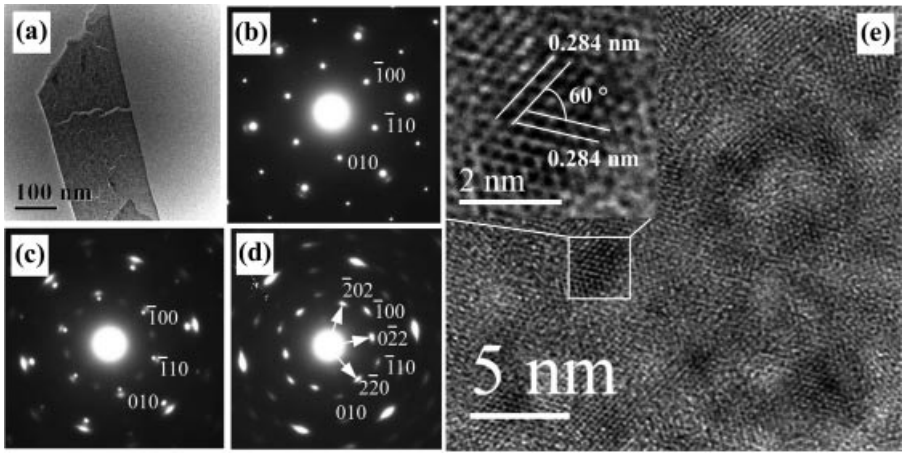

Figure 6. (a) TEM micrograph of an individual β-$Co(OH)_2$ nanosheet of sample 4; (b–d) the corresponding SAED patterns taken at different irradiation times; (e) HRTEM image taken of the individual nanosheet corresponding to the SAED pattern of (d).

tance of the crystal fringes with an angle of 60° is 2.84 nm, which is consistent with the $(\bar{2}02)$ and $(0\bar{2}2)$ planes of a cubic $Co_3O_4$ phase.

$Co_3O_4$ is obtained by thermal conversion of the β-$Co(OH)_2$ flower precursor at 400 °C after 3 h. Figure 7 shows the XRD pattern of the product. All the diffraction peaks can be indexed to a single phase of a cubic $Co_3O_4$, which matches well with the reported data (JCPDS no. 80-1541). No peaks from the β-$Co(OH)_2$ precursor are observed in the XRD pattern, thus indicating the complete transformation of β-$Co(OH)_2$ to $Co_3O_4$.

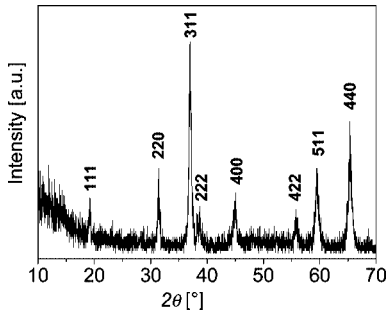

Figure 7. XRD pattern of $Co_3O_4$ (sample C1).

After the thermal conversion from β-$Co(OH)_2$ to $Co_3O_4$, the two kinds of flower-like morphology of β-$Co(OH)_2$ were almost sustained and $Co_3O_4$ flowers were obtained. In addition, a few single nanosheets were also observed, as shown in Figure 8a,b. A single nanosheet is shown in Figure 8c, from which one can see that the surface of this nanosheet is not smooth. The SAED pattern of this nanosheet, which was taken by focusing the incident electron beam along the [111] zone axis, reveals a single crystal structure that can be indexed to cubic $Co_3O_4$, consistent with the XRD results. The HRTEM image of the nanosheet shows that the spacing between clear lattice fringes with an angle of 60° is 0.284 nm, which is consistent with the $(\bar{2}02)$ and $(0\bar{2}2)$ planes of a cubic $Co_3O_4$.

## Conclusions

We have demonstrated a facile strategy to synthesize two kinds of β-$Co(OH)_2$ flowers consisting of nanosheets as the building unit. Glycerol or ethylene glycol serves as a co-solvent and also a reducing agent in this reaction system. Both the volume ratio of glycerol/EG to water and the concentration of cobalt acetate affect the phase and morphology of the product. $Co_3O_4$ flowers can be obtained by a simple thermal conversion of the β-$Co(OH)_2$ flower precursor in air; the flower-like morphology can be preserved during the thermal conversion process. β-$Co(OH)_2$ nanosheets are not stable under electron beam irradiation and are transformed into CoOOH and $Co_3O_4$. This simple synthetic method, which does not use any surfactant or template, may be extended to the synthesis of other materials with novel morphologies.

## Experimental Section

All reagents were of analytical grade and were purchased and used as received without further purification. In a typical procedure, cobalt acetate [$Co(CH_3COO)_2{\cdot}4H_2O$] (0.25 g) was dissolved in a mixture of deionized water and glycerol (30 mL) with a volume ratio

Table 1. Detailed experimental parameters for the synthesis of some typical samples (at 200 °C for all samples).

| Sample | Reaction system | Time [h] | Phase | Morphology |
|---|---|---|---|---|
| 1 | 0.25 g $Co(CH_3COO)_2{\cdot}4H_2O$ + 7.5 mL glycerol + 22.5 mL $H_2O$ | 10.5 | β-$Co(OH)_2$ | flowers |
| 2 | 0.25 g $Co(CH_3COO)_2{\cdot}4H_2O$ + 4 mL glycerol + 26 mL $H_2O$ | 10.5 | β-$Co(OH)_2$ + $Co_3O_4$ | – |
| 3 | 0.25 g $Co(CH_3COO)_2{\cdot}4H_2O$ + 4 mL glycerol + 26 mL $H_2O$ | 24.5 | β-$Co(OH)_2$ | flowers and nanosheets |
| 4 | 0.10 g $Co(CH_3COO)_2{\cdot}4H_2O$ + 7.5 mL glycerol + 22.5 mL $H_2O$ | 10.5 | β-$Co(OH)_2$ | imperfect flowers |
| 5 | 1.00 g $Co(CH_3COO)_2{\cdot}4H_2O$ + 7.5 mL glycerol + 22.5 mL $H_2O$ | 10.5 | unknown | – |
| 6 | 0.25 g $Co(CH_3COO)_2{\cdot}4H_2O$ + 20 mL ethylene glycol + 10 mL $H_2O$ | 20.5 | β-$Co(OH)_2$ | carnations |
| 7 | 0.25 g $Co(CH_3COO)_2{\cdot}4H_2O$ + 7.5 mL glycerol + 17.5 mL $H_2O$ + 5 mL NaOH (1 M) | 10.5 | β-$Co(OH)_2$ | nanosheets |

of 3:1 at room temperature, and the solution was then transferred into a Teflon-lined, 40-mL autoclave and maintained at 200 °C for 10.5 h. It was then cooled to room temperature. This sample was denoted as sample 1. The product was then collected by centrifugation and washed with deionized water and absolute ethanol repeatedly, then dried in air at 60 °C. The detailed experimental parameters for the synthesis of some typical samples are listed in Table 1. $Co_3O_4$ samples were obtained by thermal decomposition of β-$Co(OH)_2$ flowers (samples 1 and 6) in a tubular oven at 400 °C after 3 h in air. The obtained $Co_3O_4$ samples are denoted as samples C1 and C6, respectively.

Powder XRD data were collected on a Rigaku D/max 2550 V X-ray diffractometer with high-intensity Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å) and a graphite monochromator. The morphology was studied with a JEOL JSM-6700F field emission scanning electron microscope (FESEM). TEM, SAED, and HRTEM images were obtained using a JEOL JEM-2100F field emission transmission electron microscope.

# Coordination Chemistry of 3-Mercapto-2-(mercaptomethyl)propanoic Acid (Dihydroasparagusic Acid) with Iron and Nickel

**Phillip I. Volkers,[a] Thomas B. Rauchfuss,*[a] and Scott R. Wilson[a]**

**Keywords:** Iron / Nickel / S ligands / Bridging ligands / Coordination modes

The first transition-metal complexes bearing the natural product dihydroasparagusic acid, $(HSCH_2)_2CHCO_2H$, as a ligand are reported. Various coordination modes and nuclearities are demonstrated for the chelating ligand by a series of iron and nickel complexes. $Fe_2[(SCH_2)_2CHCO_2H](CO)_6$ retains carbonyl substitution reactivity typical of $Fe_2(SR)_2(CO)_6$ complexes, yet carboxy coordination to $Fe^I$ was unobserved. Coupling of the carboxylic acid with amines yields the corresponding amides $Fe_2[(SCH_2)_2CHC(O)NHR](CO)_6$ (R = Et, gly–*O*–*t*Bu). $Fe_2[(SCH_2)_2CHCO_2H](CO)_4(PMe_3)_2$ catalyzes $H_2$ production, but no better than unfunctionalized alkyl dithiolate analogs. Reactions of the ligand with $NiCl_2$(dppe) afforded mono-, di-, and trinuclear complexes. Noteworthy is $Ni_3[(SCH_2)_2CHCO_2]_2(dppe)_2$, which features an octahedrally coordinated $Ni^{II}$ center linked to a pair of square-planar $Ni^{II}$ centers.

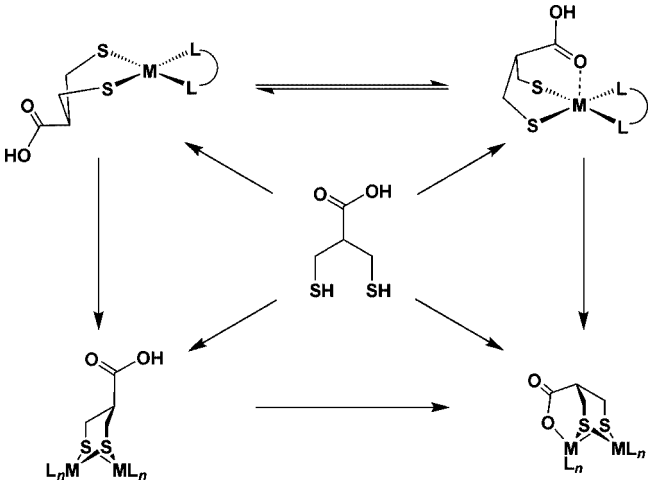
## Introduction

The coordination properties of the natural product dihydroasparagusic acid,[1] $(HSCH_2)_2CHCO_2H$, has received little attention.[2] This compound has long been known, is prepared easily, and offers the possibility of serving as a functionalized bridging dithiolate ligand.[3,4] Our interest in exploring its coordination properties was motivated by the occurrence of propanedithiolate or the isosteric 2-azapropane-1,3-dithiolate as a cofactor in the iron hydrogenases.[5–7]



Scheme 1. General coordination modes for $(HSCH_2)_2CHCO_2H$.

In considering the coordinating properties of asparagusic acid, one can anticipate several motifs: *S*,*S*-bidentate; *S*,*S*,*O*-tridentate; and dinuclear derivatives of each of these (Scheme 1). Examples of such coordination modes are presented here using iron and nickel platforms. We were particularly interested in the possibility that the carboxylic acid functionality in $Fe_2[(SCH_2)_2CHCO_2H](CO)_{6-x}L_x$ would permit attachment of functionality, affect electrocatalytic $H_2$ production,[8,9] or lead to more robust linkages between metal atoms.

## Results and Discussion

### I. Complexes with Iron

#### *$Fe_2[(SCH_2)_2CHCOOH](CO)_6$*

The air-stable parent complex, hereafter $Fe_2$(aspH)$(CO)_6$, was synthesized in 43% yield by the reaction of $Fe_3(CO)_{12}$ and dihydroasparagusic acid, $(HSCH_2)_2$CHCOOH ($aspH_3$). The preparation was more conveniently conducted in the presence of $NEt_iPr_2$, followed by acidification to produce $Fe_2$(aspH)$(CO)_6$. Crystallographic characterization of $Fe_2$(aspH)$(CO)_6$ verified the anticipated $Fe_2(SR)_2(CO)_6$ core and demonstrated hydrogen-bonding interactions between pairs of carboxyl groups (Figure 1, Table 1). The carboxylic acid occupies an equatorial position on the cyclohexane-like $FeS_2C_3$ ring, projecting orthogonally with respect to the Fe–Fe vector.

$Fe_2$(aspH)$(CO)_6$ undergoes the transformations expected for a carboxylic acid (Scheme 2). Amide-bond formation with $EtNH_2$ was effected using a phosphonium-based coup-

ling agent. The crystallographic characterization of $Fe_2[(SCH_2)_2CHCONHEt](CO)_6$ confirms the structure (Figure 2, Table 1). The amide substituent is again equatorial with respect to the cyclohexane-like $FeS_2C_3$ ring and the nitrogen is planar. The occurrence of two identical splitting patterns in the $^1$H NMR spectrum is attributed to *cisoid* and *transoid* rotamers of the amide, consistent with restricted rotation about the C(O)–N bond. Coupling of $Fe_2(aspH)(CO)_6$ with glycine *tert*-butyl ester afforded the corresponding amido ester $Fe_2[(SCH_2)_2CHCONHCH_2CO_2tBu](CO)_6$, which exhibited crystallographic features akin to those in the ethyl derivative (Figure 3, Table 1). Again, two rotamers were observed in the $^1$H NMR spectrum.

### *Acid-Base Properties*

Although only poorly soluble in MeOH, $Fe_2(aspH)(CO)_6$ was found to dissolve upon addition of $Et_3N$, indicative of the formation of $Et_3NH[Fe_2(asp)(CO)_6]$. The $\nu_{CO}$ region in the solution IR spectrum of this deprotonated compound exhibited negligible shifts relative to $Fe_2(aspH)(CO)_6$, indicating minor electronic influence of the pendant carboxy/carboxylate group on the diiron unit. The easy deprotonation of $Fe_2(aspH)(CO)_6$ interfered with experiments aimed at its decarbonylation using $Me_3NO$.[10] Rather than the usual red-to-purple color change observed upon decarbonylation of $Fe_2(SR)_2(CO)_6$,[9] solutions deposited a brown precipitate, presumably of $Me_3NOH[Fe_2(asp)(CO)_6]$.

### *Substitution Reactions of $Fe_2(aspH)(CO)_6$*

Upon heating in the presence of excess $PMe_3$, $HNEtiPr_2[Fe_2(asp)(CO)_6]$ converted readily into $HNEtiPr_2[Fe_2(asp)(CO)_4(PMe_3)_2]$. The $^{31}P$ NMR spectrum of the product showed two equally intense singlets, indicating the nonequivalency imposed by the pendant carboxylate group. IR measurements in the $\nu_{CO}$ region indicate that this salt is very similar electronically to related derivatives, e.g. $Fe_2(S_2C_3H_6)(CO)_4(PMe_3)_2$.[11]

Substitution of the CO ligands in $Fe_2(aspH)(CO)_6$ by cyanide was also explored. IR spectroscopic measurements in the $\nu_{CO}$ region established that the first equivalent of $CN^-$ deprotonated the carboxylic acid. The prevalence of monosubstituted product, $[Fe_2(asp)(CN)(CO)_5]^{2-}$ ($\nu_{CN,CO}$ = 2091, 2028, 1974, 1952, 1914), shows that the pendant carboxylate group inhibits a second cyanide ion from attacking the unsubstituted iron center. When the carboxylic acid was first deprotonated with an amine base, followed by treatment with 1 equiv. of $CN^-$, we again obtained the monosubstituted product. Upon heating in the presence of an additional equivalent of $CN^-$, $[Fe_2(asp)(CN)(CO)_5]^{2-}$ converted into the dicyanide derivative, $[Fe_2(asp)(CN)_2(CO)_4]^{3-}$, as established by IR spectroscopy ($\nu_{CN,CO}$ = 2074, 1960, 1919, 1880).

### *Electrochemical Studies*

Cyclic voltammetry studies showed that MeCN solutions of $Fe_2(aspH)(CO)_6$ reduce at –1.20 and –1.96 V vs. Ag/AgCl, corresponding to $Fe^IFe^I/Fe^0Fe^I$ and $Fe^0Fe^I/Fe^0Fe^0$ couples, respectively.[12] Addition of 1–4 equiv. of HOAc caused an increase in the cathodic current at ca. –1.8 V, characteristic of catalytic $H_2$ production.[12] The electrocatalytic properties do not, however, differ significantly from analogous $Fe_2(S_2C_3H_6)(CO)_6$. In a confirmatory experiment, a 1:1 mixture of $Fe_2(aspH)(CO)_6$ and $Fe_2(S_2C_3H_6)(CO)_6$ in acetonitrile was analyzed electrochemically. The mixture displayed reduction events at –1.20 and –1.96 V, indicating that the two compounds had overlapping reduction events. Similarly, electrochemical analyses of $Fe_2(aspH)(CO)_4(PMe_3)_2$ and HOAc or HOTs showed catalytic $H_2$ production at –1.86 or –1.21 V, respectively, typical of $Fe_2(S_2C_xH_{2x})(CO)_4(PMe_3)_2$ species.[12,13]

## II. Complexes with Nickel

### *Ni(aspH)(dppe)*

Treatment of $NiCl_2$(dppe) with a solution of $aspH_3$ and base yielded orange mononuclear Ni(aspH)(dppe) (Scheme 3).[14,15] The crystallographic characterization of Ni(aspH)(dppe) confirmed the expected square-planar coordination and intermolecular hydrogen bonding (Figure 4, Table 2). The six-membered chelate ring adopts a twist-boat conformation, which projects the carboxylic acid away from the metal center. Ni(aspH)(dppe) was only slightly soluble in MeOH; however, the salt resulting from treatment of Ni(aspH)(dppe) with $NEt_3$ was found to dissolve in both MeOH and $CH_2Cl_2$.

### *$[Ni_2(aspH)(dppe)_2]^{2+}$ and $Ni_3(asp)_2(dppe)_2$*

These di- and trinuclear species[16] were initially obtained as byproducts of the synthesis of Ni(aspH)(dppe). $[Ni_2(aspH)(dppe)_2]Cl_2$ (Scheme 3) was identified by ESI-MS, and its $^{31}P$ NMR spectrum displays two doublets. Isolation of the dinuclear dication was attempted by forming its $BPh_4^-$ salt. Surprisingly, the $^{31}P$ NMR spectrum displays only one, albeit broad, resonance for the inequivalent phosphane ligands. The dinuclear product was identified again by ESI-MS and a preliminary X-ray crystallographic analysis as its $BPh_4^-$ salt. The salt was unstable as a solid under $N_2$.

Upon standing, solutions of Ni(aspH)(dppe) and $[Ni_2(aspH)(dppe)_2](Cl)_2$ deposited crystals of the trinuclear spe-

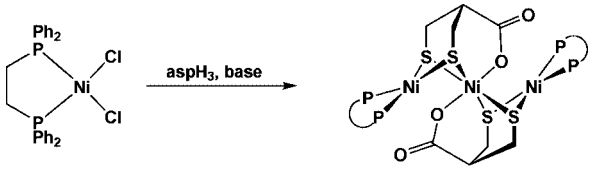
cies analyzing as $Ni_3(asp)_2(dppe)_2$ (Scheme 4). The conversion was accelerated by exposure to air, and FD-MS of the resulting supernatant revealed formation of $dppeO_2$. Crystallographic analysis (Figure 5, Table 2) confirmed a trimetallic complex featuring an unusual Ni(μ-SR)$_2$Ni(μ-SR)$_2$Ni motif.[17–20] Unlike the well-precedented $L_2$Ni(μ-SR)$_2$Ni(μ-SR)$_2$NiL$_2$ motif, the central nickel atom in $Ni_3(asp)_2(dppe)_2$ is octahedral, being bound also to the two carboxylate ligands with Ni–O distances of 2.0 Å (Figure 5). The terminal nickel centers are square-planar and low-spin. The terminal Ni$^{II}$ centers are more tightly bonded to the sulfur atoms (2.22–2.23 Å), whereas the interior nickel center exhibits longer bonds to the sulfur atoms (2.44–2.45 Å), reflecting its higher coordination number. Insolubility of the crystals precluded further analysis of, and reactivity experiments on, the trinuclear species.



Scheme 4. Synthetic route to $Ni_3(asp)_2(dppe)_2$.

## Summary

The first transition-metal complexes bearing the chelating ligand asparagusic acid are reported. Electronically, the pendant carboxyl group does not perturb the *S*,*S* coordination to metal centers, as evidenced by IR and CV studies. The ligand enables straightforward derivatization to be performed on the pendant carboxyl group. Substitution chemistry at the metal centers is also retained, but in the case of $Fe_2(aspH)(CO)_6$ the reactions are slower than the related propanedithiolate complex. In general, the bulk of the dithiolate backbone strongly influences the rates of substitution at the underlying $Fe(CO)_3$ units. The dithiolate–carboxylate can serve as a bridging tridentate chelate by binding a pair of metal centers through *S*,*S*,*O* ligation.

Pickett, Darensbourg, and our group have demonstrated the utility of pendant coordinating groups in modeling the active site of the Fe $H_2$-ases.[21–23] Such pendant ligands, however, were always soft, being phosphanes, thioethers, or alkenes. In the case of $Fe_2(aspH)(CO)_6$ or its amides, we observed no evidence of coordination of the hard oxygen ligands to Fe$^{I}$. Furthermore, we observed no indication that the carboxylic acid or its anion usefully influence the catalytic chemistry of the related $Fe_2(aspH)(CO)_4(PMe_3)_2$ complexes. This lack of an effect is consistent with a mechanism whereby catalysis is localized on the region between the two iron centers.

## Experimental Section

**General:** Nylon syringe filters (0.2 μm) were acquired from Nalgene. (Benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate (BOP) was acquired from ChemImpex Intl. All other chemicals were acquired from Aldrich and used without further purification. Solvents were dried by distillation or were dispensed through two 1-m columns of activated alumina. Solvents were further purified by degassing with a nitrogen purge. Reactions were performed under purified nitrogen using either standard Schlenk techniques or a glove box.

**Dihydroasparagusic Acid [3-Mercapto-2-(mercaptomethyl)propanoic Acid]:** The free ligand was prepared based on the method of Singh and Whitesides.[4] After concentrating the EtOAc extract, the dithiol was extracted into hexane and subsequent slow evaporation of solvent yielded white crystals in 54% yield based on 2-(bromomethyl)propenoic acid.

**$Fe_2(aspH)(CO)_6$:** NEt*i*Pr$_2$ (921 μL, 5.29 mmol) was added to a THF solution (20 mL) of 3-mercapto-2-(mercaptomethyl)propanoic acid (805 mg, 5.29 mmol). An additional 45 mL of THF was added followed by $Fe_3(CO)_{12}$ (2.421 g, 4.81 mmol). Gas evolution commenced immediately, and the color of the solution changed from green-black to yellow-red, concomitant with the formation of a yellow precipitate. The mixture was refluxed for 2.25 h. The resulting dark red solution was filtered in air through a pad of Celite; removal of the solvent gave a red oil. The product was extracted into MeOH, and this extract was filtered again through Celite and concentrated in vacuo. The residue was taken up in 15 mL of $CH_2Cl_2$, treated with trifluoroacetic acid (600 μL, 8.08 mmol), and chromatographed on silica gel, eluting with MeCN/$CH_2Cl_2$ (1:7, v:v). The second red band was collected and concentrated in vacuo to give a red crystalline product. Yield: 888 mg (43%). $C_{10}H_6Fe_2O_8S_2$ (429.98): calcd. C 27.93, H 1.41; found C 27.79, H 1.13. $^1$H NMR (500 MHz, $CD_3OD$): $\delta$ = 2.92 (dd, 2 H, SC*H*H), 2.16 (br., 1 H, C*H*COO), 1.81 (dd, 2 H, SCH*H*) ppm. The solid product decomposed at 118 °C. IR (MeOH): $\nu_{CO}$ = 2076 (vs), 2037 (vs), 1997 (vs), 1730 (m, monomer), 1710 (m, dimer) cm$^{-1}$. FD-MS: *m*/*z* = 429.8 [M$^+$], 373.8 [M$^+$ – 2 CO].

**Alternative Synthesis of $Fe_2(aspH)(CO)_6$:** A mixture of $Fe_3(CO)_{12}$ (5.00 g, 9.92 mmol) and 3-mercapto-2-(mercaptomethyl)propanoic acid (1.51 g, 9.92 mmol) in toluene (100 mL) was heated at 80 °C for 30 min, resulting in a red solution and a fine orange precipitate. The cooled reaction mixture was filtered through a pad of Celite, and the filtrate was concentrated to dryness. The product was extracted with MeCN and was filtered through a nylon membrane (0.2 μm). The solvent was removed to afford a red powder. Single crystals were grown by cooling a concentrated $CH_2Cl_2$ solution to –20 °C. Yield: 1.55 g (36%).

**$Fe_2[(SCH_2)_2CHC(O)NHEt](CO)_6$:** (Benzotriazol-1-yloxy)tris(dimethylamino)phosphonium hexafluorophosphate (103 mg, 0.233 mmol) was added to a solution of $Fe_2(aspH)(CO)_6$ (100 mg, 0.233 mmol) in $CHCl_3$ (5 mL) followed by $H_2$Net (17 μL, 0.2114 mmol). After stirring for 2 min, the coupling reaction was initiated upon addition of NEt*i*Pr$_2$ (55 μL, 0.317 mmol). The reaction was monitored by TLC. After 21 h, the reaction solution was concentrated in vacuo before being chromatographed on silica gel, eluting with MeOH/$CH_2Cl_2$ (5:95, v:v). The first red band was collected, and solvent removal by rotary evaporation yielded an orange powder. Single crystals were grown from a MeOH solution that was cooled to –20 °C. Yield: 30 mg (31%). $C_{12}H_{11}Fe_2NO_7S_2$ (457.05): calcd. C 31.54, H 2.43, N 3.06; found C 32.76, H 2.51, N 3.37. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 3.21 (dq, 2 H, NC$H_2$), 2.66 (dd, 2 H, SC$H_a$), 1.85 [m, 3 H, SC$H_b$ and $(SCH_2)_2$C*H*], 1.11 (t, 3 H, NCH$_2$C$H_3$) ppm. IR (MeOH): $\nu_{CO}$ = 2076 (vs), 2037 (vs), 1997 (vs), 1660 [m, C(O)N], 1563 (w, C–N stretch coupled to N–H deformation), 1310 (w, C–N) cm$^{-1}$. FD-MS: *m*/*z* = 456.9 (100) [M$^+$], 428.9 (23) [M$^+$ – CO], 400.8 (80%, M$^+$ – 2 CO).

**$Fe_2[(SCH_2)_2CHCONHCH_2CO_2tBu](CO)_6$:** [BOP]$PF_6$ (123 mg, 0.279 mmol) was added to a solution of $Fe_2(aspH)(CO)_6$ (120 mg, 0.279 mmol) in $CH_2Cl_2$ (5 mL) followed by the addition of Gly–*Ot*Bu·HCl (42 mg, 0.211 mmol). Addition of NEt*i*Pr$_2$ (110 μL, 0.63 mmol) and stirring for 2 h produced a clear, dark red solution. A concentrated $CH_2Cl_2$ solution was chromatographed on silica gel, eluting with MeOH/$CH_2Cl_2$ (5:95, v:v). Evaporation of solvent from the first red-orange band yielded a red-orange solid. Single crystals were grown by layering a $CH_2Cl_2$ solution of the compound with hexane followed by cooling to –20 °C. Yield: 38 mg (28%). $C_{16}H_{17}Fe_2NO_9S_2$ (543.14): calcd. C 35.38, H 3.15, N 2.58; found C 35.31, H 3.18, N 2.89. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 5.81 (t, 1 H, N*H*), 3.84 (d, 2 H, NC$H_2$), 2.71 (dd, 2 H, SCH*H*), 1.91 (m, 3 H, SC*H*H and C*H*CO), 1.46 [s, 9 H, C(C$H_3$)$_3$] ppm. IR (MeOH): $\nu_{CO}$ = 2075 (m), 2036 (vs), 1997 (s), 1748 [w, C(O)-OCMe$_3$], 1668 [w, NC(O), amide I]; 1558 (w, C–N and N–H, amide II) cm$^{-1}$. FD-MS: *m*/*z* = 542.9 [M$^+$], 487 [M$^+$ – 2 CO].

**Ni(aspH)(dppe):** NaOMe (2 equiv.) in MeOH (40 mL) was added to a mixture of $NiCl_2$(dppe) (835 mg, 1.58 mmol) and asp$H_3$ (240 mg, 1.58 mmol) in MeOH (40 mL). The immediately resulting dark red solution yielded a bright orange precipitate after 1 h. After 4 h, volatiles were removed in vacuo. The residue was washed with 3 × 5 mL of MeOH to remove $[Ni_2(\mu,\mu'\text{-aspH})(dppe)_2]^{2+}$ and other impurities, leaving a bright orange powder. Yield: 577 mg (60%). Single crystals were grown by layering a $CH_2Cl_2$ solution of the compound with $Et_2O$. $C_{30}H_{30}NiO_2P_2S_2$ (607.34): calcd. C 59.33, H 4.98; found C 59.06, H 4.93. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 10.30 (br. s, 1 H, COO*H*), 7.83–7.79 and 7.55–7.46 (m, 20 H, PC$_6H_5$), 3.10 [quint, 1 H, $(SCH_2)_2$C*H*], 2.79–2.64 (m, 4 H, SC$H_2$), 2.18 (d, 4 H, PC$H_2$) ppm. $^{31}$P NMR (202 MHz, $CDCl_3$): $\delta$ = 57.92 (s). FD-MS: *m*/*z* = 606.1 [M$^+$ – H], 398 [dppe].

**$[Ni_2(aspH)(dppe)_2](X)_2$ (X = Cl$^-$, $BPh_4^-$):** NaOMe (2 equiv.) in MeOH (5 mL) was added to a mixture of $NiCl_2$(dppe) (200 mg, 0.379 mmol) and asp$H_3$ (58 mg, 0.379 mmol) in MeOH (5 mL). The solvent was removed in vacuo from the resulting clear, dark red solution after 5.5 h. $^{31}$P NMR (202 MHz, $CD_3CN$): $\delta$ = 59.889 [s, 1 P, $NiCl_2$(dppe)], 57.738 [s, 1 P, Ni(aspH)(dppe)], 53.149 and 53.028 (d, 9 P, $[Ni_2(aspH)(dppe)_2]^{2+}$), 50.470 and 50.349 (d, 9 P, $[Ni_2(aspH)(dppe)_2]^{2+}$) ppm. ESI-MS: *m*/*z* (%) = 1099.4 (100) [{$[Ni_2(aspH)(dppe)_2]Cl$}$^+$], 1063.1 (2) $[Ni_2(asp)(dppe)_2]^+$, 532.3 (12) $[Ni_2(aspH)(dppe)_2]^{2+}$. The product was extracted into 5 mL of MeOH, filtered through a pad of Celite, and treated with a solution of $NaBPh_4$ (140 mg, 0.40791 mmol) in MeOH (3 mL). The resulting yellow-orange precipitate was washed with 15 mL MeOH and dried in vacuo. Yield: 173 mg (27%). Single crystals were grown from an acetone solution layered with methanol. $^{31}$P NMR (202 MHz, $CD_3CN$): $\delta$ = 57.46 (br. s) ppm. ESI-MS: *m*/*z* (%) = 1063.3 (10) $[Ni_2(asp)(dppe)_2]^+$, 532.0 (100) $[Ni_2(aspH)(dppe)_2]^{2+}$.

**$Ni_3(asp)_2(dppe)_2$:** A mixture of $NiCl_2$(dppe) (100 mg, 0.18939 mmol) and asp$H_3$ (28.8 mg, 0.18939 mmol) in MeCN (15 mL) in air was treated with $NEt_3$ (79.2 μL, 0.56817 mmol). Upon standing for 3 h, a crystalline black precipitate began forming. After 1 d, the supernatant was decanted. The extremely dark maroon crystalline solid was collected and dried in air. Yield: 59 mg (74%). $C_{60}H_{58}Ni_3P_4O_4S_4$ (1271.35): calcd. C 56.68, H 4.60; found C 56.41, H 4.48.

**Crystallography:** Data were collected at –80 °C with a Siemens Platform/CCD automated diffractometer. Data processing was performed with SAINT PLUS version 6.22. Structures were solved by direct methods and refined using full-matrix least squares on $F^2$ using Bruker SHELXTL version 6.10. Methyl, carboxyl, and amide H atom thermal parameters were assigned as 1.5× those of the adjacent atom. Remaining hydrogen atoms were fixed in idealized positions with thermal parameters 1.2× those of the attached carbon atoms. CCDC-613254 [$Fe_2$(aspH)$(CO)_6$], -613255 {$Fe_2$[$(SCH_2)_2$CHCONHEt]$(CO)_6$}, -613256 {$Fe_2$[$(SCH_2)_2$-CHCONHCH$_2$CO$_2$*t*Bu]$(CO)_6$}, -613252 [Ni(aspH)(dppe)], and -613253 [$Ni_3(asp)_2(dppe)_2$] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Nickel Thiolate Complexes as Ligands for Copper and Zinc: Novel Additions to a Library of Binding Modes

**Johanna A. W. Verhagen,[a] Christian Tock,[a] Martin Lutz,[b] Anthony L. Spek,[b] and Elisabeth Bouwman*[a]**

**Keywords:** Nickel / Copper / Zinc / S ligands / Cluster compounds

The reactivity of the two nickel complexes [Ni(xbsms)] and [Ni(bsms)$_2$] [H$_2$xbsms = α,α′-bis(4-mercapto-3,3-dimethyl-2-thiabutyl)-*o*-xylene; Hbsms = 4-mercapto-3,3-dimethyl-1-phenyl-2-thiabutane] towards copper iodide and zinc bromide has been investigated. The reactions yield novel aggregates of higher nuclearity with topologies that are different from previous reports; the nickel complexes in all cases can be considered as didentate S ligands. The X-ray structure of the novel octanuclear cluster [{Ni(bsms)$_2$}$_3$(CuI)$_5$] shows a unique arrangement in which the *cis*-NiS$_2$S′$_2$ units act as didentate ligands to a trigonal-bipyramidal array of five Cu$^{I}$ ions. The tetranuclear structure of [{Ni(xbsms)CuI}$_2$] shows unprecedented asymmetric bridging of the thiolate sulfur atoms, with one of the thiolate groups binding to one copper ion and the other one μ$_3$-bridging to two copper ions. The complex is located on a crystallographic twofold axis and the complex in a single crystal is enantiomerically pure. The trinuclear complex [Ni$_2$(bsms)$_3$ZnBr$_3$] is formed as a result of dissociation of the didentate bsms ligand from part of the mononuclear complex and reassembly to form a dinuclear core to which the ZnBr$_3^-$ unit is coordinated to a single thiolate sulfur atom. A complex of stoichiometry [Ni$_3$(xbsms)$_2$-(ZnBr$_3$)$_2$] has also been isolated and a structure proposal based on spectroscopic properties is given. All complexes have been characterised by analytical and spectroscopic methods.

## Introduction

It is now generally accepted that the A-cluster of acetyl-coenzyme-A-synthase/CO-dehydrogenase (ACS/CODH) in its active state contains a dinuclear nickel site bound to an iron–sulfur cluster.[1] However, due to the earlier reports of Cu- or Zn-containing structures,[2,3] attempts to synthesise structural models of the A-cluster have resulted in reports of several new heteronuclear clusters.[4–11] In most of these investigations, discrete mononuclear nickel complexes of tetradentate N$_2$S$_2$ ligands have been used as building blocks, and their reactivity towards transition metals such as Fe, Ni, Cu, Zn, Ag, Pd and Hg have been studied. The nickel complexes can be considered to react as didentate S ligands. A wealth of structures has become available, and a range of possible bridging modes for the thiolate sulfur atoms have been reported.[7] The two *cis*-thiolate sulfur atoms in the parent nickel complex may form single bridges to two different metal ions in, for example, Ni$_3$Cu$_2$, Ni$_3$Ag$_2$ or Ni$_3$Zn$_2$ clusters[4,10,12,13] or Ni$_4$Pd$_2$ paddle wheels;[10,14] they can act as a chelating ligand to one metal ion to form discrete NiCu or NiNi dinuclear complexes[4,5,8,11] or linear trinuclear Ni$_3$ or Ni$_2$Cu complexes;[8,15] or they may bind to four different metal ions through μ$_3$-S bridges in larger Ni$_2$Cu$_4$ aggregates.[16] The nuclearity of the cluster and type of aggregate that is formed is largely dependent on the stoichiometry of the reactants and the presence or absence of coordinating anions. In all of these clusters the nickel ion in the parent complex remains divalent and low-spin in a square-planar geometry. However, when using flexible ligands that allow for different geometries, in a reaction with low-valent metal centres the nickel ion may be reduced and expelled from the ligand[17,18] or it may result in clusters in which the nickel centre is coordinated by the ligand in a tetrahedral geometry and in which additional metal–metal bonds are formed.[19,20]

Numerous Cu$^{I}$ thiolate clusters have been reported. Homoleptic Cu$^{I}$ clusters with monodentate thiolate ligands have been reported as [Cu$_4$(SR)$_4$] in a square-planar or cubane arrangement, as [Cu$_4$(SR)$_6$] in a tetrahedral or adamantane arrangement, or as clusters of varying stoichiometry such as [Cu$_5$(SR)$_6$], [Cu$_5$(SR)$_7$], [Cu$_6$(SR)$_6$], [Cu$_8$(SR)$_8$], [Cu$_8$(SR)$_{12}$] and [Cu$_{12}$(SR)$_{12}$].[21] In addition, some Cu$^{I}$ clusters containing dithiolate ligands have been reported.[22] The central cores in these homoleptic clusters are remarkably similar to the heteronuclear clusters that can be obtained with the nickel complexes, in which the [NiN$_2$S$_2$] group acts as a didentate sulfur ligand.

Earlier we have synthesised nickel complexes as models for hydrogenases by making use of various ligands containing oxygen, nitrogen and sulfur donor atoms.[23–25] The reactivity of these nickel complexes with various iron sources has resulted in novel compounds, in some cases of surprising composition.[17–19] Recently, we have reported the mononuclear complexes [Ni(bsms)$_2$] and [Ni(xbsms)] in which the nickel ion is in an $S_4$ coordination environment [$H_2$xbsms = α,α′-bis(4-mercapto-3,3-dimethyl-2-thiabutyl)-*o*-xylene; Hbsms = 4-mercapto-3,3-dimethyl-1-phenyl-2-thiabutane].[26] The reactivity of these mononuclear complexes towards nickel and iron has been studied and the trinuclear nickel complexes [$Ni_3$(bsms)$_4$]($BF_4$)$_2$ and [$Ni_3$(xbsms)$_2$]($BF_4$)$_2$ have been reported.[15,27]

The reactivity of these complexes towards copper(I) and zinc(II) salts has now been investigated, resulting in a number of novel aggregates with unprecedented structures that are described below.

## Results

### Reactivity Studies

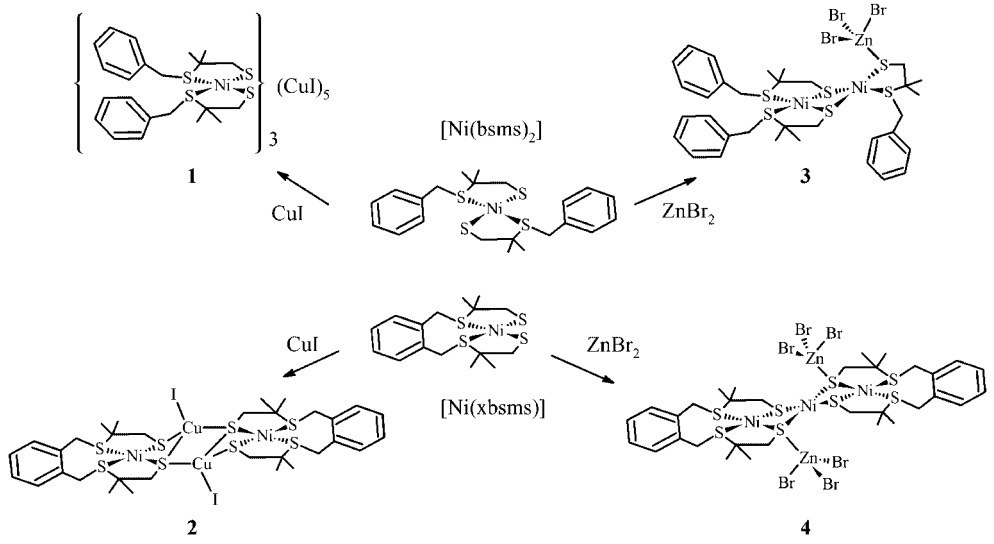
The reactivity of the mononuclear $NiS_4$ complex [Ni(xbsms)] towards $FeCl_2$, [$Fe_2(CO)_9$] and [$Fe(CO)_2(NO)_2$] appeared to be very similar to that reported for $NiN_2S_2$ complexes,[28] with the nickel complex acting as a monodentate or didentate chelating ligand to iron. Despite the *trans* orientation of the two didentate ligands in [Ni(bsms)$_2$] a similar reactivity towards $FeCl_2$ has been observed;[15] in aggregation reactions with nickel or iron the two ligands tend to rearrange to form a nickel complex with the *cis*-dithiolate conformation required for further binding. The reactivity of the mononuclear complexes [Ni(xbsms)] and [Ni(bsms)$_2$] has now been investigated in reactions with $ZnBr_2$, $ZnCl_2$ and CuI, with acetonitrile as the solvent and in 1:1 molar ratios; interesting new products of unexpected stoichiometries have been obtained (Scheme 1). The reactivity of the complexes towards $ZnBr_2$ and $ZnCl_2$ appeared to be similar as analogous products were obtained; only the results of the reactions with $ZnBr_2$ are reported.

Reactions of the related trinuclear nickel complexes [$Ni_3$(xbsms)$_2$]($BF_4$)$_2$ and [$Ni_3$(bsms)$_4$]($BF_4$)$_2$ with either CuI or $ZnBr_2$ did not generate any new compounds of different stoichiometries. The trinuclear complexes appeared to be relatively inert, and the starting materials could be recovered from most of the reactions.

### Structures of the Complexes

#### *Structure of [{Ni(bsms)$_2$}$_3$(CuI)$_5$] (1)*

The asymmetric unit contains two independent molecules of [{Ni(bsms)$_2$}$_3$(CuI)$_5$] together with four acetone molecules and two diethyl ether molecules. The differences between the two independent molecules are very small, therefore the detailed geometry of only one of them is discussed. An ORTEP projection of the structure of [{Ni(bsms)$_2$}$_3$(CuI)$_5$] is shown in Figure 1. Another projection showing the coordination environment of the nickel and copper centres is given in Figure 2. Crystal data are given in the Experimental Section and selected bond lengths and angles are summarised in Table 1. Three square-planar nickel(II) centres, three trigonal-planar copper(I) ions and two tetrahedrally coordinated copper(I) ions constitute the octanuclear cluster. The nickel ions have an $S_2S'_2$ coordination, with the coordination environment consisting of two didentate bsms ligands that bind through the thiolate groups in the *cis* positions. The trigonal-planar copper ions have an $S_2I$ coordination environment and the tetrahedral copper ions are in an $S_3I$ coordination environment.



Scheme 1. Synthesis of the novel clusters.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

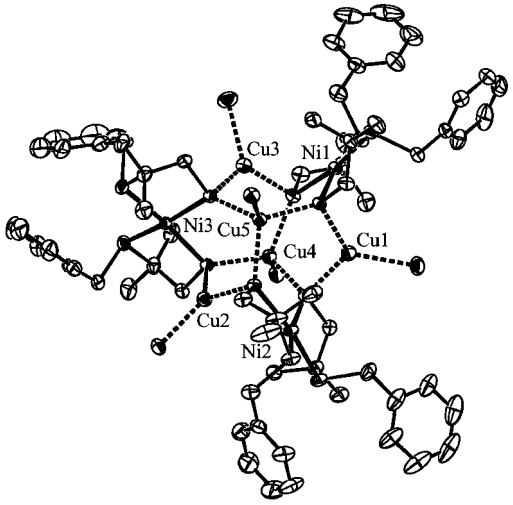


Figure 1. Displacement ellipsoid plot of one of the independent molecules of $[\{Ni(bsms)_2\}_3(CuI)_5]$ (**1**), drawn at the 50% probability level. Hydrogen atoms and the solvent molecules have been omitted and copper surroundings are indicated by dashed bonds for clarity.

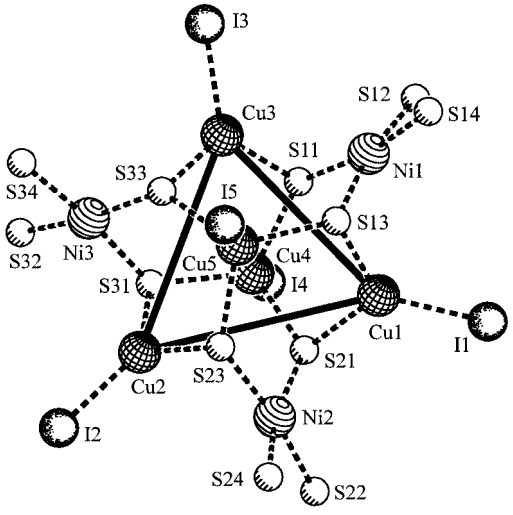

Figure 2. Projection of the central core and the coordination environment of the copper and nickel centres in **1**. View approximately along the pseudo-threefold axis of the trigonal bipyramid; the trigonal plane is indicated by solid lines.

The five copper ions are clustered in a trigonal-bipyramidal array, with the three trigonal-planar copper ions in the equatorial plane and the tetrahedral copper ions at the apices. The $NiS_2S'_2$ units are each capping two edges of the trigonal bipyramid with two $\mu_3$-bridging thiolate groups that each connect two copper ions with one nickel ion; each nickel complex thus binds to four different copper ions. Each nickel dithiolate complex bridges two equatorial copper ions to form a giant twelve-membered $Ni_3Cu_3S_6$ ring. The tetrahedral copper ions are coordinated to three thiolate groups, each from a different $NiS_2S'_2$ unit, thus capping the 12-membered crown on both sides, and as a result creating a cage. All thiolate sulfur atoms use three lone pairs in a distorted tetrahedral geometry in binding to one nickel ion and two copper ions. Finally, the coordination environment of each copper ion is completed by one iodide ion.

Table 1. Selected bond lengths [Å] and angles [°] in $[\{Ni(bsms)_2\}_3(CuI)_5]$ (**1**).

The molecule lacks crystallographic symmetry elements and therefore every nickel centre and every copper centre is unique. However, the molecule contains an approximate, non-crystallographic threefold rotation axis running through the apical copper ions that makes the differences between the three nickel ions, the three equatorial copper ions $Cu_{eq}$ and the two tetrahedrally coordinated copper ions $Cu_{ap}$ very small. The nickel–thiolate distances vary from 2.082(17) to 2.1861(18) Å, and are comparable to the distances found in the starting complex $[Ni(bsms)_2]$, and the nickel–thioether distances are 2.1966(18)–2.2108(19) Å, slightly longer than those in $[Ni(bsms)_2]$.[26] The $Cu_{eq}$–thiolate distances vary from 2.2328(19) to 2.2775(18) Å, whereas the $Cu_{ap}$–thiolate distances are slightly longer and vary from 2.3204(18) to 2.3548(18) Å. The $Cu_{eq}$–iodide distances are 2.4860(10)–2.4903(10) Å and the $Cu_{ap}$–iodide distances are 2.5775(9)–2.5801(9) Å. Because of the rigid conformation of the complex the nickel centres have a tetrahedral distortion with a dihedral angle varying from 12.09(10) to 18.44(10)° between the planes S(n1)–Ni(n)–S(n2) and S(n3)–Ni(n)–S(n4). The geometry around the $Cu_{eq}$ ions deviates only slightly from planarity and the angles around the tetrahedral $Cu_{ap}$ ions are in the range 104.64(7)–115.73(7)°.

The intramolecular Cu···Cu contacts vary from 3.4668(13) to 5.3666(14) Å, with the shortest distances between the apical and equatorial copper ions. The distances between the nickel centres range from 6.0776(15) to 6.3023(14) Å.

Although the nickel(II) ions in the solid structure have a significant tetrahedral distortion, in solution the $Ni^{II}$ ions are in a low-spin state, as shown by NMR experiments. In the $^1H$ NMR spectrum of the complex in $[D_6]$DMSO only one set of relatively sharp signals is observed for the ligand, thus confirming its rather symmetrical structure in solution.

### *Structure of [{Ni(xbsms)CuI}$_2$] (2)*

A projection of the structure of $[\{Ni(xbsms)CuI\}_2]$ is shown in Figure 3. Crystal data are given in the Experimen-

tal Section and selected bond lengths and angles are given in Table 2. The compound crystallises in the trigonal space group $P3_221$. The disordered solvent contained in this crystal structure was modelled as diffuse electron density (see Experimental Section). One tetranuclear complex contains two nickel(II) centres in square-planar surroundings and two copper(I) ions in a tetrahedral geometry. The complex is located on an exact, crystallographic twofold rotation axis and the complex in a single crystal is enantiomerically pure, with clockwise rotation along the positive *c*-axis. Because of the symmetry the compound can be considered as being a dimer of a heterodinuclear nickel-copper complex. The nickel centres have an $S_2S'_2$ coordination sphere consisting of two thiolate sulfur atoms in enforced *cis* positions and two thioether sulfur atoms. These nickel ions are in a square-planar geometry with a small tetrahedral distortion defined by a dihedral angle of 5.44(7)° between the planes Ni(1)–S(6)–S(9) and Ni(1)–S(16)–S(19). The bonds of the thioether sulfur atoms and the thiolate sulfur atoms to Ni are slightly longer than in the parent nickel complex [Ni(xbsms)][26] but are still unexceptional. Both thiolate sulfur atoms of the $NiS_4$ unit are bound as a chelating ligand to a single copper ion with one short Cu(2)–S(6) distance of 2.3010(12) Å and one long Cu(2)–S(16) distance of 2.6229(9) Å. The latter thiolate S(16) is the one that binds to the symmetry-related copper ion Cu(2a), with a short copper–thiolate distance of 2.2929(9) Å, and is therefore $\mu_3$-bridging between both copper ions and one nickel ion. The copper centres additionally have one coordinated iodide ion and are therefore in a tetrahedral $S_3I$ coordination environment. The tetranuclear molecules are arranged in a helical motif around a $3_2$ screw axis in the crystallographic *c* direction by π–π stacking of the xbsms ligands (Figure 4). The geometric centres of the stacking phenyl rings are 3.636(3) Å apart and the phenyl rings have a dihedral angle of 2.0(3)°. Large, solvent-accessible channels are located along this $3_2$ screw axis (see Experimental Section).

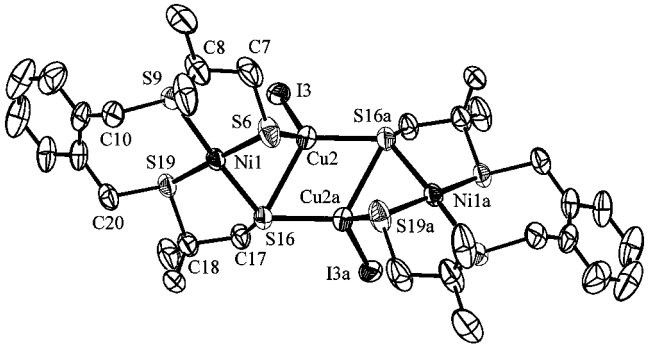

Figure 3. Displacement ellipsoid plot of [{Ni(xbsms)CuI}$_2$] (**2**), drawn at the 50% probability level. Hydrogen atoms and solvent molecules have been omitted for clarity.

The NMR spectra of **2** were obtained in $CDCl_3$ at room temperature and at 238 K. Due to the presence of the twofold rotation axis, only one set of ligand signals is expected for the tetranuclear complex. The $^1$H NMR spectrum recorded at room temperature displays signals that are broadened and only two $CH_2$ resonances can be discerned: one for the ethylene bridges and one for the xylyl-$CH_2$ groups. Furthermore, only one resonance is observed for all four methyl groups. This indicates that both sides of one ligand and both protons on a $CH_2$ group are chemically equivalent in solution on the NMR timescale at room temperature. After cooling the sample to 238 K, the spectrum is sharpened and four doublets are observed for the eight $CH_2$ protons and two singlets are observed for the four methyl groups. In addition, the protons within a $CH_2$ group show COSY and NOESY cross-peaks. This indicates that even at low temperature both sides of one ligand are still chemically equivalent: C7 and C17, C10 and C20, and C8 and C18 are mutually equivalent. So, in solution the asymmetry of the crystal structure is apparently released. Full assignment of the resonance signals could be made from the COSY and NOESY NMR spectra at 238 K. The signal of one of the benzylic protons has shifted 1.8 ppm downfield to $\delta$ = 5.6 ppm as compared to that in the parent nickel complex. This rather large shift is comparable to the shift of the signal of one benzylic proton in [Ni(xbsms)Fe(CO)$_4$].[28] From

the crystal structure, however, no apparent interactions can be discerned that may be responsible for this downfield shift; the shortest Ni···benzylic-H distance is 3.27 Å, and an iodine–H interaction of 3.1 Å is present.

### *Structure of [$Ni_2(bsms)_3ZnBr_3$] (3)*

A projection of the structure of [$Ni_2(bsms)_3ZnBr_3$] is shown in Figure 5. Crystal data are given in the Experimental Section and selected bond lengths and angles in Table 3. The asymmetric unit contains the trinuclear complex [$Ni_2(bsms)_3ZnBr_3$] and two molecules of acetone. The trinuclear complex is built up from two nickel(II) centres with square-planar surroundings and a tetrahedral zinc(II) ion. Ni(1) has an $S_2S'_2$ coordination environment originating from two bsms ligands, with the two thiolate sulfur atoms in *cis* positions. The square-planar coordination of this nickel ion has a small tetrahedral distortion, with an interplanar angle of 4.7(3)°. Both thiolate sulfur atoms are bridging to the second nickel ion, Ni(2), which is in an $S_3S'$ coordination environment consisting of the already mentioned bridging thiolate sulfur atoms and an additional didentate bsms ligand. The Ni(2) ion is also in a rather perfect square-planar geometry with a small tetrahedral distortion and a dihedral angle of only 2.9(2)°. The thiolate sulfur atom of this third bsms ligand is bridging between Ni(2) and the zinc(II) ion, which has an $SBr_3$ coordination environment. The bond lengths to nickel are similar to those in the parent nickel complex [Ni(bsms)$_2$] and are unexceptional.[26]

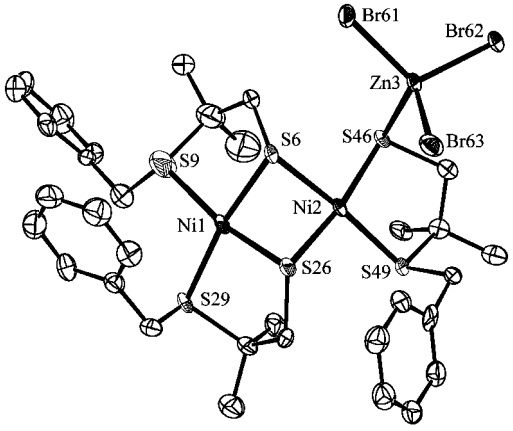

Figure 5. Displacement ellipsoid plot of [$Ni_2(bsms)_3ZnBr_3$] (**3**), drawn at the 50% probability level. Hydrogen atoms and solvent molecules are omitted for clarity.

The NMR spectroscopic results confirm the diamagnetic properties of the complex, with two square-planar low-spin nickel(II) centres and a zinc(II) ion, which is retained in solution. Quite unexpectedly, only a single set of resonances is discernible for the three ligands, which makes the spectrum quite similar to the $^1$H NMR spectrum of [Ni(bsms)$_2$].

### *Structure of [$Ni_3(xbsms)_2(ZnBr_3)_2$] (4)*

A structure proposal based on elemental analysis and IR, NMR and ligand-field spectroscopy is shown in Figure 6. The structure proposal is based on the known type of trinuclear complexes of the form $[Ni_3(xbsms)_2]^{2+}$, which are composed of a zig-zag chain of three square planes similar to that reported for $[Ni_3(bsms)_4]^{2+}$.[15] This arrangement leaves space for two $ZnBr_3$ units to coordinate above and below the trinuclear complex, similar to the binding observed in [$Ni_2(bsms)_3ZnBr_3$]. The $^1$H NMR spectrum of this compound again shows only one set of sharp signals, in agreement with a symmetrical structure and square-planar surrounding for the nickel(II) ions. The coordination of the $ZnBr_3$ groups apparently has a stabilizing effect on the fluxionality of the nickel ions as no sharp NMR spectrum could be obtained for the parent trinuclear complex, even at low temperature.[27]

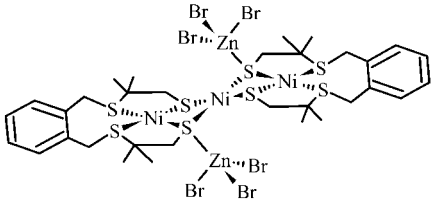

Figure 6. Proposed structure of [$Ni_3(xbsms)_2(ZnBr_3)_2$] (**4**).

## UV/Vis/NIR Spectroscopy of the Complexes

The square-planar surrounding of the nickel(II) ions in all of the mixed-metal complexes discussed above is reflected in their ligand-field spectra. The UV/Vis/NIR data are presented in Table 4. The nickel–copper complexes are black solids that yield brown solutions both in chloroform and in acetonitrile. These complexes show a very broad absorption band in the solid state with the diffuse reflectance technique. The nickel–zinc complexes are brown solids that also yield brown solutions in both chloroform and acetonitrile. [$Ni_3(xbsms)_2(ZnBr_3)_2$] (**4**) dissolves very poorly in chloroform and therefore the ligand-field data of this complex are only given for acetonitrile. For [$Ni_2(bsms)_3ZnBr_3$] (**3**), the differences in the ligand-field spectra of a solution in chloroform and a solution in acetonitrile are very small,

[a] Diffuse reflectance.

thus indicating that solvent coordination does not take place in this case. Coordination of acetonitrile cannot be excluded for the nickel–copper complexes $[\{Ni(xbsms)CuI\}_2]$ and $[\{Ni(bsms)_2\}_3(CuI)_5]$. The d–d transitions of the nickel centres in all complexes are at slightly lower energy and the ligand-to-metal charge-transfer transitions are at higher energy compared with the starting complexes $[Ni(bsms)_2]$ and [Ni(xbsms)] (see Table 4).[26] These changes are just the opposite to the shifts in energy in ligand field for the $[\{NiLFeX_2\}_2]$ complexes $[\{Ni(xbsms)FeCl_2\}_2]$, $[\{Ni(xbsms)FeBr_2\}_2]$ and $[\{Ni(xbsms)FeI_2\}_2]$.[28] Apparently, the somewhat softer CuI and $ZnBr_3$ units accept more electron density from the thiolate sulfur atoms.

## Discussion

The ability of $[NiN_2S_2]$ complexes to act as a ligand to other metal ions has long been recognized, but intense efforts to study the binding of mononuclear $[NiN_2S_2]$ to transition metal ions were triggered by the publication of the X-ray structure of ACS. Many examples of the versatile binding of nickel dithiolate complexes − as compared with "normal" didentate sulfur ligands − have now been reported. As the reactivity of the mononuclear $NiS_4$ complexes [Ni(xbsms)] and $[Ni(bsms)_2]$ towards iron sources is rather similar to that of $NiN_2S_2$ complexes, the unique products formed with copper and zinc salts were quite unexpected. Regarding the $NiS_4$ complexes as dithiolate ligands makes the novel octanuclear compound $[\{Ni(bsms)_2\}_3(CuI)_5]$ a $[Cu_5("S_2")_3]$ cluster. Numerous $Cu^I$ thiolate clusters have been reported; however, only two clusters have been reported with a related $Cu_5(SR)_6$ arrangement.[29] The copper centres in these complexes are also in a trigonal-bipyramidal array, each axial–equatorial edge of which is bridged by a thiolate sulfur atom. However, the copper ions do not have additional halogen ions coordinated and the Cu···Cu distances are much smaller and are more likely to indicate a metal–metal interaction.

The rearrangement of the didentate ligands in $[\{Ni(bsms)_2\}_3(CuI)_5]$ to form *cis*-planar nickel complexes would imply that a similar structure could possibly be obtained from [Ni(xbsms)]. However, the resulting complex $[\{Ni(xbsms)CuI\}_2]$ is obviously different and, as similar reaction conditions were applied in the two syntheses, the resulting dissimilar structures must be a consequence of packing effects. The reported[6,16] complex $[\{Ni(N_2S_2)\}_3(CuBr)_2]$ may be regarded as being derived from the present $Ni_3Cu_5$ complex by removal of the three equatorial CuI units. Structures have been reported of $[\{Ni(N_2S_2)\}_2Cu_2]^{2+}$, which have the same nickel/copper ratio as $[\{Ni(xbsms)CuI\}_2]$ but which do not contain coordinated halides and in which the sulfur binding is different.[5,7]

The reaction of $NiN_2S_2$ complexes with copper and zinc halides has been shown to result in similar structures in some cases,[12] although different topologies have also been reported.[7] Our new nickel–zinc complexes $[Ni_2(bsms)_3ZnBr_3]$ and $[Ni_3(xbsms)_2(ZnBr_3)_2]$ are noticeably different from these earlier reported structures, and are also quite different from each other, as a result of dissociation of the didentate bsms ligand from part of the mononuclear complex and re-assembly to form a dinuclear core similar to that of the nickel ethanedithiolate compound $[Ni_2(edt)_3]$.[30] The binding of the $ZnBr_3^-$ group to one thiolate sulfur atom is similar to the binding observed in the dinuclear complex $[Ni(N_2S_2)ZnCl_2(dmf)]$.[7] The proposed structure of the pentanuclear complex of general formula $[Ni_3(xbsms)_2(ZnBr_3)_2]$ is based on the assumption of a similar binding of the $ZnBr_3^-$ groups; binding at two sides of the trinuclear core is proposed for reasons of steric bulk and the existence of a symmetrical structure as indicated by NMR spectroscopy.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The structures of the products of the reactions of the mononuclear complexes [Ni(xbsms)] and [Ni(bsms)$_2$] with copper and zinc salts are remarkably different from those that have been reported earlier, and the reactivity of these products as well as that of the trinuclear nickel complexes also differ from the analogous $NiN_2S_2$ compounds. A study[6] of the reactivity of the complexes [{Ni($N_2S_2$)}$_3$($ZnCl_2$)]$^{2+}$, [{Ni($N_2S_2$)}$_3$($CuBr_2$)] and [{Ni($N_2S_2$)}$_2$Ni]$^{2+}$ towards nickel, copper and zinc salts resulted in a qualitative ranking of metal ion affinity by the nickel dithiolate ligand, i.e. $Zn^{2+} < Ni^{2+} < Cu^{+}$. With this in mind the nickel–zinc complexes [$Ni_2$(bsms)$_3$$ZnBr_3$] and [$Ni_3$(xbsms)$_2$($ZnBr_3$)$_2$] have been tested for their reactivity towards $Ni(BF_4)_2$ and CuI. Both complexes show no reactivity towards $Ni(BF_4)_2$ and only the starting complexes were recovered after 24 h. The complex [$Ni_2$(bsms)$_2$$ZnBr_3$], however, does show reactivity towards CuI; this reaction again gives the stable octanuclear cluster [{Ni(bsms)$_2$}$_3$($CuI)_5$]. The complex [$Ni_3$(xbsms)$_2$($ZnBr_3$)$_2$] does not show reactivity towards CuI, which may be related to the low solubility of this complex. The trinuclear nickel complexes appear to be comparatively inert, and from most of the reactions only the starting materials could be recovered.

## Conclusions

Four new heteronuclear aggregates of various composition have been synthesised and characterised by using the $NiS_4$ compounds [Ni(xbsms)] and [Ni(bsms)$_2$] as a ligand for copper and zinc salts. Despite the similar reactivity of these two complexes towards iron salts, the products of the reactions with CuI and $ZnBr_2$ are diverse. The novel octanuclear structure of [{Ni(bsms)$_2$}$_3$($CuI)_5$] shows a unique arrangement of copper and nickel centres, with a central trigonal-bipyramidal array of copper ions to which the three $NiS_2S'_2$ units act as capping ligands. This remarkable complex represents another important example of the structural versatility possible for the reaction products of nickel dithiolate complexes as ligands to other transition metal ions. The tetranuclear structure [{Ni(xbsms)CuI}$_2$] shows unprecedented asymmetric bridging of the thiolate sulfur atoms, with one of the thiolate groups binding to one copper ion and the other one $\mu_3$-bridging to two copper ions. The trinuclear complex [$Ni_2$(bsms)$_3$$ZnBr_3$] is formed as a result of dissociation of the didentate bsms ligand from part of the mononuclear complex and reassembly to form the dinuclear core. The *trans* binding of the didentate ligand in the starting complex [Ni(bsms)$_2$] appears not to limit its ability to bind to other transition metal ions as a chelating ligand; it does, however, result in the formation of new, unexpected aggregates. The formation of these cluster compounds as opposed to the desired dinuclear complexes emphasises the importance of the site isolation in metalloenzymes and the difficulty of controlling the product formation in vitro.

## Experimental Section

**Chemicals:** All preparations were carried out in reagent-grade solvents. All chemicals used in the syntheses were obtained from Acros or Aldrich and were used without further purification. The complexes were synthesised under argon using standard Schlenk techniques. Solvents were deoxygenated and dried with molecular sieves. The synthesis of [Ni(bsms)$_2$] and [Ni(xbsms)] has been reported earlier.[26]

**Physical Measurements:** IR spectra were recorded with a Perkin–Elmer FT-IR Paragon 1000 spectrophotometer equipped with a golden-gate ATR device, using the reflectance technique (4000–300 cm$^{-1}$; resolution 4 cm$^{-1}$). Elemental analyses were carried out with a Perkin–Elmer series II CHNS/O analyzer 2400. Metal analyses were performed with a Perkin–Elmer 3100 atomic absorption (AAS) and flame emission spectrometer using a linear calibration method. Due to the presence of variable amounts of solvent encapsulated in the complexes, some of the analytical data may be considered not satisfactory. Ligand-field spectra were obtained with a Perkin–Elmer Lambda 900 spectrophotometer. The diffuse reflectance technique, with MgO as a reference, was used for the solid compounds. Ligand-field spectra of the solutions were obtained with the solvent in the reference beam. NMR spectra were recorded with a Bruker WM 300 MHz spectrometer or a Jeol FX-200 Teqmac. $^1$H and $^{13}$C chemical shifts are quoted in ppm relative to tetramethylsilane (TMS).

**[{Ni(bsms)$_2$}$_3$($CuI)_5$] (1):** A solution of CuI (0.072 g, 0.38 mmol) in 80 mL of $CH_3CN$ was added to a solution of [Ni(bsms)$_2$] (0.18 g, 0.37 mmol) in 170 mL of $CH_3CN$, and the solution was stirred for 20 h. The solvent was then evaporated and the crude product was recrystallised from acetone/diethyl ether. Dark-red crystals suitable for X-ray diffraction were formed in a yield of 0.146 g (75%). IR: $\tilde{\nu}_{max}$ = 2960 m, 2907 m, 1495 m, 1454 m, 1386 m, 1368 m, 1256 w, 1228 w, 1199 w, 1139 m, 1083 m, 1071 m, 1028 w, 955 w, 925 w, 889 w, 772 m, 696 vs, 668 m, 476 m cm$^{-1}$. $^1$H NMR (300.13 MHz, [$D_6$]dmso, 298 K): $\delta$ = 7.31 (m, 30 H, Ph), 3.68 (s, 12 H, Ph-C$H_2$-S), 2.26 [s, 12 H, C($CH_3$)$_2$-C$H_2$-S], 1.21 (s, 36 H, C$H_3$) ppm. $C_{66}H_{90}Cu_5I_5Ni_3S_{12}$ (2396.5): calcd. C 33.08, H 3.79, Cu 13.26, Ni 7.35, S 16.05; found C 33.25, H 4.17, Cu 13.05, Ni 7.71, S 15.44.

**[{Ni(xbsms)CuI}$_2$] (2):** CuI (0.19 g, 1.0 mmol) in 80 mL of $CH_3CN$ was slowly added to a solution of [Ni(xbsms)] (0.4 g, 1.0 mmol) in 100 mL of $CH_3CN$, and the solution was stirred for 23 h. After evaporation of the solvent, the product was recrystallised from dmf/diethyl ether in a yield of 0.46 g (78%). Dark-red crystals suitable for X-ray diffraction were obtained. IR: $\tilde{\nu}_{max}$ = 2963 m, 2926 m, 1676 m, 1660 vs, 1497 m, 1454 m, 1437 m, 1382 m,1362 m, 1253 m, 1227 m, 1190 w, 1134 m, 1079 s, 956 m, 890 m, 768 s, 759 m, 743 w, 691 s, 668 s, 660 m, 606 m, 579 w, 488 m, 462 m cm$^{-1}$. $^1$H NMR (300.13 MHz, $CDCl_3$, 238 K): $\delta$ = 7.28 (m, 4 H, $C^{23}$-*H*, $C^{26}$-*H*), 7.18 (m, 4 H, $C^{24}$-*H*, $C^{25}$-*H*), 5.65 (d, $^2J$ = 12.4 Hz, 4 H, $C^{10/20}$*H*H), 3.55 (d, $^2J$ = 12.4 Hz, 4 H, $C^{10/20}$H*H*), 2.84 (d, $^2J$ = 12.9 Hz, 4 H, $C^{7/17}$H*H*), 2.45 (d, $^2J$ = 12.9 Hz, 4 H, $C^{7/17}$*H*H), 1.74 (s, 12 H, C$H_3$), 1.48 (s, 12 H, C$H'_3$) ppm; see Figure 3 for numbering scheme. $C_{32}H_{48}Cu_2I_2Ni_2S_8$ (1187.5): calcd. C 32.37, H 4.07, Cu 10.70, Ni 9.89, S 21.60; found C 33.24, H 4.45, Cu 10.55, Ni 9.86, S 18.94.

**[$Ni_2$(bsms)$_3$$ZnBr_3$] (3):** $ZnBr_2$ (0.23 g, 1.0 mmol) in 50 mL of $CH_3CN$ was added to a solution of [Ni(bsms)$_2$] (0.50 g, 1.04 mmol) in 200 mL of $CH_3CN$. The solution changed colour from light brown to dark brown and was stirred for 19 h. The solvent was evaporated and the obtained product was recrystallised from acetone/hexane. A yield of 0.48 g of red crystals suitable for X-ray diffraction was obtained (80%). IR: $\tilde{\nu}_{max}$ = 2957 w, 2920 w, 1601 w, 1495 m, 1463 m, 1455 m, 1417 m, 1385 w, 1362 m, 1264 m, 1240 m, 1221 m, 1195 m, 1141 m, 1082 m, 1070 m, 1030 w, 953 m, 879 w, 806 m, 767 s, 736 w, 699 vs, 668 w, 620 w, 585 w, 528 m, 487 s,

**Crystal Structure Determinations:** X-ray intensities were measured with a Nonius KappaCCD diffractometer with rotating anode and graphite monochromator ($\lambda$ = 0.71073 Å) at a temperature of 150(2) K. Numerical data and details of the data collection and refinement are presented in Table 5. The structures were solved by direct methods (SHELXS-97[31] for compounds **1** and **3**; SIR-97[32] for compound **2**) and refined with SHELXL97 against $F^2$ of all reflections.[31] Non-hydrogen atoms were refined freely with anisotropic displacement parameters; hydrogen atoms were refined as rigid groups. Molecular illustrations, structure checking and calculations were performed with the PLATON package.[33] CCDC-612515 (**1**), -612516 (**2**), and -612517 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. **1:** The diethyl ether solvent molecule was refined with an occupancy of 0.9. **2:** The crystal structure contains large, solvent-accessible channels along the $3_2$ screw axis (1078.9 Å$^3$ per unit cell) filled with disordered solvent molecules. Their contribution to the structure factors was secured by back Fourier transformation using the SQUEEZE routine of the program PLATON,[33] amounting to 267 electrons in the unit cell. **3:** The crystal appeared to be non-merohedrally twinned with a 180° rotation about *uvw* = [100] as the twin operation. Additionally, there was a large anisotropic mosaicity about *hkl* = (100) present. The intensity data were evaluated with EvalCCD.[34] The twin refinement[35] resulted in a twin fraction of 0.331(3).

# Dimeric Complexes of Lanthanide(III) Hexafluoroacetylacetonates with 4-Cyanopyridine *N*-Oxide: Synthesis, Crystal Structure, Magnetic and Photoluminescent Properties

**Svetlana V. Eliseeva,*[a] Mikhail Ryazanov,*[a,b] Frédéric Gumy,[c] Sergey I. Troyanov,[a] Leonid S. Lepnev,[d] Jean-Claude G. Bünzli,[c] and Natalia P. Kuzmina[a]**

**Keywords:** Lanthanides / β-Diketonates / Luminescence / Thin films / Photophysics

A series of new mixed-ligand lanthanide complexes $[Ln(hfa)_3(4\text{-cpyNO})]_2$ ($Ln = Sm^{III}$–$Ho^{III}$ and $Tm^{III}$; $hfa^-$ = hexafluoroacetylacetonate; 4-cpyNO = 4-cyanopyridine *N*-oxide) have been synthesised by treating the corresponding lanthanide hexafluoroacetylacetonates with 4-cpyNO (molar ratio 1:1) in chloroform. Single-crystal X-ray analysis revealed that $[Tb(hfa)_3(4\text{-cpyNO})]_2$ and $[Ho(hfa)_3(4\text{-cpyNO})]_2$ are isostructural and are comprised of two types of symmetrically independent dimetallic molecules. Within a dimer, the eight-fold-coordinated metal atoms are bridged by two 4-cpyNO ligands through the oxygen atoms of the *N*-oxide groups. The magnetic susceptibility data for the $Gd^{III}$ and $Tb^{III}$ complexes indicate the presence of weak antiferromagnetic interactions within the dimetallic $Ln_2O_2$ units. The thermal stability of the $[Ln(hfa)_3(4\text{-cpyNO})]_2$ adducts was studied by thermogravimetric analysis and their volatility estimated from sublimation experiments under reduced pressure. The photoluminescent properties were measured for solid samples upon excitation at 330–360 nm. The mixed-ligand complexes of $Sm^{III}$, $Eu^{III}$, $Tb^{III}$, $Dy^{III}$ and $Tm^{III}$ exhibit metal-centred luminescence in the entire visible spectral range with characteristic pink, red, green, yellow and blue emission, respectively. The introduction of ancillary 4-cpyNO molecules into the coordination sphere of the lanthanide(III) ions was found to significantly affect their luminescence quantum yields. $[Eu(hfa)_3(4\text{-cpyNO})]_2$ thin films on quartz substrates were obtained by the vacuum evaporation technique and their photoluminescent properties were found to be enhanced when compared with those of the bulk samples. This suggests that these dimers could be good candidates for the fabrication of emitting layers for light-emitting diodes.

## Introduction

Luminescent lanthanide complexes with organic ligands are of great interest since they can be used, for instance, as light-converting optical materials, light-emitting layers in electroluminescent (EL) devices,[1] contrast agents for magnetic resonance imaging[2] and luminescent probes in biology.[3] Such coordination compounds are chemically stable and provide a versatile tool for tuning their spectroscopic properties both by choosing the appropriate lanthanide ions as well as by changing the characteristics of the organic ligands, such as by introducing suitable substituents/atoms or conjugated π-electron fragments.[4,5]

The aim of this work is to develop and test highly luminescent lanthanide(III) complexes that can be utilized for fabricating light-emitting thin films. Lanthanide tris(β-diketonate) chelates are among the most investigated $Ln^{III}$ coordination compounds as they exhibit sharp emission bands in the visible and near-infrared spectral ranges. These compounds usually crystallise with solvent molecules, which are detrimental to their photophysical properties. To overcome the solvent-quenching problem, an additional β-diketonate ligand can be introduced to give anionic lanthanide(III) complexes, or, alternatively, neutral chromophoric ligands may be used as ancillary ligands to saturate the inner coordination sphere of the metal ion. In the latter case, the sensitisation of lanthanide luminescence can be additionally improved when the ancillary ligand possesses suitable energy levels to provide an effective intramolecular energy transfer from the ligand to the lanthanide ion.[5] For further

potential application of luminescent complexes as emitting layers, for example in organic light-emitting diodes, it is interesting and useful to investigate their photoluminescent properties in thin films. It is well known that the luminescence of lanthanide(III) ions, especially $Eu^{III}$, is very sensitive to the local micro-environment of the ion.[6] As a consequence, the packing of the molecules in the crystal structure, the sample form (solid/powder, thin film or solution) and even the deposition method of thin films (vacuum evaporation, spin-coating, etc.) may have a significant influence on the luminescence lifetimes and quantum yields. However, only a few studies have been devoted to this question.[7]

In this paper, we report the synthesis, structural study and thermal analysis of the new mixed-ligand lanthanide(III) complexes $[Ln(hfa)_3(4\text{-cpyNO})]_2$ (Ln = $Sm^{III}$–$Ho^{III}$, $Tm^{III}$) with 4-cyanopyridine *N*-oxide as a bridging ligand to link the metal atoms into dimetallic molecular species. The luminescent and magnetic properties of these compounds were studied and the effect of introducing the ancillary 4-cpyNO ligands on their luminescence characteristics is discussed. Furthermore, in order to assess the potential of the dimeric complexes for light-emitting layers in electroluminescent devices, thin films of $[Eu(hfa)_3(4\text{-cpyNO})]_2$ were obtained by the vacuum evaporation technique and their photoluminescent properties compared with those of the bulk samples.

## Results and Discussion

### Synthesis and Characterisation

The reaction of 4-cyanopyridine *N*-oxide with an equimolar amount of $[Ln(hfa)_3(H_2O)_2]$ in chloroform yields air-stable complexes $[Ln(hfa)_3(4\text{-cpyNO})]_2$ (Ln = $Sm^{III}$–$Ho^{III}$, and $Tm^{III}$), which were isolated as colourless ($Gd^{III}$, $Tb^{III}$), pale yellow ($Sm^{III}$, $Eu^{III}$, $Ho^{III}$ and $Dy^{III}$) or pale aquamarine ($Tm^{III}$) polycrystalline precipitates by removing part of the solvent at low pressure. The formation of the mixed-ligand lanthanide adducts was confirmed by elemental analysis and IR spectroscopy. The IR spectra of all the complexes obtained are similar, exhibiting C=O and C=C absorption bands in the region 1700–1500 $cm^{-1}$ that are typical of lanthanide chelate complexes containing fluorinated β-diketonate ligands.[8] The characteristic bands due to the terminal C≡N group and pyridine *N*-oxide C–H vibrations of the 4-cpyNO ligand appear in the ranges 2300–2200 $cm^{-1}$ and 3200–3000/900–600 $cm^{-1}$, respectively. The

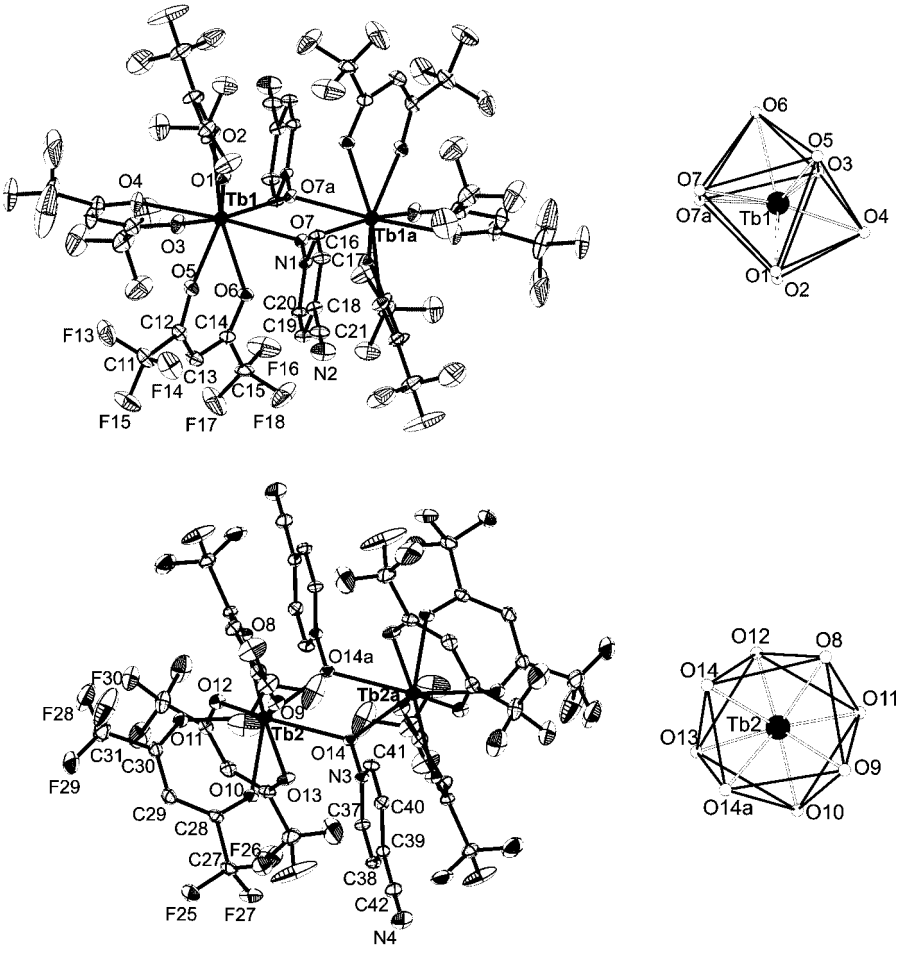

Figure 1. Molecular structures of the centrosymmetric LnL-1 and LnL-2 species in the crystal structure of $[Tb(hfa)_3(4\text{-cpyNO})]_2$ with coordination polyhedra around the metal atoms outlined (30% probability level ellipsoids). Hydrogen atoms omitted for clarity.

assignment of the bands at 1300–1100 $cm^{-1}$ is difficult due to overlap of the ν(N–O) and ν(C–F) vibrations. The absence of absorption between 3600 and 3200 $cm^{-1}$ implies that these compounds contain no water molecules.

### Crystal and Molecular Structures

Single crystals of $[Tb(hfa)_3(4\text{-cpyNO})]_2$ and $[Ho(hfa)_3(4\text{-cpyNO})]_2$ were obtained from chloroform, and their structures were determined by X-ray crystallography (see Experimental Section for further details). Both compounds are isostructural, crystallising in the monoclinic space group $P2_1/c$ with $Z = 4$. The crystal structure consists of two types of symmetrically independent centrosymmetric dimetallic $[Ln(hfa)_3(4\text{-cpyNO})]_2$ molecules, hereafter referred to as LnL-1 and LnL-2, which differ from each other mainly in the coordination geometry of the lanthanide atoms (vide infra). Perspective views of the molecules, with the $LnO_8$ polyhedra outlined, are given in Figure 1 for the $Tb^{III}$ derivative. Selected bond lengths and angles are summarised in Table 1. Within a dimer, the metal ions are eight-coordinated by oxygen atoms from two bridging μ-4-cpyNO ligands and from three $hfa^-$ anions, which act as didentate chelating ligands. The bridging LnOOLn(a) core is completely planar due to the presence of an inversion centre. Intramolecular Ln···Ln separations across the Ln–O–Ln(a) vary in the range 3.99–4.13 Å (Table 1). A detailed analysis of the molecular geometry[9,10] reveals that the metal atoms in LnL-1 have a distorted bicapped trigonal-prismatic (BCTP) coordination environment, whereas those in LnL-2 have square-antiprismatic (SAP) coordination (cf. Table 2). In the BCTP polyhedron, the trigonal faces are formed by atoms O1, O5, O7 and O2, O3, O7a, respectively, while the O4 and O6 atoms cap two quadrilateral faces of the trigonal prism. The dihedral angle between the trigonal planes is 18.4°. In the SAP polyhedron, the square faces are delimited by atoms O10, O11, O12, O13 and O8, O9, O14, O14a, respectively, with the dihedral angle between the corresponding planes being 2.8°. The different coordination patterns observed are likely due to steric effects. The planar 4-cpyNO units in LnL-1 are arranged nearly perpendicular relative to the bridging $Ln_2O_2$ plane ($\phi = 86.4°$), thus minimizing the steric hindrance of the β-diketonate ligands. These units become more twisted toward the $hfa^-$ ligands ($\phi = 80.7°$) in the LnL-2 molecules, leading to distortion of the oxygen atoms along a pathway from SAP to BCTP. It is interesting to note a structural difference between $[Tb(hfa)_3(4\text{-cpyNO})]_2$ and a related adduct of $Eu^{III}$ hexafluoroacetylacetonate with pyridine *N*-oxide, namely $[Eu_2(hfa)_6(pyNO)_3]$:[11] the crystal structure of the latter also contains dimetallic species, although the metal atoms are nine-coordinate and are bridged by three μ-pyNO ligands.

A regular deviation in the mean values of the Ln–O(β-diketonate) bond lengths and O–Ln–O angles is found when comparing the $Tb^{III}$ and $Ho^{III}$ structures (2.38–2.33 Å and 72.4–73.0°, respectively), consistent with a decreasing size of the metal atom. The Ln–O distances for the neutral 4-cpyNO ligands are longer than those for the anionic $hfa^-$ ligands, ranging from 2.416 to 2.435 Å ($Tb^{III}$) and from 2.372 to 2.393 Å ($Ho^{III}$).

The symmetrically independent LnL-1 and LnL-2 molecules in the crystal structure of $[Ln(hfa)_3(4\text{-cpyNO})]_2$ are interconnected by weak intermolecular CH···N hydrogen bonds (Table 1) and lone-pair–π interactions between the 4-cpyNO species to form two-dimensional molecular assemblies in the *ac* plane (Figure 2). In the $Tb^{III}$ complex, the substituted pyridine *N*-oxide fragments of LnL-1 and LnL-2 are aligned almost orthogonally to each other, with the nitrile N atoms being either involved in hydrogen bonding with the CH groups of neighbouring 4-cpyNO species [C(H)···N = 3.22 Å] or directed towards the pyridine ring of the neighbours with a distance to its centre of 3.54 Å.

The latter suggests interactions between nitrogen lone pairs and the π-electrons of the pyridine system. The CN groups are located substantially off the ring's centre axis so that the angle, $\alpha$, between the line pointing towards the centre of the pyridine ring and its face amounts to about 66° (see Figure 2). According to ab initio studies on the interaction of water with hexafluorobenzene,[12] a similar off-axis geometry is also favourable for this system and is likely to result from optimisation of the electrostatic interactions.

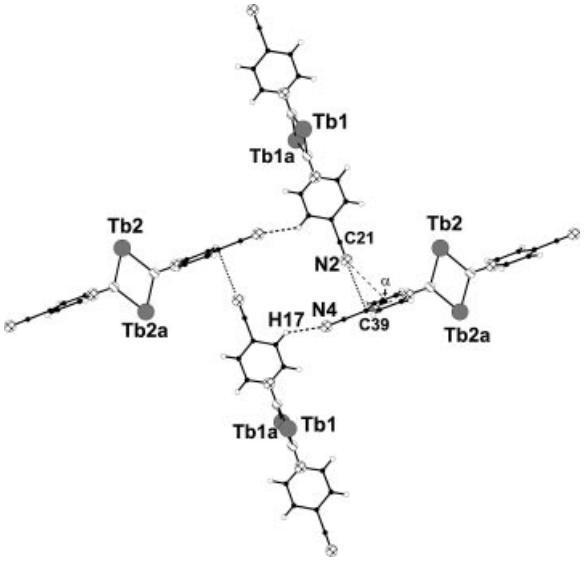

Figure 2. Packing of 4-cpyNO entities in the crystal structure of $[Tb(hfa)_3(4\text{-cpyNO})]_2$.

## Magnetic Properties

The short metal–metal distances (3.99–4.13 Å) within the $[Ln(hfa)_3(4\text{-cpyNO})]_2$ complexes make these compounds interesting for a study of the magnetic exchange interactions between the paramagnetic centres. We have recently reported the magnetic properties of a related dimeric manganese(II) complex, $[Mn(hfa)_2(4\text{-cpyNO})]_2$, which exhibits weak ferromagnetic coupling at low temperatures.[13] Here, temperature-dependent studies of the magnetic susceptibility ($\chi_m$) are presented for the gadolinium(III) and terbium(III) complexes. The former compound was found to be isostructural with the $Tb^{III}$ derivative, as evidenced by X-ray powder diffraction experiments.

The temperature dependence of the $\chi_m T$ product for $[Gd(hfa)_3(4\text{-cpyNO})]_2$ combined with a plot of $\chi_m^{-1}$ vs. $T$ is shown in Figure 3. At room temperature, the $\chi_m T$ value is about 15.7 $cm^3 mol^{-1} K$, close to that expected for two non-interacting $Gd^{III}$ ions (15.75 $cm^3 mol^{-1} K$). Upon cooling, it remains almost constant until 70 K. At lower temperatures, $\chi_m T$ passes through a small maximum at 40 K before decreasing to a value of 14.96 $cm^3 mol^{-1} K$ at 2 K. This characteristic drop in $\chi_m T$ is indicative of weak antiferromagnetic $Gd^{III}$–$Gd^{III}$ interactions within the dimeric molecules. A quantitative analysis of the magnetic data has been carried out using Equation (1) derived from the isotropic spin Hamiltonian $H = -JS_{Gd1} \cdot S_{Gd2}$, where $J$ is the exchange coupling parameter and $S_{Gd1}$ and $S_{Gd2}$ are the spin operators associated with the interacting spin centres ($S_{Gd1} = S_{Gd2} = 7/2$).

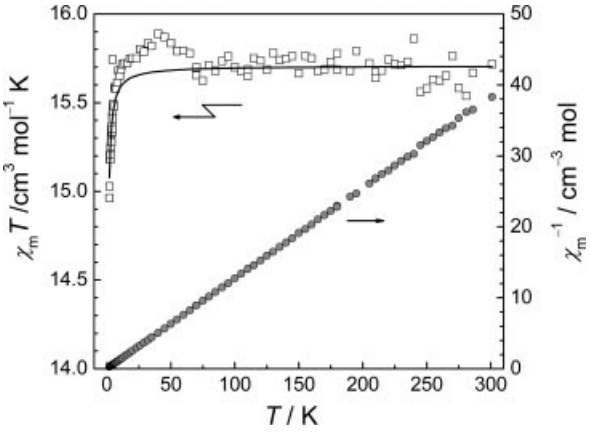

Figure 3. Temperature dependence of $\chi_m T$ (open squares) and $\chi_m^{-1}$ (filled circles) for $[Gd(hfa)_3(4\text{-cpyNO})]_2$; the solid line represents the best-fit calculated values.

$$\chi_m T = \frac{2Ng^2\mu_B^2}{k} \frac{140+91e^{7x}+55e^{13x}+30e^{18x}+14e^{22x}+5e^{25x}+e^{27x}}{15+13e^{7x}+11e^{13x}+9e^{18x}+7e^{22x}+5e^{25x}+3e^{27x}+e^{28x}}, x = -J/kT \quad (1)$$

Least-squares fitting of the experimental data with Equation (1) leads to the following parameters: $J$ = –0.010(1) $cm^{-1}$ and $g$ = 1.99. The good agreement between the observed and calculated values is reflected by a small value of the $R$ factor ($R = 2.7 \times 10^{-5}$), defined as $\Sigma[(\chi_m T)_{calc} - (\chi_m T)_{obs}]^2/\Sigma[(\chi_m T)_{obs}]^2$. The weak antiferromagnetic coupling between the $Gd^{III}$ ions in $[Gd(hfa)_3(4\text{-cpyNO})]_2$ is further evidenced by the $\chi_m^{-1}(T)$ data, which obey a Curie–Weiss law in the whole temperature range studied (Figure 3), thereby yielding an effective magnetic moment, $\mu_{eff}$, of 15.80(1) $\mu_B$ (per formula unit) and a negative Curie–Weiss temperature, $\theta$, of –0.3(1) K.

For $[Tb(hfa)_3(4\text{-cpyNO})]_2$, the room-temperature $\chi_m T$ value of 23.3 $cm^3 mol^{-1} K$ remains almost unchanged in the 70–300 K region, and compares very well with the expected value for two magnetically isolated $Tb^{III}$ ions (23.6 $cm^3 mol^{-1} K$). Upon decreasing the temperature below about 70 K, the $\chi_m T$ vs. $T$ curve begins to decrease abruptly, and exhibits a change in slope at 40 K. The dramatic drop of $\chi_m T$ from 23.3 to 11.54 $cm^3 mol^{-1} K$ at 2 K is mainly due to the crystal-field splitting of the $Tb^{III}$ ground state because of strong spin-orbit coupling, and could be indicative of a weak intramolecular antiferromagnetic coupling between the metal ions at low temperatures. The high-temperature data ($T > 100$ K) can be fitted to the Curie–Weiss law to yield an effective magnetic moment and a negative Curie–Weiss parameter of 19.3 $\mu_B$ per formula unit and –2(1) K, respectively.

### Thermal Analyses and Vacuum Sublimation

The thermogravimetric analysis of $[Ln(hfa)_3(4\text{-cpyNO})]_2$ revealed a similar thermal behaviour for all the compounds studied. Figure 4 illustrates the weight loss for the $Gd^{III}$ derivative. A single-step weight loss occurs in the range 190–280 °C, indicating that the lanthanide hexafluoroacetylacetonate adducts with 4-cyanopyridine *N*-oxide are thermally stable up to 190 °C. The total weight loss (ca. 92%) is much higher than that calculated for thermal decomposition of the complex into non-volatile gadolinium(III) oxyfluoride (ca. 79%) or $Gd_2O_3$ (ca. 80%), thus indicating partial sublimation of the sample under atmospheric pressure.

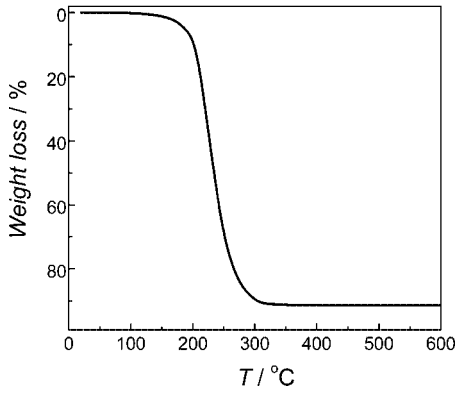

Figure 4. Thermogravimetric analysis under nitrogen for $[Gd(hfa)_3(4\text{-cpyNO})]_2$.

The vacuum sublimation experiments conducted at low pressure ($10^{-2}$ Torr) showed that all samples are quantitatively sublimed intact at 200–220 °C according to the elemental analysis and mass spectrometric studies.[14] This allowed us to obtain good-quality thin films of the $[Eu(hfa)_3(4\text{-cpyNO})]_2$ dimer (thickness 414 ± 1 nm) by vacuum evaporation at a pressure of $10^{-6}$ Torr.

### Photophysical Properties

The luminescence of lanthanide complexes upon excitation into the ligand absorption band arises from f–f transitions from the radiative level of $Ln^{III}$ to their lower-lying states. It should be emphasised that transitions between the f-states are formally parity-forbidden (Laporte's rule), which, in turn, results in long radiative lifetimes (up to the millisecond timescale) and line-like emission bands.[15,16] The excited levels of $Ln^{III}$ ions are usually populated as a result of energy transfer from the triplet level of the organic ligand, which is formed by rapid intersystem crossing. The excited level of the lanthanide(III) ion is further deactivated either radiatively with emission of light or non-radiatively by energy degradation to the vibrations of surrounding molecular groups. So, the intensity of lanthanide luminescence is determined by the ratio of the rates of radiative and non-radiative processes at all stages of the energy transfer.[17] While the emission colour and the shape of luminescence spectrum mainly depend on the electronic nature of the lanthanide ion, the energy of the triplet states of coordinated ligands plays an important role in the efficiency of the energy transfer: they should lie close to the resonant levels of the lanthanide ion but sufficiently high to prevent back energy-transfer.[18] Quenching mechanisms induced by the presence of solvent molecules in the first coordination sphere or by ligand-to-metal charge transfer (LMCT) states can also strongly influence the lanthanide luminescence.[17,19] Thus, in order to investigate the energy matching between the triplet state of the ligand and the luminescent level of the corresponding lanthanide ion, we recorded the phosphorescence spectra of solid samples of $[Gd(NO_3)_3(4\text{-cpyNO})]$, $[Gd(hfa)_3(H_2O)_2]$ and the mixed-ligand complex $[Gd(hfa)_3(4\text{-cpyNO})]_2$ at 77 K. The phosphorescence spectra of $[Gd(hfa)_3(H_2O)_2]$ and $[Gd(NO_3)_3(4\text{-cpyNO})]$ present broad bands with maxima at around 468 (21370) and 525 nm (19048 $cm^{-1}$), respectively (Figure 5). A small feature at 480 nm (20830 $cm^{-1}$) is also observed for the latter compound. The energies of zero-phonon transition of the triplet $^3\pi\pi^*$ states of the hexafluoroacetylacetonate and 4-cyanopyridine *N*-oxide ligands were thus estimated to be at around 21930 (456) and 20830 $cm^{-1}$ (480 nm), respectively. The phosphorescence spectrum of $[Gd(hfa)_3(4\text{-cpyNO})]_2$ exhibits a broad band characterised by two maxima of almost equal intensity at about 460 (21740) and 485 nm (20620 $cm^{-1}$), with a shoulder at about 515 nm (19420 $cm^{-1}$), i.e., it resembles the superposition of the phosphorescence spectra of the organic ligands (Figure 5). Therefore, in the mixed-ligand dimetallic complexes $[Ln(hfa)_3(4\text{-cpyNO})]_2$, the energy transfer originates from both $hfa^-$ and 4-cpyNO ligands. Figure 6 displays the energy diagram of the ligand triplet states and selected electronic levels of the lanthanide ions; the corresponding calculated energy gaps are listed in Table 3. According to empirical rules proposed for an optimal ligand-to-metal energy transfer $-2500 < \Delta E(^3\pi\pi^* - {}^5D_0) < 3500$ $cm^{-1}$ for $Eu^{III}$

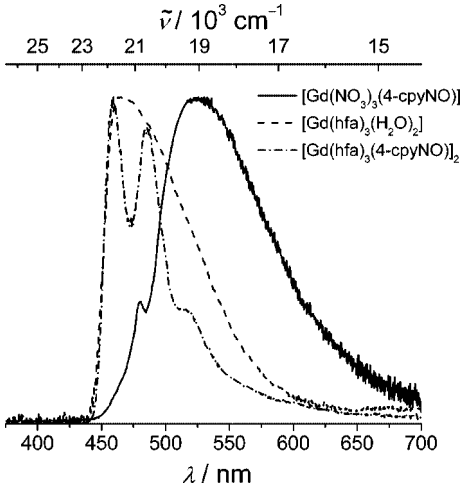

Figure 5. Phosphorescence spectra of $[Gd(NO_3)_3(4\text{-cpyNO})]$, $[Gd(hfa)_3(H_2O)_2]$ and $[Gd(hfa)_3(4\text{-cpyNO})]_2$ under excitation at 337 nm; $T$ = 77 K.

Table 3. Energy gaps [$cm^{-1}$] between the triplet states of hexafluoroacetylacetonate ($^3\pi\pi^*_{hfa}$) or 4-cyanopyridine *N*-oxide ($^3\pi\pi^*_{4\text{-cpyNO}}$) and the $^4G_{5/2}$(Sm), $^5D_0$(Eu), $^5D_4$(Tb), $^4F_{9/2}$(Dy), $^1G_4$(Tm) luminescent levels of lanthanide(III) ions.

| Triplet state | $\Delta E(^3\pi\pi^*–^4G_{5/2})$ | $\Delta E(^3\pi\pi^*–^5D_0)$ | $\Delta E(^3\pi\pi^*–^5D_4)$ | $\Delta E(^3\pi\pi^*–^4F_{9/2})$ | $\Delta E(^3\pi\pi^*–^1G_4)$ |
|---|---|---|---|---|---|
| $^3\pi\pi^*_{hfa}$ | 4030 | 4630 | 1430 | 930 | 530 |
| $^3\pi\pi^*_{4\text{-cpyNO}}$ | 2930 | 3530 | 330 | –170 | –570 |

ions and $2500 < \Delta E(^3\pi\pi^* - {}^5D_4) < 4000\ cm^{-1}$ for $Tb^{III}$ ions[20] – both the $hfa^-$ and 4-cpyNO ligands are best suited for the sensitisation of europium(III) and possibly samarium(III) luminescence. For the other Ln ions under investigation, the triplet states of the organic ligands are very close in energy to the lanthanide luminescent levels or even below, thus increasing the probability of back energy-transfer processes.

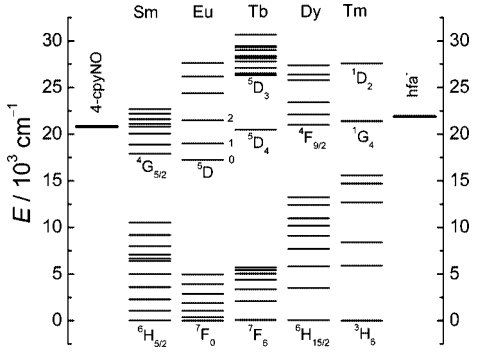

Figure 6. Energy diagram of the triplet states of the organic ligands and some energy levels of the lanthanide ions. The main luminescent and fundamental levels of the Ln ions are labelled.

To determine the influence of the substitution of water molecules by 4-cyanopyridine *N*-oxide on the photophysical properties, we compared the characteristics of solid samples of the parent $[Ln(hfa)_3(H_2O)_2]$ complexes with those of the mixed-ligand adducts $[Ln(hfa)_3(4\text{-cpyNO})]_2$.

The excitation spectra of $[Tb(hfa)_3(H_2O)_2]$ and $[Tb(hfa)_3(4\text{-cpyNO})]_2$ are very similar in shape (Figure 7) and exhibit broad bands up to 460 nm (21740 $cm^{-1}$), with two maxima at around 270 (37040) and 350 nm (28570 $cm^{-1}$) and two shoulders at 400 (25000) and 435 nm (22989 $cm^{-1}$), respectively. The excitation spectra of the europium(III) complexes are quite different from those of the terbium(III) derivatives and from each other (Figure 7). The excitation spectrum of $[Eu(hfa)_3(H_2O)_2]$ features a broad band ranging up to 400 nm (25000 $cm^{-1}$) with a maximum at around 300 nm (33333 $cm^{-1}$) and two weak shoulders at 330 (30303) and 360 nm (27778 $cm^{-1}$). In the excitation spectrum of $[Eu(hfa)_3(4\text{-cpyNO})]_2$, the intensity of the shoulders at 330 and 360 nm is larger, and they merge into a broad band extending up to 440 nm (22727 $cm^{-1}$) with a maximum at 275 nm (36363 $cm^{-1}$). Moreover, all of the excitation spectra display the characteristic bands of the metal-centred transitions at 377 and 486 nm for $Tb^{III}$, assigned to $^5D_3 \leftarrow {}^7F_6$ and $^5D_4 \leftarrow {}^7F_6$ transitions, and at 464 and 534 nm for $Eu^{III}$, corresponding to $^5D_2 \leftarrow {}^7F_0$ and $^5D_1 \leftarrow {}^7F_0$ transitions, respectively. However, the intensities of the f–f transitions are much weaker than the excitation bands of the organic ligands, thus indicating a good sensitisation of the metal-centred luminescence in these complexes through the ligand levels. As a result, under ligand excitation the $Tb^{III}$ and $Eu^{III}$ complexes $[Ln(hfa)_3(H_2O)_2]$ and $[Ln(hfa)_3(4\text{-cpyNO})]_2$ show bright green and red luminescence due to the $^5D_4 \rightarrow {}^7F_J$ ($J$ = 6–0) and $^5D_0 \rightarrow {}^7F_J$ ($J$ = 0–4) transitions,

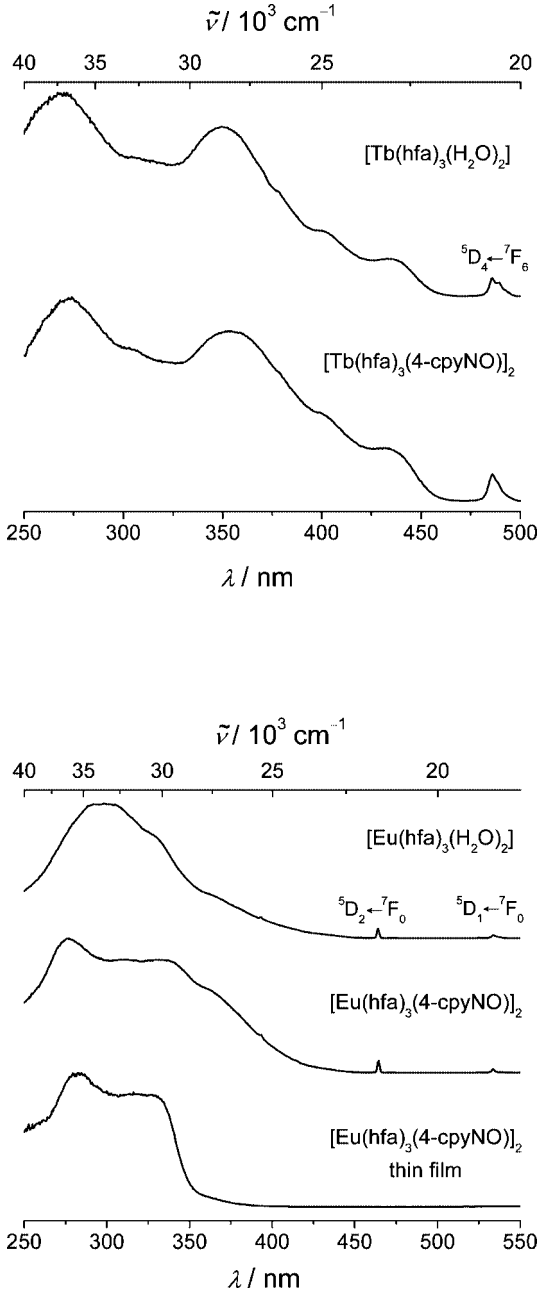

Figure 7. Excitation spectra of $[Ln(hfa)_3(H_2O)_2]$ and mixed-ligand $[Ln(hfa)_3(4\text{-cpyNO})]_2$ complexes (Ln = $Eu^{III}$, $Tb^{III}$) at 295 K.

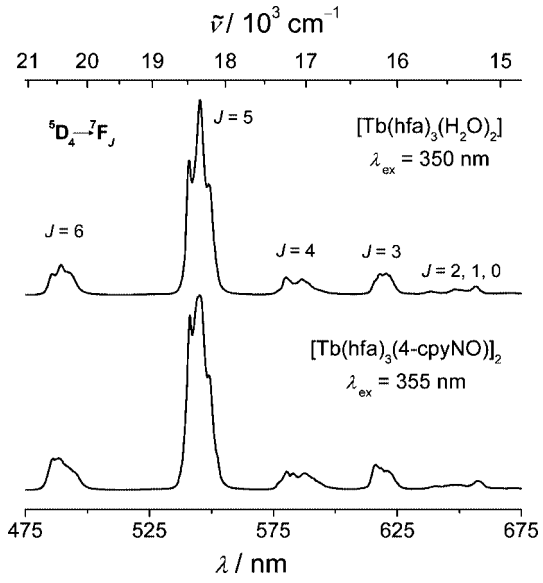
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

respectively (Figure 8). No broad-band emission is observed from the triplet states of the organic ligands, thus reflecting an efficient ligand-to-metal energy transfer. The integral intensities of the $^5D_0 \rightarrow {}^7F_J$ ($J$ = 0–4, $Eu^{III}$) and $^5D_4 \rightarrow {}^7F_J$ ($J$ = 6–0, $Tb^{III}$) transitions are compared in Table 4. The emission spectra and relative integral intensities of the $Tb^{III}$ complexes are essentially identical, in agreement with the fact that the terbium(III) emission bands are less sensitive to changes in the first coordination sphere of the metal centre than those of europium(III). For the $Eu^{III}$ derivatives, the intensity of the hypersensitive $^5D_0 \rightarrow {}^7F_{2,4}$ transitions is larger for $[Eu(hfa)_3(4\text{-cpyNO})]_2$ than for $[Eu(hfa)_3(H_2O)_2]$ (Figure 8), and this is also true for the other transitions, thus implying that the introduction of the ancillary ligand increases the nephelauxetic effect. Further, the emission spectra of both complexes show only one peak for the $^5D_0 \rightarrow {}^7F_0$ transition, which points to approximately the same chemical environment around the europium(III) ions. The substitution of water molecules by 4-cyanopyridine *N*-oxide leads to an approximately threefold increase in the lifetime of the Eu ($^5D_0$) level (Table 5). This can be explained by elimination of the non-radiative deactivation pathway through O–H vibrations, as reported previously for many hydrated lanthanide(III) β-diketonates.[5] The improvement in the luminescent properties upon introduction of 4-cpyNO is further substantiated by the determination of the absolute quantum yields ($Q^L_{Ln}$) for solid samples of the $Eu^{III}$ and $Tb^{III}$ complexes (cf. Table 5). The greatest effect is observed for $Eu^{III}$ compounds, with an approximately tenfold enhancement in $Q^L_{Ln}$, while the quantum yield of the corresponding $Tb^{III}$ dimer increases only by a factor of 2. This result is in agreement with the evaluated energy gaps between the luminescent levels of $Eu^{III}$ and $Tb^{III}$ ions and the triplet state of 4-cpyNO (vide supra, Table 3).



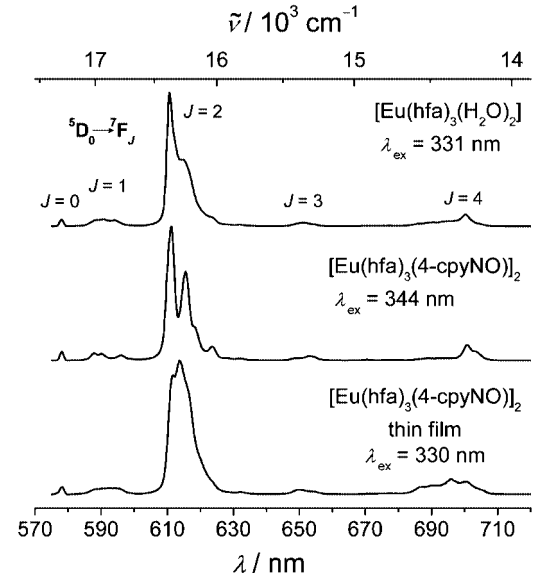


Figure 8. Emission spectra of $[Ln(hfa)_3(H_2O)_2]$ and mixed-ligand $[Ln(hfa)_3(4\text{-cpyNO})]_2$ complexes (Ln = $Eu^{III}$, $Tb^{III}$) under ligand excitation at 295 K.

For lanthanide(III) complexes, the efficiency of the overall ligand-to-metal energy transfer ($\eta_{sens}$) can be estimated from Equation (2),[21] where $Q^L_{Ln}$ is the overall quantum yield upon ligand excitation, $\eta_{et}$ is the efficiency of the $^3\pi\pi^*$–Ln energy transfer, $\eta_{isc}$ is the efficiency of the intersystem crossing, $Q^{Ln}_{Ln}$ is the intrinsic quantum yield upon direct excitation of the lanthanide(III) ion, $\tau_{obs}$ is the observed lifetime and $\tau_{rad}$ is the radiative lifetime (i.e. the lifetime in the absence of any non-radiative process).

As the intensity of the purely magnetic dipole transition ($^5D_0 \rightarrow {}^7F_1$) for europium(III) is independent of the chemical environment around the metal ion, the intrinsic quantum yield may be estimated from Equation (3),[21] where $A_{MD,0}$ = 14.65 $s^{-1}$ is the spontaneous emission probability of the magnetic dipole $^5D_0 \rightarrow {}^7F_1$ transition, $n$ is the refractive index, $I_{tot}$ is the integrated emission of the $^5D_0 \rightarrow {}^7F_J$ ($J$ = 0–4) transitions and $I_{MD}$ is the integrated emission of the $^5D_0 \rightarrow {}^7F_1$ transition.

From the data obtained (Table 5), it can be concluded that the substitution of water molecules by 4-cpyNO leads to a 3.4-fold increase in the intrinsic quantum yield (from

[a] $\tau_{rad}$, $Q^{Eu}_{Eu}$ and $\eta_{sens}$ were calculated under the assumption that refractive indices are the same for thin film and solid samples, and equal to 1.5109 for $[Eu(hfa)_3(4\text{-cpyNO})]_2$ and 1.51 for $[Eu(hfa)_3(H_2O)_2]$. [b] Not determined. [c] Calculated under the assumption that the overall quantum yield is the same as for the solid sample. [d] $\tau_{obs}$ is almost the same upon excitation of either ligand or terbium(III) levels.

$$Q^{L}_{Ln} = \eta_{sens} Q^{Ln}_{Ln} = \eta_{et}\eta_{isc} Q^{Ln}_{Ln} = \eta_{et}\eta_{isc} \cdot \frac{\tau_{obs}}{\tau_{rad}}, \quad (2)$$

$$Q^{Eu}_{Eu} = \tau_{obs} A_{MD,0} n^3 \cdot \frac{I_{tot}}{I_{MD}}, \quad (3)$$

19 to 65%) and to a 3.1-fold enhancement (from 13 to 40%) of $\eta_{sens}$, respectively. Thus, the ancillary ligand significantly contributes to the overall sensitisation process of the $Eu^{III}$ complexes and, additionally, removes part of the quenching processes. In the case of the $Tb^{III}$ compounds, the lifetimes measured upon excitation of either the ligand or the $Tb^{III}$ ion are almost the same, within experimental errors, the lifetime of the mixed-ligand $[Tb(hfa)_3(4\text{-cpyNO})]_2$ dimer being only slightly shorter than that of the parent $[Tb(hfa)_3(H_2O)_2]$ (Table 5). This can be traced back to a larger energy gap displayed by this ion, which means that the contribution of the water molecules to the non-radiative de-excitation processes is smaller than for europium(III).[20,22] Additionally, a lower energy of the triplet state in the mixed-ligand complex relative to the luminescent $Tb^{III}$ levels (Table 3) allows a more efficient back-transfer process, which means that the improvement found in the quantum yield upon binding the ancillary ligand for this ion is entirely due to better sensitisation efficiency.

In the excitation spectrum of a thin film of $[Eu(hfa)_3(4\text{-cpyNO})]_2$, the shoulder feature at 360 nm (27778 $cm^{-1}$) disappears when compared with the bulk sample (cf. Figure 6), thereby displaying a better correspondence with the reflectance/absorption spectra. This can be explained by the very strong absorption up to 330 nm in the bulk $[Eu(hfa)_3(4\text{-cpyNO})]_2$, which leads to absorption of the incident light only by the near-surface region of the sample while excitation higher than 330 nm will be absorbed throughout the bulk sample. The photoluminescence spectra of the thin film are very similar to those of the bulk sample (cf. Figure 8). On the other hand, the integral intensity of the hypersensitive $^5D_0 \rightarrow {}^7F_{2,4}$ transitions (cf. Table 4) is larger for the thin film than for the bulk sample and this is also the case for the observed luminescence lifetimes and evaluated intrinsic quantum yields (cf. Table 5). These results can be attributed to the higher order of packing of the $[Eu(hfa)_3(4\text{-cpyNO})]_2$ dimers in the thin film than in the bulk solid sample, which, in turn, results in a decrease in the energy transfer rate constants and in a longer luminescence lifetime.

The effect of the mixed-ligand complex formation with 4-cyanopyridine *N*-oxide on the luminescent properties has also been studied for the $Sm^{III}$, $Dy^{III}$ and $Tm^{III}$ hexafluoroacetylacetonates. The excitation of both $[Ln(hfa)_3(H_2O)_2]$ and $[Ln(hfa)_3(4\text{-cpyNO})]_2$ (Ln = $Sm^{III}$, $Dy^{III}$, $Tm^{III}$) into the ligand-centred band (337 nm) results in characteristic line-like emissions of the corresponding lanthanide ion (Figure 9 and Figures S2 and S3 in the Supporting Information). The luminescence spectra of $[Ln(hfa)_3(H_2O)_2]$ and $[Ln(hfa)_3(4\text{-cpyNO})]_2$ for a given lanthanide ion display the same features. It should be noted that no emission from the lowest triplet state of the ligands has been observed, which reflects the existence of a $^3\pi\pi^*$–Ln energy transfer. The samarium(III) and dysprosium(III) complexes exhibit pink and yellow emission due to $^4G_{5/2} \rightarrow {}^6H_J$ ($J$ = 5/2, 7/2, 9/2, 11/2) and $^4F_{9/2} \rightarrow {}^6H_J$ ($J$ = 13/2, 11/2, 9/2) transitions, with the most intense bands centred at 647 ($^4G_{5/2} \rightarrow {}^6H_{9/2}$) and 573 nm ($^4F_{9/2} \rightarrow {}^6H_{11/2}$), respectively. The excitation spectra of $[Ln(hfa)_3(H_2O)_2]$ and $[Ln(hfa)_3(4\text{-cpyNO})]_2$ (Ln = $Sm^{III}$ and $Dy^{III}$) are very similar in shape (Figure S1 in the Supporting Information) and present two broad bands around 270 (37000) and 350 nm (28500 $cm^{-1}$), respectively, which match the corresponding features in the reflectance spectra (see Figure S4 in the Supporting Information). This confirms that the energy transfer takes place from the organic ligands to the lanthanide ions. The excitation spectra also display features corresponding to the metal-centred transitions at around 363 ($^4D_{3/2} \leftarrow {}^6H_{5/2}$), 377 ($^6P_{7/2} \leftarrow {}^6H_{5/2}$), 405 ($^6P_{3/2} \leftarrow {}^6H_{5/2}$) and 420 nm ($^6P_{5/2}$, $^4P_{5/2} \leftarrow {}^6H_{5/2}$) for $Sm^{III}$, and around 365 ($^4M_{9/2} \leftarrow {}^6H_{15/2}$), 389 ($^4F_{7/2} \leftarrow {}^6H_{15/2}$), 434 ($^4G_{11/2} \leftarrow {}^6H_{15/2}$), 454 ($^4I_{15/2} \leftarrow {}^6H_{15/2}$) and 474 nm ($^4F_{9/2} \leftarrow {}^6H_{15/2}$) for the $Dy^{III}$ derivative. The $[Tm(hfa)_3(H_2O)_2]$ and $[Tm(hfa)_3(4\text{-cpyNO})]_2$ samples were found to be luminescent only at 77 K. Excitation in the ligand absorption band (337 nm) results in blue luminescence with a maximum at 480 nm, which can be assigned to the $^1G_4 \rightarrow {}^3H_6$ transition. The substitution of water molecules in $[Ln(hfa)_3(H_2O)_2]$ (Ln = $Sm^{III}$, $Dy^{III}$, $Tm^{III}$) by 4-cyanopyridine *N*-oxide leads to a decrease of both the luminescence intensity and quantum yields. When compared with the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

parent hydrated compounds, the relative quantum yields, $Q_{rel}^{Ln,L}$, of the mixed-ligand $Sm^{III}$ and $Dy^{III}$ complexes are $0.55 \pm 0.06$ and $0.50 \pm 0.05$, respectively. The most drastic decrease occurs for the $Tm^{III}$ adduct, leading to a $Q_{rel}^{Ln,L}$ value of $0.19 \pm 0.02$. This is probably due to multi-phonon deactivation of the excited states for the respective lanthanide ions by the N–O vibrations of 4-cyanopyridine *N*-oxide. The efficacy of this quenching process is inversely proportional to the energy gap between the emitting state and the ground state manifold: the larger the energy gap, the lower the non-radiative rate constant will be as the number of phonons necessary to bridge the gap increases in this case.[22] So, this quenching is more significant for $Sm^{III}$, $Dy^{III}$ and $Tm^{III}$ than for $Eu^{III}$ or $Tb^{III}$ because the energy gaps between the luminescent state and ground-state manifold are not large for the former (7400 for $Sm^{III}$, 7850 for $Dy^{III}$ and 5800 $cm^{-1}$ for $Tm^{III}$) when compared with the values for $Eu^{III}$ or $Tb^{III}$ (12300 and 14800 $cm^{-1}$, respectively). Although the main vibrations of the N–O bonds in 4-cpyNO are not too energetic (around 1280 $cm^{-1}$), they contribute substantially to the quenching process: approximately 6, 6, and 4–5 phonons are required to bridge the energy gap of $Sm^{III}$, $Dy^{III}$ and $Tm^{III}$, respectively. Moreover, in the mixed-ligand $Dy^{III}$ and $Tm^{III}$ complexes, poor luminescence sensitisation may be caused by poorly matched energy gaps between the triplet state of the ancillary ligand and the luminescent levels of these ions (Table 3).

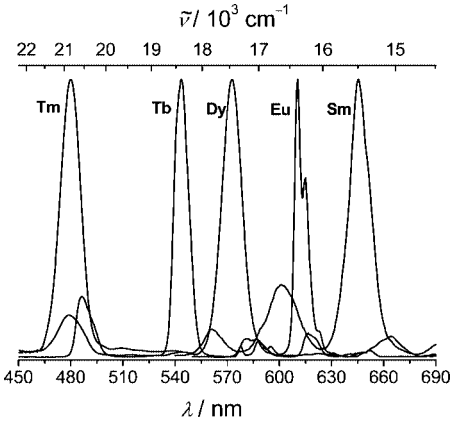

Figure 9. Emission spectra of mixed-ligand dimeric complexes $[Ln(hfa)_3(4\text{-cpyNO})]_2$ (Ln = $Tm^{III}$, $Tb^{III}$, $Dy^{III}$, $Eu^{III}$, $Sm^{III}$) under ligand excitation (see also Figure S3).

## Conclusions

The reaction of lanthanide hexafluoroacetylacetonates $[Ln(hfa)_3(H_2O)_2]$ (Ln = $Sm^{III}$–$Ho^{III}$, and $Tm^{III}$) with 4-cyanopyridine *N*-oxide in a 1:1 ratio results in the formation of $[Ln(hfa)_3(4\text{-cpyNO})]_2$ dimers in which the two metal ions are separated by about 3.99–4.13 Å. The magnetic studies reveal weak antiferromagnetic exchange interactions between neighbouring metal centres within the dimeric $[Gd(hfa)_3(4\text{-cpyNO})]_2$ units. The substitution of water molecules in the parent hydrated complexes $[Ln(hfa)_3(H_2O)_2]$ by 4-cpyNO has a large effect on the luminescence properties. Such a combination of organic ligands is able to sensitize the metal-centred luminescence of $Sm^{III}$, $Eu^{III}$, $Tb^{III}$, $Dy^{III}$ and $Tm^{III}$ ions that emit pink, red, green, yellow and blue light, respectively, i.e. within the entire spectral visible range. The introduction of the ancillary ligand leads to substantial and varying changes in the luminescence quantum yields. The greatest effect occurs for $[Eu(hfa)_3(4\text{-cpyNO})]_2$, with a tenfold increase in the absolute quantum yield (from 2.6 to 25.7%) with respect to the hydrated complex. On the other hand, a decrease in the quantum yield is observed for $Sm^{III}$, $Dy^{III}$ and $Tm^{III}$ dimers with respect to the hydrated chelates. The $[Ln(hfa)_3(4\text{-cpyNO})]_2$ dimers are thermally stable up to 190 °C and can be quantitatively sublimed at 200 °C under reduced pressure ($10^{-2}$ Torr), thus opening the way to the production of luminescent thin films, as demonstrated here with $Eu^{III}$. Both the luminescence lifetime and intrinsic quantum yield of $Eu^{III}$ are higher in thin films than in the solid sample, while the sensitisation efficacy remains approximately the same. In conclusion, high volatility, good thermal stability and efficient luminescent properties make the mixed-ligand $[Ln(hfa)_3(4\text{-cpyNO})]_2$ complexes, especially the $Eu^{III}$ and $Tb^{III}$ derivatives, good candidates for emitting layers in light-emitting diodes.

## Experimental Section

**Reagents and Physical Methods:** The commercially available starting reagents Hhfa (Merck) and 4-cyanopyridine *N*-oxide (Aldrich) were of analytical grade and used as received. Lanthanide nitrate hydrates $Ln(NO_3)_3 \cdot xH_2O$ were obtained by treating the respective lanthanide oxides $Ln_2O_3$ (99.998%) with concentrated nitric acid, followed by evaporation of the excess acid. For the synthesis of $[Ln(hfa)_3(H_2O)_2]$ (Ln = $Sm^{III}$–$Ho^{III}$, and $Tm^{III}$) the procedure described in ref.[23] was used. Elemental analysis (C, H, N) was performed by the Microanalytical Service of the Centre for Drug Chemistry (Moscow, Russia). The lanthanide content was determined by titrimetric analysis.[24] IR spectra were recorded in Nujol mull or hexachlorobutadiene between KBr plates in the range 4000–400 $cm^{-1}$ using a Perkin–Elmer 1600 FT-IR spectrometer. Thermogravimetric analyses were performed with a Q-1500 thermal analyzer under nitrogen, at a heating rate of 10 °C $min^{-1}$. Isothermal dynamic sublimation experiments were run with samples (ca. 100 mg) placed into glass test tubes at 20–220 °C and a pressure of $10^{-2}$ Torr for periods of about 30 min. Weight loss was essentially 100%. The homogeneous sublimate was collected in the cold part of the tube and analysed.

**Syntheses:** All lanthanide(III) hexafluoroacetylacetonate adducts $[Ln(hfa)_3(4\text{-cpyNO})]_2$ (Ln = $Sm^{III}$–$Ho^{III}$, $Tm^{III}$) were synthesised in a similar way. A typical preparation procedure is as follows: 4-Cyanopyridine *N*-oxide (60 mg, 0.5 mmol) was added to a solution of $[Ln(hfa)_3(H_2O)_2]$ (0.5 mmol) in chloroform (20 mL). The resulting mixture was then stirred at room temperature for 1 h. Further evaporation of the solvent under low pressure yielded a colourless ($Gd^{III}$, $Tb^{III}$), pale yellow ($Sm^{III}$, $Eu^{III}$, $Ho^{III}$ and $Dy^{III}$) or pale aquamarine ($Tm^{III}$) polycrystalline precipitate, which was filtered off and dried in air. Yield: 80–90%.

The monomeric complex $[Gd(NO_3)_3(4\text{-cpyNO})]$ was prepared in ethanol by a similar procedure as described above for $[Ln(hfa)_3(4\text{-cpyNO})]_2$. Yield: 90%. $C_6H_4GdN_5O_{10}$ (463.38): calcd. Gd 33.9; found Gd 33.9. IR: $\tilde{\nu}$ = 3116 m, 3084 m, 3062 m, 3032 m, 2246 m, 1648 m, 1620 m, 1488 m, 1456 m, 1438 m, 1378 m, 1324 s, 1238 s, 1222 m, 1180 m, 1110 w, 1044 w, 1032 m, 974 w, 864 m, 858 m, 818 w, 734 m, 634 br. w, 584 w, 560 m, 478 w, 462 w, 436 w $cm^{-1}$.

**Data Collection and Structural Refinement:** Single crystals suitable for X-ray analysis were obtained by recrystallisation of the crude products from chloroform. Diffraction data were collected with an image-plate diffractometer (Stoe IPDS) for the $Tb^{III}$ complex and with a four-circle CCD diffractometer (Stoe STADI4) for the $Ho^{III}$ derivative, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods (SHELXS-97)[25] and refined anisotropically for all non-hydrogen atoms by employing full-matrix least squares on $F^2$ (SHELXL-97).[26] The hydrogen atoms were included in the calculated positions and refined in a riding mode. Crystallographic data and some details of data collection and structure refinement are listed in Table 6. CCDC-612981 and -612982 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Diffuse Reflectivity Spectra:** UV/Vis reflectance spectra for solid samples of $Sm^{III}$, $Dy^{III}$ and $Tm^{III}$ complexes (Figure S4 in the Supporting Information) were recorded with a Lambda 35 spectrophotometer (Perkin–Elmer). The absorption spectra (absorption coefficient $\alpha$ over scattering coefficient $\sigma$ as a function of wavelength) were extracted from the diffuse reflectance spectra of the "infinitely thick" powder samples ($R_\infty$), using the Kubelka–Munk function, $\frac{\alpha}{\sigma} = \frac{(1-R_\infty)^2}{2R_\infty}$. Plots of the corresponding Kubelka–Munk functions are shown in Figure S5.

**Luminescence Measurements:** Solid samples were ground into fine powders prior to the luminescence measurements. Excitation and photoluminescence spectra of $Sm^{III}$ and $Dy^{III}$ adducts were recorded at 295 K with a Perkin–Elmer LS-55 luminescence spectrometer ($\lambda_{ex}$ = 337 nm, xenon lamp). Luminescence spectra of $Gd^{III}$ and $Tm^{III}$ complexes were measured at 77 K with a multichannel spectrometer S2000 (Ocean Optics) utilizing a nitrogen laser LGI-21 ($\lambda_{ex}$ = 337 nm) as an excitation source. The luminescence data (excitation spectra, lifetimes and absolute quantum yields) of $Eu^{III}$ and $Tb^{III}$ derivatives were recorded at 295 K with a Fluorolog FL3-22 spectrofluorimeter from Horiba–Jobin–Yvon–Spex; to prevent saturation of the signal in photon-counting mode, the emission bandpass was set to 1 nm. Excitation spectra were measured by monitoring the characteristic $^4G_{5/2}\rightarrow{}^6H_{9/2}$, $^5D_0\rightarrow{}^7F_2$, $^5D_4\rightarrow{}^7F_5$ and $^4F_{9/2}\rightarrow{}^6H_{11/2}$ transitions for $Sm^{III}$, $Eu^{III}$, $Tb^{III}$ and $Dy^{III}$, respectively. Luminescence lifetimes ($\tau_{obs}$) of the $Eu^{III}$ compounds were determined by excitation of the $^5D_2$ level (466 nm, 21459 $cm^{-1}$) and monitoring the $^5D_0\rightarrow{}^7F_2$ transition, while those of the $Tb^{III}$ complexes were measured by excitation of either the $Tb^{III}$ ion or the ligand and monitoring the $^5D_4\rightarrow{}^7F_5$ transition. Lifetimes are the averages of at least three independent measurements. All luminescence decays proved to be perfect single exponential functions. All excitation and luminescence spectra were corrected by the instrumental functions. Electronic transitions were assigned by comparing the measured spectra with those reported by Elyashevich[27] and in other previous studies.[28] Luminescence quantum yields of $[Ln(hfa)_3(H_2O)_2]$ and $[Ln(hfa)_3(4\text{-cpyNO})]_2$ (Ln = $Eu^{III}$, $Tb^{III}$) were determined for solid samples by excitation into the ligand absorption band, according to the absolute method of Wrighton.[29] Each sample was measured several times under slightly different experimental conditions. Relative quantum yields, $Q_{rel}^{Ln,L}$, of $Sm^{III}$, $Dy^{III}$ and $Tm^{III}$ chelates $[Ln(hfa)_3(4\text{-cpyNO})]_2$ were calculated relative to the respective $[Ln(hfa)_3(H_2O)_2]$ complexes (at the same excitation wavelength and experimental geometry), using Equation (4), where $Q$ is the quantum yield, $R$ is the amount of reflected excitation radiation, $\phi$ is the integrated area of the corrected luminescence spectra and the indexes $x$ and $r$ correspond to $[Ln(hfa)_3(4\text{-cpyNO})]_2$ and $[Ln(hfa)_3(H_2O)_2]$, respectively. For comparison reasons, $Q_r$ was set to 1. The estimated error for the luminescence quantum yields is ±10%.

$$Q_{rel}^{Ln,L} = \frac{Q_x}{Q_r} = \left(\frac{1-R_r}{1-R_x}\right)\left(\frac{\phi_x}{\phi_r}\right) \quad (4)$$

**Refractive Index and Thickness of Thin Films:** Thin films of $[Eu(hfa)_3(4\text{-cpyNO})]_2$ were deposited on quartz substrates by the thermal evaporation method in a vacuum chamber ($P \approx 10^{-6}$ Torr, Leybold Heraeus). The refractive index ($n$) and layer thickness ($d$) were measured with a Filmetric F20 Thin Film Analyzer. The results are averages of at least three measurements. $[Eu(hfa)_3(4\text{-cpyNO})]_2$ (thin film): $n = 1.511 \pm 0.002$, $d = 414 \pm 1$ nm.

**Magnetic Measurements:** Magnetic susceptibility data (2–300 K) for polycrystalline samples of $[Ln(hfa)_3(4\text{-cpyNO})]_2$ (Ln = $Gd^{III}$, $Tb^{III}$) were collected with a SQUID magnetometer using a Quantum Design MPMS instrument with applied DC magnetic fields of 200 and 1000 Oe, respectively. The experimental data were corrected for the sample holder contribution and for diamagnetism of the constituent atoms estimated from Pascal's increments.[30]

**Supporting Information** (see footnote on the first page of this article): Reflection, excitation and photoluminescence spectra.

## Acknowledgments

We are grateful to Prof. Ritta Szymczak and Dr. Marek Baran (Institute of Physics, Polish Academy of Sciences) for the magnetic measurements, Mr. Andrei A. Vaschenko (Lebedev Physical Institute of Russian Academy of Sciences) for his assistance in obtaining thin-film samples, and the Russian Foundation for Basic Research (RFBR, grants 05-03-33090, 04-02-17040) for financial support.

# Hydroxyapatite Nanocrystals Modified with Acidic Amino Acids

**Elisa Boanini,[a] Milena Fini,[b] Massimo Gazzano,[c] and Adriana Bigi*[a]**

**Keywords:** Hydroxyapatite / Amino acids / Nanocrystals

HA-aspartic acid (HA-ASP) and HA-glutamic acid (HA-GLU) composite nanocrystals were synthesized in aqueous medium. The relative amino acid content, determined through HPLC analysis, increases with the amino acid concentration in solution up to a maximum of about 7.8 wt.-% for HA-ASP and 4.3 wt.-% for HA-GLU composites. The dimensions of the composite nanocrystals decrease on increasing the amino acid content. The line profile analysis of the X-ray diffraction reflections was performed using: (i) the Scherrer method, (ii) the Warren–Averbach approach, and (iii) the Rietveld refinement. The results indicate that the broadening of the diffraction peaks is partly due to the decrease of crystallite size on increasing amino acid content, and even more to the simultaneous increase of microstrain. The different extent of structural disorder induced by the two amino acids, in agreement with their different incorporation, suggests a greater affinity of aspartic acid for hydroxyapatite structure.

## Introduction

The idea of mimicking designs from nature and adopting the same strategies as those utilized by living organisms to produce functional structures has entered into many areas of applied science, most notably the synthesis of new materials.[1] The biomimetic strategy is based on the principle that nucleation and growth of inorganic crystals in biological environments occurs in the presence of biological macromolecules, which may be linked to structural organic matrices or secreted as soluble polyelectrolytes in the mineralization environment.[2,3] Control occurs through specific or nonspecific interactions of biological macromolecules with the charged surfaces of the growing inorganic crystals.[3–5] This has prompted a number of studies on the preparation of hydroxyapatite nanocrystals in the presence of biomolecules.[6–8] Proteins and macromolecules, which are most active in the mediation of biologically directed mineral growth, contain amino acid residues, specifically regions rich in carboxylates, that interact with mineral surfaces.[9–11] In bone, nucleation and growth of apatite crystals involve proteins containing high amounts of aspartic and glutamic acid residues.[12] Both glutamic and aspartic acids have been reported to induce osteoblast differentiation and to increase extracellular mineralization.[13–15]

We have recently demonstrated the possibility of synthesizing hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$ (HA), containing aspartic acid (HA-ASP) and HA containing glutamic acid (HA-GLU), and we have verified that the presence of the acidic amino acids in the composite nanocrystals favours osteoblast proliferation and promotes their metabolism and differentiation.[16] Understanding how these amino acids interact with HA structure, and clarifying their role in the control of the properties of the HA crystals is of interest both for the development of biomaterials suitable to repair the skeletal system, as well as for a better understanding of the natural processes. To this aim, we have carried out a structural, morphological and chemical investigation of hydroxyapatite nanocrystals synthesized in the presence of increasing amounts of aspartic acid and of glutamic acid.

## Results and Discussion

### Sample Characterization

The powder X-ray diffraction patterns of the products synthesized in the presence of L-aspartic acid or L-glutamic acid indicate that they are constituted of hydroxyapatite as a unique crystalline phase. However, glutamic acid, and even more so aspartic acid, provokes a broadening of the diffraction peaks, which increases on increasing the amino acid concentration in solution, as is appreciable in the patterns shown in Figure 1. The reduction of the degree of crystallinity is confirmed by the results of the FT-IR absorption analysis. In fact, the FT-IR spectra of the products obtained in the presence of increasing concentration of amino acid show a decrease of the relative intensity of the absorption bands at 3572 and 630 $cm^{-1}$, caused by $OH^-$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience 

stretching and libration mode, respectively (Figure 2). Moreover, the spectra of HA samples prepared in the presence of an amino acid display, other than the bands characteristic of the hydroxide and phosphate groups, several absorption bands in the range 1700–1400 $cm^{-1}$, which are indicative of the presence of the amino acids, as can be observed for sample HA-GLU 0.20 in part b of Figure 2. This region of the spectra is quite different from that present in the previously reported spectra of mechanical mixtures containing HA and ASP or GLU, which display a number of bands due to the two discrete components of the mixture.[16] In particular, the broad absorption band centred at 1568 $cm^{-1}$ (1591 $cm^{-1}$ in the HA-ASP spectra) can be attributed to glutamic acid (aspartic acid). The small shift with respect to the position characteristic of the carboxylic stretching band in the free amino acids is in agreement with an increase of the C–O bond length due to interaction with the apatitic phase.[17] Table 1 reports the relative amount of amino acid determined through HPLC and expressed as wt.-% of the solid product. The relative quantity of amino acid in the crystals increases with the amino acid concentration in solution up to a maximum of about 7.8 wt.-% for HA-ASP and 4.3 wt.-% for HA-GLU composites. Aspartic acid incorporation into HA nanocrystals is always greater than that of glutamic acid, suggesting a greater affinity of aspartic acid for hydroxyapatite structure. Amino acid incorporation does not significantly affect the stoichiometry of hydroxyapatite as it can be deduced also from the Ca/P molar ratio of the composites which assumes a mean value of $1.68 \pm 0.03$, very close to the stoichiometric value of 1.67, independently from the amino acid content. On the contrary, the dimensions of the crystals are strongly affected by the presence of both aspartic and glutamic acid. In Figure 3, a TEM micrograph of HA crystals is compared with that of HA-amino acid composite crystals. Hydroxyapatite is constituted of platelet-shaped crystals with mean dimensions up to about 200 × 40 nm, elongated along a direction parallel to the crystallographic *c*-axis (Figure 3, a), whereas composite nanocrystals display definitely smaller dimensions (Figure 3, b–d). The dimensions decrease on increasing the amino acid content, in agreement with the reduction of the degree of crystallinity. Furthermore, the crystals with higher amino acid content, which display mean dimensions of about 50 × 10 nm, should be also extremely thin as they appear very transparent to the electron beam. In a previous study on the interaction of poly-L-aspartate with HA, we verified a remarkable increase of the length/width ratio of the composite crystallites, in agreement with a preferential adsorption of the polyamino acid on the crystal faces parallel to the *c*-axis.[18] At variance, the significant reduction of the dimensions along all the three directions induced by ASP and GLU suggests a nonspecific interaction with the HA crystal faces, and it might be interpreted as indicating

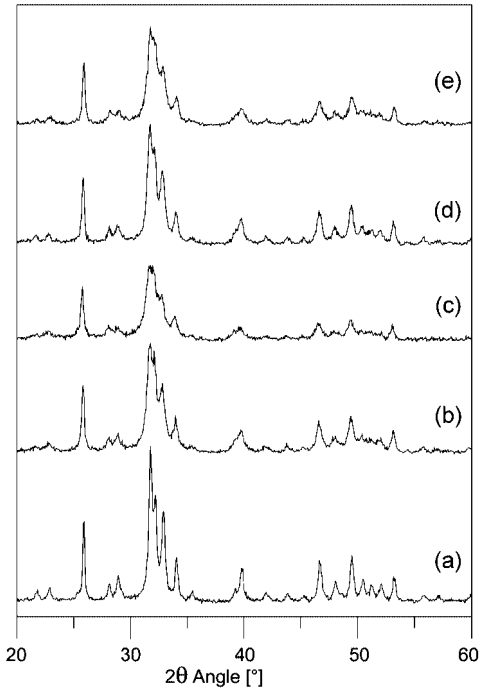

Figure 1. Powder X-ray diffraction patterns of hydroxyapatite synthesized in the absence of amino acid (a); in the presence of aspartic acid 0.10 M (b) and 0.20 M (c) and in the presence of glutamic acid 0.10 M (d) and 0.20 M (e).

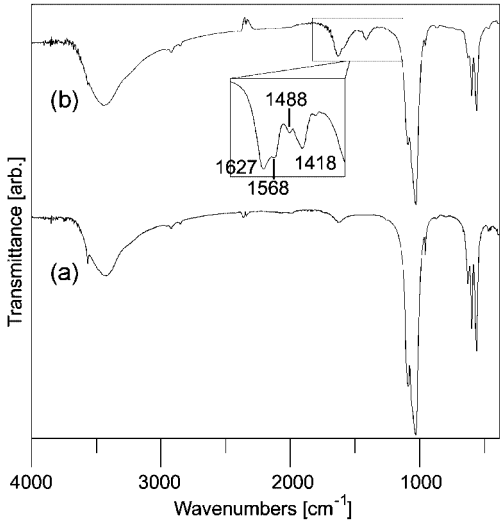

Figure 2. FT-IR adsorption spectra of the HA samples prepared in the absence of amino acid (a) and in the presence of glutamic acid 0.20 M (b). The absorption bands in the zoomed range 1700–1400 $cm^{-1}$ can be attributed to glutamic acid.

Table 1. Amount of amino acid associated to the inorganic phase evaluated through HPLC and expressed as wt.-% of the solid product.

| Amino acid concentration in solution [M] | Aspartic acid content [wt.-%] | Glutamic acid content [wt.-%] |
|---|---|---|
| 0 | – | – |
| 0.05 | 3.14 | 1.17 |
| 0.10 | 4.28 | 2.50 |
| 0.15 | 5.35 | 3.30 |
| 0.20 | 7.80 | 4.30 |

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

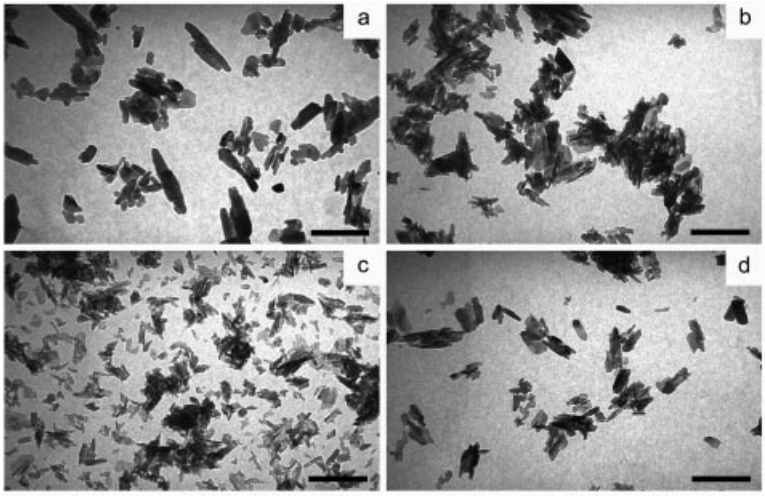

Figure 3. TEM micrographs of HA crystals synthesized in the absence of amino acid (a); in the presence of aspartic acid 0.10 M (b) and 0.20 M (c) and in the presence of glutamic acid 0.20 M (d). Scale-bar = 200 nm.

that the presence of the amino acids provokes an increase of the nucleation rate that, as a consequence, leads to a growth reduction.[15] Aspartic and glutamic acid seem to exert a similar control on crystal dimensions, as can be deduced from the comparison of Figure 3 (parts b and d).

In agreement with the crystal dimensions, the values of the specific surface area, determined applying the Brunauer–Emmett–Teller (BET) theory and reported in Table 2 increases as a function of amino acid content, up to 114 $m^2 g^{-1}$, which represents a very high value for synthetic platelet-like hydroxyapatite crystals.

Table 2. Surface areas of hydroxyapatite samples synthesized in the presence of different amino acid concentrations in solution.

| Sample | Surface area [$m^2 g^{-1}$] |
|---|---|
| HA | 60 |
| HA-ASP 0.10 | 84 |
| HA-ASP 0.20 | 114 |
| HA-GLU 0.10 | 78 |
| HA-GLU 0.20 | 86 |

## Crystallographic Investigation

Line profile analysis has been applied in order to investigate the line broadening increase observed in the XRD patterns of the samples synthesized in the presence of increasing amounts of amino acid (Figure 1).

A qualitative estimation of the size of coherently scattering domains (i.e., the crystallite size) as derived from the Scherrer equation, on the hypothesis of negligible microstrain, is reported in Table 3. $\tau_{002}$ is related to the mean crystallite size along the *c*-axis whereas $\tau_{310}$ refers to the mean crystal size along a direction perpendicular to it.

Table 3. Coherent lengths ($\tau_{hkl}$) of the perfect crystalline domains in the direction normal to 002 and to 310 planes calculated using the Scherrer method.

| Sample | $\tau_{002}$ [nm] | $\tau_{310}$ [nm] |
|---|---|---|
| HA | 44.3(9) | 22.4(6) |
| HA-ASP 0.05 | 38.9(7) | 17.0(3) |
| HA-ASP 0.10 | 35.8(3) | 15.5(2) |
| HA-ASP 0.15 | 35.2(3) | 14.8(3) |
| HA-ASP 0.20 | 29.8(4) | 11.3(3) |
| HA-GLU 0.05 | 43.8(9) | 19.9(3) |
| HA-GLU 0.10 | 35.8(6) | 15.2(2) |
| HA-GLU 0.15 | 34.6(3) | 14.7(3) |
| HA-GLU 0.20 | 33.7(3) | 12.0(3) |

The crystal sizes decrease as the aspartic or glutamic acid content increases. The contraction appears to be greater along the direction orthogonal to the *c*-axis, similarly to what was previously found for poly-L-aspartate.[18] The comparison with the data reported in Table 1 indicates that GLU incorporation provokes a greater contraction of crystal size.

In general, the nature of imperfections responsible for the broadening of the diffraction peaks could be due to (i) a reduction of the crystallite domains, (ii) the occurrence of still large domains but with lattice spacings that differ one from another, and (iii) the presence of elastic deformations and stacking faults inside the domains. In order to evaluate the relative contribution of crystallite size and microstrain to the diffraction peak broadening, some selected samples were submitted to the Warren–Averbach analysis. The analysis was performed on two pairs of reflections (002/004 and 111/222). The results are reported in Table 4. Since only two pairs of peaks were analysed, the results are rather semi-quantitative. However, the data clearly show that both amino acids provoke a reduction of the mean crystallite size, without significant differences along the two investigated directions.

Table 4. Microstructural parameters calculated using Warren–Averbach analysis.

| Sample | 002/004 | | | | 111/222 | | | |
|---|---|---|---|---|---|---|---|---|
| | $\langle D \rangle_s$ (nm) | $\langle D \rangle_v$ (nm) | $\langle \varepsilon_L^2 \rangle^{\frac{1}{2}}$ ($\times 10^3$) | $\left\langle \varepsilon^2_{\frac{\langle D \rangle_V}{2}} \right\rangle^{\frac{1}{2}}$ ($\times 10^3$) | $\langle D \rangle_s$ (nm) | $\langle D \rangle_v$ (nm) | $\langle \varepsilon_L^2 \rangle^{\frac{1}{2}}$ ($\times 10^3$) | $\left\langle \varepsilon^2_{\frac{\langle D \rangle_V}{2}} \right\rangle^{\frac{1}{2}}$ ($\times 10^3$) |
| HA | 38.7 | 28.6 | 1.34 | 1.57 | 27.7 | 26.4 | 0.97 | 0.93 |
| HA-ASP 0.10 | 18.7 | 21.9 | 1.36 | 1.56 | 17.0 | 18.0 | 1.21 | 1.71 |
| HA-ASP 0.20 | 11.3 | 11.6 | 1.33 | 2.55 | 9.8 | 10.4 | 1.43 | 2.81 |
| HA-GLU 0.10 | 18.6 | 22.4 | 1.33 | 1.78 | 16.9 | 17.9 | 1.33 | 1.76 |
| HA-GLU 0.20 | 14.7 | 18.7 | 1.59 | 2.73 | 9.7 | 12.1 | 1.53 | 2.82 |

$\langle D \rangle_s$, $\langle D \rangle_v$ are the mean sizes of crystallites weighed on the surface or volume

$\langle \varepsilon_L^2 \rangle^{\frac{1}{2}}$ is the root of mean-square lattice strain

Furthermore, all the composites show an increase of the microstrain parameters indicating that the incorporation of both amino acids provokes a significant decrease of crystal perfection, which is more evident for HA-GLU composites. The parameters obtained for the 111/222 planes are larger than those for the 002/004 planes suggesting a smaller amount of stacking faults along the *c*-axis. These data can be used to interpret the different results obtained with the Scherrer analysis. The Scherrer formula gives proper values of the mean crystallite size along the investigated direction only for strain-free samples. In spite of the different reflections analyzed by the Warren–Averbach method, the results clearly indicate that the microstrain contribution is smaller along the 00*l* direction than along the direction orthogonal to it. As a consequence, $\tau_{310}$ appeared more affected than $\tau_{002}$ simply because of the neglected microstrain contribution.

In order to verify the possible structural modifications, a full profile fitting was performed on XRD patterns of the two composites at the highest amino acid content (samples HA-ASP 0.20 and HA-GLU 0.20). The main steps of the procedure are reported in the experimental section and a comparison between the experimental and calculated pattern, as obtained at the end of the process, is reported in Figure 4 for the HA-aspartic acid sample. The final discrepancy factors *Rp* = 0.044, *Rwp* = 0.058 and *Rp* = 0.049, *Rwp* = 0.064 were achieved for HA-ASP 0.20 and HA-GLU 0.20, respectively. The results indicate that the cell parameters of the HA-amino acid composites are still the same as a stoichiometric HA [HA *a* = 0.9424(1) nm, *c* = 0.6880(1) nm; HA-ASP 0.20 *a* = 0.9427(7) nm, *c* = 0.6877(8) nm; HA-GLU 0.20 *a* = 0.9425(4) nm, *c* = 0.6884(4) nm]. The presence of an appreciable amorphous fraction in the samples has to be excluded, because leaving variable the integrated intensity of a bell-shaped curve superimposed on the background did not allow a better convergence. The Debvin program takes into account the anisotropy of the crystallite dimensions that can be used as variable parameters.[19] A good agreement index is reached when the mean value of the crystallite dimensions along the *c*-axis is almost double respect to the values along *a* and *b*, in agreement with the results of the Scherrer and Warren–Averbach analysis. No significant variation of the atomic positions and occupancy factors was detected, whereas an increase of about 20% in the thermal parameters seems to indicate an increased general disorder in the structure of the composites.

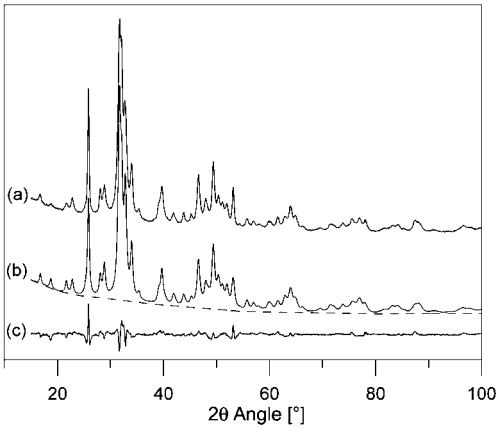

Figure 4. Comparison between the observed (a) and the calculated (b) powder diffraction patterns of HA-ASP 0.20. The dotted line is the background, while the line at the bottom (c) is the difference curve.

## Conclusions

Composite HA-ASP and HA-GLU nanocrystals have been synthesized at different amino acid content. The presence of the amino acids in the reaction solution does not inhibit nucleation of HA, but reduces the growth of the composite nanocrystals in agreement with the increase of the surface area on increasing amino acid content. TEM images confirm the reduction of dimensions, which does not modify the morphology of the composite nanocrystals. Accordingly, the results of the structural analyses showed a major contribution from microstrain to the broadening of the diffraction peaks for both HA-ASP and HA-GLU. However, glutamic acid induces a greater disorder in the HA structure, most likely because of its bigger size, which

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

could justify the greater affinity of aspartic acid for HA suggested by its greater incorporation into the composite nanocrystals.

## Experimental Section

The synthesis of hydroxyapatite was carried out under $N_2$ using a $Ca(NO_3)_2{\cdot}4H_2O$ (50 mL, 1.08 M) solution at pH adjusted to 10 with $NH_4OH$. The solution was heated at 90 °C and a $(NH_4)_2HPO_4$ solution (50 mL, 0.65 M), pH 10 adjusted with $NH_4OH$, was added dropwise whilst stirring. The precipitate was maintained in contact with the reaction solution for 5 h at 90 °C whilst stirring, then centrifuged at 10000 rpm for 10 min and repeatedly washed with $CO_2$-free distilled water. The product was dried at 37 °C overnight.

Hydroxyapatites at different amino acid contents were obtained by adding L-aspartic acid or L-glutamic acid (SIGMA) to the phosphate solution, before adjusting the pH to 10 with $NH_4OH$. The tested concentrations were 0.05, 0.10, 0.15 and 0.20 M.

X-ray diffraction analysis was carried out by means of a PANalytical X'Pert PRO powder diffractometer. Cu-$K_\alpha$ radiation was used (40 mA, 40 kV). The $2\theta$ range was from 10 to 60° at a scanning speed of 0.75°min$^{-1}$. In order to evaluate the coherence lengths of the crystals and to perform the line profile analysis, further X-ray powder data were collected in step scanning mode with a fixed counting time of 10 s for each 0.030°/step.

For FT-IR adsorption analysis, the powdered samples (1 mg) were carefully mixed with KBr (250 mg, infrared grade) and pelletized under a pressure of 10 tons for 2 min. The pellets were analyzed with a Nicolet FT 205 IR spectrophotometer to collect 32 scans in the range 4000–400 cm$^{-1}$ at a resolution of 4 cm$^{-1}$.

Amino acid contents were determined by means of HPLC, following a procedure reported elsewhere.[20] Briefly, to the starting solution containing the amino acid in HCl ($10^{-2}$ M) was added an equal volume of borate buffer (0.2 M, pH 8) and then 9-fluorenylmethyl chloroformate (FMOC-Cl) solution (in $CH_3CN$). At the end of the time allowed for derivatization (typically 1 min), excess 1-aminoamantadine (ADAM) was added to prevent hydrolysis of excess FMOC-Cl to FMOC-OH. Before injection sample solutions were filtered through Teflon filters (0.2-μm porosity). Compounds were separated on a 250 × 4 mm i.d. 5-μm Purospher column from Merck. The HPLC pump was a Varian 9012 and the injection valve a Rheodyne 7525 equipped with a 13.2 μL calibrated loop. Compounds were detected with a Hewlett–Packard 1040 diode array detector. Data were acquired and processed with an HP 9000 Chemstation.

Calcium and phosphorus contents were determined by means of a Dionex DX100 chromatography system equipped with a Dionex CD20 conductivity detector. Powders were previously dissolved in HCl (0.1 M). The chromatographic data were collected and processed with the Dionex Peaknet 5.1 program.

For TEM investigations, a small amount of powder was dispersed in ethanol and submitted to ultrasonication. A drop of the calcium phosphate suspension was transferred onto holey carbon foils supported on conventional copper microgrids. A Philips CM 100 transmission electron microscope operating at 80 kV was used.

The surface area was measured using a Carlo Erba Sorpty 1750 BET analyser using constant volume $N_2$ absorption with desorption at 100 °C.

**Line Profile Analysis**

**Scherrer Analysis:** The line broadening of the 002 and 310 reflections was used to evaluate the length of the coherent domains ($\tau_{hkl}$) along the *c*-axis and along a direction perpendicular to it. $\tau_{hkl}$ values were calculated from the widths at half maximum intensity ($\beta_{1/2}$) using the Scherrer equation (1)[21]

$$\tau_{hkl} = \frac{k\,\lambda}{\beta_{1/2}\cos\theta} \quad (1)$$

where $\lambda$ is the wavelength, $\theta$ the diffraction angle and $K$ a constant depending on crystal habit (chosen as 0.9). The silicon standard peak 111 was used to evaluate the instrumental broadening.

**Warren–Averbach Analysis:** The Warren–Averbach approach[21] was applied with the aim to separate the line broadening due to size effect from the strain contribution. The analysis was performed on two couples of reflections (002/004 and 111/222) by using the WinFit program.[22] A strain free $LaB_6$ NIST sample was used to take into account the instrumental broadening.

**Rietveld Refinement Analysis:** The DEBVIN program,[23] essentially implemented on the Rietveld routine,[24] was used to refine the structures of HA and HA-amino acid composites. The same space group ($P6_3$/m, *n*. 176), cell parameters, atomic positions and thermal parameters as those of the initial structural model of HA were introduced.[25] The background was treated as an empirical segmented line where the heights of the seven nodes are free variables. The peaks were fitted by using a Pearson VII function. Half width of the diffraction peaks as a function of $2\theta$ was evaluated by the formulation of the Caglioti model.[26] Rietveld refinement was performed in several stages, the parameters obtained in each step being deferred in the following one. In the first cycles the scale factor and the background were refined. Refinement of the other parameters is in the following order: zero shift, profile parameters, asymmetry parameter and cell parameters. Refinements of the occupancy factors and of the coordinates were tested at the latest stages of the procedure, starting with those of the two metal sites. In the last refinement cycles the overall thermal parameter was released together with the other 14 variables.

# Synthesis and Structural Characterization of Sandwich-Type Keggin-γ-Lacunary Silicotungstates with an Open Wells–Dawson-Like Structure

**Hongsheng Liu,[a] Jun Peng,*[a] Zhongnin Su,[a] Yanhui Chen,[a] Baoxia Dong,[a] Aixiang Tian,[a] Zhangang Han,[a] and Enbo Wang[a]**

**Keywords:** Polyoxometalates / Tungstosilicates / Keggin structures / Transition metals

Three novel $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ dimers, $[\{K(H_2O)\}_2\{(\mu_3\text{-}H_2O)M(H_2O)\}(\gamma\text{-}Si_2W_{20}O_{70})]^{8-}$ (M = $Mn^{2+}$, **1**; $Co^{2+}$, **2**; $Ni^{2+}$, **3**), are isolated from an aqueous acidic medium without isomerization, which is different from most reactions of $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ with first-row transition metals. They are isomorphous and crystallize in the orthorhombic system, space group *Pnma*. These species are the first examples of imidazole–potassium mixed salts of Keggin-γ-type dimers having an analogous open structure related to the Wells–Dawson anionic cluster.

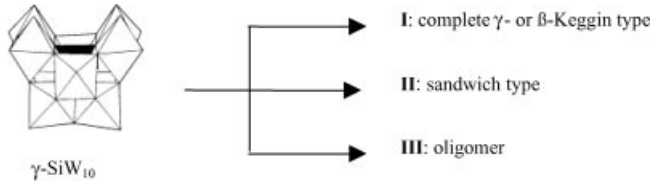
## Introduction

Polyoxometalates (POMs), a well-known, large, and unique class of inorganic polynuclear compounds, are the focus of numerous interdisciplinary projects in recent years owing to their special redox properties and tunable structure variety. This research area, as summarized in a vivid meeting review by Kögerler and Cronin, has undergone "an important transition from classical inorganic chemistry towards the chemistry of "smart", "functional materials"".[1] Among thousands of POM compounds, the metastable lacunary polyoxotungstates, such as Keggin-type 9-series $[AW_9O_{34}]^{n-}$ (A = P, Si,···), 10-series $[\gamma\text{-}AW_{10}O_{36}]^{8-}$, 11-series $[AW_{11}O_{39}]^{8-}$, and Wells–Dawson-type $[P_2W_{15}O_{56}]^{12-}$, $[P_2W_{17}O_{61}]^{10-}$, and so on, bearing an analogy with porphyrin, have drawn increasing attention as structural fragments or building blocks due to their versatility to generate unexpected species with surprising structures and multiple properties, which include catalytic, medicinal, magnetic, electronic, and optical properties.[2] Especially, mono- and trivacant α- and β-Keggin polyoxoanions have been studied for many years and are in general understood.[3] On the contrary, investigation of the divacant γ-Keggin polyoxoanion $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ (γ-$SiW_{10}$), first reported by Hervé et al.,[4] is less perhaps due to its poor stability in aqueous solution. However, extensive studies on γ-$SiW_{10}$ are prompted by very interesting results that have been reported in recent years,[5–20] from which three kinds of derivatives, **I**, **II**, and **III** symbolized in Scheme 1, can be summarized. Derivative **I** represents the derivatives in which the γ-$SiW_{10}$ anion accommodates the two vacant positions to two transition-metal atoms or other groups to generate the complete or modified γ- or β- Keggin anions; derivative **II** represents the sandwich-type derivatives in which two γ-$SiW_{10}$ subunits associate together by additional bridges; derivative **III** represents oligomeric derivatives in which the γ-$SiW_{10}$ anions are isomerized and polymerized by transition metal ions.



Scheme 1. Three kinds of derivatives synthesized from the precursor $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ anion.

Kortz and co-workers carried out a systematical study on the reaction of γ-$SiW_{10}$ anions with first-row transition metals from which they isolated a series of isomerized oligomers ranging in size from dimers to tetramers. They found that the dilacunary precursor isomerized easily in an aqueous acidic medium upon heating and in the presence of first-row transition metal ions, unlike the 9-series and 2:18-series whose structures could be preserved in the sandwich-type products. Accordingly, sandwich-type γ-$SiW_{10}$ dimers are still a challenge to obtain for POM chemists. Up to now, only Pope's group has reported a sandwich-type γ-$SiW_{10}$ dimer that was isolated as a cesium salt.[13] In our efforts to modify POM clusters,[21] we obtained three novel compounds with the $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ fragment preserved. Herein we report the syntheses and structural characterization of them. They possess an open Wells–Dawson-like

structure in which two γ-$SiW_{10}$ subunits are directly associated to each other in an eclipsed fashion. To the best of our knowledge, this type of structure that is constructed from γ-$SiW_{10}$ has not yet been reported until now. From a structure point of view, only [α-$Si_2W_{18}O_{66}$][22] was an analog.

## Results and Discussion

### Synthesis

The title compounds were isolated from an acidic solution containing γ-$SiW_{10}$, transition-metal cations, and imidazole under gentle conditions, illustrated by the reaction:

$$2\,[\gamma\text{-}SiW_{10}O_{36}]^{8-} + 4\,H^+ + 2\,K^+ + M^{2+} + 2\,H_2O \rightarrow [\{K(H_2O)\}_2(\mu_3\text{-}H_2O)M(H_2O)(\gamma\text{-}Si_2W_{20}O_{70})]^{8-}$$

It deserves to be mentioned that the γ-silicodecatungstate is a metastable species and easily isomerizes to α- or β-species, such as α-dodecasilicotungstates and β-undecasilicotungstates.[18] Therefore, a key problem is to inhibit its decomposition and isomerization during the reaction process in order to keep the anionic skeleton intact. Slight changes in the reaction conditions, such as temperature or pH, may influence the final products. The synthetic conditions of the compounds reported from precursor $K_8[\gamma\text{-}SiW_{10}O_{36}]$ are collected in Table 3. From Table 3 it can be found that lower or higher pH values ($3 > pH > 5$), elevated temperatures (≥50 °C), and long reaction times (≥30 min) are favorable for the decomposition and reassembly or isomerization of γ-$SiW_{10}$, whereas the presence of an organic solvent or bigger cations such as $K^+$, $Rb^+$, and $Cs^+$ would increase the stability of the γ-$SiW_{10}$ skeleton.[25–27] In the preparation process we controlled the reaction temperature to a maximum of 45 °C and the pH wave to not more than ±0.3. It is worthy to mention that imidazole–potassium mixed salts are obtained but only two $K^+$ ions are included in the crystal structures of the compounds even though excessive amounts of $K^+$ ions are present in the reaction solution.

The role of the $K^+$ ion in the reaction is conjectured as illustrated in Scheme 2: two $K^+$ ions occupy the pseudosymmetrical position in front of the aperture of the structure.[4] Because of the strong coordinative tendency of $K^+$ to bind to the open facial oxygen atoms,[22] two γ-$SiW_{10}$ subunits combine through them. The insertion of transition metal ions and the interjunction of two γ-$SiW_{10}$ subunits would enhance the coordination of $K^+$ to the surrounding oxo ligands, which would lead to stability of the open Wells–Dawson-like structure.

Additionally, the simulative and experimental powder X-ray diffraction patterns of **1** and **2** are coincident as well, which confirms that the as-prepared compounds are pure (see Figure S3).

### Structure Description

Compounds **1**, **2**, and **3** are isomorphic and are isolated as imidazole salts of the γ-$SiW_{10}$ derivative. The anion is a dimer of $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ subunits that are jointed together by two adjacent terminal oxygen atoms Od′ (Od′, initially marked by Hervé[4]) corner-shared with two pairs of edge-shared $WO_6$ octahedra from two parent $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ anions (see Figure 1 and Figure S1).

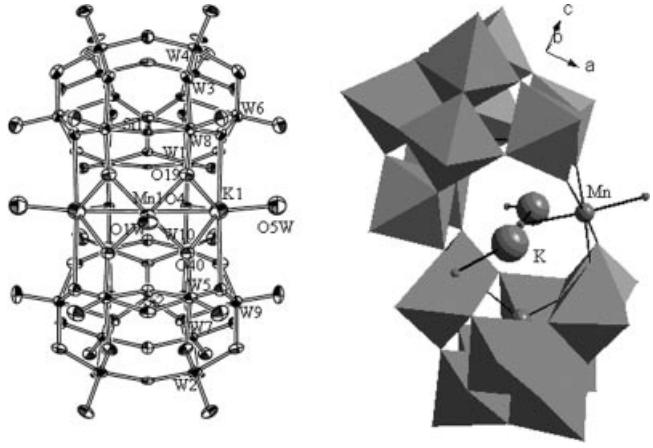

Figure 1. Structure of anion in **1**: the ORTEP view showing the atom-labeling scheme with 50% thermal ellipsoids (left); combined polyhedral/ball and stick representation (right), tungsten–oxygen octahedra, Si (big ball), oxygen (small ball), potassium (labeled), manganese (labeled). All hydrogen atoms are omitted for clarity.

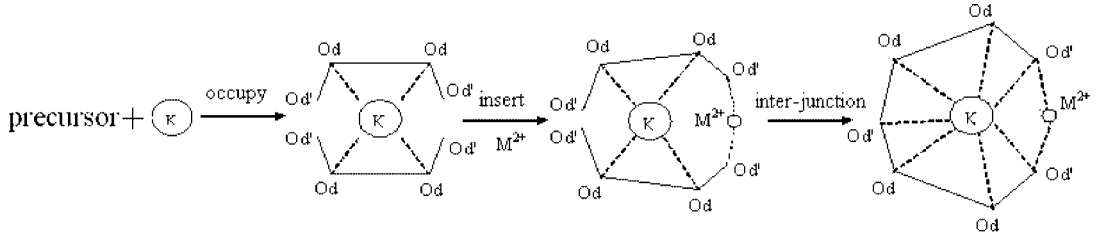
In **1**, eight open facial bridging Ob atoms (four in each γ-$SiW_{10}$ subunit), two oxygen atoms of the W–Od′–W junctions (shared between two γ-$SiW_{10}$ subunits) and the remaining four Od′ atoms (two in each γ-$SiW_{10}$ subunit), totaling fourteen oxygen atoms, delimit the open "mouth". The four Od′ atoms of the edge-shared $WO_6$ octahedral dimer in the hatch of the [γ-$Si_2W_{20}O_{70}$] cluster are strongly basic to form active sites, either for protonation or for coordination,[23] which is a characteristic reminiscent of porphyrin. One $Mn^{II}$ ion is coordinated by the four Od′ atoms like sharp incisors biting a $Mn^{II}$ ion. Perpendicular to the plane of the $MnOd'_4$, two $H_2O$ molecules coordinate to the $Mn^{II}$ center to complete an octahedral coordination environment



Scheme 2. Illustration of possible role of $K^+$ ions in the formation of the open Wells–Dawson-like structure.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of $Mn^{II}$, one towards the outside (O2W) and the other towards the inside (O1W). Interestingly, the "internal" $H_2O$, acting as a tri-bridge $H_2O$ ($\mu_3$-$H_2O$), links two $K^+$ ions in the middle point of the $K^+$-to-$K^+$ line; thus, a T-type connection composed of $K^+$, $\mu_3$-$H_2O$ and $Mn^{II}$ is formed (see Figure 2a). In fact, two $K^+$ ions are located separately on the two parotids of the "mouth", each bonding to seven oxygen atoms; thus, a nine-coordination sphere of the $K^+$ ion is accomplished by the coordination of the inside $\mu_3$-$H_2O$ and the outside $H_2O$ molecules (see Figure 2b). The K–OW bond lengths are in the range 2.80(6)–2.84(2) Å, and seven K–O bond lengths [2.96(1)–3.13(1) Å] correspond to the range (2.76–3.22 Å) reported by Hervé.[22] The W1–O4–W10 angle of the junctions is 135.1° and the bond lengths are1.85(1) Å and 2.02(1) Å, respectively, which is in the normal range for corner W–O–W bridges in each subunit (See Figure S2 for the coordination spheres of **2** and **3**).

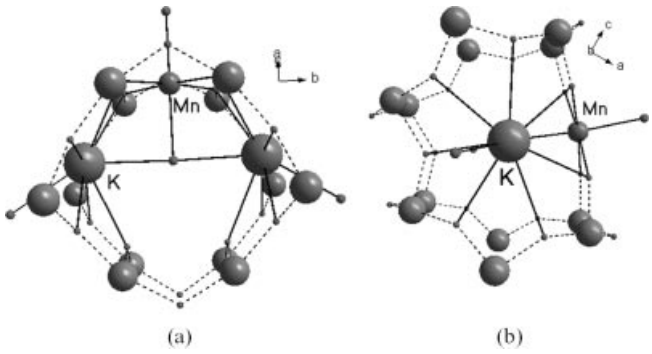


Figure 2. Coordination spheres of $K^+$ and $Mn^{2+}$ in compound **1**: (a) viewed along the normal direction of the ∇ K–M–K plane, (b) viewed along the line of K–$OW_{int}$–K, tungsten (big ball), oxygen (small ball), potassium (labeled), manganese (labeled).

It is interesting to make a comparison with the filling manners of the "mouths" for the $[\gamma\text{-}Si_2W_{20}O_{70}]$ and $[\alpha\text{-}Si_2W_{18}O_{66}]$ clusters. The "mouth" of $[\alpha\text{-}Si_2W_{18}O_{66}]$ seems to be more open than that of $[\gamma\text{-}Si_2W_{20}O_{70}]$. In the former, there exist several filling manners of the "mouth" or "pocket", such as $K_3$, KCo, and $KCo_2$, whereas in the latter the filling manners seem to be more regular, as only $K_2M$ (M = $Mn^{II}$, $Co^{II}$, or $Ni^{II}$) is found.

Selected bond lengths and angles of compounds **1**, **2**, and **3** are listed in Table 1 along with those of the $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ precursor for comparison. From Table 1 we can see that the bond lengths of Si–Oa ($W_2$ diad) (the oxygen atom belongs to a ditungstic group) are longer in compounds **1**, **2**, and **3** than those of the $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ precursor, whereas those of Si–Oa ($W_3$ triad) (the oxygen atom belongs to a tritungstic group) are shorter, that is, the Si–Oa bond lengths go to an average value that is close to 1.63 Å for $[\alpha\text{-}SiW_{12}O_{40}]^{4-}$.[1] This would enhance the stability of **1**. Other W–O bond lengths are within their normal values, except for the longer W10–Od (O31) and W10/W1–Od′ (O4) bonds which are the junctions of the two $SiW_{10}$ subunits (see Table S1). The corresponding bond lengths and bond angles of the transition metal in the hatches of $[\gamma\text{-}Si_2W_{20}O_{70}]$ for **1**, **2**, and **3** are listed in Table 2 along with those of $[\alpha\text{-}Si_2W_{18}O_{66}]$ for comparison. The average bond lengths of M–Od′ are 2.12 Å for **1**, 2.05 Å for **2**, and 2.03 Å for **3**, and the W–O–W bond angles of the junctions are smaller than that of $[\alpha\text{-}Si_2W_{18}O_{66}]$.

The anion packing diagram in the unit cell of **1** viewed down the *b* axis is given in Figure 3a. There are four anions labeled as A, A*, B, and B*. The two adjacent anions A and A* or B and B* are, respectively, related by an inversion center and associated with each other in a "mouth-to-mouth" manner by imidazole molecules with the Mn···Mn distance of 8.37 Å. Anions A* and B arrange in a "head-to-head" manner on the same plane, and B* and A run in this manner on another plane (Figure 3b). Thus A*···B···A*···B and B*···A···B*···A form zigzag chains along the *a* axis, respectively, and further extend into a 2D structure along the *c* axis by hydrogen bonding with Im

Table 1. Selected bond length ranges [Å] for **1**, **2**, and **3**.

| Bond length | $[\{K(H_2O)\}_2\{(\mu_3\text{-}H_2O)M(H_2O)\}(\gamma\text{-}Si_2W_{20}O_{70})]^{8-}$ | | | $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$[4] |
|---|---|---|---|---|
| | **1** (M = $Mn^{II}$) | **2** (M = $Co^{II}$) | **3** (M = $Ni^{II}$) | |

molecules. There are significant contacts between oxo groups of the anions and imidazole molecules along the *b* axis, which leads to a linear chain of the anions with a straight linkage of K···K···K (see Figure 4). Imidazole and water molecules fill in the space among the anions.

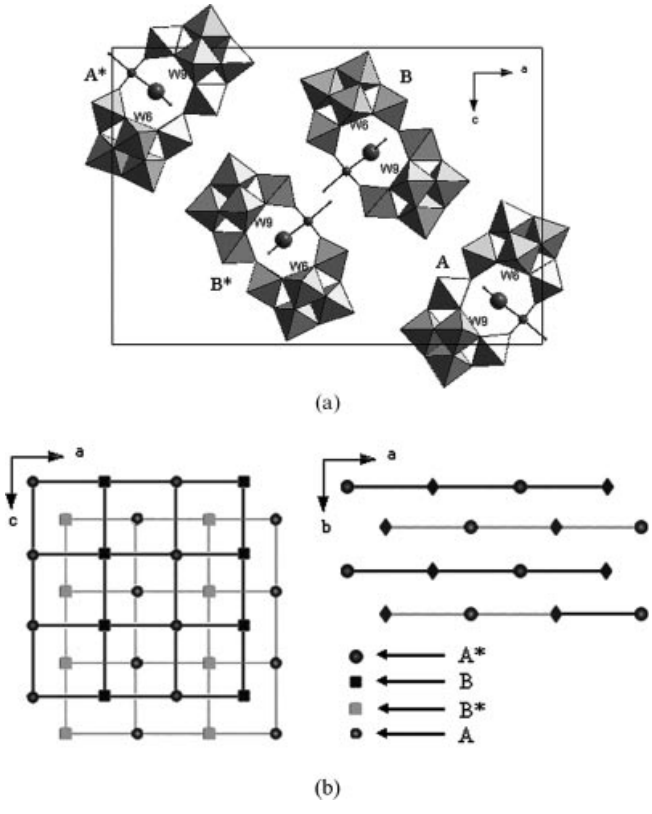

Figure 3. Schematic representation of the relative locations of the polyanions. (a) Packing diagram in **1** viewed along the *b* axis. (b) 3D supramolecular network based on the topology of anion–anion position.

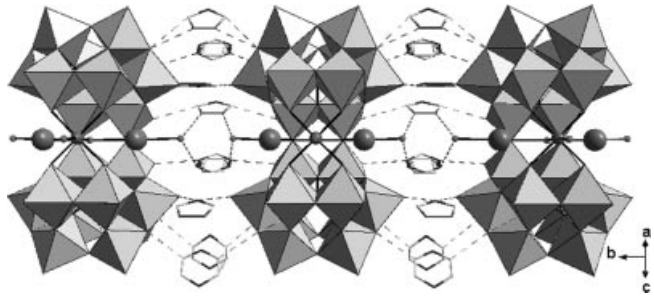

Figure 4. View of the connection between the polyanions and Im molecules through hydrogen bonding. All water molecules are omitted for clarity.

Because compounds **2** and **3** are isomorphs of **1**, structural descriptions for them are omitted. The difference between them is that the outer $H_2O$ molecule that is coordinated to the $K^+$ ion is disordered with an occupancy factor of 50% for both **2** and **3**. Additionally, there exists other disordered water and imidazole molecules in the crystal structures of these three complexes.

The assignment of the oxidation state of Mn is based on bond valence sum (BVS) calculations,[24] which gives a value of 2.064 and indicates the +2 oxidation state. The inside O atom and the outside O atom of the Mn–O bonds have much lower BVS values, 0.180 and 0.252, which suggests that they are water ligands (O1W and O2W). The BVS values of the bridge and terminal oxygen atoms show that they are not protonated. While in the acidic condition, the N atom of imidazole is easily protonated and leads to the formation of the stable salts. Thus, including $K^+$ and $M^{II}$, the anionic structure can be written as $[\{K(H_2O)\}_2\{(\mu_3\text{-}H_2O)M(H_2O)\}(Si_2W_{20}O_{70})]^{8-}$ (M = $Mn^{2+}$, $Co^{2+}$ or $Ni^{2+}$). Overall, the anions have an ideal symmetry of $C_{2v}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### IR Spectra

The infrared spectra of **1**, **2**, and **3**, measured in the range 400–1000 $cm^{-1}$, show characteristic absorptive peaks for the γ-anion at ca. 993 $cm^{-1}$ for $\nu_{as}$(W–Od), 940 $cm^{-1}$ for $\nu_{as}$(Si–Oa), 895 and 861 $cm^{-1}$ for $\nu_{as}$(W–Ob–W), 780 and 741 $cm^{-1}$ for $\nu_{as}$(W–Oc–W), which indicates the retention of the γ-tungstosilicate framework (see Figure S4).[6] In comparison with the $\nu_{as}$(W–O–W) in γ-$SiW_{10}$, the splitting of the corresponding bands in the range 700–850 $cm^{-1}$ is weakened in the title compounds and is due to the coordination of the transition metal ion, as in the case of the monosubstituted tungstosilicate. Additionally, the vibration bands in the range 1000–1200 $cm^{-1}$ are assigned to those of imidazole and around 620 $cm^{-1}$ to those of the M–O bonds.

### Thermogravimetric(TG) Analysis

The TG curve for **1** is divided into three stages. The first weight loss of 3.05% in the temperature range 45–180 °C corresponds to the release of crystal water and is in good agreement with the calculated value of 3.1%. The successive weight loss of the second step (5.68%) from 200 °C to 350 °C and the third step (7.93%) from 520 °C to 750 °C is ascribed to the release of imidazole and structural water, respectively, which is around the combined calculated value of 13.16%. No weight loss occurs above 750 °C. TG for **2** (see Figure S5) is similar to that of **1**.

### Cyclic Voltammetry (CV)

The CV behaviors of **1**, **2**, and **3** are similar (see Figure 5). Each CV curve shows two pairs of redox peaks with $E_1$ = –582 mV and $E_2$ = –685 mV for **1**, $E_1$ = –581 mV and $E_2$ = –688 mV for **2**, and $E_1$ = –570 mV and $E_2$ = –675 mV for **3**, where $E$ = ($E$pa + $E$pc)/2, in 0.5 M KAc/HAc buffer (pH 3.9). The anodic-to-cathodic peak potential difference for each pair of redox waves is ca.30 mV and the peak-to-peak distance between $E_1$ and $E_2$ is ca. 100 mV for each compound, which shows a similar electrochemical behavior to that of the parent γ-$SiW_{10}$, except that the half-wave potentials shift positively. These can be reasonably explained by the global charges of the polyanions. Both of the anions, [{$K(H_2O)$}$_2$($\mu_3$-$H_2O$)$M(H_2O)$(γ-$Si_2W_{20}O_{70}$)]$^{8-}$ and [γ-$SiW_{10}O_{36}$]$^{8-}$, are in the –8 charge state, while the anion volume of the former is double that of the latter, which leads to less electronic density on the anion global.

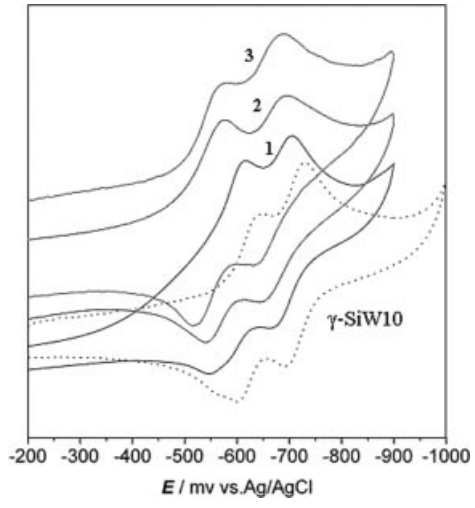

Figure 5. The cyclic voltammogram (glassy-carbon working electrode, scan-rate 50 mV $s^{-1}$, 0.5 M KAc–HAc, pH = 3.9) of compounds **1**, **2**, and **3** and precursor γ-$SiW_{10}$.

## Conclusions

In summary, three novel compounds based on γ-$SiW_{10}$ subunits have been isolated in acidic solutions. They are successful examples of the γ-$SiW_{10}$ derivative possessing an open Wells–Dawson-like sandwich structure with $K^+$ and $M^{II}$ ions symmetrically enchased in the hatch of the (γ-$SiW_{10}$)$_2$ dimer, giving the compound structural aesthetics. To check if the solid structure is stable in solution without the dissociation of the potassium cations, electrophoresis of compound **1** was carried out. The analytical result of the anodic area indicates that the potassium cations are attached to the polyoxo dimers and move towards the anode direction. This fact supports the polyanion structure formulated by [{$K(H_2O)$}$_2${($\mu_3$-$H_2O$)$M(H_2O)$}(γ-$Si_2W_{20}O_{70}$)]$^{8-}$ and that the solid structure of the dimeric anions is maintained in the solution without the dissociation of the potassium cations, under the tested pH of 3.6.

This new crystal structure suggests that the skeleton of the unstable species γ-$SiW_{10}$ could also be maintained by carefully controlling the reaction conditions. The functions of potassium and transition-metal ions in the reactions of γ-$SiW_{10}$ are not clearly understood yet and attempts to clarify them still represent a challenge. Kortz and co-workers have emphasized the crucial role of potassium ions in the synthesis medium, especially in the order of addition of the solid KCl.[13] The title compounds were isolated under similar reaction conditions to those reported by Kortz and coworkers. However, they obtained full potassium salts and we obtained imidazole–potassium mixed salts of Keggin-γ-type dimers. Besides the presence of imidazole, the difference in the order of addition of the solid KCl perhaps is the reason why mixed salts were crystallized in our case. Kortz's and our synthetic investigations both lead to the conclusion that the formation of the dimers is highly sensitive to pH and temperature variations.

The filling style in the "mouth" of the [γ-$Si_2W_{20}O_{70}$] is perhaps less random than those of the [α-$Si_2W_{18}O_{66}$] because of the feature of the opening. The external $H_2O$ ligand that is coordinated to $M^{II}$ is likely to improve the catalytic activity and would be a further derivative of the polytungstates. We will attempt to modify the framework so as to obtain more unexpected species with interesting structure and properties.

## Experimental Section

**Materials and Methods:** The precursor $K_8[\gamma\text{-}SiW_{10}O_{36}]\cdot 12H_2O$ was prepared according to the literature[28] and its purity was confirmed by infrared spectroscopy and cyclic voltammetry. All other reagents were used as purchased without further purification. Elemental analyses were carried out with a Plasma-Spec(I) ICP emission spectrometer for W, Si, and transition metal elements and with a PE-3030 atomic absorption spectrophotometer for K. To carry out the elemental analysis measurements, the samples were dissolved in water by assistance of $H_2O_2$ as these imidazole salts have poor solubility in water. Infrared spectra were recorded with an Alpha Centaurt FTIR spectrometer in the 4000–400 $cm^{-1}$ region. X-ray powder diffraction (XRPD) patterns were recorded with a Siemens D5005 diffractometer with Cu-$K_\alpha$($\lambda$ = 1.5418 Å) radiation. Thermogravimetry was carried out with a Perkin–Elmer TGA-7 instrument in flowing $N_2$ with a heating rate of 10 °C $min^{-1}$ up to 800 °C. Electrochemical data were obtained with a CHI 660 Electrochemical Workstation connected to a Digital-586 personal computer under $N_2$ gas, with the use of a conventional three-electrode system.

**Synthesis of $(HIm)_8[\{K(H_2O)\}_2\{(\mu_3\text{-}H_2O)Mn(H_2O)\}(Si_2W_{20}O_{70})]\cdot 10H_2O$(Im = imidazole) (1):** Solid $MnSO_4\cdot 2H_2O$ (0.076 g, 0.41 mmol) was added with stirring to a solution of imidazole (0.55 g, 2.3 mmol) dissolved in water (20 mL). Glacial acetic acid was then added dropwise until pH 3.6 was reached. To the resulting solution, $K_8[\gamma\text{-}SiW_{10}O_{36}]\cdot 12H_2O$ (0.226 g, 0.075 mmol) dissolved in water (2 mL) was immediately added, followed by the addition of solid KCl (2–3 g, ca. 30 mmol). Finally, the yellow solution was cooled to room temperature and filtered through a fine frit. Prism-like yellow crystals were obtained after 3 d from the filtrate. Yield: 0.142 g (65% based on $\gamma\text{-}SiW_{10}$). IR (KBr pellet): 1093, 1049, 993, 950, 894, 861, 781, 741, 621, 555 $cm^{-1}$. $C_{24}H_{35.76}K_2MnN_{16}O_{84}Si_2W_{20}$ (5758.57): calcd. W 63.22, Si 0.96, Mn 0.94, K, 1.34; found W 63.09, Si 0.92, Mn 0.96, K 1.30.

**Synthesis of $(HIm)_8[\{K(H_2O)\}_2\{(\mu_3\text{-}H_2O)Co(H_2O)\}(Si_2W_{20}O_{70})]\cdot 9H_2O$ (2):** The synthesis of **2** followed a similar procedure to that of compound **1**, except $Co(NO_3)_2\cdot 6H_2O$ (0.058 g, 0.20 mmol) was used instead of $MnSO_4\cdot 2H_2O$. The reaction solution was heated to 45 °C with stirring for 15 min and filtered for lustration. Prism-like rosy crystals were obtained after ca.6 d from the filtrate. Yield: 0.113 g (52% based on $\gamma\text{-}SiW_{10}$). IR (KBr pellet): 1098, 1051, 998, 952, 897, 863, 778, 743, 622, 549 $cm^{-1}$. $C_{24}H_{31.5}K_2CoN_{16}O_{83}Si_2W_{20}$ (5742.26): calcd. W 63.92, Si 0.97, Co 1.02, K 1.36; found W 63.73, Si 0.94, Co 1.09, K 1.32.

**Synthesis of $(HIm)_8[\{K(H_2O)\}_2\{(\mu_3\text{-}H_2O)Ni(H_2O)\}(Si_2W_{20}O_{70})]\cdot 9H_2O$ (3):** The synthesis of **3** followed a similar procedure to that of compound **2**, except $NiSO_4\cdot 6H_2O$ (0.105 g, 0.40 mmol) was used instead of $Co(NO_3)_2\cdot 6H_2O$. Prism-like slight green crystals were obtained after six months. Yield: 0.022 g (10% based on $\gamma\text{-}SiW_{10}$). IR (KBr pellet): 1091, 1049, 995, 951, 895, 861, 781, 739, 626, 554 $cm^{-1}$. $C_{24}H_{26}K_2NiN_{16}O_{83}Si_2W_{20}$ (5736.70): calcd. W 64.3, Si 0.97, Ni 1.03, K 1.36; found W 64.05, Si 0.92, Ni 0.98, K 1.29.

**X-ray Crystallography:** Single-crystals of **1** (0.37 × 0.11 × 0.10 mm), **2** (0.24 × 0.07 × 0.05 mm), and **3** (0.35 × 0.12 × 0.05 mm) were taken directly from the mother liquor and immediately cooled to 193(2) K on a Bruker SMART CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71703 Å). Semi-empirical absorption correction based on symmetry equivalent reflections was applied. A total of 53450 reflections for **1** were collected, of which 9634 were unique ($R_{(int)}$ = 0.0531), a total of 52611 reflections for **2** were collected, of which 9454 reflections were unique ($R_{(int)}$ = 0.0516), and a total of 58285 reflections for **3** were collected, of which 10568 reflections were unique ($R_{(int)}$ = 0.1003) ($1.52 < \theta < 25.01°$). The structures were solved by direct methods and difference Fourier techniques and refined by the full-matrix least-squares method on the basis of $F^2$. Structure solution, refinement, and generation of publication materials were performed with the use of the SHELXTL crystallographic software package.[29] Some C and N atoms and some water molecules were not anisotropically refined to solve disorder. The hydrogen atoms of imidazole and water were geometrically placed and refined with the use of a riding model. However, some hydrogen atoms have not been included in the final refinement because of the presence of some disordered imidazole and water. Crystallographic data are summarized in Table 4. Atomic coordinates and isotropic displacement parameters for the anions of **1**, **2**, and **3** are listed in Tables S2, S3, and S4. CCDC-294280 for **1**, -294279 for **2**, and -604702 for **3** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Syntheses, Characterization, and X-ray Crystal Structures of Mono-Lacunary Dawson Polyoxometalate-Based Organosilyl Complexes

Chika Nozaki Kato,[a] Yuhki Kasahara,[a] Kunihiko Hayashi,[a] Asuka Yamaguchi,[a] Takeshi Hasegawa,[a] and Kenji Nomiya*[a]

**Keywords:** Silicon / Polyoxometalates / X-ray diffraction / Tungsten

The syntheses and crystal structures of a series of organosilyl polyoxotungstate derivatives with the Dawson monovacant phosphotungstate $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ are described. The polyoxometalates $(Me_2NH_2)_5H[\alpha_2\text{-}P_2W_{17}O_{61}\{O[Si(CH_2)_3SH]_2\}]\cdot 6H_2O$ ($Me_2NH_2$-**1**), $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O[Si(CH_2)_3SCN]_2\}]\cdot 3H_2O$ ($Me_2NH_2$-**2**), and $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiPh)_2\}]\cdot 4H_2O$ ($Me_2NH_2$-**3**) were obtained as analytically pure, homogeneous yellow crystals by the reaction of monolacunary Dawson polyoxotungstate with $HS(CH_2)_3Si(OMe)_3$, $NCS(CH_2)_3Si(OEt)_3$, and $PhSiCl_3$, respectively, in an HCl/water/acetonitrile mixed solution or a water/acetonitrile mixed solution, followed by crystallization from water in the dark. Single-crystal X-ray structure analyses revealed that the four-coordinate –Si–O–Si– bonding of the organosilyl groups $\{O[Si(CH_2)_3SH]_2\}$, $\{O[Si(CH_2)_3SCN]_2\}$, and $\{O(SiPh)_2\}$ is attained through four oxygen atoms in the mono-lacunary site of the polyanion, resulting in an overall $C_1$ symmetry for $Me_2NH_2$-**1** and $Me_2NH_2$-**2** and $C_s$ symmetry for $Me_2NH_2$-**3**. In the molecular structures of $Me_2NH_2$-**1** and $Me_2NH_2$-**2**, a unique configuration of the organosilyl groups is observed in the solid state, i.e. the equatorial and axial bonding of each of the two $HS(CH_2)Si$ moieties in the $\{O[Si(CH_2)_3SH]_2\}$ group for $Me_2NH_2$-**1** and the two $NCS(CH_2)_3Si$ moieties oriented in a *syn* fashion in the $\{O[Si(CH_2)_3SCN]_2\}$ group for $Me_2NH_2$-**2**. The characterization of $Me_2NH_2$-(**1**–**3**) was accomplished by elemental analysis, TG/DTA, and FT-IR, solution ($^1H$, $^{13}C$, and $^{31}P$) NMR, and solid-state $^{13}C$ NMR spectroscopy.

## Introduction

Polyoxometalates (POMs) have attracted considerable attention because of their extreme versatility and unique range of properties, including catalytic and biological activities and/or photo- and electrochromism.[1] The introduction of organic groups into POMs is an efficient technology to significantly increase the number of organic–inorganic hybrid compounds and thus to improve their properties. For example, organostannyl derivatives such as $[TW_{11}O_{39}(SnCH_2CH_2X)]^{n-}$ [T (isomer) = Si (α), Ge (α), Ga (a mixture of α and β); X = COOH, $COOCH_3$, $CONH_2$, CN; *n* = 5,6],[2] $[\alpha\text{-}XW_{11}O_{39}(SnR)]^{n-}$ [X = P, As, Si; R = Me, *n*Bu, Ph, $CH_2C_6H_5$, $(CH_2)_3Br$, $(CH_2)_4Cl$, $(CH_2)_{11}CH_3$, $(CH_2)_6Br$, $C_{27}H_{45}$, CN; *n* = 5,6],[3] $[\alpha_2\text{-}X_2W_{17}O_{61}(SnR)]^{7-}$ [X = P, As; R = Me, *n*Bu, Ph, $(CH_2)_{11}CH_3$],[3] $[\alpha_2\text{-}P_2W_{17}O_{61}(SnCH_2R)]^{7-}$ (R = $CH_2COOH$, $CH_2COOEt$, $CH{=}CH_2$, $CH_2CHO$),[4] $[\alpha_1\text{-}P_2W_{17}O_{61}(SnCH_2R)]^{7-}$ (R = $CH_2COOH$, $CH_2COOEt$, $CH_2COOMenthyl$),[4] $[(\beta\text{-}APW_9O_{34})_2(RSnOH)_3]^{12-}$ (R = Ph, Bu),[5] $[\alpha\text{-}P_2W_{15}O_{59}(RSn)_3]^{9-}$ (R = Ph, Bu),[5] $[SiW_9O_{37}(RSn)_3]^{7-}$ (R, isomer: Ph, α; *n*Bu, α; Ph, β; *n*Bu, β),[6] and $[(SiW_9O_{34})_2(RSnOH)_3]^{14-}$ (R, isomer: Ph, α; *n*Bu, α; Ph, β; *n*Bu, β),[6] and $[(\gamma\text{-}SiW_{10}O_{36})_2(PhSnOH)_2]^{10-}$;[7] organophosphonyl derivatives such as $[\alpha\text{-}A\text{-}PW_9O_{34}(RPO)_2]^{5-}$ (R = Et, *n*Bu, *t*Bu, allyl, Ph),[8] $[\alpha\text{-}T^{n+}W_{11}O_{39}(PhPO)_2]^{(8-n)-}$ (T = $P^{5+}$, $Si^{4+}$),[9] $[\alpha\text{-}PW_{11}O_{39}(PhPO)][PhPO(OH)]^{4-}$,[9] $[\gamma\text{-}SiW_{10}O_{36}(RPO)_2]^{4-}$ [R = H, Et, *n*Bu, *t*Bu, $C_2H_4COOH$, Ph],[10] and $[\gamma\text{-}H_2\{(SiW_{10}O_{36})[O{=}PCH_2(C_6H_4)_nCH_2P{=}O]\}_2]^{6-}$;[11] organogermanyl derivatives such as $[TW_{11}O_{39}\{GeCH_2CH_2X\}]^{n-}$ [T (isomer) = Si (α), Ge (α), Ga (a mixture of α and β); X = COOH, $COOCH_3$, $CONH_2$, CN; *n* = 5, 6];[2] and organosilyl derivatives such as $[\alpha\text{-}SiW_{11}O_{40}(SiR)_2]^{4-}$ [R = $C_2H_5$, $CH{=}CH_2$, $C_{10}H_{21}$, Ph, $NC(CH_2)_3$, $C_3H_5$],[12] $[\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiR)_2\}]^{6-}$ {R = $C_6H_5$, 4-$[(C_2H_5O)_2P(=O)CH_2]$-$C_6H_4$, $C_3H_6SH$},[13,14] $[\gamma\text{-}PW_{10}O_{36}(t\text{BuSiOH})_2]^{3-}$,[15] $[\gamma\text{-}PW_{10}O_{36}(t\text{BuSiO})_2(SiMe_2)]^{3-}$,[15] $[\gamma\text{-}SiW_{10}O_{36}(RSiO)_4]^{4-}$ [R = Ph, $CH_2{=}C(CH_3)CO_2(CH_2)_3$],[16] $[\alpha\text{-}A\text{-}PW_9O_{34}(t\text{BuSiO})_3(SiR)]^{3-}$ [R = H, $CH_3$, Et, $CH{=}CH_2$, $CH_2\text{-}CH{=}CH_2$, $(CH_2)_4CH{=}CH_2$, $CH_2CH_2CH_2Cl$],[17,18] $[\alpha\text{-}A\text{-}TW_9O_{34}(R_2Si)_3]^{n-}$ (T = Si, P; R = Me, Ph; *n* = 3,4),[18] $[\alpha\text{-}A\text{-}PW_9O_{34}(t\text{BuSiOH})_3]^{3-}$,[18] $[\alpha\text{-}B\text{-}AsW_9O_{33}(t\text{BuSiOH})_3]^{3-}$,[18] $[\alpha\text{-}B\text{-}AsW_9O_{33}(t\text{BuSiO})_3(RSi)]^{3-}$,[18] $[\alpha\text{-}A\text{-}TW_9O_{34}(RSiO)_3(RSi)]^{n-}$ (T = Si, P; R = H, Me, $C_2H_3$, Et, *n*Bu; *n* = 3,4),[19,20] and $[\gamma\text{-}SiW_{10}O_{36}\{O(SiC_3H_6SH)_2\}]^{4-}$[21] have been reported. In particular, $[\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiC_3H_6SH)_2\}]^{6-}$

and $[\gamma\text{-}SiW_{10}O_{36}\{O(SiC_3H_6SH)_2\}]^{4-}$ are intriguing examples of the use of organic moieties having an –SH group grafted to the lacunary sites of $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ and $[\gamma\text{-}SiW_{10}O_{36}]^{8-}$ to derive new nanoscale hybrid systems in which covalent linkages between the polyoxometalate species and chlorobenzyl-functionalized polymer nanoparticles or gold nanoparticles are formed through the thiol groups. Although various types of complexes with organic groups have been prepared, the molecular structures of only a few complexes have been determined by X-ray crystallography. These include $[(\beta\text{-A-}PW_9O_{34})_2(PhSnOH)_3]^{12-}$,[5] $[\alpha\text{-}P_2W_{15}O_{59}(PhSn)_3]^{9-}$,[5] $[\beta\text{-}SiW_9O_{37}(PhSn)_3]^{7-}$,[6] $[(\alpha\text{-}SiW_9O_{34})_2(BuSnOH)_3]^{14-}$,[6] $[\alpha\text{-}PW_{11}O_{39}(PhPO)_2]^{3-}$,[9] $[\gamma\text{-}PW_{10}O_{36}(t\text{BuSiOH})_2]^{3-}$,[15] $[\alpha\text{-A-}PW_9O_{34}(t\text{BuSiO})_3(SiCH_2\text{-}CH{=}CH_2)]^{3-}$,[17] and $[\alpha\text{-A-}PW_9O_{34}(RSiO)_3(RSi)]^{3-}$ (R = $C_2H_3$, $CH_3$, $C_2H_5$).[18,20] In particular, X-ray crystal structure analyses of Dawson POM-based organic–inorganic hybrid compounds are crucial for polyoxoanion crystallography because of the difficulty in crystallizing them.

In this study, we report a series of Dawson-type POM-based organosilyl complexes containing $\{O[Si(CH_2)_3SH]_2\}$, $\{O[Si(CH_2)_3SCN]_2\}$, and $\{O(SiPh)_2\}$ groups, and the X-ray crystal structure analyses of $(Me_2NH_2)_5H[\alpha_2\text{-}P_2W_{17}O_{61}\{O[Si(CH_2)_3SH]_2\}]\cdot 6H_2O$ ($Me_2NH_2$-**1**), $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O[Si(CH_2)_3SCN]_2\}]\cdot 3H_2O$ ($Me_2NH_2$-**2**), and $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiPh)_2\}]\cdot 4H_2O$ ($Me_2NH_2$-**3**). We describe their syntheses, characterization, and the molecular structures of compounds $Me_2NH_2$-(**1**–**3**) in complete detail.

## Results and Discussion

### Syntheses, Characterization, and Molecular Structures of a Series of the Dawson-Type POM-Based Organosilyl Compounds $Me_2NH_2$-(1–3)

The three compounds $Me_2NH_2$-(**1**–**3**) containing organosilyl groups were formed by direct reaction of the organosilyl precursors [$RSiX_3$; R = $HS(CH_2)_3$, $NCS(CH_2)_3$, and Ph; X = OMe, OEt, or Cl] with the mono-lacunary Dawson POM $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ in an HCl/water/acetonitrile mixed solution or a water/acetonitrile mixed solution at room temperature in air, followed by crystallization from water in the dark. The formation of $Me_2NH_2$-(**1**–**3**) is given by the ionic balance shown in Equations (1), (2), and (3) in which the hydrolysis of Si–X bonds occurs upon addition of acid; the electrophilic organosilyl moieties then attack the lacunary surface sites of polyoxometalates.[13]

$$RSi(X)_3 + 3\ H_2O \rightarrow RSi(OH)_3 + 3\ XH \quad [R = HS(CH_2)_3,\ NCS(CH_2)_3;\ X = OMe,\ OEt] \quad (1)$$

$$[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-} + 2\ RSi(OH)_3 + 4\ H^+ \rightarrow [\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiR)_2\}]^{6-} + 5\ H_2O \quad (2)$$

$$[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-} + 2\ PhSiCl_3 + H_2O \rightarrow [\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiPh)_2\}]^{6-} + 2\ H^+ + 6\ Cl^- \quad (3)$$

The crystal structures of $Me_2NH_2$-**1** (Figure 1), $Me_2NH_2$-**2** (Figure 2), and $Me_2NH_2$-**3** (Figure 3) are composed of the mono-lacunary Dawson POM unit "$\alpha_2\text{-}P_2W_{17}O_{61}$" and the $\{O[Si(CH_2)_3SH]_2\}$, $\{O[Si(CH_2)_3SCN]_2\}$, and $\{O(SiPh)_2\}$ groups, respectively. Each silyl group is linked to two tungsten atoms located in two different positions of the mono-lacunary site through the bonding of four oxygen atoms O(2), O(3), O(6), and O(7) for $Me_2NH_2$-**1** and $Me_2NH_2$-**2**, which have $C_1$ symmetry for the polyanions **1** and **2**, and O(2), O(3), O(2A), and O(3A) for $Me_2NH_2$-**3**, which has $C_s$ symmetry for polyanion **3**. $Me_2NH_2$-**1** and $Me_2NH_2$-**2** were found as a set of enantiomeric pairs in the unit cell, as shown in Figures 1 and 2, respectively. The lengths of the Si–O bonds coordi-

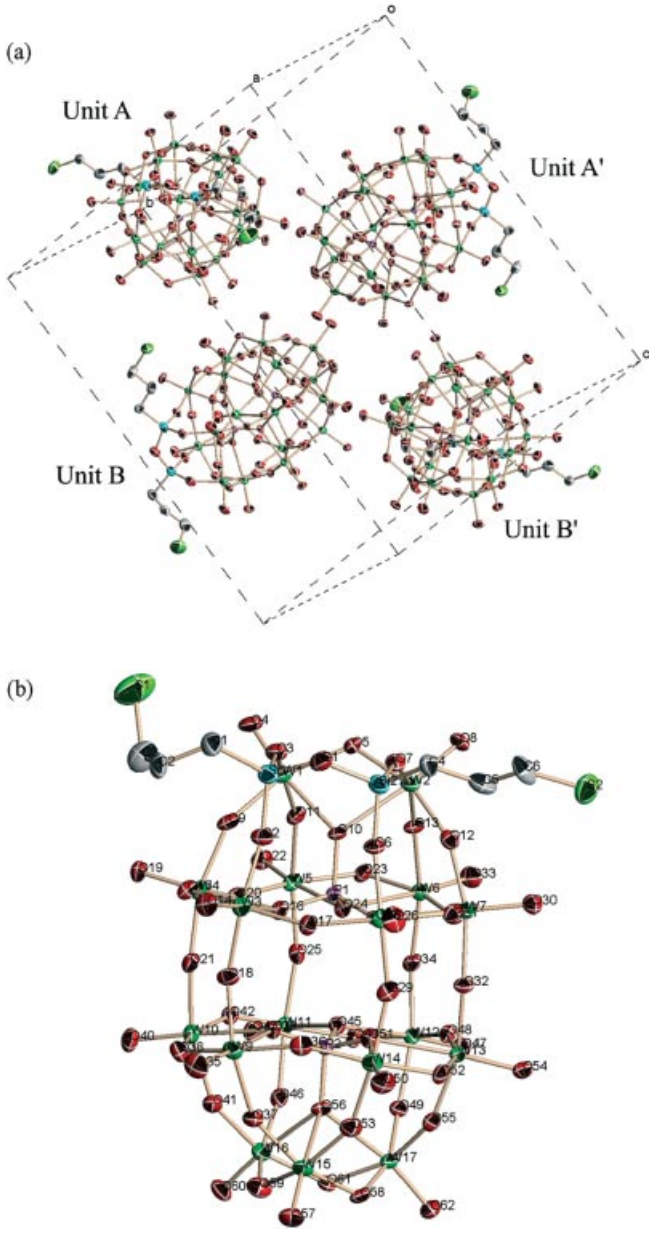

Figure 1. (a) The solid-state packing of $Me_2NH_2$-**1** ($Z$ = 4) and (b) the molecular structure of $Me_2NH_2$-**1** with 50% probability ellipsoids. In (a), units (A, A′) and (B, B′) represent different sets of enantiomeric pairs. The molecular structure of unit A is depicted in (b).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nated to the four oxygen atoms in the lacunary site are in the range 1.611(12)–1.650(13) Å (average 1.64 Å) for $Me_2NH_2$-**1**, 1.608(12)–1.647(13) Å (1.63 Å) for $Me_2NH_2$-**2**, and 1.613(8)–1.651(8) Å (1.63 Å) for $Me_2NH_2$-**3** (see Tables 1, 2, and 3, respectively, and Tables S1–S3 in the Supporting Information). These values are similar to those of $[\gamma\text{-}PW_{10}O_{36}(t\text{BuSiOH})_2]^{3-}$ (1.62–1.70 Å)[15] and $[\alpha\text{-A-}PW_9O_{34}(t\text{BuSiO})_3(SiCH_2\text{-}CH{=}CH_2)]^{3-}$ (1.59–1.65 Å),[17] which have a similar tetrahedral environment of the silicon atom. On the other hand, the W–O lengths in the vacant site are in the range 1.873–1.919 Å [W(1)–O(3), W(2)–O(7), W(3)–O(2), and W(8)–O(6)] for $Me_2NH_2$-**1**, 1.889–1.912 Å [W(1)–O(3), W(2)–O(7), W(3)–O(2), and W(8)–O(6)] for $Me_2NH_2$-**2**, and 1.898–1.914 Å [W(1)–O(3) and W(2)–O(2)] for $Me_2NH_2$-**3**; these bonds are longer than those to the terminal oxygen in $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ (ca. 1.7 Å).[22] Thus, the W–O lengths of the terminal oxygen in the vacant site of $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ are stretched by the binding of the organosilyl groups. In contrast, the W–O lengths in the $W_3$ cap and the two $W_6$ belts, i.e. W–$O_t$ ($O_t$: terminal oxygen), W–$O_e$ ($O_e$: edge-sharing oxygen), W–$O_c$ (W belt) ($O_c$: corner-sharing oxygen), and W–$O_a$ ($O_a$: oxygen coordinated to the P atom) are in the normal range.[1b,22] The Si–O–Si bond angles for $Me_2NH_2$-(**1**–**3**) are 126.3(9)°, 124.7(8)°, and 127.4(7)°, respectively, which means they are much smaller than that of $[\alpha\text{-A-}PW_9O_{34}(t\text{BuSiO})_3(SiCH_2\text{–}CH{=}CH_2)]^{3-}$ (173.7°).[17]

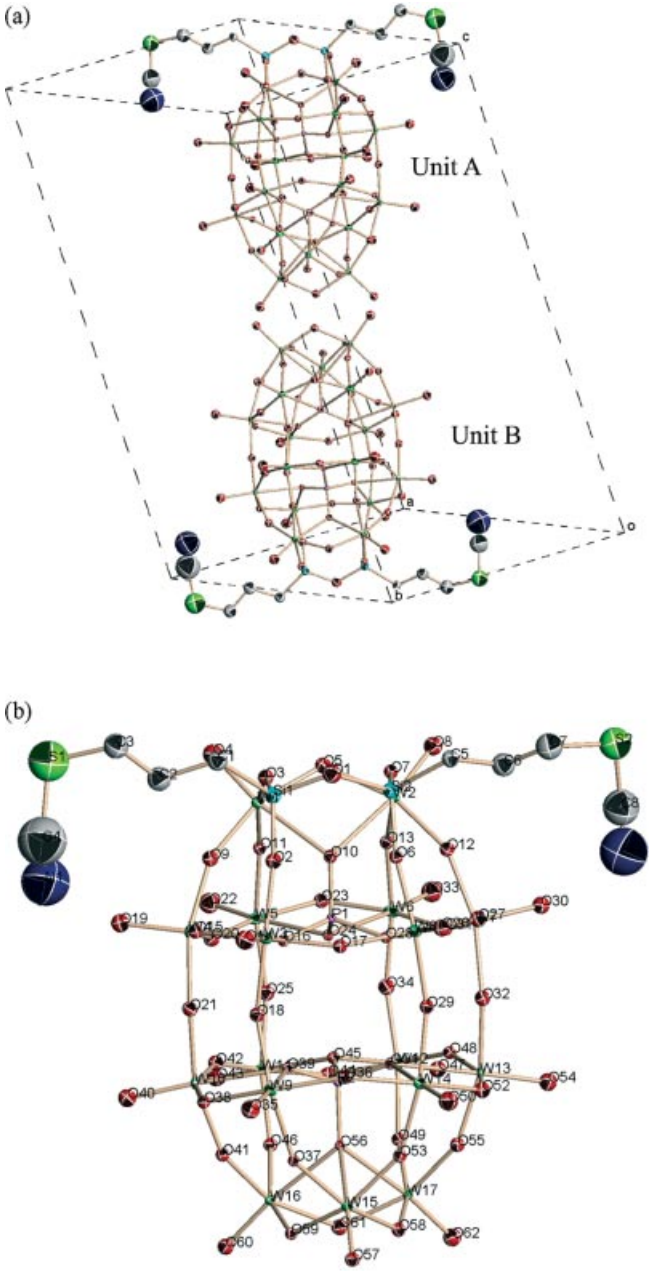

Figure 2. (a) The solid-state packing of $Me_2NH_2$-**2** ($Z$ = 2) and (b) the molecular structure of $Me_2NH_2$-**2** with 50% probability ellipsoids. In (a), (A, B) represents an enantiomeric pair. The molecular structure of unit A is depicted in (b).

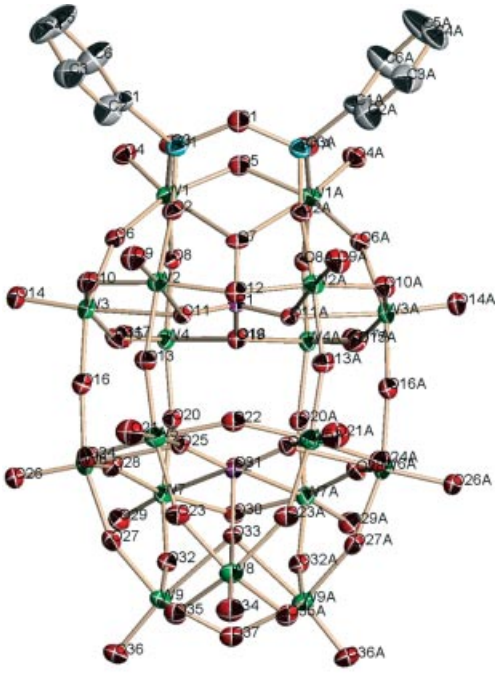

Figure 3. Molecular structure of $Me_2NH_2$-**3** with 50% probability ellipsoids.

With regard to the $\{O[Si(CH_2)_3SH]_2\}$ group of $Me_2NH_2$-**1**, it was noted that one of the two $HS(CH_2)_3Si$ moieties in this group is oriented in the equatorial direction while the other is oriented in the axial bonding direction. This unique configuration was found three times by X-ray crystallography. The Si–C bond lengths are in the range 1.86–1.87 Å and are slightly shorter than those of $[\gamma\text{-}PW_{10}O_{36}(t\text{Bu-SiOH})_2]^{3-}$ (1.94–1.97 Å).[15] The bond angles of the left $HS(CH_2)_3Si$ moiety [Si(1)–C(1)–C(2), C(1)–C(2)–C(3), and C(2)–C(3)–S(1)] are larger than those of the right moiety [Si(2)–C(4)–C(5), C(4)–C(5)–C(6), C(5)–C(6)–S(2)], as shown in Table 1. In the case of the $\{O[Si(CH_2)_3SCN]_2\}$ group of $Me_2NH_2$-**2**, the two $NCS(CH_2)_3Si$ moieties are oriented in a *syn* fashion. This configuration was also found twice by X-ray crystallography. The Si–C bond lengths are in the range 1.84–1.89 Å and are similar to those of $Me_2NH_2$-**1**. The S(1)–C(4) distance [1.97(6) Å] is somewhat longer than that of S(2)–C(8) [1.71(4) Å]. The bond angles

The bond valence sums (BVS) for $Me_2NH_2$-(**1**–**3**),[23] calculated on the basis of the observed bond lengths, are in the range 5.950–6.232 (average 6.12), 6.017–6.359 (6.18), and 6.105–6.289 (6.16) for the 17 W atoms, respectively, those of the two P atoms are in the range 4.833–4.877 (average 4.86), 4.908–5.127 (5.02), and 4.901–4.933 (4.92), respectively, and those of the 62 O atoms are in the range 1.618–2.166 (average 1.90), 1.635–2.172 (1.96), and 1.717–2.174 (1.95), respectively. These values correspond reasonably well to the formal valences $W^{6+}$, $P^{5+}$, and $O^{2-}$, respectively (see Tables S4–S6 in the Supporting Information).

The crystal structures of $Me_2NH_2$-(**1**–**3**) are consistent with the elemental analyses, TG/DTA data, and FTIR, solution NMR ($^1H$, $^{13}C$, and $^{31}P$), and solid-state $^{13}C$ NMR spectra. The elemental analyses had to be performed for compounds $Me_2NH_2$-(**1**–**3**) after drying them at room temperature at $10^{-3}$–$10^{-4}$ Torr overnight before the results were consistent with the compositions $(Me_2NH_2)_5H[\alpha_2$-$P_2W_{17}O_{61}\{O[Si(CH_2)_3SH]_2\}]$, $(Me_2NH_2)_6[\alpha_2$-$P_2W_{17}O_{61}$-$\{O[Si(CH_2)_3SCN]_2\}]$, and $(Me_2NH_2)_6[\alpha_2$-$P_2W_{17}O_{61}$-$\{O(SiPh)_2\}]$, respectively. The TG/DTA measurements performed under atmospheric conditions showed a weight loss of 2.38%, 1.27%, and 1.62%, with an endothermic point at 67, 37, and 86 °C, respectively; these values correspond to the presence of 6, 3, and 4 water molecules, respectively, due to both the intrinsic water of hydration and the water adsorbed from the atmosphere. Thus, the number of hydrated water molecules in compounds $Me_2NH_2$-(**1**–**3**) is 6, 3, and 4, respectively.

The FTIR spectra of compounds $Me_2NH_2$-(**1**–**3**) measured as a KBr disk are shown in Figure 4. The spectral patterns of these compounds are similar to those of $[\alpha_2$-$P_2W_{17}O_{61}]^{10-}$ (1086, 1054, 1016, 940, 885, 811, 741, 601, 527, and 467 $cm^{-1}$) rather than those of $[\alpha$-$P_2W_{18}O_{62}]^{6-}$ (1088, 1040, 956, 925, and 713 $cm^{-1}$). The additional bands observed at 2566 and 2154 $cm^{-1}$ in the case of compounds

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Me_2NH_2$-**1** and $Me_2NH_2$-**2** were assigned to the SH and SCN moieties, respectively.[24]

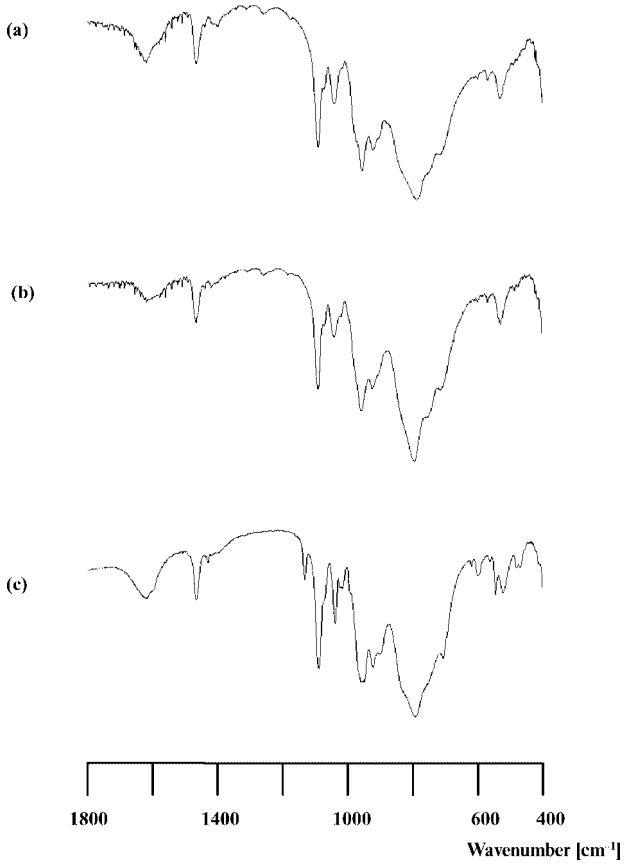

Figure 4. FTIR spectra, measured as KBr disks, in the polyoxoanion region (1800–400 $cm^{-1}$) of (a) $Me_2NH_2$-**1**, (b) $Me_2NH_2$-**2**, and (c) $Me_2NH_2$-**3**.

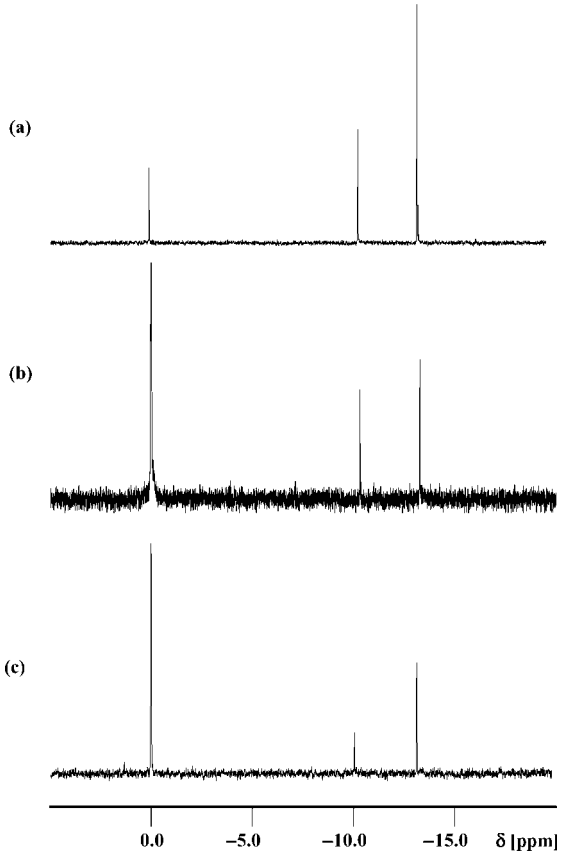

Figure 5. $^{31}P$ NMR spectra in $D_2O$ of (a) $Me_2NH_2$-**1**, (b) $Me_2NH_2$-**2**, and (c) $Me_2NH_2$-**3**.

The $^{31}P$ NMR spectra of compounds $Me_2NH_2$-(**1**–**3**) in $D_2O$ at about 25 °C show a clear two-line spectrum at $\delta$ = –10.52 and –13.50 ppm, $\delta$ = –10.33 and –13.28 ppm, and $\delta$ = –10.21 and –13.29 ppm, respectively, thereby confirming their purity and homogeneity (see Figure 5). The downfield resonance was assigned to the phosphorus closest to the organosilyl sites and the upfield resonance to the phosphorus closer to the $W_3$ cap.

The $^1H$ NMR spectra of $Me_2NH_2$-**1** and $Me_2NH_2$-**2** in $D_2O$ at about 25 °C show signals at $\delta$ = 0.93–1.03, 1.95–1.96, and 2.72–2.77 ppm and $\delta$ = 1.04–1.10, 2.18–2.21, and 3.28–3.31 ppm, respectively, arising from the two $–(CH_2)_3–$ groups in the $\{O[Si(CH_2)_3SH]_2\}$ and $\{O[Si(CH_2)_3SCN]_2\}$ groups, respectively (Table 4). For $Me_2NH_2$-**3**, $^1H$ signals assigned to the two phenyl groups in the $\{O(SiPh)_2\}$ moiety are observed at $\delta$ = 7.53–7.94 ppm. The $^{13}C$ NMR spectra of $Me_2NH_2$-**1** and $Me_2NH_2$-**2** in $D_2O$ at about 25 °C show signals at $\delta$ = 13.2, 29.1, and 29.9 ppm and $\delta$ = 12.8, 26.1, and 38.4 ppm, respectively, which can also be assigned to the two $–(CH_2)_3–$ groups in the $\{O[Si(CH_2)_3SH]_2\}$ and $\{O[Si(CH_2)_3SCN]_2\}$ groups, respectively (Table 4). The $^{13}C$ NMR spectrum of $Me_2NH_2$-**2** also shows a signal at $\delta$ = 117.9 ppm due to the SCN group. For $Me_2NH_2$-**3**, $^{13}C$ signals due to the two phenyl groups are observed at $\delta$ = 131.1–137.3 ppm. In aqueous solution, the two $HS(CH_2)_3$-Si moieties in the $\{O[Si(CH_2)_3SH]_2\}$ group and the two $NCS(CH_2)_3Si$ moieties in the $\{O[Si(CH_2)_3SCN]_2\}$ group cannot be distinguished by $^1H$ and $^{13}C$ NMR spectroscopy.

Table 4. Solution $^1H$ and $^{13}C$ NMR spectroscopic data for compounds $Me_2NH_2$-(**1**–**3**).

| | $^1H$ [$\delta$, ppm] | $^{13}C$ [$\delta$, ppm] |
|---|---|---|
| $Me_2NH_2$-**1** | 0.93–1.03 (H1) | 13.2 (C1) |
| | 1.95–1.96 (H2) | 29.1 (C3) |
| | 2.72–2.77 (H3) | 29.9 (C2) |
| | 2.80 ($Me_2NH_2$) | 37.6 ($Me_2NH_2$) |
| $Me_2NH_2$-**2** | 1.04–1.10 (H1) | 12.8 (C1) |
| | 2.18–2.21(H2) | 26.1 (C2) |
| | 3.28–3.31 (H3) | 38.4 (C3) |
| | 2.81 ($Me_2NH_2$) | 37.4 ($Me_2NH_2$) |
| | | 117.9 (S*C*N) |
| $Me_2NH_2$-**3** | 7.53–7.94 (Ph) | 131.1–137.3 (Ph) |
| | 2.76 ($Me_2NH_2$) | 37.6 ($Me_2NH_2$) |

In order to determine the configuration of the two $HS(CH_2)_3Si$ moieties in the $\{O[Si(CH_2)_3SH]_2\}$ group and the two $NCS(CH_2)_3Si$ moieties in the $\{O[Si(CH_2)_3SCN]_2\}$ group in the bulk samples, we measured the solid-state $^{13}C$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

NMR spectra for $Me_2NH_2$-**1** and $Me_2NH_2$-**2** (see Figure 6). In the spectrum of $Me_2NH_2$-**1**, C1 appears as two signals at $\delta$ = 12.7 ppm and 14.3 ppm; this is because of the different configuration, i.e. the equatorial and axial bonding of each of the two $HS(CH_2)_3Si$ moieties in the $\{O[Si(CH_2)_3SH]_2\}$ group. The C2 and C3 signals could not be identified owing to broadening of the signals. For $Me_2NH_2$-**2**, a broadening of the C1 signal is observed because of the somewhat different configurations of the two $NCS(CH_2)_3Si$ moieties, which are in a *syn* fashion in the $\{O[Si(CH_2)_3SCN]_2\}$ group (Scheme 1). The C3 signal could not be distinguished because of overlap with the $Me_2NH_2$ signal. These results are consistent with the X-ray structures and suggest that the configuration of the organosilyl groups of $Me_2NH_2$-**1** and $Me_2NH_2$-**2** observed by X-ray crystallography represents the solid structure of the bulk samples; these structures are not maintained in aqueous solution because of the mobility and/or flexibility of organosilyl groups that have straight-chain carbon structures.

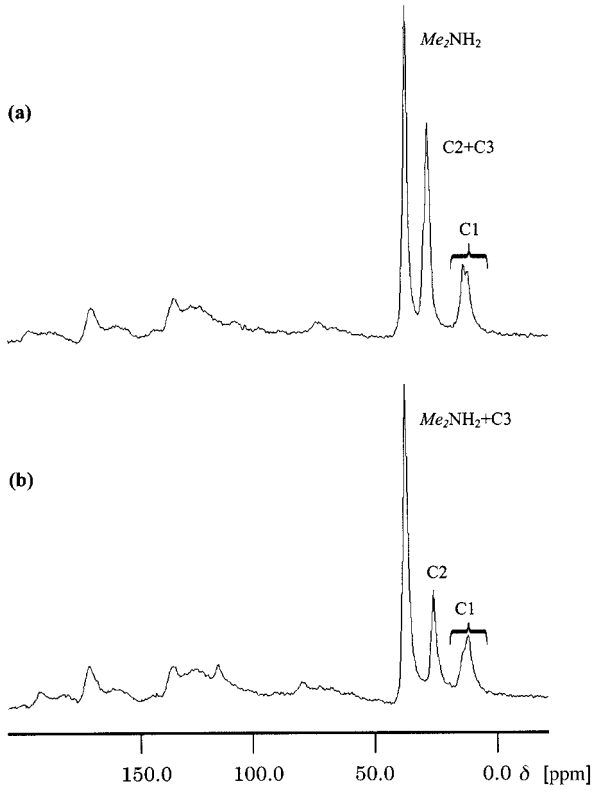

Figure 6. Solid-state $^{13}C$ NMR spectra of (a) $Me_2NH_2$-**1** and (b) $Me_2NH_2$-**2**.

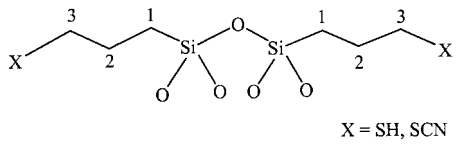

Scheme 1. Drawings of the $\{O[Si(CH_2)_3SH]_2\}$ and $\{O[Si(CH_2)_3SCN]_2\}$ groups.

## Conclusions

A series of organosilyl complexes with the Dawson mono-lacunary phosphotungstate $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ is presented. We have successfully obtained single crystals of the water-soluble dimethylammonium salts $(Me_2NH_2)_5H[\alpha_2\text{-}P_2W_{17}O_{61}\{O[Si(CH_2)_3SH]_2\}]\cdot 6H_2O$, $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O[Si(CH_2)_3SCN]_2\}]\cdot 3H_2O$, and $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiPh)_2\}]\cdot 4H_2O$ by treating the organosilyl precursors $HS(CH_2)_3Si(OMe)_3$, $NCS(CH_2)_3Si(OEt)_3$, and $PhSiCl_3$, respectively, with the mono-lacunary polyoxoanion. The characterization of compounds $Me_2NH_2$-(**1**–**3**) has been accomplished by X-ray structure analyses, elemental analysis, TG/DTA, and FTIR and solution ($^1H$, $^{13}C$, and $^{31}P$) and solid-state $^{13}C$ NMR spectroscopy. The crystal structures of $Me_2NH_2$-(**1**–**3**) reveal that each silyl group is linked to two tungsten atoms that are located in two different positions of the mono-lacunary site by the bonding of four oxygen atoms for $Me_2NH_2$-**1** and $Me_2NH_2$-**2** with $C_1$ symmetry and $Me_2NH_2$-**3** with the $C_s$ symmetry. The organosilyl groups with straight-chain carbon structures bound to the vacant site of $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$ have unique configurations, i.e. equatorial and axial bonding for each of the two $HS(CH_2)_3Si$ moieties in the $\{O[Si(CH_2)_3SH]_2\}$ group of $Me_2NH_2$-**1** and the two $NCS(CH_2)_3Si$ moieties oriented in a *syn* fashion in the $\{O[Si(CH_2)_3SCN]_2\}$ group of $Me_2NH_2$-**2**. Although these unique configurations are not maintained in aqueous solution, the crystal structures of these compounds represent the solid structures of the bulk samples. To the best of our knowledge, the X-ray crystal structures of compounds $Me_2NH_2$-(**1**–**3**) are the first examples of the molecular structures of Dawson-type polyoxometalate-based organosilyl complexes. Preliminary experiments show that it is possible to graft these polyoxometalates onto polymers.

## Experimental Section

**Materials:** $K_{10}[\alpha_2\text{-}P_2W_{17}O_{61}]\cdot 19H_2O$ was prepared as described in the literature.[25] The number of solvated water molecules was determined by TG/DTA analysis. All reagents and solvents (acetonitrile, ethanol, methanol, and diethyl ether) were obtained from commercial sources and used as received. $HS(CH_2)_3Si(OMe)_3$, $NCS(CH_2)_3Si(OEt)_3$, and $PhSiCl_3$ were obtained from Azmax.

**Instrumentation/Analytical Procedures:** Elemental analyses were carried out with a Perkin–Elmer 2400 CHNS Elemental Analyzer II (Kanagawa University) and Mikroanalytisches Labor Pascher (Remagen, Germany). The samples were dried at room temperature at $10^{-3}$–$10^{-4}$ Torr overnight before analysis. IR spectra were recorded with a Jasco 4100 FT-IR spectrometer in KBr disks at room temperature. Thermogravimetric (TG) and differential thermal analyses (DTA) data were acquired using a Rigaku Thermo Plus 2 series TG/DTA TG 8120 instrument. TG/DTA measurements were performed in air with a temperature ramp of 4 °C per minute between 20 and 500 °C. The $^1H$ (399.65 MHz), $^{13}C\{^1H\}$ (100.40 MHz), and $^{31}P\{^1H\}$ NMR (161.70 MHz) spectra in solution were recorded in 5-mm outer diameter tubes with a JEOL JNM-EX 400 FT-NMR spectrometer equipped with a JEOL EX-400 data-processing system. $^1H$ and $^{13}C\{^1H\}$ NMR spectra of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complexes were measured in $D_2O$ solution with reference to internal DSS or TSP [sodium 2,2,3,3-[$D_4$]3-(trimethylsilyl)propionate]. Chemical shifts are reported as positive for resonances downfield of DSS or TSP ($\delta$ = 0 ppm). The $^{31}P\{^1H\}$ NMR spectra were referenced to an external standard of 25% $H_3PO_4$ in $H_2O$ in a sealed capillary. Chemical shifts are reported as negative on the $\delta$ scale with resonances upfield of $H_3PO_4$ ($\delta$ = 0 ppm). Solid-state $^{13}C$ NMR spectra were recorded at 300 MHz with a JEOL JNM-ECP 300 FT-NMR spectrometer equipped with a JEOL ECP-300 data-processing system. The chemical shifts are referenced to $C_6(CH_3)_6$ and are reported to be positive on the $\delta$ scale with resonances upfield of the methyl group of $C_6(CH_3)_6$ ($\delta$ = 17.4 ppm).

**Synthesis and Crystallization of $(Me_2NH_2)_5H[\alpha_2$-$P_2W_{17}O_{61}$-$\{O[Si(CH_2)_3SH]_2\}]\cdot 6H_2O$ ($Me_2NH_2$-1):** $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]\cdot 19H_2O$ (5.00 g, 1.00 mmol) was added to a colorless clear solution of $HS(CH_2)_3Si(OMe)_3$ (380 μL, 2.00 mmol [$d$ = 1.056]) dissolved in a mixture of water (50 mL) and $CH_3CN$ (150 mL), and the pH was adjusted to 1.8 with 1 M aqueous HCl. After stirring for 30 min, the solution was evaporated to a volume of about 30 mL on a rotary evaporator at 30 °C. $Me_2NH_2Cl$ (5.5 g, 67.5 mmol) was then added to the resulting pale-yellow clear solution. Hereafter, the experiments were performed in the dark because the precipitate is sensitive to light. A yellow-white precipitate was formed, which was collected on a membrane filter (JG, 0.2 μm), and washed with methanol (3 × 30 mL) and diethyl ether (3 × 30 mL). At this stage, the crude dimethylammonium salt was obtained in 4.15 g yield. A portion of this crude product (0.5 g) was dissolved in aqueous HCl (4 mL of 6 M solution) in a water bath at about 60 °C. The clear yellow solution was then slowly evaporated at room temperature in the dark. After 2 d, clear yellow granular crystals were formed. The crystals were obtained in 14.8% (0.070 g scale) yield based on $(Me_2NH_2)_5H[\alpha_2$-$P_2W_{17}O_{61}\{O[Si(CH_2)_3SH]_2\}]\cdot 6H_2O$. $Me_2NH_2$-**1** is very soluble in acetonitrile and dimethyl sulfoxide, soluble in water, and insoluble in methanol, ethanol, acetone, ethyl acetate, dichloromethane, and diethyl ether. The solid sample gradually changes to blue upon exposure to light and is slightly hygroscopic. $(Me_2NH_2)_5H[\alpha_2$-$P_2W_{17}O_{61}\{O[Si(CH_2)_3SH]_2\}]\cdot xH_2O$ ($x$ = 0), $C_{16}H_{55}N_5O_{62}P_2W_{17}S_2Si_2$ (4617.1): calcd. C 4.16, H 1.20, N 1.52, P 1.34, S 1.39, Si 1.22, W 67.69; found C 3.52 (3.97) [3.88], H 1.14 (1.24), N 1.35 (1.39), P 1.30, S 1.29, Si 1.32, W 67.6. The values in round and square brackets are the 2nd and 3rd data, respectively, which were measured at Kanagawa University. A weight loss of 2.21% was observed during the course of overnight drying at room temperature at $10^{-3}$–$10^{-4}$ Torr before the analyses, which suggests the presence of between five and six weakly solvated or adsorbed water molecules. TG/DTA under atmospheric conditions: a weight loss of 2.38% with an endothermic point at 67 °C was observed below 137 °C; calcd. 2.29% for $x$ = 6 in $(Me_2NH_2)_5H[\alpha_2$-$P_2W_{17}O_{61}\{O[Si(CH_2)_3SH]_2\}]\cdot xH_2O$. IR (KBr disk): $\tilde{\nu}$ = 2571 (m) [SH], 1623 (s), 1507 (w), 1465 (s), 1437 (w), 1412 (w), 1399 (w), 1374 (w), 1362 (w), 1339 (w), 1308 (w), 1254 (w), 1173 (w), 1088 (vs), 1069 (w), 1038 (s), 953 (s), 920 (m), 783 (vs, br.), 714 (w), 596 (w), 565 (w), 526 (m), 486 (w), 476 (w), 431 (w), 419 (w) $cm^{-1}$. $^1H$ NMR (22.6 °C, $D_2O$): $\delta$ = 0.93–1.03 (H1), 1.95–1.96 (H2), 2.72–2.77 (H3), 2.80 ($Me_2NH_2$) ppm. $^{13}C$ NMR (25.4 °C, $D_2O$): $\delta$ = 13.2 (C1), 29.1 (C3), 29.9 (C2), 37.6 ($Me_2NH_2$) ppm. $^{31}P$ NMR (23.3 °C, $D_2O$): $\delta$ = –10.52, –13.50 ppm. The $^{183}W$ NMR measurement in $D_2O$ was unsuccessful because the concentration of $Me_2NH_2$-**1** in aqueous solution was insufficient. Solid-state $^{13}C$ NMR: $\delta$ = 12.7 (C1), 14.3 (C1), 28.8 (C2, C3), 37.8 ($Me_2NH_2$) ppm.

**Synthesis and Crystallization of $(Me_2NH_2)_6[\alpha_2$-$P_2W_{17}O_{61}$-$\{O[Si(CH_2)_3SCN]_2\}]\cdot 3H_2O$ ($Me_2NH_2$-2):** $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]\cdot 19H_2O$ (5.00 g, 1.00 mmol) was added to a colorless clear solution of $NCS(CH_2)_3Si(OEt)_3$ (767 μL, 3.00 mmol [$d$ = 1.03]) dissolved in a mixture of water (50 mL) and $CH_3CN$ (150 mL), and the pH was adjusted to 1.8 with 1 M aqueous HCl. After stirring for 30 min, the solution was evaporated to a volume of about 30 mL on a rotary evaporator at 30 °C. $Me_2NH_2Cl$ (5.0 g, 61.3 mmol) was then added to this pale-yellow clear solution. Hereafter, the experiments were performed in the dark because the precipitate is sensitive to light. A yellow-white precipitate was formed, which was collected on a membrane filter (JG, 0.2 μm) and washed with ethanol (3 × 30 mL) and diethyl ether (3 × 30 mL). At this stage the crude dimethylammonium salt was obtained in 4.31 g yield. A portion of this crude product (0.5 g) was dissolved in water (9.5 mL) in a water bath at about 80 °C and then cooled to about 25 °C. After 1 d, the crude crystalline precipitate was removed by filtering through a folded filter paper (Watman #2). The resulting clear pale-yellow solution was slowly evaporated at room temperature in the dark. After 6 d, pale-yellow plate crystals were formed. The crystals were obtained in 17.8% (0.085 g scale) yield based on $(Me_2NH_2)_6[\alpha_2$-$P_2W_{17}O_{61}\{O[Si(CH_2)_3SCN]_2\}]\cdot 3H_2O$. $Me_2NH_2$-**2** is soluble in water, dimethyl sulfoxide, and acetonitrile, while it is insoluble in methanol, ethanol, ethyl acetate, and diethyl ether. The solid sample gradually became blue upon exposure to light and is slightly hygroscopic. $(Me_2NH_2)_6[\alpha_2$-$P_2W_{17}O_{61}\{O[Si(CH_2)_3SCN]_2\}]\cdot xH_2O$ ($x$ = 0), $C_{20}H_{60}N_8O_{62}P_2W_{17}Si_2S_2$ (4712.2): calcd. C 5.10, H 1.28, N 2.38, P 1.31, S 1.36, Si 1.19, W 66.32; found C 5.03, H 1.27, N 2.40, P 1.29, S 1.27, Si 1.33, W 66.2. A weight loss of 1.55% was observed during the course of overnight drying at room temperature and $10^{-3}$–$10^{-4}$ Torr before the analyses, which suggests the presence of between four and five weakly solvated or adsorbed water molecules. TG/DTA under atmospheric conditions: a weight loss of 1.27% with an endothermic point at 37 °C was observed below 140 °C; calcd. 1.13% for $x$ = 3 in $(Me_2NH_2)_6[\alpha_2$-$P_2W_{17}O_{61}\{O(SiC_3H_6SCN)_2\}]\cdot xH_2O$. The number of solvated or adsorbed water molecules determined by TG/DTA was slightly different from that measured by Pascher (Germany) because the TG/DTA data are dependent on the conditions before analysis. Here, we used three water molecules for the X-ray crystal analysis. IR (KBr disk): $\tilde{\nu}$ = 2154 (m) [SCN], 1616 (m), 1465 (m), 1437 (w), 1418 (w), 1305 (w), 1257 (w), 1182 (w), 1089 (vs), 1069 (w), 1038 (m), 955 (vs), 922 (w), 794 (vs, br.), 710 (w), 669 (w), 597 (w), 584 (w), 566 (w), 526 (m), 484 (w), 472 (w) $cm^{-1}$. $^1H$ NMR (24.5 °C, $D_2O$): $\delta$ = 1.04–1.10 (H1), 2.18–2.21 (H2), 3.28–3.31 (H3), 2.81 ($Me_2NH_2$) ppm. $^{13}C$ NMR (25.5 °C, $D_2O$): $\delta$ = 12.8 (C1), 26.1(C2), 38.4 (C3), 37.4 ($Me_2NH_2$), 117.9 (S*C*N) ppm. $^{31}P$ NMR (23.6 °C, $D_2O$): $\delta$ = –10.33, –13.28 ppm. The $^{183}W$ NMR measurement in $D_2O$ was unsuccessful because the concentration of $Me_2NH_2$-**2** in aqueous solution was insufficient. Solid-state $^{13}C$ NMR: $\delta$ = 12.31 (sh) (C1), 26.41 (C2), 38.16 ($Me_2NH_2$, C3) ppm.

**Synthesis and Crystallization of $(Me_2NH_2)_6[\alpha_2$-$P_2W_{17}O_{61}\{O$-$(SiPh)_2\}]\cdot 4H_2O$ ($Me_2NH_2$-3):** $Me_2NH_2$-**3** was synthesized by a modification of the reported method.[13] $K_{10}[\alpha_2$-$P_2W_{17}O_{61}]\cdot 19H_2O$ (5.00 g, 1.00 mmol) was added to a colorless clear solution of $C_6H_5SiCl_3$ (325 μL, 2.00 mmol [$d$ = 1.28]) dissolved in a mixture of water (50 mL) and $CH_3CN$ (250 mL) and stirred for 1 h. The solution was evaporated to about 40 mL on a rotary evaporator at 30 °C. The pale-yellow suspension was filtered through a membrane filter (JG, 0.2 μm), and the resulting pale-yellow clear filtrate was re-evaporated to about 35 mL in a water bath at about 80 °C. After filtration through a membrane filter (JG, 0.2 μm), $Me_2NH_2Cl$ (5.5 g, 67.5 mmol) was added to the pale-yellow filtrate. Hereafter, the experiments were performed in the dark because the powder formed is sensitive to light. A white precipitate and yellow oil were formed. After stirring in the dark for 10 min in a water bath at

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

about 80 °C, the solution was cooled to room temperature. A yellow-white precipitate was formed, which was collected on a membrane filter (JG, 0.2 μm), and washed with ethanol (3 × 10 mL) and diethyl ether (3 × 30 mL). At this stage the crude dimethylammonium salt was obtained in 3.62 g yield. A portion of this crude product (2.00 g) was dissolved in water (50 mL) in a water bath at 80 °C and filtered through a folded filter paper while the solution was hot. The pale-yellow clear filtrate was slowly evaporated at room temperature in the dark. After 3 d, yellow granular crystals were formed. The crystals were obtained in 37.0% (0.74 g scale) yield based on $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiPh)_2\}]\cdot 4H_2O$. $Me_2NH_2$-**3** is very soluble in acetonitrile and dimethyl sulfoxide, soluble in water, acetone, and methanol, slightly soluble in ethanol, and insoluble in diethyl ether. The solid sample gradually became blue upon exposure to light and is slightly hygroscopic. $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiPh)_2\}]\cdot xH_2O$ ($x$ = 0), $C_{24}H_{58}N_6O_{62}Si_2P_2W_{17}$ (4666.1): calcd. C 6.18, H 1.25, N 1.80, P 1.33, Si 1.20, W 66.98; found C 6.15, H 1.23, N 1.81, P 1.29, Si 1.31, W 66.5. A weight loss of 1.91% was observed during the course of overnight drying at room temperature and $10^{-3}$–$10^{-4}$ Torr before the analyses, which suggests the presence of between five and six weakly solvated or adsorbed water molecules. TG/DTA under atmospheric conditions: a weight loss of 1.62% with an endothermic point at 83 °C was observed below 201 °C; calcd. 1.52% for $x$ = 4 in $(Me_2NH_2)_6[\alpha_2\text{-}P_2W_{17}O_{61}\{O(SiPh)_2\}]\cdot xH_2O$. The number of solvated or adsorbed water molecules determined by TG/DTA was slightly different from that measured by Pascher (Germany) because the TG/DTA data are dependent on the conditions before analysis. Here, we used four water molecules for the X-ray crystal analysis. IR (KBr disk): $\tilde{\nu}$ = 1617 (s), 1507 (w), 1466 (s), 1430 (w) [PhSi], 1133 (m) [PhSi], 1091 (vs), 1040 (s), 1026 (m), 1017 (m), 960 (s), 952 (s), 925 (m), 904 (w), 795 (vs, br.), 710 (w), 622 (w), 603 (m), 566 (w), 549 (m), 526 (m), 484 (m), 474 (w), 445 (w), 441 (w), 436 (w), 418 (w) $cm^{-1}$. $^1H$ NMR (23.0 °C, $D_2O$): $\delta$ = 2.76 ($Me_2NH_2$), 7.53–7.94 (Ph) ppm. $^{13}C$ NMR (25.7 °C, $D_2O$): $\delta$ = 37.6 ($Me_2NH_2$) 131.1–137.3 ppm (Ph). $^{31}P$ NMR (22.2 °C, $D_2O$): $\delta$ = –10.21, –13.29 ppm.

**X-ray Crystallography:** Crystals of compounds $Me_2NH_2$-(**1**–**3**) were covered with liquid paraffin to prevent their degradation. The crystal sizes were 0.11 × 0.11 × 0.07 mm, 0.10 × 0.09 × 0.03 mm, and 0.20 × 0.11 × 0.03 mm, respectively. Data collection was carried out with a Bruker SMART APEX CCD diffractometer at 90 K. The intensity data were automatically corrected for Lorentz and polarization effects during integration. The structure was obtained by direct methods (SHELXS-97),[26] followed by a subsequent difference Fourier calculation, and refined by the full-matrix least-squares procedure (SHELXL-97).[27] Absorption correction was performed with SADABS (empirical absorption correction).[28]

**Crystal Data for $Me_2NH_2$-1:** $C_{10}H_{42}N_2O_{68}P_2S_2Si_2W_{17}$, $M$ = 4586.15, monoclinic, space group $P2_1/n$, $a$ = 15.100(4), $b$ = 21.373(5), $c$ = 24.498(6) Å, $\alpha$ = 90°, $\beta$ = 92.511(4)°, $\gamma$ = 90°, $V$ = 7898(3) Å$^3$, $Z$ = 4, $D_c$ = 3.857 Mg m$^{-3}$, $\mu$(Mo-$K_\alpha$) = 24.871 mm$^{-1}$. $R_1$ = 0.0727, $wR_2$ = 0.1554 (for all data). $R_{int}$ = 0.0579, $R_1$ = 0.0562, $wR_2$ = 0.1447, GOF = 1.071 [92569 total reflections, 19693 unique reflections with $I > 2\sigma(I)$]. The maximum and minimum residual densities (12.244 and –2.629 e Å$^{-3}$) were located at 1.34 Å from O1 and 0.58 Å from W9, respectively.

**Crystal Data for $Me_2NH_2$-2:** $C_{20}H_{66}N_8O_{65}P_2S_2Si_2W_{17}$, $M$ = 4766.50, triclinic, space group $P\bar{1}$, $a$ = 13.2879(12), $b$ = 13.3218(12), $c$ = 26.190(2) Å, $\alpha$ = 80.868(2)°, $\beta$ = 80.562(2)°, $\gamma$ = 66.9000(10)°, $V$ = 4183.8(7) Å$^3$, $Z$ = 2, $D_c$ = 3.784 Mg m$^{-3}$, $\mu$(Mo-$K_\alpha$) = 23.483 mm$^{-1}$. $R_1$ = 0.0796, $wR_2$ = 0.1803 (for all data). $R_{int}$ = 0.1890, $R_1$ = 0.0612, $wR_2$ = 0.1637, GOF = 0.983 [59851 total reflections, 20747 unique reflections where $I > 2\sigma(I)$]. The maximum and minimum residual densities (10.686 and –4.776 e Å$^{-3}$) were located at 1.34 Å from O1 and 0.97 Å from W13, respectively.

**Crystal Data for $Me_2NH_2$-3:** $C_{22}H_{58}N_5O_{66}P_2Si_2W_{17}$, $M$ = 4692.30, orthorhombic, space group $Pnma$, $a$ = 20.894(4), $b$ = 20.413(4), $c$ = 18.939(3) Å, $\alpha$ = 90°, $\beta$ = 90°, $\gamma$ = 90°, $V$ = 8077(3) Å$^3$, $Z$ = 4, $D_c$ = 3.859 Mg m$^{-3}$, $\mu$(Mo-$K_\alpha$) = 24.274 mm$^{-1}$. $R_1$ = 0.0534, $wR_2$ = 0.1168 (for all data). $R_{int}$ = 0.0736, $R_1$ = 0.0386, $wR_2$ = 0.1026, GOF = 1.080 [108211 total reflections, 10317 unique reflections where $I > 2\sigma(I)$]. The maximum and minimum residual densities (6.824 and –1.646 e Å$^{-3}$) were located at 1.34 Å from O1 and 1.57 Å from O26, respectively.

For compound $Me_2NH_2$-**1**, 17 tungsten atoms, two phosphorus atoms, two silicon atoms, six carbon atoms, and two sulfur atoms were clearly identified. For compound $Me_2NH_2$-**2**, 17 tungsten atoms, two phosphorus atoms, two silicon atoms, eight carbon atoms, two nitrogen atoms, and two sulfur atoms were clearly identified. For compound $Me_2NH_2$-**3**, 17 tungsten atoms, two phosphorus atoms, two silicon atoms, and twelve carbon atoms were clearly identified. However, the resolution obtained for the structure of the salt was limited by the poor quality of the available crystals and by the considerable disorder of the countercations and the solvent of crystallization. These features are common in POM crystallography.[29]

CCDC-604936, -604937, and -604938 [$Me_2NH_2$-(**1**–**3**), respectively] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see the footnote on the first page of this article): The bond lengths, bond angles, and bond valence sums for compounds $Me_2NH_2$-(**1**–**3**) (Tables S1–S6).

# Synthesis, Crystal Structures and Photoluminescent Properties of Three Novel Cadmium(II) Compounds Constructed from 5-Sulfoisophthalic Acid ($H_3SIP$)

**Qing-Yan Liu,[a] Yu-Ling Wang,[b] and Li Xu*[a]**

**Keywords:** Cadmium compounds / Hydrothermal synthesis / Crystal structures / Photoluminescent properties

Hydrothermal reactions of $Cd(NO_3)_2$ and $NaH_2SIP$ (5-sulfoisophthalic acid monosodium salt) at pH = 2 and 7 produce $[Cd_2(\mu_2\text{-}OH_2)_2(HSIP)_2(H_2O)_6]$ (**1**) and $[Cd_5(\mu_2\text{-}OH)_2(\mu_3\text{-}OH)_2(SIP)_2(H_2O)_5]_n$ (**2**), respectively. A similar hydrothermal reaction in the presence of dpp [1,3-bis(4-pyridyl)propane] yields $\{[Cd_3(SIP)_2(dpp)_6]\cdot 4(H_2O)\}_n$ (**3**). Single-crystal X-ray diffraction reveals that compound **1** has a discrete dinuclear structure with the $[Cd_2(\mu_2\text{-}OH_2)_2]$ unit. Polymer **2** features an inorganic layer, which has centrosymmetric 12- and 24-membered rings composed of chair-shaped $[Cd_4(\mu_3\text{-}OH)_2]$ units and $Cd(\mu_2\text{-}OH)_2(CO_2)$ units, and is interconnected by SIP into a 3D framework. Complex **3** contains a 1D ladder-like $[Cd_4(SIP)_4]_n$ unit with four cadmium atoms co-planar, which is interconnected by dpp into a 2D nanosized layered structure. In the solid state, compounds **1** and **3** exhibit blue-violet photoluminescence with maxima at 436 and 409 nm upon excitation at 342 and 350 nm, respectively. However, compound **2** shows photoluminescence with the maximum at 306 nm upon excitation at 270 nm.

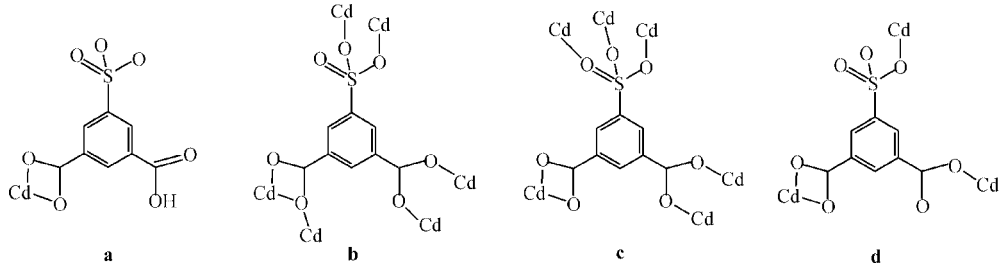
## Introduction

The design and construction of metal–organic frameworks (MOFs) has been one of the most active areas of materials research in recent years. The intense interest in these materials is driven by their potential applications as functional materials (catalysis, magnetism, electric conductivity and nonlinear optics) and intriguing structural diversities.[1–4] Assembly of these metal–organic coordination polymers allows for a wide choice of various parameters including diverse electronic properties and coordination geometries of the metal ions as well as versatile functions of organic ligands.[5–7] Consequently, a wide variety of coordination architectures with interesting structures and desired properties have been prepared through judicious choice of organic ligands and metal ions.[8–11] Recently, 5-sulfoisophthalic acid ($H_3SIP$) has been successfully used to investigate the lanthanide contraction effect[12] and the coordination polymer chemistry of a main group metal



Scheme 1. Coordination modes of 5-sulfoisophthalic acid observed in compounds **1**–**3**.

($Pb^{2+}$),[13] because of its multiple coordinating modes and the sensitivity of the sulfonate group to the surrounding chemical environment. In this contribution, SIP will serve as a probe to examine the coordination polymer chemistry of the late transition metal $Cd^{2+}$. Three novel (SIP)Cd compounds, $[Cd_2(\mu_2\text{-}OH_2)_2(HSIP)_2(H_2O)_6]$ (**1**), $[Cd_5(\mu_2\text{-}OH)_2(\mu_3\text{-}OH)_2(SIP)_2(H_2O)_5]_n$ (**2**) and $\{[Cd_3(SIP)_2(dpp)_6]\cdot 4(H_2O)\}_n$ (**3**), will be described with regard to syntheses, crystal structures, and IR spectroscopic and photolumines-

cent properties. Two unprecedented bridging coordination modes of SIP (Scheme 1, **b** and **c**) are observed in polymer **2**.

## Results and Discussion

### Preparation of the Compounds

Hydrothermal synthesis is widely employed to produce new materials with diverse structural architectures, but is still a kind of black box. This method can minimise the problems associated with ligand solubility and enhance the reactivity of reactants in favour of efficient molecular building during the crystallisation process. There are a variety of hydrothermal parameters such as reaction time, temperature, pH value, templates and molar ratio of reactants, and small changes in one or more of these parameters can have a profound influence on the final reaction outcome. Compounds **1** and **2**, with very different structures, were obtained from similar reactions but at different pH values, indicating that the hydrothermal reaction outcome of the Cd/$H_3$SIP system is pH-dependent. We also notice that N-containing auxiliary ligands such as dpp [1,3-bis(4-pyridyl)-propane] are also able to tune the framework structures. At a ratio of Cd/SIP/dpp = 3:2:6, the 2D polymer **3** is formed. Reducing the corresponding ratio to 3:2:2 results in the 1D compound $\{[Cd(SIP)(dpp)(H_2O)_3]\cdot 0.5Cd(H_2O)_6\cdot 5H_2O\}_n$,[14] indicating that the reaction products are ratio-dependent. The preparative reactions were carried out at different temperatures (140 °C, 160 °C and 180 °C) to examine the temperature dependence of their solid structures. X-ray diffraction analyses of these reaction products indicate that the same results were obtained under these reaction temperatures although the purity and yields were slightly different, indicative of the thermodynamic nature of the hydrothermal reactions.[15]

### Crystal Structure of $[Cd_2(\mu_2\text{-}OH_2)_2(HSIP)_2(H_2O)_6]$ (1)

The dinuclear structure of **1** is shown in Figure 1; it has a crystallographically imposed $C_{2h}$ symmetry, which has the $C_2$ axis passing through O7 and O7A (for symmetry code see Table 1). The two $Cd^{II}$ atoms are linked by two bridging water molecules to form the rhomboidal $[Cd_2(\mu_2\text{-}OH_2)_2]$ core with a Cd–O distance of 2.412(1) Å and O(7)–Cd(1)–O(7A) bond angle of 75.48(8)°. Each cadmium ion is bonded to two bridging water molecules, three terminal water molecules and one $HSIP^{2-}$ dianion through the chelating carboxylate group. The Cd–O distances range from 2.412(1) to 2.567(3) Å, which is consistent with those found in comparable structures.[16–19] The uncoordinated carboxylate group is protonated for charge balance, as suggested by the strong absorption at 1710 $cm^{-1}$.[20] As shown in Figure 2a, a 3D supramolecular framework is formed through three types of hydrogen bonds between (a) coordinated water molecules and sulfonate oxygen atoms [O(7)···O(5B) 2.732(2) Å, O(8)···O(6C) 2.832(2) Å and O(9)···O(6D) 2.808(2) Å]; (b) coordinated water molecules and carboxylate oxygen atoms [O(9)···O(4B) 2.867(3) Å]; and (c) a carboxylate group and a carboxylate oxygen atom [O(3)···O(2E) 2.581(3) Å]. Of particular interest is the infinite tape formed by hydrogen bonds between the $[Cd_2(\mu_2\text{-}OH_2)_2(H_2O)_2]$ units and the sulfonate groups along the crystallographic *b* axis (Figure 2b). The hydrogen-bonded tape features an eight-membered ring [the bridging $H_2O(7)$, O(5) and their equivalents], which is nearly perpendicular to the $[Cd_2(\mu_2\text{-}OH_2)_2]$ plane (95.7°). The tape is strengthened by the O(8)···O(6C) hydrogen bonds, as shown in Figure 2b. The 3D supramolecular structures are further stabilised by π–π interactions between the parallel aromatic rings in an off-set fashion with a face-to-face distance of 3.44(2) Å and a centre-to-centre distance of 3.66(3) Å. This indicates that noncovalent interactions can play a crucial role in constructing the whole packing.

### Crystal Structure of $[Cd_5(\mu_2\text{-}OH)_2(\mu_3\text{-}OH)_2(SIP)_2(H_2O)_5]_n$ (2)

Compound **2** contains five unique $Cd^{II}$ ions, four of which are six-coordinate and one [Cd(3)] five-coordinate.

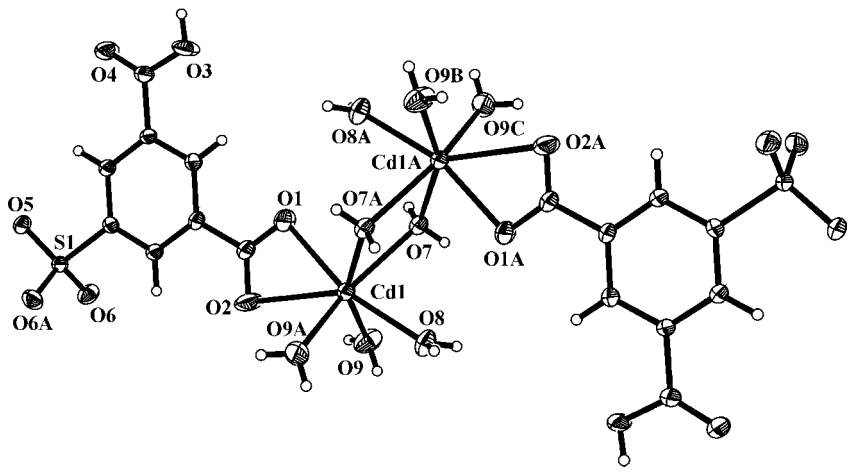

Figure 1. ORTEP drawing of **1** with 40% probability displacement ellipsoids. Hydrogen atoms are shown as small spheres of arbitrary radii.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As shown in Figure 3, Cd(1) has a distorted octahedral coordination geometry with the equatorial positions taken up by one chelating carboxylate group [O(10A) and O(11A)], one monodentate carboxylate oxygen atom [O(1)] and one $\mu_3$-hydroxy oxygen atom [O(16)]. The axial positions are occupied by one water molecule [O(15)] and one sulfonate oxygen atom [O(5B)] from the third SIP ligand. The angles formed by the equatorial atoms range from 54.97(9)° [O(10A)–Cd(1)–O(11A)] to 118.75(9)° [O(1)–Cd(1)–O(16)], indicative of a serious distortion of the [$CdO_6$] octahedron. Cd(5) has a similar coordination environment to that of Cd(1). Cd(2) also has a distorted [$CdO_6$] octahedral coordination geometry in which a pair of symmetrically related $\mu_3$-hydroxy oxygen atoms [O(16) and O(16C)], a $\mu_2$-hydroxy oxygen atom [O(18)] and a sulfonate oxygen atom [O(6B)] form the equatorial plane. The water molecule [O(17)] and the carboxylate oxygen atom [O(2)] occupy the apical positions. The coordination environment of Cd(4) is similar to that of Cd(2) but the terminal water molecule [O(21)] is located at the equatorial plane and the $\mu_2$-hydroxy oxygen atom [O(20)] occupies the apical position. The Cd(3) atom is coordinated by one $\mu_2$-hydroxy oxygen atom [O(18)], a sulfonate oxygen atom [O(12)] and one carboxylate oxygen atom [O(3)] in an equatorial plane, and the other $\mu_2$-hydroxy oxygen atom [O(20)] and the water molecule [O(19)] in the apical positions to complete its trigonal-bipyramidal coordination environment. The Cd–O distances range from 2.182(3) to 2.517(2) Å, as listed in Table 1. Two crystallographically unique SIP ligands exhibit two different coordination modes (Scheme 1, **b** and **c**). One SIP (**b**) acts as a hexadentate ligand with the bidentate sulfonate and carboxylate groups, and one $\mu_2$-$\eta^2$:$\eta^1$ carboxylate group (one oxygen atom bridges two metal atoms, the other connects one metal atom and the carboxylate group coordinates to two metal atoms). The other SIP ligand also adopts a hexadentate bridging coordination mode through its one bidentate carboxylate group, one chelate carboxylate group and the tridentate sulfonate group. To the best of our knowledge,

neither type of coordination mode of the SIP ligands is observed in the reported SIP complexes.

The 3D framework structure shown in Figure 4a is constructed by inorganic oxide layers pillared by the SIP ligands, reminiscent of reported metal biphosphonate compounds.[21,22] The inorganic oxide layer contains two types of chair-like $[Cd_4(\mu_3\text{-}OH)_2]$ cluster units formed by Cd(1)/Cd(2) and Cd(4)/Cd(5), respectively, and features two types of centrosymmetric rings: 12-membered (A) and 24-membered (B). As shown in Figure 4b, each $\mu_3$-hydroxy group (O16) as a metal linker bridges the neighbouring three Cd atoms to generate a chair-shaped tetranuclear $[Cd_4(\mu_3\text{-}OH)_2]$ cluster with Cd(2), O(16) and their equivalents related by an inversion centre defining a plane and with the two Cd(1) atoms above and below the $[Cd_2(\mu_3\text{-}OH)_2]$ plane. The Cd(1)–O(16), Cd(2)–O(16) and Cd(2C)–O(16) distances are 2.198(2), 2.276(2) and 2.260(2) Å, respectively, with surrounding angles of 105.56(9)°, 124.45(11)° and 98.80(8)° for Cd(1)–O(16)–Cd(2), Cd(1)–O(16)–Cd(2C) and Cd(2)–O(16)–Cd(2C), respectively. The chair-shaped

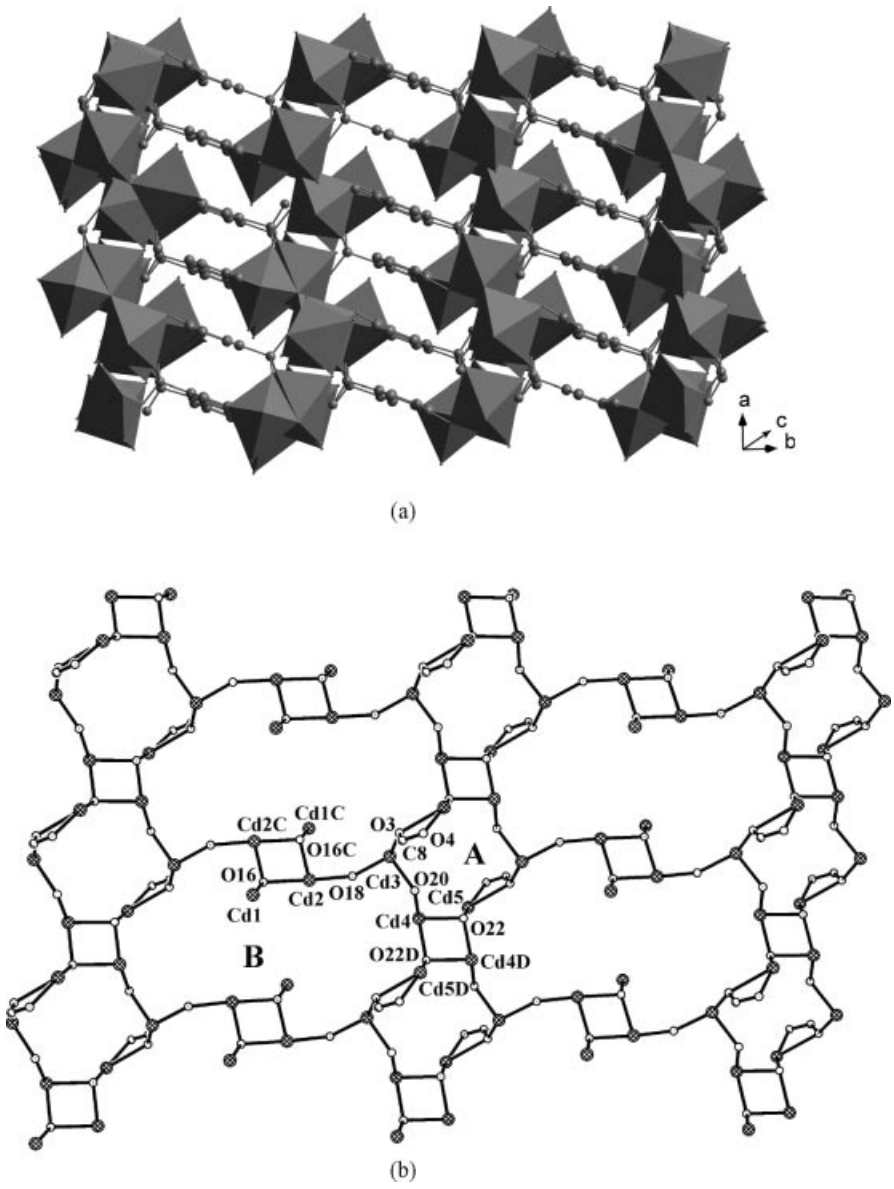

Figure 4. (a) 3D structure of **2** (the polyhedral presentation indicates the coordination environments for the Cd centre). (b) Perspective view of the 2D metal–oxide inorganic layer featuring the chair-shaped $[Cd_4(\mu_3\text{-}OH)_2]$ clusters and two types of large rings.

$[Cd_4(\mu_3\text{-}OH)_2]$ cluster formed by Cd(4)/Cd(5) has a similar geometry to that of the $[Cd_4(\mu_3\text{-}OH)_2]$ cluster formed by Cd(1)/Cd(2), with Cd(5)–O(22), Cd(4)–O(20) and Cd(4)–O(22) bond lengths of 2.193(2), 2.286(2) and 2.237(2) Å, respectively, and surrounding angles of 105.06(9)°, 121.22(10)° and 96.80(8)° for Cd(4)–O(22)–Cd(5), Cd(5)–O(22)–Cd(4D) and Cd(4)–O(22)–Cd(4D), respectively. There are several compounds containing a chair-shaped tetranuclear cadmium cluster,[23–25] but those with two capping $\mu_3$-OH groups are rare. It is even more interesting that the $[Cd_4(\mu_3\text{-}OH)_2]$ cluster units are interconnected by the $Cd(3)(\mu_2\text{-}OH)_2(CO_2)$ unit into an unusual inorganic oxide layer. Although cadmium cluster units have been known to be present in coordination polymers,[6,26–28] such cluster-based inorganic layers as subunits of a coordination polymer are still scarce. The layer has a 12-membered ring (A) with approximate dimensions of $3.8 \times 4.9$ Å$^2$, which is composed of Cd(3), Cd(4) and Cd(5) atoms and their equivalents linked by two $\mu_3$-OH, two $\mu_2$-OH and two carboxylate groups. It also contains a large 24-membered ring (B) with approximate dimensions of $4.7 \times 14.3$ Å$^2$. The inorganic oxide layer is linked by the carboxylate and sulfonate groups of the SIP ligands to form a 3D pillared framework.

### Crystal Structure of $\{[Cd_3(SIP)_2(dpp)_6]\cdot 4(H_2O)\}_n$ (3)

As shown in Figure 5, **3** contains two crystallographically independent cadmium ions; Cd(1) lies on the crystallographic inversion centre. Both $Cd^{2+}$ ions are octahedrally coordinated but their coordination environments are different. Cd(1) is coordinated to four equatorial pyridine ni-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trogen atoms [Cd–N = 2.372(3) and 2.338(3) Å] in a square-planar arrangement and two apical sulfonate oxygen atoms from two *trans*-SIP ligands [Cd–O = 2.317(2) Å]. Cd(2) is coordinated by one chelating and one monodentate carboxylate group from two different SIP ligands, and one pyridine nitrogen atom in equatorial positions with Cd–O distances of 2.346(2), 2.539(2) and 2.302(2) Å, respectively, and a Cd–N distance of 2.300(3) Å. The axial positions are taken up by two other pyridine nitrogen atoms, with Cd–N distances of 2.351(3) and 2.356(3) Å. As illustrated in Figure 6, the SIP ligands interconnect the $Cd^{2+}$ ions in coordination mode **d** (Scheme 1) into an infinite ladder structure along the *a* axis, which features the cyclic $[Cd_4(SIP)_4]$ unit with dimensions of $7.5 \times 12.8$ Å$^2$. It is interesting that the four Cd ions [Cd(1), Cd(2), Cd(1A) and Cd(2A)] are co-planar. The 1D ladder can also conveniently be regarded as resulting from two antiparallel $[Cd(SIP)]_n$ single chains bridged by Cd(1) (Figure 6).

Compound **3** contains one monodentate [N(1)···N(2)] and two bridging dpp ligands [N(3)···N(4) and N(5)···N(6)]. The flexible dpp ligand can adopt several conformations based on the orientations of the $CH_2$ groups, such as *TT*, *TG*, *GG* and *GG′* (*T* = *trans*; *G* =*gauche* ), with quite different N···N separations (6.7–10.1 Å).[29,30] In the present case, the monodentate dpp has a conformation of *TG* with an N···N distance of 8.9 Å and the bridging ones adopt *TT* conformation with an N···N separation of 9.5 Å. The 1D ladders are connected by the bridging dpp ligands to form a 2D nanolayer with a thickness of about 1.5 nm, as shown in Figure 7; the cavity is filled in by the monodentate dpp.

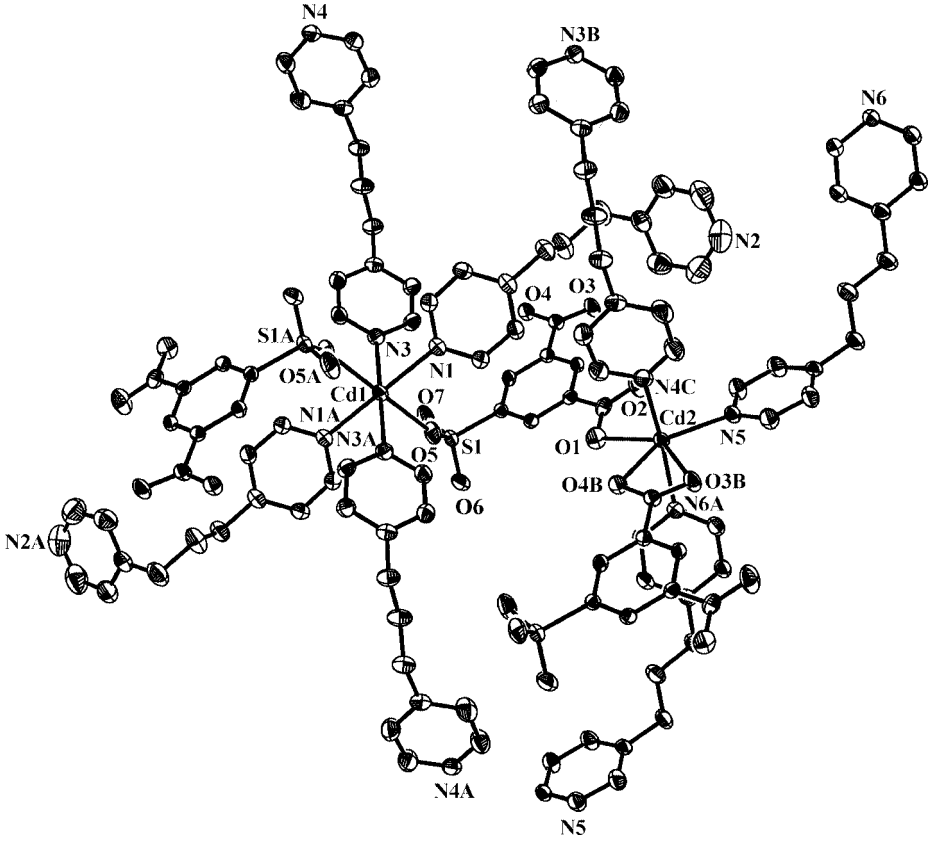

Figure 5. ORTEP drawing of **3** with 35% probability displacement ellipsoids.

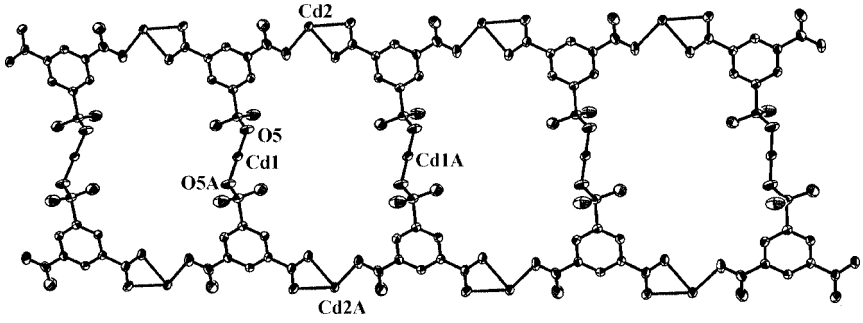

Figure 6. 1D ladder structure in compound **3** featuring the cyclic $[Cd_4(SIP)_4]$ unit.

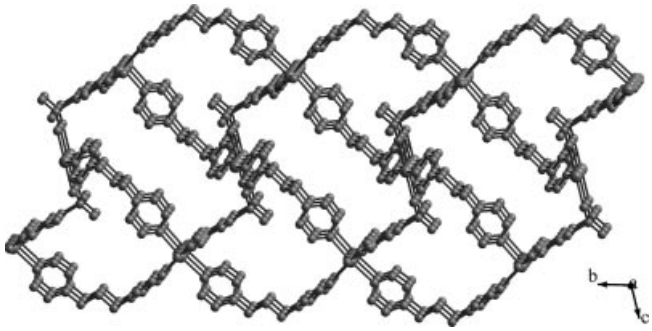

Figure 7. Perspective view of the 2D structure of **3**. Lattice water molecules and monodentate dpp molecules omitted for clarity.

### FTIR Spectra

The FTIR spectra of **1** and **3** exhibit broad absorptions centred at 3498 and 3399 $cm^{-1}$ for **1** and **3**, respectively, because of the existence of water molecules in the structures. The O–H stretching vibrations of the water molecules and hydroxy group in **2** appear at 3435 and 3159 $cm^{-1}$. The IR spectra of **1**–**3** display the typical stretching bands of carboxylate groups between 1400 and 1622 $cm^{-1}$. The characteristic band at 1710 $cm^{-1}$ in **1** is attributable to the protonated carboxylate group of $H_3SIP$ ligand. The absorptions in the region 1000–1230 $cm^{-1}$ in **1**–**3** are typical for the sulfonate groups. The strong absorptions at about 620 $cm^{-1}$ in **1**–**3** can be assigned to the S–O stretching vibrations.

### Photoluminescent Properties

Metal–organic frameworks (MOFs) are promising photoluminescent materials because of their high thermal stability, and structure- and metal-dependent emission. The combination of organic linkers and metal centres in coordination polymers provides an efficient route to a new type of photoluminescent materials with potential applications as light-emitting diodes (LEDs). The $d^{10}$ metal compounds have been shown to exhibit interesting photoluminescent properties.[31–33] In the present work, we have examined the photoluminescent properties of **1**–**3** and the free $H_3SIP$ ligand in the solid state at room temperature. Free $NaH_2SIP$ displays a photoluminescent emission at 320 nm upon excitation at 286 nm.[17] Compound **1** exhibits a broad photoluminescent emission centred at 436 nm upon excitation at 342 nm and **3** displays an emission at 409 nm upon excitation at 350 nm (Figure 8). The emissions of **1** (436 nm) and **3** (409 nm) occur at much longer wavelengths than that of the free ligand (320 nm). Such a large bathochromic shift indicates that the aromatic rings of the ligand effectively interact with the metal ion and/or with each other through π-stacking interactions, as described above. In other words, the π-electrons of the aromatic rings are delocalised over the $Cd^{2+}$ ion and/or the neighbouring ligand. With the above concerns in mind, the fluorescence emission of **1** may tentatively be assigned to the formation of the $[Cd_2(\mu_2\text{-}OH_2)_2]$ cluster, which compares to our recently reported (SIP)lead compound.[13] The emission peak of **3** at 409 nm, which is similar to that of the analogue $\{[Cd(SIP)(H_2O)_3]\cdot 0.5(H_2en)(H_2O)\}_n$[17] (412 nm), can be assigned to ligand-to-metal charge transfer (LMCT). This is consistent with the fact that the $Cd^{II}$ or $Zn^{II}$ coordination complexes with aromatic carboxylate ligands may possess an LMCT photoluminescent property.[34–36] In the case of **2**, the emission at 306 nm upon excitation at 270 nm is similar to that of the free $H_3SIP$ ligand. This indicates that the emission band of **2** is an intraligand transition. The further lifetime measurements at room temperature of each emission maximum give results of 0.61, 18 and 0.56 ns for compounds **1**, **2** and **3**, respectively. The lifetime of **2** is significantly longer than those of **1** and **3**. This is consistent with the fact that metal hydroxide (or oxide) clusters usually have longer emission lifetimes[35] because the $\mu_2/\mu_3$-OH ligands can tighten the whole framework and thus result in weaker vibrations. These observations clearly reveal the structure-dependent photoluminescent properties of coordination polymers.

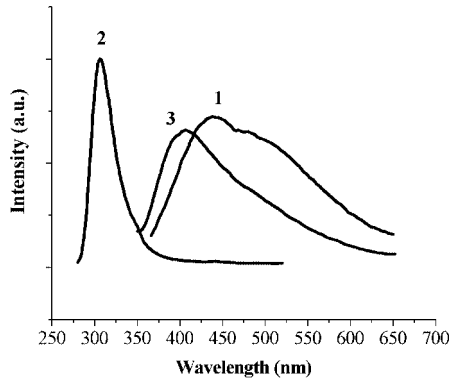

Figure 8. Solid-state emission photoluminescent spectra of **1**–**3** at room temperature.

## Conclusions

In conclusion, hydrothermal reactions of the $Cd/H_3SIP$ system are pH-dependent. Incomplete deprotonation of the $H_3SIP$ ligand occurs under acidic conditions, leading to lowered connectivity of the SIP ligand and the formation of the discrete dinuclear compound **1**. The ligand is fully deprotonated under neutral or basic conditions, accompanied by the formation of the hydroxy-bridged cadmium clusters **2**. In **2**, the chair-like $[Cd_4(\mu_3\text{-}OH)_2]$ cluster units are interconnected by the $[Cd(\mu_2\text{-}OH)_2(CO_2)]$ unit into an unprecedented inorganic oxide layer, which is pillared by the $SIP^{3-}$ ligand into a 3D framework structure. Two unprecedented coordination modes are observed in compound **2**. The addition of the auxiliary ligand dpp leads to the 2D structure of **3** containing a cyclic $[Cd_4(SIP)_4]$ unit with the Cd atoms co-planar. Compounds **1**–**3** display different photoluminescent emissions at room temperature, indicating structure-dependent photoluminescent properties of the Cd/SIP coordination polymers and thus potential application in LED technology.

## Experimental Section

**General Remarks:** All chemicals were purchased commercially and used without further purication, including 5-sulfoisophthalic acid monosodium salt (Alfa) and 1,3-bis(4-pyridyl)propane (Acros). Elemental analyses were carried out with an Elementar Vario EL III analyser and IR spectra (KBr pellets) were recorded with a Perkin–Elmer Spectrum One. Fluorescent spectra were measured at room temperature with an Edinburgh FL-FS90 TCSPC system. All complexes were synthesised by a hydrothermal method under autogenous pressure.

**Synthesis of $[Cd_2(\mu\text{-}OH_2)_2(HSIP)_2(H_2O)_6]$ (1):** A mixture of $Cd^{II}$ nitrate tetrahydrate (0.0616 g, 0.2 mmol), 5-sulfoisophthalic acid monosodium salt (0.0536 g, 0.2 mmol), triethylamine (0.01 mL) and water (15 mL) (pH = 2) was heated at 160 °C for 4 d. Colourless plate-like crystals of **1** were obtained when cooling to room temperature at 5 °C/h. The crystals were recovered by filtration, washed with distilled water and dried in air (yield: 0.05 g, 63% based on Cd). $C_{16}H_{24}Cd_2O_{22}S_2$ (857.27): calcd. C 22.33, H 2.81; found C 22.31, H 2.76. IR (KBr pellet): $\tilde{\nu}$ = 3498 s, 1710 s, 1622 s, 1580 w, 1552 s, 1436 w, 1371 s, 1231 s, 1187 s, 1118 s, 1047 s, 999 w, 857 w, 768 m, 731 w, 673 m, 624 m, 580 w $cm^{-1}$.

**Synthesis of $[Cd_5(\mu_2\text{-}OH)_2(\mu_3\text{-}OH)_2(SIP)_2(H_2O)_5]_n$ (2):** A mixture of $Cd^{II}$ nitrate tetrahydrate (0.0616 g, 0.2 mmol), 5-sulfoisophthalic acid monosodium salt (0.0536 g, 0.2 mmol), triethylamine (0.05 mL) and water (15 mL) (pH = 7) was heated at 160 °C for 4 d. Colourless prism-like crystals of **2** were obtained when cooling to room temperature at 5 °C/h. The crystals were recovered by filtration, washed with distilled water and dried in air (yield: 0.013 g, 11% based on Cd). $C_{16}H_{20}Cd_5O_{23}S_2$ (1206.44): calcd. C 15.82, H 1.66; found C 15.76, H 1.63. IR (KBr pellet): $\tilde{\nu}$ = 3435 s, 3159 s, 1615 s, 1569 w, 1553 m, 1400 s, 1216 w, 1182 s, 1106 m, 1044 s, 858 w, 833 w, 707 w, 673 m, 620 m, 447 w $cm^{-1}$.

**Synthesis of $\{[Cd_3(SIP)_2(dpp)_6]\cdot 4(H_2O)\}_n$ (3):** A mixture of $Cd^{II}$ nitrate tetrahydrate (0.0231 g, 0.075 mmol), 5-sulfoisophthalic acid monosodium salt (0.0134 g, 0.05 mmol), 1,3-bis(4-pyridyl)propane (0.0297 g, 0.15 mmol), triethylamine (0.01 mL) and water (15 mL) was heated at 160 °C for 4 d. Colourless rod-like crystals of **3** were obtained when cooling to room temperature at 5 °C/h. The crystals were recovered by filtration, washed with distilled water and dried in air (yield: 0.023 g, 46% based on Cd). $C_{94}H_{98}Cd_3N_{12}O_{18}S_2$ (2085.16): calcd. C 54.02, H 4.73, N 8.05; found C 54.03, H 4.71, N 8.02. IR (KBr pellet): $\tilde{\nu}$ = 3399 s, 2943 s, 1612 s, 1560 w, 1502 w, 1428 s, 1364 s, 1224 m, 1199 m, 1103 m, 1068 w, 1042 m, 1015 m, 925 w, 846 w, 811 m, 781 w, 728 m, 624 m, 576 w, 515 w, 448 w $cm^{-1}$.

**X-ray Crystallographic Study:** X-ray diffraction data of compounds **1**–**3** were collected with a Rigaku Mercury CCD diffractometer equipped with graphite-monochromated Mo-$K_a$ radiation ($\lambda$ = 0.71073 Å). CrystalClear software was used for data reduction and empirical absorption correction.[37] The structures were solved by the direct methods and successive Fourier difference syntheses, and refined by the full-matrix least-squares method on $F^2$ (SHELXTL Version 5.1[38]). The H atoms bonded to C atoms and N atoms were assigned to calculated positions and refined using a riding model [C–H = 0.93 Å, $U_{iso}$(H) = 1.2$U_{iso}$(C); N–H = 0.89 Å, $U_{iso}$(H) = 1.2$U_{iso}$(N)]; H atoms bonded to O atoms were located from difference maps except for one lattice water oxygen atom of compound **3**, which could not be located. The $R_1$ values are defined as $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. Details of the crystal parameters, data collection and refinement are summarised in Table 2, and selected bond lengths and bond

# Nickel-Organic Coordination Layers with Different Directional Cavities

Youfu Zhou,[a] Chengyang Yue,[a] Daqiang Yuan,[a] Lian Chen,[a] Jiutong Chen,[a] Anjian Lan,[a] Feilong Jiang,*[a] and Maochun Hong[a]

**Keywords:** Nickel / Carboxylate ligands / Coordination polymers / Magnetic properties / Luminescence

The two new metal-organic coordination frameworks $[Ni_2(pydc)_2(4,4'\text{-bpy})(H_2O)_4]_n\cdot 0.5n(4,4'\text{-bpy})2H_2O$ (**1**) and $[Ni_2(pydc)_2(2,2'\text{-bpy})_2(H_2O)_2]_n\cdot 2nH_2O$ (**2**) ($H_2$pydc = pyridine-3,4-dicarboxylic acid; bpy = bipyridine) have been synthesised under hydrothermal conditions and characterised by single-crystal X-ray diffraction analysis. The structure of **1** contains parallel rectangular channels that accommodate large 4,4′-bpy guests while that of **2** contains vertical channels coordinated to 2,2′-bpy ligands. Their magnetic analyses show that they exhibit different magnetic interactions. The red shifts of the peak in their emission spectra relative to those of the the free ligands could be attributable to the metal–ligand coordination.

## Introduction

Recently, there has been much effort devoted to developing coordination frameworks with special and accessible cavities for use in catalysis, separations, sensors and electronics.[1,2] The assembly of pre-selected building blocks represents a new approach to the formation of novel frameworks, and multidentate carboxylate ligands are widely adopted for the construction of coordination frameworks owing to their rich coordination modes.[3–5] Another common ligand is bipyridyl, which not only acts as a space filler but also provides potential π–π stacking interactions that increase the stability of the framework. It is interesting that mixed ligands can be combined to construct a great variety of frameworks, such as two-dimensional (2D) layers and three-dimensional (3D) networks, including channel-like, interpenetrating and host–guest structures. To the best of our knowledge, 2D layers with parallel channels filled with guests have seldom been reported. In addition, the effect of co-ligands on the final structures is less common. Pyridine-3,4-dicarboxylate (pydc) ligands containing different donor atoms in the 1-, 3- and 4-positions are expected to form more diverse coordination frameworks.[6,7] To investigate the cooperation between pydc and co-ligands, we have explored their assembly with transitional metal ions. Here we report the syntheses, crystal structures and magnetic and photophysical properties of two polymeric complexes with interesting frameworks, namely $[Ni_2(pydc)_2(4,4'\text{-bpy})(H_2O)_4]_n\cdot 0.5n(4,4'\text{-bpy})2H_2O$ (**1**) and $[Ni_2(pydc)_2(2,2'\text{-bpy})_2(H_2O)_2]_n\cdot 2nH_2O$ (**2**) (bpy = bipyridine).

## Results and Discussion

The hydrothermal reaction of $NiCl_2\cdot 6H_2O$, $H_2$pydc and 4,4′-bpy or 2,2′-bpy in a molar ratio of about 1:1:1 yielded green crystals of **1** or **2**, respectively. X-ray single-crystal analysis revealed that the structure of **1** consists of 2D layers with parallel channels, which are stacked by hydrogen bonding. Each $Ni^{II}$ ion is six-coordinate with two N atoms from 4,4′-bpy and pydc ligands [Ni–N = 2.087(6)–2.105(7) Å] and four O atoms from two terminal water molecules and two pydc monodentate carboxylate groups [Ni–O = 2.046(5)–2.130(5) Å], which provide a distorted octahedral coordination geometry (Figure 1). Four pairs of $Ni^{II}$ ions are linked by 4,4′-bpy ligands that act as four edges, which are further linked by four three-connecting pydc ligands in a *syn-syn* bis-monodentate mode to form a cubane-like building block (Figure 2). These building blocks are extended through the Ni–O bonds to form a 2D double-layered framework. Consequently, this gives rise to novel parallel rectangular channels ($11.99\times 7.92$ Å$^2$) along the *a* axis (Figure 3). It is interesting that 4,4′-bpy acts not only as a bridging linker but also as a guest that is accommodated within each channel in a stacked arrangement. There are π–π stacking interactions between the pyridyl rings of adjacent 4,4′-bpy guests, with a face-to-face distance of 3.263 Å; this distance consolidates the stacking. The dihedral angle between the mean plane of the pyridyl rings and the transect plane of the channel is 59.0°. The 2D layers are stacked by hydrogen bonding between the oxygen atoms of the lattice water, coordinated water and carboxylate groups. However, van der Waals interactions are not

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

observed between the 4,4′-bpy guests and the channels – the closest distance is 5.66 Å.

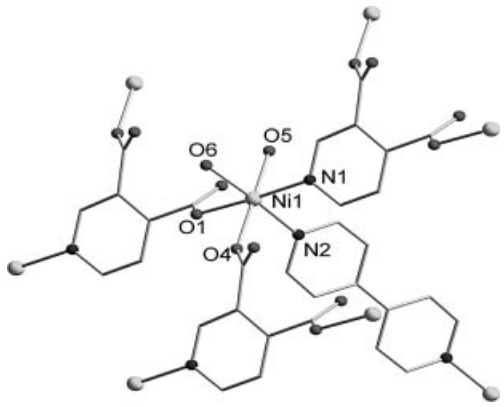

Figure 1. Coordination environments of $Ni^{II}$ atoms in compound **1**.

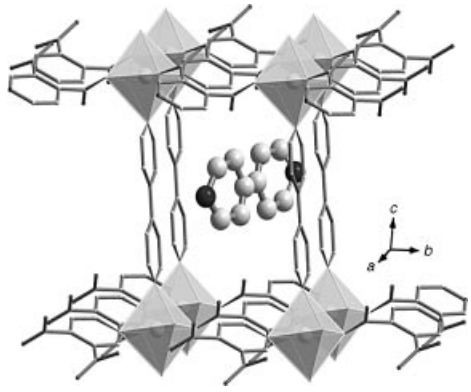

Figure 2. Cubane-like building block in **1** showing the Ni coordination octahedra and 4,4′-bpy guests.

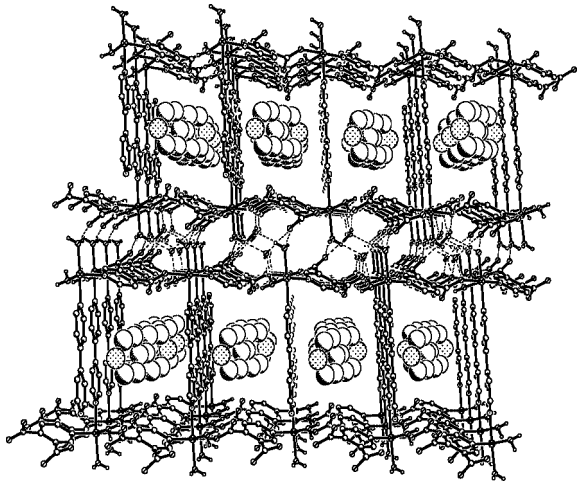

Figure 3. Packing structure of compound **1** along the *a* axis.

In compound **2**, two independent $Ni^{II}$ ions are both in distorted octahedral coordination geometries. Each of them is coordinated by three N atoms from 2,2′-bpy and pydc ligands [Ni–N = 2.058(5)–2.128(5) Å] and by three O atoms from a coordinated water molecule and two pydc carboxylate groups [Ni–O = 2.069(5)–2.094(5) Å] (Figure 4). The two independent $Ni^{II}$ ions are both bridged by two pydc ligands by *anti-syn* bis-monodentate carboxylate groups, which results in two types of binuclear units ($Ni1\cdots Ni1^{i}$ = 5.330 Å and $Ni2\cdots Ni2^{ii}$ = 5.581 Å; symmetry codes: *i*: 1 – *x*, 1 – *y*,1 – *z*; *ii*: 2 – *x*, –*y*, –*z*). Furthermore, every four binuclear units are connected through their pydc spacers alternately to form a large rectangular grid (7.3 × 10.3 $Å^2$), as shown in Figure 5. Each $Ni^{II}$ ion is attached by a chelating bpy ligand within the rectangular grid. There are π–π stacking interactions between the 2,2′-bpy pyridyl rings and the pydc aromatic rings, with face-to-face distances of 3.03–3.40 Å. The rectangular grids stretch to a 2D layer parallel to the *bc* plane in a tiled manner. The interlayer free water molecules are hydrogen bonded to the O atoms of the pydc carboxylate groups or coordinated water molecules in the adjacent layers (Figure 6). These 2D layers are stacked along the *c* axis into a 3D supramolecular architecture through hydrogen bonding.

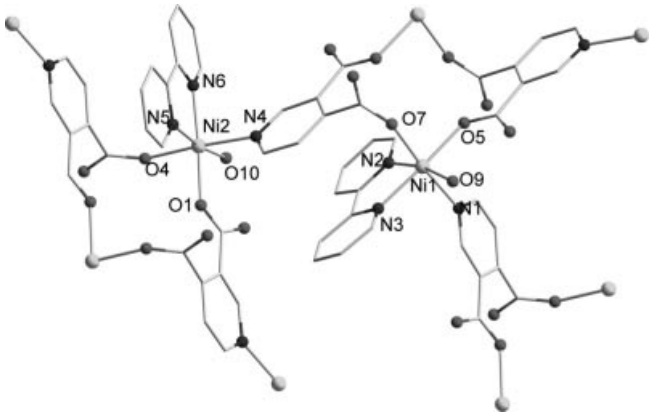

Figure 4. Coordination environments of the $Ni^{II}$ atoms in compound **2**.

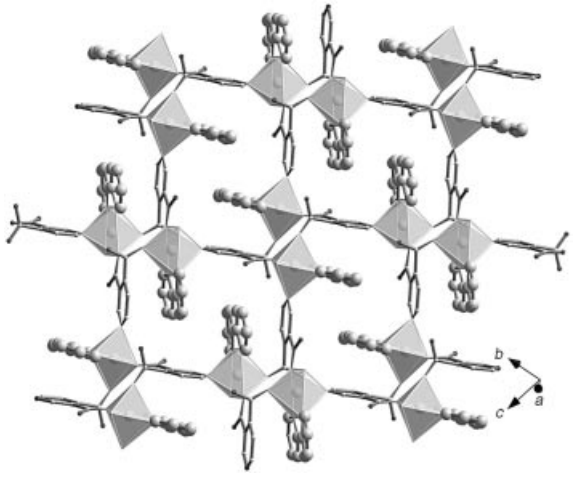

Figure 5. View of the 2D layer in compound **2**.

To investigate their thermal stabilities, thermogravimetric analyses (TGA) of **1** and **2** were carried out at a heating rate of 10 °C $min^{-1}$ under $N_2$. Compound **1** shows a two-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

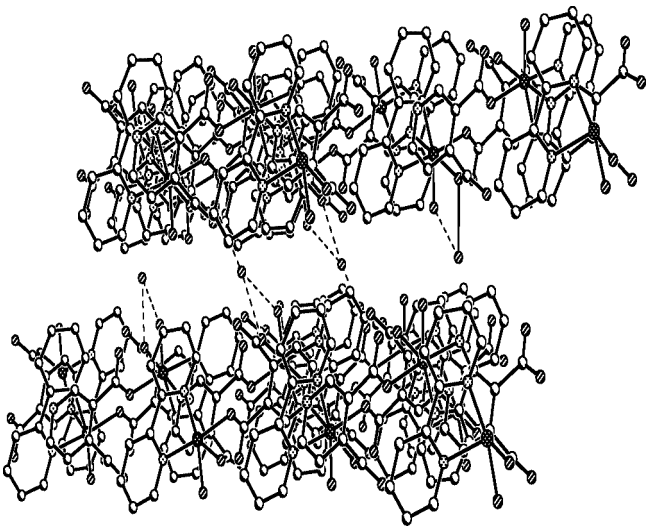

Figure 6. Packing structure of compound **2**.

step weight loss between 150 and 400 °C. The first weight loss between 150 and 230 °C cannot be distinguished clearly from the second one as the coordinated water molecules are involved in the dehydration process (observed: 14.36%; expected: 13.68%), thus implying that the big guest molecules (4,4′-bpy) cannot depart freely without the collapse of the coordination channels. The second step between 230 and 400 °C is assigned to the decomposition of organic ligands in a continuous fashion. The thermal behaviour of compound **2** shows a two-step weight loss between 145 and 430 °C. The first weight loss between 145 and 200 °C corresponds to the dehydration process (observed: 8.4%; expected: 8.6%). The second step between 290 and 430 °C is also assigned to the decomposition of organic ligands.

Temperature-dependent magnetic susceptibilities of compounds **1** and **2** were measured between 5 and 300 K (Figure 7). At room temperature, $\chi_m T$ is 2.03 $cm^3 mol^{-1} K$ for **1** and 2.14 for **2**, which is slightly higher than the expected value of 2.00 $cm^3 mol^{-1} K$ for two uncoupled spin-only $Ni^{II}$ ions ($S$ = 1/2, $g$ = 2). For **1**, $\chi_m T$ is almost constant from 300 K to 36 K, then increases as the temperature is lowered and reaches a maximum value of 2.14 $cm^3 mol^{-1} K$ at 12 K. Finally, it decreases to 1.75 $cm^3 mol^{-1} K$ at 5 K, which shows that there may be both weak ferromagnetic interactions and single-ion zero-field-splitting (D) of isolated $Ni^{II}$ ions. For **2**, the observed $\chi_m T$ value decreases slightly to 1.95 $cm^3 mol^{-1} K$ from 300 K to 40 K, and then quickly decreases to 1.11 $cm^3 mol^{-1} K$ at 5 K, which suggests that the global features of **2** are characteristic either of weak antiferromagnetic intramolecular interactions and/or of the presence of single-ion zero-field-splitting of isolated $Ni^{II}$ ions. In view of the complicated 2D structures of **1** and **2**, it is very difficult, even impossible, to estimate the magnitude of the magnetic coupling in this system. Therefore, two different simple treatments were carried out by using the Fisher model [Equation (1)] or by using the D parameter [Equation (2)] considering only a simple $Ni^{II}$ ion.[8,9]

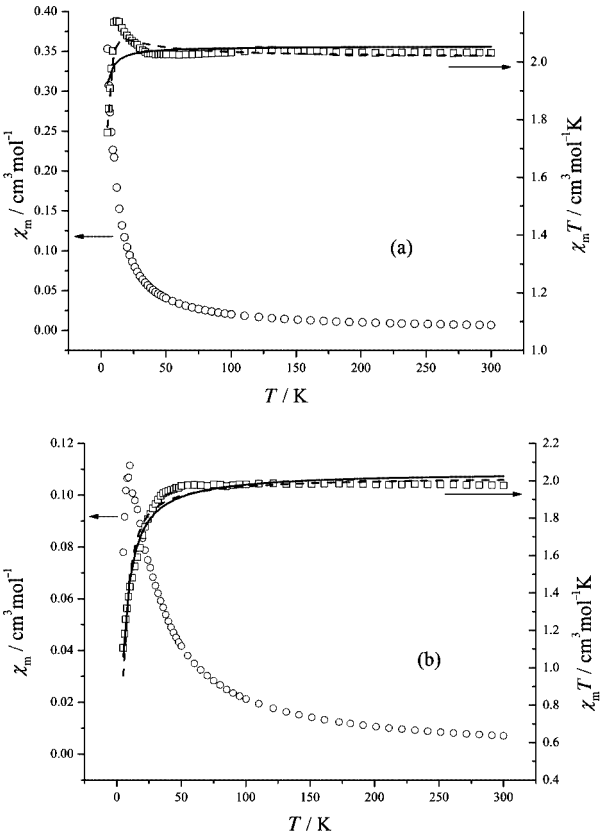

Figure 7. Plots of $\chi_m$ (○) and $\chi_m T$ (□) vs. $T$ for **1** (a) and **2** (b) (dotted lines are the best fit with parameter $D$ and solid lines the best fit with coupling parameter $J$).

$$\chi_m = \frac{\chi_{chain}}{1-(2zJ'\times\chi_{chain})/N\beta^2 g^2}$$
$$\chi_{chain} = \frac{Ng^2\beta^2 S(S+1)}{3kT}\frac{1+u}{1-u}$$
$$u = \coth\left[\frac{JS(S+1)}{kT}\right] - \left[\frac{kT}{JS(S+1)}\right] \quad (1)$$

$$\chi_m = \frac{2Ng^2\beta^2}{3k(T-\theta)}\left[\frac{2kT/D - 2kT\exp(-D/kT)/D + \exp(-D/kT)}{1+2\exp(-D/kT)}\right] \quad (2)$$

where the molecular field approximation ($zJ'$) for interchain interactions and a Weiss-like temperature correction ($\theta'$) are applied to account for intermolecular exchange effects between $Ni^{II}$ ions.

The best fit of the experimental data to Equations (1) and (2) yields $g$ = 2.09, $J$ = –0.17 $cm^{-1}$, $zJ'$ = –0.07 $cm^{-1}$ and $R = 6.3\times10^{-4}$ ($R = \Sigma[(\chi_m T)_{obsd} - (\chi_m T)_{calcd}]^2/\Sigma[(\chi_m T)_{obsd}]^2$), or $g$ = 2.01, $D$ = 11.58, $\theta$ = 3.22 and $R = 1.6\times10^{-4}$ for **1**; and $g$ = 2.05, $J$ = –1.76 $cm^{-1}$, $zJ'$ = –0.03 $cm^{-1}$ and $R = 2.0\times10^{-3}$, or $g$ = 2.01, $D$ = 20.26, $\theta$ = –8.57 and $R = 1.9\times10^{-3}$ for **2**. As expected, the fit is not very good, although we can conclude that compound **1**

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

exhibits a weak ferromagnetic interaction and **2** exhibits a weak antiferromagnetic interaction between $Ni^{II}$ ions.

The fluorescence spectra of compounds **1** and **2** in the solid state were measured at room temperature. The emission spectra of the two compounds are almost the same, as shown in Figure 8. Upon excitation at $\lambda = 427$ nm they produce intense orange fluorescence peaks at 600 nm and 602 nm, respectively, which are assigned to the metal-to-ligand charge transfer (MLCT) states.[10] As free $H_2$pydc exhibits a weak luminescence at around 490 nm in the solid state at room temperature, and free 2,2′-bpy and 4,4′-bpy display a weak luminescence at around 530 and 486 nm,[11,12] respectively, the red shifts and the luminescent enhancement for both **1** and **2** may be attributed to the coordination between the ligands and $Ni^{II}$.[11]

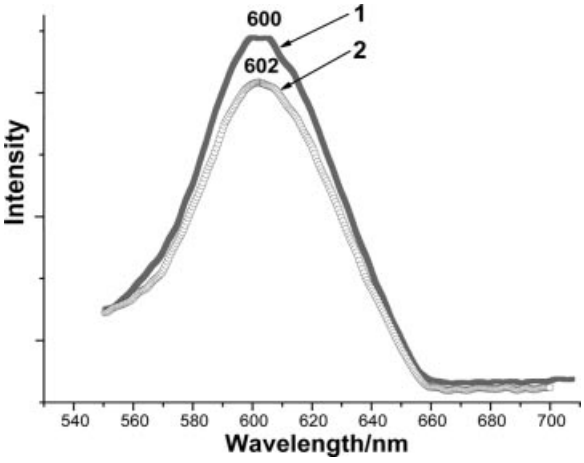

Figure 8. Fluorescent emission ($\lambda_{ex}$ = 427 nm) spectra of compounds **1** and **2** at room temperature.

## Conclusions

In summary, the assembly of $NiCl_2$, pydc and bipyridyl ligands results in two 2D layered coordination frameworks with different directional cavities. It is interesting that one structure contains parallel rectangular channels that accommodate large 4,4′-bpy guests whereas the other contains vertical channels with coordinated 2,2′-bpy ligands. The magnetic analyses show the presence of magnetic interactions. Excitation of compounds **1** and **2** produces an intense orange fluorescence.

## Experimental Section

**General:** All commercially available chemicals were of reagent grade and were used as received. Elemental analyses were determined with an Elemental Vario ELIII elemental analyzer. IR spectra were measured as KBr pellets with a Perkin–Elmer Spectrum One FTIR spectrometer in the range 200–4000 $cm^{-1}$. Thermogravimetric analyses were carried out with a Netzsch STA 449C unit from 30 to 900 °C at a heating rate of 10 °C $min^{-1}$ under nitrogen. Variable-temperature (5.0–300.0 K) magnetic susceptibility measurements were carried out in an external field of 10.0 kG with a Quantum Design PPMS model 6000 magnetometer. Fluorescent analyses were performed with a Perkin–Elmer LS55 luminescence spectrometer.

**Synthesis of 1:** A mixture of $NiCl_2 \cdot 6H_2O$ (71 mg, 0.30 mmol), $H_2$pydc (50 mg, 0.30 mmol) and 4,4′-bpy (47 mg, 0.30 mmol) in $H_2O$ (10 mL) was heated to 170 °C for 4 d. After cooling to room temperature, green crystals of **1** were collected by filtration, washed with distilled water and dried to afford a yield of 41% (41.56 mg) based on Ni. $C_{24}H_{22}N_4Ni_2O_{12}$ (675.84): calcd. C 42.65, H 3.28, N 8.29; found C 42.28, H 3.72, N 8.43. IR (KBr pellet): $\tilde{\nu}$ = 3286 (m), 1626 (s), 1574 (s), 1552 (s), 1489 (m), 1404 (s), 1223 (m), 1174 (m), 987 (m), 683 (m), 606 $cm^{-1}$ (m).

**Synthesis of 2:** A mixture of $Ni(OAc)_2 \cdot 4H_2O$ (0.25 mmol), $H_2$pydc (0.25 mmol) and bpy (0.25 mmol) in $H_2O$ (10.0 mL) was heated to 170 °C for 4 d and then cooled at a rate of 5 °C $h^{-1}$ to room temperature. Green plate-like crystals of **2** were isolated in 45% yield (46.80 mg) based on Ni. $C_{34}H_{30}N_6Ni_2O_{12}$ (832.06): calcd. C 49.08, H 3.63, N 10.10; found C 49.01, H 3.48, N 10.02. IR (KBr pellet): $\tilde{\nu}$ = 3444 (m), 3124 (m), 1614 (s), 1568 (s), 1477 (m), 1444 (m), 1390 (s), 1194 (w), 1026 (w), 827 (m), 768 (m), 683 (m), 656 $cm^{-1}$ (w).

**X-ray Crystallography:** Intensity data for compounds **1** and **2** were measured on a Siemens Smart CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 173 K. Empirical absorption corrections were applied by using the SADABS program for the Siemens area detector. The structures were solved by direct methods and all calculations were performed with the SHELXL-97 program. The metal atoms were found in the electron density map, and subsequent difference Fourier syntheses gave all the coordinates of the non-hydrogen atoms, which were refined anisotropically. All hydrogen atoms were added in the riding model and refined isotropically with C–H = 0.96 Å.

**Crystal Data for Compound 1:** Triclinic, space group $P\bar{1}$, $a$ = 7.0457(3) Å, $b$ = 7.9225(4) Å, $c$ = 16.3125(1) Å, $\alpha$ = 78.445(2)°, $\beta$ = 77.782(3)°, $\gamma$ = 75.833(3)°, $V$ = 852.20(6) $Å^3$, $Z$ = 2, $T$ = 293(2) K, $D_c$ = 1.539 g $cm^{-3}$, $\mu$(Mo-$K_\alpha$) = 1.179 $mm^{-1}$, $F$(000) = 407, 2969 independent reflections ($R_{int}$ = 0.0476) with $2\theta \leq 50.18°$. Refinement of 247 parameters converged at final $R_1$ [for selected data with $I > 2\sigma(I)$] = 0.0694, $wR_2$ = 0.2095 and $S$ = 1.107.

**Crystal Data for Compound 2:** Triclinic, space group $P\bar{1}$, $a$ = 11.5331(8) Å, $b$ = 12.0447(8) Å, $c$ = 14.4712(9) Å, $\alpha$ = 71.811(2)°, $\beta$ = 69.716(2)°, $\gamma$ = 68.285(2)°, $V$ = 1712.3(2) $Å^3$, $Z$ = 2, $T$ = 293(2) K, $D_c$ = 1.614 g $cm^{-3}$, $\mu$(Mo-$K_\alpha$) = 1.175 $mm^{-1}$, $F$(000) = 856, 5946 independent reflections ($R_{int}$ = 0.0491) with $2\theta \leq 50°$. Refinement of 511 parameters converged at final $R_1$ [for selected data with $I > 2\sigma(I)$] = 0.0640, $wR_2$ = 0.1679 and $S$ = 0.987.

CCDC-232641 (**1**) and -290754 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# "Pincer" N-Heterocyclic Carbene Complexes of Rhodium Functionalised with Pyridyl and Bipyridyl Donors

**Joseph A. Wright,[a] Andreas A. Danopoulos,*[a] William B. Motherwell,*[b] Robert J. Carroll,[b] Simon Ellwood,[c] and Jörg Saßmannshausen[d]**

**Keywords:** Rhodium / Carbene ligands / Tridentate ligands / N ligands / Ligand design

The "pincer"-type carbene complexes Rh(C–N–C)Cl and Rh(C–N–N)Cl [C–N–C = 3,3′-diaryl-1,1′-pyridine-2,6-diylbis-(imidazol-2-ylidene), C–N–N = 1-aryl-3-(2,2′-bipyridin-6-yl)-imidazol-2-ylidene] have been prepared and characterised by spectroscopic and diffraction methods. They bind CO to give cationic complexes but are inert to $H_2$. Both oxidatively add $CH_2Cl_2$ to give octahedral $Rh^{III}$ complexes. Theoretical calculations provide insight into the bonding of the Rh(C–N–C)Cl and Rh(C–N–N)Cl complexes.

## Introduction

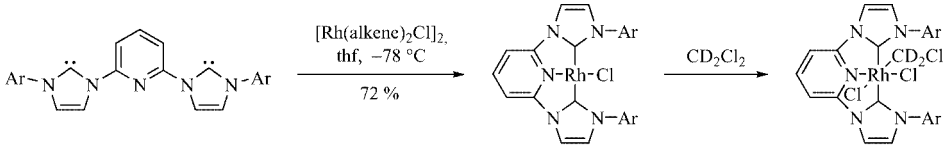
Since the development of the first route to free N-heterocyclic carbenes (NHCs),[1] ligands based around the stabilised-carbene core have become a major focus of research activity. Interest in N-heterocyclic carbene (NHC) metal complexes is now expanding to the study of new versatile ligand topologies with "classical" functional groups, which have shown promising spectator characteristics.[2] One of these is the "pincer" architecture, which provides a preorganised backbone capable of blocking meridional or pseudo-meridional coordination sites of the metal atom, leaving the remaining available for catalysis.[3] "Pincer" phosphane, amine, amide, imine, thioether and oxazoline complexes have been extensively studied and show very useful properties,[4] for example, unusually high thermal and air stability, stabilisation of uncommon oxidation states, stabilisation of unstable fragments on the metal atom, helical chirality and catalytic activity.

As part of our ongoing studies involving the use of the versatile "pincer" ligand 3,3′-diaryl-1,1′-pyridine-2,6-diylbis(imidazol-2-ylidene) (C–N–C),[5] we now report the formation and reactivity of rhodium(I) and rhodium(III) species based on this ligand system. We also detail the synthesis of a novel bipyridylcarbene ligand (C–N–N) and the formation of the derived rhodium complexes.

## Results and Discussion

### (C–N–C)$Rh^{I}$ and -$Rh^{III}$ Complexes

Interaction of the free carbene **1** with $[Rh(alkene)_2Cl]_2$ (alkene = ethene, cyclooctene) in THF at either room temperature or –78 °C gave a rapid colour change from orange to deep purple (Scheme 1).



Scheme 1. Synthesis of rhodium complexes **2** and **3** (alkene = $C_2H_4$, $C_8H_{14}$; Ar = 2,6-*i*$Pr_2C_6H_3$).

Following removal of the solvent, a deep purple microcrystalline solid was obtained, which was sparingly soluble in benzene but readily re-dissolved in THF. The planar symmetry of the complex was supported by NMR spectroscopy. The proton spectrum in [$D_8$]THF showed two doublets at δ = 1.15 and 1.44 ppm (12 H each), along with a single septet at δ = 3.06 ppm (4 H), supporting the pres-

ence of equivalent isopropyl groups on the bulky DiPP [2,6-(diisopropyl)phenyl] groups. The $^{13}C\{^1H\}$ NMR spectrum also is in agreement with a symmetric structure; however, the $C_{NHC}$ signal was not observed. Crystals of **2** suitable for X-ray diffraction were grown by slow diffusion of petroleum ether into a THF solution of the complex (Figure 1).

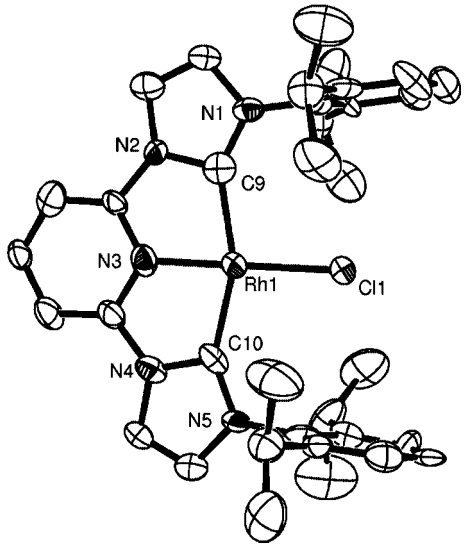

Figure 1. ORTEP representation of the structure of **2** showing 50% probability ellipsoids with hydrogen atoms omitted for clarity. Selected bond lengths [Å] and angles [°] with estimated standard deviations: Rh(1)–Cl(1) 2.331(3), Rh(1)–N(3) 1.955(8), Rh(1)–C(9) 2.001(10), Rh(1)–C(10) 1.979(9); N(3)–Rh(1)–Cl(1) 178.4(3), N(3)–Rh(1)–C(9) 78.5(4), N(3)–Rh(1)–C(10) 79.4(4), C(9)–Rh(1)–Cl(1) 101.2(3), C(10)–Rh(1)–Cl(1) 100.8(3).

The coordination sphere around the metal atom is essentially square-planar. The rhodium centre lies 0.027(4) Å out of the mean plane defined by the coordinating atoms. The Rh–$C_{NHC}$ bond lengths [2.001(10) and 1.979(9) Å] are typical for rhodium(I)–$C_{NHC}$ bond lengths. Complex **2** constitutes the first structurally characterised dicarbene complex of $Rh^I$ in which the coordination sphere is comprised of non-π-acidic ligands. The synthesis of the analogous [(C–N–C)Rh(CO)]($PF_6$), where C–N–C = 3,3′-dialkyl-1,1′-pridine-2,6-diylbis(imidazol-2-ylidene) (alkyl = methyl, ethyl, benzyl) has been recently reported, together with reactivity studies towards the oxidative addition of methyl iodide.[6] In addition, (C–N–C)$RhBr_3$ has been prepared by reaction of the corresponding imidazolium salt with $[Rh(COD)Cl]_2$ and triethylamine in acetonitrile.[7]

Dissolution of complex **2** in $CD_2Cl_2$ initially gave a purple solution, which became yellow within a few minutes. The NMR spectra of this solution showed a lowering of the molecular symmetry of the new complex compared to **2**. It comprised two signals for the methine groups (integrating for 2 H each), along with four signals for the methyl groups of the *i*Pr groups (each integrating for 6 H). However, the signals assigned to the pyridine and imidazol-2-ylidene backbones retained the same appearance as in the starting material. These changes are in line with oxidative addition to the metal centre and consistent with the structure proposed for **3** in Scheme 1. On standing, crystals of **3** formed from the $CD_2Cl_2$ solution, and these were suitable for a single-crystal diffraction study (Figure 2).

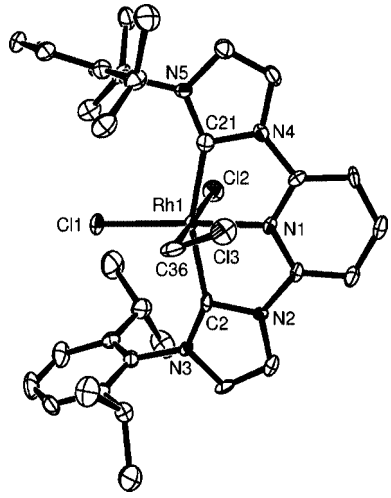

Figure 2. ORTEP representation of the structure of **3** showing 50% probability ellipsoids with hydrogen atoms and one molecule of $CD_2Cl_2$ omitted for clarity. Selected bond lengths [Å] and angles [°] with estimated standard deviations: Rh(1)–Cl(1) 2.3656(15), Rh(1)–Cl(2) 2.5164(16), Rh(1)–C(36) 2.075(6), Rh(1)–N(1) 1.978(4), Rh(1)–C(21) 2.034(6), Rh(1)–C(2) 2.040(6); N(1)–Rh(1)–Cl(1) 177.68(15), N(1)–Rh(1)–C(21) 79.1(2), N(1)–Rh(1)–C(2) 79.2(2), C(36)–Rh(1)–Cl(2) 177.22(19).

Complex **3** adopts an unsymmetrical distorted octahedral geometry, with the tridentate "pincer" occupying meridional sites with the remaining sites being occupied by two *cis*-chlorine atoms and the $CH_2Cl$ group. The Rh–$C_{NHC}$ bond lengths in complexes **2** and **3** are the same within the observed esds [averages of 1.990(13) and 2.037(8) Å, respectively]. However, the rhodium–chloride distances for the chloride ion bound *trans* to $N_{pyridine}$ are significantly different: the Rh–$N_{pyridine}$ bond in **3** [2.3656(15) Å] is longer than that in **2** [2.331(3) Å]. This is presumably due to the more crowded environment around the metal atom in the octahedral complex **3**. The two Rh–Cl distances in **3** are also significantly different from each other: the Cl ion *trans* to the $CD_2Cl$ group is approximately 0.15 Å further from the Rh atom than that *trans* to the $N_{pyridine}$ atom.

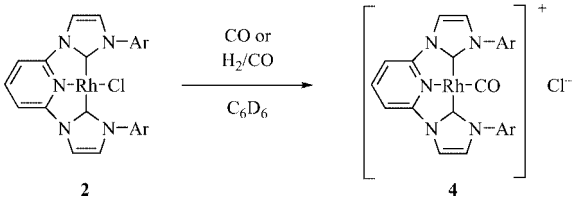
Complex **2** showed oxidative reactivity with a range of alkyl halides and pseudohalides. For example, addition of methyl iodide, 1,1,1-trichloroethane, benzyl chloride or methyl triflate to **2** in THF led to colour changes from purple to light yellow. The time taken for these reactions varied from seconds ($CH_3I$) to overnight (1,1,1-trichloroethane), presumably due to the differing reactivity of the C–halide bond. The NMR spectra of all products demonstrated the same lowering of symmetry as seen in **3**, although additional changes were also seen which could not be readily assigned. Addition of phosgene to **2** also gave a rapid and clean oxidative addition, leading to a stable unsymmetrical product. Complex **2** also reacted very fast with oxygen both in solution and in the solid state; the organometallic product from the oxidation has not been characterised.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In contrast to the rapid reactions observed with alkyl halides and oxygen, complex **2** was unreactive towards other potential reagents for oxidative addition. No reaction was observed with triethylsilane, phenyldiazomethane or PhS=CHPh.[4e] In all cases, $^1$H NMR spectra indicated that the starting material was unchanged. Similarly, no reactivity was seen with benzene (heating solutions of the complex in $C_6D_6$ in a sealed system to over 150 °C or exposure of the solution to UV light). Attempts to derivatise **2** by substitution of the chloride ion with organolithium compounds and Grignard reagents under various conditions were likewise unsuccessful.

### Reactivity with CO

Hydroformylation is a major industrial process, and (phosphane)rhodium complexes are widely used for the formation of short-chain ($C_2$ to $C_5$) aldehydes under these conditions.[8] However, some phosphane complexes are unsuitable for use with other substrates due to thermal degradation. The development of novel rhodium-based hydroformylation catalysts for heavier alkenes ($C_8$ and higher) remains a challenge. As a probe for potential hydroformylation activity, the reactivity of **2** towards synthesis gas and carbon monoxide was studied (Scheme 2).



**2** **4**

Scheme 2. Reaction of complex **2** with CO (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$).

Bubbling a mixture of $H_2$/CO (1:1) through a $C_6D_6$ solution of **3** resulted in a fast irreversible colour change from purple to pink. Evaporation of the solvent from the mixture gave a light pink, air-stable complex **4** which is noticeably more soluble in $C_6D_6$ than the parent complex. $^1$H NMR spectra indicate that the products obtained with CO and CO/$H_2$ are identical; as a confirmation of this, no reaction was observed with hydrogen gas alone. The $^1$H or $^{13}$C{$^1$H} NMR spectra of **4** show the same symmetry to **2**. However, in the $^1$H NMR spectrum, a significant change occurs in the shift of one of the imidazole backbone signals (from $\delta$ = 8.15 ppm to $\delta$ = 10.42 ppm on coordination of CO). The electrospray mass spectrum of **4** shows a single signal at *m*/*z* = 662.5, consistent with an adduct of the (pincer)rhodium core and CO. Complex **4** also shows only a single IR stretch at 1968 cm$^{-1}$. This compares with 1982 cm$^{-1}$ reported for [Rh(C–N–C)(CO)](PF$_6$) and 1980 cm$^{-1}$ for [Rh(P–N–P)(CO)]Cl {P–N–P = 2,6-bis[(diphenylphosphanyl)methyl]-pyridine}.[6,9] Attempts to grow single crystals of **4** were unsuccessful, and anion exchange also failed to give useful products.

Whilst the reactivity of **4** with carbon monoxide was rapid, the high stability of the product indicated possible problems in hydroformylation. NMR-scale addition of ethene to **2** showed no reaction. The hydroformylation activity was investigated using synthesis gas and styrene. No reaction was observed under a range of conditions, and a pink-coloured solution was recovered. Thus, it seems likely that under hydroformylation conditions an irreversible coordination of CO occurs to give **4**, whilst **2** will not bind alkenes or hydrogen.

### Bipyridyl NHC Ligands

Even though the C–N–C ligand **1** is considered a strong σ-donor, its limitations became apparent from the inactivity of **2** in hydroformylation which could be ascribed to the low lability of the Rh–$C_{NHC}$ bond hindering the formation of coordinatively unsaturated catalytic sites. In addition, due to the strong σ-donating ability of the NHC donors, **1** may be better suited for the stabilisation of Rh$^{III}$ rather than the promotion of Rh$^{I}$–Rh$^{III}$ catalytic cycles. Therefore, we decided to explore the chemistry of alternative "pincer" ligand designs by replacing one of the NHC donors of the C–N–C system with another classical donor. Whilst there is clearly a large range of potential ligands which could be constructed around this motif, we have concentrated on an NHC–bipyridyl system **7** (Scheme 4). Recently, Milstein has reported nonsymmetrical pincer-type ligands bearing phosphane and amine wingtips.[10]

The necessary bromide **4** is available in three steps from commercially available 2,2′-bipyridine.[11,12] Quaternisation of **4** with the imidazole **5** (Scheme 3) proceeds smoothly in the melt at 160 °C, giving moderate yields of the desired imidazolium bromide after purification and azeotropic drying. In contrast to the pincer imidazolium salts of the C–N–C type, deprotonation of **6** could not be readily achieved under the standard conditions[5a] which involved the reaction with KN(SiMe$_3$)$_2$ in THF at –30 °C, followed by addition of toluene (to precipitate the KBr formed in the reaction). This method gave only low yields of **7** (less than 5%). As an alternative to deprotonation, we explored the reductive deprotonation of the imidazolium salt with potassium metal, which has recently been used for the preparation of IMes from (IMesH)$^+$Cl$^-$.[13] This methodology, when applied to the preparation of **7**, resulted in improved isolated yields (ca. 30%) allowing the study of the coordination chemistry of **7**. The structure of **7** was also determined crystallographically (Figure 3).

In common with other free-carbene solid-state structures,[14] the free-carbene and pyridine rings adopt a *trans* arrangement. The three donor-atom-containing rings are virtually coplanar, with interplane angles of 3.3(2)° (carbene–pyridine) and 2.7(2)° (pyridine–pyridine). The single "wingtip" aromatic ring is nearly perpendicular to the rest of the ligand, with an interplane angle of 84.64(11)° between this and the imidazol-2-ylidene ring.

The imidazolium salt **6** has also been successfully used for the synthesis of the (carbene)silver complex **8** in good yields, by the reaction with $Ag_2O$ in dichloromethane in

4 5 6 8

Scheme 3. Formation of the "bipy" salt **6** and attempt to deprotonate (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$).

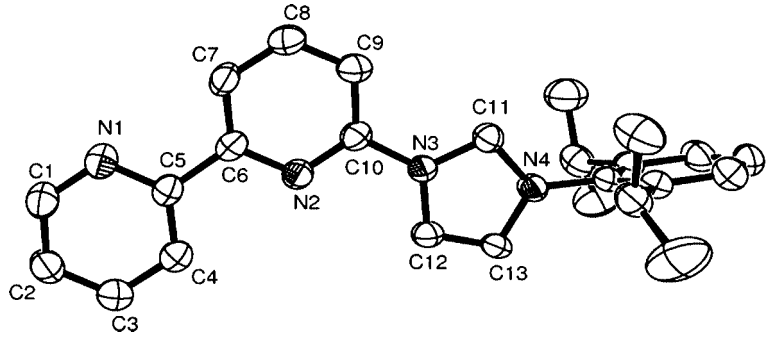

Figure 3. ORTEP representation of the structure of **7** showing 50% probability ellipsoids with hydrogen atoms omitted for clarity. Selected bond lengths [Å] and angles [°] with estimated standard deviations: C(11)–N(4) 1.361(3), C(11)–N(3) 1.375(3), C(5)–C(6) 1.486(4),C(10)–N(3) 1.427(3); N(4)–C(11)–N(3) 101.3(2).

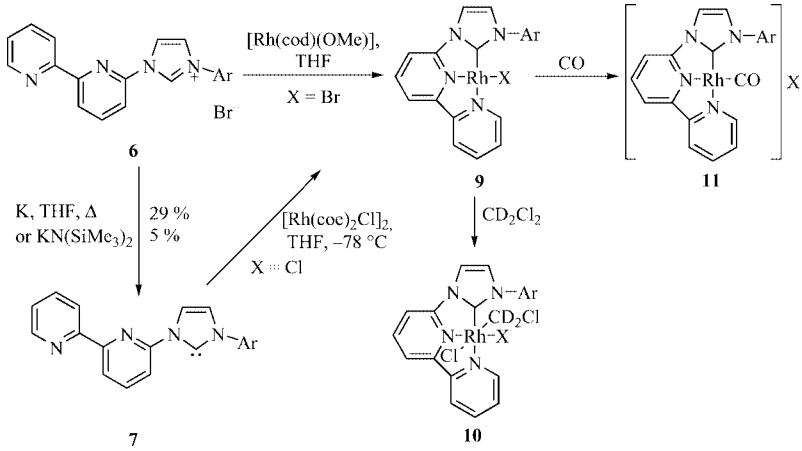
the presence of molecular sieves (4 Å). The (carbene)silver complex was characterised by spectroscopic (NMR and MS) and analytical methods.

The Rh(C–N–N)X [X = Cl (**9b**), Br (**9a**)] complexes have been synthesised by two different routes on the basis of either the reaction of **6** with [(COD)Rh(OMe)]$_2$ (**9b**) or the reaction of **7** with [(COE)$_2$RhCl]$_2$ (**9a**) (Scheme 4).

The green, very air-sensitive complex was characterised by analytical and spectroscopic methods. Even though it is sparingly soluble in non-chlorinated solvents, meaningful $^1$H NMR spectra of **9a** were recorded in [D$_8$]THF. The appearance of peaks assignable to the *i*Pr groups of the DiPP group supports the presence of a plane of symmetry in the molecule. However, the poor solubility of **9a** prevented the collection of strong $^{13}$C{$^1$H} NMR spectroscopic data even after prolonged acquisition times. It is interesting to note that silver transmetallation reactions, which have been commonly used for the synthesis of NHC–Rh complexes were not successful here due to the reactivity of the initially formed Rh$^I$ product with dichloromethane which is the



6 9 11 7 10

Scheme 4. Generation of free carbene **7** and complexes **9a** and **9b** (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$; **9a**: X = Br; **9b**: X = Cl).

commonly used solvent in reactions of this type (vide infra). The structure of the complex was unequivocally established crystallographically (Figure 4).

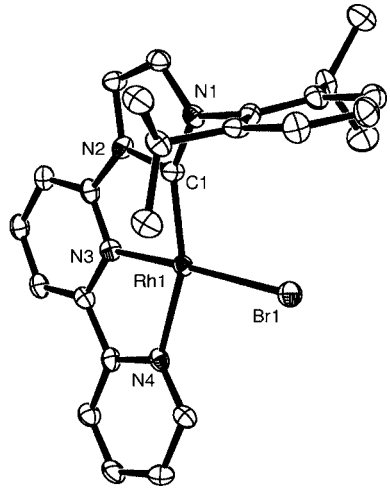

Figure 4. ORTEP representation of the structure of **9a** showing 50% probability ellipsoids with hydrogen atoms omitted for clarity. Selected bond lengths [Å] and angles [°] with estimated standard deviations: C(1)–Rh(1) 1.957(6), N(3)–Rh(1) 1.941(5), N(4)–Rh(1) 2.116(5), Br(1)–Rh(1) 2.4904(8); N(3)–Rh(1)–Br(1) 172.26(14), C(1)–Rh(1)–Br(1) 104.30(17), N(4)–Rh(1)–Br(1) 97.27(13).

The rhodium centre adopts a distorted square-planar geometry, with the rhodium atom being 0.034(2) Å out of the plane of the donor atoms. The terminal pyridine nitrogen atom N(4) is approx. 0.15 Å further from the metal centre than N(3). The Rh–$C_{NHC}$ bonds [1.957(6) Å] are slightly shorter than those reported for **2**. In comparison to the recently reported blue Rh(terpy)Cl,[15] the corresponding Rh–$N_{pyridine}$ bonds in **9a** are longer.

### Reactivity of 9a

The replacement in complex **2** of one NHC by the poorer σ-donating pyridine group to give **9** is expected to reduce the electron density on the metal atom. However, it should be more electron-rich than the metal atom in Rh(terpy)Cl.[15] In the latter, $Rh^{I}$ has been classified as electron-rich on the basis of the oxidation potential of the complex, as measured by CV and DFT calculations. Complex **9a** reacts easily with dichloromethane at room temperature giving rise to the oxidative addition adduct **10** (Scheme 4), which was characterised by NMR spectroscopy in a way analogous to **3**. It also reacts fast with CO (1 bar, room temperature). The NMR spectra of the product suggest the formation of the CO adduct **11** (Scheme 4). The $^{1}H$ NMR spectrum of **11** shows a number of changes in the aromatic region, but significantly retains the single pair of doublets in the *i*Pr region: as before, this indicates retention of the plane of symmetry in the product. The CO adduct appears to be stable, and in contrast to **9a** it can be exposed to air and chlorinated solvents without degradation.

Attempts to carry out hydroformylation using **9** were not successful. Addition of $CO/H_2$ to a solution of the complex (0.2 mol-%) and styrene in toluene gave a rapid colour change to light orange. After 3 h at 70 °C under 9 bar of $CO/H_2$, analysis of the reaction mixture by GC-MS showed no hydroformylation products.

### Theoretical Studies of Complexes 2 and 9b

In order to obtain a further insight into the bonding in the new (pincer)$Rh^{I}$ complexes we performed DFT studies on **2** and **9b**. No symmetry restriction was imposed on the molecules. The Rh(C–N–C) and Rh(C–N–N) substructures in the calculated optimised geometries of **2-dft** and **9b-dft** are in very good agreement with those observed in the crystal structures (see Supporting Information). Only the bulky DiPP substituent is slightly dislocated, presumably due to crystal-packing effects.

The HOMO orbital of both complexes has $d_{z^2}$ character. As expected, the LUMO of both **2-dft** and **9b-dft** reside on the π* system of the pyridine ligand, with some contribution of the metal atom. The HOMO–LUMO gap for **2-dft** of 2.92 eV is marginally larger than the gap for **9b-dft** (2.49 eV). For comparison, these values are much larger than the values reported for Rh(terpy)Cl (1.04 eV).[15] It is therefore plausible that this difference may lead to different reactivity of **2** and **9b** compared with Rh(terpy)Cl. This point is being investigated further in our laboratory.

For complex **2-dft**, the HOMO-1 has predominantly Cl($p_\pi$)/Rh($d_{zx}$) character, with some contribution of the pyridine ligand (see Supporting Information for plots of the orbitals). HOMO-2 is of similar character with some contribution from the NHC ligand to the Rh($d_{xy}$) atom. HOMO-3 is predominantly on the metal atom [Rh($d_{yz}$)] and HOMO-4 is predominantly on the DiPP ligands and the chloride ion.

For complex **9b-dft**, similar observations can be made: HOMO-1 is predominately of Cl($p_\pi$)/Rh($d_{zx}$) character, with some contribution of the pyridine ligand *trans* to the chloride ion. HOMO-2 is of similar character as HOMO-2 of **2-dft**; however, the pyridine ligand *trans* to the NHC is less involved in the molecular orbital. HOMO-3 is again similar to HOMO-3 of **2-dft**; again the pyridine ligand *trans* to the NHC is not involved in the molecular orbital. HOMO-4 is predominately on the DiPP ligand.

The electronic environment in the complexes was further investigated by Natural Bonding Orbital (NBO) analysis. In **2-dft**, the lone pair of the pyridine nitrogen atom is donating into an empty orbital of the Rh atom. One of the NHC ligands is donating into an empty orbital of the Rh atom and into the antibonding orbital of the other Rh–$C_{NHC}$ bond. However, unexpectedly, backdonation occurs from a filled $d_{yz}$ orbital of the metal atom to antibonding orbitals of both the NHC and the pyridine ligand. For complex **9b-dft**, similar observations have been made. The lone pairs of the pyridine nitrogen atoms are donating into an empty d-orbital of the metal atom. The nitrogen atom *trans* to the NHC is donating into the carbene–metal antibonding orbital. A smaller contribution to this bonding is made by the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nitrogen atom on the other pyridine ligand. As with **2-dft**, a filled d-orbital of the metal atom is donating into an C–N antibonding orbital of the NHC. Backdonation from a different filled d-orbital of the metal atom to the pyridine ligand *trans* to the chloride ion is also observed. Orbital representation of the NBO analysis for both complexes are detailed in the Supporting Information.

As expected, the LUMO of both **2-dft** and **9b-dft** reside on the π* system of the pyridine ligand, with some contribution of the metal atom. The higher-lying virtual orbitals of **2-dft** and **9b-dft** are almost exclusively localised on the ligands. Exceptions are the LUMO+6 of **2-dft** and LUMO+5 of **9b-dft**, which are metal-based. Metal-based high-lying LUMOs have been observed before, notably for the complex Rh(terpy)Cl (LUMO+5).[15]

## Conclusions

Highly reactive electron-rich $Rh^{I}$ complexes with the pyridine-based dicarbene and bipyridyl-based monocarbene rigid tridentate pincers and without any π-acidic co-ligands have been prepared and characterised by spectroscopic and diffraction methods. The complexes easily undergo oxidative addition reactions of C–halide bonds, but are resistant to oxidative addition of other less polar bonds (H–H, Si–H, C–H, etc.). The $Rh^{III}$ products obtained are extremely stable. The complexes also form stable adducts with the π-acidic CO, which are resistant to further reactions by alkenes, $H_2$, $O_2$, etc. The use of the new complexes as hydroformylation catalysts is hampered by rigid structures and stabilisation of the higher oxidation states by the strongly σ-donating ligand system. However, these "σ-loaded" rigid pincers may prove useful co-ligands in the stabilisation of higher oxidation states.

## Experimental Section

**General Methods:** Solvents were dried by standard methods[16] and either used directly or stored in ampoules with molecular sieves (4 Å). All air- or moisture-sensitive reactions were carried out under dry nitrogen using standard Schlenk techniques or in an M. Braun glove box. NMR spectroscopic data were recorded with Bruker AMX-300 and DPX-400 spectrometers, operating at 300 and 400 MHz ($^1$H), respectively. The spectra were referenced internally using the signal from the residual protio solvent ($^1$H) or the signals of the solvent ($^{13}$C). Mass spectra (electrospray ionisation) were obtained from acetonitrile solutions with a VG Biotec platform. The calculated isotopic envelopes agree well with the experimentally observed patterns. Commercial chemicals were from Acros, Aldrich, Lancaster and Avocado; the light petroleum ether had boiling range of 40–60 °C. The following starting materials were prepared as described in the literature: 3,3′-Bis(2,6-diisopropylphenyl)-1,1′-pyridine-2,6-diylbis(imidazol-3-ium) dibromide,[5b] 6-bromo-2,2′-bipyridine,[11,12] 3-(2,6-diisopropylphenyl)-1*H*-imidazole,[17] bis[μ-chlorobis(η$^2$-cyclooctene)rhodium(I)],[18] bis[μ-chlorobis(η$^2$-ethene)rhodium(I)][19] and bis[μ-methoxybis(η$^2$-cyclooctene)rhodium(I)].[20]

**3,3′-Bis(2,6-diisopropylphenyl)-1,1′-pyridine-2,6-diylbis(imidazol-2-ylidene) (1):** The synthesis was carried out by an improved version of the previously published procedure.[5b] Thus, the corresponding bis(imidazolium) salt (CH–N–CH)$Br_2$ (Ar = 2,6-*i*$Pr_2C_6H_3$) (6.89 g, 9.93 mmol) was suspended in THF (100 mL) in a large Schlenk tube, and cooled to –78 °C. A solution of potassium bis(trimethylsilyl)amide (4.32 g, 21.6 mmol) in THF (100 mL) was cooled to –78 °C and added to the salt suspension. The reaction mixture was warmed to room temperature overnight, the solvent evaporated and the residue dissolved in toluene (100 mL). The dark-brown solution was filtered through a pad of Celite®, and the volume reduced to ca. 20 mL. Dilution with petroleum ether (40 mL) led to the precipitation of the product, which was filtered off, washed with petroleum ether and dried under vacuum to yield a cream-colored solid (4.09 g, 77%). $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.20 (d, $J$ = 6.9 Hz, 12 H, Me), 1.29 (d, $J$ = 6.8 Hz, 6 H, Me), 3.01 [sept, $J$ = 6.9 Hz, 4 H, *C*H(CH$_3$)$_2$], 6.73 (d, $J$ = 1.7 Hz, 1 H, imidazole backbone), 7.16 (t, $J$ = 8.0 Hz, 1 H, central CH of pyridine), 7.25 (d, $J$ = 7.5 Hz, 4 H, aromatic CH), 7.35 (d, $J$ = 6.9 Hz, 1 H, aromatic CH), 7.38 (d, $J$ = 6.9 Hz, 1 H, aromatic CH), 8.17 (d, $J$ = 1.7 Hz, 2 H, imidazole backbone), 8.54 (d, $J$ = 8.0 Hz, 2 H, outer 2×CH of pyridine) ppm. $^{13}$C NMR (75.45 MHz, $C_6D_6$, 25 °C): $\delta$ = 24.0 (Me), 24.4 (Me), 28.6 [*C*H(CH$_3$)$_2$], 111.7 (aromatic CH), 116.3 (aromatic CH), 122.8 (aromatic CH), 123.8 (aromatic CH), 129.3 (aromatic CH), 138.7 (aromatic C), 140.7 (aromatic C), 146.2 (aromatic CH), 152.6 (aromatic C), 220.4 (carbene) ppm.

**3,3′-Dimesityl-1,1′-pyridine-2,6-diylbis(imidazol-2-ylidene) (1b):** This was prepared according to a similar route to **1** from the salt (CH–N–CH)$Br_2$ (Ar = mesityl) (2.78 g, 4.00 mmol) and potassium bis(trimethylsilyl)amide (1.68 g, 8.42 mmol). After the reaction, the crude solid was dissolved in benzene (60 mL) and worked up as for **1**. This gave the product as a cream-colored solid (1.07 g, 60%). $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 2.12 (s, 12 H, Me), 2.14 (s, 6 H, Me), 6.44 (d, $J$ = 1.4 Hz, 2 H, imidazole backbone), 6.79 (s, 4 H, aromatic CH), 7.09 (t, $J$ = 7.6 Hz, 1 H, central CH of pyridine), 8.11 (d, $J$ = 1.4 Hz, 2 H, imidazole backbone), 8.54 (d, $J$ = 7.6 Hz, 2 H, outer 2×CH of pyridine) ppm. $^{13}$C (75.45 MHz, $C_6D_6$, 25 °C): $\delta$ = 18.1 (Me), 21.0 (Me), 111.5 (aromatic CH), 116.5 (aromatic CH), 119.7 (aromatic CH), 129.0 (aromatic C), 129.2 (aromatic C), 130.4 (aromatic CH), 135.3 (aromatic C), 138.9 (aromatic C), 140.7 (aromatic CH), 152.69 (carbene) ppm.

**[3,3′-Bis(2,6-diisopropylphenyl)-1,1′-pyridine-2,6-diylbis(imidazol-2-ylidene)]chlororhodium(I) (2):** A solution of carbene **1** (162 mg, 0.305 mmol) in THF (10 mL) was added to a suspension of bis[μ-chlorobis(η$^2$-ethene)rhodium(I)] (60 mg, 0.154 mg) in THF (5 mL), leading to an immediate colour change to dark purple. The solution was stirred under an oil bubbler for 90 min, before evaporation of the solvent. The residue was washed with petroleum ether (2×5 mL) to leave a dark purple solid (124 mg, 61%). Layering of a THF solution of this residue with an equal volume of petroleum ether led to the formation of X-ray quality crystals. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.14 (d, $J$ = 7.0 Hz, 12 H, Me), 1.44 (d, $J$ = 6.8 Hz, 12 H, Me), 3.06 [sept, $J$ = 6.9 Hz, 4 H, C*H*(CH$_3$)$_2$], 6.08 (d, $J$ = 8.1 Hz, 2 H, pyridyl CH), 6.42 (d, $J$ = 2.0 Hz, 2 H, imidazole backbone), 6.83 (d, $J$ = 2.0 Hz, 2 H, imidazole backbone), 7.19 (d, $J$ = 7.3 Hz, 4 H, aromatic CH), 7.33 (t, $J$ = 7.3 Hz, 2 H, aromatic CH), 7.45 (t, $J$ = 8.1 Hz, 1 H, pyridyl CH) ppm. $^{13}$C NMR (75.45 MHz, [D$_8$]THF, 25 °C): $\delta$ = 24.3 (Me), 24.5 (Me), 29.3 (Me), 104.8 (aromatic CH), 114.3 (aromatic CH), 123.7 (aromatic CH), 125.6 (aromatic CH), 126.8 (aromatic CH), 129.4 (aromatic CH), 137.3 (aromatic C), 146.3 (aromatic C), 152.7 (aromatic C) ppm; carbene signal not observed. $C_{35}H_{41}ClN_5Rh$ (670.10): calcd. C 62.73, H 6.17, N 10.45; found C 62.65, H 6.05, N 10.25.

**3,3′-Bis(2,6-diisopropylphenyl)-1,1′-pyridine-2,6-diylbis(imidazol-2-ylidene)dichloro(chloromethyl)rhodium(III) (3):** Dissolution of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rhodium(I) complex **2** (ca. 15 mg) in $CD_2Cl_2$ (0.75 mL) led to a rapid colour change from purple to light yellow. Upon standing, light yellow crystals suitable for X-ray diffraction formed in quantitative yield. $^1$H NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 0.96 (d, $J$ = 7.0 Hz, 6 H, Me), 1.11 (d, $J$ = 6.8 Hz, 6 H, Me), 1.15 (d, $J$ = 6.8 Hz, 6 H, Me), 1.21 (d, $J$ = 6.5 Hz, 6 H, Me), 2.55 [sept, $J$ = 6.7 Hz, 2 H, C*H*$(CH_3)_2$], 3.36 [sept, $J$ = 6.7 Hz, 2 H, C*H*$(CH_3)_2$], 7.07 (d, $J$ = 2.4 Hz, 2 H, imidazole backbone), 7.15 (d, $J$ = 7.6 Hz, 2 H, aromatic CH), 7.19 (d, $J$ = 8.1 Hz, 2 H, aromatic CH), 7.35 (t, $J$ = 7.6 Hz, 2 H, aromatic CH), 7.49 (dm, $J$ = 8.1 Hz, 2 H, pyridyl CH), 7.85 (d, $J$ = 2.4 Hz, 2 H, imidazole backbone), 8.12 (t, $J$ = 8.1 Hz, 1 H, pyridyl CH) ppm. $^{13}$C (75.45 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 22.9 (Me), 23.0 (Me), 26.0 (Me), 26.3 (Me), 28.4 [*C*H$(CH_3)_2$], 28.5 [C*H*$(CH_3)_2$], 68.1 ($CD_2Cl$) 106.1 (aromatic CH), 116.2 (aromatic CH), 123.3 (aromatic CH), 124.2 (aromatic CH), 126.3 (aromatic CH), 130.1 (aromatic CH), 134.4 (aromatic C), 141.3 (aromatic C), 145.2 (aromatic CH), 147.8 (aromatic C), 162.8 (aromatic C) ppm, carbene not observed.

**1-(2,2′-Bipyridin-6-yl)-3-(2,6-diisopropylphenyl)-3*H*-imidazol-1-ium Bromide (6):** 6-Bromo-2,2′-bipyridine (1.40 g, 5.95 mmol) and 1-(2,6-diisopropylphenyl)imidazole (1.46 g, 6.38 mmol) were placed in a glass ampoule which was sealed under vacuum. This was completely immersed in an oil bath at 150 °C for 6 d. After cooling to room temperature, the ampoule was opened and the brown residue was dissolved in dichloromethane. After evaporation of the solvent, the product was stirred with diethyl ether at 0 °C for several hours, the solvent removed by filtration and the solid dried in vacuo. This gave the product as a brown solid (2.27 g, 82%). $C_{25}H_{27}BrN_4$ (463.42): calcd. C 64.79, H 5.87, N 12.09; found C 64.31, H 5.98, N 11.92. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.19 (d, $J$ = 6.6 Hz, 6 H, Me), 1.32 (d, $J$ = 6.6 Hz, 6 H, Me), 2.46 [sept, $J$ = 6.6 Hz, 2 H, C*H*$(CH_3)_2$], 7.37 (d, $J$ = 7.5 Hz, 2 H, aromatic CH), 7.42 (br. s, 1 H, pyridyl CH), 7.59 (t, $J$ = 7.9 Hz, 1 H, aromatic CH), 7.68 (br. s, 1 H, pyridyl CH), 8.25 (t, $J$ = 7.9 Hz, 2 H, pyridyl CH), 8.62–8.75 (m, 3 H, pyridyl CH), 9.33 (d, $J$ = 7.9 Hz, 1 H, pyridyl CH), 9.37 (br. s, 1 H, imidazole backbone), 11.30 (s, 1 H, imidazolium salt) ppm. $^{13}$C NMR (74.45 MHz, $CDCl_3$, 25 °C): $\delta$ = 24.0 (Me), 24.1 (Me), 28.6 [*C*H$(CH_3)_2$], 116.9 (aromatic CH), 121.2 (aromatic CH), 123.5 (aromatic CH), 124.5 (aromatic CH), 125.5 (aromatic CH), 125.6 (aromatic CH), 129.8 (aromatic C), 131.9 (aromatic CH), 136.2 (aromatic CH), 142.2 (aromatic CH), 144.8 (aromatic C), 145.6 (aromatic C) ppm. MS (ESI+): $m/z$ = 155.0, 367.3, 170.0, 182.1, 196.1, 213.1, 352.2, 383.3 [$M^+$].

**1-(2,2′-Bipyridin-6-yl)-3-(2,6-diisopropylphenyl)imidazol-2-ylidene (7):** The salt **6** (1.02 g, 2.21 mmol) and potassium bis(trimethylsilyl)amide (0.56 g, 2.81 mmol) were stirred under nitrogen and cooled to –78 °C. Pre-cooled THF (35 mL) was added, and the solution stirred at low temperature for 1 h. It was warmed to –30 °C, then left to stand overnight. After evaporation of the solvent, the product was filtered through Celite® as a solution in toluene (20 mL). Reduction to a volume of 2 mL was followed by addition of petroleum ether (10 mL); cooling to –30 °C gave the product as a brown solid (36 mg, 4%). Better yields are obtained as follows: Potassium metal (348 mg, 8.9 mmol) was added to **6** (3.00 g, 5.25 mmol) in THF (120 mL) and the mixture heated to reflux overnight. After cooling to room temperature, the solution was filtered through Celite® and the solvent removed in vacuo. The solid residue was dissolved in toluene (70 mL), the solution filtered and the volume reduced to ca. 15 mL. After addition of petroleum ether (50 mL), the product was crystallised at –30 °C. Filtration and washing with petroleum ether (20 mL) gave the carbene as a brown solid (586 mg, 29%). $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.13 (d, $J$ = 6.9 Hz, 6 H, Me), 1.22 (d, $J$ = 6.8 Hz, 6 H, Me), 2.94 [sept, $J$ = 6.9 Hz, 2 H, C*H*$(CH_3)_2$], 6.66 (d, $J$ = 1.6 Hz, 1 H, imidazole backbone CH), 6.74 (ddd, $J$ = 1.1, 4.7, 7.4 Hz, 1 H, aromatic CH), 7.19–7.32 (m, 5 H, aromatic CH), 8.28 (d, $J$ = 1.7 Hz, 1 H, imidazole backbone CH), 8.48–8.56 (m, 3 H, aromatic CH), 8.66 (d, $J$ = 8.2 Hz, 1 H, aromatic CH) ppm. $^{13}$C NMR (75.45 MHz, $C_6D_6$, 25 °C): $\delta$ = 22.82 (Me), 23.17 (Me), 27.36 [*C*H$(CH_3)_2$], 113.80 (aromatic CH), 115.13 (aromatic CH), 117.63 (aromatic CH), 119.61 (aromatic CH), 121.56 (aromatic CH), 122.55 (aromatic CH), 127.07 (aromatic CH), 127.98 (aromatic CH), 135.19 (aromatic CH), 138.07 (aromatic CH), 145.01 (aromatic C), 148.27 (aromatic CH), 152.34 (aromatic C), 153.46 (aromatic C), 154.98 (aromatic C) ppm; carbene carbon signal not observed. X-ray quality colourless crystals were obtained by cooling solutions of **7** in toluene/petroleum ether (50:50) at –30 °C.

**[1-(2,2′-Bipyridin-6-yl)-3-(2,6-diisopropylphenyl)imidazol-2-ylidene]-silver(I) Bromide (8):** The imidazolium salt **6** (1.00 g, 2.16 mmol), molecular sieves (4 Å) (ca. 5 g) and $Ag_2O$ were suspended in the dark in $CH_2Cl_2$ (30 mL) and the mixture refluxed overnight. After cooling to room temperature, the solution was filtered through Celite® and the solvent removed in vacuo. The product was obtained as a pale brown solid (881 mg, 71%). $C_{25}H_{26}AgBrN_4$ (570.3): calcd. C 52.65, H 4.59, N 9.82; found C 52.15, H 4.44, N 9.68. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.21 (d, $J$ = 6.6 Hz, 6 H, Me), 1.34 (d, $J$ = 6.6 Hz, 6 H, Me), 2.57 [sept, $J$ = 6.6 Hz, 2 H, C*H*$(CH_3)_2$], 7.24 (br. s, 1 H, imidazole backbone CH), 7.36 (d, $J$ = 8.0 Hz, 2 H, aromatic CH), 7.43 (m, 1 H, aromatic CH), 7.54 (t, $J$ = 8.0 Hz, 1 H, central aromatic CH), 8.12 (t, $J$ = 7.4 Hz, 1 H, aromatic CH), 8.26 (br. s, 1 H, imidazole backbone CH), 8.30 (d, $J$ = 8.1 Hz, 2 H, aromatic CH), 8.61 (m, 2 H, aromatic CH), 8.78 (br. s, 1 H, aromatic CH) ppm. $^{13}$C NMR (75.45 MHz, $CDCl_3$, 25 °C): $\delta$ = 24.40 (Me), 24.50 (Me), 28.40 [*C*H$(CH_3)_2$], 115.07 (aromatic CH), 119.94 (aromatic CH), 121.18 (aromatic CH), 124.38 (aromatic CH), 124.50 (aromatic CH), 128.18 (aromatic C), 128.90 (aromatic C), 130.75 (aromatic CH), 140.36 (aromatic CH), 145.52 (aromatic C), 149.36 (aromatic CH), 172.20 (s, carbene) ppm. MS ($ES^+$): $m/z$ = 871.5 [carbene$_2$$Ag^+$].

**[1-(2,2′-Bipyridin-6-yl)-3-(2,6-diisopropylphenyl)imidazol-2-ylidene]-rhodium(I) Halide [Halide = Br (9a), Cl (9b)]:** The salt **6** (93 mg, 0.20 mmol) was suspended in THF (5 mL) and cooled to –78 °C, and a solution of bis[μ-methoxybis(η$^2$-cyclooctene)rhodium(I)] (49 mg, 0.10 mmol) in THF (5 mL) at –78 °C was added. The solution was warmed to room temperature and became red, then brown and finally dark green. A small amount of solid was filtered off, and the solution diluted with petroleum ether (15 mL). The resulting precipitate was filtered off, dissolved in THF (5 mL) and layered with petroleum ether (5 mL). Cooling to –30 °C gave green crystals of the title compound suitable for X-ray diffraction. $C_{25}H_{26}BrN_4Rh$ (565.32): calcd. C 53.12, H 4.64, N 9.91; found C 52.78, H 4.42, N 9.73. $^1$H NMR ([D$_8$]THF): $\delta$ = 1.13 (d, $J$ = 6.9 Hz, 6 H, Me), 1.21 (d, $J$ = 6.8 Hz, 6 H, Me), 3.00 [sept, $J$ = 6.9 Hz, 2 H, C*H*$(CH_3)_2$], 7.20 (m, 3 H, aromatic CH), 7.35 (t, $J$ = 8.2 Hz, 1 H, aromatic CH), 7.44 (d, $J$ = 8.0 Hz, 1 H, aromatic CH), 7.71 (d, $J$ = 8.0 Hz, 1 H, aromatic CH), 7.76 ("t", $J$ = 6.0 Hz, 1 H, aromatic CH), 8.10 (m, 2 H, aromatic CH), 8.21 (d, $J$ = 8.0 Hz, 1 H, aromatic CH), 8.26 (t, $J$ = 8.0 Hz, 1 H, aromatic CH), 9.47 (d, 1 H, imidazole backbone CH) ppm. The chloride analogue **9b** can be obtained as green powder by the reaction of **7** generated in situ with $[Rh(COE)_2Cl]_2$ in THF at room temperature for 2 h. It exhibits identical NMR spectroscopic data to **9a**. $C_{25}H_{26}ClN_4Rh$ (520.9): calcd. C 57.65, H 5.03, N 10.76; found C 57.12, H 4.87, N 10.61.

**Oxidative Addition Adduct 10 of 9a with $CD_2Cl_2$:** Addition of $CD_2Cl_2$ to a solid sample of **9a** initially gave a dark green solution,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

but this rapidly became brown (ca. 5 min.). The product of this reaction was the oxidative addition complex **10**. Yield quantitative. $^1$H NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 1.05 (d, $J$ = 6.9 Hz, 3 H, Me), 1.17 (d, $J$ = 6.8 Hz, 3 H, Me), 1.30 (d, $J$ = 6.8 Hz, 3 H, Me), 1.35 (d, $J$ = 6.8 Hz, 3 H, Me), 2.66 [sept, $J$ = 6.8 Hz, 1 H, C*H*-$(CH_3)_2$], 3.47 [sept, $J$ = 6.6 Hz, 1 H, C*H*$(CH_3)_2$], 7.08 (d, $J$ = 2.2 Hz, 1 H, imidazole backbone CH), 7.33 (ddd, $J$ = 1.1, 7.7, 14.3 Hz, 2 H, 2 aromatic CH), 7.52 (t, $J$ = 7.8 Hz, 1 H, aromatic CH), 7.64 (m, 1 H, aromatic CH), 7.63 (t, $J$ = 6.5 Hz, 1 H, aromatic CH), 7.76 (d, $J$ = 8.1 Hz, 1 H, aromatic CH), 8.00 (m, 2 H, aromatic CH), 8.05 (dd, $J$ = 1.3, 7.8 Hz, 1 H, aromatic CH), 8.11 (t, $J$ = 8.1 Hz, 1 H, aromatic CH), 8.19 (d, $J$ = 7.9 Hz, 1 H, aromatic CH), 9.14 (d, $J$ = 4.8 Hz, 1 H, aromatic CH) ppm. $^{13}$C NMR (75.45 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 23.28 (Me), 23.59 (Me), 26.28 (Me), 26.80 (Me), 28.92 [*C*H$(CH_3)_2$], 28.99 [*C*H$(CH_3)_2$], 112.05 (aromatic CH), 117.37 (aromatic CH), 119.17 (aromatic CH), 123.92 (aromatic CH), 124.12 (aromatic CH), 124.85 (aromatic CH), 126.71 (aromatic CH), 128.31 (aromatic CH), 131.01 (aromatic CH), 134.94 (aromatic C), 139.47 (aromatic CH), 140.60 (aromatic CH), 146.01 (aromatic C), 148.25 (aromatic C), 150.90 (aromatic C), 152.04 (aromatic C), 155.90 (aromatic C) ppm; carbene and $CD_2Cl$ signals not observed. MS (ESI+): $m/z$ = 570.9 [$M^+$ – HCl], 611.9 [$M^+$ – HCl + MeCN].

**Reaction of 9a with CO:** To a green solution of **9a** in THF was bubbled CO for 1 min. The colour changed to dark red-orange within 5 min and a pink precipitate appeared after sometime which was isolated by filtration and dried. Yield: 45%. $^1$H NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 1.05 (d, $J$ = 6.9 Hz, 3 H, Me), 1.17 (d, $J$ = 6.8 Hz, 3 H, Me), 1.30 (d, $J$ = 6.8 Hz, 3 H, Me), 1.35 (d, $J$ = 6.8 Hz, 3 H, Me) 2.66 [sept, $J$ = 6.8 Hz, 1 H, C*H*$(CH_3)_2$], 3.47 [sept, $J$ = 6.8 Hz, 1 H, C*H*$(CH_3)_2$], 7.33 (ddd, $J$ = 1.1, 7.7, 14.3 Hz, 2 H, aromatic), 7.52 (t, $J$ = 7.8 Hz, 1 H, aromatic), 7.63 (t, $J$ = 6.5 Hz, 1 H, aromatic), 7.76 (d, $J$ = 8.1 Hz, 1 H, aromatic), 8.00 (m, 2 H, aromatic), 8.05 (dd, $J$ = 1.3, 7.8 Hz, 1 H, aromatic), 8.11 (t, $J$ = 8.1 Hz, 1 H, aromatic), 8.19 (d, $J$ = 7.9 Hz, 1 H, aromatic) 9.14 (d, $J$ = 4.8 Hz, 1 H, aromatic) ppm. $^{13}$C NMR (75.45 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 23.80 (Me), 24.45 (Me), 28.47 [*C*H$(CH_3)_2$], 114.46 (aromatic CH), 118.79 (aromatic CH), 120.58 (aromatic CH), 124.08 (aromatic CH), 124.35 (aromatic CH), 124.41 (aromatic CH), 128.01 (aromatic CH), 130.99 (aromatic CH), 134.18 (aromatic C), 140.53 (aromatic CH), 144.77 (aromatic CH), 145.66 (aromatic C), 152.24 (aromatic C), 154.29 (aromatic CH), 154.97 (aromatic C), 156.09 (aromatic C) ppm.

**X-ray Crystallography:** A summary of the crystal data, data collection and refinement for compounds **2**, **3**, **7**, and **9a** are given in Table 1. All data sets were collected with an Enraf–Nonius Kappa CCD area detector diffractometer, fitted with an FR591 rotating anode (Mo-$K_\alpha$ radiation) and an Oxford Cryosystems low-temperature device, operating in $\omega$-scanning mode with $\psi$- and $\omega$-scans to fill the Ewald sphere. Data collection and reduction were carried out using the software packages Collect, Scalepack, and Denzo.[21] The crystals were mounted on a glass fibre with silicon grease from Fomblin vacuo oil. In all cases refinement was carried out by full-matrix least-squares methods using SHELXL-97[22] within the WinGX program suite.[23] All non-hydrogen atoms were refined using anisotropic thermal parameters, and hydrogen atoms were added using a riding model. CCDC-607971 (**2**), -607972 (**3**), -607973 (**7**) and -607974 (**9a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** DFT calculations were carried out using the GAUSSIAN03[24] program package, running on a Mandriva Linux Dual-Opteron. Geometries have been fully optimised without symmetry constraints, involving the functional combinations according to Becke[25] (hybrid) and Lee, Yang, Parr[26] (denoted B3LYP), with the corresponding valence basis set for Rh (Stuttgart-Dresden, keyword SDD in Gaussian) and standard 6-31G* basis set for C, H, N and Cl (denoted as ECP1).[27] The stationary points were characterised as minima by analytical harmonic frequency (zero imaginary frequency), which were used without scaling for zero-point and thermal corrections. MOLDEN[28] was used for the chemical representation of the calculated compounds, and NBO-View[29] for the representation of the orbitals. Tables of Cartesian coordinates of all calculated structures are available as Supporting Information in $x$, $y$, $z$ format.

Table 1. Summary of crystallographic data for **2**, **3**, **7**, and **9a**.

| | **2** | **3** | **7** | **9a** |

# Synthesis, Characterization, and Crystal Structure of Two Manganese Metallacrowns: 30-Metallacrown-10 and 18-Metallacrown-6 with Ligands Derived from 3-Hydroxy-2-naphthalenecarbohydrazide

**Jianmin Dou,*[a] Mingli Liu,[a] Dacheng Li,[a] and Daqi Wang[a]**

**Keywords:** Metallacrowns / Manganese / Crystal structure / Supramolecular chemistry / Crown compounds

Two manganese metallacrowns $[Mn_{10}(pnhz)_{10}(DMF)_4(H_2O)_6]\cdot10.5H_2O\cdot MeOH\cdot DMF$ (**1**) and $[Mn_6(anhz)_6(DMF)_2(H_2O)_4]\cdot6DMF$ (**2**), ($H_3$pnhz = 3-hydroxy-*N*-phenyl-2-naphthalenecarbohydrazide, $H_3$anhz = *N*-acyl-3-hydroxy-2-naphthalenecarbohydrazide) have been prepared by the reactions of two pentadentate ligands, $H_3$anhz and $H_3$pnhz, with the corresponding manganese(II) salt, respectively, and characterized by elemental analysis, IR spectra, and X-ray single-crystal diffraction analysis. Complex **1** has an $[Mn–N–N]_{10}$ skeleton with two kinds of $Mn^{III}$ centers in an ···AABAB··· alignment, and the metallic centers exhibit a ···ΔΛΔΛ··· chiral configuration alignment. Adjacent molecules are linked by four intermolecular H bonds to form a 1D infinite chain structure. This is the first 1D supramolecular sample of a metallacrown formed by weak interactions. Complex **2** shows an $[Mn–N–N]_6$ skeleton with two kinds of $Mn^{III}$ centers in a ···BAA··· alignment. The successive manganese centers possess a ···ΔΛΔΛ··· chiral configuration alignment.

## Introduction

Since the first metallacrown (MC) [9-MC-3] was synthesized and confirmed by Pecoraro and coworkers[1] in 1989, this kind of metallic macrocyclic complex has received considerable attention in supramolecular chemistry, self-assembly, host–guest chemistry, and molecular recognition. Interest in the metallacrowns stems not only from their high symmetry and aesthetic molecular frameworks, but also from their magnetic properties and selective recognitions to cations and anions, along with the potential applications in chemically modified electrodes and liquid-crystal precursors.[2–10] At present, the groups of metallacrowns mainly include: (1) metallacrowns with a $[M–N–O]_n$ repeating linkage. This type of metallacrown can be synthesized by multidentate ligands such as hydroxamic,[11] ketonoxime,[11a,12] and aminohydroxamic acids[13] and their cyclic size has been enlarged from 9-MC-3 to 24-MC-8,[1,14–18] including several inverse metallacrowns.[2,19–21] (2) Metallacrowns with the $[M–N–N]_n$ repeating linkage, for example, azametallacrown, which can be synthesized by multidentate ligands such as *N*-substituted salicylhydrazide, salicylhydrazone, or 2-pyridinecarbaldehyde hydrazone. Their cyclic size has been developed from 18-MC-6 to 36-MC-12.[22–24] During the studies of the design of azametallacrowns, *N*-acyl-substituted salicylhydrazide ligands have often been used. In the last two years, the factors that control the ring size and nuclearity of azametallacrowns[25–26] have been investigated; the result shows that the nature of the *N*-acyl substituent group can influence the size and nuclearity of the macrocycle complex. Two- and three-dimensional networks can be constructed[27] if an *exo*-bidentate ligand is employed in the synthesis of azametallacrowns. To the best of our knowledge, only one azametallacrown prepared from a hydrazide that was derived from 3-hydroxy-2-naphthoic acid has been reported.[28] In this current work, we have synthesized two kinds of ligands that contain the 3-hydroxy-2-naphthyl, the *N*-acetyl-3-hydroxy-2-naphthalenecarbohydrazide, and the 3-hydroxy-*N*-phenyl-2-naphthalenecarbohydrazide groups and two azametallacrowns $[Mn_{10}(pnhz)_{10}(DMF)_4(H_2O)_6]\cdot10.5H_2O\cdot MeOH\cdot DMF$ (**1**) and $[Mn_6(anhz)_6(DMF)_2(H_2O)_4]\cdot6DMF$ (**2**) with the use of these two ligands, respectively.

## Results and Discussion

### Complex 1

Complex **1** was obtained by the reaction of manganese acetate tetrahydrate in methanol with $H_3$pnhz in DMF in a 1:1 molar ratio.[29] The crystallographic data is summarized in Table 1. The structure of complex **1** is illustrated in Figure 1. X-ray structural analysis shows that complex **1** has a planar decanuclear thirty-membered ring core. In the man-

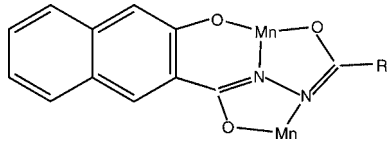
ganese complex, a crystallographic centrosymmetric [-Mn–N–N-]$_{10}$ unit is exhibited with 5.001 Å, 4.934 Å, 4.886 Å, 4.937 Å, and 4.907 Å for the neighboring Mn···Mn distances which are consistent with 4.906(1)–4.986(2) Å for the corresponding distances in $[Mn(C_{14}H_9N_2O_3)(CH_3OH)]_{10}\cdot 5CH_2Cl_2\cdot 16CH_3OH\cdot H_2O$.[6] The average angle of the successive manganese ions is 136.91° and it is comparable to the interior angle of 144° in an n-decagon. The size or dimension and even the depth of the cavity of the 30-MC-10 in this communication exceeds those of the previous 30-MC-10 in ref.[6] The size of the cavity in the metallacrown is measured between the opposite carbon atoms: 13.206 Å for C5···C5#1, 8.987 Å for C77···C77#1, 12.335 Å for C23···C23#1, 9.830 Å for C41···C41#1, and 12.014 Å for C59···C59#1. The approximate dimensions of the oval-shaped cavity are about 7.948 Å in diameter at the entrance, approximately 16.4 Å at its largest diameter at the center of the cavity, and around 7.3703 Å in depth, which is large enough to capture some neutral molecules. So the solvent hydrate molecule (O25) is drawn in the cavity at a depth of 0.9061 Å during the self-assembly.

All manganese centers have a $N_2O_4$ geometry but in two different environments. The trivalent anionic nphz$^{3-}$ acts as a pentadentate ligand chelate for two adjacent manganese atoms in a back-to-back mode by five atoms. One phenolate oxygen atom, one carbonyl oxygen atom (phenyl end), and one hydrazide nitrogen atom bind to one manganese ion; the residual carbonyl oxygen atom (naphthyl end) and the hydrazide nitrogen atom coordinate to the neighboring metal ions as illustrated in Scheme 1. Therefore, the ligands around the Mn$^{III}$ ion are forced into a propeller configuration owing to the meridional coordination of the adjacent ligand to this metal ion. The other vertex position of each octahedral geometry is occupied by either a $H_2O$ molecule or a DMF molecule, which forms two kinds of Mn centers and the geometric environments of them are named A and B, respectively. In each octahedral geometry around Mn$^{III}$, the mean axial distance of Mn–O/N is approximately 0.38 Å longer than the mean value of the basal distances. The typical Jahn–Teller elongation along the $z$ axis of Mn$^{III}$ ions that possess the high-spin d$^4$ orbit was also found in several Mn$^{III}$ complexes.[7,26] Finally, the successive Mn$^{III}$ centers show an environment with the ···AABAB··· alignment and with an alternating ···ΔΛΔΛ··· chiral configuration.[32]



Scheme 1.

Metallocrown 30-MC-10 forms a 1D chain structure through hydrogen bond interactions that are formed by a noncovalent force. Each coordinated O8 interacts with two DMF molecules through H bonds, and the O atoms in the DMF molecules further interact with O8#1 in an adjacent molecule also through H bonds. Therefore, the adjacent metallacrown molecules are linked together by two DMF molecules by four such H bonds to form a 1D chain struc-

Selected bond angles [°]: O4–Mn1–N10#1 155.4(3), N1–Mn1–O18#1 170.6(3), O3–Mn1–O1 169.1(3), O7–Mn2–O5 170.5(3), O2–Mn2–N3 170.5(3), O8–Mn2–N2 155.1(3), O12–Mn3–N4 154.8(4), N5–Mn3–O6 173.5(3), O11–Mn3–O9 170.7(3), N7–Mn4–O10 172.0(3), O16–Mn4–N6 155.9(3), O15–Mn4–O13 171.5(3), O19–Mn5–O17 170.8(3), O20–Mn5–N8 156.1(3), N9–Mn5–O14 171.6(3).

ture as illustrated in Figure 2. The H bond lengths are 2.785(18) Å and 3.026(18) Å for O8···O21#2 and O8···O21#3, respectively. Among all of the azametallacrowns reported, no supramolecule has been formed by H bonds.

### Complex 2

The reaction of manganese 2,4-pentanedionate in methanol with $H_3$anhz in DMF gives rise to the single-crystal of complex **2**; its crystallographic data is listed in Table 1. The X-ray structural analysis shown in Figure 3 reveals that complex **2** is a hexanuclear manganese azametallacrown with a $[Mn–N–N]_6$ unit. Different from previous analogues which either possess pseudo $C_{3i}$[23] or crystallographic $C_{3i}$ symmetry,[22] this 18-MC-6 is a crystallographic $C_{2i}$ symmetric molecule.

The two kinds of $Mn^{III}$ centers both reside in the octahedral geometries of the complex that is composed of $N_2O_4$: five atoms from two dianionic anhz$^{3-}$ and one O atom occupy one axial site from either $H_2O$ (A-environment for the $Mn^{III}$ center) or DMF (B-environment for the $Mn^{III}$ center). The mean axial distances [mean value 2.183 Å for Mn(A)–O and 2.221 Å for Mn(A)–N; 2.177(10) Å for Mn(B)–O and 2.247(12) Å for Mn(B)–N] are all about 0.30 Å longer than the average basal bond lengths for each $Mn^{III}$ center, which indicates that the elongation of the octahedrons takes place in the axial direction due to the Jahn–Teller distortion of the high-spin $d^4$ $Mn^{III}$ ion. The pentadentate ligands anhz$^{3-}$ not only bridge the adjacent manganese ions by -N–N-, but also forces the stereochemistry of the metal ions into a propeller configuration because of the meridional coordination of the neighboring ligands. As a result, the complex exhibits a combination of the ···BAA··· environment with the ···ΔΛΔΛ··· chiral configuration. The Mn···Mn distances fall in the range of 4.843–4.856 Å and Mn···Mn···Mn angles of 113.4–115.81°. Metallacrown **2** measures about 1.95 nm in diameter and 1.3 nm in thick-

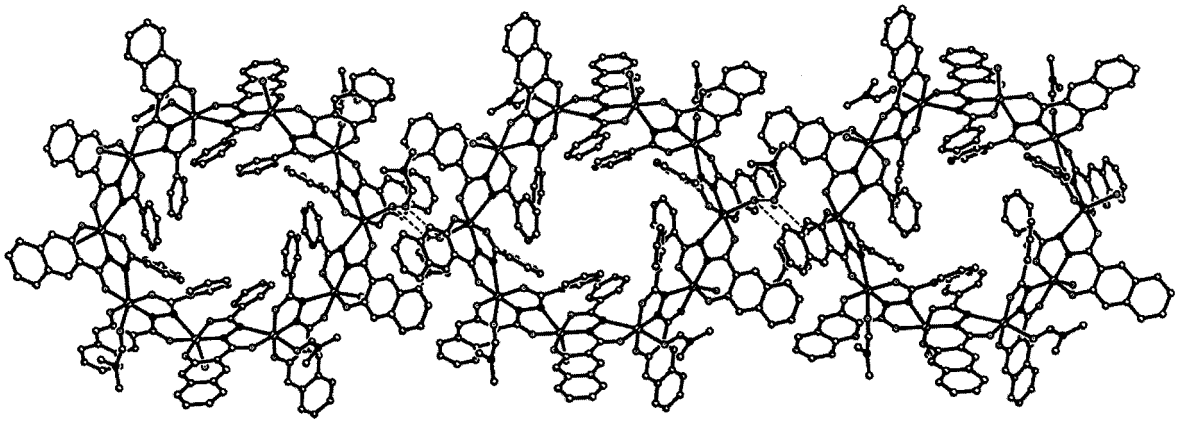

Figure 2. The 1D chain that is formed by intermolecular H bonds with the use of 30-MC-10 as a building block. H bond data [Å]: O8···O21#1 2.785(18), O8–H8A···O21#1 121.4; O8···O21#2 3.026(18), O8–H8B···O21#2 139.1. #1: $x$, $y+1$, $z$; #2: 2 $–x$, 1 $–y$, 1 $–z$.

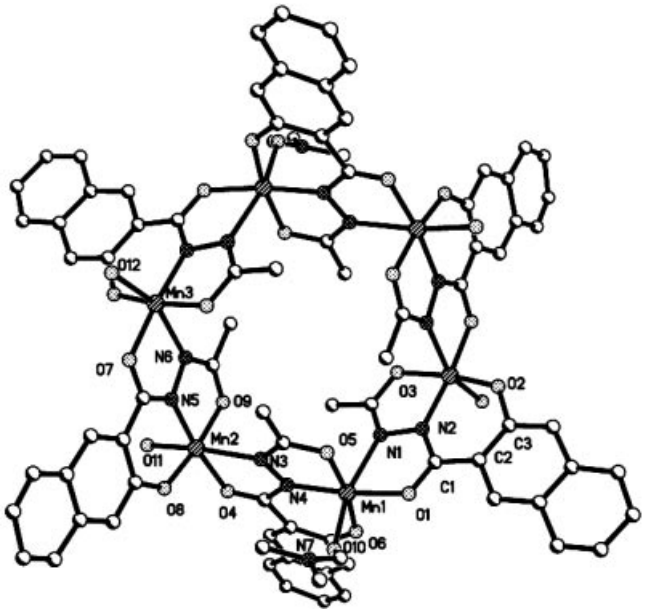

Figure 3. The molecular structure of complex **2**; all of the noncoordinated solvent molecules are removed for clarity. Selected bond lengths [Å]: Mn1–O6 1.818(10), Mn1–O5 1.919(11), Mn1–N4 1.934(12), Mn1–O1 1.953(10), Mn1–O10 2.177(10), Mn1–N1 2.247(12), Mn2–O8 1.838(11), Mn2–O9 1.887(10), Mn2–N5 1.933(12), Mn2–O4 1.941(10), Mn2–O11 2.157(12), Mn2–N3 2.249(14), Mn3–O2#1 1.821(11), Mn3–O3#1 1.910(10), Mn3–N2#1 1.91 6(11), Mn3–O7 1.960(9), Mn3–N6 2.194(13), Mn3–O12 2.209(12). Selected bond angles [°]: O6–Mn1–O5 170.3(5), N4–Mn1–O1 173.0(5), O10–Mn1–N1 160.0(5), N5–Mn2–O4 172.1(5), O11–Mn2–N3 164.0(5), O8–Mn2–O9 171.0(4), N6–Mn3–O12 155.1(5), N2#1–Mn3–O7 172.3(5), O2#1–Mn3–O3#1 170.6(5).

ness. Complex **2** possesses an empty cavity in the center of the metallacrown. Although the geometry and the chirality of the metallic center is similar to some reported 18-MC-6.[22] However, complex **2** possesses a larger cavity due to the heavier head of the 3-hydroxy-2-naphthyl groups and the paddle configuration. The size of the cavity, measured between the opposite carbon atoms, is 6.982 Å (C13···C13#1), 6.399 Å (C26···C26#1), and 6.370 Å (C39···C39#1). For the oval-shaped cavity, the minimum diameter is approximately 4.66 Å at the entrance and the maximum diameter is about 9.612 Å at the center of the cavity.

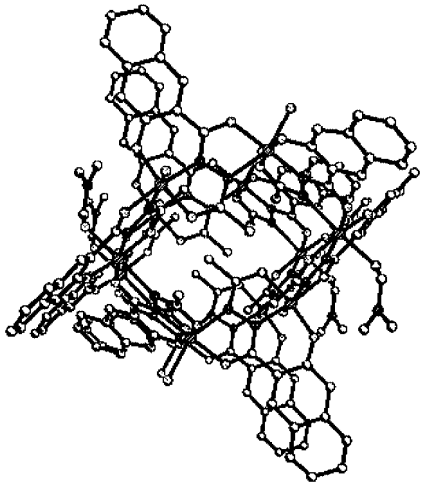

Figure 4. Crystal packing structure of complex **2**.

The crystal packing structure of complex **2** shows that the hexanuclear cluster is aligned approximately along the crystallographic *c* axis. The cavities of the clusters in the crystal structure are also aligned and one-dimensional channels are formed which is shown in Figure 4.

### Magnetism Properties

Temperature-dependent magnetic susceptibility measurements on polycrystalline samples of the title complex indicate that the complex exhibits significant antiferromagnetic coupling between manganese centers. At 300 K, the molar effective magnetic moment ($\mu_{eff}$) is equal to 4.26 $\mu_B$, which is slightly smaller than the expected value for one isolated high-spin $Mn^{III}$ center with $S = 2$ ($\mu_{eff} = 4.90\ \mu_B$). If the sample is cooled, the value decreases gradually until the temperature is about 50 K, and then the value of $\mu_{eff}$ falls rapidly. The antiferromagnetic coupling is further confirmed by a negative Weiss constant –14.85 K, which is calculated with the use of the data within $T > 50$ K and with the use of the Curie–Weiss law $\chi_m^{-1}(T) = C/(T-\theta)$. Only the coupling of the neighboring ($J_1$) and near-neighboring centers ($J_2$) are considered and interactions between the paramagnetic centers in other positions are omitted because of the long distances (Figure 5).

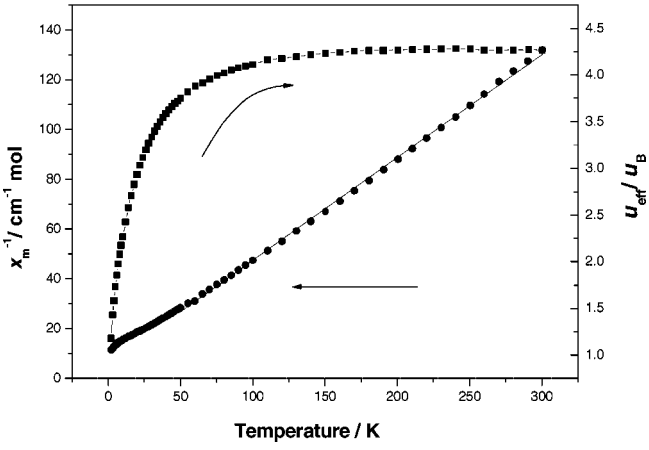

Figure 5. Plots of the effective magnetic moment ($\mu_{eff}$) and the inverse susceptibility $\chi_m^{-1}$ versus temperature for complex **1**. The square and round points represent $\mu_{eff}$ and $\chi_m^{-1}$ data and the line through the round points represents the fitting curve according to the Curie–Weiss law.

## Conclusions

Two azametallacrowns, 18-MC-6 and 30-MC-10, that contain the naphthalene group have been synthesized by introducing $H_3$anhz and $H_3$anhz as the supporting ligands.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Both crown compounds are found to possess larger cavities than those found in the corresponding metallacrowns reported previously, which indicates the higher probability that complex **1** can be used as a host to accept some ions or neutral molecules. This probability is realized by 30-MC-10 in which one cavity was able to capture a hydrate molecule. Because of the existence of free DMF in the system, a 1D chain of 30-MC-10 was assembled successfully, which is the first example of an azametallacrown supramolecule that is formed by noncovalent force.

## Experimental Section

**Materials and General Methods:** The ligands $H_3$pnhz and $H_3$anhz were prepared as described in ref.[29] All other chemicals were commercially purchased and used without further purification. Elemental analyses (C, H, and N) were performed with a Perkin–Elmer 2400II analyzer. FTIR spectra of the complex were measured with a Nicolet-460 FTIR spectrometer in the range of 4000–400 $cm^{-1}$.

**Synthesis of Complex 1:** A solution of $H_3$pnhz (0.15 mmol, 0.046 g) in DMF (20 mL) was added to a solution of manganese acetate tetrahydrate (0.15 mmol, 0.030 g) in methanol (20 mL) at room temperature. The reaction mixture was then stirred for 3 h. The resultant dark red solution was left open to air to generate a dark red block crystal after about twenty days. Yield 0.12 g, 18.9%. M.p. >300 °C (dec.). $C_{195}H_{178}Mn_{10}N_{25}O_{50.50}$ (4229.03): calcd. C 55.60, H 4.18; found C 55.81, H 4.20. FTIR (KBr): 2929(w), 1654(vs), 1626(s), 1592(s), 1515(s), 1454(m), 1360(m), 1341(w), 1262(w), 1145(w), 1103(w), 918(w), 874(m), 801(m), 705(m) $cm^{-1}$.

**Synthesis of Complex 2:** A solution of $H_3$anhz (0.25 mmol, 0.062 g) in DMF (15 mL) was added to a solution of diacetylacetone manganese (0.25 mmol, 0.064 g) in a mixture of MeOH/$CHCl_3$ (1:1; 20 mL), and the reaction mixture was then stirred for two hours. The red–brown clear solution obtained after filtration was left open to air to afford a kind of dark red column crystal after one day. Yield 0.08 g. M.p. >300 °C (dec.) $C_{102}H_{118}Mn_6N_{20}O_{30}$ (2433.88): calcd. C 50.29, H 4.85; found C 50.11, H 5.07. FTIR (KBr): 2924(w), 1652(vs), 1627(vs), 1594(s), 1518(vs), 1454(m), 1381(vs), 1337(s), 1264(m), 1229(m), 800(m), 751(m), 659(m) $cm^{-1}$.

**X-ray Crystallography:** Data was collected with a Bruker SMART 1000 CCD diffractometer with the use of Mo-$K_\alpha$ radiation. Empirical absorption corrections were applied following the procedure of Sadabs.[30] The structures were solved by direct method and expanded with the use of difference Fourier techniques with the SHELXL-97 program[31] and refined anisotropically for all nonhydrogen atoms by full-matrix least-squares calculations on $F^2$ with the use of the SHELXTL program package. Hydrogen atoms were placed geometrically and with $U_{iso}$ constrained to be 1.2 (1.5 for methyl groups and hydroxy) times $U_{eq}$ of the carrier atom. CCDC-279967 and -282855 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Oxalato-Bridged Dinuclear Copper(II) Complexes of *N*-Alkylated Derivatives of 1,4,7-Triazacyclononane: Synthesis, X-ray Crystal Structures and Magnetic Properties

**Matthew J. Belousoff,[a] Bim Graham,[a][‡] Boujemaa Moubaraki,[a] Keith S. Murray,[a] and Leone Spiccia*[a]**

**Keywords:** Dinuclear copper(II) complexes / Oxalato bridges / *N*-Alkylated 1,4,7-triazacyclononane derivatives / X-ray structures / Antiferromagnetic coupling

The synthesis, X-ray crystal structure and magnetic properties of two oxalato-bridged dinuclear $Cu^{II}$ complexes, $[L\text{-}Cu(\mu\text{-}ox)Cu\text{-}L](ClO_4)_2$, where ox = oxalate and L = 1,4,7-trimethyl-1,4,7-triazacyclononane ($Me_3$tacn) or 1-benzyl-4,7-dimethyl-1,4,7-triazacyclononane ($BzMe_2$tacn) are reported, as well as the X-ray crystal structure of the mononuclear complex, $[Cu(Me_3tacn)(OH_2)_2](ClO_4)_2$, which features an extended H-bonding network between the ligand and the perchlorate counterions. The crystal structures of the dinuclear complexes both feature a centrosymmetric complex cation in which the two copper centres exist in a distorted square-pyramidal geometry, with each end capped by a facially coordinated "tacn" unit, and are bridged by an oxalate anion. Variable-temperature magnetic susceptibility measurements revealed strong antiferromagnetic interactions between the $Cu^{II}$ centres, with 2*J* values of ca. –300 $cm^{-1}$, even though the Cu···Cu separation is very long, viz. 5.18 Å ($BzMe_2$tacn) and 5.47 Å ($Me_3$tacn). The separation for the $Me_3$tacn complex is the longest separation reported for this type of $Cu^{II}$ complex. No pattern could be detected between the *J* values and structural features for 21 oxalato-bridged complexes.

## Introduction

The magnetic properties of copper(II) complexes have been an attractive area of research. This is due to the fact that copper(II) ($d^9$) has a single unpaired electron and therefore can be used as a model system for probing the nature of magnetic exchange interactions between single unpaired electrons on two or more metal centres, and, in particular, how this interaction is mediated by the ligands that bridge the metal centres.[1–3] Hydroxo-bridged metal complexes, in which the metal atoms are linked by single-atom bridges, have been most widely studied. The data that have been obtained have been used to develop empirical correlations of the strength of magnetic coupling with key structural descriptors of the Cu–OH–Cu bridging unit(s).[4–6] Further, theoretical analyses have been undertaken in an effort to develop a molecular orbital view of coupling in these complexes.[7,8]

Oxalato-bridged complexes have also been of interest[9–15] since, in this case, the $Cu^{II}$ centres are linked by multi-atom bridges, yet they can exhibit quite strong antiferromagnetic interactions even when the $Cu^{II}$ centres are separated by more than 5 Å.[2] Whilst most of these complexes exhibit antiferromagnetic coupling, the strength of this interaction can vary from very weak [2*J* value (exchange constant) close to 0 $cm^{-1}$] to very strong (2*J* value up to –400 $cm^{-1}$). The strength of the antiferromagnetic interaction has been proposed to be related to the "square of the overlap between the magnetic orbitals located on each copper(II)".[1] In the case of the oxalato-bridged copper(II) complexes it is the overlap of the $d_{x^2-y^2}$ and the σ-bonding orbitals on the oxygen atoms of the oxalato bridge that determines the strength of the interaction.

The ligand 1,4,7-triazacyclonone (tacn) is a particularly well-studied aza-macrocycle that uses three N-donor atoms to bind to the copper atom, forming highly stable complexes. Copper(II)–tacn complexes exhibit well-defined coordination polyhedra, consistently adopting either distorted octahedral or square-pyramidal geometries. The proposal by Kahn et al. that the extent of spin coupling in dinuclear complexes could be "tuned" by changing the $Cu^{II}$ coordination sphere that supports the oxalato bridge[1] led us to investigate the effect of geometric constraints introduced by the tacn macrocycle on the extent of magnetic interaction between the metal centres in oxalato-bridged dinuclear copper(II) complexes. Herein we report the synthesis, X-ray crystal structure and magnetic properties of two new oxalato-bridged copper(II) complexes of *N*-alkylated tacn

macrocycles ($Me_3$tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane and $BzMe_2$tacn = 1-benzyl-4,7-dimethyl-1,4,7-triazacyclononane) and, for comparison, the X-ray crystal structure of $[Cu(Me_3tacn)(OH_2)_2](ClO_4)_2$ (**C1**).

## Results and Discussion

$[Cu_2(Me_3tacn)(\mu\text{-ox})](ClO_4)_2$ (**C2**) was prepared by treating the diaqua mononuclear precursor, $[Cu(Me_3tacn)(OH_2)_2](ClO_4)_2$ (**C1**),[16] with 1 equiv. of sodium oxalate (see Scheme 1). Careful concentration of the solution to dryness and recrystallisation from a mixture of methanol/ethanol (1:1) produced analytically pure blue crystals. The IR spectrum of **C2** reveals the characteristic stretching modes of the oxalato ligand at 1648 $cm^{-1}$ ($\upsilon_{asym}$) and 1467 $cm^{-1}$ ($\upsilon_{sym}$), which are typical for bridging oxalato ligands.[17] The solution UV/Vis spectrum shows the electronic d→d transitions expected for square-pyramidal copper(II) complexes at 1100 nm ($\varepsilon_{max}$ = 68 $M^{-1}cm^{-1}$) and 636 nm ($\varepsilon_{max}$ = 118 $M^{-1}cm^{-1}$).[18] Band maxima are also observed at 333 nm ($\varepsilon_{max}$ = 4160 $M^{-1}cm^{-1}$), 282 nm ($\varepsilon_{max}$ = 11100 $M^{-1}cm^{-1}$) and 195 nm ($\varepsilon_{max}$ = 11400 $M^{-1}cm^{-1}$), which could result from either charge transfer or ligand π→π* transitions.

The synthesis of $[Cu_2(BzMe_2tacn)(\mu\text{-ox})](ClO_4)_2$ (**C3**) involved first the formation of the precursor mononuclear copper(II) complex in an aqueous methanolic solution, which was then treated with sodium oxalate to yield the desired dinuclear complex as analytically pure blue crystals (see Scheme 1). The IR spectrum of **C3** again shows the expected stretching modes from the oxalato ligand at 1654 $cm^{-1}$ ($\upsilon_{asym}$) and 1466 $cm^{-1}$ ($\upsilon_{sym}$). The electronic spectrum exhibits two d→d transitions at 1090 nm ($\varepsilon_{max}$ = 67 $M^{-1}cm^{-1}$) and 644 nm ($\varepsilon_{max}$ = 110 $M^{-1}cm^{-1}$), which again suggests that the copper(II) centre exists in a square-pyramidal geometry in solution.[18] A strong band at 284 nm ($\varepsilon_{max}$ = 9100 $M^{-1}cm^{-1}$) could be an MLCT or a π→π* transition within the ligand.

### X-ray Crystal Structure Determinations

The X-ray crystal structure of **C1** reveals a mononuclear complex, in which the distorted octahedral copper(II) coordination sphere is occupied by three nitrogen donors from the $Me_3$tacn ligand, two oxygen atoms from ligated water and a distant oxygen atom from a perchlorate counteranion (see Figure 1). There is significant elongation in the axial direction of the coordination polyhedron, viz. the Cu(1)–N(1) bond is 0.19 Å longer than the Cu–N distances in the basal plane and for the weakly interacting perchlorate anion the Cu(1)–O(1) distance is 2.519(3) Å. All other bond lengths and angles are in the expected range for $(tacn)Cu^{II}$ complexes (see Table 1).

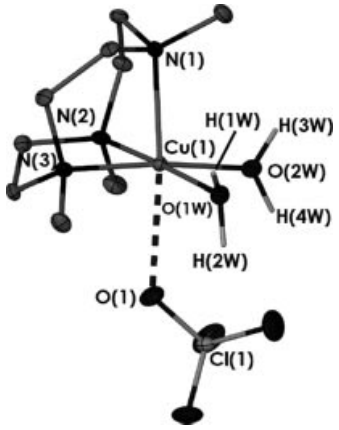

Figure 1. Thermal ellipsoid plot of **C1** (drawn at 50% probability). Dashed line indicates a weak interaction; some hydrogen atoms and a perchlorate anion have been omitted for clarity.

The hydrogen-bonding network formed by the hydrogen atoms from the coordinated water molecules and the perchlorate anions is particularly interesting. Each coordinated water molecule hydrogen-bonds to different perchlorate anions, which in turn hydrogen-bond to water molecules coordinated to different complexes (Table 2). This forms infinite two-dimensional layered sheets (see Figure 2).

| O(1W)–H(2W)···O(4) | 0.94(1) | 2.62(4) | 3.219(3) | 122(3) |

Symmetry transformations used to generate equivalent atoms: [a] $-x, -y + 1, -z + 1$. [b] $-x + 1, -y + 1, -z + 1$. [c] $-x, -y + 1, -z + 2$. [d] $-x + 1, -y + 1, -z + 2$.

The structure of **C2**, shown in Figure 3, reveals a dinuclear copper(II) complex featuring two capping $Me_3$tacn ligands and a bridging oxalato ligand that binds through all four of its oxygen atom. The complex is centrosymmetric, half existing in the asymmetric unit (ASU), with the other half generated by crystallographic symmetry. The metal centres at each end of the complex exist in a highly distorted geometry because of the geometric constraints introduced by the tacn macrocycle and the bridging oxalato ligand (see Table 3). The degree of distortion is highlighted by the three quite different Cu–N distances, which, in a five-coordinate complex, would be indicative of distortion away from square-pyramidal towards trigonal-bipyramidal geometry. An oxygen atom from a perchlorate anion is oriented in the direction of the vacant axial position of the copper(II) coordination polyhedron [Cu–O distance of 2.808(5) Å]. This distance is much longer than that in **C1**, probably because of the distortion of the coordination polyhedron beyond the usual tetragonal elongation. Whether the solid-state $Cu^{II}$ geometry is best described as distorted octahedral (6-coordinate) or distorted square-pyramidal (5-coordinate) is therefore debatable. With respect to the oxalato bridge, the two apical tacn nitrogen atoms in each dinuclear complex adopt a *trans* configuration. The two copper

Symmetry transformations used to generate equivalent atoms: [a] $-x + 1/2, -y + 1/2, -z$.

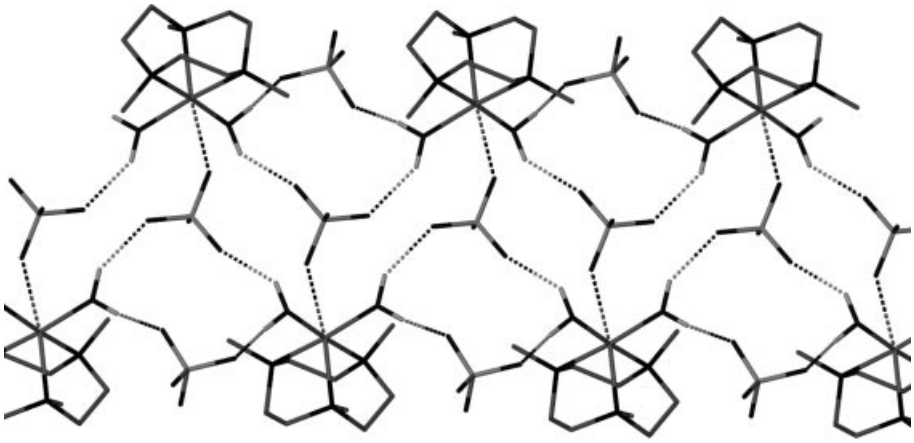

Figure 2. Infinite two-dimensional sheets formed by hydrogen-bonding interactions (dotted lines) in **C1**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms are separated by 5.467(3) Å, and the Cu–O(ox) distances of 2.026(2) and 2.091(2) Å indicate that the two pairs of stronger and weaker binding oxygen atoms adopt a *trans* configuration.

A least-squares analysis of the plane of the oxalato ligand and the O(1)–Cu(1)–O(2) plane reveals that the $CuN_2O_2$ basal unit does not lie in the same plane as the oxalato ligand (see Figure 7). The dihedral angle created by the intersection of these two planes [$\varphi$ = 4.8(3)°] means that there is a "step" between the two coordination spheres, perhaps reducing the overlap of the $d_{x^2-y^2}$ and the σ-bonding orbitals on the oxalato ligand (vide infra).

This structure is broadly similar to that found for $[Cu_2(tacn)_2(\mu\text{-ox})](ClO_4)_2$ by Zhang et al.,[19] but there are significant differences in that the Cu–O distances in **C2** are slightly longer and give rise to a Cu···Cu separation that is 0.291 Å longer in **C2** than in the tacn counterpart. One reason for this could be that extensive H-bonding involving the secondary nitrogen atoms was found in the tacn complex, which cannot be formed by the alkylated ligand in **C2**.

The overall structure of **C3** is similar to that of **C2**, the main difference being that $BzMe_2$tacn ligands cap the ends of the complex instead of $Me_3$tacn (see Figure 4). The tertiary nitrogen atom with the benzyl pendant arm occupies an apical position and, as in **C2**, this Cu–N distance is longer (by 0.24 Å) than the two in the basal plane (see Table 4), and the two apical positions are oriented *trans* with respect to the oxalato bridge. The $\varphi$ angle (see Figure 7) in **C3** is much larger [12.2(1)°] and the two copper(II) centres are closer to each other [Cu–Cu distance 5.178(11) Å]. A further significant difference is that the oxalato ligand in **C3** binds much more strongly and the bridging unit is more symmetric, viz. all the Cu–O distances [1.9908(11) and 1.9982(11) Å] are identical, while in **C2**, these distances are quite different [2.026(2) and 2.091(2) Å]. In contrast to **C2**, the two Cu–N(tacn) distances in the equatorial plane are identical (av. 2.205 Å), while those in **C2** differ by 0.09 Å (Table 3). It may have been anticipated that the $BzMe_2$tacn ligand in **C3** would have been more likely to induce structural asymmetry. The more symmetric $Cu^{II}$ coordination sphere allows for a closer approach of the weakly interacting perchlorate counterion [Cu(1)–O(3) distance of 2.648(13) Å is a little shorter than the corresponding bond in **C2**].

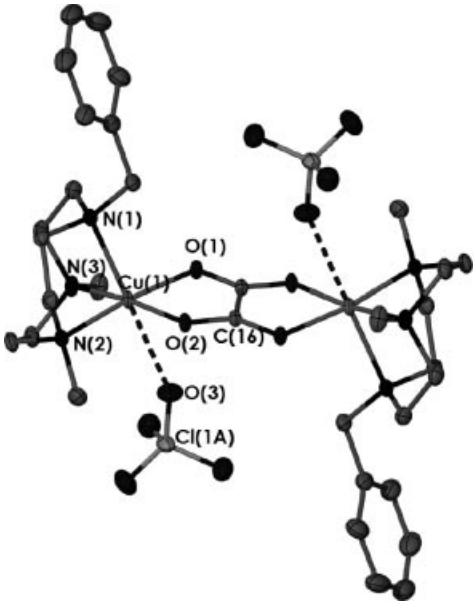

Figure 4. Thermal ellipsoid plot of **C3** (drawn at 50% probability, dashed lines indicate a weak interaction, hydrogen atoms omitted for clarity).

## Magnetic Properties

Variable-temperature magnetic susceptibility studies were carried out on powdered samples of **C2** and **C3** to determine the nature and strength of the magnetic exchange interactions between the copper(II) centres in these oxalato-bridged dinuclear complexes. The measurements were performed in the 4.2–300 K temperature range with an applied field of 1 T. Plots of the magnetic moment vs. temperature for **C2** and **C3** are given in Figures 5 and 6, respectively.

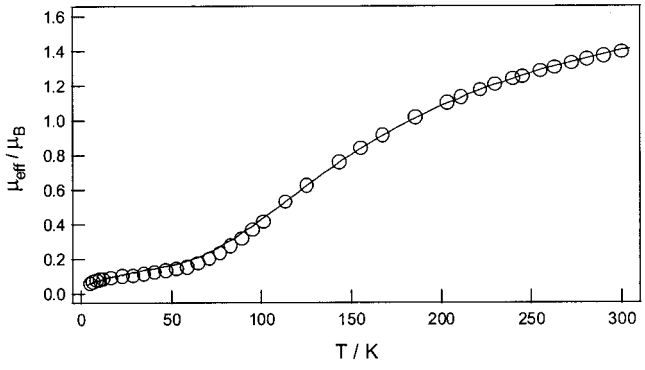

Figure 5. Plot of $\mu_{eff}$ (per Cu) vs. temperature for **C2**. The solid line is the best fit using the parameters: $g$ = 2.17, $Na$ = $60 \times 10^{-6}$ cm$^3$ mol$^{-1}$, $J$ = –159 cm$^{-1}$, monomer = 0.3%.

Figure 5 shows that the magnetic moment of **C2** decreases substantially from 1.43 $\mu_B$ (per Cu) at 300K to 0.08 $\mu_B$ at 4.2 K. This is indicative of a strong antiferromagnetic interaction between the $Cu^{II}$ centres. The data were modelled using a $-2J\bar{S}_1\cdot\bar{S}_2$ Bleaney–Bowers approach,[20] by fitting to the susceptibility Equation (1), where all the sym-

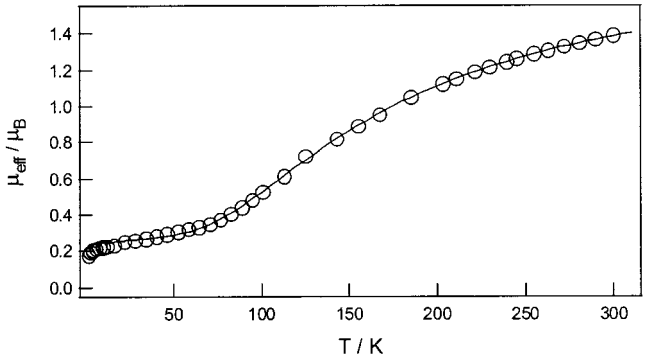

Figure 6. Plot of $\mu_{eff}$ (per Cu) vs. temperature for **C3**. The solid line is the best-fit using the parameters: $g$ = 2.03, $N\alpha$ = $60\times10^{-6}$ cm$^3$ mol$^{-1}$, $J$ = –147 cm$^{-1}$, monomer = 1.8%.

bols have their usual meaning. The best fit parameters for **C2** are $g$ = 2.17, $N\alpha$ (temperature independent paramagetism) = $60\times10^{-6}$ cm$^3$ mol$^{-1}$, $J$ = –159 cm$^{-1}$, with a monomer impurity of 0.3%.

$$\chi_M = \frac{Ng^2\beta^2}{kT}\left[\frac{2}{3+\exp\left(\frac{-2J}{kT}\right)}\right] + N\alpha \qquad (1)$$

For **C3**, the magnetic moment drops from 1.39 $\mu_B$ (per Cu) at 300 K to 0.21 $\mu_B$ at 4.2 K (Figure 6). This also indicates strong antiferromagnetic coupling. The data were fitted using the same approach as for **C2** to yield the best-fit parameters of $g$ = 2.03, $N\alpha$ = $60\times10^{-6}$ cm$^3$ mol$^{-1}$, $J$ = –147 cm$^{-1}$, monomer impurity of 1.8%.

### Magnetostructural Correlations

There has been much work aimed at determining how molecular structure influences the extent of magnetic interaction between metal centres with all types of bridging motifs.[1–5,9,10,12,13,15,19,21–25] Until recently, predictions of the extent of magnetic interactions in dinuclear copper(II) complexes have been largely based upon observations of how certain geometrical features influence magnetism. For example, Hoffmann et al.[26] determined that the coupling constant, $J$, for a d$^9$ metal complex is given by Equation (2), where $|\varepsilon_S - \varepsilon_A|^2$ is the splitting energy between the singly occupied molecular orbitals and $K_{ab}$, $J_{aa}$ and $J_{ab}$ are the two-electron integrals involving the localised orthogonal orbitals involved in the magnetic interaction.

$$2J = 2K_{ab} - \frac{|\varepsilon_S - \varepsilon_A|^2}{(J_{aa} - J_{ab})} \qquad (2)$$

Computational studies by Ruiz et al.[8,27] have led to the more general conclusion that the strength of antiferromagnetic coupling in oxalato-bridged dinuclear complexes is determined predominantly by two main geometrical factors: the out-of-plane displacement of the copper ion ($h_{Cu}$), and the dihedral angle between the plane of the oxalato ligand and the basal coordination plane ($\varphi$) (see Figure 7).

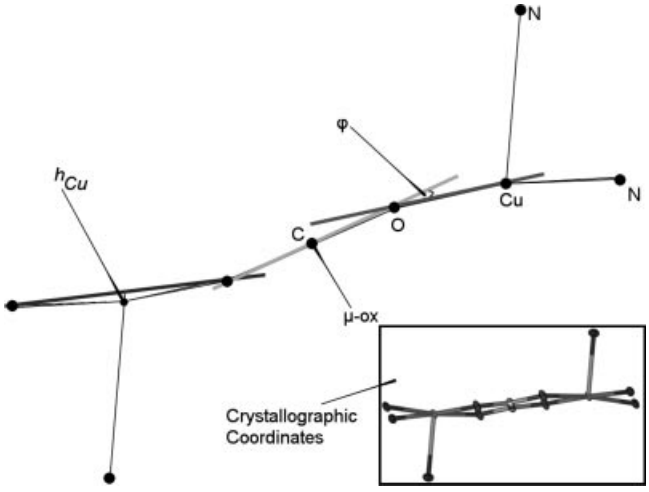

Figure 7. Representation of the core geometry of the complex cation structural motif showing the angle ($\varphi$) between the plane of the oxalato ligand and the O–Cu–O plane.

A compilation of structural and magnetic properties of related oxalato-bridged copper(II) complexes can be found in Table 5. Curiously, $[Cu_2(tacn)_2(\mu\text{-ox})](ClO_4)_2$, which has

a very similar bridging motif to both **C2** and **C3**, exhibits relatively weak antiferromagnetic coupling.[19] Both **C2** and **C3**, which have similar $J$ values, have larger $\varphi$ and $h_{Cu}$ values than the parent tacn complex but this difference does not account for the large difference in the $J$ value. In $[Cu_2(tacn)_2(\mu\text{-ox})](ClO_4)_2$, quite strong hydrogen bonding exists between the secondary amine group of the tacn ligand and oxalato oxygen atoms [N–H···O = 2.138(3) Å] on adjacent dinuclear complex units. This could withdraw electron density from the σ-bonding orbitals of the oxalato bridge, hence weakening the strength of orbital overlap with the magnetic orbitals on the copper(II) centre.

The data in Table 5 also indicate that the strength of antiferromagnetic coupling in **C2** and **C3** is similar to that found in many of the other complexes. The strength of the antiferromagnetic coupling in **C2** is of interest as this complex features the longest Cu···Cu distance (by ca. 0.2 Å) reported so far for these types of complexes. However, as can be seen from the collected structural and coupling data, there seems to be no correlation between the extent of coupling and any particular set of geometric parameters. This is clearly highlighted by the fact that **C2** and **C3** have a similar $2J$ value, but have a 7° diffence in the $\varphi$ angle, and 0.04 Å difference in $h_{Cu}$.

## Conclusions

This work has shown that *N*-alkylation of the tacn macrocycle significantly increases the strength of antiferromagnetic coupling in oxalato-bridged dinuclear copper(II) complexes to the extent that in $[Cu_2(Me_3tacn)_2(\mu\text{-ox})](ClO_4)_2$ strong coupling has been observed over a Cu···Cu distance (5.46 Å) that is 0.2 Å longer than in any other related oxalato-bridged $Cu^{II}$ complex.

## Experimental Section

**Materials and Reagents:** All solvents and reagents used were of reagent or analytical grade and used as purchased. Distilled $H_2O$ was used throughout. $[Cu(Me_3tacn)(OH_2)_2](ClO_4)_2$ (**C1**) was prepared according to Fry et al.[16] 1-Benzyl-4,7-dimethyl-1,4,7-triazacyclononane was prepared according to a previously reported method.[6]

**Instrumentation:** UV/Vis spectra were recorded in acetonitrile using a Varian Cary 5G spectrophotometer. IR spectra were recorded using a Perkin–Elmer FTIR 1600 series spectrometer at 4.0 $cm^{-1}$ resolution, using KBr discs. CHN microanalyses were carried out by the Campbell Microanalytical Laboratory, University of Otago, New Zealand. Magnetic susceptibilities were measured on samples of ca. 20 mg in mass using a Quantum Design MPMS 5 Squid instrument. Diamagnetic corrections were made for the gelatine capsule sample holder and for ligands using Pascal's constants.

***Caution:*** Although no problems were encountered in this work, transition metal perchlorates are potentially explosive and should be prepared in small quantities and handled with care.

**Synthesis of $[Cu_2(Me_3tacn)(\mu\text{-ox})](ClO_4)_2$ (C2):** A solution of $Na_2C_2O_4$ (0.096 g, 0.70 mmol) in $H_2O$ (5 mL) was added to a solution of $[Cu(Me_3tacn)(OH_2)_2](ClO_4)_2$ (0.30 g, 0.64 mmol) in $H_2O$ (10 mL). The resulting solution was heated at reflux for 1 h. The solution was then concentrated to dryness and residues were dissolved in a hot solution of MeOH/EtOH (1:1). The resulting blue solution was then filtered while hot and the filtrate slowly cooled to yield deep-blue crystals that were suitable for X-ray crystallography. Yield: 0.21 g (86%). $C_{20}H_{42}Cl_2Cu_2N_6O_{12}$ (756.58): calcd. C 31.8, H 5.6, N 11.1; found C 32.0, H 5.6, N 11.1. IR (selected bands; KBr disk): $\tilde{\nu}$ = 2996 (w), 2965 (m), 2924 (s), 1648 (s), 1467 (s), 1352 (m), 1300 (m), 1145 (s), 1078 (br. s), 1015 (s), 1006 (s), 894 (m), 786 (m), 746 (w) $cm^{-1}$. UV/Vis (MeCN): $\lambda_{max}$ ($\varepsilon_{max}$) = 1100 (68), 636 (118), 333 (4160), 282 (11100), 195 (11400 $M^{-1}cm^{-1}$) nm.

**Synthesis of $[Cu_2(BzMe_2tacn)(\mu\text{-ox})](ClO_4)_2$ (C3):** 1-Benzyl-4,7-dimethyl-1,4,7-triazacyclononane (0.21 g, 0.85 mmol) was dissolved in MeOH/$H_2O$ (1:1) (10 mL) and a solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (0.32 g, 0.87 mmol) in $H_2O$ (5 mL) was slowly added to this solu-

**X-ray Crystallography:** Intensity data for blue crystals of **C1** (0.15×0.15×0.11 mm), **C2** (0.3×0.1×0.1 mm) and **C3** (0.30×0.10×0.09 mm) were measured at 123 K with a Nonius Kappa CCD (Bruker Kappa Apex II for **C3**) fitted with graphite-monochromated Mo-$K_\alpha$ radiation (0. 71073 Å). The data were collected to a maximum $2\theta$ value of 55° (60° for **C3**) and processed using the Bruker–Nonius software. Crystal parameters and details of the data are summarised in Table 6. The structures were solved by direct methods and expanded using standard Fourier routines in the SHELX-97 software package.[32,33] All hydrogen atoms were placed in idealised positions and all non-hydrogen atoms were refined anisotropically. The water hydrogen atoms in **C1** were located on the Fourier difference map but restraints were placed upon them during refinement. The perchlorate anion in **C3** is disordered over two distinct positions, and the chlorine atoms as well as two of the perchlorate oxygen atoms had their site occupancy refined against each other. CCDC-605826 (for **C1**), -605827 (for **C2**) and -605828 (for **C3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Intramolecular Apical C–H···M Interactions in Square-Planar Nickel(II) Complexes with Dianionic Tridentate Ligands and 2-Phenylimidazole

**Abhik Mukhopadhyay[a] and Samudranil Pal*[a]**

**Keywords:** Nickel(II) complexes / Square-planar complexes / Apical C–H···Ni interactions / X-ray structures / Theoretical calculations

Two square-planar ternary nickel(II) complexes [Ni(bhac)(phim)] (**1**) and [Ni(ahac)(phim)] (**2**) with O,N,O-donor Schiff bases [acetylacetone benzoylhydrazone ($H_2$bhac) and acetylacetone acetylhydrazone ($H_2$ahac)] and $sp^2$ N-donor 2-phenylimidazole (phim) as the ancillary ligand have been synthesised and characterised by analytical, spectroscopic, magnetic and electrochemical methods. The solid-state structures of both complexes have been determined by X-ray crystallography. The asymmetric unit of **1** contains a single complex molecule while that of **2** contains four complex molecules with different conformations. The molecular structures of both complexes reveal that one of the two *ortho* C–H groups of the pendant phenyl ring of the phim ligand is very close to the metal centre at the apical site indicating the presence of an intramolecular C–H···Ni interaction. In the structures of **1** and **2**, the shape of the C–H···Ni interaction is determined by the twisting of the phim ligand and the extent of orthogonality between the planes containing the chelate rings formed by the tridentate ligand and the imidazole ring. A survey of the reported X-ray structures of similar $d^8$ metal ion complexes containing intramolecular C–H···M interactions has been performed for comparison with the structural features of **1** and **2**. The optimised molecular structures of **1** and **2** generated by calculations based on the density functional method are compared with the experimental structures. Calculations also reveal that the four molecules present in the asymmetric unit of **2** are very close in energy. Theoretical studies and the down-field shift of the proton resonance on cooling in the NMR spectra suggest three-centre four-electron hydrogen-bond character of the observed apical C–H···Ni interaction in **1** and **2**.

## Introduction

The long standing interest in the interaction of transition metal ions with proximate C–H fragments is primarily due to the C–H activation processes involved in many catalytic reactions. Such interactions have been scrutinised intensively for a better understanding of their structural and bonding features.[1–12] The C–H···M interaction in coordinatively unsaturated and electron-deficient (16-electron) species is called an agostic interaction or agostic bond where the filled C–H σ orbital interacts with an empty metal orbital. In these agostic interactions, generally the C–H fragment is side-on to the metal ion. This T-shape of the agostic C–H···M interaction facilitates the involvement of the filled metal dπ orbital and the empty C–H σ* orbital in back bonding. However, the nature of the apical C–H···M interactions in square-planar 16-electron complexes of $d^8$ metal ions is not very clear.[9–12] In such species, these interactions can be agostic bond (three-centre two-electron) as well as non-classical hydrogen bond (three-centre four-electron) in character because of the availability of the empty orbital as well as the lone pair of electrons on the metal ion. Such apical C–H···M interactions in square-planar $d^8$ systems have been described as weakly agostic bonds, nonclassical hydrogen bonds and also as repulsive because of the filled metal $d_{z^2}$ and C–H σ-orbitals.[2,12–14] Compared with the agostic interaction the nonclassical hydrogen bond is not common in metal complexes. For a metal centre to participate as the proton acceptor in a hydrogen bond, it is essential for it to be electron rich. Examples of such complexes occur mostly with $d^8$ and $d^{10}$ metal centres. It has been demonstrated that such hydrogen bonds can facilitate the oxidative addition of H–X to a metal centre.[15]

Herein we report two square-planar nickel(II) complexes with the tridentate Schiff bases $H_2$bhac and $H_2$ahac and the monodentate 2-phenylimidazole as the ancillary ligand. The deprotonated Schiff bases ($bhac^{2-}$ and $ahac^{2-}$) satisfy the +2 charge on the metal ion and three coordination sites. The $sp^2$ N atom of the neutral 2-phenylimidazole (phim) occupies the fourth coordination site and completes the $N_2O_2$ square plane around the metal ion. The ancillary ligand 2-phenylimidazole has been specifically chosen so that one of the two *ortho* C–H groups of the phenyl ring can be in close proximity with the metal ion at the apical site. The complexes, [Ni(bhac)(phim)] (**1**) and [Ni(ahac)(phim)] (**2**),

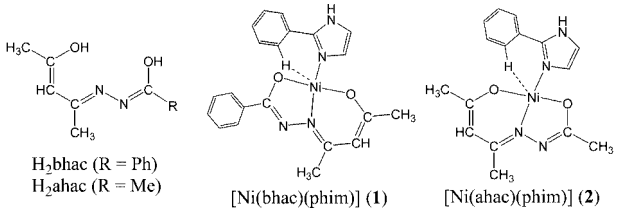
have been characterised by analytical, magnetic, spectroscopic and electrochemical measurements. The X-ray structures of **1** and **2** indeed reveal the presence of an apical C–H···M interaction in both complex molecules. We have examined the reported structures of the square-planar $d^8$ systems with similar intramolecular C–H···M interactions available in the Cambridge Structural Database for a comparison with the structural features of **1** and **2**. Calculations based on density functional methods have been performed to understand the molecular conformations and the nature of the C–H···Ni interaction observed in the X-ray structures of **1** and **2**. Variable temperature NMR spectroscopic measurements have been carried out to probe the nature of this interaction in solution.



## Results and Discussion

### Synthesis and Some Properties

The reactions of 1 equiv. each of $Ni(O_2CCH_3)_2{\cdot}4H_2O$, the Schiff bases ($H_2$bhac and $H_2$ahac) and 2-phenylimidazole in boiling methanol afford the dark brown complexes in moderate to good yields. Elemental analysis data are consistent with the molecular formula [Ni(bhac)(phim)] (**1**) and [Ni(ahac)(phim)] (**2**). Both **1** and **2** are electrically nonconducting in methanol solutions. The complexes are diamagnetic and NMR spectroscopically active. Thus in each complex, the nickel ion is in the +2 oxidation state and the coordination geometry around the metal centre is square planar.

The infrared spectra of **1** and **2** do not display any band assignable to the amide or secondary amine N–H stretch.[16] Several sharp weak bands observed in the range 2900–3150 $cm^{-1}$ are likely to be due to the C–H stretches. The absence of any band for the N–H group of the ancillary ligand phim is consistent with its involvement in strong intermolecular hydrogen bonding (vide infra). Free $H_2$bhac and $H_2$ahac display the amide C=O stretch[17] near ≈1675 $cm^{-1}$. The absence of any such band in the spectra of **1** and **2** indicates complete deprotonation of the Schiff bases in the complexes. Thus in both complexes, the dianionic tridentate ligands ($bhac^{2-}$ and $ahac^{2-}$) act as the enolate-O, the imine-N and the deprotonated amide-O donor. A strong band observed near 1590 $cm^{-1}$ might involve the C=N stretches.[18,19]

The electronic spectra were collected using methanol solutions of the complexes. Both complexes display several absorptions. For **1** the absorption bands are in the range 565–234 nm and those for **2** are within 425–235 nm. The density functional calculations show that in both **1** and **2** the lowest unoccupied molecular orbital (LUMO) is primarily localised on the ancillary ligand phim and the highest occupied molecular orbital (HOMO) is composed of d and p orbitals of the metal and coordinated O atoms, respectively. The spectra of the free Schiff bases and 2-phenylimidazole in methanol solutions display a single absorption in the range 250–215 nm. Thus the absorptions observed for **1** and **2** are possibly due to the metal-to-ligand and inter- or intra-ligand charge-transfer transitions.

Electron transfer properties of **1** and **2** have been investigated by cyclic voltammetry using acetonitrile solutions of the complexes. Both **1** and **2** display an irreversible oxidation response at 0.69 and 0.71 V, respectively. The current height of this response is comparable with known one-electron redox processes under identical conditions.[19,20] No such response is observed for the deprotonated Schiff bases and 2-phenylimidazole under the same conditions. The iron(III) and copper(II) complexes with $bhac^{2-}$ show metal-centred oxidation responses in the potential range 0.4–0.8 V.[21–23] Therefore, the oxidation responses observed for **1** and **2** are assigned to a $Ni^{II} \rightarrow Ni^{III}$ process. The nature of the HOMO in both complexes also supports this assignment. The irreversible nature of the response suggests that in each case the corresponding oxidised species is unstable on the cyclic voltammetry time scale.

### Description of X-ray Structures and C–H···Ni Interactions

The molecular structures of **1** and **2** are depicted in Figure 1. Bond parameters associated with the metal ions are listed in Table 1. The asymmetric unit of **1** contains one complex molecule while that of **2** contains four complex molecules. In each molecule, the enolate-O, the imine-N and the deprotonated amide-O donor tridentate ligand and the imine-N donor monodentate phim form a $N_2O_2$ square plane around the metal centre. There is no deviation of the metal centre from the $N_2O_2$ square plane. The Ni–O(enolate), Ni–N(imine), Ni–O(amide) and Ni–N(imidazole) bond lengths are comparable with those observed in nickel-

(II) complexes having the same coordinating atoms.[24–26] The average N–C and C–O bond lengths in the –N=C(O⁻)– fragments[21–26] and the C–C and C–O bond lengths in the –C=C(O⁻)– fragments[21–24] are consistent with the enolate form of both amide and acetylacetone moieties of the tridentate ligands.

In **1**, the tridentate ligand $bhac^{2-}$ is not planar because of the twisting of the phenyl ring plane along the C6–C16 bond (Figure 1). The dihedral angle between the phenyl ring plane and the plane constituted by the rest of the atoms in $bhac^{2-}$ is 25.56(8)°. It is also interesting to note that one of the two *ortho* C–H groups of the phenyl ring of $bhac^{2-}$ is involved in a C–H···π interaction with the phenyl ring of the ancillary ligand phim (Figure 1). The H···Cg distance and the C–H···Cg angle are 2.962 Å and 153°, respectively. Possibly this C–H···π interaction is primarily responsible for the twisting of the phenyl ring plane of $bhac^{2-}$ along the C6–C16 bond. The O1–Ni1–N3–C9 torsion angle ($\theta$) is 48.9° (Table 2). Thus the chelate forming fragment (O1,O2,N1,N2,C1–C6) of $bhac^{2-}$ and the metal coordinated imidazole ring plane are not orthogonal (Figure 1). The phim moiety is not planar because of the twisting of the imidazole ring plane and the phenyl ring plane along the C9–C10 bond (Figure 1). The extent of twisting ($\psi$) is measured by taking the average of the N3–C9–C10–C15 and N4–C9–C10–C11 torsion angles. The value of $\psi$ is calculated as 35.8°. As a result an *ortho* C–H group of the phim phenyl ring is close to the metal centre at the apical site (Figure 1). The Ni···H and Ni···C distances and the Ni···H–C angle are 2.79(2), 3.321(3) Å and 116.8(2)°, respectively (Table 2).

The bond lengths and bond angles of the four molecules present in the asymmetric unit of **2** are very similar (Table 1). However, the orthogonality ($\theta$) between the chelate forming fragment of $ahac^{2-}$ and the metal coordinated imidazole ring plane and the twisting of phim ($\psi$) differ significantly. The $\theta$ and $\psi$ values are in the ranges 72.9–91.6° and 1.6–21.6°, respectively (Table 2). Most importantly in two molecules the orientation of the phim phenyl ring with respect to the {Ni(ahac)} plane is on one side and in the other two molecules it is on the other side (Figure 2). As in **1**, one of the two *ortho* C–H groups of the phim phenyl ring is close to the metal centre at the apical site in each of the four molecules. The Ni···H and Ni···C distances and the C–H···Ni angles are within 2.42–2.69 Å, 3.20–3.36 Å, and 130.1–142.2°, respectively (Table 2).

The following trends are very clear from the above observations on the molecular structures of **1** and **2**. In **1**, only one complex molecule is present in the asymmetric unit and both the phenyl ring and the imidazole ring planes of phim are tilted toward the phenyl ring of the benzoyl fragment of $bhac^{2-}$ (Figure 1). In spite of being weak in nature we believe that the intramolecular C–H···π interaction plays a major role in restricting the phim moiety from taking random orientations and a single conformation of it is stabilized in **1**. Because of the replacement of the phenyl group of $bhac^{2-}$ by a methyl group in $ahac^{2-}$ the C–H···π interaction of the type observed in **1** is not possible in **2**. Complex **2** crystallises with four molecules in the asymmetric unit and the phim moieties are randomly oriented on both sides of the plane containing the {Ni(ahac)} moiety. Thus the lack of the C–H···π interaction facilitates free rotation of phim about the Ni–N(imidazole) bond. In addition, the imidazole plane in **2** is closer to the orthogonal arrangement with the plane containing the two chelate rings ($\theta$ = 72.9–91.6°) compared with that in **1** ($\theta$ = 48.9°). This difference is also likely to be because of the C–H···π interaction in **1**. The internal twisting of phim in **1** ($\psi$ = 35.8°) is significantly larger than that in **2** ($\psi$ = 1.6–21.6°). Possibly this difference is also partly due to the intramolecular C–H···π interaction in **1**. Despite the differences in the $\theta$ and $\psi$ values one of the two *ortho* C–H groups of the phim phenyl ring is near to the apical position of the metal ion in all the structures. In this context, it may be noted that the crystal structure of the protonated 2-phenylimidazole ($Hphim^{+}$) is known.[27] Here the $\psi$ value is 22.32°. Thus in all probability significantly different twisting of phim in **1** and **2** compared with that in $Hphim^{+}$ is due to the intramolecular C–H···π and C–H···Ni interactions observed in the present complex molecules.

A close scrutiny of the structural parameters (Table 2) related to the C–H···Ni interactions and the molecular conformations of **1** and **2** reveals the following. The longer the Ni···H distance the shorter the C–H···Ni angle. There is a satisfactory linear correlation between the Ni···H distance and the C–H···Ni angle (Figure S1, Supporting Information). The values of the Ni···H distances and the corresponding C–H···Ni angles strongly depend on the molecular conformations. In general, the Ni···H distance increases and the C–H···Ni angle decreases with the increase of the twisting ($\psi$) of phim and the decrease of the orthogonality ($\theta$) between the imidazole ring plane and the plane containing the two chelate forming fragments of the tridentate ligands (Table 2). The Ni···H distance is linearly related to the $\psi$ values as well as $\theta$ values with opposite slopes (Figure S1). Thus a large twist of the phim ligand forces a T-shape of the C–H···Ni interaction with an increase in the Ni···H distance, while a small twist of the phim ligand makes the C–H···Ni interaction more linear with a decrease in the Ni···H distance. It is clear from the above facts that the geometrical arrangement of the C–H···Ni interaction largely depends on the twist of the phim ligand in **1** and **2**. A detailed theoretical study reported previously has supported the idea that the axial M···H interactions in $d^8$ metal ion complexes are mainly repulsive in nature.[10] But a minor attractive contribution to the C–H···M interaction can not be ruled out in the present complexes. The Ni···H distances in both complexes and shorter Ni···H distances in **2** compared with that in **1**, unaided and unhindered by any geometrical constraint in the former, substantiate this idea.

### Intermolecular Hydrogen Bonds and Self-Assembly of 1 and 2

Both complex molecules contain the imidazole N–H group and metal coordinated O atoms, which are conventional hydrogen-bond donors and acceptors, respectively. In the crystal lattice, the molecules of each of the two complexes are involved in intermolecular N–H···O hydrogen bonding interactions involving the imidazole N–H groups and the metal coordinated amide O atoms of the tridentate ligands. In the case of **1**, the N···O distance and the N–H···O angle are 2.856(3) Å and 160(2)°, respectively. There are some variations in the geometrical parameters related to the N–H···O interactions for the four molecules present in the asymmetric unit of **2**. The N···O distances are in the range 2.788(8)–2.846(9) Å and the N–H···O angles are within 148–163°. In each case, self-assembly of the complex molecules through these intermolecular N–H···O hydrogen bonds leads to a one-dimensional supramolecular structure in the crystal lattice (Figure 3).

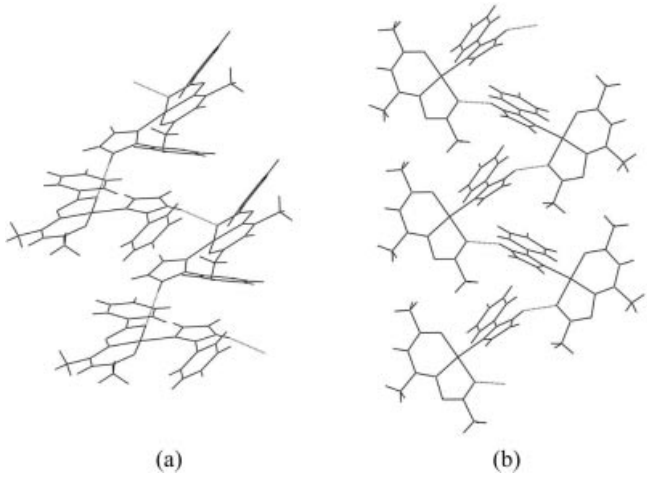

Figure 3. One-dimensional ordering of (a) [Ni(bhac)(phim)] (**1**) and (b) [Ni(ahac)(phim)] (**2**) through intermolecular N–H···O hydrogen bonds.

### Survey of the $d^8$ Metal Ion Complexes with Intramolecular C–H···M Interactions

The molecular structures of **1** and **2** show that the Ni···H distance, the C–H···Ni angle and hence the shape (T or linear) of the C–H···Ni interaction largely depend on the twisting ($\psi$) of 2-phenylimidazole (vide supra). The Ni···H distance is linearly related with $\psi$ and the C–H···Ni angle (Figure S1). To verify whether the trends observed for **1** and **2** are general or not we have performed a Cambridge Structural Database (version 5.26) search for $d^8$ metal ion com-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plexes having intramolecular C–H···M interactions. The search was based on the following criteria: (i) the metal ion is always coordinated to a N atom that is bonded to the atom X (elements of groups 14–16), (ii) X is connected to an unsubstituted/substituted phenyl ring by a single bond, (iii) the phenyl ring *ortho* C–H at the $\delta$ position is involved in the C–H···M interaction, (iv) the M···H separation is in the range 2.0–3.0 Å, (v) the $N_\alpha$–$X_\beta$–$C_\gamma$ angle is within 110–140°, (vi) the $N_\alpha$–$X_\beta$–$C_\gamma$–$C_\delta$ torsion angle ($\psi$) is in the range 0–180° and (vii) structures with *R* factors > 10 are excluded. The number of hits obtained was 44. Selected structural parameters of these 44 X-ray structures are listed in Table 3.

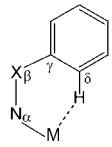
| HAPZPT10 | $Pt^{II}$ | 2.966 | 90.958 | 68.292 |
| HIXJUT | $Pt^{II}$ | 2.854, 2.976 | 125.650, 131.625 | 12.480, 33.951 |



In the structures collected in Table 3, the mean M···H distance increases in the order $Ni^{II} < Pd^{II} < Pt^{II}$. These values are 2.795, 2.841 and 2.932 Å for $Ni^{II}$, $Pd^{II}$ and $Pt^{II}$, respectively. This order is expected as the van der Waals radius increases in the order $Ni^{II} < Pd^{II} < Pt^{II}$.[10] In contrast to the structures of **1** and **2**, there is no readily apparent relationship between the M···H distance and the $N_\alpha$–$X_\beta$–$C_\gamma$–$C_\delta$ torsion angle ($\psi$). However, the scattergram of $\psi$ against the M···H distance (Figure 4a) shows the prevailing trend of long M···H distances for large $\psi$ values. On the other hand, the M···H distance generally increases with the decrease of the C–H···M angle (Figure 4b) as observed for **1** and **2**. In other words, the C–H···M interaction becomes more T-shaped with the increase of the M···H distance.

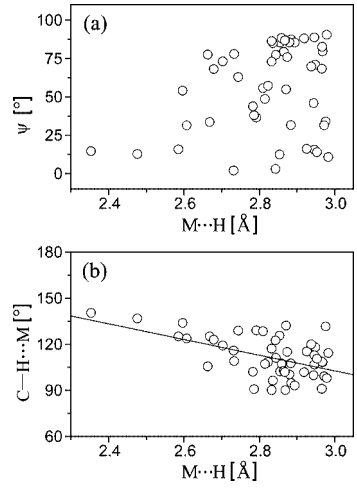


Figure 4. Scattergrams of (a) $\psi$ (see text for definition) vs. M···H distance and (b) C–H···M angle vs. M···H distance. The straight line in (b) represents the least-squares fit.

## Computational Results

Calculations based on density functional methods have been performed for structural optimisations of **1** and **2**. Each of the two complex molecules was computed as a complete system to consider all steric and electronic factors of the tridentate ligand ($bhac^{2-}$ or $ahac^{2-}$) and of the monodentate ancillary ligand 2-phenylimidazole (phim). In both cases, the atomic coordinates of the molecules obtained in the crystal structures were used as the starting points and references for geometry optimisation. The calculated structural parameters related to the C–H···Ni interaction and the molecular conformations are listed in Table 2.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In the case of **1**, the overall conformation of the molecule in the optimised structure is comparable with that found in the solid-state X-ray structure. With regard to the molecular conformation the only major difference between the optimised and the experimental structures is in the dihedral angle between the phenyl ring plane and the plane containing the rest of the atoms of the $bhac^{2-}$ ligand. In the optimised structure the whole tridentate ligand is essentially planar. It may be noted that the X-ray structure of **1** shows an intramolecular C–H···π interaction between the phenyl ring of $bhac^{2-}$ and that of phim (vide supra). It is very likely that this interaction is responsible for the nonplanarity of $bhac^{2-}$ in the experimental structure. For the present level of calculation we could not reproduce the C–H···π interaction in the optimised geometry. The calculated geometrical parameters indicate a more linear C–H···Ni interaction compared with that in the experimental structure (Table 2).

The same optimised molecular structure is obtained from the X-ray structural coordinates of the four molecules present in the asymmetric unit of **2**. The optimised molecule of **2** is very similar to that of **1** with regard to the Ni···H distance, C–H···Ni angle and $\psi$ and $\theta$ values (Table 2). However, this optimised structure is rather different when compared with the structures of the four molecules obtained in the X-ray structure of **2**. In general, the twisting of phim ($\psi$) is much less, the imidazole ring plane and the plane containing the two chelate rings are more orthogonal ($\theta$) and the Ni···H–C interaction is more linear in the experimental structures than those in the optimised structure (Table 2).

The dependence of the conformational energies of **1** and **2** on the twisting ($\psi$) of phim has been analysed by performing single point energy calculations by varying $\psi$ from 0 to 90°. The experimental structures of **1** and molecule 1 of **2** are used for these calculations. The relative energies ($\Delta E$) with respect to the lowest energy (at $\psi \approx 35°$ for **1** and $\psi \approx 15°$ for **2**) are plotted against the $\psi$ values (Figure 5). For **1** it is a symmetric well-like plot. On the other hand, for **2** below 20° the change in energy is very low compared with that above 20°. The energy increases by only 0.20 kcal mol$^{-1}$ due to the gradual decrease of $\psi$ from 20 to 0°. The small increase of energy indicates the absence of any significant steric or electronic constraint for the twisting of the phim in this range of $\psi$. For this reason, it is very likely that four molecules with $\psi$ values in the range 1.6–21.6° have been found in the asymmetric unit of **2**.

The nature of the C–H···Ni interaction in **1** and **2** has been examined by several computational methods. In a three-centre four-electron C–H···M interaction, the interacting hydrogen atom should have a more positive charge compared with the other hydrogen atoms that are away from the metal centre. The natural population analysis[28] shows that the charge on the *ortho*-hydrogen atom of the phim phenyl ring, which is at the apical site of the metal centre, is more positive (by +0.009e and +0.010e for **1** and **2**, respectively) compared with the charge on the other *ortho*-hydrogen atom of the same phenyl ring. The nickel(II) centre has an empty d orbital as well as a lone pair. Thus it can also accept electrons from the filled C–H σ orbital. The delocalisation energies for the C–H σ donation to the metal calculated through natural bond orbital analysis[28] are 0.58 and 0.63 kcal mol$^{-1}$ for **1** and **2**, respectively. These delocalisation energies are insignificant compared with those obtained for strong agostic interactions and are comparable with C–H···M hydrogen-bonding interactions.[29,30] The "atoms in molecules" theory[31] has also been used for further probing of the topological properties of the C–H···Ni interaction in **1** and **2**. The values obtained for the electron densities ($\rho_b$ = 0.011 and 0.012 a.u. for **1** and **2**, respectively) and the Laplacians ($\nabla^2\rho_b$ = 0.039 and 0.041 a.u. for **1** and **2**, respectively) at the bond critical points are well within the range reported for C–H···M interactions that are hydrogen bonds in character.[30,32–35]

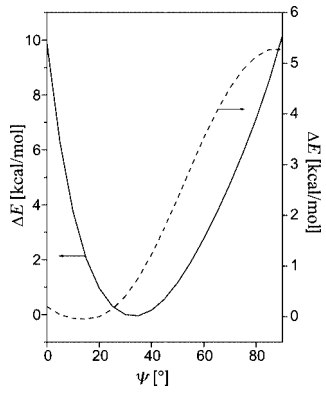

Figure 5. Relative energies of [Ni(bhac)(phim)] (**1**) (–) and [Ni(ahac)(phim)] (**2**) (----) as a function of twist angles ($\psi$) of 2-phenylimidazole (phim).

## Proton NMR Spectroscopic Studies

NMR spectroscopy is a useful tool for the diagnosis of the agostic or hydrogen-bond character of C–H···M interactions in square-planar $d^8$ metal ion complexes. The proton resonance shifts to an up-field position for agostic interactions while it shifts down-field for hydrogen-bond interactions compared with that of the free C–H group.[9,11,36] The room temperature proton NMR spectra were recorded using $(CD_3)_2CO$ solutions of **1** and **2**. The protons of the two methyl groups of the acetylacetone fragment in **1** appear as two singlets at $\delta$ = 1.47 and 2.20 ppm. The singlet observed at $\delta$ = 5.07 ppm is assigned to the –CH= group proton. The imidazole N-H proton resonates as a doublet at $\delta$ = 8.87 ppm ($J$ = 8 Hz). The multiplet observed in the range $\delta$ = 7.2–7.6 ppm is likely to be due to the imidazole ring C-H and aromatic protons. The absence of any cross-coupled peak in the 2D NMR spectrum of **1** indicates that the C–H···π interaction is probably absent in the solution state. In addition to all the above signals a broad singlet is observed at $\delta$ = 12.07 ppm. This down-field signal is attributed to the *ortho*-C-H proton of the phim phenyl ring, which is proximal to the metal centre. It may be noted that the free phim or the Schiff bases do not show any resonance in this region. The protons of the three methyl groups of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ahac$^{2-}$ in **2** are observed as three singlets at $\delta$ = 2.01, 2.11 and 2.27 ppm. The proton of the –CH= group resonates as a singlet at $\delta$ = 5.51 ppm. A broad singlet at $\delta$ = 8.89 ppm is assigned to the imidazole N-H proton. As observed for **1** the signal from the phim phenyl ring *ortho* C-H proton, close to the apical site of the metal centre, appears down-field ($\delta$ = 11.63 ppm) as a broad singlet. The multiplet in the range $\delta$ = 7.1–7.8 ppm corresponds to the imidazole ring C-H and the rest of the aromatic protons in the molecule.

We have recorded the NMR spectra of both complexes in the temperature range 20 to –80 °C and monitored the broad singlet observed at $\delta$ = 12.07 and 11.63 ppm for **1** and **2**, respectively. In each case, the signal becomes sharper and is shifted further down-field on cooling (Figure 6). The shifts are 0.75 and 0.90 ppm for **1** and **2**, respectively. The observation of the down-field signal and its behaviour on lowering the temperature suggest that the C–H···Ni interaction present in the solid-state structures of both **1** and **2** is also present in solution and it is essentially hydrogen bond in character.

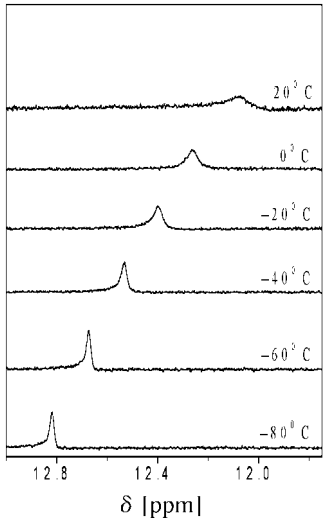

Figure 6. Temperature dependence of the down-field signal in the proton NMR spectrum of [Ni(bhac)(phim)] (**1**).

## Conclusions

The tridentate O,N,O-donor benzoyl- and acetylhydrazone of acetylacetone ($H_2$bhac and $H_2$ahac) and monodentate N-donor 2-phenylimidazole (phim) yielded square-planar nickel(II) complexes [Ni(bhac)(phim)] (**1**) and [Ni(ahac)(phim)] (**2**). X-ray crystal structures reveal that the asymmetric unit of **1** contains a single molecule while that of **2** contains four molecules with different conformations. The conformation of **1** is significantly different compared with that of any of the four molecules of **2**. Perhaps the intramolecular C–H···π interaction present in **1** is one of the factors for this difference. In each of **1** and **2**, one of the two *ortho* hydrogen atoms of the phim phenyl ring is very close to the metal centre at the apical site suggesting an intramolecular C–H···Ni interaction. The shape of the C–H···Ni interaction depends on the twisting ($\psi$) of the phim and the extent of the orthogonality ($\theta$) between the plane containing the chelate rings and the imidazole plane. The observed trends are compared with the structures of similar species reported in the literature. Theoretically optimised structures of both **1** and **2** are very similar. Energy calculations were performed by varying $\psi$ from 0 to 90° for both **1** and **2**. The conformer of **1** having a $\psi$ value of ≈35° (experimental $\psi$ = 35.8°) is at the lowest energy and the plot of the relative energies ($\Delta E$) of various conformers against $\psi$ provides a reasonably symmetric well-type curve. For **2** the lowest energy conformer has a $\psi$ value of ≈20°. However, the energy change is very little below $\psi$ = 20°. This observation explains the presence of four molecules having $\psi$ in the range 1.6–21.6° in the asymmetric unit of **2**. Theoretical investigations suggest that a hydrogen-bond description of the C–H···Ni interaction in both **1** and **2** is more appropriate. In the NMR spectra of **1** and **2**, the appearance of this interacting proton at down-field and further down-field shifts, because of the lowering of the temperature, substantiates the hydrogen-bond character of this interaction.

## Experimental Section

**Materials:** The Schiff bases $H_2$bhac and $H_2$ahac were prepared by condensation reactions of acetylacetone with benzoylhydrazine and acetylhydrazine, respectively.[21] All other chemicals and solvents used in this work were of analytical grade, available commercially and were used without further purification.

**Physical Measurements:** Microanalytical (C, H, N) data were obtained with a Thermo Finnigon Flash EA1112 series elemental analyser. Infrared spectra were collected by using KBr pellets with a Jasco-5300 FT-IR spectrophotometer. A Shimadzu 3101-PC UV/Vis/NIR spectrophotometer was used to record the electronic spectra. The proton NMR spectra were recorded with a Bruker 400 MHz spectrometer. Solution electrical conductivities were measured with a Digisun DI-909 conductivity meter. A Sherwood Scientific balance was used for magnetic susceptibility measurements. A CH-Instruments model 620A electrochemical analyser was used for cyclic voltammetric experiments with acetonitrile solutions of the complexes containing tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte. The three electrode measurements were carried out at 298 K under a dinitrogen atmosphere with a platinum disc working electrode, a platinum wire auxiliary electrode and an Ag/AgCl reference electrode.

### Synthesis of the Complexes

**[Ni(bhac)(phim)] (1):** A dry methanol solution (15 cm$^3$) of Ni$(O_2CCH_3)_2{\cdot}4H_2O$ (125 mg, 0.5 mmol) was added to a dry methanol solution (10 cm$^3$) of $H_2$bhac (110 mg, 0.5 mmol) and 2-phenylimidazole (72 mg, 0.5 mmol). The resulting deep brown mixture was kept under reflux for 2 h and then evaporated on a steam bath to approximately half of the original volume. The brown needles that separated after cooling to room temperature were collected by filtration, washed with a little ice-cold methanol and finally dried in air. The yield obtained was 160 mg (76%). A single crystal suitable for X-ray structure determination was selected from this material. $NiC_{21}H_{20}N_4O_2$ (419.12): calcd. C 60.18, H 4.81, N 13.37; found C 59.95, H 4.78, N 13.24. Electronic spectroscopic data in $CH_3OH$:

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$\lambda_{max}$ ($\varepsilon$) = 565 sh (94), 380 (14200), 366 sh (12700), 267 (19800), 234 sh (21100) nm.

**[Ni(ahac)(phim)] (2):** A dry methanol solution (15 $cm^3$) of Ni-$(O_2CCH_3)_2{\cdot}4H_2O$ (125 mg, 0.5 mmol) was added to a dry methanol solution (10 $cm^3$) of $H_2$ahac (70 mg, 0.5 mmol) and 2-phenylimidazole (72 mg, 0.5 mmol), and the mixture was kept under reflux for 2 h. A brown crystalline material was deposited on the wall of the round-bottomed flask along the surface of the solvent and formed a ring. The reaction mixture was cooled to room temperature and the almost colourless and clear mother liquor was removed carefully by using a dropper. The crystalline material was collected after drying in air. The yield obtained was 110 mg (62%). A single crystal suitable for X-ray structure determination was selected from this material. $NiC_{16}H_{18}N_4O_2$ (357.05): C 53.82, H 5.08, N 15.69; found C 53.54, H 4.86, N 15.47. Electronic spectroscopic data in $CH_3OH$: $\lambda_{max}$ ($\varepsilon$) = 425 sh (370), 358 sh (3500), 344 (4700), 330 sh (4400), 267 (18400), 235 sh (18600) nm.

**X-ray Crystallography:** Complexes **1** and **2** crystallise in the space groups $C2/c$ and $P2_1/c$, respectively. Unit cell parameters and the intensity data were obtained with a Bruker-Nonius SMART APEX CCD single-crystal diffractometer, equipped with a graphite monochromator and a Mo-$K_\alpha$ fine-focus sealed tube ($\lambda$ = 0.71073 Å) operated at 2.0 kW. The detector was placed at a distance of 6.0 cm from the crystal. Data were collected at 298 K with a scan width of 0.3° in $\omega$ and an exposure time of 30 sec/frame. The SMART software was used for data acquisition and the SAINT-Plus software was used for data extraction.[37] In each case, an absorption correction was performed with the help of the SADABS programme.[38] The structures were solved by direct methods and refined on $F^2$ by full-matrix least-squares procedures. In both structures, all non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were added at idealised positions by using a riding model. For **1** the hydrogen atoms were refined isotropically while for **2** they were not refined. The SHELX-97 programmes[39] of the WinGX package[40] were used for structure solution and refinement. The ORTEX6a[41] and Platon[42] packages were used for molecular graphics. Significant crystallographic data for **1** and **2** are summarised in Table 4.

Table 4. Selected crystallographic data for **1** and **2**.

| Complex | [Ni(bhac)(phim)] (**1**) | [Ni(ahac)(phim)] (**2**) |
|---|---|---|
| Empirical formula | $C_{21}H_{20}N_4O_2Ni$ | $C_{16}H_{18}N_4O_2Ni$ |
| Formula mass [g$mol^{-1}$] | 419.12 | 357.05 |
| Crystal system | monoclinic | monoclinic |
| Space group | $C2/c$ | $P2_1/c$ |

| GOF on $F^2$ | 0.913 | 1.025 |
| Largest peak, hole [e$Å^{-3}$] | 0.388, –0.201 | 0.400, –0.332 |

CCDC-294281 and CCDC-294282 contain the supplementary crystallographic data for **1** and **2**, respectively. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Methods:** DFT calculations for **1** and **2** were performed at the B3LYP/6-311G(d,p) level.[43–45] The starting points of the geometry optimisations were the X-ray structural coordinates of the single molecule of **1** and of the four independent molecules of **2** found in the corresponding asymmetric units. The Gaussian 03[46] suite of programmes was used for all calculations.

**Supporting Information** (see footnote on the first page of this article): Plots of C–H···Ni angles, $\psi$ and $\theta$ (see text for definitions) against the Ni···H distances for **1** and **2** (Figure S1).

## Acknowledgments

Financial support for this work was provided by the Council of Scientific and Industrial Research (CSIR) [Grant No. 01(1880)/03/EMR-II]. A. Mukhopadhyay thanks the CSIR for a research fellowship. We thank B. Pathak and T. S. Thakur for helpful discussions on the theoretical calculations. All calculations were done using the computational facility at the Centre for Modelling, Simulation and Design, University of Hyderabad. X-ray crystallographic studies were performed at the National Single Crystal Diffractometer Facility, School of Chemistry, University of Hyderabad (funded by the Department of Science and Technology). We thank the University Grants Commission for the facilities provided under the UPE and CAS programmes.

# The Assembly of Dinuclear Alkoxido-Bridged $Cu^{II}$ Halide Complexes of Pyridine Alcohols To Form Tetranuclear and Polynuclear Compounds: Synthesis, Structure, and Magnetic Properties

**Nina Lah,*[a] Ivan Leban,[a] and Rodolphe Clérac*[b]**

**Keywords:** Pyridine alcohol ligands / Alkoxido ligands / Copper(II) defect dicubanes / Copper(II) coordination polymers / X-ray structures / Magnetic properties

Reaction of $CuX_2$ (X = Cl, Br) with pyridine alcohol ligands [2-(hydroxymethyl)pyridine = Hhmp, 2-(hydroxyethyl)pyridine = Hhep and 2-(hydroxypropyl)pyridine = Hhpp] affords a series of new $Cu^{II}$ alkoxide complexes with a similar $Cu_2O_2$ structural motif: a dinuclear complex, $[Cu_2(hpp)_2Br_2]$ (**1**), two tetranuclear compounds, $[Cu_4(hpp)_4Br_4]$ (**2**) and $[Cu_4(hpp)_4Cl_4]$ (**3**), and polynuclear chains, $[Cu_2(hep)_2Cl_2]_n$ (**4**) and $[Cu_2(Hhmp)_2Cl_4]_n$ (**5**). The dinuclear complex **1** represents the basic building unit of the four other materials. In this family of compounds, the pyridine alcohol type ligands (Hhmp, Hhep, or Hhpp) provide the two alkoxido functions that bridge the $Cu^{II}$ centers. The tetranuclear analogues exhibit an unusual structure of the defect dicubane-like type with two missing vertices. The one-dimensional polymers **4** and **5** are composed of $Cu_2O_2$ dinuclear units interlinked through bridging chlorido ligands to form infinite chains. The analysis of the magnetic susceptibility measurements indicates the presence of strong antiferromagnetic coupling between the $S = 1/2$ $Cu^{II}$ metal ions through the bis(alkoxido) bridge.

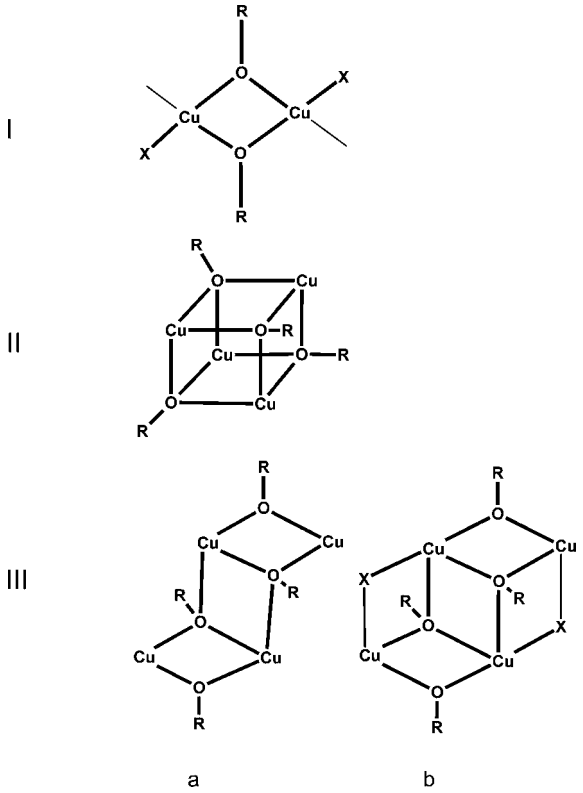
## Introduction

The aggregation of small well-defined coordination building blocks to form larger architectures is one of the major trends of research in coordination chemistry.[1–4] $Cu^{II}$ complexes are particularly popular since the metal ion is paramagnetic and affords easy formation of polynuclear clusters. Dinuclear $Cu^{II}$ complexes have often been used as models to study the magnetic-exchange interactions and as building blocks for the construction of polynuclear compounds with interesting magnetic properties.[5] Among them, $Cu^{II}$ carboxylates with a paddle-wheel structure and doubly bridged dinuclear complexes containing hydroxido alkoxido or halide bridging ligands have drawn considerable interest.[6] Our quest has been the preparation of new complexes based on the dinuclear $[Cu_2(OR)_2X_2]$ core. This motif consists of two copper atoms bridged by two alkoxido oxygen atoms from alkoxypyridine-type ligands. Moreover, each of the $Cu^{II}$ metal ions displays a pseudo-square-planar coordination geometry completed by two halogen anions in *trans* positions (Scheme 1, I) and by the pyridine function of the chosen ligand. The tendency of copper ions to accept



Scheme 1. The $[Cu_2(OR)_2X_2]$ structural core (I) and the tetranuclear species of cubane type (II), stepped-cubane type (IIIa) and "defect dicubane type" (IIIb).

a fifth ligand at the axial coordination site and the ability of alkoxido ligands to participate in bridging allow for the possibility of associating these dinuclear units into discrete oligonuclear and polynuclear compounds. The assembly of two dinuclear units leads to two types of tetranuclear aggregates: the cubane type (Scheme 1, II) and the so-called stepped-cubane type (Scheme 1, IIIa). Both types are known in $Cu^{II}$ alkoxide chemistry. While abundant structural data on cubane-type complexes is available in the literature,[7] the stepped cubanes appear much less frequently,[8] particularly, compounds that contain a halide ligand as one of the equatorial ligands of the copper centers in the dinuclear core. Upon association of the type I dinuclear units (Scheme 1), one of the two terminal halogenide ligands of each dimeric unit bridges neighboring $Cu_2(OR)_2$ building blocks to give rise to an unusual structural type (Scheme 1, IIIb). The resulting complex may be envisioned as an arrangement of two fused cubes, each missing one apex. It is worth noting that as far as we know, only one structurally characterized $[Cu_4(OR)_4X_4]$ species of this type has been reported in the literature.[9]

Although a considerable amount of research is currently focused on the rational design of premeditated architectures and complexes, it is often difficult, if not impossible, to answer the question why one complex is obtained rather than another. Progress in understanding self-assembly processes is likely to be developed by studying the aggregation of relatively simple and small building units. Herein we report on the preparation and structural characterization of copper(II) complexes that have the $Cu_2(OR)_2X_2$ core with three simple chelating pyridine-based alkoxido ligands (Scheme 2): 2-(hydroxymethyl)pyridine (Hhmp), 2-(hydroxyethyl)pyridine (Hhep), and 2-(hydroxypropyl)-pyridine (Hhpp). Five new compounds are presented, spanning diverse architectures from dinuclear $[Cu_2(hpp)_2Br_2]$ to two tetranuclear complexes with a dicubane-type structure, ($[Cu_4(hpp)_4Br_4]$ and $[Cu_4(hpp)_4Cl_4]$), and two polymeric chain compounds with the composition $[Cu_2(hep)_2Cl_2]_n$ and $[Cu_2(Hhmp)_2Cl_4]_n$. In addition to the synthesis and the structural characterization, the magnetic properties of the $Cu_2(OR)_2X_2$ core will be discussed.

## Results and Discussion

Simple pyridine-based alcohols such as 2-(hydroxymethyl)- (Hhmp), 2-(hydroxyethyl)- (Hhep) and 2-(hydroxypropyl)pyridine (Hhpp) have the ability to act as chelating and/or bridging ligands in their neutral and ionic forms, where the OH groups are deprotonated. Surprisingly, these simple commercially available substances have not been employed widely as ligands in coordination chemistry. Only in recent years, the simplest one from the above homologue series, Hhmp, has been used in manganese chemistry to obtain new single-molecule magnets (SMMs) or extended networks of SMMs.[10] Among the structurally characterized $Cu^{II}$ complexes based on the ligands listed above, the compounds with (hydroxymethyl)pyridine (Hhmp) prevail. The search through the Cambridge Structural Database (CSD) revealed six structures containing Hhmp and $Cu^{II}$ metal ions.[11] All of these examples are mononuclear species with six-coordinate $Cu^{II}$ centers to which Hhmp binds as a chelating ligand. In addition, it is worth noting that there is only one report on a structure with the anionic hmp ligand that adopts a chelating-bridging mode, which results in a tetranuclear complex $[Cu_4(hmp)_4(CH_3COO)_4]$ of a cubane type.[12] Structures with Hhep/hep and Hhpp/hpp appear even less frequently. Two $Cu^{II}$ mononuclear complexes with Hhep have been found in the CSD, while no example seems to exist with the ligand in its deprotonated form.[13] Only one mononuclear compound with Hhpp and one dinuclear example with the ligand in its deprotonated form (hpp) have been reported so far on the basis of a CSD search.[14]

We have carried out the syntheses by using simple bromide and chloride copper(II) salts ($CuX_2$ with X = Br, Cl) with Hhmp, Hhep, and Hhpp in methanol, ethanol, or a mixture of both alcohols. While the reactions with Hhep and Hhpp lead to the deprotonation of the ligand and thus alkoxido-bridged complexes (**1**–**4**), the Hhmp ligands stay protonated in **5**. The origin of this difference and the mechanism that assists the deprotonation of the coordinated alcohol in the case of the Hhep and Hhpp ligands is not clear. We have no explanation for the formation of alkoxido-bridged rather than hydroxido-bridged complexes, since the metal salts were not dried and water was not excluded from the reaction mixture. Analogically, the deprotonation of Hhmp under similar reaction conditions was expected even if the chelating mode of Hhmp coordination is apparently favored over the bridging mode. Indeed, this tendency to form five-membered chelating rings for the Hhmp ligand is also reflected in the CSD and in the occurrence of structures containing Hhmp.

### Structural Descriptions

#### *Dinuclear Complex $[Cu_2(hpp)_2Br_2]$ (1)*

Compound **1** represents the smallest complex in terms of nuclearity in this study (Figure 1). It consists of two copper atoms doubly bridged by chelating μ-hpp ligands. The remaining sites of the distorted square-planar environment around the copper centers are occupied by two bromido ligands that are arranged in a *trans* fashion. The two copper atoms are symmetry related by an inversion center and are separated by 3.0642(5) Å. The μ-O bridge is asymmetrical

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with Cu–O distances of 1.9179(13) and 1.9489(13) Å and a Cu–O–Cu angle of 104.8°. Basic geometric parameters, relevant to the Cu coordination sphere, are summarized in Table 1. There are no covalent interactions between the dimeric units.

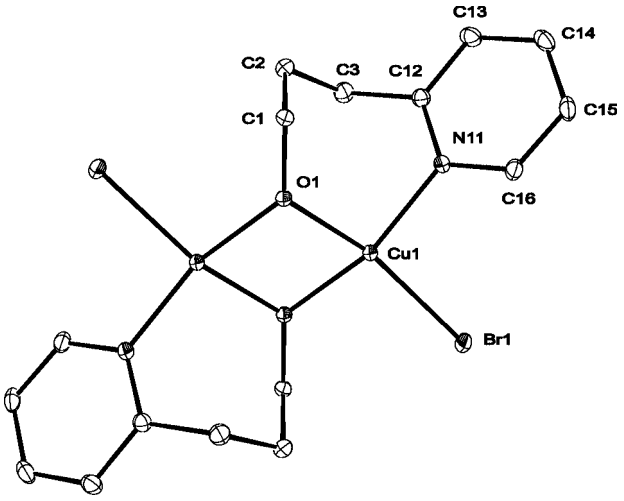

Figure 1. View of a centrosymmetric dinuclear unit in **1** (30% probability thermal ellipsoids). Only the atoms of the asymmetric unit are labeled.

### *Tetramers [Cu$_4$(hpp)$_4$Br$_4$] (2) and [Cu$_4$(hpp)$_4$Cl$_4$] (3)*

The basic molecular motif of these two materials is similar and is composed of four copper centers arranged to form a planar "rhombic" geometry (Scheme 1, IIIb). These tetranuclear complexes can be described as two [Cu$_2$(hpp)$_2$X$_2$] (with X: Br or Cl) dinuclear units, one lying on top of the other and slipped with respect to each other. One of the two bridging hpp oxygen atoms of each dinuclear unit is triply bridging and connects the two [Cu$_2$(hpp)$_2$X$_2$] moieties to form a stepped-cubane-type geometry. The tetranuclear aggregate is further stabilized by two halogen bridges inducing the "defect dicubane type" geometry: a pair of uncompleted cubes connected by a common Cu$_2$O$_2$ face. The bromido complex **2** crystallizes in a noncentrosymmetric space group $P2_1$ with the whole tetranuclear molecule as the asymmetric unit (Figure 2). The geometry of the two dinuclear moieties is essentially the same as can be seen from bond lengths and angles given in Table 2. The copper centers, which are doubly bridged by alkoxido oxygen atoms, are separated by 3.0421(9) and 3.0464(9) Å, while the distances between the copper atoms belonging to different dinuclear units are longer. Those involving $\mu_3$-O- and μ-Br-bridged Cu atoms are 3.6003(9) and 3.6113(9) Å for the Cu1–Cu3 and Cu4–Cu2 pairs, respectively. The ($\mu_3$-O)$_2$-bridged pair of copper atoms (Cu1 and Cu2) is separated by 3.3555(8) Å. The chloride analogue **3** crystallizes in the space group $P2_1/n$ with an inversion center located in the center of the Cu$_2$($\mu_3$-O)$_2$ plane (Figure 3). Thus, the asymmetric unit here is composed only of a dimeric half of the tetranuclear complex [Cu$_2$(hpp)$_2$X$_2$]. The geometry of this dinuclear unit (Table 2) is similar to that of the bromido analogue. Again, the bridging alkoxido group from one [Cu$_2$(hpp)$_2$X$_2$] motif coordinates to the copper ions of the other moiety, thereby becoming a $\mu_3$ ligand. Additionally, two chlorido bridges consolidate the tetranuclear core to form a centrosymmetric complex with a IIIb topology (Scheme 1), as presented in Figure 3. In these aggregates, two types of Cu$^{II}$ ions with a square-pyramidal coordination sphere can be distinguished: (i) Cu1 and Cu2 in **2** or Cu2 in **3** possess a CuXNO$_3$ environment with a basal plane occupied by a triply bridging hmp oxygen atom, a halogen ion, a pyridine-type nitrogen atom, and μ-O atom from a chelating hmp. The apical site is occupied by a $\mu_3$-O atom from the neighboring dinuclear unit. The remaining

two copper centers, Cu3 and Cu4 in **2** or Cu1 in **3**, possess a $CuX_2NO_2$ geometry. The equatorial plane is formed by a μ-O atom from a bridging hmp ligand, a halogen ion, a pyridine-type nitrogen atom, and a $\mu_3$-O atom from a chelating hmp. The axial site is occupied by a halogen ion from the adjacent dinuclear unit. It is worth noting that the assembly of two alkoxido-bridged dicopper units usually results in a compact cube-like complex, particularly when the dinuclear unit contains halide ligands. To the best of our knowledge, there is only one structure known, $[Cu_4(M3)_2(\mu_3\text{-}OMe)_2(\mu\text{-}Cl)_2Cl_2]$, that contains the $[Cu_4(\mu\text{-}OR)_2(\mu_3\text{-}OR)_2(\mu\text{-}X)_2X_2]$ tetranuclear defect dicubane core.[9] However, the arrangement of the bridging and terminal halogenide ligands in the present tetranuclear complexes differ from that observed in the reported structure. In **2** and **3**, the basic dinuclear moiety contains halogen ions located in a *trans* fashion, whereas in the aforementioned complex, the Cl ions are coordinated to the $Cu^{II}$ centers in *cis* positions. The $[Cu_4(M3)_2(\mu_3\text{-}OMe)_2(\mu\text{-}Cl)_2Cl_2]$ complex contains two different alkoxido ligands: $\mu_3$-bridging methoxy groups and a tridentate macrocyclic ligand (M3) that offers a μ-bridging phenoxo group and occupies, by its two nitrogen atoms, the two (*cis*) equatorial positions of each of the copper metal ions. This peculiar macrocyclic ligand geometry thus prevents the chlorido ligands from adopting *trans* positions.

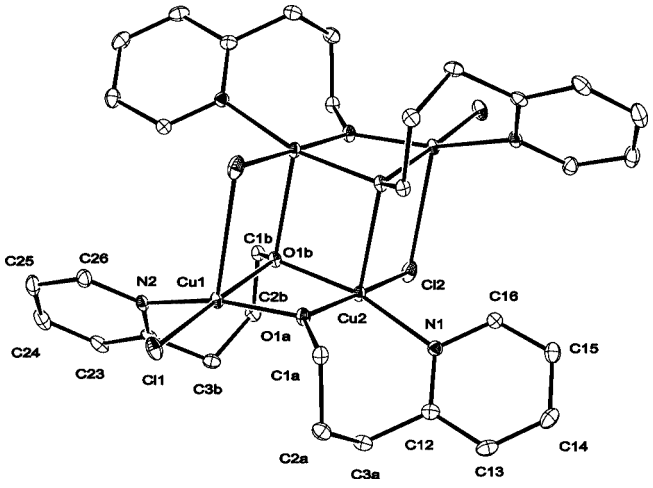

Figure 3. Structural representation of a centrosymmetric tetranuclear core of **3** (30% probability thermal ellipsoids).

### *Polymer $[Cu_2(hep)_2Cl_2]_n$ (4)*

In **4**, the centrosymmetric dimeric units (Figure 4, Table 3) assemble through weak interactions arising from two bridging chlorido ligands to form a linear chain shown in Figure 5. The distance between the copper centers within the alkoxido dimer is 3.0833(4) Å, whereas the distance between the copper centers that are doubly bridged by μ-Cl is longer: 3.8080(5) Å. The consecutive bridging planes ($Cu_2O_2$ and $Cu_2Cl_2$) are twisted with respect to each other and the dihedral angle is 77.93(5)°. The overall structure may be compared to the one observed in the complex $[Cu(nhep)Cl]_2$ containing 1-(2-hydroxyethyl)pyrazole (nhep) as the alkoxido bridging ligand.[15] In this compound, the basic dinuclear unit has no center of symmetry but connects through weak inter-dimer interactions arising from two bridging chlorido ligands to form polynuclear chains with di-μ-O and di-μ-Cl bridges, as described here.

[a] Symmetry codes: (i) $-x+1$, $-y$, $-z+1$, (ii) $-x+2$, $-y$, $-z+1$, (iii) $-x$, $-y$, $-z+2$, (iv) $-x+1$, $-y$, $-z+2$.

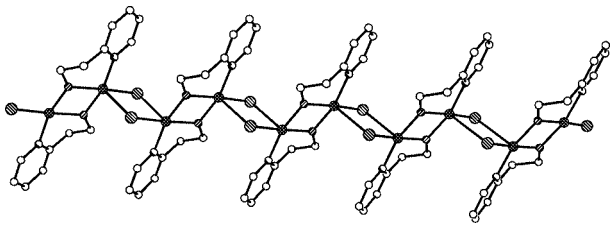

Figure 5. The one-dimensional chain structure of **4**.

### *Polymer $[Cu_2(Hhmp)_2Cl_4]_n \cdot 2nCH_3OH$ (5)*

Complex **5** contains 2-(hydroxymethyl)pyridine (Hhmp) in its protonated form. The polymeric chain is built up from centrosymmetric dinuclear $[Cu_2Hhmp_2Cl_4]$ units presented in Figure 6. The two Cu atoms, separated by 3.8641(5) Å, are doubly bridged by two chlorido ligands. The bridge is far from symmetrical with Cu1–Cl2 and Cu1–Cl2* (with *: $-x$, $-y$ $-z+2$) distances of 2.2418(5) and 2.9415(6) Å, respectively, and a Cu1–Cl2–Cu1* bridging angle of 95.45°. The Hhmp ligand binds to a single Cu metal ion within the dimer in a chelating manner [Cu1–N11: 1.9957(17) Å and Cu1–O1: 1.9959(16) Å]. The fifth coordination site is occupied by a terminal chlorido ligand at a distance of 2.2607(6) Å. Additionally, copper ions show rather weak in-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

teractions with the Hhmp oxygen atom from a neighboring dimer with a distance between Cu1 and O1* (with *: $-x+1$, $-y$ $-z+2$) of 2.9073(16) Å. As a result of this weak interaction, infinite chains are formed in which $[Cu_2Hhmp_2Cl_4]$ dimers are further doubly bridged by Hhmp oxygen atoms as illustrated by Figure 7. The inter-dimer Cu–Cu separation is 3.9191(5) Å. The consecutive bridging planes $Cu_2Cl_2$ and $Cu_2O_2$ are almost perpendicular to each other [dihedral angle of 88.34(5)°]. Topologically, the chain structure of compound **5** is related to that of **4**. Its formation may as well be described as $[Cu_2Hhmp_2Cl_2]$ dimers connected into chains through μ-Cl ligands. Because Hhmp exists in **5** in the neutral form, such a chain would bear a positive charge. Thus, an additional terminal chlorido ligand is bound to each copper atom to compensate for the charge and complete the six-coordinate geometry of the Cu centers. The compound crystallizes as methanol solvate with two solvate molecules per dimeric unit. Both alcohols, Hhmp and methanol, are involved in hydrogen-bond interactions [O1–O2* with *: $-x+1$, $-y$, $-z+2$ = 2.583(2) Å; O2–Cl1* with *: $x+1$, $y$, $z$ = 3.090(2) Å].

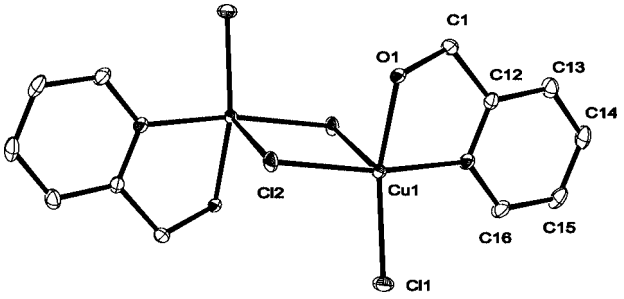

Figure 6. Structural representation of the centrosymmetric dinuclear unit in **5** (30% probability thermal ellipsoids).

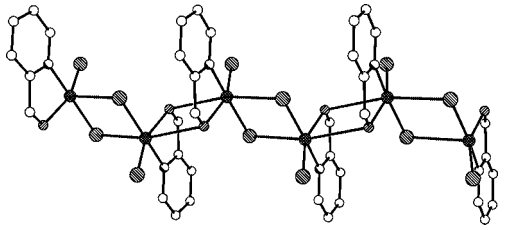

Figure 7. The one-dimensional chain structure of **5**.

### Magnetic Behavior

The variable temperature magnetic susceptibility measurements for compound **1** are shown in Figure 8 as an $\chi T$ vs. $T$ plot. By lowering the temperature, the $\chi T$ product that reaches 0.06 $cm^3\,K\,mol^{-1}$ at room temperature continuously decreases down to 130 K. Below 130 K, the compound displays a diamagnetic ground state. This magnetic behavior is typically observed for dinuclear $Cu^{II}$ complexes that possess a strong intracomplex antiferromagnetic interaction. A simple dinuclear Heisenberg $S = 1/2$ model[16] has been used to fit the magnetic susceptibility (Figure 8) by considering the following spin Hamiltonian: $H = -2J\ \{S_{Cu1}\cdot S_{Cu2}\}$ (where $S_{Cu1}$ and $S_{Cu2}$ are the spin operators with $S_{Cu1} = S_{Cu2} = 1/2$). The best set of parameters obtained for **1** by using the above model is: $J/k_B = -580(20)$ K, $g = 2.1(1)$ and $\rho = 0.002$ [this $\rho$ parameter has been added to the model in order to take into account a residual paramagnetic Curie component as $\chi = (1-\rho)\,\chi_{dimer} + \rho C_{S=1/2}/T$]. From a magnetic point of view, all the other compounds, **2**, **3**, and **4**, can be described as $CuO_2Cu$ dinuclear complexes by considering only the magnetic interactions through the bis(alkoxido) bridge. The assembly of these dinuclear units takes place through the axial sites of each copper ion and thus the bis(chlorido) bridge is likely to be much weaker. Therefore, the magnetic susceptibility of compounds **2**, **3**, and **4** can be modeled by using the above-described magnetic Heisenberg approach (Figure 8). The best set of parameters obtained by using this model is: $J/k_B = -586(20)$ K, $g = 2.3(1)$, $\rho = 0.026$ for **2**, $J/k_B = -641(25)$ K, $g = 2.2(1)$, $\rho = 0.021$ for **3**, and $J/k_b = -850(30)$ K, $g = 2.1(1)$, $\rho = 0.02$ for **4**. It is worth noting that similar magnetic behavior and antiferromagnetic interactions have been found for bis(alkoxido) dinuclear copper(II) complexes.[9,15] The present compounds thus possess a diamagnetic ground state that is the only thermally populated state above 130 K.

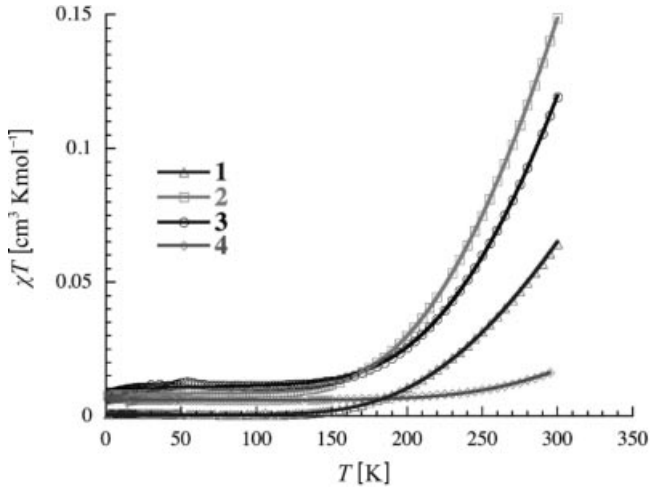

Figure 8. $\chi T$ vs. $T$ data (where $\chi = M/H$) for compound **1**, **2**, **3**, and **4** measured at 1000 Oe. The solid lines are the best fits obtained with the Heisenberg model described in the text.

## Concluding Remarks

The reactions of copper(II) halides with three pyridine alcohol ligands afforded a series of new complexes based on a dinuclear $Cu_2(OR)_2X_2$ core. Among them, two tetranuclear compounds (**2**, **3**) exhibit a defect dicubane structure with two missing vertices, which is rarely observed in $Cu^{II}$ alkoxide chemistry. As shown by the magnetic properties of **1**, this dinuclear $Cu_2(OR)_2X_2$ building block possesses a singlet ground state and thus induces all the resulting complexes based on this unit to also exhibit a diamagnetic ground state. The paramagnetic triplet state is thermally populated above 130 K for all the reported mate-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rials. The existence of neutral and deprotonated forms of the coordinated ligands warrants further investigation on the reaction conditions necessary for ligand deprotonation.

## Experimental Section

**General Procedures and Materials:** All manipulations were carried out under ambient conditions by using commercial grade solvents. Chemicals were used as received (Aldrich) without further purification.

**Synthesis**

**$[Cu_2(hpp)_2Br_2]$ (1):** $CuBr_2$ (0.11 g) was dissolved in a mixture of methanol (10.0 mL) and ethanol (10.0 mL). On adding the disodium salt of succinic acid (0.05 g), a blue product precipitated. After the addition of 2-(hydroxypropyl)pyridine (0.13 mL), the mixture was heated to boiling and then cooled to ambient temperature. The remaining blue product was filtered off. Slow cooling of the green filtrate to 5 °C gave bluish-green plate-like crystals of **1**. Yield: 0.023 g (16%). $C_{16}H_{20}Br_2Cu_2N_2O_2$ (559.24): calcd. C 34.36, H 3.60, N 5.01; found C 34.55, H 3.76, N 4.95.

**$[Cu_4(hpp)_4Br_4]$ (2):** $CuBr_2$ (0.11 g) was dissolved in methanol (9.0 mL) and 2-(hydroxypropyl)pyridine (0.13 mL) was added. Slow cooling of the resulting olive-green solution to 5 °C gave grass-green rod-like crystals. Yield: 0.067 g (48%). $C_{32}H_{40}Br_4Cu_4N_4O_4$ (1118.48): calcd. C 34.36, H 3.60, N 5.01; found C 34.57, H 3.72, N 4.90.

**$[Cu_4(hpp)_4Cl_4]$ (3):** $CuCl_2{\cdot}2H_2O$ (0.11 g) was dissolved in methanol (10 mL). 2-(Hydroxypropyl)pyridine (0.13 mL) was then added whilst stirring. Upon ligand addition, the color of the solution changed from light blue to olive green. Green crystals precipitated on standing overnight at ambient conditions. Yield: 0.073 g (62%). $C_{32}H_{40}Cl_4Cu_4N_4O_4$ (940.68): calcd. C 40.85, H 4.29, N 5.96; found C 40.89 H, 4.39, N 5.81.

**$[Cu_2(hep)_2Cl_2]_n$ (4):** $CuCl_2{\cdot}2H_2O$ (0.11 g) was dissolved in methanol (15 mL). 2-(Hydroxyethyl)pyridine (0.13 mL) was then added whilst stirring. Upon ligand addition, the color of the solution changed from light blue to grass green. Green crystals precipitated on standing overnight at room temperature. Yield: 0.078 g (27%). $C_{14}H_{16}Cl_2Cu_2N_2O_2$ (442.28): calcd. C 38.02, H 3.65, N 6.33; found C 38.16, H 3.74, N 6.21.

**$[Cu_2(Hhmp)_2Cl_4]_n{\cdot}2nCH_3OH$ (5):** $CuCl_2{\cdot}2H_2O$ (0.11 g) was dissolved in methanol (10 mL). 2-(Hydroxymethyl)pyridine (0.20 mL) was then added whilst stirring. Upon ligand addition, the color of the solution changed from light blue to grass green. On standing at room temperature, a green microcrystalline product precipitated, which was then filtered off. The mother liquor was cooled slowly to 5 °C, which resulted in the precipitation of grass-green elongated blocks, unstable in air.

**Physical Measurements:** Elemental analyses were measured at the Faculty of Chemistry and Chemical Technology, University of Ljubljana with a Perkin–Elmer 240 C, H, N analyzer. IR spectra were recorded with a Perkin–Elmer 2000 spectrometer. Spectra can be obtained from authors upon request. Magnetic susceptibility measurements were obtained with the use of a Quantum Design SQUID MPMS-XL magnetometer. Measurements were performed on finely ground crystalline samples: 25.13 mg (**1**), 13.48 mg (**2**), 32.14 mg (**3**), and 25.73 mg (**4**) over the temperature range 1.8–300 K. The magnetic data were corrected for the sample holder, and the diamagnetic contribution calculated from Pascal's constants.[17] The presence of ferromagnetic impurities has been systematically checked by measuring the magnetization as a function of the field at 100 K. No presence of ferromagnetic impurities was seen in **1**, **3**, and **4**. For **2**, the susceptibility obtained at 100 K from the $M$ vs. $H$ data has been used to correct the extrinsic ferromagnetic contribution. Physical characterizations of **5** have not been possible because of its high instability in air.

**Crystallography:** X-ray single-crystal data were collected with a Nonius Kappa CCD diffractometer with graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 150 K for compounds **1**, **3**, and **5** and at 293 K for compounds **2** and **4**. The data were processed by using DENZO and SCALEPACK.[18] The structures were solved by direct methods implemented in the SHELX-97 package[19] and refined by a full-matrix least-squares method on $F^2$ against all reflections by using the same program. Hydrogen atoms were placed in geometrically calculated positions and were refined using a riding model, except those of the alcohol groups in compound **5**, which were found from a Fourier difference map and freely refined. Compound **2** crystallizes in the noncentrosymmetric space group $P2_1$. The value of the Flack parameter 0.495(12) indicates possible racemic twinning. Crystallographic data are listed in Table 4. CCDC-602082, -602083, -602084, -611672, and -611673 contain the supplementary crystallographic data for this paper. These data

# Cobalt and Nickel Complexes Bearing Pyrazolyliminophosphorane Ligands: Synthesis, Characterisation and Catalytic Ethylene Oligomerisation Behaviour

**Cheng Zhang,[a] Wen-Hua Sun,[b] and Zhong-Xia Wang*[a]**

**Keywords:** Cobalt / Nickel / Homogeneous catalysis / Ethylene / Oligomerisation

Treatment of 1-(2′-azidophenyl)-3,5-dimethylpyrazole (**1**) with $Ph_2PR$ (R = Ph, Me) and $(Ph_2P)_2CH_2$, respectively, affords the pyrazolyliminophosphoranes **2**, **3** and **4**. Reaction of **2** or **3** with $[NiCl_2(dme)]$ or $NiBr_2$ yields the N,N-chelate nickel complexes **5**–**8**, and with $CoCl_2$ complexes **9** and **10**. Reaction of **4** with $[NiCl_2(dme)]$, $NiBr_2$ and $CoCl_2$, respectively, affords the N,N,P-chelate complexes **11**–**13**. Compounds **2**–**4** were characterised by $^1H$, $^{13}C$, $^{31}P$ NMR and IR spectroscopy and elemental analysis, while complexes **5**–**13** were characterised by IR spectroscopy and elemental analysis. The structures of complexes **5**, **9** and **12** were further characterised by single-crystal X-ray diffraction techniques. Complexes **5**–**13** are active catalysts for ethylene oligomerisation upon activation with alkylaluminium derivatives ($Et_2AlCl$, MAO or MMAO). These complexes exhibit good to high catalytic activities (up to $3.54 \times 10^6$ g mol$^{-1}$ h atm for the nickel complexes and $5.48 \times 10^5$ g mol$^{-1}$ h atm for the cobalt complexes). The effects of varying ethylene pressure, temperature and aluminium co-catalyst/Ni or Co ratios with complexes **5**, **9**, **11** and **12** are reported.

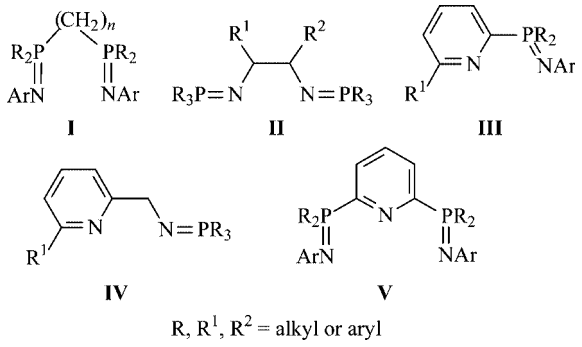
## Introduction

Ethylene oligomerisation to form linear α-olefins has become a topic of considerable interest in both academia and industry as these oligomers are used as co-monomers with ethylene and for the preparation of a variety of important compounds such as detergents, synthetic lubricants, additives for high-density polyethylene production and surfactants.[1] Late transition metal complexes have demonstrated potential as catalysts for ethylene oligomerisation. A representative example is the nickel catalysts in the Shell higher olefin process (SHOP).[2] Other late transition metal complexes have also proved to be active. These complexes are supported by extensive didentate and tridentate ligands, including N,N,[3] N,P,[1,4] N,O,[5] P,O,[6] P,P,[7] N,N,P,[8] N,N,N,[1b,3b,9] N,P,N[10] and P,N,P[11] ligands. Recently, chelating nitrogen ligands featuring iminophosphorane moieties have attracted considerable attention. Examples include **I**–**V** (Scheme 1).[3a–3d,12] Some of the late transition metal complexes with these ligands exhibit ethylene polymerisation or oligomerisation activities in the presence of appropriate co-catalysts. Pyrazole-based ligands have also received extensive attention in recent years for the preparation of olefin polymerisation catalysts, including poly(pyrazolyl)borates, didentate bis-pyrazolyl ligands and mixed donor ligands.[1b,4f,9b,13] Our aim was to examine a set of new ligands that combine pyrazolyl and iminophosphorane units for late transition metals relevant for catalysis of ethylene polymerisation or oligomerisation. Herein we report the synthesis, characterisation and catalytic performance for ethylene oligomerisation of cobalt and nickel complexes bearing pyrazolyliminophosphorane ligands.



Scheme 1.

## Results and Discussion

### Synthesis and Characterisation of Compounds 2–13

Compound **1** was prepared according to a literature method.[4f,14] Syntheses of ligands **2**–**4** and cobalt and nickel complexes **5**–**13** are summarised in Scheme 2. Treatment of **1** with one equivalent of phosphane $Ph_2PR$ (R = Ph or Me) or $Ph_2PCH_2PPh_2$ yielded iminophosphoranes **2**–**4** in high yields. Reaction of **2** or **3** with $MX_2$ (M = Ni, X

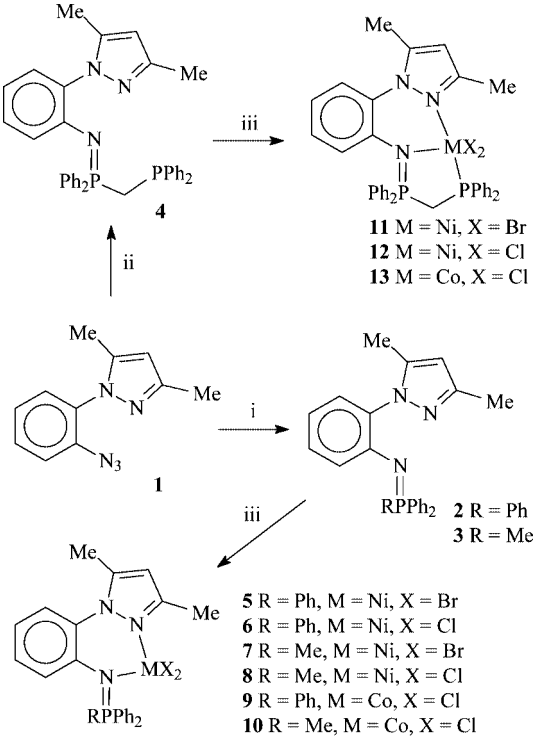
= Br; M = Co, X = Cl) or [$NiCl_2$(dme)] afforded complexes **5**–**10** in good to excellent yields. A similar reaction between **4** and the metal halides gave complexes **11**–**13**. Compounds **2**–**4** are yellow (**2** and **4**) or orange (**3**) solids and were fully characterised by $^1H$, $^{13}C$ and $^{31}P$ NMR spectroscopy and elemental analyses. Complexes **5**–**13** are blue (**5**–**10** and **13**), purple (**11**) or yellow (**12**) crystals or powder. Complexes **5** and **7**–**13** are air stable and complex **6** forms an $H_2O$ adduct after being exposed to air for a long period. These complexes are paramagnetic and were characterised by IR spectroscopy and elemental analyses, as well as by single-crystal X-ray diffraction techniques (for **5**, **9** and **12**).



Scheme 2. Synthesis of compounds **2**–**13**. Reagents and conditions: i) $Ph_2PR$ (R = Ph, Me), $CH_2Cl_2$, room temperature, 12 h; ii) $Ph_2PCH_2PPh_2$, $CH_2Cl_2$, room temperature, 12 h; iii) $MX_2$ (M = Ni, X = Br; M = Co, X = Cl) or [$NiCl_2$(dme)], thf, room temperature, 15 h.

The structure of **5** is presented in Figure 1. Crystalline **5** is monomeric. Its Ni atom is four coordinate and has a distorted tetrahedral geometry. The N1–C19–C24–N2 atoms lie in the same plane. The N1–Ni1–N3–N2 atoms are also approximately co-planar, with a torsion angle of 4°. The six-membered metallacycle shows a boat conformation. The Ni1–N1 distance of 2.002(6) Å is longer than those found in [{2-[$Ph_2P$=N($C_6H_3Me_2$-2′,6′)]-6-($SiMe_3$)-$C_5H_3N$}$NiBr_2$] [1.996(8) Å] and [{2-($Ph_3P$=$NCH_2$)-6-$MeC_5H_3N$}$NiBr_2$] [1.983(3) Å].[3c] The Ni1–N3 distance of 2.007(6) Å is close to that in [{1-(2′-$Ph_2PC_6H_4$)-3,5-$Me_2C_3HN_2$}$NiCl_2$] [2.003(4) Å],[4f] but slightly shorter than those found in [{NH(1-$CH_2CH_2$-3,5-$Me_2$-$C_3HN_2)_2$}$NiCl_2$] [2.069(2) and 2.0334(19) Å, respectively].[1b] The two Ni–Br bond lengths are very similar and are typical for this class of compounds.[3c,15] The P–N distance of 1.624(6) Å is normal for metal-coordinated iminophosphoranes.[3b,16]

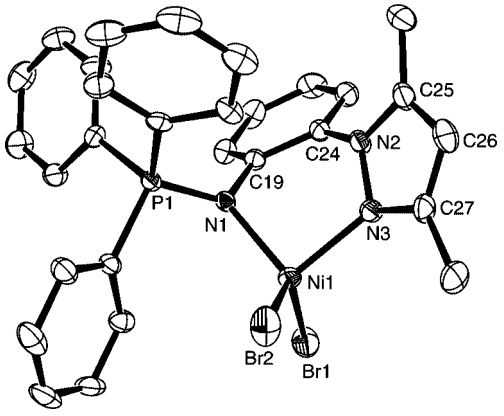


Figure 1. ORTEP drawing of complex **5** (thermal ellipsoids at 30% probability). Selected bond lengths [Å] and angles [°]: Ni(1)–N(1) 2.002(6), Ni(1)–N(3) 2.007(6), Ni(1)–Br(1) 2.3614(13), Ni(1)–Br(2) 2.3743(13), P(1)–N(1) 1.624(6), N(1)–C(19) 1.421(9), N(2)–N(3) 1.388(8), N(2)–C(24) 1.434(9), C(19)–C(24) 1.412(10); N(1)–Ni(1)–N(3) 92.2(2), N(1)–Ni(1)–Br(1) 104.75(17), N(3)–Ni(1)–Br(1) 108.5(2), N(1)–Ni(1)–Br(2) 113.81(16), N(3)–Ni(1)–Br(2) 106.71(18), Br(1)–Ni(1)–Br(2) 125.71(6), C(19)–N(1)–Ni(1) 113.3(4), P(1)–N(1)–Ni(1) 124.4(3), C(27)–N(3)–Ni(1) 127.4(5), N(2)–N(3)–Ni(1) 118.3(4), C(19)–N(1)–P(1) 121.5(5), N(3)–N(2)–C(24) 119.1(6).

The structure of **9** is shown in Figure 2. Crystalline **9** is monomeric and the Co centre is in a distorted tetrahedral environment. Like complex **5**, the six-membered metallacycle also exists in a boat conformation in the solid state. The Co–N distance (av. 2.045 Å) is close to that in [{$CH_2$($Ph_2P$=NPh)$_2$}$CoCl_2$] (av. 2.032 Å).[3b] The Co–Cl

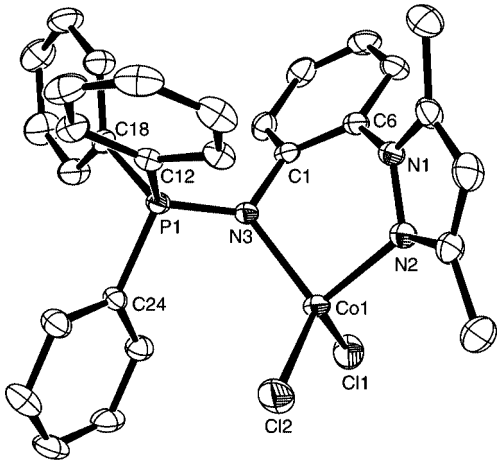

Figure 2. ORTEP drawing of complex **9** (thermal ellipsoids at 30% probability). Selected bond lengths [Å] and angles [°]: Co(1)–N(2) 2.052(2), Co(1)–N(3) 2.038(2), Co(1)–Cl(1) 2.2376(10), Co(1)–Cl(2) 2.2476(10), P(1)–N(3) 1.610(2), N(1)–N(2) 1.385(3), N(1)–C(6) 1.435(4), C(1)–C(6) 1.401(4), N(3)–C(1) 1.427(3); N(3)–Co(1)–N(2) 91.54(9), N(3)–Co(1)–Cl(1) 108.60(7), N(2)–Co(1)–Cl(1) 113.27(8), N(3)–Co(1)–Cl(2) 115.95(7), N(2)–Co(1)–Cl(2) 107.75(8), Cl(1)–Co(1)–Cl(2) 117.01(4), N(1)–N(2)–Co(1) 117.84(18), C(1)–N(3)–Co(1) 111.62(17), N(2)–N(1)–C(6) 119.4(2), C(1)–N(3)–P(1) 122.10(18), C(1)–N(3)–Co(1) 111.62(17), P(1)–N(3)–Co(1) 125.55(13).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

distances [2.2376(10) and 2.2476(10) Å, respectively] are within the normal range for four-coordinate Co complexes.[3b,3c,17]

Single crystals of complex **12** suitable for X-ray crystallography were grown from toluene. The molecular structure of complex **12** is presented in Figure 3. Complex **12** is monomeric and co-crystallises with one toluene molecule. The coordination geometry around the nickel atom is distorted trigonal bipyramidal in which the P1–Ni1–N3 angle is 167.57(9)° as a result of the strain imposed by the five- and six-membered chelate rings. The N1–Ni1–Cl1–Cl2 atoms are nearly co-planar. The N1–C26–P2–Ni1 atoms are also approximately in the same plane, the sum of the angles around N1 being 359.92°. The Ni–N distance (av. 2.063 Å) is slightly longer than that in complex **5** and comparable to those in [{NH(1-$CH_2CH_2$-3,5-$Me_2C_3HN_2$)$_2$}$NiCl_2$] [2.069(2) and 2.0334(19) Å, respectively].[1b] Both P1 and P2 exhibit distorted tetrahedral geometries. The Ni1–P1 distance of 2.4001(11) Å is longer than that in [{1-(2′-$Ph_2PC_6H_4$)-3,5-$Me_2C_3HN_2$}$NiCl_2$] [2.281(2) Å],[4f] but still within the normal range.[8]

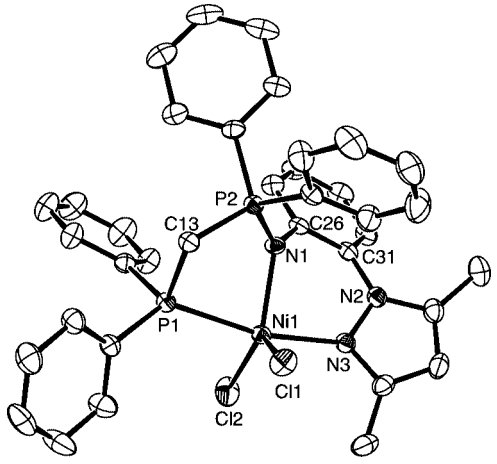

Figure 3. ORTEP drawing of complex **12** (thermal ellipsoids at 30% probability). ## Catalytic Properties of Complexes 5–13 for Ethylene Oligomerisation

We initially examined the catalytic activities of complexes **5**–**10** using $Et_2AlCl$ as activator; the results are displayed in Table 1. At an Al/metal molar ratio of 300 and 20 °C under 1 atm of ethylene the cobalt complexes **9** and **10** are inactive, whereas complexes **5**–**8** catalyse the dimerisation and trimerisation of ethylene with high activity ($2.09 \times 10^5$ to $1.86 \times 10^6$ g mol$^{-1}$ h; entries 3 and 11–13 in Table 1). The influence of the Al/Ni ratio, the reaction temperature and ethylene pressure was investigated for complex **5**. At 20 °C under 1 atm of ethylene, when the ratio of Al to Ni was 300 complex **5** showed the highest catalytic activity ($1.34 \times 10^6$ g mol$^{-1}$ h atm). Variation of the reaction temperature also influences the catalytic activity and product distribution. Thus, with a rise of the temperature from 20 °C to 40 °C and finally to 55 °C the catalytic activity of **5** gradually decreased and the proportion of $C_6$ component increased (entries 3, 7 and 8 in Table 1). At 0 °C the catalytic activity of **5** was close to that at 40 °C. However, the proportion of $C_6$ component at 0 °C was far lower than that at 40 °C (entry 3 in Table 1). This decrease of catalytic activity with a rise of temperature may be attributable to the lower solubility of ethylene and the decomposition of the active sites at higher temperature. The catalytic activities of complexes **6** and **7** at 20 °C under 1 atm of ethylene and with a 300:1 Al/Ni molar ratio ($7.67 \times 10^5$ and $2.09 \times 10^5$ g mol$^{-1}$ h atm, respectively) are lower than that of complex **5**. Complex **8** exhibits the highest catalytic activity ($1.86 \times 10^6$ g mol$^{-1}$ h atm). Enhancement of the ethylene pressure does not increase the catalytic activity of **5** in unit pressure (entry 10 in Table 1). Comparison of the catalytic

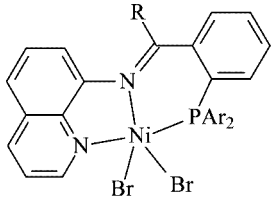
| 14 | **12** | 300 | 1 | 0.5 | 60 | 1.88 | 66.0 | 34.0 |

[a] Conditions: 5 μmol of pre-catalyst, $Et_2AlCl$ as co-catalyst, 30 mL of toluene (120 mL of toluene when determined at 10 atm). [b] $10^6$ g mol$^{-1}$ h. [c] Weight percent determined by GC analysis.

activities of complexes **5**–**8** showed that under the same conditions the activity order is **8** > **5** > **6** > **7**. Unfortunately, it is difficult to establish a relationship between the catalytic activities and the electronic and steric effects of the groups attached to the phosphorus and nickel atoms from these results.

It has been reported that the nickel complexes of N,N,P-tridentate ligands **VI** show high catalytic activity for ethylene oligomerisation in the presence of $EtAlCl_2$.[8] We therefore added a $Ph_2P$ group to the *P*-methyl of ligand **3** to construct the new N,N,P tridentate ligand **4**. The nickel complexes of the ligand (**11** and **12**) show high catalytic activity for ethylene oligomerisation in the presence of $Et_2AlCl$ (Table 2). In each case the reaction produced a mixture of $C_4$ and $C_6$ species. The quantity of aluminium co-catalyst affected the outcome of the reaction. For complex **11**, enhancement of the Al/Ni molar ratio from 50:1 to 300:1 gave an increase in catalytic activity. With further augmentation of the Al/Ni ratio the catalytic activity gradually decreased (entries 1–5 in Table 2). The effect of reaction temperature was also studied. The reaction was carried out at 0, 20, 40 and 60 °C, and the results showed that the highest catalytic activity was achieved at 40 °C. It seems that in this example the lowering of ethylene solubility at higher temperature is not the main factor affecting the catalytic activity of **11**. It was also noted that prolonging the reaction time led to a decrease of catalytic activity and an increase of the $C_6$ fraction in the products. This increase of the proportion of $C_6$ component may be due to co-oligomerisation of $C_4$ accumulated in the reaction vessel. The influence of pressure was similar to that with complex **5**. Thus, an increase of ethylene pressure did not obviously



**VI**

enhance the catalytic activity of **11** in unit pressure (entry 10 in Table 2). For complex **12**, the highest activity was observed at 20 °C and 1 atm of ethylene in the presence of 300 equiv. of $Et_2AlCl$.

In addition, compared with the nickel complexes with didentate ligands **5**–**8**, complexes **11** and **12** exhibit higher catalytic activity under similar reaction conditions.

The nature of the aluminium co-catalyst affects the catalytic properties of the pre-catalysts greatly. As we mentioned above, the cobalt complexes are inactive for ethylene oligomerisation with $Et_2AlCl$ as co-catalyst. However, they showed good catalytic activities for ethylene oligomerisation with MAO or MMAO as activator (Table 3). Complexes **9**, **10** and **13** showed similar catalytic activities when MAO was used as co-catalyst (Al/Co = 2400) at 20 °C under 1 atm of ethylene. The catalytic reaction yielded a mixture of $C_4$ and $C_6$ species.

When MMAO was used as co-catalyst, **13** revealed lower activity than **9** and **10**. However, each of complexes **9**, **10** and **13** exhibits higher activities than that with MAO as activator under similar reaction conditions. We also tested the effect of the Al/Co ratio for complex **9**. Increase of the MAO/Co or MMAO/Co ratio resulted in an enhancement of catalytic activities (entries 1–7 and 10–15 in Table 3). An important feature of the cobalt complex/MMAO systems was the selectivity: in each case the reaction gave almost single $C_4$ species.

## Conclusions

We have synthesised and characterised a set of novel N,N and N,N,P chelating ligands and their nickel and cobalt complexes. Upon activation with $Et_2AlCl$, the nickel complexes reveal high catalytic activity for the dimerisation and trimerisation of ethylene under the optimal conditions, whereas the cobalt complexes are inactive. When activated with MAO or MMAO the cobalt complexes exhibit high catalytic activities. It was also observed that the catalytic activity of complex **9** increases with an increase of the Al/Co ratio. When activated with MMAO, the cobalt complexes show high selectivity, forming almost single $C_4$ species. Investigation of the action of the ligands revealed that the nickel complexes with the tridentate ligand have a higher catalytic activity than those with didentate ligands when activated with $Et_2AlCl$. However, the cobalt complexes with tridentate ligands exhibit lower activity than those with didentate ligands when activated with MMAO. When MAO was used as activator, the cobalt complexes with either tridentate or didentate ligands show similar catalytic activity.

## Experimental Section

**General Procedure:** All air- or moisture-sensitive manipulations were performed under dry $N_2$ using standard Schlenk and vacuum-line techniques. Solvents were distilled under $N_2$ over sodium/benzophenone (toluene, *n*-hexane, thf and $Et_2O$) or $CaH_2$ ($CH_2Cl_2$) and degassed prior to use. NMR spectra were recorded with a Bruker av300 spectrometer at ambient temperature (300 MHz for $^1H$, 75.5 MHz for $^{13}C$ and 121.5 MHz for $^{31}P$). The chemical shifts of $^1H$ and $^{13}C$ NMR spectra are referenced to internal solvent resonances; the $^{31}P$ NMR spectra are referenced to external 85% $H_3PO_4$. IR spectra were recorded with a Bruker VECTOR-22 spectrometer. Elemental analyses were performed by the Analytical Centre of the University of Science and Technology of China. GC analyses were performed with a Carlo Erba Strumentazione gas chromatograph equipped with a flame ionisation detector and a 30 m (0.25 mm i.d., 0.25 μm film thickness) DM-1 silica capillary column. High purity ethylene was purchased from Beijing Yanshan Petrochemical Co. and used as received. Methylaluminoxane (MAO, 1.46 M in toluene) and modified methylaluminoxane (MMAO, 1.93 M in heptane) were purchased from Akzo Nobel Corp. $Et_2AlCl$ was purchased from Fluka as a 1.90 M solution in hexane. 3,5-Dimethyl-1-(2′-azidophenyl)pyrazole and [$NiCl_2$(dme)] were prepared according to literature methods.[4f,14,18]

**Preparations**

**1-{*o*-($Ph_3PN$)$C_6H_4$}-3,5-$Me_2C_3HN_2$ (2):** A solution of **1** (2.09 g, 9.8 mmol) in $CH_2Cl_2$ (20 mL) was added to a stirred solution of $PPh_3$ (2.57 g, 9.8 mmol) in $CH_2Cl_2$ (10 mL) at room temperature and the mixture was stirred overnight. Volatiles were removed in vacuo and the residue was dissolved in diethyl ether. Filtration of the solution and concentration of the filtrate afforded **2** as a yellow powder (3.95 g, 90.2%), m.p. 126–127 °C. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.02 (s, 3 H, $CH_3$), 2.25 (s, 3 H, $CH_3$), 5.89 (s, 1 H, CH), 6.42 (d, $J$ = 7.8 Hz, 1 H, $C_6H_4$), 6.58 (t, $J$ = 7.5 Hz, 1 H, $C_6H_4$), 6.81 (dt, $J$ = 7.5, 8.1 Hz, 1 H, $C_6H_4$), 7.14–7.20 (m, 1 H, $C_6H_4$), 7.25–7.31 (m, 6 H, Ph), 7.35–7.39 (m, 3 H, Ph), 7.47–7.54 (m, 6 H, Ph) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 11.8, 13.9, 104.0, 117.1, 122.1 (d, $J$ = 9.4 Hz), 128.5 (d, $J$ = 12.1 Hz), 128.7, 130.5, 131.6 (d, $J$ = 2.7 Hz), 131.8, 132.6 (d, $J$ = 9.8 Hz), 134.5, 134.8, 141.7, 147.5 ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = –3.56 ppm. IR: $\tilde{\nu}$ = 3049 $cm^{-1}$ w, 3017 vw, 2960 vw, 2925 w, 1591 m, 1548 m, 1496 vs, 1472 s, 1460 s, 1438 s, 1378 m, 1366 m, 1343 vs, 1314 m, 1288 m, 1164 w, 1137 w, 1109 vs, 1054 m, 1033 m, 1020 m, 997 m, 930 w, 780 m, 768 m, 764 s, 718 vs, 694 s, 657 w, 648 w. $C_{29}H_{26}N_3P$ (447.511): calcd. found C 62.60, H 5.16, N 5.35. Single crystals suitable for X-ray diffraction analysis were obtained by recrystallisation of **12** from toluene (thf was removed from **12**·THF under vacuum prior to recrystallisation).

**[{1-[*o*-($Ph_2PCH_2PPh_2N$)$C_6H_4$]-3,5-$Me_2C_3HN_2$}$CoCl_2$] (13):** A solution of **4** (0.482 g, 0.85 mmol) in thf (10 mL) was added to a suspension of $CoCl_2$ (0.110 g, 0.85 mmol) in thf (10 mL) at room temperature with stirring. The volatiles were then removed under vacuum and the residue was dissolved in $CH_2Cl_2$. The solution was filtered and the filtrate was concentrated to about 2 mL. Toluene was added to produce blue crystals of **13**·0.75$C_7H_8$ (0.567 g, 86.8%), m.p. 129–130 °C. IR (KBr): $\tilde{\nu}$ = 3052 cm$^{-1}$ m, 3021 m, 2950 m, 2924 m, 2902 m, 1590 s, 1572 w, 1556 s, 1495 s, 1481 s, 1467 s, 1435 vs, 1372 s, 1361 s, 1301 s, 1267 vs, 1239 s, 1189 w, 1158 w, 1139 s, 1111 vs, 1057 s, 1044 s, 1028 m, 991 vs, 938 w, 922 w, 825 w, 800 s, 782 vs, 769 vs, 739 vs, 717 vs, 694 vs, 662 s, 638 m, 616 m. $C_{36}H_{33}Cl_2CoN_3P_2$·0.75$C_7H_8$ (768.56): calcd. C 64.46, H 5.11, N 5.46; found C 64.24, H 5.16, N 5.41.

**X-ray Crystallography:** Crystals were mounted in Lindemann capillaries under $N_2$. Diffraction data were collected on a Siemens CCD area detector at 294(2) K with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). A semi-empirical absorption correction was applied to the data. The structures were solved by direct methods using SHELXS-97[19] and refined against $F^2$ by full-matrix least-squares using SHELXL-97.[20] Crystal data and experimental details of the structure determinations are listed in Table 4.
CCDC-606680 (for **5**), -606681 (for **9**) and -617850 (for **12**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**General Procedure for Ethylene Oligomerisation:** The oligomerisation with 1 atm of ethylene was carried out in a Schlenk tube. Thus, the pre-catalyst (5 μmol) was added to a dried Schlenk tube and then the tube was back-filled three times with $N_2$ and twice with ethylene. Toluene (30 mL) was added to the tube and then the appropriate co-catalyst solution was added with a syringe. The reaction mixture was vigorously stirred at the given temperature under 1 atm of ethylene. After the desired period of time (30 or 60 min), the reaction was terminated by adding 10% HCl solution (30 mL). About 1 mL of the organic layer was dried with anhydrous $Na_2SO_4$ for GC analysis. Ethanol (100 mL) was added to the remaining solution; no polymer was observed.

The oligomerisation with 10 atm of ethylene was carried out in a stainless-steel autoclave (250 mL capacity) equipped with a gas ballast through a solenoid valve for continuous feeding of ethylene at constant pressure. Toluene (120 mL) containing the pre-catalyst was transferred into the fully dried reactor under $N_2$ atmosphere. The required amount of co-catalyst was injected into the reactor with a syringe. Once the desired temperature had been reached the reactor was pressurised to 10 atm. After stirring for 30 min, the reaction was quenched and worked-up using the same procedure as described above for the reaction at 1 atm.

# Bulky-Hindrance-Controlled Ligand Transformation from Linked Bis(amidinate) to Linked Imido-Amidinate Promoted by a Mono(cyclopentadienyl)titanium Group

**Sheng-Di Bai,[a] Jian-Ping Guo,*[a] Dian-Sheng Liu,*[a] and Wai-Yeung Wong[b]**

**Keywords:** Titanium / Bis(amidinate) / Bulky hindrance / Ligand transformation / Crystal structure / Steric hindrance

A novel class of silyl-linked bis(amidinate) ligands [$SiMe_2$-{NC(Ph)N(2,6-$R_2$Ph)Li}$_2$] [**L$^1$** (R = H), **L$^2$** (R = Me), and **L$^3$** (R = *i*Pr)] reacted with $TiCl_3(C_5H_5)$ to produce the half-sandwich titanium complexes **1**, **2**, and **3**. The molecular structures of **1**–**3** were confirmed successfully by X-ray crystallography. An unprecedented intramolecular ligand transformation from the linked bis(amidinate) configuration to the linked imido-amidinate configuration took place in the cases of **L$^1$** and **L$^2$**. It was found that the rearrangement process was related to the steric hindrance of the terminal substituents.

## Introduction

Both cyclopentadienyl and amidinate ligands have been extensively studied for decades because of their high adaptability to a wide variety of metals in coordination chemistry. The corresponding metal complexes have shown remarkable utility as homogeneous catalysts for olefin polymerization.[1,2] As a further step, systematic investigations on the metal compounds with a mixed-ligand environment containing these two types of ancillary ligands have been carried out in the past few years, involving the new generation of Ziegler–Natta catalysts, carbon mono- or dioxide reactants, and Kharasch reaction catalysts.[3–9] These merits have made the chemistry of half-sandwich compounds an attractive research field. On the other hand, much attention has recently been paid to metal compounds incorporated with the linked bis(amidinate) ligands, as these unique dianionic ligands have the advantage of affording dinuclear complexes or mononuclear complexes analogous to "ansa-metallocenes", leading to valuable geometric structures and properties. Nevertheless, there have been few reports on linked bis(amidinate) half-sandwich compounds.[4a,9]

A novel class of linked bis(amidinate) ligands (**L$^1$**, **L$^2$**, and **L$^3$**) were developed in our laboratory. They displayed close contact between the two amidinate moieties; that is in contrast to other common examples reported in the literature.[10] We next attempted the preparation of the half-sandwich derivatives from the reactions of ligands with $TiCl_3(C_5H_5)$. It was found, to our surprise, that in the cases of the substituents attached to the terminal nitrogen atoms, which were less bulky, the N–C–N–Si–N–C–N backbone of these dianionic ligands could be transformed to a new class of linked imido-amidinate ligands. We believe that the metal center of mono(cyclopentadienyl)titanium complexes promoted the rearrangement reaction.

## Result and Discussion

### Synthesis and Structural Characterization

The analogous silyl-linked bis(amidinate) ligands **L$^1$**, **L$^2$**, and **L$^3$** were prepared in our previous work. They demonstrated a trend of increasing steric hindrance by variation of the 2,6-substituents of the corresponding phenyl analogue. Treatment of **L$^1$** with 1 equiv. of $TiCl_3(C_5H_5)$ in thf gave, after extraction with $CH_2Cl_2$ and crystallization, compound **1** as red crystals in 82% yield. Complexes **2** and **3** were prepared under similar synthetic procedures in yields of 48% and 65%, respectively (Scheme 1). These half-sandwich titanium compounds were characterized by NMR spectroscopy, elemental analysis, and single-crystal X-ray diffraction analysis.

The molecular structure of **1** is shown in Figure 1 and the key bonding parameters are listed in Table 1. The ligand coordinating to the titanium center does not keep the configuration in **L$^1$**. The original linked bis(amidinate) ligand was expected to coordinate to the metal center in a tetradentate mode. However, the ligand is tridentate in compound **1**. On both sides of the silyl bridge, the two amidinate moieties exhibit different coordination styles to the Ti ion. One is chelating and the other is monodentate. Moreover, the latter one adopts the opposite direction involving a phenyl migration from N4 to N3. It gives a new imido

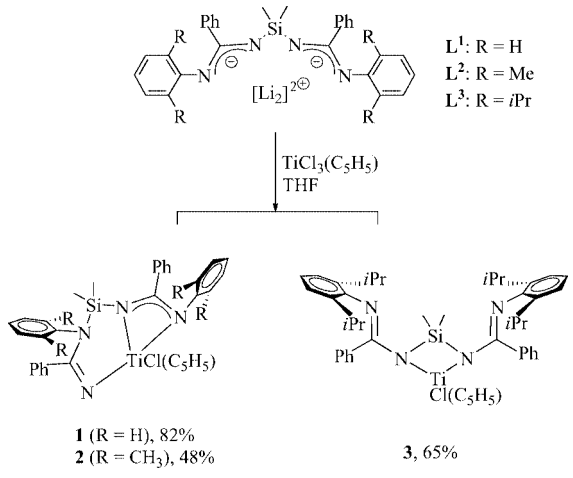

Scheme 1.

group [demonstrated by N3–C22 being 1.385(4) Å and N4–C22 being 1.288(4) Å]. On the other hand, the five-membered skeleton of N4–C22–N3–Si1–N2 displays analogous structural features, with an N2–Ti1–N4 angle of 84.70(13)°, as in some reported titanium β-diketiminates, such as [(Ar)NC(CH$_3$)CHC(CH$_3$)N(Ar)]Ti=NAr(OTf).[11] The Ti–N$_{imido}$ bond [1.847(3) Å] is much shorter than the Ti–N$_{amidinate}$ bonds [2.220(3) and 2.111(3) Å]. The "unsymmetrical" distribution of the two N–C–N moieties leads to a difference of 0.09 Å between the silyl bridge and the neighboring nitrogen atoms on either side.

Compound **2** was derived from **L$^2$**, which was more bulky than **L$^1$**, by introducing 2,6-dimethyl groups onto the terminal phenyl rings. Complex **2** is almost isostructural to **1** except for the presence of additional methyl groups. Structural analysis indicates that the increased steric bulk ascribed to the methyl groups plays no role in differentiating

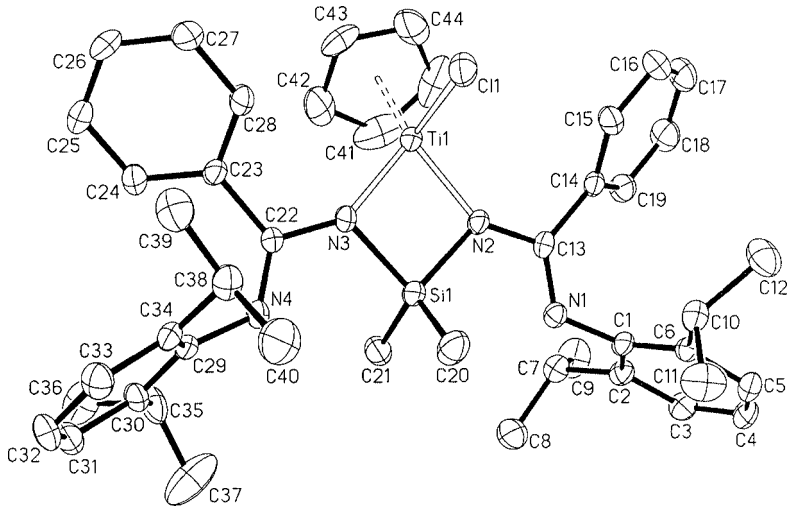

Figure 2. ORTEP drawing (30% probability level) of the molecular structure of compound **3**. Hydrogen atoms are omitted for clarity.

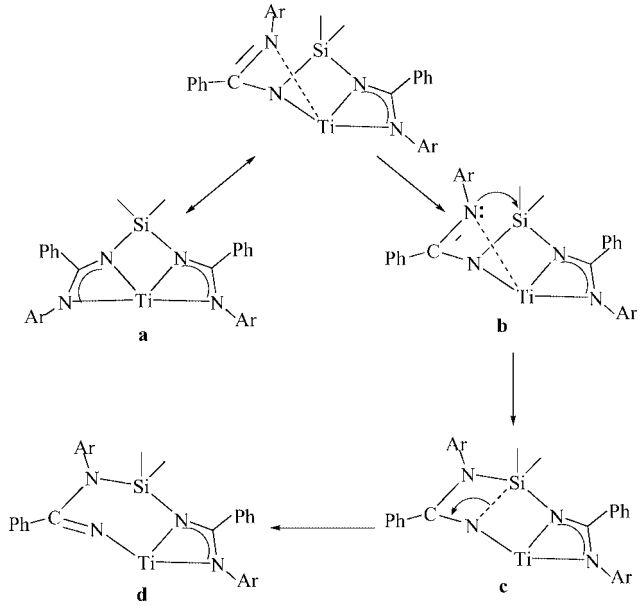
the configuration of **2** from that of **1**. However, the sterically more demanding isopropyl groups do make compound **3** saliently different from **1** and **2**. The ligand framework of **3** (Figure 2) is identical to that of ligand $\mathbf{L^3}$. It should be pointed out that the ligand of **3** adopts the diamido configuration rather than the linked bis(amidinate) configuration. The Ti–$N_{amido}$ bonds in **3** are much shorter than the Ti–$N_{amidinato}$ bonds in **1** and **2**. The two terminal nitrogen atoms have no bonding contacts with the metal center and they are converted into imino groups. The resulting diamido ligand bites the titanium ion at a right angle and it exhibits a planar Ti–N–Si–N tetragonal core. The tetragonal square is perpendicular to another coincident plane composed of C20–Si1–C21 and Cl1–Ti1–Cp(centroid) (with a dihedral angle of 89.8°).

### Intramolecular Rearrangement Reaction

The tetradentate bonding mode between the ligands and the Ti center is not preferred because the common electron count of the titanium ion is 12 or 14. Apparently, the steric bulk of the terminal group plays an important role in the determination of the resulting configuration of compounds **1**, **2**, and **3**. In the absence of sterically demanding substituents, such as in $\mathbf{L^1}$ and $\mathbf{L^2}$, one amidinate moiety of the ligand tends to take the end-contact mode rather than the general chelating mode in order to obtain 14 outer electrons for the Ti ion. The initial terminal nitrogen atom is linked to a phenyl group, which decreases the electronegativity of that N atom and the bond strength of the corresponding N–Ti edge. Comparatively, N4 in **1** or **2** becomes an imido nitrogen atom after rearrangement and the new N–Ti bond is greatly reinforced. These factors in combination drive the ligand transformation process in **1** and **2**.

The proposed mechanism for the formation of **1** and **2** is outlined in Scheme 2. Combination of the linked bis(amidinate) ligands and titanium salt gives the expected compounds with the tetradentate coordination environment (**a**). Induced by the electronically deficient metal center, one amidinate moiety is polarized, and its C–N double bond is located at the outer position because of the electronic withdrawal from the aromatic group. The electronically rich imino nitrogen atom then attacks the silicon atom (**b**). It forms an N–C–N–Si four-membered ring and a notable five-coordinate silicon transition state. The original N–Si bond is then weakened (**c**). Rearrangement is completed after electron transfer to form an imido group (**d**). It should be pointed out that the N–C–N–Si–N–C–N fragment in



Scheme 2.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

these ligands is quite flexible. The intramolecular N–Si coupling could be fulfilled without shielding from sterically demanding substituents. This is the crucial step for the transformation. On the contrary, the isopropyl groups in **L³** are bulky enough to stop that terminal N atom from being bonded to the Ti center or approaching the silyl bridge. This gives compound **3** with the ligand remaining intact and the Ti center with 12 outer electrons.

## Conclusions

A novel intramolecular rearrangement of linked bis(amidinate) ligands was demonstrated. It was promoted by the active titanium ion but could be tuned by the bulky hindrance of terminal substituents. We are currently exploring the reactions between the ligands and other metal salts so as to investigate the generalization of this type of chemical transformation.

## Experimental Section

**General Procedures:** All reactions were carried out under nitrogen in flame-dried Schlenk-type glassware on a dual-manifold Schlenk line. Solvents were dried prior to use. The ligand transfer reagents **L¹**, **L²**, and **L³** were prepared according to the reported methods.[10] $TiCl_3(C_5H_5)$ was prepared according to literature procedures.[12] $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker DRX-300 spectrometer. Elemental analyses were performed with a Vario EL-III instrument. Melting points were taken with a Sanyo Gallenkamp Variable Heater.

**Preparation of 1:** A solution of **L¹** (1.88 mmol) in thf (20 mL) was added to a solution of $TiCl_3(C_5H_5)$ (0.41 g, 1.88 mmol) in thf (10 mL) at 0 °C. The red solution was stirred at room temperature for 12 h and then concentrated under vacuum. The residue was extracted with $CH_2Cl_2$ (20 mL) and the solution filtered. The filtrate was concentrated to give compound **1** as red crystals. Yield: 1.05 g (82%); m.p. 171–172 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.61–6.99 (m, 20 H, phenyl), 6.67, 6.50, 6.13 (t, 5 H, Cp), 0.57, –0.47 (d, 6 H, Si*Me*$_2$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 174.7, 163.4 (N-*C*-N), 148.9–125.9 (phenyl), 120.5, 118.9, 116.7 (Cp), 4.7, 2.9 (Si*Me*$_2$) ppm. $C_{33}H_{31}ClN_4SiTi{\cdot}CH_2Cl_2$ (679.98): calcd. C 60.06, H 4.89, N 8.24; found C 59.82, H 4.90, N 8.18.

**Preparation of 2:** A solution of **L²** (2.51 mmol) in thf (20 mL) was added to a solution of $TiCl_3(C_5H_5)$ (0.55 g, 2.51 mmol) in thf (10 mL) at 0 °C. The red solution was stirred at room temperature for 12 h and then concentrated under vacuum. The residue was extracted with $CH_2Cl_2$ (20 mL) and the solution filtered. The filtrate was concentrated to give compound **2** as red crystals. Yield: 0.79 g (48%); m.p. 179–180 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.60–6.68 (m, 16 H, phenyl), 6.55, 6.48 (d, 5 H, Cp), 2.74–2.04 (m, 12 H, methyl), 0.70, –0.24, –0.95 (t, 6 H, Si*Me*$_2$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 179.3, 17.6, 168.5 (N-*C*-N), 149.8–124.2 (phenyl), 120.6, 117.1 (Cp), 27.1–24.9 (methyl), 9.5, 4.5 (Si*Me*$_2$) ppm. $C_{37}H_{39}ClN_4SiTi{\cdot}(CH_2Cl_2)_{0.25}$ (672.37): calcd. C 66.54, H 5.92, N 8.33; found C 66.89, H 5.97, N 8.31.

**Preparation of 3:** A solution of **L³** (1.55 mmol) in thf (20 mL) was added to a solution of $TiCl_3(C_5H_5)$ (0.34 g, 1.55 mmol) in thf (10 mL) at 0 °C. The red solution was stirred at room temperature for 12 h and then concentrated under vacuum. The residue was extracted with $CH_2Cl_2$ (20 mL) and the solution filtered. The filtrate was concentrated to give compound **3** as red crystals. Yield: 0.77 g (65%); m.p. 186–187 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.50–6.87 (m, 16 H, phenyl), 6.44, 5.83 (d, 5 H, Cp), 3.49, 2.78 (d, 4 H, *CH* of *i*Pr), 1.36–0.86 (m, 24 H, methyl of *i*Pr), 0.56, 0.18, (d, 6 H, Si*Me*$_2$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 166.7 (N-*C*-N), 143.8–123.6 (phenyl), 117.5 (Cp), 28.6, 27.8, 25.1, 22.8 (*i*Pr on phenyl), 2.3, –0.6 (Si*Me*$_2$) ppm. $C_{45}H_{55}ClN_4SiTi$ (763.37): calcd. C 70.80, H 7.26, N 7.34; found C 70.41, H 7.25, N 7.27.

**X-ray Crystallography:** Single crystals of **1**, **2**, and **3** suitable for X-ray diffraction studies were obtained by crystallization from $CH_2Cl_2$. X-ray diffraction data were collected using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) with a Bruker Smart Apex CCD diffractometer, equipped with an Oxford Cryosystems CRYOSTREAM device. The collected frames were processed with the proprietary software SAINT and an absorption correction was applied (SADABS) to the collected reflections.[13,14] The structures of these molecules were solved by direct methods and ex-

# Phase Formation and Properties in the System $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$

**Terrell A. Vanderah,[a] Theo Siegrist,[b] Michael W. Lufaso,*[a][‡] Margaret C. Yeager,[a] Robert S. Roth,[a] Juan C. Nino,[c] and Samantha Yates[c]**

**Keywords:** Pyrochlore / Displacive disorder / Bismuth cobalt niobates / Bi–Co–Nb–O / Phase equilibria / Phase diagram / Dielectric properties / Magnetic properties

Subsolidus phase relations have been determined for the Bi–Co–Nb–O system in air (750–925 °C). Ternary compound formation was limited to pyrochlore ($A_2B_2O_6O'$), which formed a substantial solid solution region at Bi-deficient stoichiometries (relative to $Bi_2Co_{2/3}Nb_{4/3}O_7$) suggesting that about 8 to 25 % of the A sites are occupied by Co. X-ray powder diffraction data confirmed that all Bi–Co–Nb–O pyrochlores exhibit displacive behavior. A structural refinement of the pyrochlore $Bi_{1.56}Co_{0.96}Nb_{1.48}O_7$ using single-crystal X-ray diffraction data is reported with the A and O′ atoms displaced (0.34 Å and 0.45 Å, respectively) from ideal positions to 96g sites and 32e sites, respectively [$Fd\bar{3}m$ (#227), $a$ = 10.551(1) Å]. The displacive structural behavior is similar to that found in analogous Bi–M–Nb–O pyrochlores (M = Zn, Fe, Mn). Bi–Co–Nb–O pyrochlores exhibited overall paramagnetic behavior with negative Curie–Weiss temperature intercepts indicating weak antiferromagnetic interactions. At 250 K and 1 MHz the relative dielectric permittivity of the pyrochlore 0.4400:0.2100:0.3500 $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ was ca. 115 with tan $\delta$ = 0.06; however, at lower frequencies the sample was conductive. Low-temperature dielectric relaxation such as that observed for $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$ and other bismuth-based pyrochlores was not observed. Consideration of bond lengths, effective magnetic moments, and dielectric properties suggests that the average oxidation state of Co in the pyrochlore phases is close to but slightly higher than 2.0.

## Introduction

Multiferroic ceramics which exhibit magnetoelectric effects display coupling between cooperative phenomena such as ferroelectricity and ferromagnetism, and have attracted considerable attention owing to their scientific and practical interest.[1] The possibility of manipulating the magnetic or dielectric properties of a single material by an applied electric or magnetic field, respectively, opens up entirely new device applications in microelectronics and data storage.[2–4] Only a few compounds are known to exhibit these properties,[3,5,6] including several Fe-[3,7] and Mn-containing[8–12] complex oxides. Currently, however, single-phase materials with magnetoelectric responses sufficiently robust for practical exploitation are not known. The present study of the $Bi_2O_3$–$2CoO_{1+x}$–$Nb_2O_5$ system was undertaken to characterize the formation and properties of ternary compounds that form from strongly polarizable ($Bi_2O_3$, $Nb_2O_5$) and magnetic ($CoO_{1+x}$) components.

## Results and Discussion

### Phase Formation

The results of the phase-equilibrium study are presented in Figure 1. In the Co–Nb–O subsystem the $Co^{2+}$ compounds $CoNb_2O_6$ and $Co_4Nb_2O_9$ were observed.[13] The $CoO$:$Nb_2O_5$ intergrowth phases reported to form at molar ratios of 1:7, 1:18, and 1:34, respectively,[13,14] were difficult to equilibrate and exhibited highly complex X-ray powder diffraction patterns related to that of $Nb_2O_5$ (as expected); this region of the phase diagram is depicted to obey the phase rule but was not investigated in detail. Phase-equilibria information for the $Bi_2O_3$–$CoO_{1+x}$ system has not, to the best of our knowledge, been reported. In the present study only a single phase of the sillenite-type was observed to form at $Bi_{25}CoO_{40-\delta}$.[15,16] Specimens equilibrated at 0.500:0.500 and 0.333:0.667 $Bi_2O_3$:$2CoO_{1+x}$ (800 °C) were mixtures of the sillenite phase and $Co_3O_4$ – the former composition formed considerable liquid at 850 °C, the latter at 900 °C. Giant electric polarization has been predicted for $BiCoO_3$ using first-principles methods;[17] however, the synthesis of this phase has not, to the best of our knowledge, been reported. The binary Bi–Nb–O phases observed were in general agreement with the comprehensive study reported by Roth[18] except for the high-$Bi_2O_3$ (≥0.75 mol fraction) region, represented in Figure 1 as a "fluorite" solid solution extending from 75:25 $Bi_2O_3$:$Nb_2O_5$ ($Bi_3Nb_2O_7$)

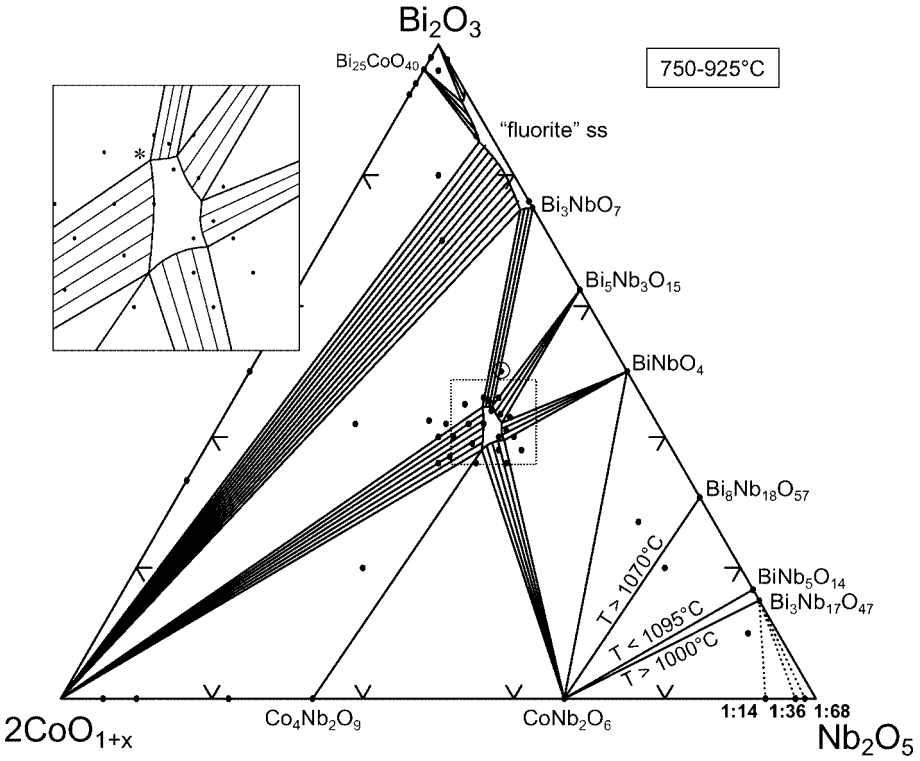

Figure 1. Subsolidus phase equilibrium diagram in air for the $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ system. Black dots denote the compositions of specimens prepared in the study; concentrations are on a molar fraction basis. Ternary phase formation is limited to pyrochlore, which forms an appreciable solid solution near the center of the diagram (enlarged in the inset). The "pyrochlore-like" composition $Bi_2Co_{2/3}Nb_{4/3}O_7$ (open circle) is not included in the solid solution region, but rather forms a three-phase mixture of $Bi_3NbO_7$, pyrochlore, and $Bi_5Nb_3O_{15}$. The limiting compositions of the pyrochlore field suggested by the present data are (inset: clockwise beginning with the cusp marked with an asterisk) $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ = 0.446:0.220:0.334 [$Bi_{1.79}Co_{0.88}Nb_{1.34}O_7$, $a$ = 10.580(1) Å], 0.448:0.205:0.347 [$Bi_{1.78}Co_{0.81}Nb_{1.38}O_7$, $a$ = 10.589(1) Å], 0.422:0.205:0.373 [$Bi_{1.65}Co_{0.80}Nb_{1.46}O_7$, $a$ = 10.571(1) Å], 0.395:0.215:0.390 [$Bi_{1.53}Co_{0.83}Nb_{1.51}O_7$, $a$ = 10.556(1) Å], and 0.380:0.253:0.367 [$Bi_{1.51}Co_{1.00}Nb_{1.46}O_7$, $a$ = 10.544(1) Å] (all formulas assume $Co^{2.2+}$). The temperature-dependent joins between $CoNb_2O_6$ and the binary Bi–Nb–O phases are consistent with established $Bi_2O_3$–$Nb_2O_5$ phase relations. The compound $BiCoO_3$ was not observed under the conditions of this study.

to 93:7 $Bi_2O_3$:$Nb_2O_5$. This region has received considerable attention as it forms a series of structurally complex, modulated superstructures[19–23] with variable and potentially useful dielectric properties.[24,25] Reported differences in the detailed phase relations in this region likely arise from kinetic effects, variations in synthesis (especially cooling methods), and/or differences in characterization methods (e.g. X-ray or electron diffraction). For example, the present study, in agreement with early studies,[18] did not find a sillenite-type compound at the composition $Bi_{12}Nb_{0.29}O_{20-x}$.[20] This specimen was a mixture of monoclinic $Bi_2O_3$ and the fluorite-type solid solution after repeated heatings at 700 °C for a total of 414 h; however, a different heat treatment may have resulted in the metastable body-centered cubic form of $Bi_2O_3$ (sillenite-type)[26] instead of the monoclinic polymorph.

Ternary phase formation in the $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ system was found to be limited to pyrochlore, which forms an appreciable solid solution region (Figure 1). During synthesis, the pyrochlore phase formed early in partially reacted samples and was readily purified within the single-phase region, suggesting high thermodynamic stability. Numerous descriptions can be found for the pyrochlore crystal structure, $^{VIII}A_2{}^{VI}B_2O_7$, which is unusual in that it can be considered as two relatively independent interpenetrating networks of [$BO_6$] octahedra sharing all vertices and [$O'A_4$] tetrahedra in an *anti*-cristobalite-type arrangement.[27–30] The formula is often written as ($A_2O'$)($B_2O_6$) or $A_2B_2O_6O'$ to emphasize this interesting structural character and distinguish the two networks. The larger A-cations are eight-fold (= 6+2) coordinated by six oxygen atoms in puckered rings formed by the $B_2O_6$ network plus two O′ oxygen atoms above and below in the $A_2O'$ network. The structure inherently facilitates non-stoichiometry as the $A_2O'$ network can be partially occupied, or in some cases completely absent; furthermore, numerous non-oxide and halide pyrochlores are known. In addition to extensive compositional ranges, pyrochlores exhibit a remarkable variety of exploitable physical properties, hence the considerable technical importance of this class of solids.[29]

Bi–Co–Nb–O pyrochlores have been previously reported to form at the stoichiometries $Bi_2Co_{2/3}Nb_{4/3}O_7$,[31] $Bi_2Co_3Nb_2O_{12+y}$, $Bi_2Co_4Nb_2O_{13+y}$, and $Bi_2CoNb_2O_{9+y}$;[32] however, under the conditions of the present study none of these compositions are included in the pyrochlore single-phase field: Composition $Bi_2Co_{2/3}Nb_{4/3}O_7$ formed a three-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phase mixture as described in Figure 1; $Bi_2Co_3Nb_2O_{12+y}$ and $Bi_2Co_4Nb_2O_{13+y}$ both occur in three-phase fields consisting of pyrochlore, $CoO/Co_3O_4$, and a small amount of $CoNb_2O_6$;[33] and the stoichiometry $Bi_2CoNb_2O_{9+y}$ resulted in a three-phase mixture of pyrochlore, $BiNbO_4$, and a small amount of $CoNb_2O_6$. As shown on the diagram (Figure 1), Bi–Co–Nb–O pyrochlores form thermodynamically stable mixtures with the $Bi_3NbO_7$ solid solution, $Bi_5Nb_3O_{15}$, $BiNbO_4$, $CoNb_2O_6$, $Co_4Nb_2O_9$, and $CoO/Co_3O_4$. Compositions, nominal formulas, and refined unit cell parameters for single-phase Bi–Co–Nb–O pyrochlores (all dull dark greenish gray in color) prepared in the present study are given in Table 1.[34] The trends in unit cell parameters show a strong dependence on Bi concentration.

Table 1. Compositions, nominal formulas, and unit cell parameters (*a*, space group $Fd\bar{3}m$, #227) for single-phase pyrochlore specimens prepared in this study. These compositions correspond to the points within the five-sided pyrochlore region shown in Figure 1.[34]

| $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ | Nominal formula ($Co^{2.2+}$) | *a* [Å] |
|---|---|---|
| 0.4400:0.2100:0.3500 | $Bi_{1.744}Co_{0.8324}Nb_{1.387}O_7$ | 10.580(1) |
| 0.4200:0.2300:0.3500 | $Bi_{1.672}Co_{0.9158}Nb_{1.394}O_7$ | 10.566(1) |
| 0.4000:0.2200:0.3800 | $Bi_{1.562}Co_{0.8594}Nb_{1.484}O_7$ | 10.556(1) |

Observed, indexed X-ray powder diffraction data for the pyrochlore with composition 0.4400:0.2100:0.3500 $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ are given in Table 2. As noted previously,[29] the 442 reflection, forbidden for an ideal pyrochlore structure, was easily observed in this pattern and in *all* patterns of pyrochlore and pyrochlore-containing specimens prepared in this study. The 442 reflection was also observed in precession photos of single crystals. Similar to the Bi–Zn–Nb–O pyrochlores,[29,35] the observation of this diagnostic reflection indicates the presence of displacements from ideal crystallographic sites. The consistent observation of this reflection indicates that *all* Bi–Co–Nb–O pyrochlores exhibit positional displacements. Furthermore, the stoichiometric location of the pyrochlore phase field, as also found for the analogous Bi–M–Nb–O systems (M = Zn,[29] Fe,[36] Mn[37]), occurs at substantially lower Bi concentrations than conventional formulations placing only Bi on the A sites and the smaller M/Nb cations on the B sites. The pyrochlore field includes compositions with "excess" B cations that require mixing of some Co on the A sites with $Bi^{3+}$, as found for Zn in *all* Bi–Zn–Nb–O pyrochlores.[29] The limiting compositions observed for the pyrochlore field (Figure 1) suggest that the Co concentration on the A sites can range from ca. 8 to 25%,[38] which is comparable to the analogous ranges observed for other Bi–M–Nb–O pyrochlores with Co replaced by Zn (≈ 16 to 26%),[29] Fe (ca. 4 to 15%),[36] and Mn (ca. 14 to 30%).[37]

Table 2. Observed X-ray powder diffraction data for the pyrochlore with composition $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ = 0.4400:0.2100:0.3500 [space group $Fd\bar{3}m$, #227, *a* = 10.580(1) Å]. The nominal pyrochlore formula is $Bi_{1.744}Co_{0.8324}Nb_{1.387}O_7$; however, the actual O′ occupancy factor and precise Co oxidation state are uncertain.

## Structural Refinement of the Pyrochlore Phase

The highly symmetrical ideal pyrochlore structure $A_2B_2O_6O'$ crystallizes in space group $Fd\bar{3}m$ with A and B cations on two special positions (16d, 16c) and oxygen atoms on two sites, 48f (O) and 8b (O′), resulting in a single positional variable (*x* for the 48f-site oxygen atoms in the $B_2O_6$ octahedral network). As expected, this model resulted in anomalously large thermal parameters for the A-site cations and the O′ oxygen atoms in an initial refinement using single-crystal X-ray diffraction data [$R_f$(obsd.) = 0.325, $R_w$(obsd.) = 0.237]. The disordered structure was therefore modeled assuming static displacements of the A and O′ atoms, similar to the analogous Bi–M–Nb–O pyrochlores (M = Zn,[35] Fe,[36] Mn[37]) whose structures were refined using neutron powder diffraction data. The Bi:Co:Nb ratio of the single crystal was fixed at a stoichiometry inferred from the refined unit cell parameter of ground crystals [*a* = 10.551(1) Å] taken from the same batch. This value, compared to that for the single-phase pyrochlore powder from which the crystals were grown [*a* = 10.580(1) Å] indicates reduced Bi concentrations in the crystals. When compared to the unit cell parameters obtained for other single-phase pyrochlores (Table 1) and for the limiting compositions of the phase field (cusps, Figure 1), the metal stoichiometry extrapolated for the single crystal was 39.0:24.0:37.0 Bi:Co:Nb. The oxygen content of the crystal was calculated by assuming an average Co oxidation state of 2+, for simplicity, and the O′ sites were assumed to be filled, resulting in an overall formula of $Bi_{1.56}Co_{0.96}Nb_{1.48}O_7$ for the crystals, with fully occupied metal positions.

The refinement of the positional parameters for the disordered metal sites was carried out assuming displacements of the $A_2O'$ network, as found for a number of other pyrochlores.[29,35–37,39–42] Refinement with only Bi displaced gave residuals for observed reflections of $R_f$ = 0.116 and $R_w$ = 0.072 – improved results were obtained when O′ was also displaced. The A site Bi/Co metals were displaced to six partially filled 96g sites; however, the corresponding 96g position for O′ was not stable, and difference Fourier maps consistently showed peaks at and around the ideal 8b site (5/8, 1/8, 1/8). Refinement of the O′ isotropic thermal pa-

rameter diverged, so a displaced position using the 32e site was chosen. Other combinations were not stable. The O′ oxygen position was refined assuming a total contribution of 8 oxygen atoms, hence the occupancy factor of 0.25. The final refinement results are given in Table 3 and illustrated in Figure 2. In the present study, the scattering was dominated by the much heavier Bi and Nb atoms, resulting in limited definition of the displaced oxygen O′ positions. In addition, the disorder on the A and B metal sites hampered a proper refinement of the scale factor due to strong correlations with occupancy parameters. Furthermore, the oxidation state of Co (and therefore oxygen content) and the level of vacancies (if any) on the A and O′ sites were uncertain.[43]

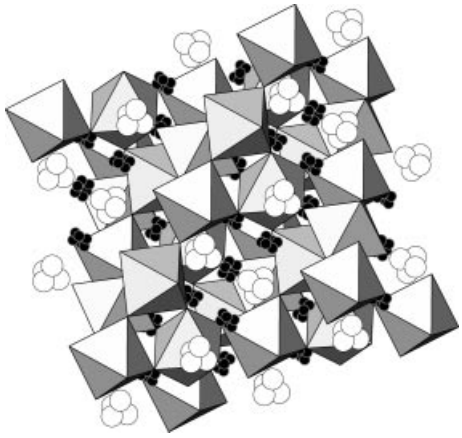

Figure 2. Crystal structure of the pyrochlore $Bi_{1.56}Co_{0.96}Nb_{1.48}O_7$ illustrating the displacive disorder of the $A_2O'$ network (Table 3). The vertex-linked polyhedra represent the octahedral $B_2O_6$ = $(Co,Nb)_2O_6$ network. The puckered rings of black spheres represent the six equivalent, partially filled 96g sites for the A-site Bi/Co cations; the tetrahedral clusters of larger white spheres denote the four possible positions for O′ oxygens displaced to the 32e sites. The results indicate that the A-site cations are displaced 0.34 Å from the ideal 16d position, while O′ oxygen atoms on 32e sites are displaced 0.45 Å from the high-symmetry 8b position.

The [(Co,Nb)$O_6$] octahedra in the $B_2O_6$ network are nearly regular, with metal–oxygen distances of 2.01(1) Å (×6), and O–B–O angles deviating about 3.7° from 90°. The observed bond valence sums calculated about this site[44] using the $R_o$ parameters for $Nb^{5+}$ and $Co^{2+}$ are 4.55 v.u. and 2.52 v.u., respectively. The bonds are therefore longer than expected for Nb–O, suggesting that Co is predominantly present in the 2+ oxidation state, which has a larger sixfold ionic radius (0.745 Å, HS) than $Nb^{5+}$ (0.64 Å) (whereas $Co^{3+}$ is smaller at 0.61 Å, HS).[45] The observed and theoretical bond valence sums for the Nb/Co site using the occupancy factors in Table 3 and assuming the presence of $Nb^{5+}$/$Co^{2+}$ are 4.03 v.u. and 4.22 v.u., respectively, which are in reasonable agreement given the uncertainties in composition. The A-site Bi/Co metal positions and associated O′ positions are displacively disordered, therefore the A-site coordination sphere is variable. Observed Bi/Co–O distances range from 2.05(5) Å up to 2.96(1) Å. Of these, the distances to the octahedral framework O atoms tend to be longer, ranging from 2.34(1) Å to 2.96(1) Å (with an average of 2.66 Å). The distances between Bi/Co and the displaced O′(32e) atoms are shorter (with an average 2.34 Å) and include the shortest values of 2.05(5) Å, 2.15(5) Å (2x), and 2.25(7) Å (2×), which could reasonably accommodate the smaller Co cations. The equivalent isotropic displacement parameter obtained for the Bi/Co site corresponds to a mean-square displacement of 0.2 Å, as compared with the displacement of 0.34 Å from the ideal site. Similarly, the large displacement parameter for O′ corresponds to a mean-square displacement of 0.25 Å whereas the displacement from the ideal site is 0.45 Å. These values suggest that the large thermal parameters reflect disorder on these sites rather than thermal motion.

The displacive model in Table 3 for the Bi–Co–Nb–O pyrochlore is similar to that reported for a Bi–Fe–Nb–O pyrochlore[36] wherein the A-site cations were displaced 0.43 Å to 96g sites with O′ displaced 0.29 Å to 32e sites. The considerably larger O′ displacement in the Co system (0.45 Å) may reflect the higher concentration of smaller B-type ions on the A sites (≈ 22% compared to <10% in the Fe system). Displacive models for analogous Bi–Zn–Nb–O[35] and Bi–Mn–Nb–O[37] pyrochlores also displaced A sites to 96g sites (0.39 Å and 0.36 Å, respectively), but O′ was displaced differently, to 96g sites (0.46 Å for Zn, 0.33 Å for Mn). Differences in the details of the structural displacements are not unexpected, since the local crystal chemistry and any short-range correlations should be affected by different concentrations of small B-type ions on the A sites as well as variations in the concentrations of vacancies on both the A sites and the O′ sites.

## Magnetic Properties of Pyrochlore Phases

Magnetic data obtained for three different single-phase Bi–Co–Nb–O pyrochlore samples indicated qualitatively similar properties. The field dependence of the magnetization confirmed that all samples were overall paramagnetic in nature. The temperature dependence of the magnetic susceptibility, and its inverse, for the pyrochlore with com-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

position 0.4000:0.2200:0.3800 $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ are shown in Figure 3. Above 100 K the inverse magnetic susceptibility was linear and that range was fit to the Curie Weiss law; the results are given in Table 4. For all three compounds, the extrapolation of the linear fits indicated small negative temperature intercepts, suggesting the presence of weak antiferromagnetic cooperative interactions. All of the observed effective magnetic moments calculated from the slopes of the Curie–Weiss fits are higher than the high-spin, spin-only values expected for $Co^{2+}$ ($3d^7$, $S$ = 3/2, 3.87 $\mu\beta$) and $Co^{3+}$ ($3d^6$, S = 2, 4.90 $\mu\beta$), suggesting considerable unquenched orbital contributions, as observed for other Co-containing pyrochlores.[46] Given the range of values previously reported for high-spin $Co^{2+}$ (4.6–5.2 $\mu\beta$/Co) and high-spin $Co^{3+}$ (5.1–5.7 $\mu\beta$/Co)[47] compounds, the observed effective moments for the pyrochlore phases are consistent with the presence of divalent, or mixed divalent-trivalent Co. Slight curvature is observed in the magnetization vs. field data at 10 K (Figure 3, inset). The complex magnetic behavior exhibited by the Bi–Co–Nb–O pyrochlores is

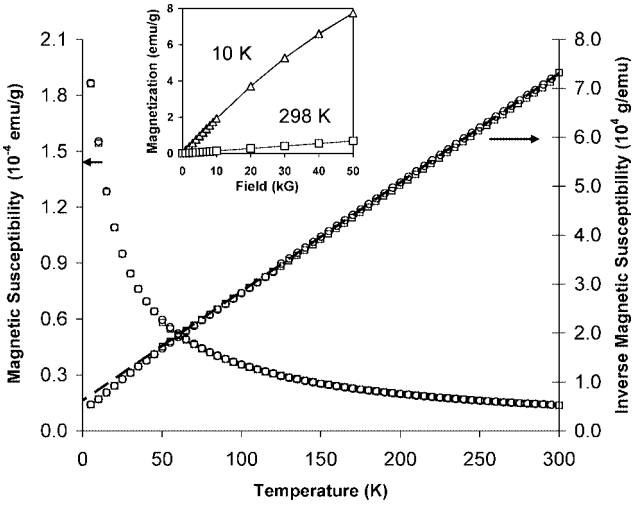

Figure 3. Temperature dependence of the zero-field-cooled (circles) and field-cooled (squares) mass susceptibility and inverse mass susceptibility for the single-phase pyrochlore 0.4000:0.2200:0.3800 $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ at an applied field of 50 kG. The inset shows the field dependence of the magnetization measured at 10 K (triangles) and 298 K (squares). (Lines are present to guide the eye.) Slight curvature is observed in the low-temperature data. (Units: To convert susceptibility values in emu/g to SI units $m^3$/kg, multiply by $4\pi/10^3$. To convert field values in Oe (or G) to SI units A/m, multiply by $10^3/4\pi$. Magnetization values in emu/g units are numerically equal to SI units of $A\,m^2$/kg.[48]).

Table 4. Magnetic data for single-phase Bi–Co–Nb–O pyrochlore specimens listed in Table 1. The observed effective moments ($\mu_{eff}$/mol Co) and temperature-axis intercepts ($\theta$, K) were obtained from linear fits of the inverse susceptibility data in the temperature range 100–300 K.

| Composition $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ | $\mu_{eff}$/mol Co [$\mu\beta$] | $\theta$ [K] |
|---|---|---|
| 0.4400:0.2100:0.3500 | 5.1 | –35 |
| 0.4000:0.2200:0.3800 | 5.1 | –26 |
| 0.4200:0.2300:0.3500 | 5.0 | –35 |

not unexpected given the triangular symmetry of the metal lattices which results in geometric magnetic frustration.[49–50] Pyrochlore compounds are known to exhibit a wide range of cooperative magnetic properties and, for example, are of significant interest as "spin-ice" systems.[51–53]

### Dielectric Properties of the Pyrochlore Phase

The relative permittivity (corrected for 10% porosity) and dielectric loss as a function of temperature and frequency for the single-phase pyrochlore with composition 0.4400:0.2100:0.3500 $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ are shown in Figure 4. The upturns in the data above 250 K indicate that the sample becomes predominantly conductive, and the onset of conductivity is frequency dependent. For example, at 250 K and 1 MHz the sample is still insulating and exhibits a relative permittivity of ca. 115 and tan $\delta$ = 0.06, yet at 10 kHz tan $\delta$ is greater than 0.2, indicating conductivity. This behavior is in sharp contrast with previously reported bismuth based pyrochlores for which dielectric relaxation is observed.[36,54] The temperature- and frequency-dependent behavior observed is consistent with interfacial polarization mediated by the presence of multivalent Co ions – similar properties were observed for pyrochlores in the Bi–Mn–Nb–O system.[37]

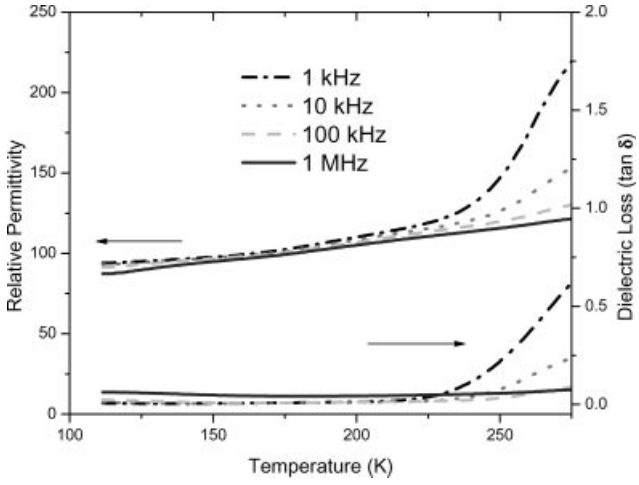

Figure 4. Relative dielectric permittivity (corrected for porosity) and dielectric loss for the single-phase pyrochlore with composition 0.4400:0.2100:0.3500 $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$ at frequencies of 10 kHz, 100 kHz and 1 MHz. The sample is predominantly conductive at temperatures above 250 K and the onset of conductivity is frequency dependent; these effects likely reflect the presence of mixed-valent $Co^{2+/3+}$.

## Conclusions

Subsolidus phase relations have been determined for the Bi–Co–Nb–O system in air using specimens equilibrated at 750–925 °C. Ternary phase formation was limited to pyrochlore, which forms a considerable solid solution region at stoichiometries that are "Bi-deficient" compared to conven-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tional $A_2B_2O_7$-type formulations with Bi on the A sites and Co/Nb on the B sites. The location of the pyrochlore field suggests that approximately 8 to 25% of the A sites can be occupied by Co. All Bi–Co–Nb–O pyrochlores form with positional displacements off ideal crystallographic positions, as also found for analogous Bi–M–Nb–O pyrochlores with M = Zn, Fe, and Mn. A structural refinement of the pyrochlore $Bi_{1.56}Co_{0.96}Nb_{1.48}O_7$ using single–crystal X-ray diffraction data is reported with displacements in the $A_2O'$ network. Bi–Co–Nb–O pyrochlores exhibited overall paramagnetic behavior with weak antiferromagnetic interactions; observed effective moments were consistent with the presence of $Co^{2+}$ or $Co^{2+/3+}$ mixtures; however, the observed bond lengths suggest that Co is present predominantly as the larger 2+ ion. Measurements of relative dielectric permittivity and dielectric loss between 110 and 450 K indicated conductive, frequency-dependent properties consistent with the presence of mixed-valent Co. In contrast to $Bi_{1.5}Zn_{0.92}Nb_{1.5}O_{6.92}$, no low-temperature dielectric relaxation was observed. The Bi–Co–Nb–O pyrochlores form thermodynamically stable mixtures with the $Bi_3NbO_7$ solid solution, $Bi_5Nb_3O_{15}$, $BiNbO_4$, $CoNb_2O_6$, $Co_4Nb_2O_9$, and $CoO/Co_3O_4$.

## Experimental Section

Forty-seven polycrystalline specimens (3–4 g each) were prepared in air by solid-state reactions using $Bi_2O_3$ (99.999%), $Co_3O_4$ (99.9985%, pre-analyzed by X-ray powder diffraction), and $Nb_2O_5$ (99.999%). Prior to each heating, each sample was mixed by grinding with an agate mortar and pestle for 15 min, pelletized, and placed on a bed of sacrificial powder of the same composition supported on alumina ceramic. After an initial calcinations overnight at 800 °C (below the m.p. of $Bi_2O_3$, 825 °C) multiple 1–3 d heatings (with intermediate grinding and re-pelletizing) were carried out at 875–925 °C.[55] Samples were furnace-cooled to ca. 700 °C and then air-quenched on the bench-top. Metastable melting in non-equilibrated ternary specimens (an initial problem owing to large differences in the melting points of $Bi_2O_3$, $CoO_x$, and $Nb_2O_5$) was avoided by soaking samples at 875 °C for 1–3 d for the second heating, followed by a third heating at 925 °C for 2–3 d. Equilibrium was presumed when no further changes could be detected in the weakest peaks observed in the X-ray powder diffraction patterns. A eutectic in the ternary system may occur near 42:40:18 $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$, which formed liquid at 900 °C. $Bi_2O_3$ volatilization was observed above the solidus by thermogravimetric analysis, but was not detectable in the subsolidus study. Pyrochlore-type crystals were easily obtained by heating a single-phase polycrystalline specimen (composition 0.4400:0.2100:0.3500 $Bi_2O_3$:$2CoO_{1+x}$:$Nb_2O_5$) in a Pt capsule (sealed by welding) to 1300 °C, followed by slow cooling (4 °C/h) to below the freezing point (≈1160 °C). The crystals exhibited conchoidal fracture and were obtained as brown-black shards.

Phase assemblages were ascertained using the disappearing phase method[56,57] and X-ray powder diffraction data obtained with a Philips[58] diffractometer equipped with incident Soller slits, a theta-compensating slit and graphite monochromator, and a scintillation detector. Samples were mounted in welled glass slides. Patterns were collected at ambient temperatures using Cu-$K_\alpha$ radiation over the range 3–70° 2$\theta$ with a 0.02° 2$\theta$ step size and a 2 s count time. Intensity data measured as relative peak heights above background were obtained using the DATASCAN software package, and processed using JADE. For unit cell refinements, observed 2$\theta$ line positions were first corrected using SRM 660, $LaB_6$,[59] as an external calibrant. Lattice parameters were refined using JADE (2$\theta$ values, Cu-$K_{\alpha1}$ = 1.540593 Å).

Preliminary characterization of pyrochlore-type single crystals was carried out using the precession camera method (Zr-filtered Mo-$K_\alpha$ radiation) to assess quality, cell parameter, and space group. Data for structural refinement were collected with an Oxford Diffraction Xcalibur 2 CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation. Due to the strong absorption coefficient of 50.2 $mm^{-1}$, several small crystals with approximate dimensions 0.03 mm × 0.04 mm × 0.04 mm were chosen, and measurements included 2$\theta$ angles up to 100°. However, large absorption corrections were still required and limited the range of observable reflections. Further details of the crystal-structure investigation may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-416601.

Magnetic properties were characterized with a Quantum Design SQUID magnetometer and single-phase polycrystalline samples. Magnetization was measured as a function of temperature between 2 K and 300 K after cooling in the absence of an applied field (zero-field cooled, ZFC) and while cooling in a magnetic field (field-cooled, FC) of 50 kG between 2 K and 300 K. In addition, measurements at 10 K and at 298 K were carried out to determine the field dependence of the magnetization in applied fields between 0 and 50 kG.

Dielectric properties were evaluated using pellets prepared from single-phase powders mixed with 2 wt.-% PVA (polyvinyl alcohol) to assist forming. Mixtures were ground using a mortar and pestle, sieved (300 μm mesh), and then dried at 120 °C for 5 min. Approximately 0.6 g of the mixture was uniaxially pressed into a disk (ca. 1 mm thick, ca. 10 mm diameter) using a pressure of ca. 180 MPa. The green pellets were then sintered in air at 975 °C for 4 h. The density of the sintered samples was measured in water using Archimedes's principle and compared to the theoretical density of the material. Gold/palladium electrodes (ca. 75 nm thick) were sputtered onto the top and bottom surfaces to form parallel plate capacitors. The complex dielectric permittivity was measured between 1 kHz and 1 MHz using an Agilent 4284 LCR meter. The sample temperature was controlled with a programmable 9023 Delta Design for measurements between 110 and 450 K.

[33] More accurately, these points occur within the four-phase compatibility volume ($Bi_2O_3$–CoO–$Co_3O_4$–$CoNb_2O_6$). The relations in the four-component system actually studied here ($Bi_2O_3$–CoO–$Co_3O_4$–$Nb_2O_5$) have been projected onto a ternary slice (Figure 1) to simplify presentation of the results.
[34] Although the metal ratios given here are precise, the actual populations on the A and B sites depend on the O′ occupancy factor and Co oxidation state(s), which are uncertain and which may vary in each pyrochlore. Expressions for the structural formulas for the pyrochlore phases are therefore ambiguous. For purposes of comparison, the formulas have been normalized to seven oxygens (full occupancy of the O′ site) and assume an average oxidation state of 2.2+ for Co; the reasons for the latter assumption are described in the text.

# Silver, Palladium and Rhodium Complexes of Acenaphthylene-Anullated N-Heterocyclic Carbene Ligands: A Comparative Study

**Hayati Türkmen,[a] Onur Şahin,[b] Orhan Büyükgüngör,[b] and Bekir Çetinkaya*[a]**

**Keywords:** N-Heterocyclic carbenes / Silver complexes / Thiones / Palladium complexes / Rhodium complexes / C–C coupling

The newly prepared carbene precursor 1,3-dimesitylacenaphtho[1,2-*d*]imidazolinium chloride, (NHC–H)Cl, **3**, could be readily converted into the NHC-silver(I) complex, **4**, which is an efficient carbene transfer agent and has been used to synthesise thione **5**, *trans*-[$PdCl_2(NHC)_2$], **6** and [RhCl(NHC)(COD)], **7**. All compounds synthesised were characterised by elemental analysis, NMR spectroscopy and the molecular structures of the thione **5** and complex **7** were determined by X-ray crystallography. Complex **7** was converted into *cis*-[$RhCl(NHC)(CO)_2$] and the electron donating properties and *trans* influence of the NHC ligand were compared with nonanullated counterparts. The catalytic activity in the Heck reaction of **6** and the in situ formed palladium complex was evaluated. The activity of the in situ formed complexes for the Heck coupling of alkenes was high.

## Introduction

Owing to their bonding versatility and the relative ease with which their electronic and steric properties can be modified, increasing attention has been focused on using imidazole-based N-heterocyclic carbene (NHC) compounds as ancillary ligands for a number of transition metal mediated catalytic reactions.[1–4] Their donating properties are superior to those of the most basic phosphanes. The ability of NHCs to coordinate to metal centres makes them excellent candidates for the design of well-defined catalysts. In a recent study, we observed that the variation of *p*-substituents on the phenyl ring of 1,3-diarylimidazolin-2-ylidenepalladium(II) complexes has a significant influence on the catalytic behaviour of the Suzuki coupling of NHC-Pd complexes.[5] Increasing knowledge of the chemical properties of ligands and complexes derived from them has led to a growing demand for systems with more and more complex structures. Anullated NHCs have attracted increasing attention in recent years since the introduction of carbo- and heterocyclic groups may give an opportunity for better control of the stability of the active species and improve catalytic activity. In this context, benzo-, pyrido-, naphtha- and quinoxalino-anullated imidazol-2-ylidenes have been reported.[6] These studies have demonstrated that the electron density at $C^2$ varies with the π donor/acceptor properties of the anullated rings. The 4,5-positions of the imidazolidine ring seem to be ideally suited for substitution since they are quite far from the catalytically active metal site. Therefore, we focused on the design of an acenaphthylene-anullated NHC ligand to modify the environment of the metal centre. Model studies showed that the tetracyclic ring system is highly strained. Our main aim was to determine how these properties are reflected in the electron donating properties of its complexes.

## Results and Discussion

### Preparation of Ligand Precursor 3, Thione 5 and NHC Complexes 6–8

The general route to the targeted NHC ligand precursor and metal complexes is shown in Scheme 1. The amine **2** was readily synthesised in good yield as a red, crystalline solid by means of the reduction of the corresponding imine **1** which served as a chelating ligand for several transition metal complexes.[7] Cyclisation of **2** with $CH(OEt)_3$ in the presence of one equiv. of $NH_4Cl$ gave the diazolinium salt **3**. For the sake of comparison, the 4,5-dimethyl-1,3-dimesityl imidazolinium salt and related compounds (**4′**–**8′**) were also prepared (Scheme 2).

Treatment of **3** with NaO*t*Bu or NaH/NaO*t*Bu resulted in the deprotonation of the imidazolinium salt. However, attempted isolation of the free carbene failed. These precursor salts were subsequently deprotonated using basic silver oxide. Silver(I) NHC complexes are easy to make and can be used as air- and moisture-stable carbene transfer agents.[8] Such silver(I) NHC complexes with coordinating halides are well known to oligomerise by means of silver-silver interactions, bridging halides or carbenes[9] and they

have been characterised by $^1H$ and $^{13}C$ NMR spectroscopy.

The clearest spectroscopic evidence identifying **4** as a silver NHC complex is the appearance of a highly deshielded $^{13}C$ NMR signal for $C_{carb}$ at $\delta$ = 205.5 ppm [dd, $^1J_{^{109}Ag,C}$ = 221.9, $^1J_{^{107}Ag,C}$ = 255.4 Hz]. The chemical shift and splitting pattern is consistent with the monomeric structure of **4**.[10] By comparison, the dimers consisting of $(NHC)_2Ag^+$ cations and $AgX_2^-$ anions or $(NHC–Ag–\mu–X)_2$ structures display $C_{carb}$ singlets due to partial dissociation and monomer/dimer equilibrium in solution. Ionic $(NHC)_2Ag^+$ complexes exhibit smaller $J_{^{107,109}Ag,C}$ coupling constants (180–190 and 200–215 Hz).[9] The chemical shift is also indicative of the donating nature of the carbene in the carbene–Ag interaction (Scheme 1).

Despite its large coupling constant, complex **4** is a good carbene transfer agent. Interaction of **4** with elemental sulfur readily afforded the thione **5**. This thione is a stable crystalline substance, the structure of which was elucidated by NMR spectroscopy and X-ray analysis. The most important peak in the $^{13}C$ NMR spectrum is the peak corresponding to C=S at $\delta$ = 179.6 ppm. X-ray diffraction analysis of **5** allowed us to draw some conclusions about the structure of **5**. The structure and the atom numbering scheme are shown in Figure 1. Very few cyclic thiones with bulky substituents at the N atoms of the NHC ligand have been reported[8] and this appears to be the first such compound with an anullated group.

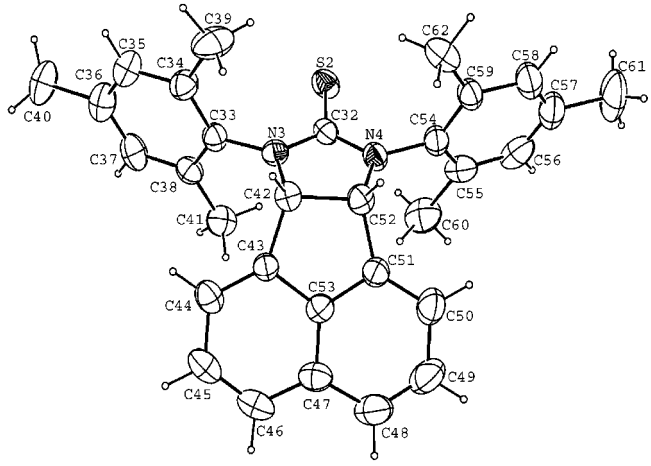

Figure 1. Molecular structure of **5**. Selected bond lengths [Å] and bond angles [°]: C32–S2 1.661(6), C32–N3 1.357(7), C32–N4 1.344(6), C33–N3 1.357(7), C54–N4 1.442(5), C42–C52 1.553(5); N3–C32–N4 108.6(5), N3–C32–S2 124.9(4), N4–C32–S2 126.5(4).

Crystallographic data for the structural analysis of **5** are given in Table 3. An ORTEP representation of the structure is shown in Figure 1 and selected bond lengths and angles are listed in the caption. The C(1)–S(1) bond length of 1.661 Å in **5** compares well with known C(32)–S(2) bond lengths in derivatives of imidazolidin-2-thiones.[8,11]

The reaction of the Ag complex **4** with palladium species bearing weakly coordinated $CH_3CN$ ligands yielded the disubstituted carbene complexes **6**. The *trans* configuration of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the carbene ligands was confirmed by $^{13}C$ NMR spectroscopy in which the $C_2$ signal occurs at $\delta$ = 198.9 ppm, a value typical for *trans* carbene complexes.[12] At room temperature, the $^1H$ NMR spectrum of **6** shows that the NHC ligands are nonequivalent. Four signals can be observed at 1.22, 1.27, 2.25 and 2.33 ppm for each $CH_3$ group in the 2,6-positions of the aryl ring. This indicates that there is hindered rotation around the Pd–$C_{carb}$ bond arising from the bulky phenyl substituent on the NHC ligand. The $Pd^{II}$ carbene complex **6** and the in situ formed complexes between **3** and $Pd(OAc)_2$ were tested as catalysts in C–C coupling reactions.

In a similar fashion to that described for **6**, the reaction between **4** and the dimer $[RhCl(COD)]_2$ in boiling toluene generates the monocarbene complex **7**. The $^1H$ NMR spectrum shows singlets at $\delta$ = 1.46, 1.86, 2.53 and 2.82 ppm for the *o*-Me groups and 6.90, 6.99, 7.01 and 7.11 ppm for the *m*-protons of the mesityl groups, respectively, presumably because of the restricted rotation around the Rh–$C_{carb}$ bond.[13] The detection of a doublet at $\delta$ = 213.7 ppm in the $^{13}C$ NMR spectrum together with a characteristic $J_{103Rh,13C}$ coupling of 48.8 Hz indicated the formation of the proposed complex. Further information was obtained from the crystal structure of [RhCl(NHC)(COD)], **7**, presented in Figure 2.

The single-crystal X-ray diffraction study of complex **7** confirmed the square-planar coordination geometry of the rhodium atom. The structure is represented in Figure 2 and selected bond lengths and angles are listed in the caption. The structural parameters of **7** are similar to those in other rhodium carbene complexes. The rhodium-carbene distance Rh(1)–C(1) [2.047(3) Å] is slightly longer than that observed in saturated analogues (2.003 Å), which may reflect the steric hindrance. However, the distance Rh(1)–Cl(1) [2.3768(9) Å] lies within the expected range.[14] The N(1)–C(1)–N(2) angle of 107.6° is close to that of thione **5** but slightly larger than that reported for [RhCl(SIMes)(COD)].[15] The difference in the *trans* influences of the carbene and the chloride ligands leads to different C=C bond lengths in the coordinated COD ligand: C32–C33 1.355(6) Å and C36–C37 1.385(6) Å.

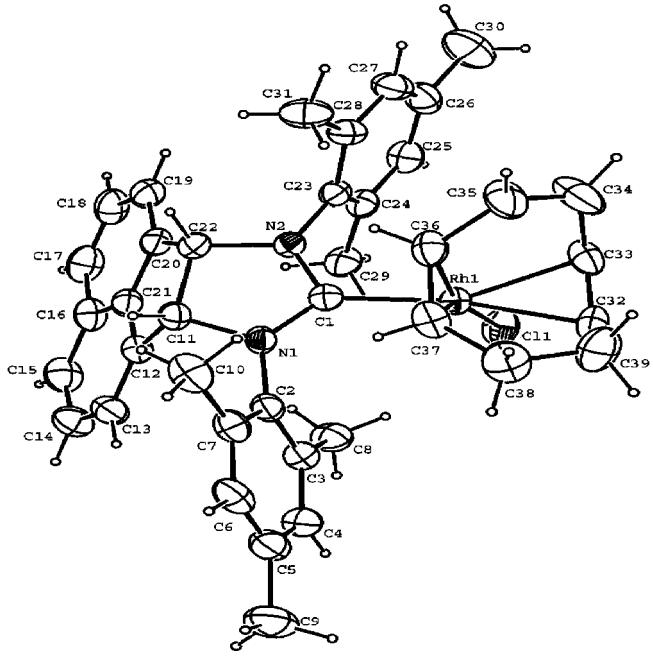

Figure 2. Structure of one molecule of **7** in the crystal. Selected bond lengths [Å] and bond angles [°]: C1–Rh1 2.047(3), C1–N1 1.357(4), C1–N2 1.341(4), C2–N1 1.427(4), C11–N1 1.476(4), C11–C22 1.538(5), C22–N2 1.488(4), C23–N2 1.435(4), C32–Rh1 2.219 (3), C32–C33 1.355(6), C33–Rh1 2.181(4), C36–Rh1 2.114(3), C36–C37 1.385(6), C37–Rh1 2.106(3), Cl1–Rh1 2.376(9); N1–C1–N2 107.6(3), N1–C1–Rh1 128.9(2), N2–C1–Rh1 122.7(2), N1–C11–C12 116.4(3), N1–C11–C22 102.3(2), N2–C22–C11 102.1(2), N2–C22–C20 114.9(3), C1–Rh1–Cl1 96.63(8).

The C–O stretching frequencies of *cis*-$[RhCl(CO)_2(NHC)]$ are considered as an excellent measure for the σ donor/π acceptor properties of the NHC ligands.[15] Therefore, we synthesised complexes of the type **8/8′** by replacing the COD ligand with excess CO. The IR spectra of **8/8′** revealed two bands corresponding to symmetric and asym-

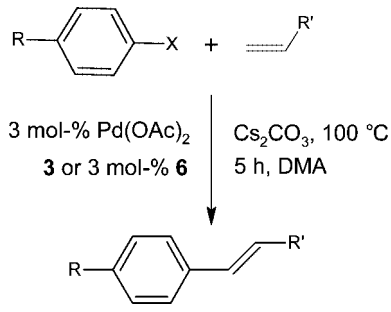
metric vibrations. A comparison of IR data compiled for *cis*-[RhCl(CO)$_2$(NHC)] complexes of NHCs in Table 1 shows that acenaphthylene-anullated NHCs are stronger donors than corresponding nonanullated analogues bearing the imidazole skeleton.

### Catalytic Arylation of Alkenes

We were interested in exploring the influence of substituents located at the 4,5-positions of the imidazolidine ring. Consequently, we tested in situ formed complexes [by use of 3 mol-% Pd(OAc)$_2$ and 3 mol-% **3**] and preformed **6** for activity in the Heck reaction[16] using a set of standard substrates, under standard reaction conditions in terms of solvent, temperature and base (Table 2).

Table 2. The Heck reaction catalysed by in situ formed [**3** + Pd(OAc)$_2$] or preformed complex **6**.[a]



| Entry | Cat | R | R′ | X | Yield (%) |

| 11 | SIMesHCl | Me(O)C | COO*n*Bu | Br | 62 |

[a] Reactions conditions: 1.0 mmol of the aryl halide, 1.5 mmol of olefin, 1.5 mmol $Cs_2CO_3$, 3 mL DMA, 100 °C, 5 h. GC yields (diethylene glycol dibutyl ether used as internal standard, average of two runs).

The coupling of 4-bromoacetophenone or 4-bromotoluene with alkenes was found to proceed in good yield in the presence of 3% of in situ formed catalyst (entries 1, 3 and 5). In the presence of preformed catalyst **6**, deactivated aryl bromides and activated 4-chloroacetophenone were less reactive under the same reaction conditions (entries 2, 4 and 6). The electron-donating capability of the substituents located at the 4,5-positions of the imidazolidine ring appear to play a role in the complex's catalytic activity. Thus, yields of 80%, 67% and 62% were achieved with complexes formed in situ between Pd(OAc)$_2$ and the salts **3**, **3′** and SIMesHCl, respectively, under identical conditions (entries 9–11). Clearly, acenapthene anullation has an unexpected effect of increasing the complex reactivity. This is somewhat surprising, since there is no conjugation between the imidazoline and naphthalene rings.

## Conclusions

In order to further extend the possibilities of ligand tuning and the scope of NHC based catalysts, anullation of the imidazole ring by acenaphthylene was studied. Thione **5** and the transition metal complexes **6**–**8** of the anullated NHC ligand were easily obtainable from the silver-NHC complex **4** which was prepared from the salt **3** and $Ag_2O$. Silver is readily replaced by other metals to give, for example, $Pd^{II}$ and $Rh^{I}$ complexes in high yield. A comparison of NMR and IR spectroscopic data indicates that the new carbene seems to range between saturated and unsaturated imidazol-2-ylidene in terms of its electronic properties. A preliminary study has indicated that the in situ formed palladium complex is an active catalyst for arylation of alkenes.

The greater rigidity of the NHC complexes afforded by the tetracyclic imidazole framework exemplified by **6**–**8** can be anticipated to provide selective transformations. Investigations along these lines are in progress.

## Experimental Section

**General:** All manipulations were carried out in vacuo using Schlenk techniques. Anhydrous solvents were either distilled from appropriate drying agents or purchased from Merck and were degassed prior to use by purging with dry argon. The solvents were then kept over molecular sieves. All other reagents were commercially available and were used as received.

NMR spectra were recorded at 297 K on a Varian Mercury AS 400 instrument at 400 MHz ($^1$H) or 100.56 MHz ($^{13}$C). Elemental analyses were carried out by the analytical service of TUBITAK with a Carlo–Erba Strumentazione Model 1106 instrument. FTIR Spectra were recorded on a Perkin–Elmer Spectrum 100 series instrument. Compound **1** was prepared according to the literature.[18] The structural characterisations of **1′**, **2′**, **3′** and **6′** are given elsewhere.[5]

### Starting Materials

**1,2-Bis(mesitylamino)acenaphthylene (2):** A suspension of **1** (2250 mg, 5.4 mmol) in MeOH (50 mL) was treated at room temperature under argon with $NaCNBH_3$ (2050 mg, 32.6 mmol) in portions of 1 g over a period of 20 min. To the resultant mixture was added bromocresol green and then 0.1 N HCl was added until the colour changed from green to yellow. The solution was stirred for 20 h and heated subsequently for 4 h under reflux. The mixture was then cooled to room temperature and 0.1 N KOH (10 mL), $H_2O$ (100 mL) and $CH_2Cl_2$ (50 mL) were added. The aqueous phase was washed with $CH_2Cl_2$ several times. After this step, the $CH_2Cl_2$ washings were combined and dried with $MgSO_4$. The solvent was concentrated and then methanol was added. The precipitate was separated and washed with methanol. Drying under vacuum provided NMR spectroscopically pure off-white crystals of **2**. Yield: 1.82 g, 81%. M.p. 156–157 °C. $C_{30}H_{32}N_2$ (420.59): calcd. C 85.67, H 7.67, N 6.66; found C 86.10, H 7.82, N 6.93. $^1$H NMR (400 MHz, $CDCl_3$, 297 K): $\delta$ = 2.18 (s, 12 H, $H^{12,13}$), 2.31 (s, 6 H, $H^{14}$), 3.84 (s, 2 H, NH), 5.31 (s, 2 H, $H^{4,5}$), 6.86 (s, 2 H, $H^{8,10}$),

**1,3-Dimesitylacenaphtho[1,2-*d*]imidazolinium Chloride (3):** A mixture of **2** (1170 mg, 2.78 mmol), triethyl orthoformate (10 mL) and ammonium chloride (150 mg, 2.84 mmol) was heated in a distillation apparatus until the ethanol distillation ceased. The temperature of the reaction mixture reached 130 °C. After cooling to room temp., ether (30 mL) was added. A colourless solid precipitated which was collected by filtration. Purification was achieved by repeated recrystallisations from ethanol/ether. Yield: 1.20 g, 93%. M.p. 393–395 °C. $C_{31}H_{31}N_2Cl$ (467.05): calcd. C 79.72, H 6.69, N 6.00; found C 79.10, H 7.02, N 6.13. $^1H$ NMR (400 MHz, $CDCl_3$, 297 K): $\delta$ = 1.56, 2.34 (s, 12 H, $H^{12,13}$), 2.68 (s, 6 H, $H^{14}$), 6.61 (s, 2 H, $H^{4,5}$), 6.86 (d, $J$ = 1.8 Hz, 2 H, $H^{16}$), 6.88 (s, 2 H, $H^{8,10}$), 7.08 (s, 2 H, $H^{8,10}$), 7.48 (t, $J$ = 1.9 Hz, 2 H, $H^{17}$), 7.89 (d, $J$ = 2.2 Hz, 2 H, $H^{18}$), 10.21 (s, 1 H, $H^2$) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$, 297 K): $\delta$ = 18.5, 19.1 ($C^{12,13}$), 21.4 ($C^{14}$), 70.6 ($C^{4,5}$), 122.3 ($C^{16}$), 126.9 ($C^{18}$), 128.7 ($C^{17}$), 129.1 ($C^{8}$), 130.4 ($C^{10}$), 130.7 ($C^{19}$), 131.9 ($C^{9}$), 135.4 ($C^{20}$), 136.3 ($C^{7}$), 136.4 ($C^{11}$), 137.5 ($C^{6}$), 140.8 ($C^{15}$), 159.3 ($C^{2}$) ppm.

**Chloro(1,3-dimesitylacenaphtho[1,2-*d*]imidazolin-2-ylidene)silver(I) (4):** A suspension of **3** (470 mg, 1 mmol) and an equivalent amount of $Ag_2O$ in dichloromethane (50 mL) was stirred at room temperature for 24 h with exclusion of light. The colour of the suspension gradually changed from black to colorless. The suspension was then filtered, washed with dichloromethane and dried under vacuum to give a white solid. 0.52 g, 90%. M.p. 363–365 °C. $C_{31}H_{30}AgClN_2$ (573.90): calcd. IR (KBr): $\tilde{\nu}$ = 2074, 1988 (CO) cm$^{-1}$.

**Chloro(dicarbonyl)(1,3-dimesityl-4,5-dimethylimidazolidin-2-ylidene)rhodium(I) (8′):** Yield: 41.9 mg, 92%. M.p. 149–151 °C (dec.). $C_{25}H_{30}ClN_2O_2Rh$ (528.87): calcd. C 56.77, H 5.72, N 5.30; found: C 56.86, H 5.65, N 5.33. $^1$H NMR (400 MHz, $CDCl_3$, 297 K): $\delta$ = 1.13 –1.27 [s, 6 H, NCH($CH_3$)CH($CH_3$)N], 1.99 (s, 6 H, *p*-$CH_3$), 2.05, 2.13 (s, 12 H, *o*-$CH_3$), 3.98–4.01 [m, 2 H, NCH($CH_3$)-CH($CH_3$)N], 7.11, 7.20 (s, 4 H, Mes) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$, 297 K): $\delta$ = 18.0, 18.2, [NCH($CH_3$)CH($CH_3$)N],19.9 (*p*-$CH_3$), 20.9, 21.4 (*o*-$CH_3$), 53.1, 53.3 [NCH($CH_3$)CH($CH_3$)N], 128.9, 130.3, 130.4, 137.8, 138.9, 139.5 (Mes), 182.8 [d, CO, $^1J_{^{103}Rh,^{13}C}$ = 73.3 Hz], 185.0 [d, CO, $^1J_{^{103}Rh,^{13}C}$ = 52.5 Hz], 206.7 [d, $^1J_{^{103}Rh,^{13}C}$ = 41.4 Hz, Rh-$C^2$] ppm. IR (KBr): $\tilde{\nu}$ = 2078, 1994 (CO) cm$^{-1}$.

**General Procedure for Heck Coupling Reactions:** A two-necked 25 mL flask fitted with a reflux condenser was charged with aryl halide (1.0 mmol), olefin (1.5 mmol), $Cs_2CO_3$ (1.5 mmol), diethylene glycol dibutyl ether (internal standard), DMA (3 mL) and 3 mol-% of in situ formed catalyst or preformed complex **6**. The mixture, under an atmosphere of argon, was placed in a preheated oil bath (100 °C) and stirred for 5 h. The conversion was monitored by gas chromatography.

**X-ray Structural Analyses of 5 and 7:** Crystals of thione **5** suitable for X-ray analysis were obtained from a dichloromethane solution layered with hexane. Similarly, we obtained crystals of **7**, suitable for X-ray analysis, from $CH_2Cl_2$ layered with EtOH.

A colourless single-crystal of **5** and a yellow crystal of **7** suitable for data collection were mounted on glass fibres and data collection was performed on a STOE IPDS II diffractometer with graphite monochromated Mo-$K_\alpha$ radiation at 296 K. The structures were solved by direct-methods using SHELXS-97[20] and refined by full-matrix least-squares methods on $F^2$ using SHELXL-97[21] from within the WINGX[22,23] suite of software. All non-hydrogen atoms were refined with anisotropic parameters. Hydrogen atoms bonded to carbon were placed in calculated positions (C–H = 0.93–0.98 Å) and treated using a riding model with *U* = 1.2 times the *U* value of the parent atom for CH, $CH_2$ and $CH_3$. Molecular diagrams were created using ORTEP-III.[24] Geometric calculations were performed with Platon.[25] Atomic coordinates and equivalent isotropic displacement parameters are listed in Table 3.

Table 3. Crystal data and structural refinements for **5** and **7**.

# 4-Thiolatobenzoato-Bridged Rhodium/Zirconium Complexes: 32-Membered Metallamacrocycles and Their Linear Dinuclear Counterparts

**Ulrike Helmstedt,[a] Peter Lönnecke,[a][‡] and Joachim Reinhold,[b][‡‡] and Evamarie Hey-Hawkins*[a]**

**Keywords:** Heterometallic complexes / Metallacycles / Bridging ligands / Metal–metal interactions / Rhodium / Zirconocenes / S,O ligands

The heterometallic dinuclear complex $[Cp^*_2Zr(Me)\{(\mu\text{-}OOCC_6H_4S)Rh(PEt_3)_3\}]$ (**3**) is readily obtained by methane elimination in the reaction of $[Rh(SC_6H_4COOH)(PEt_3)_3]$ with $[Cp^*_2ZrMe_2]$ in a 1:1 ratio. Complex **3** reacts with 1 equiv. of water to give $[Cp^*_2Zr(OH)\{(\mu\text{-}OOCC_6H_4S)Rh(PEt_3)_3\}]$ (**4**), a rare example of a terminal hydroxo complex of a zirconocene. Complexes **3** and **4** are isotypic. The influence of the zirconocene group on the properties of the rhodium complex was evaluated with $^{31}P$ NMR spectroscopy, cyclic voltammetry and DFT calculations. $[Cp^*_2ZrMe_2]$ reacts with $[\{Rh(\mu\text{-}SC_6H_4COOH)(PPh_3)_2\}_2]$ (even in a 1:1 ratio at room temperature) or with $[Rh(SC_6H_4COOH)(PEt_3)_3]$ (in a 1:2 ratio at elevated temperature) to give 32-membered metallamacrocycles containing four rhodium and two zirconium atoms, in which each zirconocene group bridges two $\{Rh(SC_6H_4COO)(PR_3)_2\}_2$ units [R = Ph (**5**), Et (**6**)]. The only significant structural difference in **5** and **6** is the presence of two different isomers, in which the bridging thiolato ligands occupy either the *exo* or the *endo* position of the $Rh_2S_2$ ring. However, this small difference has a significant influence on the size of the macrocyclic cavity.

## Introduction

Interest in early/late heterobimetallics (ELHBs) has strongly increased in the last few decades.[1] The reasons for this are mainly the elucidation of mechanisms of enzymes whose active centres include more than one metal centre,[2] the explanation of the strong metal–support interaction phenomenon in heterogeneous catalysis[3] and the applicability of cooperative effects between different metal centres for catalysts[4] and magnetic materials.[5] Of special interest for these applications is the investigation of metal–metal interactions. These can be achieved either by direct contact of the metal centres within the compounds[6] or with the help of bridging ligands which allow electronic interactions through π-conjugated bridges.[7]

To elucidate the influence of the second metal centre, it is useful to compare the properties of the heterometallic complexes with those of their mononuclear precursors. Therefore, the preferred synthesis of ELHBs starts with the preparation of a monometallic complex, which is then employed as a so-called metalloligand to coordinate the second metal centre. To selectively coordinate the first metal centre to one coordination site of a di- or multifunctional, potentially bridging ligand, different concepts are known from the literature, for example exploitation of the chelate effect[8] or the use of donor atoms with different coordination behaviour[9] according to the hard and soft acids and bases concept of Pearson.[10]

We have previously employed S,O ligands, such as mercaptocarboxylic acids, which show high bonding selectivity in the synthesis of heterometallic complexes[11] if they cannot bind in a chelating fashion.[12] By changing the bridging ligand from saturated mercaptocarboxylic acids to unsaturated ones, we have now extended our studies to the 4-thiolatobenzoate dianion and have already prepared several rhodium(I) complexes of 4-thiolatobenzoic acid.[13] The special feature of these complexes is the free carboxyl group, which allows further coordination to a second metal ion. For this, we chose zirconocene derivatives, which are known to form stable carboxylato complexes.[14]

## Results and Discussion

The reaction of the metalloligands $[\{Rh(SC_6H_4COOH)(PPh_3)_2\}_2]$ (**1**)[13] and $[Rh(SC_6H_4COOH)(PEt_3)_3]$ (**2**)[13] with $[Cp^*_2ZrMe_2]$ ($Cp^* = C_5Me_5$) yielded the mono- and bis(carboxylato) complexes of the zirconocenes, depending on the stoichiometry and the reactivity of the starting materials. At room temperature, **2** gives only the monosubstitution product (Scheme 1), while disubstitution is achieved at ele-

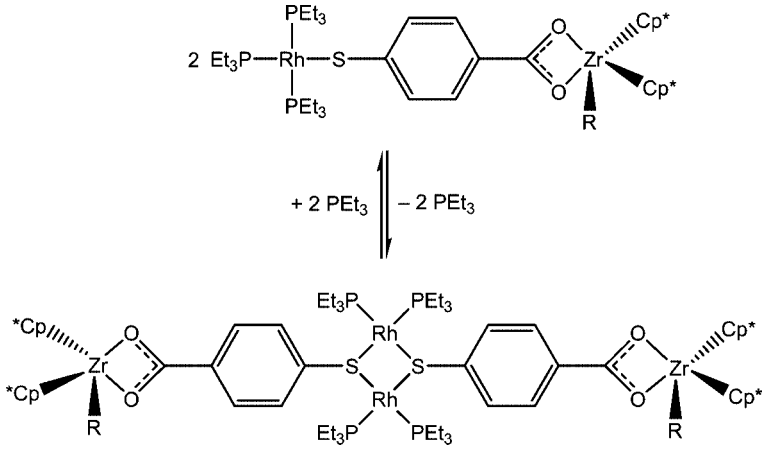
vated temperatures. In contrast, **1** readily reacts with the zirconocene derivative even at room temperature with elimination of 2 equiv. of methane (Scheme 2). Purification of the highly air- and moisture-sensitive complexes was facilitated by the fact that only methane was produced as byproduct.

### Mono(carboxylato)zirconocene Complexes

As shown previously, **2** dimerises in solution with phosphane dissociation (Scheme 3). To stabilise the monomeric form, an excess of triethylphosphane must be used. Complex **2** reacts with 1 equiv. of $[Cp^*_2ZrMe_2]$ in the presence



Scheme 3. R = Me (**3**) or OH (**4**).

of an excess of $PEt_3$ to yield [Cp*$_2$Zr(Me){(μ-$O_2CC_6H_4S$)-Rh($PEt_3$)$_3$}] (**3**) exclusively. Complex **3** could be isolated as orange crystals; the molecular structure in the solid state is shown in Figure 1.

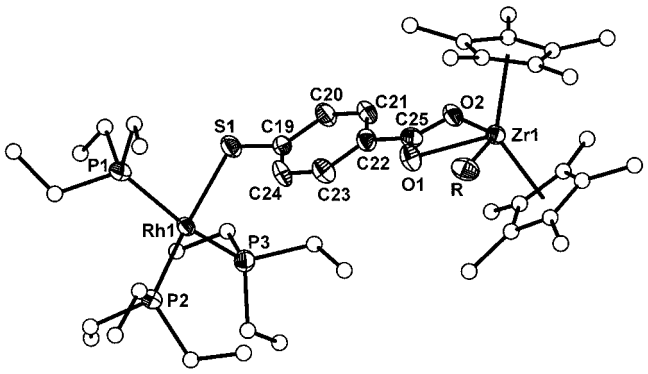

Figure 1. View of the molecular structure of [Cp*$_2$Zr(Me){(μ-$O_2CC_6H_4S$)Rh($PEt_3$)$_3$}] (**3**) (R = Me) and [Cp*$_2$Zr(OH){(μ-$O_2CC_6H_4S$)Rh($PEt_3$)$_3$}] (**4**) (R = OH). Hydrogen atoms are omitted for clarity. Thermal ellipsoid level 50%. The atoms not shown as ellipsoids are the carbon atoms of the coligands. Selected bond lengths [pm] and bond angles [°] for **3**: Zr1–O1 230.3(4), Zr1–O2 227.1(4), Zr1–C46 226.9(8), O1–C25 126.3(8), O2–C25 126.9(7), Rh1–S1 241.4(2), Rh1–P1 230.5(2), Rh1–P2 224.7(2), Rh1–P3 232.7(2); O1–Zr1–O2 56.6(2), O1–Zr1–C46 73.8(3), O1–C25–O2 117.9(6), S1–Rh1–P1 82.93(6), S1–Rh1–P2 166.98(7), S1–Rh1–P3 83.94(6), P1–Rh1–P2 96.76(6), P2–Rh1–P3 101.05(6), P1–Rh1–P3 153.70(7), Rh1–S1–C19 104.8(2). Selected bond lengths [pm] and bond angles [°] for **4**: Zr1–O1 229.5(5), Zr1–O2 228.6(5), Zr1–O3 207.8(6), O1–C25 128(1), O2–C25 124.8(9), Rh1–S1 241.4(2), Rh1–P1 231.0(2), Rh1–P2 225.0(3), Rh1–P3 232.6(3); O1–Zr1–O2 56.4(2), O1–Zr1–O3 76.8(2), O1–C25–O2 117.6(8), S1–Rh1–P1 83.06(9), S1–Rh1–P2 167.39(9), S1–Rh1–P3 84.25(9), P1–Rh1–P2 96.39(9), P2–Rh1–P3 100.64(9), P3–Rh1–P1 154.79(9), Rh1–S1–C19 106.2(3).

Complex **3** crystallises in the monoclinic space group $P2_1/c$ with four molecules per unit cell. The rhodium atom is coordinated by three triethylphosphane and one thiolato ligand in a tetrahedrally distorted square-planar fashion [S1–Rh1–P2 166.98(7)°, P1–Rh1–P3 153.70(7)°]. The carboxylato group coordinates in a bidentate mode, resulting in the zirconium atom being an 18-valence-electron species. The two oxygen atoms, the carbon atom of the methyl group and the zirconium atom are coplanar. The plane defined by Zr1, O1 and O2 forms an angle of 9.12° with the plane of the aromatic ring. The bond lengths C25–O1 [126.3(8) pm] and C25–O2 [126.9(7) pm] as well as Zr1–O1 [230.3(4) pm] and Zr1–O2 [227.1(4) pm] are similar, and this indicates delocalisation of the lone pair of electrons. This is supported by the IR spectrum (KBr), which shows symmetric and asymmetric COO vibrations at 1561 and at 1420 $cm^{-1}$ instead of discrete C=O and C–O vibrations.

By treating a solution of **3** with 1 equiv. of water, the methyl group can be exchanged selectively with an OH group to form [Cp*$_2$Zr(OH){(μ-$OOCC_6H_4S$)Rh($PEt_3$)$_3$}] (**4**), a rare example of a terminal hydroxo complex of a zirconocene. Stabilisation by the sterically bulky Cp* ligands prevents dimerisation with formation of oxo bridges, which usually occurs with elimination of water,[15] as first described by Hillhouse et al.[16] and Bortolin et al.[17] Complex **4** is the first heteroleptic carboxylato hydroxo complex structurally characterised by X-ray crystallography. Pellny et al. reported the NMR spectroscopic observation of the compounds [Cp*$_2$Zr(OH){OOC–C($SiMe_3$)=CHPh}] and [Cp*$_2$Zr(OH){OOC–CPh=CH($SiMe_3$)}], but could not isolate them.[18] Yellow needle-like crystals of **4** were structurally characterised by X-ray crystallography. Complex **4** crystallises isotypic to **3** (Figure 1).

The short Zr–O bond length of 207.8 pm corresponds to those in other structurally characterised compounds of this kind.[17,19] The O3···O1 distance of 272.1 pm seems to indicate the presence of a hydrogen bond between them. As the C46···O1 distance in **3** is also only 274.6 pm, it appears that the two atoms are forced into close proximity due to the high steric demand of the Cp* rings. The steric crowding is also apparent from the deviation of the methyl groups from the $C_5$ ring plane where the two rings are in close proximity.

The OH stretching vibration (3658 $cm^{-1}$) has very low intensity but could be observed in the IR spectra of a KBr pellet and of a single crystal. The intensities of OH vibrations reported in the literature also differ.[19a,19b]

In the $^1$H NMR spectrum, the signals of the protons of the aromatic ring of the 4-thiolatobenzoate ligand (AA′BB′ spin system) are broader than the other signals. This indicates hindered rotation of the $SC_6H_4COOZr(R)Cp^*_2$ group (R = Me, OH) and prevents simulation of the spectra to determine the coupling constants. As can be observed with the help of $^{31}$P NMR spectroscopy, **3** and **4** dimerise in solution with dissociation of 1 equiv. of $PEt_3$ per rhodium atom, as already described for **2** (Scheme 3). The equilibrium can be shifted towards the monomer by adding an excess of triethylphosphane.

### Bis(carboxylato)zirconocene Complexes

Treatment of **1** with [Cp*$_2$Z$rMe_2$] in a 1:1 ratio as well as of **2** with [Cp*$_2$Z$rMe_2$] in a 2:1 ratio results in the formation of compounds of the type [(Cp*$_2$Zr{(μ-$O_2CC_6H_4S$)-Rh($PR_3$)$_2$}$_2$)$_2$] [R = Ph (**5**), R = Et (**6**)]. In the solid state both compounds reveal a nearly identical molecular structure, that is, a 32-membered macrocycle containing two dimeric $Rh_2(SR)_2$ units, as observed in metalloligand **1**, which are deprotonated and bridged by two zirconocene groups (Scheme 2).

Both compounds crystallise in the triclinic space group $P\bar{1}$, and one molecule in the unit cell is located on a crystallographic centre of inversion (Figures 2 and 3). Co-crystallisation of 12 molecules of thf (two of them disordered) for **5** and one molecule of diethyl ether for **6** is observed per unit cell.

The typical bonding mode for zirconocene bis(carboxylato) complexes[20,24–26] is also observed in **5** and **6**: one carboxylato ligand coordinates in a bidentate fashion and the other in a monodentate one. All coordinating oxygen atoms are coplanar with the zirconium atom. In contrast to **3** and

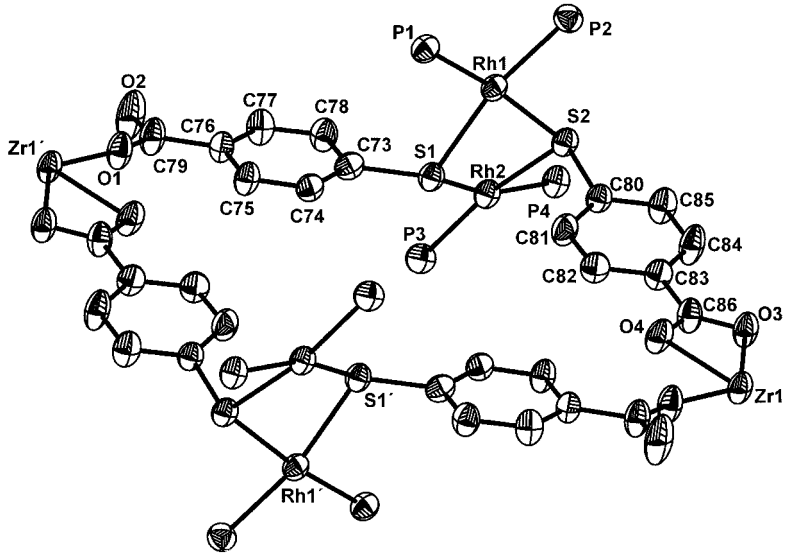

Figure 2. View of the molecular structure of $[(Cp^*_2Zr\{(\mu\text{-}O_2CC_6H_4S)Rh(PPh_3)_2\}_2)_2]$ (**5**). Thermal ellipsoid level 50%. Hydrogen atoms and the carbon atoms of the coligands and thf molecules are omitted for clarity. Selected bond lengths [pm] and bond angles [°]: Zr1–O1 207.1(2), Zr1–O3 232.2(2), Zr1–O4 223.9(2), Rh1–S1 244.12(9), Rh1–S2 237.73(9), Rh1–P1 228.0(1), Rh1–P2 224.3(1), Rh2–S1 236.72(9), Rh2–S2 239.41(9), Rh2–P3 224.8(1), Rh2–P4 226.6(1), C79–O1 129.9(4), C79–O2 122.4(4), C86–O3 126.9(4), C86–O4 127.5(4); O3–Zr1–O4 56.94(8), S1–Rh1–S2 78.76(3), P1–Rh1–S1 96.64(3), P1–Rh1–P2 94.36(4), S1–Rh2–S2 79.91(3), P3–Rh2–S1 99.75(3), P3–Rh2–P4 98.13(4), (S1–Rh1–S2)/(S1–Rh2–S2) 146.46(5).

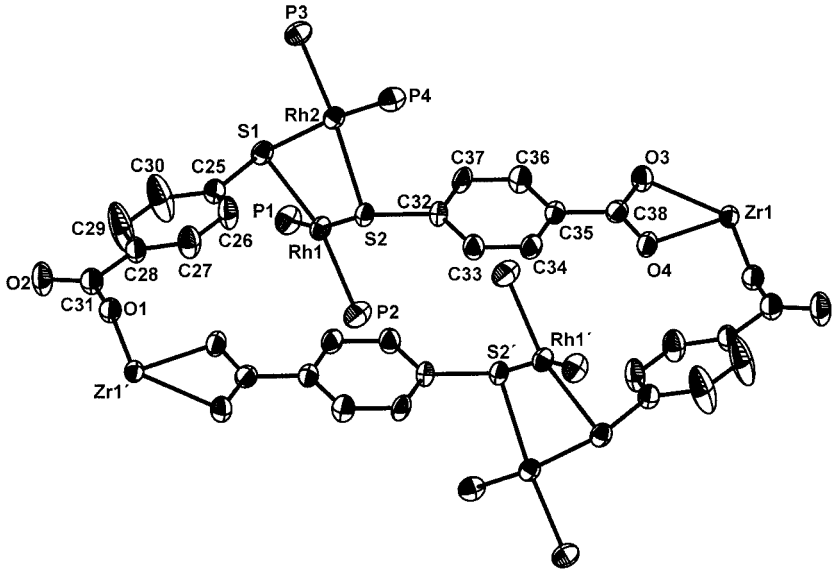

Figure 3. View of the molecular structure of $[(Cp^*_2Zr\{(\mu\text{-}O_2CC_6H_4S)Rh(PEt_3)_2\}_2)_2]$ (**6**). Thermal ellipsoid level 50%. Diethyl ether, hydrogen atoms and the carbon atoms of the coligands are omitted for clarity. Selected bond lengths [pm] and bond angles [°]: Zr1–O1 206.9(3), Zr1–O3 236.1(3), Zr1–O4 222.2(3), Rh1–S1 239.8(1), Rh1–S2 241.3(1), Rh1–P1 224.3(1), Rh1–P2 226.5(1), Rh2–S1 240.6(1), Rh2–S2 242.2(1), Rh2–P3 224.5(1), Rh2–P4 224.5(1), C31–O1 131.2(5), C31–O2 121.9(5), C38–O3 126.3(5), C38–O4 127.6(5); O3–Zr1–O4 56.6(2), S1–Rh1–S2 81.47(4), P1–Rh1–S1 85.33(4), P1–Rh1–P2 102.08(5), S1–Rh2–S2 81.47(4), P3–Rh2–S1 93.40(4), P3–Rh2–P4 97.69(5), (S1–Rh1–S2)/(S1–Rh2–S2) 145.50(5).

**4**, the Zr–O bond lengths of the bidentate ligand differ by 8 pm (**5**) and 14 pm (**6**) and are thus indicative of the strain imposed by the macrocycle. This is also supported by the IR spectrum (KBr), in which the COO vibration is observed at 1633 $cm^{-1}$ (**5**) and 1635 $cm^{-1}$ (**6**), which are in between the values for a C=O bond [1678 $cm^{-1}$ for $HSC_6H_4(C{=}O)$-OH] and a symmetric vibration of the COO group as expected for unstrained molecules {e.g. 1561 $cm^{-1}$ for $[Cp^*_2Zr(Me)\{(\mu\text{-}O_2CC_6H_4S)Rh(PEt_3)_3\}]$ (**3**) and $[Cp^*_2Zr(OH)\{(\mu\text{-}O_2CC_6H_4S)Rh(PEt_3)_3\}]$ (**4**)}. The position of the asymmetric COO vibration could not be identified because of overlap with other bands.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In both compounds, the $Rh_2S_2$ ring is puckered and shows an *anti* conformation. The angle between the S–Rh–S planes is 147° for **5** and 146° for **6**. The only considerable difference is that in **5** the thiolato ligands occupy the *exo* position of the $Rh_2S_2$ ring, and the *endo* position in **6**. This has a crucial influence on the size and shape of the macrocyclic cavity (Figure 4). For **5** the cavity is rhombohedral with internal edges of 470 and 331 pm, while in **6**, because of the different conformation of the $Rh_2S_2$ ring and the different orientation of the arylene bridges, the cavity is divided into two smaller cavities with dimensions of $87 \times 380$ pm.

The cavity is shielded by coligands, as shown exemplarily for **6** in Figure 5. Thus, the solvent molecules are not located inside the cavity. Figure 5 also shows that the 32-membered rings are almost planar, with the exception of

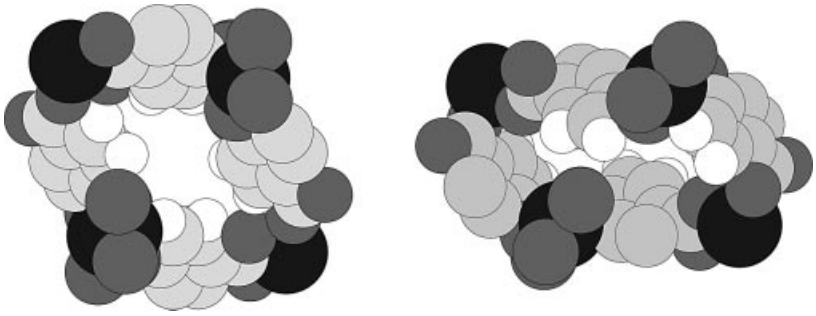

Figure 4. Space-filling model of the macrocycles **5** (left) and **6** (right). The carbon atoms of the coligands and those hydrogen atoms that do not influence the size of the cavities are omitted for clarity. The metal atoms are black, the heteroatoms (oxygen, sulfur and phosphorus) grey, the carbon atoms light grey and the hydrogen atoms white.

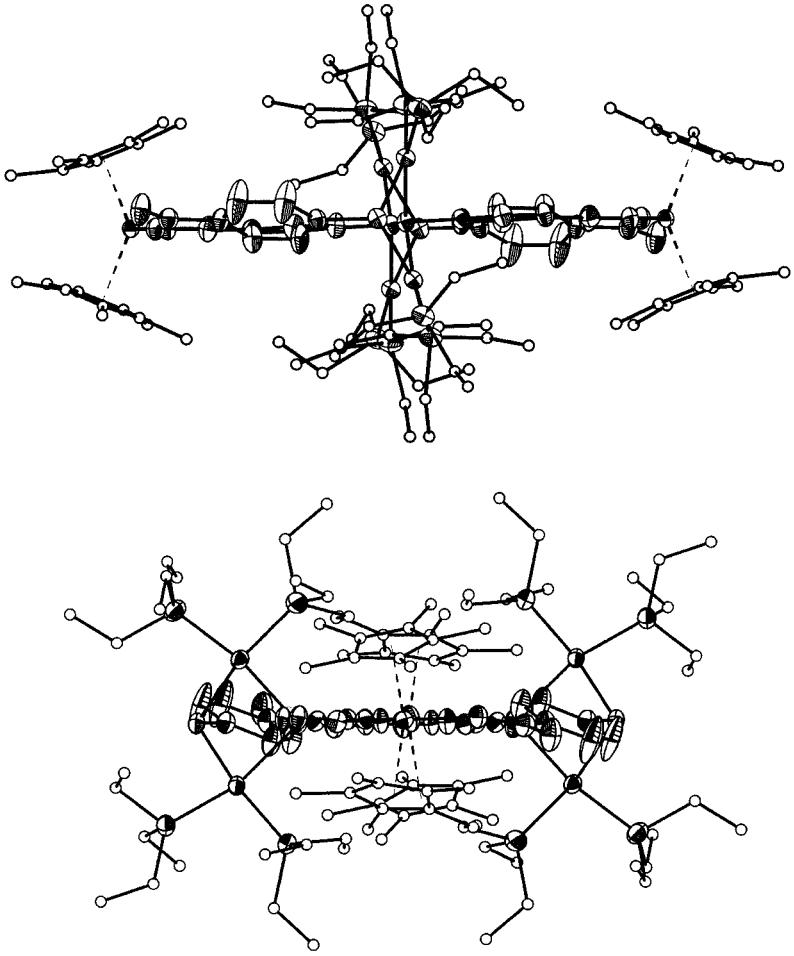

Figure 5. View of the molecular structure of $[(Cp^*_2Zr\{(\mu\text{-}O_2CC_6H_4S)Rh(PEt_3)_2\}_2)_2]$ (**6**). Thermal ellipsoid level 50%. Hydrogen atoms and $Et_2O$ have been omitted for clarity. The atoms not shown as ellipsoids are the carbon atoms of the coligands. Top: View along the axis through the $Rh_2S_2$ rings. Bottom: View along the axis through the zirconocene groups.

the aromatic rings of two of the bridging thiolatobenzoato ligands.

The solubility of **5** and **6** in common organic solvents (*n*-hexane, toluene, thf, $Et_2O$, $CH_3CN$, dmf and dmso) is very low. A sufficient concentration for $^{31}P\{^1H\}$ NMR studies was achieved solely for **5** in thf. At room temperature, a very broad signal is observed at $\delta$ = 38 ppm, which splits into two broad doublets ($\delta$ =37.7 ppm, $^1J_{P\text{-}Rh}$ = 153 Hz, $PPh_3$ of isomer 1, and 38.4 ppm, $^1J_{P\text{-}Rh}$ = 149 Hz, $PPh_3$ of isomer 2) on cooling the sample to –100 °C. Considering that fluxional behaviour of zirconocene bis(carboxylato) complexes in solution is known from the literature[12b] (one of the ligands coordinates alternatingly in a mono- or bidentate fashion) and that dynamic behaviour, that is exchange between different conformers of the $Rh_2S_2$ ring, could be observed for **1**,[13] one could consider different isomers in solution. However, because of solvent restrictions, the sample could not be cooled down sufficiently to achieve fine splitting and to gain deeper insights into the species present in solution.

### Comparison of the Spectroscopic and Electrochemical Properties of 2 and 3

Information about the change in electron density at the rhodium atom after introduction of the second metal centre can be obtained by comparing the spectroscopic and electrochemical properties of the monometallic complex $[Rh(SC_6H_4COOH)(PEt_3)_3]$ (**2**)[13] and the corresponding heterometallic complex $[Cp^*_2Zr(Me)\{(\mu\text{-}O_2CC_6H_4S)\text{-}Rh(PEt_3)_3\}]$ (**3**). For this purpose, the $^{31}P$ NMR chemical shifts of the phosphorus nuclei of the phosphane ligands, the oxidation potentials (Table 1) and the wavelengths of the S–Rh charge-transfer bands of **2** and **3** (Figure 6) were compared.

Table 1. Anodic peak potentials vs. SCE, $^{31}P$ NMR shifts of the phosphorus nucleus *trans* ($\delta_{trans}$) and *cis* ($\delta_{cis}$) to the thiolato ligand and the lowest energy UV/Vis absorption bands.

| Compound | $E_{pa}$ [V] | $\delta_{trans}$ [ppm] | $\delta_{cis}$ [ppm] | $\lambda_{max}$ [nm] |
|---|---|---|---|---|
| **2** | 1.28 | 26.7 | 12.1 | 337 |
| **3** | 1.32 | 28.4 | 13.5 | 358 |

After introduction of the zirconium atom as the second metal centre, the $^{31}P$ chemical shifts of the phosphorus nuclei *cis* and *trans* to the thiolato ligand are shifted to lower field by 1.4 and 1.7 ppm, respectively. This indicates a weak electron-withdrawing character of the Lewis-acidic zirconium atom. This is also shown by a 40-mV shift of the oxidation potential of **3** compared to **2**. The oxidation is irreversible, as known for other rhodium(I) complexes.[21] The observation of a small cathodic peak at –0.72 V in both cases proposes a following chemical reaction and the reduction of its reaction product.

The DFT calculations were carried out for the model compounds $[Rh(SC_6H_4COOH)(PMe_3)_3]$ (for **2**) and $[Cp_2ZrCH_3\{(\mu\text{-}OOCC_6H_4S)Rh(PMe_3)_3\}]$ (for **3**; Cp = $C_5H_5$). According to these calculations for both model compounds, the highest occupied molecular orbitals (HOMO) have both sulfur lone pair and rhodium d character. The HOMO itself is mainly sulfur-centred with some rhodium contribution. The lowest unoccupied molecular orbitals (LUMO) correspond to the σ* orbitals of the almost square-planar coordination sphere of the rhodium(I) centre.

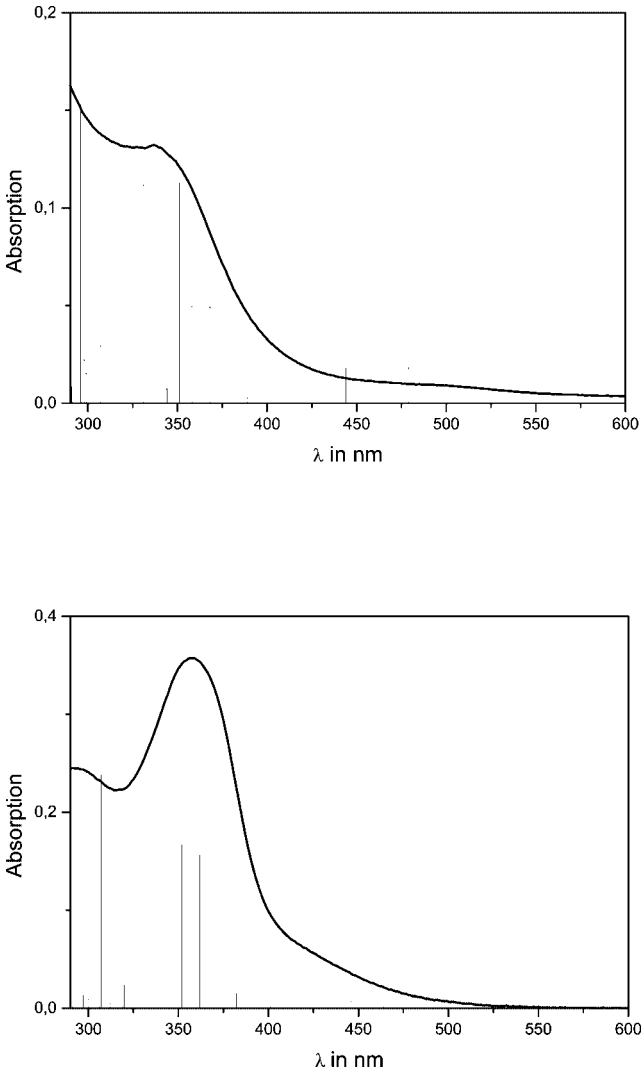

Figure 6. Comparison of the observed UV/Vis spectra of **2** (top) and **3** (bottom) in thf with the calculated transitions (line spectra).

The UV/Vis spectra of **2** and **3** are dominated by one broad band at 337 nm for **2** and 358 nm for **3**. TD-DFT studies show that for both model compounds this band can be assigned to several HOMO-to-LUMO excitations (Figure 6). Cp→Zr charge transfer processes, usually reported for the UV/Vis spectra of zirconocene complexes,[22] seem to play no role for **3**. They are calculated to be of too high energy and too low oscillator strength to be observable in the spectrum.

## Conclusions

While [Cp*$_2$ZrMe$_2$] reacts with [Rh(SC$_6$H$_4$COOH)(PEt$_3$)$_3$] to give selectively either the 1:1 or the 2:4 product, [Cp*$_2$Zr(Me){(μ-OOCC$_6$H$_4$S)Rh(PEt$_3$)$_3$}] (**3**) or [(Cp*$_2$Zr{(μ-O$_2$CC$_6$H$_4$S)Rh(PEt$_3$)$_2$}$_2$)$_2$] (**6**), the reaction with [{Rh(μ-SC$_6$H$_4$COO)(PPh$_3$)$_2$}$_2$] (more labile phosphane ligands) gives exclusively the 2:4 product, [(Cp*$_2$Zr{(μ-O$_2$CC$_6$H$_4$S)Rh(PPh$_3$)$_2$}$_2$)$_2$] (**5**).

Complex **3** reacts with 1 equiv. of water to yield [Cp*$_2$Zr(OH){(μ-OOCC$_6$H$_4$S)Rh(PEt$_3$)$_3$}] (**4**), a rare example of a terminal hydroxo complex of a zirconocene. Complexes **3** and **4** are isotypic in the solid state. The introduction of the Lewis-acidic zirconium atom in **3** has a weak electron-withdrawing effect on the rhodium centre.

The hexanuclear complexes **5** and **6** consist of 32-membered metallacycles in which two zirconocene groups bridge two {Rh(SC$_6$H$_4$COO)(PR$_3$)$_2$}$_2$ units [R = Ph (**5**), Et (**6**)]. The main structural difference in **5** and **6** is the presence of two different isomers, in which the bridging thiolato ligands occupy either the *exo* or the *endo* position of the Rh$_2$S$_2$ ring, which has, however, a significant influence on the size of the macrocyclic cavity.

## Experimental Section

**General Remarks:** All reactions were performed under nitrogen using standard Schlenk techniques. Solvents were dried with the appropriate drying agents and distilled under nitrogen. K(Hmba) (H$_2$mba = 4-mercaptobenzoic acid),[13] [RhCl(PPh$_3$)$_3$],[23] [RhCl(PEt$_3$)$_3$][24] and [Cp*$_2$ZrMe$_2$][25] were prepared according to literature procedures. Complexes **1** and **2** were prepared in situ; their synthesis and spectroscopic data are given in ref.[13] NMR spectra were recorded with a Bruker AVANCE DRX 400 ($^1$H NMR 400.13 MHz, $^{13}$C NMR 100.3 MHz, $^{31}$P NMR 161.97 MHz); Si(CH$_3$)$_4$ was used as internal standard in the $^1$H NMR spectra. All heteronuclei spectra were referenced to Si(CH$_3$)$_4$ with the Ξ scale.[26] NMR spectra of **3** and **4** were measured in the presence of excess PEt$_3$. IR spectra were recorded with an FTIR spectrometer Perkin–Elmer Spektrum 2000 (KBr) in the range of 350–4000 cm$^{-1}$; a single crystal of **4** was measured with a Perkin–Elmer AutoImage microscope system with a diamond cell. The elemental composition was determined with a Hereaus CHN-O-S Analyzer. The melting points were determined in sealed capillaries (under nitrogen) using a Gallenkamp apparatus and are uncorrected. Cyclovoltammetry experiments were performed in an airtight three-electrode cell attached to a Schlenk line. The working electrode was a platinum disc electrode (diameter 2 mm), the counter electrode a platinum sheet and a silver wire was used as pseudoreference electrode. The working electrode was polished on alumina according to standard procedures. The measurements were performed in $5 \times 10^{-3}$ M solutions of the substances in thf containing 0.1 mol of [*n*Bu$_4$N]BF$_4$ per L. The potentials were referenced to the ferrocene/ferrocenium redox couple ($E_{1/2}$ = 0.54 V vs. saturated calomel electrode). UV/Vis spectra were recorded with a Perkin–Elmer UV/Vis/NIR spectrometer Lambda 900.

**(Methyl-1κ*C*)bis(pentamethylcyclopentadienyl-1κ$^5$*C*)(μ-4-thiolatobenzoato-1κ$^2$*O*:2κ*S*)tris(triethylphosphane-2κ*P*)zirconiumrhodium (3):** Complex **2** was prepared in situ by adding a solution of [RhCl(PEt$_3$)$_3$] (243 mg, 0.5 mmol) and PEt$_3$ (1 mL) in thf (15 mL) to a suspension of K(Hmba) (100 mg, 0.5 mmol) in thf (10 mL) at 0 °C. The suspension was warmed to room temperature over 1 h and was then stirred for 16 h. The red solution was filtered and added to a solution of [Cp*$_2$ZrMe$_2$] (194 mg, 0.5 mmol) in thf (5 mL). After stirring at room temperature overnight, the solvent was removed in vacuo and the resulting red solid was washed with cold diethyl ether (2 mL) and cold *n*-hexane (2 mL). Recrystallisation from *n*-hexane/PEt$_3$ gave 380 mg (77%) of orange needles. M.p. 175–180 °C (dec.). C$_{46}$H$_{82}$O$_2$P$_3$RhSZr (986.26): calcd. IR (KBr): $\tilde{\nu}$ = 3050 m, 3000 w, 1633 m, 1585 m, 1495 m, 1481 m, 1432 s, 1380 w, 1306 s, 1262 m, 1170 w, 1135 w, 1091 m (sh), 1027 m, 1016 m, 872 w, 848 w, 805 w, 775 w, 740 m, 694 s, 619 w, 534 m, 522 s, 492 w, 458 w, 437 w cm$^{-1}$.

**Bis[bis(pentamethylcyclopentadienyl-1κ$^5$*C*)(μ-4-thiolatobenzoato-1κ$^2$*O*:2κ*S*)bis(triethylphosphane-2κ*P*)zirconiumdirhodium] (6):** [RhCl(PEt$_3$)$_3$] (162 mg, 0.33 mmol) was dissolved in thf (7 mL) and added to a suspension of K(Hmba) (67 mg, 0.35 mmol) in thf (7 mL) at 0 °C. The suspension was warmed to room temperature over 1 h and then stirred for 16 h. The red solution was filtered, treated with a solution of [Cp*$_2$ZrMe$_2$] (65 mg, 0.17 mmol) in thf (5 mL) and heated to reflux for 3 h. After cooling, the solvent was reduced to half its volume. Vapour diffusion with diethyl ether yielded dark red crystals (170 mg, 37%), which were washed with *n*-hexane and dried in vacuo. M.p. 239–242 °C (dec.). $C_{116}H_{196}O_8P_8Rh_4S_4Zr_2$ (2688.97): calcd. C 51.81, H 7.35; found C 51.28, H 7.69. IR (KBr): $\tilde{\nu}$ = 2958, 2908, 2873, 1635, 1585, 1494, 1429, 1392, 1379, 1301, 1261, 1169, 1136, 1094, 1032, 873, 848, 807, 766, 730, 702, 658, 622, 549, 515, 480, 413 cm$^{-1}$.

**X-ray Crystallography:** X-ray data were collected with a Siemens CCD Smart diffractometer for **3**, **5** and **6**, and with a Stoe IPDS1 for **4** using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Absorption correction was performed with the program SADABS[27] for **3**, **5** and **6**, and numerically for **4**. Structure solution and refinement were performed with WinGX,[28] SHELXS-97 and SHELXL-97.[29] All non-hydrogen atoms were refined anisotropically; most hydrogen atoms were refined in calculated positions. Visualisation was carried out with the program DIAMOND. The crystallographic data are summarised in Table 2. CCDC-609917 (for **3**), -609918 (for **4**), -609915 (for **5**) and -609916 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**DFT Calculations:** The calculations were carried out with the Gaussian03 program package[30] using B3LYP[31] hybrid functionals. For the metal atoms, effective core potentials were used;[32] the outer core electrons were considered explicitly. For the coordinating atoms, the standard 6-31g(d) basis set was used.[33] The calculations of the ultraviolet spectra were performed with time-dependent density functional theory based on the optimised ground-state structure for **2** and on the experimental structure for **3**.

# Synthesis, Crystal Structures, and Magnetic Properties of 2D Manganese(II) and 1D Gadolinium(III) Coordination Polymers with 1*H*-1,2,3-Triazole-4,5-dicarboxylic Acid

**Wei Shi,[a] Xiao-Yan Chen,[a] Na Xu,[a] Hai-Bin Song,[b] Bin Zhao,[a] Peng Cheng,*[a] Dai-Zheng Liao,[a] and Shi-Ping Yan[a]**

**Keywords:** Manganese / Gadolinium / Coordination polymers / Magnetic properties / N,O ligands

Two new coordination polymers, namely $[\{Mn_3(tda)_2(H_2O)_6\}\cdot 6H_2O]_n$ (**1**) and $[\{Gd(H_2O)_4(Htda)\}\cdot(H_2tda)\cdot H_2O]_n$ (**2**) ($H_3tda$ = 1*H*-1,2,3-triazole-4,5-dicarboxylic acid), have been prepared and characterized by IR spectroscopy, elemental analysis, and single-crystal X-ray diffraction. Polymer **1** is a novel 2D stair-like coordination polymer, while **2** is a 1D chain. Temperature-dependent magnetic measurements indicate the existence of antiferromagnetic interactions in both **1** and **2**.

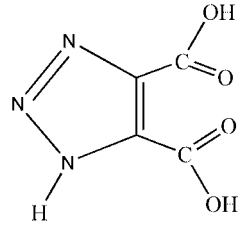
## Introduction

The design and construction of architectures with appealing topologies have been attracting considerable attention in supramolecular chemistry and crystal engineering in recent years.[1] Among them, the use of metal ions as nodes and bridging ligands as spacers has had a large impact on the building of coordination polymers with novel structures and is expected to lead to the development of exploitable properties such as magnetism, molecular sensors, luminescent materials, absorption materials, and so on.[2] Although many intriguing complexes have been well documented as 1D chains[3] and ladders,[4] 2D grids,[5] 3D frameworks, and helical staircase networks[6] in previous studies, the rational design of specific complexes with the above-mentioned properties is still a challenge for chemists.

The selection of polydentate organic compounds as ligands is a key point in the design and assembly of the expected complexes. In our previous studies, pyridine-2,6-dicarboxylic acid, pyridine-2,5-dicarboxylic acid, pyridine-2,4,6-tricarboxylic acid, and related derivatives have been employed for the construction of novel structures with dimensionalities from discrete to 3D, and with useful properties such as luminescence.[7] This type of ligand is based on the six-membered aromatic ring of pyridine with carboxylic groups in different sites as substituents. As a continuation of this work, we focus our attention here on the ligand based on the five-membered heterocycle dicarboxylic derivative $H_3tda$ ($H_3tda$ = 1*H*-1,2,3-triazole-4,5-dicarboxylic acid). The molecular structure of this ligand is shown in Scheme 1. Most studies of $H_3tda$ with metal ions are in the solution state,[8] and only two examples of rhodium(II) and copper(II) complexes with crystal structures of this ligand have been reported as far as we know.[9]



Scheme 1.

In this contribution, two coordination polymers, namely $[\{Mn_3(tda)_2(H_2O)_6\}\cdot 6H_2O]_n$ (**1**) and $[\{Gd(H_2O)_4(Htda)\}\cdot(H_2tda)\cdot H_2O]_n$ (**2**), are reported. The metal ions manganese(II) and gadolinium(III) were used for magnetic studies for two reasons: (a) they possess the highest spin ground state in transition metal ions and lanthanide metal ions ($^6A_{1g}$ for $Mn^{II}$ and $^8S_{7/2}$ for $Gd^{III}$), and always show important magnetic behaviors; (b) the first-order orbital moment of these two metal ions is completely quenched by the ligand field so that the magnetic behavior can be effectively analyzed with the expression derived from the pure spin Hamiltonian. Both of the complexes were characterized by IR spectroscopy, elemental analysis, and single-crystal X-ray diffraction. Polymer **1** is a novel stair-like 2D network based on trinuclear isosceles triangular Mn3 secondary building units, while **2** is a 1D coordination polymer. Tem-

perature-dependent magnetic measurements show that there are antiferromagnetic interactions in both **1** and **2**.

## Results and Discussion

### Description of the Structure

#### *[{Mn$_3$(tda)$_2$(H$_2$O)$_6$}·6H$_2$O]$_n$ (1)*

Polymer **1** crystallizes in the orthorhombic space group *Pmna* with two crystallographically independent $Mn^{II}$ ions in the crystal lattice, as shown in Figure 1. Mn1 lies in a distorted octahedral environment. The equatorial plane contains O1 and O1A [Mn1–O1(O1A) 2.219(2) Å] from the carboxylate groups and O3 and O3A [Mn1–O3(O3A) 2.139(3) Å] from coordinated water molecules. N1 and N1A [Mn1–N1 2.240(3) Å] from the $tda^{3-}$ ligand occupy the axial direction with an N1–Mn1–N1A angle of 162.22(14)°. Mn2 lies in a centrosymmetrical octahedral environment, which is completed by O2, O2A, O2B, and O2C [Mn2–O2 2.158(2) Å] from the carboxylate groups in the equatorial plane and O4 and O4A [Mn2–O4 2.190(4) Å] from the coordinated water molecules in the axial positions. O2, O2A, O2B, and O2C are perfectly coplanar, and O4, Mn2, and O4A are completely co-linear. The $tda^{3-}$ ligand exhibits an unusual hexadentate binding mode, chelating three $Mn^{II}$ ions. It should be noted that all the atoms of every $tda^{3-}$ ligand are essentially coplanar. The maximum deviation from the plane containing N1, N2, and N1A is 0.07 Å, with an average value of 0.00 Å. This suggests that a conjugated $\pi_{11}^{14}$ bond delocalized over both the triazole ring and the carboxylate groups may exist in the structure. The Mn1···Mn1A and Mn1···Mn2 distances are 6.579(6) and 6.190(5) Å, respectively. As shown in Figure 2 (a), every $tda^{3-}$ ligand further bridges two crystallographically identical Mn1 ions to form a 1D chain in the *a* direction. Furthermore, these chains are linked through the Mn2 ions coordinated to the carboxylate groups of $tda^{3-}$ in the *c* direction to form a 1D ladder-like structure comprising Mn6 coordination rings. Importantly, the molecular planes of the $tda^{3-}$ anions in the 1D chain are perpendicular to each other, and the 1D ladders are further assembled into a novel 2D stair-like network in which the plane of every ladder is also perpendicular (Figure 2, b). This particular supramolecular structure is rather rare among known molecular

frameworks.[10] In the crystal, the 2D networks are connected by hydrogen bonds to form a 3D supramolecular architecture containing 1D channels along the *b* direction, as shown in Figure 3.

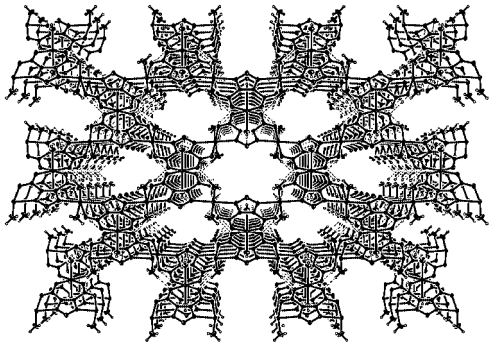

Figure 3. The 3D supramolecular architecture of **1** viewed down the *b* axis. Lattice water molecules in the channel have been omitted for clarity.

### *[{Gd(H$_2$O)$_4$(Htda)}·(H$_2$tda)·H$_2$O]$_n$ (2)*

Polymer **2** crystallizes in the monoclinic space group *C*2/*c*. There is only one crystallographically independent Gd$^{III}$ ion in the crystal lattice. As shown in Figure 4 this Gd$^{III}$ ion is eight-coordinate, with three oxygen atoms and one nitrogen atom from the Htda$^{2-}$ ligand and four water molecules, which together form a square-antiprismatic coordination environment. The Gd–N bond length is 2.582(5) Å, and that of Gd–O is in the range 2.318(4)–2.437(4) Å, with an average value of 2.379(4) Å. Every Htda$^{2-}$ ligand links two Gd$^{III}$ ions to form a 1D zigzag chain in the *b* direction, as shown in Figure 5. Moreover, the 1D zigzag chains are linked by intermolecular hydrogen bonds between the nitrogen atoms in the triazole ring and the oxygen atoms of the carboxylate groups to form 2D layers. These layers are further linked through the counterions of H$_2$tda$^-$ and lattice water molecules into a 3D supramolecular network, as shown in Figure 6.

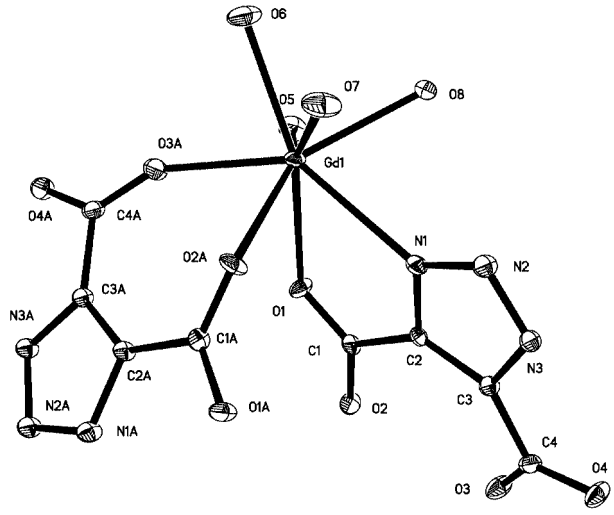

Figure 4. Diagram showing the coordination environment of the Gd$^{III}$ ion in **2**. Hydrogen atoms have been omitted for clarity.

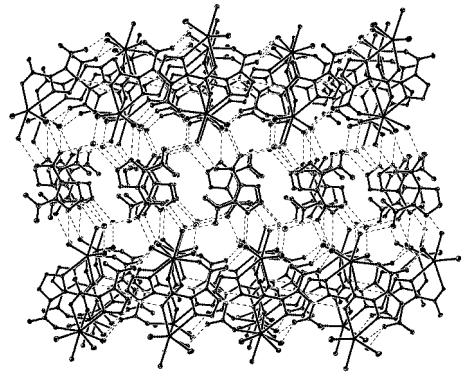

Figure 6. The 3D supramolecular architecture of **2** linked through the counterions of Htda$^-$. Dotted lines represent hydrogen bonding interactions.

The coordination modes of **1** and **2** are shown in Scheme 2. The proton in the 1-position in the triazole ring plays an important role in the formation of the two different coordination modes. For charge neutralization, it is suggested that the ligand is completely deprotonated, existing as tda$^{3-}$ in **1**. The nitrogen atoms in the 1- and 3-positions in the triazole ring become identical from a chemical viewpoint and the tda$^{3-}$ ligand therefore has $C_2$ symmetry. In **2**, the ligand is only doubly deprotonated (at the carboxylate groups) therefore it exists as Htda$^{2-}$ and only has $C_1$ sym-

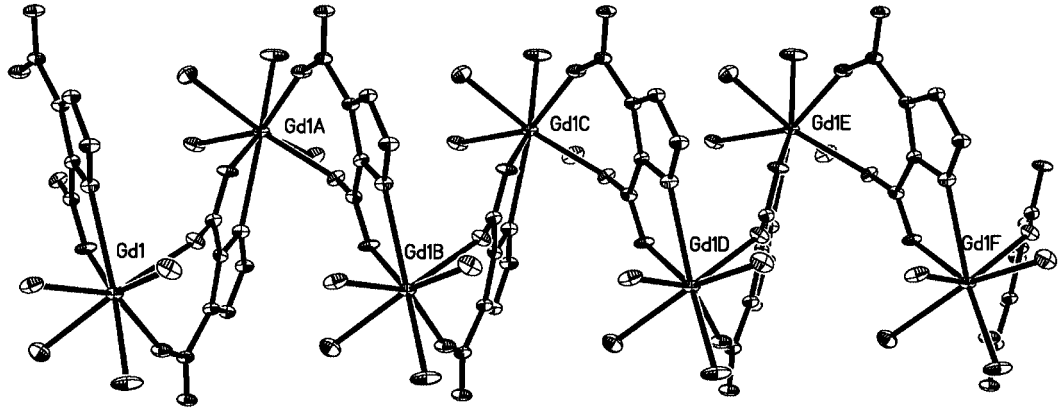

Figure 5. Diagram showing the 1D zigzag chain of **2**. Hydrogen atoms have been omitted for clarity.

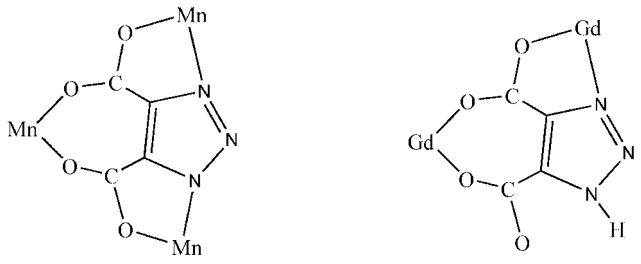
metry. The different symmetries of the ligands result in different coordination modes.



Scheme 2.

### Infrared Spectra

The main features in the IR spectra of both **1** and **2** mainly concern the carboxylate groups and the triazole rings. In **1**, a very strong band appears at around 1595 $cm^{-1}$ due to the antisymmetric stretching ($\nu_{as}$) of the carboxylate group; the symmetrical stretching ($\nu_s$) band of this group appears at 1470 and 1445 $cm^{-1}$, respectively. The difference between $\nu_{as}$ and $\nu_s$ is lower than 200 $cm^{-1}$, which indicates the $\mu_{1,3}$-bridging mode of the carboxylate group to the metal ion, in agreement with the X-ray crystal analysis.[11] In **2**, the $\nu_{as}$ and $\nu_s$ absorptions appear at 1631 and 1380 $cm^{-1}$, respectively. The bands at 1499, 1464, 1016, and 781 $cm^{-1}$ may be attributed to the $\nu$(C–N) stretching of the triazole ring.

### Magnetic Properties

In order to understand the magnetic interactions between the paramagnetic ions via the $H_3$tda ligand in such 1D and 2D structures, the magnetic susceptibilities ($\chi_M$) of both compounds were measured on a Quantum Design MPMS-5S SQUID magnetometer in a field of 1000 Oe. The plots of $\chi_M$ and $\mu_{eff}$ vs. $T$ are shown in Figures 7 and 8 for **1** and **2**, respectively. For **1**, the magnetic susceptibilities were measured in the temperature range from 2 to 300 K. The room-temperature value of 10.23 $\mu_B$ for $\mu_{eff}$ is close to the value of 10.25 $\mu_B$, which is the spin-only value expected for three free $Mn^{II}$ ions with isotropic $g$ = 2.00. As the temperature decreases, the value of $\mu_{eff}$ decreases smoothly, and below 50 K it decreases abruptly to a minimum of 3.52 $\mu_B$ at 2 K. This curve is in agreement with an antiferromagnetic coupling between the $Mn^{II}$ ions. An analytical expression of magnetic susceptibilities for this kind of 2D $Mn^{II}$ complex is not available and only an approximate approach based on both the structural and magnetic data can be performed.[12] Here, we first use the Curie–Weiss law to analyze the experimental data. The best fit gives a Curie constant, $C$, of 4.57 emu K $mol^{-1}$ and a Weiss constant, $\theta$, of –15.47 K, which is consistent with the $\mu_{eff}$ vs. $T$ curve for the antiferromagnetic interactions in **1**. Secondly, based on the crystal data, there are two main pathways (Mn–O–C–O–Mn and Mn–N–N–N–Mn) to transfer the magnetic interactions. By considering that the isosceles triangular Mn3 unit is the basic building block, the expression derived from the Hamiltonian $H = -2J_1S_2(S_1 + S_3) - 2J_2S_1S_3$ (where $J_1$ is the coupling constant between Mn1 and Mn2, and $J_2$ is the coupling constant between Mn1 and Mn1A; see Figure 1 and Scheme 3) was used to fit the data.[13] Because the trinuclear units further assemble into a 2D structure, a $\theta$ parameter was considered to correct the possible secondary effects such as the interactions between the Mn3 units and/or the zero-field splitting of the $Mn^{II}$ ion.[13] The least-squares fit gives $J_1$ = –17.99 $cm^{-1}$, $J_2$ = –9.3 $cm^{-1}$, $\theta$ = –3.9 K, and $g$ = 2.00, with an agreement factor, $R$, of $9.54 \times 10^{-4}$ ($R = \Sigma(\chi_{obsd} - \chi_{calcd})^2/\Sigma(\chi^2_{obsd})$. The $J_1$ value of **1** is obviously larger than other single carboxylato-bridged $Mn^{II}$ complexes, such as $[\{Mn(bipy)_2(H_2O)\}_2\{(CH_3)_3NCH_2CO_2\}](ClO_4)_4 \cdot 2H_2O$ ($g$ = 1.97, $J$ = –0.193 $cm^{-1}$) and $[Mn(MCPA)_2(H_2O)_2]_n$ (MCPA = 2-methyl-4-chlorophenoxyacetic acid; $g$ = 1.90, $J$ = –0.30 $cm^{-1}$).[14] The reason for this may be that the delocalized electrons not only appear around the carboxylate groups but also reside on the $tda^{3-}$

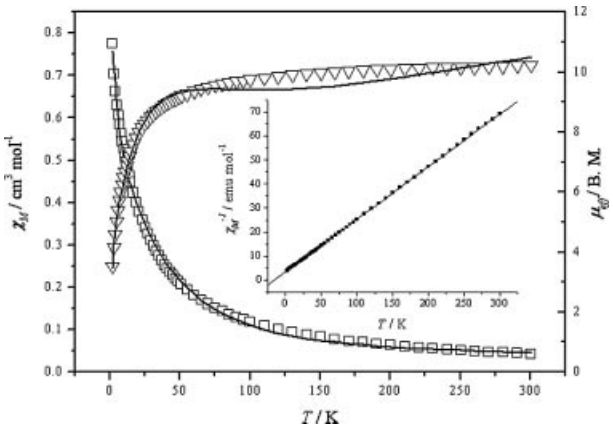


Figure 7. Plots of $\chi_M$ (□) and $\mu_{eff}$ (∇) vs. the temperature for **1**; the solid line represents the best fit. Inset: the Curie–Weiss fit.

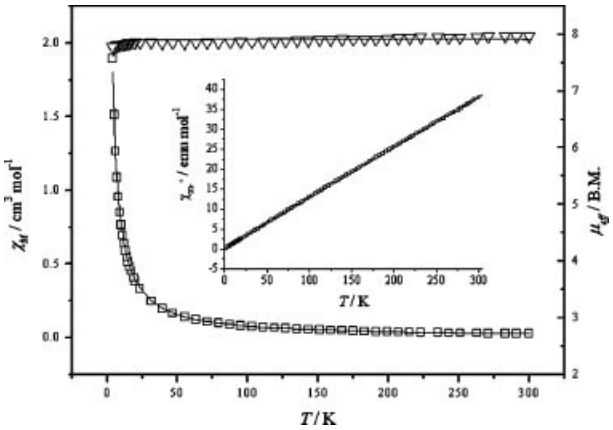

Figure 8. Plots of $\chi_M$ (□) and $\mu_{eff}$ (∇) vs. the temperature for **2**; the solid line represents the best fit.

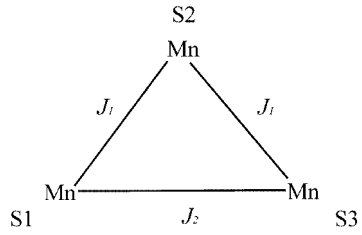
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

anion, which enhances the capability for magnetic exchange. By comparing the $J_1$ and $J_2$ values, the ability of triazole for magnetic exchange is seen to be smaller than that of the carboxylate group. These results indicate that the $tda^{3-}$ anion is a favorable bridging ligand for magnetic exchange of paramagnetic metal ions.



Scheme 3.

Since the $Gd^{III}$ ion in **2** lies in the $^8S_{7/2}$ singlet ground state and does not possess a first-order orbital moment, its magnetic properties are amenable to a rather simple analysis based on a spin-only Hamiltonian. The $\mu_{eff}$ value of **2** at room temperature is 7.97 $\mu_B$, which compares well with the theoretical value of 7.94 $\mu_B$ for one isolated $Gd^{III}$ ion with an isotropic $g$ value of 2.00. The $\mu_{eff}$ value remains almost constant with a decrease of temperature to 2 K, which indicates that the interactions transferred through the $H_3tda$ ligand are very weak. The Curie–Weiss fit for the experimental data gives a Curie constant of 7.89 emu K $mol^{-1}$ and a Weiss constant of –0.85 K. The theoretical $\chi_m$ is given by the following expression, which is based on the spin Hamiltonian $H = -J\sum S_i S_{i+1}$ with the quantum numbers $S_{Gd} = 7/2$:[15]

$$\chi_M = \frac{N\beta^2 g^2 S(S+1)}{3kT} \cdot \frac{1+u}{1-u}$$

$$u = \coth\left[\frac{JS(S+1)}{kT}\right] - \left[\frac{kT}{JS(S+1)}\right]$$

Least-squares fitting of the experimental data leads to $J = -0.10$ $cm^{-1}$, $g = 2.00$, and an agreement factor, $R$, of $6.9 \times 10^{-4}$. These results indicate a very weak antiferromagnetic interaction between the $Gd^{III}$ ions. The magnitude of $J$ is small but is of the same order as other $Gd^{III}$ complexes.[16] The reason for this may be that the 4f electrons lie closer to the metal center than the 5d and 6s electrons and are less influenced by the surrounding environment.

A qualitative interpretation of the magnetic interactions in such metal ions with half-filled orbitals can be made by the well-known Kahn model. The exchange integral ($J$) can be decomposed into two terms, one involving ferromagnetic ($J_F$) and the other antiferromagnetic contributions ($J_{AF}$).[17] The value of $J_{AF}$ is proportional to the square of the integral overlap and is always much larger in magnitude than $J_F$. Since the orbitals of $Mn^{II}$ and $Gd^{III}$ ions are both half-filled such that the electron cloud is completely symmetrical, the nonzero overlap integral of the magnetic orbitals of $Gd^{III}$ or $Mn^{II}$ would result in an antiferromagnetic interaction.

### EPR Spectra

The manganese(II) ion has an $S = 5/2$ electronic spin, and $^{55}Mn$ has a high natural abundance of 100% and an $I = 5/2$ nuclear spin. The X-band EPR spectra of **1** in both the solid state and dmso solution were recorded at room temperature. Only broad bands centered at $g \approx 2.00$ were observed, and no hyperfine pattern could be resolved. This may be due to the strong antiferromagnetic between manganese(II) ions and/or the resonance from the zero-field splitting.[13]

### Theoretical Investigation of $tda^{3-}$

As mentioned in the crystal structure discussion, a conjugated $\pi_{11}^{14}$ bond may exist in the $tda^{3-}$ anion as all its atoms are almost coplanar. A charge density distribution calculation was performed on $tda^{3-}$ at the DFT/B3LYP/6-311G* level using the Gaussian 98 program.[18] The atomic coordinates for input were taken from the crystal data. The calculation result shows that the three negative charges are almost averagely delocalized over the whole $tda^{3-}$ anion, which indicates the existence of a conjugated $\pi_{11}^{14}$ bond.

## Conclusions

We have synthesized two new coordination polymers with 1*H*-1,2,3-triazole-4,5-dicarboxylic acid. The results show that **1** is a novel 2D stair-like coordination polymer based on trinuclear isosceles triangular Mn3 secondary building units, while **2** exists as a 1D chain. Although temperature-dependent magnetic measurements indicate only antiferromagnetic interactions in both **1** and **2**, the interesting structures with variable coordination modes of $H_3tda$ indicate that further studies of this ligand should be made, especially for the construction of 3d–4f complexes.

## Experimental Section

**General Remarks:** All reagents and solvents employed were commercially available and used as received without further purification. $H_3tda$ was synthesized according to the literature method.[19]

**Synthesis of $[\{Mn_3(tda)_2(H_2O)_6\}\cdot 6H_2O]_n$ (1):** A mixture of $Mn(ClO_4)_2\cdot 6H_2O$ (0.145 g, 0.40 mmol), $H_3tda$ (0.156 g, 1.0 mmol), and $H_2O$ (8 mL) was put in a 20-mL acid digestion bomb and heated at 150 °C for three days. The colorless crystals obtained were collected after washing with water (2 × 5 mL) in a yield of 52% (92 mg). $C_8H_{24}Mn_3N_6O_{20}$ (689.15): calcd. C 13.94, H 3.51, N 12.19; found C 14.31, H 3.77, N 12.55.

**Synthesis of $[\{Gd(H_2O)_4(Htda)\}\cdot(H_2tda)\cdot H_2O]_n$ (2):** A mixture of $Mn(ClO_4)_2\cdot 6H_2O$ (0.091 g, 0.25 mmol), $H_3tda$ (0.039 g, 0.25 mmol), $Gd(ClO_4)_3\cdot 6H_2O$ (0.282 g, 0.25 mmol), and $H_2O$ (15 mL) was refluxed in a 100-mL round-bottomed flask for 2 h. The precipitate was filtered off and the filtrate was left to stand at room temperature. Slow concentration of the resulting solution under ambient conditions led to the formation of colorless single crystals of **2** as the only solid with a yield of 86% (68 mg). Without the admixture of $Mn(ClO_4)_2\cdot 6H_2O$ under the same conditions only

**X-ray Crystallographic Studies:** The structural determinations of **1** and **2** were performed by single-crystal XRD analyses. Determinations of the unit cell and data collection were performed with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) on a Bruker Smart 1000 diffractometer equipped with a CCD camera. The ω–φ scan technique was employed. Crystal parameters and structure refinements for **1** and **2** are summarized in Table 1. Selected bond lengths and angles are listed in Table 2.

The structures were solved primarily by direct methods and Fourier difference techniques and refined by the full-matrix least-squares method. The computations were performed with the SHELXL-97 program.[20] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were set in calculated positions and refined as riding atoms with a common fixed isotropic thermal parameter.

CCDC-290628 (for **1**) and -287164 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Selective Precipitation of Alkaline Earth Metal Cations with Dipicrylamine Anion: Structure–Selectivity Correlation

**Pragati Agnihotri,[a] Subrata Patra,[a] Eringathodi Suresh,[a] Parimal Paul,*[a] and Pushpito K. Ghosh*[a]**

**Keywords:** O ligands / Alkaline earth metals / Selectivity / Structure–selectivity correlation

Salts of dipicrylamine anion and alkaline earth metal ions are highly soluble in water, unlike the salts formed with $K^+$, $Rb^+$, and $Cs^+$. We report here that when $DPA^-$ is added to a solution containing $Mg^{2+}$, $Ca^{2+}$, $Sr^{2+}$, and $Ba^{2+}$, $Ba^{2+}$ can be precipitated out with high yield and selectivity by optimizing the concentrations. When $[DPA^-] = 0.17$ M and the molar ratio of each metal ion to $DPA^-$ is 1:1, $Sr^{2+}$ and $Ba^{2+}$ are precipitated out in about 90% overall yield (with respect to $DPA^-$) and 85% selectivity of $Ba^{2+}$. Salts of $Mg^{2+}$ and $Ca^{2+}$ are virtually absent. Single-crystal XRD of the pure $Sr^{2+}$ and $Ba^{2+}$ compounds has been performed. Layered structures are observed with clear evidence that the salts exist in the form of complexes with the composition $[M(DPA)_2(H_2O)_4]$. This is different to the case of alkali metal ions, where the complexes have no coordinated water molecules. The $Ba^{2+}$ complex has a more compact layered structure than the $Sr^{2+}$ complex, with reduced exposure of the polar entities. As a result it would be expected to have relatively lower solubility in water, which would account for its selective precipitation over the $Sr^{2+}$ complex. That it is legitimate to rationalize the precipitation behavior from the structure deduced by single crystal XRD is verified due to the close similarity between the experimental powder XRD data of the precipitate and the simulated powder XRD pattern obtained from the single-crystal data.

## Introduction

Dipicrylamine (2,2′,4,4′,6,6′-hexanitrodiphenylamine, DPA) possesses some interesting structural features (Figure 1), namely six nitro groups that are flexible and can interact and adjust in the space and partial delocalization of the resultant charge mediated by the aromatic rings that facilitates coordination of the oxygen atoms with suitable metal ions. Recently, crystal structures of DPA and a computational study on the intermolecular interactions observed in the crystal structure have been reported.[1] The crystal structures of some of its organic salts have also been reported.[2] $DPA^-$ has been used for quantitative estimation of potassium by Winkel and Mass.[3] It has also been used for the recovery of $K^+$ from seawater,[4] and recovery of $Cs^+$ from radioactive waste.[5,6] Studies have also been conducted with a mixture of cations (e.g. $K^+$, $Rb^+$, and $Cs^+$) and $DPA^-$ to assess the relative selectivity of the metal ion.[7] In spite of the voluminous reports on the utility of $DPA^-$, little is known about the factors that control its selectivity towards different alkali and alkaline earth metal ions. We recently undertook a systematic study with $Na^+$, $K^+$, $Rb^+$, and $Cs^+$ to understand the factors that control the selective precipitation behavior.[8] By applying this reaction to the complex sea bittern system, highly pure and concentrated aqueous KCl could be extracted and the same KCl solution could be utilized in a novel process for the preparation of potassium sulfate.[9]

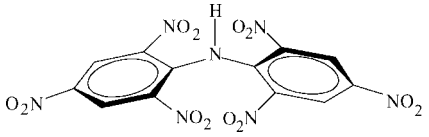

Figure 1. Structure of dipicrylamine (DPA).

Alkaline earth metal ions are dicationic ($Mg^{2+}$, $Ca^{2+}$, $Sr^{2+}$, and $Ba^{2+}$) and their hydration enthalpies (–459.1, –376.9, –344.9, and –311.9 kcal mol$^{-1}$, respectively) are significantly higher than those of the alkali metal ions ($Na^+$: –97, $K^+$: –77, $Rb^+$: –70, and $Cs^+$: –63 kcal mol$^{-1}$). Because of this difference in ionic charge and hydration enthalpy, their structural network and selective precipitation properties are expected to be significantly different from that of

the alkali metal ions. Herein, we report our study on the selective precipitation of $Ba^{2+}$ in high yield from a solution containing the $DPA^-$ anion and an equimolar mixture of $Mg^{2+}$, $Ca^{2+}$, $Sr^{2+}$, and $Ba^{2+}$. This precipitation is induced at high concentrations (ca. 0.15–0.50 M) of $DPA^-$. We have also isolated single crystals of the $Sr^{2+}$ and $Ba^{2+}$ salts of $DPA^-$ to deduce their structures and to unravel the causes underlining this selective precipitation.

## Results and Discussion

### Ion Selectivity

Ion selectivity was determined by analyzing the concentrations of metal ions in the precipitate formed upon addition of 1 mL of an aqueous solution containing $Mg^{2+}$, $Sr^{2+}$, and $Ba^{2+}$ (0.5 M each) to 2 mL of an aqueous solution containing 0.25 M $Ca(DPA)_2$ to yield the overall composition: 0.333 M $DPA^-$ and 0.166 M each of the four metal ions prior to precipitation. The relative proportions of metal ions in the precipitate were assayed by ion chromatography using a reference standard for the purpose of comparison (Figure 2). The tiny peaks corresponding to $Mg^{2+}$ and $Ca^{2+}$ in the ion chromatogram of the precipitate are possibly due to entrapped impurities in the solid (such impurities can remain since washing was avoided to prevent re-dissolution of the precipitate). The molar percentages of $Sr^{2+}$ and $Ba^{2+}$ in the precipitate were 24.1 and 75.9, respectively, while the total molar yield, i.e. sum of the molar yields of $Sr(DPA)_2$ and $Ba(DPA)_2$, was 91% with respect to $DPA^-$ taken up. When all of the concentrations in the solution were halved, the molar percentages of $Sr^{2+}$and $Ba^{2+}$ in the precipitate were 15.0 and 84.9, respectively, while the total molar yield remained virtually constant at 90%. In other words, there was higher recovery of $Ba^{2+}$ (76% in the latter case relative to 69% in the former case) with enhanced selectivity (84.9% in the latter case relative to 75.9% in the former case). This encouraging trend suggests that further increases in recovery and selectivity of $Ba^{2+}$ are possible, although such optimization studies were not carried out. It has been shown previously that understanding of the structures of the solid-state complexes obtained with alkali metal ions can provide valuable insight into their solubility characteristics and precipitation behavior. To extend this understanding to the present system, $Sr^{2+}$and $Ba^{2+}$ complexes of $DPA^-$ were synthesized and structurally characterized.

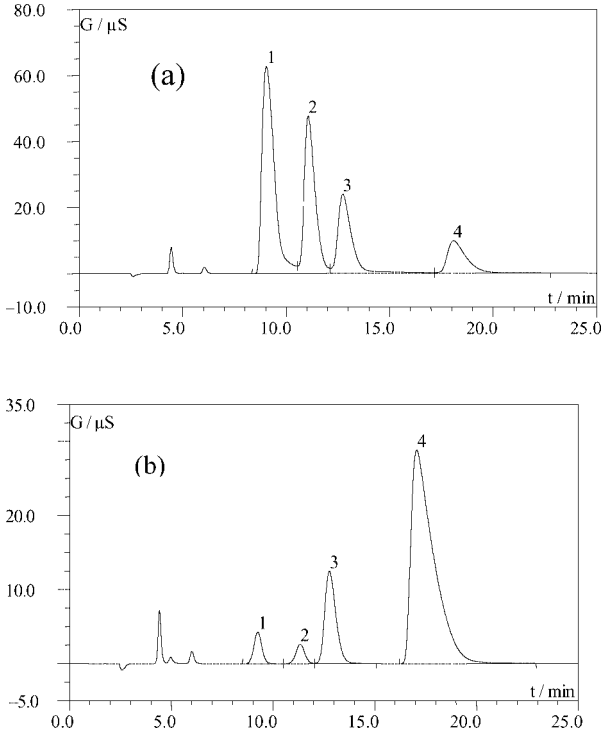

Figure 2. Ion chromatograms of (a) a standard solution containing $MgCl_2$, $CaCl_2$, $SrCl_2$, and $BaCl_2$ (20 ppm each); 1 ($Mg^{2+}$): 9.037, 2 ($Ca^{2+}$): 11.067, 3 ($Sr^{2+}$): 12.740, 4 ($Ba^{2+}$): 18.090 min; and (b) the precipitate separated from the mixture containing 0.17 M of each metal ion; 1 ($Mg^{2+}$): 9.247, 2 ($Ca^{2+}$): 11.333, 3 ($Sr^{2+}$): 12.777, 4 ($Ba^{2+}$): 17.070 min. The tiny peaks of $Mg^{2+}$ and $Ca^{2+}$ found in (b) are probably due to trace amounts of these ions trapped in the precipitate as it was not washed with water to avoid dissolution of the complexes.

### Synthesis of Complexes

$Sr^{2+}$and $Ba^{2+}$ complexes of $DPA^-$ were synthesized by adding an aqueous solution of 0.2 M $Ca(DPA)_2$ to a 0.2 M aqueous solution of the respective chloride salt ($SrCl_2$ and $BaCl_2$), as described in the Experimental Section. The $Sr^{2+}$ complex was partially precipitated during the reaction, and a second crop of the precipitate was obtained when the volume of the filtrate was reduced; even so, the yield was only 72%. In the case of the $Ba^{2+}$ complex, precipitation was nearly instantaneous and almost quantitative (92%), even without recourse to evaporation, which is clearly indicative of its lower solubility than the $Sr^{2+}$ complex. C, H, and N analyses corresponded to the compositions $[Sr(DPA)_2(H_2O)_4]$ (**1**) and $[Ba(DPA)_2(H_2O)_4]$ (**2**). X-ray quality single crystals of **1** and **2** were grown by slow evaporation of dilute aqueous solutions of the complexes at room temperature, and the molecular structures were established by single-crystal X-ray diffraction (see below). To verify whether the bulk precipitates are structurally similar to the single crystals, powder XRD patterns of the bulk precipitates were recorded and compared to those obtained from the single-crystal X-ray data by simulation. The close similarity between the experimental and simulated diffractograms of both **1** and **2** (Figure 3) led us to conclude that the former are indeed structurally similar to the latter and, therefore, understanding of the crystal structures may provide vital information about the solubility/selectivity trend.

## Crystal Structures

### *[Sr(DPA)$_2$(H$_2$O)$_4$] (1)*

This molecule crystallizes in the acentric space group $P322_1$ – the $Sr^{2+}$ atom possesses a twofold symmetry. The $Sr^{2+}$ ion, which occupies a special position, is coordinated to ten oxygen atoms, six oxygen atoms from the nitro groups of four symmetry-related $DPA^-$ moieties and four oxygen atoms from water molecules. An ORTEP view of the binding of $DPA^-$ to the metal ion is available as Supporting Information (Figure S1). Interactions between the $DPA^-$ anion and the metal ions generate a layered, one-dimensional network, as depicted in Figure 4. The Sr···Sr distance is 9.401 Å, and the angle subtended by the metal ions within the layer is 113.89°. The Sr···O distances are in the range 2.785(2)–2.852(2) Å, and the average Sr···O distance is 2.810(2) Å (Table 1). The oxygen atoms of the coordinated water molecules interact even more strongly with the metal ion [Sr···O13 = 2.534(2) and Sr···O14 = 2.595(2) Å]. The Sr···O distances observed from the structural data (Table 1) are in close agreement with the reported values.[10] The phenyl rings of $DPA^-$ in the complex are almost orthogonal to each other, and the mean plane distortion between them is 75.55°. The coordinated *o*-nitro groups N1–O1/O2 and N5–O7/O8 are rotated by 11.98° and 30.66°, respectively, with respect to the phenyl rings to which they are attached. The uncoordinated *o*-nitro groups N3–O5/O6 and N7–O11/O12 also show significant rotation (88.56° and 19.55°, respectively) from the respective phenyl rings (C1–C6 and C7–C12) to which they are attached. The *p*-nitro groups N2–O3/O4 and N6–O9/O10 are almost in the same plane with respect to the phenyl rings C1–C6 and C7–C12 (deviation 0.82° and 0.54°). It appears that these rotations are self-optimized in order to make effective coordination with the metal ion to propagate the doubly bridged $Sr^{2+}$-$DPA^-$ corrugated network.

The molecular packing shows strong intermolecular O–H···O interactions. The hydrogen atoms of the symmetrically disposed coordinated water molecules (H131 and H132 attached to O13, and H141 and H142 attached to O14) on either side act as donors and participate in H-bonding with the nitro oxygen atoms O5, O9, O3, and O12 to bridge the adjacent corrugated layers into a two-dimensional H-bonded network. The nitro oxygen atom O10 is also involved in an intermolecular C–H···O interaction with the phenyl hydrogen H4. Details of the hydrogen-bonding parameters are given in Table 2.

### *[Ba(DPA)$_2$(H$_2$O)$_4$] (2)*

The metal ion in compound **2** sits on a center of symmetry and can accommodate twelve coordinating atoms (eight nitro oxygen atoms from six surrounding DPA$^-$ moieties and four oxygen atoms from coordinated water molecules). An ORTEP view of the binding of DPA$^-$ to the metal ion is available as Supporting Information (Figure S2). The Ba···O distances involving the nitro oxygen atoms are in the range 2.991–3.120 Å (Table 1; average Ba···O = 3.0386 Å). The Ba···O distances involving O13 and O14 of the water molecules are 2.845 and 2.791 Å, respectively, which are in close agreement with the reported values.[11] The Ba···O interaction involving the nitro oxygen atoms O1, O2, and O3 creates a layered doubly bridged architecture in the *ab* plane. However, an additional short contact formed by the nitro oxygen O7 from either side bridges the neighboring layers and extends the layered motif into a two-dimensional sheet-like arrangement, as depicted in Figure 5. The Ba···Ba distance within the coordination network is 9.189 and 6.635 Å along the *a* and *b* axes, respectively. The mean plane distortion between the phenyl rings of DPA$^-$ is 71.78°, which is 3.77° less than that in complex **1**. The coordinated *o*-nitro groups N1–O1/O2 and N5–O7/O8 are rotated with respect to the phenyl rings to which they are attached by 15.49° and 10.06°, respectively, whereas the coordinated *p*-nitro group N2–O3/O4 shows a comparatively smaller rotation (4.68°) with respect to the phenyl ring C1–C6. The uncoordinated *o*-nitro groups N3–O5/O6 and N7–O11/O12 and the *p*-nitro group N6–O9/10 make angles of 29.17°, 5.39°, and 4.35° with respect to the phenyl rings to which they are attached.

Analysis of the molecular packing reveals that both the hydrogen atoms from all the coordinated symmetry-related water molecules act as donors and are involved in intra- and intermolecular O–H···O interactions with the nitro oxygen atoms. Details of the hydrogen-bonding parameters are given in Table 2. These intermolecular H-bonding interactions not only connect the adjacent two-dimensional sheets but also stabilize the network in the crystal lattice.

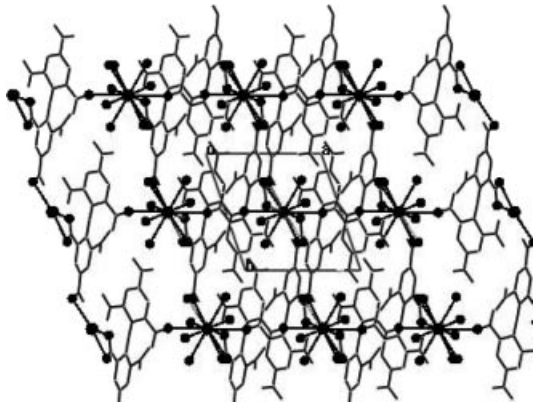

Figure 5. Packing diagram (Mercury) viewed down the *c* axis showing the two-dimensional coordination networks in complex **2**.

### Structure–Selectivity Correlation

Competitive precipitation of a metal ion from a mixture of cations determines selectivity. $Sr^{2+}$ and $Ba^{2+}$ complexes with DPA$^-$ have identical compositions, therefore selective precipitation of a particular complex should be related to the structural arrangement in the solid state, which can profoundly influence the solubility in water. As can be seen from the single-crystal structures of **1** and **2**, these structures are held in place by M···O and C–H···O interactions that form an extended network. From the packing diagrams it is clear that the metal ions are encapsulated in the cavities at regular intervals in the structural network. This self-assembled system reduces the solubility of the complex, and consequently precipitation occurs. Space-filling models of the respective cavities comprising the metal ion and metal-bound oxygen atoms have been generated from the packing diagrams of **1** and **2** (Figure 6 and Figure 7, respectively). The ten oxygen atoms around $Sr^{2+}$ and the twelve oxygen atoms around $Ba^{2+}$ form near-spherical cavities, the approximate diameter of which can be determined from the average distance between the *trans* oxygen atoms having O–M–O angles ≤ 150°. The approximate diameters of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cavities thus obtained are 5.43 and 6.08 Å for $Sr^{2+}$ and $Ba^{2+}$, respectively. These diameters qualitatively follow the order of the ionic sizes of these cations (2.26 and 2.68 Å for $Sr^{2+}$ and $Ba^{2+}$, respectively).[12] $Mg^{2+}$and $Ca^{2+}$, with ionic sizes of 1.30 and 1.98 Å, respectively, may be too small to fit in this cavity and make the significant M···O interactions needed to form a stable assembly, provided a similar structure were to apply in their case also. Alternative structures with smaller cavity sizes are, of course, possible with a lower number of ligands around the metal ion with reduced steric hindrance. However, due to the lack of a sufficient number of M···O and intermolecular C–H···O interactions for such an arrangement, it may not be possible to form the stable assembly essential for precipitation. In the case of alkali metal ions, $Na^+$, which has a smaller ionic size (1.94 Å), does not precipitate out in the presence of $DPA^-$ either due to the lack of formation of a supramolecular network. However, $K^+$, $Rb^+$, and $Cs^+$, which have ionic sizes of 2.66, 2.94, and 3.34 Å, respectively, precipitate out spontaneously in the presence of $DPA^-$.[8] Therefore, the size of the cation is an important factor for the formation of the network structure and thus precipitation.

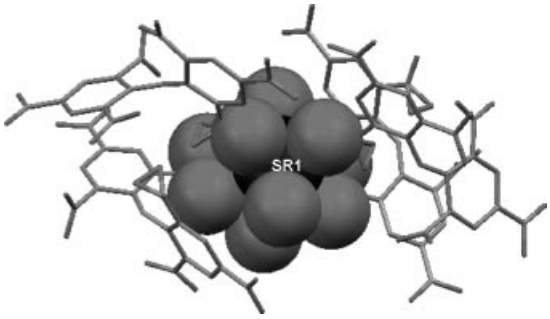

Figure 6. Space-filling model (Mercury diagram) of the cavity comprising the $Sr^{2+}$ ion and metal-bound oxygen atoms.

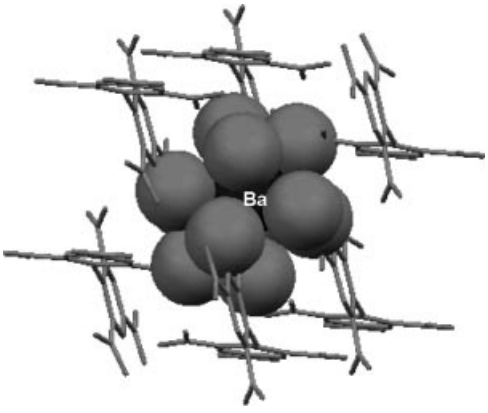

Figure 7. Space-filling model (Mercury diagram) of the cavity comprising the $Ba^{2+}$ ion and metal-bound oxygen atoms.

There can be variations in solubility even for complexes exhibiting a network structure. Reduced exposure of the metal ion and the polar groups of the ligand to water (by tying these up internally in the structure) would lead to reduced solubility and, consequently, more favorable precipitation. In the $Ba^{2+}$ complex, the metal ion is twelve coordinate, unlike in the case of the $Sr^{2+}$ complex in which the coordination number is 10. Moreover, analysis of the packing diagram shows that H-bonding interactions connect the adjacent two-dimensional sheets, which makes the structure more compact than that of the $Sr^{2+}$ complex and reduces the possibility of contact between the polar groups of the ligand and/or coordinated water molecules with the solvent (water). The higher expected stability of the network (Figure 5), coupled with the expectation of reduced solubility due to the reasons above, leads to its higher selectivity over $Sr^{2+}$. Even so, the above solid complexes are much more "exposed" to the solvent than the earlier complexes reported for alkali metal ions ($K^+$, $Rb^+$, $Cs^+$), both in terms of their networked structure and also in terms of their microenvironment, which contains four coordinated water molecules.

Hydration enthalpy is another factor to consider. The hydration enthalpies of $Mg^{2+}$, $Ca^{2+}$, $Sr^{2+}$, and $Ba^{2+}$ are –459.1, –376.9, –344.9, and –311.9 kcal mol$^{-1}$, respectively.[13] Therefore, the displacement of water from the hydrated ions is least facile for $Mg^{2+}$ and most facile for $Ba^{2+}$. This would promote complex formation with $DPA^-$ in the case of $Ba^{2+}$, which, in turn, would allow formation of the network structure required for precipitation. A similar trend was also observed for the alkali metal ions $Na^+$, $K^+$, $Rb^+$, and $Cs^+$. However, that the other factors alluded to above are also critically important is evident from the fact that $Na^+$, despite a much lower hydration enthalpy (–97 kcal mol$^{-1}$) than $Sr^{2+}$ and $Ba^{2+}$, does not form a complex whereas the latter ions do. Moreover, the charge of the cation is also expected to play an important role in complexation. The doubly positive charge on the alkaline earth metal ions obviously attracts $O^{\delta-}$ of the ligand more strongly than monovalent cations. This stronger interaction partially compensates the opposite force due to the high hydration enthalpy of the cations in the complexation process.

## Conclusion

We conclude from the present study that precipitation of alkaline earth metal ions with $DPA^-$ requires the formation of stable assemblies. Simple salts such as $Ca(DPA)_2$, which are unable to form network structures, are highly soluble in water. Formation of such an assembly primarily depends on the ionic size, hydration enthalpy, and ionic charge. Ionic size should be such that the metal ion can fit into the cavity and provide the strong M···O interactions needed to form a stable complex. A smaller ionic size, typically ≤2.0 Å − the ionic sizes of $Mg^{2+}$, $Ca^{2+}$, and $Na^+$ are 1.30, 1.98, and 1.94 Å, respectively − is unfavorable for formation of this assembly. The possibility of complex formation decreases for cations having the same charge with increasing hydration enthalpy. With a mixture of cations, the selectivity depends on the ease of complex formation and the consequent structures of the assemblies: the lower the exposure of the metal ion and polar groups of the ligand to the sol-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vent (water), the higher the selectivity to precipitation. Taking both the alkali and alkaline earth metal ions jointly, the selectivity towards precipitation in the presence of $DPA^-$ follows the overall trend: $Cs^+ > Rb^+ > K^+ > Ba^{2+} > Sr^{2+} >> Na^+, Ca^{2+}, Mg^{2+}$.

## Experimental Section

**Materials:** Dipicrylamine was purchased from National Chemical Co., India, and was used as received. AR grade $MgCl_2$, $SrCl_2$, $BaCl_2$, and CaO were obtained from S. D. Fine Chemicals. Doubly distilled water was used for the preparation of all complexes.

**Instrumentation:** Elemental analyses (C, H, N) were performed on a model 2400 Perkin–Elmer elemental analyzer. Cation concentration was measured with a Dionex 500 ion chromatograph. X-ray powder diffraction data were collected with a Philips X' Pert MPD system with Cu-$K_\alpha$ radiation. Single-crystal structures were determined with a Bruker SMART APEX (CCD) diffractometer.

**Competitive Precipitation Study with $DPA^-$:** $Ca(DPA)_2$ was obtained by stoichiometric reaction of CaO and DPA in an aqueous medium; this compound is highly soluble in water. The $Sr^{2+}$ complex was found to be less soluble in water and the $Ba^{2+}$ complex is the least soluble among these salts. For the competitive precipitation study an aqueous solution of $Ca(DPA)_2$ was added to a solution containing equimolar amounts of $Mg^{2+}$, $Sr^{2+}$, and $Ba^{2+}$. In a typical experiment, an aqueous solution (2 mL) of $Ca(DPA)_2$ (0.25 M), obtained by the reaction of CaO (0.5 mmol) and DPA (1.0 mmol), was added to a solution (1 mL) containing a mixture of $MgCl_2$, $SrCl_2$, and $BaCl_2$ (0.5 M with respect to each metal ion). The reaction mixture was then stirred for 30 min at room temperature, and the orange precipitate thus obtained was isolated by filtration on a frit and dried in vacuo overnight to yield 488 mg (91%) of a solid with a similar powder XRD pattern to that of $[M(DPA)_2(H_2O)_4]$ (M = Ba, Sr). The precipitate was not washed with water to avoid possible dissolution of some of it. The concentrations of metal ions in the precipitate were assessed by ion chromatography. The solubility of the $Sr^{2+}$ complex in water is significant, therefore, the amount of this complex in the precipitate obtained from the mixture of cations should decrease upon decreasing the concentration of the metal ion in the reaction mixture. Therefore, another set of experiments was conducted under similar experimental conditions, with the exception of the concentration of the metal ions – in this case 4 mL of a solution containing 0.5 mmol of each metal ion (0.125 M) was used. Yield: 485 mg (90%) with respect to $DPA^-$.

To estimate the relative concentrations of metal ions in the precipitate, a standard solution containing chloride salts of $Mg^{2+}$, $Ca^{2+}$, $Sr^{2+}$, and $Ba^{2+}$ (20 ppm each) was analyzed by ion chromatography on an Ion Pac CS12 (2 mm) analytical column with 20 mM methylsulfonic acid as eluent (flow rate: 0.25 mL min$^{-1}$). Subsequently, 7.4 mg of the precipitate obtained above was dissolved in 10 mL of Milli-Q (Millipore Corporation) water and filtered through 0.2-μm filter paper. Peaks were obtained at the same retention times as above suggesting that the $[M(DPA)_2(H_2O)_4]$ complexes dissociate under dilute conditions to yield the fully hydrated ions as in the case of solutions made from the simple chloride salts. Analytical results (in mol-%) obtained for the first experiment (0.333 M of each metal ion): $Ba^{2+}$: 75.9; $Sr^{2+}$: 24.0; $Mg^{2+}$ and $Ca^{2+}$: traces; for the second experiment (0.17 M of each metal ion): $Ba^{2+}$: 84.9; $Sr^{2+}$: 15.0; $Mg^{2+}$ and $Ca^{2+}$: traces.

**Synthesis of Metal Salts of $DPA^-$**

**$[Sr(DPA)_2(H_2O)_4]$ (1):** Solid CaO (1.1 mmol, 61.7 mg) was added to DPA (2 mmol, 878 mg) suspended in water (5 mL). After 10 min of stirring at room temperature, the dark-red solution was filtered, and the filtrate containing $Ca(DPA)_2$ was added dropwise to an aqueous solution (5 mL) of $SrCl_2{\cdot}6H_2O$ (1 mmol, 266.6 mg). The reaction mixture was stirred for 1 h, during which some of the $Sr^{2+}$ complex precipitated. The compound was separated by filtration, and the filtrate was allowed to evaporate to dryness at room temperature. After 2 d another crop of microcrystalline complex was obtained. Combined yield: 0.72 g (70%). X-ray quality crystals were obtained by slow evaporation (ca. two weeks) of an aqueous solution of the complex. $C_{24}H_{16}N_{14}O_{28}Sr$ (1036.1): calcd. C 27.82, H 1.56, N 18.93; found C 28.10, H 1.45, N 18.62.

**$[Ba(DPA)_2(H_2O)_4]$ (2):** This compound was synthesized following the same procedure as that described for complex **1**, except $BaCl_2{\cdot}4H_2O$ was used in place of $SrCl_2{\cdot}6H_2O$. In this case almost the entire amount of compound was precipitated during stirring, and the filtrate was not processed further to obtain another crop. Yield: 1.0 g (92%). X-ray quality crystals were obtained following the same method as that described for compound **1**. $C_{24}H_{16}BaN_{14}O_{28}$ (1085.8): calcd. C 26.54, H 1.49, N 18.06; found C 26.29, H 1.36, N 17.91.

**X-ray Crystallography:** Crystal data collection and refinement parameters for complexes **1** and **2** are given in Table 3. Data sets were obtained on a Bruker Smart Apex diffractometer with a CCD area detector using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 100 K. Data frames were processed using the Bruker SAINT program.[14] Intensities were corrected for Lorentz, polarization, and decay effects, and an absorption correction was applied using SADABS.[15] The structure was solved by direct methods using SHELXS-97[16] and refined on $F^2$ using SHELXL-97.[17] The non-hydrogen atoms were located directly by successive difference Fourier calculations, and anisotropic full-matrix refinement of all atoms was carried out using SHELXL-97 until convergence was reached, which showed no significant peaks in the difference Fourier map. H-atoms attached to the phenyl rings of the DPA moiety in both the complexes were calculated on the basis of geometric criteria and were treated with a riding model in subsequent refine-

ments using the SHELXL default parameters. Hydrogen atoms attached to the water oxygen atoms in both the complexes were located from the difference Fourier map. In the case of **1**, water hydrogen atoms were kept fixed and included only in the structure factor calculation whereas in **2** they were refined isotropically. Molecular graphics of the crystal structures were generated using ORTEP, PLATON, and Mercury.[18–20]

CCDC-610046 and -610047 (for **1** and **2**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Powder X-ray Data Collection:** Powder X-ray data of the bulk precipitates of **1** and **2** were collected at room temperature in continuous scan mode in the $2\theta$ range 5–60° with a step size of 0.02° $2\theta$ and a count time of 4 s per step. Powder XRD patterns of **1** and **2** were also obtained by simulation from the single-crystal X-ray data using the Mercury program.[20]

**Supporting Information** (see footnote on the first page of this article): ORTEP views of complexes **1** (Figure S1) and **2** (Figure S2).

## Acknowledgments

We are grateful to the Department of Science and Technology (DST), Government of India, for financial support. We also thank CSIR, New Delhi, for generous support towards infrastructures and core competency development. P.A. gratefully acknowledges CSIR for their award of a Senior Research Fellowship. We thank Dr. (Mrs.) P. Bhatt for the powder XRD measurements.

## COVER PICTURE

**The cover picture shows** the constellation scorpio (lat. scorpius), which symbolises the heteroscorpionate ligands described in the article. To the left, a complex bearing such a heteroscorpionate ligand is fixed on a solid phase. In the back, another ligand with a linker for immobilisation is approaching the resin. The IR spectra (from bottom to top) correspond to a homogenous tricarbonylmanganese complex, the solid phase, a control experiment and a tricarbonyl complex grafted on the solid phase. The $A_1$ and two E bands prove the facial coordination of the ligands and the fixation of the ligand on the solid phase. Details are discussed in the article by N. Burzlaff et al. on p. 4989 ff.

# Cobalt and Nickel Oxide Architectures in Metal Carboxylate Frameworks: From Coordination Polymers to 3D Inorganic Skeletons

**Nathalie Guillou,*[a] Carine Livage,[a] and Gérard Férey[a]**

**Keywords:** Cobalt / Nickel / Organic–inorganic hybrids / Solvothermal synthesis / Microporous materials

This microreview is devoted to the synthesis and properties of nickel and cobalt polycarboxylates, which are classified in terms of the geometries of the organic moieties. It is divided into three main sections — dicarboxylates, tricarboxylates and tetra- and hexacarboxylates — and discusses the extreme diversity of these architectures. Numerous topologies can be obtained, ranging from coordination polymers to 3D inorganic skeletons. This microreview begins with the widely studied cobalt succinate system, for which, to date, seven compounds have been reported. Then, examples from malonate to pimelate illustrate the influence of the length of the organic ligand, whereas examples from fumarate to diphenate illustrate the effects of rigidity and complexity. In the same way, examples from trimesate to mellitate show the effects of "multiconnecting" organic partners. These latter seem to disadvantage metal oxide condensation, since the two 3D inorganic frameworks contain linear dicarboxylate ions. On the other hand, 3D nickel oxide skeletons seem to be easier to synthesise than cobalt ones. Moreover, under similar hydrothermal conditions, using cobalt and nickel generally leads to different architectures.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The wide utility of zeolites in the domains of catalysis, gas separation and ion-exchange has provoked widespread interest in new families of nanoporous materials.[1] Moreover, the opportunity to combine the exciting functionality of transition metal compounds, such as magnetic, electronic conductivity and optical properties, with the porosity of zeolites has become very attractive.[2] The first examples of 3D open frameworks incorporating transition metals were alumino- and gallophosphates substituted by metal ions in the skeleton; those based on cobalt were found to be some of the most promising catalysts.[3] Pure 3D metal phosphates were then synthesised and our first investigations with nickel showed that it could generate microporous materials with novel 3D M–O–M connectivities with face-, edge- and/or corner-sharing polyhedra that present interesting catalytic properties and good thermal stability.[4] The use of phosphate usually reduces electronic interactions and the preparation technique is, most of the time, a limiting factor for obtaining large pores. Indeed, metal phosphates are usually obtained by a templating method, therefore the removal of organic cationic templates generally leads to the collapse of the network. New synthetic approaches avoiding templating agents were therefore developed, with the use of donor ligands that can be part of the framework.[2] In this respect, the ability of carboxylates to strongly connect cobalt and nickel is very fruitful for building new architectures and often leads to a readily accessible porosity as well as physical properties that are usually encountered in dense solids.

The aim of this microreview is to focus on the structural variety and properties of nickel and cobalt polycarboxylates. The diversity of these organic partners offers a great potential to modulate structural architectures and the use of hydrothermal conditions considerably enlarges the range of possible arrangements arising from a metal and an organic molecule. Moreover, the electronic properties of cobalt and nickel significantly extend the potential applications of this type of compounds, especially in the field of porous magnetic materials. Although their ionic radii are similar, nickel and cobalt generally form different architectures. For $Ni^{2+}$ ($d^7$) the ligand-field stabilisation energies strongly favour octahedral coordination, whereas for $Co^{2+}$ ($d^8$) the tetrahedral environment is less disadvantaged.

The field of porous hybrid solids is very topical and is, of course, much wider. The use of oxalate, monocarboxylates or other organic linkers containing N-donor ligands (solely or in addition to carboxylates) will not be tackled here. For an overall overview of porous hybrid materials, we refer the reader to the reviews of Rao et al.,[5] which is devoted to metal carboxylates with open architectures, and of Kitagawa et al.,[6] which deals with functional porous coordination polymers.

The carboxylates presented in this review are classified in terms of the geometries of the organic partners. The first

section is devoted to dicarboxylates and begins with the widely explored succinates. The influence of length, rigidity and complexity of the organic moieties is then presented. The second and the third parts are devoted to tricarboxylates and tetra- and hexacarboxylates, respectively.

## Dicarboxylates

### The Case of Succinate

The best characterised system of transition metal polycarboxylates is the cobalt succinate family. Altogether, seven phases containing cobalt, succinate, water and hydroxide have been discovered, mainly by varying the reaction temperature. The first of the series, $[Co(H_2O)_4(C_4H_4O_4)]$ (**1**), which is obtained at room temperature, was first identified in the Sixties[7] and is constructed from chains of cobalt octahedra bridged by succinate ions.[8] Upon increasing the temperature, inorganic condensation occurs to form edge-sharing octahedral trimers linked by carboxylates into the one-dimensional polymer $[Co(H_2O)_2(C_4H_4O_4)]$ (**2**).[9] A higher degree of condensation occurs under hydrothermal conditions, leading to the formation of open networks with extended M–O–M connectivity. $[Co_5(OH)_2(C_4H_4O_4)_4]$ (MIL-9, **3**), synthesised by Livage et al.,[10] is a nice example of a 2D metal oxide framework pillared by an organic moiety in a 3D coordination polymer. It is constructed from zig-zag layers of edge-sharing cobalt octahedra that generate 12-membered ring cavities with a lozenge shape (Figure 1, a). Half of the succinates are localised within the windows and the other half act as bridges between the sheets. In a more dilute medium, $[Co_4(OH)_2(H_2O)_2(C_4H_4O_4)_3{\cdot}2H_2O]$ (MIL-16, **4**) is formed.[11] It contains a 2D oxide network with 14-membered ring windows (Figure 1, b) and can easily be described as parallel "helicoidal" chains (light grey) connected by tetrameric units of co-planar octahedra (dark grey). Occluded and coordinated water can be removed from this compound in a reversible process. $[Co_6(OH)_2(C_4H_4O_4)_5{\cdot}H_2O]$ (**5**), synthesised by Long et al., is three-dimensional.[12] It presents layers similar to those of MIL-16 with the same helicoidal chains (light grey) but with the tetramers being replaced by dimers of edge-sharing square pyramids (dark grey, Figure 1, c). Four deprotonated succinates are located around the layers, although only one acts as a pillar. The originality of this compound lies in the presence of penta- and hexacoordinate metal centres, which are rather rare in the family of cobalt carboxylates. Forster et al. have recently demonstrated that these five compounds, and also **8**, which was previously obtained with nickel and is described below, can be obtained from the same starting mixture simply by varying the temperature.[9,13] The overall dimensionality of the materials, as well as the degree of M–O–M condensation, increases with temperature. The compounds present chains up to 125 °C, then the inorganic skeleton is two-dimensional, and above 190 °C a 3D overall dimensionality is observed (see Figure 2).[13]

Changing the solvent to a methanol/water mixture, at room temperature, leads to $[Co_3(OH)_2(H_2O)_4(C_4H_4O_4)_2{\cdot}6H_2O]$ (**6**).[14] This hybrid presents an interesting architec

*Nathalie Guillou studied Materials Sciences in Brittany at the University of Rennes, where she obtained her PhD in Chemistry in 1994 under the supervision of Daniel Louër in the "Powder Crystallography and Reactivity of solids" group. She worked on cerium nitrates as precursors of nanocrystalline oxides. In 1995 she joined the Technical University of Darmstadt, as a postdoctoral research fellow, to work on nanostructured materials. Since October 1996, she has held a permanent position as Chargée de Recherche CNRS at the Institut Lavoisier of Versailles. Her current research interests focus on hybrid organic–inorganic porous materials and their structural determination by powder X-ray diffraction.*

*Carine Livage studied chemistry in the University of Orsay (Paris XI) and received her Ph.D. degree in 1991 working on the synthesis of molecular conductors and their characterisation under the supervision of Dr. Patrick Batail in the Laboratoire de physique des solides. (1991–1993). She undertook postdoctoral research in the group of Professor Lisa Klein in the Department of Ceramics of Rutgers University (New Jersey, USA) on the solution syntheses of ferroelectric thin films. She joined the Department of Chemistry of the University of Versailles in 1993 as an associate professor. Her field of research is mainly directed toward the synthesis and characterisation of porous transition metal hybrids.*

*Gérard Férey was born in Normandy, France, in 1941. After education in Caen, he became Professor at Le Mans University and moved to Versailles in 1996 to create the Institut Lavoisier. After a long period dedicated to magnetic inorganic fluorides, he is currently interested in the field of inorganic and hybrid porous solids in which he develops a global approach to these phases, from synthesis to applications through the mechanisms of reaction and prediction of structures. He is now Professor at the Institut Universitaire de France and member of the French Academy of Sciences.*

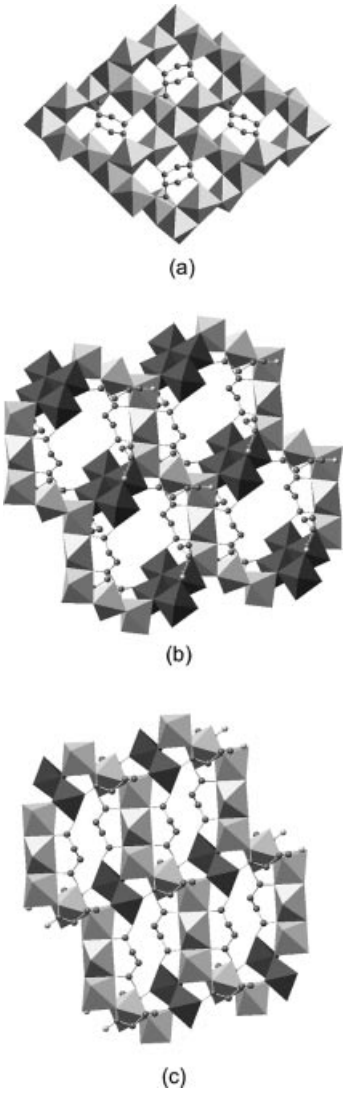

Figure 1. (a) Polyhedral representation of the 12-membered ring cavities lined by organic moieties in MIL-9 (**3**); (b) polyhedral view of MIL-16 (**4**) showing the connectivity between cobalt octahedra within the tetrameric unit (dark grey) and the helicoidal chain (light grey); (c) polyhedral view of **5** showing the connectivity between dimers of square pyramids (dark grey) and the helicoidal chain (light grey).

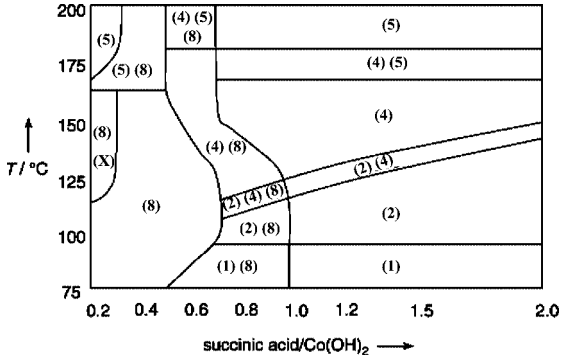

Figure 2. Crystallisation diagram in the succinate system (reproduced with permission from A. K. Cheetham[13]). The phases are indicated by their number code. The phase labelled X is still unknown.

ture that is often encountered with rigid linkers. Its structure can be described as metal oxide chains linked by the organic moiety into a 3D architecture with lozenge-shaped tunnels (see Figure 7). This topology bears a striking resemblance to a vanadium terephthalate isolated by Barthelet et al.[15]

As shown by these few examples, metal organic frameworks obtained with cobalt often exhibit interesting open architectures, although metal oxide condensation is most of the time "classical" with edge- or corner-sharing polyhedra. The architectures obtained hydrothermally with nickel, even though its radius and electronegativity are nearly identical to those of cobalt, are often different and the inorganic condensation more diverse. To date, two nickel succinate compounds have been described. Forster and Cheetham obtained the first metal carboxylate to present a three-dimensional oxide network, namely $[Ni_7(OH)_2(C_4H_4O_4)_6(H_2O)_2 \cdot 2H_2O]$ (**7**).[16] Its structure can be described as layers of edge-sharing octahedra constructed from circular 12-rings surrounded by six truncated triangular 15-rings (Figure 3, a). The three-dimensionality is ensured by "isolated" corner-sharing octahedra (dark grey in the inset of Figure 3, a). This arrangement leads to a remarkable honeycomb framework with 1D pores lined by succinate anions. $[Ni_7(OH)_6(C_4H_4O_4)_4(H_2O)_3 \cdot 7H_2O]$ (MIL-73, **8**), which is obtained under similar synthetic conditions, presents hybrid layers constructed from corrugated chains of nickel oxide connected by succinate ions (Figure 3, b).[17] The inorganic chains are made from hexanuclear metallic octahedral units (light grey) connected by a seventh octahedron (dark grey).

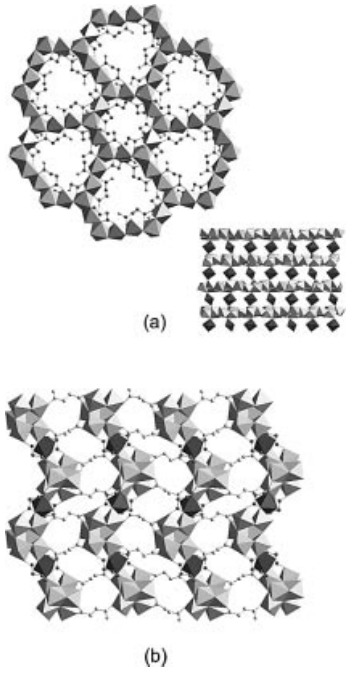

Figure 3. (a) View of a single nickel oxide layer in **7**; connection of the layers through isolated corner-sharing octahedra (dark grey) is shown in the inset; (b) view of one hybrid layer of **8**, where hexanickel units (light grey) are connected to bridging Ni octahedra (dark grey). Decorating succinate ions are represented in dark grey and bridging ones in light grey.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

This hexameric unit is unusual and is built up from a dimer of face-sharing octahedra grafted onto a tetramer formed by two edge-sharing dimers connected by their corners. A pseudo-3D framework is formed due to the presence of strong hydrogen bonds between adjacent layers. This arrangement presents hydrated channels, where water molecules can be easily removed and reabsorbed. An isostructural phase has recently been obtained with cobalt using high-throughput synthesis.[18] Its structure, as determined by X-ray single crystal diffraction, confirmed the accuracy of the ab initio structural investigation of the nickel analogue, in spite of its high complexity due to the large number of independent atoms.

### Changing the Length of the Aliphatic Chain

The reaction of malonic acid with transition metal ions has been reported, but most of the time in the presence of an additional co-ligand such as 2,2′-bipyrimidine.[19] One 2D cobalt malonate, **9**, which is isostructural with a nickel compound, has been obtained by Delgado et al.[20] Its structure consists of "isolated" metal octahedra connected through bridging carboxylate groups to four other metal centres (see Figure 4) to form layers with a pseudo square geometry.

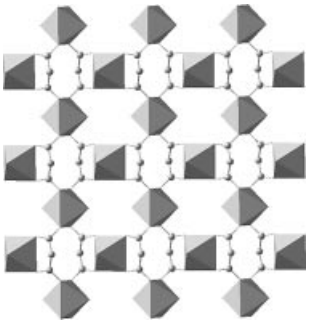

Figure 4. View of a layer of **9** showing the interconnection of metal octahedra through malonate ions.

Two compounds have been reported with glutaric acid: one with cobalt and the other with nickel. $[Co(C_5H_6O_4)]$ (**10**), reported by Lee et al.,[21] is a 3D coordination polymer constructed from cobalt tetrahedra linked by glutarate anions. Its topology will be described below (Figure 6, b) with that of its pimelic acid analogue MIL-36.[26] Cubic $[Ni_{20}(H_2O)_8(C_5H_6O_4)_{20}\cdot 40H_2O]$ (MIL-77, **11**), reported by us, presents an amazing chiral three-dimensional metal oxide network.[22] Its skeleton can be described as helices of edge-sharing octahedra connected to four parallel neighbouring ones through a nickel octahedron (dark grey in Figure 5, a). This induces the formation of perpendicular helices and generates corrugated 20-membered rings (Figure 5, b), which intersect to construct very large crossing tunnels in the [111] direction (Figure 5, c). The oxide framework is walled by two independent glutarate anions: the first one (light grey) is located on the twofold axis and the second one (dark grey) on the threefold one, with a statistical occupancy of 2/3. The nickel environments present bridging water molecules, and the tunnels contain disordered water molecules which can easily be removed by heating, leading to a porous compound (346 $m^2 g^{-1}$). MIL-77 is also a pure ferromagnet at low temperature. More recently, the adaptability of this 3D inorganic skeleton has been proved by obtaining the same topology with 3-methylglutaric acid.[23] The main difference between MIL-77 and this compound is the position of the second organic molecule. Unfortunately, this has drastic consequences for the porosity — its surface area is about half that of MIL-77.

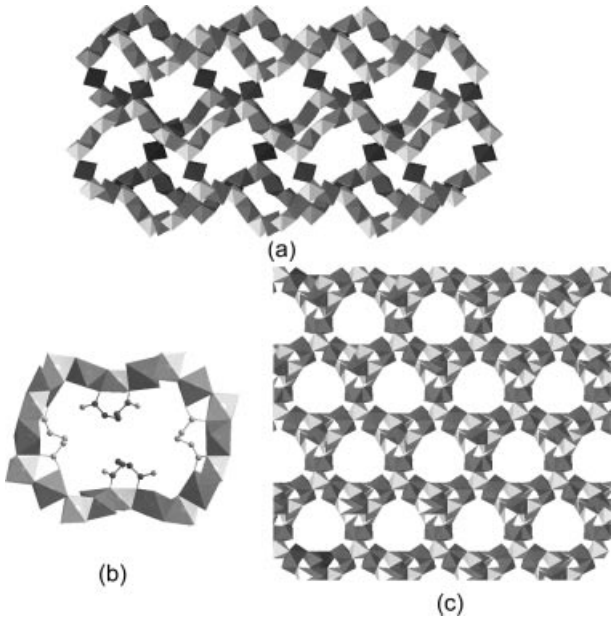

Figure 5. Views of the structure of MIL-77 (**11**): (a) view of six helices connected by nickel octahedra (dark grey); (b) polyhedral view of a corrugated 20- membered ring with the two independent glutarate ions; (c) view of the nickel oxide tunnels down [111].

Two compounds are obtained at room temperature upon increasing the aliphatic chain length by one carbon: $[Ni(H_2O)_4(C_6H_8O_4)]$ (**12**),[24] which presents a 1D metal-organic chain and layered $[Co_2(H_2O)_6(C_6H_8O_4)_2\cdot 4H_2O]$ (**13**).[25] The latter is constructed from corner-sharing octahedral chains where $Co(H_2O)_6$ shares its *trans*-$H_2O$ molecules with two neighbouring $[CoO_4(H_2O)_2]$ polyhedra (Figure 6, a). These chains are connected by adipates to generate the 2D open network.

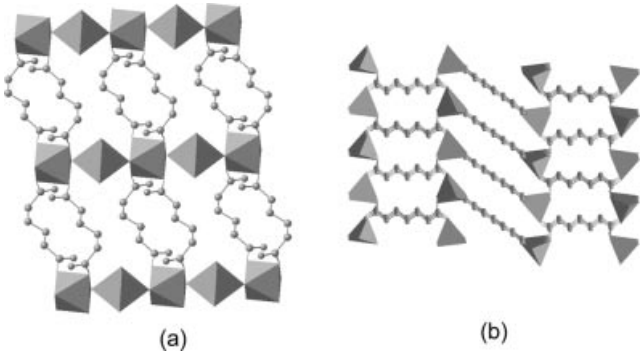

Figure 6. (a) View of a layer of **13** showing inorganic chains bound by adipate ions; (b) view of the 3D coordination polymer MIL-36 (**14**).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

With pimelic acid, only $[Co(C_7H_{10}O_4)]$ (MIL-36, **14**) has been reported in the literature.[26] It is a 3D coordination polymer built up from cobalt tetrahedra where Co–$CO_2$–Co linkages give rise to infinite two-dimensional networks linked by the aliphatic chains. Therefore, hydrophobic carbon chains form the "walls" of two types of channels and act as spacers to generate an open structure (Figure 6, b). This type of arrangement has also been observed with adipate linkers.[27]

### Using Unsaturated Chains

The use of fumaric acid leads to the formation of $[M_3(OH)_2(H_2O)_4(C_4H_2O_4)_2{\cdot}2H_2O]$ (**15**) with both cobalt and nickel, but with totally different synthetic procedures: the nickel compound was obtained under hydrothermal conditions[28] whereas its cobalt analogue was synthesised at 50 °C.[29] Their structure consists of chains of metal octahedra connected by fumarate ions to form a 3D framework (Figure 7). A remarkable feature is the presence of perpendicular intersecting tunnels. These have a large lozenge shape down the *a* axis and are delineated by four walls of fumarate-linked nickel oxide chains (Figure 7, a). The tunnels down the *b* axis are delimited by the space between two fumarate pillars (Figure 7, b). The repeating structural motif in the metal oxide chain is a trimer consisting of two edge-sharing octahedra linked by a $\mu_3$-OH to a vertex of a third one (Figure 7, c). The carboxylic functions are bidentate and bridge successive metal atoms of the chains. It is interesting to note that the same topology can also be obtained with succinic acid.[14] The main difference concerns the aperture of the lozenge tunnels, which is more open in the case of the succinate. The cavity located at the intersection of the two perpendicular tunnels contains one water molecule for the fumarate and three for the succinate. Two other 1D compounds have been synthesised by Konar et al. simultaneously in the same batch: *cis*-$[Co(H_2O)_4(C_4H_2O_4){\cdot}2H_2O]$ (**16**) and *trans*-$[Co(H_2O)_4(C_4H_2O_4)]$ (**17**).[30] Both structures are built up from isolated cobalt octahedra linked by carboxylate in a bis-monodendate fashion. With acetylenedicarboxylic acid, only $[M(H_2O)_4(C_4O_4){\cdot}2H_2O]$ (**18**) (M = Co, Ni) has been described.[31] Heating it to 100 °C leads to $[M(H_2O)_2(C_4O_4)]$ (**19**). This latter solid presents a metal organic framework where octahedra are connected by dicarboxylate ligands into a compact 3D network.

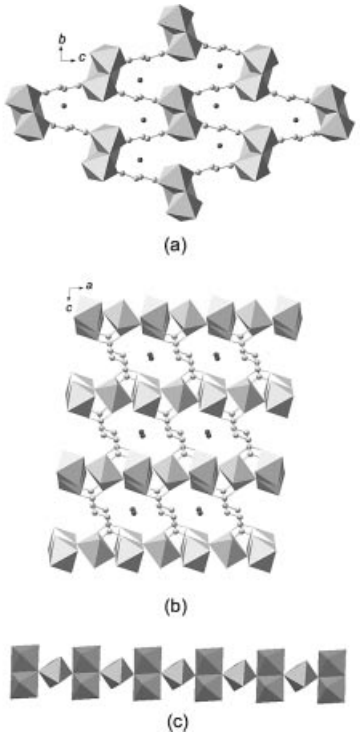

Figure 7. (a) View of the structure of **15** along *a* showing the lozenge-shaped tunnel topology; (b) view of the tunnels of **15** along the *b* axis; (c) the inorganic chain encountered in **6** and **15**.

### Using Carboxylates Containing One Cycle

Two 3D compounds, namely $[Co_2(OH)_2(1,4\text{-BDC})]$ (**20**)[32,33] and $[Co(H_2O)_2(1,4\text{-BDC})]$ (**21**)[33] have been isolated with 1,4-benzenedicarboxylic acid (1,4-$H_2$BDC; also known as terephthalic acid). Compound **20** is built up from inorganic layers where two types of parallel tilted chains of edge-sharing octahedra are linked by OH bridges (Figure 8, a). The cobalt atoms of the light-grey chain are surrounded in the equatorial plane by four terephthalate oxygen atoms and in the apical positions by two OH groups, whereas those of the dark-grey chain are coordinated to four OH groups in the equatorial plane and two carboxylate oxygens. The layers are then connected together through terephthalate into a 3D architecture. The second coordination polymer, **21**, was obtained hydrothermally. Its structure

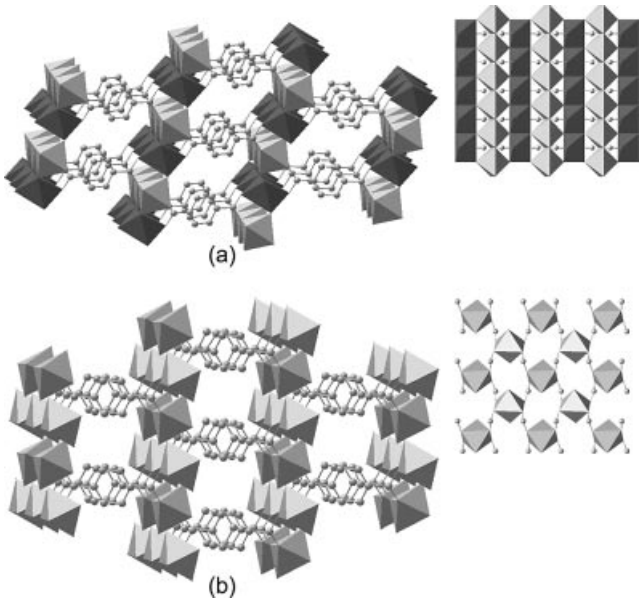

Figure 8. (a) Polyhedral view of the structure of **20** constructed from cobalt hydroxide layers (shown as inset) pillared by terephthalate ions; (b) polyhedral representation of the coordination polymer **21** with layers of a pseudo square symmetry shown as the inset.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

presents isolated cobalt octahedra bridged by carboxylates into layers with a pseudo square symmetry (Figure 8, b). As for **20**, these layers are connected through terephthalate into a 3D network.

With 1,3-benzenedicarboxylic acid (1,3-$H_2$BDC; isophthalic acid) only one compound, namely [$Na_3${$Co_6O$(OH)(1,3-BDC)$_6$}·$H_2O$] (MIL-104, **22**), has been reported.[34] Its structure is constructed from an unprecedented hexanuclear octahedral "cluster". The hexameric cobalt unit may be viewed as the association of two trimers connected through six $\mu_2$-O vertices, each trimer being composed of octahedra sharing a central $\mu_3$-O atom (Figure 9, a). The octahedra are highly distorted due to the chelating mode of one of the carboxylate groups. Indeed, the "bite" of the rigid acid group is too short for a cobalt octahedral coordination, therefore the angle is very narrow and Co–O distances are longer than usual. The architecture is a classical metal organic framework (MOF), with each hexamer joined by isophthalate ions to six neighbouring ones and serving as an octahedral node of a cuboid net (Figure 9, b). The small cavities left free by the hexamer packing are occupied by sodium cations. Each hexanuclear cluster is connected to six sodium ions to form a larger "super octahedron". In terms of "scale chemistry",[35] the topology is the same as that found for $ReO_3$, with {$Na_6Co_6O_{26}$} units as giant octahedra.

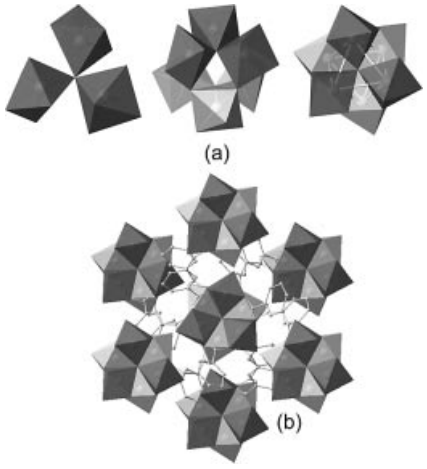

Figure 9. (a) Schematic representation of the hexameric unit of MIL-104 (**22**) showing its octahedral geometry; (b) projection of the structure showing the connection of one unit to six neighbouring ones that lie at the corners of an octahedron.

[$Co_3(OH)_2(C_8H_4O_4)_2$] (**23**) has been obtained hydrothermally with phthalic acid.[36] Its 2D structure consists of inorganic layers of edge-sharing octahedra which generate eight-membered ring cavities (Figure 10). Phthalate ions are grafted onto the layers within the window and organic part is localised up and down the inorganic layer.

One cobalt compound [$Co(C_8H_8O_4)$], (**24**) has been reported with 4-cyclohexene-1,2-dicarboxylic acid.[37] The originality of its structure lies in the tetrahedral coordination of the metal, which is less common than octahedral

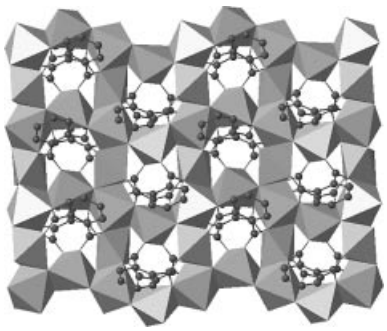

Figure 10. Polyhedral representation of **23** showing the eight-membered ring cavities lined by organic moieties.

under hydrothermal conditions. It is interesting to note that the starting material was the *cis* form of the dicarboxylic acid whereas the resulting compound presents the *trans* one. Such changes are not unusual under hydrothermal conditions.[38] The structure is formed from isolated distorted tetrahedra linked by carboxylates into layers (see Figure 11). Two facing tetrahedra are first doubly bridged by carboxylates to form dimers, which are then bridged by the second carboxylate function to construct ribbons. These chains are connected through the organic moiety into a 2D network. As for the phthalate compound, the organic moiety is localised on the surface of the layer. As shown by these two last examples, the presence of a hydrophobic region opposite the carboxylate groups favours lamellar systems.

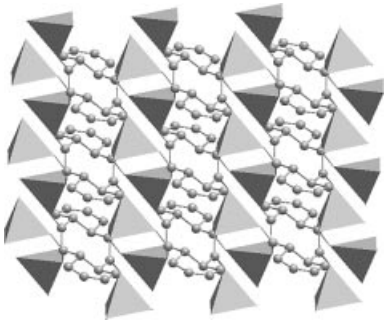

Figure 11. View of a layer of **24** showing the connection of cobalt tetrahedra by organic moieties.

The compound [$Co_5(OH)_8$(CHDC)·$4H_2O$] (**25**) has been synthesised hydrothermally from 1,4-cyclohexanedicarboxylic acid ($H_2$CHDC).[39] Although the starting material was a mixture of *cis* and *trans* $H_2$CHDC, this compound is formed only with the *trans* conformation. Its structure is based on metal–hydroxide octahedral–tetrahedral layers pillared by dicarboxylate ions. These layers are closely related to the brucite type but with one out of every four octahedra removed and replaced by two tetrahedra above and below the layer (Figure 12). Each tetrahedron shares three corners with octahedra and the cobalt coordination is completed by unidentate carboxylate groups of CHDC pillars. A 3D framework is thus formed that contains channels filled with water. The dehydration–rehydration process is reversible,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thereby conferring to this hybrid some porous properties. Removal of the water molecules leads to a shift of the layers combined with a tilt and a rotation of the organic moieties and a shortening of the interlayer space of about 1 Å (Figure 12). Moreover, this material presents a spontaneous ferrimagnetic magnetisation around 60 K, a temperature that is among the highest observed for this kind of compounds.

### Use of More Complex Aromatic Carboxylates

The coordination polymer $[Co(H_2O)_2(C_{10}H_6O_4)]$ (**26**) has been obtained hydrothermally with 4-carboxycinnamic acid.[40] Its structure presents the same topology as that described for its analogue obtained with terephthalic acid (**21**).[33] With 1,4-naphthalenedicarboxylic acid, one 3D hybrid compound, namely $[Co(C_{12}H_6O_4)]$ (**27**), has been obtained by Maji et al. (Figure 13, a).[41] Its structure is similar to that of the fumarates (**15**),[28,29] with chains of metal octahedra connected by an organic moiety into a 3D framework. The main difference between this structure and those previously described is the topology of the chain, which here is zig-zag and is only constructed from edge-sharing cobalt octahedra (Figure 13, c).

With 2,6-naphthalenedicarboxylic acid, only a 1D compound, namely $[M(H_2O)_4(C_{12}H_6O_4)]$ (**28**), has been reported with both cobalt and nickel. It is constructed from chains of isolated metal octahedra bridged by organic ions.[42]

Two compounds have been isolated under hydrothermal conditions using 1,1′-biphenyl-2,2′-dicarboxylic acid.[43] $[M(H_2O)_4(C_{14}H_8O_4)]$ (**29**) presents chains of isolated cobalt or nickel octahedra bridged by dicarboxylate ions. Nevertheless, a peculiar geometry of the organic moiety allows the formation of a chain with an interesting helical geometry (Figure 14, a). $[Co_6(OH)_2(H_2O)_4(C_{14}H_8O_4)_5]$ (**30**) is also 1D but with an infinite M–O–M connectivity. Its metal oxide chain is constituted of pentameric units of edge-sharing octahedra connected to its neighbour by a corner-sharing tetrahedron (Figure 14, b). The pentameric unit has a cross shape made of two linear trimers sharing a central octahedron.

## Tricarboxylates

Rigid, triangular 1,3,5-benzenetricarboxylic acid ($H_3BTC$), commonly named trimesic acid, has been exten-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sively used to construct hybrid porous materials.[44] With cobalt and nickel, Yaghi et al. have reported the 1D polymer $[M_3(H_2O)_{12}(BTC)_2]$ (**31**) under hydrothermal conditions.[45] This compound, constructed from zig-zag chains of isolated octahedra connected through trimesate ions, can reversibly liberate eleven aqua ligands. The metal atoms at the centre of the sinusoid are surrounded by four water molecules in an equatorial plane, and the coordination environment is completed by two unidentate carboxylate ions (Figure 15, a). One side of the sinusoid is occupied by dangling carboxylate ions and the other one is taken up by metal octahedra. Compound **31** can also been obtained by thermal treatment of $[M_3(H_2O)_{14}(BTC)_2{\cdot}4H_2O]$,[46,47] the structure of which can be described as the juxtaposition of molecular motifs composed of three isolated octahedra linearly connected by two unidentate carboxylate ions. $[NaCo_3(OH)(H_2O)_{11}(BTC)_2{\cdot}1.5\,H_2O]$ (**32**) is another example of a 1D compound which has been synthesised at room temperature from trimesic acid.[47] Its structure consists of trinuclear units of *cis* edge-sharing metal octahedra, $\{Co_3O_6(\mu_3\text{-}OH)(\mu_2\text{-}OH_2)_2(H_2O)_5\}$, surrounded by three bridging carboxylate functions and connected by trimesate ions to construct the chains (Figure 15, b).

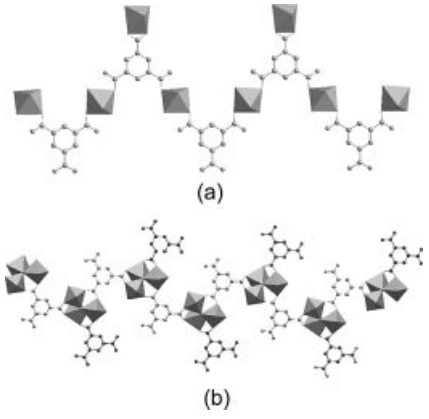

Figure 15. (a) View of a hybrid chain of **31** with isolated octahedra; (b) view of a hybrid chain of **32** showing trimers of edge-sharing octahedra.

$[Ni_3(H_2O)_8(BTC)_2]$ (**33**), a 2D compound obtained by us under hydrothermal conditions, is also constructed from $\{Ni_3O_8(\mu_2\text{-}OH_2)_2(H_2O)_6\}$ trimers.[48] These trimers are linear, with corner-sharing octahedra connected by $\mu_2$-$H_2O$ molecules, the stability of which is reinforced by the closeness of an unprotonated carboxylate and strong hydrogen bonds. Each trimer is surrounded by six carboxylate ions, two of which bridge the central nickel octahedron to its neighbour while the other four are unidentate (Figure 16, a). Six bridging trimesates connect each trimer to six neighbouring ones to construct an infinite 2D pseudo-hexagonal network. The planes are interpenetrated and positioned to favour π–π interactions (Figure 16, b). These planes can also be described as "double layers" of parallel organic rings connected through trimers.

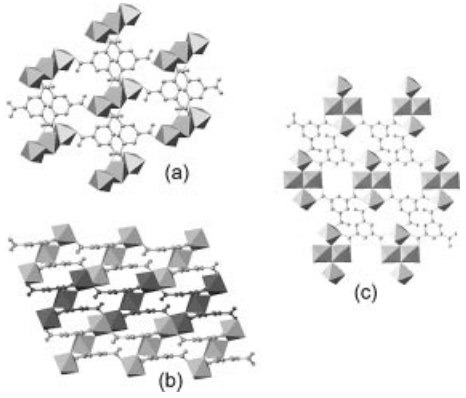

Figure 16. (a) Projection of the structure of **33** showing one nickel cluster connected to six equivalent ones; (b) view of the stacking of the layers of **33** dominated by π–π interactions; (c) view of the structure of **34** showing one nickel cluster connected to six equivalent ones.

$[Ni_2F(H_2O)_4(BTC){\cdot}2H_2O]$ (**34**) has been obtained by incorporating hydrofluoric acid into the starting hydrothermal mixture,[49] which is rather common for the synthesis of weakly soluble main group cations.[2] Its structure is very similar to that of **33** previously described and presents "double layers" of parallel organic rings, although here they are connected through tetrameric $\{Ni_4O_{10}(\mu_3\text{-}F)_2(H_2O)_8\}$ clusters, where the four nickel octahedra are connected by two $\mu_3$-F atoms. Each tetramer is also connected to six neighbours through bridging trimesate ions (Figure 16, c). Four bridging carboxylates are in a planar arrangement in the tetramer, whereas the two additional monodentate ones are localised above and below this plane, which is here nearly parallel to the benzene rings.

$[Co_3(H_2O)_6(BTC)(HBTC)(H_2BTC){\cdot}2H_2O]$ (**35**) is also layered and its construction is dominated by π–π interactions with a mean interlayer distance of 3.4 Å.[50] The cobalt atoms have distorted octahedral environments, with carboxylate oxygen atoms in the four equatorial positions and water molecules in the apical ones. Distortion of the octahedra is due to the chelating connecting mode of one carboxylate. Due to this important distortion, only one carboxylate at a time can bind the metal in a chelating way and the metal environment is completed by monodentate ligands. The organic moiety acts as a triangular connector for the cobalt octahedra and presents the three states of protonation, which indicates that protonation depends not only on the pH of the medium but mostly upon condensation. This connection leads to the formation of a nearly planar infinite net with a pseudo-threefold symmetry that presents triangular cavities made from three cobalt octahedra and three trimesate ions (Figure 17, a), half of which are occupied by water molecules. The solid is formed by the stacking of six types of layers that are chemically identical but shifted (Figure 17, b). The only compound synthesised with trimesic acid that presents a 3D open structure is $[K\{Co_3(BTC)(HBTC)_2\}{\cdot}5H_2O]$, (**36**).[50] Its structure is based on sinusoidal chains of cobalt octahedra whose

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

period is strongly correlated to the geometry of the organic molecule (Figure 17, c). The chains are connected to four other parallel sinusoids through two types of perpendicular carboxylates, leading to a 3D structure with rectangular tunnels. The oxide chains are constructed from dimeric units of edge-sharing octahedra that are connected by a vertex-sharing octahedron. The cobalt atoms of the dimer are surrounded by the organic moiety in a strongly distorted environment due to the chelating mode of one carboxylate. The protonated carboxylate group of HBTC points toward the centre of the channels delineated by four sinusoidal metal oxide chains connected by trimesate ions. Water molecules and potassium (in half occupancy) are located inside these rectangular tunnels (Figure 17, d).

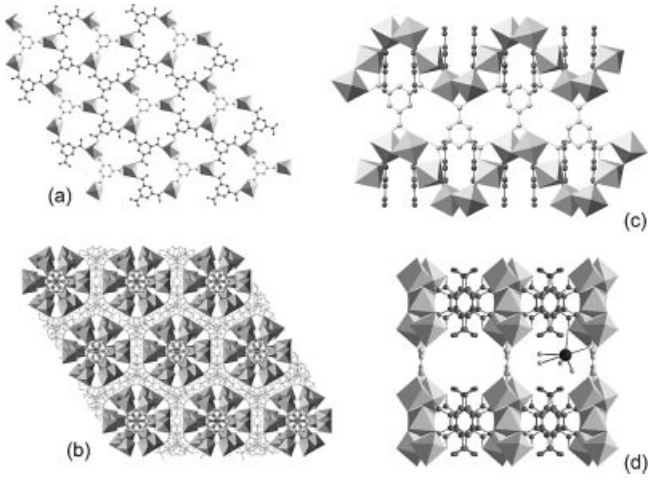

Figure 17. (a) Projection of one layer showing the triangular cavities in **35**; (b) projection of six equivalent layers in **35**; (c) projection of the structure of **36** showing the sinusoidal chains of cobalt octahedra; (d) view of two rectangular channels delineated by four cobalt and trimesate ions with a disordered potassium cation in **36**.

By changing the position of the carboxylate groups and using 1,2,3-benzenetricarboxylic acid (1,2,3-$H_3$BTC), two compounds have been obtained by Gutschke et al.[51] Both compounds, $[Co_2(OH)(H_2O)(1,2,3\text{-BTC})\cdot H_2O]$ (**37**) and $[Co_2(OH)(H_2O)(1,2,3\text{-BTC})]$ (**38**), are constructed from inorganic chains presenting a Δ topology. In **37**, the chains are constructed from corner-sharing polyhedra, with a backbone where cobalt octahedra and tetrahedra alternate and on which pendant trigonal-bipyramids are grafted (Figure 18, a). These metal oxide strips run perpendicularly but never intersect. The connection of a chain to the orthogonal ones by carboxylate forms an amazing 3D network (Figure 18, b). In **38**, *trans* corner-sharing octahedra build the backbone of the chain, on which tetrahedra are attached by sharing edges with octahedra (Figure 18, c). Parallel chains are connected through the organic moiety to construct a 2D framework.

With *cis,cis*-cyclohexane-1,3,5-tricarboxylic acid ($H_3$CTC), one 3D hybrid compound with both cobalt and nickel, namely $[M_3(H_2O)_4(CTC)_2\cdot 5H_2O]$ (**39**), has been synthesised hydrothermally by Kumagai et al.[52] It presents a

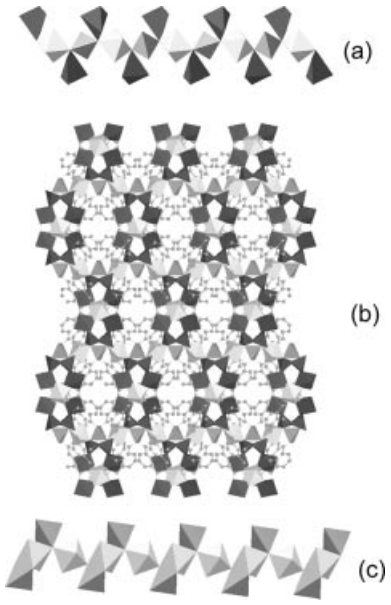

Figure 18. (a) View of the inorganic chain presenting a Δ topology in **37** with a backbone constructed from cobalt octahedra (light grey) and tetrahedra (medium grey), on which pendant trigonal bipyramids (dark grey) are grafted; (b) view of the structure of **37** showing the linking of the polyhedra by the organic moieties; (c) view of the inorganic chain presenting a Δ topology in **38** with a backbone constructed from cobalt octahedra (light grey), on which tetrahedra (medium grey) are grafted.

structure derived from the lozenge-shaped tunnel topology with inorganic chains connected by the organic moiety. The four oxide chains in this compound are all connected through two central tricarboxylates (Figure 13, b) in one lozenge, and are slightly different to those reported previously. Dimers of edge-sharing octahedra are connected through a third octahedron which shares its *trans* vertices with two neighbouring dimers through a $\mu_2$-$OH_2$ (Figure 13, d).

## Tetra- and Hexacarboxylates

The three compounds synthesised hydrothermally with 1,2,4,5-benzenetetracarboxylic (pyromellitic) acid ($H_4$PM) have 3D architectures. $[Co_2(H_2O)_4(PM)\cdot 2H_2O]$ (**40**) and $[Co_2(PM)]$ (**41**) have been reported by Kumagai et al.[53] Compound **40** is a coordination polymer built up from cobalt octahedra bridged by carboxylates to construct layers with a pseudo square geometry similar to that observed in **20**. These layers are connected through organic moieties into a 3D network which presents cavities filled with water molecules. Compound **41** is formed from edge-sharing cobalt octahedra chains connected by pyromellitates.

$[Co_5(OH)_2(H_2O)_4(PM)_2]$ (**42**) has been synthesised by Gutschke et al. simply by increasing the reaction temperature.[54] Its 3D structure is very similar to that of the fumarates (Figure 7) and presents, once again,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lozenge-shaped tunnels with chains of cobalt octahedra connected by the organic moiety. Nevertheless, the topology of the oxide chain is really original, with parallel linear trimers of edge-sharing octahedra bridged by two corner-sharing octahedra (Figure 13, e).

With benzenehexacarboxylic (mellitic) acid ($H_6$MLT), only one 2D compound has been reported, namely $[Ni_4(OH)_2(H_2O)_6(MLT)]$ (**43**).[55] Its structure consists of inorganic chains generated by dimers of edge-sharing octahedra connected through a $\mu_3$-OH group. These chains are further bridged by mellitates to construct corrugated layers.

## Concluding Remarks

Although it is difficult to predict structures on the basis of the ligand and metal chosen, the results presented here allow us to draw some conclusions. This review reveals the extreme diversity of the cobalt and nickel oxide architectures obtained by the use of carboxylate ligands: "from coordination polymers to 3D inorganic skeletons". One of the reasons for the richness of these systems relates first to the electronic structure of $Co^{2+}$ ($d^7$) and $Ni^{2+}$ ($d^8$). Moreover, at variance with what is observed in templated metallophosphates[56] and metal organic frameworks based on $Cu^{2+}$ and $Zn^{2+}$,[57] in which the number of secondary building units (SBUs) is rather limited, the systems based on $Co^{2+}$ and $Ni^{2+}$ are, in terms of SBUs, extremely rich and diverse, and almost all structures present their own polyhedral building blocks. In the inorganic framework, one indeed observes monomeric moieties, in tetrahedral (Co) and octahedral (Ni, Co) coordination, along with dimers, trimers, tetramers, pentamers and hexamers with polyhedra sharing either vertices, edges or faces, as well as their connections into chains, layers and 3D networks (Figure 19). This diversity implies much more numerous possibilities of connection with the organic moieties, which are also numerous as shown in this review. Therefore, the exploration of the richness of these systems is still in its infancy, although careful attention must be paid to the experimental conditions as, besides the already shown effect of temperature and its influence on the condensation of the oligomers, the pH of the reaction mixture is also very important for the reactivity of these cations.

In terms of topologies, some of them are represented by one member, such as the remarkable honeycomb oxide framework with 1D pores of $[Ni_7(OH)_2(C_4H_4O_4)_6(H_2O)_2 \cdot 2H_2O]$, whereas others appear regularly, with rigid or flexible organic molecules and with di- or tetracarboxylates. This is the case for the lozenge-shaped tunnel topology with inorganic chains connected by organic bridges. This architectural type is observed with both cobalt and nickel and has been obtained with dicarboxylates ions as diverse as small fumarate and cumbersome naphthalene-1,4-dicarboxylate and 1,2,4,5-benzenetetracarboxylate. These few examples demonstrate how much the oxide backbone can adopt diverse M–O–M connectivities to adapt to the organic moiety. More recently, this family has been enlarged with a new member obtained with 1,4-cyclohexanedicarboxylate, which presents the same chains as those observed with fumarate or succinate.[58,59] It is obvious that metal oxide condensation in solution is favoured by an increase of temperature. Nevertheless, it is interesting to note the counter-example of 1,4-cyclohexanedicarboxylate, which demonstrates the high complexity of these systems.[58] Indeed, simply by increasing the temperature from 140 to 170 °C, the lozenge-shaped tunnel topology is replaced by a layered compound constructed from remarkable hexanuclear prismatic nickel clusters (Figure 19l) connected through the organic moiety.

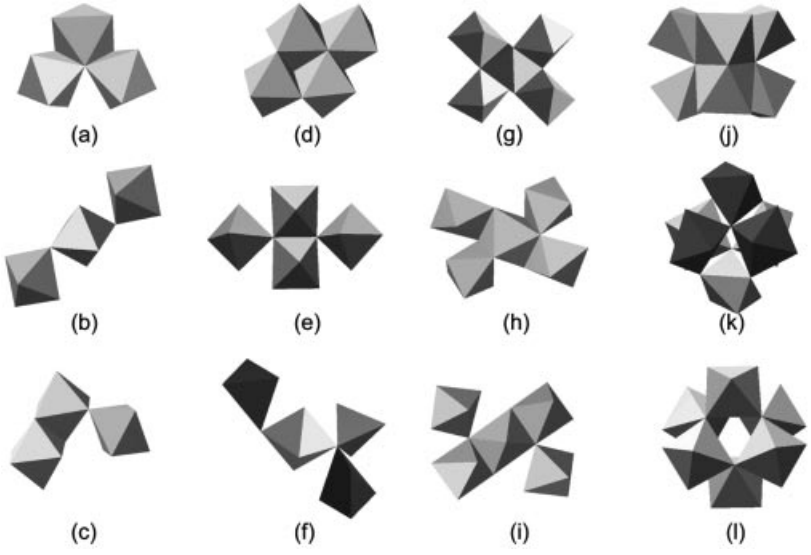

Figure 19. View of a few of the oligomers encountered in nickel and cobalt carboxylates: isolated trimers in **32** (a) or **33** (b) and the trimer of the inorganic chain of **39** (c); tetramers of the 2D oxide framework of MIL-16 (**4**, d), of the coordination polymer **34** (e), of the chain of **37** (f); pentamers of the inorganic layer of MIL-9 (**3**, g), of the oxide chains of **30** (h) and **42** (i); hexamers of the inorganic chains of MIL-73 (**8**, j) and those encountered in the coordination polymers MIL-104 (**22**, k) and $[Ni_6(OH)_6(C_8H_{10}O_4)_3(H_2O)_6 \cdot 2H_2O]$ (l) reported recently.[58]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

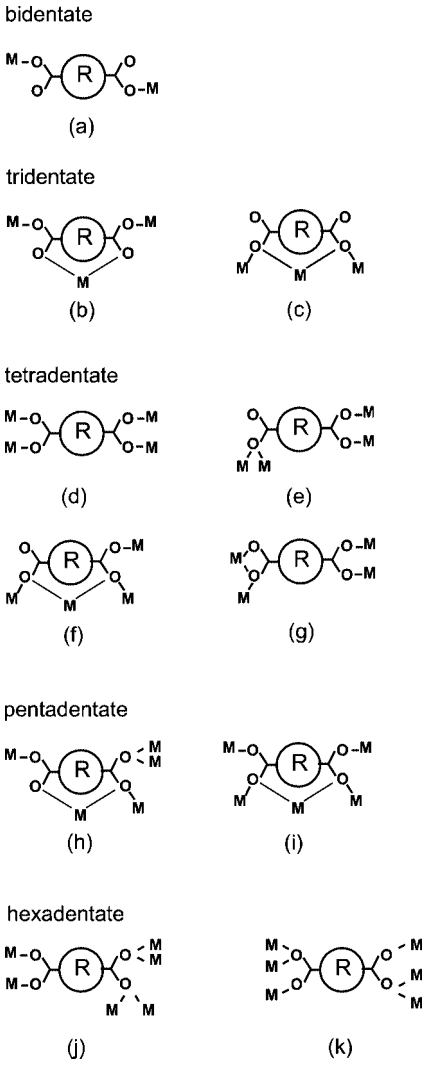
The topology of the extended inorganic network depends strongly on the geometry and connectivity of the organic partner. Inorganic condensation is favoured with small flexible organic molecules such as succinate but disfavoured with large and/or rigid ones. Glutarate is at the interface, since it allows the formation of an amazing 3D inorganic skeleton[22] as well as the construction of a metal organic framework with isolated tetrahedra.[21] With longer linear carboxylates, the final organisation is driven by weak interactions (hydrophobic) between alkyl chains.

In water, the use of rigid organic partners with benzene rings disfavours the formation of an extended oxide network and, most of the time, 3D coordination polymers or layered compounds dominated by π–π interactions are obtained. The example of the trimesate system illustrates the competition between covalent linkages and π–π interactions, which seems to be the decisive factor in the final architecture, well. It is difficult to draw rules from just two examples, but "multiconnecting" organics also seem to disadvantage oxide condensation. Indeed, the two 3D oxide frameworks have been synthesised with linear dicarboxylate ions. In both cases, the organic partner lines the oxide skeleton and is flexible enough to act as a chelate ligand for one metal via the oxygen atoms of neighbouring carboxylate groups. All modes of coordination of the organic moieties observed in the compounds described here are represented below. Only three coordination modes are present in the two 3D inorganic skeletons (modes c, i and f in Scheme 1). Mode a is mostly observed for 1D compounds with metal–organic chains, whereas mode d is present in several metal–organic frameworks (MOF). Others, such as modes b, e, g, h and j have been observed only once to date and seem to be rather scarce.

For tricarboxylates (see Scheme 2), the number of connecting modes is higher than the number of compounds and only one mode (j) has been observed in two compounds.

The connecting modes of tetra- and hexacarboxylates (Scheme 3) are also diverse and their number corresponds to that of described compounds. The ratio (number of metal atoms)/(number of organic moieties) (M/org) is given in Table 1 and varies from 1/2 for 1D compounds with metal–organic chains to 5 for **25**, which is constructed from hydroxide layers linked by organic pillars.[39] In the two 3D oxide frameworks, M/org is equal, or very close (7/6), to one.

Under hydrothermal conditions, the reactivity of cobalt and nickel is very different and similar synthetic conditions most of the time lead to totally different structural types. Isostructural compounds can sometimes be isolated but often under very distinct experimental procedures, as illustrated by the example of MIL-73, which is obtained hydrothermally with nickel and under reflux with cobalt. Under "basic" hydrothermal conditions it seems to be easier to isolate 3D inorganic skeletons with nickel than with cobalt. On the other hand, 2D oxide frameworks are very common with cobalt, whereas none have been isolated with nickel and polycarboxylates yet. Whereas only structures containing octahedra are reported for nickel carboxylates, the cobalt environment is more diverse, with the presence of tetrahedra and pentacoordinate metal. This is easily understandable in light of the coordinational flexibility of cobalt, which is higher than that of nickel due to its field anisotropy. On the other hand, the growth of nickel crystallites is most of the time limited compared to cobalt, therefore nickel compounds generally need structural determinations from powder diffraction data.



Scheme 1. Modes of coordination of the dicarboxylate ions observed in compounds **1**–**30**.

It is also interesting to comment here on the success of Neeraj et al. in the synthesis of sodalite networks based on cobalt and squarate,[60a] an organic moiety which is not so far from carboxylates. The six four-membered $Al_2Si_2$ rings of the sodalite cage are replaced here by the four-membered squarate (C4) rings, and are now linked by 12 cobalt octahedra instead of oxygen atoms. This organisation has already been encountered for a few other metal ions,[60b–60d] particularly nickel,[60b] and is therefore certainly a thermodynamically stable topology.

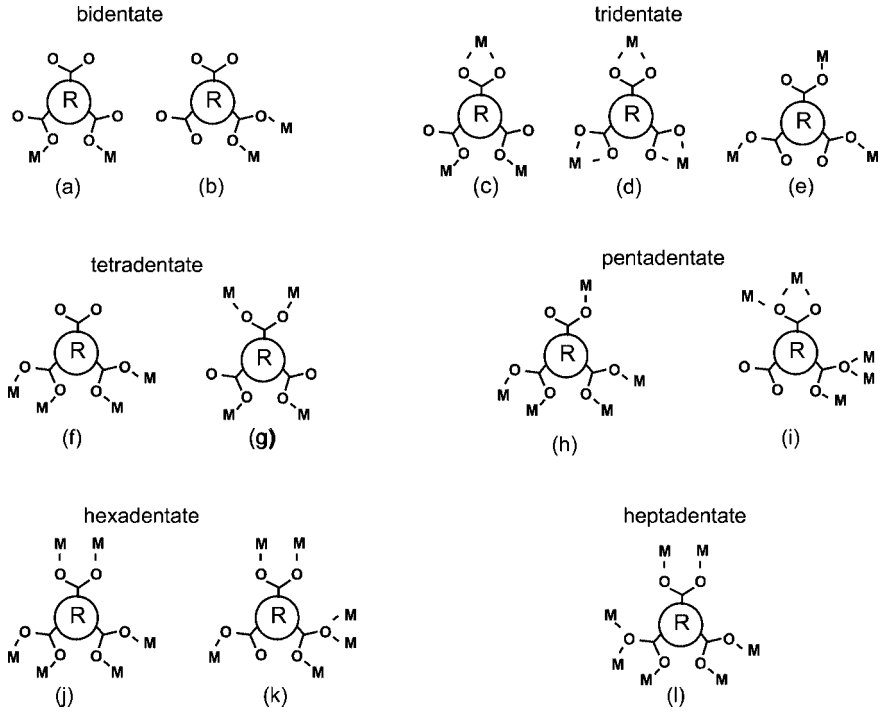
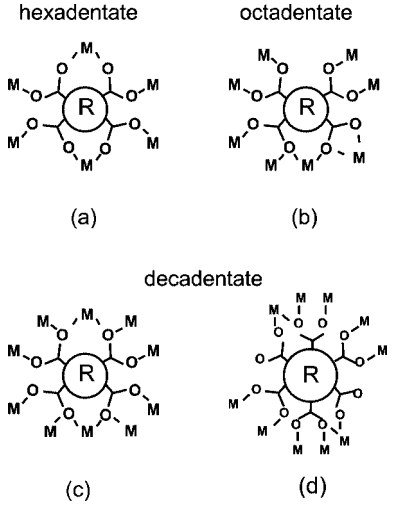


Scheme 2. Modes of coordination of the tricarboxylate ions observed in compounds **31**–**39**.



Scheme 3. Modes of coordination of the tetra- and hexacarboxylate ions observed in compounds **40**–**43**.

Magnetic measurements have been undertaken for most of the listed compounds and show diverse and usually extremely complicated behaviours, with competition between antiferromagnetic (AF) and ferromagnetic (F) interactions. This can be explained by the diversity of the inorganic networks and, of course, by their complexity. It is usual to have several independent metal centres, in a single architecture, showing various bond lengths and angles and sometimes, with cobalt, different geometries.

It is well known that connections with large M–O–M angles favour antiferromagnetic superexchange whereas connections with angles close to 90° favour ferromagnetic interactions,[61] although the M–O–C–O–M pathway should also be taken into account as well as the weak coupling between metal assemblies via organic bridges. The complexity of the M–O–M connectivity, as illustrated by MIL-73, in which octahedra are linked by faces, edges and corners, means that compounds often present interactions with different signs and strengths and are often frustrated. The only porous 3D oxide network described as a pure ferromagnet, MIL-77, is cubic with two independent octahedrally nickel atoms connected by sharing edges.

The two compounds with a lozenge-shaped topology and the same inorganic backbone, namely **15** and $[Ni_3(OH)_2(trans\text{-}C_8H_{10}O_4)_2(H_2O)_4{\cdot}4H_2O]$, both present a ferrimagnetic behaviour, with a lower critical temperature for the second compound, which may be due to the difference of the organic moieties.[59] $[Ni_3(OH)_2(cis\text{-}C_8H_{10}O_4)_2(H_2O)_4{\cdot}2H_2O]$ has also been synthesised recently by Kurmoo et al. and can be described as being formed from the same oxide chains but connected by a *cis*-1,4-cyclohexanedicarboxylate instead of a *trans* one.[59] It also exhibits a ferrimagnetic ordering that reversibly transforms into a ferromagnetic one upon partial dehydration, thus showing once again the complexity of the interaction pathways.

It is also not unusual that isostructural compounds obtained with cobalt and nickel display different dominant magnetic interactions[20,52] — antiferromagnetic for cobalt compounds and ferromagnetic for their nickel analogues.

Finally, the numerous nickel and cobalt carboxylates presented above illustrate the variety of structural architectures. Taking into account their great diversity, carboxylates

# New Type of Photoluminescent Iridium Complex: Novel Synthetic Route for Cationic *trans*-Bis(2-phenylpyridinato)iridium(III) Complex

**Chong Shik Chin,*[a] Min-Sik Eum,[a] Song yi Kim,[a] Choongil Kim,[a] and Sung Kwon Kang[b]**

**Keywords:** Isomerization / Iridium / Photoluminescence / Synthetic methods / Bis(ppy) complex

A new type of iridium(III) complex [*trans*-Ir(ppy)$_2$(PPh$_3$)$_2$]$^+$ (**1**) has been prepared by a novel synthetic method and its structural and photoluminescent characteristics have been compared with those of the *cis* analogue, [*cis*-Ir(ppy)$_2$(PPh$_3$)-(P(OPh)$_3$)]$^+$ (**2**) which has also been newly prepared in this study.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Studies on iridium(III) complexes of 2-phenylpyridinato (ppy) and related ligands have been extensively carried out as their characteristic luminescent properties seem to be utilizable in the display industry.[1] There are three different types of compounds reported thus far: tris-ppy complexes, *fac*- and *mer*-Ir(ppy)$_3$;[1c,2] bis-ppy complexes, *cis*-Ir(ppy)$_2$(L)(L′);[3] and mono-ppy complexes, *trans,cis*-Ir(ppy)(PR$_3$)$_2$(L)(L′) [*trans*-(PR$_3$)$_2$, *cis*-(L)(L′)].[1a] Emission characteristics such as $\lambda_{max}$, $\Phi_{PL}$, and $\tau$ are somewhat successfully controlled by modifying the ppy ligand and by introducing diverse ancillary ligands (L and L′).[1–4]

There has been no report of *trans*-Ir(ppy)$_2$(L)(L′) containing two ppy ligands *trans* to each other probably because of the lack of the established synthetic procedures, although these *trans* bis-ppy complexes are expected to show emission properties that are comparable with those of *cis*-Ir(ppy)$_2$(L)(L′); the properties may also be tunable by modifying the ppy ligand and by varying ancillary ligands. The *trans*-M(ppy)$_2$ moiety is only observed in four-coordinate Pt(ppy)$_2$[5,6] and Pd(ppy)$_2$,[6] which also emit strongly in the visible region.

We now report the synthesis of new complexes [*trans*-Ir(ppy)$_2$(PPh$_3$)$_2$]$^+$ (**1**) with the two nitrogen atoms *cis* to each other and [*cis*-Ir(ppy)$_2$(PPh$_3$){P(OPh)$_3$}]$^+$ (**2**) and their emission characteristics.

**2**

## Results and Discussion

### Synthesis

Complex **1**, [*trans*-Ir(ppy)$_2$(PPh$_3$)$_2$]$^+$(OTf), is synthesized in high yield following the procedure depicted in Equation (1) where the ppy ligands are added to the metal one by one. Complex **3** was chosen as the starting material because of its unique reactivity that results from the four equatorial ligands (H)$_2$(MeCN)$_2$. These equatorial ligands can be readily replaced by two anionic hydrocarbyls and two other neutral ligands.[7] The mono-ppy complex [Ir(ppy)-(H)(NCMe)(PPh$_3$)$_2$]$^+$ (**4**) has to be isolated in good purity for the next step (**4**→**5**) to obtain **1** in high purity and yield. An analogous mono-ppy complex [Ir(ppy)(H)(OC-Me$_2$)(PPh$_3$)$_2$]$^+$ was previously prepared.[8] The two ligands (H)(MeCN) of **3** are readily replaced with one ppy ligand to give complex **4** by facile dissociation of the MeCN ligand along with H$_2$ evolution. Complex **4**, however, does not react further with ppyH in refluxing toluene. The reaction mixture of **4** and ppyH in C$_3$H$_7$OC$_2$H$_4$OH (b.p. 150 °C) heated at reflux affords **1** with unknown materials, whereas the reaction in refluxing C$_2$H$_5$OC$_2$H$_4$OH (b.p. 133 °C) gives a stable complex [*trans*-Ir(ppy)(ppyH)(H)(PPh$_3$)$_2$]$^+$ (**6**) [Equation (2)] which does not undergo further reaction. Replacement of the labile MeCN ligand by ppyH was also

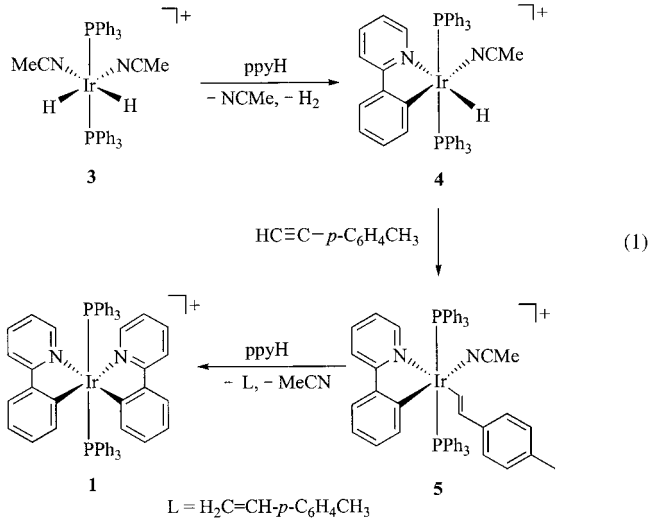
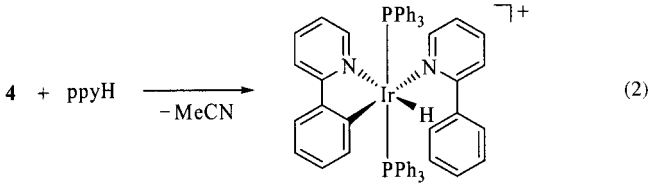
observed in the reaction of $[Ir^{I}(NCMe)(CO)(PPh_3)_2]^+$ at 25 °C to give $[Ir^{I}(CO)(ppyH)(PPh_3)_2]^+$ which undergoes oxidative addition of ppyH to produce $[Ir(ppy)(H)(CO)(PPh_3)_2]^+$ at the elevated temperature.[9] Insertion of a bulky alkyne into the Ir–H bond of **4** makes abstraction of the bulky alkenyl ligand, –CH=CH–*p*-$C_6H_4CH_3$, of **5** facile to give **1**. Alkyne insertion into the Ir–H bond of **6** has not been observed yet. Formation of stable hydrocarbon $CH_2$=CH–*p*-$C_6H_4CH_3$ may facilitate the production of **1** from **5**. Attempts to replace one $PPh_3$ of **1** with $P(OPh)_3$ to prepare [*trans*-$Ir(ppy)_2(PPh_3)\{P(OPh)_3\}]^+$ have been unsuccessful thus far.



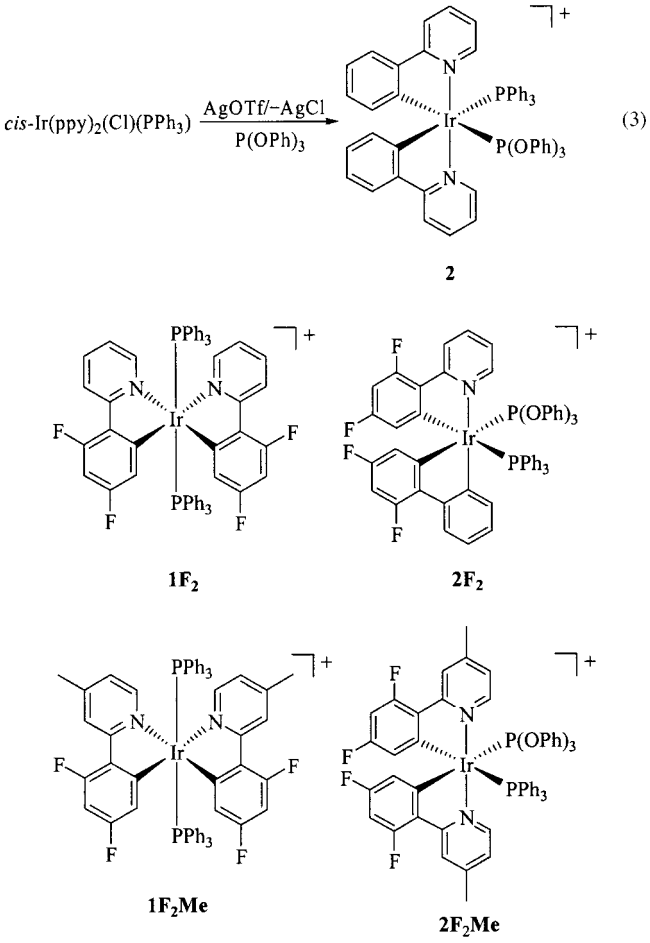
**3** **4** (1) **1** **5**



(2) **6**

Complex **2**, [*cis*-$Ir(ppy)_2(PPh_3)\{P(OPh)_3\}]^+$(OTf), has been synthesized [Equation (3)] in order to compare its properties with those of **1**. Attempts to prepare [*cis*-$Ir(ppy)_2(PPh_3)_2]^+$ have been unsuccessful, probably because $PPh_3$ is too large for the *cis*-$Ir(ppy)_2$ moiety to have two $PPh_3$ in the *cis* position[10] (see below for the crystal structure of **2**). Although monophosphorus ligand complexes such as *cis*-$Ir(ppy)_2(PR_3)(X)$ (X = Cl, CN; R = Ph, *n*Bu, OPh)[3c] have been previously prepared, no report of a bis(phosphorus base ligand) complex such as [*cis*-$Ir(ppy)_2(PR_3)\{P(OPh)_3\}]^+$ (**2**) has been made.

Complexes **1**$F_2$, **1**$F_2$Me, **2**$F_2$, and **2**$F_2$Me have also been prepared by the same procedures shown in Equations (1) and (3) to investigate the effects that modification of the ppy ligand would have on the emission characteristics of complexes **1** and **2**.



(3)

Newly prepared complexes **1**, **1**$F_2$, **1**$F_2$Me, **2**, **2**$F_2$, **2**$F_2$Me, **4**, **5**, and **6** have been unambiguously characterized by detailed spectral ($^1$H-, $^{13}$C-, $^{31}$P NMR, IR, TOF mass) and elemental analysis data and also crystal X-ray diffraction data analysis for **1** and **2**. Assignment of the spectral signals is mostly straightforward (see Supporting Information for spectra and detailed assignments).

## Crystal Structures

Figures 1 and 2 show the two nitrogen atoms that are *cis* to each other in *trans*-isomer **1** but *trans* to each other in *cis*-isomer **2**. Figure 2 shows the two ppy groups being pushed away from the two phosphorus ligands, which results in a notable difference between the two Ir–N distances (2.089 and 2.042 Å) and the N–Ir–N bond angle (164°), which is far smaller than 180°. It seems less likely for *cis*-bis(ppy) complex **2** to maintain two bulky $PPh_3$ groups in the *cis* position without severe steric hindrance. Density function theory calculations suggest that the HOMO of $Ir(ppy)_3$,[1c,11] $Ir(ppy)_2L_2$,[1f,11] and $Pt(ppy)L_2$[12] involve dπ-orbitals of the metal and whose energy level is closely related to the bond lengths between the metal and the ligands. Both Ir–N and Ir–C distances for **1** are very close to those of *fac*-$Ir(ppy)_3$ and *fac*-$Ir(tpy)_3$ (see Table 1) where all N

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms are *trans* to the C atoms. The Ir–N distances are longer in *trans* complex **1** than those in *cis* complexes **2** and *cis*-Ir(tpy)$_2$(P–P) (Table 1). The Ir–P [phosphite, P(OPh)$_3$] distances are shorter than those in Ir–P [phosphane, PPh$_3$, (PPh$_2$CH$_2$)$_2$BPh$_2$] (see Table 1).

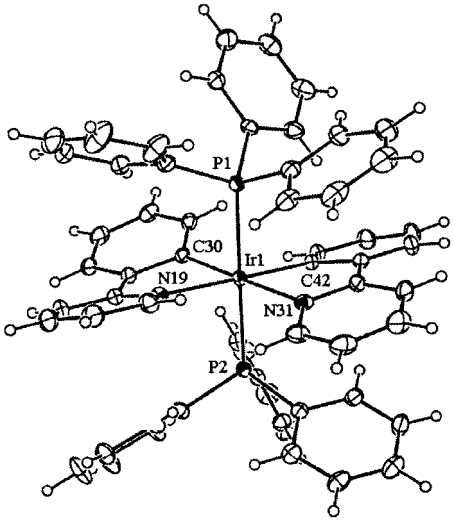


Figure 1. ORTEP drawing of [*trans*-Ir(ppy)$_2$(PPh$_3$)$_2$]$^+$ (**1**) with thermal ellipsoids drawn at the 50% probability level. Selected bond lengths [Å]: Ir1–C42 = 2.050(5); Ir1–C30 = 2.052(5); Ir1–N31 = 2.160(4); Ir1–N19 = 2.168(4); Ir1–P2 = 2.3802(12); Ir1–P1 = 2.3891(12). Selected bond angles [°]: C30–Ir–N31 = 178.99(16); C42–Ir–N19 = 178.81(17); P1–Ir–P2 = 179.19(4).

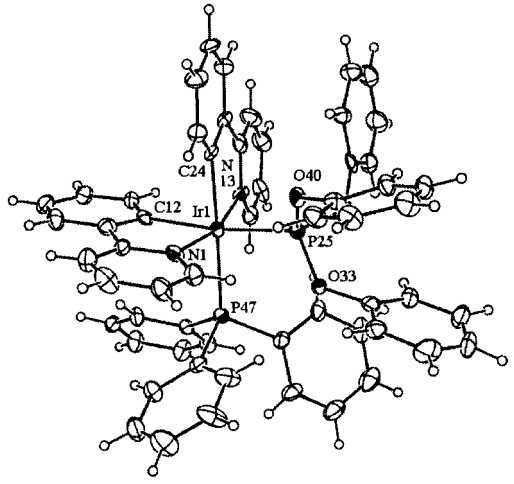

Figure 2. ORTEP drawing of [*cis*-Ir(ppy)$_2$(PPh$_3$){P(OPh)$_3$}]$^+$ (**2**) with thermal ellipsoids drawn at the 50% probability level. Selected bond lengths [Å]: Ir–N1 = 2.089(11); Ir–N13 = 2.042(11); Ir–C12 = 2.072(13); Ir–C24 = 2.071(12); Ir–P25 = 2.307(3); Ir–P47 = 2.433(3). Selected bond angle [°]: N1–Ir–N13 = 164.3(4); C12–Ir–P25 = 169.3(4); C24–Ir–P47 = 177.0(4).

### Emission Spectral Data

Both *trans*- and *cis*- complexes (**1** and **2**, respectively) display relatively strong emission in the green–blue color region (see $\lambda_{max}$ in Table 2). *trans*-Bis(PPh$_3$) complex **1** shows the $\lambda_{max}$ emission at a somewhat longer wavelength than that of *cis*-(PPh$_3$)[P(OPh)$_3$] complex **2**. This small difference in $\lambda_{max}$ may be due to the P(OPh)$_3$ in **2** since *cis*-Ir(ppy)$_2$-X(PPh$_3$) complexes show their emission at longer wavelengths than do *cis*-Ir(ppy)$_2$X[P(OPh)$_3$] complexes.[3c]

Table 2. Photoluminescence spectroscopic data in degassed MeCN at 25 °C for [*trans*-Ir(ppy)$_2$(PPh$_3$)$_2$]$^+$ (**1**), [*trans*-Ir(F$_2$ppy)$_2$-(PPh$_3$)$_2$]$^+$ (**1**F$_2$), [*trans*-Ir(F$_2$Meppy)$_2$(PPh$_3$)$_2$]$^+$ (**1**F$_2$Me), [*cis*-Ir-(ppy)$_2$(PPh$_3$){P(OPh$_3$}]$^+$ (**2**), [*cis*-Ir(F$_2$ppy)$_2$(PPh$_3$)$_2$]$^+$ (**2**F$_2$) and [*cis*-Ir(F$_2$Meppy)$_2$ (PPh$_3$)$_2$]$^+$ (**2**F$_2$Me). [Ir] = 1·10$^{-5}$ M.

| Complex | $\lambda_{max}$ [nm] | $\Phi_{PL}$ | $\tau$ [μs] |
|---|---|---|---|
| **1** | 470, 497 | 0.24 | 4.4 |
| **1**F$_2$ | 452, 479 | 0.36 | 4.8 |
| **1**F$_2$Me | 450, 475 | 0.37 | 3.5 |
| **2** | 458, 488 | 0.18 | 0.31 |
| **2**F$_2$ | 444, 473 | 0.91 | 2.8 |
| **2**F$_2$Me | 442, 470 | 0.72 | 2.9 |

It is well-established that $\lambda_{max}$ emission bands for *cis*-Ir(ppy)$_2$(L)(L′) are shifted to shorter wavelengths when the ppy ligand is F-substituted on the phenyl ring and Me-substituted on the pyridyl ring.[1c,g,3b,4] It is noticed that the blueshifts, which result from the exchange of a ppy ligand to either a F$_2$ppy or F$_2$Meppy ligand, are greater for the *trans* complexes (**1**, **1**F$_2$, **1**F$_2$Me) than they are for the *cis* complexes (**2**, **2**F$_2$, **2**F$_2$Me) (see Table 2). It is also noticed that quantum yields are significantly larger for F$_2$ppy (**1**F$_2$) and F$_2$Meppy (**1**F$_2$Me) complexes than for ppy (**1**) complexes. A striking increase in $\Phi_{PL}$ is observed when the ppy ligand of **2** is replaced with either a F$_2$ppy or F$_2$Meppy ligand (Table 2).

In conclusion, a new type of iridium(III) complex [*trans*-Ir(ppy)$_2$(PPh$_3$)$_2$]$^+$ (**1**) has been prepared by a novel synthetic method and its structural and photoluminescent characteristics have been compared with those of the *cis* analogue, [*cis*-Ir(ppy)$_2$(PPh$_3$){P(OPh)$_3$}]$^+$ (**2**), which has also been newly prepared in this study. No significant differences have been found for their photoluminescent properties because of the geometric differences between *trans*-**1** and *cis*-**2**. Sky

Table 1. Structural and Photoemission data for [*trans*-Ir(ppy)$_2$(PPh$_3$)$_2$]$^+$ (**1**), [*cis*-Ir(ppy)$_2$(PPh$_3$){P(OPh)$_3$}]$^+$ (**2**) and related complexes.

| Complex | Ir–C [Å] | Ir–N [Å] | Ir–P [Å] | $\lambda_{max}$ [nm] |
|---|---|---|---|---|
| [*trans*-(ppy)$_2$Ir(PPh$_3$)$_2$]$^+$ (**1**) | 2.050, 2.052 | 2,160, 2.168 | 2.380, 2.389 | 470, 497 |
| [*cis*-(ppy)$_2$Ir(PPh$_3$){P(OPh)$_3$}]$^+$ (**2**) | 2.072, 2.071 | 2.089, 2.042 | 2.307, 2.433 | 458, 488 |
| *fac*-Ir(ppy)$_3$[1d] | 2.035 | 2.167 | | 545 |
| *fac*-Ir(tpy)$_3$[a],[1c] | 2.024 | 2.132 | | 510 |
| *mer*-Ir(tpy)$_3$[a],[1c] | 2.076, 2.086, 2.020[c] | 2.151,[d] 2.044, 2.065 | | 512 |
| *cis*-(tpy)$_2$Ir(P–P)[a,b],[1f] | 2.047, 2.057 | 2.082, 2.083 | 2.420, 2.431 | 468 |

[a] tpy = 2-(*p*-tolyl)pyridinato. [b] P–P = (PPh$_2$CH$_2$)$_2$BPh$_2$. [c] *trans* to N. [d] *trans* to C.

blue color emission can be obtained by replacing the ppy ligands of **1** or **2**, which produce greenish–blue light, with either $F_2$ppy or $F_2$Meppy ligands. New synthetic methods are currently under investigation to replace the $PPh_3$ axial ligand of **1** with a variety of ligands to prepare [*trans*-$Ir(ppy)_2(L)(L')]^{+,0}$ (L, L′ = neutral or anionic C, N, P, O-base) which would show diverse luminescent characteristics. Finally, we wish this study to open a new research field that deals with light emitting iridium complexes containing two ppy ligands and related cyclometalated ligands *trans* to each other.

# Mesoporous Nanocrystalline Mixed Metal Oxides from Heterometallic Alkoxide Precursors: Cobalt–Nickel Oxide Spinels for Propane Oxidation

**Moises A. Carreon,*[a] Vadim V. Guliants,*[b] Li Yuan,[b] Andrew R. Hughett,[b] Alan Dozier,[c] Gulaim A. Seisenbaeva,[d] and Vadim G. Kessler[d]**

**Keywords:** Mesoporous Co–Ni oxides / Oligomeric surfactants / Nanocrystalline spinels / Thermal stability / Hydrocarbon combustion

Uniform nanocrystalline mesoporous mixed cobalt–nickel spinel phases displaying unimodal pores in the 7–12 nm range and relatively high specific surface areas up to 83 $m^2$/g were prepared by a novel low temperature synthesis approach in which the desired metal oxide stoichiometries were introduced on a molecular level by reacting heterometallic alkoxide precursors in the presence of supramolecular liquid crystalline phases. The resultant phases, composed mainly of ca. 8–11 nm uniform cobalt–nickel spinel nanoparticles, were highly promising as low-temperature hydrocarbon combustion catalysts investigated in a model reaction of propane oxidation.

## Introduction

Since the discovery of periodic mesoporous silicas[1] there has been a great interest in developing new materials with diverse compositions, properties and functionalities.[2] In particular, cobalt and nickel oxides are important materials for current technologies. These materials find applications as heterogeneous catalysts, sensors, electrochromic, electrical and optoelectronic devices.[3] Cobalt-based catalysts are of great interest in the field of heterogeneous catalysis. In the oxidized state they are active catalysts for the total combustion of organic molecules.[4] In combination with Mo or W dispersed on an alumina support, they are precursors of sulfided catalysts for hydrosulfurization;[5] and after prereduction, they are highly efficient Fischer–Tropsch synthesis catalysts.[6] The Co–Fe–O system has been used as a catalyst for low-temperature oxidation of phenol into nontoxic compounds,[7] while NiO was investigated as a catalyst for the oxidation of CO.[8] It is well documented that spinels containing transition-metal ions function as efficient catalysts in a number of heterogeneous processes, such as CO oxidation,[9] catalytic combustion of hydrocarbons[10] and selective oxidation and reduction of organic molecules.[11] In particular, Co- and Ni-based mixed oxides including spinels are frequently used as highly efficient hydrocarbon combustion and partial oxidation catalysts.[12]

In the past, cobalt–nickel oxide spinels have been prepared by diverse synthetic routes, such as co-precipitation,[13a,13b] sol-gel[13c,13d] carbonate decomposition,[13c] cryochemical,[13b] spray-pyrolysis.[13b,13e] However, these synthesis approaches have shown poor control over composition and crystal-size homogeneity. Chi et al.[13a] prepared hexagonal $NiCo_2O_4$ spinels (ca. 200 nm) by a co-precipitation method. Although the particle sizes became uniform at calcination temperatures above 400 °C, NiO was present as secondary phase. Lapham and Tseung[13b] reported the synthesis of $NiCo_2O_4$ spinels by several synthesis methods, including co-precipitation, salts decomposition, cryochemical and spray-pyrolysis. Although spinel crystal sizes in the order of 5–16 nm were obtained, these phases were composed of non-homogeneous particles with poorly crystalline structures. Furthermore, the presence of undesirable phases such as NiO, $Co_3O_4$ and $NiCoO_2$ confirmed metal oxide segregation. Attempts to synthesize $NiCo_2O_4$ spinels employing sol-gel chemistry have led to poorly crystalline phases with the presence of undesirable NiO, $Co_3O_4$.[13c,13d]

Herein, we present the novel soft chemical synthesis of mesoporous nanocrystalline cobalt–nickel spinel by the self-assembly of heterometallic alkoxides in the presence of supramolecular liquid crystalline phases. The use of heterometallic alkoxide precursors allows one to incorporate the desired metal oxide stoichiometries. This novel soft-chemistry approach affords desired bulk compositions in nanocrystalline mixed metal oxides under mild conditions, which prevents metal oxide segregation and eliminates the need for high synthesis temperatures commonly required for so-

lid-state reactions. The resultant mesophases were investigated in the model reaction of propane oxidation.

## Results and Discussion

Several promising synthesis strategies to overcome the limited thermal stability of mesostructured mixed transition-metal oxides have been recently reviewed.[14] One of these strategies was adopted in this work, i.e. the elimination of strong electrostatic interactions at the inorganic–organic interface by directing the synthesis by weak hydrogen-bonding interactions, and consequently improving the thermal stability of the final mesostructure.[14a] This was accomplished by using the non-ionic oligomeric surfactant Brij-35 as a structure-directing agent. As inorganic source, an heterometallic single-source precursor $(Ni_{0.33}Co_{0.67})$-(OMe)(acac)(MeOH) was used for the synthesis of mesoporous nanocrystalline cobalt–nickel oxide spinels. 1-Butanol was chosen as a solvent due to its relatively hydrophobic nature, which promotes an enhanced phase separation between the template and the inorganic phase leading to a better defined mesostructure with robust inorganic walls.[15]

The mesoscopic order of the as-synthesized mixed oxide mesophase was confirmed by SAXS. The SAXS pattern of the as-synthesized mesoporous Co–Ni oxide phases (Figure 1) showed a single broad peak at a *d* spacing of ca. 13.5 nm suggesting the formation of a wormhole mesostructure. Upon calcination at 350, 400 and 450 °C, the low $2\Theta$ angle peak disappeared and the amorphous walls of the as-synthesized mesophase began to crystallize. In spite of the low $2\Theta$ angle peak disappearance for the calcined samples, highly porous mesostructures were observed as confirmed by porosimetry studies. The nitrogen adsorption–desorption isotherms and BJH pore-size distributions on the basis of the adsorption branches of the $N_2$ isotherms for mesoporous Co–Ni oxide phases calcined at different temperatures are shown in Figure 2. The sample calcined at 350 °C showed a type IV isotherm representative of mesoporous solids with an H2 hysteresis loop, suggesting the presence of ink-bottle-shaped or cage-type pores.[16] It had a specific surface area of ca. 83 $m^2/g$ with average unimodal pore diameter of 7 nm. The sample calcined at 400 °C also showed a type IV isotherm with an H2 hysteresis loop. It possessed a specific surface area of ca. 35 $m^2/g$ with average unimodal pore diameter of 11.5 nm. Higher calcination temperature led to the collapse of the mesoporous structure as shown in part c of Figure 2. This sample calcined at 450 °C shows only a specific surface area of ca. 12 $m^2/g$ with disordered random pore-size distribution, indicating the formation of a nonmesoporous structure. The moderate alkaline conditions employed in our synthesis near the isoelectric point of both hydroxo systems, i.e. pH ca. 8 for $Co^{3+}$ and pH ca. 8–10 for $Ni^{2+}$,[17] enhanced the condensation of the Co and Ni ions at the micellar interface. Furthermore, the synthesis conditions near the isoelectric point were favorable for the mesostructural organization of the Co–Ni–O species enabling the formation of heterometallic sol particles. The enhancement in cross-linking of the inorganic framework may be in part responsible for the thermal stability of these mesophases. Furthermore, the TEM image of the thermally stable mesoporous Co–Ni oxide phase shown in Figure 3 confirmed the presence of highly porous nanostructured aggregates. An average pore diameter of ca. 7–8 nm can be observed in agreement with the nitrogen porosimetry data.

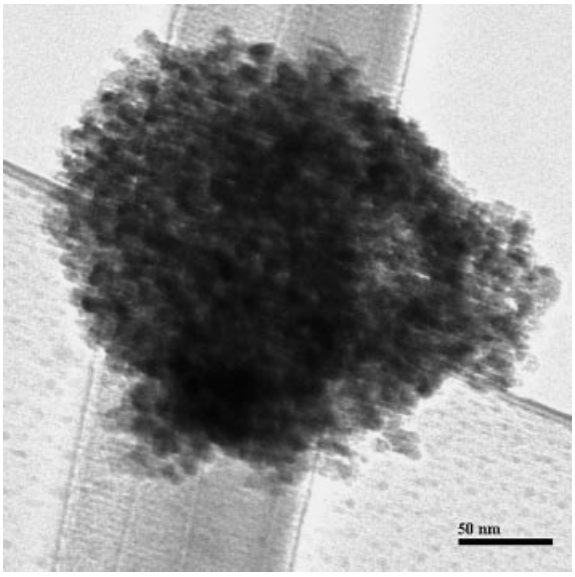

Figure 3. TEM image of mesoporous nanocrystalline cobalt–nickel oxide spinel calcined at 350 °C.

These uniform mesoporous nanostructures were composed of $NiCo_2O_4$ and NiO nanocrystals. Despite the crystallization of amorphous walls upon calcination, the composition of the spinel phase remained essentially the same as that of the original heterometallic alkoxide precursor. Table 1 summarizes the textural properties and spinel average crystal size of the mesoporous cobalt–nickel oxide phases at different calcination temperatures. Figure 4 shows the PXRD patterns of the cobalt–nickel oxide phases as a function of calcination temperature, whereas Table 2 summarizes their compositional and structural properties. The structural properties of the uniform nanocrystalline mesoporous phases were determined using Topas profile fitting software.[18] These findings indicated that the spinel content remained practically unchanged at 81–84% for samples calcined at 350 °C and 400 °C, whereas the nanoparticle size increased from 8.4 nm to 11.1 nm, respectively, due to progressive crystal growth. A remarkable change in compositional and structural properties is evident for the sample calcined at 450 °C. This particular sample contained only 73% of 20.6 nm spinel nanocrystals. The excessive crystal growth at higher calcination temperatures was responsible

Table 1. Selected textural properties and spinel average crystal size of mesoporous nanocrystalline cobalt–nickel oxides as a function of calcination temperature.

| Sample | Average pore size [nm] | Specific surface area [$m^2$/g] | $NiCo_2O_4$ particle size [nm] |
|---|---|---|---|
| mesoporous/350 °C | 7.0 | 83.8 | 8.4 |
| mesoporous/400 °C | 11.5 | 35.0 | 11.1 |
| mesoporous/450 °C | – | 12.1 | 20.6 |

Table 3. Catalytic properties of dense Co–Ni–O spinel and mesoporous Co–Ni–O oxides in propane combustion at 280 °C. Feed: 6.3 vol.-% propane, 9.4 vol.-% $O_2$ and balance He.

| Catalyst | $C_3$ conversion mol-% | $S(CO)$[a] mol-% | $S(CO_2)$ mol-% | $C_3$ combustion rate nanomol/$m^2$s |
|---|---|---|---|---|
| dense spinel | 11 | 79 | 21 | 1.76 |
| mesoporous/350 °C | 59 | 37 | 63 | 1.40 |
| mesoporous/400 °C | 64 | 31 | 69 | 3.59 |
| mesoporous/450 °C | 9 | 29 | 71 | 1.42 |

[a] $S$ = selectivity.

for the mesostructure collapse. Traces of Ni and Co metals were also detected in all three mesoporous samples.

The morphological changes of the uniform mesoporous mixed Co–Ni oxide phases as a function of calcination temperature are shown in Figure 5. The sample calcined at 350 °C was very uniform containing spheroidal ca. 8.4-nm spinel nanoparticles. The sample calcined at 400 °C contained spheroidal ca. 11.1-nm spinel nanoparticles as well as rhombohedral crystals of some minority phase, probably NiO. Excessive growth of spinel nanocrystals within the channel walls of the inorganic framework led to the formation of well-defined hexagonal and rhombohedral 20-nm spinel nanocrystals which disrupted the mesoporous structure.

The CH analysis (Robertson Microlit Laboratories) indicated that only 0.42, 0.66 and 0.30% C remained in the 350, 400 and 450 °C calcined mesoporous Co–Ni oxide phases, respectively.

Table 3 shows representative catalytic properties of the uniform mesoporous Co–Ni oxides and a dense Co–Ni oxide spinel in propane combustion. The mesoporous catalysts calcined at 350 and 400 °C were much more active in propane combustion than the dense spinel and mesoporous catalyst calcined at 450 °C. These catalysts showed a high degree of propane conversion to CO and $CO_2$ at the same gas space velocity indicating that these mesoporous Co–Ni oxides contained a higher number of active surface sites, whereas the catalytic behavior of the mesoporous Co–Ni oxide calcined at 450 °C was similar to that of the dense spinel, confirming that the former phase was no longer mesoporous. The catalytic data were further analyzed in terms of propane combustion rate normalized by the surface areas of these model catalysts. Some variation of the propane combustion rate was observed (Table 3) suggesting that the nature of the active surface sites was largely unaffected by the self-assembly process. Moreover, the mesoporous catalysts calcined at 350 and 400 °C were significantly more selective to $CO_2$ than CO as compared to the dense spinel phase, which is highly desirable for catalytic combustion applications. We believe that the mesoporous samples showed superior catalytic behavior not only due to their greater surface areas and mesoporous structure, but also because of the relatively small size of the spinel crystallites. In particular, the higher combustion rate observed for the mesoporous sample calcined at 400 °C suggests the existence of optimal crystallite size in the nanoscale regime. Furthermore, the presence of mesoporous channels enhanced the diffusion of reactant and product molecules and improved the mass-transfer characteristics of Co–Ni–O spinels.

## Conclusions

Uniform nanocrystalline mesoporous cobalt–nickel oxide spinels were prepared by employing a heterometallic

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

alkoxide precursor and oligomeric alkyl-ethylene oxide surfactant as a structure-directing agent. These resultant mesoporous phases displayed unimodal pores in the 7–12 nm range and relatively high specific surface areas up to 83 $m^2$/g. The mesoporous phases were composed mainly of ca. 8–11 nm Co–Ni–O spinel nanocrystals. These nanocrystalline uniform cobalt–nickel oxides were studied as catalysts in the combustion of propane, showing higher propane conversion to CO and $CO_2$ as compared to a conventional dense spinel. This improved catalytic behavior may be related to their morphological and structural advantages such as larger surface area and mesoporous structure, and to the relatively small size of the spinel crystallites. Furthermore, this soft chemistry method is highly promising for the general synthesis of nanocrystalline and mesoporous mixed metal oxides with desired bulk stoichiometries from heterometallic alkoxide precursors in the presence of supramolecular liquid crystalline phases.

## Experimental Section

**Synthesis of the Heterometallic Single-Source Alkoxide Precursor:** The heterometallic single-source precursor $(Ni_{0.33}Co_{0.67})$(OMe)(acac)(MeOH) was obtained as follows. Na (2.517 g, 109 mmol) was refluxed in a solution of anhydrous toluene (50 mL), 2-methoxyethanol (12.5 mL, 164 mmol) and acetylacetone (5.5 mL). A mixture anhydrous $CoCl_2$ (4.934 g, 36.5 mmol) and $Ni(NH_3)_6Cl_2$ (4.209 g, 18.2 mol) was added to the above solution under vigorous stirring. The resultant heterogeneous mixture was refluxed for 2 h, diluted with additional 20 mL of toluene and refluxed again for another 2 h. The voluminous sediment of NaCl was precipitated overnight and the purple solution transferred into a separate flask and the solvents evaporated to dryness leaving a viscous purple liquid. It was dissolved then in 50 mL of anhydrous MeOH. The formation of purple red prismatic crystals started almost immediately. The mixture was left overnight in a freezer at –30 °C and the solid product was then separated by decantation, washed with 5 mL of cold MeOH and dried in vacuo. The purity of the resultant heterometallic Co–Ni alkoxide was confirmed by elemental analysis and IR. Yield: 9.124 g (76%). $(Ni_{0.33}Co_{0.67})$(OMe)(acac)(MeOH) (221.04): calcd. C 38.0, H 6.4; found C 37.6, H 6.3. IR: $\tilde{\nu}$ = 3221 (s br), 1603 (vs br), 1515 (s), 1397 (s), 1255 (m), 1193 (w), 1124 (w), 1045 (s), 1033 (sh), 1014 (m), 922 (m), 765 (m), 636 (w), 571 (m), 554 (m), 435 (s), 416 (s) $cm^{-1}$. This heterometallic Co–Ni alkoxide was used as inorganic precursor.

**Synthesis of Mesoporous Nanocrystalline Cobalt–Nickel Oxide Spinels:** The mesoporous nanocrystalline cobalt–nickel oxide spinels were prepared as follows. The synthesized heterometallic single-source alkoxide precursor (see above) was dissolved in 1-butanol (Aldrich, 99.9%) and heated at 70 °C. Separately, the oligomeric alkyl-ethylene oxide surfactant Brij-35 $[C_{12}H_{25}(OCH_2CH_2)_{23}OH$, Aldrich] was dissolved in butanol and then added to the inorganic precursor solution. This solution was stirred at room temperature for 3 h, and then precipitated with $NH_4OH$ 1 M (Fisher Chemicals) at pH = 8.0–9.0. The resultant grayish slurry was aged in an open Petri dish at 50 °C for 2 d, and then dried at 90 °C for 1 d to yield brownish powders upon evaporation. The as-synthesized powders were calcined at 350 °C, 400 °C and 450 °C to remove the template and increase crosslinking of the inorganic framework. Typical synthesis compositions on weight basis were 1-butanol:surfactant = 21–26; precursor:surfactant = 0.55–0.60; precursor:solvent = 0.023–0.026. The surfactant volume fraction expressed as $V_{template}/(V_{template} + V_{inorganic})$ was kept constant at Ø = 0.20–0.25. A reference sample of dense Co–Ni oxide spinel was also prepared as described above, but without the addition of the structure directing agent. This dense phase was calcined at 450 °C.

**Characterization:** The nitrogen adsorption–desorption isotherms were measured with a TRI-STAR 3000 porosimeter. The pore-size distributions were calculated from the adsorption branch of the isotherm using the BJH method. The PXRD was measured with a Siemens D5000 diffractometer using high power Ni-filtered Cu-$K_\alpha$ radiation with $\lambda$ = 1.54178 Å source operating at 50 kV/35 mA. High-resolution SEM analysis was performed with Hitachi S-5200 (30 kV, 10 mA). The samples for SEM were deposited onto carbon film-supported 200 mesh copper grids. The SAXS pattern was collected in a Hi-Star area two-dimensional multiwire proportional counter detector (BRUKER AXS GADDS system, $\lambda$ = 1.5418 Å). The TEM image was captured with a GATAN multi-scan digital camera mounted on a JEOL 2010F. The TEM sample was prepared by depositing a small amount of powder on a lacey carbon 200 mesh copper TEM grid. Propane oxidation was conducted at 350–450 °C using a feed of 6.3 vol.-% propane, 9.4 vol.-% oxygen and balance He and ca. 0.1 g of catalyst packed in a 3/8"-quartz tubular microreactor in a programmable oven. The flow rate was 4.2 $cm^3$/min in all cases. An HP 5890II gas chromatograph equipped with an FID and TCD was employed for the reaction product analysis. The carbon balances agreed within 5 mol%.

# Synthesis and Transition Metal Complexes of Novel *N*,*N*,*O* Scorpionate Ligands Suitable for Solid Phase Immobilisation

**Eike Hübner,[a] Thomas Haas,[b] and Nicolai Burzlaff*[a]**

**Keywords:** Solid phase / Immobilisation / Tripodal ligands / *N*,*N*,*O* ligands / Tricarbonyl complexes

Introduction of an allyl or a hydroxymethyl group to bis(3,5-dimethylpyrazol-1-yl)acetic acid (**1**) at the bridging carbon atom leads to the new tripodal *N*,*N*,*O* ligands 2,2-bis(3,5-dimethylpyrazol-1-yl)pent-4-enoic acid (Hbdmpzpen) (**2**) and 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionic acid (Hbdmpzhp) (**3**). These ligands exhibit similar chemical behaviour to that of **1**, but they have the additional possibility to be immobilised to a solid phase. Esterification of the hydroxymethyl linker of **3** yields 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-acetatopropionic acid (Hbdmpzap) (**4**). The molecular structures of **2**, **3** and **4** all exhibit intramolecular hydrogen bridges. Introduction of a hydroxymethyl group to methyl bis(3,5-dimethylpyrazol-1-yl)acetate (**5**) yields methyl 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionate (Mebdmpzhp) (**6**), which can be immobilised on Merrifield polymer to yield modified resin **P**-**6**. To investigate the reactivity of these new ligands, manganese and rhenium complexes of **2**, **3** and **4** have been studied. The molecular structures of the two manganese complexes [Mn(bdmpzpen)(CO)$_3$] (**7**) and [Mn(bdmpzap)(CO)$_3$] (**8**) have been confirmed by single-crystal X-ray structure determination. Saponification of polymer resin **P**-**6** and subsequent reaction with [ReBr(CO)$_5$] yields rhenium tricarbonyl complexes anchored on Merrifield polymer (**P**-Re). Solid phase immobilisation of the [Mn(bdmpzpen)(CO)$_3$] (**7**) and [Re(bdmpzpen)(CO)$_3$] (**9**) complexes on 3-mercaptopropyl functionalised silica is initialised by AIBN. The tripodal coordination of manganese and rhenium in these functionalised Merrifield resins (**P**-Re) and silica (**S**-Mn, **S**-Re) is proven by a single A$_1$ and two E signals in the IR spectra that are typical for unsymmetrical "piano stool" type carbonyl complexes.

## Introduction

Bis(pyrazol-1-yl)acetic acids have proved to be a versatile class of *N*,*N*,*O* ligands, structurally related to the well-known hydrotris(pyrazol-1-yl)borate (Tp). Different synthetic routes for achiral, chiral and enantiopure bis(pyrazol-1-yl)acetic acids have been developed since their introduction to coordination chemistry in 1999 by A. Otero.[1,2] A broad spectrum of transition metal complexes bearing these ligands revealed their behaviour as weak electron-donating ligands in inorganic chemistry,[2a,2c] which often behave almost identically to Tp ligands. Typical examples are the manganese and rhenium tricarbonyl complexes [Mn(bdmpza)(CO)$_3$] and [Re(bdmpza)(CO)$_3$] [bdmpza: bis(3,5-dimethylpyrazol-1-yl)acetate].[2a] Furthermore, model complexes with iron(II) and zinc(II) show their potential to mimic the active site of metalloenzymes with a 2-His-1-carboxylate motif.[2b,2e–2g]

Fixation of these ligands on a solid phase is of particular interest, especially with regard to the potential use as catalysts with easy work up or to achieve dedicated structural environments with sterically less hindered ligands. Most methods used for immobilisation of ligands or transition metal complexes introduce a linker group to the ligand which connects the ligand through stable covalent bonds to the solid material.[3] Isolated double bonds as in allyl or acryl groups open up a broad field of methods available to immobilise the ligand.[4,5] Common examples are copolymerisation, metathesis reactions and especially radical-induced carbon–sulfur bond formations.[5] Recent investigations on structurally related bis(oxazoline) ligands have shown the feasibility of immobilising such ligands while maintaining catalytic activity of the resulting immobilised complexes.[5b] Alternatively, a hydroxymethyl linker would allow solid phase fixation by esterification or ether synthesis.

## Results and Discussion

We found bis(3,5-dimethylpyrazol-1-yl)acetic acid (Hbdmpza) (**1**) to be a convenient starting material for linker modified ligands, which is accessible from dibromo- or dichloroacetic acid in a one-step synthesis.[2a,2b] Deprotonation of the remaining hydrogen at the bridging carbon atom in **1** with excess LDA in THF at –80 °C and subse-

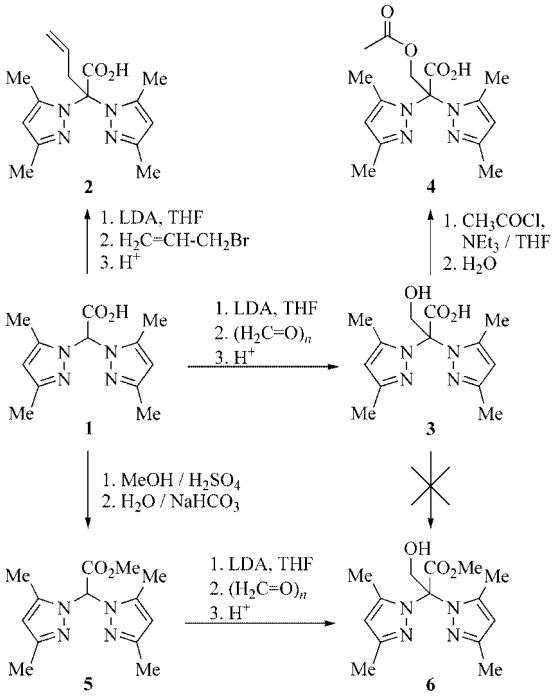
quent alkylation with allyl bromide leads to 2,2-bis(3,5-dimethylpyrazol-1-yl)pent-4-enoic acid (Hbdmpzpen) (**2**) (Scheme 1). Similar modifications of tris(pyrazolyl)methane ligands with various bases such as *n*BuLi or LiN[Si(CH$_3$)$_3$]$_2$ have been reported recently by D. L. Reger et al.[6]



Scheme 1.

Despite heating under reflux, no reaction of the deprotonated carboxylate group with allyl bromide is observed, although this is a well-known reaction, for example in the case of fluoroacetic acid.[7] Thus, the asymmetric carboxylate IR band (THF) is found at 1729 cm$^{-1}$. The molecular structure of **2** (Figure 1) was determined by X-ray crystallography, which revealed an intramolecular hydrogen bridge [d(O1–N11) = 2.504(2) Å] between the carboxylate and the pyrazolyl group. The $^1$H and $^{13}$C NMR spectroscopic data of resulting ligand **2** are almost identical to those of **1**, except for the lack of a $^1$H NMR resonance of the bridging CH group and the additional allyl resonances. This is consistent with a $C_s$ symmetry in solution.

A quite similar reaction with paraformaldehyde instead of allyl bromide yields 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionic acid (Hbdmpzhp) (**3**) (Scheme 1).

Again, the result of an X-ray structure determination of **3** exhibits an intramolecular hydrogen bond [d(O3–N21) = 2.715(3) Å], in this case between the hydroxy and the pyrazolyl group (Figure 2).

According to the NMR spectroscopic data, the molecular structure exhibits $C_s$ symmetry in solution as well. The IR band (KBr) at 1752 cm$^{-1}$ is assigned to the carboxylate signal. In solution, two IR bands occur for the carboxylate group (THF, 1750 and 1716 cm$^{-1}$), which indicates that there is hydrogen bonding between the carboxylate group and the OH-linker.

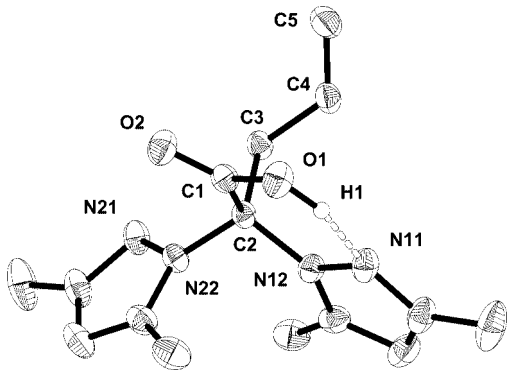


Figure 1. Molecular structure of 2,2-bis(3,5-dimethylpyrazol-1-yl)-pent-4-enoic acid (**2**); thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: d(C1–O1) = 1.3194(18), d(C1–O2) = 1.2058(17), d(O1–N11) = 2.504(2), ∠(N12,C2,N22)=108.09(11).

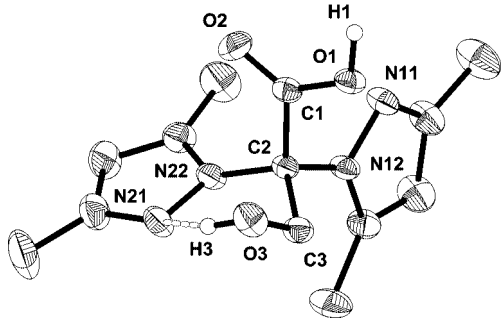

Figure 2. Molecular structure of 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionic acid (**3**); thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: d(C1–O1) = 1.320(3), d(C1–O2) = 1.201(3), d(C3–O3) = 1.414(3), d(O3–N21) = 2.715(3), ∠(N12,C2,N22) = 109.6(2).

Because the linker groups are introduced at the bridging carbon atom, this concept may be extended to homochiral bis(pyrazol-1-yl)acetic acids, which we reported on recently,[2h,2i] without breaking the chirality or chiral induction.

Besides direct solid phase fixation, the functional OH-group of **3** may be used for further modifications. Possible applications would be linking biomolecules by esterification or the addition of new linking groups. Esterification with acetyl chloride at the OH-linker (Scheme 1) leads to **4** and provides a heteroscorpionate ligand with the protected OH-linker.

The intramolecular hydrogen group is found in the X-ray structure, too, [d(O1–N21) = 2.478(3) Å] between the carboxylic acid and the pyrazole nitrogen (Figure 3).

On the other hand, ligand **3** may be modified at the carboxylate donor instead of the OH-linker. This is necessary depending on the applied procedure of solid phase fixation (see below) to prevent the carboxylate donor from acting as a linking group. Although the most obvious protecting group is methyl ester **6** (Scheme 1), direct esterification of **5** results in 2,2-bis(3,5-dimethylpyrazol-1-yl)-1-ethanol caused by decarboxylation. Therefore, methyl ester **6** is synthesised by esterification of **1** in a first step and subsequent

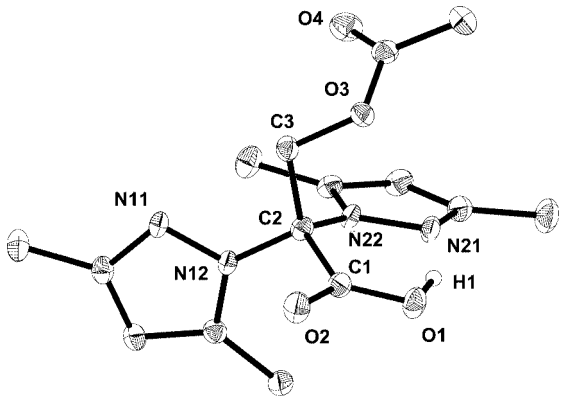

Figure 3. Molecular structure of 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-acetatopropionic acid (**4**); thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: d(C1–O1) = 1.306(3), d(C1–O2) = 1.203(3), d(O1–N21) = 2.478(3), ∠(N12,C2,N22)=108.72(18).

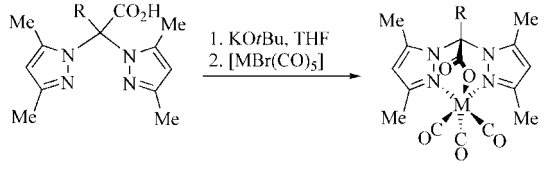
reaction of **5** with LDA and paraformaldehyde to **6** (Scheme 1).

To study the potential of these new ligands, **2**, **3**, **4** and **6**, in coordination chemistry and to examine their chemical behaviour, tricarbonyl complexes with manganese and rhenium were synthesised. The general synthesis of such tricarbonyl metal complexes starts from $[MnBr(CO)_5]$ and $[ReBr(CO)_5]$, respectively, and leads after reaction with potassium bis(pyrazol-1-yl)carboxylates to the corresponding tricarbonyl complexes.[2a]

To verify tripodal binding of the solid-bound ligand, manganese and rhenium complexes of ligand **4**, which bears the acetyl protected OH-linker, were synthesised accordingly (Scheme 2). The protected OH linker in **4** acts as model for the solid phase bound ligand.



Scheme 2.

In contrast to **3**, ligand **4** reacts with the metal carbonyls as it is well known for the heteroscorpionate ligand Hbdmpza.[2a] This is also observed with allyl-functionalised ligand **2** (Scheme 2).

The formation of tricarbonyl complexes **7** to **10** can be monitored by IR spectroscopy during the reaction. The presence of the tricarbonyl complexes is indicated by a single $A_1$ and two E signals typical for unsymmetrical "piano stool" type carbonyl complexes[2a] [**7**: $\tilde{\nu}$(CO) = 2033, 1939 and 1911 $cm^{-1}$; **9**: $\tilde{\nu}$(CO) = 2023, 1915 and 1892 $cm^{-1}$; **8**: $\tilde{\nu}$(CO) = 2034, 1940 and 1913 $cm^{-1}$; **10**: $\tilde{\nu}$(CO) = 2024, 1918 and 1894 $cm^{-1}$]. These IR absorptions are in good agreement with those of the complexes $[M(bdmpza)(CO)_3]$ (M = Mn, Re) we reported on earlier and prove the desired $\kappa^3$-*N,N,O* coordination of the ligands.[2a] The IR bands at 1687 (**7**), 1697 (**9**), 1692 (**8**) and 1702 (**10**) $cm^{-1}$ are assigned to the asymmetric carboxylate vibration $\tilde{\nu}_{asym}(CO_2^-)$. Complexes **8** and **10** show an additional IR signal at 1761 and 1762 $cm^{-1}$, respectively, which was assigned to the asymmetric carboxylate vibration in the acetyl residue. The complexes are also confirmed by the $[M + H]^+$ peaks in the FAB and FD mass spectra. In the case of **7**, in accordance with $[Mn(bdmpza)(CO)_3]$, the $^1H$ NMR spectra consists of broad signals without clear couplings. Nevertheless, the signals can be assigned unambiguously. Also the $^1H$ and $^{13}C$ NMR spectra of **9** show a clear set of signals for the coordinated bdmpzpen ligand. The carboxylate group shows a $^{13}C$ NMR resonance at $\delta$ = 164.5 ppm. Two $^{13}C$ NMR resonances are observed for the carbonyl ligands of complexes **7** and **9** (**7**: 220.6 ppm, 222.4 ppm, **9**: 195.7 ppm, 196.0 ppm).

Finally, X-ray structure analyses of **7** (Figure 4) and **8** (Figure 5) doubtless reveal the $\kappa^3$-*N,N,O* coordination of tripodal *N,N,O* ligands **2** and **4**. Complex **8** crystallised in a chiral conformation with the acetyl protected linker group positioned between one pyrazole donor and the carboxylate donor (Figure 5 and Scheme 3). Both possible enantiomers are found in the cell because of the space group P-1.

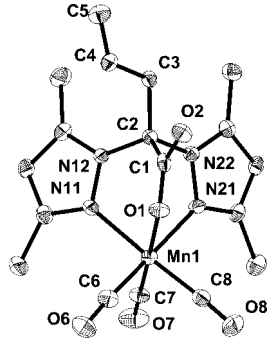


Figure 4. Molecular structure of $[Mn(bdmpzpen)(CO)_3]$ (**7**); thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: d(C1–O1) = 1.266(5), d(C1–O2) = 1.233(4), d(Mn1–N11) = 2.049(3), d(Mn1–N21) = 2.090(3), d(Mn1–O1) = 1.993(3), d(Mn1–C6) = 1.813(4), d(Mn1–C7) = 1.805(4), d(Mn1–C8) = 1.817(4), d(C6–O6) = 1.153(5), d(C7–O7) = 1.149(5), d(C8–O8) = 1.149(5), ∠(N11,Mn1,C8) = 175.15(16), ∠(N21,Mn1,C6) = 176.41(15), ∠(O1,Mn1,C7) = 175.61(14), ∠(N11,Mn1,O1) = 83.72(12), ∠(N21,Mn1,O1) = 85.02(12), ∠(N21,Mn1,C7) = 91.77(15), ∠(N11,Mn1,C7) = 93.09(16), ∠(N11,Mn1,N21) = 86.22(12).

Thus, the coordination of the new ligands is not hindered by the additional linker groups at the bridging carbon atom. Coordination of the linker to the metal centre instead of the carboxylate donor does not take place in the case of **2**. The position of the allyl group in **7** (Figure 3), as well as of the acetyl group in **8**, indicate its ability to act as a linking group to solid phase. The agreement of the bond lengths and angles of **7** and **8** with those of the previously reported $[Mn(bdmpza)(CO)_3]$[2a] implies similar ligand properties of **2**, **3** and **4** in comparison to those of **1**.

Both complexes $[Mn(bdmpzap)(CO)_3]$ (**8**) and $[Re(bdmpzap)(CO)_3]$ (**10**) exhibit an AB system in the $^1H$ NMR spectrum for the -$CH_2O$- protons because of the chi-

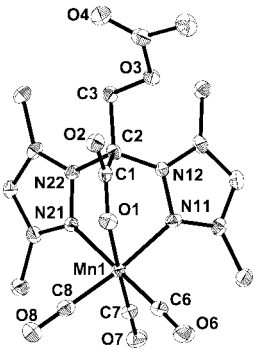

Figure 5. Molecular structure of [Mn(bdmpzap)$(CO)_3$] (**8**); thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: d(C1–O1) = 1.263(4), d(C1–O2) = 1.226(4), d(Mn1–N11) = 2.037(3), d(Mn1–N21) = 2.060(3), d(Mn1–O1) = 1.999(3), d(Mn1–C6) = 1.809(4), d(Mn1–C7) = 1.786(4), d(Mn1–C8) = 1.808(5), d(C6–O6) = 1.150(4), d(C7–O7) = 1.157(5), d(C8–O8) = 1.152(5), ∠(N11,Mn1,C8) = 173.26(16), ∠(N21,Mn1,C6) = 176.70(17), ∠(O1,Mn1,C7) = 177.21(15), ∠(N11,Mn1,O1) = 84.22(11), ∠(N21,Mn1,O1) = 86.51(11), ∠(N21,Mn1,C7) = 92.22(15) ∠(N11,Mn1,C7) = 93.19(16), ∠(N11,Mn1,N21) = 84.39(12).

Scheme 3. Dynamic interconversion of the two enantiomers of complexes **8** and **10**. The Newman projection shows the view along the C3–C2 axis. The numbering was carried out according to Figure 5.

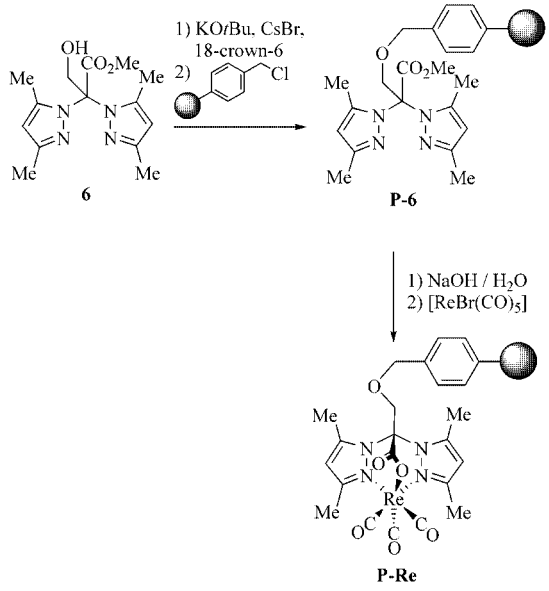
rality described above. These AB systems, as well as the signals of the two methyl groups, are rather broad due to a dynamic interconversion of the two possible enantiomers (Scheme 3). This dynamic interconversion might also explain why rather weak $^{13}C$ NMR spectroscopic data were obtained for manganese and rhenium complexes **8** and **10**.

In the case of OH-functionalised ligand **3**, the IR spectra of the manganese and the rhenium compounds indicate the formation of at least two species because several bands for the CO signals appear. This is backed by NMR spectra, which shows more than one set of signals for the methyl groups of the pyrazole donors. Furthermore, the NMR signals are broadened and especially the carboxylate group is not clearly visible in the IR spectra. Although we could not solve this problem in detail, this might indicate a dynamic equilibrium in which either the carboxylate donor or the hydroxo linker coordinates towards the metal centre. A related dynamic behaviour was reported recently by W. Kläui and coworkers.[8] After binding the hydroxymethyl linker to solid phase, this part of the molecule will presumably act no longer as a donor towards the metal centre as shown in complex **8**. Thus, this behaviour will not interfere with the future use of ligands **3** or **6** as a solid-bound *N*,*N*,*O* ligand.

## Solid Phase Binding

The purpose of our efforts, as mentioned above, is to bind monoanionic *N*,*N*,*O* ligands to various solid phases. This solid phase fixation of the ligands and their complexes should strongly affect their chemical properties. For instance, the formation of bisligand complexes [$ML_2$] as well as the autoxidation or dimerisation of complexes should be prevented.

Chloromethylated resin, so called Merrifield polymer, is one of the most popular solid phase supports. Thus, we used this resin in our first attempt to bind linker modified bis(pyrazol-1-yl)acetic acids to a solid phase. Primarily, Merrifield polymer was designed to bind carboxylic acids. Thus, we had to use the ester methyl 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionate (**6**) instead of the 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionic acid (**3**). Fixation on the resin is achieved by nucleophilic substitution of the benzylic chlorine for the deprotonated OH-linker of **6** (Scheme 4). The best result was obtained by using a mixture of KO*t*Bu, 18-crown-6 and CsBr in this reaction. To verify the functionalisation of the polymer, elemental analyses of solid phase samples were accomplished. Determination of the nitrogen content does not only prove the binding of ligand **6** to the solid phase, but also enables the calculation of the degree of functionalisation (Table 1). Usually, an occupancy of more than 20% of the theoretical sites was achieved. Subsequent saponification of functionalised Merrifield resin **P-6** with $H_2O$/NaOH/THF leads to the targeted monoanionic *N*,*N*,*O* functionalised solid phase. Further reaction with [$ReBr(CO)_5$] afforded polymer mounted tricarbonyl rhenium complex **P**-Re (Scheme 4). A similar reaction with [$MnBr(CO)_5$] has not been successful so far.



Scheme 4.

The IR spectra of **P**-Re exhibits a single $A_1$ and two E signals [$\tilde{\nu}$(CO) = 2022, 1915 and 1890 $cm^{-1}$] (Figure 6c). The location of these signals is almost identical to those of the complex [Re(bdmpzap)$(CO)_3$] (**10**) (Figure 6a) which we described above. An additional signal at 1964 $cm^{-1}$ is caused by the Merrifield polymer (Figure 6b and Fig-

Table 1. Occupancy of the functionalised solid phases **P-6**, **S-2**, **S**-Mn and **S**-Re.

| Solid phase | Linker [mmol g$^{-1}$] | Functionalised solid phase | Nitrogen content [%] | Ligand/ complex [mmol g$^{-1}$] | Occupancy of sites [%] |
|---|---|---|---|---|---|
| Merrifield polymer | 1.1 | **P-6** | 1.26 | 0.23 | 21 |
| Mercaptopropyl silica | 0.98 | **S-2** | 0.97 | 0.17 | 18 |
| Mercaptopropyl silica[a] | 0.98 | **S**-Mn | 0.20 | 0.036 | 4 |
| Mercaptopropyl silica[b] | 0.98 | **S**-Mn-II | 0.35 | 0.063 | 6 |
| Mercaptopropyl silica[a] | 0.98 | **S**-Re | 0.23 | 0.041 | 4 |
| Mercaptopropyl silica[b] | 0.98 | **S**-Re-II | 0.44 | 0.078 | 8 |

[a] After 8 h. [b] After 48 h.

ure 6c). A control experiment with unfunctionalised methyl bis(3,5-dimethylpyrazol-1-yl)acetate (**5**) showed no occupancy of the polymer sites and subsequently no $A_1$ and E signals but a typical IR spectrum of Merrifield polymer (Figure 6b). Therefore, the results of our experiments prove a solid phase fixation of the ligand and the resulting tricarbonyl complex as well as a facial coordination of rhenium(I) by the monoanionic *N,N,O* tripod ligand.

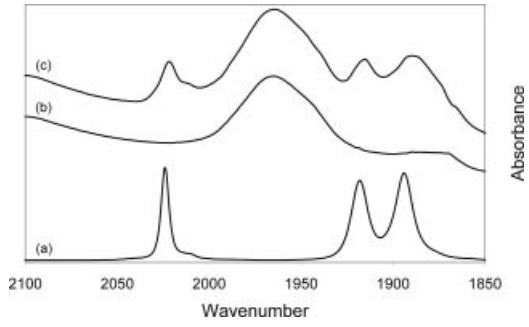

Figure 6. IR spectra of (a) [Re(bdmpzap)(CO)$_3$] (**10**) (THF), (b) Merrifield polymer (THF) and (c) **P**-Re – the rhenium tricarbonyl complex anchored on Merrifield polymer (THF).

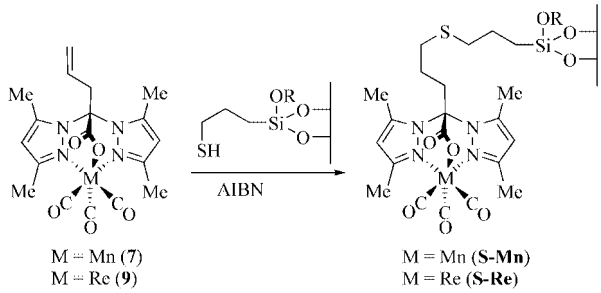
Unfortunately, the solvents compatible to reactions with Merrifield polymer are quite limited. Especially, reactions in water are almost impossible. To overcome this limitation for future applications, the fixation on silica solid phase can be achieved by mercaptopropyl functionalised silica. Immobilisation of chelating *N,N* ligands bearing allyl linker groups on such functionalised silica has been reported recently by Mayoral et al.[5b] Following a similar procedure, 2,2-bis(3,5-dimethylpyrazol-1-yl)pent-4-enoic acid (**2**) was immobilised by a radical induced reaction with mercaptopropyl silica in the presence of azobisisobutyronitrile (AIBN). An analysis of the nitrogen content of resulting silica **S-2** showed an occupancy of more than 17% of the mercaptopropyl sites (Table 1). Unfortunately, the mercaptopropyl functionalised silica itself as well as the modified silica **S-2** can undergo complexation with [MnBr(CO)$_5$] and [ReBr(CO)$_5$]. After reaction with [ReBr(CO)$_5$], both silica exhibit various rather broad IR signals, which could be assigned to signals of various carbonyl species.

In an attempt to overcome this problem we tried to immobilise the [Mn(bdmpzpen)(CO)$_3$] (**7**) and [Re(bdmpzpen)(CO)$_3$] (**9**) complexes themselves. On following this approach, complexes **7** and **9** were grafted onto mercaptopropyl silica in the presence of AIBN (Scheme 5).



Scheme 5.

Elemental analyses of resulting silica samples **S**-Mn and **S**-Re were accomplished to determine the nitrogen content. The deduced occupancy of mercaptopropyl sites by the tricarbonyl complexes add up to 3.6% (**S**-Mn) and 4.2% (**S**-Re) (Table 1). IR spectra of silica phases **S**-Mn and **S**-Re show signals that can be assigned to the $A_1$ and E signals of the grafted manganese and rhenium tricarbonyl complexes [**S**-Mn: $\tilde{\nu}$(CO) = 2039, 1948 and 1923 cm$^{-1}$ (Figure 7d); **S**-Re: $\tilde{\nu}$(CO) = 2027, 1920 and 1905 cm$^{-1}$ (Figure 7f)]. A longer reaction time (48 h) results in higher occupancies

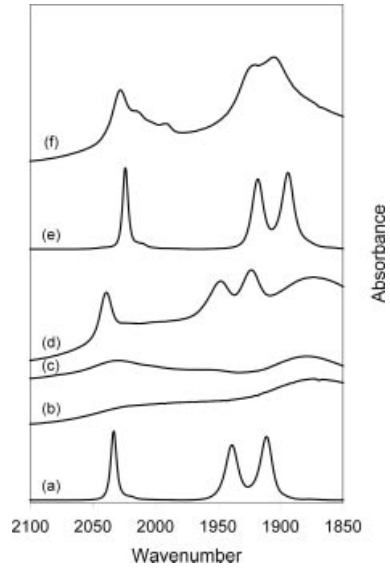


Figure 7. IR spectra of (a) [Mn(bdmpzpen)(CO)$_3$] (**7**) (THF), (b) mercaptopropyl silica (Nujol), (c) control experiment with [Mn(bdmpza)(CO)$_3$], (d) manganese tricarbonyl complex **7** immobilised on silica (**S**-Mn) (Nujol), (e) [Re(bdmpzpen)(CO)$_3$] (**9**) (THF) and (f) rhenium tricarbonyl complex **9** immobilised on silica (**S**-Re) (Nujol).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[6.4% (**S**-Mn-II) and 8.0% (**S**-Re-II)], but caused also obscure IR spectra probably due to degradation of the carbonyl complexes or a further reaction with surrounding non innocent free SH-groups.

Neither the IR spectra of the mercaptopropyl functionalised silica (Figure 7b) nor that of a control experiment with the unfunctionalised complex [Mn(bdmpza)$(CO)_3$] (Figure 7c) show any signals in this region. Thus, these results prove an immobilisation of manganese and rhenium tricarbonyl complexes on silica through a *N*,*N*,*O* tripod ligand with an allyl linker.

## Conclusions

In conclusion, modifications to the in coordination chemistry well-established ligand Hbdmpza (**1**) led to the new functionalised ligands 2,2-bis(3,5-dimethylpyrazol-1-yl)pent-4-enoic acid (**2**) and 2,2-bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionic acid (**3**) bearing an allyl or an hydroxymethyl linker for solid phase fixation. These ligands, or their protected analogues, provide similar coordination properties as **1**, proven by the synthesis of various transition metal carbonyl complexes. By way of well-known solid phase coupling reactions, **2** and **3** have been grafted on silica and on Merrifield polymer. The degree of functionalisation of the solid phase can be determined by elemental analysis. Furthermore, we were able to prove the typical tripodal monoanionic *N*,*N*,*O* binding behaviour by the characteristic IR spectra of immobilised tricarbonyl complexes.

## Experimental Section

**General Remarks:** All operations were carried out under an inert gas atmosphere by using conventional Schlenk techniques. Solvents were freshly distilled and degassed prior to use from appropriate drying agents. The yields refer to analytically pure substances and were not optimised. IR spectra were recorded with a Biorad FTS 60 spectrometer or a Varian Excalibur FTS-3500 FTIR spectrometer in $CaF_2$ cuvettes (0.2 mm) or in Nujol. $^1H$ and $^{13}C$ NMR spectra were measured with Bruker AC 250 MHz, Varian Inova 400 MHz or Bruker DPX300 instruments. $\delta$ values are measured relative to TMS or the deuterated solvent. Mass spectra were recorded with a modified Finnigan MAT 312 instrument by using either EI or FAB technique with 3-nitrobenzyl alcohol as matrix for complexes **7** and **9** and glycerine/NaI as matrix for ligands **2** and **3** or were recorded on a Jeol JMS-700 instrument using FD technique. Elemental analyses were measured with a Heraeus CHN-O-Rapid, Euro EA 3000 (Euro Vector) and EA 1108 (Carlo Erba) ($\sigma \pm 1$% of the measured content). A modified Siemens P4 diffractometer and a STOE IPDS II diffractometer were used for X-ray structure determination. Chemicals were used as purchased without further purification. Chloromethylated resin, "Merrifield polymer" [polystyrene-divinylbenzene, 1% cross linking, 1.1 mmol Cl $g^{-1}$, 200–400 mesh (Fluka)] and 3-mercaptopropyl functionalised silica [0.98 mmol S $g^{-1}$ (Aldrich)] were used as purchased. Both solid phases were evacuated for 2 h ($10^{-2}$ mbar) and flushed with dry nitrogen prior to use. Bis(3,5-dimethylpyrazol-1-yl)acetic acid (**1**) was synthesised as described earlier but starting from dichloroacetic acid instead of dibromoacetic acid and with a reaction time of 72 h.[2b] [$ReBr(CO)_5$], [$MnBr(CO)_5$] and [Mn(bdmpza)$(CO)_3$] were synthesised according to the literature.[2a,9a,9b] Solid phase fixation on mercaptopropyl silica was achieved according to the literature.[5b]

**Synthesis of 2,2-Bis(3,5-dimethylpyrazol-1-yl)pent-4-enoic Acid (2):** A solution of Hbdmpza (**1**) (3.30 g, 13.3 mmol) in dry THF (200 mL) was treated with LDA (≈ 1.8 M in heptane/THF/ethylbenzene, 23.0 mL, 41.4 mmol) at –80 °C. The solution was warmed up to –40 °C over a period of 2 h and was stirred for 1 h at –40 °C. Allyl bromide (9.00 mL, 12.6 g, 104 mmol) was added, and the mixture was warmed up to ambient temperature. The solution was heated under reflux for 30 min and then stirred overnight. The solvent was removed in vacuo, and the residue was dissolved in water. The aqueous solution was acidified with dilute HCl to pH 7–8 and extracted with pentane ($1 \times 100$ mL) to remove impurities. The aqueous solution was further acidified to pH 4 and **2** precipitated immediately. The crude mixture was extracted with pentane ($4 \times 200$ mL) and the combined organic layers were dried with $Na_2SO_4$ and concentrated in vacuo. Product **2** was recrystallised from pentane in colourless blocks suitable for X-ray structure determination. Yield: 1.68 g (5.82 mmol, 44%). M.p. 84–86 °C. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.71 [d, $J_{H,H}$ = 0.4 Hz (through space), 6 H, $C^5$-$CH_3$], 2.27 (s, 6 H, $C^3$-$CH_3$), 3.57 (dd, $^3J_{H,H}$ = 7.5 Hz, $^4J_{H,H}$ = 1.0 Hz, 2 H, $CH_2$), 5.09 (ddt, $^3J_{H,H}$ = 16.9 Hz, $^2J_{H,H}$ = 1.6 Hz, $^4J_{H,H}$ = 1.2 Hz, 1 H, =$CH_{2,allyl}$), 5.10 (ddt, $^3J_{H,H}$ = 10.2 Hz, $^2J_{H,H}$ = 1.6 Hz, $^4J_{H,H}$ = 0.8 Hz, 1 H, =$CH_{2,allyl}$), 5.59 [dddt, $^3J_{H,H}$ = 16.3 Hz, $^3J_{H,H}$ = 10.8 Hz, $^3J_{H,H}$ = 7.4 Hz, $J_{H,H}$ = 1.1 Hz (through space), 1 H, =$CH_{allyl}$], 5.87 (s, 2 H, $H_{pz}$) ppm. $^{13}C$ NMR (100.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 10.7 ($C^5$-$CH_3$), 13.2 ($C^3$-$CH_3$), 44.0 ($CH_2$), 80.9 ($C_{bridge}$), 108.7 ($C_{pz}$-H), 121.2 (=$CH_{2,allyl}$), 129.3 ($CH_{allyl}$), 141.5 ($C^5_{pz}$), 146.3 ($C^3_{pz}$), 168.7 ($CO_2H$) ppm. IR (THF): $\tilde{\nu}$ = 1729 ($CO_2H$), 1563 (C=N) $cm^{-1}$. FAB-MS: *m*/*z* (%) = 311 (18) $[M + Na]^+$, 289 (28) $[M + H]^+$, 193 (28) $[M - pz]^+$, 149 (100) $[M - pz - CO_2H]^+$, 95 (62) $[pz]^+$. $C_{15}H_{20}N_4O_2$ (288.35): calcd. C 62.48, H 6.99, N 19.43; found C 62.46, H 6.81, N 18.91.

**Synthesis of 2,2-Bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionic Acid (3):** A solution of Hbdmpza (**1**) (3.30 g, 13.3 mmol) in dry THF (200 mL) was treated with LDA (≈ 1.8 M in heptane/THF/ethylbenzene, 23.0 mL, 41.4 mmol) at –80 °C and warmed up to –40 °C over a period of 2 h. After 1 h at –40 °C, paraformaldehyde (4.00 g, 132 mmol) was added. The mixture was warmed up to ambient temperature and finally heated under reflux for 60 min and stirred overnight. The solvent was removed in vacuo, the residue was dissolved in water and washed with pentane (200 mL). The aqueous phase was acidified with dilute HCl (pH 2) and extracted with diethyl ether ($4 \times 200$ mL). The combined diethyl ether layers were dried ($Na_2SO_4$) and concentrated under reduced pressure. Product **3** was recrystallised from diethyl ether. Yield: 2.12 g (7.62 mmol, 57%). M.p. 119–121 °C. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.72 (s, 6 H, $C^5$-$CH_3$), 2.29 (s, 6 H, $C^3$-$CH_3$), 4.43 (s, 2 H, $HOCH_2$) 5.96 (s, 2 H, $H_{pz}$) ppm. $^{13}C$ NMR (100.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 10.6 ($C^5$-$CH_3$), 13.2 ($C^3$-$CH_3$), 68.8 ($CH_2$-OH), 81.5 ($C_{bridge}$), 108.5 ($C_{pz}$-H), 143.1 ($C^5_{pz}$), 148.0 ($C^3_{pz}$), 168.9 ($CO_2H$) ppm. IR (KBr): $\tilde{\nu}$ = 1752 ($CO_2H$), 1561 (C=N) $cm^{-1}$. FAB-MS: *m*/*z* (%) = 300 (18) $[M + Na]^+$, 217 (100) $[M - CO_2H - OH]^+$, 203 (100) $[M - CO_2H - CH_2OH]^+$. $C_{13}H_{18}N_4O_3$ (278.31): calcd. C 56.10, H 6.52, N 20.13; found C 56.62, H 6.75, N 19.91.

**Synthesis of 2,2-Bis(3,5-dimethylpyrazol-1-yl)-3-acetatopropionic Acid (4):** To a solution of Hbdmpzhp (**3**) (1.00 g, 3.60 mmol) in dichloromethane (100 mL), excess $NEt_3$ (4.00 mL, 2.92 g,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

28.9 mmol) was added. Acetyl chloride (0.64 mL, 0.71 g, 9.00 mmol) was then added dropwise under continuous stirring. The mixture was stirred for 1 d. Water (20 mL) was added slowly and the two-phased mixture was vigourously stirred for 3 h. The solvents were removed in vacuo. The slurry residue was dissolved in water, acidified with dilute HCl (pH 2) and extracted with diethyl ether (4 × 200 mL). The combined organic layers were dried ($Na_2SO_4$) and concentrated under reduced pressure to the oily residue of **4**. Product **4** was recrystallised from acetone in colourless blocks suitable for X-ray structure determination. Yield: 612 mg (2.65 mmol, 53%). M.p. 107–109 °C. $^1$H NMR ($CDCl_3$, 300 MHz, 25 °C): $\delta$ = 1.74 (s, 6 H, $C^5$-$CH_3$), 1.97 (s, 3 H, $CH_3CO$), 2.27 (s, 6 H, $C^3$-$CH_3$), 5.32 (s, 2 H, OCO-$CH_2$-), 5.93 (s, 2 H, $H_{pz}$) ppm. $^{13}$C NMR ($CDCl_3$, 75.5 MHz, 25 °C): $\delta$ = 10.6 ($C^5$-$CH_3$), 13.2 ($C^3$-$CH_3$), 20.4 ($CH_3$-CO), 66.6 ($CH_2$-O), 78.3 ($C_{bridge}$), 108.8 ($C_{pz}$-H), 142.0 ($C^5{}_{pz}$), 147.2 ($C^3{}_{pz}$), 167.9 (COOH), 169.4 ($CH_3CO$) ppm. IR (THF): $\tilde{\nu}$ = 1759 ($CO_2H$), 1718 ($CH_3CO$), 1565 (C=N) cm$^{-1}$. FD-MS: *m*/*z* (%) = 322 (100) [M + H]$^+$, 276 (60) [M + H – $CO_2$H]$^+$, 234 (28) [M + H – $CO_2H$ – $CH_3CO$]$^+$. $C_{15}H_{20}N_4O_4$ (320.35): calcd. **Synthesis of Methyl 2,2-Bis(3,5-dimethylpyrazol-1-yl)acetate (5):** To a solution of Hbdmpza (**1**) (1.00 g, 4.03 mmol) in excess methanol (100 mL), conc. $H_2SO_4$ (0.15 mL, 0.28 g, 2.86 mmol) was added and stirred at ambient temperature for 3 d. The solvent was removed in vacuo and diethyl ether (200 mL) was added to the residue. The organic phase was extracted with a saturated aqueous solution of $NaHCO_3$ and dried with $Na_2SO_4$. The organic layer was concentrated in vacuo to a yellow crystalline powder of **5**. Recrystallisation from petroleum ether/ethyl acetate (3:1) yielded colourless blocks suitable for X-ray structure determination. Yield: 887 mg (3.38 mmol, 84%). M.p. 117–119 °C. $^1$H NMR ($CDCl_3$, 300 MHz, 25 °C): $\delta$ = 2.11 (s, 6 H, $C^5$-$CH_3$), 2.19 (s, 6 H, $C^3$-$CH_3$), 3.89 (s, 3 H, $OCH_3$), 5.85 (s, 2 H, $H_{pz}$), 6.95 (s, 1 H, $H_{bridge}$) ppm. $^{13}$C NMR ($CDCl_3$, 75.5 MHz, 25 °C): $\delta$ = 11.0 ($C^5$-$CH_3$), 13.5 ($C^3$-$CH_3$), 53.4 ($OCH_3$), 73.0 ($C_{bridge}$), 107.6 ($C_{pz}$-H), 141.3 ($C^5{}_{pz}$), 148.5 ($C^3{}_{pz}$), 165.3 (COOH) ppm. IR (THF): $\tilde{\nu}$ = 1771 ($CO_2H$), 1561 (C=N) cm$^{-1}$. FD-MS: *m*/*z* (%) = 263 (100) [M + H]$^+$. $C_{13}H_{18}N_4O_2$ (262.31): calcd. C 59.51, H 6.92, N 21.37; found C 59.88, H 7.20, N 21.11.

**Synthesis of Methyl 2,2-Bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionate (6):** A solution of Mebdmpza (**5**) (0.75 g, 2.86 mmol) in dry THF (100 mL) was treated with LDA (≈ 1.8 M in heptane/THF/ethylbenzene, 1.8 mL, 3.24 mmol) at –80 °C and warmed up to –40 °C over a period of 2 h. After 1 h at –40 °C, paraformaldehyde (0.90 g, 27.0 mmol) was added. The mixture was warmed up to ambient temperature and finally heated under reflux for 60 min and stirred overnight. The solvent was removed in vacuo, the residue was dissolved in water and extracted with diethyl ether (3 × 150 mL). The combined diethyl ether layers were dried ($Na_2SO_4$) and concentrated under reduced pressure. Recrystallisation from hexane/acetone (1:1) yielded **6** as colourless blocks. Yield: 0.63 g (2.16 mmol, 76%). M.p. 116–118 °C. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.69 (s, 6 H, $C^5$-$CH_3$), 2.20 (s, 6 H, $C^3$-$CH_3$), 3.98 (s, 3 H, $OCH_3$), 4.65 (d, $^3J_{H,H}$ = 7.5 Hz, 2 H, $OCH_2$), 5.34 (t, $^3J_{H,H}$ = 7.5 Hz, 1 H, OH), 5.86 (s, 2 H, $H_{pz}$) ppm. $^{13}$C NMR (75.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 11.2 ($C^5$-$CH_3$), 13.9 ($C^3$-$CH_3$), 53.9 ($OCH_3$), 66.7 ($CH_2$-OH), 84.3 ($C_{bridge}$), 108.8 ($C_{pz}$-H), 142.5 ($C^5{}_{pz}$), 148.3 ($C^3{}_{pz}$), 166.3 ($CO_2$R) ppm. IR (THF): $\tilde{\nu}$ = 1762 ($CO_2$Me), 1562 (C=N) cm$^{-1}$. FD-MS: *m*/*z* (%) = 292 (100) [M]$^+$, 234 (12) [M + H –$CO_2$Me]$^+$. $C_{14}H_{20}N_4O_3$ (292.34): calcd. (458.31): calcd. C 47.16, H 4.18, N 12.23; no suitable elemental analysis was obtained.

**Synthesis of [Re(bdmpzap)(CO)$_3$] (10):** To Hbdmpzap (**4**) (247 mg, 0.77 mmol) in dry THF (50 mL), KO*t*Bu (86 mg, 0.77 mmol) was added, and the reaction mixture was stirred at ambient temperature for 30 min. [ReBr(CO)$_5$] (313 mg, 0.77 mmol) was added, and the reaction mixture was heated under reflux and controlled by IR on a regular basis. After 20 h, the reaction was complete, and the solution was filtered. The filtrate was concentrated in vacuo, washed with water (2 × 2 mL) and diethyl ether (2 × 2 mL) and dried in vacuo. Yield: 305 mg (0.52 mmol, 52%). M.p. 233–236 °C. $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.05 (s, 3 H, $CH_3CO$), 2.46 (s, 12 H, $CH_3$), 5.11, 5.73 (AB system, $J_{AB}$ = 9.6 Hz, 2 H, $CH_2O$), 5.98 (br., 1 H, $H_{pz}$), 6.03 (br., 1 H, $H_{pz}$) ppm. $^{13}$C NMR (100.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 15.3 ($CH_3$), 16.4 ($CH_3$), 20.8 ($CH_3$), 61.6 ($CH_2O$), 82.9 ($C_{bridge}$), 111.8 ($C_{pz}$-H), 143.2 ($C_{pz}$), 154.5 ($C_{pz}$), 163.5 ($CO_2$), 169.5 ($O_2CCH_3$), 195.5 (2 × CO), 195.5 (CO) ppm. IR (THF): $\tilde{\nu}$ = 2024 (s, C=O), 1918 (s, C=O), 1894 (s, C=O), 1762 (m, $O_2CCH_3$), 1702 (m, $CO_2^-$) cm$^{-1}$. FD-MS: *m*/*z* (%) = 591 (100) $[M + H]^+$. $C_{18}H_{19}N_4O_7Re$ (589.58): calcd. C 36.67, H 3.25, N 9.50; found C 37.12, H 3.34, N 9.14.

**Solid Phase Fixation of Methyl 2,2-Bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionate (P-6):** A suspension of a chloromethylated resin [0.45 g, loading 1.1 mmol g$^{-1}$, 0.50 equiv.], Mebdmpzhp (**6**) (439 mg, 1.5 mmol), KO*t*Bu (112 mg, 1.0 mmol), 18-crown-6 (264 mg, 1.0 mmol) and CsBr (212 mg, 1.0 mmol) in dry THF was heated under reflux for 48 h under a nitrogen atmosphere. The suspension was filtered through a sintered glass filter with suction and washed thoroughly with THF, methanol and water and the remaining polymer was dried in vacuo. The content of ligand on the polymer is determined by elemental analysis to 0.23 mmol g$^{-1}$.

**Ester Hydrolysis of Methyl 2,2-Bis(3,5-dimethylpyrazol-1-yl)-3-hydroxypropionate on Solid Phase – Polymer P-3:** To a suspension of **P-6** (0.45 g) and NaOH (40 mg, 1.0 mmol) in THF (50 mL), excess water (1 mL, 1 g, 55.5 mmol) was added, and the suspension was heated under reflux for 12 h. The suspension was filtered through a sintered glass filter with suction and washed thoroughly with THF, water and again THF and the remaining polymer **P-3** with the deprotonated and solid phase bound ligand **3** was dried in vacuo.

**Polymer Bound Rhenium Tricarbonyl Complexes:** A suspension of polymer **P-3** (90 mg) in THF and [Re(CO)$_5$Br] (0.25 mmol, 102 mg) was heated under reflux for 48 h, filtered through a sintered glass filter with suction and washed thoroughly with THF, water, methanol and dichloromethane. IR (THF): $\tilde{\nu}$ = 2022 (CO), 1915 (CO), 1890 (CO) cm$^{-1}$.

**Solid Phase Fixation of 2,2-Bis(3,5-dimethylpyrazol-1-yl)pent-4-enoic Acid (S-2):** A suspension of mercaptopropyl silica [0.5 g, loading 0.98 mmol g$^{-1}$, 0.49 equiv.], Hbdmpzpen (**2**) (141 mg, 0.49 mmol) and azobisisobutyronitrile (10 mg, 0.06 mmol) in dry chloroform was heated at reflux for 48 h under a nitrogen atmosphere. The suspension was filtered through a sintered glass filter with suction and washed thoroughly with dichloromethane, toluene and methanol and the remaining silica was dried in vacuo. The procedure was repeated once. The content of ligand on the silica is determined by elemental analysis to 0.17 mmol g$^{-1}$.

**Silica Bound Manganese Tricarbonyl Complexes:** A suspension of mercaptopropyl silica [0.20 g, loading 0.98 mmol g$^{-1}$, 0.20 equiv.],

[Mn(bdmpzpen)$(CO)_3$] (**2**) (85 mg, 0.20 mmol) and azobisisobutyronitrile (10 mg, 0.06 mmol) in dry chloroform was heated at reflux for 8 h under a nitrogen atmosphere. The suspension was filtered through a sintered glass filter with suction and washed thoroughly with dichloromethane, THF, toluene and methanol and the remaining yellow silica was dried in vacuo. The content of ligand on the silica is determined by elemental analysis to 0.036 mmol $g^{-1}$. A longer reaction time of 48 h leads to a content of 0.063 mmol $g^{-1}$. IR (nujol): $\tilde{\nu}$ = 2039 (CO), 1948 (CO), 1923 (CO) $cm^{-1}$.

**Silica Bound Rhenium Tricarbonyl Complexes:** A suspension of mercaptopropyl silica [0.20 g, loading 0.98 mmol $g^{-1}$, 0.20 equiv.], [Re(bdmpzpen)$(CO)_3$] (**9**) (112 mg, 0.20 mmol) and azobisisobutyronitrile (10 mg, 0.06 mmol) in dry chloroform was heated under reflux for 8 h under a nitrogen atmosphere. The suspension was filtered through a sintered glass filter with suction and washed thoroughly with dichloromethane, THF, toluene and methanol and the remaining silica was dried in vacuo. The content of ligand on the silica is determined by elemental analysis to 0.041 mmol $g^{-1}$. A longer reaction time of 48 h leads to a content of 0.078 mmol $g^{-1}$. IR (nujol): $\tilde{\nu}$ = 2027 (CO), 1920 (CO), 1905 (CO) $cm^{-1}$.

**X-ray Structure Determinations:** Single crystals of **2**, **3**, **4**, **7** and **8** were mounted with Paratone-N or glue on a glass fibre. A modified Siemens P4-Diffractometer and a STOE IPDS II diffractometer were used for data collection (graphite monochromator, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å). The structures were solved by using direct methods and refined with full-matrix least-squares against $F^2$ {Siemens SHELX-97}.[10] A weighting scheme was applied in the last steps of the refinement with $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ and $P = [2F_c^2 + \max(F_o^2,0)]/3$. Most hydrogen atoms were included in their calculated positions and refined in a riding model. The protons of carboxylic acids (**2**–**4**) were found and their coordinates were refined freely. All details and parameters of the measurements are summarised in Table 2. The structure pictures were prepared with the program Diamond 2.1e.[11] CCDC-232648 (for **2**), CCDC-289443 (for **3**), CCDC-619381 (for **4**), CCDC-289442 (for **7**) and CCDC-619380 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Chemical and Structural Features of $NMe_2Et$ Adducts of the Silanimines $Me_2Si{=}NSi\mathit{t}Bu_3$ and $\mathit{t}Bu_2Si{=}NSiCl\mathit{t}Bu_2$

**Hans-Wolfram Lerner,*[a] Michael Bolte,[a] Klaus Schurz,[b] Nils Wiberg,[b] Gerhard Baum,[c] Dieter Fenske,[c] Jan W. Bats,[d] and Matthias Wagner[a]**

**Keywords:** Silanimines / Amines / Donor adduct / Wittig reaction / Stevens rearrangement

In contrast to $\mathit{t}Bu_2SiN(Li)SiX\mathit{t}Bu_2$ (X = Cl, *t*Bu), the silyl amide $Me_2SiClN(Li)Si\mathit{t}Bu_3$ is unstable towards LiCl elimination, which means that the silanimine donor adduct $Me_2Si{=}NSi\mathit{t}Bu_3{\cdot}NMe_2Et$ can be synthesized in high yield from the reaction of $Me_2SiClN(H)Si\mathit{t}Bu_3$ with *n*BuLi in the presence of $NMe_2Et$. The silanimine adduct $\mathit{t}Bu_2Si{=}NSiCl\mathit{t}Bu_2{\cdot}NMe_2Et$, with bulky *t*Bu substituents at the unsaturated Si center, is accessible by treating the donor-free silanimine $\mathit{t}Bu_2Si{=}NSiCl\mathit{t}Bu_2$ with $NMe_2Et$. X-ray quality crystals of the silanimine amine adduct $Me_2Si{=}NSi\mathit{t}Bu_3{\cdot}NMe_2Et$ (monoclinic, $P2_1/n$) were grown from pentane at –25 °C. During thermolysis of the adducts $Me_2Si{=}NSi\mathit{t}Bu_3{\cdot}NMe_2Et$ and $\mathit{t}Bu_2Si{=}NSiCl\mathit{t}Bu_2{\cdot}NMe_2Et$ in $NMe_2Et$ as solvent a Stevens rearrangement takes place to produce $EtN(Me)CH_2SiMe_2N(H)Si\mathit{t}Bu_3$ and $EtN(Me)CH[Me_2SiN(H)Si\mathit{t}Bu_3]_2$, and $EtN(Me)CH_2Si\mathit{t}Bu_2N(H)SiCl\mathit{t}Bu_2$, respectively. In contrast, the thermolysis of $Me_2Si{=}NSi\mathit{t}Bu_3{\cdot}NMe_2Et$ in vacuo gives the silanimine dimer $(Me_2SiNSi\mathit{t}Bu_3)_2$ (monoclinic, $P2_1/n$) in 80 % yield. The benzophenone imine $Ph_2C{=}NSi\mathit{t}Bu_3$ (triclinic, $P\bar{1}$) was obtained from the Wittig-like reaction of $Me_2Si{=}N{-}Si\mathit{t}Bu_3$ with $Ph_2CO$.

## Introduction

Ab initio calculations have shown that the silanimine $H_2Si{=}NSiH_3$ possesses an almost linear Si–N–Si skeleton with a short Si=N double bond and a short Si–N single bond.[1] Moreover, these calculations reveal a negative charge of 1.71 on the N center of $H_2Si{=}NSiH_3$. It is interesting to note that in the solid state the stable, substituted silanimine $\mathit{t}Bu_2Si{=}N{-}Si\mathit{t}Bu_3$, which contains bulky *t*Bu groups,[2] features nearly the same Si=NSi skeleton as that calculated for $H_2Si{=}NSiH_3$. Obviously only electronic effects, namely the difference in electronegativity between Si and N, determine the molecular structure of this type of silanimine (Scheme 1).

Silanimines are highly reactive compounds therefore their syntheses should be carried out under mild conditions. We have found that at low temperature in the weakly polar solvent $Bu_2O$ the reaction of the silyl azide $\mathit{t}Bu_2SiClN_3$ with the silanides $\mathit{t}Bu_3SiNa$ and $\mathit{t}Bu_2PhSiNa$, respectively, in a 1:1 stoichiometry, leads cleanly to the silanimines $\mathit{t}Bu_2Si{=}NSi\mathit{t}Bu_3$ [**1a**(*t*Bu)] and $\mathit{t}Bu_2Si{=}NSiPh\mathit{t}Bu_2$ [**1a**(Ph)].[2,3] In contrast, when $\mathit{t}Bu_2ClSiN_3$ is treated with $\mathit{t}Bu_3SiNa$ in the polar solvent tetrahydrofuran, the sodium amide $\mathit{t}Bu_2Si{-}ClN(Na)Si\mathit{t}Bu_3$ is formed rather than the silanimine **1a**(*t*Bu).[4] As reported earlier, LiCl elimination of silyl amides can also be carried out at higher temperatures in vacuo to give silanimines.[5] As we noted previously, the silanimine $\mathit{t}Bu_2Si{=}NSiCl\mathit{t}Bu_2$ [**1a**(Cl)] can be synthesized by a [3+2] cycloreversion reaction.[6] Surprisingly, in the thermolysis of the silatetrazoline **2**(Cl) the silanimine **1a**(Cl) and the silyl azide $\mathit{t}Bu_3SiN_3$ are produced, as shown in Scheme 2.[6,7]

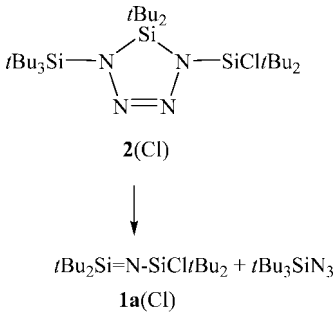


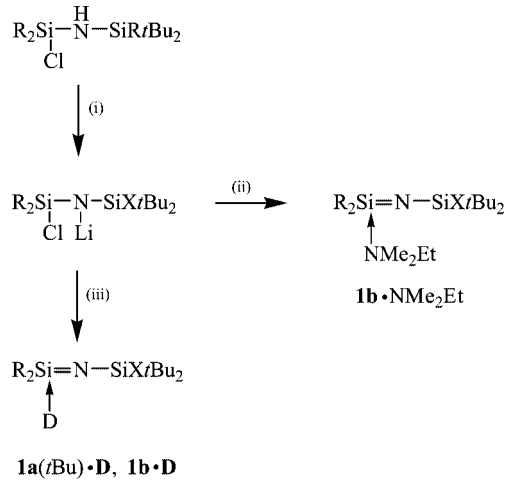
Scheme 2.

In this paper, the syntheses and thermolysis reactions of the silanamine aminates Me$_2$Si=NSi*t*Bu$_3$·NMe$_2$Et and *t*Bu$_2$Si=NSiCl*t*Bu$_2$·NMe$_2$Et are described. We also report the crystal structures of the silanimine aminate Me$_2$Si=NSi*t*Bu$_3$·NMe$_2$Et, the silanimine dimer (Me$_2$SiN-Si*t*Bu$_3$)$_2$, the benzophenone imine Ph$_2$C=NSi*t*Bu$_3$, and the silylamine *t*Bu$_2$SiClN(H)Si*t*Bu$_3$.

## Results and Discussion

### Syntheses

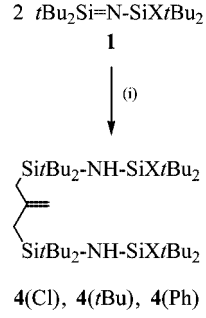
The silyl amides *t*Bu$_2$SiClN(Li)SiX*t*Bu$_2$ (X = Cl, *t*Bu) can be cleanly prepared from the precursor silylamines *t*Bu$_2$SiClN(H)SiX*t*Bu$_2$ (X = Cl, *t*Bu) [**3**(Cl), **3**(*t*Bu)] and alkyllithium reagents like MeLi or *n*BuLi. The NMR spectra of *t*Bu$_2$SiClN(Li)SiX*t*Bu$_2$ (X = Cl, *t*Bu) reveal that elimination of LiCl does not take place in the presence of thf or Et$_2$O at ambient or lower temperatures, whereas the silyl amide Me$_2$SiClN(Li)Si*t*Bu$_3$ eliminates LiCl at low temperature in Et$_2$O. An important factor influencing LiCl elimination of these silyl amides appears to be the degree of steric crowding around the unsaturated silicon center. In earlier reports we described the synthesis of several donor adducts of the silanimines **1a**(*t*Bu) and Me$_2$Si=NSi*t*Bu$_3$ (**1b**),[8,9] and we found that donor adducts of the silanimines **1a**(*t*Bu) and **1b** can be generated by reaction of the silyl amides *t*Bu$_2$SiClN(Li)Si*t*Bu$_3$ and Me$_2$SiClN(Li)Si*t*Bu$_3$, respectively, with CF$_3$SO$_3$SiMe$_3$.[8,9] In this paper we describe a synthesis that does not require CF$_3$SO$_3$SiMe$_3$ by which the silanimine aminate **1b**·NMe$_2$Et can be produced in large amounts. The silanimine amine adduct **1b**·NMe$_2$Et was synthesized from the reaction of Me$_2$SiClN(H)Si*t*Bu$_3$ with *n*BuLi in the presence of NMe$_2$Et at –78 °C in Et$_2$O. X-ray quality crystals of **1b**·NMe$_2$Et (monoclinic, $P2_1/n$) were grown from a pentane solution at –25 °C (Scheme 3). The adduct of silanimine **1a**(Cl) with NMe$_2$Et, which possesses a bulky *t*Bu substituent at the unsaturated Si center, is accessible by treating the donor-free silanimine **1a**(Cl) with NMe$_2$Et.



Scheme 3. (i) +RLi, –RH; (ii) +NMe$_2$Et, –LiCl (R = Me, X = *t*Bu); (iii) +CF$_3$SO$_3$SiMe$_3$, +D (D = thf, Et$_2$O, NEt$_3$), –Me$_3$SiCl, –CF$_3$SO$_3$Li (R = Me, *t*Bu; X = *t*Bu).

### Reactivity of Me$_2$Si=NSi*t*Bu$_3$·NMe$_2$Et and *t*Bu$_2$Si=NSiCl*t*Bu$_2$·NMe$_2$Et

Thermolysis of the donor-free silanimines **1a**(Cl), **1a**(*t*Bu), and **1a**(Ph) in [D$_6$]benzene at ambient temperature gave the compounds **4**(Cl), **4**(*t*Bu), and **4**(Ph), respectively, as isolable products (Scheme 4).[6,10] The formation of these products can be explained by an ene reaction of isobutene with two molecules of the silanimine. Obviously, the *t*Bu-substituted silanimines **1a**(Cl), **1a**(*t*Bu), and **1a**(Ph) are the source of isobutene at ambient temperature. Thus, these silanimines undergo a β-elimination reaction to form isobutene, which reacts twice with the undegraded silanimines to give the corresponding ene reaction products.

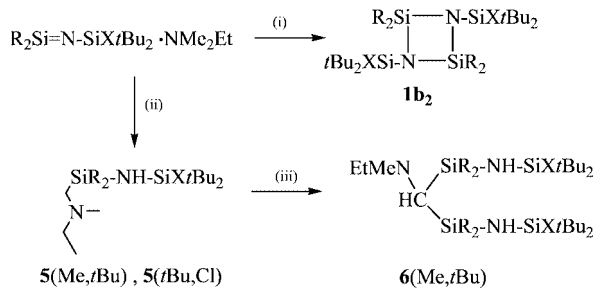


Scheme 4. (i) +CH$_2$=C(CH$_3$)$_2$ (X = Cl, *t*Bu, Ph).

In contrast to the degradation reaction of donor-free silanimines **1a**(Cl), **1a**(*t*Bu), and **1a**(Ph), during thermolysis of the silanimine amine adducts **1a**(Cl)·NMe$_2$Et and **1b**·NMe$_2$Et in dimethylethylamine as solvent a Stevens rearrangement takes place to produce EtN(Me)CH$_2$Si-Me$_2$N(H)Si*t*Bu$_3$ [**5**(Me,*t*Bu)] and EtN(Me)CH[Me$_2$SiN(H)-Si*t*Bu$_3$]$_2$ [**6**(Me,*t*Bu)], and EtN(Me)CH$_2$Si*t*Bu$_2$N(H)-SiCl*t*Bu$_2$ [**5**(*t*Bu,Cl)], respectively. A similar reaction was observed in the thermolysis of the pyridine adduct of **1a**(Ph).[11] It is interesting to note that the thermolysis reaction of **1b**·NMe$_2$Et leads to two products [80% **5**(Me,*t*Bu) and 20% **6**(Me,*t*Bu) in NMe$_2$Et; 10% **5**(Me,*t*Bu) and 90%

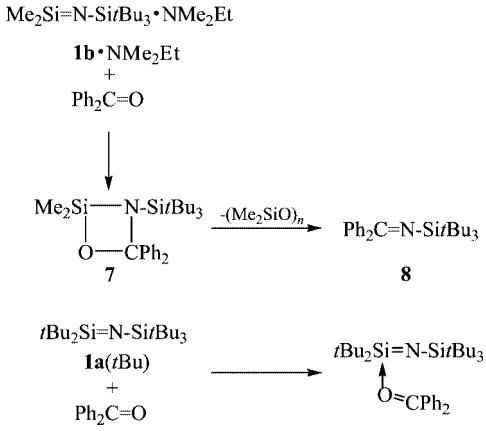
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**6**(Me,*t*Bu) in [$D_6$]benzene; Scheme 5]. The thermolysis of **1b**·$NMe_2Et$ in vacuo gives the silanimine dimer ($Me_2SiN$-$SitBu_3$)$_2$ (**1b$_2$**) in 80% yield. The silylamines **5**(Me,*t*Bu) and **6**(Me,*t*Bu) were produced as side products in this reaction, as shown in Scheme 5. The silanimine dimer **1b$_2$** was characterized by X-ray crystallography (see below).



Scheme 5. (i) in vacuo (R = Me, X = *t*Bu); (ii) R = Me, X = *t*Bu; R = *t*Bu, X = Cl; (iii) +$Me_2SiNSitBu_3$ (R = Me, X = *t*Bu).

Generally, the reactivity of the silanimine–$NMe_2Et$ adducts of **1a**(Cl) and **1b** resemble those of the corresponding donor-free silanimines. In earlier reports we discussed the reactivity of the silanimines **1a**(Cl) and **1b** in detail.[6,8] In contrast to the reaction of **1a**(*t*Bu) with benzophenone, in which a stable silanimine adduct is formed due to steric hindrance,[12] the silanimine **1b**·$NMe_2Et$ reacts with benzophenone to produce benzophenone imine **8**, via the oxaazasilacyclobutane **7**, by a Wittig-like reaction, as depicted in Scheme 6. The benzophenone imine **8** was obtained in 53% yield. X-ray quality crystals of this compound were obtained by sublimation at 105 °C/0.001 mbar.



Scheme 6.

## NMR Spectra

When considering the $^{29}Si$ NMR spectra of the silanimines of the type $R_2Si(1)=NSi(2)R_3$ and their donor adducts, certain general trends can be observed. As is to be expected for the unsaturated Si centers of silanimines, the $^{29}Si$ signals of these nuclei are shifted extremely downfield whereas the silanimine donor adducts show signals for the unsaturated Si center that are shifted upfield, as listed in Table 1. Due to anisotropy effects the signals of both Si atoms of $R_2Si(1)=NSi(2)R_3$ are shifted upfield. The linearity of the silanimine $R_2Si(1)=NSi(2)R_3$ skeleton [Si(1)–N–Si(2) angle] is therefore recognizable by the $^{29}Si$ NMR shift of the Si(2) center. If a strong donor is coordinated to the silanimine the skeleton deviates more from linearity than if a weak one is bonded. In this case, the signal of the Si(2) center will be shifted further downfield than the Si(2) signal of a weak adduct. Therefore, the strength of a silanimine donor can be measured by the $^{29}Si$ NMR shift of Si(2) of these adducts. In contrast to **1b**, the silanimines **1a**(Cl) and **1a**(*t*Bu) form weaker adducts with $NMe_2Et$ than with thf.[6,9] As shown in Table 1, this trend can also be seen in their $^{29}Si$ NMR spectra.

Table 1. $^{29}Si$ NMR shifts (in $C_6D_6$ if not indicated otherwise) of silanimines $R_2Si(1)=NSi(2)R_3$.

| | $\delta^{29}$Si(1) | $\delta^{29}$Si(2) | Ref. |
|---|---|---|---|
| $tBu_2Si(1)=NSi(2)tBu_3$ | 78.4 | –7.7 | [2] |
| $tBu_2Si(1)=NSi(2)PhtBu_2$ | 81.8 | –13.1 | [3] |
| $tBu_2Si(1)=NSi(2)CltBu_2$ | 3.0 | 3.0 | [6] |
| $Me_2Si(1)=NSi(2)tBu_3$·$NMe_2Et$ | –8.9 | –10.3 | – |
| $tBu_2Si(1)=NSi(2)CltBu_2$·$NMe_2Et$ | –3.4 | –6.4 | – |
| $Me_2Si(1)=NSi(2)tBu_3$·THF | –4.4 | –11.1 | [2] |
| $tBu_2Si(1)=NSi(2)tBu_3$·THF | 1.1 | –14.7 | [2] |
| $tBu_2Si(1)=NSi(2)CltBu_2$·THF | 2.9 | –5.2 | [6] |
| $Me_2Si(1)=NSi(2)tBu_3$·$Et_2O$ | –1.5[a] | –11.1[a] | [8] |
| $tBu_2Si(1)=NSi(2)CltBu_2$·$Et_2O$ | –0.2[a] | –6.5[a] | [6] |

[a] Recorded in $Et_2O$.

It is interesting to note that in contrast to the NMR spectra of the donor-free silanimine **1a**(Cl),[6] which reveal only one signal set for both silyl groups, the NMR spectra of its $NMe_2Et$ complex show signals that can be assigned to two different silyl groups.

## Structure of $Me_2Si=NSitBu_3$·$NMe_2Et$

Figure 1 shows the molecular structure of the silanimine amine adduct **1b**·$NMe_2Et$ (monoclinic, $P2_1/n$); selected bond lengths and angles are listed in the figure caption.

As shown in Table 2, the silanimine amine adduct **1b**·$NMe_2Et$ has an Si–N–Si angle smaller than 180° and smaller than those in the donor-free silanimines **1a**(*t*Bu), and **1a**(Ph) and in the corresponding thf adduct **1b**·thf [**1a**(*t*Bu): Si–N–Si 177.8(2)°; **1a**(Ph): Si–N–Si 168.34(16)° and 172.95(18)°; **1b**·thf: Si–N–Si 161.0(6)° and 161.5(6)°; **1b**·$NMe_2Et$: Si–N–Si 156.44(10)°]. The Si=N double bond in **1b**·$NMe_2Et$ [1.6036(13) Å] is somewhat longer than those of the donor-free silanimines **1a**(*t*Bu) and **1a**(Ph) and the corresponding thf adduct **1b**·thf [**1a**(*t*Bu): Si=N 1.568(3) Å; **1a**(Ph): Si=N 1.573(3) Å; **1b**·thf: Si=N 1.574(10) and 1.588(9) Å]. As depicted in Table 2, the N–Si single bonds in the silanimines **1a**(*t*Bu), **1a**(Ph), and in the silanimines adducts **1b**·$NMe_2Et$ and **1b**·thf, however, are remarkably shorter than those found in related supersilylated nitrogen compounds [e.g. **1b$_2$**, **3**(*t*Bu), and **8**; Table 3]. Due to the higher Lewis acidity of silanimines in comparison to that of silenes, the distance between the unsaturated Si center

ent temperature. It crystallizes in the monoclinic space group $P2_1/n$. As depicted in Figure 2, the central core of **1b$_2$** is a planar four-membered ring. The corners of this four-membered ring are alternately occupied by two Si and two N atoms [Si–N–Si (av) 88.49(9)°; N–Si–N 91.51(10)°]. The Si–N bond lengths of **1b$_2$** are longer than those of the silanimines **1a**(*t*Bu), **1a**(Ph), **1b**·thf, and **1b**·$NMe_2Et$, and those of the silylamine **3**(*t*Bu) (see Tables 2 and 3).

### Structure of the Benzophenone Imine $Ph_2C{=}NSitBu_3$

X-ray quality crystals of the benzophenone imine **8** were obtained by sublimation at 105 °C/0.001 mbar. It crystallizes in the triclinic space group $P\bar{1}$. It is interesting to note that the solid-state structure features three independent molecules in the asymmetric unit. As depicted in Figure 3, the C=N–Si skeleton deviates much more from linearity [C–N–Si 154.6(3)°, 154.9(3)°, and 153.5(3)°] than the Si=N–Si skeleton of **1a**(*t*Bu). The structure of **8** contains a C=N double bond [1.253(4), 1.263(5), and 1.261(5) Å] and, in comparison with the silanimine **1a**(*t*Bu), a longer Si–N single bond, as shown in Tables 2 and 3 [**1a**(*t*Bu): N–Si*t*Bu$_3$ 1.695(3) Å; **8**: N–Si*t*Bu$_3$ 1.722(3), 1.720(3), and 1.721(4) Å; Figure 3].

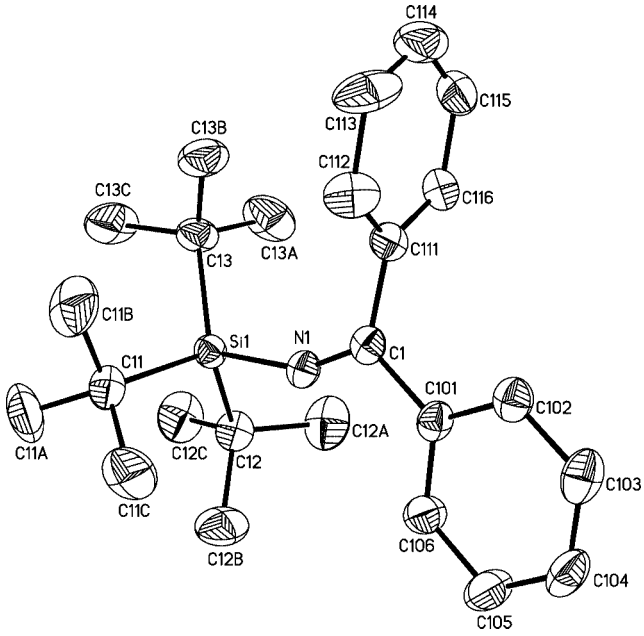

Figure 3. Thermal ellipsoid plot of one of three independent molecules in the asymmetric unit of $Ph_2C{=}NSitBu_3$ (**8**) showing the atom numbering scheme. The displacement ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: Si(1)–N(1) 1.722(3), Si(1)–C(11) 1.919(4), Si(1)–C(13) 1.922(4), Si(1)–C(12) 1.929(4), N(1)–C(1) 1.253(4), C(1)–C(101) 1.510(5), C(1)–C(111) 1.512(5); N(1)–Si(1)–C(11) 102.30(18), N(1)–Si(1)–C(13) 116.02(18), C(11)–Si(1)–C(13) 112.1(2), N(1)–Si(1)–C(12) 101.14(18), C(11)–Si(1)–C(12) 113.6(2), C(13)–Si(1)–C(12) 111.1(2), C(1)–N(1)–Si(1) 154.6(3), N(1)–C(1)–C(101) 119.8(4), N(1)–C(1)–C(111) 123.9(4), C(101)–C(1)–C(111) 116.2(4).

### Structure of the Silylamine $tBu_2SiClN(H)Sitbu_3$

The solid-state structure of the silylamine $tBu_2SiClN(H)$-Si*t*Bu$_3$ [**3**(*t*Bu)] (triclinic, $P\bar{1}$) shows two symmetrically independent molecules in the unit cell. As shown in Table 3, **3**(*t*Bu) possesses Si–N–Si angles of 164.2(5)° and 158.5(5)°, respectively, which can be compared to the values for **1a**(*t*Bu) [177.8(2)°], **1a**(Ph) [172.95(18)°], **1b**·thf [161.0(6)° and 161.5(6)°], and **1b**·$NMe_2Et$ [156.44(10)°]. The Si(Cl)–N bond [av. 1.694(7) Å] in **3**(*t*Bu) lies in the range of the N–Si*t*Bu$_3$ bond lengths for the supersilyl-substituted silanimines **1a**(*t*Bu), **1a**(Ph), **1b**·thf, and **1b**·$NMe_2Et$ but is shorter than the Si–N single bonds of the silanimine dimer **1b$_2$** and the benzophenone imine **8** (Table 3). On the other hand, the length of the N–Si*t*Bu$_3$ bond in **3**(*t*Bu) is similar to those found in the silanimine dimer **1b$_2$** and the benzophenone imine **8**. Both molecules of **3**(*t*Bu) show large thermal displacements, resulting in distorted structural parameters and a large difference density. The molecular structure of **3**(*t*Bu) shows that the N–H groups are extremely shielded by the *t*Bu groups and are not involved in hydrogen bonding (Figure 4 and Table 4).

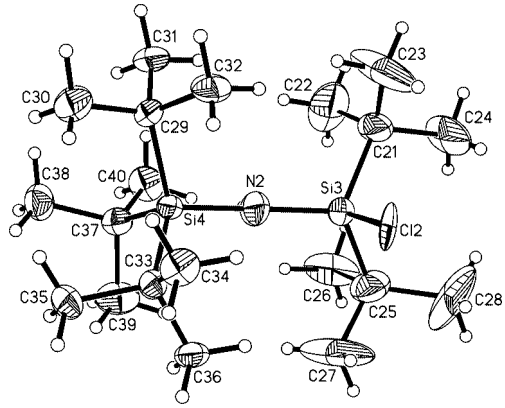

Figure 4. Thermal ellipsoid plot of one of the two independent molecules in the asymmetric unit of the silylamine $tBu_2SiClN(H)$ Si*t*Bu$_3$ [**3**(*t*Bu)]. The displacement ellipsoids are drawn at the 30% probability level. Selected bond lengths [Å] and angles [°]: Si(4)–N(2) 1.733(6), Si(4)–C(29) 1.918(7), Si(4)–C(33) 1.925(7), Si(4)–C(37) 1.935(8), Cl(2)–Si(3) 2.293(3) Si(3)–N(2) 1.679(7), Si(3)–C(25) 1.851(9), Si(3)–C(21) 1.908(9); Si(3)–N(2)–Si(4) 164.2(5), N(2)–Si(4)–C(29) 109.5(3), N(2)–Si(4)–C(33) 111.2(3), C(29)–Si(4)–C(33) 110.8(3), N(2)–Si(4)–C(37) 102.8(4), C(29)–Si(4)–C(37) 110.5(3), C(33)–Si(4)–C(37) 111.9(3), N(2)–Si(3)–C(25) 114.6(4), N(2)–Si(3)–C(21) 112.3(4), C(25)–Si(3)–C(21) 114.3(5), N(2)–Si(3)–Cl(2) 101.9(3), C(25)–Si(3)–Cl(2) 105.1(4), C(21)–Si(3)–Cl(2) 107.3(5).

## Conclusions

In summary, we have shown that in contrast to $tBu_2SiN$-(Li)Si*X*t*Bu*$_2$ (X = Cl, *t*Bu), the silyl amide $Me_2SiClN(Li)$-Si*t*Bu$_3$ is unstable towards LiCl elimination, which means that the silanimine aminate **1b**·$NMe_2Et$ can be synthesized in high yield from the reaction of $Me_2SiClN(H)Sitbu_3$ with *n*BuLi in the presence of $NMe_2Et$. The silanimine adduct **1a(Cl)·NMe$_2$Et**, which possesses the bulky *t*Bu substituent

on the unsaturated Si center, is accessible by treating the donor-free silanimine **1a**(Cl) with $NMe_2Et$.

In contrast to the degradation reaction of the donor-free silanimines **1a**(Cl), **1a**(*t*Bu), and **1a**(Ph), a Stevens rearrangement takes place in the thermolysis of the silanimine amine adducts **1a**(Cl)·$NMe_2Et$ and **1b**·$NMe_2Et$ in dimethylethylamine to produce $EtN(Me)CH_2SiMe_2N(H)SitBu_3$ and $EtN(Me)CH[Me_2SiN(H)SitBu_3]_2$, and $EtN(Me)CH_2Si$-$tBu_2N(H)SiCltBu_2$, respectively. The thermolysis of **1b**·$NMe_2Et$ in vacuo gives the silanimine dimer **1b$_2$** in 80% yield. In contrast to the reaction of **1a**(*t*Bu) with benzophenone, in which a stable silanimine adduct is formed, the silanimine amine complex **1b**·$NMe_2Et$ reacts with benzophenone to produce benzophenone imine **8**, via oxaazasilacyclobutane **7**, by a Wittig-like reaction. Due to the anisotropy effect the $^{29}$Si NMR spectra of silanimines of the type $R_2Si(1){=}NSi(2)R_3$ reveal upfield-shifted signals for both Si nuclei, therefore the linearity of the silanimine skeleton can be determined from the $^{29}$Si shift of the Si(2) center.

## Experimental Section

**General Remarks:** All experiments were carried out under dry nitrogen or argon with strict exclusion of air and moisture using standard Schlenk techniques. $tBu_2Si{=}NSiCltBu_2$,[6] $tBu_2SiFH$,[20] $tBu_2SiClH$,[20] and $Me_2SiClN(H)SitBu_3$[8] were prepared according to literature procedures. All other starting materials were purchased from commercial sources and used without further purification. The solvents were distilled from sodium/benzophenone (benzene, toluene, tetrahydrofuran, diethyl ether) or Na/Pb alloy (pentane, hexane, heptane) prior to use. $C_6D_6$ was dried with molecular sieves and stored under dry nitrogen. The NMR spectra were recorded with a Jeol FX 90, a Jeol GSX 270, a Bruker AM 250, a Bruker DPX 250, or a Bruker Avance 400 spectrometer. The $^{29}$Si NMR spectra were recorded using the INEPT pulse sequence with empirically optimized parameters for polarization transfer from the *t*Bu substituents.

**Synthesis of $tBu_2SiClN(H)SitBu_3$ [3(*t*Bu)]:** This compound was prepared according to a literature procedure.[4] X-ray quality crystals of **3**(*t*Bu) were grown from benzene at ambient temperature. Selected data: thermal decomposition of **3**(*t*Bu) occurs at 113 °C. $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 1.19 (s, 18 H, $tBu_2SiCl$), 1.21 (s, 27 H, $tBu_3Si$) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$, internal TMS): $\delta$ = 23.6 (3 C, $CMe_3$), 24.5 (2 C, $CMe_3$), 29.3 (6 C, $CMe_3$), 31.3 (9 C, $CMe_3$) ppm. $^{29}Si\{^1H\}$ NMR ($C_6D_6$, external TMS): $\delta$ = 8.4 ($SitBu_3$), 16.0 ($SiCltBu_3$) ppm. $C_{20}H_{46}ClNSi$ (392.22): calcd. C 61.25, H 11.82, N 3.57; found C 62.02, H 12.05, N 3.18. EI MS: *m*/*z* (%) 334 (100) $[M - tBu]^+$.

**Synthesis of $tBu_2Si(H)NH_2$:** $tBu_2SiClH$ (10.05 g, 56.2 mmol) was added to 10 mL of liquid $NH_3$ at –60 °C and stirred for 6 h. After heating to room temperature the reaction product was distilled at 93 °C/100 Torr: Yield: 5.72 g (68%). $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 0.97 (s, 18 H, $tBu_2Si$), 4.03 (br., HSi) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$, internal TMS): $\delta$ = 18.9 ($CMe_3$), 27.7 ($CMe_3$) ppm. $^{29}Si\{^1H\}$ NMR ($C_6D_6$, external TMS): $\delta$ = 7.1 ppm ($SitBu_2$). $C_8H_{21}NSi$ (159.35): calcd. C 60.30, H 13.28, N 8.78; found C 59.13, H 13.14, N 8.02. EI MS: *m*/*z* (%) 159 (13) $[M]^+$, 102 (100) $[M - tBu]^+$.

**Synthesis of $tBu_2Si(H)N(H)SiHtBu_2$:** A mixture of $LiNH_2$ (4.60 g, 200 mmol) and $tBu_2SiFH$ (16.20 g, 100 mmol) in tetrahydrofuran (100 mL) was refluxed for 24 h. After addition of methanol

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(40 mL), all volatile compounds were removed in vacuo and the residue was extracted into 150 mL of pentane. After filtration, the solvent was removed in vacuo to give $t$Bu$_2$Si(H)N(H)SiH$t$Bu$_2$ as a colorless oil: Yield: 10.93 g (72%). B.p. 58 °C/0.01 mbar. $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 1.07 (s, 36 H, $t$Bu$_2$Si), 4.23 (d, HSi) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 20.6 (*C*Me$_3$), 28.5 (C*Me$_3$*) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = 7.0 ppm (Si$t$Bu$_2$). $C_{16}H_{39}NSi_2$ (301.67): calcd. C 63.70, H 13.03, N 4.64; found C 63.04, H 12.95, N 4.72. EI MS: *m*/*z* (%) 301 (5) [M]$^+$, 244 (100) [M – $t$Bu]$^+$.

***Note:*** $t$Bu$_2$Si(H)N(H)SiH$t$Bu$_2$ can also be synthesized from $t$Bu$_2$Si(H)NHLi and $t$Bu$_2$SiFH in tetrahydrofuran by heating.

**Synthesis of $t$Bu$_2$SiClN(H)SiCl$t$Bu$_2$ [3(Cl)]:** A mixture of *N*-chlorosuccinimide (23.79 g, 178.1 mmol) and $t$Bu$_2$Si(H)N(H)SiH$t$Bu$_2$ (9.775 g, 32.4 mmol) in $CCl_4$ (75 mL) was refluxed for 48 h. After filtration, the solvent was removed in vacuo and the obtained solid reaction product was sublimed at 60 °C/10$^{-4}$ Torr: Yield: 9.36 g (80%). $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 1.12 (s, 36 H, $t$Bu$_2$Si) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 23.4 (*C*Me$_3$), 28.1 (C*Me$_3$*) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = 17.9 ppm (Si$t$Bu$_2$). $C_{16}H_{37}Cl_2NSi_2$ (370.56): calcd. C 51.86, H 10.06, N 3.78; found C 50.74, H 9.89, N 3.42. EI MS: *m*/*z* (%) 369 (1) [M]$^+$, 312 (100) [M – $t$Bu]$^+$.

**Synthesis of the Silanimine Adduct $t$Bu$_2$Si=NSiCl$t$Bu$_2$·NMe$_2$Et [1a(Cl)·NMe$_2$Et]:** NMe$_2$Et (2 mL) was added to a solution of $t$Bu$_2$Si=NSiCl$t$Bu$_2$ (0.8 mmol) in 5 mL of benzene. After removing all volatile compounds in vacuo **1a**(Cl)·NMe$_2$Et was obtained as a colorless solid. $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 1.18 (s, 18 H, $t$Bu$_2$SiCl), 1.46 (s, 18 H, $t$Bu$_2$Si), 0.63 (t, $^3J$ = 7.2 Hz, 3 H, CH$_3$), 2.89 (q, $^3J$ = 7.2 Hz, 2 H, NCH$_2$), 2.11 (s, 6 H, NMe$_2$) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 9.7 (CH$_3$), 25.3 (*C*Me$_3$), 25.7 (*C*Me$_3$), 30.3 (C*Me$_3$*), 31.8 (C*Me$_3$*), 44.8 (NCH$_2$), 52.9 (NMe$_2$) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = –6.4 (SiCl$t$Bu$_2$), –3.4 (Si$t$Bu$_2$) ppm.

**Synthesis of the Silanimine Adduct Me$_2$Si=NSi$t$Bu$_3$·NMe$_2$Et (1b·NMe$_2$Et):** *n*BuLi (7.89 mmol) in hexane (5.1 mL) was added to a solution of Me$_2$SiClN(H)Si$t$Bu$_3$ (2.43 g, 7.89 mmol) and 10 mL of NMe$_2$Et in 50 mL of Et$_2$O at –78 °C and stirred for 4 h. After heating to room temperature the volatile compounds were removed in vacuo and the solid reaction product was extracted into 30 mL of pentane. After filtration, single crystals of **1b**·NMe$_2$Et were obtained from the pentane filtrate at –25 °C. Yield: 1.47 g (54%). $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 0.12 (s, 6 H Me$_2$Si), 0.32 (t, 3 H, CH$_3$), 1.45 (s, 27 H, $t$Bu$_3$Si), 1.77 (s, 6 H, NMe$_2$), 2.50 (q, 2 H, NCH$_2$) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 1.9 (Me$_2$Si), 6.5 (CH$_3$), 24.5 (*C*Me$_3$), 32.1 (C*Me$_3$*), 41.5 (NCH$_2$), 51.0 (NMe$_2$) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = –8.9 (Me$_2$Si), –10.3 (Si$t$Bu$_3$) ppm.

**Synthesis of the Silanimine Dimer (Me$_2$SiNSi$t$Bu$_3$)$_2$ (1b$_2$):** Compound **1b**·NMe$_2$Et (0.608 g, 1.76 mmol) was heated at 120 °C in vacuo (0.01 mbar) for 4 h, then the obtained solid was extracted into 10 mL of benzene. **1b$_2$** was crystallized from this solution at ambient temperature. Yield: 0.382 g (80%). The NMR spectra of the mother liquid show the signals of **1b$_2$** and small signals which can be assigned to **5**(Me,*t*Bu) and **6**(Me,*t*Bu). Selected data for **1b$_2$**: m.p. 268 °C. $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 0.79 (s, 12 H Me$_2$Si), 1.23 (s, 54 H, $t$Bu$_3$Si) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 12.1 (Me$_2$Si), 23.8 (*C*Me$_3$), 32.6 (C*Me$_3$*) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = 7.4 (Me$_2$Si), 4.6 (Si$t$Bu$_3$) ppm. $C_{28}H_{66}N_2Si_4$ (543.18): calcd. C 61.91, H 12.95, N 5.16; found C 61.28, H 12.62, N 5.09.

**Thermolysis of the Silanimine Adduct Me$_2$SiNSi$t$Bu$_3$·NMe$_2$Et (1b·NMe$_2$Et):** A solution of **1b·NMe$_2$Et** (0.168 g, 0.487 mmol) in 0.8 mL of NMe$_2$Et was heated at 135 °C for 30 h. The NMR ($^1$H, $^{13}$C, $^{29}$Si) spectra showed the signals of **5**(Me,*t*Bu) (80%) and **6**(Me,*t*Bu) (20%). After removing all volatile compounds at room temp. and 0.001 mbar, colorless **5**(Me,*t*Bu) was distilled at 70 °C/0.001 mbar from the obtained mixture. Analytically pure **6**(Me,*t*Bu) remained as the distillation residue.

**5(Me,*t*Bu):** $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 0.26 (s, 6 H Me$_2$Si), 0.96 (t, $^1J$ = 7.1 Hz, 3 H, CH$_3$), 1.20 (s, 27 H, $t$Bu$_3$Si), 1.74 (s, 2 H, SiCH$_2$N), 2.15 (s, 3 H, NCH$_3$), 2.30 (q, $^1J$ = 7.1 Hz, 2 H, NCH$_2$) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 3.64 (Me$_2$Si), 13.3 (CH$_3$), 23.0 (*C*Me$_3$), 30.7 (C*Me$_3$*), 45.4 (NCH$_3$), 50.2 (NCH$_2$Si), 55.7 (NCH$_2$) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = –3.7 (Me$_2$Si), 6.4 (Si$t$Bu$_3$) ppm. $C_{18}H_{44}N_2Si_2$ (344.74): calcd. C 62.71, H 12.87, N 8.13; found C 63.01, H 12.14, N 8.52. EI MS: *m*/*z* (%) 344 (7) [M]$^+$, 287 (100) [M – $t$Bu]$^+$.

**6(Me,*t*Bu):** M.p. 116 °C. $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 0.41 (s, 6 H MeSi), 0.44 (s, 6 H MeSi), 1.06 (t, $^1J$ = 7.1 Hz, 3 H, CH$_3$), 1.20 (s, 54 H, $t$Bu$_3$Si), 1.76 (s, 1 H, Si$_2$CHN), 2.49 (s, 3 H, NCH$_3$), 2.81 (q, $^1J$ = 7.1 Hz, 2 H, NCH$_2$) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 6.1 (MeSi), 6.2 (MeSi), 14.7 (CH$_3$), 23.0 (*C*Me$_3$), 30.9 (C*Me$_3$*), 44.0 (NCH$_3$), 53.6 (NCHSi$_2$), 54.0 (NCH$_2$) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = –1.6 (Me$_2$Si), 6.7 (Si$t$Bu$_3$) ppm. $C_{32}H_{77}N_3Si_4$ (616.33): calcd. C 62.36, H 12.60, N 6.80; found C 62.00, H 12.83, N 6.65. EI MS: *m*/*z* (%) 615 (3) [M]$^+$, 558 (100) [M – $t$Bu]$^+$.

***Remark:*** A solution of **1b**·NMe$_2$Et (0.025 g, 0.073 mmol), 0.1 mL of NMe$_2$Et and 1 mL of $C_6D_6$ was heated at 120 °C for 24 h. The NMR ($^1$H, $^{13}$C, $^{29}$Si) spectra showed the signals of **5**(Me,*t*Bu) (10%) and **6**(Me,*t*Bu) (90%).

**Thermolysis of the Silanimine Adduct $t$Bu$_2$Si=NSiCl$t$Bu$_2$·NMe$_2$Et [1a(Cl)·NMe$_2$Et]:** A solution of **1a**(Cl)·NMe$_2$Et (0.5 mmol) in 2 mL of NMe$_2$Et was stored for 2 weeks at ambient temperature. The NMR ($^1$H, $^{13}$C, $^{29}$Si) spectra showed only the signals of **5**(*t*Bu,Cl). $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 0.96 (t, $^1J$ = 7.33 Hz, 3 H, CH$_3$), 1.14 (s, 18 H, $t$Bu$_2$Si), 1.23 (s, 18 H, $t$Bu$_2$Si), 2.06 (s, 3 H, NCH$_3$), 2.15 (q, $^1J$ = 7.33 Hz, 2 H, NCH$_2$), 2.35 (s, 2 H, SiCH$_2$N) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 13.1 (CH$_3$), 23.3 (*C*Me$_3$), 23.6 (*C*Me$_3$), 28.7 (C*Me$_3$*), 29.5 (C*Me$_3$*), 39.2 (NCH$_2$Si), 45.1 (NCH$_3$), 53.7 (NCH$_2$) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = 17.5 ($t$Bu$_2$SiCl), 0.6 (Si$t$Bu$_2$) ppm. EI MS: *m*/*z* (%) 334 (43) [M – $t$Bu]$^+$, 166 (100) [Me$_2$SiNHSiClMe$_2$]$^+$.

***Note:*** A solution of **1a**(Cl)·NMe$_2$Et (0.134 g, 0.329 mmol) in 0.6 mL of $C_6D_6$ was stored at ambient temperature for a week. The NMR ($^1$H, $^{13}$C, $^{29}$Si) spectra showed the signals of **5**(*t*Bu,Cl).

**Reaction of the Silanimine Adduct Me$_2$Si=NSi$t$Bu$_3$·NMe$_2$Et (1b·NMe$_2$Et) with Ph$_2$CO:** A solution of Ph$_2$C=O (0.275 g, 1.50 mmol) in 10 mL of Et$_2$O was added to a solution of **1b**·NMe$_2$Et (0.520 g, 1.51 mmol) in 10 mL of Et$_2$O at –78 °C. The NMR ($^1$H, $^{13}$C, $^{29}$Si) spectra showed the signals of Ph$_2$C=NSi$t$Bu$_3$ (**8**) and other compounds containing Me$_2$SiO groups.[8] After removing all volatile compounds in vacuo (0.001 mbar), single crystals of **8** were obtained by sublimation at 105 °C/0.001 mbar. Yield: 0.301 g (53%). M.p. 98 °C. $^1$H NMR ($C_6D_6$, internal TMS): $\delta$ = 1.18 (s, 27 H, $t$Bu$_3$Si), 7.08 (m, 6 H, *o*/*p*-Ph), 7.387 (m, 4 H, *m*-Ph) ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$, internal TMS): $\delta$ = 23.7 (*C*Me$_3$), 30.9 (C*Me$_3$*), 128.26 (*m*/*o*-Ph), 128.29 (*m*/*o*-Ph), 129.3 (*p*-Ph), 143.3 (*i*-Ph), 170.3 (C=N) ppm. $^{29}$Si{$^1$H} NMR ($C_6D_6$, external TMS): $\delta$ = –4.9 ppm (Si$t$Bu$_3$). $C_{19}H_{39}NSi_2$ (379.66): calcd. C 79.01, H 9.81, N 3.69; found C 78.54, H 9.65, N 3.72. EI MS: *m*/*z* (%) 322 (100)

$[M - tBu]^+$. IR: $\nu_{C=N}$ = 1692 $cm^{-1}$. UV/Vis: $\lambda_{max}$ = 401 nm ($\varepsilon_{401}$ = 7.48 $M^{-1}cm^{-1}$).

**Lithiation of $tBu_2SiClN(H)SiXtBu_2$ (X = Cl, *t*Bu) [3(Cl), 3(*t*Bu)]:** A solution of RLi [X = Cl(thf): RLi = 3.16 mmol of *n*BuLi in 2 mL of hexane and 10 mL of thf; X = Cl(thf): RLi = 1.93 mmol of MeLi in 3 mL of $Et_2O$; X = Cl($Et_2O$): RLi = 1.05 mmol of *n*BuLi in 0.7 mL of hexane and 10 mL of $Et_2O$] was added to a solution of $tBu_2SiClN(H)SiXtBu_2$ (in 10 mL of thf, X = Cl, 1.162 g, 3.14 mmol; in 6 mL of thf, X = *t*Bu, 0.756 g, 1.93 mmol; in 10 mL $Et_2O$, X = Cl, 0.385 g, 1.05 mmol) at –78 °C. After removing the solvent, the silylated amides $tBu_2SiClN(Li)SiXtBu_2$ (X = Cl, *t*Bu) were obtained as colorless solids. The NMR spectra of the reaction solution showed only the signals of the silylated amides $tBu_2SiClN(Li)SiXtBu_2$ (X = Cl, *t*Bu).

**$tBu_2SiClNLi(thf)SiCltBu_2$:** $^1H$ NMR ($C_6D_6$, internal TMS): $\delta$ = 1.32 (m, 4 H, $CH_2$), 1.36 (s, 36 H, $tBu_2Si$), 3.47 (m, 4 H $OCH_2$). $^{13}C\{^1H\}$ NMR ($C_6D_6$, internal TMS): $\delta$ = 24.8 ($CMe_3$), 25.2 ($CH_2$), 28.9 ($CMe_3$), 68.7 ($OCH_2$) ppm. $^{29}Si\{^1H\}$ NMR ($C_6D_6$, external TMS): $\delta$ = 4.8 ppm ($SitBu_2$).

**$tBu_2SiClNLi(thf)SitBu_3$:** $^1H$ NMR ($C_6D_6$, internal TMS): $\delta$ = 1.17 (m, 4 H, $CH_2$), 1.32 (s, 27 H, $tBu_3Si$), 1.44 (s, 18 H, $tBu_2Si$), 3.35 (s, 8 H $OCH_2$) ppm.

**$tBu_2SiCl$-NLi($Et_2O$)$SiCltBu_2$:** $^1H$ NMR ($C_6D_6$, internal TMS): $\delta$ = 0.904 (t, 6 H, $CH_3$), 1.315 (s, 36 H, $tBu_2Si$), 3.181 (q, 4 H $OCH_2$) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$, internal TMS): $\delta$ = 14.8 ($CH_3$), 24.8 ($CMe_3$), 29.0 ($CMe_3$), 65.8 ($OCH_2$) ppm. $^{29}Si\{^1H\}$ NMR ($C_6D_6$, external TMS): $\delta$ = 5.5 ppm ($SitBu_2$).

***Note:*** Treatment of one equivalent of $tBu_2SiClN(Li)SiXtBu_2$ (X = Cl, *t*Bu) with one equivalent of MeOH leads quantitatively to the formation of **3**(Cl) and **3**(*t*Bu).

**X-ray Crystallographic Study:** Data collection was performed with either a Stoe-IPDS-II diffractometer or a Siemens CCD three-circle diffractometer. Empirical absorption correction was performed with MULABS[21] and SADABS,[22] structure solution by direct methods,[23] and structure refinement by full-matrix least-squares on $F^2$ with SHELXL-97.[24] Hydrogen atoms were placed at ideal positions and refined with fixed isotropic displacement parameters using a riding model.

CCDC-602102 (for **1b**·$NMe_2Et$), -602101 (for **1b$_2$**), -609530 [for **3**(*t*Bu)], and -609686 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# π-Conjugated α,ω-Diphenylpolyene Complexes of RuClCp* Fragment(s) in $\eta^4$-*s*-*cis* Conformation

**Hiroki Fukumoto[a] and Kazushi Mashima*[b]**

**Keywords:** π-Conjugated polyenes / Coordination modes / Fluxionality / Multinuclear complexes / Ruthenium

π-Conjugated polyene complexes of the general formula $(RuClCp^{\star})_n$(polyene) [**2**: $n$ = 1, polyene = 1,4-diphenylbuta-1,3-diene; **3**: $n$ = 1, polyene = 1,6-diphenylhexa-1,3,5-triene; **4**: $n$ = 2, polyene = 1,8-diphenylocta-1,3,5,7-tetraene; **5**: $n$ = 2, polyene = 1,10-diphenyldeca-1,3,5,7,9-pentaene; **6**: $n$ = 3, polyene = 1,12-diphenyldodeca-1,3,5,7,9,11-hexaene], in which each ruthenium(II) atom has $Cp^{\star}$ ($Cp^{\star}$ = $\eta^5$-$C_5Me_5$) and chlorido ligands, were prepared by treating [Ru($\mu_3$-Cl)-$Cp^{\star}$]$_4$ (**1**) with the corresponding α,ω-diphenylpolyenes. All diene units of the complexes were fully metalated by the coordination of "RuClCp$^{\star}$" fragments in an $\eta^4$-*s*-*cis* conformation.

## Introduction

One-dimensional π-conjugated polyenes are excellent supporting ligands to which plural transition metals can coordinate, and their metal complexes are expected to show unique properties on the basis of an extended pπ–dπ conjugated organometallic system.[1] Their physical properties are thus controlled by not only the number of transition metals bound to the polyene ligand but also their coordination features such as nuclearity (mono-,[2,3] di-,[4] or polynuclear[5]), stereochemistry (*syn* and *anti* for polynuclear complexes), and fluxionality[6,7] (metal migration on a polyene). Moreover, ancillary ligands on a metal center also play an important role in controlling the structure and properties of π-conjugated polyene complexes. We have recently reported the systematic preparation of α,ω-diphenylpolyene complexes bearing $Ru(acac)_2$ (acac = acetylacetonato) fragments, which coordinate to all diene units of the polyene in an $\eta^4$-*s*-*trans* fashion,[8a] resulting in the full metalation of all diene units of the polyenes. In contrast, ruthenium fragments with Cp* (Cp* = $C_5Me_5$) and chlorido ligands prefer to coordinate to a diene moiety of diene and tetraene in an $\eta^4$-*s*-*cis* fashion revealed by our previous work.[8b] The selectivity of coordination mode originating from the difference of ancillary ligands on a ruthenium center has attracted interest. Furthermore, "RuClCp*" fragments as well as "$Ru(acac)_2$"[8a] and "$Fe(CO)_3$"[7] fragments are also expected to move on a π-conjugated polyene with an odd number of olefinic parts such as triene and pentaene. As an extension of our continuing interest in this area, we have investigated the complexation of the "RuClCp*" fragment with longer polyenes. Here, we report the synthesis of a series of α,ω-diphenylpolyene complexes (polyene = di-, tri-, tetra-, penta-, and hexaene) bearing RuClCp* fragments and their structural features.

## Results and Discussion

The reaction of α,ω-diphenylpolyenes with [Ru($\mu_3$-Cl)-Cp*]$_4$ (**1**)[2g] in THF or dichloromethane at room temperature gave the corresponding chlorido($\eta^5$-pentamethylcyclopentadienyl)ruthenium(II) complexes of the general formula $(RuClCp^*)_n$(polyene) [**2**: $n$ = 1, polyene = 1,4-diphenylbuta-1,3-diene; **3**: $n$ = 1, polyene = 1,6-diphenylhexa-1,3,5-triene; **4**: $n$ = 2, polyene = 1,8-diphenylocta-1,3,5,7-tetraene; **5**: $n$ = 2, polyene = 1,10-diphenyldeca-1,3,5,7,9-pentaene; **6**: $n$ = 3, polyene = 1,12-diphenyldodeca-1,3,5,7,9,11-hexaene] in modest yields [Equation (1)]. Among them, the diene and tetraene complexes **2** and **4** had previously been prepared and characterized.[8b] Both complexes are stable to air and moisture in the solid state, but are not stable in solution. Complexes **3**, **5**, and **6** are soluble in dichloromethane and chloroform, and are slightly soluble in THF. The treatment of **1** with longer polyenes such as 1,14-diphenyltetradeca-1,3,5,7,9,11,13-heptaene and 1,16-diphenylhexadeca-1,3,5,7,9,11,13,15-octaene did not yield any products because of the low solubility of heptaene and octaene ligands in any common organic solvent.

In the obtained complexes, RuClCp* fragments coordinated in an $\eta^4$-*s*-*cis* fashion to all diene units of the polyenes. The $^1$H NMR spectra of all complexes (except **2**) showed signals of the outer protons of coordinated diene

(1)

units in the range of δ = 2.5–4.0 ppm. Siganls of the inner protons of the *s*-*cis* diene moieties are observed at δ ≈ 5 ppm, with a smaller coupling constant ($^3J$ = 5.9 Hz),[2] in sharp contrast to those ($^3J$ = 7–8 Hz) observed for $\eta^4$-*s*-*trans*-diene[3] complexes of $Ru(acac)_2$ fragments.

The conformation of a diene moiety around a ruthenium center can be explained by the electron influence of ancillary ligands.[1b] Some (diene)ruthenium complexes, $Ru(acac)_2(\eta^4$-1,3-diene),[3f] TpRuCl($\eta^4$-1,3-diene),[3h] and $[Ru(NH_3)_4(\eta^4$-1,3-diene)]$^{2+}$,[3i] prefer the *s*-*trans* mode, presumably because the electronic deficiency around the ruthenium center of each fragment, as compared with the "RuClCp*" fragment, is compensated for by electron donation from the *s*-*trans*-diene ligand. In addition, the overall stereochemistry at a ruthenium center may influence the conformation mode. The above *s*-*trans*-diene complexes have a hexacoordinate octahedral structure when the *s*-*trans*-diene moiety is regarded as a bidentate chelating ligand. In the case of RuClCp*($\eta^4$-1,3-diene), the regular octahedral structure of the $Ru^{II}$ complex is deviated by a bulky tridentate Cp* ligand. Thus, the diene moiety of the polyene complexes prefers the *s*-*cis* coordination.

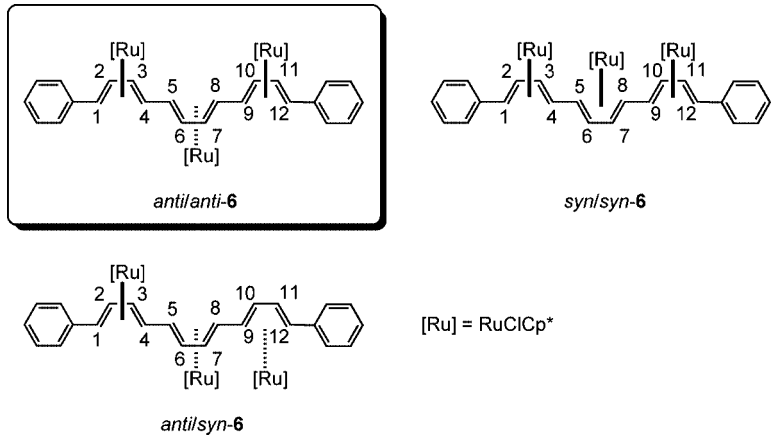
UV/Vis spectroscopic data of **2**–**6** together with those of $\eta^4$-*s*-*trans*-polyene complexes with $Ru(acac)_2$ fragments[8a] are summarized in Table 1. The absorption maxima of **2**–**6** shift to a longer wavelength as the number of diene units of the polyene ligand increases, indicating that the π-conjugated system along the polyene chain is kept even after the dπ orbital of the RuClCp* fragment is incorporated in the pπ orbital of the polyene, consistent with the results of the X-ray analysis of **4**.[8b] In contrast, we observed that $\eta^4$-*s*-*trans*-polyene complexes containing $Ru(acac)_2$ fragments have almost the same absorption maxima because their π-conjugation systems are separated into individual diene units due to the structural deformation of ruthenium-coordinated diene units. These UV/Vis data also suggest that ancillary ligands (Cp* or acac) on a ruthenium center can control not only their structural shape, such as the metal coordination mode (*s*-*cis* or *s*-*trans* for diene complexation), but also the planarity of the polyene backbone.

Table 1. UV/Vis spectroscopic data of (polyene)ruthenium complexes, [Ru](α,ω-diphenylpolyene) in $CH_2Cl_2$.

| Diphenylpolyene | $\lambda_{max}$/nm (ε/M cm$^{-1}$) | |
|---|---|---|
| | [Ru] = RuClCp* | [Ru] = $Ru(acac)_2$ |
| Butadiene | 481 (5900) (**2**) | 325 (1300)[a] |
| Hexatriene | 492 (6800) (**3**) | 340 (21000)[b] |
| Octatetraene | 518 (11400) (**4**) | 340 (2600)[a] |
| Decapentaene | 525 (16500) (**5**) | 343 (35000)[b] |
| Dodecahexaene | 525 (–) (**6**)[c] | 340 (43000)[b] |

[a] Ref.[8b] [b] Ref.[8a] [c] Because of the low solubility of **6**, we could not estimate the ε value.

The $^1$H NMR spectra of **2**, **4**, and **6** displayed no peaks assignable to the uncoordinated olefinic protons in the range of δ = 6–7 ppm, indicating that polyenes with an even number of olefinic parts are fully metalated.[8] For **4**, we attempted to carry out the reaction of a tetraene ligand with 1 equiv. of **1** to obtain a mononuclear complex; however, no partly metalated olefinic parts with one ruthenium fragment was observed, and a mixture of **4** and a free tetraene was detected by NMR analysis. Likewise, the reaction of **1** with a hexaene gave **6**, without any complexes, having one or two ruthenium fragments. For the multinuclear complexes **4** and **6**, there are several possible *syn* and *anti* isomers owing to the relative face selection of sequential metal coordination across the polyene ligand. For the tetraene complex **4**, an *anti* structure of two RuClCp* fragments coordinated to a tetraene has been revealed by X-ray analysis.[8b] The $^1$H NMR spectrum of the trinuclear hexaene complex **6** in $CDCl_3$ showed only one set of six olefinic protons together with two methyl protons (1:2 ratio) of Cp*



Scheme 1.

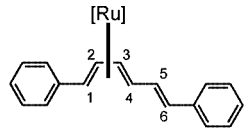
ligands, suggesting that **6** may have a $C_2$ axis or a mirror plane passing through the central ruthenium atom and the center of the hexaene ligand. For **6**, four isomers are possible, which are categorized into three types: *syn*/*syn*-, *anti*/*anti*-, and *anti*/*syn*- (= *syn*/*anti*-) **-6**, as depicted in Scheme 1. On the basis of the $^1$H NMR spectrum of **6**, the structurally unsymmetrical isomer *anti*/*syn*-**6** is excluded. Furthermore, *syn*/*syn*-**6** is also ruled out because of steric repulsion among the three bulky RuClCp* fragments. Thus, it is reasonably conceivable that **6** has an *anti*/*anti* structure.

In contrast to those of **4** and **6**, the $^1$H NMR spectrum of the triene complex **3** exhibited six signals of magnetically nonequivalent nuclei: four peaks in the range of δ = 3.3–5.4 ppm were from olefinic protons of the diene part bound to a ruthenium atom and the other two signals observed at δ ≈ 6.5 ppm were assignable to noncoordinating olefin protons. The RuClCp* fragment coordinated in an *s*-*cis* fashion to a diene part of the triene, as judged from a typical coupling constant ($^3J$ = 5.9 Hz) between the inner protons $H^2$ and $H^3$ (signals observed at $\delta$ = 5.28 and 4.90 ppm).[2] The coupling constants $J_{4,5}$ (10.3 Hz) and $J_{5,6}$ (15.6 Hz) further indicated that the C(3)–C(4)–C(5)–C(6) sequence is *s*-*trans*.



**3**

[Ru] = RuClCp*

The dinuclear pentaene complex **5** was isolated as a mixture of two isomers: **5a** (major, 90%) and **5b** (minor, 10%). In the 2D COSY and NOESY spectra of **5** (Figures 1 and 2), 10 signals of magnetically nonequivalent nuclei assignable to the major isomer **5a** revealed that two ruthenium fragments coordinated to two neighboring diene moieties (1,2,3,4-$\eta^4$ and 5,6,7,8-$\eta^4$ coordination); five peaks due to the minor isomer **5b** indicated that two ruthenium fragments coordinated at separated positions (1,2,3,4-$\eta^4$ and 7,8,9,10-$\eta^4$ coordination).

There are four (= $2^2$) possible structures of complex **5**: two *syn* and two *anti* isomers are schematically depicted in Scheme 2. When the pentaene ligand reacted with **1**, it is assumed that there were two partly metalated intermediates (1,2,3,4-$\eta^4$-**7** and 3,4,5,6-$\eta^4$-**7**). For the latter intermediate,

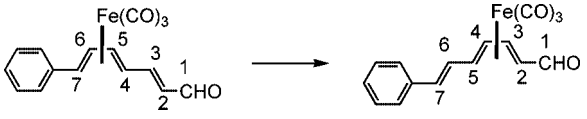
one diene part [C(7)–C(8)–C(9)–C(10)] remained intact and was applicable to the coordination of another RuClCp* fragment, giving *anti*-**5a** and *syn*-**5a**. On the other hand, the former one has a triene part, to which the coordination of another ruthenium fragment affords four possible isomers (*anti*-**5a**, *syn*-**5a**, *anti*-**5b**, and *syn*-**5b**). Among these isomers, *syn*-**5a** was ruled out because of steric repulsion between the two Cp* rings. Thus, the structure of the major isomer **5a** was concluded to be *anti*-**5a**. In contrast, from the $^1$H NMR spectrum of **5b**, the stereochemistry of the minor product **5b** could not be determined because two possible isomers (*anti*-**5b** and *syn*-**5b**) displayed the same signals (magnetically equivalent nuclei) due to the inversion at the center of C(5)–C(6) in the pentaene ligand for *anti*-**5b**, and the $C_2$ axis passing through the center of the pentaene backbone for *syn*-**5b**.[8a]

The minor product **5b** remained even at elevated temperatures; the percentage of **5b** did not change on heating the chloroform solution of **5**, indicating that either *syn*-**5b** or *anti*-**5b** is thermodynamically stable. As shown in Scheme 2, the major isomer *anti*-**5a** was also produced by the migration of an RuClCp* fragment of *anti*-**5b** via the $\eta^2$-intermediate *anti*-**8**, based on the assumption that a ruthenium fragment suprafacially moved over the pentaene ligand. On the other hand, the suprafacial migration of a ruthenium fragment on *syn*-**5b** did not proceed via *syn*-**8**, because of the steric congestion between two RuClCp* fragments of *syn*-**5a**. Thus, *syn*-**5b** was observed as the minor product and its percentage did not change. Scheme 3 depicts an example of metal migration on a polyene ligand for a trienal complex of the iron compound $Fe(CO)_3$(7-phenyl-2,4,6-heptatrienal). An isomer with an iron fragment at neighboring positions of a phenyl group has been isomerized to another isomer with an iron fragment at neighboring positions of an electron-withdrawing formyl group through the migration of a tricarbonyliron fragment over a trienal ligand.[7b] Accordingly, it is concluded that the treatment of **1** with a pentaene ligand finally gives *anti*-**5a** and *syn*-**5b** as major and minor products, respectively.



Scheme 3.

## Conclusions

We demonstrated that the ruthenium fragment RuClCp* coordinates in an *s-cis* fashion to α,ω-diphenylpolyenes to afford the corresponding polyene complexes **2**–**6**, in sharp contrast to the case of $\eta^4$-*s-trans*-polyene complexes with $Ru(acac)_2$ fragments. All diene units were fully metalated with RuClCp* fragments. We also found that the coordination of RuClCp* fragments maintains a long π-conjugation system along the polyene chain in comparison with $\eta^4$-*s-trans*-polyene complexes with $Ru(acac)_2$ fragments, as revealed by UV/Vis spectroscopy. We also discussed the structures of pentaene and hexaene complexes on the basis of the bulkiness of RuClCp* moieties: the hexaene complex **6** was assumed to have *anti*/*anti* geometry. The pentaene complex **5** was isolated as a mixture of two isomers: **5a** (major) and **5b** (minor). The RuClCp* fragment of one minor isomer, *anti*-**5b**, suprafacially moved over the pentaene backbone to afford the major isomer *anti*-**5a**, and the other isomer, *syn*-**5b**, remained as the minor product. This supports our previous conclusion that ancillary ligands (Cp* or acac) on a ruthenium center play an important role in controlling their structural shape, such as the metal coordination mode (*s-cis* or *s-trans* for diene complexation) and planarity of the polyene backbone.

## Experimental Section

**General Procedure:** All manipulations involving air- and moisture-sensitive organometallic compounds were carried out using standard Schlenk techniques under argon. THF, hexane, toluene, and diethyl ether were dried and deoxygenated by distillation from sodium/benzophenone ketyl under argon. Dichloromethane was purified by distillation after drying with $CaH_2$. 1,6-Diphenyl-1,3,5-hexatriene was purchased from Aldrich Chemical Co., Inc.; $[Ru(\mu_3\text{-}Cl)Cp^*]_4$,[2g] 1,10-diphenyl-1,3,5,7,9-decapentaene,[9] and 1,12-diphenyl-1,3,5,7,9,11-dodecahexaene[9] were prepared according to literature procedures. The preparation of **2** and **4** has already been reported.[8b] NMR [$^1$H (400 MHz)] spectra were measured using a JEOL JNM-GSK400 spectrometer. The assignments of the $^1$H NMR peaks of some complexes were aided by 2D COSY and NOESY spectra. Other spectra were recorded using the following instruments: IR: Jasco FTIR-120 and Hitachi 295; low- and high-resolution MS: JEOL SX-102. UV/Vis: Jasco Ubest-30 and Shimadzu UV-265FS. Elemental analyses were performed with a Perkin–Elmer 2400 instrument at the Faculty of Engineering Science, Osaka University. All melting points were measured in sealed tubes and are not corrected.

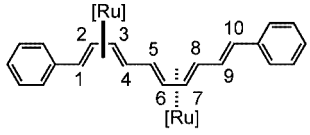
### Synthetic Procedures

**Complex 3:** 1,6-Diphenyl-1,3,5-hexatriene (0.092 g, 0.40 mmol) was added to a solution of $[Ru(\mu_3\text{-}Cl)Cp^*]_4$ (**1**) (0.120 g, 0.11 mmol) in THF (50 mL) at 25 °C. The color of the reaction mixture turned bright red, and then red solids precipitated. After the reaction mixture was stirred for 3 h, the red precipitates were collected and washed with hexane (5 mL). Recrystallization from dichloromethane afforded **3** (0.12 g, 60% yield) as red microcrystals, m.p. 220–230 °C (dec.). $^1$H NMR ($CDCl_3$, 30 °C): $\delta$ = 7.17–7.52 (m, 10 H, $C_6H_5$), 6.82 (d, $J_{5,6}$ = 15.6 Hz, 1 H, H$^6$), 6.44 (dd, $J_{4,5}$ = 10.3 Hz, 1 H, H$^5$), 5.28 (dd, $J_{1,2}$ = 10.7 and $J_{2,3}$ = 5.9 Hz, 1 H, H$^2$), 4.90 (dd, $J_{3,4}$ = 10.7 Hz, 1 H, H$^3$), 3.68 (d, 1 H, H$^1$), 3.40 (dd, 1 H, H$^4$), 1.36 (s, 15 H, $C_5Me_5$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 492 nm (6800 L mol$^{-1}$ cm$^{-1}$). MS (FAB): *m*/*z* = 504 [M$^+$]. $C_{28}H_{31}ClRu$ (504.07): calcd. C 66.72, H 6.20; found C 66.43, H 6.30.

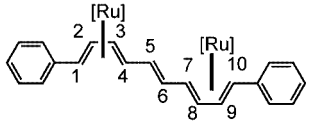
**Complex 5:** 1,10-Diphenyl-1,3,5,7,9-decapentaene (0.170 g, 0.60 mmol) was added to a dichloromethane (50 mL) solution of **1** (0.350 g, 0.32 mmol), and the reaction mixture was stirred at room temperature for 3 h. After removing insoluble impurities by centrifugation, the resulting red solution was concentrated to approximately 5 mL and kept at –20 °C, affording **5** (0.26 g, 52% yield) as red microcrystals, m.p. 190–200 °C (dec.). Major isomer (*anti*-**5a**): $^1$H NMR ($CDCl_3$, 30 °C): $\delta$ = 7.10–7.50 (m, 10 H, $C_6H_5$), 6.74 (d,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$J_{9,10}$ = 15.6 Hz, 1 H, $H^{10}$), 6.38 (dd, $J_{8,9}$ = 10.3 Hz, 1 H, $H^9$), 5.15 (dd, $J_{1,2}$ = 10.3 and $J_{2,3}$ = 5.9 Hz, 1 H, $H^2$), 5.14 (dd, $J_{3,4}$ = 9.3 Hz, 1 H, $H^3$), 5.10 (dd, $J_{6,7}$ = 5.9 and $J_{5,6}$ = 9.3 Hz, 1 H, $H^6$), 4.75 (dd, $J_{7,8}$ = 10.3 Hz, 1 H, $H^7$), 3.52 (d, 1 H, $H^1$), 3.15 (t, 1 H, $H^8$), 2.85 (dd, $J_{4,5}$ = 10.3 Hz, 1 H, $H^4$), 2.81 (dd, 1 H, $H^5$), 1.53 (s, 15 H, $C_5Me_5$), 1.31 (s, 15 H, $C_5Me_5$) ppm. Minor isomer (*syn*-**5b**): $^1$H NMR ($CDCl_3$, 30 °C): $\delta$ = 7.10–7.50 (m, 10 H, $C_6H_5$), 6.12 (m, 2 H, $H^5$ and $H^6$), 5.21 (dd, $J_{2,3}$ and $J_{8,9}$ = 5.9, $J_{1,2}$ and $J_{9,10}$ = 10.7 Hz, 2 H, $H^2$ and $H^9$), 4.89 (dd, $J_{3,4}$ and $J_{7,8}$ = 10.3 Hz, 2 H, $H^3$ and $H^8$), 3.62 (d, 2 H, $H^1$ and $H^{10}$), 3.15 (m, 2 H, $H^4$ and $H^7$), 1.32 (s, 30 H, $C_5Me_5$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 525 nm (16000 L mol$^{-1}$ cm$^{-1}$). MS (FAB): *m*/*z* = 556 [$M^+$ – RuCp*Cl]. $C_{42}H_{50}Cl_2Ru_2$ (827.89): calcd. C 60.92, H 6.09; found: C 60.44, H 5.90.



*anti*-**5a**



*syn*-**5b**

[Ru] = RuClCp*

**Complex 6:** A reaction mixture of **1** (0.0820 g, 0.075 mmol) and 1,12-diphenyl-1,3,5,7,9,11-dodecahexaene (0.0310 g, 0.10 mmol) in $CH_2Cl_2$ (30 mL) was stirred at 25 °C for 3 h to give a red precipitate. The precipitate was filtered and then washed with hexane (5 mL). Recrystallization from dichloromethane afforded **6** (0.043 g, 38% yield) as red microcrystals, m.p. 195–200 °C (dec.). $^1$H NMR ($CDCl_3$, 30 °C): $\delta$ = 7.12–7.46 (m, 10 H, $C_6H_5$), 5.15 (dd, 2 H, $H^2$ and $H^{11}$), 5.09 (dd, $J_{2,3}$ and $J_{10,11}$ = 5.9 Hz, 2 H, $H^3$ and $H^{10}$), 5.01 (dd, $J_{6,7}$ = 4.4 and $J_{5,6}$ and $J_{7,8}$ = 9.3 Hz, 2 H, $H^6$ and $H^7$), 3.53 (d, $J_{1,2}$ and $J_{11,12}$ = 10.7 Hz, 2 H, $H^1$ and $H^{12}$), 2.91 (dd, $J_{3,4}$ and $J_{9,10}$ = 10.3 and $J_{4,5}$ and $J_{8,9}$ = 9.8 Hz, 2 H, $H^4$ and $H^9$), 2.69 (dd, 2 H, $H^5$ and $H^8$), 1.52 (s, 15 H, $C_5Me_5$), 1.32 (s, 30 H, $C_5Me_5$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ = 525 nm. MS (FAB): *m*/*z* = 547 [$M^+$ – 2 Cp*RuCl – Cl]. The low solubilities of both the complex and 1,12-diphenyl-1,3,5,7,9,11-dodecahexaene prevented the separation of the polyene by repeated crystallizations, and an elemental analysis of the complexes could not be performed.

# Neutral, Radical [CpNi(dithiolene)] Complexes with Flexible, Nonplanar Seven-Membered Rings: [CpNi{$S_2C_2S_2(CH_2)_2X$}] (X = $CH_2$, $CF_2$, C=$CH_2$, S, C=O)

**Mitsushiro Nomura,[a] Michel Geoffroy,[b] Prashant Adkine,[b] and Marc Fourmigué*[a]**

**Keywords:** Nickel / S ligands / Radicals / Metallacycles / Magnetic properties

Neutral, radical [CpNi(dithiolene)] complexes fused with seven-membered rings, formulated as [CpNi{$S_2C_2S_2(CH_2)_2$-X}] (X = $CH_2$, $CF_2$, C=$CH_2$, S), have been synthesized in 30–60 % yields from the reactions of nickelocene with the corresponding neutral, square-planar, (dithiolene)nickel complexes [Ni{$S_2C_2S_2(CH_2)_2X$}$_2$]. [CpNi{$S_2C_2S_2(CH_2)_2X$}] (X = C=O) was prepared from nickelocene and [1,3]dithiolo[4,5-*b*][1,4]dithiepine-2,6-dione under thermal or photochemical conditions. All complexes exhibit reversible oxidation and reduction waves to the cation and anion form, respectively. The terminal groups (X) in the seven-membered ring shift their redox potentials to anodic potentials in the following order: $CF_2$ > C=O > S > C=$CH_2$ > $CH_2$. The singlet EPR responses of [CpNi{$S_2C_2S_2(CH_2)_2$(X)}] appear at $g \approx 2.0514$–$2.0529$ in dichloromethane solution at room temperature. An NIR absorption is observed at $\lambda_{max} \approx 798$–$848$ nm ($\varepsilon \approx 1700$–$2400$ $M^{-1}$ $cm^{-1}$) in dichloromethane solution. The X-ray structures of the five complexes show two-legged piano-stool geometries around the central nickel atom (formally $Ni^{III}$) and strong distortions from planarity of the seven-membered $C_2S_2(CH_2)_2X$ rings. In the solid state, those radical ($S$ = 1/2) species adopt either one-dimensional alternating chain-like motifs (X = $CH_2$, C=$CH_2$, S) or dimeric entities characterized by a singlet–triplet magnetic behavior (X = $CF_2$, C=O).

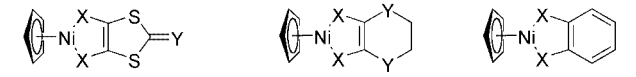
## Introduction

(Dithiolene)nickel complexes are currently being extensively investigated from the viewpoint of optical,[1] magnetic,[2] and conductivity studies.[3] Most of these studies involve square-planar bis(dithiolene) complexes,[4] although several mono(dithiolene)nickel complexes formulated as [Ni(dithiolene)$L_2$] have been described where L is an imine or a phosphane.[5] Heteroleptic complexes involving dithiolene and $\eta^5$-cyclopentadienido (Cp) ligands are also known with various Cp/dithiolene ratios and different metal centers.[6] Among them, different series of paramagnetic complexes such as the $d^1$ cation [$Cp_2$Mo(dithiolene)]$^+$ have shown a wide variety of magnetic behaviors, ranging from uniform spin chains to spin ladders or antiferromagnetic ground states.[7] In this respect, the half-metallocene (dithiolene)nickel complexes formulated as [CpNi(dithiolene)] are particularly attractive since they are neutral radical ($S$ = 1/2) species. We have recently investigated the synthesis and electronic properties of a variety of such [CpNi(dithiolene)] complexes, which are characterized by very attractive features such as a strong NIR absorption or a highly delocalized spin density.[8] Among them, [CpNi($S_2C_2R_2$)] complexes bearing simple substituents (R = CN, COOMe, $CF_3$, Ph, and Me) have been synthesized by several dithiolene transfer reactions from the square-planar nickel complex [Ni($S_2C_2R_2$)$_2$] to [$Cp_2$Ni].[8b] Complexes involving 1,2-dithiolato ligands fused with five-membered rings, such as [CpNi(dmit)],[9] [CpNi(dmid)], and [CpNi(dsit)] (dmit = 1,3-dithiol-2-thione-4,5-dithiolato; dmid = 1,3-dithiol-2-one-4,5-dithiolato; dsit = 1,3-dithiol-2-thione-4,5-diselenolato) exhibit a set of three-dimensional intermolecular interactions in the solid state that stabilize an ordered 3D antiferromagnetic ground state.[8a]



We also recently reported the CpNi(dithiolene) and -(diselenolene) complexes fused with a six-membered ring such as benzene, 5,6-dihydro-1,4-dithiine, or 5,6-dihydro-1,4-diselenine rings, as in [CpNi(dddt)], [CpNi(dsdt)], [CpNi(ddds)], [CpNi(bdt)], and [CpNi(bds)] (dddt = 5,6-dihydro-1,4-dithiine-2,3-dithiolato; ddds = 5,6-dihydro-1,4-dithiine-2,3-diselenolato; dsdt = 5,6-dihydro-1,4-diselenine-2,3-dithiolato; bdt = 1,2-benzenedithiolato; bds = 1,2-benzenediselenolato).[8c] Efficient synthetic methods were developed, and structural and magnetic investigation revealed, besides the recurrent dithiolene/dithiolene interactions, an original antiferromagnetic interaction mediated by

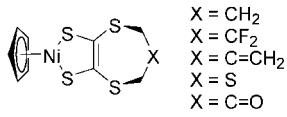
Cp···Cp overlap. We wanted to further develop these attractive series by also investigating *nonplanar* dithiolate ligands as the added flexibility in the dithiolene ligand could provide novel association patterns in the solid state for such neutral radical complexes. We report here the synthesis and electronic, structural, and magnetic properties of five paramagnetic complexes formulated as [CpNi{$S_2C_2S_2(CH_2)_2X$}] (X = $CH_2$, $CF_2$, C=$CH_2$, S, and C=O).

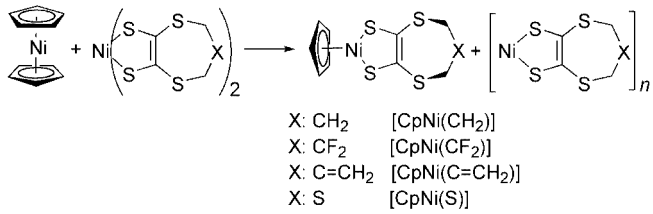


Square-planar bis(dithiolene)nickel complexes have been described with such dithiolato ligands fused with a $C_2S_2(CH_2)_2X$ seven-membered motif, all of which exhibit strong distortions from planarity, as reported for X = $CH_2$,[10] $CF_2$,[11] C=$CH_2$,[12] and S.[13] We wanted to investigate how those distortions might modify the electronic absorptions, crystal structures, and solid-state properties of the radical [CpNi(dithiolene)] complexes. Within this series, the dithiolato ligands where X = $CF_2$ and S can be considered as isosteric, as are those where X = C=$CH_2$ and C=O. It is therefore interesting to compare their solid-state structures to evaluate the precise role played by every X moiety in the definition of the pertinent intermolecular interactions that control their organization in the solid state. We report here the syntheses, structures, and properties of these novel complexes, which will be referred to as follows according to the nature of X: [CpNi($CH_2$)], [CpNi($CF_2$)], [CpNi(C=$CH_2$)], [CpNi(S)] and [CpNi(C=O)].

## Results and Discussion

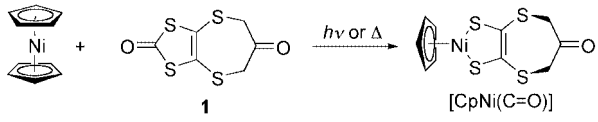
### Syntheses and Molecular Properties

Faulmann et al. have reported the serendipitous formation of [CpNi(dmit)] from the reaction of [$Cp_2Ni$]($BF_4$) with Na[Ni(dmit)$_2$].[9] We have found that this complex can also be obtained in good yields from the reaction of neutral [$Cp_2Ni$] with the neutral square-planar nickel complexes [Ni(dithiolene)$_2$]$^0$.[8] Accordingly, the reaction of [$Cp_2Ni$] with [Ni($CH_2$)$_2$]$^0$, [Ni($CF_2$)$_2$]$^0$, [Ni(C=$CH_2$)$_2$]$^0$, and [Ni($S_2$)]$^0$ at 80 °C affords the corresponding [CpNi(dithiolene)] complexes in good to fair yields: [CpNi($CH_2$)] (54%), [CpNi($CF_2$)] (41%), [CpNi(C=$CH_2$)] (30%), and [CpNi(S)] (61%) (see Scheme 1 and Entries 1–4 in Table 1).



Scheme 1.

The corresponding square-planar dithiolene complex [Ni(C=O)$_2$]$^0$ could not be prepared in a similar manner because of the complete insolubility of the anionic precursor ($Bu_4N$)[Ni(C=O)$_2$], which also does not react directly with [$Cp_2Ni$]($BF_4$) (Faulmann method) for the same reason (Entry 5). We therefore envisioned alternative routes involving thermal or photochemical reactions starting from the corresponding 1,3-dithiol-2-one derivative [1,3]dithiolo-[4,5-*b*][1,4]dithiepine-2,6-dione (**1**) (Scheme 2). Its reaction with [$Cp_2Ni$] at 110 °C or whilst being irradiated for 24 h indeed afforded [CpNi(C=O)], but only in 9% yield. King has also reported the synthesis of [CpNi(tfd)] [tfd = bis-(trifluoromethyl)-1,2-ethenedithiolate] from the reaction of [CpNi(CO)]$_2$ with bis(trifluoromethyl)-1,2-dithiete [$S_2C_2(CF_3)_2$].[14] Accordingly, we performed the reaction of the 1,3-dithiol-2-one **1** with 0.5 equiv. of [CpNi(CO)]$_2$ at 110 °C for 6 h to obtain [CpNi(C=O)] in a slightly improved yield of 15%. Note that 1,2-dithioketones have been postulated as plausible intermediates in these thermal and photochemical reactions of 1,3-dithiol-2-ones.[15] All five complexes are air-stable compounds that are soluble in typical organic solvents (dichloromethane, toluene, acetone, and thf). Their solubility decreases upon addition of *n*-hexane.



Scheme 2.

Table 1. Syntheses of CpNi(dithiolene) complexes.

| Entry | Dithiolene source | CpNi source | Molar ratio | Solvent | Temperature | Time [h] | Product | Yield [%][a] |
|---|---|---|---|---|---|---|---|---|
| 1 | [Ni($CH_2$)$_2$] | [$Cp_2Ni$] | 1:1 | toluene | 80 °C | 2 | [CpNi($CH_2$)] | 54 |
| 2 | [Ni($CF_2$)$_2$] | [$Cp_2Ni$] | 1:1 | toluene | 80 °C | 2 | [CpNi($CF_2$)] | 41 |
| 3 | [Ni(C=$CH_2$)$_2$] | [$Cp_2Ni$] | 1:1 | toluene | 80 °C | 2 | [CpNi(C=$CH_2$)] | 30 |
| 4 | [Ni($S_2$)] | [$Cp_2Ni$] | 1:1 | toluene | 80 °C | 2 | [CpNi(S)] | 61 |
| 5 | [Ni(C=O)$_2$]$^{-}$[b] | [$Cp_2Ni$]($BF_4$) | 1:1 | MeOH | reflux | 2 | –[c] | 0 |
| 6 | **1** | [$Cp_2Ni$] | 1:1 | toluene | reflux | 24 | [CpNi(C=O)] | 9 |
| 7 | **1** | [$Cp_2Ni$] | 1:1 | toluene | *hν* | 24 | [CpNi(C=O)] | 9 |
| 8 | **1** | [CpNi(CO)]$_2$ | 2:1 | toluene | reflux | 6 | [CpNi(C=O)] | 15 |

[a] Yield of isolated product. [b] As $Bu_4N^+$ salt. [c] No reaction.

In the reaction shown in Scheme 1, some mono(dithiolene)nickel oligomers, formulated as $[Ni\{S_2C_2S_2(CH_2)_2(X)\}]_n$ (X = $CH_2$, $CF_2$), were obtained as by-products (4–5% yields). The by-products were identified as hexamers ($n$ = 6) by TOF mass spectrometry.[16] The other oligomers (X = C=$CH_2$, S) could not be isolated by column chromatography as their solubility is too low. We consider that this dithiolene transfer reaction using [Ni(dithiolene)$_2$] is different from that using $(R_4N)_2$[Zn(dithiolene)$_2$].[17] Although the Zn complex can provide both dithiolene ligands, the Ni complex can release only one of two dithiolene ligands and the remaining [Ni(dithiolene)] moiety then oligomerizes.

Characteristic cyclic voltammograms (CVs) of the [CpNi(dithiolene)] complexes $[CpNi\{S_2C_2S_2(CH_2)_2X\}]$ are shown in Figure 1, and the redox potentials of the five complexes (vs. $Fc/Fc^+$), together with their $\Delta E$ and $\Delta E_p$ values, are collected in Table 2. The CVs show reversible, well-defined oxidation and reduction waves.

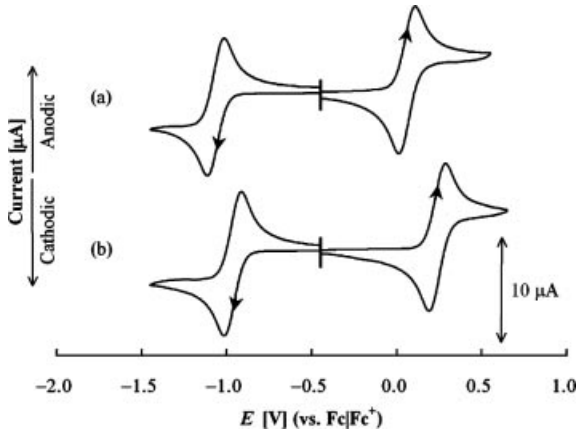

Figure 1. Cyclic voltammograms of (a) [CpNi($CH_2$)] and (b) [CpNi($CF_2$)] ($v$ = 100 mV s$^{-1}$, working electrode 1.6 mm in diameter, Pt disk) in dichloromethane solution containing $Bu_4NPF_6$ (0.1 M).

The nature of the terminal X group in the seven-membered ring shifts their redox potentials to anodic potentials in the following order: $CF_2$ > C=O > S > C=$CH_2$ > $CH_2$. A similar tendency is also found for the redox potentials [$E_{1/2}$(–2/–1) and $E_{1/2}$(–1/0)] of the corresponding square-planar nickel complexes $[Ni\{S_2C_2S_2(CH_2)_2(X)\}_2]^n$ ($n$ = –2, –1, 0).

The EPR spectra of the five complexes were measured in dichloromethane solution at room temperature. Singlet signals were found for [CpNi($CH_2$)] ($g$ = 2.0514), [CpNi($CF_2$)] ($g$ = 2.0529), [CpNi(C=$CH_2$)] ($g$ = 2.0518), [CpNi(S)] ($g$ = 2.0524), and [CpNi(C=O)] ($g$ = 2.0525). These $g$ values are almost identical to those of the other CpNi(dithiolene) complexes ($g$ = 2.041–2.054),[8] and are smaller then those of the CpNi(diselenolene) complexes ($g$ = 2.088–2.095).[8c] Note also that the $g$ values of the isoelectronic (17-electron) cobalt complexes $[CpCo(tfd)]^-$ ($g$ = 2.454)[18] and $[CpCo(mnt)]^-$ ($g \approx 2.5$)[19] are larger, thus demonstrating that the 17-electron Co(dithiolene) complexes have a large spin contribution on the metal center (formal $Co^{II}$), while the spin density of the nickel complex is largely delocalized on the ligands.[8]

The UV/Vis/NIR absorption spectra (Figure 2) exhibit a characteristic NIR absorption centered at ca. 800–850 nm. Their maximum absorption wavelengths ($\lambda_{max}$) and molar absorption coefficients ($\varepsilon$) are summarized in Table 3. Interestingly, the $\lambda_{max}$ evolution with the nature of X follows the electrochemical series identified above, with the lowest energy absorption observed with the most electron-rich dithiolato ligands.

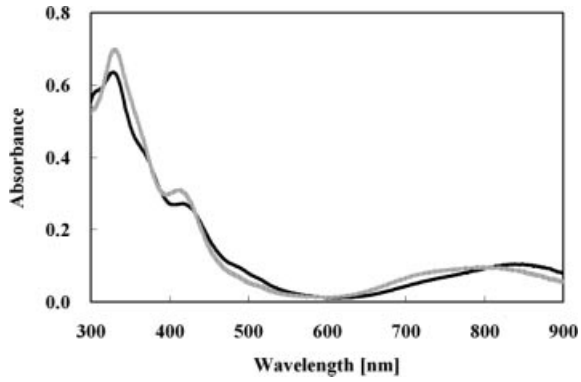

Figure 2. UV/Vis/NIR spectra of [CpNi($CH_2$)] (black line) and [CpNi($CF_2$)] (grey line) in dichloromethane solution ($c$ = $5 \times 10^{-5}$ M).

### Solid-State Structural and Magnetic Properties

X-ray structure determinations were performed for the five new CpNi(dithiolene) complexes, which are not isostructural despite their closely related molecular structures: [CpNi($CH_2$)] (triclinic, $P\bar{1}$), [CpNi($CF_2$)] (orthorhombic, *Pbca*), [CpNi($C{=}CH_2$)] (monoclinic, $P2_1$), [CpNi(S)] (monoclinic, $P2_1/c$), and [CpNi(C=O)] (monoclinic, $P2_1/n$). The ORTEP drawings are shown in Figures 3 and 4.

Selected bond lengths and bond angles are summarized in Tables 4 and 5, respectively. The Ni–S bond lengths are ca. 2.12 Å and are therefore similar to those of the other CpNi(dithiolene) complexes (Table 4) but slightly shorter than in monoanionic square-planar bis(dithiolene) complexes such as $[Ni(CH_2)_2]^-$,[10a] $[Ni(CF_2)_2]^-$,[11a] $[Ni(C{=}CH_2)_2]^-$,[12a] and $[Ni(S)_2]^-$[13] (ca. 2.14 Å). Similarly, we observe that the C–S and C=C distances are slightly shorter and slightly longer, respectively, in the [CpNi(dithiolene)] complexes than in the anionic Ni(dithiolene)$_2^-$ complexes. Since both types of complexes are formally $Ni^{III}$ $d^7$ species, the evolution of the bond lengths within the dithiolato ligand gives an indication of its contribution to the SOMO (singly occupied molecular orbital) of the complexes. Indeed, the two-electron oxidation of the dithiolato ligand leads to the corresponding dithioketone species, thus implying that partial oxidation of this ligand results in a shortening of the C–S bonds and associated lengthening of the C=C bond of the metallacycle. The fact that these trends are more marked in the [CpNi(dithiolene)] com-

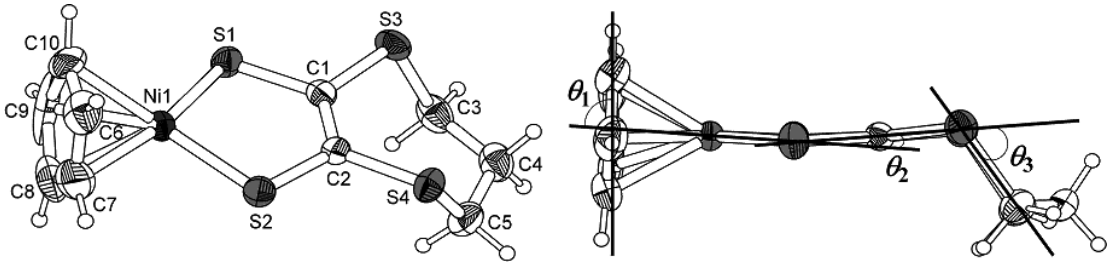

Figure 3. Left: ORTEP drawing of [CpNi($CH_2$)], thermal ellipsoids are drawn at 50% probability level. plexes than in the corresponding square-planar bis(dithiolene) ones clearly indicates a stronger participation of the dithiolato ligand in the SOMO.

These complexes adopt typical two-legged piano-stool geometries. The dihedral angle $\theta_1$ between the Cp and $NiS_2$ mean planes (see Figure 3) is close to 90°, a geometry comparable to that of 16-electron $CpCo^{III}$,[20] $CpRh^{III}$,[21] $CpIr^{III}$,[22] and ($\eta^6$-arene)$Ru^{II}$[23] dithiolene complexes. The $NiS_2C_2$ metallacycle is not perfectly planar but is slightly folded along the S···S hinge with $\theta_2$ values of between 2 and 8°, as is also observed with the complexes with dithiolato ligands fused with rigid five- (dmit, dmid) or six-membered (dddt, bdt) rings.[8] Furthermore, the dihedral angles ($\theta_3$ in Figure 3) between the C1–C2–S3–S4 and S3–S4–C3–C5 mean planes are found in the range 61–67° (Table 5).

The solid-state organization of the complexes differs strongly from one to the other. Considering that these molecules are radicals ($S$ = 1/2), with the spin density largely delocalized on the nickel atom, the dithiolene ligand, and the cyclopentadienido ring,[8c] their crystal structure can be analyzed in the light of possible paths for direct exchange magnetic interactions based on short contacts between the sulfur atoms of the dithiolene ligands and eventually between the Cp rings. Applying this procedure to the parent [CpNi($CH_2$)] complex first reveals (Figure 5) that the only short intermolecular contact involves the sulfur atoms of the metallacycles, affording chains running along the *c*-axis with two similar S···S intermolecular distances of 3.80 and 3.83 Å.

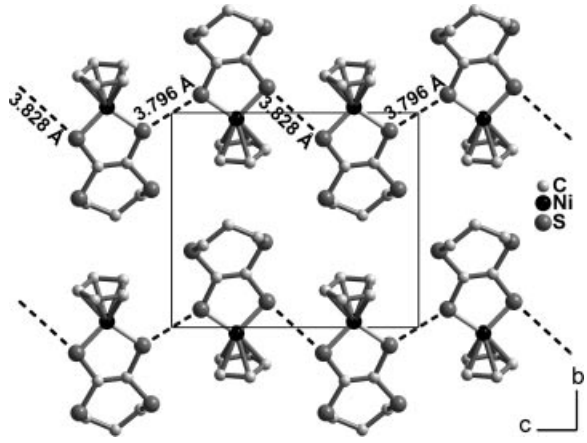

Figure 5. Projection view of the unit cell of [CpNi($CH_2$)] along the *a*-axis showing the chain motif.

As shown in Figure 6, a similar chain motif is also identified in [CpNi(C=$CH_2$)], which gives rise, for symmetry reasons, to a uniform chain structure with equivalent S···S distances of a slightly shorter 3.75 Å.

On the other hand, a projection view of [CpNi(S)] along the *b*-axis of the structure (Figure 7) does not reveal any short intermolecular contacts; the metallacycles are almost perpendicular to each other and the shortest S···S intermolecular distance of 4.0 Å involves the sulfur atom of the thioether moiety. All other S···S contacts exceed 4.5 Å.

However, looking at the stacking of the radical complexes in the perpendicular direction (along the monoclinic

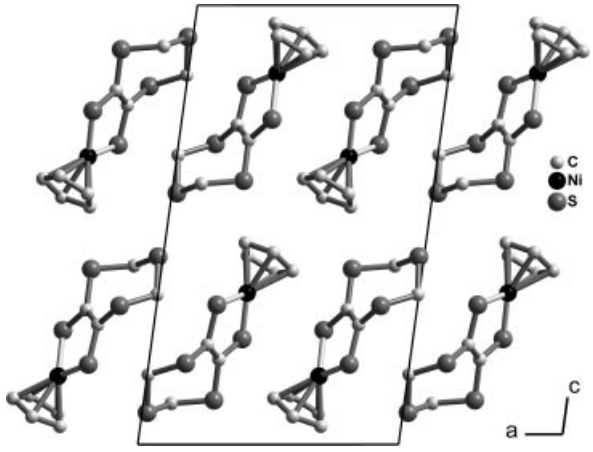

Figure 7. Projection view of [CpNi(S)] along the *b*-axis.

*b*-axis, Figure 8), the complexes form uniform chains that are characterized by a set on S···S intermolecular distances of between 3.69 and 4.06 Å that involve not only the sulfur atoms of the metallacycle, as already observed above in [CpNi($CH_2$)] and [CpNi(C=$CH_2$)], but also the outer sulfur atoms of the seven-membered metallacycle.

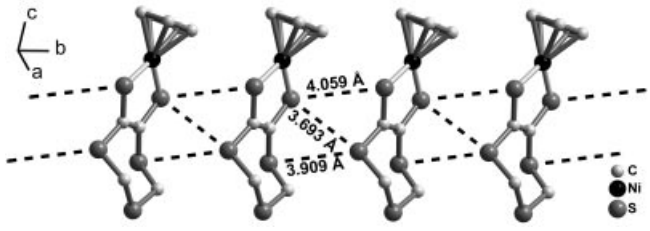

Figure 8. View of the chain-like structure of [CpNi(S)].

It is therefore expected from this structural analysis that [CpNi(S)] most probably experiences weaker antiferromagnetic interactions than the other two derivatives, as indeed observed from the temperature dependence of their magnetic susceptibility. As shown in Figure 9, all three exhibit a smooth maximum at low temperatures, characteristic of a Bonner–Fischer-type behavior of a Heisenberg uniform chain.[24] The molar susceptibility can be properly fitted in the whole temperature range (2–300 K) to the expression $\chi = \chi_0 + (1 - \rho)\cdot 0.375/T + \rho\cdot\chi_{BF}$, where $\chi_0$ is a temperature-independent value, $(1 - \rho)\cdot 0.375/T$ ($\chi_C$) represents a contribution of paramagnetic defaults (Curie tail), and $\rho\cdot\chi_{BF}$ is the contribution of the uniform chain; this also takes into account the *g* value of the different complexes determined from the solution EPR measurements (see above). *J*/*k* values of –39.2(3), –21.4(1), and –6.3(1) K, that is 27.2, 14.8, and 4.4 $cm^{-1}$, were found for [CpNi($CH_2$)], [CpNi(C=$CH_2$)], and [CpNi(S)], respectively, with Curie tail contributions not exceeding 0.4% of $S = 1/2$ species. Note that for [CpNi($CH_2$)] the chain is not really uniform from a structural point of view (Figure 5). However, attempts to use an alternating chain model to fit the data, even with a weak alternation, were unsuccessful.

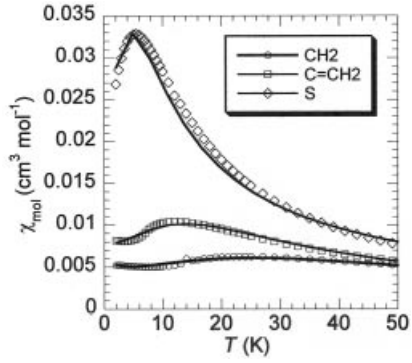

Figure 9. Temperature dependence of the magnetic susceptibility in [CpNi($CH_2$)], [CpNi(C=$CH_2$)], and [CpNi(S)]. Solid lines are fits to the uniform spin-chain model (see text).

The situation is completely different in the two other complexes, thereby illustrating the flexibility and adaptability of these series. As shown in Figure 10, [CpNi($CF_2$)] molecules are organized into layers perpendicular to the *c*-axis.

Within these layers, inversion-centered dyadic motifs are identified, which are most probably stabilized by two, almost linear, C–H···F hydrogen bonds (Figure 11). Similar C–H···F hydrogen bonds, although weak, have been shown to play a crucial role in halogenated molecules in the solid state.[25] Their geometrical characteristics [H···F = 2.508 Å, C(–H)···F = 3.430(6) Å, C–H···F = 171.5°] compare favorably with those described, for example, in *p*-difluorobenzene, whose H···F distances have been reported to be 2.49 Å,[26] as well as in several tetrathiafulvalene derivatives incorporating the very same seven-membered motif.[27]

This dyadic motif, with the $CH_2CF_2CH_2$ moiety bent away from the neighboring molecule, allows for an almost perfect eclipsed overlap between the planar $C_2S_4$ moieties of both complexes, although with large S···S distances of

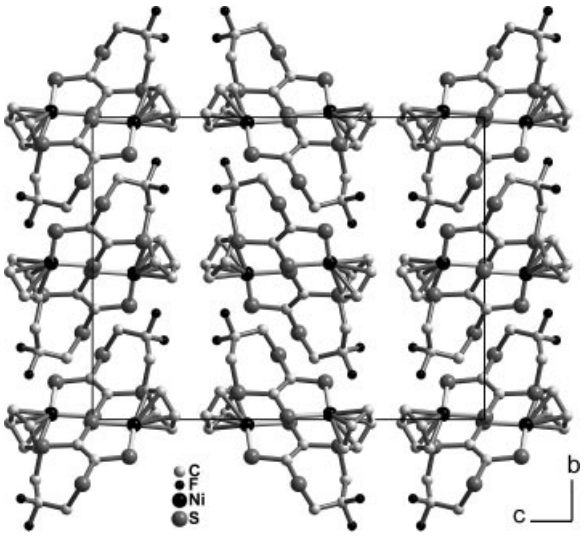

Figure 10. Projection view of the unit cell of [CpNi($CF_2$)] along the *a*-axis.

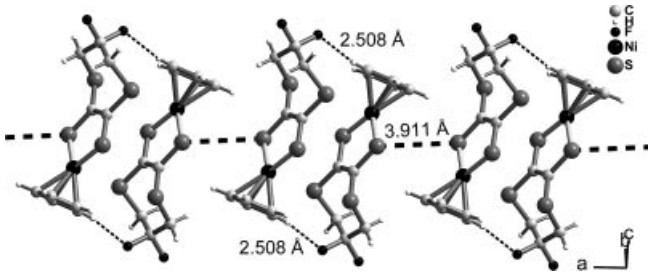

Figure 11. View of the solid-state organization of [CpNi($CF_2$)] showing the C–H···F hydrogen bonds and the shortest S···S intermolecular interactions.

between 4.06 and 4.10 Å. A notably shorter S···S contact [3.911(1) Å], which furthermore involves the sulfur atoms of the metallacycles, connects these dyads together and offers a more efficient path for direct magnetic exchange interactions. The temperature dependence of the magnetic susceptibility of [CpNi($CF_2$)] (Figure 12) confirms this analysis and the associated singlet–triplet behavior. Indeed, the susceptibility goes through a maximum upon cooling and decreases abruptly, as expected for a singlet ground state. It can be properly fitted to the expression $\chi = \chi_0 + (1 - \rho)\cdot 0.375/T + \rho\cdot\chi_{ST}$, where $\chi_0$ is a temperature-independent value, $(1 - \rho)\cdot 0.375/T$ the contribution of a small fraction of Curie-type magnetic defaults, and $\rho\cdot\chi_{ST}$ the contribution of the dyads with:

$$\chi_{ST} = [(Ng^2\beta^2)/k]\cdot\{1/[3 + \exp(-J/kT)]\}$$

This affords a $J_{CF_2}/k$ value of –11.9(1) K (8.3 $cm^{-1}$) with a Curie tail contribution of 3% of $S = 1/2$ magnetic defaults, thus demonstrating that at S···S distances of ca. 4 Å the overlap interaction is indeed very weak, as already noted above in the chain behavior of [CpNi(S)].

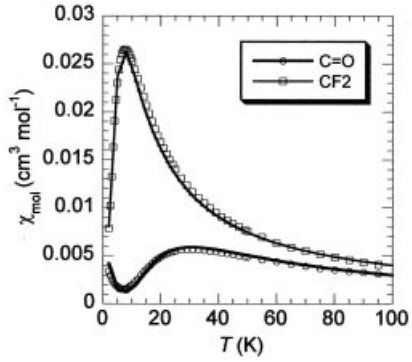

Figure 12. Temperature dependence of the magnetic susceptibility in [CpNi(C=O)] and [CpNi($CF_2$)]. Solid lines are fits to the singlet–triplet model (see text).

In [CpNi(C=O)], a similar singlet–triplet behavior is observed, although with much stronger interactions since the fit of the magnetic data, performed as described above for [CpNi($CF_2$)], affords a $J_{CO}/k$ value of –50.6(4) K (35.2 $cm^{-1}$), together with a Curie tail contribution of 2.3% of $S = 1/2$ species.

A projection view of the unit cell of [CpNi(C=O)] is shown in Figure 13. A close observation of the solid-state organization in the structure of [CpNi(C=O)] also shows the presence of inversion-centered dyadic motifs (Figure 14), with a complex set of S···S short distances between 3.69 and 4.02 Å within columns of dyads running along the *b*-axis. Such a magnetic system is related to spin ladder systems with a singlet state as ground state, as also observed experimentally from the temperature dependence of the susceptibility. However, no analytical model is available to fit the behavior of such a complex interaction network. Therefore, the singlet–triplet fit described above can only be considered as an estimation of the strongest interaction.

## Conclusions

The regular evolution of the electrochemical and absorption properties experimentally observed here in solution with the order $CF_2 > C=O > S > C=CH_2 > CH_2$ offers an attractive series, particularly when it comes to evaluating the origin of the NIR absorption band in these complexes. Theoretical calculations are under way to determine the nature of the transitions involved in this absorption band. The diversity of structural and magnetic behaviors encountered in this isosteric series of radical complexes demonstrates that the nature of the terminal group has a strong influence on the solid-state organization, which complements earlier observations. Indeed, while the S/Se substitution in the metallacycle was found to afford isostructural compounds as in the dithiolene/diselenolene pairs [CpNi(dmit)] vs. [CpNi(dsit)],[8a] [CpNi(dddt)] vs. [CpNi(ddds)],[8c] and [CpNi(bdt)] vs. [CpNi(bds)],[8c] a limited modification of the dithiolate ligand affecting the side heterocycle strongly modifies their crystal structure, as already observed in the following pairs, which are not isostructural: [CpNi(dmit)] vs. [CpNi(dmid)][8a] or [CpNi(dddt)] vs. [CpNi(dsdt)].[8c] More generally, the strong folding of the dithiolato ligand in the five complexes hinders the face-to-face overlap on the ligand, thus favoring one-dimensional spin chains through side-by-side interactions between sulfur atoms of the metallacycles.

## Experimental Section

**General Remarks:** All reactions were carried out under argon by means of standard Schlenk techniques. All solvents for chemical reactions were dried and distilled from Na/benzophenone (for toluene) or $CaH_2$ (for methanol) before use. The square-planar (dithiolene)nickel complexes [Ni(pddt)$_2$],[10] [Ni($F_2$pddt)$_2$],[11] [Ni(dpdt)$_2$],[12] and [Ni(dtdt)$_2$][13] were synthesized according to literature methods. [1,3]Dithiolo[4,5-*b*][1,4]dithiepine-2,6-dione[28] and [$Cp_2$Ni]($BF_4$)[29] were also prepared according to literature methods. [$Cp_2$Ni] and [CpNi(CO)]$_2$ were obtained from Strem Chemicals and Aldrich Chemicals, respectively. Silica gel (Silica gel 60) was obtained from Merck, Ltd. TOF mass spectra were recorded with a Bruker Daltonics MALDI-TOF BIFLEX III mass spectrometer. UV/Vis and NIR spectra were recorded with a Hitachi Model UV-2500PC and a Perkin Elmer Model Lambda 19 UV/Vis/NIR spectrometer, respectively. Elemental analyses were performed by the "Service d'Analyse du CNRS" at Gif/Yvette, France. UV irradiation for the photoreaction was performed with a high-pressure Hg lamp (Applied Photophysics, Ltd).

**General Procedure for the Synthesis of [CpNi($CH_2$)], [CpNi($CF_2$)], [CpNi(C=$CH_2$)], and [CpNi(S)]:** A toluene solution of [$Cp_2$Ni] (38 mg, 0.2 mmol) and the square-planar dithiolene complex [Ni(dithiolene)$_2$] (0.2 mmol) was heated at 80 °C for 2 h. After removal of the solvent under reduced pressure, the residue was extracted and separated by column chromatography (silica gel; dichloromethane/*n*-hexane, 1:1 v/v). The product was further purified by recrystallization (*n*-hexane/dichloromethane) to afford the corresponding CpNi(dithiolene) complexes: [CpNi($CH_2$)] (black needles, 34.4 mg, 54% yield); [CpNi($CF_2$)] (black plates, 29 mg, 41% yield); [CpNi(C=$CH_2$)] (black needles, 19.8 mg, 30% yield); [CpNi(S)] (dark-green blocks, 41 mg, 61% yield). Details are summarized in Table 2. In the reactions of [Ni($CH_2$)$_2$] and [Ni($CF_2$)$_2$] with [$Cp_2$Ni], the mono(dithiolene)nickel oligomers [Ni($CH_2$)]$_n$ and [Ni($CF_2$)]$_n$ were also obtained by column chromatography (silica gel; dichloromethane). These brown products (a few mg) were identified as hexamers ($n$ = 6).

**[CpNi($CH_2$)]:** TOF-MS (EI$^+$, 1.3 kV): $m/z$ = 317 [M$^+$], 275 [M$^+$ – ($CH_2$)$_3$]. UV/Vis/NIR ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 848 nm (2100 $M^{-1}cm^{-1}$), 417 (5400), 329 (13000), 271 (12000). $C_{10}H_{11}NiS_4$ (318.15): calcd. **[CpNi($CF_2$)]:** TOF-MS (EI$^+$, 1.3 kV): $m/z$ = 353 [M$^+$]. UV/Vis/NIR ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 798 nm (2000 $M^{-1}cm^{-1}$), 411 (6400), 330 (15000), 264 (13000). $C_{10}H_9F_2NiS_4$ (354.13): calcd. C 33.92, H 2.56, S 36.22; found C 34.02, H 2.83, S 36.14.

**[CpNi(C=$CH_2$)]:** TOF-MS (EI$^+$, 1.3 kV): $m/z$ = 329 [M$^+$], 301 [M$^+$ – ($CH_2$)$_2$], 275 [M$^+$ – ($CH_2$)$_2$C=$CH_2$]. UV/Vis/NIR ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 840 nm (2400 $M^{-1}cm^{-1}$), 419 (6500), 327 (15000), 266 (12000). $C_{11}H_{11}NiS_4$ (330.16): calcd. C 40.02, H 3.36, S 38.85; found C 40.22, H 3.65, S 38.56.

**[CpNi(S)]:** TOF-MS (EI$^+$, 1.3 kV): $m/z$ = 335 [M$^+$]. UV/Vis/NIR ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 823 nm (1800 $M^{-1}cm^{-1}$), 418 (5900), 321 (14000). $C_9H_9NiS_5$ (336.19): calcd. C 32.15, H 2.70, S 47.69; found C 32.24, H 2.55, S 47.79.

**Synthesis of [CpNi(C=O)]. (a) Thermal Conditions:** A solution of [$Cp_2$Ni] (94 mg, 0.5 mmol) and [1,3]dithiolo[4,5-*b*][1,4]dithiepine-2,6-dione (118 mg, 0.5 mmol) was heated in refluxing toluene for 24 h. Silica gel was then added to the solution to oxidize remaining [$Cp_2$Ni] in the reaction mixture. The solvent was removed under reduced pressure, and the residue was separated by column chromatography (silica gel; dichloromethane/*n*-hexane, 1:1 v/v) to afford [CpNi(C=O)] as a black solid (15 mg, 9% yield). The same reaction performed with 2 equiv. of [1,3]dithiolo[4,5-*b*][1,4]dithiepine-2,6-dione and a shorter reaction time (6 h) afforded 25 mg of [CpNi(C=O)] in a slightly improved 15% yield. **(b) Photochemical Conditions:** A toluene solution (300 mL) of [$Cp_2$Ni] (57 mg, 0.3 mmol, $c = 1.0 \times 10^{-3}$ M) and [1,3]dithiolo[4,5-*b*][1,4]dithiepine-2,6-dione (71 mg, 0.3 mmol, $c = 1.0 \times 10^{-3}$ M) was irradiated with a high-pressure Hg lamp (400 W) for 24 h. A black precipitate was filtered off, and the solvent removed under reduced pressure. The reaction mixture was separated by column chromatography (silica gel; dichloromethane/*n*-hexane, 1:1 v/v) to afford [CpNi(C=O)] as a black solid (15 mg, 9% yield).

**[CpNi(C=O)]:** TOF-MS (EI$^+$, 1.3 kV): $m/z$ = 331 [M$^+$], 275 [M$^+$ – ($CH_2$)$_2$C=O]. UV/Vis/NIR ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 806 nm (1700 $M^{-1}cm^{-1}$), 416 (5600), 325 (13000), 264 (11000). $C_{10}H_9NiOS_4$

**CV Measurements:** All electrochemical measurements were performed under argon. Solvents for electrochemical measurements were dried over molecular sieves (4 Å) before use. A platinum wire served as a counter electrode, and the reference electrode (Ag/AgCl) was corrected for junction potentials by being referenced internally to the ferrocene/ferrocenium ($Fc/Fc^+$) couple. A stationary platinum disk (1.6 mm in diameter) was used as working electrode. A Model CV-50W instrument from BAS Co. was used for cyclic voltammetry (CV) measurements. CVs were measured in 1 mM dichloromethane solutions of complexes containing 0.1 M tetrabutylammonium hexafluorophosphate ($Bu_4NPF_6$) at 25 °C.

**EPR Measurements:** EPR spectra were recorded with a Bruker ESP 300 spectrometer (X-band) equipped with a variable-temperature attachment from 1 mM dichloromethane solutions of complexes. Optimizations and simulations of the frozen solution spectra were carried out with a program, based on the Levenberg–Marquardt least-squares fit, which compares the position of the experimental resonance lines with those calculated by second-order perturbation theory.

**X-ray Diffraction Studies:** Single crystals of [CpNi(dithiolene)] complexes were obtained by recrystallization from dichloromethane solution and then vapor diffusion of *n*-hexane into these solutions. A crystal was mounted on the top of a thin glass fiber. Data were collected with a Stoe Imaging Plate Diffraction System (IPDS) with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature. Structures were solved by direct methods (SHELXS-97) and refined (SHELXL-97)[30] by full-matrix least-squares methods, as implemented in the WinGX software package.[31] Absorption corrections were applied. Hydrogen atoms were introduced at calculated positions (riding model), included in structure factor calculations, and not refined. Crystallographic data of complexes are summarized in Table 6. CCDC-614018 {[CpNi(C=$CH_2$)]}, -614019 {[CpNi($CF_2$)}, -614020 {[CpNi($CH_2$)]}, -614021 {[CpNi(C=O)]} and -614022 {[CpNi(S)]} contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We thank Prof. Masatsugu Kajitani (Sophia University) for his help with the CV measurements. We also thank the Ministère de la Recherche (France) for a postdoctoral grant (to M. N.) and the CNRS (France) and the National Swiss Foundation for financial support.

# Synthesis of Methyl Metallocenecarboxylates [{η⁴-Ph$_{4-n}$(SiMe$_3$)$_n$C$_4$}Co{η⁵-MeOC(O)C$_5$H$_4$}] (*n* = 1, 2) and Their Desilylation Reactions: Structural Studies and Conversion to Metallocenecarboxylic Acids and Their Alcohol Derivatives

**Hanuman P. Gupta,[a] M. Senthil Kumar,[a] Shailesh Upreti,[a] and Anil J. Elias*[a]**

**Keywords:** Cobalt / Alkynes / Desilylation / Metallocenes / Carboxylic acids

The reaction of (2-phenylethynyl)trimethylsilane (Me$_3$SiC≡CPh) with [{η⁵-MeOC(O)C$_5$H$_4$}Co(PPh$_3$)$_2$] generated in situ results in the exclusive formation of two isomers of methyl metallocenecarboxylates, namely [{*trans*-η⁴-Ph$_2$(Me$_3$Si)$_2$C$_4$}Co{η⁵-MeOC(O)C$_5$H$_4$}] (**1**) and [{*cis*-η⁴-Ph$_2$(Me$_3$Si)$_2$C$_4$}Co{η⁵-MeOC(O)C$_5$H$_4$}] (**2**). The reaction of [{η⁵-MeOC(O)C$_5$H$_4$}Co(PPh$_3$)(Me$_3$SiC≡CPh)] with PhC≡CPh yields the methyl metallocenecarboxylate [{η⁴-Ph$_3$(Me$_3$Si)C$_4$}Co{η⁵-MeOC(O)C$_5$H$_4$}] (**3**) along with [{η⁴-Ph$_4$C$_4$}Co{η⁵-MeOC(O)C$_5$H$_4$}] (**4**). The reactions of **1**, **2** and **3** with Bu$_4$NF in dmso results in the desilylated complexes [(*trans*-η⁴-Ph$_2$H$_2$C$_4$)Co{η⁵-MeOC(O)C$_5$H$_4$}] (**5**), [(*cis*-η⁴-Ph$_2$H$_2$C$_4$)Co{η⁵-MeOC(O)C$_5$H$_4$}] (**6**) and [(η⁴-Ph$_3$HC$_4$)Co{η⁵-MeOC(O)C$_5$H$_4$}] (**7**), respectively. Compounds **5**, **6** and **7** yield the carboxylic acids [(*trans*-η⁴-Ph$_2$H$_2$C$_4$)Co{η⁵-HOC(O)C$_5$H$_4$}] (**8**), [(*cis*-η⁴-Ph$_2$H$_2$C$_4$)Co{η⁵-HOC(O)C$_5$H$_4$}] (**9**) and [(η⁴-Ph$_3$HC$_4$)Co{η⁵-HOC(O)C$_5$H$_4$}] (**10**) upon treatment with KO*t*Bu in dmso. Reduction of **5** and **7** with LiAlH$_4$ in thf gives the alcohol complexes [(*trans*-η⁴-Ph$_2$H$_2$C$_4$)Co(η⁵-HOCH$_2$C$_5$H$_4$)] (**11**) and [(η⁴-Ph$_3$HC$_4$)Co(η⁵-HOCH$_2$C$_5$H$_4$)] (**12**) in good yields. Compounds **1**–**7** and **11** were characterized structurally. These structural studies show interesting variations in the orientations of the cyclobutadiene-bound phenyl groups when the silyl groups are systematically removed from the cyclobutadiene moiety.

## Introduction

Stable metallocenecarboxylic acids and their alcohol derivatives are excellent precursors for a host of organometallic molecules with a wide range of potential applications. The most well-known among these is ferrocenecarboxylic acid, which, for example, is widely used in the design and development of electrochemical biosensors for monitoring of glucose and lactate,[1] in electrochemical DNA sensors,[2] in the design of stable electroactive multi(ferrocenyl)stannoxane clusters,[3] and as a reagent for the synthesis of prochiral ferrocene catalysts bearing oxazoline substituents.[4] Unlike ferrocenecarboxylic acid, whose rich chemistry has been well documented, the chemistry of other metallocenecarboxylic acids is still being developed. Among these, (η⁵-carboxycyclopentadienyl)(η⁴-tetraphenylcyclobutadiene)cobalt, a highly stable cyclobutadienylcobaltocenecarboxylic acid, has shown great promise in terms of stability and reactivity.[5,6] Cobalt(I) oxazoline palladacycles (COP) such as COP-OAc and COP-Cl, which are commercially available and are prepared from this carboxylic acid, effectively promote the asymmetric rearrangement of allylic trichloroacetimidates and *N*-(4-methoxyphenyl)trifluoroacetimidates, which provides easy access to allylic amines and allylic alcohols of high enantiomeric purity.[7,8] Pioneering work by Richards and co-worker has simplified the preparation of this carboxylic acid by the generation of [{MeOC(O)C$_5$H$_4$}Co(PPh$_3$)$_2$] in situ instead of the older and more expensive method involving [CpCo(CO)$_2$].[9,10] However, it has been observed that the steric bulkiness of the tetraphenylcyclobutadiene moiety of [(η⁴-Ph$_4$C$_4$)Co(η⁵-C$_5$H$_4$COOH)] significantly influences the nature of the products formed from its reactions, often reducing its reactivity in comparison to ferrocenecarboxylic acid.[11] We were interested in reducing the steric bulkiness of the tetraphenylcyclobutadiene part of this complex by systematically replacing the phenyl substituents with hydrogen atoms so as to fine-tune its reactivity while maintaining its high stability and accessibility. The method adopted was to initially make metallocenes containing a varying number of phenyl and trimethylsilyl groups on the cyclobutadiene moiety and then removing the silyl groups.

An added interest in this study stems from the difference in reactivity of the cobalt-bound cyclopentadienyl and cyclobutadienyl groups. Rosenblum and co-workers have shown that for the parent complex, (η⁵-cyclopentadienyl)(η⁴-cyclobutadiene)cobalt, the hydrogen atoms of the

(+)-(*S*)-COP-OAc ( R= OAc)
(+)-(*S*)-COP-Cl (R = Cl)

cyclobutadiene ring are more reactive towards electrophilic substitution reactions than those of the cyclopentadiene ring.[12] In this paper we describe our efforts to prepare examples of sterically less hindered ($\eta^5$-cyclopentadienyl)($\eta^4$-phenylcyclobutadiene)cobalt-based carboxylic esters, carboxylic acids and their alcohols derivatives with varying numbers of hydrogen atoms and phenyl groups bound to the cyclobutadiene unit. Structural studies on the silylated and desilylated metallocenes indicate interesting orientational changes of the phenyl groups around the cyclobutadiene moiety upon removal of the trimethylsilyl groups.

## Results and Discussion

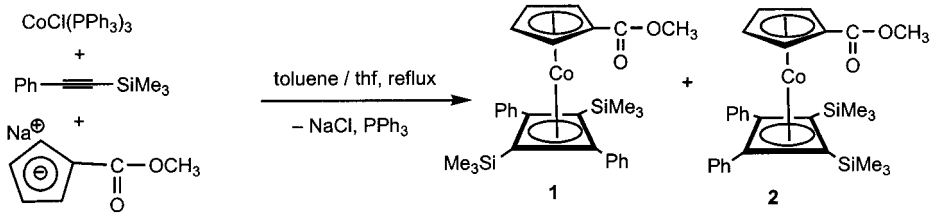
The generation of [$\eta^5$-MeOC(O)$C_5H_4$]Co($PPh_3$)$_2$ in situ was carried out by the preparation of [(methoxycarbonyl)-cyclopentadienyl]sodium from cyclopentadienylsodium and dimethyl carbonate followed by the reaction with chloridotris(triphenylphosphane)cobalt. The alkyne, (2-phenylethynyl)trimethylsilane, was then added to this solution of [{$\eta^5$-MeOC(O)$C_5H_4$}Co($PPh_3$)$_2$] in the required molar ratio.

It has been observed that the reaction of the half-sandwich complex [CpCo(CO)$_2$] with disubstituted acetylenes differs significantly from that of the phosphane complex [CpCo($PPh_3$)$_2$].[13] Thus, while the former results in the formation of cobaltocenes having $\eta^5$-cyclopentadienide and $\eta^4$-cyclobutadiene groups often along with another metallocene having a carbonyl-inserted $\eta^4$-cyclopentenone moiety, the latter has often been found to form $PPh_3$-stabilized cobaltocyclopentadiene metallacycles along with ($\eta^5$-cyclopentadienyl)($\eta^4$-cyclobutadiene)cobaltocenes. It is of interest to note that in all the reactions that were carried out in the present study using (2-phenylethynyl)trimethylsilane, no $PPh_3$-stabilized cobaltocyclopentadiene metallacycles were found to form. The reaction of equimolar amounts of [CoCl($PPh_3$)$_3$] with [(methoxycarbonyl)cyclopentadienyl]-sodium in a mixture of thf and toluene followed by the reaction with 2 equiv. of (2-phenylethynyl)trimethylsilane under reflux conditions resulted in the formation of the *cis* and *trans* isomers of [$\eta^5$-(methoxycarbonyl)cyclopentadienyl]($\eta^4$-diphenylbis(trimethylsilyl)cyclobutadiene)-cobalt, [{*trans*-$\eta^4$-$Ph_2(Me_3Si)_2C_4$}Co{$\eta^5$-MeOC(O)-$C_5H_4$}] (**1**) and [{*cis*-$\eta^4$-$Ph_2(Me_3Si)_2C_4$}Co{$\eta^5$-MeOC(O)-$C_5H_4$}] (**2**) (Scheme 1).

Compounds **1** and **2** were formed in a ca. 3:1 ratio and were purified by column chromatography. While the *trans* isomer crystallized readily from the mixture, purification and crystallization of the *cis* isomer proved time-consuming. Pure crystals of **2** (15%) were isolated by repeated fractional crystallization after removal of **1** (41%) from the mixture. Spectral studies and a crystal-structure analysis of **1** and **2** confirmed their identity.

With a view to preparing complexes having one or three phenyl groups on the cyclobutadiene ring, a different strategy was adopted. The stoichiometry of the reagents and the reaction parameters were controlled so as to synthesize a cobalt complex having only one $Me_3SiC{\equiv}CPh$ moiety coordinated to it in situ. It was expected that this complex would react with another equivalent of PhC≡CPh or $Me_3SiC{\equiv}CSiMe_3$ to yield the expected complexes. However, the equimolar reaction of [CoCl($PPh_3$)$_3$] with [(methoxycarbonyl)cyclopentadienyl]sodium and (2-phenylethynyl)trimethylsilane followed by the reaction with 1 equiv. of diphenylacetylene did not result in the monosilylated product **3**, but gave **1** along with the tetraphenylcyclobutadienyl derivative **4**. From independent studies it was observed that the intermediate complex having one acetylene moiety is formed in only around 50% yield. Changing the stoichiometry of the reactants by halving the amounts of (2-phenylethynyl)trimethylsilane followed by the reaction with diphenylacetylene gave the triphenyl(trimethylsilyl)cyclobutadienyl-substituted complex **3** along with the tetraphenylcyclobutadienyl derivative **4** (Scheme 2). Similar attempts to prepare metallocenes containing three trimethylsilyl groups bound to the cyclobutadiene ring by the reaction of [CpCo($PPh_3$)(PhC≡$CSiMe_3$)] with $Me_3SiC{\equiv}CSiMe_3$ were found not to proceed, even under reflux conditions in toluene.

Compounds **1**–**3** were found to readily undergo desilylation when treated with $Bu_4NF$ in dmso at 70 °C for 24 h, resulting in *cis* and *trans* isomers of diphenyl- (**5**, **6**) and triphenyl-substituted (**7**) cyclobutadienyl complexes (Scheme 3). The yields of the products varied from 87 to



Scheme 1.

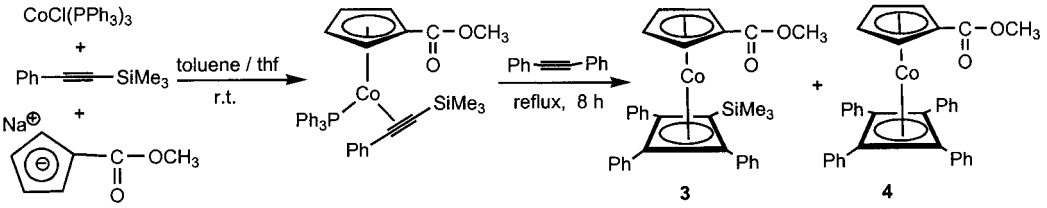
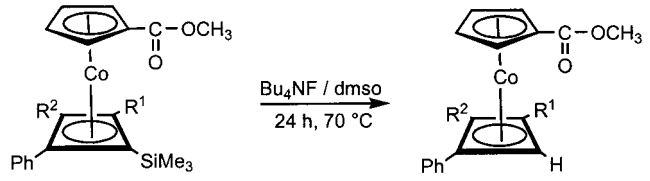


Scheme 2.

93%. The silylated and desilylated methyl esters have $^{13}C$ NMR chemical shifts in the range $\delta$ = 166.12–167.25 ppm for the ester group.



| | | | |
|---|---|---|---|
| $R^1$ = Ph, $R^2$ = $SiMe_3$ | **1** | $R^1$ = Ph, $R^2$ = H | **5** |
| $R^1$ = $SiMe_3$, $R^2$ = Ph | **2** | $R^1$ = H, $R^2$ = Ph | **6** |
| $R^1$ = $R^2$ = Ph | **3** | $R^1$ = $R^2$ = Ph | **7** |

Scheme 3.

We observed that high yields of desilylated products were obtained by using tetrabutylammonium fluoride as the desilylating reagent. Compounds **5**–**7** are quite stable to hydrolysis and were purified by column chromatography on silica gel. The $^1H$ NMR spectra of these complexes clearly show the presence of the cyclobutadienyl protons. For complexes **5** and **7**, for example, the cyclobutadienyl proton signals are observed at $\delta$ = 4.96 and 5.02 ppm, while for the *cis* isomer **6** they are observed at $\delta$ = 4.47 ppm. It is of interest to note that the signal for the cyclobutadiene protons is observed at $\delta$ = 3.66 ppm for the parent unsubstituted complex,[12] and at $\delta$ = 4.04 ppm for tricarbonyl(cyclobutadiene)iron.[14] The deshielding of the cyclobutadiene protons in **5** and **7** is possibly due to the anisotropy effect of the phenyl groups on both sides of the cyclobutadiene-bound hydrogen atoms. The cyclopentadienyl hydrogen atoms appear as a set of two peaks, one in the range $\delta$ = 4.60–4.88 ppm and the other in the range $\delta$ = 5.24–5.33 ppm. The molecular ion peaks in the FAB mass spectra of complexes **5**–**7** also confirm their identity.

Esters **5**–**7** were converted into the corresponding carboxylic acids **8**–**10** by treatment with potassium *tert*-butoxide in dmso at room temperature (Scheme 4). The yields of the carboxylic acids varied from 78 to 85%. The IR spectra of the carboxylic acids **8**–**10** show the acid carbonyl stretching bands at 1658, 1671 and 1674 $cm^{-1}$, respectively, while those for the corresponding esters are observed at 1708, 1706 and 1714 $cm^{-1}$, respectively. The $^1H$ NMR spectra also show similar variations in the cyclopentadienyl peaks ($\delta$ = 4.60–4.88 and 5.24–5.33 ppm for the esters and $\delta$ = 4.71–4.75 and 5.18–5.40 ppm for the carboxylic acids). The $^{13}C$ NMR spectra of the complex ($\eta^5$-carboxycyclopentadienyl)($\eta^4$-tetraphenylcyclobutadiene)cobalt show a chemical shift of $\delta$ = 191.1 ppm for the carboxylic acid carbon atom,[9] and the carboxylic acid carbon atoms of the acid complexes **8**, **9** and **10** show $^{13}C$ chemical shifts in the range $\delta$ = 192.26–193.45 ppm. Mass spectral analysis also further confirms the identity of the carboxylic acids. Due to the difficulty in growing suitable crystals, structural analysis of these complexes could not be performed.

| $R^1$ = $R^2$ = Ph | **7** | $R^1$ = $R^2$ = Ph | **10** |

Scheme 4.

The carboxylates **5** and **7** were reduced to the corresponding alcohols **11** and **12** by treatment with lithium aluminium hydride in diethyl ether at room temperature (Scheme 5). The stable alcohols were obtained in 69 and 86% yield, respectively, as crystalline solids and were purified by column chromatography. The identity of the *trans*-diphenyl-substituted alcohol **11** was further confirmed by single-crystal X-ray structural analysis. Reduction of the carboxylate **6** could not be carried out as the quantity needed for the reaction was not available due to the poor yield of its precursor complex **2**.

## Electrochemical Studies of Complexes 1–12

Cyclic voltammetric studies on complexes **1**–**12** were carried out using a 0.005 M solution of each complex in 0.1 M tetrabutylammonium perchlorate as supporting electrolyte in dichloromethane solution. Compounds **1**–**3** and **5**–**12** show a quasi-reversible redox couple in the potential range

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.0–1.5 V at a scan rate of 0.1 $Vs^{-1}$ in the positive direction. Interestingly, under identical measurement conditions the voltammogram of the tetraphenylcyclobutadienyl ester [($\eta^4$-$Ph_4C_4$)Co{$\eta^5$-$MeOC(O)C_5H_4$}] shows an almost reversible redox couple while that of the tetraphenyl acid [($\eta^4$-$Ph_4C_4$)Co{$\eta^5$-$HOC(O)C_5H_4$}] shows a fully reversible redox couple. The $E_{1/2}$ values given in Table 1 were calculated by averaging the anodic and cathodic potential of the respective redox couple with respect to the ferrocene/ferrocenium redox couple. On increasing the number of cycles, the height of both the anodic and cathodic peaks decreases, although this reduction is minimal after the second cycle; this indicates partial decomposition of the complex at the electrode surface. It is interesting to note that on going from the silylated complexes **1**, **2** and **3** to the desilylated complexes **5**, **6** and **7** there is a negative shift in $E_{1/2}$ values. From the desilylated complexes **5**, **6** and **7** to the carboxylic acids (**8**, **9** and **10**) and alcohols (**11** and **12**) a further negative shift in $E_{1/2}$ values is observed. This indicates that the system is more electroactive towards oxidation on going from silylated complexes through desilylated complexes to carboxylic acids and their alcohol derivatives. The $E_{1/2}$ value for complex **4**, which bears four phenyl rings on the cyclobutadiene ring, is 0.570 V. On removing the phenyl rings one by one, the $E_{1/2}$ values decrease and oxidation becomes easier.

Table 1. Cyclic voltammetric data of complexes **1**–**12**.

| Entry | Complex | $E_{1/2}$ vs. $Fc/Fc^+$ [V] |

### Structural Studies on Complexes 1–7 and 11

Detailed structural analysis were carried out on the silylated and desilylated carboxylates **1**–**7** and the alcohol **11** as there is only a preliminary communication available in the literature on the structures of the *cis*- and *trans*-metallocenes [$CpCo\{(Me_3Si)_2Ph_2C_4\}$], which contain unsubstituted cyclopentadienyl rings.[15] The crystal structures of complexes **1**–**7** and **11** are given in Figures 1, 2, 3, 4, 5, 6, 7 and 8, respectively. Selected bond lengths and angles are given in Tables 2 and 3 and details of data collection, solution and crystal parameters are given in the Experimental Section. The structural studies on complexes **1**–**7** indicate no significant variation in the structure and orientation of the ester-substituted cyclopentadienyl group. However, on comparing structures of complexes **1**–**3** with those of **5**–**7**, the structural changes associated with the cyclobutadiene ring and its substituents were found to be quite significant. As such, the four phenyl rings of the tetraphenylcyclobutadiene ring of **4** are displaced at angles of 37.39°, 48.44°, 29.25° and 60.49° with respect to the cyclobutadiene ring. A comparison of **4** with the corresponding carboxylic acid also shows that the relative orientation of the phenyl rings with

respect to the cyclobutadiene ring varies significantly from 7.05° to 89.20°.[11] It was therefore of interest to see whether desilylation, which results in lower crowding around the cyclobutadiene ring, will affect the orientation of the phenyl groups in complexes **5**–**7**. In addition, complex **4** is a propeller-type molecule, and such complexes show promise in the design of molecular devices. This study therefore provides information on structural changes at the molecular level accompanying the removal of substituents that are akin to the blades of such propeller-type molecules.

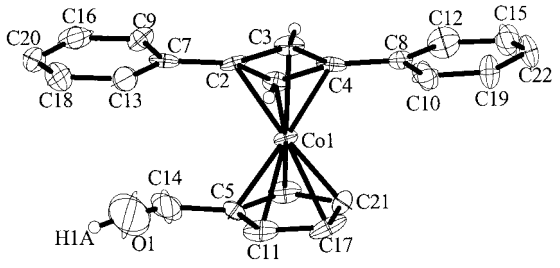

Figure 8. Thermal ellipsoid view of complex **11** with 30% probability ellipsoids (all H atoms, except those of the cyclobutadiene moiety, omitted for clarity).

On comparing the structures of complexes **1**–**3** with their desilylated analogues **5**–**7** it can be seen that, basically, two noticeable structural changes occur. The phenyl groups, which are pushed away from the plane of the cyclobutadienyl ring in complexes **1**–**3**, tend to come close to the plane of the cyclobutadiene ring in complexes **5**–**7**. More interestingly, however, the phenyl groups rotate and take up orientations which tend to align with the planarity of the cyclobutadiene ring. Both these structural changes indicate a tendency to gain better π-delocalization of the phenyl groups with the metal-coordinated cyclobutadiene ring (Scheme 6).

The angle ($\theta$) between the mean plane of the cyclobutadiene ring and the mean plane of a substituted phenyl ring represents the extent of deviation of the phenyl rings from the plane of the cyclobutadiene ring. For complex **1**, which has a *trans* orientation of two phenyl substituents, the values of $\theta$ are 32.68° and 43.97°. The corresponding desilylated complex **5** has $\theta$ reduced to 5.34° and 3.09° (5.45° and 2.15° for the other crystallographically independent structure in the unit cell). For the *cis*-oriented complex **2**, the values of $\theta$ are 63.14° and 43.98°, which are reduced to 24.75° and 12.45° for the desilylated complex **6**. Similarly for the triphenyl(trimethylsilyl)cyclobutadiene complex **3**, the $\theta$ values are 34. 26°, 31.47° and 64.19°, which are reduced in complex **7** to 14.14°, 12.26° and 54.13° respectively (13.97°, 12.26° and 53.98° for the other crystallographically independent structure in the unit cell). These results clearly indicate that removing the steric crowding around the cyclobutadiene unit tends to make the phenyl groups become more aligned to the cyclobutadiene ring.

The other interesting difference observed on comparing complexes **1**–**3** with complexes **5**–**7** is the distortion from planarity observed for the exocyclic cyclobutadiene–phenyl bonds. Although the bond connecting the phenyl ring to the cyclobutadiene ring should ideally lie in the same plane

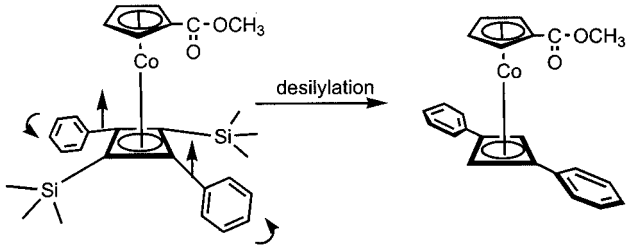

Scheme 6.

as that of the cyclobutadiene ring, what is observed is that all the exocyclic bonds from the cyclobutadiene ring to the phenyl groups are displaced at an angle ($\phi$) to the plane of the cyclobutadiene ring with the displacement directed away from the cyclopentadienylcobalt moiety. The value of $\phi$ varies from 167.50° to 177.11° for the phenyl substituents. A comparison of the silylated metallocenes **1**–**3** and desilylated metallocenes **5**–**7** indicates that this distortion decreases upon desilylation, with the angles coming closer to 180°. The values of $\phi$ for complex **1** are 172.54° and 175.48° which become 176.14° and 177.11° in **5** upon desilylation. For **2**, the values of $\phi$ are 174.36° and 167.50°, which in-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

creases to 174.56° and 173.44° for complex **6**. A similar, while minor, increase is seen when $\phi$ is compared for complexes **3** and **7**.

Both these structural variations clearly indicate that, in the absence of steric repulsion, the phenyl groups would prefer to lie aligned with the plane of the cyclobutadiene ring, which possibly helps to extend the aromatic conjugation between the phenyl rings and the cobalt-bound cyclobutadienyl ring. We have also observed that these variations in structural parameters are not affected by the orientation of the ester groups on this ring. This study provides a good comparison to the structure of biphenyl.[16] In the case of biphenyl, the two phenyl groups do not lie in the same plane due to the *ortho* effect of the hydrogen atoms. Such an effect does not exist in the case of complexes such as **5**. It has also been reported that the C–C bond connecting the two phenyl rings in biphenyl is 1.507 Å. In the case of complexes **1**–**4**, the bond length between the cyclobutadiene and phenyl groups varies from 1.458(3) to 1.501(3) Å, while for complexes **5**–**7** and **11** the same distance varies from 1.444(7) to 1.486(8) Å, which is between those of a carbon–carbon single and double bond.

The crystal structure of the alcohol complex **11** is quite similar to that of complex **5**, with the values of $\theta$ being 1.19° and 6.01°. This indicates that both the phenyl groups and the cyclobutadiene ring are almost in the same plane, further increasing their aromatic conjugation. The hydroxy group of the complex is disordered and the oxygen atom has two independent crystallographic positions (occupancy factors of 0.8 and 0.2).

## Conclusions

In conclusion, we have described a method to prepare examples of sterically less hindered and stable carboxylic acid analogues of [($\eta^5$-Cp)Co($\eta^4$-$C_4Ph_4$)] and their alcohol derivatives by desilyation, de-esterification and reduction of the trimethylsilyl-derived metallocenecarboxylates. The carboxylic acids are potential reagents for preparing catalysts such as cobalt(I) oxazoline palladacycles and a host of other similar catalysts and reagents with less steric bulkiness than [($\eta^5$-Cp)Co($\eta^4$-$C_4Ph_4$)] on the cyclobutadiene ring. The silylated and desilylated carboxylates have been structurally characterized and this study provides an opportunity to compare structural changes around the cyclobutadiene moiety accompanying the desilylation reactions. It has been observed that two major structural changes occur upon desilylation of the silylated esters: the phenyl groups rotate around their bonds to the cyclobutadiene ring and also bend towards the plane of the cyclobutadiene ring, tending to become more aligned and parallel to its plane. This possibly helps to extend the delocalization of electron density of the phenyl groups to that of the cobalt-bound cyclobutadiene ring. Further work exploring the chemistry of these new metallocenecarboxylic acids and their alcohol derivatives is in progress.

## Experimental Section

**General Remarks:** All manipulations of the complexes were carried out using standard Schlenk techniques under nitrogen. Toluene and thf were freshly distilled from sodium benzophenone ketyl under nitrogen before use. The sodium salt of (methoxycarbonyl)cyclopentadiene,[9] chloridotris(triphenylphosphane)cobalt[17] and (2-phenylethynyl)trimethylsilane[18] were prepared according to literature procedures. Diphenylacetylene, dimethyl carbonate and triphenylphosphane (Aldrich) were used as received. $^1$H and $^{13}$C{$^1$H} NMR spectra were recorded with a Bruker Spectrospin DPX-300 NMR spectrometer at 300 and 75.47 MHz, respectively. IR spectra in the range 4000–250 cm$^{-1}$ were recorded with a Nicolet Protége 460 FT-IR spectrometer as KBr pellets. Elemental analyses were carried out with a Carlo Erba CHNSO 1108 elemental analyzer. Mass spectra were recorded in the FAB mode using a JEOL SX 102/DA-6000 mass spectrometer and in the electrospray mode with a Micromass Quattro II triple quadrupole mass spectrometer.

**Electrochemical Studies:** All electrochemical measurements were performed with a basic electrochemistry system CHI 604A, using a three-electrode configuration of a Pt working electrode (0.1 mm diameter), a commercially available Ag/AgCl electrode as the reference electrode and a Pt mesh electrode as the counter electrode. Half-wave potentials were measured as the average of the cathodic and anodic peak potentials. The voltammograms were recorded in $CH_2Cl_2$ containing 0.1 M tetrabutylammonium perchlorate as the supporting electrolyte, and the potential was scanned from 0 to +1.5 V at various scan rates. Ferrocene gave a reversible single redox couple with $E_{1/2}$ at 652 mV under the same experimental conditions.

**Preparation of [{*trans*-$\eta^4$-$Ph_2(Me_3Si)_2C_4$}Co{$\eta^5$-MeOC(O)$C_5H_4$}] (1) and [{*cis*-$\eta^4$-$Ph_2(Me_3Si)_2C_4$}Co{$\eta^5$-MeOC(O)$C_5H_4$}] (2):** A solution of chloridotris(triphenylphosphane)cobalt(I) (5.06 g, 5.73 mmol) in toluene (30 mL) was added to a solution of [(methoxycarbonyl)cyclopentadienyl]sodium (0.84 g, 5.73 mmol) in thf (10 mL). The resulting red solution was stirred for 0.5 h and then added to (2-phenylethynyl)trimethylsilane (2.00 g, 11.5 mmol). The solution turned dark brown on stirring at room temperature for 0.5 h. The resulting mixture was heated at reflux for 8 h and then cooled to room temperature. The solvent was removed in vacuo and the residue dissolved in hexane and filtered to give a yellow filtrate. This was concentrated and cooled to partially remove triphenylphosphane by fractional crystallization. The residue was chromatographed on silica gel using a mixture of hexane and ethyl acetate as eluent to give a mixture of **1** and **2**. Compound **1** (1.20 g, 41%) crystallized readily upon cooling the solution and complex **2** (0.42 g 15%) was isolated by repeated fractional crystallization of the remaining solution.

**Preparation of [{η⁴-Ph₃(Me₃Si)C₄}Co{η⁵-MeOC(O)C₅H₄}] (3) and [(η⁴-Ph₄C₄)Co{η⁵-MeOC(O)C₅H₄}] (4):** A solution of chloridotris-(triphenylphosphane)cobalt(I) (5.16 g, 5.84 mmol) in toluene (30 mL) was added to a solution of [(methoxycarbonyl)cyclopentadienyl]sodium (0.86 g, 5.85 mmol) in thf (5 mL). The resulting red solution was stirred at room temperature for 0.5 h and then a solution of (2-phenylethynyl)trimethylsilane (0.61 g, 3.50 mmol) in toluene was added and stirred at room temperature for 1 h to give a brown solution. A solution of diphenylacetylene (1.04 g, 5.85 mmol) in toluene was added and the resulting mixture was stirred at room temperature for 10 min and thereafter refluxed for 8 h and cooled to room temperature. The solvent was removed in vacuo and the residue suspended in 20% ethyl acetate in hexane and filtered. The filtrate was concentrated and chromatographed on silica gel, eluting with a hexane/ethyl acetate mixture (2% ethyl acetate) to give a yellow solution, which upon slow cooling gave crystals of **3** (0.52 g, 29%). On increasing the polarity of the eluent (10% ethyl acetate) a dark yellow solution was obtained, which on cooling gave crystals of **4** (0.76 g, 24%). The physical and spectral properties of **4** were found to agree well with those reported in the literature.[9]

**[{η⁴-Ph₃(Me₃Si)C₄}Co{η⁵-MeOC(O)C₅H₄}] (3):** M.p. 75 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 0.27 (s, 9 H, $SiMe_3$), 3.33 (s, 3 H, $CH_3$), 4.94 (s, 2 H, CpH), 5.37 (s, 2 H, CpH), 7.28–7.34 (m, 9 H, PhH), 7.47–7.48 (m, 6 H, PhH) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 1.1 ($SiMe_3$), 51.1 ($CO_2Me$), 63.1, 82.5 ($C_4$ ring), 83.6, 84.3, 86.9 (CpC), 135.9, 135.1, 129.6, 129.0, 128.0, 127.7, 126.7, 126.5 (PhC), 167.2 (C=O) ppm. IR (KBr): $\tilde{\nu}$ = 3051 m, 3020 w, 2950 m, 1717 vs, 1596 m, 1495 m, 1469 m, 1444 m, 1364 m, 1280 vs, 1250 s, 1229 m, 1145 s, 1066 w, 826 s, 768 s, 694 s, 585 s $cm^{-1}$. C 71.89, H 5.84; found C 71.80, H 5.90.

**General Procedure for the Desilylation of Compounds 1–3:** The silylated cobalt complex (1.0 mmol) and a slight excess of tetrabutylammonium fluoride (1 M solution in thf) were dissolved in dmso (10 mL) and the mixture was stirred at 70 °C under nitrogen for 24 h. The product was extracted with ethyl acetate, and the solution was washed repeatedly with water to remove any trace of dmso. The ethyl acetate solution was dried with anhydrous $MgSO_4$ and concentrated to give a dark yellow powder, which was chromatographed on silica gel with an appropriate eluent.

**[{*trans*-η⁴-Ph₂H₂C₄}Co{η⁵-MeOC(O)C₅H₄}] (5):** Chromatographed on silica gel with hexane as eluent to give 0.36 g (93%) of **5**. **X-ray Crystallographic Study:** Suitable crystals of complexes **1**–**7** and **11** were obtained by slow concentration of their saturated solutions in ethyl acetate/hexane solvent mixtures. Details of data collection and solution and crystal parameters are given in Tables 4 and 5. Single-crystal diffraction studies were carried out with a Bruker SMART APEX CCD diffractometer with an Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) sealed-tube radiation source. All crystal structures were solved by direct methods. The program SAINT (version 6.22) was used for integration of the intensity of reflections and scaling. The program SADABS was used for absorption correction.[19] The crystal structures were solved and refined using the SHELXTL (version 6.12) package.[20] All hydrogen atoms were included in idealized positions, and a riding model was used. Non-hydrogen atoms were refined with anisotropic displacement parameters. Because of the poor crystal quality of complex **1**, higher 2$\theta$ reflections were omitted to bring the value of the residual factor down. The oxygen atom of the alcohol group present in the cyclopentadienyl ring of complex **11** shows disorder and occupies two crystallographically independent positions which could be located from the additional residual electron density observed in the difference map. The site occupancy factors were refined with the help of the free variable

# Redox Chemistry of a Dimanganese(II,III) Complex with an Unsymmetric Ligand: Water Binding, Deprotonation and Accumulative Light-Induced Oxidation

**Magnus F. Anderlund,[a] Joakim Högblom,[b] Wei Shi,[a] Ping Huang,[a] Lars Eriksson,[c] Högni Weihe,[d] Stenbjörn Styring,[a] Björn Åkermark,[e] Reiner Lomoth,*[a] and Ann Magnuson*[a]**

**Keywords:** Manganese / Bioinorganic chemistry / Ligand exchange / EPR spectroscopy / IR spectroscopy

A dinuclear manganese complex {[$Mn_2^{II,III}$L(μ-$OAc)_2$]-$ClO_4$} has been synthesised, where L is the dianion of 2-{[bis-(pyrid-2-ylmethyl)amino]methyl}-6-{[(3,5-di-*tert*-butyl-2-hydroxybenzyl)(pyrid-2-ylmethyl)amino]methyl}-4-methylphenol, an unsymmetric binucleating ligand with two coordinating phenol groups. The two manganese ions, with a Mn–Mn distance of 3.498 Å, are bridged by the two bidentate acetate ligands and the 4-methylphenolate group of the ligand, resulting in a $N_3O_3$ and $N_2O_4$ donor set of $Mn^{II}$ and $Mn^{III}$, respectively. Electrochemically [$Mn_2^{II,III}$L(μ-$OAc)_2$]$^+$ is reduced to [$Mn_2^{II,II}$L(μ-$OAc)_2$] at $E_{1/2}(1)$ = –0.53 V versus $Fc^{+/0}$ and oxidised to [$Mn_2^{III,III}$L(μ-$OAc)_2$]$^{2+}$ at $E_{1/2}(2)$ = 0.38 V versus $Fc^{+/0}$. All three redox states have been characterised by EPR, IR and UV/Vis spectroscopy. Subsequent oxidation of [$Mn_2^{II,III}$L(μ-$OAc)_2$]$^{2+}$ [$E_{1/2}(3)$ = 0.75 V vs. $Fc^{+/0}$] in dry acetonitrile results in an unstable primary product with a lifetime of about 100 ms. At high scan rates quasireversible voltammetric behaviour is found for all three electrode processes, with particularly slow electron transfer for the II,III/II,II [$k°(1)$ = 0.002 cm s$^{-1}$] and III,III/II,III [$k°(2)$ = 0.005 cm s$^{-1}$] couples, which can be rationalised in terms of major distortions of the $Mn^{III}$ centres. In aqueous media the bridging acetates are replaced by water-derived ligands. Deprotonation of these stabilises higher valence states, and photo-induced oxidation of the manganese complex results in a $Mn_2^{III,IV}$L complex with oxo or hydroxo bridging ligands, which is further oxidised to an EPR-silent product. These results demonstrate that a larger number of metal-centred oxidations can be compressed in a narrow potential range if build up of charge is avoided by charge-compensating reactions.

## Introduction

The utilisation of solar energy for fuel production, through a molecular system for artificial photosynthesis, is an attractive solution to the need for renewable energy.[1] In natural photosynthesis, solar energy is used to extract electrons from water.[2] Photo-induced charge separation in the Photosystem II (PSII) reaction centre leads to oxidation of the water-oxidising complex (WOC), a catalyst consisting of a protein-bound cluster with four manganese ions and one calcium ion.[3,4] After four consecutive one-electron transfer events, the WOC retrieves four electrons from water and releases molecular oxygen.[3,5] During catalysis, the WOC cycles through five redox states.[6,7] The manganese ions are mostly in the $Mn^{III}$ oxidation state or higher, and several of the intermediates involve manganese-centred oxidation.[7–9]

Synthetic manganese complexes have been extensively studied as model systems for the WOC but functional mimics that are able to evolve molecular oxygen from water are very few in number.[10,11] They require electrochemical oxidation at highly anodic potentials or strong chemical oxidants. In the latter case the formation of the important Mn-oxo intermediate often relies on oxygen atom transfer from the oxidant rather than from water.[11]

In our work towards artificial photosynthesis, we pursue supramolecular complexes in which the Mn portion undergoes accumulative oxidation by *light-induced* charge separation.[12–14] With the ultimate goal of photochemical water splitting, this requires Mn complexes that can un-

dergo four oxidation steps within the thermodynamic limit of the photo-oxidant. On the other hand, all stored oxidation equivalents need to be sufficiently oxidising, with an average potential of 0.8 V (at pH 7), to be capable of driving the catalytic oxidation of water.[15] In the WOC all four single-electron oxidations of the $Ca(Mn)_4$ cluster occur within an interval of only 0.25–0.3 V at potentials close to the limit (ca. 1 V vs. NHE[15]) given by the oxidising $Tyr_Z$ radical. This compression of oxidation potentials is a result of charge-compensating deprotonation reactions and it is evident that a suitable mechanism for charge compensation is a central feature in the design of synthetic mimics.

In previous studies we could show that oxidation of the manganese dimer $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^+$[16] in the presence of water involves exchange of the bridging acetates for water-derived ligands that are increasingly deprotonated in higher oxidation states.[17,18] The resulting charge compensation stabilises higher valence states and thereby allows for three metal-centred oxidations, from the $Mn_2^{II,II}$ dimer to a $Mn_2^{III,IV}$ species, to be driven by photo-generated $Ru^{II\text{-}I}(bpy)_3$.[13,17,19,20] The binding of water, deprotonation of bridging ligands and accumulative, light-induced oxidation of $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^+$ mimic important aspects of the catalytic complex in PSII and we therefore set out to investigate modifications of the structural motif. With consideration to the prevalence of high-valent manganese species and the high O/N ratio in the ligand sphere of the $Ca(Mn)_4$ complex in PSII, we synthesised analogous dinuclear manganese complexes, with an increased number of phenolic ligand functions. In $[Mn_2(bhpp)(\mu\text{-}OAc)_2]^+$[19,21] two additional phenol groups of the bhpp ligand result in an oxygen-to-nitrogen ratio of 4:2. Compared to $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^+$ with O/N = 3:3, the potentials for the manganese redox couples are lowered substantially and the oxidation equivalents stored on $[Mn_2(bhpp)(\mu\text{-}OAc)_2]^+$ are on average not sufficiently oxidising with respect to water oxidation.

In the present study we report a new di-μ-acetato-bridged dinuclear manganese complex, **5** ($[Mn_2L(\mu\text{-}OAc)_2]^+$), with an unsymmetric ligand molecule, L = 2-{[bis(pyrid-2-ylmethyl)amino]methyl}-6-{[(3,5-di-*tert*-butyl-2-hydroxybenzyl)(pyrid-2-ylmethyl)amino]methyl}-4-methylphenol. With a $N_3O_3/N_2O_4$ coordination sphere, the new complex is an intermediate between the $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^+$ and $[Mn_2(bhpp)(\mu\text{-}OAc)_2]^+$ complexes. We chose to synthesise an unsymmetric ligand, as we anticipated that a compromise between the need for high valent Mn states and sufficiently high redox potentials could be accomplished with the intermediate O/N ratio. Here we present the synthesis and characterisation of the new manganese complex and its redox properties in anhydrous and partially aqueous solutions, including photo-oxidation studies.

Unsymmetric ligands have previously been used to a limited extent for coordinating manganese, mainly for mimicking the active site of manganese catalases,[22–25] or to support the formation of heterobinuclear metal complexes.[22,26] As a novelty in the present study, photo-oxidation of complex **5** generates products beyond the $Mn_2^{III,IV}$ level, which is not the case with $[Mn_2(bpmp)(\mu\text{-}OAc)_2]$, while the potentials are above those of $[Mn_2(bhpp)(\mu\text{-}OAc)_2]^+$. The favourable behaviour of the novel complex can be attributed to the combination of the flexible bridging motif that is inherent to this type of complex and the intermediate O/N ratio of the chelating ligand. These findings point to the intricate balance of donor properties in the set of permanent and flexible ligands that will be needed for functional mimics of the WOC suitable for photo-induced water oxidation.

## Results and Discussion

### Synthesis and Characterisation

#### *Synthesis*

The synthesis route for the preparation of compound **5** is described in Scheme 1. The synthesis of the unsymmetrical ligand $H_2L$ (**4**) is based on the unsymmetrical phenol **1**.[27] Compound **2** was obtained by letting phenol **1** react with 1 equiv. of (3,5-di-*tert*-butyl-2-hydroxybenzyl)(2-pyridylmethyl)amine[21] and 2 equiv. of $Et_3N$ in $CH_2Cl_2$ under reflux. Compound **3** was then obtained by reduction of **2** with $NaBH_4$ in methanol and thereafter chlorinated with $SOCl_2$ in dry $CH_2Cl_2$.

The unsymmetrical ligand $H_2L$ (**4**) is produced by amination by nucleophilic attack on the benzylic chloride in **3** with bis-picolylamine[28] and $Et_3N$ in $CH_2Cl_2$ under reflux. The yield was excellent in the first two steps (95.1 and 97.5%) but only moderate in the last step (67.4%), possibly because of steric hindrance of the two *tert*-butyl groups on the phenol.

The complexation of $H_2L$ with $MnOAc_3{\cdot}2H_2O$ in ethanol under argon affords the stable dimanganese(II,III) complex **5** after addition of $NaClO_4{\cdot}H_2O$ in 52% yield. We have not been able to isolate any $Mn_2^{III,III}$ complex under these conditions. The reduction of $Mn^{III}$ to $Mn^{II}$ was possibly done by the solvent or by disproportionation of $Mn^{III}$ to $MnO_2$ and $Mn^{II}$ in the presence of water. Though we have not detected any $MnO_2$, we cannot rule out that colloidal $MnO_2$ was present in the solution after the complexation. However, the slow and well-behaved crystal growth, as well as the purity of the crystals established by elemental analysis, indicates that any impurities in the mother liquor were successfully removed prior to characterisation of **5**.

#### *X-ray Structure Determination*

The crystal structure of **5** (Figure 1) is of a monovalent cation, counterbalanced with a perchlorate ion (not shown). The displacement parameters of the perchlorate are heavily anisotropic, in agreement with a weakly coordinated perchlorate ion, and there are no ordered solvent molecules present in the structure. The manganese ions are bridged by the oxygen in the central 4-methylphenolate and the two bidentate acetates. The slightly distorted octahedral coordination of Mn(1) is completed by the two pyridyl nitrogen

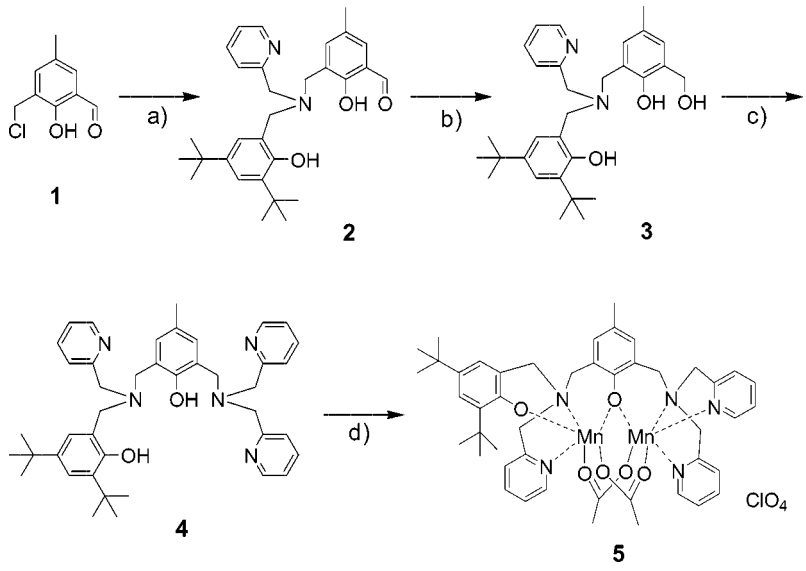

Scheme 1. Reaction conditions are as follows: (a) (3,5-di-*tert*-butylbenzyl-2-hydroxy)(2-pyridylmethyl)amine, $CH_2Cl_2$, reflux; (b) $NaBH_4$, MeOH, room temperature; (c) 1. $SOCl_2$, $CH_2Cl_2$, 2. DPA, $Et_3N$, $CH_2Cl_2$, reflux; (d) $MnOAc_3{\cdot}2H_2O$, EtOH, 60 °C, $NaClO_4{\cdot}H_2O$.

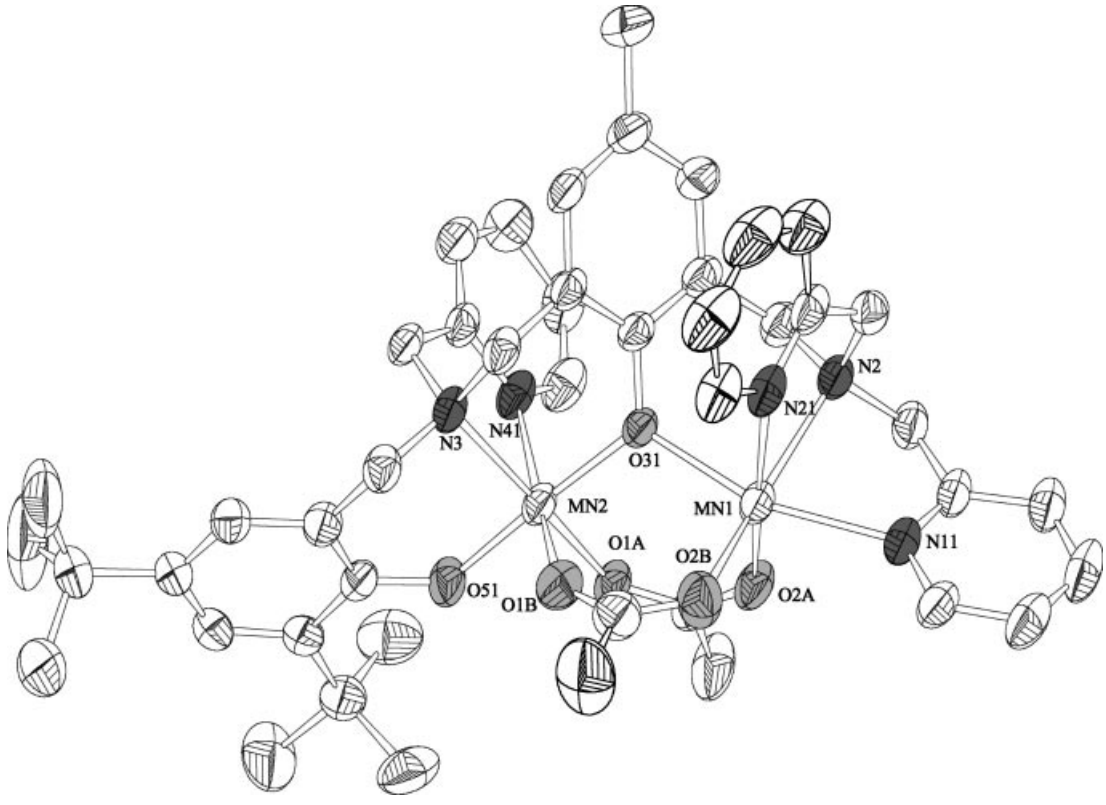

Figure 1. ORTEP view (30% probability ellipsoids) of **5** with atomic numbering for all non-hydrogen atoms. The hydrogen atoms were geometrically placed and shown as small circles of arbitrary radii. Figure drawn by Diamond.

atoms and one amine nitrogen atom of one branch of the ligand, resulting in a $N_3O_3$ ligand sphere. The oxygen atom from the *tert*-butyl-substituted phenolate coordinates Mn(2) in a *trans* position to the bridging phenolate group. The $N_2O_4$ coordination sphere of Mn(2) is completed by the pyridyl and amine nitrogens.

Selected bond lengths and angles are found in Table 1. Bond valence calculations gave 2.1 for Mn(1) and 3.2 for Mn(2) in agreement with the different donor sets and coordination symmetries of the two manganese ions.[29]

Mn(2) has a more distorted octahedral geometry, consistent with its assignment as $Mn^{III}$. For Mn(2), the shortest

Mn–O bond length is that of the *tert*-butyl-substituted phenoxyl (O51), and the bridging phenoxyl provides the second shortest Mn–O bond length. Thus, in contrast to the coordination sphere of Mn(1), the two bridging acetate ligands provide the longest Mn–O bonds. A similar, although less enhanced, effect was also observed for the $Mn^{III}$ ion in the $[Mn_2^{II,III}(bpmp)(\mu\text{-}OAc)_2]^{2+}$ structure.[16] The ligand sphere of Mn(2) is therefore very compressed along the O–Mn–O axis, which is 0.21 Å shorter than the corresponding molecular axis of the $Mn^{III}$ ion in $[Mn_2^{II,III}(bpmp)(\mu\text{-}OAc)_2]^{2+}$. The O–Mn–N axis formed by the pyridyl nitrogen and the carboxyl oxygen *trans* to it is quite long, making the Mn(2) coordination even more distorted, consistent with the Jahn–Teller effects that are common for $Mn^{III}$ complexes. The Mn–Mn distance is 3.498 Å, and the $Mn^{II}$–O–$Mn^{III}$ angle is 116.95°, which is in the range of other $Mn_2^{II,III}$ complexes.[16,25,30]

In conclusion, the crystal structure shows that the terminal phenoxyl in one branch of the ligand favours coordination of $Mn^{III}$ over $Mn^{II}$, and that its axial position introduces an unusually large distortion away from octahedral symmetry.

### *Magnetic Susceptibility*

The experimentally determined magnetic susceptibilities in the temperature range 4.45–301 K are shown in Figure 2. At room temperature, the effective magnetic moment is 7.20, which is slightly lower than the value 7.68 expected for a $Mn^{II}Mn^{III}$ dimer in which the metals are weakly antiferromagnetically interacting. The magnetic moment decreased smoothly from 298 K to 50 K, and then more abruptly down to 3 K. This behaviour is expected for an antiferromagnetically coupled $Mn_2^{II,III}$ complex with moderate exchange coupling.[16,30] At the lowest temperatures the magnetic moment was 1.79, which compares well with the value 1.73 expected for an $S = 1/2$ ground state.

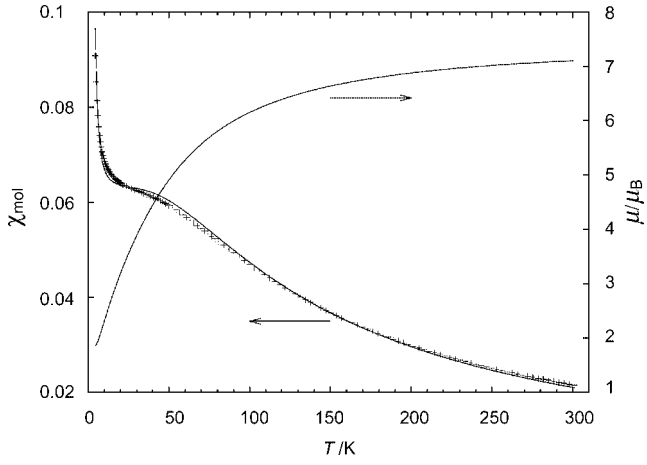

Figure 2. The magnetic susceptibility (+) and a fitted curve based on Equation (1) (solid line) in CGS units, as well as the effective magnetic moment as a function of temperature.

For known $Mn_2^{II,III}$ complexes the exchange coupling between the two manganese ions is rather weak, compared to that in $Mn_2^{III,IV}$ complexes, and typically ranges between about 0 and 10 $cm^{-1}$.[25,30,31] When analysing the susceptibility data for **5**, it proved impossible to satisfactorily interpret the magnetic susceptibilities in terms of an isotropic spin Hamiltonian (Model 1 in Table 2). As the zero-field splitting parameter $D$ of $Mn^{III}$ is often of the same order of magnitude as the exchange coupling $J$, the Hamiltonian was augmented with a term accounting for the magnetic anisotropy of the $Mn^{III}$ ion,

$$H = J\,\hat{\mathbf{S}}_2\cdot\hat{\mathbf{S}}_3 + \mu_B\mathbf{B}\cdot\mathbf{g}\cdot(\hat{\mathbf{S}}_2 + \hat{\mathbf{S}}_3) + D_3[\hat{\mathbf{S}}^2_{3z} - \frac{1}{3}S(S+1)] \quad (1)$$

Table 2. Results from fitting magnetic susceptibility data. Models 1 and 2 refer to Equation (1) without and with the third term, respectively.

| | Model 1 | Model 2 |
|---|---|---|
| $J$ [$cm^{-1}$] | $11.0 \pm 0.05$ | $10.9 \pm 0.3$ |
| $D_3$ [$cm^{-1}$] | – | $3.35 \pm 0.4$ |
| TIP ($\times 10^{-12}$) | $-5.05 \pm 1.19$ | $-3.95 \pm 4.97$ |
| Curie ($\times 10^{-11}$) | $4.04 \pm 1.90$ | $25 \pm 4.5$ |
| $\chi^2$ | 131.9 | 100 |
| $f$-test | – | 0.07 |
| No. of fit parameters | 3 | 4 |
| Degrees of freedom | 137 | 136 |
| No. of points | 140 | 140 |

In Equation (1) the subscripts refer to the oxidation numbers of the metal ions. By inclusion of the last term in Equation (1), the following parameters were obtained: $J = 10.9 \pm 0.3$ $cm^{-1}$ and $D_3 = 3.35$ $cm^{-1}$ (Model 2 in Table 2). The relatively large and positive zero-field parameter $D_3$ reflects to some degree the coordination geometry of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Mn^{III}$ ion. Six-coordinated $Mn^{III}$ complexes with distorted octahedral coordination typically display $D$ values of –3 to –4 $cm^{-1}$. However, deviations occur, for example, when the ligand field has low symmetry in the equatorial plane, as in **5**, and the increased rhombicity of the ZFS parameters can lead to a change in sign to positive values of $D$.[32]

### *IR Spectroscopy*

The IR spectrum of **5** in a KBr pellet was recorded between 4000 and 400 $cm^{-1}$ (Supporting information). Based on characteristic frequencies the following assignments are suggested in agreement with the composition of the complex: 3062 (w, $\nu$C–H, aryl); 2952, 2867 (m, $\nu$C–H, alkyl); 1590 (s, $\nu_a$C–O, carboxylate); 1441 (s, $\nu_s$C–O, carboxylate); 1477, 1435 (s, $\nu$C–C, aryl); 1094 (s, $\nu_a$Cl–O, perchlorate); 623 (m, $\delta_a$Cl–O, perchlorate) $cm^{-1}$.

The IR spectrum of **5** in [$D_3$]acetonitrile solution (Supporting Information) is identical to the solid state spectrum, which provides strong evidence that the di-μ-acetato bridging structure established for crystalline **5** is maintained in anhydrous acetonitrile solution.

### *EPR Spectroscopy*

The EPR spectrum of **5** in anhydrous acetonitrile is shown in Figure 3, spectrum a. The spectrum recorded at 4 K shows the $Mn_2^{II,III}$ $S$ = 1/2 ground-state EPR signal, centred at $g$ = 2 and displaying 16–20 hyperfine-lines, with a peak split of 110–140 gauss. The mixed-valence forms of dinuclear manganese complexes, $Mn_2^{II,III}$ and $Mn_2^{III,IV}$, are known to display similar ground-state EPR signals in the $g$ = 2 region at cryogenic temperatures.[33] The acetato-bridged $Mn_2^{II,III}$ complexes normally show a weaker exchange coupling than μ-oxo-bridged $Mn_2^{III,IV}$ complexes, because of less orbital overlap between the Mn ions. The excited $S$ = 3/2 and $S$ = 5/2 states in the $Mn_2^{II,III}$ complexes will then give rise to transitions at low field, at relatively low temperatures (5–20 K). Thus, when the temperature was raised from 4 K to 5–11 K, the first excited state ($S$ = 3/2) gave rise to a signal at $g$ = 5.4 (Figure 3, inset).

The spectrum from complex **5** (Figure 3, a) could be simulated assuming an effective spin of $S$ = 1/2, and using the spin Hamiltonian

$$\hat{H} = \beta\,\hat{\mathbf{S}}\cdot\mathbf{g}\cdot\mathbf{B} + \hat{\mathbf{I}}_1\cdot\mathbf{A}_1\cdot\hat{\mathbf{S}} + \hat{\mathbf{I}}_2\cdot\mathbf{A}_2\cdot\hat{\mathbf{S}} \quad (2)$$

(A full account of the EPR simulation parameters at both X- and Q-bands, as well as simulated spectra, was published by Huang et al.[34]) The obtained hyperfine tensors showed considerable anisotropy,[35] which could be explained by a significant Jahn–Teller distortion of $Mn^{III}$, taking into account the unexpected positive sign of the zero-field parameter $D$. These spectroscopic properties are a direct result of the rhombic distortion of the $Mn^{III}$ coordination sphere.

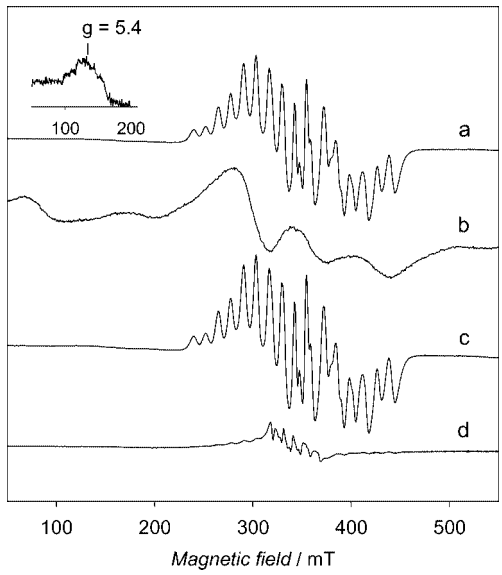

Figure 3. EPR spectra recorded by exposing **5** to controlled potentials. (a) After applying –0.08 V to the sample solution. The spectrum arises from the $S$ = 1/2 ground spin state of the $Mn_2^{II,III}$ complex. No current was recorded at this potential. (b) After reduction at –0.93 V a spectrum typical of a weakly coupled $Mn_2^{II,II}$ complex is observed. (c) Recovery of the $Mn_2^{II,III}$ complex after reoxidation at –0.08 V of the sample giving spectrum b. (d) After oxidation at 0.57 V. The spectrum can be identified as a remaining fraction (5%) of $Mn_2^{II,III}$ complexes, still present after bulk electrolysis. In the centre of the spectrum, a six-line signal from monomeric $Mn^{II}$ can be distinguished, corresponding to less than 2% of the manganese. Spectrometer settings: microwave frequency, 9.6 GHz; modulation amplitude, 10 G; microwave power spectrum a and c, 20 mW; in spectrum b, 2 mW; temperature in spectra a, c and d, 4 K; in spectrum b, 12 K. Insert: the signal at $g$ = 5 arising from the excited $S$ = 3/2 spin state of **5**, observed at $T > 5$ K.

## Redox Properties in Anhydrous Media

### *Electrochemistry*

The redox behaviour of **5** in acetonitrile was studied by cyclic voltammetry (CV), differential pulse voltammetry (DPV) and controlled potential electrolysis. The products of the oxidation and reduction processes were characterised by EPR spectroscopy and UV/Vis and IR spectroelectrochemisty. The electrochemical data are compiled in Table 3. All potentials are referenced versus ferrocene as redox standard and about 0.4 V should be added to these values in order to compare them with potentials in aqueous solution versus NHE.[36]

Voltammograms of **5** in acetonitrile solution (Figure 4) showed reversible to quasireversible CV waves for reduction at $E_{1/2}$ = –0.53 V (1) and oxidation at $E_{1/2}$ = 0.38 V versus $Fc^+/Fc^0$ (2) while further oxidation was irreversible on the normal CV time scale ($v$ = 0.100 $V\,s^{-1}$). At higher scan rates on a microelectrode, the second oxidation gave rise to a quasireversible CV wave with the half-wave potential $E_{1/2}$ = 0.75 V (3) in good agreement with the DPV peak potential. Chemical reversibility was obtained for scan rates of $v \geq$ 10 $V\,s^{-1}$ and a lower limit of the lifetime of the product of the second oxidation of about 100 ms (at room tempera-

ture) could be estimated. The reduction and the first oxidation of **5** are one-electron processes as evidenced by coulometry during controlled potential electrolysis at –0.93 and 0.57 V, respectively. We could not obtain reliable coulometric data for the second oxidation because of the instability of the product, but the voltammetric peak heights suggested the assignment to a one-electron process.[37]

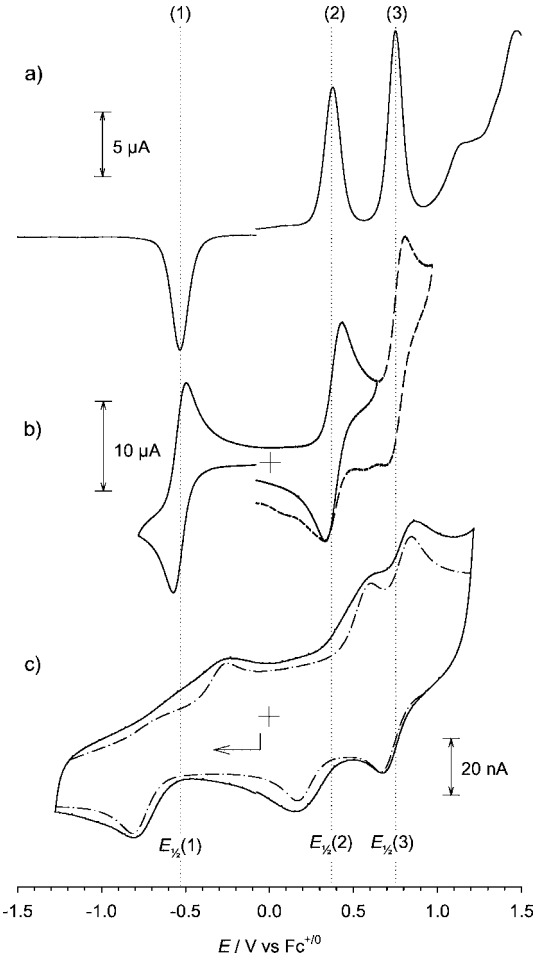

Figure 4. Voltammograms of **5** (1 mM) in acetonitrile with $(n\text{-}C_4H_9)_4N{\cdot}ClO_4$ (0.1 M) as supporting electrolyte. (a) Differential pulse voltammogram (step potential 5 mV, modulation amplitude 25 mV, modulation time 50 ms, interval time 100 ms, glassy carbon disk, 3 mm). (b) Cyclic voltammograms ($v = 0.100$ V s$^{-1}$, glassy carbon disk, 3 mm). (c) Cyclic voltammogram ($v = 100$ V s$^{-1}$, Pt microdisk, 25 μm) and digital simulation (– · –) with the parameters from Table 1.

The electrode processes (1) and (2) exhibited much larger CV peak splits at high scan rates than process (3) (Figure 4). This strongly non-Nernstian behaviour is indicative of slow heterogeneous electron transfer. We could obtain the standard rate constants $k^\circ$ to a close approximation by digital simulations (Figure 4, c) using a model of three quasireversible waves and the parameters given in Table 3. Neglecting work terms, the standard rate constant for a heterogeneous electron transfer reaction is given by

$$k^\circ = Z_{het}\left\{e^{-\lambda/(4kT)}\right\} \quad (3)$$

where $Z_{het}$ is the collision factor and $\lambda$ is the reorganisation energy.[38] For **5** we obtain

$$Z_{het} = (RT/2\pi M)^{1/2} = 2.2 \times 10^3 \text{ cm s}^{-1} \quad (4)$$

($M = 883$ g mol$^{-1}$) and can estimate approximate reorganisation energies of 1.4, 1.3 and 1.0 eV for the electrode processes (1), (2) and (3), respectively. The contribution of the solvent reorganisation can be estimated as $\lambda_{solv} \leq 0.3$ eV.[39] This would indicate that the electrode reactions, in particular (1) and (2), are associated with large inner reorganisation energies of $\lambda_i \approx 1$ eV. A similar estimate of $\lambda_i$ based on crystallographic data for the II,III/II,II couple of $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^{2+/+}$ has been presented and can explain the unusually slow electron transfer observed in electron transfer dyads and triads that involve manganese complexes as donor units.[14,40] For the $Mn^{II}/Mn^{III}$ couples this can be attributed to the Jahn–Teller distortion associated with the high-spin $d^4$ configuration of the $Mn^{III}$ centre. The significantly smaller reorganisation energy for the second oxidation implies that the coordination geometry changes are less pronounced between $Mn^{III}$ and $Mn^{IV}$ or that this process is a ligand-based rather than a metal-centred oxidation.

### *Spectroscopic Characterisation of the Oxidation and Reduction Products*

The one-electron reduction product was prepared by bulk electrolysis at –0.93 V. Its EPR spectrum (Figure 3b) is typical for a weakly antiferromagnetically coupled $Mn_2^{II,II}$ complex and the reduction of **5** can be attributed to the metal-centred process (5).

$$[Mn_2^{II,III}L(\mu\text{-}OAc)_2]^+ + e^- \rightarrow [Mn_2^{II,II}L(\mu\text{-}OAc)_2] \quad (5)$$

$Mn_2^{II,II}$ is an integral spin system, where the diamagnetic ($S = 0$) ground state dominates at liquid He temperatures and accordingly we did not detect any EPR signals at 4 K. Weakly coupled $Mn_2^{II,II}$ complexes are, on the other hand, known to display EPR-active excited states at temperatures above about 7 K, similar to that in Figure 3, spectrum b.[41] We therefore conclude that the spectrum in Figure 3 (b), which was recorded at 12 K, originates from a superposition of one or more excited spin states from $Mn_2^{II,II}$ with $S = 1, 2, \ldots$. When $[Mn^{II}{}_2L(\mu\text{-}OAc)_2]$ was reoxidised by elec-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trolysis at –0.08 V, the $Mn_2^{II,III}$ spectrum of **5** was quantitatively recovered (Figure 3, c), confirming the stability of $[Mn^{II}{}_2L(\mu\text{-}OAc)_2]$.

The one-electron oxidation product was produced by bulk electrolysis at 0.57 V. The product is EPR-silent and the spectrum only showed a residual (5%) of the original $Mn_2^{II,III}$ signal (Figure 3, d). $Mn_2^{III,III}$, which is an integral spin system, might produce EPR-active states at higher temperatures, but so far no EPR signals from this valence state in either parallel or perpendicular mode EPR at X-band frequencies have been found by us or other researchers. Therefore, the EPR-silent product of the first oxidation can be assigned to$[Mn_2^{III,III}L(\mu\text{-}OAc)_2]^{2+}$ according to equation (6).

$$[Mn_2^{II,III}L(\mu\text{-}OAc)_2]^{+} \rightarrow [Mn_2^{III,III}L(\mu\text{-}OAc)_2]^{2+} + e^- \quad (6)$$

After reduction of $[Mn_2^{III,III}L(\mu\text{-}OAc)_2]^{2+}$at –0.08 V about 95% of the original $Mn_2^{II,III}$ signal was recovered (not shown). A slow degradation reaction of $[Mn_2^{III,III}L(\mu\text{-}OAc)_2]^{2+}$ resulted in the release of minor amounts of monomeric $Mn^{II}$ that could be observed in the spectra of the oxidised and re-reduced material (2% and 5% of the total Mn respectively), where it gave rise to the weak EPR signal around $g = 2$ with six hyperfine lines at a separation of about 100 gauss (Figure 4, d).

The short-lived primary product of the second oxidation could not be prepared by bulk electrolysis. After electrolysis at 0.82 V a significant amount of monomeric $Mn^{II}$ was observed by EPR, obscuring any other paramagnetic species that might be present in the solution (not shown). The instability of the oxidised complex on longer timescales can be attributed to oxidative degradation of the ligand, as evidenced by the release of monomeric $Mn^{II}$ ions. This reaction might be triggered either by a transiently formed high-valent metal centre (7a) or by direct ligand oxidation (7b).

$$[Mn_2^{III,III}L(\mu\text{-}OAc)_2]^{2+} \rightarrow [Mn_2^{III,IV}L(\mu\text{-}OAc)_2]^{3+} + e^- \quad (7a)$$

$$[Mn_2^{III,III}L(\mu\text{-}OAc)_2]^{2+} \rightarrow [Mn_2^{III,III}L^{\cdot}(\mu\text{-}OAc)_2]^{3+} + e^- \quad (7b)$$

### *UV/Vis Spectroelectrochemistry*

The electronic absorption spectra of $[Mn_2L(\mu\text{-}OAc)_2]^{n+}$ ($n = 0, 1, 2$) in the UV and visible range are shown in Figure 5 and Table 4. The spectra after one-electron reduction and one-electron oxidisation of **5** were obtained by spectroelectrochemistry. The spectral changes induced by reduction and the first oxidation were fully reversible and isosbestic points (221, 242, 260, 306, 332 nm) were maintained in the course of the reduction (Figure 5, left panel). In the $Mn_2^{II,II}$ state the complex displayed basically no visible absorption as metal-to-ligand charge transfer (MLCT) bands of $Mn^{II}$ complexes are usually of low intensity. The visible absorption bands of the $Mn_2^{II,III}$ and $Mn_2^{III,III}$ states (Figure 5, right panel) can be attributed to ligand-to-metal charge transfer (LMCT) transitions from multiple donor functions to the $Mn^{III}$ centres. No additional band of the mixed-valence complex could be detected including the near infrared spectrum ($\leq$ 2700 nm). With a free energy change of $\Delta G° \approx 0.5$ eV for the metal-to-metal charge transfer (8) and $\lambda > 1$ eV per metal centre, the intervalence charge transfer transitions might be superimposed on the LMCT bands in the UV/Vis range.

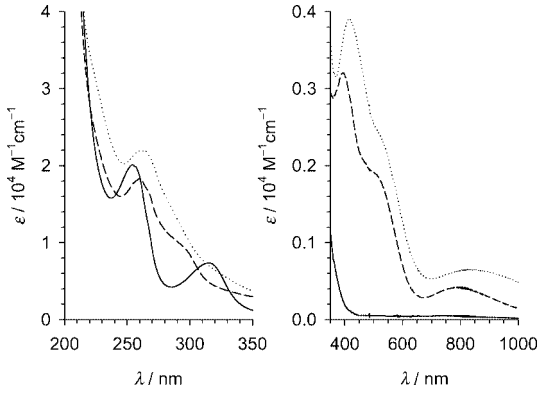

Figure 5. Electronic spectra of $[Mn_2L(\mu\text{-}OAc)_2]$ (–), $[Mn_2L(\mu\text{-}OAc)_2]^{+}$ (– –) and $[Mn_2L(\mu\text{-}OAc)_2]^{2+}$ (· · ·) in acetonitrile with $(n\text{-}C_4H_9)_4N{\cdot}ClO_4$ (0.1 M).

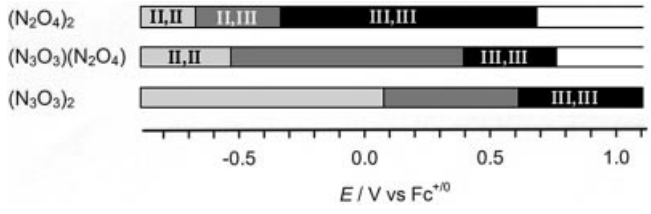
Table 4. UV/Vis absorption data of $[Mn_2L(\mu\text{-}OAc)_2]^{n+}$ in acetonitrile.

| $n$ | Mn oxidation state | $\lambda_{max}$ [nm] ($\varepsilon$ [$M^{-1}cm^{-1}$]) |
|---|---|---|
| 0 | II,II | 202 (61200), 253 (20100), 315 (7350) |
| 1 | II,III | 260 (18300), 393 (3200), 795 (420) |
| 2 | III,III | 262 (22000), 417 (3900), 830 (650) |

$$[(N)_3Mn^{II}(\mu\text{-}O\text{-}\phi)(\mu\text{-}OAc)_2Mn^{III}(N)_2(O)] \rightarrow [(N)_3Mn^{III}(\mu\text{-}O\text{-}\phi)(\mu\text{-}OAc)_2Mn^{II}(N)_2(O)] \quad (8)$$

Upon the second oxidation the optical absorption above 377 nm and below 310 nm was bleached and an increasing absorption was initially observed between these wavelengths. The isosbestic points were, however, not maintained and a pure spectrum of the initial product could not be obtained.

Scheme 2 compares the redox properties of **5** to those of the symmetric analogues $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^{+}$ and $[Mn_2(bhpp)(\mu\text{-}OAc)_2]^{+}$ with $(N_3O_3)_2$ and $(N_2O_4)_2$ donor sets, respectively.[17,21] It illustrates the stabilisation of high-valent metal centres by the increasing number of oxygen donors. For the unsymmetric complex the mixed $(N_3O_3)/(N_2O_4)$ donor set results in localisation of and an extended stability to the mixed-valence $Mn_2^{II,III}$ state, with a free energy of comproportionation of $\Delta G_c = -88$ kJ mol$^{-1}$ [$K_c = \exp(\Delta E_{1/2}F/RT) = 5.49 \times 10^{15}$ at 293 K] as compared to –54.0 and –34.7 kJ mol$^{-1}$ in the $(N_3O_3)_2$ and $(N_2O_4)_2$ ana-



Scheme 2.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

logues, respectively. For **5**, as for the symmetric analogues, no metal oxidation state higher than $Mn_2^{III,III}$ could be obtained by bulk electrolysis in nonaqueous solvents, and the second oxidation of **5** resulted in a short-lived product that could not be characterised. This demonstrates the general problem that several accumulative oxidations without charge compensation will be spread over a large potential range, placing the potentials for generating the higher metal oxidation states so high that oxidative degradation of the complexes is inevitable.

### *IR Spectroelectrochemistry*

IR spectra of the isovalent complexes $[Mn_2^{II,II}L(\mu\text{-}OAc)_2]$ and $[Mn_2^{III,III}L(\mu\text{-}OAc)_2]^{2+}$ (see Supporting Information) were obtained by spectroelectrochemistry that gave fully reversible absorption changes for reduction and oxidation of **5**. For the $\nu_{as}$ mode of the acetate ligands only a minor shift to higher frequency is observed upon reduction, while oxidation results in a broader, less symmetric $\nu_{as}$ band. The absorption between 1440 and 1440 $cm^{-1}$ can be assigned to the $\nu_s$ mode of the acetate ligands superimposed on absorptions of the binucleating ligand. The spectral changes induced by reduction and oxidation suggest a shift towards higher frequency in the II,II state and to lower frequency in the III,III state. The same trend has been found for the $Mn_2(bpmp)(\mu\text{-}OAc)_2$ complex[18] and the values of $\Delta\tilde{\nu} = \tilde{\nu}_{as} - \tilde{\nu}_s$ of about 120, 170 and 220 $cm^{-1}$ would be in agreement with bridging coordination of the acetate in all three oxidation states.

## Redox Properties in Partially Aqueous Media

In previous studies of $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^+$ and $[Mn_2(bhpp)(\mu\text{-}OAc)_2]^+$, we have shown that complexes in higher oxidation states can be generated in partially aqueous solutions.[17–19] For $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^+$ we could show that the exchange of acetate bridges for water-derived ligands ($H_2O$, $OH^-$, $O^{2-}$) accounts for the changes in redox behaviour in the presence of water. We were able to identify the products of the ligand exchange reactions and could demonstrate that increasing deprotonation of water-derived ligands provides the charge compensation needed for the stabilisation of high metal oxidation states.[18] In this way a di-μ-oxo-bridged dimer $[Mn_2^{III,IV}(bpmp)(\mu\text{-}O)_2]^{2+}$ can be obtained by three-electron oxidation of $[Mn_2^{II,II}(bpmp)(\mu\text{-}OAc)_2]^+$ that cannot be oxidised beyond the $Mn_2^{III,III}$ state, in its original di-μ-acetato form.

It could be anticipated that similar ligand exchange processes might take place in **5**. We therefore wanted to investigate the extent of these processes in **5**, and if complexes with oxidation states higher than $Mn_2^{III,III}$ could be formed from **5** as a result of ligand exchange in aqueous media.

### *IR Spectroscopy*

The exchange of acetate ligands for water-derived ligands was monitored by IR spectroscopy in $CD_3CN/D_2O$ mixtures (Figure 6, a). With increasing water concentration the sharp absorption peak arising from the acetate ligands ($\nu_{as}$, 1590 $cm^{-1}$, $\varepsilon$ = 4170 $M^{-1}cm^{-1}$) is depleted and replaced by the broader and weaker $\nu_{as}$ band of free acetate ions that can be observed at lower frequency (1574 $cm^{-1}$, $\varepsilon$ = 840 $M^{-1}cm^{-1}$).[18] The ratio of free versus bound acetate approaches unity, indicating that on average only one acetate per molecule of **5** is lost, even for the highest water concentration (inset in Figure 6, a). Assuming that the absorption changes represent a uniform reaction, this indicates that either all complexes have lost one acetate or half of them have lost both ligands. The dependence of the acetate concentration on the water content (Figure 6, b) is in good agreement with (9), with an equilibrium constant $K_9$ = $7.6 \times 10^{-5}$ $M^{-1}$ (Figure 6, c), while other obvious possibilities (10, 11) are not in agreement with the IR data.

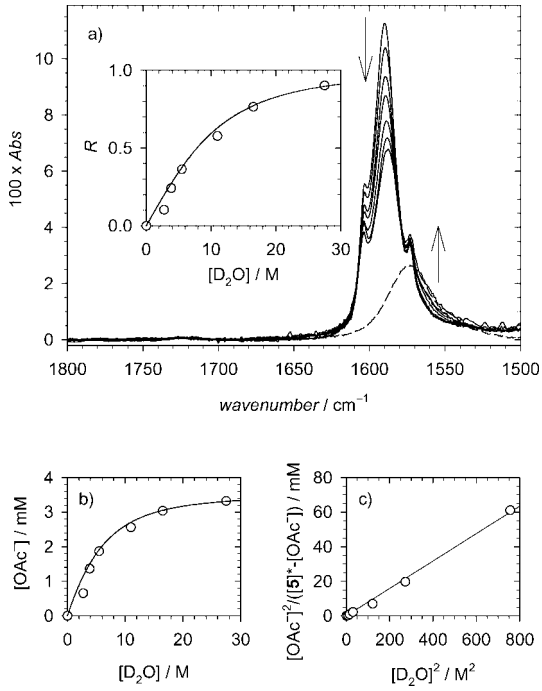


Figure 6. (a) IR spectra of **5** (3.5 mM) in $[D_3]$acetonitrile and $[D_3]$-acetonitrile/water ($D_2O$) mixtures. Arrows indicate direction of absorbance changes for increasing $D_2O$ concentration. Dashed line is the spectrum of ionic acetate (3.5 mM as NaOAc). Inset: ratio $R$ = $[OAc^-]/[M\text{-}OAc]$ of ionic vs. coordinated acetate as a function of water concentration. (b) Absolute concentration of ionic acetate and (c) plot according to Reaction (9) with a slope of $K_9$ = $7.6 \times 10^{-5}$ $M^{-1}$. [Lines in (a) inset and (b) are computed with this value of $K_9$.]

$$[Mn_2L(\mu\text{-}OAc)_2]^+ + 2H_2O \leftrightarrows [Mn_2L(\mu\text{-}OAc)(H_2O)_2]^{2+} + OAc^- \quad (9)$$

$$[Mn_2L(\mu\text{-}OAc)_2]^+ + H_2O \leftrightarrows [Mn_2L(\mu\text{-}OAc)(\mu\text{-}H_2O)]^{2+} + OAc^- \quad (10)$$

$$[Mn_2L(\mu\text{-}OAc)_2]^+ + 2H_2O \leftrightarrows [Mn_2L(\mu\text{-}H_2O)_2]^{3+} + 2OAc^- \quad (11)$$

In summary, the IR data suggest that one of the acetate bridges is lost more readily and is replaced by two terminal aquo ligands while the second acetate remains coordinated to the Mn centres even at the highest water concentrations. In this respect **5** behaves differently from the bpmp ana-

logues where the $Mn_2^{II,II}$ complex, which has the same charge as **5**, as well as the $Mn_2^{II,III}$ complex, in the same valence state as **5**, release both acetate ligands under comparable conditions.[18] Another difference between **5** and $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^{2+}$ is the protonation state of the water-derived ligands. For the bpmp complex it was observed that the reaction of the $Mn_2^{II,III}$ state with water results in free acetate as well as acetic acid, which can be rationalised in terms of deprotonation of the water-derived ligands, resulting in the formation of oxo- and hydroxo bridges. In the case of **5** the absence of acetic acid hence implies that the aquo ligands are less acidic and remain protonated when bound to the $Mn_2^{II,III}$ complex. It is therefore likely that the water-derived ligands are terminal and not bridging in this valence state, although the formation of bridging aqueous ligands cannot be ruled out.

### *Electrochemistry*

The effect of the ligand exchange reactions on the redox behaviour of **5** was studied by cyclic voltammetry in different acetonitrile/water mixtures (Figure 7). With lower water concentration (1% v:v, 0.55 M) the ligand exchange equilibrium is largely on the left hand side and the magnitude of the first oxidation wave (2) is identical to dry acetonitrile solution (Figure 7, a and b). Also the reversibility of this wave (2) as well as the magnitude and reversibility of the reduction wave (1) (not shown) are unaffected. This indicates that under these conditions **5** does not react with water to a sizeable extent neither in the initial $Mn_2^{II,III}$ nor in the $Mn_2^{III,III}$ or $Mn_2^{II,II}$ forms.

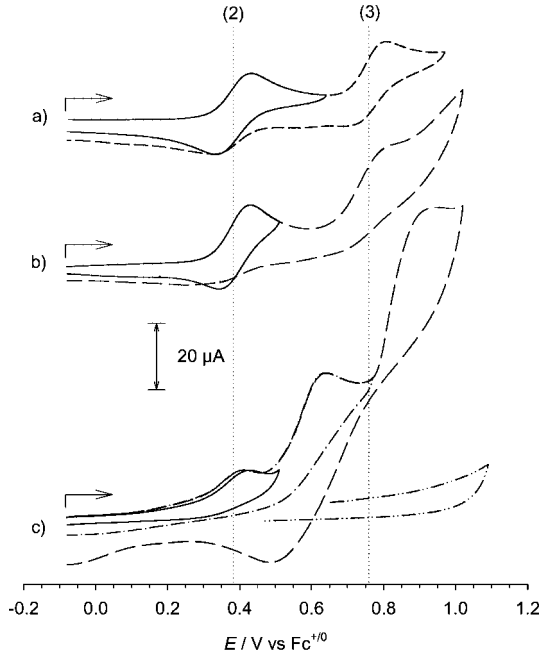

Figure 7. Cyclic voltammograms ($v$ = 0.100 V s$^{-1}$, first scans) of **5** (1 mM) with ($n$-$C_4H_9)_4N{\cdot}ClO_4$ (0.1 M) as supporting electrolyte. (a) Anhydrous acetonitrile. (b) Acetonitrile with 1% water (v:v). (c) Acetonitrile with 10% water (v:v). The dashed and dotted line shows the solvent background with 10% water.

With higher water concentration (10% v:v, 5.5 M) the first oxidation wave (2) is already depleted and fully irreversible while the second oxidation wave (3) of the original complex is absent (Figure 7, c). This shows that with the increased water content more than half of the complexes react with water already in the initial $Mn_2^{II,III}$ state, and the more reactive $Mn_2^{III,III}$ state is converted completely by the ligand exchange reactions. The additional anodic peaks around 0.6 and 0.9 V can be attributed to the oxidation of the products from the ligand exchange reactions. The first attempts to investigate the ligand exchanged oxidation products by EPR spectroscopy after bulk electrolysis of **5** in partially aqueous solutions were unsuccessful however. We therefore sought information on the oxidation products from IR spectroscopy, which benefits from more rapid electrochemical conversion in the thin-layer cell employed for IR spectroelectrochemistry.

### *IR Spectroelectrochemistry*

Figure 8 shows the IR absorption changes induced by oxidation of **5** in acetonitrile solution with 10% water. Electrolysis at the potential of the first oxidation (0.47 V vs. $Fc^{+/0}$) generates acetic acid (1725, 1380 and 1300 cm$^{-1}$) as well as free acetate ions with their absorption band (1575 cm$^{-1}$) partly cancelled by the bleach of the acetate ligand band (1590 cm$^{-1}$). This is in line with the notion that higher oxidation states are more reactive towards water (see Electrochemistry) and demonstrates that the water-derived ligands are at least partly deprotonated upon oxidation of the Mn centres. Subsequent oxidation at 0.72 V versus $Fc^{+/0}$ transforms the remaining acetate ligands as well as the acetate released in the previous oxidation step into acetic acid. This shows that the product(s) generated in the second oxidation wave peaking at 0.6 V do not carry any acetate ligands and that the water-derived ligands are further deprotonated.

Therefore, it can be concluded that the most oxidised products are oxo- ore hydroxo-bridged complexes. For $[Mn_2^{II,II}(bpmp)(\mu\text{-}OAc)_2]^+$ we showed that $[Mn_2^{III,IV}(bpmp)(\mu\text{-}O)_2]^{2+}$ was formed close to the potential of the III,III/II,III couple of the parent complex. The product was identified by rapid on-line transfer of the electrolysis products to a mass spectrometer.[18] The same product complex was also detected by EPR spectroscopy after light-induced oxidation of $[Mn_2^{II,II}(bpmp)(\mu\text{-}OAc)_2]^+$ via $[Ru^{III}(bpy)_3]^{3+}$ and rapid freezing of the products.[17,19] With the increased O/N ratio of complex **5** we anticipated that product complexes at least at the $Mn_2^{III,IV}$ level or even higher might be formed with the $Ru^{III}$ oxidant ($E_{1/2}$ = 0.90 V vs. $Fc^{+/0}$) and be detected by a combination of photo-oxidation and EPR spectroscopy.

### *EPR Spectroscopy of Photo-Oxidised Samples*

The oxidant $[Ru^{III}(bpy)_3]^{3+}$ was generated by oxidative quenching of photoexcited $[Ru^{II}(bpy)_3]^{2+}$. The sacrificial electron acceptor $[Co^{III}(NH_3)_5Cl]^{2+}$ avoids electron recombination, and thereby allows for accumulative oxidation of the manganese complex. To dissolve a sufficient amount of

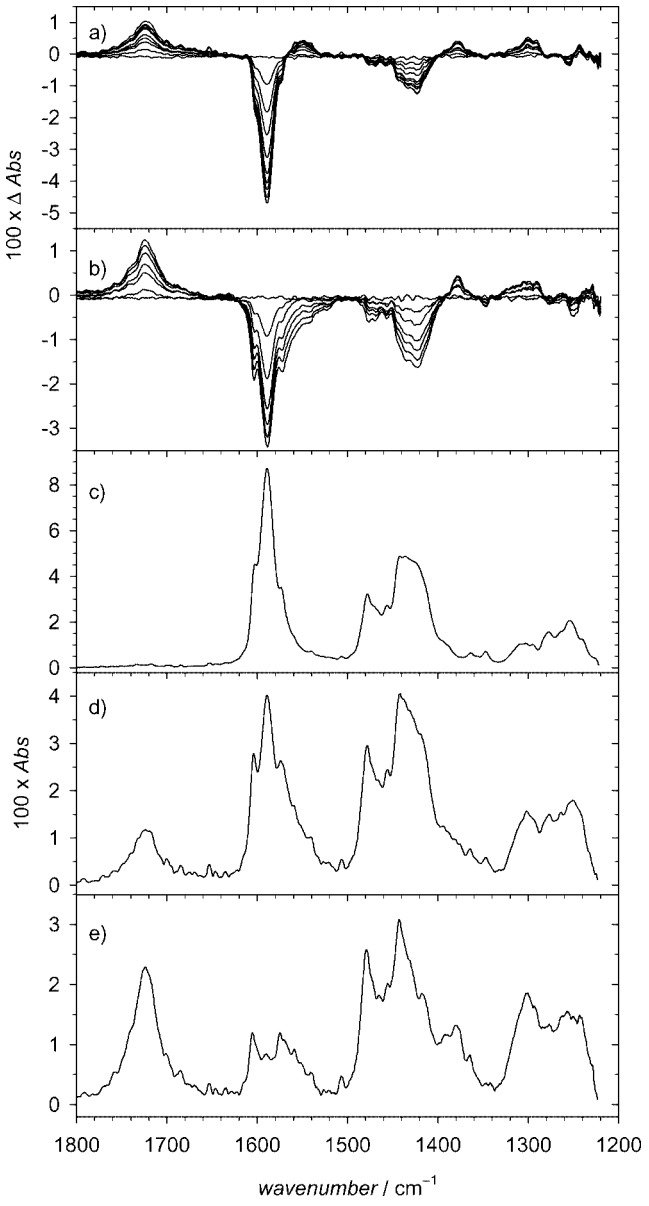

Figure 8. IR spectroelectrochemistry of **5** (3.5 mM) in [$D_3$]acetonitrile with 5.5 M water ($D_2O$). Absorbance changes upon oxidation at 0.47 V vs. $Fc^{+/0}$ (a) and subsequent oxidation at 0.72 V vs. $Fc^{+/0}$ (b). Spectra before oxidation (c) and after exhaustive oxidation at 0.47 V (d) and 0.72 V (e).

the acceptor, a high water content (1:1 water/acetonitrile) was needed for these measurements. The results from the IR spectra demonstrate that under these conditions each complex loses one of the acetate ligands already in the initial $Mn_2^{II,III}$ state. When **5** was dissolved in the reaction mixture, the 17 hyperfine lines in the $Mn_2^{II,III}$ EPR spectrum were broadened, and a signal with less-resolved hyperfine structure dominated the spectrum of the starting material (Figure 9, spectrum a). However, the integrated area of the spectrum was almost the same as for the well-resolved $Mn_2^{II,III}$ spectrum in acetonitrile (the magnitude of the EPR signal corresponds to about 80% of the nominal concentration), which indicates that essentially the entire sample remained in the original valence state. This demonstrates that even at this very high water content the major part of the material prevails as coupled $Mn_2^{II,III}$ dimers, and the broadened hyperfine structure can be attributed to strain effects due to accessibility to the bulk solution.

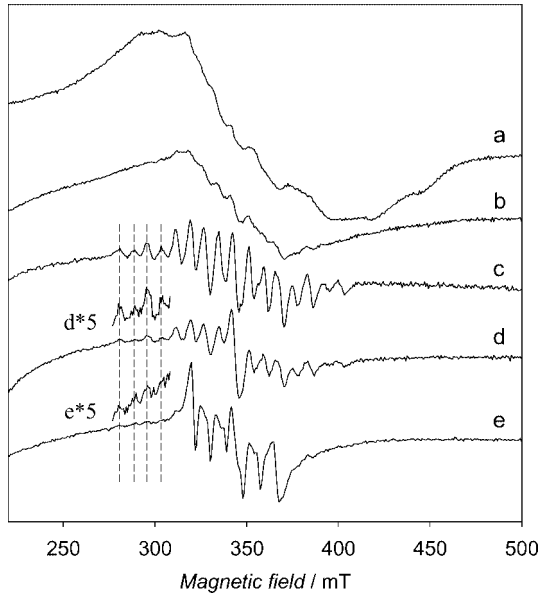

Figure 9. EPR spectra of **5** (0.5 mM) exposed to a variable number of laser flashes at 20 °C in the presence of $[Ru^{II}(bpy)_3]^{2+}$ (4 mM) and $[Co^{III}(NH_3)_5Cl]^{2+}$ (8 mM) in acetonitrile/aqueous solution (1:1 v/v). The spectra were recorded from the same sample, exposed to 0 (a), 20 (b), 100 (c), 180 (d) and 380 (e) laser flashes. In spectra d and e the magnified parts on the low-field side show the remaining presence of the EPR signal from $Mn_2^{III,IV}$. Spectrometer settings as in Figure 4.

Upon illumination with an increasing number of laser flashes, the initial EPR signal from $Mn_2^{II,III}$ decreased successively (Figure 10). To ensure accurate quantification of $Mn_2^{II,III}$, all measurements were made at 4 K, where all complexes are in the $S = 1/2$ ground state.[36] The simultaneously increasing EPR signal from the reduced electron acceptor $[Co^{II}(NH_3)_x(H_2O)_y]^{2+}$ ($g = 5$, not shown but cf. Huang et al.[17]) showed that the depletion of the $Mn_2^{II,III}$ signal is due to oxidation with the photogenerated $[Ru^{III}(bpy)_3]^{3+}$.

After 40 flashes a new signal at $g = 2$ appeared (Figure 9, spectrum c). It bears the typical signatures of a $S = 1/2$ ground state of a strongly coupled $Mn_2^{III,IV}$ complex, being about 2300 gauss wide and displaying 16 hyperfine lines with a spacing of 75–80 gauss.[34,42] The hyperfine splitting arises because of strong antiferromagnetic coupling typical of di-μ-oxo- or di-μ-hydroxo-bridged $Mn_2^{III,IV}$ dimers. For $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^+$ we could demonstrate that the aquo and hydroxo complexes formed by ligand exchange in the lower oxidation states were ultimately transformed into the di-μ-oxo complex upon oxidation to the $Mn_2^{III,IV}$ level.[18] With the additional phenolate donor ligand in **5**, a μ-oxo-μ-hydroxo complex is the most probable structure for this oxidation state.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

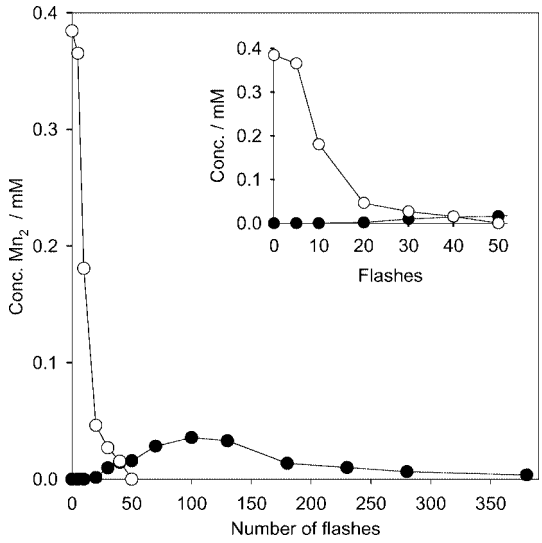

Figure 10. Flash-dependent concentrations of $Mn_2^{II,III}$ (–○–) and $Mn_2^{III,IV}$ (–●–). The data are obtained after quantification of $Mn_2^{II,III}$ and $Mn_2^{III,IV}$ from EPR spectra similar to those in Figure 7. All $Mn_2^{II,III}$ is quantitatively oxidised after 50 flashes, and the maximum observed amount of $Mn_2^{III,IV}$ appears after 100 flashes. The intermediate, $Mn_2^{III,III}$, cannot be observed by EPR. The inset shows a magnification of the data obtained between flashes 0 and 50, to highlight the lag phase in formation of $Mn_2^{III,IV}$.

Oxidation of the $Mn_2^{II,III}$ complexes to the $Mn_2^{III,IV}$ product with the one-electron photo-oxidant $Ru^{III}(bpy)_3$ should proceed via intermediates at the $Mn_2^{III,III}$ level. These are expected to be EPR-silent and not observable by EPR, which explains the lag phase between complete disappearance of the $Mn_2^{II,III}$ EPR spectrum and the maximum intensity of the $Mn_2^{III,IV}$ EPR signal (Figure 10). After 40 flashes, approximately equal concentrations of the $Mn_2^{II,III}$ and $Mn_2^{III,IV}$ species coexist in the reaction solution mixture, demonstrating that the high oxidation state in the $Mn_2^{III,IV}$ species possesses the desired stability. If we assume that the potential of the III,III/II,III couple of the species we observe under the experimental conditions of flash photolysis is similar to that of the di-μ-acetato complex (0.38 V vs. $Fc^{+/0}$), we can assume a similar potential for the III,IV/III,III couple of the $Mn_2^{III,IV}$ species. We made an analogous estimation of potentials for $[Mn_2(bpmp)(\mu\text{-}OAc)_2]^+$, where the mass spectrometry data indicated formation of $[Mn_2^{III,IV}(bpmp)(\mu\text{-}O)_2]^{2+}$ at potentials close to the III,III/II,III couple of the parent complex.[18] This compression of multiple redox reactions in a narrow potential range, which is a consequence of the ligand exchange reactions, indicates that disproportionation of III,III intermediates might contribute to the formation of the $Mn_2^{III,IV}$ species.

The $Mn_2^{III,IV}$ species reached a maximum concentration of about 10% relative to the initial $Mn_2^{II,III}$ signal before it started to decrease after about 100 flashes (Figure 10). The $Mn_2^{III,IV}$ spectrum was not immediately replaced by any other EPR-active species, suggesting that the $Mn_2^{III,IV}$ complex was further oxidised to an EPR-silent product. This could be either a $Mn_2^{IV,IV}$ complex or a $Mn_2^{III,IV}L^{\cdot}$ form with a ligand-based radical strongly coupled to the metal. Subsequent oxidation could also account for the relatively low yield of $Mn_2^{III,IV}$ species. When the $Mn_2^{III,IV}$ signal was almost fully depleted, a weak radical signal could be observed (Figure 9, in the centre of spectrum d) that was about 70 G wide (peak-to-trough) and had enhanced relaxation properties, as a consequence of being close to a paramagnetic metal centre. It is similar to the radical spectrum observed upon oxidation of the analogous $[Mn_2(bhpp)(OAc)_2]$ complex[21] and most likely arises from the oxidised *tert*-butyl-substituted phenol group. If it is the case that further oxidation of the $Mn_2^{III,IV}$ species results in formation of $Mn_2^{III,IV}L^{\cdot}$, the detected radical signal might arise from a minor fraction of the product where the oxidised phenol ligand has been detached from the manganese, while the major fraction with the radical coordinated to the metal centre is EPR-silent. The disappearance of the $Mn_2^{III,IV}$ EPR species cannot be explained by disintegration of the complexes, as that usually results in the release of monomeric $Mn^{II}$. In contrast, only a small quantity of $Mn^{II}$ (about 2% of the total Mn concentration) was released according to its EPR signal consisting of six lines at $g = 2$ (Figure 9, spectrum e).[43]

In summary, the results of photo-oxidation show that oxidation of **5** in partly aqueous solution generates a $Mn_2^{III,IV}$ complex, most likely with a di-μ-oxo or di-μ-oxo/hydroxo bridging motif replacing the acetate ligands. In addition, our data indicate that further photoinduced oxidation of this complex might result in a $Mn_2^{IV,IV}$ or $Mn_2^{III,IV}$-$L^{\cdot}$ product.

## Conclusions

The unsymmetric ligand in the mixed-valent manganese complex **5** ($[Mn_2^{II,III}L(\mu\text{-}OAc)_2]ClO_4$) provides, together with the bridging acetates, a $N_3O_3$ and a $N_2O_4$ donor set to the $Mn^{II}$ and $Mn^{III}$ centres respectively. Compared to the symmetric ligand analogues bpmp[16] and bhpp,[21] the unsymmetric ligand provides an intermediate O/N ratio and substantially stabilises the mixed-valence state, where the higher-valent metal ion is localised in the $N_3O_3$ environment. The pseudo-octahedral coordination geometry is largely distorted and conversion to the isovalent states is associated with large inner reorganisation energies resulting in slow electron transfer reactions.

Complex **5** displays two oxidation processes in nonaqueous solvents, where charge accumulation precludes the formation of stable oxidation states beyond the $Mn_2^{III,III}$ state. This situation changes in aqueous media where the acetate bridges of **5** are replaced by water-derived ligands. These provide charge compensation by deprotonation upon oxidation of the metal centres.[18,44] As a result, the potential interval for accumulative oxidations becomes more compressed, so that three metal-centred oxidation processes can be driven by $[Ru^{III}(bpy)_3]^{3+}$ ($E_{1/2}$ = 1.27 V vs. NHE). Moreover, the ability to acquire water-derived ligands is an essen-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tial characteristic of any functional model for the water-oxidising complex in PSII.

The product of the photoinduced oxidation is a $Mn_2^{III,IV}$ complex, which can be further oxidised to, most likely, a $Mn_2^{IV,IV}$ complex. The high-valent complexes are oxo- or hydroxo-bridged, which is supported by the EPR spectrum observed for the $Mn_2^{III,IV}$ complex, which is consistent with a strongly antiferromagnetically coupled complex.

These results demonstrate that four, possibly five, manganese valence states can be sustained in the same binucleating ligand, as the build-up of charge can be balanced because of the flexibility of the bridging motif. Water oxidation in PSII is believed to involve at least $Mn^{IV}$ or even $Mn^{V}$ to provide sufficiently electrophilic oxo ligands that can engage in O–O bond formation.[5,7,45] Compared to the related $[Mn_2(bpmp)(OAc)_2]^+$ we note that the increased O/N ratio of **5** stabilises higher valence states, which results in oxidation of the ligand exchange products beyond the $Mn_2^{III,IV}$ level. This is a significant improvement in view of prospective biomimetic water oxidation catalysts. It is however important to note that there is an unavoidable trade-off between stabilising higher oxidation states and maintaining sufficient oxidising potential. For the $Mn_2^{III,IV}$ complex derived from **5** the estimated oxidation potential of the III,IV/III,III couple is probably comparable to the III,III/II,III couple of the parent complex (≈0.4 V vs. $Fc^{+/0}$, ≈0.8 V vs. NHE). This suggests that all oxidation products derived from **5** are within a desirable potential range with respect to the average potential of 0.81 V versus NHE (at pH 7) required for water oxidation. Thus, the O/N ratio in **5** seems to create close to an optimal balance between oxidising potential and valence state stabilisation.

## Experimental Section

**Materials:** 2-(Chloromethyl)-6-formyl-4-methylphenol,[27] dipicolylamine[28] and (3,5-di-*tert*-butyl-2-hydroxybenzyl)(2-pyridylmethyl)amine[21] were prepared according to the literature procedures. Dichloromethane and triethylamine were distilled under argon over sodium/benzophenone and calcium hydride, respectively. Column chromatography was performed using silica gel (60–80 mesh). All other reagents were of reagent grade quality and used as received. $^1$H NMR spectra were recorded with a Varian 400-MHz spectrometer.

**2-{[(3,5-Di-*tert*-butyl-2-hydroxybenzyl)(pyrid-2-ylmethyl)amino]-methyl}-6-formyl-4-methylphenol (2):** (3,5-Di-*tert*-butyl-2-hydroxybenzyl)(pyrid-2-ylmethyl)amine (1.64 g, 5.0 mmol) and triethylamine (0.62 g, 6.1 mmol) in $CH_2Cl_2$ (15 mL) under argon were added to a solution of 2-(chloromethyl)-6-formyl-4-methylphenol (**1**) (1.03 g, 5.6 mmol) in $CH_2Cl_2$ (15 mL). The reaction mixture was refluxed overnight under argon. The reaction was poured into water and extracted with $CH_2Cl_2$. The combined organic phases were dried with anhydrous sodium sulfate, filtered and evaporated under reduce pressure. The residue was purified by column chromatography, eluting with $CH_2Cl_2$/MeOH, 97:3. Yield 1.84 g (95%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.26 (s, 9 H), 1.42 (s, 9 H), 2.28 (s, 3 H), 3.77 (s, 2 H), 3.79 (s, 2 H), 3.84 (s, 2 H), 6.86 (d, 1 H), 7.16–7.20 (m, 2 H), 7.28–7.34 (m, 3 H), 7.65 (dt, 1 H), 8.56 (dd, 1 H), 9.95 (s, 1 H), 10.9 (s broad, 2 H) ppm.

**2-{[(3,5-Di-*tert*-butyl-2-hydroxybenzyl)(pyrid-2-ylmethyl)amino]-methyl}-6-(hydroxymethyl)-4-methylphenol (3):** Complex **2** (0.94 g, 2.0 mmol) was dissolved in methanol (20 mL) and treated with sodium borohydride (0.17 g, 4.4 mmol). The reaction was stirred at room temperature overnight. The solution was evaporated under reduced pressure and the residue was dissolved in water, acidified to pH 2–3 and stirred for 1 h. The pH was adjusted to 7–8 with sodium hydrogen carbonate and then extracted with dichloromethane. The combined organic phases were washed with brine, dried with anhydrous sodium sulfate and filtered. Evaporation under reduced pressure of the solvent afforded 0.92 g of **3** (97%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.27 (s, 9 H), 1.41 (s, 9 H), 2.24 (s, 3 H), 3.77 (s, 2 H), 3.78 (s, 2 H), 3.85 (s, 2 H), 4.68 (s, 2 H), 6.84 (d, 1 H), 8.90 (d, 1 H), 6.96 (d, 1 H), 7.17 (d, 1 H), 7.22 (d, 1 H), 7.32 (dt, 1 H), 7.74 (dt, 1 H), 8.86 (dd, 1 H), 10.80 (s broad, 2 H) ppm.

**2-{[Bis(pyrid-2-ylmethyl)amino]methyl}-6-{[(3,5-di-*tert*-butyl-2-hydroxybenzyl)(pyrid-2-ylmethyl)amino]methyl}-4-methylphenol, $H_2L$ (4):** Complex **3** (2.27 g, 4.8 mmol) was dissolved in freshly distilled thionyl chloride (5 mL) and $CH_2Cl_2$ (30 mL). The solution was stirred at room temperature for 2.5 h and then distilled under reduced pressure. The residue was dissolved in $CH_2Cl_2$ and washed with a cooled sodium hydrogen carbonate solution. The organic phase was dried with anhydrous sodium sulfate, filtered and evaporated under reduced pressure. The residue was dissolved in $CH_2Cl_2$ and added to a solution of bis-picolylamine (0.95 g, 4.8 mmol) and triethylamine (1.03 g, 10 mmol) and refluxed overnight under argon. The solution was washed with brine and dried with anhydrous sodium sulfate. After filtration and evaporation under reduced pressure the crude product was purified by column chromatography on silica gel, eluting with $CH_2Cl_2$/MeOH, 95:5. Yield 2.10 g (67%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.25 (s, 9 H), 1.38 (s, 9 H), 2.19 (s, 3 H), 3.73 (s, 2 H), 3.79 (s, 2 H), 3.82 (s, 2 H), 3.83 (s, 2 H), 3.86 (s, 4 H), 6.79 (d, 1 H), 6.84 (d, 1 H), 6.96 (d, 1 H), 7.06–7.15 (m, 4 H), 7.34 (d, 2 H), 7.42 (d, 2 H), 7.51–7.59 (m, 3 H), 8.49 (d, 1 H), 8.58 (d, 1 H), 10.90 (s broad, 2 H) ppm.

**$Mn_2L(OAc)_2{\cdot}ClO_4$ (5):** $Mn(OAc)_3{\cdot}(H_2O)_2$ (1.04 g, 3.9 mmol) was added to an ethanol solution (9 mL) of **4** (1.05 g, 1.6 mmol) in one portion. The dark red-brown solution was heated to 60 °C under argon for 20 min. A solution of $NaClO_4{\cdot}H_2O$ (0.58 g, 4.1 mol) in ethanol/water (3:1, 4 mL) was added dropwise and the reaction solution was slowly cooled to room temperature and then stored in a freezer (–18 °C) for 48 h. The dark red-brown microcrystalline solid was filtered and washed with cooled ethanol and diethyl ether. The solid was recrystallised from ethanol/hexane to give 0.79 g dark red-brown rod-like crystals (yield 52%) suitable for X-ray diffraction. ESI-MS: (*m*/*z*) (%) = 883.3354 $[M - ClO_4]^+$. $C_{46}H_{55}N_5O_6Mn_2^+$ (883.2913): found C 56.03, H 5.71, N 7.08, Cl 3.48, Mn 11.05. $C_{46}H_{55}Mn_2N_5O_6{\cdot}ClO_4$: calcd. C 56.19, H 5.64, N 7.12, Cl 3.61, Mn 11.17.

**X-ray Crystallography:** Single crystal X-ray diffraction patterns were recorded with a Stoe IPDS diffractometer on a rotating anode Mo-radiation source ($\lambda$ = 0.71073 Å) with &phis; scans of 1° width. The total rotation range was 200°. The sample-detector distance was 70 mm and with the diameter of the image plate being 180 mm this gave max $2\theta \approx 52°$. Measuring further out in $2\theta$ proved to give very little significant extra data. Suitable single crystals were chosen from the crystallisation (see "Synthesis" above) and were mounted and measured inside sealed glass capillaries with mother liquor surrounding the crystals. Crystals that were simply glued to a glass pin ceased to diffract after a few minutes. Indexing, cell refinements and integration of reflection intensities were performed with STOE IPDS software (Stoe & Cie GmbH, Darmstadt). Numerical ab-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sorption correction was performed with the program X-RED (Stoe & Cie GmbH, Darmstadt) and the crystal shape was verified with the program X-SHAPE (Stoe & Cie GmbH, Darmstadt) using multiple measurements of symmetry equivalent reflections. The structure was solved by direct methods using SHELXS97 giving electron density maps where most non-hydrogen atoms could be resolved.[46] The rest of the non-hydrogen atoms were located from difference electron density maps and the structure model was refined with full-matrix least-squares calculations on $F^2$ using the program SHELXL97-2.[47] All non-hydrogen atoms were refined with anisotropic displacement parameters and the hydrogens, which were placed at geometrically calculated positions and let to ride on the atoms they were bonded to, were given isotropic displacement parameters calculated as $\xi \cdot U_{eq.}$ for the non-hydrogen atoms with $\xi = 1.5$ for methyl H atoms ($-CH_3$) and $\xi = 1.2$ for methylenic ($-CH_2-$) and aromatic H atoms.

Only 39.2% of the reflections fulfilled the significance criterion $I > 2\sigma(I)$, thus the residual values calculated from all reflection are larger than those calculated from the significant reflections.

CCDC-256953 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Magnetic Susceptibility:** The magnetic susceptibility in the temperature range 4–300 K was measured on a powder sample of **5** at a magnetic field of 1.35 T using a Faraday balance. Correction for diamagnetism was made using Pascal's constants.

**Electrochemistry:** All solutions were prepared from dry acetonitrile (Merck, spectroscopy grade, dried with MS 3 Å) with 0.1 M tetrabutylammonium perchlorate that had been dried in a vacuum at 353 K (Fluka, electrochemical grade) as the supporting electrolyte. Before all measurements, oxygen was removed by bubbling the stirred solutions with solvent-saturated argon and the samples were kept under argon during measurements. Cyclic voltammetry, differential pulse voltammetry and controlled potential electrolysis were carried out using an Autolab PGSTAT 100 potentiostat with a GPES 4.9 electrochemical interface (Eco Chemie). The working electrode was a glassy carbon disc (diameter 3 mm, freshly polished) for voltammetry, a Pt disk microelectrode (CH Instruments, diameter 25 μm, freshly polished with alumina 0.3 μm) for fast voltammetry or a platinum grid for bulk electrolysis. A platinum spiral in a compartment separated from the bulk solution by a fritted disk was used as the counter electrode. The reference electrode was a nonaqueous $Ag/Ag^+$ electrode (CH Instruments, 0.01 M $AgNO_3$ in acetonitrile) with a potential of –0.08 V versus the ferrocenium/ferrocene ($Fc^+/Fc$) couple in acetonitrile as an external standard. All potentials reported here are versus the $Fc^+/Fc$ couple, which is obtained by adding –0.08 V to the potentials measured versus the $Ag/Ag^+$ electrode. No compensation for $iR$ drop has been made. With a specific conductivity of $\kappa > 0.01\ S\,cm^{-1}$ of the electrolyte the resistance for the microelectrode ($r = 12.5$ μm) is $R = 1/(4\kappa r) < 20$ kΩ With voltammetric peak currents $i < 100$ nA, the $iR$ drop is negligible (<2 mV) in the microelectrode measurements. Digital simulations of the cyclic voltammograms have been performed with GPES 4.9 software (Eco Chemie). The simulated voltammograms have been composed from the faradic current of a quasireversible and a two-component quasireversible model superimposed on a linear nonfaradic background. The heterogeneous electron transfer rate constants are reported as apparent standard rate constants without corrections for double-layer effects.

**UV/Vis Spectroscopy:** The electronic absorption spectrum was recorded with a UV/Vis-NIR spectrophotometer (Varian CARY 2400) between 200 and 2700 nm. Spectroelectrochemical measurements were made in a OTTLE-type quartz cell with an optical path length of 1 mm. A platinum grid with a size of $10 \times 30\ mm^2$ and 400 meshes per $cm^2$ was used as the working electrode. The counter and reference electrodes were of the same type as described in the electrochemistry paragraph. Samples were bubbled for 20 min with solvent-saturated argon and transferred to the argon-flushed cell with the argon stream. The spectra were recorded with a UV/Vis diode array spectrophotometer (Hewlett Packard 8435) with the background collected on electrolyte solution in the potential free OTTLE cell.

**IR Spectroscopy:** IR absorption spectra were recorded at a resolution of $1\ cm^{-1}$ with a Bruker FTIR spectrometer (IFS 66v/S) with the sample as a KBr pellet or as solution in a liquid-sample cell (Bruker A140) between $CaF_2$ windows and with a path length of 125 μm. The solutions were prepared in $CD_3CN$ (Aldrich, 99.8 atom-% D) or mixtures of $CD_3CN$ with $D_2O$ (Aldrich, 99 atom-% D).

The ratio of free versus coordinated acetate ($R = [OAc^-]/[M\text{-}OAc]$) was determined from the absorbance at $1590\ cm^{-1}$ $\{Abs_{1590} = d(\varepsilon_{OAc^-}[OAc^-] + \varepsilon_{M\text{-}OAc}[M\text{-}OAc]) = d\varepsilon[OAc]\}$ as

$$R = (\varepsilon_{M\text{-}OAc} - \varepsilon)/(\varepsilon - \varepsilon_{OAc^-})$$

where $\varepsilon$ is a formal extinction coefficient and $[OAc] = 2 \times [\mathbf{5}]$ is the total acetate concentration. The concentration of free acetate is then given by

$$[OAc^-] = \{1 - 1/(R + 1)\}[OAc]$$

For Reaction (9) the equilibrium constant is defined as

$$K_9 = \{[Mn_2L(OAc)(H_2O)_2]\ [OAc^-])/([Mn_2L(OAc)_2]\ [H_2O]^2\} = [OAc^-]^2/\{([\mathbf{5}] - [OAc^-])\ [H_2O]^2\}$$

and was determined from a plot of $[OAc^-]^2/([\mathbf{5}] - [OAc^-])$ over $[H_2O]^2$.

IR spectroelectrochemical measurements were performed on solutions of **5** in $CD_3CN$ or $CD_3CN/D_2O$ with $KPF_6$ (0.1 M). The spectra were recorded in a thin-layer cell equipped with $CaF_2$ windows and an optical path length of 90 μm. The working electrode was a carbon fibre mesh (49% open area) and the counter electrode was a Pt cylinder concentric with the working electrode. The reference electrode was of the same type as described for electrochemistry and connected to the cell by a salt bridge (0.5 M $KPF_6$ in $CD_3CN$). $CD_3CN$, $D_2O$ and $KPF_6$ were purchased from Sigma Aldrich. $CD_3CN$ was dried with molecular sieves (3 Å) prior to use and $KPF_6$ was dried overnight at 353 K in vacuo.

**EPR Spectroscopy:** The electrochemical preparation of EPR samples was performed by bulk electrolysis of 1-mM solutions at controlled potentials. After electrolysis, 250-μL samples were taken with an argon-filled syringe via a septum from the electrolysis vessel and transferred to argon-flushed EPR tubes. The samples were immediately frozen and kept in liquid nitrogen. X-band EPR measurements were performed at cryogenic temperatures with a Bruker E500 ELEXSYS spectrometer equipped with a $TE_{102}$ resonator, an Oxford Instruments ESR 900 flow cryostat and an ITC 503 temperature controller.

For flash photolysis, a 1-mM solution of **5** in dry acetonitrile was mixed at a 1:1 ratio with an aqueous solution containing tris(2,2′-bipyridyl)dichloro-ruthenium(II) hexahydrate ($[Ru^{II}(bpy)_3]^{2+}$) (8 mM), and penta-aminechlorocobalt(III) chloride ($[Co^{III}(NH_3)_5Cl]^{2+}$) (16 mM), as described previously.[32] The solution was transferred to EPR tubes and the samples were immediately frozen in an ethanol/dry ice bath ($T = 198$ K) and then frozen at 77 K. All

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sample mixing and handling took place under dim red light and inert atmosphere, and care was taken to minimise the interval between mixing and freezing of the samples (mix–freeze time < 1 min). Laser flashes from a frequency doubled Spectra Physics DCR 3G Nd:YAG laser at 5 Hz and 532 nm (6 ns pulse width, about 250 mJ flash$^{-1}$) were given at room temperature to the pre-thawed EPR samples. The incident laser light was adjusted with lenses to cover the entire EPR sample volume. After the designated number of flashes, the sample was frozen in an ethanol/dry ice bath within 2 s and then quickly transferred to liquid $N_2$ until further use. X-band EPR spectra were recorded before and after flash illumination of the EPR samples. Evaluation of the change in $Mn_2^{II,III}$ concentration was done by double integration of the ground-state EPR signal at 4 K, and comparison with a reference $Mn_2^{II,III}$ spectrum from a known concentration of **5** in acetonitrile. To quantify the formation of $Mn_2$(III,IV) we used $Mn_2^{III,IV}(bpy)_4(\mu\text{-}O)_2$ as spectroscopic reference.[48] The concentration of $Mn_2^{III,IV}(bpy)_4(\mu\text{-}O)_2$ in acetonitrile was determined by UV/Vis spectrophotometry, using the extinction coefficient $\varepsilon = 900\ M^{-1}cm^{-1}$ at $\lambda$ = 687 nm. Simulations of EPR spectra were made using the Xsophe-Sophe-Xepr-View® software suite from Bruker GmbH.

**Supporting Information** (see footnote on the first page of this article): Figure S1 shows IR spectroelectrochemistry of **5**. IR spectra of **5** in KBr, and of the isovalent products $[Mn_2^{II,II}L(\mu\text{-}OAc)_2]$ and $[Mn_2^{III,III}L(\mu\text{-}OAc)_2]^{2+}$ in [$D_3$]acetonitrile solution. Selected crystallographic data not shown in Table 1.

[35] In ref.[34] the spin Hamiltonian $\hat{H} = \beta\,\hat{\mathbf{S}}\cdot\mathbf{g}\cdot\mathbf{B} + \hat{\mathbf{I}}_1\cdot\hat{\mathbf{A}}_1\cdot\hat{\mathbf{S}} + \hat{\mathbf{I}}_2\cdot\hat{\mathbf{A}}_2\cdot\hat{\mathbf{S}}$ was used, resulting in the hyperfine parameters $A_{1,x} = 171\times10^{-4}\ \mathrm{cm}^{-1}$, $A_{1,y} = 148\times10^{-4}\ \mathrm{cm}^{-1}$, $A_{1,z} = 261\times10^{-4}\ \mathrm{cm}^{-1}$ and $A_{2,x} = 55\times10^{-4}\ \mathrm{cm}^{-1}$, $A_{2,y} = 90\times10^{-4}\ \mathrm{cm}^{-1}$, $A_{2,z} = 122\times10^{-4}\ \mathrm{cm}^{-1}$ for manganese 1 and 2 respectively.
[36] a) This is based on the potential of the $[Ru(bpy)_3]^{3/2+}$ couple that is considered to be largely solvent independent and amounts to 0.90 V versus $Fc^{+/0}$ in acetonitrile (1.27 V vs. NHE in water). Potentials in nonaqueous solvents are frequently measured and reported versus the aqueous SCE. This introduces unknown junction potentials, however, and a comparison of such data with potentials obtained in other solvents like water is not meaningful even if the potentials are formally given versus the same reference electrode like SCE or NHE. Independent of this problem, electrochemical potentials are intrinsically solvent dependent and any comparison between data in different solvents can only be approximate; b) I. Rubinstein, A. J. Bard, *J. Am. Chem. Soc.* **1981**, *103*, 512–516.
[37] Electrolysis at 0.92 V appears to be a multielectron process presumably because of the oxidation of degradation products.

# Contribution to the Reactivity of *N*,*N*′-Diaryl-1,4-diazabutadienes Aryl–N=CH–CH=N–Aryl (Aryl = 2,6-Dimethylphenyl; 2,4,6-Trimethylphenyl) Towards Boron Trichloride

**Lothar Weber,*[a] Jan Förster,[a] Hans-Georg Stammler,[a] and Beate Neumann[a]**

**Keywords:** Diazabutadienes / Diazaboroles / Aminoboranes / Structures / Boron

The reaction of Aryl–N=CH–CH=N–Aryl (**3a**: Aryl = 2,6-$Me_2C_6H_3$; **3b**: Aryl = 2,4,6-$Me_3C_6H_2$) with 2 equiv. $BCl_3$ in a toluene/hexane mixture at –50 °C led to an inseparable mixture of borolium salts [Aryl–N$^a$=CH–CH=N(Aryl)$BCl_2$($N^a$–$B$)]$^+BCl_4^-$ (**4a**: Aryl = 2,6-$Me_2C_6H_3$; **9a**: Aryl = 2,4,6-$Me_3C_6H_2$) and [Aryl–N$^a$=CH–C(Cl)=N(Aryl)$BCl_2$($N^a$–$B$)]$^+BCl_4^-$ (**4b**: Aryl = 2,6-$Me_2C_6H_3$; **9b**: Aryl = 2,4,6-$Me_3C_6H_2$) and the bicyclic species [HC$^a$=N(Aryl)$BCl_2$N(Aryl)–C$^b$=($C^a$–$C^b$)]$_2$ (**5**: Aryl = 2,6-$Me_2C_6H_3$; **10**: Aryl = 2,4,6-$Me_3C_6H_2$). Sodium amalgam reduction of borolium salts **4a**,**b** and **9a**,**b** afforded inseparable mixtures of the diazaboroles 2,6-$Me_2C_6H_3N^aCH$=CR–N$^b$(2,6-$Me_2C_6H_3$)BCl($N^a$–$B$) (**1**: R = H; **6**: R = Cl) and 2,4,6-$Me_3C_6H_2N^aCH$=CR–N$^b$(2,4,6-$Me_3C_6H_2$)BCl($N^a$–$B$) (**2**: R = H; **11**: R = Cl). In order to obtain pure **1** and **2**, diazabutadienes **3a** and **3b** were slowly combined with 2 equiv. $BCl_3$ in the same solvents at –78 °C. The acyclic adducts $Cl_3BN$(Aryl)=CH–CH=N(Aryl)$BCl_3$ (**7a**: Aryl = 2,6-$Me_2C_6H_3$; **7b**: Aryl = 2,4,6-$Me_3C_6H_2$) were reduced with sodium amalgam to furnish the aminoboranes $Cl_2BN$(Aryl)CH=CH–N(Aryl)$BCl_2$ (**8**: Aryl = 2,6-$Me_2C_6H_3$; **12**: Aryl = 2,4,6-$Me_3C_6H_2$). Stirring solutions of **8** and **12** in the presence of $CaH_2$ cleanly gave the diazaboroles **1** and **2**, respectively. The novel compounds were characterized by elemental analyses and $^1$H-, $^{11}$B-, $^{13}$C NMR and mass spectra. The molecular structures of **1**, **4a**, **5** and **8** were elucidated by single X-ray diffraction analyses.

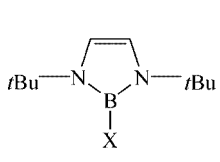
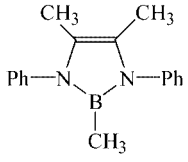
## Introduction

The synthesis and reactivity of 1,3-dialkyl-2-halo-2,3-dihydro-1*H*-1,3,2-diazaboroles **I** as well as their molecular structures have been thoroughly investigated and documented in the literature.[1–12] More recently, the electrochemical and optophysical properties of such compounds have attracted our interest. The electrochemical oxidation of 1,3-di-*tert*-butyl-2,3-dihydro-1*H*-1,3,2-diazaboroles by cyclic voltammetry displays clean but irreversible waves, and the oxidation potentials $E_{ox,1/2}$ vary strongly with the substitution pattern at the boron atom.[13] Diazaboroles that are functionalized at the boron center by thienyl-, dithienyl- or biphenyl groups are highly luminescent, emitting bright blue light upon UV irradiation.[14,15] With respect to this, we planned to extend the scope of our diazaboroles to representatives with aryl groups at both ring nitrogen atoms.

In an early paper, we described the preparation of heterocycle **II** by treatment of diacetyldianil with methylboron dibromide and subsequent reduction of the obtained borolium salt with an excess of sodium amalgam.[3]



**I**



**II**

Later this route was followed to synthesize the 2-chloro-1,3-dixylyl-2,3-dihydro-1*H*-1,3,2-diazaborole (**1**).[10] An alternative route to **1** and to the corresponding 2-bromo derivative was based on the reduction of the corresponding diazabutadiene with lithium metal and the cyclocondensation of the dilithiated species with $BX_3$ (X = Cl, Br).[10] In this contribution we report on the reaction of *N*,*N*′-diaryl-1,4-diazabutadienes with $BCl_3$. It was found that the reactivity of the *N*,*N*′-diaryl-1,4-diazabutadienes towards $BCl_3$ is far less straightforward than that of *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene.

## Results and Discussion

For the synthesis of **1**, it was obvious to follow the procedure that we previously elaborated.[10] In only one instance did the combination of diazabutadiene **3a** with two molar equivalents of boron trichloride in a mixture of toluene and hexane at –50 °C and subsequent stirring for 15 h

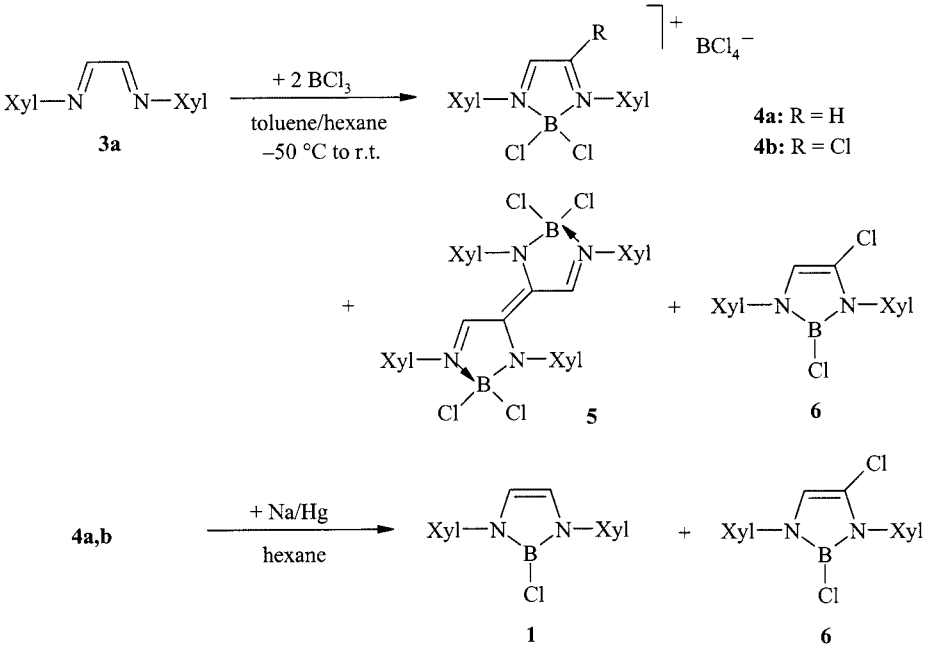
at 20 °C lead to the precipitation of the burgundy-red borolium salt **4a** in about 70% yield. In all the other cases, however, a black solid precipitated, which was identified as an inseparable mixture of **4a** and its analogue **4b** with a chlorine substituent at a ring carbon atom (about 30% yield). After filtration, the mother liquor was placed for 14 d at +4 °C, and compound **5** separated as deep red crystals in 18% yield. When the supernatant solution was decanted and concentrated to one-third of its volume, impure diazaborole **6** was isolated after storing this solution for 2 d at –4 °C. Recrystallization from pentane led to a few crystals of pure compound **6**, which is chlorinated at the C=C double bond.

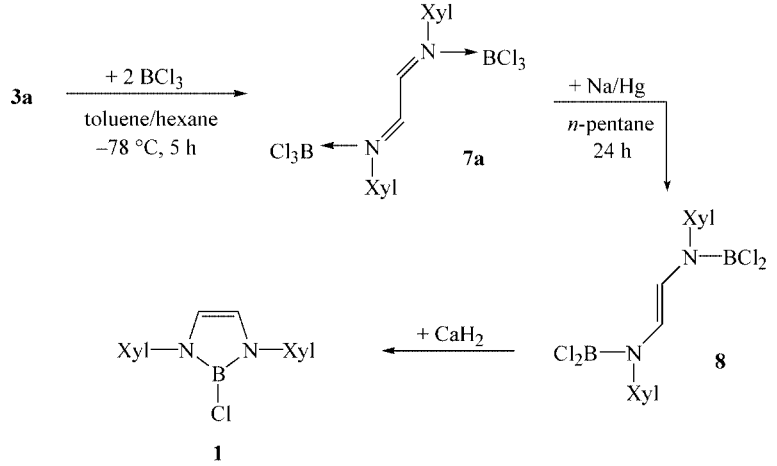
The usual reduction of the mixture of **4a** and **4b** with sodium amalgam in hexane afforded an inseparable mixture of the diazaboroles **1** and **6**. A **1**/**6** ratio of 10:1 was determined by $^1$H NMR spectroscopy. Although the reaction of pure salt **4a** gave a sample of pure **1** in one case, this synthetic pathway was discarded because of its poor reproducibility (Scheme 1).

Slow combination (4–5 h) of a toluene solution of **3a** with a cold (–78 °C) solution of $BCl_3$ in pentane in a molar ratio of 1:2 gave a precipitate of the red-brown adduct **7a** (60% yield). A slurry of this material in *n*-pentane was treated with sodium amalgam at 20 °C. From the supernatant solution, the acyclic doubly borylated (*E*)-*N*,*N*′-diaminoethene **8** was isolated as colorless crystals in about 70% yield. Stirring a solution of **8** in pentane in the presence of $CaH_2$ led to cyclization and the formation of diazaborole **1** (46% yield) (Scheme 2).

The reaction of diazabutadiene **3b** with 2 equiv. $BCl_3$ at –50 °C in a toluene/hexane mixture was performed analogously. A 1:1 mixture of the borolium salts **9a** (R = H) and **9b** (R = Cl) precipitated as a black solid (about 20% yield).



Scheme 1.



Scheme 2.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

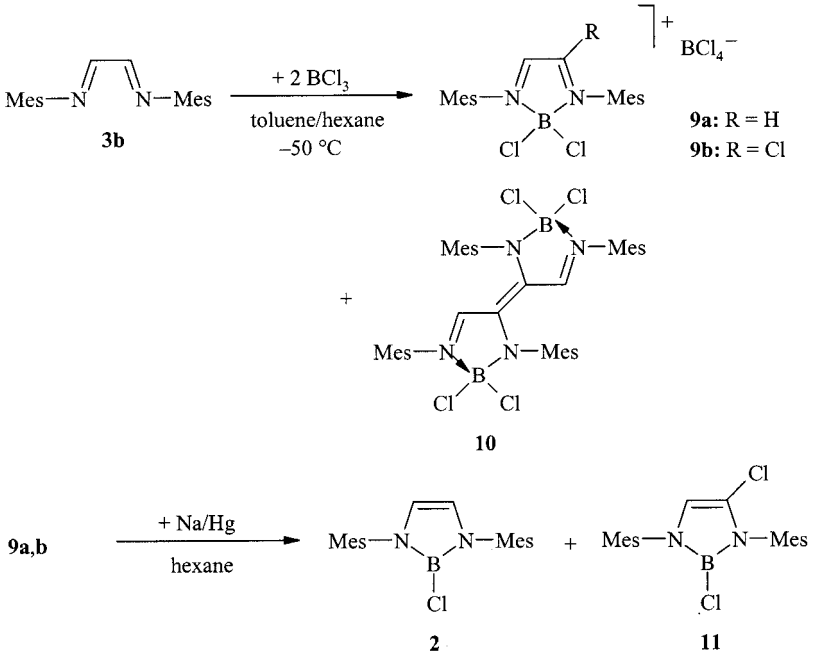
The mother liquor was concentrated and stored at +4 °C for 14 d, after which product **10** separated as deep green crystals in 14% yield (Scheme 3).

In the $^{11}B$ NMR spectrum of the mother liquor, a small singlet at $\delta$ = 21.8 ppm indicates small amounts of a 1,3,2-diazaborole. Its isolation, however, failed. The reduction of **9a**,**b** with sodium amalgam led to an inseparable mixture of the diazaboroles **2** and **11**. The generation of pure **2** first required the preparation of the violet adduct **7b** from the reaction of **3b** and 2 equiv. $BCl_3$ at –78 °C for 4–5 h (70% yield). The sodium amalgam reduction of **7b** afforded the acyclic aminoborane **12**, which upon treatment with $CaH_2$ cyclized to **2** in 54% yield (Scheme 4).

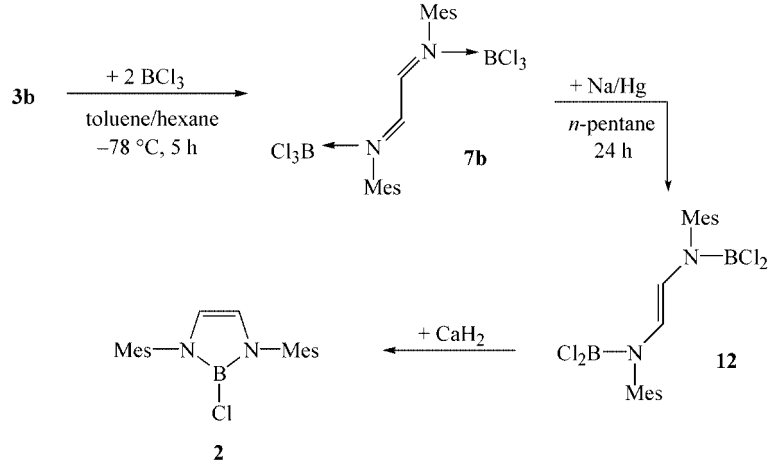
In order to suppress undesired side reactions at the carbon atom of the heterocycle, diacetyl[bis(2,6-dimethylphenylimine)] **13** was subjected to reaction with 2 equiv. $BCl_3$ in *n*-hexane. The green borolium salt **14** (yield 63%) was reduced with sodium amalgam to furnish, near quantitatively, the expected diazaborole **15** (Scheme 5).

Because of the pronounced thermolability of the 2-chloro-1,3,2-diazaborole **15**, this compound was converted immediately into the more stable 2-cyano-1,3,2-diazaborole **16** by reaction with silver cyanide in acetonitrile (Scheme 5).

The $^{11}B$ NMR spectra of the borolium salts show singlets ($\delta$ = 7.7 ppm) in the typical region for tetracoordinate boron atoms. For the tetracoordinate boron atoms in the binuclear compounds **5** and **10**, singlets are observed at $\delta$ = 8.6 and 8.5 ppm, respectively. The 2-chloroboroles **1**, **2**, **6** and **11** give rise to $^{11}B$ NMR signals at $\delta$ = 21.1–21.8 ppm. An influence of the Cl substituent at the C=C bond is not visible. In the $^{11}B$ NMR spectra of 2-cyanoborole **16**, the $^{11}B$ resonance appears as a singlet at $\delta$ = 13.5 ppm. The $^{11}B$ NMR resonances of the acyclic aminodichloroboranes **8** and **12** are at $\delta$ = 32.5 ppm. The signals for the ring protons



Scheme 3.



Scheme 4.

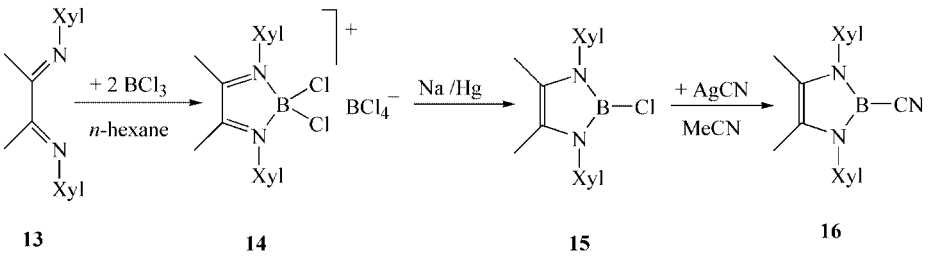

Scheme 5.

in the diazaboroles **1**, **2**, **6** and **11** are observed in the range from 5.51 to 5.93 ppm. The protons at the 1,6-diazahexatriene backbone of **5** and **10** are assigned as singlets at $\delta$ = 6.85 ppm. In the (*E*)-configured diaminoethenes **7** and **12**, the protons at the double bond give rise to singlets at $\delta$ = 6.40 ppm.

In the $^{13}C\{^1H\}$ NMR spectra of diazaboroles **1** and **2**, singlets at $\delta$ = 117.7 and 117.8 ppm, respectively, are assigned to the identical carbon atoms of the C=C group of the rings. The corresponding carbon atoms in the chlorinated derivative **6** give rise to two singlets at $\delta(^{13}C)$ = 113.7 and 126.8 ppm. The carbon atoms of the $N_2C_4$ backbone of **5** and **10** are attributed to singlets at $\delta$ = 161.3 and 170.3 ppm, respectively.

## X-ray Structural Analysis of 1

Single crystals of **1** were grown from the crude reaction mixture at +4 °C. The molecular structure of **1** (Figure 1, Table 1) features a planar 1,3,2-diazaborole ring with two almost orthogonally oriented *ortho*-xylyl substituents at the nitrogen atoms (interplanar angle between the heterocycle and arene ring $\varphi$ = 82.2°). A $C_2$ axis bisects the molecule along the B(1)–Cl(1) vector. The bond length B(1)–Cl(1) [1.768(2) Å] is close to the sum of the covalent radii of bo-

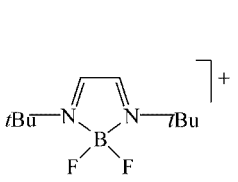
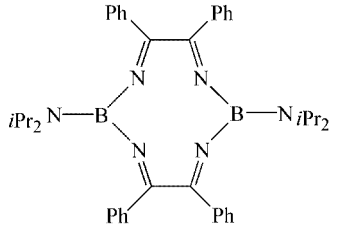
ron (0.81 Å) and chlorine (0.99 Å)[16] and compares well with the corresponding value in solid $B_2Cl_4$ (1.75 Å).[17] Atomic distances and valence angles within the diazaborole ring are in good agreement with the corresponding data for XylN[a]–CH=CH–N[b](Xyl)BI(*N[a]–B*)[10] and need no particular discussion at this point.



**III**



**IV**

## X-ray Structural Analysis of 4a

Red plates of **4a** suitable for an X-ray diffraction study (Table 1) were grown from the toluene/hexane mother liquor after removal of solid **4a**. The analysis features a planar diazaborolium cation [sum of bond angles 539.3°(1)], in addition to a tetrachloroborate anion (Figure 2).

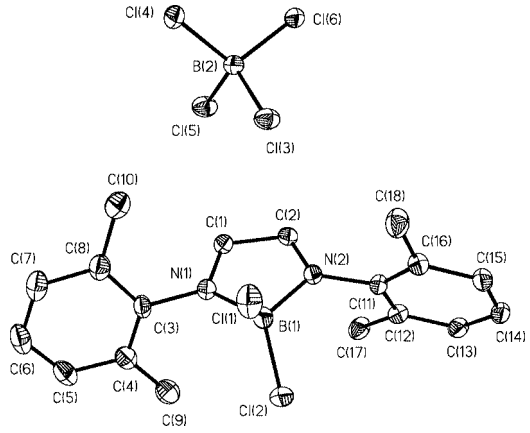


Figure 2. Molecular structure of **4a** in the crystal; H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: B(1)–Cl(1) 1.813(2), B(1)–Cl(2) 1.791(2), B(2)–Cl(3) 1.872(2), B(2)–Cl(4) 1.830(2), B(2)–Cl(5) 1.844(2), B(2)–Cl(6) 1.866(2), B(1)–N(1) 1.615(2), B(1)–N(2) 1.594(2), N(1)=C(1) 1.276(2), N(1)–C(3) 1.462(2), N(2)=C(2) 1.279(2), N(2)–C(11) 1.464(2), C(1)–C(2) 1.477(2); N(1)–B(1)–N(2) 95.8(1), B(1)–N(1)–C(1) 110.7(1), B(1)–N(1)–C(3) 127.4(1), B(1)–N(2)–C(2) 111.5(1), B(1)–N(2)–C(11) 125.9(1), C(1)–N(1)–C(3) 121.2(1), C(2)–N(2)–C(11) 121.7(1), N(1)–C(1)–C(2) 110.7(1), N(2)–C(2)–C(1) 110.6(1), Cl(1)–B(1)–Cl(2) 113.3(1), B(2)–Cl(3–6) 107.4(1)–111.2(1).

There are no bonding contacts between the cation and the anion. The bond lengths B(1)–Cl(1) [1.813(2) Å] and B(1)–Cl(2) [1.791(2) Å] are slightly shorter than the B–Cl bonds in $BCl_4^-$, which range from 1.830(2) to 1.872(2) Å. The boron–nitrogen bond lengths [B(1)–N(1) 1.615(2) Å, B(1)–N(2) 1.594(2) Å] slightly exceed the average value for the B–N single bond (1.59 Å) found in aminoboranes[18] and compare well with the corresponding bond lengths in cation **III** [1.607(3) and 1.611(3) Å].[19]

In 1,3,2-diazaboroles B–N bond lengths range from 1.40 to 1.45 Å. The endocyclic C–N bond lengths [C(1)–N(1) 1.276(2) Å, C(2)–N(2) 1.279(2) Å] are characteristic for double bonds and compare well with those in the cyclic ketiminoborane **IV** [1.273(3)–1.277(2) Å].[20]

The carbon–carbon bond length in the cation [1.477(2) Å] indicates a bond order of unity, whereas in diazaboroles, double bonds [1.362(8) Å in **1**] are typical. In comparison with **1** [106.9(4)°], the angle at the boron atom is compressed to 95.8(1)°, whereas the endocyclic angles B(1)–N(1)–C(1) [110.7(1)°], B(1)–N(1)–C(2) [111.5(1)°], N(1)–C(1)–C(2) [110.7(1)°] and N(2)–C(2)–C(1) [110.6(1)°] are slightly more obtuse than that in **1** [107.2(1), 109.4(1)°].

## X-ray Structural Analysis of 5

The X-ray analysis (Figure 3, Table 1) discloses a molecule in which two planar $BN_2C_2$ rings (sum of angles 539.7°) are fused by an elongated C(1)–C(1A) multiple bond [1.398(3) Å] ($C{=}C_{calcd.}$ = 1.33 Å) with an inversion center in the middle of the bond. The bond C(1)–N(1) [1.387(2) Å] is between the double bond N(2)=C(2) [1.300(2) Å] on the one hand and the single bonds N(1)–C(3) [1.440(2) Å] and N(2)–C(11) [1.447(2) Å] on the other hand. The distance C(1)–C(2) [1.437(2) Å] corresponds to a single bond.

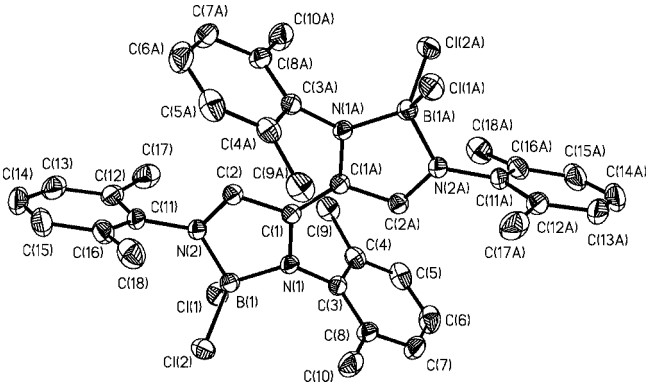

Figure 3. Molecular structure of **5** in the crystal. Selected bond lengths [Å] and angles [°]: B(1)–Cl(1) 1.840(2), B(1)–Cl(2) 1.878(2), B(1)–N(1) 1.518(2), B(1)–N(2) 1.576(2), N(1)–C(1) 1.387(2), N(1)–C(3) 1.440(2), N(2)=C(2) 1.300(2), N(2)–C(11) 1.447(2), C(1)–C(2) 1.437(2), C(1)=C(1A) 1.398(3); Cl(1)–B(1)–Cl(2) 106.6(1), N(1)–B(1)–N(2) 98.5(1), B(1)–N(1)–C(1) 111.4(1), B(1)–N(2)–C(2) 110.2(1), B(1)–N(1)–C(3) 125.4(1), B(1)–N(2)–C(11) 129.1(1), N(1)–C(1)–C(2) 107.0(1), N(1)–C(1)–C(1A) 128.7(2), N(2)–C(2)–C(1) 112.6(1), C(2)–N(2)–C(11) 120.3(1).

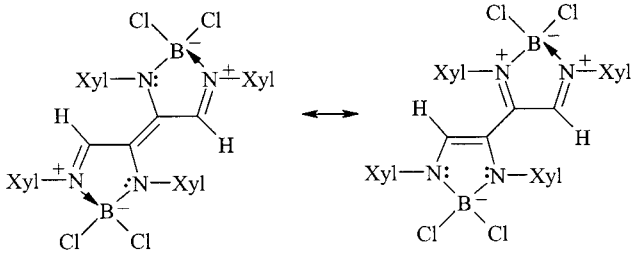
The boron–nitrogen bond B(1)–N(1) [1.518(2) Å] reflects a single bond between a tetracoordinate boron atom and an $sp^2$-hybridized nitrogen atom. It is markedly shorter than the coordinative bond B(1)–N(2) [1.576(2) Å]. The B–Cl bond lengths [1.840(2) and 1.878(2) Å] are longer than

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

those in ring **4** [1.791(2) and 1.813(2) Å] and compare with the B–Cl bond lengths in the $BCl_4^-$ ion.

The shortening of bond N(1)–C(1) and the elongation of bond C(1)=C(1A) are consistent with an extensive delocalization of charge as indicated by the two limiting formulae (Scheme 6).



Scheme 6.

The xylyl rings are oriented in a near perpendicular fashion to the plane defined by the two heterocycles, with interplanar angles of $\varphi$ = 99.3° at N(1) and $\varphi$ = 88.1° at N(2). The angle B(1)–N(1)–N(2) [98.5(1)°] is markedly more acute than those in 1,3,2-diazaboroles [cf. 106.9(1) in **1**]. The angles B(1)–N(1)–C(1) [111.4(1)°] and B(1)–N(2)–C(2) [110.2(1)°] compare with those in the chloroborolium cation of **4a** [110.7(1) and 111.5(1)°] and are slightly more obtuse than that in diazaborole **1** [107.2(1)°]

## X-ray Structural Analysis of 8

Single crystals of **8**, suitable for an X-ray structural study, were grown from a toluene/hexane mixture at 4 °C. The analysis shows the features of a planar 2,5-diaza-1,6-dibora-hexa-1,3,5-triene with an inversion center in the middle of the C=C bond (Figure 4, Table 1). The planes of the two xylyl substituents at the nitrogen atoms are perpendicularly oriented to the plane of the chain ($\varphi$ = 85.8°). The chlorine atoms at the boron are located in the plane of the molecule and feature single bonds with lengths of 1.766(1) and 1.767(1) Å. The B–N bond length of 1.395(1) Å is consistent with a double bond, as is the central bond length C(1)–C(1A) of 1.333(2) Å. The distances N(1)–C(1) [1.422(1) Å] and N(1)–C(2) [1.451(1) Å] reflect single bonds.

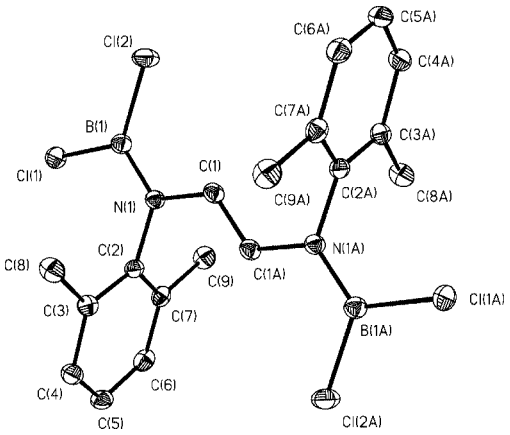


Figure 4. Molecular structure of **8** in the crystal; H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: B(1)–Cl(1) 1.766(1), B(1)–Cl(2) 1.767(1), B(1)–N(1) 1.395(1), N(1)–C(1) 1.422(1), N(1)–C(2) 1.451(1), C(1)=C(1A) 1.333(2); Cl(1)–B(1)–Cl(2) 118.1(1), Cl(1)–B(1)–N(1) 120.2(8), Cl(2)–B(1)–N(1) 121.7(1), B(1)–N(1)–C(1) 123.2(1), B(1)–N(1)–C(2) 121.1(1), C(1)–N(1)–C(2) 115.7(1), N(1)–C(1)–C(1A) 123.2(1).

In going from diazaboroles with various alkyl substituents at the ring atoms to xylyl and mesityl units, the generation of diazaboroles with one chlorine atom at the C=C bond was unexpected. In the case of compound **15** in which the double bond is substituted by two methyl groups, such a behavior could not be observed. Here, a recent paper on the reactivity of $BCl_3$ towards glyoxal[bis(2,6-diisopropylphenylimine)] by Mair et al. seems relevant.[21] He postulated the initial formation of a borolium salt **V**, the cation of which undergoes a twofold nucleophilic attack by chloride ions to eventually yield the trichlorinated diazaborolidine **VII** (Scheme 7). If, in our case, transient diazaborolidines are dehydrochlorinated by a base, diazaboroles such as **6** and **11** would be the products. It is conceivable that the carbon chlorination of diaryldiazabutadienes is favored by bulky arene groups.

The initial step in the formation of **5** and **10** is most likely the electrophilic attack of one immonium carbon atom of **4a** or **9a** at the C=C bond of **6** or **11** to give intermediate **VIII**. Elimination of HCl leads to cation **IX**, which finally adds a chloride ion at the tricoordinate boron atom to yield products **5** or **10** (Scheme 8).

## Conclusions

The extension of methodologies for the synthesis of 1,3-dialkyl-2,3-dihydro-1*H*-1,3,2-diazaboroles to the construction of 1,3-diaryl-2,3-dihydro-1*H*-1,3,2-diazaboroles is not straightforward. The direct combination of *N*,*N*′-diaryl-1,4-diazabutadienes with 2 equiv. boron trichloride and the reduction of the obtained borolium salts by sodium amalgam invariably afforded mixtures of singly and doubly chlorinated products. Thus, a detour to pure 2-chloro-1,3-diaryl-2,3-dihydro-1*H*-1,3,2-diazaboroles was developed. Reaction of the components at –78 °C gave a 1:2 adduct, the reduction of which furnished aminoboranes $Cl_2BN(Aryl)$-$CH{=}CHN(Aryl)BCl_2$. Cyclization of these molecules to 2-chloro-1,3,2-diazaboroles was effected by solid calcium hydride.

## Experimental Section

**General:** All experiments were performed under dry, oxygen-free dinitrogen by using standard Schlenk techniques. Solvents were dried with appropriate drying agents and freshly distilled under $N_2$ before use. The following compounds were prepared according to literature procedures: $2,6\text{-}Me_2C_6H_3N{=}CHCH{=}NC_6H_3Me_2$-2,6 (**3a**)[22], $2,4,6\text{-}Me_3C_6H_2N{=}CHCH{=}NC_6H_2Me_3$-2,4,6 (**3b**)[23] and $2,6\text{-}Me_2C_6H_3N{=}C(Me)C(Me){=}NC_6H_3Me_2$-2,6 (**13**).[24,25] $^1H$, $^{11}B$ and $^{13}C$ NMR spectra were recorded at ambient temperature in $C_6D_6$ except for **5** and **10**, which were investigated in $CD_2Cl_2$ with a Bruker AM Avance DRX 500 instrument ($^1H$: 500.13 MHz; $^{11}B$: 160.46 MHz; $^{13}C$: 125.75 MHz). The spectra were referenced versus $SiMe_4$ ($^1H$, $^{13}C$) and $BF_3{\cdot}OEt_2$ ($^{11}B$) standards. Boron trichloride, glyoxal, 2,6-dimethylaniline and 2,4,6-trimethylaniline were purchased commercially.

**Reaction of Glyoxal-bis(2,6-dimethylphenylimine) (3a) with Boron Trichloride:** A solution of **3a** (18.2 g, 69.0 mmol) in a mixture of toluene (300 mL) and hexane (100 mL) was added over 4.5 h to a chilled solution (–50 °C) of boron trichloride (16.4 g, 140.0 mmol) in hexane (250 mL). After stirring at –50 °C for another hour, it was warmed up to ambient temperature and stirring was continued for 15 h. A microcrystalline solid was filtered off, washed with hexane and dried in vacuo to give 11.0 g of a mixture of borolium salts **4a** and **4b**. The filtrate was stored for 14 d at +4 °C, and dark red crystals of **5** (4.2 g, 18%) separated. In the supernatant liquid, the presence of a 1,3,2-diazaborole was evidenced by $^{11}B$ NMR spectroscopy ($\delta$ = 21.6 ppm). The filtrate was concentrated to 30% of its volume and stored for 2 d at –4 °C, from which crystals of impure **6** were formed. Recrystallization from pentane yielded a few crystals of pure **6**.

In only one case did the reaction of **3a** and $BCl_3$ cleanly afford the burgundy red borolium salt **4a** in about 70% yield. A slurry of the borolium salts **4a** and **4b** (11.0 g) in a mixture of toluene (150 mL) and hexane (300 mL) was treated with sodium amalgam (300 g of a 1% alloy) and vigorously stirred for 20 h. The solution was decanted, filtered, and the solvents evaporated to dryness to give 4.8 g of an inseparable mixture of **1** and **6**. If the solution, after having been separated from mercury, was kept for 14 d at +4 °C, a few crystals of pure **1**[10] could be separated.

**1:** $^1H$ NMR: $\delta$ = 2.17 (s, 12 H, $CH_3$), 5.85 (s, 2 H, HC=N), 6.99 (m, 6 H, aryl-H) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 18.1 (s, $CH_3$), 117.7 (s, HC=N), 127.3 (s, *p*-aryl-C), 135.8 (s, *o*-aryl-C), 139.9 (s, *i*-aryl-C) ppm. $^{11}B\{^1H\}$NMR: $\delta$ = 21.1 (s) ppm. EI-MS: *m*/*z* (%) = 310 (100) [$M^+$].

**6:** $^1H$ NMR: $\delta$ = 2.11 (s, 6 H, $CH_3$), 2.16 (s, 6 H, $CH_3$), 5.75 (s, 1 H, HC=N), 6.98 (m, 6 H, aryl-H) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 18.02 (s, $CH_3$), 18.05 (s, $CH_3$), 113.7 (s, HC=N), 126.6 (s, ClC=N), 127.2 (s, *p*-aryl-C), 127.7 (s, *p*-aryl-C), 127.9 (s, *m*-aryl-C), 129.1 (s, *m*-aryl-C), 135.5 (s, *o*-aryl-C), 136.7 (s, *o*-aryl-C), 138.9 (s, *i*-aryl-C), 138.5 (s, *i*-aryl-C) ppm. $^{11}B\{^1H\}$ NMR: $\delta$ = 21.6 (s) ppm. EI-MS: *m*/*z* (%) = 344.1 (100) [$M^+$], 309.1 (79) [$M^+$ – Cl]. $C_{18}H_{19}BCl_2N_2$ (345.06): calcd. C 62.65, H 5.55, N 8.12; found C 62.67, H 5.44, N 8.15.

**5:** $^1H$ NMR: $\delta$ = 2.24 (s, 12 H, $CH_3$), 2.45 (s, 12 H, $CH_3$), 6.85 (s, 2 H, HC=N), 7.15 (m, 12 H, aryl-H) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 19.1 (s, $CH_3$), 19.7 (s, $CH_3$), 128.9 (s, *p*-aryl-C), 129.2 (s, *p*-aryl-C), 130.9 (s, *m*-aryl-C), 133.7 (s, *o*-aryl-C), 136.8 (s, *o*-aryl-C), 137.7 (s, *i*-aryl-C), 139.1 (s, *i*-aryl-C), 161.3 (s, HC=N) ppm. $^{11}B\{^1H\}$ NMR: $\delta$ = 8.6 (s) ppm. [$M^+$ – Cl], 618.2 (82) [$M^+$ – 2 Cl]. $C_{36}H_{38}B_2Cl_4N_4$ (690.12): calcd. C 62.65, H 5.55, N 8.12; found C 62.71, H 5.38, N 8.09. Because of the poor solubility, no reliable NMR spectra of the borolium salts **4a**,**b** were obtained.

**(*E*)-$Cl_2$B(*o*-Xyl)N–CH=CH–N(*o*-Xyl)B$Cl_2$ (8):** A solution of **3a** (5.29 g, 20.0 mmol) in toluene (100 mL) was added dropwise over 4–5 h to a chilled solution (–78 °C) of $BCl_3$ (4.67 g, 40 mmol) in pentane (75 mL). Immediately after the addition, the red-brown precipitate of the adduct **7a** was collected by filtration and dried at $10^{-3}$ bar. Reduction of the adduct was effected by treatment with sodium amalgam (100 g of a 1% alloy) in pentane (150 mL) over 24 h. The supernatant liquid was separated and concentrated to about 100 mL. Storage overnight at +4 °C afforded colorless crystals of **8** (5.13 g, 60%). $^1$H NMR: $\delta$ = 1.99 (s, 12 H, $CH_3$), 6.40 (s, 2 H, NCH=), 6.92 (m, 6 H, aryl-H) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 17.3 (s, $CH_3$), 120.5 (s, NCH=), 128.3 (s, *p*-aryl-C), 129.3 (s, *m*-aryl-C), 134.6 (s, *o*-aryl-C), 139.3 (s, *i*-aryl-C) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 32.6 (s) ppm. EI-MS: *m*/*z* (%) = 428.0 (100) [$M^+$], 395.2 (6) [$M^+$ – Cl], 310.1 (73) [$M^+$ – $BCl_3$]. $C_{18}H_{20}B_2Cl_4N_2$ (427.79): calcd. C 50.54, H 4.71, N 6.55; found C 50.26, H 4.82, N 6.43. Because of the low solubility of **7a**, no useful NMR spectra were obtained.

**Cyclization of 8 to 1:** A sample of **8** (0.50 g, 1.2 mmol) was dissolved in hexane (50 mL). $CaH_2$ (0.05 g) was added, and the slurry was stirred at ambient temperature for 48 h. It was filtered, and the filtrate concentrated to 10 mL and stored at –4 °C, after which crystalline **1** (0.175 g, 46%) separated.

**Reaction of Glyoxal-bis(2,4,6-trimethylphenylimine) (3b) with Boron Trichloride:** Analogously to the reaction of **3a** with $BCl_3$, a solution of **3b** (14.55 g, 50.0 mmol) in a mixture of toluene (200 mL) and hexane (50 mL) was combined with a chilled solution (–50 °C) of $BCl_3$ (11.8 g, 100.0 mmol) in hexane (250 mL) over a period of 4.5 h. Stirring was continued for 1 h at –50 °C and then for 15 h at 20 °C. The microcrystalline black precipitate was filtered off and dried (5.6 g of a mixture of salts **9a** and **9b**). Storage of the mother liquor for 2 weeks at +4 °C afforded dark green crystals of **10** (2.7 g, 14%). Sodium amalgam (200 g of a 1% alloy) was added to a slurry of the borolium salts (5.6 g) in a mixture of toluene (100 mL) and hexane (200 mL). The mixture was vigorously stirred for 20 h. The organic phase was decanted, and the solvents were removed in vacuo. An inseparable 4:1 mixture (2.4 g) of **2** and **11** as a white powder was obtained.

**10:** $^1$H NMR: $\delta$ = 2.17 (s, 18 H, $CH_3$), 2.29 (s, 6 H, $CH_3$), 2.36 (s, 12 H, $CH_3$), 6.85 (s, 2 H, =CHN), 6.93 (s, 4 H, aryl-H), 6.98 (s, 4 H, aryl-H) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 18.6 (s, $CH_3$), 20.5 (s, $CH_3$), 20.6 (s, $CH_3$), 129.4, 130.1, 131.2, 133.0, 134.2, 135.1, 136.0, 136.3, 138.6, 139.0 (10 s, aryl-C), 161.2 (s, =CHN) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 8.5 (s) ppm. EI-MS: *m*/*z* (%) = 744.2 (2) [$M^+$], 710.3 (100) [$M^+$ – Cl], 674.4 (66) [$M^+$ – 2 Cl]. $C_{40}H_{46}B_2Cl_4N_4$ (746.27): calcd. C 64.32, H 6.21, N 7.51; found C 64.30, H 6.11, N 7.52.

**2 and 11:** $^{11}$B{$^1$H} NMR: $\delta$ = 21.8 (s) ppm. This mixture was not analyzed further. Because of the poor solubility, no reliable NMR spectra of the borolium salts **9a**,**b** were obtained.

**(*E*)-$Cl_2$B(Mes)N–CH=CH–N(Mes)B$Cl_2$ (12):** By analogy to the preparation of **8**, compounds **3b** (5.84 g, 20.0 mmol) and $BCl_3$ (4.67 g, 40 mmol) were combined in a toluene/pentane mixture at –78 °C over 4–5 h. A violet precipitate was filtered off and dried at $10^{-3}$ mbar. Sodium amalgam reduction of this solid (150 g, 1% Na/Hg) was effected in pentane (150 mL) for 24 h. Concentration of the organic phase to about 100 mL and storage of the liquid overnight at +4 °C afforded colorless crystals of **12** (5.93 g, 65%). $^1$H NMR: $\delta$ = 2.03 (s, 12 H, *o*-$CH_3$), 2.04 (s, 6 H, *p*-$CH_3$), 6.50 [s, 2 H, NC(H)=C], 6.75 (s, 4 H, aryl-H) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 17.3 (s, *o*-$CH_3$), 20.9 (s, *p*-$CH_3$), 120.9 (s, CH=CH), 130.1 (s, *m*-aryl-C), 134.2 (s, *o*-aryl-C), 136.9 (s, *p*-aryl-C), 137.8 (s, *i*-aryl-C) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 32.6(s) ppm. EI-MS: *m*/*z* (%) = 338 (100) [$M^+$ – $BCl_3$]. $C_{20}H_{24}B_2Cl_4N_2$ (455.85): calcd. C 52.69, H 5.33, N 6.14; found C 52.63, H 5.35, N 6.13.

**Cyclization of 12 to 2:** A mixture of **12** (0.50 g, 1.1 mmol), $CaH_2$ (0.05 g) and hexane (50 mL) was stirred at 25 °C for 48 h and then filtered, and the filtrate was concentrated to 10 mL. Crystallization at –4 °C afforded pure **2** (0.20 g, 54%). $^1$H NMR: $\delta$ = 2.13 (s, 6 H, *p*-aryl-$CH_3$), 2.19 (s, 12 H, *o*-aryl-$CH_3$), 5.92 [s, 2 H, NC(H)=C], 6.79 (m, 4 H, aryl-H) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 18.0 (s, *o*-aryl-$CH_3$), 20.9 (s, *p*-aryl-$CH_3$), 117.8 (s, N–CH), 129.2 (s, *m*-aryl-C), 135.3 (s, *o*-aryl-C), 136.4 (s, *p*-aryl-C), 137.4 (s, *i*-aryl-C) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 21.9 (s) ppm. EI-MS: *m*/*z* (%) = 338.2 (100) [$M^+$]. $C_{20}H_{24}BClN_2$ (338.68): calcd. C 70.93, H 7.14, N 8.27; found C 70.68, H 7.20, N 8.16.

**Xyl–N$^a$C(CH$_3$)=C(CH$_3$)–N$^b$(Xyl)BCN(*N$^a$*–*B*) (16):** A solution of **13** (6.80 g, 23.0 mmol) in hexane (250 mL) was added dropwise over 4.5 h to a chilled solution (–50 °C) of $BCl_3$ (5.39 g, 46.0 mmol) in hexane (250 mL). Stirring was continued for 1 h at –50 °C and 15 h at ambient temperature. Green borolium salt **14** (7.6 g, 63%) was filtered off and dried at $10^{-1}$ bar. The slurry of the salt in hexane (350 mL) was reduced with sodium amalgam (150 g of a 1% alloy, 20 h). Decanting of the organic phase was followed by evaporation to dryness to afford crude **15** (4.5 g, 98.6%) as a light grey powder. A sample of solid AgCN (3.2 g, 24.0 mmol) was added to a solution of **15** in acetonitrile (350 mL), and the mixture was stirred for 20 h at 20 °C. It was filtered, and the filtrate was concentrated, after which **16** (3.10 g, 41.0%) was obtained. $^1$H NMR: $\delta$ = 1.44 [s, 6 H, =C($CH_3$)N], 2.03 (s, 12 H, aryl-$CH_3$), 6.99 (m, 6 H, aryl-H) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 9.8 [s, =C(*C*H$_3$)N], 17.9 (s, aryl-$CH_3$), 121.2 [s, *C*($CH_3$)=*C*($CH_3$)], 127.6 (s, *p*-aryl-C), 128.2 (s, BCN), 128.5 (s, *m*-aryl-C), 135.6 (s, *o*-aryl-C), 138.1 (s, *i*-aryl-C) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 13.5 (s) ppm. EI-MS: *m*/*z* (%) = 329.2 (100) [$M^+$], 314.2 (12) [$M^+$ – $CH_3$]. $C_{21}H_{24}BN_3$ (329.24): calcd. C 76.61, H 7.35, N 12.76; found C 76.59, H 7.42, N 12.65.

**15:** $^1$H NMR: $\delta$ = 1.57 [s, 6 H, =C($CH_3$)N], 2.15 (s, 12 H, aryl-$CH_3$), 7.02 (s, 6 H, aryl-H) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 10.2 [s, =C(*C*H$_3$)N], 18.2 (s, aryl-$CH_3$), 118.9 [s, =*C*($CH_3$)N], 127.2 (s, *p*-aryl-C), 128.3 (s, *m*-aryl-C), 136.6 (s, *o*-aryl-C), 138.6 (s, *i*-aryl-C) ppm. $^{11}$B{$^1$H} = 21.3 (s) ppm. EI-MS: *m*/*z* = 338.2 [$M^+$].

**X-ray Structural Analyses:** Crystal data were measured on a Nonius Kappa CCD-diffractometer and are given in Table 1. CCDC-616595 (**1**), -616596 (**4a**), -616597 (**5**) and -616598 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Surface and Structural Features of Co-Fe Oxide Nanoparticles Deposited on a Silica Substrate

Víctor A. de la Peña O'Shea,*[a,b] M. Consuelo Álvarez-Galván,[a] José M. Campos-Martin,[a] Nieves N. Menéndez,[c] Jesús D. Tornero,[c] and José L. G. Fierro*[a]

**Keywords:** Cobalt / Iron / Oxides / Metal–metal interactions / Materials science

Mono- and dimetallic cobalt- and iron oxide nanoparticles deposited on the surface of a silica substrate have been prepared by an impregnation technique. Both the bulk and surface structures of these particles have been characterised by different physical and chemical techniques. The results provided by X-ray diffraction, Mössbauer and X-ray photoelectron spectroscopy show the formation of separate $Co_3O_4$ and $Fe_2O_3$ nanoparticles in oxide samples, but in no case were cobalt–iron mixed oxides detected. Quantitative data also showed that the dispersion degree of cobalt- and iron oxides is rather low. It was also observed that pretreatment of the supported metal oxide nanoparticles under a hydrogen atmosphere does not promote the formation of a metal–support interaction, although a cobalt–iron interaction is observed in the dimetallic systems. The diffraction patterns and photoelectron and Mössbauer spectra of these dimetallic samples provide conclusive proof for the formation of both metallic $Co^0$ and iron-cobalt ($Co_7Fe_3$) alloy phases in the hydrogen-reduced samples. It was also found that the crystallite size of the alloyed $Co_7Fe_3$ phase increases with increasing iron content, i.e. 11 and 23 nm for samples containing 1 % and 5 % Fe added to the base Co sample, respectively, while that of $Co^0$ was constant (10 nm).

## Introduction

Nowadays, composite materials give rise to numerous studies with a view to improving their mechanical, thermal, optical and other properties, which hold promise for novel technological applications. Transition metal oxides are being widely used, and Fe-Co materials are of particular interest in catalytic reactions such as the Fischer–Tropsch synthesis (FTS),[1–6] methanol decomposition,[7–9] $NH_3$ synthesis,[10] carbon nanotube synthesis.[11–13] Furthermore, their interesting magnetic properties[14] suggest that they will have many applications in magneto-optical recording media, displays and devices such as wave-guides, insulators, modulators and switches.[15–17]

This fact has provoked several reports in which these mixtures are prepared by different synthetic methods such as sol–gel,[18,19] co-precipitation,[20] plasma coating,[21] sintering[22] and thermal decomposition.[23] Co- and/or Fe-supported systems prepared by wetness- or incipient wetness impregnation methods from nitrate precursors have also been reported.[6,14] Dimetallic catalysts prepared by the incipient wetness method show reactivities different from that of equivalent Fe- or Co single-metal catalysts, thus indicating that the intimate interaction between Fe and Co is important.[24,25] A synthesis of iron-cobalt nanoparticles dispersed in a silica matrix has also been reported, and the authors noted the formation of magnetic cobalt ferrite nanocomposites, $Co_3O_4$ and ferrihydrite or Co-Fe alloys, depending on the Fe and Co precursors.[19] Fe/Co catalyst mixtures have been prepared on several supports, including alumina,[24] carbon,[26,27] zirconia[28] and titania.[14,25,29,30]

A viable methodology that has been developed for controlling the property of a metal is that of alloying.[31–35] Three structures have been found for the metal in the iron-cobalt alloy, depending on the synthesis temperature and the subsequent thermal treatment: a bcc structure, an α-Mn-like structure and a fcc structure that appears after thermal treatment.[36,37] The bcc and fcc structures are classical structures for iron- and cobalt-based alloys. These alloys exhibit outstanding properties, particularly the cobalt-enriched composites. Indeed, these latter are active in the FTS and favour the formation of olefins without producing high amounts of $CO_2$[4,38] and alcohol production.[6]

A large body of work has been developed over the past decades on the performance of supported cobalt catalysts, especially with regard to the effect of promoters,[39–43] sup-

ports[44–46] and preparation[47–52] methods. Cobalt catalysts produce high yields of long-chain alkenes in the FTS. They are also characterised by a low ability to yield oxygenates. In addition, cobalt catalysts exhibit considerable stability in the metallic state.

Iron is the other active phase that is most often used in the hydrogenation reactions of carbon oxides. It is know that several forms of iron (iron, iron carbides, iron oxide) exist in iron-based catalysts when subjected to FTS, and there are many studies dealing with the role of iron phases in the FTS.[53–55] Iron catalysts used in CO hydrogenation are usually promoted to obtain a high stability and catalytic activity. These systems produce higher yields of oxygenated products and can perform the water gas-shift reaction. The incorporation of cobalt and iron phases onto a support substrate results in substantial changes in both activity and product distribution as, when used together, they do not simply give the additive properties (activity, selectivity) expected from knowledge of the properties of the individual metals. These dimetallic CoFe catalysts proved to be much more attractive in terms of alcohol formation and give rise to the production of ethanol and propanol, depending on the iron content.[6] Taking this into account, the possible interaction of cobalt and iron, in the form of cobalt ferrite or alloys, when used together as active phases for catalytic reactions such as FTS or as a possible magnetic composite should be studied by different characterisation techniques.

In light of the above, the present work was undertaken with the aim of analysing the effect of the incorporation of both cobalt and iron species supported on a silica matrix on the structural, textural and morphological characteristics relative to the properties shown by the monometallic systems. In particular, emphasis is placed on the formation of CoFe intermetallic compounds after catalyst activation. Some clues to the nature of the bulk and surface structures generated on the silica-supported cobalt-iron catalysts were obtained by XRD, X-ray photoelectron spectroscopy (XPS), Mössbauer spectroscopy and temperature-programmed reduction (TPR). The synergism between cobalt and iron, two FT active metals, will be explored in a subsequent work that will consider whether the above metals, when used together, give the additive properties (activity and selectivity) expected of the individual metals or not.

## Results and Discussion

### Chemical Composition and Textural Properties

The chemical composition of the oxide samples was determined by ICP-AES; results are compiled in Table 1. These results indicate that cobalt- and/or iron loadings are close to the nominal values. The BET specific areas and pore volumes of the fresh metal oxide loaded samples and the bare $SiO_2$ support, also summarised in Table 1, indicate that incorporation of cobalt and/or iron onto the $SiO_2$ substrate leads to a drop in both specific area and pore volume. A decrease in the BET area of around 20–30% is found upon incorporation of iron and cobalt, and a similar drop is found for the other two dimetallic (CoFe10/1-c and CoFe10/5-c) samples. The pore-size distributions of the metal-oxide-loaded samples and $SiO_2$ reference are displayed in Figure 1. The pore-size distributions of the samples do not change upon incorporation of cobalt- and/or iron oxides during the preparation step. The simultaneous drop in BET area and pore volume and the almost unchanged pore distribution of the metal-oxide-loaded sam-

ples point to a preferential location of big cobalt- and/or iron oxide particles in the interparticle voids between silica particles. Thus, the decrease in the pore volume as a result of pore locking does not change the pore-size distribution and is in accordance with the greater decrease in pore volume, which is higher than the weight fraction of deposited metal phases. However, deposition of very small metal oxide particles within the smallest pores of silica, and more specifically for the Co10-c sample, cannot be ruled out.

## Crystalline Structure

### *Calcined Samples*

The crystal structures of the supported cobalt and iron phases of oxide samples were determined by X-ray diffraction (Figure 2A). The monometallic Co10-c sample displays sharp and narrow diffraction lines that fit very well with that of $Co_3O_4$ spinel (JCPDS card 78-1970).[56] The obtained lattice parameter for this phase is $a$ = 8.088 Å, which is similar to that obtained for the cobalt oxide spinel phase. A broad band centred at about 22° 2$\theta$ belongs to the amorphous structure of silica. A detailed examination of the spectrum was done to ensure that no other crystalline Co-containing phases, such as $Co_2SiO_4$, had developed. As $Co_3O_4$ and $CoSiO_4$ species have similar interplanar distances, differentiation between both compounds is not easy unless they are very well crystallised. It should be emphasised that formation of a crystalline $Co_2SiO_4$ phase is only possible upon calcination of the impregnate at temperatures substantially higher than that (773 K) employed in this work.[57] Note that the formation of a cobalt-oxide–silica interacting layer cannot be ruled out from this XRD pattern.

The diffraction pattern of the calcined Fe10-c sample shows all the lines of crystalline $Fe_2O_3$[58,59] (JCPDS card 85-0599), together with the broad feature of silica at about 22° 2$\theta$ (see above). No peaks of any other iron-containing compound are observed.

The XRD patterns of calcined CoFe10/5-c and CoFe10/1-c samples are also included in Figure 2A. Both samples show diffraction lines that correspond to the $Fe_2O_3$ phase; these lines, as expected, are more intense in the sample with a higher Fe loading (CoFe10/5-c). Some of the $Fe_2O_3$ lines are overlapped by those of the $Co_3O_4$ spinel,[58,60] and the rather low intensity of the lines corresponding to $Fe_2O_3$ indicates the low crystallinity of the $Fe_2O_3$ particles. A weak interaction between $Fe_2O_3$ and $Co_3O_4$ phases is possible and could affect the crystallinity of the iron oxide particles without producing any modification in the structure of the oxides. These results indicate that the two oxides remain as separate phases at the scale of the XRD technique, which is above 3–4 nm. The lattice parameters found for the dimetallic systems CoFe10/5-c and CoFe10/1-c are $a$ = 8.090 and 8.089 Å, respectively, and are very similar to that of $Co_3O_4$, which indicates that a CoFe mixed composite has not been formed. The presence of a mixed cobalt–iron oxide phase would give a higher value of the lattice parameter.

The mean particle size of the supported cobalt- and/or iron oxides was calculated from the Scherrer equation by selecting the most intense diffraction line for each oxide — the crystal planes (311) for $Co_3O_4$ and (220) for $Fe_2O_3$ — and by assuming a spherical geometry for the oxide particles. The results compiled in Table 2 reveal that the larger size corresponds to $Co_3O_4$ particles in the monometallic catalyst (21 nm), while it is slightly reduced (17 nm) for the parent Fe10-c sample. It can also be seen that the size of the $Co_3O_4$ particles decreases upon adding iron, and this drop is even more marked for sample CoFe10/5-c. Finally,

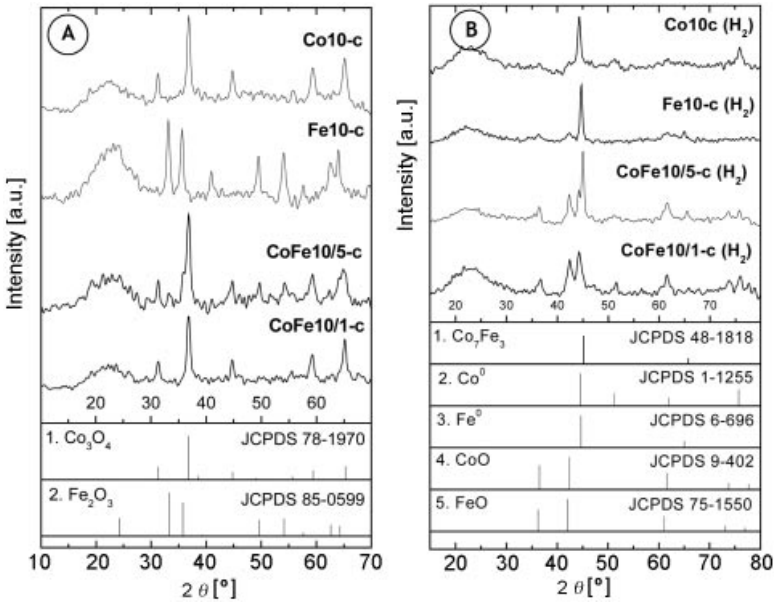

Figure 2. X-ray diffraction pattern of Co/Fe($SiO_2$): (A) calcined, (B) after $H_2$ reduction at 773 K.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

no attempt was made to calculate the size of the iron oxide particles in the CoFe10/1-c sample because of the extreme broadening of the $Fe_2O_3$ diffraction lines. This fact indicates that the particle size should be below 5 nm, which is the limit for applying the Scherrer equation.

Table 2. Crystallite size of supported nanoparticles for the calcined and reduced systems.

| Sample | XRD phases | $2\theta$ [°] | Crystal size [nm] |
|---|---|---|---|
| Co10-c | $Co_3O_4$ | 44.38 | 21 |
| Fe10-c | $Fe_2O_3$ | 44.75 | 18 |
| CoFe10/5-c | $Co_3O_4$ | 44.22 | 14 |
| | $Fe_2O_3$ | 45.03 | 14 |
| CoFe10/1-c | $Co_3O_4$ | 44.33 | 17 |
| | $Fe_2O_3$ | 42.49 | – |
| Co10-c ($H_2$) | $Co^0$ | 44.38 | 17 |
| Fe10-c ($H_2$) | $Fe^0$ | 44.75 | 22 |
| CoFe10/5-c ($H_2$) | $Co^0$ | 44.22 | 10 |
| | $Fe_3Co_7$ | 45.03 | 23 |
| CoFe10/1-c ($H_2$) | $Co^0$ | 44.33 | 10 |
| | $Fe_3Co_7$ | 42.49 | 11 |

### *Reduced Samples*

The pattern of the Co10-c sample reduced in $H_2$ at 773 K shows diffraction lines belonging to the (111), (220) and (311) planes of the fcc $Co^0$ crystallites (JCPDS card 1-1255). The lattice parameter found for cubic $Co^0$ is $a$ = 3.541 Å. No hexagonal structure is observed because the reduction temperature is too high to achieve this type of crystal structure. The diffraction lines of CoO are still observed, which indicates than the cobalt phase has not been reduced completely, although their intensity is lower than that of the oxide sample. A broad feature at about 22° $2\theta$ arising from the amorphous silica substrate is also found.

The reduction profile of the Fe10-c sample is shown in Figure 2B. Diffraction lines of metallic α-Fe (JCPDS card 6-696) and FeO (JCPDS card 75-1150) are observed, although the intensity of the peaks of the latter phase is weak. The absence of hematite ($Fe_2O_3$) or magnetite ($Fe_3O_4$) phases indicates that the reduction is in the final stage. The lattice parameter found for this species is $a$ = 2.863 Å.

The diffraction profiles of the dimetallic CoFe10/5-c and CoFe10/1-c samples are also displayed in Figure 2B. Besides the species found in the monometallic samples, new diffraction lines belonging to a FeCo phase are observed. These new peaks — the most intense one in both diffraction patterns occurrs at $2\theta \approx 45°$ — correspond to the (110) plane of the $Co_7Fe_3$ alloy (JCPDS card 48-1818) with a bcc crystal structure. This indicates that most of the cobalt and iron phases are involved in this alloy. Some additional peaks observed in both reduced samples can be indexed to metallic Co and cobalt oxide, although apparently no lines for a metallic iron phase are present. This fact could be due to an overlapping of these lines with those assigned to cobalt and to the $Co_7Fe_3$ alloy, since the ionic radii are very similar. The intensity of the main diffraction line characteristic of the alloy in the reduced CoFe10/1-c sample is lower than that of metallic $Co^0$, which contrasts with the proportion obtained for the reduced CoFe10/5-c sample and is in accordance with the relative proportions of Co and Fe in this sample. Both metallic species found in the dimetallic systems present very similar lattice parameters. The following lattice parameters are found for both systems: $a$ = 2.842 Å, which corresponds to $Co^0$, and $a$ = 3.541 Å, which corresponds to the CoFe alloy.

The mean particle size was determined by X-ray line broadening according to the Scherrer equation (Table 2). For this calculation, the (111) plane of metallic Co, the (110) plane for metallic Fe and the (110) plane for the Co-Fe alloy phases were selected. A comparison of the crystallite sizes for both reduced and calcined samples shows an increase in crystallite phase during the reduction because of sintering of the metal phase. In addition, the extent of sintering is higher in Fe10-c than in Co10-c. For the dimetallic catalysts, an increase in alloy particle size is observed in CoFe10/5-c. Finally, the crystallite size of $Co^0$ in both dimetallic samples is similar but lower than for Co10-c, which suggests that alloy formation inhibits the sintering of $Co^0$ particles.

## Morphology and Phase Distribution

### *Calcined Samples*

The morphology of the samples was studied by electron microscopy and line profile analysis (LPA). The LPA technique allows the determination of the catalyst surface topology as well as the active-phase disposition, the metallic particle size and the surface state of the support. Figures 3A and 3C show SEM micrographs of cobalt, while Figures 3B and 3D display micrographs of monometallic silica-supported samples taken at two different magnifications. No differences were found for these two types of samples. The surface is made up of particles of irregular shape and size ranging from 2 to 25 μm. The particles are delimited by well-defined faces formed by laminar exfoliation (A and B). Higher magnification images (C and D) indicate

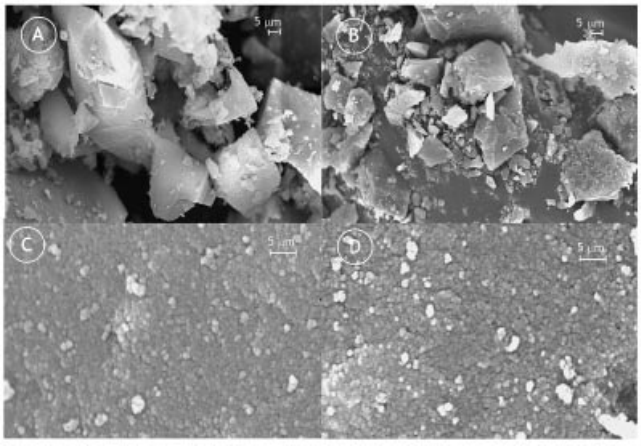

Figure 3. SEM images of calcined Co10-c (A and C) and Fe10-c (B and D).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the presence of uniformly developed spherical particles, about 0.2 μm in size, with compact packing. The SEM micrographs of the dimetallic samples do not show any differences with respect to those of the monometallic samples.

The LPA analysis indicates a very irregular profile for silicon, with holes and protuberances of different sizes, depths and heights. However, the profile belonging to cobalt is more homogeneous and is consistent with a well-dispersed phase. Similarly, LPA analysis of the monometallic Fe10-c sample shows a silicon profile resembling that of the cobalt counterpart (Co10-c), although the iron profile reflects a wider size distribution of the iron oxide particles. In addition, the LPA profiles for the dimetallic CoFe10/5-c and CoFe10/1-c samples indicate that both cobalt and iron profiles are more homogeneous than in the monometallic ones, thereby suggesting a better distribution of the $Co_3O_4$ and $Fe_2O_3$ phases across the surface.

The cobalt and iron mono- and dimetallic systems were also analysed by TEM with the aim of determining the form, shape and distribution of the particles on the silica support. The TEM images of Co10-c show spherical particles with non-uniform sizes within each $SiO_2$ particle. The same is true for other $SiO_2$ particles. The size of the cobalt oxide particles falls between 0.1 and 1 μm (Figure 4A). Riva et al.[61] have performed a TEM analysis of silica-supported cobalt oxides and found that metal oxide particles form spherical aggregates both inside and on the surface of silica particles, with non-uniform sizes and a mean diameter of between 0.3 and 0.5 μm. On the contrary, the micrograph of Fe10-c shows that iron oxide particles are not spherical as in the case of Co10-c (Figure 4B). In addition, non-uniform aggregates, with sizes ranging from 0.1 to 1 μm, are formed on each silica particle. Elemental analysis was also performed on individual particles, and the results indicated that they are mainly made up of iron and oxygen. XRD, XPS and Mössbauer spectroscopy revealed $Fe_2O_3$ to be the only phase present. Finally, the TEM images of CoFe10/5-c and CoFe10/1-c revealed that the particle size diminishes with respect to the monometallic samples, which is in good agreement with the Mössbauer data.

### *Reduced Samples*

Co10-c, Fe10-c and dimetallic samples reduced in hydrogen at 773 K were analysed by TEM with the aim of comparing the size, shape and distribution of the metal particles with respect to the fresh counterparts. The TEM images of Co10-c show that the size and shape of some particles remain unchanged upon reduction. In addition, a certain fraction of particles lose their spherical form and form other non-uniform aggregates. The reduced Fe10-c sample behaves similarly. The TEM image of reduced CoFe10/5-c displayed in Figure 4B reveals that the particles present an irregular shape and appear better dispersed on the silica substrate. Electron nanodiffraction taken on a large particle (Figure 4B) confirms the formation of an iron-cobalt alloy. This phase was also confirmed by XRD, XPS and Mössbauer spectroscopy.

## Bulk Structures of Iron-Containing Catalysts (Mössbauer Spectroscopy)

### *Oxide Samples*

The bulk structure of iron-containing catalysts was revealed by Mössbauer spectroscopy, and both the chemical state and relative abundance of iron and cobalt at the catalyst surface was determined by photoelectron spectroscopy. The iron-containing samples were characterised by Mössbauer spectroscopy with the aim of determining the local environment of the iron species and their concentration. Only the two calcined Fe10-c and CoFe10/5-c samples were analysed by this technique. The other dimetallic sample (CoFe10/1-c), which contains a much lower amount of iron (1 wt.-%), was not studied since its signal is too weak to get reliable information. Figure 5A displays the Mössbauer spectrum of sample Fe10-c. It includes two components: a paramagnetic doublet assigned to highly dispersed $Fe^{3+}$ and a magnetic sextet related to iron(III) oxide particles with a particle size larger than that responsible for the doublet. The hyperfine field corresponding to the sextet (50.4 T) is lower than that of bulk α-$Fe_2O_3$ (51.5 T).[62,63] This fact points to the presence of small α-$Fe_2O_3$ particles with a diameter of between 7 and 12 nm.[64] α-$Fe_2O_3$ species are the only species detected by Mössbauer analysis of the calcined Fe10-c sample, in agreement with the XRD pattern analysis presented above. The isomer shift ($\delta$), quadrupolar shift ($QS$), quadrupolar magnetic field ($H_{hf}$) and weight concentration of each species were measured and are reported in Table 3. It can be seen that α-$Fe_2O_3$ crystallites form the major phase (71%), while the proportion of $Fe^{3+}$ nanoparticles is substantially lower (29%). In addition, these results indicate that the dispersion degree of the major phase (α-$Fe_2O_3$) is rather low.

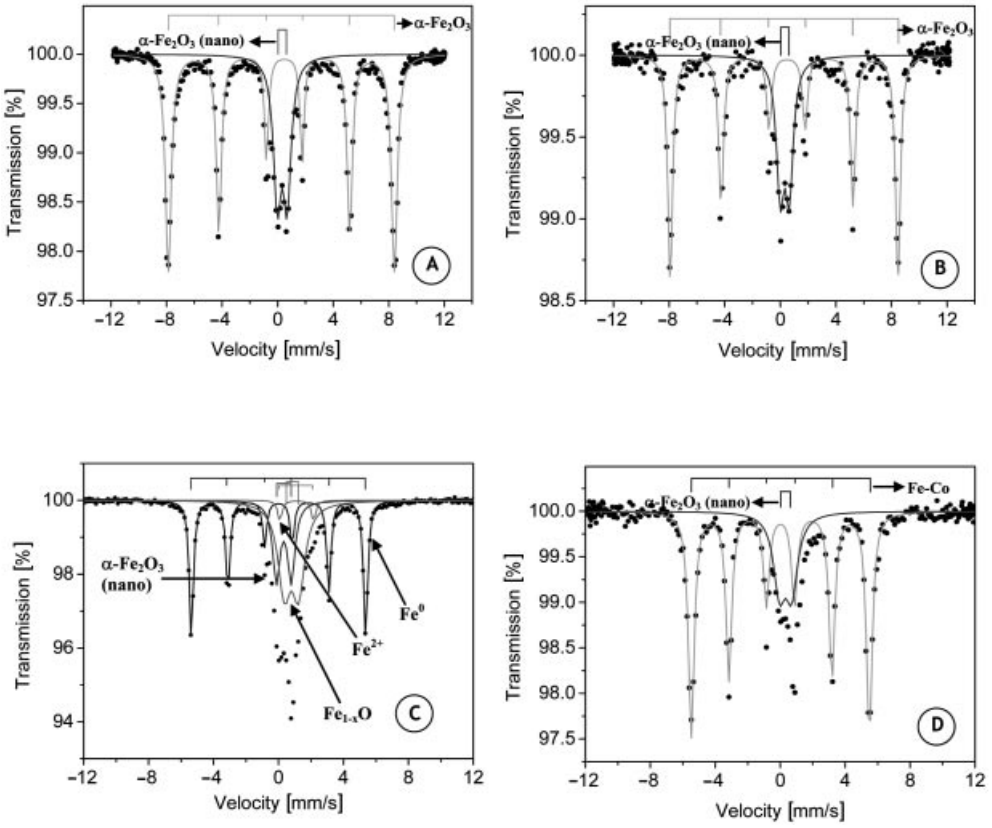

Figure 5. Mössbauer spectra of calcined (A) Fe10-c and (B) CoFe10/5-c; Mössbauer spectra of (C) Fe10-c and (D) CoFe10/5-c reduced in $H_2$ at 773 K.

Table 3. Mössbauer parameters for the systems Fe10-c and CoFe10/5-c calcined and reduced with $H_2$ at 773 K.

| Sample | Components | $\delta$ [mm s$^{-1}$] | $QS$ [mm s$^{-1}$] | $H_{hf}$ [T] | % |
|---|---|---|---|---|---|
| Fe10-c | α-$Fe_2O_3$ | 0.37 | 0.21 | 50.4 | 71 |
| | α-$Fe_2O_3$ (nano-size) | 0.33 | 0.71 | – | 29 |
| CoFe10/5-c | α-$Fe_2O_3$ | 0.37 | 0.21 | 50.7 | 69 |
| | α-$Fe_2O_3$ (nano-size) | 0.32 | 0.71 | – | 31 |
| Fe10-c ($H_2$) | α-Fe | 0.00 | 0.01 | 33.2 | 39 |
| | α-$Fe_2O_3$ (nano-size) | 0.33 | 0.92 | – | 20 |
| | $Fe_{1-x}O$ | 0.79 | 0.87 | – | 38 |
| | $Fe^{2+}$ ($Fe_2SiO_4$) | 1.12 | 2.07 | – | 3 |
| CoFe10/5-c ($H_2$) | Co-Fe | 0.01 | 0.01 | 33.9 | 76 |
| | α-$Fe_2O_3$ (nano-size) | 0.32 | 0.71 | – | 24 |

The Mössbauer spectrum of the calcined CoFe10/5-c sample (Figure 5B) is quite similar to that of the monometallic Fe10-c sample. The appearance of a sextet suggests the presence of ferromagnetic particles that correspond to iron(III) oxide, while the doublet ($\delta$ = 0.32 mm s$^{-1}$, $QS$ = 0.71 mm s$^{-1}$) is characteristic of highly dispersed $Fe^{3+}$ ions, thus revealing the existence of nanometre-sized particles (5–10 nm). From the data collected in Table 3, it can be inferred that the proportion of α-$Fe_2O_3$ and nano-sized $Fe^{III}$ oxide particles in the calcined CoFe10/5-c sample is similar to that found in monometallic Fe10-c.

### *Reduced Samples*

The local environment of the iron atoms in $H_2$-reduced iron-containing samples was revealed by Mössbauer spectroscopy. The Mössbauer spectrum of Fe10-c after reduction with hydrogen at 773 K for 2 h is displayed in Figure 5C. This spectrum can be fitted by four components: (i) a magnetic sextet that corresponds to α-Fe, (ii) a paramagnetic doublet due to small iron oxide particles (α-$Fe_2O_3$) similar to the one found in the calcined sample, and (iii) two paramagnetic doublets corresponding to $Fe^{2+}$ species. It should be emphasised that one of these latter doublets has a low isomer shift, which suggests that the $Fe^{2+}$ ions have a low coordination number (tetrahedral coordination), while the other doublet has an isomer shift characteristic of octahedral coordination.[65,66] No magnetic component belonging to $Fe_3O_4$ was found after hydrogen reduction. This observation agrees with previous studies by Yuen et al.[67] and Weilers et al.[68] Thus, for hydrogen-reduced silica-supported iron samples, Yuen et al.[54] observed the presence of two doublets corresponding to $Fe^{2+}$ species with different coordination environments: an inner doublet attributed to low-coordinate cations strongly interacting with the substrate and an external doublet assigned to high-coordinate $Fe^{2+}$ cations present in highly dispersed iron oxide particles. A somewhat different interpretation of these two doublets was proposed by Bjerne et al.[69] These authors suggested that both components correspond to superficial iron silicates with different symmetry (tetrahedral and octahedral environment). The Mössbauer parameters found in the $H_2$-reduced Fe10-c sample are collected in Table 3 and are similar to the ones reported by these authors. The assignment of the parameters was done on the basis of studies by Cagnoli et al.[70] and Hobson et al.,[66] in which the doublet with $\delta$ = 0.76 mm s$^{-1}$ and $\Delta QS$ = 0.98 mm s$^{-1}$ was assigned to small FeO crystallites supported on the $SiO_2$ substrate. For the second doublet, the large differences between the obtained quadrupole shift and the one reported in the literature for $Fe_{1-x}O$ species suggests the existence of $Fe^{2+}$ particles interacting strongly with the support. The quadrupole shift of this second doublet is similar to that reported in the literature for different $Fe_2SiO_4$ species.[71,72] Indeed, the reduction of these iron silicate species to iron metal [Equation (1)] is extremely difficult and hence requires high temperatures.

$$Fe_2SiO_4 + H_2 \rightarrow 2\,Fe + SiO_2 + H_2O \quad (1)$$

Figure 5D depicts the Mössbauer spectrum of the CoFe10/5-c sample reduced under hydrogen at 773 K for 2 h. The Mössbauer spectrum of this sample arises from the convolution of a magnetic sextet and a paramagnetic doublet. The values of the hyperfine field ($H$) obtained for the sextet points to the appearance of the CoFe alloy. Johnson et al.[73] have collected a sequence of values for different CoFe alloys between 34.6 and 35.6 T. The value of the hyperfine field (33.9 T) found for the $H_2$-reduced CoFe10/5-c sample is similar to that reported by other authors.[74,75] The paramagnetic doublet can be assigned to small $Fe_2O_3$ particles highly dispersed on the silica surface. In favour of this assignment is the work of Huang et al.,[76] who proposed that this paramagnetic doublet arises from iron(III) particles exchanged with the silica, which are, indeed, very difficult to reduce.

## Surface Structures

### *Oxide Samples*

The chemical state and relative abundance of cobalt- and/or iron oxides at the silica surface were determined by photoelectron spectroscopy. Figure 6A shows the energy region corresponding to the Co $2p_{3/2}$ core levels in calcined Co10-c. This peak can be resolved, after curve-fitting procedures, into two components belonging to the $Co^{2+}$ and $Co^{3+}$ ions present in the two samples. From this comparison, it is evident that the $Co_3O_4$ spinel phase is present in the sample Co10-c. The first peak at 780.0 eV can be ascribed to $Co^{3+}$ in an octahedral environment, while that at 782.5 eV can be assigned to $Co^{2+}$ ions in a tetrahedral environment.[57] Similarly, the XP spectrum of the Fe $2p_{3/2}$ core level of calcined Fe10-c is displayed in Figure 6B. This suggests that hematite ($Fe_2O_3$) is the only species present in the calcined Fe10-c sample.

Figures 6C and 6D show the energy regions corresponding to the Co $2p_{3/2}$ and Fe 2p3/2 core-levels of the calcined CoFe10/5-c sample. The similarity between the peak posi-

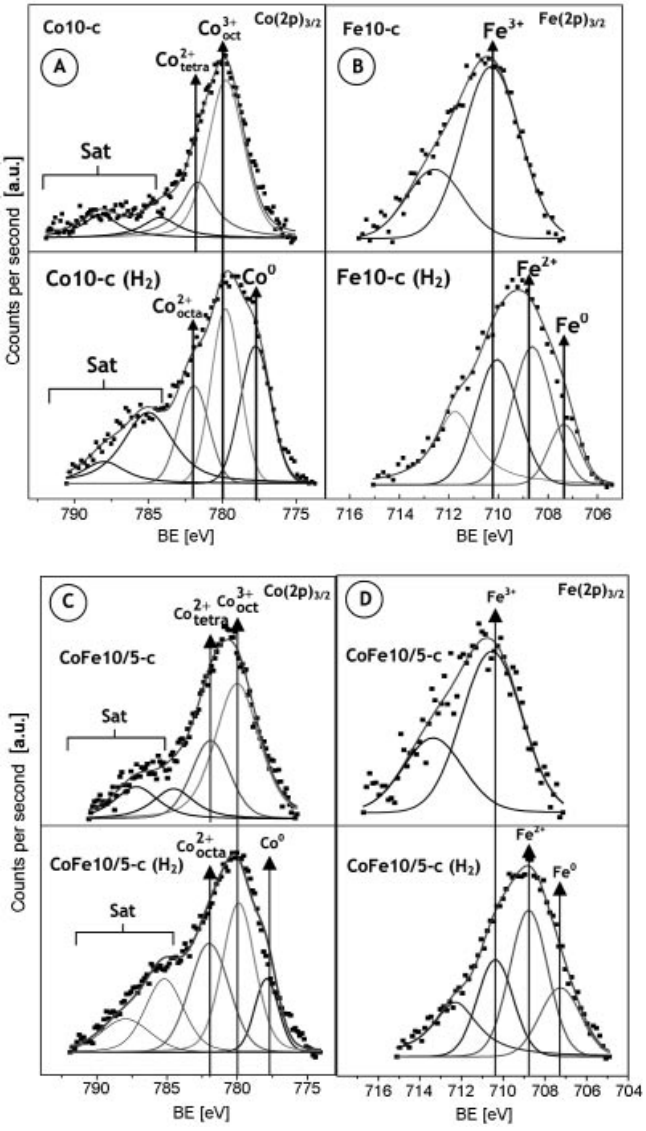

Figure 6. XPS profiles of (A) Co10-c, (B) Fe10-c and (C and D) CoFe10/5-c calcined and reduced with $H_2$ at 773 K.

tions and line profiles in the Co $2p_{3/2}$ and Fe $2p_{3/2}$ regions for the calcined CoFe10/5-c sample and those of the respective Co10-c and Fe10-c monometallic samples is an indication that the cobalt- and iron oxide phases are the same as in the monometallic systems, that is, $Co_3O_4$ and $Fe_2O_3$ are the only phases detected. As is the case with Co10-c, a shift in the binding energy of the Co $2p_{3/2}$ peak of CoFe10/5 is observed relative to bulk $Co_3O_4$ because of the presence of metal–substrate interactions. As the binding energies of the Co $2p_{3/2}$ and Fe $2p_{3/2}$ levels for CoFe10/5-c are practically the same as those found for the monometallic samples, it can be inferred that the Co–Fe interaction in the calcined sample, if any, is very weak. Finally, it should be emphasised that both CoFe10/5-c and CoFe10/1-c were analysed but the signal-to-noise ratio in the Fe $2p_{3/2}$ region for the latter sample was too low to be measured accurately and hence no further attention was paid to this level.

### *Reduced Samples*

The chemical state of the elements and their relative abundances on the catalyst surface after reduction were revealed by photoelectron spectroscopy. Figure 6A depicts the Co $2p_{3/2}$ peaks of Co10-c after reduction. The calcined Co10-c sample shows two components: one associated with $Co^{3+}$ in an octahedral position and the other assigned to $Co^{2+}$ in the tetrahedral position of the $Co_3O_4$ spinel.[77,78] Upon reduction with $H_2$, three components are observed: octahedral $Co^{3+}$ ions present in an unreduced $Co_3O_4$ phase,[57,77] octahedral $Co^{2+}$ ions in CoO[79–81] and $Co^0$.[81–83] Figure 6B shows the Fe $2p_{3/2}$ core-level spectrum of Fe10-c after reduction. The fresh sample exhibits one component assigned to $Fe^{3+}$ ($Fe_2O_3$), whereas the reduced sample displays three components, one due to $Fe^{3+}$ in a non-reduced $Fe_2O_3$[84] phase, the second due to $Fe^{2+}$ (FeO),[85,86] and the third due to metallic iron.[84,87]

Figure 6C shows the Co $2p_{3/2}$ and Fe $2p_{3/2}$ regions of CoFe10/5-c. Some differences are observed for the reduced samples. Although the profiles of the dimetallic and monometallic samples are similar, the binding energies of the $Co^0$ and $Fe^0$ species are different, which suggests that a Co-Fe alloy is formed in the dimetallic samples. It is apparent from the binding energies that the reduction of iron oxide is facilitated in the presence of cobalt,[88] while the reduction of cobalt oxide in close interaction with iron oxide is partly inhibited. This observation agrees with the results reported in the literature[89] and is consistent with the TPR data. Table 4 shows the metal/support surface ratios. An increase in the amount of surface metallic phase is observed for the dimetallic catalyst after reduction.

Table 4. Surface metal/Si ratios obtained by XPS.

| Sample | Oxide | | $H_2$ reduced (773 K) | |
|---|---|---|---|---|
| | Co/Si | Fe/Si | Co/Si | Fe/Si |
| Co10-c | 0.01 | – | 0.01 | – |
| Fe10-c | – | 0.01 | – | 0.01 |
| CoFe10/5-c | 0.01 | 0.01 | 0.02 | 0.02 |

## Redox Properties

An insight into the structure of the supported metal oxide phase can be derived from programmed reduction experiments. The reduction profile of Co10-c and a bulk $Co_3O_4$ reference are shown in Figure 7A. The reduction profile of Co10-c shows two peaks that are similar to those observed in the bulk $Co_3O_4$ oxide. These profiles point to a two-step reduction process: the first one involving low $H_2$ consumption starts at about 475 K and overlaps with the more intense second one whose maximum is placed at about 630 K. Thus, the reduction of $Co_3O_4$ can be described by the reduction of $Co^{3+}$ ions present in the spinel structure to $Co^{2+}$ [Equation (2)], with the subsequent structural change to CoO, followed by the reduction of CoO to metallic cobalt [Equation (3)].[90–92]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

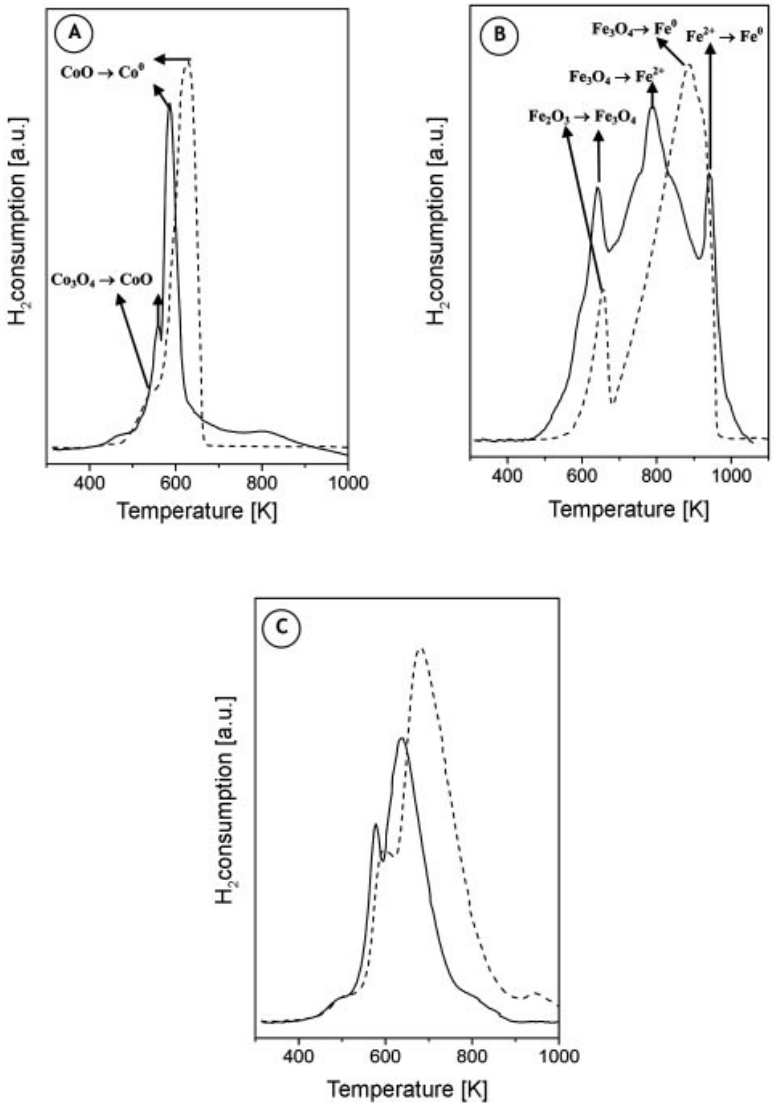

Figure 7. A comparison of the TPR profiles: (A) $Co_3O_4$ (dashed line) vs. Co10-c (solid line); (B) $Fe_2O_3$ (dashed line) vs. Fe10-c (solid line); (C) CoFe101/5-c (dashed line) and CoFe10/1-c (solid line).

$$Co_3O_4 + H_2 \rightarrow 3\,CoO + H_2O \quad (2)$$

$$3\,CoO + 3\,H_2 \rightarrow 3\,Co + 3H_2O \quad (3)$$

The reduction profile of Co10-c shows a very intense peak, which includes contributions at 558 and 587 K, associated to the two reduction steps found in bulk $Co_3O_4$, although shifted to lower temperatures as a consequence of lower crystallite sizes of supported phase. Deconvolution of the reduction peak into two components reveals that the ratio between the hydrogen consumption for the first peak and the second peak is 1:3, which is consistent with the two-step reduction depicted in Equations (2) and (3) and agrees with literature findings.[93–98] $H_2$ consumption still continues in the range 770–1000 K, and then tends to increase again at higher temperature. The broad $H_2$ consumption peak in the range 770–1000 K could reasonably be attributed to the reduction of cobalt species placed in the internal cavities of the support, where the reduction process should be limited by $H_2O$ diffusion through the pores.[90,93] This interpretation is supported by the XPS results, which point to a low surface concentration of $Co^{2+}$. The hydrogen consumption between 950 and 1000 K could be due to the reduction of a cobalt silicate phase, which could not be detected by other techniques. Therefore, the similarity of the reduction profiles for Co10-c and bulk $Co_3O_4$ up to 770 K can be taken as an indication that most of the cobalt oxide species in Co10-c interact weakly with the silica substrate.

Figure 7B shows the reduction profiles of calcined Fe10-c and bulk $Fe_2O_3$ as reference. The reduction of bulk hematite ($\alpha$-$Fe_2O_3$) occurs via magnetite ($Fe_3O_4$) and wustite (FeO) to zero-valent metallic iron.[99,100] FeO formation is not observed as wustite is a metastable phase below 843 K[99,100] and disproportionates into $Fe_3O_4$ and $Fe^0$. Two well-defined peaks are observed in the $Fe_2O_3$ reduction profile: the first is narrow, with a maximum at 654 K, and the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

second is wider and asymmetric, with a maximum at 886 K. Thus, the two-stage reduction of $Fe_2O_3$ can be described by Equations (4) and (5).

$$3\,Fe_2O_3 + H_2 \rightarrow 3\,Fe_3O_4 \quad (4)$$

$$Fe_3O_4 + 4\,H_2 \rightarrow 3\,Fe + 4H_2O \quad (5)$$

FeO formation is not detected under the reduction conditions employed in this work. However, the reduction profile of Fe10-c exhibits three peaks arising from the reduction of iron species through the consecutive steps $Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow Fe^0$ according to Equations (6), (7) and (8).[99]

$$3\,Fe_2O_3 + H_2 \rightarrow 3\,Fe_3O_4 \quad (6)$$

$$Fe_3O_4 + H_2 \rightarrow 2\,FeO \quad (7)$$

$$FeO + H_2 \rightarrow 2\,Fe + H_2O \quad (8)$$

The similarity in reduction temperatures for both bulk $Fe_2O_3$ and Fe10-c suggests a weak metal–support interaction in the first reduction stage, as for Co10-c. The only major difference between them is the absence of the reduction stage of magnetite to wustite.

The reduction profiles of mono- and dimetallic cobalt samples were also recorded and are compared in Figure 7C. Quantitative analysis of these reduction profiles is difficult because the iron oxide reduction steps are overshadowed by the cobalt oxide ones. Nevertheless an interaction between both oxides can be inferred from the changes in the reduction of both iron- and cobalt oxides. It appears that the cobalt oxide reduction is inhibited by iron oxide — this is more evident for CoFe10/5-c — while the iron oxide reduction is favoured by the presence of cobalt oxide. As can be seen by Mössbauer spectroscopy, a CoFe alloy is formed in this sample upon reduction. Thus, it is likely that this interaction between both metal oxides is responsible for alloy formation.

An important observation for all reduction profiles is that $H_2$ consumption continues above 1100 K. As mentioned above, the species that are reduced at high temperature could be metallic silicates, i.e. $Co_2SiO_4$ and $Fe_2SiO_4$, or ionic species placed inside the support cavities.

## Conclusions

A detailed analysis of the data derived from mono- and dimetallic silica-supported cobalt-iron systems has allowed us to draw the following conclusions: (i) the textural properties of the supported oxide phases are not influenced by the calcination of the oxide precursors; (ii) the results obtained by XRD, XPS and Mössbauer spectroscopy do not show the development of a cobalt–iron interaction in the calcined oxides — the dimetallic systems only show separate $Co_3O_4$ and $Fe_2O_3$ phases and in no case are cobalt–iron mixed oxides detected. The quantitative data also show that the dispersion degree of the cobalt- and iron oxides is very low; (iii) pre-treatment of the supported cobalt oxide nanoparticles under a hydrogen atmosphere does not promote the formation of a metal–support interaction; (iv) a cobalt–iron interaction is observed in dimetallic systems after reduction, and as a result of this interaction, the reducibility of cobalt oxide is partly inhibited while that of iron oxide follows an opposite trend. The XRD patterns and photoelectron and Mössbauer spectra are conclusive for the formation of an iron-cobalt alloy in the hydrogen-reduced samples.

## Experimental Section

**Catalyst Preparation:** Silica-supported cobalt- and/or iron oxides were prepared by the wetness impregnation method on a silica carrier (Grace Davison; specific surface area of 310 $m^2 g^{-1}$, pore volume of 1.22 $m^2 g^{-1}$) with aqueous solutions of cobalt nitrate [$Co(NO_3)_2 \cdot 6H_2O$, Merck reagent grade] and iron nitrate [$Fe(NO_3)_3 \cdot 9H_2O$, Merck reagent grade]. Monometallic cobalt and iron catalysts were prepared by the appropriate concentration of the above salts to achieve a final metal amount of 10 wt.-%. These samples are labelled Co10-c and Fe10-c, respectively. Two dimetallic FeCo-supported catalysts containing a fixed amount of cobalt (10 wt.-%) and different amounts of Fe (1 and 5 wt.-%, labelled CoFe10/1-c and CoFe10–5c, respectively) were prepared by simultaneous impregnation with a solution containing both cobalt and iron salts. All impregnates were dried at 393 K overnight and calcined at 773 K under flowing air for 2 h.

**Catalyst Characterisation:** The cobalt content of the catalyst was determined by the ICP technique using a Perkin–Elmer Optima 3300 DV apparatus. Specific areas were calculated using the BET method from the nitrogen adsorption isotherms, recorded at the temperature of liquid nitrogen using a Micromeritics apparatus (model ASAP-2000) with a value of 0.162 $nm^2$ for the cross-sectional area of the $N_2$ molecule adsorbed at 77 K. Samples were degassed at 423 K prior to adsorption measurements.

The powder XRD patterns of the precursor and calcined samples were recorded with a Seifert 3000 P diffractometer using nickel-filtered Cu-$K_{\alpha 1}$ ($\lambda$ = 0.15406 nm) radiation. A scanning step of 0.02° was taken between 5 and 80° Bragg angles.

Temperature-programmed reduction (TPR) experiments were carried out with a Micromeritics TPD/TPR 2900 apparatus equipped with a thermal conductivity detector. Reduction profiles were obtained by passing a 10% $H_2$/Ar flow at a rate of 50 mL (STP) per minute through the sample (weight about 30 mg). The temperature was increased from 300 to 1273 K at a rate of 10 K $min^{-1}$, and the amount of hydrogen consumed was determined as a function of temperature. Under these conditions, the line profile and peak position can be measured accurately. The effluent gas was passed through a cold trap placed before the TCD in order to remove water from the exit stream of the reactor.

SEM images were recorded with an ISI DS-130 microscope coupled to a solid-state Si/Li Kevex detector and a SUN SparcStation 5 for acquiring and processing energy-dispersive X-ray (EDX) spectra. Powder samples were converted into flat pellets and coated with a thin graphite layer to prevent the accumulation of static charge derived from the electron beam. Transmission electron micrographs were recorded with a Fei Tecnai G30 microscope. The acceleration voltage was set at 200 kV. The powdered sample was first suspended in acetone, after which a drop of the suspension was deposited on a copper grid covered with a fine carbon film evaporated under vacuum.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Surface analysis was carried out with a VG Escalab 200R electron spectrometer equipped with an Mg-$K_\alpha$ X-ray source and a hemispherical electron analyser. The powder samples were pressed in 8-mm-diameter copper troughs and then mounted on a sample rod placed in a pre-treatment chamber and heated under vacuum at 373 K for 1 h prior to being moved into the analysis chamber. The base pressure in the analysis chamber was maintained below $4 \times 10^{-9}$ mbar during data acquisition. The area under analysis was about 2.4 $mm^2$, and the pass energy of the analyser was set at 50 eV, for which the resolution as measured by the full width at half maximum (FWHM) of the Au $4f_{7/2}$ core level was 1.7 eV. The binding energies were referenced to the C 1s peak at 284.9 eV due to adventitious carbon. Data processing was performed with the *XPS peak* program, the spectra were decomposed with the least-squares fitting routine provided with the software with Gaussian/Lorentzian (90/10) product function and after subtracting a Shirley background. Atomic fractions were calculated using peak areas normalised on the basis of sensitivity factors.[101]

Mössbauer spectra were recorded in a sinusoidal mode using a transmission spectrometer with a $^{57}$Co/Rh source. Spectral analyses were performed by non-linear fit using the NORMOS[102] program, and energy calibrations were accomplished with an α-Fe (6 μm) foil.

# Computational Determination of Iron Hyperfine Interactions in Organometallics Using Small Transverse External Magnetic Fields

**Israel Nowik*[a] and Rolfe H. Herber[a]**

**Keywords:** Mössbauer spectroscopy / Metallocenes / Quadrupole splitting / Magnetic hyperfine field / External magnetic field perturbation / Iron

A number of organometallic and related iron-containing compounds have been examined by transmission $^{57}$Fe Mössbauer spectroscopy in modest (0–2.4 T) magnetic fields in order to determine the sign of the quadrupole-splitting hyperfine parameter ($QS$) as well as the internal magnetic field in derived paramagnetic solids. A computer program has been developed to extract these parameters from the spectroscopic data. The sign of the $QS$ is found to be positive in the neutral ferrocenoid solids and negative in the derived cationic complexes. The internal hyperfine field makes a positive contribution in the cationic ferrocenoids and a negative contribution in $FeF_2$ and $Fe(phen)_2(SCN)_2$.

## Introduction

Diamagnetic and paramagnetic iron compounds may display $^{57}$Fe Mössbauer spectra composed of a pure quadrupole doublet. The quadrupole splitting ($QS$) of this doublet is given by:

$$QS = \tfrac{1}{2}\, e^2qQ(1 + \tfrac{1}{3}\eta^2)^{1/2}$$

where $e^2qQ$ is the quadrupole interaction and $\eta$ is the value of the electric field gradient anisotropy [$\eta = (\mathbf{V}_{xx} - \mathbf{V}_{yy})/\mathbf{V}_{zz}$]. It is well known that magnetic fields acting on the Mössbauer absorber nuclei will change the spectra in such a way that the sign of the quadrupole interaction can be obtained. However, perturbations that will yield definite and readily observable results require magnetic fields above 2 T. Such measurements have been carried out in the past and the underlying theory has been worked out to various degrees of approximation.[1]

Here we present a theoretical treatment for the case of an applied magnetic field perpendicular to the γ-ray. The theory contains the diagonalization of the full Hamiltonian for any orientation of the local electric field gradient (EFG) main axis to the magnetic field. For powder samples an averaging over all possible random orientations is performed, taking into account the anisotropy of the Mössbauer recoil-free fraction. A computer program has been developed that uses this theory to least-square fit the simulated spectra to the experimental spectra, yielding the sign of the quadrupole interaction even for the low applied magnetic fields available in most laboratories. In addition to the value of the quadrupole interaction and $\eta$, the spectra yield the effective magnetic field acting on the nucleus. In paramagnetic compounds this is not necessarily equal to the applied magnetic field, and yields the value and sign of the induced magnetic internal hyperfine field. For axial cases ($\eta = 0$) the analysis also yields the mean square vibrational anisotropy parameter $N = k^2(\langle x^2_{par}\rangle - \langle x^2_{per}\rangle)$.[2] If the samples studied contain texture effects, the theory will take this into account and determine the fraction aligned in the plane of the absorber. The method is applied to the study of powders of diamagnetic and paramagnetic iron-containing organometallics.

### Theory

We have chosen the laboratory coordinate system ($x$, $y$, $z$) in which the γ-ray is along the "$x$" axis, and the magnetic field is in the plane of the absorber, along the "$z$" axis. The orientation of the randomly distributed axial EFG is along ($\sin\theta\cos\phi$, $\sin\theta\sin\phi$, $\cos\theta$), defined as the local coordinate system $z'$ axis (see Figure 1). For calculating the Mössbauer nuclear level energies and transition probabilities the quantization axis is chosen to be that of the magnetic field, the laboratory "$z$" axis. This simplifies the considerations of the absorption line intensities' dependence on the direction of the γ-ray.

Thus the Hamiltonian $\mathbf{H}$ for the $^{57}$Fe excited level ($I = 3/2$) has the general, non-axial quadrupole form (1):

$$\mathbf{H} = g_{exc}H_{eff}I_z + (e^2qQ/12)[3I_{z'}^2 - I(I+1) + \eta(I_{x'}^2 - I_{y'}^2)] \quad (1)$$

Here the magnetic term is defined in the laboratory system, whereas the quadrupole interaction is in the local coordinate system. In the case of axial symmetry, when $\eta = 0$, the calculation of the matrix elements of the quadrupole

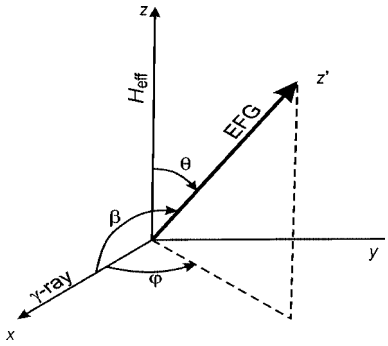

Figure 1. The experimental layout in the laboratory coordinate system. The γ-ray is in the $z = 0$ plane; its direction is chosen to be the $x$ axis so that the absorber is in the $x = 0$ plane.

interaction term in the laboratory coordinate system becomes very simple. The formulas for the matrix elements have all been calculated.[3] The Hamiltonian matrix is real symmetric, and its eigenvalues and eigenvectors do not depend on the angle $\phi$, as is also obvious from the symmetry of the experimental situation shown in Figure 1. Thus the diagonalization of this Hamiltonian and that of the ground state (in the particular choice of quantization axis chosen here, no diagonalization is required for the ground state, $I = ½$) yields the energies $E_{exc}(i)$ ($i = 1, 4$) and $E_{gr}(j)$ ($j = 1, 2$) and the corresponding wave functions $|\psi_{exc},i\rangle$ and $|\psi_{gr},j\rangle$, where all depend on $H_{eff}$, $eqQ$, and $\theta$. These wave functions are mixtures of pure $|I,m\rangle$ nuclear wave functions. The nuclear transition probabilities for the nuclear magnetic dipole transition operator $T_q$, where $q = \Delta m = -1, 0, 1$ corresponding to the $\Delta m = 0$ and $\Delta m = \pm 1$ pure nuclear transitions, is given by: $|\langle\psi_{exc},i|T_q|\psi_{gr},j\rangle|^2$. The matrix elements $\langle m_{ex}|T_q|m_{gr}\rangle$ are proportional to the Clebsch–Gordan coefficients yielding the 3:2:1 line intensities for a normal magnetic powder Mössbauer spectrum. As our quantization $z$ axis is at an angle $\pi/2$ relative to the γ-ray, the γ-ray is along an arbitrary chosen "$x$" axis, and the electric field gradient $z'$ axis is at angle $\beta$ [$\cos(\beta) = \sin(\theta)\cos(\phi)$] relative to the γ-ray, the total $T_{ij}$ intensity, considering angular dependence of the various nuclear transitions, will be given by the equations in ref.[4] or ref.[5], which leads to (2):

$$T_{ij}(\theta, \phi) = \Sigma_{q=-1,0,1} |\langle\psi_{exc}, i|T_q|\psi_{gr}, j\rangle|^2 P_q \exp(-N\cos^2\beta) \quad (2)$$

Here the constants $P_q$ are: $P_0 = 1$ and $P_{\pm 1} = ½$. The exponent $\exp(-N\cos^2\beta)$ reflects the anisotropy in the recoil-free fraction defined earlier.[2] The Mössbauer spectrum for a perfect powder sample is now given by the double integral over all orientations of the EFG, namely (3):

$$S_P(\omega) = (1/4\pi)\int_{0\to\pi} \sin\theta\, d\theta\, \Sigma_{i,j} L[\omega, \Gamma, E_{ij}(\theta)] \int_{0\to 2\pi} T_{ij}(\theta, \phi)\, d\phi \quad (3)$$

where $L(\omega, \Gamma, E)$ is the Lorentzian Mössbauer absorption line shape, and $\omega$ and $\Gamma$ are the γ-ray energy and the natural absorption line width, respectively. In the case of non-axial symmetry ($\eta \neq 0$), the full Hamiltonian of Equation (1) has to be diagonalized and then the energies and wave functions depend on all three Euler angles of the transformation between the local and the laboratory coordinate system, which makes the situation more complicated and will be discussed below.

### The Texture Effect

If intentionally (or unintentionally) the crystallites in the absorber holder are aligned in the plane, namely their local $z'$ axis (Figure 1) is randomly distributed in the $x = 0$ absorber plane, the calculation of the expected Mössbauer spectrum is simplified. In the present case the angle $\phi$ is fixed to the value ½π, which means that in Equation (2) we have to replace $\phi$ by ½π ($\cos\phi = 0$), and the formula for the final spectrum (3) takes the form (4):

$$S_{Tex}(\omega) = (1/\pi)\int_{0\to\pi} \Sigma_{i,j} L[\omega, \Gamma, E_{ij}(\theta)]\, T_{ij}(\theta)\, d\theta \quad (4)$$

If the texture effect is partial, then the observed experimental spectrum is a superposition of Equations (3) and (4), namely (5):

$$S_{Total}(\omega) = a\, S_P(\omega) + (1 - a)\, S_{Tex}(\omega) \quad (5)$$

Thus if a texture effect is present it adds only one extra parameter ($a$) to the least-square fitting procedure.

### Non-Axial Quadrupole Interactions

In the general case where $\eta \neq 0$ in Equation (1) one has to transform the electric field gradient second-order tensor expressed as a diagonal matrix ($\mathbf{V}_{x'x'}$, $\mathbf{V}_{y'y'}$, $\mathbf{V}_{z'z'}$) in the local ($x'$, $y'$, $z'$) coordinate system into the ($x$, $y$, $z$) laboratory coordinate system by three Eulerian angles ($\phi$, $\theta$, $\psi$),[6] and one obtains a nondiagonal, though symmetric, matrix ($\mathbf{V}_{ij}$). Then it is necessary to calculate all the matrix elements of the Hamiltonian in Equation (1), which is now a complex, Hermitian matrix. The quadrupole Hamiltonian has now its more general form (6):

$$\mathbf{H}_Q = ½\, \Sigma_{ij}\, \mathbf{V}_{ij}\, Q_{ij} \quad (6)$$

where the nuclear operators are:[7] $Q_{ij} = ½\,(I_i\, I_j + I_j\, I_i) - {}^1/_3\, \delta_{ij}\, I(I + 1)$

If we identify $\mathbf{V}'_{z'z'}$ with $e^2qQ/12$ and $\mathbf{V}$ as the rotational second-order tensor matrix transform of $\mathbf{V}'$, then the matrix elements of $\mathbf{H}_Q$ are as shown in (7):

$$\begin{aligned}
&\langle m\,|\mathbf{H}_Q|\,m\rangle = \mathrm{V}_{zz}\,(3m^2 - I(I+1)) \\
&\langle m+1\,|\mathbf{H}_Q|\,m\rangle = (\mathbf{V}_{xz} - i\mathbf{V}_{yz})\,(2m+1)\,(I(I+1) - m(m+1))^{½} \\
&\langle m+2\,|\mathbf{H}_Q|\,m\rangle = ½\,(\mathbf{V}_{xx} - \mathbf{V}_{yy} - 2i\mathrm{V}_{xy})\,((I(I+1) - \\
&\qquad m(m+1))\,((I(I+1) - (m+1)(m+2)))^{½}
\end{aligned} \quad (7)$$

After diagonalization of the total Hamiltonian it is possible to calculate the associated spectra and average out over all possible orientations of the electric field gradient ($z'$ axis in Figure 1). Here an additional averaging over the angle $\psi$ has to be performed. The angle between the quantization axis and γ-ray is still $\pi/2$. The anisotropy in the recoil-free fraction is now non-axial and the parameter $N$ is not enough to represent the real situation. However we include this term in the program, as it is better than to ignore

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

it completely. The angle $\beta$ between the local $z'$ axis and the $\gamma$-ray is still $\cos(\beta) = \sin(\theta)\cos(\phi)$, as is obvious from Figure 1. This procedure was converted to two computer programs. One program is very simple, used only for $\eta = 0$, and works very fast (five least-square fit iterations with eight free parameters and 400 points on the unit sphere), within less than a second on an HP AlphaServer DS20E computer. The other program, used for $\eta \neq 0$, also works well, though it consumes much more (several minutes) computing time than the former. In order to test the programs, simulated spectra for various $\eta$ values (keeping a positive quadrupole interaction QS = 2.5 mm s$^{-1}$ and $H_{ext}$ = 2.4 T) have been calculated and are shown in Figure 2. One observes that for $\eta = 1$ the spectrum is symmetric and for $\eta = 3$ the spectrum is identical to the $\eta = 0$ case but with a negative quadrupole interaction. These observations are in agreement with those expected theoretically, and thus show that the program yields correct results.

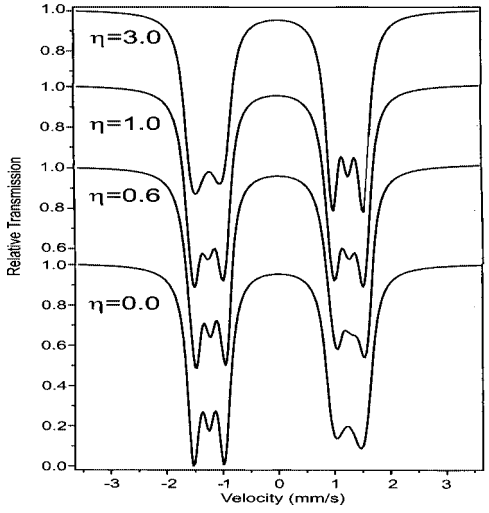

Figure 2. Mössbauer spectra simulations, for various $\eta$ values, employing the program described in the text.

### Paramagnetic Compounds

In the case of paramagnetic compounds, the effective magnetic field ($H_{eff}$) acting on the nucleus is not equal to the external magnetic field ($H_{ext}$). $H_{ext}$ can be accurately measured by a diamagnetic compound situated with identical geometry in the field. The unpaired electrons, which produce a fluctuating magnetic field averaged to zero in the absence of an external field, contribute in the presence of an external field at a temperature $T$ the additional term $H_p$ given by (8):

$$H_p = H_{hf}\, B_S(g\mu_B S H_{ext}/kT) \quad (8)$$

where $g\mu_B S$ is the total magnetic moment of the ground state of the magnetic ion ($\mu_B$ is the Bohr magneton and $g$ is the gyromagnetic factor), $B_S$ is the spin S Brillouin function, and $H_{hf}$ is the hyperfine magnetic field produced by this electronic state. For $\mu_B H_{ext}/kT << 1$, one can write the simple approximate relation (9):

$$H_p = [g\mu_B(S + 1)H_{hf}/3kT]H_{ext} \quad (9)$$

Namely, the effective field acting on the nucleus is given now by (10):

$$H_{eff} = \{1 + [g\mu_B(S + 1)H_{hf}/3kT]\}H_{ext} \quad (10)$$

In the cases where the magnetic ion has a ground-state Kramers doublet with an effective spin $S = ½$, common in the magnetic organometallics, formula (10) obtains the form (11):

$$H_{eff} = [1 + (g_{eff}\mu_B S H_{hfa}/kT)]H_{ext} \quad (11)$$

where in powders $g_{eff} = {}^1/_3\, g_{\parallel} + {}^2/_3\, g_{\perp}$ and $H_{hfa}$ is a similar average of $H_{hf}$. Thus a measurement of a paramagnetic compound in an external magnetic field may yield the average value of $H_{hf}$ with its sign (12):

$$H_{hfa} = (kT/g_{eff}\mu_B S H_{ext})(H_{eff} - H_{ext}) \quad (12)$$

In strongly covalent systems, such as diamagnetic organometallics, $H_{hf}$ can be very large and positive. Indeed we observe, for example, in paramagnetic octamethylferrocenium tetrafluoroborate ($OMFc^+BF_4^-$) and decamethylferrocenium hexafluorophosphate ($DMFc^+PF_6^-$), that $H_{eff}$ is much larger than $H_{ext}$, as will be discussed below.

## Results and Discussion

As a test case for the procedure, a sample of $FeF_2$, containing an impurity (probably $FeF_3{\cdot}3H_2O \approx 10\%$), whose hyperfine interaction parameters are known,[8,9] has been studied. The spectra in zero external magnetic field and in an external field of 2.13 T are displayed in Figure 3. Using the known starting parameters (isomer shift, quadrupole interaction, and saturation magnetic hyperfine field) of both

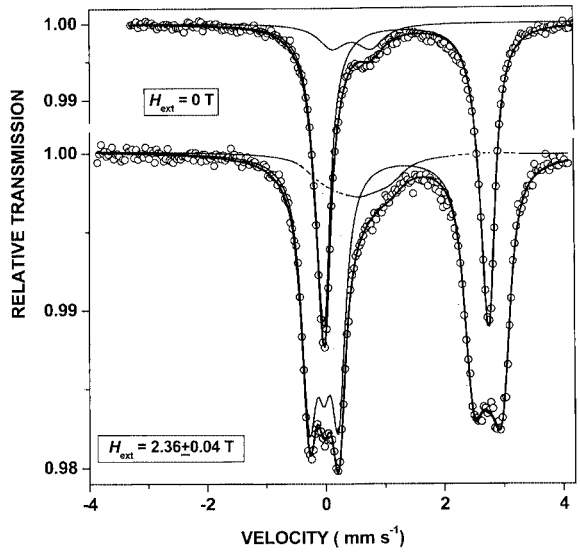

Figure 3. Mössbauer spectra of (predominantly) $FeF_2$ in $H_{ext}$ = 0 (upper trace) and $H_{ext}$ = 2.36 T (lower trace). The solid curve represents the program least-square fit, yielding the parameters given in Table 1.

[a] Contains 10% impurity, probably $FeF_3\cdot 3H_2O$.

$FeF_2$ and $FeF_3\cdot 3H_2O$ (averaged over the two phases[9]), we obtain, from the computer least-square fit, the solid curve shown in the lower trace of Figure 3. The fit to the experimental spectrum is quite satisfactory, and the numerical data, including the hyperfine parameters $\eta$, $H_{eff}$, and $H_{hf}$, are summarized in Table 1. It is noted that $\eta$ of $FeF_2$ is determined to relatively good precision. As both compounds have significant ionic character in the iron–ligand bonding, the magnetic hyperfine fields are negative, and the effective field acting on the metal atom nuclei is smaller than the external field.

Turning next to the application of this methodology to the study of primarily covalent iron organometallics, a typical application of transverse magnetic field measurements to decamethylferrocene is summarized graphically in Figure 4. The upper ME spectrum is in zero applied field and yields the parameters $IS = 0.420 \pm 0.003\ mm\,s^{-1}$ and $QS = +2.478 \pm 0.004\ mm\,s^{-1}$ in good agreement with the previously published values.[10] The line width ($\Gamma$, FWHM) = $0.339 \pm 0.002\ mm\,s^{-1}$ is slightly broadened from its theoretical value because of the effect of the long (38 cm) source drive rod. The lower spectrum is that recorded with the same sample in a transverse applied field. The hyperfine parameters obtained from the least-square fit to the above outlined theoretical calculations are: $IS = 0.412 \pm 0.009\ mm\,s^{-1}$, $\Gamma = 0.302 \pm 0.002\ mm\,s^{-1}$, $QS = +2.473 \pm 0.009\ mm\,s^{-1}$, $H_{ext} = 2.36 \pm 0.04$ T, $\eta \leq 0.02$, and $N \leq 0.05$. It is immediately obvious from the lower trace that the peak at negative velocities consists of three lines, while the peak at positive velocities is composed of an asymmetric doublet. Comparing these results with those of Collins and Travis[1] (for ferrocene), it is clear (even visually) that the QS is positive in DMFc, as it is in ferrocene itself.

In order to test the sensitivity of the computer program in determining the sign of the quadrupole interaction, we repeated the measurement in external fields of 0.81, 1.34, 1.86, and 2.34 T. In the case of the lowest field, one notices in Figure 5 that the sign cannot be determined visually, or by measuring the line width of the two components. However the computer program least-square fit yields quite a large difference in $\chi^2$ values between assumed positive and negative quadrupole interactions, with QS consistently positive. An obvious extension of these results is to the paramagnetic decamethyl ferricinium tetrafluoroborate ($DMFc^+BF_4^-$). In zero field, the resonance spectrum consists of a broadened absorption line, which can be fitted to a spin relaxation model calculation and corresponds to IS = $0.401 \pm 0.006\ mm\,s^{-1}$ and QS = $-0.272 \pm 0.006\ mm\,s^{-1}$. This spectrum is shown in the upper trace of Figure 6. When

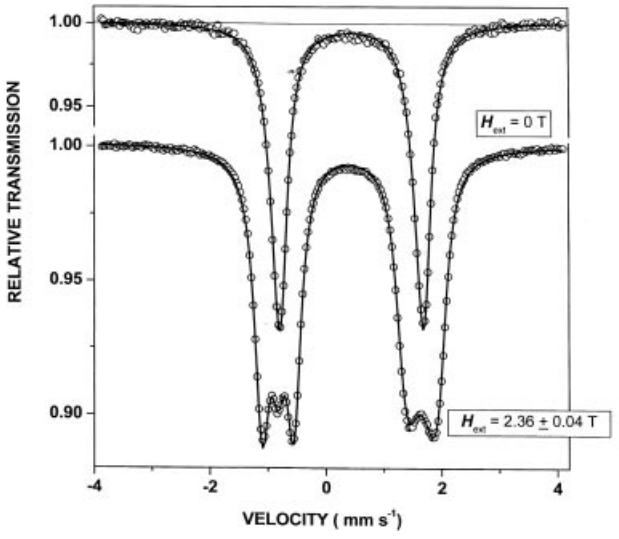

Figure 4. Mössbauer spectra of decamethylferrocene, in $H_{ext} = 0$ (upper trace) and $H_{ext} = 2.36$ T (lower trace). The solid curve represents the program least-square fit, yielding the parameters given in Table 1.

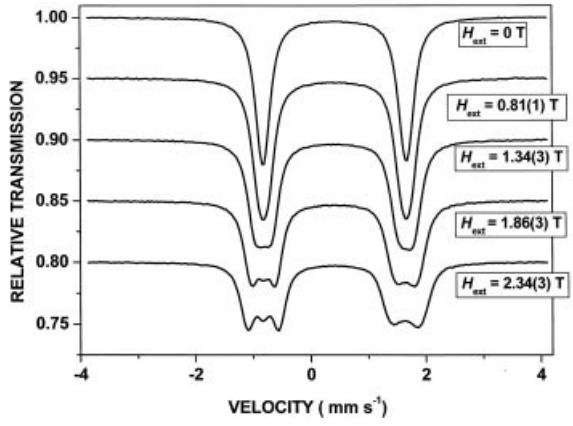

Figure 5. Mössbauer spectra of decamethylferrocene in a series of external magnetic field values. The ordinate offsets were arbitrarily fixed at 5% but all spectra were accumulated under identical conditions.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

this sample is examined in a transverse magnetic field the resonance line is broadened to give an asymmetric doublet, as shown in the lower trace of Figure 6. The internal field is $H_{eff} = 2.58 \pm 0.03$ T. The value of the QS was frozen to its zero-field value of –0.272 mm s$^{-1}$. The negative sign of the quadrupole interaction is derived not only from the zero-field spectrum (Figure 6), but also from the fact that the $\chi^2$ value of the computer fit is consistently smaller for a negative value of this parameter than for a positive value also in the in-field spectrum. It should be noted that $H_{eff}$ for the cationic complex, under identical conditions, is larger than that observed for the neutral complex by ≈0.19 T, which, according to Equation (12), leads to a positive value for the internal magnetic hyperfine field, $H_{hf} \approx +38$ T.

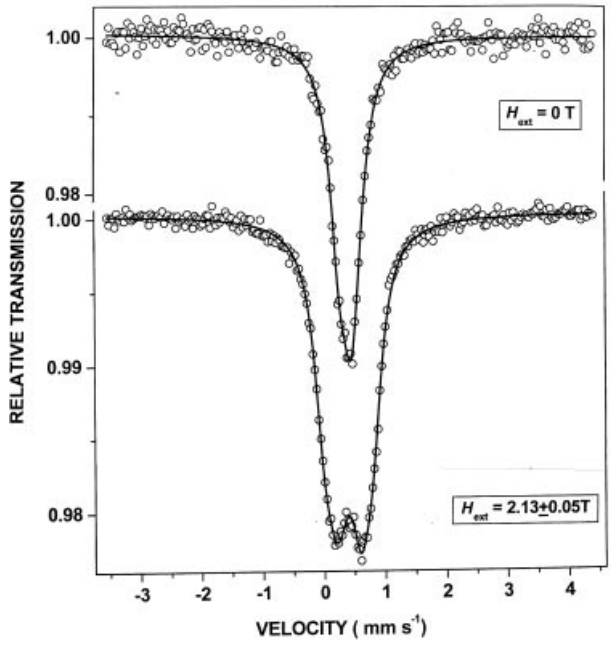

Figure 6. Mössbauer spectra of decamethylferrocenium tetrafluoroborate ($DMFc^+BF_4^-$), in $H_{ext} = 0$ (upper trace) and $H_{ext} = 2.36$ T (lower trace). The solid curve represents the program least-square fit, yielding the parameters given in Table 1.

A comparable set of experiments has been carried out with $^{57}$Fe OMFc and $^{57}$Fe $OMFc^+BF_4^-$, and the parameters extracted from the corresponding Mössbauer spectra are included in Table 1. As in the case of the DMFc complexes, the QS parameter is clearly positive in the neutral compound and negative in the cationic homologue.

We observe in paramagnetic $OMFc^+BF_4^-$ that $H_{eff}$ is significantly larger than $H_{ext}$, and yields a magnetic hyperfine field $H_{hf}$ (assuming that $g_{eff}\mu_B S$ is about 1 $\mu_B$) of about +40 T. Such large positive hyperfine fields have been previously observed and interpreted as due to orbital contributions to the hyperfine field.[11,12] Once $H_{hf}$ is estimated, one can use this value for the analysis of the zero external field Mössbauer spectra from which spin relaxation rates can be derived, using a simple spin ½ up down formula.[13] The reduced hyperfine interaction parameters from the least-square fitting of the various Mössbauer spectra are all summarized in Table 1.

The above experiments were carried out on $^{57}$Fe-enriched ferrocenoid complexes in which the shape of the electric field around the metal atom is expected to be oblate, because of the $C_{5v}$ symmetry of the ring ligands.

These measurements have been further extended to an iron complex in which the shape of the electric field around the metal atom is expected to be prolate, of which $Fe(phen)_2(SCN)_2$ (phen = 1,10 phenanthroline) is a representative example. This compound has been extensively studied by Mössbauer effect spectroscopy[14,20] in view of its interesting high spin–low spin transition at ca. 175 K. At room temperature the iron is in a high-spin state and has an effective moment of ca. 5 $\mu_B$, indicating the presence of four unpaired electrons ($S = 2$). The two SCN ligands occupy *cis* positions, and hence the asymmetry parameter $\eta \neq 0$. These experiments were carried out with natural abundance iron, so that relatively long data acquisition times (up to 72 h) were required to record statistically significant data. The brass sample cavity in this case was $0.4 \times 0.4 \times 1$ cm$^3$, and typically holds 0.7–1.0 mmol of solid. As before, the pole piece gap was 0.6 cm. A typical data set is summarized graphically in Figure 7, where again the zero-field resonance spectrum is shown in the upper trace, and the in-field absorbance in the lower. Although the magnetic splitting is smaller than that observed in the ferrocenoid complexes, it is clear that in an applied field of $2.36 \pm 0.04$ T the absorbance at negative velocities is due to an asymmetric doublet, while that at positive velocities arises from a triplet, in agreement with the existence of a negative QS. The least-square fit analysis yields the hyperfine interaction parameters given in Table 1. The striking result is that in the present case, $H_{eff}$ is smaller (!) than the external field,

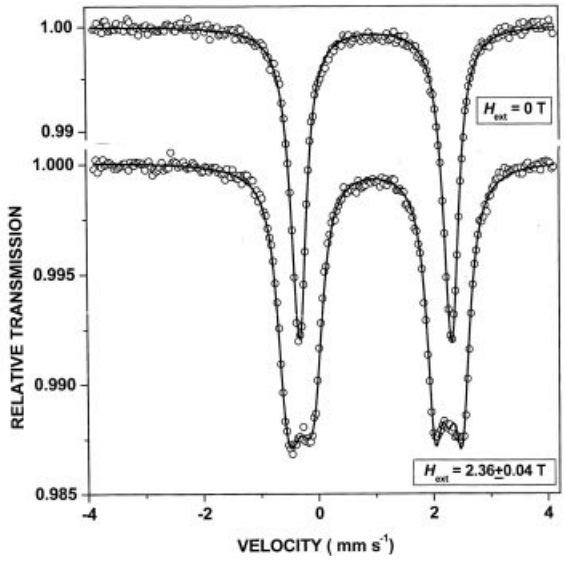

Figure 7. Mössbauer spectra of bis(phenanthroline)bis(thiocyanato)iron(II), in $H_{ext} = 0$ (upper trace) and $H_{ext} = 2.36$ T (lower trace). The solid curve represents the program least-square fit, yielding the parameters given in Table 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

namely the induced internal hyperfine field is negative and leads according to Equation (10) to the value of $H_{hf} \approx -28$ T.

An example of a compound in which $\eta$ is expected to be equal or close to zero is provided by $Na_2Fe[(CN)_5NO]\cdot 2H_2O$, SNP, which has again been thoroughly investigated by Mössbauer techniques,[15,21] in part because of its interesting optical properties and ease of preparation of high-purity single crystals. An early high-precision study of very thin samples has been published by Grant et al.[16] Single-crystal X-ray diffraction studies[17] have shown that the local site symmetry is $C_{4v}$ and the space group is $P_{nnm}$ and $\eta \leq 0.04$. A magnetic field experiment carried out on a finely crushed powder sample is summarized graphically in Figure 8 and the derived hyperfine parameters are included in Table 1. From Figure 8 it is evident that the quadrupole splitting ($1.713 \pm 0.005$ mm s$^{-1}$ at room temperature) is positive, in consonance with the results reported by Grant.[18] The $\eta$ value obtained from the data processed by the $\eta \neq 0$ program is 0.5, although the $\chi^2$ value is not very much smaller than for $\eta = 0$.

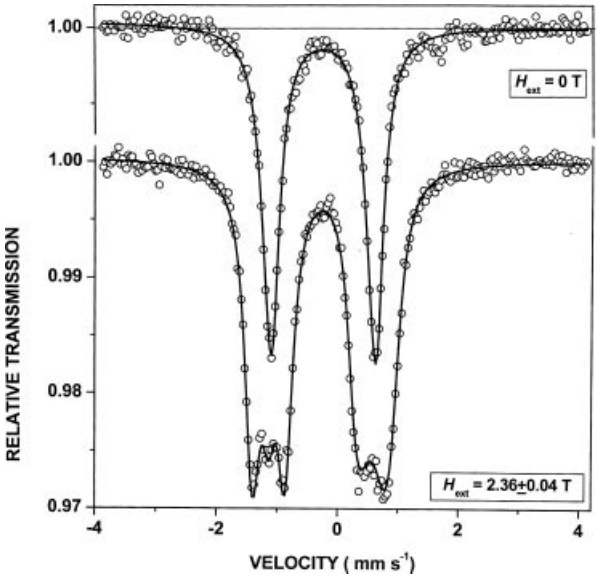

Figure 8. Mössbauer spectra of sodium nitroprusside dihydrate [$Fe^{II}$ in $H_{ext} = 0$ (upper trace) and $H_{ext} = 2.36$ T (lower trace)]. The solid curve represents the program least-square fit, yielding the parameters given in Table 1.

## Conclusions

Using a standard laboratory electromagnet having 3-cm pole pieces and operating at about 7 A, in conjunction with transmission Mössbauer spectroscopy it has been possible to determine the sign of the quadrupole splitting in a series of organometallic iron compounds at room temperature. In addition, the application of a complete diagonalization program of the full Hamiltonian for powder samples averaging over all possible random orientations makes it possible to extract the internal hyperfine field in both diamagnetic and paramagnetic complexes. While the use of enriched ($^{57}$Fe) samples reduces the required data acquisition time, even natural abundance samples employing in the order of 1 mmol of iron complex permits the acquisition of statistically reliable parameter information in reasonable data-acquisition times. The quadrupole splitting is positive in diamagnetic complexes such as OMFc, DMFc, and Fe(phen)$_2$(SCN)$_2$ (as it is in ferrocene itself), and negative in the associated one-electron oxidation products. In addition, corresponding data are presented for $FeF_2$.

## Experimental Section

A sample of natural abundance $FeF_2$, produced by microwave irradiation of $Fe(NO_3)_3\cdot 9H_2O$ in the presence of $BMIBF_4$,[8,19] was generously made available to us by Prof. A. Gedanken of Bar Ilan University and used as received. Samples of $^{57}$Fe-enriched decamethylferrocene (DMFc), decamethylferrocenium hexafluorophosphate ($DMFc^+PF_6^-$), octamethylferrocene (OMFc), and octamethylferrocinium tetrafluoroborate ($OMFc^+BF_4^-$) were generously made available by Prof. H. S. Schottenberger of the University of Innsbruck. Bis(phenanthroline)bis(thiocyanato)iron(II) [Fe(phen)$_2$(SCN)$_2$] was prepared by literature methods[9] and its purity was checked by FTIR measurements. Sodium nitroprusside [$Na_2Fe(CN)_5NO\cdot 2H_2O$][10] was taken from high-purity single-crystal material. All solids were ground with Pyrex powder and mixed with BN to assure the absence of texture-induced asymmetry in the spectra. The powdered enriched $Fe^{57}$ samples were transferred to a rectangular brass holder of 6 mm width and 2 mm thickness (unless otherwise noted), having a sample cavity of 0.08 cm$^3$, which will hold (typically) about 0.4–0.6 mmol of an organometallic solid. The sample space was windowed with 5 N Al foil and the holder assembly clamped between the pole pieces of an electromagnet. The DC electromagnet used in this study was a Newport Instruments model 369 having gap-adjustable shaped pole faces, which allowed variable field intensities to be investigated. The standard pole piece gap was 0.6 cm. Normal operating conditions were 55 V and 6–7 A at room temperature. The Mössbauer effect measurements were carried out in transmission geometry, with the 100 mCi $^{57}$Co (Rh) source mounted on a 38 cm long stainless steel tube driven by a standard triangular wave velocity drive. As was noted above, this arrangement leads to only a small (less than 0.05 mm s$^{-1}$) broadening of the resonance lines. Spectrometer calibration was effected in magnet geometry ($H = 0$) by standard α-Fe absorption, and all IS are reported with respect to the centroid of this spectrum.

Data analysis was effected in the usual manner, by the above-described programs. These computer programs are available upon request from the corresponding author.

## Acknowledgments

The authors are indebted to Prof. H. Schottenberger for providing samples of the enriched compounds examined in this study, and to O. Levy for the preparation of high-purity Fe(phen)$_2$(SCN)$_2$.

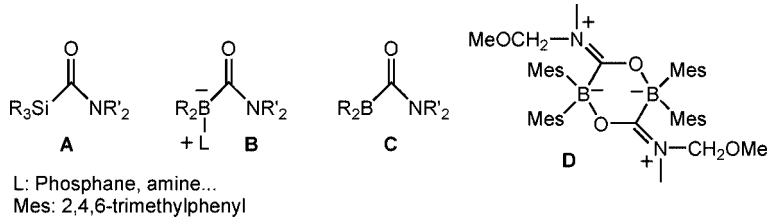
# A Facile Synthesis of Carbamoylsilanes, -boranes and -phosphane Oxides – Isolation of the First Uncomplexed Carbamoylborane

Yves Canac,[a] Greg E. Aniol,[a] Salvador Conejero,[a] Bruno Donnadieu,[a] and Guy Bertrand*[a]

**Keywords:** Carbenes / Rearrangement / Boron / Silicon

*C*-(Trimethylsilyloxy)-, *C*-(triisopropylsilyloxy)-, *C*-(diphenylboryloxy), *C*-[bis(diisopropylamino)boryloxy]- and *C*-(di-*tert*-butylphosphoryloxy)-*N*,*N*-diisopropylaldiminium salts are readily prepared in good to excellent yields from either diisopropylformamide or (chloromethylene)diisopropylammonium chloride. Deprotonation of these aldiminium salts leads to transient (amino)(oxy)carbenes, which cleanly rearrange to carbamoyl derivatives. This synthetic methodology gives access to sterically hindered carbamoylsilanes, -boranes and phosphane oxides that are hardly accessible by other routes. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

Although first described over 30 years ago,[1] the carbamoylsilanes **A** remain difficult to prepare. Most of the known synthetic routes[2] have a rather limited scope of application and/or proceed in low to medium yields. The most powerful preparative methods are the low-temperature metalation/silylation of the corresponding *N*,*N*-dialkylformamide,[3] and the *trans*-silylation of carbamoylsilanes with the desired silyl chloride.[4] These synthetic routes, however, are inefficient when bulky substrates are involved. Despite the difficulties associated with their synthesis, carbamoylsilanes have found various synthetic applications.[4,5] In the boron series, the *B*-complexed carbamoylboranes **B**[6] have been known for a long time, and have even been described as potent cytotoxic agents in different cancer cells,[7] but so far no examples of free carbamoylboranes **C** have been reported. Even with bulky aryl groups at the boron atom, Cunico et al. have shown that carbamoylboranes spontaneously dimerize to give the six-membered heterocycles **D**[8] (Scheme 1).



Scheme 1.

Here we describe a general route for the high-yield synthesis of carbamoyl derivatives, which include sterically relatively hindered carbamoylsilanes, as well as the first example of a noncomplexed carbamoylborane. The latter has been characterized by a single-crystal X-ray diffraction study. To further demonstrate the broad scope of application of our synthetic methodology, the preparation of a carbamoylphosphane oxide[9] is also described.

Moss et al.[10] have shown that the (phenylcarbonyloxy)-carbenes **E** quickly rearrange to 1,2-diketones, due to the carbanion-like attack of the carbene lone pair at the electrophilic carbonyl group (Scheme 2). Accordingly, any nucleophilic carbenes,[11] featuring an electrophilic center in β-position should rearrange as well. In contrast with most carbenes,[12] highly nucleophilic transient and even stable aminocarbenes[13] are readily accessible, and therefore our synthetic strategy towards carbamoyl derivatives is based on

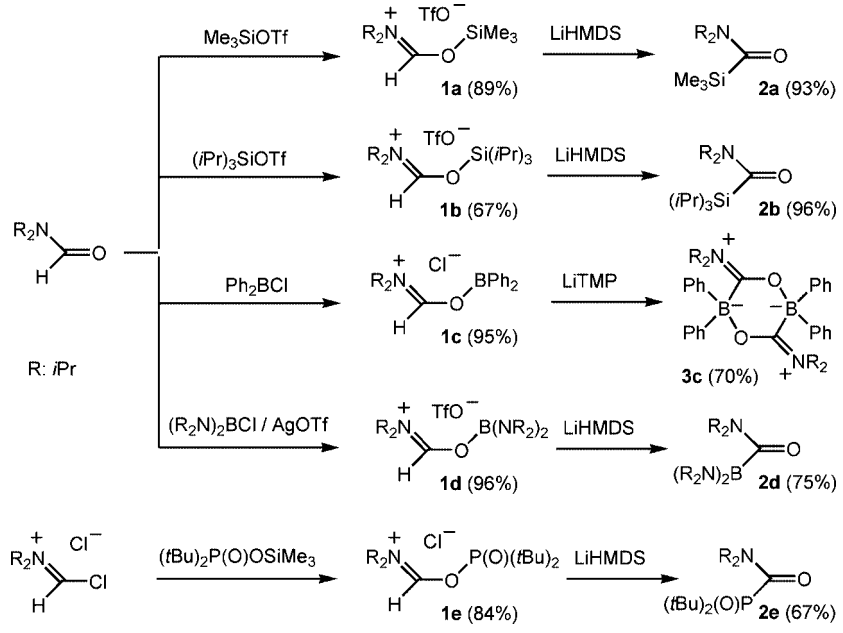
the rearrangement of the appropriately substituted aminocarbenes.

The classical precursors for aminocarbenes are the corresponding aldiminium salts. The desired silyloxy derivative **1a** was readily obtained in 89% yield by treatment of diisopropylformamide with 1 equiv. of trimethylsilyl trifluoromethanesulfonate at –78 °C. Subsequent deprotonation of **1a** with lithium bis(trimethylsilyl)amide (LiHMDS) in THF quickly occurred at –78 °C, and after work up the carbamoylsilane **2a** was isolated in 93% yield (Scheme 3). The overall yield for this two-step process (83%) is comparable to that obtained using the metalation/silylation route (81%).[3b] To demonstrate the potential synthetic utility of this new route, we extended our approach to the triisopropylsilyl analogue **2b**, which was reported to be not accessible by the other routes due to steric hindrance.[4] Using triisopropylsilyl trifluoromethanesulfonate, the aldiminium salt **1b** was obtained in 67% yield, and after subsequent deprotonation with LiHMDS, **2b** was isolated in 96% yield. All attempts to spectroscopically characterize the initially formed aminocarbene ($i$Pr$_2$N–C–OSi$i$Pr$_3$) failed; unsurprisingly the rearrangement to the carbamoyl isomer is not sensitive to the steric bulk.

We then turned our attention to the group 13 carbamoyl derivatives. Treatment of diisopropylformamide with 1 equiv. of chlorodiphenylborane in diethyl ether at room temperature led, after workup, to the iminium salt **1c** in 95% yield. Deprotonation of **1c** with the lithium salt of 2,2,6,6-tetramethylpiperidine occurred at –78 °C in THF. After purification by chromatography on silica gel and recrystallization in hexane at –20 °C, the derivative **3c** was isolated as white crystals (70% yield, m.p. 261–263 °C). Compound **3c** displayed a broad signal at $\delta$ = 1.8 ppm in the $^{11}$B NMR spectrum, consistent with a tetracoordinate boron atom possessing anionic character. Despite the poor quality of the crystals, a single-crystal X-ray diffraction study showed that **3c** has a structure similar to the previously reported compound **D**.[8] Taking advantage of the possibility of using sterically hindered substrates, we investigated the possibility of preparing an isolable uncomplexed carbamoylborane. We chose diisopropylamino substituents at the boron atom, their π-donating properties also imparting electronic protection to the molecule. The iminium salt **1d** was prepared in 96% yield by the reaction of diisopropylformamide with 1 equiv. of chlorobis(diisopropylamino)borane in the presence of a stoichiometric amount of silver trifluoromethanesulfonate. As expected, deprotonation of **1d** with LiHMDS in THF afforded the carbamoylborane **2d**, which after recrystallization was obtained as thermally highly stable colorless crystals in 75% yield (m.p. 228–230 °C). The $^{11}$B NMR spectrum of **2d** exhibits a signal at $\delta$ = 29.2 ppm, which is in agreement with a tricoordinate boron atom possessing two amino groups. The $^{13}$C NMR spectrum shows the presence of a signal at rather low field ($\delta$ =190.0 ppm) consistent with an amide-type carbon atom substituted by an electron-withdrawing group. The single-crystal X-ray diffraction study confirms the monomeric nature of the carbamoyl borane **2d** (Figure 1). As expected, N1, C1, B1, N2 and N3 are in a perfectly planar environment, which demonstrates the interaction of N1 with the carbonyl group, and N2 and N3 with the boron center. It is noteworthy that all attempts to characterize the putative carbene intermediate here also failed, even when the deprotonation reaction was monitored by NMR spectroscopy at –78 °C.

In order to broaden the scope of this synthetic methodology, we also prepared the phosphane oxide substituted iminium salt **1e** (84% yield) by treatment of (chloromethylene)diisopropylammonium chloride with 1 equiv. of $t$Bu$_2$P(O)OSiMe$_3$. Deprotonation of **1e** with LiHMDS in



Scheme 3.

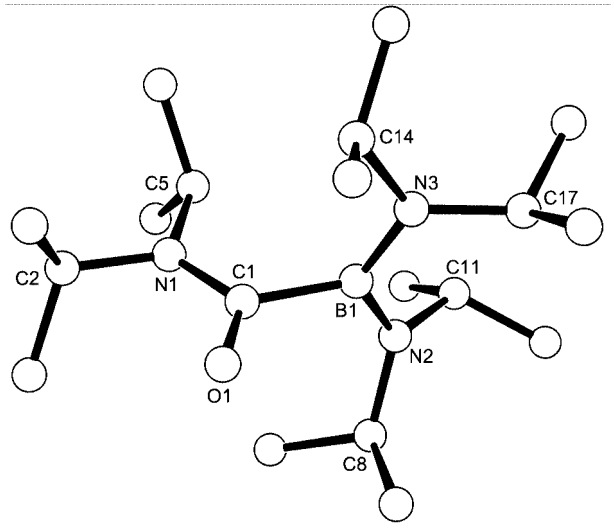

Figure 1. Molecular view of the crystal structure of **2d** (H atoms omitted). Selected bond lengths [Å] and angles [°]: B1–N2 1.4394(17), B1–N3 1.4223(17), B1–C1 1.6185(18), C1–O1 1.2449(14), C1–N1 1.3644(15); N3–B1–N2 124.35(11), N3–B1–C1 116.22(11), N2–B1–C1 119.31(11), O1–C1–N1 121.04(11), O1–C1–B1 118.54(10), N1–C1–B1 120.43(10), C1–N1–C5 120.89(10), C1–N1–C2 121.91(10), C5–N1–C2 117.07(10), B1–N2–C11 122.20(10), B1–N2–C8 122.68(10), C11–N2–C8 114.98(10), B1–N3–C17 120.08(10), B1–N3–C14 118.84(10), C17–N3–C14 120.33(10).

THF afforded the carbamoylphosphane oxide **2e**, which was isolated in 67% yield (Scheme 3).

This work is a new demonstration of the usefulness of the readily available aminocarbenes in organic synthesis. Moreover, the ready availability of these carbamoyl derivatives should favour their use for various synthetic applications.

## Experimental Section

**General:** All manipulations were performed under argon using standard Schlenk techniques. Dry, oxygen-free solvents were employed. $^{1}$H, $^{13}$C, $^{31}$P and $^{11}$B NMR spectra were recorded with Varian Inova 300, 500 and Bruker Avance 300 spectrometers. The high purity of all isolated products have been confirmed by multinuclear NMR spectroscopy.

***N*,*N*-Diisopropyl-*C*-(trimethylsilyloxy)aldiminium Salt 1a:** $Me_3Si$-OTf (0.69 mL, 3.9 mmol) was added dropwise to a solution of diisopropylformamide (0.56 mL, 3.9 mmol) in $CH_2Cl_2$ (10 mL) at –78 °C. The suspension was warmed to room temperature and stirred for 30 min. After evaporation of the solvent, the solid residue was washed with $Et_2O$ (15 mL) to afford aldiminium salt **1a** as a white solid (1.21 g, 89%). $^{1}$H NMR ($CD_3CN$, 25 °C): $\delta$ = 0.47 [s, 9 H, Si(C$H_3$)$_3$], 1.37 (d, $^{3}J$ = 6.9 Hz, 12 H, CHC$H_3$), 4.14 (m, 2 H, C$H$CH$_3$), 8.11 (s, 1 H, C$H$) ppm. $^{13}$C NMR ($CD_3CN$, 25 °C): $\delta$ = –0.3 [Si(*C*H$_3$)$_3$], 20.0 (CH*C*H$_3$), 21.2 (CH*C*H$_3$), 51.5 (*C*HCH$_3$), 56.9 (*C*HCH$_3$), 120.9 (q, $^{1}J$ = 319.5 Hz, *C*F$_3$SO$_3$), 164.6 (*C*H) ppm.

**(Diisopropylcarbamoyl)trimethylsilane (2a):** A 1:1 mixture of LiHMDS/aldiminium salt **1a** (7.4 mmol) was cooled to –78 °C and THF (20 mL) was added. The suspension was warmed to room temperature and stirred for 30 min. After evaporation of the solvent, the solid residue was washed with hexane (30 mL). Extraction with $CH_2Cl_2$ (15 mL) gave, after concentration, a white solid (1.39 g, 93%). The physical and spectroscopic data are identical to those reported previously.[3b]

***N*,*N*-Diisopropyl-*C*-(triisopropylsilyloxy)aldiminium Salt 1b:** $i$Pr$_3$Si-OTf (2.0 mL, 7.7 mmol) was added dropwise at –78 °C to a solution of diisopropylformamide (1.12 mL, 7.7 mmol) in $CH_2Cl_2$ (20 mL). The suspension was warmed to room temperature and stirred for 2 h. After evaporation of the solvent, the solid residue was washed with $Et_2O$ (20 mL) to afford aldiminium salt **1b** as a white solid (2.25 g, 67%). $^{1}$H NMR ($CDCl_3$, 25 °C): $\delta$ = 1.11 [d, $^{3}J$ = 7.2 Hz, 18 H, Si(CHC$H_3$)$_3$], 1.39 (d, $^{3}J$ = 7.2 Hz, 6 H, CHC$H_3$), 1.42 (d, $^{3}J$ = 7.2 Hz, 6 H, CHC$H_3$), 1.48 [sept, $^{3}J$ = 7.2 Hz, 3 H, Si(C$H$CH$_3$)$_3$], 4.09 (sept, $^{3}J$ = 7.2 Hz, 1 H, C$H$CH$_3$), 4.52 (m, 1 H, C$H$CH$_3$), 8.70 (s, 1 H, C$H$) ppm. $^{13}$C NMR ($CDCl_3$, 25 °C): $\delta$ = 11.6 [Si(*C*HCH$_3$)$_3$], 17.2 [Si(CH*C*H$_3$)$_3$], 19.7 (CH*C*H$_3$), 20.9 (CH*C*H$_3$), 50.0 (*C*HCH$_3$), 56.4 (*C*HCH$_3$), 120.9 (q, $^{1}J_{CF}$ = 319.0 Hz, *C*F$_3$SO$_3$), 163.5 (*C*H) ppm.

**(Diisopropylcarbamoyl)triisopropylsilane (2b):** A 1:1 mixture of LiHMDS/aldiminium salt **1b** (1.1 mmol) was cooled to –78 °C and THF (10 mL) was added. The suspension was warmed to room temperature and stirred for 30 min. After evaporation of the solvent and extraction with $CH_2Cl_2$ (10 mL), a white solid was isolated (0.31 g, 96%). $^{1}$H NMR ([D$_8$]THF, 25 °C): $\delta$ = 1.11 [d, $^{3}J$ = 6.8 Hz, 18 H, Si(CHC$H_3$)$_3$], 1.19 (d, $^{3}J$ = 6.6 Hz, 6 H, CHC$H_3$), 1.25 [m, 3 H, Si(C$H$CH$_3$)$_3$], 1.40 (d, $^{3}J$ = 6.8 Hz, 6 H, CHC$H_3$), 3.35 (sept, $^{3}J$ = 6.8 Hz, 1 H, C$H$CH$_3$), 3.92 (sept, $^{3}J$ = 6.6 Hz, 1 H, C$H$CH$_3$) ppm. $^{13}$C NMR ([D$_8$]THF, 25 °C): $\delta$ = 13.9 [Si(*C*HCH$_3$)$_3$], 19.7 [Si(CH*C*H$_3$)$_3$], 21.3 (CH*C*H$_3$), 22.1 (CH*C*H$_3$), 46.9 (*C*HCH$_3$), 49.5 (*C*HCH$_3$), 186.0 (*C*) ppm.

***C*-(Diphenylboryloxy)-*N*,*N*-diisopropylaldiminium Salt 1c:** A $Et_2O$ solution (10 mL) of diisopropylformamide (0.58 mL, 4.0 mmol) was added at –78 °C to a $Et_2O$ solution (10 mL) of chlorodiphenylborane (0.70 mL, 4.0 mmol), and the suspension was stirred at room temperature for 12 h. After filtration, the solid residue was washed with $Et_2O$ (20 mL) to afford aldiminium salt **1c** as a white solid (1.25 g, 95%). $^{1}$H NMR ($CDCl_3$, 25 °C): $\delta$ = 1.46 (d, $^{3}J$ = 6.9 Hz, 6 H, CHC$H_3$), 1.57 (d, $^{3}J$ = 6.6 Hz, 6 H, CHC$H_3$), 3.93 (sept, $^{3}J$ = 6.6 Hz, 1 H, C$H$CH$_3$), 4.41 (sept, $^{3}J$ = 6.9 Hz, 1 H, C$H$CH$_3$), 7.30–7.42 and 7.63–7.67 (m, 10 H, $H_{ar}$), 8.48 (s, 1 H, C$H$) ppm. $^{13}$C NMR ($CDCl_3$, 25 °C): $\delta$ = 20.1 (CH*C*H$_3$), 22.7 (CH*C*H$_3$), 48.6 (*C*HCH$_3$), 52.7 (*C*HCH$_3$), 126.5 ($C_{ar}$), 127.5 ($C_{ar}$), 128.5 ($C_{ar}$), 132.3 ($C_{ar}$), 165.6 (*C*H) ppm. $^{11}$B NMR ($CDCl_3$, 25 °C): $\delta$ = 11.6 ppm.

**Carbamoylborane Dimer 3c:** A 1:1 mixture of TMPLi/aldiminium salt **1c** (1.0 mmol) was cooled to –78 °C and THF (10 mL) was added. The suspension was warmed to room temperature and stirred for 30 min. After evaporation of the solvent under vacuum, purification by chromatography on silica gel (hexane/ethyl acetate) gave a solid residue, which was recrystallized at –20 °C from hexane (0.20 g, 70%, m.p. 261–263 °C). $^{1}$H NMR ($CDCl_3$, 25 °C): $\delta$ = 0.45 (d, $^{3}J$ = 6.3 Hz, 12 H, CHC$H_3$), 1.16 (d, $^{3}J$ = 6.3 Hz, 12 H, CHC$H_3$), 3.20 (sept, $^{3}J$ = 6.6 Hz, 2 H, C$H$CH$_3$), 4.05 (sept, $^{3}J$ = 6.9 Hz, 2 H, C$H$CH$_3$), 7.15–7.27 and 7.41–7.45 (m, 20 H, $H_{ar}$) ppm. $^{13}$C NMR ($CDCl_3$, 25 °C): $\delta$ = 19.3 (CH*C*H$_3$), 21.1 (CH*C*H$_3$), 48.3 (*C*HCH$_3$), 53.4 (*C*HCH$_3$), 126.7 ($C_{ar}$), 127.2 ($C_{ar}$), 127.3 ($C_{ar}$), 127.9 ($C_{ar}$), 132.2 ($C_{ar}$), 134.3 ($C_{ar}$), 144.9 ($C_{ar}$), 147.4 ($C_{ar}$), 198.8 (*C*) ppm. $^{11}$B NMR ($CDCl_3$, 25 °C): $\delta$ = 1.8 ppm.

***C*-[Bis(diisopropylamino)boryloxy]-*N*,*N*-diisopropylaldiminium Salt 1d:** A $CH_2Cl_2$ solution (10 mL) of AgOTf (2.03 g, 7.9 mmol) was added at –78 °C to a $CH_2Cl_2$ solution (10 mL) of diisopropylformamide (1.15 mL, 7.9 mmol) and chlorobis(diisopropylamino)borane (2.03 mL, 7.9 mmol). The suspension was then stirred at room temperature for 12 h. After filtration and evaporation of the sol-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vent, the solid residue was washed with $Et_2O$ (30 mL) to afford **1d** as a white solid (3.70 g, 96%). $^1H$ NMR ($CDCl_3$, 25 °C): $\delta$ = 1.16 (d, $^3J$ = 6.5 Hz, 24 H, CHC$H_3$), 1.48 (d, $^3J$ = 7.0 Hz, 6 H, CHC$H_3$), 1.53 (d, $^3J$ = 7.0 Hz, 6 H, CHC$H_3$), 3.44 (sept, $^3J$ = 6.5 Hz, 4 H, C*H*CH$_3$), 4.33 (sept, $^3J$ = 7.0 Hz, 1 H, C*H*CH$_3$), 4.63 (sept, $^3J$ = 7.0 Hz, 1 H, C*H*CH$_3$), 8.70 (s, 1 H, C*H*) ppm. $^{13}C$ NMR ($CDCl_3$, 25 °C): $\delta$ = 19.6 (CH*C*H$_3$), 22.9 (CH*C*H$_3$), 23.8 (CH*C*H$_3$), 46.4 (*C*HCH$_3$), 50.9 (*C*HCH$_3$), 53.0 (*C*HCH$_3$), 120.9 (q, $^1J$ = 319.5 Hz, *C*F$_3$SO$_3^-$), 164.6 (*C*H) ppm. $^{11}B$ NMR ($CDCl_3$, 25 °C): $\delta$ = 27.7 ppm.

**Bis(diisopropylamino)(diisopropylcarbamoyl)borane (2d):** A 1:1 mixture of LiHMDS/aldiminium salt **1d** (5.0 mmol) was cooled to –78 °C and THF (20 mL) was added. The suspension was then warmed to room temperature and stirred for 30 min. After evaporation of the solvent and extraction with $Et_2O$ (40 mL), a solid residue was obtained. After washing with hexane (10 mL) and extraction with $CH_2Cl_2$ (30 mL), evaporation of the solvent gave a white solid that was recrystallized from $Et_2O$ at –20 °C to give **2d** as colorless crystals (1.27 g, 75%, m.p. 228–230 °C). $^1H$ NMR ($CDCl_3$, 25 °C): $\delta$ = 1.20 (d, $^3J$ = 6.9 Hz, 18 H, CHC$H_3$), 1.23 (d, $^3J$ = 7.2 Hz, 12 H, CHC$H_3$), 1.45 (d, $^3J$ = 6.9 Hz, 6 H, CHC$H_3$), 3.28 (sept, $^3J$ = 6.9 Hz, 1 H, C*H*CH$_3$), 3.53 (sept, $^3J$ = 7.2 Hz, 4 H, C*H*CH$_3$), 3.86 (sept, $^3J$ = 6.9 Hz, 1 H, C*H*CH$_3$) ppm. $^{13}C$ NMR ($CDCl_3$, 25 °C): $\delta$ = 20.3 (CH*C*H$_3$), 21.1 (CH*C*H$_3$), 24.6 (CH*C*H$_3$), 25.0 (CH*C*H$_3$), 45.0 (*C*HCH$_3$), 48.2 (*C*HCH$_3$), 49.7 (*C*HCH$_3$), 190.0 (*C*) ppm. $^{11}B$ NMR ($CDCl_3$, 25 °C): $\delta$ = 29.2 ppm.

***C*-(Di-*tert*-butylphosphoryloxy)-*N*,*N*-diisopropylaldiminium Salt 1e:** A $CH_3CN$ solution (10 mL) of di-*tert*-butyl(trimethylsilyloxy)phosphane oxide (0.50 g, 2.0 mmol) was added at –78 °C to a $CH_3CN$ solution (10 mL) of (chloromethylene)diisopropylammonium chloride (0.37 g, 2.0 mmol). The suspension was stirred at room temperature for 3 h. After evaporation of the solvent, the solid residue was washed with $Et_2O$ (15 mL) to afford **1e** as a white solid (0.55 g, 84%). $^{31}P$ NMR ($CDCl_3$, 25 °C): $\delta$ = +87.8 ppm. $^1H$ NMR ($CDCl_3$, 25 °C): $\delta$ = 1.35 [d, $^3J$ = 15.9 Hz, 18 H, C(C$H_3$)$_3$], 1.47 (d, $^3J$ = 6.6 Hz, 6 H, CHC$H_3$), 1.54 (d, $^3J$ = 6.3 Hz, 6 H, CHC$H_3$), 4.30 (sept, $^3J$ = 6.6 Hz, 1 H, C*H*CH$_3$), 5.18 (sept, $^3J$ = 6.3 Hz, 1 H, C*H*CH$_3$), 9.38 (d, $^3J$ = 6.6 Hz, 1 H, C*H*) ppm. $^{13}C$ NMR ($CDCl_3$, 25 °C): $\delta$ = 20.4 (CH*C*H$_3$), 20.6 (CH*C*H$_3$), 26.1 [C(*C*H$_3$)], 37.5 [d, $^1J$ = 67.9 Hz, *C*(CH$_3$)], 51.4 (*C*HCH$_3$), 59.0 (*C*HCH$_3$), 162.0 (*C*H) ppm.

**Di-*tert*-butyl(diisopropylcarbamoyl)phosphane Oxide (2e):** A 1:1 mixture of LiHMDS/salt **1e** (1.0 mmol) was cooled to –78 °C and THF (10 mL) was added. The suspension was warmed to room temperature and stirred for 20 min. After evaporation of the solvent and extraction with hexane (10 mL), a solid residue was obtained (0.19 g, 67%). $^{31}P$ NMR ($CDCl_3$, 25 °C): $\delta$ = +52.3 ppm. $^1H$ NMR ($CDCl_3$, 25 °C): $\delta$ = 1.17 (d, $^3J$ = 6.3 Hz, 6 H, CHC$H_3$), 1.32 [d, $^3J$ = 14.1 Hz, 18 H, C(C$H_3$)$_3$], 1.41 (d, $^3J$ = 6.3 Hz, 6 H, CHC$H_3$), 3.43 (sept, $^3J$ = 6.3 Hz, 1 H, C*H*CH$_3$), 5.80 (m, 1 H, C*H*CH$_3$) ppm. $^{13}C$ NMR ($CDCl_3$, 25 °C): $\delta$ = 19.9 (CH*C*H$_3$), 20.8 (CH*C*H$_3$), 26.9 [C(*C*H$_3$)], 36.5 [d, $^1J$ = 57.6 Hz, *C*(CH$_3$)], 46.6 (*C*HCH$_3$), 47.6 (*C*HCH$_3$), 169.2 (d, $^1J$ = 97.0 Hz, *C*) ppm.

**Crystal Structure Determination of Carbamoylborane 2d:** A Bruker X8-APEX X-ray diffraction instrument with Mo radiation was used for data collection. All data frames were collected at low temperatures ($T$ = 100 K) using an $\omega/\varphi$-scan mode (–0.5° $\omega$-scan width, hemisphere of reflections) and integrated using a Bruker SAINTPLUS software package. The intensity data were corrected for Lorentzian polarization. Absorption corrections were performed using the SADABS program. A Sir92 software package was used for direct methods of phase determination and structure refinement. Atomic coordinates, isotropic and anisotropic displacement parameters of all the non-hydrogen atoms were refined by means of a full-matrix least-squares procedure on $F^2$. All hydrogen atoms were included in the refinement in calculated positions riding on the atoms to which they were attached. Drawings of molecules were performed using ORTEP 3. Crystal and structure parameters of **2d**: size 0.38 × 0.20 × 0.09 mm, triclinic, space group $P\bar{1}$, $a$ = 9.7141(6) Å, $b$ = 12.2962(7) Å, $c$ = 18.7798(12) Å, $\alpha$ = 92.122(4)°, $\beta$ = 101.343(4)°, $\gamma$ = 93.291(4)°, $V$ = 2193.1(2) Å$^3$, $\rho_{calcd.}$ = 1.028 g/cm$^3$, $2\theta_{max}$ = 55.76°, Mo radiation ($\lambda$ = 0.71073 Å), temperature = 100(2)° K, reflections collected = 33410, independent reflections = 10433, $R_{int}$ = 0.0301, absorption coefficient $\mu$ = 0.062 mm$^{-1}$; max/min transmission = 0.9945/0.9769, 457 parameters were refined and converged at $R_1$ = 0.0457, $wR_2$ = 0.1132, with intensity $I > 2\sigma(I)$, the final difference map was 0.986–0.337 e·Å$^{-3}$. CCDC-618399 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# μ-Coordination Chemistry of NO Ligands: Adducts of *trans*-Mo(dmpe)$_2$(Cl)-(NO) with Lithium Salts

**Fupei Liang,[a] Helmut W. Schmalle,[b] and Heinz Berke*[b]**

**Keywords:** Coordination polymers / Bridging ligands / Phosphane ligands / Lithium / Molybdenum

Reaction of *trans*-Mo(dmpe)$_2$(Cl)(NO) (**1**) [dmpe = bis(dimethylphosphanyl)ethane] with lithium triethylborohydride and lithium bis(trimethylsilyl)amide affords the adducts [Mo(dmpe)$_2$(Cl)(NO)(LiHBEt$_3$)]$_n$ (**2**) and {Mo(dmpe)$_2$(Cl)-(NO)[LiN(SiMe$_3$)$_2$]$_2$}$_n$ (**3**), respectively, and the reaction of **1** with *n*-butyllithium and iodomethane generates the complex [Mo(dmpe)$_2$(Cl)(NO)]$_3$(LiI)$_2$ (**4**). Complexes **2**–**4** have been characterized by elemental analysis, IR spectroscopy, NMR spectroscopy, and single-crystal X-ray diffraction analysis. The structure of **2** shows an infinite one-dimensional "zigzag" chain constructed from an alternating arrangement of Mo(dmpe)$_2$(Cl)(NO) and LiHBEt$_3$ moieties, whereas the structure of **3** exhibits an infinite linear chain generated by the alternating arrangement of the Mo(dmpe)$_2$(Cl)(NO) moiety and the dimeric [LiN(SiMe$_3$)$_2$]$_2$ unit. In both compounds, the Mo(dmpe)$_2$(Cl)(NO) moieties act as bridging ligands by coordination of the nitrosyl oxygen atom and the chlorine atom to the lithium ions. Complex **4** displays a discrete structure formed by two separate monomeric LiI units that are bridged by the nitrosyl oxygen atoms of three Mo(dmpe)$_2$-(Cl)(NO) moieties. The chlorine atoms of **4** are not involved in coordination.

Transition metal nitrosyl complexes have received considerable attention for many years due to their potential applications as catalysts in organic synthesis and small molecule activation.[1,2] Our interest in this field lies mainly in the chemistry of nitrosyl hydrido transition metal complexes. In this context a series of compounds of manganese,[3] rhenium,[4] chromium,[5] tungsten,[6] and molybdenum[7] have been synthesized and explored in particular with regard to hydride-transfer chemistry. It has been found that the nitrosyl group exhibits versatile functions in such compounds. It can stabilize the different oxidation states of the metal center,[1,8] and it can induce quite strong hydridic polarization by the "nitrosyl effect"; thus the nitrosyl group promotes the activation of the metal–hydrogen bond.[9] Additionally, the nitrosyl group can show a certain amount of Lewis base behavior by interacting with Lewis acids at the oxygen atom site.[8,10]

The nitrosyl ligand/Lewis acid interactions have been found to sometimes play a key role in organic (organometallic) syntheses and reactions. For example, the catalytic oxidation of alcohols by a cobalt nitro/nitrosyl couple with the use of molecular oxygen as an oxidant was found to be facilitated by Lewis acids such as $BF_3{\cdot}Et_2O$ or $LiPF_6$.[11] The effects of the Lewis acids in the reaction were attributed to their interactions with nitro and nitrosyl ligands. In dinitrosyl complexes Re(H)(NO)$_2$(PR$_3$)$_2$ (R = *i*Pr, Cy), one nitrosyl group was found to be capable of coordinating to one or two $BF_3$ molecules, and the interaction of a second $BF_3$ molecule caused the bending of the nitrosyl group; thus, a new coordination site in the metal sphere is provided.[12] The coordination of the nitrosyl group to the lithium ions in the compounds [Cp*Mo(NO)(CH$_2$SiMe$_3$)-(=CHSiMe$_3$)]$_2$[Li$_2$(THF)$_3$], [($\eta^5$,$\eta^1$-C$_5$Me$_4$CH$_2$)Mo(NO)-(CH$_2$Si- Me$_3$)$_2$][Li(THF)$_3$], and {[Cp*Mo(NO)(CH$_2$SiMe$_3$)$_2$]-[Li(THF)]}$_2$ was thought to further stabilize the corresponding anionic complexes thus facilitating the isolations of these species.[13] Despite the apparent significance of coordinated nitrosyl ligand/Lewis acid interactions, studies on such interactions are relatively rare[14] in contrast to the rich chemistry of the Lewis basicity of coordinated carbonyl ligands.[15] We describe here the isolation and structural characterization of the compounds formed by *trans*-Mo-(dmpe)$_2$(Cl)(NO) (**1**) [dmpe = bis(dimethylphosphanyl)-ethane] with lithium reagents. To the best of our knowledge, fully structurally characterized adducts formed by neutral nitrosyl complexes with metal ions by the coordination of bound nitrosyl have not yet been reported.

## Results

### Preparation and Characterization of 2, 3, and 4

#### *Complex 2*

Treatment of **1** with 1 equiv. of lithium triethylborohydride in diethyl ether did not provide the product of a H/Cl

metathetical reaction, but the polymeric **1**/$LiHBEt_3$ adduct of $[Mo(dmpe)_2(Cl)(NO)LiHBEt_3]_n$ (**2**), [Equation (1)] which was isolated as yellow crystals in 88% yield after slow evaporation of the solvent at room temperature. Complex **2** is apparently stable enough to resist hydride formation and no further conversion was observed even under forced reaction conditions, for example, the application of up to 5 equiv. of lithium triethylborohydride and heating to 50 °C for two days. Complex **2** has been characterized by IR spectroscopy, NMR spectroscopy, elemental analysis, and a single-crystal X-ray diffraction study. The IR spectrum of **2** in a Nujol mull shows a nitrosyl stretching band at 1486 $cm^{-1}$, which is 52 $cm^{-1}$ lower in energy than the corresponding nitrosyl band of **1** ($\nu_{NO}$ = 1538 $cm^{-1}$ in Nujol). The lowering of the nitrosyl stretching frequency typically indicates the coordination of the $O_{NO}$ atom to the lithium ion. The $^1$H- and $^{13}C\{^1H\}$ NMR spectra of **2** in $C_6D_6$ display all of the resonances that correspond to the $Mo(dmpe)_2(Cl)(NO)$ and $LiHB(C_2H_5)_3$ moieties. The chemical shifts of the $^1$H-, $^{13}$C-, and $^{31}$P NMR resonances for the $Mo(dmpe)_2(Cl)(NO)$ moiety in **2** are similar to those exhibited by **1**. The fact that the $^7$Li NMR spectrum shows a singlet at 2.1 ppm and that the $^{11}$B NMR spectrum displays a broad singlet at $\delta$ = –2.76 ppm further confirms the presence of the $LiHB(C_2H_5)_3$ moiety in the molecule. The elemental analysis is in good agreement with the composition of a 1:1 adduct of $Mo(dmpe)_2(Cl)(NO)$ and $LiHBEt_3$.

$$z{\cdot}x\ Mo(dmpe)_2(Cl)(NO) + z{\cdot}y LiX \rightarrow \{[Mo(dmpe)_2(Cl)(NO)]_x(LiX)_y\}_z$$
**2**: $x = y = 1$; $z = \infty$; X = $HBEt_3$
**3**: $x = 1$; $y = 2$; $z = \infty$; X = $N(SiMe_3)_2$
**4**: $x = 3$; $y = 2$; $z = 1$; X = I (1)

### *Complex 3*

The reaction of **1** with lithium bis(trimethylsilyl)amide in diethyl ether produced $\{Mo(dmpe)_2(Cl)(NO)[LiN(SiMe_3)_2]_2\}_n$ (**3**) with a 1:2 ratio of **1** and $LiN(SiMe_3)_2$ [Equation (1)]. It is found that this ratio is independent on the initially employed amounts of lithium bis(trimethylsilyl)amide. Treatment of **1** with an equimolar amount or with 2 equiv. of $LiN(SiMe_3)_2$ always resulted in **3**. In a typical reaction, **3** was isolated as yellow crystals in a yield of 84%. Once it has been isolated **3** is difficult to redissolve in diethyl ether, but is readily soluble in THF. Dissolution of the complex in chlorinated solvents such as $CH_2Cl_2$ and $HCCl_3$ resulted in immediate decomposition. In the IR spectrum of **3** (in Nujol) the nitrosyl stretching band appears at 1489 $cm^{-1}$. This value is 49 $cm^{-1}$ lower than that of precursor **1** ($\nu_{NO}$ = 1538 $cm^{-1}$). The decrease in the nitrosyl stretching frequency is again indicative of the coordination of the $O_{NO}$ atom. The $^1$H NMR spectrum of **3** in $[D_8]$THF displays two multiplets at $\delta$ = 1.68 and 1.55 ppm and two singlets at 1.48 and 1.43 ppm, which correspond to the resonances of the methylene and methyl groups of the dmpe ligands, respectively. The signal for the $SiMe_3$ moieties is observed as a singlet at $\delta$ = –0.16 ppm. The $^{13}$C- and $^{31}$P NMR spectra for the $Mo(dmpe)_2(Cl)(NO)$ moiety are similar to those exhibited by **1**. The $^{13}$C NMR resonance for the $SiMe_3$ group appears as a singlet at 6.2 ppm. In the $^7$Li NMR spectrum, a singlet is found at $\delta$ = 4.26 ppm, which, together with its resemblance to the $^1$H- and $^{13}$C NMR spectra of **1**, may imply dissociation of **3** in THF.

### *Complex 4*

To extend the scope of these investigations, the capability of **1** to form adducts with inorganic lithium salts has also been probed. According to literature reports, lithium halides form an extremely variable and structurally diverse family of complexes with simple nitrogen- or oxygen-containing ligands.[16] However, compounds of lithium halides with complexes as ligands have been reported only in rare instances.[17] An in situ generation of the lithium halide has been proven to be superior for the syntheses of its adducts.[16] Thus, the reactions of a **1**/*n*BuLi mixture with *n*BuCl, $SiMe_3Cl$, and *n*BuBr were investigated. They failed to produce any **1**/LiCl or **1**/LiBr adduct. However, a unique **1**/LiI adduct could be prepared from the reaction of **1**/*n*BuLi with MeI. In a typical batch, complex **1** (0.061 mmol) in toluene (2 mL) was mixed with equimolar amounts of *n*BuLi and iodomethane in that order. The final mixture was left undisturbed at room temperature. Overnight, well-defined crystals of a **1**/LiI adduct $[Mo(dmpe)_2(Cl)(NO)]_3(LiI)_2$ (**4**) precipitated from the solution [Equation (1)], which was isolated in 70% yield. Complex **4** has been characterized by elemental analysis, IR and NMR spectroscopy. The elemental analysis is consistent with the composition of a 3:2 **1**/LiI adduct stoichiometry. The IR spectrum of **4** in Nujol mull displays a nitrosyl band at 1449 $cm^{-1}$, which is 89 $cm^{-1}$ lower than that of precursor **1**. It is worth noting that the decrease in the $\nu_{NO}$ vibration of **4** appears at significantly higher wavenumbers than those observed for **2** and **3**, which is presumably caused by the bridging mode of the nitrosyl oxygen (vide infra). The $^1$H NMR spectrum of **4** in $CD_2Cl_2$ exhibits resonances for the methylene and methyl groups of the dmpe ligands as a multiplet at $\delta$ = 1.51 ppm and as a singlet at $\delta$ = 1.42 ppm. The $^{13}$C NMR spectrum is similar to that exhibited by precursor **1**. The signals for the methylene and the methyl carbon atoms appear at $\delta$ = 29.8 ppm (quintet) and 15.3 and 14.6 ppm (two quintets), respectively. The $^{31}$P NMR spectrum displays a singlet at $\delta$ = 34.6 ppm and in the $^7$Li NMR spectrum a singlet is observed at $\delta$ = 3.28 ppm.

## Structures of 2, 3, and 4

### *Structure of 2*

The molecular structure of **2** has been established by X-ray diffraction analysis. Suitable crystals were obtained by the slow evaporation of a diethyl ether solution. An ORTEP representation of the molecule is shown in Figure 1 and reveals the NO group and chlorine atom disorder. Selected bond lengths and bond angles are listed in Table 1. The striking feature of the structure of **2** is its infinite one-di-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

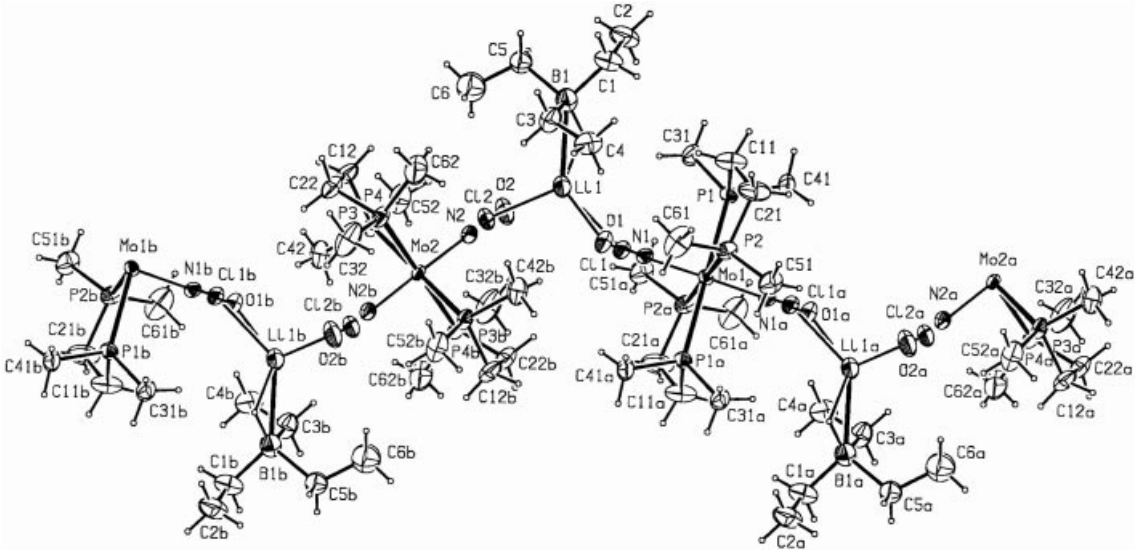

Figure 1. ORTEP plot of the structure of **2**. Displacement ellipsoids are drawn with 50% probability. The chloride and NO group display positional disorder.

mensional "zigzag" chain. The $Mo(dmpe)_2(Cl)(NO)$ moiety acts as a bridging "complex ligand", and two adjacent $LiHB(C_2H_5)_3$ moieties are $O_{NO}$ and Cl connected to the Li atoms by the $Mo(dmpe)_2(Cl)(NO)$ moieties. The two $LiHB(C_2H_5)_3$ moieties on the two sides of a $Mo(dmpe)_2(Cl)(NO)$ molecule create an inversion at the Mo atom center. Infinite repetition of these motifs build a polymeric chain of alternating $Mo(dmpe)_2(Cl)(NO)$ and $LiHB(C_2H_5)_3$ units. The lithium ion of **2** is tricoordinated by oxygen and furthermore by one chlorine and a hydrogen atom. The coordination geometry at the Li center can be described as pseudopyramidal where the three bond angles at the Li center are O1–Li1–H1, Cl2–Li1–H1, and O1–Li1–Cl2 with the values 120.2(9)°, 125.5(9)°, and 103.9(3)°, respectively. The Li1–H1 distance of 1.76(3) Å is comparable to that in the $(LiH)_\infty$ lattice (av. 1.78 Å)[18], but shorter than those found for the complexes containing $Li(\mu_2\text{-}H)_2B$ or $Li(\mu_2\text{-}H)_3B$ bridges (ca. 1.90–2.20 Å).[19] The B1–Li1 distance of 2.420(5) Å is similar to that in $LiBH_4{\cdot}3(py)$ [2.401(7) Å].[20] The O1–Li1 distance of 1.944(6) Å and the Cl2–Li1 distance of 2.329(4) Å are in the normal ranges of O–Li and Cl–Li bond lengths in organolithium compounds.[17] The coordination geometry around Mo is close to that of parent complex **1**, which becomes particularly evident from a comparison of the Mo–P bond lengths and P–Mo–P angles. The Mo1–N1 bond length of 1.832(5) Å and the Mo2–N2 bond length of 1.826(5) Å are shorter than that found in **1** (1.851(4) Å[7b]), whereas the N1–O1 and N2–O2 bond lengths of 1.229(6) and 1.230(5) Å are longer than the N–O distance of 1.187(4) Å in **1**. The shortening of the Mo–N bond and the lengthening of the N–O bond can be explained by the lithium induced enhancement of the Mo→NO back-bonding. The average Mo–Cl bond length is close to that of **1**. The N1–O1–Li1 and Mo2–Cl2–Li1 linkages show a certain extent of bending [145.1(6)° and 156.76(13)°, respectively], which is presumably due to the steric interaction between neighboring $Mo(dmpe)_2(Cl)(NO)$ and $B(C_2H_5)_3$ moieties.

Table 1. Selected bond lengths [Å] and bond angles [°] of **2**.

| Bond lengths | | Bond angles | |
|---|---|---|---|
| Mo1–N1 | 1.832(5) | N1–Mo1–P1 | 87.44(13) |
| Mo1–Cl1 | 2.5088(19) | N1–Mo1–P2 | 92.47(16) |
| Mo1–P1 | 2.4598(5) | Cl1–Mo1–P1 | 91.37(4) |
| Mo1–P2 | 2.4601(5) | Cl1–Mo1–P2 | 86.92(5) |

### *Structure of 3*

The molecular structure of **3**, established by single-crystal X-ray crystallographic analysis, is arranged as an infinite linear chain as shown in Figure 2. The molecular chain can be viewed as being composed of alternating $Mo(dmpe)_2(Cl)(NO)$ moieties and dimeric $[LiN(SiMe_3)_2]_2$ units. Two neighboring units of the dimeric $[LiN(SiMe_3)_2]_2$ part are thus linked by the "complex ligand" of $Mo(dmpe)_2(Cl)(NO)$ acting as a bridging unit. The complex $LiN(SiMe_3)_2$ has previously been reported to be trimeric.[21] The

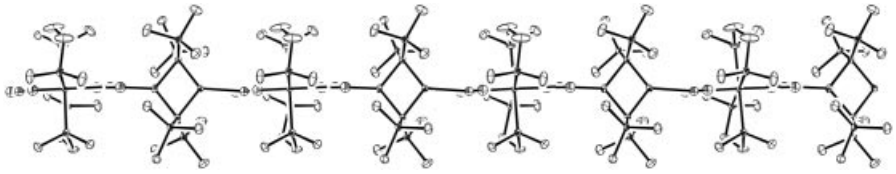

Figure 2. One-dimensional chain structure of **3**. The hydrogen atoms have been omitted for clarity.

solvated species $[Li(Et_2O)N(SiMe_3)_2]_2$[22] and $[Li(THF)N(SiMe_3)_2]_2$[23] were found to be dimeric. Figure 3 displays the asymmetric unit of the structure of **3**. In the dimeric $[LiN(SiMe_3)_2]_2$ unit, each lithium ion possesses a triangular-coordination geometry built up from two nitrogen atoms of the amides and one $O_{NO}$ or a chlorine atom of the $Mo(dmpe)_2(Cl)(NO)$ moiety. The average Li–N distances are 2.034(4) Å for Li1 and 2.053(4) Å for Li2 (Table 2). They are comparable to those distances found in some symmetric dimeric lithium amides such as $[Li\{HN(iPr)_2\}N\text{-}1\text{-}c\text{-}C_6H_9Ph]_2$ (Li–N = 2.05 Å),[24] $[Li(THF)HMCTS]_2$ (Li–N = 2.04 Å),[25] $[Li(THF)NSiMe_3HMCTS]_2$ (Li–N = 2.04 Å)[26] etc. and are in the same range as for $[Li(THF)N(SiMe_3)_2]_2$[23] [2.025(9) Å] and for $[Li(Et_2O)N(SiMe_3)_2]_2$[22] [2.055(5) Å]. However, both bond lengths are longer than those observed in trimeric $[LiN(SiMe_3)_2]_3$ [Li–N = 2.00(2) Å],[21] which is presumably due to the higher coordination number of the Li ion and the bridging mode of the $[N(SiMe_3)_2]^-$ ligand in **3**. The average Li–N–Li angle of 75.76(16)° and N–Li–N angle of 104.24(17)° are similar to related bond angles observed in $[Li(Et_2O)N(SiMe_3)_2]_2$[22] and $[Li(THF)N(SiMe_3)_2]_2$.[23] Because of enhanced Mo→NO back-bonding in the $Mo(dmpe)_2(Cl)(NO)$ moiety of **3**, the average Mo–N bond length of 1.753(6) Å is 0.098 Å shorter and the average N–O bond length of 1.253(7) Å is 0.066 Å longer than the corresponding ones in **1**. The coordination of the chloride ligand to the lithium center does not induce a significant change in the Mo–Cl bond length [2.4937(15) Å in **3** versus 2.4881(14) Å in **1**], which may indicate only a weak interaction of the chlorine atom with the lithium center. In contrast to **2**, the N–O–Li and Mo–Cl–Li linkages are almost straight with average bond angles of 171.8(4)° and 172.94(12)°, which provokes the chain structure of **3**, composed of an MoCl–Li–Li–O–N–Mo backbone, to be linear overall as shown in Figure 2.

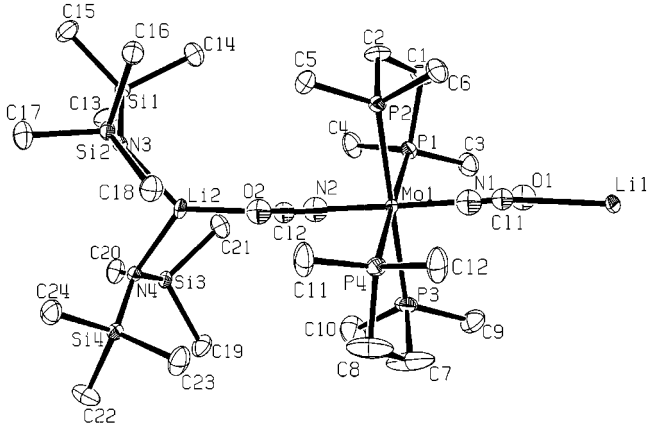

Figure 3. The asymmetrical unit of **3**. Displacement ellipsoids are drawn with 50% probability. The chloride ion and nitrosyl group show disorder.

### *Structure of 4*

An ORTEP plot of **4** is shown in Figure 4. Selected bond lengths and bond angles are listed in Table 3. As shown in Figure 4, complex **4** can be formulated as $\{[Mo(dmpe)_2(Cl)(NO)]_3(LiI)_2\}$ with a 2:3 Li/Mo stoichiometry. Its structure can be described as two unique LiI units that are bridged by the nitrosyl oxygen atoms of three "$Mo(dmpe)_2(Cl)(NO)$ ligands". For LiI-containing adducts 1:1 (Li:ligand), 1:2, and 1:3 monomers,[27] 1:1 and 1:2 dimers,[28] a 1:1 tetramer,[29] and ion-pair coordinated species[30] have been reported. A 2:3 adduct of LiI with 2,4,6-trimethylpyridine (tmpy) was found in fact to be a tetramer with the formulation $[(LiI)_4(tmpy)_6]$.[31] In dimers and higher agglomerates the iodine anion usually acts as a bridging ligand. The observation of the 2:3 stoichiometry and the structural feature of the donor-connected LiI monomers in **4** is quite unusual. To the best of our knowledge, only the case of a $[(LiBr)_2(HMPA)_3(toluene)_{0.5}]$ molecule (HMPA = hexamethylphosphoramide)[32] provides further analogy.

[a] Symmetry transformations used to generate equivalent atoms: $i_1 = x, y, -z+1/2$; $i_2 = -y+1, x-y, z$; $i_3 = -x+y+1, -x+1, z$).

Unlike the three-coordinate Li ion in **2** and **3**, the lithium cation of **4** is tetra-coordinated in a pseudotetrahedral geometry and has one iodine atom and three oxygen atoms of the three "Mo(dmpe)$_2$(Cl)(NO) ligands" attached. In agreement with the higher coordination number of the Li ion in **4**, the O–Li distance of 2.040(10) Å is significantly longer than those observed in **2** and **3** [1.944(6) Å and 1.921(6) Å, respectively]. The I–Li bond length of 2.622(16) Å is particularly short compared with other tetra-coordinated LiI complexes (usually in the range of 2.70 to 2.95 Å[27–31]). The transannular Li–Li "contact" is 2.38(3) Å, which is also particularly short [the shortest Li–Li distance reported in LiI complexes is 3.575(6) Å[29] and in **3** it is 2.509(5) Å]. The observation of unusually short Li–halide and Li–Li distances in **4** is similar to that of the structurally analogous complex [(LiBr)$_2$(HMPA)$_3$-(toluene)$_{0.5}$].[32] In this context, it is noteworthy that the Li–Li distances in both complexes are very close [2.36(3) Å in the LiBr complex]. The Mo–P bond lengths of **4** do not differ significantly from the bond of precursor **1**. However, related Cl–Mo–P bond angles are smaller than those exhibited by **1**, which indicating further bending of the dmpe ligands towards the chlorine side. This bending is apparently due to the mutual repulsion of the three "Mo-(dmpe)$_2$(Cl)(NO) ligands". As a consequence of this bending, the Mo–Cl bond lengths increase distinctly from 2.4881(14) Å in **1** to 2.574(3) Å in **4**.

## Discussion

The reactions of halide-containing transition metal complexes with organic lithium reagents normally afford metathetical products.[7] However, the reaction of **1** with the reagents LiHBEt$_3$, LiN(SiMe$_3$)$_2$, and *n*BuLi led to lithium reagent/**1** adduct formation. This result can be attributed to a relatively strong donicity of the $O_{NO}$ atom in **1** induced by strongly σ-donating dmpe ligands, which cause charge accumulation on the molybdenum center and concomitantly strong electron transfer to the NO group.

Compounds **2**, **3**, and **4** show different **1**/Li ratios and various structural features. Compound **2** exhibits an infinite one-dimensional "zigzag" chain with a 1:1 ratio of **1**/LiHBEt$_3$, whereas compound **3** displays an infinite linear chain with a 1:2 ratio of **1** and LiN(SiMe$_3$)$_2$. The strong bridging ability of the N(SiMe$_3$)$_2^-$ anion eases formation of a polymeric structure for the LiN(SiMe$_3$)$_2$ part. In addition, this is the main reason for **3** to adopt a higher **1**/Li ratio as compared to **1**. In **2** and **3**, complex **1** acts as a bridging ligand by coordinating the $O_{NO}$ and Cl atoms. The capability of the Cl atom to participate in the coordination can be ascribed to the strong Lewis acidic property and high reactivity of the Li$^+$ ion in LiHBEt$_3$ and LiN(SiMe$_3$)$_2$. In contrast to **2** and **3**, complex **4** forms a structure of distinct molecules with a 3:2 **1**/Li ratio. The chlorine atom of **4** is not involved in coordination. The fact that **4** prefers a small unit structure may be ascribed to the relatively small size of the iodine counterion in comparison with the bulky organic anions of **2** and **3** and the competition between the oxygen and iodine bridges. As a result, the $O_{NO}$ atom of **4** adopts a $\mu_2$-bridging coordination mode rather than a terminal mode as in **2** and **3**, which allows for the formation of distinct molecular units in **4**.

The adducts formed from LiHBEt$_3$ and donor ligands have rarely been reported, and although the compounds formed from LiN(SiMe$_3$)$_2$ and LiI with ligands containing O- or N-donor atoms have been well documented, those with a metal complex as a ligand are not. The three compounds described here represent the first examples of lithium adducts with a complex as a ligand. The work documents not only excellent Lewis basicity of the NO ligand, but also shows the great structural diversity that such μ-NO complexation may lead to.

## Conclusions

In summary, the reactions of the chloride complex Mo(dmpe)$_2$(Cl)(NO) (**1**) with the lithium reagents LiHB(C$_2$H$_5$)$_3$, LiN(SiMe$_3$)$_2$, and the mixture of *n*BuLi/MeI did not provide the usual products of a H/Cl metathetical reaction, but rather afforded the adducts of **1** with lithium salts because of the coordination of the nitrosyl group to the lithium ion. A relatively strong donicity of the bound

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nitrosyl group in **1** is indicated, which may be attributed, for the most part, to the effect of the strongly σ-donating dmpe ligands. The two dmpe ligands cause charge accumulation on the molybdenum center and thus enhance the electron density on the nitrosyl oxygen atom. The resulting propensity to act as a σ donor for the nitrosyl oxygen atom may also have implications on the reactivity of **1**, as for instance in the conversion of **1** to the corresponding borohydride $Mo(dmpe)_2(HBH_3)(NO)$, where the isolation of the borohydride proved to be troublesome presumably because of the adduct formation with the alkaline element borohydride starting material.[7b]

## Experimental Section

All reactions and manipulations were carried out under an atmosphere of dry nitrogen with the use of conventional Schlenk techniques or a glove box. Solvents were dried by standard methods and freshly distilled under an atmosphere of nitrogen before use. *trans*-$Mo(dmpe)_2(Cl)(NO)$ (**1**) was prepared as described previously.[7b] Other reagents were purchased from Fluka or Aldrich. NMR spectra were recorded with the following spectrometers: Varian Gemini-300 instrument for $^1$H-, $^{13}$C-, $^{31}$P-, and $^{11}$B NMR; Bruker DRX-500 instrument for $^7$Li NMR. $\delta(^1H)$ and $\delta(^{13}C)$ are relative to $SiMe_4$, $\delta(^{31}P)$ is relative to 85% $H_3PO_4$, $\delta(^{11}B)$ is relative to $BF_3{\cdot}OEt_2$, and $\delta(^7Li)$ is relative to $LiClO_4$ in $H_2O$. IR spectra were recorded with a Biorad FTS-45 instrument. Elemental analyses were performed with a Leco CHN(S)-932 instrument.

**$[Mo(dmpe)_2(Cl)(NO)LiHB(C_2H_5)_3]_n$ (2):** A lithium triethylborohydride solution (0.13 mL, 1.0 M solution in THF) was added to a solution of **1** (0.055 g, 0.12 mmol) in diethyl ether (15 mL). The mixture was stirred for 3 h and then left undisturbed at room temperature to allow the solvent to evaporate. Slow evaporation of the diethyl ether for 3 d provided **2** as yellow crystals that were suitable for an X-ray diffraction study. Yield: 0.060 g (88%). IR (Nujol): $\tilde{\nu}$ = 1486 (NO) cm$^{-1}$. $^1$H NMR (300.1 MHz, $C_6D_6$): $\delta$ = 1.43 (m, 4 H, $PCH_2$), 1.24 (m, 4 H, $PCH_2'$), 1.32 (s, 12 H, PMe), 1.28 (s, 12 H, PMe′), 1.21 [t, $^3J_{H,H}$ = 7.2 Hz, 9 H, Me of $B(C_2H_5)_3$], 0.85 [m, 6 H, $CH_2$ of $B(C_2H_5)_3$] ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $C_6D_6$): $\delta$ = 29.5 (quint, $^1J_{C,P}$ = 9.7 Hz, $PCH_2$), 15.0 (quint, $^1J_{C,P}$ = 5.0 Hz, PMe), 14.5 (quint, $^1J_{C,P}$ = 5.0 Hz, PMe′), 15.5 [br., $CH_2$ of $B(C_2H_5)_3$], 11.2 [br., Me of $B(C_2H_5)_3$] ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $C_6D_6$): $\delta$ = 34.6 (s) ppm. $^{11}$B NMR (96.2 MHz, $C_6D_6$): $\delta$ = –2.76 (s, br) ppm. $^7$Li NMR (194.4 MHz, $C_6D_6$): $\delta$ = 2.10 (s) ppm. $C_{18}H_{48}BClLiMoNOP_4$ (567.63): calcd. C 38.08, H 8.54, N 2.47; found C 38.33, H 8.17, N 2.44.

**$\{Mo(dmpe)_2(Cl)(NO)[LiN(SiMe_3)_2]_2\}_n$ (3):** A mixture of **1** (0.022 g, 0.048 mmol) and lithium bis(trimethylsilyl)amide (0.017 g, 0.102 mmol) was dissolved in diethyl ether (15 mL) and the resulting solution was stirred for 3 h. The solvent was then evaporated slowly at room temperature for 4 d to afford **3** as yellow crystals. Yield: 0.032 g (84%). IR (Nujol): $\tilde{\nu}$ = 1489 (NO) cm$^{-1}$. $^1$H NMR (300.1 MHz, [D$_8$]THF): $\delta$ = 1.68 (m, 4 H, $PCH_2$), 1.55 (m, 4 H, $PCH_2'$), 1.48 (s, 12 H, PMe), 1.43 (s, 12 H, PMe′), –0.16 (s, 36 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, [D$_8$]THF): $\delta$ = 30.6 (quint, $^1J_{C,P}$ = 10 Hz, $PCH_2$), 15.0 (quint, $^1J_{C,P}$ = 5.0 Hz, PMe), 14.8 (quint, $^1J_{C,P}$ = 5.0 Hz, PMe′), 6.2 (s, $SiMe_3$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, [D$_8$]THF): $\delta$ = 36.3 (s) ppm. $^7$Li NMR (194.4 MHz, [D$_8$]THF): $\delta$ = 4.26 (s) ppm. $C_{24}H_{68}ClLi_2MoN_3OP_4Si_4$ (796.34): calcd. C 36.19, H 8.62, N 5.28; found C 36.52, H 8.40, N 5.31.

**$[Mo(dmpe)_2(Cl)(NO)]_3(LiI)_2$ (4):** A butyllithium solution (0.038 mL, 0.061 mmol, 1.6 M solution in hexane) and iodomethane (3.8 μL, 0.061 mmol) were added to a solution of **1** (0.028 g

(0.061 mmol) in toluene (ca. 2 mL). The mixture was stirred to obtain a homogeneous solution and then stood undisturbed at room temperature overnight. Large orange crystals of **4** were obtained. Yield: 0.023 g (70%). IR (Nujol): $\tilde{\nu}$ = 1449 (NO) $cm^{-1}$. $^1H$ NMR (300.1 MHz, $CD_2Cl_2$): $\delta$ = 1.51 (m, 8 H, $PCH_2$), 1.42 (s, 24 H, PMe) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CD_2Cl_2$): $\delta$ = 29.8 (quint, $^1J_{C,P}$ = 9.6 Hz, $PCH_2$), 15.3 (quint, $^1J_{C,P}$ = 4.7 Hz, PMe), 14.6 (quint, $^1J_{C,P}$ = 4.7 Hz, PMe′) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_2Cl_2$): $\delta$ = 34.6 (s) ppm. $^7Li$ NMR (194.4 MHz, $CD_2Cl_2$): $\delta$ = 3.28 (s) ppm. $C_{36}H_{96}Cl_3I_2Li_2Mo_3N_3O_3P_{12}$ (1652.73): calcd. C 26.16, H 5.87, N 2.54; found C 26.29, H 6.11, N 2.71.

**X-ray Crystal Structure Analyses:** The X-ray diffraction data were collected at 173(2) K (**2**), 123(2) K (**3**), and 183(2) K (**4**) with the use of an imaging plate detector system (Stoe IPDS) with graphite monochromated Mo-$K_\alpha$ radiation. A total of 180, 167, and 167 images were exposed at constant times of 4.00, 3.00, and 2.80 min/image for compounds **2**, **3**, and **4**, respectively. The crystal-to-image distances were set to 50, 50, and 60 mm, respectively. The corresponding $\theta_{max}$ values were 30.29°, 30.29°, and 27.99°, respectively. $\phi$-oscillation (**2**, **3**) or rotation scan modes (**4**) were selected for the $\phi$ increments of 1.0°,1.2°, and 1.2° per exposure in each case. Total exposure times for the three compounds were 25, 20, and 19 hours, respectively. After integrations and corrections for Lorentz and polarization effects, a total of 8000 reflections were selected out of the whole limiting sphere for the cell-parameter refinements. A total of 30218, 49957, and 33867 reflections were collected, of which 8134, 12831, and 2899 reflections were unique ($R_{int}$ = 4.74%, 4.93%, and 4.90%); data reduction and numerical absorption corrections used 15, 18, and 17 indexed crystal faces.[33] The structures were solved by the Patterson method with the use of the program SHELXS-97,[34] and they were refined with SHELXL-97.[35] The X-ray data collections and the processing parameters are given in Table 4.

CCDC-606806 -606808 (for **2**, **3**, and **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Characterization of Some New 22-Membered Chalcogenoaza Macrocycles and Their $Co^{II}$ and $Ni^{II}$ Complexes

**Upali Patel,[a] Harkesh B. Singh,*[a] and Ray J. Butcher[b]**

**Keywords:** Cobalt / Magnetic properties / N ligands / Selenium / Tellurium

The [2+2] cyclocondensation of bis(*o*-formylphenyl)chalcogenides (**9**, **10**) with *trans*-1,2-diaminocyclohexane affords novel macrocyclic ligands **11** and **12** in very good yields. Crystals of **11** are triclinic, space group $P\bar{1}$ with $a$ = 11.4037(11), $b$ = 11.8184(12), $c$ = 14.6835(14) Å, $Z$ = 4 and those of **12** are triclinic, space group $P\bar{1}$ with $a$ = 11.2692(9), $b$ = 12.8612(11), $c$ = 15.2439(12) Å and $Z$ = 2. Reduction of **11** with sodium borohydride affords macrocycle **13**. The coordination chemistry of **11** has been studied with the "hard" metal ions $Ni^{II}$ and $Co^{II}$. Reaction of $NiCl_2{\cdot}6H_2O$ with one molar equivalent of **11** in refluxing methanol followed by addition of $NH_4PF_6$ affords $Ni^{II}$ complex **14**. The assignment of an octahedral geometry to **14** follows from its paramagnetism ($\mu_{eff}$ = 2.50 $\mu_B$) and UV/Vis spectrum and was further confirmed by single-crystal X-ray diffraction studies. The crystal structure of **14** consists of a distorted octahedral nickel center coordinated by two selenium and four nitrogen atoms. Complex **14**: hexagonal, space group $P6_1$, $a$ = 17.0747(16), $b$ = 17.0747(16), $c$ = 29.958(4) Å, $Z$ = 6. $Co^{II}$ complexes **15** and **16** of selenaaza macrocycles were prepared by the reaction of $Co(ClO_4)_2{\cdot}6H_2O$ with **11** and **3**, respectively. Complex **16**: monoclinic, space group $C_2$, $a$ = 17.160(2), $b$ = 10.9660(14), $c$ = 9.4941(12) Å, $Z$ = 2. The cyclic voltammograms of **15** and **16** in MeCN solution show well-behaved quasi-reversible couples.

## Introduction

Over the last decade mixed-donor chalcogen (N, O, S, Se, Te) macrocycles have attracted considerable attention.[1–7] Among them, the chalcogenoaza macrocycles containing heavier chalcogens (Se, Te) have been less studied. Our group has been involved in the synthesis and complexation studies of Schiff base selenaaza and telluraaza macrocycles **1**–**5**.[6,7] Interestingly, Schiff base macrocycle **2** shows a tendency to undergo transmetalation with $Pt^{II}$ and $Hg^{II}$ cations,[6a] and **1** hydrolyzed with $Pd^{II}$ cation leads to cleavage of the macrocycle.[6b] Macrocycles **5** and **6** exhibit contrasting ligating behavior with $Pd^{II}$ and $Pt^{II}$. Thus, macrocycle **5** forms a 23-membered metallamacrocycle on ligation with $Pt^{II}$ where oxidative addition of the C–Se bond to the $Pt^{II}$ center occurs to form a hexacoordinate $Pt^{IV}$ complex.[7c] The synthesis and structure of complexes of $Hg_2^{2+}$ and $Pb^{II}$ with 28-membered selenaaza macrocycle **4** have also been reported.[7d] There are limited examples of $Ni^{II}$ complexes of mixed-donor selenaaza macrocycles,[7b,7e] and there are no reports on the structures of $Co^{II}$ complexes of selenaethers or selenaaza macrocycles in the literature. However, two examples of structurally characterized $Co^{III}$ complexes of selenamacrocycles have been reported. The $Co^{III}$ complex of sarcophagine theme, with an N3Se3 donor (**7**), has been obtained from the reaction of $CoCl_3$ with $\{MeC[CH_2Se(CH_2)_2{-}NH_2]_3\}$ in HCHO and $MeNO_2$.[5] The complex $[CoX_2([16]aneSe_4)]PF_6$ (X = Br) (**8**) has been prepared by the reaction of $CoX_2$ (X = Cl, Br, I) with $[16aneSe_4]$ and $NH_4PF_6$, where the original $Co^{II}$ has been oxidized to $Co^{III}$.[8] Here we report the synthesis and characterization of some new 22-membered selenaaza and telluraaza macrocycles derived from *trans*-1,2-diaminocyclohex-

ane, which imposes some rigidity on the macrocycle ring, and the coordination properties of the selenaaza macrocycles towards $Co^{II}$ and $Ni^{II}$. Although we have earlier reported the synthesis of a $Co^{II}$ complex with **1**, our attempts to characterize the complex by single crystal structure determination were unsuccessful.[7b] Now we report the first X-ray structural characterization of a $Co^{II}$ complex with a selenaaza macrocycle and its detailed magnetic properties. The coordination behavior of the telluraaza macrocycles with $Pd^{II}$ is also studied.

## Results and Discussion

Compounds **3**,[7b] **9**,[7a] and **10**[6a] were synthesized by the reported procedures. Ligands **11** and **12** were obtained in good yield by the stoichiometric reaction of bis(*o*-formylphenyl) chalcogenides **9** and **10** with *trans*-1,2-diaminocyclohexane as white and yellow solids, respectively (Scheme 1). Reduction of Schiff-base ligand **11** with an excess amount of sodium borohydride in ethanol afforded tetraamino derivative **13** as a white solid in good yield (Scheme 1). All these ligands were characterized by elemental analysis, IR-, $^1$H-, $^{13}$C-, and $^{77}$Se/$^{125}$Te NMR spectroscopy, and ESI mass spectrometry. Both of the Schiff-base ligands (**11**, **12**) were also characterized by single-crystal X-ray crystallography.

For ligand **11**, broadening of the $^1$H- and $^{13}$C NMR signals was observed at room temperature; hence the spectra were recorded at –50 °C. There were no significant changes in the $^1$H NMR spectrum even at –50 °C. However, the $^{13}$C NMR spectrum shows two sets of well-resolved peaks at low temperature, which may be due to the fluxional behavior of **11**.

The observation of single signals in the $^{77}$Se NMR spectra of the macrocycles **11** and **13** confirmed the equivalence of the selenium atoms. The $^{77}$Se NMR signals are observed at $\delta$ = 404 and 340 ppm for **11** and **13**, respectively. These values are comparable to the corresponding values for 22-membered selenaaza Schiff base **1** and reduced derivative **5**.[7b] Ligand **12** exhibits the $^{125}$Te NMR signal at $\delta$ = 581 ppm.

### Crystal Structures of 11 and 12

An ORTEP view of **11** is shown in Figure 1 and selected bond lengths and angles are listed in Table 1. The compound crystallizes in the triclinic crystal system with the space group $P\bar{1}$. N1A and N2A are intramolecularly coordinated to Se1 and Se2, respectively, making the geometry around selenium T-shaped. The Se1···N1A and Se2···N2A bond lengths (2.816 and 2.782 Å, respectively) are only slightly longer than the Se···N distance observed for 22-membered selenaaza macrocycles **1** and **5**[7b,7e] (2.723 and 2.729 Å, respectively). The Se1···N1B and Se2···N2B the distances (4.409 and 4.322 Å, respectively) are longer than the sum of the van der Waals radii (3.5 Å) and indicate no intramolecular interaction. Surprisingly, the transannular Se···Se distance (5.881 Å) is longer than that in **1** (3.808 Å).[7b] The bond angles C1A–Se1–C1B and C20A–Se2–C20B are 97.79(13)° and 97.10(13)°, respectively, and are smaller than those of macrocycle **1** [100.2(3)°].

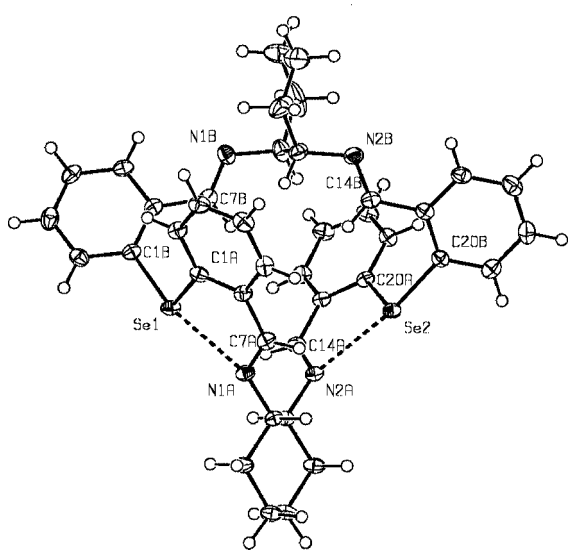

Figure 1. ORTEP diagram of **11**.

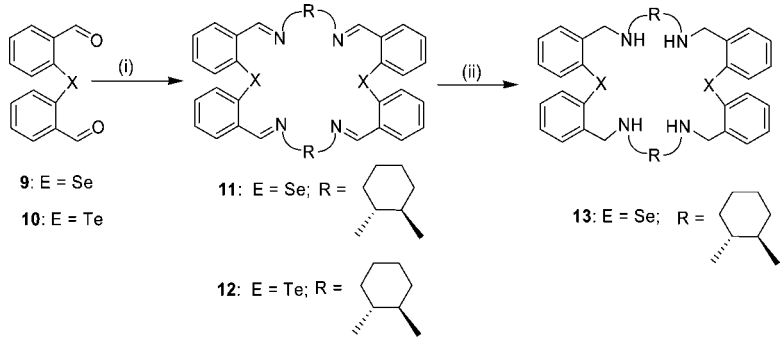
An ORTEP view of compound **12** is represented in Figure 2 and selected bond lengths and angles are listed in Table 2. Similar to macrocycle **11**, only one of the nitrogen atoms is coordinated to each tellurium in **12**. The



Scheme 1. Reagents: (i) *trans*-1,2-diaminocyclohexylamine, $CH_3CN$; (ii) $NaBH_4$, EtOH, reflux.

Table 1. Significant bond lengths [Å] and angles [°] for **11**.

| | | | |
|---|---|---|---|
| Se1–C1A | 1.917(3) | Se1–C1B | 1.927(3) |
| Se2–C20A | 1.921(3) | Se2–C20B | 1.932(3) |
| N1A–C7A | 1.259(4) | N2A–C14A | 1.263(4) |
| C1A–Se1–C1B | 97.79(13) | C20A–Se2–C20B | 97.10(13) |

Te2···N2B#2 and Te2#2···N2B bond lengths are 2.662 and 2.667 Å, respectively, and are similar to the Te···N bond length of 2.701 Å in **2**.[6a] The Te2#2···N1B#2 (4.707 Å) and Te2···N1B (4.708 Å) distances indicate no intramolecular interaction. The transannular Te···Te distance (4.904 Å) is comparable to that observed for the 22-membered telluraza macrocycle **2** (4.979 Å)[6a] and longer than the sum of the van der Waals radii (4 Å). The C1B–Te2–C20B#2 bond angle is 94.49°, which is comparable to that observed for telluraaza macrocycle **2**. The packing diagram shows hydrogen bonding between the macrocyclic N atom and the H of solvent dichloromethane.

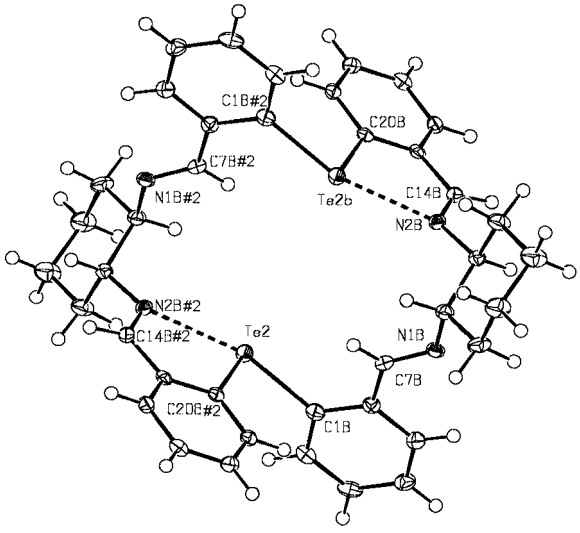

Figure 2. ORTEP diagram of **12**.

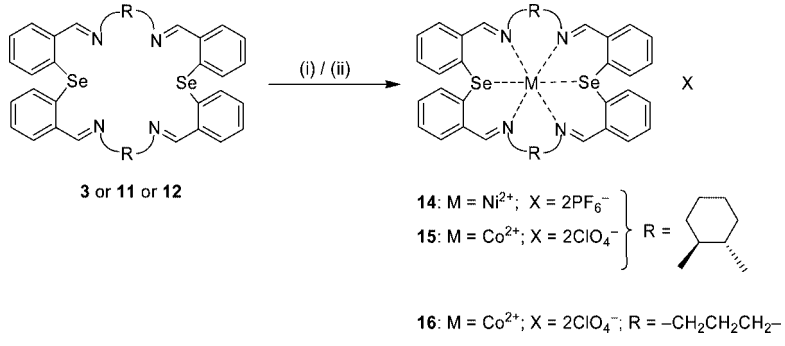
## Complexation

With the objective of synthesizing metal complexes, macrocycles **11**, **3**, and **12** were treated with the transition metal ions $Ni^{II}$, $Co^{II}$, and $Pd^{II}$ in a 1:1 molar ratio to afford complexes **14**, **15**, **16**, and **17**.

### *Complex 14*

Refluxing equimolar amounts of ligand **11** and $NiCl_2·6H_2O$ in a 1:1 ratio and subsequent addition of ammonium hexafluorophosphate gave reddish-brown, air-stable complex **14** (Scheme 2). The IR spectrum of **14** shows the presence of the $PF_6^-$ anion [$\nu$(P–F) = 848, $\delta$(F–P–F) = 565 $cm^{-1}$] and also displays the characteristic $\nu$(C=N) stretching frequency at 1627 $cm^{-1}$, which is shifted slightly compared with the $\nu$(C=N) of free ligand **11** (1642 $cm^{-1}$). The electronic spectrum (UV/Vis) of complex **14** was recorded at room temperature in $CH_3CN$. It shows four bands at 218 (12752), 348 (613), 450 (123) and 850 nm (50 $M^{-1}cm^{-1}$), which can be assigned to the intraligand π–π* and $^3A_{2g}\rightarrow{}^3T_{1g(P)}$, $^3A_{2g}\rightarrow{}^3T_{2g}$, and $^3A_{2g}\rightarrow{}^3T_{1g(F)}$ transitions, respectively.[9] The assignment of an octahedral geometry to complex **14** [Ni(**11**)]$(PF_6)_2$ follows from its paramagnetism ($\mu_{eff}$ = 2.50 $\mu_B$), which indicates an $n = 2$, $S = 1$ high-spin complex with two unpaired electrons. This was further confirmed by single-crystal X-ray studies (vide infra). As expected for octahedral $Ni^{II}$ complexes, complex **14** is ESR silent.[10,11]

The structure of **14** (Figure 3) shows that $Ni^{II}$ occupies the macrocycle cavity and is bonded to all four nitrogen and two selenium donors to complete the distorted octahedral geometry [Ni–N2A = 2.052(5), Ni–N1B = 2.086(5), Ni–N1A = 2.059(5), Ni–N2B = 2.095(5), Ni–Se2 = 2.508(10), and Ni–Se1 = 2.510(10) Å; Table 3]. The average Ni–Se distance (2.509 Å) is comparable to the average Ni–Se distance (2.52 Å) observed for [Ni(**1**)]$(PF_6)_2$ but smaller than the average Ni–Se distances in [Ni(**3**)]$(PF_6)_2$[7b] (2.568 Å) and



Scheme 2. Reagents: (i) $NiCl_2·6H_2O$, $NH_4PF_6$, MeOH; (ii) $Co(ClO_4)_2·6H_2O$, $CH_3CN$.

$[Ni(\mathbf{5})](PF_6)_2$ (2.618 Å).[7e] The C1A–Se1–C1B angle [98.3(3)°] differs slightly from that of the ligand (97.79°). The angles around the central metal atom lie in the range 77.8(2)–101.54(19)° for those involving mutually *cis* donor atoms and 165.22(14)–179.12(17)° for the mutually *trans* donor atoms, thereby deviating only slightly from those expected for a regular octahedral geometry.

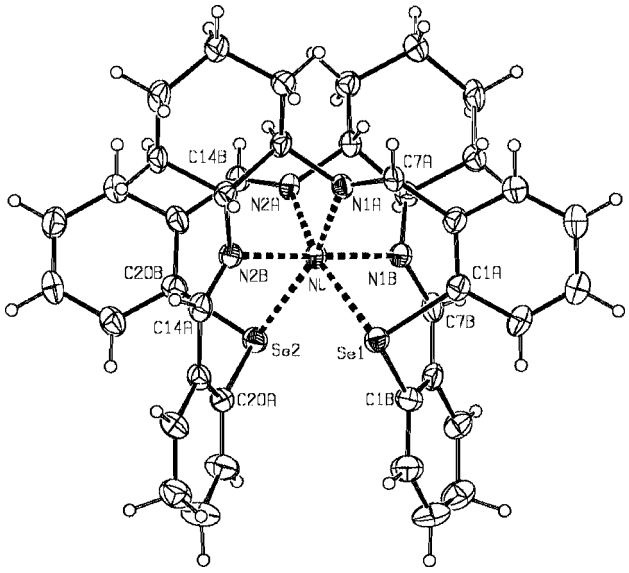

Figure 3. ORTEP diagram of **14** ($PF_6$ anion and H atoms have been omitted for clarity).

Table 3. Significant bond lengths [Å] and angles [°] for **14**.

### *Complex 15*

The reaction of ligand **11** and $Co(ClO_4)_2{\cdot}6H_2O$ in a 1:1 ratio afforded brown complex **15**. Complex **15** is soluble in $CH_3CN$ and acetone but decomposes in DMSO. The IR spectrum shows the $\nu$(C=N) band shifted from 1642 to 1617 $cm^{-1}$, thus implying the coordination of all the imine nitrogens to the metal. The molecular ion peak is not observed in the ESI mass spectrum of the complex, although the peaks at $m/z$ = 894 and 795 correspond to $[M - ClO_4]^+$ and $[M - 2ClO_4]^+$, respectively, and confirm the formation of complex **15**. The bands at 222 (15162) and 356 nm (1487) in the UV/Vis spectrum can be assigned to intraligand π–π* transitions and the band at around 546 nm (218) is due to the $^4T_{1g(F)} \rightarrow {}^4T_{1g(P)}$ transitions. The cyclic voltammogram in acetonitrile solution reveals a quasireversible wave at $E_{1/2}$ = 0.236 V versus saturated calomel electrode (SCE) with a $\Delta E$ value of 0.070 V.

### *Complex 16*

$Co^{II}$ complex **16** was synthesized similarly with a 1:1 ratio of ligand **3** and $Co(ClO_4)_2{\cdot}6H_2O$ in acetonitrile. This complex is also soluble in acetone and acetonitrile but decomposes in DMSO. The elemental analysis data of complex **16** suggest the formation of a 1:1 product. The IR spectroscopic measurements show that the $\nu$(C=N) absorption of **16** has shifted from 1642 to 1627 $cm^{-1}$. In the ESI mass spectrum the highest recorded peak for complex **16** is found at $m/z$ = 814 and can be assigned to $[\mathbf{16} - ClO_4]^+$,which confirms the formation of the complex. The cyclic voltammetric study shows a well-behaved, quasireversible redox wave with $E_{1/2}$ = 0.249 V versus saturated calomel electrode (SCE) and a $\Delta E$ value of 0.062 V. The UV/Vis spectrum of **16** consists of three bands at 224 (18141), 354 (1734), 546 nm (285) due to π–π* and d–d transitions. The structure was confirmed by X-ray crystallographic studies.

Selected bond lengths and angles are given in Table 4 and the ORTEP diagram is shown in Figure 4. The complex crystallizes in the triclinic system with space group $C_2$. The $Co^{II}$ ion is bound to the hexadentate macrocycle **3** by two selenium donors and four nitrogen donors. The notable feature of this structure is the $Co^{II}$–Se intermolecular interaction: the $Co^{II}$–Se distances [Co–Se1 = 2.593(6), Co–Sea = 2.593(6) Å] are longer then the $Co^{III}$–Se distance (2.340 Å) observed in the structure of macrobicyclic cage $[CoL]^{3+}$ (L = 8-methyl-1-nitro-6,10,19-triselena-3,13,16-triazabicyclo-[6.6.6]icosane) (**7**).[5] The angles around the central metal atom lie in the range 84.22(9)–98.89(18)° for those involving mutually *cis* donor atoms and 171.12(9)–174.6(2)° for those mutually *trans* donor atoms. Thus, they do not deviate greatly from the values of 90° and 180° expected for a regular octahedron. The Co–N bond lengths are Co–N1 = 2.128(3), Co–N1#1 = 2.129(3), Co–N2#1 = 2.157(3), and Co–N2 = 2.157(3) Å. The Se–C distances [Se–C17#1 = 1.927(4), Se–C1 = 1.928(3), C17–Se#1 = 1.927(4) Å] are comparable to the parent ligand and are close to the sum of the Pauling covalent radii for selenium (1.17 Å) and an $sp^2$-hybridized carbon (0.74 Å). The C–Se–C angle [C17#1–Se–C1 = 96.56(15)°, C17#1–Se–C = 97.44(11)°] deviate slightly from the C–Se–C angle (97.44°) in the ligand.

Table 4. Significant bond lengths [Å] and angles [°] for **16**.

| | | | |
|---|---|---|---|
| Co–N1 | 2.128(3) | Co–N1#1 | 2.129(3) |
| Co–N1#1 | 2.129(3) | Co–N2#1 | 2.157(3) |
| Co–N2 | 2.157(3) | C17–Se#1 | 1.927(4) |
| Co–Se | 2.5931(6) | Co–Se#1 | 2.5931(6) |
| Se–C17#1 | 1.927(4) | Se–C1 | 1.928(3) |
| N1–C7 | 1.290(5) | N2–C11 | 1.262(6) |

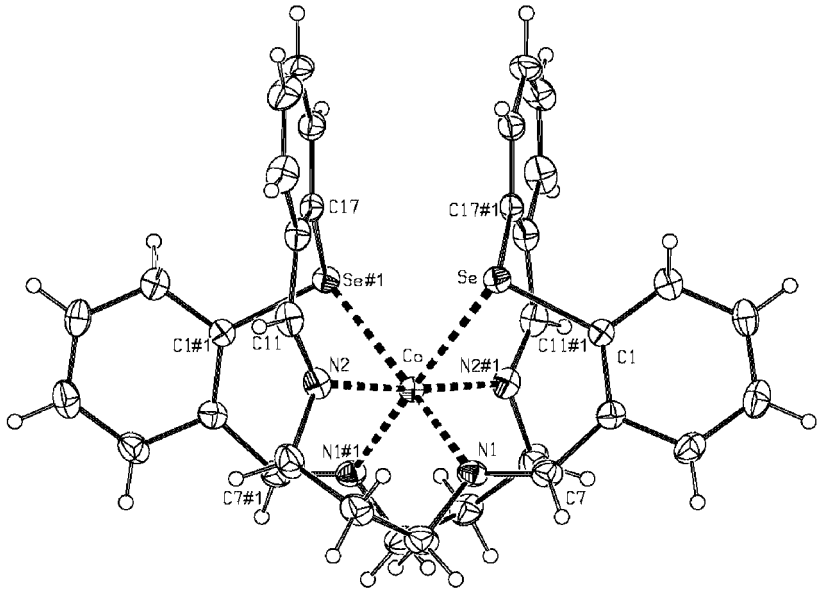

Figure 4. ORTEP diagram of **16** ($ClO_4$ has been omitted for clarity).

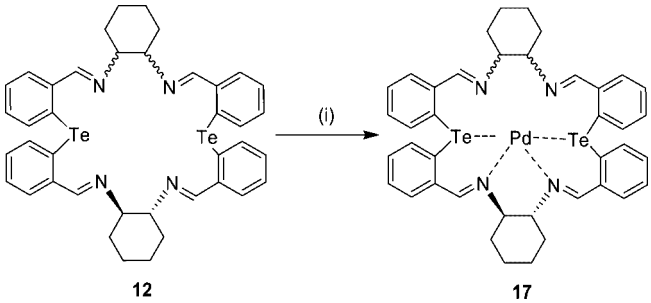
### *Complex 17*

The reaction of **12** with $[PdCl_2(C_6H_5CN)_2]$ followed by the addition of an excess amount of ammonium hexafluorophosphate afforded yellow complex **17** (Scheme 3). The elemental analysis data suggest the formation of a 1:1 ligand/metal complex. The $^1H$ NMR spectrum exhibits two sets of signals for each kind of proton. Two singlets at $\delta$ = 8.5 and 9.0 ppm are observed for the imine protons, with one singlet being shifted downfield from $\delta$ = 8.5 ppm (for the parent imine proton) to $\delta$ = 9.0 ppm. The N-C*H*-$CH_2$ protons also appear as two singlets, with one of these singlets being shifted downfield relative to the parent compound. The $^{13}C$ NMR spectrum also shows two sets of signal. The $^{125}Te$ NMR signal of complex **17** at $\delta$ = 751 ppm is shifted downfield relative to the parent compound ($\delta$ = 581 ppm), which indicates that tellurium is coordinated to the palladium. All NMR spectroscopic data confirm the coordination of the two imine nitrogens and two telluriums to palladium to form a square-planar geometry around it,[6c] which explains the two sets of signals, one for the coordinated part and another for the uncoordinated part. In the ESI mass spectrum the peaks at *m*/*z* = 934 and 1085 correspond to $[M - 2PF_6]^+$ and $[M - PF_6]^+$ and confirm the formation of complex **17**.



Scheme 3. Reagents: (i) $[PdCl_2(C_6H_5CN)_2]$, $CHCl_3/CH_2Cl_2$.

### Magnetic Properties and ESR Data of 15 and 16

The thermal dependence of the molar magnetic susceptibility ($\chi_M$) vs. *T* plot and the $\mu_{eff}$ vs. *T* plot are shown in the Figure 5. The molar magnetic susceptibility ($\chi_M$) increases with a decrease in temperature, as expected for normal paramagnetic samples. The magnetic moment measurement in the temperature range 4 K ($\mu_{eff}$ = 1.3 $\mu_B$) to 300 K ($\mu_{eff}$ = 2.3 $\mu_B$) implies that compound **15** is a low-spin $Co^{II}$ complex ($t_{2g}^6 e_g^1$) with one unpaired electron.

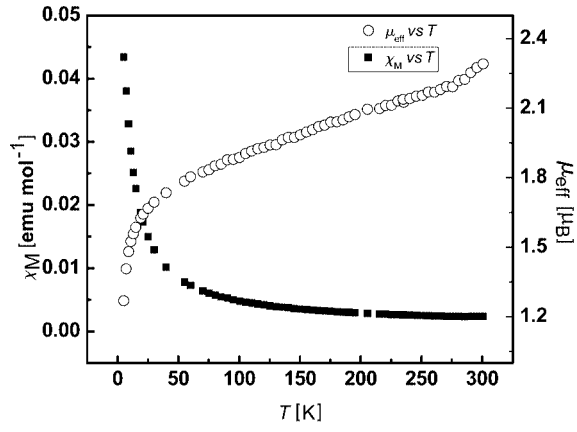


Figure 5. Magnetic properties of **15**: $\chi_M$ vs. *T* plot and $\mu_{eff}$ vs. *T* plot.

The distinct axial-type EPR spectrum of complex **15** is shown in Figure 6 ($g_1 = g_2 = 2.19$, $g_3 = 2.03$). The complex does not show a clear EPR signal at 298 K, which may be due to spin-lattice relaxation of the $Co^{II}$ ion in an octahedral field at room temperature.[12] However, the signal starts developing from 268 K downwards (shown in Figure 6). The hyperfine splitting due to $^{57}Co$ ($I$ = 5/2) is not seen even at 77 K.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

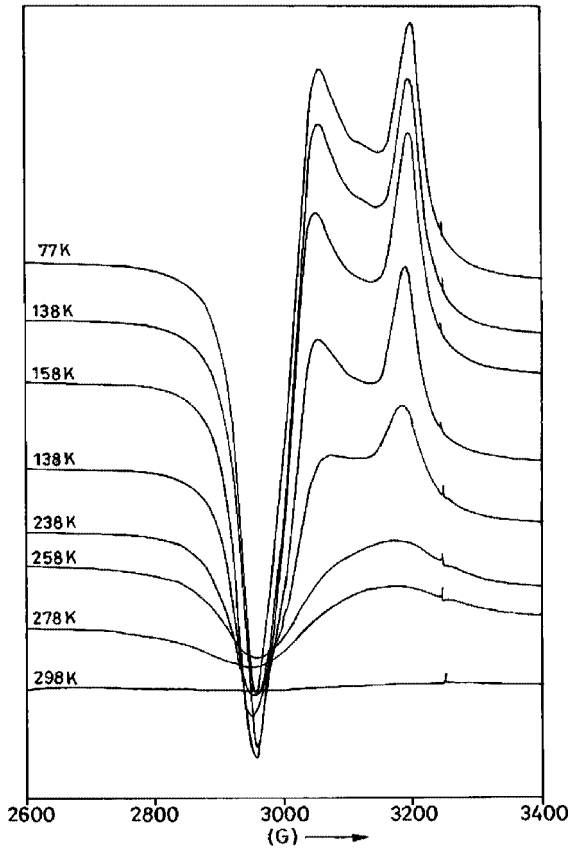

Figure 6. ESR spectra of **15** at variable temperature.

The variable-temperature magnetic susceptibility measurements for **16** were performed on powdered samples between 4 and 300 K. The $\chi_M$ vs. $T$ and $\mu_{eff}$ = 2.84 $(\chi_M T)^{1/2}$ vs. $T$ plots are shown in Figure 7. The molar magnetic susceptibility ($\chi_M$) of **16** increases with a decrease in temperature, as expected for normal paramagnetic samples. The magnetic moment of **16** shows an $\mu_{eff}$ value ranging from 4.0 to 4.9 $\mu_B$, which is higher than that expected for high-spin $Co^{II}$ ($t_{2g}^4 e_g^2$) with three unpaired electrons ($\mu_s$ = 3.8 $\mu_B$) and indicates the presence of an orbital contribution. However, these values are in good agreement with those observed for $Co^{II}$ ions in a distorted octahedral arrangement.

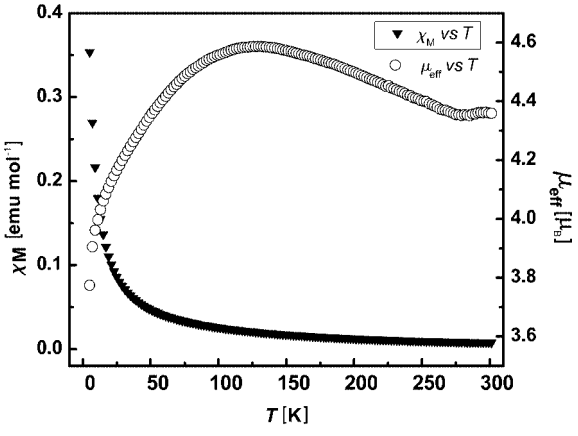

Figure 7. Magnetic properties of **16**: $\chi_M$ vs. $T$ plot and $\mu_{eff}$ vs. $T$ plot.

The complex does not show any EPR signal at 298 K, which may be due to spin lattice relaxation.[12] However, it starts growing from 218 K and the intensity increases appreciably with a further lowering in temperature (Figure 8). At 77 K it shows a clear axial-type EPR spectrum, with $g_1$ = $g_2$ = 2.19, and $g_3$ = 2.03. The expected signal at around $g$ = 5 could not be resolved, even at 77 K.

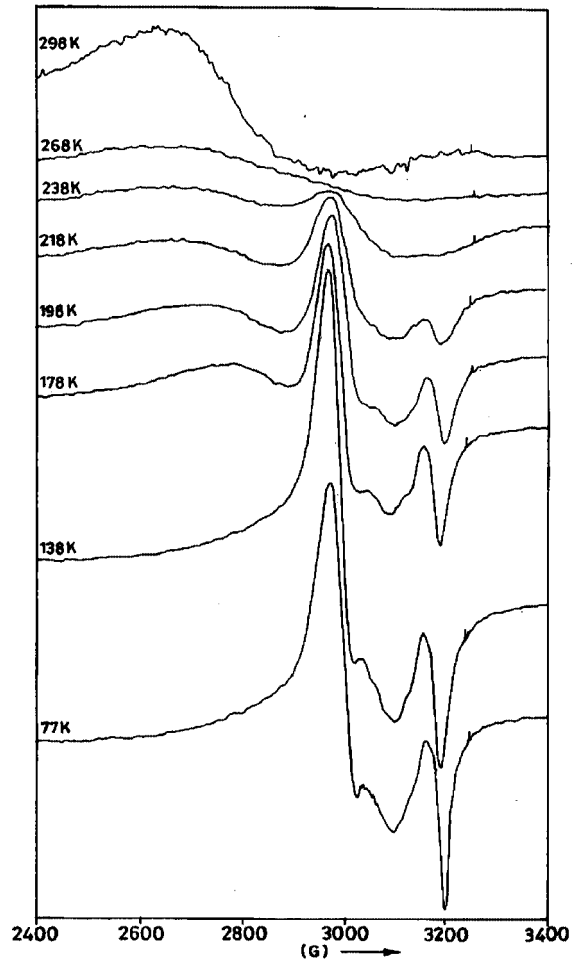

Figure 8. ESR spectra of **16** at variable temperature.

## Conclusions

The crystal structures of macrocycles **11** and **12** confirm the formation of 22-membered selenaaza and telluraaza macrocycles incorporating a 1,2-cyclohexane bridge. The replacement of an ethylene bridge with a cyclohexane bridge leads to a significant change in the cavity size. The Se···Se transannular distance for **11** is 5.881 Å, compared with 3.808 Å for **1**, whereas comparison of **2** with **12** indicates a stronger Te···N interaction in **12**. Ligands **3** and **11** both stabilize $Co^{II}$ ion and, as expected, **16** has a longer $Co^{II}$–Se distance than the $Co^{III}$–Se bond length. Surprisingly, $Co^{II}$ complex **15** is low-spin whereas **16** is high-spin; both show ESR signals at low temperatures.

## Experimental Section

**General:** Bis(*o*-formylphenyl)selenide,[7a] bis(*o*-formylphenyl)telluride,[6a] ligand **3**, [7b] and $[PdCl_2(C_6H_5CN)_2]$[13] were prepared by reported procedures. Air-sensitive reactions were carried out under an inert atmosphere. Solvents were purified by standard techniques and were freshly distilled prior to use. *trans*-1,2-Diaminocyclohexane was obtained from Aldrich and used as such; 1,3-diaminopropane was reagent grade and was dried and distilled prior to use. Melting points were recorded in capillary tubes and are uncorrected. IR spectra were recorded as KBr pellets on a Perkin–Elmer precisely FTIR spectrometer. Electronic absorption spectra were obtained in $CHCl_3/CH_3CN$ at 25 °C in a 1-cm quartz cuvette with a JASCO V-570 spectrophotometer. $^1H$-, $^{13}C$-, $^{77}Se$-, and $^{125}Te$ NMR spectra were recorded with a Varian VXR 300S or Varian 400 MHz spectrometer. Chemical shifts cited were referenced to TMS ($^1H$, $^{13}C$) as internal or $SeMe_2$ ($^{77}Se$) or $TeMe_2$ ($^{125}Te$) as external standard. Elemental analyses were performed with a Carlo–Erba model 1106 elemental analyzer. ESI mass spectra were recorded at room temperature with a Q-Tof micro (YA-105) mass spectrometer. Variable-temperature magnetic susceptibility data in the temperature range 4–300 K for a polycrystalline sample of **15** and **16** were measured with a Quantum design MPMS squid magnetometer equipped with a closed-cycle cryostat (Air products). $Hg[Co(NCS)_4]$ was used as a standard. Experimental susceptibility data were corrected for diamagnetic contributions. The magnetic moments at various temperatures were calculated by using the expression $2.84(\chi_M T)^{1/2}$. The magnetic susceptibility of **14** was determined at room temperature on a Faraday balance and standardized with mercury tetracyanocobaltate(II) [$\chi = 16.44 \times 10^{-6}\ cm^3\,mol^{-1}$]. The molar susceptibilities were corrected for diamagnetism with the use of Pascal's constants. The effective magnetic moments were calculated by using the expression $\mu_{eff} = 2.84(\chi_M T)^{1/2}$. The ESR measurements for **14**, **15**, and **16** (powder sample) were performed with a Varian model 109CE-line X-band spectrometer fitted with a quartz Dewar for measurements at 77 K and at variable temperature. Cyclic voltammetry experiments were performed with a Scanning Potentiostat EG and G PARC Model 362 instrument, which consists of a one-compartment cell with platinum working and counter electrodes and a standard calomel as reference electrode. Tetrabutylammonium tetrafluoroborate (Aldrich) was used as the supporting electrolyte. All solutions were purged with nitrogen before the CV data were recorded. Measurements were conducted in 0.1 M $NBu_4BF_4$ in acetonitrile with a sample concentration 0.05 mM. Ferrocene was taken as standard.

**Synthesis of Schiff-Base Macrocycle 11:** A solution of bis(*o*-formylphenyl)selenide (**9**; 0.313 g, 1 mmol) in acetonitrile (100 mL) was added dropwise to a stirred solution of *trans*-1,2-diaminocyclohexane (0.114 g, 1 mmol) in acetonitrile (200 mL) over a period of five to six hours. The mixture was stirred overnight and the precipitated white powder was filtered off. The solvent was evaporated under reduced pressure and the compound obtained was washed with acetonitrile two or three times. Crystals were grown from a chloroform/hexane mixture. Yield: 0.30 g (76%). M.p. 197–99 °C. $^1H$ NMR (299.9 MHz, $CDCl_3$, –50 °C): $\delta$ = 1.41–2.0 (m, $NCHCH_2CH_2$, 16 H), 3.50 (s, 4 H, $NCHCH_2$), 8.49 (s, 4 H, CH=N), 6.9–7.8 (m, 16 H, Ar-*H*) ppm. $^{13}C$ NMR (100.5 MHz, $CDCl_3$, room temp.): $\delta$ = 23.6, 31.8, 73.7, 126.9, 130.1, 130.1, 135.2, 136.9, 161.1 ppm; all peaks are broad). $^{13}C$ NMR (75.4 MHz, $CDCl_3$, –50 °C): $\delta$ = 20.5, 24.1, 26.3, 32.5, 71.8, 75.2, 124.6, 127.9, 129.6 (t), 130.4, 131.7, 133.4, 135.1, 136.5, 136.8, 138.8, 160.1, 161.6 ppm. $^{77}Se$ NMR (57.2 MHz, $CDCl_3$): $\delta$ = 404 ppm. IR (KBr): $\tilde{\nu}$ = 1641 $cm^{-1}$ $\nu$(C=N). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}\,cm^{-1}$) = 240 (12938), 332 nm (1869). ESI-MS ($CHCl_3$): *m*/*z* (%) = 737 (100) $[M]^+$. $C_{40}H_{40}N_4Se_2$: calcd. C 65.40, H 5.48, N 7.62; found C 65.20, H 5.51, N 7.51.

**Synthesis of Schiff-Base Macrocycle 12:** A solution of bis(*o*-formylphenyl)telluride (**10**; 0.398 g, 1 mmol) in acetonitrile was added dropwise to a stirred solution of *trans*-1,2-diaminocyclohexane (0.114 g, 1 mmol) in acetonitrile (200 mL) over a period of five to six hours. The mixture was stirred overnight and the precipitated white powder was filtered off. The solvent was evaporated under reduced pressure and the compound obtained was washed with acetonitrile two or three times. Yield: 0.28 g (57%). M.p. 200–202 °C. $^1H$ NMR (399.99 MHz, $CDCl_3$): $\delta$ = 1.45–1.90 (m, 16 H, $NCHCH_2CH_2$), 3.63 (s, 4 H, $NCHCH_2$), 7.09–8.01 (m, Ar-H, 16 H), 8.53 (s, 4 H, N=CH) ppm. $^{13}C$ NMR (100.5 MHz, $CDCl_3$): $\delta$ = 58.1, 126.3, 130.1, 132.9, 138.5, 144.5, 166.7, 167.3 ppm. $^{125}Te$ NMR (94.78 MHz, $CDCl_3$): $\delta$ = 581 ppm. IR (KBr): $\tilde{\nu}$ = 1637 $cm^{-1}$ $\nu$(C=N). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}\,cm^{-1}$) = 368 (16676), 332 nm (2541). ESI-MS ($CHCl_3$): *m*/*z* (%) = 832 (100) $[M]^+$. $C_{40}H_{40}N_4Te_2$: calcd. C 57.74, H 4.84, N 6.73; found C 57.88, H 5.20, N 7.18.

**Synthesis of Reduced Macrocycle 13:** An excess of $NaBH_4$ was added, in small portions, to a suspension of **11** (0.734 g, 1 mmol) in ethanol, and the reaction mixture was stirred for 4 h at room temperature, after which time it was heated at reflux for 3–4 h. The excess of ethanol was removed under reduced pressure. Water was added to the residue and the product was extracted with chloroform and kept over sodium sulfate. It was filtered and the solvents evaporated to dryness. The residue was used for characterization. Colour: white. Yield: 0.49 g (66%). M.p. 240–242 °C. $^1H$ NMR (399.99 MHz, $CDCl_3$): $\delta$ = 1.0 (br. s, 4 H, $CH_2NH$), 1.2 (m, 8 H, $CHCH_2CH_2$), 1.7 (m, 8 H, $CHCH_2CH_2$), 2.3 (m, 4 H, NCH), 3.9 (dd, *J* = 13.4 Hz, 8 H, $NCH_2$), 6.95–7.25 (m, 16 H) ppm. $^{13}C$ NMR (75.43 MHz, $CDCl_3$): $\delta$ = 30.1, 50.4, 24.4, 58.2, 126.2, 127.6, 129.1, 129.9, 130.9, 140.8 ppm. $^{77}Se$ NMR (57.2 MHz, $CDCl_3$): $\delta$ = 340 ppm. IR (KBr): $\tilde{\nu}$ = 3300, 3277, 3165, 3053, 1460 (N-H bending). ESI-MS: *m*/*z* = 743 $[M]^+$. $C_{40}H_{48}N_4Se_2$: calcd. C 64.69, H 6.51, N 7.54; found C 64.52, H 6.93, N 7.29.

**Synthesis of Complex 14:** Schiff-base ligand **11** (0.245 g, 0.33 mmol) was added to a two-necked, round-bottomed flask along with methanol (20 mL). After stirring for some time, $NiCl_2{\cdot}6H_2O$ (0.08 g, 0.33 mmol) was added and the mixture refluxed for one hour, the color of the reaction mixture changing to a clear reddish-brown. An excess of ammonium hexafluorophosphate was then added. The reddish-brown precipitate formed was filtered off and washed with methanol. Complex **14** was recrystallized as reddish-brown needles by slow diffusion of diethyl ether into a MeCN solution. Yield: 0.30 g (84%). M.p. 250–252 °C (dec.). IR (KBr): $\tilde{\nu}$ = 2935, 1627, 1291, 848, 766, 586 $cm^{-1}$. UV/Vis (MeCN): $\lambda_{max}$ ($\varepsilon$, $M^{-1}\,cm^{-1}$) = 218 (12752), 348 (613), 450 (123), 850 nm (50). $\mu_{eff}$ = 2.5 $\mu_B$. ESI-MS: *m*/*z* (%) = 793 (100) $[M - 2PF_6]^+$, 939 (50) $[M - PF_6]^+$. $C_{40}H_{40}F_{12}N_4NiP_2Se_2$: calcd. C 44.35, H 3.72, N 5.17; found C 44.59, H 3.48, N 5.25.

**Synthesis of Complex 15:** $Co(ClO_4)_2{\cdot}6H_2O$ (0.12 g, 0.33 mmol) was added to a suspension of ligand **11** (0.25 g, 0.33 mmol) in acetonitrile. The color of the reaction mixture changed from light brown to dark brown, and after stirring for 4–5 h a clear brown solution had formed. The reaction mixture was stirred overnight and was then filtered and evaporated to 15 mL. It was kept as such for crystallization, which produced a black, crystalline compound. Yield: 0.23 g (68%). IR (KBr): $\tilde{\nu}$ = 1617 $cm^{-1}$ $\nu$(C=N), 1591, 1092, 624. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}\,cm^{-1}$) = 222 (15162), 356 (1487), 546 nm (218). ESI-MS: *m*/*z* (%) = 795 (50) $[M - 2ClO_4]^+$, 894 (20)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[M - ClO_4]^+$. $C_{40}H_{40}Cl_2CoN_4O_8Se_2$: calcd. C 48.41, H 4.06, N 5.64; found C 48.29, H 4.14, N 5.94.

**Synthesis of Complex 16:** $Co(ClO_4)_2 \cdot 6H_2O$ (0.10 g, 0.33 mmol) was added to a suspension of ligand **3** (0.22 g, 0.33 mmol) in acetonitrile (60 mL) and stirred for overnight. The solution was then filtered and evaporated to 20 mL. Diethyl ether was added to this solution to induce crystallization. The brown, crystalline product that separated was used for characterization. Yield: 0.20 g (65%). UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 224 (18141), 354 (1734), 546 nm (285). ESI-MS: *m/z* (%) = 814 (50) $[M - 2ClO_4]^+$. $C_{34}H_{32}Cl_2CoN_4O_8Se_2$: calcd. C 44.76, H 3.53, N 6.14; found C 44.58, H 3.12, N 6.24.

**Synthesis of Complex 17:** $[PdCl_2(C_6H_5CN)_2]$ (0.13 g, 0.33 mmol) in dichloromethane (10 mL) was added dropwise to a chloroform (10 mL) solution of **12** (0.33 mmol, 0.28 g). On stirring for 2 h, a yellow solution formed. After stirring for a further 2 h the yellow solution was evaporated and the residue was dissolved in methanol (5 mL), to which an excess of $NH_4PF_6$ was added. The yellow product formed was washed with diethyl ether and recrystallized from acetonitrile. Yield: 0.24 g (58%). M.p. 260–62 °C (dec.). $^1H$ NMR (399.99 MHz, $CD_3CN$): $\delta$ = 1.4–2.5 (m, 16 H, NCHC$H_2$C$H_2$), 3.6 (d, $J$ = 8.9 Hz, 2 H, NC$H$C$H_2$), 4.0 (d, $J$ = 3.9 Hz, 2 H, NC$H$C$H_2$), 7.0 (d, $J$ = 7.8 Hz, 2 H), 7.32 (t, $J$ = 7.8 Hz, 2 H), 7.4 (m, 4 H), 7.55 (m, 4 H), 7.92 (d, $J$ = 7.4 Hz, 2 H), 8.2 (d, $J$ = 7.4 Hz, 2 H), 8.5 (s, 2 H, C$H$=N), 9.0 (s, 2 H, C$H$=N) ppm. $^{13}C$ NMR (100.5 MHz, $CD_3CN$): $\delta$ = 25.4, 25.6, 31.9, 33.6, 68.5, 75.3, 119.4, 122.2, 132.1, 132.8, 134.1, 135.2, 135.3, 135.8, 137.2, 138.9, 139.2, 140.6, 162.4, 168.9 ppm. $^{125}Te$ NMR (94.87 MHz, $CD_3CN$): $\delta$ = 751 ppm. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 218 (17794), 304 (5044), 394 nm (1583). ESI-MS ($CH_3CN$): *m/z* (%) = 939 (20) $[M - 2PF_6]^+$, 957 (70) $[M - 2PF_6 + H_2O]^+$, 1085 (50) $[M - PF_6]^+$.

**X-ray Crystallographic Studies:** The diffraction measurements for the ligands as well as the complexes were performed at room temperature with a "Bruker P4" diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The data were corrected for Lorentz, polarization, and absorption effects The structures were determined by routine heavy-atom and Fourier methods by using SHELXS 97[14] and refined by full-matrix least-squares with the non-hydrogen atoms anisotropic and hydrogen with fixed isotropic thermal parameters of 0.07 Å by means of the SHELXL 97[15] program. The hydrogens were partially located from difference electron-density maps and the rest were fixed at predetermined positions. Scattering factors were from common sources.[16] Some details of data collection and refinement are given in Tables 5 and 6.

# Kinetics and Mechanism of Ligand Substitution in Some Chromium(III) Tetraaza Macrocyclic Complexes in Acidic Media: Differences in Reactivity Between *cis* and *trans* Isomers

**Edyta Madej,[a] Anna Katafias,*[a] Przemysław Kita,*[a] Jette Eriksen,[b] and Ole Mønsted*[b]**

**Keywords:** Chromium / Structure–activity relationships / Ligand substitution / Macrocyclic complexes / Kinetics

Thiocyanate anation of the macrocyclic complexes *cis*-$[Cr(cyc\mathit{b})(OH_2)_2]^{3+}$ and *trans*-$[Cr(cyc\mathit{a})(OH_2)_2]^{3+}$ (cyc*b* and cyc*a* are *rac*- and *meso*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane, respectively), and mercury(II)-induced aquation of the product thiocyanato-*N* complexes, has been studied in acidic solution. The rate retardation with an increase of the acid concentration for both types of reactions follows the rate expression $k_{obs} = (k_1 + k_2K_a/[H^+_{(aq)}])/(1 + K_a/[H^+_{(aq)}])$, corresponding to parallel reaction paths through aqua and hydroxo complexes. Some general trends in the differences in reactivity between the two geometrical isomers have been observed and are discussed.

## Introduction

Recent advances in the elucidation of the mechanisms of ligand-substitution reactions in solution have been reviewed in a series of articles.[1] The chemistry of transition metal complexes of macrocyclic ligands is an area that has attracted considerable interest in recent years.[2–6] These complexes exhibit a range of characteristic properties that are frequently so markedly different from those of their acyclic analogues that the special, but not very informative, label "macrocyclic effects" has been introduced to describe the differences.

Cyclic tetraaza ligands are among the more readily available macrocyclic ligands, and these ligands have been coordinated to most metal ions of the periodic table. Macrocyclic ligands are usually robustly bound, even to metal ions otherwise characterized as "labile", but knowledge of their ability to modify reactivities at the coordination positions not occupied by the macrocyclic ligand is very sparse for most metal ions.

Base hydrolysis of *cis*-$[Cr(cyc\mathit{b})(OH)X]^+$- and *trans*-$[Cr(cyc\mathit{a})(OH)X]^+$-type species ($X^-$ = $Cl^-$, $NCS^-$, or $N_3^-$), leading to liberation of the X ligand and formation of the dihydroxo complexes, has been studied previously.[7] These processes occur without any stereochemical changes or aquation of the macrocyclic amine ligand, even at higher temperatures and in strongly basic solution. However, they are markedly influenced by the composition of the ionic medium, and this has been rationalized by a competitive ion-pair formation between hydroxide ions and the anion of the supporting electrolyte.

The aim of the present work is to gain further insight into the mechanism of ligand substitution in this type of complexes in acidic media by comparison of the reactivity of the two geometrical isomers in two types of reactions, namely anation of the diaqua complexes *cis*-$[Cr(cyc\mathit{b})(OH_2)_2]^{3+}$ and *trans*-$[Cr(cyc\mathit{a})(OH_2)_2]^{3+}$ by thiocyanate and mercury(II)-induced aquation of the thiocyanato ligand by formation of the heterodinuclear ions *cis*-$[(cyc\mathit{b})(H_2O)Cr\text{-}NCS\text{-}Hg]^{4+}$ and *trans*-$[(cyc\mathit{a})(H_2O)Cr\text{-}NCS\text{-}Hg]^{4+}$.

## Results and Discussion

### Characteristics of the Systems Studied

Direct structural investigations on chromium(III) complexes of the ligands cyc*a*[8] and cyc*b*[9] (Scheme 1), as well as other types of evidence, point towards structures of the diaqua complexes with two equivalent water ligands. Consequently, substitution of a water ligand with another monodentate ligand will give only one product. For the thiocyanato ligand, this has previously been demonstrated by isolation of solutions of aquathiocyanato-type complexes formed by thiocyanate anation of *cis*-$[Cr(cyc\mathit{b})(OH_2)_2]^{3+}$ and *trans*-$[Cr(cyc\mathit{a})(OH_2)_2]^{3+}$, in which only one isomer was present.[7]

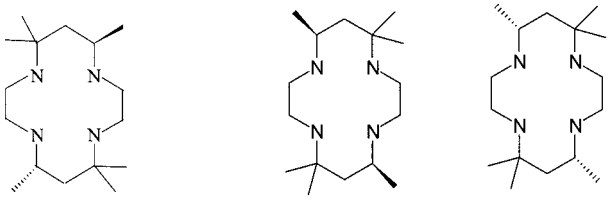

Scheme 1.

The thiocyanato ligand in these complexes is sufficiently robustly coordinated for complexation of mercury(II) to the uncoordinated sulfur atom of the thiocyanato ligand to be studied free from complications due to aquation of this ligand. Preliminary results demonstrated that anation of the diaqua complexes by thiocyanate and mercury(II)-assisted aquation of the monothiocyanato-*N* derivatives proceed, for both the macrocyclic ligands studied, according to Equations (1) and (2):

$$[Cr(cyc)(OH_2)_2]^{3+} + NCS^- \rightarrow [Cr(cyc)(OH_2)(NCS)]^{2+} + H_2O \quad (1)$$

$$[Cr(cyc)(OH_2)(NCS)]^{2+} + Hg^{II} + H_2O \rightarrow [Cr(cyc)(OH_2)_2]^{3+} + Hg(SCN)^+_{aq} \quad (2)$$

Complete retention of configuration is observed in these reaction sequences and the possible aquation of the macrocyclic ligand does not interfere with the reactions under the conditions applied in the present work. This conclusion is based on the results of chromatographic separations and electronic spectra of the eluted chromium(III) species.

The value of the formation constant, at 298 K, for mercury(II) complexation to cationic complexes is usually between $10^3$ and $10^4$ $M^{-1}$, and for complexation to anionic complexes usually somewhat higher[10,11] (frequently over $10^5$ $M^{-1}$). The values found for the present cationic macrocyclic complexes (Table 1) are similar, $3.9 \times 10^3$ $M^{-1}$ for the *trans* and $8.5 \times 10^3$ $M^{-1}$ for the *cis* isomer. The complexation reactions are both significantly exothermic (with small negative entropies of reaction), as expected for the interaction between a "soft" metal center and a "soft" ligand.

The macrocyclic chromium(III) complexes were further characterized by their acid/base properties; the acidity constants determined for the aquathiocyanato and the diaqua complexes are presented in Table 2. It can be seen that the acidity constants for the monothiocyanato 2+ complexes are over one order of magnitude lower than those of the diaqua 3+ complexes, which is as expected from the overall charge variation of the complexes. A direct titrimetric determination of the acidity constants for the dinuclear Cr–NCS–$Hg^{4+}$ species was not possible because of the need for a large excess of mercury(II), which exhibits similar acid/base properties to the investigated complexes.[12] In the hydrogen concentration range selected for kinetic measurements, deprotonation of the aqua complexes is stoichiometrically unimportant.

### Kinetics of the Mercury(II)-Induced Aquation Reaction

Mercury(II) aquaion is known to efficiently induce aquation of both halide and pseudo-halide ligands in robust classical complexes[13] as well as in organometallic species.[14] A rate enhancement of up to four orders of magnitude[10,11] has been observed for thiocyanato ligand aquation due to coordination of mercury(II) to the uncoordinated sulfur atom of this ligand. Examples are known, however, of mercury(II) causing rate retardation by coordination at another available position and not at the ligand which is the leaving group.[15]

The mercury(II)-induced aquation reactions of the present macrocyclic complexes have been studied in the presence of an excess of mercury(II) sufficient to transform the aquathiocyanatochromium(III) reagents into [$Cr^{III}$–NCS–$Hg^{II}$]-type complexes with a degree of conversion exceeding 95%. This guarantees independence of the observed rate constant on the mercury(II) concentration. The two macrocyclic thiocyanatochromium(III) complexes aquate, with a rate that decreases with an increase in acid concentration, as shown in Figure 1.

Table 1. Equilibrium constants ($K_{Hg}$ at 298 K) and reaction enthalpies ($\Delta_r H°$) for mercury(II) complexation to aquathiocyanato complexes of two macrocyclic chromium(III) complexes in 2.0 M (Na/H)$ClO_4$. Standard deviations are given in parentheses.

| Chromium(III) complex | $K_{Hg}$ (298 K) [$M^{-1}$] | $\Delta_r H°$ [kJ mol$^{-1}$] | $\Delta_r S°$ [J K$^{-1}$ mol$^{-1}$] |
|---|---|---|---|
| *trans*-[Cr(cyc*a*)$(OH_2)(NCS)]^{2+}$ | $3.90(10) \times 10^3$ | –28.5(10) | –27(3) |
| *cis*-[Cr(cyc*b*)$(OH_2)(NCS)]^{2+}$ | $8.5(2) \times 10^3$ | –25.0(10) | –9(3) |

Table 2. Acidity constants, $K_{a1}$, for monoaqua complexes at 298 K and 313 K, $K_{a1}$ and $K_{a2}$ for diaqua complexes at 298 K, and reaction enthalpies, $\Delta_r H°$, determined by acid/base titrations in 1.0 M NaBr. Standard deviations are given in parentheses.

| Complex | –log($K_a$/M) (298 K) | –log($K_a$/M) (313 K) | $\Delta_r H°$ [kJ mol$^{-1}$] |
|---|---|---|---|
| *trans*-[Cr(cyc*a*)$(OH_2)_2]^{3+}$ | 2.44(3) | | 29(8) |
| | 6.929(12) | | 38(2) |
| *trans*-[Cr(cyc*a*)$(OH_2)(NCS)]^{2+}$ | 3.817(8) | 3.70(4)[a] | 24(3) |
| *cis*-[Cr(cyc*b*)$(OH_2)_2]^{3+}$ | 3.490(8) | | 29.4(10) |
| | 7.112(6) | | 41.7(13) |
| *cis*-[Cr(cyc*b*)$(OH_2)(NCS)]^{2+}$ | 5.298(5) | 4.91(2)[a] | 30(7) |

[a] Noticeable decomposition during titration. The $\Delta_r H°$ values given are those from Table 4.

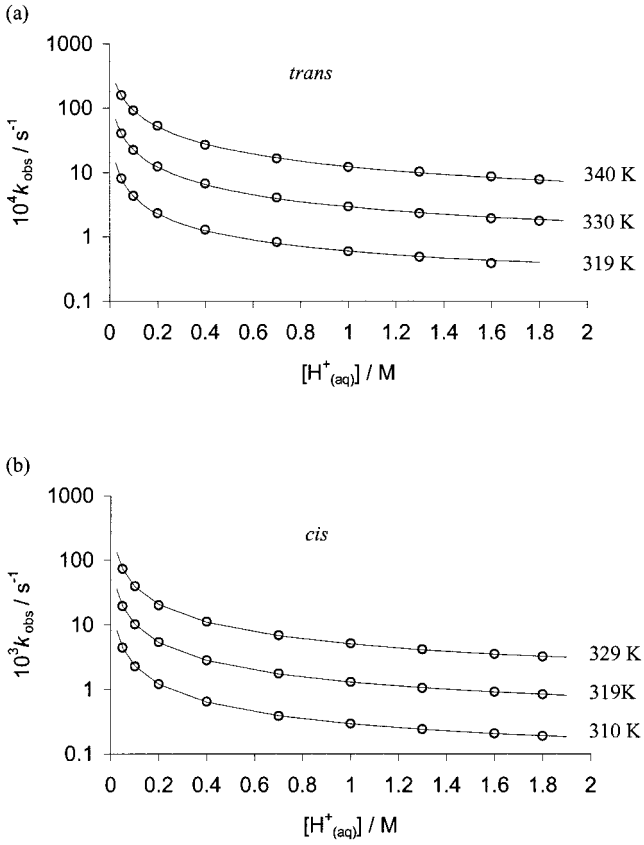

Figure 1. Pseudo-first-order rate constants for aquation of *trans*-[(cyc*a*)($H_2O$)Cr-NCS-Hg]$^{4+}$ (a) and *cis*-[(cyc*b*)($H_2O$)Cr-NCS-Hg]$^{4+}$ (b) complexes as a function of the hydrogen ion concentration in 2.0 M (H/Na)$ClO_4$; [$Hg^{II}$] = 25 mM.

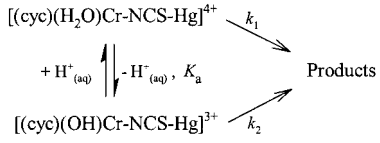
The observed pseudo-first-order rate constant, $k_{obs}$, vs. [$H^+_{(aq)}$] data can be reproduced by Equation (3) which is derived by assuming a fast protolytic equilibrium step followed by the parallel substitution of the thiocyanato-*S*–mercury(II) ion from the aqua and the hydroxo forms of the reagents, as shown in Scheme 2.

$$k_{obs} = (k_1 + k_2 \cdot K_a/[H^+_{(aq)}])/(1 + K_a/[H^+_{(aq)}]) \quad (3)$$



Scheme 2.

Non-linear regression analysis was used to give the parameters in Table 3. The data in this table show that the values of the rate constants and the acid dissociation constants are obtained with significant errors despite the good fit of the data to the theoretical equation. This is mainly caused by the relatively narrow range of hydrogen ion concentrations that had to be used.

The values of the acidity constants, $K_a$, for both isomers of [Cr(cyc)($H_2O$–NCS–Hg)]$^{4+}$-type (see Table 3) seem to be reasonable and are remarkably higher than those for the [Cr(cyc)($H_2O$)(NCS)]$^{2+}$-type isomers (Table 2), as can be expected due to the higher charge of the cationic complexes. However, the acidity constants for the *trans*- and *cis*-thiocyanato ions differ significantly (about 30 times), whereas the values for the mercury(II) derivatives are very similar.

The reactivity comparison of the *cis* and the *trans* isomers in the aqua ($k_1$) and hydroxo ($k_2$) forms is based on the two parameters in Equation (3). The $k_1$ and $k_2$ values at 298 K for the *cis* isomer are about 20 times higher than for the *trans* one in spite of the higher value of the activation energy. The $k_2/k_1$ quotient is a measure of the labilizing effect of $OH^-$ *trans* and *cis* to the leaving ligand. These values are similar for both isomers — about 1330 for the *cis* and about 1000 for the *trans* species. The rate constant increase due to deprotonation of the coordinated water molecule is larger for the studied macrocyclic complexes than for many other chromium(III) complexes; [$Cr(H_2O)_5(OH)]^{2+}$, for example, exchanges its water molecule only 75 times faster than [$Cr(H_2O)_6]^{3+}$.[1] The significant uncertainties in the activation parameters make mechanistic con-

Table 3. Rate constants ($k_1$ and $k_2$ at 298 K and 323 K), acidity constants ($K_a$ at 298 K and 323 K), activation energies ($E_a$) and reaction enthalpies ($\Delta_r H°$) for mercury(II)-induced aquation of two macrocyclic chromium(III) complexes in 2.0 M (Na/H)$ClO_4$ [see Scheme 2 and Equation (3)]. Standard deviations are given in parentheses.[a]

| *trans*-[Cr(cyc*a*)($OH_2$)(NCS)]$^{2+}$ | 298 K | 323 K | $E_a$ or $\Delta_r H°$ [kJ mol$^{-1}$] |

[a] It should be noted that the functional form of the mathematical equation used to interpret the data does not allow a particularly well-defined separation of the $k_2$ and the $K_a$ parameters for the present set of data. Consequently, the significantly better defined parameter product $k_2K_a$ is also given in the table.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

siderations difficult, although the rate enhancement is accompanied by a lowering of the activation energy (Table 3) rather than the increase observed if the mechanism changes from $I_a$ to $I_d$ as the result of the deprotonation. Remarkably, the $k_1$ rate constants for the studied macrocyclic complexes are three to four orders of magnitude lower than those for other $Cr^{III}$–NCS–Hg type species that are thought to be very inert.[10,11] Thus, the "kinetic macrocyclic effect" manifests itself first of all in the extreme inertness of both geometrical isomers and in a strong reactivity difference between the aqua and the hydroxo forms of the complexes.

### Kinetics of the Anation Reaction

Both *cis*-$[Cr(cyc\textit{b})(OH_2)_2]^{3+}$ and *trans*-$[Cr(cyc\textit{a})(OH_2)_2]^{3+}$ isomers undergo slow anation by thiocyanate in acidic media to give the corresponding monothiocyanato complexes. At lower temperatures — 298–318 K for the *cis* and 308–328 K for the *trans* complex — the reaction is so slow that it can be conveniently studied by applying an initial rate analysis. The pseudo-zero-order rate constants, $k^{(0)}$, were found to be proportional to the chromium(III) concentration, and were converted to pseudo-first-order rate constants, $k^{(1)}$, with [Equation (4)].

$$k^{(1)} = k^{(0)}/[Cr^{III}] \quad (4)$$

These constants depend on the thiocyanate and hydrogen ion concentrations, as demonstrated in Figures 2 and 3. For thiocyanate concentrations below 0.1 M, the pseudo-first-order rate constant is proportional to the thiocyanate concentration, whereas at higher thiocyanate concentrations a non-linear behaviour is seen. In the simple anation model two parameters — the encounter complex formation constant $Q$ and the rate constant $k$ — describe the reaction of a particular reagent. However, the non-linear kinetics of the reaction observed at higher $NCS^-$ concentration (Figure 3) does not allow for the separation of these parameters and are ignored in the following discussion.

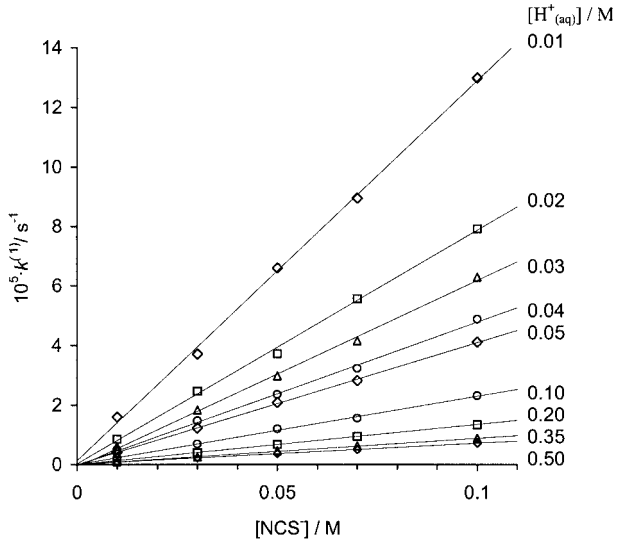

Figure 2. Pseudo-first-order rate constants for anation of *cis*-$[Cr(cyc\textit{b})(H_2O)_2]^{3+}$ as a function of the thiocyanate concentration in 1.0 M (H/Na)(Br/NCS); $T$ = 298 K.

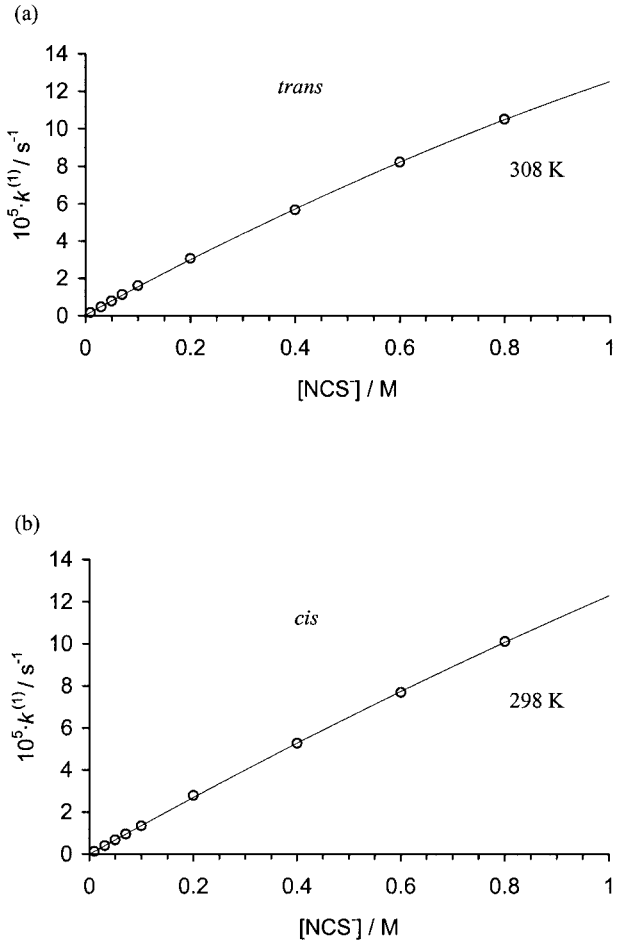

Figure 3. Pseudo-first-order rate constants for anation of *trans*-$[Cr(cyc\textit{a})(H_2O)_2]^{3+}$ (a) and *cis*-$[Cr(cyc\textit{b})(H_2O)_2]^{3+}$ (b) as a function of the thiocyanate concentration in 1.0 M (H/Na)(Br/NCS); $[H^+_{(aq)}]$ = 0.2 M.

At higher temperatures — 318–338 K for the *cis* and 328–348 K for the *trans* complex — reactions were monitored under pseudo-first-order conditions with thiocyanate in substantial excess over the chromium(III) reagent. Under such conditions the reactions are of first order, and the pseudo-first-order rate constant is proportional to the thiocyanate concentration, in agreement with the results at lower temperatures. Ignoring the data demonstrating deviations from linearity at thiocyanate concentrations higher than 0.1 M, the reactions are found to be of second order, first order in complex and first order in thiocyanate, corresponding to the second-order anation rate constant, $k_{an}$, given by Equation (5) where $k_{an}$ can be interpreted, in terms of a simple anation model, as the product of the encounter complex formation constant $Q$ and the rate constant $k$ [Equation (6)] if the pre-equilibrium step is shifted to the left.

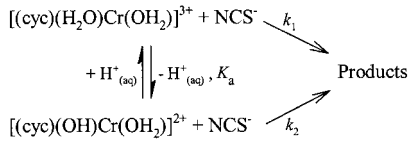
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$k_{an} = k^{(1)}/[NCS^-] \quad (5)$$

$$M\text{-}OH_2 + X \overset{Q}{\rightleftharpoons} MOH_2, X \xrightarrow{k} MX \quad (6)$$

The hydrogen ion concentration dependence of the second-order rate constant is shown in Figure 4. The significant rate retardation at high acidities can be rationalized in terms of the reaction given in Scheme 3, which shows parallel reaction paths by water ligand substitution in the diaqua and the aquahydroxo complexes and gives the expression in Equation (7) for the second-order anation rate constant.

$$k_{an} = (k_1 + k_2 \cdot K_a/[H^+_{(aq)}])/(1 + K_a/[H^+_{(aq)}]) \quad (7)$$



Scheme 3.

The parameters obtained by combining the rate data for all the kinetic experiments are given in Table 4. The validity of the proposed reaction scheme can be verified by comparison of the kinetically determined acidity constants, $K_a$, with those determined independently by titration experiments (see Table 2). A very good agreement of these two sets of parameters supports the correctness of the postulated reaction model.

The data in Table 4 show that, as in the case of the aquation, the values of the rate constants and the acid dissociation constants have been determined with significant errors.

The results obtained for the anation demonstrate, as for the aquation, a higher reactivity of the *cis* isomer; the ratio of $k_1$ for the *cis* and *trans* isomers is about 7 whereas the same ratio for $k_2$ is even higher at about 380. Deprotonation of the coordinated water molecule increases the reactivity, as in the case of the aquation, although the extent of this effect is different for the isomers: the $k_2/k_1$ quotient is about 1100 for the *cis* but only around 20 for the *trans* isomer. However, it should be noted that the $k_1$ and $k_2$ parameters are composite quantities, interpreted in terms of a simple

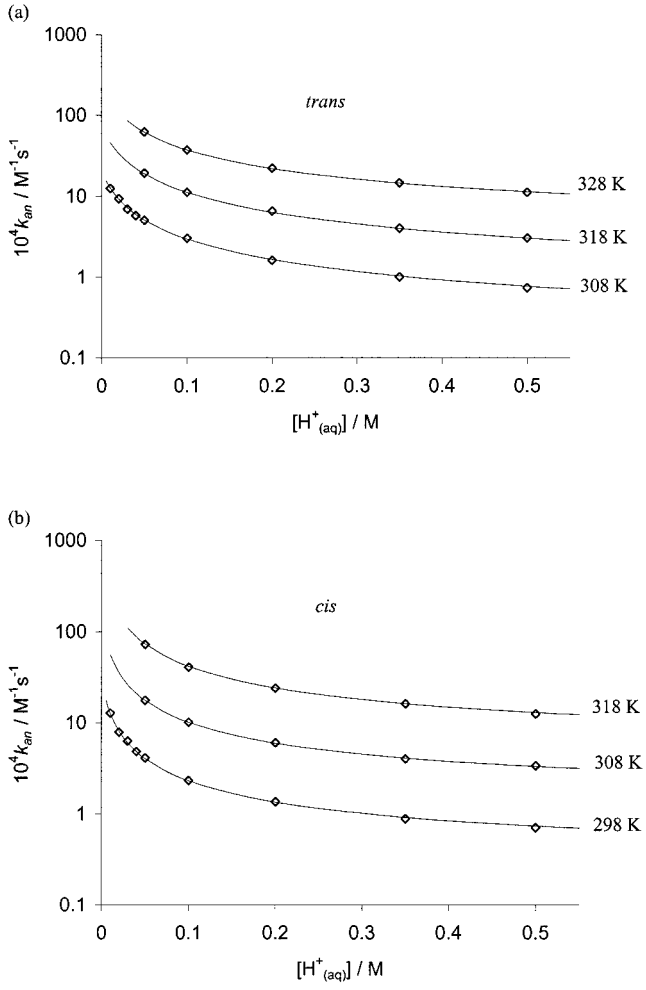


Figure 4. Pseudo-second-order rate constants for the anation of *trans*-$[Cr(cyc\mathit{a})(H_2O)_2]^{3+}$ (a) and *cis*-$[Cr(cyc\mathit{b})(H_2O)_2]^{3+}$ (b) complexes by $NCS^-$ as a function of $[H^+_{(aq)}]$; $I$ = 1.0 M (H/Na)(Br/NCS).

Table 4. Rate constants ($k_1$ and $k_2$ at 298 K and 323 K), acidity constants ($K_a$ at 298 K and 323 K), activation energies ($E_a$) and reaction enthalpies ($\Delta_r H°$) for thiocyanate anation of two macrocyclic chromium(III) complexes in 1.0 M (Na/H)(Br/NCS) [see Scheme 3 and Equation (7)]. Standard deviations are given in parentheses.[a]

| *trans*-$[Cr(cyc\mathit{a})(OH_2)_2]^{3+}$ | 298 K | 323 K | $E_a$ or $\Delta_r H°$ [kJ mol$^{-1}$] |
|---|---|---|---|
| $k_1$ [s$^{-1}$] | $6.5(9) \times 10^{-6}$ | $2.61(18) \times 10^{-4}$ | 119(6) |
| $k_2K_a$ [M$^{-1}$ s$^{-1}$] | $4.92(14) \times 10^{-6}$ | $2.42(4) \times 10^{-4}$ | 124.9(8) |
| $k_2$ [s$^{-1}$] | $1.25(6) \times 10^{-3}$ | $2.95(8) \times 10^{-2}$ | 101.3(12) |
| $-\log(K_a/M)$ | 2.40(3) | 2.084(16) | 23.6(15) |
| *cis*-$[Cr(cyc\mathit{b})(OH_2)_2]^{3+}$ | 298 K | 323 K | $E_a$ or $\Delta_r H°$ [kJ mol$^{-1}$] |
| $k_1$ [s$^{-1}$] | $4.2(3) \times 10^{-5}$ | $9.4(11) \times 10^{-4}$ | 100(5) |
| $k_2K_a$ [M$^{-1}$ s$^{-1}$] | $1.73(5) \times 10^{-5}$ | $9.38(13) \times 10^{-3}$ | 128.0(8) |
| $k_2$ [s$^{-1}$] | $4.8(11) \times 10^{-2}$ | 1.03(8) | 98(7) |
| $-\log(K_a/M)$ | 3.44(11) | 3.04(4) | 30(8) |

[a] It should be noted that the functional form of the mathematical equation used to interpret the data does not allow a particularly well-defined separation of the $k_2$ and the $K_a$ parameters for the set of data for the *cis* isomer. Consequently, the significantly better defined parameter product $k_2K_a$ is also given in the table.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

anation model, as the product of the encounter complex formation constant $Q$ and the rate constant $k$ [see Equation (6)].

The significant uncertainties in the apparent activation parameters for the anation make them almost unusable for mechanistic considerations.

## Summary and Conclusions

Data for the presently investigated reactions, supplemented with base hydrolysis data for complexes of the same macrocyclic ligands,[7] are shown in the form of a linear free energy relationship at 298 K in Figure 5. The same trend in the relative rates is observed for the *cis* and the *trans* series of complexes, with the *trans* complexes reacting between 6.5 and 38 times slower than the *cis* complexes. The linearized correlation in Figure 5 corresponds to the rate constant relationship $k_{cis} \approx 20\,k_{trans}$, or to a difference in the free energy of activation of about 8 kJ mol$^{-1}$. Regrettably, the activation parameters are not accurate enough to separate the free energy into well-defined enthalpy and entropy contributions.

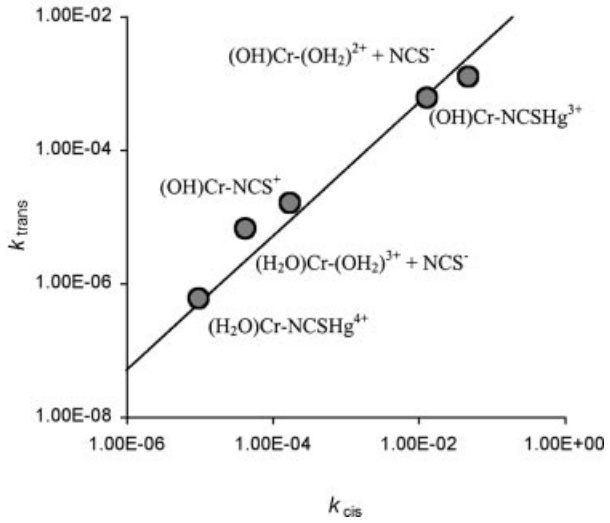

Figure 5. Correlation between free energies of activation for reactions of *cis*-Cr(cyc*b*) and *trans*-Cr(cyc*a*) complexes at 298 K. The data are from this work and from ref.[7] Rate constants are given in units of s$^{-1}$ or M$^{-1}$ s$^{-1}$ according to the type of reaction. The line drawn corresponds to $k_{cis} \approx 20\,k_{trans}$.

Some other general trends are worth pointing out explicitly. For example, the exceptional inertness and stereorigidity is a characteristic feature of the studied macrocyclic complexes. An increased acidity of the water ligands coordinated to the macrocyclic complexes with a highly hydrophobic coordination sphere is also seen. For the present complexes, this manifests itself in dominating reactivity contributions from deprotonated complexes, even in strongly acidic solution. The strong increase in reactivity caused by the coordinated water molecule deprotonation may be correlated with a lowering of the energy of activation. Regrettably, however, the present data are not accurate enough to determine whether this is the only effect operating. This effect is practically non-directional for the aquation but, unexpectedly, is much stronger in the *cis* position for the anation. The general reactivity pattern of the present reactions follows that normally seen for complexes of chromium(III) involving slow substitution processes of and by thiocyanate ligands.

## Experimental Section

**Materials:** *cis*-[Cr(cyc*b*)(OH$_2$)$_2$]Br$_3$·2H$_2$O was prepared according to a literature method;[16] *trans*-[Cr(cyc*a*)(OH$_2$)$_2$]Br$_3$·3H$_2$O was prepared analogously;[16] *cis*-[Cr(cyc*b*)(OH$_2$)(NCS)]$^{2+}$ and *trans*-[Cr(cyc*a*)(OH$_2$)(NCS)]$^{2+}$ complexes were prepared and characterised in solution as described previously.[7] Sephadex SP C-25 ($Na^+$,$H^+$) was used for chromatographic separations. Other chemicals were the best available commercial grades. For all solutions doubly distilled water was used.

**Determination of the Formation Constant for the Cr$^{III}$–NCS–Hg$^{II}$ Complexes:** Equilibrium constants, $K_{Hg}$, for reactions of the type shown in Equation (8) were determined spectrophotometrically at $\lambda$ = 312 nm for the *cis* isomer and at $\lambda$ = 309 nm for the *trans* isomer, using a Perkin–Elmer Lambda-20 spectrophotometer.

$$[Cr(cyc)(OH_2)(NCS)]^{2+}_{(aq)} + Hg^{2+}_{(aq)} \rightleftharpoons [Cr(cyc)(OH_2)(NCS\text{-}Hg)]^{4+}_{(aq)} \quad (8)$$

Spectra were taken immediately after mixing of the reactants, and effects of subsequent aquation reactions were not observed during the time of the experiments. A decrease of the thiocyanatochromium(III) charge-transfer bands with an increase of the mercury(II) concentration was observed for both isomers. An example is shown in Figure S1 (see Supporting Information). The equilibria in Equation (8) were examined at three temperatures (293.7–330.1 K) at a hydrogen ion concentration of 0.5 M and an ionic strength of 2.0 M maintained by the addition of $NaClO_4$. The concentration of the chromium(III) species was about 0.4 mM and the mercury(II) concentration was varied between 0.1 and 2.5 mM. The equilibrium constants, $K_{Hg}$, were calculated from Equation (9) which is derived from the relevant mass-action expressions in Equation (10) where [C] = [S] + [P], P = [Cr(cyc)(OH$_2$)(NCS–Hg)]$^{4+}_{(aq)}$, S = [Cr(cyc)-(OH$_2$)(NCS)]$^{2+}_{(aq)}$, [P] = $(A_i - A_s)/\Delta\varepsilon$, $\Delta\varepsilon = \varepsilon_p - \varepsilon_s$, assuming $\varepsilon_p$ = 0. The results are given in Table 1.

$$A_i = \frac{[Hg^{2+}_{(aq)}]_i \varepsilon_s K_{Hg} + A_s K_{Hg} + \varepsilon_s + \sqrt{K_{Hg}^2([Hg^{2+}_{(aq)}]_i \varepsilon_s + A_s)^2 + 2K_{Hg}([Hg^{2+}_{(aq)}]_i \varepsilon_s^2 - A_s \varepsilon_s) + \varepsilon_s^2}}{2K_{Hg}} \quad (9)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$K = \frac{[P]}{([C]-[P])([Hg^{2+}_{(aq)}]_i - [P])} \quad (10)$$

**Identification of Reaction Products:** Stoichiometric studies of the aquation of the $Cr^{III}$–NCS–$Hg^{II}$ complexes were carried out to 95% conversion and anation of the diaqua isomers by thiocyanate to 5% conversion. The reaction mixtures were chromatographed and the chromium(III) species were eluted with 0.1–0.5 M $HClO_4$. The complexes were identified by their UV/Vis spectra. Chromium concentrations were determined by atomic absorption spectrometry using a Varian ABQ-20 instrument.

**Mercury(II)-Assisted Aquation Kinetics:** These reactions were monitored spectrophotometrically using a Shimadzu UV-1601 PC spectrophotometer equipped with a Shimadzu CPS-240A digital temperature controller. Absorbance/time data were collected at $\lambda$ = 270 nm for the *cis* isomer and at $\lambda$ = 265 nm for the *trans* isomer; the decrease of absorbance was up to 0.4. The kinetic experiments covered the temperature range 298–329 K for the *cis* and 298–340 K for the *trans* isomer and the hydrogen ion concentration range 0.02–1.8 M, giving half-lives of the reactions of between 6 and 18000 s. The chromium(III) concentration was kept at 0.25 mM in most of the experiments but was varied in the range 0.2–0.5 mM. The concentration of mercury(II) necessary for greater than 95% transformation of the starting complexes into the dinuclear compounds was kept at 25 mM in most experiments but was varied in the concentration range 0.02–0.1 M. The ionic strength was maintained constant at 2.0 M by the addition of $NaClO_4$. Reactions were initiated by injecting a portion of the stock complex solution (0.2 mL) into a thermostatted solution (1.8 mL) containing all other components. Kinetic runs were repeated three times, five times at the lowest $H^+_{(aq)}$ concentration. The pseudo-first-order rate constants, $k_{obs}$, were calculated by standard non-linear regression analysis from the absorbance, $A_{obs}$, vs. time, $t$, data using the formula $A_{obs} \approx A_{calc} = A_0 + A_1 \cdot e^{-k_{obs} \cdot t}$. Data up to four half-lives were used for the rate-constant calculations. The obtained rate constants were practically independent of the chromium(III) concentration and independent of mercury(II) concentrations at levels above 0.02 M. The average reproduction in the final calculations to give the rate constants and activation parameters of Table 3 was about 1.0% for the *cis* reagent and 3.6% for the *trans* reagent.

**Thiocyanate Anation Kinetics:** The thiocyanate anation reactions were monitored spectrophotometrically at $\lambda$ = 310 nm using Perkin–Elmer Lambda 18 and Lambda 20 spectrophotometers, with cell holders thermostatted with a Perkin–Elmer or a Julabo F-25 thermostat. The ionic strength was kept constant at 1.0 M with $H^+$, $Na^+$, $Br^-$ and $NCS^-$. Kinetic measurements at the lower temperatures were done by applying an initial rate method, under pseudo-zero-order conditions, where the increase of absorbance was recorded up to less than 5% of the conversion degree. Absorbance changes for the *trans* isomer are shown in Figure S2 in the Supporting Information. The absorbance changes for the *cis* complex are analogous to those seen for the *trans* complex, as could be expected. The experiments covered the temperature range 298–318 K for the *cis* and 308–328 K for the *trans* complex and the concentration ranges $[Cr^{III}]$ = 5–15 mM, $[NCS^-]$ = 0.01–0.8 M and $[H^+_{(aq)}]$ = 0.01–0.5 M. The reactions were initiated by injection of a stock NaNCS solution (0.1 mL) into a thermostatted solution (1.9 mL) containing all other components. All kinetic runs were repeated three times. The pseudo-zero-order rate constants, $k_{obs}^{(0)}$, were calculated by linear regression analysis from the absorbance, $A$, vs. time, $t$, data using the expression $A_{obs} \approx A_{calc} = A_0 + k_{obs}^{(0)} \cdot \varepsilon_{310} \cdot t$, where $\varepsilon_{310}$ is the molar absorption coefficient for the complexes. The pseudo-first-order rate constants $k^{(1)}$, calculated as $k_{obs}^{(0)}/[Cr^{III}] = k^{(1)}$, are directly proportional to the thiocyanate concentration at $[NCS^-] << 0.1$ M. The kinetic parameters obtained in this way are, of course, strongly dependent on the accuracy of the determination of the reactant concentrations and accurate determination of the molar absorption coefficients for the examined complexes. However, a good agreement between the values found by this method at lower temperatures and by the experimental approach described below for the higher temperatures was obtained. Kinetic measurements at these latter conditions were performed under conventional pseudo-first-order conditions with $[Cr^{III}]$ (0.1 mM) << $[NCS^-]$ (0.035–0.1 M). These experiments covered the temperature range 318–338 K for the *cis* and 328–348 K for the *trans* complex and the hydrogen ion concentration range 0.002–0.1 M. The reactions were initiated by injection of a stock solution of the complex (0.1 mL) into a thermostatted solution (3.0 mL) containing all other components. The pseudo-first-order rate constants, $k_{obs}^{(1)}$, were calculated by non-linear regression from the absorbance, $A_{obs}$, vs. time, $t$, data using the formula $A_{obs} \approx A_{calc} = A_0 + A_1 \cdot e^{-k_{obs}^{(1)} \cdot t}$. At higher thiocyanate concentrations a deviation from the linear behaviour is seen. The pseudo-first-order rate constants at the lower thiocyanate concentrations were converted into second-order rate constants, and these data are the basis for the average rate constants and activation parameters listed in Table 4. The reproduction of the individual rate constants in this final calculation was about 4.7% for the *cis* reagent and 3.6% for the *trans* reagent.

**Determination of Acidity Constants:** Acidity constants were determined by potentiometric titrations at 298 and 313 K. The ionic strength was kept constant at 1.0 M by the addition of NaBr. The results are given in Table 2.

**Supporting Information** (see footnote on the first page of this article): Spectral changes accompanying the addition of mercury(II) to *cis*-$[Cr(cyc\textit{b})(H_2O)(NCS)]^{2+}$ and anation of *trans*-$[Cr(cyc\textit{a})(OH_2)_2]^{3+}$ by thiocyanate.

# New Bis(silyl)cyclopentadienidoniobium and -tantalum Complexes: X-ray Crystal Structures of [NbCp^Cl$_4$] and [NbCp^Cl$_4$(CNAr)] [Cp^ = η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$); Ar = 2,6-Me$_2$C$_6$H$_3$]

**Manuel Gómez,*[a] Pilar Gómez-Sal,[a] and José Manuel Hernández[a]**

**Keywords:** Niobium / Tantalum / Cyclopentadienyl complexes

The [bis(silyl)cyclopentadienido]tetrachloroniobium and -tantalum complexes [MCp^Cl$_4$] [Cp^ = η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$); M = Nb **3**, Ta **4**] were synthesized by reaction of the pentachlorides MCl$_5$ with C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)$_2$ (**1**). Although the Lewis acidity of tetrachloro complexes **3** and **4** is lower than that of the pentahalides, two adducts [M{η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)}Cl$_4$(CNAr)] (Ar = 2,6-Me$_2$C$_6$H$_3$; M = Nb **5**, Ta **6**) have been isolated by reaction with ArNC. Complexes **3** and **4** react with *tert*-butylamine or lithium amides to afford the dichloroimido and amidochloroimido complexes [M{η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)}Cl$_2$(NR)] (R = *t*Bu, M = Nb **7**, Ta **8**; R = Me, M = Nb **9**) and [Ta{η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)}Cl(NH*t*Bu)(N*t*Bu)] (**10**), respectively. In addition, **7** and **8** can be prepared by treatment of the pentachlorides with [C$_5$H$_3$(SiMe$_2$NH*t*Bu)(SiMe$_3$)$_2$] (**2**) by elimination of **1**. The tetrachloro compound **3** reacts with four equivalents of *t*BuNH$_2$ to give the constrained-geometry derivative [Nb{η$^5$-C$_5$H$_3$(SiMe$_2$N*t*Bu-κ*N*)(SiMe$_3$)}Cl(N*t*Bu)] (**11**), whereas the treatment of toluene solutions of **3** and **4** with H$_2$NCH$_2$CH$_2$NH$_2$ in the presence of triethylamine leads to the trichloro complexes [M{η$^5$-C$_5$H$_3$(SiMe$_2$NCH$_2$CH$_2$NH$_2$-κ$^2$*N*,*N*)(SiMe$_3$)}Cl$_3$] (M = Nb **12**, Ta **13**). All the reported complexes were studied by IR and NMR spectroscopy and the molecular structures of complexes **3** and **5** were determined by X-ray diffraction methods.

## Introduction

Mono- and bis(cyclopentadienido) complexes of early transition metals with silyl-substituted cyclopentadienido rings have been extensively used as reagents in organic synthesis and also as precursors to prepare soluble Ziegler–Natta-type olefin polymerization catalysts.[1] The presence of different substituents in the cyclopentadienido moiety modifies the steric and electronic requirements of the central metal atom, particularly when such substituents contain reactive functional groups. Thus, when chlorine is present in these silyl groups the complex offers a new reactivity center that allows their fixation on silica supports and the cyclopentadienido ring loses its exclusive role as an ancillary ligand. In the last few years various studies have been published regarding the comparative reactivity between the Si–Cl and M–Cl bonds of different chlorosilylcyclopentadienido complexes[2] that have been used as versatile starting compounds in significant synthetic strategies for constrained-geometry catalysts[2d,3] with bidentate η$^5$-silylcyclopentadienido-η$^1$-amido ligands.

The imido group is a strong π-donor ligand that is useful for stabilizing high-valent metal complexes.[4] It is isolobal with the cyclopentadienido moiety[5] and therefore provides group 5 metal complexes that are isoelectronic with the group 4 metallocenes that are extensively used as Ziegler–Natta catalysts. Furthermore, the easy modification of the steric and electronic properties of the imido ligand by varying its alkyl moiety make this type of compound very versatile. For these reasons a rich chemistry of imido group 5 metal complexes has been reported in the last few years.[6]

As part our interest in the structure–reactivity relationship analysis in group 5 metal monocyclopentadienido compounds, we report here the synthesis of new bis(silyl)-cyclopentadienidoniobium and -tantalum complexes and the results obtained in the study of the simultaneous aminolysis of Si–Cl and M–Cl bonds. In addition, the molecular structures of complexes **3** and **5**, as determined by X-ray diffraction methods, are reported.

## Results and Discussion

The synthesis of C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)$_2$ (**1**) was effected by treatment of a tetrahydrofuran suspension of the lithium salt [Li{C$_5$H$_3$(SiMe$_3$)$_2$}][7] with dichlorodimethylsilane at –78 °C (Scheme 1). After work-up, **1** was obtained as a yellow oil which can be stored in the dark under an inert atmosphere for several weeks (yield 85%) and was identified by $^1$H NMR spectroscopy (see Experimental Section) as an equilibrium mixture of isomers in which 1-(chlorodimethyl-

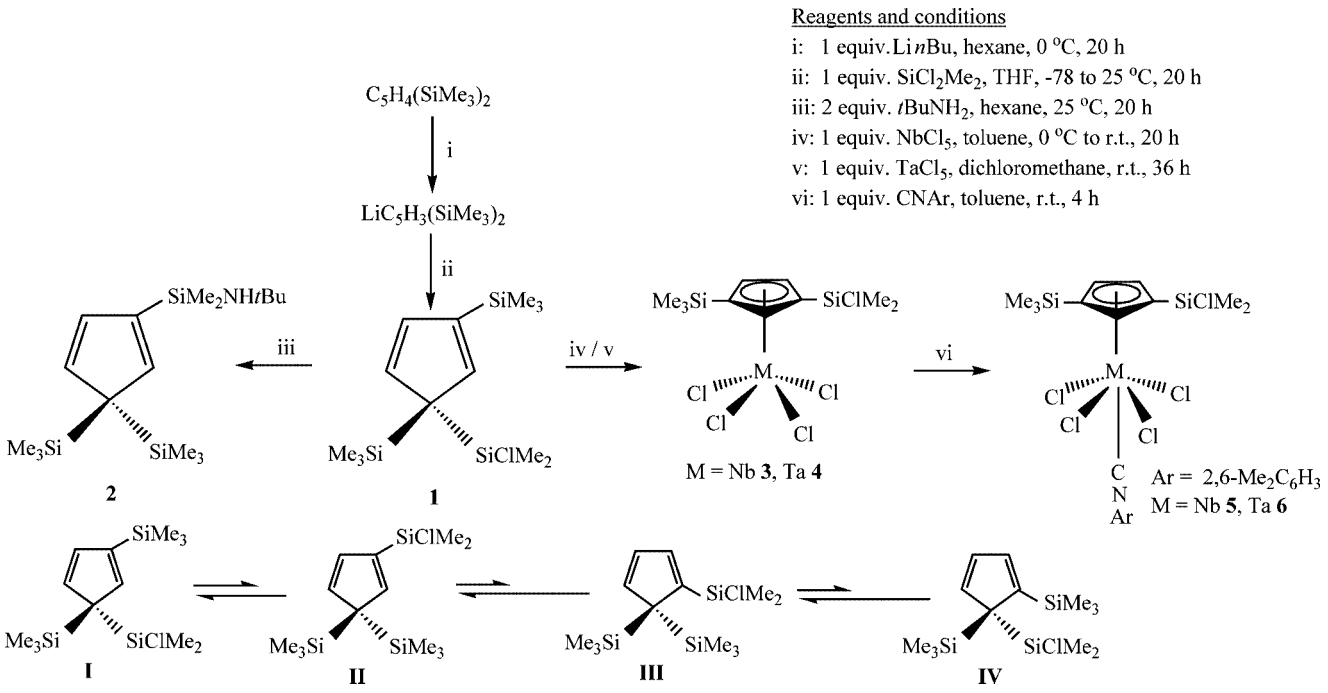

Scheme 1.

silyl)-1,3-bis(trimethylsilyl)cyclopentadiene (**I**) and 1,1-bis-(trimethylsilyl)-3-(chlorodimethylsilyl)cyclopentadiene (**II**) are the major components in a 3:2 ratio, as usually occurs in all cyclopentadienes of the type $C_5H_3X_2Y$.[8]

The precursor $C_5H_3(SiMe_2NHtBu)(SiMe_3)_2$ (**2**) was prepared in good yields (90%) as an orange oil by treatment of **1** with two equivalents of *tert*-butylamine in hexane at room temperature. Compound **2** was characterized by NMR spectroscopy as essentially the only product of the reaction.

Compound **1** reacts with one equivalent of the pentachlorides $MCl_5$ (M = Nb, Ta) in toluene (M = Nb) or dichloromethane (M = Ta) at 0 °C (M = Nb) or room temperature (M = Ta) to give the corresponding monocyclopentadienido complexes $[M\{\eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)\}Cl_4]$ (M = Nb **3**, Ta, **4**) with elimination of $SiClMe_3$. The red (M = Nb) and green (M = Ta) compounds were isolated in 90 and 70% yield, respectively, upon cooling their solutions to –20 °C. Both tetrachloro complexes **3** and **4** show a Lewis acidic character and adducts $[M\{\eta^5\text{-}C_5H_3(SiMe_3)(SiClMe_2)\}Cl_4(CNAr)]$ (Ar = 2,6-$Me_2C_6H_3$; M = Nb **5**, Ta, **6**) can be isolated by addition of one equivalent of 2,6-$Me_2C_6H_3NC$ to their toluene solutions.

The molecular structure and atom-labeling scheme of **3** are shown in Figure 1, while the most relevant geometrical parameters are summarized in Table 1. In the solid state, this complex presents a dimeric structure with the two half moieties related by a symmetric center and the niobium atoms bonded through two asymmetrically bridging chlorine atoms. The coordination sphere of the niobium atom

[a] Cp(1) is the centroid of C(1)–C(5); symmetry operation #1: $-x + 2, -y + 1, -z$.

can be described as elongated octahedral, with the cyclopentadienido ring and a chlorine atom in the apical positions and with four chlorine atoms in the equatorial plane. The niobium atom is located 0.6 Å above the equatorial plane.[6d,6f,9,10] The Nb–$Cl_{equatorial}$ bond lengths range from 2.375(2) to 2.482(2) Å, with the largest distance corresponding to the chlorine atom implicated in the bridging system that is also bonded at the apical position of the symmetry-related niobium atom, although in this case with a larger distance of 2.763(2) Å. The Cp–Nb–$Cl(4)_{apical}$ angle and the Nb–Cp distance are 175.03° and 1.235 Å, respectively, both of which are in the normal range. A similar asymmetric bridge has been described for the complexes $[\{(NbCl_2)_2(\mu\text{-}O)(\mu\text{-}Cl)_2\}\{(\eta^5\text{-}C_5H_4)_2(Me_2SiOSiMe_2)\}]$[6c] and $[\{Nb(\eta^5\text{-}C_5H_4SiMe_3)Cl_2\}_2(\mu\text{-}O)(\mu\text{-}Cl)_2]$,[11] although in these cases a bridging oxygen atom is also present.

The two silicon atoms of the substituents in the cyclopentadienido ring [Si(1) and Si(2)] are located above the Cp plane by 0.37 and 0.39 Å, respectively, and the chlorine atom is perpendicular to this plane. This position for the chlorine atom has been described in other complexes containing a $C_5H_4(SiClMe_2)$ ring.[12] It is relevant to note that no other similar structures with a disubstituted Cp ring have been described.

A view of the molecular structure of complex **5** is shown in Figure 2 together with the atom-numbering scheme. Selected bond lengths and angles are given in Table 2. The Cp^ ring is bound to the niobium atom in a nearly symmetric $\eta^5$-fashion with the distance between the metal and the centroid of the ring being 2.137 Å and with the two silicon atoms of the substituents Si(6) and Si(7) located 0.31 Å above the ring plane. The isocyanide ligand is linearly bound to the niobium atom, the values of the Nb–C(6) bond length and of the Nb–C(6)–N(1) and C(6)–N(1)–C(7) angles being 2.215(13) Å and 176.3(11)° and 175.2(13)°, respectively; the length of the N(1)–C(6) bond [1.192(15) Å] is in agreement with a triple bond.[6,13] The coordination around the niobium atom is completed by four chlorine atoms with Nb–Cl bond lengths ranging from 2.412(3) to 2.442(3) Å. Complex **5** is pseudo-octahedral if the centroid of the Cp^ ring is considered as occupying a coordination site, although the niobium atom is displaced by 0.60 Å from the mean equatorial plane passing through the four chlorine atoms toward the cyclopentadienido ring.

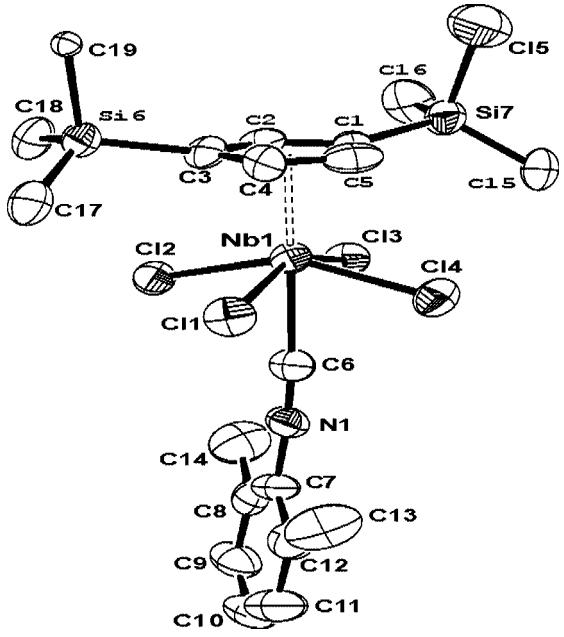

Figure 2. ORTEP drawing of compound **5** with thermal ellipsoids at the 50% probability level.

The comparative reactivity of the two different types of Si–Cl and M–Cl bonds present in the starting tetrachloro complexes **3** and **4** was studied in reactions with amines and amides. Related studies with chlorocyclopentadienidotitanium[3g,3h,14] and -niobium[2d] derivatives led to the formation of constrained monomeric cyclic species containing the pendant amido group of the cyclopentadienido ligand coordinated to the metal center. The dichloroimido complexes $[MCp^{\wedge}Cl_2(NR)]$ [$Cp^{\wedge} = \eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)$; R =

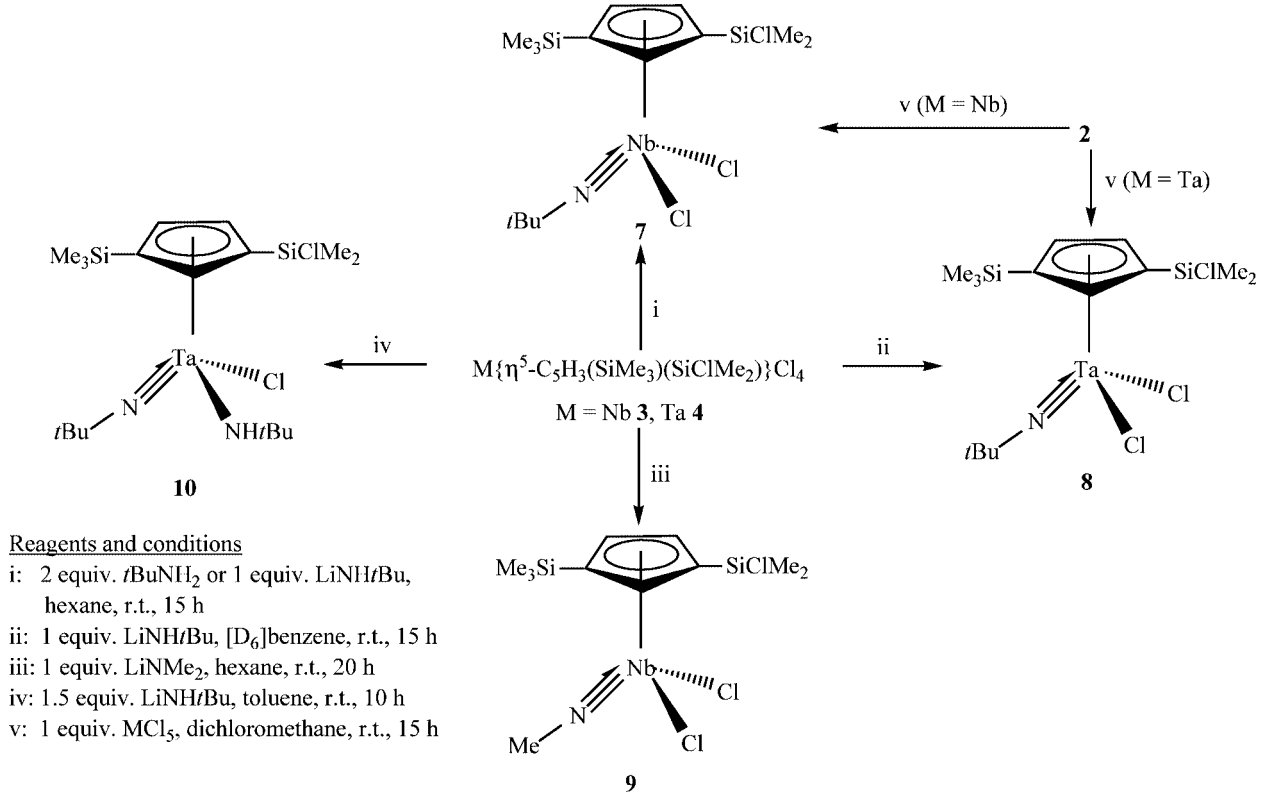
[a] Cp is the centroid of C(1)–C(5).

*t*Bu, M = Nb **7**, Ta, **8**; R = Me, M = Nb **9**] were isolated in good yields upon treatment of **3** and **4** with one equivalent of the appropriate lithium amide (see Scheme 2). Complex **7** also can be prepared with two equivalents of *tert*-butylamine, whereas the treatment of **4** with 1.5 equivalents of LiNH*t*Bu leads to the amidochloroimido complex [Ta{η$^5$-$C_5H_3(SiMe_3)(SiClMe_2)$}Cl(NH*t*Bu)(N*t*Bu)] (**10**). The formation of the imido complexes **7**–**10** takes place with elimination of LiCl and HCl but the Si–Cl bond of the cyclopentadienido ring remaining unaltered.

Alternatively, the reaction of **2** with niobium and tantalum pentachlorides in a 1:1 ratio leads to the dichloroimido compounds **7** and **8**, respectively, by elimination of HCl, cyclopentadiene **1**, and a mixture of other, unidentified products.

Partial substitution of the chloride moieties occurs upon treatment of a hexane solution of **3** with four equivalents of $tBuNH_2$ (Scheme 3) and leads to the constrained-geometry complex [Nb{η$^5$-$C_5H_3(SiMe_3)(SiMe_2N$*t*Bu-κ*N*)}Cl(N*t*Bu)] (**11**) with evolution of HCl. Furthermore, the addition of



Scheme 2.

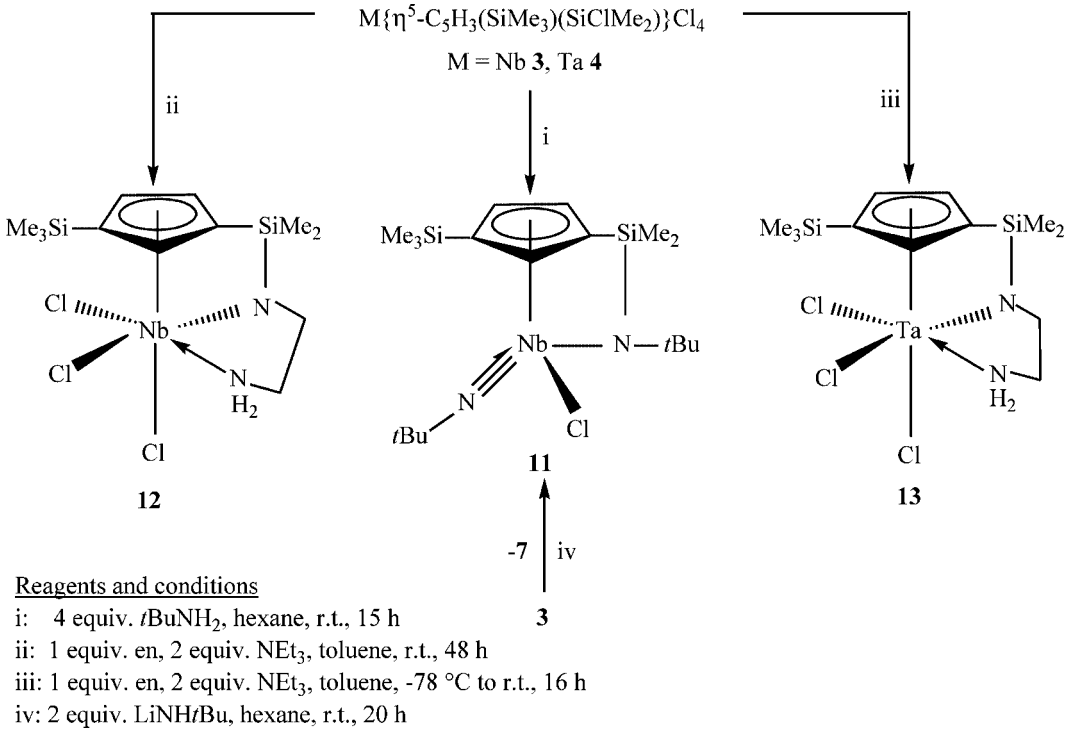

Scheme 3.

one equivalent of ethylenediamine and two equivalents of $NEt_3$ to toluene solutions of the tetrachloro complexes **3** and **4** gives, after separation of the ammonium salt formed, the pseudo-octahedral trichloro species $[M\{\eta^5\text{-}C_5H_3(SiMe_3)[SiMe_2N(CH_2)_2NH_2\text{-}\kappa^2N,N\}Cl_3]$ (M = Nb **12**, Ta **13**). However, a mixture of complexes **7** and **11** was obtained upon treatment of **3** with two equivalents of LiNH*t*Bu.

Complexes **3**–**13** are soluble in most organic solvents, including saturated hydrocarbons. They are extremely air- and moisture-sensitive, so rigorously dried solvents and handling under dry inert atmosphere were found to be imperative for successful preparations. Their spectroscopic data (see Experimental Section) are in agreement with the proposed structures. The IR spectra show the characteristic absorptions for a cyclopentadienido ring ($\nu_{C-H} \approx 839\ cm^{-1}$)[15] and the trimethylsilyl substituent [$\delta_s(CH_3) \approx 1254\ cm^{-1}$].[6f,15] Complexes **5** and **6** show $\nu_{C\equiv N}$[6a,13] at around 2221 $cm^{-1}$, whereas the imido complexes show the $\nu_{M=N}$[6,15,16] IR absorption at about 1348 $cm^{-1}$. The M–C, M–N, and N–H stretching vibrations are observed at $\tilde{\nu} \approx$ 469,[6a,17] 594,[6d] and 3248 $cm^{-1}$,[6a,18] respectively.

The $^1H$ NMR spectra of complexes **3** and **4** show the expected resonances for the methyl groups bonded to silicon. Three broad multiplets corresponding to an ABC spin system are observed for the cyclopentadienido ring protons. These assignments were confirmed by the $^{13}C\{^1H\}$ NMR spectra. The NMR spectroscopic data of adducts **5** and **6** are in agreement with the expected behavior for pseudo-octahedral compounds[6a,13] with the cyclopentadienido ring and the isocyanide ligand mutually *trans*. The *o*-methylphenyl isocyanide groups are equivalent and, in addition, three and five resonances for the $C_5H_3(SiClMe_2)(SiMe_3)$ ring protons and carbons are observed, respectively.

Although the structures of complexes **7**–**10** in the solid state have not been determined, we assume them to be monomers that are pseudo-tetrahedral and isostructural with other half-sandwich imido group 5 metal derivatives.[6b,6d,6e] Their formulation as dichloroimido complexes is supported by analytical and spectroscopic data (see Experimental Section) according to the behavior expected for three-legged piano-stool species.

Complex **11** is a disymmetric molecule due to the enantiotopic faces of the cyclopentadienido ring and the niobium atom. Its $^1H$ NMR spectrum shows a singlet for the equivalent methyl protons of the $SiMe_3$ substituent, two singlets for the inequivalent methyl groups bonded to the silicon in the $SiClMe_2$ moiety, and three low-field multiplets for the ring protons due to the presence of the chiral niobium center. In addition, three methylsilyl resonances, two N*t*Bu signals, and five ring carbon resonances appear in the $^{13}C\{^1H\}$ NMR spectrum.

The trichloro complexes **12** and **13** show a similar NMR behavior to that discussed above for **11**, and all these *ansa* compounds exhibit a characteristic $^{13}C$ signal due to the ring carbon $C^1$–$SiClMe_2$ [$\delta$ = 110 (**11**), 106 (**12**), 105.2 ppm (**13**)], which is shifted upfield with respect to the other ring carbon resonances.[3h,19]

## Conclusions

The tetrachlorobis(silyl)cyclopentadienidoniobium and -tantalum complexes $[M\{\eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)\}Cl_4]$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(M = Nb **3**, Ta **4**) have been prepared by a conventional reaction between $MCl_5$ and $C_5H_3(SiClMe_2)(SiMe_3)_2$ (**1**). Its Lewis acid character has been established by reaction with isocyanides to give $[M\{\eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)\}Cl_4L]$ (M = Nb **5**, Ta **6**; L = 2,6-$Me_2C_6H_3NC$), while in the presence of stoichiometric amounts of amines or lithium amides the dichloroimido and amidochloroimido complexes $[M\{\eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)\}Cl_2(NR)]$ (R = *t*Bu, M = Nb **7**, Ta **8**; R = Me, M = Nb **9**) and $[Ta\{\eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)\}Cl(NH\textit{t}Bu)(N\textit{t}Bu)]$ (**10**), respectively, are isolated. In addition, the constrained-geometry niobium derivative $[Nb\{\eta^5\text{-}C_5H_3(SiMe_2N\textit{t}Bu\text{-}\kappa\textit{N})(SiMe_3)\}Cl(N\textit{t}Bu)]$ (**11**) can be prepared by treatment of the tetrachloro compound with four equivlents of $\textit{t}BuNH_2$, whereas with ethylenediamine the pseudo-octahedral trichloro complexes $[M\{\eta^5\text{-}C_5H_3(SiMe_2NCH_2CH_2NH_2\text{-}\kappa^2\textit{N},\textit{N})(SiMe_3)\}Cl_3]$ (M = Nb **12**, Ta **13**) were obtained.

## Experimental Section

**General:** All reactions and manipulations were carried out under argon using standard Schlenk-tube and globe-box techniques. Solvents were refluxed in the presence of an appropriate drying agent and distilled and degassed prior use: [$D_6$]benzene and hexane (Na/K alloy), [D]chloroform (NaH), tetrahydrofuran (Na/benzophenone), dichloromethane ($P_2O_5$), and toluene (Na). Bis(trimethylsilyl)cyclopentadienide[7d] was synthesized as described previously, while LiNH*t*Bu was prepared by treatment of $\textit{t}BuNH_2$ with Li*n*Bu. Reagent-grade chemicals were purchased from commercial sources and used without further purification: $SiClMe_3$, $SiCl_2Me_2$, $\textit{t}BuNH_2$, $TaCl_5$, Li*n*Bu (1.6 M in hexanes), $LiNMe_2$, $NEt_3$, and $H_2N\text{–}(CH_2)_2\text{–}NH_2$ from Aldrich, and $NbCl_5$ from Fluka. Infrared spectra were recorded with a Perkin–Elmer Spectrum 2000 spectrophotometer (4000–400 $cm^{-1}$) with samples as KBr pellets. $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a "Unity 300" or a "Mercury VX 300" (Varian NMR Systems) spectrometer; chemical shifts are referenced to the $^1H$ ($\delta$ = 7.15 and 7.24 ppm) and $^{13}C$ ($\delta$ = 128 and 77 ppm) residual resonances of [$D_6$]benzene and [$D_1$]-chloroform, respectively. Microanalyses (C,H,N) were performed with a LECO CHNS 932 microanalyzer.

**$[C_5H_3(SiClMe_2)(SiMe_3)_2]$ (1):** A 1.6 M hexane solution of Li*n*Bu (62.5 mL, 100 mmol) was added dropwise at 0 °C to a solution of freshly distilled $C_5H_4(SiMe_3)_2$ (21.02 g, 100 mmol) in hexane (400 mL). The reaction mixture was slowly warmed to room temperature and stirred for 20 h to afford a white precipitate, which, after filtration, was washed with hexane (2 × 100 mL), dried under vacuum, and identified as $LiC_5H_3(SiMe_3)_2$ (19.45 g, 90.00 mmol, 90%).

A suspension of $LiC_5H_3(SiMe_3)_2$ (19.45 g, 90.00 mmol) in tetrahydrofuran (300 mL) was treated with $SiCl_2Me_2$ (10.92 mL, 90.00 mmol) at –78 °C. The reaction mixture was then warmed to room temperature and stirred for 20 h. After filtration, the solvent was removed by evaporation under vacuum and the residue extracted with hexane (2 × 100 mL). The solvent was again removed to give a yellow oil, which was characterized as compound **1** (23.18 g, 80.00 mmol, 85%). $^1H$ NMR ([$D_6$]benzene, 25 °C): **I** (*major*): $\delta$ = 6.85 (m, 1 H, $C_5H_3$), 6.81 (m, 1 H, $C_5H_3$), 6.49 (m, 1 H, $C_5H_3$), 0.24 (s, 9 H, $SiMe_3$), 0.19 (s, 3 H, $SiClMe_2$), 0.16 (s, 3 H, $SiClMe_2$), 0.07 ppm (s, 9 H, $SiMe_3$); **II** (*minor*): $\delta$ = 6.95 (m, 1 H, $C_5H_3$), 6.90 (m, 1 H, $C_5H_3$), 6.46 (m, 1 H, $C_5H_3$), 0.54 (s, 6 H, $SiClMe_2$), –0.04 ppm (s, 18 H, $SiMe_3$). $^{13}C\{^1H\}$ NMR ([$D_6$]benzene, 25 °C): **I** (*major*): $\delta$ = 147.3 ($C^3$), 143.2, 136.7, 135.2, 71.5 (br., $C^1$ of $C^5$ ring), 1.8, 1.4 ($SiClMe_2$), –0.77 ($SiMe_3$), –0.83 ppm ($SiMe_3$); **II** (*minor*): $\delta$ = 147.1 ($C^3$), 137.5, 135.3, 133.6, 71.5 (br., $C^1$ of $C^5$ ring), 2.7 ($SiClMe_2$), –0.7 ppm ($SiMe_3$). $^{29}Si$ NMR ([$D_6$]-benzene, 25 °C): **I** (*major*): $\delta$ = 19.7 ($SiClMe_2$), –1.0 ($SiMe_3$), –10.4 ppm ($SiMe_3$); **II** (*minor*): $\delta$ = 14.4 ($SiClMe_2$), –1.9 ppm ($SiMe_3$).

**$[C_5H_3(SiMe_2NH\textit{t}Bu)(SiMe_3)_2]$ (2):** A solution of **1** (10.00 g, 33.00 mmol) in hexane (150 mL) was treated with *tert*-butylamine (4.83 g, 66.00 mmol) at room temperature. The reaction mixture was stirred for 20 h and then the resulting suspension was filtered. The solvent was evaporated to dryness to give an orange oil, which was identified as compound **2**. Yield: 7.95 g (90%). $^1H$ NMR ([$D_6$]-benzene, 25 °C): $\delta$ = 7.00 (m, 1 H, $C_5H_3$), 6.85 (m, 1 H, $C_5H_3$), 6.51 (m, 1 H, $C_5H_3$), 1.17 (s, 9 H, *t*Bu), 0.36 (s, 6 H, $SiMe_2NH\textit{t}Bu$), –0.02 ppm (s, 18 H, $SiMe_3$); N*H* signal not detected. $^{13}C\{^1H\}$ NMR ([$D_6$]benzene, 25 °C): $\delta$ = 146.7 ($C^3$), 145.3, 136.2, 135.3, 60 ($C^1$ of $C^5$ ring), 49.6 ($CMe_3$), 33.9 ($CMe_3$), 2.0 ($SiMe_2$), –0.5 ppm ($SiMe_3$).

**$[Nb\{\eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)\}Cl_4]$ (3):** Compound **1** (2.24 g, 7.40 mmol) was added to a suspension of $NbCl_5$ (2.00 g, 7.40 mmol) in toluene (150 mL) at 0 °C. The reaction was slowly warmed at room temperature and stirred for 20 h. After filtration, the resulting solution was concentrated to about 25 mL and cooled to –20 °C to give a dark red microcrystalline solid which was characterized as **3**. Yield: 3.10 g (90%). IR (KBr): $\tilde{\nu}$ = 3091 $cm^{-1}$ w, 1397 m, 1262 vs, 1089 m, 839 vs, 488 vs, 455 s. $^1H$ NMR ([$D_1$]chloroform, 25 °C): $\delta$ = 7.49 (br., 1 H, $C_5H_3$), 7.41 (br., 1 H, $C_5H_3$), 7.20 (br., 1 H, $C_5H_3$), 0.92 (s, 6 H, $SiClMe_2$), 0.43 ppm (s, 9 H, $SiMe_3$). $^{13}C\{^1H\}$ NMR ([$D_1$]chloroform, 25 °C): $\delta$ = 146.6 ($C^1$), 139.7 ($C^3$), 134, 133.6, 133.2 ($C_5H_3$), 1.9 ($SiClMe_2$), –0.6 ppm ($SiMe_3$). $C_{10}H_{18}Cl_5NbSi_2$ (464.60): calcd. C 25.85, H 3.90; found C 25.78, H 3.63.

**$[Ta\{\eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)\}Cl_4]$ (4):** A mixture of equimolar amounts of **1** (2.53 g, 8.36 mmol) and freshly sublimed $TaCl_5$ (3.00 g, 8.36 mmol) in dichloromethane (200 mL) was stirred at room temperature for 36 h in a sealed ampoule. After the ampoule was opened, the suspension was filtered and the resulting green solution was concentrated to about 25 mL and cooled to –20 °C to give **4** as a green microcrystalline solid. Yield: 3.23 g (70%). IR (KBr): $\tilde{\nu}$ = 3093 $cm^{-1}$ w, 1393 m, 1252 vs, 1093 s, 831 vs, 497 vs, 455 s. $^1H$ NMR ([$D_1$]chloroform, 25 °C): $\delta$ = 7.32 (m, 1 H, $C_5H_3$), 7.23 (m, 1 H, $C_5H_3$), 7.00 (m, 1 H, $C_5H_3$), 0.91 (s, 6 H, $SiClMe_2$), 0.42 ppm (s, 9 H, $SiMe_3$). $^{13}C\{^1H\}$ NMR ([$D_1$]chloroform, 25 °C): $\delta$ = 142.5 ($C^1$), 131.6 ($C^3$), 131.1, 130.9, 130.8 ($C_5H_3$), 2.0 ($SiClMe_2$), –0.5 ppm ($SiMe_3$). $C_{10}H_{18}Cl_5Si_2Ta$ (552.64): calcd. C 21.73, H 3.28; found C 21.65, H 3.13.

**$[M\{\eta^5\text{-}C_5H_3(SiClMe_2)(SiMe_3)\}Cl_4(CNAr)]$ [Ar = 2,6-$Me_2C_6H_3$; M = Nb (5), Ta (6)]:** 2,6-$Me_2C_6H_3NC$ (0.17 g, 1.30 mmol) was added to a toluene (70 mL) solution of **3** (0.60 g, 1.30 mmol) or **4** (0.72 g, 1.30 mmol) under rigorously anhydrous conditions. The mixture was stirred for 4 h and then filtered. Concentration and cooling of the filtrate gave **5** and **6** as rose (**5**) and green (**6**) microcrystalline solids.

**5:** Yield: 0.70 g (90%). IR (KBr): $\tilde{\nu}$ = 3100 $cm^{-1}$ w, 2957 m, 2218 s, 1625 m, 1473 m, 1401 m, 1255 vs, 1089 s, 842 vs, 484 vs, 455 vs. $^1H$ NMR ([$D_1$]chloroform, 25 °C): $\delta$ = 7.52 (t, $^3J_{H,H}$ = 2.1 Hz, 1 H, $C_5H_3$), 7.41 (t, $^3J_{H,H}$ = 2.1 Hz, 1 H, $C_5H_3$), 7.21 (t, $^3J_{H,H}$ = 2.1 Hz, 1 H, $C_5H_3$), 7.25 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, *p*-$C_6H_3$), 7.11 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, *m*-$C_6H_3$), 2.54 (s, 6 H, $C_6H_3Me_2NC$), 0.95 (s, 3 H, $SiClMe_2$), 0.88 (s, 3 H, $SiClMe_2$), 0.41 ppm (s, 9 H, $SiMe_3$).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$^{13}C\{^1H\}$ NMR ([D$_1$]chloroform, 25 °C ): $\delta$ = 195 (*C*N), 142.4, 139.2, 139, 138.4, 136.8 ($C_5H_3$), 130.5 ($C^{2,6}$), 129 ($C^1$), 128.1 ($C^{3,5}$), 125.3 ($C^4$, $C_6H_3Me_2NC$), 18.4 ($C_6H_3Me_2NC$), 3.02, 2.97 (SiCl*Me*$_2$), 0.03 ppm (Si*Me*$_3$). $C_{19}H_{27}Cl_5NNbSi_2$ (595.775): calcd. C 38.30, H 4.57, N 2.35; found C 38.49, H 4.65, N 2.30.

**6:** Yield: 0.62 g (70%). IR (KBr): $\tilde{\nu}$ = 3098 cm$^{-1}$ w, 2954 m, 2223 s, 1629 s, 1474 m, 1403 m, 1252 vs, 1091 s, 840 vs, 490 vs, 457 s. $^1H$ NMR ([D$_1$]chloroform, 25 °C): $\delta$ = 7.23 (t, 1 H), 7.20 (t, 1 H), 6.88 (t, $^3J_{H,H}$ = 2.1 Hz, 1 H, $C_5H_3$), 7.10 (m, 3 H, $C_6H_3Me_2NC$), 2.52 (s, 6 H, $C_6H_3Me_2NC$), 0.99 (s, 3 H, SiCl*Me*$_2$), 0.88 (s, 3 H, SiCl*Me*$_2$), 0.41 ppm (s, 9 H, Si*Me*$_3$). $C_{19}H_{27}Cl_5NSi_2Ta$ (683.817): calcd. C 33.37, H 3.98, N 2.05; found C 33.17, H 3.83, N 2.00.

**[Nb{η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)}Cl$_2$(N*t*Bu)] (7):** Complex **7** can be prepared by two synthetic methods.

**Method A:** *t*BuNH$_2$ (0.07 g, 0.96 mmol) was added under rigorously anhydrous conditions to a solution of **3** (0.22 g, 0.48 mmol) in hexane (50 mL) and the reaction mixture was stirred for 15 h. The solution was filtered and the solvent reduced to dryness to give an orange oil which was identified as **7**.

**Method B:** A solution of LiN*H*t*Bu (0.04 g, 0.48 mmol) in hexane (15 mL) was added to a solution of **3** (0.22 g, 0.48 mmol) in hexane (50 mL) at room temperature. The reaction mixture was stirred for 15 h. Filtration of the supernatant solution from the solid, followed by concentration to dryness, produced **7** as an orange oil. Yield: 0.16 g (70%). IR (KBr): $\tilde{\nu}$ = 3190 cm$^{-1}$ w, 2973 m, 1404 m, 1359 m, 1254 vs, 1084 vs, 840 vs, 503 vs, 459 m. $^1H$ NMR ([D$_6$]benzene, 25 °C): $\delta$ = 7.04 (m, 1 H, $C_5H_3$), 6.49 (m, 1 H, $C_5H_3$), 6.45 (m, 1 H, $C_5H_3$), 1.13(s, 9 H, N*t*Bu), 0.59 (s, 6 H, SiCl*Me*$_2$), 0.21 ppm (s, 9 H, Si*Me*$_3$). $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 25 °C ): $\delta$ = 130 ($C^1$), 129.3 ($C^3$), 124.4, 122.1, 121.6 ($C_5H_3$), 70.2 [N(*C*Me$_3$)], 30.5 [N(C*Me*$_3$)], 3.6, 3.1 (SiCl*Me*$_2$), 0.02 ppm (Si*Me*$_3$). $C_{14}H_{27}Cl_3NNbSi_2$ (464.814): calcd. C 36.18, H 5.85, N 3.01; found C 35.93, H 5.96, N 2.90.

**[Ta{η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)}Cl$_2$(N*t*Bu)] (8):** LiN*H*t*Bu (0.003 g, 0.040 mmol) was added to a solution of **4** (0.20 g, 0.40 mmol) in [D$_6$]benzene (0.7 mL) in a valved NMR tube under rigorously anhydrous conditions. The reaction was monitored by $^1H$ NMR spectroscopy until no further changes were observed. The final spectrum was indicative of complete transformation of the starting material and confirmed the formation of **8** in quantitative yield. Evaporation of the solvent gave **8** as a yellow oil. Yield: 0.17 g (75%). $^1H$ NMR ([D$_6$]benzene, 25 °C): $\delta$ = 7.03 (m, 1 H, $C_5H_3$), 6.42 (m, 2 H, $C_5H_3$), 1.20 (s, 9 H, N*t*Bu), 0.58 (s, 3 H, SiCl*Me*$_2$), 0.56 (s, 3 H, SiCl*Me*$_2$), 0.2 ppm (s, 9 H, Si*Me*$_3$). $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 25 °C): $\delta$ = 127 ($C^1$), 127.3, 122.3, 121.6, 121.2 ($C_5H_3$), 66.6 [N(*C*Me$_3$)], 32.1 [N(C*Me*$_3$)], 3.4, 3.0 (SiCl*Me*$_2$), –0.1 ppm (Si*Me*$_3$). $C_{14}H_{27}Cl_3NNbSi_2$ (552.86): calcd. C 30.42, H 4.92, N 2.53; found C 30.44, H 4.71, N 2.37.

**Reaction of C$_5$H$_3$(SiMe$_2$NH*t*Bu)(SiMe$_2$) (2) with MCl$_5$ (M = Nb, Ta):** $C_5H_3$(SiMe$_2$NH*t*Bu)(SiMe$_2$) (0.63 g, 1.85 mmol) was added to a suspension of $NbCl_5$ (0.50 g, 1.85 mmol) in dichloromethane (80 mL) and the reaction mixture stirred for 15 h. After filtration, the volatiles were removed under vacuum to give a yellow oil, which was identified as a mixture of **1** and **7** by $^1H$ NMR spectroscopy. With $TaCl_5$ a mixture of **1** and **8** was identified by $^1H$ NMR spectroscopy.

**[Nb{η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)}Cl$_2$(NMe)] (9):** A mixture of **3** (0.30 g, 0.64 mmol) and $LiNMe_2$ (0.03 g, 0.64 mmol) was dissolved in hexane (50 mL) under rigorously anhydrous conditions. The reaction mixture was stirred for 20 h at room temperature and then filtered. The filtrate was evaporated to dryness and the residue extracted with hexane (2 × 10 mL). Concentration and cooling of the filtrate produced **9** as a brown solid. Yield: 0.10 g (37%). $^1H$ NMR ([D$_6$]benzene, 25 °C): $\delta$ = 6.85 (m, 1 H, $C_5H_3$), 6.34 (m, 1 H, $C_5H_3$), 6.27 (m, 1 H, $C_5H_3$), 3.31(s, 3 H, N*Me*), 0.55 (s, 3 H, SiCl*Me*$_2$), 0.53 (s, 3 H, SiCl*Me*$_2$), 0.17 ppm (s, 9 H, Si*Me*$_3$). $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 25 °C): $\delta$ = 129.5, 122.7, 122.5, 122.1, 121.6 ($C_5H_3$), 54.3 (N*Me*), 3.2, 2.7 (SiCl*Me*$_2$), –0.3 ppm (Si*Me*$_3$). $C_{11}H_{21}Cl_3NSi_2Ta$ (422.733): calcd. C 31.25, H 5.01, N 3.31; found C 31.12, H 4.94, N 3.25.

**[Ta{η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)}Cl(NH*t*Bu)(N*t*Bu)] (10):** A toluene (15 mL) solution of LiN*H*t*Bu (0.06 g, 0.81 mmol) was slowly added to a solution of **4** (0.30 g, 0.54 mmol) in toluene (60 mL) and the reaction mixture was stirred overnight. The resulting suspension was filtered and the solvent evaporated to dryness. The residue was extracted with hexane (2 × 10 mL) and the solution was concentrated and cooled to –20 °C to give an oily yellow product which was characterized as **10**. Yield: 0.09 g (30%). IR (KBr): $\tilde{\nu}$ = 3083 cm$^{-1}$ w, 1403 m, 1358 s, 1261 vs, 1085 vs, 840 vs, 633 m, 504 s, 548 m. $^1H$ NMR ([D$_1$]chloroform, 25 °C): $\delta$ = 8.09 (br., 1 H, N*H*t*Bu), 7.05 (m, 1 H, $C_5H_3$), 6.79 (m, 2 H, $C_5H_3$), 1.24 (s, 18 H, NH*t*Bu + N*t*Bu), 0.74 (s, 3 H, SiCl*Me*$_2$), 0.72 (s, 3 H, SiCl*Me*$_2$), 0.31 ppm (s, 9 H, Si*Me*$_3$). $^{13}C\{^1H\}$ NMR ([D$_1$]chloroform, 25 °C): $\delta$ = 134.8, 127.8, 127.3, 121.6, 121.2 ($C_5H_3$), 66.6 (N*C*Me$_3$), 53.2 (NH*C*Me$_3$), 32.1 (NHC*Me*$_3$ + NC*Me*$_3$), 3.4 (SiCl*Me*$_2$), 2.9 (SiCl*Me*$_2$), –0.1 ppm (Si*Me*$_3$). $C_{18}H_{37}Cl_2N_2Si_2Ta$ (589.53): calcd. C 36.67, H 6.33, N 4.75; found C 36.47, H 6.43, N 4.57.

**[Nb{η$^5$-C$_5$H$_3$(SiMe$_2$N*t*Bu-κ*N*)(SiMe$_3$)}Cl(N*t*Bu)] (11):** A solution of **3** (0.22 g, 0.48 mmol) in hexane (50 mL) was treated with *t*BuNH$_2$ (0.14 g, 1.92 mmol). The mixture was stirred at room temperature for 15 h and then filtered. Solvent was removed from the resulting solution to give **11** as a yellow oil. Yield: 0.14 g (60%). IR (KBr): $\tilde{\nu}$ = 3196 cm$^{-1}$ w, 1448 m, 1359 s, 1250 vs, 1081 vs, 841 vs, 633 m, 499 m. $^1H$ NMR ([D$_6$]benzene, 25 °C): $\delta$ = 7.09 (m, 1 H, $C_5H_3$), 6.64 (m, 1 H, $C_5H_3$), 6.50 (m, 1 H, $C_5H_3$), 1.19 (s, 9 H, *t*Bu), 1.03 (s, 9 H, *t*Bu), 0.48 (s, 3 H, Si*Me*$_2$), 0.42 (s, 3 H, Si*Me*$_2$), 0.27 ppm (s, 9 H, Si*Me*$_3$). $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 25 °C): $\delta$ = 137.3 ($C^1$), 123.1, 122.2, 122.1, 110 ($C^3$, $C_5H_3$), 49.9, 48.5 (N*C*Me$_3$), 33.8, 30.6 (NC*Me*$_3$), 2.9, 2.7 (Si*Me*$_2$), 0.15 ppm (Si*Me*$_3$). $C_{18}H_{36}ClN_2NbSi_2$ (465.03): calcd. C 46.49, H 7.80, N 6.02; found C 46.38, H 7.69, N 5.92.

**Reaction of [Nb{η$^5$-C$_5$H$_3$(SiClMe$_2$)(SiMe$_3$)}Cl$_4$] (3) with LiN*H*t*Bu:** LiN*H*t*Bu (0.07 g, 0.86 mmol) was added to a solution of **3** (0.20 g, 0.43 mmol) in hexane (30 mL). The reaction mixture was stirred for 20 h and the solvent was then completely removed under vacuum. The resulting oily brown product was characterized as a mixture of complexes **7** and **11** by $^1H$ NMR spectroscopy.

**[Nb{η$^5$-C$_5$H$_3$(SiMe$_2$NCH$_2$CH$_2$NH$_2$-κ$^2$*N*,*N*)(SiMe$_3$)}Cl$_3$] (12):** A solution of **3** (1.40 g, 3.00 mmol) in toluene (150 mL) was treated at room temperature with a solution of ethylenediamine (0.18 g, 3.00 mmol) and triethylamine (0.61 g, 6.00 mmol) in toluene (20 mL). The reaction mixture was stirred for 48 h and the solvent was evaporated to dryness. The resulting yellow residue was washed with cool hexane (2 × 5 mL) and the solid was dried in vacuo and identified as **12**. The result was similar when **3** was treated with 2 equiv. of ethylenediamine. Yield: 1.00 g (75%). IR (KBr): $\tilde{\nu}$ = 3249 cm$^{-1}$ m, 3072 w, 1448 w, 1259 vs, 1248 vs, 1089 s, 836 vs, 553 s, 493 m. $^1H$ NMR ([D$_6$]benzene, 25 °C): $\delta$ = 6.94 (m, 1 H, $C_5H_3$), 6.86 (m, 2 H, $C_5H_3$), 4.60 (br, 2 H, $CH_2CH_2NH_2$), 3.27 (m, 2 H, $NCH_2CH_2$), 2.68 (m, 2 H, $NCH_2CH_2$), 0.51 (s, 9 H, Si*Me*$_3$), 0.08 (s, 3 H, Si*Me*$_2$), 0.05 ppm (s, 3 H, Si*Me*$_2$). $^{13}C\{^1H\}$ NMR ([D$_6$]-benzene, 25 °C): $\delta$ = 140.8 ($C^1$), 133.4, 130.1, 130, 106 [$C^3$, $C_5H_3$(SiMe$_2$NCH$_2$CH$_2$NH$_2$)(SiMe$_3$)], 59.7 (N*C*H$_2$CH$_2$), 45.4 (NCH$_2$*C*H$_2$),

0.05 (Si*Me*$_3$), –3.9 (Si*Me*$_2$), –5.4 ppm (Si*Me*$_2$). $^{29}$Si NMR ([D$_6$]-benzene, 25 °C): $\delta$ = –3.9 (*Si*Me$_3$), –12.3 ppm (*Si*Me$_2$). $C_{12}H_{24}Cl_3N_2NbSi_2$ (451.78): calcd. C 31.90, H 5.35, N 6.20; found C 32.00, H 5.32, N 5.73.

**[Ta{η$^5$-C$_5$H$_3$(SiMe$_2$NCH$_2$CH$_2$NH$_2$-κ$^2$*N*,*N*)(SiMe$_3$)}Cl$_3$] (13):** A solution of ethylenediamine (0.039 g, 0.65 mmol) and triethylamine (0.13 g, 1.30 mmol) in toluene (10 mL) was slowly added to a solution of **4** (0.36 g, 0.65 mmol) in toluene (50 mL) at –78 °C. The reaction mixture was warmed to room temperature and stirred for 16 h. The volatiles were removed in vacuo and the residue was extracted with hexane (2 × 10 mL). The resulting solution was concentrated and cooled to –20 °C to afford **11** as a pale-yellow crystalline solid. Yield: 0.15 g (40%). IR (KBr): $\tilde{\nu}$ = 3247 cm$^{-1}$ br. s, 3073 w, 1443 w, 1248 vs, 1089 s, 847 vs, 556 s, 492 m. $^1$H NMR ([D$_6$]benzene, 25 °C): $\delta$ = 6.79 (d, $^3J_{H,H}$ = 2.1 Hz, 1 H, C$_5H_3$), 6.67 (d, $^3J_{H,H}$ = 2.1 Hz, 2 H, C$_5H_3$), 4.28 (br, 2 H, CH$_2$CH$_2$N*H*$_2$), 3.54 (m, 2 H, C*H*$_2$CH$_2$NH$_2$), 2.63 (m, 2 H, CH$_2$C*H*$_2$NH$_2$), 0.51 (s, 9 H, Si*Me*$_3$), 0.12 (s, 3 H, Si*Me*$_2$), 0.09 ppm (s, 3 H, Si*Me*$_2$). $^{13}$C{$^1$H} NMR ([D$_6$]benzene, 25 °C): $\delta$ = 131.3 (*C*$^1$), 129.3, 126.4, 125.6, 105.2 (*C*$^3$, *C*$_5$H$_3$), 55.4, 45.3 (*C*H$_2$*C*H$_2$NH$_2$), 1.4 (Si*Me*$_3$), 0.4 (Si*Me*$_2$), 0.2 ppm (Si*Me*$_2$). $^{29}$Si NMR ([D$_6$]benzene, 25 °C): $\delta$ = –4.5 (*Si*Me$_3$), –13.2 ppm (*Si*Me$_2$). $C_{12}H_{24}Cl_3N_2Si_2Ta$ (539.82): calcd. C 26.70, H 4.48, N 5.19; found C 26.55, H 4.33, N 5.25.

**X-ray Structure Determination of 3 and 5:** Crystallographic and experimental details of the crystal structure determinations are given in Table 3. Suitable crystals of complexes **3** and **5** were covered with mineral oil and mounted in the N$_2$ stream of a Bruker-Nonius Kappa CCD diffractometer; data were collected using graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data collections were performed at low temperature (see Table 3), in the case of compound **3** with an exposure time of 8 s per frame (5 sets; 391 frames) and for compound **5** with an exposure time of 36 s per frame (5 sets; 240 frames). Raw data were corrected for Lorenz and polarization effects.

Both structures were solved by direct methods, completed by the subsequent difference Fourier techniques, and refined by full-matrix least-squares on $F^2$ with SHELXL-97.[20] Anisotropic thermal parameters were used in the last cycles of refinement for the non hydrogen atoms. The hydrogen atoms were included from geometrical calculations and refined using a riding model. All the calculations were made using the WINGX system.[21]

CCDC-613239 (for **3**) and -613240 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Coordinative Versatility of Guanazole [3,5-Diamino-1,2,4-triazole]: Synthesis, Crystal Structure, EPR, and Magnetic Properties of a Dinuclear and a Linear Trinuclear Copper(II) Complex Containing Small Bridges and Triazole Ligands

**Elena Aznar,[a] Sacramento Ferrer,*[a] Joaquín Borrás,[a] Francesc Lloret,[a] Malva Liu-González,[b] Héctor Rodríguez-Prieto,[c] and Santiago García-Granda[c]**

**Keywords:** Copper / 1,2,4-Triazole ligands / Polynuclear compounds / X-ray structures / Magnetic properties

New complexes with guanazole (3,5-diamino-1,2,4-triazole = Hdatrz), $[Cu_2(Hdatrz)_2(\mu\text{-}OH_2)(H_2O)_4(SO_4)](SO_4)\cdot 3.5H_2O$ (**1**) and $[Cu_3(Hdatrz)_4(\mu\text{-}Cl)_2(H_2O)_4(SO_4)_2]\cdot 11.4H_2O$ (**2**), have been prepared and structurally characterized. Complex **1** is a noncentrosymmetric dinuclear compound in which the copper(II) ions are bridged by two triazole ligands and one $\mu$-$OH_2$ molecule, with a Cu(1)···Cu(2) distance of 3.4945(8) Å. The chromophores are $Cu(1)N_2O_2O'$ (square pyramidal), and $Cu(2)N_2O_2O'O''$ (octahedral). Complex **2** has a linear trinuclear copper(II) structure, with two crystallographically independent copper(II) atoms. Neighboring copper(II) ions are linked by two triazole ligands and one slightly asymmetric chlorido bridge. The intratrimeric Cu(1)···Cu(2) distance is 3.5602 (4) Å. Cu(2), the central copper, is coordinated to $N_4Cl_2$ (octahedral) while Cu(1), the terminal copper, is coordinated to $N_2O_2ClO'$ (also octahedral). Magnetic susceptibility measurements (2–300 K) are in accordance with the dinuclear (**1**) and trinuclear (**2**) nature of these compounds. The best-fit parameters, obtained with the Hamiltonian $\mathbf{H} = -J\Sigma_{i<j}\mathbf{S}_i\mathbf{S}_j$, are as follows: $g = 2.10(1)$ and $J = -94.3(2)$ cm$^{-1}$ for **1**; and $g_{central} = 2.12(1)$, $g_{peripheral} = 2.07(1)$, and $J = -89.9(3)$ cm$^{-1}$ for **2**. Compound **1**, which has an unprecedented *folded* bridging $\{Cu(N\text{–}N)_2Cu\}$ system, exhibits a magnetic exchange comparable to that of related *planar* compounds. Comparison of the magneto-structural properties of **2** with those of analogous linear trinuclear compounds has made a first approach to the relative magnitude of the *J* value possible. The Q-band powder spectra, which were recorded in a range from 4 K to room temperature, are in agreement with the magnetic susceptibility measurements.

## Introduction

A variety of coordination compounds with 3,5-disubstituted 1,2,4-triazoles as ligands coordinating to transition-metal ions have been reported.[1–3] The interesting magnetic properties of the coordination compounds of iron(II) and copper(II) with 1,2,4-triazole ligands have been investigated extensively; among these, polynuclear (1,2,4-triazole)-iron(II) compounds have been found to show spin-crossover behavior.[4–7] These ligands allow for two general bridging modes, one involving only triazole bridges and another also containing either small bridging anions, such as $Cl^-$, $F^-$, $NCS^-$, $N_3^-$ or $OH^-$, or small bridging molecules such as $H_2O$.[1]

Even though guanazole (3,5-diamino-1,2,4-triazole = Hdatrz) (Figure 1) is a simple molecule and an inexpensive chemical, only nine X-ray structures of complexes of this triazole have been documented to date and, to the best of our knowledge, none with $Cu^{II}$ have been reported thus far. There is a similar lack of publications concerning the related unsubstituted 1,2,4-triazole ligand. In the latter case, the scarcity of structures has been attributed in part to the fact that the ligand often immediately produces a microcrystalline, insoluble precipitate with transition-metal ions.[1] The structures described for guanazole include one mononuclear compound with $Pt^{II}$;[8] two two-dimensional polymers: one with $Cd^{II}$[9] and one with $Mn^{II}$;[10] two cyclic trinuclear compounds of $Pd^{II}$;[11,12] and four linear trinuclear compounds with $[M_3\{(H)datrz\}_6L_6]$ (L = $H_2O$ or

$NCS^-$) units: one with Co(II,III)[13] and three with $Ni^{II}$.[14–16] No dinuclear structures have been reported. It has been suggested that, because the substituents in position 3 and 5 are apparently capable of forming hydrogen bonds, the linking of metal ions by triple bridges is preferred.[1,17]

In the aforementioned structures, guanazole is known to coordinate in three different ways, either unidentate through *N*1, or bridging-bidentate through *N*1,*N*2 or *N*2,*N*4. Moreover, Hdatrz can occur in three different chemical forms, namely neutral (in most cases), anionic (with deprotonation at *N*4),[13] or cationic (with protonation at *N*2).[8] Especially interesting is the compound $[Co_3(datrz)_2(Hdatrz)_4(H_2O)_6]Cl_3{\cdot}9H_2O$, which includes mixed valences of cobalt ions and triazole/triazolate mixed ligand bridges.[13] Thus, in spite of its apparent simplicity, guanazole is quite a versatile ligand. As a result, we have found that the reaction solution often affords a mixture of compounds.

In this paper, we report on the isolation of two $Cu^{II}$ compounds of Hdatrz with different nuclearity, one dinuclear (**1**) and the other linear trinuclear (**2**). Both compounds present double-triazole bridges and an additional small bridge, which is water in the case of **1** or chlorido in the case of **2**. Both compounds also contain the neutral *N*1,*N*2-bidentate ligand guanazole. We describe here the structural and spectroscopic characterization of these compounds, as well as the study of their magnetic properties in the context of related compounds.

## Results and Discussion

### Crystal Structure of $[Cu_2(Hdatrz)_2(\mu\text{-}OH_2)(H_2O)_4(SO_4)](SO_4){\cdot}3.5H_2O$ (1)

The structure of complex **1** is made up of dinuclear cations, one sulfate anion per cation, and non-coordinated water molecules, one of which is located on a symmetry site. There is one O(7) lattice water molecule per four $Cu^{II}$ ions. An ORTEP view of the structure, together with its numbering scheme, is depicted in Figure 2. Selected bond lengths and angles are presented in Table 1.

Table 1. Selected bond lengths [Å] and bond angles [°] for **1**.

| O(3)–Cu(1)–O(4) | 91.4(2) | | |

In the dinuclear unit, the two copper centers, which are crystallographically independent, are bridged by two neutral guanazole ligands and one water molecule. The coordination environment around Cu(1) is distorted square pyramidal, with two triazole N atoms and two water O atoms in equatorial positions and the bridging water O atom in the axial position [Cu(1)–O(5) = 2.474(4) Å]. The second $Cu^{II}$ has a similar environment, but it is octahedrally coordinated; the second axial coordination position is achieved by one sulfate O atom [Cu(2)–O(5) = 2.382(5), Cu(2)–O(11) = 2.425(4) Å]. The observed Cu–N distances, ranging from 1.986(5) to 2.005(4) Å, are common for dinuclear *N*1,*N*2-

Figure 2. ORTEP drawing of **1** showing the atomic labeling system (a) and the noncoplanarity of the $\{Cu(N–N)_2Cu\}$ framework (b).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

triazole-bridged $Cu^{II}$ compounds[1,18,19] and comparable to the Cu–O water distances, which range from 1.968(5) to 2.000(4) Å. Cu(1) and Cu(2) are displaced from their corresponding equatorial planes by 0.0104(7) Å and 0.0416(9) Å, respectively. The two equatorial planes are almost perpendicular; the dihedral angle between them measures 80.3(2)°.

The two Cu–O(5) distances differ slightly. The angle Cu(1)–O(5)–Cu(2) is 92.0(2)°. The combination of both bridges gives rise to a Cu···Cu′ distance of 3.4945(8)°. This distance is significantly shorter than that found in double-triazole-bridged $Cu^{II}$ compounds without a third bridge. For example, the Cu···Cu′ distances compiled by Slangen et al.[18] and Ferrer et al.[19] for dimeric compounds oscillate between 4.085(1) and 3.854(6) Å, which indicates that the μ-$OH_2$ causes the bridging system to fold. It must be taken into account, however, that since the referred compounds all contain *N*,*N*-bridging ligands with N/O-chelating substituents that form five/six-membered chelate rings, the situation is not strictly comparable with that of our structure. In the triazole bridge, the Cu–N–N angles of **1**, which range from 119.9(3) to 123.3(3)°, also differ clearly from those of the aforementioned dimeric $Cu^{II}$ structures, all of which have at least one Cu–N–N angle larger than 128°; besides, those with five-membered chelating rings all have at least two Cu–N–N angles close to 135°.[18,19]

On the other hand, as will be discussed in the next section, the Cu···Cu′ distance of **1** is shorter than the equivalent distance in the analogous linear trinuclear structure of **2** [3.5602(4) Å], which also has an additional small bridge, but a different donor atom size ($O_{H_2O}$ in **1**; $Cl^-$ in **2**).

Another difference between **1** and the dinuclear $Cu^{II}$ complexes mentioned in the literature is that in the latter the {Cu–$(N–N)_2$–Cu} framework is nearly planar,[17] whereas in **1** this group of atoms deviates significantly from planarity (the N atoms deviate from the least-squares plane by 0.8–0.9 Å). In fact, in the double-triazole bridging system of **1**, the dihedral angle between the planes defined by [Cu(1),N(1a),N(2a),Cu(2)] and [Cu(1),N(2b),N(1b),Cu(2)] is 64.3(1)° (Figure 2b).

Complex **1** is, to the best of our knowledge, the second example of a binuclear compound with two bridging triazoles and one bridging oxygen atom. The first example reported, the Cd compound $[Cd_2(deatrz)_2(H_2O)Br_4]$ (deatrz = 3,5-diethyl-4-amino-1,2,4-triazole), forms a 1D chain through hydrogen-bonding contacts.[20] This complex has a Cd···Cd′ distance of 3.819 Å.[21]

Finally, complex **1** presents strong intermolecular hydrogen bonds between the bridging water molecule and the sulfate anions: O(5)–H(w5a)···O(23) (from the non-coordinated sulfate) [2.874(9) Å, 148(5)°] and O(5)–H(w5b)···$O(14^{\#})$ [from the coordinated sulfate of a different asymmetric unit; $O(14^{\#})$ is generated by the symmetry operation: $x - 1/2, -y + 1/2 + 1, + z - 1/2$] [2.723(4) Å, 161(5)°]. Such contacts should play an important role in the stabilization of the structure.

### Crystal Structure of $[Cu_3(Hdatrz)_4(\mu\text{-}Cl)_2(H_2O)_4(SO_4)_2]\cdot 11.4H_2O$ (2)

The structure of complex **2** consists of discrete trinuclear entities and randomly placed water of crystallization. The fractional number of water molecules arises from the fact that 2 out of the 7 crystallographically different crystallization water molecules found in the structure do not have a 100% occupancy factor; actually, that of O(5) is 40%, while that of O(9) is only 30%. An ORTEP projection of the structure and the atom-labeling scheme are given in Figure 3. Selected bond lengths and angles are listed in Table 2.

In the linear trinuclear units the metal ions are bridged by two neutral guanazole ligands and one chloride anion. The central copper atom, located at the inversion center, exhibits a tetragonally distorted coordination afforded by four nitrogen atoms from the bridging *N*1,*N*2-triazole ligands and the two bridging chloride anions. Because the copper is situated at the inversion center, the nitrogen atoms are in a nearly regular square, with Cu(2)–N distances of 2.024(3) and 2.003(3) Å. Again, these distances are within

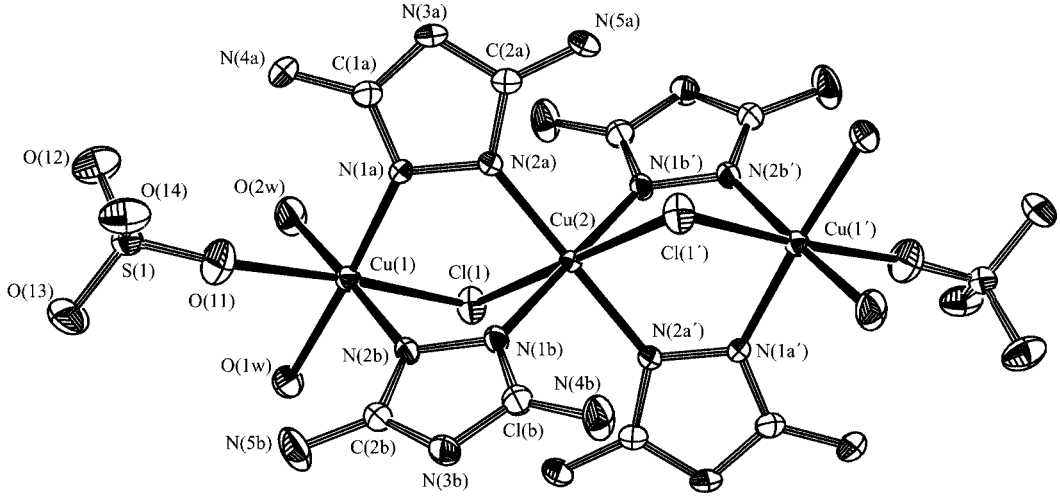

Figure 3. ORTEP drawing of **2** showing the atomic labeling system. H atoms have been omitted for clarity.

[a] Primed atoms are generated by $-x, -y, -z$.

the normal range for *N*1,*N*2-bridging 1,2,4-triazole ligands.[1,18,19,22] The two chloride anions act as axial ligands at semi-coordinating distances [Cu(2)–Cl(1) = 2.785(2) Å]; the distance from the bridging chloride to the terminal metal ion is comparable [Cu(1)–Cl(1) = 2.624(2) Å]. Thus, the chlorido bridge, with a Cu(1)–Cl(1)–Cu(2) angle of 82.28(3)°, is rather symmetrical.

The chlorido bridging system of **2** is different from that found in the analogous compound reported by van Koningsbruggen et al., $[Cu_3(H_2ahmt)_6Cl_4]Cl_2$ [$H_2$ahmt = 4-amino-3,5-bis(hydroxymethyl)-1,2,4-triazole] (compound **6**, Table 3), in which not only are the μ-$Cl^-$ located at equatorial instead of axial positions in the environment of the central $Cu^{II}$, but also the bridging distances are very asymmetric [Cu(1)–Cl(1) = 2.296(1), Cu(2)–Cl(1) = 2.688(1) Å].[22] This situation is probably related to the steric hindrance produced by bulkier substituents on the ring of the $H_2$ahmt ligand. In contrast, **2** is more comparable with the compound described by Keij and co-workers, $[Cu_3(tmtz)_8F_2](BF_4)_4{\cdot}2H_2O$ [tmtz = 3,4,5-trimethyl-1,2,4-triazole] (**7**), although the latter has one $F^-$ instead of one $Cl^-$ bridge [Cu(1)–F(1) = 2.20(1), Cu(2)–F(1) = 1.91(1) Å].[23]

The terminal copper ions of **2** are hexacoordinated by two nitrogen atoms from bridging triazole ligands and two oxygen atoms from two water molecules, all in equatorial positions, and by the bridging chloride anion and an oxygen atom from a sulfate anion in apical positions [Cu(1)–O(1) = 2.511(3) Å]. The Cu(1)(terminal)–N distances [1.995(3), 1.987(3) Å] are slightly shorter that the Cu(2)(central)–N distances [2.003(3), 2.024(3) Å], but it can be considered that the $H_2$datrz ligands also bridge the copper(II) ions in an almost symmetrical way, as evidenced by the close values of the Cu–N–N angles, which range from 122.0(3) to 123.1(2)°, and those of the N–Cu–N angles, with values of 89.4(2) and 91.7(2)°. The Cu–N–N–Cu torsion angles [–4.2(4) and –9.4(4) Å], indicate that the triazole ligands tend to twist out of the equatorial plane formed by the two $Cu^{II}$ ions involved.

The equatorial coordination planes around Cu(1) and Cu(2) form a dihedral angle of 79.0(1)°. Thus, they are almost perpendicular, as was also observed in the dimeric structure of **1**. The dihedral angle between the least-squares planes through the triazole rings linking Cu(1) and Cu(2) measures 55.7(2) Å (Figure 3).

The Cu(1)–Cu(2) distance is 3.5602(4) Å, which is similar to that found in related linear trinuclear double-μ-*N*1,*N*2-triazole-bridged $Cu^{II}$ complexes with an additional small bridging anion such as $Cl^-$ [3.5426(1), 3.620(3), and 3.5682(5) Å, for complexes **3**, **4**, and **6**, respectively][22,24] or $N_3^-$ [3.5034(6) Å for **5**],[25] but longer than that of the analogous complex with an $F^-$ bridge [3.362(3) Å for **7**].[23] This is probably due to the small size of the $F^-$ ion (Table 3). It should be noted that the Cu···Cu′ separation in **2** is shorter than that in triple-μ-*N*1,*N*2-triazole-bridged copper(II) compounds, such as $[Cu_3(metrz)_6(H_2O)_4](CF_3SO_3)_6{\cdot}4H_2O$ (metrz = 3-methyl-4-ethyl-1,2,4-triazole) [3.719(7) Å][26] or $[Cu(hyetrz)_3](ClO_4)_2{\cdot}3H_2O$ [hyetrz = 4-(2-hydroxyethyl)-1,2,4-triazole] [3.853(2) and 3.829(2) Å].[27] This indicates that, when the third triazole is replaced by monatomic bridges, the Cu···Cu′ distance tends to shorten, as previously reported[25,27] and, indeed, as expected due to the larger size of the third bridge.

We have carried out a review of the literature in order to compare more systematically some structural parameters of **2** with those of analogous compounds. Several linear trinuclear coordination compounds of this type, i.e. containing *two* 1,2,4-triazole ligands bridging through *N*1,*N*2 atoms and either a halogen anion or a second small bridging anion, have been previously reported: (a) three $Co^{II}$ compounds with $F^-$[28,29] or *N*-bridging $NCS^-$ ligands,[30] (b) three $Ni^{II}$–*N*($NCS^-$) compounds,[30–32] (c) one Mn(II,III,II) complex with hydroxido bridges,[33] (d) two $Cd^{II}$ compounds containing $Cl^-$[20] or *N*,*N*-isothiocyanato bridges,[20] and (e) a few $Cu^{II}$ compounds (Table 3). The first structurally characterized (triazole)copper(II) compound to include μ-chloride ions was [{Cu(Htrz)$Cl_2$}$_\infty$], but it consists of an infinite chain with two $Cl^-$ and a *single* triazole ligand per pair of copper atoms instead of one $Cl^-$ and two triazole ligands.[34] To the best of our knowledge, only five $Cu^{II}$ compounds strictly comparable to **2** as regards bridging systems have been published to date (all have been mentioned above): one containing μ-fluoride anions (**7**),[23] three with chlorido bridges (**3**, **4**, and **6**; of which **3** and **4** have an unusual chelating tetradentate triazole ligand), and one in which the small bridging anion is the azido $N_3^-$ group (**5**).[25] Table 3 lists several structural parameters, including coordination distances, which will be considered in the magnetism section.

## Magnetic Properties

### *Magnetic Properties of 1*

Figure 4 displays the magnetic behavior of **1** in the form of a $\chi_M T$ and $\chi_M$ vs. *T* plot, where $\chi_M$ is the magnetic susceptibility per two $Cu^{II}$ ions. Upon cooling, the $\chi_M T$ values decrease continuously from room temperature (0.73 $cm^3 \cdot mol^{-1} \cdot K$) until they vanish at 20 K. The $\chi_M$ curve shows a maximum at 90 K. This behavior is characteristic of an antiferromagnetic interaction between $Cu^{II}$ ions with a singlet spin ground state.

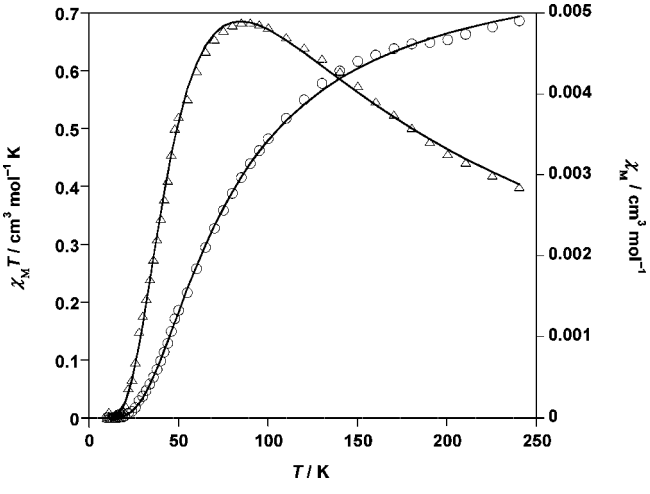

Figure 4. Thermal dependence of $\chi_M T$ (○) and $\chi_M$ (Δ) for **1** (solid lines represent theoretical curves, see text).

The magnetic data have been interpreted in accordance with the actual dinuclear nature of the complex by using the spin Hamiltonian $\mathbf{H} = -J\mathbf{S}_1\mathbf{S}_2$, from which the following susceptibility equation can be derived [Equation (1)]:

$$\chi_M = \frac{2N\beta^2 g^2}{kT} \frac{1}{3 + \exp(-\frac{J}{kT})} \quad (1)$$

Assuming that the *g* factors for both $Cu^{II}$ atoms are identical, the fit of the magnetic data with this expression results in $g = 2.10(1)$ and $J = -94.3(2)$ $cm^{-1}$.

From the molecular structure, it could be concluded that the magnetic exchange occurs via the $d_{x^2-y^2}$ orbitals on the $Cu^{II}$ ions that overlap with the σ orbitals of the nitrogen atoms of the triazole bridges, which are placed at equatorial positions. Exchange interaction through the pathway provided by the large axial bonding (through the μ-$OH_2$) can be expected to have little relevance (see Figure 2b) because of the low unpaired electron density along de $d_{z^2}$ orbital in the octahedral coordination around the copper atoms. In principle, then, at least from a magnetic point of view, compound **1** could be compared to related bis(μ-triazole)-bridged $Cu^{II}$ complexes.

Although the literature contains many examples of copper(II) complexes with bridging triazole or triazolate functionalities, only 15 acyclic complexes with metal centers bridged by two triazole-triazolate units have been structurally characterized to date,[18,19,36–42] and for only 10 of these has a magnetic study been performed; Table 4 offers a compilation of these studies.[18,19,35–39,41] As a first attempt at establishing magneto-structural correlations, Haasnoot and co-workers,[18] working with a set of compounds, concluded that Cu–$N_{trz}$–$N_{trz}$ angles of 134–135° in symmetrically doubly bridged systems lead to the largest possible coupling, with $|J| \approx 240$ $cm^{-1}$. Table 4, however, shows that, taken separately, neither the symmetry nor the Cu–$N_{trz}$–$N_{trz}$ angles allow for a prediction of the magnitude of the exchange coupling. The last two compounds in Table 4, both of which exhibit fairly symmetrical {Cu–N–N}$_2$ frameworks, present the lowest $|J|$ values. Moreover, in spite of its smaller Cu–$N_{trz}$–$N_{trz}$ angles, compound **1** displays an absolute value for *J* that is larger than that for [Cu(daat)-($NO_3$)($H_2O$)]$_2$. In this context, and with the aim of determining the factors that dominate the magnetic interaction, we carried out several DFT calculations. Trials with models including fixed Cu–N distances and variable bridging angles turned out to be unsuccessful in that they could not reproduce the trend of the experimental *J* values. In fact, the only conclusion was that the bridging angles are related with, but do not determine, the *J* value, as we had already deduced from Table 4. On the other hand, it should be noticed that, as mentioned above, in all the previously reported complexes, the [$Cu_2L_2$] unit is planar; compound **1** is the only described instance of a folded dicopper(II) complex with acyclic triazole ligands.[43] In a series of closely related dicobalt(II) complexes, a decrease in magnetic exchange interactions was observed for folded dico-

[d] Measurements performed on partially desolvated sample (and in the presence of some monomeric impurities).

balt(II) complexes as compared to their planar analogues.[43,44] This behavior is reasonable since the distortion leads to less overlap between the magnetic orbitals of the metal centers and the σ orbital of the ligand. In contrast, compound **1** exhibits larger coupling than the planar $[Cu(daat)(NO_3)(H_2O)]_2$ compound, thereby excluding coplanarity as a main factor in the magnitude of the interaction. In summary, several parameters seem to influence the magnetic exchange in the double-triazole-bridged dinuclear compounds; more examples are needed to derive a clear magneto-structural relationship.

### *Magnetic Properties of 2*

The magnetic behavior of **2** is depicted in Figure 5 in the form of a $\chi_M T$ vs. $T$ plot, where $\chi_M$ is the magnetic susceptibility per three $Cu^{II}$ ions. At room temperature, the $\chi_M T$ value is 1.00 $cm^3·mol^{-1}·K$. Upon cooling, the $\chi_M T$ values decrease, reaching a plateau with a value of 0.43 $cm^3·mol^{-1}·K$ at approximately 25 K. This behavior is characteristic for compounds with an overall antiferromagnetic interaction between the $Cu^{II}$ ions, which induces a spin doublet ground state.

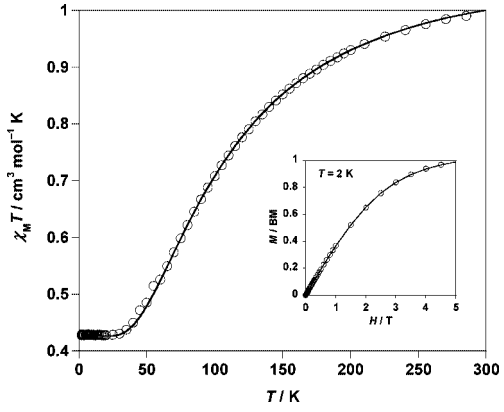

Figure 5. Thermal dependence of $\chi_M T$ for **2** (the solid line represents the theoretical curve, see text). The inset displays the magnetization curve at 2 K for **2** (the solid line is drawn to guide the eye).

In order to obtain the relevant magnetic parameters, the experimental data have been fitted by using Equation (2), derived from the spin Hamiltonian $\mathbf{H} = -J(\mathbf{S}_1\mathbf{S}_2 + \mathbf{S}_2\mathbf{S}_3)$, where $\mathbf{S}_1$ and $\mathbf{S}_3$ correspond to the peripheral $Cu^{II}$ ions ($g_1 = g_3 = g_p$) and $\mathbf{S}_2$ to the central one ($g_2 = g_c$).

$$\chi_M = \frac{N\beta^2}{4kT}\frac{g_{1/2,1}^2 + g_{1/2,0}^2\exp(\frac{J}{kT}) + 10g_{3/2,1}^2\exp(\frac{3J}{2kT})}{1+\exp(\frac{J}{kT})+2\exp(\frac{3J}{2kT})} \quad (2)$$

where:

$$g_{1/2,1} = \frac{4g_p - g_c}{3}$$
$$g_{3/2,1} = \frac{2g_p + g_c}{3} \quad (3)$$
$$g_{1/2,0} = g_c$$

The exchange constant between the terminal copper ions is assumed to be negligible. This assumption is justified from the study of the triple triazole-bridged $Fe^{II}$–$Fe^{II}$–$Fe^{II}$[45] and $Co^{II}$–$Co^{III}$–$Co^{II}$[13] trinuclear clusters, in which the central metal ion is diamagnetic, and no magnetic interactions are detected between the paramagnetic terminal ions. Moreover, these interactions only affect the relative position of the excited spin doublet with respect to the ground spin doublet and the excited spin quartet. The effect of these interactions on magnetic properties, if any, is insignificant.[46,47]

The best-fit parameters obtained were: $J = -89.9(3)$ $cm^{-1}$, $g_{central} = 2.12(1)$, and $g_{peripheral} = 2.07(1)$. The $J$ value of **2** is thus very similar to that observed for the dinuclear compound **1**, as could be expected from the identical nature of the main bridge and the similar distortion of the cores (the dihedral angles between the equatorial $Cu^{II}$ planes are 80° in **1** and 79° in **2**).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Selected magneto-structural data for the known linear trinuclear $Cu^{II}$ compounds with double μ-triazole bridges and an additional small bridge are listed in Table 3. Two groups of compounds can be established from the magnitude of the exchange: (a) those with $J$ values around –75 $cm^{-1}$ (compounds **2**–**4**), and (b) those with $J$ values close to –34 $cm^{-1}$ (compounds **5** and **6**). This trend in the $J$ values can be understood on the basis of simple orbital symmetry considerations (see Figure 6) and also by taking into account that the magnitude of the antiferromagnetic coupling, $J_{AF}$, is proportional to the overlap integral between the magnetic orbitals.[48]

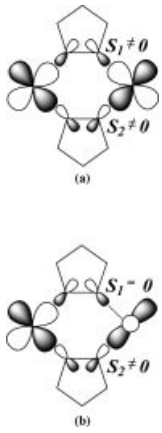

Figure 6. Orbital models for the triazole bridging system.

For compounds **2**–**4** (Figure 6a), in which both triazole bridges are located at equatorial positions as deduced from the coordination distances (see Table 3), the unpaired electron on each $Cu^{II}$ ion is in a $d_{x^2-y^2}$ type magnetic orbital, where the $x$ and $y$ axes are roughly described by the copper–$N_{triazole}$ bonds. Both magnetic orbitals exhibit good sigma overlap on each side of the bridge. As for compounds **5** and **6** (Figure 6b), only one triazole bridge is at an equatorial position (see coordination distances in Table 3). As a consequence, one of the magnetic orbitals (that corresponding to the axial site) is reversed and thus perpendicular to the triazole ring, whereas the other magnetic orbital remains coplanar. Because of the relative orientation of these magnetic orbitals, the interaction only occurs through one side of the bridge. The experimental $J$ values for both groups of compounds, that is, around –75 $cm^{-1}$ for **2**–**4** and around –34 $cm^{-1}$ for **5** and **6**, are in agreement with this simple orbital model.

## Spectroscopic Properties

### *IR Spectra*

The IR spectrum of guanazole has already been studied in detail by Desseyn et al.[9] and Kumar et al.[49] The assignment of the main peaks of the ligand and complexes **1** and **2** is indicated in the experimental section. Especially noteworthy is the fact that the IR spectra of both compounds are almost indistinguishable; this is related to the similarity in the coordination of the ligand and to the presence of similar IR-active groups such as uncoordinated and/or monocoordinated sulfate and coordinated and uncoordinated water molecules in both **1** and **2**. A minor difference is observed in the first band of the spectrum (at around 3400 $cm^{-1}$), which appears at a higher frequency in **1** than in **2**. This could be attributed to the vibrations of the μ-$OH_2$ bridge. Characteristic absorbances in agreement with both coordinated ($C_{3v}$ symmetry) and uncoordinated sulfate can be appreciated in the spectra of both complexes.[50]

### *Electronic Spectra*

The UV/Vis spectra of both compounds, recorded by using solid samples (diffuse-reflectance technique), show asymmetric bands centered at around 700 nm (**1**) and 710 nm (**2**). This feature is in agreement with the presence of two different chromophores in each complex and with the distorted tetragonal (square-pyramidal or octahedral) geometry of the copper(II) ions present in the two structures.[51] Furthermore, a clearly distinguishable maximum is observed at ca. 400 nm (**1**) and ca. 415 nm (**2**), which could be attributed either to a charge-transfer band or, in the case of **1**, to the high-energy absorption for copper(II) dimers frequently present in this region of the spectra.[19,35,52,53]

### *EPR Spectra*

Powder EPR spectra of the complexes have been recorded at room temperature at the X-band frequencies (0–5000 G), and from room temperature to 4 K at the Q-band frequencies (0–15000 G). To exclude the presence of impurities, different measurements were performed with samples obtained by powdering single crystals from different preparations. Figure 7 (for **1**) and Figure 8 (for **2**) exhibit selected Q-band spectra.

The room-temperature X-band EPR spectrum of **1** exhibits a very weak half-field ($\Delta M_s = \pm 2$) signal, centered at 1550 G, typical of a spin-coupled binuclear copper(II) system with significant population at the triplet state. An isotropic $\Delta M_s = \pm 1$ transition is also observed at $g = 2.16$. As for the Q-band frequencies, the room-temperature spectrum of **1** can be described either as inverted axial or as slightly rhombic (Figure 7a). No signal corresponding to the forbidden transition (around 4000 G) could be detected. At lower temperatures, the spectrum becomes progressively more resolved. At 30 K (Figure 7b), the spectrum shows an anisotropic signal at 10910 G and a signal at 11960 G, which can be assigned to one of the perpendicular and parallel transitions, respectively, of the excited triplet state ($S = 1$).[51] Finally, as expected, the spectrum vanishes below 30 K because of the antiferromagnetic interaction in the dimer, which leads to a diamagnetic $S = 0$ state.

The exchange interaction parameter $J$ can be determined from the temperature variation of the EPR absorption lines. The relative intensity of the absorption is expressed by Equation (3):[54]

$$R \propto (1/T)\,[(e^{-J/kT})/(1 + 3\,e^{-J/kT})] \quad (3)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

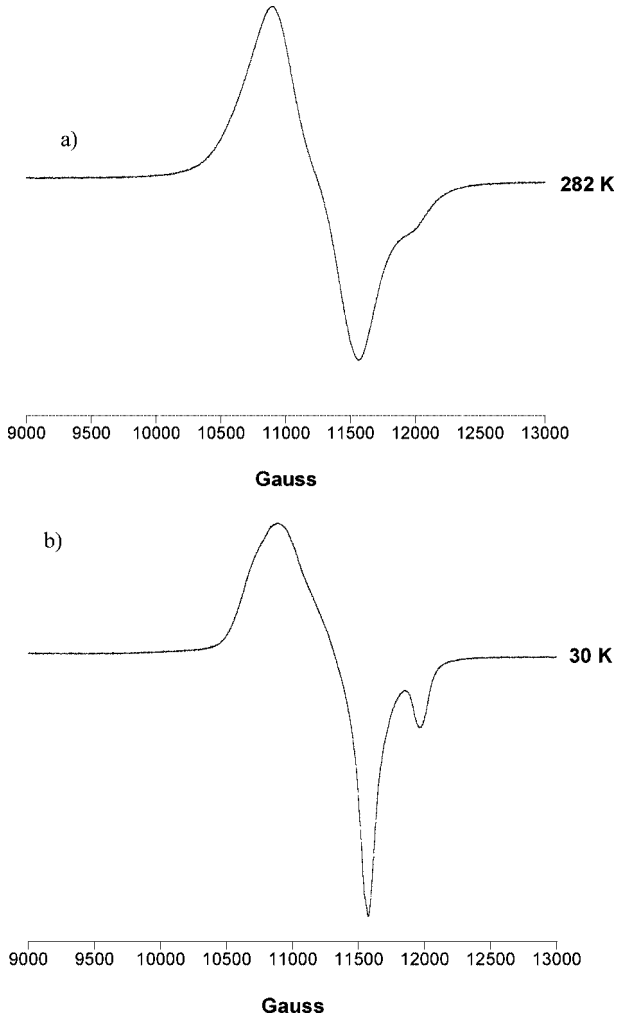

Figure 7. EPR for **1** at (a) 282 K and (b) 30 K.

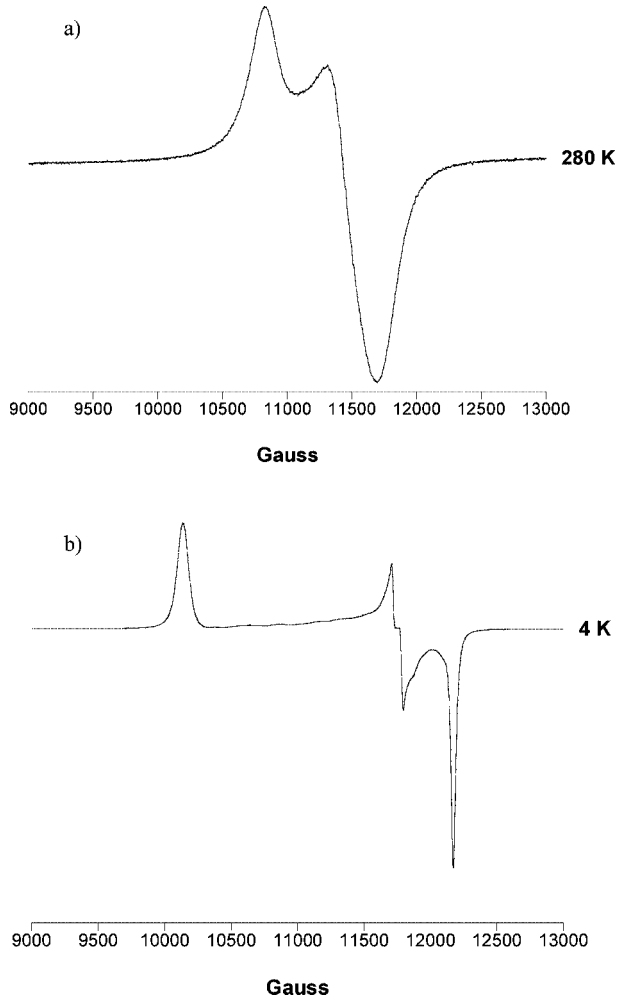

Figure 8. EPR for **2** at (a) 280 K and (b) 4 K.

This approach was applied to compound **1**. A value of $-J = 89\ cm^{-1}$ was obtained, which is very close to the value calculated from the magnetic measurements [$J = -94.3(2)\ cm^{-1}$].

For **2**, the X-band EPR spectrum recorded at room temperature is isotropic, with a signal centered at $g = 2.13$. The room temperature Q-band spectrum is axial (Figure 8a). At lower temperatures, the signals become better defined and the spectra are rhombic. Figure 8b displays the spectrum at 4 K; it is clearly rhombic, with signals at $g_3 = 2.39$, $g_2 = 2.07$, and $g_1 = 2.00$, which is in agreement with both the stereochemistry of the copper(II) ions[51] and the spin doublet ground state.[55]

## Concluding Remarks

Control of appropriate conditions for synthesis has permitted the isolation of two $Cu^{II}$ compounds of guanazole, **1** and **2**, with different nuclearity. To the best of our knowledge, these compounds represent the first structurally characterized $Cu^{II}$ compounds of this ligand. In both cases, the guanazole acts in its neutral form through its *N*1,*N*2-bidentate bridging mode. While compound **1** is dimeric, **2** is a linear trinuclear complex. The two copper atoms in **1**, and the two nearest copper atoms in **2**, are linked by double triazole bridges and by a third, small $H_2O$ (in **1**) or $Cl^-$ (in **2**) bridge. Compound **1** is the second reported case of a compound that uses triazole ligands together with $\mu$-$OH_2$ as bridges.[21]

For both compounds, a significant antiferromagnetic interaction of similar magnitude [$J = -94.3(2)\ cm^{-1}$ (**1**), $J = -89.9(3)\ cm^{-1}$ (**2**)] has been observed. This is in agreement with the similarity of the bridging triazole systems, which comprise the main exchange pathways. Compound **1** has presented us with the opportunity of testing the influence of a nonplanar $\{Cu(N–N)_2Cu\}$ framework on the magnitude of the AF exchange. For its part, compound **2** exhibits one of the largest magnetic exchange constants found in linear trinuclear double/triple-triazole bridged $Cu^{II}$ complexes to date; this has likewise been rationalized for the first time in terms of simple orbital symmetry models.

## Experimental Section

**Instrumentation:** Elemental analyses were performed with a CE EA 1110 CHNS instrument. Infrared spectra were recorded with a Mattson Satellite FT-IR spectrophotometer from 4000 to 400 $cm^{-1}$ by using KBr disks. Ligand field spectra were obtained from 800 to 200 nm with a Shimadzu 2101-PC UV/Vis instrument, by using the diffuse-reflectance technique, with Nujol mulls. EPR spectra of powdered samples were collected on a Bruker ELEXSYS spectrometer at variable temperature operating at Q-band frequencies, and at room temperature operating at X-band frequencies. Magnetic susceptibility measurements of polycrystalline samples were measured over the temperature range 2–300 K with a Quantum Design SQUID magnetometer by using an applied magnetic field of 1000 G. Diamagnetic corrections of the constituent atoms were estimated from Pascal's constants. Experimental susceptibilities were also corrected for the temperature-independent paramagnetism [$-60 \times 10^{-6}$ $cm^3 \cdot mol^{-1}$ per copper(II)] and for the magnetization of the sample holder.

**Chemicals:** The guanazole ligand (Hdatrz) was obtained from Janssen Chimica. The 3,5-diacetylamino-1,2,4-triazole ligand (Hdaatrz) was prepared as indicated by van den Bos[56] and recrystallized from boiling water. Copper salts and solvents of high purity were commercially available and used as such.

**Synthesis of $[Cu_2(Hdatrz)_2(\mu\text{-}OH_2)(H_2O)_4(SO_4)](SO_4)\cdot 3.5H_2O$ (1):** (a) Copper(II) sulfate (6 mmol, 1.52 g) and Hdaatrz (1 mmol, 0.14 g) were mixed in water (40 mL) with continuous stirring. The resulting green solution was allowed to stand at room temperature. In about one month, a precipitate appeared which was filtered off, and the resulting solution was kept in the freezer. After about six months, large, green, hexagonal prism-shaped crystals of **1** (ca. 0.23 g, 70%) were observed together with a few smaller, lighter green crystals. Crystals of **1** were manually isolated on filter paper. One of those crystals was selected for X-ray measurements. The X-ray analysis revealed that Hdaatrz, in the presence of a high proportion of aqueous copper(II) [$Cu^{II}$:Hdaatrz is 6:1], had undergone hydrolysis to form a (guanazole)copper(II) compound. (b) Single crystals of **1** could also be obtained directly from guanazole as follows: Copper(II) sulfate (1 mmol, 0.25 g) was added to a hot aqueous solution of guanazole (1 mmol, 0.10 g, in 30 mL) with continuous stirring (so that the ratio $Cu^{II}$: guanazole is 1:1). A precipitate was immediately formed, which was separated by filtration. The resulting green solution was allowed to stand at room temperature. After ca. one month, single crystals of **1** (ca. 0.10 g, 30%) appeared together with other brownish green, needle-shaped crystals. Crystals of **1** were manually isolated on filter paper. The synthesis from guanazole (b) gave a lower yield than that from Hdaatrz (a).

**Synthesis of $[Cu_3(Hdatrz)_4(\mu\text{-}Cl)_2(H_2O)_4(SO_4)_2]\cdot 11.4H_2O$ (2):** Copper(II) sulfate (0.5 mmol, 0.13 g) was mixed with a hot aqueous solution of guanazole (1 mmol, 0.10 g, in 30 mL) with continuous stirring. A precipitate was formed immediately. Then, copper(II) chloride (3 mmol, 0.51 g) was added to the suspension, and the precipitate was redissolved (so that the ratio $Cu^{II}$:Hdatrz was 3.5:1). The resulting brownish green solution was allowed to stand in the freezer. After less than one week, large, dark green, prism-shaped crystals of **2** (ca. 0.10 g, 70%) were observed and isolated on filter paper. These crystals, however, are unstable at room temperature and turn to powder after ca. one hour after being taken out of the freezer, due to water loss (as indicated by the corresponding elemental analysis). So, all analyses and measurements had to be performed directly after isolation of the crystals.

**Analysis:** For **1**: $C_4H_{27}Cu_2N_{10}O_{16.5}S_2$ (670.56): calcd. C 7.16, H 4.06, N 20.89, S 9.56; found C 7.37, H 4.20, N 21.02, S 10.01 (on the sample synthesized by method b). Crystals of **1** from synthesis (a) were only analyzed by X-ray diffraction (Table 5). For **2**: $C_4H_{25.4}Cl_1Cu_{1.5}N_{10}O_{11.7}S_1$ (563.76): calcd. C 8.52, H 4.54, N 24.85, S 5.69; found C 8.27, H 4.85, N 24.46, S 5.70.

**Spectroscopy**

$\tilde{\nu}_{max}$ for Hdatrz: [$\upsilon(N\text{–}H)_{NH,NH_2}$] 3398 (m), 3368 (sh), 3312 (m), 3237 (w); [$\upsilon$(C=N)/ring stretching vibrations + $\delta(N\text{–}H)_{NH,NH_2}$] 1628 (vs), 1582–1563 (split,s), 1489 (s), 1417 (s); other peaks: 1346 (m), 1152 (w), 1126 (w), 1064 (m), 1015 (w), 808 (m), 727 (w), 647–616 (broad,m), 539 (w) $cm^{-1}$.

$\lambda_{max}$ (solid sample, diffuse-reflectance technique) for **1**: ca. 400, ca. 700 nm; $\tilde{\nu}_{max}$ for **1**: [$\upsilon(O\text{–}H)_{H2O}$ + $\upsilon(N\text{–}H)_{NH,NH_2}$] 3426 (m); [$\upsilon$(C=N)/ring stretching vibrations + $\delta(N\text{–}H)_{NH,NH_2}$] 1705 (sh), 1663–1644(split,s); [$\upsilon_3(SO_4)$] 1187 (sh), 1115 (vs); [$\upsilon_4(SO_4)$] 620 (m) $cm^{-1}$.

$\lambda_{max}$ (solid sample, diffuse-reflectance technique) for **2**: 415, ca. 710 nm; $\tilde{\nu}_{max}$ for **2**: [$\upsilon(O\text{–}H)_{H2O}$ + $\upsilon(N\text{–}H)_{NH,NH_2}$] 3407–3315(br,m); [$\upsilon$(C=N)/ring stretching vibrations + $\delta(N\text{–}H)_{NH,NH_2}$] 1647 (vs); [$\upsilon_3(SO_4)$] 1195 (w), 1115 (s), 1061 (sh); [$\upsilon_4(SO_4)$] 624 (m) $cm^{-1}$.

**Crystal Structure Determination:** Crystallographic data for **1** and **2** are summarized in Table 5. One light green (**1**) and one dark green (**2**) prism-shaped crystal were selected. That of **2** was mounted with Vaseline on a capillary. Throughout the experiment Cu-$K_\alpha$ (**1**) or Mo-$K_\alpha$ (**2**) was used with a graphite crystal monochromator on a Nonius Kappa-CCD [$\lambda$ = 1.54184 Å (**1**); $\lambda$ = 0.71073 Å (**2**)] single-crystal diffractometer. Unit cell dimensions were determined from the angular settings of 4343 (**1**) and 3966 (**2**) reflections with $\theta$ between 0.883° to 70.076° (**1**) and 0.998° to 27.485° (**2**), and refined with the programs HKL Denzo and Scalepack.[57] Space groups were determined to be monoclinic $C2/c$ (**1**) or triclinic $P\bar{1}$ (**2**), from systematic absences (**1**) or from structure determination (**2**). Crystal-detector distance was fixed at 30 mm, and a total of 1732 (**1**)/183 (**2**) images were collected by using the oscillation method, with scan angle per frame 2° oscillation and 5 s exposure time per image. The data collection strategy was calculated with the program Collect.[58] Structure **1** was solved by using DIRDIF;[59] structure **2** by using SIR97;[60] isotropic least-squares refinements on $F^2$ were made by using SHELX97;[61] during the final stages of refinements on $F^2$ the positional parameters and the anisotropic thermal parameters of the non-H atoms were refined. Some hydrogen atoms were located by Fourier difference synthesis and the rest were geometrically placed. H atoms on triazole N atoms were found in a Fourier map for **1** and geometrically placed in **2**. The final difference Fourier map for **1** showed the highest peaks of 2.055 e $A^{-3}$ at 1.41 Å from O(24) and of 1.89 e $A^{-3}$ at 1.25 Å from O(21); the rest of them were lower than 0.67 e $A^{-3}$, the deepest hole being –1.109 e $A^{-3}$ at 0.62 Å from Cu(1). The same map for **2** showed the highest peak of 1.044 e $A^{-3}$ at 0.7 Å from O(5w) and the deepest hole of –0.723 e $A^{-3}$ at 0.14 Å from H(6a). Figure 1 and Figure 2, made with ORTEP,[62] show the atomic numbering schemes. Atomic scattering factors were taken from ref.[63]. Geometrical calculations were made with PARST.[64] CCDC-293618 (**1**) and CCDC-293619 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 5. Crystallographic data and structure refinement for compounds **1** and **2**.[a]

| Compound | **1** | **2** |
|---|---|---|
| Empirical formula | $C_4H_{27}Cu_2N_{10}O_{16.5}S_2$ | $C_4H_{25.4}Cu_{1.5}N_{10}O_{11.7}S_1Cl_1$ |
| Formula weight | 670.56 | 563.76 |
| Temperature [K] | 293(2) | 293(2) |
| Wavelength [Å] | 1.54184 | 0.71073 |
| Crystal system, space group | monoclinic, *C*2/c | triclinic, $P\bar{1}$ |
| *a* [Å] | 19.0944(4) | 10.2780(2) |
| *b* [Å] | 21.3853(4) | 10.5110(2) |
| *c* [Å] | 14.4018(3) | 11.4020(2) |
| *α* [°] | | 77.6520(12) |
| *β* [°] | 129.8510(10) | 63.3760(10) |
| *γ* [°] | | 81.7600(10) |
| Volume [Å$^3$] | 4514.78(16) | 1074.11(3) |
| *Z*, calculated density [Mg/m$^3$] | 8, 1.973 | 2, 1.743 |
| Absorption coefficient [mm$^{-1}$] | 4.962 | 1.791 |
| *F*(000) | 2744 | 579 |
| Crystal size [mm] | $0.20 \times 0.15 \times 0.08$ | $0.32 \times 0.25 \times 0.20$ |
| *θ* range for data collection [°] | 3.66 to 69.54 | 2.03 to 27.48 |
| Index ranges | $0 \le h \le 23$, $0 \le k \le 25$, $-17 \le l \le 13$ | $-13 \le h \le 13$, $-13 \le k \le 12$, $-14 \le l \le 11$ |
| Reflections collected/unique | 4251/4251 | 7843/4879 |
| Refinement method | full-matrix least squares on $F^2$ | full-matrix least squares on $F^2$ |
| Data/restraints/parameters | 4251/25/416 | 4879/2/296 |
| Goodness-of-fit on $F^2$ | 1.048 | 1.068 |
| Final *R* indices [$I > 2\sigma(I)$] ($R_1$, $wR_2$) | 0.0597, 0.1612 | 0.0451, 0.1225 |
| *R* indices (all data) ($R_1$, $wR_2$) | 0.0643, 0.1676 | 0.0620, 0.1358 |
| Largest diff. peak and hole [e·Å$^{-3}$] | 2.055 and –1.109 | 1.044 and –0.723 |

[a] GOOF = $\{\Sigma[w(F_o^2 - F_c^2)^2]/(n-p)\}^{1}/_{2}$, $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1}/_{2}$, $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = [\max(F_o^2,0) + 2F_c^2]/3$; $a = 0.1163$, $b = 18.2879$ for **1** and $a = 0.0678$, $b = 2.2442$ for **2**.

# A DFT Study on the Electronic and Redox Properties of $[PW_{11}O_{39}(ReN)]^{n-}$ ($n$ = 3, 4, 5) and $[PW_{11}O_{39}(OsN)]^{2-}$

Li-Kai Yan,[a] Zhuo Dou,[a] Wei Guan,[a] Shao-Qing Shi,[a] and Zhong-Min Su*[a]

**Keywords:** Electronic properties / DFT / Nitrido-functionalized / Polyoxometalates / Redox properties

DFT calculations were carried out to investigate the electronic and redox properties of nitrido-functionalized polyoxometalate species, $[PW_{11}O_{39}(ReN)]^{n-}$ ($n$ = 3, 4, 5) and $[PW_{11}O_{39}(OsN)]^{2-}$. The rhenium- and osmium-nitrido effectively modify the electronic properties. The LUMOs in fully oxidized $[PW_{11}O_{39}(ReN)]^{3-}$ and $[PW_{11}O_{39}(OsN)]^{2-}$ are mainly concentrated on the Re and Os centers. The high-valent transition metals Re and Os modify the components and energies of the LUMO. The LUMO energies of $[PW_{11}O_{39}(ReN)]^{3-}$ and $[PW_{11}O_{39}(OsN)]^{2-}$ are lower than that of related Keggin $[PW_{12}O_{40}]^{3-}$. In addition, Re centers will prefer to accept the electrons in the first and second reduced process of fully oxidized $[PW_{11}O_{39}(ReN)]^{3-}$.

## Introduction

Polyoxometalates (POMs) are anionic clusters of discrete structure commonly based on molybdenum or tungsten oxides.[1–3] Most POMs possess an extensive and reversible redox chemistry and some contain multiple unpaired d-electrons that make them useful in several fields including catalysis, material science, and magnetochemistry.

One of the important applications of POMs is based on their potential to act as an electron acceptor, which leads to the possibility of the formation of charge-transfer or electron donor-acceptor materials with interesting electronic and magnetic properties.[4,5] Over the past few years, research on POMs has greatly expanded to investigate functionalized POMs by the incorporation or coordination of organic or organometallic moieties to produce novel systems.[6–9] The modification and functionalization of POMs have provided the means to more fully exploit these desirable attributes. Rhenium is known to incorporate into Keggin structures by virtue of its appropriate radius and ability to form short terminal M=O bonds.[10] Three nitrido-functionalized polyoxometalate species, $(n\text{Bu}_4\text{N})_4[PW_{11}O_{39}(OsN)]$, $(n\text{Bu}_4\text{N})_4[PW_{11}O_{39}(ReN)]$, and $(n\text{Bu}_4\text{N})_3[PW_{11}O_{39}(ReN)]$, which feature the incorporation of $[Os^{VI}{\equiv}N]^{3+}$, $[Re^{VI}{\equiv}N]^{3+}$, and $[Re^{VII}{\equiv}N]^{4+}$ fragments into the framework of a Keggin-type heteropolyanion were reported by Maatta.[11] It is the first time that rhenium- and osmium-nitrido were inserted into the polyoxometalate. Several questions drew our attention. First, how does the rhenium- or osmium-nitrido modify the structural and electronic properties? Second, how are the redox properties of POMs modified by the rhenium-nitrido segment? Third, does the rhenium atom prefer to accept an electron when the $[PW_{11}O_{39}(ReN)]^{3-}$ is reduced? Following our investigations of the electronic properties, bonding nature, stabilities, and nonlinear optical properties of POMs,[12–16] density functional theory (DFT), which has been proven to be a significant tool for understanding and rationalizing the electronic and magnetic properties of polyanions,[17–26] was employed to pursue the questions mentioned above. Our main objective was to investigate the effect of high-valent metal nitrido on the electronic and redox properties of POMs.

### Methodology

All calculations reported in this work were carried out with the ADF2005.01 program.[27] The local density approximation (LDA) characterized by the Vosko–Wilk–Nusair (VWN)[28] parameterization for correlation was used. Becke[29]and Perdew[30] gradient corrections were used for the exchange and correlation energy, respectively. Triple-ζ plus polarization Slater basis sets were used to describe the electrons of main group elements (O, C, H) and the valence electrons of all transitional-metal atoms (Re, Os, W). The internal or core electrons (1s–4d for Re, Os, W) were frozen and described by single Slater functions. The relativistic effects were taken into account by means of the zero-order regular approximation (ZORA).[31] The integration parameter in the molecular calculations, which determines the precision of the numerical integral, was set to 5.0. The default optimization convergence criteria in the ADF were used.

For purposes of comparison, calculations were also carried out on $[PW_{12}O_{40}]^{3-}$. A short-hand notation is used for the polyanions, without oxygen atoms and anion charge, and it specifies the number of blue electrons as well as the substituted transition metal oxidation states (e.g. $[PW_{12}O_{40}]^{3-}$ = $PW_{12}$, $[PW_{11}O_{39}(ReN)]^{3-}$ = $PW_{11}ReN$, and $[PW_{11}O_{39}(ReN)]^{4-}$ = $PW_{11}ReN1e$, where e specifies the electrons which the polyanion accepted).

## Results and Discussion

### The Effect of the Rhenium- or Osmium-Nitrido Segment on Geometrical Structure

The Keggin anion is made of an assembly of 12 $MO_6$ octahedrons sharing their corners or edges with a central $XO_4$ tetrahedron. The metal–oxygen bonds in the Keggin framework can be divided into three sets according to whether their oxygen atoms are tetrahedral ($O_a$), bridging ($O_b$), or terminal ($O_t$). From the point-of-view of structure, the transition metals Re and Os are inserted into a lacunary position of $PW_{12}$. At the same time, Re and Os link to the nitrogen atom instead of the terminal oxygen atom ($O_t$). Figure 1 shows the optimized structure of $PW_{11}ReN$, and other structures in this article are all similar to it.

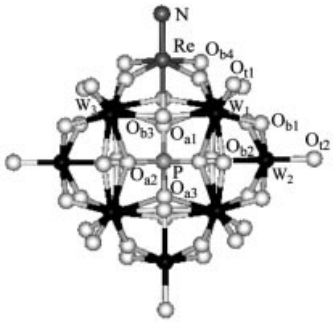

Figure 1. The calculation model $PW_{11}ReN$.

Some selected bond lengths are listed in Table 1. Compared with $PW_{12}$, the bonds in $PW_{11}ReN$ are lengthened, while the bonds in $PW_{11}OsN$ are shortened. The calculated atomic radii[32] of tungsten, rhenium, and osmium are 1.93, 1.88, and 1.85 Å, respectively. The $PW_{11}OsN$ is contracted when the osmium-nitrido segment substitutes the W=O unit because the radius of $Os^{VIII}$ is smaller than that of $W^{VI}$. Although the radius of $Re^{VII}$ is slightly smaller than that of $W^{VI}$, the cluster size of $PW_{11}ReN$ is enlarged. This may be due to the slightly weak interaction between Re and its adjacent atoms compared with related bonds in $PW_{12}$. As Poblet demonstrated that the reduction of a fully oxidized anion is accompanied by an expansion of the geometry,[33] the bonds in single- and double-electron reduced polyanions of $PW_{11}ReN$ are elongated. So, the reduced polyanions are loosened by adding reduced electrons. The lengthening of the bond would lead to a weakening of the bond strength, and then the electronic properties would be changed.

Table 1. Selected bond lengths [Å] of systems.

| | $PW_{12}$ | $PW_{11}ReN$ | $PW_{11}ReN1e$ | $PW_{11}ReN2e$ | $PW_{11}OsN$ |
|---|---|---|---|---|---|
| $W_1$–$O_{b1}$ | 1.938 | 1.941 | 1.958 | 1.969 | 1.922 |

### Electronic Properties of Fully Oxidized $PW_{11}ReN$ and $PW_{11}OsN$

For fully oxidized polyanions, one of the remarkable properties concerns redox behavior. The molecular orbital distribution will give reasonable information about the redox properties of $PW_{11}Re$ and $PW_{11}Os$. In order to investigate the effect of the rhenium- or osmium-nitrido segment on the electronic properties of polyanions, the frontier molecular orbitals (FMO) of $PW_{12}$, $PW_{11}ReN$, and $PW_{11}OsN$ are compared. For Keggin anion $PW_{12}$, the ground-state configuration is typical of a fully oxidized polyanion for which the highest molecular orbital (HOMO) delocalizes over oxo-ligands, and the lowest molecular orbital (LUMO) delocalizes over the d-shells of tungsten atoms with some antibonding participation of oxygen orbitals (Figure 2).[24] The LUMO is a doubly degenerate orbital of symmetry $e$, and the LUMO+1 is a triply degenerate orbital of symmetry $t_1$.

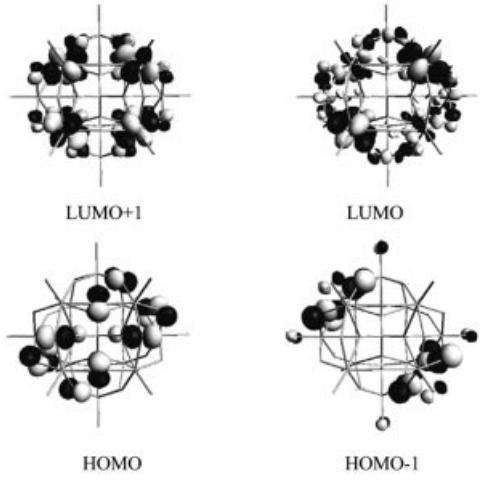

Figure 2. The molecular orbitals of $PW_{12}$.

The doubly degenerate HOMO and LUMO in $PW_{12}$ split into two orbitals of symmetry $a'$ and $a''$ in $PW_{11}ReN$ and $PW_{11}OsN$. The HOMO in $PW_{11}ReN$ is mainly delocalized over the bridge oxygen atoms, but the nitrogen atom has a contribution (6.58%; Figure 3). The LUMO is quite different from that of $PW_{12}$ and is mainly localized on the Re atom (39.76%), although there is some contribution from

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the tungsten atoms (16.46%). The LUMO+1 in $PW_{11}ReN$ concentrates on the tungsten and bridge oxygen atoms, which is similar to the LUMO in $PW_{12}$. It can be proposed that the rhenium-nitrido segment mainly modifies the unoccupied orbitals and the redox properties would be modified as the redox property of a polyanion depends on the energy and compositions of the LUMO. The LUMO energy and the HOMO–LUMO energy gap are lower than that of $PW_{12}$ (Figure 4), so the electron transition between HOMO and LUMO is much easier.

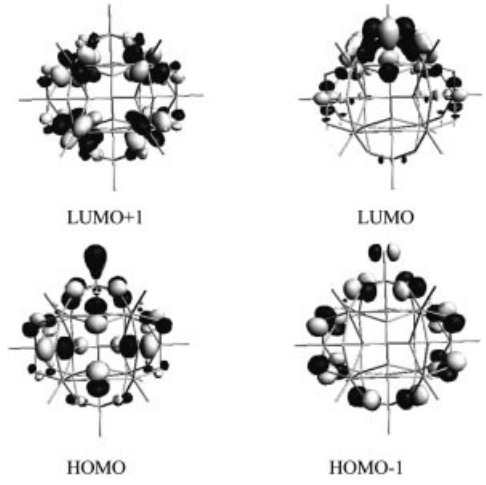

Figure 3. The molecular orbitals of $PW_{11}ReN$.

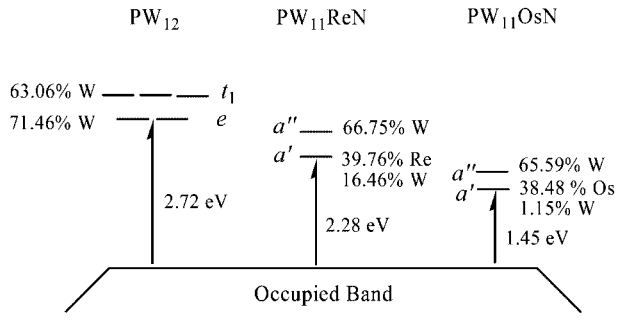

Figure 4. The energy level of $PW_{12}$, $PW_{11}Re$, and $PW_{11}Os$.

Let us now consider the osmium–nitrido substituted derivative $PW_{11}OsN$. The FMOs are presented in Figure 5. Here, the situation is somewhat different. The HOMO and HOMO-1 for $PW_{11}OsN$ are similar to $PW_{12}$, whereas the lowest metal orbitals are mainly localized on osmium (38.48%), and the contribution of tungsten atoms is only 1.15%. The d-osmium orbitals are lower in energy than the tungsten orbitals and strong competition between the osmium and tungsten orbitals would occur; $PW_{11}OsN$ tends to have a lower HOMO–LUMO energy gap and LUMO energy as presented in Figure 4.

The question we are now concerned with is whether tungsten or high-valent transition-metal Re or Os accept the extra electrons when the cluster is reduced. Taking $PW_{11}Re$ as an example, we investigated the reduction process in detail. It is known that the redox properties depend on the energy and composition of the LUMO, as the

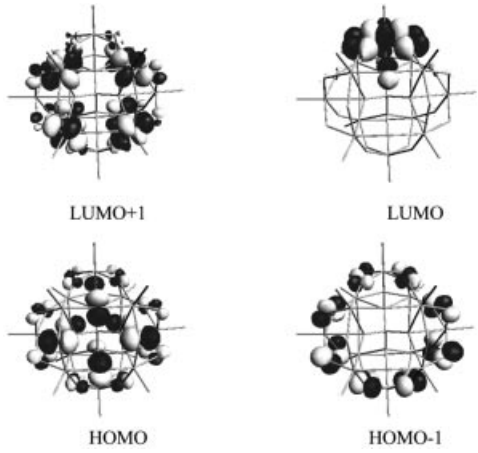

Figure 5. The molecular orbitals of $PW_{11}OsN$.

LUMO formally delocalizes over the metal atoms, which determine the redox properties of POMs.[21]

The LUMO of $PW_{11}Re$ is composed of 39.76% Re and 16.46%W contributions. It is more likely that Re will prefer to accept extra electrons when the cluster is reduced. In order to investigate the reduced center, the reduced species $PW_{11}Re1e$ and $PW_{11}Re2e$ were calculated. Table 2 shows the spin density for two reduced species of $PW_{11}Re$, which indicates that the extra electron in the monoreduced $PW_{11}Re1e$ localizes on the Re center with a 0.67 spin alpha electron. This suggests that $PW_{11}Re^{VII}$ is reduced to $PW_{11}Re^{VI}$ when the cluster accepts one electron.

Table 2. Spin density (α-β) for $PW_{11}Re1e$ and $PW_{11}Re2e$.

| | $PW_{11}ReN1e$ | $PW_{11}ReN2e$ |
|---|---|---|
| Re | 0.6700 | 0.6533 |
| W | 0.0008~0.0456 | 0.0081~0.1618 |

The LUMO in monoreduced $PW_{11}Re1e$ has a participation of Re orbitals (35.23%), and the contribution of tungsten increases to 27.36% (Figure 6). The spin density analysis indicates that 65% of the spin density is localized over the Re center and the rest of the spin density is delocalized over the polar tungsten atoms. The HOMO is entirely localized over the oxygen atoms. The additional electron mainly goes to the sphere of Re and $PW_{11}Re^{VI}N$ would be reduced to $PW_{11}Re^{V}N$. In addition, the LUMO in $PW_{11}Re2e$ has a little participation of the Re orbitals (1.91%). So, this suggests that the first and second reduced process of $PW_{11}ReN$ is $Re^{VII} \rightarrow Re^{VI} \rightarrow Re^{V}$, which is in agreement with the experimental investigation.[11]

## Conclusions

The effect of rhenium or osmium-nitrido on the electronic and redox properties of POMs was investigated by means of density functional calculations. The above results can be summarized in three principal conclusions: (1) Re and Os mainly modified the unoccupied orbitals of $[PW_{11}O_{39}(ReN)]^{3-}$ and $[PW_{11}O_{39}(OsN)]^{2-}$, especially the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

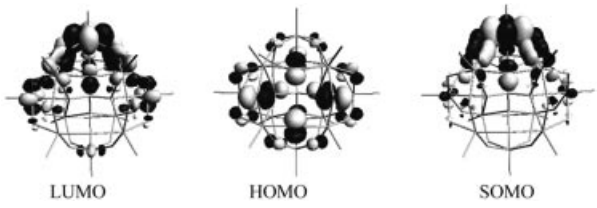

Figure 6. The molecular orbitals of $PW_{11}ReN1e$.

LUMO. The LUMO of fully oxidized $[PW_{11}O_{39}(ReN)]^{3-}$ is quite different from that of $[PW_{12}O_{40}]^{3-}$ and is localized on the Re atom, and the tungsten atoms also contribute to some extent. The LUMO of $[PW_{11}O_{39}(OsN)]^{2-}$ is mainly localized on osmium, and the contribution from the tungsten atoms is quite small. (2) Compared to Keggin $[PW_{12}O_{40}]^{3-}$, the LUMO energy in $[PW_{11}O_{39}(ReN)]^{3-}$ and $[PW_{11}O_{39}(OsN)]^{2-}$ is lower than that of $[PW_{12}O_{40}]^{3-}$, and the electron transition between HOMO and LUMO of nitrido-functionalized polyoxometalate species $[PW_{11}O_{39}(OsN)]^{2-}$ and $[PW_{11}O_{39}(ReN)]^{3-}$ is much easier compared with that of Keggin $[PW_{12}O_{40}]^{3-}$. (3) The Re center prefers to accept the extra electrons in the first and second reduced process of $PW_{11}ReN$, so the reduced process is $[PW_{11}O_{39}(Re^{VII}N)]^{3-} \rightarrow [PW_{11}O_{39}(Re^{VI}N)]^{4-} \rightarrow [PW_{11}O_{39}(Re^{V}N)]^{5-}$.

**Supporting Information** (see footnote on the first page of this article): Cartesian coordinates for the BP/TZP optimized $[PW_{11}O_{39}(ReN)]^{3-}$, $[PW_{11}O_{39}(ReN)]^{4-}$, $[PW_{11}O_{39}(ReN)]^{5-}$, $[PW_{11}O_{39}(OsN)]^{2-}$, and $[PW_{12}O_{40}]^{3-}$ structures.

# Synthesis, Structure and Surface Photovoltage of a Series of $Ni^{II}$ Coordination Polymers

Li-Ping Sun,[a] Shu-Yun Niu,*[a] Jing Jin,[a] Guang-Di Yang,[b] and Ling Ye[b]

**Keywords:** Coordination polymers / Nickel / Hydrogen bonds / Surface photovoltage spectroscopy

Three novel $Ni^{II}$ coordination polymers $[Ni_2(HCOO)_4(H_2O)_4]_n$ (**1**), $[Na_2Ni(btec)(H_2O)_8]_n$ (**2**; $H_4$btec = 1,2,4,5-benzenetetracarboxylic acid) and $[\{Ni(pdc)(H_2O)_2\}\cdot H_2O]_n$ (**3**; $H_2$pdc = pyridine-2,5-dicarboxylic acid) have been hydrothermally synthesized and their structures determined by single-crystal X-ray diffraction. The formate groups in complex **1** bridge the $Ni^{II}$ ions to form a infinite 3D structure. Complex **2** also possesses a infinite 3D structure and the coordination environment of the $Ni^{II}$ ion is a perfect octahedron. Complex **3** is a 2D infinite coordination polymer. The surface photovoltage spectra of complexes **1**–**3** indicate that they all show three positive surface photovoltage (SPV) responses in the range of 300–800 nm and all show p-type semiconductor characteristics. Although the intensities of the SPV responses are obviously different, this can mainly be attributed to the difference of their structures. The field-induced surface photovoltage spectra (FISPS) of complexes **1**–**3** confirm their p-type semiconductor characteristics.

## Introduction

Metal–organic coordination polymers are receiving ever increasing attention owing to their potential applications in functional materials for use in fields such as magnetism, catalysis, electrical conductivity, optical materials, host–guest chemistry, and biomimetic chemistry.[1–5] The design and synthesis of the coordination polymers have therefore undergone rapid development in the areas of coordination and supramolecular chemistry.[6–9] Carboxylate groups often play an important role in the construction of polynuclear complexes as they can adapt many types of bridging pattern, e.g. *syn-syn*, *anti-anti*, *syn-anti* and mono-monodentate and mono-didentate etc.,[10–12] which result in a variety of structural frameworks. They can also act as both donors and acceptors of hydrogen bonds depending on whether the carboxylic O atoms are deprotonated or not.[13] The existence of a variety of hydrogen bonds therefore enriches the function of a coordination supramolecule.

The energy gaps of some transition metal coordination polymers with unique structures are sometimes in the region of those of semiconductors, which means that they can show semiconductor characteristics and can therefore be regarded as a kind of inorganic–organic hybrid semiconductor. The detection of the surface charge behavior and photoelectric properties of the coordination polymers would therefore allow further research on the function of these coordination polymers. To date, reports on this aspect have focused mainly on coordination complexes with phthalocyanines or porphyrins as ligands;[14–17] there are few reports on the coordination polymers.[18] Surface photovoltage spectroscopy (SPS) is a highly sensitive tool that can be used to investigate the photophysics of photogenerated species or excited states without any sample contamination or destruction.[19,20] This technique has been used to investigate photoelectric processes such as charge transfer and photocatalysis.[21] On the basis of the principle of SPS, Wang et al. have developed a field-induced surface photovoltage spectroscopy (FISPS) technique,[22,23] which they have used to investigate the photoelectric properties of semiconductors under the effect of an external electric field. We have also attempted to detect the surface charge behavior of coordination polymers with semiconductor characteristics using these techniques. In this paper we report the synthesis, structure, and surface photovoltage properties of three $Ni^{II}$ coordination polymers. The three complexes all contain carboxylic groups as the basic building unit. Their similarities and differences in the structures are beneficial when it comes to exploring the relationship between the structural and photoelectric properties.

## Result and Discussion

### Synthesis and General Discussion

The synthesis of complex **1** is intriguing. The ligand in complex **1** is a formate, which was not added as one of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

starting materials. The starting materials *o*-phthalic acid and 2,2′-bipyridyl do not take part in the coordination. The synthetic procedure involves dmf and $H_2O$ as solvents, and we think the formate group comes from dmf. This phenomenon has been reported previously,[24] and it has long been known that dmf can be hydrolyzed to formate and dma and that the rate of this process increases under basic conditions. We repeated the synthesis of complex **1** in the absence of dmf and obtained the complex [Ni(*o*-phthalate)(2,2′-bipyridyl)($H_2O$)]·$H_2O$, which further confirms the involvement of dmf in the synthesis of complex **1**.

The synthesis of complex **2** is also interesting. The original purpose of adding NaOH was to deprotonate and to adjust the pH. However, the $Na^+$ ions not only balance the charge but also participate in coordination.

## Structure Descriptions

The crystal data and structure refinement of complexes **1**–**3** are summarized in the Experimental Section; selected bond lengths and angles are listed in Table 1.

### $[Ni_2(HCOO)_4(H_2O)_4]_n$ (1)

The single-crystal X-ray diffraction analysis revealed that complex **1** exhibits a infinite 3D framework structure whose building unit is $[Ni_2(HCOO)_4(H_2O)_4]$ (Figure 1). There are two kinds of crystallographically independent $Ni^{II}$ ions. Ni1 is coordinated by six O atoms from six different formate O atoms, with O1, O1d, O3, and O3d atoms comprising the equatorial plane. The Ni1–O1 and Ni1–O3 bond lengths are 2.058(2) and 2.104(2) Å, respectively. The O1–Ni1–O1d and O3–Ni1–O3d bond angles are both 180°, and the O1–Ni1–O3 and O1d–Ni1–O3 bond angles are 92.98(8)° and 87.02(8)°, respectively. O2 and O2e occupy the apical positions. The Ni1–O2 bond length of 2.039(2) Å and the O2–Ni1–O2e bond angle of 180° mean that the coordination environment of Ni1 is a perfect octahedron. The other crystallographically independent Ni2 ion is also six coordinate, with two O atoms from two bridging formate O atoms and the other four O atoms from four coordinated water molecules. The formate groups in the crystal adopt an *anti-anti* coordination mode that links the Ni1 ions into a 1D infinite chain. The Ni1 ions of adjacent chains are further con-

nected to another 1D infinite chain along the perpendicular direction with the same mode, which means that the Ni1 ions are linked into a 2D layer in the *bc* plane (Figure 2). The coplanarity of this 2D layer is very good, and the Ni2 ions array regularly between the 2D layers. The formate groups, which lie between the Ni1 and Ni2 ions, connect these ions in a *syn-anti* mode to form a 1D infinite chain. This 1D infinite chain is perpendicular to the 2D layer, and the 2D layers are further connected into a infinite 3D structure (Figure 3). When projected along the *a* axis, it can clearly be seen that every four Ni1 ions form a rhombic hole. The sides of each rhombus are 5.808 Å and they extend infinitely along the *a* axis. The Ni2 ions lie between the holes (Figure 4).

### $[Na_2Ni(btec)(H_2O)_8]_n$ (2)

Complex **2** possesses a infinite 3D structure and its building unit is $[Na_2Ni(btec)(H_2O)_8]$ (Figure 5). Each $Ni^{II}$ ion is coordinated by six O atoms and its coordination environment is a perfect octahedron. Four O atoms (O1, O1A, O1B, O1C) are from four different btec groups, and these

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

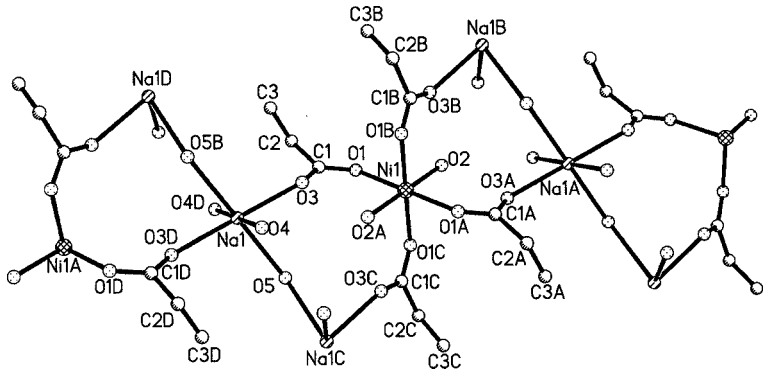

Figure 5. The building unit of complex **2**.

comprise the equatorial plane. The Ni–O1 bond length is 2.0767(15) Å and the O1A–Ni1–O1 and O1B–Ni1–O1C bond angles are all 180°. The O1–Ni1–O1B and O1–Ni1–O1C bond angles are 86.86(9)° and 93.14(9)°, respectively. The other two O atoms (O2, O2A) are from two coordinated water molecules and they occupy the apical positions of the octahedron. The Ni–O2 bond length is 2.075(2) Å and the O2–Ni–O2A bond angle is 180°.

The $Na^{I}$ ion is coordinated by six O atoms. Two O atoms are from two btec groups and four O atoms from four coordinated water molecules, all of which comprise the distorted octahedral coordination environment of $Na^{I}$. In the crystal, each btec group coordinates to four different $Ni^{II}$ ions through the four deprotonated carboxylic O atoms in a monodentate manner. Thus, the $Ni^{II}$ ions are connected to two perpendicular 1D chains in the *bc* plane. The coplanarity of the *bc* layer is very good. The *o*- and *m*-carboxylate moieties of each btec group separately link the different $Ni^{II}$ ions and form two kinds of multi-membered rings. The Ni1G–Ni1H (along the *c* axis) and Ni1H–Ni1B (along the *b* axis) distances are 6.086 and 9.488 Å, respectively (Figure 6). The $Na^{I}$ ions array along the *bc* plane and link two $Ni^{II}$ ions in the adjacent layer through the carboxylate group, which means that the 2D layers are further connected to form an infinite 3D structure (Figure 7). In addition, there are a lot of hydrogen bonds in the crystal. There are interactions between the coordinated water molecules and coordinated water molecules [O2–H···O5 2.808(3), O4–H···O4 3.145(6) Å] as well as coordinated carboxylate O atoms [O4–H···O3 3.098(3), O2–H···O3 2.608(2), O4–H···O1 3.098(3) Å]. These hydrogen bonds increase the stability of the structure.

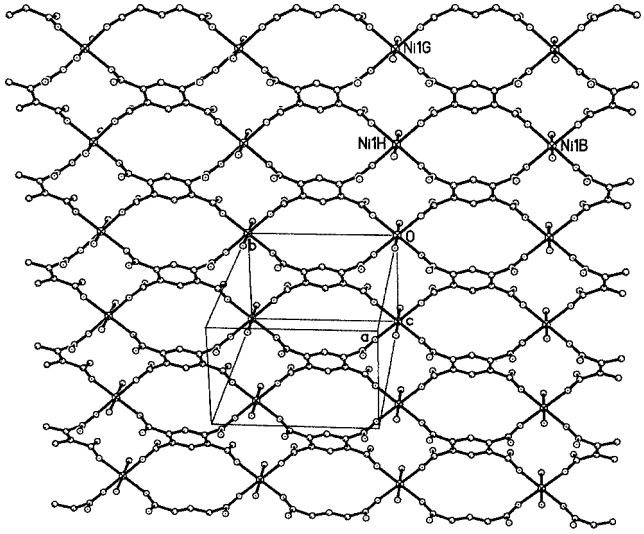

Figure 6. The 2D infinite layered structure of $Ni^{II}$ ions in complex **2**.

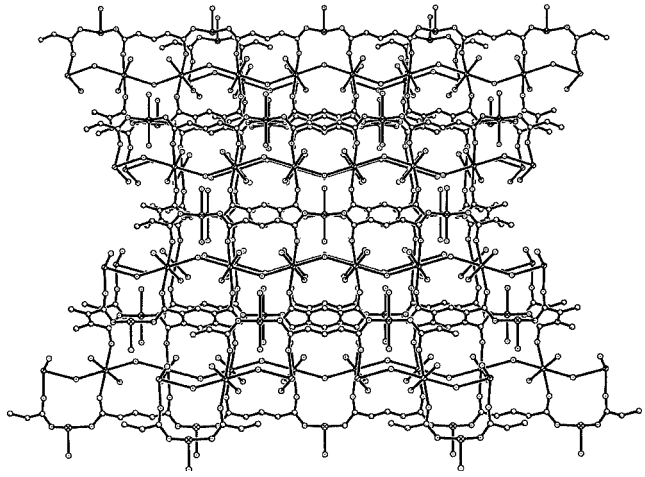

Figure 7. The 3D structure of complex **2**.

### $[\{Ni(pdc)(H_2O)_2\}\cdot H_2O]_n$ (3)

The structure of complex **3** has been reported previously by Min, Dongwon et al.,[25] therefore here we place more emphasis on its SPS and FISPS properties. Complex **3** is a 2D infinite coordination polymer and its asymmetric unit is $[\{Ni(pdc)(H_2O)_2\}\cdot H_2O]$. Each $Ni^{II}$ ion is coordinated by five O atoms and one N atom. One O atom and one N atom are from the same pdc group; the other four O atoms are from two different pdc groups and two coordinated water molecules (Figure 8). The coordination geometry around the $Ni^{II}$ ion is a distorted octahedron. The equatorial plane is defined by O2, O7, O4, and N1 and the apical position is occupied by O3 and O1. The O3–Ni–O1 bond

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

angle is 173.04(6)°. In the crystal, the pdc group plays a bridging role: the α-carboxylate O atom together with the pyridine N atom coordinate to one $Ni^{II}$ ion and the other carboxylate O atom coordinates to another $Ni^{II}$ ion in a monodentate mode. The $Ni^{II}$ ions are linked into a 1D infinite chain along the *a* axis. Each β-carboxylate O atom of the pdc group binds to one $Ni^{II}$ ion in a monodentate mode to form a zigzag chain along the *b* axis, so complex **3** is further connected into a 2D waved structure (Figure 9). There are five kinds of O–H···O hydrogen bonds in the crystal. These are the interactions between the coordinated water molecules and coordinated carboxylic O atoms [O7–H···O4 2.687(12), O1–H···O3 2.696(2) Å] as well as the uncoordinated carboxylic O atom [O1–H···O5 2.726(2) Å]. The other three types of hydrogen bond are between the lattice water molecule and the coordinated water molecule [O7–H···O6 2.625(3) Å], the coordinated carboxylic O atom [O6–H···O2 2.904(3) Å], and the uncoordinated carboxylic O atom [O6–H···O5 3.051(3) Å]. Complex **3** is further connected into a 3D web by hydrogen bonds (Figure 10).

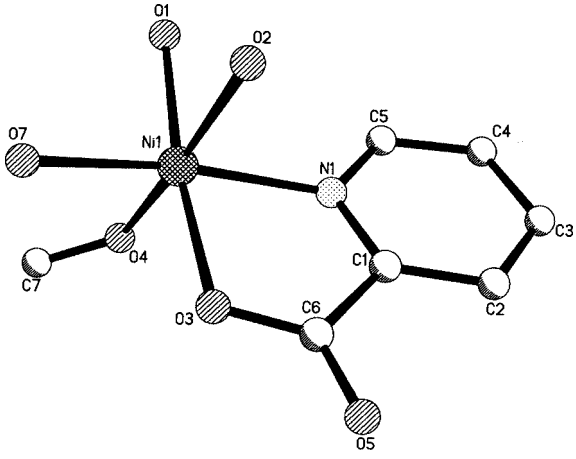

Figure 8. The asymmetric unit of complex **3**.

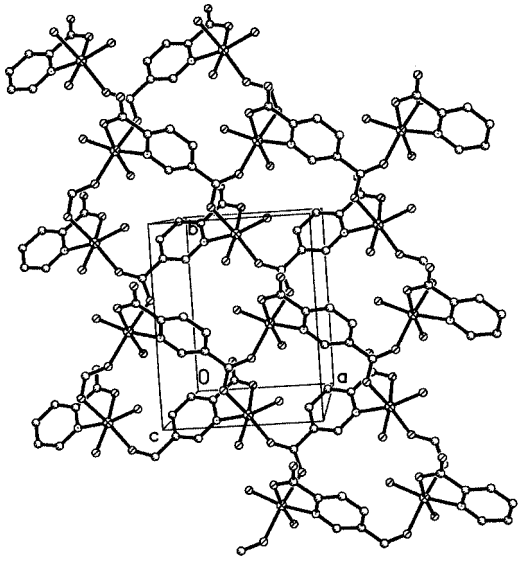

Figure 9. The 2D infinite structure of complex **3**.

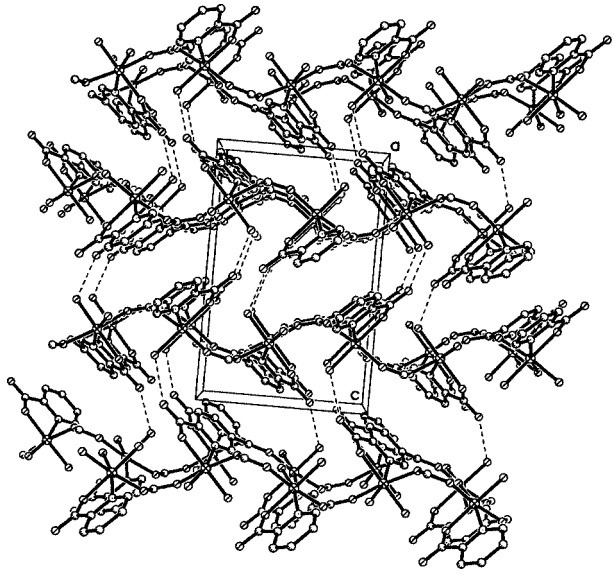

Figure 10. The 3D structure of complex **3**. Dotted lines indicate hydrogen bonds.

### Surface Photovoltage Spectra of Complexes

Surface photovoltage spectra were measured with a solid junction photovoltaic cell (ITO/sample/ITO) in the range 300–800 nm. A signal detected by SPS is equivalent to the change in the surface potential barrier on illumination ($\delta V_s$), which is given by the equation

$$\delta V_s = V_s' - V_s°$$

where $V_s°$ and $V_s'$ are the surface potential barriers before and after illumination, respectively. As far as band-to-band transitions are concerned, a positive response of SPV ($\delta V_s > 0$) means that the sample is characterized as a p-type semiconductor, whereas a negative response means that the sample is an n-type semiconductor. The magnitude of the surface potential barrier depends on the number of surface net charges. Figures 11 and 12 show the SPS spectra of complexes **1** and **3**, respectively. The SPS spectrum of complex **2** is similar to that of complex **1**. The SPV responses at 300–500 nm show some overlap, but they can be separated by treating them with the program Origin 7.0[26]. Complexes **1**–**3** all show three positive SPV responses in the range 300–800 nm, which indicates that they all have p-type semiconductor characteristics. The response bands at $\lambda_{max}$ = 342 nm can be attributed to an LMCT (ligand to metal charge transfer) transition. In contrast with a previous report,[18] the LMCT bands are blue-shifted. The complexes reported here are mainly coordinated by O atoms, in contrast to the other complexes, which are mainly coordinated by N atoms,[18] therefore, as the electronegativity of oxygen is larger than that of nitrogen, more energy is needed to produce the LMCT, which means that the LMCT band is blue-shifted. The responses at $\lambda_{max}$ = 392 (**1**), 387 (**2**), and 396 nm (**3**) can be assigned to the d→d* transition of $Ni^{II}$ [$^3A_{2g}\rightarrow{}^3T_{1g}$ ($^3P$)], and the response bands between 600 and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

800 nm can be attributed to the d→d* transition of $Ni^{II}$ [$^3A_{2g}\rightarrow{}^3T_{1g}$ ($^3F$); Table 2]. The surface photovoltage spectra of complexes **1**–**3** match their absorption spectra.

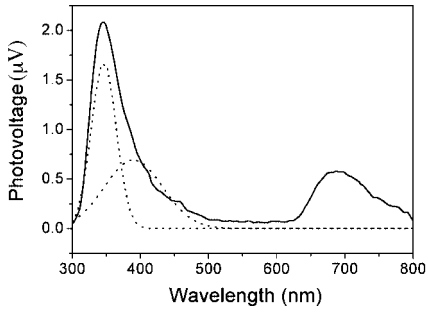

Figure 11. The surface photovoltage spectrum of complex **1**. The dotted lines are the peaks obtained after treatment with Origin 7.0.

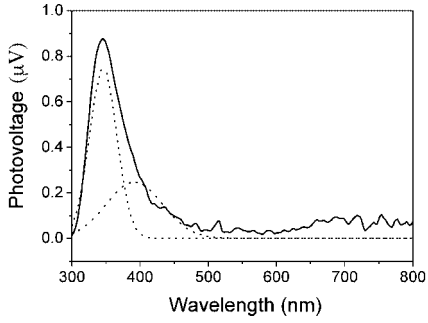

Figure 12. The surface photovoltage spectrum of complex **3**. The dotted lines are the peaks obtained after treatment with Origin 7.0.

Table 2. Assignment of the surface photovoltage spectra.

| | $\lambda_{max}$ [nm] | $\lambda_{max}$ [nm] | $\lambda_{max}$ [nm] |
|---|---|---|---|
| **1** | 342 | 392 | 690 |
| **2** | 342 | 387 | 700 |
| **3** | 342 | 396 | 689 |
| Assignment | LMCT | $^3A_{2g}\rightarrow{}^3T_{1g}(^3P)$ | $^3A_{2g}\rightarrow{}^3T_{1g}(^3F)$ |

Comparing the SPV responses of complexes **1**–**3** (Figure 13), it can be seen that without the external electric field the values of the three complexes' response bands are the same, although their intensities are obviously different; complex **1** is the strongest and complex **3** is the weakest. This intensity difference is mainly due to the differences in their structures. Complex **1** is an infinite 3D coordination polymer where the coordination environment of Ni1 is a perfect octahedron. The 2D layer which is formed by two perpendicularly 1D infinite chains is beneficial to the conduction of electrons or holes. Furthermore, another Ni 1D chain which is perpendicular to this 2D layer also provides a transmission passage for the electrons or holes, which means that more electrons diffuse to the surface, resulting in an increase of the SPV response intensities. Complex **2** possesses a infinite 3D structure and the coordination environment of $Ni^{II}$ ion is a perfect octahedron. The planarity of the 2D layer in complex **2** is very good therefore this 2D planar structure is also beneficial to transfer the electrons or holes. Another 1D infinite chain plumbing to the 2D layer intermingles $Na^I$ ions, which may also have certain effects on the transfer of electrons and holes. The intensity of the SPV in complex **2** is lower than that in complex **1**. In complex **3**, the irregularly spaced structure affects the transport of electrons or holes therefore the SPV response's intensity is the weakest. In addition, the types of bonds in the crystal have different effects when it comes to transferring electrons or holes. Complexes **1**–**3** all possess infinite 3D structures. Among them, the 3D structures of complexes **1** and **2** are formed by coordination bonds, whereas in complex **3** the 2D structure is formed by coordination bonds and the 2D layer is further connected into a 3D structure by hydrogen bonds. As hydrogen bonds are weak, their ability to transfer electrons or holes is much lower than that of coordination bonds, therefore the intensity of the SPV of complex **3** is lower than that of complexes **1** and **2**. Moreover, in the range 600–800 nm, it can be seen that the SPV response band of complexes **1** and **2** is a sine wave, whereas the response band of complex **3** shows obvious splitting. These phenomena are mainly attributed to the different symmetries of the $Ni^{II}$ coordination environments: the coordination environment of $Ni^{II}$ in complexes **1** and **2** is a perfect octahedron, whereas in complex **3** it is a distorted octahedron.

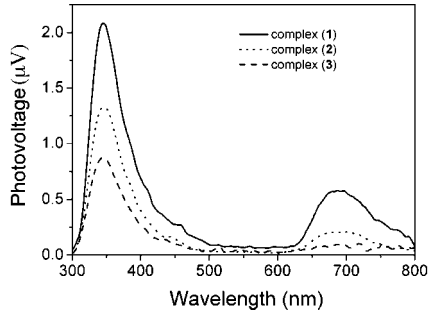

Figure 13. A comparative SPS diagram of complexes **1**–**3**.

## FISPS of Complexes

FISPS can determine the direction of the built-in field and the mobile direction of photogeneration carriers. If we apply a positive electric field (the illuminated surface is positive) vertically to the p-type semiconductor surface, whose direction is the same as the direction of the built-in field, the separation efficiency of the photogeneration carriers is increased and the intensity of SPV response increases in the original direction. If a negative electric field, whose direction is opposite to that of the built-in field, is applied, the separation efficiency of the photogenerated carriers reduces and the intensity of the SPV response is weakened, even in the reverse direction. In contrast to p-type semiconductors, the SPV response intensity of n-type semiconductors increases as a negative field is applied and reduces as a positive electric field is applied. The FISP spectrum of complex **1** is given in Figure 14; those of complexes **2** and **3** are analogous with complex **1**. The responses in the range 300–500 nm in all three complexes increase linearly with a posi-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tive electric field, which shows that the direction of this external electric field is consistent with the built-in field. This enhances the separation efficiency of the photoexcited electron–hole pairs and results in an increase of the surface potential, thus confirming that complexes **1**–**3** have p-type semiconductor characteristics.

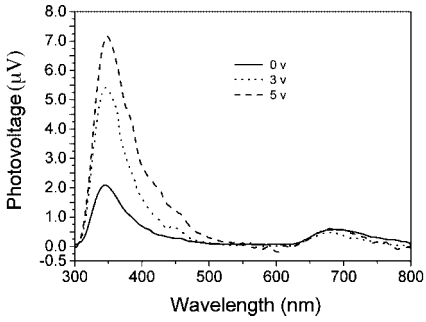

Figure 14. The FISP spectrum of complex **1**. The intensities of the SPV response increase linearly with the external positive electric field.

## Conclusion

Three $Ni^{II}$ coordination polymers have been synthesized by hydrothermal methods. Complexes **1** and **2** are both infinite 3D coordination polymers and complex **3** possesses a 2D infinite structure. The surface photovoltage spectra of complexes **1**–**3** show that they all have three positive responses in the range 300–800 nm and all take on p-type semiconductor characteristics. However, the intensities of the SPV response bands are obviously different, mainly due to their different structures. The coordination environment of the $Ni^{II}$ ion affects the shape of the SPV responses, and the FISP spectra confirm the p-type semiconductor characteristics of complexes **1**–**3**.

## Experimental Section

**Materials and Methods:** All reagents were of A.R. grade. IR spectra were recorded in the range 220–4000 $cm^{-1}$ with a JASCO FT-IR/480 spectrophotometer with KBr pellets. The elemental composition of the complexes was determined with a PE-240C analyzer and a TLASMA-II ICP instrument. SPS and FISPS measurements were conducted with the sample in a sandwich cell (ITO/sample/ITO) with the light source-monochromator-lock-in detection technique. All the measurements were performed under atmospheric pressure and at ambient temperature.

**$[Ni_2(HCOO)_4(H_2O)_4]_n$ (1):** A solution of $NiSO_4{\cdot}6H_2O$ (0.26 g, 1 mmol) in water (10 mL) was added to a solution of *o*-phthalic acid (0.17 g, 1 mmol) in water (10 mL), and 2,2′-bipyridyl (0.08 g, 0.5 mmol) and 5 mL of dmf were added to the above solution. The solution was then transferred into a Parr Teflon®-lined stainless steel vessel, which was sealed and heated to 100 °C for 5 d. After cooling to room temperature, the solution was filtered. Green crystals of complex **1** were obtained by leaving the solution to evaporate at room temperature for about one month. $C_4H_{12}Ni_2O_{12}$ (369.56): calcd. C 13.00, H 3.27, Ni 31.77; found C 13.25, H 3.31, Ni 31.53. IR (KBr): $\tilde{\nu}$ = 3360 $cm^{-1}$, 3277, 3206 ($\nu_{OH}$); 1574 ($\nu_{asCOO}$); 1378 ($\nu_{sCOO}$); 889, 850, 771 ($\delta_{C-H}$); 566, 357, 311 ($\nu_{Ni-O}$).

**$[Na_2Ni(btec)(H_2O)_8]_n$ (2):** A solution of $NiSO_4{\cdot}6H_2O$ (0.26 g, 1 mmol) in water (10 mL) was added to a solution of $H_4$btec (0.13 g, 0.5 mmol) and NaOH (0.08 g, 2 mmol) in water (10 mL), and NaSCN (0.08 g, 1 mmol) and 5 mL of dmf were added to the above solution. The mixture was then transferred into a Parr Teflon®-lined stainless steel vessel, which was sealed and heated to 100 °C for 5 d. After cooling to room temperature, green crystals of complex **2** were collected. $C_{10}H_{18}Na_2NiO_{16}$ (498.93): calcd. **X-ray Crystallographic Study:** Crystallographic data for complexes **1** and **2** were collected on a Rigaku R-AXIS-RAPID diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 293 K. Crystal data for complex **3** was collected on a Smart APEX II CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 293 K. Further details are given in Table 3. All data were corrected for Lorentz polarization factors and empirical absorption. The structures were solved by direct methods and refined by full-matrix least-squares calculations on $F^2$ using the SHELXTL 97 program. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were found by mixed methods. Selected bond lengths and angles for complexes **1**–**3** are listed in Table 1.

CCDC-615921 (for **1**), -615922 (for **2**) and -615923 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): In the Supporting Information, there include three correlated structure figures of complexes **1** and **2**, the IR and UV/Vis spectra of complexes **1**–**3**, the SPS spectrum of complex **2** and the FISPS spectra of complexes **2** and **3**.

# A Comparative Study of Chalcogenated Phosphanylborohydrides $[EPR_2BH_3]^-$ (R = Ph, *t*Bu) and Triorganophosphane Chalcogenides $EPPh_2CH_3$ (E = O, S, Se, Te)

**Franz Dornhaus,[a] Michael Bolte,[a] Hans-Wolfram Lerner,[a] and Matthias Wagner*[a]**

**Keywords:** P ligands / Boranes / Ligand design / Chalcogens / Isoelectronic analogues

Chalcogenation of the phosphanylborohydrides $K(PPh_2BH_3)$ and $K(PtBu_2BH_3)$ with $N_2O$, $S_8$, $Se_\infty$, and $Te_\infty$ leads to the corresponding species $K(EPR_2BH_3)$ in excellent yield (E = O–Te; R = Ph, *t*Bu). The parent systems as well as all the chalcogen derivatives have been structurally characterised as their 18-crown-6 adducts by X-ray crystallography. In the case of $[K(18\text{-c-}6)][EPPh_2BH_3]$ the anionic ligand binds to the $K^+$ ion through both its E atom and its $BH_3$ substituent. Significantly larger K–B distances together with shorter K–E contacts are observed in the sterically more congested *tert*-butyl derivatives $[K(18\text{-c-}6)][EPtBu_2BH_3]$. Based on a comparison of characteristic NMR parameters (e.g. $^1J_{P,B}$, $^1J_{P,C}$) of $K(EPPh_2BH_3)$ and $EPPh_2CH_3$, we come to the conclusion that the formal replacement of $CH_3^+$ by $BH_3$ leads to a significant increase in the p character of the E–P bond, which therefore indicates that $[PPh_2BH_3]^-$ is better suited to direct electron density towards an acceptor atom than its triorganophosphane congener $PPh_2CH_3$. In line with this interpretation, displacement experiments between $K(PPh_2BH_3)$ and $EPPh_2CH_3$ (E = S–Te) resulted in the quantitative formation of $K(EPPh_2BH_3)$ and $PPh_2CH_3$.

## Introduction

Organophosphanes are among the most abundant ligands in coordination chemistry,[1] therefore much effort is still devoted to the design of improved phosphane ligand systems with customised steric and electronic properties. Of particular importance is a targeted tuning of the Lewis basicity of the phosphorus atom in triorganophosphanes ($PR_3$) by careful variation of the R substituents. For example, aryl substituents result in phosphanes of medium donor strength (cf. $PPh_3$), while more electron-releasing alkyl substituents lead to an increased σ-donor ability (cf. $PEt_3$).[2] Given this background, it is interesting to explore whether replacement of an alkyl side-chain by the even less electronegative $BH_3$ fragment further promotes the capability of the phosphorus centre to deliver charge density to a coordinated acceptor atom. So far, the chemistry of such phosphanylborohydrides $[PR_2BH_3]^-$ has not been systematically developed, although a number of publications already exist that clearly prove the potential of phosphanylborohydrides in areas as diverse as the synthesis of polymeric materials containing group 13 and group 15 elements,[3] the preparation of chiral organophosphanes,[4–7] general coordination chemistry,[8–10] and homogeneous catalysis.[11] Our group has recently reported an assessment of the relative Lewis basicities of $[PPh_2BH_3]^-$, $PPh_2CH_3$ and $PPh_2H$ towards the Lewis acids $H^+$, $[CH_3]^+$ and $BH_3$.[12] In the corresponding adducts the ligands were treated as σ-donors and effects of π-backbonding, which, if present, are only relevant in the $BH_3$ adducts,[13] were neglected. The situation changes when triorganophosphane chalcogenides ($EPR_3$) and chalcogenated phosphanylborohydrides $[EPR_2BH_3]^-$ are included in the discussion. Especially in the case of phosphane oxides, the great stability of the OP group is most likely derived from multiple bonding. A nowadays widely accepted description of the multiple bond in the phosphoryl fragment suggests a donor–acceptor interaction between the electron lone-pair on phosphorus and the oxygen atom (σ-bond) superimposed by a transfer of electron density from two filled 2p orbitals on oxygen to a set of antibonding orbitals of e symmetry on the $PR_3$ fragment (π-bonds; *negative hyperconjugation*[14]).[15] Other theories, however, explain the short, strong and highly polar O–$PR_3$ bond by means of σ donation from P to O, which leads to a pronounced charge separation of the form $^-O\text{-}^+PR_3$ and, in turn, strengthens and shortens the O–P bond due to electrostatic attraction.[16,17]

The purpose of this paper is to compare the structural and NMR spectroscopic properties of compounds $[EPR_2BH_3]^-$ with those of related triorganylphosphane chalcogenides. Electronegative groups on phosphorus are known[18] to increase the degree of multiple bonding in $OPR_3$ compounds and it is therefore interesting to unveil

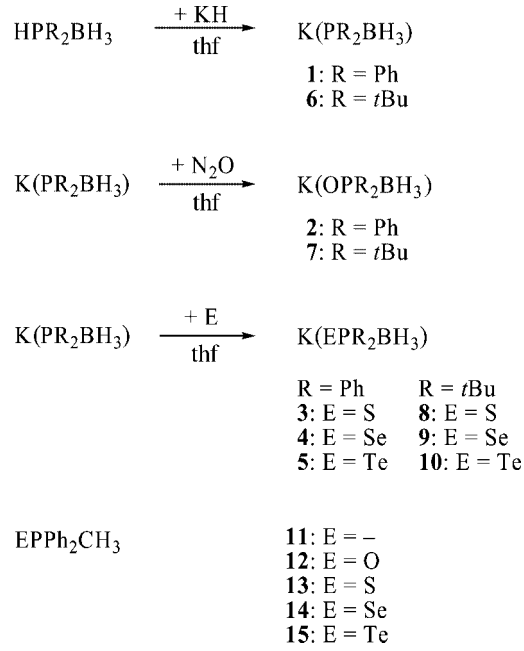
the influence of the electropositive $BH_3$ substituent on the electron distribution within the $[EPR_2BH_3]^-$ framework. Since it is well-known that a delicate interplay exists between steric and electronic effects in phosphane ligands,[2] we have chosen methylbis(phenyl)phosphane ($PPh_2CH_3$) and bis(phenyl)phosphanylborohydride $[PPh_2BH_3]^-$ for our comparative studies since these two compounds are largely isostructural. To elucidate the consequences of steric bulk on the ligand properties of phosphanylborohydrides the *tert*-butyl derivative $[PtBu_2BH_3]^-$ was also included in our investigation.

## Results and Discussion

### Syntheses

The phosphanylborohydrides $K(PR_2BH_3)$ [R = Ph (**1**), *t*Bu (**6**); Scheme 1] are readily accessible by deprotonation of the corresponding phosphane–borane adducts $HPR_2BH_3$ with potassium hydride in thf. Stirring of thf solutions of $K(PR_2BH_3)$ under an atmosphere of dry nitrous oxide leads to the clean formation of $K(OPR_2BH_3)$ (**2**, **7**). Complexes of the heavier chalcogens (**3**–**5** and **8**–**10**) were obtained upon treatment of $K(PR_2BH_3)$ with elemental sulfur, grey selenium or tellurium in thf (Scheme 1). In all cases, the yields were high. The molecules contain a P–B bond and there is no migration of $BH_3$ from the phosphorus to the chalcogen atom. Similar to this, secondary phosphane oxides also prefer $R_2(O)PH$ structures over the tautomeric forms $R_2POH$.[18] $R_2(O)PH$ compounds are weak acids and the proton on phosphorus can be removed with appropriate bases. In most transformations the resulting $[R_2(O)P:]^-$ intermediates react with electrophiles at the phosphorus site, thus preserving the phosphoryl group in the product. Consequently, our derivatives $K(OPR_2BH_3)$ (**2**, **7**) may be viewed as Lewis acid–base adducts between $BH_3$ and $K[R_2(O)P:]$. The O, S and Se derivatives **2**–**4** and **7**–**9** are reasonably stable towards air and moisture. Exposure of the Te derivatives **5** and **10** to water, however, instantaneously leads to the liberation of elemental tellurium together with the formation of $HPR_2BH_3$. The compounds also lose tellurium upon contact with silicone grease. It is interesting to note that **5**, even though it is not a very stable compound, can be synthesised, isolated and structurally characterised. This stands in marked contrast to the related triorganophosphane telluride $TePPh_2CH_3$, which forms only as minor component in a dynamic equilibrium when the phosphane $PPh_2CH_3$ is treated with tellurium in thf solution. Since this result already indicates phosphanylborohydrides $[PR_2BH_3]^-$ to be stronger Lewis bases than their triorganylphosphane counterparts, it prompted us to investigate whether a displacement reaction occurs between $K(PPh_2BH_3)$ (**1**) and the chalcogenides $EPPh_2CH_3$ (E = O, S, Se; **12**–**14**). Indeed, in situ $^{31}P$ NMR spectroscopy revealed quantitative transfer of the E atom from **13** and **14** to the phosphanylborohydride **1** in thf solution. In the case of **1**/**14**, the exchange of the selenium atom proceeds instantaneously at room temp., whereas sulfur transfer from **13** to **1** requires heating of the reaction mixture to 65 °C for 18 h. Under the same conditions an equimolar mixture of **1** and **12** remains unchanged. We believe that the reaction between **1** and **12**, even though thermodynamically favourable, is prevented by a high activation barrier.



Scheme 1. Synthesis of the potassium phosphanylborohydrides **1** and **6** and their chalcogenation to **2**–**5** and **7**–**10**, along with the numbering scheme of the related methylbis(phenyl)phosphane **11** and its chalcogenides **12**–**15**.

The IR stretching frequency of the EP bond is a useful characteristic of compounds $K(EPR_2BH_3)$ (R = Ph, *t*Bu). Unfortunately, it was not possible to unambiguously assign the band of the EP stretch in the fingerprint region of the IR spectrum of any of the molecules under investigation here.

### X-ray Crystallography

X-ray quality crystals of the 18-crown-6 adducts **1**$^c$–**5**$^c$ were obtained by gas-phase diffusion of diethyl ether onto solutions containing **1**–**5** and equimolar amounts of 18-crown-6. Single-crystals of the adducts **6**$^c$–**10**$^c$ were grown by cooling their concentrated solutions in diethyl ether to –30 °C. Neutral methylbis(phenyl)phosphane oxide (**12**) was crystallised by allowing its hot, saturated, hexane solution to cool to room temp. Crystallographic data for compounds **1**$^c$–**10**$^c$ and **12** are given in the Experimental Section; selected bond lengths and angles are compiled in Table 1.

Each $K^+$ ion in **1**$^c$–**10**$^c$ is bonded to the six oxygen atoms of one 18-crown-6 ligand and to one chalcogenophosphorylic anion. In most cases, short K···B distances indicate $K^+$ coordination of the $BH_3$ substituent in addition to K–E adduct formation (Table 1; E = O, S, Se, Te). According to Edelstein's correlation[19] of metal···boron distances as a measure of the denticity of borohydride groups, values of

$1.6 \pm 0.1$ and $1.36 \pm 0.06$ Å are estimated for the ionic radii of didentate and tridentate borohydride ligands, respectively. Deduction of an effective ionic radius of a unidentate $BH_4^-$ group is less straightforward, however, mainly because of the greater flexibility of the M–H–B linkage (cf. $r(BH_4^-)$ = 2.23 Å in $[Fe(\eta^1\text{-}BH_4)H(dmpe)_2]$;[20] $r(BH_4^-)$ = 1.92 Å in $[Cu(\eta^1\text{-}BH_4)(PPh_2Me)_3]$[20,21]). However, it has been suggested that if subtraction of the metal ionic radius from the M···B distance in a tetrahydroborate complex gives a value of 1.8 Å or greater, it is likely that the $BH_4^-$ ligand is unidentate.[20] These data lead to the conclusion that K···B distances of about 3.5, 3.25 and 3.01 Å are to be expected for mono-, di and tridentate coordination modes, respectively (ionic radius of octacoordinate $K^+$ = 1.65 Å[22]).

We start our discussion of the molecular structures with a comparison of the two parent phosphanylborohydrides $[K(18\text{-c-}6)][PPh_2BH_3]$ (**1**$^{c}$; Figure 1) and $[K(18\text{-c-}6)][PtBu_2BH_3]$ (**6**$^{c}$; Figure 2) which differ substantially in the steric demand of their organyl substituents. The K–P contact in compound **1**$^{c}$ amounts to 3.320(2) Å and is thus significantly shorter than the sum (3.55 Å) of the van der Waals radius of phosphorus (1.9 Å[23]) and the ionic radius of $K^+$ [angle K–P–B = 68.1(2)°]. The corresponding K···B distance (3.162 Å) suggests an additional $\eta^2$-coordination of the $BH_3$ fragment. In contrast to **1**$^{c}$, the K–P distances of 4.92 and 4.94 Å in **6**$^{c}$ (two crystallographically independent molecules in the asymmetric unit) and K–B–P angles of 149° and 166° clearly exclude any bonding interaction between $K^+$ and the electron lone-pair at phosphorus. Similar to **1**$^{c}$, **6**$^{c}$ features short K···B contacts in the solid state (3.133 and 3.029 Å). In one of the two molecules, K–B coordination is therefore somewhere between $\eta^2$ and $\eta^3$, whereas the second ion-pair is linked by an $\eta^3$-coordinated $BH_3$ fragment. The differences between the solid-state

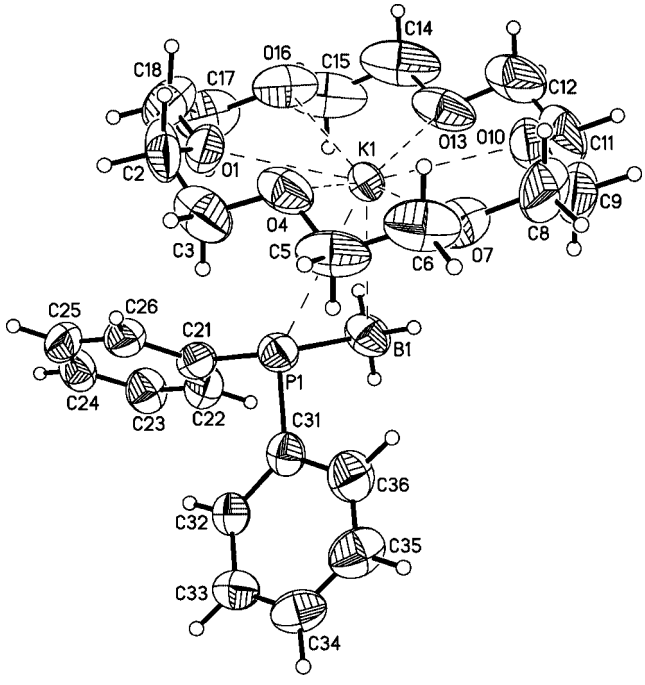

Figure 1. Molecular structure and numbering scheme of compound **1**$^{c}$; thermal ellipsoids shown at the 50% probability level.

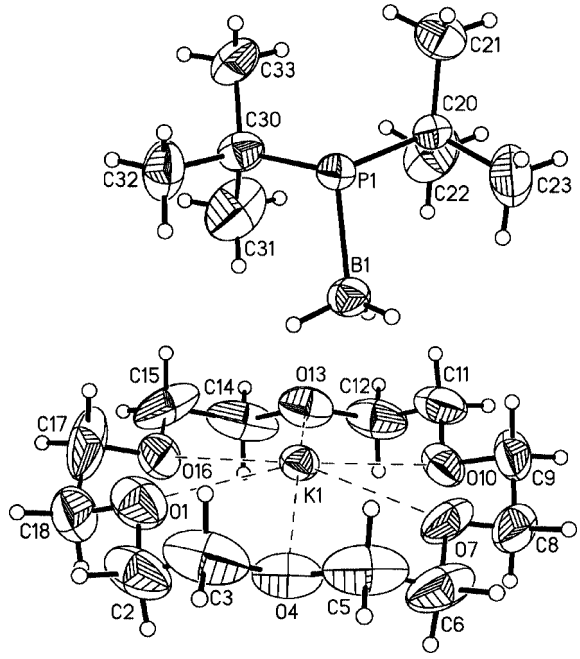

Figure 2. Molecular structure and numbering scheme of compound **6**$^{c}$; thermal ellipsoids shown at the 50% probability level. Only one of the two crystallographically independent $[K(18\text{-c-}6)][PtBu_2BH_3]$ units is shown.

structures of **1**[c] and **6**[c] clearly originate from the fact that the bulky *tert*-butyl substituents in the latter compound force the phosphorus centre away from the $[K(18\text{-c-}6)]^+$ plane.

The $[EPPh_2BH_3]^-$ anions of **2**[c]–**5**[c] all coordinate to the $K^+$ ion through both their chalcogen atom and their $BH_3$ groups ($\eta^2$ in the case of the sulfur and selenium derivatives **3**[c] and **4**[c], $\eta^1$ mode in the case of the oxygen and tellurium derivatives **2**[c] and **5**[c]; cf. K···B distances in Table 1). Replacement of phenyl by *tert*-butyl substituents (**7**[c]–**10**[c]) leads to longer K···B distances but shorter K–E bonds (the only exception is the K–Te bond of **10**[c], which is somewhat longer than the K–Te bond in **5**[c]). Provided that the steric requirements are met, as in the case of **2**[c]–**5**[c], it is thus apparent that $BH_3$ coordination to the $K^+$ ion can successfully compete with chalcogen binding. Even though the steric demand of two *tert*-butyl substituents in **7**[c]–**10**[c] precludes the close approach between $K^+$ and B required for the formation of 3c–2e KHB bonds, we nevertheless assume a significant electrostatic attraction between the negative partial charge residing on the $BH_3$ unit and the $K^+$ cation in the *tert*-butyl derivatives as well. As representative examples the molecular structures of $[K(18\text{-c-}6)][OPPh_2BH_3]$ (**2**[c]), $[K(18\text{-c-}6)][OPtBu_2BH_3]$ (**7**[c]), $[K(18\text{-c-}6)][TePPh_2BH_3]$ (**5**[c]) and $[K(18\text{-c-}6)][TePtBu_2BH_3]$ (**10**[c]) are shown in Figures 3, 4, 5 and 6, respectively.

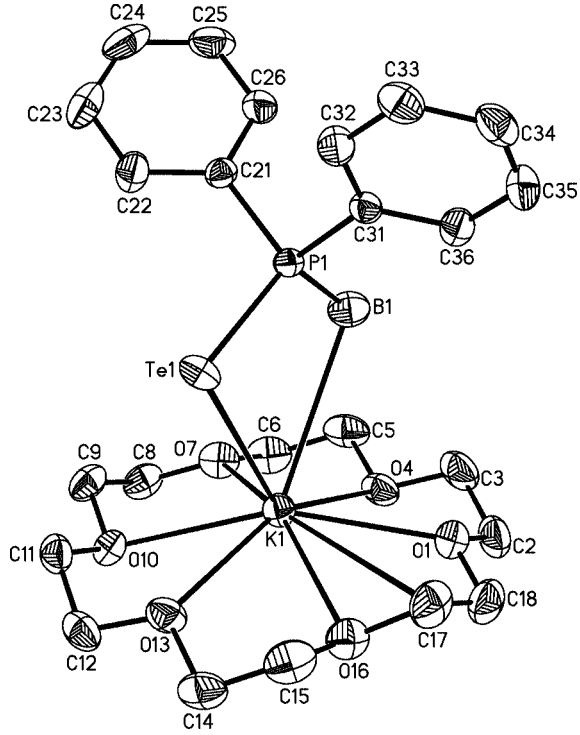

Figure 5. Molecular structure and numbering scheme of compound **5**[c]; thermal ellipsoids shown at the 50% probability level; hydrogen atoms omitted for clarity.

The vast majority of M–E–P angles in metal complexes of chalcogenophosphorylic ligands either fall in the range between 180° and 140° ($L_nM\text{-}OPR_3$) or 115° and 98° ($L_nM\text{-}EPR_3$; E = S, Se).[24] A similar trend is observed for our $[K(18\text{-c-}6)][EPR_2BH_3]$ derivatives in that the largest K–E–P angle within each of the two series is established by the oxo species. However, the *absolute* values of the K–E–P angles in $[K(18\text{-c-}6)][EPR_2BH_3]$ are generally much smaller

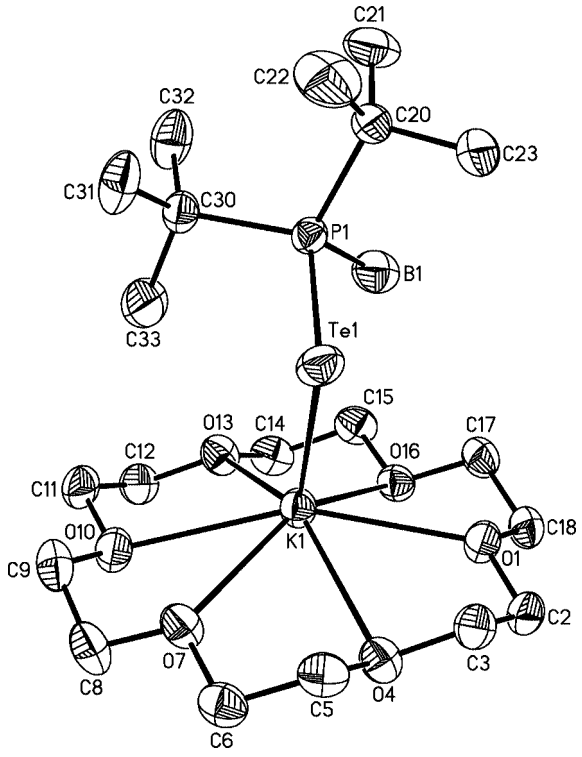

Figure 6. Molecular structure and numbering scheme of compound **10**$^{c}$; thermal ellipsoids shown at the 50% probability level; hydrogen atoms omitted for clarity.

than those of the corresponding M–E–P angles in $L_nM$-$EPR_3$, which is most likely the result of the auxiliary K–$H_3B$ interaction discussed above.

Looking at the series of compounds **2**$^{c}$–**5**$^{c}$ and **7**$^{c}$–**10**$^{c}$ as well as at related triorganylphosphane chalcogenides, it is our goal to find out whether differences in the electron density distribution at phosphorus can be correlated to systematic trends in key structural parameters such as the E–P and P–C bond lengths or the C–P–C′ bond angles. For example, it is generally accepted[25] that a tetracoordinate atom A directs hybrids of greater p character toward more electronegative substituents S and S′, which, in turn, leads to smaller S–A–S′ bond angles.

A comparison of E–P bond lengths in **2**$^{c}$–**5**$^{c}$ with those of related molecules **7**$^{c}$–**10**$^{c}$ reveals larger E–P distances in the *tert*-butyl derivatives **7**$^{c}$, **8**$^{c}$ and **10**$^{c}$ (Table 1). However, the differences are very small, and in the case of the Se compounds the order is even reversed (**9**$^{c}$ < **4**$^{c}$). Our negatively charged molecules $[EPPh_2BH_3]^-$ possess slightly longer E–P bonds than comparable neutral triorganophosphane chalcogenides (Table 2). This effect may either result from $K^+$ coordination[26] or from the presence of the electron-releasing $BH_3$ fragment in **2**$^{c}$–**5**$^{c}$. Irrespective of whether E→P backbonding via *negative hyperconjugation* or electrostatic attraction in a highly polar $^{-}E\text{-}^{+}PR_3$ adduct is the more adequate description of the E–P bond, both factors are likely less pronounced in compounds $K(EPR_2BH_3)$ than in $EPR_2CH_3$ as a consequence of the more negative formal charge on phosphorus in the $BH_3$-containing molecules. Correlations between the length of a polar bond determined in the solid state and the bond strength or bond order must, however, not be overemphasised because crystal packing effects also have to be taken into consideration. An interesting trend is evident for the C(phenyl)–P–C′(phenyl) angles, which are significantly more acute in the ionic species **2**$^{c}$, **3**$^{c}$ and **4**$^{c}$ than in the neutral triorganophosphane chalcogenides (Table 2). Replacement of one organyl substituent by the $BH_3$ group thus results in an increased p character of the two remaining P–C(phenyl) bonds, which is in agreement with the isovalent hybridisation hypothesis.[25] This conclusion is further supported by the fact that the P–C(phenyl) bond is considerably longer in **2**$^{c}$ [1.832(1) Å] than in $OPPh_2CH_3$ [**12**; 1.808(3) Å]. In the case of the heavier homologues **3**$^{c}$/$SPPh_3$ and **4**$^{c}$/$SePPh_3$, however, this bond length difference is levelled out to such an extent that it is no longer of diagnostic significance (Table 2).

Table 2. Comparison of the ionic species **2**$^{c}$, **3**$^{c}$, **4**$^{c}$, and **5**$^{c}$ with their triorganyl analogues.

## NMR Spectroscopy

Characteristic NMR parameters of compounds **1**–**15** (Scheme 1) are compiled in Table 3. For comparability and solubility reasons, all NMR spectra were recorded at 300 K for thf solutions.

The phosphanylborohydrides $K(PPh_2BH_3)$ (**1**) and $K(P\textit{t}Bu_2BH_3)$ (**6**) possess $^{31}P$ NMR shifts of $\delta$ = –28.8 and 12.8 ppm, respectively, remarkably close to the values of the isoelectronic triorganylphosphanes $PPh_2CH_3$ (**11**; $\delta$ = –26.1 ppm[12]) and $P\textit{t}Bu_2CH_3$ ($\delta$ = 11.3 ppm). The pronounced deshielding of the $^{31}P$ NMR resonance upon going from the phenyl to the *tert*-butyl derivatives is attributable to the high steric demand of the alkyl substituents, which enforces a widening of the C–P–C′ angles by an increased admixture of the 3s orbital to the P–C bond.[18] As a consequence, the phosphorus lone-pair is depleted of s character and, in turn, loses some of its shielding effect. In the case of the tetra-coordinated chalcogen compounds the $^{31}P$ NMR resonances of the phenyl derivatives **2**–**5** also appear at higher field than the signals of the corresponding *tert*-butyl derivatives **7**–**10**. The shift difference lies between 30.0 ppm (**2/7**) and 64.6 ppm (**5/10**). We also note that varying the chalcogeno substituent has a much more pronounced effect on the resonance frequency of the $^{31}P$ nucleus in the

borohydride derivatives **2**–**5** and **7**–**10** than in the triorganophosphane chalcogenides **12**–**15** (Table 3).

The $^{11}$B NMR shifts of **1**–**10** range from $\delta$ = –28.1 (**5**) to –39.4 ppm (**7**) and are typical of phosphane–borane adducts.[27]

$^1J_{P,X}$ coupling constants are valuable diagnostic tools for an assessment of the degree of s character in the P–X bonding orbitals (X = B, C, Se, Te).[28] In many cases, linear correlations between both parameters have been established. This can easily be rationalised if we assume that NMR coupling constants via a certain bond are governed by the Fermi contact term, which increases with increasing s orbital admixture to the respective bond.[28] Moreover, the magnitude of $^1J_{P,B}$ coupling constants in phosphane–borane adducts serves as a qualitative measure of the strength of the P–B bond.[13,29–31] Looking at the coupling constants via the P–B ($^1J_{P,B}$), P–CH$_3$ ($^1J_{P,C}$) and P–C(phenyl) bonds ($^1J_{P,Ci}$), there is always the same qualitative trend: all these coupling constants increase substantially upon attachment of chalcogeno substituents to the phosphorus centres of the parent molecules K(PPh$_2$BH$_3$) (**1**), K(P*t*Bu$_2$BH$_3$) (**6**) and PPh$_2$CH$_3$ (**11**). This effect is strongest for the oxo systems **2**, **7** and **12** and decreases monotonously along the series O > S > Se > Te. From these data it becomes evident that P–E bond formation is accompanied by an increase in s character of the P–BH$_3$/P–CH$_3$ and P–C(phenyl) bonds. Concomitantly, the former phosphorus lone-pair gains p character as it becomes involved in covalent bonding to the chalcogen atom. In line with Bent's rule,[25] this gain is most pronounced for compounds containing the chalcogen atom of highest electronegativity (O); it is intermediate for S and Se and least pronounced for the chalcogen atom of lowest electronegativity (Te). Interestingly, the $^1J_{P,X}$ values of the sulfur derivatives **3**, **8** and **13** are consistently larger than those of the corresponding Se-containing species **4**, **9** and **14** even though the electronegativity of S ($\chi$ = 2.44[23]) is *smaller* than the electronegativity of Se ($\chi$ = 2.48[23]). It is thus obvious that additional effects have to be taken into account for a more detailed understanding of trends in the $^1J_{P,X}$ constants and that the degree of E→P $\pi$ backbonding in particular must not be neglected. Differences in the $^1J_{P,B}$ values of species K(EPPh$_2$BH$_3$) and K(EP*t*Bu$_2$BH$_3$) bearing the same kind of atom E become larger with increasing atomic number of E. Thus, the influence of the organic substituents on the strength of the P–B bond is smallest in the oxo derivatives and most pronounced in the tellurium species.

The $^{77}$Se and $^{125}$Te NMR spectra of **4**, **5**, **9**, **10**, **14** and **15**[32] were measured and the data included in Table 3. Triorganophosphane selenides are known to possess $^1J_{P,Se}$ coupling constants in the range between 700 and 1100 Hz.[28] For SePPh$_2$CH$_3$ (**14**) we have determined a chemical shift value of –305.7 ppm with a $^1J_{P,Se}$ coupling constant of 744 Hz. Formal replacement of CH$_3$ by BH$_3$ (**14** → **4**) leads to a downfield shift of the $^{77}$Se resonance by 41.2 ppm (**4**: $\delta$ = –264.5 ppm) together with a decrease of the absolute value of the coupling constant by 200 Hz (**4**: $^1J_{P,Se}$ = 544 Hz).

## Conclusions

Two complete series of chalcogenated phosphanylborohydrides K(EPR$_2$BH$_3$) (E = O-Te; R = Ph, *t*Bu) have been synthesised and all compounds investigated by NMR spectroscopy and X-ray crystallography (in the latter case as 18-crown-6 adducts). In all cases the molecules contain a P–B bond and there is no migration of BH$_3$ from the phosphorus to the chalcogen atom. A comparison of characteristic structural [e.g. E–P bond lengths, C(phenyl)–P–C′(phenyl) bond angles] and NMR spectroscopic (e.g. $^1J_{P,X}$ coupling constants; X = B, C, Se, Te) parameters of the isoelectronic and isostructural species [EPPh$_2$BH$_3$]$^-$ and EPPh$_2$CH$_3$ leads to the conclusion that [PPh$_2$BH$_3$]$^-$ directs a $\sigma$ orbital of higher p character towards the respective chalcogen atom than PPh$_2$CH$_3$. All trends in the above mentioned parameters are nicely correlated to the changes in the electronegativities of the atoms E, as predicted by

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Bent's rule.[25] We have already found similar correlations in pure σ adducts of $[PPh_2BH_3]^-$ and $PPh_2CH_3$,[12] which leads us to the conclusion that no influence of E→P backbonding is discernible in our study.

All structural and NMR spectroscopic data indicate the E–P bonds to be stronger with $[PPh_2BH_3]^-$ than with $PPh_2CH_3$ as ligand. This conclusion is supported by the fact that the telluride $K(TePPh_2BH_3)$ is isolable in good yield whereas $TePPh_2CH_3$ forms from a thf solution of $PPh_2CH_3$ and $Te_\infty$ only in trace amounts in a dynamic equilibrium. Moreover, displacement experiments between $K(PPh_2BH_3)$ and $EPPh_2CH_3$ (E = S, Se) resulted in the quantitative formation of $K(EPPh_2BH_3)$ and $PPh_2CH_3$. A similar reaction between $K(PPh_2BH_3)$ and $OPPh_2CH_3$ does not take place (thf, 65 °C, 18 h), most likely due to kinetic rather than thermodynamic reasons. As in triorganylphosphanes the *tert*-butyl derivative $[PtBu_2BH_3]^-$ appears to be an even better Lewis base than its counterpart $[PPh_2BH_3]^-$, most likely for both electronic (+I effect of alkyl substituents) and steric (widening of the C–P–C angle due to steric crowding) reasons.

From an inspection of the molecular structures of [K(18-c-6)][$EPPh_2BH_3$] it becomes evident that $[EPPh_2BH_3]^-$ ligands have to be considered as potentially chelating, with one donor site being the chalcogen atom E and the second the $BH_3$ moiety, which can bind to a metal centre through its hydride substituents. We are presently systematically exploring the potential of phosphanylborohydrides as anionic analogues of triorganophosphanes in coordination chemistry.

## Experimental Section

**General Considerations:** All reactions and manipulations of air-sensitive compounds were carried out under an atmosphere of dry nitrogen using standard Schlenk techniques. Solvents were freshly distilled under argon from sodium/benzophenone (thf, diethyl ether, toluene) or sodium-lead alloy (pentane, hexane) prior to use. NMR spectra were recorded with Bruker AMX 250, DPX 250, AV 300 and AV 400 spectrometers. Approximately 0.1 mL of $C_6D_6$ was added to all samples recorded in undeuterated thf (0.6 mL) to provide a lock signal. $^1H$ and $^{13}C$ NMR shifts are reported relative to tetramethylsilane and were referenced against residual solvent peaks ($C_6D_5H$: $\delta$ = 7.16, $C_6D_6$: $\delta$ = 128.06 ppm; $CHCl_3$: $\delta$ = 7.26, $CDCl_3$: $\delta$ = 77.16 ppm).[33] $^{11}B$ NMR spectra were referenced against external $BF_3{\cdot}OEt_2$, $^{31}P$ NMR spectra against external $H_3PO_4$ (85%) and $^{77}Se$ NMR spectra against external concentrated aqueous $H_2SeO_3$ ($\delta$ = 1300 ppm vs. $Me_2Se$).[34] $^{125}Te$ NMR spectra were referenced against external concentrated aqueous $H_6TeO_6$ ($\delta$ = 712 ppm vs. $Me_2Te$).[35] Abbreviations: s = singlet, d = doublet, q = quartet, dq = doublet of quartets, m = multiplet, n.r. = multiplet expected in the NMR spectrum but not resolved, *i* = *ipso*, *o* = *ortho*, *m* = *meta*, *p* = *para*. Elemental analyses were performed by the microanalytical laboratory of the J. W. Goethe-University, Frankfurt/Main, Germany.

**Materials:** Lithium, $PPh_3$, $PPh_2CH_3$, $PtBu_2H$, KH, $N_2O$, $S_8$, $Se_\infty$, $Te_\infty$, $BH_3{\cdot}THF$ solution (1 M in thf) and 18-crown-6 were purchased from Aldrich or Fluka and used as received. $HPPh_2$ was obtained by reductive cleavage of triphenylphosphane with lithium powder in thf and subsequent hydrolysis and distillation following a literature procedure.[36] The $BH_3$ adduct $HPPh_2BH_3$ was synthesised as described previously.[12] The same procedure was also used to make $HPtBu_2BH_3$.[37] The phosphane chalcogenides $EPPh_2CH_3$ (**12**–**15**) were synthesised by the reaction of $PPh_2CH_3$ with $H_2O_2$, $S_8$, grey $Se_\infty$ or $Te_\infty$ in thf at room temperature.[38–40] $TePPh_2CH_3$ could not be obtained in pure form; the $^{31}P$ NMR spectrum of the yellow reaction mixture showed a yield of approximately 6% of the target compound (dynamic equilibrium between $TePPh_2CH_3$, $Te_\infty$ and $PPh_2CH_3$).

**Synthesis of $K(PPh_2BH_3)$ (1):** A solution of $HPPh_2BH_3$ (2.29 g, 11.4 mmol) in thf (5 mL) was added to a suspension of KH (480 mg, 12.0 mmol) in thf (10 mL) with stirring at –78 °C. The mixture was then warmed to room temp. overnight. After filtration from residual KH, all volatiles were removed in vacuo. The resulting yellow oily residue solidified upon treatment with pentane. Yield: 2.40 g (88%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 0.9 (m, 3 H, $BH_3$), 6.79–6.87 (m, 2 H, H-*p*), 6.90–6.98 (m, 4 H, H-*m*), 7.41–7.49 (m, 4 H, H-*o*) ppm. $^{11}B$ NMR (thf, 128.38 MHz): $\delta$ = –30.1 ppm (dq, $^1J_{P,B}$ = 32.1, $^1J_{B,H}$ = 89.9 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 124.5 (n.r., C-*p*), 127.0 (d, $^3J_{P,C}$ = 5.1 Hz, C-*m*), 133.9 (d, $^2J_{P,C}$ = 14.0 Hz, C-*o*), 150.2 (d, $^1J_{P,C}$ = 20.1 Hz, C-*i*) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = –28.8 ppm (m). $C_{24}H_{37}BKO_6P$ (502.42): calcd. C 57.37, H 7.42; found C 57.25, H 7.39.

**Synthesis of $K(OPPh_2BH_3)$ (2):** A solution of **1** (479 mg, 2.01 mmol) in thf (5 mL) was stirred at room temp. under an atmosphere of $N_2O$ until the gas evolution had entirely stopped and the pale-yellow colour had disappeared (ca. 5 min). All volatiles were then removed in vacuo to give a colourless crystalline solid. Yield: 500 mg (98%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 0.9 (m, 3 H, $BH_3$), 7.03–7.13 (m, 6 H, H-*m*,*p*), 7.64–7.75 (m, 4 H, H-*o*) ppm. $^{11}B\{^1H\}$ NMR (thf, 128.38 MHz): $\delta$ = –35.7 ppm (d, $^1J_{P,B}$ = 98.7 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 127.8 (d, $^3J_{P,C}$ = 8.4 Hz, C-*m*), 128.7 (n.r., C-*p*), 130.7 (d, $^2J_{P,C}$ = 9.9 Hz, C-*o*), 145.4 (d, $^1J_{P,C}$ = 54.0 Hz, C-*i*) ppm. $^{31}P\{^1H\}$ NMR (thf, 101.25 MHz): $\delta$ = 64.0 ppm (m). $C_{24}H_{37}BKO_7P$ (518.42): calcd. C 55.60, H 7.19; found C 55.65, H 7.20.

**Synthesis of $K(SPPh_2BH_3)$ (3):** A solution of **1** (476 mg, 2.00 mmol) in thf (5 mL) was added to a suspension of $S_8$ (70 mg, 2.18 mmol $S_1$) in thf (6 mL) with stirring at –78 °C. The mixture was then warmed to room temp. overnight. All volatiles were removed in vacuo and the resulting pale-yellow solid was triturated with toluene (2 × 5 mL). Yield: 513 mg (95%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 1.3 (m, 3 H, $BH_3$), 7.20–7.30 (m, 6 H, H-*m*,*p*), 8.11–8.23 (m, 4 H, H-*o*) ppm. $^{11}B\{^1H\}$ NMR (thf, 128.38 MHz): $\delta$ = –31.3 ppm (d, $^1J_{P,B}$ = 78.2 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 127.3 (d, $^3J_{P,C}$ = 9.6 Hz, C-*m*), 128.2 (d, $^4J_{P,C}$ = 2.4 Hz, C-*p*), 131.8 (d, $^2J_{P,C}$ = 10.1 Hz, C-*o*), 143.3 (d, $^1J_{P,C}$ = 44.3 Hz, C-*i*) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 42.1 ppm (m). $C_{24}H_{37}BKO_6PS$ (534.48): calcd. C 53.93, H 6.98; found C 53.34, H 6.52.

**Synthesis of $K(SePPh_2BH_3)$ (4):** A solution of **1** (500 mg, 2.10 mmol) in thf (5 mL) was added with stirring at –78 °C to a suspension of grey $Se_\infty$ (166 mg, 2.10 mmol $Se_1$) in thf (2 mL). The mixture was warmed to room temp. overnight whereupon the $Se_\infty$ completely dissolved. All volatiles were then removed in vacuo. The resulting pale-yellow solid was triturated with pentane (2 mL). Yield: 613 mg (92%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 1.4 (m, 3 H, $BH_3$), 6.95–7.11 (m, 6 H, H-*m*,*p*), 7.93–8.05 (m, 4 H, H-*o*) ppm. $^{11}B\{^1H\}$ NMR (thf, 128.38 MHz): $\delta$ = –30.3 ppm (d, $^1J_{P,B}$ = 67.0 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 127.3 (d, $^3J_{P,C}$ = 9.6 Hz, C-*m*), 128.5 (n.r., C-*p*), 132.5 (d, $^2J_{P,C}$ = 10.0 Hz, C-*o*),

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

141.3 (d, $^1J_{P,C}$ = 40.1 Hz, C-*i*) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 21.8 ppm (m). $^{77}Se$ NMR (thf, 47.69 MHz): $\delta$ = –264.5 ppm (d, $^1J_{P,Se}$ = 544 Hz). $C_{24}H_{37}BKO_6PSe$ (581.38): calcd. C 49.58, H 6.41; found C 49.11, H 6.03.

**Synthesis of K(TePPh$_2$BH$_3$) (5):** A solution of **1** (414 mg, 1.74 mmol) in thf (6 mL) was added to a suspension of Te$_\infty$ (222 mg, 1.74 mmol Te$_1$) in thf (4 mL) with stirring at –78 °C. The mixture was then warmed to room temp. overnight. The resulting yellow solution was filtered and all volatiles removed in vacuo. The remaining yellow solid was triturated with pentane (2 mL). Yield: 605 mg (95%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 1.8 (m, 3 H, BH$_3$), 6.93–7.09 (m, 6 H, H-*m*,*p*), 7.89–8.00 (m, 4 H, H-*o*) ppm. $^{11}B\{^1H\}$ NMR (thf, 128.38 MHz): $\delta$ = –28.1 ppm (d, $^1J_{P,B}$ = 51.2 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 127.3 (d, $^3J_{P,C}$ = 9.5 Hz, C-*m*), 128.5 (n.r., C-*p*), 133.5 (d, $^2J_{P,C}$ = 9.6 Hz, C-*o*), 139.6 (d, $^1J_{P,C}$ = 35.5 Hz, C-*i*) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = –30.9 ppm (m). $^{125}Te\{^1H\}$ NMR (thf, 78.88 MHz): $\delta$ = –509.3 ppm (d, $^1J_{P,Te}$ = 1249 Hz). $C_{24}H_{37}BKO_6PTe$ (630.02): calcd. C 45.75, H 5.92; found C 45.53, H 5.65.

**Synthesis of K(P*t*Bu$_2$BH$_3$) (6):** A solution of HP*t*Bu$_2$BH$_3$ (1.14 g, 7.12 mmol) in thf (5 mL) was added to a suspension of KH (290 mg, 7.23 mmol) in thf (6 mL) with stirring at –78 °C. The mixture was then warmed to room temp. overnight. After filtration from residual KH all volatiles were removed in vacuo. Yield: 1.15 g (82%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 0.28 (q, $^1J_{B,H}$ = 88 Hz, 3 H, BH$_3$), 1.16 (d, $^3J_{P,H}$ = 9.8 Hz, 18 H, CH$_3$) ppm. $^{11}B\{^1H\}$ NMR (thf, 128.38 MHz): $\delta$ = –34.7 ppm (d, $^1J_{P,B}$ = 33.8 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 29.6 (d, $^2J_{P,C}$ = 2.8 Hz, CH$_3$), 32.4 (d, $^1J_{P,C}$ = 12.5 Hz, *C*CH$_3$) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 12.8 ppm (m). $C_{20}H_{45}BKO_6P$ (462.44): calcd. C 51.94, H 9.81; due to the extreme air and moisture sensitivity of the compound a decent elemental analysis was not obtained, even from a single crystalline sample.

**Synthesis of K(OP*t*Bu$_2$BH$_3$) (7):** A solution of **6** (240 mg, 1.21 mmol) in thf (3 mL) was stirred at room temp. under an atmosphere of $N_2O$ until the gas evolution had entirely stopped (ca. 5 min). After all volatiles had been removed in vacuo, the product was obtained as a colourless crystalline solid. Yield: 255 mg (98%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 0.4 (m, 3 H, BH$_3$), 1.14 (d, $^3J_{P,H}$ = 11.2 Hz, 18 H, CH$_3$) ppm. $^{11}B\{^1H\}$ NMR (thf, 128.38 MHz): $\delta$ = –39.4 ppm (d, $^1J_{P,B}$ = 100.6 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 27.8 (d, $^2J_{P,C}$ = 2.3 Hz, CH$_3$), 34.8 (d, $^1J_{P,C}$ = 30.1 Hz, *C*CH$_3$) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 94.0 ppm (m). $C_{20}H_{45}BKO_7P$ (478.44): calcd. C 50.21, H 9.48; found C 49.97, H 9.58.

**Synthesis of K(SP*t*Bu$_2$BH$_3$) (8):** A solution of **6** (283 mg, 1.43 mmol) in thf (3 mL) was added to a suspension of S$_8$ (48 mg, 1.50 mmol S$_1$) in thf (3 mL) with stirring at –78 °C. The mixture was then warmed to room temp. overnight. After all volatiles had been removed in vacuo, the resulting colourless solid was triturated with pentane (2 × 2 mL). Yield: 322 mg (98%). $^1H$ NMR (thf, 300.03 MHz): $\delta$ = 0.52 (q, $^1J_{B,H}$ = 92 Hz, 3 H, BH$_3$), 1.19 (d, $^3J_{P,H}$ = 12.0 Hz, 18 H, CH$_3$) ppm. $^{11}B\{^1H\}$ NMR (thf, 96.26 MHz): $\delta$ = –35.3 ppm (d, $^1J_{P,B}$ = 80.8 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 28.5 (d, $^2J_{P,C}$ = 2.9 Hz, CH$_3$), 35.2 (d, $^1J_{P,C}$ = 21.6 Hz, *C*CH$_3$) ppm. $^{31}P\{^1H\}$ NMR (thf, 121.46 MHz): $\delta$ = 76.6 ppm (q, $^1J_{P,B}$ = 80.8 Hz). $C_{20}H_{45}BKO_6PS$ (494.50): calcd. C 48.58, H 9.17; found C 48.68, H 9.23.

**Synthesis of K(SeP*t*Bu$_2$BH$_3$) (9):** A solution of **6** (279 mg, 1.41 mmol) in thf (3 mL) was added to a suspension of grey Se$_\infty$ (111 mg, 1.41 mmol Se$_1$) in thf (2 mL) with stirring at –78 °C. The mixture was then warmed to room temp. overnight, whereupon the Se$_\infty$ dissolved completely. The reaction mixture was evaporated to dryness in vacuo and the resulting colourless solid triturated with pentane (2 mL). Yield: 357 mg (91%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 0.75 (q, $^1J_{B,H}$ = 93 Hz, 3 H, BH$_3$), 1.27 (d, $^3J_{P,H}$ = 12.6 Hz, 18 H, CH$_3$) ppm. $^{11}B\{^1H\}$ NMR (thf, 128.38 MHz): $\delta$ = –34.4 ppm (d, $^1J_{P,B}$ = 72.9 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 29.0 (d, $^2J_{P,C}$ = 3.0 Hz, CH$_3$), 34.0 (d, $^1J_{P,C}$ = 17.0 Hz, *C*CH$_3$) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 68.4 ppm (m). $^{77}Se$ NMR (thf, 76.30 MHz): $\delta$ = –379.8 ppm (d, $^1J_{P,Se}$ = 514 Hz). $C_{20}H_{45}BKO_6PSe$ (541.40): calcd. C 44.37, H 8.38; found C 44.35, H 8.50.

**Synthesis of K(TeP*t*Bu$_2$BH$_3$) (10):** A solution of **6** (302 mg, 1.52 mmol) in thf (3 mL) was added to a suspension of Te$_\infty$ (195 mg, 1.53 mmol Te$_1$) in thf (3 mL) with stirring at –78 °C. The mixture was then warmed to room temp. overnight. The resulting yellow solution was filtered and all volatiles removed in vacuo. The yellow solid residue was triturated with pentane (2 × 2 mL). Yield: 490 mg (99%). $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 1.2 (m, 3 H, BH$_3$), 1.34 (d, $^3J_{P,H}$ = 12.8 Hz, 18 H, CH$_3$) ppm. $^{11}B\{^1H\}$ NMR (thf, 128.38 MHz): $\delta$ = –32.2 ppm (d, $^1J_{P,B}$ = 64.3 Hz). $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 29.6 (d, $^2J_{P,C}$ = 2.8 Hz, CH$_3$), 32.4 (d, $^1J_{P,C}$ = 12.5 Hz, *C*CH$_3$) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 33.7 ppm (m). $^{125}Te\{^1H\}$ NMR (thf, 78.88 MHz): $\delta$ = –782.0 (d, $^1J_{P,Te}$ = 1170 Hz). $C_{20}H_{45}BKO_6PTe$ (590.04): calcd. C 40.71, H 7.69; found C 40.38, H 7.27.

**OPPh$_2$CH$_3$ (12):** $^1H$ NMR (thf, 400.13 MHz): $\delta$ = 1.80 (d, $^2J_{P,H}$ = 13.4 Hz, 3 H, CH$_3$), 7.20–7.30 (m, 6 H, H-*m*,*p*), 7.66–7.74 (m, 4 H, H-*o*) ppm. $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 16.2 (d, $^1J_{P,C}$ = 73.2 Hz, CH$_3$), 128.8 (d, $^3J_{P,C}$ = 11.7 Hz, C-*m*), 130.9 (d, $^2J_{P,C}$ = 9.6 Hz, C-*o*), 131.6 (d, $^4J_{P,C}$ = 2.8 Hz, C-*p*), 135.8 (d, $^1J_{P,C}$ = 99.8 Hz, C-*i*) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 28.3 ppm (s).

**SPPh$_2$CH$_3$ (13):** $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 2.04 (d, $^2J_{P,H}$ = 13.3 Hz, 3 H, CH$_3$), 7.19–7.30 (m, 6 H, H-*m*,*p*), 7.69–7.79 (m, 4 H, H-*o*) ppm. $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 21.4 (d, $^1J_{P,C}$ = 60.1 Hz, CH$_3$), 128.7 (d, $^3J_{P,C}$ = 12.1 Hz, C-*m*), 131.2 (d, $^2J_{P,C}$ = 10.6 Hz, C-*o*), 131.3 (d, $^4J_{P,C}$ = 2.7 Hz, C-*p*), 135.7 (d, $^1J_{P,C}$ = 81.2 Hz, C-*i*) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 35.8 ppm (s).

**SePPh$_2$CH$_3$ (14):** $^1H$ NMR (thf, 250.13 MHz): $\delta$ = 2.24 (d, $^2J_{P,H}$ = 13.6 Hz, 3 H, CH$_3$), 7.21–7.28 (m, 6 H, H-*m*,*p*), 7.71–7.79 (m, 4 H, H-*o*) ppm. $^{13}C\{^1H\}$ NMR (thf, 62.90 MHz): $\delta$ = 21.9 (d, $^1J_{P,C}$ = 53.3 Hz, CH$_3$), 128.7 (d, $^3J_{P,C}$ = 12.1 Hz, C-*m*), 131.4 (d, $^4J_{P,C}$ = 2.9 Hz, C-*p*), 131.6 (d, $^2J_{P,C}$ = 10.8 Hz, C-*o*), 134.4 (d, $^1J_{P,C}$ = 73.1 Hz, C-*i*) ppm. $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 24.3 ppm (s, $^1J_{PSe}$ = 744 Hz). $^{77}Se$ NMR (thf, 76.31 MHz): $\delta$ = –305.7 ppm (d, $^1J_{P,Se}$ = 744 Hz).

**TePPh$_2$CH$_3$ (15):** $^{31}P\{^1H\}$ NMR (thf, 161.98 MHz): $\delta$ = 25.6 ppm (s). $^{125}Te\{^1H\}$ NMR (thf, 126.19 MHz): $\delta$ = –554.5 ppm (s).

**X-ray Structural Characterisation:** Data collections were performed on a Stoe IPDS-II two-circle diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation (see Tables 4 and 5). Empirical absorption corrections were performed with the MULABS option[41] in the program PLATON.[42] Equivalent reflections were averaged. The structures were solved by direct methods[43] and refined with full-matrix least-squares on $F^2$ using the program SHELXL-97.[44] Hydrogen atoms bonded to carbon and boron were placed at ideal positions and refined with fixed isotropic displacement parameters using a riding model.

# New Chiral Ferrocene-Bridged Phosphole–Phosphane Ligands

**Jose Guadalupe Lopez Cortes,[a][‡] Olivier Ramon,[a] Sandrine Vincendeau,[a] Daniel Serra,[a] Franck Lamy,[a] Jean-Claude Daran,[a] Eric Manoury,*[a] and Maryse Gouygou*[a]**

**Keywords:** Ferrocenes / Phospholes / P,P ligands / Asymmetric catalysis / X-ray diffraction

A convenient synthesis of new chiral ferrocenene-bridged phosphole–phosphane ligands in an enantiomerically pure form has been developed. These new chiral P,P ligands have been tested in a palladium-catalysed allylic substitution reaction. High activities and moderate enantioselectivities (up to 61 %) were observed. A palladium(II) complex has been isolated and its crystal structure established.

## Introduction

Considerable efforts have been devoted to the development of new chiral ligands owing to the growing importance of transition-metal-catalysed asymmetric synthesis.[1] Among these chiral ligands, ferrocene-containing ligands are among the most interesting because of their stability, easy introduction of planar chirality and special electronic and stereoproperties of the ferrocene skeleton.[2] Amongst the chiral ferrocene-based ligands, enantiopure 1,2-disubstituted ferrocene derivatives, especially ferrocenediyldiphosphane ligands, played a dominant role.[3] Typical examples are Trap ligands,[4] and diphosphane Josiphos ligands,[5] in particular the industrially important Xyliphos,[6] Taniaphos[7] or Walphos-type ligands[8] (Figure 1). Common characteristics of these ligands include the ferrocenylethyl backbone and the presence of both planar and central chiralities. Little attention has been paid to ligands based on a ferrocenylmethyl backbone or more generally to those having ferrocene possessing planar chirality as their only element of chirality. Reported examples include Trap (**I**),[9] Josiphos[10] analogues (**II**) or diphosphanes (**III**)[11] developed by Kagan et al. (Figure 2).

Recently, we have extended the family of 1,2-disubstituted planar-chiral ferrocene by introduction of a phosphole group leading to planar-chiral ferrocene-bridged phosphole–amine ligands.[12] Chiral phosphole-based ligands[13] have been rather infrequently used for asymmetric catalysis,[14] despite the fact that phospholes are efficient ligands in homogeneous transition-metal catalysis.[15] However, introduction of a phosphole group, which possesses different steric and electronic effects with respect to phosphanes, may modulate the ligand properties. Other advantages of this type of ligand are related to chiral flexibility of unsymmetrically substituted phosphole due to the low inversion barrier of the phosphorus atom in phosphole.[16]

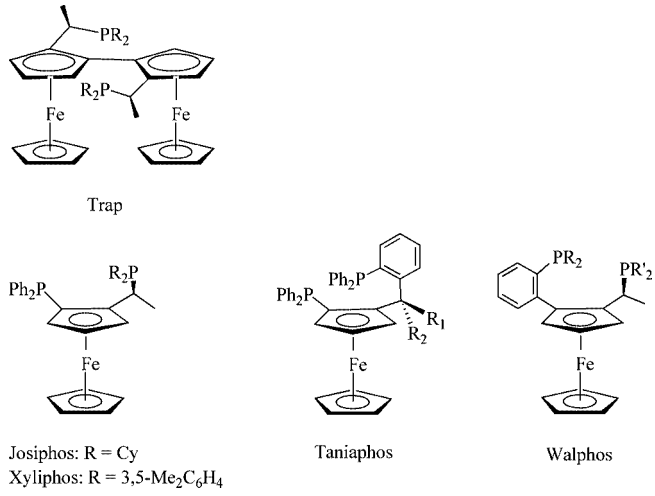

Figure 1. Well-known ferrocenyldiphosphane ligands combining both planar and central chiralities.

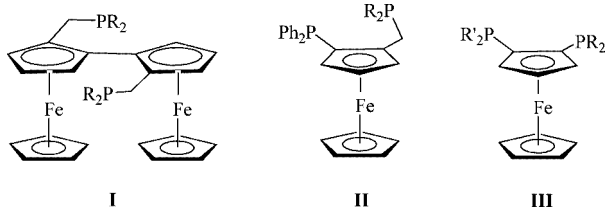

Figure 2. Ferrocenyldiphosphane ligands possessing planar chirality as their only element of chirality.

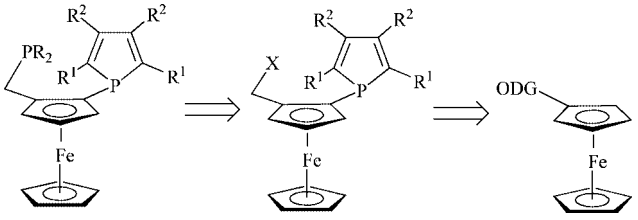
A chirally flexible phosphole can (i) adjust the configuration to accommodate the metal centre and (ii) magnify the chiral part of the catalytic system.[17]

As part of our continuing interest in ferrocene chemistry[18] and in the design and synthesis of new chiral phosphole-based ligands,[19] we were interested in ferrocene-derived phosphole ligands with only planar chirality for asymmetric catalysis. In this paper, we describe the synthesis of new 1,2-disubstituted ferrocene-bridged phosphole–phosphane ligands involving the introduction of various phospholyl groups on Kagan's acetal derivatives. The coordination chemistry and the catalytic properties of these new chiral ferrocene-bridged phosphole–phosphane ligands are also reported.

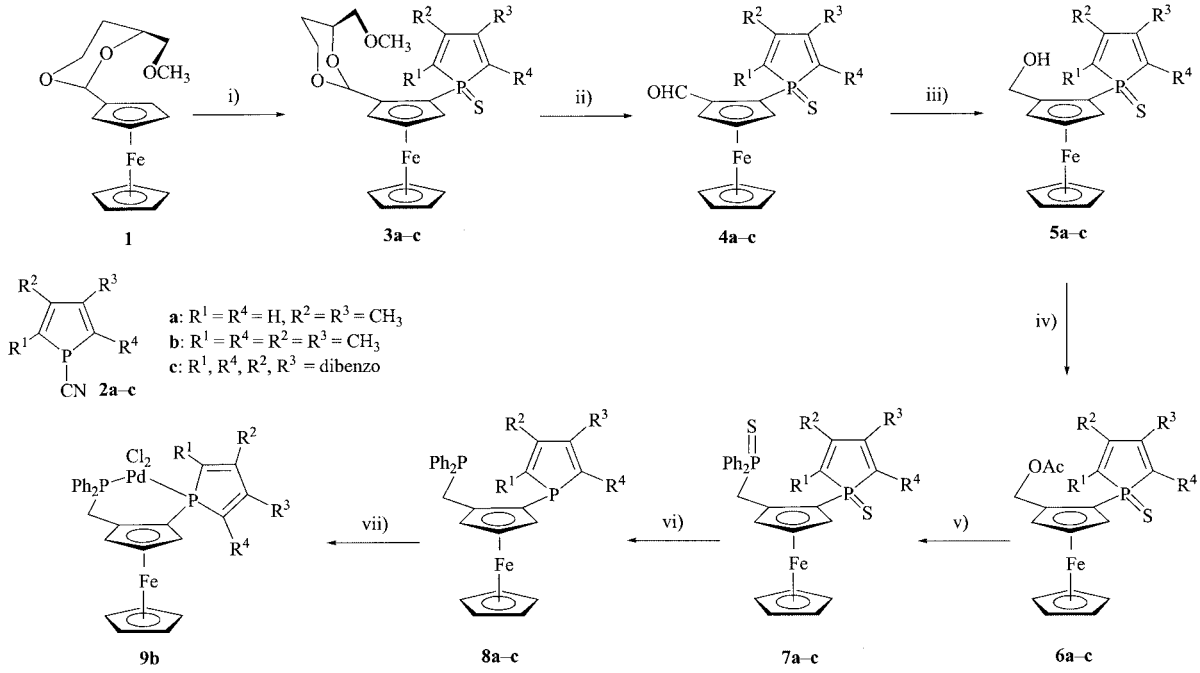
## Results and Discussion

The synthetic approach of 1,2-disubtituted ferrocene-based phosphane by nucleophilic displacement of a leaving group (Scheme 1), as described by Hayashi et al.[20] or Togni et al.,[21] could be used to prepare the target molecules. This strategy required the introduction of the planar chirality in the first step by a stereoselective *ortho* metallation step, which required a chiral auxiliary to achieve stereochemically controlled addition of the phospholyl group on the ferrocene moiety. The stereoselective *ortho* metallations reported to date include cyclopalladation of [(dimethylamino)methyl]ferrocene, ortholithiation of ferrocenyl sulfoxides, dioxanes, amines, oxazolines, hydrazones or oxazaphospholidine oxides and so forth.[2c,22,23]



Scheme 1. Retrosynthetic synthesis of ferrocene-bridged phosphole–phosphane ligands.

To control planar chirality, we chose Kagan's method[24] starting from a chiral dioxane. So, the synthetic pathway used is based on six stereochemically controlled reactions, as shown in Scheme 2. In the first step, diastereoselective *ortho* lithiation of acetal **1** was achieved with *t*BuLi. The lithio intermediate reacted cleanly with various 1-cyanophospholes (**2a**,[25] **2b**[14k] and **2c**) as electrophilic reagents to afford the corresponding ferrocenylphosphole products. To facilitate the purification and the characterisation of these compounds, they were converted in situ into air-stable sulfur derivatives **3a–c** by using an excess of sulfur in dichloromethane at room temperature. Compounds **3a**, **3b** and **3c**, isolated after column-chromatographic purification, were obtained in each case as an enantiomerically pure diastereoisomer as confirmed by $^{1}H$, $^{31}P$ and $^{13}C$ NMR analysis and X-ray diffraction studies. The (*S*) configuration for the planar chirality, which is expected from the literature,[24] was confirmed by X-ray analysis on monocrystals in the case of **3b**. A molecular view of compounds (*S*)-**3b** is shown in Figure 3 with the atom-labelling scheme. As expected, the phosphole ring is planar, with the largest deviation [0.028(2) Å] at C11. The phosphorus atom P1 deviates slightly by 0.132(5) Å from the plane of the Cp ring to



Scheme 2. Synthesis of **8**: (i) *t*BuLi, –78 °C to room temperature; 1-cyanophosphole **2**, –30 °C; $S_8$, $CH_2Cl_2$, room temperature; (ii) $H^+$, $H_2O/CH_2Cl_2$, reflux; (iii) $NaBH_4$, room temperature; (iv) AcCl/$NEt_3$, 0 °C to room temperature; $CH_2Cl_2$; (v) $R_2PH$, toluene, reflux, $S_8$, $CH_2Cl_2$, room temperature; (vi) $P(NMe_2)_3$, toluene reflux; (vii) $PdCl_2(CH_3CN)_2$, $CH_2Cl_2$, room temperature.

which it is attached, whereas the atom S1 is *endo* with respect to this Cp ring. The phosphole and the Cp rings are roughly perpendicular, with a dihedral angle of 83.1(1)°. The dioxane ring is distorted and the puckering parameters[26] show that its conformation is close to that of a chair: the $\theta$ and $\varphi$ angles calculated for the atom sequence C21–O22–C23–C24–C25–O26 are 177.2(3)° and 147(6)°, respectively. Owing to steric hindrance, the dioxane ring is twisted by 53.3(1)° with respect to the Cp ring. The two Cp rings are nearly eclipsed, with a twisted angle of only 2.9°.

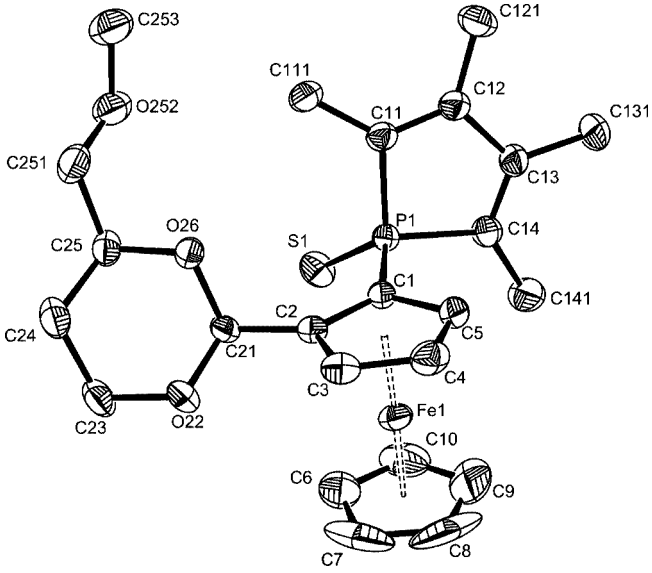

Figure 3. Molecular view of **3b** with atom-labelling scheme. Ellipsoids represent 50% probability. Selected bond lengths [Å] and bond angles [°]: P(1)–S(1) 1.9487(11), P(1)–C(1) 1.790(3), P(1)–C(11) 1.796(3), P(1)–C(14) 1.809(3), C(2)–C(21) 1.504(4), Fe(1)–Cg(1) 1.645(9), Fe(1)–Cg(2) 1.660(9); Cg(1)–Fe(1)–Cg(2) 178.2(6). Cg(1) and Cg(2) are the centroids of the (C1,C2,C3,C4,C5) Cp ring and the (C6,C7,C8,C9,C10) Cp ring, respectively.

In the next step, the acid hydrolysis of the acetal (*S*)-**3a**–**c** was performed with *p*-toluenesulfonic acid to quantitatively yield the corresponding aldehydes (*S*)-**4a**–**c**. Reduction of the crude aldehydes (*S*)-**4a**–**c** of low stabilities was then readily achieved by using an excess of sodium tetrahydroborate. The corresponding alcohols (*S*)-**5a**–**c** were obtained in good yields after column-chromatographic purification. The (*S*) configuration of compound **5b** was again confirmed by X-ray diffraction analysis. A molecular view of alcohol (*S*)-**5b** is shown in Figure 4 with the atom-labelling scheme. As previously noticed, the phosphole ring is planar, with the largest deviation [–0.022(1) Å] at C14 and a dihedral angle of 89.93(7)° with the Cp ring to which it is attached. The atom P1 deviates from the plane of the Cp ring by 0.223(3) Å, certainly minimising steric hindrance, whereas the atom S1 is slightly *endo* by 0.341(4) Å with respect to this Cp ring. The two Cp rings are twisted relative to each other by 10.7°. An interesting feature is the occurrence of an O–H···S intermolecular hydrogen bond [O–H = 0.84 Å, H···S = 2.53 Å, O···S = 3.2700(15) Å, O–H···S = 147.3°] linking the molecules to form a chain developing parallel to the *a*-axis.

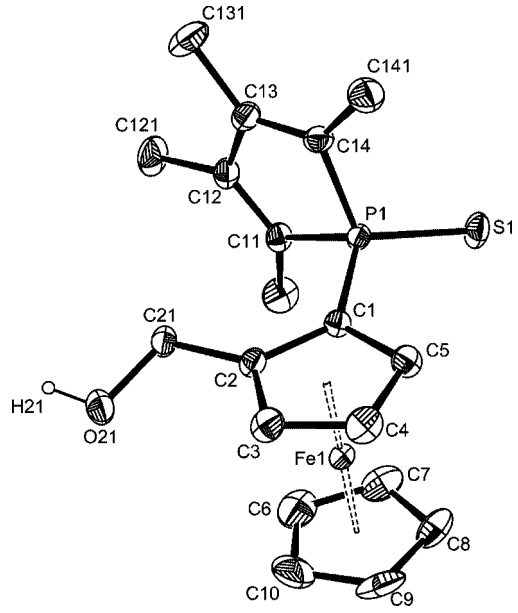

Figure 4. Molecular view of **5b** with atom-labelling scheme. Ellipsoids represent 30% probability. Selected bond lengths [Å] and bond angles [°]: P(1)–S(1) 1.9677(6), P(1)–C(1) 1.790(2), P(1)–C(11) 1.797(2), P(1)–C(14) 1.799(2), C(2)–C(21) 1.505(3), C(21)–O(21) 1.423(2), Fe(1)–Cg(1) 1.636(8), Fe(1)–Cg(2) 1.646(8), Cg(1)–Fe(1)–Cg(2) 176.6(3). Cg(1) and Cg(2) are the centroids of the (C1,C2,C3,C4,C5) Cp ring and the (C6,C7,C8,C9,C10) Cp ring, respectively.

Alcohols (*S*)-**5a**–**c** were quantitatively transformed into acetates (*S*)-**6a**–**c** by treatment with acetyl chloride. Subsequent nucleophilic substitution reactions with secondary phosphanes followed by sulfuration reaction led to ferrocene-bridged phosphole–phosphanes as disulfide derivatives **7a**–**c**. Compounds (*S*)-**7a**, (*S*)-**7b** and (*S*)-**7c**, obtained in 57%, 74% and 78% yield, respectively, were fully characterised.

In the last step, deprotection was successfully achieved with tris(dimethylamino)phosphane in refluxing toluene providing the ferrocene-bridged phosphole–phosphanes (*S*)-**8b** and (*S*)-**8c**. However, this procedure gave only low yields of (*S*)-**8a**, which could not be isolated in a pure form and was only identified by mass spectrometry. The structure of (*S*)-**8b** was determined by X-ray diffraction analysis. A molecular view of complex (*S*)-**8b** is shown in Figure 5. As already observed in free phosphole ligands,[27] the phosphorus atom is located above the butadiene fragment [0.208 (5) Å]. The atom P1 deviates from the plane of the Cp ring by 0.189(5) Å. The atom P2 is oriented *exo* with respect to the Cp ring and is located 1.518(6) Å above it. The two Cp rings are perfectly eclipsed with a twist angle of only 0.5°. The two phenyl rings are roughly perpendicular with a dihedral angle of 87.1(1)°. It is interesting to note that the lone pairs of the two phosphorus atoms are in the correct arrangement for chelating on a metal precursor.

The mode of complexation of new ligands **8** was checked by forming palladium(II) complexes. Ligand **8b** reacted in dichloromethane at room temperature with

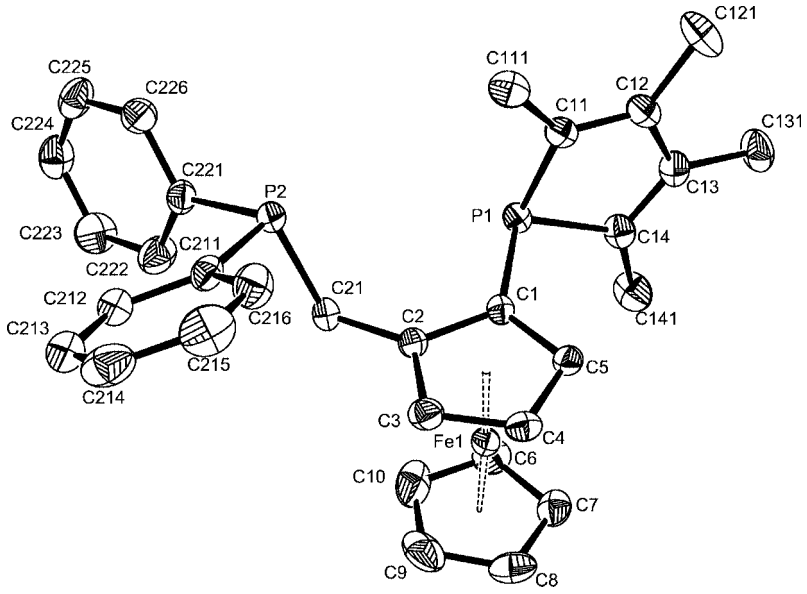

Figure 5. Molecular view of **8b** with atom-labelling scheme. Ellipsoids represent 30% probability. Selected bond lengths [Å] and bond angles [°]: P(1)–C(1) 1.809(3), P(1)–C(11) 1.800(3), P(1)–C(14) 1.807(3), C(2)–C(21) 1.515(5), C(21)–P(2) 1.842(3), P(2)–C(211) 1.835(4), P(2)–C(221) 1.842(3), Fe(1)–Cg(1) 1.6391(4), Fe(1)–Cg(2) 1.6587(4), Cg(1)–Fe(1)–Cg(2) 176.03(3). Cg(1) and Cg(2) are the centroids of the (C1,C2,C3,C4,C5) Cp ring and the (C6,C7,C8,C9,C10) Cp ring, respectively.

$[PdCl_2(CH_3CN)_2]$ in 30 min to afford complex (*S*)-**9b** (80% yield) of formula $[PdCl_2$(**8b**)] as indicated by $^1H$, $^{13}C$ and $^{31}P$ NMR spectroscopy and mass spectrometry. The molecular structure of complex (*S*)-**9b** was established by X-ray diffraction study. There are two molecules in the asymmetric unit with nearly identical geometry. A view of molecule A is depicted in Figure 6. If the phosphole and the Cp form a dihedral angle of 86.3(4)° [88.5(4) for molecule B], a value close to that observed in the free ligand, the atom P2 of the diphenylphosphanyl group is now oriented *endo* with respect to the Cp ring to accommodate the $PdCl_2$ unit. The geometry of the chelating group is closely related to the recently reported structure of {1-(diphenylphosphanyl)-2,1′-[(1-diphenylphosphanyl)butane-1,3-diyl]ferrocene}-$PdCl_2$.[28] As expected, the $Pd^{II}$ atom is square-planar coordinated, with the largest deviation from the least-squares plane being 0.016(2) Å [0.010(2) Å for molecule B] at the Pd atom. The chelating six-membered ring Pd1–P1–C1–C2–C21–P2 is folded around the P1···C21 axis with a dihedral angle of 30.0(4)° [32.8(3)° for molecule B]. The coordination results in a larger twist angle between the two Cp rings of 10.8° (12.2° for molecule B).

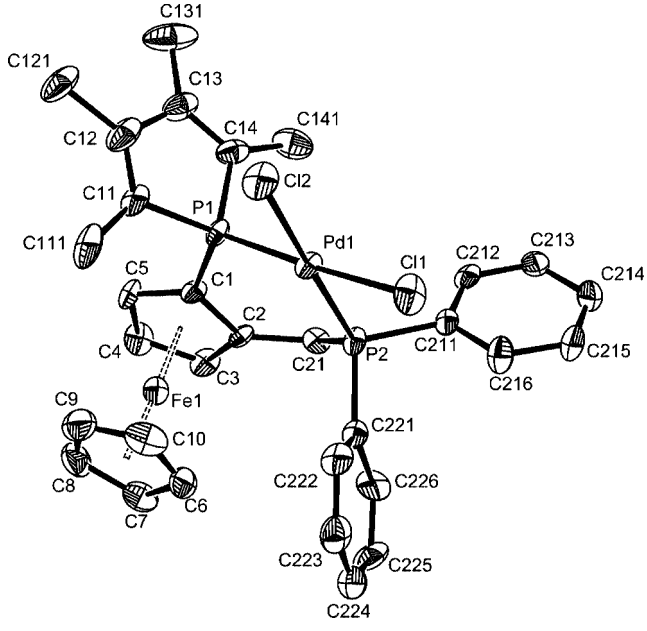

Figure 6. Molecular view of **9b** with atom labelling. Ellipsoids represent 30% probability. Selected bond lengths [Å] and bond angles [°]: Pd–Cl(1) 2.347(3) [2.348(3)], Pd–Cl(2) 2.360(3) [2.363(3)], Pd–P(1) 2.237(3) [2.245(3)], Pd–P(2) 2.261(3) [2.262(3)], P(1)–C(1) 1.791(10) [1.788(10)], C(2)–C(21) 1.487(15) [1.510(15)], P(2)–C(21) 1.828(10) [1.823(11)], Fe(1)–Cg(1) 1.656(3) [1.665(3)], Fe(1)–Cg(2) 1.669(3) [1.666(3)]; Cg(1)–Fe(1)–Cg(2) 174.8(4). Cg(1) and Cg(2) are the centroids of the (C1,C2,C3,C4,C5) Cp ring and the (C6,C7,C8,C9,C10) Cp ring, respectively. The values in square brackets refer to molecule B.

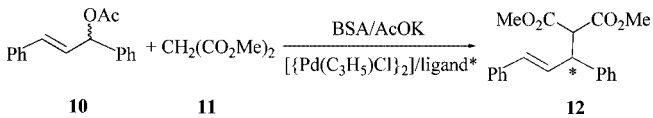
The chiral ligands (*S*)-**8b** and (*S*)-**8c** were evaluated in the palladium-catalysed asymmetric allylic substitution.[29] The reaction of 1,3-diphenylprop-2-enyl acetate (**10**) with the anion of dimethyl malonate (**11**) was carried out in the presence of $[Pd(C_3H_5)Cl]_2$ (1 mol-%) and the chiral ligands **8b**,**c** (1 mol-%) (see Scheme 3). Using the ligand (*S*)-**8b**, the allylic acetate **10** in $CH_2Cl_2$ was quantitatively converted within 1 h at room temperature to the desired product (*S*)-**12** in 38% *ee*. Under similar conditions, the ligand (*S*)-**8c**



Scheme 3. Asymmetric allylic substitution reaction.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

led also to the quantitative conversion of **10** within 1 h to (*S*)-**12**, but with a better enantioselectivity (61% *ee*).

## Conclusions

A new and convenient preparation of ferrocene-bridged phosphole–phosphane ligands in an enantiomerically pure form has been achieved. Their coordination chemistry and their abilities for catalysis in a palladium-catalysed asymmetric allylic substitution reaction have been checked. Use of these new unusual chiral P,P ligands in other asymmetric catalytic reactions as well as optimisation of ligands by modifying the phosphole ring part or the phosphane part are currently being developed in our laboratories.

## Experimental Section

**General:** All reactions were carried out under dry argon by using Schlenk glassware and vacuum-line techniques. Solvents were freshly distilled from standard drying agents. $^{1}H$, $^{13}C\{^{1}H, ^{31}P\}$ and $^{31}P\{^{1}H\}$ NMR spectra were recorded with a Bruker WMX 400 instrument operating at 400, 162 and 100 MHz respectively. Chemical shifts are reported in ppm relative to $Me_4Si$ ($^{1}H$ and $^{13}C$) or 85% $H_3PO_4$ ($^{31}P$). Mass spectra were obtained with a Nermag R10-10 instrument (DCI, FAB) and with an Applied Biosystem API 365 instrument (APCI). Elemental analysis was performed by the "Service d'Analyse du Laboratoire de Chimie de Coordination" at Toulouse. Optical rotations were measured with a Perkin–Elmer 241 polarimeter. Acetal **1**,[24b] 1-cyano-2,3,4,5-tetramethylphosphole (**2b**),[14k] 1-phenyldibenzophosphole[30] and compounds **3a**, **4a**, **5a** and **6a**[12] were prepared as described in the literature.

**1-Cyanodibenzophosphole (2c):** A solution of 1-phenyldibenzophosphole (2 g, 7.7 mmol) in THF (15 mL) was added at room temperature to a suspension of lithium (0.16 g, 23 mmol) in THF (5 mL). The reaction mixture was stirred at room temperature for 4 h. The red suspension was filtered (to remove unreacted lithium) into another Schlenk tube, cooled to –20 °C, and anhydrous $AlCl_3$ (0.35 g, 2.6 mmol) was added. The reaction mixture was warmed to 0 °C, stirred for 0.5 h and then transferred by cannula to a solution of BrCN (1.63 g, 15.4 mmol) in THF (5 mL) cooled to –78 °C. The mixture was stirred at –78 °C for 0.5 h, then warmed to room temperature and stirred overnight. The mixture was concentrated to dryness and the resulting residue was extracted with small portions of diethyl ether. The combined diethyl ether extracts were filtered through Celite and the solvents were evaporated to give crude compound **2c** as a white solid (0.93 g, 58%). This was used without purification. $^{1}H$ NMR ($CDCl_3$): $\delta$ = 7.47 (m, 2 H, Ar), 7.59 (m, 2 H, Ar), 7.90 (m, 4 H, Ar) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = –51.6 ppm.

**General Procedure for Synthesis of Dioxanes 3:** In a Schlenk tube, a 1.5 M solution of *tert*-butyllithium in pentane (8.1 mL, 12.1 mmol, 1.1 equiv.) was added dropwise, at –78 °C under argon, to a solution of acetal **1** (3.47 g, 11 mmol) in dry diethyl ether (40 mL). The solution was stirred at –78 °C for 15 min, then at room temperature for 2 h. The solution was cooled to –30 °C and a solution of 1-cyanophosphole **2** (1.2 equiv.) in dry diethyl ether (20 mL) was introduced by cannula. The reaction mixture was stirred at room temperature overnight. Dry triethylamine (0.5 mL) was introduced by syringe, followed by water (2 mL). Under argon, the reaction mixture was extracted with diethyl ether and washed with brine. The organic fraction was dried with sodium sulfate and the solvents were evaporated in vacuo to yield an orange oil. This oil was dissolved in dichloromethane (30 mL). Sulfur (5.7 equiv.) was added and the mixture was stirred overnight. After concentration, the mixture was chromatographed on silica gel using a pentane/dichloromethane mixture (3:7, v/v).

**(2*S*,4*S*,$S_{Fc}$)-2-[(2,3,4,5-Tetramethyl-1-thioxo-1*H*-1λ$^5$-phosphol-1-yl)-ferrocenyl]-4-(methoxymethyl)-1,3-dioxane (3b):** Yellow-orange oil (yield 68%). Crystals suitable for X-ray analysis were obtained by diffusion of pentane into a dichloromethane solution. $^{1}H$ NMR ($CDCl_3$): $\delta$ = 1.51 (br. d, $J$ = 13.3 Hz, 1 H, $CH_2CH_2CH$), 1.83 (m, 1 H, $CH_2CH_2CH$), 1.85 (br. s, 3 H, $CH_3$), 1.94 (br. s, 3 H, $CH_3$), 2.01 (d, $J_{H,P}$ = 13.3 Hz, 3 H, $CH_3$), 2.13 (d, $J_{H,P}$ = 12.8 Hz, 3 H, $CH_3$), 3.32 (s, 3 H, $OCH_3$), 3.35 (dd, ABX system, $J$ = 10.1 and 5.1 Hz, 1 H, $CH_2OCH_3$), 3.44 (dd, ABX system, $J$ = 10.1 and 5.2 Hz, 1 H, $CH_2OCH_3$), 3.95–4.10 (m, 2 H, CH, $OCH_2CH_2$), 4.02 (m, 1 H, subst. **General Procedure for the Synthesis of Ferrocenecarbaldehyde 4:** Acetal **3** (7.3 mmol), dichloromethane (120 mL) and an aqueous

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solution (50 mL) of *p*-toluenesulfonic acid monohydrate (1.5 equiv. for **3b** or 2 equiv. for **3c**) were introduced into a round-bottomed flask equipped with a condenser and placed under argon. The reaction mixture was stirred at reflux for 26 h (**3b**) or 54 h (**3c**). After cooling to room temperature, the dark red solution was extracted with dichloromethane, washed with distilled water, dried with sodium sulfate and the solvents were evaporated. Compounds **4**, obtained quantitatively as red oils, were only characterised by $^{31}P$ and $^{1}H$ NMR spectroscopy and used without purification.

**($S_{Fc}$)-2-(2,3,4,5-Tetramethyl-1-thioxo-1*H*-1λ$^5$-phosphol-1-yl)ferrocenecarbaldehyde (4b):** $^{1}H$ NMR ($CDCl_3$): $\delta$ = 1.89 (br. s, 3 H, $CH_3$), 1.95 (br. s, 3 H, $CH_3$), 1.98 (d, $J_{H,P}$ = 13.7 Hz, 3 H, $CH_3$), 2.07 (d, $J_{H,P}$ = 13.7 Hz, 3 H, $CH_3$), 4.52 (s, 5 H, Cp), 4.61 (m, 1 H, subst. Cp), 4.72 (m, 1 H, subst. Cp), 5.16 (m, 1 H, subst. Cp), 10.58 (s, 1 H, CHO) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 55.8 ppm.

**($S_{Fc}$)-2-(Dibenzo-1-thioxo-1*H*-1λ$^5$-phosphol-1-yl)ferrocenecarbaldehyde (4c):** $^{1}H$ NMR ($CDCl_3$): $\delta$ = 3.38 (m, 1 H, subst. Cp), 4.25 (m, 1 H, subst. Cp), 4.43 (s, 5 H, Cp), 5.56 (m, 1 H, subst. Cp), 7.48–7.88 (m, 8 H, Ar), 10.57 (s, 1 H, CHO) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 38.6 ppm.

**General Procedure for Synthesis of Alcohols 5:** Crude compound **4** (7.3 mmol) was dissolved in methanol (200 mL) and an aqueous solution (140 mL) of sodium borohydride (2.78 g, 18.3 mmol) and sodium hydroxide (11.2 g, 280 mmol) was added. The solution turned rapidly from red to orange. After 15 min of stirring at room temperature, the reaction mixture was extracted with dichloromethane. The organic phase was washed with diluted hydrochloric acid, then water, and finally dried with sodium sulfate. After evaporation of the solvents, the crude material was purified by flash chromatography on silica gel using a pentane/diethyl ether mixture (2:8, v/v).

**($S_{Fc}$)-[2-(2,3,4,5-Tetramethyl-1-thioxo-1*H*-1λ$^5$-phosphol-1-yl)ferrocenyl]methanol (5b):** Yellow-orange oil (yield 51% from **3b**). Crystals suitable for X-ray analysis were obtained by diffusion of pentane into a dichloromethane solution. M.p. 85 °C. $^{1}H$ NMR ($CDCl_3$): $\delta$ = 1.86 (br. s, 3 H, $CH_3$ β), 1.93 (br. d, $J_{H,P}$ = 12.1 Hz, 3 H, $CH_3$ α), 1.96 (br. s, 3 H, $CH_3$ β), 2.15 (br. d, $J_{H,P}$ = 13.0 Hz, 3 H, $CH_3$ α), 3.39 (dd, $J$ = 7.8 and 5.9 Hz, 1 H, OH), 4.03 (m, 1 H, subst. **($S_{Fc}$)-(Acetoxy)[2-(dibenzo-1-thioxo-1*H*-1λ$^5$-phosphol-1-yl)ferrocenyl]methane (6c):** Orange-red oil. $^{1}H$ NMR ($CDCl_3$): $\delta$ = 1.98 [s, 3 H, $C(O)CH_3$], 4.02 (m, 1 H, subst. Cp), 4.26 (m, 1 H, subst. Cp), 4.48 (s, 5 H, Cp), 4.51 (m, 1 H, subst. Cp), 5.11 (d, $J$ = 12.1 Hz, 1 H, $CH_2$), 5.27 (d, $J$ = 12.1 Hz, 1 H, $CH_2$), 7.3–8.1 (m, 8 H, Ar) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 39.8 ppm.

**General Procedure for Synthesis of Compounds 7:** Diphenylphosphane (2.5 equiv.) was added at room temperature to a solution of crude **6** (0.7 mmol) in degassed toluene (10 mL). The reaction mixture was stirred under reflux for 24 h (**7a**, **7b**) or 36 h (**7c**) and then concentrated in vacuo to yield an orange oil. This oil was dissolved in dichloromethane (10 mL). Sulfur (5 equiv.) was added and the mixture was stirred overnight. After concentration, the mixture was chromatographed on silica gel using a pentane/diethyl ether mixture (80:20).

MS (FAB, MNBA): *m*/*z* (%) = 663 (100) $[M - Cl]^+$.

**General Procedure for Palladium-Catalysed Allylic Substitution:** A mixture of ligand **8**, 1,3-diphenylprop-2-enyl acetate (**10**) (0.454 g, 1.8 mmol) and $[(Pd(C_3H_5)Cl)]_2$ (3.3 mg, 0.009 mmol) in dry dichloromethane (20 mL) was stirred at room temperature for 2 h. Dimethyl malonate (**11**) (0.411 mL, 3.6 mmol), potassium acetate and BSA (0.880 mL, 3.6 mmol) were added to the resulting solution. The reaction was carried out at room temperature and monitored by TLC for the disappearance of the acetate. After the reaction was complete, the resulting mixture was diluted with diethyl ether (5 mL) and quenched with a saturated aqueous solution of ammonium chloride (5 mL). The aqueous phase was extracted with diethyl ether, the combined organic layers were dried with magnesium sulfate, filtered and the solvents evaporated. The conversion was calculated from the crude reaction mixture by $^1$H NMR spectroscopy. Subsequent purification by chromatography on silica eluting with ethyl acetate/pentane (15:85) afforded the product as a white solid. The enantiomeric excess was determined by $^1$H NMR using the chiral shift reagent $Eu(hfc)_3$.

**X-ray Structure Determinations:** A single crystal of each compound was mounted under inert perfluoropolyether at the tip of a glass fibre and cooled in the cryostream of a Stoe IPDS diffractometer for **3b**, **8b** and **9b** or an Oxford Diffraction XCALIBUR CCD diffractometer for **5b**. Data were collected using monochromatic Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073). The structures were solved by direct methods (SIR97[31]) and refined by least-squares procedures on $F^2$ using SHELXL-97.[32] All H atoms were introduced in the calculation in idealised positions and treated as riding on their parent atoms. The absolute configuration was confirmed by refinement of the Flack's enantiopole parameter[33] and careful examination of sensitive reflections. Molecules were drawn with the help of ORTEP32.[34] Crystal data and refinement parameters are shown in Table 1. CCDC-605992 to -605995 contain the supplementary crys-

# "Inhibition" of the Enzyme Model $Tp^{Ph,Me}Zn$–OH by Diketo Compounds

Teame Tekeste[a] and Heinrich Vahrenkamp*[a]

**Keywords:** Zinc / Bioinorganic chemistry / Enzyme inhibition / Diketo compounds

In order to gain a structural understanding of zinc enzyme inhibition, the model complex $Tp^{Ph,Me}Zn$–OH was treated with various diketo compounds. α-Keto carboxylic acids were attached to the zinc ion as anionic O,O-chelate ligands, of which benzoylformate was oxidatively decarboxylated in air to form the benzoate complex. Two functionalized β-diketones did not use their functionality in forming the β-diketonate complexes. Of the α-diketones, 2,3-pentanedione formed the α-keto enolate complex, while 1-phenyl-1,2-propanedione underwent oxidative C–C coupling resulting in a red dinuclear bis(α-keto enolato) complex. Of the diaryl-α-diketones, benzil did not react, but pyridil underwent hydrolytic cleavage to pyridine-2-carbaldehyde and picolinate, of which the latter was bound to the zinc ion as an N,O-chelate ligand.

## Introduction

The inhibition of zinc enzymes is an active field of drug research, as it may be relevant for the treatment of such diseases as arthritis, high blood pressure, multiple sclerosis, and even cancer.[1,2] Studies towards this end can benefit from the fact that not only are a large number of zinc enzymes known, but many of them have been fully characterized by structure determinations.[3,4] Thus, there is an excellent basis for target-oriented drug design for zinc-enzyme-related diseases.

Despite this, development in this field is still mostly a matter of trial and error, and the number of zinc-specific inhibitor types is still relatively small.[2,5,6] The oldest of them, which have been successful in various fields, are the sulfonamides.[5] The best investigated are the hydroxamates.[2] They are attractive because the hydroxamate function is a very good zinc-binding group, but until now none of them has made it through all clinical tests, which is due in part to their unsuitability for oral administration as well as their potential chronic toxicity.[1,2,7]

It is therefore attractive to investigate inhibitors with other zinc-binding groups.[1,2] Studies of this kind have been reported for carboxylates,[8] β-keto enolates,[2,5] and some thiolate-containing chelators.[2,9] Considering the state of the art in the coordination chemistry of zinc and the large number of well-established zinc-binding functions, one must say that amazingly little of the knowledge accumulated has reached the field of drug design.

We have tackled this subject sporadically. After some basic studies of zinc complexes of drug substances,[10–14] we used our enzyme models, the TpZn–OH complexes, to study the interactions between zinc and pharmaceutically relevant substrates.[15–19] From these studies we found a striking structural similarity between the geometries at the zinc centers of the enzyme and the model complex in the hydroxamate-bound state,[20] and this enabled our mechanistic proposal for the zinc-enzyme-catalyzed hydrolysis of esters and peptides.[21,22]

Until recently, none of our investigations in this field was focused on a systematic survey of zinc-binding groups against a background of enzyme inhibition. Yet, one of our enzyme models, the $Tp^{Ph,Me}Zn$–OH complex, was used by Cohen et al. for studies of this kind, addressing the interactions between zinc and hydroxamates, pyridinones, chelating Schiff bases, and various kinds of bidentate thiolates.[23–27] This provided quite a diverse structural chemistry and some important aspects of the stability of enzyme model inhibitor complexes.

Independent of Cohen's work, we also started a systematic study scanning potentially bidentate zinc-binding groups and using the same enzyme model $Tp^{Ph,Me}Zn$–OH (**1**). Fortunately, so far the parallel work in both groups (with one exception, complex **11**, see below) has not produced any overlap. After some variations of the theme of hydroxamates and oximates,[28] we turned to zinc-binding groups that should be expected to bind through oxygen atoms only and which should be good chelators. This paper describes our results with such ligands containing two carbonyl functions: α-keto carboxylates, β-diketonates, α-diketones, and ligands derived from them.

## Results and Discussion

### α-Keto Carboxylic Acids

After the hydroxamic acids, the carboxylic acids are the second most investigated group of zinc enzyme inhibitors.[1] However, at physiological pH the carboxylate function binds 100–2000 times less efficiently to the zinc centers than the hydroxamate function.[1,29] It therefore seems suitable to enhance the carboxylates' binding capacity by introducing additional donor functions that make the carboxylate function part of a bidentate chelating ligand. With this in mind we applied pyruvic acid, benzoylformic acid, and oxamidic acid as inhibitor models.

The reaction between pyruvic acid and **1** was quantitative and yielded the pyruvate complex **2**. As expected, the pyruvato ligand in **2** is bound in a bidentate fashion, forming a five-membered chelate ring. This was already evident from the $^1$H NMR spectrum, in which the pyruvate's methyl resonance experienced a high-field shift of 1 ppm upon coordination, indicating that it was embedded between the Tp's phenyl rings. This was confirmed by the structure determination (see Figure 1).

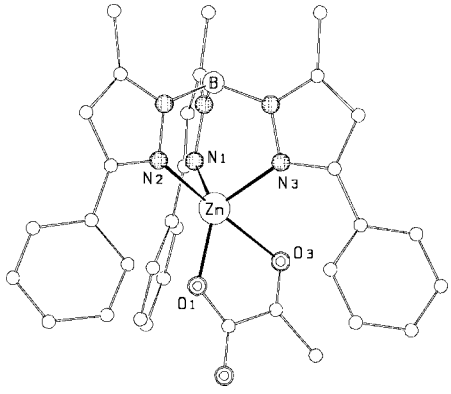

Figure 1. Molecular structure of complex **2**. Selected bond lengths [Å] and angles [°]: Zn–N1 2.020(3), Zn–N2 2.138(3), Zn–N3 2.017(3), Zn–O1 1.901(3), Zn–O3 2.397(3); O3–Zn–O1 75.6(1), O3–Zn–N1 89.7(1), O3–Zn–N3 87.7(1), O3–Zn–N2 177.5(1).

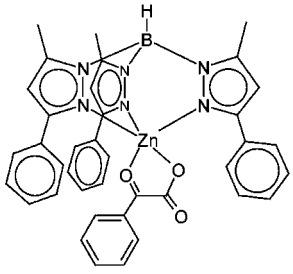
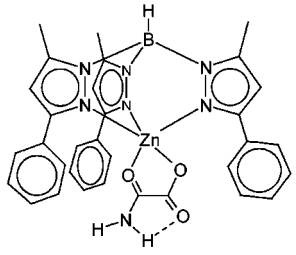
The major zinc–pyruvate interaction lies in the Zn–O bond to the carboxylate oxygen atom, which is 0.5 Å shorter than the other Zn–O bond. In part, this lengthening of the Zn–O3 bond can be ascribed to the fact that it represents the axis of a trigonal bipyramid around the zinc ion, with the Zn–N2 bond, which has also been lengthened, as the other axis. According to the Holmes definition,[30] the complex is 75% trigonal-bipyramidal and 25% square-pyramidal. Thereby **2** is one of the best examples of trigonal-bipyramidal coordination in TpZn complexes.[21]

We are not aware of any other zinc complexes of α-keto carboxylato ligands. There is, however, an iron–pyruvate complex of the $Tp^{Ph,Ph}$ ligand, the geometry of which is very similar to that of **2**.[31]

The reactions of **1** with benzoylformic acid and oxamidic acid proceeded equally straightforwardly and yielded complexes **3** and **4**. Their spectroscopic data indicate that their α-keto carboxylate functions are bound to the zinc ion in a chelating fashion, like in **2**. The main pieces of evidence are again the $^1$H NMR resonances of the phenyl group in **3** and one of the $NH_2$ hydrogen atoms in **4**, which have experienced significant high-field shifts. There is a second NH signal for **4**, 2 ppm down-field from the first one. We take this as an indication that this second hydrogen atom is involved in an N–H···O hydrogen bond, as indicated in the formula drawing. Support for our structural assignments comes from two structurally characterized related complexes: a TpFe complex of benzoylformate[31] and an aqua–zinc complex of oxamidate.[32]

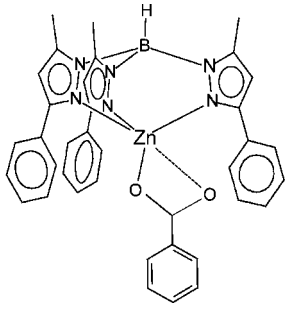


**3**



**4**

When solutions of **3** were exposed to air they turned yellow. $^1$H NMR spectroscopy indicated that **3** was consumed and replaced by another complex. Rigorous stirring in dichloromethane completed this process within hours and led to the isolation of the benzoate complex **5** in good yields. Complex **5** was identified by a structure determination (see Exp. Sect.), which is not discussed here as it revealed no unusual features.



**5**

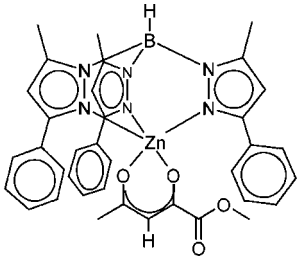
The conversion of **3** to **5** is an oxidative decarboxylation, a very typical reaction of α-keto carboxylic acids, which in organic chemistry is performed in the presence of $Fe^{II}$ and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

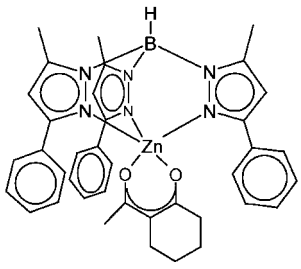
in biology by Fe-containing enzymes.[33] It is not known whether zinc enzymes catalyze such a reaction. The model complex $Tp^{Ph,Ph}$Fe–benzoylformate, a close relative of **3**, was found, however, to undergo the same reaction with concomitant hydroxylation of one of the Tp's phenyl groups.[31]

### β-Diketones

Until now the reactions of TpZn complexes with β-diketones have yielded, without exception, the expected TpZn–β-diketonate complexes with the classical six-membered chelate rings.[20,21,34,35] In the present work we tried to find out whether additional functionality on the β-diketones changes this picture. For this purpose we chose methyl 2,4-dioxopentanoate, which is prone to ester cleavage by $Tp^{Ph,Me}$Zn–OH, and 2-acetylcyclohexanone, which has an unusually low p$K_a$ of the acidic CH function. Both diketones, however, behaved conventionally toward **1**, producing complexes **6** and **7** in good yields.



**6**



**7**

Both complexes were identified by structure determinations, the results of which are summarized in Table 1. In both cases the geometry around the zinc ion is square-pyramidal to a very high degree (96 and 93%, respectively, according to Holmes' definition[30]). In both cases the uniformity of the Zn–O bond lengths demonstrates the symmetrical attachment of the β-diketonates, despite their unsymmetrical nature. This, together with the high stability of the complexes, qualifies the β-diketones as particularly reliable chelators for zinc ions, which deserve intensified use in enzyme inhibitor studies.

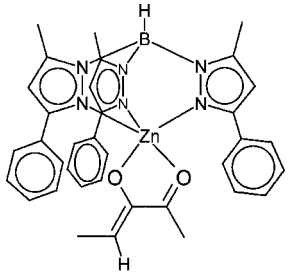
Table 1. Structural details of **6** and **7**.

| | **6** | **7** |
|---|---|---|
| Zn–O1 | 2.005(4) | 1.988(5) |
| Zn–O2 | 2.039(4) | 2.000(4) |
| Zn–N1 | 2.088(4) | 2.133(6) |
| Zn–N2 | 2.137(5) | 2.123(6) |
| Zn–N3 | 2.088(5) | 2.079(5) |
| O1–Zn–N1 | 155.6(2) | 158.2(2) |
| O2–Zn–N2 | 155.8(2) | 155.6(2) |
| N3–Zn–O1 | 108.1(2) | 106.3(2) |
| N3–Zn–O2 | 110.5(2) | 111.0(2) |
| N3–Zn–N1 | 95.2(2) | 94.9(2) |
| N3–Zn–N2 | 93.7(2) | 93.0(2) |

### Aliphatic α-Diketones

Unlike the β-diketones, the α-diketones cannot form resonance-stabilized anions after deprotonation, and their reactive anionic four-electron three-center enolate systems are not favorable as ligands. Accordingly, there seem to be no zinc–α-keto enolate complexes so far. Nevertheless, the attachment of both oxygen atoms of an α-keto enolate should lead to a complex with a favorable five-membered chelate ring. With this in mind we tested diacetyl, 2,3-pentanedione, and 1-phenyl-1,2-propanedione.

Diacetyl did not react with **1**. However, in boiling methanol, **1** and 2,3-pentanedione underwent the desired elimination of water and formation of the chelate complex **8**. Complex **8** could easily be identified by its $^1$H NMR spectrum (see Exp. Sect.), and its constitution was confirmed by a structure determination (see Figure 2).



**8**

The enolate ligand in **8** is bound in a reasonably symmetrical five-membered chelate ring. Like in **2**, the Zn–O bond to the formally anionic oxygen atom is considerably shorter than the other one. The geometry at the zinc center is halfway between trigonal-bipyramidal and square-pyramidal (52% according to the Holmes definition[30]). In the trigonal bipyramid N2 and O2 would be the axial donor atoms, and in the square pyramid N1 would be at the apex.

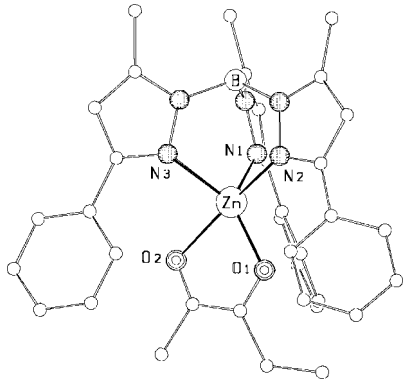


Figure 2. Molecular structure of complex **8**. Selected bond lengths [Å] and angles [°]: Zn–N1 2.067(4), Zn–N2 2.138(4), Zn–N3 2.064(4), Zn–O1 1.900(4), Zn–O2 2.255(4); N2–Zn–O2 169.0(1), N3–Zn–O1 141.7(2).

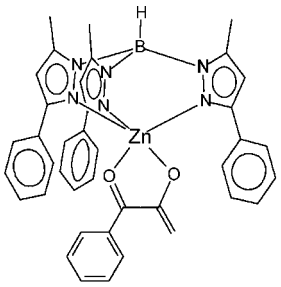
The course of the reaction between **1** and 1-phenyl-1,2-propanedione allows the assumption that its initial product is complex **9**, which is analogous to **8**. However, **9** could not be isolated, being consumed quickly by two consecutive reactions.

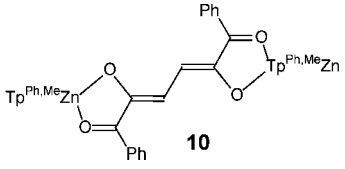
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



**9**

The reaction mixture turned red even in the absence of air. In the presence of air the color quickly became red-purple. Only after this could the two reaction products be isolated by fractional crystallization. One of them is the benzoate complex **5**. Its formation requires the oxidative cleavage of **9** with release of ketene, which is probably oxidized at the same time.

The second product is the red dinuclear complex **10**. Its formation can also be described as an oxidation of **9**: removal of one hydrogen atom from the vinyl group leaves a radical, the natural fate of which is dimerization leading to **10**. Although organic chemistry knows many radical dimerizations, we are not aware of an oxidative one that compares with this. Like in the formation of **5** from **4**, zinc seems to have a role here that is normally reserved for the redox-active metals.



**10**

The identification of **10** came from a structure determination (see Figure 3). In **10**, which is centrosymmetrical, the ligand environment of the zinc ions and its geometry is practically identical to that in **8**: in both complexes the zinc ions are attached to vinyl-substituted α-diketonato ligands. The interesting part of **10** is the conjugated system of four (*E*)-oriented double bonds (2 C=C and 2 C=O). Its eight atoms are coplanar to a good approximation (maximum deviation 0.18 Å), and the conjugation along the chain is obvious from the slight shortening of the single bonds. This delocalization is also the reason for the intense color of the complex.

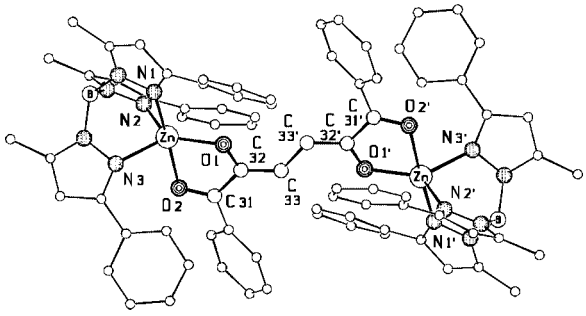


Figure 3. Molecular structure of the centrosymmetrical complex **10**. Selected bond lengths [Å]: Zn–O1 1.934(2), Zn–O2 2.281(3), Zn–N1 2.159(3), Zn–N2 2.078(3), Zn–N3 2.057(3), O1–C32 1.301(4), O2–C31 1.241(4), C31–C32 1.481(4), C32–C33 1.382(4), C33–C33′ 1.421(4).

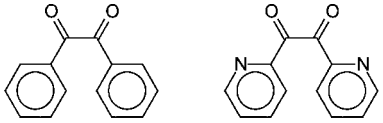
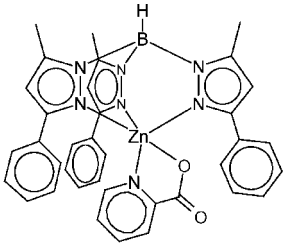
### Aromatic α-Diketones

Unlike the aliphatic α-diketones, benzil and pyridil cannot form enolates. If they react at all with a TpZn–OH complex, they can either function as uncharged donor ligands or suffer nucleophilic attack by the strong Zn–OH nucleophiles. It turned out that the former does not happen, but the latter is the case.



benzil pyridil

There was no reaction between **1** and benzil. Complex **1** and pyridil did react in dichloromethane at room temperature. The isolated product of this reaction was the picolinato complex **11**, which was obtained previously directly from **1** and picolinic acid.[9] The second product, pyridine-2-carbaldehyde, was identified by $^1$H NMR spectroscopy in the reaction solution. Thus, the course of the reaction is the unusual hydrolysis of pyridil at its central C–C bond, during which the oxygen atom of the Zn–OH function ends up in the picolinate while the hydrogen atom becomes the aldehydic hydrogen atom of the pyridinecarbaldehyde. Again we are not aware that there is precedence for such a hydrolytic reaction, and again it must be assumed that initial coordination of the substrate to the zinc ion (this time through the pyridyl nitrogen atom) is an essential part of its mechanism.



**11**

The favorable attachment of the picolinato ligand to the zinc ion by a five-membered chelate ring was confirmed by a structure determination (see Figure 4). The coordination geometry of the zinc ion is very close to trigonal-bipyramidal (73% according to the Holmes definition[30]) with the pyridine nitrogen atom and one Tp nitrogen atom on the axis. All atoms of the picolinato ligand are coplanar (strongest deviation 0.12 Å), and the short Zn–O bond indicates a quite strong zinc–picolinate interaction. Considering this, it is somewhat surprising that **11** is the first TpZn chelate complex of this kind, particularly as it is known that the complex $[Tp^{Cum,Me}Zn\text{-}Py]^+$ exists,[36] which demonstrates the strength of the TpZn–pyridine interaction by being a rare example of the cationic TpZn–X complexes.

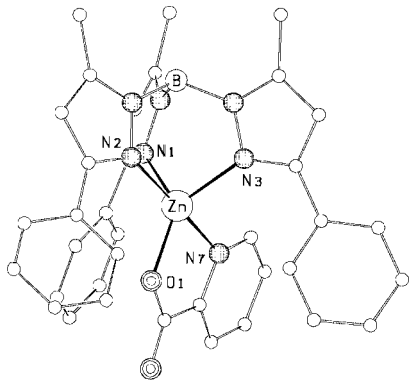

Figure 4. Molecular structure of complex **11**. Selected bond lengths [Å] and angles [°]: Zn–N1 2.051(3), Zn–N2 2.226(3), Zn–N3 2.052(3), Zn–N7 2.193(3), Zn–O1 1.966(3); N2–Zn–N7 177.5(1).

## Conclusions

A general rule for zinc complexes of 3,5-substituted Tp ligands is that the Tp ligand is a "tetrahedral enforcer", that is, four-coordinate TpZn–X complexes are preferred. This paper, however, has shown again that with suitable chelating ligands this rule is broken and very stable TpZn(X,Y) complexes are obtained. In the present case the chelators were mostly bidentate O,O donors forming five-membered chelate rings.

In the context of zinc enzyme inhibition the new complexes give further support to the hypothesis that the enzyme–inhibitor complexes are transition-state analogs, as the transition state of a zinc-enzyme-catalyzed hydrolysis has the zinc ion in a fivefold coordination with a geometry halfway between trigonal-bipyramidal and square-pyramidal.[22] As we have shown here and before,[21] the TpZn complexes of O,O chelators are very variable in their geometry, covering almost the whole range of geometries for $ZnL_5$ systems.

Of the chelate ligands employed here, the α-keto carboxylates and the α-diketo enolates have not been used before in zinc chemistry. Their stable TpZn complexes, and the even more stable TpZn complexes of the β-diketonates and the picolinate, indicate that it should be worthwhile studying compounds with these donor groups more thoroughly as potential inhibitors for zinc enzymes. It is altogether surprising how few donor functions have been employed in such studies so far.[1,2]

An unexpected, but welcome, byproduct of these investigations were the three substrate cleavage reactions. Both the two oxidative ones leading to **5** and **10** and the hydrolytic one leading to **11** are unprecedented in zinc chemistry, and one can only guess about their mechanisms. They please the zinc chemist by demonstrating once again that the "boring element" is not so boring after all.

## Experimental Section

**General:** For general working and measuring procedures see ref.[37] Complex **1** was prepared as described.[38] Organic reagents were obtained commercially. All IR spectra were recorded from KBr pellets. All $^1$H NMR spectra were obtained from $CDCl_3$ solutions. The resonances of the $Tp^{Ph,Me}$ ligands in all complexes were observed at practically identical positions: $\delta$ = 2.5 [s, 9 H, Me(pz)], 6.2 [s, 3 H, H(pz)], 7.2–7.4 [m, 9 H, Ph(3,4,5)], 7.5–7.7 [m, 6 H, Ph(2,6)] ppm. Hence, only the $^1$H NMR resonances of the co-ligands are reported here.

**Complex 2:** A solution of pyruvic acid (24 mg, 0.35 mmol) in methanol (5 mL) was added to a solution of **1** (200 mg, 0.35 mmol) in dichloromethane (20 mL). After stirring for 3 h, all volatiles were removed in vacuo. Crystallization by slow concentration from dichloromethane/methanol yielded **2** (199 mg, 81%) as colorless crystals, m.p. 186 °C. $C_{33}H_{31}BN_6O_3Zn$ (653.86): calcd. C 62.34, H 4.91, N 13.22; found C 62.10, H 5.02, N 13.22. IR (KBr): $\tilde{\nu}$ = 2552 m (BH), 1701 s, 1687 s (CO) cm$^{-1}$. $^1$H NMR: $\delta$ = 1.33 (s, 3 H, $CH_3$) ppm.

**Complex 3:** A solution of benzoylformic acid (80 mg, 0.53 mmol) in methanol (20 mL) was added to a solution of **1** (300 mg, 0.53 mmol) in dichloromethane (20 mL). After stirring for 3 h, the volume of the solution was reduced to one half in vacuo. The resulting colorless precipitate was filtered off and washed with methanol (5 mL). Crystallization by slow concentration from dichloromethane/methanol yielded **3** (314 mg, 85%) as colorless crystals, m.p. 190 °C. $C_{38}H_{33}BN_6O_3Zn$ (697.92): calcd. C 65.40, H 4.77, N 12.04; found C 65.23, H 4.85, N 11.94. IR (KBr): $\tilde{\nu}$ = 2539 m (BH), 1676 vs, 1645 s (CO) cm$^{-1}$. $^1$H NMR: $\delta$ = 7.01–7.18 [m, 12 H, Ph(Tp) and Ph], 7.42–7.53 [m, 8 H, Ph(Tp) and Ph] ppm.

**Complex 4:** As for **3**, from oxamidic acid (31 mg, 0.35 mmol) and **1** (200 mg, 0.35 mmol). Yield: **4** (161 mg, 72%) as colorless crystals, m.p. 210 °C. $C_{32}H_{30}BN_7O_3Zn$ (636.84): calcd. C 60.35, H 4.75, N 15.40; found C 59.51, H 4.84, N 15.18. IR (KBr): $\tilde{\nu}$ = 2544 m (BH), 1666 vs (CO) cm$^{-1}$. $^1$H NMR: $\delta$ = 4.45 (s, 1 H, NH), 6.51 (s, 1 H, NH) ppm.

**Complex 5:** A solution of **4** (100 mg, 0.14 mmol) in dichloromethane (20 mL) was stirred in an open flask for 2 h. The solvent was removed in vacuo and the residue crystallized by slow concentration from dichloromethane/methanol, yielding **5** (59 mg, 62%) as yellowish crystals, m.p. 224 °C. $C_{37}H_{33}BN_6O_2Zn$ (669.91): calcd. C 65.46, H 5.05, N 12.38; found C 65.36, H 5.06, N 12.37. IR (KBr): $\tilde{\nu}$ = 2541 m (BH), 1615 s, 1438 s (CO) cm$^{-1}$. $^1$H NMR: $\delta$ = 7.12–7.25 [m, 12 H, Ph(Tp) and Ph], 7.61–7.67 [m, 8 H, Ph(Tp) and Ph] ppm.

**Complex 6:** As for **2**, from methyl 2,3-dioxopentanoate (39 mg, 0.27 mmol) and **1** (150 mg, 0.27 mmol). Yield: **6** (155 mg, 83%) as colorless crystals, m.p. 187 °C. $C_{36}H_{35}BN_6O_4Zn$ (691.88): calcd. C 62.49, H 5.10, N 12.15; found C 62.19, H 5.39, N 12.03. IR (KBr): $\tilde{\nu}$ = 2540 m (BH), 1743 s, 1617 s (CO) cm$^{-1}$. $^1$H NMR: $\delta$ = 1.09 (s, 3 H, $CH_3$), 3.38 (s, 3 H, $OCH_3$), 4.75 (s, 1 H, CH) ppm.

**Complex 7:** As for **3**, from 2-acetylcyclohexanone (49 mg, 0.35 mmol) and **1** (200 mg, 0.35 mmol). Yield: **7** (161 mg, 67%) as colorless crystals, m.p. 191 °C. $C_{38}H_{39}BN_6O_2Zn{\cdot}CH_2Cl_2$ (687.97 + 84.93): calcd. C 60.61, H 5.35, N 10.87; found C 60.89, H 5.49, N 11.09. IR (KBr): $\tilde{\nu}$ = 2541 m (BH), 1593 vs (CO) cm$^{-1}$. $^1$H NMR: $\delta$ = 1.11 (s, 3 H, $CH_3CO$), 1.14–2.07 (m, 8 H, cyclohexyl), 5.29 (s, 2 H, $CH_2Cl_2$) ppm.

**Complex 8:** A solution of 2,3-pentanedione (44 mg, 46 μL, 0.44 mmol) in methanol (10 mL) was added to a suspension of **1** (250 mg, 0.44 mmol) in methanol (30 mL). After refluxing for 4 h, all volatiles were removed in vacuo. Crystallization by slow concentration from dichloromethane/methanol yielded **8** (225 mg, 79%) as yellow crystals, m.p. 172 °C. $C_{35}H_{35}BN_6O_2Zn$ (647.90): calcd. C 64.88, H 5.44, N 12.97; found C 64.29, H 5.51, N 12.85. IR (KBr):

$\tilde{\nu}$ = 2541 m (BH), 1635 vs (CO) cm$^{-1}$. $^1$H NMR: $\delta$ = 1.11 (s, 3 H, $CH_3CO$), 1.83 (d, $J$ = 7.0 Hz, 3 H, $CH_3$), 5.27 (q, $J$ = 7.0 Hz, 1 H, CH) pm.

**Complex 10:** A solution of 1-phenyl-1,2-propanedione (52 mg, 47 μL, 0.35 mmol) in methanol (20 mL) was added to a solution of **1** (200 mg, 0.35 mmol) in dichloromethane (20 mL). After stirring in an open flask for 6 h, all volatiles were removed in vacuo. The residue was dissolved in a mixture of methanol (10 mL) and dichloromethane (5 mL) and subjected to slow concentration until most of the dichloromethane was evaporated. The resulting precipitate, which was filtered off, washed with methanol (3 mL), and dried in vacuo, consisted of **10** (78 mg, 32%) as a red powder, m.p. 230 °C. $C_{78}H_{68}B_2N_{12}O_4Zn_2\cdot 1.5CH_2Cl_2$ (1389.88 + 127.40): calcd. C 62.93, H 4.72, N 11.08; found C 62.52, H 4.62, N 11.15. IR (KBr): $\tilde{\nu}$ = 2541 m (BH), 1613 vs (CO) cm$^{-1}$. $^1$H NMR: $\delta$ = 5.29 (s, 3 H, $CH_2Cl_2$), 6.73 (s, 2 H, CH) ppm.

**Complex 11:** A solution of pyridil (74 mg, 0.35 mmol) in dichloromethane (10 mL) was added to a solution of **1** (200 mg, 0.35 mmol) in dichloromethane (10 mL). After stirring for 3 h, the mixture was filtered and the filtrate treated dropwise with methanol until a precipitate started forming. After stirring for another 30 min, the precipitate was filtered off and washed with methanol (5 mL). Recrystallization from hot methanol yielded **11** (132 mg, 56%) as yellow crystals, m.p. 226 °C. $C_{36}H_{32}BN_7O_2Zn\cdot CH_3OH$ (670.90 + 32.04): calcd. C 63.82, H 4.99, N 14.27; found C 63.21, H 4.75, N 13.97. IR (KBr): $\tilde{\nu}$ = 2539 m (BH), 1665 m and 1646 vs (CO and Py) cm$^{-1}$. $^1$H NMR: $\delta$ = 3.48 (s, 3 H, $CH_3OH$), 6.49 [t, $J$ = 7.0 Hz, 1 H, Py(4)], 6.96 [d, $J$ = 7.0 Hz, 1 H, Py(3)], 7.23 [t, $J$ = 7.0 Hz, 1 H, Py(5)], 7.62 [d, $J$ = 6.9 Hz, 1 H, Py(6)] ppm.

**Structure Determinations:** Crystals of **10** were obtained by recrystallization from dichloromethane. All other crystals were obtained as described above. Diffraction data were recorded at 240 K with a Bruker Smart CCD diffractometer with Mo-$K_\alpha$ radiation and subjected to empirical absorption corrections (program SADABS). The structures were solved with direct methods and refined anisotropically with the SHELX program suite.[39] Drawings were produced with SCHAKAL.[40] Table 2 lists the crystallographic data. CCDC-614607 (for **2**), -614608 (for **5**), -614609 (for **6**), -614610 (for **7**), -614611 (for **8**), -614612 (for **10**), and -614613 (for **11**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

This work was supported by the Fonds der Chemischen Industrie. We are indebted to Drs. H. Brombacher, G. Steinfeld, and W. Deck for advice and technical assistance, and to Ms. M. Handloser for help in the laboratory.
